MINI-REVIEW / MINI-SYNTHÈSE

Self-assembly in Schiff base lanthanide complexes — From supramolecular dimers to coordination polymers[1]

Wanda Radecka-Paryzek

Abstract: A review is given of the latest contribution of the author's research group to the coordination chemistry of Schiff base polyaza macrocycles and acyclic salicylaldimines. Focus is placed on the effectiveness of lanthanides in supramolecular self-assembly of the components leading to the formation of compounds with unusual properties and structures.

Key words: Schiff base macrocycles, salicylaldimines, lanthanides, self-assembly, template synthesis.

Résumé : On passe en revue les contributions récentes du groupe de recherche de l'auteur à la chimie de coordination de bases de Schiff salicylaldimines acycliques et macrocycliques polyazotés. On met l'emphase sur l'efficacité des lanthanides dans l'autoassemblage supramoléculaire des composants qui conduisent à la formation de composés comportant des propriétés et des structures inhabituelles.

Mots-clés : bases de Schiff macrocycliques, salicylaldimines, lanthanides, autoassemblage, synthèse sur gabarit.

[Traduit par la Rédaction]

Introduction

Schiff bases have been known since 1864 when Hugo Schiff reported the condensation of primary amines with carbonyl compounds (1). Nowadays, the research field dealing with Schiff base coordination chemistry has expanded enormously. The importance of Schiff base complexes for bioinorganic chemistry, biomedical applications, supramolecular chemistry, catalysis and material science, separation and encapsulation processes, and formation of compounds with unusual properties and structures has been well-recognized and reviewed (2). In this paper, we would like to show, on the basis of the latest contribution of the author's research group, that although the coordination chemistry of Schiff bases is very rich, it still remains an interesting and unpredictable area. Our research effort for the last 30 years has been focused on the investigation of the coordination template effect in generating new supramolecular mono- and homo- or hetero-dinuclear polyaza and polyoxaaza Schiff base macrocyclic and acyclic complexes. We have found the lanthanide metal ions to be very effective templates in the synthesis of the complexes of this type (3). Lanthanides have little or no stereochemical requirements and can be accommodated by the particular constraints enforced by the template process. The structural versatility of the lanthanide complexes arises from the lack of strong crystal field effects for 4f-electronic configuration and from the large ionic radii of these metal ions. In the lanthanides, the 4f-orbitals are shielded by the 5s- and 5p-electrons, and their ionic radii decrease monotonically with the increasing atomic number (lanthanide contraction). The large ionic radii of the lanthanide ions together with the increased ionic character of the metal–ligand bonding in their complexes led to the generation of complexes with higher coordination numbers ranging from 8 to 12. The effective ionic diameters of the Ln(III) ions (Ln is symbol for any one of the lanthanides from lanthanum to lutetium) strongly depend on both the atomic number and the coordination number: a difference of about 0.4 Å is found between La(III) and Lu(III) and, for a given Ln(III) ion, between coordination numbers 8 and 12.

The peculiar chemical, structural, spectroscopic, and magnetic properties of the trivalent lanthanide ions associated with their $4f^{1-14}$ configuration make them suitable for development of novel interesting systems relating to general chemistry and application.

Pentaazadentate Schiff base lanthanide macrocyclic complexes as a result of self-assembly process

The interest in exploring the encapsulation of the lanthanide elements by macrocycles has continually been increasing, as they can be used in imaging, medical and material processing as well as analytical, environmental, and telecommunication areas. These new applications of the macrocyclic systems, in particular those containing nitrogen-donor atoms, involve their use as supramolecular devices (4–7), bioinorganic probes for the active sites in metallobiomolecules (8, 9), as magnetic resonance imaging contrast-enhancing agents (10–24), chemotherapeutics (25–27), potential radioimmunopharmaceuticals for monoclonal antibody technology (28–33) and sensitizers for photodynamic therapy (34), and finally as synthetic nucleases for in vivo applications (35–40). While searching for new stable complexes of rare-earth elements in view of their potential applications, we have recently reported the first examples of lutetium and ytterbium macrocyclic complexes with the seven-coordination and pentagonal bipyramidal structure and their peroxo-bridged dimeric derivatives containing a biologically significant and unprecedented among lanthanide macrocyclic complexes planar side-on μ-η^2:η^2 coordination mode of the peroxide (41–44). Template reactions of 2,6-diacetylpyridine with 3,7-diazanonane-1,9-diamine were carried out in the presence of mixed lutetium or ytterbium chloride and perchlorate salts under argon (Scheme 1).

Recrystallization produced 16-membered macrocyclic complexes with an N_5 set of donor atoms as a result of a [1+1] Schiff base cyclocondensation. X-ray analysis reveals that these two complexes of formula $\{LnMe_2pyo[16]trieneN_5Cl_2\}ClO_4$, where Ln is Lu^{3+} or Yb^{3+} and $Me_2pyo[16]trieneN_5$ is 2,14-dimethyl-3,6,10,13,19-pentaazabicyclo[13.3.1]nonadeca-1(19),2,13,15,17-pentaene, are isostructural. The Lu(III) and Yb(III) are seven-coordinate with the pentagonal bipyramidal coordination geometry (Fig. 1) (41, 43).

These complexes show no tendency to include solvent molecules in either the metal coordination sphere or the crystal lattice. The electronic and steric requirements of central metal atoms appear to be fully satisfied by the coordination to the five nitrogen donors of the macrocycle and two chlorine donors. The organizational role of the lanthanide cation in the assembly of the pentaaza macrocycle was proved by the recovery of insoluble yellow materials of indefinite composition when the condensation of 2,6-diacetylpyridine with 3,7-diazanonane-1,9-diamine was carried out in the absence of the metal ion. The failure of this system to undergo complete condensation and cyclization confirms the importance of the metal ion in directing the steric course of the condensation process, which ultimately ends with ring closure.

UV–vis, NIR, ^{1}H NMR, and ESI spectral data reveal that the integrity of the complexes is maintained in solution. The

Scheme 1.

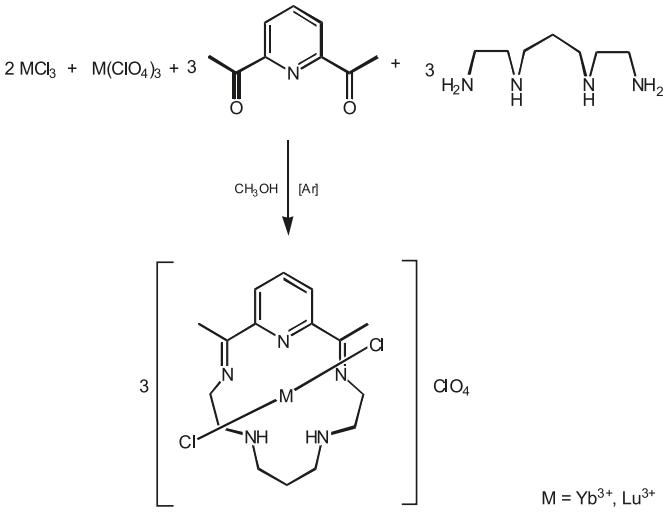

Fig. 1. Structure of 16-membered pentaazadentate macrocyclic lutetium(III) and ytterbium(III) complex cations.

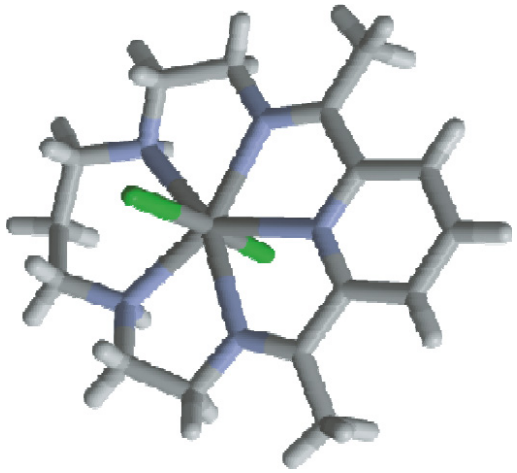

properties of this ytterbium complex were found to be very important and promising in the area of ytterbium physicochemistry. For the first time, the spectrum of the $^2F_{7/2} \rightarrow {}^2F_{5/2}$ transition has been obtained for a molecular complex of ytterbium with organic ligands in which all ligand-field components of the ground and excited state are well-displayed at room temperature (Fig. 2) (44).

These pentaaza macrocyclic complexes exhibit a structural similarity to lutetium texaphyrins, which have been tested as photosensitizers for use in the photodynamic treatment of recurrent breast cancer (LUTRIN), photoangioplastic reduction of atherosclerosis (ANTRIN), and light-based treatment of age-related macular degeneration (OPTRIN) (34). Moreover, Yb^{3+} complexes are now of increasing interest due to their potential application in various areas of biomedical sciences and technology as probes for fluoroimmunoassays, as effective therapeutic and diagnostic agents, in optical amplification, and in laser systems (45–51).

The template Schiff base condensation of 2,6-diacetylpyridine with 3,7-diazanonane-1,9-diamine carried out on air in the presence of the lutetium(III) ion followed by a slow crystallization process yielded, to our surprise, a

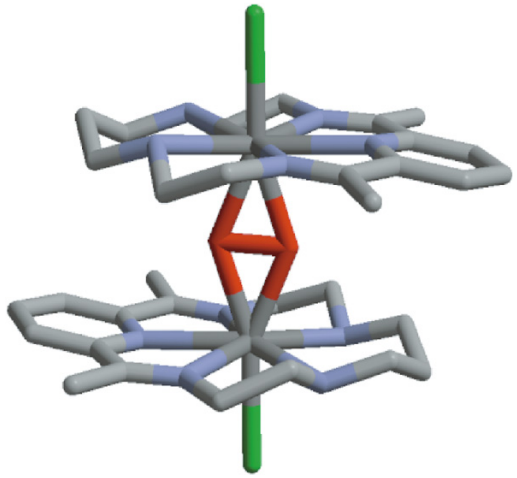
dimeric peroxo-bridged derivative of formula $[\{LuClMe_2pyo[16]trieneN_5\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}O_2)](ClO_4)_2$ with a planar side-on doubly bidentate coordination mode of the peroxide, unprecedented so far among lanthanide macrocyclic complexes (42). The isolation and definitive identification of an isostructural ytterbium(III) peroxo complex $[\{YbClMe_2pyo[16]trieneN_5\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}O_2)](ClO_4)_2$ allowed us to exclude the serendipity of this unexpected result of template cyclocondensation reaction (Fig. 3) (43, 44).

The complexes consist of two lanthanide(III) centers, five macrocycle nitrogen atoms make the equatorial plane of the coordination polyhedron, and the outer axial positions are filled by chlorine atoms. The position between the metal ions is occupied by the peroxide fragment. All Ln–O bond lengths are equivalent within the experimental error, clearly proving the planar side-on $\mu\text{-}\eta^2\text{:}\eta^2$ coordination mode of the peroxide. These results expand the unique series of compounds containing this particular coordination mode of the peroxide, which is considered biologically significant because it is known to occur in some oxyhemocyanins and it is postulated as a new mode of binding or activation of dioxygen in other biological systems. The first solid evidence for the formation of an entirely novel planar $\mu\text{-}\eta^2\text{:}\eta^2$-peroxide geometry was found in peroxo bis(trimethylsilyl)-amido dinuclear lanthanum species (52) and remained the only known and structurally characterized example of such a coordination mode of O_2^{2-} in lanthanide chemistry. The peroxo group showed previously unreported behaviour, acting as a symmetrical doubly bidentate bridge between the two metal atoms. The use of appropriately positioned, highly hindered tris(pyrazolyl)borate ligands made it possible to structurally establish this novel coordination mode of the peroxide in d-block element complexes (53). These $\mu\text{-}\eta^2\text{:}\eta^2$-peroxo dinuclear copper(II) complexes were found to have physicochemical properties strikingly similar to those of oxyhemocyanin. Subsequently, the crystal structure of oxyhemocyanin from the horseshoe crab (*Limulus polyphemus*) was solved, revealing the presence of precisely this type of $\mu\text{-}\eta^2\text{:}\eta^2$-peroxide moiety (54). In this case, accurate structural model compounds preceded the determination of the protein structure. Based on reports involving binuclear Cu(II) peroxo species, the formation of a $\mu\text{-}\eta^2\text{:}\eta^2$-peroxo intermediate was proposed as an attractive novel possibility for

Fig. 3. Structure of $\mu\text{-}\eta^2\text{:}\eta^2$-peroxo bridged 16-membered pentaazadentate macrocyclic lutetium(III) and ytterbium(III) complex cations.



the mechanism of water oxidation and O_2 evolution during photosynthesis catalyzed by tetranuclear manganese clusters, although no such Mn complex has been synthesized yet (55). It seems worthy to note that the synthesis of the first lanthanum(III) and copper(II) $\mu\text{-}\eta^2\text{:}\eta^2$-peroxo complexes required severe conditions: treatment with H_2O_2 under anaerobic conditions or low-temperature (ca. –70 °C) direct dioxygen addition. The formation of Schiff base macrocyclic lanthanide $\mu\text{-}\eta^2\text{:}\eta^2$-peroxo complexes appears to be a result of a one-step template synthesis followed by slow crystallization in air. Moreover, the O–O bond distances in these complexes are consistent with the value observed in dinuclear Cu(II) $\mu\text{-}\eta^2\text{:}\eta^2$-peroxide bridged species, of interest as oxyhemocyanin and oxytyrosinase models (53, 56). By comparison, in previously mentioned first lanthanum(III) $\mu\text{-}\eta^2\text{:}\eta^2$-peroxo complex, the O–O bond distance was found to be extremely large, probably due to their artificial elongation caused by the effects of crystal decomposition (52).

Inclusion of an appropriate solvent molecule into the crystal structure of $[\{LnClMe_2pyo[16]trieneN_5\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}O_2)](ClO_4)_2$ ($Ln=Lu^{3+}$ or Yb^{3+}) peroxo dinuclear complexes generates a tetrameric supramolecular architecture in which the solvent-controlled self-assembly is observed (43, 44). To some extent at least, the shape, symmetry, and hydrogen bonding (or in more general terms: weak interactions) properties of the solvent molecule influence the resulting three-dimensional structure of the crystal (43, 44).

The building block of the crystal structure of the dioxane solvate of four $\mu\text{-}\eta^2\text{:}\eta^2$-peroxo bridged lutetium(III) and ytterbium(III) dimers is created by a centrosymmetric hydrogen-bonded tetramer of complexes, perchlorate anions, and dioxane molecule (Fig. 4) (42–44). The shape, symmetry, and hydrogen-bond accepting properties of dioxane are compatible with the shape and properties of the tetrameric network.

The two three-dimensional structures of crystals of $\mu\text{-}\eta^2\text{:}\eta^2$-peroxo ytterbium(III) complexes obtained from simple aromatic solvents, benzene (43) and toluene (44), are almost identical (in fact, the crystals are highly isomorphous). They contain chains of molecules connected by hydrogen bonds;

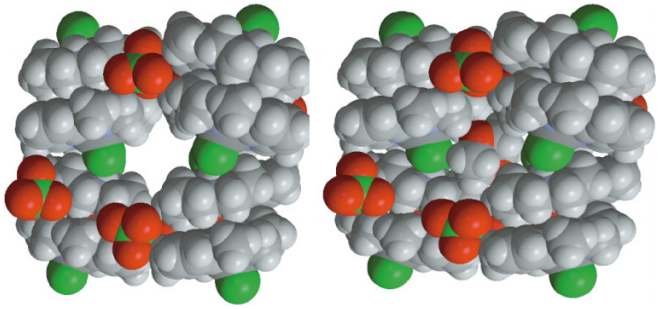

Fig. 5. The van der Waals radii representation of the building block of the μ-η^2:η^2-peroxo bridged ytterbium complex without (left) and with (right) a toluene or benzene molecule.

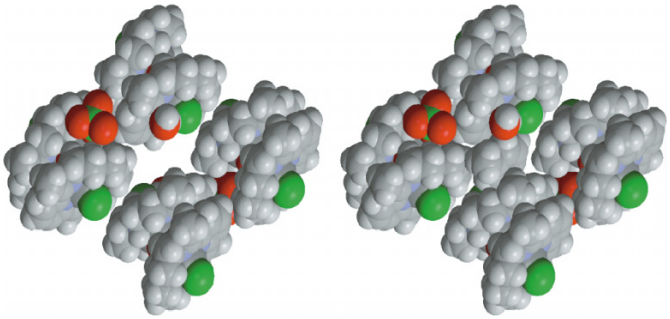

these chains are interconnected via perchlorate anions, and this tetrameric network can accommodate small flat molecules of the solvent. Because there are no specific interactions between these guest molecules and macrocyclic complex host, only very weak π-stacking, solvent molecules are highly disordered (Fig. 5) (43, 44).

Crystals of the methanol solvate of the ytterbium(III) complex are a very special case (44). The unit cell contains two different dimeric complex cations, four chloride, and four perchlorate anions and one methanol molecule. In one of them, formulated as $[\{Yb(H_2O)Me_2pyo[16]trieneN_5\}_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}O_2)]^{4+}$, there is a μ-$\eta^2$:$\eta^2$-peroxo bridge between the two Yb^{3+} centers, while the other, formulated as $[\{Yb(H_2O)Me_2pyo[16]trieneN_5\}_2(\mu\text{-}OH)_2)]^{4+}$, has two μ-OH hydroxyl bridges between the ytterbium ions. The molecule with a μ-η^2:η^2-peroxo bridge is similar to the previous ones except for the molecules occupying the axial positions (water molecules instead of chlorides). The molecule with two hydroxyl bridges is more folded. In both molecules, due to symmetry requirements, the central Yb–O–Yb–O fragments are exactly planar. The structural and spectral results afford some insight into the origin of the peroxo group. It seems reasonable to assume that the hydrolysis/oxidation of $\{LnMe_2pyo[16]trieneN_5Cl_2\}ClO_4$ occurs during the slow crystallization. The OH groups may replace axial chlorides in the coordination sphere of the metal ion yielding a di-μ-hydroxo species. These two OH groups may oxidatively form the peroxide and give rise to the complexes containing a planar side-on doubly bidentate coordination mode of the peroxide.

These results provide an interesting example of three-level inorganic self-organization involving templating as the first step of the assembly of well-defined supramolecular architectures of higher complexity. The lanthanide(III) ions serve as templates to orient the reacting groups of linear precursors in the desired conformation for the condensation process, which ultimately ends with the pentaaza macrocyclic Schiff base complexes. The stabilization of seven-coordination and pentagonal bipyramidal geometry in these complexes, relatively uncommon in the lanthanide series, seems to be a consequence of the "best fit" between the size of cations and the cavity of the macrocycle generated during the template process. In the dimerization step, these complexes are able to activate atmospheric oxygen and form the unique dimeric species linked through the biologically significant μ-η^2:η^2 peroxo bridge. The driving force underlying this unusual behaviour may be attributed to the stabilizing effect provided by the specific steric arrangement of the two macrocycles. In the crystal structure, packing as the next level of self-assembly is observed. The solvent molecules determine the three-dimensional disposition of the dimers. The supramolecular tetrameric network is created by the molecules of the peroxo complex acting as a host for the solvent guest.

Self-assembled salicylaldimine lanthanide complexes

Continuing our systematic investigation on the coordination template effect of lanthanides in generating supramolecular macrocyclic and acyclic Schiff base systems, we extended our studies to salicylaldimines. Transition-metal salicylaldimines have been studied broadly due to the number of applications in catalysis and material, biomimetic, and medicinal chemistry. They can be used as enantioselective epoxidation catalysts (57–61), components for the assembly of supramolecular architectures displaying interesting structures and properties (62–73), as models for active sites of metalloenzymes, and as therapeutic agents with superoxide dismutase and catalase activity (74–78). X-ray structure data reveal that, in the metal complexes of this type, the Schiff bases generally act as deprotonated tetradentate ligands with the N_2O_2 set of donor atoms capable of effective coordination in the planar fashion. Recently, we have communicated the definitive structural details correlated with spectral characterization of the salicylaldimine lanthanide nitrate complexes with unusual coordination mode (79, 80). These complexes are formed in situ in a one-step lanthanide promoted reaction between salicylaldehyde and rigid aromatic 4-methyl-1,3-phenylenediamine or flexible aliphatic 1,4-butanediamine (putrescine, biogenic amine) (Scheme 2).

They self-assemble into finite dimer or infinite two-dimensional coordination polymer depending on the type of diamine precursors.

In the crystal structure, the *N,N′*-bis(salicylidene)-4-methyl–1,3-phenylenediamine gadolinium(III) nitrate complex exists as a centrosymmetric dimer with 2:4 metal–ligand ratio (Fig. 6) (79).

The gadolinium(III) ions are nine-coordinate, and the geometry around the central ions can be described as a distorted tricapped trigonal prism. Each metal ion is ligated by

Scheme 2.

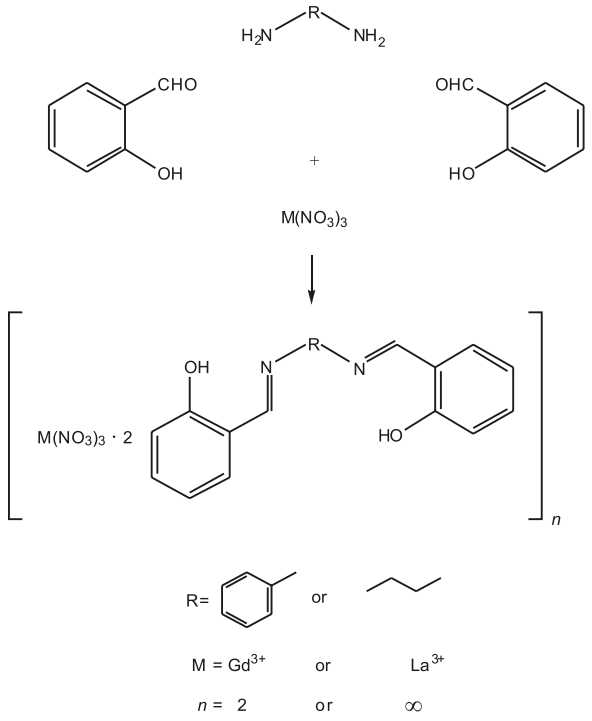

Fig. 6. Structure of the *N,N′*-bis(salicylidene)-4-methyl–1,3-phenylenediamine gadolinium(III) nitrate complex.

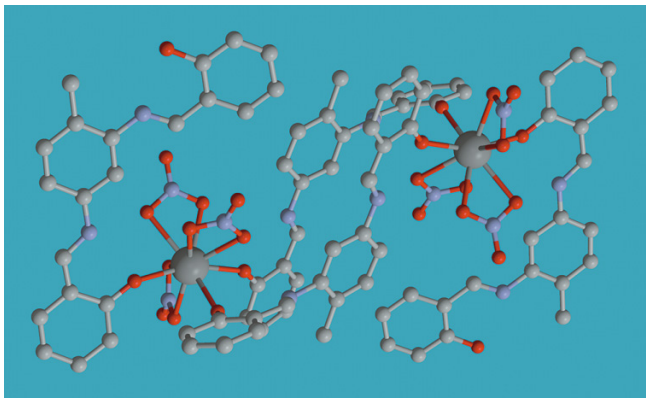
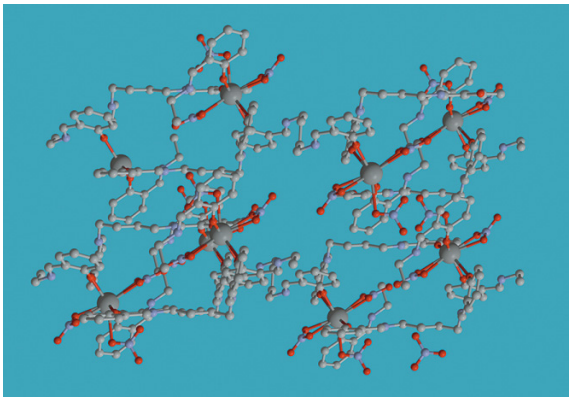


three bidentate nitrate counterions and three neutral salicylaldimine ligands that utilize only hydroxy oxygen atoms while the nitrogen atoms remain uncoordinated. The two ditopic O-donor ligands bridge the gadolinium ions, while the third ligand appears to involve only one oxygen atom in coordination. The second oxygen atom of this ligand does not take part in any intermolecular interactions.

The *N,N′*-bis(salicylidene)-1,4-butanediamine lanthanum(III) nitrate complex displays infinite two-dimensional polymeric structure composed of networks of ten-coordinated La(III) nodes linked by bridging neutral salicylaldimine ligands (Fig. 7) (80).

The coordination polyhedron around the lanthanum ions can be described as a distorted bicapped dodecahedron. Interestingly, only the oxygen atoms take part in the coordination; they come from three nitrate groups (six atoms) and from four neutral salicylaldimine ligand molecules (one oxygen from each molecule). This polymer might be described as composed of columns of dimers connected into chains, via the flexible parts of ligands.

Fig. 7. Structure of the *N,N′*-bis(salicylidene)-1,4-butanediamine lanthanum(III) nitrate complex.



These two complexes provide the examples of a rare coordination pattern of salicylaldimine ligands revealed by X-ray crystallography and correlated with spectroscopic characterization. Salicylaldimine ligands use exclusively the oxygen atoms as donor atoms with the nitrogen atoms not being involved in coordination. All the hydroxy groups of the ligands do not undergo deprotonation. The observed profound changes in the C–O and C=N bond lengths of the ligands upon coordination are consistent with the zwitterionic, charge-separated form in which the positive and negative charges reside on the azomethine function and on the metal coordination sphere, respectively. This point is proved by the results of spectral characterization of these complexes with reference to the free ligands obtained separately and identified for comparison purposes. The neutral O-donor type of coordination is in a marked contrast to the dianionic tetradentate N_2O_2 donor-set arrangement typically found in salicylaldimine complexes. An inspection of the available data for the structures of the related tetradentate N_2O_2 salicylaldiminato metal complexes reveals that the effects on the bond lengths of the coordination of the metal ion through oxygen only are remarkably similar to those caused by the removal of protons by ionization and coordination of all oxygen and nitrogen atoms. Therefore, the coordination mode might have been incorrectly inferred from spectroscopic analysis alone. The characterization of the complexes by both X-ray crystallography and spectroscopic methods is found to be useful in guiding and confirming interpretations concerning coordination modes in similar complexes for which no crystal data are available.

It is worth noticing that these two lanthanide nitrate complexes were obtained in similar experimental conditions and display similar spectral properties; for both complexes, analytical data indicate 1:2 metal – salicylaldimine ligand ratio. Obviously, it is going to be very difficult to differentiate these two coordination frameworks without detailed structural information gained from single-crystal X-ray crystallography. In these complexes, the nitrate counterions act as bidentate chelators occupying six coordination sites around the lanthanide cations and leaving the remaining sites available for salicylaldimine coordination. The lanthanide ions

© 2008 NRC Canada

may thus be regarded as assembling and templating joints for the ligands formed through the self-assembly process including the metal template-induced Schiff base condensation as the first step of self-organization. It could account for the unusual coordination mode of salicylaldimines in these complexes. The high coordination number and hardness of lanthanide(III) centers along with the nature of ligand spacers (length, flexibility, aromacity) and counterions seem to have a crucial bearing on the building of inorganic supramolecular arrays.

Conclusion

These findings confirm that the results of supramolecular self-assembly processes are sometimes unexpected and surprising. Many interesting supramolecular structures could not have been predicted. However, their retrospective analysis may provide necessary information in the attempts to intentionally design new materials with specific functions and properties. The difficulty in controlling the coordination environments is especially seen in lanthanide ions, which display high and variable coordination numbers with little or no stereochemical preferences. The new lanthanide structures with peculiar characteristics hold the potential to become powerful tools used to define interesting features relating both to general chemistry and application.

Acknowledgements

I would like to express my deep gratitude to Professor Richard J. Puddephatt for his invaluable scientific guidance and advice, which I received during my stay as visiting scientist in the University of Western Ontario in 1985 (joining the group of Dick's desperados).

My thanks are due to the co-workers whose names appear in the references and to the referees for helpful comments. The financial support from the Polish Ministry of Science and Higher Education (grants 4T09A 05624 and N N204 031733) is appreciated.

REVIEW / SYNTHÈSE

B–N as a C–C substitute in aromatic systems[1]

Michael J.D. Bosdet and Warren E. Piers

Abstract: The substitution of isoelectronic B–N units for C–C units in aromatic hydrocarbons produces novel heterocycles with structural similarities to the all-carbon frameworks, but with fundamentally altered electronic properties and chemistry. Since the pioneering work of Dewar some 50 years ago, the relationship between B–N and C–C and the wealth of parent all-carbon aromatics has captured the imagination of organic, inorganic, materials, and computational chemists alike, particularly in recent years. New applications in biological chemistry, new materials, and novel ligands for transition-metal complexes have emerged from these studies. This review is aimed at surveying activity in the area in the past couple of decades. Its organization is based on ring size and type of the all-carbon or heterocyclic subunit that the B–N analog is derived from. Structural aspects pertaining to the retention of aromaticity are emphasized, along with delineation of significant differences in physical properties of the B–N compound as compared to the C–C parent.

Key words: boron–nitrogen heterocycles, aromaticity, organic materials, main-group chemistry.

Résumé : La substitution d'unités C–C par des unités B–N, dans des hydrocarbures aromatiques, conduit à la production de nouveaux hétérocycles comportant des similarités structurales avec tous les squelettes carbonés, mais dont la chimie et les propriétés électroniques sont fondamentalement modifiées. Depuis les travaux de pionnier de Dewar, il y a plus de cinquante ans, la relation entre B–N et C–C et la richesse de tous les produits aromatiques carbonés parents a capturé l'imagination des praticiens de la chimie organique, de la chimie inorganique, de la chimie des matériaux aussi bien que des chimistes théoriciens, particulièrement dans les années récentes. De nouvelles applications dans le domaine de la chimie biologique, des nouveaux matériaux et des nouveaux ligands pour les complexes de métaux de transition ont émergé de ces études. Cette revue est orientée vers une évaluation de l'activité dans ce domaine dans les deux dernières décades. Son organisation est basée sur la taille du cycle et sur le type de sous unité entièrement carbonée ou hétérocyclique à partir de laquelle l'analogue B–N est dérivé. Les aspects structuraux relatifs à la rétention de l'aromaticité sont mis en évidence, avec une délimitation des différences significatives dans les propriétés physiques du composé B–N par comparaison avec le composé C–C.

Mots-clés : hétérocycles bore–azote, aromaticité, matériaux organiques, chimie du groupe principal.

[Traduit par la Rédaction]

Introduction

The isoelectronic relationship between "B–N" and "C–C" has been appreciated and exploited for several decades. The substitution of one or more B–N fragments for C–C fragments in classic aromatic hydrocarbons was first explored in the seminal work of Dewar and co-workers in the 1950s and 1960s. More recent investigations have revealed the potential for boron-doped aromatic species in new generations of materials with desirable photophysical and electrochemical properties (1, 2) or biological activity (3). First hinted at via computational investigations, these improved properties have begun to be observed experimentally and with recent development of new methods for synthesizing BN substituted aromatic species, the potential for access to new compounds has reinvigorated research into elemental isomers (4) of classic aromatic species. The recent resurgence of interest in this field of research and the fact that 2008 is the 50th anniversary of Dewar's initial report (5) on a BN phenanthrene derivative has prompted this review. While the focus of this account is recent chemistry of analogues of aromatic hydrocarbons incorporating a BN moiety, some of the early work

summarized in the last review (6) will be briefly discussed to give context.

Perhaps, the quintessential BN hydrocarbon analog is borazine ($B_3N_3H_6$), commonly referred to as "inorganic benzene", an extreme in the continuum of BN for CC substitution in a six-membered aromatic ring. The chemical and physical properties of borazine are well-established, though the debate as to whether or not it can be referred to as "aromatic" continues (7). The sequential replacement of CC moieties for BN in six-membered and more complex aromatic systems has been less thoroughly investigated, and it is therefore interesting to consider the compounds that exhibit such sequential replacements and to elucidate the effects on their structural, electronic, and photophysical properties. As such, this review deals exclusively with compounds obtained by incompletely replacing CC for BN in conjugated systems. That is, fully heteroatomic analogues of cyclopentadienyl and benzene (i.e., borazine) are beyond the scope of this article and have not been included. The intent here is to focus on the intermediate range from organic to inorganic benzene and polycyclic species derived from these. Indeed, there have been numerous accounts examining borazine (8), fully heteroatomic BN-cyclopentadienyl analogues (9–11), linear BN-acenes (12–14), as well as the analogues of graphite, such as hexagonal boron nitride (15), but these will not be specifically addressed here. To further limit the scope of this review, the omission of graphitic structures composed of boron, carbon, and nitrogen commonly referred to as BCN materials, is justified on the basis that the materials so formed have an ill-defined arrangement of BN and CC moieties; that is, the heteroatom substitutions are not at prescribed positions (2, 16, 17). Investigations of BN substitution with "defined" locations in such structures will be addressed.

From the onset of BN aromatic chemistry, several groups have investigated the relative stabilities of the three possible C_4BN benzene isomers, with much the same findings (6, 18–20). The BN-benzene formed by adjacent BN substitution, the 1,2-isomer (Chart 1**a**), is by far the most stable owing to the complimentary π- and σ-donations from nitrogen and boron, respectively. The "disconnected" 1,4-isomer **b** has been predicted to be significantly less stable than **a**, though polycyclic derivatives are known. The least stable substitution pattern is the 1,3-isomer **c**, for which no classical uncharged bonding depiction can be drawn. Indeed, no examples of this isomer have been reported.

Based on atomic radii, the expected bond length for a B–N single bond is 1.58 Å, while that for a B=N double bond is 1.40 Å (21). Just as the CC bond lengths in benzene are intermediate in length between double and single bonds, the participation of the BN fragment in aromatic systems can also be anticipated to result in a bond length between that of a purely single or double bond. Clearly, this bonding situation is indicative of π-character, and as such an appropriate depiction of this bond is shown in Chart 2**b**, which also highlights the dipolar nature of this moiety. However, it has been shown that the B and N atoms do not become significantly polarized due to opposing σ- and π-electron polarizations (Chart 2**c**), and the net formal charges are actually quite similar, even resulting in a net negative charge at nitrogen (6, 22). Given the suppressed polarization, the resonance

Chart 1.

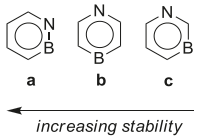

Chart 2.

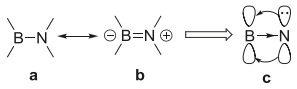

form shown in Chart 2**a** is also valid (and commonly depicted), and though it does not highlight the multiple bond character, this depiction will be used throughout this review for the sake of clarity.

In terms of organization, we classify and discuss BN heterocycles on the basis of the parent azaborinine ring only, and appended rings are considered as substituents on the core heteroaromatic ring of interest. That said, polycyclic systems are regularly referred to in such a way as to highlight their similarity to common aromatic compounds: BN-naphthalene, B_2N_2-triphenylene, and so forth. The abbreviated nomenclature for azaborinines proposed by Thakkar (20) has been adopted in this review, particularly as it pertains to $C_2B_2N_2$ rings. Thus, for example, in describing $C_2B_2N_2$ heterocycles, the first two numbers indicate the nitrogen atom positions, and the latter two indicate the boron atoms.

Six-membered rings

Heterocycles with one BN moiety: 1,2-azaborinines

Benzene analogues

The simplest ring to consider is 1,2-azaborinine, in which one CC pair of benzene has been substituted with a BN unit. As yet, the parent system has eluded isolation, though Dewar and co-workers were able to detect this species via mass spectroscopy (23). Their attempts at forming this parent ring led to rapid polymerization although the products of decomposition were ill-defined. The first substituted examples of this system were prepared by Dewar via desulfurization of **1** with Raney nickel to give **2** (Scheme 1) (5) and by White via dehydrogenation of azaboracyclohexane **3** giving phenyl-substituted **4** (Scheme 2) (24).

In 1980, new derivatives of BN-benzene were prepared by Gronowitz (25, 26), following the analogous desulfurization protocol to that originally utilized by Dewar (Scheme 3). Incorporating a non-fused thiophene moiety at the position α to boron, monodesulfurization yielded only the ethyl derivative **6**, which could then be reacted further to produce the target compound **7**, with an aliphatic, rather than aromatic, group at the α position. Note that utilizing the regioisomer **5**, Gronowitz was able to obtain the isomer **7** having an aliphatic substituent at position 4 as opposed to position 3 (26). Derivatives were assessed by UV-vis and NMR spectroscopies.

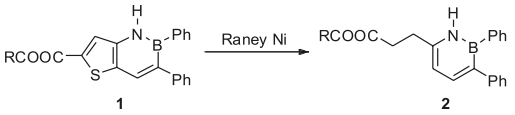
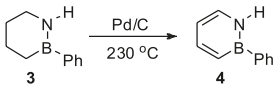
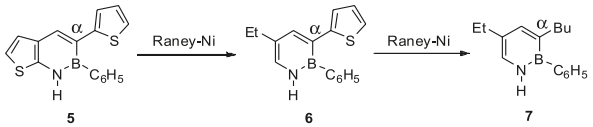


Scheme 2.



Scheme 3.



In 2000, a communication by Ashe reported the synthesis of **8a** via condensation of in situ generated allylboron dichloride with ethylallylamine, followed by installation of the B-phenyl group, ring-closing metathesis, and oxidation with DDQ (Scheme 4) (27). In the subsequent year, this same group reported the synthesis of compounds **8** via a ring-expansion reaction of **9** with CH_2Cl_2 and an appropriate lithium base (Scheme 5) (28); overall yields in this latter methodology showed a modest improvement (~35% vs. ~25%). Complexation with $Cr(CO)_3$ and $Mo(CO)_3$ showed compounds **8** to be viable π-ligands, and allowed the first crystallographic characterization of the BN-benzene ring. Here, the BN bond was found to be 1.466(6) Å, suggesting delocalized π-bonding.

The reaction of **10** (the conjugate base of **4**) with $[Cp^*RuCl]_4$ gave rise to mixed sandwich Ru complex **11** (Scheme 6) (29). The N atom of this complex could be protonated by acetic acid, and the acid was determined to have a pK_a of 9.21 ± 0.10 in 85% MeOH/H_2O. This complex was also examined for utility as a nucleophilic catalyst in the acylation of benzyl alcohol with phenylethylketene, but was found to have significantly lower activity than conventional catalysts.

Crystallographic analysis of a derivative of **4** without a directly coordinated metal was first accomplished by Ashe and co-workers in 2006 on the 2-($PhCr(CO)_3$) substituted compound **12** (Fig. 1, Scheme 7) (30). The B–N bond length of 1.430(5) Å was in the appropriate range for a BN double bond, while the bond lengths throughout this ring provided evidence for significant π delocalization. Complex **12** was formed as the thermodynamic product of **4** with $(MeCN)_3Cr(CO)_3$ in THF (Scheme 7), whereas the kinetic product was found to be **13**, suggesting that the phenyl ring serves as the better π-ligand to $Cr(CO)_3$. Conversely, the deprotonated analogues **14** and **15** exhibited the reverse haptotropic tendency, with 1,2-azaboratabenzene serving as the superior π-ligand in the anionic complexes. These migrations were determined to be largely intramolecular via deuterium-labeling studies.

Complimentary crystallographic data as well as reactivity towards electrophiles were communicated in 2007 by Ashe (31). This first investigation of classic aromatic substitution chemistry on a BN-benzene derivative (other than borazine)

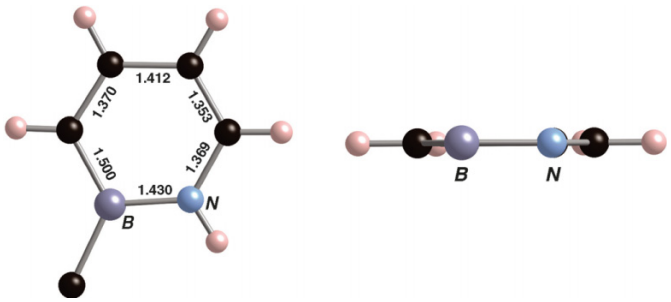
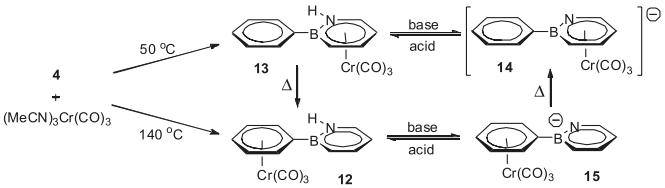


Scheme 7.



(32) revealed that the positions α (ortho) and γ (para) to boron were susceptible to electrophilic substitution (Scheme 8), in agreement with early investigations by Dewar on larger ring systems (vide infra) (33) as well as previous computations and predicted resonance stabilization (19). Compounds **16a–16c** and **17d–17e** were formed in poor-to-good yields (10%–91%).

Derivatization of the BN-benzene via nucleophilic substitution at boron was recently reported by Liu and co-workers (34). Thus, the reaction of chloro boron species **18** with several anionic nucleophiles, including H^-, proceeded in good yields (Scheme 9). A demonstration of the synthetic utility came with the formation of the BN analog of the hypolipidemic agent methyl 2-ethylphenoxyacetate **19i**, which was achieved through reaction of **18** with methyl glycolate.

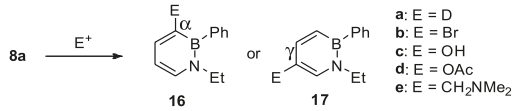
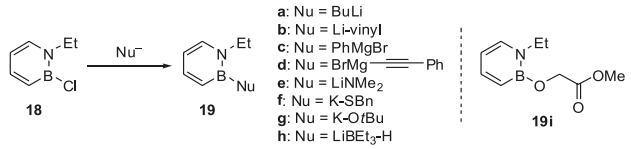


Scheme 9.



Bicyclic systems

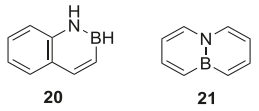
Bicyclic aromatics incorporating the isoelectronic BN unit were first synthesized by Dewar, utilizing condensation reactions of BCl_3 with appropriate olefinic amines to give the framework **20** (Chart 3) (35). Dewar also introduced the internalized BN-naphthalene isomer **21**, via hydroboration/cyclization of di-3-butenylamine with subsequent dehydrogenation (33). Spectroscopic and reactivity studies on **21** substantiated the claims that aromaticity was retained upon heteroatom substitution in the rings. The stability of BN-naphthalene **21** to ambient atmosphere is noteworthy, as hydrolysis of **20** had been observed to be appreciable under such conditions; this highlights the chemical stability imparted by "internalizing" the heteroatoms at ring junctions.

The ring-closing metathesis methodology introduced by Ashe (vide supra) was extended to give access to the **3a**,**7a**-azaborindenyl framework, isoelectronic to the indenyl framework (Scheme 10) (36). A zirconium complex of this ligand was structurally analogous to that of the all-carbon indenyl-supported zirconocene in that the metal associated most strongly with the three non-bridgehead atoms of the five-membered ring. Complexation with $Cr(CO)_3$ showed the formally anionic five-membered ring to be coordinating in the thermodynamic product, just as in BN-benzene complex **14** (30). Competition studies with the zirconium complex in the presence of indene showed the all-carbon system to be a superior π-ligand with free **22** recovered.

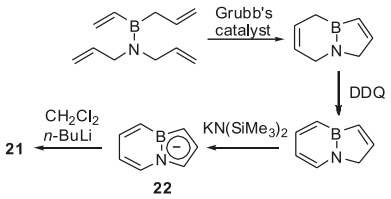
A new synthetic route to the BN-naphthalene isomer **21** was introduced by Ashe and co-workers in 2006, utilizing their ring-expansion methodology (vide supra) from **22** (Scheme 10). Overall yields of 5.6%, while still far from desirable, represented an improvement on the 0.2% optimized yield of the original synthesis (33). Importantly, the fully unsubstituted BN-naphthalene **21** was assessed by X-ray diffraction, and found to be isostructural with naphthalene, having an analogous herringbone morphology dominated by CH-π interactions and no π-stacking. Furthermore, the short BN bond (1.461(1) Å) was again in the appropriate range for this moiety within an aromatic ring.

The BN-naphthalene isomer **20** was re-visited by Paetzold and co-workers in 2004 (37). Following the procedure originally outlined by Dewar, they were able to access both halogenated and alkylated (at B) derivatives via condensation of 2-aminostyrene with appropriate haloboranes (Scheme 11). Introduction of water to the chloro derivative **23a** resulted in an equilibrium mixture of the oxide **24** with the 2-hydroxy derivative **23d**. Such behaviour, in which the B–OH group serves as a protic acid, has been noted in several boron aromatics and has been taken as evidence for their aromatic stability, as boron more commonly serves as a Lewis acid under similar conditions (6).

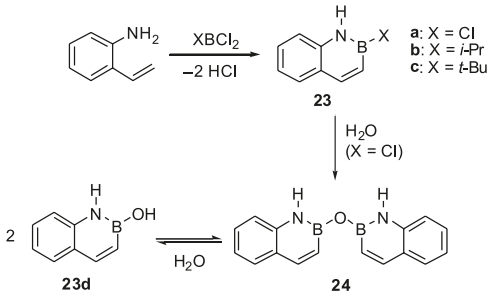
Chart 3.



Scheme 10.



Scheme 11.



Using a different approach, derivatives were also obtained in an electrophilic addition of *N*-methyl aminoborane **25** to phenylacetylene, giving **26** (Scheme 12). Reaction of this derivative with $(MeCN)_3Cr(CO)_3$ afforded an η^6 complex with the transition-metal fragment associated with the annulated homoaromatic C6 ring only.

Kar and co-workers computed the stabilities of mono-BN-naphthalenes and determined the isomer **27** to be most stable (Chart 4) (12). Interestingly, this derivative is the "inverse" of isomer **20** (i.e., formed by interchanging B and N atoms), which was omitted from Kar's study. The internalized isomer **21** was third in this stability study, 2 kcal mol^{-1} higher in energy than **28** and almost equivalent in energy to **29**. The least stable variant was **30**, the inverse of **28**, though no rationale for this disparity was offered.

Tricyclic systems

Among the first BN isoelectronic aromatics synthesized by Dewar were the BN-phenanthrenes **31** (Scheme 13), which he studied extensively (5, 38, 39). The original synthesis involved condensation of 2-aminobiphenyl with BCl_3, followed by heating of the crude product to 170 °C with $AlCl_3$. Treatment of the chloride **31a** with $LiAlH_4$ afforded the unsubstituted **31b**, which was found to be air- and moisture-stable. Similar strategies produced analogues of anthracene incorporating two BN moieties (40). Recently, **31b** was utilized as a precursor in the interest of developing boron-doped mesophase pitches, with thermostability superior to that of carbonaceous materials (41).

Scheme 12.

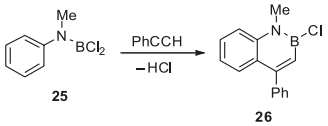

Chart 4.

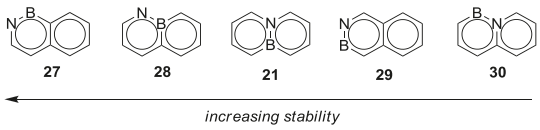
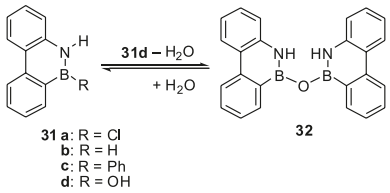


Scheme 13.



The hydroxy derivative **31d** was investigated in a crystal-engineering study by Philp and co-workers (42, 43), thus providing the first crystallographic analysis of Dewar's BN-phenanthrene framework and verifying the π character of the B–N bond. Drawing an analogy between BN aromatics and carboxylic acids, empirical predictions regarding the intermolecular behaviour were verified in the solid-state structure (Fig. 2), though the dimerization did not appear to be general. Their studies further utilized the ease of dehydration of **31d**, leading to the anhydride **32** (Scheme 13).

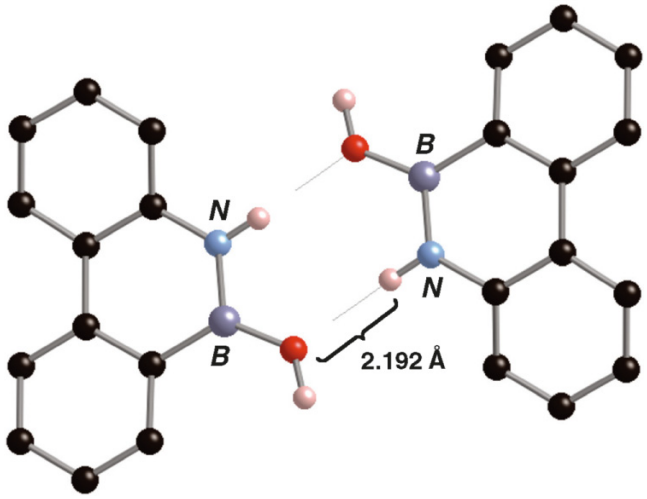
A different route into this BN-phenanthrene skeleton was attempted by Zanirato, who explored the reactivity of dichlorophenylborane with various aromatic azides (44). Formation of the transient Lewis acid–base adduct led to extrusion of dinitrogen with the simultaneous 1,2 shift of the phenyl group to the aryl nitrogen (Scheme 14). Intramolecular condensation with the loss of HCl resulted in the desired C_4BN framework. This methodology was found to lack generality, and in fact was successful only with thiophene derivatives giving **33** and its regioisomers; reaction with 2-azidobiphenyl produced a mixture of phenylated aminobiphenyl and carbazole.

Zanirato's work followed from work with Gronowitz on bisthiophene-annulated BN-benzene derivatives such as **33** (45). Several isomers were formed, differing in the orientation of the annulated thiophenes, though all were found to have comparable absorption features to that of benz-annulated derivatives **31**.

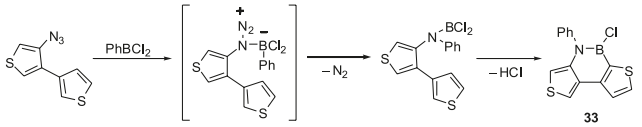
Dewar also introduced the isomer **34**, featuring "internalized" B and N atoms (Scheme 15) (46). Relatively little work was done on this species, despite the predicted stability of the ring system bearing heteroatoms at the ring junctions. The analogous reaction scheme was utilized by Dewar to access "internalized" BN- (47) and B_3N_3-triphenylenes (23).

Another isomeric BN-phenanthrene permutation, **36**, was reported in 2007 by Piers and co-workers (48). The new isomer, also featuring internalized heteroatoms, was formed via cycloisomerization of the transient alkynyl substituted borabenzene–pyridine adduct **35** (Scheme 16).

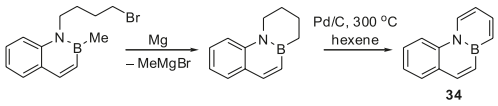
Fig. 2. Hydrogen-bonded dimer of **31d**, highlighting the similarity to the dimeric association of carboxylic acids in the solid state. Hydrogen atoms on the homoaromatic rings have been omitted for clarity.



Scheme 14.



Scheme 15.



BN-phenanthrenes **36a**–**36e** were found to be stable to aqueous media but suffered decomposition upon prolonged exposure to molecular oxygen. Blue fluorescence was exhibited, with good quantum efficiencies (ϕ_f = 0.38–0.62). As with **36a**, the quantum yield of the isomer **31b** was also found to be significantly greater than that of the all-carbon analog, though the emission wavelength remained indicative of an "organic" fluorophore. That is, whereas the BN moiety of **36** clearly participated in the fluorescence event, the same cannot be said of this moiety in **31**, where the role was more that of an inorganic linker that orients the biphenyl chromophore. Crystallographic analysis revealed the BN bond to be slightly longer than is typical for BN aromatics (1.491(2) Å), but this is consistent with the elongation of the corresponding C–C bond in phenanthrene (49).

Dimeric BN-phenanthrene analogues have also been investigated (50). Compounds **37** and **38** were prepared in one step from the reaction of 2 equiv. of 2-ethynylpyridines with either 2,2′-(51) or 4,4′-diborabiphenyl precursors (Scheme 17) (52). In the crystal structure of **38**, the two BN-phenanthrene units were observed to be orthogonal to each other, resulting in no significant intra- or intermolecular π–π stacking interactions. Both compounds exhibited fluorescence that was significantly red-shifted relative to the monomer **36**, suggestive of communication between the BN-phenanthrene moieties. That these compounds were observed to be emissive is

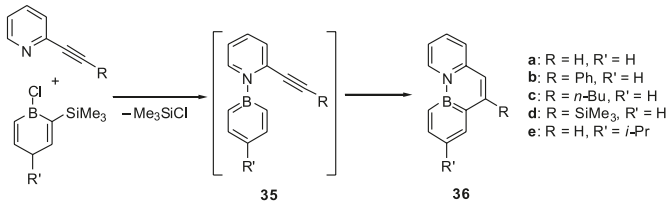
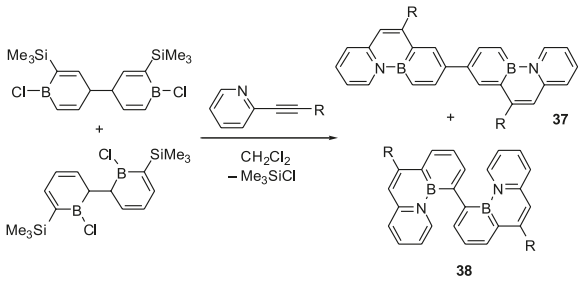


Scheme 17.



in contrast to B_2N_2-quaterphenyl analogues without "buttressing" ethene groups (vide infra).

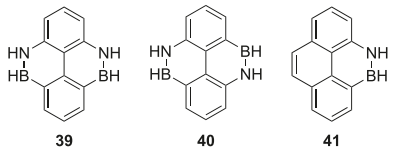
Tetracyclic systems

The original BN-pyrene **39** was synthesized from 2,6-diaminobiphenyl by Dewar and co-workers following an analogous route to that for **31** (Chart 5) (35, 40). Interestingly, the isomer **40** could not be obtained in this manner, presumably due to deactivation of the C6 ring toward Friedel–Crafts substitution by the first cyclization event. Additionally, the BN-pyrene **41** was formed from 4-aminophenanthrene, albeit with some difficultly (53).

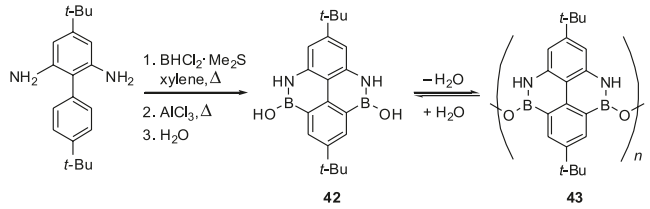
Philp and co-workers revisited the original synthesis in 2001, but also expanded on this system by incorporating solubilizing *t*-Bu groups in addition to forming the B-hydroxy (**42**) and methoxy derivatives (Scheme 18) (54). This investigation provided a crystallographic analysis, which again showed the π character of the B–N bond, with a distance of 1.427 Å. The formation of B–O–B anhydride oligomers **43** in solutions of **42** was assessed by MALDI-TOF, whereby it was shown that removal of trace water by 4 Å molecular sieves shifted the equilibrium to anhydride formation.

Again utilizing an ene-yne cycloisomerization strategy, Piers and co-workers reported the synthesis of **46** (Scheme 19) in which the BN moiety was fully encapsulated within an all-carbon framework (55). Starting from appropriately substituted 2,6-bis(alkynyl)pyridines, reaction with 4-alkyl-1-chloro-2-(trimethylsilyl)boracyclohexa-2,5-dienes gave **45** as the isolable product, though the transient borabenzene–pyridine adduct **44** could be isolated when R′ = –$SiMe_3$. Treatment of the intermediates **45** with catalytic $PtCl_2$ afforded the desired BN-pyrene analogues in good yields. As with **36**, the photophysical properties were found to be strongly influenced by the heteroatoms, giving green fluorescence in dilute solution, a bathochromic shift of ~120 nm compared with pyrene (56). As with the all-carbon analogue, **46a** was found to form excimers in concentrated cyclohexane solution, though the red-shift in excimer emission was much less pronounced than that observed with pyrene. The BN-pyrenes **46** were also found to undergo reversible one-electron reductions at potentials anodic to pyrene, and

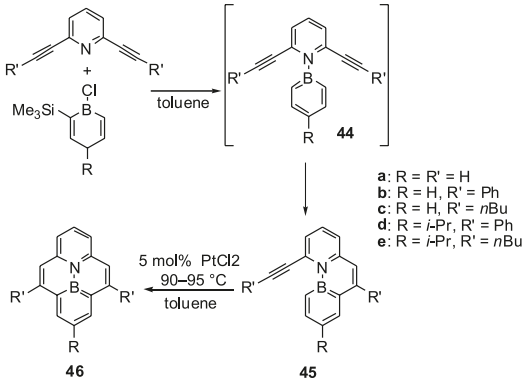
Chart 5.



Scheme 18.

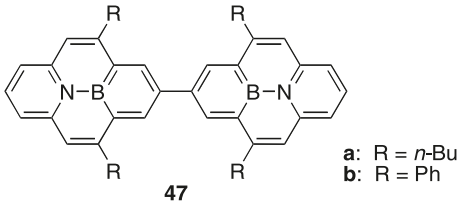


Scheme 19.



indeed radical anionic species were formed upon treatment with alkali metals.

As with the BN-phenanthrenes **37**, dimeric BN-pyrenes have been investigated (50). The emissive properties of derivatives **47a** and **47b** were found to deviate only slightly from the corresponding monomeric BN-pyrenes, despite the apparently extended π-system. The lack of π-communication between the two BN-pyrene units was attributed to the steric repulsion of the R substitutents, which forced the units to remain rigidly orthogonal to each other.



Nöth and co-workers formed the C_4BN framework within a tetracyclic framework via the cyclization of 9-fluorenylidene-tetramethylpiperidino-borane **48** with nitriles, giving rise to **49**, a BN analog of the PAH fluoranthene (Scheme 20) (57). The reaction was presumed to proceed by initial association of the Lewis basic nitrile nitrogen to the boron, followed by electrophilic attack of the nitrile carbon on the adjacent aromatic ring. Crystallographic analysis demonstrated the formed heterocyclic ring was not truly aromatic, as the endocyclic B–N bond in **49** was only slightly shorter than the exocyclic B–N bond (1.469(5) and 1.477(5) Å,

© 2008 NRC Canada

respectively), the former being somewhat longer than is typically realized in BN aromatics. Conversely, the C–B bond length of 1.490(5) Å was short, and indeed the ring consisted of alternating short and long bonds.

Heterocycles with two BN moieties

1,3-Diaza-2,4-diborinines

Of the $C_2B_2N_2$ aromatic ring structures, the 1,3-diaza-2,4-diborinine structure has been computed to be the most thermodynamically stable (20, 58). This result has not been borne out in synthetic work, though a few examples do exist. The benzene analogue **51** was reported first by Paetzold and co-workers and was formed from the 4 + 2 cycloaddition of dimethylacetylenedicarboxylate with diazadiboretidine **50** (Scheme 21) (59). No reaction was observed with less active dienophiles, such as 2-butyne or diphenylacetylene. Crystal structure analysis of **51** showed the ring to be highly twisted, with dihedral angles ranging from 7° to 29°, likely due to the bulky *t*-Bu substituents. Nevertheless, B–N bond lengths were in the range for typical structures (1.447(8)–1.460(8) Å).

A somewhat more generalized route to this ring system was first reported by Köster and Iwasaki and involved the dimerization of aromatic amine-borane adducts (Scheme 22) (60). The resulting B_2N_2-naphthalene **52** was readily susceptible to hydrolysis but stable to dry air. Notably, of the unsubstituted B_2N_2-naphthalenes, this isomer has been computed to be the most thermodynamically stable (12).

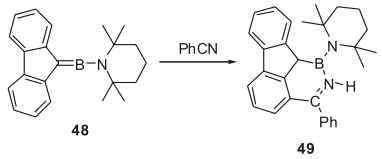
Work on this system since the time of the last review (6) has largely been accomplished by Frange and co-workers, who have investigated several such B_2N_2-naphthalenes with various substituents on the benzo and heteroaromatic rings. The crystal structure of methyl substituted **52** showed shortened, though alternating, B–N bond lengths of 1.405(4), 1.454(4), and 1.424(4) Å (61). The dihedral angles through the heteroaromatic ring show it to be significantly more planar than **51**, though still with minor puckering (maximum dihedral angle of 4.2°).

Frange's group extended the condensation methodology to include the formation of B_2N_2-phenanthrene **53** (62, 63) and B_2N_2-benz[*a*]anthracene **54** (Chart 6) (64). While not general, the formation of the "dimeric" 1,3,2,4 ring system (as opposed to the thermodynamic "trimeric" borazine products) was improved via the use of BBr_3 or BI_3 vs. the lighter haloboranes (61).

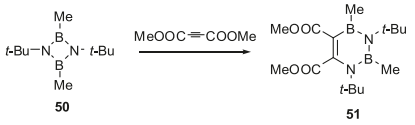
The reactivity of the heterocyclic framework **52** towards electrophilic metal centers has been investigated (65–67), and it was found that complexation occurred exclusively on the annulated homoaromatic C6 rings, giving a mixture of atropisomers. Bond lengths in the complexed ring were elongated by an average of 0.025 Å relative to the uncomplexed species, whereas in the heteroaromatic ring, bond lengths were increased by less than half this amount (67).

Bowser and co-workers have suggested that **55** (Chart 7), a bicyclic variant of the 1,3,2,4 ring system, may serve as a synthon for $C_{12}B_{24}N_{24}$ analogues of buckminsterfullerene (vide infra) (68, 69). While stoichiometrically appropriate, there have been no reports on the synthesis of either this precursor or the fullerene product. Additionally, this heterocyclic naphthalene isomer was not included in a computational study of the possible (and yet unknown) B_4N_4-naphthalenes, though the closely related **56** was deemed to have relatively low thermodynamic stability (12).

Scheme 20.



Scheme 21.



Scheme 22.

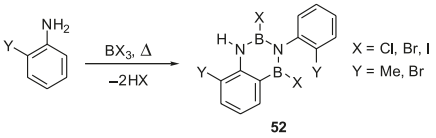


Chart 6.

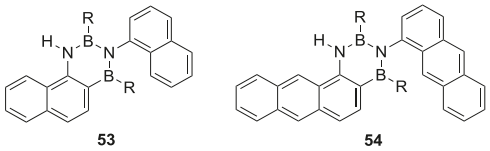

2,3-Diaza-1,4-diborinines

The 2,3-diaza-1,4-diborinine ring system was the first isolated example of an isoelectronic analogue of benzene with two BN units, despite computations suggesting this heterocycle to be less stable than the 1,3-diaza-2,4-diborinine ring by over 50 kcal/mol (20, 58). The substituted derivative **57** was achieved by Siebert via the reaction of thiadiborolenes with hydrazines, giving an air-sensitive liquid (Scheme 23) (70, 71). Crystals suitable for X-ray analysis were isolated at low temperature, and revealed a planar structure with endocyclic bond lengths indicative of a delocalized system, though the very short B–N bonds (1.387(4) Å) were closer to that of a pure B–N double bond. Subsequent treatment of **57** with $(MeCN)_3Cr(CO)_3$ afforded the corresponding η^6-$Cr(CO)_3$ complexes **58**, which were also studied crystallographically. Here, metal complexation in **58a** caused elongation of the B–N bonds to 1.41(2) and 1.44(1) Å, as well as a considerable upfield shift in the ^{11}B NMR resonance, from 33.9 (**57a**) to 22.8 (**58a**) ppm, both in accordance with the participation of the π-orbitals in the metal interaction.

The first polycyclic compounds with this ring system were B_2N_2-triphenylene analogues **59**–**61**, prepared by Piers

© 2008 NRC Canada

Chart 7.

55 **56**

et al. (51, 52). Formed via reaction of a 2,2′-diborabiphenyl precursor with pyridazine Lewis bases (Scheme 24), the polycyclic species were found to undergo (in most examples) two reversible one-electron reductions, and indeed radical anionic species were crystallograpically characterized for two derivatives upon reduction with $CoCp^*_2$. A marked increase in the B–N bond length was observed in going from the neutral species **59a** ($B–N_{avg.}$ = 1.458 Å) to the radical anion ($B–N_{avg.}$ = 1.484 Å), in agreement with the predicted B–N antibonding character of the SOMO (52). Derivatives **59a** and **60** were also found to be weakly fluorescent (ϕ_f = 0.02–0.08), with yellow–orange (**59a**) to green emission (**60**), which correlates well with the emissive efficiency of all-carbon triphenylene (ϕ_f = 0.07). Compounds **59b** and **61** were found to be non-fluorescent due to large twists imposed by steric interactions with protons α to boron, thereby disrupting the conjugation through the molecules.

1,4-Diaza-2,3-diborinines

Relatively few examples of the 1,4-diaza-2,3-diborinine ring system have been reported, and there are no examples of a monocyclic species, though calculations suggest that the ring should be more stable than the 2,3-diaza-1,4-diborinine ring by ~10 kcal/mol (20, 58). At the time of the previous review, there were only three examples of the 1,4-diaza-2,3-diborinine ring, all offered by Nöth and co-workers (6). Analogues of naphthalene (**63**), phenanthrene (**64**), and anthracene (**65**) were formed via condensation of dialkyldiborabis(dimethylamide)s with an appropriate *ortho*-diamino aromatic precursor (Chart 8) (72). It was later shown that complexation of **63** with $Cr(CO)_3$ occurred at the homoaromatic ring, as evidenced by the small downfield shift in the ^{11}B NMR and the considerable upfield shift of the aromatic protons in the ^1H NMR (73).

More recently, Cowley, Marder, and Norman prepared **66**, which can be considered an *oxo*-bridged dimer of the 1,4-diaza-2,3-diborinine heterocycle (74). This product resulted from the reaction of $B_2(OMe)_4$ with Li_2[dab] (dab = 1,4-di-*tert*-butyl-1,4-diazabutadiene), and was obtained as colourless crystals (Scheme 25). Though the focus of this account was the central B_4O_2 ring, the bond lengths for the external heterocycles were found to be in the appropriate ranges for typical BN compounds, with average distances of 1.429, 1.405, and 1.338(3) Å for B–N, N–C, and C–C bonds, respectively. Notably, this is the only reported crystal structure of a six-membered aromatic ring incorporating a B–B bond, which was found to be 1.683(3) Å. Comparison with average B–B lengths of 1.731 Å in similar structures having a B_4O_2 ring with acyclic groups on the B atoms shows that the B–B distances of **66** are appreciably shortened (75), presumably due to conjugation through these atoms. Furthermore, the

Scheme 23.

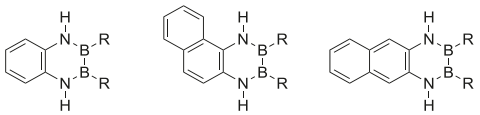
60 **61**

Chart 8.



63 **64** **65**

$C_2B_2N_2$ ring in **66** was found to be planar, with a maximum dihedral angle of 4.5°.

1,5-Diaza-2,4-diborinines

The only example of the 1,5-diaza-2,4-diborinine ring system was reported by Roesler and co-workers in 2006 (76). The six π-electron ring **67** was achieved in two steps starting from the condensation of a trimethylsilyl formamidinate with 1,1-bis(methylchloroboryl)ethane in the presence of trimethylsilyl triflate (Scheme 26). Crystallographic analysis of both **67** and deprotonated **68** revealed a planar arrangement of the ring atoms, though the relatively long B–N bond lengths (avg. = 1.498 Å) suggested that the π electrons were distributed over hetero-allyl fragments (B_2C^- and N_2C^+) rather than being fully delocalized around the ring. This bonding situation was previously predicted using MNDO calculations (58), though more recent analysis of the electronic structure suggests some degree of aromaticity (77).

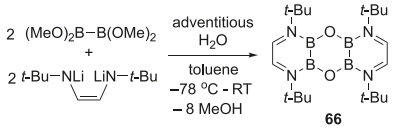
Five-membered rings

Cyclopentadiene analogues with one BN moiety

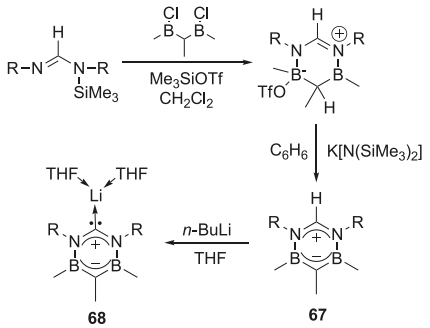
Numerous studies have considered the influence of incorporating BN into fullerene and nanotube frameworks. It is

© 2008 NRC Canada

Scheme 25.



Scheme 26.



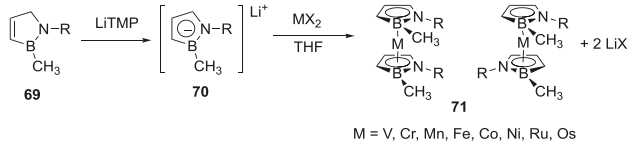
thus useful to consider not only BN substitution in six-membered rings, but also five-membered rings.

The BN analogue of the cyclopentadienyl anion (Cp), 1,2-azaborolyl (abbreviated here as Ab), was first reported by Schmid in the 1980s (78). His compounds were formed via deprotonation of **69** with LTMP affording the lithium salts **70**, which were subsequently ligated to numerous transition metals via salt elimination (Scheme 27). The sandwich complexes **71** displayed predictable bonding arrangements in the solid state. Thus, complexes with relatively electron-rich metals, such as Co and Ni, had significantly diminished interaction with the donor N atom of the Ab ring, to such an extreme in the nickelocene analog that the bonding was more accurately depicted as η^3, in which the BN unit served as a linker for an allyl ligand. Conversely, the sandwich complex formed with Fe showed delocalized bonding throughout the ligand and as such the Ab ring was appreciably isoelectronic and isosteric with Cp. The *meso* and *rac* diastereomers formed in these syntheses were formed in equal proportions and were thus energetically equivalent.

Schmid has also reported complexes of Ab with main-group elements. One such study addressed the structural behaviour of beryllocene, taking advantage of the diastereomeric Ab_2Be complexes to better assess both solid-state and solution behaviour (79). As in beryllocene, Ab_2Be was found to assume η^5 binding to one ligand, and η^1 bonding to a carbon atom of the other. Upon isolating by fractional crystallization one of the Ab_2Be diastereomers and storing this in C_6D_6 or toluene-d_8 for five days, a 1:1 mixture of diastereomers was re-established. Further, the mixed complex AbCpBe **72** could be formed by combining solutions of Ab_2Be and Cp_2Be. These results suggested that dissociation of one of the ligated rings was occurring to give an ion pair (Scheme 28). This was confirmed by variable temperature (VT)-NMR experiments, as well as the observation that THF solutions of AbCpBe were significantly conductive.

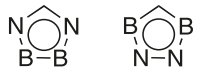
More recently, the groups of Ashe and Fu have reported more synthetically useful methodologies to the BN–Cp framework. In 2000, the former group employed the ruthenium-catalyzed ring-closing metathesis of a vinyl/allyl substituted aminoborane to give the cyclic heterocycle **73**, which upon deprotonation gave the desired 1,2-azaborolyl **9d** (Scheme 29) (27). Fu's method was very similar to that of Schmid, but involved treatment of the B–Cl heterocycle **74** with various nucleophiles prior to salt metathesis (Scheme 30) (80), thereby introducing a "tunability" at boron. Indeed, the donor properties as a function of Nu could be monitored by measuring the CO stretching frequencies of $Cr(CO)_3$ complexes **77** via IR spectroscopy. Both groups reported the facile coordination of the BN–Cp analogue to various transition metals, including Zr, Ru, and Co, giving analogues of known Cp complexes (27, 80, 81).

Scheme 27.



Fu has also generated enantiopure iron(II) complexes with the Ab ligand and shown them to be viable in promoting highly stereoselective aldol reactions (82). Starting from complex **78**, a racemic mixture of the B–OH compounds **79** could be achieved (Scheme 31), which was subsequently resolved by chiral HPLC.

Cyclopentadiene analogues with two BN moieties



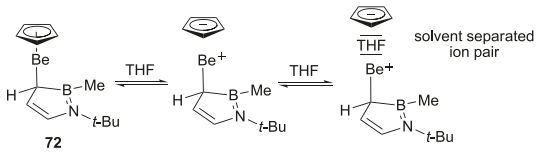
A heterocyclic Cp analogue with two BN moieties was first communicated by Roesler and co-workers (83, 84). Thus, condensation of $MeCH(RBCl)_2$ with di*iso*propylhydrazine afforded **80**, which was subsequently deprotonated with an appropriate alkali-metal base to give **81** (Scheme 32). All alkali-metal salts were observed to exist as sandwich complexes in the solid state, though none via η^5 coordination. This is in contrast to analogous η^5 Cp complexes, and coupled with the longer metal–ligand atom distances, suggests that the heterocycles are poorer π ligands than Cp. Endocyclic B–C and B–N bonds lengths were comparable to those in other BN heterocycles (1.50 Å and 1.46 Å avg., respectively), though the N–N bond lengths of 1.45–1.46 Å were indicative of a single bond. Slight deviations from planarity in the ring were noted in the structures of **81c** and **81d**.

Reaction of the alkali-metal salts **81** with group 12 metal dihalides resulted in sandwich complexes **82**, which demonstrated η^1:η^1 (M′ = Hg, Cd) or η^3:η^3 (M′ = Zn) binding centered at the ring carbon atom (83, 85). While structurally comparable to bis cyclopentadienyl analogues, the lessened σ character of the ring carbon in the heterocyclic complexes suggested increased π stabilization through the electron-deficient boron atoms relative to that afforded by the cyclopentadienyl ligand.

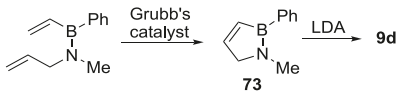
The B_2N_2 N-heterocyclic carbene **84** also recently reported by Roesler and co-workers (86), while formally isoelectronic to Cp, was found to be non-aromatic

© 2008 NRC Canada

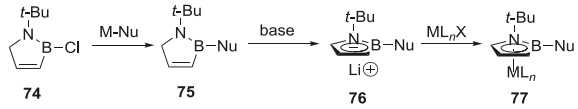
Scheme 28.



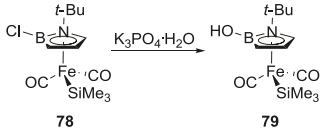
Scheme 29.



Scheme 30.



Scheme 31.



(Scheme 33). Specifically, the use of dimethylamino substituents at boron resulted in short exocyclic B–N bonds (1.377 Å avg.) and long endocyclic B–N bonds (1.465 Å avg.), and as such, the resulting heterocycle mirrored the bonding parameters of *iso*-propyl substituted N-heterocyclic carbenes; this was indeed reflected in the chemical behaviour of the B_2N_2 heterocycle. A subsequent computational study further verified the non-aromatic nature of **84** (77).

BN substitution in classic heteroaromatic compounds

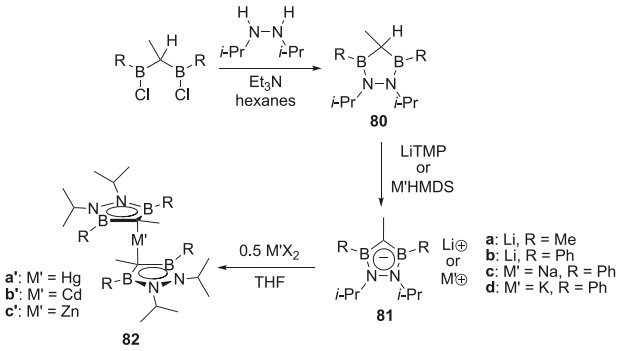
BN analogues of pyrazole, indole, and indolizine

Monocyclic pyrazole analogues

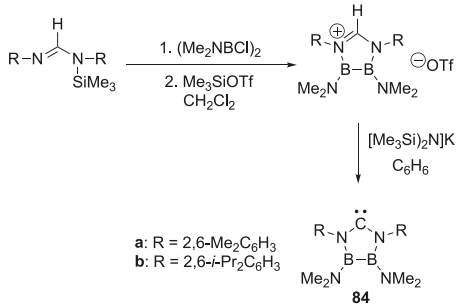
Diazaboroles are formed by the replacement of CC with BN in pyrrole. The first examples of this ring system without annulated rings were the work of Niedenzu (87) and Schmid (88). The synthesis and reactivity of these rings were the subject of a review in 2001 (89), and as such, only a few examples prior to that date are provided for comparison to other BN heterocycles.

The first $Cr(CO)_3$ complexes were reported in 1977 by the group of Schmid (90, 91). In these investigations, the *N*-phenyl heterocycle formed the phenyl-complexed derivative **85** as opposed to η^5 coordination to the heteroaromatic ring. Without phenyl substituents, η^5 bound **86** was formed, and subsequent treatment with $NOPF_6$ afforded the cationic nitrosyl complex **87** (Scheme 34) (91).

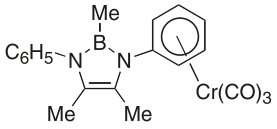
Scheme 32.



Scheme 33.

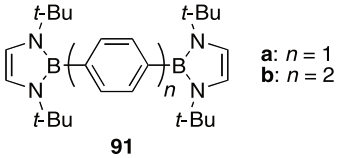


Subsequent work by Schmid led to a crystallographic analysis of the derivative **89**, which verified the planar geometry and sp^2 hybridization of the ring atoms (92). In the case of precursor **88**, dehydrogenation also resulted in dimerization to give **90** (Scheme 35), though the two rings were canted out of conjugation in the solid-state structure.



85

More recently, Weber and co-workers have investigated bis(diazaborole) compounds with bridging aromatic groups (93). Thus, phenyl- and biphenyl-bridged derivatives **91a** and **91b** were characterized by multinuclear NMR, UV–vis, and fluorescence spectroscopies, though only **91b** was found to be emissive. Additionally, a 1,3,5-trisubstituted benzene derivative was reported and crystallographically characterized. Cyclic voltammetry showed that compounds **91** undergo irreversible oxidation.

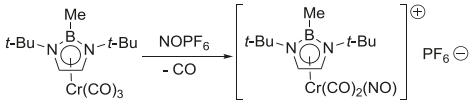


91

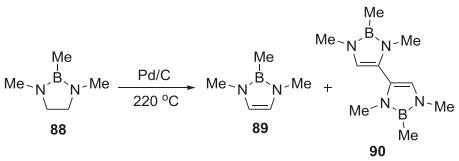
Ferrocenyl derivatives **92** and **93** were obtained by the reaction of (dibromoboryl)ferrocene or 1,1′-bis(dibromoboryl)ferrocene with diazabutadienes, followed by sodium amalgam reduction (Scheme 36) (94). Solid-state structures

© 2008 NRC Canada

Scheme 34.



Scheme 35.

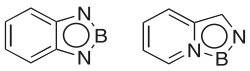


showed the absence of conjugation between the BN-pyrrole and the cyclopentadienyl ligands, though the heterocycles did serve as electron donors, leading to cathodic shifts in the oxidation potential of the iron center.

A relatively new line of investigation concerning this framework has been directed at producing boron heterocycles that are anionic and isoelectronic to Arduengo-type carbenes. Carbenes of this type are known to have some aromatic character, though this is a relatively minor contributor to the overall stability of the molecule (95). Initial computations by Schoeller suggested that Group IIIa carbenes of this ilk were viable synthetic targets, with boron retaining significant electron density (96). The carbene analogue boronide **96** was presumed as an intermediate in reductions of bromide **94** with alkali metals, which produced a mixture of **97** and **98** (Scheme 37) (97); no confirmatory evidence or further investigation of the novel species was provided in this report.

Subsequently, Yamashita and Nozaki succeeded in isolating and structurally characterizing the boryl anion **100** in 2006 (Scheme 38) (98). The lithium salt was obtained by reduction of 2,6-di*iso*propylphenyl substituted **99** with lithium naphthalide, and was structurally characterized. While formally a carbene analogue, the planar structure and shortened intracyclic bonds of **100** supports the existence of a delocalized π electron system (99). The boron center was protonated in the presence of water, giving borane **101**.

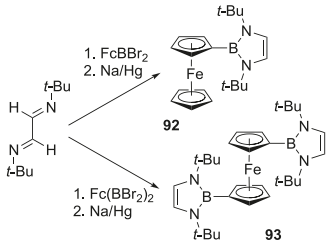
Polycyclic pyrazole analogues



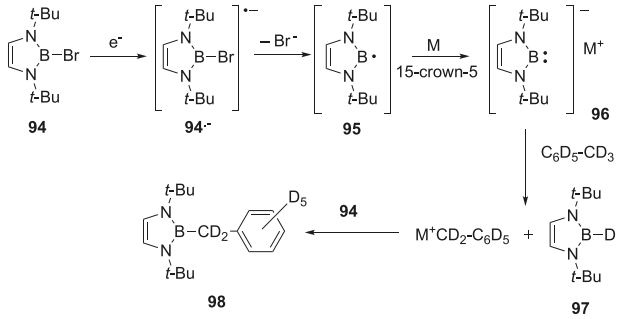
Much more extensively studied than their monocyclic counterparts are the bicyclic diazaborinine derivatives, which are BN derivatives of indole; in fact, this was the very first BN aromatic formed (100). The chemistry of this heterocycle was extensively reviewed by Fritsch (6), though there has been renewed interest in this system, as the appended benzene ring tends to enhance the emissive quantum efficiencies relative to the monocyclic BN-pyrroles (89).

A particularly facile synthesis of this ring system is the condensation of an *ortho*-phenylenediamine with boronic acids, a reaction that has even been shown to occur smoothly in the solid state (101). A useful synthon for various B-substituted analogues is **102a**, which can be obtained by

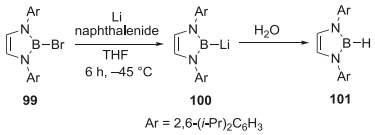
Scheme 36.



Scheme 37.



Scheme 38.



treating *N*,*N*′-diethyl-*o*-phenylenediamine with BBr_3, followed by CaH_2 (Scheme 39) (102). Thus, reaction of **102a** with AgCN or MeLi gave rise to B-cyano (**102b**) and B-methyl (**102c**) derivatives, respectively, whereas reaction with Na/K alloy gave the dimer **103**.

An interesting route to this heterocycle involved the thermally induced reductive transposition of B and C in borane adducts of 1,3-benzazoles **104** to give 1,3,2-benzazaboroles **105** (Scheme 40) (103). Isolobal products were formed, such that the X–C(sp^2)–N(sp^2)–B(sp^3) fragment became X–B(sp^2)–N(sp^2)–C(sp^3) (X = NH, O, S), as evidenced, in particular, by the marked downfield shift in the ^{11}B NMR (from approximately –22 to 23 ppm). In the case of the borane adduct of 1-ethyl-2-(*o*-methoxyphenyl)benzimidazole **106**, transposition was accompanied by loss of methane to give the tetracyclic product **107** (Scheme 41).

Parent complex **108** was functionalized at the nitrogen atoms by treatment with 2 equiv. of BuLi, affording **109**, which was subsequently quenched with Me_3SiCl to give **110** (Scheme 42) (104).

In 2002, Maruyama and Kawanishi reported the synthesis and photophysical properties of bis(diazaboroles) **111** and the more extensively conjugated derivatives **112** and **113** (Chart 9) (105). Compounds **111** and **112** were found to fluoresce violet–blue with excellent quantum efficiencies; **111b** had a quantum yield near unity. Phenalene-type derivative **113** was found to be non-emissive. Oxidation potentials for **111a**–**111c** were obtained and reflected the electron withdrawing/releasing nature of the substituents; these molecules were not stable to electrochemical reduction.

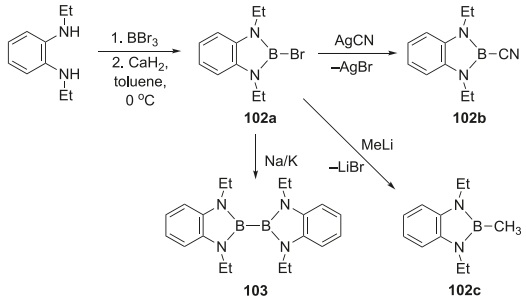
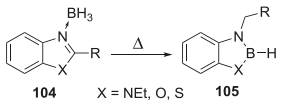
Scheme 39.



Scheme 40.



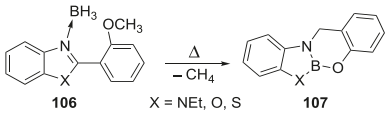
A series of BN-indole derivatives substituted or bridged by thiophene moieties were studied by Weber and coworkers in 2006 (Chart 10) (106). Compounds **114**–**115** were obtained via salt elimination from **102a** (Scheme 39) and lithiated thiophenes. Biphenyl bridged **118** was also investigated and had the largest Stokes shift (123 nm) of all compounds in this study. Bisthiophene derivative **117** was characterized crystallographically and showed the 1,3,2-benzodiazaborole group to be planar with BN bond lengths of 1.431(5) and 1.440(4) Å. Additionally, **114a** and **114b** were found to serve as fluoride-ion sensors, as monitored by the reversible quenching of fluorescence upon addition of *n*-Bu_4NF.

Alkyne-functionalized examples of both BN-pyrroles and BN-indoles were achieved, again via salt-elimination protocols (107). Successful formation of the terminal alkyne **120** came by way of the B-cyano derivative **119** (Scheme 43), though the same reaction with **122** led to an ethylenediamine-linked dimer **123** (Scheme 44) (102). Alkyne-bridged species **121** was accessible from **120**, and these were observed to undergo two oxidative processes, suggesting communication between the two heterocycles across the C_2 bridge.

Polymeric species incorporating this BN heterocycle have also been investigated (108). Polyacenaphthalene with diazaborole side chains was formed by thalliation of the parent polymer with thallium trifluoroacetate, followed by borylation and hydration to give a polymer with boronic acid functions on ca. 30% of the acenaphthalene units (Scheme 45). Subsequent treatment with *p*-nitro-*o*-phenylenediamine gave polymer **124**.

In follow-up work, this bicyclic BN aromatic was more intimately incorporated into the polymer chain, giving rise to photoluminescent polyphenylene derivatives (109). Thus, Suzuki coupling of 1,4-dibromo-2,3-phenylenediamine with 2,7-bis(1,3,2-dioxaborolan-2-yl)-9,9′-dioctylfluorene gave copolymer **125** in high yields. Reaction with aryl boronic acids gave the polymer **126**, with >80% incorporation of the boron substituents (Scheme 46). Polymer **126** exhibited both higher quantum efficiencies and higher oxidation potentials than **125**, clearly manifesting the benefits of incorporation of BN functions into these frameworks.

Scheme 41.



Scheme 42.

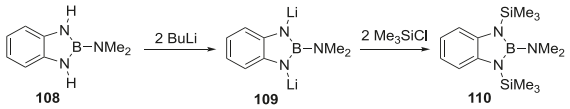


Chart 9.

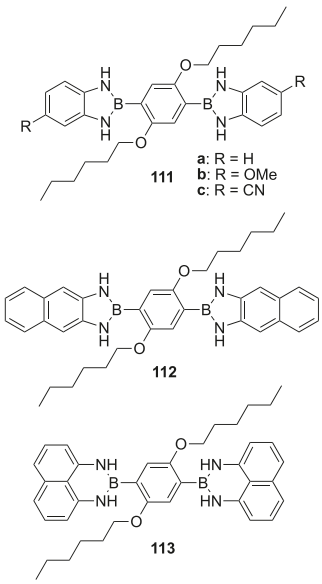

Chart 10.

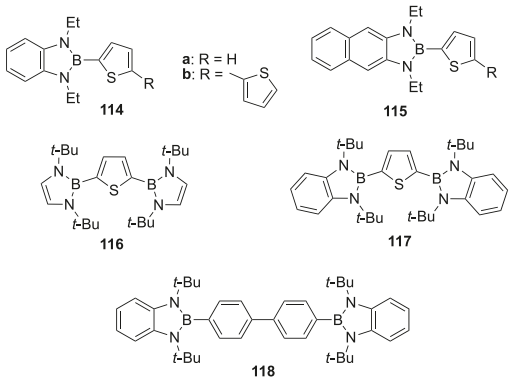

Habereder and Nöth used salt elimination strategies to access derivatives **128** with Group 14 elements in the interest of preparing versatile intermediates for organic chemistry via oxidative addition to Pt(0) (Scheme 47) (110). Examples of all were obtained and crystallographically characterized, though only the trimethylstannyl derivative **128d** was observed to undergo oxidative addition of the B–E bond to $(\eta^2\text{-}C_2H_4)Pt(PPh_3)_3$, giving the cis Pt complex. The bromo-derivative **127** was the only other heterocycle to oxidatively add to the Pt(0) reagent but gave the trans product.

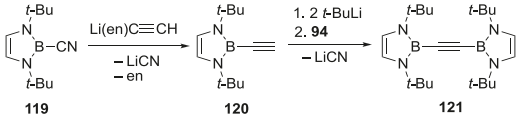
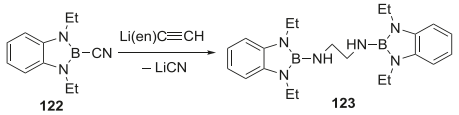
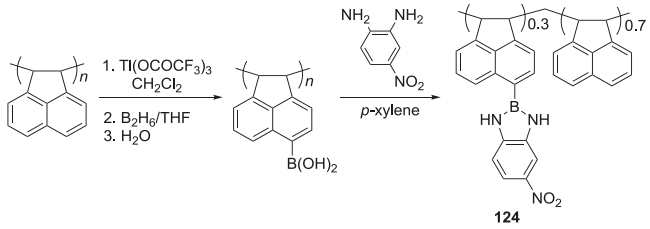
Scheme 43.



Scheme 44.

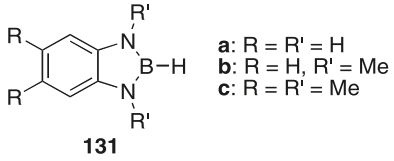


Scheme 45.



The oxidative addition of the B–CN bond of **129** to palladium(0) was studied by Suginome and co-workers (111). Thus, in the presence of 5 mol% Pd catalyst, alkynes could be cyanoborated in near quantitative yields, giving substituted acrylonitriles **130** (Scheme 48). Good regioselectivities were observed with unsymmetrical alkynes. Mechanistic studies corroborated the reversible nature of the oxidative addition (112).

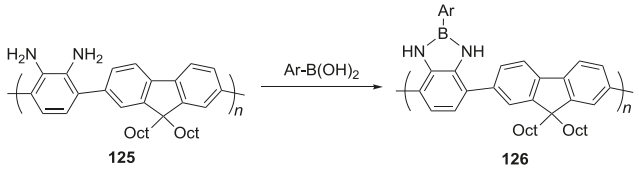
Rhodium-catalyzed hydroborations of terminal olefins with **131** were investigated by Hadebe and Robinson, and showed the diazaborinine to be a competent reagent for functionalization of olefins (113). No reaction with internal olefins was observed. Further, **131** was particularly robust relative to the more common pinacol- and catechol-boranes, as no disproportionation of the borane was observed. The resistance of **131** towards forming metal boryl complexes has also been noted in the case of Ru(II) (114), though Hartwig was able to crystallographically characterize a family of boryl-bridged Ru dimers with the *N*-methyl derivatives **131a** and **131b** (115).



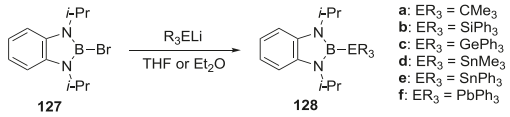
a: R = R' = H
b: R = H, R' = Me
c: R = R' = Me

A BN analogue of indolizine was first reported by Weber and co-workers in 2001 (116). Reaction of a pyridine carbaldimine with BBr_3 afforded the bicyclic diazaborolium salt **132**, which was subsequently reduced with excess sodium amalgam to give **133** in good yield (Scheme 49). Heterocycle **133** could be readily converted into a number of different B-substituted derivatives by standard means. Crystallographic analysis of the B-cyano derivative revealed alternating bond lengths in the pyridine ring but an overall planar structure with BN bond lengths of 1.420(2) and 1.429(2) Å. Attempts to form diazomethane complexes were marginally successful, as the products could not be purified (117). Similarly, a ferrocenyl derivative analogous to **92** was formed but also proved relatively unstable (94).

Scheme 46.



Scheme 47.



Scheme 48.

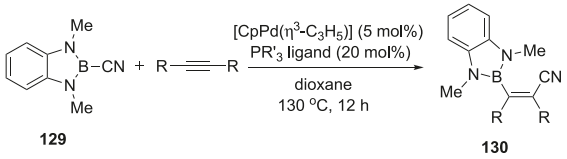


Chart 11.

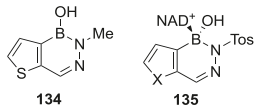

BN analogues of pyridine and related polycycles

An interesting class of heteroaromatic compounds arising from BN substitution is the BN-isoquinoline series, formed by the conceptual annulation of a (hetero)aromatic ring to a BN-pyridine analogue. First reported by Dewar (118), these compounds have been extensively studied as antibacterial agents since the late 1960s, and more recently have also been found to inhibit the growth of yeast cells (119). The mechanism of action has been increasingly well-understood, though detailed discussion of the biochemical activity is deferred to the recent literature (3, 120–123). Crystallographic analysis of the 2-methyl substituted 2,3,1-benzodiazaborine **134** showed the rings to be planar, with a B–N distance of 1.433(3) Å (124), though Baldock and co-workers were able to characterize the tetrahedral borate complex **135** in the active site of enoyl reductase (Chart 11), indicating that the Lewis acidity of the B center is important in the function of these compounds (121). Thus, in the presence of NAD^+ the molecule forms a borate complex, which binds strongly to the active site of enoyl reductase. Replacement of the BN moiety with CC resulted in an analogue devoid of biological activity (125), demonstrating the key importance of the B-hydroxy group.

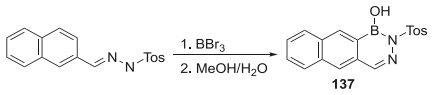

Chart 12.

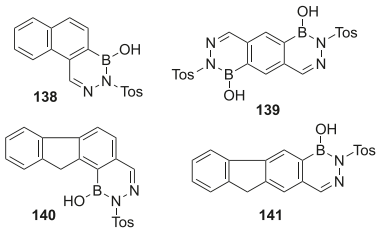
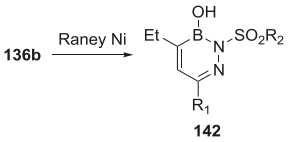


The original synthesis involved reaction of *ortho*-formylbenzeneboronic acids with hydrazine or its derivatives (118). Müller and Grassberger independently reported an alternative, more versatile route, which made use of a Lewis acid to promote the electrophilic attack of trihaloboranes on (organosulfonyl)hydrazones of (hetero)aromatic aldehydes and ketones, giving the target compounds **136** (Scheme 50) (125, 126). This route was tolerant to numerous functional groups on the (hetero)aromatic ring, though yields were significantly diminished with electron-withdrawing groups. Attempts by Müller to form tricyclic derivatives of this ilk resulted in the formation of anthracene-type derivative **137** only (Scheme 51), with no evidence of the conceivable phenanthrene-type analog (126). Grassberger reported the synthesis of another phenanthrene-type isomer **138**, as well as bifunctional **139** and tetracyclic analogues **140** and **141** (Chart 12) (125) using similar methodologies.

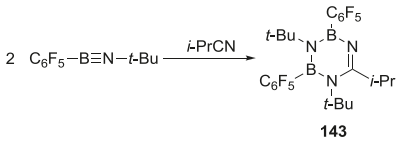
Numerous derivatives of this framework were reported by Gronowitz, most with an annulated thiophene moiety, as in **136b** (127). Reactivity of the BN-isoquinolines towards various electrophiles was extensively discussed in both Gronowitz's and Fritsch's reviews (6, 127).

Desulfurization of thiophene annulated derivatives such as **136b** with Raney nickel afforded BN-pyridine analogues **142** (Scheme 52), which were found to be much more stable than related BN-benzene derivatives and less polar than corresponding pyridines (128, 129). Indeed, Doerksen and Thakkar have recently calculated the polarity to be less than 0.71 D (11). Of the 10 possible BN-pyridines, these researchers found this N–N–B isomer to be 23.4 kcal/mol higher in energy than the isomer with N–B–N bonding.

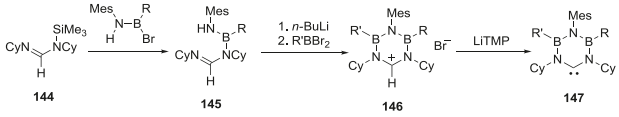
Scheme 52.



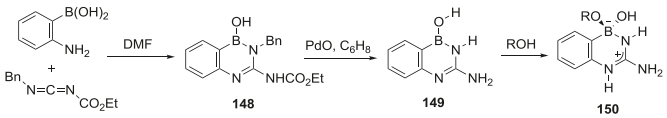
Scheme 53.



Scheme 54.



Scheme 55.



Substitution of two pyridine CC units with BN via the cycloaddition of *iso*propylnitrile to iminoborane **143** leads to formation of a B_2N_2-pyridine (Scheme 53) (130). In the solid-state structure, some degree of bond alternation was evident, though all were within the range expected for a delocalized π system (1.415–1.450 Å). The synthesis was not general and depended strongly on the nitrile used. Notably, this was computed to be the most stable substitution pattern of 16 possible B_2N_2-pyridines (11).

A related ring system was recently investigated by Bertrand as a heterocyclic carbene precursor (Scheme 54) (131). Derivatives without amino substituents at boron were prepared by reacting *N*-silylated formamide **144** with an appropriately substituted aminoborane, giving **145**. Deprotonation with *n*BuLi followed by the introduction of R′BBr_2 gave cationic **146**, which could be converted to the carbene **147** with LiTMP. Here, the reported structure was isoelectronic to benzene as opposed to pyridine, and π-electron delocalization was evident in the solid-state structure with B–N bond lengths of 1.43–1.44 Å. Indeed, electronic-structure calculations suggest some degree of aromaticity in this heterocyclic carbene (95). Upon introduction of 0.5 equiv. of bis(μ-chlorocyclooctadienerhodium), **147** served as a strong σ donor to the metal centre (131).

Groziak and co-workers have also investigated several BN heteroaromatic derivatives, and highlighted some similarities to biologically relevant molecules. Thus, condensation of 2-aminophenylboronic acid with 1-benzyl-3-(ethoxycarbonyl)carbodiimide afforded the BN-quinoline **148**, from which purine analogue **149** could be obtained via catalytic transfer hydrogenolysis (Scheme 55) (132). Exposure of **149** to weak nucleophiles, such as water or methanol, resulted in reversible 1,4-addition to the B and transannular N, giving **150**. More derivatives of this heterocyclic system, including

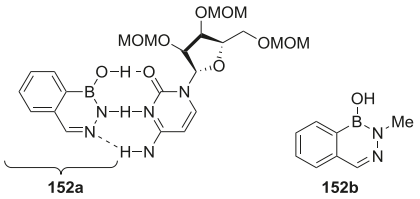
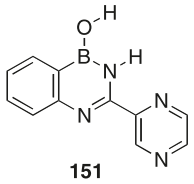
Chart 13.



152a 152b

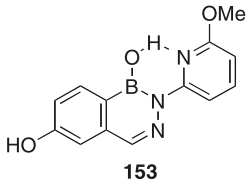
151, were synthesized by an analogous condensation procedure and tested for activity against *M. tuberculosis* by Martin and co-workers, though **151** was found to be quite ineffective (133).



151

In 1997, both the solid-state and solution hydrogen-bonding interactions of BN-isoquinolines were assessed, and similarities to the hydrogen-bonding motifs of nucleic acids were found (134). Specifically, hydroxy compound **152a** was shown to participate in hydrogen-bonding interactions with 2′,3′,5′-tri-*O*-(methoxymethyl)cytidine in the solid state, and in solution as demonstrated by VT-NMR spectroscopy (Chart 13). The hydrogen bonding was disrupted in the 2-methyl substituted derivative **152b** (124).

Groziak also reported the construction of derivative **153**, which, via intramolecular hydrogen bonding, resembled the tetracyclic molecule estrogen, both in solution and in the solid state (135). The maintenance of a downfield-shifted ^{1}H NMR resonance for BO*H* in DMSO-d_6 solution was indicative of a strong hydrogen bond in solutions, while X-ray crystallography established this interaction in the solid state.



153

Another ring system, which was hoped to have biological significance was the bicyclic BN-quinazoline **154** (Scheme 56), due to a resemblance to purine compounds (136). The reaction of lithium tris(trimethylenedioxyboryl)methide with 4,6-dichloro-5-formylpyrimidine, followed by treatment with liquid ammonia at 75 °C gave low yields of the desired product, though **154** proved exceedingly difficult to purify and characterize.

BN substitution in graphene morphologies

The graphene allotropes of carbon are well-known to exhibit interesting properties. Numerous computational investigations have examined the influence on doping these structures with boron and nitrogen, where interest stems from the possibility of tuning electronic properties by mixing appropriate stoichiometries of conductive (graphite) and insulating (boron nitride) species (2, 137, 138).

Scheme 56.

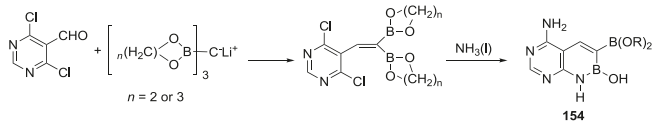


Chart 14.

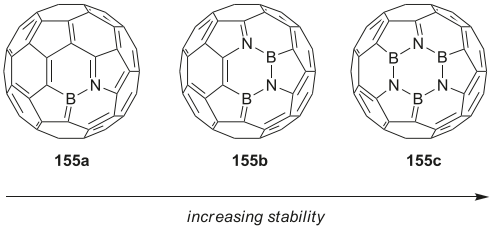


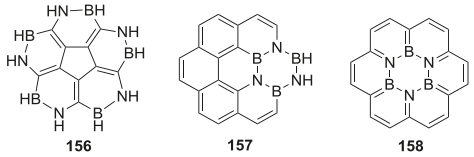
BN fullerenes

There have been numerous investigations of BN as a CC substitute in fullerenes, and much the same stability rules have been computed: greater stability is attained in substituting a contiguous BN unit as opposed to disconnected B and N atoms, and there is a preference for maximizing the number of B–N bonds when more than one CC group is replaced (139). For BN-fullerenes, the preferred site of BN substitution can be specifically located at the site of attachment between two six-membered rings, as in **155a** (Chart 14) (140, 141). Introduction of a second BN moiety favourably continues the alternating BN substitution within one of the hexagons (**155b**), while the third BN completes the six-membered ring, essentially forming the encapsulated borazine **155c** (142). The sequential introduction of more than three BN pairs has been investigated by Kar and co-workers by semi-empirical MNDO (142) and density functional theory (143), and similar substitution rules apply. Additionally, the requirement for maximizing the number of B–N bonds was found to result in the separation of heteroatom and carbon domains in more highly substituted analogues (143). In the case of $C_{48}B_6N_6$ isomers, the two structures containing two borazine rings on opposing sides of the molecule were found to be lowest in energy, with the S_6 symmetric isomer being lower in energy than the very similar D_3 isomer by only 2.9 kcal/mol (144). This result is in much better agreement with Kar's substitution rules than a previous study on the structures of $C_{48}B_6N_6$ isomers (145).

In general, BN-fullerenes are expected to exhibit lower HOMO–LUMO gaps, with the major contributor being higher energy HOMO levels (142). This suggests that the BN doped fullerenes should be more readily oxidized than C_{60}. More recent work suggests that this should be true for heterofullerenes with 10 or less BN units incorporated, while more highly heteroatom-substituted fullerenes may have a larger band gap than C_{60}, owing to higher LUMO levels (146). This trend was also observed in a recent time-dependent density functional theory study on the absorption properties of some B_xN_x-fullerenes (147). Hirsch, Thiel, and co-workers used nucleus independent chemical shift (NICS) calculations to show that the lower BN analogues ($C_{58}BN$,

© 2008 NRC Canada

Chart 15.



156 157 158

$C_{54}(BN)_3$, and $C_{48}(BN)_6$) should be more aromatic than all-carbon fullerene, whereas $C_{12}(BN)_{24}$ should be slightly less aromatic (148).

In light of the predicted destabilizing effects of B–B and N–N bonds in any of these heteroaromatic systems, the derivative $C_{12}(BN)_{24}$ represents the most highly BN-substituted derivative, which may be formed without forming any such bonds. It has been shown by numerous computational methods that this derivative should be stable, with a larger HOMO–LUMO gap than C_{60} (68, 69, 149–151), and minimal structural deviation (<5%) from that of the all-carbon analogue (150).

Isoelectronic BN substitution has also been investigated in other fullerene morphologies. Substitution in small fullerenes having anywhere from 20 to 50 atoms has been computed by several groups, from mono-BN (152, 153) to derivatives having "BN-belts" (154, 155) (as is found in $C_{12}(BN)_{24}$). Additionally, there has been one investigation of a $C_{129}BN$ bisfullerene (156). All of these investigations suggest that incorporation of BN significantly alters the electronic properties of the molecules without great structural perturbation.

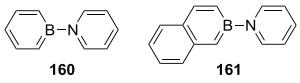
BN nanotubes

The effect of BN-doping in armchair single-walled carbon nanotubes (ASWCNTs) was recently investigated by AM1 methods by Zhang and co-workers (157). Their studies reiterated the importance of inserting a BN pair as opposed to isolated B and N atoms in mono-substituted ASWCNTs, while in di- and tri-BN-substituted species, isomers with sequential B–N–B–N and B–N–B–N–B–N contacts in a single ring were the thermodynamically favoured derivatives, just as in the substituted fullerenes (vide supra). Additionally, ionization potentials (IPs) were lowered and electron affinities (EAs) increased with increasing BN incorporation, resulting in larger HOMO–LUMO gaps relative to the all-carbon derivatives.

Computations on other morphologies

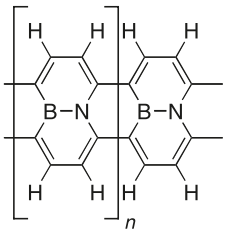
Substitution to give BN-corannulenes and BN-coronenes has been investigated by a couple of groups. Disch and Schulman found that substituting the five peripheral HCCH moieties of corannulene with HBNH units, giving **156** (Chart 15), drastically reduced the inversion barrier to less than 1 kcal/mol (158). Türker determined the effect of replacing an entire benzene unit from the periphery of coronenes with borazine and found the resulting structure **157** to be thermodynamically viable, with little influence on the HOMO–LUMO gap (159). In the same year, Fowler and co-workers investigated the structure and magnetic properties of internally borazine-substituted coronene **158**. Their computations predicted a planar D_{3h} structure with an internal diatropic ring current, as opposed to the paratropic internal ring current of coronene. They found the structure not only to be viable but also to possess an aromaticity very similar to that of the parent hydrocarbon (160). It has been proposed that the electronic eigenvalues of larger BN aromatics, such as coronenes, may be readily predicted via density functional theory (161).

Chart 16.



160 161

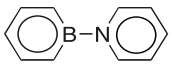
Finally, Tanaka and co-workers computed the HOMO–LUMO gap for BN-substituted polyperylene **159**, essentially a polymeric form of **21** (162). The isoelectronic substitution was found to decrease the band gap relative to the all-carbon system, by lowering the ionization potential and raising the electron affinity.



159

Other isoelectronic analogues of conjugated hydrocarbons

Intercyclic BN sustitution



The borabenzene–pyridine system **160** represents another mode of B–N substitution in aromatic systems (Chart 16). Specifically, the B–N pair substitutes a formal C–C single bond, and indeed the B–N bond lengths in these systems tend to be indicative of a B–N single bond. Nonetheless, the heteroatoms play a key role in the properties of the aromatic systems, and as such, they are worthy of comment here.

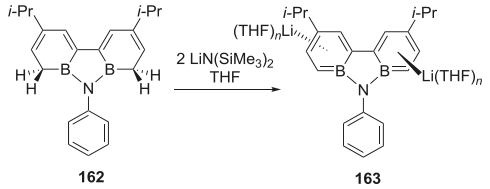
Reviews of borabenzene and boratabenzene chemistry were published in 1986 (163) and again in 2001 (164). The borabenzene–pyridine adduct was first described by Herberich in 1970, and the $Cr(CO)_3$ complex of this in 1985 by Schmid (165). Since the last review, investigations into the reactivity of this heteroaromatic framework have been largely the efforts of the group of Piers (vide infra) (166).

Schmid reported the synthesis of 2-boranaphthalene and its pyridine adduct **161** (167). The B–N bond of this adduct was notably shorter than that of **160**, which was attributed to extended conjugation between the ring systems. The $Cr(CO)_3$ complex was also reported, and was found, via crystallography, to be η^6 bound to the borabenzene ring, rather than the homoaromatic benzo ring (165).

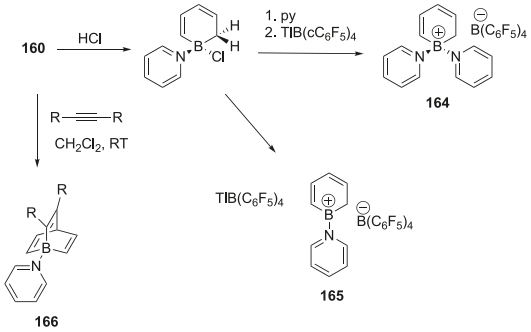
Piers and co-workers have attempted to exploit known reactivity patterns in these adducts to development methods for systematic functionalization of these heterocycles. For example, the carbon atoms α to boron are prone to

© 2008 NRC Canada

Scheme 57.



Scheme 58.



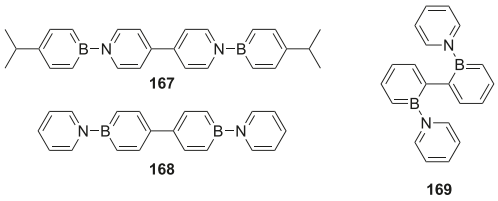
electrophilic attack, including protonation. They were thus able to access the dianionic B_2N analogue of fluorene **163** via **162** in the reaction depicted in Scheme 57 (168, 169). They also studied the reactivity of the parent compound **160** with pyridinium salts, giving access to rare examples of both four-coordinate boronium **164** and three-coordinate borenium ions **165** (Scheme 58) (170). Additionally, they discovered a new reactivity pattern for borabenzenes upon analysis of the frontier orbitals of the adduct **160**; these computations suggested that the HOMO of **160** was well-suited to serve as a diene for Diels–Alder-type reactivity, and indeed cycloadducts **166** were formed upon reaction with various dienophiles (Scheme 58). The products were dubbed "borabarrellene" adducts, highlighting the analogy to all-carbon barrellene.

More extended borabenzene–pyridine adducts have also been investigated by Piers' group, giving rise to B_2N_2 analogues of *ortho*- and *para*-quaterphenyl (Chart 17) (50). Two analogues of *p*-quaterphenyl, **167** and **168**, were investigated, and both were found to be non-fluorescent, in contrast to the parent hydrocarbon. The crystal structure of **167** showed it to possess a helical twist of the aromatic groups, hindering communication between the aromatic rings. The molecular structure of *o*-quaterphenyl analogue **169** demonstrated intramolecular π-stacking of the pyridine moieties, though this forced the aromatic rings out of coplanarity, and as such, this derivative was also found to be non-fluorescent.

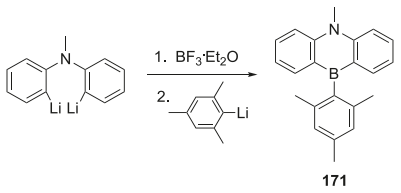
Disconnected B–N substitution: 1,4-azaborinines

The installation of B and N at disconnected ring positions has been computed to give rise to isoelectronic aromatic species, which are thermodynamically less stable than the more widely studied adjacent 1,2 substitution pattern (18–20). While a monocyclic derivative has not been reported, the 1,4

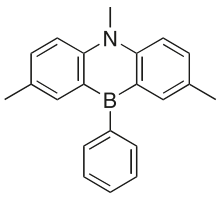
Chart 17.



Scheme 59.



system is viable and was first reported by Maitlis as the anthracene analogue **170** (171). In the presence of base, the corresponding borate was formed, though this could be reversed by re-acidification.



Crystallographic analysis of **170** was first reported by Reikhsfel'd and co-workers (172, 173) and suggested significant participation of the B atom in the conjugated system; in particular, the endocyclic B–C bonds (1.512 Å avg.) were found to be considerably shorter than the exocyclic B–C_{phenyl} bond (1.594 Å). Further, despite the potential donor–acceptor behaviour of the heteroatoms, they found no evidence of a transannular B···N bonding interaction.

This same anthracene core was synthesized a few years later by Clark via the reaction of 2,2′-dilithiodiphenylmethylamine with $BF_3{\cdot}Et_2O$, followed by treatment with mesityl lithium (Scheme 59) (174). The crystal structure of the resulting BN-anthracene analogue **171** showed the tricylic system to be quite planar, with endocyclic C–B bonds slightly shorter than those in triphenylborane (1.537 Å avg.). That said, the ^{11}B NMR chemical shift of 54.0 ppm was in the same region as triphenylborane, prompting them to assign this ring as a conjugated C=C–N–C=C unit bridged by boron, despite the shortened B–C bonds. This same group also mentioned the synthesis of a pentacyclic derivative, though no confirming evidence or data was provided (19).

Some interesting examples of the 1,4-substitution pattern have recently been reported by Kawashima and co-workers (Scheme 60) (175–177). The pentacene analogue **172** was found to be highly fluorescent (ϕ_f = 0.69) and was air- and moisture-stable, owing to the steric protection of the mesityl groups at boron. A crystallographic study of **172** showed it to be quite planar, though no significant intermolecular interactions could be discerned, presumably due to the large, out-of-plane mesityl substituents. The methodology was ex-

© 2008 NRC Canada

Scheme 60.

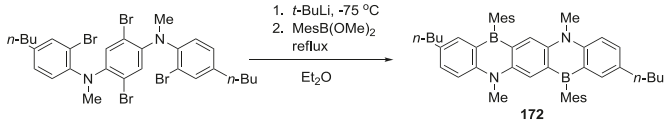


Chart 18.

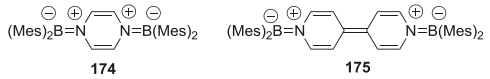
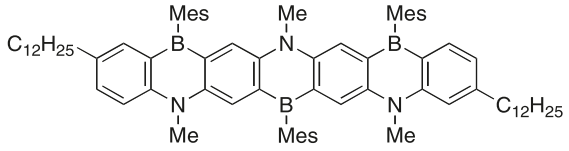


tended to give heptacene derivative **173**, which exhibited the expected bathochromic shifts in both absorption and emission spectra. Further, derivatives of **172** functionalized with carbazol-9-yl groups were found to have near-unity quantum efficiencies (176).



Exocyclic BN substitution

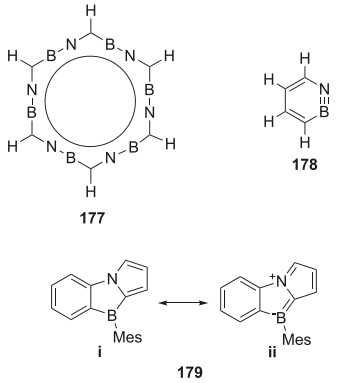
Some further interesting examples of BN substitution for CC were disclosed by Kaim and co-workers (178, 179). Thus, exocyclic substitution of Thiele's and Chichibabin's hydrocarbons incorporated the BN moiety in a conjugated quinoidal, rather than aromatic, framework (Chart 18) (double bonds have been included to highlight the π-character of this exocyclic bond). This π distribution was verified crystallographically for compound **174**, with B–N bond lengths of 1.444(3) Å, and alternating single and double C–C bonds. Both **174** and **175** were found to undergo reversible one-electron oxidations, and indeed, the radical cations formed could be studied by EPR and ENDOR spectroscopies. The extremely small hyperfine coupling constants supported the substantial π-character in the B–N bonds, as well as significant π-electron delocalization in the radical cation as compared with the neutral system.

Aminoboratabenzene complexes reported by Bazan and by Herberich can also be regarded as conjugated BN systems with an exocyclic BN π bond. Indeed, crystalline derivatives of complexes such as **176** exhibit very short BN bonds (1.396(6) Å), with intra-ring delocalization centered on the carbon atoms, as shown by the η^5 bonding arrangement with Zr (180). Additionally, in the case of **176**, the *N*-isopropyl groups were observed to be diastereotopic by virtue of restricted rotation about BN, further confirming the π character of the B–N bond. (181). A more detailed discussion of these compounds is deferred to Fu's review (164).

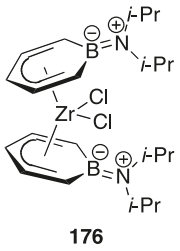
Other systems

Chart 19 shows some miscellaneous systems that have been reported or proposed. The unique 18-π-electron aromatic ring **177** was proposed by Fowler and co-workers (182). The optimized geometry and magnetic properties computed by ab initio methods supported the potential for aromaticity. The stability of BN derivatives of benzyne were

Chart 19.



recently investigated by Fazen and Burke (183). They surmised that azaborine **178** was the most stable derivative



formed by replacing a pair of carbon atoms, and that it was significantly aromatic.

To date, there has been only one investigation of a BN *anti*-aromatic compound, which was communicated by Kaufmann in 1999 (184). Their reported 8-mesityl-8-borafluorazene **179** was found to be air- and moisture-sensitive, though thermally tolerant (purified by high vacuum distillation at 140 °C). High-level ab initio calculations on their compound suggested some contribution of resonance form **ii**, in agreement with the computed electronic distribution of the parent 12-π-electron benzopentalene (Chart 19).

Summary and concluding remarks

Azaborinine compounds have been the focus of numerous computational studies, many of which have addressed the validity of classifying such molecules as "aromatic". Chemically, this classification seems justified, since the tricoordinate boron in these rings is generally much less Lewis acidic than a typical borane. Heterocyclic B–OH derivatives often behave like Brönsted acids rather than Lewis acids, and the rings themselves are more likely to undergo electrophilic substitution than addition reactions. Indeed, most BN aromatics are amenable to classic electrophilic aromatic substitution chemistry, as has been extensively examined. The electropositive nature of the B atom renders the ortho and para positions susceptible to attack by electrophiles, while nucleophilic substitution at B–X (X = Cl, Br) represents a facile means of tuning electronics in the heteroaromatics. Furthermore, the rings serve as suitable π-donors towards metal centres, particularly tricarbonylchromium(0) fragments, forming complexes that are structurally comparable to complexes with corresponding

© 2008 NRC Canada

hydrocarbon aromatics. The case for aromaticity in isoelectronic BN analogues is bolstered by the intermediacy of the bond lengths between single and double bonding as well as the planar nature of the heterocycles. The inability to isolate any examples of unsubstituted BN- or B_2N_2-benzene analogues has made direct comparisons with benzene or borazine impossible, though qualitative evaluations do support the classification as aromatic species.

While there have been significant advances in aromatic BN chemistry in the decades since the last review (6), several of the BN-substituted benzene derivatives remain to be synthesized. Most notable is the 1,3-azaborinine ring, which represents a significant synthetic challenge due to its predicted instability. While the 1,4-azaborinine ring has been achieved in heterocyclic acenes, the monocyclic species remains elusive. A fully unsubstituted derivative of this system may be particularly exigent and could be prone to polymerization. Of the yet unknown B_2N_2-benzene analogues, the 1,4,2,5-, 1,3,2,5-, and 1,4,2,6-diazadiborinine ring structures are the most likely to be achievable based on computed stabilities (20, 58). The former is a particularly interesting challenge, as it is the only remaining B_2N_2 derivative with substitution by BN pairs that has not yet been synthesized.

Though relatively little computational work has been done on the BN-cyclopentadienyl analogues, there are isomers here too that have yet to be prepared experimentally. Specifically, there have been no reports of either 1,3-azaborylyl or 1,3-diaza-2,4-diborylyl rings, though Kaufmann's antiaromatic compound **179** could arguably be considered a representative of the former. It should be noted that predicted properties of the possible BN-substituted pyrroles, pyrazoles, and furans has been reported (11). Studies on BN-cyclopentadienyl derivatives have largely been with the intent of producing Cp surrogates. On the other hand, studies of six-membered BN-containing rings have traditionally been less focused on applications, though resurgence in studies comes from the promise of materials with interesting properties, with compounds such as Piers' BN-phenanthrenes or Kawashima's BN-acenes validating this potential. The substitution of CC by an isoelectronic BN moiety thus remains both of intense fundamental interest and of high potential for furnishing novel materials for applications in a variety of areas.

Acknowledgements

WEP would like to thank the Piers group colleagues who have contributed to our efforts in this area over the past several years; they are named in the cited references. The authors would like to thank Thomas Wood, Lauren Mercier, and Prof. Shih-Yuan Liu (University of Oregon) for reading the manuscript and providing helpful comments. The work described here from the Piers group was funded by NSERC's Discovery Grant Program; MJDB thanks NSERC for PGS funding and the Alberta Ingenuity Fund for a Studentship.

An improved synthesis of sitophilure[1]

Cuifen Lu, Junqi Nie, Guichun Yang, and Zuxing Chen

Abstract: The asymmetric synthesis of sitophilure was carried out in 8 steps, with 42% overall yield and 97% enantiomeric excess from propionaldehyde. The synthesis relied on an approach employing an asymmetric acyl-thiazolidinethione propionate aldol reaction to establish two stereogenic centers.

Key words: sitophilure, thiazolidinethione, chiral auxiliary, synthesis.

Résumé : Utilisant le propionaldéhyde comme produit de départ, on a réalisé une synthèse asymétrique du sitophilure en huit étapes, avec un rendement global de 42% et un excès énantiomérique de 97%. La synthèse repose sur une approche dans laquelle on utilise une réaction asymétrique aldolique acyl-propionate de thiazolidinethione pour générer deux centres stéréogéniques.

Mots-clés : sitophilure, thiazolidinethione, auxiliaire chiral, synthèse.

[Traduit par la Rédaction]

Introduction

The rice weevil *Sitophilus oryzae L.* and the maize weevil *Sitophilu zeamaais M.* are both pests that cause commercially serious damage to stored cereal grains. Effective, cost-efficient grain weevil management could be accomplished by monitoring the pest populations with pheromone-baited insect traps and applying control methods only when pest densities reach economic thresholds. Their common aggregation pheromone, sitophilure, was identified by Schmuff et al. (1) as (4*R*, 5*S*)-5-hydroxy-4-methyl-3-heptanone. A synthesis of the four sitophilure stereoisomers was reported by Mori (2) to clarify the stereochemistry–bioactivity relationship. Bioassay of Mori's samples by Walgenbach et al. (3) revealed (4*S*,5*R*) stereoisomer **1** to be the pheromone sitophilure (Fig. 1). Since effective and cost-efficient control of both maize and rice weevils populations can be foreseen with the aid of the aggregation pheromone, several total syntheses of the racemic and the natural forms of sitophilure **1** have been published (4).

Carbon–carbon bond-forming reactions involving asymmetric aldol additions have emerged as powerful tools in organic synthesis. As demonstrated by the pioneering work of Evans et al. (5), Heathcock and co-workers (6), and Crimmins et al. (7), additions of enolates of acyl oxazolidinones, oxazolidinethiones, and thiazolidinethiones to aldehydes can be highly effective at selectively generating enantiomerically pure *syn* and *anti* aldol products. Among these chiral auxilaries, 4-mono substituted thiazolidinethiones derived from natural amino acids are more useful in asymmetric synthesis because they can be removed from the thiazolidinthiones after completion of the chiral induction easily (8). For these reasons, we have chosen to pursue this line of work and applied this system to the synthesis of the pheromone sitophilure using 4-monosubstituted thiazolidinethiones as chiral auxiliary (Scheme 1). In comparison with the published syntheses, this synthesis is very short and the overall yield very high.

Results and discussion

As shown in Scheme 1, we used 4-benzyl-1,3-thiazolidine-2-thione as starting material. Acylation of thiazolidinethione by propionyl chloride using DMAP as catalyst at room temperature afforded *N*-acylthiazolidinthiones **2** in 95% yield (7*a*). Compound **2** was treated with $TiCl_4$, *N*,*N*-diisopropylethylamine (DIPEA), and *N*-methylpyrrolidone (NMP) in turn, and the resulting complex reacted with propionaldehyde to give alcohol **3** in 98% yield (7*c*). The aldol product could be easily protected with *tert*-butyldimethylsilyl chloride (TBDMSCl) using lutidine as base (9). The compound, obtained by the protection of **3**, was reduced to alcohol **4** with sodium borohydride in the presence of ethanol. Oxidation of alcohol **4** with $Py{\cdot}O_3$ in the presence of DIPEA gave aldehyde **5** in 84% yield. Compound **5** was treated with excess EtMgBr to give a diastereoisomeric mixture of alcohols **6** (4*c*). The diastereoisomeric mixtures were not separated and were directly treated with pyridinium chlorochromate (PCC) and anhydrous sodium acetate in CH_2Cl_2, affording a ketone. Deprotection of the TBS group with tetrabutylammonium fluoride afforded sitophilure **1** (89% yield, 42% overall yield, and 97% ee, based on the reported rotation of +27.0) (2).

Conclusion

In summary, an efficient synthesis (8 steps, 42% overall yield, and 97% enantiomeric excess) of enantiomerically enriched sitophilure **1** was developed from propionaldehyde using 4-benzyl-1,3-thiazolidine-2-thione as chiral auxiliary.

Experimental

General

All organic solvents and base were dried by standard methods. TLCs were performed on precoated plates of silica gel HF254 (0.5 mm, Yantai, China). Flash column chromatography was performed on silica gel H (Yantai, China). Melting points were measured on a WRS-1A digital melting point apparatus and are uncorrected. Optical rotations were determined with a PerkinElmer Model 241 MC polarimeter. IR spectra were recorded on an IR-spectrum one (PE) spectrometer. ^{1}H NMR (600 MHz) and ^{13}C NMR (150 MHz) spectra were recorded on a Varian Unity INOVA 600 spectrometer in $CDCl_3$ using TMS as internal standard. Mass spectra were recorded on Finnigan LCQ DUO MS system.

Synthesis of (*S*)-4-benzyl-3-propionyl-1, 3-thiazolidine-2-thione (2)

To a solution of the thiazolidinethione (7.5 g, 35.89 mmol) in dry CH_2Cl_2 (150 mL) at room temperature was added DMAP (0.88 g, 7.18 mmol) and triethylamine (6.0 mL, 43.06 mmol). Freshly distilled propionyl chloride (4.1 mL, 46.65 mmol) was added dropwise over 5 min and the mixture was stirred for 3 h at room temperature. The reaction mixture was quenched into saturated NH_4Cl (25 mL) and the organic phase was separated. The aqueous layer was extracted with CH_2Cl_2 (50 mL) and the organic extracts were combined, washed with aqueous saturated $NaHCO_3$ and brine, dried over $MgSO_4$, and the solvent was evaporated. The crude product was recrystallized from CH_3CN to yield a yellow solid **2** (9.03 g, 95%), mp 101.1–101.5 °C. IR (KBr, cm^{-1}): 1703, 1261, 1163, 1033, 759, 706. ^{1}H NMR (600 MHz, $CDCl_3$) δ: 7.27-7.35 (m, 5H), 5.38 (m, 1H), 3.21 (dd, *J* = 9.6 Hz, 3.6 Hz, 1H), 3.13 (dd, *J* = 10.8 Hz, 7.2 Hz, 1H), 3.05 (dd, *J* = 10.8 Hz, 2.4 Hz, 1H), 2.88 (dd, *J* = 10.2 Hz, 3.0 Hz, 1H),1.19 (t, *J* = 7.2 Hz, 3H). ^{13}C NMR (150 MHz, $CDCl_3$) δ: 202.5, 174.8, 137.4, 130.0, 129.3, 69.1, 37.3, 33.0, 32.3, 9.8.

Synthesis of (*S*)-4-benzyl-3-((2′S, 3′*R*)-3′-hydroxy-2′-methylpentanoyl)-thiazolidine-2-thione (3)

To solution of compound **2** (4.99 g, 18.82 mmol) in anhyd. CH_2Cl_2 (100 mL) at 0 °C under N_2 was added $TiCl_4$ (2.17 mL, 19.76 mmol), and the solution was stirred for 15 min. DIPEA (3.60 mL, 20.70 mmol) was added dropwise to the mixture, and the solution was stirred for 40 min. NMP (3.61 mL, 37.65 mmol) was added at 0 °C and the mixture was stirred for an additional 10 min. Freshly distilled propionaldehyde (1.51 mL, 20.70 mmol) was then added to the enolate. The reaction was allowed to stir for 2 h followed by the addition of satd. NH_4Cl (10 mL). The organic layer was separated and the aqueous layer was extracted with CH_2Cl_2 (50 mL). The combined organic layers were dried over anhyd. $MgSO_4$, filtered and concentrated, the crude product was purified by column chromatography on silica gel (*n*-hexane/EtOAc, 10:1 *v*/*v*) to afford a yellow oil **3** (5.95 g, 98%). $[\alpha]_D^{25}$ = +130.3° (c 1.30, $CHCl_3$). IR (KBr, cm^{-1}): 3344, 2963, 1693, 1260, 1164, 743, 701. ^{1}H NMR (600 MHz, $CDCl_3$) δ: 7.12–7.27 (m, 5H), 5.25 (m, 1H), 4.43 (m, 1H), 3.77 (m, 1H), 3.31 (dd, *J* = 6.6 Hz, 4.8 Hz, 1H), 3.13 (dd, *J* = 9.6 Hz, 3.6 Hz, 1H), 2.95 (dd, *J* = 10.2 Hz, 2.4 Hz, 1H), 2.80 (d, *J* = 11.4 Hz, 1H), 1.46 (q, *J* = 7.2 Hz, 1H), 1.37 (q, *J* = 6.0 Hz, 1H), 1.16 (d, *J* = 7.2 Hz, 3H), 0.87 (t, *J* = 7.2 Hz, 3H). ^{13}C NMR (150 MHz, $CDCl_3$) δ: 201.2, 178.1, 136.2, 129.3, 128.9, 128.8, 128.7, 127.2, 73.5, 68.7, 42.7, 37.9, 31.9, 27.1, 10.2, 10.1.

Synthesis of (2*R*, 3*R*)-3-(*t*-butyldimethylsilanyloxy)-2-methyl-1-pentanol (4)

To a stirred solution of **3** (4.89 g, 15.13 mmol) in CH_2Cl_2 (50 mL) was added lutidine (2.65 mL, 22.74 mmol) and *t*-butyldimethylsilyl chloride (4.56 g, 37.77 mmol). After stirring for 3 h at room temperature, the reaction mixture was diluted with CH_2Cl_2 and washed with CH_2Cl_2 (50 mL) and brine. The organic layers were dried over $MgSO_4$, filtered, and concentrated in vacuum to give a green oil product (5.30 g). The green oil product (5.30 g, 14.18 mmol) was dissolved in anhyd. ethanol (50mL) and treated with sodium borohydride (2.25 g, 14.25 mmol) with cooling (ice-water bath) and stirring. After stirring for 1 h, 1 N HCl was added to quench the reaction. The reaction mixture was extracted with ethyl acetate and dried over $MgSO_4$. The solvent was evaporated and the crude product was purified by column chromatography on silica gel (*n*-hexane/EtOAc, 5:1 *v*/*v*) to afford a colorless oil **4** (2.92 g, 72%). $[\alpha]_D^{25}$ = +6.68° (c 1.30, $CHCl_3$) [lit. value (4*c*) $[\alpha]_D^{25}$ = +6.65° (c 1.30,

$CHCl_3$)]. IR (KBr, cm^{-1}): 3362, 2959, 1463, 1254. ^1H NMR (600 MHz, $CDCl_3$) δ: 3.61 (m, 2H), 3.44 (m, 1H), 2.43 (s, 1H), 1.91 (m, 1H), 1.44 (m, 2H), 0.83 (s, 9H), 0.74 (t, J = 7.2 Hz, 3H), 0.02 (m, 6H). ^{13}C NMR (150 MHz, $CDCl_3$) δ: 66.0, 39.2, 25.8, 25.2, 18.0, 11.8, 10.7, -4.4, -4.6.

Synthesis of 3-(*t*-butyldimethylsilanyloxy)-2-methylpentanal (5)

A solution of Py·SO_3 (1.88 g, 11.80 mmol) in dry DMSO (15 mL) was added dropwise to a solution of **4** (0.74 g, 3.19 mmol) and DIPEA (4.5 mL, 27.2 mmol) in dry CH_2Cl_2 (5 mL) and stirred in an ice-water bath. The mixture was stirred for 3 h, added to brine, and extracted with ether. The combined organic fractions were dried over $MgSO_4$, filtered and concentrated in vacuum, and the residue was chromatographed on silica gel (*n*-hexane/EtOAc, 10:1 *v*/*v*) to yield a colorless oil **5** (0.62 g, 84%). $[\alpha]_D^{25}$ = +22.9° (c 2.4, $CHCl_3$) [lit. value (10) $[\alpha]_D^{25}$ = +22.7° (c 2.4, $CHCl_3$)]. IR (KBr, cm^{-1}): 2959, 1727, 1463, 1258. ^1H NMR (600MHz, $CDCl_3$) δ: 9.73 (s,1H), 4.01 (m, 1H), 2.42 (m, 1H), 1.49 (m, 2H), 1.02 (m, 3H), 0.84 (s, 9H), 0.03 (m, 6H). ^{13}C NMR (150 MHz, $CDCl_3$) δ: 205.3, 73.3, 50.7, 27.3, 25.7, 17.9, 10.0, 7.4, –4.3, –4.8.

Synthesis of (3*R*,4*R*,5*RS*)-5-(*t*-butyldimethylsilanyloxy)-4-methyl-3-heptanol (6)

To a cooled (–78 °C) solution of **5** (0.50 g, 2.17 mmol) in ether (10 mL) was added ethylmagnesium bromide (2 mL, 6 mmol of a 3.0 mol/L solution in Et_2O) over a 5 min period under N_2. After the addition, the cooling bath was removed, the reaction mixture was allowed to warm to room temperature, and stirred for an additional 2 h. Saturated aq. NH_4Cl (10 mL) was added to quench the reaction. The reaction mixture was extracted with CH_2Cl_2 (20 mL) and dried over $MgSO_4$, filtered and concentrated, the crude product was purified by column chromatography (*n*-hexane/EtOAc, 10:1 *v*/*v*) to afford a colorless oil **6** (0.47 g, 83%). IR (KBr, cm^{-1}): 3441, 1463, 1259. ^1H NMR (600 MHz, $CDCl_3$) δ: 3.67 (m, 1H), 3.55 (m, 1H), 2.52 (s, 1H), 1.42–1.46 (m, 5H), 0.83 (t, J = 7.2 Hz, 3H), 0.79 (s, 9H), 0.76 (t, J = 7.2 Hz, 3H), 0.72 (t, J = 7.2Hz, 3H), 0.02 (m, 6H). ^{13}C NMR (150 MHz, $CDCl_3$) δ: 79.2, 76.8, 38.2, 27.9, 27.5, 25.8, 18.0, 10.4, 9.8, 5.3, –3.7, –4.6.

Synthesis of (4*S*,5*R*)-5-hydroxy-4-methyl-3-pentanone(1)

To a solution of pyridinium chlorochromate (0.47 g, 2.23 mmol) and anhydrous sodium acetate (0.04 g, 0.44 mmol) in CH_2Cl_2 (10 mL) was added **6** (0.37 g, 1.44 mmol) at room temperature. The reaction was stirred for 4 h, followed by the addition of ether (20 mL). The resulting solution was filtered through a column of silica, dried over $MgSO_4$, and concentrated under reduced pressure. The residue (0.36 g) was dissolved in anhyd. THF (15 mL) and treated with tetrabutyl ammonium fluoride (0.37 g, 1.41 mmol). The resulting solution was stirred for 18 h before being diluted with ether (20 mL). The mixture was washed with satd. aq. NH_4Cl and brine, dried over $MgSO_4$, filtered, and concentrated, and the crude product was purified by column chromatography (*n*-hexane/EtOAc, 10:1 *v*/*v*) to afford a colorless oil **1** (0.18 g, 89%), $[\alpha]_D^{25}$ = +26.3° (c 1.24, Et_2O) [lit. value (2) $[\alpha]_D^{25}$ = +27.0° (c 1.24, Et_2O)]. IR (KBr, cm^{-1}): 3445, 2959, 2930, 1710, 1462, 1255. ^1H NMR (600 MHz, $CDCl_3$) δ: 3.75 (m, 1H), 3.55 (s, 1H), 2.51 (m, 1H), 1.29–1.50 (m, 4H), 1.06 (d, J = 3.6 Hz, 3H), 0.98 (t, J = 7.2 Hz, 6.6 Hz, 3H), 0.88 (t, J = 7.2 Hz, 3H). ^{13}C NMR (150 MHz, $CDCl_3$) δ: 216.6, 72.5, 49.2, 34.7, 26.7, 11.5, 10.2, 9.9.

DFT mechanistic studies on the epoxidation of cyclohexene by non-heme tetraaza manganese complexes[1]

Alicja Haras and Tom Ziegler

Abstract: Herein, we report density functional calculations on the epoxidation of cyclohexene with H_2O_2 activated by $(Me_2EBC)MnCl_2$ (Me_2EBC stands for 4,11-dimethyl-1,4,8,11-tetraazabicyclo[6.6.2]hexadecane). The computed energy landscapes for different interaction modes of cyclohexene with the Mn^{IV}-hydroperoxo complex and the Mn^{V}-oxo species support recent experimental findings by Busch and co-workers [J. Am. Chem. Soc. **127**, 17170 (2005)], according to which the Mn^{IV}-hydroperoxo species is the active complex for olefin epoxidation. Thus, the dominant olefin epoxidation pathway is via direct transfer of the distal protonated oxygen of the hydroperoxo adduct without changes in the oxydation state of its tetravalent metal centre, i.e., the mechanism commonly observed in the uncatalyzed epoxidation by peracids. The homolytic decomposition of the O–OH bond in the active manganese complex leading to the Mn^{V}-oxo species is found to be the only epoxidation pathway that could possibly compete with the O_β transfer from the hydroperoxo adduct. However, the generated Mn^{V}-oxo is shown to be a rather poor oxidant resulting in low yields of the target epoxy cyclohexane.

Key words: epoxidation, density functional theory, permanganic acid, peracid.

Résumé : Dans ce travail, on rapporte les résultats de calculs effectués sur la base de la théorie de la fonction de densité pour la réaction d'époxydation du cyclohexène, à l'aide de H_2O_2 catalysé par le $(Me_2EBC)MnCl_2$ (Me_2EBC = 4,11-diméthyl-1,4,8,11-tétraazabicyclo[6.6.2]hexadécane). L'énergie calculée pour les paysages des divers modes d'interaction du cyclohexène avec le complexe Mn(IV)-hydroperoxo et l'espèce Mn(V)-oxo est en accord avec les résultats expérimentaux obtenus récemment par Busch et al. [J. Am. Chem. Soc, **127**, 17170 (2005)] selon lesquels l'espèce Mn(IV)-hydroperoxo est le complexe actif pour l'époxydation de l'oléfine. En conséquence, la voie réactionnelle principale dominante pour l'époxydation de l'oléfine implique un transfert direct de l'oxygène protoné distal de l'adduit hydroperoxo, sans changements de l'état d'oxydation de sont centre métallique tétravalent, c'est-à-dire le mécanisme généralement observé dans l'époxydation par les peracides non catalysée. La décomposition homolytique de la liaison O–OH du complexe activé du manganèse conduisant à la formation de l'espèce Mn(V)-oxo serait la seule voie d'époxydation qui pourrait entrer en compétition avec le transfert O_β à partir de l'adduit hydroperoxo. Toutefois, on a démontré que l'entité Mn(V)-oxo qui est générée est un mauvais oxydant qui ne conduit qu'à de faibles rendements de l'époxycyclohexane recherché.

Mots-clés : époxydation, théorie de la fonction de densité, acide permanganique, peracide.

[Traduit par la Rédaction]

Introduction

The development of an efficient route of oxygen transfer into an olefin double bond with hydrogen peroxide as the epoxidizing agent has been a long term goal in organic syntheses (1, 2). Such a process would be an enviroment-friendly alterative to the existing technologies for epoxide production. Unfortunately, the oxidant itself is not sufficiently active, and transition-metal complexes that might serve as catalysts for the process can rather easily undergo homolytic or heterolytic decomposition. The tetraaza-macrocyclam manganese systems proposed by Busch and co-workers (3–6) and shown in Fig. 1 are the first known examples (5) of manganese complexes that can generate a Mn–OOH adduct active and stable enough to directly epoxidize terminal olefins as demonstrated by oxygen-labelling experiments performed by Busch and co-workers (3, 4).

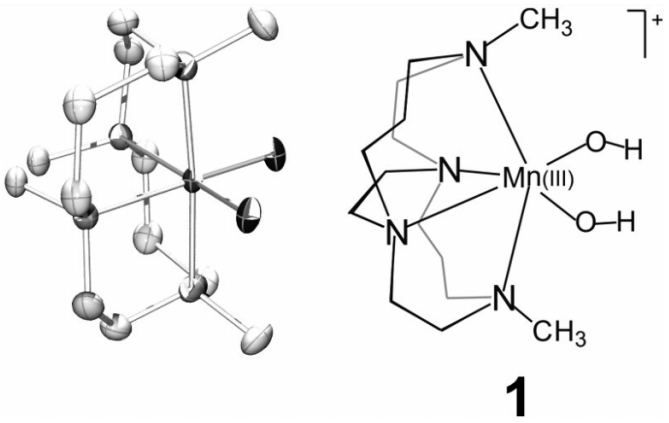
Fig. 1. Crystallographic structure (4) and schematic display of the $(Me_2EBC)Mn^{IV}(OH)_2^{2+}$ cation. Hydrogen atoms are omitted for clarity.



In the present work, we present DFT calculations on the epoxidation of cyclohexene in the presence of the novel Mn(II) complexes bearing the bridged cyclam tetraaza ligand (see Fig. 1). The chosen substrate (olefin) was taken as the smallest among the various olefins epoxidized by Busch and coworkers (4), since it is the most convenient for theoretical studies. We concentrate our attention on the tetravalent manganese-hydroperoxo adduct, $(Me_2EBC)Mn^{IV}(O)(OOH)^+$, as the acive epoxidizing agent. Based on experimental findings (4), the complex formulated as "permanganic acid" was proposed to be formed under catalytic conditions from $(Me_2EBC)Mn^{IV}(O)(OH)^+$ according to eq. [1] at pH < 7.

$$[1] \quad (Me_2EBC)Mn^{IV}(O)(OH)^+ + H_2O_2 \leftrightarrow (Me_2EBC)Mn^{IV}(O)(OOH)^+ H_2O$$

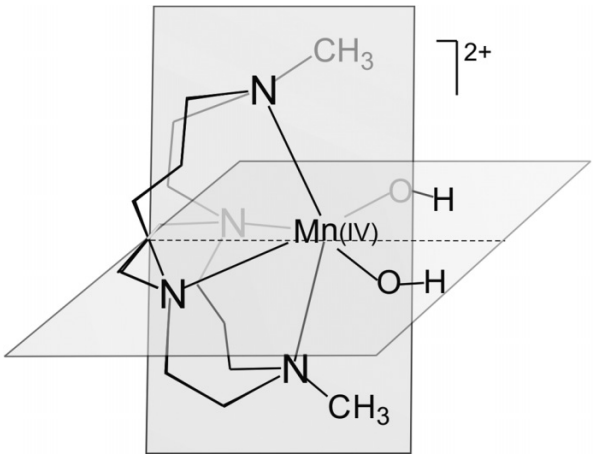
It is the objective of the present study to understand the unique behaviour of the Busch system as a catalyst for epoxidation of olefins by hydrogen peroxide. To this end we shall explore why the manganese-hydroperoxo adduct $(Me_2EBC)Mn^{IV}(O)(OOH)^+$, as observed by Busch and coworkers, serves as the oxygen transfer agents rather than the $(Me_2EBC)Mn^{V}$-oxo and $(Me_2EBC)Mn^{IV}$-oxo species. We present here a detailed study of the different reaction channels for cyclohexene epoxidized in the presence of **1** of Fig. 1 involving $(Me_2EBC)Mn^{IV}(O)(OOH)^+$ as well as $(Me_2EBC)Mn^{V}$-oxo species.

Model and method

The crystallographic structure of the studied manganese tetraaza catalyst without the counterion (PF^-_6) is displayed in Fig. 1.

The "butterfly"-like structure of the catalytic system has a distorted octahedral geometry with the bridged cyclam ligand coordinated to the metal centre through the four nitrogen atoms. The Mn–N bond distances are not equal, ranging from 2.115 to 2.327 Å. In the basal plane formed by manganese and two nitrogens bridged by an ethylene group, there are two additional coordination sites at the metal centre occupied by chlorine atoms in the starting complex. Under catalytic conditions, the two Cl atoms are exchanged with oxygen-containing ligands that can further serve as an oxygen source in the cyclohexene epoxidation process. Different from the in-plane nitrogens, the two out-of-plane N atoms with methyl groups (labelled as N′) are not bridged to each other. Overall, the system has a C_2 symmetry with the symmetry axis bisecting the Cl–Mn–Cl and the N′–Mn–N′ angles (see Fig. 2).

Fig. 2. Schematic structure of the $(Me_2EBC)Mn^{IV}(OH)_2^{2+}$ complex with the two symmetry axes.



All spin-unrestricted DFT computations presented here have been carried out with the program package ADF 2006.01 (7). The complexes considered here were high-spin with all d electrons unpaired. Geometry optimzations at the BP86 level of theory (8–10) with the DZ basis sets for H and the DZP basis sets for Mn, C, O, and N have been performed to calculate the energies and structures involved in the studied processes. The inner cores of manganese (1s 2s 2p) as well as the carbon, nitrogen, and oxygen (1s) shell have been treated by the frozen core approximation. Neither thermochemistry corrections nor corrections for zero-point vibration energy have been applied. Transition states TS1–TS6 all had a Hessian with a single negative eigenvalue. Solvent effects (acetone/water mixture in 4:1 ratio) have been systematically estimated using the COSMO continuum model as inplemented in ADF (11). The dielectric constant employed had a value of 68. The atomic radii of manganese (2.4 Å), nitrogen (1.4 Å), carbon (2.3 Å), oxygen (1.4 Å), and hydrogen (1.16 Å) have been used for construction of the cavity in the solvent (12, 13). Geometry optimizations were carried out without constraints.

Results and discussion

Epoxidation with $(Me_2EB)Mn^{IV}(O)(OOH)^+$

We begin the computational investigations of cyclohexene epoxidation with **1** as the catalyst by exploring possible stable conformers of **1**. The first conformation **1a** of Fig. 3 has the hydrogen on the β-oxygen pointing away from the α′-oxygen, whereas the second conformation **1b** displays a bonding interaction between the β-hydrogen and the α′-oxygen. The difference in relative energy of **1a** and **1b** was calculated to be 7 kcal/mol (1 cal = 4.184 J) in favour of **1b**.

We have also explored the interconversion of **1a** and **1b**. We find a barrier of 16.8 kcal/mol in going from the more stable conformation **1b** over the transition state shown as

Fig. 3. Two stable configurations of **1** along with transition state for their interconversion (1 cal = 4.184 J).

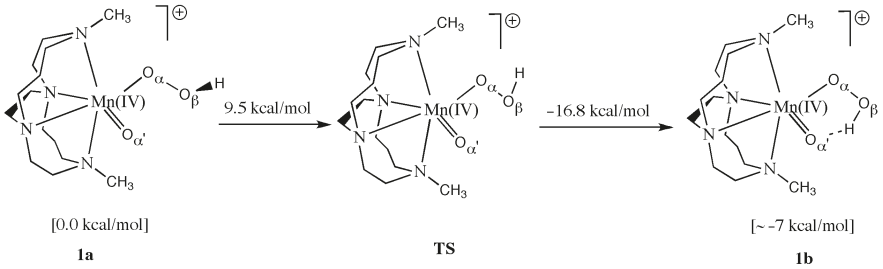

Fig. 4. Transition-state geometries for the symmetric and asymmetric O_β uptake from **1b**. Bonds in the process of breaking or forming are shown with dashed lines; bond distances are in Å.

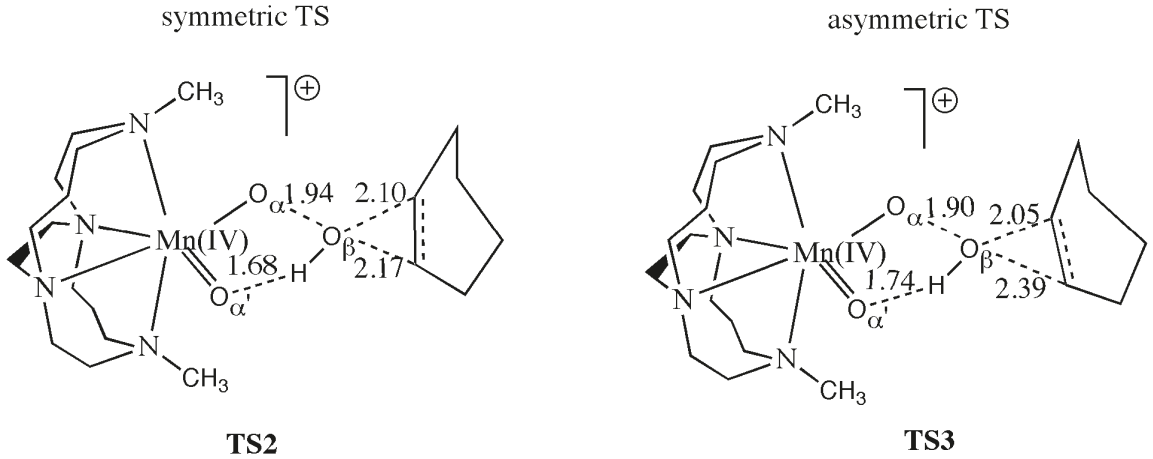


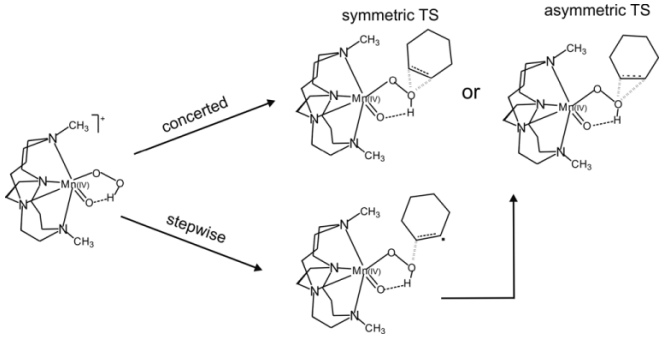
TS1 in Fig. 3 to **1a**. In TS1, the hydrogen bond is completely broken. An additional factor is the loss of conjugation between the occupied p_π orbitals on the two oxygens and empty d orbitals on the metal center. This loss is responsible for the barrier in going from **1a** to **1b**.

By looking at the structures of the two conformers of **1**, it is clear that the higher stability of **1b** is a result of the weak hydrogen interactions between the distal hydrated oxygen in OOH and its neighbouring oxo group. The close proximity of the two groups directly coordinated to the metal centre makes the complex structurally similar to the organic peracids widely used in oxygen-transfer reactions. It is thus possible that **1** of Fig. 3 epoxidizes olefins in a way similar to that observed for peracids. To explore this possibility, we shall now turn to the reaction of **1** with cyclohexene.

Scheme 1 presents all the studied reaction pathways for the direct epoxidation of cyclohexene by **1**. As one can notice, an oxygen atom can be directly transferred from the studied manganese hydroperoxo complex either via the concerted or the stepwise mechanism. Moreover, the presence of two distinct oxygen atoms in the hydroperoxo group coordinated to the metal centre increases the number of possible reaction channels for epoxidation by a factor of two. For simplicity, the oxygen atom that is directly coordinated to the metal centre and the distal protonated oxygen will be referred to thereafter as O_α and O_β, respectively.

Let us concentrate first on the O_β transfer. In the presence of **1b**, the mechanism would be analogeous to the one observed in the case of the uncatalyzed olefin epoxidation by peroxy acids, known in organic chemistry as the Prilezahev reaction (14), in which the oxygen uptake is accompanied by

Scheme 1. All studied reaction paths for the direct cyclohexene epoxidation by **1**.



simultaneous transfer of H to the neighbouring oxo group. When the process takes place in the presence of **1a**, there must be transfer of the H atom from O_β to another oxygen before the oxygen transfer can take place. The explored potential energy surfaces for the synchronous (TS2 of Fig. 4) and the asynchronous O_β (TS3 of Fig. 4) uptakes with **1b** reveal rather low energy barriers in both cases (10.75 and 9.2 kcal/mol, respectively). On route to the transition state, a precomplex is formed that is stabilized relative to the separate reactants by 7–8 kcal/mol. In the transiton state structures shown in Fig. 4, the reacting oxygen atom and the carbon atoms from the olefin double bond are within 2 Å. At the same time, the O–O bond in the OOH group coordinated to the metal centre is elongated to 1.9 Å, and the distance between the hydrogen atom at O_β and the O'_α group is reduced to 1.7 Å, indicating the onset of an H–O bond.

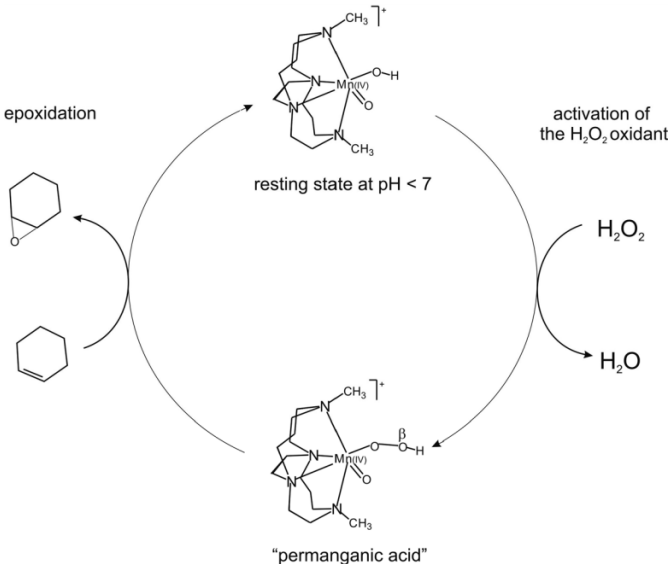
Scheme 2. Catalytic cycle for the most facile O_β uptake from the more stable conformer of **1**.



Although one might expect that the coordination of the tetraaza ligand coordinated to the metal centre via four nitrogen atoms would somehow be influenced by epoxidation, there are no significant ligand deformations observed in the identified TS geometries. After passing the transition states, the transfer of the H atom to the O'_α group is spontaneous, resulting in the formation of epoxy cyclohexane and regeneration of the $(Me_2EBC)Mn^{IV}(O)(OH)^+$ unit from which the active hydroperoxo complex is formed. The overall catalytic cycle for the process is displayed in Scheme 2.

We have also explored passways involving the transfer of O_β in **1a** to the olefin. However, attempts to make the necessary transfer of hydrogen from O_β to O'_α prior to the β-oxygen uptake by olefin were unsucessful. Thus, all the explored pathways resulted in a high energy process involving dissociation of the OH group from the active hydroperoxo complex. Consequently, we are lead to conclude that this process will lead to the decomposition of **1a** rather than to the epoxidation of cyclohexene.

Next, the reaction paths for the epoxidation by O_α were explored, again for both stable conformations of **1** (Scheme 3). Analyzing the less stable **1a**, one could imagine that the olefin uptake of O_α can be assisted by the formation of an adduct in which the distal oxygen of the hydroperoxo group weakly interacts with the metal centre. Such an interaction in the presence of olefin would further facilitate the O_α uptake and would lead to the regeneration of $(Me_2EBC)Mn^{IV}(O)(OH)^+$, which is a resting state under catalytic conditions and completes the catalytic cycle (Scheme 3).

Starting from the isolated reagents, the approaching olefin forms a precomplex that is stabilized by 6.0 kcal/mol both for the asymmetric attack as well as the symmetric interactions of O_α with the olefinic double bond. The asymmetric attack results in the transition state with no changes in the O–O distance of the OOH group but with elongation of the Mn–O bond to 2.63 Å. The first transition states for the asymmetric O_α uptake in the presence of **1a** and **1b** are destabilized by 42.2 kcal/mol with respect to the stable

Scheme 3. Possible reaction pathways for O_a uptake by cyclohexene from **1**.

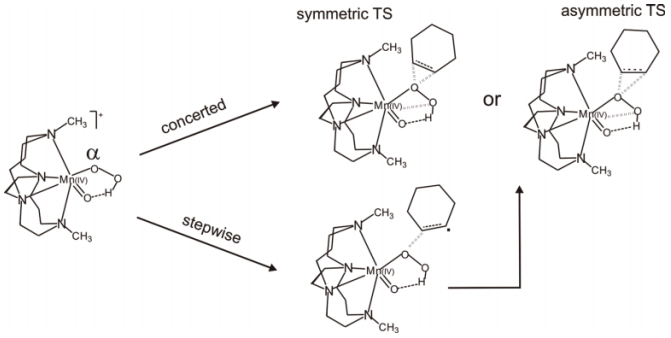


Fig. 5. Transition state for breaking the O–OH bond in **1b** (TS4). Bonds in the process of breaking or forming are shown with dashed lines; bond distances are in Å.

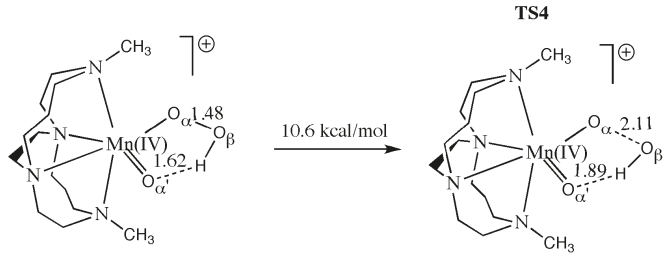

precomplexes. We note further that the attack by olefin on **1a** and **1b** leads to the same transition state because of the rapid rearrangement of **1a** once the olefin approaches the reactive oxygen. It is clear from our calculations that a direct attack of the OOH group coordinated to the **1b** metal center on the olefin is much more facile for the O_β oxygen than the O_α oxygen in **1**. We have for that reason not explored the O_α uptake process in full details (see Scheme 3).

Epoxidation with $(Me_2EBC)Mn^V(O)_2^+$

It is conceivable that the active $(Me_2EBC)Mn^{IV}(O)(OOH)^+$ complex can undergo homolytic decomposition of the O–OH bond to generate the $(Me_2EBC)Mn^V(O)_2^+$ system that can further participate in the epoxidation of cyclohexene. Some $Mn(O)_2$ units are well-known to be strong epoxidizing agents in the oxygen-transfer processes catalyzed by the Mn-heme and Mn-salen complexes studied extensively both by theoretical as well as experimental methods (14). We have as a consequence explored the energetics of breaking the O–OH bond in the more stable configuration of **1** as well as the potential of the resulting $(Me_2EBC)Mn^V(O)_2^+$ complex as an epoxidizing agent.

The optimized transition state TS4 for breaking the O–OH bond is situated 10.6 kcal/mol above the substrate complex with the $R(O_\alpha–O_\beta)$ reaction coordinate being elongated to 2.11 Å (see Fig. 5). The notable differences between the transition state geometry and the stable **1b** complex is the reduced distance between the β-hydrogen of the OOH ligand and the neighbouring O'_α group as well as the elongation of the O–O bond. Here, it is worth to notice that the obtained energy barrier is comparable to the one required to insert the

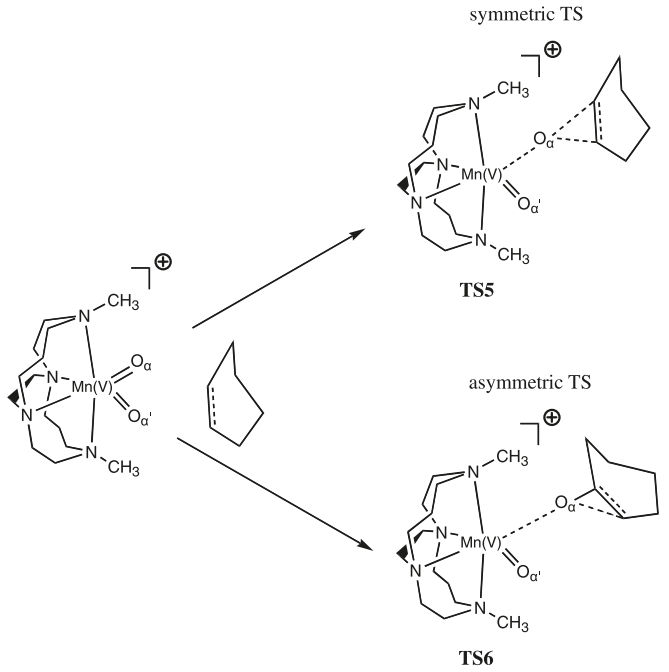
Scheme 4. All studied reaction paths for the cyclohexene epoxidation by the Mn^{V}-oxo species.

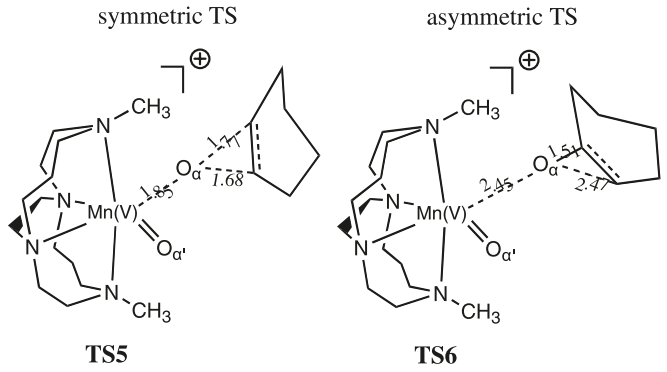


reactive O_β atom into the olefin double bond. This would suggest that the decomposition process can only be competitive to O_β epoxidation (Scheme 2) at low olefin concentrations. We note that Busch and co-workers never observed OH radicals or $Mn^{V}(O)_2^{+}$ species. Nevertheless, we shall in the following briefly examine whether an oxo group of the postulated $Mn^{V}(O)_2^{+}$ species can be transferred into the olefin double bond either in a sequential or concerted manner resulting in the reduced manganese centre. The studied possibilities are displayed in Scheme 4.

Starting from the symmetric interaction mode, the Mn^{V}-oxo species does not form any stable precomplex with the incoming cyclohexene, but there is a steady increase in energy observed once the distance between the reacting oxo group and the two carbon atoms of the olefinic double bond is reduced. At the distance of about 1.8 Å between the oxygen from the Mn^{V}-oxo and the two carbon atoms of the interacting double bond, the saddle point TS5 is located with the energy of 35.5 kcal/mol above the isolated reacting species. The identified transition-state geometry is very symmetric, as the bond to be broken between manganese and the reacting oxygen atom is similar (1.85 Å) to the two new bonds formed by the oxygen with cyclohexene (1.68 and 177 Å, TS5 of Fig. 6).

When the cyclohexene approach is asynchronous, the activation energy to form the first bond with the incoming olefin amounts to 16.4 kcal/mol (TS6 of Fig. 6). Again, the distance between the atoms forming a new bond in TS6 and the bond that is broken in the active manganese complexes are almost the same (1.77 and 1.74 Å, respectively), resulting in the formation of an intermediate with the olefin being oriented perpendicular to the basal plane formed by manganese and the two oxo groups coordinated to the metal centre. The formed intermediate product is very unstable with an energy of 13.4 kcal/mol above the reactants, which precludes the

Fig. 6. Synchronous (TS5) and asynchronous (TS6) transition states for epoxidation of cyclohexene by $(Me_2EBC)Mn^{V}$=O species.



mechanism from being competitive to the uptake of O_β from the $(Me_2EBC)Mn^{IV}(O)(OOH)^{+}$ complex that is required to overcome an energy barrier of only 10 kcal/mol as shown in the preceding section.

Conclusions

We have, in the computational study present here, investigated the mechanistic aspects of cyclohexene epoxidation with H_2O_2 activated by the manganese tetraaza bridged cyclam catalyst **1**. Two active manganese complexes have been considered as the potential oxygen source: the tetravalent manganese hydroperoxo adduct, $LMn^{IV}(O)(OOH)^{+}$, **1**, in its two stable conformations, **1a** and **1b**, and the product from the homolytic decomposition of **1**, i.e., $LMn^{V}(O)_2^{+}$. We have probed different modes for the transfer of oxygen from the active manganese species into olefin. Our investigation has provided clear evidence in favour of the acid–base mechanism in which the transfer of the hydrated oxygen (O_β) of the coordinated OOH group to the metal center is accompanied by the simultaneous transfer of H to the proximal oxo group. The mechanism is facilitated by the unique architecture of the catalyst ligand, which orients the oxo and hydroperoxo ligands in a cis position relative to each other. It is interesting to note that the more stable configuration of the active manganese hydroperoxo complex **1b** closely resembles the one observed in peroxyacids allowing for the spontaneous hydrogen transfer to the neighbouring oxo group during the oxygen uptake process.

An analysis of the frontier orbitals (not shown) provides support for the stabilizing effect of the proximal oxo group on the π orbital of the reactive oxygen, which donated electrons into the π^* orbital on the olefin double bond. In addition, the high-valent manganese centre analogeously to the electron-withdrawing carbonyl group in peroxyacids tends to attract the electron density from the OOH ligand jointly promoting the transfer of its distal oxygen atom to the double bond of the incoming olefin.

Acknowledgements

We wish to thank the Procter & Gamble company for providing us with a crystallographic structure of the studied manganese system and for sharing with us details of the performed experimental research. The computations reported

Gold complexes of ditelluridoimidodiphosphinate ligands — Reversible oxidation of Au(I) to Au(III) via insertion of gold into a phosphorus–tellurium bond[1]

Dana J. Eisler, Stuart D. Robertson, and Tristram Chivers

Abstract: The reaction of (THT)AuCl with (TMEDA)Na[N($TePR_2$)$_2$] (R = Ph, *i*-Pr, *t*-Bu) produces a series of gold (III) complexes of the type [{R_2PNP(Te)R_2}Au(μ-Te)]$_2$ (**4a**, R = *i*-Pr; **4b**, R = Ph; **4c**, R = *t*-Bu) rather than the expected homoleptic Au(I) complexes of the ditelluridoimidodiphosphinate ligands. A combination of solution- and solid-state NMR studies shows that both cis and trans isomers of **4a**–**4c** are formed in these reactions. X-ray structural determinations of the trans isomers of **4a**–**4c** reveal a centrosymmetric arrangement with a central four-membered Au_2Te_2 ring formed by the formal insertion of gold into a P–Te bond; this insertion process was shown to be reversible upon addition of PPh_3 to **4a** to give the monomeric gold(I) complex $Ph_3PAu[N\{TeP(i\text{-}Pr)_2\}_2]$. The X-ray structure of *cis*-**4b** is also described.

Key words: gold, tellurium, redox, X-ray structures, imidodiphosphinate.

Résumé : La réaction du (THT)AuCl avec le (TMEDA)Na[N($TePr_2$)$_2$] (R = Ph, *i*-Pr et *t*-Bu) conduit à la formation d'une série de complexes d'or(III) du type [{R_2PNP(Te)R_2}Au(μ-Te)]$_2$ (**4a**, R = *i*-Pr; **4b**, R = Ph; **4c**, R = *t*-Bu) plutôt qu'aux complexes homoleptiques Au(I) des ligands ditelluridoimidodiphosphinate. Une combinaison d'études RMN en solution et à l'état solide a permis de montrer que dans ces réactions il y a formation des isomères cis- et trans- des produits **4a**–**4c**. Des déterminations de structures par diffraction des rayons X des isomères trans- des produits **4a**–**4c** indiquent qu'ils existent dans un arrangement centrosymétrique, avec un cycle central à quatre membres de Au_2Te_2 obtenu par l'insertion formelle d'or dans la liaison P-Te; on a démontré que ce processus d'insertion est réversible par addition de PPh_3 au produit **4a** qui conduit à la formation du complexe monomère d'or(I), $Ph_3PAu[N\{TeP(i\text{-}Pr)_2\}_2]$. On décrit aussi la structure du produit *cis*-**4b** telle que déterminée par diffraction des rayons X.

Mots-clés : or, tellure, redox, structures déterminées par diffraction des rayons X, imidodiphosphinate.

[Traduit par la Rédaction]

Introduction

Prior to 2002, the chemistry of dichalcogenidoimidodiphosphinate ligands of the type **1** was restricted to derivatives in which E = O, S, or Se. A number of uses or potential uses for metal complexes of these inorganic analogues of acetylacetonates have been identified in review articles (1–3), e.g., as luminescent materials or lanthanide shift reagents, as well as in metal extraction processes. In the last 5–6 years, a renaissance of the interest in such metal complexes has occurred as a result of (*i*) extensive studies by O'Brien and co-workers, which have demonstrated that metal complexes of the selenium analogue of **1a** are suitable single-source precursors for the deposition of pure thin films of metal selenides by using CVD techniques (4) and (*ii*) the discovery of a synthesis of alkali-metal derivatives of the ditellurido derivatives **1a**–**1c** (5–7). The latter development has opened the door to investigations of the fundamental chemistry of these tellurium-containing ligands, as well as applications of their metal complexes as single-source precursors for binary metal tellurides that are of interest for use, inter alia, in solar cells (CdTe, HgTe) or infrared detectors (SnTe), and as thermoelectric materials (Sb_2Te_3, Bi_2Te_3) (8).

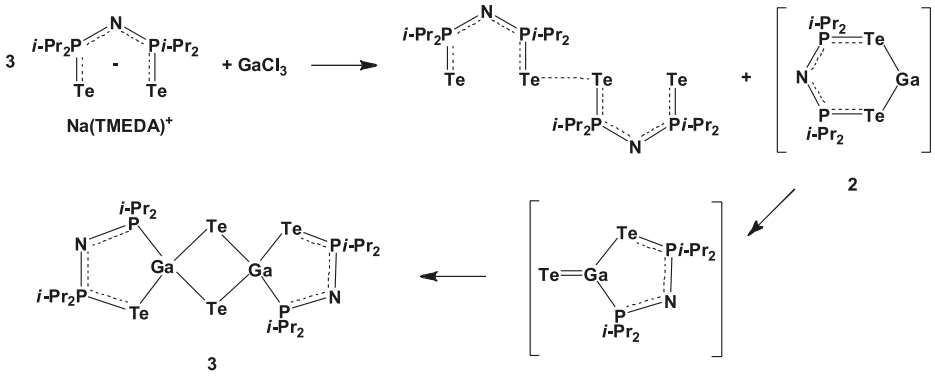
Scheme 1.



Investigations of the redox behaviour of **1a** revealed new aspects of the well-studied chemistry of dichalcogenidoimidodiphosphinate ligands in which one-electron oxidation with iodine produces the dimeric ditelluride $TePR_2NR_2PTe–TePR_2NPR_2Te$ (**2**: R = *i*-Pr) (see Scheme 1) with an elongated central tellurium–tellurium bond (9). Similar dichalcogenides are also obtained upon oxidation of the disulfido and diselenido ligands (**1**: E = S, R = *t*-Bu; E = Se, R = *i*-Pr, *t*-Bu) (7). In the case of **1c**, however, a structural isomer comprised of a contact ion pair in which a $[(TeP\text{-}t\text{-}Bu_2)_2N]^-$ anion is Te, Te chelated to one Te atom of an incipient cyclic cation $[(TeP\text{-}t\text{-}Bu_2)_2N]^+$ is obtained (7). The five-membered cations $[(EPR_2)_2N]^+$ (E = S, Se, Te; R = *i*-Pr, *t*-Bu) are obtained, as iodide salts, by two-electron oxidation of the corresponding anions with iodine (7, 10).

Homoleptic complexes of **1a** with group 12 (Zn, Cd, Hg) and group 15 (Sb, Bi) metals are obtained via metathesis with the appropriate metal halide (6), and the cadmium and antimony complexes have been shown to be effective single-source precursors for pure CdTe (11) and Sb_2Te_3 (12) thin films, respectively, using the technique of aerosol-assisted chemical vapour deposition (AACVD) (8). Homoleptic complexes may also be prepared for coinage metals, although the ditellurido ligands **1a** and **1b** give rise to higher oligomers with silver(I) (specifically, a hexamer for **1a** and a tetramer for **1b**) (13) compared to the trimeric complexes observed for **1** (E = S, Se; R = *i*-Pr) (14). Interestingly, the ditellurido ligands in both copper(I) and silver(I) complexes exhibit the ability to act as doubly bridging ligands, a feature that brings two metal centres in close proximity suggesting the possibility of metallophilic (d^{10}–d^{10}) interactions. The strong reducing power of **1a** is evident in the reaction of the sodium salt with AuCl, which immediately deposits a gold mirror; however, this reduction may be pre-empted by the addition of PPh_3, leading to the isolation of the monomeric gold(I) complex $Ph_3PAu[N\{TeP(i\text{-}Pr)_2\}_2]$ (13). Although tellurium occurs in combination with gold in certain minerals (e.g., krennerite, $AuTe_2$), only a few gold–tellurium complexes have been structurally characterized. Some representative examples include the ternary gold tellurium halides AuTeI (15) and $AuTe_2X$ (X = Cl, I) (16), the tetrameric gold(I) tellurolate $Au_4[TeC(SiMe_3)_3]_4$ (17), the monomeric gold(I) tellurolate $Ph_3PAu[TeC(SiMe_3)_3]$ (17), and a variety of binary gold–tellurium anions, e.g. $Au_4Te_4^{4-}$ (18), $Au_3Te_4^{3-}$ (19), and $AuTe_7^{3-}$ (20).

Another fascinating difference between the behaviour of the ditellurido ligand **1a** and the dithio or diselenido analogues (**1**: E = S, Se; R = *i*-Pr) is observed in the reactions with group 13 dihalides (21). For example, the reaction of $GaCl_3$ with 3 equiv. of Na(TMEDA)**1a** produces the dimeric complex $\{Ga(\mu\text{-}Te)[i\text{-}Pr_2P(Te)NPi\text{-}Pr_2]\}_2$ (3) as a mixture of cis and trans isomers, together with a high yield of the ditelluride **2**. As indicated in Scheme 1, the formation of the four-membered Ga_2Te_2 ring in **3** was proposed to occur via initial formation of the homoleptic gallium(III) complex $Ga[N\{TeP(i\text{-}Pr)_2\}]_3$, followed by reductive elimination and formation of the gallium(I) complex $Ga[N\{TeP(i\text{-}Pr)_2\}]$ (**2**). Subsequent rearrangement of this Ga(I) complex to the corresponding gallatellurone followed by dimerisation gives **3** in which the gallium centres are P, Te-chelated by the monotellurido $[TePR_2PNPR_2]^-$ (R = *i*-Pr) ligand. The synthesis of the lithium derivative of this anion and its use as an in situ reagent for the preparation of homoleptic complexes of group 12 metals has been reported recently (22).

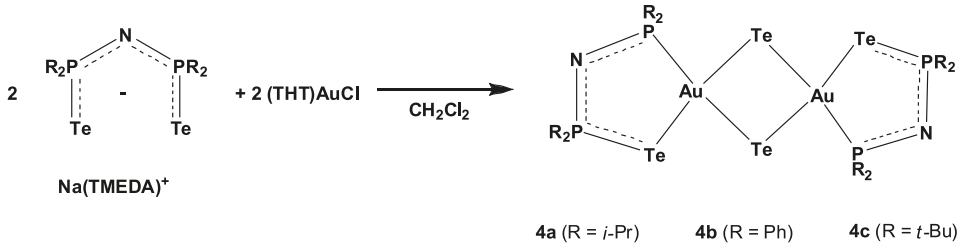
To determine whether a more labile two-electron donor than PPh_3 would allow the formation of oligomeric gold complexes of ditelluridoimidodiphosphinate ligands similar to those observed for Cu(I) and Ag(I) (13), we have investigated the reactions of the sodium salts of **1a–1c** with the soluble gold(I) complex (THT)AuCl (THT = tetrahydrothiophene). Interestingly, these reactions give rise to the formation of the gold (III) complexes $[\{R_2PNP(Te)R_2\}Au(\mu\text{-}Te)]_2$ (**4a**, R = *i*-Pr; **4b**, R = Ph; **4c**, R = *t*-Bu) rather than the expected homoleptic Au(I) complexes of **1a–1c**. The characterisation of these new gold(III) complexes in the solid state by X-ray structural determinations and ^{31}P NMR spectroscopy (**4a**) and in solution by multinuclear (^1H, ^{31}P, and ^{125}Te) NMR spectroscopy is discussed.

Results and discussion

The 1:1 reaction of the ditelluridoimidodiphosphinate anions **1a**–**1c**, as their sodium salts, with (THT)AuCl proceeds rapidly in dichloromethane at room temperature producing deeply coloured solutions of the gold complexes **4a**–**4c**, as depicted in Scheme 2. While the *iso*-propyl complex **4a** is moderately soluble in THF and CH_2Cl_2, the phenyl and *tert*-butyl derivatives **4b** and **4c** exhibit poor solubility in common organic solvents. The complexes **4a**–**4c** were all obtained in high purity as crystalline solids, which are stable to

© 2008 NRC Canada

Scheme 2.



light, air, and moisture in the solid state, but decompose slowly (weeks) in solution at room temperature. The purity of the bulk crystalline samples was confirmed in each case by elemental analysis.

X-ray diffraction studies were carried out on crystalline samples of all three complexes **4a**–**4c**. The most significant difference between the structures involves the substituents on the phosphorus centres, and so the structure of *trans*-**4b** is shown in Fig. 1 as a representative example; a selection of geometrical parameters is given in Table 1. In each case, it was found that the complexes adopt a dimeric structure, which is comprised of a central $[Au_2Te_2]^{2+}$ four-membered ring bound to two monotelluridoimidodiphosphinate anions $[R_2P(Te)NPR_2]^-$ (22) that are arranged in a trans fashion (Fig. 1). A similar structure has been observed previously in the gallium complex **3** (Scheme 1), although in that case, the metal centres are tetrahedral, whereas the gold centres in the complexes **4a**–**4c** are approximately square-planar.

The solid-state structures of the complexes **4a**–**4c** clearly indicate that the gold centres have been oxidized from Au(I) to Au(III). This oxidation formally involves insertion of Au(I) into a phosphorus–tellurium bond of the ditelluridoimidodiphosphinate ligand, with concomitant reduction of one of the P(V) centres to P(III). Oxidation of Au(I) to Au(III) with reagents such as alkyl halides and halogens is well-documented and known to be facile (23). Oxidation by chalcogens has been observed before in the reaction of AuCN with Na_2Se_5, which produced $[Au_2Se_2(Se_4)_2]^{2-}$ (24) containing an Au_2Se_2 ring similar to the central Au_2Te_2 ring observed in the complexes **4a**–**4c**. However, the current work appears to be the only example of the oxidation of Au(I) to Au(III) by insertion into a phosphorus–chalcogen bond. The formation of the Au_2Te_2 ring in **4a**–**4c**, presumably via the initial production of a gold(I) complex of **1a**–**1c**, parallels the transformation depicted in Scheme 1 for the generation of a Ga_2Te_2 ring, except that the Ga(I) complex is generated by reductive elimination rather than an initial metathesis.

As expected for Au(III) (d^8 configuration), the geometry at the gold centres is square-planar, although there are significant deviations from the ideal 90° angles, which likely arise from the softness of the Au–P and Au–Te bonds (Table 1). Regardless of the deviation from the ideal angles, the sum of the bond angles is near 360° for all three complexes (*trans*-**4a**, 359.93°; *trans*-**4b**, 360.60°; *trans*-**4c**, 359.81°). In each case, the most acute angle is the endocyclic Te(2)–Au(1)–Te(2A) angle [*trans*-**4a**, 78.34(4)°; *trans*-**4b**, 79.18(2)°; *trans*-**4c**, 74.75(4)°], while the widest angles are those involving P(2)–Au(1)–Te(2) [*trans*-**4a**, 98.95(7)°; *trans*-**4b**, 97.43(4)°; *trans*-**4c**, 104.66(6)°]. The increase in this latter angle, and compression of the former angles, correlates with an increase in the bulk of the substituents on the phosphorus centres, and may arise from unfavourable steric interactions between these groups and the central Au_2Te_2 ring. The Au–Te–Au angles in the planar four-membered Au_2Te_2 ring in *trans*-**4a**–**4c** are larger than the corresponding Te–Au–Te angles by 23.3–30.5° leading to transannular distances of 3.20–3.35 Å that are well within the sum of van der Waals radii for two tellurium atoms (4.40 Å). For comparison, the Te—Te separation in the four-

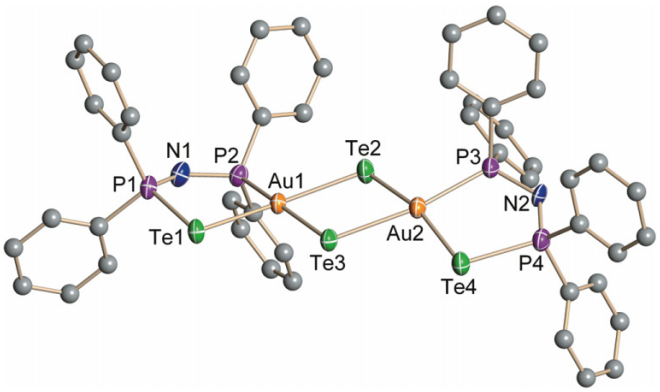
Fig. 2. Thermal ellipsoid diagram for one of the two crystallographically independent molecules of the complex *cis*-**4b**. Hydrogen atoms have been removed for clarity.



membered Au_2Te_2 rings in AuTeI is 3.235 Å (15). The Au—Te bond lengths fall in a very narrow range for all three complexes [2.6149(8)–2.649(1) Å] and are similar to other reported Au–Te distances (14–20).

During this work, it was found that rapid crystallization of **4b** from concentrated THF or CH_2Cl_2 solutions resulted in the formation of two distinct crystal morphologies: deep red, rhombohedral plates and orange rectangular plates, the latter of which were identified as *trans*-**4b** by determination of the unit cell. An X-ray crystallographic study on a rhombohedral plate revealed the presence of the cis isomer of complex **4b** (Fig. 2). There are two crystallographically independent, but chemically equivalent, molecules of *cis*-**4b** present in the asymmetric unit, which have very similar metrical parameters.

The geometrical parameters of *cis*-**4b** are similar to those observed for *trans*-**4b**. The geometry of the gold(III) centres is best described as distorted square-planar, with significant deviations from the ideal 90° bond angles (Table 2). The most compressed angles are those contained within the central Au_2Te_2 ring [Te2–Au1–Te3, 78.60(5)°; Te2–Au2–Te3, 78.28° (5)], while the widest angles are P2–Au1–Te2, 98.1(1)° and P3–Au2–Te2, 96.2(1)°. The Au–Te bond distances [range: 2.612(2)–2.655(2) Å] are similar to those observed in the trans complexes of **4a**–**4c**. Like the trans complexes of **4a**–**4c**, the four-membered Au_2Te_2 ring of *cis*-**4b** is planar, with the Au–Te–Au bond angles more than 20° larger than the Te–Au–Te angles. As a consequence, the transannular Te–Te distance is 3.35 Å, which is virtually identical to that of *trans*-**4b**. Regardless of the similarity between the cis and trans structures, there is a clear preference in the solid state for the trans isomer. Slow crystallization of all of the complexes **4a**–**4c** consistently resulted in the isolation of the trans isomer in the solid state; only a single crystal morphology was observed and random testing of multiple crystals from each sample using X-ray crystallography provided exclusively the unit cell for the trans isomer. All attempts to isolate crystals of *cis*-**4a** and *cis*-**4c** were unsuccessful.

The solution-state NMR spectra obtained for the complexes **4a**–**4c** revealed the presence of two closely related species in solution. For example, in the ^{31}P NMR spectra, two sets of phosphorus resonances, with very similar chemical shifts and coupling constants, were observed in each case. However, the two species were not present in equal quantities, but in a ratio of nearly 2:1 in each case. The observed spectroscopic data can be explained by the presence of both the cis and trans isomers in solution, with one isomer clearly predominating. While it is tempting to assign the resonances of the major component present in solution to the trans isomer, solid-state NMR studies suggest that it is the cis isomer that predominates in solution.

The solid-state ^{31}P NMR spectrum of a crystalline sample of **4a** grown slowly from dichloromethane is compared with the solution-state spectrum in Fig. 3. It is clear from these two spectra that the isomer that predominates in the solid state is, in fact, the minor component present in solution. The unit cell was determined for multiple crystals from this solid-state sample, and in each case the presence of the trans isomer was confirmed. It should be noted that the solid-state ^{31}P NMR spectrum indicates that there is a small quantity of the cis isomer present in the sample. Nonetheless, crystals of the cis isomer could not be detected visually or by crystallographic methods. In contrast, the solid-state ^{31}P NMR spectrum obtained on a sample of **4b** that had been rapidly crystallized showed that the ratio of the two isomers was largely unchanged from that present in solution. This obser-

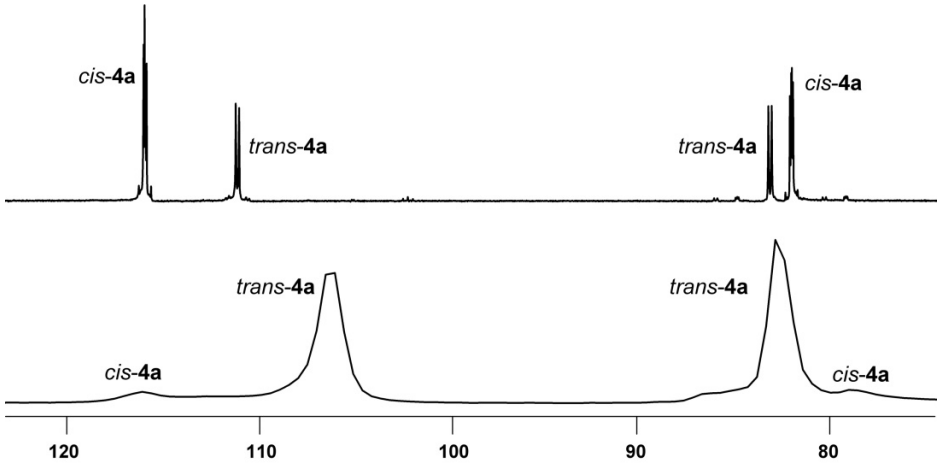
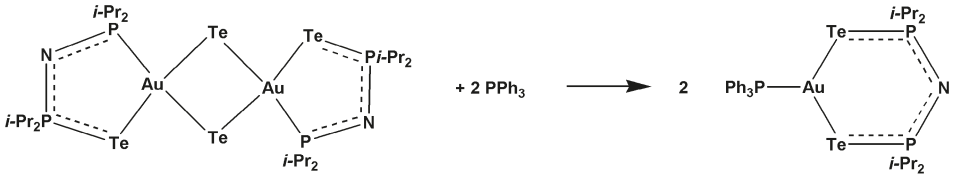


Scheme 3.



vation, in conjunction with the relative quantities of crystals of *cis*- and *trans*-**4b** noted in rapidly crystallized samples, also suggests that it is the cis isomer that is the major component in solution. Although it is possible that the trans isomer crystallizes preferentially, leaving the cis isomer in solution, the ^{31}P NMR spectrum obtained for a single crystal of *trans*-**4a** was found to be identical to that of bulk samples of **4a**, with the two sets of resonances in a 2:1 intensity ratio. Thus, it is clear that the cis and trans isomers are readily able to interconvert in solution, although the mechanism by which this occurs is not clear.

Finally, we note a minor difference in the ^{31}P NMR spectra of the cis and trans isomers. The trans isomers exhibit one set of mutually coupled doublets, whereas the resonances for the cis isomers exhibit second-order behaviour and appear as more complex multiplets, as observed for the related square-planar complexes *cis*-[M{$Ph_2P(E)NPPh_2$}$_2$] (M = Pd, Pt; E = S, Se) (25).

In light of the facile oxidation of Au(I) to Au(III) observed in this work and the previous observation that Ph_3P stabilizes a homoleptic Au(I) complex of **1a** (13), we decided to investigate the reaction of **4a** with Ph_3P. Addition of Ph_3P to solutions of **4a** resulted in the immediate and quantitative formation of the known complex Ph_3PAu[N{TeP(*i*-$Pr)_2$}$_2$] (13), which was identified by ^{31}P NMR spectroscopy (Scheme 3). To further confirm the identity of the complex, it was shown that the addition of an authentic sample of Ph_3PAu[N{TeP(*i*-$Pr)_2$}$_2$] to the solution used to obtain the NMR spectrum resulted only in an increase in the intensity of the NMR resonances; no additional resonances were observed.

Conclusions

The reaction of the soluble Au(I) complex (THT)AuCl with the ditelluridoimidodiphosphinate complexes **1a–1c** was found to produce the stable dimeric complexes **4a**–**4c**, in which the gold centres have been oxidized to Au(III). This oxidation involves the formal insertion of the gold centres into a phosphorus–tellurium bond and converts a ditelluridoimidodiphosphinate ligand to a monotelluridoimidodiphosphinate with the formation of an Au_2Te_2 ring. The insertion of a metal centre into a P–Te bond has been observed previously in the formation of the gallium complex {Ga(μ-Te)[*i*Pr_2P(Te)NP*i*Pr_2]}$_2$ (3). Taken together, these results indicate that reactions of the ditellurido ligands **1a**–**1c** with metals that have two easily accessible oxidation states, separated by two units, may be complicated by redox chemistry. The reversibility of the redox chemistry that was observed in the current work is unprecedented and may have significant implications in the formation of metal complexes of ditelluridoimidodiphosphinate ligands; in particular, an investigation of the possible occurrence of a similar process for the gallium(III) complex **3** is warranted.

Experimental section

Reagents and general procedures

Solvents were dried and distilled before use: *n*-hexane, THF, and toluene (Na/benzophenone); CH_2Cl_2 (calcium hydride). The ditelluridoimidodiphosphinate complexes **1a** (6), **1b** (5), and **1c** (7) and the complex (THT)AuCl (26) were prepared according to the literature procedures. The handling of air- and moisture-sensitive materials was performed

under an atmosphere of argon gas using standard Schlenk techniques or a glovebox. ^{1}H, ^{31}P, and ^{125}Te NMR spectra were collected using a Bruker AC-300, AMX-300, or DRX-400 spectrometer, and chemical shifts are reported relative to Me_4Si (^{1}H), 85% H_3PO_4 (^{31}P), and Te_2Ph_2 (^{125}Te). Solid-state ^{31}P NMR spectra were collected on a Bruker AM300 wide-bore spectrometer in a 4 mm tube, and chemical shifts are reported relative to $(NH_4)H_2PO_4$. The Analytical Services Laboratory of the Department of Chemistry, University of Calgary, provided elemental analyses.

Preparation of [(*i*-Pr$_2$PNP(Te)*i*-Pr$_2$)Au(μ-Te)]$_2$ (4a)

A solution of **1a** (0.200 g, 0.31 mmol) in CH_2Cl_2 (25 mL) was added to a darkened flask containing a solution of (THT)AuCl (0.100 g, 0.31 mmol) in CH_2Cl_2 (15 mL), resulting in the immediate formation of a dark red solution. The mixture was stirred for 15 min and then filtered through Celite. The solution was stored at –30 °C for 72 h giving dark red crystals of **4a**, suitable for X-ray analysis (0.158 g, 0.11 mmol, 73%). ^{1}H NMR (D_8-THF) δ: 2.35 (m $(CH_3)_2CH$, *trans*-**4a**), 2.25 (m, $(CH_3)_2CH$, *cis*-**4a**), 1.23 (m, $(CH_3)_2CH$, *cis*-**4a**, *trans*-**4a**). ^{31}P NMR (D_8-THF) δ: 113.94 (m, *P*Au, *cis*-**4a**), 108.88 (d, $^{2}J_{PP}$ = 29 Hz, *P*Au, *trans*-**4a**), 80.70 (d, $^{2}J_{PP}$ = 29 Hz, $^{1}J_{TeP}$ = 946 Hz, *P*Te, *trans*-**4a**), 79.15 (m, $^{1}J_{TeP}$ = 948 Hz, *P*Te, *cis*-**4a**). ^{125}Te NMR δ: 292.0 (d, $^{1}J_{TeP}$ = 950 Hz, P*Te*, *trans*-**4a**), 281.0 (d, $^{1}J_{TeP}$ = 943 Hz, P*Te*, *cis*-**4a**), –38.4 (s, μ-Te, *trans*-**4a**), –397.4 (s, μ-Te, *cis*-**4a**). Solid-state ^{31}P NMR δ: 116.17 (*P*Au, *cis*-**4a**), 106.15 (*P*Au, *trans*-**4a**), 82.27 (*P*Te, *trans*-**4a**), 78.28 (*P*Te, *cis*-**4a**). Anal. calcd. for $C_{24}H_{56}Au_2N_2P_4Te_4$ (%): C 20.58, H 4.03, N 2.00; found: C 21.06, H, 3.94, N 1.95.

Preparation of [(Ph$_2$PNP(Te)Ph$_2$)Au(μ-Te)]$_2$ (4b)

A solution of **1b** (0.243 g, 0.31 mmol) in CH_2Cl_2 (25 mL) was added to a darkened flask containing a solution of (THT)AuCl (0.100 g, 0.31 mmol) in CH_2Cl_2 (15 mL), resulting in the immediate formation of a dark green solution. The mixture was stirred for 15 min and then filtered through Celite, concentrated to ~15 mL and then stored at –30 °C for 24 h giving crystalline **4b** (0.112 g, 0.07 mmol, 43%). ^{1}H NMR (D_8-THF) δ: 7.69, 7.35 (m, Phenyl-*H*; *cis*-, *trans*-**4b**). ^{31}P NMR (CD_2Cl_2) δ: 78.29 (m, *P*Au, *cis*-**4b**), 70.21 (d, $^{2}J_{PP}$ = 80 Hz, *P*Au, *trans*-**4b**), 30.41 (m, $^{1}J_{TeP}$ = 982 Hz, *P*Te, *cis*-**4b**), 30.22 (d, $^{2}J_{PP}$ = 80 Hz, $^{1}J_{TeP}$ = 982 Hz, *P*Te, *trans*-**4b**). Anal. calcd. for $C_{48}H_{40}Au_2N_2P_4Te_4$ (%): C 34.46, H 2.41, N 1.67; found: C 34.56, H, 2.19, N 1.61. X-ray quality crystals of *trans*-**4b** were grown by slow evaporation of a solution of the complex in CH_2Cl_2. A suitable crystal for X-ray analysis of the complex *cis*-**4b** was obtained from a concentrated solution of the complex in THF.

Preparation of [(*t*-Bu$_2$PNP(Te)*t*-Bu$_2$)Au(μ-Te)]$_2$ (4c)

A solution of **1c** (0.218 g, 0.31 mmol) in CH_2Cl_2 (30 mL) was added to a darkened flask containing a solution of (THT)AuCl (0.100 g, 0.31 mmol) in CH_2Cl_2 (30 mL), resulting in the immediate formation of a dark red solution. The mixture was stirred for 15 min and then filtered through Celite. The solution was concentrated to ~30 mL and stored at –30 °C for 72 h giving crystalline **4c** (0.080 g, 0.05 mmol, 34%). ^{1}H NMR (CD_2Cl_2) δ: 1.39, (m, $C(CH_3)_3$, *cis*-**4c**), 1.18 (m, $C(CH_3)_3$, *trans*-**4c**). ^{31}P NMR (CD_2Cl_2) δ: 129.17 (m, *P*Au, *cis*-**4c**), 124.14 (d, $^{2}J_{PP}$ = 27 Hz, *P*Au, *trans*-**4c**), 94.71 (d, $^{2}J_{PP}$ = 27 Hz, $^{1}J_{TeP}$ = 980 Hz, *P*Te, *trans*-**4c**), 94.02 (m, $^{1}J_{TeP}$ = 980 Hz, *P*Te, *cis*-**4c**). Anal. calcd. for $C_{32}H_{72}Au_2N_2P_4Te_4$ (%): C 25.40, H 4.80, N 1.85; found: C 25.43, H, 4.48, N 1.75. X-ray quality crystals of *trans*-**4c** were grown by slow evaporation of a solution of the complex in CH_2Cl_2.

X-ray structural analyses

Crystal data for *trans*-**4a**, *trans*-**4b**, *cis*-**4b**, and *trans*-**4c** are summarized in Table 3.[3] A suitable crystal of the complex was selected, coated in Paratone oil, and mounted on a glass fibre. Data were collected at 173 K (273 K = 0 °C) on a Nonius Kappa CCD diffractometer using Mo Kα radiation (λ = 0.71073 Å) via ω and φ scans. The unit-cell parameters were calculated and refined from the full data set. Crystal cell refinement and data reduction were carried out using the Nonius DENZO package. After data reduction, the data were corrected for absorption using SORTAV (27). The structures were solved using the automated Patterson routine within SHELXS-97 (28) and refinement was carried out on F^2 against all independent reflections by the full-matrix least-squares method using the SHELXL-97 program (29). The hydrogen atoms were calculated geometrically and were riding on their respective atoms unless otherwise noted. For the complexes *trans*-**4a**, *trans*-**4b**, and *trans*-**4c**, all non-hydrogen atoms were refined with anisotropic thermal parameters. In each case, only one-half of the molecule was located in the difference Fourier map as the molecule is situated around a centre of symmetry. In the case of complex *cis*-**4b**, the crystals diffracted weakly, and so a relatively poor-quality dataset was obtained. The complex crystallizes with two chemically equivalent, but crystallographically independent, molecules in the asymmetric unit. Four of the phenyl substituents were disordered and each was modelled as an isotropic 50:50 mixture with geometric restraints; all other phenyl rings were constrained to be regular hexagons and were refined with isotropic thermal displacement parameters. The lattice-bound THF molecules were poorly ordered, and each was modelled as an isotropic 50:50 mixture with geometric restraints. Due to the low quality of the data, only the Au, Te, P, and N atoms making up the core of the structure were refined with anisotropic thermal displacement parameters.

Catalytic synthesis of carbon nanotubes from the decomposition of methane over a Ni–Co/La_2O_3 catalyst[1]

Long Chen, Haitao Liu, Keli Yang, Jiankang Wang, and Xiaolai Wang

Abstract: The production of multi-walled carbon nanotubes (MWNTs) by the catalytic chemical vapour deposition (CCVD) method was examined over a series of Ni–Co/La_2O_3 catalysts with methane as the carbon source. The catalyst composition and the reaction conditions were optimized by analyzing the effluent gas with gas chromatography. Various techniques, such as X-ray diffraction (XRD), Transmission electron microscopy (TEM), Raman spectra, and Thermal gravimetric analysis (TGA) were used to characterize the catalysts and products. The results indicate that the unreduced catalyst 30Ni–10Co/La_2O_3 showed the highest activity for methane decomposition, and the highest carbon yield, being 624.2%, was obtained over this catalyst at 700 °C after 60 min of reaction with hydrogen as carrier gas. TGA results suggest that the purity of carbon nanotubes (CNTs) can reach up to 98 wt% after a single-step purification by hydrochloric acid.

Key words: carbon nanotubes, catalytic chemical vapour deposition, methane decomposition, Ni–Co/La_2O_3 catalyst.

Résumé : On a examiné la production de nanotubes de carbones à parois multiples (NTCPM) par la méthode de déposition de vapeur chimique catalytique (DVCC) sur une série de catalyseurs de Ni-Co/La_2O_3, en n'utilisant que du méthane comme source de carbone. On a optimisé les conditions réactionnelles et la décomposition du catalyseur en procédant à l'analyse des gaz effluents par chromatographie gazeuse. La caractérisation des catalyseurs et des produits a été effectuée en utilisant diverses techniques, tels les patrons de diffusion des rayons X (DRX), la microscopie de transmission électronique (MTE), la spectrométrie Raman et l'analyse par thermogravimétrie (ATG). Les résultats indiquent que les catalyseurs non réduits, 30Ni-10Co/La_2O_3 présentent la plus grande activité pour la décomposition du méthane et le rendement le plus élevé en carbone, 624,2%, a été obtenu sur ce catalyseur, à 700 °C, après 60 minutes de réaction avec de l'hydrogène comme gaz porteur. Les résultats de ATG suggèrent que la pureté des nanotubes de carbone (NTC) peut atteindre 98% en poids après une seule purification avec de l'acide chlorhydrique.

Mots-clés : nanotubes de carbone, déposition de vapeur chimique catalytique, décomposition du méthane, catalyseur de Ni-Co/La_2O_3.

[Traduit par la Rédaction]

Introduction

Carbon nanotubes have been widely studied not only for their unique structural, electronic, and mechanical properties but also for their potential applications in electronic devices, displays, and in the field of hydrogen storage (1). To realize various applications of CNTs, large quantities of high-quality CNTs are inevitably necessary. Over the past decade, different production techniques have been developed, including arc discharge (2, 3), laser ablation (4, 5), and chemical vapour deposition (6–8). Among these techniques, the catalytic chemical vapour deposition (CCVD) method is regarded as the most promising method to commercialize the CNT growth owing to the advantages in its low cost, high yield, and easy control (9–11).

In the CCVD method, CNTs are produced from the thermal decomposition of the carbon-containing molecules on desirable metal catalyst (commonly, Fe, Co, and Ni). For nanotube nucleation and growth, it is crucial to select an effective catalyst with the appropriate size of active metal. Mixed metal oxides as perovskites have been recently investigated as the precursor of catalyst for CNT growth (12–16). Liang et al. (14) reported bulk synthesis of CNTs from CH_4 using La_2NiO_4 as the catalyst precursor. Liu et al. (13, 16) have utilized $LaCoO_3$ and $LaFeO_3$ as catalyst precursors for CNT growth. They obtained multi-walled carbon nanotubes on $LaCoO_3$ and bundles of single-walled carbon nanotubes on $LaFeO_3$. With these kinds of catalyst, some important advantages of preparing nanotubes are obvious. The product yield is higher and the reaction temperature is lower, com-

pared with other methods. The diameter of the CNTs is uniform and their purification and separation is easy because La_2O_3 is easily dissolved in hydrochloric acid, so most of the residual catalyst can be eliminated from the CNT product.

In the present work, novel $Ni–Co/La_2O_3$ catalysts have been prepared to produce CNTs by the CCVD method with methane as the carbon source. By analyzing the effluent gas with gas chromatography, the catalytic activities of these catalysts were determined. The effects of Ni and Co content, hydrogen-reduction pretreatment, and carrier gas on the activity and stability of the catalysts were also investigated.

Experimental

Catalysts preparation

The catalysts were prepared by combustion synthesis, with citric acid as a foaming and combustion additive. The designation and metal loading of the catalysts studied herein are given in Table 1. For all the catalysts, the total Ni and Co metal loading was adjusted to 40 wt%. A high metal loading was chosen to obtain a longer catalytic activity (17). The catalysts were prepared as follows: to aqueous solutions of $Ni(NO_3)_2·6H_2O$, $Co(NO_3)_2·6H_2O$, and $La(NO_3)_3·6H_2O$ having the required amount of metals, stoichiometry amount of citric acid was added. The resulting gel was evaporated at 80 °C under vacuum until a viscous syrup was formed. The viscous syrup was dried at 120 °C for 5 h, and a foamy material was obtained. Then, the foamy material was directly burned in air at 500 °C for 1 h and subsequently calcined at 800 °C for 5 h, and finally ground into a fine powder.

Carbon nanotubes synthesis

Catalytic tests were carried out in a fixed-bed horizontal quartz tube reactor with an outer diameter of 30 mm and a length of 600 mm. Initially, 50 mg of catalyst powder was sprayed uniformly into a quartz boat, which was inserted in the center of the reactor. Two reaction modes were adopted. First, the unreduced catalysts were directly used to decompose methane at 700 °C. Second, the catalysts were first reduced by hydrogen at 700 °C for 30 min and then used to decompose methane at the same temperature. N_2 and H_2 were used as carrier gas with the flows of the mixture CH_4/N_2 and CH_4/H_2 of 30/30 ml/min and 30/6 ml/min, respectively. The reaction lasted for 60 min during which the effluent gas was sampled out for the gas chromatography analysis. After the reaction, the system was cooled to room temperature under N_2 protection. The as-prepared product was removed from the reactor, purified in concentrated hydrochloride solution and filtered. It was then washed with distilled water and dried at 120 °C.

The carbon yield was calculated based on the following equation: Carbon yield (%) = 100 $(M_{total} - M_{cat})/M_{cat}$, where M_{total} denotes the total mass of carbon product and catalyst after 60 min of reaction and M_{cat} is the mass of catalyst before reaction.

Materials characterization

The XRD patterns of the catalysts were recorded on a PANalytical X Pert PRO with Cu radiation at a scanning rate of 4°/min. The TEM images of samples were obtained on a JEOL-1200EX TEM operating at 80 KV. The TGA profiles were obtained on a PerkinElmer Diamond TG/DTA under a flow of air with the heating rate of 10 °C/min. Raman studies were performed on a Renishaw 1000 micro-Raman spectrometer using Ar^+ laser with the excitation of 514.5 nm.

Results and discussion

Characterization of the catalysts

Figure 1 shows the XRD patterns of the catalysts before reduction. In the XRD pattern of the catalyst $40Ni/La_2O_3$ (Fig. 1*a*), the diffraction peaks at 32.8°, 47.3° and 58.7° were those of $LaNiO_3$. The diffraction peaks due to NiO were observed at 2θ = 37.2°, 43.3°, and 62.9°. For the catalyst $40Co/La_2O_3$ (Fig. 1*b*), the diffraction peaks at 32.9°, 33.3°, and 47.5° were characteristic lines of $LaCoO_3$, and the diffraction peaks at 31.3°, 36.9°, and 65.4° corresponded to Co_3O_4 phase. In the XRD pattern of the catalyst $30Ni–10Co/La_2O_3$ (Fig. 1*c*), the diffraction peaks at 32.8°, 33.1°, and 47.4° were attributed to $LaNi_{0.6}Co_{0.4}O_3$. The presence of NiO in the catalyst was also observed. From the XRD patterns, it can be observed that the catalysts mainly exist in the form of perovskites $LaNiO_3$, $LaCoO_3$, or $LaNi_{0.6}Co_{0.4}O_3$ and metal oxides NiO or Co_3O_4. This is because at high calcination temperature, the transition metals and the rare earth ox-

ide La_2O_3 can easily form perovskites, as already reported previously (12–16).

Figure 2 shows the XRD pattern of the catalysts 40Co/La_2O_3 and 30Ni–10Co/La_2O_3 after reduction. Compared with the unreduced catalyst (Fig. 1), the diffraction peaks due to perovskites $LaCoO_3$ and $LaNi_{0.6}Co_{0.4}O_3$ disappeared, and a new series of diffraction lines attributed to La_2O_3 appeared for the reduced catalysts. Ni and Co metal peaks were also observed in the samples at $2\theta = 44.5°$, 52.0°, and 76.3°, indicating the presence of Ni and Co particles. It is considered that the rare earth oxide La_2O_3 can prevent the transition metal from agglomerating and promote the dispersion of the nano-scale particle after reduction, which is frequently responsible for CNT growth (14).

Performance of the catalysts

Effects of Ni and Co content on carbon yield

The CNT synthesis was carried out by decomposition of CH_4 at 700 °C for 60 min. The yield of deposited carbon was measured by varying the content of Ni and Co in the Ni–Co/La_2O_3 catalysts to examine the effect of the catalyst composition on the activity of the catalysts. All the catalysts studied were not reduced before reaction, and N_2 was used as carrier gas. As shown in Table 1, with the nickel content in the catalyst increasing, the carbon yield slightly decreased from 290.4% to 207.8% over the catalysts 40Co/La_2O_3 and 10Ni–30Co/La_2O_3, respectively. Then, it increased to 515.4% over the catalyst 20Ni–20Co/La_2O_3. The highest carbon yield, being 552%, was obtained for the catalyst 30Ni–10Co/La_2O_3. Nevertheless, the carbon yield declined to 431% for the catalyst 40Ni/La_2O_3. Compared with the monometallic catalysts 40Ni/La_2O_3 and 40Co/La_2O_3, the bimetallic catalysts showed higher carbon yield except the catalyst 10Ni–30Co/La_2O_3. This suggests that the bimetallic catalysts are more active than the monometallic ones. The results reported here are consistent with the previous work (18–20). The catalytic activity of bimetallic catalyst is superior to that of monometallic catalyst because of its catalytic synergies in producing CNTs from CH_4.

Effects of hydrogen-reduction pretreatment

It is well-documented that prior reduction of catalysts with hydrogen is not necessary during the synthesis of CNTs by CCVD method, because it is commonly known that metal oxides will be reduced in the reaction environment by means of methane gas (21, 22). However, to the best of our knowledge, few studies reported the effects of hydrogen-reduction pretreatment on the activity of the catalysts. In this study, the effects of hydrogen-reduction pretreatment on the activity of the catalysts were examined over two monometallic catalysts 40Ni/La_2O_3 and 40Co/La_2O_3 and one bimetallic catalyst 30Ni–10Co/La_2O_3. Figure 3 shows the change of the methane conversion with time on stream in the methane decomposition at 700 °C. All the catalysts studied were not reduced before reaction, and N_2 was used as carrier gas. It should be pointed out that at the first contact of methane with these catalysts, no product was observed. After a period of time, the product H_2 was detected by chromatography, and we attributed this point to the beginning of the reaction. The contact of methane with these catalysts causes reduction of the metal-oxide species into small metal particles, which grow CNTs (21, 22). It is likely that there is a minimum particle size required for transition metals to grow CNTs through methane decomposition (23). At the first contact of methane with the catalysts, highly dispersed metal-oxide particles are reduced and aggregated into small metal particles. As soon as the particle size of the metals reaches that required to grow CNTs, the metal particles decompose methane to grow CNTs. As shown in Fig. 3, for all the catalysts, methane decomposition proceeded selectively to form hydrogen only as a gaseous product. Methane conversion was the highest at the beginning of the reaction, and it gradually decreased and finally terminated. It was also found that the catalytic activity was strongly dependent on the type of the catalysts and decreased in the order of 30Ni–10Co/La_2O_3

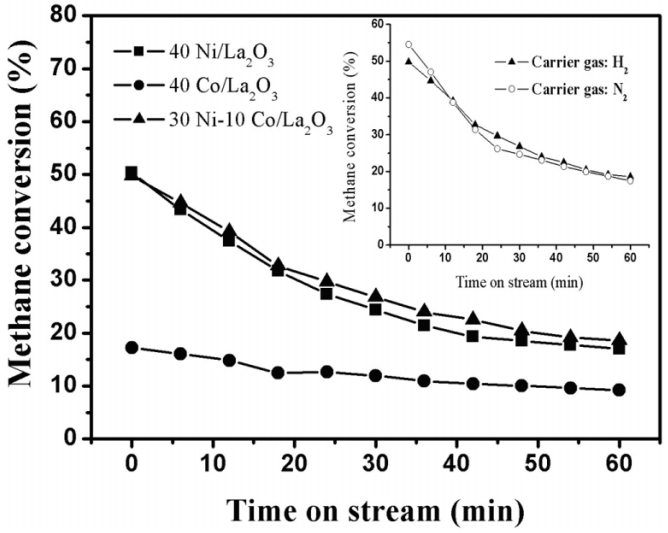
> $40Ni/La_2O_3$ > $40Co/La_2O_3$, which was in accordance with the carbon yield shown in Table 1.

For comparison, another series of the catalysts that had been reduced by hydrogen for 30 min before reaction were examined for methane decomposition, as shown in Fig. 4. The catalytic activity of the reduced catalysts decreased notably compared with that of the unreduced catalysts shown in Fig. 3. The catalyst $40Co/La_2O_3$ was almost inactive in methane decomposition. Correspondingly, the carbon yield declined to 185.8%, 350.2%, and 0 (Table 1) for the catalysts $30Ni–10Co/La_2O_3$, $40Ni/La_2O_3$, and $40Co/La_2O_3$, respectively. According to the experimental results presented above, we concluded that hydrogen-reduction pretreatment had a suppressing effect on the activity of the catalysts. The suppressing effect might be ascribed to the following reasons. First, the metal particles in the catalysts were aggregated during the period of the reduction to form large particles. According to Scherrer equation, the sizes of metal particles reached up to 23 and 26 nm for the catalysts $30Ni–10Co/La_2O_3$ and $40Co/La_2O_3$, respectively, after reduction (Fig. 2). Perhaps, these large particles caused the low catalytic activity for CNT synthesis and even no catalytic activity in the case of $40Co/La_2O_3$ (24, 25). Second, the lattice oxygen on the unreduced catalysts had positive effect on the activity of the catalysts, in presence of which the simultaneous catalyst reduction provided energy for the endothermic methane decomposition and consumed part of hydrogen and carbon (to the H_2O and CO), making the equilibrium of methane decomposition shift to the direction of hydrogen and CNT production in a much higher reaction rate (21).

Effects of carrier gas

In the CCVD method, H_2 is often used as carrier gas, especially when a liquid hydrocarbon like xylene, toluene, or benzene is used as the carbon source. Here, the effects of the H_2 as carrier gas on the activity of the catalysts were examined. Figure 5 shows the change of the methane conversion with time on stream in the methane decomposition at

Fig. 5. Change of the methane conversion with time on stream in the methane decomposition over the unreduced catalysts at 700 °C with H_2 as Carrier gas. Inset shows the conversion of methane as a function of time on stream in the methane decomposition over the unreduced catalyst $30Ni–10Co/La_2O_3$, with N_2 and H_2 as carrier gas, respectively.



700 °C. All the catalysts studied were not reduced before reaction, and H_2 was used as carrier gas. As shown in Fig. 5, the catalytic activity of the catalysts also decreased in the order of $30Ni–10Co/La_2O_3$ > $40Ni/La_2O_3$ > $40Co/La_2O_3$. Compared with N_2 as carrier gas (Fig. 5, inset), although the initial activity of the catalyst $30Ni–10Co/La_2O_3$ decreased, the stability of the catalyst was slightly improved with H_2 as carrier gas. Generally, in the CCVD method, CNT growth involves the decomposition of hydrocarbons on one side of a nanometer-sized catalyst particle, subsequent diffusion of carbon atoms through the volume or surface of the particle, and then precipitation of CNTs on its other side (8). For continuous growth of CNTs, the decomposition rate of hy-

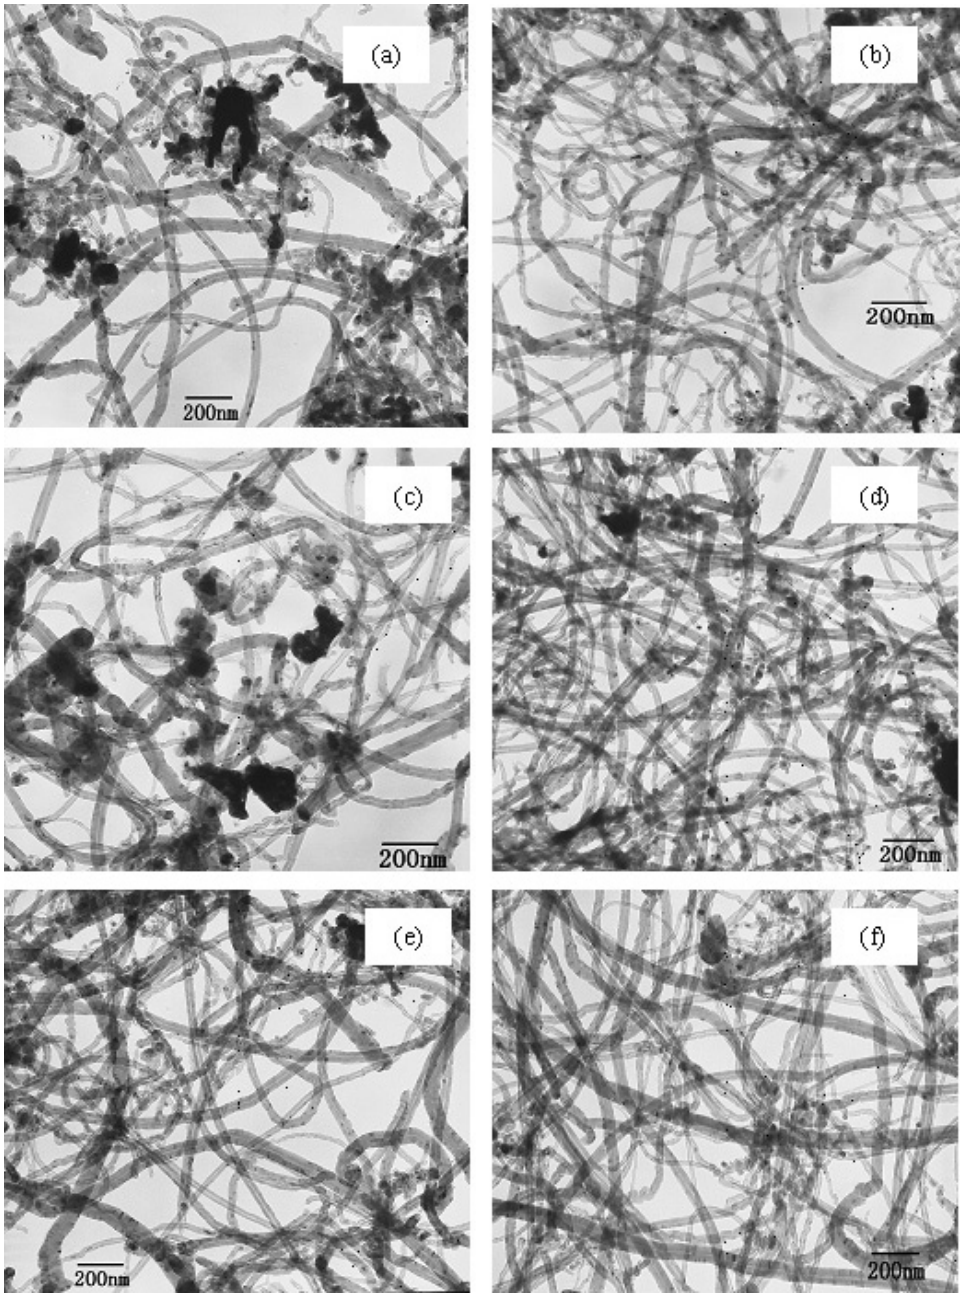
Fig. 6. TEM images of as-grown CNTs produced by catalytic decomposition of CH_4 at 700 °C over (*a*) and (*b*) 40Ni/La_2O_3, (*c*) and (*d*) 40Co/La_2O_3, (*e*) and (*f*) 30Ni–10Co/La_2O_3. All the catalysts used were not reduced before reaction, and the carrier gases were N_2 for (*a*) (*c*) (*e*) and H_2 for (*b*) (*d*) (*f*).



drocarbons must match well with the diffusion rate of carbon atoms. The formation of encapsulated carbon is regarded as the main reason for the deactivation of the catalysts. The results in Fig. 5 imply that the role of H_2 as carrier gas is to limit or alleviate the poisoning of the metal catalysts by elemental carbon, which can explain why the stability of the catalysts was improved with H_2 as carrier gas. After 60 min reaction, the carbon yields were 624.2%, 554.2%, and 190.4% for the catalysts 30Ni–10Co/La_2O_3, 40Ni/La_2O_3, and 40Co/La_2O_3, respectively. It should be pointed out that the carbon yield for the catalyst 30Ni–10Co/La_2O_3 is remarkably high. Compared with the data reported earlier (17, 26, 27), the presently observed carbon yield indicates that the activity of the catalyst 30Ni–10Co/La_2O_3 is very good for the growth of CNTs.

Characterization of the CNTs

The morphology of the carbon products obtained was characterized by TEM. Figure 6*a*–6*f* shows TEM images of as-grown CNTs synthesized by methane decomposition at 700 °C over the unreduced catalysts with N_2 and H_2 as carrier gas, respectively. It was observed that dense multi-walled carbon nanotubes were grown on the surfaces of all the catalysts. The morphologies of the MWNTs produced over these catalysts were similar to each other with relatively uniform diameters from 10 to 60 nm. Some catalyst particles

© 2008 NRC Canada

were found to be present at the tip of the CNTs, which suggested that the growth of the CNTs in the present work followed the tip growth mechanism (28). In the TEM measurement, some impurities such as amorphous carbon and carbon nanofibers were also observed in the samples, and the purity of CNTs was always higher for the carbon deposit synthesized with H_2 as carrier gas than for that synthesized with N_2 as carrier gas, which suggested that hydrogen could inhibit the formation of less-ordered and thermodynamically stable impurities so that the more-ordered and thermodynamically stable CNTs could be produced (29).

Raman spectroscopy is a useful technique for the characterization of CNTs. Figure 7 shows the Raman spectra of the CNTs grown over 30Ni–10Co/La_2O_3 with N_2 and H_2 as carrier gas, respectively. For all the Raman spectra, three major bands were observed, representing D, G, and 2D bands. The D band, observed at 1350 cm^{-1}, is known as either the disorder induced due to the wall disorder or the presence of amorphous carbon deposited on the outer surface of nanotubes (30). The G band, observed at 1590 cm^{-1}, can be attributed to the degree of graphitization of CNTs (30). The relative intensity ratio of D band to G band is known as an index to determine the structure of CNTs (31). It is found that the CNTs deposited on the catalyst with H_2 as carrier gas show smaller I_D/I_G ratio as compared with those with N_2 as carrier gas. This reveals that H_2 as carrier gas could provoke the formation of better graphitized CNTs and inhibit the formation of amorphous carbon in the products, which is consistent with TEM characterization discussed before.

Purification after the synthesis process is a very important part of the CNT production process. It involves the separation and the removal of the catalytic particles, support material, and amorphous particles from CNTs. We studied the purification of the CNTs by hydrochloric acid. Figure 8 shows TGA curves of the raw and purified CNTs produced by methane decomposition at 700 °C over the catalyst 30Ni–10Co/La_2O_3 with H_2 as carrier gas. These curves are very useful for the characterization of CNTs, since they provide simple and direct evidence for the purity grade and structural characteristics of the obtained CNT samples. For the raw sample, the slight mass loss occurred at 352 °C was due to the combustion of amorphous carbon present in the sample. The significant mass loss in TGA curve, which started near 521 °C and ended at about 612.4 °C was mainly attributed to oxidation of CNTs. The remaining quantity was 6.6 wt%, which was the mass of oxidized catalyst with La_2O_3. For the purified sample, the 98 wt% mass loss in TG curve was mainly attributed to oxidation of CNTs, and the 2 wt% residual could be assigned to the metallic particles that were either covered by a carbon cage or were located inside the tubes, being thus protected from acid attack (32). Thus, after a single-step purification by hydrochloric acid, most of the impurities were eliminated, and the purity of CNTs reached up to 98 wt%. The high purity of CNTs is achieved in this study owing to the fact that the use of La_2O_3 as catalyst support simplifies somewhat the purification process because it is easily dissolved in hydrochloric acid. However, in the case of zeolite or silica, which is widely used as catalyst support for CNT synthesis, only concentrated hydrofluoric acid can dissolve the support material. That is quite harmful for the integrity of the nanotubes themselves (33).

Fig. 7. Raman spectra for CNTs grown over 30Ni–10Co/La_2O_3 catalyst with N_2 and H_2 as carrier gas, respectively: (*a*) N_2 (*b*) H_2.

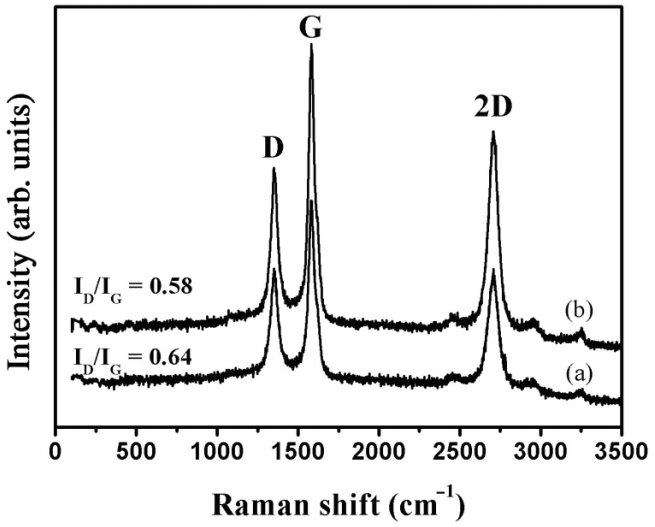


Fig. 8. TGA curves of the raw and purified CNTs produced by catalytic decomposition of CH_4 at 700 °C over the 30Ni–10Co/La_2O_3 catalyst with H_2 as carrier gas.

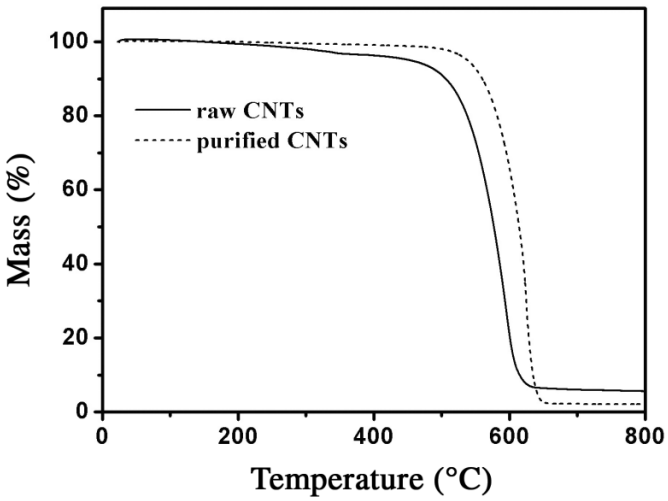

Conclusion

Novel Ni–Co/La_2O_3 catalysts have been prepared to produce CNTs by the CCVD method with methane as the carbon source. The effects of Ni and Co content, hydrogen-reduction pretreatment, and carrier gas on the activity and stability of the catalysts were investigated. The results indicate that the unreduced catalyst 30Ni–10Co/La_2O_3 showed the highest activity for methane decomposition and the carbon yields, being 552% and 624.2%, were obtained over this catalyst at 700 °C with nitrogen and hydrogen as carrier gas, respectively. The aggregation of metal particles and the lack of lattice oxygen caused the reduced catalysts to show lower catalytic activity than the unreduced ones. Hydrogen as carrier gas could limit or alleviate the poisoning of the metal

© 2008 NRC Canada

catalysts by elemental carbon and inhibit the formation of the impurities; thus, it improved the stability of the catalysts and reduced the quantity of the impurities present in the products. After a single-step purification by hydrochloric acid, the purity of the CNTs produced by methane decomposition over the unreduced catalyst 30Ni–10Co/La_2O_3 with hydrogen as carrier gas can reach up to 98 wt%, which makes the catalyst a very promising industrial product to produce high-quality CNTs on a large scale and at a low cost.

A DFT investigation into the origin of regioselectivity in palladium-catalyzed allylic amination[1]

Marco Zimmer De Iuliis, Iain D.G. Watson, Andrei K. Yudin, and Robert H. Morris

Abstract: The addition of amines or aziridines to prenylacetate is catalyzed by palladium phosphine complexes. The first-formed products have recently been shown to be the branched olefins $R_2NCMe_2CH{=}CH_2$, R = alkyl, or R_2 = 1,2-C_6H_{10}, for example. DFT calculations using the MPW1K functional were performed on reactions of the suspected intermediate η^3-prenyl complex $[Pd(\eta^3\text{-}Me_2CCHCH_2)(PH_3)_2]^+$ with dimethylamine and ethylene imine. The activation barrier for the nucleophilic attack by the amine or the aziridine is calculated to be similar for either the sterically hindered site of the π-allyl ligand to produce the branched olefin complex or the unhindered site to give the linear olefin complex. Therefore, these calculations do not reveal the experimentally observed preference for attack. This observation, along with the experimental observation of lack of isomerization of the branched olefin product of the aziridine reactions, appears to rule out the intermediacy of a π-allyl complex $[Pd(\eta^3\text{-}Me_2CCHCH_2)L_2]^+$, L = phosphine or L_2 = diphosphine in the C–N bond-forming reaction.

Key words: allyl palladium, amine, aziridine, DFT, mechanism, catalysis.

Résumé : L'addition d'amines ou d'aziridines à l'acétate de prényle est catalysée par les complexes des phosphines de palladium. Il a été démontré récemment que les premiers produits formés sont des oléfines ramifiées, telles les $R_2NCMe_2CH{=}CH_2$ dans lesquelles R = alkyle ou R_2 = 1,2-C_6H_{10}. On a effectué des calculs théoriques de la fonctionnelle de densité à l'aide d'une fonction MW1K sur les réactions de l'intermédiaire prévu, le complexe η^3-prényle $[Pd(\eta^3\text{-}Me_2CCHCH_2)(PH_3)_3]^+$ avec la diméthylamine et l'éthylèneimine. On a calculé que la barrière d'activation à l'attaque nucléophile par l'amide ou l'aziridine est semblable que ce soit pour le site stériquement empêché du ligand π-allyle à produire la complexe à oléfine ramifiée ou le site non empêché à donner le complexe de l'oléfine linéaire. Ces calculs ne permettent donc pas de confirmer la préférence observée expérimentalement pour cette attaque. Cette observation ainsi que l'observation expérimentale que l'oléfine ramifiée des réactions de l'aziridine ne conduit pas à une isomérisation semble éliminer la possibilité que le complexe π-allyle $[Pd(\eta^3\text{-}Me_2CCHCH_2)L_2]^+$, L = phosphine ou L_2 = diphosphine, soit un intermédiaire dans la réaction de formation de la liaison C–N.

Mots-clés : allylpalladium, amine, aziridine, calculs théoriques de la fonctionnelle de densité, mécanisme, catalyse.

[Traduit par la Rédaction]

Introduction

Transition-metal-catalyzed allylic substitution has found broad applications in synthesis (1–3). Efficient catalysts are available to carry out allylic alkylation with high degrees of efficiency and selectivity, and chiral ligands can be employed to effect the reaction, affording products with high enantioselectivities (1). The use of nitrogen nucleophiles (4) in allylic amination enables the synthesis of allylamines, fundamental building blocks in organic chemistry. Allylamines are important synthetic intermediates for a range of biologically active compounds (1) such as α- and β-amino acids (5) and alkaloids (6). The generally accepted mechanism is thought to proceed by nucleophilic attack of Pd(0) at an allyl position of an olefinic compound and an oxidative addition to produce a cationic π-allyl palladium complex. The key step is proposed to be the subsequent nucleophilic attack by the amine nucleophile at the π-allyl palladium complex, resulting in formation of the allylamine product (Scheme l) (7).

There are two possible sites for nucleophilic attack at an unsymmetrical allyl π system, leading to distinct regioisomeric products. The regiochemistry of attack in allylic substitution varies greatly with respect to the metal, ligands, nucleophile, and allyl substituent type. For example, if there is an electron-accepting substituent (R) on the allyl group, then attack at the more substituted position is preferred (8–10). In contrast, if R is an electron-donating group, attack at the less substituted position is more favoured (11–15). Therefore, it was surprising to find that for the addition of amines or aziridines to prenylacetate catalyzed by palladium phosphine complexes, the first-formed products were found to be the branched olefins $R_2NCMe_2CH{=}CH_2$ where R is

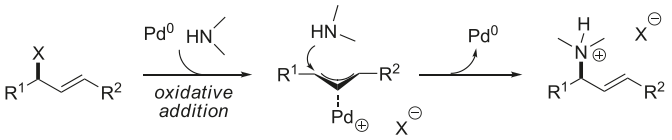
Scheme 1. Proposed mechanism of Pd-catalyzed allylic amination.



Me or R_2 is 1,2-C_6H_{10}, or other substituents (16–18). A possible explanation is that a π-allyl complex such as the η^3-prenyl palladium complex **A** forms (Scheme 2) (19, 20) and is attacked preferentially by an amine nucleophile at position *a* in complex **A** to give initially the branched product under basic conditions (18). This is followed by a branched to linear (b/l) isomerization to form the thermodynamically more stable linear product (16, 17). It was later found that protic acid generated during the reaction is the prerequisite for product isomerization (18). Palladium coordination to the double bond of the protonated allylamine initiates ionization of the kinetically favoured branched product (Scheme 2). Surprisingly, the unsubstituted aziridine nucleophiles gave only the kinetic branched products and these did not undergo the b/l isomerization (16, 17).

We were interested in determining the reasons behind the b/l isomerization by utilizing DFT calculations, with particular regard to the Pd-coordinated intermediates. Density functional theoretical (DFT) calculations have been found to be very useful in exploring reaction mechanisms and the origin of selectivities found in transition-metal-catalyzed processes. In particular, DFT calculations have been used to study attack of nucleophiles on η^3-allylpalladium complexes containing phosphine ligands (21–24), phosphorus–nitrogen ligands (25, 26), and chlorine and amine ligands (25, 27–29).

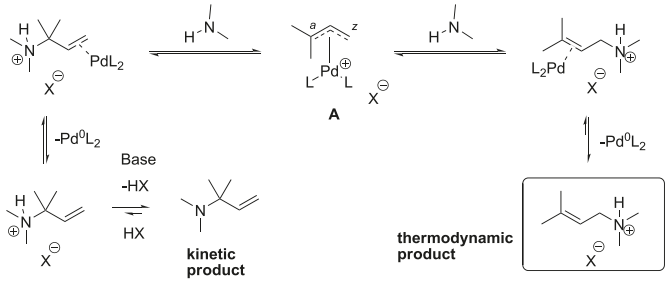
One such study by Delbeq et al. investigated the regioselectivity of nucleophilic attack by NH_3 on three model complexes with substituted η^3-allyl ligands; one of which was an η^3-prenyl ligand (30). They found that, in the gas phase, attack at the substituted carbon is always favoured. This trend was rationalized based on the interaction of the HOMO and LUMO of the η^3-allyl species with the HOMO of the NH_3; that is, the larger the coefficient in the LUMO on a carbon in the direction of attack, the more selective the nucleophile is for that particular carbon.

We wondered if attack at the key η^3-palladium π-allyl complex **A** (Scheme 2) explains the reasons for the observed b/l ratios and the isomerization of the branched products to the linear product, but only in the case of amine and not aziridine. Also, does a switch in nucleophile from a simple amine to an aziridine cause a change in the regiochemistry of attack at complex **A**? This study was based on a model η^3-prenyl palladium catalyst using $HNMe_2$ and HNC_2H_4 as the aminating agents. To the best of our knowledge, this is the first mechanistic DFT study of allylic amination of an η^3-prenyl palladium complex using these nucleophiles.

Computational details

All calculations were performed using Gaussian03 (31). The calculations were performed on a workstation with two

Scheme 2. Possible mechanism for the branched-to-linear isomerization of allylamines in Pd-catalyzed allylic aminations



2.8 GHz Opteron X2 processors with 4 GB of RAM using the Red Hat Linux Enterprise Edition operating system. All calculations used the MPW1K density functional method, since it has been shown to provide accurate barrier heights for thermochemical kinetics (32–34). The MPW1PW91 method was also used for the complete system, resulting in the same findings. Palladium was treated with the SDD basis set to include relativistic effects and an effective core potential and H, C, N, and P were treated with the triple zeta basis set 6-311++G**, which includes diffuse functionals and additional p orbitals on H as well as additional d orbitals on C, N, and P. The structures were optimized in the gas phase at 1 atm of pressure and 298 K (1 atm = 101.325 kPa, 0 °C = 273 K). Full vibrational analyses were performed on the optimized structure to obtain values of ΔG, ΔH, and ΔS. The QST2 or QST3 method was utilized to locate transition states. All transition states were found to have one imaginary frequency. The calculated atomic polar tensor (APT) charges are used. The APT charge is the derivative of the forces on the atoms with respect to an applied external electric field and yields atomic charges that more accurately reflect the charge distribution rather than individual atomic charges (35).

Solvation by tetrahydrofuran (THF) was modeled using the polarized continuum model (PCM). Single-point energy calculations were performed on the gas-phase optimized structures. The following modifications to the PCM model were used: the bondi radii were used to specify explicit hydrogen atoms and scfvac keyword was added to calculate $\Delta G_{solvation}$. The default solvent parameters included in Gaussian03 were used for THF. PCM solvation has been successfully utilized to calculate solvation free energies of neutral and ionic organic and inorganic molecules (36–40). This method has also been effectively applied to the investigation of organometallic reaction mechanisms (41–45).

Supporting information about this work includes lists of atomic coordinates for all of the calculated structures, details of the calculation of solvation energies, and results using the MPW1PW91 method.[3]

Results and discussion

The starting point for our calculations was the optimization of the palladium(II) η^3-allyl complex $[Pd(\eta^3\text{-}Me_2CCHCH_2)(PH_3)_2]^+$ (**1**, Fig. 1). A simplification made to

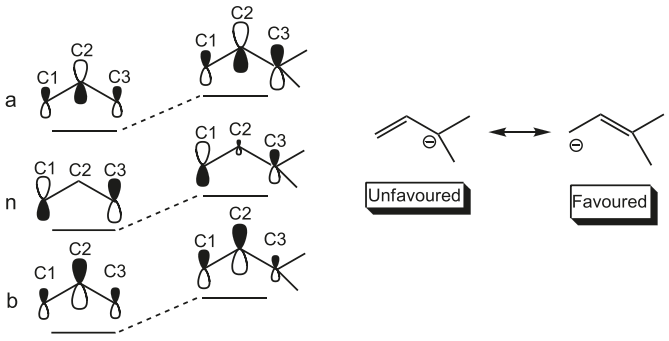
the real system $[Pd(\eta^3\text{-}Me_2CCHCH_2)(PR_3)_2]^+$ is the use of PH_3 for the phosphine ligands. Experimentally, modification of the sterics by varying the phosphine groups R did not greatly affect the conversion or the selectivity. For example, the b/l ratio changed little between different phosphine bidentate ligands, such as BINAP (bite angle of 92.8°, 8/92 b/l ratio) and Xantphos (bite angle of 104.6°, 4/96 b ratio), or monodentate ligands, such as PPh_3 (cone angle 145° (46)) and $P(OEt)_3$ (cone angle of 109° (47)) (16). Both the model complex and the actual catalysts are cationic, which aids in the activation of the allyl group for nucleophilic attack (48). Another simplification was to ignore the role of the acetate or chloride counter ions.

In Table 1, the calculated geometry of the model complex is compared to that of the structures of prenyl η^3-allyl phosphine palladium complexes determined by single-crystal X-ray diffraction. The agreement is quite good. For the remainder of this paper, C1 will denote the sterically less hindered, terminal carbon of the prenyl ligand, C2 will denote the central carbon, and C3 will denote the sterically hindered, methyl substituted carbon.

Of note is the difference between the Pd–C1 and Pd–C3 distances in Table 1. A previous theoretical study (25) attributed this difference to phosphine ligand asymmetry, but this is not the case here. An X-ray study of $[Pd(\eta^3\text{-prenyl})(\text{diphosphine})]^+$ complexes (49) concluded that the Pd–C3 distance was long due to steric effects, but we find the same lengthening in $[Pd(\eta^3\text{- preny1})(PH_3)_2]^+$ where there is no steric interaction between the phosphines and the η^3-prenyl ligand. Branchadell et al. have attributed the difference to the nature of the substituents on the allyl group (50). They reported that if a methoxy group (electron-donating) is present on a terminal allyl carbon, then the other terminal carbon will have the shortest Pd–C bond of the allyl ligand. Conversely, if a nitro group (electron-withdrawing) is bound to a terminal allyl carbon, the nitro-bound carbon will have the shortest metal–carbon bond. In the structure reported here,

Fig. 2. Effect of electron-donating groups bound to the terminal carbon on molecular orbitals of the allyl ligand.



the methyl groups are ineffective in stabilizing negative charge at C3 (Fig. 2). This allows a stronger interaction between the metal and C1. The left hand side of Fig. 2 shows a schematic representation of the MOs of the allyl ligand. Addition of methyl groups onto the parent allyl fragment causes an increase in the orbital energies and allows for mixing of the various orbitals, since the ligand is no longer symmetric. The asymmetry causes polarization of n–π orbital towards C1 and results in the short Pd–C1 distance.

The calculated charge distributions for complex I are shown in Fig. 1. The charges are not distributed evenly over C1, C2, and C3. C3 has a charge equal to 0.45, which is more than 0.3 ESU greater than either C1 or C2, making it more susceptible to nucleophilic attack.

Nucleophilic attack of dimethylamine

The calculated reaction pathway for the nucleophilic attack of $HNMe_2$ on **1** is outlined in Scheme 3. The reaction pathway for nucleophilic attack by NH_3 was also calculated for comparison with the results of Delbeq et al. (30). There are two possible sites of attack for the amine: either C1, which is the sterically unhindered site and is shown in the right-hand side, or C3, which is the sterically hindered site, on the left-hand side.

Both reaction pathways were found to involve three essential steps. The first involves the approach of the $HNMe_2$ to either C1 or C3. The second step is the formation of a transition state for the nucleophilic attack in which a new C–N bond is formed. Finally, there is the formation of the palladium(0) olefin complex. In considering the reaction coordinate diagram for $HNMe_2$ attack, the sum of the calculated free energies of **1** and $HNMe_2$ will be used as the zero energy reference point, and all other energies will be relative to this value (Fig. 3).

© 2008 NRC Canada

Scheme 3. Calculated reaction pathway for $HNMe_2$ attack on the π-allyl complex **1**.

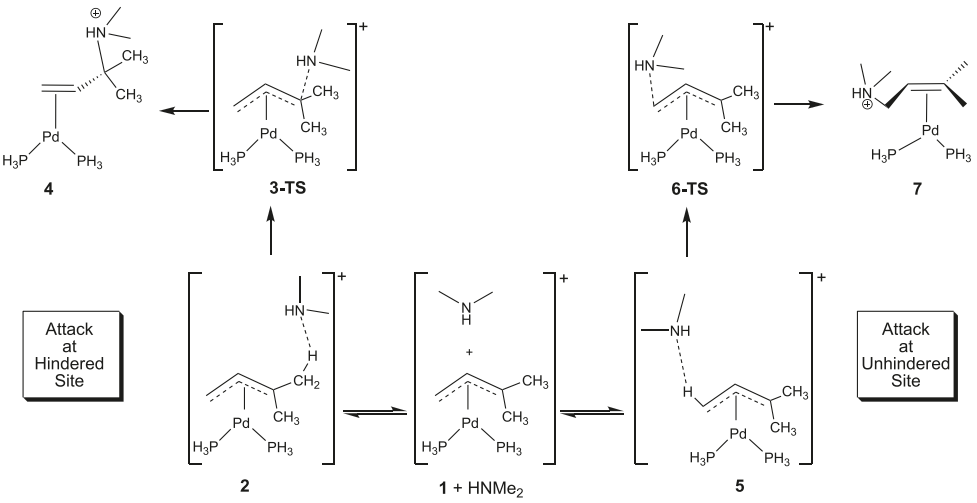


Fig. 3. Reaction coordinate diagram (free energies at 298 K, 1 atm) for the reaction of $HNMe_2$ (black lines) and NH_3 (grey lines) with the π-allyl complex **1** in the gas phase (solid line) and with THF solvation (dotted line).

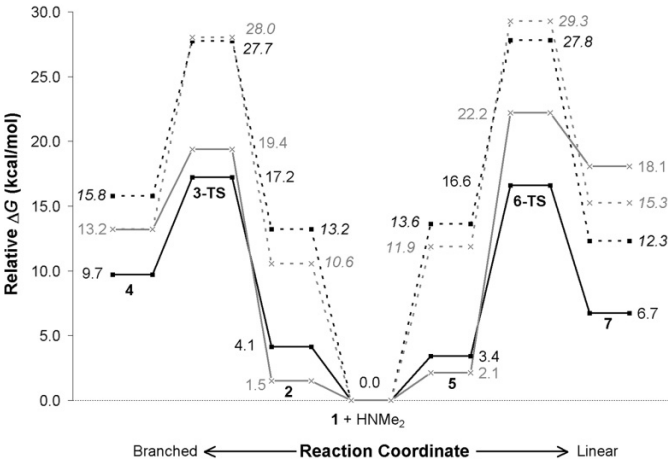

We will first examine the left-hand side of Scheme 3, leading to the branched allylamine. A weakly interacting adduct **2** with a linear N1···H17–C5 interaction provides a metastable starting point (Fig. 4). The C1–C2 and C2–C3 bond distances of the η^3-allyl system have the same value of 1.41 Å, which indicates that at this point in the reaction, there is still a delocalized π system present. In **2**, N1 is negative, at –0.59 ESU while the charge on C3 is 0.53, which suggests that attack of N1 on C3 is electrostatically favourable (Fig. 4).

In the gas phase, the free energy of **2** is 4.1 kcal/mol greater than the starting reactants, while in solution it is 13.2 kcal/mol. The increase in free energy is due to the loss of entropy in going from free reactants to this adduct.

The reaction progresses from **2** to the transition state for the attack of $HNMe_2$ on C3 (**3-TS**). In this case, the N1–C3 distance is 2.23 Å, and the $HNMe_2$ is oriented directly above the plane of the prenyl cation. The methyl groups on C3 are pushed downward toward the palladium and below the plane created by C1, C2, and C3. Also of note is the "slipped" nature of the π-prenyl ligand. The Pd–C3 distance is now 2.84 Å, which is more than 0.6 Å longer than either Pd–C2 or Pd–C1. This rearrangement allows for the maximum orbital overlap of the attacking nucleophile on the electrophile (Fig. 5) (51). There are only minor changes in the Pd–P distances and the Pl–Pd–P2 angle throughout the reaction.

The charges in the transition state are dramatically different from those of **2**. The charge on C3, where a new C–N bond is forming, has increased from 0.50 to 1.33 ESU, and N1 has become more negative, going to –0.72. A noticeable trend in both complexes **2** and **3** is that the charges of N1, C3, C2, and C1 alternate between negative (N1, C2) and positive (C3, C1). This is true for all of the structures calculated. The activation energy calculated for attack on the hindered site, which corresponds to the free energy of **3-TS**, is 17.2 kcal/mol in the gas phase and 27.7 kcal/mol in solution. Animation of the single imaginary frequency, 199*i* cm^{-1} shows the N1–C3 bond shortening with the geometry of C3 going from nearly planar to tetrahedral.

The product of attack is the palladium(0) olefin complex **4**. In this case, C1 and C2 form a C=C double bond of 1.41 Å, while C3 and C2 form a single bond with a bond length of 1.51 Å. The charges have been re-distributed on N1 and C3 to reflect the new C–N bond that has formed, with the N1 now = –0.50 and C3 = 0.57 ESU. The relative energy of **4** is 9.7 kcal/mol in the gas phase and 15.8 kcal/mol in solution. Other steps in the catalytic cycle would have to drive this endothermic reaction if this mechanism is operating.

We now turn to the right-hand side of Scheme 3 in which $HNMe_2$ attacks C1 to yield the linear product. Structural diagrams of **5**, **6-TS**, and **7** are shown in Fig. 6 along with selected geometric parameters and APT charges.

The starting point for attack on the less hindered carbon C1 is a weak adduct **5**. The N1–H2 distance is 2.36 Å and the N1–H2–C1 angle is 171.2°. The charge on C1 is 0.09 ESU, which is 0.41 ESU less than that of C3 in **2**, the analogous structure for branched attack. The charges of N1 are similar in both **2** and **5**. The relative free energy of **5** is greater than the free reactants by a similar amount to that of **2** both in the gas and solution phases (Fig. 3). **6-TS** is very similar in structure to **3-TS**, with a N1–C1 distance of 2.10 Å and the slipping of allyl ligand such that the C1–Pd

Fig. 4. Calculated Structures of **2**, **3-TS**, and **4**. Selected bond distances (Å) and angles (°): **2**: P1—Pd = 2.34, P2—Pd = 2.33. Pd—C1 = 2.14, Pd—C2 = 2.16. Pd—C3 = 2.28, N1···H7 = 2.33, P1–Pd–P2 = 103.5. **3-TS**: P1—Pd = 2.36, P2—Pd = 2.31. Pd—C1 = 2.08, Pd—C2 = 2.19, Pd—C3 = 2.84, N1—C3 = 2.23, P1–Pd–P2 = 104.0. **4**: P1—Pd = 2.34, P2—Pd = 2.34, Pd—C1 = 2.09, Pd—C2 = 2.14, Pd—C3 = 3.14, N1—C1 = 1.57, P1–Pd–P2 = 102.9. Selected APT charges (ESU): **2**: C1 = 0.15, C2 = –0.08, C3 = 0.50, N1 = –0.62. **3-TS**: C1 = 0.36. C2 = –0.55, C3 = 1.33, N1 = –0.72. **4**: C1 = 0.19. C2 = –0.05, C3 = 0.57, N1 = –0.50.

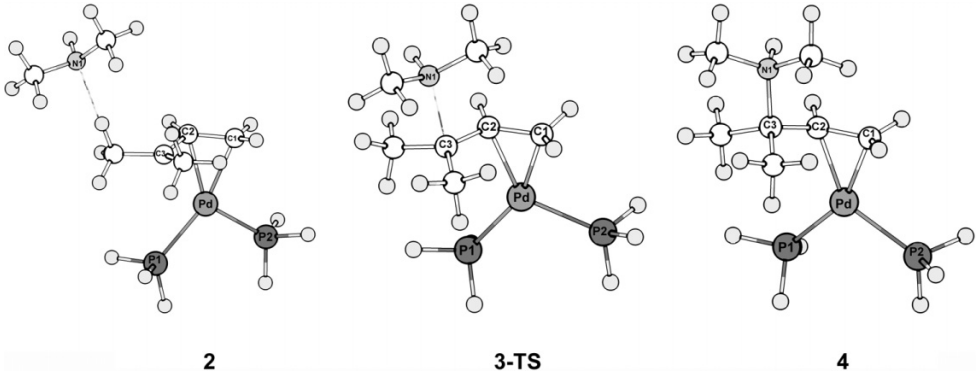

Fig. 5. Molecular orbital diagram for **3-TS** showing the HOMO-5 orbital with constructive orbital overlap between C3 and N1.

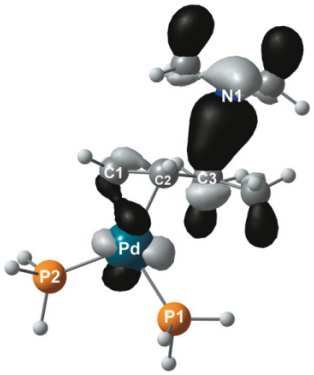

bond is elongated compared with the Pd–C2 and Pd–C3 bonds. The charge distribution changes to reflect the C–N bond formation. C1 and N1 are highly polarized with charges of 1.16 and –0.84 ESU, respectively, reflecting the electrostatic attraction of the nucleophilic N1 to the electrophilic C3. The activation energy for attack on C1 is 16.6 kcal/mol in the gas phase and 27.8 kcal/mol in solution. Again, this value does not differ significantly from that for **3-TS**. Animation of the imaginary frequency, 292*i* cm^{-1}, shows N1 approaching C1 and the planar geometry of C1 changing to tetrahedral.

The palladium(0) linear olefin complex **7** has a C=C double bond of length = 1.41 Å formed between C3 and C2, with a C–C single bond between C1 and C2. The polarized charges observed in **6-TS** have been re-distributed, with C1 having a 0.49 ESU charge and N1 with –0.50 ESU. These charges are very similar to those of the branched olefin product **4**. The relative free energy for **7** is greater than the reactants by 6.7 kcal/mol in the gas phase and 12.3 in solution. Compared with **4**, **7** is more stable by 3.0 kcal/mol in the gas phase and 3.5 kcal/mol in solution.

To determine the relative energies of the uncomplexed branched vs. linear allylammonium products, the energy-minimized conformations of simplified isomeric protonated allylamines were calculated. The difference in the calculated total energy was 8.5 kcal/mol in the gas phase and 8.9 kcal/mol in THF, with the linear *N*-allylammonium having a lower calculated total energy (Fig. 7). The greater degree of olefin substitution is likely the reason for the lower energy of the linear allylamine, a result of increased hyperconjugation. Therefore, the calculated energy-minimized conformers of the protonated branched and linear allylamines verify that the linear allylamine is the thermodynamic product of the reaction.

These results indicate that for attack on η^3-prenyl palladium complex **A**, neither of the calculated pathways is significantly energetically different. The same reaction pathway using NH_3 as a nucleophile also shows that the energy barrier for attack at either side is equally favourable. This is not the conclusion that Delbeq et al. arrived upon in their study; however, the DFT method and basis sets utilized in the current study are different. Delbeq et al used the B3LYP method, since it was shown to yield results similar to the MP2 method (52). However, since the principle focus of the present study is to determine if there is a preference for attack at either end of an unsymmetrical π-allyl palladium complex, the MPW1K method was utilized, since it has been optimized for kinetics (32–34). The basis sets employed by Delbeq et al (LANL2DZ ecp for Pd and P, D95V* for C and N, and D95V for H) are double zeta rather than triple zeta and do not include diffuse functionals, which were included here by using the 6-311++G** basis set for H, N, C, and P.

Experimentally, formation of the branched allylamine is observed initially, with high selectivity. The reaction pathway of Scheme 2 does not explain this kinetic preference because the calculated barriers to re-isomerization are similar for the branched and linear allylamines. Since experimental observations show high selectivity, it is unlikely that the mechanism calculated here is operating, and therefore, these results indicate that other allyl-palladium complexes may be responsible for the observed results.

Nucleophilic attack of aziridine

The reaction proceeds in an analogous way to the amine attack and is shown in Scheme 4. Again, the left-hand side details attack on the hindered site at C3 while the right-hand side depicts attack on the unhindered site at C1. The reaction

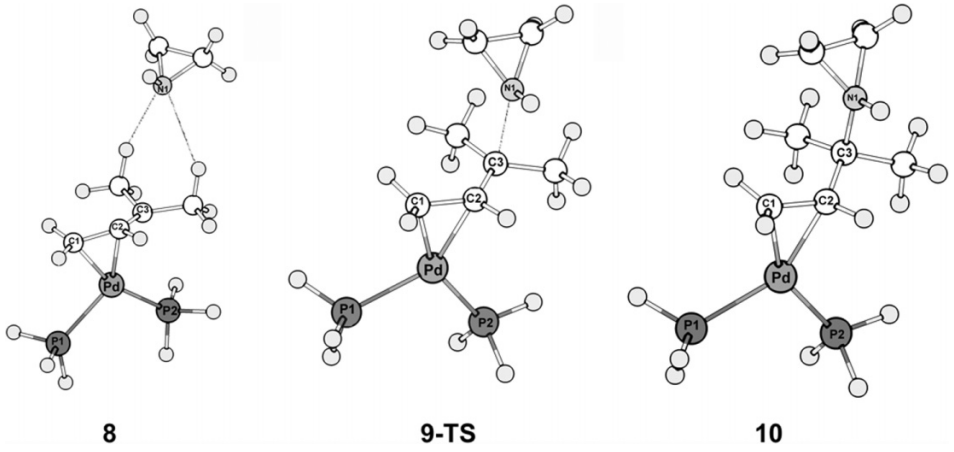

Fig. 10. Calculated Structures of **11**, **12-TS**, and **13**. Selected bond distances (Å) and angles (°): **11**: P1—Pd = 2.34, P2—Pd = 2.33, Pd—C1 = 2.15, Pd—C2 = 2.16, Pd—C3 = 2.26, N1···H2 = 2.28, P1–Pd–P2 = 103.6. **12-TS**: P1—Pd = 2.33, P2—Pd = 2.36, Pd—C1 = 2.61, Pd—C2 = 2.16, Pd—C3 = 2.15, N1—C1 = 2.02, P1–Pd–P2 = 103.2. **13**: P1—Pd = 2.33, P2—Pd = 2.35. Pd—C1 = 3.02, Pd—C2 = 2.12, Pd—C3 = 2.13, N1—C1 = 1.50, P1–Pd–P2 = 104.2. Selected APT charges (ESU): **11**: C1 = 0.09, C2 = –0.06, C3 = 0.43, N1 = –0.53. **12-TS**: C1 = 1.26, C2 = –0.44, C3 = 0.59, N1 –0.88. **13**: C1 = 0.55, C2 = –0.12, C3 = 0.45, N1 = –0.57.

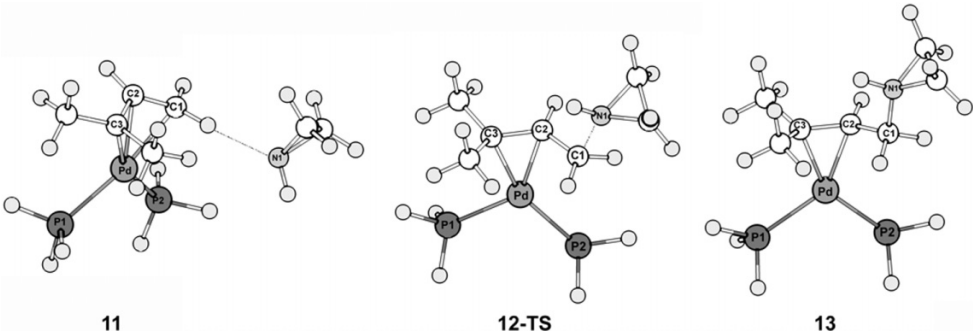

0.50 ESU, showing that the interaction has caused some polarization, making the C3 more electrophilic. As in the case of the amine attack, **8** has a greater relative energy, 2.0 kcal/mol in the gas phase and 16.1 kcal/mol in solution, than the free reactants.

In the transition state, **9-TS**, the aziridine nitrogen is 2.15 Å from C3 and is oriented directly above the plane of the η^3-preny1 ligand. The methyl groups on C3 are also beginning to bend away from the incoming aziridine. The slippage of the π-prenyl ligand is now very evident, as C3 is now more than 0.65 Å farther from the Pd than either C2 or C3. The APT charges in **9-TS** reflect the electrophilic and nucleophilic characters of C3, 1.40 ESU, and N, –0.80 ESU, respectively. Animation of the single imaginary frequency, 239*i* cm^{-1}, shows the C3–N1 distance decreasing and the methyl groups on C3 bending away from the incoming aziridine. **9-TS** is 16.1 kcal/mol in the gas phase, and 28.3 kcal/mol in solution, higher than the free reactants, which corresponds to the activation energy for this reaction. Thus, the barrier for attack of aziridine on C3 (**9-TS**) in the gas phase is 1 kcal/mol less than that of the amine attack on C3 (**3-TS**). It is 0.6 kcal/mol higher in THF solution. Finally, there is the formation of the branched olefin complex **10**, which has a C=C double bond between C2 and C1 (1.41 Å). The APT charges are no longer as polarized and are similar in magnitude to those of **8**. The relative free energy of **10** is 7.6 kcal/mol in the gas phase and 13.9 kcal/mol greater than the free reactants. These are slightly (~2 kcal/mol) higher than the analogous energies for $HNMe_2$ attack on C3.

Looking at the right-hand side of Scheme 4, we may examine attack at C1. The initial adduct, **11**, involves the interaction of the nitrogen of HNC_2H_4 with one of the protons on C1 (Fig. 10). The features of the reaction are very similar to those of the amine attack on C1.

The imaginary frequency of **12-TS** is 336*i* cm^{-1}. In **12-TS**, C1 is more than 0.45 Å farther away from the Pd than either C2 or C3, and there is a high degree of polarization of the charges of C1 (1.26 ESU) and N1 (–0.88 ESU). The activation barrier for the attack on the unhindered side is calculated to be 17.6 kcal/mol in the gas phase and 29.6 kcal/mol in solution, only 1.5 kcal/mol higher than that of the attack on the hindered side. Similar to the left-hand side, the reaction ends with the formation of an olefin palladium(0) com-

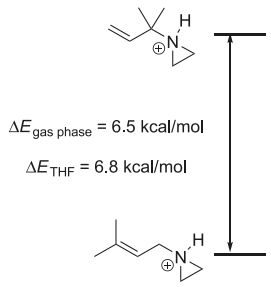
Fig. 11. Relative stabilities of decomplexed isomeric allyl aziridinium products in the gas phase.



plex, which lies 8.7 kcal/mol and 14.3 kcal/mol higher in energy than the free reactants.

The difference in the calculated total energies of the uncomplexed protonated linear and branched allyl aziridines is 6.5 kcal/mol in the gas phase and 6.8 kcal/mol in THF, with linear allyl aziridinium having a lower calculated total energy (Fig. 11). These results agree with those of the protonated allylamine regioisomers. Indeed, the linear allyl aziridine would be the thermodynamic product if isomerization occurred between these substrates.

Experiments show that with cyclohexene imine as the nucleophile, the branched product is observed in high yields with only a small fraction of the linear product, yet our calculations on the mechanism of unsubstituted aziridine attack at η^3-prenyl palladium complex **A** provide no evidence for such a selectivity. Therefore, as with the calculations of the allylamine complexes, these results indicate that other reaction intermediates must be responsible for the observed results.

Conclusions

The mechanism of nucleophilic attack of $HNMe_2$ and HNC_2H_4 on the model complex $[Pd(\eta^3\text{-}Me_2CHCH_2)(PH_3)_2]^+$ (**1**) found here by computation involves at least three steps. First, there is the interaction of the nucleophile with hydrogens of the η^3-prenyl ligand. Next is the transition state, in which the π- prenyl ligand is slipped and C–N bond formation occurs (**3-TS**, **6-TS**, **9-TS**, and **12-TS**). The slippage is known to facilitate orbital overlap with the incoming nucleophile (51). Finally, a palladium(0) olefin complex is formed (**4**, **7**, **10**, and **13**).

The calculated activation barriers for attack at either C1 or C3 by either $HNMe_2$ or HNC_2H_4 differ by about 1 kcal/mol. Therefore, there does not appear to be a preferred site of attack on the π-allyl in $[Pd(\eta^3\text{-}Me_2CHCH_2)(PH_3)_2]^+$ according to Scheme 2. This suggests that there may be a different palladium intermediate that causes the initial, selective formation of the branched products observed experimentally. Work is underway to look for alternative mechanisms, for example, those that involve the counter anion or an η^1- allyl complex (16), as well as to verify that that the use of PH_3 in this study is justified.

Examining the relative energies of the decomplexed *N*-allylammonium and *N*-allylaziridinium products, it is found that the linear isomer is more stable than the branched counterpart by at least 5 kcal/mol, and hence isomerization to the linear product should occur when either $HNMe_2$ or HNC_2H_4 is the nucleophile. However, experimentally, it is found that the branched aziridine adduct does not isomerize. This observation is not explained by the mechanism of Scheme 2 involving the intermediate $[Pd(\eta^3\text{-}Me_2CHCH_2)(PH_3)_2]^+$. Hence, alternative mechanisms and reaction intermediates still to be discovered are responsible for the observed selectivities.

DFT studies of the σ-donor/π-acceptor properties of $[SnCB_{10}H_{11}]^-$ and its relationship to $[SnCl_3]^-$, CO, PF_3, $[SnB_{11}H_{11}]^{2-}$, $SnC_2B_9H_{11}$, and related $SnC_2B_nH_{n+2}$ compounds[1]

Mark A. Fox, Todd B. Marder, and Lars Wesemann

Abstract: The 1,2-carbastanna-closo-dodecaborate, $[SnCB_{10}H_{11}]^-$, was found via DFT calculations to have intermediate σ-donor/π-acceptor properties between those of $[SnB_{11}H_{11}]^{2-}$ and 3,1,2-$SnC_2B_9H_{11}$, and quite similar HOMO and LUMO energies and shapes to those of $[SnCl_3]^-$, which is a stronger σ-donor and weaker π-acceptor than CO or PF_3. The non-carbon containing cluster $[SnB_{11}H_{11}]^{2-}$ is shown to be a very strong donor, whereas the dicarbon cluster 3,1,2-$SnC_2B_9H_{11}$ is a poor σ-donor but good Lewis acid, consistent with experimental results. Thus, these systems can be tuned across a very wide range via isolobal replacement of $[BH]^-$ for CH vertices. The higher negative charge in the non-carbon-containing systems, as well as the fact that boron is more electropositive than carbon, contribute to the increased energies of both HOMO and LUMO in the stannaboranes compared to the stannacarboranes, explaining their relative donor and acceptor properties.

Key words: DFT calculations, tin, borane cluster.

Résumé : Sur la base de calculs théoriques effectués par la méthode de la fonctionnelle de la densité (DFT), nous mettons en évidence les propriétés donneur σ/accepteur π du 1,2-carbastanna-*closo*-dodécaborate, $[SnCB_{10}H_{11}]^-$, sont intermédiaires entre celles de $[SnB_{11}H_{11}]^{2-}$ et celles de 3,2,1-$SnC_2B_9H_{11}$. Les énergies et les formes de l'orbitale la plus haute occupée (HOMO) et de l'orbitale la plus basse vacante (LUMO) sont quelque peu similaires à celles de $[SnCl_3]^-$, qui est plus donneur σ et moins accepteur π que CO ou PF_3. Nous montrons que, en accord avec les données expérimentales, l'agrégat non carboné $[SnB_{11}H_{11}]^{2-}$ est un très bon donneur σ, au contraire de $SnC_2B_9H_{11}$ qui est un mauvais donneur σ mais un bon acide de Lewis. Ainsi, il est possible de jouer de façon importante sur les propriétés de tels systèmes par le remplacement isolobal de sommets $[BH]^-$ par des sommets CH. La charge négative plus importante dans les systèmes non carbonés, ainsi que le fait que le bore soit plus électropositif que le carbone, contribuent à l'augmentation des énergies des HOMO et LUMO dans les stannaboranes, comparée aux stannacarboranes, expliquant leurs propriétés de donneurs et d'accepteurs relatives.

Mots-clés : calculs théoriques de la fonctionnelle de densité, étain, agrégat de borane.

Introduction

Recently, one of us reported the synthesis and coordination chemistry of the new 1,2-carbastanna-closo-dodecaborate, $[SnCB_{10}H_{11}]^-$ (1). We were intrigued by the structure of the unusual dianion $[Rh(PPh_3)_2(SnCB_{10}H_{11})_3]^{2-}$ (**1**), which has a trigonal bipyramidal (tbp) geometry with axial PPh_3 ligands and equatorial anionic $SnCB_{10}H_{11}$ ligands (Scheme 1). It was formed from the reaction of Wilkinson's catalyst $[Rh(PPh_3)_3Cl]$ with three equivalents of the anion $[SnCB_{10}H_{11}]^-$. In a d^8-ML_5 trigonal bipyramidal Rh(I) complex, it is well known that the strongest σ-donors occupy axial positions, whereas the strongest π-acceptors occupy equatorial positions, the latter owing to the fact that the HOMO for a C_{2v}-d^8-ML_4 fragment is a π-orbital lying in the equatorial plane (2). Thus, it would appear that the anionic $[SnCB_{10}H_{11}]^-$ ligand must be a reasonably strong π-acceptor. It was noted that the structure resembles that proposed for $[Rh(CNcy)_2(SnCl_3)_3]^-$, for which the authors had pointed out (3) that the $SnCl_3$ must be the stronger π-acceptor and CNcy (cyclohexyl isonitrile) must be the stronger σ-donor. In addition, we noted the similarity of the value for the $J_{Rh\text{-}P}$ for **1**, 88 Hz, to that reported for $[Rh(PPh_3)_2(CO)_3]^+$ (**2**), 72 Hz (4) which also has a (fluxional) tbp geometry,

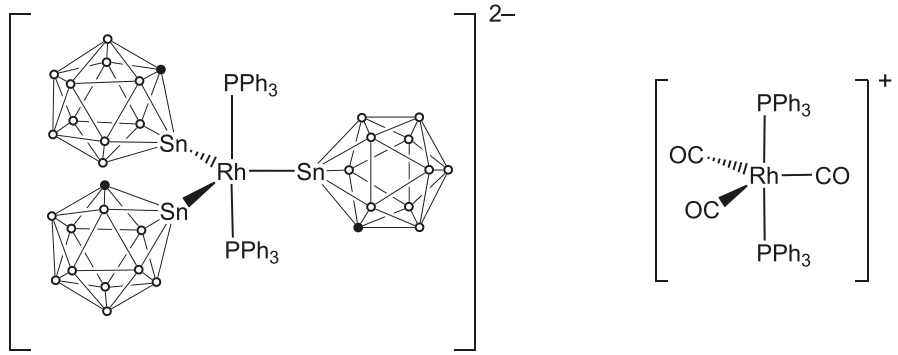
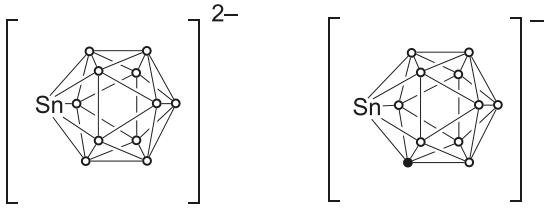
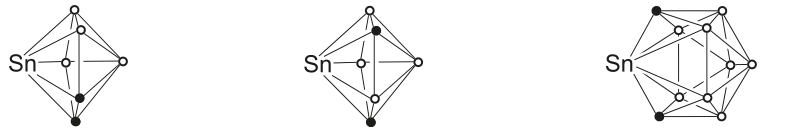
Scheme 1. Schematic representations of the key compounds discussed in the paper. Solid circles represent C–H vertices whereas open circles represent B–H vertices.



1 **2**



$SnB_{11}H_{11}^{2-}$ 2,1-$SnCB_{10}H_{11}^{-}$ 3,1,2-$SnC_2B_9H_{11}$



1,2,3-$SnC_2B_4H_6$ 1,2,4-$SnC_2B_4H_6$ 1,2,3-$SnC_2B_8H_{10}$

4,1,6-$SnC_2B_{10}H_{12}$ 4,1,2-$SnC_2B_{10}H_{12}$

with axial PPh_3 groups and equatorial CO ligands, as expected. That the $J_{Rh\text{-}P}$ value for **1** was slightly larger than that for **2** suggested that the $[SnCB_{10}H_{11}]^-$ ligand was probably a stronger σ-donor and weaker π-acceptor than CO. Nonetheless, it was clear that the $[SnCB_{10}H_{11}]^-$ ligand must be a reasonably strong π-acceptor for all three of them to occupy equatorial positions. Before we begin a detailed examination of the frontier orbitals of the $[SnCB_{10}H_{11}]^-$ ligand, it is worth pointing out that the isoelectronic dianionic stannaborane $[SnB_{11}H_{11}]^{2-}$ ligand is strongly nucleophilic at the tin center (5, 6), exhibits an extremely strong trans-influence, and forms numerous transition metal coordination complexes (7, 8), including such unusual homoleptic species as $[M(SnB_{11}H_{11})_4]^{4-}$ and $[M(SnB_{11}H_{11})_6]^{8-}$ (M = Ni, Pd, Pt) (9), the latter complexes involving the Group 10 metals in their formal IV oxidation state. In contrast, the neutral analogue 3,1,2-$SnC_2B_9H_{11}$ is distinctly electrophilic (10, 11). Considering this to be a possible stable stannylene analogue, as early as 1976, one of us attempted to coordinate it to photochemically generated $Cr(CO)_5(THF)$, but we were unsuc-

© 2008 NRC Canada

cessful in obtaining evidence for a Cr–Sn complex (12). Indeed, it is now known that 1,2-Me_2-3,1,2-$SnC_2B_9H_9$ is capable of binding either one or two N, O, or P-ligands at the Sn-center to provide slipped-stannacarboranes (13, 14). Likewise, C-substituted analogues of the smaller $SnC_2B_4H_6$ system also bind ligands such as 2,2′-bipyridine and 2,2′-bipyrimidine (15–18), but do not react with BH_3·THF or BF_3 to form adducts (19). The lack of σ-donating ability of the $SnC_2B_4H_{6-n}R_n$ systems was ascribed to the diffuse nature of the exo-polyhedral lone pair on the tin center (19) and to the symmetric electron distribution in some of the lower-lying filled MOs which the authors associated with the Sn "lone pair" (15). In their MNDO calculations on $SnC_2B_4H_6$, the authors indicated that the HOMO is localized on the cage borons (15). We show below, via DFT MO calculations, that $[SnCB_{10}H_{11}]^-$ has σ-donor/π-acceptor properties intermediate between those of $[SnB_{11}H_{11}]^{2-}$ and 3,1,2-$SnC_2B_9H_{11}$, and quite similar HOMO and LUMO energies and shapes to those of $[SnCl_3]^-$, a stronger σ-donor and weaker π-acceptor than CO or PF_3. We also report the shapes, energies, and atomic compositions of the orbitals for these systems as well as for related dicarbastannaboranes (13–24).

Computational details

All ab initio computations were carried out with the Gaussian 03 package (25). The geometries of the six compounds described here were optimized using the B3LYP functional (26) with no symmetry constraints. The basis sets used here were 6-31G* for all atoms (27) except for Sn, for which the LANL2DZ basis set (28) incorporating pseudopotentials was employed. Frequency calculations were performed using these optimized geometries at the same levels of theory, and the lack of any imaginary frequencies confirms that all optimized geometries are true minima. The MO diagrams and orbital contributions were generated with the aid of the Gabedit (29) and GaussSum (30) packages, respectively. Total energies in hartrees for the compounds are $[SnB_{11}H_{11}]^{2-}$: –283.572 67, [2,1-$SnCB_{10}H_{11}]^-$: –296.873 90, 3,1,2-$SnC_2B_9H_{11}$: –310.000 74, 1,2-Me_2-3,1,2-$SnC_2B_9H_9$: –388.620 55, 1,2,3-$SnC_2B_8H_{10}$: –284.532 53, 1,2,3-$SnC_2B_4H_6$: –182.631 95, 1,2,4-$SnC_2B_4H_6$: –182.655 17, 4,1,6-$SnC_2B_{10}H_{12}$: –335.459 61, 1,6-Me_2-4,1,6-$SnC_2B_{10}H_{10}$: –414.083 63, 1,2-μ-($CH_2CH{=}CHCH_2$)-4,1,2-$SnC_2B_{10}H_{12}$: –490.260 82, $[SnCl_3]^-$: –1384.204 88, PF_3: –640.956 47, and CO: –113.309 45. The computed Sn bond distances in Å for 1,2,4-$SnC_2B_4H_6$ are Sn–C(2,4): 2.412, Sn–B(3): 2.467, and Sn–B(5,6): 2.431. Calculated Sn bond distances in Å for 1,2-μ-($CH_2CH{=}CHCH_2$)-4,1,2-$SnC_2B_{10}H_{10}$ are Sn–C(1,2): 2.437, Sn–B(3,6): 2.434, and Sn–B(7,10): 2.380, using a cage numbering scheme described elsewhere (31).

Calculated NMR shifts at the GIAO-B3LYP level were obtained from the optimized geometries using the same basis sets. Theoretical ^{11}B chemical shifts at the GIAO-B3LYP level were referenced to B_2H_6 (16.6 ppm) and converted to the usual BF_3·OEt_2 scale: $\delta(^{11}B) = 110.0 - \sigma(^{11}B)$. The ^{13}C and ^1H chemical shifts were referenced to TMS: $\delta(^{13}C) = 189.1 - \sigma(^{13}C)$; $\delta(^1H) = 32.15 - \sigma(^1H)$. Agreements between observed and calculated ^{11}B (and ^{13}C) NMR shifts generated from optimized geometries are generally very good for heteroboranes (32). Agreements between observed and calculated ^1H NMR shifts in heteroboranes are often not as good owing to a narrow ppm range (ca. 12 ppm) and substantial solvent effects on ^1H shift measurements (33). Calculated ^1H NMR shifts for the hydrogens attached to cage carbons are also in very good agreement with observed data. However, hydrogens attached to cage borons have been assigned only for one closo-carbastannaborane, 1,2,3-$SnC_2B_8H_{10}$, and in this case the agreement between computed and observed shifts is surprisingly poor. Agreements between observed and calculated ^{119}Sn NMR shifts are poor owing to two factors: the ^{119}Sn NMR shift measurements depend strongly on the solvent, and the pseudopotentials and the basis set for Sn used to compute ^{119}Sn NMR shifts are not considered to be appropriate (34).

Results and Discussion

Our main interest in these systems was to compare the frontier orbitals and σ-donor/π-acceptor abilities of a series of isolectronic stannaboranes and stannacarboranes containing one tin and zero, one, or two carbon atoms in the cage and, especially, to examine those of $[SnCB_{10}H_{11}]^-$, which seemed, on the basis of the reported structure of the rhodium complex **1**, vide supra, to have both good σ-donor and good π-acceptor properties (1). The metal complexes and borane ligands of interest here are shown in Scheme 1. Optimized geometries of $[SnB_{11}H_{11}]^{2-}$ and [2,1-$SnCB_{10}H_{11}]^-$ at the DFT level of theory are in excellent agreement with their X-ray-determined molecular structures (1, 6) as demonstrated by a comparison of bond lengths involving the tin atom listed in **Table 1.** However, the dicarbastannaborane, 3,1,2-$SnC_2B_9H_{11}$, and its dimethyl derivative have not been structurally characterized. The optimized geometry of 3,1,2-$SnC_2B_9H_{11}$ reveals a slipped Sn vertex with Sn–C bonds being longer than Sn–B bonds, and the trend of the Sn vertex slippage is evident on going from $[SnB_{11}H_{11}]^{2-}$ to [2,1-$SnCB_{10}H_{11}]^-$ and 3,1,2-$SnC_2B_9H_{11}$.

Plots of the frontier orbitals of $[SnB_{11}H_{11}]^{2-}$, $[SnCB_{10}H_{11}]^-$, and 3,1,2-$SnC_2B_9H_{11}$ are displayed in **Fig. 1,** and their energies and coefficients (on Sn, CH, upper belt BH, lower belt BH, and unique BH vertices) are given in Tables 2–4, respectively. For comparison, the frontier orbitals of the well-known π-acceptor ligands $[SnCl_3]^-$, PF_3, and CO are displayed in Fig. 2, and their energies are given in **Tables 5–7,** respectively. These all have non-degenerate, σ-symmetry HOMOs and degenerate, π-symmetry LUMOs, and the similarity of their orbitals is quite obvious. Their σ-donating ability decreases and their π-accepting ability increases in the order $[SnCl_3]^-$, PF_3, and CO, as evidenced by the orbital energies listed in Tables 5–7.

Noting that $[SnB_{11}H_{11}]^{2-}$ has five-fold symmetry, belonging to the point group C_{5v}, and that the LUMO is thus doubly degenerate (shown in Fig. 1 and Table 2 as LUMO and LUMO+1 for consistency), whereas for $[SnCB_{10}H_{11}]^-$ and 3,1,2-$SnC_2B_9H_{11}$, the only symmetry element is a mirror plane, and thus, in the C_s point group, there are no degeneracies, one can still see right away the general similarities of the orbital shapes. It is important to note also that for $[SnB_{11}H_{11}]^{2-}$, while the HOMO is largely of π-symmetry and is heavily localized on the upper belt of the cage, lying

at nearly the same energy are two degenerate and effectively σ-symmetry orbitals. Thus, we will consider the HOMO-1 and HOMO-2 orbitals for this ligand as those suitable for σ-donation to a metal center. We can see from Table 2 that the HOMO-1 and HOMO-2 orbitals are comprised of a mixture of mainly Sn and the top belt of the cage, but lie at very high energy (+1.43 eV), and are thus both strong donor levels, well above that of $[SnCl_3]^-$ (–2.45 eV). The degenerate LUMO orbitals are of π-symmetry, but are also quite high in energy, lying at +7.23 eV, well above those of CO (–0.59 eV), and are thus too high to act as π-acceptor levels, although they are almost completely localized on Sn.

An examination of the two carbon-containing cages, $[SnCB_{10}H_{11}]^-$ and 3,1,2-$SnC_2B_9H_{11}$, shows that they have very similar frontier orbitals (Fig. 1) comprising an essentially σ-symmetry HOMO and the non-degenerate π-symmetry LUMO and LUMO+1 levels. While the σ-symmetry HOMO in each case is slightly "tipped" towards the carbon vertices, nonetheless these are of suitable symmetry and have at least modest (46% and 39%, respectively) Sn-content to act as potential σ-donors. For comparison, the σ-donor HOMO levels of $[SnCl_3]^-$, PF_3, and CO are 45% localized on Sn, 64% localized on P, and 90% localized on C, respectively. Thus, while the HOMO of 3,1,2-$SnC_2B_9H_{11}$ lies at –7.33 eV, which is below that of $[SnCl_3]^-$ (–2.45 eV), but above those of PF_3 (–8.78 eV) and CO (–10.11 eV), the combination of relatively low energy and diminished content on the potential donor atom make this a poor σ-donor. In contrast, the LUMO and LUMO+1 energies of 3,1,2-$SnC_2B_9H_{11}$ are well below those of any of the "conventional" π-acceptor ligands, and are 87 and 76% localized on Sn, which makes them directly susceptible to nucleophilic attack by one or two Lewis basic ligands.

Now it is useful to consider the case of $[SnCB_{10}H_{11}]^-$ in more detail. Both the HOMO and LUMO/LUMO+1 orbital energies are between those of $[SnB_{11}H_{11}]^{2-}$ and 3,1,2-$SnC_2B_9H_{11}$, and their Sn-contents are 46, 84, and 77%, respectively, (cf. $[SnCl_3]^-$, for which the Sn-content of the HOMO is 45%, and the degenerate LUMO is 95%). A comparison of the orbital energies of $[SnCB_{10}H_{11}]^-$ and $[SnCl_3]^-$ is also informative, and we see that these are also quite similar; the HOMOs are –2.87 eV and –2.45 eV, respectively, and the LUMOs are +2.45 and +2.93 for the former and +3.25 eV for the latter. $[SnCB_{10}H_{11}]^-$ would be expected to be a slightly poorer σ-donor and slightly better π-acceptor than $[SnCl_3]^-$, but the differences are both small. Thus, $[SnCB_{10}H_{11}]^-$ and $[SnCl_3]^-$ are very similar ligands, with regard both to their energies and to the orbital overlaps with a metal center. Therefore, it is not surprising to find that it is possible to prepare trigonal bipyramidal Rh(I) complexes bearing three $[SnCB_{10}H_{11}]^-$ ligands, or that they should all lie in the equatorial plane, as expected for strong π-acceptor ligands.

While only one cage geometry of each of the closo systems, the $[SnB_nH_n]^{2-}$ dianions and the $[SnCB_nH_{n+1}]^-$ anions, is known, there are many different geometries of $SnC_2B_nH_{n+2}$ clusters with n = 4, 8, 9, and 10 reported in the literature (13–24). Molecular structures of dicarbastannaboranes with n = 4 and n = 10 have been structurally characterised (13, 15, 18, 22) and optimized geometries for each

Fig. 1. Frontier orbitals for $[SnB_{11}H_{11}]^{2-}$, $[SnCB_{10}H_{11}]^{-}$, and 3,1,2-$SnC_2B_9H_{11}$. Note that for $[SnB_{11}H_{11}]^{2-}$, LUMO and LUMO+1 constitute a degenerate pair, in contrast to $[SnCB_{10}H_{11}]^{-}$ and 3,1,2-$SnC_2B_9H_{11}$, for which there are no degeneracies.

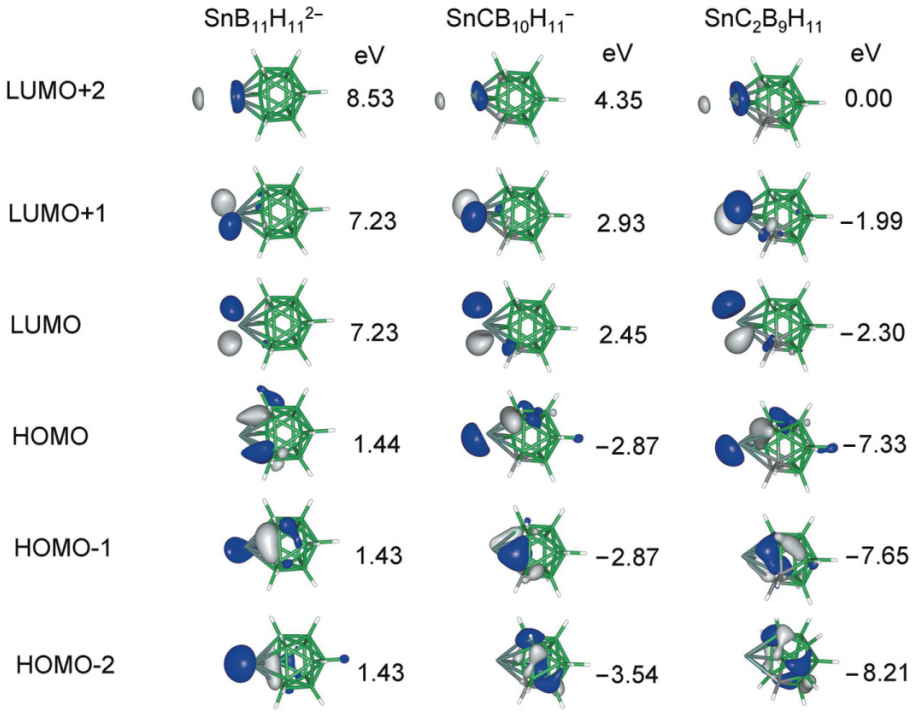

Fig. 2. Frontier orbitals for $[SnCl_3]^{-}$, PF_3, and CO. Note that orbitals labelled HOMO-1 and HOMO-2 are a degenerate pair as are LUMO and LUMO+1.

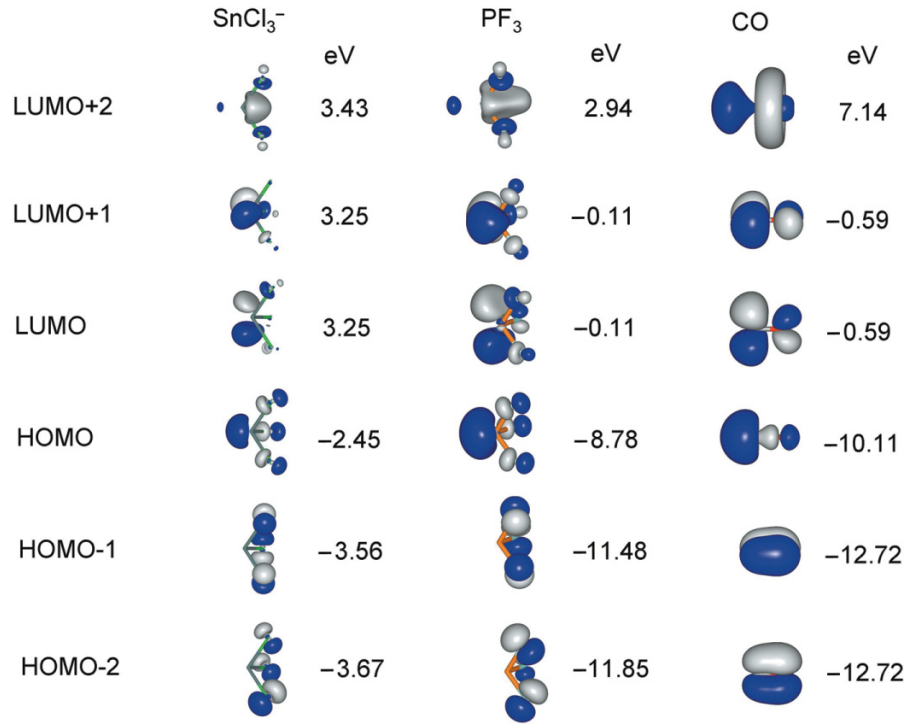

system are in very good agreement with experimental data (Table 1). The crystallographically determined molecular structures of the supraicosahedral stannacarboranes, 4,1,6-$SnC_2B_{10}H_{12}$ and 1,6-Me_2-4,1,6-$SnC_2B_{10}H_{10}$, contain asymmetrical geometries in the solid state which are in excellent agreement with optimized "gas-phase" calculated geometries, as shown in Table 1 for the Sn–C and Sn–B bond lengths in 1,6-Me_2-4,1,6-$SnC_2B_{10}H_{10}$ (22). One cage carbon is a 4-connected vertex and the other carbon is a 5-connected vertex. Agreement between experimental and optimized geometries for 2-Me_3Si-1,2,3-$SnC_2B_4H_5$ is also very good as shown in Table 1 (13, 15). The slippage of the Sn

[a]Computed values are based on the ground-state optimized "gas-phase" and experimental "solid-state" asymmetric geometry.
[b]Computed values are based on fluxionality between two ground-state asymmetric geometries in solution. Shifts for the pairs C1/6, B8/13, B5/12, B3/10 and their exo-hydrogens are averaged.

vertices for the 2-Me_3Si-1,2,3-$SnC_2B_4H_5$ geometries is rather less pronounced than for the optimized geometries of 3,1,2-$SnC_2B_9H_{11}$ and 1,2-Me_2-3,1,2-$SnC_2B_9H_9$.

Geometry optimizations of known $SnC_2B_nH_{n+2}$ systems with n = 4, 8, and 10 were carried out and the electronic structures at these geometries were examined. The orbitals and their energies for these neutral systems are all similar to 3,1,2-$SnC_2B_9H_{11}$ (Table 8). This is perhaps not surprising as these systems exhibit similar Lewis acid properties. On this basis, the unknown non-icosahedral $[SnB_nH_n]^{2-}$ and $[SnCB_nH_{n+1}]^-$ ligands would be expected to have similar donor and acceptor properties to those of the icosahedral systems $[SnB_{11}H_{11}]^{2-}$ and $[SnCB_{10}H_{11}]^-$, respectively.

If ^{11}B and ^{13}C NMR shifts computed from an optimized geometry of a heteroborane at the DFT or MP2 level of theory show a very good correlation with its experimental solution-state NMR data, then the optimized geometry is considered the best representation of its molecular structure in solution (32). Comparison of the observed and computed ^{11}B and ^{13}C NMR data listed in Table 9 reveals that the optimized geometries of the 12-vertex dicarbastannaboranes 3,1,2-$SnC_2B_9H_{11}$ and 1,2-Me_2-3,1,2-$SnC_2B_9H_9$ with slipped tin vertices are also likely to be found in solution.

However, the calculated ^{11}B and ^{13}C NMR data from the asymmetrical "gas-phase" optimized geometry of the supraicosahedral system 4,1,6-$SnC_2B_{10}H_{12}$ are in poor agreement with the observed solution NMR data (22). This 13-vertex dicarbastannaborane 4,1,6-$SnC_2B_{10}H_{12}$ is fluxional in solution, interconverting between two mirror-related isomers of the asymmetric geometry via a double diamond-square process with a C_s symmetry transition state (22). Averaging of the computed NMR shifts of the relevant pairs of atoms gave very good agreement with the experimental values listed in Table 9, consistent with the fluxionality of the supraicosahedral cluster taking place in solution. The 11-vertex dicarbastannaborane 1,2,3-$SnC_2B_8H_{10}$ has the expected closo-11-vertex geometry based on the excellent agreement between the experimentally-assigned solution state (23) and the computed ^{11}B NMR data (Table 9). The optimized geometry reveals short Sn–C bond distances of 2.265 and long Sn–B bond distances of 2.695 Å compared to the corresponding bond distances listed in Table 1. Of interest are the calculated ^{13}C NMR chemical shifts for the two 4-connected carbon vertices in 1,2,3-$SnC_2B_8H_{10}$ (105.8 ppm) and the 4-connected carbon vertex in 4,1,6-$SnC_2B_{10}H_{12}$ (118.3 ppm) which are significantly different from those 5-connected vertices in other stannacarboranes (47.7-65.2 ppm) listed in Table 9.

Conclusions

DFT MO calculations show that $[SnCB_{10}H_{11}]^-$ has intermediate σ-donor/π-acceptor properties between those of the very strong σ-donor $[SnB_{11}H_{11}]^{2-}$ and the poor donor but good Lewis acid 3,1,2-$SnC_2B_9H_{11}$, and quite similar HOMO and LUMO energies and shapes to those of $[SnCl_3]^-$, a stronger σ-donor and weaker π-acceptor than CO or PF_3. Other $SnC_2B_nH_{n+2}$ systems show similar HOMO and LUMO energies to those of 3,1,2-$SnC_2B_9H_{11}$, both well below those of $[SnCB_{10}H_{11}]^-$, and are thus capable of binding one or two σ-donor ligands, but are poor σ-donors themselves. In contrast, the frontier orbital energies of $[SnB_{11}H_{11}]^{2-}$ are quite high in energy, resulting in excellent σ-donor but poor π-acceptor behavior, accounting for the strong trans-influence of this ligand, and its ability to stabilize metals in unusually high oxidation states. The higher negative charge in the non-carbon-containing systems, as well as the fact that boron is more electropositive than carbon, contribute to the increased energies of both HOMO and LUMO in the stannaboranes compared to the stannacarboranes, explaining their relative donor and acceptor properties.

Exploring the utility of a new chiral phosphoramidite *P,N*-ligand derived from (*R*)-BINOL and 7-azaindole in asymmetric catalysis[1]

Dominik Wechsler and Mark Stradiotto

Abstract: Lithiation of 7-azaindole, followed by quenching with [(*R*)-(1,1′-binaphthalene-2,2′-diyl)]chlorophosphite afforded the new chiral phosphoramidite **1** in 92% isolated yield. Treatment of 0.5 equiv. of $[(COD)MCl]_2$ (M = Rh, Ir; COD = η^4-1,5-cyclooctadiene) with 2 equiv. of **1** afforded the corresponding [(κ^1-*P,N*-**1**)(κ^2-*P,N*-**1**)MCl] complexes in 68% (**2a**, Rh) and 72% (**2b**, Ir) yield, while treatment of $(PPh_3)_3RhCl$ with 1 equiv. of **1** afforded [(PPh_3)(κ^2-*P,N*-**1**)RhCl] (**3**) as an analytically pure solid in 74% isolated yield. In examining the reaction of **1** with a mixture of 0.5 equiv. of $[(COD)RhCl]_2$ and 1 equiv. of $AgBF_4$, an inseparable mixture of [(κ^2-*P,N*-**1**)$_2$Rh]$^+BF_4^-$ (**4a**) and [(COD)(κ^2-*P,N*-**1**)Rh]$^+BF_4^-$ (**5a**) was generated. Under analogous conditions employing $[(COD)IrCl]_2$, the complex [(COD)(κ^2-*P,N*-**1**)Ir]$^+BF_4^-$ (**5b**) was obtained in 86% isolated yield. Treatment of 0.5 equiv. of [(η^3-allyl)$PdCl]_2$ with **1** afforded [(η^3-allyl)(κ^2-*P,N*-**1**)Pd]$^+Cl^-$ (**6**) in 86% isolated yield. The application of **1** in platinum group metal-mediated asymmetric chemical transformations, including alkene hydrogenation and hydroboration, ketone hydrosilylation, and allylic alkylation, was examined.

Key words: chiral, ligand, phosphoramidite, asymmetric catalysis.

Résumé : La lithiation du 7-azaindole, suivie d'un piégeage avec du chlorophosphite de [(*R*)-(1,1′-binaphtalène-2,2′-diyle) conduit à la formation du nouveau phospharamidite chiral, **1**, avec un rendement de 92% en produit isolé. Le traitement de 0,5 équiv. de $[(COD)MCl]_2$ (M= Rh, Ir; COD = η^4-cycloocta-1,5-diène) avec deux équiv. de **1** conduit à la formation des complexes correspondants [κ^1-*P,N*-**1**)(κ^2-*P,N*-**1**)MCl avec des rendements de 68% (**2a**, Rh) et de 72% (**2b**, Ir) alors que le traitement de $(PPh_3)_3RhCl$ avec 1 équiv. de **1** conduit à la formation du [(PPh_3)(κ^2-*P,N*-**1**)(RhCl] (**3**) qui a été isolé avec un rendement de 74% sous la forme d'un solide analytiquement pur. La réaction du produit **1** avec un mélange de 0,5 équiv. de $[(COD)RhCl]_2$ et un équiv. de $AgBF_4$ conduit à un mélange inextricable de [(κ^2-*P,N*-**1**)$_2$Rh]$^+BF_4^-$ et de [(COD)(κ^2-*P,N*-**1**)Rh]$^+BF_4^-$ (**5a**); dans des conditions impliquant l'utilisation du $[(COD)IrCl]_2$, on obtient le complexe [(COD)(κ^2-*P,N*-**1**)Ir]$^+BF_4^-$ (**5b**) avec un rendement isolé de 86%. Le traitement de 0,5 équiv. de [(η^3-allyl)$PdCl]_2$ avec le produit **1** conduit à la formation du produit [(η^3-allyl)(κ^2-*P,N*-**1**)Pd]$^+Cl^-$ (**6**) avec un rendement d 86% en produit isolé. On a examiné l'application du composé **1** dans les transformations chimiques asymétriques catalysées par un métal du groupe du platine, y compris les réactions d'hydrogénation et d'hydroboration des alcènes, d'hydrosilylation de cétones et d'alkylation allylique.

Mots-clés : chiral, ligand, phosphoramidite, catalyse asymétrique.

[Traduit par la Rédaction]

Introduction

Transition metal-catalyzed asymmetric synthesis represents one of the most effective approaches for the preparation of chiral non-racemic molecules on both benchtop and industrial scales (1). Platinum-group metal (PGM) complexes supported by chiral, heterobidentate *P,N*-ligands have proven particularly effective in mediating important transformations of this type, including the asymmetric addition of E–H bonds to unsaturated substrates (E = H, B, Si, etc.) and the enantioselective formation of C–C linkages (2). As a result, the pursuit of chiral *P,N*-ligands that can enable new and (or) improved asymmetric substrate transformations represents an important theme of modern catalysis research.

One facet of our research program focuses on the development of novel *P,N*-ligands for use in metal-mediated catalytic applications (3). In building upon this theme and encouraged by the utility of monodentate phosphoramidite (MonoPhos) ligands (4) as well as rigid κ^2-*P,N* phosphinooxazoline (PHOX) ligands (5) in PGM catalysis, we identified potentially bidentate chiral phosphoramidite ligands derived from 7-azaindole as attractive and readily prepared synthetic targets. Notably, while two reports by Woolins and

co-workers (6) and Burrows et al. (7) document the PGM coordination chemistry of achiral κ^2-*P*,*N*-(7-aza-*N*-indolyl)phosphines, the preparation and application in asymmetric catalysis of chiral variants of such ligands has not been reported. Herein we report on the synthesis and characterization of a new chiral phosphoramidite ligand **1**, a preliminary account of the Rh, Ir, and Pd coordination chemistry of this ligand, and the application of **1** in PGM-mediated asymmetric chemical transformations including alkene hydrogenation and hydroboration, ketone hydrosilylation, and allylic alkylation.

Experimental

General Considerations

All manipulations were conducted in the absence of oxygen and water under an atmosphere of dinitrogen, either by use of standard Schlenk methods or within an mBraun glovebox apparatus, utilizing glassware that was oven-dried (130 °C) and evacuated while hot prior to use. Celite was oven-dried for 5 d and then evacuated for 24 h prior to use. The non-deuterated solvents tetrahydrofuran, diethyl ether, benzene, toluene, hexanes, and pentane were deoxygenated and dried by sparging with dinitrogen gas, followed by passage through a double-column solvent purification system purchased from mBraun Inc. Tetrahydrofuran and diethyl ether were purified over two alumina-packed columns, while benzene, toluene, hexanes, and pentane were purified over one alumina-packed column and one column packed with copper-Q5 reactant. All solvents used within the glovebox were stored over activated 4 Å molecular sieves. CD_2Cl_2 (Cambridge Isotopes) was degassed by using three repeated freeze–pump–thaw cycles, dried over CaH_2 for 7 days, distilled in vacuo, and stored over 4 Å molecular sieves for 24 h prior to use. C_6D_6 (Cambridge Isotopes) was degassed by using three repeated freeze–pump–thaw cycles and then dried over 4 Å molecular sieves for 24 h prior to use; styrene (Sigma-Aldrich, containing 10–15 ppm 4-*tert*-butylcatechol as inhibitor) was degassed in a similar manner, but was not stored over molecular sieves. Ph_2SiH_2 (Gelest, shipped under argon) was not degassed and was dried over 4 Å molecular sieves for 24 h prior to use. Hydrogen (99.999%, UHP Grade) gas was obtained from Air Liquide and was used as received. [(*R*)-(1,1′-binaphthalene-2,2′-diyl)]chlorophosphite (8) and (±)-(*E*)-1,3-diphenylprop-2-enyl acetate (9) were prepared by the use of literature procedures, while the transition metal reagents and silver salts were purchased from Strem Chemicals Inc. All purchased and prepared solid reagents were dried in vacuo for 24 h prior to use. Otherwise, all other commercial reagents were obtained from Sigma-Aldrich or Fluka and were used as received. ^{1}H, ^{13}C, and ^{31}P NMR characterization data were collected at 300 K on a Bruker AV-500 spectrometer operating at 500.1, 125.8, and 202.5 MHz (respectively) with chemical shifts reported in parts per million downfield of $SiMe_4$ (for ^{1}H and ^{13}C) or 85% H_3PO_4 in D_2O (for ^{31}P). ^{1}H and ^{13}C NMR chemical shift assignments are made on the basis of data obtained from ^{13}C-DEPT, ^{1}H-^{1}H COSY, ^{1}H-^{13}C HSQC, and ^{1}H-^{13}C HMBC NMR experiments. In some cases, fewer than expected unique ^{13}C NMR resonances were observed, despite prolonged acquisition times. Elemental analyses were performed by Canadian Microanalytical Service Ltd., Delta, British Columbia, Canada.

Synthesis of 1

A 1.6 mol/L hexanes solution (pre-cooled to –35 °C) of *n*-BuLi (0.51 mL, 0.82 mmol) was added dropwise to a vial containing a magnetically stirred solution (pre-cooled to –35 °C) of 7-azaindole (0.097 g, 0.82 mmol) in THF (4 mL), producing a colorless solution. The reaction mixture was stirred for 0.75 h at ambient temperature, followed by cooling to –35 °C. A pre-cooled (–35 °C) mixture of [(*R*)-(1,1′-binaphthalene-2,2′-diyl)]chlorophosphite (0.29 g, 0.82 mmol) and THF (5 mL) was then transferred slowly to the reaction mixture via Pasteur pipette. Upon completion of transfer, the resulting mixture was stirred for 2 h, after which the THF and other volatile materials were removed in vacuo. The residue was dissolved in a mixture of diethyl ether (4 mL) and benzene (2 mL) and filtered through Celite. The filtrate was dried in vacuo yielding **1** as an analytically pure, white solid (0.33 g, 0.76 mmol, 92%). ^{1}H NMR (C_6D_6) δ: 8.42 (d of d, $^3J_{HH}$ = 4.5 Hz, *J* = 1.5 Hz, 1H, C4-H or C6-H Aza.), 7.61 (d, $^3J_{HH}$ = 8.5 Hz, 1H, C-H Naph.), 7.57 (d, $^3J_{HH}$ = 9.0 Hz, 1H, C-H Naph.), 7.55 (d, $^3J_{HH}$ = 4.0 Hz, 1H, C-H Naph.), 7.53 (d, $^3J_{HH}$ = 4.5 Hz, 1H, C-H Naph.), 7.45 (d, $^3J_{HH}$ = 7.5 Hz, 1H, C6-H or C4-H Aza.), 7.41 (d, $^3J_{HH}$ = 8.5 Hz, 1H, C-H Naph.), 7.32 (d, $^3J_{HH}$ = 2.0 Hz, 1H, C-H Naph.), 7.30 (d, $^3J_{HH}$ = 2.5 Hz, 1H, C-H Naph.), 7.17–7.10 (m, 2H, C-H Naph.), 6.97 (m, 1H, C-H Naph.), 6.93 (m, 1H, C-H Naph.), 6.81 (d of d, $^3J_{HH}$ = 5.0 Hz, $^3J_{HH}$ = 8.0 Hz, 1H, C5-H Aza.), 6.76 (d, $^3J_{HH}$ = 4.0 Hz, 1H, C2-H or C3-H Aza.), 6.65 (d, $^3J_{HH}$ = 9.0 Hz, 1H, C-H Naph.), 5.92 (d of d, $^3J_{HH}$ = 4.0 Hz, *J* = 1.0 Hz, C3-H or C2-H Aza.). ^{13}C{^{1}H} NMR (C_6D_6) δ: 152.8 (d, *J* = 16.0 Hz, quat Aza.), 148.4 (quat Naph.), 148.0 (d, *J* = 4.2 Hz, quat Naph.), 143.7 (C4 or C6 Aza.), 133.0 (quat Naph.), 132.6 (quat Naph.), 131.7 (quat Naph.), 131.4 (quat Naph.), 131.1 (C-H Naph.), 130.1 (C-H Naph.), 128.5 (C-H Naph.), 128.4 (C-H Naph.), 128.2 (C6 or C4 Aza.), 127.0 (C-H Naph.), 126.9 (C-H Naph.), 126.5 (C-H Naph.), 126.4 (C-H Naph.), 126.2 (d, *J* = 4.3 Hz, C2 or C3 Aza.), 125.2 (C-H Naph.), 125.1 (C-H Naph.), 124.5 (d, *J* = 5.4 Hz, quat Aza.), 123.6 (quat Naph.), 122.3 (quat Naph.), 121.5 (C-H Naph.), 121.3 (C-H Naph.), 117.7 (C5 Aza.), 104.2 (C3 or C2 Aza.). ^{31}P{^{1}H} NMR (C_6D_6) δ: 133.8. Synthesis of 2a

To a vial containing a magnetically stirred solution of **1** (0.056 g, 0.13 mmol) in THF (2 mL) was added dropwise a solution of $[(COD)RhCl]_2$ (0.016 g, 0.032 mmol) in THF (2 mL). The reaction mixture was stirred for 1 h, after which the solvent and other volatiles were removed in vacuo. The residue was washed with pentane (2 mL) and dried in vacuo, yielding **2a** as a pale yellow solid (0.044 g, 0.044 mmol, 68%). ^{1}H NMR (C_6D_6) δ: 9.34 (1H, C-H), 8.50–8.45 (m, 2H, C-Hs), 8.40 (d, $^3J_{HH}$ = 8.8 Hz, 1H, C-H), 7.68–7.63 (m, 2H, C-Hs), 7.60 (d, *J* = 8.75 Hz, 1H, C-H), 7.55–7.45 (m, 3H, C-Hs), 7.41 (d, $^3J_{HH}$ = 8.1 Hz, 1H, C-H), 7.35 (d, $^3J_{HH}$ = 8.2 Hz, 1H, C-H), 7.30–7.26 (m, 2H, C-Hs), 7.23 (d, $^3J_{HH}$ = 8.6 Hz, 1H, C-H), 7.13 (m, 1H, C-H), 7.07–6.98 (m, 3H, C-Hs), 6.97–6.82 (m, 4H, C-Hs), 6.81–6.75 (m, 2H, C-Hs),

Synthesis of 5b

To a vial containing a magnetically stirred suspension of $[(COD)IrCl]_2$ (0.074 g, 0.11 mmol) in THF (2 mL) was added a suspension of $AgBF_4$ (0.043 g, 0.22 mmol) in THF (2 mL). An orange solution was generated immediately along with a white precipitate. The supernatant solution was separated from the precipitate by filtration through Celite, and the solution was transferred to a vial containing a magnetically stirred solution of **1** (0.095 g, 0.22 mmol) in THF (2 mL). The reaction mixture was stirred for an additional 3 h at ambient temperature, during which the solution developed a red-orange coloration. The reaction mixture was then filtered through a plug of Celite, followed by removal of the solvent and other volatiles in vacuo to yield **5b** as a bright red-orange solid (0.16 g, 0.19 mmol, 86%). ^1H NMR (CD_2Cl_2) δ: 8.43 (d, $^3J_{HH}$ = 8.0 Hz, 1H, C-H), 8.31 (d, $^3J_{HH}$ = 5.5 Hz, 1H, C-H), 8.24 (d, $^3J_{HH}$ = 9.0 Hz, 1H, C-H), 8.21 (d, $^3J_{HH}$ = 8.5 Hz, 1H, C-H), 8.15–8.10 (m, 2H, C-Hs), 7.76 (d, $^3J_{HH}$ = 9.0 Hz, 1H, C-H), 7.68–7.60 (m, 3H, C-Hs), 7.47–7.39 (m, 5H, C-Hs), 7.14 (d, $^3J_{HH}$ = 4.0 Hz, 1H, C-H), 6.43 (d of d, *J* = 2.0 Hz, *J* = 3.5 Hz, 1H, C-H), 6.04 (br s, 1H, COD), 5.98 (br s, 1H, COD), 4.19 (br s, 1H, COD), 4.13 (br s, 1H, COD), 2.52–2.18 (m, 8H, COD). $^{13}C\{^1H\}$ NMR (CD_2Cl_2) δ: 156.9 (quat), 146.8 (d, *J* = 13.7 Hz, quat), 145.8 (d, *J* = 7.0 Hz, quat), 142.4 (C-H), 135.1 (C-H), 132.4 (quaJune 24, 2008t), 132.2 (quat), 132.1 (C-H), 132.0 (C-H), 128.8 (C-H), 128.8 (C-H), 127.5 (2 C-Hs), 127.0 (C-H), 127.0 (C-H), 126.7 (C-H), 126.6 (C-H), 124.6 (d, *J* = 6.0 Hz, C-H), 122.3 (quat), 122.0 (quat), 121.1 (d, *J* = 8.3 Hz, quat), 120.0 (C-H), 119.8 (C-H), 119.7 (C-H), 111.9 (C-H), 70.3 (m, C-H), 62.2 (C-H), 33.2 (CH_2), 33.0 (CH_2), 29.0 (CH_2), 28.8 (CH_2). $^{31}P\{^1H\}$ NMR (CD_2Cl_2) δ: 115.3. General protocol for the metal-catalyzed hydrogenation experiments

A solution of metal (M = Rh or Ir) precursor (0.025 mmol in 0.5 mL) and **1** (1.2 equiv. relative to M; 0.030 mmol in 0.5 mL) in the desired solvent were combined to give a 0.025 mol/L solution of the catalyst (based on M). The solution was allowed to equilibrate for 0.75 h, at which point methyl 2-acetamidoacrylate (0.50 mmol in 0.5 mL) was added by use of an Eppendorf pipette. The mixture was placed in glass reactor cell, which was equipped with a magnetic stir bar and sealed under nitrogen with a PTFE valve. The cell was transferred to a Schlenk line, and the mixture was degassed by use of three freeze–pump–thaw cycles, followed by the addition of ca. 1 atm of H_2 (1 atm = 101.325 kPa), while magnetically stirring the solution. At the desired sampling time, the reaction mixture was concentrated in vacuo and extracted with diethyl ether (2 mL). The catalyst was removed by passing the diethyl ether extract through a plug of silica (0.6 cm × 2 cm) from which a clear, colorless solution eluted. This solution was transferred to a GC vial and sealed. Quantitative data were obtained from chiral GC-FID analysis using a Varian CHIRAL-L-VAL column.

General protocol for the metal-catalyzed hydroboration experiments

The general protocol employed herein for the hydroboration of styrene with HBpin has been described elsewhere (10). For reactions in which HBcat was employed, pinacol (2.1 equiv.) was added to the reaction mixture after 24 h followed by stirring for an additional 24 h. The subsequent work up procedure employed was the same as that undertaken for reactions involving HBpin.

General protocol for the metal-catalyzed hydrosilylation experiments

A solution of metal precursor (0.045 mmol in 0.75 mL) and **1** (1.2 equiv.; 0.054 mmol in 0.75 mL) in the desired solvent were combined to give a 0.030 mol/L solution of the catalyst (based on the metal). The solution was allowed to equilibrate for 0.75 h, at which point the ketone (0.90 mmol) was added by use of an Eppendorf pipette. The vial was then sealed, shaken vigorously, and cooled to –35 °C. Subsequently, pre-cooled (–35 °C) Ph_2SiH_2 (1.6 mmol) was added dropwise by use of an Eppendorf pipette to the reaction mixture, and the vial was then sealed and the reaction mixture was magnetically stirred for 18 h at ambient temperature. The reaction mixture was then cooled to 0 °C, and 1 mol/L HCl (5 mL) and acetone (5 mL) were added. The mixture was stirred for 1.5 h at 0 °C followed by 0.5 h at ambient temperature. A solution of saturated sodium bicarbonate was added, and the reaction mixture was stirred until no more gas evolution was observed (approx. 0.25 h). The reaction mixture was extracted with diethyl ether (2 × 5 mL). The combined organic layers were dried over Na_2SO_4, and the catalyst was removed by passing the solution through a plug of alumina (0.6 cm × 2 cm) from which a clear, colorless solution eluted. This solution was transferred to a GC vial and sealed. Products were identified by use of GC-MS while quantitative data were obtained from chiral GC-FID analysis by using a Supelco BETA-DEX 120 column.

Representative protocol for the metal-catalyzed allylic alkylation experiments

A 0.020 mol/L stock solution of catalyst was prepared by adding [(η^3-allyl)PdCl]$_2$ (0.0073 g, 0.020 mmol) in THF (1 mL) to ligand **1** (0.017 g, 0.040 mmol) in THF (1 mL), followed by stirring for 0.5 h. A 0.40 mol/L stock solution of the substrate was prepared by dissolving (±)-(*E*)-1,3-diphenylprop-2-enyl acetate (0.27 g, 1.1 mmol) in THF (2.7 mL). A 0.12 mL aliquot was taken from each of the two stock solutions and combined; this reaction mixture was stirred for 0.25 h and was then diluted with THF to a total volume of 12 mL to produce a final substrate concentration of 0.004 mol/L. Dimethyl malonate (6.6 μL, 0.058 mmol, 1.1 equiv.), *N*,*O*-bis(trimethylsilyl)acetamide (14.1 μL, 0.058 mmol, 1.1 equiv.), and KOAc (catalytic amount) were added to the reaction mixture, and the resulting suspension was stirred at 24 °C for 72–100 h. The reaction mixture was then concentrated in vacuo, passed through a short silica gel column (0.6 cm × 5 cm), and eluted with diethyl ether/hexanes (2:1). A portion of the eluent was transferred to a GC vial and sealed, while the remaining eluent was concentrated in vacuo. The reaction products were identified by use of GC-MS, while quantitative data were obtained from GC-FID analysis using a Supelco DB200 column. The enantiomeric excess of **11** was determined by use of ^{1}H NMR methods through the addition of Eu(hfc)$_3$ (8–10 mg) in $CDCl_3$ (0.6 mL) to the reaction sample. Isomer assignments are given on the basis of literature data (11).

Results and discussion

Ligand synthesis and coordination chemistry

The new chiral phosphoramidite **1** was prepared in 92% isolated yield (Scheme 1) via lithiation of 7-azaindole, followed by quenching with [(*R*)-(1,1′-binaphthalene-2,2′-diyl)]chlorophosphite prepared from the commercially available reagents *R*-BINOL and PCl_3. Prior to evaluating the

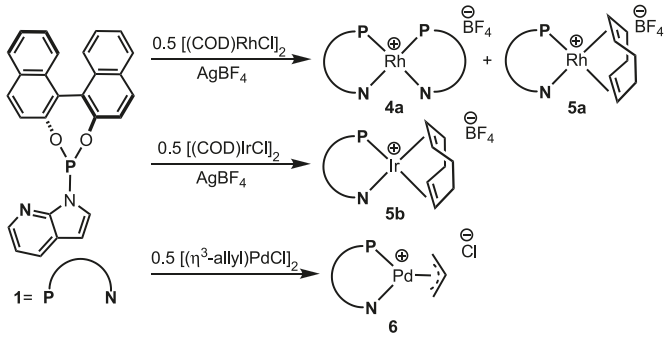
utility of **1** as a chiral ancillary ligand in PGM-mediated catalysis, we sought to examine the coordination chemistry of this new ligand. Treatment of 0.5 equiv. of $[(COD)MCl]_2$ (M = Rh, Ir; COD = η^4-1,5-cyclooctadiene) with 1 equiv. of **1** did not afford $[(COD)(\kappa^1\text{-}\mathbf{1})MCl]$; instead, a clean mixture of 0.5 equiv. of $[(\kappa^1\text{-}P,N\text{-}\mathbf{1})(\kappa^2\text{-}P,N\text{-}\mathbf{1})MCl]$ **2a** and **2b** and 0.25 equiv. of unreacted $[(COD)MCl]_2$ was observed by use of NMR spectroscopic methods (Scheme 2). Compounds **2a** and **2b** are observed as the only phosphorus-containing product when a **1**/M ratio of 2:1 is employed, thereby allowing for the convenient isolation of **2a** and **2b** as analytically pure solids in 68% (**2a**, Rh) and 72% (**2b**, Ir) yields, respectively. The observation of ^{31}P-^{31}P coupling between the magnetically non-equivalent phosphorus centers in the ^{31}P NMR spectra of **2a** and **2b** (as well as the clearly discernable ^{103}Rh coupling in the case of **2a**) is consistent with the existence of P-M-P′ linkages in **2a** and **2b**. Moreover, the cis-disposition of the phosphorus fragments in **2a** and **2b** as depicted in Scheme 2 is in keeping with the magnitude of the observed $^2J_{PP}$ value (ca. 64 Hz) for these complexes. Whereas **2a** is also formed upon treatment of $(PPh_3)_3RhCl$ with 2 equiv. of **1**, the use of only 1 equiv. of **1** under similar conditions afforded $[(PPh_3)(\kappa^2\text{-}P,N\text{-}\mathbf{1})RhCl]$ **3** as an analytically pure solid in 74% isolated yield.

In the pursuit of $[(COD)(\kappa^2\text{-}P,N\text{-}\mathbf{1})M]^+X^-$ complexes (M = Rh, Ir), the reaction of **1** with mixtures of 0.5 equiv. of $[(COD)MCl]_2$ and 1 equiv. of $AgBF_4$ in THF was examined. For M = Rh, NMR analysis revealed the formation of an inseparable mixture of $[(\kappa^2\text{-}P,N\text{-}\mathbf{1})_2Rh]^+BF_4^-$ **4a** and $[(COD)(\kappa^2\text{-}P,N\text{-}\mathbf{1})Rh]^+BF_4^-$ **5a** (12) as depicted in Scheme 3. Compound **4a** was also observed as a major phosphorus-

Scheme 3. Reactivity of 1 with $[(COD)MCl]_2/AgBF_4$ (M = Rh, Ir; COD = η^4-1,5-cyclooctadiene) and $[(\eta^3\text{-allyl})PdCl]_2$.



containing product in such reactions when the **1**/Rh ratio was reduced to 0.5:1. Conversely, reactions employing **1**:Ir in a 1:1 ratio afforded $[(COD)(\kappa^2\text{-}P,N\text{-}\mathbf{1})Ir]^+BF_4^-$ **5b** as the major product, thereby allowing for the isolation of this species in 86% yield.

The ability of **1** to form 1:1 complexes with Pd was confirmed upon treatment of 0.5 equiv. of $[(\eta^3\text{-allyl})PdCl]_2$ with **1**; the corresponding salt $[(\eta^3\text{-allyl})(\kappa^2\text{-}P,N\text{-}\mathbf{1})Pd]^+Cl^-$ **6** was obtained as an analytically pure solid in 86% isolated yield (Scheme 3). While shortly following dissolution the ^{31}P NMR spectrum of **6** exhibits a single resonance at 133.1 ppm, a new signal at 129.4 ppm was observed to grow in over the course of 3 h. Although we are presently unable to comment definitively regarding the relationship between these two phosphorus-containing species, the propensity of $[(\eta^3\text{-allyl})(\kappa^2\text{-}P,N)Pd]^+X^-$ complexes to exhibit complicated dynamic behavior is well-established (13). Having briefly explored the coordination chemistry of **1** with Rh, Ir, and Pd, the utility of this new chiral *P,N*-ligand in PGM-mediated asymmetric synthesis was surveyed. For convenience, catalyst complexes were prepared in situ by using an appropriate metal precursor in combination with **1** (except where noted).

Asymmetric hydrogenation

The Rh- and Ir-mediated asymmetric hydrogenation of methyl-2-acetamidoacrylate **7** to afford **8** (eq. [1]) under mild conditions (24 °C, ca. 1 atm H_2, 5.0 mol% Rh or Ir) was selected as a preliminary catalytic test reaction to use in benchmarking the performance of **1** (14); key results of these hydrogenation studies are collected in Table 1. Control experiments confirmed the ability of catalyst mixtures derived from 0.5 $[(COD)RhCl]_2$ and $AgBF_4$ in THF (without added **1**) to mediate the reduction of **7** (Table 1, entry 1–1). Under analogous conditions employing 6.0 mol% of **1** (1.2 equiv. relative to Rh), the quantitative reduction of **7** was also achieved, affording **8** in 65% ee (Table 1, entry 1–2). However, increasing the amount of **1** to 12.0 mol% (Table 1, entry 1–3) in such transformations was found to diminish both the conversion (78%) and the enantioselectivity (50% ee), possibly because of the preferential formation of less effective catalytic intermediates derived from $[(\kappa^2\text{-}P,N\text{-}\mathbf{1})_2Rh]^+BF_4^-$ **4a**. On the basis of this postulate and in light of the established preference of **1** to form **4a** (and not $[(COD)(\kappa^2\text{-}P,N\text{-}\mathbf{1})Rh]^+BF_4^-$ **5a**) when combined with $[(COD)Rh(THF)_2]^+BF_4^-$ (vide supra), it is likely that the results featured in entry 1–2 (Table 1) do not truly reflect the

performance of the target pre-catalyst complex **5a** alone; rather, the previously discussed coordination chemistry studies indicate that each of $[(COD)Rh(THF)_2]^+BF_4^-$, **4a**, and **5a** are likely to be present as pre-catalysts under these experimental conditions. In this regard, the inherent enantioselectivity of **5a** is likely underestimated, owing to the significant background reactivity associated with $[(COD)Rh(THF)_2]^+BF_4^-$ (Table 1, entry 1–1) and the generally inferior performance of **4a**, as based on entry 1–3. In an effort to possibly promote the formation of **5a**, the reaction solvent was changed to CH_2Cl_2; however, all such reactions employing $[(COD)Rh(THF)_2]^+BF_4^-$ (pre-formed in THF) in combination with 0, 1.2, or 2.4 equiv. of **1** relative to Rh afforded no conversion of the alkene substrate (15). Similarly, the pre-formed Rh complex **3** proved to be catalytically inactive in either THF or CH_2Cl_2. While $[(COD)Ir(THF)_2]^+BF_4^-$ mediated the quantitative conversion of **7** to **8** in CH_2Cl_2 (Table 1, entry 1–4), the activity of Ir in this chemistry was completely inhibited by the addition of 1.2 equiv. of **1** for reactions carried out in CH_2Cl_2 or THF.

[1] 
Asymmetric hydroboration

The asymmetric hydroboration of styrene (16) employing either pinacolborane (HBpin) or catecholborane (HBcat) was selected as an alternative E–H addition reaction with which to evaluate the ability of **1** to promote chemo-, regio-, and enantioselectivity in PGM-mediated catalysis (eq. [2] and Table 2). For reactions employing HBpin, catalyst mixtures derived from 5.0 mol% $[(COD)_2Rh]^+BF_4^-$ and 5.5 mol% **1** were found to exhibit modest selectivity towards the desired branched isomer **9a** over the linear isomer **9b** at substrate concentrations of 0.19 mol/L (Table 2, entry 2–1) and 0.046 mol/L (Table 2, entry 2–2); inferior selectivity was noted for analogous reactions in which HBcat was used (Table 2, entries 2–3 and 2–4). Unfortunately, no enantioselectivity (in **9a**) was achieved in the aforementioned hydroboration reactions, and analogous reactions employing 5.0 mol% $[(COD)_2Ir]^+BF_4^-$ and 5.5 mol% **1** afforded exclusively the linear product **9b**.

[2] 
Asymmetric hydrosilylation

The asymmetric hydrosilylation of ketones represents an appealing synthetic route to chiral secondary alcohols. While highly effective PGM catalysts for this challenging enantioselective transformation are relatively few, a report by Tao and Fu (17) highlights the utility of appropriately designed chiral *P*,*N*-ligands in Rh-catalyzed transformations of this type. Key results of our investigation of asymmetric hydrosilylation of acetophenone with Ph_2SiH_2 (eq. [3]) in THF are collected in Table 3. In preliminary experiments using a catalyst mixture comprised of 0.25 mol% $[(COD)RhCl]_2$ and 6.0 mol% **1**, 50% conversion of the ketone was achieved; however, the derived secondary alcohol formed upon acidic workup was obtained in only 32% ee (Table 3, entry 3–1). When employing catalyst mixtures featuring **1**/Rh in a 2:1 ratio, no conversion was achieved (Table 3, entry 3–2), thereby indirectly suggesting that **2a** is

an ineffective pre-catalyst for this transformation. While the use of 5.0 mol% $[(COD)Rh(THF)_2]^+BF_4^-$ in combination with **1** (6.0 or 12.0 mol%) afforded a correspondingly more active catalyst system (Table 3, entries 3–3 and 3–4), only modest enantioselectivities (<30% ee) were achieved.

[3] 
10

Asymmetric allylic alkylation

The Pd-mediated asymmetric allylic alkylation of (±)-(*E*)-1,3-diphenylprop-2-enyl acetate with dimethyl malonate (eq. [4]) is a well-established C–C bond forming reaction that is used commonly as a means of benchmarking the utility of chiral *P*,*N*-ligands in enantioselective catalysis (13, 18). Table 4 summarizes some key results of our catalytic studies employing catalyst mixtures of derived from 2.5 mol% $[(\eta^3\text{-allyl})PdCl]_2$ and **1** under standard conditions (18a) employing *N*,*O*-bis(trimethylsilyl)acetamide (BSA) and a catalytic amount of potassium acetate as base. In a preliminary catalytic survey (5.0 mol% **1**, 24 h), the influence of solvent (CH_2Cl_2, THF), substrate concentration (0.2 mol/L, 0.04 mol/L), and the ratio of (±)-(*E*)-1,3-diphenylprop-2-enyl acetate to dimethyl malonate (1:1.1, 1:3) on conversion and enantioselectivity was examined (Table 4, entries 4–1 to 4–8). Whereas a number of experimental conditions were identified that could provide >99% conversion to **11**, reactions employing 0.04 mol/L (±)-(*E*)-1,3-diphenylprop-2-enyl acetate and 1.1 equiv. of dimethyl malonate in THF (Table 4, entry 4–6) afforded what we viewed as the best balance between conversion (93%) and enantioselectivity (57%). Schenkel and Ellman (19) have reported that improved enantioselectivity in Pd-catalyzed asymmetric allylic alkylation can be achieved by conducting the reaction under dilute conditions. In this context, a series of catalytic reactions were carried out employing a substrate concentration of 0.004 mol/L and in which the amount of added **1** was varied (0.5, 1.0, 2.0, and 3.0 equiv. relative to Pd; Table 4, entries 4–9 to 4–12). While a 1:1 ratio of **1**/Pd (Table 4, entry 4–10) produced the most effective catalyst system, resulting in >99% conversion (after 100 h) and affording *R*-**11** in 66% ee, it is noteworthy that the catalyst system obtained, when employing 2.0 or 3.0 equiv. of **1** relative to Pd, exhibits a modest preference for the formation of the opposite enantiomer *S*-**11** (Table 4, entries 4–11 and 4–12). Although these preliminary results are somewhat promising, it is important to recognize that the overall performance of **1** in the Pd-mediated enantioselective synthesis of **11** is not competitive with the best chiral *P*,*N*-ligands, including PHOX (5) and alternative phosphoramidite ligands (20), which offer >99% conversion and >95% ee for this enantioselective transformation (18a).

[4] 
11

Summary and conclusions

In conclusion, we have reported herein on the synthesis and characterization of a new chiral heterobidentate phosphoramidite ligand **1**, which is easily prepared in high yield from the commercially available reagents 7-azaindole, *R*-BINOL, and PCl_3. Preliminary coordination chemistry studies confirm the ability of **1** to form isolable κ^2-*P*,*N* complexes with Rh, Ir, and Pd. However, in the course of such synthetic studies, Rh (and in some cases Ir) exhibited a marked propensity to form M(**1**)$_2$ complexes; such behavior may contribute in part to the generally lacklustre catalytic performance exhibited by mixtures of **1** and Rh precursor complexes in the asymmetric addition of E–H fragments (E = H, B, Si) to unsaturated substrates. While under certain conditions, mixtures of **1** and $[(\eta^3\text{-allyl})PdCl]_2$ proved capable of mediating the addition of dimethyl malonate to

© 2008 NRC Canada

(±)-(*E*)-1,3-diphenylprop-2-enyl acetate with >99% conversion and a maximum ee of 66%, the rather low enantioselectivity achieved suggests that **1** is not competitive with more well-established chiral *P*,*N*-ligands for such asymmetric transformations.

Synthesis of platinum(II) cyclometallated compounds derived from imines containing pyridyl or pyrimidyl groups[1]

Margarita Crespo, Craig M. Anderson, and Joseph M. Tanski

Abstract: The reaction of compounds $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$ and *cis*-$[PtPh_2(SMe_2)_2]$ with ligands 4-(2′-C_5H_4N)$C_6H_4CHNCH_2CH_2NMe_2$ (**1a**) and 4-(3′,5′-$C_4H_3N_2$)$C_6H_4CHNCH_2CH_2NMe_2$ (**1b**) carried out in acetone at room temperature produced compounds in which the imines act as bidentate [*N,N*′] ligands. Analogous compounds could be obtained in refluxing methanol when *cis*-$[PtCl_2(DMSO)_2]$ was used as starting material. The corresponding cyclometallation processes leading to platinum(II) compounds with a tridentate [*C,N,N*′] ligand took place under different reaction conditions, except for metallation of **1a** with *cis*-$[PtPh_2(SMe_2)_2]$, which could not be achieved. All compounds were characterized by usual techniques and [PtMe{4-(3′,5′-$C_4H_3N_2$)$C_6H_3CHNCH_2CH_2NMe_2$}] (**3bMe**) was also characterized crystallographically.

Key words: platinum, imines, pyridyl, pyrimidyl, cyclometallation, crystal structure.

Résumé : Opérant en solution dans l'acétone et à la température ambiante on a effectué la réaction des produits $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$ et *cis*-$[PtPh_2(SMe_2)_2]$ avec les ligands 4-(2′-C_5H_4N)$C_6H_4CHNCH_2CH_2NMe_2$ (**1a**) et 4-(3′,5′-$C_4H_3N_2$)$C_6H_4CHNCH_2CH_2NMe_2$ (**1b**) et on en a isolé des produits dans lesquels les imines agissent comme des ligands [*N,N*′]-bidentates. On a aussi pu obtenir des composés analogues en opérant dans le méthanol au reflux en présence de *cis*-$[PtCl_2(dmso)_2]$ utilisé comme substrat. Les processus de cyclométallation correspondants qui conduisent à la formation de composés du platine(II) avec un ligand tridentate [*C,N,N*′] se produit aussi dans des conditions réactionnelles différentes, mais la métallation du composé **1a** par le *cis*-$[PtPh_2(SMe_2)_2$ ne peut pas être réalisée. On a caractérisé tous les produits par les techniques usuelles et on a fait appel à la diffraction des rayons X pour caractériser le [PtMe{4-(3′,5′-$C_4H_3N_2$)$C_6H_3CHNCH_2CH_2NMe_2$}] (**3bMe**).

Mots-clés : platine, imines; pyridyle, pyrimidyle, cyclométallatation, structure cristalline.

[Traduit par la Rédaction]

Introduction

Cycloplatinated compounds have been a topic of interest in the last years as a consequence of the wide range of their potential applications in many areas (1–8). In spite of the large number of this type of compound described so far, the factors that control the cyclometallation process are not fully understood. Besides gross electronic and steric factors, subtle differences in the substituents of the ligands to be metallated can be decisive in the course of the reaction (9, 10). Following our studies of cycloplatination of imines containing aromatic groups such as benzene (11, 12), thiophene (13), furane (14), naphthalene (15), phenanthrene and anthracene (16), and biphenyls (17, 18), we now report the reactions of imines derived from 4-(2-pyridyl)benzaldehyde (**1a**) and 5-(4-formylphenyl)pyrimidine (**1b**) with metallating agents $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$, *cis*-$[PtPh_2(SMe_2)_2]$ and *cis*-$[PtCl_2(DMSO)_2]$. The aim of this study is to evaluate the influence of pyridyl or pyrimidyl substituents in the aryl group as well as of the metallating substrate used in the synthesis of novel platinacycles. For all these systems, the labile sulfide or sulfoxide ligands should be easily replaced by the two nitrogen atoms of the ligands leading to isolation of [*N,N*′] coordination compounds. The intramolecular C–H bond activation may occur through either oxidative addition or electrophilic substitution pathways (19). Moreover, the presence of one or two nitrogen atoms in the aromatic moiety introduces reactive sites on the ligands and allows further chemical reactions of the corresponding cyclometallated compounds (20).

Results and discussion

Ligands 4-(2′-C_5H_4N)$C_6H_4CHNCH_2CH_2NMe_2$ (**1a**) and 4-(3′,5′-$C_4H_3N_2$)$C_6H_4CHNCH_2CH_2NMe_2$ (**1b**) were prepared from the condensation reactions of *N,N*-dimethylethylenediamine and the corresponding aldehyde carried out in toluene at room temperature. The resulting imines were characterized by ^{1}H NMR spectroscopy.

Reactions of ligands 1a and 1b with $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$

The reactions of $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$ with potentially tridentate ligands **1a** and **1b** carried out in acetone at room temperature produced the compounds $[PtMe_2\{4\text{-}(2'\text{-}C_5H_4N)\text{-}C_6H_4CHNCH_2CH_2NMe_2\}]$ (**2aMe**) and $[PtMe_2\{4\text{-}(3',5'\text{-}C_4H_3N_2)C_6H_4CHNCH_2CH_2NMe_2\}]$ (**2bMe**), respectively, in which the imines act as bidentate [*N,N*′] ligands (see Chart 1).

Compound **2aMe** was characterized by elemental analyses, mass spectrometry, and ^{1}H NMR spectra. Compound **2bMe** was characterized in solution by NMR spectroscopy but it could not be isolated in a pure form, since further reaction at room temperature produces the corresponding cyclometallated compound **3bMe** within 1 h (see below). In the ^{1}H NMR spectra, two distinct resonances appear in the methyl region, both coupled with ^{195}Pt. The one at higher field with a larger coupling to ^{195}Pt is assigned to the methyl trans to the NMe_2 moiety (see Table 1). The coordination of the ligand through both nitrogen atoms is confirmed by the coupling of both amine and imine protons to platinum. The *J*(H–Pt) values for the imine proton indicate an *E* conformation of the imine as previously observed for analogous compounds (11–18).

methane elimination to yield [*C,N,N′*] cycloplatinated compounds took place at room temperature for **2bMe** and when a toluene solution of compound **2aMe** was refluxed for 2 h. Compounds **3aMe** and **3bMe** were characterized by mass spectrometry, NMR spectroscopy, and elemental analyses. In addition, **3bMe** was also characterized crystallographically. In the ^{1}H NMR spectra, the methyl ligand, the dimethylamino, and the imine groups are coupled to platinum, and the values of the coupling constants are in the usual range for analogous compounds (11–18). In agreement with previous data, the J(H–Pt) values of the imine group increase from the coordination compounds to the cyclometallated compounds (see Table 1). In addition, the aromatic proton adjacent to the metallation site is also coupled to platinum and provides evidence of the cyclometallation process.

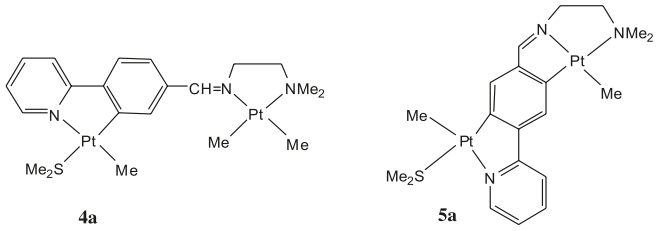
Imine **1a** derived from 4-(2-pyridyl)benzaldehyde could in principle produce binuclear compounds either mono- or doubly-cyclometallated such as **4a** and **5a** shown in Chart 2. Doubly cyclometallated compounds have been described for both platinum and palladium (21, 22). With this aim, the reaction of $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$ with an equimolar amount of imine **1a** was carried out in acetone.

Unfortunately, the obtained orange solid was too insoluble for NMR or mass spectra and could only be characterized by elemental analyses, which were consistent with formation of **4a**. This result indicates the ability of imine **1a** to participate in further reactions through the pyridyl nitrogen atom. Attempts to produce a doubly cyclometallated compound using longer reaction times in acetone at room temperature or refluxing a toluene suspension of compound **4a** for several hours gave insoluble materials that could not be identified. Because of the difficulties arising from the low solubility of these binuclear compounds, no further studies were carried out.

Reactions of ligands 1a and 1b with *cis*-$[PtPh_2(SMe_2)_2]$

The reactions carried out in acetone at room temperature produced compounds $[PtPh_2\{4\text{-}(2'\text{-}C_5H_4N)C_6H_4CHNCH_2CH_2NMe_2\}]$ (**2aPh**) and $[PtPh_2\{4\text{-}(3',5'\text{-}C_4H_3N_2)C_6H_4CHNCH_2CH_2NMe_2\}]$ (**2bPh**) in good yields. The obtained compounds were characterized by elemental analyses, mass spectrometry, and ^{1}H NMR spectroscopy. As for the compounds above, the coordination of the ligand through both nitrogen atoms is confirmed by the coupling of both amine and imine protons to platinum, and the J(H–Pt) values for the imine proton indicate an *E* conformation.

Chart 2.



Formation of the corresponding cyclometallated compounds was attempted by refluxing toluene solutions of **2aPh** or **2bPh** for 6 h, a method previously reported for the synthesis of analogous compounds with biphenyl ligands (18), which consists in intramolecular activation of a $C_{aromatic}$–H bond along with elimination of benzene. Using this procedure for **2bPh**, the corresponding [*C,N,N′*] cyclometallated compound $[PtPh\{4\text{-}(3',5'\text{-}C_4H_3N_2)C_6H_3CHNCH_2CH_2NMe_2\}]$ (**3bPh**) was obtained as an orange red solid. Compound **3bPh** was characterized by elemental analyses, mass spectrometry, and NMR spectra. As shown in Table 1, the coupling constant of the imine proton to platinum increases slightly compared with compound **2bPh** as a result of the formation of a metallacycle. Under the same experimental conditions, the analogous compound **3aPh** was not obtained, since red solutions were formed, and the NMR spectra taken for the final residue show only intense aldehyde signals, which indicate hydrolysis of the imine bond, along with peaks for unidentified products. Hydrolysis of imines with adventitious water in the solvent has been reported under metallation conditions with palladium or platinum substrates (23, 24). Using shorter refluxing times did not improve the results. Therefore, the synthesis of cyclometallated compound **3aPh** was attempted under milder conditions such as stirring at room temperature a solution of **2aPh** in acetone. After several hours, a new compound was formed and its spectral data, in particular a small value of J(H–Pt) for the imine proton (J(H–Pt) = 27.9 Hz), suggest isomerization of the imine from the initial *E* conformation observed in **2aPh** to the less congested *Z* form leading to compound **2a′Ph**. After 24 h, the ratio **2a′Ph/2aPh** is 0.54:1.00, and the amount of **2a′Ph** increases slowly up to a ratio of ~ 1.00:1.00 after 5 days in solution. No evidence of formation of the expected cyclometallated compound is observed in the ^{1}H NMR spectra, while small amounts of the aldehyde are formed. Isomerization from the most favoured *E* conformation of the free ligand to the *Z* conformation upon coordination to a platinum centre has been previously observed for analogous systems (18) and can be explained by the steric crowding in the coordination sphere of the platinum(II) centre, which is minimized through this conformational change. It has to be noted, however, that the adequate arrangement for producing cyclometallation at the aromatic group is the *E* conformation, since isomerization to the less

© 2008 NRC Canada

congested *Z* form places the aromatic group away from the platinum centre. Therefore, the reaction at room temperature was not a good strategy for cyclometallation of **2aPh**.

Reactions of ligands 1a and 1b with *cis*-[$PtCl_2(DMSO)_2$]

When equimolar amounts of *cis*-[$PtCl_2(DMSO)_2$] and ligand **1a** were refluxed in methanol for 5 h, the corresponding compound [$PtCl_2$\{\{4-(2′-C_5H_4N)$C_6H_4CHNCH_2CH_2NMe_2$\}] (**2aCl**) was obtained in good yield. As previously noticed for analogous systems (25), a *Z* conformation around the C=N bond is adopted with the imine proton close to the platinum nucleus, which is evidenced in the ^{1}H NMR spectrum by the downfield shift of the imine signal (δ = 9.58 ppm). This fact suggests that coordination of a bidentate ligand to a $PtCl_2$ moiety produces a conformational change from the most stable *E* conformation of the free ligand to the *Z,* and consequently *Z–E* isomerization should precede the cyclometallation step as previously reported for analogous systems. The corresponding reaction for ligand **1b** produced compound [$PtCl_2$\{4-(3′,5′-$C_4H_3N_2$)$C_6H_4CHNCH_2CH_2NMe_2$\}] (**2bCl**) as a rather insoluble impure solid; attempts to obtain **2bCl** in a pure form were unsuccessful because of its low solubility.

The most widely used conditions for converting compounds analogous to **2aCl** and **2bCl** into cycloplatinated derivatives are refluxing for several hours in either toluene or in a donor solvent such as methanol or ethanol, in some cases in the presence of an external base, which favours the formal elimination of HCl (25–30). When **2aCl** was treated with an equimolar amount of sodium acetate in refluxing methanol for 48 h, cyclometallated compound **3aCl** was produced. The process requires an initial step in which *Z* to *E* imine isomerization brings the aryl ring closer to platinum followed by the actual intramolecular C–H bond activation, which leads to a five-membered metallacycle.

Alternatively, **3aCl** could be obtained when equimolar amounts of *cis*-[$PtCl_2(DMSO)_2$], ligand **1a** and sodium acetate were refluxed in methanol for 48 h. This method was also used to obtain **3bCl**. The obtained yields were lower than those obtained for analogous compounds derived from biphenyl such as [PtCl\{4-$C_6H_5C_6H_3CHNCH_2CH_2NMe_2$\}] and [PtCl\{2-$C_6H_5C_6H_3CHNCH_2CH_2NMe_2$\}] (18). Furthermore, using prolonged reaction times, toluene–methanol mixtures, and higher reaction temperatures (26–30) did not improve the yields, since metallic platinum and high amounts of aldehyde were formed under these conditions. Compounds **3aCl** and **3bCl** were characterized by elemental analyses, mass spectrometry, and NMR spectra. In the ^{1}H NMR spectra, a significant increase in the coupling constant of the imine proton to platinum is observed upon cyclometallation. The obtained values shown in Table 1 are in the range reported for analogous cyclometallated compounds in which a chloro ligand is in a trans position to the imine (18). As a whole, analysis of the ^{1}H NMR data reported in Table 1 indicate that the *J*(H–Pt) values for the imine proton increase in the order: **2a′Ph** (28 Hz) < **2bMe**, **2bPh**, **2aPh**, **2aMe** (42–45 Hz) < **2aCl** (52 Hz) < **3bPh**, **3aMe**, **3bMe** (57–58 Hz) << **3aCl**, **3bCl** (140–141 Hz).

This sequence is consistent with the larger *J*(H–Pt) values expected for: (*i*) cyclometallated vs. non-cyclometallated compounds, (*ii*) imine moieties trans to a chloro ligand vs. trans to a methyl or a phenyl ligand, and (*iii*) *E* vs. *Z* conformation of the imine.

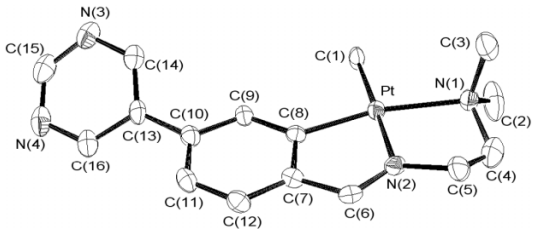
Fig. 1. Molecular structure of compound **3bMe**.



Crystal structure of 3bMe

Suitable crystals of **3bMe** were grown by slow diffusion of a CH_2Cl_2 solution into MeOH. The crystal structure is composed of discrete molecules separated by van der Waals interactions. Selected bond lengths and angles are given in Table 2, and a molecular view is shown in Fig. 1.[3]

The ligand behaves as [*C,N,N′*]-tridentate and a three fused [*6,5,5*] ring system containing a five-membered endo metallacycle is formed. A methyl ligand completes the square-planar coordination of the platinum atom. The metallacycle is approximately planar as suggested by the sum of internal angles, which is close to 540° (31) and nearly co-planar with both the metallated phenyl and the mean coordination plane. The dihedral angle between phenyl and pyrimidyl groups is 31.8(2)°, which suggests, aside from

© 2008 NRC Canada

packing effects, a compromise between van der Waals repulsion of the ortho hydrogen atoms and the co-planarity required for resonance extended to both aryl rings. Tilt angles ranging from 10.4° to 49.9° have been obtained for biphenyl systems in analogous platinum(II) and platinum(IV) cyclometallated compounds (17, 18). Bond lengths and angles are in the expected range for analogous compounds (11–13, 15–18). The Pt–NMe_2 distance is longer (2.169(4) Å) than the Pt–NCH (2.017(4) Å), which is consistent with the relatively weak coordinating ability of tertiary amines for platinum. Bond angles at platinum are close to the ideal value of 90°, and the smallest angles correspond to those involving the tridentate ligand with "bite" angles C(8)–Pt–N(2) and N(1)–Pt–N(2) being 81.1(2)° and 81.9 (2)°, respectively.

Conclusions

The results here presented indicate that [*C,N,N′*] cyclometallated compounds derived from **1a** and **1b** can be easily obtained when $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$ is used as a metallation agent. The presence of two nitrogen atoms in the pyrimidyl substituent in **1b** facilitates the reaction, which takes place under milder conditions than for **1a**. When *cis*-$[PtPh_2(SMe_2)_2]$ is used as starting material, the corresponding [*C,N,N′*] cyclometallated compound could only be obtained for the more activated **1b** ligand. For both substrates $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$ and *cis*-$[PtPh_2(SMe_2)_2]$, the mechanism consists of oxidative addition followed by elimination of methane (32) or benzene (33), and therefore, the presence of an additional nitrogen atom, more electronegative than a carbon atom, should have a similar activating effect in both cases.

The failure to produce cyclometallation of ligand **1a** with *cis*-$[PtPh_2(SMe_2)_2]$ is however unexpected taking into account that this metallation agent was effective for 4-biphenylimine and even for the more sterically demanding 2- biphenylimine (17, 18), and that, in this case, the presence of one nitrogen atom in **1a** should facilitate the process. Based on the observed presence of aldehyde in the attempted cyclometallation reaction, we might assume that ligand **1a** is more prone to experience hydrolysis than the corresponding biphenyl ligands. This fact along with the lower reactivity of *cis*-$[PtPh_2(SMe_2)_2]$ vs. $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$ (18) may account for the observed results.

When *cis*-$[PtCl_2(DMSO)_2]$ was used as starting material, the corresponding [*C,N,N′*] cyclometallated compounds could also be obtained, although with poor yields. As previously indicated for analogous systems (18, 25), the greater steric requirements of chloro vs. methyl or phenyl ligands in the platinum substrate leads to a *Z* conformation of the imine group in the [*N,N′*] compounds, and therefore, *Z* to *E* isomerization should precede the cyclometallation. Moreover, the lower yields compared with those obtained for biphenyl ligands (18) could be related to the higher proclivity of ligands **1a** and **1b** to hydrolysis as well as to the reduced reactivity towards an electrophilic reagent expected for ligands containing electron-withdrawing substituents.

As a whole, the above results indicate that pyridyl or pyrimidyl substituents on the aryl group may have a decisive influence in the cyclometallation process, which is attributed more to electronic than to steric effects, since the substituents are away from the metallation position. In addition to determining the success and ease of the cyclometallation, these substituents emphasize the differences observed when different metallating agents such as $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$, *cis*-$[PtPh_2(SMe_2)_2]$, and *cis*-$[PtCl_2(DMSO)_2]$ are used, which is further evidence of the different mechanisms operating for such substrates (19). Further work aimed at evaluating the ability of free pyridyl or pyrimidyl groups in the new compounds to coordinate a second metallic fragment is in progress.

Experimental

General

NMR spectra were performed at the Unitat de RMN d'Alt Camp de la Universitat de Barcelona using Mercury 400 and Varian 300 spectrometers and referenced to $SiMe_4$. δ values are given in ppm and *J* values in Hz. *J*(H–Pt) values were measured at 300 MHz to avoid errors arising from broadening of the ^{195}Pt satellites observed at 400 MHz. Labelling of the compounds is as shown in Chart 1. ES-mass spectra were performed at the Servei d'Espectrometria de Masses de la Universitat de Barcelona using a VG-Quattro spectrometer. Microanalyses were performed by the Servei de Recursos Científics i Tècnics de la Universitat Rovira i Virgili (Tarragona).

All starting materials were purchased from commercial sources and used as received. Toluene was distilled from sodium–benzophenone. Compounds $[Pt_2Me_4(\mu\text{-}SMe_2)_2]$ (34), *cis*-$[PtPh_2(SMe_2)_2]$ (35, 36), and *cis*-$[PtCl_2(DMSO)_2]$ (37) were prepared according to literature methods.

Preparation of the compounds

Compounds **1** were prepared by the reaction of equimolar amounts of *N*,*N*-dimethylethylenediamine and the corresponding aldehyde in toluene (20 mL). The mixture was stirred for 1 h and dried over Na_2SO_4. The solvent was removed in a rotary evaporator to yield yellow oils.

4-(2′-C_5H_4N)$C_6H_4CHNCH_2CH_2NMe_2$ (1a)

Obtained from 0.5 g (2.90×10^{-3} mol) of 4-(2-pyridyl)benzaldehyde and 0.26 g of *N*,*N*-dimethylethylenediamine. Yield: 0.5 g (67%). ^1H NMR (400 MHz, $CDCl_3$) δ: 2.32 [s, 6H, H^a], 2.67 [t, *J*(H–H) = 7.2, 2H, H^b], 3.78 [td, *J*(H–H) = 7.2, 0.8, 2H, H^c], 7.26 [m, 1H, H^h], 7.77 [m, 2H, $H^{i,j}$], 7.84 [d, *J*(H–H) = 8.4, 2H, H^f], 8.05 [d, *J*(H–H) = 8.4, 2H, H^e], 8.37 [s, 1H, H^d], 8.71 [dt, *J*(H–H) = 4.4, 1.4, 1H, H^g].

4-(3′,5′-$C_4H_3N_2$)$C_6H_4CHNCH_2CH_2NMe_2$ (1b)

Obtained from 0.4 g of 5-(4-formylphenyl)pyrimidine (2.17×10^{-3} mol) and 0.19 g of *N*,*N*-dimethylethylenediamine. Yield: 0.4 g (72%). ^1H NMR (400 MHz, $CDCl_3$) δ: 2.34 [s, 6H, H^a], 2.69 [t, *J*(H–H) = 7.2, 2H, H^b], 3.80 [t, *J*(H–H) = 7.2, 2H, H^c], {7.64 [d, *J*(H–H) = 8.4, 2H], 7.89 [d, *J*(H–H) = 8.4, 2H], $H^{e,f}$}, 8.38 [s, 1H, H^d], 8.98 [s, 2H, H^g], 9.23 [s, 1H, H^h].

[PtMe$_2${4-(2′-C$_5$H$_4$N)C$_6$H$_4$CHNCH$_2$CH$_2$NMe$_2$}] (2aMe)

Compound **2aMe** was obtained from 88 mg (3.49×10^{-4} mol) of ligand **1a** and 100 mg (1.74×10^{-4} mol) of compound [Pt$_2$Me$_4$(μ-SMe$_2$)$_2$] in acetone (20 mL). The mixture was stirred for 30 min at room temperature. **2aMe** was obtained as an orange solid upon removal of the acetone in a rotary evaporator and washing of the residue with ether (3×2 mL).

Yield: 150 mg (90%). ^{1}H NMR (400 MHz, CDCl$_3$) δ: 0.25 [s, ^2J(Pt–H) = 90, 3H, H^k], 0.63 [s, ^2J(Pt–H) = 84, 3H, H^l], 2.71 [t, J(H–H) = 5.2, 2H, H^b], 2.84 [s, ^3J(H–Pt) = 19, 6H, H^a], 4.07 [t, J(H–H) = 5.2, 2H, H^c], 7.76–7.79 [m, 3H, H^{h,i,j}], {8.01 [d, J(H–H) = 8.2, 2H], 8.37 [d, J(H–H) = 8.2, 2H],H^{e,f}}, 8.70 [d, J(H–H) = 5.2, 1H, H^g], 9.03 [s, ^3J(Pt–H) = 45, 1H, H^d]. ES (+)-MS (MeCN – H$_2$O): 504 [M – Me + MeCN], 489 [M – 2Me + MeCN], 463 [M – Me], 448 [M – 2Me]. Anal. found: C, 44.5; H, 5.9; N, 8.5. Calcd. for C$_{18}$H$_{25}$N$_3$Pt: C, 45.18; H, 5.26; N, 8.78 (%).

[PtMe$_2${4-(3′,5′-C$_4$H$_3$N$_2$)C$_6$H$_4$CHNCH$_2$CH$_2$NMe$_2$}] (2bMe)

Compound **2bMe** was obtained following the same procedure from 18 mg of ligand **1b** and 20 mg (0.35×10^{-4} mol) of compound [Pt$_2$Me$_4$(μ-SMe$_2$)$_2$] in acetone (10 mL). Compound **2bMe** could be characterized in solution, and within an hour, produces **3bMe** (see below).

^{1}H NMR (400 MHz, CDCl$_3$) δ: 0.21 [s, ^2J(Pt–H) = 90, 3H, H^i], 0.64 [s, ^2J(Pt–H) = 84, 3H, H^j], 2.72 [m, 2H, H^b], 2.85 [s, ^3J(H–Pt) = 20, 6H, H^a], 4.11 [m, 2H, H^c], {7.60 [d, J(H–H) = 8.4, 2H], 8.45 [d, J(H–H) = 8.4, 2H], H^{e,f}}, 9.00 [s, 2H, H^g], 9.07 [s, ^3J(Pt–H) = 42, 1H, H^d], 9.24 [s, 1H, H^h].

[PtPh$_2${4-(2′-C$_5$H$_4$N)C$_6$H$_4$CHNCH$_2$CH$_2$NMe$_2$}] (2aPh)

Compound **2aPh** was obtained as a yellow solid following the same procedure as for **2aMe** from 48 mg (0.19 mmol) of ligand **1a** and the equimolar amount of compound *cis*-[PtPh$_2$(SMe$_2$)$_2$] (90 mg) in acetone (10 mL).

Yield: 80 mg (70%). ^{1}H NMR (400 MHz, CDCl$_3$) δ: 2.67 [s, ^3J(Pt–H) = 17, 6H, Me^a], 2.79 [t, J(H–H) = 5.0, 2H, H^b], 4.21 [t, J(H–H) = 5.0, 2H, H^c], {6.28 [t, J(H–H) = 7.0, 1H], 6.38 [t, J(H–H) = 7.4, 2H], 6.81 [t, J(H–H) = 7.2, 1H], 6.93 [m, 4H], 7.23 [ddd, J(H–H) = 7.6, 4.8, 1.2, 1H], 7.48 [d, J(H–H) = 8.0, 2H], 7.55–7.58 [m, 3H], 7.73 [td, J(H–H) = 7.6, 2, 1H], 8.14 [d, J(H–H) = 8.4, 2H], 8.65 [ddd, J(H–H) = 4.4, 1.6, 1.0, 1H]}, 8.84 [s, ^3J(Pt–H) = 44, 1H, H^d]. ES (+)-MS (MeCN – H$_2$O): 603 [M + H], 525 [M – Ph], 448 [M – 2Ph]. Anal. found: C, 54.5; H, 4.9; N, 6.5. Calcd. for C$_{28}$H$_{29}$N$_3$Pt·H$_2$O: C, 54.18; H, 5.03; N, 6.77 (%). Isomerization to **2a′Ph** (*Z* isomer) took place in acetone at room temperature. ^{1}H NMR (400 MHz, CDCl$_3$) δ: 2.62 [s, ^2J(Pt–H) = 21, 6H, Me^a], 2.76 [t, J(H–H) = 6.0, 2H, H^b], 4.02 [td, J(H–H) = 6.0, 2,0, 2H, H^c], 8.43 [s, ^3J(Pt–H) = 28, 1H, H^d].

[PtPh$_2${4-(3′,5′-C$_4$H$_3$N$_2$)C$_6$H$_4$CHNCH$_2$CH$_2$NMe$_2$}] (2bPh)

Compound **2bPh** was obtained as a yellow solid following the same procedure as for **2aMe** from 48.3 mg (0.19 mmol) of ligand **1b** and the equimolar amount of compound *cis*-[PtPh$_2$(SMe$_2$)$_2$] (90 mg) in acetone (10 mL).

Yield: 90 mg (78%). ^{1}H NMR (400 MHz, CDCl$_3$) δ: 2.67 [s, ^3J(Pt–H) = 18, 6H, Me^a], 2.80 [t, J(H–H) = 5.0, 2H, H^b], 4.20 [t, J(H–H) = 5.0, 2H, H^c], {6.34–6.36 [m, 2H], 6.80 [t, J(H–H) = 8.0, 2H], 6.89–6.92 [m, 3H], 7.12 [d, J(H–H) = 8.4, 2H], 7.44–7.46 [m, 3H], 8.12 [d, J(H–H) = 8.0, 2H], 8.81 [s, 2H], 9.20 [s, 1H], aromatics}, 8.87 [s, ^3J(Pt–H) = 43, 1H, H^d]. ES (+)-MS (MeCN – H$_2$O): 604 [M + H], 526 [M – Ph], 449 [M – 2Ph]. Anal. found: C, 53.2; H, 4.8; N, 9.0. Calcd. for C$_{27}$H$_{28}$N$_4$Pt: C, 53.72; H, 4.67; N, 9.28 (%).

[PtCl$_2${4-(2′-C$_5$H$_4$N)C$_6$H$_4$CHNCH$_2$CH$_2$NMe$_2$}] (2aCl)

Compound **2aCl** was obtained from 150 mg (3.50×10^{-4} mol) of *cis*-[PtCl$_2$(DMSO)$_2$] and the equimolar amount (90.0 mg) of **1a** after refluxing the mixture in methanol for 5 h. On cooling, a light yellow solid is formed.

Yield: 120 mg (65%). ^{1}H NMR (400 MHz, CDCl$_3$) δ: 2.70 [t, ^2J(H–H) = 6.0, 2H, H^b], 3.14 [s, 6H, Me^a], 4.09 [td, ^2J(H–H) = 6.0, 2.0, 2H, H^c], 7.33 [ddd, J(H–H) = 6.8, 4.8, 2, 1H, H^h], 7.64 [d, ^3J(H–H) = 8.4, 2H, H^e or H^f], 7.80–7.82 [m, 2H, H^i, H^j], 8.13 [d, ^3J(H–H) = 8.4, 2H, H^e or H^f], 8.73 [dt, J(H–H) = 4.8, 2, 1H, H^g], 9.58 [s, ^3J(Pt–H) = 52, 1H, H^d]. ESI-MS: 520 [M + H], 484 [M – Cl]. Anal. found: C, 36.2; H, 3.7; N, 8.0. Calcd. for C$_{16}$H$_{19}$Cl$_2$N$_3$Pt·H$_2$O: C, 35.76; H, 3.94; N, 7.82 (%).

[PtCl$_2${4-(3′,5′-C$_4$H$_3$N)C$_6$H$_4$CHNCH$_2$CH$_2$NMe$_2$}] (2bCl)

Compound **2bCl** was obtained as an insoluble impure solid following the procedure reported above for **2aCl**.

^{1}H NMR (400 MHz, CDCl$_3$) δ: 2.72 [m, 2H, H^b], 3.15 [s, 6H, Me^a], 4.08 [t ^2J(H–H) = 6.0, 2H, H^c], 7.73–7.76 [m, 4H], 8.99 [s, 2H,], 9.29 [s, 1H], 9.57 [s, 1H, H^d].

[PtMe{4-(2′-C$_5$H$_4$N)C$_6$H$_3$CHNCH$_2$CH$_2$NMe$_2$}] (3aMe)

Compound **3aMe** was obtained after refluxing a toluene solution (20 mL) containing 50 mg of compound **2aMe** for 2 h. Toluene was totally removed, and the residue was recrystallized from CH$_2$Cl$_2$–MeOH to yield **3aMe** as a red solid.

Yield: 40 mg (83%). ^{1}H NMR (400 MHz, CDCl$_3$) δ: 1.06 [s, ^2J(Pt–H) = 79, 3H, H^l], 2.86 [s, ^3J(H–Pt) = 20, 6H, H^a], 3.19 [t, J(H–H) = 5.2, 2H, H^b], 4.09 [t, J(H–H) = 5.2, 2H, H^c], 7.19 [m, 2H, H^{i,j}], {7.37 [d, J(H–H) = 8.0, 2H], 7.82 [d, J(H–H) = 8.0, 2H],H^{e,f}}, 7.73 [d, J(H–H) = 6.8, 1H, H^k], 8.07 [d, J(H–H) = 2, ^3J(Pt–H) = 67, 1H, H^g], 8.64 [s, ^3J(H–Pt) = 58, 1H, H^d], 8.67 [d, J(H–H) = 4.8, 1H, H^h]. ES (+)-MS (MeCN – H$_2$O): 488 [M – Me + MeCN], 462 [M]. Anal. found: C, 44.0; H, 4.7; N, 8.5. Calcd. for C$_{17}$H$_{21}$N$_3$Pt: C, 44.15; H, 4.58; N, 9.09 (%).

[PtMe{4-(3′,5′-C$_4$H$_3$N$_2$)C$_6$H$_3$CHNCH$_2$CH$_2$NMe$_2$}] (3bMe)

Compound **3bMe** was obtained from 89 mg (3.49×10^{-4} mol) of ligand **1b** and 100 mg (1.74×10^{-4} mol) of compound [Pt$_2$Me$_4$(μ-SMe$_2$)$_2$] in acetone (20 mL). The mixture was stirred for 1 h at room temperature, metallic platinum was filtered off, and acetone was removed in a rotary evaporator. Red crystals of **3bMe** were obtained upon recrystallization of the residue from CH$_2$Cl$_2$–MeOH.

Yield: 100 mg (62%). ^{1}H NMR (400 MHz, CDCl$_3$) δ: 1.04 [s, ^2J(Pt–H) = 78, 3H, H^j], 2.87 [s, ^3J(H–Pt) = 21, 6H, H^a], 3.21 [t, J(H–H) = 6.0, 2H, H^b], 4.12 [td, J(H–H) = 6.0, 1.2, 2H, H^c], 7.16 [dd, J(H–H) = 7.6, 1.6, 1H, H^f], 7.38 [d, J(H–H) = 7.6, ^4J(H–Pt) = 10, 1H, H^e], 7.82 [d, J(H–H) = 2.0, ^3J(H–Pt) = 65, 1H, H^g], 8.68 [s, ^3J(H–Pt) = 59, 1H, H^d],

© 2008 NRC Canada

8.97 [s, 2H, H^h], 9.17 [s, 1H, H^i]. ES (+)-MS (MeCN – H_2O): 489 [M – Me + MeCN], 463 [M], 448 [M – Me]. Anal. found: C, 41.0; H, 4.3 N, 11.7. Calcd. for $C_{16}H_{20}N_4Pt$: C, 41.47; H, 4.35; N, 12.09 (%).

[PtPh{4-(3′,5′-$C_4H_3N_2$)$C_6H_3CHNCH_2CH_2NMe_2$}] (3bPh)

Compound **3bPh** was obtained from 50 mg (8.3×10^{-5} mol) of **2bPh** in 20 mL of toluene. The mixture was refluxed for 6 h, and toluene was removed in a rotary evaporator. The residue was washed with ether to yield an orange–red solid.

Yield: 33 mg (76%). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.80 [s, ^3J(H–Pt) = 21, 6H, H^a], 3.24 [t, J(H–H) = 6.0, 2H, H^b], 4.11 [td, J(H–H) = 6.0, 1.2, 2H, H^c], 6.95 [tt, J(H–H) = 7.4, 1.6, 1H, *p*-Ph], 7.10 [t, J(H–H) = 7.4, 2H, *m*-Ph], 7.15 [dd, J(H–H) = 7.4, 1.6, 1H, H^g], 7.32 [d, J(H–H) = 1.6, 1H, H^e], 7.37 [d, J(H–H) = 8, 1H, H^f], 7.55 [dd, J(H–H) = 8, 1.6, ^3J(H–Pt) = 59, 2H, *o*-Ph], 8.56 [s, ^3J(H–Pt) = 57, 1H, H^d], 8.79 [s, 2H, H^h], 9.10 [s, 1H, H^i]. 4a

Compound **4a** was prepared from 22 mg (8.7×10^{-5} mol) of ligand **1a** and 50 mg (8.7×10^{-5} mol) of compound [$Pt_2Me_4(\mu\text{-}SMe_2)_2$] in acetone (20 mL). The mixture was stirred for 5 h at room temperature, and the resulting orange solid was filtered.

Yield: 60 mg (92%). **4a** was too insoluble for NMR or mass spectra. Anal. found: C, 33.3; H, 4.9 N, 5.2. Calcd. for $C_{21}H_{34}N_3Pt_2S$: C, 33.60; H, 4.56; N, 5.60 (%).

5a

The preparation of compound **5a** was attempted using a procedure consisting of refluxing a toluene suspension of compound **4a** for 2 h. The obtained solid was too insoluble for NMR or mass spectra, and the elemental analysis was not consistent with the expected formula. An alternative procedure detailed below gave analogous results: 25 mg (5.2×10^{-5} mol) of compound **3a** and 15 mg (2.6×10^{-5} mol) of compound [$Pt_2Me_4(\mu\text{-}SMe_2)_2$] were allowed to react in acetone at room temperature for 16 h. The resulting insoluble solid was filtered. Yield: 30 mg (79%, based on the expected formula $C_{20}H_{30}N_3Pt_2S$).

X-ray structure determination

X-ray diffraction data were collected on a Bruker APEX 2 CCD platform diffractometer (Mo Kα, λ = 0.71073 Å) at 125 K (0 °C = 273.15 K). A suitable crystal was mounted in a nylon loop with Paratone–*N* cryoprotectant oil. During data examination and space-group determination with XPREP, the σ(I) values were normalized and multiplied by a factor of 0.5. The structure was solved using direct methods and standard difference map techniques, and was refined by full-matrix least-squares procedures on F^2 with SHELXTL (Version 6.14) (38). All non-hydrogen atoms were refined

© 2008 NRC Canada

anisotropically. Hydrogen atoms were included in calculated positions and were refined using a riding model. Crystal data and refinement details are presented in Table 3.

Oxalate bridged heteronuclear compounds containing MM quadruple bonds (M = Mo and W) and their radical cations[1]

Malcolm H. Chisholm and Nathan J. Patmore

Abstract: The heteronuclear MM quadruply bonded oxalate bridged compound $[(t\text{-}BuCO_2)_3MoW]_2(\mu\text{-}C_2O_4)$ **(I)** has been prepared from the reaction between $MoW(O_2Ct\text{-}Bu)_4$ and oxalic acid and characterized by elemental analysis, ^{1}H NMR and UV-vis spectroscopy, and electrochemical studies. Single electron oxidation of **I** by reaction with $Ag^+PF_6^-$ leads to the formation of the kinetically labile radical cation $\mathbf{I}^+$, which has been characterized by UV-vis, NIR, and EPR spectroscopy. The latter results are compared with the properties of their related homonuclear Mo_4- and W_4-oxalate bridged compounds and their respective radical cations. The spectroscopic features of the related radical cations $[(t\text{-}BuCO_2)_6Mo_xW_y(\mu\text{-}C_2O_4)]^+$, where x = 1, 2, 3 and $y = 4 - x$, are also described with the conclusion that the $[(t\text{-}BuCO_2)_3Mo_2(\mu\text{-}C_2O_4)W_2(O_2Ct\text{-}Bu)_3]^+$ and $[(t\text{-}BuCO_2)_3Mo_2(\mu\text{-}C_2O_4)MoW(O_2Ct\text{-}Bu)_3]^+$ cations are valence trapped on the Robin and Day scheme for the classification of mixed valence compounds.

Key words: molybdenum, tungsten, mixed valence.

Résumé : La réaction du $MoW(O_2Ct\text{-}Bu)_4$ avec l'acide oxalique permet de préparer le composé hétéronucléaire MM, à liaison quadruple et pont d'oxalate, $[(t\text{-}Bu(CO_2)_3MoW]_2(\mu\text{-}C_2O_4)$, **I**, qu'on a caractérisé par analyse élémentaire, par spectroscopie UV-vis et RMN du ^{1}H ainsi que par des études électrochimiques. La réaction d'oxydation du composé **I** par un électron à l'aide du $Ag^+PF_6^-$ conduit à la formation du cation radical cinétiquement labile, $\mathbf{I}^+$, qu'on a caractérisé par spectroscopies RPE et UV-vis et proche infrarouge. On a comparé ces derniers résultats aux propriétés de leurs composés homonucléaires apparentés Mo_4- et W_4- liés à l'oxalate et leurs cations radicaux respectifs. On décrit aussi les caractéristiques spectroscopiques des cations radicaux apparentés $[(t\text{-}Bu(CO_2)_6Mo_xW_y(\mu\text{-}C_2O_4)]^+$ dans lesquels x = 1,2,3 et $y = 4 - x$ et on en conclut que les cations $[(t\text{-}Bu(CO_2)_3Mo_2(\mu\text{-}C_2O_4)W_2(O_2C\text{-}tBu)_3]^+$ et $[(t\text{-}Bu(CO_2)_3Mo_2(\mu\text{-}C_2O_4)MoW(O_2C\text{-}tBu)_3]^+$ sont liés par leur valence dans le schéma de Robin et Day de classification des composés de valence mixte.

Mots-clés : molybdène, tungstène, valence mixte.

[Traduit par la Rédaction]

Introduction

Electron transfer and electron delocalization are closely related phenomena, and each is fundamental to numerous chemically, physically, and biologically important processes (1). Indeed, in a molecular system the interconversion of valence-trapped and fully delocalized states corresponds to a molecular switch being "off" or "on", respectively, although it should be recognized that molecular systems and assemblies may never fully replicate the properties of solid-state inorganic based semiconductor (SiMOS) devices. It is, however, easily recognized that molecules can more easily store and impart data and signal recognition at the subnanamoter scale than any solid state device. Thus, the desire to develop molecular electronic and infomatic devices is a topic of considerable focus in current research (2). An understanding of how redox active centers (X) interact in molecular bridged systems (X-bridge-X) in their neutral, singly oxidized and (or) reduced and photoexcited states is thus of fundamental importance, be the redox active center a metal or an organic moiety.

In this paper we describe our studies of oxalate bridged MM quadruply bonded complexes where the redox active metal centers M = Mo or W. Specifically, we examine the heteronuclear complexes containing Mo_xW_y where x = 1, 2, and 3 in relation to $y = 4 - x$ (3, 4).

Results and discussion

Preparations

In our previous studies, we have prepared the oxalate bridged compounds according to the reaction outlined in eq. [1] (3, 4). The desired tetranuclear compound was isolated by its preferential precipitation from toluene in what is otherwise an equilibrium mixture of products and reactants.

[1] $$2M_2(O_2Ct\text{-}Bu)_4 + HO_2CCO_2H \xrightarrow[\text{Toulene}]{25°C} [(t\text{-}BuCO_2)_3M_2]_2(\mu\text{-}O_2CCO_2) + 2t\text{-}BuCO_2H$$

In this study, the well-characterized compound $[(t\text{-}BuCO_2)_3MoW]_2(\mu\text{-}O_2CCO_2)$ (**I**) was similarly prepared from the known compound $MoW(O_2Ct\text{-}Bu)_4$ (5) and its reaction with oxalic acid. The other mixed metal containing complexes shown in Scheme 1 were prepared similarly but were not separable in a pure manner from their respective derivatives of the combinations of starting materials. For example, the complex $[(t\text{-}BuCO_2)_3Mo_2(\mu\text{-}O_2CCO_2)W_2(O_2Ct\text{-}Bu)_3]$ (**II**) was formed in the reaction between oxalic acid and a 1:1 equivalent of the respective homonuclear complexes $M_2(O_2Ct\text{-}Bu)_4$ (M = Mo or W), eq. [2], but was not separable from the homometallic M_4-oxalate bridged compounds $[(t\text{-}BuCO_2)_3Mo_2]_2(\mu\text{-}O_2CCO_2)$ (**V**) and $[(t\text{-}BuCO_2)_3W_2]_2(\mu\text{-}O_2CCO_2)$ (**VI**). The ^1H NMR spectrum of the products indicated a near statistical distribution of products in a 1:2:1 ratio. Spectroscopically, however, the Mo_2W_2-oxalate compound **II** and its radical cation $\mathbf{II}^+$, formed in situ by oxidation with $Ag^+PF_6^-$, were detectable in the presence of the known spectral features of the homometallic compounds. Similarly in reactions employing $M_2(O_2Ct\text{-}Bu)_4$ (M = Mo or W) and $MoW(O_2Ct\text{-}Bu)_4$ with oxalic acid, eqs. [3] and [4], the heterometallic species containing Mo_3W-oxalate (**III**) and W_3Mo-oxalate (**IV**) can be identified along with their radical cations formed by single electron oxidation.

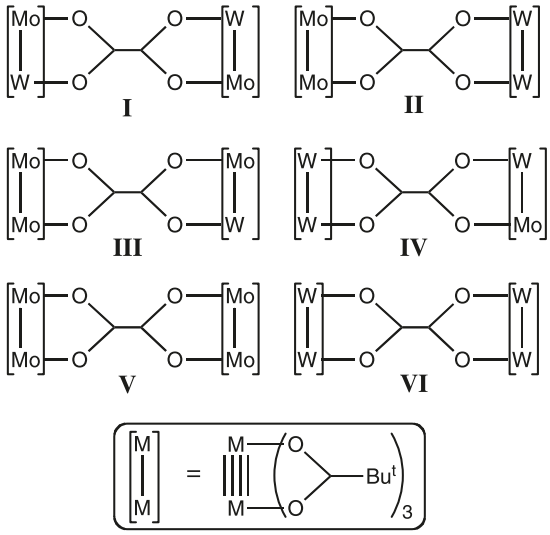
[2] $$4Mo_2(O_2Ct\text{-}Bu)_4 + 4W_2(O_2Ct\text{-}Bu)_4 + 4HO_2CCO_2H \xrightarrow[\text{Toulene}]{25°C} [Mo_2]\text{-}O_2CCO_2\text{-}[Mo_2] + 2[Mo_2]\text{-}O_2CCO_2\text{-}[W_2] + [W_2]\text{-}O_2CCO_2\text{-}[W_2]$$

[3] $$4Mo_2(O_2Ct\text{-}Bu)_4 + 4MoW(O_2Ct\text{-}Bu)_4 + 4HO_2CCO_2H \xrightarrow[\text{Toulene}]{25°C} [Mo_2]\text{-}O_2CCO_2\text{-}[Mo_2] + 2[Mo_2]\text{-}O_2CCO_2\text{-}[MoW] + [MoW]\text{-}O_2CCO_2\text{-}[MoW]$$

[4] $$4W_2(O_2Ct\text{-}Bu)_4 + 4MoW(O_2Ct\text{-}Bu)_4 + 4HO_2CCO_2H \xrightarrow[\text{Toulene}]{25°C} [MoW]\text{-}O_2CCO_2\text{-}[MoW] + 2[W_2]\text{-}O_2CCO_2\text{-}[MoW] + [W_2]\text{-}O_2CCO_2\text{-}[W_2]$$

where $M_2 = (t\text{-}BuCO_2)_3M_2$

Scheme 1.



Due to the synthetic constraints associated with compounds **II**–**IV** (eqs. [2–4]), the only well-defined and fully characterized heterometallic compound is the $(MoW)_2$-oxalate bridged complex **I** and its radical cation $\mathbf{I}^+$. The nature of the other heterometallic species are inferred based on spectroscopic properties of mixtures.

Electronic structure calculations

Given that compounds **II**–**IV** cannot be isolated cleanly from other product combinations, the calculated electronic structure and spectroscopic features will be of help in interpreting their properties. Calculations employing density functional theory (DFT) using the Gaussian 2003 suite of programs were performed on the formate substituted model compounds $[(HCO_2)_6Mo_xW_y(\mu\text{-}C_2O_4)]^{0/+}$, where $x = 0$ (**VI′**), 1 (**IV′**), 2 (**I′** and **II′**), 3 (**III′**), 4 (**V′**) and $y = 4 - x$. The structure of each complex was determined by geometry optimization, and in each instance the oxalate bridge in the ground state structure adopted a planar configuration. The planar bridge maximizes MM′-δ to oxalate-π* backbonding. For compound **I′**, there are two possible geometric forms of a planar oxalate core that can be termed as the syn (C_{2v} symmetry) and anti (C_{2h} symmetry) isomers with respect to the Mo atoms. The syn form of **I′** would be expected to have an overall dipole moment due to the polarity of the MoW bond. The calculated ground state energy, electronic structure, and spectroscopic properties of both isomers are nearly identical, and hence only the properties of the anti isomer are reported.

For all of the oxalate bridged M4-containing compounds, the HOMO-1 and the HOMO are the in-phase and out-of-phase MM δ-orbital combinations, respectively. They interact with the oxalate π-system as shown in Scheme 2, and of these two interactions the one involving the oxalate π* orbital is the most important, based on energy considerations. The Mo_2-δ^* orbital is lower in energy than the unoccupied oxalate-π* orbital, and for complexes containing Mo_2 cores (**II′**, **III′**, **V′**) the LUMO is a Mo_2-δ*. Due to the decrease in electronegativity for tungsten, the δ^* orbitals of MoW and W_2 cores are higher in energy than for Mo_2, and the LUMO is the oxalate-π* orbital for complexes **I′**, **IV′** and **VI′**. Scheme 2.

ble of the calculated frontier MO energies and assignments for all complexes is given in the Supplementary Data.[4]

The calculated electronic absorption spectra show intense MM′-δ to oxalate-π* MLCT (metal to ligand charge transfer) transitions for all compounds in the visible region, summarized in Table 1. MLCT transitions involving W are predicted to be more intense, and the general trend of MLCT absorption *energy* follows the order Mo_2 > MoW > W_2. This reflects the smaller HOMO–oxalate-π* gaps due to the higher energy of MoW-δ and W_2-δ orbitals and greater radial extension of the W 5d orbitals, features that have been discussed in other studies of [(*t*-$BuCO_2$)$_3M_2$]$_2$(μ-dicarboxylate) systems (6). For the radical cations, the energy, intensity, and shape of the charge resonance band (HOMO-1 to SOMO transition) can be used to quantify the extent of electron delocalization (7, 8). The calculated energies of the HOMO-1 to SOMO (δ to δ) absorptions of the radical cation mixed-valence species **I′**$^{+}$–**VI′**$^{+}$, calculated from the geometry optimized structures, are also included in Table 1. The trends predicted by the gas-phase calculations are observed experimentally in solution (see later in Figs. 1 and 2), though the observed spectral features are all red-shifted.

[(*t*-$BuCO_2$)$_3$MoW]$_2$(μ-O_2CCO_2) and its radical cation

The compound **I**, formed in a reaction related to eq. [1] but involving MoW(O_2C*t*-Bu)$_4$, is a purple microcrystalline compound only sparingly soluble in benzene and toluene but more soluble in the polar solvents THF and DMSO. The compound was characterized by ^{1}H NMR and MALDI-TOF spectroscopy and elemental analysis.

The intense color of compound **I** in THF is due to the fully allowed HOMO to LUMO electronic transition, which is MLCT involving a MoW-δ combination and the oxalate bridge π* orbital. The electronic absorption spectrum is shown in Fig. 1, where a comparison is made with the

Fig. 1. Electronic absorption spectra of **I** (black), **V** (red), and **VI** (blue) in THF at room temperature.

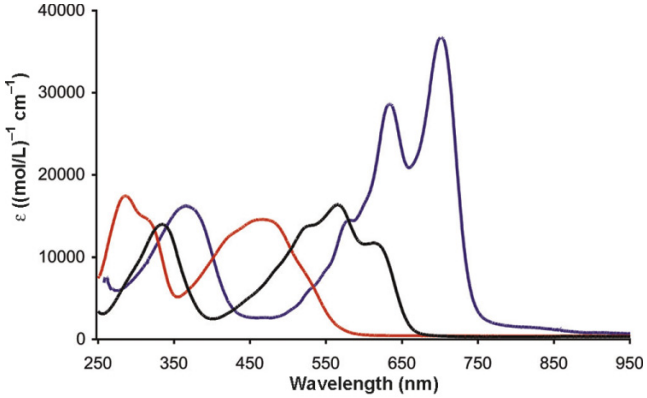

Fig. 2. Electronic absorption spectra of **I** (gray) and **I**$^{+}$$PF_6^{-}$ (black) in THF at room temperature. The inset shows an expansion of the charge resonance band region for **I**$^{+}$$PF_6^{-}$, including the bands of **V**$^{+}$$PF_6^{-}$ (red) and **VI**$^{+}$$PF_6^{-}$ (blue) for comparison. The spectral feature at ca. 4400 cm^{-1} corresponds to a sample cell absorption.

[b]Non-symmetrical absorption, hence band-width determined from the high-energy side of the band to avoid low-energy cutoff effects.

respective homometallic Mo_4 (**V**) and W_4 (**VI**) containing complexes. The intermediate energy of this electronic transition is consistent with the calculated trend in M_2-δ orbital energies and the electrochemical oxidation potentials.

Electrochemical studies by both cyclic voltammetry and differential pulse voltammetry reveal two oxidation waves for **I**, the first being reversible on the electrochemical timescale and the second being quasi-reversible. The first oxidation potential and the separation between the first and the second $\Delta E_{1/2}$ are intermediate between the respective homometallic compounds **V** and **VI**. Electrochemical data for these compounds are summarized in Table 2.

The single oxidation of compound **I** in THF was carried out by reaction with one equivalent of $AgPF_6$, and the radical cation $\mathbf{I}^+PF_6^-$ was characterized by both its electronic absorption spectrum and by EPR spectroscopy.

Oxidation of **I** to $\mathbf{I}^+$ causes a red shift of the intense MLCT band and the generation of a low-energy absorption in the near-infrared (NIR) that corresponds to a HOMO-1 → SOMO (δ → δ) transition. The spectra of **I** and $\mathbf{I}^+$ in THF are compared in Fig. 2. The low energy band at 5110 cm^{-1} is readily assignable to a charge resonance band of a Class III fully delocalized radical cation on the Robin and Day scheme (11) for mixed valence complexes, based upon the intensity and narrower than predicted peak width of the transition (12). The extent of electronic coupling can be quantified by the cross coupling matrix element, H_{ab}, that is determined by application of Hush theory (13) to the transition. The H_{ab} value for $\mathbf{I}^+PF_6^-$ of 2555 cm^{-1} is, as expected, intermediate between that observed for $\mathbf{V}^+PF_6^-$ (2025 cm^{-1}) and $\mathbf{VI}^+PF_6^-$ (3000 cm^{-1}). The NIR spectra for these mixed-valence species are compared in the inset in Fig. 2, and the spectroscopic data for the charge resonance bands of the radical cations summarized in Table 3.

The EPR spectrum of $\mathbf{I}^+PF_6^-$ in 2-MeTHF at 250 K is shown in Fig. 3. This isotropic spectrum shows a central signal at g = 1.868 due to the presence of the isotopomers $(MoW)_2$ with spin inactive nuclei and a satellite spectrum arising from the presence of ^{183}W (I = 1/2, 14.5% natural abundance) and $^{95/97}Mo$ (I = 5/2, 25.4% total natural abundance). The EPR spectrum is entirely consistent with a fully delocalized electron in a δ combination orbital for the $(MoW)_2^+$ moiety. Notably, the hyperfine coupling to $^{95/97}Mo$, I = 5/2 is larger than in the related $\mathbf{V}^+PF_6^-$ Mo_4-containing radical cation, while the coupling to ^{183}W, I = 1/2 is smaller than in the $\mathbf{VI}^+PF_6^-$ W_4-containing cation. These data are summarized in Table 4 and clearly indicate the polarized nature of the MoW δ-orbital, as seen in the respective $MoW(O_2Ct\text{-}Bu)^+PF_6^-$ radical cation (9). On a relative scale, Mo(2+) is more electronegative than W(2+). This is largely a result of the more effective shielding of the valence electrons by the number of core electrons and is seen in the fact that oxidizing powers of the cations follows the order $Cr^{6+} > Mo^{6+} > W^{6+}$ for the d^0 metal ions in their oxides MO_3 and their oxometallate anions MO_4^{2-}.

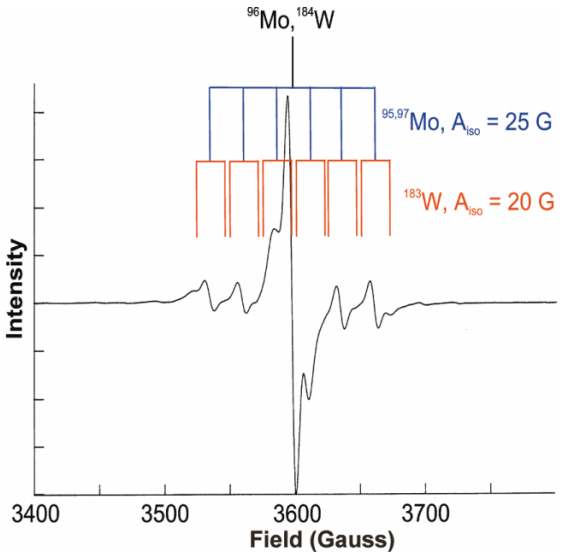

Fig. 4. Differential pulse voltammograms in 0.1 mol/L $NBu^n{}_4PF_6$/THF solutions of the product mixtures formed from the intended synthesis of **IV** (top), **II** (middle), and **III** (bottom).

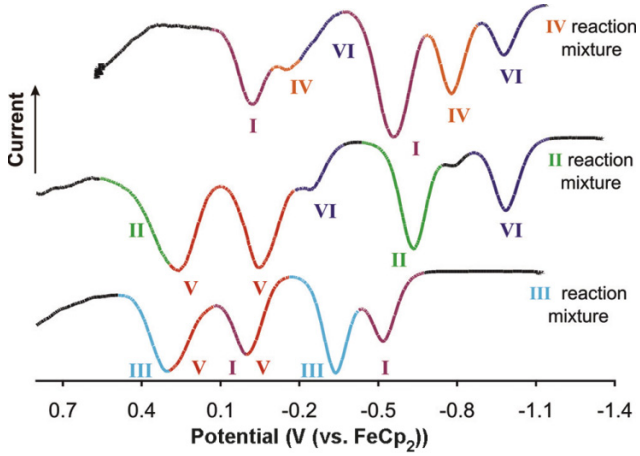

The radical cations of II, III, and IV

The reaction between a 1:1:1 mixture of $Mo_2(O_2Ct\text{-}Bu)_4$, $W_2(O_2Ct\text{-}Bu)_4$, and oxalic acid (eq. [2]) gives a mixture of the previously characterized homometallic M_4-oxalate bridged complexes (**V** and **VI**) in addition to the Mo_2W_2-oxalate bridged compound **II**. ^{1}H NMR spectroscopy shows a statistical mixture of the products is formed, indicating that the reaction of both $Mo_2(O_2Ct\text{-}Bu)_4$ and $W_2(O_2Ct\text{-}Bu)_4$ with oxalic acid proceeds with similar kinetics. The cyclic voltammogram of this mixture (Fig. 4) shows six oxidation waves, four of which are associated with the known homonuclear compounds **V** and **VI**. The remaining two oxidation waves at –0.63 and 0.34 V represent successive oxidation of the W_2 and Mo_2 units of compound **II**. The Mo_3W-oxalate (**III**) and W_3Mo-oxalate (**IV**) compounds were prepared in a similar fashion (eqs. [3] and [4]), and the redox potentials of the compounds extrapolated from the reaction mixtures is shown in Fig. 4 and summarized in Table 2.

For the spectroscopic studies on the radical cation $\mathbf{II}^+PF_6^-$, just enough $Ag^+PF_6^-$ was added in situ to preferentially oxidize **VI** and **II** by one electron, preventing formation of the $\mathbf{V}^+PF_6^-$ radical cation that could further complicate the spectra. The notable spectroscopic features of the new mixed valence ion are the absence of any electronic absorption band in the region 7000–3000 cm^{-1} and a signal in the EPR spectrum at g = 1.831 with coupling to ^{183}W (A_{iso} = 48 G). This, together with the relative intensities of the satellites in the EPR spectrum and the absence of any hyperfine coupling to $^{95/97}$Mo, is a clear indication of this mixed valence complex being valence-trapped. The W_2 center is oxidized and the unpaired electron resides in a W_{2-} δ orbital.

Unfortunately, because of similar g values and overlapping spectra for the $\mathbf{III}^+$ and $\mathbf{I}^+$ radical cations, reliable values for the $^{95/97}$Mo and ^{183}W coupling constants could not be obtained from the EPR spectrum of $\mathbf{III}^+PF_6^-$. No absorption bands were observed in the NIR region 7000–3000 cm^{-1} for $\mathbf{III}^+PF_6^-$, indicating that the radical cation is likely to be valence-trapped with the single electron residing in a polarized MoW-δ orbital.

In contrast, the spectroscopic features of the W_3Mo-containing $\mathbf{IV}^+PF_6^-$ radical cation may be classified as mixed valence fully delocalized or Class III on the Robin and Day scheme (11), based upon the appearance of low

© 2008 NRC Canada

energy electronic absorption bands in the region 7000–3000 cm^{-1} (see Supplementary Data).[4] As expected, the absorption falls in an energy region between the $\mathbf{I}^+$ and $\mathbf{VI}^+$ bands. The EPR spectrum of this mixture is once again sufficiently complicated that assignment of the hyperfine coupling constants to $^{95/97}$Mo and ^{183}W could not be made.

Concluding remarks

The spectroscopic features of the mixed metal complex **I** and its radical cation $\mathbf{I}^+$ are, as expected, intermediative between the respective homometallic complexes and their radical cations. The mixed valence radical cation $\mathbf{I}^+$ can be classified as fully delocalized on the Robin and Day scheme (11), and from the hyperfine satellite spectrum we can see that greater electron density lies on the Mo atoms. This is consistent with the observed polarization of the single electron toward the Mo atom in the $MoW(O_2Ct\text{-}Bu)_4^+$ δ^1 orbital (10). The properties of the $[W_3Mo]^+$-containing ion, $\mathbf{IV}^+$, is also indicative of Class III behavior, whilst the $[Mo_2W_2]^+$- and $[Mo_3W]^+$-containing ions, $\mathbf{II}^+$ and $\mathbf{III}^+$, are valence-trapped. The latter might well have been anticipated given that the first oxidation potential of the homometallic complexes $M_2(O_2Ct\text{-}Bu)_4$ differ by ~0.5 V for Mo = Mo and W. Compound **I**, having a planar ground state due to (MoW) to oxalate π^* back-bonding, can exist as two geometric forms that could be termed with respect to the Mo atoms as syn and anti. Given the polarity of the MoW quadruple bond the former, the syn geometric isomer would be expected to have a dipole moment. In the present study the spectroscopic features do not allow us to distinguish between these, and regrettably the kinetic lability of these species toward decomposition has not allowed us to interrogate this by single crystal X-ray crystallography.

Experimental section

Physical procedures

Because of the air sensitive nature of the reactants and products, all experimental manipulations were performed under nitrogen and argon atmospheres. Solvents were distilled prior to use over the appropriate drying agent. The Schlenk flasks containing the reaction mixtures were centrifuged, as opposed to filtered, to improve the reaction yield. The compounds $Mo_2(O_2Ct\text{-}Bu)_4$ (14), $MoW(O_2Ct\text{-}Bu)_4$ (6), $W_2(O_2Ct\text{-}Bu)_4$ (15), $[(t\text{-}BuCO_2)_3Mo_2(\mu\text{-}O_2CCO_2)W_2(O_2Ct\text{-}Bu)_3]$ (**II**) (16), $[(t\text{-}BuCO_2)_3Mo_2]_2(\mu\text{-}O_2CCO_2)$ (**V**) (4), and $[(t\text{-}BuCO_2)_3W_2]_2(\mu\text{-}O_2CCO_2)$ (**VI**) (4), were prepared according to literature procedures. The radical cations were synthesized by addition of a stoichiometric amount of $AgPF_6$ to solutions of the neutral compounds immediately prior to spectroscopic measurements.

Microanalysis was performed by Atlantic Microlab, Inc. Electronic absorption spectra were recorded on a PerkinElmer Lambda 900 UV–vis and NIR spectrometer, with nitrogen purging, employing IR quartz cells with 1.00 mm path lengths and sample concentrations of ~10^{-4} mol/L. A 400 MHz Bruker DPX Avance spectrometer was used to record ^{1}H NMR spectra that were referenced to residual protio signals of d_8-THF at δ 3.58 and 1.73 ppm. Electrochemical measurements were performed using a Princeton Applied Research (PAR) 173A potentiostat-galvanostat equipped with a PAR 176 current-to-voltage converter using 0.1 mol/L solutions of $n\text{-}Bu_4NPF_6$ in THF. The voltammetric cell was equipped with a platinum wire auxiliary electrode, a platinum working electrode, and a pseudo-reference electrode consisting of a silver wire in 0.1 mol/L $n\text{-}Bu_4NPF_6$/THF separated from the bulk solution by a Vycor tip. The potentials are referenced internally to the $FeCp_2^{0/+}$ couple by the addition of a small amount of $FeCp_2$ to the solutions. X-band EPR spectra were recorded using a Bruker ESP300 electron spin resonance spectrometer. Temperature regulation was achieved by employing a Bruker Variable Temperature unit.

Preparation of $[(MoW)(O_2Ct\text{-}Bu)_3]_2(\mu\text{-}O_2CCO_2)$ (I)

A suspension of $MoW(O_2Ct\text{-}Bu)_4$ (250 mg, 0.37 mmol) and oxalic acid (16 mg, 0.18 mmol) in 5 mL of toluene was stirred for 10 days in a Schlenk flask, during which a purple precipitate formed. The purple precipitate was isolated by centrifugation of the Schlenk flask, then washed with two aliquots of toluene and one aliquot of hexane, before drying in vacuo. Yield 151 mg (67%). UV-vis (0.478 mmol/L in THF, 295 K, values of $\varepsilon \times 10^{-3}$ are given in parentheses): 615 (11.4), 565 (16.0), 525 (13.4), 334 (13.7), 221 (7.6) nm. ^{1}H NMR (THF-d_8) δ: 1.40 (s, 38H), 1.42 (s, 18H). Elemental anal. calcd. for $Mo_2W_2O_{16}C_{32}H_{54}$: C 30.64, H 4.34; found: C 30.65, H 4.45. MALDI-TOF calcd. monoisotopic MW for $Mo_2W_2O_{16}C_{32}H_{54}$: 1258.05 (M+); found, 1257.77.

Preparation of $[(t\text{-}BuCO_2)_3Mo_2(\mu\text{-}O_2CCO_2)MoW(O_2Ct\text{-}Bu)_3]$ (III)

A Schlenk flask was charged with $MoW(O_2Ct\text{-}Bu)_4$ (125 mg, 0.18 mmol), $Mo_2(O_2Ct\text{-}Bu)_4$ (109 mg, 0.18 mmol), and oxalic acid (16 mg, 0.18 mmol). Toluene (2 mL) was added and the suspension stirred for 10 days, during which a purple precipitate formed. The precipitate was isolated by centrifugation, then washed with toluene (2 × 10 mL aliquots) and hexane (1 × 10 mL aliquot), before drying in vacuo. Yield 159 mg. The ^{1}H NMR of the product mixture displayed a number of peaks in the range 1.40–1.46 ppm. The MALDI-TOF spectrum of the product mixture showed peaks corresponding to **V** [calcd. monoisotopic MW, 1085.96 (M^+); found 1086.02], **I** [calcd. monoisotopic MW, 1258.05 (M^+); found 1258.23] as well as compound **III** [calcd. monoisotopic MW, 1172.01 (M^+); found, 1172.09]. Assuming the products **V**, **III**, and **I** formed a 1:2:1 statistical mixture, the elemental anal. calcd. for $Mo_3W_1O_{16}C_{32}H_{54}$: C 32.95, H 4.67; found: C 32.85, H, 4.58.

Preparation of $[(t\text{-}BuCO_2)_3W_2(\mu\text{-}O_2CCO_2)MoW(O_2Ct\text{-}Bu)_3]$ (IV)

Toluene (2 mL) was added to a Schlenk flask charged with $MoW(O_2Ct\text{-}Bu)_4$ (125 mg, 0.18 mmol), $W_2(O_2Ct\text{-}Bu)_4$ (141 mg, 0.18 mmol) and oxalic acid (16 mg, 0.18 mmol). The suspension stirred for 10 days, during which a blue precipitate formed. The precipitate was isolated by centrifugation, then washed with toluene (2 × 10 mL aliquots) and hexane (1 × 10 mL aliquot), before drying in vacuo. Yield 123 mg. The ^{1}H NMR of the product mixture displayed a number of peaks in the range 1.37–1.42 ppm. The MALDI-TOF spectrum of the product mixture showed peaks corre-

sponding to **I** [calcd. monoisotopic MW, 1258.05 (M^+); found 1258.18], **VI** [calcd. monoisotopic MW, 1430.14 (M^+); found 1430.43], as well as compound **IV** [calcd. monoisotopic MW, 1342.25 (M^+); found 1342.33].

Electronic structure calculations

Molecular and electronic structure calculations on the neutral model compounds **I′–VI′** and the radical cations **I′$^+$–VI′$^+$**, were performed using density functional theory as implemented in the Gaussian 2003 suite of programs (17). The B3LYP functional (18) was used along with the 6–31G* basis set for O, C, H^{19}, and SDD energy-consistent pseudopotentials for Mo and W (19). All geometries were fully optimized and confirmed to be minima on the potential energy surface using harmonic vibrational frequency analysis. Electronic absorption spectra were predicted using the time-dependent DFT (TD-DFT) method.

A weakly coordinating anion as a tripodal "Br_3"-ligand for platinum(IV) — Structure of [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$][1]

Antonio G. De Crisci, Jesse Kleingardner, Alan J. Lough, Anna Larsen, and Ulrich Fekl

Abstract: Synthesis, structure, and NMR spectroscopic data for [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$] are reported. This neutral platinum(IV) complex contains the *closo*-$CB_{11}H_6Br_6^-$ anion bonded to the trimethylplatinum(IV) cation via three boron-bound bromines. *Closo*-$CB_{11}H_6Br_6^-$, which often acts as weakly coordinating or even non-coordinating anion, adopts here a role still very rare for this anion: it acts as a tripodal capping ligand enabling a pseudo-octahedral geometry at a d^6 metal center. Three bromines from the lower hemisphere of the hexahalogenated carboranate coordinate to Pt(IV), and distortions from ideal octahedral angles at Pt are marginal (<3°). Pt-Br bond lengths are 2.7279(18), 2.7129(17), and 2.7671(18) Å. Using the $^2J_{PtH}$ coupling constant of Pt-bonded methyl groups (79.0 Hz) as indicator of the donor strength of the tripodal cap, the prediction is obtained that *closo*-$CB_{11}H_6Br_6^-$ is a relatively weak donor toward the trimethylplatinum(IV) cation. Ligand competition equilibria can be expected to depend on both the intrinsic donor strengths of competing ligands and on the effects of charge and geometry. We observe that *closo*-$CB_{11}H_6Br_6^-$ is capable of replacing acetone from $Me_3Pt(acetone)_3^+$, whereas BF_4^- counterion is unable to replace acetone under similar conditions.

Key words: non-coordinating anion, platinum(IV), trimethyl, *closo*-carboranate, tripodal, trans-influence, NMR spectroscopy.

Résumé : On a réalisé la synthèse et on a déterminé la structure et les données de spectroscopie RMN relative au [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$]. Ce complexe neutre de platine(IV) contient un anion *closo*-$CB_{11}H_6Br_6^-$ lié à un cation triméthylplatine(IV) par le biais de trois atomes de bore liés à des atomes de brome. L'anion *closo*-$CB_{11}H_6Br_6^-$ qui agit souvent comme un anion de coordination faible, qui est même quelquefois non coordinant, adopte dans notre cas un rôle encore plus rare pour cet anion, à savoir celui de ligand tripode qui sert de cap et qui permet d'avoir une géométrie pseudo-tétraédrique au niveau d^6 du centre métallique. Les trois atomes de brome de la partie inférieure de l'hémisphère du carboranate hexahalogéné se lient par coordination au Pt(IV) et les distorsions par rapport aux angles octaédriques idéaux au niveau du platine sont marginales (<3°), alors que les longueurs des liaisons Pt-Br sont de 2,7279(18), 2,7129(17) et 2,6771(18) Å. Utilisant la constante de couplage $^2J_{PtH}$ des groupes méthyles liés au platine (79,0 Hz) comme indicateur de la force du cap trigonal, on arrive à la prédiction que l'anion *closo*-$CB_{11}H_6Br_6^-$ est un donneur relativement faible par rapport au cation triméthylplatine(IV). On peut s'attendre à ce que l'équilibre de compétition pour le ligand dépende à la fois des forces intrinsèques comme donneurs des ligands en compétition et sur les effets de charge et de géométrie. On a observé que l'anion *closo*-$CB_{11}H_6Br_6^-$ est capable de remplacer l'acétone du complexe $Me_3Pt(acétone)_3^+$ alors que le contre-ion BF_4^- n'est pas capable de remplacer l'acétone dans de telles conditions.

Mots-clés : anion non coordinant, platine(IV), triméthyle, *closo*-carboranate, tripode, influence *trans*, spectroscopie RMN.

[Traduit par la Rédaction]

Introduction

The development of noncoordinating (or very weakly coordinating) anions has led to tremendous progress in the field of highly Brønsted-acidic or Lewis-acidic species (1). *Closo*-carboranates (2) have proven excellent alternatives to tetraarylborates. Furthermore, the *closo*-carboranate framework seems to be nontoxic (3). Carboranates have recently

been used, for example, as counter-anions for the isolation of reactive silylium ions (4), as well as to furnish inert conjugate bases for superacids used to obtain crystalline hydronium ions and protonated arenes (5). Cluster anions such as *closo*-$CB_{11}H_{12}^-$ and substituted derivatives often act as noncoordinating or very weakly coordinating anions in systems containing transition metals (2, 6, 7). Cases do exist, however, where *closo*-carboranates coordinate to metal centers. Even for the rather electron-deficient carboranate *closo*-$CB_{11}H_6Br_6^-$, examples have been reported recently where coordination to metals occurs, and it is just beginning to become clear to which metals this carboranate may bind and under which conditions. The ability of *closo*-$CB_{11}H_6Br_6^-$ to coordinate should depend on the metal in question, its oxidation state, and its ligand environment. The vast majority of examples where metal coordination to *closo*-$CB_{11}H_6Br_6^-$ and closely related carboranates occurs involve the highly Lewis-acidic Ag(I) (8, 9). A few d^8 metal examples are known where coordination to rhodium(I) (7*a*) or iridium(I) (7*a*) could be observed. However, only very recently (2007) a crystallographically characterized example was reported where $CB_{11}H_6Br_6^-$ acted as a tripodal ligand toward a d^6 metal center, namely toward a rhodium(III) dihydride supported by an additional tricyclohexylphosphine (10). The question arises as to whether the ability of *closo*-$CB_{11}H_6Br_6^-$ to act as a tripodal cap for an octahedral complex may be extended to other platinum group metals. An excellent candidate is the trimethylplatinum(IV) unit, an often very stable moiety. A recent determination of the Lewis-acidity of the Me_3Pt^+ unit found it to be moderately Lewis-acidic (11). We can now report here that a stable pseudo-octahedral complex is formed when *closo*-$CB_{11}H_6Br_6^-$ reacts with a good source of the Me_3Pt^+ synthon.

Results and discussion

Synthesis

A salt metathesis of the cesium carboranate (12) [Cs][*closo*-$CB_{11}H_6Br_6$] with tetrameric trimethylplatinum(IV) triflate (13), a good source of the Me_3Pt^+ synthon, in a weakly coordinating nonpolar solvent (such as benzene) forms the highly soluble [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$] in quantitative yield, while insoluble cesium triflate (CsOTf = $Cs(F_3CSO_3)$) precipitates. In dry form, the compound is isolated as a shiny white microcrystalline powder. While we avoided exposing the compound to significant amounts of water, we found it very stable towards air or oxygen. We found no decomposition in noncoordinating solvents at room temperature and very little decomposition on a sample that was heated to 60 °C in CD_2Cl_2 for 8 months! Considering that many trimethylplatinum(IV) complexes undergo carbon–carbon reductive elimination (to form ethane) rather readily, the inertness of [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$] towards reductive elimination may appear surprising at first but is entirely in agreement with our current very detailed knowledge of reductive elimination in platinum(IV) systems: sp^3-sp^3 carbon–carbon reductive elimination from platinum(IV) is always *relatively* slow, for example, much slower than carbon–hydrogen reductive elimination in comparable methyl(hydrido) systems (14). Two factors have major influence on the barrier to C–C reductive elimination: (*i*) the ease of formation of a five-coordinate intermediate (15) and (*ii*) electronic effects, namely the donor strength of the spectator ligands. Alkyl–alkyl reductive elimination from Pt(IV) generally requires that the complex can assume a five-coordinate geometry (14–18), and the barrier to forming such a five-coordinate geometry contributes to the overall barrier for reductive elimination. While the ground-state geometry of [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$] is six-coordinate and octahedral (see below), a five-coordinate geometry should be accessible (if the tripodal carboranate partially dechelates) and only slightly uphill. Electronic effects are most likely responsible for the inertness observed here: for C–C reductive elimination to be fast, the coordination environment has to contain strongly donating spectator ligands (such as phosphines (14, 16, 17) systems having a less donating nitrogen-based ligand enviroment are comparably resistant to reductive elimination) (17), and the observed lack of reductive elimination for [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$] indicates that *closo*-$CB_{11}H_6Br_6^-$ acts as a rather weakly donating spectator ligand.

X-ray crystal structure

Crystals suitable for X-ray diffraction were obtained by slowly reducing the volume of a saturated dichloromethane solution of [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$] under nitrogen. Data were collected on a Nonius-Kappa CCD diffractometer at 150(1) K, and the crystal structure was solved by direct methods and refined on F^2 against all reflections.[3] Crystal data are summarized in Table 1. The structure contains discrete units of molecular [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$], shown in Fig. 1 (selected distances and angles in the legend). The most striking feature is the almost perfectly pseudo-octahedral environment of platinum(IV), where deviations from ideal angles are less than 3°. The average of the three Pt-Br distances (2.7279(18), 2.7129(17), 2.7671(18) Å) is 2.74 Å. This is 8% longer than the Pt-Br distance for Br^- ion coordinated to platinum(IV) in a terminal fashion (2.5394(6) Å for Pt-Br in a bromotriorganylplatinum(IV) complex chelated by a substituted bipyridine (19)) but only 3% longer than the Pt-Br distance in tetrameric trimethylplatinum(IV) bromide (20), which contains triply bridging bromide (2.67(1) Å).

Coupling constant correlation

The trimethylplatinum(IV) unit is a convenient tool to gauge the donor strength of coordinated ligands (21). *Trans*-influence effects weaken a Pt-CH_3 bond proportionally to the donor strength of the ligand *trans* to it, an effect that transmits into the $^2J_{PtH}$ coupling constant of the methyl.

Capping the three positions *trans* to the *fac*-trimethyls in a trimethylplatinum(IV) complex with three strongly donating phosphine donors leads to a very low coupling constant, and $^2J_{PtH}$ = 55 Hz is observed for the complex containing the tris(phosphino)borate $PhB(CH_2PPh_2)_3^-$ (22). Having three relatively donating nitrogen donors normally leads to a $^2J_{PtH}$ around 72 Hz. The $^2J_{PtH}$ coupling constant is sensitive to fairly subtle electronic effects related to the donor strength of the ligand. For example, $^2J_{PtH}$ = 72 Hz is observed in the presence of the tris(pyrazolyl)methane cap *trans* to $PtMe_3$ (23), whereas $^2J_{PtH}$ = 70 Hz is observed in the presence of the more electron-rich tris(3,5-dimethylpyrazolyl)borate cap *trans* to $PtMe_3$ (21c). An analogous complex having trifluoromethyl groups instead of methyl groups on the pyrazolates is less donating because of inductive effects, and an increased $^2J_{PtH}$ is observed for the Pt methyls, namely 75.4 Hz (21c). Among the weakest donors toward platinum(IV) are oxygen donors, and a weakly coordinating "O_3" environment typically leads to a $^2J_{PtH}$ value for platinum trimethyls between 76 and 82 Hz (21c). The 82 Hz extreme value belongs to trimethylplatinum(IV) in the tetrameric structure $\{Me_3Pt(OTf)\}_4$, which contains octahedral platinum(IV) and triply bridging triflate (13, 24). The $^2J_{PtH}$ value for the methyls in the aqua complex $Me_3Pt(OH_2)_3^+$ is 80.6 Hz (25). The coupling constant observed for [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$], 79.0 Hz (in benzene-d_6), leads us to conclude that the "Br_3" environment is roughly as donating toward Pt(IV) as an oxygen-donor environment. It will be of interest to investigate how efficiently *closo*-$CB_{11}H_6Br_6^-$ competes for the Me_3Pt^+ unit if other relatively weakly donating ligands are present in an equilibrium mixture.

Ligand competition experiments

We feel that the $^2J_{PtH}$ of the platinum-bound methyls is a reasonable indicator of the ligand donor strength because of *trans*-influence arguments, as discussed above. Regarding the strengths of the ligand-metal interactions in a thermodynamic sense, as measured in complexation equilibria, we would expect that a semi-quantitative prediction should be possible based on donor strength judged by $^2J_{PtH}$. An absolutely accurate prediction cannot be expected, in particular in cases where $^2J_{PtH}$ values are very similar and in cases where a competition between ligands bearing different charges or having very different steric requirements is considered. To test our hypothesis that donor strengths as indicated by $^2J_{PtH}$ have significant value for predicting complexation equilibria, we performed several experiments where *closo*-$CB_{11}H_6Br_6^-$ was competing against other ligands for complexation to Me_3Pt^+. We reacted [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$], which contains a tripodal monoanionic ligand, with the tripodal monoanionic ligand $CpCo[P(O)(OCH_3)_2]_3^-$ ("Kläui ligand", added as the sodium

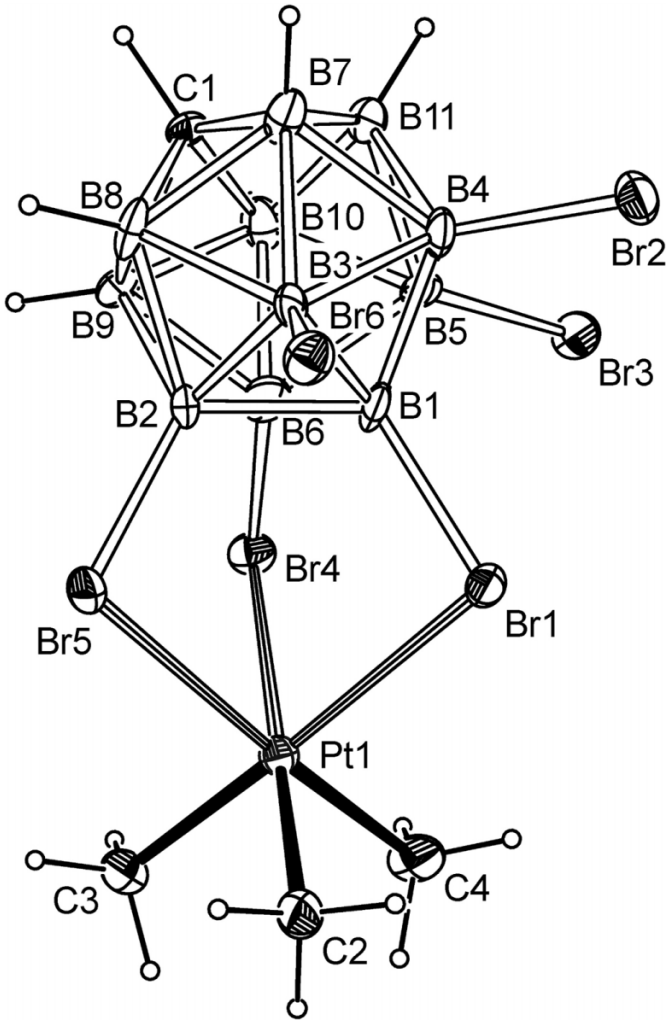
Fig. 1. Molecular structure of [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$], using 30% probability thermal ellipsoids. Selected distances (Å) and angles (°): Pt1–C2 2.006(17); Pt1–C3 2.047(18); Pt1–C4 2.036(18); Pt1–Br1 2.7279(18); Pt1–Br4 2.7129(17); Pt1–Br5 2.7671(18); Br1–B1 1.961(15); Br2–B4 1.968(19); Br3–B5 1.979(19); C2-Pt1-C4 89.1(7); C2-Pt1-C3 88.1(7); C4-Pt1-C3 88.3(8); C2-Pt1-Br4 178.2(6); C4-Pt1-Br4 92.3(5); C3-Pt1-Br4 92.9(5); C2-Pt1-Br1 92.8(5); C4-Pt1-Br1 94.0(6); C3-Pt1-Br1 177.6(5).



salt; Cp = η^5-C_5H_5). Based on $^2J_{PtH}$ arguments, it would be expected that the Kläui ligand is more donating ($^2J_{PtH}$ = 78.5 Hz *trans* to Kläui ligand; $^2J_{PtH}$ = 79.3 Hz *trans* to *closo*-$CB_{11}H_6Br_6^-$ in 1,2-dichloroethane-d_4). In agreement with this prediction, we observed that addition of 1 equiv. of Kläui ligand led to complete decoordination of *closo*-$CB_{11}H_6Br_6^-$ and to formation of {CpCo[P(O)$(OCH_3)_2$]$_3$$PtMe_3$}, as observed by ^{1}H and ^{11}B NMR spectra (26). On the other hand, it would be interesting to test for competition equilibria between *closo*-$CB_{11}H_6Br_6^-$ and ligands where $^2J_{PtH}$ predicts lower donor strength than *closo*-$CB_{11}H_6Br_6^-$. We are not aware of any ligand that complies with the above $^2J_{PtH}$ requirement *and* is tripodal *and* monoanionic. We therefore decided to use neutral monodentate ligands to test for their ability to coordinate to Pt(IV) and release *closo*-$CB_{11}H_6Br_6^-$ as a noncoordinating anion. $^2J_{PtH}$ arguments would predict that acetone is less donating than $CB_{11}H_6Br_6^-$ ($^2J_{PtH}$ = 79.8 Hz *trans* to acetone, in $Me_3Pt(acetone)_3^+$; $^2J_{PtH}$ = 79.3 Hz *trans* to *closo*-$CB_{11}H_6Br_6^-$; 1,2-dichloroethane-d^4 solvent). Although acetone is charge-neutral, such that there does exist some electrostatic bias towards carboranate-coordination, it still can be expected that a neutral molecule should replace the carboranate if that neutral molecule were vastly more donating than the carboranate. Even after addition of 38 equiv. of acetone to a solution containing [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$] (3.5 mmol/L in 1,2-dichloroethane-d^4), we observe no carboranate decoordination (^{11}B NMR) and no acetone coordination to Pt (^{1}H NMR). To test for whether a more donating solvent, as judged by $^2J_{PtH}$, leads to carboranate replacement, we used tetrahydrofuran (thf), which we would predict to be more coordinating than *closo*-$CB_{11}H_6Br_6^-$ ($^2J_{PtH}$ = 76.8 Hz in $Me_3Pt(thf)_3^+$ compared with 79.3 Hz for [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$] in 1,2-dichloroethane-d_4). In accord with this prediction, we observed rapid decoordination of *closo*-$CB_{11}H_6Br_6^-$ when titrating in small amounts of thf to the platinum complex (3.6 mmol/L in 1,2-dichloroethane-d^4), and after the addition of 38 equiv. of thf, the carboranate was essentially fully decoordinated (96%; after addition of 48 equiv. of thf, 100% decoordination was achieved). It seems, indeed, that donor strengths, as judged by $^2J_{PtH}$, have bearing on competition equilibria. Regarding acetone versus a weakly coordinating anion, again it is significant that $Me_3Pt(acetone)_3^+$ can be obtained reliably using a BF_4^- counter-ion and even crystallized (29). In contrast, $Me_3Pt(acetone)_3^+$ cannot be obtained using *closo*-$CB_{11}H_6Br_6^-$ anion. We confirmed this by reacting [$Me_3Pt(acetone)_3$][BF_4] with 0.87 equiv. of [Cs][*closo*-$CB_{11}H_6Br_6$], where we observed partial acetone substitution and carboranate coordination. It should be interesting to compare the coordinating ability of *closo*-$CB_{11}H_6Br_6^-$ with the coordinating ability of triflate. Both anions are generally regarded as weakly coordinating, and it is known for both anions that they can coordinate to the trimethylplatinum(IV) unit; triflate-coordination to trimethylplatinum(IV) is well-known (13, 24), and *closo*-$CB_{11}H_6Br_6^-$ coordination to trimethylplatinum(IV) has been shown in the present work. While $^2J_{PtH}$ for Pt-Me is 82.0 Hz in tetrameric trimethyl platinum triflate, {$Me_3Pt(O_3SCF_3)$}$_4$, $^2J_{PtH}$ of 79.0 Hz is observed for [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$] (both in CD_2Cl_2), which would indicate that the carboranate is more donating. When we reacted [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$] with 0.97 equiv. of a soluble triflate salt, (NBu_4)(F_3CSO_3), in 340 µL of 1,2-dichloroethane-d^4, we observed partial decoordination (57%) of the *closo*-$CB_{11}H_6Br_6^-$ anion in the equilibrium mixture, and both the carboranate and triflate were effectively competing for the trimethylplatinum(IV) moiety. Qualitatively, we conclude that triflate and *closo*-$CB_{11}H_6Br_6^-$ are of very similar coordinating ability toward trimethylplatinum(IV); if triflate were much more donating, 97% of the carboranate would have been released as free noncoordinating anion, as opposed to the 57% free carboranate observed. We remain with a qualitative conclusion regarding the triflate versus *closo*-$CB_{11}H_6Br_6^-$ competition, since the tetrameric nature of trimethylplatinum triflate leads to a rather complex reaction stoichiometry instead of a straightforward ligand-for-ligand substitution. The reaction

© 2008 NRC Canada

stoichiometry is as follows: 4 [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$] + 4 NBu_4^+ + 4 $F_3CSO_3^-$ → $\{Me_3Pt(O_3SCF_3)\}_4$ + 4 NBu_4^+ + 4 $CB_{11}H_6Br_6^-$. For practical purposes, the coordinating ability of *closo*-$CB_{11}H_6Br_6^-$ toward Me_3Pt^+ may be described as "less coordinating than the Kläui ligand, approximately as coordinating as triflate, more coordinating than tetrafluoroborate". It should be noted here that this *relatively* high propensity of *closo*-$CB_{11}H_6Br_6^-$ to coordinate to Me_3Pt^+ is likely due to the fact that the bromine donors, "soft" donor atoms, are relatively good ligands for a soft metal such as platinum. Geometric reasons certainly contribute as well, since the Br_3 donor "cap" enables an octahedral geometry for platinum(IV).

Summary and conclusion

The brominated carboranate *closo*-$CB_{11}H_6Br_6^-$ acts as a tripodal Br_3 donor ligand cap in the new compound [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$], made using a salt metathesis of the cesium carboranate [Cs][closo-$CB_{11}H_6Br_6$] with tetrameric trimethylplatinum(IV) triflate in nonpolar solvents, where the precipitation of insoluble cesium triflate provides the driving force. The Br_3 donor cap enables an octahedral geometry for platinum(IV). *Closo*-$CB_{11}H_6Br_6^-$ is among the weakly donating ligands towards $PtMe_3^+$ but in effect more coordinating, in this particular system than tetrafluoroborate, since it substitutes acetone from $Me_3Pt(acetone)_3^+$. In contrast, the BF_4^- counter-ion is unable to replace acetone under similar conditions. A reasonable estimate of the donor strengths of ligands for trimethylplatinum(IV) can be obtained using the $^2J_{PtH}$ coupling constant seen for the Pt-bound methyls, and such an approach appears to have qualitative and (or) semi-quantitative predictive power for ligand competition equilibria.

Experimental section

General information, reagents, and precursors

All manipulations involving organometallic compounds were carried out with the use of vacuum line and dry glove box using oven-dried glassware and J. Young NMR tubes. ^1H and $^{13}C\{^1H\}$ NMR spectra were obtained on a on Varian Gemini 200 MHz, Bruker Avance III 400 MHz NMR, or Unity Inova Varian 500 MHz spectrometers (Mississauga, platinum complexes) or JEOL 400 MHz NMR spectrometer (Ithaca, cesium carboranates).[3] ^{19}F NMR data were recorded on a Bruker Avance III 400 MHz NMR (Mississauga) spectrometer at 376 MHz and referenced to an internal standard, neat trifluoroacetic acid (capillary within the sample tube) set at δ 78.50 ppm. $^{11}B\{^1H\}$ and ^{11}B NMR spectra were taken on a JEOL 400 MHz NMR (Ithaca) and Bruker Avance III 400 MHz NMR (Mississauga) spectrometer and referenced relative to neat $BF_3{\cdot}OEt_2$ (capillary within the sample tube) set at δ 0 ppm. All NMR spectra were taken at 20 °C unless otherwise noted. Solvent peaks were used as reference: ^1H (δ, ppm, dichloromethane-d_2, 5.32; 1,2-dichloroethane-d_4, 3.72; benzene-d_6, 7.16; acetone-d_6, 2.05), ^{13}C (δ, ppm, dichloromethane-d_2, 53.8; benzene-d_6, 128.0; acetone-d_6, 29.8 (-*C*D_3)). CD_2Cl_2 (obtained from Cambridge Isotopes, 99.9% D), $ClCD_2CD_2Cl$ and CH_2Cl_2 were dried over CaH_2 and vacuum-transferred before use. $(CD_3)_2CO$ (99.9% D) and $(CH_3)_2CO$ was dried over activated 3 Å molecular sieves. C_6D_6 (99.5% D) and $(CD_3)_2CO$ were purchased from Cambridge Isotopes. Trifluoroacetic acid, 1,2-dichloroethane-d_4, (99% D), fluorene (98%) were purchased from Sigma-Aldrich. Iodotrimethylplatinum (99.8%) was purchased from Strem Chemicals. Decaborane, used for the synthesis (27) of $CsCB_{11}H_{12}$, precursor for [Cs][*closo*-$CB_{11}H_6Br_6$], was purchased from Katchem spol. s.r.o. (Ltd.), Czech Republic. Silver trifluoromethanesulfonate, silver tetrafluoroborate (98%), and tetrabutylammonium trifluoromethanesulfonate (≥99.0%) and all other chemicals where a supplier is not explicitly mentioned were purchased from Sigma-Aldrich (≥99.8%). Tetrahydrofuran (THF) and benzene (protio and deuterated) were dried over sodium-benzophenone and vacuum-transferred before use. Elemental analyses were conducted at Analytical Laboratory for Environmental Science and Research Training (ANALEST), Toronto, ON, Canada. Cs[*closo*-$CB_{11}H_6Br_6$] was synthesized using the literature method (12) from $CsCB_{11}H_{12}$ (27). It was obtained in 75% yield and found to be analytically pure by elemental analysis (Calcd. for [Cs][*closo*-$CH_6B_{11}Br_6$]: C 1.60, H 0.81; found: C 1.90, H 1.07) and NMR (^1H NMR (500 MHz, $(CD_3)_2CO$) δ: 3.07–1.82 (6H, br, B-H); $^{13}C\{^1H\}$ NMR (125 MHz, $(CD_3)_2CO$) δ: 41.71 (C_{cage}); $^{11}B\{^1H\}$ NMR (128.34 MHz, $(CD_3)_2CO$, 22 °C) δ: –2.0 (s, 1B, Br-*B* opposite to carbon apex), –9.8 (s, 5B, Br-*B* of lower ring), –20.3 (s, 5B, H-*B*)). The tetrameric trimethylplatinum(IV) triflate precursor was synthesized using literature methods in THF solvent (13). $\{Me_3Pt(OTf)\}_4$: ^1H NMR 500 MHz, (C_6D_6) δ: 1.49 (9H, s+d, Pt-Me_3, $^2J_{PtH}$ = 82.0 Hz); $^{13}C\{^1H\}$ NMR (125 MHz, C_6D_6) δ: –9.71 (s+d, Pt-Me_3, J_{PtC} = 827.5 Hz); ^{19}F NMR (376 MHz, C_6D_6) δ: –79.10 (s, 3F).

[(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$]

[Cs][*closo*-$CB_{11}H_6Br_6$] (11.4 mg, 749.3 g/mol, 0.0153 mmol) was added to a 540 µL of benzene-d_6 solution containing $\{Me_3Pt(OTf)\}_4$ (6.0 mg, 0.0154 mmol in Pt) and shaken for 30 s. Sonication of the solution aids in the dissolution of $CsCB_{11}H_6Br_6$. The reaction was monitored by ^1H NMR spectroscopy using the platinum methyl signal and was completed within 1 h. The solvent was removed under vacuum and extracted with dichloromethane (where CsOTf is insoluble). The residue was washed with 1 mL portions of dichloromethane, allowing CsOTf to settle between each washing. Removal of the solvent yielded the product as white crystals. NMR conversion is quantitative, isolated yield is 73%. ^1H NMR 500 MHz, (C_6D_6) δ: 3.3–1.9 (5H, br, B_{cage}-H), 1.66 (1H, s, C_{cage}-H), 1.17 (9H, s+d, Pt-Me_3, $^2J_{PtH}$ = 79.0 Hz). $^{13}C\{^1H\}$ NMR (125 MHz, CD_2Cl_2) δ: 45.10 (s, C_{cage}), 4.42 (s+d, Pt-Me_3, J_{PtC} = 714.25 Hz). $^{11}B\{^1H\}$ NMR 128.38 MHz, (CD_2Cl_2, 25 °C) δ: 0.6 (s, 1B, Br-*B* opposite to carbon apex, –8.9 (s, 5B, Br-*B* of lower ring), –20.2 (s, 5B, H-*B*). ^{11}B NMR 128.38 MHz, (CD_2Cl_2, 25 °C) δ: 0.6 (s, 1B, Br-*B* opposite to carbon apex, –8.9 (s, 5B, Br-*B* of lower ring), –20.2 (br d, 5B, H-*B*, $^1J_{BH}$ = 169 Hz). All NMR data indicate an apparent three-fold rotational symmetry of the $PtMe_3$ unit and an apparent five-fold symmetry of the boranate cage, in contrast to the approximate C_s symmetry of the molecule in the crystal structure. We suggest that the $PtMe_3$ unit rapidly migrates around the (brominated) lower rim of the cage, as proposed by Weller

© 2008 NRC Canada

and co-workers (10) for rhodium(III) complexes of the same carboranate. Calcd. for $C_4H_{15}B_{11}Br_6Pt$: C 5.61, H 1.77, N 0.00; found: C 5.73, H 1.74, N not detected.

Ligand competition experiments

General considerations

All competition experiments were conducted in 1,2-dichloroethane-d_4 at room temperature (25 °C) in J. Young NMR tubes. Reactions were monitored using ^{1}H, ^{11}B, and ^{11}B{1H} NMR. Fluorene (unless otherwise stated) was employed as an internal standard for the fully relaxed ^{1}H NMR with a delay time of D_1 = 60 s. Neat BF_3-Et_2O was used as the internal reference (capillary in tube) for the ^{11}B and ^{11}B{^{1}H} NMR and set to 0 ppm. To increase accuracy for those competition experiments where not a solid sample (μg balance) was added but rather a liquid via 2.0 microliter syringe, ^{1}H NMR spectral integration (with sufficient relaxation delay for the acquisition) was used in conjunction with an added internal standard (fluorene). ^{11}B NMR spectroscopy is very useful for demonstrating whether the carboranate is coordinated or not to trimethylplatinum. When the carboranate is decoordinated to some extent in an equilibrium mixture, two species are seen in the ^{11}B NMR spectrum, the coordinated species and that of the noncoordinated species. The noncoordinated species exhibits the most pronounced upfield shift on two peaks of its three-peak spectrum. The two ^{11}B peaks that shift the most on going from the coordinated to noncoordinated (or vice versa) are the peaks at the Br-*B* opposite to carbon apex and that of the lower Br-*B* ring (the peaks that contain the Me_3Pt moiety). These peaks experience an upfield shift of approximately 2.5 ppm and 1.2 ppm, respectively, when the carboranate becomes decoordinated. The third ^{11}B peak, belonging to the "upper ring" (5 BH), remains virtually unchanged (± 0.1 ppm).

Solution data for [(closo-$CB_{11}H_6Br_6$)$PtMe_3$]

^{1}H NMR 400 MHz, ($ClCD_2CD_2Cl$) δ: 3.4–1.5 (5H, br, B_{cage}-H), 2.98 (overlap with B_{cage}-H region, 1H, s, C_{cage}-H), 1.84 (overlap with B_{cage}-H region, 9H, s+d, Pt-Me_3, $^2J_{PtH}$ = 79.3 Hz). ^{11}B{^{1}H} NMR 128.38 MHz, ($ClCD_2CD_2Cl$, 25 °C) δ: 0.6 (br s, 1B, Br-*B* opposite to carbon apex, –9.0 (s, 5B, Br-*B* of lower ring), –20.5 (br s, 5B, H-*B*).

Solution data for [Cs][closo-$CB_{11}H_6Br_6$]

^{11}B{^{1}H} NMR 128.38 MHz, ($ClCD_2CD_2Cl$, 25 °C) δ: –2.0 (br s, 1B, Br-*B* opposite to carbon apex), –10.2 (br s, 5B, Br-*B* of lower ring), –20.6 (br s, 5B, H-*B*)).

Competition Experiment with Kläui Ligand (Sodium(cyclopentadienyl) tris(dimethylphosphito)cobaltate(I))

To a solution containing 1.09 mg (0.001 27 mmol) of [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$] and 1.23 mg (0.007 40 mmol) of fluorene in 470 μL of 1,2-dichloroethane-d_4 (0.002 71 mol/L in Pt) was added the Kläui ligand ([Na][(CpCo[P(O)-$(OCH_3)_2]_3$], FW: 474.1 g/mol) in approximately 0.3 to 0.4 equiv. per Pt per titrant, aided with sonication. A total of 2.08 equiv. were added. After adding 1 equiv. of Kläui ligand, the carboranate becomes fully decoordinated and a different Pt species is observed in quantitative yield in the ^{1}H NMR. The newly formed species has a ^{1}H NMR shift value of 0.92 ppm and $^2J_{PtH}$ = 78.5 Hz, in contrast with the starting [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$] with a chemical shift value of 1.84 ppm and $^2J_{PtH}$ = 79.3 Hz. After adding more than one equiv. of ligand, the ^{1}H displays two Kläui Cp ligand environments, namely that of the coordinated [Me_3Pt(CpCo[P(O)$(OCH_3)_2]_3$)] at 5.15 ppm and an additional peak belonging to the Cp ligand of the free [Na][(CpCo[P(O)$(OCH_3)_2]_3$] at 5.37 ppm (28). The ^{11}B{^{1}H} NMR shows that the new noncoordinated species has chemical shift values similar to those of [Cs][*closo*-($CB_{11}H_6Br_6$)] in the same solvent, leading us to conclude that the noncoordinated carboranate species is [Na][*closo*-($CB_{11}H_6Br_6$)]. ^{11}B spectra, internally referenced (BF_3-Et_2O), were also acquired, and they confirm that during the titration the amount of [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$] decreases, whereas a new species grows in. ^{11}B{^{1}H} shows that peak at the Br-*B*, opposite to the carbon apex, has shifted from +0.60 ppm to –2.10 ppm on going from the coordinated to noncoordinated *closo*-$CB_{11}H_6Br_6^-$, while the peak at Br-*B* of the lower ring, the ring which contains the Me_3Pt^+, shifts from –9.06 ppm to –10.36 ppm on going from the coordinated to noncoordinated *closo*-$CB_{11}H_6Br_6^-$, while the B-H ring peaks remain virtually unchanged at –20.51 ppm. The largest ^{11}B shifts observed are those that contain the Me_3Pt^+ bound moiety.

Competition experiment with THF

To a solution containing 1.73 mg (0.002 02 mmol) of [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$], 2.37 mg (0.0143 mmol) of fluorene in 560 μL of 1,2-dichloroethane-d_4 (0.00361 mol/L in Pt) was added THF (peaks appear as broad singlets at 3.65 ppm and 1.79 ppm) in amounts corresponding to approximately 8 equiv. per Pt, until *closo*-$CB_{11}H_6Br_6^-$ becomes fully decoordinated. It is interesting to note that it required 7.9 μL (0.0974 mmol) of thf (or 48 equiv.) per Pt to fully decoordinate the carboranate. Observed is the formation of a new species, assigned as $Me_3Pt(thf)_3^+$, with a chemical shift of 1.23 ppm for the Pt-methyl and $^2J_{PtH}$ = 76.8 Hz, clearly distinct from the starting [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$] having its methyl resonance at 1.84 ppm ($^2J_{PtH}$ = 79.3 Hz). The ^{11}B NMR spectrum confirms that the carboranate becomes noncoordinating, where the chemical shifts of the new species are very similar to [Cs][*closo*-($CB_{11}H_6Br_6$)] in the same solvent, which confirms the assignment as noncoordinating *closo*-$CB_{11}H_6Br_6^-$. The internally referenced (BF_3-Et_2O). The ^{11}B{^{1}H} NMR spectrum shows that peak at Br-*B* opposite to the carbon apex has shifted upfield 2.59 ppm to δ –2.15 ppm on going from the coordinated to noncoordinated *closo*-$CB_{11}H_6Br_6^-$, while the peak at Br-*B* of the lower ring, the ring which contains the Me_3Pt^+, has shifted upfield 1.28 ppm to δ –10.25 ppm on going from the coordinated to noncoordinated *closo*-$CB_{11}H_6Br_6^-$, while the B-H ring peaks remains virtually unchanged at –20.60 ppm.

Competition experiment with acetone

In a similar fashion to the thf experiment, the acetone experiment was conducted. To a solution containing 1.67 mg (0.001 95 mmol) of [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$], 1.57 mg (0.009 45 mmol) of fluorene in 560 μL of 1,2-dichloroethane-d_4 (0.003 48 mol/L in Pt) was added 5.3 μL

© 2008 NRC Canada

(0.0722 mmol) of acetone (peak appears as a singlet at 2.08 ppm), which is approximately 38 equiv. per Pt. The ^{1}H NMR shows a slightly broadened $PtMe_3$ environment at with a chemical shift value of 1.82 ppm, and a $^2J_{PtH}$ is unresolved (because of overlap of the carbon satellites of the added acetone and a broadening of the Me_3Pt peaks), compared with the starting material of chemical shift value of 1.84 ppm. The $^{11}B\{^1H\}$ spectrum shows *one* species *only* and is that of the starting coordinated carboranate ligand, [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$], with slight broadening of base peaks for the two B-Br peaks directly coordinated to the Me_3Pt^+ moiety. The internally referenced (BF_3-Et_2O) $^{11}B\{^1H\}$ shows that the peak at Br-*B* opposite to the carbon apex has shifted slightly upfield 0.264 ppm to broad singlet at δ 0.25 ppm (compared with a approximately 2.6 ppm upfield shift for full decoordination experiments), while the peak at Br-*B* of the lower ring, the ring which contains the $[Me_3Pt]^+$, has shifted upfield 0.09 ppm to δ –9.13 ppm, while the B-H ring peaks remains virtually unchanged at –20.54 ppm). The data show that substantial decoordination of the carboranate does not occur. The very small chemical shift differences that are observed may indicate a weak outer-sphere association of acetone.

Competition experiment with NBu_4OTf

This experiment was performed using an accurate analytical mass balance with a ± 0.01 mg error. To a solution containing 1.33 mg (0.001 55 mmol) of [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$] was added 0.59 mg (0.001 51 mmol, 0.97 equiv. per Pt, FW: 391.53 g/mol) of NBu_4OTf in 340 µL (0.00456 mol/L in Pt) of 1,2-dichloroethane-d_4. The $^{11}B\{^1H\}$ spectrum shows the partial decoordination in a 43:57 ratio of coordinated-to-noncoordinated. The decoordinated species $^{11}B\{^1H\}$ peaks appear at –2.05 ppm, –10.25 ppm, and –20.65 ppm in the given reaction conditions.

Reverse competition experiment with $[Me_3Pt(acetone)_3][BF_4]$

The tris-acetone complex was prepared using modified literature methods (11, 29), similar to the preparation of $[Me_3Pt(benzaldehyde)_3][BF_4]$ but using acetone instead of benzaldehyde and using 1,2-dichloroethane-d_4 instead of dichloromethane-d_2 solvent. ^{1}H NMR 400 MHz, ($ClCD_2CD_2Cl$) δ: 2.24 (18H, s), 1.48 (9H, s+d, Pt-Me_3, $^2J_{PtH}$ = 79.8 Hz). $^{11}B\{^1H\}$ NMR 128.38 MHz, ($ClCD_2CD_2Cl$, 25 °C) δ: –1.52 (s, 1B, BF_4). Titrating in 0.21 to 1.87 equiv. of [Cs][*closo*-$CB_{11}H_6Br_6$] into a 420 µL solution of 1,2-dichloroethane-d_4 (0.0227 mol/L in Pt) containing 4.77 mg (0.009 52 mmol) of $[Me_3Pt(acetone)_3][BF_4]$ (FW: 501.23 g/mol), partial decoordination of the acetone complex occurs as shown by the ^{1}H NMR shift of acetone moving upfield from 2.24 ppm to 2.10 ppm. A new Me_3Pt species at 1.78 ppm, appears downfield from the starting species. Due to the relative broadness of the Pt satellites, it is difficult to accurately assess the $^2J_{PtH}$. Also formed is an insoluble precipitate, consistent with a reaction forming insoluble $CsBF_4$. The $^{11}B\{^1H\}$ NMR spectrum shows the disappearance of the sharp BF_4 peak at or near the equivalence point of Cs salt addition. Despite the broadened nature of the $^{11}B\{^1H\}$ spectrum, it shows that there are two *distinct* species present in solution at the 1.8 equivalence point, assigned as [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$] at $^{11}B\{^1H\}$ } 0.1 ppm, –9.32 ppm, and –20.48 ppm, as well as free, excess [Cs][*closo*-$CB_{11}H_6Br_6$] at –2.02 ppm, –10.17 ppm, and –20.48 ppm.

Crystallography[3]

The crystal was refined as a non-merohedral twin with the ratio of the twin components refining to 0.818(2):182(2). In addition, a large electron density peak located in the final difference Fourier map refined to the equivalent of ca. 5% of a Pt atom. Hence the structure was refined as containing "whole molecule disorder" with only the Pt atom being refined over two sites. The refined occupancies of the maximum and minimum components are 0.951(3) and 0.049(3). All other atoms were refined with full occupancy.

Acknowledgment

Funding by the Natural Science and Engineering Research Council (NSERC) of Canada, the Canadian Foundation of Innovation, and the University of Toronto (Connaught Foundation) is gratefully acknowledged (UF), as well as a PRF 44692.01-GB award from the American Chemical Society and the Cottrell College Award CC6755 from Research Corporation (AL). 28. It seems that, aided by the relative nonpolarity of the NMR solvent, the excess Kläui ligand ($[Na][(CpCo[P(O)(OCH_3)_2]_3]$) present after more than 1 equiv. (relative to Pt) has been added, partially associates with the "free" Na^+ of the $[Na][closo\text{-}(CB_{11}H_6Br_6)]$ in the titration solution. This results in a slight downfield shift (by 0.36 ppm) of the Cp protons in such excess Kläui ligand, where the resonance is observed at 5.36 ppm as opposed to the 5.00 ppm value observed for the pure ligand $[Na][(CpCo[P(O)(OCH_3)_2]_3]$ in the same solvent. Solution data of Kläui ligand, ($[Na][(CpCo[P(O)(OCH_3)_2]_3]$, in the absence of extra sodium: ^{1}H NMR 400 MHz, ($ClCD_2CD_2Cl$) δ: 5.00 (5H, s, Cp ligand), 3.54 (18H, dd, J_{HH} = 3.8, 6.5 Hz).

Alkyne adducts of paramagnetic and diamagnetic tripalladium clusters supported by dppm ligands[1]

Cyril Cugnet, Sophie Dal Molin, David Brevet, Dominique Lucas, Yves Mugnier, Pierre D. Harvey, and René T. Boeré

Abstract: The unsaturated redox-active cluster $[Pd_3(dppm)_3(CO)]^{n+}$ (n = 0,1, or 2) reacts with ethylene dicarboxylic esters and a variety of terminal acetylenes (but not PhC≡CPh) in all three charge states. In particular, the radical cations $[Pd_3(dppm)_3(CO)(RC{\equiv}CR')]^{\cdot+}$ can be produced by several routes: one-electron electrochemical reduction of the dication adducts, comproportionation of the neutral and dicationic adducts, as well as the direct complexation of alkyne to the known radical cation $[Pd_3(dppm)_3(CO)]^{\cdot+}$. Compared with the latter, each of the adducts have significantly extended lifetimes and classify as persistent radicals in solution. The alkyne adducts have been characterized by voltammetry (cyclic and rotating disk electrode), by UV–vis titrations and by MALDI-TOF mass spectra from dithranol matrices. Isotropic solution EPR spectra of the adducts with R = R′ = MeOC(O) and EtOC(O), as well as those with R′ = H and R = C_6H_5, FC_6H_4, $HC{\equiv}CC_6H_4$, and EtO have been obtained. Full line shape fitting simulations demonstrate that all display coupling to six different ^{31}P (I = 1/2) and to one to three ^{106}Pd (I = 5/2) nuclei. The $A(^{31}P)$ values range from a low of 3.0×10^4 to a high of 180.5×10^4 cm^{-1}; this variation is caused by changes in the contribution of P s orbitals to the SOMO resulting from structural distortions of the Pd_3P_6 core upon alkyne coordination.

Key words: electrochemistry, redox state, electron paramagnetic resonance, catalytic model, palladium, bridging phosphine.

Résumé : Le cluster insaturé $[Pd_3(dppm)_3(CO)]^{n+}$ (n = 0,1, ou 2) réagit, quelle que soit sa charge, sur des dérivés acétyléniques de formule générale RCCR′ comme des di-esters acétyléniques et sur une variété de dérives acétyléniques vrais R′CCH mais pas sur PhC≡CPh pour conduire aux adduits $[Pd_3(dppm)_3(CO)(RCCR')]^{n+}$ (n = 0,1,2). En particulier les radicaux cations $[Pd_3(dppm)_3(CO)(RC{\equiv}CR')]^{\cdot+}$ peuvent être générés par plusieurs voies : soit par réduction monoélectronique de l'adduit dicationique correspondant $[Pd_3(dppm)_3(CO)(RC{\equiv}CR']^{2+}$ soit par une réaction d' antidismutation entre l'adduit neutre et l'adduit dicationique et enfin par la complexation directe de l'alcyne sur l'espèce monocationique paramagnétique électrogénéré $[Pd_3(dppm)_3(CO)]^{\cdot+}$. Comparé à ce dernier, chacun des adduits paramagnétiques obtenus sont beaucoup plus stables et peuvent donc être plus facilement caractérisés en solution. Les différentes méthodes mises en oeuvre pour la caractérisation des adduits reposent sur la voltammétrie cyclique et sur électrode tournante, la spectroscopie UV–visible, la spectrométrie de masse (MALDI-TOF) et par analyse RPE, méthode pour laquelle des spectres des adduits $[Pd_3(dppm)_3(CO)(RC{\equiv}CR')]^{\cdot+}$ avec R = R′ = MeOC(O) and EtOC(O) d'une part et avec R′ = H, R = C_6H_5, FC_6H_4, $HC{\equiv}CC_6H_4$ et EtO d'autre part, ont été obtenus avec une bonne résolution. La simulation des spectres a permis de tirer toutes les constantes de couplage aux six atomes de phosphore ^{31}P (I = 1/2) et avec un, deux ou trois des atomes de palladium ^{106}Pd (I = 5/2). Pour expliquer la variation importante des différentes valeurs des constantes $A(^{31}P)$ qui correspond à 3.0×10^4 pour la valeur la plus faible à 180.5×10^4 cm^{-1} pour celle la plus élevée, un changement de la contribution de l'orbitale s du phosphore à l'orbitale SOMO, est retenue qui résulte d'une distorsion structurale du cœur Pd_3P_6 par coordination de l'alcyne.

Introduction

Puddephatt and co-workers (1–3) first reported a convenient synthetic route to trifluoracetate and hexafluorophosphate salts of the cyclic tripalladium cluster $[Pd_3(dppm)_3(\mu_3\text{-}CO)]^{2+}$ in which each diphenylphosphinomethane (dppm) ligand bridges two Pd atoms. These workers also reported structural characterization of the former by X-ray crystallography (1–3). This interesting complex is formed from Pd(II) precursors via a redox reaction and is both electronically delocalized with an average Pd oxidation state of 2/3 and coordinatively unsaturated. The approximately planar Pd_3P_6 core is surrounded by a "picket fence" of ligand phenyl rings (Scheme 1), creating a cavity on the side opposite to the triply bridged carbonyl ligand. A wide variety of ligands and ions are able to occupy this cavity, including small anions, Cl^- (2, 4–6), Br^- (7), I^- (3), and larger ions, PF_6^- (8), NO_3^- (9), $CF_3CO_2^-$ (1, 8), and $PO_2F_2^-$, that appear to be held in place by electrostatic attraction to the positively charged core (10). The delocalized electronic structure of the $[Pd_3(dppm)_3(\mu_3\text{-}CO)]^{2+}$ cluster leads to a rich redox chemistry that we have investigated through an exhaustive electrochemical study that led inter alia to the discovery of the persistent radical cation $[Pd_3(dppm)_3(\mu_3\text{–}CO)]^{\cdot+}$ (11). This success may be contrasted with the initial failure to reduce this compound by chemical means (1).

The $[Pd_3(dppm)_3(CO)]^{2+}$ system has been thoroughly studied because it represents an excellent solution-phase model for a close-packed metal surface with Pd atoms in triangular relationship (3, 12, 13). We have discovered both stoichiometric and catalytic reactivity under conditions of reductive electrochemical activation with halocarbons and acid halides (7, 10, 14, 15). Thus, reducing the positive charge at the Pd_3P_6 centre is postulated to decrease the attraction of the cluster counterions, thereby increasing reactivity towards neutral substrates. When alkynes are employed, we demonstrated a stronger affinity for binding to the cluster in lower oxidation states, which enables the quantitative reversal of binding from the alkynes by monoanionic ligands such as I^- or NO_3^- after reoxidation of the adducts (16). In this initial study, the persistence of the $[Pd_3(dppm)_3(CO)]^+$ monocation radical state was shown to be significantly extended in $[Pd_3(dppm)_3(CO)(RC{\equiv}CR')]^{\cdot+}$ for two alkynes with quite different properties, PhC≡CH and $MeCO_2C{\equiv}CCO_2Me$. This increase in stability was attributed to the protection from outside contaminants provided by the coordinated alkynes (Scheme 1).

We have now extended the study of such alkyne adducts to six different examples with quite different electronic and steric properties (Chart 1). In this paper we compare the electrochemical responses of the six alkyne adducts in stepwise reduction first with the paramagnetic monocations and subsequently with neutral clusters. The alkyne-containing monocation radicals, all of which have enhanced stability over the parent species, have been unambiguously characterized using electron paramagnetic resonance (EPR) spectroscopy. The "parent" radical cation $[Pd_3(dppm)_3(CO)]^{\cdot+}$ (**1b**), displays a symmetric septet pattern with intensities in the expected Pascal's triangle ratios for six equivalent $I = 1/2$ nuclei (10). Despite relatively broad main lines, satellite signals are observed extending from the outer set of lines attributable to the equal-intensity sextet that is expected from, on-average, a single ^{105}Pd nucleus per trimer (22.2% natural abundance). By comparison, each of the alkyne adduct monocations **2b**–**7b** display EPR spectra that clearly demonstrate the presence of one major species in solution that has significantly reduced symmetry, consistent with coordination of the alkyne to the "open" face of the cluster.

Scheme 1. Alkyne adducts with $n = 2, 1, 0$.

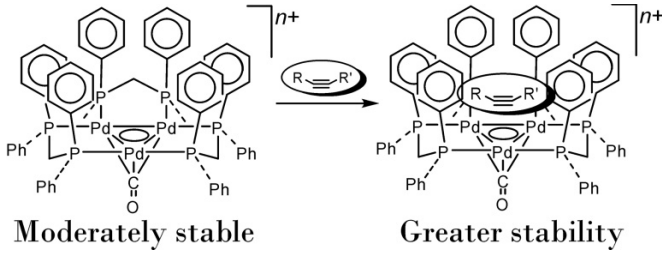

Chart 1. Composition of the ethynyl adducts; precise location and coordination of the CO and RC≡CR′ ligands is uncertain.

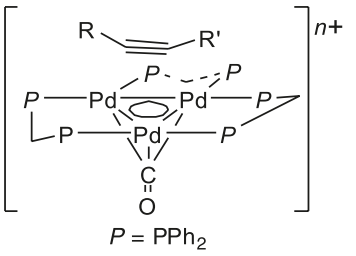

1 Without alkyne
2 R = R' = EtO(CO)
3 R = R' = MeO(CO)
4 R = Ph, R' = H
5 R = 4-FC_6H_4, R' = H
6 R = 4-PhC≡CC_6H_4, R' = H
7 R = EtO, R' = H
a, n=2; **b**, n=1; **c**, n=0

These EPR spectra are important because it has not yet been possible to obtain crystal structures of any of these alkyne adducts because of their limited stability over very long periods of time. However, the structure of the CO-displaced monocation $[Pd_3(dppm)_3(O_2CCF_3)(MeCO_2C{\equiv}CCO_2Me)]^+$ demonstrates significant distortion of the Pd_3P_6 frame and the generation of a square-planar geometry at one of the three metal atoms where the trifluoroacetate ligand is coordinated trans to one of the alkyne C atoms (17). This demonstrates that significant symmetry lowering can accompany substrate activation, though in each of our examples decarbonylation does not occur and therefore the substrate coordination can be reversed.

Results and discussion

Reversible adduct formation

The formation of the alkyne adducts was monitored by UV–vis spectroscopy, as demonstrated in the earlier work (16). In addition, the diamagnetic alkyne adducts $[Pd_3(dppm)_3(CO)(RC{\equiv}CR')]^{2+}$ could be characterized from evaporation of the THF solutions without removal of the electrolyte by means of MALDI ionization. The resulting mass spectra fit in most cases for gas-phase species of the type $[Pd_3(dppm)_3(RC{\equiv}CR')]^+$, i.e., through loss of the CO ligand, although in one case, $[Pd_3(dppm)_3(CO)(FC_6H_4C{\equiv}CH)]^+$, the CO ligand is retained. The results of the MALDI-TOF MS experiments are summarized in Table 1. Attempts to verify the presence of CO by IR spectroscopy were inconclusive (see discussion in ref. 16). The complete reversibility of the alkyne coordination demonstrates, however, that the

Voltammetric and electrolytic study

Corroboration of alkyne adduct formation is provided by electrochemistry. A typical experiment can be exemplified from rotating disk electrode (RDE) voltammetry as follows. The parent cluster $[Pd_3(dppm)_3(CO)]^{2+}$ (as the PF_6^- salt) exhibits two reversible one-electron waves A_1 and A_2 (Fig. 1) at –0.210 and –0.470 V, respectively, which correspond to sequential one-electron reductions of the dication to the monocation and on to the neutral cluster $[Pd_3(dppm)_3(CO)]^0$. In the presence of alkyne, two new reversible one-electron reduction waves, P_1 and P_2, corresponding to the following two reactions, replace the original waves.

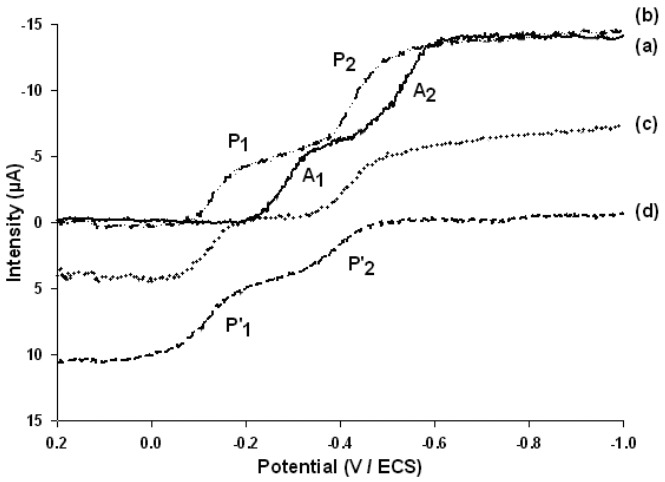
[1] $$[Pd_3(dppm)_3(CO)(RCCR')]^{2+} + 1e^- \rightleftarrows [Pd_3(dppm)_3(CO)(RCCR')]^+ \quad (P_1/P_1')$$

[2] $$[Pd_3(dppm)_3(CO)(RCCR')]^+ + 1e^- \rightleftarrows [Pd_3(dppm)_3(CO)(RCCR')]^0 \quad (P_2/P_2')$$

Electrolysis performed at the potential of the first wave consumes one electron-equivalent yielding the monocationic species $[Pd_3(dppm)_3(CO)(RCCR')]^{\cdot+}$, which exhibits reduction wave P_2 and oxidation wave P_1' by RDE voltammetry (Fig. 1). After electrolysis at the potential of wave P_2, two electron-equivalents are consumed and the RDE voltammetry of the resulting solution shows two oxidation waves P_1' and P_2' characteristic of the neutral cluster $[Pd_3(dppm)_3(CO)(RCCR')]^0$ (Fig. 1).

A more interesting way to obtain the paramagnetic monocationic cluster can be performed as follows: electrolysis is performed directly at the potential of the second wave P_2, but after a quantity of electricity equal to one electron has been passed, the electrolysis is stopped, whereupon the monocationic cluster is obtained. Its formation can be explained from comproportionation of the neutral and dicationic clusters as indicated in the following reactions:

Fig. 1. Rotating disk electrode voltammograms of $[Pd_3(dppm)_3(CO)]^{2+}$ in THF–NBu_4PF_6 solution. (*a*) $[Pd_3(dppm)_3(CO)]^{2+}$ alone. (*b*) $[Pd_3(dppm)_3(CO)]^{2+}$ with 2 equiv. of $C_6H_6O_4$ and a delay of 45 min. (*c*) After electrolysis at –0.3 V and consumption of one electron. (*d*) After electrolysis at –1 V and consumption of one further electron.



[3] $$[Pd_3(dppm)_3(CO)(RCCR')]^{2+} + 2e^- \rightleftarrows [Pd_3(dppm)_3(CO)(RCCR')]^0$$

[4] $$[Pd_3(dppm)_3(CO)(RCCR')]^{2+} + [Pd_3(dppm)_3(CO)(RCCR')]^0 \rightleftarrows 2[Pd_3(dppm)_3(CO)(RCCR')]^+$$

A third variant for preparing the monocationic clusters consists of first producing $[Pd_3(dppm)_3(CO)]^{\cdot+}$ by one-electron reduction of the parent dicationic cluster and then adding RC≡CR′. Here too, the initial oxidation and reduction waves A_1' and A_2 become oxidation and reduction steps P_1' and P_2, according to the reaction

[5] $$[Pd_3(dppm)_3(CO)]^+ + RCCR' \rightarrow [Pd_3(dppm)_3(CO)(RCCR')]^+$$

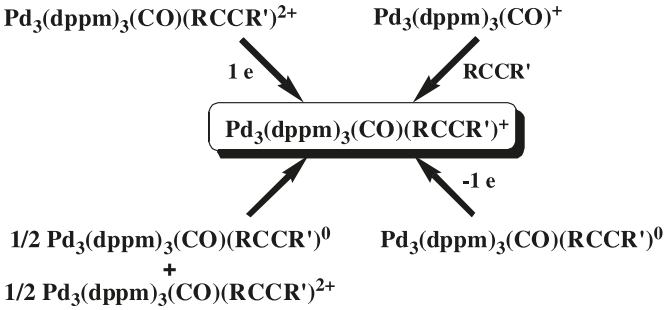
Scheme 2. Feasible routes to $[Pd_3(dppm)_3(CO)(RCCR')]^{+}$.



The various approaches that successfully lead to the monocationic paramagnetic clusters are summarized in Scheme 2.

In the case of the bifunctional alkyne $HC{\equiv}CC_6H_4C{\equiv}CH$, formation of a tetracationic diadduct such as $[\{Pd_3(dppm)_3(CO)\}_2(HCCC_6H_4CCH)]^{4+}$ does not occur, since in the presence of 0.5 equiv of alkyne, reduction peaks A_1, P_1, A_2, and P_2 are all detected by cyclic voltammetry in the reaction mixture. On the other hand, it is interesting to note that no interaction occurs between $[Pd_3(dppm)_3(CO)]^{n+}$ and PhC≡CPh, since reduction waves A_1 and A_2 are not modified even in the presence of an excess of PhC≡CPh. Steric hindrance from the two bulky substituents seems to be a likely explanation for this observation.

If we now compare the redox potentials of **1**–**7** (Table 2), we see that the two alkyne ester adducts are reduced *more easily* than the parent cluster **1** in both processes, whereas **4**–**7** are all *more difficult* to reduce. This is consistent with the electron-deficient alkyne esters acting as net withdrawers of electron density, whereas the aryl and alkoxy alkynes act as net electron donors to the palladium cluster. A measure of these donating and withdrawing effects can be estimated by calculating the (vertical) first ionization energies of the alkynes using semiempirical PM3 calculations. These are graphed against the P_1/P_1' and P_2/P_2' potentials in Fig. 2. Reasonable linear fits are observed (R^2 values of 0.84 and 0.86, respectively), although the $C_2H_5OC{\equiv}CH$ adduct **7** is in poor agreement (either the calculated ionization energy is wrong, or the redox potentials are not what we would expect for this system). The similarity in the slopes of the two lines reflects the consistency of the ΔE for the two processes, which is 0.34 ± 0.03 V for the alkyne adducts. Note that this ΔE is considerably larger than what is observed for the parent cluster **1** (0.22 V).

EPR characterization of the monocations

Bulk one-electron reductive electrolyses of $[Pd_3(dppm)_3(CO)(RC{\equiv}CR')]^{2+}$ adducts lead to the corresponding paramagnetic monocations **2b**–**7b**, all of which are stable for several hours in solution at room temperature (RT). Each of the six adducts that we have investigated can be simulated using combinations of hyperfine coupling constants (hfcc) for six different ^{31}P nuclei. The EPR parameters determined by simulation and measurement are summarized in Table 3 along with those previously determined for **1b**. Spectral traces of the new complexes are provided in Figs. 3–6; for similar diagrams of the previously reported **1b** (10) and **3b** and **4b** (16) see the indicated references.

Table 2. Voltammetric data for the complexes (in volts).

Complex[a]	Alkyne	E_0 (P_1/P_1')	E_0 (P_2/P_2')

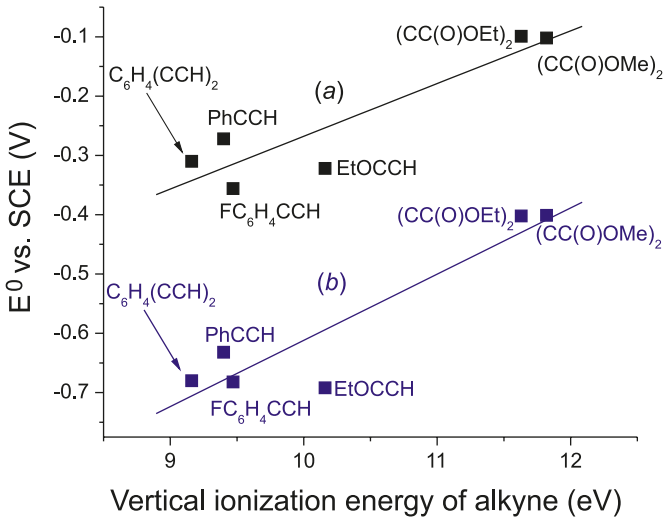
Fig. 2. Correlation of the (*a*) first and (*b*) second reduction potentials of $[Pd_3(dppm)_3(CO)(RC{\equiv}CR')]^{2+}$ with the vertical first ionization energies of the alkynes from PM3 calculations.



The experimental spectrum measured for the diethyl acetylene dicarboxylate complex **2b** is displayed in Fig. 3*a*. There are several features that apply to all the EPR spectra measured for the alkyne adducts. First of all, the spectra cover a large field–frequency range, which in the case of **2b** encompasses more than 40 mT and for some of the other adducts closer to 50 mT and are significantly distorted in the high-field branches. This asymmetry in the continuous wave (CW) spectra can safely be attributed to motional line broadening, a phenomenon that is common for relatively large paramagnetic molecules in X-band EPR spectroscopy (18, 19) that undergo slow tumbling on the EPR timescale.

The simulation (Fig. 3*b*) was obtained by a computerized line-fitting procedure as implemented in the software WinSim version 0.98 using a simplex minimization algorithm and starting from approximate hfcc obtained from measurements taken off the experimental spectrum (20). It can be seen that there is excellent agreement between the calculated and simulated spectra, with most of the large and small features in the measured spectrum accounted for other than the effect of the motional line broadening. Because of the expected symmetry of dispersive EPR signals, the computer line fitting can be restricted to the low-field half of the spectrum; hfcc are extracted from the simulations, as are the line widths (Table 3). Excellent agreement is obtained for all the spectra using purely Lorentzian line shapes, which sug-

Fig. 3. (*a*) Experimental and (*b*) simulated EPR spectra of $[Pd_3(dppm)_3(CO)\{CH_3CH_2OC(O)C\}_2]^{\bullet+}$ (**2b**) recorded in THF–$^nBu_4NPF_6$ at ambient temperature. The experimental spectrum is broadened at high field because of slow tumbling and has been corrected for baseline drift.

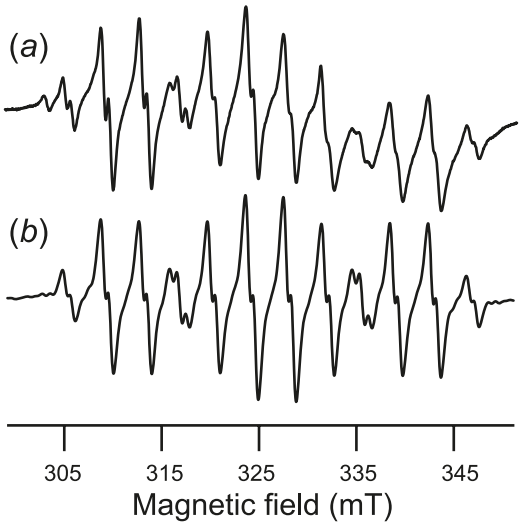

Fig. 4. (*a*) Experimental and (*b*) simulated EPR spectra of $[Pd_3(dppm)_3(CO)(FC_6H_4C{\equiv}CH)]^{\bullet+}$ (**5b**) recorded in THF–$^nBu_4NPF_6$ at ambient temperature. The experimental spectrum is broadened at high field because of slow tumbling and has been corrected for baseline drift.

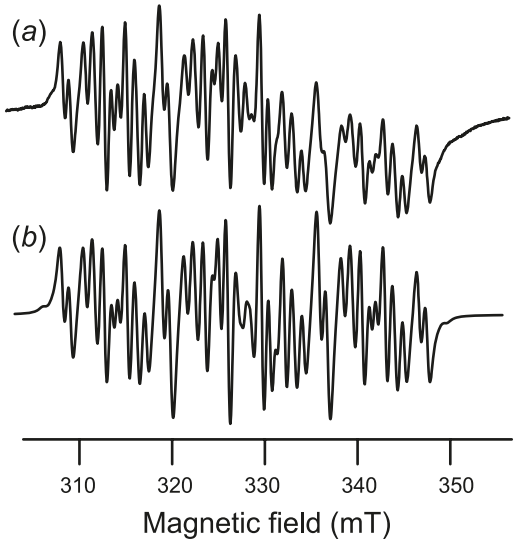

gests that there is little residual coupling to other nuclei in the spectra of any of these radical cations.

The hfcc to ^{31}P thus obtained for the two acetylene dicarboxylate containing cation radicals **2b** and **3b** comprise one very large, one medium, three small and apparently identical, and one very small value, ranging from 180.5×10^4 to 7.0×10^4 cm^{-1}. We say "apparently identical" because the lines are quite broad (the line width parameter used in the simulations is ca. 5×10^4 cm^{-1}) so that small variations in coupling will not be observable. When we compare the spectra of these two complexes with that of the parent cation radical **1b**, for which all six ^{31}P hfcc are 74.0×10^4 cm^{-1}, we note that ΣA(P) does not differ greatly (ca. 406 or 407 vs. 444×10^4 cm^{-1}), so that the total size of coupling to phosphorus seems to remain similar, but the *distribution* thereof among the six phosphorus nuclei is very strongly perturbed.

The experimental and simulated spectrum of 4-fluorophenylethyne complex **5b**, obtained by a very similar procedure, is presented in Fig. 4. Here too all the large and small features of the experimental spectrum have been accurately captured by the full line shape simulation, which also employs a Lorentzian line shape. As seen for **2b**, there are one large, one medium, three similar *but not identical*, and one very small hfcc values. The loss of (approximate) equivalence of the middle three coupling constants has a dramatic effect on the appearance of the spectrum, which looks much more complex than that shown in Fig. 3. Almost all the *A*(P) values are smaller than in **2b** and **3b**, so that ΣA(P) is now noticeably smaller. Note also that the parameters for **4b** and **5b** are quite similar, suggesting that the coordination of the PhC≡CH unit is only mildly affected by *para* fluorine substitution.

The experimental and simulated spectrum of the *p*-diethynylbenzene complex **6b** is shown in Fig. 5. Here too the fit between the measured and experimental spectrum is generally excellent, although there is a slight mismatch for a few lines at the centre of the spectrum. In all likelihood the discrepancy can be attributed to a line width effect because this spectrum seems to be somewhat more strongly affected

Fig. 5. (*a*) Experimental and (*b*) simulated EPR spectra of $[Pd_3(dppm)_3(CO)(HC{\equiv}CC_6H_4C{\equiv}CH)]^{\cdot+}$ (**6b**) recorded in THF–$^n Bu_4NPF_6$ at ambient temperature. The experimental spectrum is broadened at high field because of slow tumbling and has been corrected for baseline drift.

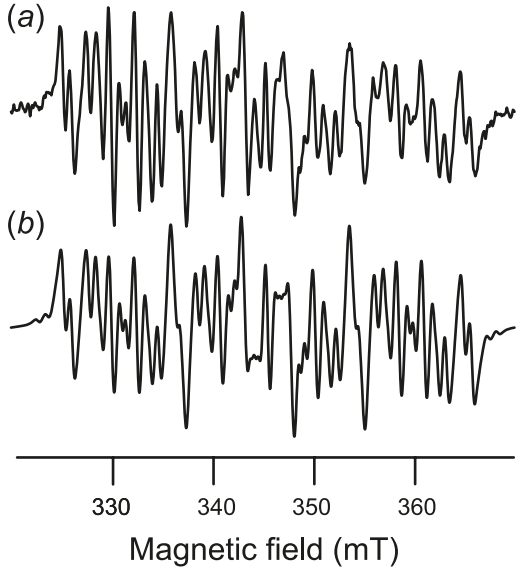

Fig. 6. (*a*) Experimental and (*b*) simulated EPR spectra of $[Pd_3(dppm)_3(CO)(CH_3CH_2OC{\equiv}CH)]^{\cdot+}$ (**7b**) recorded in THF–$^n Bu_4NPF_6$ at ambient temperature. The experimental spectrum is broadened at high field because of slow tumbling and has been corrected for baseline drift. The features indicated by the arrows in the experimental spectrum appear to be associated with hyperline coupling to the ^{106}Pd nuclei.

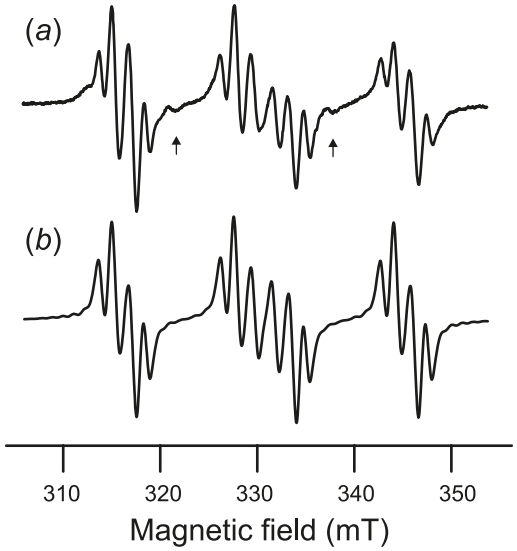

by motional broadening than those of the others, an effect that may be associated with the extended length of the 4-$HC{\equiv}CC_6H_4$ "tail" causing slower tumbling in solution. It seems certain, however, from the close agreement between the parameters for **6b**, **5b**, and **4b** that only one of the two alkyne groups in this ligand interacts with the Pd_3 centre, a conclusion that substantiates the evidence provided by voltammetry (see previous discussion). The second alkyne group will then presumably act through normal aryl substituent influences on the coordinated moiety.

The spectrum and simulation obtained for the monoethoxyethyne complex **7b** is shown in Fig. 6. This spectrum has a deceptively simple appearance, since the complex does not, in fact, have very similar hfcc values. As observed for the three ArylC≡CH complexes **4b**, **5b**, and **6b**, here too there are two larger, three medium, and one very small coupling, except that all the values are smaller (other than that of A(P2), which is larger and hence the most similar to A(P1)). Consistently, ΣA(P) is the smallest of the series.

In each of these complexes, the evidence from the good simulations achieved and the use of Lorentzian line shapes suggests that the unpaired electron spin does not get significantly redistributed in the different monocation radicals. Thus, we have to look elsewhere for the origin of the observed variation in ΣA(P) for the six adducts. A possible source of this effect is suggested by the different X-ray crystal structures mentioned in the Introduction (albeit for derivatives of the dication $[Pd_3(dppm)_3(\mu_3\text{-}CO)]^{+2}$). Whereas all these complexes retain the planar Pd_3 framework, ligand substitution leads to variable amounts of distortion of phosphorus positions out of the plane of the three metal atoms. On the reasonable assumption that similar distortions apply in **2**–**7**, subtle changes in the s- and p-orbital contributions of different phosphorus atoms to the singly occupied molecular orbital (SOMO) will occur. By comparison to the parent complex, some of the P nuclei gain and some lose the s-orbital contribution that is essential for hfcc via the Fermi contact mechanism (19). There is a ca. 30% *decrease* in $\Sigma A(^{31}P)$ from the parent complex **1b** to the monoethoxyethyne complex **7b**, whereas there is no good reason to think that these differing ligands lead to a redistribution of spin density of such magnitude away from the P nuclei. This also points, we believe, to variations in geometry that affect the amount of s-orbital contributions to the SOMO.

In addition to the $A(^{31}P)$ values, each of these spectra show evidence of the presence of the 22.2% abundant ^{105}Pd nuclei, but the complexity of the spectra and broad lines greatly limit the accuracy with which we can assign these hfcc values. Finally, there is a significant change in the g value between **1b** and *all* the alkyne adducts, but amongst the different adducts no meaningful pattern seems to be present. The variation in g values most likely reflects differences in the population of the excited states of these radical cations (19).

Conclusions

The tripalladium cluster $[Pd_3(dppm)_3(CO)]^{2+}$ first prepared by Puddephatt and co-workers (1–3) has in our hands been shown to be redox-active with stepwise and reversible reduction first to a monocation radical and subsequently to a neutral cluster. Coordination of alkynes to the framework causes significant variation in the E_0 values for both the P_1/P_1' and P_2/P_2' processes. The unambiguous identification of the monocation radicals by EPR spectroscopy provides strong evidence for the correctness of the proposed mechanisms deduced by voltammetry. Finally, the reversible nature of the alkyne coordination and the dependency thereof on redox state suggests the possibility of developing a "molecular

© 2008 NRC Canada

shuttle" in which $[Pd_3(dppm)_3(CO)]^{n+}$ could transport alkynes through a cell as a result of a charge gradient. The exploitation of this idea is a subject of ongoing research in our laboratories.

Experimental

General procedures

The solvent tetrahydrofuran was distilled over Na-benzophenone under protection of Ar. Alkynes were obtained from Sigma-Aldrich and were used as received. The $[Pd_3(dppm)_3(CO)](PF_6)_2$ salt was prepared according to a literature procedure (1, 21). The UV–vis spectra were acquired on a Varian Cary 50 spectrophotometer. MALDI-TOF mass spectra were obtained on a Bruker ProFLEX III spectrometer using 1,8-dihydroxy-10*H*-anthracen-9-one (dithranol) as matrix. The EPR spectra were acquired on a Bruker Elexsys E500 spectrometer.[3]

Electrochemistry and EPR spectroscopy

All manipulations were performed using Schlenk techniques in an atmosphere of dry oxygen-free argon. The supporting electrolyte, $^nBu_4NPF_6$, was degassed under vacuum before use and then dissolved to a concentration of 0.2 mol L^{-1}. For cyclic voltammetry experiments, the concentrations of the analyte were slightly less than 1×10^{-3} mol L^{-1}. Voltammetric analyses were carried out in a standard three-electrode cell using an EG&G Princeton Applied Research (PAR) model 263A potentiostat, interfaced to a computer running Electrochemistry Power Suite software. The reference electrode was a saturated calomel electrode (SCE) separated from the solution by a sintered glass disk. The auxiliary electrode was a platinum wire. For all voltammetric measurements, the working electrode was a vitreous carbon disk (nominal diameter = 3 mm). Under these conditions, when operating in THF, the formal potential for the ferrocene (+/0) couple was found to be +0.56 V vs. the SCE. Controlled potential electrolysis was performed with an Amel 552 potentiostat coupled with an Amel 721 electronic integrator. Bulk electrolyses were performed in a cell with three compartments separated by glass frits of medium porosity. Carbon gauze was used as the working electrode, a platinum plate was used as the counter electrode, and a saturated calomel electrode was used as the reference electrode.

Study of aerobic oxidation of phenyl Pt^{II} complexes (dpms)Pt^{II}Ph(L) (dpms = di(2-pyridyl)methanesulfonate; L = water, methanol, or aniline)[1]

Julia R. Khusnutdinova, Peter Y. Zavalij, and Andrei N. Vedernikov

Abstract: Oxidation of phenyl Pt^{II} complexes K[(dpms)$Pt^{II}Ph_2$], **1**, (dpms)Pt^{II}Ph(MeOH), **2**, (dpms)Pt^{II}Ph(OH_2), **3**, and methyl Pt^{II} complex (dpms)Pt^{II}Me(NH_2Ph), **6**, with O_2 in aqueous or methanol solutions under ambient conditions leads to corresponding (dpms)Pt^{IV}R(X)OH complexes (R = X = Ph, **7**; R = Ph, X = OH, **8**; R = Ph, X = OMe, **9**; R = Me, X = NHPh; **11**; dpms = di(2-pyridyl)methanesulfonate). Complexes **7–9** could be isolated in high yield. Complex **11** as well as its phenyl analogue (dpms)Pt^{IV}Ph(NHPh)OH, **10** can be prepared in high yield by oxidation of corresponding (dpms)Pt^{II}R(NH_2Ph) with H_2O_2 in methanol. Phenyl Pt^{II} complexes (dpms)Pt^{II}Ph(HX) derived from HX = aniline and DMSO, **4** and **5**, respectively, are inert toward O_2. The rate of oxidation of **1–5** with O_2 decreases in the order **1** > **3** ≈ **2** » **4**, and **5** is unreactive. Methyl analogues are significantly more reactive compared with their phenyl counterparts. Proposed mechanism of oxidation with O_2 includes formation of anionic species (dpms)Pt^{II}R(X)$^-$ responsible for reaction with dioxygen. Attempts at C–O and C–N reductive elimination from phenyl Pt^{IV} complexes **7–10** do not lead to phenyl derivatives PhX at 80–100 °C, consistent with the results of the DFT estimates of corresponding activation barriers, ΔG^0 exceeding 28 kcal/mol.

Key words: platinum phenyl complexes, oxidation, dioxygen, aqueous solution, mechanism.

Résumé : L'oxydation des complexes phénylés du Pt(II), K[(dpms)$Pt^{II}Ph_2$], **1**, (dpms)Pt^{II}Ph(MeOH), **2**, (dpms)Pt^{II}Ph(OH_2), **3**, ainsi que du complexe méthylé du Pt(II), (dpms)Pt^{II}Me(NH_2Ph), **6**, effectuée avec de l'oxygène (O_2), en solutions aqueuses ou méthanoliques et dans des conditions ambiantes, conduit à la formation des dérivés (dpms)Pt^{IV}R(X)OH correspondants (R = X = Ph, **7**; R = Ph, X = OH, **8**; R = Ph, X = OMe, **9**; R = Me, X = NPh, **11**; dpms = di(2-pyridyl)méthanesulfonate). Les complexes **7–9** ont été isolés avec des rendements élevés. Le complexe **11** ainsi que son analogue phénylé, (dpms)Pt^{IV}Ph(NHPh)OH, **10**, peuvent être préparés avec d'excellents rendements par oxydation du (dpms)Pt^{II}R(NH_2Ph) avec du H_2O_2 dans le méthanol. Les complexes phénylés du Pt(II), (dpms)Pt^{II}Ph(HX), dans lesquels X représente l'aniline (**5**) et le DMSO (**6**) sont inertes vis-à-vis de l'oxygène. Les vitesses d'oxydation des produits **1-5** par l'oxygène diminuent dans l'ordre **1** > **3** ≈ **2** > **4,5** (inerte). Les analogues méthylés sont sensiblement plus réactifs que leurs analogues phénylés. Le mécanisme d'oxydation proposé pour l'action de l'oxygène implique la formation d'espèces anioniques (dpms)Pt^{II}R(X)$^-$ qui seraient responsables de la réaction avec le dioxygène. Les essais réalisés entre 80 et 100°C en vue d'effectuer une élimination réductrice C–O et C–N à partir des complexes phénylés **7-10** n'ont pas conduit à la formation de dérivés phénylés, PhX; ces résultats sont en accord avec les résultats d'évaluations, faites à l'aide de la théorie de la densité fonctionnelle (TDF), des barrières d'activation correspondantes, ΔG^0, qui seraient supérieures à 28 kcal/mol.

Mots-clés : complexes phénylés du platine, oxydation, dioxygène, solution aqueuse, mécanisme.

[Traduit par la Rédaction]

Introduction

The use of oxygen as the terminal oxidant for selective transition-metal-mediated functionalization of organic substrates is an important practical goal (1). One of the possible approaches to selective aerobic CH functionalization may include a sequence of the following transformations: (*i*) selective CH activation with a Pt^{II} complex, (*ii*) aerobic conversion of resulting hydrocarbyl Pt^{II} to a Pt^{IV} complex, and (*iii*) reductive elimination of organic products from the Pt^{IV} intermediate (Scheme 1).

Recently, we reported facile aerobic dpms-enabled (2) functionalization of alkyl Pt^{II} complexes in water leading to methanol (3), methyl ether (4), and olefin oxides (5, 6).

Scheme 1. Aerobic Pt^{II}-mediated CH functionalization.

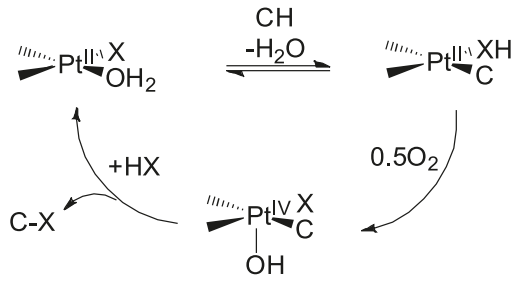

Chart 1. dpms Ligand and derived phenyl Pt^{II} complexes.

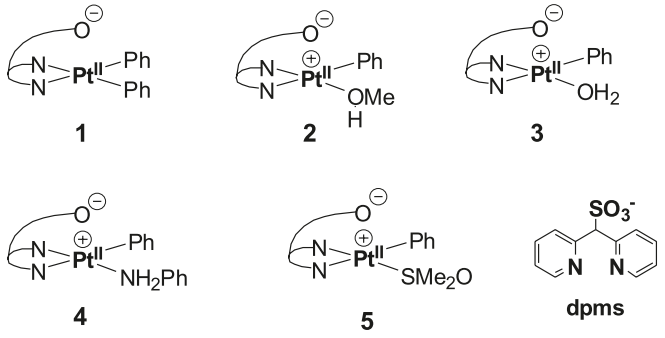


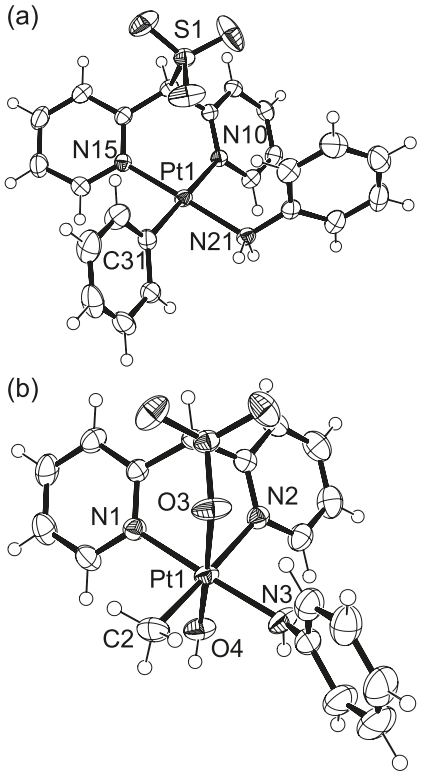
These transformations include selective aerobic conversion of Pt^{II} alkyls to isolable Pt^{IV} hydroxo alkyl complexes with subsequent clean reductive C–O elimination of a functionalized alkane product from a Pt^{IV} center. A similar reaction sequence might also be probed for aryl Pt derivatives. Aromatic CH activation with Pt^{II} (7, 8) complexes is well-established, but oxidation of monohydrocarbyl $Pt^{II}Ar$ and diaryl $Pt^{II}Ar_2$ complexes with O_2 was never observed. Slow aerobic oxidation of a mixed alkyl aryl (tmeda)-Pt^{II}(Ph)Me complex in methanol was reported but reaction products were not characterized (9). In this work, we present first examples of clean aerobic conversion of an anionic diphenyl Pt^{II} and several neutral monohydrocarbyl Pt^{II}Ph(HX) complexes to corresponding Pt^{IV}Ph derivatives (Chart 1), all enabled by dpms ligand. We also report results of attempted C(sp^2)–O and C(sp^2)–N reductive elimination from derived Pt^{IV}Ph species in water and (or) some organic solvents.

Results and discussion

(dpms)Pt^{II} Complexes 2–6

Methanol complex (dpms)Pt^{II}Ph(MeOH) (**2**) can be synthesized by reductive elimination of benzene from diphenyl Pt^{IV} hydride complex (dpms)$Pt^{IV}Ph_2H$ in methanol at 50 °C (eq. [1]). The latter complex can be prepared by protonation of anionic diphenyl Pt^{II} species K[(dpms)$Pt^{II}Ph_2$], **1** (2). Due to the poor solubility of the hydride, elevated temperatures and a prolonged time (5 h) are required to bring reaction to completion. In contrast to (dpms)$Pt^{IV}Ph_2H$, the methanol adduct **2** is soluble in warm MeOH. As a result, the reaction endpoint can be readily recognized when the entire solid disappears. Other solvento complexes studied in this work, **3**, HX = H_2O; **4**, HX = $PhNH_2$; and **5**, HX = Me_2SO, can be prepared most conveniently by a ligand exchange between methanol complex **2** and an appropriate ligand HX (eq. [2]; R = Ph).

Fig. 1. ORTEP plots (50% probability ellipsoids) for complexes **4** (*a*) and **11** (*b*).



[1] (dpms)$Pt^{IV}Ph_2H$ + MeOH → (dpms)Pt^{II}Ph(MeOH) + PhH

[2] (dpms)Pt^{II}R(MeOH) + HX → (dpms)Pt^{II}R(HX) + MeOH

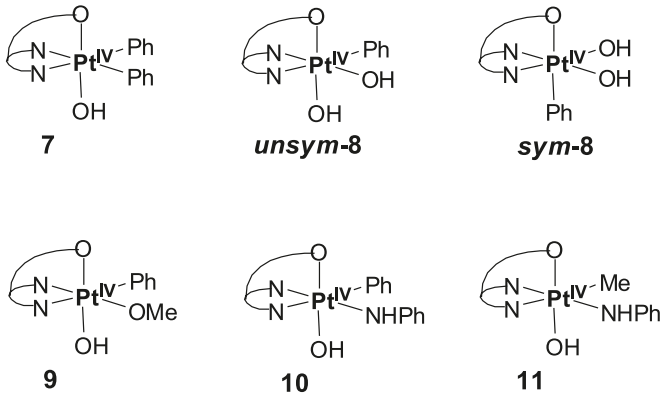
For instance, dissolution of **2** in water or DMSO produces quantitatively the corresponding aqua or DMSO adducts. The aniline derivative **4** can be synthesized by reacting **2** with 17 equiv. of aniline in methanol solution. Complexes **2** and **4** were prepared in an analytically pure form.

All complexes **2–5** were characterized by ^{1}H NMR spectroscopy and electrospray ionization mass spectrometry (ESI-MS). Poor solubility of **2–4** in cold methanol or water prevented us from obtaining high quality ^{13}C NMR spectra. Two sets of signals originating from pyridyl protons could be found in NMR spectra of **2–5**, indicating the presence of two non-equivalent pyridyl fragments and a low C_1 molecular symmetry of these complexes. In particular, two readily recognizable most downfield-shifted ^{1}H NMR signals of pyridyl ortho protons integrating as 1H each could be found in spectra of **2–5** in the range of 8–9 ppm. The signals appear as virtual doublets with characteristic small H–H coupling constant $^3J_{HH}$ = 5–6 Hz.

Complex **4** was characterized by single-crystal X-ray diffraction. X-ray quality crystals of **4** could be obtained by slow crystallization from a reaction mixture. Platinum atom in complex **4** has an idealized square-planar environment (Fig. 1*a*). The Pt1–N15 bond, which is trans to aniline ligand, is 2.024(3) Å long and is shorter than Pt1–N10, 2.102(3) Å, which is trans to phenyl, consistent with a

© 2008 NRC Canada

Chart 2. Products of oxidation of complexes **1**–**4** and **6**.



stronger trans influence of the phenyl compared with aniline ligand (10). The Pt1–N21 distance between the metal and the nitrogen atom of the aniline ligand is 2.066(3) Å. Both NH bonds of the aniline ligand point away from the sulfonate group. The shortest Pt1–sulfonate oxygen contact is non-bonding, 3.186 Å.

The mode of coordination of DMSO ligand to the metal in complex **5** could be established by IR spectroscopy. IR spectra of **5** exhibit the presence of the ν(S=O) band of S-coordinated DMSO at 1131 cm^{-1}, typical for S-coordinated DMSO complexes (11).

Solvento complexes derived from water, **3**, and methanol, **2**, are air-sensitive, whereas aniline derivative **4** and DMSO adduct **5** are stable under air. Reactivity of phenyl (dpms)Pt^{II} solvento complexes **2**–**4** toward O_2 will be compared with that of their methyl analogues (dpms)Pt^{II}Me(HX) (vide infra) whose aerobic oxidation chemistry was reported recently (HX = H_2O (3), MeOH (4)). The aniline methyl Pt^{II} complex (dpms)Pt^{II}Me(NH_2Ph) (**6**) was unknown and was prepared in this work.

For the preparation of **6**, a procedure similar to that utilized for its phenyl analogue **4** was used (eq. [2]; R = Me). Upon mixing of methanolic solutions of (dpms)Pt^{II}Me(MeOH) (4) with 1.2 equiv. of aniline and removal of the solvent, the target compound could be isolated as a colourless solid in 87% yield.

^{1}H NMR spectral patterns of **6** in D_2O are consistent with the C_1 molecular symmetry. The spectrum shows the presence of a Pt^{II}Me group resonance at 0.79 ppm (J_{195PtH} = 72 Hz) integrating as 3H, a singlet of the dpms ligand CH bridge at 5.91 ppm integrating as 1H, a set of partially overlapping signals of the aniline phenyl group, and signals of two non-equivalent pyridyl fragments. Two virtual doublets of ortho H atoms of two pyridyls integrating as 1H each can be observed at 8.14 ppm (J = 5.5 Hz) and 8.73 ppm (J = 5.9 Hz, $^3J_{195PtH}$ = 56 Hz). ESI-mass spectrum of aqueous solution of **6** shows single ^{195}Pt-derived peak with m/z = 553.1 (calculated for (dpms)$^{195}Pt^{II}$Me(NH_2Ph)·H^+, $C_{18}H_{20}N_3SO_3{}^{195}$Pt, 553.1).

(dpms)Pt^{IV} Complexes — Oxidation of (dpms)Pt^{II}R complexes with O_2 in water or methanol

Diphenyl complex sym-*(dpms)$Pt^{IV}Ph_2$(OH) (7)*

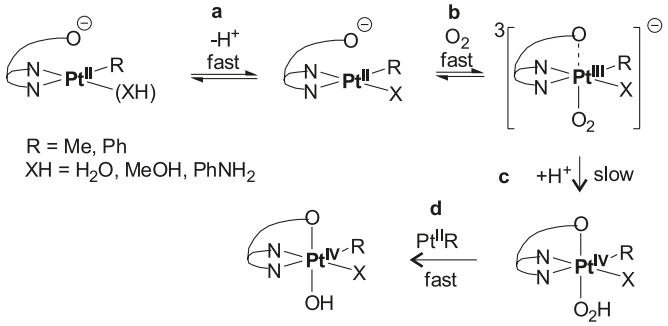
Oxidation of K[(dpms)$Pt^{II}Ph_2$] (2) with O_2 in water is facile and is complete in about 2 h at 22 °C. The target compound, *sym*-(dpms)$Pt^{IV}Ph_2$(OH), **7** (Chart 2) is poorly soluble in the reaction medium and can be isolated in an analytically pure form by filtration from the strongly alkaline aqueous solution containing KOH (eq. [3]).

[3] $$2\ K[(dpms)Pt^{II}Ph_2] + O_2 + 2\ H_2O \rightarrow 2\ sym\text{-}(dpms)Pt^{IV}Ph_2(OH) + 2\ KOH$$

Complex **7** dissolved in DMSO-d_6 exhibits in its ^{1}H NMR spectrum a broad singlet at 2.56 ppm with ^{195}Pt satellites (J = 36 Hz) integrating as 1H and corresponding to the Pt^{IV}(OH) proton. A doublet of doublets at 8.30 ppm (J = 5.5, 1.5 Hz) integrating as 2H, which is seen in the most downfield region of the spectrum was assigned to the pyridyl ortho protons. Accordingly, there are nine signals corresponding to two symmetry-related pyridyls and two symmetry-related phenyl ligands in the aromatic region of the ^{13}C NMR spectrum of **7**, evidencing the mirror symmetry of the product.

High reactivity of anionic diphenyl Pt^{II} complex **1** toward O_2 in aqueous solution and the retention of the planar arrangement of the four donor atoms at the Pt center upon oxidation of **1** to mirror symmetric **7** are similar to the behaviour of the dimethyl analogue K[(dpms)$Pt^{II}Me_2$] in its reaction with O_2 (2). Based on the stereochemical outcome of these reactions and also reactions including (dpms)Pt^{II}Me(HX), HX = H_2O (3), L = MeOH (4) and (dpms)$Pt^{II}(C_2H_4OH)OH^-$ (5), we suggest that the mechanisms of oxidation of these complexes might be also similar (Scheme 2; X = Me or Ph, steps **b**–**d** only) (5).

Scheme 2. Plausible mechanism of aerobic oxidation of (dpms)Pt^{II} complexes.



The mechanism presented in Scheme 2 was discussed previously (5) and is based on the idea of the axial attack of electrophilic O_2 at Pt^{II} center (9) that allows to account for the retention of the configuration at the Pt atom in the course of oxidation reaction. At the same time, we presume that in the case of neutral monophenyl complexes (dpms)Pt^{II}Ph(HX) only anionic species (dpms)Pt^{II}Ph$(X)^-$ can accept such an attack as it was shown previously for some monoalkyl analogues (5).

Notably, aerobic oxidation of diphenyl Pt^{II} complexes to form $Pt^{IV}Ph_2$ products has never been reported. In particular, (tmeda)$Pt^{II}Ph_2$ is unreactive toward O_2. In contrast, presumably electron-richer mixed-ligand phenyl methyl analogue (tmeda)Pt^{II}(Ph)Me can be oxidized with O_2 (9). Hence, the presence of the pendant axial sulfonate group (see Fig. 1*a*, for example) in anionic (dpms)Pt^{II} species is sufficient to raise energy levels of neutral $Pt^{II}Ph_2$ fragment and enable

© 2008 NRC Canada

electron transfer between Pt^{II} atom present in complex **1** and dioxygen (Scheme 2, steps **b**–**c**) (5).

***Phenyl dihydroxo complex* unsym-*(dpms)Pt^{IV}Ph(OH)$_2$* (8)**

Solutions of aqua complex **3** in water react slowly with O_2 at atmospheric pressure and ambient temperature to produce colourless unsymmetrical phenyl dihydroxo complex *unsym*-(dpms)$Pt^{IV}Ph(OH)_2$, *unsym*-**8** (Chart 2), that can be isolated in an analytically pure form in 93% yield (eq. [4]):

[4] $$2\ (\text{dpms})Pt^{II}Ph(OH_2) + O_2 \rightarrow 2\ \textit{unsym}\text{-}(\text{dpms})Pt^{IV}Ph(OH)_2$$

The presence of two non-equivalent pyridyl groups and hence the C_1 molecular symmetry of *unsym*-**8** are evident from data of ^{1}H and ^{13}C NMR spectroscopy in aqueous and DMSO solutions of *unsym*-**8**. Interestingly, two hydroxo ligands present in this complex give rise to two individual signals that integrate as 1H each and appear as broad singlets at 1.45 ppm (no resolved ^{195}Pt satellites) and 2.99 ppm ($^2J_{195PtH}$ = 30 Hz). Based on the analogy with complex **7**, the latter signal might be assigned to the proton of the axial OH ligand of complex *unsym*-**8**, whereas the signal at 1.45 ppm might be assigned to the proton of the equatorial OH ligand. Aqueous solutions of **8** acidified with HBF_4 show the presence of monoprotonated species **8**·H^+, *m*/*z* = 556.1 (calculated for (dpms)^{195}PtPh(OH)$_2$·H^+, $C_{17}H_{17}N_2SO_5{}^{195}Pt$, 556.1).

The rate of reaction in eq. [4] is much slower than that for K[(dpms)$Pt^{II}Ph_2$] (eq. [3]); an estimated half-life of **3** is 8.8 h. This fact may be related to the neutral character of **3** in contrast to anionic complex **1**, and therefore, a much lower fraction of anionic hydrocarbyl (dpms)Pt^{II} species is available for attack with O_2 in the case of **3**.

As in the case of bishydrocarbyl complexes K[(dpms)$Pt^{II}R_2$], R = Me or Ph, aerobic oxidation of monohydrocarbyl species (dpms)$Pt^{II}R(OH_2)$ leads to Pt^{IV} hydroxo derivatives *unsym*-(dpms)$Pt^{IV}R(OH)_2$ for both R = Me (3, 5) and Ph. Based on available estimates of half-life of (dpms)$Pt^{II}R(OH_2)$ measured under identical conditions in neutral aqueous solutions at 22 °C, the reactivity of complexes (dpms)$Pt^{II}R(OH_2)$ decreases in the order Me ($\tau_{1/2} \approx$ 15min) (5) > Ph ($\tau_{1/2} \approx$ 8.8 h). Assuming that mechanisms of these aerobic oxidation reactions are also similar (Scheme 2, steps **a**–**d**), this difference can be related to the electron-poorer character of the phenyl complex **3**. On one hand, electron-poorer complex **3** is more acidic than its methyl analogue. That increases the fraction of anionic (dpms)$Pt^{II}R(OH)^-$ species available for reaction with O_2 (5) and makes complex **3** more reactive. On the other hand, an electron-poorer Pt^{II} center in anionic intermediate (dpms)$Pt^{II}Ph(OH)^-$ is more difficult to oxidize that leads to an overall lower reactivity of the phenyl aqua complex **3**.

Notably, no *mono*phenyl Pt^{II} complexes were known that are able to react with O_2 to produce Pt^{IV}Ph derivatives. As in the case of complex **1**, we assume that the anionic pendant sulfonate tail present in dpms ligand allows to raise energy levels of neutral Pt^{II}Ph(OH) fragment to an extent, which is sufficient to enable electron transfer from Pt^{II} atom present in this species to O_2.

Taking these considerations into account, one can suggest that methanol analogue of aqua adduct **3**, complex **2** containing an almost equally acidic but more donating methanol ligand will be more reactive toward O_2. This was proven correct in the experiments described below.

***Phenyl hydroxo methoxo complex (dpms)Pt^{IV}Ph(OH)(OMe)* (9)**

Oxidation of methanol phenyl complex **2** was performed in methanol at ambient temperature. In the course of the reaction, solid complex **2** dissolves to produce a more soluble colourless hydroxo methoxo phenyl complex (dpms)Pt^{IV}Ph(OH)(OMe), **9**. The product was isolated in analytically pure form in 91% yield (eq. [5]).

[5] $$2\ (\text{dpms})Pt^{II}Ph(MeOH) + O_2 \rightarrow 2\ (\text{dpms})Pt^{IV}Ph(OH)(OMe)$$

According to ^{1}H NMR spectroscopy, complex **9** in DMSO-d_6 exhibits a broad singlet of the Pt^{IV}(OH) proton at 2.52 ppm integrating as 1H and a singlet of the methoxo ligand at 2.94 ppm with discernible ^{195}Pt satellites ($^3J_{195PtH}$ = 33 Hz) integrating as 3H. An ESI-mass spectrum of solution of **9** in MeOH acidified with HBF_4 shows the presence of a peak with *m*/*z* = 570.1 that corresponds to a monoprotonated species (dpms)^{195}PtPh(OCH$_3$)(OH)·H^+, (calculated for $C_{18}H_{19}N_2SO_5{}^{195}Pt$, 570.1).

Assuming that oxidation of methanol adducts (dpms)$Pt^{II}R(MeOH)$ proceeds via similar mechanisms for R = Me and Ph and implies retention of the configuration of both R and MeO ligands at the Pt center, complex **9** was tentatively assigned the same configuration (see Chart 2) as the product of aerobic oxidation of the methyl analogue. In the latter case, as established by a single-crystal X-ray diffraction analysis of the reaction product, (dpms)Pt^{IV}Me(OMe)OH methyl and methoxo fragments retain their positions in the equatorial plane of the product (4).

Half-life of complex **2** (eq. [5]) determined at 22 °C and 1 atm (1 atm = 101.325 kPa) partial pressure of O_2 was estimated to be 5.5 h. This result means that the reactivity of methanolic solutions of **2** is slightly higher than that of aqueous solutions of its aqua-analogue **3**.

A comparison of reactivity of analogous methanol complexes (dpms)$Pt^{II}R(HX)$, HX = MeOH, R = Me and Ph shows that the methanol phenyl complex **2** is less reactive compared with the electron-richer methanol methyl complex: Me ($\tau_{1/2}$ < 1 h) (4) > Ph ($\tau_{1/2} \approx$ 5.5 h). The same trend was observed for aqua complexes, HX = H_2O, R = Me and Ph.

Considering oxidation of the aniline derivatives **4** and **6** with O_2, one can expect poor reactivity because the acidity of aniline is many orders of magnitude lower than that of H_2O or MeOH that serve as ligands in species **2** and **3** (12). Hence, anionic intermediates (dpms)$Pt^{II}R(NHPh)^-$ required for oxidation may be available in exceedingly low concentrations only. Similarly, dimethylsulfoxide ligand present in adduct **5** is even less acidic than aniline. Therefore, complex **5** may be even less reactive toward O_2. Reactivity of aniline adducts **4** and **6** as well as that of DMSO adduct **5** toward O_2 was tested in the following experiments.

© 2008 NRC Canada

Phenylamido complexes (dpms)Pt^{IV}Ph(NHPh)(OH) (10) and (dpms)Pt^{IV}Me(NHPh)(OH) (11)

Methanolic solutions of complexes **4** and **5** are inert toward O_2. No changes were observed by ^{1}H NMR spectroscopy as well as no new species were detected by ESI-MS after 7 days of exposure of the above solutions to O_2 (1 atm) at ambient temperature.

To be able to test reductive elimination chemistry of an amido phenyl (dpms)Pt^{IV}(OH) complex, which can be derived from the aniline adduct **4**, oxidation of **4** was performed with hydrogen peroxide (eq. [6]).

[6] $$(dpms)Pt^{II}Ph(PhNH_2) + H_2O_2 \rightarrow (dpms)Pt^{IV}Ph(NHPh)(OH) + H_2O$$

Treatment of complex **4** dissolved in methanol with 2.5 equiv. of 30% H_2O_2 produced complex **10** in a quantitative yield, according to ^{1}H NMR spectroscopy. The colourless product could be precipitated with diethyl ether and isolated in an analytically pure form in 90% yield.

Phenylamido phenyl Pt^{IV} complex **10** was fully characterized by ^{1}H and ^{13}C NMR spectroscopy and ESI-mass spectrometry. ^{1}H NMR spectrum of **10** in DMSO-d_6 solutions shows two broad singlets, one at 3.01 ppm and another at 4.36 ppm integrating as 1H each that can be attributed to OH and NH protons, respectively. Both ^{1}H and ^{13}C NMR spectra reveal a low C_1 molecular symmetry of **10**. ESI-mass spectra of **10** dissolved in methanol exhibit single ^{195}Pt-derived peak at m/z = 631.1 that corresponds to (dpms)^{195}PtPh(NHPh)(OH)H$^+$ (calculated for $C_{23}H_{22}N_3O_4{}^{195}$Pt S, 631.1).

Based on presumed common mechanism of oxidation of (dpms)Pt^{II}R(HX) species, R = Me and Ph, the configuration of complex **10** at the Pt atom was assumed to be the same as for its methyl analogue **11** (Chart 2; vide infra).

Reactivity of an analogous methyl Pt^{II} aniline adduct **6** toward O_2 was also tested. Notably, upon stirring of aqueous solution of **6** under O_2 atmosphere (1 atm) at an ambient temperature, slow oxidation leading to complex (dpms)Pt^{IV}Me(NHPh)(OH), **11**, (Chart 2) was evident by ^{1}H NMR spectroscopy and ESI-mass spectrometry (eq. [7]). The reaction half-life was estimated to be 30 h.

[7] $$2\ (dpms)Pt^{II}Me(PhNH_2) + O_2 \rightarrow 2\ (dpms)Pt^{IV}Me(NHPh)(OH)$$

Similar to **10**, complex **11** could be prepared by oxidation of methanolic solution of **6** with 1.1 equiv. of H_2O_2. The reaction is quantitative by NMR spectroscopy.

Aqueous solutions of **11** are weakly basic (pH ≈ 9) presumably due to reversible protonation on the nitrogen atom of the phenylamido ligand.

As in the case of phenyl Pt^{II} complex **10**, the ^{1}H NMR spectrum of **11** in DMSO-d_6 shows the presence of two broad singlets at 2.22 ppm and 4.17 ppm, corresponding to OH and NH fragments, respectively. Both ^{1}H and ^{13}C NMR spectroscopy suggests a low C_1 molecular symmetry of complex **11**. ESI-mass spectra of aqueous solutions **11** exhibit single ^{195}Pt-derived peak with m/z = 569.1 (calculates for (dpms)^{195}PtMe(NHPh)(OH)·H$^+$, $C_{18}H_{20}N_3SO_4{}^{195}$Pt, 569.1).

X-ray quality crystals of **11** could be obtained by slow diffusion of ether vapours into solution of **11** in methanol. The structure of complex **11** reveals the presence of a Pt atom in a slightly distorted octahedral environment (Fig. 1*b*). As in the case of the Pt^{II}Ph aniline adduct **4**, the Pt1–N2 bond trans to hydrocarbyl is longer than the Pt1–N1 bond trans to phenylamido ligand, 2.189(3) Å vs. 2.089(3) Å, respectively. The Pt1–N3 bond with formally anionic phenylamido ligand is about 0.05 Å shorter than the Pt–N bond in the Pt^{II} adduct **4** with neutral aniline ligand, 2.018(3) Å. One of the sulfonate oxygen atoms in the Pt^{IV} complex **11** is bound to the metal with a short Pt1–O3 distance of 2.102(3) Å.

The configuration of complex **11** shows that the methyl and phenylamido fragments retain their equatorial positions in the course of oxidation of the Pt^{II} precursor **6** with H_2O_2.

Different ability of aniline-derived methyl and phenyl (dpms)Pt^{II} complexes **4** and **6** to react with O_2 in water is remarkable. Though the acidity of coordinated aniline may be expected to be many orders of magnitude lower compared with that of Pt^{II}-bound water or methanol ligands, corresponding anionic phenylamido Pt^{II} species (dpms)Pt^{II}R(NHPh)$^-$ required for reaction with O_2 (Scheme 2, steps **b**–**c**) may still be available in sufficient concentration in the case of R = Me. At the same time, the electron-poorer nature of phenyl ligand might be responsible for precluding a facile electron transfer between the Pt^{II} center in (dpms)Pt^{II}R(NHPh)$^-$ and dioxygen.

Finally, the inertness of complex **5** toward O_2 is consistent with its virtual inability to produce an anionic phenyl Pt^{II} complex required for aerobic reaction (Scheme 2, step **a**).

Attempted reductive elimination from (dpms)Pt^{IV}Ph complexes

It is assumed that C–X reductive elimination from Pt^{IV} center (X = O, N, C, H) is most facile if it proceeds via five-coordinate intermediates with a coordination vacancy trans to the hydrocarbyl being eliminated (13, 14). The ability of a d^6 metal complex to produce low-coordinate transients and therefore the presence of a good leaving group may be critical for fast reductive elimination chemistry at a Pt^{IV} center. The best leaving group available in (dpms)Pt^{IV} complexes **7**–**11** is the sulfonate but it is cis to hydrocarbyl ligands in all of the complexes. As a result, reductive elimination from **7**–**11** might be expected to be preceded by their isomerization. Indeed, when alkyl (dpms)Pt^{IV}(OH) complexes with an alkyl group cis to the sulfonate are submitted to reductive elimination experiments, intermediates with the alkyl trans to the sulfonate are actual reactive species involved in C–O reductive elimination reactions. These species can be detected by NMR spectroscopy in reaction mixtures and, in a number of cases, isolated in analytically pure form (3–6). Whereas C(sp^3)–X elimination from Pt^{IV} can operate an S_N2 (X = O, N) (15, 16) or a recently discovered direct C(sp^3)–O elimination mechanism (6), in the case of aryl Pt^{IV} derivatives, a direct C(sp^2)–X elimination was observed only (17). Hence, a direct C(sp^2)–X reductive elimination from complexes **7**–**10** might be expected.

Heating complex **7** in DMSO at 100 °C for 6 days resulted in clean isomerization to *unsym*-**7** featuring one of the phenyl groups in the axial position. No other products were detected in the solution.

Similarly, unsymmetrical phenyl dihydroxo complex **8** dissolved in water and exposed to 100 °C for 3 days cleanly

© 2008 NRC Canada

produced the more stable isomer *sym*-**8** with the aryl in the axial position (half-life ≈ 12.5 h). No other products were found. The latter complex is C_s symmetric, according to ^{1}H and ^{13}C NMR spectroscopy and produces the same signal in ESI-mass spectra as its unsymmetrical precursor.

To probe the effects of solvent and pH on reactivity of *sym*-**8**, its samples were submitted to C–O reductive elimination in DMSO and also acidic and alkaline aqueous solutions at 100 °C. No changes were detected in these solutions by ^{1}H NMR spectroscopy after 5 days, suggesting that the Gibbs activation energy for direct C–O elimination from Pt^{IV} exceeds 30 kcal/mol in all these cases.

Reductive elimination reactions from complexes **9** and **10** were probed in aprotic DMSO-d_6, CD_3CN, and DMF-d_7.

In the case of **9** in DMSO-d_6 solution slow formation of a single Pt^{II} complex **5-*d*$_6$** and methanol was detected by ^{1}H NMR spectroscopy and ESI-MS at 100 °C. No anisole or phenol was detected. The reaction was clean and involved presumably the solvent as a reductant (eq. [8]).

[8] $$(dpms)Pt^{IV}Ph(OMe)OH + 2\ Me_2SO \rightarrow (dpms)Pt^{II}Ph(dmso) + MeOH + Me_2SO_2$$

A complex mixture of unidentified products formed in DMF-d_7 and CD_3CN solutions of **9** at 100 °C already after several hours, but no anisole or phenol was detected by ^{1}H NMR spectroscopy either.

Phenylamido complex **10** in CD_3CN solution produced a soluble Pt^{II} complex $(dpms)Pt^{II}Ph(CD_3CN)$ along with a complex mixture of solids of unknown composition after 5 h at 80 °C. No diphenylamine or phenol was detected by ^{1}H NMR spectroscopy.

Similarly, a complex mixture of products not containing diphenylamine formed when a solution of complex **10** in DMF-d_7 was heated at 80 °C for 24 h. ESI-MS spectra of acidified reaction mixtures diluted with methanol exhibited a peak of unreacted starting material, *m*/*z* 631.1, and two new peaks with *m*/*z* = 1225.2 and *m*/*z* = 613.1 that might be assigned to a mono- and doubly-protonated dinuclear species $[(dpms)_2Pt^{IV}{}_2Ph_2(\mu\text{-}NPh)(\mu\text{-}NHPh)]^+$ (calcd. $C_{46}H_{39}N_6O_6{}^{195}Pt_2S2$ 1225.1) and $[(dpms)_2Pt^{IV}{}_2Ph_2(\mu\text{-}NHPh)_2]^{2+}$ (calcd. 613.1), respectively.

Therefore, none of complexes **7**–**10** reacted via Pt^{IV}–Ph bond cleavage, and none can be used for arene CH functionalization such as the one shown in Scheme 1. Oxidation of a solvent (complex **9** in DMSO) or, presumably phenylamido ligand (complex **10** in MeCN), or formation of insoluble polynuclear complexes (complex **10** in DMF) was seen instead.

Our DFT estimates of the Gibbs activation energy for the "direct" C–O or C–N elimination from $(dpms)Pt^{IV}Ph$ phenyl complexes **8**–**10** provided high barriers for these reactions. In particular, the Gibbs activation energy for PhOH elimination from *sym*-**8** is 29.4 kcal/mol. The same value was found for PhOMe elimination from an isomer of complex **9** with phenyl ligand in the axial position. Finally, the Gibbs activation energy for Ph_2NH elimination from an isomer of complex **10** with the axial $Pt^{IV}Ph$ group is 28.7 kcal/mol. Hence, the results of DFT modeling are qualitatively consistent with our experimental observations.

Summary

Though none of the Pt^{IV} phenyl complexes $(dpms)Pt^{IV}Ph(X)OH$ exhibited C–X reductive elimination chemistry in the temperature range of 20–100 °C, results of this study may be important for understanding of factors affecting reactivity of hydrocarbyl Pt^{II} complexes toward O_2. When observed, aerobic oxidation of dipyridylmethanesulfonate monohydrocarbyl Pt^{II} complexes $(dpms)Pt^{II}R(HX)$ derived from water, methanol, and aniline (HX) leads to Pt^{IV} hydroxo complexes $(dpms)Pt^{IV}Ph(X)OH$. This reactivity depends both on the solvento ligand HX and the donicity of the hydrocarbyl R. Among phenyl Pt^{II} species, the anionic diphenyl complex is the most reactive, whereas aniline and DMSO adducts are inert: X = Ph > MeO ≈ HO » PhNH, DMSO. In turn, methyl derivatives are more reactive than their phenyl counterparts, R = Me > Ph; even the aniline adduct can be oxidized with O_2 when R = Me.

Experimental section

General

All manipulations were carried out under purified argon using standard Schlenk and glovebox techniques. All reagents for which synthesis is not given are commercially available from Sigma-Aldrich, Acros, Alfa Aesar, or Pressure Chemicals and were used as received without further purification. Potassium di(2-pyridyl)methanesulfonate was synthesized as described previously (2). DMSO-d_6, CD_3CN, DMF-d_7, and CD_3OD from Cambridge Isotope Laboratories were dried over CaH_2, vacuum-transferred, and stored in Teflon-sealed flasks in an argon-filled glovebox. Water was deaerated by repeating freezing-pumping cycles and stored under argon in a Teflon-sealed Schlenk flask in a glovebox. ^{1}H (400 MHz) and ^{13}C NMR (125 MHz) spectra were recorded on a Bruker AVANCE 400 or Bruker DRX-500 spectrometers. Chemical shifts are reported in ppm and referenced to residual solvent resonance peaks. IR spectra were recorded on a JASCO FT/IR 4100 spectrometer. ESI-MS experiments were performed using a JEOL AccuTOF-CS instrument. Elemental analyses were carried out by Chemisar Laboratories Inc., Guelph, Canada.[3]

Computational details

Theoretical calculations in this work have been performed using density functional theory (DFT) method (18), specifically functional PBE (19), implemented in an original program package "Priroda" (20). In PBE calculations, relativistic Stevens–Basch–Krauss (SBK) effective core potentials (ECP) (21), optimized for DFT calculations, have been used. Basis set was 311-split for main-group elements with one additional polarization p-function for hydrogen and additional two polarization d-functions for elements of higher periods. Full geometry optimization has been performed without constraints on symmetry. For all species under investigation, frequency analysis has been carried out.

[3] Caution: methanol flash point is 12 °C and is lower under pure O_2 atmosphere.

© 2008 NRC Canada

All minima have been checked for the absence of imaginary frequencies. All transition states possessed just one imaginary frequency. Using method of intrinsic reaction coordinate, reactants, products, and the corresponding transition states were proven to be connected by a single minimal energy reaction path.

Preparation of (dpms)Pt^{II}Ph(MeOH) (2)

(dpms)PtPh$_2$H (184 mg, 306 μmol), prepared according to the literature procedure (2), in MeOH (30 mL) was placed into a 100 mL Schlenk tube equipped with a stirring bar under an argon atmosphere, and the reaction mixture was stirred at 50 °C. Colourless solution formed after 5 h. The solution was filtered under argon, reduced in volume to 2–3 mL under vacuum, and the resulting suspension was cooled down to –20 °C. White precipitate of **2** was filtered, washed with cold methanol, and dried under vacuum for 12 h. Yield: 127 mg, 75%. White solid, oxidizes in air, poorly soluble in methanol, dissolves in water and DMSO with the loss of methanol ligand and formation of (dpms)PtPh(OH$_2$) and (dpms)PtPh(DMSO), respectively.

IR (KBr) ν: 3394 (w, br), 3046 (w), 2949 (w), 2764 (w), 1602 (w), 1572 (w), 1480 (w), 1438 (w), 1252 (m), 1168 (m), 1033 (s), 767 (m), 742 (m), 702 (m), 687 (m) cm^{-1}. ^{1}H NMR (CD$_3$OD, 22 °C) δ: 6.02 (s, 1H), 6.86–6.92 (m, 1H), 6.98 (vt, *J* = 7.5 Hz,), 7.04 (ddd, *J* = 7.8, 5.7, 1.5 Hz, 1H), 7.43 (dd, *J* = 7.5, 1.1 Hz, $^3J_{PtH}$ = 32 Hz, 2H), 7.62 (ddd, *J* = 7.9, 5.4, 1.6 Hz, 1H), 7.80 (dd, *J* = 7.9, 1.5 Hz, 1H), 7.94 (d, *J* = 7.8 Hz, 1H), 7.98 (td, *J* = 7.8, 1.6 Hz, 1H), 8.11 (td, *J* = 7.9, 1.7 Hz, 1H), 8.43 (dd, *J* = 5.7, 1.7 Hz, 1H), 8.81 (d, *J* = 5.4 Hz, 1H). ^{13}C spectrum of (dpms)PtPh(MeOH) could not be obtained due to its low solubility in methanol. ESI of dilute solution in methanol, *m*/*z* 554.1. Calculated for (dpms)Pt^{II}Ph(MeOH)·H$^+$, $C_{23}H_{21}N_3O_3{}^{195}$PtS: 554.1. Anal. found: C, 39.36; H, 3.47; N, 5.19. Calcd. for $C_{18}H_{19}N_2O_4$PtS: C, 39.06; H, 3.28; N, 5.06.

Preparation of (dpms)Pt^{II}Ph(OH$_2$) (3)

(dpms)PtPh(MeOH) (20 mg, 36 μmol) and 20 mL of deaerated water were placed into a 50 mL round-bottomed flask and stirred at room temperature until complete dissolution of the starting material. ^{1}H NMR spectrum of the sample diluted with D$_2$O recorded after 20 min showed complete conversion of **2** into (dpms)PtPh(OH$_2$) and 1 equiv. of methanol. The mixture was evaporated to dryness, and the resulting solid was dried under vacuum for 8 h. Yield: 19 mg, 97%. White solid, oxidizes in air, poorly soluble in water.

^{1}H NMR (D$_2$O, 22 °C) δ: 6.08 (s, 1H), 6.98–7.12 (m, 4H), 7.23 (d, *J* = 7.5 Hz, 2H), 7.63 (ddd, *J* = 7.7, 5.5, 1.3 Hz, 1H), 7.77 (dd, *J* = 7.7, 1.5 Hz, 1H), 7.89 (d, *J* = 7.9 Hz, 1H), 8.01 (td, *J* = 7.7, 1.6 Hz, 1H), 8.10 (td, *J* = 7.7, 1.5 Hz, 1H), 8.31 (dd, *J* = 6.0, 1.5 Hz, 1H), 8.74 (vd, *J* = 5.5 Hz, 1H). ^{13}C spectrum of (dpms)PtPh(OH$_2$) could not be obtained due to its low solubility in water. ESI of aqueous solution, acidified with HBF$_4$, *m*/*z* 540.1. Calculated for (dpms)PtPh(OH$_2$)·H$^+$, $C_{17}H_{17}N_2O_4{}^{195}$PtS: 540.1.

Preparation of (dpms)Pt^{II}Ph(NH$_2$Ph) (4)

(dpms)PtPh(MeOH) (65 mg, 117 μmol) was placed into a 10 mL vial equipped with a stirring bar. Deaerated methanol (2 mL) and 185 mg of aniline (2 mmol, 17 equiv.) were added, and a white suspension was stirred at RT. (dpms)PtPh(MeOH) dissolved after 10 min, and the target complex (dpms)PtPh(NH$_2$Ph) formed as large crystals. The reaction mixture was placed into a freezer at –20 °C for 4 h. White precipitate of **4** was filtered off, washed with 0.5 mL of cold methanol, and dried under vacuum for 12 h. Yield: 60 mg (97.6 μmol), 83%. White solid, poorly soluble in methanol and water.

IR (KBr) ν: 3494 (w, br), 3056 (w), 2828 (w), 1603 (w), 1573 (w), 1494 (w), 1436 (w), 1252 (m), 1222 (m) 1166 (m), 1031 (s), 757 (m), 686 (m) cm^{-1}. ^{1}H NMR (D$_2$O, 22 °C) δ: 6.00 (s, 1H), 6.94–7.00 (m, 1H), 7.01–7.16 (m, 6H), 7.20–7.27 (m, 3H), 7.31 (d, *J* = 7.1 Hz, $^3J_{PtH}$ = 40 Hz, 2H), 7.77 (vd, *J* = 7.8 Hz, 2H), 7.89 (td, *J* = 7.8, 1.4 Hz, 1H), 7.98 (td, *J* = 7.8, 1.6 Hz, 1H), 8.34 (dd, *J* = 6.0, 1.4 Hz, 1H), 8.43 (dd, *J* = 5.6, 1.6 Hz, 1H). ^{13}C spectrum of (dpms)PtPh(MeOH) could not be obtained due to its low solubility. ESI of solution in MeOH/H$_2$O (1:1 *v*/*v*), *m*/*z* 615.1. Calculated for (dpms)PtPh(NH$_2$Ph)·H$^+$, $C_{23}H_{22}N_3O_3{}^{195}$PtS: 615.1. Anal. found: C, 44.63; H, 3.27; N, 6.61. Calcd. for $C_{23}H_{21}N_3O_3$PtS: C, 44.95; H, 3.44; N, 6.84.

Preparation of (dpms)Pt^{II}Ph(dmso) (5)

(dpms)PtPh(MeOH) (55.6 mg, 100 μmol) and 5 mL of dry degassed DMSO were placed into a 25 mL Schlenk tube under an argon atmosphere. The reaction mixture was stirred for 1 h at RT to produce a clear solution. The solvent was removed by vacuum distillation. The resulting solid was washed with cold methanol and ether and dried under vacuum for 24 h at 65 °C. Yield: 51.1 mg, 85%. White solid, soluble in methanol and DMSO. The complex is stable in MeOH solutions at RT for several days; ligand exchange occurs in DMSO-d_6 solutions to give (dpms)PtPh(DMSO-d_6) ($\tau_{1/2}$ = 1.2 h at RT).

IR (KBr) ν: 3048 (w), 2924 (w), 1606 (w), 1574 (w), 1483 (w), 1435 (w), 1231 (m), 1167 (m), 1131 (m), 1031 (s), 765 (m), 685 (m) cm^{-1}. The ν(S=O) band of S-coordinated dimethylsulfoxide at 1131 cm^{-1} is missing in IR spectra of other Pt^{II} sulfonate complexes reported here. The frequency is typical for Me$_2$SO ligand coordinated to a metal through the sulfur atom (11) and similar to S=O frequency of (dpms)Pt(dmso)(OH) (1127 cm^{-1}) (6).

^{1}H NMR (CD$_3$OD, 22 °C) δ: 3.07 (s, $^3J_{195PtH}$ = 36 Hz, 3H), 3.19 (s, $^3J_{195PtH}$ = 30 Hz, 3H), 6.17 (s, 1H), 6.90 (td, *J* = 7.3, 1.3 Hz, 1H), 7.01 (t, *J* = 7.3, 1.3 Hz, 1H), 7.17–7.27 (m, 2H), 7.39 (d, *J* = 7.3, $^3J_{195PtH}$ = 40 Hz, 1H), 7.58 (ddd, *J* = 7.9, 5.5, 1.3 Hz, 1H), 7.70 (d, *J* = 7.3 Hz, $^3J_{195PtH}$ = 35 Hz, 1H), 7.95 (d, *J* = 7.9 Hz, 1H), 7.98 (d, *J* = 7.9 Hz, 1H), 8.04 (td, *J* = 7.9, 1.5 Hz, 1H), 8.12 (td, *J* = 7.9, 1.5 Hz, 1H), 8.30 (dd, *J* = 5.5, 1.5 Hz, $^3J_{195PtH}$ = 55 Hz, 1H), 9.11 (dd, *J* = 5.5, 1.5 Hz, $^3J_{195PtH}$ = 23 Hz, 1H). ^{1}H NMR (DMSO-d_6, 22 °C) δ: 3.06 (s, $^3J_{195PtH}$ = 30 Hz, 3H), 3.09 (s, $^3J_{195PtH}$ = 30 Hz, 3H), 6.20 (s, 1H), 6.86 (td, *J* = 7.4, 1.5 Hz, 1H), 6.97 (t, *J* = 7.4, 1H), 7.16 (td, *J* = 7.4, 1.5 Hz, 1H), 7.28 (ddd, *J* = 7.9, 5.5, 1.1 Hz, 1H), 7.35 (d, *J* = 7.4, $^3J_{195PtH}$ = 30 Hz, 1H), 7.58 (ddd, *J* = 7.9, 5.5, 1.1 Hz, 1H), 7.62 (d, *J* = 7.4, $^3J_{195PtH}$ = 30 Hz, 1H), 7.90 (d, *J* = 7.9 Hz, 1H), 7.93 (d, *J* = 7.9 Hz, 1H), 8.06 (td, *J* = 7.9, 1.4 Hz, 1H), 8.10–8.17 (m, 2H), 8.98 (dd, *J* = 5.5, 1.4 Hz, 1H). ^{13}C NMR (DMSO-d_6, 22 °C) δ: 43.8 (CH$_3$), 44.4 (CH$_3$), 75.4, 124.1, 124.4, 127.3, 128.1 (Cq), 128.2, 129.3, 136.3, 137.3, 140.1,

© 2008 NRC Canada

140.8, 151.5, 152.5 (Cq), 153.2, 154.0 (Cq). Carbon assignments were made from DEPT experiments. ESI of solution in methanol acidified with HBF_4, *m/z* 600.1. Calculated for (dpms)PtPh(Me_2SO)·H^+, $C_{19}H_{21}N_2S_2O_4{}^{195}Pt$: 600.1. (dpms)PtPh(DMSO-d_6): ESI of solution in methanol acidified with HBF_4, *m/z* 606.1. Calculated for (dpms)PtPh((CD_3)$_2$SO)·H^+, $C_{19}H_{15}D_6N_2S_2O_4{}^{195}Pt$: 606.1.

Preparation of (dpms)$Pt^{II}Me(NH_2Ph)$ (6)

Solution of (dpms)PtMe(MeOH) (192 μmol) in deaerated methanol (10 mL), prepared from isomeric hydrides (dpms)$PtMe_2H$ (91.4 mg, 192 μmol) (5), was placed in a 50 mL Schlenk tube and combined with distilled aniline (18.1 mg; 194 μmol, 1.01 equiv.). The mixture was stirred at room temperature for 15 min. According to ^{1}H NMR, ligand exchange was complete in 15 min. The reaction mixture was evaporated to dryness; the resulting colourless solid was washed with ether and dried under vacuum for 6 h. Yield: 92.9 mg, 87%. White solid, soluble in methanol and water, slowly oxidizes in air.

^{1}H NMR (D_2O, 22 °C) δ: 0.79 ($^2J_{195PtH}$ = 72 Hz, 3H), 5.91 (s, 1H), 7.05–7.33 (m, 6H), 7.38 (m, 1H), 7.74 (vd, *J* = 7.8 Hz, 2H), 7.88 (vt, *J* = 7.8 Hz, 1H), 8.03 (vt, *J* = 7.8 Hz, 1H), 8.14 (d, *J* = 5.5 Hz, 1H), 8.73 (d, *J* = 5.9 Hz, $^3J_{195PtH}$ = 56 Hz, 1H). ESI-MS of aqueous solution of (dpms)PtMe(NH_2Ph), *m/z* observed: 553.1. Calcd. for (dpms)PtMe(NH_2Ph)·H^+, $C_{18}H_{20}N_3SO_3{}^{195}Pt$: 553.1.

Preparation of *sym*-(dpms)$Pt^{IV}Ph_2OH$ (7) by oxidation of K(dpms)$Pt^{II}Ph_2$ (1) with O_2

K[(dpms)$PtPh_2$] (55.9 mg, 88 μmol) (2) was dissolved in 2 mL of deaerated water and placed into a 10 mL vial equipped with a magnetic stirring bar. The vial was filled with O_2, and the solution was stirred at room temperature for 2 h. No K(dpms)$PtPh_2$ was detected in solution after that time; the solution pH was ~12. White precipitate was filtered off and washed with water until neutral reaction of the filtrate. The product was dried under vacuum for 6 h. Yield: 47.0 mg, 87%. White solid, soluble in dichloromethane and DMSO, insoluble in water.

IR (KBr) ν: 3583 (w, br), 3055 (w), 2981 (w), 1604 (w), 1574 (w), 1472 (w), 1449 (w), 1294 (m), 1203 (w), 1143 (s), 1025 (m), 981 (s), 736 (m), 695 (m) cm^{-1}. ^{1}H NMR (DMSO-d_6, 22 °C) δ: 2.56 (br s, $^2J_{195PtH}$ = 36 Hz, 1H), 6.89 (s, 1H), 6.92–7.04 (m, 6H), 7.34 (dd, *J* = 8.0, 1.7 Hz, $^3J_{195PtH}$ = 30 Hz, 4H), 7.65 (ddd, *J* = 7.8, 5.5, 1.2 Hz, 2H), 8.08 (d, *J* = 7.8 Hz, 2H), 8.23 (td, *J* = 7.8, 1.5 Hz, 2H), 8.30 (dd, *J* = 5.5, 1.5 Hz, 2H). ^{13}C NMR (DMSO-d_6, 22 °C) δ: 70.7, 124.9, 125.9, 126.4 (Cq), 126.5, 127.3, 130.9, 141.8, 149.6, 151.4 (Cq). Quaternary carbon assignments are from DEPT experiment. ESI of solution in MeOH/CH_2Cl_2 (1:1 *v/v*) acidified with HBF_4, *m/z* 616.1. Calculated for (dpms)$PtPh_2$(OH)·H^+, $C_{23}H_{21}N_2SO_4{}^{195}Pt$: 616.1. Anal. found: C, 44.81; H, 3.45; N, 4.24. Calcd. for $C_{23}H_{20}N_2O_4PtS$: C, 44.88; H, 3.27; N, 4.55.

Preparation of *unsym*-(dpms)$Pt^{IV}Ph(OH)_2$ (8) by oxidation of (dpms)$Pt^{II}Ph(OH_2)$ with O_2

(dpms)PtPh(MeOH) (99.1 mg, 179 μmol) and 100 mL of deaerated water were placed into 250 mL round-bottomed flask. This suspension was stirred for 30 min under argon. Resulting clear solution was stirred under O_2 at room temperature. After 48 h, the solution was reduced in volume to 1 mL under vacuum. Resulting suspension was left at 5 °C for 1 h. White precipitate was filtered off, washed with 0.5 mL of cold water, and dried under vacuum for 8 h. Yield: 92.3 mg, 93%. White solid, very soluble in water, methanol, and DMSO.

IR (KBr) ν: 3548 (w, br), 3070 (w), 2928 (w), 1607 (w), 1574 (w), 1481 (w), 1445 (w), 1301 (m), 1210 (w), 1142 (s), 1027 (w), 966 (s), 737 (m), 698 (s) cm^{-1}. ^{1}H NMR (DMSO-d_6, 22 °C) δ: 1.45 (br s, 1H), 2.99 (br s, $^2J_{195PtH}$ = 30 Hz, 1H), 6.93 (s. 1H), 7.03–7.23 (m, 5H), 7.60 (ddd, *J* = 7.8, 5.5, 1.3 Hz, 1H), 7.88–8.00 (m, 2H), 8.06 (dd, *J* = 7.8, 1.3 Hz, 1H), 8.09 (d, *J* = 7.8 Hz, 1H), 8.26 (td, *J* = 7.8, 1.5 Hz, 1H), 8.33 (td, *J* = 7.8, 1.5 Hz, 1H), 8.96 (dd, *J* = 5.5, 1.5 Hz, 1H). ^{1}H NMR (D_2O, 22 °C) δ: 6.84 (s, 1H), 7.03 (d, *J* = 8.0 Hz, $^3J_{195PtH}$ = 20 Hz, 2H), 7.22–7.35 (m, 3H), 7.58 (ddd, *J* = 7.9, 5.9, 1.3 Hz, 1H), 7.97 (ddd, *J* = 7.9, 5.5, 1.2 Hz, 1H), 8.03 (dd, *J* = 5.9, 1.4 Hz, 1H), 8.10 (dd, *J* = 7.9, 1.3 Hz, 1H), 8.16 (d, *J* = 7.9 Hz, 1H), 8.29 (td, *J* = 7.9, 1.4 Hz, 1H), 8.35 (td, *J* = 7.9, 1.4 Hz, 1H), 8.95 (dd, *J* = 5.5, 1.4 Hz, 1H). ^{13}C NMR (DMSO-d_6, 22 °C) δ: 70.7, 125.6, 126.2, 126.5, 126.8, 127.1, 127.3 (Cq), 127.6, 132.2, 141.9, 142.7, 148.3, 149.5 (Cq), 151.1, 152.7 (Cq). Quaternary carbon assignments are from DEPT experiment. ESI of solution in MeOH/H_2O (1:1 *v/v*) acidified with HBF_4, *m/z* 556.1. Calculated for (dpms)PtPh(OH)$_2$·H^+, $C_{17}H_{17}N_2SO_5{}^{195}Pt$: 556.1. Anal. found: C, 36.48; H, 3.29; N, 4.74. Calcd. for $C_{17}H_{16}N_2O_5PtS$: C, 36.76; H, 2.90; N, 5.04.

Preparation of (dpms)$Pt^{IV}Ph(OMe)(OH)$ (9) by oxidation of (dpms)$Pt^{II}Ph$(MeOH) with O_2

(dpms)PtPh(MeOH) (98.2 mg, 177 μmol) in 75 mL of dry methanol was placed into a 250 mL round-bottomed flask equipped with a magnetic stirring bar. The flask was filled with O_2, and the reaction mixture was stirred vigorously at RT. After 40 h, the clear solution was reduced in volume to ~0.3 mL under vacuum. Resulting suspension was left at –20 °C for 1 h. White precipitate was filtered off, washed with small amount of cold methanol, and dried under vacuum for 12 h. Yield: 91.8 mg, 91%. White solid, soluble in methanol and DMSO.

(dpms)PtPh(OCH_3)(OH)·H^+, $C_{18}H_{19}N_2SO_5{}^{195}Pt$: 570.1. Anal. found: C, 37.79; H, 3.41; N, 4.77. Calcd. for $C_{18}H_{18}N_2O_5PtS$: C, 37.96; H, 3.19; N, 4.92.

Attempted oxidation of (dpms)Pt^{II}Ph(NH_2Ph) (4) and (dpms)Pt^{II}Ph(dmso) (5) with O_2

Solution of (dpms)PtPh(NH_2Ph) (2 mg, 3 μmol) in 2 mL of CD_3OD was placed into a 10 mL round-bottomed flask equipped with a magnetic stirring bar. The flask was filled with oxygen, and the solution was stirred vigorously at room temperature. According to ^{1}H NMR, the starting material remained unchanged after 7 days. No traces of (dpms)Pt^{IV}Ph(NHPh)(OH) or other products were detected in the solution by ESI-MS; no precipitate formed.

An analogous procedure was used for attempted oxidation of (dpms)PtPh(dmso) (2 mg, 3 μmol) in CD_3OD (1 mL) with O_2. According to ^{1}H NMR, after 7 days of stirring under O_2 at RT, only starting material (dpms)Pt^{II}Ph(dmso) was present in solution; no other products were detected in the amounts exceeding 2%; no precipitate formed.

Preparation of (dpms)Pt^{IV}Ph(NHPh)(OH) (10)

(dpms)PtPh(NH_2Ph) (53.8 mg, 87.5 μmol) and 2 mL of MeOH were placed into a 10 mL vial equipped with a stirring bar, and 25 μL of 30% aq. H_2O_2 were added slowly upon stirring. Stirring continued for 1 h at RT. Solid (dpms)PtPh(NH_2Ph) dissolved, and reddish solution formed. The yield of **10** is quantitative according to ^{1}H NMR spectroscopy. Ether (2 mL) was slowly added to the solution, and the resulting mixture was stored for 1 day at RT. Crystalline precipitate of (dpms)PtPh(NHPh)(OH) was filtered off, washed with ether and pentane; yield: 36 mg. An additional fraction of the product was obtained by evaporation of the filtrate. Dry solid was washed with water (10 mL), ether (5 mL), and pentane (5 mL) and dried under vacuum for 10 h; yield: 13.9 mg. Combined yield: 50 mg (79 μmol), 90%.

IR (KBr) ν: 3555 (w, br), 3050 (w), 2970 (w), 1592 (w), 1574 (w), 1489 (w), 1298 (m), 1207 (w), 1145 (s), 1026 (m), 980 (s), 760 (s), 695 (s) cm^{-1}. ^{1}H NMR (DMSO-d_6, 22 °C) δ: 3.01 (br s, 1H), 4.36 (br s, 1H), 6.28–6.40 (m, 1H), 6.44–6.70 (m, 4H), 6.95 (s, 1H), 6.97–7.06 (m, 3H), 7.07–7.27 (m, 2H), 7.59 (ddd, J = 7.8, 5.5, 1.1 Hz, 1H), 7.78–7.84 (m, 1H), 7.97 (d, J = 5.5 Hz, 1H), 8.08 (d, J = 7.8 Hz, 1H), 8.10 (d, J = 7.8 Hz, 1H), 8.25 (td, J = 7.8, 1.3 Hz, 1H), 8.29 (td, J = 7.8, 1.3 Hz, 1H), 8.90 (d, J = 4.3 Hz, 1H). ^{1}H NMR (CD_3OD, 22 °C) δ: 6.57 (s, 1H), 6.65–6.79 (m, 3H), 6.92 (d, J = 7.8 Hz, 2H), 7.02–7.13 (m, 3H), 7.19 (dd, J = 7.7, 1.9 Hz, $^3J_{195PtH}$ = 23 Hz, 2H), 7.45–7.54 (m, 2H), 8.03 (d, J = 7.8 Hz, 1H), 8.04 (d, J = 7.6 Hz, 1H), 8.08 (d, J = 5.8 Hz, 1H), 8.13 (td, J = 7.8, 1.5 Hz, 1H), 8.17 (td, J = 7.6, 1.5 Hz, 1H), 8.60 (d, J = 5.6 Hz, 1H). ^{13}C NMR (DMSO-d_6, 22 °C) δ: 70.4, 115.6, 118.7, 125.4, 125.8, 126.3, 126.8, 127.2, 127.7, 127.8, 128.2 (Cq), 131.6, 141.8, 142.6, 149.0, 150.0 (Cq), 150.9, 152.1 (Cq), 155.4 (Cq). Quaternary carbon assignments were made based on DEPT experiment. ESI of solution in methanol, m/z 631.1. Calculated for (dpms)PtPh(NHPh)(OH)·H^+, $C_{23}H_{22}N_3O_4{}^{195}PtS$: 631.1. Preparation of (dpms)Pt^{IV}Me(NHPh)(OH) (11)

Distilled aniline (33.3 mg, 358 μmol, 1.2 equiv.) was added to a solution of (dpms)PtMe(MeOH) prepared from 140.1 mg (295 μmol) isomeric hydrides (dpms)$PtMe_2H$ and 15 mL MeOH (5). According to ^{1}H NMR, the ligand exchange was complete in 15 min to give (dpms)PtMe(NH_2Ph), which was used in the next step without isolation. The mixture was placed into an ice bath; 35 mg of 30% H_2O_2 (~308 μmol) were slowly added to the stirred reaction mixture. Mixture turned yellow immediately after addition of H_2O_2. According to ^{1}H NMR, oxidation was complete in less than 15 min to give (dpms)PtMe(NHPh)(OH) quantitatively. The resulting solution was reduced in volume to 2 mL; the product was precipitated with 6 mL of ether, filtered off, and dried under vacuum for 3 h. Yield: 106.2 mg, 63%. The product is soluble in methanol, DMSO, and water; aqueous solutions have weakly basic reaction (pH ~9).

IR (KBr) ν: 3548 (w, br), 3087 (w), 2973 (w), 1592 (w), 1489 (w), 1448 (w), 1296 (m), 1212 (m), 1154 (s), 980 (m), 750 (m), 688 (m) cm^{-1}. ^{1}H NMR (DMSO-d_6, 22 °C) δ: 2.22 (br s, 1H), 4.17 (br s, 1H), 6.40–6.87 (m, 5H), 7.26 (s, 1H), 7.68–7.77 (m, 1H), 7.80 (ddd, J = 7.9, 5.7, 1.2 Hz, 1H), 8.02 (d, J = 7.9 Hz, 1H), 8.06 (d, J = 7.9 Hz, 1H), 8.23 (td, J = 7.9, 1.9 Hz, 1H), 8.30 (td, J = 7.9, 1.2 Hz, 1H), 8.63 (dd, J = 5.7, 1.2 Hz, 1H), 8.67–8.77 (m, 1H). ^{1}H NMR (CD_3OD, 22 °C) δ: 2.19 ($^2J_{195PtH}$ = 68 Hz, 3H), 6.49 (s, 1H), 6.82 (m, 1H), 6.90 (m, 2H), 7.07 (d, J = 7.7 Hz, 2H), 7.41 (ddd, J = 7.7, 5.8, 1.1 Hz, 1H), 7.77 (ddd, J = 8.0, 5.8, 1.2 Hz, 1H), 7.96 (d, J = 7.7 Hz, 1H), 8.02 (d, J = 7.7 Hz, 1H), 8.07 (td, J = 7.7, 1.5 Hz, 1H), 8.23 (td, J = 7.7, 1.5 Hz, 1H), 8.33 (d, J = 5.8 Hz, 1H), 8.67 (d, J = 5.8 Hz, 1H). ^{13}C NMR (DMSO-d_6, 22 °C) δ: 2.2 ($^1J_{195PtC}$ = 606 Hz), 70.4, 116.0, 119.4, 125.8, 126.7, 126.9, 128.0, 128.2, 141.5, 142.4, 148.3, 149.7, 150.0, 152.2, 155.8. Calcd. for $C_{18}H_{19}O_4N_3PtS$, H, 3.37; C, 38.03; N, 7.39; S, 5.64.

Oxidation of (dpms)Pt^{II}Me(NH_2Ph) (6) with O_2

(dpms)Pt^{II}Me($PhNH_2$) (40 mg, 72 μmol) and 10 mL of water were placed into a 50 mL round-bottomed flask equipped with a magnetic stirring bar. The flask was filled with O_2, and the solution was stirred vigorously under O_2 atmosphere at room temperature. According to ^{1}H NMR spectroscopy, slow oxidation occurred to give (dpms)PtMe(NHPh)(OH) as the only Pt^{IV} product. The reaction half-life is ~30 h at RT. Signals corresponding to protonated starting material (m/z 553.1) and oxidation product (dpms)Pt^{IV}Me(NHPh)(OH) (m/z 569.1) were detected by ESI-MS.

Isomerization of unsym-(*dpms*)Pt^{IV}Ph$(OH)_2$ (unsym-8) into sym-(dpms)Pt^{IV}Ph$(OH)_2$ (sym-8)

Solution of *unsym*-(dpms)PtPh$(OH)_2$ (103 mg, 180 μmol) in water (30 mL) was placed into a 50 mL round-bottomed flask equipped with a magnetic stirring bar and a condenser. The mixture was heated at 100 °C. After 70 h, the reaction mixture was reduced in volume to ~1 mL under vacuum and

Attempted reductive elimination from *sym*-(dpms)Pt^{IV}Ph$_2$(OH) (*sym*-7) in DMSO-d_6 solution

A sample of *sym*-(dpms)PtPh$_2$(OH) (2 mg, 3.2 μmol) was dissolved in dry DMSO-d_6 (0.7 mL), and solution was placed into an NMR Young tube under an argon atmosphere. The Young tube was heated at 100 °C in a silicon-oil bath. The only reaction observed was isomerization of **7** into corresponding unsymmetrical isomer (half-life is 26 h). After 6 days, the isomerization was complete, yield of *unsym*-**7** > 97% by ^{1}H NMR spectroscopy. No biphenyl or phenol were detected.

^{1}H NMR (DMSO-d_6, 22 °C) δ: 1.37 (br s, 1H), 6.65 (d, *J* = 8.2 Hz, $^3J_{195PtH}$ = 44 Hz, 2H), 6.78 (s, 1H), 6.88–7.12 (m, 6H), 7.20–7.39 (m, 2H), 7.59 (ddd, *J* = 7.9, 5.9, 1.5 Hz, 1H), 7.65 (ddd, *J* = 7.9, 5.7, 1.3 Hz, 1H), 8.00 (dd, *J* = 5.7, 1.5 Hz, 1H), 8.08 (d, *J* = 7.9 Hz, 1H), 8.14 (dd, *J* = 7.9, 1.5 Hz, 1H), 8.20 (dd, *J* = 5.9, 1.5 Hz, 1H), 8.25 (td, *J* = 7.9, 1.5 Hz, 1H), 8.34 (td, *J* = 7.9, 1.5 Hz, 1H). ^{13}C NMR (DMSO-d_6, 22 °C), δ: 71.9, 124.3, 125.1, 125.5, 125.8, 126.9, 127.1, 127.3, 127.4, 128.4, 128.7, 132.7, 133.8, 141.6, 142.6, 148.7, 150.3, 152.7, 152.9.

Attempted reductive elimination from *sym*-(dpms)Pt^{IV}Ph(OH)$_2$ (*sym*-8)

Four samples of *sym*-(dpms)PtPh(OH)$_2$ (2.5 mg each, 4.5 μmol) were dissolved in neutral D_2O (0.8 mL), 50 mmol/L solution of HBF_4 in D_2O (0.8 mL), 11 mmol/L NaOD/D_2O solution (0.8 mL), and DMSO-d_6 (0.8 mL) under argon. The solutions were placed into NMR Young tubes and Teflon-sealed. Residual solvent peaks were used as internal standards. The solutions were heated at 100 °C. According to ^{1}H NMR spectroscopy, concentration of *sym*-(dpms)PtPh(OH)$_2$ remained unchanged after 5 days; no products were detected by ^{1}H NMR.

Attempted reductive elimination from (dpms)Pt^{IV}Ph(OH)(OMe) (9)

Reaction in DMSO-d_6

A sample of (dpms)PtPh(OMe)(OH) (2 mg, 3.5 μmol) was dissolved in 0.7 mL of DMSO-d_6. The solution was placed into an NMR Young tube and Teflon-sealed under argon. The solution was heated at 80–100 °C, periodically cooled down to room temperature and analyzed by ^{1}H NMR. Slow reaction occurred at 80 °C with a half-life of ~47 h. The reaction continued at 100 °C with a half-life of 4.5 h; quantitative formation of only one platinum-containing product, (dpms)PtPh(DMSO-d_6), was observed. ^{1}H NMR of the product was identical to that of (dpms)PtPh(DMSO-d_6) obtained by dissolving (dpms)Pt(MeOH) in DMSO-d_6; ESI of acidified solution diluted with methanol showed the presence of a signal with *m/z* = 606.1 (calcd. For (dpms)PtPh(C_2D_6SO)H$^+$, $C_{19}H_{15}D_6N_2S_2O_4{}^{195}$Pt, *m/z* 606.1). One equivalent of methanol was released into solution, according to ^{1}H NMR spectroscopy.

Reactions in DMF-d_7 *and* CD_3CN

Analogous procedure was applied to reactions in DMF-d_7 and CD_3CN as solvents. NMR Young tubes with the samples were heated at 100 °C and periodically monitored by ^{1}H

© 2008 NRC Canada

NMR. Formation of a complex mixture of unidentified products was evident by ^{1}H NMR spectroscopy.

Attempted reductive elimination from (dpms)Pt^{IV}Ph(NHPh)(OH) (10)

Reaction in CD_3CN

A sample of (dpms)PtPh(NHPh)(OH) (3 mg, 5 μmol) and 0.7 mL of CD_3CN were placed into an NMR Young tube and Teflon-sealed under argon. The reaction mixture was heated at 80 °C for 5 h; dark precipitate and dark-coloured solution formed. The only product present in the solution after 5 h was (dpms)PtPh(CD_3CN), according to ^{1}H NMR spectroscopy and ESI-MS. Characteristics of the product are identical to those of (dpms)PtPh(CD_3CN) obtained by dissolving (dpms)PtPh(MeOH) in CD_3CN.

^{1}H NMR (CD_3CN, 22 °C) δ: 5.82 (s, 1H), 6.92–7.03 (m, 4H), 7.24 (dd, J = 7.5, 1.5 Hz, $^3J_{195PtH}$ = 45 Hz, 2H), 7.52 (ddd, J = 7.9, 5.5, 1.5 Hz, 1H), 7.74 (dd, J = 7.9, 1.5 Hz, 1H), 7.85 (d, J = 7.9 Hz, 1H), 7.97 (td, J = 7.9, 1.5 Hz, 1H), 8.07 (td, J = 7.9, 1.5 Hz, 1H), 8.15 (dd, J = 5.7, 1.5 Hz, $^3J_{195PtH}$ = 63 Hz, 1H), 8.85 (dd, J = 5.5, 1.5 Hz, 1H). ESI of acidified solution diluted with methanol exhibited only one peak, m/z 566.1 (Calcd. for (dpms)^{195}PtPh(CD_3CN)H$^+$, $C_{19}H_{15}D_3N_3O_3{}^{195}$PtS: 566.1).

The precipitate formed in the reaction mixture was dissolved in DMSO-d_6; ^{1}H NMR spectrum of the resulting solution showed the presence of a complex mixture of unidentified products. No diphenylamine was detected by ^{1}H NMR.

Reaction in DMF-$\mathbf{d_7}$

Upon heating at 60 °C, the starting material slowly disappeared, and an insoluble product formed. After heating the sample at 80 °C for 24 h, complex mixture of product formed in DMF-d_7 solution and a dark precipitate.

X-ray structure determinations

The X-ray intensity data were measured at 220(2) K (0 K = 273.15 °C) on a three-circle diffractometer system equipped with Bruker Smart1000 CCD area detector using a graphite monochromator and a Mo Kα fine-focus sealed tube (λ = 0.71073 Å) operated at 50 kV and 40 mA. Details of the data collections and structure refinements are given in Table 1. Supplementary information for this article is available on the Web.[4]

The synthesis and X-ray crystal structures of rare earth(III) perfluoroadipate complexes — Novel coordination polymers[1]

Glen B. Deacon, Winfried Elgersma, Rita Harika, Peter C. Junk, Brian W. Skelton, and Allan H. White

Abstract: A representative series of polymeric hydrated lanthanoid perfluoroadipates $[Ln_2(pfad)_3(H_2O)_n]\cdot mH_2O$ (Ln = La, Ce, Nd, Gd, Yb) has been prepared from the reaction of perfluoroadipic acid with either the appropriate lanthanoid oxide or $Ce_2(CO_3)_3$ in water. X-ray crystal structures showed $[Ln_2(pfad)_3(H_2O)_{10}]\cdot 4H_2O$ (La, Nd) to be two-dimensional inorganic polymers, which contain nine-coordinate Ln atoms to which are attached five water molecules and four carboxylate oxygen atoms. Two pfad ligands bridge two Ln atoms through one carboxylate group, the other being free, whilst one pfad ligand bridges four Ln atoms in a μ_4-($\eta^1,\eta^1/\eta^1,\eta^1$) manner. In two-dimensional polymeric $[Yb_2(pfad)_2(H_2O)_8](pfad)\cdot 6H_2O$, each eight-coordinate ytterbium atom has four water ligands and four carboxylate oxygen donor atoms. The two carboxylate ligands bind in a μ_4-($\eta^1,\eta^1/\eta^1,\eta^1$) manner, and there is one pfad counter-ion per two ytterbium atoms. These structures show features quite different from those of many lanthanoid adipate complexes $[Ln_2(ad)_3(H_2O)_n]\cdot mH_2O$, but there is no F-Ln coordination. From the reaction of $[Nd_2(pfad)_3(H_2O)_{10}]\cdot 4H_2O$ with benzene-1,2-disulfonic acid (H_2bds), the mixed ligand complex $[Nd_2(bds)_2(pfad)(H_2O)_8]$ was isolated. This is a one-dimensional polymer featuring $Nd_2(bds)_2$ units linked together by μ-η^2,η^2 pfad ligands. Each Nd atom is nine-coordinate with three sulfonate oxygen donors, two carboxylate oxygen atoms, and four water ligands, and the bds ligands bind in the new μ-$\eta^2(O,O')$,$\eta^1(O'')$ manner for Ln complexes. Surprisingly, $[Na_2pfad]$ was isolated unhydrated from water, the six-coordinate Na atoms being coordinated by four carboxylate oxygen atoms and two (C)-F atoms in an octahedral array. The ligands are duodecadentate, each $-CF_2CO_2$ unit binding to five different sodium ions through four oxygen and one α-F atom with the second α-F atom bound to a sodium ion in a OC(O)CF-Na chelate ring.

Key words: rare earths, lanthanoid, X-ray crystal structures, adipates, carboxylates.

Résumé : On a préparé une série représentative de perfluoroadipates de lanthanoïdes hydratés et polymères $[Ln_2(pfad)_3(H_2O)_n]\cdot mH_2O$ (Ln = La, Ce, Nd, Gd, Yb) en faisant réagir de l'acide perfluoroadipique avec l'oxyde de lanthanoïde approprié ou avec du $Ce_2(CO_3)_3$ dans l'eau. Les structures cristallines déterminées par diffraction des rayons X montrent que les dérivés $[Ln_2(pfad)_3(H_2O)_{10}]\cdot 4H_2O$ (Ln = La, Nd) sont des polymères inorganiques bidimensionnels qui contiennent des atomes de Ln nonacoordinés auxquels sont liés cinq molécules d'eau et quatre atomes d'oxygène provenant du carboxylate. Deux ligands pfad servent de pont entre deux atomes de Ln par le biais d'un groupe carboxylate et l'autre est libre alors qu'un ligand pfad sert de pont à quatre atomes de Ln d'une manière $\mu_4(\eta^1,\eta^1/\eta^1,\eta^1)$. Dans le composé $[Yb_2(pfad)_2(H_2O)_8)\cdot 6H_2O$, chaque atome d'ytterbium octacoordiné est associé à quatre molécules d'eau agissant comme ligands alors que quatre atomes d'oxygène de groupes carboxylates agissent comme donneurs. Les deux ligands carboxylates se lient d'une façon $\mu_4(\eta^1,\eta^1/\eta^1,\eta^1)$ et il y a un contre ion pfad pour deux atomes d'ytterbium. Ces structures présentent des caractéristiques fort différentes de celles observées avec plusieurs complexes de $[Ln_2(ad)_3(H_2O)_n]\cdot mH_2O$, mais on n'observe aucune coordination F-Ln. La réaction du $[Nd_2(pfad)_3(H_2O)_{10}]\cdot 4H_2O$ avec l'acide benzène-1,2-disulfonique (H_2bds) permet d'isoler le complexe $[Nd_2(bds)_2(pfad)(H_2O)_8]$. Ce produit est un polymère unidimensionnel comportant des unités $Nd_2(bds)_2$ liées ensemble par des ligands pfad μ-η^2,η^2. Chaque atome de Nd est nonacoordiné par trois atomes d'oxygène donneurs du sulfonate, deux atomes d'oxygène de carboxylate et

quatre ligands d'eau alors que les ligands bds se lient d'une nouvelle façon, μ-η^2(O,O′),η^1(O,O″), D'une façon surprenante, le produit [Na_2pfad] a pu être isolé non hydraté à partir d'une solution aqueuse et les six atomes de sodium sont coordinés d'une façon octaédrique par quatre atomes d'oxygène de carboxylates et deux atomes (C)–F. Les ligands sont des duodécadentate dans lesquels chaque unité $-CF_2CO_2$ se lie à cinq ions sodium différents par le biais de quatre atomes d'oxygène et un atome α de fluor et un deuxième atomes α de fluor qui est lié à un ion sodium dans un noyau chélate de structure OC(=O)CFNa.

[Traduit par la Rédaction]

Introduction

Carboxylate ions are popular ligands for lanthanoid ions (1–5), as their binding mode versatility makes them suitable to satisfy the high coordination appetite of the large lanthanoid ions (6). Di- and poly-carboxylate ions are common building blocks for the construction of molecular frameworks and coordination polymers (7–9), including those of lanthanoid ions (4, 10). The use of aromatic carboxylates optimizes control in crystal engineering owing to their structural rigidity. Nevertheless, the flexibility of alkanedicarboxylates is an attraction in building rare earth polymeric coordination networks. Thus, adipate (hexanedioate) ions have given rise to a wide range of rare earth polymers (11–22), even based on "simple" hydrated rare earth adipates [$Ln_2(ad)_3(H_2O)_n$]. Thus, the following crystallographically distinct species have been defined: [$Ln_2(ad)_3(H_2O)_4$]·$6H_2O$ (Ln = Pr (12, 14), Nd (12, 14), La (11), Ce (12, 13)), [$Ln_2(ad)_3(H_2O)_4$]·H_2O (Ln = Nd, Sm (12)), [$Ln_2(ad)_3(H_2O)_4$] (Ln = Gd (12), Eu (15), Dy (16)), [$Ln_2(ad)_3(H_2O)_2$]·$4H_2O$·H_2ad (Ln = Nd (17–19), Pr, Ce (13), La (17)), [$Nd_2(ad)_3(H_2O)_2$]·H_2O (14, 20), [$Ln_2(ad)_3(H_2O)_2$] (Ln = Nd (20), Ce (21)), [$Ln_2(ad)_3(H_2O)_2$]·bpy (Ln = Pr (18), Eu (22), bpy = 4,4′-bipyridine), [$Pr_4(ad)_6(H_2O)_4$]·H_2O (18), [$Eu_4(ad)_6(H_2O)_2$]·$2H_2O$ (15). In addition, the complexes [Ln(ad)(H_2O)$_5$]X (Ln = Gd, Er; X = NO_3; Ln = Er, X = Cl (17)) have been isolated, as well as a mixed oxalate–adipate complex (23) and a mixed metal (La–Cu) species (24). The coordination number nine predominates with occasional examples of ten (14, 19–21) and a mixed eight- and nine-coordinate complex (17). Early to mid lanthanoid elements dominate the complexes studied, but nine-coordinate [Er(ad)(H_2O)$_4$]X (X = Cl, NO_3) complexes, a different composition, provide exceptions.

We now report a detailed study of the structures of lanthanoid perfluoroadipates encompassing virtually the whole range of Ln^{3+} sizes, as well as the structure of sodium perfluoroadipate, a metathesis synthon, and a mixed perfluoroadipate–benzene-1,2-disulfonate complex. As perfluoroadipic acid is a much stronger acid than adipic acid, reduced donor properties of the carboxylate groups might be expected and might impinge on coordination polymer formation. In addition, C-F-Ln binding is possible, as has been previously detected for perfluoroalkyl groups (25,26), and it is known that in encapsulation of La^{3+} in a cage with fluoroaromatic, and N and O donors, F–La bonds are shorter than N(O)–La bonds (27).

Results and discussion

Syntheses

Initially studied in this work was the preparation and structural characterization of the sodium salt of perfluoroadipic acid [Na_2(pfad)] (**1**), which was conveniently prepared by the treatment of perfluoroadipic acid with NaOH in ethanol (eq. [1]). Colourless single crystals were obtained upon slow evaporation of the reaction mixture.

$$[1] \quad 2NaOH + H_2pfad \xrightarrow{EtOH} [Na_2(pfad)] + 2H_2O$$

The compound was originally intended as a metathesis reagent for the synthesis of lanthanoid perfluoroadipates, but a more convenient route based on the high acidity of perfluoroadipic acid is now preferred.

Treatment of Ln_2O_3 or $Ce_2(CO_3)_3$ with perfluoroadipic acid in water under reflux conditions led to the formation of complexes of the type $Ln_2(pfad)_3{\cdot}xH_2O$ (Ln = La, (**2**); Ce, (**3**); Nd, (**4**); Gd, (**5**); Yb (**6**)) (eq. [2]). Single crystals of the complexes [$Ln_2(pfad)_3(H_2O)_{10}$]·$4H_2O$ (Ln = La, (**2**); Nd, (**4**)) and [$Yb_2(pfad)_2(H_2O)_8$](pfad)·$6H_2O$ (Ln = Yb, (**6**)) were obtained upon cooling of the reaction mixture, and their structures were characterized by X-ray crystallography (see below).

$$[2] \quad Ln_2O_3 + 3H_2pfad \xrightarrow{H_2O} [Ln_2(pfad)_3(H_2O)_x]{\cdot}yH_2O + 3H_2O$$

Single crystals of [$Nd_2(bds)_2(pfad)(H_2O)_8$] (**7**) were obtained by a fortuitous synthesis from the treatment of Nd_2O_3 (contaminated with H_2pfad) with benzene-1,2-disulfonic acid (H_2bds). A deliberate synthesis of **7** was possible by the reaction of $Nd_2(pfad)_3$ with a stoichiometric amount of H_2bds (28) (eq. [3]). The reaction of $Nd_2(bds)_3$ (28) with H_2pfad did not yield **7**. These preparative observations suggest that the disulfonic acid is a stronger acid than perfluoroadipic acid.

$$[3] \quad Nd_2(pfad)_3 + 2H_2bds + 8H_2O \rightarrow [Nd_2(bds)_2(pfad)(H_2O)_8] + 2H_2pfad$$

Microanalyses and (or) metal analyses of **2**, **4**, and **6** indicate less water than in the X-ray determined composition, hence the compounds effloresce readily. Thus **3** and **5**, which were not investigated crystallographically, may have more water when freshly isolated than indicated by analysis. The ability of the compounds to retain water on standing increases with increasing atomic number, as attested by the an-

alytical compositions **2**, **3**·6H_2O, **4**·9H_2O, **5**, **6**·12H_2O. The visible and near IR spectra of complexes **4**, **6**, and **7** showed the features expected for the appropriate Ln^{3+} ion (29, 30). The main peak or cluster exhibited in the negative electrospray mass spectra (solvent = methanol/water), for all of the complexes of the type $Ln_2(pfad)_3$ in aqueous methanol, was assigned to $[Ln(pfad)_2]^-$ species, resulting from the breakdown of the polymeric structures (below). The mass spectra of the $Ln_2(bds)_3$·xH_2O complexes showed a similar feature (28), viz., $[Ln(bds)_2]^-$. ^{19}F NMR spectra and IR data provided further support for the structural features of **1**–**7**. Two fluorine resonances were exhibited in the ^{19}F NMR spectra, consistent with the two different fluorine chemical environments within the structures. The lack of paramagnetic shifting for the resonances of **3**–**6** suggests substantial ionization of the pfad ligands, a reflection of weak donor ability and (or) little transmission of the paramagnetic affect beyond the carboxyl group, owing to weak coordination. The IR spectra of **2**–**6** showed two distinct ν(OH) absorptions, the higher (3658–3628 cm^{-1}) attributable to coordinated water, and the lower, broader band (3397–3382 cm^{-1}) attributable to lattice water. Carboxylate absorptions are assigned at ca. 1670 cm^{-1} ($\nu_{as}(CO_2)$) and ca. 1460 cm^{-1} ($\nu_s(CO_2)$), and ν(CF) at 1187–1179 and 1127–1123 cm^{-1}.

X-ray crystal structures

Single crystal X-ray structure determinations have been conducted for **1**, **2**, **4**, **6**, and **7**. The structures of the lanthanoid complexes, the main theme of the paper, are discussed first.

For the lanthanum complex **2**, the results of the X-ray study are consistent with its formulation as $[La_2(pfad)_3(H_2O)_{10}]$·4$H_2O$ (the water molecules being secured by location and refinement of all hydrogen atoms). The neodymium complex **4** is isomorphous, with the series presumably extending beyond Nd to some as yet undefined limit short of the Ln = Yb analogue $[Yb_2(pfad)_2(H_2O)_8](pfad)$·6$H_2O$ **6**, which, although isostoichiometric, is of a different structural form. The La and Nd pair crystallize with one half of the formula unit, comprising the asymmetric unit of the structure. This entails one lanthanoid atom, seven water molecules, and one and a half ligands. Ligand 1 is fully independent, but ligand 2 is disposed with its central bond located on a crystallographic inversion centre. The lanthanoid atoms are nine-coordinate, with tricapped trigonal prismatic stereochemistry. Water molecules O(1,2,4) provide the capping atoms, water molecules O(3,5) and carboxylate O(211) one of the trigonal faces, and carboxylate O(111,112^i,212^{ii}) the other (Fig. 1*a*, Table 1). All Ln–O bond lengths are similar for both sets of donor atoms and tightly ranged throughout (≤0.12 Å) for both **2** and **4**, the differences between the two sets of values being consistent with expectations of the lanthanoid contraction. The lanthanoid atoms are linked into a two-dimensional polymer normal to *c* by the perfluoroadipate ligands, which bridge in different manners, successive layers being linked by hydrogen bonding (Fig. 1*b*). A string of lanthanoid atoms is linked along *a* by centrosymmetric $Ln(OCO)_2Ln$ units, alternately composed of pairs of ligand 2 and ligand 1 carboxylate units. The ligand 2 bridges are of interest, the Ln-O-C linkages being quasi-linear, with the associated Ln···Ln distances longer than in the unit bridged by the carboxylate 1 units, where Ln-O-C are more usual in their values. Ligand 1 displays μ-η^1:η^1 coordination through one carboxylate group, with the other being free. By contrast, centrosymmetric ligand 2 bridges μ-η^1:η^1 through both carboxylate groups. Seemingly, the water molecule and carboxylate oxygen atoms are similar in their coordinating capacity, components of both types being coordinated and uncoordinated. Thus, the water molecules O(6,7), and the carboxylate comprised of C(16) and O(161,162), are noncoordinating. Hydrogen bonding (Table 2) occurs to oxygen atoms of both types. Torsion angles are essentially trans throughout the fluorocarbon strings except for C(21)-C(22)-C(23)-C(23′), which is 60.2(1)°. All fluorine atoms are >3.7Å from the Ln atoms and are noncoordinating.

Although the ytterbium derivative **6** is isostoichiometric, it has a different structure, which can be represented as $[Yb_2(pfad)_2(H_2O)_8](pfad)$·6$H_2O$, although it forms a polymer of the same dimensionality. Again, the asymmetric unit of the structure is a single lanthanoid atom, seven water molecules, and one and a half ligands (Fig. 2*a*, Tables 3 and 4). The last component, however, is comprised of three halves of three independent perfluoroadipate ions. However, of the three available carboxylate groups, only two are involved in coordination, utilizing all oxygen atoms again as bridging groups, but this time both link the same pair of lanthanoid atoms and extend from there to create a web in two dimensions (Fig. 2*b*). They exhibit μ-η^1:η^1 binding of both carboxylate groups. The third ligand does not coordinate through any of its oxygen atoms but serves to link the two-dimensional sheet in the third dimension by hydrogen bonds from coordinated water molecules at either end. The ytterbium environment, in keeping with the diminished ionic radius, is now eight-coordinate with a square-antiprismatic arrangement. Interestingly, the two square faces of the coordination polyhedron are comprised in each case of either water molecule oxygen atoms O(1–4), or carboxylic oxygen atoms O(111,112^i,211,212^i), <Ln–O> 2.35(4) (range: 2.305(2)–2.388(2)), 2.29(3) (2.263(2)–2.334(2) Å), respectively, and the resulting (centrosymmetric) unit is $[(H_2O)_4Yb(OCO)_4Yb(OH_2)_4]$). The carboxylate oxygen faces of the two ytterbium atoms that they bridge are eclipsed (Yb···Yb 4.5698(3) Å). The hydrogen-bonding array is less inclusive than in the La–Nd complexes, some involving fluorine rather than oxygen atoms. The effect of the strut-like nature of the uncoordinated anion 3 between successive sheets (made up of binuclear units linked by extended struts) is that voids are created, occupied by the uncoordinated water molecules. Torsions in the C-C-C-C (non-central) components of the perfluoroadipate strings are –177.9(2) (string 2), 58.2(3)° (string 3); in string 1, disorder of the central atom is such that the linkage across the inversion centre appears to be C-*C*-*C*′-C with a torsion of 62.3(4)°.

It is reasonable to conclude that the cerium complex **3** is isostructural with **2** and **4** as Ce^{3+} is of intermediate size between La^{3+} and Nd^{3+}, but speculation as to the structure of the gadolinium derivative **5** would be premature.

The structures of the lanthanoid perfluoroadipate (pfad) complexes are compared with those of lanthanoid adipates

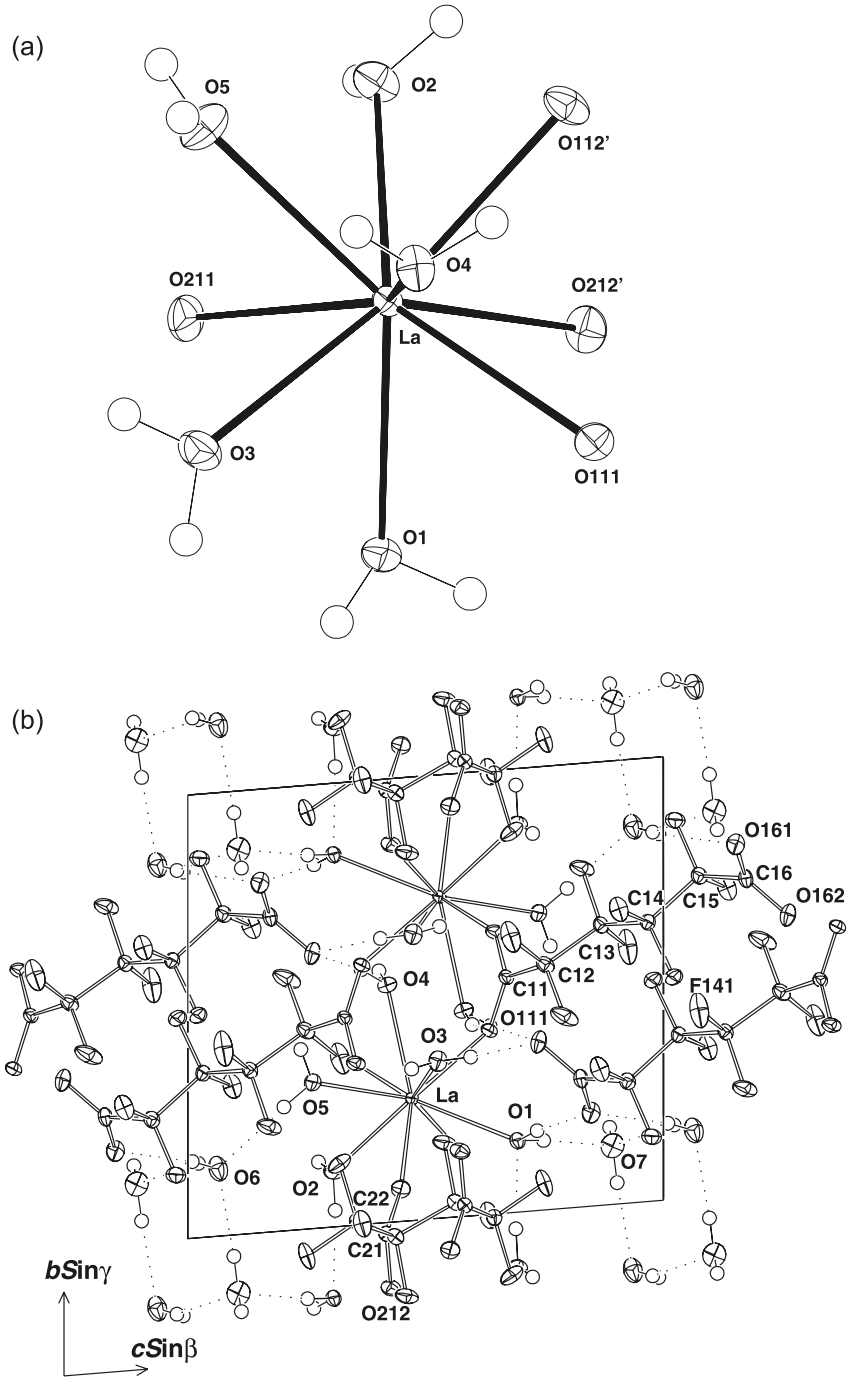
Fig. 1. (*a*) The lanthanum environment in $[La_2(pfad)_3(H_2O)_{10}]\cdot 4H_2O$ **2**. Compound **4** is isomorphous. (*b*) Unit cell contents of **[**$La_2(pfad)_3(H_2O)_{10}]\cdot 4H_2O$ **2** projected down *a*.



(ad) in Table 5. Despite the large number of $[Ln_2(ad)_3(H_2O)_n]\cdot mH_2O$ structures (11–23), there are none for heavier lanthanoids beyond Dy, the two erbium structures being for $[Er(ad)(H_2O)_5]X$ (X = Cl, NO_3) (20) species. Thus, the present structure of $[Yb_2(pfad)_2(H_2O)_8](pfad)\cdot 6H_2O$ (**6**) is unique at this time. What is striking on comparing the pfad and ad structures is the far more extensive coordination of water in the former with $5H_2O$/La, Nd (**2**, **4**) and $4H_2O$/Yb **6**, whereas $2H_2O$/Ln is the maximum observed in the ad species (11–16). This can be attributed to the weaker donor ability of the pfad ligand owing to the electron-withdrawing properties of the fluorine substituents. Unlike the sodium derivative **1**, there is no C-F-metal binding to reinforce the carboxylate coordination. Furthermore, the μ_4-(η^1,η^1/η^1,η^1) coordination mode, ubiquitous in **2**, **4**, and **6**, has only been observed in two ad complexes, viz. $[Ln_2(ad)_3(H_2O)_2]\cdot$bpy (Ln = Pr, Eu), which, oddly, each contain a noncoordinating 4,4′-bipyridine molecule in the lattice (18, 22). Unique to the present Ln complexes is observation of the μ-(η^1,η^1/–) coordination mode, in which one carboxylate group remains uncoordinated. In ad complexes of non-lanthanoid metals bound at only one end, the free

Note: Transformations of the asymmetric unit (see Table; iii: $\bar{x}$, $1-y$, $2-z$; iv: $\bar{x}$, $1-y$, $1-z$; v: x, y, $z-1$; vi: $1-x$, $1-y$, $2-z$. [a]O(2,112^{i}) are in the coordination sphere of the same lanthanoid.

carboxylate group is protonated (31, 32). Both of these features and the observation of a free pfad^{2-} ion in **6** also reflect the weaker donor ability of pfad than ad.

For the neodymium mixed ligand complex **7**, the results of the single crystal X-ray study are consistent with the formulation $[Nd_2(bds)_2(pfad)(H_2O)_8]$, one half of the binuclear formula unit comprising the asymmetric unit of the structure. The array is an infinite one-dimensional polymer (Figs. 3*a*, 3*b*)). About the nine-coordinate neodymium atom of tricapped trigonal prismatic stereochemistry (Table 6), a disulfonate ligand acts as a chelate through one oxygen atom of each sulfonate group (seven-membered ring), and a single oxygen atom from another disulfonate ligand is also bound. The coordination sphere is completed by four unidentate water molecules and a chelating carboxylate group. Pairs of metal centres are linked (*i*) by centrosymmetric pfad ligands (one-half per asymmetric unit), each end behaving as a chelate giving overall μ-η^2:η^2 coordination (Figs. 3*a*, 3*b*), and (*ii*) about other inversion centres by one of the non-chelating sulfonate oxygen atoms from each ligand, forming eight-membered (NdOSONdOSO-) rings (Figs. 3*a*, 3*b*). The benzene-1,2-disulfonate ligand binds in a μ-η^2(O,O′);η^1(O″) manner, a new disposition towards lanthanoid ions, though the seven-membered chelation component is known in Ln complexes (28, 33) and μ-η^2(O,O′);η^2(O″,O‴) binding is also known (33). Torsions in the adipate chain are 180° (necessarily) in the central C–C bond and 163.8(2)° in the adjacent. All hydrogen atoms form strong hydrogen bonds (Table 7), linking adjacent chains of the polymer predominantly to sulfonate but also to carboxylate and other water molecule oxygen atoms.

The sodium salt is unsolvated $[Na_2(pfad)]$ **1**, one-half of the formula unit comprising the asymmetric unit of the structure; the anion is disposed with its mid-point at a crystallographic inversion centre, the other backbone torsion in C(3)-C(2) being –175.87(6)° with C(3)-C(2)-C(1)-O(11,21)

duodecadentate. Each carboxylate oxygen atom of the centrosymmetric ion bridges two different sodium ions resulting in μ_4-η^1:η^1:η^1:η^1 binding of each carboxylate group. Both α-F atoms bind to sodium ions, one to a sodium also ligated by one of the adjacent carboxylate oxygen atoms, and one to a sodium otherwise unattached to this primary ligand. Overall, each ligand is attached to ten different sodium ions. No water is coordinated or present in the lattice despite crystallization from aqueous solution.

During the course of this work, crystals of perfluoroadipic acid were grown from aqueous solution. The X-ray crystal structure of this compound had been previously published (34), data being measured at room temperature using a single counter instrument. It crystallizes as the dihydrate $H_2pfad\cdot 2H_2O$, one half of the formula unit comprising the asymmetric unit of the structure with the centre of the central C–C bond of the molecule at *y* = 0.72 lying disposed on a crystallographic *2*-axis in space group *C*2/*c*. The unit cell contents are shown in projection down the short crystallographic axis *b* in Fig. 5*a*, the molecule quasi-normal to that axis disposed about a plane at ca. *y* = 0.72, together with the water molecule. Interactions with inversion and (or) screw related entities at ca. 0.28 through the associated hydrogen atoms result in a hydrogen-bonded web about the plane *x* = 0.25 (Fig. 5*b*). The acidic hydrogen atom is associated with carboxylate O(1) (C(1)-O(1,2) 1.287(1), 1.211(1) Å; O(1)-C(1)-O(2) 128.01(7), C(2)-C(1)-O(1,2) 111.62(7), 120.37(7); O(1)-H(1) 0.97(2) Å, H(1)-O(1)-C(1) 111.4(1)°), and hydrogen-bonds to the water-molecule oxygen atom (H(1)···O(3)(*x*, 1–*y*, 1/2+*z*) 1.54(2) Å). Within the water molecule, O(3)–H(3A,B) are 0.85(1), 0.83(1) Å respectively, with H(3A)-O(3)-H(3B) 109.8(1)°, the two hydrogen atoms hydrogen-bonding to different and (or) symmetry-related O(2) (O(2)···H(3A) 1.98(2), O(2)···H(3B) (1/2 – *x*, 1/2 – *y*, 1 – *z*) 2.13(1) Å). The torsion angle in C(2)-C(3) of the acid backbone is –163.99(7), with C(3)-C(2)-C(1)-O(1,2) –62.0(1), 118.8(1) and C(2)-C(3)-C(3′)-C(2′) –159.08(6)°. There are some similarities between the structures of the sodium salt **1** and the acid dihydrate $H_2pfad\cdot 2H_2O$ (Figs. 4*a*, 5*a*).

Conclusions

Lanthanoid complexes of the perfluoroadipate ligand show different structures to those of the many for lanthanoid adipates. $[Ln_2(pfad)_3(H_2O)_{10}]\cdot 4H_2O$ (Ln = La or Nd) (**2**, **4**) and $[Yb_2(pfad)_2(H_2O)_8](pfad)\cdot 6H_2O$ (**6**) exhibit more coordinated water than in adipate counterparts, and there is no adipate complex with a free dicarboxylate counterion as in the ytterbium complex **6**. The predominant pfad binding mode in **2**, **4**, **6**, viz., μ_4-η^1,η^1/η^1,η^1 is rarely seen in ad coordination to Ln^{3+}, and the μ-η^1,η^1/– single end binding observed for **2** and **4** has no counterpart in lanthanoid adipate coordination. Many of the features of pfad binding are consistent with it being a weaker donor than ad. In the mixed ligand complex **7**, a new binding mode to Ln^{3+} of the benzene-1,2-disulfonate ion was observed. It is reasonable to conclude the cerium complex **3** is isostructural with **2** and **4**, as Ce^{3+} is of intermediate size between La^{3+} and Nd^{3+}, but speculation as to the structure of the gadolinium derivative **5** would be premature.

Experimental

General procedures

The rare earth oxides used were purchased from Grace Davison Chemicals, Unilab, Riedel de Haën and Allied Signal, cerium(III) carbonate was from Sigma-Aldrich, the perfluoroadipic acid was from Bristol Organic Limited, and dipotassium 1,2-benzenedisulfonate was from Sigma-Aldrich. 1,2-benzenedisulfonic acid was prepared as outlined in the literature (33), but using the anhydrous compound instead of dipotassium 1,2-benzenedisulfonic acid monohydrate. The metal analyses were adapted from the method described previously (35) but without the need of an acid digestion. The Campbell Microanalytical Laboratory of the University of Otago, New Zealand, performed the microanalyses. Listed IR data using a PerkinElmer 1600 FTIR spectrometer are of Nujol and hexachlorobutadiene mulls for the region 4000–650 cm^{-1} (only for the sulfo-

in ethanol (50 mL), which formed a white solid on standing. Yield 2.23 g (67%). IR (cm^{-1}): 3362w, 1699s, 1400vs. (br), 1194s, 1123s, 818s, 722m, 653s. ^{19}F NMR (D_2O) δ: –116.4 (m, 4F, CF_2CO_2), –122.1 (m, 4F, CF_2CF_2). *m*/*z* (-ve ES, 35v): 311 (100%, $[NaL]^-$).

General syntheses of $[Ln_2(pfad)_3]$ derivatives

Perfluoroadipic acid and the appropriate lanthanoid(III) oxide (or cerium carbonate, $Ce_2(CO_3)_3.11H_2O$) were refluxed in water. The mixture was then filtered though a Celite pad and the water was evaporated to dryness. The crude product was then redissolved in the minimum amount of water and refiltered though Celite, and the solvent was removed until the solution became viscous when it was left to crystallize. The product was then collected and drained on a sinter.

Synthesis of $[La_2(pfad)_3(H_2O)_{10}]·4H_2O$ (2)

Lanthanum(III) oxide (1.04 g, 3.19 mmol) and perfluoroadipic acid (1.39 g, 4.79 mmol) were brought to reflux in water (50 mL) by heating for 12 h. After the work-up of the mixture, single colourless crystals of **2** were obtained and characterized by X-ray crystallography. Yield 1.48 g (74%). IR (cm^{-1}): 3635m, 3487m (br), 1657s, 1460vs, 1179vs, 1127s, 808m, 722m, 653m. ^{19}F NMR (D_2O) δ: –116.46 (m, 12F, CF_2CO_2), –122.07 (m, 12F, CF_2CF_2). *m*/*z* (–ve ES, 35v): 465 (11%, $[La(pfad)F_2]^-$), 715 (100, $[La(pfad)_2]^-$), 1073 (5, $[La_3(pfad)_6H]^{2-}$), 1096 (5, $[La_3(pfad)_6(HCO_2)H_2]^{2-}$), 1286 (7, $[La_4(pfad)_7]^{2-}$). Elemental anal. calcd. for $La_2(pfad)_3(H_2O)_6$, $C_{18}H_{12}F_{24}La_2O_{18}$ (%): La 22.22; found: La 22.08.

Synthesis of $[Ce_2(pfad)_3(H_2O)_{10}]·4H_2O$ (3)

Cerium carbonate, $Ce_2(CO_3)_3·11H_2O$ (2.94 g, 7.38 mmol) and perfluoroadipic acid (2.78 g, 9.58 mmol) were heated to reflux in water (100 mL) for 12 h. Single colourless crystals of **3** were obtained after the work-up of the solution. Yield 2.98 g (75%). IR (cm^{-1}): 3628m, 3397m (br), 1662s, 1460vs, 1179s, 1126s, 808m, 722m, 652m. ^{19}F NMR (D_2O)

Synthesis of [Nd$_2$(pfad)$_3$(H$_2$O)$_{10}$]·4H$_2$O (4)

Neodymium oxide (1.08 g, 3.21 mmol) and perfluoroadipic acid (1.39 g, 4.79 mmol) were added to water (50 mL) and the mixture was brought to reflux for 12 h. After work-up of the reaction mixture, pink crystals formed and were established to be **4** by X-ray crystallography. Yield 1.48 g (70%). Visible/near IR [λ_{max}, nm (ε), H$_2$O]: 329 (3), 347 (5), 354 (7), 427 (2), 461 (2), 469 (2), 475 (2), 512 (4), 521 (8), 575 (15), 679 (2), 732 (9), 740 (15), 794 (22), 799 (13), 864 (7), 889 (2). IR (cm^{-1}): 3635m, 3396m (br), 1752m, 1666vs, 1606s, 1456vs, 1179vs, 1127vs, 807m, 726w, 652m. ^{19}F NMR (D$_2$O) δ: –116.45 (m, 12F, C**F**$_2$CO$_2$), –122.07 (m, 12F, C**F**$_2$C**F**$_2$). *m/z* (–ve ES, 35v): 468 (11%, [Nd(pfad)F$_2$]$^-$), 718 (100, [Nd(pfad)$_2$]$^-$), 1080 (5, [Nd$_3$(pfad)$_6$H]$^{2-}$), 1103 (5, [Nd$_3$(pfad)$_6$(HCO$_2$)H$_2$]$^{2-}$), 1296 (9, [Nd$_4$(pfad)$_7$]$^{2-}$). Elemental anal. calcd. for Nd$_2$(pfad)$_3$(H$_2$O)$_9$, $C_{18}H_{18}F_{24}Nd_2O_{21}$ (%): C 16.44, H 1.38, Nd 21.94; found: C16.47, H 1.03, Nd 21.76.

Synthesis of [Gd$_2$(pfad)$_3$(H$_2$O)$_{12}$] (5)

Gadolinium oxide (1.16 g, 3.20 mmol) and perfluoroadipic acid (1.39 g, 4.79 mmol) were heated to reflux for 12 h in water (50 mL). Upon work-up of the solution, a white powdery product was collected and analysed to be **5**. Yield 1.04 g (47%). IR (cm^{-1}): 3638m, 3392m (br), 1670 s, 1460vs, 1178s, 1127s, 809m, 625m. ^{19}F NMR (D$_2$O) δ: –116.24 (m, 12F, C**F**$_2$CO$_2$), –122.50 (m, 12F, C**F**$_2$C**F**$_2$). *m/z* (–ve ES, 35v): 734 (100%, [Gd(pfad)$_2$]$^-$), 1100 (4, [Gd$_3$(pfad)$_6$H]$^{2-}$), 1126 (8, [Gd$_3$(pfad)$_6$(CO$_2$)H$_2$]$^{2-}$), 1323 (8, [Gd$_4$(pfad)$_7$]$^{2-}$). Elemental anal. calcd. for $C_{18}H_{24}F_{24}Gd_2O_{24}$ (%): Gd 21.55; found: Gd 22.96.

Synthesis of [Yb$_2$(pfad)$_2$(H$_2$O)$_8$](pfad)·6H$_2$O (6)

Ytterbium oxide (1.26 g, 3.20 mmol) and perfluoroadipic acid (1.39 g, 4.79 mmol) were brought to reflux in water (50 mL) for 12 h. The work-up product was found to be **6** by X-ray determination. Yield 1.14 g (50%). IR (cm^{-1}): 3658m, 3382m, 1753s, 1666s, 1464vs, 1187s, 1124s, 808m, 721s, 658m. ^{19}F NMR (D$_2$O) δ: –116.41 (m, 12F, C**F**$_2$CO$_2$), –122.04 (m, 12F, C**F**$_2$C**F**$_2$). *m/z* (–ve ES, 35v): 500 (7%, [Yb(pfad)F$_2$]$^-$), 750 (100, [Yb(pfad)$_2$]$^-$), 1123 (7, [Yb$_3$(pfad)$_6$H]$^{2-}$), 1146 (8, [Yb$_3$(pfad)$_6$(HCO$_2$)H$_2$]$^{2-}$), 1354 (8, [Yb$_4$(pfad)$_7$]$^{2-}$). Visible/near IR [λ_{max}, nm (ε), H$_2$O]: 938 (2), 974 (5). Elemental anal. calcd. for Yb$_2$(pfad)$_3$(H$_2$O)$_{12}$, $C_{18}H_{24}F_{24}O_{24}Yb_2$ (%): Yb 24.26; found: Yb 24.67.

Synthesis of $[Nd_2(bds)_2(pfad)(H_2O)_8]$ (7)

Neodymium(III) perfluoroadipate (0.50 g, 0.37 mmol) was heated to reflux with 1,2-benzenedisulfonic acid (1.8 g, 7.54 mmol) in water (30 mL) for 24 h. Work-up was as for **2**, but ethanol was also added to induce crystallization. Pink single crystals of **7** were obtained, collected, and crystallographically characterized. The bulk product was found to be $[Nd_2(bds)_2(pfad)(H_2O)_7]$. Yield 0.54 g (93%), mp >360 °C. IR (cm^{-1}): 3388s (br), 2961w, 2922w, 2856w, 1644s, 1431m, 1417s, 1224vs, 1196vs, 1173vs, 1131vs, 1119vs, 1081s, 1062vs, 1038s, 1012s, 872m, 818m, 778s, 757m, 690s, 658s. ^{1}H NMR (D_2O) δ: 7.31 (m, 4H, **H**4,5), 7.64 (m, 4H, **H**3,6). ^{19}F NMR (D_2O) δ: –116.46 (m, 4F, C**F**$_2$CO$_2$), –122.10 (m, 4F, C**F**$_2$C**F**$_2$). *m*/*z* (–ve ES, 50v): 616 (100%, $[Nd(bds)_2]^-$), 668 (49, $[Nd(bds)(pfad)]^-$), 720 (8, $[Nd(pfad)_2]^-$), 899.5 (10, $[Nd_3(bds)_2(pfad)_3(MeO)]^{2-}$), 951 (4). Visible/near IR [λ_{max}, nm (ε), H_2O]: 327 (16), 338 (14), 347 (16), 354 (18), 427 (7), 461 (6), 469 (6), 475 (6), 512 (8), 522 (12), 575 (19), 679 (4), 732 (12), 740 (17), 794 (25), 799 (17), 865 (9), 889 (3). Elemental anal. calcd. for $C_{18}H_{22}F_{16}Nd_2O_{23}S_4$ (%): C 18.40, H 1.89, Nd 24.55; found: C 18.36, H 2.01, Nd 24.50. The compound was initially fortuitously obtained from what was considered to be neodymium oxide (0.62 g) and 1,2-benzenedisulfonic acid (0.62 g, 2.61 mmol) in water (30 mL) at reflux for 24 h. Reaction of $Nd_2(C_6H_4(SO_3)_2\text{-}1,2)_3$ with $HO_2C(CF_2)_4CO_2H$ did not yield **7**.

Structure determinations

Full spheres of CCD area-detector diffractometer data were measured (Bruker AXS instrument, ω-scans, monochromatic Mo Kα radiation, λ = 0.710 73 Å, T *ca.* 153K) yielding $N_{t(otal)}$ reflections, these merging to N unique (R_{int} cited) after "empirical"/multiscan absorption correction (proprietary software), N_o with $I > 2\sigma(I)$ being considered "observed". All reflections were used in the full matrix refinements on F^2, refining anisotropic displacement parameter forms for the non-hydrogen atoms, $(x, y, z, U_{iso})_H$ being refined for 1,2,7 (reflection weights: $(\sigma^2(F^2) + (aP)^2 (+ bP))^{-1}$ ($P = (F^2_o + 2F^2_c/3)$). Neutral atom complex scattering factors were employed within the SHELXL 97 program (36). Pertinent results are given above (Table 9) and in the tables and figures, the latter showing 50% displacement envelope probability amplitudes for the non-hydrogen atoms, where hydrogen atoms, where shown, have arbitrary radii of 0.1 Å. Where metal atom environment tables are presented in matrix form, r (Å) is the metal···ligand atom distance, with other entries being the angles (°) subtended at the metal atom by the relevant atoms at the head of the row and columns. Full cif. depositions, excluding structure factor amplitudes are supplied in the Supplementary data.[3]

Synthesis and electrochemical properties of bimetallic η^5-indenyl ruthenium complexes[1]

Quan Yuan Hu and Guochen Jia

Abstract: Treatment of RuCl(dppm)(η^5-C_9H_7) with alkynes HC≡C(C_6H_4)$_n$C≡CH (n = 1, 2) in the presence of $TlPF_6$ and *t*-BuONa affords the bimetallic ruthenium acetylide complexes [(η^5-C_9H_7)(dppm)Ru]$_2$(μ-C≡C(C_6H_4)$_n$C≡C). Reactions of the hydride complex RuH(dppm)(η^5-C_9H_7) with HC≡C(C_6H_4)$_n$C≡CH (n = 1, 2) in refluxing toluene give the bimetallic ruthenium alkenyl complexes [(η^5-C_9H_7)(dppm)Ru]$_2$(μ-CH=CH(C_6H_4)$_n$CH=CH). The electrochemical properties of the new complexes have been investigated by cyclic voltammetry, which reveals that the organic spacer –CH=CHC_6H_4CH=CH– is more effective than –C≡CC_6H_4C≡C– in mediating electronic communication between the two ruthenium moieties.

Key words: ruthenium, bimetallic, acetylide, insertion, electrochemistry.

Résumé : La réaction du RuCl(dppm)(η^5-C_9H_7) avec les alcynes HC≡C(C_6H_4)$_n$C≡CH (n = 1, 2), en présence de $TlPF_6$ et de *t*-BuONa conduit à la formation des bimétalliques d'acétylures de ruthénium, [η^5-C_9H_7)(dppm)Ru]$_2$[μ-C≡C(C_6H_4)$_n$C≡C]. Les réactions de l'hydrure complexe RuH(dppm)(η^5-C_9H_7) avec le HC≡C(C_6H_4)$_n$C≡CH (n = 1, 2), dans le toluène au reflux, conduit à la formation des complexes bimétalliques d'alcénylruthénium [(η^5-C_9H_7)(dppm)Ru]$_2$[μ-C=C(C_6H_4)$_n$C=C]. Les propriétés électrochimiques des nouveaux complexes ont été évaluées par voltampérométrie cyclique et elles révèlent que par rapport au groupe organique d'espacement –C≡C(C_6H_4)$_n$C≡C–, le groupe –C=C(C_6H_4)$_n$C=C– permet une meilleure communication électronique entre les deux portions contenant du ruthénium.

Mots-clés : ruthénium, bimétallique, acétylure, insertion, électrochimie.

[Traduit par la Rédaction]

Introduction

Bimetallic complexes with a π-conjugated hydrocarbon bridge have attracted much interest for their synthesis and physical properties (1). Examples of common conjugated bimetallic complexes include acetylide complexes $L_nMC{\equiv}C(C{\equiv}C)_mC{\equiv}CML_n$ (2, 3) and $L_nMC{\equiv}C(CH{=}CH)_mC{\equiv}CML_n$ (4), and alkenyl complexes $L_nMCH{=}CH(CH{=}CH)_mCH{=}CHML_n$ (5, 6). Electrochemical properties of many of these carbon-rich bimetallic complexes have been investigated to evaluate whether electron delocalization takes place or whether electronic communication occurs.

Organic spacers play an important role in mediating electronic communication. To study the effect of organic spacers, it is desirable to have bimetallic complexes with the same metal moieties but different organic bridges. The diethynyl units –C≡C(C_6H_4)$_n$C≡C– (7–9) and divinyl units –CH=CH(C_6H_4)$_n$CH=CH– (10) are often used as a bridge in constructing bimetallic or polymetallic complexes. However, bimetallic complexes with the same metal moieties containing these bridging ligands are rare. In this work, we have obtained bimetallic complexes with the same metal moiety Ru(dppm)(η^5-C_9H_7) linked by –C≡C(C_6H_4)$_n$C≡C– or –CH=CH(C_6H_4)$_n$CH=CH– (n = 1, 2), using precursors RuCl(dppm)(η^5-C_9H_7) (11) and RuH(dppm)(η^5-C_9H_7) (12) as the starting materials. We have also investigated the electrochemical properties of the new complexes by cyclic voltammetry. The details of the investigations are reported in this paper.

Results and discussion

Synthesis of metal complexes

Treatment of RuCl(dppm)(η^5-C_9H_7) (**1**) with 1 equiv. $TlPF_6$ in THF gave a solution of the putative intermediate [Ru(THF)(dppm)(η^5-C_9H_7)]PF_6 (**2**), which reacted with HC≡CC_6H_4C≡CH at refluxing temperature in the presence of *t*-BuONa to give a brown solution, from which the bimetallic σ-alkynyl complexes [(η^5-C_9H_7)(dppm)Ru]$_2$(μ-C≡CC_6H_4C≡C) (**3**) (Scheme 1) can be isolated.

A similar reaction between **2** and HC≡C$C_6H_4C_6H_4$C≡CH gave the bimetallic complex [(η^5-C_9H_7)(dppm)Ru]$_2$(μ-

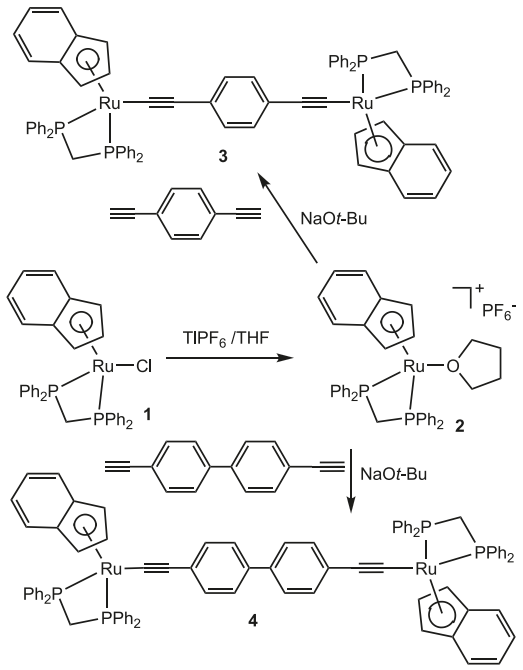
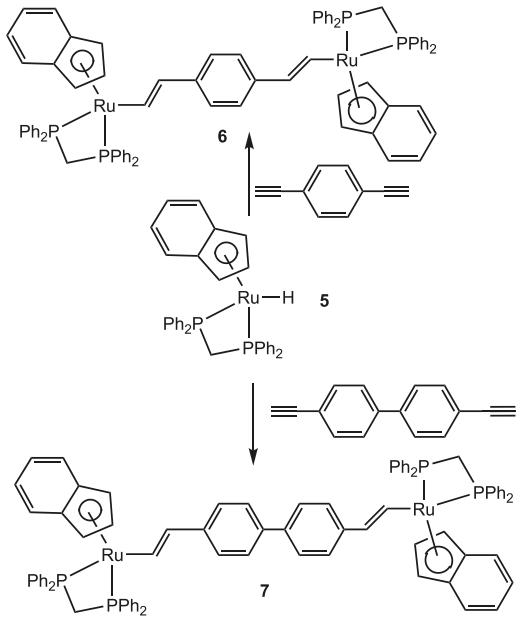
Scheme 1.



Scheme 2.



C≡CC$_6$H$_4$C$_6$H$_4$C≡C) (**4**). Attempts to prepare complexes **3** and **4** by the reactions of RuCl(dppm)(η^5-C$_9$H$_7$) with HC≡CC$_6$H$_4$C≡CH or HC≡CC$_6$H$_4$C$_6$H$_4$C≡CH in the presence of $NaPF_6$ and NEt_3 were unsuccessful.

The bimetallic acetylide complexes **3** and **4** have been characterized analytically and spectroscopically. The IR spectra exhibit a characteristic υ(C≡C) peak at 2070 and 2074 cm^{-1} for **3** and **4**, respectively. The $^{31}P\{^1H\}$ NMR spectra in $CDCl_3$ show a singlet at 17.8 ppm for **3** and 17.6 ppm for **4**, indicating the chemical equivalence of the phosphorus atoms. The chemical shifts are close to those of Ru(C≡CC(Ph) = CH$_2$)(η^5-C$_9$H$_7$)(dppm) (13), Ru(C≡CPh)(η^5-C$_9$H$_7$)(dppm) (14), and Ru(C≡CC$_6$H$_4$NO$_2$-4)(η^5-C$_9$H$_7$)(dppm) (15) (being 19.50, 19.02, and 18.79 ppm, respectively). The $^{13}C\{^1H\}$ NMR spectra display a characteristic triplet signal of RuC_α at 117.5 ppm for **3** and 116.6 ppm for **4** with a $^3J_{CP}$ of ~22.5 Hz. The resonance of C_β of RuC$_\alpha$≡C_β appears as a singlet at 112.3 ppm for **3** and 112.2 ppm for **4**. In the ^1H and $^{13}C\{^1H\}$ NMR spectra, the chemical shifts of the signals associated with the indenyl and dppm ligands are similar to those of the known mononuclear compounds Ru(C≡CR)(dppm)(η^5-C$_9$H$_7$) (13–15).

The hydrido complex RuH(η^5-C$_9$H$_7$)(dppm) (**5**) is known to undergo insertion reactions with alkynes RC≡CR to give σ-alkenyl complexes Ru(CR=CHR)(η^5-C$_9$H$_7$)(dppm) (16). Thus, we expect that the reaction of RuH(η^5-C$_9$H$_7$)(dppm) with HC≡CRC≡CH may give bimetallic complex [(η^5-C$_9$H$_7$)(dppm)Ru]$_2$(μ-CH=CHRCH=CH). Indeed, reaction of RuH(η^5-C$_9$H$_7$)(dppm) (**5**) with 0.5 equiv. of HC≡CC$_6$H$_4$C≡CH in toluene at refluxing temperature leads to a brown solution from which the bimetallic σ-alkenyl complex [(η^5-C$_9$H$_7$)(dppm)Ru]$_2$(μ-CH=CHC$_6$H$_4$CH=CH) (**6**) can be isolated as a red solid (Scheme 2). Similar reaction between RuH(η^5-C$_9$H$_7$)(dppm) and HC≡CC$_6$H$_4$C$_6$H$_4$C≡CH gave the analogous complex [(η^5-C$_9$H$_7$)(dppm)Ru]$_2$(μ-CH=CHC$_6$H$_4$C$_6$H$_4$CH=CH) (**7**). As monitored by $^{31}P\{^1H\}$ NMR spectroscopy, compared to the reaction of RuH(η^5-C$_9$H$_7$)(dppm) with phenylacetylene (80 °C, 3 h) (16*a*), complete formation of bimetallic complexes **6** and **7** requires a higher temperature and a longer time, especially for the formation of **6**, due to steric effect.

Complexes **6** and **7** have been characterized by elemental analysis and NMR ($^{31}P\{^1H\}$, ^1H, and $^{13}C\{^1H\}$) spectroscopy. The spectroscopic data associated with indenyl and dppm ligands are similar to those of Ru(*E*-CH=CHR)(η^5-C$_9$H$_7$)(dppm) (16). The $^{31}P\{^1H\}$ NMR spectra show a singlet at δ 22.5 ppm for **6** and at 21.4 ppm for **7**. The trans stereochemistry of the alkenyl ligand is indicated by the ^1H NMR data. In particular, the ^1H NMR spectrum of **6** in $CDCl_3$ shows the signals of RuC_αH and RuCH=CH_β at 7.78 and 5.79 ppm, respectively, with a $^3J_{HH}$ of 16.2 Hz. The ^1H NMR spectrum of **7** in $CDCl_3$ shows the signals of RuC_αH and RuCH=CH_β at 8.12 and 5.93 ppm with a $^3J_{HH}$ of 16.2 Hz. The magnitude of the $^3J_{HH}$ coupling constants supports the trans geometry of RuCH=CH double bond. In the $^{13}C\{^1H\}$ NMR spectrum of **6** in CD_2Cl_2, the signals of the alkenyl ligand appear at 147.5 (C$_\alpha$) and 139.5 (C$_\beta$) ppm. For complex **7**, the C$_\alpha$ and C$_\beta$ signals of the alkenyl ligand appear at 153.4 and 138.8 ppm, respectively.

Electrochemical properties

To study the electrochemical properties of complexes **3**, **4**, **6**, and **7**, their cyclic voltammograms were collected in CH_2Cl_2 supported by *n*-Bu$_4$NPF$_6$ at 25 °C with a scanning rate of 20 mV/s. The results are collected in Table 1, where the potentials are referenced to that of Fc/Fc$^+$.

The cyclic voltammogram of **3** in CH_2Cl_2 exhibits two reversible waves at 0.053 and 0.241 V vs. Fc/Fc$^+$. These two oxidation waves can be attributed to the formation of [(η^5-C$_9$H$_7$)(dppm)RuC≡CC$_6$H$_4$C≡CRu(dppm)(η^5-C$_9$H$_7$)]$^+$ and [(η^5-C$_9$H$_7$)(dppm)Ru=C=C=C$_6$H$_4$=C=C=Ru(dppm)(η^5-C$_9$H$_7$)]$^{2+}$ (Scheme 3). The peak separation of the two waves is 0.195 V, implying the presence of metal–metal interaction. Similar results have been observed for related homobimetallic com-

Table 1. Electrochemical data for complexes **3**, **4**, **6**, and **7**.

Complex	E_p^a (V)	E_p^c (V)	$E_{1/2}$ (V)	n-Bu_4NPF_6 (mol/L)
3	0.101	0.005	0.053	0.10
	0.296	0.186	0.241	
4	–0.080	–0.154	–0.117	0.50
6	–0.269	–0.343	–0.306	0.50
	–0.013	–0.087	–0.050	
7	–0.285	–0.359	–0.322	0.50

Note: $E_{1/2} = (E_p^a + E_p^c)/2$.

plexes, such as $Cl(dppm)_2RuC{\equiv}CC_6H_4C{\equiv}CRu(dppm)_2Cl$ ($E_{1/2}$ = –0.30 and 0.00 V vs. Fc/Fc^+) (9a), $Cl(dppm)_2OsC{\equiv}CC_6H_4C{\equiv}COs(dppm)_2Cl$ ($E_{1/2}$ = –0.51 and –0.21 V vs. Fc/Fc^+) (9a), $Cl(dppe)_2RuC{\equiv}CC_6H_4C{\equiv}CRu(dppe)_2Cl$ ($E_{1/2}$ = 0.15 and 0.51 V vs. SCE) (9*b*), $[(\eta^5\text{-}C_5Me_5)(dppe)FeC{\equiv}CC_6H_4C{\equiv}CFe(dppe)(\eta^5\text{-}C_5Me_5)]$ ($E_{1/2}$ = –0.315 and –0.050 V vs. SCE) (9c), and $Cl(depe)_2FeC{\equiv}CC_6H_4C{\equiv}CFe(depe)_2Cl$ (9*a*) ($E_{1/2}$ = –0.63 and –0.47 V vs. Fc/Fc^+), where the peak separations are 0.30, 0.30, 0.36, 0.265, and 0.16 V, respectively.

Similarly, the cyclic voltammogram of **6** in CH_2Cl_2 also exhibits two reversible waves at –0.306 and –0.050 V vs. Fc/Fc^+ with a peak separation of 0.256 V. The two oxidation waves can be attributed to the generation of $[(\eta^5\text{-}C_9H_7)(dppm)RuCH{=}CHC_6H_4CH{=}CHRu(dppm)(\eta^5\text{-}C_9H_7)]^+$ and $[(\eta^5\text{-}C_9H_7)(dppm)Ru{=}CHCH{=}C_6H_4{=}CH\text{-}CH{=}Ru(dppm)(\eta^5\text{-}C_9H_7)]^{2+}$ (Scheme 4). The peak potentials suggest that it is easier to oxidize complex **7** ($E_{1/2}$ = –0.306 and –0.050 V vs. Fc/Fc^+, respectively) than complex **3** ($E_{1/2}$ = 0.053 and 0.241 V vs. Fc/Fc^+, respectively). The observation of a peak separation of 0.256 V for **6** clearly indicates a communication between the two ruthenium centers in **6**. The value is bigger than that of complex **3** (0.195 V), which has the conjugated bridge –C≡C–C_6H_4–C≡C–. The results reveal that –CH=CHC_6H_4CH=CH– is more efficient in mediating electron transfer or electronic delocalization than –C≡CC_6H_4C≡C– in homobimetallic complexes.

In contrast, the cyclic voltammograms of the acetylide complex **4** and the vinyl complex **7** only exhibit one reversible oxidation wave at –0.117 V vs. Fc/Fc^+ and –0.322 V vs. Fc/Fc^+, respectively. Apparently, the biphenyl group reduces the interaction between the two ruthenium moieties. The peak potentials again suggest that it is easier to oxidize the vinyl complex **7** than the analogous acetylide complex **4**.

In summary, we have successfully prepared bimetallic complexes $[(\eta^5\text{-}C_9H_7)(dppm)Ru]_2(\mu\text{-}C{\equiv}C(C_6H_4)_nC{\equiv}C)$ (n = 1, 2) and $[(\eta^5\text{-}C_9H_7)(dppm)Ru]_2(\mu\text{-}CH{=}CH(C_6H_4)_nCH{=}CH)$ (n = 1, 2). Cyclic voltammetry studies reveal that complexes bridged with –C≡CC_6H_4C≡C– or –CH=CHC_6H_4CH=CH– show two reversible redox waves, while complexes bridged with –C≡$CC_6H_4C_6H_4$C≡C– or –CH=$CHC_6H_4C_6H_4$CH=CH– exhibit one reversible redox wave. The studies also suggest that the organic spacer –CH=CHC_6H_4CH=CH– is better than –C≡CC_6H_4C≡C– in mediating electronic communication between the two ruthenium moieties.

Experimental section

All manipulations were carried out at room temperature under a nitrogen atmosphere using standard Schlenk techniques unless otherwise stated. Solvents were distilled under nitrogen from sodium benzophenone (hexane, ether, and THF), sodium (benzene), or calcium hydride (CH_2Cl_2). The starting materials $RuCl(dppm)(\eta^5\text{-}C_9H_7)$ (11) and $RuH(dppm)(\eta^5\text{-}C_9H_7)$ (12) were prepared following the procedures described in literature. All other reagents were used as purchased from Sigma-Aldrich Chemical Co., USA.

Microanalyses were performed by M-H-W Laboratories (Phoenix, AZ). ^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ spectra were collected on a Bruker ARX 300 MHz spectrometer. ^1H and ^{13}C NMR chemical shifts are referenced relative to TMS, and ^{31}P NMR chemical shifts are referenced relative to 85% H_3PO_4. FTIR spectra were recorded on a PerkinElmer Spectrum-One spectrometer. MS spectra were recorded on a Finnigan TSQ7000 spectrometer. The electrochemical measurements were performed with a CHI 660 potentiostat. A three-component electrochemical cell was used with a glassy-carbon electrode as the working electrode, a platinum wire as the counter electrode, and an Ag/AgCl electrode as the reference electrode. The cyclic voltammograms were collected with a scan rate of 20 mV/s in CH_2Cl_2 containing 0.10 or 0.50 mol/L n-Bu_4NPF_6 as the supporting electrolyte. The peak potentials reported are referenced to the ferrocene/ferrocenium redox couple (Fc/Fc^+).

Synthesis, characterization, and reactivity of a novel thallium arylspiroboronate ester[1]

Nathan R. Halcovitch, Christopher M. Vogels, Andreas Decken, and Stephen A. Westcott

Abstract: Addition of 3,5-di-*tert*-butylcatechol (butcat) to solutions of $H_3B{\cdot}SMe_2$ gave the novel diboron species $B_2(butcat)_3$ (**2**) in moderate to high yields. Compound **2** reacts with Tl(acac) to give butcatB(acac) (**4**) and $Tl(Bbutcat_2)$ (**5**). Attempts to abstract the chlorides from $[(dppb)Rh(\mu\text{-}Cl)]_2$ (where dppb = 1,4-bis(diphenylphosphino)buthane) using **5** led to the unusual dimer $[(dppb)Rh(\mu\text{-}Cl)_2(\mu\text{-}Tl)Rh(dppb)][Bbutcat_2]$ (**6**), which contains an unsymmetrical Rh–Tl–Rh bridge.

Key words: arylspiroboronate ester, non-coordinating anion, rhodium, thallium.

Résumé : L'addition du 3,5-di-*tert*-butylcatéchol (butcat) à des solutions de $H_3B{\cdot}SMe_2$ conduit à la formation de nouvelles espèces de dibore, $B_2(butcat)_3$ (**2**), avec des rendements allants de modérés à élevés. Le composé **2** réagit avec le Tl(acac) pour conduire à la formation de butcatB(acac) (**4**) et de $Tl(Bbutcat_2)$ (**5**). Des essais effectués en vue d'utiliser le produit (**5**) pour enlever les ions chlorures à partir du $[(dppb)R(\mu\text{-}Cl)]_2$ (dans lesquels dppb = 1,4-bis(diphénylphosphino)buthane) ont conduit à la formation du dimère inhabituel $[(dppb)Rh(\mu\text{-}Cl)_2(\mu\text{-}Tl)Rh(dppb)][Bbutcat_2]$ (**6**) qui comporte un pont asymétrique Rh–Tl–Rh.

Mots-clés : ester d'acide arylspiroboronique, anion non coordinant, rhodium, thallium.

[Traduit par la Rédaction]

Introduction

The transition metal catalysed hydroboration of alkenes and alkynes has become a well-established technique in organic synthesis (1). One of the most active and selective groups of catalyst precursors for hydroborations using catecholborane (HBcat; cat = 1,2-$O_2C_6H_4$) are those derived from addition of diphosphines to $Rh(acac)(coe)_2$ (acac = acetylacetonato and coe = cyclooctene) (2). The actual catalyst resting state using these systems is believed to be a zwitterionic complex of the type $Rh(\eta^6\text{-}catBcat)(P_2)$ (where P_2 = diphosphine), arising from the redistribution of substituents on HBcat. The arylspiroboronate ester anion $Bcat_2^-$ is bound to the rhodium centre via one of the arene rings as shown in Fig. 1. In an elegant study, Marder and co-workers have found that addition of B_2cat_3 to $Rh(acac)(P_2)$ led to the zwitterionic complexes $Rh(\eta^6\text{-}catBcat)(P_2)$ in high yields, along with concomitant formation of acacBcat (3). The diboron species B_2cat_3 can be generated as a decomposition product in nucleophilic reactions with HBcat or when HBcat is heated at elevated temperatures (4). This species can also be prepared by the direction addition of catechol to solutions of $BH_3{\cdot}THF$ (5).

We have begun a detailed investigation into the synthesis of other zwitterionic complexes containing this arylspiroboronate ester ligand (6) and expanding the role of this class of ligand in organometallic chemistry. The limiting factor in using this methodology lies in the rather small number of metal acetylacetonato complexes, compared with the more common metal halides. As such, we have prepared a novel thallium arylspiroboronate ester compound for its use in reactions with metal halides. Initial results are presented herein.

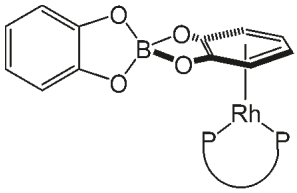
Results and discussion

We have found that reactions of B_2cat_3 with Tl(acac) affords the desired thallium salt $Tl(Bcat_2)$ (**1**) in high yields. The use of thallium salts to abstract metal halides is a well-documented and established technique in organometallic chemistry (7). Unfortunately, compound **1** was insoluble in all organic solvents, and all attempts to use this compound to abstract metal halides proved unsuccessful. We then decided to prepare the analogous diboron species using commercially available 3,5-di-*tert*-butylcatechol (butcat), where the two bulky alkyl groups were chosen to increase solubility in organic solvents. Addition of this diol to solutions of

 doi:10.1139/V08-107 © 2008 NRC Canada

Fig. 1. Zwitterionic rhodium diphosphine complexes.



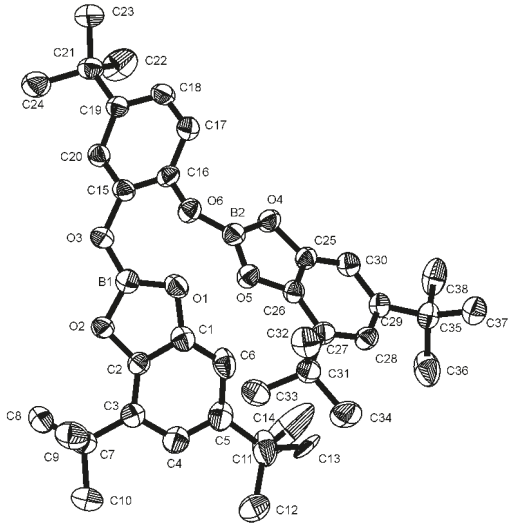
$BH_3{\cdot}SMe_2$ gave the corresponding diboron analogue $B_2(butcat)_3$ (**2**) in moderate to high yields (up to 85%). Compound **2** appears to be a mixture of isomers, as ascertained by the different number of *tert*-butyl groups in the ^1H NMR spectrum. Although attempts to characterize **2** by X-ray diffraction proved unsuccessful, we were able to grow suitable crystals of **3**, where the bridging catecholato unit was replaced by a minor impurity in 3,5-*tert*-butylcatechol that is difficult to separate from the starting material, viz 4-*tert*-butylcatechol. The molecular structure of one of the molecules in the asymmetric unit for **3** is shown in Fig. 2 (8).[4] Crystallographic data for **3** are given in Table 1.

Addition of Tl(acac) to a solution of **2** (Scheme 1) in toluene gave high yields (82%) of compound **5**, $Tl(Bbutcat_2)$, along with concomitant formation of the mixed species butcatB(acac) (**4**). Compound **4** has a peak in the ^{11}B NMR spectrum at δ 8 ppm characteristic of a four-coordinate boron atom bonded to four oxygen atoms. A single-crystal X-ray diffraction study was also conducted on **4** to confirm the formation of this by-product, the molecular structure of which is shown in Fig. 3. The boron–oxygen bond lengths for the catecholato group of B(1)–O(1), 1.450(4), and B(1)–O(2), 1.436(4), are slightly shorter than those for the acac group with B(1)-O(3), 1.505(4), and B(1)-O(4), 1.500(4), respectively, but are similar to those reported earlier (9).

Compound **5** has been characterized by a number of physical methods including multinuclear NMR spectroscopy. The ^1H NMR spectrum for **5** shows two peaks for the different *tert*-butyl groups at δ 1.35 and 1.26 ppm. This observation is in agreement with the $^{13}C\{^1H\}$ NMR spectrum with peaks at δ 34.9 and 34.5 ppm for the quaternary carbons and δ 32.4 and 30.2 ppm for the corresponding methyl groups. The ^{11}B NMR spectrum shows a sharp singlet at δ 13 ppm for the four-coordinate boron atom.

We then decided to examine the reactivity of **5** with $[(P_2)Rh(\mu\text{-}Cl)]_2$ in an attempt to generate complexes of the type $Rh(\eta^6\text{-}butcatBbutcat)(P_2)$. Interestingly, we have found that addition of **5** to a mixture of $[RhCl(coe)_2]_2$ and 2 equiv. of 1,4-bis(diphenylphosphino)butane (dppb) did not lead to the expected zwitterionic product, but gave the novel thallium bridged dimer $[(dppb)Rh(\mu\text{-}Cl)_2(\mu\text{-}Tl)Rh(dppb)][Bbutcat_2]$ (**6**) as the only new rhodium containing species. The $^{31}P\{^1H\}$ NMR data for **6** consists of a doublet at δ 40.2 ppm with coupling to rhodium with J_{PRh} = 178 Hz. The ^{11}B NMR resonance remains at ca. 14 ppm for the noncoordinated

Fig. 2. The molecular structure of **3** with ellipsoids drawn at 50% probability level. Hydrogen atoms are omitted for clarity. Selected bond distances (Å) and angles (°): B(1)–O(3), 1.355(4); B(1)–O(1), 1.378(4); B(1)–O(2), 1.392(4); B(2)–O(6), 1.358(4); B(2)–O(5), 1.389(4); B(2)–O(4), 1.389(4); O(3)-B(1)-O(1), 127.1(3); O(3)-B(1)-O(2), 120.0(3); O(1)-B(1)-O(2), 112.8(3); O(6)-B(2)-O(5), 120.6(3); O(6)-B(2)-O(4), 126.3(3); O(5)-B(2)-O(4), 113.1(2).



$Bbutcat_2$ anion (10). Complex **6** has also been characterized by a single-crystal X-ray diffraction study, the molecular diagrams of which are shown in Figs. 4–6. Complexes containing thallium transition metal bonds, particularly with Tl(I), are quite rare (11). Indeed, to the best of our knowledge, only one rhodium–thallium complex has been characterized structurally (11*b*). This heterobimetallic complex, $[TlRh_4(\mu\text{-}pyS_2)_2(cod)][PF_6]$ (where pyS = 2,6-pyridineditholate and cod = 1,5-cyclooctadiene), has an almost linear arrangement for the Rh–Tl–Rh subunit with roughly equivalent Rh–Tl bond distances of 2.7686(9) and 2.7706(9) Å. Complex **6** is remarkable, however, in that the Tl bridge is unsymmetrical. Indeed, the Rh–Tl bonds are disparate at Tl(1)–Rh(1), 2.8050(4) Å, and Tl(1)–Rh(2), 3.1234(4) Å, with an angle of Rh(1)–Tl(1)–Rh(2), 68.042(7)°. Metal $M(d^8)$–Tl(I)–$M(d^8)$ units with bridging thallium atoms have also been reported previously for $[Ir_2Tl(CO)_2Cl_2\{\mu\text{-}Ph_2PCH_2)_2AsPh\}_2]$ (11*c*) and $[(H_3N)_2Pt(1\text{-}MeT)_2Tl(1\text{-}MeT)_2Pt(NH_3)_2]^+$ (1-MeT = 1-methylthymine anion) (11*d*), where the bonding in these molecules has been rationalized in terms of the stereoactive $6s^2$ thallium inert pair where the thallium atom acts a Lewis acid to metal centre and a Lewis base to the other. The observation that *both* rhodium centres are distorted square-planar configurations, however, does not support this bonding motif, nor is there any evidence of asymmetry seen in the solution spectra of the complex. The asymmetry in **6** may be a result of a solid-state phenomenon

[b] $wR2 = \{\sum[w(F_o^2 - F_c^2)2]/\sum(F_o^4)\}^{1/2}$; where $w = 1/[\sigma^2(F_o^2) + (0.066P)^2 + (02976P)]$ for **3**, $w = 1/[\sigma^2(F_c^2) + (0.0516P)^2 + (2.5455P)]$ for **4**, and $w = [\sigma^2(F_o^2) + (0.0391P)^2 + (4.9242P)]$ for **6**, where $P = (\max(F_o^2,0)) + 2F^{2c})3$.

Scheme 1. Preparation of the thallium salt $Tl(Bbutcat_2)$ (**5**).

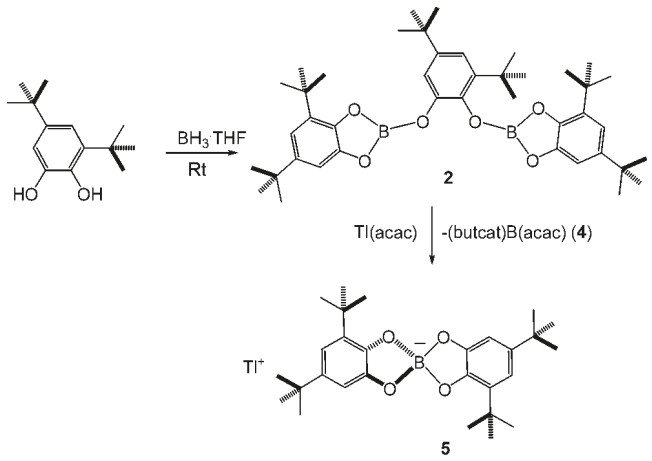

Fig. 3. The molecular structure of **4** with ellipsoids drawn at 50% probability level. Hydrogen atoms are omitted for clarity. Selected bond distances (Å) and angles (°): B(1)–O(2), 1.436(4); B(1)–O(1), 1.450(4); B(1)–O(4), 1.500(4); B(1)–O(3), 1.505(4); O(1)–C(1), 1.379(3); O(2)–C(2), 1.385(3); O(3)–C(15), 1.304(3); O(4)–C(17), 1.302(3); O(2)-B(1)-O(1), 108.3(2); O(2)-B(1)-O(4), 111.3(2); O(1)-B(1)-O(4), 109.4(3); O(2)-B(1)-O(3), 110.0(3); O(1)-B(1)-O(3), 110.2(2); O(4)-B(1)-O(3), 107.6(2).

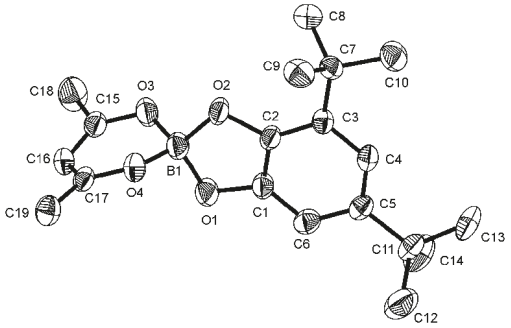

arising from close contact between two phenyl groups from the phosphine ligands with the bridging thallium atom (Fig. 5). Thallium–arene interactions have been reported previously where the hapticity of the arene ring can vary from η^1 to η^6 (12). In the case of **6**, the two phenyl rings are coplanar, and it appears that in one arene ring there are three "short" Tl–C bonds (Tl(1)–C(7), 3.1728(29); Tl(1)–C(8), 3.3866(32); and Tl(1)–C(12), 3.4849(34)) and three "long" Tl–C interactions (Tl(1)–C(9), 3.8870(35); Tl(1)–C(10), 4.1531(36); and Tl(1)–C(11), 3.9539(37)), whereas the other has "two" short (Tl(1)–C(35), 3.2701(29); and Tl(1)–C(36), 3.2086(31)) and four "long" (Tl(1)–C(37), 3.5663(36); Tl(1)–C(38), 3.9320(40); Tl(1)–C(39), 3.9754(38); and Tl(1)–C(40), 3.6745(34)) interactions. An η^3 bonding mode was reported recently for Tl[ArNC(*t*-Bu)NAr] (Ar = 2,6-*i*-Pr-C_6H_3) (12*b*), and bond distances in **6** are within the range reported for these other examples.

The long Rh···Rh separation of 3.3274(4) Å suggests no significant interaction exists between the two d^8 metal centres (13). The bond distances and angles in the noncoordinating $Bbutcat_2^-$ anion are well within those observed for other arylspiroboronate esters derived from catechols (14).

Interestingly, all attempts (elevated temperatures and different solvents) to abstract the chlorides from $[(dppb)Rh(\mu\text{-}Cl)]_2$ using **5** proved unsuccessful, even with reactions utilizing microwave radiation. We are in the process of examining the unusual bonding in complex **6** in more detail and will report our findings in due course. Initial results show that addition of **5** to $[RhCl(coe)_2]_2$ and other diphosphines all give products with similar ^{31}P coupling constants to **6**. As considerable research has focused on the development of novel catalyst systems containing noncoordinating or weakly coordinating counteranions (15), we have also begun an in-depth look at the use of this thallium salt with other metal halides.

Conclusion

We have found that addition of 3,5-di-*tert*-butylcatechol (butcat) to solutions of $H_3B{\cdot}SMe_2$ gave the novel diboron species $B_2(butcat)_3$ (**2**) in moderate to high yields. Compound **2** reacts readily with Tl(acac) to give butcatB(acac) (**4**) and $Tl(Bbutcat_2)$ (**5**). Attempts to abstract the chloride from $[(dppb)Rh(\mu\text{-}Cl)]_2$ using this new thallium salt led to the formation of an unusual dimer $[(dppb)Rh(\mu\text{-}Cl)_2(\mu\text{-}Tl)Rh(dppb)][Bbutcat_2]$ (**6**), which contains a unique unsymmetrical Rh–Tl–Rh bridge. All attempts to remove the chloride ligands proved unsuccessful and future work will investigate the ability of this bulky $Bbutcat_2^-$ anion to bind to other metal centres.

Experimental

General

Reagents and solvents used were purchased from Sigma-Aldrich Chemicals. NMR spectra were recorded on a JEOL JNM-GSX270 FT spectrometer. ^1H NMR chemical shifts are reported in ppm and referenced to residual solvent protons in

© 2008 NRC Canada

deuterated solvent at 270 MHz. ^{11}B NMR chemical shifts are reported in ppm and are referenced to $BF_3{\cdot}OEt_2$ as an external standard at 87 MHz. ^{13}C NMR chemical shifts are referenced to solvent carbon resonances as internal standards at 68 MHz and are reported in ppm. ^{31}P NMR chemical shifts are reported in ppm and are referenced to H_3PO_4 as an external standard at 109 MHz. Multiplicities are reported as singlet (s), doublet (d), triplet (t), multiplet (m), broad (br), and overlapping (ov). All reactions were carried out under an atmosphere of dinitrogen. Microanalyses for C and H were carried out at Guelph Chemical Laboratories (Guelph, Ontario). $[RhCl(coe)_2]_2$ was prepared by an established method (16).

Tl(Bcat$_2$) (1)

To a stirred THF (5 mL) solution of thallium(I) acetylacetonate (0.20 g, 0.66 mmol) was added a THF (5 mL) solution of B_2cat_3 (0.23 g, 0.66 mmol). The reaction was allowed to proceed for 18 h at which point a white precipitate was collected by suction filtration and washed with THF (2 × 3 mL) to afford **1**. Yield: 0.25 g (88%); mp: decomposes above 350 °C (decomp.). Spectroscopic NMR data (in DMSO-d_6): ^{1}H NMR δ: 6.47 (br ov m, Ar); ^{11}B NMR δ: 13 (sharp); ^{13}C{^{1}H} NMR δ: 152.1, 117.8, 108.2. Anal. calcd. (%) for $C_{12}H_8BO_4Tl$ (431.39): C 33.41, H 1.87; found: C 33.25, H 1.81.

B$_2$butcat$_3$ (2)

To a stirred toluene (10 mL) solution of 3,5-di-*tert*-butylcatechol (5.97 g, 0.027 mol) was added a 2.0 mol/L toluene solution of $Me_2S{\cdot}BH_3$ (9.0 mL, 0.018 mol). The reaction was heated at reflux for 18 h at which point the solvent was removed under vacuum. The residual sticky solid was triturated with hexane (2 × 5 mL) and collected by suction filtration to afford **2** as a white solid. Yield: 7.83 g (85%). FT-IR (Nujol): 2951, 2935, 2910, 2862, 1462, 1410, 1377, 1363, 1300, 1263, 1223, 1209, 1142, 1126, 976, 856. Spectroscopic NMR data (in $CDCl_3$): ^{1}H NMR δ: 7.29 (d, J = 2.0 Hz, 1H, Ar), 7.19 (d, J = 2.0 Hz, 1H, Ar), 7.02 (d, J = 1.5 Hz, 1H, Ar), 6.91 (d, J = 1.7 Hz, 1H, Ar), 6.89 (d, J = 1.5 Hz, 1H, Ar), 6.51 (d, J = 1.7 Hz, 1H, Ar), 1.42 (s, 9H, *t*-Bu), 1.35 (s, 9H, *t*-Bu), 1.34 (s, 9H, *t*-Bu), 1.28 (s, 9H, *t*-B), 1.18 (s, 9H, *t*-Bu), 1.10 (s, 9H, *t*-But); ^{13}C{^{1}H} NMR δ: 147.6, 147.5, 146.5, 145.3, 145.0, 143.5, 143.2, 143.0, 140.5, 140.1, 134.6, 134.4, 119.4, 116.4, 116.2, 115.7, 107.4, 107.1, 35.5, 35.0, 34.8, 34.7, 34.3, 34.1, 31.8, 31.7, 31.6, 30.2, 29.7, 29.4; ^{11}B NMR δ: 21 (br). Anal. calcd. (%) for $C_{42}H_{60}B_2O_6$ (682.64): C 73.89, H 8.88; found: C 74.22, H 8.53.

butcatB(acac) (4)

To a stirred toluene (10 mL) suspension of $B_2butcat_3$ (2.00 g, 2.92 mmol) was added thallium(I) acetylacetonate (0.88 g, 2.92 mmol) as a solid. The reaction was allowed to proceed for 18 h at which point a white precipitate was collected by suction filtration. Upon storing the toluene filtrate at –30 °C, a white solid precipitated and was collected by suction filtration. The solid was washed with hexane (2 × 1 mL) to afford **4**. Yield: 0.53 g (55%); mp: 220–222 °C. FT-IR (Nujol): 2980, 2829, 1556, 1471, 1444, 1375, 1288, 1265, 1240, 1205, 1097, 1009, 947, 854, 802, 723, 658. Spectroscopic NMR data (in $CDCl_3$): ^{1}H NMR δ: 6.77 (s, 2H, Ar), 6.00 (s, 1H, C*H*C(O)CH$_3$), 2.30 (s, 6H, CHC(O)C*H*$_3$), 1.41 (s, 9H, *t*-Bu), 1.29 (s, 9H, *t*-Bu); ^{13}C{^{1}H} NMR δ: 191.3, 149.8, 145.6, 142.2, 131.6, 113.8, 105.5, 102.2, 34.8, 34.4, 32.1, 29.9, 24.5; ^{11}B NMR δ: 8 (sharp). Anal. calcd. (%) for $C_{19}H_{27}BO_4$ (330.23): C 69.11, H 8.24; found: C 69.16, H 8.37.

Tl(Bbutcat$_2$) (5)

To a stirred toluene (10 mL) suspension of $B_2butcat_3$ (2.00 g, 2.92 mmol) was added thallium(I) acetylacetonate (0.88 g, 2.92 mmol) as a solid. The reaction was allowed to proceed for 18 h at which point a white precipitate was collected by suction filtration and washed with toluene (2 × 5 mL) to afford **5**. Yield: 1.57 g (82%); mp: 212 °C (decomp.). Spectroscopic NMR data (in $CDCl_3$): ^{1}H NMR δ: 6.81 (s, 4H, Ar), 1.35 (s, 18H, *t*-Bu), 1.26 (s, 18H, *t*-Bu); ^{13}C{^{1}H} NMR δ: 149.1, 147.0, 142.1, 132.8, 114.8, 106.1, 34.9, 34.5, 32.4, 30.2; ^{11}B NMR δ: 13 (sharp). Anal. calcd. (%) for $C_{28}H_{40}BO_4Tl$ (655.80): C 51.28, H 6.15; found: C 51.53, H 6.33.

[(dppb)Rh(μ-Tl)Rh(dppb)][(Bbutcat$_2$)] (6)

To a stirred toluene (10 mL) suspension of $[RhCl(coe)_2]_2$ (0.50 g, 0.70 mmol) was added a toluene (10 mL) solution of dppb (0.59 g, 1.40 mmol) and the reaction was allowed to proceed for 2 h. To the clear burgundy solution, TlBbutcat$_2$ (1.00 g, 1.53 mmol) was added as a solid and the mixture was stirred for 18 h. Following filtration to remove a small amount of precipitate, the volume of the clear orange solution was decreased to 5 mL under vacuum. The solution was stored at –30 °C whereupon an orange precipitate was collected by suction filtration and washed with hexane (2 × 3 mL) to afford **6**. Yield: 0.62 g (45%); mp: 215 °C (decomp.). FT-IR (Nujol): 2952, 2919, 2856, 1459, 1432, 1231, 1185, 1095, 1071, 1027, 993, 904, 846, 740, 697, 655. Spectroscopic NMR data (in THF-d_8): ^{1}H NMR δ: 7.48 (br m, 16H, Ar), 7.32–7.19 (ov m, 24H, Ar), 6.52 (d, J = 1.7 Hz, 2H, Ar), 6.44 (d, J = 1.7 Hz, 2H, Ar), 2.36 (br m, 8H, C*H*$_2$), 1.36 (s, 18H, *t*-Bu), 1.19 (s, 18H, *t*-Bu), 0.88 (m, 8H, C*H*$_2$); ^{13}C{^{1}H} NMR δ: 152.0, 148.2, 137.6, 135.8 (t, J_{CP} = 23.5 Hz, *C*-P), 133.1 (br), 129.6, 128.2, 125.1, 110.2, 103.8, 34.5, 33.8, 31.8, 29.3, 27.8 (t, J_{CP} = 12.8 Hz, *C*H$_2$-P), 22.1; ^{11}B NMR δ: 14 (sharp); ^{31}P{^{1}H} NMR δ: 40.2 (d, J_{PRh} = 178 Hz). Anal. calcd. (%) for $C_{84}H_{96}BCl_2O_4P_4Rh_2Tl$ (1785.78): C 56.49, H 5.43; found: C 55.72, H 5.38.

X-ray crystallography

Crystals of **3** were grown from saturated hexane solutions, crystals of **4** from saturated diethyl ether solutions, and crystals of **6** from saturated methanol solutions layered with hexanes, all at –30 °C. Single crystals were coated with Paratone-N oil, mounted using a glass fibre, and frozen in the cold stream of the goniometer. A hemisphere of data were collected on a Bruker AXS P4/SMART 1000 diffractometer using ω and θ scans with a scan width of 0.3° and exposure times of 30 s (**3**), 40 s (**4**), and 10 s (**6**). The detector distances were 5 cm. The data were reduced (SAINT) (17) and corrected for absorption (SADABS). The structures were solved by direct methods and refined by full-matrix least-squares on F2(SHELXTL). One of the *tert*-butyl

© 2008 NRC Canada

groups of **3** was disordered and the site occupancy determined using an isotropic model as 0.9 (C(12)-C(14)) and 0.1 (C(12a)-C(14a)) and fixed in subsequent refinement cycles. Likewise, one of the *tert*-butyl groups in **4** was disordered and the site occupancy determined using an isotropic model as 0.60 (C(12)-C(14)) and 0.4 (C(12′)-C(14′)) and fixed in subsequent refinement cycles. All non-hydrogen atoms were refined using anisotropic displacement parameters. Hydrogen atoms were included in calculated positions and refined using a riding model. Hexane solvent molecules in **6** were modeled using disordered electron densities.

Acknowledgements

This paper is dedicated to Dr. R.J. Puddephatt in recognition of his outstanding contributions to chemistry. Thanks are gratefully extended to the Natural Sciences and Engineering Research Council (NSERC) of Canada, Canada Research Chairs Programme, Canadian Foundation for Innovation–Atlantic Innovation Fund, and Mount Allison University for financial support. We also thank Roger Smith and Dan Durant for their expert technical assistance and anonymous reviewers for helpful comments, especially with respect to bonding in complex **6**.

Synthesis and structures of palladium(II) and platinum(II) complexes containing heterocyclic thiolate ligands formed by cycloaddition reactions of coordinated azides[1]

Angela Fleischer, Alexander Roller, Vladimir B. Arion, Bernhard K. Keppler, and Fabian Mohr

Abstract: The phosphine-stabilized azido complexes $[M(N_3)_2(PTA)_2]$ (M = Pd, Pt; PTA = 1,3,5-triaza–7-phosphaadamantane) were prepared in high yields by a ligand exchange reaction from *cis*-$[Pd(N_3)_2(tmeda)]$ and *cis*-$[Pt(N_3)_2(cod)]$, respectively. The Pd and Pt complexes $[M(N_3)_2(PTA)_2]$ undergo cycloaddition reactions with various isothiocyanates to give complexes containing anionic, S-coordinated tetrazole-thiolate ligands of the type *trans*-$[M(SCN_4R)_2(PTA)_2]$ (M = Pd, Pt; R = Et, allyl, Me, Ph). The molecular structures of several of these derivatives were determined by X-ray crystallography.

Key words: palladium, platinum, thiolate, heterocycle, azide, cycloaddition.

Résumé : On a préparé les complexes azido stabilisés par une phosphine $[M(N_3)_2(PTA)_2]$ [M= Pd, Pt; PTA = 1,3,5-triaza-7-phosphaadamantane] avec des rendements élevés en procédant à une réaction d'échange de ligand à partir respectivement du *cis*-$[Pd(N_3)_2(tmeda)]$ et *cis*-$[Pt(N_3)_2(cod)]$. Les complexes du Pd et du Pt $[M(N_3)_2(PTA)_2]$ subissent des réactions de cycloaddition avec divers isothiocyanates pour conduire à la formation de complexes contenant des ligands anioniques tétrazole-thiolate, S-coordinés, du type *trans*-$[M(SCN_4R)_2(PTA)_2]$ (M = Pd, Pt; R = Et, allyle, Me, Ph). Les structures molécules de plusieurs de ces dérivés ont été déterminées par la diffraction des rayons X.

Mots-clés : palladium, platine, thiolate, hétérocycle, azide, cycloaddition.

[Traduit par la Rédaction]

Introduction

Azido complexes of palladium stabilized by phosphine ligands were first reported by Beck et al. in 1965 (1). In a series of papers, the group showed that the coordinated azido groups undergo cycloaddition reactions with nitriles, alkynes, and isothiocyanates to give metal-coordinated tetrazolates (Chart 1) (2–6). Since then, several groups have studied reactions of phosphine-stabilized Pd and, to a much lesser extent, Pt azido complexes with various nitriles and isocyanides. In contrast, cycloaddition reactions with isothiocyanates have only recently been studied in detail (7–9). These results show that the resulting heterocycle is S-coordinated to the metal (Chart 1) rather than N-coordinated, as originally suggested by Beck and co-workers in 1972 (5). A computational study of the reaction mechanism leading to the S-coordinated tetrazole-thiolato complex has also been carried out (10).

We have been exploring the structures and reactivity of precious metal complexes containing the water-soluble phosphine ligand 1,3,5-triaza–7-phosphaadamantane (PTA) (11–14). In this context, water-soluble Pt(II) complexes containing heterocyclic thiolate ligands showed promising in vitro cytotoxicity against various tumour cell lines (15). To generate a library of new water-soluble Pd and Pt complexes with a variety of substituted tetrazole-thiolates from one common precursor, we investigated the cycloaddition of isothiocyanates to PTA-stabilized Pd and Pt azido complexes. Some preliminary results of this study are reported herein.

Results and discussion

The PTA stabilized Pd and Pt bis(azido) complexes $[M(N_3)_2(PTA)_2]$ (M = Pd **1**, Pt **2**) are readily prepared in high yields by displacement of the tmeda or cod ligands from *cis*-$[Pd(N_3)_2(tmeda)]$ and *cis*-$[Pt(N_3)_2(cod)]$, respectively. Both complexes are poorly soluble in water and insoluble in chlorinated solvents, acetone, and alcohols, but readily soluble in DMSO. The $^{31}P\{^1H\}$ NMR spectra of

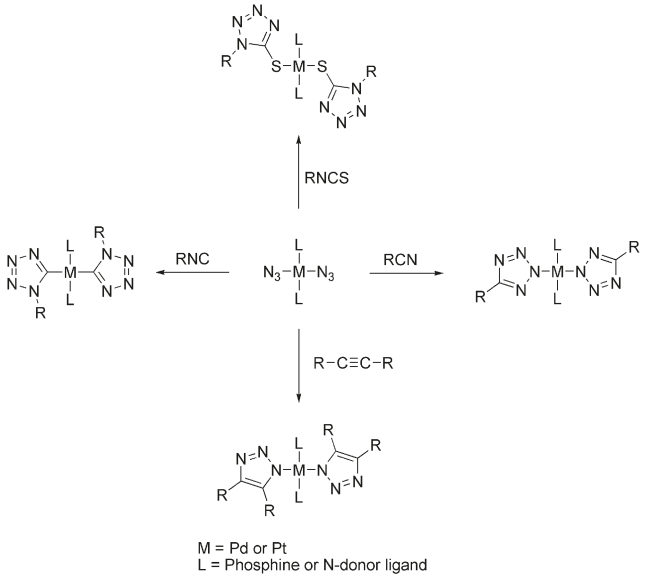
Chart 1.



Scheme 1.

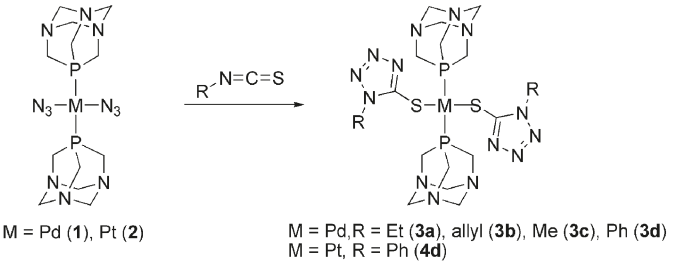


Fig. 1. Molecular structure of complex **3a**. Ellipsoids show 50% probability levels. Hydrogen atoms have been omitted for clarity. Selected bond distances (Å) and angles (°): Pd1–P1 2.3054(4), Pd1–S1 2.3434(4), S1–C7 1.7250(15), C7–N5 1.3348(18), C7–N4 1.3485(18), N4–N7 1.3576(17), N7–N6 1.2934(18); P1–Pd1–S1 89.390(13), C7–S1–Pd1 100.88(5).

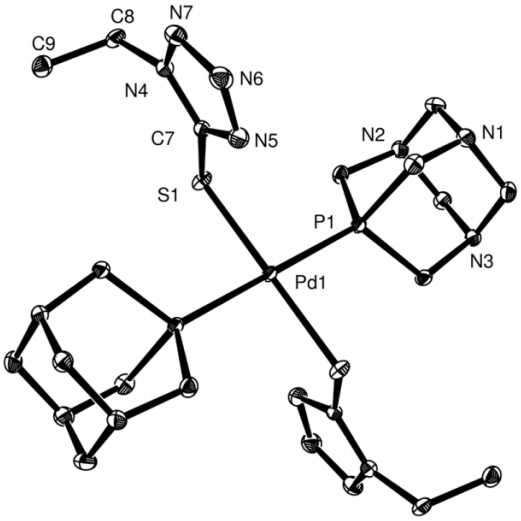

complexes **1** and **2** show singlet resonances at –29.90 and –59.09 ppm, respectively. The IR spectra of both compounds show strong bands between 2020 and 2050 cm^{-1} due to the coordinated azido ligand. The positive ion ES-MS spectra of both complexes show a single, intense peak with *m/z* of 527 (**1**) and 616 (**2**), corresponding to the Na adduct of the molecular ions. The observed isotopic distribution patterns are in perfect agreement with the proposed formulas. Attempts to obtain X-ray diffraction quality crystals of these complexes failed, as the initially yellow or colorless DMSO solutions darkened and eventually decomposed to give a metallic mirror over a period of 2–3 days. However, the solid samples are stable in air at ambient temperatures for months.

Complex **1** reacts with the isothiocyanates RNCS (R = Et, allyl, Me, Ph) in CH_2Cl_2 at room temperature over a period of ca. 18 h to give orange solutions, which, upon layering with Et_2O, afford crystals of the Pd tetrazole-thiolato complexes *trans*-[$Pd(SCN_4R)_2(PTA)_2$] (R = Et **3a**, allyl **3b**, Me **3c**, Ph **3d**) after several days (Scheme 1).

The structures of complexes **3a**, **3b**, and **3d** were determined by X-ray crystallography, and in addition, ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded. Since we were at this stage not interested in isolating bulk samples of the materials, only NMR scale experiments were performed, and thus no other analytical techniques were used to characterize the compounds. In the case of the Me derivative (**3c**), the crystals were of poor quality so only ^1H and $^{31}P\{^1H\}$ NMR spectra are available for this compound. The $^{31}P\{^1H\}$ NMR spectra of complexes **3a**–**3d** consist of a singlet resonance at ca. –56 ppm, which is shifted by ca. 27 ppm from that of the azido precursor. These chemical shifts are very similar to those observed in other Pd PTA complexes containing thiolate ligands (14). The ^1H NMR spectra of complexes **3a**–**3d** show, in addition to the signals from the tetrazole substituents, a singlet and an AB-quartet because of the PCH_2N and NCH_2N protons of the PTA ligands, respectively. The proposed structures of the complexes were confirmed by X-ray diffraction studies of compounds **3a**, **3b**, and **3d**; the molecular structures are shown in Figs. 1–3.

In all three complexes, the palladium is coordinated by two tetrazolate-thiolates (via the sulfur atom) and two PTA ligands in a square planar geometry with a *trans* configuration. The Pd–P and Pd–S bond distances of (ca. 2.30 and 2.34 Å, respectively) are very similar to those observed in other PTA complexes of palladium containing thiolate ligands, e.g., *trans*-[$Pd(SPyridine)_2(PTA)_2$] (14). The C–S bond lengths of ca. 1.72 Å are also similar to those observed in other tetrazole-thiolate complexes of Pd (7) but shorter than in Pd complexes containing pyridine thiolate ligands (1.75 Å) (14).

It was also attempted to prepare analogous complexes using the Pt precursor [$Pt(N_3)_2(PTA)_2$] **2**. In this case, however, the cycloaddition reaction was considerable slower (ca. 2–3 days were required for all of complex **2** to be consumed), compared with the Pd series. This difference in reaction rate between Pd and Pt complexes has also been observed by Kim et al. (7). Furthermore, it was only possible to obtain crystalline material for the product derived from phenyl isothiocyanate (**4d**) upon layering the sample with Et_2O. The spectroscopic data of complex **4d** is essentially identical to that of its Pd congener **3d**. The $^1J_{Pt\text{-}P}$ coupling constant of

Fig. 2. Molecular structure of complex **3b**. Ellipsoids show 50% probability levels. Hydrogen atoms have been omitted for clarity. Selected bond distances (Å) and angles (°): Pd1–P1 2.2949(4), Pd1–S1 2.3328(4), S1–C7 1.7213(14), C7–N5 1.3472(18), C7–N4 1.3345(18), N4–N7 1.3672(18), N7–N6 1.2944(1); P1–Pd1–S1 93.400(13), C7–S1–Pd1 104.14(5).

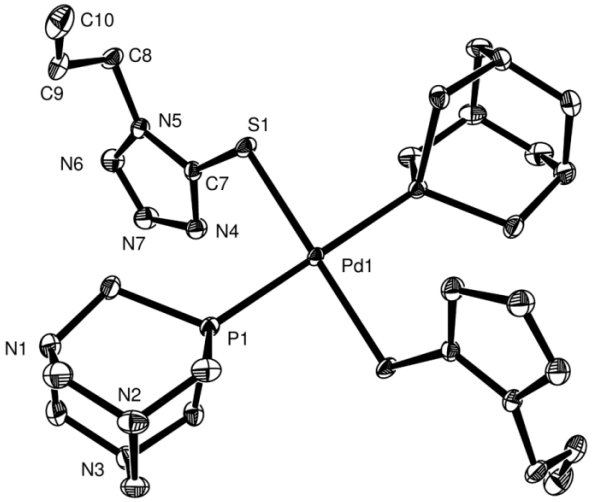

Fig. 3. Molecular structure of complex **3d**. Ellipsoids show 50% probability levels. Hydrogen atoms have been omitted for clarity. Selected bond distances (Å) and angles (°): Pd1–P1 2.3018(7), Pd1–S1 2.3406(6), S1–C7 1.717(3), C7–N4 1.349(3), C7–N7 1.324(3), N4–N5 1.365(3), N5–N6 1.292(3); P1–Pd1–S1 90.98(2), C7–S1–Pd1 101.29(9).

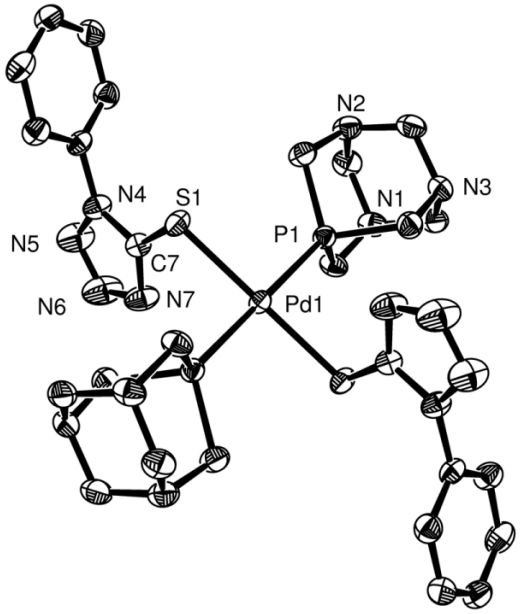
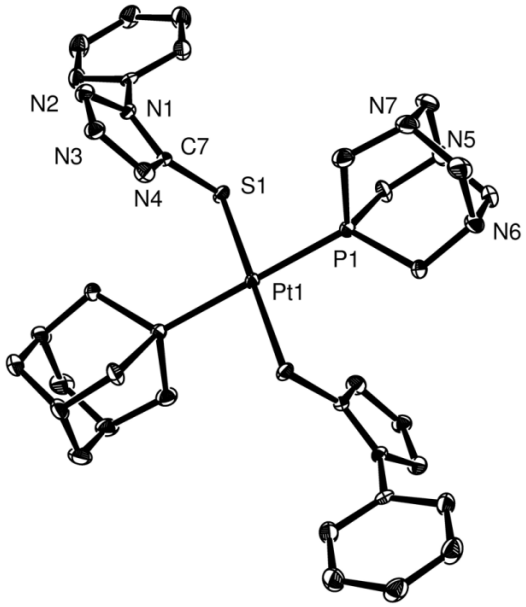


2458 Hz observed in the $^{31}P\{^{1}H\}$ NMR spectrum of **4d** is consistent with a *trans* configuration, similar to what has been reported for other *trans* Pt complexes containing PTA and thiolate ligands (15). This trans geometry was confirmed by X-ray crystallography; the molecular structure of **4d**·CH_2Cl_2 is shown in Fig. 4.

Fig. 4. Molecular structure of complex **4d**·CH_2Cl_2. Ellipsoids show 50% probability levels. Hydrogen atoms and the disordered CH_2Cl_2 molecule have been omitted for clarity. Selected bond distances (Å) and angles (°): Pt1–P1 2.2897(10), Pt1–S1 2.3393(9), S1-C7 1.717(4), C7–N4 1.331(5), C7–N1 1.355(5), N4–N3 1.364(5), N3–N2 1.282(5); P1–Pt1–S1 87.21(3), C7–S1–Pt1 102.44(13).



The molecular structure of **4d** is very similar to that of the Pd derivative **3d**: Pt shows square planar coordination geometry with a *trans* arrangement of pairs of identical ligands. Bond lengths and angles in **4d** are also typical for complexes of this kind.

In conclusion, we have shown that the reaction of various isothiocyanates with a PTA-stabilized Pd azido complex gives *trans* Pd complexes containing anionic, S-coordinated tetrazole-thiolate ligands. This coordination mode of the cycloaddition product was confirmed by crystallographic studies. In the case of platinum, the same reaction occurs, but the rate of the reaction is considerably slower. Further work is currently in progress to develop a suitable preparation method for larger quantities of these complexes and to study their biological activity.

Experimental

PTA (1,3,5-triaza–7-phosphaadamantane), *cis*-[$Pt(N_3)_2$(cod)] (cod = 1,5-cyclooctadiene), and *cis*-[$Pd(N_3)_2$(tmeda)] (tmeda = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine) were prepared following published procedures (16, 17). All solvents and chemicals were sourced commercially and used as received. ^{1}H, ^{13}C, and $^{31}P\{^{1}H\}$ NMR spectra were recorded on a Bruker Avance III 500 MHz instrument using residual solvent signals as reference. Mass spectra (ES-MS positive ion mode) were measured on a Bruker Esquire 3000 spectrometer and IR spectra on a Bruker FT-IR instrument as KBr disks. Elemental analyses were carried out by staff of the microanalytical laboratory of the Institute of Inorganic Chemistry at the University of Vienna.

$[Pd(N_3)_2(PTA)_2]$ (1)

To a CH_2Cl_2 solution of *cis*-$[Pd(N_3)(tmeda)]$ (0.300 g, 1.142 mmol) was added a solution of PTA (0.359 g, 2.284 mmol) in CH_2Cl_2 (15 mL). After stirring the mixture for 2 h, the yellow solid was isolated by filtration, washed with Et_2O, and dried. Yield: 0.496 g, 86%. IR (KBr disk, cm^{-1}) ν (N_3): 2040, 2019. ^1H NMR (500 MHz, DMSO-d_6, 25 °C, ppm) δ: 4.47 (AB quart, J = 12.6 Hz, 12 H, NCH_2N), 4.35 (s, 12 H, PCH_2P). $^{13}C\{^1H\}$ NMR (126 MHz, DMSO-d_6, 25 °C, ppm) δ: 51.30 (br s, PCH_2N), 71.64 (s, NCH_2N). $^{31}P\{^1H\}$ NMR (202 MHz, DMSO-d_6, 25 °C, ppm) δ: –29.90. ES-MS *m/z*: 527 $[M + Na]^+$. Calcd. for $C_{12}H_{24}N_{12}P_2Pd$ (504.77): C 28.55, H 4.79, N 33.30; found C 28.72, H 4.81, N 33.06.

$[Pt(N_3)_2(PTA)_2]$ (2)

To a suspension of *cis*-$[Pt(N_3)_2(cod)]$ (0.100 g, 0.258 mmol) in CH_2Cl_2 was added PTA (0.081 g, 0.516 mmol). After stirring for ca. 2 h, the colourless solid was isolated by filtration, washed with Et_2O, and dried to give 0.129 g (84%) of the complex. IR (KBr disk, cm^{-1}) ν(N_3): 2052, 2036. ^1H NMR (400 MHz, DMSO-d_6, 25 °C, ppm) δ: 4.46 (AB quart, J = 12.6 Hz, 12 H, NCH_2N), 4.25 (s, 12 H, PCH_2P). $^{31}P\{^1H\}$ NMR (162 MHz, DMSO-d_6, 25 °C, ppm) δ: –59.09 ($J_{Pt\text{-}P}$ = 3140 Hz). ES MS *m/z*: 616 $[M + Na]^+$. Calcd. for $C_{12}H_{24}N_2P_2Pt$ (593.42): C 24.29, H 4.08, N 28.32; found C 24.50, H 4.03, N 28.39.

Preparation of the cycloaddition products

To a suspension of $[M(N_3)_2(PTA)_2]$ (M = Pd, Pt) (25 mg) in CH_2Cl_2 (5 mL) was added an excess (ca. 0.2 mL) of RNCS (R = Et, allyl, Me, Ph). The mixture was left to stir for ca. 18 h at room temperature during which all solid had dissolved. Et_2O was carefully layered onto the solution and after standing for 2–4 days, crystals could be harvested. NMR data was obtained by re-dissolving the crystals in a suitable deuterated solvent. In case of the Pt derivative, the reaction required much longer time (assessed by the time taken for **2** to completely dissolve), and crystals were only obtained when using phenyl isothiocyanate. Using this procedure the following compounds were prepared.

***trans*-$[Pd\{SCN_4(Et)\}_2(PTA)_2]$ (3a)**

Orange crystals. ^1H NMR (500 MHz, $CDCl_3$, 25 °C, ppm) δ: 4.34–4.43 (m, 18 H, NCH_2N, CH_3CH_2N), 4.15 (s, 12 H, PCH_2P), 1.58 (t, J = 7.3 Hz, 6 H, CH_3CH_2N). $^{31}P\{^1H\}$ NMR (202 MHz, $CDCl_3$, 25 °C, ppm) δ: –56.12.

***trans*-$[Pd\{SCN_4(CH_2CHCH_2)\}_2(PTA)_2]$ (3b)**

Orange crystals. ^1H NMR (500 MHz, $CDCl_3$, 25 °C, ppm) δ: 5.98–6.09 (m, 2 H, $NCH_2CH{=}CH_2$) 5.39 (d, J = 10.1 Hz, 2 H, $NCH_2CH{=}CH_2$), 5.32 (d, J = 17.0 Hz, 2 H, $NCH_2CH{=}CH_2$), 4.96 (d, J = 5.9 Hz, 4 H, $NCH_2CH{=}CH_2$), 4.38 (AB quart, J = 12.6 Hz, 12 H, NCH_2N), 4.14 (s, 12 H, PCH_2P). $^{31}P\{^1H\}$ NMR (202 MHz, $CDCl_3$, 25 °C, ppm) δ: –55.84.

***trans*-$[Pd\{SCN_4(Me)\}_2(PTA)_2]$ (3c)**

Yellow crystals. ^1H NMR (500 MHz, $CDCl_3$, 25 °C, ppm) δ: 4.33–4.49 (m, 12 H, NCH_2N), 4.16 (s, 12 H, PCH_2P), 4.00 (s, 6 H, Me). $^{31}P\{^1H\}$ NMR (202 MHz, $CDCl_3$, 25 °C, ppm) δ: –56.25.

trans-*$[Pd\{SCN_4(Ph)\}_2(PTA)_2]$ (3d)*

Orange crystals. ^1H NMR (500 MHz, $CDCl_3$, 25 °C, ppm) δ: 7.87 (d, J = 7.6 Hz, 4 H, *o*-Ph), 7.60 (t, J = 7.6 Hz, 4 H, *m*-Ph), 7.54 (t, J = 7.3 Hz, 2 H, *p*-Ph), 4.36 (AB quart, J = 13.2 Hz, 12 H, NCH_2N), 4.16 (s, 12 H, PCH_2P). $^{31}P\{^1H\}$ NMR (202 MHz, $CDCl_3$, 25 °C, ppm) δ: –55.61.

trans-*$[Pt\{SCN_4(Ph)\}_2(PTA)_2]$ (4d)*

Colourless crystals. ^1H NMR (500 MHz, $CDCl_3$, 25 °C, ppm) δ: 7.84 (d, J = 7.6 Hz, 4 H, *o*-Ph), 7.62 (t, J = 6.9 Hz, 4 H, *m*-Ph), 7.56 (t, J = 7.3 Hz, 2 H, *p*-Ph), 4.37 (AB quart, J = 13.2 Hz, 12 H, NCH_2N), 4.17 (s, 12 H, PCH_2P). $^{31}P\{^1H\}$ NMR (202 MHz, $CDCl_3$, 25 °C, ppm) δ: –63.80 ($J_{P\text{-}Pt}$ = 2458 Hz).

X-ray crystal structure determinations[3]

X-ray diffraction quality crystals of compounds **3a**, **3b**, **3d**, and **4d**·CH_2Cl_2 were mounted in a cryoloop with a drop of oil and placed into the cold stream (100 K) of a Bruker X8 APEX II CCD diffractometer with graphite-monochromated Mo Kα radiation (λ = 0.710 73 Å), controlled by a Pentium-based PC running the SAINT software package (18). Single crystals were positioned at 40 mm from the detector and 1843, 2075, 1599, and 4656 frames were measured, each for 70, 20, 70, and 5 s over 1° scan width for **3a**, **3b**, **3d**, and **4d**·CH_2Cl_2, correspondingly. Crystal data, data collection parameters, and structure refinement details for **3a**, **3b**, **3d**, and **4d**·CH_2Cl_2 are given in Table 1. The structures were solved by direct methods and refined on F^2 by full-matrix least-squares techniques using the SHELXTL software package (19, 20); scattering factors were taken from the literature (21). The co-crystallized CH_2Cl_2 molecule in **4d**·CH_2Cl_2 was found disordered over two positions with site occupation factors 0.61:0.39. The disorder was solved by using SADI and EADP restraints. All non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were placed at calculated positions or localized on difference Fourier maps and isotropically refined. Calculated hydrogen atoms have assigned thermal parameters equal to either 1.5 (methyl hydrogen atoms) or 1.2 (non-methyl hydrogen atoms) times the thermal parameters of the atom to which they were attached. The graphics were prepared by using ORTEP (22).

Octahedral perfluoroalkyl complexes of Ir(III) formed by oxidative addition of perfluoroalkyl iodides to Ir(acac)$(CO)_2$[1]

Hui Huang, N. Raluca Hurubeanu, Cheryl J. Bourgeois, Sue-Mei Cheah, Jian Yuan, Arnold L. Rheingold, and Russell P. Hughes

Abstract: Oxidative addition of primary, secondary, or benzylic perfluoroalkyl iodides (R_F–I) to the phosphine free Ir(I) precursor Ir(acac)(CO)**2 1** (acac = 2,4-pentanedionato) proceeds smoothly to afford octahedral Ir(III) products Ir(acac)(I)(R_F)$(CO)_2$, A combination of X-ray crystallographic studies and solution spectroscopy shows that these products are the result of overall trans-addition of the C–I bond to iridium, probably a result of thermodynamic control; evidence for a kinetic product resulting from net cis-addition is obtained in one case. Treatment of the Ir(III) compounds with AgOTf (Tf = CF_3SO_3) illustrates that the iodo ligand is replaced by triflate with retention of stereochemistry at Ir. The resulting triflate complexes are inert to displacement by H_2O or H_2. The Ir(III) products exhibit very high CO stretching frequencies in the IR, indicating that the CO ligands may be non-classical. A quantitative estimation of the degree of backbonding to the CO ligands in these compounds, and a comparison of the π-acceptor properties of CO and fluoroalkyl ligands, is made using an approach based on Density Functional Theory (DFT) and Natural Bond Orbital analyses.

Key words: iridium, fluoroalkyl, oxidation, carbonyl, DFT.

Résumé : L'addition oxydante d'iodures primaires, secondaires ou benzyliques perfluoroalkylés (R_F–I) sur le précurseur Ir(I) sans phosphine, Ir(acac)$(CO)_2$ (**1**) (acac = 2,4-pentanedionato), s'effectue sans problème et elle conduit à la formation de produits Ir(III) octaédriques Ir(acac)((I)(R_F)$(CO)_2$. Des études cristallographiques par diffraction des rayons X et d'autres réalisées par spectroscopie en solution permettent de montrer que ces produits sont le résultat d'une addition nette *trans* de la liaison C–I sur l'iridium, probablement sous l'influence d'un contrôle thermodynamique; dans un cas, on a toutefois été en mesure de mettre en évidence d'un produit cinétique résultant d'une addition nette *cis*. Le traitement des composés Ir(III) avec du AgOTf (Tf = CF_3SO_3) permet d'illustrer que le ligand iodo est remplacé par le triflate avec rétention de la stéréochimie au niveau de l'iridium. Les complexes triflates qui en résultent sont inertes aux déplacements par l'eau ou l'hydrogène. Les produits Ir(III) présentent des spectres infrarouges dans lesquels les fréquences d'élongation du CO sont très élevées, ce qui suggère que les ligands CO ne sont pas classiques. Faisant appel à la théorie de la densité fonctionnelle et une analyse des orbitales de liaison naturelle, on a fait une évaluation quantitative du degré de retour de liaison vers les ligands CO dans ces composés ainsi qu'une comparaison des propriétés des ligands CO et fluoroalkyles comme accepteurs π.

Mots-clés : iridium, fluoroalkyle, oxydation, carbonyle, théorie de la densité fonctionnelle (TDF).

[Traduit par la Rédaction]

Introduction

The oxidative addition of carbon–halogen bonds to low-valent transition metal complexes is a fundamental organometallic reaction that plays a key role in many useful catalytic transformations (1). An important example is the addition of CH_3I to *cis*-$[MI_2(CO)_2]^-$ (M = Rh or Ir) in the carbonylation of methanol to form acetic acid (2–6). Corresponding oxidative addition of a large variety of substrates to square-planar d^8 complexes of platinum has also been a subject of great interest and the source of a great many significant contributions from the Puddephatt group over the

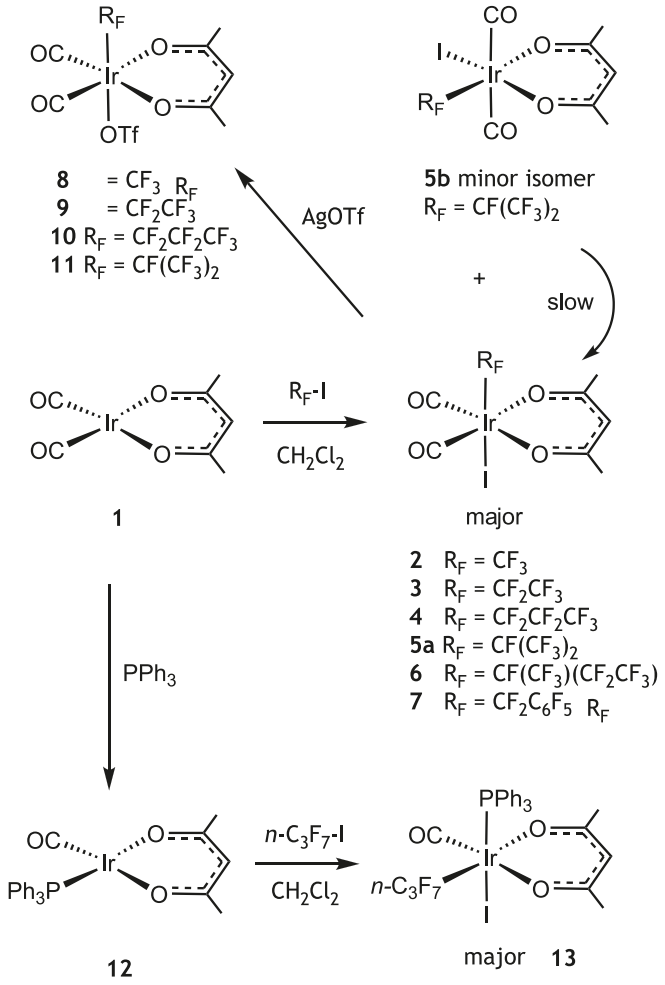
Scheme 1.



past three decades, only representative examples of which are referenced here (7–27). Our group has had a long-standing interest in using analogous oxidative addition reactions of perfluoroalkyl iodides, based on reactions originally reported in the 1960s (28, 29), to prepare perfluoroalkyl complexes of the late transition metals, including iridium (30–32), rhodium (31–36), palladium (37, 38), and platinum (39–43).

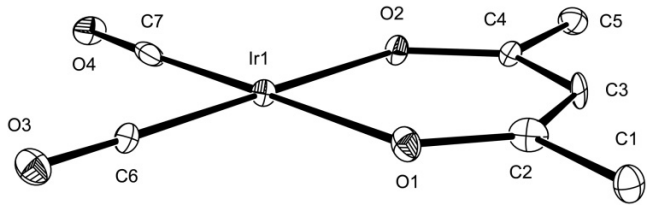
The square-planar iridium(I) complex **1** (Scheme 1) (44) is a commercially available catalyst for anti-Markovnikov arylation of olefins and olefin isomerization (45) and has been broadly employed to prepare other organometallic complexes through ligand substitution (46, 47) or cluster formation (48, 49). Simple oxidative addition reactions to this 16-electron complex do not appear to have been reported. Here, we report syntheses, reactivity, and DFT studies of a series of new perfluoroalkyl iridium complexes, obtained by oxidative addition of **1** with perfluoroalkyl iodides, which have been characterized spectroscopically, and in some cases, crystallographically.

Results and discussion

Synthesis and molecular structure of 1

Despite being known for four decades and being a compound of some synthetic utility (vide supra), the molecular structure of **1** has apparently not been determined accurately. A search of the Cambridge Structure Database (50) revealed a single report (code ACRHCO) of a 12% structure with no deposited coordinates, resulting from a Ph.D. thesis (51). In our hands, when **1** was synthesized according to the reported method (52), good quality crystals were obtained and were subjected to a single-crystal X-ray diffraction study. An ORTEP is shown in Fig. 1, details of the crystal data are presented in Table 1, and selected bond lengths and angles for the coordination sphere of Ir are given in Table 2. The intramolecular structure is unremarkable, but the crystal packing diagram shown in Fig. 2 reveals the expected face-to-face stacking of the individual planar molecules to give a linear chain structure with an Ir–Ir separation of 3.192 Å. Despite the absence of a deposited crystal structure, several studies of phenomena resulting from intermolecular interactions in the solid-state structure of this molecule have already been reported (53–58).

Fig. 1. ORTEP diagram of **1** with ellipsoids drawn at the 30% probability level. Hydrogen atoms are omitted for clarity. Selected bond lengths and angles are presented in Table 2.



Oxidative addition of perfluoroalkyl iodides to 1

Treatment of **1** with primary, secondary, and benzylic perfluoroalkyl iodides (R_F–I) in CH_2Cl_2 at room temperature afforded oxidative addition of the R_F–I bond to give the Ir(III) complexes **2**–**7** in excellent yields as shown in Scheme 1. Crystal structures were obtained for complexes **4** and **5**; ORTEP diagrams are presented in Figs. 3 and 4, respectively, and details of the crystal data and structure determinations are presented in Table 1. Selected bond lengths and angles for the coordination sphere of Ir are given in Table 2.

The structures establish an approximate octahedral coordination around iridium, with the fluoroalkyl and iodo ligands mutually trans to each other. Analogous trans-stereochemistry for the oxidative addition of fluoroalkyl iodides to square-planar compounds has previously been observed in reactions of Pt(II) complexes (37, 42, 59).

As previously observed for Pd(II) (38) and other Ir(III) (30) complexes, the Ir–R_F bond length to the primary fluoroalkyl group in **4** [2.093(5) Å] is significantly shorter than that to the much bulkier (60) secondary fluoroalkyl in **5** [2.139(3) Å]. The Ir–C(O) bond lengths in **4** [1.893(5), 1.907(5) Å] and **5** [1.897(4), 1.900(4) Å] are slightly longer than those in the Ir(I) precursor **1** [1.856(10), 1.883(14) Å], while the Ir–O(acac) bond lengths in **4** [2.037(3), 2.037(3) Å] and **5** [2.031(2), 2.035(2) Å] are slightly shorter than those in **1** [2.053(6), 2.078(8) Å]; both these features are consistent with formal oxidation at iridium and less backbonding from Ir → CO. A more quantitative discussion of the degree of backbonding to the CO ligands is presented later. The Ir–I bond lengths for **4** [2.7363(4) Å] and **5**

[2.7205(3) Å] are essentially the same. As previously observed in Pd(II) complexes (38), the secondary α-C–F bond lengths in **4** [1.359(6), 1.375(6) Å] are shorter than the tertiary α-C–F bond length in **5** [1.398(4) Å].

Solution spectroscopy is also consistent with trans-stereochemistries for compounds **2**–**5a** and **7**. Observation of a single methyl resonance for the acac CH_3 groups is consistent with a structure having a plane of symmetry perpendicu-

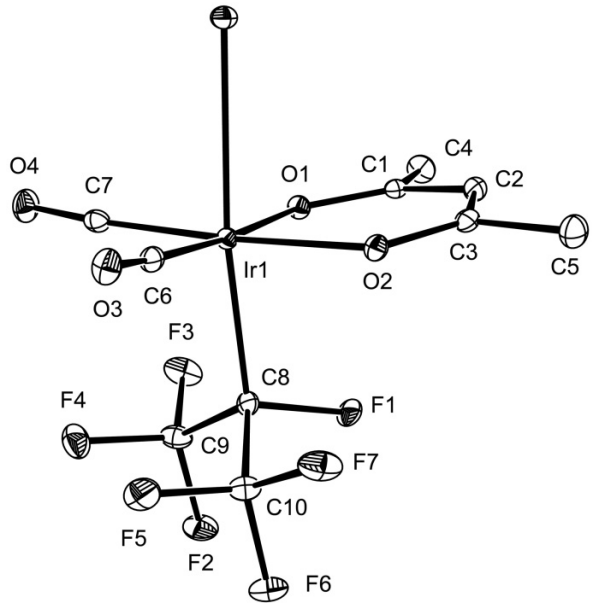
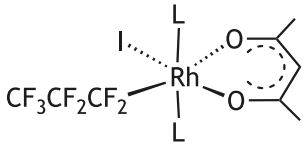
lar to the acac plane, and observation of symmetry equivalent α-CF_2 fluorines in **4** or β-CF_3 groups in **5a** is only consistent with a plane of symmetry including the α-carbon of the fluoroalkyl group. Only the illustrated trans-stereochemistries satisfy both these requirements. The overall structure of compound **6** is not unambiguously defined by spectroscopy, as the stereocenter at the α-carbon precludes any symmetry planes, yet only one CH_3 group is observed for the acac ligand; we assume that this arises due to accidental isochronicity of these methyl resonances and that the structure of **6** is analogous to those of its relatives. Curiously, in the reaction of **1** with perfluoro-*iso*-propyl iodide, a second set of transient peaks was observed in the reaction mixture; only a single CF_3 resonance was observed in the ^{19}F NMR spectrum and two methyl resonances were observed in the ^1H NMR spectrum. These observations are only consistent with the structure of this second compound being **5b** (Scheme 1). These peaks disappear over a short

Fig. 4. ORTEP diagram of **5a** with ellipsoids drawn at the 30% probability level. Hydrogen atoms are omitted for clarity. Selected bond lengths and angles are presented in Table 2.



time, leaving **5a** as the only isolable product. This observation suggests that, at least in the case of perfluoro-*iso*-propyl iodide, the kinetic stereochemistry of oxidative addition is cis, and perhaps that in all cases described here, the final observed trans-stereochemistry may be the result of thermodynamic control. It is interesting to note that cis oxidative addition was reported in the oxidative addition of perfluoro-*n*-propyl iodide to Rh(acac)L_2 (L = PPh_3, $PMePh_2$) to give compounds **14** (61) but that trans-stereochemistries are the demonstrable kinetically controlled norm for oxidative addition of perfluoroalkyl iodides to Pt(II) systems (37, 42).



14 (L = PPh_3, $PMePh_2$)

We have shown previously that the iodide ligand in Cp*Ir(PMe_3)(R_F)(I) compounds is easily substituted by triflate on treatment with AgOTf, to give Cp*Ir(PMe_3)(R_F)(OTf) complexes, in which the triflate ligand can readily be substituted by water to give cationic Cp*Ir(PMe_3)(R_F)(OH_2)][OTf] compounds (32). These water compounds proved to be useful precursors for heterolytic activation of H_2, with subsequent hydrogenolysis of α-CF bonds to liberate hydrofluorocarbon products (62, 63). To see whether analogous reactivity could be observed in triflates derived from the systems described here, compounds **2**–**5a** were treated with AgOTf in CH_2Cl_2 to afford the corresponding triflate analogues **8**–**11** (Scheme 1). Crystal structures of **8** and **9** were carried out; ORTEP diagrams are provided in Figs. 5 and 6, respectively. Crystallographic

data are presented in Table 1 and selected bond lengths and angles in Table 2.

The crystal structures confirm the trans-stereochemistries of **8** and **9**, and solution NMR data are also consistent with this stereochemistry for all compounds **8**–**11**; replacement of iodide with triflate clearly proceeds via a mechanism in which overall stereochemistry at iridium is retained. However, no reaction of these compounds with either water or H_2 was observed, in contrast to our previous observations on pentamethylcyclopentadienyl analogues (62, 63) and in contrast with the observations of Eisenberg on dicationic Ir(III)–CF_3 complexes (64). Compounds **8**–**11** appear to possess the classic inertness expected for low spin d^6 compounds of the third transition series.

Finally, **1** was treated with 1 equiv. of PPh_3 to prepare the phosphine analogue **12** (Scheme 1) according to the reported method (44). Treatment of **12** with perfluoro-*n*-propyl iodide resulted in smooth oxidative addition, but NMR spectroscopy of the reaction mixture showed the presence of two isomeric products whose relative concentration did not change with time. Crystallization afforded single crystals of the major isomer, whose structure was obtained by X-ray diffraction and shown to be **13** (Scheme 1). An ORTEP diagram is presented in Fig. 7; crystallographic details are in Table 1, and selected bond lengths and angles in Table 2. The structure shows the perfluoropropyl group cis to iodide and also cis to PPh_3, with these three ligands adopting a mutually meridional configuration. The structure of the minor isomer remains unknown.

Computational studies

The expected increase in the IR stretching frequencies of the CO ligands is observed on formation of compounds **2**–**7** from **1**; values of ν_{CO} are shown in Table 3. It is interesting to note that in the Ir(III)–iodo complexes **2**–**7**, one of the CO stretching vibrations (ν_{sym}) occurs at a value higher than that of free CO (2143 cm^{-1}), illustrating that in these phosphine-donor-free Ir(III) complexes, the CO ligands may be non-

classical (65–67), and that relatively little backbonding from Ir → CO π* may be present. Replacement of iodide by the more electronegative triflate ligand in compounds **8**–**11** increases ν_{CO} even further, but there is no significant effect on the CO frequencies by changing the fluoroalkyl ligand structure (CF_3, primary, or secondary).

The advent of density functional theory (DFT) (68–71), natural bond orbital (NBO) (72, 73), and natural population analysis (NPA) (74) as powerful tools for probing electronic structure in main-group and transition metal compounds(75) led us to apply these methods to representative compounds discussed here.

Four compounds were studied by DFT/NBO. The structures of starting material **1**, **2**, **3**, and **5a**, containing representative CF_3, primary (C_2F_5) and secondary [$(CF_3)_2CF$] ligands were optimized using the B3LYP functional with the LACV3P**++ basis set, as implemented in the Jaguar suite of programs(76); extended core potentials were used for Ir and I, with all other atoms treated using a 6–311G**++ basis set. For compounds **1** and **5a**, this procedure reproduced the crystallographically determined bond lengths within 0.02 Å and angles within 1°. The computed structures were confirmed as energy minima by calculating the vibrational frequencies by second derivative analytic methods and confirming the absence of negative frequencies. The use of second-order perturbative NBO analysis for estimating metal–ligand backbonding interaction energies (ΔE_{bb}), obtained from the off-diagonal Fock matrix element expressed in the NBO basis, has been thoroughly described and is now well-established (77–79). In our molecules, appropriate values of ΔE_{bb} reflect the energies of delocalization of the three formal "lone pairs" on Ir [the non-bonding d_{xy}, d_{xz}, and d_{yz} orbitals of d^6 Ir(III) in the NBO analysis] into the π* antibonding orbitals of the two CO ligands. Corresponding delocalization energies from the same metal orbital set into the C–F or C–C σ* antibonding orbitals on the α-carbon of the fluoroalkyl ligand can likewise be obtained. These values of ΔE_{bb} for compounds **1, 2, 3,** and **5a** are presented in Table 4, which also tabulates the natural charges from the NPA on iridium and the CO ligand atoms arising from the NBO treatment (80).

The data in Table 4 clearly show that when square-planar **1** reacts with fluoroalkyl iodides to form the oxidative addition products, the iridium is indeed oxidized, with an approximate doubling of the positive charge at the metal center. The carbon atoms of the CO ligands become more positive while the corresponding O atoms become more negative, resulting in a more polar CO ligand relative to the corresponding situation in **1**. This increase in positive charge on iridium results in a dramatic reduction in backbonding from Ir → CO (π*), illustrated by the loss of one third of the corresponding delocalization energy (ΔE_{bb}). The changes in formal charges on Ir and the CO ligand atoms are independent of the fluoroalkyl ligand. The fluoroalkyl ligands themselves are very weak π-acceptors compared to CO. The number of fluorines on the α-carbon dominates the extent of backbonding, with CF_3 being the best; replacement of the acceptor C–F (σ*) orbitals with C–C (σ*) orbitals results in progressively poorer π-acceptor properties. The relative π-acceptor properties of CF_3 and CO agree well with those recently reported for Mn and Tc carbonyl complexes (77), and it is clear that in a competition for backbonding with CO ligands, fluoroalkyl ligands fare poorly. We concur with other authors that the increase in CO stretching frequencies on oxidation of a metal center results from two factors: increased polarization of the C–O bond and reduced population of CO π* antibonding orbitals (81).

Table 4. NPA charges on Ir and CO ligands, and Ir–CO and Ir–R_F backbonding interaction energies (ΔE_{bb} kcal/mol).

Experimental

General data

Air-sensitive reactions were performed in oven-dried glassware using standard Schlenk techniques under an atmosphere of nitrogen, which was deoxygenated over BASF catalyst and dried over Aquasorb or in a Braun drybox. Methylene chloride, hexanes, diethyl ether, tetrahydrofuran, and toluene were dried over an alumina column under nitrogen (82). NMR spectra were recorded on a Varian Unity Plus 300 or 500 FT spectrometer. ^1H NMR spectra were referenced to the protio impurity in the solvent: C_6D_6 (7.16 ppm), CD_2Cl_2 (5.32 ppm). ^{19}F NMR spectra were referenced to external $CFCl_3$ (0.00 ppm). $^{13}C\{^1H\}$ NMR spectra were referenced to the deuterium solvent. Coupling constants are reported in units of Hertz and are absolute values. IR spectra were recorded on a PerkinElmer FTIR 1600 Series spectrophotometer. Elemental analyses were performed by Schwartzkopf (Woodside, NY) and X-ray crystallographic analyses at the University of California, San Diego.

$IrCl_3 \cdot xH_2O$ (Pressure Chemicals), Hacac and *sec*-C_4F_9–I (Alfa Aesar), AgOTf, and R_F–I (R_F = CF_3, C_2F_5, *n*-C_3F_7, *i*-C_3F_7, $CF_2C_6F_5$) (Synquest) were commercially available. Ir(acac)$(CO)_2$ (52) and Ir(acac)(CO)(PPh_3) (44) were prepared using literature procedures.

Computations

Structures were optimized at the DFT (B3LYP) level of theory, using ECP values on Ir and I atoms and a 6–311G**++ basis set for all other atoms, as implemented by Jaguar, versions 6.5 and 7.0 (76). Optimized geometries are provided in the Supplementary Data.[3] NPA (72–75) were carried out at the B3LYP level of theory using the NBO program (80), also implemented as part of the Jaguar suite. As part of the NBO program, second-order perturbation analysis was used to estimate metal–ligand backbonding energies (ΔE_{bb}) with the overall value obtained by summing all second-order perturbation $E(2)$ terms between the relevant metal d-orbital donor lone pair and the appropriate π* C–O or σ* C–F or σ* C–C acceptor orbitals

$Ir(CO)_2(acac)$ (1) (52)

IR (hexane, cm^{-1}): 2074, 1999; IR (CH_2Cl_2, cm^{-1}): 2072, 1994. ^1H NMR (C_6D_6, 500 MHz, 25 °C) δ: 5.07 (s, H, CH), 1.54 (s, 6H, $2CH_3$). Crystals suitable for X-ray diffraction were grown from CH_2Cl_2/hexanes.

$Ir(CO)_2(acac)(CF_3)$(I) (2)

CF_3I was bubbled into a yellow CH_2Cl_2 (15 mL) solution of $Ir(CO)_2(acac)$ (174 mg, 0.500 mmol) for 5 s. The solution turned brown-red gradually, then back to yellow again. After 6 h, IR showed no peak for starting materials. The solvent was removed under vacuum to give a yellow solid, which was crystallized from CH_2Cl_2/hexane at –30 °C to give yellow crystals (230 mg, 86%). IR (CH_2Cl_2, cm^{-1}): 2150 (s), 2106 (vs). ^1H NMR (C_6D_6, 500 MHz, 25 ºC) δ: 5.10 (H, s, CH), 1.53 (6H, s, $2CH_3$). ^{19}F NMR (C_6D_6, 470 MHz, 25 °C) δ: –22.4 (F, s, CF_3). Anal. calcd. for $C_8H_7F_3IIrO_4$ (%): C 17.69, H 1.30; found (%): C 17.77, H 1.38.

$Ir(CO)_2(acac)(CF_2CF_3)$(I) (3)

C_2F_5I was bubbled into a yellow CH_2Cl_2 (15 mL) solution of $Ir(CO)_2(acac)$ (87 mg, 0.250 mmol) for 5 s. The solution turned brown-red gradually, and was allowed to react overnight to give a brown solution. IR showed the reaction had finished. The solvent was removed under vacuum to give a brown solid, which was crystallized from CH_2Cl_2/hexane at –30 °C to give a yellow crystalline solid (128 mg, 86%). IR (CH_2Cl_2, cm^{-1}): 2148 (s), 2105 (vs). ^1H NMR (C_6D_6, 300 MHz, 25 °C) δ: 5.11 (H, s, CH), 1.54 (6H, s, $2CH_3$). ^{19}F NMR (C_6D_6, 282.2 MHz, 25 °C) δ: –83.7 (s), –91.0 (s). Anal. calcd. for $C_9H_7F_5IIrO_4$ (%): C 18.22, H 1.19; found (%): C 18.82, H 1.07.

$Ir(CO)_2(acac)(CF_2CF_2CF_3)$(I) (4)

To a yellow CH_2Cl_2 (20 mL) solution of $Ir(CO)_2(acac)$ (274 mg, 0.790 mmol) was added n-C_3F_7–I (0.11 mL, 0.79 mmol) at 0 °C. The colour turned to yellow → orange → yellow over 5 min. After 4.5 h, ^{19}F NMR showed some residual peaks for n-C_3F_7–I, and the mixture was allowed to react overnight to give a light yellow solution. The solvent was removed to give a light orange-yellow solid, which was crystallized from CH_2Cl_2/hexane at –30 °C to give a yellow crystalline solid (439 mg, 86%). The solid was recrystallized from ether/hexane at –60 °C to give crystals suitable for X-ray diffraction. IR (hexane, cm^{-1}): 2145 (s), 2103 (s). ^1H NMR (C_6D_6, 500 MHz, 25 °C) δ: 5.09 (H, s, CH), 1.52 (6H, s, $2CH_3$). ^{19}F NMR (C_6D_6, 470 MHz, 25 °C) δ: –79.3 (3F, t, $^3J_{FF}$ = 11 Hz, CF_3); –89.3 (2F, q, $^3J_{FF}$ = 11 Hz, α-CF_2); –118.7 (2F, s, β-CF_2). Anal. calcd. for $C_{10}H_7F_7IIrO_4$ (%): C 18.67, H 1.10; found: C 18.84, H 1.22.

$Ir(CO)_2(acac)[CF(CF_3)_2]$(I) (5a, 5b)

To a yellow CH_2Cl_2 (20 mL) solution of $Ir(CO)_2(acac)$ (204 mg, 0.600 mmol) was added i-C_3F_7–I (0.09 mL, 0.6 mmol) at 0 °C. There was no apparent colour change, and the mixture was allowed to react overnight to give a light yellow solution. IR showed no peak for starting materials, and two sets of ^1H and ^{19}F NMR signals, corresponding to two product isomers **5a** (major) and **5b** (minor) were observed. On standing at room temperature, the mixture evolved to give only **5a**. The solvent was removed to give a yellow solid (292 mg, 82%), which was recrystallized from ether/hexane at –60 °C to give crystals suitable for X-ray diffraction.

5a

IR (hexane, cm^{-1}): 2145 (s), 2103 (s); IR (CH_2Cl_2, cm^{-1}): 2149 (s), 2104 (s). ^1H NMR (C_6D_6, 500 MHz, 25 °C) 5.04 (H, s, CH), 1.51 (6H, s, $2CH_3$). ^{19}F NMR (C_6D_6, 470 Hz, 25 °C) δ: –71.0 (d, 6F, $^3J_{FF}$ = 10 Hz, CF_3), –166.8 (sept, 1F, $^3J_{FF}$ = 10 Hz, CF).

5b

^1H NMR (C_6D_6, 500 MHz, 25 °C) 5.14 (H, s, CH), 1.54 (3H, s, CH_3), 1.49 (3H, s, CH_3). ^{19}F NMR (C_6D_6, 470 Hz, 25 °C) δ: –70.5 (6F, d, $^3J_{FF}$ = 10 Hz, CF_3), –179.8 (1F, sept, $^3J_{FF}$ = 10 Hz, CF).

Anal. calcd. for $C_{10}H_7IIrF_7O_4$ (%): C 18.67, H 1.10; found: C 18.74, H 1.20.

$Ir(CO)_2(acac)[CF(CF_3)(CF_2CF_3)]$(I) (6)

To a CH_2Cl_2 (30 mL) solution of $Ir(CO)_2(acac)$ (34.7 mg, 0.1 mmol) was added sec-C_4F_9I (0.02 mL), and an immediate colour change from yellow to orange was observed. The mixture was stirred at room temperature for 2 h, and the solvent was removed to give a yellow-orange solid, which was recrystallized from CH_2Cl_2/hexane at –30 °C to give a yellow crystalline solid (253 mg, 76%). IR (CH_2Cl_2, cm^{-1}): 2147 (s), 2104 (s). ^1H NMR (C_6D_6, 300 MHz, 25 °C) δ: 5.01 (1H, s, CH), 1.49 (6H, s, CH_3). ^{19}F NMR (C_6D_6, 282 MHz, 25 °C) δ: –69.67 (3F, s, γ-CF_3); –79.41 (3F, s, β-CF_3); –106.3 (F, d, $^2J_{FF}$ = 302 Hz, CF_A); –111.4 (F, d, $^2J_{FF}$ = 302

Hz, CF_B); –169.22 (F, s, CF). Anal. calcd. for $C_{11}H_7F_9IIrO_4$ (%): C 19.06, H 1.02; found: C 19.46, H 1.44.

$Ir(CO)_2(acac)(CF_2C_6F_5)(I)$ (7)

To a CH_2Cl_2 (30 mL) solution of $Ir(CO)_2(acac)$ (56 mg, 0.16 mmol) was added C_7F_7I (0.03 mL), and an immediate colour change from yellow to orange was observed. The mixture was stirred at room temperature for 2 h, and the solvent was removed to give a yellow-orange solid, which was recrystallized from CH_2Cl_2/hexane at –30 °C to give a yellow crystalline solid (34 mg, 75%). IR (CH_2Cl_2, cm^{-1}): 2147 (s), 2104 (s). ^1H NMR (C_6D_6, 300 MHz, 25 °C) δ: 4.66 (1H, s, CH), 1.29 (6H, s, CH_3). ^{19}F NMR (C_6D_6, 282 MHz, 25 °C) δ: –37.62 (2F, s, CF_2); –141.4 (2F, s, *o*-CF); –149.9 (F, s, *p*-CF); –161.1 (2F, s, *m*-CF). Anal. calcd. for $C_{14}H_7F_7IIrO_4$ (%) C 24.32, H 1.02; found (%): C, 24.76, H 1.34.

$Ir(CO)_2(acac)(CF_3)(OTf)$ (8)

To a CH_2Cl_2 (10 mL) suspension of AgOTf (104 mg, 0.405 mmol) was added a yellow CH_2Cl_2 (10 mL) solution of $Ir(CO)_2(acac)(CF_3)(I)$ (200 mg, 0.368 mmol) at room temperature. The solution was stirred overnight to give a yellow solution and yellow precipitate. The solution was filtered to give a pale yellow solution. The solvent was removed under vacuum to give a white solid with some dark brown impurities, which was recrystallized by CH_2Cl_2/hexane to give yellow crystals suitable for X-ray diffraction (182 mg, 87%). IR (CH_2Cl_2, cm^{-1}): 2168 (s), 2125 (vs). ^1H NMR (C_6D_6, 300 MHz, 25 °C) δ: 5.02 (H, s, CH), 1.48 (6H, s, $2CH_3$). ^{19}F NMR (C_6D_6, 282 MHz, 25 °C) δ: –15.5 (3F, s, CF_3), –77.3 (3F, s, OTf). Anal. calcd. for $C_9H_7F_6IrO_7S$ (%): C 19.12, H 1.25; found (%): C 19.54, H 1.66.

$Ir(CO)_2(acac)(CF_2CF_3)(OTf)$ (9)

To a CH_2Cl_2 (5 mL) suspension of AgOTf (130 mg, 0.510 mmol) was added a CH_2Cl_2 (10 mL) solution of $Ir(CO)_2(acac)(C_2F_5)(I)$ (260 mg, 0.440 mmol) at room temperature. The white AgOTf turned quickly to a brown-yellow solid, and after 1 h the solution was filtered to give a yellow solution. The solvent was removed to give a yellow solid, which was recrystallized from CH_2Cl_2/hexane at –30 °C to give yellow crystals suitable for X-ray diffraction (220 mg, 86%). IR (CH_2Cl_2, cm^{-1}): 2167 (s), 2125 (vs). ^1H NMR (C_6D_6, 300 MHz, 25 °C) δ: 5.03 (H, s, CH), 1.53 (6H, s, $2CH_3$). ^{19}F NMR (C_6D_6, 282 MHz, 25 °C) δ: –77.3 (3F, s, CF_3), –78.0 (3F, s, OTf), –83.6 (2F, s, CF_2). Anal. calcd. for $C_{10}H_7F_8IrO_7S$ (%): C 19.52, H 1.15; found (%): C 19.64, H 1.21.

$Ir(CO)_2(acac)(CF_2CF_2CF_3)(OTf)$ (10)

$Ir(CO)_2(I)(n\text{-}C_3F_7)(acac)$ (221 mg, 0.343 mmol) and AgOTf (106 mg, 0.412 mmol) were stirred in CH_2Cl_2 (15 mL) overnight to give a pale yellow solution with a pale yellow precipitate, which was filtered to give a yellow solution. The solvent was removed to give a yellow solid, which was recrystallized from CH_2Cl_2/hexane at –30 °C to give yellow crystals (206 mg, 91%). IR (CH_2Cl_2, cm^{-1}): 2167 (s), 2125 (s). ^1H NMR (C_6D_6, 500 MHz, 25 °C) δ: 5.03 (H, s, CH), 1.53 (6H, s, $2CH_3$). ^{19}F NMR (C_6D_6, 470 MHz, 25 °C) δ: –76.9 (d, $^4J_{FF}$ = 11 Hz, α-CF_2), –77.3 (3F, s, OTf), –79.6 (3F, t, $^4J_{FF}$ = 11 Hz, CF_3), –119.3 (2F, s, β-CF_2). Anal. calcd. for $C_{11}H_7F_{10}IrO_7S$ (%): C 19.85, H 1.06; found (%): C 20.20, H 1.11.

$Ir(CO)_2(acac)[(CF(CF_3)_2](OTf)$ (11)

A mixture of $Ir(CO)_2(I)(i\text{-}C_3F_7)(acac)$ (214 mg, 0.333 mmol) and AgOTf (100 mg, 0.33 mmol) was stirred in CH_2Cl_2 (15 mL) overnight to give a pale yellow solution with pale yellow precipitate, which was filtered to give a yellow solution. The solvent was removed to give a yellow solid (200 mg, 90%), which was recrystallized from CH_2Cl_2/hexane at –30 °C to give yellow crystals. IR (CH_2Cl_2, cm^{-1}): 2169 (s), 2129 (s). ^1H NMR (C_6D_6, 500 MHz, 25 °C) δ: 4.87 (H, s, CH), 1.47 (6H, s, $2CH_3$). ^{19}F NMR (C_6D_6, 470 MHz, 25 °C) δ: –70.7 (6F, d, $^3J_{FF}$ = 9 Hz, $2CF_3$), –77.1 (3F, s, OTf), –145.7 (F, hept, $^3J_{FF}$ = 9 Hz, CF). Anal. calcd. for $C_{11}H_7F_{10}IrO_7S$ (%): C 19.85, H 1.06; found (%): C 19.64, H 1.30.

$Ir(CO)(PPh_3)(acac)(CF_2CF_2CF_3)(I)$ (13)

To a yellow CH_2Cl_2 (10 mL) solution of $Ir(CO)(PPh_3)(acac)$ (50 mg, 0.086 mmol) was added excess $n\text{-}C_3F_7$–I (0.05 mL, 0.38 mmol) at 0 °C. The reaction was monitored by ^{19}F NMR and IR. After 90 minutes, ^{19}F NMR showed two sets of peaks for two different isomers. IR (CH_2Cl_2) showed no peak for $Ir(CO)(PPh_3)(acac)$. The solvent was removed under vacuum to give a yellow solid, which was recrystallized through slow evaporation from hexane/ether solution to give crystals of the major isomer (70 mg, 93%).

Major

IR (CH_2Cl_2, cm^{-1}): 2063 (s). ^1H NMR (C_6D_6, 500 MHz, 25 °C) δ: 7.58–7.41 (15H, m, PPh_3), 5.09 (H, s, CH), 1.70 (3H, s, CH_3), 1.67 (3H, s, CH_3). ^{19}F NMR (C_6D_6, 470 Hz, 25 °C) δ: –67.6 (F, mq, J_{FF} = 264 Hz, α-F), –72.6 (F, mq, $^2J_{FF}$ = 264 Hz, α-F), –80.0 (3F, t, $^3J_{FF}$ = 13 Hz, CF_3), –112.7 (F, mq, $^2J_{FF}$ = 282 Hz, β-F), –114.6 (F, mq, $^2J_{FF}$ = 282 Hz, β-F). $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 202 MHz, 25 °C) δ: –4.89 (P, d, $^3J_{PF}$ = 34 Hz, PPh_3).

Minor

IR (CH_2Cl_2, cm^{-1}): 2063 (s). ^1H NMR (C_6D_6, 500 MHz, 25 °C) δ: 7.90–7.81 (15H, m, PPh_3), 5.71 (H, s, CH), 2.03 (3H, s, CH_3), 1.98 (3H, s, CH_3). ^{19}F NMR (C_6D_6, 470 MHz, 25 °C) δ: –71.4 (F, mq, $^2J_{FF}$ = 265 Hz, α-F), –93.4 (F, mq, $^2J_{FF}$ = 265 Hz, α-F), –80.2 (3F, t, $^3J_{FF}$ = 11 Hz, CF_3), –117.5 (F, mq, $^2J_{FF}$ = 288 Hz, β-F), –122.2 (F, mq, $^2J_{FF}$ = 289 Hz, β-F). $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 202 MHz, 25 °C) δ: –17.4 (P, d, $^3J_{PF}$ = 24 Hz, PPh_3). Anal. calcd. for $C_{27}H_{22}F_7IIrO_3P$ (%): C 36.95, H 2.53; found (%): C 37.27, H 3.17.

Structural and spectroscopic studies of some adducts of silver(I) salts with ethylenethiourea[1]

Graham A. Bowmaker, Narongsak Chaichit, Chaveng Pakawatchai, Brian W. Skelton, and Allan H. White

Abstract: Syntheses, single crystal X-ray structural and spectroscopic characterizations are described for a variety of adducts of silver salts with ethylenethiourea (etu). Ag_2SO_4/etu (1:6) is isomorphous with its previously studied copper(I) counterpart, the $[Ag(S\text{-etu})_3]^+$ species disposed with their silver atoms on crystallographic 3-axes, one of the two independent cations being slightly perturbed by a distant *O*-sulfate approach along that axis. In AgCl/etu (1:3), the silver atom is in a four-coordinate $ClAgS_3$ environment, while $AgNO_3$/etu (1:3) takes the form $[(etu)_2Ag(\mu\text{-}S\text{-}etu)_2Ag(etu)_2](NO_3)_2$. AgBr/etu (1:2) is binuclear $[(etu)_2Ag(\mu\text{-}Br)_2Ag(etu)_2)]$, unlike its previously studied copper counterpart, which is $[(etu)BrCu(\mu\text{-}S\text{-}etu)_2CuBr(etu)]$. AgCl/etu (4:6) is an interesting ionic polymer $[ClAg_4(etu)_6]_{(\infty|\infty)}Cl_3$, containing a novel one-dimensional polymeric cation. Bands in the far IR spectra of these compounds are assigned to ν(AgS) and ν(AgX) (X = halogen) modes, and a correlation between ν(AgS) and the Ag–S bond length *d*(AgS) is established for silver complexes involving the etu ligand.

Key words: silver, sulfur ligands, X-ray crystal structure, coordination chemistry, complexes.

Résumé : On décrit les synthèses, les caractérisations spectroscopiques et par diffraction des rayons X d'une variété d'adduits de sels d'argent à l'éthylènethiourée (etu). L'adduit Ag_2SO_4/etu (1:6) est isomorphe avec sa contrepartie cuivreuse, Cu(I), étudiée antérieurement et les espèces $[Ag(S\text{-etu})_3]^+$ sont disposées d'une façon telle que les atomes d'argent sont sur les 3-axes cristallographiques, l'un des deux cations indépendants étant faiblement perturbé par une approche distant du *O*-sulfate le long de cet axe. Dans le cas de l'adduit AgCl/etu (1:3), l'atome d'argent se trouve dans un environnement tétracoordiné $ClAgS_3$, alors que le cas de l'adduit $AgNO_3$/etu (1:3), prend la forme $[(etu)_2Ag(\mu\text{-}S\text{-}etu)_2Ag(etu)_2](NO_3)_2$. L'adduit AgBr/etu (1:2) est binucléaire $[(etu)_2Ag(\mu\text{-}Br)_2Ag(etu)_2]$, contrairement à sa contrepartie cuivreuse, Cu(I), étudiée antérieurement, qui est de la forme $[(etu)BrCu(\mu\text{-}S\text{-}etu)_2CuBr(etu)]$. L'adduit AgCl/etu (4:6) est un polymère ionique intéressant $[ClAg_4(etu)_6]_{(\infty|\infty)}Cl_3$ qui contient un nouveau cation polymère monodimensionnel. On a attribué les bandes du spectre infrarouge éloigné aux modes ν(AgS) et ν(AgX) (X = halogène) et, pour les complexes impliquant un ligand etu, on a établi une corrélation entre ν(AgS) et la valeur de la longueur de la liaison AgS, *d*(AgS).

Mots-clés : argent, ligands sulfurés, structure cristalline par diffraction des rayons X, chimie de coordination, complexes.

[Traduit par la Rédaction]

Introduction

Sulfur-donor ligands derivative of thiourea (tu) have been utilized in a variety of forms to access coordination complexes, most notably of type B or "soft" metal ions. In its simplest form, the ligand is unsubstituted, $SC(NR_2)_2$, R = H, but it may be obtained with diverse R, which may entail incorporation of the nitrogen atoms into heterocyclic rings; these, if saturated, behave as "normal" unidentate donors, but, if unsaturated, aromatic, or otherwise deprotonated, then the now unsubstituted nitrogen atom(s) may also attain donor capability. We exclude these last from present considerations, focussing only on *S*-donor forms in the "simpler" substituted thiourea ligands, xtu (Scheme 1) in their complexes with metal(I) systems. In the adducts with simple salts of gold(I), the structural chemistry of the considerable

etu

xtu = mtu (R, R' = H; R'' = Me
dmtu (R = H; R', R'' = Me
tmtu (R, R', R'' = Me)
detu (R = H; R', R'' = Et)

array of structurally characterized compounds is dominated by that of linearly coordinated two-coordinate S-Au-S systems; with copper(I) and silver(I), the coordination number may rise as high as (quasi-tetrahedral) four, and indeed, four unidentate *S*-coordinated thiourea ligands are to be found in the hexafluorosilicate(IV) salt, $[Cu(tu)_4]_2(SiF_6)$ (1–3*a*). No counterpart $[Ag((x)tu)_4]^+$ example has yet been so defined for silver(I), the highest AgX/xtu stoichiometry thus far structurally authenticated being 1:3, although formation of a complex $[Ag(etu)_4](NO_3)$ (etu = ethylenethiourea = imidazolidine-2-thione; $(CH_2NH)_2CS$; see Scheme 1) was claimed in an early study (4). Adducts AgX/xtu (1:3) may be found in mononuclear or binuclear form. The latter are found with non-coordinating or feebly coordinating anions as ionic $[(xtu)_2Ag(\mu\text{-}S\text{-}xtu)_2Ag(xtu)_2]^{2+}$ arrays, for adducts of silver(I) perchlorate with tu (5), dmtu (6), etu (7), [dmtu = $(MeHN)_2CS$]. Mononuclear arrays, also essentially ionic, with (only distant contacts of the anion to) a trigonal planar silver(I) atom, $[Ag(xtu)_3]^+X^-$ are found for the cyclic 1-methylimidazole-2-thione (Hmimt) (8), tetrahydro-1,3-pyridine-2-thione (thpt) (9), X = NO_3, tfs = trifluoromethanesulfonate, respectively. With (pseudo-)halide or other soft anion, the X becomes coordinated, yielding four-coordinate $[XAg(xtu)_3]$, defined for X = Cl/tu (preliminary data only) (10) or MeNH·CS·NH_2 (mtu) (11), $(EtNH)_2CS$ (Br/detu) (12), I/detu (13), HS/Et_2N·CS·NH·COPh (14). For adducts of 1:2 stoichiometry, mononuclear species have been defined, both as ionic arrays $[AgL_2]^+X^-$ with linear two-coordinate silver(I) atoms, for X/xtu = ClO_4/etu (15) and NO_3/Et_2N·CS·NC(Ph)NH_2 (16), although the NO_3/MeCONH·CS·NH_2 adduct (17) contains a polymeric cation with one of the ligands μ_2-S and three-coordinate silver(I). The SCN/tu adduct is molecular $[(NCS)Ag(tu)_2]$ (18), with three-coordinate silver(I), the etu analogue weakly dimerizing (19). Polymers involving coordination of a less "innocent" anion are found for the Cl/tu (20) and Cl/etu (21) adducts, the chloride and one ligand being terminal donors in four-coordinate silver(I) environments, but in the Br/thpt adduct (22), all ligands bridge, leaving the bromide ions uncoordinated. The Br/etu adduct (21) is binuclear $[L_2Ag(\mu\text{-}Br)_2AgL_2]$, while the perchlorate/dmtu adduct has a one-dimensional polymeric cation (6). The CN/tu adduct has one ligand and the cyanide bonding terminally in a four-coordinate silver atom environment in a one-dimensional polymer (23); CN/tu, mtu, dmtu, $(Me_2N)_2CS$ (tmtu), etu all form adducts of 1:1 stoichiometry with diverse types of cyanide and xtu donor ligands about four-coordinate silver(I) atoms, except in the AgCN/tmtu adduct, which is ···LAg(CN)LAg(CN)··· with the silver atom three-coordinate (23). The adduct of AgI/Hmimt is of 1:0.5 stoichiometry and has a two-dimensional polymeric sheet structure with ligand (sulfur) and halide both bridging and the silver atom four-coordinate (24).

In the above context, we record the results of a number of our own studies with the ligand etu, also exploring the behaviour of the sulfate anion as donor or otherwise, in these contexts; all ligands derivative of thiourea behave as unidentate or bridging *S*-donor ligands in the present array of compounds, none of the nitrogen atoms behaving as donors, although the NH hydrogen atoms are widely involved in hydrogen-bonding interactions that may be influential in determining the form of the product. These compounds have also been studied by IR spectroscopy to establish correlations between the structures and the vibrational spectra, particularly in the far IR region where metal–sulfur and metal–halogen bands are expected to occur. Two of the compounds (AgCl/etu (1,2:3)) have been the subject of a preliminary communication (25).

Syntheses

Ag_2SO_4/etu (1:6)

A mixture of silver(I) sulfate (0.62 g, 2 mmol) and ethylenethiourea (1.23 g, 12 mmol) in water (20 ml) was heated until all of the solid material dissolved. Colourless crystals of the product separated upon cooling. Yield 1.70 g (92%). Anal. calcd. for $C_{18}H_{36}Ag_2N_{12}O_4S_7$: C 23.38, H 3.92, N 18.18; found: C 23.4, H 4.1, N 18.3%.

$AgNO_3$/etu (1:1.5)

A hot solution of ethylenethiourea (0.31 g, 3 mmol) in water (10 mL) was added to a hot solution of $AgNO_3$ (0.34 g, 2 mmol) in water (10 mL). A colourless, fibrous mass of product formed upon cooling. Yield 0.63 g (97%). Anal. calcd. for $C_{4.5}H_9AgN_4OS_{1.5}$: C 16.73, H 2.81, N 17.34; found: C 17.0, H 3.3, N 17.3%.

$AgNO_3$/etu (2:6)

A hot solution of silver(I) nitrate (0.34 g, 2 mmol) in water (5 mL) was added to a hot solution of ethylenethiourea (0.63 g, 6 mmol) in water (5 mL). Colourless crystals of the product separated upon cooling. Yield 0.60 g (62%). Anal. calcd. for $C_{18}H_{36}Ag_2N_{14}O_6S_6$: C, 22.69, H 3.81, N 20.58; found: C 22.6, H 3.9, N 20.5%.

$AgNO_3$/etu (1:4)

A hot solution of silver(I) nitrate (0.34 g, 2 mmol) in water (5 mL) was added to a hot solution of ethylenethiourea (1.02 g, 10 mmol) in water (5 mL). Colourless crystals of the product separated upon cooling. Yield 1.00 g (87%). Anal. calcd. for $C_{12}H_{24}AgN_9O_3S_4$: C 24.91, H 4.18, N 21.79; found: C 24.4, H 4.4, N 21.1%. Calcd. for $C_{12}H_{26}AgN_9O_4S_4$ (the monohydrate): C 24.16, H 4.39, N 21.13.

AgCl/etu (4:6)

A mixture of silver(I) chloride (0.29 g, 2 mmol) and ethylenethiourea (0.31 g, 3 mmol) in water (10 mL) was heated to boiling with stirring and filtered while hot to re-

© 2008 NRC Canada

move a slightly grey insoluble residue. Colourless crystals of the product separated upon cooling. Yield 0.19 g (32%). Anal. calcd. for $C_{18}H_{36}Ag_4Cl_4N_{12}S_6$: C 18.23, H 3.06, N 14.17; found: C 18.4, H 3.3, N 14.2%.

AgCl/etu (1:3)

A mixture of silver(I) chloride (0.29 g, 2 mmol) and ethylenethiourea (0.62 g, 6 mmol) in water (10 mL) was heated to boiling with stirring until all of the solids had dissolved. The resulting hot solution was diluted with water (10 mL) and allowed to stand. Colourless crystals of product separated upon standing overnight. Yield 0.70 g (78%). Anal. calcd. for $C_9H_{18}AgClN_6S_3$: C 24.03, H 4.03, N 18.68; found: C 24.1, H 4.1, N 18.6%.

AgBr/etu (2:4)

A mixture of silver(I) bromide (0.38 g, 2 mmol) and ethylenethiourea (1.23 g, 12 mmol) in water (25 mL) was heated to boiling with stirring until all of the solids had dissolved. The resulting hot solution was diluted with water (10 mL) and allowed to stand. Colourless crystals of product separated upon standing. Yield 0.60 g (76%). Anal. calcd. for $C_{12}H_{24}Ag_2Br_2N_8S_4$: C 18.38, H 3.09, N 14.29; found: C 18.6, H 3.3, N 14.35%.

AgBr/etu (1:3)

A mixture of silver(I) bromide (0.38 g, 2 mmol) and ethylenethiourea (0.82 g, 8 mmol) in water (15 mL) was heated to boiling with stirring and filtered while hot to remove an insoluble yellow residue. Colourless crystals of product separated upon standing. Yield 0.64 g (81%). Anal. calcd. for $C_9H_{18}AgBrN_6S_3$: C 21.87, H 3.67, N 17.00; found: C 21.7, H 3.8, N 16.7%. A sample of this compound was ground in an agate mortar and pestle with a small amount of water, just sufficient to form a paste, and the IR spectrum of the dried product showed that it had converted completely to a mixture of the 1:2 complex and uncomplexed etu.

AgI/etu (1:0.5)

A hot solution of potassium iodide (0.33 g, 2 mmol) in water (10 mL) was added to a hot solution of silver nitrate (0.34 g, 2 mmol) and ethylenethiourea (0.61 g, 6 mmol) in water (10 mL). There was an immediate dense white precipitate. The mixture was filtered while warm and the product was washed with water. Yield 0.56 g (99%). Anal. calcd. for $C_{1.5}H_3AgINS_{0.5}$: C 6.30, H 1.06, N 4.90; found: C 6.6, H 1.2; N 5.0%.

Structure determinations

Full spheres of CCD area-detector diffractometer data were measured (ω-scans, monochromatic Mo Kα radiation, λ = 0.710 73 Å) yielding $N_{t(otal)}$ reflections, these merging to N unique (R_{int} cited) after "empirical"/multiscan absorption correction (proprietary software), N_o with $F > 4\sigma(F)$ being considered "observed". Anisotropic displacement parameter forms were refined (full matrix on F^2) for the non-hydrogen atoms, hydrogen atom treatment following a riding model unless otherwise noted (reflection weights: $(\sigma^2(F^2) + (aP)^2 + bP)^{-1}$ ($P = (F_o + 2F_c)/3$)). Neutral atom complex scattering factors were employed within the SHELXL 97 program (26). Pertinent results are given below and in the Tables and Figures, the latter showing 50% (low temperature) or 20% (room temperature) displacement envelopes for the non-hydrogen atoms, hydrogen atoms, where shown, having arbitrary radii of 0.1 Å.[3]

Crystal/refinement data

AgCl/etu (1:3)

$C_9H_{18}AgClN_6S_3$, M = 449.8; rhombohedral, space group $R3c$ (C_{3v}^6, No. 161) (hexagonal setting), a = 14.7380(1) Å, c = 12.2965(1) Å, V = 2313 Å^3; D_{calcd} (Z = 6) = 1.937 g cm^{-3}; μ_{Mo} = 1.9 mm^{-1}; specimen = 0.33 mm × 0.24 mm × 0.20 mm; $T_{min/max}$ = 0.81; $2\theta_{max}$ = 87°; N_t = 49899, N = 3907 (R_{int} = 0.023), N_o = 3807; R_1 = 0.015, wR_2 = 0.037 (a = 0.021, b = 0.951); S = 1.10. $|\Delta\rho_{max}|$ = 0.3 e Å^{-3}; x_{abs} = –0.016(11); T ca. 100 K.

AgCl/etu (4:6)

$C_{18}H_{36}Ag_4Cl_4N_{12}S_6$, M = 1186.3; othorhombic, space group $C222_1$ (D_2^5, No. 20), a = 15.9435(2) Å, b = 16.2883(2) Å, c = 14.6276(2) Å, V = 3799 Å^3; D_{calcd} (Z = 4) = 2.074 g cm^{-3}; μ_{Mo} = 2.7 mm^{-1}; specimen = 0.40 mm × 0.30 mm × 0.30 mm; $T_{min/max}$ not recorded; $2\theta_{max}$ = 57°; N_t = 12883, N = 4621 (R_{int} = 0.019), N_o = 4361; R_1 = 0.036, wR_2 = 0.092 (a = 0.0491, b = 13.687); S = 1.09. $|\Delta\rho_{max}|$ = 1.9 e Å^{-3}; x_{abs} = 0.01(4); T ca. 298 K.

AgBr/etu (2:4)

$C_{12}H_{24}Ag_2Br_2N_8S_4$, M = 784.2; monoclinic, space group $P2_1/n$ (C_{2h}^5, No. 14; variant), a = 8.975(1) Å, b = 10.457(1) Å, c = 13.158(2) Å, β = 103.421(2)°, V = 1201 Å^3; D_{calcd} (Z = 2) = 2.168 g cm^{-3}; μ_{Mo} = 5.3 mm^{-1}; specimen = 0.32 mm × 0.22 mm × 0.18 mm; $T_{min/max}$ = 0.71; $2\theta_{max}$ = 57°; N_t = 13226, N = 2968 (R_{int} = 0.025), N_o = 2743; R_1 = 0.019, wR_2 = 0.049 (a = 0.0278, b = 0.4579); S = 1.13. $|\Delta\rho_{max}|$ = 1.02 e Å^{-3}; T ca. 153 K. This structure has been previously determined at room temperature (21).

$AgNO_3$/etu (2:6)

$C_{18}H_{36}Ag_2N_{14}O_6S_6$, M = 952.7; monoclinic, space group $P2_1/n$, a = 6.544(2) Å, b = 23.300(9) Å, c = 11.792(3) Å, β = 100.69(2)°, V = 1767 Å^3; D_{calcd} (Z = 2) = 1.791 g cm^{-3}; μ_{Mo} = 1.52 mm^{-1}; specimen = 0.48 mm × 0.42 mm × 0.32 mm; $T_{min/max}$ = 0.83; $2\theta_{max}$ = 50°; N = 3058, N_o = 2720; R_1 = 0.029, wR_2 = 0.067 (a = 0.0104, b = 2.0506); S = 1.10. $|\Delta\rho_{max}|$ = 0.46 e Å^{-3}; T ca. 295 K. Data were measured using a single counter instrument; a Gaussian absorption correction was applied.

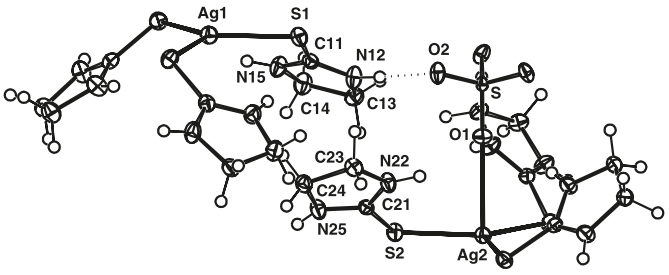
Fig. 1. The two cations of $[Ag(etu)_3]_2(SO_4)$, showing the interaction of one with the sulfate, and the associated hydrogen-bonding.



Ag_2SO_4/etu (1:6)

$C_{18}H_{36}Ag_2N_{12}O_4S_7$, M = 924.8; rhombohedral, space group $R3c$, a = 12.998(2) Å, c = 34.675(7) Å, V = 5073 Å^3; D_{calcd} (Z = 6) = 1.816 g cm^{-3}; μ_{Mo} = 1.64 mm^{-1}; specimen = 0.56 mm × 0.45 mm × 0.27 mm; $T_{min/max}$ = 0.72; $2\theta_{max}$ = 56°; N_t = 18947, N = 2839 (R_{int} = 0.022), N_o = 2815; R_1 = 0.014, wR_2 = 0.038 (a = 0.0221, b = 4.3079); S = 1.10. $|\Delta\rho_{max}|$ = 0.29 e Å^{-3}; x_{abs} = 0.03(2); T ca. 153 K. The structure is isomorphous with the previously determined copper(I) counterpart (27).

IR spectroscopy

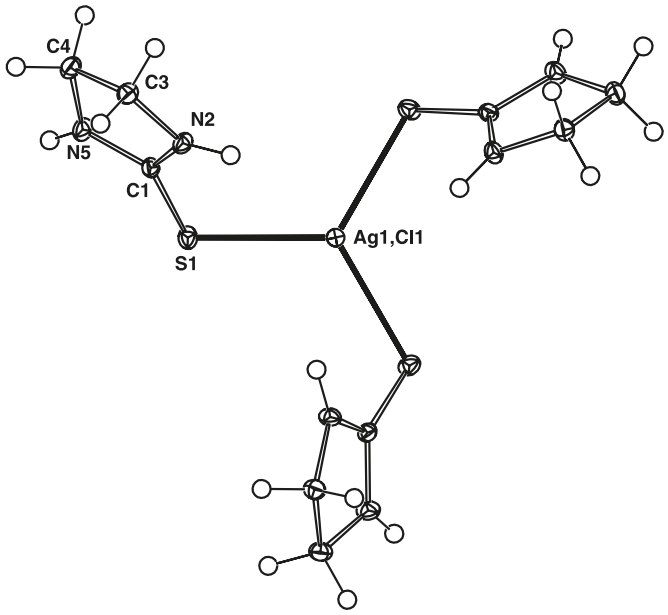
IR spectra were recorded at 4 cm^{-1} resolution on dry powders using a PerkinElmer Spectrum 100 FT-IR spectrometer equipped with a Universal ATR sampling accessory, or on Nujol mulls between KBr plates using a PerkinElmer Spectrum 1000 Fourier transform IR spectrometer. Far IR spectra were recorded at 4 cm^{-1} resolution using a Nicolet 8700 FTIR spectrometer on samples suspended in Polythene disks.

Results and Discussion

Syntheses

In an early study of silver(I)/etu complexes involving aqueous solution syntheses, Morgan and Burstall suggested the existence of AgX/etu (1:n) complexes with n = 3, 2, 1 for X = Cl, Br, I, respectively (4), but our initial studies of these complexes showed that the situation is more complicated than this. Thus, syntheses from aqueous 1:3 AgCl/etu solutions initially yielded crystals of a 1:1.5 complex, shown by a single crystal X-ray study to be $[ClAg_4(etu)_6]Cl_3$ (see below). IR studies of the products of mechanochemical syntheses established the existence of the 1:3 chloride complex (25), and this was subsequently prepared as a crystalline solid from aqueous solution by the method described in the Experimental section above. While the chloride complex could be obtained from a 1:3 AgCl/etu reaction mixture, the bromide could only be obtained from solutions containing excess etu because of the low solubility of AgBr in the reaction medium, and there was a strong tendency for the 1:2 complex to crystallize, particularly from less concentrated solutions; the 1:3 complex was obtained on only one occasion, and mechanochemical treatment of this compound with water showed that it is unstable with respect to the 1:2 complex and etu under ambient conditions (see Experimental). This is in contrast to the situation for the 1:3 chloride, which

Fig. 2. A molecule of $[ClAg(etu)_3]$ projected down the Cl–Ag bond, coincident with a crystallographic 3-axis.



can be prepared by mechanochemical synthesis from a mixture of the 1:1.5 complex and 1.5 equivalents of etu in the presence of water (25). No AgCl/etu complex of composition between 1:3 and 1:1.5 could be prepared from aqueous solution, in agreement with mechanochemical experiments that demonstrated the non-existence of a 1:2 complex (25). This contrasts with a previous report that claims the existence of such a complex, but which was unsupported by elemental analysis or structural data (21). The 1:0.5 AgI/etu complex was prepared by reaction of one equivalent of potassium iodide with an aqueous solution of $[Ag(etu)_4](NO_3)$ (see Experimental). The low ligand content in the product has been attributed to dissociation during washing of an unstable 1:2 complex, whose existence was established by a mechanochemical method (25).

Morgan and Burstall reported the formation of 1:1.5 and 1:4 $AgNO_3$/etu complexes (4). The present study confirmed the existence of the 1:1.5 complex, which forms very thin fibrous crystals that were unsuitable for single crystal X-ray studies and resulted in the identification of a 1:3 complex, whose structure is described below. Attempts to prepare a 1:4 complex resulted in products with lower than the required C, H, and N composition, despite the use of a 1:5 ratio of reactants, the crystals again not being appropriate for X-ray work.

Crystal structures

Silver(I) sulfate, crystallized with etu (in 1:6 ratio) from aqueous solution, forms a 1:6 adduct, shown by the results of the single crystal X-ray study to be isomorphous with its previously studied copper(I) counterpart (27). The silver complex is the same as a recently reported compound obtained from dimethylformamide solution (28). There are two independent cations in the structure, each disposed with the metal atom on a crystallographic 3-axis, lying closely coplanar with the S_3 plane of the three symmetry related ligands, with the metal atom of cation 2 approached by one of

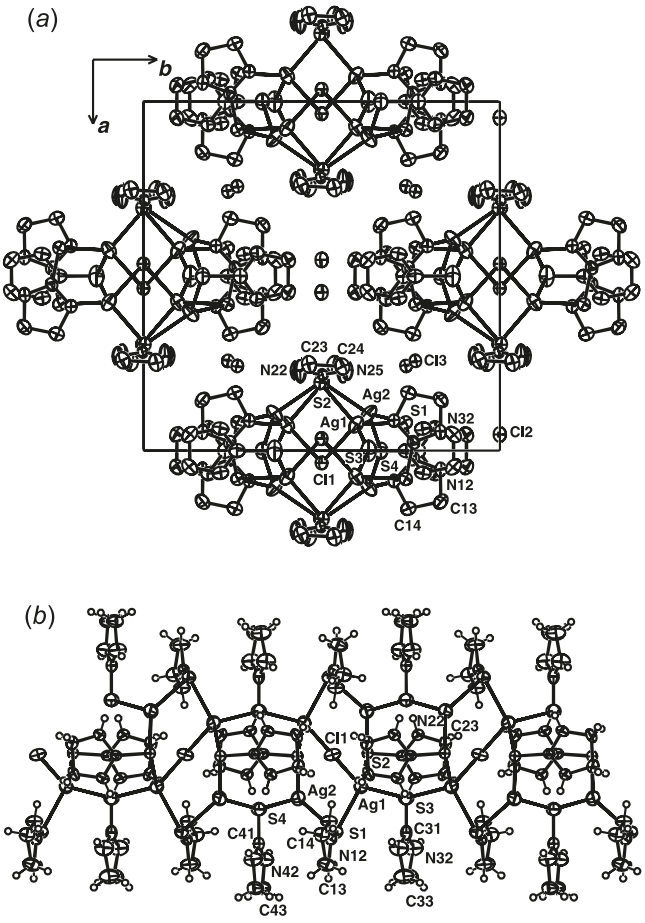
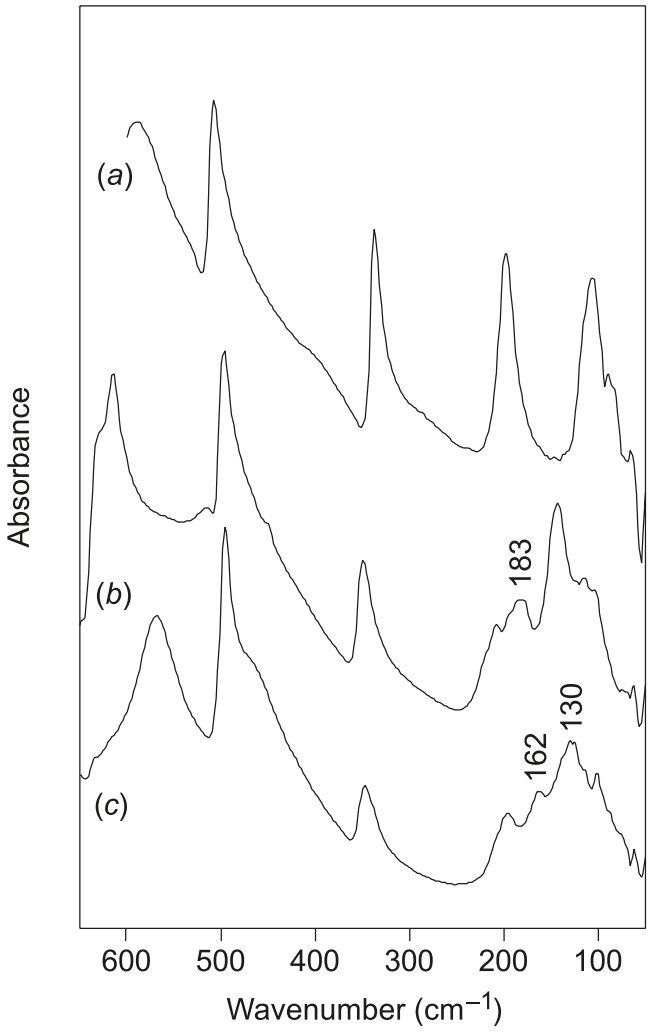
Fig. 4. (*a*) Unit cell contents of $[ClAg_4(etu)_6]Cl_3$ projected down *c*. (*b*) Projection of part of the complex cation $[ClAg_4(etu)_6]_{(\infty|\infty)}^{+}$.



The geometry about the silver atoms in Ag_2SO_4/etu (1:6) may be compared with that found in $[ClAg(etu)_3]$ where the anion firmly coordinates, and the complex is similarly disposed on three-fold axes of the same space group, there being only one independent complex in this case, (Fig. 2). Ag–S,Cl are 2.5468(2), 2.8295(2) Å, with S–Ag–S,Cl 117.534(3)°, 99.126(5)°, with intramolecular N,H(2)···Cl 3.2306(5), 2.40 Å (est.). The silver atom lies 0.40(1) Å above the S_3 plane and 1.192(2) Å out of the ligand plane, the latter making a dihedral angle of 63.82(3)° with the S_3 plane. It is of interest to compare the geometry of the present complex with that of molecule 2 of the preceding sulfate complex, wherein there is an interchange of the approaching axial donor from hard to soft ligand, the distortion from trigonal planar geometry being greater in the present chloride, despite the longer Ag–X distance.

The 1:3 adduct of $AgNO_3$ with etu crystallizes as a binuclear array, $[(etu)_2Ag(\mu\text{-}S\text{-}etu)_2Ag(etu)_2](NO_3)_2$, one half of that unit comprising the asymmetric unit of the structure, the cation being centrosymmetric (Table 1, Fig. 3*a*) and the anion uncoordinated, as in the perchlorate counterpart (7); in binuclear AgBr/etu (1:2) (Fig. 3*b*), the Ag···Ag′ distance is greatly increased consequent on replacement of the bridging sulfur atom by the bromide atom. This latter structure provides a remarkable contrast with counterpart copper(I) systems, where, on passing from similarly binuclear CuX/xtu

Fig. 5. Far IR spectra of (*a*) ethylenethiourea, (*b*) $[Ag(etu)_3]_2(SO_4)$, (*c*) $[Ag_2(etu)_6](NO_3)_2$. Bands assigned as ν(AgS) are labelled with their wavenumbers.



$(1:3)_2$ arrays (e.g. X = ClO_4, xtu = etu (29)) to CuBr/xtu $(1:2)_2$ species, it is a terminal xtu ligand that is replaced by the bromine atom (3*b*), perhaps dependent to some extent on the niceties of the associated hydrogen bonds evident in all such structures, which must play some part in their relative stabilities.

Notwithstanding the low AgCl/L ratio in AgCl/etu (1:1.5), we find uncoordinated chloride ions as companions to a novel one-dimensional polymeric cation, oriented along *c*. One $(AgCl_{(2|2)})_2(etu)_3$ formula unit (Table 2, Fig. 4) comprises the asymmetric unit of the structure. Of the two independent silver atoms, one, Ag(1) is four-coordinated by a chloride atom Cl(1), the latter disposed on a crystallographic 2-axis that bridges a pair of such symmetry-related silver atoms and three sulfur atoms from three independent etu ligands, one of the those, S(3), also disposed on a 2-axis and bridging to a symmetry-related silver atom (different to that related by the Cl(1) bridge). S(1,2) are also bridging, to diverse Ag(2). Ag(2) is three-coordinated (angle sum: 359.4°) by three etu ligand sulfur atoms, all bridging. Cl(1) bridges the two Ag(1) atoms of an eight-membered macrocycle

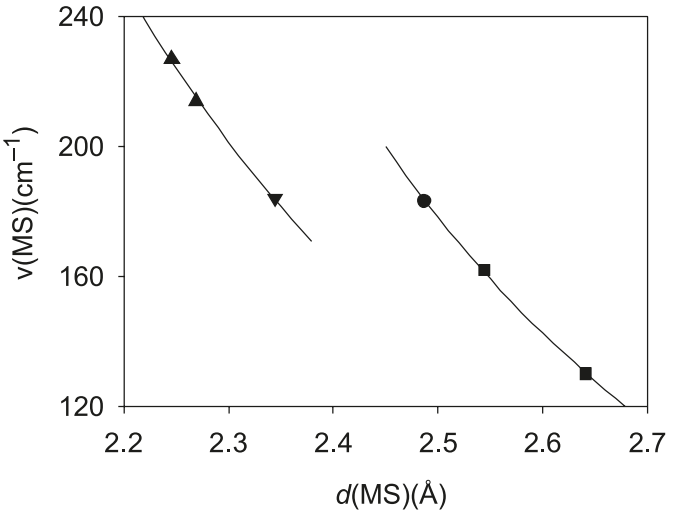
Fig. 6. Correlation between ν(MS) and the M–S bond length *d*(MS) for $[Ag(etu)_3]_2(SO_4)$ (●) and $[Ag_2(etu)_6](NO_3)_2$ (■) (this work) and for $[Cu(etu)_3]_2(SO_4)$ (▲) and $[Cu(etu)_4](NO_3)$ (▼) (Refs. 27 and 32).



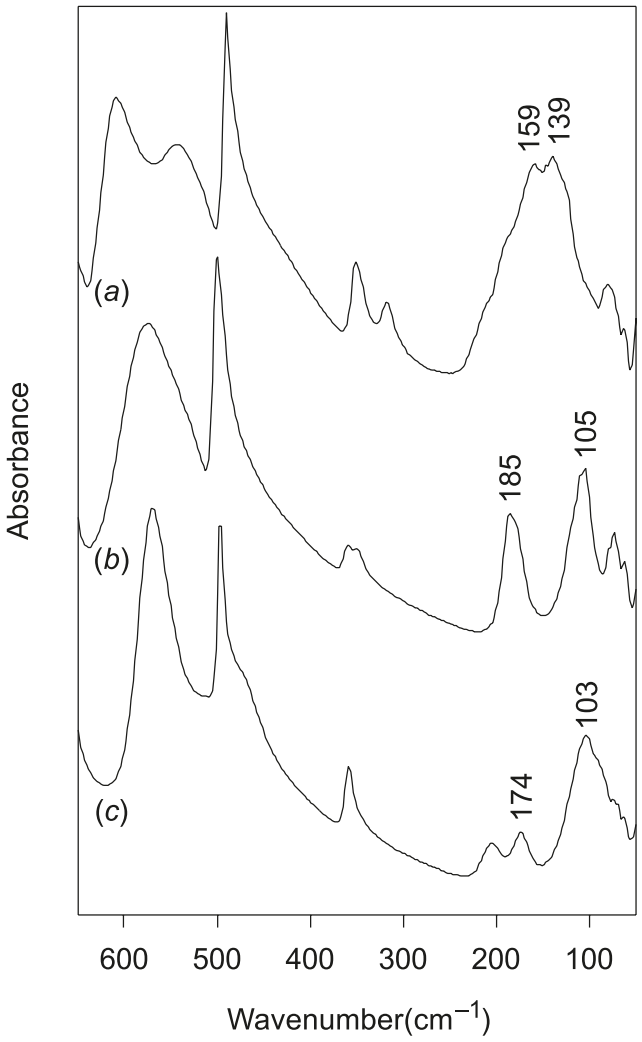
through the centre of which its two-fold axis (parallel to *a*) passes, thus $\{S(2),Ag(1),S(1),Ag(2)\}_2$. A second 2-axis, parallel to *b*, passes through the S–C bonds of ligands 3,4 generating a second eight-membered ring $\{S(3),Ag(1),S(2),Ag(2)(x, 1 – y, 1 – z), S(4)(x, 1 –y, 1 – z)\}_2$, the polymer being generated by a fusion of alternating ring types through successive unit cells. (All sulfur atoms are μ_2). In projection down *c*, it is seen that the polymeric array is sheathed in stacks of quasi-parallel ring planes of ligands 1,3,4 (C_3N_2/C_3N_2 interplanar dihedral angles: 1/3 49.0(2)°, 5.5(2)°, 3/4 35(3)°) up *c* and on the *b* faces of the column, while ligands 2 sheath the polymer, lying quasi-parallel to *c* on the *a* face, reinforced with intra-polymer hydrogen bonds from the NH hydrogen atoms of ligand 1 to Cl(1), but the remainder to the lattice anions, Cl(2,3).

IR spectroscopy

The far IR spectra of the etu ligand and the two complexes $[Ag(etu)_3]_2(SO_4)$ and $[Ag_2(etu)_6](NO_3)_2$ are shown in Fig. 5. Ethylenethiourea shows bands due to internal vibrational modes at 337 and 198 cm^{-1}; an additional band at 106 cm^{-1} has been assigned as a lattice mode (30). Previous studies of the far IR and Raman spectra of thiourea and ethylenethiourea complexes have shown that the metal–sulfur stretching modes ν(MS) occur in the region 170-330 cm^{-1} (27, 30-32). The bands at 208 cm^{-1} in the sulfate and 196 cm^{-1} in the nitrate are assigned to the ligand band that occurs at 198 cm^{-1} in the uncomplexed ligand. The band at 183 cm^{-1} in the sulfate and 162 cm^{-1} in the nitrate are as-

© 2008 NRC Canada

Fig. 7. Far IR spectra of (*a*) $[ClAg_4(etu)_6]Cl_3$, (*b*) $[Br_2Ag_2(etu)_4]$, (*c*) $[IAg(etu)_{0.5}]$. Bands assigned as ν(AgS) or ν(AgX) are labelled with their wavenumbers.

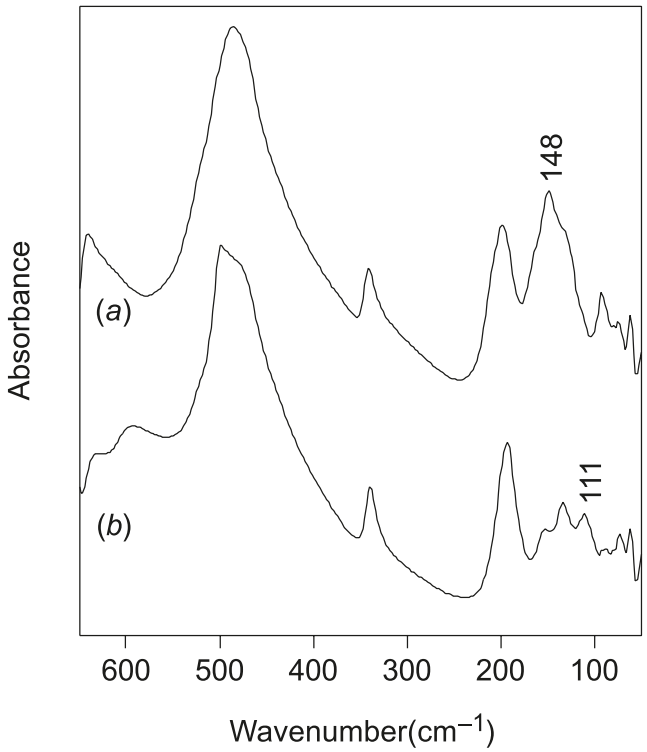


signed to the ν(AgS) vibrations involving the terminal etu ligands in these complexes. As expected, these occur at lower wavenumbers than the ν(CuS) modes previously assigned in related copper(I) complexes (27). The nitrate complex also contains bridging etu ligands with longer Ag–S bonds (see above), which should give rise to ν(AgS) bands at lower wavenumber than those involving the terminal etu ligands. The peak at 130 cm^{-1} in the spectrum of $[Ag_2(etu)_6](NO_3)_2$ (Fig. 5*c*) is assigned to vibrations of this type, and the dependence of the ν(AgS) vibrational frequencies on the mean Ag–S bond lengths shown in Fig. 6 supports this assignment. As has been shown previously in the case of the related copper(I) complexes (32), the data in Fig. 6 can be fitted to an equation of the form,

$$[1] \qquad \nu\ (cm^{-1}) = b(r\ (Å))^{-m}$$

with b = 11 450 and 33 360, and m = 4.85 and 5.71 for the copper(I) and silver(I) complexes, respectively. Similar correlations have previously been found for the Cu–X bonds in a range of copper(I) and silver(I) halide complexes with phosphine and amine ligands, and an increase in the values

Fig. 8. Far IR spectra of (*a*) $[ClAg(etu)_3]$ and (*b*) $[BrAg(etu)_3]$. Bands assigned as ν(AgX) are labelled with their wavenumbers.



of the b and m parameters from copper to silver was observed in these cases as well (33, 34).

The far IR spectrum of $[ClAg_4(etu)_6]Cl_3$ is shown in Fig. 7*a*. According to the correlation for Ag–S bonds in eq. [1], six ν(AgS) bands are expected to occur in the range 120–170 cm^{-1}, while the corresponding correlation for Ag–Cl bonds (34) predicts ν(AgCl) at 131 cm^{-1}. The strong, broad absorption band in the range 120–170 cm^{-1} is therefore assigned to overlapping ν(AgS) and ν(AgCl) bands, the complexity of absorption in this region reflecting the complex molecular structure of this compound. By contrast, the far IR spectrum of the strucurally much simpler compound $[Br_2Ag_2(etu)_4]$ shows only two, well- resolved bands in the 100–200 cm^{-1} region (Fig. 7*b*). The Ag–S bonds are very nearly equal in length, with a mean value of 2.483 Å, corresponding to ν(AgS) = 185 cm^{-1} (eq. [1]). Likewise, the Ag–Br bonds are all similar in length, with a mean value of 2.816 Å, which corresponds to ν(AgBr) = 105 cm^{-1}. These two predicted frequencies correspond exactly to the observed values 185 and 105 cm^{-1}, which are therefore assigned as ν(AgS) and ν(AgBr), respectively. The far IR spectrum of $[IAg(etu)_{0.5}]$ is shown in Fig. 7*c*. ν(AgS) and ν(AgI) are assigned at 174 and 103 cm^{-1} respectively. The structure of this compound is not known at present, but one possibility is suggested by that of the closely related compound $[Ag_2I_2(Hmimt)]_n$, which has a polymeric sheet structure containing planar four-membered $Ag_2(\mu_3\text{-}I)_2$ rings, which are linked to form ladders that are bridged by the Hmimt ligands.

The far IR spectra of $[XAg(etu)_3]$ (X = Cl, Br) are shown in Fig. 8. ν(AgX) are 148 and 111 cm^{-1} for X = Cl and Br respectively.

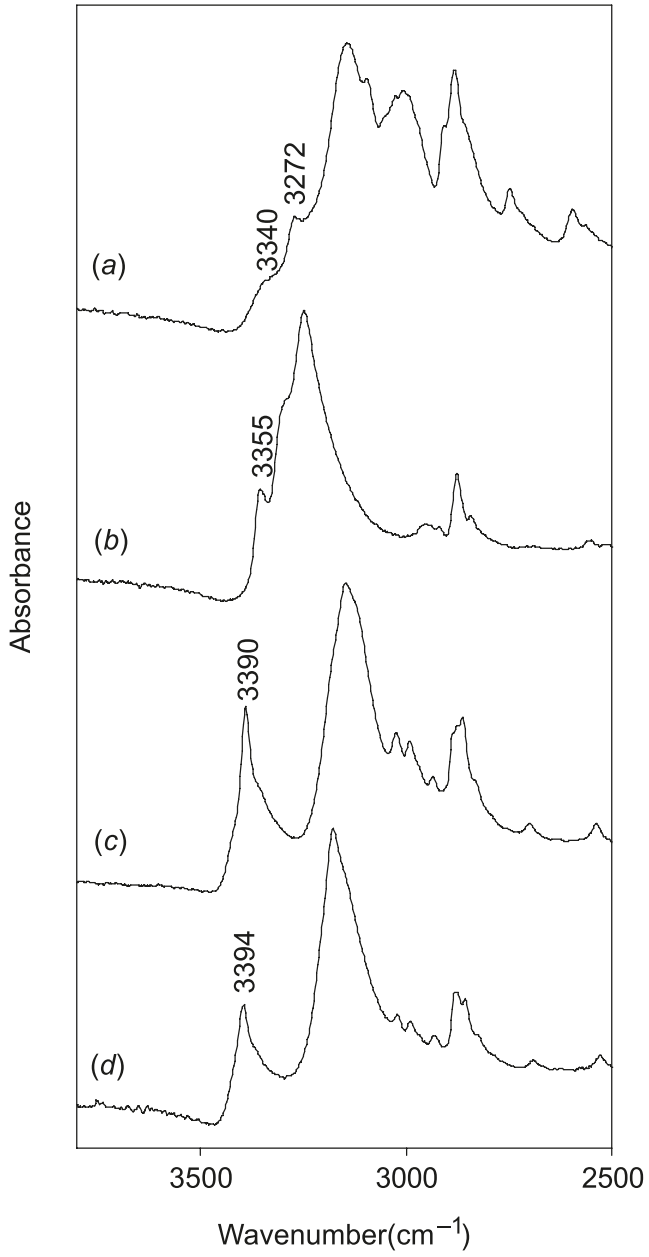
Fig. 9. IR spectra in the ν(NH) region of (*a*) $[ClAg_4(etu)_6]Cl_3$, (*b*) $[Br_2Ag_2(etu)_4]$, (*c*) $[ClAg(etu)_3]$, (*d*) $[BrAg(etu)_3]$. The highest wavenumber ν(NH) bands are labelled with their wavenumbers.



The mid IR spectra contain bands due to the coordinated thiourea ligand, and the bands in the ν(NH) region are particularly sensitive to changes in stoichiometry and structure (25). The spectra of $[ClAg_4(etu)_6]Cl_3$, $[Br_2Ag_2(etu)_4]$, $[ClAg(etu)_3]$, and $[BrAg(etu)_3]$ in the ν(NH) region are shown in Fig. 9. Particularly noticeable is the variation in the position of the highest wavenumber ν(NH) band with increasing etu/AgX ratio. This is attributed to changes in the degree of hydrogen bonding; the N-H hydrogens are involved to varying degrees in hydrogen bonding with the halogen atoms in the structure, and in $[ClAg(etu)_3]$ there is a clear distinction between the hydrogen atoms that are involved in hydrogen bonding to the chlorine atom and those that are not (Fig. 2). The band at 3390 cm^{-1} is assigned to the non hydrogen-bonded N-H hydrogen in this complex. A similar pattern of bands in the spectrum of $[BrAg(etu)_3]$ indicates that this complex is isostructural with the chloride. We have previously shown that the ν(NH) bands in these types of complex are useful for identifying different kinds of complex. The presence of a band at 3357 cm^{-1} in the spectrum of AgI/etu (1:2) is indicative of of a complex with a structure similar to that of the Br analogue, $[Br_2Ag_2(etu)_4]$ (25).

A band in the mid IR spectrum of $AgNO_3$/etu (1:4) at 1634 cm^{-1}, which has no counterpart in the spectra of the other complexes, is assigned to the bending mode of H_2O, present as water of crystallization. This complex is thus formulated as the monohydrate $[Ag(etu)_4](NO_3)\cdot H_2O$, which is consistent with its elemental analysis (see Experimental). The mid IR spectra of the three nitrate complexes $[Ag(etu)_4](NO_3)\cdot H_2O$, $[Ag_2(etu)_6](NO_3)_2$ and $AgNO_3$/etu (1:1.5) contain bands due to the nitrate ion and the coordinated thiourea ligand. Bands due to the $\nu_3(E')$ mode of nitrate, which occurs at about 1380 cm^{-1} in the uncomplexed ion in KNO_3 (35), are obscured by strong bands due to the etu ligand in this region. However, the nitrate $\nu_2(A_2'')$ band is clearly visible in all three cases, occurring at 826, 826, and 819 cm^{-1} respectively. The first two are close to the value of 828 cm^{-1} for the uncomplexed ion (35), and this is consistent with the crystal structure in the case of $[Ag_2(etu)_6](NO_3)_2$. The significantly lower value of this frequency observed for $AgNO_3$/etu (1:1.5) suggests that the nitrate is incorporated in the silver coordination environment in this complex.

Conclusion

Syntheses, single crystal X-ray structural, and spectroscopic characterizations are described for a variety of adducts of silver salts with ethylenethiourea. Ag_2SO_4/etu (1:6) is isomorphous with its previously studied copper(I) counterpart, while $AgNO_3$/etu (1:3) takes the form $[(etu)_2Ag(\mu\text{-}S\text{-}etu)_2Ag(etu)_2](NO_3)_2$, for which there is no published copper(I) counterpart. In AgCl/etu (1:3), the silver atom is in a four-coordinate $ClAgS_3$ environment. AgBr/etu (1:2) is binuclear $[(etu)_2Ag(\mu\text{-}Br)_2Ag(etu)_2)]$, unlike its previously studied copper counterpart, which is $[(etu)BrCu(\mu\text{-}S\text{-}etu)_2CuBr(etu)]$. AgCl/etu (4:6) is an interesting ionic polymer $[ClAg_4(etu)_6]_{(\infty|\infty)}Cl_3$, containing a novel one-dimensional polymeric cation. Bands in the IR spectra in the ν(NH) region prove to be particularly sensitive to the composition and structure of the halide complexes. Bands in the far IR spectra are assigned to ν(AgS) and ν(AgX) (X = halogen) modes, and a correlation between ν(AgS) and the Ag–S bond length *d*(AgS) is established for silver complexes involving the etu ligand. Subsequent work on the $AgNo_3$/etu (1:4) complex produced crystals that were suitable for an X-ray structure determination, which confirmed that the compound is $[Ag(etu)_4](NO_3)\cdot H_2O$ as formulated above (3*a*).

Ferrocenyl phosphine–oxazaphospholidine oxide ligands for the Suzuki–Miyaura coupling of hindered aryl bromides and chlorides[1]

Daniele Vinci, Nelson Martins, Ourida Saidi, John Bacsa, Amadeu Brigas, and Jianliang Xiao

Abstract: A series of ferrocenyl oxazaphospholidine phosphines that differ electronically and sterically were investigated as ligands for the Suzuki–Miyaura cross-coupling reactions. One of these compounds, **1**, was shown to be highly effective in the coupling reactions of bulky aryl bromides with boronic acids when combined with $Pd(OAc)_2$, while another, **2**, was capable of coupling aryl chlorides with boronic acids. However, these ligands were less effective in asymmetric induction.

Key words: Suzuki–Miyaura coupling, ferrocenyl phosphines, aryl bromides, aryl chlorides, palladium.

Résumé : Une série de ferrocényl oxazaphospholidine phosphines qui présentent des différences tant électroniques que stériques a été étudiée comme ligands pour les réactions de couplage croisé de Suzuki–Miyaura. On a montré qu'un de ces composés, **1**, lorsqu'il est combiné au $Pd(OAc)_2$, est très efficacle dans les réactions de couplage de bromures d'aryles avec des acides boroniques alors que le composé **2** permet d'effectuer le couplage de chlorures d'aryles avec les acides boroniques. Toutefois, ces ligands sont moins efficaces dans l'induction asymétrique.

Mots-clés : couplage de Suzuki–Miyaura, ferrocényl phosphines, bromures d'aryles, chlorures d'aryles, palladium.

[Traduit par la Rédaction]

Introduction

The palladium-catalyzed cross-coupling reactions of organoboron compounds and organic halides or triflates have emerged as a powerful and general methodology for the formation of carbon–carbon bonds (1–7). Advances in recent years have made the reactions scalable and cost effective (8). However, methods that are generally applicable to the synthesis of bulky and axially chiral biaryls, common structural motifs in natural products and chiral ligands, are still rare (9–17). Although reasonably good results in the enantioselective Suzuki coupling have been achieved using P^N ligands based on biaryl and ferrocene backbones, the reaction times, scope of substrates, and catalyst loadings remain to be improved (18, 19).

Suzuki–Miyaura coupling of hindered aryl bromides and chlorides is a particularly challenging area of research. Recently, new and improved catalytic systems for the coupling of these demanding substrates have been developed and described (20–28). In particular, biaryl monophosphine ligands have proven to be highly effective, partially meeting the requirement of increased catalytic performance (29). However, there remain some key issues that need to be addressed; these include problems such as hydrolysis of Pd–Ar complexes, slow transmetalation or slow trans to cis isomerization of intermediate palladium species, leading to the formation of unwanted byproducts (18, 29–34).

Ferrocene-based ligands have been employed successfully in many catalytic transformations (35) due to their ease of functionalization and the stability of most of its derivatives. Its proven record in homogeneous catalysis has been demonstrated. The Suzuki–Miyaura reaction is no exception to this trend (36, 37). Recently, we reported a new series of ferrocenyl-phosphine ligands that were synthesized by ortholithiation of (2*R*,4*S*,5*R*)-3,4-dimethyl-2-ferrocenyl-5-phenyl-[1,3,2]oxazaphospholidine 2-oxide (Scheme 1) (38). Herein, we present our findings on the application of the ligands **1**–**4** in the Suzuki–Miyaura reactions.

Experimental[3]

Procedures for Suzuki–Miyaura coupling reactions

The coupling of 1-bromo-2-methoxynaphthalene with 1-naphthalene boronic acid to give 2-methoxy-1,1′-binaphthyl, **5**, is described as a typical example. An oven-dried carousel reaction tube was charged with 1-naphthalene boronic acid (0.75 mmol), CsF (1.5 mmol), **1** (10 μmol), and $Pd(OAc)_2$ (5 μmmol). The aryl bromide (0.5 mmol) was introduced at this stage (or after degassing by injection through a rubber septum in case of a liquid). The reaction vessel was evacuated and backfilled with N_2. This process was repeated five times, after which dioxane (3 mL) was introduced. The reaction mixture was then heated at 100 °C for 4 h. After cooling down to ambient temperature, the conversion was determined from the crude ^{1}H NMR, and isolated yield was obtained after a standard work-up and purification by flash chromatography (100% hexane). The product 2-methoxy-1,1′-binaphthyl, **5**, was obtained in 98% yield. Analytic details: mp 106 to 107 °C. ^{1}H NMR ($CDCl_3$, 400 MHz, ppm) δ: 3.75 (s, 3H), 7.14 (d, 1H, J = 8.8 Hz), 7.19–7.28 (m, 2H), 7.30–7.33 (m, 2H), 7.42–7.47 (m, 3H), 7.61 (t, 1H, J = 7.7 Hz), 7.86 (d, 1H, J = 8.0 Hz), 7.93 (d, 1H, J = 8.0 Hz), 7.94 (d, 1H, J = 8.0 Hz), 7.97 (d, 1H, J = 8.8 Hz). ^{13}C NMR ($CDCl_3$, 100 MHz, ppm) δ: 56.8, 113.8, 123.2, 123.5, 125.5, 125.5, 125.7, 125.8, 126.2, 126.4, 127.7, 127.8, 128.2, 128.4, 129.0, 129.4, 132.9, 133.7, 134.2, 134.5, 154.6. MS *m/z*: 284 (M^+). The products **6**–**19** were obtained in a similar manner.

X-ray structural determination of Pd-1

The complex **Pd-1** was synthesized by heating $PdCl_2(PhCN)_2$ with **1** in dry dichloromethane with a 91% yield. ^{1}H NMR ($CDCl_3$, 400 MHz, ppm) δ: 0.78 (s, br, 3H), 2.00 (d, 3H, J = 11.2 Hz), 3.69 (m, 1H), 4.15 (br, 1H), 4.75 (s, 5H), 4.80 (br, 1H), 4.83 (br, 1H), 5.70 (br, 1H), 7.30–7.90 (m, 15H). ^{31}P NMR ($CDCl_3$, 162 MHz, ppm) δ: 16.4(s), 46.6(s). HR-MS (ES+) *m/z*: calcd. for $C_{32}H_{31}{}^{37}Cl^{54}FeNO_2P_2Pd$: 719.9920, $C_{32}H_{31}{}^{35}Cl^{56}FeNO_2P_2Pd$: 719.9903 $[M - Cl]^+$; found: 719.9918.

Single crystal X-ray data were collected on a Bruker D8 diffractometer with an APEX detector using graphite monochromated Mo Kα radiation (λ = 0.710 73 Å). The crystal was cooled to T = 110(2) K. A total of 19537 reflections was collected with $2\theta_{max}$ = 55.1°. Of these reflections, 13146 were unique (R_{int} = 0.0406). The reflection data were integrated using SAINT v6.45a (39). The data were corrected for absorption, decay, and other errors using SADABS V2007-2 (40). The structure was solved by direct methods and refined using SHELX (41). X-SEED (42), a graphical interface to SHELX, was used to generate representations of the crystal structure.

Crystal data: $2(C_{32}H_{31}Cl_2FeNO_2P_2Pd)$, C_7H_5N, $CHCl_3$, M = 1701.38, orange block, 0.20 mm × 0.20 mm × 0.10 mm, monoclinic, space group $P2_1$ (No. 4), a = 9.4590(19), b = 19.219(4), c = 19.677(4) Å, β = 96.99(3)°, V = 3550.5(12) Å^3, Z = 2, $D_{calcd.}$ = 1.591 g/cm^3, F_{000} = 1720. Final GoF = 1.011, $R1$ = 0.0517, $wR2$ = 0.1042, R indices based on 10244 reflections with $I > 2\sigma(I)$ (refinement on F^2), 842 parameters, 1 restraint, μ = 1.266 mm^{-1}. how this difference would impact the palladium-catalyzed Suzuki coupling. At the outset, we examined the coupling between the sterically hindered 1-bromo-2-methoxynaphthalene and 1-naphthalene boronic acid and compared the results with a similar but less bulky phosphine. The results are reported in Table 1.

As can be seen, ligand **1** showed excellent results when the ligand/catalyst ratio was set to 2. The reaction was complete after 4 h and the coupling product was recovered in 98% yield after purification by column chromatography (Table 1, entry 1). At a lower concentration of ligand, the reaction slowed down, lowering the yield to 63% (Table 1, entry 2). In contrast, the reaction with ligand **2** was found to go to completion when a 1/1 ligand/palladium (L/Pd) ratio was used (Table 1, entry 4). At higher concentrations, the rate dropped dramatically (Table 1, entry 3). Ligands **3** and **4** show similar behaviour and their results are somewhat similar to those obtained with the ligand **1**. To better appreciate the differences among the ligands, the coupling time was reduced. As is seen from the entries 9–12 in Table 1, the ligand **1** gave the best yields, and it appears that an electron rich phosphine does not benefit the coupling. The coupling was considerably less efficient with the less bulky ligand $FePPh_2$ (Fc = ferrocenyl) (Table 1). Thus, the oxazaphospholidine moiety of **1**–**4**, in combination with the phosphine group, is able to stabilize the active palladium species and accelerate the reaction rate. The differences between **1** and **2** could partially be explained by assuming a stable, active Pd species requires two equivalents of **1** but only one equivalent of the bulkier **2** (43).

The X-ray crystal structure of the complex, **Pd-1**, formed between **1** and $PdCl_2(PhCN)_2$, confirms that **1** behaves as a chelating ligand, with both the phosphorus atom and the phosphoryl oxygen atom of the oxazaphospholidine ring coordinating to the Pd(II) centre (Fig. 1). The compound crystallizes in the chiral space group $P2_1$ with 2 **Pd-1** molecules, a benzonitrile, and a chloroform molecule in the asymmetric unit, but the two organometallic molecules are chemically and nearly structurally identical. Examination of the orientation of the two molecules and the crystal packing reveals no missing symmetry elements, and the refined absolute structure parameter is further evidence that the crystals are indeed chiral. The molecular structure of one of the two molecules is shown in Fig. 1. The coordination geometry about the Pd(II) atom is square planar, with P, O, and the two Cl atoms cis to each other. The two Pd–Cl bonds are noticeably different [2.262(2) and 2.364(2) Å]. The longer Pd–Cl bond, which is trans to P(1), is likely to be due to the stronger trans effect of a P atom than an O atom. The three chiral centres of P(2), C(4), and C(5) have *R*, *S*, and *R* configurations, respectively. The complex is also planar chiral with a *R* configuration.

Note: Reaction conditions: 1.0 equiv. of aryl bromide, 1.5 equiv. of boronic acid, 3 equiv. of CsF, 100 °C in dioxane, 1 mol% $Pd(OAc)_2$, 2 mol% **1**. Yield refers to isolated yields.

[a]Hydrolysis product was observed.

[b]NEt_3 (3 equiv.) and toluene as solvent were used.

During the Suzuki coupling, the phosphoryl oxygen could dissociate from the palladium to facilitate the transmetalation and recoordinate to induce a faster reductive elimination. This may well be the case with the bulkier **2**. In the case of **1**, **3**, and **4**, however, the need for 2 equiv. of ligand for a more efficient coupling appears to suggest that the phosphoryl oxygen is replaced by the phosphine group of a second ligand.

Aryl bromides as substrates

One of the biggest challenges in the use of a Suzuki–Miyaura reaction is the coupling of hindered substrates. Since the ligand **1** afforded the best results in the coupling of 1-bromo-2-methoxynaphthalene and 1-naphthalene boronic acid, its catalytic activity towards other hindered substrates was studied. The results of the coupling of various sterically

10			24	89	**7**

Note: Reaction conditions: 1.0 equiv. of aryl chloride, 1.5 equiv. of boronic acid, 3.0 equiv. of CsF, 105 °C in dioxane, 1 mol% $Pd(OAc)_2$, 1 mol% ligand **2**. Yield refers to isolated yields.
[a]$Pd(OAc)_2$ (0.1 mol%).

hindered aryl bromides and sterically hindered aryl boronic acids employing ligand **1** are reported in Table 2.

The couplings involving the formation of the trisubstituted biaryls proceeded smoothly to completion. The reactions were complete after 4 h and no hydrolysis byproducts were observed in the crude mixtures. However, the reaction leading to tetra-substituted biaryl compounds resulted in low yields (Table 2, entries 7 and 8), and a significant amount of hydrolysis product, 2-methoxynaphthalene.

The important factor that impedes the coupling of partners in entry 7 of Table 2 is likely to be the increased steric bulk of the boronic acid, which makes the transmetallation difficult. This may in turn give preference to protonolysis of the Pd–Ar intermediate, leading to the hydrolysis product. Accordingly, a combination of CsF and NEt_3 as base and a nonprotic solvent like toluene afforded some improvement in the conversion. The yield increased from 12% to 43% (Table 2, entry 8), although 2-methoxynaphthalene was still observed.

Aryl chlorides as substrates

To find the best ligand for these substrates, we screened the ligands **1–4** for the coupling of the activated 4-chloroacetophenone with phenylboronic. In sharp contrast to the coupling of the bromides, only the ligand **2** was found to give satisfactory results; hence, the other ligands were not studied further. Apparently, a more electron-rich ligand is needed for the aryl chlorides, which are expected to be less reactive in the oxidative addition at Pd(0) than the corresponding bromides. The results of the coupling reactions obtained with **2** are summarized in Table 3.

The reaction between 4-chloroacetophenone and phenylboronic acid at 105 °C using 1 mol% of Pd and 1 equiv. of **2** was complete in just 1 h (Table 3, entry 1). Reducing the amount of palladium to 0.1 mol% resulted in a predictable decrease of the reaction rate; complete conversion was reached after 18 h (Table 3, entry 2). Increasing the steric bulk on the boronic acid also resulted in a decrease in the reaction rate (Table 3, entry 3). Although the coupling of the 4-chloroacetophenone with 2-tolylboronic acid also occurred at a 0.1 mol% Pd loading, the reaction took more than one day to reach completion. The rest of the reactions were therefore performed using 1 mol% Pd.

As can be seen from Table 3, going from an activated chloride to a deactivated one like 2-chlorotoluene, the yield was not affected under the conditions employed. The coupling of sterically hindered boronic acids, such as 1-naphthylboronic acid and 2-tolylboronic acid (Table 3, entries 6 and 7), ran smoothly to completion after 8 h. However, a further increase in the steric bulk of the chlorides did eventually affect the reaction rate. Thus, with 2-chloro-meta-xylene as substrate, the coupling reactions went to completion only after 24 h (entries 8–10). The results obtained with **2** are better than or comparable with those obtained using related electron-rich ferrocenyl phosphines (44, 45).

Table 4. Asymmetric Suzuki coupling.

[a]Determined by HPLC using a DAICEL OJ column (90/10 hexane/iPrOH).

Asymmetric coupling

So far, few catalysts have been developed for asymmetric Suzuki cross-coupling reactions (18, 19). In the course of this study, we examined the ligands **1–4** for the asymmetric coupling of 1-naphthylboronic acid and 1-bromo-2-methoxynaphthylboronic acid. The reaction conditions are slightly different from the ones reported in Table 1. The conversions and ee values obtained are reported in Table 4.

Ligand **1** yielded a 85% conversion and 26% ee as its best results (Table 4, entry 1). Decreasing the temperature or the L/Pd ratio did not bring about any amelioration. Although the ligand **2** was previously found to give a higher activity using a lower L/Pd ratio (Table 1, entry 4), it gave a higher enantioselectivity (27% ee) when 2 equiv. of the ligand were used (Table 4, entry 5). Most notably, the configuration of the product was reversed in the case of the latter, suggesting that the active catalyst varies with the L/Pd ratio. The higher ee for the L/Pd ratio of 2 is probably due to

© 2008 NRC Canada

the formation of a Pd-diphosphine species, which increases the steric bulk around the palladium. Ligand **4**, the electron-poor analogue of **1**, afforded the poorest enantioselectivity, which may partly stem from its ease of dissociation from the metal centre. However, it is difficult to draw conclusions relating the electronic and steric properties of ligand with the asymmetric induction observed, not least because there are probably more than one active catalytic species operating in the reaction media.

Conclusion

This paper presents results on the application of a series of electronically and sterically varied ferrocenyl ligands to the Suzuki–Miyaura cross-coupling reactions of aryl bromides and chlorides. Ligands **1** and **2** were proven to generate very effective catalysts for the coupling of sterically hindered partners. However, ligand **1** was ineffective in the coupling of aryl chlorides. For these substrates, including deactivated ones, the bulkier, electron-rich ligand **2** was necessary. A strong dependence of the catalytic activity on the L/Pd ratio was observed and this varied with the nature of the ligand. In contrast with **1**, an active catalyst was formed when 1 equiv. of **2** relative to the palladium was used, a scenario reminiscent of those observed with other bulky, electron-rich phosphines (43). The satisfying performance of the ligands in terms of reaction rates and substrate scope could partly be ascribed to the presence of the oxazaphospholidine moiety, which renders the ligand to be potentially hemilabile during the catalysis, thereby stabilizing the active palladium species. These ligands were also shown to induce enantioselection in the Suzuki coupling reaction; however, their performance remains to be improved in this respect.

Synthesis and organic group transfer of organodiplatinum complex with a 1,2-bis(diphenylphosphino)ethane ligand[1]

Nobuyuki Komine, Tomoko Ishiwata, Jun-ya Kasahara, Erino Matsumoto, Masafumi Hirano, and Sanshiro Komiya

Abstract: A series of homometallic alkyl- and phenyldinuclear complexes containing one platinum–platinum bond, (dppe)RPt–Pt(η^5-Cp)(CO) (R = Me, Et, CH_2CMe_3, Ph), have been prepared by oxidative addition of the Pt–C bond of PtR(η^5-Cp) to Pt(styrene)(dppe), and were characterized by spectroscopic methods and (or) X-ray structure analysis. The geometry at Pt with a dppe ligand is square planar, and the carbonyl and Cp ligand of the Pt(η^5-Cp)(CO) moiety lie orthogonal to the coordination plane of former platinum. Competitive organic group transfer reactions along the Pt–Pt bond in these complexes took place to give PtR(η^5-Cp)(CO) and PtR(η^1-Cp)(dppe) on thermolysis. Alkyl or aryl transfer from Pt with a dppe ligand were enhanced by addition of olefin, whereas treatment with CO and tertiary phosphine ligands causes Cp transfer from Pt(η^5-Cp)(CO).

Key words: organoplatinum–platinum complex, organic group transfer.

Résumé : On a préparé une série de complexes alkyl- et phényldinucléaires homométalliques contenant une liaison platine-platine, (dppe)RPt-Pt(η^5-Cp)(CO) (R = Me, Et, CH_2CMe_3, PH) par le biais d'une réaction d'addition oxydante de la liaison Pt-C du PtR(η^5-Cp) sur du Pt(styrène)(dppe) et on les a caractérisés par des méthodes spectroscopiques ainsi que par des analyses de structure par diffraction des rayons X. La géométrie au niveau du Pt portant un ligand dppe est plan carré et le groupement carbonyle et le ligand Cp de la portion Pt(η^5-Cp)(CO) se trouve en position orthogonale par rapport au plan de coordination du premier atome de platine. Il se produit des réactions compétitives de transfert des groupes organiques le long de la liaison Pt-Pt de ces complexes et elles conduisent à la formation de PtR(η^5-Cp)(CO) et PtR(η^5-Cp)(dppe) par thermolyse. Les transferts de groupes alkyles ou aryles à partir des dérivés de Pt portant le ligand dppe sont rendus plus fréquents par l'addition d'oléfine alors que des traitements par du CO ou des ligands phosphines tertiaires provoquent des transfert de Cp du Pt(η^5-Cp)(CO).

Mots-clés : complexe organique de platine–platine, transfert de groupe organique.

[Traduit par la Rédaction]

Introduction

The cooperative effect in multimetallic catalysis is one of the most intriguing and interesting unsolved problems at the molecular level both in homo- and heterogeneous catalyses (1). As the simplest model for active intermediates in various transition metal catalyzed reactions promoted by heterometallic catalysts, we previously reported the synthesis and some reactions of heterodinuclear organometallic complexes containing group 10 metals, having both M–R and M–M′ bonds, $L_nRM–M'L'_m$ (M = Pt, Pd; M′ = Mo, W, Co, Fe, Mn, Re; R = Me, Et, Ph, H, Ac, allyl; L_n = cod, dppe, bpy, phen, tmeda; L′ = η^5-Cp, CO) (2). They show unique reactions such as organic group transfer between different metal centers (2*a*, 2*c*, 2*d*, 2*e*, 2*h*, 2*k*, 2*q*), significant acceleration of β-hydrogen elimination (2*f*, 2*i*), enhanced CO insertion reactions into the Pd–C bond (2*g*, 2*l*), and regio- and stereoselective insertion reactions of thiiranes into the Pt–Mn (or –Re) bond controlled by an ancillary alkyl ligand (2*j*). On the other hand, organoplatinum- (or palladium-) cobalt complexes show catalytic activities in carbonylation of thietane (2*m*) and copolymerization of aziridine and CO (2*p*, 2*s*). Among these reactions, organic group transfer reactions attract interest as a simple model for easy σ-organic group movement on the heterometallic catalyst surface. The process is found to be essentially reversible and is regarded as reductive elimination of transition metal and organic groups at the transition metal. In most of the complexes we have investigated, an organic group on the platinum metal moves to other metals with small electronegativity. In this work, we investigated the synthesis and reaction of homometallic

alkyl- and aryl-dinuclear complexes containing one platinum–platinum bond (3). These complexes were synthesized by oxidative addition of the Pt–C bond of PtR(η^5-Cp)(CO) to a platinum(0) complex containing a 1,2-bis(diphenylphosphino)ethane ligand (dppe). In these dinuclear complexes, two competitive organic group transfers took place simultaneously and the reaction selectivity was controlled by additives such as olefins, carbon monoxide, and phosphine lignads.

Results and discussion

Synthesis and characterization of alkyl- (or phenyl-) platinum–platinum complexes

Treatment of the zero-valent platinum complex, Pt(η^2-CH_2=CHPh)(dppe) (**1**) with carbonyl(η^5-cyclopentadienyl)methylplatinum, PtMe(η^5-Cp)(CO) (**2a**) (4), prepared by treatment of PtMe(η^1-Cp)(cod) with CO, smoothly gave methyldiplatinum complex, (dppe)MePt–Pt(η^5-Cp)(CO) (**3a**), in 62% yield in benzene at room temperature (eq. [1]). Similar reactions with other organoplatinum complexes PtR(η^5-Cp)(CO) (R = Et (**2b**), CH_2CMe_3 (**2c**), Ph (**2d**)) also gave the corresponding organodiplatinum complexes, (dppe)RPt–Pt(η^5-Cp)(CO) (R = Et (**3b**), CH_2CMe_3 (**3c**), Ph (**3d**)). These complexes **3a**–**3d** were characterized by ^{1}H and ^{31}P{^{1}H} NMR and IR spectroscopies and elemental analysis. Single crystals of complexes **3a** and **3c** suitable for X-ray structure analysis were obtained by recrystallization from Et_2O or toluene–hexane. Figure 1 depicts an ORTEP drawing of **3a** and **3c** showing the formation of both Pt–Pt and C–Pt bonds by oxidative addition of the Pt–C bond to Pt(0). The Pt(1)–Pt(2) bond distances for **3a** and **3c** are 2.6415(10) and 2.6489(5) Å, respectively. The Pt(1)–C(1) bond distances for **3c** (2.136(9) Å) is slightly longer than for **3a** (1.98(2) Å). The geometry of the Pt metal coordinated by 1,2-bis(diphenylphosphino)ethane is essentially square planar, where the Pt(η^5-Cp)(CO) moiety and the methyl or neopentyl group are placed cis to each other. This square planar geometry is consistent with the d^8 configuration of Pt(II). The carbonyl and Cp ligands in these complexes lie orthogonal to the coordination plane of the Pt metal bearing a 1,2-bis(diphenylphosphino)ethane ligand. The Pt(2)–C(33)–O(1) [177(2)°] linkage in **3a** and Pt(2)–C(37)–O(1) [176.5(8)°] linkage in **3c** are linear compared with the corresponding linkages of heterodinuclear complexes, suggesting that these carbonyl ligands have no bridging interaction with Pt metal coordinated with dppe.

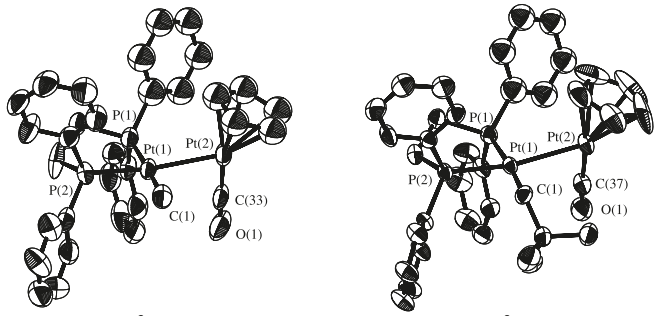
Ph (**3d**) (72%)

The IR spectra of **3a**–**3d** show a strong ν(CO) band at ca. 1940 cm^{-1}. The value is considerably lower than that for the known Pt(II) complex PtMe(η^5-Cp)(CO) (2036 cm^{-1}) (3*a*), suggesting strong π back-donation from the Pt metal. From these data, the actual oxidation state of the Pt metal with dppe and an organic group and of the Pt metal with CO and Cp ligands were calculated to be close to two and zero, respectively, though the formal oxidation state of each is one.

Fig. 1. Molecular structures of (dppe)MePt–Pt(η^5-Cp)(CO) (**3a**) and (dppe)(Me_3CCH_2)Pt–Pt(η^5-Cp)(CO) (**3c**). All hydrogen atoms and solvent are omitted for clarity. Elipsoids represent 50% probability. Selected bond distances (Å) for **3a**: Pt(1)–Pt(2) 2.6415(10), Pt(1)–P(1) 2.210(5), Pt(1)–P(2) 2.290(5), Pt(1)–C(1) 1.98(2), Pt(2)–C(33) 1.73(2), C(33)–O(1) 1.20(3). Selected bond angles (°) for **3a**: Pt(2)–Pt(1)–C(1) 86.8(6), P(1)–Pt(1)–P(2) 86.51(18), P(1)–Pt(1)–C(1) 91.3(7), Pt(2)–Pt(1)–P(2) 95.50(13), Pt(2)–C(33)–O(1) 177(2). Selected bond distances (Å) for **3c**: Pt(1)–Pt(2) 2.6489(5), Pt(1)–P(1) 2.221(2), Pt(1)–P(2) 2.298(2), Pt(1)–C(1) 2.136(9), Pt(2)–C(37) 1.777(10), C(37)–O(1) 1.151(12). Selected bond angles (°) for **3c**: Pt(2)–Pt(1)–C(1) 91.6(2), P(1)–Pt(1)–P(2) 85.63(8), P(1)–Pt(1)–C(1) 88.9(2), Pt(2)–Pt(1)–P(2) 93.77(6), Pt(2)–C(37)–O(1) 176.5(8).



The ^{31}P{^{1}H} NMR spectrum of **3a** shows two sets of resonances centered at δ 43.0 and 51.1, both of which are accompanied by two ^{195}Pt satellite peaks. No apparent P–P coupling is observed. The P–Pt coupling constants for the resonance at δ 43.0 (3377 and 950 Hz) are smaller than those for the resonance at δ 51.1 (1733 and 125 Hz), suggesting that the former signal is assigned to the P nucleus *trans* to the methyl ligand and the latter *trans* to Pt, since the *trans* influence of the methyl is larger than that of Pt metal (2*b*, 2*c*, 2*d*). A large second coupling constant (950 Hz) for the resonance at δ 51.1 is also consistent with the *trans* configuration between this P and Pt nuclei. ^{31}P{^{1}H} NMR spectra of complexes **3b**–**3d** showed similar patterns. All observations of two ^{195}Pt satellites in ^{31}P nuclei are consistent with the dinuclear structure with a Pt–Pt bond.

The ^{1}H NMR spectrum of **3a** in benzene-d_6 shows a double doublet with ^{195}Pt satellite for the methyl group, owing to couplings with two different P nuclei at room temperature. Cp protons in **3a** appear as a singlet at δ 5.58. The *ortho* protons of Ph in the dppe ligand are observed as two separated sets of multiplets at δ 7.7 and 7.9, each with 4H intensity. Inequivalency of the two phosphorus nuclei in dppe of **3a** is consistent with the structural result. The phenyl analogue **3d** also show similar results. On the other hand, the ethyl complex **3b** shows broad signals for the ethyl and the *ortho* protons of phenyl in the dppe ligand at room temperature. When the temperature is raised to 70 °C, clear signals consisting of a double quartet (2H) and a double triplet (3H) with Pt satellites owing to the ethyl ligand and two multiplets (4H each) for the *ortho* protons are observed. The

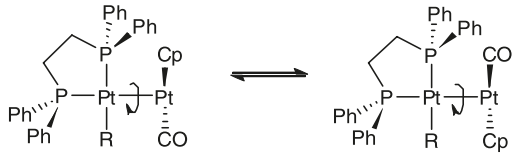
Scheme 1. Rotation of platinum–platinum bond.



results indicate that these complexes involve some fluxionality in solution without Pt–P bond rupture. When these complexes in acetone-d_6 are cooled to –40 °C, two multiplets for the *ortho* protons further split to four multiplets with 2H intensity, though unfortunately the ethyl signals are not well resolved. The result suggests that four aryl groups in dppe become magnetically inequivalent at low temperature. Such a situation becomes more clear for the ^{1}H NMR of neopentyl derivative **3c**: four separated *ortho* protons are observed at room temperature. Furthermore, methylene signals owing to the neopentyl group appear as an AB quartet that further splits into double doublets by coupling with two P nuclei with Pt satellites. Observation of the diastereotopic methylene signals indicates that **3c** is stereochemically rigid as shown by X-ray structure analysis, where CO and Cp ligands are fixed above and below the square planar coordination plane of Pt metal with dppe ligand. Therefore the observed fluxionality in **3a** and **3b** is considered to be due to the rotation of the Pt–Pt bond without any bond dissociation (Scheme 1). The qualitative ease of the Pt–Pt bond rotation decreases in the order **3a**≈**3d** > **3b** > **3c**, reflecting the increase of steric bulkiness of the alkyl ligands. The importance of steric bulk in the dinuclear system is also previously reported in the structural study of alkyl, acyl, and hydrido heterodinuclear complexes (2*r*).

To clarify the polarization of the platinum–platinum bond, reactions of methyl and ethylplatinum–platinum complexes with an electrophile were investigated (eq. [2]). The reaction of methylplatinum–platinum complex **3a** with methyl iodide in acetone-d_6 gave PtMe(η^5-Cp)(CO) (**1a**, 86%) and PtMeI(dppe) (**4a**, 95%) but no PtI(η^5-Cp)(CO) or $PtMe_2$(dppe) (eq. [2]). A similar result was obtained for the reaction of **3a** with EtI and **3b** with MeI. These results indicate that Pt with dppe is essentially electrophilic and Pt with CO is nucleophilic in both cases, being consistent with Pt(II)–Pt(0) formalism, and also with IR and X-ray structural data.

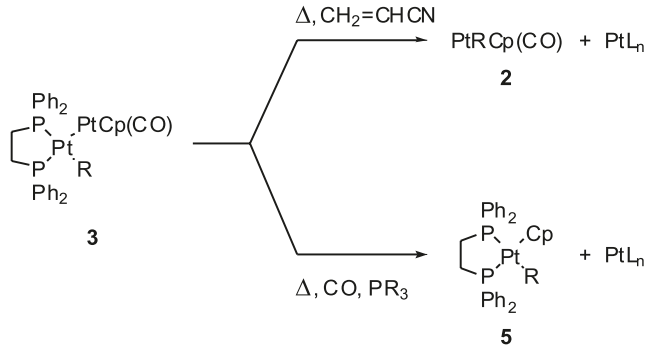
Controlled organic group transfer along the platinum–platinum bond

Thermolysis of 3a–3d

Thermolysis of organodiplatinum complexes **3a**–**3d** (Scheme 2) was carried out and the results are summarized in Table 1. Heating of methyl complex **3a** in C_6D_6 at 70 °C

Scheme 2. Controlled organic group transfer along platinum–platinum bond.



led to the migration of the Cp ligand to the other Pt atom giving PtMe(η^1-Cp)(dppe) (**5a**) in 55% yield with a small amount of PtMe(η^5-Cp)(CO) (**2a**) (Table 1, entry 1). The progress of the thermolysis of **3a** monitored by ^{1}H NMR indicated that **2a** and **5a** were formed simultaneously in the same ratio. Thermolysis of ethyl complex **3b** at 70 °C also gave PtEt(η^1-Cp)(dppe) (30%) accompanied by the evolution of ethylene (59%) (entry 2). Only a trace of **2b** was detected. In contrast, heating of neopentyl derivative **3c** in C_6D_6 at 70 °C led to the migration of the neopentyl ligand to the other Pt atom giving Pt(CH_2CMe_3)(η^5-Cp)(CO) (**2c**) (Table 1, entry 3) preferentially. Phenyl derivative **3d** was relatively stable and when thermolysis of **3d** was performed under similar conditions, PtPh(η^1-Cp)(dppe) (**5d**) was formed in lower yield and no **2d** was detected (entry 4). These results show that reductive elimination occurs at both Pt metals giving PtR(η^5-Cp)(CO) and PtR(η^1-Cp)(dppe). **3c** favors the organic transfer from square planar Pt but Cp ligand selectively moves to square planar Pt in the cases of **3a**, **3b**, and **3d**. In other words, reductive elimination at square planer Pt is preferred for the former, but that of Pt and Cp at the Pt(CO) site for the latter. These results are in sharp contrast with the previously reported thermal reductive elimination of the alkyl or aryl and transition metal at Pt in L_2RPt–M(η^5-Cp)L_n giving only MR(η^5-Cp)L_n (2*a*, 2*c*, 2*d*, 2*e*), in which β-hydrogen elimination of ethylplatinum–molybdenum (or –tungsten) complexes (2*d*, 2*i*) and no Cp transfer were observed. Unfortunately, corresponding Pt(0) products were not identified. The stronger electron-donating property of the neopentyl ligand may accelerate the reductive elimination (5). The origin of the present selectivity difference of organic group transfer is not clear at present and further detailed kinetic and theoretical studies are required.

Organic group transfer assisted by olefins, carbon monoxide, or phosphine ligands

When the organodiplatinum complexes **3a**–**3d** were treated with olefins, CO, and tertiary phosphine ligands, organic transfer reactions were enhanced. Results of the reactions at room temperature are also summarized in Table 1.

Treatment of **3a** with 5 equiv. of acrylonitrile in C_6D_6 gave **2a** (35%) and **5a** (19%) in 2 h, showing acceleration of methyl transfer at the square planar platinum site (Table 1, entry 5) (6). Reaction with methyl acrylate also produced a similar result, though the rate was relatively slow (Table 1, entry 6). Styrene showed no large effect on reductive elimi-

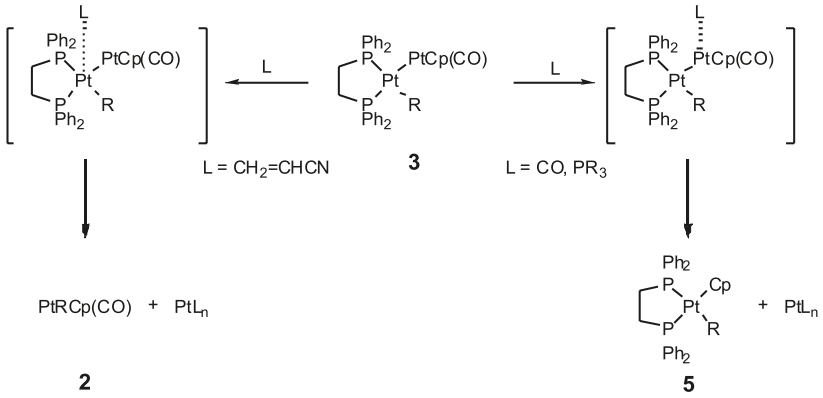
Scheme 3. A possible mechanism for controlled organic group transfer along platinum–platinum bond.



nation (Table 1, entry 7). A similar trend was also observed in the reactions of **3b** and **3d** (Table 1, entries 8 and 10). No significant effect was observed for the neopentyl derivative **3c** (Table 1, entry 9). These results can be reasonably understood by the coordination of these substituted olefins to the square planar platinum atom enhancing the reductive elimination of PtR(η^5-Cp)(CO) complexes, similar to the organic transfer of heterodinuclear organoplatinum complexes assisted by electron deficient olefins, which was previously reported by us (2*a*, 2*c*, 2*d*, 2*e*). Coordination of electron-deficient olefins to the square planar platinum complexes enhances the reductive elimination. Therefore the relatively electron-rich styrene showed no significant effect. The low acceleration by added acrylonitrile to the neopentyl complex **3c** could be due to the fact that the sterically bulky neopentyl ligand discourages coordination. The importance of steric bulkiness of the neopentyl ligand is also discussed in the NMR study (vide supra).

In contrast, reaction of a C_6D_6 solution of **3a**, **3c**, **3d** with CO (1 atm) at room temperature afforded PtR(η^1-Cp)(dppe) (R = Me (**5a**), CH_2CMe_3 (**5c**), Ph (**5d**)) as the major product (Table 1, entries 11–13). When **3a** was treated with a tertiary phosphine ligand such as 1,2-bis(diphenylphosphino)ethane (dppe) or PPh_3 in C_6D_6 at room temperature, selective Cp group transfer took place to give only PtMe(η^1-Cp)(dppe) (**5a**) in high yield (Table 1, entries 14, 15).

Possible mechanism for controlled organic group transfer along platinum–platinum bond

As shown in Scheme 3, competitive organic group transfer reactions along the Pt–Pt bond in organodiplatinum complexes (dppe)RPt–Pt(η^5-Cp)(CO) take place to give PtR(η^5-Cp)(CO) and PtR(η^1-Cp)(dppe) on thermolysis. The reaction was enhanced by the coordination of additives such as olefin, CO, and tertiary phosphine ligands. The selectivity of the reaction is affected by the coordination site of the added substrate. Specifically, the organic group transfer at square planar platinum is favored by interaction with electron-deficient olefin, whereas Cp group transfer from Pt(η^5-Cp)(CO) to PtR(dppe) is enhanced by tertiary phosphine ligands or carbon monoxide. Probably, these ligands favor the

© 2008 NRC Canada

coordination at the Pt(η^5-Cp)(CO) site to enhance the Cp migration, while preferred coordination of π-accepting ligands such as acrylonitrile to the Pt metal with an electron-donating dppe ligand gives PtR(η^5-Cp)(CO). The acceleration effect of added olefin on the alkyl transfer reaction is well established in the reductive elimination of square planar diorganonickel (or palladium) complexes (7) and heterodinuclear organometallic complexes containing platinum (2*a*, 2*c*, 2*d*). The observed selective reaction caused by ligands could be due to the thermodynamic stability of products. For example, reductive elimination at the (dppe)Pt site favors Pt(0) product such as Pt(olefin)(dppe) rather than a putative complex Pt(olefin)$(CO)_n$ with ligands with all strong π-back-donation. Further detailed study including a theoretical approach is required to clarify the origin of this selectivity.

Experimental

General

All manipulations were carried out under dry nitrogen or argon atmosphere using standard Schlenk and vacuum line techniques. Solvents (benzene, toluene, hexane, and THF) were refluxed over and distilled from sodium benzophenone ketyl under N_2. Deuterated solvents were degassed by three freeze-pump-thaw cycles and then vacuum-transferred from appropriate drying agents (C_6D_6 from sodium wire, acetone-d_6 from drierite). The zero-valent platinum complex, Pt(η^2-CH_2=CHPh)(dppe) was prepared by the reaction of PtI_2(dppe) with $NaBH_4$ in the presence of a large excess of the styrene according to the analogous literature method (2*k*). PtR(η^1-Cp)(cod) were prepared by the reaction of PtRCl(cod) and NaCp according to the analogous literature methods with modifications (3). PtR(η^1-Cp)(dppe) (R = Me (**5a**), Et (**5b**), CH_2CMe_3 (**5d**), Ph (**5e**)) were prepared for assignment, according to the analogous literature methods (8). NMR spectra were recorded on a JEOL LA-300 spectrometer (300.4 MHz for ^{1}H, 121.6 MHz for ^{31}P). Chemical shifts were reported in ppm downfield from TMS for ^{1}H and from 85% H_3PO_4 in D_2O for ^{31}P. IR spectra were recorded on a JASCO FT–IR-410 spectrometer using KBr disks. Elemental analyses were carried out with a Perkin-Elmer 2400 series II CHN analyzer.

Synthesis of organoplatinum–platinum complexes

As a typical procedure, the oxidative addition of methyl(η^5-cyclopentadienyl)(monocarbonyl)platinum complex (**2a**) to the zero-valent platinum complex, Pt(η^2-CH_2=CHPh)(dppe) (**1**) to afford (dppe)MePt–Pt(η^5-Cp)(CO) (**3a**) is described. PtMe(η^5-Cp)(CO) was first prepared by treating PtMe(η^1-Cp)(cod) (69.9 mg, 0.169 mmol) with CO and dissolving it in benzene (3 mL). This was then added to a solution of Pt(η^2-CH_2=CHPh)(dppe) (105.2 mg, 0.1507 mmol) in benzene (10 mL). The reaction mixture was stirred at room temperature for 1 h. After the solution was concentrated under reduced pressure, excess hexane was added to give a yellow powder. The product was filtered, washed with hexane, and dried under vacuum at room temperature. Recrystallization from ether gave yellow crystals (yield: 62%). IR (KBr, cm^{-1}) ν(CO): 1933. ^{1}H NMR (C_6D_6, RT, 300.4 MHz) δ: 1.6–1.8 (m, 4H, dppe CH_2), 1.80 (dd, $^3J_{PH}$ = 7.4, 5.1 Hz, $^2J_{PtH}$ = 64.9 Hz, 3H, PtCH_3), 5.58 (m, 5H, *Cp*), 6.8–7.3 (m, 12H, *m,p-Ph*), 7.66 (m, 4H, *o-Ph*), 7.80 (m, 4H, *o-Ph*). ^{1}H NMR (acetone-d_6, RT, 300.4 MHz) δ: 1.01 (dd, $^3J_{PH}$ = 7.6, 4.9 Hz, $^2J_{PtH}$ = 66.4 Hz, 3H, PtCH_3), 2.15–2.42 (m, 4H, dppe CH_2), 5.25 (m, 5H, *Cp*), 7.40–7.65 (m, 12H, *m,p-Ph*), 7.70–7.95 (m, 8H, *o-Ph*). ^{31}P{^{1}H} NMR (C_6D_6, RT, 121.6 MHz) δ: 41.7 (s, $^1J_{PtP}$ = 3289 Hz, $^2J_{PtP}$ = 1010 Hz), 51.7 (s, $^1J_{PtP}$ = 1702 Hz, $^2J_{PtP}$ = 132 Hz). ^{31}P{^{1}H} NMR (acetone-d_6, RT, 121.6 MHz) δ: 43.0 (s, $^1J_{PtP}$ = 3377 Hz, $^2J_{PtP}$ = 950 Hz), 51.1 (s, $^1J_{PtP}$ = 1733 Hz, $^2J_{PtP}$ = 125 Hz). Reactions with alkyl halide

A typical procedure for **3a** with methyl iodide in acetone-d_6 is given. Acetone-d_6 (0.5 mL) was vacuum-transferred to an NMR tube (5 mmϕ × 180 mm) containing **3a** (5.3 mg, 5.9×10^{-3} mmol), and 1,4-dioxane was added as an internal standard to the solution. Then 1 equivalent of methyl iodide

© 2008 NRC Canada

was introduced into the NMR tube. NMR spectra were periodically measured to follow the reactions. Results are summarized in Table 1.

Thermolysis

A typical procedure for **3a** in C_6D_6 is given. C_6D_6 (0.5 mL) was vacuum-transferred to an NMR tube containing **3a**, and 1,4-dioxane was added as an internal standard to the solution. Then the NMR tube was heated on oil bath. NMR spectra were periodically measured to follow the reactions. Results are summarized in Table 1.

Reactions with olefin or phosphine ligand

A typical procedure for **3a** in C_6D_6 is given. C_6D_6 (0.5 mL) was vacuum-transferred to an NMR tube containing **3a**, and 1,4-dioxane was added as an internal standard to the solution. Then olefin or phosphine ligand was introduced into the NMR tube. NMR spectra were periodically measured to follow the reactions. Results are summarized in Table 1.

Reactions with CO

A typical procedure for **3a** is given. C_6D_6 (0.5 mL) was vacuum-transferred to an NMR tube containing **3a**, and 1,4-dioxane was added as an internal standard to the solution. The solution was degassed by freeze-pump-thaw cycles and CO (0.1 MPa) was introduced. NMR spectra were periodically measured to follow the reaction. Results are summarized in Table 1.

X-ray structure data[3]

The crystallographic data were measured on a Rigaku RASA-7R four-circle diffractometer using Mo Kα (λ = 0.710 69 Å) radiation with a graphite crystal monochromator at –73 °C. A single crystal was selected by means of a polarized microscope and mounted in a capillary tube (GLASS, 0.7 mmϕ), which was sealed by small flame torch, or onto a glass capillary with Paraton N oil. The unit cell dimensions were obtained by a least-squares fit of 20 centered reflections. Intensity data were collected using the ω-2θ technique to a maximum 2θ of 55.0°. The scan rates were 16.0 deg/min. Three standard reflections were monitored in every 150 reflections. Intensities were corrected for Lorentz and polarization effects. The data were processed using the Crystal Structure (9, 10) crystallographic software package. The structure of **3a** and **3c** was solved by Patterson methods (DIRDIF99 PATTY). An absorption correction for **3c** was applied with the program PSI SCAN method. All non-hydrogen atoms were found on difference maps.

(dppe)MePt–Pt(η^5-Cp)(CO) (3a)

For complex **3a**, all non-hydrogen atoms were refined with anisotropic displacement parameters except for one of the phenyl rings of dppe, Cp ring atoms, and the incorporated solvent molecule, which were treated as a fixed group. Crystallographic data: **3a**·Et_2O: $C_{37}H_{42}O_2P_2Pt_2$, FW: 970.83, triclinic. *P*1 (No. 2) *a*: 11.952(7) Å, *b*: 18.217(16) Å, *c*: 8.955(2) Å, α: 101.24(5)°, β: 99.72(3)°, γ: 71.37(7)°. *V*: 1800.1(19) Å^3. *Z*: 2. D_{calcd}: 1.791 g cm^{-3}. 5356 unique reflections with $I > 3\sigma(I)$. R_1: 0.080, wR_2: 0.099.

(dppe)(Me$_3$CCH$_2$)Pt–Pt(η^5-Cp)(CO) (3c)

For complex **3c**, all non-hydrogen atoms were refined with anisotropic displacement parameters except for one of the phenyl rings of dppe and the incorporated solvent molecule. The solvent molecule was refined with isotropic displacement parameters, and one phenyl ring of dppe was treated as a fixed group. Crystallographic data: **3c**·$2C_6H_6$: $C_{49}H_{52}OP_2Pt_2$, FW: 1109.08, monoclinic. $P2_1/n$ (No. 14) *a*: 11.61(7) Å, *b*: 20.43(9) Å, *c*: 18.67(6) Å, β = 91.8(3)°. *V*: 4425.1(346) Å^3. *Z*: 4, D_{calcd}: = 1.665 g·cm^{-3}. 7679 unique reflections with $I > 3\sigma(I)$. R_1: 0.0462, wR_2: 0.0622.

Reactivity of $IrCl(PPh_3)_3$ with diphenylacetylene — A direct route to 1-iridaindene[1]

Joyanta Choudhury, Sanjay Pratihar, Arnab Kumar Maity, and Sujit Roy

Abstract: The 1-iridaindene complex, $Ir[C_8H_5(Ph\text{-}2)]Cl(PPh_3)_2$ (**2**), has been prepared from the reaction of $IrCl(PPh_3)_3$ with PhC≡CPh by a novel direct cycloiridation reaction. A plausible mechanistic pathway has been suggested involving π-coordination assisted *ortho*- C–H activation and subsequent alkyne hydroiridation reaction to provide the five-member iridacycle.

Key words: iridium, diphenylacetylene, C–H activation, cyclometallation, metallacycle.

Résumé : On a préparé le complexe du 1-iridaindène, $Ir[C_8H_5(ph\text{-}2)]Cl(PPh_3)_2$ (**2**), par réaction du $IrCl(PPh_3)_3$ avec le PhC≡CPh par une nouvelle réaction de cycloiridation directe. On propose une voie mécanistique plausible impliquant une activation du C–H en *ortho* qui serait assistée par une coordination π et qui serait suivie par une réaction d'hydroiridation de l'alcyne conduisant à la formation de l'iridacycle à cinq chaînons.

Mots-clés : iridium, diphénylacétylène, activation d'une liaison C–H, cyclométallation, métallacycle.

[Traduit par la Rédaction]

Introduction

Metallacycles are important synthons as well as intermediates in many catalytic organic and organometallic reactions (1–12). Iridaindene motifs can be viewed as metallacyclopentadienes that are intermediates in metal-mediated [2+2+2] cyclotrimerization of alkynes to provide aromatic six-membered rings (13–18). There are also examples of [2+2+1] cyclotrimerization reactions with the intermediacy of metallacyclopentadienes (19–25). Moreover, the metallacyclopentadiene complexes are utilized for the synthesis of metallabenzenes, which are interesting structural units, compared with simple aromatics (26–28). To our knowledge, a direct and unassisted route for the preparation of such metallacycles by the activation of organic precursors with appropriate metal complexes is hitherto unknown. The more common routes involve (*i*) an indirect transmetallation method, which commonly uses organomercury compounds and (*ii*) carbon monoxide assisted cyclocarbonylation using alkynes or allenes leading to metallacyclopentadienones.

With specific reference to iridium, an iridaindene complex $Ir[C_8H_5(Ph\text{-}2)](C_5H_5)(P^iPr_3)$ was prepared earlier from $Ir(PhC{\equiv}CPh)(C_5H_5)(P^iPr_3)$ via the formation of a vinyl complex $Ir(PhC{=}CHPh)(OCOCF_3)(C_5H_5)(P^iPr_3)$ by CF_3COOH and subsequent reaction with NH_4PF_6 in methanol (29). Recently, Wright and co-workers (30) reported a transmetallation route for the synthesis of a substituted 1-iridaindene $Ir[C_8H_5(Ph\text{-}3)]Cl(PPh_3)_2$ (**1**) from the corresponding organomercury compound $Hg(CH{=}CPh_2)_2$ and $IrHCl_2(PPh_3)_3$ (Scheme 1*a*). Earlier, they isolated **1** as a side product from the reaction of $Hg(CH{=}CPh_2)_2$ and $IrCl(CS)(PPh_3)_2$ in only 20% yield (Scheme 1*b*) (31).

Our recent interest in iridium chemistry, particularly on the activation and coupling of organic functionalities (32–37) led us to investigate the activation of alkynes. Herein we report the first example of a direct cycloiridation from the reaction of $IrCl(PPh_3)_3$ with PhC≡CPh, leading to a new air-stable 1-iridaindene complex, $Ir[C_8H_5(Ph\text{-}2)]Cl(PPh_3)_2$ (**2**). We also describe the structural characterization of **2** by single crystal X-ray diffraction and propose a plausible mechanism involving C–H activation followed by ring closure.

At this point it should be noted that our result is quite interesting because the 16-electron iridium(I) complex $IrCl(PPh_3)_3$ was reported earlier to react with various alkynes. With terminal alkynes, the oxidative addition products resulted (38). But in the case of diphenylacetylene, the π-complex, $IrCl(PhC{\equiv}CPh)(PPh_3)_2$ (**3**), was reported to be formed (vide ^{1}H NMR and IR) with the substitution of one phosphine ligand (Scheme 2*a*) (38). The complex **3** was also synthesized as yellow crystals by the reaction of $IrCl(N_2)(PPh_3)_2$ with diphenylacetylene (Scheme 2*b*) (39).

Results and discussion

The reaction of $IrCl(PPh_3)_3$ with diphenylacetylene in refluxing benzene was accompanied by a gradual color change from yellow to red, which is noticeable to the naked eye within 4–6 h. Ex-situ UV–vis monitoring of the solution in benzene showed the appearance of a new peak at 510 nm. After reflux for 18 h, evaporation of the solvent in vacuum and subsequent recrystallization of the resulting solid resi-

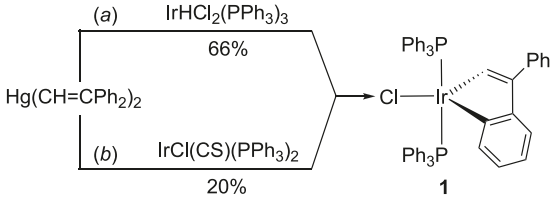
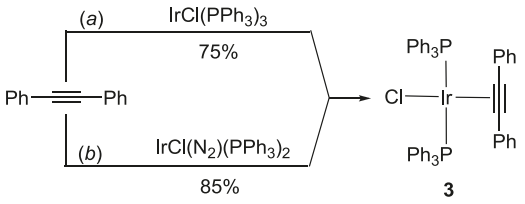
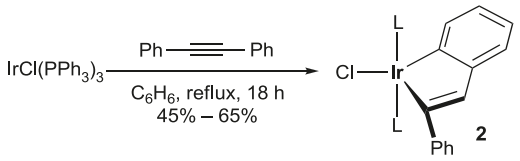


Scheme 2.



Scheme 3.

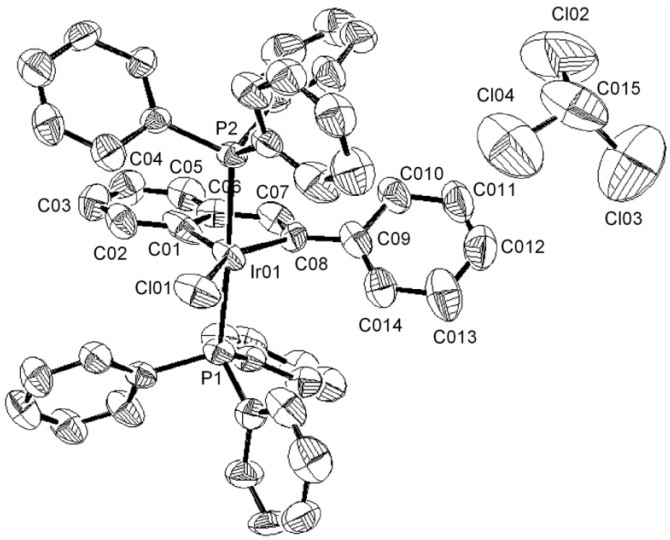


due from chloroform/ethanol or dichloromethane/ethanol afforded **2** as deep red block-like air-stable crystals, the 1st crop yield being 45%–65% (Scheme 3).

The IR spectrum of **2** in KBr discs shows no characteristic peak for coordinated alkyne. The $\nu_{C\equiv C}$ frequency in IR of the known η^2-alkyne complex **3** appears within 1850–1865 cm^{-1} (31, 32). In the ^1H NMR spectrum of **2**, there is a clean signature for the resonances of the iridaindene fragment. The sharp singlet at 5.65 ppm is assigned to the resonance of the C*H* of the five-membered iridacycle. The remaining four protons of the iridaindene six-membered ring resonate as an unresolved doublet of doublet at 5.99 ppm ($J_{H\text{-}H}$= 7.2, 7.6 Hz), a doublet at 6.10 ppm ($J_{H\text{-}H}$ = 7.2 Hz), an apparent triplet at 6.43 ppm (formally doublet of doublet, $J_{H\text{-}H}$ = 7.2, 7.2 Hz), and a doublet at 6.91 ppm ($J_{H\text{-}H}$ = 7.6 Hz), respectively. In the ^{13}C NMR spectrum, the signals of two carbon atoms bonded to iridium, viz., vinyl-*C*(Ph)Ir and aryl-*C*Ir appear as unresolved triplets at 133.9 and 145.9 ppm, respectively. The assignment is made according to a literature comparison (31). The carbon atoms of the iridaindene six-membered ring and phenyl substituent of iridaindene resonate separately as singlets between 120.1 and 133.0 ppm. The ^{31}P NMR signal appears at 22.78 ppm.

A single crystal of **2** suitable for an X-ray diffraction study was obtained by slow diffusion of ethanol into a chloroform solution of the compound at room temperature. The solid-state molecular structure of **2** is illustrated in Fig. 1. The structure contains a $CHCl_3$ molecule as solvent of crystallization. The geometry around the iridium atom is trigonal bipyramidal with axial phosphines (∠P1-Ir01-P2 = 176.73(16)°), while the equatorial plane is occupied by the chlorine atom and the two carbon atoms (∠Cl01-Ir01-C01 = 133.1(5)°, ∠Cl01-Ir01-C08 = 149.6(6)°, ∠C01-Ir01-C08 = 77.3(8)°). The iridaindene ring is found to be planar, while

Fig. 1. ORTEP representation for the molecular structure of **2·CHCl$_3$** (50% thermal ellipsoids). H atoms have been omitted for clarity. Selected bond lengths (Å) and angles (°): Ir(01)–P(1), 2.349(4); Ir(01)–P(2), 2.341(4); Ir(01)–Cl(01), 2.411(4); Ir(01)–C(01), 2.00(2); Ir(01)–C(08), 2.035(15); C(06)–C(07), 1.42(3); C(01)–C(06), 1.40(2); C(07)–C(08), 1.36(3); ∠P(1)-Ir(01)-P(2), 176.73(16); ∠Cl(01)-Ir(01)-C(01), 133.1(5); ∠Cl(01)-Ir(01)-C(08), 149.6(6); ∠C(01)-Ir(01)-C(08), 77.3(8).



the phenyl group at the 2 position is slightly tilted away from the plane. In the five-membered iridacycle, the two Ir–C bond lengths are 2.00(2) and 2.035(15) Å, which signify some degree of multiple bond nature instead of single bond character. The other three C–C bond lengths within this ring are 1.42(3) Å (C06–C07), 1.40(2) Å (C01–C06), and 1.36(3) Å (C07–C08), indicating little delocalization within the ring. The two triphenylphosphine ligands are mutually trans with Ir–P distances of 2.349(4) and 2.341(4) Å. The Ir–Cl distance is 2.411(4) Å.

To gain some insight into the plausible mechanistic pathway of this cycloiridation process, the aliquots from a 1:1 reaction mixture of $IrCl(PPh_3)_3$ and PhC≡CPh in C_6D_6 at 30, 60, and 90 °C (oil-bath temperature) were subjected to ^1H NMR spectral analysis. The formation of complex **2** was observed only under reflux conditions, as revealed from the appearance of new and characteristic peaks at 5.50, 5.84, 5.98, 6.25, and 6.37 ppm due to the iridaindene fragment. These characteristic peaks were observed at slightly downfield region in $CDCl_3$ solution of **2** (see the Experimental section). The temperature effect suggests that sufficient thermal energy was required for the C–H activation–cycloiridation to take place.

A plausible route for the formation of **2** is suggested in Scheme 4, invoking prior dissociation of a phosphine ligand from $IrCl(PPh_3)_3$ in solution, followed by the π coordination of the alkyne ligand forming the complex **A**. This proximal π-alkyne coordination in **A** adopts one of the alkyne phenyl rings, such that the iridium center can access the *ortho* C–H bond for the purpose of orthometallation. Though alkyne is less well-known to serve such a role of tethering for orthometallation, compared with other donor groups such as carbonyl, halide, or amine (40, 41), recently Hill et al. (42)

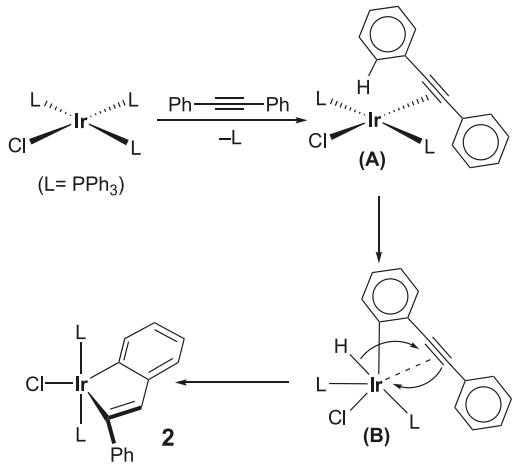
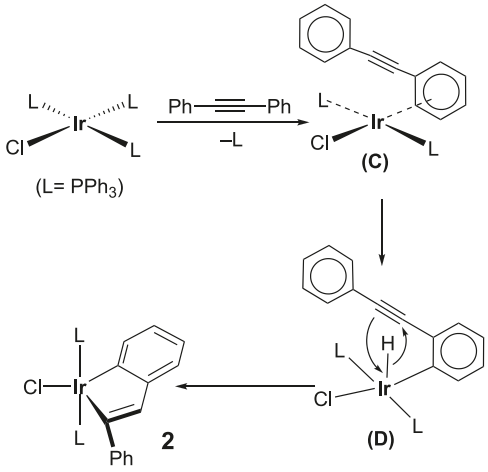
Scheme 4.



Scheme 5.



proposed such a phenomenon during the formation of a ruthenaindenone complex. Accordingly, in our proposal the iridium-hydride intermediate **B** resulting from the *ortho* C–H activation then undergoes alkyne hydroiridation to generate the iridacycle **2**. At this stage we cannot rule out another alternative mechanism (Scheme 5), involving the η^2 alkyne as dead-end, with the coordination of iridium to phenyl group leading to the hypothetical intermediate **C**. The latter, upon *ortho* C–H insertion, would produce intermediate **D**, which subsequently converts to the iridacycle **2**. Complexes featuring the binding of a phenyl group of diphenylacetylene to the metal in a η^2- or η^6-fashion (as in intermediate **C**, vide Scheme 5) have precedents in the literature. Examples from late transition metal complexes include $[Os(NH_3)_5(\eta^2\text{-}C_6H_5C{\equiv}CPh)](OTf)_2$ (43) and $[CpRu(\eta^6\text{-}C_6H_5C{\equiv}CPh)](OTf)$ (44). Two examples of η^6-bound diphenylacetylene complexes of early transition metals are $[(CO)_3Cr(\eta^6\text{-}C_6H_5C{\equiv}CPh)]$ (45) and $[(CO)_3Mo(\eta^6\text{-}C_6H_5C{\equiv}CPh)]$ (46). Recently, Legzdins and co-workers reported the formation of tungsten complexes of the type **D** having a pendent dead η^2-alkyne moiety (40). The observation of selective *ortho* C–H activation may be due to the driving force of the subsequent ring-closure reaction to a stable product, whereas the insertion into *meta* or *para* C–H bonds would be reversible.

The possibility of catalysis in the presence of traces of acid impurity (29) in our reaction mixture was also considered. We ruled out this possibility because even in the presence of 1 equiv. of Na_2CO_3, the reaction of $IrCl(PPh_3)_3$ with diphenylacetylene proceeded well, leading to the formation of the desired iridacycle **2**.

In summary, we have demonstrated here a direct cycloiridation reaction leading to an iridaindene molecule that is poised towards further functionalization of the activated indene moiety to useful organic end-product(s). A plausible mechanistic pathway has also been suggested involving π-coordination assisted *ortho* C–H activation and subsequent alkyne hydroiridation reaction to provide the five-membered iridacycle. Work is underway to explore the generality of the reaction, the reactivity of the iridacycle, and deducing the mechanism.

Experimental

General

All preparations and manipulations have been performed under a dry, oxygen-free argon atmosphere using standard vacuum lines and Schlenk techniques. All solvents have been dried and distilled by standard methods and previously deoxygenated in the vacuum line. ^1H (400 MHz), ^{13}C NMR (100 MHz), and ^{31}P NMR (162 MHz) spectra were recorded on Bruker Avance II 400 MHz spectrometer at 300 K. Tetramethylsilane was used as internal reference for ^1H and ^{13}C, while H_3PO_4 was used as external reference for ^{31}P NMR. FT-IR (4000-500 cm^{-1}; using KBr pellets) spectra were obtained using a PerkinElmer FTIR Spectrometer (Spectrum RX-I). UV–vis spectra were recorded in a Chemito Spectroscan UV 2600 spectrophotometer using HPLC-grade benzene. Elemental analyses were performed on PerkinElmer Instruments 2400 Series II CHNS/O Analyzer. $IrCl(PPh_3)_3$ was prepared according to literature procedure (47). Diphenylacetylene (Lancaster, 99%) either used directly or after recrystallization from ethanol, yielded identical results. All other chemicals were obtained commercially and used without further purification.

Synthesis and characterization details of 2[3]

In a typical example, $IrCl(PPh_3)_3$ (0.1 mmol, 101 mg) and diphenylacetylene (0.3 mmol, 54 mg) were placed in a Schlenk flask under argon. Following dissolution in dry benzene (3 ml), the solution was refluxed for 18 h. The color of the solution gradually changed from yellow to deep red. After this period, the solvent was removed under vacuum at 300 K, and the resulting solid residue was recrystallized

Anal. calcd. for $C_{50}H_{40}ClP_2Ir.CHCl_3$: C 58.35, H 3.94; found: C 57.82, H 4.36.

X-ray structure determination of 2·$CHCl_3$

Single crystals of **2** suitable for X-ray diffraction study were obtained from slow diffusion of ethanol into a solution of **2** in chloroform or dichloromethane at room temperature. A suitable deep-red blocklike crystal of the complex **2** obtained from $CHCl_3$/EtOH solution was subjected to an Enraf Nonius Turbo CAD4 diffractometer with Graphite monochromated Mo Kα (λ= 0.710 73 Å). Unit cell parameters were obtained from a least-square refinement of 25 reflections. The structure was solved by SHELXS-97 and refined by full-matrix least squares on F^2 with SHELXL-97 methods (48, 49). The non-hydrogen atoms were refined anisotropically. All calculations were performed using WinGX crystallographic software package (50). Crystallographic data as well as structure solution and refinement details for **2**: $C_{50}H_{40}Cl_1P_2Ir_1.CHCl_3$; triclinic, P-1; a = 10.3295(15) Å, b = 12.4243(19) Å, c = 17.544(3) Å; α = 94.005(11)°, β = 98.539(13)°, γ = 98.581(12)°; V = 2191.9(6) Å^3; Z = 2; T = 293(2) K; λ (Mo K α) = 0.710 73 Å; D_{calc} = 1.591 mg/m^3; μ = 3.398 mm^{-1}; F(000) = 1044; Θ (min–max) = 1.18–25.00°; independent reflection = 6440; R_{int} = 0.0201; T (min, max) = 0.6124, 0.7727; data, restraints, parameters = 6440, 0, 524; final R indices ($I>2\sigma(I)$) R_1 = 0.0711, wR_2 = 0.1693; R indices (all data) R_1 = 0.1339, wR_2 = 0.2386; GOF on F^2 = 1.137.

$Pt(2,2'\text{-bpy})(O_2CCF_3)_2$ as a terminator for $[Ag(O_2CCF_3)]_n$ aggregates — Syntheses and structures of heterobimetallic $Pt^{II}Ag^{I}$ complexes[1]

Yi Sun, Bryan Ross, Rui-Yao Wang, and Suning Wang

Abstract: The reactions between $Pt(2,2'\text{-bpy})(O_2CCF_3)_2$ and $Ag(O_2CCF_3)$ have been found to consistently produce heterobimetallic complexes where the $[Pt(2,2'\text{-bpy})]^{2+}$ unit acts as a terminator for various $[Ag(O_2CCF_3)]_n$ aggregates. The stoichiometry and the structure of the heterobimetallic complex obtained is dependent on the ratio of $Pt(2,2'\text{-bpy})(O_2CCF_3)_2$ and $Ag(O_2CCF_3)$ used in the synthesis. When a 1:1 ratio of Pt/Ag was used, a heteronuclear complex $Pt_2Ag_2(2,2'\text{-bpy})_2(O_2CCF_3)_6$ (**1a**) was obtained where the four metal ions have a linear Pt-Ag-Ag-Pt arrangement. Molecules of **1a** stack in the crystal lattice via intermolecular Pt···Pt interactions to form a linear 1D extended structure. A structural isomer of **1a**, $Pt_2Ag_2(2,2'\text{-bpy})_2(O_2CCF_3)_6$ (**1b**), where the four metal ions have an "L"-shaped arrangement was also identified and characterized, which forms a zig-zag 1D extended structure via intermolecular Pt···Pt interactions. When the 1:2 and the 1:3 ratios of Pt/Ag were used, heteronuclear complexes $Pt_2Ag_4(2,2'\text{-bpy})_2(O_2CCF_3)_8$ (**2**) and $Pt_2Ag_6(2,2'\text{-bpy})_2(O_2CCF_3)_{10}$ (**3**) were isolated, respectively, where the Ag(I) ions form cyclic structures with the $Pt(2,2'\text{-bpy})(O_2CCF_3)_2$ units at the terminal positions. Further increase of the amount of $Ag(O_2CCF_3)$ used in the synthesis did not lead to the isolation of larger aggregates. The structures of compounds **1a**, **1b**, **2**, and **3** were determined by single-crystal X-ray diffraction analyses. ^{19}F NMR spectroscopic analysis established that these heterobimetallic complexes undergo dynamic exchanges in solution.

Key words: heterobimetallic complexes, structure, silver, platinum, metal-metal interaction.

Résumé : On a observé que les réactions du $Pt(2,2'\text{-bpy})(O_2CCF_3)$ avec le $Ag(O_2CCF_3)$ conduisent d'une façon systématique à la formation de complexes bimétalliques dans lesquels l'entité $[Pt(2,2'\text{-bpy})]^{2+}$ agit comme unité terminale de divers agrégats $[Ag(O_2CCF_3)]_n$. La stoechiométrie et la structure de complexe hétérobimétallique obtenu dépend du rapport entre les quantités de $Pt(2,2'\text{-bpy})(O_2CCF_3)_2$ et de $Ag(O_2CCF_3)$ utilisés dans la synthèse. Avec un rapport Pt:Ag égal à l'unité, on obtient un complexe $Pt_2Ag_2(2,2'\text{-bpy})_2(O_2CCF_3)_6$ (**1a**) dans lequel les quatre ions métalliques Pt-Ag-Ag-Pt forment un arrangement linéaire. Les molécules de **1a** s'empilent dans le réseau cristallin par le biais d'interactions Pt···Pt intramoléculaires qui forment une structure linéaire unidimensionnelle étendue. On a aussi mis en évidence la présence et caractérisé un isomère de structure du produit **1a**, $Pt_2Ag_2(2,2'\text{-bpy})_2(O_2CCF_3)_6$ (**1b**) dans lequel les quatre ions métalliques adoptent un arrangement en forme de « L » et qui forment une structure étendue unidimensionnelle en zigzag par le biais d'interactions Pt···Pt intramoléculaires. Avec des rapports de Pt:Ag égaux à 2 ou 3, on a isolé respectivement les complexes hétéronucléaires $Pt_2Ag_4(2,2'\text{-bpy})_2(O_2CCF_3)_8$ (**2**) et $Pt_2Ag_6(2,2'\text{-bpy})_2(O_2CCF_3)_{10}$ (**3**) dans lesquels les ions Ag(I) forment des structures cycliques avec des unités $Pt(2,2'\text{-bpy})(O_2CCF_3)_2$ en positions terminales. Une utilisation dans les synthèses de quantités plus grandes de $Ag(O_2CCF_3)$ ne conduit pas à la formation d'agrégats plus gros. On a déterminé les structures des composés **1a**, **1b**, **2** et **3** par les techniques de diffraction des rayons X par un cristal unique. Une analyse par RMN du ^{19}F a permis d'établir que ces complexes hétérobimétalliques donnent lieu à des échangent dynamiques en solution.

Mots-clés : complexes hétérobimétalliques, structure, argent, platine, interaction métal-métal.

[Traduit par la Rédaction]

Introduction

Coordination polymers have attracted much research attention recently because of their various potential applications in materials science, catalysis, etc. (1). One key challenge in coordination polymer synthesis is the control of the stoichiometry, the structure, and the chain length of the polymeric species (1). The most commonly used strategy in coordination polymer synthesis is the use of a linker ligand or hydrogen bonds that direct the propagation of the extended structure (1). In heterobimetallic coordination polymers, achieving effective control of the stoichiometry and the structure of the polymeric species becomes more com-

plex and challenging. Therefore, useful synthetic protocols that allow controlled and systematic syntheses of coordination polymers or oligomers, especially the heterobimetallic ones, are always highly desired to the coordination polymer and solid-state inorganic chemistry community. Silver(I) acetate and analogues are well-known to have the tendency to form various aggregates in the solid state via the carboxylate bridge (2). Many structures that contain aggregates of $[Ag(O_2CR)]_n$ have been reported in the literature (2). We have recently discovered serendipitously that the Pt(2,2′-bpy)$(O_2CCF_3)_2$ complex can be used effectively as a chelate ligand for binding to Ag(I) ions and for controlling the size of the $[Ag(O_2CCF_3)]_n$ aggregates, which in turn allows the controlled and easy synthesis of a number of new heterobimetallic Pt–Ag complexes without the use of any linker ligands other than the $CF_3CO_2^-$ anion in the starting metal complexes. The synthetic and structural details of the new heterobimetallic complexes are reported herein.

Experimental

All reactions were performed under an inert atmosphere of dry N_2 with standard Schlenk techniques, unless otherwise noted. All starting materials were purchased from Sigma-Aldrich Chemical Co. and used without further purification. CH_2Cl_2 was distilled over P_2O_5, Et_2O was purified using a solvent purification system (Innovation Technologies Co.). Deuterated solvents such as CD_2Cl_2 (Cambridge Isotopes) were used as received without further drying. NMR spectra were recorded on a Bruker Avance 400 spectrometer (400.13 MHz for ^{1}H, 100.62 MHz for ^{13}C, 376.50 MHz for ^{19}F), chemical shifts are referenced to the residual solvent peaks and have been reported in parts per million (ppm) relative to TMS (^{1}H and ^{13}C) and $CFCl_3$ (^{19}F). Elemental analyses were performed at the Analytical Laboratory for Environmental Science Research, Department of Chemistry, University of Toronto, Toronto, Ontario and Canadian Microanalytical Service LTD, Delta, BC. Pt(2,2′-bpy)Cl_2 was prepared by a modified method described in the literature (3).

Preparation of Pt(2,2′-bpy)$(O_2CCF_3)_2$

To a solution in a Schlenk flask containing 0.422 g (1.0 mmol) of Pt(2,2′-bpy)$(Cl)_2$ and 120 mL of CH_2Cl_2 was added 0.454 g (2.0 mmol) of $Ag(O_2CCF_3)$. The reaction mixture was stirred at 25 °C for 2 h in the dark. The precipitation was filtered and the filtrate was concentrated to ~10 mL under a reduced pressure, followed by the addition of diethyl ether to precipitate the product. Collection and drying under vacuum gave a light yellow solid, 470 mg (81%) of Pt(2,2′-bpy)$(O_2CCF_3)_2$. ^{1}H NMR (400 MHz, CD_2Cl_2, ppm) δ: 8.61 (d, ^3J = 8.0 Hz, 2H, py), 8.26 (t, ^3J = 8.0 Hz, 2H, py), 8.02 (d, ^3J = 8.0 Hz, 2H, py), 7.67 (t, ^3J = 8.0 Hz, 2H, py). ^{19}F NMR (376.50 MHz, CD_2Cl_2, ppm) δ: –176.0. Anal. calcd. for $C_{14}H_8F_6N_2O_4Pt$: C, 29.13, H 1.40, N 4.85; found: C 29.25, H 1.48, N 4.76.

Preparation of Pt_2Ag_2(2,2′-bpy)$_2(O_2CCF_3)_6$ (1a)

A CH_2Cl_2 (15 mL) solution of Pt(2,2′-bpy)$(O_2CCF_3)_2$ (20 mg, 0.035 mmol) was mixed with a CH_2Cl_2 (15 mL) solution of $Ag(O_2CCF_3)$ (7.7 mg, 0.035 mmol). Slow evaporation of the solvents afforded yellow crystals of **1a**, 16 mg (58%), mp 125–126 °C. ^{1}H NMR (400 MHz, CD_2Cl_2, ppm) δ: 8.52 (d, ^3J = 8.0 Hz, 2H, py), 8.27 (t, ^3J = 8.0 Hz, 2H, py), 8.03 (d, ^3J = 8.0 Hz, 2H, py), 7.67 (t, ^3J = 8.0 Hz, 2H, py). ^{19}F NMR (376.50 MHz, CD_2Cl_2, ppm) δ: –174.2, –175.8. IR (KBr disk, cm^{-1}) ν(COO$^-$): 1713s, 1691s, 1409m. Anal. calcd. for $C_{32}H_{22}Ag_2F_{18}N_4O_{12}Pt_2$: C 23.99, H 1.38, N 3.50; found: C 23.76, H 1.03, N 3.49.

Compound **1b** has the same formula as that of **1a**. It was isolated as a minor product from the reaction of Pt(B2bpy)Cl_2, B2bpy = 5,5′-bis[B(mesityl)$_2$]-2,2′-bpy (4) with excess $Ag(O_2CCF_3)$ in CH_2Cl_2 where the B–C bond on the B2bpy ligand was cleaved by the Ag(I) ion. Mechanistic investigation on this B–C bond cleavage reaction will be reported in due course. We have not been able to produce compound **1b** in a logical synthesis. All synthetic attempts led to the isolation of the isomer **1a**. The ^{1}H NMR of **1b** is identical to that of **1a**.

Preparation of Pt_2Ag_4(2,2′-bpy)$_2(O_2CCF_3)_8$ (2)

In the same manner as for the preparation of **1a**, 20 mg (0.035 mmol) of Pt(2,2′-bpy)$(O_2CCF_3)_2$ was mixed with 16 mg (0.070 mmol) of $Ag(O_2CCF_3)$ in 50 mL of CH_2Cl_2. Slow evaporation of the solvent afforded yellow crystals of **2**, 18 mg (51%), mp > 235 °C dec. ^{1}H NMR (400 MHz, CD_2Cl_2, ppm) δ: 8.47 (d, ^3J = 8.0 Hz, 2H, py), 8.27 (t, ^3J = 8.0 Hz, 2H, py), 8.03 (d, ^3J = 8.0 Hz, 2H, py), 7.67 (t, ^3J = 8.0 Hz, 2H, py). ^{19}F NMR (376.50 MHz, CD_2Cl_2, ppm) δ: –174.1, –175.7. IR (KBr disk, cm^{-1}) ν(COO$^-$): 1712s, 1683s, 1409m. Anal. calcd. for $C_{36}H_{24}Ag_4F_{24}N_4O_{16}Pt_2$: C 21.13, H 1.18, N 2.74; found: C 20.78, H 0.77, N 2.42.

Preparation of Pt_2Ag_6(2,2′-bpy)$_2(O_2CCF_3)_{10}$ (3)

In the same manner as for the preparation of **1a**, 20 mg (0.035 mmol) of Pt(2,2′-bpy)$(O_2CCF_3)_2$ was mixed with 23 mg (0.105 mmol) of $Ag(O_2CCF_3)$ in 60 mL of CH_2Cl_2. Slow evaporation of the solvents afforded yellow crystals of **3**, 20 mg (46%), mp 142–144 °C. ^{1}H NMR (400 MHz, CD_2Cl_2, ppm) δ: 8.49 (d, ^3J = 8.0 Hz, 2H, py), 8.27 (t, ^3J = 8.0 Hz, 2H, py), 8.03 (d, ^3J = 8.0 Hz, 2H, py), 7.67 (t, ^3J = 8.0 Hz, 2H, py). ^{19}F NMR (376.50 MHz, CD_2Cl_2, ppm) δ: –174.1, –175.7. IR (KBr disk, cm^{-1}) ν(COO$^-$): 1710s, 1681s, 1407m. Anal. calcd. for $C_{40}H_{26}Ag_6F_{30}N_4O_{20}Pt_2$: C 19.29, H 1.05, N 2.25; found: C 19.21, H 0.61, N 2.42.

X-ray crystallographic analyses

Single crystals of compounds **1a**, **1b**, **2**, and **3** were mounted on glass fibers in a brass pin, and the data were collected on a Bruker AXS Apex II single-crystal X-ray diffractometer with graphite-monochromated Mo Kα radiation operating at 50 kV and 30 mA at 180 K. No significant decay was observed during the data collection. Data were processed on a Pentium PC using Bruker AXS SHELXTL software package (version 6.14). Empirical absorption corrections were applied to all crystals. The crystals of **1a**, **1b**, and **2** belong to the triclinic space group *P*-1, while the crystals of **3** belong to the monoclinic space group *C*2/*c*. The structures were solved by direct methods. Some of the CF_3 groups in these complexes display rotational disorders that were modeled and refined successfully. All non-hydrogen atoms were refined anisotropically except some of the disor-

dered F atoms. The positions of hydrogen atoms were calculated, and their contributions in structural factor calculations were included. The crystal data are provided in Table 1. Selected bond lengths and angles are given in Table 2.

Results

Syntheses and characterization of the heterobimetallic complexes

Three new heterobimetallic complexes $Pt_2Ag_2(2,2'\text{-bpy})_2(O_2CCF_3)_6$ (**1a**), $Pt_2Ag_4(2,2'\text{-bpy})_2(O_2CCF_3)_8$ (**2**), and $Pt_2Ag_6(2,2'\text{-bpy})_2(O_2CCF_3)_{10}$ (**3**) were obtained from the reactions of $Pt(2,2'\text{-bpy})(O_2CCF_3)_2$ and $Ag(O_2CCF_3)$ in 1:1, 1:2, and 1:3 ratios, respectively, as yellow crystals in moderate yields. Attempts were made to achieve Pt–Ag complexes that have more than 3 Ag(I) per Pt(II) by increasing the amount of $Ag(O_2CCF_3)$ used in the reaction, relative to that of $Pt(2,2'\text{-bpy})(O_2CCF_3)_2$. However, these attempts only led to the isolation of compound **3**. It is conceivable that larger heterobimetallic molecules did form when a greater amount of $Ag(O_2CCF_3)$ was used. However, the problem we encountered was that as the amount of $Ag(O_2CCF_3)$ increased, more insoluble products formed that were very difficult to separate

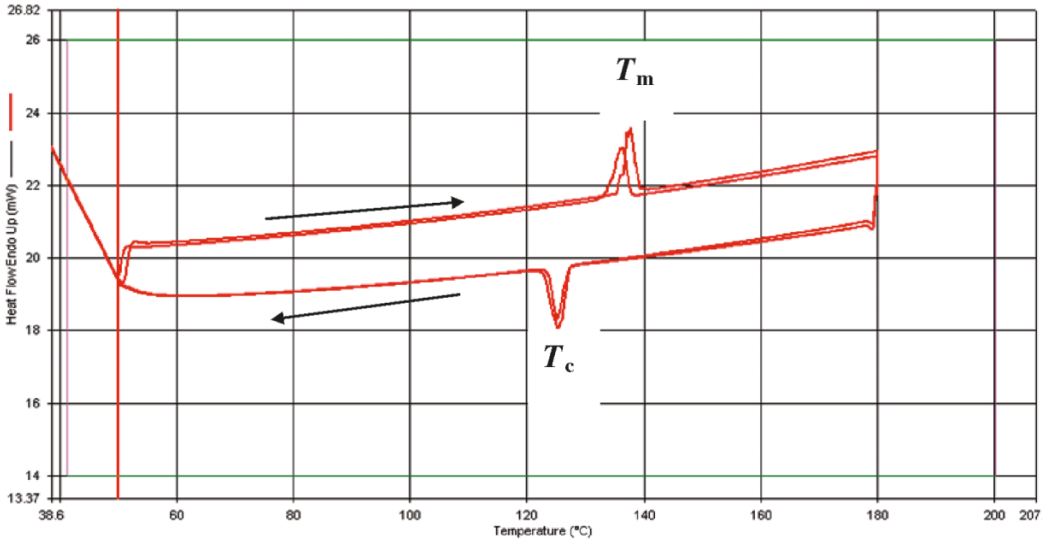
Fig. 1. The DSC diagram of **1a** with two heating and two cooling cycles (heating and cooling rate = 5.0 min.)



and characterize. Compound **1b**, a crystal isomer of **1a**, was isolated as a minor product from the reaction of Pt(B2bpy)Cl_2 with excess Ag(O_2CCF_3), where B2bpy = 5,5′- bis[B(mesityl)$_2$]-2,2′-bpy (4). Our investigation has established that the Ag(I) ion played a key role in the B–C bond cleavage in this reaction, and the details will be reported in due course. All our attempts to obtain compound **1b** via logical syntheses led to the isolation of compound **1a**. The compositions of all compounds were established by elemental analysis and ^{19}F NMR spectroscopic study. The ^{1}H NMR spectra for **1a**, **2**, and **3** in CD_2Cl_2 are nearly identical, with only a small notable difference for the chemical shift of the 6-H atoms on the 2,2′-bpy ring, an indication that the chemical environment for the 2,2′-bpy ligand in these complexes is similar. Compounds **1a** and **1b** have identical ^{1}H NMR spectra, supporting the notion that they have the same structure in solution. DSC diagrams of **1a** did not show any phase transition up to 180 (mp ~126) as shown in Fig. 1, an indication that **1a** and **1b** do not interconvert in the solid state. ^{19}F NMR spectra display two distinct and identical ^{19}F peaks at ca. –174 and ca. –176 ppm that were observed for all compounds at ambient temperature with the ratio of integrated intensities (1:2 for **1a** (**1b**), 1:1 for **2**, and 3:2 for **3**), which match well with the ratio of the number of $CF_3CO_2^-$ anions associated with Ag(I) and Pt(II), respectively, as used in the reaction for each compound. However, they are similar to those of the starting materials Ag(O_2CCF_3) (–174.1 ppm) and Pt(2,2′-bpy)(O_2CCF_3)$_2$ (–176.0 ppm), respectively, an indication that these complexes likely dissociate or undergo a dynamic exchange in solution. Indeed, as shown in Fig. 2, variable temperature ^{19}F NMR data showed that both peaks broaden with a decrease of temperature, confirming the presence of dynamic exchange processes. Due to the poor solubility of our complexes in common organic solvents, $^{107/109}$Ag and ^{195}Pt NMR studies were not possible. The IR spectra of compounds **1a**, **2**, and **3** have similar patterns. The carboxylate peak at 1712 cm^{-1} has two shoulder peaks (1731 and 1683 cm^{-1}) with somewhat different intensity ratios for each compound (see Supplementary Data).[3] None of the heterobimetallic complexes display luminescence at ambient temperature or at 77 K. The crystal structures of the new complexes were established by the single-crystal X-ray diffraction experiments and are shown schematically in Chart 1.

Crystal structures

Structures of 1a and 1b

The structures of Pt_2Ag_2(2,2′-bpy)$_2$(O_2CCF_3)$_6$ (**1a**) and its crystal isomer **1b** are shown in Figs. 3, 4, and 5, respectively. Both complexes consist of two Pt(II) ions, two Ag(I) ions, and six carboxylate anions. The two Pt(2,2′-bpy)(O_2CCF_3)$_2$ units act as chelate ligands to two Ag(I) ions. The structure of **1a** has a crystallographically imposed inversion center symmetry. The four metal ions have a linear Pt-Ag-Ag-Pt arrangement with the Pt(1)-Ag(1)-Ag(1′) angle being 173.12(2)° and two $CF_3CO_2^-$ ligands bridging every two metal ions. The Pt(1)–Ag(1) distance of 2.8412(3) Å in **1a** is fairly short and less than the sum of the atomic radii (2.83 Å), supporting the presence of Pt–Ag interactions (5). Similar Pt–Ag separation distances are known in the literature (6, 7). The Ag(1)–Ag(1′) separation distance of 2.8570(5) Å is longer than the Ag–Ag distance in metallic silver (2.889 Å) (5), indicating weak Ag–Ag interactions. Other reported Ag–Ag distances where metal–metal interactions were considered to occur range from 2.740 to 3.085 Å (2). The coordination geometry of the Pt center is square planar with normal Pt–N and Pt–O bond lengths. The Ag center has a highly distorted octahedral geometry with one Pt and one Ag atoms occupying the 5th and the 6th positions. The Ag–O bond lengths in **1a** range from 2.323(3) to 2.537(3) Å compared well with those observed in related complexes (2). In the crystal lattice, mole-

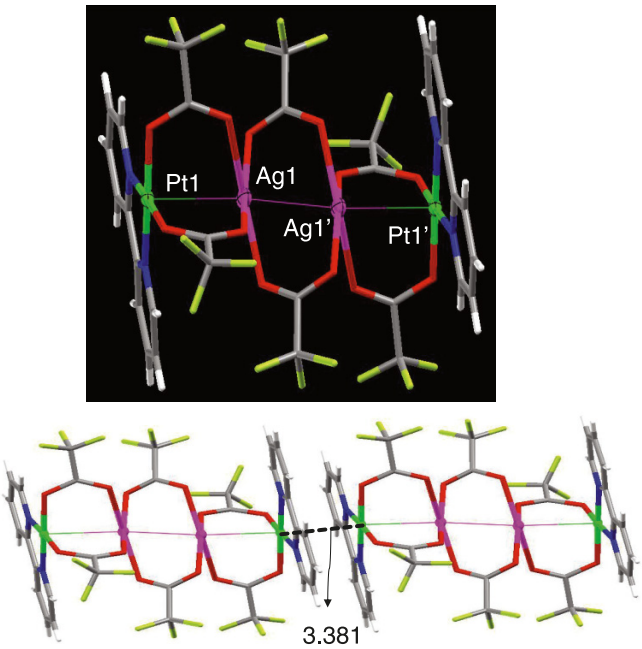
cules of **1a** form extended linear chains via weak intermolecular Pt··Pt interactions as indicated by the Pt(1)–Pt(1′) separation distance of 3.381(1) Å. The 1D metal chain of **1a** is not fully insulated by the $CF_3CO_2^-$ ligands, as shown by the space-filling diagram in Fig. 4.

Fig. 3. The crystal structure of **1a** (top) and the extended 1D structure (bottom) showing Pt··Pt interactions (right). For clarity, all non-metal atoms are shown in stick styles and only one set of fluorine atoms are shown for the disordered CF_3 groups.



In contrast to the linear structure **1a**, the four metal ions in **1b** have an "L"-shaped arrangement with the Pt(1)-Ag(1)-Ag(2) and Pt(2)-Ag(2)-Ag(1) angles being 163.93(3)° and 110.13(3)° respectively. The metal–metal separation distances in **1b** are much longer than those in **1a** (Pt(1)–Ag(1) = 2.9149(7), Pt(2)–Ag(2) = 2.9061(6), Ag(1)–Ag(2) = 2.9607(8) Å) because of the increased steric interactions among the ligands. The Ag(1) center is three-coordinate with the Ag(1)–O bond lengths being 2.302(6) to 2.362(5) Å, while the Ag(2) center is four-coordinate with the Ag(2)–O bond lengths being 2.283(5) to 2.498(5) Å. The carboxylate groups that span two metal centers are all oriented approximately *cis* to each other instead of *trans*, as observed in **1b**. One of the carboxylates on the Pt(1) center acts as a termi-

Fig. 4. A space-filling view of the diagram shown in Fig. 3 (bottom) showing that the "metallic wire" is not fully insulated by the trifluoroacetate ligands.

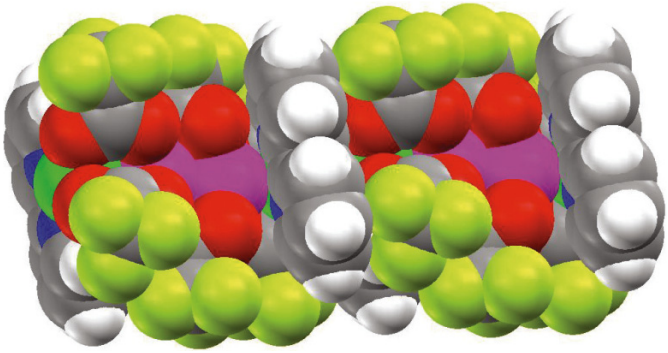

Fig. 5. The crystal structure of **1b** (top) and the extended 1D structure (bottom) showing Pt···Pt interactions (right). For clarity, all non-metal atoms are shown in stick styles and only one set of fluorine atoms are shown for the disordered CF_3 groups.

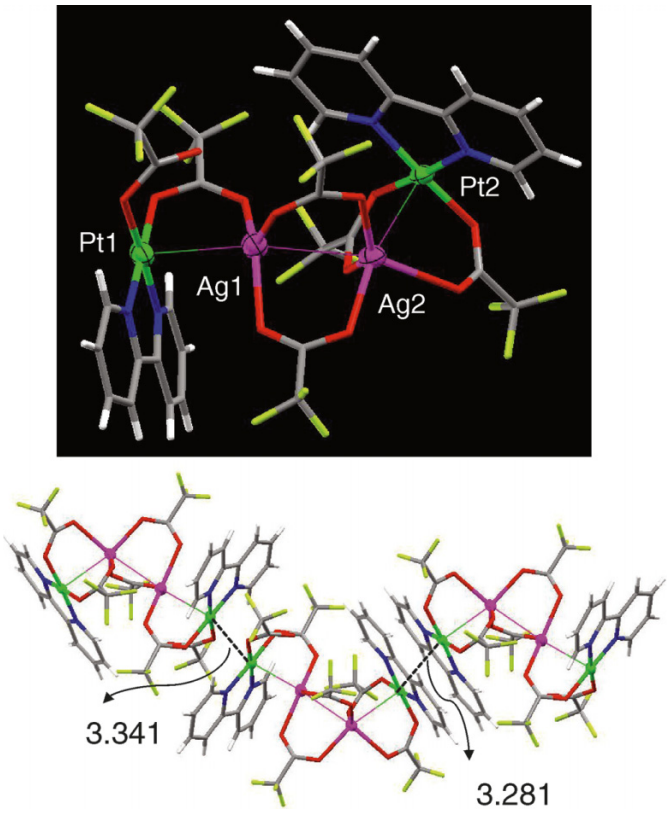
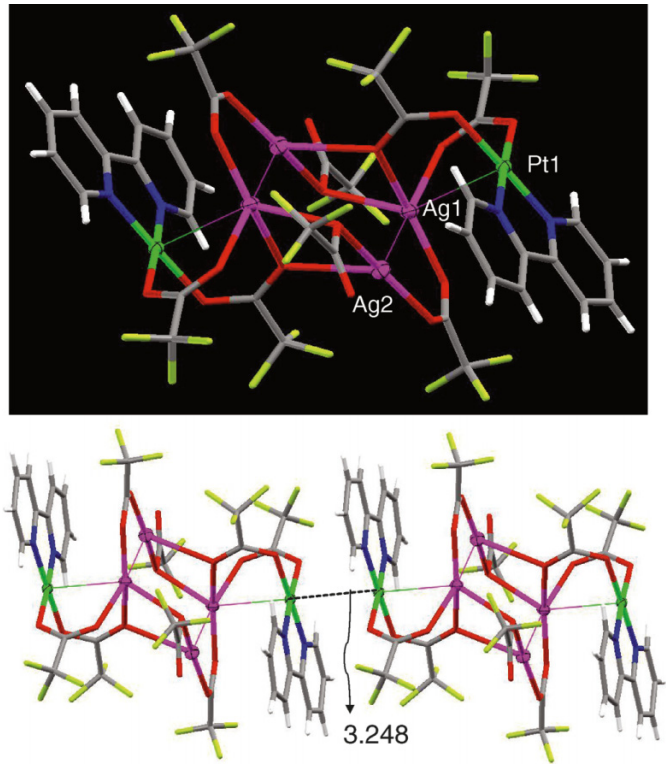


nal ligand (the non-coordinate oxygen atom on this ligand is 2.86 Å away from the Ag(1) center). In the crystal lattice, molecules of **1b** form an extended zig-zag chain via intermolecular Pt···Pt interactions (Pt(1)···Pt(1′) = 3.341(1), Pt(2)···Pt(2′) = 3.281(1) Å). Based on the results of our attempts to reproduce the structure **1b** that consistently led to the formation of **1a**, **1b** may be the less common form among the two structural isomers in the solid state.

Fig. 6. The crystal structure of **2** (top) and the extended 1D structure (bottom) showing Pt···Pt interactions (right). For clarity, all non-metal atoms are shown in stick styles and only one set of fluorine atoms are shown for the disordered CF_3 groups.



Structure of 2

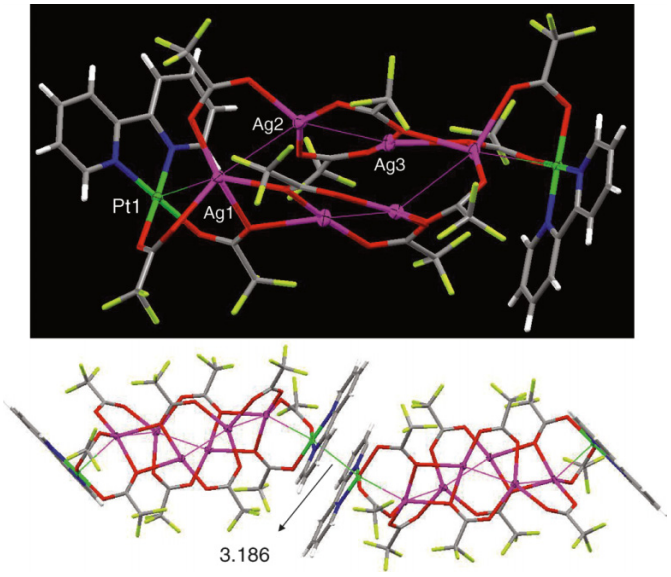
The structure of compound **2** is shown in Fig. 6. Compound **2** has a crystallographically imposed inversion center. There are four Ag(I) ions and two Pt(II) centers in **2**. As observed in **1a** and **1b**, the $[Pt(2,2'\text{-bpy})]^{2+}$ units are at the terminal positions of the cluster. The four Ag(I) ions have a rectangular arrangement with two short and two long Ag–Ag separation distances (Ag(1)–Ag(2) = 2.9315(4) and Ag(2)–Ag(1′) = 3.729(1) Å). The Pt(1)–Ag(1) distance is 2.9565(4) Å, longer than those in **1a** and **1b**. The 8 $CF_3CO_2^-$ ligands display three different bonding modes, (η^2, μ_2)–, (η^2, μ_3)–, and (η, μ_2)–. The Ag(1) atoms are three-coordinate while the Ag(2) atoms are four-coordinate. In the crystal lattice, molecules of **2** form an extended one dimensional structure via intermolecular Pt···Pt interactions (3.248(1) Å).

Structure of 3

The structure of **3** is shown in Fig. 7. The molecule of **3** possesses a crystallographically imposed inversion center with 6 Ag(I) ions that have an elliptical arrangement and two $[Pt(2,2'\text{-bpy})]^{2+}$ units at the terminal positions. Two of the carboxylates display an η^2,μ_3-bonding mode, while the remaining carboxylates have the typical η^2,μ_2-bonding modes. The Pt(1)–Ag(1) distance is fairly short at 2.8865(3) Å. The Ag(1)–Ag(2) and Ag(2)–Ag(3) separation distances are 3.2170(4) and 2.9638(5) Å, respectively. Short Ag–Ag distances are also found between Ag(2)–Ag(3′) (3.3204(5) Å) and Ag(3)–Ag(3′) (3.3027(7) Å). In the crystal lattice, molecules of **3** also form an extended one dimensional structure

© 2008 NRC Canada

Fig. 7. The crystal structure of **3** (top) and the extended structure (bottom) showing Pt···Pt interactions (right). For clarity, all non-metal atoms are shown in stick styles and only one set of fluorine atoms are shown for the disordered CF_3 groups.



via intermolecular Pt···Pt interactions (3.1859(3) Å). Two of the oxygen atoms bound to the Ag(3) center have an O-Ag-O angle of 171.74(11)° and significantly much shorter Ag–O bond lengths (2.121(3) and 2.163(3) Å) than others in **3**, which can be attributed to the much weaker Ag–O bond by the 3rd oxygen atom (Ag–O = 2.576(3) Å) on the same Ag center.

Discussion

The structures of **1a**, **1b**, **2**, and **3** demonstrate that the Pt(2,2′-bpy)$(O_2CCF_3)_2$ group is capable of forming various heterobimetallic PtAg complexes with Ag(O_2CCF_3) in different Pt/Ag ratios. Most importantly is that these structures show that the Pt(2,2′-bpy) unit allows the size control of the Ag(I) aggregate formed by acting as a terminating agent. Although the formation mechanism of the new bimetallic Pt–Ag complexes has not been understood, the Pt(2,2′-bpy)$(O_2CCF_3)_2$ molecule consistently acts as a bidentate chelate ligand to bind to a Ag(I) ion in all structures. The structures of the Ag(I) aggregates within these new bimetallic complexes, and the carboxylate bonding modes resemble many previously known examples in the literature (2). Although it is difficult to predict the exact structure of the $[Ag(O_2CCF_3)]_n$ aggregate for a given number of Ag(I) ions because of the flexible coordination number and geometry around the Ag(I) center and the multiple bonding modes of the carboxylate ligands, as shown by the distinctly different structures of **1a** and **1b**, our investigation shows that it is possible to control the stoichiometry and the size of the aggregate by using the Pt(2,2′-bpy) unit. This may have value in the controlled formation of Ag(I) or Ag–Pt(II) nanoparticles. A number of heterobimetallic Pt–Ag complexes are previously known in the literature (6, 7), however, none are based on the simple trifluoroacetate and 2,2′-bipyridine ligands, and none show any logical size control of the cluster or aggregate formed. It is important to point out that molecules **1a**, **1b**, **2**, and **3** are in general elongated along the Pt–Pt vector (the intramolecular Pt–Pt separation distances for **1a**, **1b**, **2**, and **3** are 8.53, 7.35, 8.93, and 13.06 Å, respectively). The capping or the terminating location of the Pt(2,2′-bpy) group is in general along the long axis of the molecule. In other words, the terminating effect of the Pt unit seems highly directional (one dimensional in all our compounds). We in fact have examined a number of crystals obtained from the syntheses of compounds **2** and **3** to see if other structural variations exist. As yet, no new structures have been found. Crystal lattice packing efficiency and solubility may be important factors in the formation of the crystal structures reported here. The directionality of the terminating group can be at least partially attributed to the intermolecular Pt···Pt attraction, which is persistent in all four structures. Square planar Pt(II) complexes are well-known to form highly anisotropic one-dimensional structures in the solid state via Pt···Pt interactions (1*c*, 8). The intermolecular Pt···Pt separation distances in crystals **1a**–**3** are within the typical range reported previously for one dimensional Pt(II)-extended structures (1*c*, 7, 8). Nonetheless, when the central core contains a large number of Ag(I) ions such as the case in **3**, two-dimensional structures via two-dimensional intermolecular Pt···Pt interactions are conceivable. The lack of such two-dimensional structures in our systems may be attributed to the fact that Ag(O_2CCF_3) has the tendency to form one-dimensional chain structures via the carboxylate bridge (2). If the carboxylate anion is replaced by other anionic ligands, such as $CF_3SO_3^-$, achieving two- or three-dimensional extended structures directed by intermolecular Pt···Pt interactions may be possible.

In summary, three new heterobimetallic Pt–Ag complexes have been synthesized and fully characterized. The Pt(2,2′-bpy)$(O_2CCF_3)_2$ group has been found to play a key role in the selective formation of the target complex. The intermolecular Pt···Pt attractions have been found to direct the assembly of the one-dimensional extended structures of the heterobimetallic complexes. Two distinct structures for $Pt_2Ag_2(O_2CCF_3)_6$ have been observed. Our results establish that it is possible to control the stoichiometry and the size of the heterobimetallic clusters by using the Pt(2,2′-bpy)$(O_2CCF_3)_2$ molecule as the terminating group. The applicability of this strategy to other heterobimetallic systems will be investigated by our group.

Tungsten coordination chemistry of 1,4-bisdiphenylphosphinobutadiyne — Synthesis of coordination macrocycles and factors controlling diyne cycloaddition[1]

Jordan A. Tsui, Timothy M. Bolton, and Brian T. Sterenberg

Abstract: The 1:1 reaction of $[W(CO)_4(2\text{-picoline})_2]$ (**1**) with $Ph_2PC{\equiv}C\text{-}C{\equiv}CPPh_2$ (**2**) led to $\{[cis\text{-}W(CO)_4]_2(\mu\text{-}Ph_2PC_4PPh_2)_2\}$ (**3**), in which two bis(diphenylphosphino)butadiyne ligands bridge two tetracarbonyltungsten centres. Reaction of **1** with excess **2** led to $[cis\text{-}W(CO)_4(Ph_2PC_4PPh_2\text{-}\kappa^1\text{-}P)_2]$ (**4**), in which two dangling bis-phosphines are coordinated to one metal centre, and reaction of **2** with two equivalents of **1** led to $\{[W(2\text{-picoline})(CO)_4]_2(\mu\text{-}Ph_2PC_4PPh_2)\}$ (**5**), in which one ligand bridges two tungsten centres. Combination of **4** and **5** led to the trimeric complex $\{[cis\text{-}W(CO)_4]_3(\mu\text{-}Ph_2PC_4PPh_2)_3\}$ (**6**), in which three tetracarbonyltungsten centres are bridged by three bisdiphenylphosphinobutadiyne ligands. The dimeric complex **3** showed no reactivity towards alkyne cycloaddition; however, the trimeric complex **6** undergoes cycloaddition at moderate temperatures to form $\{[W(CO)_4]_3[\mu_3\text{-}C_{12}(Ph_2P)_6]\}$ (**8**), which contains a cyclododecatrienetriyene ring. Comparison of structural data for the template complexes **3** and **6**, as well that of previously described platinum template complexes, suggests that alkyne cycloaddition reactions are favoured by proximity of the alkynyl carbons α to phosphorus in adjacent ligands.

Key words: coordination chemistry, diyne, cycloaddition, templated reaction, tungsten.

Résumé : La réaction 1:1 du $[W(CO)_4(2\text{-picoline})]$ (**1**) avec le $Ph_2PC{\equiv}C\text{–}C{\equiv}CPPh_2$ (**2**) conduit à la formation du produit $\{[cis\text{-}W(CO)_4]_2(\mu\text{-}Ph_2PC_4PPh_2)_2\}$ (**3**) dans lequel deux ligands bis(diphénylophosino)butadiynes agissent comme ponts entre deux centres tétracarbonyltungstène. La réaction du produit **1** avec un excès de **2** conduit à la formation de $[cis\text{-}W(CO)_4(Ph_2PC_4PPh_2\text{-}\kappa^1\text{-}P)_2]$ dans lequel deux bisphosphines pendantes sont coordinées à un centre métallique alors que la réaction de **2** avec deux équivalents de **1** conduit à la formation de $\{[W(2\text{-picoline})(CO_4)]_2(\mu\text{-}Ph_2PC_4PPh_2)\}$, **5**, dans lequel un ligand sert de pont entre deux centres tungstènes. La combinaison des produits **4** et **5** conduit à la formation du complexe trimère $\{[cis\text{-}W(CO)_4]_3(\mu\text{-}Ph_2PC_4PPh_2)_3\}$, **6**, dans lequel trois centres tétracarbonyltungstène sont liés à trois ligands bisdiphénylphosphinobutadiyne. Le complexe dimère **3** ne présente aucune réactivité vis-à-vis d'une cycloaddition d'alcyne; toutefois, le complexe trimère **6** conduit à une cycloaddition à température modérée avec formation de $\{[W(CO)_4]_3[\mu_3\text{-}C_{12}(Ph_2P)_6]\}$, **8**, qui contient un noyau cyclododécatrièneтriyne. Une comparaison des données structurales des complexes gabarits **3** et **6** avec ceux des complexes gabarits du platine décrits antérieurement suggère que les réactions de cycloaddition de l'alcyne sont favorisées par la proximité des atomes de carbone alcynyles α au phosphore dans les ligands adjacents.

Mots-clés : chimie de coordination, diyne, cycloaddition, réaction sur gabarit, tungstène.

Introduction

The construction of large macrocycles of controlled shape including triangles and squares by combining transition metal centres with rigid bi- or polydentate ligands is receiving increased attention (1–19). In addition to their inherent beauty, these macrocyclic structures have potential applications as catalysts (20, 21) and sensors (22). Our interest in coordination macrocycles stems from the potential of metal coordination to template unique reactions of unsaturated backbones of ligand substrates. Metal templation has been applied to many synthetic challenges including macrocycles (23), catenanes, and rotaxanes (24). Templation has also been used to control cycloaddition reactions of alkenes and

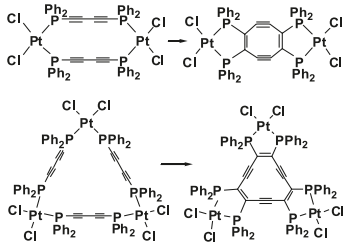
Scheme 1.



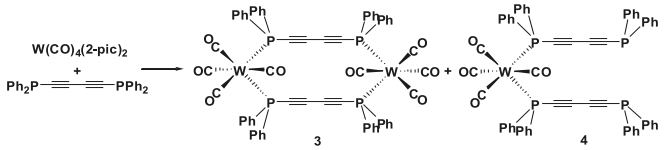
alkynes; however, in most cases, the substrate–template interaction used has been hydrogen bonding (25). We are exploring the use of metal coordination in template cycloaddition reactions, particularly cycloaddition reactions of unsaturated phosphines. This approach has been used previously to control reactivity of the alkyne units in alkynyl phosphines (26–31).

As a part an ongoing project, we have been examining the coordination chemistry of bis(diphenylphosphino)butadiyne (32). The phosphino groups of this substrate readily coordinate to a variety of transition metals (33–36). By using the appropriate metal template molecule, the spatial relationship between the reactive diyne functionalities in two or more substrate molecules can be controlled, allowing for selective cycloaddition reactions. In the absence of metal coordination, this substrate polymerizes to a material containing enyne units (37). In a previous paper (38), we showed that coordination of two or three substrate molecules to a $PtCl_2$ template fragment resulted in cycloaddition to form either a novel cyclooctadienediyne ring or a cyclododecatienetriyne ring (Scheme 1). Surprisingly, a very similar $Pt(CH_3)_2$ fragment did not induce the cycloaddition reaction under the same mild conditions. At that point, it was not obvious which structural parameters of the template complexes controlled the cycloaddition reaction.

The major disadvantage of the $PtCl_2$ system is the very poor solubility of the metal complexes, which prevented us from exploring the potentially interesting spectroscopy of the highly coloured cyclooctadienediyne ring complex. The poor solubility also made it impossible to control product distribution between the dimeric and trimeric template complexes. As a result, we set out to find a metal template fragment that would lead to soluble metal complexes as products. In addition, by surveying a number of different metal templates, we were aiming to better understand the structural features of the template complexes that control the cycloaddition reaction. A clear understanding of these factors will allow us to expand the range of metal-templated reactions to other unsaturated phosphine containing substrates.

Our work with platinum complexes suggests that bringing the substrate molecules into close enough proximity to react requires *cis*-coordination with a 90° or smaller angle between two phosphine ligands at the metal complex. In the platinum system, this was achieved by *cis* coordination of the phosphine moieties to a square planar metal centre. The same relative arrangement of phosphine ligands could also be achieved in a *cis*-octahedral metal complex. In this paper, we report our investigation of the coordination chemistry of bis-diphenylphosphinobutadiyne with *cis*-octahedral tungsten complexes. Some tungsten coordination chemistry of

Scheme 2.



bis-diphenylphosphinobutadiyne has been reported; however in these complexes only one ligand was used to bridge two tungsten centres (32). Although the octahedral geometry of the tungsten fragment in the targeted template complexes provides the same 90° angle between the two substrate molecules as the square planar $PtCl_2$ template, the larger atomic radius of tungsten and the steric influence of the octahedral metal centre are expected to affect the geometrical relationship of the substrate molecules. We will use this comparison as a probe of the effect of the structural parameters of the template complexes on the reactivity of the diyne substrates.

Results

The tungsten precursor used for this work was [*cis*-$W(CO)_4$(2-picoline)$_2$] (**1**) (39), which provides an octahedral W(0) centre with two labile *cis* ligands. The *ortho* methyl groups in the 2-picoline ligands make them more labile than the pyridine ligands in [*cis*-$W(CO)_4(py)_2$], allowing substitution reactions to take place under milder conditions. A one-to-one reaction of **1** and $Ph_2PC{\equiv}C\text{-}C{\equiv}CPPh_2$ (**2**) at 60°C led to a mixture of two phosphine complexes in a 2:1 ratio (Scheme 2). The reaction mixture also contained unidentified tungsten carbonyl decomposition products, as indicated by IR spectroscopy. The two phosphine complexes were readily isolated using column chromatography. The first of these compounds was shown to be the anticipated dimer [{*cis*-$W(CO)_4$}$_2$(μ-$Ph_2PC_4PPh_2$)$_2$] (**3**), in which two substrate molecules bridge two tungsten centres. The ^{31}P NMR spectrum of **3** shows a singlet at δ 2.80 with ^{195}W satellites and $^1J_{WP}$ of 241 Hz. An ORTEP diagram of the molecular structure is shown in Fig. 1. Each tungsten centre is coordinated by four carbonyls and two phosphines, which are *cis* to each other. The overall complex has a twisted boat shaped configuration, with both tungsten centres directed to the same side of complex. This configuration results in alkyne centre-to-centre distances of 3.499 and 3.482 Å. For comparison, alkyne centre-to-centre distances in analogous platinum complexes range from 3.236 to 3.38 Å.

The second reaction product was [*cis*-$W(CO)_4$($Ph_2PC_4PPh_2$-κ^1-P)$_2$] (**4**), in which two equivalents of the bisphosphine ligand coordinate to one tungsten centre. This product is favoured by excess phosphine ligand. However, it cannot be formed independently of Compound **3** and requires purification by column chromatography. The ^{31}P NMR spectrum of **3** shows two peaks at δ 1.3 and –30.0. The first peak shows tungsten satellites, and the chemical shift is similar to that of **2**, consistent with a $W(CO)_4P_2$ unit. The second peak is very close to that of the free ligand (δ –29.2) and is attributed to the dangling phosphines. There was no evidence of trimer formation in this reaction, as was observed in the platinum system (38). The apparent deficiency of tungsten in the isolated products of the 1:1 reaction resulted

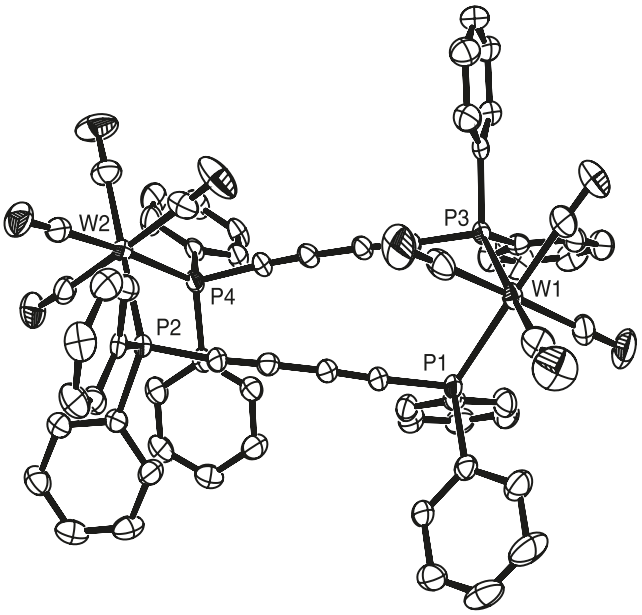
Fig. 1. ORTEP diagram showing the molecular structure of Compound **3**. Hydrogen atoms have been omitted for clarity.



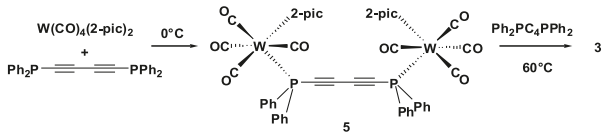
from the decomposition of **2** into other tungsten carbonyl complexes, which do not contain the phosphines ligand.

The kinetics of the 2-picoline–phosphine substitution reactions were studied to allow us to optimize the synthetic reactions. The substitution of the two 2-picoline ligands at each tungsten centre for phosphine ligands occured in two distinct steps with very different rates. Substitution of the first 2-picoline ligand at tungsten occured rapidly at room temperature, with both ends of the ligand coordinating to tungsten to form the intermediate $[W(2\text{-picoline})(CO)_4]_2(\mu\text{-}Ph_2PC_4PPh_2)$ (**5**) (Scheme 3). This reaction was first order in metal complex, consistent with a dissociative substitution mechanism, which is expected for 18-electron W(0) complexes (40). The half-time for the disappearance of **2** at 0°C was 18 minutes, so preparative reactions to form **5** were run for 3 hr (10 half lives).

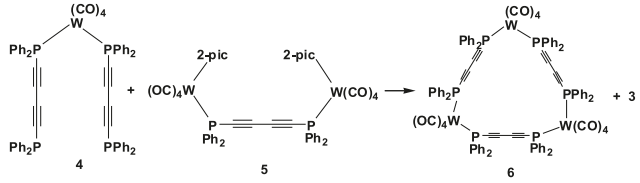
The second substitution step, which leads to **3**, occured much more slowly at room temperature, typically requiring several days to go to completion. At 0°C, the second substitution was suppressed completely. Because of the long reaction times, the kinetics of the second substitution were not studied in detail. The disparate rates between the first and second substitution steps allowed us to isolate compound **5** by reacting the ligand with two equivalent of the tungsten precursor at 0°C. The dimer **3** could also be formed free of compound **4** by stirring the ligand with $[cis\text{-}W(CO)_4(2\text{-picoline})_2]$ (**1**) at 0°C for 3 h to form **5**, and then heating to 60°C for 1.5 h to coordinate the second ligand (Scheme 3). Isolated yield after chromatography and recrystalization was 44%.

Our ability to isolate compounds **4** and **5** allowed us to conceive a convergent route to a larger coordination macrocycle. Reaction of compound **5**, in which one ligand is coordinated to two metal complexes, with compound **4**, in which two equivalents of ligand are coordinated to one metal complex, led to a mixture of the dimer **3** and a new compound,

Scheme 3.



Scheme 4.



which has been identified as the trimeric complex $[\{cis\text{-}W(CO)_4\}_3(\text{-}Ph_2PC_4PPh_2)_3]$ (**6**) (Scheme 4). The three-fold symmetry of **6** means that its spectroscopic parameters are nearly identical to those of **3**, with a ^{31}P chemical shift of δ 3.0, and nearly super-imposable IR spectra. The formation of significant quantities of **3** in the reaction suggests that phosphine–phosphine displacement reactions are competitive with the phosphine–picoline substitution reactions. The reaction was optimized for temperature and solvent, and it was shown that higher temperatures favour the formation of **3**. The optimal reaction conditions were room temperature and THF solvent, which gave a mixture of **3** (dimer) and **6** (trimer) in a 3:5 ratio. Darkly coloured material formed in the reaction suggests that some decomposition is also occuring. Although a lower temperature might increase the proportion of **6**, below room temperature the reaction becomes too slow to be useful. The isolated yield of **6** after chromatography is 12%. The low isolated yield is a result of decomposition during reaction and decomposition on the column.

An ORTEP diagram of the molecular structure of **6** is shown in Fig. 2. The molecule adopts a helical structure, with each diyne unit crossing the plane formed by the three tungsten atoms. A side view of the molecule, emphasizing the helical structure is shown in Fig. 3. The helical nature of the molecule means that it is chiral, and the compound crystallizes the chiral space group $P2_13$, indicating that the two enantiomers crystallize independently. However, the two types of crystals could not be visually distinguished. The conformation of **6** brings the alkyne moieties of adjacent phosphines much closer together than those in the dimer **3**, with an alkyne centre-to-centre distance of 3.335 Å, compared with 3.499 Å in the dimer. The shorter alkyne-alkyne distance in the trimer suggests that it may be more reactive towards cycloaddition.

An alternate convergent route to the trimeric complex involves reaction of **4** with two equivalents of $[cis\text{-}W(CO)_4(2\text{-picoline})_2]$ (**1**) to form **7** (Scheme 5). Although the first step of this route was successful, reaction of **7** with an additional equivalent of the ligand **1** did not close the ring, but instead led primarily to the dimer **3**.

Heating the dimeric compound **3** to temperatures up to 140°C did not result in any cycloaddition reaction. In fact, compound **3** is thermally very robust and shows no significant decomposition at this temperature. Similarly, photolysis

© 2008 NRC Canada

Fig. 2. ORTEP diagram showing the molecular structure of Compound **6**. Hydrogen atoms and co-crystalized solvent have been omitted for clarity. The molecule lies on a crystallographic three-fold axis meaning that the three tungsten centres are crystallographically equivalent.

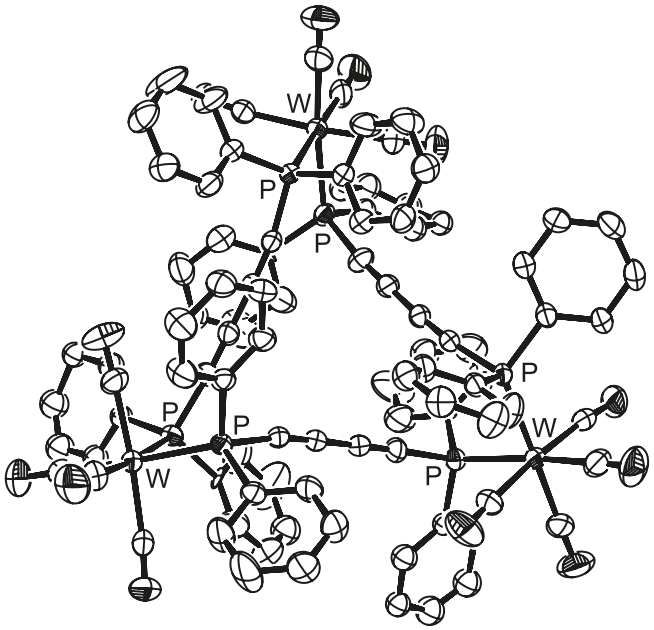


Fig. 3. Side view of the molecular structure of Compound **6** emphasizing its helical structure. Phenyl groups have been omitted for clarity.

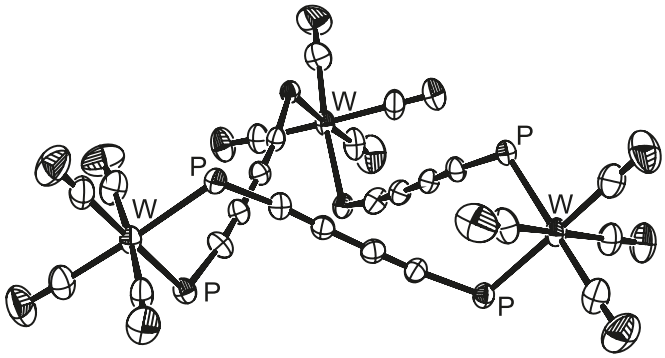
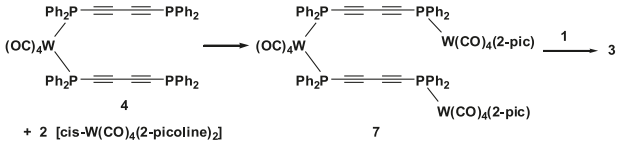


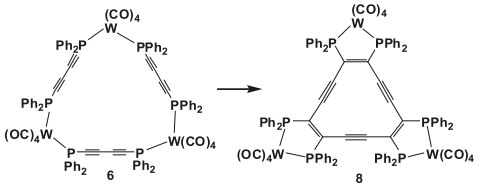
Scheme 5.



resulted in no reaction. The stability of **3** toward cycloaddition is not surprising given the large separation between the alkynes on adjacent phosphines.

In contrast, compound **6** underwent slow reaction over several weeks at room temperature if exposed to light. More rapid reaction could also be thermally induced by heating to 60°C. Compound **8**, the product of the reaction, has been assigned as the tungsten complex of the phosphine substituted cyclododecatrienetriyne ring, which results from the 4+4+4

Scheme 6.



cycloaddition of the three diynes (Scheme 6). It is analogous to the product observed in the Pt system. Although crystals were grown, twinning problems could not be resolved, so **8** has been characterized spectroscopically and by analogy to the Pt complexes. Upon cycloadditon, the ^{31}P chemical shift changed from δ 3.0 to δ 60.1. This large chemical shift change is a result of the conversion of the alkynyl substituent on the phosphine to an alkenyl substituent. The alkynyl substituent is strongly deshielding, while the alkenyl substituent is shielding, resulting in the large downfield shift (41). A nearly identical downfield shift was observed in the cycloaddition reactions of the analogous platinum complexes (38).

The IR spectrum of **8** shows the characteristic pattern for the *cis*-$W(CO)_4$ moiety, indicating that the metal geometry is unchanged. However, the C≡C stretch observed in **6** has disappeared as a result of the transformation of the unsymmetrical IR-active alkynes in **6**, into symmetrical, IR inactive alkyne in **8**. The carbonyl region of the ^{13}C NMR spectrum of **8** shows two carbonyl peaks as expected for this metal geometry (*cis* and *trans* with respect to the phosphines). The spectrum also shows a single alkene carbon resonance at δ 155.7 and a single alkyne carbon resonance at δ 106.2, rather than the two chemically non-equivalent alkyne carbons expected in the diyne structure, supporting the formation of the cyclododecatrienetriyne ring. The alkene carbons show one-bond and two-bond couplings to phosphorus of 46 and 31 Hz. For comparison, the alkene carbons of diphenylvinyl phosphine show coupling constants of 24 and 14 Hz (42). The alkyne carbon is also coupled to phosphorus with a two-bond coupling constant of 23 Hz.

The UV–vis spectrum of **8** is very broad and generally uninformative; however, a comparison with the spectrum of the precursor, complex **6**, reveals changes that result from the formation of the 12-membered ring. Compound **6** shows a single broad peak centred at 350 nm (ε 4000 $(mol/L)^{-1}cm^{-1}$). Compound **8** shows peaks at 280 nm (ε 17000 $(mol/L)^{-1}cm^{-1}$), 350 nm (ε 3000 $(mol/L)^{-1}cm^{-1}$), and 500 nm (ε 400 $(mol/L)^{-1}cm^{-1}$). The peaks at 280 and 500 nm can clearly be attributed to the ring since the remaining chromophores are the same in both compounds. For comparison, the spectrum of the parent cyclododecatrienetriyne ring shows peaks at 239 nm (ε = 38700), 247.5 nm (ε 57200), and 457 nm (ε 177) (43, 44).

Discussion

Table 1 summarizes key structural parameters in template complexes of $Ph_2PC_4PPh_2$ (**2**). It is apparent from the data that the primary structural parameter that determines the reactivity of templated alkynes is the α-carbon–α-carbon separation, rather than M–P bond lengths or alkyne centre-to-centre distances or angles. The cycloaddition reaction is ob-

$PtCl_2$ dimer[b]	—	—	—	—	Yes	< 0 °C	38

[a]Lowest temperature at which cycloaddition is observed. Temperatures for preparative reactions are higher.
[b]The $PtCl_2$ dimer was not structurally characterized because its cycloaddition reaction occurs too quickly.

served in all template complexes where this distance is approximately 3.2 Å or lower. This distance also appears to correlate well with the temperature required to induce cycloaddition. Template complexes with shorter α-carbon–α-carbon separation undergo cycloaddition at lower temperatures. The separation between the α carbons on adjacent alkynyl phosphine ligands is controlled by the metal–phosphorus distance and by the relative rotations of the two phosphine ligands (rotation about the M–P bond). The first parameter is readily controlled by the choice of metal. However, the second parameter depends on the overall conformation of the template complex, and is thus harder to predict and control. The trimeric complexes have a stronger tendency to adopt a conformation that brings the α carbons closer together. We are currently using the dimeric tungsten complex **3** to test if the conformation can be affected by substitution of carbonyls for larger ligands, or by oxidative addition to form 7-coordinate tungsten.

Compound **4**, which has two dangling bis-phosphine ligands, also provides us with an opportunity to form heterobimetallic complexes by reaction with another metal precursor. By combining large radius tungsten with a smaller radius metal such as platinum, we may be able to induce unique cycloaddition reactions. This work is underway and will be published in a subsequent paper. Compound **5**, in which one diyne substrate is coordinated to two metal complexes, will allow us to mix the diyne ligand with other phosphine-substituted substrates to template other reactions, including alkene–alkyne cycloadditions, and additions across the triple bonds.

In summary, we have synthesised bimetallic and trimetallic tungsten coordination macrocycles of bis(diphenylphosphino)butadiyne. We have used the structural parameters and reactivity of these complexes, along with those of the related platinum macrocycles, to elucidate the structural relationships that support diyne cycloaddition reactions.

Experimental section

All procedures were carried out under nitrogen using standard Schenk techniques. Dichloromethane and hexane were purified using solvent purification columns containing alumina (dichloromethane) or alumina and copper catalyst (hexane and toluene). THF was distilled from sodium–benzophenone under a dinitrogen atmosphere. Deuterated chloroform was vacuum distilled from P_2O_5. The NMR spectra were recorded in $CDCl_3$ at 300.1 MHz (^1H), 121.5 MHz ($^{31}P\{^1H\}$), or 75.5 ($^{13}C\{^1H\}$). The compounds $W(CO)_6$, Ph_2PCl, hexachlorobutadiene, 2-picoline, and *n*-BuLi (2.5 M in hexane) were purchased from Sigma-Aldrich and used as received.

Synthesis of [*cis*-$W(CO)_4$(2-picoline)$_2$] (1)

This compound was prepared according to the method developed by Tosh and Mihichuk (39). The compound $[W(CO)_6]$ (2.00 g, 5.68 mmol) was dissolved in 2-picoline (10 mL) in a flask equipped with a reflux condenser. The resulting solution was degassed by purging with N_2 for 10 min. The solution was heated at 130°C and the reaction progress was monitored by FTIR until product formation was complete (5–6 hr, ν(CO): 2006, 1875, 1870sh, 1825 cm^{-1}). The solution was cooled to rt and the product was precipitated as a bright yellow microcrystalline solid by rapid addition of hexane (40 mL). Yield: 2.007 g, 4.163 mmol, 73%.

Synthesis of $Ph_2PC_4PPh_2$ (2)

This compound was prepared according to a procedure developed by Martin-Redondo et al. (38). A solution of *n*-BuLi (51 mL of 2.5 M in hexane, 128 mmol) in THF (80 mL) was cooled to –78°C and protected from light. A solution of hexachlorobutadiene (5.0 mL, 32 mmol) in THF (20 mL) was added dropwise over a period of 30 min. Once addition was complete, the solution was stirred for an additional 15 min at –78°C, warmed to rt over 15 min, then stirred for 2 h at rt. The reaction mixture was again cooled to –78°C and PPh_2Cl (11.5 mL, 64 mmol) was added dropwise via syringe over a period of 30 min. Once addition was complete, the solution was stirred for 15 min at –78°C, warmed to rt over 15 min, and then stirred for 15 min at rt. The solution was hydrolyzed with water (40 mL). The organic phase was separated, dried over $MgSO_4$ and charcoal, and filtered. The solvent was removed in vacuo to leave behind a black, viscous residue. The residue was extracted into dichloromethane (50 mL) and passed through a florisil column (1.5 cm × 15 cm) to remove viscous black material. The column was washed three times using dichloromethane (25 mL). The extracts were combined, the solvent was removed in vacuo, and the residue was recrystallized from CH_2Cl_2–hexane at –25°C. Yield: 6.294 g, 15.04 mmol, 47%.

Synthesis of {[$W(CO)_4$]$_2$(μ-$Ph_2PC_4PPh_2$)$_2$} (3)

A Schlenk tube was charged with $Ph_2PC_4PPh_2$ (**2**, 100 mg, 0.239 mmol) and [*cis*-$W(CO)_4$(2-picoline)$_2$] (**1**) (115 mg, 0.239 mmol), cooled to 0°C, and protected from light. THF

© 2008 NRC Canada

(10 mL) was added and the resulting solution was stirred at 0°C for 2.5 h, and then heated under reflux for 1.5 h. The solution was cooled to rt and solvent was removed in vacuo. The residue was extracted into CH_2Cl_2 (10 mL) and passed through a short florisil column. The solvent was removed and the residue was extracted into a minimal quantity of CH_2Cl_2. Addition of hexane (20 mL) resulted in the precipitation of **3** as a pale yellow microcrystalline solid, which was washed twice with hexane (5 mL) and dried under vacuum. Yield: 75 mg, 0.052 mmol, 44%. X-ray quality crystals of **3** were grown by slow diffusion of hexane into a CH_2Cl_2 solution. IR (CH_2Cl_2, cm^{-1}) ν: 2089s (C≡C), 2026s (CO), 1930sh (CO), 1909s (CO). ^1H NMR δ: 7.26–7.4 (m, C_6H_5), 7.5–7.7 (m, C_6H_5). $^{13}C\{^1H\}$ NMR δ: 203.9 (2nd order mult., ^1J(WC) = 148 Hz, *trans*-W(CO)), 201.4 (t, ^2J(PC) = 7 Hz, ^1J(WC) = 126 Hz, *cis*-W(CO)), 134.4 (2nd order mult., Ph), 131.6 (2nd order mult., Ph), 130.46 (s, Ph), 128.8 (2nd order mult., Ph), 92.1 (2nd order mult., PC≡C), 80.5 (2nd order mult., PC≡C). $^{31}P\{^1H\}$ NMR δ: 2.8 (s, ^1J(WP) = 241 Hz). Anal. calcd. for $C_{64}H_{40}O_8P_4W_2$: C 53.81, H 2.82; found: C 53.93, H 2.80.

Synthesis of {[W(CO)$_4$](Ph$_2$PC$_4$PPh$_2$-*K^1*-*P*)$_2$} (4)

A Schlenk tube was charged with $Ph_2PC_4PPh_2$ (**2**, 260 mg, 0.622 mmol) and [*cis*-W(CO)$_4$(2-picoline)$_2$] (**1**) (**1**, 100 mg, 0.207 mmol), cooled to 0°C and protected from light. THF (40 mL) was added via syringe and the mixture was stirred for 2.5 h at 0 °C, and then heated to 60 °C for 1.5 h. The solution was cooled to rt and the solvent was removed in vacuo. The residue was shown to be a mixture of {[W(CO)$_4$](Ph$_2$PC$_4$PPh$_2$)$_2$} **4** and {[W(CO)$_4$]$_2$(μ-Ph$_2$PC$_4$PPh$_2$)$_2$} **3** in approximately 2:1 ratio. Column chromatography was used to isolate **4** (silica gel, ethyl acetate – hexane 10:90 gradient to 20:80). Fractions containing **4** were collected and solvent was removed, resulting in a microcrystalline solid, which was used without further purification. Yield: 97 mg, 0.086 mmol, 41%. IR (CH_2Cl_2, cm^{-1}) ν: 2079w (CC), 2027s (CO), 1939sh (CO), 1913s (CO). ^1H NMR δ: 7.24–7.4 (m, C_6H_5), 7.5–7.66 (m, C_6H_5). $^{13}C\{^1H\}$ NMR δ: 204.0 (2nd order mult., ^1J(WC) = 53 Hz, *trans*-W(CO)), 201.3 (t, ^2J(PC) = 14 Hz, ^1J(WC) = 127 Hz, *cis*-W(CO)), 134.6 (2nd order mult., Ph), 133.1 (s, Ph), 132.8 (s, Ph), 131.7 (2nd order mult., Ph), 130.1 (s, Ph), 129.6 (s, Ph), 128.9 (2nd order mult., Ph), 128.6 (2nd order mult., Ph), 92.0 (2nd order mult., WPC≡C), 90.4 (2nd order mult. C≡CP), 84.511 (s, C≡CP), 84.276 (s, WPC≡C). $^{31}P\{^1H\}$ NMR δ: 1.3 (s, ^1J(WP) = 242 Hz), –29.2 (s). Anal. calcd. for $C_{60}H_{40}O_4P_4W$: C 63.62, H 3.56; found: C 63.36, H 3.58.

Synthesis of {[W(CO)$_4$(CH$_3$C$_5$H$_4$N)]$_2$(μ-Ph$_2$PC$_4$PPh$_2$)} (5)

A Schlenk tube was charged with $Ph_2PC_4PPh_2$ (100 mg, 0.239 mmol) and [*cis*-W(CO)$_4$(2-picoline)$_2$] (**1**) (230 mg, 0.479 mmol), cooled to 0°C and protected from light. Dichloromethane (15 mL) was added via syringe and the resulting solution was stirred for 3 h at 0 °C. The solvent was removed in vacuo and the residue was extracted into a minimum quantity of CH_2Cl_2. Rapid addition of hexane (20 ml) resulted in the precipitation of an oily yellow powder, which was washed twice with hexane and dried under vacuum. Yield: 239 mg, 0.200 mmol, 83.5%. IR (CH_2Cl_2, cm^{-1}) νCO: 2015s, 1900sh, 1886s, 1856s. ^1H NMR δ: 8.78 (d, ^2J(HH) = 5.6 Hz, $CH_3C_5H_4N$), 7.5–7.7 (m, Ph, $CH_3C_5H_4N$), 7.25–7.4 (m, Ph), 7.07 (d, ^2J(HH) = 7.9 Hz, $CH_3C_5H_4N$), 6.67 (m, $CH_3C_5H_4N$), 2.64 (s, $CH_3C_5H_4N$). ^{13}C NMR δ: 208.8 (d, ^2J(PC) = 3 Hz, *cis*-W(CO)), 208.1 (d, ^2J(PC) = 35 Hz, *trans*-W(CO)), 204.2 (d, ^2J(PC) = 8 Hz, axial W(CO)), 162.2 (2-picoline), 157.6 (2-picoline), 137.8 (2-picoline), 133.7 (Ph), 133.0 (Ph), 132.3 (Ph) 132.1(Ph), 130.74 (Ph), 130.71(Ph), 129.1(Ph), 129.0 (Ph), 126.3(2-picoline). 121.9(2-picoline), 91.3 (dd, ^2J(PC) = 11 Hz, ^3J(PC) = 4 Hz, PC≡C), 79.6 (d, ^1J(PC) = 55 Hz, PC≡C), 30.7 (s, CH_3). ^{31}P NMR δ: 12.28 (s, ^1J(WP) = 244.4 Hz).

Synthesis of {[W(CO)$_4$]$_3$(μ-Ph$_2$PC$_4$PPh$_2$)$_3$} (6)

A Schlenk tube was charged with {[W(CO)$_4$](Ph$_2$PC$_4$-PPh$_2$-*K^1*-*P*)$_2$} (**4**, 100 mg, 0.088 mmol) and {[W(CO)$_4$(CH$_3$C$_5$H$_4$N)]$_2$(μ-Ph$_2$PC$_4$PPh$_2$)} (**5**, 106 mg, 0.088 mmol) and protected from light. THF (7 mL) was added and the resulting solution was stirred for 5 days. The solvent was removed in vacuo. The ^{31}P NMR spectrum showed the residue to be a mixture of **3** and **6** (3:5). The residue was separated by column chromatography (silica gel, THF–hexane 40:60). Three bands were isolated and identified as **3**, **6**, and **8**. Fractions containing **6** were collected and the solution was concentrated under reduced pressure until yellow precipitate formed. The supernatant was decanted and the product was dried under vacuum. Yield: 23 mg, 0.011 mmol, 12%. The low yield of **6** is attributed to decomposition during the reaction, and decomposition on the column primarily via conversion to **8**. X-ray quality crystals were grown by slow diffusion of hexane into a CH_2Cl_2 solution of **6**. UV–vis (ε 4000 $M^{-1}cm^{-1}$): 350 nm. IR (CH_2Cl_2 solution, cm^{-1}) ν: 2088w (CC), 2023s (CO), 1930sh (CO), 1908s (CO). ^1H δ: 7.5–7.7 (m, C_6H_5), 7.26–7.4 (m, C_6H_5). ^{31}P NMR δ: 3.0 (s, ^1J(WP) = 243 Hz).

Synthesis of {[W(CO)$_4$]$_3$[μ$_3$-C$_{12}$(Ph$_2$P)$_6$]} (8)

Pure samples of **6** were converted to **8** by heating CH_2Cl_2 solutions at 60°C for 2.5 h in a closed tube. The ^{31}P NMR spectrum showed quantitative conversion of **6** to **8**. Because the isolated yield of **6** was so low, however, the most efficient preparative synthesis of **8** was to repeat the procedure given above for the preparation of **6**, but to collect and isolate fractions containing **8**. X-ray quality crystals of **8** were grown by slow diffusion of hexane into CH_2Cl_2 solutions of **8**; however twinning problems could not be resolved, so a successful structure of **8** could not be obtained. UV–vis $\lambda_{max}(\varepsilon)$: 280 (17000), 350 (3000), 500 (400). IR (CH_2Cl_2, cm^{-1}) ν_{CO}: 2021s, 1925sh, 1905s. ^1H NMR δ: 7.18–7.25 (m, C_6H_5), 7.02–7.14 (m, C_6H_5). $^{13}C\{^1H\}$ NMR δ: 207.2 (dd, ^2J(CP) = 25 Hz, ^2J(CP) = 6 Hz, *trans*-W(CO)), 200.7 (t, ^2J(PC) = 6 Hz, *cis*-W(CO)), 153.3 (dd, ^1J(PC) = 46 Hz, ^2J(PC) = 31 Hz, PC=CP), 133.2 (dd, ^1J(PC) = 42 Hz, ^4J(PC) = 3, *ipso* Ph), 131.5 (s, Ph), 131.3 (s, Ph), 130.4 (s, Ph), 128.9 (s, Ph), 128.7 (s, Ph), 106.1 (d, $^2J_{PC}$ = 23 Hz, C≡C). ^{31}P NMR δ: 60.1 (s, ^1J(WP) = 237 Hz). Anal. calcd. for $C_{96}H_{60}O_{12}P_6W_3$: C 53.81, H 2.82; found: C 53.81, H 2.71.

Kinetics measurements

The kinetics of the reaction of [W(CO)$_4$(2-picoline)$_2$] (**1**) with $Ph_2PC{\equiv}C\text{-}C{\equiv}CPPh_2$ (**2**) were monitored via in-situ ATR IR spectroscopy (ReactIR™, SiComp probe, Mettler

Toledo AutoChem, 2002). In a typical experiment, $[W(CO)_4(2\text{-picoline})_2]$ (**1**) (100 mg, 0.207 mmol) was dissolved in 5 ml of CH_2Cl_2. The solution was cooled to 0°C and IR spectra were recorded at 3 min intervals. Solid $Ph_2PC{\equiv}C\text{-}C{\equiv}CPPh_2$ (**2**) (43 mg, 0.207, 0.10 mmol) was added to the solution. The reaction was monitored for 270 min. The resulting spectral data was deconvoluted using ConcIRT™ (Mettler-Toledo Autochem, 2002), which identified two major components, $[W(CO)_4(2\text{-picoline})_2]$ (**1**) and $\{[W(CO)_4(CH_3C_5H_4N)]_2(\mu\text{-}Ph_2PC_4PPh_2)\}$ (**5**). The disappearance of **1** was fitted to first order kinetics by plotting the ln of the relative concentration of **1** vs. t. The reaction rate was independent of the concentration of $Ph_2PC{\equiv}C\text{-}C{\equiv}CPPh_2$ (**2**). Full details of the kinetic studies are given in the Supplementary Data.[3]

X-ray crystallography

Suitable crystals of compounds **3** and **6** were mounted on glass fibres. Programs for diffractometer operation, data collection, cell indexing, data reduction and absorption correction were those supplied by Bruker AXS Inc., Madison, WI. Diffraction measurements were made on a PLATFORM diffractometer/SMART 1000 CCD using graphite-monochromated Mo-Kα radiation at –80°C. The unit cell was determined from randomly selected reflections obtained using the SMART CCD automatic search, centre, index, and least-squares routines. Integration was carried out using the program SAINT and an absorption correction was performed using SADABS. The crystal used for data collection on Compound **3** was found to display non-merohedral twinning. Both components of the twin were indexed with the program CELL_NOW. The second twin component can be related to the first component by 180º rotation about the [1 –1 0] axis in both real and reciprocal space. Integrated intensities for the reflections from the two components were written into a SHELXL-93 HKLF 5 reflection file with the data integration program SAINT (version 7.06A), using all reflection data (exactly overlapped, partially overlapped, and non-overlapped). The data were corrected for absorption through use of a multi-scan model, as implemented in the program TWINABS. Crystal data and collection parameters are listed in Table 2. Structure solution was carried out using the SHELX97 (45) suite of programs and the WinGX graphical interface (46). Initial solutions were obtained by direct methods and refined by successive least-squares cycles. The structure of **6** contained two disordered phenyl groups which were modeled using two different phenyl group rotations and restrained to regular hexagons. One pair of disordered phenyl rings was modeled with isotropic thermal parameters, while the other could be successfully refined anisotropically. The structure also contained highly disordered solvent molecules lying on symmetry special positions, which were mod-

Formation of a [2]rotaxane and [2]catenane based on $PdBr_2L_2$ as a template[1]

Barry A. Blight, James A. Wisner, and Michael C. Jennings

Abstract: Previous studies have determined that neutral palladium(II) dibromide complexes template the formation of [2]pseudorotaxanes, albeit with weaker affinities than the analogous palladium(II) dichloride species. Here, the self-assembly of both [2]rotaxane (**2**) and [2]catenane (**5**) were attempted using a $PdBr_2L_2$ centre as the template, resulting in the desired interlocked structures. The structures were confirmed by NMR spectroscopy, CSI-MS, and single crystal X-ray diffraction analyses. [2]Rotaxane **2** was isolated in 53% and [2]catenane **5** in 41% yields. The lower yields observed in comparison to the chloride analogues can be attributed to the reduced template effect of the palladium(II) dibromide subunits, caused by both the poor steric fit of the bromides in the isophthalamide cleft and bromide's reduced capacity as a hydrogen bond acceptor.

Key words: rotaxane, catenane, hydrogen bonding, interlocked, supramolecular chemistry.

Résumé : Des études antérieures ont permis de déterminer que les complexes de dibromure de palladium(II) neutre peuvent être utilisés comme gabarit pour la formation de [2]pseudorotoxanes, même si leur affinité est plus faible que celle des espèces analogues à base de dichlorure de palladium(II). Dans ce travail, on a tenté de réaliser l'autoassemblage du [2]rotoxane (**2**) et du [2]caténane (**5**) en utilisant un gabarit à base de $PdBr_2I_2$ et on a obtenu les structures comportant les interrelations désirées. Les structures ont été confirmées par spectroscopie RMN, par spectrométrie de masse avec ionisation par nébulisation à froid (SM-INF) et par des analyse de diffraction des rayons X par un cristal unique. On a isolé le [2]rotoxane (**2**) avec un rendement de 53% et le [2]caténane (**5**) avec un rendement de 41%. Ces rendements plus faibles que ceux obtenus avec les analogues chlorés peuvent être attribués à l'effet de gabarit réduit des unités de dibromure de palladium(II) qui est provoqué par le mauvais ajustement stérique des bromures dans les espaces disponibles de l'isophtalamide ainsi que par la capacité réduite du bromure comme accepteur d'une liaison hydrogène.

Mots-clés : rotaxane, caténane, liaison hydrogène, interrelié, chimie supramoléculaire.

[Traduit par la Rédaction]

Introduction

The study of interlocked molecules (e.g., rotaxanes and catenanes) (1), conceptual precursors to molecular machines (2), has largely been possible because of the potentially high yields of products that self-assemble by applying modern template-based synthetic methods (1, 2). In this context, the use of transition metals in these assemblies generally falls into one of two categories. The metal may be used as a reversible connection point in the backbone of one or more of the components (3). Alternatively, the metal can participate in the template process to organize accompanying ligands in a desired spatial arrangement (4). The simultaneous use of the metal in both roles is rare but offers a possible route to further simplify syntheses of these interlocked products (5).

We have previously reported a study (6) that examined the complexation of *trans*-bis-pyridine palladium(II) dihalide axles by the well-known isophthalamide-based macrocycle **1** (7). Their combination resulted in [2]pseudorotaxane formation, employing second-sphere coordination of the halide ligands (hydrogen-bond acceptors) by the isophthalamide clefts (hydrogen-bond donors) of **1** as the template. It was concluded that the size of the $PdCl_2$ subunit of a *trans*-$PdCl_2Py_2$ axle was a complimentary fit to the size of the hydrogen-bond donating macrocyclic cavity (K_a = 5000 $(mol/L)^{-1}$ in $CDCl_3$ at 298 K). Nitrogen-based ligand exchange allowed us to then apply this template strategy in the facile self-assembly of palladium(II) dichloride templated [2]rotaxane (8) and [2]catenane superstructures (9).

Anion recognition studies by Crabtree and co-workers (10), Smith and co-workers (11), Beer and co-workers (12), and Gale and co-workers (13) have demonstrated that neutral isophthalamide-based acyclic receptors associate with a variety of anions through hydrogen bonding in solution. Studies specifically examining isophthalamide–halide complexation in solution revealed an inferior affinity for bromide compared with chloride, which can be rationalized by a reduced hydrogen-bond acceptor ability and a poorer steric fit of bromide anions for such receptors. [2]Pseudorotaxanes formed between **1** and a *trans*-$PdBr_2Py_2$ axle exhibit a similarly reduced affinity (K_a = 750 $(mol/L)^{-1}$ in $CDCl_3$ at 298 K) in

comparison with the chloride analogue, which can be explained using similar arguments (6). To date, however, there are no literature examples of bromide anions or ligands acting as, or in, the organizational template to form a finite interlocked structure. We sought to examine this potential phenomenon by observing whether bromide can indeed be used to template interlocked products, and, if so, how they compare structurally to other bromide-bound isophthalamide-based receptors. Herein, we describe the syntheses and characterization of a [2]rotaxane (**2**) and [2]catenane (**5**) templated by second-sphere coordination of palladium(II) dibromide complexes via hydrogen bonding (Scheme 1) and rendered interlocked through first-sphere ligation.

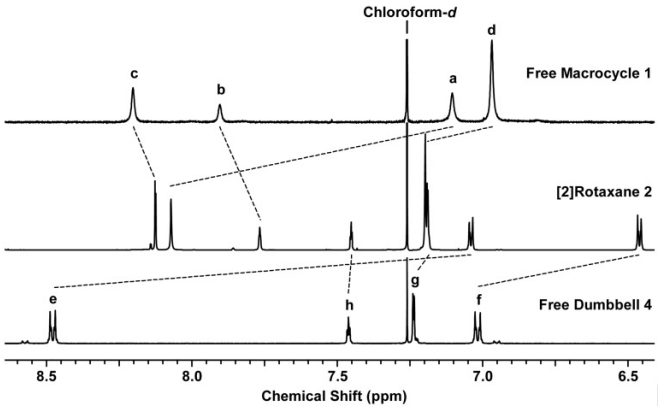
Results and discussion

[2]Rotaxane (2)

Ligand substitution of benzonitrile from *trans*-bis-benzonitrile palladium(II) dibromide (14) by sterically demanding pyridine co-ligands (4-(3,5-di-tert-butylbenzyl)-oxypyridine) **3** (8) in the presence of **1** (2 equiv.) results in the synthesis of interlocked **2** in modest yields (Scheme 1). Its preparation proceeds via dissolution of the above three components in chloroform and allowing them to stir for 4 h at room temperature. After selective crystallization of macrocycle **1** and precipitation of the remaining liquor's contents into hexanes, flash column chromatography was required to separate the product from the reaction mixture, affording [2]rotaxane **2** in 53% yield.

Comparison of the ^1H NMR spectra of the free components macrocycle **1** and dumbbell **4** with the pale yellow powder isolated from chromatography supported the expected interlocked geometry in solution (Fig. 1). Hydrogen-bonding interactions with the bromide ligands result in the deshielding of the macrocyclic amide protons (H_a $\Delta\delta = 0.94$ ppm). As a consequence of the interpenetrated nature of the structure, both pyridyl-protons (H_e $\Delta\delta = -1.44$ ppm, H_f $\Delta\delta = -0.55$ ppm) are shifted upfield from the frequency of their free components due to C-H$\cdots\pi$ interactions with the diphenylcyclohexyl sidewalls of the macrocycle, which also results in deshielding of the diphenylcyclohexyl arene protons (H_d $\Delta\delta = 0.23$ ppm). Cold spray ionization mass spectrometry (CSI-MS) confirmed the presence of the solvated

Illustrated are the observed perturbations in chemical shift between free and interlocked components (dashed lines). COSY, and ROESY NMR experiments were performed to determine individual ^1H NMR spectroscopic assignments.



superstructure with ions of $[M - Br]^+$ at 1797.9 amu and $[M - 2Br]^{2+}$ at 858.5.3 amu, signals that do not appear in solutions of **1** and (or) **4** subjected to the same conditions.

Determination of the solid-state structure by single crystal X-ray diffraction analysis confirmed the solution evidence for the interlocked geometry (Fig. 2). Colorless plate-like single crystals were grown by slow diffusion of diisopropylether into a concentrated chloroform solution of **2**. The anticipated interlocked architecture crystallized in space group *P*(-1) and contained structural similarities to isophthalamide–bromide complexes in the existing literature (10–13). In these cases, hydrogen-bond contacts are slightly longer (3.42 to 3.63 Å) than the sums of the Van der Waals radii (3.40 Å), with the exception of one isophthalamide–bromide conjugate reported by Smith and co-workers (3.28 and 3.39 Å) and are in agreement with those measured in **2**. The larger size of bromide anions (or ligands) also causes each amide nitrogen from these examples, including **2**, to deviate from coplanarity from the central isophthalamide ring in the direction of bromide (by >20°) resembling a perching-type geometry. This also results in a 2.11 Å dis-

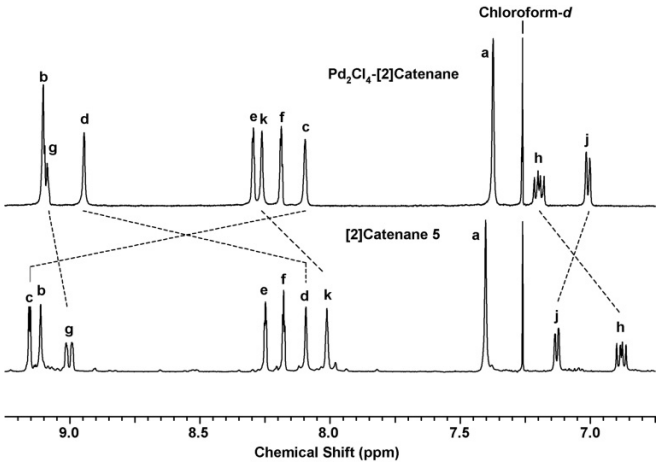
placement of the palladium centre from the least-squares plane of the macrocyclic ring (plane defined by the four carbonyl carbons), caused by the poor steric fit of the bromide ligands in the isophthalamide clefts of **1**. The dissymmetric geometry of **2**, in the solid state, prompted us to investigate its potential shuttling activity in solution (15). However, low temperature ^{1}H NMR showed no sign of exchange broadening down to –50 °C (248 K). Contact distances and angles of interest include: N(25)···Br(1) = 3.46 Å (N-H···Br = 156°), N(40)···Br(1) = 3.45 Å (N-H···Br = 153°), N(63)···Br(2) = 3.57 Å (N-H···Br = 164°), N(78)···Br(2) = 3.67 Å (N-H···Br = 150°).

[2]Catenane (5)

[2]Catenane **5** is designed to employ a *trans*-bidentate ligand **6** (9) that incorporates the structural components of both macrocycle **1** and the required pyridine co-ligands (Scheme 1). A chloroform–acetonitrile solution of **6** and *trans*-bis-benzonitrile palladium(II) dibromide (14) were refluxed for 18 h. The reaction mixture was concentrated, precipitated into hexanes to remove residual benzonitrile, and the resulting orange solid subjected to column chromatography to afford [2]catenane **5** (a yellow powder) in 41% yield.

^{1}H NMR spectral comparison of the reaction product to the previously synthesized Pd_2Cl_4-based [2]catenane (9) confirmed in solution that the desired interlocked geometry was likely obtained using palladium(II) dibromide to template [2]catenane formation (Fig. 3). Similar chemical shifts of protons H_a, H_b, H_e, H_f, H_g, H_h, H_j, and H_k between **5** and its Pd_2Cl_4-counterpart lead us to this conclusion. In this case, however, H_h is more shielded ($\Delta\delta$ = –0.32 ppm) and H_j is less shielded ($\Delta\delta$ = 0.13 ppm) than observed in the Pd_2Cl_4-based [2]catenane, which may be attributed to stronger and (or) more frequent C-H···π interactions of H_h (resulting in weaker interactions with H_j) with the diphenylcyclohexyl cavity of the opposing macrocycle. Unexpectedly, amide proton H_d is extremely shielded ($\Delta\delta$ = –0.87 ppm) and H_c deshielded ($\Delta\delta$ = 1.07 ppm) in comparison with the Pd_2Cl_4-[2]catenane, and although examination of the ^{1}H NMR evi-

Fig. 3. The aromatic region of the ^{1}H NMR spectra (600 MHz, 298 K) of Pd_2Cl_4-[2]catenane (top), and [2]catenane **5** (bottom). Individual proton assignments are compared between the two superstructures (dashed lines). NOESY, and ROESY NMR experiments were performed to determine individual ^{1}H NMR assignments.



dence could not explain these two proton assignments, a reasonable explanation presented itself upon receipt of the solid-state structure. CSI-MS also confirmed the presence of [2]catenane **5** in solution with ions of $[M + H]^+$ at 2300.8 amu and $[M + 2H]^{2+}$ at 1150.3 amu. Compound **5** was then dissolved in 1 mol/L of DMSO-d_6 and monitored by ^{1}H NMR spectroscopy in an attempt to disassemble it into its degenerate macrocyclic components. Unfortunately, the system completely degrades under these conditions, giving rise to a mixture of unidentifiable polymeric materials.

Orange platelike single crystals were grown from a concentrated chloroform solution of **5** by slow diffusion of diisopropyl ether crystallizing in space group *P*2(1)/*c* and subjected to single crystal X-ray diffraction analysis. Structural elucidation of **5** established the desired interlocked geometry in the solid state (Fig. 4), which unexpectedly contained two exotopically arranged amide functionalities (with respect to the NH groups) in the structure of *macrocycle B* (all eight amide NHs of the Pd_2Cl_4-[2]catenane are endotopic). We posit that competition for hydrogen-bond acceptors ($PdBr_2$ subunits and the carbonyl-oxygen atoms in the backbone of each macrocyclic component) by the hydrogen-bond donating clefts results in an overall geometry containing a blend of structural elements from Crabtree's isophthalamide–bromide complex (10) and the amide-based [2]catenanes of Hunter (16), Vögtle and co-workers (17), and Leigh and co-workers (18) in the solid state.

The isophthalamide subunit of *macrocycle A* participates in the mutual recognition of Br(2B) (N(17A)···Br(2B) = 3.37 Å (N-H-Br = 165°), N(32A)···Br(2B) = 3.36 Å (N-H-Br = 166°)), resembling those of the isophthalamide–bromide conjugates previously discussed (10–13), as well as **2**. The second isophthalamide subunit of *macrocycle A* bifurcates O(69B) of *macrocycle B* with its NH groups (N(55A)···O(69B) = 3.75 Å (N-H-O = 158°), N(70A)···O(69B) = 2.95 Å (N-H-O = 171°), while the exotopically arranged NHs of *macrocycle B* are independently engaged in hydrogen bonding with adjacent *macrocycle A* units through the crystal lattice (N(32B)···O(57A) =

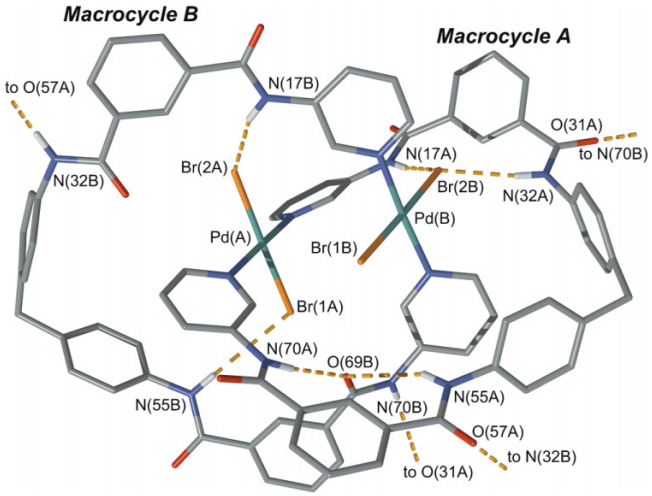
Fig. 4. Stick representation of [2]catenane **5** in the solid state. All C-H hydrogen atoms, methyl, cyclohexyl, and *t*-butyl groups have been removed for clarity. Hydrogen bonds and weak contacts have been represented by yellow dashed lines. Color code: C gray, H white, N blue, O red, Br orange, Pd teal.



2.91 Å (N-H-O = 158°), N(70B)···O(31A) = 2.98 Å (N-H-O = 141°)) and are both features of the mentioned amide-based [2]catenanes in the solid state. Each isophthalamide subunit of *macrocycle B* is singularly engaged in weak hydrogen-bond contacts with the opposing bromide ligands of *macrocycle A* (N(17B)···Br(2A) = 3.67 Å (N-H-Br = 151°), N(55B)···Br(2A) = 3.99 Å (N-H-Br = 155°). As in **2,** the Br-Pd-Br subunits in **5** are also too large for the macrocyclic cavity, which forces the displacement of each $PdBr_2$ from the centre of its respective host macrocycle (macrocyclic-plane-A···Pd(B) = 1.48 Å, macrocyclic-plane-B···Pd(A) = 2.40 Å). This results in perched geometries of both $PdBr_2$ subunits in the mouths of their respective macrocyclic components, with all amides engaged in bromide–ligand contacts deviating from coplanarity with their respective isophthalamide phenyl ring (>20°) but one. Finally, from the solid-state structure we can postulate that the unusual upfield ^{1}H NMR shift of H_d (N(32A), N(55A), N(32B), N(55B)) is likely due to this hydrogen-bond competition resulting in increased exposure to the bulk solvent, while the downfield shift of H_c (C(21A), C(59A), C(21B), C(59B)) may be the result of positioning in the deshielding cone of a neighboring endotopically arranged carbonyl-oxygen atom.

Conclusion

In summary, palladium(II) dibromide metal centres have been used successfully to self-assemble both a [2]rotaxane and [2]catenane despite the reduced magnitude of the template interactions present in comparison with previously reported palladium(II) dichloride analogues. The reduced ability of the macrocycle to hydrogen bond to the bromide ligands of the metal complex gives rise to distortions of the resulting interlocked molecules from the planned template geometry, yielding recognizable structural elements from other known isophthalamide-containing supramolecules in the solid state. The [2]catenane generated using the PdBr2 template was unstable to attempts to dissociate the two catenated rings, using DMSO as a competitive solvent for both hydrogen bonding and ligand exchange.

Experimental

General

All reactions were performed in dry solvents and under an inert $N_{2(g)}$ atmosphere. All organic reagents, including palladium(II) dibromide, were purchased from Sigma-Aldrich Chemical Company and all were used without further purification. 1D NMR spectral analyses of **4** for characterization purposes were performed on a Varian Mercury 400MHz instrument. 1D NMR and 2D NMR spectral analyses of **2** and **5** or individual assignments were performed on a Varian Inova 600MHz instrument. Cold-spray ionization mass determinations were performed with Micromass LCT instrumentation with carrier gases cooled to 200 K.

X-ray crystallographic analyses

Single crystal X-ray diffraction data, for both **2** and **5** (grown from a concentrated chloroform solution of **2** or **5** by slow vapor diffusion of diisopropyl ether), was obtained from a programmed hemisphere scan routine on a Nonius Kappa-CCD diffractometer. The unit cell parameters were calculated and refined from the full data set. Crystal cell refinement and data reduction were carried out using DENZO (Nonius B.V., 1998). The data were scaled using SCALEPACK (Nonius B.V., 1998). The solution for **2** was solved by Patterson methods, and the solution for **5** by direct methods, followed by difference Fourier syntheses to find the remaining atoms in each subsequent structure. Refinement was with full-matrix least-squares methods using SHELXTL-NT 6.1 (G.M. Sheldrick, Madison, Wisconsin, USA, 2000). The organic material and the metal center(s) were very well resolved in both structures. All of the non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atom positions were calculated geometrically and were included as riding on their respective carbon atoms. A summary of the data collection, solution, and refinement parameters are listed in Table 1.[3]

Procedures

[2]Rotaxane (2)

Macrocycle **1** (50 mg, 0.049 mmol) and *trans*-bis-benzonitrile palladium(II) dibromide (14) (12 mg, 0.025 mmol) were dissolved in chloroform (10 mL) in a 25 mL round-bottomed flask and stirred for 10 min. 4-(3,5-Di-*tert*-

butylbenzyl)-oxypyridine **3** (15 mg, 0.049 mmol) was dissolved in chloroform (2 mL) and added dropwise via pipette. The solution was stirred for 4 h, followed by cooling in the freezer to selectively crystallize unreacted macrocycle. The precipitate was isolated via vacuum filtration, and volume of the filtrate reduced under reduced pressure to approximately 2 mL of solvent. This concentrated solution was then added dropwise to a beaker of hexanes to precipitate the product away from the high-boiling benzonitrile. The precipitate was collected via vacuum filtration. The crude product was then chromatographed (5% EtOAc in DCM, leading band) to afford 24 mg (0.013 mmol, 53% yield) of pure [2]rotaxane **2**. ^{1}H NMR ($CDCl_3$, 600 MHz) δ: 8.13 (d, 4H, 6 Hz), 8.07 (s, 4H), 7.77 (t, 4H, 6 Hz), 7.45, (t, 2H, 5 Hz), 7.20 (s, 8H), 7.19 (d, 4H, 5 Hz), 7.04 (d, 4H, 12 Hz), 6.46 (d, 4H, 12 Hz), 5.07 (s, 4H), 2.48 (bs, 8H), 2.10 (s, 24H), 1.70 (bs, 8H), 1.57 (bs, 4H), 1.37 (s, 18H), 1.30 (s, 36H). ^{13}C NMR ($CDCl_3$, 600 MHz) δ: 166.13, 166.00, 153.49,152.91, 151.91, 135.11, 134.53, 133.11, 131.56, 129.00, 123.38, 123.11, 121.70, 112.20, 71.82, 35.26, 34.90, 34.73, 31.40, 31.36, 31.20, 22.79, 19.30, 19.19. LR CSI-MS (MeOH matrix in $CHCl_3$) $[M - 2Br]^{2+}$ *m*/*z*: 858.5.3, $[M - Br]^+$ *m*/*z*: 1797.9.

Dumbbell (4)

In a 10 mL round-bottomed flask, *trans*-bis-benzonitrile palladium(II) dibromide (14) (40.0 mg, 0.085 mmol) was dissolved in dry acetonitrile (3 mL) and allowed to stir for 5 minutes. 4-(3,5-Di-*tert*-butylbenzyl)-oxypyridine **3** (14) (50.5 mg, 0.17 mmol) was dissolved in dry acetonitrile (1 mL) and added dropwise to the bulk solution. The reaction was stirred for 30 min to allow ample time for precipitation of the desired product. The product was isolated via vacuum filtration (65.1 mg, 0.076mmol, 88% Yield). ^{1}H NMR ($CDCl_3$, 400 MHz) δ: 8.48 (d, 4H, 8 Hz), 7.46 (t, 2H, 4 Hz), 7.24 (d, 4H, 4 Hz), 7.02 (d, 4H, 8 Hz), 5.10 (s, 4H), 1.34 (s, 36H). ^{13}C NMR ($CDCl_3$, 400 MHz) δ: 166.28, 154.90, 151.51, 133.42, 123.09, 122.31, 111.89, 71.69, 34.88, 31.39. LR-ESI MS (MeOH matrix in $CHCl_3$) $[M - Br]^+$ *m*/*z*: 781.2, $[M - 2Br + H]^+$ *m*/*z*: 699.3.

[2]Catenane (5)

Dipyridyl ligand **6** (50 mg, 0.057 mmol) was dissolved in a 3:1 chloroform/acetonitrile solvent mixture (10 ml). A chloroform solution (2 ml) of *trans*-bis-benzonitrile palladium(II) dibromide (14) (27 mg, 0.057 mmol) was added dropwise to the reaction mixture, and the reaction refluxed for 18 h. The crude reaction mixture was filtered through celite to remove any precipitate, and solvent removed under reduced pressure. The resulting solid was dissolved in a minimum amount of dichloromethane and precipitated into hexanes to remove residual benzonitrile. The precipitate was collected via vacuum filtration and the crude product was then chromatographed (5% EtOAc in DCM, leading band) to afford 27 mg (0.012 mmol, 42% yield) of pure [2]catenane **5**. ^{1}H NMR ($CDCl_3$, 600 MHz) δ: 9.16 (d, 4H, 1.8 Hz), 9.12 (s, 4H), 9.01 (d, 4H, 8.4 Hz), 8.26 (dd, 4H, 1.8 and 1.8 Hz), 8.18 (dd, 4H, 1.8 Hz and 1.8 Hz), 8.09 (s, 4H), 8.02 (s, 4H), 7.40 (s, 8H), 7.14 (d, 4H, 5.4 Hz), 6.88 (dd, 4H, 8.4 Hz and 5.4 Hz) 2.61 (bs, 8H), 2.22 (s, 24H), 1.77 (bs 8H), 1.61 (bs,

Dinuclear organoplatinum(II) complexes containing *N*-methylbenzamide[1]

Michael G. Crisp and Louis M. Rendina

Abstract: The preparation and characterization of cationic, dinuclear complexes of the type *trans*-[$Pt(PPh_3)_2$(σ-C_6H_4NHMe)-μ-L-$Pt(PPh_3)_2$(σ-C_6H_4NHMe)]$(OTf)_2$ (L = 4,4′-bipyridine, 4,7-phenanthroline, 4,4′-dipyrazolylmethane, and 1,1′-diphenyl-4,4′-dipyrazolylmethane; OTf = trifluoromethanesulfonate (triflate)) containing two C^3-*N*-methylbenzamide ligands are described. The key structural feature of the cationic complexes is the presence of two convergent amide groups that may allow for charge-assisted, H-bonding interactions in solution with suitable heteroaromatic guest molecules such as nucleobases.

Key words: organoplatinum(II) complex, organometallic host, dinuclear complex, *N*-methylbenzamide.

Résumé : On décrit la préparation et la caractérisation de complexes cationiques dinucléaires du type *trans*-[$Pt(PPh_3)_2$ (σ-C_6H_4NHMe)-μ-L-$Pt(PPh_3)_2$(σ-C_6H_4NHMe)]$(OTf)_2$ [L= 4,4′-bipyridine; 4,7-phénanthroline; 4,4′-dipyrazolylméthane; et 1,1′-diphényl-4,4′-dipyrazolylméthane; OTf = trifluorométhanesulfonate (triflate)] contenant deux ligands C^3-*N*-méthylbenzamide. La caractéristique structurale clé des complexes cationiques est la présence de deux groupes amides convergents qui, en solution, peuvent favoriser des interactions de liaisons hydrogènes assistées par des charges avec des molécules hôtes hétéroaromatiques appropriées, telles des nucléobases.

Mots-clés : complexe organique du platine(II), hôte organométallique, complexe dinucléaire, *N*-méthylbenzamide.

[Traduit par la Rédaction]

Introduction

There is great interest in the study of synthetic receptors for the selective binding of nucleobases (1, 2), owing to their many important functional roles in biological systems, e.g., intracellular energy transfer, signal transduction, and nucleic-acid synthesis. Various modes of hydrogen-bonding recognition have been shown to occur between nucleobases and simple carboxylic acids, for example, and it has been demonstrated that many aromatic carboxylic acids preferentially bind Hoogsteen sites, whereas aliphatic carboxylic acids bind preferentially at the Watson–Crick site (3, 4). In addition to hydrogen-bonding, π-stacking is usually found to augment the interaction involving aromatic hosts and nucleobase guests, and both macrocyclic and non-macrocyclic molecular receptors containing hydrogen-bonding and (or) π-stacking binding domains have been studied previously (5–18), all of which have the capacity to target nucleobases such as adenine and its derivatives. Theoretical studies have also complemented the work (10, 11).

Macrocyclic nucleobase receptors can discriminate their guest molecule by attributes such as size, electronic properties, nature of the hydrogen-bonding groups, and the π-stacking surface area (5, 6, 12). In contrast, non-macrocyclic "molecular tweezers" possess two binding sites with convergent functionality, which are linked together by a spacer unit (7–9, 13–18). Molecular tweezers usually possess one or more hydrogen-bonding functionalities, such as carboxylic acids or amides, and, in some cases, converging aromatic surfaces that have the capacity to undergo π-stacking interactions. Organometallic complexes in which direct coordination of adenine to the metal centre is augmented by H-bonding and π-stacking interactions are also known (19, 20), but to our knowledge there exist no examples of where metal coordination does not play a key role in the recognition motif. Instead, the formation of strong H-bonding interactions with the guest molecule is the result of the complementary shape of the cationic host, which can be further augmented by charge assistance (21).

We have previously reported the preparation, pK_a data, and X-ray structures of σ-arylplatinum(II) complexes bearing carboxylic acid functionalities (22–24) some of which have been shown to possess interesting supramolecular properties in non-aqueous solution, e.g., the formation of discrete, multimeric cyclic arrays with nanoscale dimensions (24). The use of a protection–deprotection strategy was required in the oxidative addition reactions involving aryl iodides bearing a carboxylic acid functionality owing to their high reactivity with platinum(0) precursor compounds. Furthermore, in some cases, we found that carboxylic acids

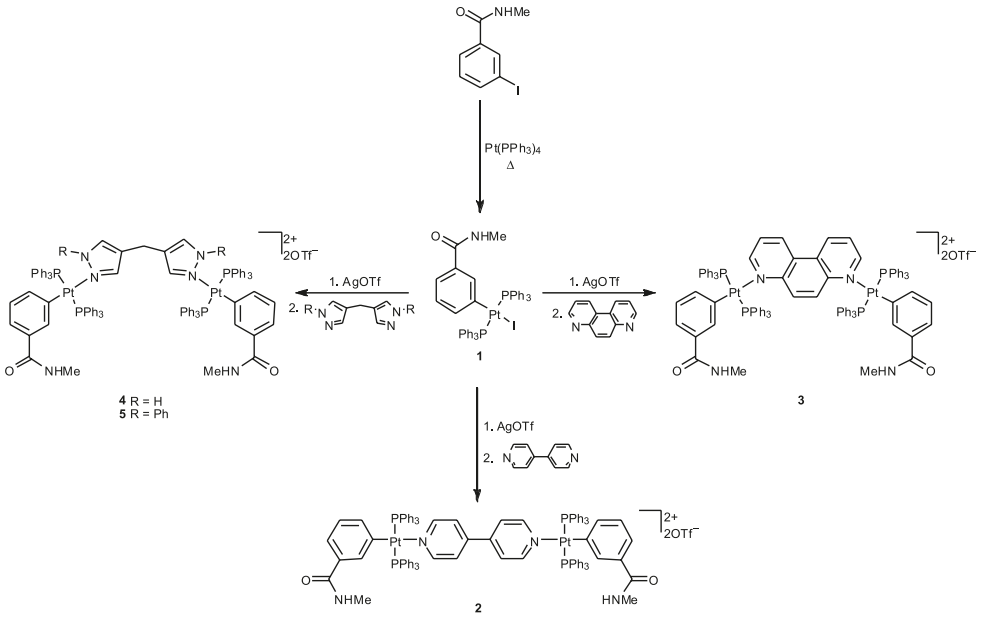
Scheme 1.



readily H-bonded to counter-ions (e.g., triflate) both in low-polarity solvents and in the solid-state, thus markedly complicating the assembly and (or) molecular-recognition studies (22, 23). The use of N-substituted σ-benzamide ligands instead of pyridine carboxylic acids was expected to address many of these issues largely because of the markedly lower acidity of the amide N–H group compared with that of a carboxylic acid. Herein, we describe the synthesis and characterization of dinuclear organoplatinum(II) derivatives bearing convergent *N*-methylamide functionalities for potential application as molecular receptors for nucleobases.

Results and discussion

The oxidative addition of the C–I bond of 3-iodo-*N*-methylbenzamide to $Pt(PPh_3)_4$ proceeded cleanly to afford the iodoplatinum(II) complex **1** in good yield (Scheme 1). The ^{1}H NMR spectrum of **1** displayed four distinct signals at δ 6.67, 6.72, 6.24, and 6.96 ppm, which are assigned to the H^2, H^4, H^5, and H^6 protons of the σ-aryl ligand, respectively. The methyl protons of the NHMe group appeared as a doublet at δ 2.76 ppm ($^3J_{HH}$ = 4.8 Hz), and the NH proton appeared as a broad multiplet at δ 4.98 ppm. Complex **1** was readily converted to the labile triflato derivative by the use of AgOTf. Two equivalents of this species were then treated immediately with 1 equiv. of the bridging bidentate, N-donor ligand 4,4′-bipyridine, 4,7-phenanthroline, 4,4′-dipyrazolylmethane, or 1,1′-phenyl-4,4′-dipyrazolylmethane to form the desired diplatinum(II) complexes (**2**–**5**) in good yield and purity (Scheme 1).

Complex **2** displayed a doublet signal in the ^{1}H NMR spectrum at δ 7.03 ppm ($^3J_{HH}$ = 7.5 Hz), which is attributed to the H^6 proton of the σ-aryl ligand. The signal due to the H^4 proton appeared as a doublet at δ 6.81 ppm ($^3J_{HH}$ = 7.5 Hz), and the H^5 proton gave rise to a triplet signal at δ 6.39 ppm ($^3J_{HH}$ = 7.8 Hz). The ortho protons of the 4,4′-bipyridine were masked by the PPh_3 signals at δ 7.34–7.19 ppm, whilst the meta hydrogens appeared at δ 6.83 ppm as a distinct signal, which is assigned to the XX′ portion of a AA′XX′ spin system. The NMR spectra of **3** were measured in CD_2Cl_2 solution instead of $CDCl_3$ as the complex was found to dissociate to afford free 4,7-phenanthroline over a period of a few hours at room temperature in $CDCl_3$ but remained stable for indefinite periods in CD_2Cl_2 solution. This effect has been previously observed in the ESI-MS of these and related complexes (vide infra) (22–25), and it is most probably the result of the strong trans effect associated with the σ-aryl ligand. Interestingly, a Pd_6 hexagon prepared from 4,7-phenanthroline and dinuclear organopalladium(II) precursor complexes appears to remain intact both in solution and in the gas phase despite the presence of a σ-aryl ligand located trans to the coordinated N-atom (26).

The assignment of the aromatic proton resonances in **2**–**5** was facilitated by 2D ^{1}H COSY (correlation spectroscopy) NMR experiments at 600 MHz, whereby distinct cross-peaks were observed for coupled protons of the σ-aryl ring systems, as seen in the NMR spectrum of **4** (Fig. 1). For this complex, protons H^4 and H^6 appeared as doublets at δ 6.77 and δ 7.00 ppm, respectively. The H^5 proton appeared as a triplet ($^3J_{HH}$ = 7.2 Hz) at δ 6.35 ppm. The signal due to H^2 appeared as a sharp singlet at δ 6.10 ppm. The N–Me protons appeared as a doublet at δ 2.83 ppm ($^3J_{HH}$ = 4.8 Hz), and the amide N–H proton gave rise to a broad singlet at δ 6.01 ppm. The signal due to the methylene bridge protons appeared as a sharp singlet at δ 2.53 ppm, and the N–H signal of the pyrazolyl ring was located downfield at δ 12.45 ppm.

Compared to the ^{1}H NMR spectrum of complex **4**, the related complex **5** had many broad unresolved signals, with all the σ-aryl signals appearing as broad singlets. This effect is most likely related to the dynamic phenomena of analogous platinum(II) species (23), whereby free rotation of the 1,1′-diphenyl-4,4′-dipyrazolylmethane ligand about the Pt–N bond is restricted owing to the considerable steric interactions between the N–Ph group and the bulky PPh_3 ligands. This proposal is also supported by the fact that the related 4,4′-dipyrazolylmethane complex **4** does not exhibit this re-

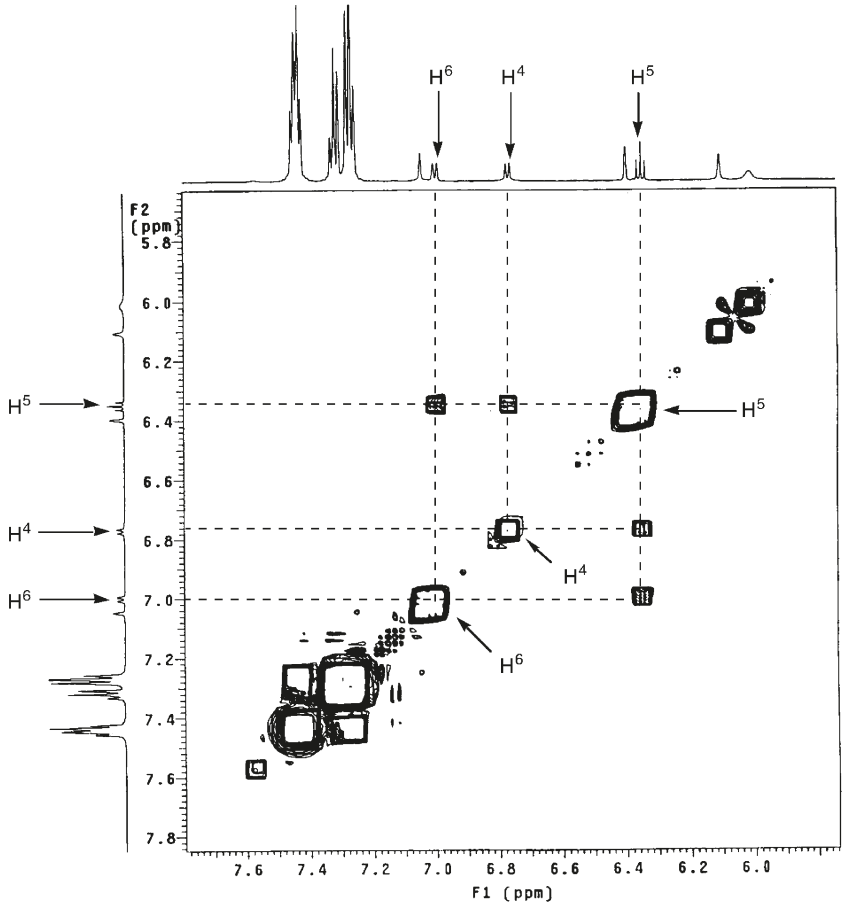
Fig. 1. Expanded ^{1}H COSY NMR spectrum (600 MHz) of **4** in $CDCl_3$ solution showing key couplings and peak assignments for the σ-aryl protons.



lated NMR behaviour, suggesting that in this case there exists free rotation around the Pt–N bond.

All complexes prepared in this work displayed a sharp singlet between δ 20–25 ppm in the $^{31}P\{^1H\}$ NMR spectrum, and it was always flanked by ^{195}Pt satellite signals. The magnitude of $^1J_{PtP}$ (~3000 Hz) for all complexes falls in the range that is expected for trans-substituted σ-arylplatinum(II) complexes (28, 29). Only minor differences were observed in the magnitude of $^1J_{PtP}$ upon substitution of the iodo ligand with N-donor ligands, largely because the ^{195}Pt–^{31}P coupling is predominantly influenced by the nature of the trans ligand (PPh_3).

Positive ion ESI-MS studies failed to show any evidence of an intact species in the spectra of **2**–**5** and, instead, the N-donor ligands (L) were readily lost, and peaks corresponding to $[M–OTf–L]^+$ were observed. The strong trans-effect associated with the σ-aryl ligand would account for the facile labilization of the N-donor ligand in the gas phase, and similar behaviour has also been observed in the ESI-MS of related systems (22–25).

Conclusion

In this work, we have demonstrated the facile synthesis of organplatinum(II) complexes bearing convergent H-bonding amide functionalities by exploiting an oxidative addition reaction involving a platinum(0) precursor. The low reactivity of the amide N–H group ensures that unwanted side reactions involving the N–H bond do not occur, and C–I bond cleavage is favoured exclusively. We are in the process of investigating the "molecular chelation" properties of selected complexes with various guest molecules, such as derivatives of purine bases, including adenine and guanine. Indeed, preliminary molecular modelling studies (SYBYL force field) demonstrate that a stable 1:1 species between **4** and adenine is feasible in the gas phase in which the exocyclic NH_2, N-7, and N-1 atoms of the guest molecule are all involved in strong H-bonding interactions with both amide groups of the complex, and we are currently investigating the host–guest chemistry of **2**–**5** and related complexes in various solvents. The results of this work will be reported in due course.

Experimental

All complexes were synthesised under a N_2 atmosphere using standard Schlenk techniques. All solvents were dried and purified in the following manner: CH_2Cl_2 was distilled from CaH_2, and toluene was pre-dried over $CaSO_4$ followed by distillation from sodium. The solvents were stored under N_2 over 4 Å molecular sieves.

All 1D NMR spectra were recorded at 298 K by means of a Varian Gemini 2000 NMR spectrometer with an Oxford 300 MHz magnet (^{1}H at 300.10 MHz, ^{31}P at 121.50 MHz);

© 2008 NRC Canada

2D NMR (^{1}H COSY) spectra were recorded by using a 600 MHz magnet. ^{1}H NMR chemical shifts were reported in ppm relative to tetramethylsilane (TMS). ^{31}P{^{1}H} NMR spectra were referenced to sealed external standard of 85% phosphoric acid. IR spectra were recorded as Nujol mulls in the range 4000–400 cm^{-1} on a PerkinElmer FTIR spectrophotometer. ESI-MS were obtained by means of a Finnegan LCQ mass spectrometer in the positive-ion mode using HPLC-grade MeOH as the solvent. Elemental analysis was performed by CMAS (Chemical and Microanalytical Services, Pty. Ltd.), Belmont, Victoria.

3-Iodo-*N*-methylbenzamide (27), tetrakis(triphenylphosphine)platinum(0) (30), 4,4′-dipyrazolylmethane (31), and 1,1′-phenyl-4,4′-dipyrazolylmethane (32) were prepared and purified according to the literature procedures.

Trans-iodo(*N*-methylbenzamide-*C*^{3})bis(triphenylphosphine)platinum(II) (1)

3-Iodo-*N*-methylbenzamide (0.110 g, 0.402 mmol) was placed in a Schlenk flask with $Pt(PPh_3)_4$ (0.500 g, 0.402 mmol). Toluene (20 mL) was added to the flask, and the solution was stirred for 16 h at 80 °C. Hexane (20 mL) was slowly added to the solution to precipitate the product, which was collected by filtration to afford **1** as a colourless, microcrystalline solid (0.344 g, 88%). IR (Nujol): 1632 ν(C=O) cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 7.56–7.22 (m, 30H, PPh_3), 6.96 (d, 1H, $^3J_{HH}$ = 7.5 Hz, $^1J_{PtH}$ = 29.3 Hz, H^6), 6.72 (d, 1H, $^3J_{HH}$ = 8.4 Hz, H^4), 6.67 (s, 1H, $^1J_{PtH}$ = 28.8 Hz, H^2), 6.24 (t, 1H, $^3J_{HH}$ = 7.8 Hz, H^5), 4.98 (br m, 1H, NH), 2.76 (d, 3H, $^3J_{HH}$ = 4.8 Hz, NCH_3). ^{31}P{^{1}H} NMR ($CDCl_3$) δ: 22.0 ($^1J_{PtP}$ = 3029 Hz). Anal. calcd. for $C_{44}H_{38}INOP_2Pt$: C, 53.89; H, 3.91; N, 1.43. Found: C, 53.37; H, 3.85; N, 1.45.

Trans-μ-4,4′-bipyridinebis[(*N*-methylbenzamide-*C*^{3})bis(triphenylphosphine) platinum(II)] bis(triflate) (2)

Complex **1** (0.400 g, 0.401 mmol) was treated with AgOTf (0.103 g, 0.401 mmol) in CH_2Cl_2 (25 mL), and the reaction mixture was stirred at room temperature for 3 h in the absence of light. AgI was then removed by filtration through Celite filter aid. 4,4′-Bipyridine (0.031 g, 0.201 mmol) was added to the clear solution and then stirred overnight at room temperature. The solvent was reduced in vacuo to afford **2** as a colourless, microcrystalline solid (0.260 g, 60%). IR (Nujol): 1655 ν(C=O) cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 7.34–7.19 (m, 60H, PPh_3), 7.03 (d, 2H, $^3J_{HH}$ = 7.5 Hz, H^6), 6.83 (s, 2H, H^2), 6.83 (XX′ portion of AA′ XX′, 4H, H_m), 6.81 (d, 2H, $^3J_{HH}$ = 7.5 Hz, H^4), 6.39 (t, 2H, $^3J_{HH}$ = 7.8 Hz, H^5). ^{31}P{^{1}H} NMR ($CDCl_3$) δ: 20.9 ($^1J_{PtP}$ = 3008 Hz). Anal. calcd. for $C_{44}H_{38}INOP_2Pt$: C, 55.56; H, 3.92; N, 2.59. Found: C, 55.62; H, 3.51; N, 2.64.

Trans-μ-4,7-phenanthrolinebis[*N*-methylbenzamide-*C*^{3})bis(triphenylphosphine) platinum(II)] bis(triflate) (3)

Following a procedure similar to that described for complex **2**, complex **1** (0.400 g, 0.401 mmol) was treated with AgOTf (0.103 g, 0.401 mmol) followed by the addition of 4,7-phenanthroline (0.036 g, 0.201 mmol) to afford **3** as a colourless, microcrystalline solid (0.360 g, 55%). IR (Nujol): 1641 ν(C=O) cm^{-1}. ^{1}H NMR (CD_2Cl_2) δ: 9.40 (d, 2H, $^3J_{HH}$ = 9.3 Hz, H^{1,10}), 9.07 (d, 1H, $^3J_{HH}$ = 4.2 Hz, H^{3,8}), 9.05 (s, 2H, H^{5,6}), 7.41–7.11 (m, 20H, PPh_3), 6.88 (d, 2H, $^3J_{HH}$ = 7.8 Hz, H^{14}), 6.38 (t, 2H, $^3J_{HH}$ = 8.1 Hz, H^{15}), 5.96 (br s, 2H, NH), 2.84 (d, 6H, $^3J_{HH}$ = 4.8 Hz, NMe). ^{31}P{^{1}H} NMR (CD_2Cl_2) δ: 19.5 ($^1J_{PtP}$ = 3003 Hz). Anal. calcd. for $C_{102}H_{84}F_6N_4O_8P_4Pt_2S_2$: C, 56.04; H, 3.87; N, 2.56. Found: C, 55.94; H, 3.45; N, 2.18.

Trans-μ-4,4′-dipyrazolylmethanebis[(*N*-methylbenzamide-*C*^{3})bis(triphenylphosphine)platinum(II)] bis(triflate) (4)

Following a procedure similar to that described for **2**, complex **1** (0.400 g, 0.401 mmol) was treated with AgOTf (0.103 g, 0.401 mmol) followed by the addition of 4,4′-dipyrazolylmethane (0.029 g, 0.201 mmol) to afford **4** as a colourless, microcrystalline solid (0.369 g, 81%). IR (Nujol): 1643 ν(C=O), 3400 ν(N–H) cm^{-1}. ^{1}H NMR ($CDCl_3$) δ: 12.45 (s, 2H, pyrazolyl NH), 7.45–7.25 (m, 60H, PPh_3), 7.04 (s, 2H, H^9), 7.00 (d, 2H, $^3J_{HH}$ = 7.8 Hz, H^6), 6.77 (t, 2H, $^3J_{HH}$ = 7.2 Hz), 6.40 (s, 2H, H^2), 6.35 (t, 2H, $^3J_{HH}$ = 7.2 Hz, H^5), 6.10 (s, 2H, H^{10}), 6.01 (m, 2H, amide NH), 2.83 (d, 6H, $^3J_{HH}$ = 4.8 Hz, NHMe), 2.53 (s, 2H, CH_2). ^{31}P{^{1}H} NMR ($CDCl_3$) δ: 20.8 ($^1J_{PtP}$ = 3022 Hz). Anal. calcd. for $C_{97}H_{84}F_6N_6O_8P_4Pt_2S_2$: C, 54.09; H, 3.93; N, 3.90. Found: C, 53.98; H, 4.09; N, 3.71.

Trans-μ-(1,1′-phenyl-4,4′-dipyrazolylmethane)bis[(*N*-methylbenzamide- C^3)bis(triphenylphosphine)platinum(II)] bis(triflate) (5)

Following a procedure similar to that described for **2**, complex **1** (0.400 g, 0.401 mmol) was treated with AgOTf (0.103 g, 0.401 mmol) followed by the addition of 1,1′-phenyl-4,4′-dipyrazolylmethane (0.060 g, 0.201 mmol) to afford **5** as a colourless, microcrystalline solid (0.129 g, 54%). ^{1}H NMR ($CDCl_3$) δ: 6.94 (br s, 2H, H^6), 6.69 (br s, 2H, H^2), 6.58 (br s, 2H), 6.25 (br s, 2H, H^5), 5.70 (m, 2H, NH), 3.11 (s, 2H, CH_2), 2.84 (d, 6H, $^3J_{HH}$ = 4.5 Hz, NHMe), 7.64–7.28 (m, 60H, PPh_3). ^{31}P{^{1}H} NMR ($CDCl_3$) δ: 25.0 ($^1J_{PtP}$ = 3084 Hz). Anal. calcd. for $C_{109}H_{92}F_6N_6O_8P_4Pt_2S_2$: C, 56.77; H, 4.02; N, 3.64. Found: C, 56.57; H, 4.09; N, 3.49.

Top-down meets bottom-up — Electron-beam induced metalorganic deposition of amorphous iron oxide nanostructures[1]

Simon Trudel and Ross H. Hill

Abstract: We present the use of a metalorganic precursor, iron(III) 2-ethylhexanoate, as a precursor for the electron-beam induced deposition of amorphous iron oxide nanostructures. Exposing this precursor to an area dose of 1.560 mC/cm^2 with 10 keV electrons affords a material that can be developed and was determined to be amorphous iron oxide when examined by TEM, electron diffraction, and energy dispersive X-ray spectroscopy. Single point exposure yields free-standing hollow nanorods with diameters from 85 to 255 nm controlled by the exposure dose. The patterning of sub 40 nm nanowires with low (<3 nm) line edge and width roughnesses is also presented.

Key words: electron beam lithography, amorphous iron oxide, nanotubes, nanowires, coordination polymer precursor.

Résumé : Dans ce travail, on propose l'utilisation d'un composé organométallique, le 2-éthylhexanoate de Fe(III), comme précurseur pour le dépôt de nanostructures d'oxyde de fer induit par un faisceau d'électron. Lorsqu'on expose ce précurseur à une dose superficielle de 1,560 mC/cm^2 à l'aide d'électrons à 10 keV, il se forme un matériau qui peut être développé et qui, sur la base de la microscopie électronique à transmission (MET), la diffraction des électrons et la spectroscopie des rayons X à dispersion d'énergie, serait de l'oxyde de fer amorphe. Des expositions en un seul point conduisent à la formation de nanotiges de diamètres variant de 85 à 225 nm et contrôlés par la dose d'exposition. On rapporte aussi les résultats obtenus en vue de déterminer les patrons des nanofils de tailles inférieures à 40 nm comportant des lisières et des largeurs de rugosité faibles (<3 nm).

Mots-clés : lithographie à faisceau électronique, oxyde de fer amorphe, nanotubes, nanofils, précurseur d'une polymère de coordination.

[Traduit par la Rédaction]

Introduction

In this contribution, we report on the electron-beam metalorganic deposition (EMOD) of amorphous metal oxide nanostructures, including nanowires and nanotubes. As an example, we demonstrate the deposition of iron oxide nanostructures using radiation sensitive iron(III) 2-ethylhexanoate.

Several metal oxides are technologically important materials, and the controlled patterned deposition of nanostructures made of such materials is thus relevant to the fabrication of nanoscaled devices (1–4). For example, nanowire structures are attractive for several devices (3, 5). However, the controlled placement of nanowires onto surfaces remains challenging. In conventional microfabrication, metal oxide nanostructures can be used as ultrathin resists (6) and etch-resistant top-side resists (7).

Iron oxide nanostructures are attractive for applications as magnetic elements in spintronic devices (8–10) and can be used as catalysts for the controlled deposition of single-walled carbon nanotubes (11). However, no control over the position of these iron oxide nanostructures was achieved when the nanostructures were deposited onto substrates, as they were deposited from suspensions of preformed nanostructures (8–11).

Iron oxide nanostructures have been deposited lithographically by introducing $Fe(CO)_5$ in the gas phase in the path of the focused electron beam (12, 13). The material was either amorphous (13) or nanocrystalline (12) iron oxide, depending on whether the carrier gas was water vapour or oxygen, respectively.

Previous work within our group has extensively explored the use of metal 2-ethylhexanoates for the lithographic photochemical metalorganic deposition (PMOD) of metal oxides (14, 15) and nanocomposites (16). These precursors are sensitive to ultraviolet light. Upon irradiation, the molecule is destabilized and will fragment, ultimately losing its ligands as volatile organic products. In air, a metal oxide is obtained. Upon developing in an appropriate solvent, unconverted precursor in the unexposed areas is removed, leaving a pattern of the metal oxide on the substrate.

An alternative approach to the patterning of nanostructures is the use of an electron beam to induce a chemical reaction in a precursor, as in PMOD. EMOD is a convenient approach to the direct, controlled patterning of functional materials onto surfaces. For example, materials such as conducting PdC (17) and Pd (18), Au nanoparticles (19), etch-resistant titanium oxide (7), superconducting Y-Ba-Cu oxide (20), ferromagnetic Fe-Co containing ceramics (21), and uranium oxide for X-ray masks (22) have been prepared using metalorganic precursors. This approach to the patterning of functional materials is at the convergence of the "top-down" and "bottom-up" technologies. It uses traditional micro-fabrication tools to modify and "assemble" molecular building blocks into the desired material. A post-development thermal treatment is usually required to obtain the final material (7, 18–21).

Experimental

Chemicals, substrates, and intruments

The metalorganic precursor iron(III) 2-ethylhexanoate was purchased from Strem as a solution in mineral spirits. Silicon substrates were purchased from WaferNet. The CaF_2 disk used for the acquisition of the FTIR spectrum was purchased from Wilmad.

Fourier-transform infrared (FTIR) spectra were obtained on a BOMEM Michelson 120 FTIR spectrophotometer operating at a 4 cm^{-1} resolution, whose sample chamber was maintained under a nitrogen atmosphere. Spectroscopic ellipsometry measurements were carried with a Jobin-Yvon UVISEL NIR phase modulated ellipsometer. Measurements were carried out every 5 nm from 300 to 900 nm. The measured spectrum was fit using the DeltaPsi2 software, using a Forouhi–Bloomer model (23). Electron beam exposure and SEM imaging was carried out in a Raith e-LINE system, equipped with a field-emission electron gun. All writing was done by performing a raster of vector scans of the Gaussian shaped electron beam as the stage remained fixed. Atomic force microscopy (AFM) was carried out using a Thermo Microscopes Explorer microscope and Microlever Si_3N_4 cantilevers. Transmission electron microscopy (TEM) was carried out on a FEI Tecnai 20 operating at an acceleration voltage of 200 kV, equipped with an EDAX energy dispersive X-ray spectroscopy unit.

Preparation of precursor thin film and e-beam exposure

A solution containing 15% by weight of the precursor in methyl *iso*-butylketone (MIBK) was used to saturate the surface of an approximately 2 cm × 2 cm piece of [100] oriented silicon. The silicon substrate was then spun to disperse the precursor (6000 rpm, 60 s). This yielded a highly uniform, optical quality precursor thin film. Spectroscopic ellipsometry measurements indicate a precursor thin film thickness of ~240 nm (see Fig. S1).[3] This precursor thin film was loaded into the electron beam lithography system. Electrons accelerated to 10 keV were used to expose this precursor thin film, using a beam current of 235 pA. Area, line, and point doses (in units of mC/cm^2, nC/cm, and pC, respectively) were used to control the exposure. The sample was developed by dipping the substrate into MIBK maintained at 19 °C, for a period of 3 s. The sample was blown dry under a stream of nitrogen and inspected by scanning electron microscopy (SEM). Contact-mode AFM images were also acquired.

The same procedure was used to spin coat a thin film of iron(III) 2-ethylhexanoate on a CaF_2 disk.

Preparation of TEM samples

Samples suitable for TEM investigation were prepared as described above, except the thin film of iron(III) 2-ethylhexanoate was coated on a 75 nm thick Si_3N_4 membrane TEM grid (SPI Supplies), and that a beam current of 126.8 pA was used. The sample was inspected using TEM in bright field (BF) imaging and electron diffraction mode, as well as scanning TEM using a high-angle annular dark field (HAADF) detector.

Results

The FTIR spectrum of a thin film of iron(III) 2-ethylhexanoate is shown in Fig. 1. The observed absorption bands are associated with symmetric and asymmetric vibrations of the C–O groups of the ligand, 2-ethylhexanoate, and 2-ethylhexanoic acid. The absorption bands at 1690, 1589, and 1553 cm^{-1} are tentatively assigned as the asymmetric stretches, and the absorption bands at 1460 and 1424 cm^{-1} as symmetric stretches.

The absorption band at 1690 cm^{-1} is associated to coordinated acid (14). The binding mode of the acid can be determined based on the difference between the asymmetric and symmetric absorption bands (24). Bridging and bidentate binding modes are observed in this thin film. The presence of bridging binding modes suggests that an oligomeric (or polymeric) form of iron(III) 2-ethylhexanoate is present in the thin film. The proposed molecular structure of this coordination polymer is shown in Scheme 1. This coordination polymer tentatively contains chains propagated via bridging carboxylates. This type of polymer has been suggested in previous studies of PMOD using metal 2-ethylhexanoates (14).

We examined arrays of elements exposed to various doses (Fig. 2*a*) to determine the dose required for patterning large areas with a 10 kV acceleration voltage. Figure 2*a* shows an SEM image of a region that was exposed with seven different doses. The central elongated element was exposed with a dose of 1.560 mC/cm^2. The top of the image, where three elements were exposed with doses of 12.5, 25, and 50% the

[3] Supplementary Data includes spectroscopic ellipsometry fit spectra (Fig. S1) and best fit parameters (Table S1), measured hight of large areas as a function of exposure dose (Fig. S2), SEM images of nanowires patterned with different line doses (Fig. S3), a scheme showing the difference between LER and LWR (Scheme S1), and the equations used to calculate LER and LWR (SE-1 and SE-2). Scheme 1. Proposed structure of oligomeric (or polymeric) iron(III) 2-ethylhexanoate precursor. R = CH(Et)Bu.

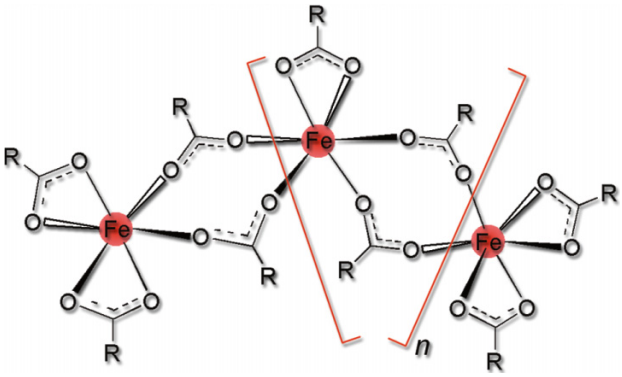

Fig. 2. (*a*) SEM image of elements exposed with doses of (from left to right, top to bottom) 0.195, 0.390, 0.780, 1.560, 3.120, 6.240, and 12.480 mC/cm^2. (*b*) SEM image of 31 nm wide wire on silicon (exposure dose = 34.2 nC/cm).

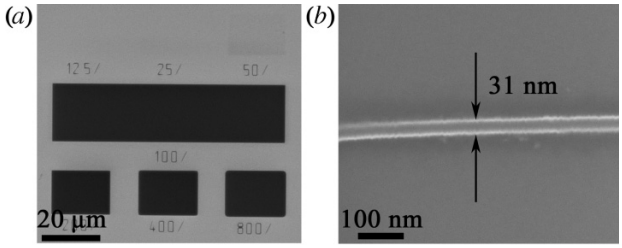
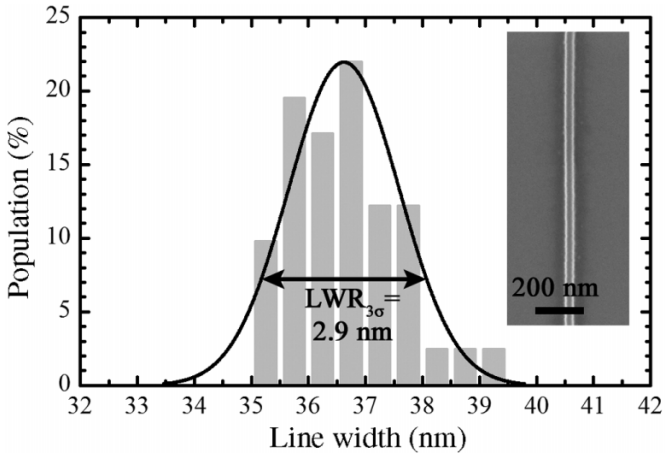


dose of 1.560 mC/cm^2, showed no material remained on the silicon surface after development. The bottom image shows elements exposed with 2, 4, and 8 times the dose of 1.560 mC/cm^2. While material is deposited, rounding at the corner of these elements suggest over-exposure. As such, we determined that a dose of 1.560 mC/cm^2 is required for patterning areas.

The thickness of large areas exposed to various doses were measured by AFM (see Fig. S2).[3] At a dose of 1.4 mC/cm^2, the thickness is ~58 nm. The thickness increases with increasing exposure dose to a maximum of ~110 nm at a dose of 2.8 mC/cm^2. Further increases in dose results in a decrease in the thickness of the structure. Above

Fig. 3. Normal distribution of 41 line width measurements, made every ~30 nm along the line segment of the SEM image shown in the inset.



a dose of 10 mC/cm^2, the thickness of the feature is independent of dose and about ~40 nm. This result is consistent with the formation of an insoluble material that densifies with further exposure.

This dose compares favorably to other EMOD precursors. For example, precursors containing high atomic number metals such as palladium(II) acetylacetonate and polystyrene-based gold(I) thiolate require doses of 4 and 9.8 mC/cm^2 at 10 and 20 kV, respectively, (17, 19), while mixtures of metal neodecanoates used for the deposition of $YBa_2Cu_4O_x$ required a dose of 1.200 mC/cm^2 at 25 kV (20). Our reported dose of 1.560 mC/cm^2 for iron(III) 2-ethylhexanoate is essentially the same as the dose of 1.500 mC/cm^2 at 10 kV reported by Henderson and co-workers (7) for the patterning of sub-100 nm lines using the closely related titanium(IV) di-*n*-butoxide bis(2-ethylhexanoate).

Henderson also reports that a pre-exposure bake can improve by a factor of almost seven the sensitivity of this titanium precursor. This may be an avenue to decrease the required dose to print in our system, even though it may be expected that the effect of a pre-exposure thermal treatment may not be as pronounced as with a thermally sensitive alkoxide-based precursor.

The deposition of 31 nm wide nanowires on a silicon substrate was achieved when the iron(III) 2-ethylhexanoate thin film was exposed with a dose of 34.2 nC/cm (Fig. 2*b*). The width of the deposited nanowires could be controlled by varying the exposure dose (see Fig. S3).[3] Using the EMOD approach described in this paper, we have patterned 37 nm wide nanowires with line-edge roughness (LER$_{3\sigma}$) and linewidth roughness (LWR$_{3\sigma}$) of 2.7 and 2.9 nm, respectively, (see eqs. SE-6 and 7 as well as Scheme S1).[3] The LWR measurements are shown in Fig. 3.

In the same fashion, features could be patterned by exposing single spots for a predetermined dwell time (Fig. 4*a*). Such features appear to be dots, but on closer examination of such features exposed with a lower dose, elongated structures can be seen instead of dots (Fig. 4*b*). The diameter of the pillar could be tuned by changing the exposure dose. The diameter roughly depends on the logarithm of the dose (Fig. 4*c*). The height of the standing pillars seems to be in-

Fig. 4. (*a*) SEM image of pillars on silicon. The dose increases from 0.19 (bottom) to 1.34 pC (top). (*b*) Standing and fallen pillars. (*c*) Diameter of the obtained pillar as a function of exposure dose.

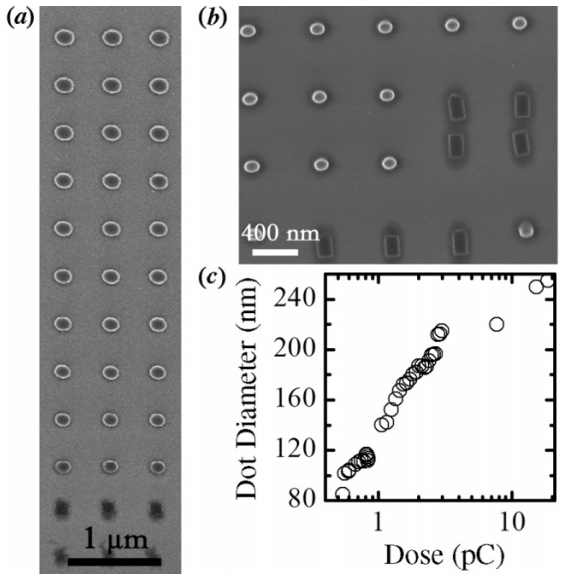

Fig. 5. AFM images of dot arrays. (*a*) Image at the threshold dose, which is ~0.504 pC. The dose increases from left (~0.204 pC) to right (~0.588 pC). Images taken for dots exposed below (*b*) and above (*c*) the threshold dose.

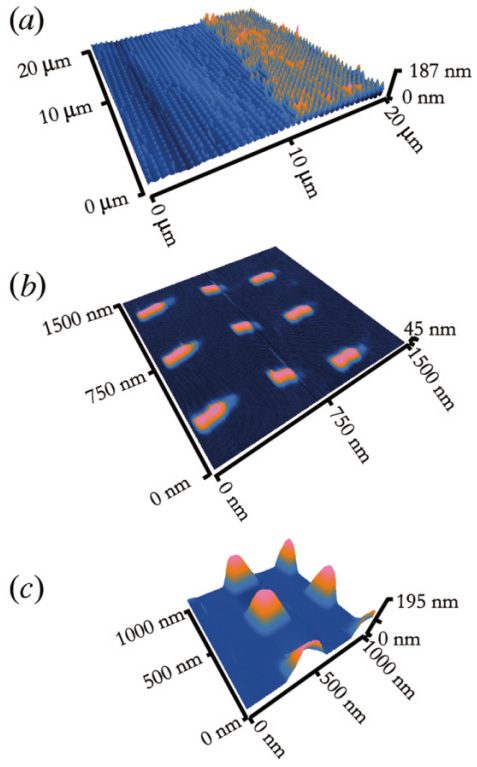
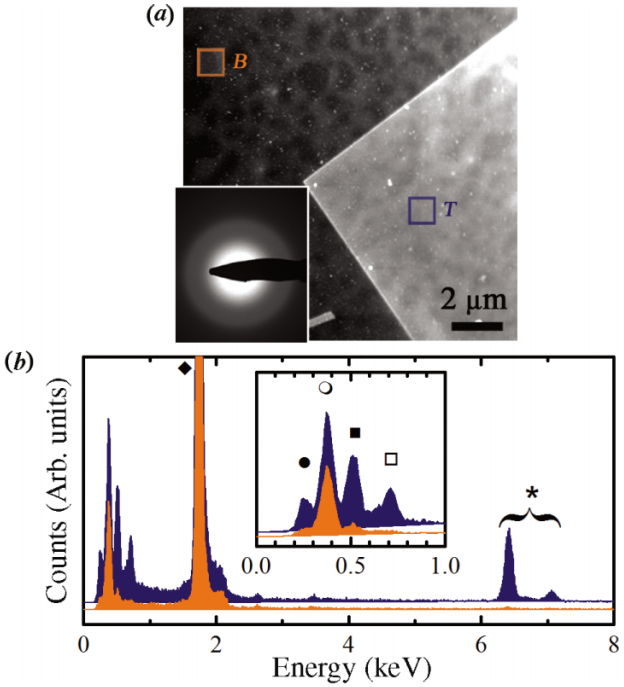


dependent of exposure dose as seen from AFM imaging (Fig. 5*a*) and is more likely to be a function of the precursor film thickness. The precursor thickness can be controlled by adjusting the spin-coating conditions.

Fig. 6. (*a*) HAADF-STEM image of patterned area and associated electron diffraction. The bright area is the material deposited by EMOD. (*b*) Energy dispersive X-ray spectroscopy of areas highlighted in (*a*). The top spectrum corresponds to the area labelled *T* in (*a*), while the bottom spectrum corresponds to the area labelled *B*. The peaks are attributed to C *K* (●), N *K* (○), O *K* (■), Fe $L_{1,2,3}$ (□), Si K_{α} (◆), and Fe $K_{\alpha/\beta}$ (*) X-ray lines.



We believe spot exposure leads to the deposition of pillar structures, and that the elongated features are actually pillars fallen onto their side. This was verified by AFM. Representative images are shown in Fig. 5. A large area view of an exposed dot array is shown in Fig. 5*a*, in which the exposure dose increases from left to right from ~0.204 to ~0.588 pC. It is clear that below a threshold dose (~0.504 pC), the structures have fallen over. For example, Fig. 5*b* shows fallen nanopillars, similar to the elongated features shown in Fig. 4*b*. Above this dose, free standing nanopillars are obtained (Fig. 5*c*), similar to the circular features seen by SEM in Fig. 4*b*.

The falling of the pillars is possibly due to mechanical failure during the development. The preferential alignment of the fallen pillars might suggest that failure occurs during the drying step where a stream of gas flowing in one direction is used. Based on SEM and AFM imaging, we estimate the 85 nm wide pillars have an aspect ratio of ~2.5.

Samples prepared on 75 nm thick Si_3N_4 membranes were inspected using TEM. A large area view is shown in Fig. 6*a*. The electron diffraction pattern showed no features apart from diffuse scattering, which suggests an amorphous product is obtained (Fig. 6*a*, inset). The same area was examined by energy dispersive X-ray analysis. In addition to the lines due to the Si_3N_4 substrate (N *K* and Si *K*α), lines were observed for C *K*, O *K*, and Fe $L_{1,2,3}$ and $K_{\alpha/\beta}$ X-ray emission. This indicates that the deposited material is iron oxide with some carbon. It is unclear whether the carbon is due to residual iron(III) 2-ethylhexanoate or comes from the develop-

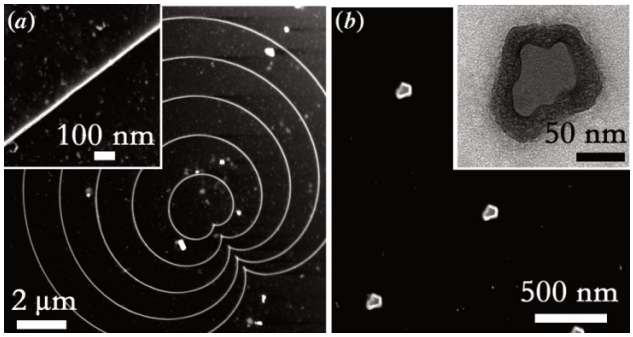
Fig. 7. (*a*) HAADF-STEM image of patterned lines on Si_3N_4 membrane. The line in the inset is 22 nm wide. (*b*) HAADF-STEM and BF-TEM (inset) images of single dot exposures.

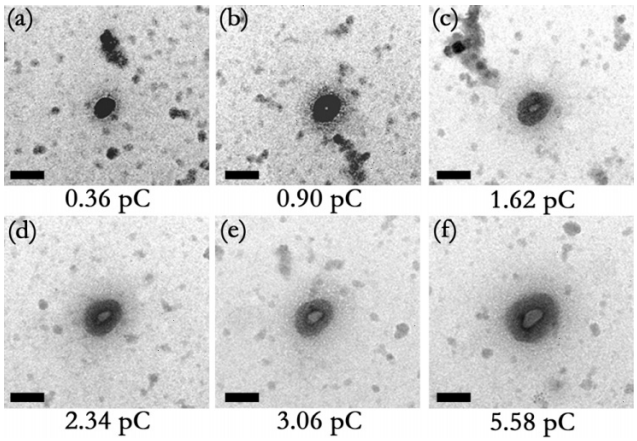


ment process. However, the presence of carbon is not unexpected as full conversion of the precursor is not required for development to be feasible. The production of an amorphous metal oxide is consistent with our previous observations of PMOD using metal 2-ethylhexanoate precursors (14, 15). While EMOD was carried out under high vacuum (~5×10^{-6} mbar, 1 bar = 100 kPa), we believe the deposited material is readily oxidized when removed from the chamber of the exposure tool and exposed to air. We are currently designing experiments to carry out the characterization of the deposited product (obtained by either of PMOD or EMOD) in the absence of oxygen.

Nanowires patterned on thin substrates are shown in Fig. 7*a*. The inset of this figure shows a 22 nm wide nanowire. The amount of backscattered and secondary electrons generated through electron–solid interactions will depend on the thickness as well as the atomic number of the substrate material (25). It is expected that fewer backscattered and secondary electrons are generated when a thin, lower atomic number Si_3N_4 membrane is used as a substrate (when compared with a bulk silicon substrate). This explains the lower line widths observed on the silicon nitride membrane.

Imaging of the pillar structures using TEM and STEM shows a modulation of the averaged density of material within an individual pillar. In a BF-TEM image (Fig. 7*b*, inset), the center of the pillar appears as brighter than the ~20 nm at the periphery of the pillar, without however being as bright as the surrounding unpatterned areas. A similar modulation in the density of material can be seen in a HAADF-STEM image, although the contrast is inverted between the BF and DF images (Fig. 7*b*). We believe the irregular, but reproducible, shape of the pillar is due to the crude electron-beam astigmatism correction used when this sample was patterned. A series of pillars exposed to different exposure doses are shown in Figs. 8*a*–8*f*. It can be seen in this series of images that at low doses, the pillar does not have a central feature (Fig. 8*a*). As higher doses are used, the central features increase in diameter, as does the outer diameter of the pillar.

Fig. 8. Pillar structures obtained with various exposure doses indicated below each image. The field of view is the same in all images, and the scale bars = 50 nm.



Discussion

Line edge and line width resolutions

One of the major resolution problems currently encountered with organic resists are the line-edge roughness (LER) and the line-width roughness (LWR). The LWR represents the uniformity of the line width, while the LER represents how smooth the edge of a patterned line is (see Scheme S1).[3]

The effect of the LER/LWR on semiconducting devices has been demonstrated to be in general detrimental to device performance. The threshold voltage and the off-state current leakage are both dependent on the LER/LWR in sub 100 nm devices (26–29). The off-state leakage current now accounts for as much power consumption as the actual use of the device and is a major challenge to further microprocessor miniaturization (30). As such, lithographic methods with low line edge and line width roughnesses are desirable.

A multitude of factors have been attributed as contributing to the LER and LWR in organic resists, such as the type, molecular weight, and the dispersity of the polymer resists; the concentration, distribution, and diffusibility of the photoacid generator; the development time; the swelling of the resists; and finally the LER/LWR of the photomask itself (when photolithography is carried out), to name but a few (31, 32). These defects are then transferred from the resist to the substrate/patterned material during the subsequent etch step (33). For example, LER values of 5 to 15 and 6 to 17 nm for chemically amplified UV-5 (34) and UV-6 (35) resists have been reported, respectively. Sub 9 nm LER values were reported for PMMA (3.5 to 7 nm) (35) and polyphenol resists with and without photoacid generators (2.3 to 8.4 nm) (36).

The method presented here is capable of achieving sub 3 nm LER and LWR. When considering the factors that contribute to LER/LWR in organic resists, it is apparent that many of them are not applicable to our metalorganic deposition method. For instance, no photogenerated acid is used. The size of organic polymer molecules used as resists is such that the removal of a single molecule during the development step can affect the edge roughness. In our system, small molecules are used, and as such the effect of the removal of single molecules is far less noticeable in terms of edge roughness. Our method requires very short (~3 s) development times, and a metal oxide material is far less likely to uptake solvent. This greatly minimizes swelling.

In our system, the deposited metal oxide can be used directly as a device-active component, or it can be used as an

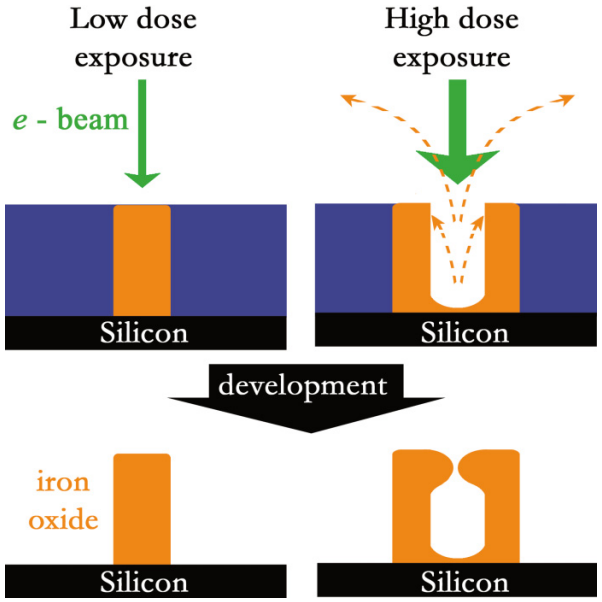
Scheme 2. Proposed mechanism for the formation of free-standing iron oxide nanotubes. On the left-hand side, a low exposure dose yields free-standing, solid pillar. On the right-hand side, a higher exposure dose leads to heating of the core and the thermal evaporation of material (shown as dotted arrows), leaving a free-standing nanotube on the substrate.



utlrathin top-side resist. In both instances, a low LER/LWR is expected in the final structure.

Patterning of free-standing nanotubes

The observation of two different regions in the BF-TEM images of pillars (see Figs. 7 and 8) could be interpreted as either due to (*i*) two different materials (either compositionally or – density), (*ii*) different crystallinity, or (*iii*) modulation of *overall* averaged density of material. No indication of materials other than iron oxide was found, and the whole structure was seen to be amorphous when inspected using high-resolution TEM and electron diffraction. However, if the total amount of a given material changes within the structure, with less material present in the middle, images as those presented here would be expected. As such, we suggest the pillars are partially hollowed.

The dependence of the diameter of the interior region with exposure dose is consistent with our expectation for thermal evaporation from the core leading to hollowing of the pillar (see Scheme 2). As the exposure dose increases, the outer diameter of the pillar increases. If only a low exposure dose is used, a solid pillar is obtained, as shown in Fig. 8*a* and depicted on the left hand side of Scheme 2. If the pillar is subjected to a higher dose, local heating occurs in the central region where the primary beam is hitting the newly formed iron oxide. This ultimately leads to electron beam induced thermal evaporation of material from the central region of the pillar, yielding a free-standing nanotube (Scheme 2, right hand side). Incomplete thermal evaporation of the core will probably leave some material in the core of the nanotube. Capping of the nanotube is also expected. This can be due to a collapse of the edge of the nanotube or to the redeposition of thermally evaporated material at the lip of the nanotube, or a combination of both.

The observed TEM and STEM images are consistent with the model presented above. Presumably, the increased overall density of the interior of these features with respect to the supporting membrane is associated with the capping of the nanotube by iron oxide. Capping is also consistent with the SEM and AFM images presented here. Thus, we suggest that the pillars are hollow, free standing iron oxide nanotubes.

Conclusions

We have shown the deposition of sub 100 nm iron oxide nanostructures using electron beam metalorganic deposition. Sub 40 nm nanowires with low line edge and line width roughness were patterned onto silicon surfaces. This method has the advantage over the deposition from the gas phase that the amount of deposit is easily controlled through the initial coating process. The process itself can be conducted on standard e-beam lithography tools without modification.

The patterning of free-standing, hollow nanotubes when using electron beam metalorganic deposition is, to our knowledge, unprecedented. The use of electron beam lithography affords the tunability of the external diameter of the nanotube, as well as the ability to address the position of the nanotube. The preparation of such structures with positional control is hard to achieve using either top- down or bottom-up fabrication strategies.

Zinc and iron complexes of a helix-directing (1*R*,2*R*)-cyclohexyl salen ligand with phenanthryl sidearms[1]

Alexander V. Wiznycia, John Desper, and Christopher J. Levy

Abstract: A symmetrical salen ligand is formed by the condensation of (1*R*,2*R*)-diaminocyclohexane with 4-hydroxy-3-phenanthrenecarboxaldehyde. Crystallographic characterization of the metal complexes (Zn^{II}, Fe^{II}, and Fe^{III}) show 1:1 mixtures of diastereomeric *M* and *P* helical molecules. ECD spectra of the Zn^{II} complex combined with DFT simulations strongly suggest that the *M* conformation is dominant in solution. This is supported by ^{1}H and ^{13}C NMR data, which are consistent with a single species in solution.

Key words: zinc, iron, ECD, DFT, salen complexes.

Résumé : La condensation du (1*R*,2*R*)-diaminocyclohexane avec le 4-hydroxyphénanthracène-3-carboxaldéhyde conduit à la formation d'un ligand salen symétrique. La cristallisation cristallographique des complexes métalliques (Zn^{II}, Fe^{II} et Fe^{III}) montre la présence de mélanges 1:1 de molécules hélicoïdales *M* et *P* diastéréoisomères. Les spectres de DCE du complexe de Zn(II), combinés aux résultats de calculs suivant la théorie de la théorie de la fonctionnelle de densité (TFD) suggèrent que la conformation *M* est prépondérante en solution. Cette conclusion est appuyée par les données de RMN du ^{1}H et du ^{13}C qui sont en accord avec la présence d'une seule entité en solution.

Mots-clés : zinc, fer, DCE, TFD, complexes salen.

[Traduit par la Rédaction]

Introduction

The helix is an important chiral motif in natural systems, and there is increasing development of helical transition metal complexes and related supramolecular structures (1). A simple single-stranded monohelical complex can be constructed by wrapping a multidentate ligand around a metal centre. For resolved chiral ligands there will generally be a preference for either the plus (*P*) or minus (*M*) conformation of the helix. In previous studies we have examined monohelical complexes based on salen ligands with chiral backbones and polyaromatic sidearms (2). In this report we extend this work and detail our results for systems with the (1*R*,2*R*)-cyclohexyl backbone and phenanthryl sidearms. X-ray structural characterization combined with electronic circular dichroism (ECD) spectroscopy and DFT spectral simulations indicate an unusual solution to solid state optical switching of diastereomeric helical conformations for these complexes (2, 3).

Results and discussion

Synthesis

The ligand (*R*,*R*)-**1** was prepared by condensation of the aldehyde precursor, 4-hydroxy-3-phenanthrenecarbox-aldehyde, with (1*R*,2*R*)-diaminocyclohexane [(*R*,*R*)-DAC] in ethanol (Scheme 1). (*R*,*R*)-**1** was then metalated by combination with the appropriate metal chloride in the presence of excess sodium methoxide (Scheme 1). A solvent mixture (CH_2Cl_2/ethanol or THF/ethanol) in the metalation reactions allowed for sufficient solubility of the metal salt and the deprotonated ligand (formed in situ) for reactions to be completed in reasonable times. Dissolution of the crude products in THF followed by precipitation and washings with CH_2Cl_2 and EtOH yielded pure products. The Fe^{III} complex had considerably lower solubility than the M^{II} complexes, and the crude product was only partially redissolved in THF, resulting in a lower yield for this compound. The metalation reactions do not proceed in the absence of base, but triethylamine can be used in place of sodium methoxide. Product isolation from MeOH/NaOMe is generally easier than from $HNEt_3Cl/NEt_3$ via solubility protocols, making NaOMe the preferred base for these reactions. Drying of the M^{II} complexes in vacuo yields compounds without coordinated solvent or additional solvent of crystallization, as indicated by combustion analysis and NMR spectroscopy.

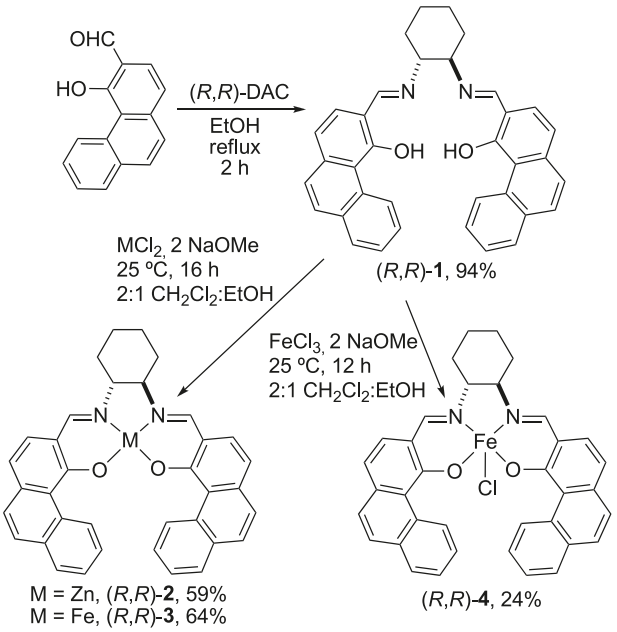
Scheme 1. Synthesis of the ligand (*R*,*R*)-**1** and its divalent metal complexes.



X-ray structural characterization

Crystal data for the structures reported in this article are presented in Table 1.

Crystals of the ligand (*R*,*R*)-**1** suitable for X-ray analysis could not be grown under the conditions examined, but solvent diffusion techniques did produce good quality crystals of (*rac*)-**1**. The structure shows two distinct molecules with the *R*,*R* configuration in the unit cell: they differ in both the sidearm positions and the arrangement of the acidic protons (Fig. 1). Molecule A has one sidearm roughly parallel and one roughly perpendicular to the cyclohexyl ring. There are two N–H···O hydrogen-bonding interactions such that the molecule exists in the di(keto-amine) form. Molecule B has both sidearms roughly perpendicular to the cyclohexyl backbone but in opposite orientations, resulting in pseudo-C_2 symmetry. In this tautomer there is one N–H···O and one O–H···N hydrogen bond. The O–H···N moiety is characterized by the position of the hydrogen as well as the shorter N=C and longer O–C bonds, compared with those associated with the N–H···O units (Fig. 1). The keto-amine to enol-imine isomerization indicated here is well-known for aromatic Schiff bases (4). The two molecules with *S*,*S* configuration (not shown) are related to the *R*,*R* molecules by the centre of inversion in the centrosymmetric P(-1) space group.

The Zn^{II}, Fe^{II}, and Fe^{III} complexes all crystallize in the $P2_1$ space group. In each case, the metal centre has a distorted square pyramidal geometry with the metal sitting above the square plane of donors by 0.34–0.52 Å. There are also two distinct diastereomeric conformations, *M* and *P*, that are in a 1:1 ratio and are related by a pseudo-inversion centre. Each form has diequatorial cyclohexyl backbones, and there is little difference in the N-C-C-N dihedral between them (Table 2). Instead, it is the pivoting of the phenanthryl arms about the C-O-Zn linkages and the accompanying tilting of the phenanthryl rings that relates the two conformers.

Looking at the structures in more detail, the Zn^{II} and Fe^{II} complexes are very similar (Fig. 2): both have axial pyridine donors and closely comparable bond lengths and angles (Table 2). This isostructural relationship is not unexpected, given the similar sizes of the divalent ions and strong (largely ionic) bonding to the phenoxide donors. The phenanthryl arms of both the Zn^{II} and Fe^{II} complexes are significantly tilted with respect to one another. For (*R*,*R*)-**2**(py) the interplanar angles are 48.8° (*M*) and 54.0° (*P*), while for (*R*,*R*)-**3**(py) the angles are 47.9° (*M*) and 53.7° (*P*). It appears that the repulsive steric interactions between the edge and face of the two phenanthryl groups are not sufficient to force them into a more coplanar arrangement. However, these interactions do contribute to significant curvature of the phenanthryl rings away from one another. A measure of curvature is the interplanar angle between the phenol and terminal rings of each phenanthryl group: this is 5.5° and 6.4° for the *M* helix and 3.5° and 10.6° for the *P* helix of (*R*,*R*)-**2**(py). The same trend is seen for (*R*,*R*)-**3**(py) (Table 2).

Some insight into the preference for the 1:1 crystallization of diastereomeric helices may be obtained from examining the crystal packing of (*R*,*R*)-**2**(py). Along the crystallographic *a* axis are arranged columns of molecules with the same conformation and orientation. The arrangement of stacks of *M* and *P* molecules in the crystallographic *bc* plane is shown in Fig. 2*d*. Although columns of homohelical molecules is an efficient packing motif, the axial pyridine ligands

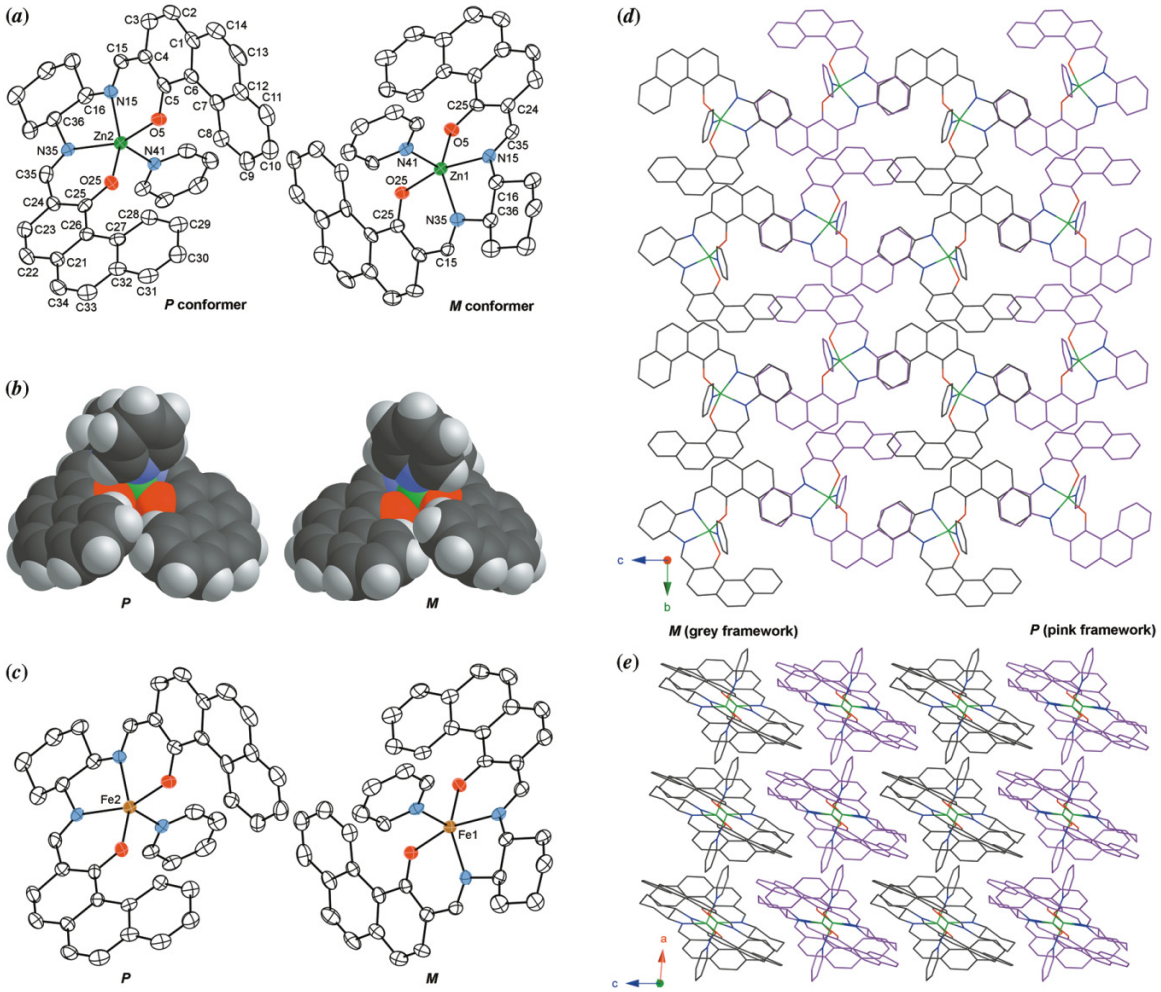
Fig 2. (*a*) Thermal ellipsoid plot (50%) of (*R*,*R*)-**2**(py) showing the relative positions of the two conformers in the unit cell. (*b*) Space-filling plots of the *P* and *M* conformers of (*R*,*R*)-**2**(py). (*c*) Thermal ellipsoid plot (50%) of (*R*,*R*)-**3**(py) showing the relative positions of the two conformers in the unit cell. (*d*) Crystal packing of (*R*,*R*)-**2**(py) viewed down *a*. (*e*) Crystal packing of (*R*,*R*)-**2**(py) viewed down *b*.



do not allow the close approach required for effective space-filling. This is compensated for by partial interlocking of adjacent *M* and *P* molecular stacks: the sidearm termini of *M* molecules are located over the cyclohexyl rings or sidearm termini of molecules with the *P* conformation (Figs. 2*d* and 2*e*). The interlocking of alternate stacks appears to be an important factor favouring the observed 1:1 *M*/*P* composition of the crystal. The iron complex (*R*,*R*)-**3**(py) has the same packing arrangement as (*R*,*R*)-**2**(py).

The Fe^{III} complex (*R*,*R*)-**4** has the same general molecular structure (Fig. 3) as seen for the divalent metal complexes, except that there is now an axial chloro ligand and the interplanar angles between the phenathryl rings are considerably smaller (11.2° for *M* and 12.0° for *P*). The flatter nature of this complex can be readily understood in terms of the stronger M–O bonding for the Fe^{III} complex, which pulls the phenathryl groups closer to one another and increases edge-to-face repulsions, forcing the rings to be more parallel. The lower steric requirements of the axial chloro compared with the pyridine is also a likely factor here. The curvature of the sidearms for (*R*,*R*)-**4** is 12.1° and 11.3° for the *M* conformer and 14.4° and 8.5° for the *P* conformer. The greater degree of curvature seen here is consistent with the closer proximity of the phenathryl rings to one another compared with the divalent complexes.

The crystal packing in (*R*,*R*)-**4** is significantly different than for the divalent metal complexes. Here there is a close 1:1 pairing between the *M* and *P* conformers: they have parallel molecular planes and are rotated 180° with respect to each other. This arrangement can be seen in Fig. 3*a*, and it allows for the helices to pack efficiently because of the complementary shape matching.

NMR Characterization

The ^{1}H and ^{13}C spectra of the ligand (*R*,*R*)-**1** are consistent with a single C_2 symmetric species in solution. The ^{1}H spectrum shows 9 resonances in the 7–11 ppm range, consistent with the aromatic and N=CH signals of a single species. Notable signals in this range are the imine N=C-H protons at 8.61 ppm and the signal at 10.61 ppm, which is due to the bay region hydrogens at the 5-positions of the phenanthryl rings. The bay protons are affected by edge position aromatic deshielding and anisotropic deshielding from the hydroxyl group at the nearby 4-position (5). The

Fig. 3. (*a*) Thermal ellipsoid plot (50%, depth fading) of (*R*,*R*)-**4** showing the relative positions of the two conformers in the unit cell. (*b*) Space-filling plots of the *P* and *M* conformers of (*R*,*R*)-**4**.

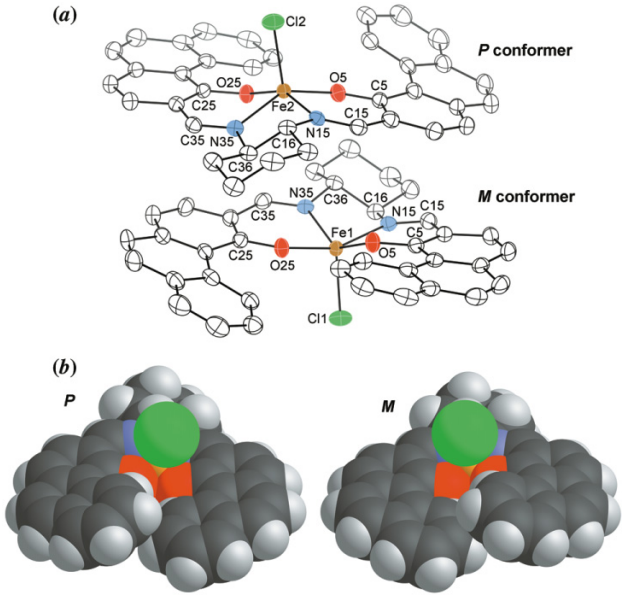

Fig. 4. Top: ECD spectrum of (*R*,*R*)-**1** in THF (2.5×10^{-5} mol/L). Bottom: electronic spectra of (*R*,*R*)-**1** (2.5×10^{-5} mol/L) in 1:1 THF/MeOH, THF, and, cyclohexane.

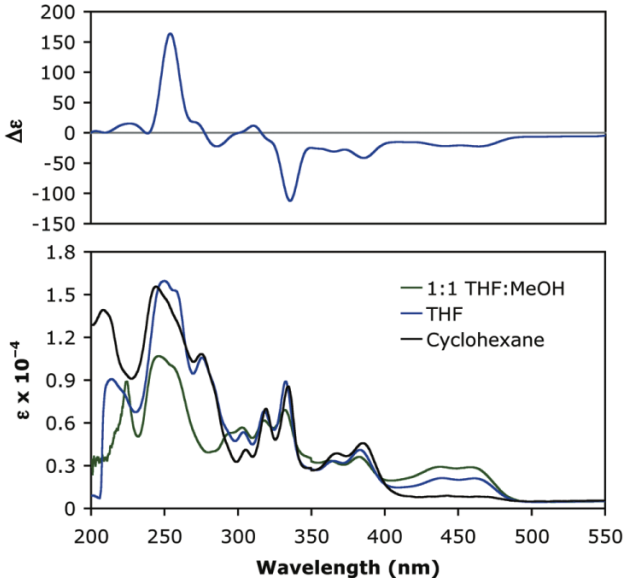

intramolecularly hydrogen-bonded protons appear at 15.97 ppm. While tautomerization is evident from the crystal structure, only an averaged ^{1}H NMR signal is observed, due to rapid proton transfer.

The diamagnetic Zn^{II} complex (*R*,*R*)-**2** has ^{1}H and ^{13}C spectra similar to those of the uncomplexed ligand and they show signals consistent with a C_2 symmetric molecule in solution. The most notable differences with the ligand ^{1}H spectrum are the absence of the phenolic resonance and the significant downfield shift of the bay region proton to 11.79 ppm. This shift is mainly the result of increased anisotropic deshielding by the phenoxide donor at the 4-position (5). The most significant aspect of the spectra of this complex is that they are not consistent with the 1:1 diastereomeric mixture in solution, unless rapid equilibration of *M* and *P* conformers is occurring. This is unlikely, given the significant molecular motions of large groups that would be required. Further support for this conclusion is provided by the –90 °C ^{1}H NMR spectrum of (*R*,*R*)-**2**, which shows signals for only one metal complex. A minor set of signals consistent with another helical conformation is not resolved at this temperature. Thus, the NMR spectra suggest that there is predominantly one thermodynamically favoured conformation in solution (>95%).

The paramagnetic iron complexes have broad ^{1}H NMR spectra over a wide chemical shift range (–28 to +42 and –3 to +17 for (*R*,*R*)-**3** and (*R*,*R*)-**4**, respectively), and ^{1}H-^{1}H couplings are not resolved. However, the number of signals present for each of these complexes is consistent with one major C_2 symmetric complex in solution. Just as for the Zn^{II} complex, the NMR data of the iron complexes are at odds with the solid state structures, which show a 1:1 *M*/*P* mixture.

Electronic and ECD spectroscopy

Neutral uncomplexed Schiff bases and salens can exist as an equilibrium mixture of keto-amine and the enol- imine tautomers, and the differences in electronic spectra of the two species is often diagnostic (4). The most notable difference is a lower energy $\pi \rightarrow \pi^*$ transition for the ketone compared with that of the imine. This is evident in the electronic spectrum of (*R*,*R*)-**1**: the ketone bands appear at 438 and 461 nm, while the imine bands are at 365 and 383 nm. The position of the equilibrium can be shifted by a change in solvent polarity, with more polar solvents favouring the keto-amine isomer, as has been seen for other Schiff bases (4). Figure 4 shows the electronic spectra collected in cyclohexane, THF, and a 1:1 MeOH/THF mixture. A progression to a larger proportion of keto-amine isomer in this series is seen and is especially evident in the 350–500 nm region.

The electronic and ECD spectra of (*R*,*R*)-**2** and (*R*,*R*)-**3** (Fig. 5) are similar in appearance, with the iron complex having broader absorptions, especially in the ECD spectrum. The low-energy envelope (350–460 nm) is attributable primarily to the π-π^* transition of the imine groups and is shifted to lower energy compared with the free ligand, as expected (6). The negative Cotton effect associated with this transition confirms a diequatorial 1*R*,2*R* configuration and non-coplanar imines (7). The appearance of the 200–380 nm spectral region is consistent with that of substituted phenanthrenes (8). The ECD spectra show strong signals, suggesting that there is one dominant helical form in solution, as opposed to a pseudo-racemic 1:1 *M*/*P* mixture (as observed in the solid). This is supported by DFT simulated spectra (Fig. 5*c*), which show a good match between the experimental spectrum of (*R*,*R*)-**2** and the simulated spectrum of the *M* conformer. Correspondingly, the *P* conformer simulated spectrum resembles the mirror image of both the experimental spectrum and the *M* conformer simulated spectrum.

DFT calculations (B3LYP/6-31G(d,p)) for (*R*, *R*)-**2**(py) indicate that the *M* conformer is thermodynamically favoured over the *P* conformer. The calculated energy difference is 2.5 kcal mol^{-1} (1 cal = 4.184 J) based on the crystal struc-

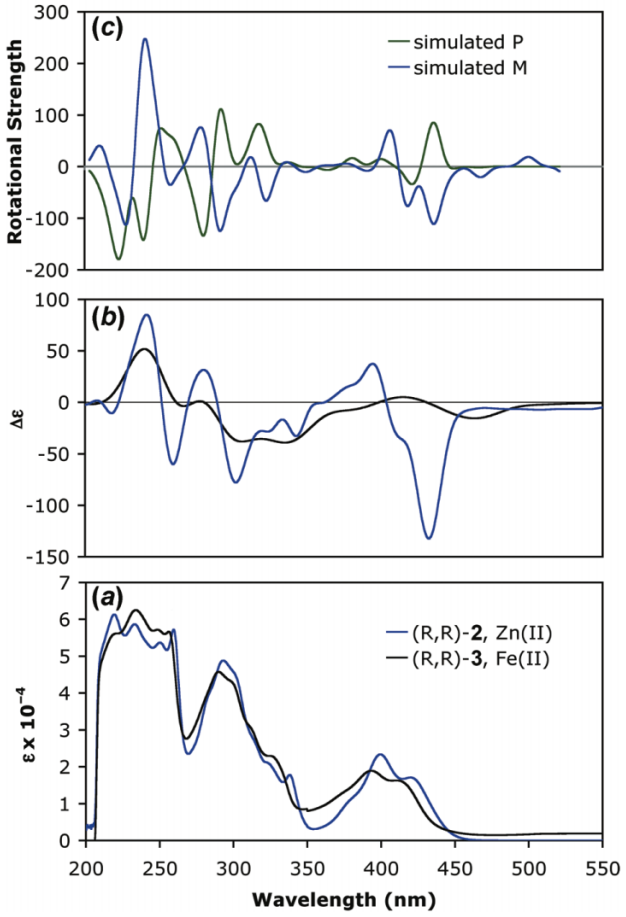
Fig. 5. (*a*) Electronic spectra and (*b*) ECD spectra of (*R*,*R*)-**2** (2.5×10^{-5} mol/L) and (*R*,*R*)-**3** (2.0×10^{-5} mol/L) in THF ($\Delta\varepsilon$ is in units of $(mol/L)^{-1}\ cm^{-1}$). (*c*) Simulated ECD spectra of the *M* and *P* forms of (*R*,*R*)-**2** (rotational strength is in 10^{-40} esu cm erg G^{-1}).



ture geometries and 1.5 kcal mol^{-1} based on AM1 minimized structures. This suggests that the *M* conformer is the major species in solution, consistent with the conclusion from the ECD simulations.

Experimental section[3]

General methods

The sidearm precursor 4-hydroxy-3-phenanthrenecarboxaldehyde was synthesized as reported previously (2). All air and (or) moisture sensitive compounds were manipulated using standard Schlenk techniques or in a glove box under a nitrogen atmosphere (9). All solvents were stored under vacuum over sodium benzophenone ketyl, magnesium, or calcium hydride prior to use. Solvents used in metalation reactions were degassed before use and inert gas was purified by passing through 4 Å molecular sieves and Engelhard Q5 catalyst. UV–vis data were collected on a Varian Cary 500 spectrometer and CD data were collected using a JASCO 720 Spectropolarimeter. Solution samples for these techniques were prepared using dried spectroscopic grade tetrahydrofuran, and solutions were loaded into a 1.00 cm quartz cell. UV–vis and CD data were collected at ambient temperature. NMR data were collected on a Varian Unity 400 MHz spectrometer using the residual solvent protons as an internal standard.

ECD simulations

All DFT computations relating to ECD spectroscopy were carried out using version 2005.0 lb of the Amsterdam density functional (ADF) software suite. Minimized geometries were obtained from crystallographic data employing a triple-ζ Slater-type basis set, including one polarization function (TZP) and the Vosko–Wilk–Nusair (10) (VWN) local density approximation. The addition of a second polarization function yielded minimal, if any, improvement in the results. For Zn, the 1s, 2s, and 2p orbitals were kept frozen. For C, N, and O, only the 1s orbital was kept frozen. The same TZP basis set and other parameters were utilized in the spectroscopic computations. Excitation energies and rotational strengths were calculated for the first 250 non zero strength transitions of (*R*,*R*)-**2**. When compared with experimental data, it is evident that the energies are overestimated by an average of ca. 0.1 eV. This is not unexpected given the approximations inherent in the LDA functional employed (11). In view of the overestimation, a 0.1 eV correction was applied to the calculated energies. Gaussian shaped distributions were subsequently generated from the computed data using a line width ($\Delta\lambda_{1/2}$) of 11 nm, and the simulated spectra were obtained by superposition of the individual Gaussian curves.

3,3′-[(1*R*,2*R*)-1,2-Cyclohexanediylbis-(nitrilomethylidyne)]bis-4-phenanthrenol (*R*,*R*)-1

A mixture of (1*R*,2*R*)- diaminocyclohexane (0.39 g, 3.4 mmol) and 4-hydroxy-3-phenanthrenecarboxaldehyde (1.50 g, 6.80 mmol) in ethanol (80 mL) was refluxed for 2 h. The resulting suspension was filtered while hot, and the yellow precipitate was collected, washed with boiling ethanol (40 mL), and dried in vacuo to give (*R*,*R*)-**1** (1.662 g, 94% yield). ^{1}H NMR ($CDCl_3$, 400 MHz) δ: 1.50–1.63 (m, 2 H, CH), 1.82–1.94 (m, 2 H, CH), 1.95–2.04 (m, 2 H, CH), 2.17–2.25 (m, 2 H, CH), 3.46–3.55 (m, 2 H, CH), 7.07 (d, 2 H, *J* = 8.3 Hz, CH), 7.14 (d, 2 H, *J* = 8.3 Hz, CH), 7.54–7.61 (m, 4 H, CH), 7.68–7.73 (m, 2 H, CH), 7.79 (d, 2 H, *J* = 8.7 Hz, CH), 7.84 (dd, 2 H, *J* = 1.2, 7.9, CH), 8.32 (d, 2 H, *J* = 3.7 Hz, CH), 10.09 (d, 2 H, *J* = 8.7 Hz, CH), 15.42 (br, s, 2 H, OH). ^{13}C NMR ($CDCl_3$, 100 MHz) δ: 24.51, 33.07, 70.51, 114.15, 118.08, 121.06, 125.95, 127.11, 127.33, 128.47, 129.25, 129.25, 130.68, 131.88, 132.59, 137.29, 165.09, 167.92. Anal. calc. for $C_{36}H_{30}N_2O_2$: C 82.73, H 5.79, N 5.36; found: C 82.62, H 6.01, N 5.36.

3,3′-[*trans*-1,2-Cyclohexanediylbis-(nitrilomethylidyne)]bis-4-phenanthrenol (*rac*)-1

The procedure for (*R*,*R*)-**1** was followed using *trans*-1,2-diaminocyclohexane in place of the *R*,*R* enantiomer to give *rac*-**1** (0.339 g, 96% yield). ^{1}H and ^{13}C NMR spectra were

identical to that of compound (*R*,*R*)-**1**. Anal. calc. for $C_{36}H_{30}N_2O_2$: C 82.73, H 5.79, N 5.36; found: C 82.41, H 5.82, N 5.37. Single crystals suitable for X-ray analysis were grown by slow diffusion of hexanes into a solution of *rac*-**1** in methylene chloride.

(*R*,*R*)-2 (Zn^{II} complex of (*R*,*R*)-1)

Anhydrous zinc(II) chloride (0.079 g, 0.58 mmol), sodium methoxide (0.093 g, 1.73 mmol), and (*R*,*R*)-**1** (0.30 g, 0.58 mmol) were suspended in a 2:1 mixture of methylene chloride/ethanol (15 mL). After stirring for 12 h, the reaction mixture was concentrated to a yellow solid that was then dissolved into THF (20 mL). The solution was filtered to remove fine insoluble solids, and the clear filtrate was diluted with ethanol (40 mL). Stirring for 3 h resulted in the gradual formation of a yellow precipitate. The precipitate was collected and washed consecutively with methylene chloride (5 mL) and ethanol (5 mL) to afford (*R*,*R*)-**2** (0.200 g, 59% yield). ^{1}H NMR (pyridine-d_5, 400 MHz) δ: 1.20–1.34 (m, 4 H, CH), 1.79 (br, s, 2 H, CH), 2.31 (br, s, 2 H, CH), 3.22 (br, s, 2 H, CH), 7.30 (d, 2 H, *J* = 8.2 Hz, CH), 7.57–7.66 (m, 4 H, CH), 7.80–7.87 (m, 4 H, CH), 7.96 (d, 2 H, *J* = 8.6 Hz, CH), 8.01 (d, 2 H, *J* = 7.9 Hz, CH), 8.63 (s, 2 H, CH), 11.79 (d, 2 H, *J* = 8.5 Hz, CH). ^{13}C NMR (pyridine-d_5, 100 MHz) δ: 25.08, 28.79, 66.31, 114.43, 117.48, 125.31, 125.69, 128.36, 128.55, 128.95, 130.04, 130.84, 133.31, 134.26, 134.98, 138.71, 166.27, 174.70. Anal. calc. for $C_{36}H_{28}N_2O_2Zn$: C 73.79, H 4.82, N 4.78; found: C 73.60, H 5.01, N 4.68. Lowering and raising (–90 to +50 °C) the temperature of a 1:1 CD_2Cl_2/pyridine-d_5 solution did not appreciably change the spectra, and no exchange was evident. Single crystals of (*R*,*R*)-**2** suitable for X-ray analysis were grown via slow cooling from boiling pyridine.

(*R*,*R*)-3 (Fe^{II} complex of (*R*,*R*)-1)

Anhydrous iron(II) chloride (0.073 g, 0.58 mmol), sodium methoxide (0.093 g, 1.7 mmol), and (*R*,*R*)-**1** (0.30 g, 0.58 mmol) were suspended into a 2:1 mixture of methylene chloride/ethanol (15 mL). After stirring for 12 h, the solvent was removed in vacuo to give a green-brown solid. The solid was dissolved into THF (15 mL), and the solution was filtered to remove fine insoluble solids. The resulting clear filtrate was diluted with ethanol (45 mL) and stirred for 30 min, resulting in the formation of a purple precipitate. This was collected and then suspended into methylene chloride (10 mL). After stirring for 15 min, the solid was recollected and dried in vacuo to afford (*R*,*R*)-**3** (0.21 g, 64% yield). ^{1}H NMR (pyridine-d_5, 400 MHz) δ: –25.11 (br, s, 2 H, CH), –11.69 (s, 2 H, CH), –4.80 (br, s, 2 H, CH), –3.28 (s, 2 H, CH), 1.66 (s, 2 H, CH), 5.26 (s, 2 H, CH), 10.13 (s, 2 H, CH), 10.90 (s, 2 H, CH), 17.14 (s, 2 H, CH), 24.61 (s, 2 H, CH), 40.42 (br, s, 2 H, CH). Anal. calcd. for $C_{36}H_{28}N_2O_2Fe$: C 75.01, H 4.90, N 4.86; found: C 74.94, H 5.00, N 4.71. Single crystals suitable for X-ray analysis were grown by slow diffusion of methanol into a pyridine solution of (*R*,*R*)-**3**.

(*R*,*R*)-4 (Fe^{III} complex of (*R*,*R*)-1)

Anhydrous iron(III) chloride (0.093 g, 0.56 mmol), sodium methoxide (0.093 g, 1.7 mmol), and (*R*,*R*)-**1** (0.29 g, 0.56 mmol) were suspended into a 2:1 mixture of THF/ethanol (15 mL) and stirred for 12 h. The solvent was removed in vacuo, and THF (80 mL) was added to the resulting solid. After stirring for 15 min, the insoluble material was removed by filtration and the red-black solution was diluted with ethanol (80 mL). Upon concentration to 1/2 volume, a black precipitate formed that was collected and dried in vacuo to afford (*R*,*R*)-**4** (0.082 g, 24%). The ^{1}H NMR spectrum consisted of broad overlapping signals that were not readily assignable. Anal. calcd. for $C_{36}H_{28}N_2O_2FeCl$: C 70.66, H 4.61, N 4.58; found: C 70.40, H 4.34, N 4.52. Single crystals suitable for X-ray analysis were grown by slow diffusion of diethyl ether into a methylene chloride solution of (*R*,*R*)-**4**.

Conclusions

Two diastereomeric conformers crystallize in a 1:1 ratio for each of the metal complexes. This is an unusual assembly mode, which has been observed in only a few systems, (12,13), in addition to our previous studies of an analogous Fe^{II} complex with an extended benz[*a*]anthryl sidearm (2). For the complexes of (*R*,*R*)-**1,** the adoption of *pseudo*-enantiomeric helical conformers is favoured in the crystalline solid. This appears to be the result of more efficient packing when *M* and *P* helices, which have complementary shapes, can associate in the crystal. For these complexes the packing forces can dominate the crystal composition since the conformers readily interconvert and the energy difference between them is small (~2 kcal mol^{-1}). However, the energy difference is large enough that the thermodynamically preferred *M* conformer dominates in solution. Thus, there is a solution to solid chiral switching that occurs for these complexes, although the rate of the process is as yet unknown. We are currently investigating other metal complexes of (*R*,*R*)-**1** and examining their utility as asymmetric catalysts.

Unexpectedly different reactions of $[(arene)Mn(CO)_3]^+$ cations (arene = trindane, indane, tetralin, or dibenzosuberane) with potassium *t*-butoxide — C-H insertions, haptotropic shifts, dimerization, or elimination[1]

Nada Reginato, Laura E. Harrington, Yannick Ortin, and Michael J. McGlinchey

Abstract: [(η^6-Trindane)$Mn(CO)_3$][BF_4] (**1**) reacts with *tert*-BuOK in THF in the presence of alkyl halides (CH_2=$CHCH_2Br$, CH_3I) to yield the corresponding (η^6-$C_{15}H_{18}$)$Mn(CO)_2X$, where X = Br (**3**) or I (**4**). In contrast, **1** and *tert*-BuOK react, in the presence of a donor ligand, to generate (η^5-$C_{15}H_{15}$)$Mn(CO)_2L$, where L = CO (**7**), $P(OMe)_3$ (**8**), or PPh_3 (**9**), in which the metal has migrated from the central ring onto a peripheral ring that has lost three hydrogens; [(η^6-indane)$Mn(CO)_3$][BF_4] behaves similarly. A mechanism is proposed in which the initially formed (η^6-trindane)$Mn(CO)_2CO_2$-*tert*-Bu suffers the loss of CO_2 and isobutene to yield the hydride, (η^6-trindane)$Mn(CO)_2H$, that in turn undergoes three successive C-H insertions with concomitant loss of two molecules of dihydrogen. In contrast, [(η^6-tetralin)$Mn(CO)_3$][PF_6] (**17**) and [(η^6-dibenzosuberane)$Mn(CO)_3$][BF_4] (**23**) each suffer deprotonation at a benzylic site. In the first case, the zwitterion formed attacks its progenitor to yield a tetralenyl-substituted (η^5-cyclohexadienyl)$Mn(CO)_3$ complex (**21**); however, for the dibenzosuberane complex (**23**) the elimination product (**28**) is stable. X-ray crystal structures are reported for **3**, **4**, **7**, **8**, **23**, **28**, and for the phosphite complexes [(η^6-trindane)$Mn(CO)\{P(OMe)_3\}_2$][BF_4] (**15**) and [(η^6-tetralin)$Mn(CO)_2\{P(OMe)_3\}$][PF_6] (**20**).

Key words: arene–manganese, organometallic cations, deprotonations, X-ray crystallography.

Résumé : Le [(η^6-trindane)$Mn(CO)_3$[BF_4] (**1**) réagit avec le *tert*-BuOK, dans le THF, en présence d'halogénures d'alkyles (CH_2=$CHCH_2Br$ et le CH_3I) pour conduire à la formation des (η^6-$C_{15}H_{18}$)$Mn(CO)_2X$ dans lesquels X = Br (**3**) ou I (**4**). Par opposition, le composé **1** réagit avec la *tert*-BuOK, en présence d'un ligand donneur, pour générer les complexes (η^5-$C_{15}H_{15}$)$Mn(CO)_2L$ dans lesquels L = CO (**7**), $P(OMe)_3$ (**8**) ou PPh_3 (**9**) alors que le métal a migré du noyau central vers un noyau périphérique avec perte de trois atomes d'hydrogène; Le [(η^6-indane)$Mn(CO_3)$][BF_4] se comporte de la même manière. On propose un mécanisme dans lequel l'entité (η^6-trindane)$Mn(CO)_2CO_2$-*tert*-Bu subit une perte de CO_2 et d'isobutène pour fournir l'hydrure (η^6-trindane)$Mn(CO)_2H$ qui subit à son tour trois insertions successives de C-H avec la perte concomitante de deux molécules de dihydrogène. Par ailleurs, le [(η^6-tétraline)$Mn(CO)_3$][PF_6] (**17**) et le [(η^6-dibenzosubérane)$Mn(CO)_3$[BF_4] (**23**) subissent chacun une déprotonation au niveau du site benzylique. Dans le premier cas, le zwitterion qui est formé attaque son progéniteur pour conduire à la formation d'un complexe (η^5-cyclohexadiényl)$Mn(CO)_3$ portant un substituant tétralényle (**21**); toutefois, pour le complexe avec le dibenzosubérane (**23**), le produit d'élimination (**28**) est stable. Faisant appel à la diffraction des rayons X, on a déterminé et on décrit les structures cristallines des composés **3**, **4**, **7**, **8**, **23** et **28** ainsi que celles des complexes de phosphite, [(η^6-trindane)$Mn(CO)\{P(OMe_3\}_2$][BF_4] (**15**) et [(η^6-tétraline)$Mn(CO)_2\{P(OMe_3\}$][BF_6] (**20**),

Mots-clés : arène-manganèse, cations organométalliques, déprotonations, cristallographie par diffraction des rayons X.

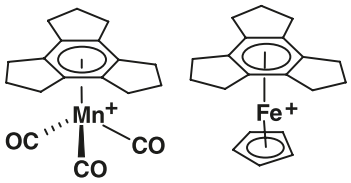
Introduction

As part of a program directed towards an organometallic route to sumanene (1), we began to develop the organometallic chemistry of tri(cyclopentano)benzene (trindane) (2, 3), a tetracyclic substructure of the target molecule. To this end, we chose to attempt the alkylation of all six *exo*-benzylic positions of (η^6-trindane)ML_n using the now classic Astruc methodology (4). Since Eyman and co-workers (5) have already shown that [(hexamethylbenzene)$Mn(CO)_3$]$^+$ readily undergoes abstraction of a benzylic proton to yield the corresponding cyclohexadienyl system that reacts with electrophiles to functionalize the benzylic site (5), we decided to study the reactions of [(η^6-trindane)$Mn(CO)_3$] [BF_4] (**1**) and [(η^6-trindane)$Fe(C_5H_5)$][PF_6] (**2**) with potassium *tert*-butoxide, and subsequently with alkyl halides. However, as reported in a preliminary communication (6), the reactions of **1** led to unexpected rearrangement products. We now describe these studies more fully, and also report how the reactions have been extended to the analogous [(η^6-arene)$Mn(CO)_3$]$^+$ systems, whereby the five-membered rings in trindane or indane have been replaced by six- and seven-membered rings in tetralin and dibenzosuberane, respectively.



1 **2**

Results and discussion

The activation of benzylic sites by incorporation of a π-complexed organometallic moiety is a well-established phenomenon, and has been attributed to a combination of the electron-withdrawing effect of the metal and the resonance stabilization of the conjugate base (7). Typically, molecules of the type (η^6-arene)ML_n, where ML_n is $Cr(CO)_3$, $Mn(CO)_3^+$, or $Fe(C_5H_5)^+$, undergo ready deprotonation at benzylic positions; subsequent treatment with alkyl halides leads to attack at the benzylic site. Particularly elegant examples are provided by Jaouen et al.'s (8) specific functionalization at the 6β position in (3-methoxyestradiol)[α-$Cr(CO)_3$], and by Astruc's (9) systematic construction of organometallic dendrimers. Another very ingenious application that takes advantage of the steric blocking of one face of the arene by a metal tripod is the preparation of an artificial receptor, whereby trindane was benzylated at the three *exo*-wingtip positions (10).

Reactions of [(η^6-trindane)$Fe(C_5H_5)$][PF_6]

In light of these precedents, [(η^6-trindane)$Fe(C_5H_5)$][PF_6] (**2**) and *tert*-BuOK were mixed as dry solids and then treated with excess allyl bromide (or methyl iodide) in THF in the hope that all six *exo*-benzylic sites would be alkylated. In a previous study (2), we had noted that the corresponding reaction of **2** and *tert*-BuOK in the presence of DMSO-d_6 yielded dodeca-deuterated **2** as the major product; that is, all twelve benzylic positions, both exo and endo, had undergone exchange. Interestingly, use of either allyl bromide or methyl iodide again led to extensive multiple alkylation, and mass spectrometric data indicated the incorporation of at least ten, and possibly twelve, allyl or methyl substituents. After many attempts to obtain a sample of the polymethylated complex appropriate for an X-ray study, data sets were acquired on several crystals of rather poor quality, but disorder problems have so far prevented the satisfactory resolution of these structures.

Reactions of [(η^6-trindane)$Mn(CO)_3$][BF_4]

Since an $M(CO)_3$ moiety (M = Cr, Mn) has been shown to generate a larger cone angle than an $Fe(C_5H_5)$ fragment (11), the tripodal group $Mn(CO)_3^+$ was selected as an activating agent, not only to enhance the acidity at the benzylic positions but in addition to act as a stereodirecting group by blocking one π-face of the arene ligand. Consequently, our focus switched to the manganese cation, **1**, which, when mixed with *tert*-BuOK as dry solids, and then treated with excess allyl bromide in THF furnished after chromatographic separation a deep red crystalline material whose NMR, mass, and IR spectra indicated it to be (η^6-trindane)$Mn(CO)_2Br$ (**3**). The analogous reaction of **1**, *tert*-BuOK, and methyl iodide gave the corresponding (η^6-trindane)$Mn(CO)_2I$ (**4**).

The X-ray crystal structures of **3** and **4** appear in Figs. 1*a* and 1*b*, respectively, and are reminiscent of the geometry previously reported for (η^6-C_6Me_6)$Mn(CO)_2Cl$ whereby the tripod is staggered relative to the alkyl substituents (12). Moreover, the cyclopentene rings in **3** (and **4**) adopt envelope conformations such that the "wingtip" methylene groups are folded endo with respect to the plane of the central six-membered ring, as was previously found in both (η^6-trindane)$Cr(CO)_3$ and [(η^6-trindane)$RuCl_2${$P(OMe)_3$}] (2, 3). The structures of **3** and **4** may also be compared with the known complexes [tri(cyclohexano)benzene]ML_n, where ML_n = $Cr(CO)_3$ or $Mn(CO)_3^+$, whereby the $M(CO)_3$ unit displays the typical staggered orientation and the peripheral rings exhibit the "half-boat" conformation (13).

Another structural feature of interest for compounds **3** and **4** is that, in each case, the central ring is slightly folded such that the arene carbons C(1) and C(2), trans to the halogen atom, are slightly closer to the manganese atom than are the other four carbons [i.e., C(3), C(4), C(5), C(6)]. Whether this folding is attributable to packing effects, or to the weaker trans influence of the halide, is not clear; however, it parallels the folding found in (η^6-C_6Me_6)$Mn(CO)_2Cl$. The manganese atoms in **3** and **4** are located 1.677 and 1.678 Å, respectively, below the centroid of the six-membered ring, slightly closer than is found in (η^6-C_6Me_6)$Mn(CO)_2Cl$ (1.706(3) Å) (12). The Mn–CO bond lengths are normal (1.781(8)–1.802(10) Å), the Mn-C-O angles are slightly less than 180°, and the Mn-ring-carbon distances range from 2.133(7) to 2.230(4) Å.

As expected, the carbonyl IR stretching frequencies in the series (η^6-trindane)$Mn(CO)_2X$ decrease as a result of the transformation from a cationic to a neutral species: X = Cl (1980, 1931 cm^{-1}), X = Br (1971, 1927 cm^{-1}), X = I (1973, 1926 cm^{-1}). The starting material, [(η^6-trindane)$Mn(CO)_3$][BF_4] (**1**) exhibits carbonyl stretches at 2056 and 1997 cm^{-1}. These data are similar to the ν_{CO} values previously reported for (η^6-C_6Me_6)$Mn(CO)_2X$ complexes: 1972, 1920 cm^{-1}; 1971,

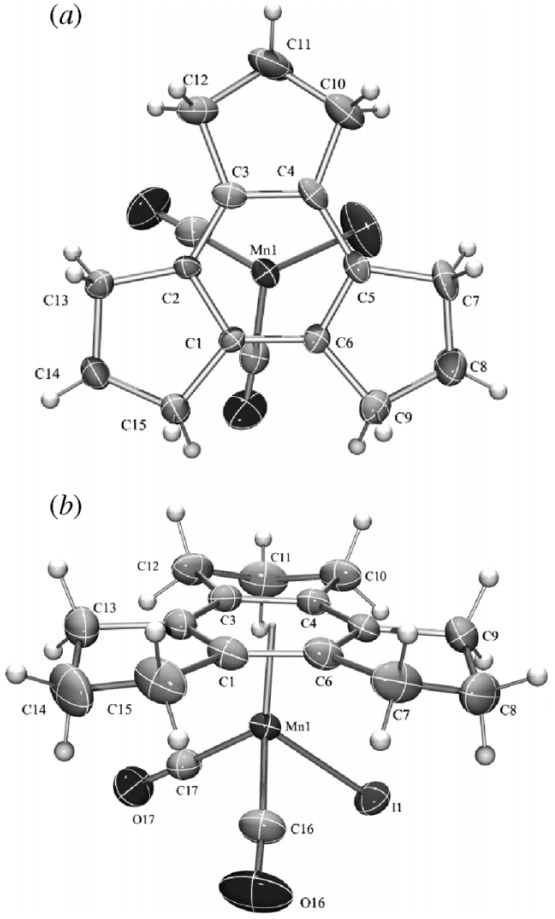
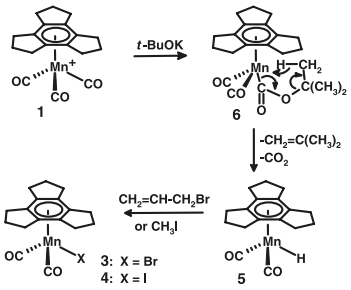
Fig. 1. (*a*) The molecular structure of (η^6-trindane)$Mn(CO)_2Br$ (**3**) showing the staggered orientation of the tripodal $Mn(CO)_2Br$ moiety. (*b*) The molecular structure of (η^6-trindane)$Mn(CO)_2I$ (**4**) illustrating the envelope conformation of the peripheral rings. Thermal ellipsoids are shown at the 30% probability level.



1921 cm^{-1}; and 1968, 1920 cm^{-1}; where X = Cl, Br, and I, respectively (12).

Since replacement of a carbonyl by a phosphine or a halide in $[(\eta^6\text{-}C_6Me_6)Mn(CO)_3]^+$ normally requires either photolysis or use of Me_3NO (14, 15), it was somewhat surprising that the formation of the (η^6-trindane)$Mn(CO)_2X$ species, **3** and **4**, should have occurred so readily. Moreover, because (η^6-C_6Me_6)$Mn(CO)_2H$ is known to yield (η^6-C_6Me_6)$Mn(CO)_2Cl$ in the presence of CCl_4 or $CHCl_3$ (but not CH_2Cl_2) (12), one is tempted to invoke the intermediacy of (η^6-trindane)$Mn(CO)_2H$ (**5**). Eyman and co-workers (16) have shown that (η^6-C_6Me_6)$Mn(CO)_2I$ reacts with *tert*-butyllithium to yield thermally stable (η^6-C_6Me_6)$Mn(CO)_2H$, apparently via loss of isobutene from the presumed *tert*-butyl intermediate. Furthermore, as the cationic complexes $[(\eta^6\text{-arene})Mn(CO)_3]^+$, (arene = C_6H_6 or C_6Me_6), are known to react with methoxide in methanol to yield the rather unstable esters, (η^6-arene)$Mn(CO)_2CO_2Me$ (17), one might propose that a reaction between **1** and *tert*-BuOK could generate the *tert*-butyl ester (**6**) that readily eliminates both isobutene and carbon dioxide via a very favorable six-membered transition state to produce **5**, as depicted in Scheme 1. Interestingly, treatment of **1** with *tert*-BuOK in CH_2Cl_2 gave (η^6-trindane)$Mn(CO)_2Cl$, suggesting that **5** is more reactive than $(C_6Me_6)Mn(CO)_2H$ towards alkyl halides.

Scheme 1. Proposed mechanism of formation of **3** and **4**.



Although it is well established that $(C_6Me_6)Mn(CO)_2H$ can be prepared by treatment of $(C_6Me_6)Mn(CO)_2Br$ with $[Bu_4N][BH_4]$ (12), numerous attempts to synthesize (η^6-trindane)$Mn(CO)_2H$ from the corresponding bromide **3** by this route, or to detect the hydride signal by NMR at low temperature, were unsuccessful. Consequently, we chose to try to intercept the purported hydride **5**, either as (trindane)$Mn(CO)(PR_3)H$, or as the formyl complex (trindane)$Mn(CO)(CHO)(PR_3)$, in the absence of RBr.

When the cation **1** and *tert*-BuOK were treated with trimethyl phosphite in THF and allowed to stir at 40 °C for 20 h, to our surprise, the two products isolated after chromatographic separation, were yellow crystalline materials **7** and **8** whose ^1H and ^{13}C NMR spectra indicated that the three-fold symmetry of the trindane ligand had been broken. The mass spectra of **7** and **8** exhibited parent peaks at *m*/*z* = 334 and 430, respectively, indicating a molecular formula of $(C_{15}H_{15})Mn(CO)_2L$, where L = CO for **7**, and L = $P(OMe)_3$ for **8**. Both products were definitively characterized by X-ray crystallography as η^5-indenyl complexes in which the manganese has migrated from the central arene onto a five-membered ring that has evidently lost three hydrogens. The analogous complex (**9**), where L = PPh_3, is also accessible in this manner. Likewise, the corresponding reactions of [(η^6-indane)$Mn(CO)_3$][BF_4] (**10**) and *tert*-BuOK yield the known complexes (η^5-indenyl)$Mn(CO)_2L$, where L = $P(OMe)_3$ or PPh_3 (18). The IR spectra of **7** (ν_{CO} absorptions at 2016 and 1934 cm^{-1}) and **8** (ν_{CO} at 1944 and 1876 cm^{-1}) each exhibit two carbonyl bands, and are in accord with those of the closely analogous systems (η^5-C_5H_5)$Mn(CO)_3$ (ν_{CO} at 2025 and 1938 cm^{-1}) and (η^5-C_5H_5)$Mn(CO)_2[P(OMe)_3]$ (ν_{CO} at 1948 and 1884 cm^{-1}).

The structures of the rearranged molecules **7** and **8** are shown in Figs. 2*a* and 2*b*, respectively, and reveal in each case a "piano stool" structure with the $Mn(CO)_2L$ tripod coordinated in an η^5-fashion to a peripheral five-membered ring. The manganese atoms in **7** and **8** lie 1.824 and 1.797 Å, respectively, below the centroid of the five-membered ring. The Mn-to-cyclopentadienyl-carbon distances range from 2.114(2) to 2.235(2) Å, and are comparable to those reported for (η^5-cyclopenta[*def*]phenanthrenyl)$Mn(CO)_3$ (19).

In Scheme 2, a mechanistic rationale to account for these novel products is offered. We suggest that in the absence of an alkyl halide, the initially generated (trindane)$Mn(CO)_2H$ (**5**) undergoes a hydrogen migration (presumably via an agostic interaction) from an *endo*-benzyl site onto the metal thus producing the cyclohexadienyl complex (**11**) that in turn

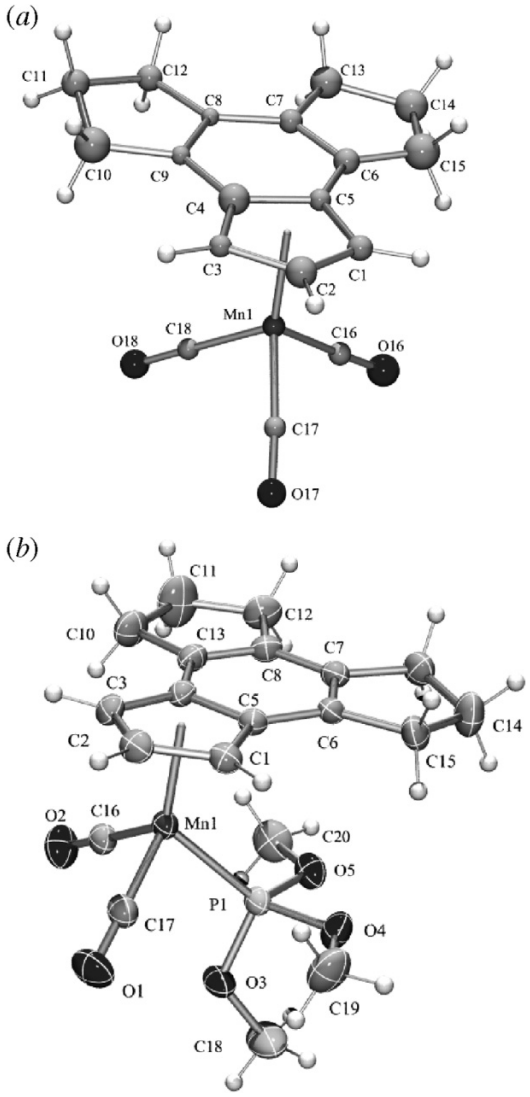
Fig. 2. (*a*) Molecular structure of $(C_{15}H_{15})Mn(CO)_3$ (**7**). (*b*) Molecular structure of $(C_{15}H_{15})Mn(CO)_2[P(OMe)_3]$ (**8**). Thermal ellipsoids are shown at the 30% probability level.



loses dihydrogen to give **12**. A second *endo*-benzyl hydrogen migration to yield the isoindene framework (**13**) is followed by the final hydrogen migration producing **14**. Loss of dihydrogen and incorporation of either a carbonyl or a phosphite ligand would give the observed products **7** or **8**, respectively.

In seeking a precedent for the proposal outlined above, we note the report by Crabtree and Parnell (20) wherein $[(\eta^6\text{-indane})Ir(PPh_3)_2]^+$ undergoes dehydrogenation and an η^6-to-η^5 haptotropic shift at 80 °C to furnish $[(\eta^5\text{-indenyl})Ir(PPh_3)_2(H)]^+$. Moreover, Ustynyuk and co-workers (21) have shown that $(\eta^5\text{-indenyl})Cr(CO)_3Me$ undergoes a "ricochet reaction" in which the methyl is delivered onto the five-membered ring and the tricarbonylchromium fragment migrates to the six-membered ring, as depicted in Scheme 3. Density functional theory calculations by these workers indicate that the reaction proceeds through an isoindene structure in which the chromium is bonded to the diene portion of the six-membered ring and one double bond of the

cyclopentadiene ring and provide some justification for the structures **12** and **13** proposed in Scheme 2.

Other (trindane)ML_3 complexes (M = Mn, Re)

With the aim of selectively deprotonating only the *exo*-benzylic positions of trindane, we chose to replace one or more of the carbonyl ligands in **1** with somewhat more sterically demanding phosphite substituents, even though such an approach could diminish the acidic character of the benzylic sites. Thus, treatment of $[(\eta^6\text{-trindane})Mn(CO)_3][BF_4]$ (**1**) with trimethyl phosphite and trimethylamine N-oxide furnished a yellow crystalline solid that was characterized spectroscopically and by X-ray crystallography as $[(\eta^6\text{-trindane})Mn(CO)\{P(OMe)_3\}_2][BF_4]$ (**15**). The IR spectrum displayed a single carbonyl stretch at 1911 cm^{-1}, similar to that previously reported for $[(\eta^6\text{-}C_6Me_6)Mn(CO)\{P(OMe)_3\}_2][PF_6]$ (14). Figure 3*a* depicts the cationic portion of **15**, which has the conventional piano stool structure typical of half-sandwich complexes; the carbonyl and the two trimethyl phosphite ligands adopt a staggered conformation relative to the carbon atoms of the arene ring, and the manganese atom is located 1.724 Å below the centroid of the arene. The Mn–C (arene) bond lengths range from 2.194(4) to 2.237(3) Å, the Mn-CO and two Mn-P distances are 1.772(4), 2.1996(12), and 2.2174(14) Å, respectively, and the Mn-C-O angle is reduced to 173.9(4)°. As far as we are aware, the only other (arene)manganese-bisphosphite complex to have been crystallographically characterized is $[(\eta^6\text{-toluene})Mn(CO)\{P(OEt)_3\}_2][PF_6]$ (22); the bis-chelated di-tertiary phosphine, $[(\eta^6\text{-}C_6H_6)Mn(CO)\{\eta^2\text{-}PPh_2(CH_2)_3PPh_2\}][PF_6]\cdot 2CH_3CN$ and $(\eta^5\text{-}C_6Me_6H)Mn(CO)[P(OMe)_3]_2$ have also been reported (23, 24).

Figure 3*b* shows a space-filling view of **15** that emphasises the degree of crowding on the endo side of the complexed trindane ligand, thus restricting access to that face. However, because of the rather poor yield (11%) of **15**, deprotonation or other further reactions of this system were not investigated. This low yield follows the trend observed for analogous compounds such as $[(\eta^6\text{-toluene})Mn(CO)\{P(OR)_3\}_2][PF_6]$ where R is Me or Et (22). Likewise, treatment of $[(\eta^6\text{-toluene})Mn(CO)_3][PF_6]$ with Me_3NO and PPh_3 failed to bring about substitution of the carbonyl groups by triphenylphosphine (24).

In the hope that the hydride $(\eta^6\text{-trindane})Re(CO)_2H$ might show enhanced stability relative to its manganese counter-

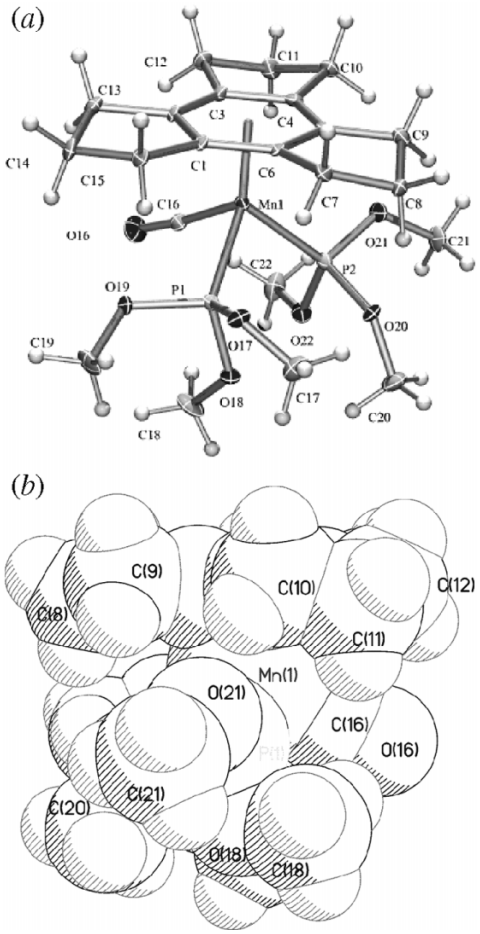
Fig. 3. (*a*) Molecular structure of the cation [(η^6-trindane)Mn(CO){P(OMe)$_3$}$_2$]$^+$ (**15**). Thermal ellipsoids are shown at the 30% probability level. (*b*) Space-filling view of **15** accentuating the degree of crowding induced by the tripodal fragment.

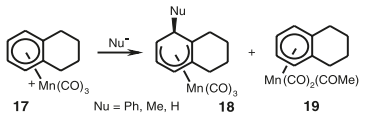


part **5**, it was deemed worthwhile to attempt the synthesis of the analogous [(η^6-trindane)Re(CO)$_3$]$^+$ cation (**16**). Indeed, **16** can be prepared from BrRe(CO)$_5$, AlCl$_3$, and trindane, but the yield, as is sometimes the case with arene–rhenium complexes (14), is very poor (2%). Nevertheless, the [(η^6-trindane)Re(CO)$_3$]$^+$ cation was readily characterized by IR (ν_{CO} at 2058 and 1966 cm^{-1}) and by electrospray mass spectrometry, which gave rise to distinctive molecular ion peaks at *m*/*z* 467 and 469 that exhibited the 37:63 isotopic abundance ratio diagnostic for the presence of ^{185}Re and ^{187}Re. Moreover, the ^{1}H NMR spectrum exhibited the four chemical environments characteristic of trindane metal carbonyl complexes.

Reactions of [(η^6-tetralin)Mn(CO)$_3$][PF$_6$]

To probe the generality of the reaction leading to formation of a hydride intermediate, as in (η^6-trindane)Mn(CO)$_2$H, and the possibility of dehydrogenation concomitant with a haptotropic shift, the corresponding six-membered tetrahydronaphthalene (tetralin) system was synthesized and treated with potassium *tert*-butoxide and trimethyl phosphite. Following the literature precedent (25), tetralin was treated with bromo(pentacarbonyl)manganese in the presence of aluminum trichloride; subsequent anion exchange furnished [(η^6-tetralin)Mn(CO)$_3$][PF$_6$] (**17**) in 80% yield. We are aware of only one report on the reactivity of the cation **17**, whereby Lee and co-workers (25) found that nucleophilic addition afforded adducts at the α-position, as in **18**, except when treated with MeMgBr in THF at 0 °C, which also yielded the acyl compound **19** (Scheme 4). Related studies by Sweigart and co-workers (26) on hormonal steroidal systems bearing a [Mn(CO)$_3$]$^+$ moiety on the aromatic A ring likewise underwent exo addition at C-1 when treated with a range of nucleophiles.

Scheme 4. Reactions of [(η^6-tetralin)Mn(CO)$_3$]$^+$ (**17**) with nucleophiles.



The reaction of [(η^6-tetralin)Mn(CO)$_3$][PF$_6$] (**17**) with *tert*-BuOK and P(OMe)$_3$ in THF gave, even after repeated chromatographic separations, multiple products each in such low yield as to preclude definitive identification. As a result of the complexity of the reaction, it was decided to investigate the effects of each reagent separately to help clarify their roles in the overall reaction. When trimethyl phosphite in THF was added to [(η^6-tetralin)Mn(CO)$_3$][PF$_6$] in the dark, no change was observed, as monitored by in situ IR spectroscopy. However, when exposed to sunlight, the reaction yielded a yellow crystalline solid that was identified by ^{1}H, ^{13}C, and ^{31}P NMR and mass spectrometry as [(η^6-tetralin)Mn(CO)$_2${P(OMe)$_3$}][PF$_6$] (**20**); the assignment was verified by means of a single crystal X-ray diffraction study. The molecule exhibited carbonyl IR stretches at 2008 and 1961 cm^{-1}, and ^{31}P NMR resonances for each of the phosphorus environments, i.e., for the trimethyl phosphite ligand and the hexafluorophosphate anion.

As shown in Figs. 4*a* and 4*b*, the tripodal [Mn(CO)$_2${P(OMe)$_3$}] unit lies in an essentially staggered orientation, typical of such polycyclic manganese complexes (26). The cyclohexene ring adopts a twisted half-chair conformation, with one of the homobenzylic ring carbon atoms lying below, and the other lying above, the molecular plane defined by the arene ring, which is itself planar. The manganese atom is located 1.679 Å below the plane of the arene ring, and the Mn-C(arene) distances range from 2.179(2) to 2.207(2) Å. The hexafluorophosphate anion was disordered, and two orientations were found.

X-ray crystal structures of related systems in which the tetralin fragment is bound to a Cr(CO)$_3$ moiety have been reported by Schmalz and co-workers (27). Moreover, these workers investigated the regioselectivity of the deprotonation/alkylation process. Their data revealed that, in the case of two competing exo hydrogen atoms having comparable steric environments, it is not necessarily the *exo*-benzylic hydrogen atom that adopts a pseudoaxial position that is preferentially abstracted. It was concluded that the conformation of the chromium tricarbonyl tripod may influence the regioselectivity of benzylic deprotonation in chiral (arene)Cr(CO)$_3$ complexes (27), as had been suggested previously (28).

Treatment of [(η^6-tetralin)Mn(CO)$_3$][PF$_6$] (**17**) with potassium *tert*-butoxide in THF afforded a yellow-orange oil that,

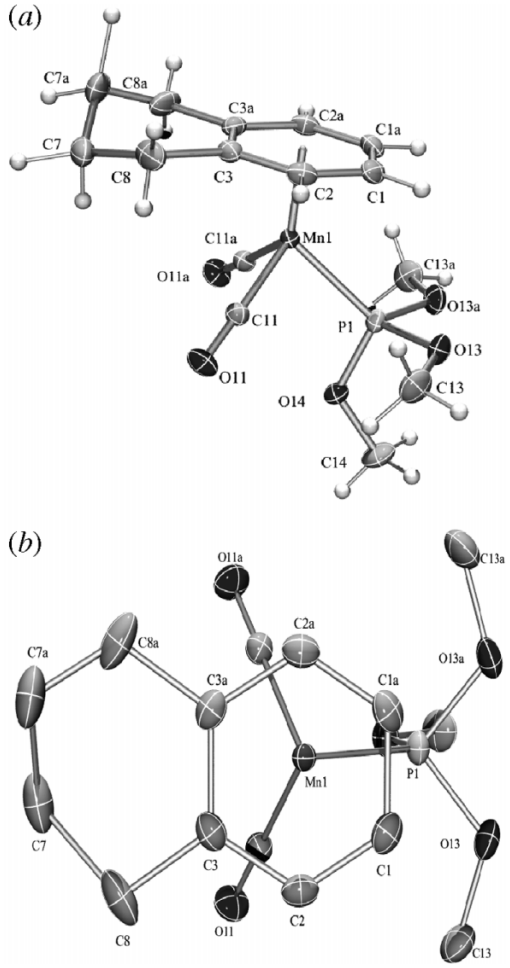
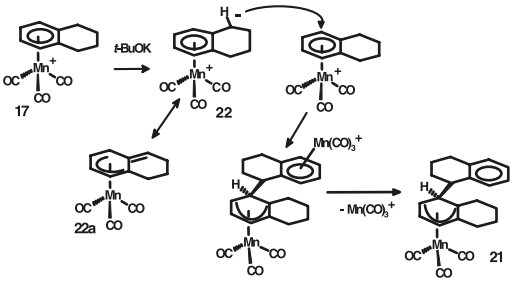
Fig. 4. (*a*) Molecular structure of the cation in [(η^6-tetralin)Mn(CO)$_2${P(OMe)$_3$}][PF$_6$] (**20**); (*b*) Bird's eye view of **20** illustrates the staggered orientation of the tripodal manganese fragment. Thermal ellipsoids are shown at the 30% probability level.



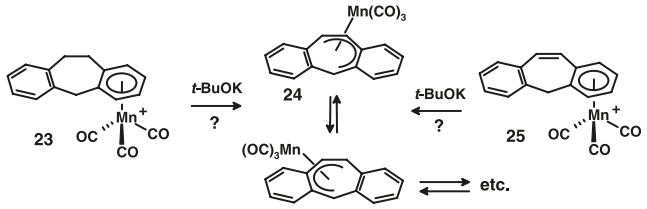
despite repeated efforts, did not yield a crystalline product. Nevertheless, the mass spectrometric and IR data provide strong evidence that the product may be assigned as the tetralenyl-substituted cyclohexadienyl manganese complex **21**. Carbonyl IR absorptions at 2007 and 1927 cm^{-1} (neat) are indicative of a (cyclohexadienyl)Mn(CO)$_3$ system. For example, nucleophilic attack on [(tetralin)Mn(CO)$_3$]$^+$ by hydride, methyl, or phenyl gave the 4-exo-substituted compounds (**18**) that exhibited ν_{CO} peaks (in NaCl) at 2000/1910 cm^{-1}, 2000/1920 cm^{-1}, and 2004/1916 cm^{-1}, respectively, (25). Chemical ionization data for **21** revealed an [M + H]$^+$ peak at *m*/*z* 403, followed by loss of 131 corresponding to $C_{10}H_{11}$. Subsequent fragmentation revealed the presence of a tricarbonylmanganese moiety. Because of considerable peak overlap, the ^{1}H and ^{13}C NMR spectra of **21** have not yet been fully assigned unequivocally, however, efforts to grow X-ray quality crystals are continuing.

A straightforward mechanistic proposal to account for the formation of **21** is depicted in Scheme 5. Deprotonation of [(η^6-tetralin)Mn(CO)$_3$][PF$_6$] by *tert*-BuOK to yield the zwitterionic species **22** (perhaps better represented by the η^5 structure **22a**) can be followed by nucleophilic attack on **17**; subsequent loss of the [Mn(CO)$_3$]$^+$ moiety leads directly to **21**.

Scheme 5. Proposed mechanism for the formation of **21**.



Scheme 6. Possible rearrangement reactions of **23** and **25**.



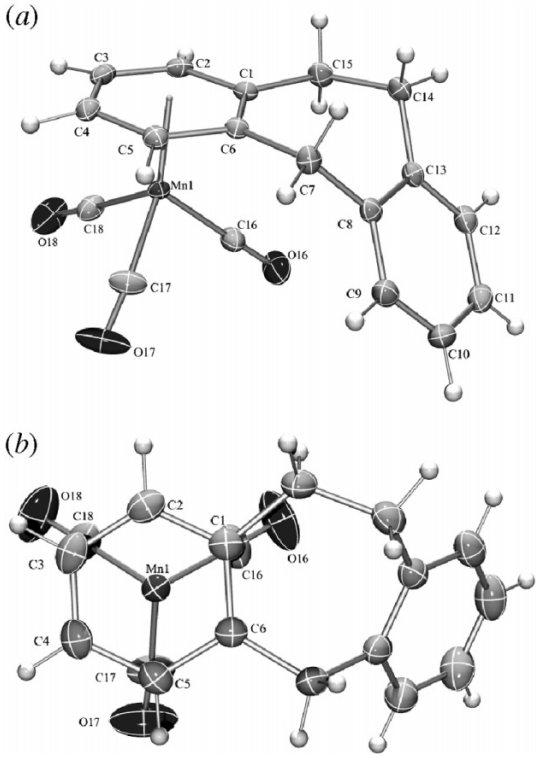
Reactions of [(η^6-dibenzosuberane)Mn(CO)$_3$][BF$_4$]

In light of the previously described reactions of the cations [(η^6-trindane)Mn(CO)$_3$]$^+$ (**1**) and [(η^6-indane)Mn(CO)$_3$]$^+$ (**10**) with *tert*-BuOK and P(OMe)$_3$, whereby dehydrogenation of a five-membered ring and concomitant haptotropic shifts yield η^5 complexes, we chose to extend this study to include systems in which the manganese-complexed arene ring was joined to a seven-membered ring. If the reaction of [(η^6-dibenzosuberane)Mn(CO)$_3$][BF$_4$], **23**, were to proceed in a manner analogous to that of the trindane system, **1**, then one might anticipate loss of three hydrogen atoms from the central ring and formation of a (η^5-dibenzocycloheptatrienyl)Mn(CO)$_3$ complex, such as **24**, which might exhibit a fluxional process (Scheme 6) that would equilibrate the two six-membered rings. It has previously been reported that deprotonation of (η^6-benzocycloheptatriene)Cr(CO)$_3$ leads to an η^6-to-η^5 haptotropic shift such that the metal, which was originally located on the arene ring, is now bonded in an η^5 fashion in the seven-membered ring (29). If an analogous migration were to occur upon deprotonation of [(η^6-dibenzosuberene)Mn(CO)$_3$]$^+$, **25**, the centrally bonded manganese in **24** would presumably exhibit fluxionality, as does (η^5-C$_7$H$_7$)Mn(CO)$_3$ (30).

To this end, [(η^6-dibenzosuberane)Mn(CO)$_3$][BF$_4$] (**23**) was prepared by reaction of dibenzosuberane, bromopentacarbonylmanganese, and silver tetrafluoroborate in dichloromethane and was characterized spectroscopically and by X-ray crystallography. Electrospray mass spectrometry revealed a parent ion at *m*/*z* 333, with fragmentation peaks at 277 and 249 corresponding to loss of two and three carbonyls, respectively. The carbonyl IR stretching vibrations peaks at 2065 and 2014 cm^{-1} are typical of arene–manganese tricarbonyl cations, and the ^{1}H and ^{13}C NMR spectra reveal the presence of one coordinated and one uncoordinated arene ring, and three methylene groups; in each case the methylene protons are rendered nonequivalent by the presence of the metal tripod on one face of the molecule. The X-ray crystal structure of **23** is shown in Figs. 5*a* and 5*b* and reveals that the [Mn(CO)$_3$] fragment is situated on the con-

© 2008 NRC Canada

Fig. 5. (*a*) Molecular structure of the [(η^6-dibenzosuberane)Mn-$(CO)_3$]$^+$ cation in **23**, illustrating the positioning of the $Mn(CO)_3$ tripod on the concave face of the ligand. (*b*) Bird's eye view showing the eclipsed orientation of the tripod. Thermal ellipsoids are shown at the 30% probability level.



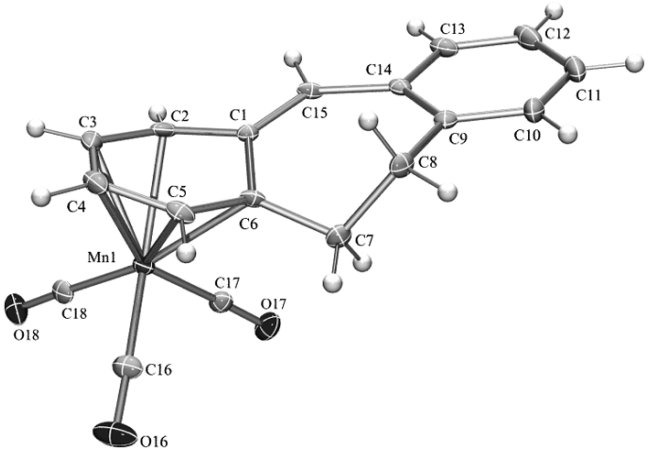
cave face of the tricyclic dibenzosuberane skeleton. The interplanar angle between the two arene rings in **23** is 129°, somewhat larger than the corresponding angle (123°) found in uncomplexed dibenzosuberane (31).

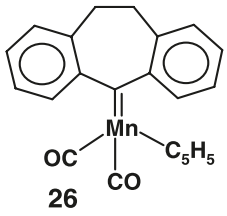
This result contrasts with the structures of the previously reported (η^6-dibenzosuberane)$Cr(CO)_3$ and (η^6-dibenzosuberone)$Cr(CO)_3$ in which the metal tripod lies on the exo (convex) side of the ligand, but follows the example of (η^6-dibenzosuberanol)$Cr(CO)_3$, which, like **23**, places the metal on the endo (concave) face (32). In the manganese case, this preference for the concave face may be a consequence of the need to pack both the organometallic cation and the tetrafluoroborate counterion as efficiently as possible.

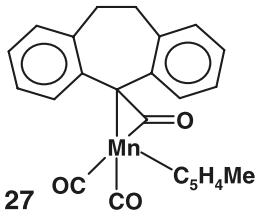
It is common for polycyclic molecules that are π-complexed to metal fragments to fold away from the metal: examples include both α- and β-$Cr(CO)_3$ complexes of O-methyl podocarpate (33), as well as ruthenium (34), chromium (35), and manganese (26) derivatives of estradiol and estrone. Other crystallographically characterized molecules that contain manganese and the suberane skeleton are the carbene complex, **26**, and the η^2-ketene derivative, **27** (36).

Treatment of the (dibenzosuberane)tricarbonylmanganese cationic complex (**23**) with potassium *tert*-butoxide and trimethyl phosphite yielded, after chromatographic separation, a number of products in quantities too small to characterize unambiguously. Consequently, as was done in the case of [(η^6-tetralin)$Mn(CO)_3$][PF_6], each reagent was treated separately with [(η^6-dibenzosuberane)$Mn(CO)_3$][BF_4]. Although, in the absence of light, trimethyl phosphite alone did

Fig. 6. Molecular structure of (η^5-$C_{15}H_{13}$)$Mn(CO)_3$ (**28**); thermal ellipsoids are shown at the 30% probability level.





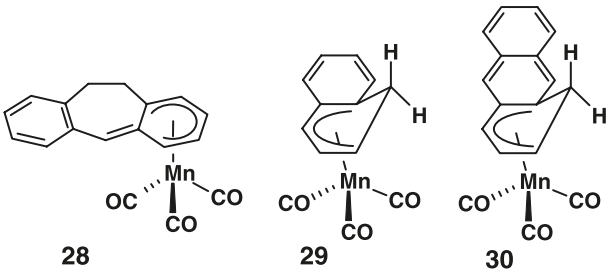


not lead to substitution of a carbonyl ligand, the reaction of **23** with *tert*-BuOK in THF gave as the major product an orange powder exhibiting carbonyl IR absorptions at 2022 and 1950 cm^{-1} and a parent peak in the mass spectrum at *m*/*z* 332. This material was characterized by X-ray crystallography as (η^5-$C_{15}H_{13}$)$Mn(CO)_3$ (**28**), in which deprotonation of the benzylic proton had occurred resulting in generation of a double bond in the central seven-membered ring. The structure of compound **28** appears in Fig. 6 and shows that the metal tripod is coordinated in an η^5-fashion to one of the outer six-membered rings, such that the manganese is located 1.718 Å below the ring.

The manganese-dienyl carbon bond distances in **28** range from 2.126(5) to 2.287(5) Å, typical for cyclohexadienyl manganese complexes, while the C(1)–C(15) bond length of 1.358(6) Å is significantly shorter than C(1)–C(6) (1.468(6) Å), and indicates double bond character. The carbon–carbon distances of the cyclohexadienyl ring average 1.407 Å and the cyclohexadienyl unit exhibits a deviation from planarity of only 0.002 Å, but the distortion from planarity of the cyclohexadienyl ring, i.e., the angle between planes C(2)-C(3)-C(4)-C(5)-C(6) and C(2)-C(1)-C(6) is 31°. This dihedral angle θ is smaller than is found in (η^5-C_6H_7)$Mn(CO)_3$ (43°) (37) or *endo*-(η^5-C_6Me_6H)$Mn(CO)_2${$P(OMe)_3$} (47.5°) (14) but is similar to those observed in the polycyclic systems **29** and **30**, derived from naphthalene or anthracene, in which the cyclohexadienyl ring is bent through 36° and 33°, respectively (38, 39).

The product derived from the reaction of [(η^6-dibenzosuberane)$Mn(CO)_3$][BF_4] (**23**) with potassium *tert*-butoxide is reminiscent of the behavior of the [(η^6-fluorene)ML_n]$^+$ cation (**31**) [ML_n = Fe(C_5H_5) or $Mn(CO)_3$], which upon deprotonation yielded (η^5-fluorenyl)ML_n, (**32**) (40, 41). In principle, these neutral molecules can be represented either

© 2008 NRC Canada



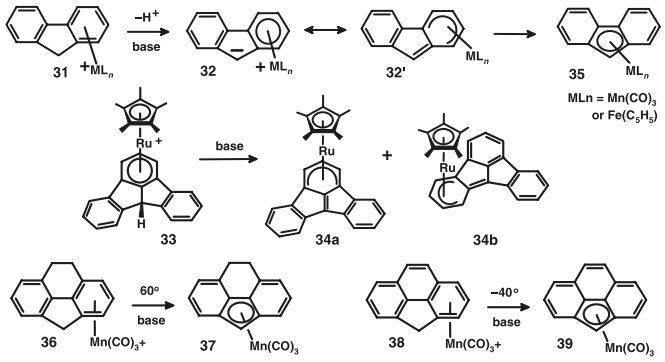
as zwitterions or as possessing a formal double bond in the central ring, as in **32′**. However, the X-ray crystal structures probably favored the latter interpretation in which the cyclohexadienyl ring is folded through 11° (Fe) or 15° (Mn), and the bond from the ring junction carbon to the benzylic carbon is 1.38 Å (Fe) (40) or 1.37 Å (Mn) (41). The (fluoradene)Ru(C_5Me_5) complexes **33** and **34** behave similarly (42). When (η^5-fluorenyl)ML_n (**32**), where ML_n = $Mn(CO)_3$ or Fe(C_5H_5), is heated, the organometallic moiety undergoes a haptotropic shift onto the central five-membered ring to produce **35** (41). As shown in Scheme 7, analogous behavior has also been reported for the (8,9-dihydrocyclopenta[*def*]phenanthrenyl)$Mn(CO)_3$ complexes **36** and **37** (19). Interestingly, the η^6-to-η^5 haptotropic shift of the organometallic fragment in the (cyclopenta[*def*]phenanthrenyl)$Mn(CO)_3$ complexes **38** and **39** occurs readily at –40 °C, and this has been rationalized in terms of the enhanced aromatic character of the transition state (43).

Why are the reactions so different?

We must now ask ourselves why the arene–manganese tricarbonyl cations **1**, **17**, and **23** possessing five-, six-, or seven-membered rings, respectively, exhibit such different behavior when treated with *tert*-BuOK. The trindane (or indane) system apparently yields a metal hydride that subsequently suffers a series of hydrogen eliminations, presumably via agostic interactions with suitably positioned benzylic hydrogens. The tetralin complex **17** appears to undergo proton abstraction to generate a nucleophile that can attack its progenitor, whereas deprotonation of the dibenzosuberane-complexed cation **23** yielded a stable elimination product.

Evidently, there can be competition between deprotonation at a benzylic site and nucleophilic attack by the alkoxide at a carbonyl ligand. Moreover, even if a manganese-hydride were to be generated in each case, one must then consider not only the ease or difficulty of forming an agostic Mn···H···C linkage, but also the strength of the manganese-to-ligand binding subsequent to the haptotropic shift. Taking the X-ray crystallographic data for (η^6-trindane)$Mn(CO)_2Br$ (**3**), [(η^6-tetralin)$Mn(CO)_2${P($OMe)_3$}]$^+$ (**20**), and [(η^6-dibenzosuberane)$Mn(CO)_3]^+$ (**23**), we note that the Mn-to-benzyl *endo*-H distances generally lie in the range 3.42–3.52 Å, considerably longer than might be anticipated for a manganese···hydrogen agostic interaction (~1.8 Å) (44). However, manganese-hydrogen agostic interactions have been invoked by Cooper and co-workers (38) to explain the fluxional behavior of the anthracenyl complex **29** whereby an endo benzylic hydrogen undergoes a 1,4 migration via the metal center. In that case, the metal-hydrogen distance in the ground state was determined crystallographically to be 3.13 Å, but such a process requires a flattening of the six-membered ring and an elongation of the C–H bond.

Scheme 7. Haptotropic shifts in polycyclic systems.



The transformation of (η^6-trindane)$Mn(CO)_2H$ (**5**) into (η^5-$C_{15}H_{15}$)$Mn(CO)_3$ (**7**) involves C-H and Mn-H cleavage with concomitant formation of a manganese–carbonyl bond and two molecules of dihydrogen. The requisite bond energies are BE(C-H) 413 kJ mol^{-1}, BE(Mn-H) 288 kJ mol^{-1} [calculated value (45)], BE(H-H) 436 kJ mol^{-1}, and BE(Mn-CO) ~190 kJ mol^{-1}(46). Thus, cleavage of three C–H bonds and one Mn–H bond has an energy cost of approximately 1527 kJ mol^{-1} of which only ~1060 kJ mol^{-1} are recovered as one Mn–CO and two H–H bonds. The overall free energy change must be controlled by the stronger bonding of the manganese to the five-membered ring and, of course, by the very favorable increase in entropy brought about by the liberation of two moles of dihydrogen.

The complex [(η^6-trindane)$Mn(CO)_3]^+$ (**1**) preferentially undergoes nucleophilic attack by the *tert*-butoxide anion on a metal carbonyl ligand, whereas in the tetralin and dibenzosuberane complexes, **17** and **23**, deprotonation at a benzylic site is favored. Steric considerations would suggest that in **23** the positioning of the metal tripod on the concave face of the dibenzosuberane ligand seriously hinders the approach of a relatively bulky *tert*-butoxide; in contrast, the $Mn(CO)_3$ moiety in the trindane complex **1** is staggered with respect to the five-membered rings, and the alkoxide can readily gain access to a carbonyl ligand. Upon removal of a benzylic proton from [(η^6-dibenzosuberane)$Mn(CO)_3]^+$, the resulting neutral species **28** is sufficiently flexible to allow the seven-membered ring to fold away from the metal and so adopt a conventional η^5-cyclohexadienyl conformation; this molecular deformation may be more difficult for the deprotonated tetralene complex **22**, which therefore retains its nucleophilic character and attacks the starting material to yield the "dimeric tetralenyl" η^5-cyclohexadienyl product **21**.

To conclude, the reactions of potassium *tert*-butoxide with the arene manganese tricarbonyl cations derived from trindane, indane, tetralin, or dibenzosuberane yield very different products and pose interesting mechanistic questions.

Experimental section

General procedures

All reactions were carried out under an atmosphere of dry nitrogen employing conventional benchtop and glovebag techniques. Silica gel (particle size 20–45 μm) was employed for flash column chromatography. Radial chromatog-

© 2008 NRC Canada

raphy was performed using a Chromatotron (7942T, Harrison Research, Inc.) with silica-coated plates (TLC grade 7749 with gypsum binder and fluorescent indicator; thickness: 1, 2, or 4 mm). ^{1}H, ^{13}C, and ^{31}P NMR data were acquired on Bruker Avance 500, 300, or 200 MHz spectrometers, and chemical shifts are given relative to residual ^{1}H or ^{13}C solvent signal, or externally referenced relative to 85% H_3PO_4 in D_2O. IR spectra were recorded on a Bio-Rad FTS-40 single beam spectrometer using KBr pellets or NaCl windows. In situ IR spectra were recorded on an ASI Applied Systems ReactIR 1000 with a SiComp probe. Mass spectrometric data were obtained on a Finnigan EI/CI mass spectrometer system, using direct electron impact and chemical ionization methods. The positive ion electrospray mass spectra were obtained on a Micromass Quattro LC triple quadrupole mass spectrometer. Melting and decomposition points were measured on a Fischer-Johns melting point apparatus and are not corrected. Microanalytical data are from Guelph Chemical Laboratories (Guelph, Ontario) or from the Microanalytical Laboratory at University College Dublin.

[(η^6-Trindane)$Mn(CO)_3$][BF_4] (**1**) and [(η^6-trindane)Fe(C_5H_5)][PF_6] (**2**) were prepared as previously described (2). Following the literature procedure (47), dibenzosuberane was obtained in 77% yield by reduction of dibenzosuberone with iodine and hypophosphorous acid in acetic acid.

Reaction of [(η^6-trindane)$Mn(CO)_3$][BF_4] with *tert*-BuOK and allyl bromide

A three-neck round-bottomed flask equipped with a side-arm, condenser, septum, and stir bar was charged with [(η^6-trindane)$Mn(CO)_3$][BF_4] (**1**) (0.500 g, 1.18 mmol) and *tert*-BuOK (1.33 g, 11.87 mmol) and held under vacuum for 3 h at 40 °C. A solution of allyl bromide (1.02 mL, 11.8 mmol) in THF (25 mL) was added via cannula, under N_2, and produced a green solution that was maintained at 40 °C, which eventually turned brownish-orange. After 20.5 h, the solvent was removed under reduced pressure and the pinkish-red residue was dissolved in CH_2Cl_2, filtered, and extracted with H_2O (3 × 10 mL). The organic layers were combined, dried with Na_2SO_4, and filtered, and the solvent was removed by rotary evaporation. After drying under vacuum, **3** was obtained as a dark red powder (0.077 g, 0.198 mmol; 17%), mp 128–130 °C (dec). IR (NaCl windows, $CDCl_3$, cm^{-1}) ν_{CO}: 1971(s), 1927 (s). ^{1}H NMR (200 MHz, CD_2Cl_2) δ: 2.76 (br, 12H, benzylic CH_2), 2.04 (br, 6H, wingtip CH_2). ^{13}C NMR (50 MHz, CD_2Cl_2) δ: 110.3 (aromatic C), 30.1 (benzylic CH_2), 24.1 (wingtip CH_2). Mass spectrum (MS) (DEI, *m/z* (%)): 198 (100, $[C_{15}H_{18}]^+$), 115 (5, $[C_9H_7]^+$). (As with (C_6Me_6)$Mn(CO)_2Br$, no parent ion was detectable; only peaks attributable to the ligand were observed.) Anal. calcd. for $C_{17}H_{18}MnBrO_2$ (%): C 52.47, H 4.66; found: C 52.04, H 4.92. A crystal suitable for an X-ray diffraction study was obtained by slow evaporation of dichloromethane at room temperature under an atmosphere of nitrogen.

Alternative route to (η^6-trindane)$Mn(CO)_2Br$ (3)

The second synthesis of **3** is based on the previously reported preparation of (η^6-C_6Me_6)$Mn(CO)_2Br$ (12). [(η^6-Trindane)$Mn(CO)_3$][BF_4] (0.501 g, 1.18 mmol), Me_3NO (0.107 g, 1.29 mmol), and (n-Bu)$_4$NBr (0.566 g, 1.433 mmol) were combined in a two-neck round-bottomed flask. The system was evacuated, flushed with N_2 (three times), and CH_2Cl_2 (25 mL) was added. The resulting red solution was left to stir under N_2 for 2 h, after which time the solvent was removed under reduced pressure. The crude product was chromatographed on a silica gel column (eluent hexane/acetone 50:50) affording **3** (0.425 g, 1.092 mmol, 93%). NOTE: trimethylamine *N*-oxide hydrate ($Me_3NO{\cdot}2H_2O$) was dehydrated by azeotroping the water from a toluene solution.

Reaction of [(η^6-trindane)$Mn(CO)_3$][BF_4] with *tert*-BuOK and methyl iodide

Analogously to the preparation of **3**, [(η^6-trindane)-$Mn(CO)_3$][BF_4] (0.513 g, 1.21 mmol), *tert*-BuOK (2.65 g, 23.6 mmol), and methyl iodide (1.47 mL, 23.6 mmol) in THF (25 mL) produced a purple solution that eventually turned yellow-cream. Work-up was as above, and separation by rotary chromatography (Chromatotron, eluent hexane/CH_2Cl2 20:80) yielded (η^6-trindane)$Mn(CO)_2I$ (**4**) (0.078 g, 0.18 mmol; 15%). IR (NaCl windows, $CDCl_3$, cm^{-1}) ν_{CO}: 1973 (s), 1926 (s). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 2.80 (m, 12H, benzylic CH_2), 2.09 (br, 6H, wingtip CH_2). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 108.8 (aromatic C), 30.1 (benzylic CH_2), 23.7 (wingtip CH_2). MS (DEI, *m/z* (%)): 380 (40, [M – 2CO]$^+$), 253 (10, [M – 2CO – I]$^+$), 198 (100, $[C_{15}H_{18}]^+$). Anal. calcd. for $C_{17}H_{18}MnIO_2$ (%): C 46.81, H 4.16; found: C 47.02, H 4.32. A crystal suitable for an X-ray diffraction study was obtained by slow evaporation of dichloromethane at room temperature under an atmosphere of nitrogen.

Reaction of [(η^6-trindane)$Mn(CO)_3$][BF_4] with *tert*-BuOK and trimethyl phosphite

Likewise, [(η^6-trindane)$Mn(CO)_3$][BF_4] (0.500 g, 1.18 mmol), *tert*-BuOK (2.65 g, 23.6 mmol), and $P(OMe)_3$ (2.78 mL, 23.6 mmol) in THF (30 mL) produced a red solution that eventually turned orange-brown. Workup was as above, and chromatography on a silica gel column (eluent hexane/CH_2Cl2 70:30) yielded two fractions, (η^5-$C_{15}H_{15}$)$Mn(CO)_3$ (**7**) (0.080 g, 0.240 mmol; 20%), mp 87–90 °C and (η^5-$C_{15}H_{15}$)$Mn(CO)_2P(OMe)_3$] (**8**) (0.055 g, 0.130 mmol; 11%), mp 124–126 °C.

Data for **7**: ^{1}H NMR (200 MHz, $CDCl_3$) δ: 5.03 (d, 2H, CH), 4.94 (t, 1H, CH), 2.93 (m, 4H, benzylic CH_2), 2.79 (m, 4H, benzylic CH_2), 2.13 (m, 4H, wingtip CH_2). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 225.4 (Mn-CO), 139.4 (C6/C9 or C7/C8, C=C), 135.2 (C6/C9 or C7/C8, C=C), 101.1 (C4/C5), 87.4 (C2, CH), 69.7 (C1/C3, CH), 32.1 (benzylic CH_2), 25.5 (wingtip CH_2), 32.1 (benzylic CH_2). Anal. calcd. for $C_{18}H_{15}MnO_3$ (%): C 64.68, H 4.52; found: C 65.01, H 4.67. After numerous attempts, yellow crystals were grown from chloroform at 0 °C under an atmosphere of nitrogen, but were not of ideal quality. Nevertheless, an X-ray diffraction study was undertaken and the molecular structure was determined.

Data for **8**: IR (NaCl windows, $CDCl_3$, cm^{-1}) ν_{CO}: 1944 (s), 1876 (s). ^{1}H NMR (500 MHz, $CDCl_3$) δ: 4.84 (m, 3H, CH), 3.38 (d, $^3J_{H\text{-}P}$ = 11.7 Hz, 9H, OCH_3), 3.04 (m, 2H, benzylic CH_2), 2.92 (m, 2H, benzylic CH_2), 2.84 (m, 2H, benzylic CH_2), 2.75 (m, 2H, benzylic CH_2), 2.16 (m, 4H, wingtip CH_2). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 137.9 (C6/C9 or C7/C8, C=C), 135.8 (C6/C9 or C7/C8, C=C), 100.9

MS (DEI, *m/z* (%)): 430 (11, $[M]^+$), 374 (100, $[M - 2CO]^+$), 281(21, $[M - 2CO - 3(OMe)]^+$), 251 (51, $[M - 2CO - P(OMe)_3^+$), 195 (44, $[(C_{15}H_{15})]^+$). Anal. calcd. for $C_{20}H_{24}MnO_5P$ (%): C 55.82, H 5.62; found: C 55.45, H 5.96. A yellow crystal suitable for an X-ray diffraction study was grown from chloroform at 0 °C under an atmosphere of nitrogen.

Reaction of [(η⁶-trindane)Mn(CO)₃][BF₄] with *tert*-BuOK and triphenylphosphine

Analogously to the preparation of **8**, [(η⁶-trindane)$Mn(CO)_3$][BF_4] (0.500 g, 1.182 mmol), *tert*-BuOK (2.65 g, 23.6 mmol), THF (30 mL), and PPh_3 (619 g, 23.6 mmol) yielded three fractions after separation on a Chromatron (eluent hexane/CH_2Cl2 90:10): PPh_3, (η⁵-$C_{15}H_{15}$)$Mn(CO)_3$ (**7**), and (η⁵-$C_{15}H_{15}$)$Mn(CO)_2[PPh_3]$ (**9**) (0.060g, 0.1056 mmol; 9%), mp 179–180 °C (dec). IR (NaCl windows, $CDCl_3$, cm^{-1}) ν_{CO}: 1929 (s), 1862 (s). ^1H NMR (500 MHz, $CDCl_3$) δ: 7.31 (m, 15H, aromatic CH), 4.60 (d, 2H, CH), 4.47 (m, 1H, CH), 2.51 (m, 8H, benzylic CH_2), 2.08 (m, 4H, wingtip CH_2). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 138.1, 137.8, 136.1, 133.1 ($J_{C\text{-}P}$ = 10.4 Hz), 129.5, 128.1 ($J_{C\text{-}P}$ = 9.3 Hz), 100.7 (C4/C5), 89.0 (C2, CH), 70.7 (C1/C3, CH), 32.3 (benzylic CH_2), 32.0 (benzylic CH_2), 24.6 (wingtip CH_2). ^{31}P NMR (81.04 MHz, $CDCl_3$) δ: 94.3. MS (DEI, *m/z* (%)): 569 (100, $[M + H]^+$), 512 (58, $[M - 2CO]^+$), 195 (62, $[C_{15}H_{15}]^+$); (CI, NH_3, *m/z* (%)): 569 (100, $[M + H]^+$), 512 (58, $[M - 2CO]^+$), 195 (63, $[C_{15}H_{15}]^+$). Anal. calcd. for $C_{35}H_{30}MnO_2P$ (%): C 73.94, H 5.28; found: C 74.18, H 5.49.

Preparation of [(η⁶-indane)Mn(CO)₃][BF₄] (10)

A mixture of $Mn(CO)_5Br$ (1.08 g, 4.029 mmol) and $AgBF_4$ (0.78 g, 4.029 mmol) in dry CH_2Cl_2 (40 mL) was heated at reflux for 3 h under nitrogen and then cooled to room temperature. To the reaction mixture, a solution of indane (0.493 mL, 4.029 mmol) in dry CH_2Cl_2 (10 mL) was added, and the reaction mixture was heated at reflux for 18 h. After cooling and filtration, the filtrate was passed through Celite and concentrated to approximately one-third its volume under reduced pressure, and excess hexane (80 mL) was added. The resulting yellow solid was filtered and dried in vacuo to furnish **10** (0.658 g, 1.918 mmol, 50%). IR (NaCl windows, $CDCl_3$, cm^{-1}) υ_{CO}: 2065 (s), 2008 (s). ^1H NMR (200 MHz, CD_2Cl_2) δ: 6.53 (m, 4H, aromatic), 3.03 (m, 4H, benzylic CH_2), 2.44 (m, 1H, wingtip CH_2), 2.10 (m, 1H, wingtip CH_2). ^{13}C NMR (50 MHz, CD_2Cl_2) δ: 227.2 (Mn-CO), 99.3 (aromatic C), 98.2 (aromatic C), 32.2 (benzylic CH_2), 23.7 (wingtip CH_2). MS (positive ESI, *m/z* (%)): 258 (M + 1, 24% of $[M]^+$), 257 (100, $[M]^+$), 229 (5.3, $[M - CO]^+$), 201 (2.7, $[M - 2CO]^+$), 173 (1.9, $[M - 3CO]^+$). Anal. calcd. for $C_{12}H_{10}O_3MnBF_4$ (%): C 41.90, H 2.93; found: C 41.69, H 2.76.

Reaction of [(η⁶-indane)Mn(CO)₃][BF₄] with *tert*-BuOK and triphenylphosphine

Following the procedure for **3**, [(η⁶-indane)$Mn(CO)_3$][BF_4] (0.106 g, 0.3089 mmol), *t*-BuOK (0.693 g, 6.178 mmol), and PPh_3 (1.620 g, 6.178 mmol) in THF (35 mL) produced a reddish-orange solution. Work-up yielded (η⁵-indenyl)$Mn(CO)_2PPh_3$ (0.017 g, 0.0348 mmol, 11%). IR (NaCl windows, $CDCl_3$, cm^{-1}) ν_{CO}: 1934 (s), 1866 (s), lit. (18); (nujol) υ_{CO}: 1931(s), 1863 (s). ^1H NMR (300 MHz, CD_2Cl_2) δ: 7.09 (m, 19H, aromatic C and CH=CH), 4.65 (m, 3H, Cp). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 232.8 (Mn-CO), 133.7, 133.5, 130.1, 128.6, 128.5, 126.1, 125.9, 90.1 (Cp), 72.9 (Cp). ^{31}P NMR (81.05 MHz, CD_2Cl_2) δ: 92.4 (s). MS (DEI, *m/z* (%)): 488 (6, $[M]^+$), 432 (92, $[M - 2CO]^+$), 377 (1, $[M - 2CO - Mn]^+$), 115 (100, $[C_9H_7]^+$).

Reaction of [(η⁶-indane)Mn(CO)₃][BF₄] with *tert*-BuOK and trimethyl phosphite

As for the reaction with triphenylphosphine, [(η⁶-indane)$Mn(CO)_3$][BF_4] (0.500 g, 1.457 mmol), *t*-BuOK (3.27 g, 29.0 mmol), and $P(OMe)_3$ (619 g, 23.6 mmol) in THF (30 mL) yielded (η⁵-indenyl)$Mn(CO)_2[P(OMe)_3]$ (0.001 g, 2.857 mmol, 2%). IR (NaCl windows, $CDCl_3$, cm^{-1}) ν_{CO}: 1950 (s), 1881 (s). ^1H NMR (200 MHz, $CDCl_3$) δ: 7.40 (m, 2H, CH=CH), 7.02 (m, 2H, CH=CH), 4.97 (m, 2H, CH), 4.83 (m, 1H, CH), 3.42 (d, 9H, $^3J_{C\text{-}P}$ = 11.7 Hz, OCH_3). ^{31}P NMR (81.05 MHz, CD_2Cl_2) δ: 211.4 (s). MS (DEI, *m/z* (%)): 350 (12, $[M]^+$), 322 (5, $[M - CO]^+$), 294 (100, $[M - 2CO]^+$), 170 (29, $[C_9H_7Mn]^+$), 115 (41, $[C_9H_7]^+$).

Preparation of [(η⁶-trindane)Mn(CO){P(OMe)₃}₂][BF₄] (15)

[(η⁶-Trindane)$Mn(CO)_3$][BF_4] (0.463 g, 1.095 mmol) and Me_3NO (0.173 g, 2.307 mmol) were stirred in CH_2Cl_2 (55 mL) under N_2. To the yellow solution was added $P(OMe)_3$ (0.20 mL, 1.696 mmol) whereupon the solution turned red instantaneously. The solution was allowed to stir under N_2 for 6 h at room temperature, the solvent was removed under pressure, and the crude material was purified by chromatographic separation on a silica gel column (eluent CH_2Cl_2/acetone 90:10) giving rise to two fractions. The first fraction was identified as trindane and the second was **15** (0.071 g, 0.115 mmol, 11%). IR (NaCl windows, $CDCl_3$, cm^{-1}) υ_{CO}: 1911 (s). ^1H NMR (300 MHz, CD_2Cl_2) δ: 3.71 (t, 18H, $^3J_{P\text{-}H}$ = 5.0 Hz, $P(OMe)_3$), 2.74 (m, 12H, benzylic CH_2), 2.08 (m, 6H, wingtip CH_2). ^{13}C NMR (75 MHz, CD_2Cl_2) δ: 111.7 (aromatic C), 54.5 (OCH_3), 30.4 (benzylic CH_2), 23.2 (wingtip CH_2). ^{31}P NMR (121.51 MHz, CD_2Cl_2) δ: 185.5 (s). MS (positive ESI, *m/z* (%)): 529 (100, $[M^+]$), 405 (3, $[M - P(OMe)_3]^+$), 377 (8, $[M - P(OMe)_3 - CO]^+$). Anal. calcd. for $C_{22}H_{36}MnO_7P_2$ (%): C 42.88, H 5.89; found: C 42.69, H 5.86. A sample suitable for single-crystal X-ray diffraction was obtained by crystallization from dichloromethane by slow evaporation under nitrogen at room temperature.

Preparation of [(η⁶-trindane)Re(CO)₃][PF₆] (16)

In a 100 mL round-bottomed flask, $BrRe(CO)_5$ (0.944 g, 2.324 mmol), trindane (0.765 g, 3.864 mmol), $AlCl_3$ (1.630 g, 12.22 mmol), and petroleum ether (55 mL) were heated at reflux under nitrogen for 16.5 h. The solution was cooled in an ice-bath, followed by addition of an ice-water slush (25 mL). The petroleum ether layer was decanted, and the remaining water layer was washed with cold diethyl ether followed by the addition of excess NH_4PF_6 in water (5 mL). The resultant white precipitate (0.028 g, 0.0456 mmol, 2%) was filtered and washed with cold water

and methanol. IR (KBr pellet, cm^{-1}) υ_{CO}: 2052 (s), 1956 (s). IR (NaCl windows, $CDCl_3$, cm^{-1}) υ_{CO}: 2058 (s), 1966 (s). ^1H NMR (500 MHz, CD_2Cl_2) δ: 3.38 (m, 6H, benzylic CH_2), 2.95 (m, 6H, benzylic CH_2), 2.44 (m, 3H, wingtip CH_2), 1.91 (m, 3H, wingtip CH_2). ^{13}C NMR (125.773 MHz, CD_2Cl_2) δ: 185.7 (Mn-CO), 118.7 (aromatic C), 30.4 (benzylic CH_2), 24.7 (wingtip CH_2). MS (positive ESI, *m/z* (%)): 469 (100, $[M]^+$).

Attempted synthesis of $[(\eta^6\text{-}(CH_3)_{12}C_{15}H_6)FeCp][PF_6]$

$[(\eta^6\text{-}C_{15}H_{18})FeCp][PF_6]$ (**2**) (0.124 g, 0.267 mmol) and potassium *tert*-butoxide (7.20 g, 64 mmol) were stirred together under vacuum for 3 h, and a solution of methyl iodide (3.98 mL, 64 mmol) in freshly distilled THF (60 mL) was introduced by syringe. The solution became deep red in colour and continued to change colour (dark purple to mauve to pink) until the solution remained yellowish-cream in colour. After 48 h under nitrogen at 40 °C in the dark, the product was worked up as before, and chromatographed on an alumina neutral column (eluent hexane/acetone 90:10) to afford three orange products. The ^1H and ^{13}C NMR spectra of each fraction still indicated a mixture of compounds. Similarly positive ESI mass spectrometric data exhibited signals at *m/z* 459, 473, and 487 corresponding to the incorporation of 10, 11, and 12 methyls, respectively. Two samples suitable for structural determination by single-crystal X-ray diffraction were obtained by recrystallization from hexanes/acetone mixture; however, the structure has not been satisfactorily refined as a result of a disorder in the trindane fragment.

Attempted synthesis of $[(\eta^6\text{-}(CH_2CHCH_2)_{12}C_{15}H_6)FeCp][PF_6]$

Similarly, $[(\eta^6\text{-}C_{15}H_{18})FeCp][PF_6]$, **2**, (0.233 g, 0.502 mmol), potassium *tert*-butoxide (13.5 g, 120 mmol), and allyl bromide (10.43 mL, 120 mmol) in THF (60 mL) became deep red in colour and continued to change colour (pink to violet to mauve) until the solution remained yellowish-cream in colour. After work-up, the crude product was chromatographed on an alumina neutral column (eluent hexane) affording two yellow products. The ^1H and ^{13}C NMR spectra of each fraction still indicated a mixture of compounds. Similarly positive ESI mass spectrometric data exhibited signals consistent with the incorporation of 12 allyl groups at *m/z* 799, followed by consecutive losses of multiples of 40 to a *m/z* of 319 (which corresponds to $[(\eta^6\text{-}C_{15}H_{18})FeCp]^+$).

Preparation of $[(\eta^6\text{-tetralin})Mn(CO)_3][PF_6]$ (17)

As described in the literature (25), $Mn(CO)_5Br$ (1.97 g, 7.16 mmol), $AlCl_3$ (1.91 g, 14.3 mmol), tetralin (1.88 mL, 0.0138 mmol), and cyclohexane (50 mL) were heated at reflux for 5 h under N_2. The solution was cooled, followed by the addition of ice-cold H_2O (40 mL). To the aqueous layer, NH_4PF_6 (2.21 g, 0.0138 mmol) was added, yielding a yellow precipitate that was filtered and dried under vacuum. The product (2.383 g, 5.73 mmol, 80%) was recrystallized from a mixture of acetone and diethyl ether. Complete spectroscopic assignment of this compound had not been published prior to this study. IR (NaCl windows, $CDCl_3$, cm^{-1}) υ_{CO}: 2068 (s), 2025 (s), 2003 (s), lit. (25) (NaCl) υ_{CO}: 2056 (s), 2016 (s). ^1H NMR (200 MHz, acetone-d_6) δ: 6.84 (s, 4H, CH), 3.13 (m, 4H, CH_2), 2.30 (m, 4H, CH_2). ^{13}C NMR (50 MHz, acetone-d_6) δ: 216.9, 119.5, 101.9, 99.8, 28.2, 21.6. MS (positive ESI, *m/z* (%)): 271 (100, $[M]^+$), 243 (8, $[M - CO]^+$), 214 (23, $[M - 2CO]^+$), 187 (7, $[M - 3CO]^+$).

Reaction of $[(\eta^6\text{-tetralin})Mn(CO)_3][PF_6]$ with trimethyl phosphite

A 100 mL Schlenk flask equipped with a side arm and stir bar was charged with $[(\eta^6\text{-tetralin})Mn(CO)_3][PF_6]$ (**17**) (0.902 g, 2.168 mmol) and evacuated and purged with N_2 three times. A solution of THF (30 mL) containing $P(OMe)_3$ (5.11 mL, 43.4 mmol) was added dropwise under N_2, the solution was yellow in colour. The solution was stirred for 20 h under N_2 and the solvent was then removed under reduced pressure. The residue was dissolved in CH_2Cl_2 and hexanes, a precipitate formed, and it was filtered. The remaining solution was chromatographed on a silica gel column (eluent 100% hexane) affording **20**, a yellow compound (0.658 g, 1.285 mmol, 59%), mp 86–88 °C. IR (NaCl windows, $CDCl_3$, cm^{-1}) υ_{CO}: 2008 (s), 1961 (s). ^1H NMR (200 MHz, $CDCl_3$) δ: 5.94 (m, 4H, aromatic CH), 3.70 (t, 9H, $^3J_{H\text{-}P}$ = 11.6 Hz, OCH_3), 2.73 (m, 4H, CH_2), 1.79 (m, 4H, CH_2). ^{13}C NMR (50 MHz, $CDCl_3$) δ: 220.3 (d, $^2J_{C\text{-}P}$ = 43.2 Hz, Mn-CO), 113.9 (C1/C6), 97.8 (C2/C5 or C3/C4), 96.7 (C2/C5 or C3/C4), 54.1 (d, $^2J_{C\text{-}P}$ = 7.3 Hz, OCH_3), 27.5 (C7/C10), 21.1 (C7/C10). ^{31}P NMR (81.04 MHz, $CDCl_3$) δ: 182.1 (s, $P(OMe)_3$), –167.4 (septet, PF_6). MS (positive ESI, *m/z* (%)): 367 (100, $[M^+]$), 311 (19, $[M - 2CO]^+$). Anal. calcd. for $C_{15}H_{21}MnO_5P_2F_6$ (%): C 35.17, H 4.13; found: C 35.51, H 3.96. A sample suitable for single-crystal X-ray diffraction was obtained by crystallization from chloroform by slow evaporation under an atmosphere of nitrogen at room temperature.

Reaction of $[(\eta^6\text{-tetralin})Mn(CO)_3][PF_6]$ with *tert*-BuOK

A round-bottomed flask equipped with a side arm and stir bar was charged with $[(\eta^6\text{-tetralin})Mn(CO)_3][PF_6]$ (**17**) (0.952 g, 2.288 mmol) and *t*-BuOK (5.14 g, 45.8 mmol) and evacuated and purged with N_2 three times. This was followed by the addition of THF (30 mL) under N_2, which produced a dark orange-brown solution, which was stirred for 6 h under N_2. The solvent was removed under reduced pressure and the residue was dissolved in methylene chloride. Hexanes were added to the solution and, after filtration, the solvent was removed by rotary evaporation yielding a yellow-orange oil that was separated on a Chromatotron (eluent hexane with gradual addition of CH_2Cl_2) furnishing **21** (0.114 g, 0.284 mmol, 12%). IR (NaCl windows, neat, cm^{-1}) υ_{CO}: 2007 (s), 1927 (s). MS (CI, NH_3, *m/z* (%)): 403 (100, $[M + 1]^+$), 271 (57, $[M - C_{10}H_{11}]^+$), 187 (3, $M - C_{10}H_{11} - 3CO]^+$, 131 (8, $[C_{10}H_{11}]^+$).

Preparation of $[(\eta^6\text{-dibenzosuberane})Mn(CO)_3][BF_4]$ (23)

A mixture of $Mn(CO)_5Br$ (1.90 g, 6.92 mmol) and $AgBF_4$ (1.48 g, 7.61 mmol) in dry CH_2Cl_2 (50 mL) was heated at reflux for 3 h under nitrogen and then cooled to room temperature. To the reaction was added a solution of dibenzosuberane (1.78 g, 9.20 mmol) in dry CH_2Cl_2 (15 mL), and the mixture was heated at reflux overnight. After cooling and filtration, the filtrate was passed through Celite and concentrated to approximately one-third its volume under reduced pressure, and excess hexane (100 mL)

A sample suitable for structural determination by single-crystal X-ray diffraction was obtained by crystallization from acetone at room temperature.

Reaction of [(η^6-dibenzosuberane)$Mn(CO)_3$][BF_4] with *tert*-BuOK

A round-bottomed flask equipped with a side arm and stir bar was charged with [(η^6-dibenzosuberane)$Mn(CO)_3$][BF_4] (**23**) (0.377 g, 0.90 mmol) and *t*-BuOK (2.02 g, 18.0 mmol) and evacuated and purged with N_2 three times. This was followed by the addition of THF (25 mL) under N_2, which produced a dark red-brown-orange solution, which was stirred for 4 h under N_2. The solvent was removed under reduced pressure and the residue was dissolved in ether. Water (40 mL) was added to the ether solution and extracted with ether (2 × 10 mL). The organic layers were combined, dried with $MgSO_4$, and filtered. The solvent was removed by rotary evaporation yielding a red-orange material that was separated on a Chromatotron (eluent hexane with gradual addition of CH_2Cl_2) furnishing **28**, as an orange powder

Anal. calcd. for $C_{18}H_{13}MnO_3$ (%): C 65.06, H 3.92; found: C 65.45, H 3.96. A rod-shaped, orange crystalline sample suitable for structural determination by single-crystal X-ray diffraction studies was grown from dichloromethane by slow evaporation under an atmosphere of nitrogen at room temperature.

X-ray crystal structure determinations[3]

X-ray crystallographic data (see Tables 1 and 2) were collected from single crystal samples, each of which was mounted on a glass fibre. Data were collected using a P4 Bruker diffractometer, equipped with a Bruker SMART 1K charge coupled device (CCD) area detector, using the program SMART (48), and a rotating anode, using graphite-

monochromated Mo Kα radiation (λ = 0.71 073 Å). The crystal-to-detector distance was 4.987 cm, and the data collection was carried out in 512 × 512 pixel mode, utilizing 2 × 2 pixel binning. The initial unit cell parameters were determined by a least-squares fit of the angular settings of the strong reflections, collected by a 12° scan in 40 frames over three different sections of reciprocal space (160 frames in total). A hemisphere of data was collected with high redundancy, to better than 0.8 Å resolution at 153 K. Upon completion of the data collection, the first 40 frames were recollected to improve the decay correction analyses. Processing was carried out using the program SAINT (49), which applied Lorentz and polarization corrections to the three-dimensionally integrated diffraction spots. The program SADABS (50), was utilized for the scaling of the diffraction data, the application of a decay correction, and an empirical absorption correction based on redundant reflections for the data set. The structures were solved by using the direct-methods procedure in the Bruker SHELXTL program library (51), and refined by full-matrix least-squares methods on F^2 with anisotropic thermal parameters for all nonhydrogen atoms. Hydrogen atoms were either found and added from the difference map, and allowed to refine isotropically, or were added as fixed contributors at calculated positions, with isotropic thermal parameters based on the carbon atom to which they were bonded.

The structure of **3** exhibited a disorder between one of the carbonyl groups and a bromine atom and hence, the occupancy of the two conformations was allowed to refine as a free variable (final ratio of approximately 70:30). Likewise, the final structure of **4** was based on a disorder model in which the $Mn(CO)_2I$ tripod could exist in two conformations. The occupancy of the two conformations was allowed to refine as a free variable (final ratio of approximately 88:12). In the case of $[(\eta^6\text{-tetralin})Mn(CO)_2P(OMe)_3][PF_6]$ (**20**) the molecule lies on a crystallographic mirror plane; thus only half of the molecule was refined and the other half was generated by the mirror plane. This arises because of a disorder between C(7) and C(7a) such that there are two twisted half-chair conformations. Also, the anion was disordered, and two orientations were found for the PF_6 anion.[3]

Acknowledgements

Financial support from the Natural Sciences and Engineering Research Council of Canada (NSERC), from Science Foundation Ireland, and from University College Dublin, is gratefully acknowledged. Mass spectra were acquired courtesy of Dr. Kirk Green of the McMaster Regional Mass Spectrometry Facility. We also thank Dr. James F. Britten for X-ray crystallographic advice.

A microporous alkaline-earth phosphonate sustained by one-dimensional inorganic and organic units[1]

Ramanathan Vaidhyanathan, Amir H. Mahmoudkhani, and George K.H. Shimizu

Abstract: The single-crystal X-ray structure of a microporous alkaline-earth phosphonate incorporating a new triphosphonate ligand is presented. $Sr_2(H_2L)(CH_3OH)(H_2O)_4$, where L = 1,3,5-tris(4-phosphonophenyl)benzene, crystallizes in triclinic space group *P*-1 (a = 6.9230(4) Å, b = 15.3370(9) Å, c = 16.1930(11) Å, α = 62.201(3)°, β = 85.288(4)°, γ = 86.665(4)°). The solid is sustained by cooperative interactions between both one-dimensional inorganic and organic columns and forms a two-fold interpenetrated microporous structure. Gas and vapour sorption experiments confirm the microporosity. Based upon the sustaining interactions, this compound can serve as a model for more porous structures as extension of its structure disfavours further interpenetration.

Key words: metal–organic framework, coordination polymer, phosphonate, microporous, alkaline earth.

Résumé : Faisant appel à la diffraction des rayons X par un cristal unique, on a déterminé la structure cristalline d'un phosphonate de terre alcaline microporeuse incorporant un nouveau ligand triphosphonate. Le $Sr_2(H_2L)(CH_3OH)(H_2O)_4$ dans lequel L = 1,3,5-tris(4-phosphonophényl)benzène cristallise dans le groupe d'espèce *P*-1 [a = 6,9230(4) Å, b = 15,3370(9) Å et c = 16,1930(11) Å, α = 62,201(3)°, β = 85,288(4)° et γ = 86,665(4)°]. Le solide est soutenu par des interactions coopératives entre les colonnes unidimensionnelles inorganiques et organiques et il forme une structure microporeuse binaire dans laquelle on observe une interpénétration. Des expériences de sorption de gaz et de vapeur confirment la microporosité. Sur la base des interactions de soutien, ce composé peut servir de modèle pour des structures plus poreuses puisque l'extension de sa structure défavorise d'autre interpénétration.

Mots-clés : squelette organométallique, polymère de coordination, phosphonate, microporeux, terre alcaline.

Introduction

With the illustration that network coordination compounds can sustain permanent pores (1) has come an interest in the design principles for such materials (2) and a concurrent upsurge in the coordination chemistry of new ligands for their formation. The majority of research in this area has focused on polycarboxylate or polypyridyl ligands (3). The phosphine group is not a widely examined functionality for the formation of networks. Much of the available literature comes from the Puddephatt group who have reported numerous elegant examples of phosphine-based coordination polymers illustrating the breadth of different discrete and infinite assemblies possible (4). They have also conducted research on the dynamics of assembly (and disassembly) of coordination polymers (5). Most of our work has concerned sulfonate frameworks (6), which can range from highly flexible (**6a**–**6d**) to robust (**6e**, **6f**) even when sustained by H-bonding (7). There is a structural analogy with this group to the phosphonate chemistry illustrated by a predisposition to layered solids as well as observed intercalation phenomena (8). Also, both represent "adaptable" functionalities (9).

Phosphonates are strongly ligating functional groups that readily coordinate to a wide range of metal ions (10). Owing to the strength of these interactions, phosphonate groups have been extensively examined as ligands for the formation of porous solids (10). With most simple phosphonate ligands, the default structure observed is a layered motif, and many efforts have been made to perform chemistry in between the layers of these materials (11). With the potential of the layers to swell with solvation, the gallery height and hence chemical confinement of species can be variable. Pillaring the layers can form pores, with appropriate spacer phosphate or phosphonate groups between pillars, but these pores can be irregular (12). Simple linear diphosphonates typically will not yield a porous structure (13); however, we

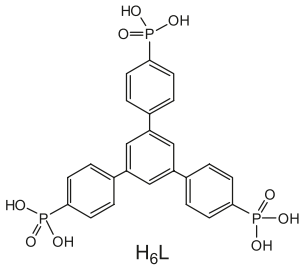
have recently reported an exception with 2,5-dihydroxy-1,4-benzenediphosphonate (14).



H_6L

Several polyphosphonate ligands have been reported, which have been designed to direct the metal phosphonate aggregate away from a layered motif and generate pores (15–17). A challenge with this strategy is that, with the various coordination modes/protonation states accessible to a RPO_3^{2-} group and the strength of its ligation, solids can readily precipitate in an amorphous state. While these materials may be porous, they would not be amenable to characterization by X-ray diffraction and likely possess a high dispersity of pore sizes. However, under appropriate conditions, crystalline and porous phosphonates have been attained (16), more typically with divalent metal ions (17), as more highly charged ions increase the likelihood of a less ordered, albeit more robust solid. Here, we report an alkaline-earth phosphonate framework with the new ligand 1,3,5-tris(4-phosphonophenyl)benzene, H_6L. The ligand possesses a rigid and sizeable trigonal core, which makes formation of an efficiently packed layered motif impossible. With Sr^{2+}, a doubly interpenetrated, three-dimensional crystalline solid is obtained, $Sr_2(H_2L)(CH_3OH)(H_2O)_4$, **1**. Gas and vapour sorption studies confirm permanent porosity. The structure is sustained by both one-dimensional inorganic and π-stacked organic columns, which mutually reinforce one another. The structure also presents a starting point for design of larger pore crystalline materials.

Experimental[3]

General

NMR spectra in solution were recorded on a Bruker WP-200 instrument at 200 MHz for ^1H and 50.3 MHz for ^{13}C and referenced internally to residual solvent peaks. Solid-state ^{31}P NMR spectra were recorded in a 2.5 mm MAS probe at 25 °C on a Bruker AMX300 spectrometer operating at a resonance frequency of 121.50 MHz. Thermal analysis (TG–DSC) data were recorded on a Netzsch STA 449C apparatus with a heating rate of 5 °C /min using an aluminum pan as a reference standard in N_2 atmosphere. Water vapour adsorption/desorption and CO_2 adsorption/desorption at room temperature were also studied on the same instrument. Infrared spectra were recorded on a Nicolet Nexus 470 FTIR spectrometer in the range of 4000–400 cm^{-1} by using dry KBr pellets containing about 1%–2% of the sample. The adsorption isotherm of CO_2 was carried out at 273 K using an Autosorb-1 from Quantachrome. Samples were outgassed at 120 °C for 24 h under vacuum before each measurement.

Synthesis of 1,3,5-tris(4-phosphonophenyl)benzene (H_6L)

The phosphonate diethylester of L was prepared using a slight modification of the Michaelis–Arbuzov reaction by following a published process (18). Tris(4-bromophenyl)benzene (1.2 g, 2.2 mmol), anhyd. $NiCl_2$ (28 mg, 0.22 mmol), and 80 mL of 1,3-diisopropylbenzene were added to a 250 mL three-necked flask fitted with reflux condenser, N_2 inlet, and an addition funnel. The flask was fitted into a regulated heating mantle with magnetic stirring. Triethylphosphite (2.3 mL, 13.2 mmol) and 1,3-diisopropylbenzene (20 mL) were transferred into addition funnel. The system was purged with N_2 for 10 min and kept under static atmosphere of the inert gas. The solution was brought to reflux when triethylphosphite solution was added over a period of 3 h. The mixture was refluxed for 24 h and allowed to cool overnight. The resulting dark black solution was vacuum distilled to remove the excess triethylphosphite and the solvent. The product was extracted using 50 mL $CHCl_3$. Removing the solvent by rotary evaporation leaving a yellow oily viscous liquid of the product with 84% yield (1.3 g). ^{31}P NMR: 19.42 (methanol-d_4) or 18.48 (acetone-d_6 or $CDCl_3$) ppm. ^1H NMR (acetone-d_6): 7.81–8.23 (m, 15H), 4.11 (p, 12H), 1.29 (t, 18H). EI-MS *m/z*: (M + H) 715.3 (100%), 658.1, 578.4, 529.1, 448.1, 366.2, 241.2, 155.1.

Hydrolysis of the diethyl ester using concentrated HCl afforded the corresponding phosphonic acid as a white powder at 90% yield. Solid-state CP MAS ^{31}P NMR: 19.10 ppm.

Synthesis of $Sr_2(H_2L)(CH_3OH)(H_2O)_4$ (1)

Compound **1** can be synthesized as a poorly crystalline solid by a reaction of H_6L with $Sr(OH)_2$, $SrCl_2$, or $SrCO_3$. Efforts to crystallize the compound by redissolving it in dilute hydrochloric acid and slow evaporation were unsuccessful. However, crystallinity can be improved by prolonged hydrothermal dissolution of the powder at elevated temperatures, as followed by PXRD. By careful examination of variation of reactants ratio, a reaction of $Sr(OH)_2$ with H_6L at 1:1 ratio was found to be promising. Crystals of **1** were grown hydrothermally by a reaction of H_6L (200 mg, 0.36 mmol) and $Sr(OH)_2$ (44 mg, 0.36 mmol) in a mixture of distilled water (7 mL) and methanol (3 mL) in a Teflon-lined Parr autoclave with the capacity of 23 mL. A temperature program is used as the following: rising from RT to 140 °C (30 min), isothermal at 140 °C for 2 day, and cooling to room temp during 3 day. Colourless needle crystals were ob-

X-ray crystallography

A colourless needle crystal of **1** with dimension of 0.6 × 0.08 × 0.04 mm^3 was mounted on the tip of a glass capillary using oil technique. Data were collected on a Nonius Kappa CCD fitted with an Oxford Cryosystem Series 700 Cryostream low-temperature device with graphite monochromated Mo Kα radiation (λ = 0.71 073 Å). The data were integrated using DENZO SMN (19) and processed using DENZOX (19). Absorption effects were empirically corrected by Gaussian quadrature using Sortav (20). Full-matrix least-squares refinement on F^2 was carried out using SHLEXL97 (21). All calculations were carried out using the WinGX software package (22). The results are summarized in Table 1. Selected bond distances and angles are in Table 2.

Results and discussion

can be synthesized as a poor solid by a reaction of H_6L with $Sr(OH)_2$, $SrCl_2$, or $SrCO_3$. Efforts to crystallize the compound by dissolution in dilute hydrochloric acid and slow evaporation were unsuccessful. Crystallinity can be improved by prolonged hydrothermal dissolution of the powder at elevated temperatures; however, loss of water from the structure results in a slight change of lattice parameters, as followed by PXRD and the material loses crystallinity after 24 h. Crystals suitable for single-crystal X-ray diffraction were grown hydrothermally by a reaction of H_6L and $Sr(OH)_2$.

The three-dimensional structure of **1** is built up from the linking of one-dimensional SrO chains by the organophosphonate ligand, L, into a three-dimensional honeycomb-like net (Fig. 1). The inorganic backbone is composed of face-sharing SrO_8 monocapped pentagonal biprisms. The two crystallographically independent Sr centers are each coordinated by five phosphonate oxygen atoms (Sr–O = 2.450(4)–2.854(4) Å), a μ_2 bridging methanol oxygen (Sr–O5 = 2.693(7), 2.742(7) Å), and two water molecules (Sr–O = 2.551(6)–2.736(6) Å). The phosphonate groups of L show two different binding modes, while P1 binds only through one oxygen to two different Sr centers, P2 and P3 each bind through two of their oxygens to three different Sr centers. Thus, each ligand connects to three different SrO chains and vice versa. Such connectivities result in a three-dimensional framework with large one-dimensional channels (19.34(1) × 14.83(1) Å) along the *a* axis visible in Fig. 1. Parts of the channels are lined by the hydrophobic phenyl rings of L, and the rest by the polar phosphonate groups. From any single one-dimensional inorganic column, the three pendant organic groups of L are separated by 6.92(1) Å along the *a* axis, a distance suited to including another aromatic ring. Considering these one-dimensional inorganic columns as infinite SBUs, structure **1** can be described as having a hms rod packing (23). From examination of a single net, the structure appears three-dimensionally porous; however, both the large pores and spacing between L molecules are sufficient to allow two-fold interpenetration of the structure (Fig. 2). This interpenetration results in the efficient pi-stacking of only the central aryl rings of L molecules from different nets (centroid–centroid distance = 3.52(1) Å), which serve to augment the stability of the framework. The two independent nets are offset by 60° so that while the central aryl rings of L are pi-stacked, clefts remain between the three peripheral aryl rings (Fig. 2, inset). The spacing of these rings is well-suited to enclathrate another aromatic ring, and so this was examined along with other sorption features.

Stability, porosity, and guest inclusion of 1

The stability of **1** was examined using thermogravimetric analysis carried out under N_2 atmosphere. Compound **1** exhibits a two-step mass loss of 13.54% observed in the temperature region of 65–400 °C, corresponding to the loss of four water molecules and the methanol (13.64% calcd.). All experiments to show that **1** sorbed aromatic molecules failed to show any uptake, even with benzene. The gas sorption isotherm of **1** using CO_2 indicated that it is porous, giving a Type 1 isotherm with significant hysteresis evident (Fig. 3). The BET fit gave a surface area of 146 m^2/g. This is a modest value for a surface area, but this is due to the interpenetrated structure. In a separate experiment, the reversible

Fig. 2. Wireframe diagram showing the relation of the two interpenetrated nets (shown in red and blue). The inset is a space-filling diagram of the pi-stacking down the *a* axis of the central arene ring of staggered L molecules that further augments the stability.

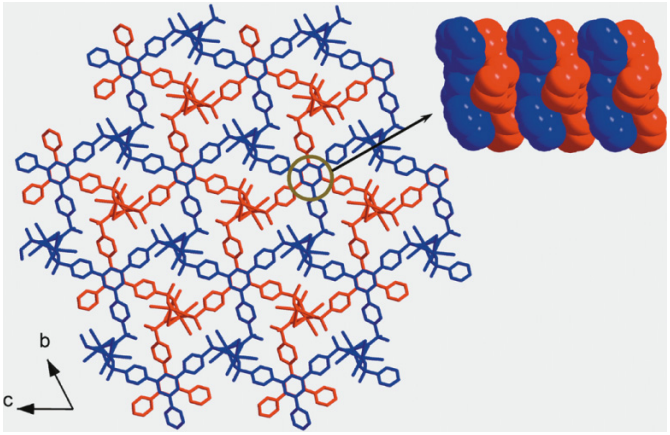

Fig. 3. CO_2 sorption and desorption isotherm for **1** at 273 K.

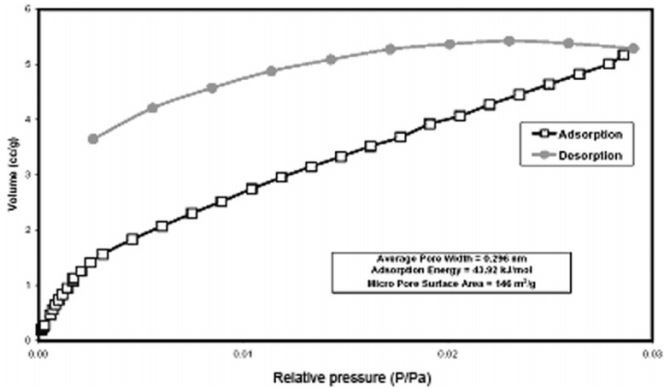

Fig. 4. Reversible uptake of water vapour by **1** upon successive heating and hydration cycles (water vapour introduced as flow gas) as monitored by thermogravimetry: blue, mass; red, temperature; green, DSC.

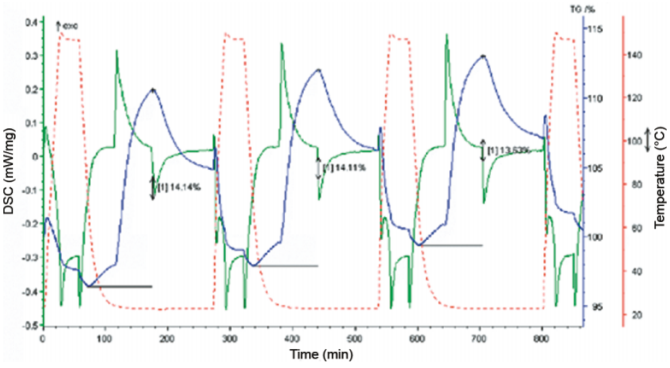

uptake of water vapour by **1** was examined over three heating–cooling cycles from 25 to 150 °C. Compound **1** takes up 14.14%, 14.11%, and 13.63% in the successive cycles (Fig. 4). Carbon dioxide uptake was investigated by heating **1** up to 100 °C in dry N_2 on the TG, to lose solvent

Fig. 5. CO_2 uptake by **1**. The blue trace shows the thermogravimetric analysis of a sample of **1** heated to first desolvate the sample. CO_2 was introduced at 50 min.

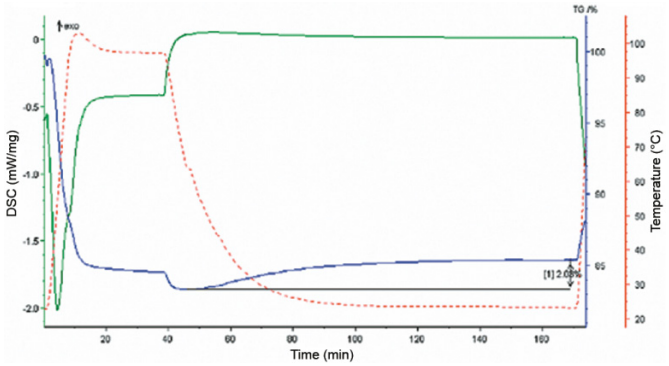

Fig. 6. IR spectrum of **1** before (top) and after (bottom) exposure to CO_2 gas. Peaks at ~2350 cm^{-1} correspond to the asymmetric stretch of CO_2.

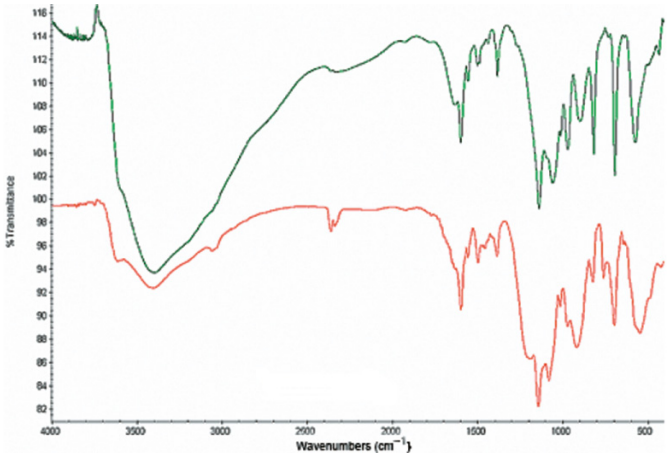

molecules, and then it was allowed to stand at RT under CO_2 for 2 h (Fig. 5). A 2% mass gain, corresponding to 0.4 mol of CO_2/formula unit, was observed. IR spectroscopy (Fig. 6) corroborated the presence of CO_2 in the samples as shown by the growth of peaks at 2350 cm^{-1}. Over three sorption–desorption cycles in the temperature range of 25 to 300 °C, a 2.5%–3% CO_2 uptake was observed. This observation of selective CO_2 uptake by this material is intriguing given the global interest in CO_2 sequestration and the recent work concerning application of MOFs for this target (24).

Design implications

With respect to phosphonate ligands in general, the coordination to metals is not so regular as to offer any zero-dimensional or one-dimensional aggregates (25) that could truly be called SBUs. The ligand L was designed specifically to disfavour a densely packed solid, and the rigid trigonal core directs the formation of a two-fold interpenetrated microporous structure. The framework is stabilized both by the one-dimensional inorganic columns, which could be regarded as infinite SBUs (23), and pi-stacked central aryl groups of L molecules that result from the two-fold interpenetration. The topology of **1** has design implications. The obvious means of increasing porosity would be to add

© 2008 NRC Canada

additional phenyl spacers in L off the core. With the π-stacked L molecules being specifically enabled by two-fold interpenetration, lengthening the pendant arms in L would not lead to a more interpenetrated structure, as with diamondoid networks (26), without compromising the stabilizing π-stacked column. Thus, porosity should be able to be systematically enhanced. Furthermore, an extension of this thinking would be that any planar aromatic polyphosphonate, trigonal or not, would favour the formation of one-dimensional alkaline-earth phosphonate columns likely augmented by π-stacked aromatics. Thus, **1** provides several structural insights on how phosphonate SBUs can be used to form more porous solids.

Conclusions

A new alkaline-earth phosphonate has been presented. The topology is that of hexagonal sheets linked in one-dimension by inorganic columns. Small clefts are present in the structure giving a degree of microporosity as confirmed by gas adsorption. Compound **1** has an affinity for CO_2 (albeit a small capacity) as confirmed by gravimetry and IR experiments. The topology of this network should allow extension of the ligand L to form larger pore solids without increasing the likelihood of higher degrees of interpenetration that would offset any increase to the pore volume.

Synthesis and photophysical properties of naphthyl-, phenanthryl-, and pyrenyl-appended bis(pyridyl)triazine ligands and their Zn(II) and Ru(II) complexes[1]

Francesco Nastasi, Frédérique Loiseau, Sebastiano Campagna, Elaine A. Medlycott, Marie-Pierre Santoni, and Garry S. Hanan

Abstract: A family made of four bis(pyridyl)triazine ligands with appended aryl rings, including three fused aromatic rings, have been synthesized, and their corresponding homoleptic Ru(II) and Zn(II) complexes have been prepared and characterized by several means. The free ligands 2,4-di(2-pyridyl)-6-phenyl-1,3,5-triazine (**L1**); 2,4-di(2-pyridyl)-6-(1-naphthyl)-1,3,5-triazine (**L2**); 2,4-di(2-pyridyl)-6-(9-phenanthryl)-1,3,5-triazine (**L3**); and 2,4-di(2-pyridyl)-6-(1-pyrenyl)-1,3,5-triazine (**L4**) were formed in triazine ring-forming reactions from the reactions of the cyano-functionalized aromatic rings with $LiNMe_2$ followed by the addition of 2 equiv. of 2-cyanopyridine. The metal complexes examined in this study are the homoleptic Ru(II) complexes $Ru(\mathbf{L1})_2^{2+}$ (**2a**), $Ru(\mathbf{L2})_2^{2+}$ (**2b**), $Ru(\mathbf{L3})_2^{2+}$ (**2c**), and $Ru(\mathbf{L4})_2^{2+}$ (**2d**) and Zn(II) complexes $Zn(\mathbf{L1})_2^{2+}$ (**3a**), $Zn(\mathbf{L2})_2^{2+}$ (**3b**), $Zn(\mathbf{L3})_2^{2+}$ (**3c**), and $Zn(\mathbf{L4})_2^{2+}$ (**3d**). Also, crystallographic data for the free ligands and Zn(II) and Ru(II) complexes have been obtained in some cases. The redox behaviour and absorption spectra of all the species have been investigated, together with the luminescence properties of the free ligands at room temperature in fluid solution and of the Ru(II) complexes both at room temperature in fluid solution and at 77 K in rigid matrix. The redox data indicate that the free ligands are reduced twice at relatively mild potentials (< –2.30 V vs. SCE), with the first reduction almost independent of the nature of the substituted aryl group. The UV absorption spectra of all the compounds are dominated by intense spin-allowed π–π* transitions mainly centered on the bis(pyridyl)triazine moiety; however, in **L2**–**L4**, moderately intense intraligand charge-transfer (ILCT) bands are also present. Such bands are red-shifted in the Zn(II) compounds, while they are obscured in the Ru(II) species by the more intense spin-allowed metal-to-ligand charge-transfer (MLCT) bands. The free ligands exhibit interesting emission properties, ranging from fluorescence from π–π* states to excimeric (in **L4**) and ILCT (in **L2** and **L3**) emission. In the Ru(II) complexes, strong emission is found at 77 K from triplet MLCT states. For **2c** and **2d**, the emissive MLCT states are mixed with low-lying triplet ligand-centered states.

Key words: triazine ligands, ruthenium complexes, zinc complexes, ILCT emission.

Résumé : On a effectué la synthèse d'une famille formée de quatre ligands bis(pyridyl)triazine portant des noyaux aromatiques, y compris trois noyaux aromatiques dont on a préparé et caractérisé les complexes homoleptiques correspondants du Ru(II) et du Zn(II). Les ligands libres 2,4-di(2-pyridyl)-6-phényl-1,3,5-triazine (**L1**), 2,4-di(2-pyridyl)-6-(1-naphtyl)-1,3,5-triazine (**L2**), 2,4-di(2-pyridyl)-6-(9-phénanthryl)-1,3,5-triazine (**L3**) et 2,4-di(2-pyridyl)-6-(1-pyrényl)-1,3,5-triazine (**L4**) ont été obtenus par des réactions conduisant à des triazines et impliquant l'action du $LiNMe_2$ sur des cyano portés par noyaux aromatiques fonctionnalisés, suivie par l'addition de deux équivalents de 2-cyanopyridine. Les complexes métalliques examinés dans cette étude sont les complexes homoleptiques du Ru(II), $Ru(\mathbf{L1})_2^{2+}$ (**2a**), $Ru(\mathbf{L2})_2^{2+}$ (**2b**), $Ru(\mathbf{L3})_2^{2+}$ (**2c**) et $Ru(\mathbf{L4})_2^{2+}$ (**2d**) et du Zn(II), $Zn(\mathbf{L1})_2^{2+}$ (**3a**), $Zn(\mathbf{L2})_2^{2+}$ (**3b**), $Zn(\mathbf{L3})_2^{2+}$ (**3c**) et $Zn(\mathbf{L4})_2^{2+}$ (**3d**). Dans certains cas, on a aussi obtenu des données cristallographiques pour les ligands libres et des complexes du Zn(II) et du Ru(II). On a étudié le comportement redox et les spectres d'absorption de toutes les

espèces, de même que les propriétés de luminescence des ligands libres, à la température ambiante et en solution fluide ainsi que celles des complexes du Ru(II) tant à la température ambiante, en solution fluide, que celles à 77 K, dans une matrice solide. Les données redox indiquent que les ligands libres sont réduits deux fois à des potentiels relativement faibles (< –2,30 V vs SCE) et que la première réduction est pratiquement indépendante de la nature du substituant aryle. La région UV des spectres d'absorption de tous les composés est dominée par d'intenses transitions π–π* permises par les spins et centrés principalement sur la portion bis(pyridyl)triazine; toutefois, dans les ligands **L2**–**L4**, on observe aussi la présence de bandes de transfert de charge intraligand (TCIL) d'intensité moyenne. Ces bandes sont déplacées vers le rouge dans les composés du Zn(II) alors que dans les espèces Ru(II) elles sont obscurcies par les bandes de transfert de charge métal à ligand (TCML) permises par les spins et de grande intensité. Les ligands libres possèdent des propriétés d'émission intéressantes allant de la fluorescence des états π–π* aux émissions excimères (dans **L4**) et aux bandes de transfert de charge intraligand (dans **L2** et **L3**). Dans les complexes du Ru(II), à 77 K, on observe une émission intense de transfert de charge métal à ligand à partir des états triplets. Pour les composés **2c** et **2d**, les états d'émission TCML sont mixtes avec des états triplets de basse énergie centrés sur le ligand.

Mots-clés : ligands de triazine, complexes du ruthénium, complexes du zinc, émission de transfert de charge intraligand (TCIL).

[Traduit par la Rédaction]

Introduction

Complexes of polypyridine ligands have been the subject of intense research because of their promising photophysical properties and potential applications in areas of light-harvesting devices, luminescent sensors, and photocatalysis. In particular, complexes of d^6 transition-metal ions show promise in these fields because of their relatively long excited-state lifetimes and emission through low-lying MLCT (metal-to-ligand charge-transfer) states (1–5). Over the last two decades, there has been considerable efforts to optimize the photophysical properties of Ru(II) complexes based on 2,2′:6′,2″-terpyridine (tpy) (2, 6). Indeed, the tridentate motif offers synthetic advantages over bidentate ligands based on 2,2′-bipyridine (bpy), as the latter creates stereocentres in metal complexes with octahedral geometry. Consequently, in larger polynuclear systems, the separation of diastereomers can be problematic despite synthetic advances in the purification of isomers (7, 8). Unfortunately, Ru(II) tpy-type complexes have poor photophysical properties, as the steric strain imposed in N–N–N coordination in tridentate ligand lowers the energy of non-emissive, metal-centred (MC) states, which can be thermally accessed at room temperature. Synthetic strategies have been developed to overcome the deactivation of MLCT excited states, primarily focusing on manipulating the energy of ^{3}MLCT states relative to ^{3}MC states. Alternatively, ligand systems have been developed with low energy emissive intraligand charge-transfer (ILCT) states (9). The excited-state energy of the ILCT state in Ru(II) complexes, or complexes of other transition-metal ions, must be significantly lower in energy than the MLCT/MC states to influence the excited-state lifetime (10–14). Alternatively, d^{10} Zn(II) metal ions can be employed to study the ILCT emission, as these polypyridine complexes of such metal ions do not exhibit MLCT or MC states at low energies, and their eventual emission can involve ILCT states (13–16). An ILCT transition requires a coordinating motif to acts as an electron acceptor and an appended organic group to act as an electron donor. Tpy is typically an electron acceptor, and a variety of organic groups act as the electron donor. Fused aromatic rings have previously been employed as the organic, electron donating motif, as they offer interesting properties in the excited state through excimer and exciplex formation as well as offering a means of aggregating cations in the solid state through π–π interactions (12, 14, 15, 17–19). Herein, we report the synthesis and characterization of a family of triazine ligands with fused aromatic rings appended. The absorption spectra and redox properties of free ligands and of their Zn(II) and Ru(II) complexes are also discussed, together with the luminescence properties of free ligands and Ru(II) complexes.

Results and discussion

Synthesis

The ligands were synthesized by using a slightly modified version of a previously reported procedure (see Supplementary data for full ligand structures) (20, 21).[3] $LiNMe_2$ was generated in situ through the slow addition of *n*-BuLi to $HNMe_2$ in anhyd. diethylether. On addition of the cyano-precursors, an amidinate intermediate formed, which was converted to the appropriate triazine ligand by the addition of 2 equiv. of 2-cyanopyridine. The reaction proceeded slower than previously reported syntheses for non-symmetric triazine ligands and with slightly lower yields. The presence of the adjacent fused aromatic ring may lead to a stabilized amidinate intermediate by intramolecular H-bonding with the $C{=}N^-$ motif, which interferes with the cyclization reaction (Scheme 1).

Complexes **2** were synthesized by addition of $RuCl_3{\cdot}3H_2O$ to 2 equiv. of the ligand, with 3 equiv. of $AgNO_3$ in EtOH. The complexes were purified by column chromatography followed by anion exchange to afford complexes **2b**–**2d** in 56%, 23%, and 11% yields, respectively. The Zn(II) complexes were synthesized by the addition of $Zn(ClO_4)_2{\cdot}6H_2O$ to a solution of the appropriate ligand in acetonitrile at reflux for 15 min. Precipitation of the product by the addition

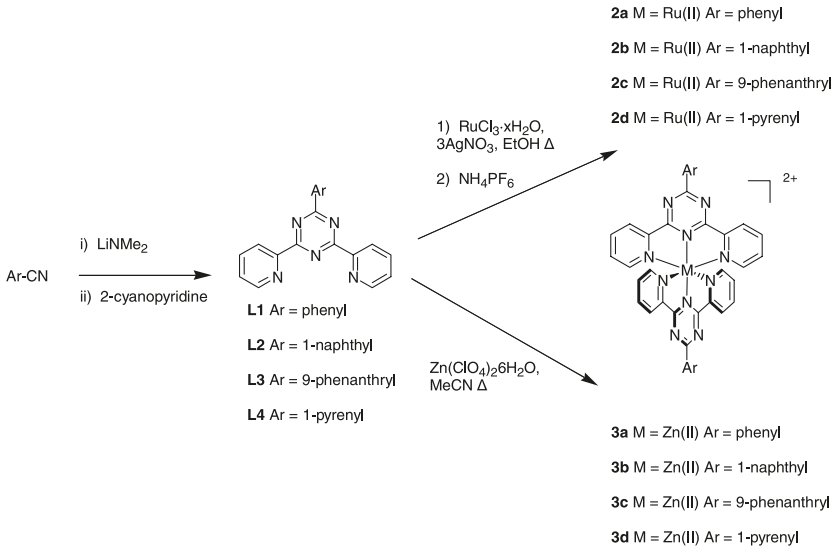
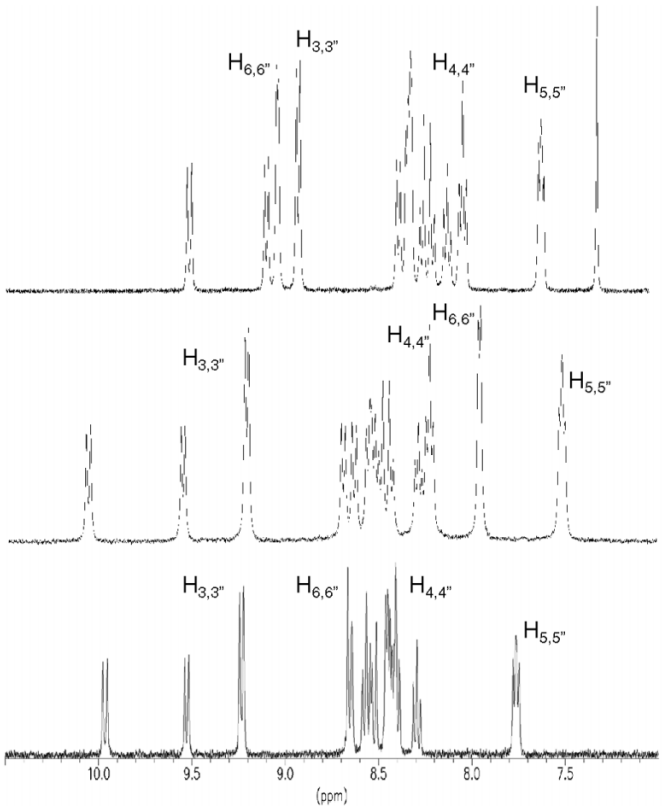
Scheme 1. Synthesis of ligands **L1**–**L4** and the complexation of the ligands to form the Ru(II) complexes **2a**–**2d** and Zn(II) complexes **3a**–**3d**.



of diethyl ether afforded the complexes **3a**–**3d** in 68%, 55%, 74%, and 84% yields, respectively. The complexes were characterized in solution by ^{1}H NMR and in the solid state by elemental analyses.

On complexation to the Ru(II) or Zn(II) metal ions, the pyridyl and pyrenyl signals of ligands are both shifted to lower field owing to the electron-withdrawing effect of the metal ions (Fig. 1). The Zn(II) ion in complex **3d** has a greater electron-withdrawing effect on the pyridyl protons closest to the metal centre ($H_{5,5''}$ and $H_{6,6''}$) when compared with the Ru(II) complex **2d**. Complex **3d** has limited solubility and reaches saturation point in solution very rapidly as compared with **2d** presumably owing to aggregation caused by the pyrenyl group.

Fig. 1. ^{1}H NMR spectra of **L4** in $CDCl_3$ (above), **2d** (middle), and **3d** (below) in CD_3CN. $H_{3,3''}$, $H_{4,4''}$, $H_{5,5''}$, and $H_{6,6''}$ refer to the pyridyl protons.



Solid-state structures

Crystals suitable for analyses of **L2** were obtained by slow diffusion of hexane into a concentrated solution of **L2** in chloroform. One molecule of water is found in the asymmetric unit with H-bonding to *N*-pyridyl atoms with N–H distances of 2.15 and 2.14 Å. Significant face-to-face π-stacking interactions are observed in the extended lattice with each triazine ring overlaying pyridyl rings above and below the plane with centroid-to-centroid distances of 3.6–3.8 Å (Fig. 2).

Attempts to crystallize **2b** and **3b** as the PF_6 and ClO_4 salts, respectively, were unsuccessful. Red crystals of **2b** were obtained by addition of excess NH_4BF_4 in methanol to a concentrated solution of **2b** in acetonitrile followed by slow diffusion of isopropyl ether. The complex crystallized in the monoclinic space group *P*2(1)/*n* with two cations, four anions, (three PF_6^- anions and one BF_4^- anion) and four molecules of acetonitrile. The Zn(II) complexes could be synthesized as the PF_6^- salts according to a literature procedure (22), and crystals of **3b** were obtained as the PF_6^- salt by slow diffusion of isopropyl ether into an acetonitrile solution of the complex. Complex **3b** crystallized in the non-centrosymmetric space group *P*2(1) with two cations, four PF_6 counter-ions and three acetonitrile solvent molecules. In both crystal structures, significant π-stacking interactions were observed in the extended lattice between naphthyl groups and coordinating pyridyl rings with centroid-centroid distances of 3.66 and 3.71 Å for complex **2b** and 3.89 and 3.96 Å in complex **3b** (Fig. 3). The use of non-covalent interactions to aggregate functional assemblies through crystal engineering is appealing as conventional, covalent ap-

proaches require multistep syntheses (4, 17, 19, 22). Naphthyl-pyridyl, π-stacking interactions were previously observed in naphthyl-appended tpy-based Ru(II) and Fe(II) complexes (19). We previously reported similar interactions in the solid-state structure of complex **2c** in which phenanthryl groups π-stack with pyridyl groups (20). The naphthyl groups twist away from the central triazine rings by 16.6°–36.9° in complex **2b** and 21.5°–29.1° in complex **3b** for the four ligands of the two cations. Intramolecular C–H–N(triazine) H-bonding interactions are still favouring minimal twisting of the naphthyl group relative to the triazine ring and thereby favouring significant mixing of molecular orbitals.

The M–N bond distances in both **2b** and **3b** are shorter to the central triazine ring compared with the terminal pyridyl rings as expected owing to the constrained bite angle imposed by tridentate ligands. The Ru–N bond distances, 1.97–1.98 Å to the central triazine ring and 2.09–2.11 Å to the terminal pyridyl rings, are in agreement to those previously reported for related Ru(II) complexes of triazine-based ligands (20, 21). The Zn–N bond distances are slightly longer and similar to those reported for tpy-type ligands (22).

Electrochemical properties

The redox data for the ligands and their complexes are gathered in Table 1. The redox data of ligands **L1**, **L2**, and **L4** are reported in DMF owing to their poor solubility in acetonitrile. In all of the ligands, an initial reversible

[c]From ref. 21.

triazine-based reduction is observed at –1.40 to –1.42 V vs. SCE. The negligible potential difference among all four ligands indicates that the aryl substituent on the triazine has little influence on this process. A second triazine-based reduction is observed at –2.15 to –2.17 V in **L2**–**L4**. This same reduction shifts to a more negative potential in **L1** (–2.25 V), indicating the LUMO +1 molecular orbital involves non-negligible mixing of the aromatic and triazine motifs. An additional pyrenyl-based reduction is observed in **L4** at –1.84 V. No oxidative processes are observed in **L1**–**L3** within the solvent potential limits. However, the pyrene motif is oxidized at +1.54 V in **L4**, which is more positive than the tpy-pyrene ligand (+1.49 V) owing to the stabilizing effect of the electron-deficient triazine ring (12). However, overall a lower energy HOMO–LUMO gap is estimated by electrochemistry: 2.94 V for **L4** as compared to 3.15 V for tpy-pyrene (12).

The oxidative potentials for the Ru(II)/(III) couple in complexes **2a**–**2c** are in agreement with those previously reported for Ru(II) complexes of triazine ligands (20, 21). However, in complex **2d**, the pyrene motif is oxidized prior to the Ru(II) centre at +1.46 V, and the Ru(II)/(III) couple is consequently at a more positive potential and irreversible. In the Zn(II) complex **3d**, the pyrene motif is oxidized at +1.45 V. The electron-withdrawing effect of metal coordination results in significant positive shifts in the potentials for the triazine-based reductions for both Ru(II) complexes **2a**–**2d** and Zn(II) complexes **3a**–**3d**. Each triazine ligand has two reductions giving a total of four reductions for complexes **2a**–**2d** and **3a**–**3c**.

Absorption spectra

The absorption spectral data for the ligands and their complexes are gathered in Table 2. Figure 4 shows the absorption spectra of some representative compounds. At wavelengths shorter than 350 nm, ligand-based spin-allowed π–π* transitions dominate the spectra. However, less intense bands are also present at longer wavelengths even for the free ligands, particularly for **L2**–**L4**. These bands are assigned to aryl-to-bis(pyridyl)triazine charge-transfer transitions (intraligand charge transfer, ILCT). Compound **L1** does not exhibit a similar low energy absorption band, since the phenyl group is a worse electron-donor group compared with the other fused aromatic rings. On metal complexation, such ILCT bands are expected to shift to lower energy, since the bipyridyltriazine orbitals are stabilized by metal coordination. This is clearly evidenced in the Zn(II) complexes, which exhibit ILCT absorption bands that extend to the visible, in particular for complexes **3b**–**3d** (see Fig. 4, bottom). The ILCT transitions are red-shifted in comparison to Zn(II) tpy complexes with fused aromatic rings (17), as a consequence of the better acceptor properties of the bis(pyridyl)triazine group compared with the terpy. In Ru(II) complexes **2a**–**2d**, the ILCT bands are largely obscured by the spin-allowed metal-to-ligand charge-transfer (MLCT) transitions, which are responsible for the relatively strong absorption bands in the 450–560 nm region (Table 2, Fig. 4, middle). However, the absorption in the 450–560 nm region increases on passing from **2a** (not shown in Fig. 4, middle) and **2b** to **2c**, and even further on going to **2d**, which exhibits a maximum at lower energy than the other complexes. This cannot be attributed only to contribution of the ILCT

bands in the visible, since the lowest energy bands in **3d**, assigned to the ILCT transition, maximizes at 460 nm, with negligible contribution at wavelengths longer than 500 nm. Most likely, it is the intensity of the spin-allowed MLCT bands, which increases in the series.

The absorption spectra of all the compounds are stable for at least three days and do not exhibit any significant dependence on the concentration, within the range investigated ($8 \times 10^{-6} - 5 \times 10^{-5}$ mol/L).

Luminescence properties

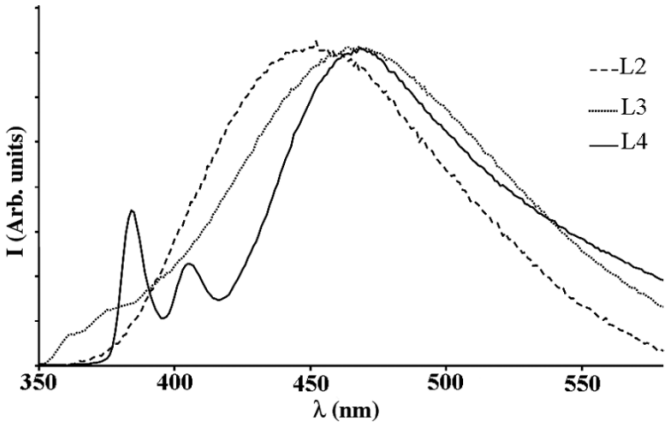
The luminescence properties of the free ligands were studied in air-equilibrated acetonitrile solutions at room temperature. The luminescence data of the ligands are collected in Table 3, and the emission spectra of **L2**, **L3**, and **L4** are shown in Fig. 5.

Table 3. Luminescence properties of the free ligands.

	λ_{max} (nm)	τ (ns)
L1	414	1.7
L2	450	2.6
L3	376 sh	20 (67%), 2.3(33%)
	470	2.0
L4	384, 406	22 (85%), 1.7 (15%)
	471	2.2

Note: In acetonitrile at 298 K. The percentage of the decay in the biexponential analysis is reported in parentheses. The excitation wavelength is 308 nm.

Fig. 5. Emission spectra of **L2**, **L3**, and **L4** in acetonitrile.



L1 is weakly emissive, with an unstructured emission with a maximum at 414 nm in acetonitrile with an excited-state lifetime of 1.7 ns. The emission is assigned to fluorescence from the π–π* singlet state, with only a partial phenyl-to-bis(pyridyl)triazine charge-transfer character.

L2 exhibits a broad band with maximum at 450 nm and a lifetime of 2.6 ns. The emission is too low-lying to be π–π* fluorescence from the naphthalene subunit (23, 24), and also too much red-shifted from that of **L1** to be π–π* fluorescence mainly involving the bis(pyridyl)triazine. In fact, naphthalene derivatives often exhibit a low-energy emission of excimeric nature. However, naphthalene excimer emission is normally in the range of 400–425 nm (23, 24). On the basis of such comments, we assign the emission of **L2** to a (naphthalene-to-bis(pyridyl)triazine) intraligand charge-transfer (ILCT) excited state. Such a state should be very sensitive to the presence of protons, since the acceptor subunit is protonable; indeed, addition of triflic acid leads to disappearance of the 450 nm emission band. As testified by the change in the absorption spectrum of **L2** upon triflic acid addition (see Supplementary data, Fig. S1: the ILCT absorption band is significantly red shifted), protonation of the acceptor subunit leads to a stabilization of the ILCT level, which apparently becomes non emissive.[3]

As far as **L3** is concerned, an emission band is present with maximum at 470 nm and 2.0 ns lifetime. However, on the blue-edge of the emission band, another emission feature appears, structured (see Fig. 5). When the emission decay is

© 2008 NRC Canada

Fig. 6. Change of the emission spectrum of **L3** upon protonation. Concentration of **L3** is 7.1×10^{-6} mol/L, and concentration of H^+ is 1.95×10^{-3} mol/L (molar ratio of **L3**:$H^+$is 1:3), (λ_{exc} = 303 nm, the isosbestic point).

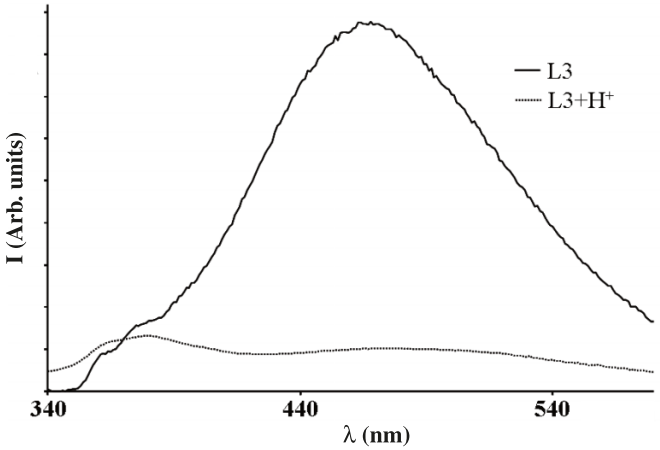


Fig. 7. Change of the emission spectrum of **L4** upon protonation. Concentration of **L4** is 4.9×10^{-6} mol/L, and concentration of H^+ is 1.95×10^{-3} mol/L (molar ratio of **L4**:$H^+$is 1:3), (λ_{exc} = 340 nm).

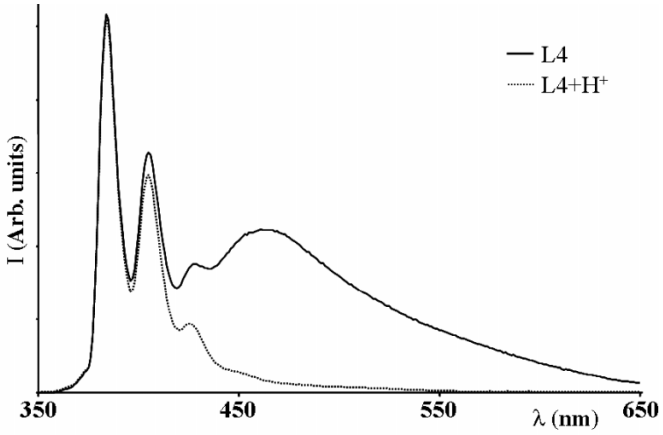

analyzed at 380 nm, a biexponential decay is found (see Table 3), with a long-lived component (20 ns) following a short-lived component (2.3 ns). The short-lived component is assigned to the contribution of the emission with a maximum at 470 nm, and indeed its lifetime agrees with the monoexponential decay recorded at 470 nm (Table 3), whereas the longer-lived component is assigned to the structured emission taking place in the range of 350–400 nm. This latter emission is attributed to fluorescence from the phenanthryl-based π–π* singlet, and the dominant, lower-energy emission is attributed to the ILCT excited state. To support such an assignment, phenanthrene fluorescence in polar solvents is reported to occur at 347 nm with a lifetime of 60.7 ns (24, 25), values in good agreement with those obtained for our substituted phenanthrene species. As for **L2**, protonation stabilizes the ILCT level of **L3**, leading to red shift of the low-energy absorption band and disappearence of the ILCT emission (Figs. S2 and 6).[3]

L4 clearly exhibits a double emission: a structured band, with a maximum at 380 nm, and a broad emission with maximum at about 470 nm (Table 3, Fig. 5). The higher energy emission is assigned to the π–π* singlet state of the pyrenyl subunit, which is reported to occur at about 375 nm in polar solvents (24, 26), and the lowest-energy emission is assigned to the excimer. Indeed, pyrene excimeric emission is reported to occur at the same energy (23). Moreover, the eventual ILCT emission should occur at significantly lower energy than 470 nm, as the ILCT level in **L4** is stabilized compared with the same level in **L3** (see absorption spectra) (27). A supporting experiment for the assignment of the low-energy emission of **L4** to an excimeric state is also the concentration dependence of the emission spectrum; indeed on increasing concentration (e.g., from 5×10^{-6} mol/L to 2×10^{-5} mol/L), the low-energy emission band significantly increases with respect to the high-energy emission feature. As for what found for **L3**, the analysis of the emission decay at 480 nm yields a monoexponential behaviour, while analysis of the decay at 380 nm gives a biexponential behaviour, with the shorter-lived component corresponding (within the experimental uncertainties) to the 480 nm emission lifetime (Table 3).

As for **L2** and **L3**, addition of triflic acid leads to disappearance of the lower-energy band, while the higher-energy π–π* (monomeric) emission remains unaffected (Fig. 7; for the changes on absorption spectrum upon acid addition, see Supplementary data).[3] Whereas the emission changes upon acid addition of **L4** are experimentally equivalent to those of **L3**, their interpretation is slightly different, as the origin of the 470 nm broad emission is different in the two compounds. In principle, proton addition is not expected to have a direct effect on excimer formation; in this case, it could change the association constant for excimer formation, since the pyrene "substituent" (i.e., the bis(pyridyl)triazine subunit) is protonable, and the excimer would become positively charged. However, if this would happen, the monomer emission would increase, and this is not found experimentally; therefore, protonation seems to not affect monomer/excimer ratio. This strongly suggests that the consequence of the protonation is that the ILCT state, potentially a quencher for both monomer and excimer emission, is displaced to lower energy, thereby increasing the driving force for the quenching process(es). This is supported by the effect of protonation on the absorption spectrum of **L4** (see Supplementary data).[3] It is suggested that quenching of the excimer emission of **L4** upon acid addition can be attributed to deactivation of the excimer to the proton-stabilized ILCT state (non emissive), which in the protonated species is significantly lower-lying than the excimeric state, where it was almost isoenergetic in the non-protonated species, so that the change in driving force is significant (it would pass from a very small value to a significant value). Most likely, the monomer emission is already partially quenched in **L4** by the ILCT state and increasing the driving force for this quenching process as a consequence of protonation has only negligible effects on monomer emission. However, this explanation should be considered as tentative, since we cannot perform quantitative calculations based on the effective driving force values, which are unknown.

Unfortunately, the study of the luminescence properties of the Zn(II) complexes **3a**–**3d** gave non reproducible results,

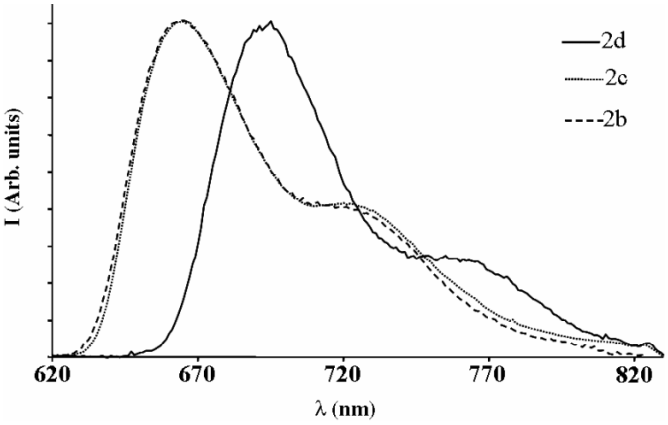
[a]Higher-energy feature.
[b]From ref. 21.

most likely since the compounds were poorly stable at the concentrations used for the luminescence experiments (lower than 8×10^{-6} mol/L), a somewhat not unexpected behaviour for Zn(II) polypyridine complexes (15). Luminescence properties of the Zn(II) compounds **3a**–**3d** are therefore not investigated here.

Ru(II) polypyridine complexes based on tridentate ligands are very weakly emitting at room temperature (Table 4) because of the presence of a low-lying metal-centered (MC) state, which deactivates the potentially luminescent MLCT state (2, 3, 5, 28). This is evidently even more true for Ru(II) complexes of bis(pyridyl)triazine ligands, as this ligand has probably a weaker ligand field strength than tpy, like the absence of room-temperature emission of other homoleptic Ru(II) complexes based on substituted bis(pyridyl)triazine ligands seems to suggest (21). As a matter of fact, **2b**, **2c**, and **2d** are not luminescent at all at room temperature, and **2a** (21) is only weakly luminescent (λ = 710 nm, τ = 8 ns, $\Phi = 9 \times 10^{-5}$). All of the four Ru(II) complexes are emissive at 77 K from their lowest energy MLCT triplet (Table 4, Fig. 8), demonstrating that the MC state is no longer populated in this condition. The emission is partially structured, as expected for a MLCT emission at low temperature (29, 30), and the vibrational progression is typical of C=C and C=N stretching. However, the 77 K emission properties of **2a**–**2d** show interesting differences, the larger one being the longer lifetimes (one order of magnitude longer, see Table 4) exhibited by **2c** and **2d** compared with **2a** and **2b**. The reason for such longer lifetimes can have two origins: (*i*) delocalization of the MLCT state towards the larger phenanthryl and pyrenyl moieties, which can be coplanar with the triazine ring, so that the geometry of the excited state becomes closer to the geometry of the ground state, decreasing Franck–Condon factor for radiationless decay; (*ii*) mixing of the MLCT state with a closely-lying, longer-lived ligand-centered (^{3}LC) state. This ^{3}LC state could be the triplet of the ILCT state, which is expected to be lower in energy for the phenanthryl- and pyrenyl-containing ligands. In fact, hypothesis (*i*) would suggest that the first reduction potentials of **2c** and **2d** are less negative than those of the other two ruthenium(II) complexes, but this is not the case (see Table 1). Moreover, delocatization of the MLCT state over the aryl moieties should red shift the emission spectrum of **2c** compared with **2a** and **2b**, and this is not experimentally found. For these reasons, hypothesis (*ii*) appears to be preferred. At this point, it should be recalled that the presence of closely-lying states have already been reported to be able to influence the dynamics of the luminescent level, even at 77 K and without affecting the energy of the emitting level (31).

Fig. 8. Luminescence properties of **2b**, **2c**, and **2d** in EtOH/MeOH 4:1 (*v*/*v*) at 77 K.



Conclusion

Introducing fused aromatic rings to the triazine-based tridentate ligands offers a means to significantly stabilize the ILCT band compared with their analogous systems based on tpy. As a consequence, room-temperature emission studies of **L2**–**L4** indicate that some of their emissive excited states have significant charge-transfer character. In the case of **L4**, an excimer emission is also found. On complexation, the ILCT states are red-shifted in the Zn(II) complex, as clearly evidenced by the absorption spectra. Unfortunately, luminescence of the Zn(II) complexes cannot be investigated, since the compounds are poorly stable at the low concentrations needed for luminescence experiments. In Ru(II) complexes, the potentially emissive MLCT excited states are quenched at room temperature by the presence of low-lying metal-centered states, whereas MLCT emission takes place at 77 K in rigid matrix with (for **2c** and **2d**) some contribution from closely lying LC (most likely, ILCT) triplet states.

Experimental section

General methods and equipment

NMR spectra were recorded in CD_3CN at RT on a Bruker AV400 spectrometer at 400 MHz for ^{1}H NMR and at 100 MHz for ^{13}C NMR. Chemical shifts are reported in ppm relative to residual solvent protons (1.93 ppm for acetonitrile-d_3) and the carbon resonance of the solvent. Absorption spectra were measured on a Cary 500i UV–vis NIR spectrophotometer. Luminescence spectra were obtained with a Horiba Jobin–Yvon Fluoromax P spectrofluorimeter equipped with a Hamamatsu R3896 photomultiplier and were corrected for photomultiplier response using a program purchased with the fluorimeter. Emission lifetimes were measured with an Edinburgh OB-900 single-photon counting spectrometer equipped with a Hamamatsu PLP-2 laser diode (pulse width at 408 nm, 59 ps) and with a PicoQuant PDL 800-D pulsed laser diode (pulse width at 308 nm, 50 ps). The emission decay traces (emission lifetimes measured at about the emission maximum wavelengths) were analyzed

© 2008 NRC Canada

by Marquadt algorithm. For each measurement, at least five determinations were carried out.

Electrochemical measurements were carried out in argon-purged acetonitrile at RT with a BAS CV50W multipurpose equipment interfaced to a PC. The working electrode was a Pt electrode. The counter electrode was a Pt wire, and the pseudo-reference electrode was a silver wire. The reference was set using an internal 1 mmol/L ferrocene/ferrocinium sample at 395 mV vs. SCE in acetonitrile and 432 mV in DMF. The concentration of the compounds was about 1 mmol/L. Tetrabutylammonium hexafluorophosphate was used as supporting electrolyte, and its concentration was 0.10 mol/L. Cyclic voltammograms were obtained at scan rates of 50, 100, 200, and 500 mV/s. For irreversible oxidation processes, the cathodic peak was used as *E*, and the anodic peak was used for irreversible reduction processes. The criteria for reversibility were the separation of approximately 60 mV between cathodic and anodic peaks, the close to unity ratio of the intensities of the cathodic and anodic currents, and the constancy of the peak potential on changing scan rate. The number of exchanged electrons was measured with OSWV and by taking advantage of the presence of ferrocene used as the internal reference.

Experimental uncertainties are as follows: absorption maxima, ±2 nm; molar absorption coefficient, 10%; emission maxima, ±5 nm; excited-state lifetimes, 10%; and redox potentials, ±10 mV.

Synthesis

Compounds **L1**, **L3**, **2a**, **2c**, and **3c** were synthesized as previously described (20, 21).

General procedure for L2 and L4

n-BuLi (1.6 mol/L in hexanes, 1.1 equiv.) was added dropwise to a stirred solution of $HNMe_2$ (2 mol/L in THF, 1.1 equiv.) in anhyd. Et_2O under an inert atmosphere. The mixture was stirred for 20 min until a white suspension formed and the cyano-arene (1 equiv.) was added to the mixture. The mixture was stirred for 4 h further followed by addition of 2-cyanopyridine (2 equiv.). The reaction mixture was stirred overnight and worked up by stirring for 30 min in air followed by removal of Et_2O under reduced pressure. The residue was recrystallized three times from water:ethanol and the solid collected, washed with diethyl ether to yield **L2** as a white solid in 35% yield and **L4** as a yellow solid in 26% yield.

L2

As per the general procedure using *n*-BuLi (1.6 mol/L in hexanes, 5.1 mL, 8.1 mmol), $HNMe_2$ (2 mol/L in THF, 4.1 mL, 8.1 mmol), 9-cyanophenathrene (1.50 g, 7.39 mmol), and 2-cyanopyridine (1.44 mL, 15.0 mmol) in 150 mL anhyd. ether. ^{1}H NMR (400 MHz, $CDCl_3$): 9.07 (d, 1H, J = 8.6 Hz) H_{nap}; 8.99 (dd, 2H, J = 4.3, 0.5 Hz) $H_{6,6''}$; 8.86 (d, 2H, J = 8.0 Hz) $H_{3,3''}$; 8.58 (d, 1H, J = 7.3 Hz) H_{nap}; 8.09 (d, 1H, J = 8.2 Hz) H_{nap}; 7.99 (m, 3H) $H_{4,4''}$, H_{nap}; 7.67 (2H, m) $2H_{nap}$; 7.60 (3H, m) $H_{5,5''}$, H_{nap}. ^{13}C NMR (400 MHz, $CDCl_3$): 124.59, 124.80, 125.31, 125.83,126.21, 127.20, 128.42, 130.83, 130.87, 132.35, 132.87, 133.76, 136.92, 150.03, 152.84, 170.95, 175.00. Anal. calcd. $C_{23}H_{15}N_5 \cdot H_2O$: C 72.8, H 4.5, N 18.5; found: C 72.6, H 4.6, N 18.5.

L4

As per the general procedure using *n*-BuLi (1.6 mol/L in hexanes, 5.1 mL, 8.1 mmol), $HNMe_2$ (2 mol/L in THF, 4.1 mL, 8.1 mmol), 1-cyanopyrene (1.68 g, 7.42 mmol), and 2-cyanopyridine (1.44 mL, 15.0 mmol) in 150 mL anhyd. ether. ^{1}H NMR ($CDCl_3$, 400 MHz): 9.51 (d, J = 10 Hz, 1H) H_{py}; 9.12 (d, J = 8 Hz, 1H), H_{py}; 9.06 (d, J = 4 Hz, 2H) $H_{6,6''}$; 8.94 (d, J = 8 Hz, 2H) $H_{3,3''}$; 8.39–8.07 (m, 7H) $7H_{py}$; 8.05 (td, J = 2 Hz, 8 Hz, 2H) $H_{4,4''}$; 7.61 (dd, J = 5 Hz, 6 Hz, 2H) $H_{5,5''}$. ^{13}C NMR (100 MHz, $CDCl_3$): 124.19, 124.49, 124.65, 124.84, 125.56, 125.82, 125.89, 126.09, 127.07, 128.90, 129.07, 129.33, 129.73, 130.27, 130.30, 130.84, 133.63, 136.82, 150.22, 153.13, 171.15, 175.46, 176.75. Anal. calcd. $C_{29}H_{18}N_5 \cdot 0.5H_2O$: C 78.4, H 4.1, N 15.8; found: C 78.7, H 3.3, N 15.5.

Ruthenium triazine complexes 2b and 2d

$RuCl_3 \cdot 3H_2O$ (0.032 g, 0.12 mmol) was added to a stirred solution of the appropriate ligand (0.24 mmol) in EtOH (15 mL). The mixture was stirred at RT for 15 min and then heated to reflux for 1 h. The reaction mixture was cooled and satd. KPF_6 (aq., 5 mL) was added. The solution was diluted with a 100 mL of water and the red solid collected and injected onto a silica column and eluted with acetone/water/KNO_3(satd.) 9:0.9:0.1. The nitrate salt was metathesized to the PF_6 salt by the addition of NH_4PF_6 and the solvent removed under reduced pressure. The product was collected by dissolving the solid in acetonitrile and precipitated by addition to water and recrystallized from acetonitrile/ether to afford **2b** and **2d** as red solids.

2b

Red solid, 56%. ^{1}H NMR (400 MHz, CD_3CN): 9.68 (d, J = 9 Hz, 2H) H_{nap}; 9.11 (d, J = 7 Hz, 4H) $H_{3,3''}$; 9.09 (m, 2H) H_{nap}; 8.40 (d, J = 8 Hz, 2H) H_{nap}; 8.23 (d, J = 8 Hz, 2H) H_{nap}; 8.17 (td, J = 8 Hz, 1 Hz, 4H) $H_{4,4''}$; 7.90–7.98 (m, 4H) H_{nap}; 7.88 (d, J = 6 Hz, 4H) $H_{6,6''}$; 7.81 (t, J = 8 Hz, 2H) H_{nap}; 7.46 (td, J = 6, 2Hz, 4H) $H_{5,5''}$. HR-MS: M^{2+} ($-2PF_6$) = 462.0845. Anal. calcd. $C_{46}H_{30}N_{10}RuP_2F_{12} \cdot 4H_2O$: C 46.6, H 3.2, N 11.8; found: C 46.4, H 2.7, N 11.7.

2d

Red solid, 11%. ^{1}H NMR (400 MHz, CD_3CN): 10.03 (d, J = 10 Hz, 2H) H_{pyrene}; 9.52 (d, J = 8.3 Hz, 2H) H_{pyrene}; 9.18 (d, J = 8 Hz, 4H) $H_{3,3''}$; 8.66 (d, J = 8 Hz, 2H) H_{pyrene}; 8.60 (d, J = 9.3 Hz, 2H) H_{pyrene}; 8.38–8.53 (m, 8H) $4H_{pyrene}$; 8.25 (t, J = 7 Hz, 2H) H_{pyrene}; 8.19 (t, J = 8 Hz, 4H) $H_{4,4''}$;7.92 (d, J = 5 Hz, 4H) $H_{6,6''}$; 7.47 (dd, J = 6 Hz, 6Hz, 4H) $H_{5,5''}$. Mechanistic investigations of bipyrimidine-promoted palladium-catalyzed allylic acetoxylation of olefins[1]

Bo-Lin Lin, Jay A. Labinger, and John E. Bercaw

Abstract: Several pyridine-like ligands were found to improve $Pd(OAc)_2$-catalyzed allylic oxidation of allylbenzene to cinnamyl acetate by *p*-benzoquinone in acetic acid. The best ligand examined, bipyrimidine, was used to identify the catalyst precursor for this system, (bipyrimidine)$Pd(OAc)_2$, which was fully characterized. Mechanistic studies suggest the reaction takes place through disproportionation of (bipyrimidine)$Pd(OAc)_2$ to form a bipyrimidine-bridged dimer, which reacts with olefin to form a Pd^{II}-olefin adduct, followed by allylic C–H activation to produce (η^3-allyl)Pd^{II} species. The (η^3-allyl)Pd^{II} intermediate undergoes a reversible acetate attack to generate a Pd^0-(allyl acetate) adduct, which subsequently reacts with *p*-benzoquinone to release allyl acetate and regenerate (bipyrimidine)$Pd(OAc)_2$. No KIE is observed for the competition experiment between allylbenzene-d_0 and allylbenzene-d_5 (CD_2=$CDCD_2C_6H_5$), suggesting that allylic C–H activation is not rate-determining. Catalytic allylic acetoxylations of other terminal olefins as well as cyclohexene were also effected by (bipyrimidine)$Pd(OAc)_2$.

Key words: olefin, palladium catalysis, allylic C–H oxidation, *p*-benzoquinone, bipyrimidine.

Résumé : On a observé que plusieurs ligands apparentés à la pyridine améliorent l'oxydation allylique de l'allylbenzène en acétate de cinnamyle par la *p*-benzoquinone dans l'acide acétique et catalysée par le $Pd(OAc)_2$. On a utilisé le meilleur ligand étudié, la bipyrimidine, pour identifier le précurseur du catalyseur pour ce système, le (bipyrimidine)$Pd(OAc)_2$, qui a été complètement caractérisé. Des études mécanistiques suggèrent que la réaction se produit par le biais d'une réaction de dismutation du (bipyrimidine)$Pd(OAc)_2$ qui conduit à la formation d'un dimère à pont bipyrimidine qui réagit avec l'oléfine pour conduire à un adduit Pd(II)-oléfine, le tout suivi de l'activation du C–H allylique conduisant à la formation de l'espèce (η^3-allyl)Pd(II). L'intermédiaire (η^3-allyl)Pd(II) subit une attaque réversible par l'ion acétate qui génère un adduit Pd°-(acétate d'allyle) qui réagit subséquemment avec la *p*-benzoquinone pour libérer l'acétate d'allyle et régénérer le (bipyrimidine)$Pd(OAc)_2$. On n'observe aucun effet isotopique cinétique pour l'expérience de compétition entre l'allylbenzène-d_0 et l'allylbenzène-d_5 (CD_2=$CDCD_2C_6H_5$); ce résultat suggère que l'activation allylique n'est pas l'étape cinétiquement déterminante. Les acétoxylations allyliques catalytiques du cyclohexène et d'autres oléfines terminales sont aussi affectées par le (bipyrimidine)$Pd(OAc)_2$.

Mots-clés : oléfine, catalyseur de palladium, oxydation de C–H allylique, *p*-benzoquinone, bipyrimidine.

[Traduit par la Rédaction]

Introduction

The selective oxidation of allylic C–H bonds offers a valuable approach to the construction of complex molecules (1). While earlier catalysts based on copper or selenium suffer from problems, such as limited substrate scope, low yields, and poor selectivities (2), extensive work on systems based on Pd(II) has led to some remarkably selective allylic C–H activations and oxidations (3, 4). The solvent often plays a key role in achieving selective oxidation to allyl acetates: in neat acetic acid, only symmetrical cyclic olefins are selectively oxidized with $Pd(OAc)_2$ (5), whereas terminal olefins can be selectively oxidized in DMSO/acetic acid (6), and yields can be further improved in dimethylacetamide (DMA) (7). The combination of Pd(II) with sulfoxide ligands also selectively oxidizes terminal olefins (8); this reaction has been successfully applied for catalytic allylic aminations (9) and macrolactonizations (10).

To date, no catalytic system has been reported to selectively oxidize both terminal and internal olefins to allyl acetates. Furthermore, in no case has the active catalytic species been characterized, which complicates the study and understanding of reaction mechanisms and impedes further development of new catalysts. Herein, we disclose a well-defined new catalyst precursor, (bipyrimidine)$Pd(OAc)_2$, that effects selective allylic acetoxylations of terminal olefins and

cyclohexene in acetic acid, and offer evidence for its mechanism of operation.

Experimental

All starting materials are commercially available and used as received without any further purification. $[(\eta^3\text{-}1\text{-phenylallyl})PdCl]_2$ (11) and $[(\eta^3\text{-}1\text{-phenylallyl})Pd(OAc)]_2$ (12) were synthesized according to literature procedures. Allylbenzene-d_5 ($C_6H_5CD_2CD{=}CD_2$) was synthesized by a modified literature procedure (13) where allyl bromide-d_5 was used instead of allyl bromide-d_0. Unless otherwise noted, all manipulations were carried out in air. ^1H and ^{13}C NMR spectra were recorded at room temperature on Varian Mercury 300 (^1H, 299.8 MHz; ^{13}C, 125.9 MHz) spectrometers. NMR spectra were referenced to residual solvent peak ($CDCl_3$: ^1H, 7.26 ppm; ^{13}C, 77.23 ppm; CD_3COOD: ^1H, 2.04 ppm) and reported in parts per million (ppm). Multiplicities were reported as follows: singlet (s), doublet (d), doublet of doublets (dd), doublet of triplets (dt), triplet (t), quartet (q), multiplet (m), and broad resonance (br). GC measurements were taken on an Agilent 6890 series GC instrument with an Agilent HP-5 column. The X-ray structure was obtained at Caltech X-ray Crystallography Laboratory. High-resolution mass spectra were obtained at Caltech Mass Spectrometry Laboratory. Reaction yields are corrected for the purities of the starting materials.

(Bipyrimidine)$Pd(OAc)_2$ (1)

A solution of 25 mg $Pd(OAc)_2$ and 17.8 mg bipyrimidine (BPM) in 4.5 mL glacial acetic acid was stirred for 30 min, resulting in a clear yellow solution. After removing the solvent under vacuum, $(BPM)Pd(OAc)_2$ (**1**) was obtained as a yellow powder, pure enough for NMR analyses. A yellow crystal of $[(BPM)Pd(OAc)_2{\cdot}H_2O]$ was obtained by slow evaporation of a chloroform solution of a 1:1:1 mixture of BPM, $Pd(OAc)_2$, and acetic acid under air. ^1H NMR ($CDCl_3$) δ: 9.20 (dd, 2H, $^3J_{HH}$ = 4.8 Hz, $^4J_{HH}$ = 2.2 Hz), 8.68 (dd, 2H, $^3J_{HH}$ = 5.7 Hz, $^4J_{HH}$ = 2.2 Hz), 7.73 (dd, 2H, $^3J_{HH}$ = 5.7 Hz, 4.8 Hz), 2.13 (s, 6H). ^{13}C NMR ($CDCl_3$) δ: 178.9, 160.5, 157.6, 124.2, 23.3. HR-MS (FAB+) *m/z* calcd. for $C_{10}H_9N_4O_2Pd^+$: $(M - OAc)^+$ 322.9796; found: 322.9774.[3]

General procedure for allylic oxidation (Table 2, entries 1, 2, 3, 5, and 6)

A solution of 25 mg $Pd(OAc)_2$ and 17.6 mg BPM in 4.5 mL glacial acetic acid was stirred for ~30 min, followed by sequential additions of 10 equiv. of olefin and 20 equiv. of benzoquinone. The mixture was heated at 70 °C with stirring, in a 20 mL glass vial sealed with a Teflon-lined cap and PTFE tape. After the reported time, the reaction mixture was cooled to room temperature in a water bath and neutralized with 50 mL of an aqueous solution of 6.2 g NaOH. The resultant mixture was extracted with 3 × 100 mL CH_2Cl_2. Organic portions were combined and dried over $MgSO_4$. Volatiles were removed under vacuum. The resultant oil was further purified by flash silica-gel column chromatography.

trans-*Cinnamyl acetate (Table 2, entry 1)*

Allylbenzene: 98% pure. Reaction time: 34 h. Eluent: 1:10 (*v/v*) EtOAc/hexanes. The product was isolated as a mixture of cis and trans isomers. Mass: 146 mg; overall yield: 76%; NMR yield of the trans isomer: 72%. ^1H NMR ($CDCl_3$) δ: 7.20–7.45 (m, 5H), 6.60–6.71 (d, 1H, $^3J_{HH}$ = 15.9 Hz), 6.24–6.35 (dt, 1H, $^3J_{HH}$ = 15.9 Hz, 6.6 Hz), 4.71–4.76 (dd, 2H, $^3J_{HH}$ = 6.6 Hz, $^4J_{HH}$ = 1.3 Hz), 2.11 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 171.1, 136.4, 134.4, 128.9, 128.3, 126.9, 123.4, 65.3, 21.3. HR-MS (FAB+) *m/z* calcd. for $C_{11}H_{12}O_2$: 176.0837; found: 176.0832.

trans-p-*Methylcinnamyl acetate (Table 2, entry 2)*

p-Allyltoluene: 99% pure. Reaction time: 32 h 46 min. Eluent: 1:10 (*v/v*) EtOAc/hexanes. The product was isolated as a mixture of cis and trans isomers. Mass: 165 mg; overall yield: 78%; NMR yield of the trans isomer: 75%. ^1H NMR ($CDCl_3$) δ: 7.26–7.32 (d, 2H, $^3J_{HH}$ = 8.1 Hz), 7.10–7.17 (d, 2H, $^3J_{HH}$ = 8.1 Hz), 6.58–6.68 (d, 1H, $^3J_{HH}$ = 15.9 Hz), 6.18–6.30 (dt, 1H, $^3J_{HH}$ = 15.9 Hz, 6.6 Hz), 4.68–4.76 (dd, 2H, $^3J_{HH}$ = 6.6 Hz, $^4J_{HH}$ = 1.3 Hz), 2.35 (s, 3H), 2.10 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 171.1, 138.2, 134.5, 133.6, 129.6, 126.8, 122.3, 65.5, 21.5, 21.3. HR-MS (FAB+) *m/z* calcd. for $C_{12}H_{14}O_2$: 190.0994; found: 190.0995.

trans-p-*Methoxycinnamyl acetate (Table 2, entry 3)*

p-Methoxyallylbenzene: 98% pure. Reaction time: 16 h. Eluent: 1.5:10 (*v/v*) EtOAc/hexanes. The product was isolated as a mixture of cis and trans isomers. Mass: 118 mg; overall yield: 53%; NMR yield of the trans isomer: 50%. ^1H NMR ($CDCl_3$) δ: 7.30–7.36 (d, 2H, $^3J_{HH}$ = 8.4 Hz), 6.82–6.89 (d, 2H, $^3J_{HH}$ = 8.4 Hz), 6.55–6.64 (d, 1H, $^3J_{HH}$ = 15.3 Hz), 6.10–6.21 (dt, 1H, $^3J_{HH}$ = 15.3 Hz, 6.6 Hz), 4.66–4.74 (dd, 2H, $^3J_{HH}$ = 6.6 Hz, $^4J_{HH}$ = 1.3 Hz), 3.80 (s, 3H), 2.09 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 171.2, 159.8, 134.3, 129.2, 128.1, 121.0, 114.2, 65.6, 55.5, 21.3. HR-MS (FAB+) *m/z* calcd. for $C_{12}H_{14}O_3$: 206.0943; found: 206.0952.

1-Acetoxy-trans-*2-decene (Table 2, entry 5)*

Reaction time: 20 h. Eluent: 1:10 (*v/v*) EtOAc/hexanes. The product was isolated as a mixture of allylic acetates along with (1-acetoxy-)3-, 4-, and 5-decenes. Both ^1H NMR and GC gave the estimated ratio of allylic acetates (sum of *trans*-primary allylic acetate, *cis*-primary allylic acetate, and secondary allylic acetate) to other isomers to be ~3.8. Only 1-acetoxy-*trans*-2-decene was fully characterized. Mass: 171 mg; overall yield: 78%; NMR yield of 1-acetoxy-*trans*-2-decene: 54%. ^1H NMR ($CDCl_3$) δ: 5.70–5.83 (m, 1H), 5.49–5.62 (m, 1H), 4.47–4.53 (dd, 2H, $^3J_{HH}$ = 6.6 Hz, $^4J_{HH}$ = 1 Hz), 2.06 (s, 3H), 1.92–2.08 (m, 2H), 1.27 (br s, 10H), 0.87 (t, 3H, $^3J_{HH}$ = 6.9 Hz). ^{13}C NMR ($CDCl_3$) δ: 171.1, 137.0, 123.9, 65.6, 32.5, 32.0, 29.6, 29.3, 29.1, 22.9, 21.3, 14.3. HR-MS (FAB+) *m/z* calcd. for $C_{12}H_{14}O_2$: 198.1620; found: 198.1625.

1-Acetoxy-3-cyclohexyl-trans-*2-propene (Table 2, entry 6)*

Allylcyclohexane: 96% pure. Reaction time: 20 h. Eluent: 1:10 (*v/v*) EtOAc/hexanes. The product was isolated as a mixture of allylic acetates, 3-cyclohexylidenepropyl acetate, and 3-cyclohexenylpropyl acetates. The ratio of allylic acetates (sum of *trans*-primary allylic acetate, *cis*-primary allylic acetate, and secondary allylic acetate) to other isomers was estimated to be ~6.2 by ^1H NMR and GC. Only 1-acetoxy-3-cyclohexyl-*trans*-2-propene was fully characterized. Mass: 150 mg; overall yield: 77%; NMR yield of 1-acetoxy-3-cyclohexyl-*trans*-2-propene: 65%. ^1H NMR

[c]No product detected.

($CDCl_3$) δ: 5.66–5.75 (dd, 1H, $^3J_{HH} \approx 15.6$ Hz, 6.3 Hz), 5.44–5.55 (dtd, 1H, $^3J_{HH} = 15.6$ Hz, 6.6 Hz, $^4J_{HH} = 1.1$ Hz), 4.46–4.52 (d, 2H, $^3J_{HH} = 6.6$ Hz), 2.05 (s, 3H), 1.84–2.05 (m, 1H), 0.94–1.79 (m, 10H). ^{13}C NMR ($CDCl_3$) δ: 171.1, 142.4, 121.5, 65.8, 40.6, 32.7, 26.3, 26.2, 21.3. HR-MS (FAB+) *m/z* calcd. for $C_{11}H_{18}O_2$: 182.1307; found: 182.1313.

Allyl acetate (Table 2, entry 4)

A 5 mL round-bottom flask was charged with 27.1 mg (BPM)$Pd(OAc)_2$ (10 mol%), 153 mg BQ (2 equiv.), 20 µL nitrobenzene, and 2.2 mL glacial acetic acid. Propylene (15.7 mL, 1 atm) was then condensed into the flask by liquid nitrogen after degassing (1 atm = 101.325 kPa). The mixture was stirred and heated at 70 °C for 24 h. An aliquot of the reaction mixture was taken and filtered through a short pipette of silica gel with Et_2O as the eluent for GC analysis. The GC-peak area of allyl acetate relative to nitrobenzene was used to calculate the yield. Allyl acetate was the only allylic oxidation product observed by ^1H NMR. GC Yield: 45%.

Cyclohexenyl acetates (Table 2, entry 7)

The general procedure above was followed, except for the use of 20 equiv. of cyclohexene and 24 equiv. of benzoquinone, and heating at 80 °C. After 24 h, the mixture was cooled to room temperature by water bath and neutralized by 6.2 g NaOH in 50 mL H_2O. The resultant mixture was extracted by 3 × 100 mL CH_2Cl_2. Organic portions were combined and dried over $MgSO_4$. Volatiles were removed under vacuum. The resultant oil was further purified by reduced-pressure distillation. A ~2.8:1 mixture of cyclohex-2-enyl acetate and cyclohex-3-enyl acetate was obtained. Mass: 160 mg; overall yield: 51.3%.

Cyclohex-2-enyl acetate

^1H NMR ($CDCl_3$) δ: 5.87–5.98 (m, 1H), 5.63–5.73 (m, 1H), 5.18–5.27 (m, 1H), 2.03 (s, 3H), 1.53–2.45 (m, 6H). ^{13}C NMR ($CDCl_3$) δ: 171.0, 132.9, 125.9, 68.3, 28.5, 25.1, 21.6, 19.1. HR-MS (FAB+) *m/z* calcd. for $C_8H_{12}O_2$: 140.0837; found: 140.0841.

Cyclohex-3-enyl acetate

^1H NMR ($CDCl_3$) δ: 5.62–5.67 (m, 1H), 5.51–5.60 (m, 1H), 4.93–5.03 (m, 1H), 2.03 (s, 3H), 1.53–2.45 (m, 6H).

[(Bipyrimidine)Pd(η^3-1-phenylallyl)]$^+$(OAc)$^-$ (2)

Route 1

A mixture of 8.6 mg (BPM)Pd(OAc)$_2$ and 29.5 μL allylbenzene in 0.7 mL CD_3COOD was heated in a J–Young NMR tube under nitrogen at 80 °C for 96 h. The yield of compound **2** based on Pd was 89%, as estimated by ^{1}H NMR.

Route 2

A 2:1 ratio of AgOAc (3.8 mg) and [(η^3-1-phenylallyl)PdCl]$_2$ (5.5 mg) was stirred in 1 mL of acetone at room temperature for 30 min. After filtering off the precipitate, solvent was pumped away under vacuum. To the resultant yellow solid was added 3.6 mg BPM and 0.7 mL CD_3COOD. ^{1}H NMR shows that [(BPM)Pd(η^3-1-phenylallyl)]$^+$(OAc)$^-$ was formed quantitatively. Unfortunately, compound **2** is not isolable owing to rapid decomposition to Pd metal in the absence of acetic acid. ^{1}H NMR (CD_3COOD) δ: 9.24 (br s 4H), 7.78 (br s 2H), 7.46–7.82 (m, 5H), 6.59 (app dt, 1H, $^3J_{HH}$ = 12.3 Hz, 7.2 Hz), 5.06 (d, 1H, $^3J_{HH}$ = 12.3 Hz), 4.68 (d, 1H, $^3J_{HH}$ = 7.2 Hz), 3.87(d, 1H, $^3J_{HH}$ = 12.3 Hz). HR-MS (FAB+) *m*/*z* calcd. for $C_{17}H_{15}N_4Pd^+$: (M – OAc)$^+$ 381.0332; found: 381.0343.

(Bipyrimidine)[Pd(OAc)$_2$]$_2$ (3)

3.6 mg BPM and 10 mg Pd(OAc)$_2$ (2 equiv.) were mixed with 0.7 mL CD_3COOD. A clear yellow solution was obtained after stirring for 2 h. The solution contained an equilibrated mixture of Pd(OAc)$_2$, (BPM)Pd(OAc)$_2$ (**1**), and (BPM)[Pd(OAc)$_2$]$_2$ (**3**). The equilibrium constant was estimated to be ~25 mol^{-1} L by ^{1}H NMR. NMR yield of compound **3** based on BPM: 35%. ^{1}H NMR (CD_3COOD) δ: 8.75 (d, 4H, $^3J_{HH}$ = 5.7 Hz), 7.78 (t, 2H, $^3J_{HH}$ = 5.7 Hz). MS (MALDI) *m*/*z* calcd. for $C_{16}H_{18}N_4Pd_2^+$: (M$^+$) 605.919; found: 605.7228.

[(Bipyrimidine)Pd(η^3-2-propenyl)]$^+$(OAc)$^-$

To a solution of compound **1** in 0.7 mL CD_3COOD was added 2.4 μL allyl acetate (1 equiv.). After degassing, the solution was heated at 80 °C for 15 h. According to the ^{1}H NMR spectrum, ~50% of the starting material was converted to [(BPM)Pd(η^3-2-propenyl)]$^+$. ^{1}H NMR (CD_3COOD) δ: 9.32 (br s 4H), 7.99 (br s 2H), 6.03–6.19 (tt, 1H, $^3J_{HH}$ = 6.6 Hz, 12.6 Hz), 4.72–4.76 (dd, 2H, $^2J_{HH}$ = 1.3 Hz, $^3J_{HH}$ = 6.6 Hz), 3.60–3.72 (d, 2H, $^3J_{HH}$ = 12.6 Hz). HR-MS (FAB+) *m*/*z* calcd. for $C_{11}H_{11}N_4Pd^+$: (M – OAc)$^+$ 305.0019; found: 305.0044.

Exchange between *trans*-cinnamyl acetate and CD_3COOD

A mixture of compound **2** and 10 μL *trans*-cinnamyl acetate (3 equiv.) in 0.7 mL CD_3COOD was heated in a J–Young NMR tube under nitrogen at 80 °C. After 16 h 5 min, 20% of the starting $PhCH{=}CHCO_2CH_3$ was converted to $PhCH{=}CHCO_2CD_3$. No change of compound **2** was detected. Control experiments were carried out under similar conditions except that compound **2** was absent or replaced by an equimolar amount of NaOAc. In neither case was acetate scrambling detected by ^{1}H NMR.

Competition between allylbenzene-d_0 and allylbenzene-d_5

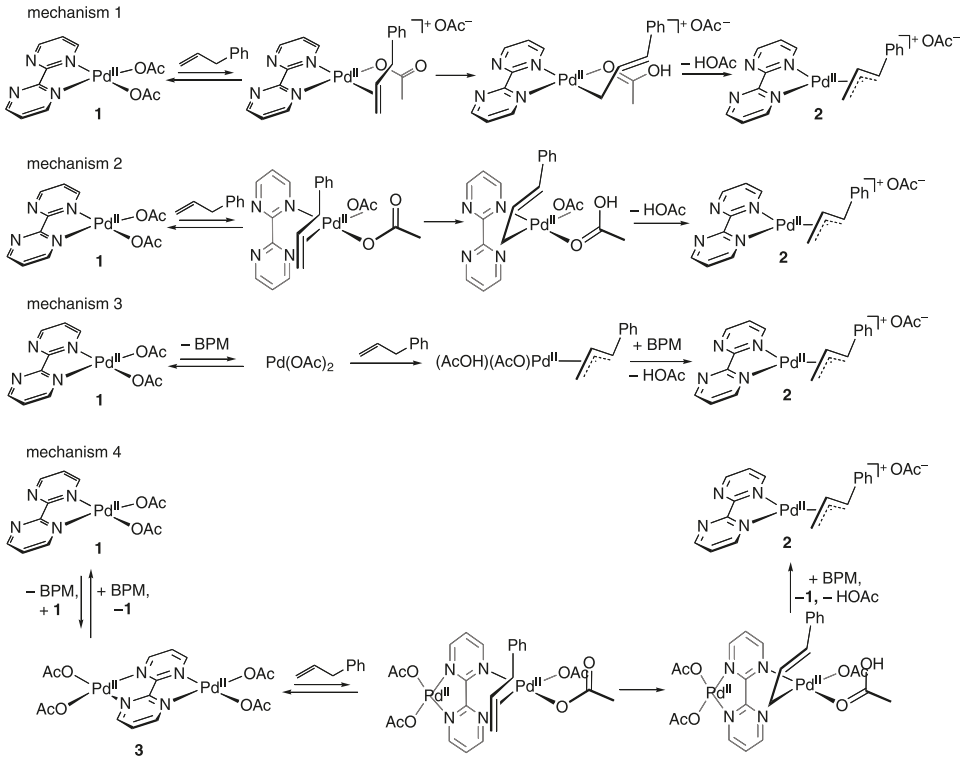
A mixture of 4.3 mg (BPM)Pd(OAc)$_2$ (~5 mol%), 10 μL nitrobenzene (internal standard), 15 μL allylbenzene-d_0, 15 μL allylbenzene-d_5, 25 mg BQ, and 0.35 mL CH_3COOH was heated in a sealed vial with stirring at 80 °C. Aliquots (~5 μL) were taken at certain times by microsyringe for GC analysis. The GC signals of allylbenzene-d_0 and allylbenzene-d_5 are fully separated, but those of the two isotopologs of *trans*-cinnamyl acetate are not.

Results and discussion

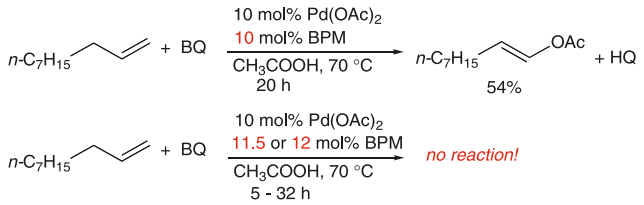
The oxidation of allylbenzene by *p*-benzoquinone (BQ) in acetic acid at 80 °C, with Pd(OAc)$_2$ as the catalyst, leads to only a 13% yield of cinnamyl acetate (100% consumption of allylbenzene). Several other unidentified products, probably

© 2008 NRC Canada

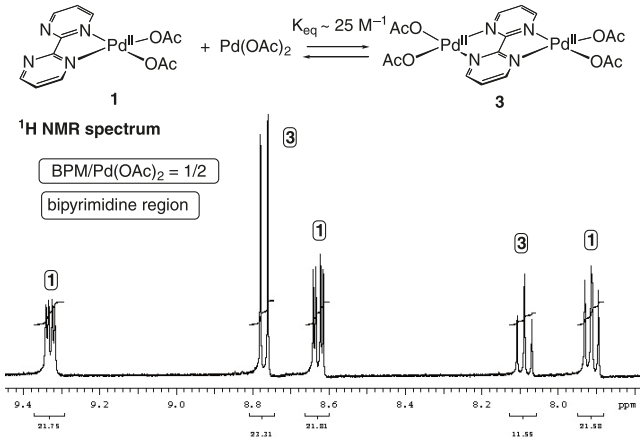
Scheme 2.



Scheme 3.



Scheme 4.



including the same Wacker-type products previously reported from reaction at 40 °C (6b), are observed. The selectivity for cinnamyl acetate is significantly improved by the addition of pyridine-like nitrogen ligands (with the exception of 2,2′-bipyridine, which shuts down the reaction) (Table 1). Among the ligands tested, bipyrimidine (BPM) is the best, leading to a 76% yield of cinnamyl acetate in 16 h at 80 °C.

Studies of substrate scope (Table 2) indicate that both benzylic C–H and methoxy groups are compatible with the acetoxylation (Table 2, entries 2 and 3). Unfortunately, the yield for olefins with alkyl groups at the allylic position (Table 2, entries 5 and 6) suffers from olefin isomerization, giving byproducts such as homoallylic acetates. Cyclohexene is also an active substrate for the reaction, producing a mixture of cyclohex-2-enyl acetate and cyclohex-3-enyl acetate (~ 2.8:1) (Table 2, entry 7). Interestingly, cyclohex-2-enyl acetate becomes the only allylic oxidation product if (1,10-phenanthroline)$Pd(OAc)_2$ or *bis*(oxazoline)$Pd(OAc)_2$ (14) is used as the catalyst.

The reaction of bipyrimidine with $Pd(OAc)_2$ in CD_3COOD forms $(BPM)Pd(OAc)_2$ (**1**) in quantitative yield after 30 min at room temperature, as monitored by ^1H NMR. A crystal structure for $(BPM)Pd(OAc)_2 \cdot H_2O$ was obtained (Fig. 1; Table 3).[3] Heating $(BPM)Pd(OAc)_2$ with allylbenzene (10 equiv.) in CD_3COOD at 80 °C for ~4 day affords $[(BPM)Pd(\eta^3\text{-}1\text{-phenylallyl})]^+(OAc)^-$ (**2**), the product

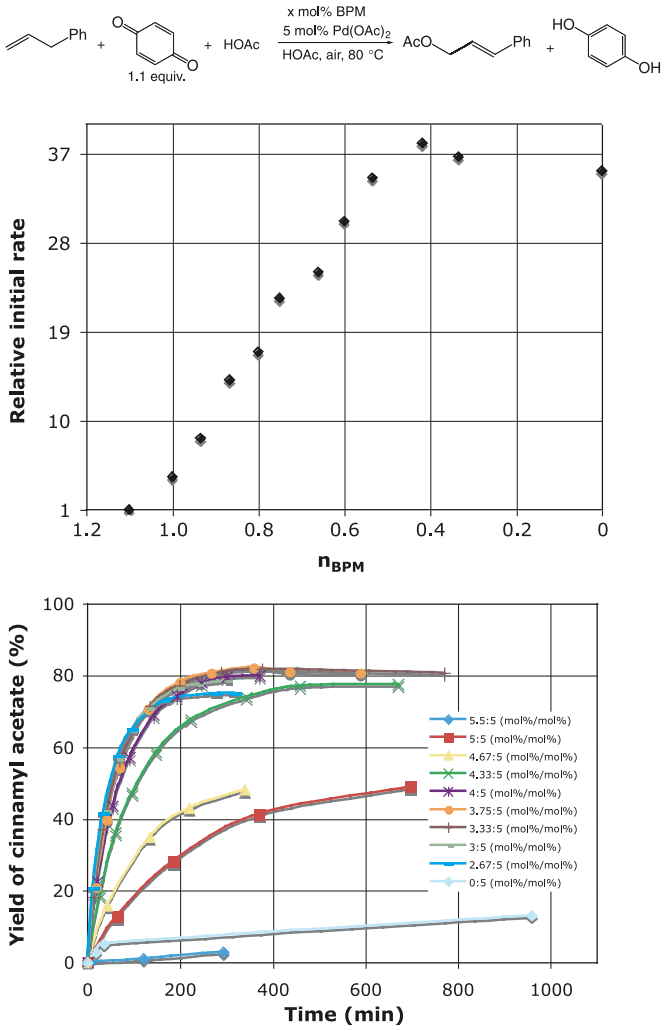
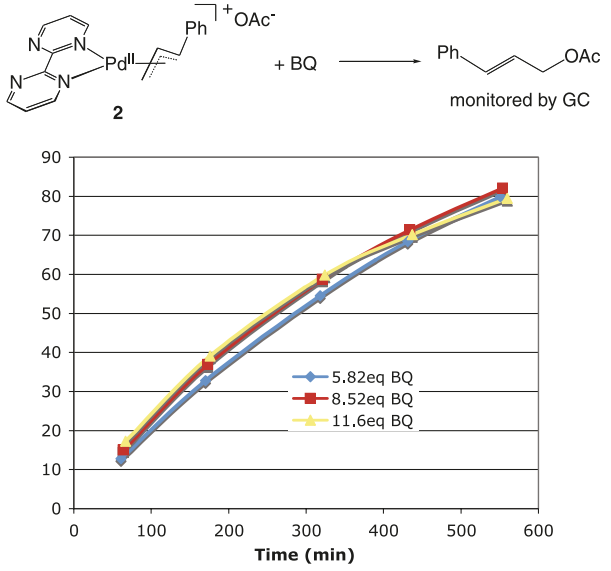
Fig. 2. Effect of BPM to $Pd(OAc)_2$ ratio on allylic oxidation of allylbenzene by benzoquinone, $Pd(OAc)_2$ fixed to be 5 mol%. Upper graph: initial rates of the disappearance of allylbenzene relative to that of n(BPM)/n(Pd) = 1.1; lower graph: appearance of cinnamyl acetate.



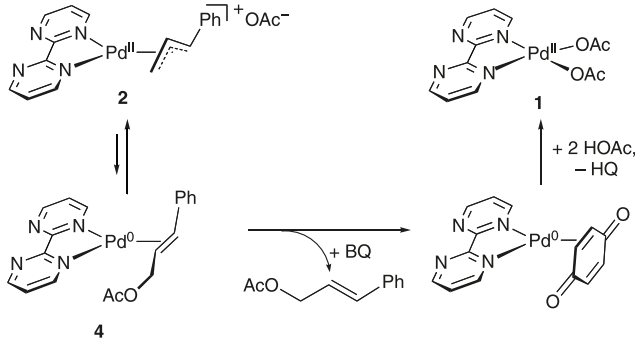
of allylic C–H activation, in ~89% yield (Scheme 1). Furthermore, the allylic C–H activation is irreversible, because neither olefin exchange nor deuterium incorporation into the allyl fragment is observed after heating **2** with *p*-allyltoluene in CD_3COOD at 80 °C for 15 h (Scheme 1). Similar irreversibility was also proposed for the sulfoxide–$Pd(OAc)_2$ system (8).

The reaction between allylbenzene and (BPM)$Pd(OAc)_2$ could occur via the displacement by the olefin of either an acetate or a coordinated BPM nitrogen to form a Pd(II)–olefin adduct, followed by allylic C–H activation to form **2** (Scheme 2, mechanisms 1 and 2). For either mechanism, addition of excess BPM should not have a significant effect on the reaction rate (a mixture of $Pd(OAc)_2$ and 1.15 equiv. BPM in CD_3COOD affords 1 equiv. (BPM)$Pd(OAc)_2$ and 0.15 equiv. free BPM (NMR)). However, no reaction is seen for allylbenzene or 1-decene when a slight excess (≤20 mol% relative to $Pd(OAc)_2$) of BPM is added (Scheme 3), clearly ruling out either mechanism for the acetoxylation.

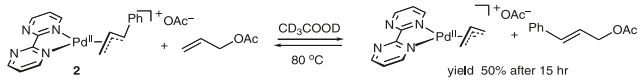
Fig. 3. Oxidation of (η^3-allyl)Pd^{II} by benzoquinone is independent of the concentration of benzoquinone.



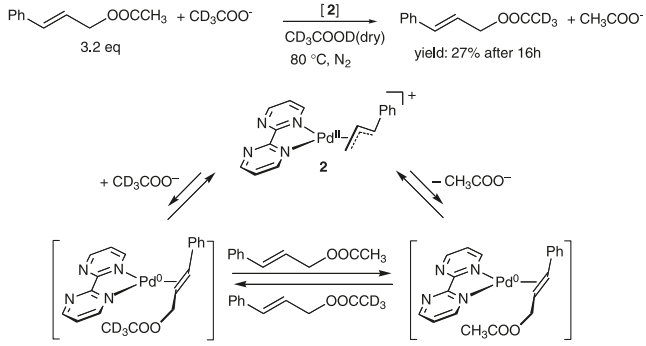
Scheme 5.



Scheme 6.



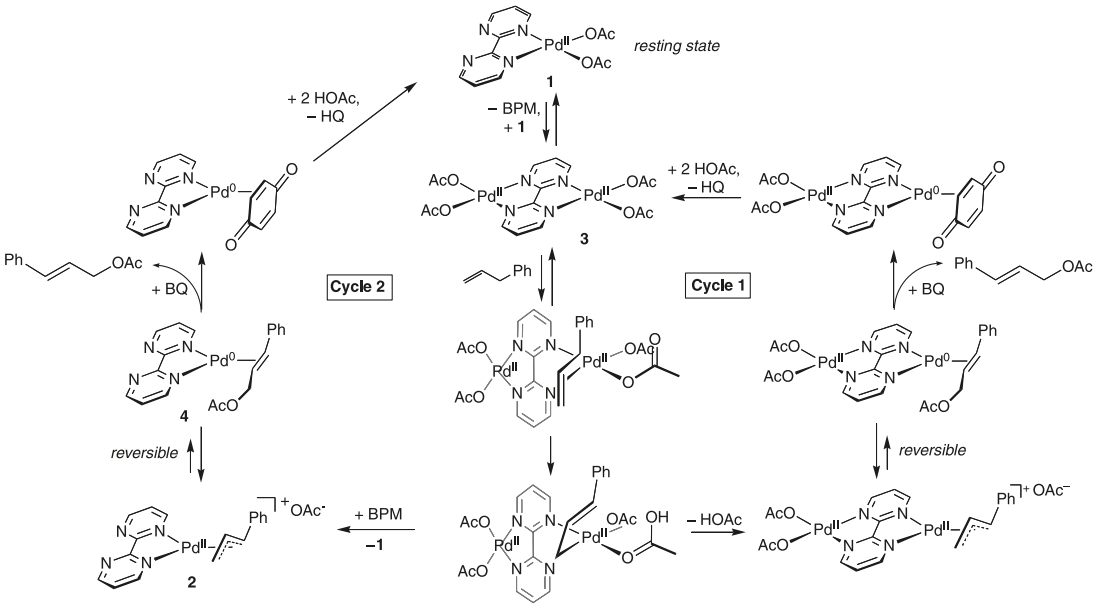
Scheme 7.



Full dissociation of BPM from (BPM)$Pd(OAc)_2$, forming $Pd(OAc)_2$, which then catalyzes the reaction, would be consistent with the inhibitory effect of excess BPM (Scheme 2,

© 2008 NRC Canada

Scheme 8.

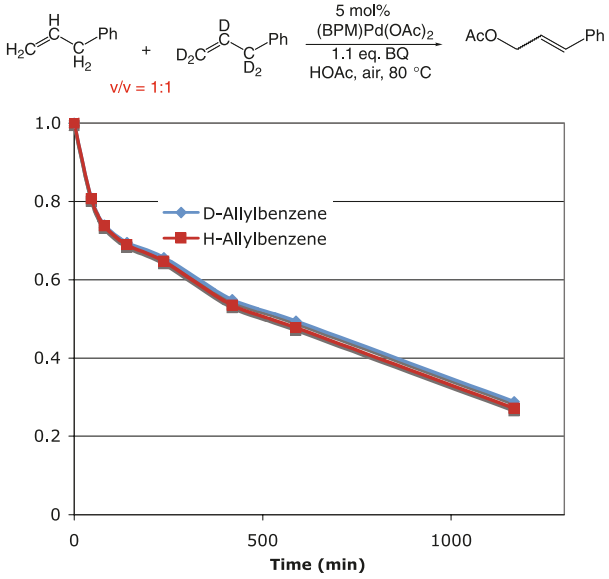


mechanism 3), but this is also unlikely to be the mechanism because $Pd(OAc)_2$ does not lead to selective allylic oxidation under current catalytic conditions (Table 1, entry 1). The nonselective oxidation catalyzed by $Pd(OAc)_2$ must originate in the allylic C–H activation of allylbenzene by $Pd(OAc)_2$ rather than a subsequent step, because the solvolysis of $[(\eta^3\text{-1-phenylallyl})Pd(OAc)]_2$ in wet acetic acid at 75 °C quantitatively forms allylic oxidation products (allylic acetates and cinnamaldehyde; the latter results from water as the nucleophile) (15).

In a further experiment, a mixture of $(BPM)Pd(OAc)_2$ and $Pd(OAc)_2$ in CD_3COOD (generated in situ by combining $Pd(OAc)_2$ and BPM in a 2:1 ratio) reacts to form a new species, characterized by ^{1}H NMR and MALDI as the BPM-bridged $Pd(OAc)_2$ dimer **3** (Scheme 4). The reaction does not reach 100% conversion, but equilibrates with K_{eq} ~ 25 mol^{-1} L, as estimated by ^{1}H NMR. The resultant mixture reacts with allylbenzene under air *at room temperature* to form an η^3-allyl species, cinnamyl acetate, and palladium black.

We propose that dimer **3** is the active species for the reaction with allylbenzene, because the $Pd(OAc)_2$-only system results in less selective oxidation of allylbenzene, while heating is required for the reaction between $(BPM)Pd(OAc)_2$ and allylbenzene. According to our proposal, in the latter reaction, small amounts of dimer and free BPM are formed via disproportionation of $(BPM)Pd(OAc)_2$, explaining the inhibition by excess BPM. The coordination of a second equivalent of $Pd(OAc)_2$ to BPM would be expected to weaken a Pd–N bond and thus facilitate the coordination of olefin; the Pd–olefin adduct subsequently undergoes allylic C–H activation to form **2** (Scheme 2, mechanism 4). This mechanism is further supported by the observation that the initial consumption rate of allylbenzene increases as the ratio of BPM to $Pd(OAc)_2$ decreases; the best overall yields (~82%) were obtained by combining 3–4 mol% BPM with 5 mol% $Pd(OAc)_2$ (Fig. 2).

Fig. 4. No significant KIE is observed for competition reaction between allylbenzene-d_0 and allylbenzene-d_5.



Although **2** is stable in CD_3COOD at 80 °C, the addition of benzoquinone (BQ) releases cinnamyl acetate (16) and generates $(BPM)Pd(OAc)_2$ and hydroquinone (HQ). It has been proposed that coordination of benzoquinone to Pd^{II} induces acetate attack (8, 17), but we find that the rate of the reaction between **2** and benzoquinone in acetic acid is independent of the benzoquinone concentration when at least 5.8 equiv. are used (Fig. 3), which argues against this mechanism.

Instead, we believe that reversible attack of acetate at the η^3-allyl moiety (18) occurs in the absence of benzoquinone to form the (unobservable) Pd^0(allyl acetate) species **4** (Scheme 5). Such a route is suggested by the reaction between allyl acetate and **2** in CD_3COOD, which generates

© 2008 NRC Canada

cinnamyl acetate and [(BPM)Pd(η^3-propenyl)]$^+$(OAc)$^-$ (Scheme 6), and by the fact that **2** catalyzes exchange of labeled and unlabeled acetate between *trans*-cinnamyl acetate and CD_3COOD (Scheme 7). (BPM)Pd^0(cinnamyl acetate) complex **4** then reacts with BQ to release cinnamyl acetate and form (BPM)Pd^0(BQ) (19), followed by a redox reaction with acetic acid to generate (BPM)$Pd(OAc)_2$ and hydroquinone (HQ) to complete the catalytic cycle (Scheme 5).

Scheme 8 shows a mechanism consistent with all current observations. Allylic C–H activation of allybenzene by dimer **3** leads to a dimeric (η^3-allyl)Pd^{II} complex, which can react either with benzoquinone to release cinnamyl acetate and regenerate the active dimer **3** (Scheme 8, cycle 1), or with free BPM (generated from the disproportionation) to form the monomeric (η^3-allyl)Pd^{II} **2**, followed by reaction with benzoquinone to release cinnamyl acetate and regenerate (BPM)$Pd(OAc)_2$ (Scheme 8, cycle 2). We assume that the mechanistic inferences from the stoichiometric reactions described above, which would be rigorously applicable only to the monomeric intermediates in cycle 2, most probably would be valid for the analogous dimeric intermediates of cycle 1 as well.

If cycle 2 is the dominant pathway, the rate-determining step for the whole catalytic cycle must occur before the formation of (η^3-allyl)Pd^{II} because the only Pd species observed by ^{1}H NMR during the reaction is (BPM)$Pd(OAc)_2$. In addition, the BPM inhibitory effect suggests a pre-equilibrium between (BPM)$Pd(OAc)_2$ and **3**. Therefore, either the olefin coordination or allylic C–H activation would be rate-determining. A competition experiment using a 1:1 (*v*/*v*) ratio of allylbenzene-d_0 and allylbenzene-d_5 (CD_2=$CDCD_2C_6H_5$) shows no kinetic isotope effect for the consumption rate of allylbenzene (Fig. 4), suggesting olefin coordination rather than C–H activation is rate-determining.

However, if cycle 1 is the dominant pathway, we cannot rule out the possibility that acetate attack on the dimeric (η^3-allyl)Pd^{II} complex is rate-determining. In that case, the dimeric (η^3-allyl)Pd^{II} complex would be the major species *within* the actual catalytic cycle, but it could still be unobservable if the equilibrium between **1** and **3** strongly favours the former. Since at present we do not know which cycle is dominant, we cannot conclusively identify the rate-determining step.

In summary, we have reported (BPM)$Pd(OAc)_2$ as a well-defined new catalyst for allylic C–H oxidation of olefins. Mechanistic studies have provided insight to understand the catalysis and led to further improvement of the reaction yield for the oxidation of allylbenzene. More studies are underway to explore the potential of the dimeric species and its derivatives in catalytic allylic C–H oxidations.

Kaolinite–poly(methacrylamide) intercalated nanocomposite via in situ polymerization[1]

Tamer A. Elbokl and Christian Detellier

Abstract: The preparation and characterization of a kaolinite–methacrylamide intercalation compound was achieved by a guest-displacement method, the direct treatment of a dimethylsulfoxide (DMSO) pre-intercalate with an aqueous solution of methacrylamide under mild conditions, giving intercalation ratios up to 92% and an expansion of 0.53 nm of the interlayer space. The DMSO molecules were fully displaced from the interlayer space by methacrylamide. Only partial intercalation could be obtained with *N*-methylformamide (NMF) pre-intercalate. After intercalation, the monomer was thermally polymerized at 100 or 150 °C with various heating times. XRD, FTIR, ^{13}C CP/MAS NMR, and thermogravimetric analysis confirmed that polymerization was partially achieved in the interlayer spaces, while the layered structure of kaolinite was maintained, constraining the polymer in an interlayer space of 0.57 nm in the *c*-direction. In good agreement with the TG data, elemental analysis gave a stoichiometry of $Al_2Si_2O_5(OH)_4{\cdot}(C_4H_7NO)_{0.52}$ for the thermally treated methacrylamide intercalate, corresponding to a ratio of one methacrylamide unit per two kaolinite structural units. The thermal stability of the methacrylamide intercalate was increased after thermal treatment and polymerization.

Key words: kaolinite, intercalation, nanocomposites, aluminosilicates, layered materials, interlayer polymerization, poly(methacrylamide).

Résumé : La préparation et la caractérisation d'un composé d'intercalation de la kaolinite avec la méthacrylamide ont été obtenues par une méthode de déplacement d'une molécule hôte, soit par le traitement direct d'un pré-intercalat de diméthylsulfoxide (DMSO) par une solution aqueuse de méthacrylamide sous des conditions douces. Des rapports d'intercalation de 92% furent obtenus avec une expansion de 0,53 nm de l'espace interfoliaire. Les molécules de DMSO furent complètement déplacées de l'espace interfoliaire par la méthacrylamide. Seulement une intercalation partielle put être obtenue à partir d'un pré-intercalat de *N*-méthylformamide. Après intercalation, le monomère fut polymérisé thermiquement à 100 ou 150 °C sous divers temps de chauffage. La diffraction des rayons X, l'IRTF, la RMN PC/RAM du ^{13}C et l'analyse thermogravimétrique ont confirmé que la polymérisation avait été obtenue partiellement dans l'espace interfoliaire, alors que la structure de la kaolinite était maintenue, contraignant le polymère dans un espace interfoliaire de 0,57 nm dans la direction *c*. En bon accord avec les données gravimétriques, l'analyse élémentaire a fourni une stoéchiométrie $Al_2Si_2O_5(OH)_4{\cdot}(C_4H_7NO)_{0.52}$ pour l'intercalat de méthacrylamide thermiquement traité, correspondant à un rapport d'une unité de méthacrylamide pour deux unités structurales de kaolinite. La stabilité thermique de l'intercalat de méthacrylamide est accru par le traitement thermique et la polymérisation.

Mots-clés : kaolinite, intercalation, nanocomposites, matériaux en couches, polymérisation interfoliaire, poly(méthacrylamide).

[Traduit par la Rédaction]

Introduction

A variety of organic–inorganic nanohybrid materials have been prepared and characterized in recent years (1). Among them, polymer nanocomposites, such as polymer–layered silicate (PLS), have become an effective alternative to conventional polymer composites in many applications. They exhibit enhanced mechanical and thermal properties, decreased gas permeability, improved flame-retardation properties, and increased solvent resistance (2, 3). Smectites have been widely used for the preparation of PLS nanocomposites. In general, two types of polymer–layered clay nanocomposites can be obtained, intercalates and exfoliates (4–7). Melt intercalation is the most common method of synthesis of PLS nanocomposites, as it is applicable to a wide range of polymers. Other strategies include in situ polymerization of a previously intercalated monomer and solution polymerization.

Smectites are the most used class of phyllosilicates for the elaboration of nanohybrid and nanocomposite materials due to their swelling properties, their high exchange capacity, and surface area. On the other hand, the interlayer chemistry of kaolinite (Kao), one of the most abundant clay minerals on Earth, is much less developed.

Kaolinite is a 1:1 layered dioctahedral aluminosilicate, characterized by the chemical composition $Al_2Si_2O_5(OH)_4$ (8*a*). The individual layers are linked together through hydrogen bonds between the aluminol groups of the octahedral sheet on one side, and the siloxane macrorings of the tetrahedral sheets on the other side. They are also linked by the strong dipole interactions between the non-centrosymmetric layers (8*b*). These structural characteristics result in interlayer spaces that are not easily accessible by guest molecules. Consequently, kaolinite is not yet commonly used as the inorganic component of nanocomposites.

However, a few examples of intercalated kaolinite–polymer nanocomposites have been reported so far (9–18*a*). Direct intercalation from the melt was achieved in a few cases (9, 13). Other kaolinite–polymer nanocomposites were obtained either by the intercalation of the monomer followed by polymerization (10, 11, 14, 15, 17) or by direct intercalation of the polymer using a guest-displacement method (16).

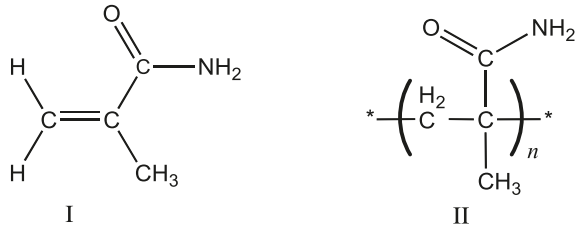
In this paper, the synthesis of a new kaolinite–methacrylamide intercalation compound was achieved by direct treatment of an intermediate with an aqueous solution of methacrylamide. The surface modification of kaolinite particles by (trimethoxysilyl)propylmethacrylate (A174) followed by copolymerization with methacrylamide acid monomers has been reported (18*b*). However, in this work, for the first time, a kaolinite–poly(methacrylamide) intercalated nanocomposite was synthesized by in situ polycondensation of the pre-intercalated methacrylamide monomer. Methacrylamide (Chart 1) was first intercalated into kaolinite by a guest-displacement method, using kaolinite–dimethylsulfoxide (Kao–DMSO) as an effective intermediate. The intercalated monomer adopted a monolayer arrangement between the layers, confirmed by XRD analysis. Free-radical polymerization of methacrylamide was reported in the interlamellar spaces of Na-montmorillonite (19). Herein, the polymerization was achieved by thermal treatment of kaolinite–methacrylamide intercalation compound at ~150 °C for 2 h in air atmosphere. ^{13}C MAS NMR analysis confirmed the polymerization with the presence of residual monomeric species in the interlamellar space. The polymerization product had a high thermal stability, compared with the kaolinite–methacrylamide intercalation compound, as evidenced by thermogravimetric analysis. Analyses results confirmed the feasibility of the synthesis of an intercalated Kao–polymer nanocomposite, using in situ polymerization strategy.

Experimental

Chemicals and reagents

All chemicals used were of reagent-grade quality and were not further purified. Methacrylamide (C_4H_7NO, 98%) was obtained from Sigma-Aldrich and was used without further purification. Well-crystallized kaolinite from Georgia (labeled KGa-1b) was obtained from the Source Clays Repository of the Clay minerals Society (Purdue University, West Lafayette, Indiana, USA). This was purified according to previously reported sedimentation techniques (20), and the < 2 μm size fraction was used.

Chart 1.



Analysis and characterization

XRD powder patterns were obtained on a Philips PW 3710 diffractometer using a generator voltage of 45 kV and a generator current of 40 mA. Typically, a step size of 0.04° (2θ) was used with a dwell time of 0.5 s/step in a continuous scan mode. The sample was spun during the acquisition, and a 12 mm automatic divergence slit was used together with a 0.2 mm fixed receiving slit, 1° secondary antiscatter slit, and a 10 mm fixed incident-beam mask. The ratio of intercalation (RI) was calculated as an approximation from the relative intensities of the (001) reflections of the organo-kaolinite phase and of the residual kaolinite phase.

Infrared spectra were acquired on a Thermo–Nicolet Nexus 670 FTIR spectrometer under dry air using 32–256 scans with a resolution of 2–4 cm^{-1}. The samples were prepared as KBr pellets from 50 mg of a mixture of 0.25–0.5 wt% sample in KBr. Peak positions were either picked manually or automatically, using the instrument installed software.

^{13}C CP/MAS NMR spectra were obtained on a Bruker ASX-200 instrument operating at 50.31 MHz at a spinning rate of 4.0–5.0 kHz and a contact time of 2 ms in most cases. The spectra were referenced to adamantane at δ = 38.4 ppm.

^{29}Si CP/MAS NMR spectra were obtained on a Bruker AVANCE-500 instrument operating at 99.35 MHz at a spinning rate of 6.0 kHz and a contact time of 8–10 ms. The spectra were referenced to tetramethylsilane (TMS) at 0.0 ppm.

All thermal analyses (TG, DTA, and DTG) were carried out on an SDT 2960 Simultaneous DSC–TGA instrument (TA Instruments) under air flow (100 mL min^{-1}) at a heating rate of 10–20 °C min^{-1}. Approximately 10–20 mg samples were used for each run. In all cases, the given TG mass-loss data were determined approximately.

Organic elemental analyses (CHNOS; combustion analysis) were performed on selected samples by Chemisar Laboratories Inc., Guelph, Ontario, Canada.

Preparation and characterization of Kao–DMSO intercalate

Kao–DMSO intercalate was typically prepared by mixing 20 g of KGa-1b with 100 mL of DMSO in a sealed container for a sufficient time (2 month) with occasional stirring to achieve maximum intercalation. The product was vacuum-filtered and washed with 1,4-dioxane to remove excess DMSO and then air-dried to yield an off-white powder.

Table 1. Summary of product codes, reaction conditions, and product X-ray characterization for the preparation of kaolinite–methacrylamide nanohybrids.

	Reaction conditions[a]		Product X-ray characterization	
Produced nanohybrid code	Starting material (SM)[b]	t_r[c] (h)	d_{001}[d] (Å)	RI[e] (%)
Kao–MAC1	Kao–NMF	22	12.6	9
Kao–MAC2	Kao–DMSO	21	12.5	50.3
Kao–MAC3	Kao–DMSO	67	12.5	92.0
Kao–MAC4	Kao–DMSO	48	12.5	91.4
Kao–MAC5	Kaolinite (KGa-1b)	72	7.15	—

Note: Reaction details are given in the Experimental section.
[a]All reactions took place at ambient temperature, and the reaction medium was 10% methacrylamide solution *w*/*v*, in all cases.
[b]Kaolinite (Kao), methacrylamide (MAC), *N*-methyl formamide (NMF), and dimethyl sulfoxide (DMSO).
[c]Approximate reaction time.
[d]The specified interlayer distance (d) is that of the principal product phase calculated using (00l) reflections; d_{001} reflections of the residual unexpanded kaolinite (d_{001K}) always gave a value of ~7.15 Å.
[e]Ratio of intercalation is the ratio of the intensities of the d_{001} reflection of the modified phase over the sum total of all the d_{001} reflections of the modified phase(s) and residual unexpanded kaolinite.

XRD: d_{001} = 11.16 Å (100.0), d_{001}(Kao) = 7.15 Å (9.7), d_{002} = 5.6 Å (4.2), d_{003} = 3.72 Å (45.7), d_{002}(Kao) = 3.57 Å (14.6), d_{004} = 2.8 Å (1.8), d_{060} = 1.49 Å (7.6), RI = 0.91–0.98 (various samples).

Preparation of Kao–NMF intercalate

Approximately 20 g of KGa-1b were mixed with 100 mL of *N*-methyl formamide in a sealed container for a sufficient time (~1 month) with occasional stirring to achieve maximum intercalation. After that, the product was filtered and washed with 1,4-dioxane to remove excess NMF and then air-dried. A representative sample gave XRD: d_{001} = 10.71 Å (100.0), d_{001}(Kao) = 7.15 Å (18.9), d_{002} = 5.28 Å (0.6), d_{003} = 3.58 Å (71.7), RI = 0.87.

Preparation of Kao–MAC by the reaction of methacrylamide with Kao–NMF (Kao–MAC1)

Kao–MAC1 was prepared by the displacement of NMF from the Kao–NMF intercalate with methacrylamide (Sigma-Aldrich). The mixture of Kao–NMF (1 g) and an aqueous solution of methacrylamide (10% *w*/*v*, 100 mL) was stirred for 22 h at room temperature, and the product was vacuum-filtered, washed with 2-propanol, and air-dried to yield an off-white powder. Prolonged reaction times did not increase the ratio of intercalation, since NMF was de-intercalated with the recovery of pristine kaolinite.

Preparation of Kao–MAC by the reaction of methacrylamide with Kao–DMSO (Kao–MAC2, –MAC3, and –MAC4)

In a series of experiments, Kao–MAC was prepared by displacing DMSO with methacrylamide. A mixture of Kao–DMSO (1 g) and an aqueous solution of methacrylamide (10% *w*/*v*, 100 mL) was stirred for 21, 67, and 48 h, respectively, at room temperature, and the products were vacuum-filtered, washed with 2-propanol, and air-dried. Prolonged reaction times had a positive effect on the ratio of intercalation with the optimum reaction time being ≈ 48 h.

The reaction of methacrylamide with KGa-1b

A mixture of KGa-1b (1 g) and an aqueous solution of methacrylamide (10% *w*/*v*, 100 mL) was stirred for 72 h at room temperature, and the product was vacuum-filtered, washed with 2-propanol, and air-dried to yield an off-white powder. XRD showed that no reaction has taken place, as the d_{001} observed was that of the pure kaolinite = 7.15 Å.

Results and discussion

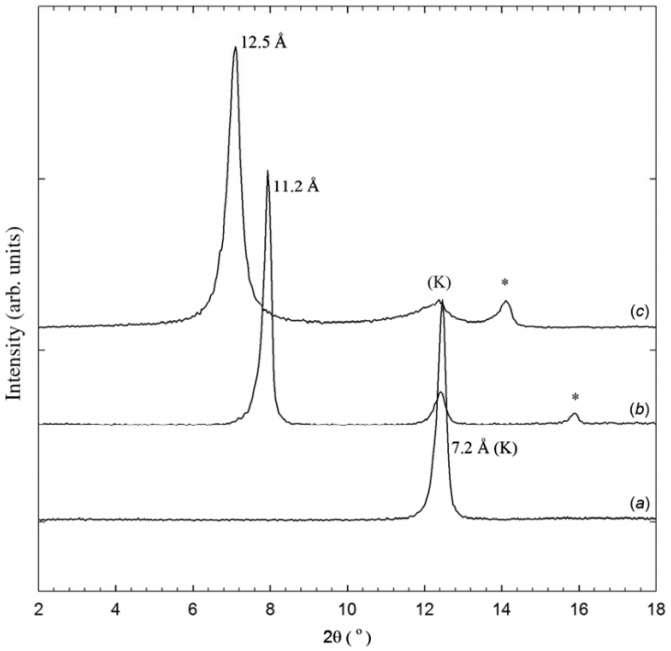
Synthesis and XRD analysis

The preparation of the Kao–methacrylamide (MAC) intercalate was carried out at room temperature using what can be described as a "soft guest-displacement method" (21), most effectively from the DMSO intercalate of kaolinite by direct treatment with 10% aqueous solution of methacrylamide (98%, Sigma-Aldrich). First, a kaolinite–DMSO intercalation compound (abbreviated as Kao–DMSO) or a kaolinite – *N*-methyl formamide (Kao–NMF) was prepared as an intermediate according to the methods reported previously (22, 23). Table 1 summarizes the product names and codes, the reaction conditions, and the d_{001} values of the resulting materials. In the case of kaolinite (KGa-1b) as starting material, kaolinite was fully recovered, and the characteristic d_{001} reflection could be observed at ~7.2 Å. However, when the Kao–DMSO was used as an intermediate, a reflection at 12.5 Å was observed, indicative of the methacrylamide intercalation into the interlamellar spaces of kaolinite, since Kao–DMSO intercalate exhibits a d_{001} reflection at ~11.1 Å (24) (see Fig. 1). In a typical reaction, 1–2 g of Kao–DMSO intercalate were mixed with ~50–100 mL of 10% solution (*w*/*v*) of methacrylamide (MAC). The mixture was stirred at room temperature for a given period of time, followed by the reaction workup (washing with excess 2-propanol, vacuum filtration, and drying in vacuum). The ratio of intercalation was up to ~92%. Another intercalate was used as a starting material, Kao–NMF. The production of materials with d_{001} = 12.6 Å was observed when the Kao–NMF intercalate was used (d_{001} = 10.8 Å for Kao–NMF), but with a ratio of intercalation as low as 9%. It is worth noting that the reaction was unsuccessful from the melt, as methacrylamide sublimes at the melting temperature.

X-ray powder patterns of the starting materials (kaolinite and Kao–DMSO) and of the materials resulting from a typical reaction are shown in Fig. 1, for the range of 2–18° (2θ).

© 2008 NRC Canada

Fig. 1. XRD powder diffraction patterns (2θ = 2°–18°) of (*a*) kaolinite, (*b*) Kao–DMSO, and (*c*) Kao–MAC (d_{002} of the intercalate is marked by an asterisk).



Notably, the layered structure of kaolinite remains largely unaffected, as the d_{060} reflection remains at 1.49 Å, characteristic of a dioctahedral clay mineral (not shown). The d_{001} reflection of the Kao–MAC intercalate corresponds to an expansion in the interlamellar distances by ~5.3 Å (subtracting a kaolinite layer thickness of 7.2 Å from the observed d_{001}). Since the ^{13}C NMR results show the complete disappearance of the intermediate organic intercalate (DMSO) after the reaction (see later sections), the expansion can be attributed only to the intercalation of the amide.

Methacrylamide can be polymerized in aqueous solutions in the presence of a free-radical initiator, e.g., benzoyl peroxide (19). Thermal treatment is used in this study to polymerize the intercalated amide in the interlamellar spaces without using an initiator. Figure 2 shows powder XRD patterns of Kao–MAC sample before and after thermal treatment. The sample was heated at a rate of 4 °C min^{-1} in a programmable furnace and then kept for 2 h at 150 °C or 30 h at 100 °C. The samples were allowed to cool to room temperature, and their XRD powder patterns were recorded. Heating the samples at higher temperatures would cause the intercalated kaolinite layers to collapse as a result of the deintercalation of the amide (see TG Section).

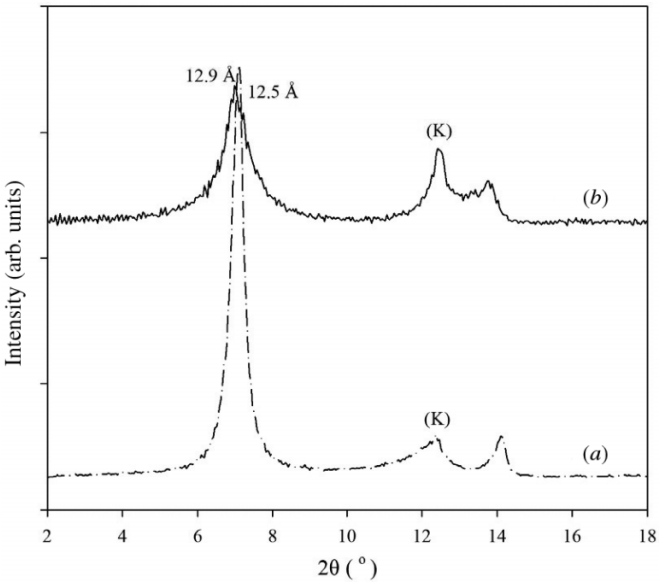
Thermal treatment (Fig. 2) causes the polymerization of methacrylamide molecules into the interlayer spaces. This can be observed by a slight expansion of the interlayer spacing from 12.5 Å to 12.9 Å for the polymerization product Kao–PMAC.

FTIR analysis

Detailed assignments of the major observed bands in the FTIR spectra of the produced nanohybrids before and after polymerization are given in Table 2.

The O–H stretching patterns for Kao–MAC and Kao–PMAC (Figs. 3*b* and 3*c*, respectively) are significantly different from the starting material, Kao–DMSO (Fig. 3*a*) (25). The Kao–DMSO band at 3665 cm^{-1} disappeared completely, and new bands appeared for Kao–MAC at ~3652, 3639, 3602, and 3547 cm^{-1}, suggesting the formation of a new pattern of strong H-bonding in the interlayer space between the intercalated methacrylamide molecules and the hydroxyls of the aluminol surface. After thermal treatment, the intensity of the band at 3652 cm^{-1} was greatly reduced, and the bands at 3602 and 3547 cm^{-1} disappeared. The NH stretching bands, characteristic of a primary amide, can be observed before and after the heat treatment (see Table 2). In both cases, the asymmetric and symmetric CH stretching bands are observed in the range of ~2980–2930 cm^{-1}.

Fig. 2. XRD powder diffraction patterns (2θ = 2°–18°) of Kao–MAC (*a*) before and (*b*) after thermal treatment.



The FTIR spectra for the intercalation products before and after thermal treatment are depicted in Figs. 4*a* and 4*b*, respectively. The C=O stretching band was observed at ~1663 cm^{-1} in both cases. CH deformation bands and CN stretching bands are also observed in the range of ~1380–1460 cm^{-1} in both cases. Also, δ(NH) band is observed at ~1580 cm^{-1} (19, 26). The major change in the IR spectrum after heating is that the band at ~1620 cm^{-1}, attributed to the C=C stretching of the intercalated monomer, was considerably reduced after thermal treatment (Fig. 4), thus verifying that polymerization took place upon thermal treatment.

Solid-state NMR analysis

^{13}C NMR analysis

To identify the nature of the intercalated molecules, the results of ^{13}C NMR CP/MAS experiments (50.31 MHz) on the produced Kao–MAC nanohybrid and the intercalated Kao–PMAC nanocomposite were studied. The spectra are stacked in Fig. 5. The observed ^{13}C chemical shifts for the starting material (Kao–DMSO) are in agreement with literature data (see Fig. 5*a*) (27).

The ^{13}C NMR spectrum of the produced Kao–MAC nanohybrid confirmed the intercalation of methacrylamide in the interlayer spaces, and it is shown in Fig. 5*b*.

Note: The absorptions are designated as weak (w), medium (m), strong (s), very weak (vw), very strong (vs), shoulder (sh), and broad (br).

Fig. 3. FTIR spectra (4000–2600 cm^{-1}) of (*a*) Kao–DMSO, (*b*) Kao–MAC, and (*c*) Kao–PMAC.

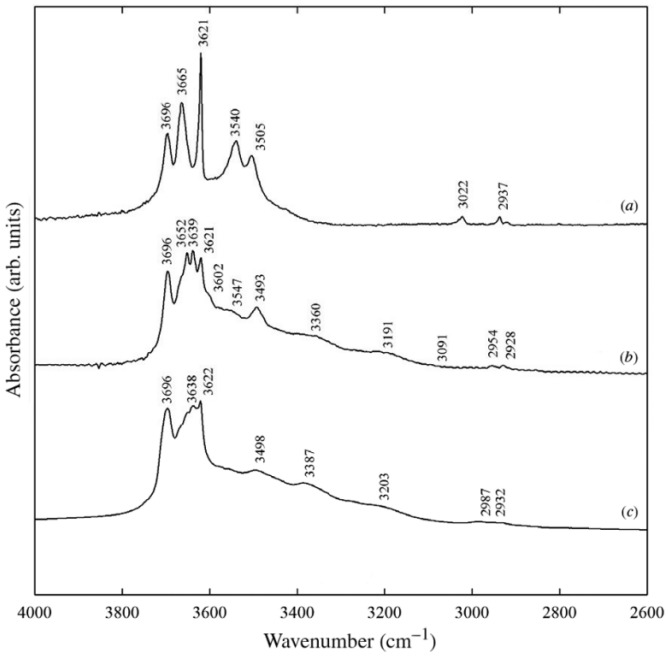

Fig. 4. FTIR spectra (2000–1200 cm^{-1}) of (*a*) Kao–MAC and (*b*) Kao–PMAC.

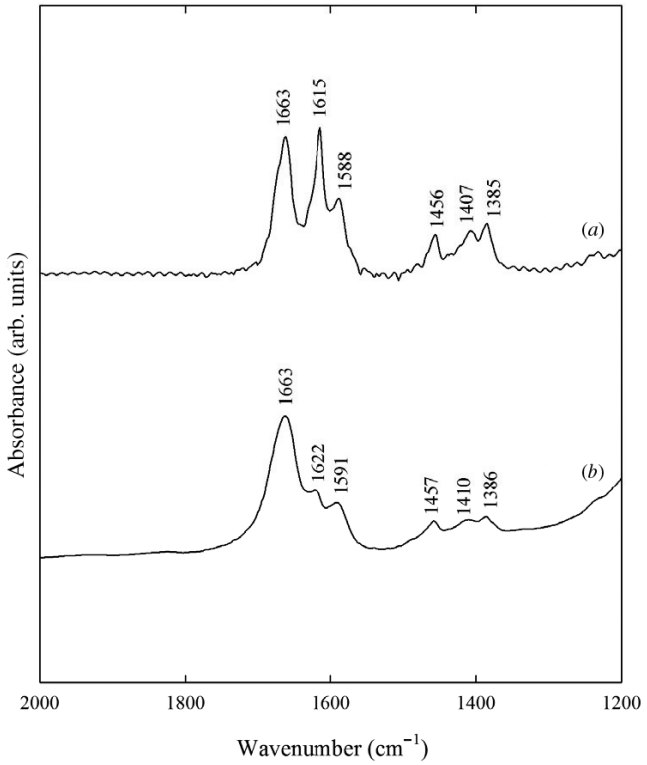

Methacrylamide signals can be observed at ~19.0 ppm (methyl carbon), and two signals at ~126 and 139 ppm are unambiguously attributed to the unsaturated carbons of the methacrylamide molecule. The signal at ~171 ppm is attributed to the amide carbonyl groups. No DMSO resonances were detected in the spectrum, indicating the complete displacement of the intermediate by methacrylamide (28, 29).

^{13}C NMR spectroscopy also confirmed the polymerization of methacrylamide by both the 150 °C and the 100 °C treatments. The spectra in Figs. 5*c* and 5*d* belong to the heat treated Kao–MAC intercalate at 150 °C and 100 °C, respectively. The main features in the spectra of the polymerized samples are the shift of the carbonyl signal to ~183 ppm and the appearance of new signals at ~45 and 55 ppm, attributed to the saturated carbons of the polymeric chain. These signals are in excellent agreement with the values reported in the literature (28, 29) for poly(methacrylamide). The presence of residual amounts of monomer indicates partial polymerization.

^{29}Si CP/MAS NMR

The ^{29}Si CP/MAS NMR spectrum (99.35 MHz) of kaolinite is given in Fig. 6*a*, displaying two well-resolved signals at –91.5 and –90.9 ppm. The ^{29}Si CP/MAS spectrum of Kao–DMSO intercalate is given in Fig. 6*b*. In addition to the residual signals of unexpanded kaolinite, one signal is observed at –92.7 ppm. Figure 6*c* gives the ^{29}Si CP/MAS

NMR spectra of the methacrylamide intercalate. The signal is slightly shifted to –92.9 ppm, and the signals due to the unexpanded kaolinite can also be observed, indicating a similar perturbation of the silicon environment by the intercalated methacrylamide molecules to that observed for the Kao–DMSO (30–32).

Thermogravimetric analysis

The TG thermogram of the Kao–MAC intercalate in air atmosphere is exhibited in Fig. 7*b*. The compound showed thermal stability comparable with that of the Kao–DMSO (Fig. 7*a*). The results also confirmed the displacement of DMSO molecules by methacrylamide in the interlayer spaces. In the case of Kao–MAC, the dehydroxylation step is observed at ~492 °C (see Fig. 8*a*), amounting to ~13% dehydroxylation mass loss. An additional mass loss (~14%) is observed with a maximum near 172 °C in the DTG, corresponding to the loss of the organic moieties via deintercalation. The final mass loss of ~1.0% is attributed to the trapped carbonaceous residue of the decomposed methacrylamide, released with the spinel-phase crystallization observed in this case near 935 °C (33).

The thermogram of the polymerized intercalated methacrylamide sample with prior thermal treatment shows enhanced thermal stability compared with the Kao–monomer sample (Fig. 7*c*). The dehydroxylation stage of kaolinite, giving rise to 13% mass loss, can be observed with a maximum at 503 °C in the DTG trace (Fig. 8*b*), which is similar to other reported dehydroxylation temperatures for Kao–polymer intercalated nanocomposites (9, 13, 16). Moreover, the mass-loss stage due to the decomposition of the organic material was shifted to a much-higher temperature with two signals in the DTG at 246 and 398 °C, with a total mass loss of ~13%. Also, the amount of the carbonaceous residue is increased to ~2.5%. The enhanced thermal stability of the polymerized sample Kao–PMAC, compared with the Kao–MAC sample, is an indication that the polymerization of methacrylamide was achieved in the interlamellar space by thermal treatment.

Elemental analysis

Elemental analyses were performed on a typical Kao–MAC sample and on the polymerized sample (after thermal treatment). Kao–MAC sample gave C 8.72%, H 2.37%, and N 2.60%. Thus, the calculated stoichiometry of this sample, based on the average of the results, is $Al_2Si_2O_5(OH)_4 \cdot (C_4H_7NO)_{0.66}$. Notably, this sample was free of the residual co-intercalated DMSO. After heat treatment, Kao–PMAC sample gave C 6.24%, H 2.16%, and N 1.84%. Similarly, the stoichiometry of this sample is $Al_2Si_2O_5(OH)_4 \cdot (C_4H_7NO)_{0.52}$. The higher average occupancy value of ~0.66 unit of MAC per unit cell of kaolinite, compared with that of the polymerized sample (0.52), is expected because of the partial de-intercalation upon heat treatment.

Conclusion

The preparation and characterization of a kaolinite–methacrylamide intercalation compound was achieved by direct treatment of a DMSO pre-intercalate with an aqueous solution of methacrylamide under mild conditions. The DMSO molecules were fully displaced from the interlayer space by methacrylamide. Only partial intercalation could be obtained with an NMF pre-intercalate. After intercalation, the monomer was thermally polymerized. XRD, spectroscopic, and thermogravimetric analysis confirmed that polymerization was partially achieved in the interlayer spaces.

This study confirms the feasibility of using in situ polymerization as a method to obtain intercalated nanocomposites from kaolinite. The intercalation of polymers in kaolinite to create nanohybrid materials, based on this abundant and non-centrosymmetric mineral, is a direction in the development of the interlayer chemistry of kaolinite. Joined to the intercalation of large organic cations, such as in the case of imidazolium ionic liquids (34), and to the functionalization of the interlayer aluminol surfaces by silanization (35) or by grafting of organic units (36), these studies demonstrate the potential of kaolinite as a promising raw material for the design of new advanced materials.

Phenylsilane dehydrocoupling and addition to styrene catalyzed by (R-indenyl)Ni(phosphine)(methyl) complexes[1]

Yaofeng Chen and Davit Zargarian

Abstract: This report describes the synthesis and characterization of the Ni–Me complexes (R-indenyl)Ni(PR′$_3$)Me (R = 1-*i*-Pr, 1-SiMe$_3$, and 1,3-(SiMe$_3$)$_2$; R′= Me, Ph) and outlines their catalytic reactivities in the dehydrogenative oligomerization of PhSiH$_3$ and its addition to styrene in the absence of initiators/activators. Observation of higher hydrosilylation activities for PPh$_3$-based compounds featuring bulky substituents on the indenyl ligand confirms earlier suggestions that phosphine dissociation is an important component of the catalytic cycle for this reaction. In contrast, oligomerization of PhSiH$_3$ is more facile with PMe$_3$-based precursors and independent of the steric bulk of the indenyl ligand, implying that this reaction does not involve phosphine dissociation. These conclusions are consistent with the variable-temperature ^{1}H NMR spectra of {1,3,-(SiMe$_3$)$_2$-indenyl}Ni(PR′$_3$)Me and various structural parameters observed in the solid-state structures of {1,3,-(SiMe$_3$)$_2$-indenyl}Ni(PPh$_3$)Me, {1,3,-(SiMe$_3$)$_2$-indenyl}Ni(PMe$_3$)Cl, and {1-SiMe$_3$-indenyl}Ni(PMe$_3$)Me.

Key words: nickel-indenyl complexes, hydrosilylation, hydrosilane oligomerization.

Résumé : Ce rapport présente la synthèse et la caractérisation des complexes (R-indényle)Ni(PR′$_3$)Me (R = 1-*i*-Pr, 1-SiMe$_3$ et 1,3-(SiMe$_3$)$_2$; R′= Me et Ph) ainsi que la réactivité catalytique de ces composés dans l'oligomérisation déshydrogénative du PhSiH$_3$ et dans son addition au styrène en absence d'un initiateur ou d'un activateur. L'observation des plus grandes activités d'hydrosilylation chez les composés à base de PPh$_3$ et portant des substituants volumineux sur le ligand indényle indique que le cycle catalytique implique la dissociation de la phosphine. D'ailleurs, l'oligomérisation du PhSiH$_3$ est plus facile avec les composés à base de la PMe$_3$ et indépendante de la taille des substituents de l'indényle, ce qui semble indiquer que cette réaction n'implique pas la dissociation de la phosphine. Ces conclusions sont concordantes avec d'autres observations tirées des spectres RMN ^{1}H à températures variables des composés {1,3,-(SiMe$_3$)$_2$-indényle}Ni(PR′$_3$)Me et des études des structures des composés {1,3,-(SiMe$_3$)$_2$-indényle}Ni(PPh$_3$)Me, {1,3,-(SiMe$_3$)$_2$-indényle}Ni(PMe$_3$)Cl et {1-SiMe$_3$-indényle}Ni(PMe$_3$)Me.

Mots-clés : composés nickel-indényles, hydrosilylation, oligomérisation des hydrosilanes.

[Traduit par la Rédaction]

Introduction

Recent reports have shown that the complexes IndNi(L)X (Ind= indenyl and its substituted derivatives; L= neutral ligands such as phosphines or *N*-heterocyclic carbenes; X= anionic ligands such as halides, alkyls, triflate, and so forth) (1) promote the polymerization of ethylene (2), alkynes (3), or PhSiH$_3$ (4) in the presence of activators such as methylaluminoxanes. The in situ activation of these precursors can also be done using cationic initiators, such as AgBF$_4$, NaBPh$_4$, or AlCl$_3$, all of which generate the electronically unsaturated and highly electrophilic cations [IndNi(PR$_3$)]$^+$ (5); these intermediates promote the oligomerization of some olefins (6) as well as the hydrosilylation of olefins and ketones (7). Cationic species can also be generated in the absence of initiators by using the precursors (*i*-Pr-Ind)Ni(PPh$_3$)(OSO$_2$CF$_3$) (8) or [(η^5,η^1-Ind^NR$_2$)Ni(PR$_3$)]$^+$ (^ = various side chains tethering the amine moiety to the Ind ligand) (9), or by heating the complexes [IndNi(PR$_3$)$_2$]$^+$ bearing bulky phosphine ligands (10).

A number of recent studies have shown that of the reactions promoted by IndNi(PR$_3$)X, only those involving hydrosilanes can proceed in the absence of activators/initiators. Thus, the Ni–Me complexes (1-Me-Ind)Ni(PR$_3$)Me (R = Me, Ph, Cy) act as single-component precursors for the dehydrogenative oligomerization of PhSiH$_3$ (11), whereas the Ni–Cl complexes (R-Ind)Ni(PPh$_3$)Cl promote the addition of PhSiH$_3$ to styrene in the absence of any activator/initiator (12). The available mechanistic information indicates that these reactions are sensitive to the steric bulk and (or)

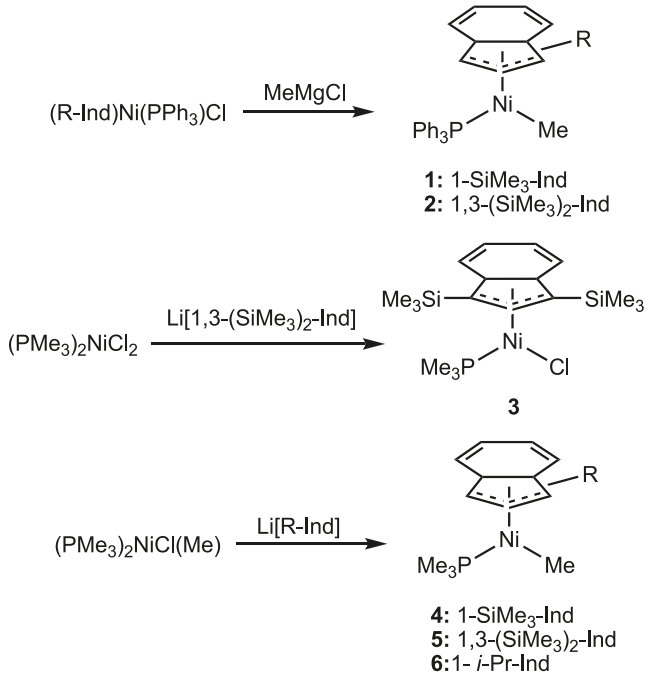
Scheme 1.



nucleophilicity of the phosphine ligand, the rates following the order $PMe_3 > PPh_3 > PCy_3$ for silane oligomerization (11) and $PPh_3 > PMe_3$ for the hydrosilylation (7). The latter reaction is also favoured by compounds featuring bulkier indenyl ligands (1,3-$(SiMe_3)_2$-Ind > 1-$SiMe_3$-Ind > 1-Me-Ind) (13). These and a number of other observations led us to propose that the hydrosilylation requires the dissociation of the phosphine ligand (12).

As a continuation of our studies on the structure–activity relationships in Ni–indenyl complexes, we have prepared a new series of IndNi(PR_3)Me complexes and studied their structures and reactivities in the oligomerization of $PhSiH_3$ and its addition to styrene as a function of Ind substituents and the phosphine ligands. This report presents the synthesis, characterization, and reactivity studies for the complexes (1-$SiMe_3$-Ind)Ni(PPh_3)Me (**1**), {1,3-$(SiMe_3)_2$-Ind}Ni(PPh_3)Me (**2**), {1,3-$(SiMe_3)_2$-Ind}Ni(PMe_3)Cl (**3**), (1-$SiMe_3$-Ind)Ni(PMe_3)Me (**4**), {1,3-$(SiMe_3)_2$-Ind}Ni(PMe_3)Me (**5**), and {1-*i*-Pr-Ind}Ni(PMe_3)Me (**6**), including the X-ray diffraction studies for **2**–**4**.

Results and discussion

Syntheses

Reaction of (R-Ind)Ni(PPh_3)Cl with MeMgCl gave the corresponding Ni–Me complexes in moderate yields (Scheme 1; R = 1-$SiMe_3$ (**1**, 73%), 1,3-$(SiMe_3)_2$-Ind (**2**, 66%)), but this approach did not work well for the preparation of the analogous PMe_3 complexes because of the difficult purification of the analogous Ni–Cl precursors. For instance, reacting equimolar quantities of Li[1,3-$(SiMe_3)_2$-Ind] and Ni$(PMe_3)_2Cl_2$ gave the desired {1,3-$(SiMe_3)_2$-Ind}Ni(PMe_3)Cl (**3**) in ~50% crude yield. As noted previously, however, the main challenge in the synthesis of Ni–indenyl compounds bearing PMe_3 is avoiding a side reaction that generates Ni$(PMe_3)_4$ and reducing the yield of the desired product (14). Removal of the PMe_3 released during the synthesis by periodic pumping of the reaction mixture helps minimize this decomposition pathway, but does not eliminate it altogether. In the case of **3**, the presence of small quantities of Ni$(PMe_3)_4$ in the reaction mixture complicated the purification, since both species appear to be highly soluble in most solvents, including hexane. However, solution NMR spectra and X-ray analysis of crystals obtained by removal of the oily impurities helped establish the identity of this compound unambiguously (vide infra).

The difficult purification of **3** encouraged us to seek an alternative pathway to the desired Ni–Me compounds. We found that the direct reaction of Li[R-Ind] with $(PMe_3)_2$NiCl(Me) gave reasonable yields of (R-Ind)Ni(PMe_3)Me (Scheme 1; R = 1-$SiMe_3$ (**4**, 87%), 1,3-$(SiMe_3)_2$-Ind (**5**, 64%), *i*-Pr (**6**, 77%)). The purification of **5** was also challenging, but **4** and **6** were obtained in good purity. The characterization of compounds **1**–**6** by solution NMR spectra and, in the case of **2**–**4**, by X-ray diffraction studies was straightforward, as described below.

NMR characterization

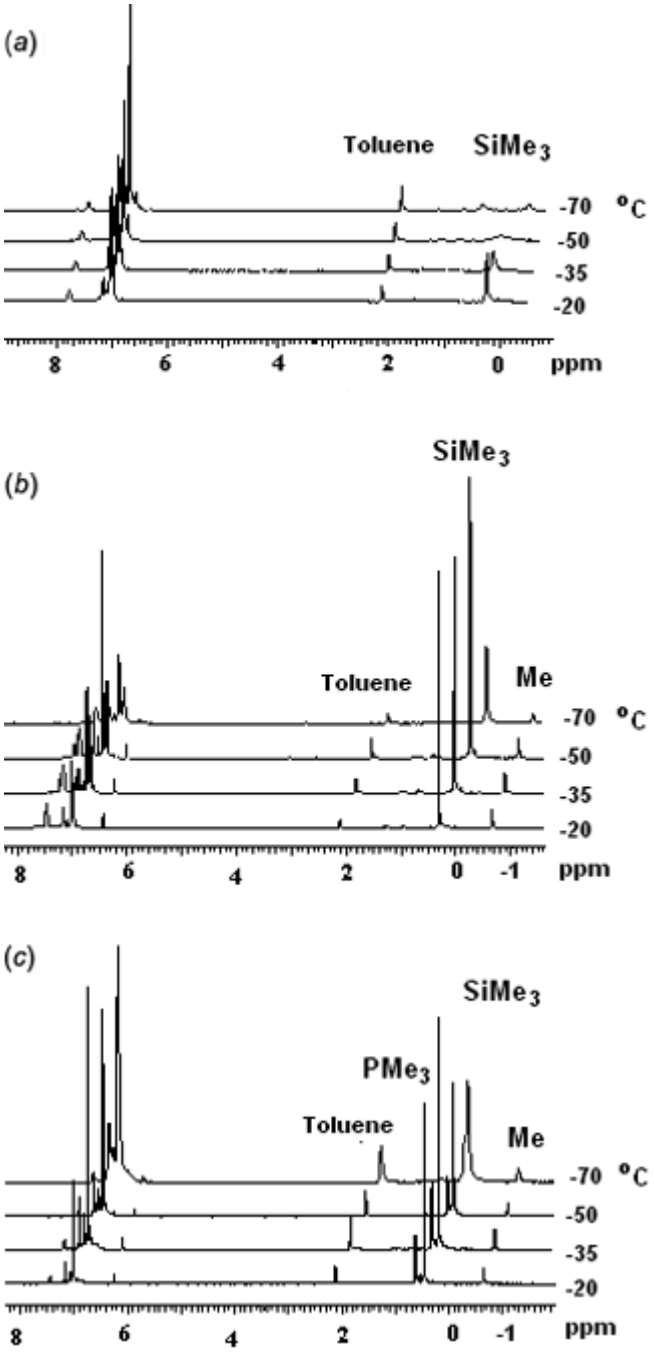
All of the complexes showed a single resonance in their $^{31}P\{^1H\}$ NMR spectra at chemical shifts that are characteristic of each type of complex. Thus, **1** and **2** gave singlets at ~47 and 44 ppm, respectively (cf. 48 ppm for (1-Me-Ind)Ni(PPh_3)Me) (15), **3** gave a singlet at ~ –18 ppm (cf. –11 ppm for (1-Me-Ind)Ni(PMe_3)Cl) (14), and **4**–**6** gave singlets at ~ –9 (**5**) and –4 ppm (**4** and **6**) (cf. –3.7 ppm for (1-Me-Ind)Ni(PMe_3)Me) (11).

The ^1H NMR spectra showed a number of characteristic signals for the Ni–Me moiety (~ –0.7 ppm), the $SiMe_3$ substituents (~0.3–0.5 ppm), the PMe_3 ligand (~0.6–0.8 ppm), and H2 of the Ind ligands (~6.1–6.7 ppm). It is interesting to note that methylation of the Ni–Cl bond shifts δ H2 upfield in {1,3-$(SiMe_3)_2$-Ind}Ni(PMe_3)X (from 6.72 to 6.13 ppm), {1,3-$(SiMe_3)_2$-Ind}Ni(PPh_3)X (from ~7 to 6.33 ppm), and (1-$SiMe_3$-Ind)Ni(PPh_3)X (from 6.65 to 6.42 ppm). This upfield shift likely arises from the greater delocalization induced in the five-membered ring moiety of the Ind ligands in Ni–alkyl vs. Ni–halide derivatives (1, 15). Finally, the phenyl rings of the PPh_3 ligand exert some shielding influence on H3 of the Ind ligand that is evident from a comparison of the δH3 in **1** (4.23 ppm) vs. **4** (4.62 ppm) and **6** (4.44 ppm).

We studied the variable-temperature ^1H NMR spectra of **2** and **5** (Fig. 1) and compared them to those of {1,3-$(SiMe_3)_2$-Ind}Ni(PPh_3)Cl to probe the issue of phosphine lability in the Ni–Me derivatives. It is worthwhile to recall that the low-temperature spectra of {1,3-$(SiMe_3)_2$-Ind}Ni(PPh_3)Cl showed a gradual sharpening of the $^{31}P\{^1H\}$ signal as well as the splitting of the ^1H singlet due to the $Si(CH_3)_3$ protons (Fig. 1*a*). The relatively small $\Delta G^{\ddagger}$ value of ~10 kcal/mol (1 cal = 4.184 J) calculated for this exchange process, as well as a number of parameters from the solid-state structure of {1,3-$(SiMe_3)_2$-Ind}Ni(PPh_3)Cl, convinced us that the dynamic exchange observed for this compound was caused by a rapid dissociation/re-association of the PPh_3 ligand as opposed to the hindered rotation of the 1,3-$(SiMe_3)_2$-Ind ligand (12). The lability of the PPh_3 ligand was ascribed to the significant steric interaction with the $SiMe_3$ substituents.

© 2008 NRC Canada

Fig. 1. The variable-temperature ^{1}H NMR spectra (toluene-d_8, 400 MHz) for {1,3-$(SiMe_3)_2$Ind}Ni(PPh_3)Cl (*a*), {1,3-$(SiMe_3)_2$Ind}-Ni(PPh_3)Me (**2**, *b*), and {1,3-$(SiMe_3)_2$Ind}Ni(PMe_3)Me (**5**, *c*).



In contrast to the above discussed temperature-dependence of the {1,3-$(SiMe_3)_2$-Ind}Ni(PPh_3)Cl spectra, low-temperature spectra of the Ni–Me derivatives **2** and **5** showed no change in the linewidths of the ^{31}P signals or the multiplicities of the Si(CH_3)$_3$ singlets (Figs. 1*b* and 1*c*) down to –70 °C. These observations can be understood when we consider that methylation of the Ni–Cl bond is anticipated to reinforce the Ni–P bond strength and increase the delocalization of bonding in the five-membered-ring moiety of the Ind ligands; these changes would, in turn, lead to less facile phosphine dissociation and a less hindered Ind rotation. Since the NMR spectra indicate that the exchange process responsible for the equivalence of the $SiMe_3$ substituents in **2** and **5** is faster than the corresponding process in the Ni–Cl complex {1,3-$(SiMe_3)_2$-Ind}Ni(PPh_3)Cl, we conclude that these observations are more consistent with the rapid rotation of the 1,3-$(SiMe_3)_2$-Ind ligand as opposed to a dissociation/re-association of PR_3. The lower lability of their phosphine ligands should influence the hydrosilylation activities of the Ni–Me compounds (vide infra).

Solid-state structures

Single crystals obtained for **2**–**4** allowed us to examine their solid-state structures, which were found to be free of disorder and refined to a good degree of precision, as reflected in the *R* values of 3.77% (**2**), 4.16% (**3**), and 3.62% (**4**). The ORTEP diagrams for these compounds are shown in Fig. 2, and a selection of structural parameters is listed in Table 1; the full list of structural refinement parameters and the crystal data are provided as Supplementary data.[4]

In all three compounds, the coordination geometry around the Ni atom can be described as distorted square-planar, with the largest distortion arising from the small C1–Ni–C3 angles of ~67°. As commonly observed in this family of complexes (1), the Ind–Ni interaction in **2**–**4** is primarily through the allylic carbons, while the Ni–C bond distances for the benzo carbons are longer. This "slippage" away from an ideal η^5 hapticity is attributed to the tendency of Ni(II) to favour forming 16-electron complexes.

Another common type of slippage in this family of complexes is the so-called "sideways slippage", which is reflected in the unsymmetrical Ni–C bonds involving the allylic carbons (Ni–C1 > Ni–C3) and caused by the unequal trans influences of the PR_3 and X ligands (X= halides, phthalimidato, thiolato, triflato, and so forth). Little or no "sideways slippage" is evident in the PMe_3 compounds **3** and **4** (ΔNi–C(1,3) is within 6 esd values), which is consistent with the similar trans influences of PR_3 and Me ligands (1). On the other hand, complex **2** exhibits fairly different Ni–C bond lengths (ΔNi–C(1,3) = 50 × esd). We suspect that this anomalous elongation of the Ni–C3 bond in **2** is due primarily to the steric repulsion between PPh_3 and its neighbouring $SiMe_3$ group. This repulsion is also manifested in the greater C3–Ni–P angle in **2** (111°) compared with **3** (106°) and **4** (104°). Similar observations have been noted for the analogous complexes {$(SiMe_3)_n$-Ind}Ni(PPh_3)Cl (n = 1 or 2) (12).

Finally, the shorter Ni–P bond distance in **4** relative to **2** is consistent with both the greater nucleophilicity of PMe_3 and the larger Tolman cone angle for PPh_3, whereas the shorter

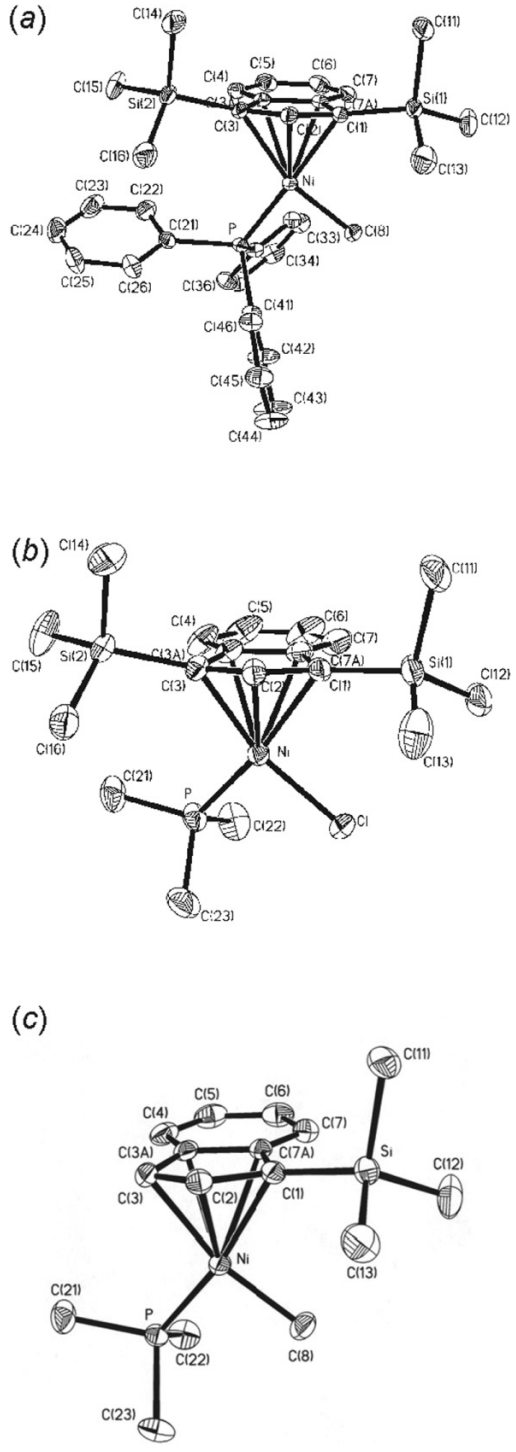
Fig. 2. ORTEP diagrams for complexes **2** (*a*), **3** (*b*), and **4** (*c*). Thermal ellipsoids are shown at the 30% probability level. Hydrogen atoms are omitted for clarity.



Ni–P bond in **4** relative to **3** reflects the tendency of the Ni–alkyl compounds to form stronger Ni–P interactions compared to their Ni–Cl counterparts (17). To the extent that solid state bond distances can correlate with the kinetic labilities of phosphines, the shorter Ni–P distance in **4** signals lower hydrosilylation activities for this complex (vide infra).

Catalytic reactivities

The hydrosilylation activities of the Ni–Me complexes were examined for comparison with those of the corresponding Ni–Cl precursors. In addition, we hoped to determine the influence of factors such as nature of the phosphine ligand and the Ind substituents on these reactivities. The addition of $PhSiH_3$ to styrene was selected as a model system to allow comparison to our previous studies. The catalysis is initiated by the direct reaction of $PhSiH_3$ with the Ni–Me moiety, obviating the need for an activator/initiator. The main product of this reaction, $PhCH(Me)(SiPhH_2)$, arises from regioselective (>95%) α-addition of the silyl moiety (eq. [1]); as will be discussed later, appreciable quantities of silane oligomers, $(PhSiH)_n$, are also produced in some cases (vide infra). The catalytic runs were carried out at room temperature with Ni/styrene/$PhSiH_3$ ratios of 1:50:75 or 1:100:125; the excess of $PhSiH_3$ was meant as a compensation for its possible loss in the competitive silane oligomerization side reaction, thus ensuring the availability of sufficient quantities of silane for the desired hydrosilylation reaction. Analysis of the products and quantification of the yields were done according to previously published procedures (12).

[1] 
The results of the catalytic hydrosilylation reactions are shown in Table 2. The main point arising from the data is that the Ni–Me derivatives studied display more or less the same level of hydrosilylation activity as their analogous $IndNi(PPh_3)Cl$ complexes when the latter are used in the absence of any initiators (18). For instance, the addition of $PhSiH_3$ to styrene using the complexes $\{1,3\text{-}(SiMe_3)_2\text{-}Ind\}Ni(PPh_3)X$ under the same conditions proceeded with an 82% yield with X = Cl (12) vs. 79% with X = Me (Run 4). The similar catalytic activities of the Ni–Me and Ni–Cl pre-

Table 2. Hydrosilylation of Styrene with $PhSiH_3$ catalyzed by $IndNi(PR_3)Me$.

Run	Ind	PR_3	Ni:Styrene:$PhSiH_3$	Time (h)	Conversion (%)
1	1-Me-Ind	PPh_3[a]	1:50:75	5	37
2	1-$SiMe_3$-Ind	PPh_3	1:50:75	5	26
3	1,3-$(SiMe_3)_2$-Ind	PPh_3	1:50:75	5	74
4	1,3-$(SiMe_3)_2$-Ind	PPh_3	1:100:125	5	79
5	1-Me-Ind	PMe_3[b]	1:100:125	3	18
				5	22
6	1-*i*-Pr-Ind	PMe_3	1:100:125	3	29
				5	31
7	1-$SiMe_3$-Ind	PMe_3	1:100:125	3	11
				5	14
8	1,3-$(SiMe_3)_2$-Ind	PMe_3	1:100:125	3	35
				5	36

Note: Unless otherwise specified, the catalytic runs were conducted at room temperature in 394 mL of benzene using 5 μmol of the Ni precursor.
[a]The runs using PPh_3-based precursors gave traces only of cyclic and linear $(PhSiH)_n$ oligomers.
[b]The runs using PMe_3-based precursors gave variable quantities of cyclic and linear $(PhSiH)_n$ oligomers.

catalysts can be rationalized by noting that both of these precursors generate the same catalytically active intermediates beyond the initiation step.

Inspection of the data listed in Table 2 indicates that the PPh_3 derivatives are more active than their corresponding PMe_3 counterparts (Runs 1–3 vs. 5, 7, and 8), particularly for the precursors featuring the bulky 1,3-$(SiMe)_3$-Ind ligand, the most effective pre-catalyst being complex **2** (Runs 3 and 4). These observations confirm that hydrosilylation activity correlates with steric bulk of the Ind ligand (1,3-$SiMe_3$-Ind > 1-*i*-Pr-Ind > 1-Me-Ind) and phosphine lability (PPh_3 > PMe_3; Ni–Me < Ni–Cl). Interestingly, the Ni:substrate ratio does not appear to have a significant impact on the reactivities (Run 3 vs. 4).

As mentioned above, the PMe_3-based precursors exhibit lower hydrosilylation activities because of the less labile Ni–PMe_3 (12). On the other hand, the PMe_3-based complexes are efficient promoters of the competitive dehydrocoupling of $PhSiH_3$ (eq. [2]), whereas their PPh_3 counterparts are nearly inactive for this reaction; this implies that the dehydrocoupling does not require phosphine dissociation. Upon a closer examination of the silane dehydrocoupling reaction with the $IndNi(PMe_3)Me$ precursors, we found that the outcome of the catalysis was virtually independent of the specific Ind ligand used (Table 3). This implies that all of the $IndNi(PMe_3)Me$ precursors generate the same intermediate (e.g., $Ni^0(PMe_3)_n$) that acts as the active catalyst for the Si–Si bond formation reaction. It is worth noting that previous studies in our group have shown that most $Ni^0(PR_3)_n$ react with $PhSiH_3$ to produce mixtures of cyclic and linear oligomers (19), but the involvement of in situ generated Ni^0 species in the present studies has not been confirmed.

[2] $$PhSiH_3 \xrightarrow[-\ H_2]{IndNi(PMe_3)Me} (PhSiH)_n$$

Conclusion

This study supports our earlier observation that phosphine dissociation is an important step in the addition of $PhSiH_3$ to styrene catalyzed by IndNi(phosphine)X. It follows that PPh_3 derivatives are better catalyst precursors compared to their PMe_3 counterparts, and that bulky indenyl ligands facilitate the catalysis, presumably by favouring the phosphine dissociation step. Contrary to our expectation that stronger Ni–P interactions in the Ni–Me derivatives (supported by both solution and solid-state data) should mean a less facile phosphine dissociation step and hence lower hydrosilylation activities in these complexes, reactivity data showed that the nature of the ligand X (Cl or Me) has no significant impact on the catalysis. Studies are in progress to elucidate the intimate mechanisms of hydrosilylation and silane oligomerization reactions as catalyzed by indenyl–nickel complexes.

Table 3. Dehydrocoupling of $PhSiH_3$ catalyzed by $IndNi(PMe_3)Me$.

Note: Unless otherwise indicated, the catalytic runs were conducted by stirring the Ni precursor (18 μmol) and $PhSiH_3$ (200 equiv.) in toluene (0.25 mL) at –35 °C for 7 day.
[a]This experiment was run in THF.
[b]This experiment was run at 25 °C.
[c]This experiment was run for 4 days.

Experimental section

General

All manipulations were performed under nitrogen atmosphere using standard Schlenk techniques and a glovebox. Dry, oxygen-free solvents were employed throughout. The Ni precursors $Ni(PR_3)_2Cl_2$ were prepared from $NiCl_2{\cdot}6H_2O$ and PPh_3 or $NiCl_2$ and PMe_3, respectively. The syntheses of 1-$SiMe_3$-IndH and 1,3-$(SiMe_3)_2$-IndH and their Ni deriva-

tives (1-$SiMe_3$-Ind)Ni(PPh_3)Cl and {1,3-($SiMe_3$)$_2$-Ind}Ni(PPh_3)Cl have been described previously;12 1-*i*-Pr-IndH and Li[*i*-Pr-Ind] were prepared as described previously (3*b*, 6*a*). Ni(PMe_3)$_2$MeCl (21) was prepared by reacting Ni(PMe_3)$_2$Cl$_2$ with 1 equiv. of MeMgCl in THF at –30 °C, and characterized by ^{1}H NMR and ^{31}P NMR spectroscopy. All other reagents used in the experiments were obtained from commercial sources and used as received. A Bruker ARX 400 spectrometer was used for recording ^{1}H (400 MHz), ^{13}C{H^1}(100.56 MHz), and ^{31}P{H^1}(161.92 MHz). Unless otherwise noted, the NMR spectra were recorded at 25 °C. The elemental analyses were performed by the Laboratoire d'Analyse Élémentaire (Université de Montréal). The molecular masses of $(PhSiH)_n$ oligomers were measured by a Waters 1525 GPC system with a refractive-index detector, using THF as eluent and polystyrene standards.

(1-$SiMe_3$-Ind)Ni(PPh_3)Me (1)

MeMgCl (0.43 mL of a 3 mol/L solution in THF, 1.30 mmol) was added dropwise to a stirring solution of (1-$SiMe_3$-Ind)Ni(PPh_3)Cl (0.64 g, 1.18, in 40 mL of Et_2O) at room temperature. The reaction mixture was stirred for 30 min after the addition was completed, the solution was concentrated to about 5 mL under vacuum, and the resulting residue was extracted into hexane (40 mL). The extracts were concentrated to about 8 mL and cooled to –30 °C to give a brown solid (0.45 g, 73% yield).

^{1}H NMR (C_6D_6): 7.38 (d, $^3J_{H–H}$ = 8.0 Hz; H4 or H7), 7.35 (m; aromatic protons of PPh_3), 7.28 and 7.05 (t, $^3J_{H–H}$ = 7.6 Hz; H5 and H6), 7.00 (m; aromatic protons of PPh_3), 6.81 (d, $^3J_{H–H}$ = 8.0 Hz; H4 or H7), 6.42 (s; H2), 4.23 (s; H3), 0.53 (s; Si(CH_3)$_3$), –0.52 (d, $^3J_{P–H}$ = 6.0 Hz; Ni–CH_3). ^{13}C{H^1} NMR ($CDCl_3$): 134.2 (d, $^1J_{P–C}$ = 43 Hz; C_{ipso}), 133.9 (d, $^2J_{P–C}$ = 11 Hz; C_{ortho}), 128.9 (C_{para}), 128.1 (d, $^3J_{P–C}$ = 10 Hz; C_{meta}), 125.0, 124.0, 122.9, 121.5, 118.9, and 117.7 (C3A, C4, C5, C6, C7and C7A), 106.3 (d, $^2J_{C–P}$ = 6 Hz; C2), 82.0 (d, $^2J_{C–P}$ = 9 Hz; C3), 82.0 (d, $^2J_{C–P}$ = 12 Hz; C1), 0.2 (–$SiMe_3$), –24.4 (d, $^2J_{P–C}$ = 27 Hz; Ni–CH_3). ^{31}P{H^1} NMR (C_6D_6): 47.1 (s). Anal. calcd. for $C_{31}H_{33}Ni_1P_1Si_1$: C, 71.14; H, 6.36. Found: C, 70.29; H, 6.62.

{1,3-($SiMe_3$)$_2$-Ind}Ni(PPh_3)Me (2)

MeMgCl (0.35 mL of a 3 mol/L solution in THF, 1.05 mmol) was added dropwise to a stirring solution of {1,3-($SiMe_3$)$_2$-Ind}Ni(PPh_3)Cl (0.59 g, 0.95 mmol, in 30 mL of Et_2O) at room temperature. The reaction mixture was stirred for 30 min after the addition was complete, the solvent was removed under vacuum, and the residue was extracted with hexane (~60 mL). The extracts were concentrated to ~5 mL and allowed to stand at room temperature, which gave a brown solid (0.41 g, 66% yield). Single crystals of this compound were grown from cold, concentrated hexane solutions and subjected to X-ray diffraction studies.

^{1}H NMR (C_6D_6): 7.49–7.41 (m; PPh_3), 7.06–6.98 (m; aromatic protons of Ind and PPh_3), 6.33 (s; H2), 0.28 (s; Si(CH_3)$_3$), –0.70 (d, $^3J_{P–H}$ = 7.0 Hz; Ni–CH_3). ^{13}C{H^1} ($CDCl_3$): 134.4 (d, $^2J_{P–C}$ = 11 Hz; C_{ortho}), 134.3 (d, $^1J_{P–C}$ = 43 Hz; C_{ipso}), 129.8 (C_{para}), 128.0 (d, $^3J_{P–C}$ = 10 Hz; C_{meta}), 125.8, 121.9 and 120.7 (C3A, C7A, C5, C6, C4 and C7), 112.1 (C2), 87.9 (C1 and C3), 0.5 ($SiMe_3$), –24.4 (d, $^2J_{P–C}$ = 28 Hz; Ni–CH_3). ^{31}P{H^1} NMR (C_6D_6): 44.0 (s). Anal. calcd. for $C_{34}H_{41}Ni_1P_1Si_2$: C, 68.57; H, 6.94. Found: C, 67.94; H, 7.13.

{1,3-($SiMe_3$)$_2$-Ind}NiPMe_3Cl (3)

A THF solution (100 mL) of Li[1,3-($SiMe_3$)$_2$-Ind] (0.611 g, 2.29 mmol) was added dropwise to a stirring solution of Ni(PMe_3)$_2$Cl$_2$ (0.646 g, 2.29 mmol, in 30 mL of THF) at room temperature. The reaction vessel was placed under vacuum for 30 s at regular intervals (following the addition of each 15 mL aliquot of the Li[1,3-($SiMe_3$)$_2$-Ind] solution) to remove the free PMe_3 released from the reaction (inefficient removal of PMe_3 results in the decomposition of the product and the formation of side-products such as Ni(PMe_3)$_4$). The reaction mixture was stirred for 10 min after the addition was complete, then the solvent was removed under vacuum, and the resulting residue was extracted with hexane (~15 mL). The extracts were concentrated to about 3 mL and allowed to stand at room temperature, which gave red crystals that were covered with a viscous oil (0.457 g, 51% crude yield). Repeated attempts to purify this product were not successful due to the high solubility of the desired product and the main impurity (Ni(PMe_3)$_4$).

^{1}H NMR (C_6D_6): 7.02–6.91 (m; H4, H5, H6 and H7), 6.72 (s; H2), 0.83 (d, $^2J_{P–H}$ = 9.0 Hz; P–CH_3), 0.33 (s; Si(CH_3)$_3$). ^{13}C{H^1} NMR (C_6D_6): 134.4, 125.8 and 120.1 (C3A, C7A, C5, C6, C4 and C7), 116.0 (C2), 86.0 (C1 and C3), 15.3 (d, $^1J_{P–C}$ = 28 Hz; P–CH_3), 0.4 (Si(CH_3)$_3$). ^{31}P{H^1} NMR (C_6D_6): –18.1 (s).

(1-$SiMe_3$-Ind)Ni(PMe_3)Me (4)

A THF solution (30 mL) of Li[1-($SiMe_3$)Ind] (0.232 g, 1.19 mmol) was added dropwise to a stirring THF (30 mL) solution of Ni(PMe_3)$_2$MeCl (0.297 g, 1.13 mmol) at RT. The reaction vessel was placed under vacuum for 30 s at regular intervals (following the addition of each ~7 mL aliquot of the Li[1-($SiMe_3$)Ind] solution) to remove the free PMe_3 released from the reaction (inefficient removal of PMe_3 results in the decomposition of the product and the formation of side-products such as Ni(PMe_3)$_4$). The reaction mixture was stirred for 10 min after the addition was complete, the solvent was removed under vacuum, and the residue was extracted with 20 mL hexane. The solution was concentrated to about 5 mL and cooled to –78 °C to yield a dark red solid (0.332 g, 87% yield).

^{1}H NMR (C_6D_6): 7.51 (d, $^3J_{H–H}$= 7.6 Hz; H4 or H7), 7.14–7.12 (m; aromatic protons of Ind), 7.04 (t, $^3J_{H–H}$ = 7.0 Hz; H5 or H6), 6.27 (bs; H2), 4.62 (b s; H3), 0.60 (d, $^2J_{P–H}$ = 9.1 Hz; P–CH_3), 0.50 (s; Si(CH_3)$_3$), –0.64 (d, $^3J_{P–H}$ = 6.4 Hz; Ni–CH_3). ^{13}C{H^1} NMR (C_6D_6): 126.6, 125.4, 123.1, 122.0, 119.6 and 117.4 (C3A, C7A, C5, C6, C4 and C7), 106.6 (C2), 81.7 (d, $^2J_{C–P}$ = 11 Hz; C1), 76.9 (C3), 16.5 (d, $^1J_{P–C}$ = 28 Hz; P–CH_3), 0.6 ($SiMe_3$), –28.4 (d, $^2J_{P–C}$ = 28 Hz; Ni–CH_3). ^{31}P{H^1} NMR (C_6D_6): –3.5 (s). Anal. calcd. for $C_{16}H_{27}Ni_1P_1Si_1$: C, 57.00; H, 8.07. Found: C, 57.37; H, 8.06.

{1,3-($SiMe_3$)$_2$-Ind}Ni(PMe_3)Me (5)

The procedure used for preparation of complex **4** was used here with Li[1,3-($SiMe_3$)$_2$-Ind] (0.351 g, 1.32 mmol) and Ni(PMe_3)$_2$MeCl (0.328 g, 1.25 mmol). The reaction

© 2008 NRC Canada

mixture was stirred for 10 min after the addition was complete, and then the solvent was removed under vacuum. Recrystallization attempts were unsuccessful because products are highly soluble in non polar solvents such as toluene and hexane. The residue was sublimated at 85–95 °C at 3 Torr (1 Torr = 101 325/760 Pa), and the initially obtained oily solid ((Ni(PMe_3)$_4$)) was cleaned and the sublimation restarted to collect the target product as a dark brown solid (0.301 g, 64% yield).

^{1}H NMR (C_6D_6): 7.45–7.43 and 6.99–6.96 (m; aromatic protons of Ind), 6.13 (s; H2), 0.64 (d, $^2J_{P-H}$ = 9.2 Hz; P–CH_3), 0.42 (s; Si(CH_3)$_3$), –0.71 (d, $^3J_{P-H}$ = 7.2 Hz; Ni–CH_3). ^{13}C{^{1}H} NMR (C_6D_6): 126.4, 122.2 and 121.4 (C3A, C7A, C5, C6, C4 and C7), 111.2 (C2), 87.1 (C1 and C3), 16.3 (d, $^1J_{P-C}$ = 29; P–CH_3), 1.2 ($SiMe_3$), –29.6 (d, $^2J_{P-C}$ = 31 Hz; Ni–CH_3). ^{31}P{^{1}H} NMR (C_6D_6): –8.6 (s). Anal. calcd. for $C_{19}H_{35}Ni_1P_1Si_2$: C, 55.75; H, 8.62. Found: C, 53.83; H, 8.85.

(1-*i*-Pr-Ind)Ni(PMe_3)Me (6)

The procedure used for preparation of complex **4** was used here with Li[1-*i*-Pr-Ind] (0.214 g, 1.30 mmol) and Ni(PMe_3)$_2$MeCl (0.310 g, 1.18 mmol) to give the target complex as a dark red solid (0.277 g, 77% yield).

^{1}H NMR (C_6D_6): 7.21–7.00 (m; aromatic protons of Ind), 6.15 (b s, H2), 4.44 (b s; H3), 2.87 (septet, $^3J_{H-H}$ = 6.8 Hz; C*H*Me_2), 1.39 and 1.35 (d, $^3J_{H-H}$ = 6.8 Hz, CH(CH_3)$_2$), 0.65 (d, $^2J_{P-H}$ = 9.0 Hz; P–CH_3), –0.77 (d, $^3J_{P-H}$ = 6.4 Hz; Ni–CH_3). ^{13}C{^{1}H} NMR (C_6D_6): 122.4, 122.1, 121.5, 120.2, 116.8 and 116.8 (C3A, C7A, C5, C6, C4 and C7), 100.8 (d, $^2J_{C-P}$ = 12 Hz; C1), 97.3 (C2), 70.2 (C3), 25.3 (*i*Pr–CH), 23.8 (*i*Pr–CH_3), 21.1 (*i*Pr–CH_3), 16.5 (d, $^1J_{P-C}$ = 28 Hz; P–CH_3), –22.2 (d, $^2J_{P-C}$ = 25 Hz; Ni–CH_3). ^{31}P{^{1}H} NMR (C_6D_6): –4.0 (s). Anal. calcd. for $C_{16}H_{25}Ni_1P_1$: C, 62.59; H, 8.21. Found: C, 61.93; H, 8.20.

General procedure for catalytic runs

The catalytic runs were carried out by stirring the substrates and the Ni precursors in benzene (hydrosilylations) or toluene (dehydrogenative oligomerizations) at the specified temperatures. The characterization of the products and yield determinations were done on the basis of NMR and GC–MS, as described in our previous report (12).

X-ray crystallographic studies

Crystals suitable for X-ray diffraction studies were obtained by recrystallization of the purified solids (for **2** and **4**) or crude material (for **3**) from hexane solutions. The crystallographic data were collected on a Bruker AXS SMART 2K diffractometer with graphite-monochromated Cu Kα radiation (λ = 1.54178 Å) at 220(2) K, using SMART (20). Cell refinement and data reduction were done using SAINT (21). A SADABS (22) absorption correction was applied. The structures were solved by direct methods using SHELXS97 (23) and difmap synthesis using SHELXL97 (24); the refinements were done on F^2 by full-matrix least squares. The PPh_3 and Cl groups in **2** are disordered. Details of data collection and refinement are listed in Table 1, while a selection of structural parameters is listed in Table 2. Complete crystallographic data for these structures are included in the Supplementary data.[4]

13. For instance, the addition of $PhSiH_3$ to styrene catalyzed by IndNi(PPh_3)Cl in the absence of any activator/initiator gives yields of 7% (1-Me-Ind), 56% (1-$SiMe_3$-Ind), and 82% (1,3-($SiMe_3$)$_2$-Ind) (see ref. 12). It is important to emphasize, however, that for reactions run in the presence of initiators/activators, the steric bulk has little or no favourable influence on the reactivities unless the Ind ligand is substituted at both 1- and 3-positions. For instance, the addition of $PhSiH_3$ to styrene catalyzed by the combination of (1-R-Ind)Ni(PPh_3)Cl and $NaBPh_4$ is no more effective with R = *i*-Pr (61%) than Me (69%) (see ref. 7). This can be understood by recalling that the complexes (1-R-Ind)Ni(PPh_3)X always adopt a configuration that places the PPh_3 ligand away from the more bulky Ind substituent to avoid steric congestion (see ref. 1); hence, placing a substituent at the 1-position has no advantage for increasing the lability of the phosphine ligand or the catalytic activities.

17. Ni–PR_3 interactions in IndNi(PR_3)X compounds can be understood in the following terms. Relatively soft X ligands like alkyls result in more effective interactions and shorter Ni–P bonds, whereas harder X ligands such as halides give less effective and longer Ni–P bonds. An alternative explanation for the less effective Ni–X bonds is in terms of cis-labilizing interactions between the occupied d_{z2} orbital on Ni and the lone pair of electrons on ligands X (halide, OR, NR_2, and so forth).
18. It should be added that the Ni–Cl precursors form much more efficient catalysts when used in conjunction with cationic initiators such as $NaBPh_4$ (12).

Approaches to alkane functionalization with Tp′Pt and (nacnac)Pt reagents[1]

Nathan M. West and Joseph L. Templeton

Abstract: In this perspective article we give an overview of our studies of C–H activation with platinum over the past decade. The scorpionate ligand Tp′ (Tp′ = hydrotris(3,5-dimethylpyrazolyl)borate) has exhibited the ability to stabilize both Pt(IV) and Pt(II) complexes due to flexibility between κ^3 and κ^2 binding modes. Control of the Tp′ coordination mode and Pt oxidation state is tightly coupled with acid/base chemistry. This ability allowed us to model a spectrum of intermediates in C–H activation reactions, including Pt(IV) alkyl hydrides, five-coordinate Pt(IV) silyl hydrides, and Pt(II) benzene complexes. We have been able to observe sturdy Pt(II) benzene complexes and probe their equilibria with the respective C–H activated Pt(IV) species in the presence of an added ligand. We have also taken steps toward functionalizing hydrocarbons with Tp′Pt by dehydrogenation of alkanes and by arylation of olefins. We have recently turned to bidentate nacnac (nacnac = N-phenyl-β-enamineimine) ligands in the hopes of catalytically functionalizing hydrocarbons.

Key words: C–H activation, reductive elimination, Tp′Pt, five-coordinate, β-diiminate.

Résumé : Dans cet article de perspective, on donne une vue d'ensemble de nos études sur l'activation des liaisons C–H par le platine qui ont été réalisées sur une période de quarante ans. Le ligand scorpionate, Tp′ (Tp′ = hydroxytris(3,5-diméthylpyrazolyl)borate a montré une habilité à stabilizer les complexes tant du Pt(IV) que ceux du Pt(II) en raison de la flexibilité entre les modes de fixation κ^3 et κ^2. Le contrôle du mode de coordination du Tp′ et l'état d'oxydation du platine sont fortement couplés avec la chimie acide/base. Cette habilité nous a permis de faire un modèle des spectres d'intermédiaires dans les réactions d'activation d'une liaison C–H, dont les hydrures d'alkyle-platine(IV), d'hydrures pentacoordinés de silyle-platine(IV) et de complexes Pt(II)-benzène. Il a été possible d'observer les complexes solides de Pt(II)-benzène et d'étudier leurs équilibres avec les espèces respectives de liaisons C–H activées par le platine(IV), en présence d'un ligand ajouté. On a aussi tenter de fonctionnaliser des hydrocarbures à l'aide du Tp′Pt en procédant à la déshydrogénation d'alcanes et l'arylation d'oléfines. Dans le but de fonctionnaliser des hydrocarbures d'une façon catalytique, on s'est récemment tourner vers les ligands bidentates nacnac (nacnac = *N*-phényl-β-énamineinimine).

Mots-clés : activation de liaisons C–H, élimination réductrice, Tp′Ph, pentacoordination, β-diiminate.

Introduction

Platinum-catalyzed C–H functionalization

Selective oxidation of alkanes has been an important goal for decades. This challenging reaction continues to attract widespread attention as fossil fuels are consumed and the price of energy soars (1). Even as fossil fuel supplies are depleted, alkanes from petroleum, particularly natural gas, remain abundant (1–4). Alkanes have high C–C and C–H bond strengths and are relatively inert (3, 5, 6). Dehydrogenation of alkanes can be accomplished thermally, but only at high temperatures (5). Radical oxidation reactions are capable of alkane functionalization, but they are not regioselective; furthermore, the partially oxidized products have weaker C–H bonds than the starting alkane, so they are poised to undergo overoxidation (7, 8).

Because of the expense required to capture, transport, and store gases, methane, the primary component of natural gas, is not being fully exploited as a fuel source. Low cost direct conversion of methane to a liquid fuel would allow its use as an alternative to traditional fossil fuels. The chemical reactivity limitations of alkanes have prevented industrial syntheses of methanol directly from methane; it is currently formed from syngas (H_2/CO). Organometallic reagents have demonstrated the ability to selectively activate and oxidize the C–H bonds of alkanes without overoxidation; further development of these catalysts may allow for the selective functionalization of alkanes under mild conditions (2, 3, 5–7, 9–18).

One of the first examples of alkane functionalization was Shilov and co-workers's report (18) of the oxidation of

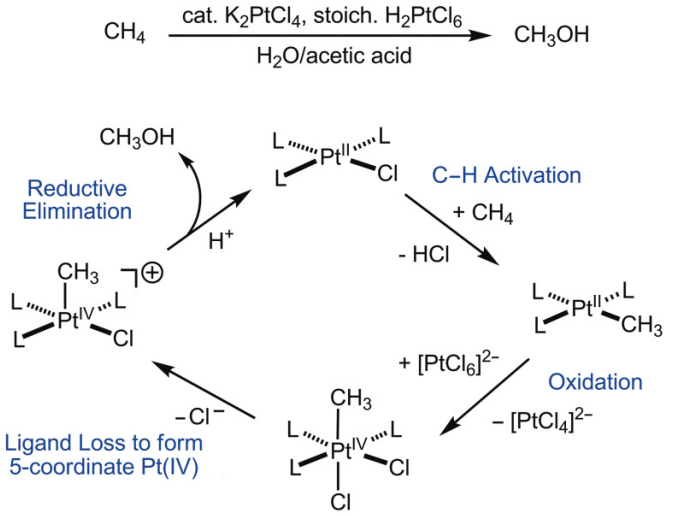
Scheme 1. Shilov oxidation of methane to methanol.



methane to methanol catalyzed by Pt(II) (Scheme 1). Good selectivity for methane activation was observed and many research groups have since focused on studying d^8 metal reagents for alkane functionalization. Recent successes have intensified research efforts directed toward methane oxidation catalysts based on platinum (16).

The Shilov system is impractical due to the stoichiometric consumption of Pt(IV) as the oxidant. There have been significant improvements in utilizing cheaper oxidants, but no industrially feasible process for converting methane to methanol has been discovered. The most successful methane oxidation system reported to date is a bipyrimidine ligated Pt(II) catalyst used in fuming sulfuric acid (Scheme 2), which gives high yields of the methanol surrogate $MeOSO_3H$. Economic factors and harsh reaction conditions, however, have prevented it from being utilized industrially (16). Despite considerable strides, there continues to be a need to study the activation and functionalization of alkanes in the hope of developing a catalyst for selective alkane oxidation (5, 19).

The mechanism of the Shilov oxidation, studied extensively by Bercaw and Labinger (5), is proposed to proceed by three key steps: oxidative addition of the C–H bond to Pt(II) followed by loss of a proton, oxidation of a Pt(II)Me species to a Pt(IV)Me intermediate, and reductive elimination of C–X (X = OH, Cl) (8). Reactive five-coordinate species are proposed as key intermediates formed from C–H activation and leading to C–X bond formation, respectively. An array of bidentate nitrogen ligands has been used to stabilize Pt(II) intermediates relevant to the Shilov oxidation. Monomethyl Pt(II) species, like the one involved in the catalytic oxidation, can often be formed by protonation of a dimethyl Pt precursor since methane loss results in many cases. If D^+ is used rather than H^+ then scrambling of the deuterium into the remaining Pt bound methyl group occurs, indicating that reductive elimination and oxidative addition of CH_4 are reversible and a σ-methane adduct must be involved (Scheme 3) (20, 21).

Isolation of five-coordinate intermediates involved in C–H activation, particularly alkyl hydrides, has proven challenging due to their propensity to undergo reductive elimination

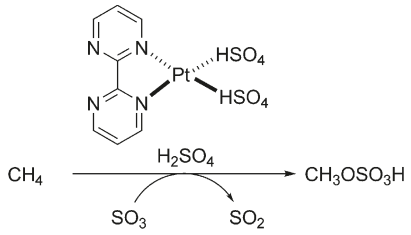
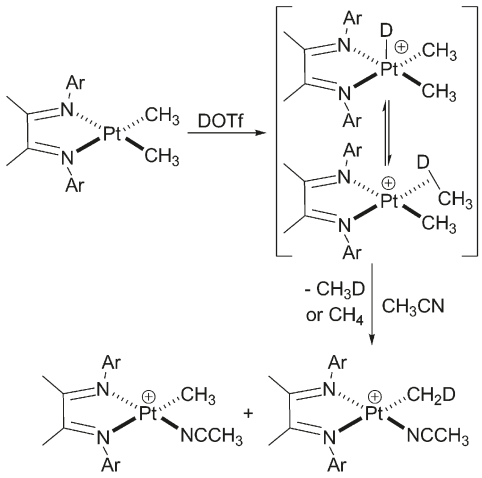


Scheme 3. Modeling Pt(II) intermediates with α-diimine ligands.



(22, 23). To access these Pt(IV) species we have employed scorpionate tris(pyrazolyl)borate ligands. These ligands are capable of binding in a κ^2 fashion in Pt(II) square-planar compounds, but they can coordinate in a κ^3 fashion to stabilize Pt(IV) octahedral complexes after oxidative addition of Pt(II).

Discussion

Accessing models of reactive Pt(IV) intermediates via reactions of Tp′PtMe$_2$H

The Pt(II) precursors [K][TpPtMe$_2$] Tp (Tp = hydridotris(pyrazolyl)borate) and [K][Tp′PtMe$_2$] Tp′ (Tp′ = hydridotris(3,5-dimethylpyrazolyl)borate) can be protonated with weak acids to form a five-coordinate dialkylhydride, which is immediately trapped by the third arm of the pyrazolyl borate ligand before elimination of methane can occur. The results of these reactions were the first thermally stable Pt(IV) complexes with cis alkyl hydride ligands, TpPtMe$_2$H and Tp′PtMe$_2$H; the latter was structurally characterized (24, 25). Wick and Goldberg (26) reported that addition of the Lewis acid $B(C_6F_5)_3$ to the anionic dimethyl Pt(II) precursor [K][Tp′PtMe$_2$] results in methide abstraction to form the Tp′PtMe fragment and then C–H activation of alkane solvent forms stable Pt(IV) alkyl hydride complexes (Scheme 4). Other tridentate nitrogen donor ligands have also demonstrated the ability to stabilize Pt(IV) species by inhibiting the formation of five-coordinate species (27–31). Early Tp′Pt chemistry was reviewed in Activation and functionalization of C–H bonds (32).

Thermolysis of Tp′PtMe$_2$H in arene solvent resulted in loss of methane at temperatures above 100 °C. Methane loss

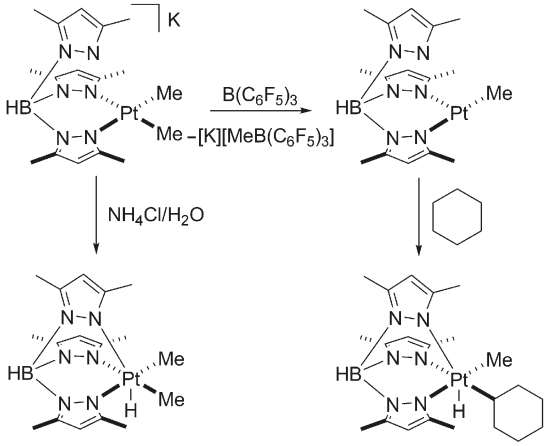
Scheme 4. Stabilization of Pt(IV) alkyl hydrides with Tp′.

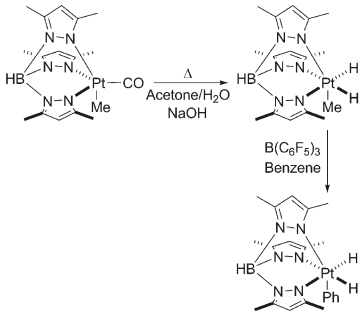


is followed by arene C–H activation, and formation of an aryl alkyl hydride Pt(IV) complex results. This complex then loses a second equivalent of methane to ultimately produce a diaryl hydride complex as the final product (33). The high temperatures required for reductive elimination reflect the stability of the six-coordinate Pt(IV) complex that is anchored by the tridentate Tp′ ligand. The thermodynamic parameters for elimination of the first equivalent of methane are $\Delta H^{\ddagger} = 35.0 \pm 1.1$ kcal/mol and $\Delta S^{\ddagger} = 13 \pm 3$ cal/mol deg (34). If the complex is thermolyzed in deuterated benzene, a mixture of methane isotopologs is observed. The first equivalent of methane eliminated is CH_4, but the second equivalent is a mixture of CH_3D, CH_2D_2, and CHD_3 (CD_4 may be present but it is invisible by ^{1}H NMR). If reductive coupling of methane were irreversible only CH_3D would be observed; the presence of methane isotopologs indicates that reductive coupling of methane to form a sigma Pt(CH_4) complex is reversible. This reductive coupling within the coordination sphere was examined by thermolysis of Tp′PtMe$_2$D at temperatures well below 100 °C, and Tp′PtMe(CH_2D)H was formed with no loss of methane. The thermodynamic parameters for this process are $\Delta H^{\ddagger} = 26 \pm 1$ kcal/mol and $\Delta S^{\ddagger} = 1 \pm 4$ cal/mol deg. The significantly lower barrier to reductive coupling to form methane than for elimination of methane indicates that it is dissociation of methane that is rate limiting; the activation entropy values also support this.

Reductive elimination of methane from Tp′PtMe$_2$H via protonation

Addition of strong acid to Tp′PtMe$_2$H resulted in protonation and dechelation of one of the Tp′ arms from the platinum center. The resulting five-coordinate complex reductively eliminates methane, even at –78 °C, and forms [(Hpz*)HB(pz*)$_2$Pt(Me)(solv)]$^+$, which binds a variety of trapping ligands (35). This low temperature pathway to reductive elimination of methane provided a useful alternative to high temperature thermolysis for the synthesis of Pt(II) products. The protonated Tp′ ligand is ineffective at stabilizing Pt(IV) alkyl hydride complexes, so the Tp′ ligand combines with acid/base chemistry to model both Pt(IV) and Pt(II) intermediates in the Shilov oxidation. Addition of D$^+$ to the dimethyl hydride complex resulted in no deuterium incorporation into either the Pt methyl groups or the evolved methane, so protonation of the Pt–N bond at nitrogen is the only detectable process. Note that protonation of Tp′PtMe$_2$D resulted in the loss of both CH_3D and CH_4 along with scrambling of deuterium into the remaining Pt methyl group. With one Tp′ arm protonated, reductive coupling to form methane is rapid and reversible and precedes methane elimination. Here, too, a sturdy sigma adduct of methane forms as an intermediate after reductive coupling builds the C–H link.

Scheme 5. Nucleophilic attack of the CO ligand in Tp′PtMeCO.



Moving from Tp′PtMe$_2$H to Tp′PtMeH$_2$ (36) and from Tp′PtMeH$_2$ to Tp′PtH$_3$ (37, 38) was accomplished by heating Tp′Pt(R)CO (R = Me, H) in acetone and water in the presence of base (Scheme 5). Haskel and Keinan (39) first reported a similar procedure for converting TpPtMeCO to TpPtMeH$_2$. Our modified procedure included the addition of a base, which increased the reaction rate. Presumably, the CO ligand is attacked by hydroxide and then elimination of CO_2 reduces the metal and allows for protonation by water. This reaction represents one half of the water-gas shift reaction, which interconverts H_2O and CO with H_2 and CO_2, respectively. Hydrogen formation from the Pt(IV) dihydride complex would complete the water-gas shift cycle.

The methyl dihydride species Tp′PtMeH$_2$ can be converted into an aryl dihydride Tp′PtArH$_2$ by gentle heating with $B(C_6F_5)_3$ in arene solvent (33). Methane loss and arene C–H activation occur yielding the desired compound.

Reversible C–H activation of a coordinated benzene complex

We have used thermolysis experiments to study C–H activation of benzene at high temperatures, but protonation makes it possible to observe arene C–H activation at low temperatures. Protonation of Tp′Pt(Ph)(H)$_2$ at low temperatures leads to reductive elimination of benzene, but below –30 °C the benzene remained in the inner coordination sphere in an η^2 fashion as evident in the crystal structure of [κ^2-HTp′Pt(H)(C_6H_6)][BAr′$_4$] (40, 41). Such η^2-coordinated benzene complexes had been previously observed by NMR (42). They bear some similarities to the elusive coordinated alkane adducts that precede alkane C–H activation. These η^2-benzene complexes undergo rapid and reversible C–H activation to form an unobserved five-coordinate Pt(IV) phenyl dihydride intermediate. The equilibrium lies far toward the Pt(II) benzene complex on the left, but activation of the C–H bonds was confirmed by spin-saturation transfer experiments in the ^{1}H NMR that showed exchange between the platinum hydride and the benzene protons (Scheme 6).

Five-coordinate Pt(IV) complexes are proposed as intermediates in most Pt(II)/Pt(IV) oxidative addition/reductive

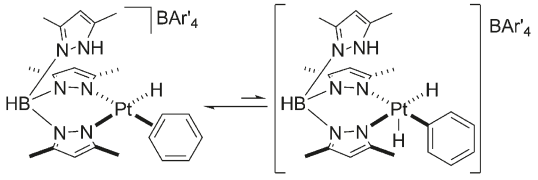
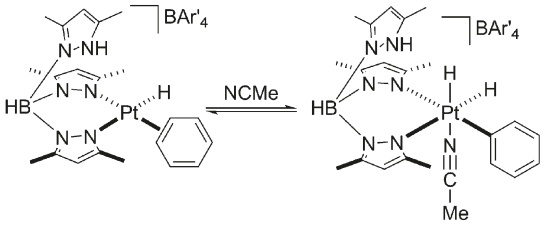
Scheme 6. Reversible C–H activation of a coordinated benzene molecule.



Scheme 7. Trapping of a five-coordinate phenyl dihydride intermediate with CH_3CN.



elimination processes, but only a handful of five-coordinate Pt(IV) complexes have been either directly observed or isolated (43). While we could not directly observe the five-coordinate species formed from C–H activation of benzene, we have spectroscopic and chemical reactivity evidence to support its existence. Several isolated examples of five-coordinate Pt(IV) complexes contain the $PtMe_3$ fragment (44–48); one is built around a (N-N)$Pt(SiMe_3)Me_2$ framework (49) and another is formulated as [κ^2-HTp′$Pt(H)_2(SiR_3)$][BAr′4] (50). Of these five-coordinate Pt(IV) complexes, the only one formed by bond activation is the latter complex, which was formed by oxidative addition of the Si–H bond in $HSiR_3$ to Pt(II) in [κ^2-HTp′Pt(H)(solv)][BAr'_4].

The barrier to arene C–H activation was determined by line broadening measurements on the platinum hydride signal and was found to have a $\Delta G^{\ddagger}$ of 12.7 kcal/mol at 241 K with $\Delta H^{\ddagger}$ = 11.7 ± 0.5 cal/mol deg and $\Delta S^{\ddagger}$ = –3.8 ± 2 cal/mol deg. The phenyl benzene complex [κ^2-HTp′Pt(Ph)(C_6H_6)][BAr'_4] had a $\Delta G^{\ddagger}$ of 12.9 kcal/mol at 241 K, while the deuterated version, [κ^2-HTp′Pt(C_6D_5)(C_6D_6)][BAr'_4], had a $\Delta G^{\ddagger}$ of 13.6 kcal/mol at 241 K.

It is important to note that addition of excess benzene to a solution of [κ^2-HTp′Pt(H)(C_6H_6)][BAr'_4] did not result in the exchange of free and coordinated benzene; alkenes, on the other hand, easily displace the benzene (vida infra). Furthermore, formation of [κ^2-HTp′Pt(H)(solv)][BAr′4] via protonation of Tp′$PtMeH_2$ in the presence of benzene did not result in the formation of a Pt-benzene adduct. The kinetic reluctance of benzene to trap the putative [κ^2-HTp′Pt(H)(solv)]$^+$ cation is almost certainly due to the energetic cost of breaking the aromaticity of benzene to coordinate it to the metal. Aromaticity also helps explain the low barrier to C–H activation because the phenyl group regains its aromaticity during conversion from η^2 to being σ-bound to the metal.

Given the stability of the benzene hydride complex at low temperatures we hypothesized that the addition of a weak ligand might allow us to trap the proposed five-coordinate Pt(IV) phenyl dihydride, but not displace the coordinated benzene. Upon addition of acetonitrile to [κ^2-HTp′Pt(H)(C_6H_6)][BAr'_4] below –30 °C we observed a mixture of the six-coordinate Pt(IV) phenyl dihydride nitrile adduct [κ^2-HTp′$Pt(H)_2$(Ph)($NCCH_3$)][BAr′4], in which the two hydrides were inequivalent, and the four-coordinate [κ^2-HTp′Pt(H)(C_6H_6)][BAr'_4] (51). In the dihydride complex, one hydride resided trans to acetonitrile and one was trans to a pyrazolyl nitrogen. The hydride trans to the acetonitrile resonated at –23.4 ppm and had a $^1J_{Pt\text{-}H}$ value of 1525 Hz, whereas the other hydride resonated at –19.4 ppm and had $^1J_{Pt\text{-}H}$ equal to 1279 Hz; the large coupling constant of the hydride at –23.4 indicated that the acetonitrile was weakly bound.

Thus, the nitrile trapping result substantiated the existence of the unobserved five-coordinate intermediate. The two compounds, square planar Pt(II) and octahedral Pt(IV), are in dynamic equilibrium and the six-coordinate acetonitrile product is favored by only 0.3 kcal/mol at 230 K (Scheme 7). Not surprisingly, as the nucleophilicity of the nitrile is increased the equilibrium shifts towards the six-coordinate species; at 201 K the K_{eq} value for *p*-OMe benzonitrile is 17.0 compared to 0.54 for *p*-CF_3 benzonitrile. For CH_3CN, *p*-OMe benzonitrile, and *p*-CF_3 benzonitrile ΔH° values of –5.9, –5.0, and –4.0 kcal/mol were determined, respectively, indicating that the more electron rich alkyl nitriles favor Pt(IV) more than the aryl nitriles. This result couples with ΔS° values near –20 cal/mol deg to indicate that nitrile coordination to the metal is the key element that determines the equilibrium constant.

Trapping of five-coordinate alkyl dihydride and trihydride species with added ligand

We have used similar trapping methods to study five-coordinate intermediates involved in reductive elimination of methane. Protonation of the methyl dihydride complex at a low temperature followed by addition of acetonitrile resulted in trapping to form an observable six-coordinate Pt(IV) dihydride species, [κ^2-HTp′$Pt(H)_2$(Me)(NCMe)][BAr'_4] (38). As in the benzene case, the two hydrides were inequivalent with one trans to the nitrile and one trans to a pyrazolyl nitrogen. One hydride appeared at –24.0 ppm with a $^1J_{Pt\text{-}H}$ of 1496 Hz and the other at –20.7 ppm with a $^1J_{Pt\text{-}H}$ of 1265 Hz; these values are similar to those of the trapped phenyl dihydride species. This product was the only one formed, and while it may be in equilibrium with a σ methane adduct, we did not observe such a species (Scheme 8).

Once again, trapping with nitrile supplied evidence for the intermediacy of a five-coordinate species involved in C–H activation. Methane elimination occurred to form [κ^2-HTp′Pt(H)(NCMe)][BAr'_4] when the six-coordinate Pt(IV) methyl dihydride acetonitrile adduct was allowed to reach temperatures above –30 °C. Assuming that nitrile loss is essential for reductive coupling to form the C–H bond of methane from a five-coordinate species, the σ-methane ligand is not easily displaced by the trapping the acetonitrile ligand at low temperatures. Note that we observed no elimination of dihydrogen; this was also true when Tp′$PtMeH_2$ was protonated without added trapping ligand.

One of our goals has been to study reductive elimination, or lack thereof, of hydrogen from the Tp′Pt(IV) system in hopes of learning why we do not observe H_2 loss from

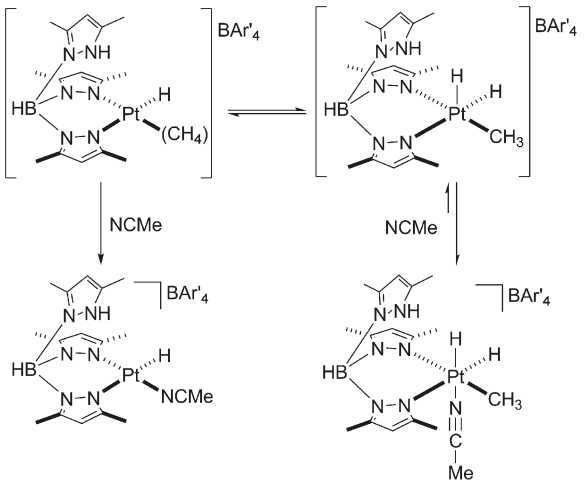
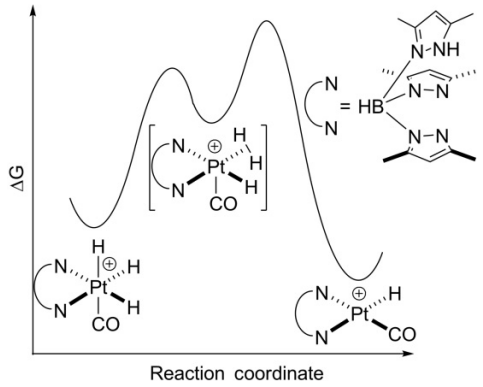
Scheme 8. Trapping of a five-coordinate methyl dihydride intermediate with CH_3CN.



Tp′Pt(R)$(H)_2$ (R = Me, Ph). To stack the deck in favor of H_2 elimination we began by studying the trihydride, Tp′PtH_3, because it has no alkane option for reductive elimination. Protonation of the trihydride complex with $[H(OEt_2)_2][BAr'_4]$ did not result in reductive elimination of H_2; rather, it formed an unidentified species, which decomposes to regenerate starting material and Pt black. In an attempt to identify the unidentified species, we added acetonitrile as a trapping reagent as we had done in the other low temperature reductive elimination studies. Once again the trapping ligand worked beautifully, and the result was a quantitative formation of $[\kappa^2$-HTp′Pt$(H)_3$(NCMe)$][BAr'_4]$. The compound displayed one unique and two equivalent hydrides by ^{1}H NMR, with chemical shifts of –24.1 ppm for the unique hydride and –20.0 ppm for the two equivalent hydrides. Warming the complex did not result in reductive elimination of hydrogen; only starting material was detected.

Different results were obtained when CO was used as the trapping ligand in place of acetonitrile. The CO coordinated to the metal, forming the six-coordinate trihydride $[\kappa^2$-HTp′Pt$(H)_3$(CO)$][BAr'_4]$ just as the nitrile did, but now upon warming, reductive elimination of hydrogen occured and the Pt(II) hydride product, $[\kappa^2$-HTp′Pt(H)(CO)$][BAr'_4]$, formed (Scheme 9). The six-coordinate precursor species displayed one hydride signal at –12.3 ppm with a $^1J_{Pt\text{-}H}$ of 1126 Hz and two equivalent hydrides appeared at –17.5 ppm with a $^1J_{Pt\text{-}H}$ of 1114 Hz. The downfield of the unique hydride trans to CO indicated that it resided trans to a strong π-acid ligand. Kinetic measurements of the H_2 elimination yielded thermodynamic parameters of $\Delta H^{\ddagger}$ = 23.0 (1.0) kcal/mol and $\Delta S^{\ddagger}$ = 24.5 (4.0) cal/mol deg. The positive entropy and the exclusion of other possible mechanisms lead us to believe that H_2 reductive elimination occurs directly from the six-coordinate trihydride carbonyl complex and that *dissociation* of H_2 is rate limiting. Thermal reductive elimination of methane from Tp′$PtMe_2H$ proceeds with rate-limiting dissociation as well. This hydrogen forming reaction is a rare example of reductive elimination from a six-coordinate Pt(IV) species; reductive elimination typically occurs from a five-coordinate Pt(IV) species (52). We believe the strong π-acid properties of the CO ligand promote hydrogen formation.

Scheme 9. Possible reaction coordinate for carbon monoxide promoted hydrogen elimination from $[HTp'PtH_3]^+$.



The nitrile adduct is presumably too electron rich to support formation and elimination of H_2.

Re-examination of the protonation and trapping of Tp′$PtMeH_2$ using CO instead of acetonitrile yielded different results. When CO was used, both methane and hydrogen were eliminated. The ratio of methane loss to hydrogen loss was about 5:1. While methane loss still dominates, this result further supports the claim that H_2 elimination is favored by the π-acid character of the CO ligand. An attractive hypothesis is that H_2 loss can occur from a saturated six-coordinate intermediate, while reversible CO binding allows methane to be eliminated from an unsaturated five-coordinate intermediate.

Olefin insertion into the Pt-phenyl bond of Tp′PtPh(olefin)

While mechanistic studies of C–H activation are essential for intelligent design of future catalysts, the C–X (X = C, heteroatom) bond formation required for functionalizing molecules often proves even more challenging. To this end we were eager to explore C–C bond forming reactions for hydrocarbon functionalization. We decided to probe olefin insertion reactions as a means to form new C–C bonds.

Low temperature protonation/deprotonation has been used to synthesize Tp′Pt(ethylene)(Ph) complexes starting from the diphenyl hydride reagent, Tp′$PtPh_2H$. An X-ray crystal structure of the ethylene phenyl complex was obtained, and as anticipated in view of the π-acidity of ethylene, the Tp′ ligand was found to be coordinated in a κ^3 manner (53). The three Pt–N bond distances are 2.14, 2.17, and 2.22 Å and the ethylene is oriented orthogonal to the Pt–C phenyl bond. The ethylene C=C double bond has been lengthened to 1.43 Å due to back-bonding into the π* orbital from the metal. All of these features indicate that formulating the complex as a Pt(IV) octahedral compound with a metallacyclopropane ring is useful even though the classic Pt(II) olefin formulation is of course a legitimate description, too.

Heating this complex resulted in insertion of ethylene into the Pt–Ph bond, and this was quickly followed by oxidative addition of an ortho C–H bond on the phenyl ring to yield the observed product, a Pt(IV) metallacycle hydride complex (Scheme 10). The reaction was promoted at room temperature by the addition of the Lewis acid $B(C_6F_5)_3$, which facili-

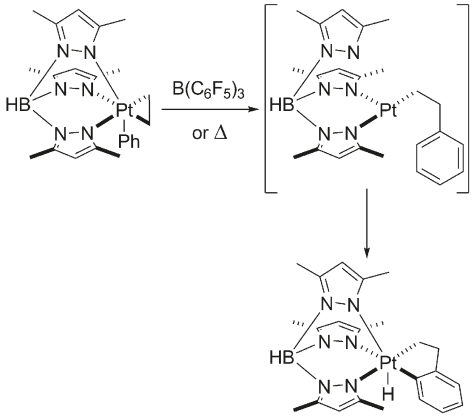
Scheme 10. Metallacycle formation by ethylene insertion into the Pt–Ph bond.

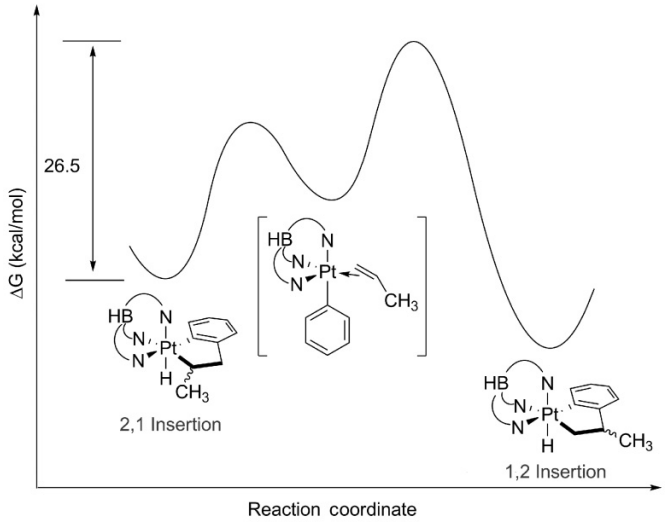


tates dechelation of one Tp′ arm. This indicated that removal of one Tp′ arm to form a five-coordinate intermediate was essential to the insertion process. The crystal structure of the ethylene complex shows it to be compatible with a Pt(IV) formulation, and this may be one way to rationalize the relative ease of insertion. Within the Pt(IV) formalism mentioned above, this net insertion reaction could be considered to be a reductive elimination forming a new C–C bond, and of course reductive eliminations from Pt(IV) often require formation of a five-coordinate intermediate to proceed. Within this Pt(IV) framework the generation of a five-coordinate intermediate and the ease of migration of the phenyl group to the adjacent methylene carbon are well precedented reactions.

The thermodynamic stability of these metallacycle compounds was further demonstrated by thermolytic C–H activation of ethyl benzene. Thermolysis of Tp′PtMe$_2$H with borane in ethyl benzene led to formation of the same metallacyclic product as the one formed from the insertion of ethylene into the Pt–Ph bond. The first step in the reaction with ethyl benzene is presumably reversible arene C–H activation, and once an ortho C–H bond is activated, the ethyl group is positioned for activation of a methyl C–H bond to yield the observed product. Even though activation at an ortho position is initially unfavorable because of steric interactions (21, 41, 54, 55), it eventually occurs. It then accounts for the final product because of the thermodynamic driving force favoring metallacycle formation.

When propylene was used as the coordinated olefin instead of ethylene, three platinum products were obtained: a 2,1 insertion product and both diastereomers of the 1,2 insertion product. Initially, the 2,1 product was obtained as the major product, but if the mixture of products was heated to 80 °C, isomerization eventually yielded the 1,2 insertion products as the major products. It is not surprising that the 2,1 (anti-Markovnikov) product is the kinetic product and the 1,2 (Markovnikov) product is the thermodynamic product, but it is surprising that interconversion of these isomers has a barrier of only 26.5 kcal/mol (Scheme 11). These low barriers to C–C coupling and C–C cleavage were encouraging signs that the complex may catalyze the hydroarylation of olefins, but the thermodynamic well associated with the

Scheme 11. Energy diagram for the interconversion of propylene insertion products.



ortho C–H activation product proved too great to overcome by addition of external arene, and catalysis did not occur.

Lewis acid assisted thermal C–H activation of alkanes

Thus far we have discussed three different ways in which Tp′Pt derivatives can oxidatively add and reductively eliminate C–H bonds: high temperature thermolysis of a Pt(IV) alkyl hydride, low temperature protonation of a Pt(IV) alkyl hydride, and direct generation of Tp′PtR from a Pt(II) precursor. Another method is a hybrid of the low and high temperature routes to C–H activation following elimination of methane from a Pt(IV) alkyl hydride. Reductive elimination and C–H activation starting from Tp′PtMe(R)H were catalyzed by the Lewis acid $B(C_6F_5)_3$. The Lewis acid works in the same manner as H^+ in that it promotes formation of a reactive five-coordinate species, which can eliminate methane. The difference is that the Lewis acid reversibly binds to a Tp′ arm (catalysis by trace H^+ cannot be ruled out). Following methane elimination, the Lewis acid can decoordinate from Tp′ to form the reactive Tp′Pt(R) (R = Me, H, Ar) fragment, which can activate C–H bonds of the solvent. Addition of the borane Lewis acid allowed C–H activation of alkane or arene solvents between 25 and 50 °C (33, 56), far milder conditions than the 110 °C temperature required for direct thermal activation of arenes (34). Stirring the borane reagent with Tp′Pt(Me)(H)$_2$ in arene solvent facilitated methane elimination and benzene C–H activation.

When high temperature thermolyses of Tp′PtMe$_2$H were performed in alkane solvents only Pt black was isolated, but small amounts of olefins were also observed in solution indicating that some C–H activation was occurring (34). Lewis acid catalyzed C–H activation can be accomplished with Tp′PtMe$_2$H under milder conditions, and this allowed isolation of Tp′Pt(η^2-olefin)(H) complexes from reaction with alkanes. These products form from oxidative addition of an alkane C–H bond to Tp′PtMe followed by reductive elimination of a second equivalent of methane to form Tp′Pt(alkyl). This Pt(II) alkyl fragment then undergoes β-H elimination to form the observed η^2-olefin hydride complexes. Monitoring

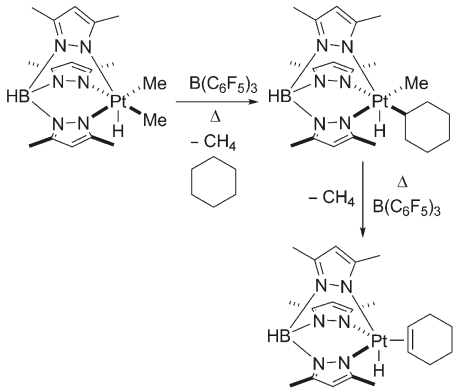
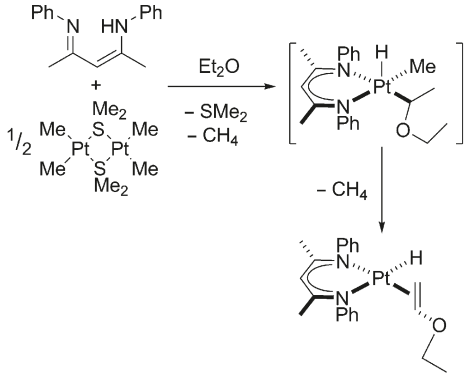


Scheme 13. Ether dehydrogenation by (nacnac)PtMe



the reactions by ^{1}H NMR allowed observation of the unsymmetrical intermediate, Tp′Pt(Me)(alkyl)(H), for which the hydride had a chemical shift and Pt coupling constant similar to the parent Tp′PtMe$_2$H values (Scheme 12).

Alkane dehydrogenation is one of the simplest ways to functionalize alkanes; the alkenes formed from dehydrogenation are far more useful reagents than the parent alkanes. Alkenes are heavily used in polymer synthesis, and numerous basic organic reactions are available for functionalization or oxidation of alkenes. In contrast, few selective reactions are available with alkane reagents. Recently, alkane dehydrogenation has been utilized as a key step in alkane metathesis as described by Goldman et al. (57). While alkane dehydrogenation has been successfully catalyzed with various Rh and Ir reagents (58–61), only a few examples of alkane dehydrogenation with Pt have been reported (45, 62–65), and only one platinum example is catalytic (66).

Activation of *n*-pentane by Tp′PtMe$_2$H/B(C$_6$F$_5$)$_3$ appeared to favor oxidative addition of primary C–H bonds, initially forming the intermediate Tp′Pt(Me)(*n*-pentyl)(H) (56). Elimination of the second equivalent of methane from this complex and subsequent β-H elimination would yield the 1-pentene isomer of the η^2-olefin hydride complex. Selective formation of this isomer is desirable in part because the internal olefin isomers are favored thermodynamically and thus it is difficult to isolate only the terminal isomer. In addition, only the terminal isomer can be used for copolymerization with other olefins. While the major product of pentane dehydrogenation was the 1-pentene isomer, the 2-pentene isomer slowly appeared (56). So the reaction appeared to be kinetically selective for the formation of 1-pentene, but the α-olefin isomerized to the internal olefin as the reaction continues. This is typical for transition metal mediated alkane dehydrogenation as these systems tend to favor primary C–H bond activation (67), but they also tend to catalyze alkene isomerization (68, 69).

The complex Tp′Pt(H)(neohexene) was tested for catalytic activity toward transfer dehydrogenation of alkanes in the presence of B(C$_6$F$_5$)$_3$. Neohexene was used as the hydrogen acceptor and cyclohexane as the alkane to be dehydrogenated. Stoichiometric dehydrogenation of both neohexane and cyclohexane by Tp′PtMe$_2$H/B(C$_6$F$_5$)$_3$ was facile. Displacement of neohexene from Tp′Pt(H)(neohexene) by cyclohexene occured, forming Tp′Pt(H)(cyclohexene). While individual steps required for transfer dehydrogenation proceed, no transfer dehydrogenation catalysis of cyclohexane has been observed. This may be due to complications that arise from the presence of a large excess of alkene or from undesired reactions with the borane.

Alkane dehydrogenation with a (nacnac)PtMe fragment

To find a more active system for catalytic C–H bond functionalization we moved away from the tridentate Tp′ ligand to the monoanionic bidentate nacnac (nacnac = bis-*N*-aryl-β-enamineimine) ligand. This bidentate ligand will stabilize square planar Pt(II) complexes but not octahedral Pt(IV) complexes; this should enhance catalytic activity as we want reductive elimination from Pt(IV) intermediates to be facile. A bidentate ligand obviates the need for an external promoter, such as borane, to remove the third Tp′ arm and generate five-coordinate Pt(IV) intermediates.

Goldberg and co-workers (44, 45, 70) have reported several five-coordinate (nacnac)PtMe$_3$ complexes in which the nacnac ligand contained aryl groups with bulky alkyl substituents at the ortho positions. These complexes reductively eliminated ethane under mild conditions. Once the complexes had eliminated ethane, they could activate C–H bonds either in the ortho-alkyl substituent of the nacnac ligand or in an alkane solvent molecule. The olefin complexes resulting from alkane dehydrogenation were not susceptible to facile associative ligand exchange due to the bulky ortho groups on the *N*-phenyls blocking access to the metal. Slow ligand substitution rates prevented these complexes from functioning as catalysts for transfer dehydrogenation of alkanes.

We chose to use a nacnac ligand with no ortho substituents on the phenyl groups to allow access to the metal in hopes of promoting facile associative ligand exchange. Stirring Me$_4$Pt$_2$(μ-SMe$_2$)$_2$ with nacnacH (*N*-aryl, aryl = phenyl) in *n*-pentane overnight resulted in C–H activation and dehydrogenation of pentane to form (nacnac)Pt(H)(1-pentene) (Scheme 13) (65). Unlike the Tp′ case, this 1-pentene complex did not isomerize to the 2-pentene analog, and only the 1-pentene complex was observed. More surprising was the observation that conducting the reaction in Et$_2$O rather than pentane resulted in dehydrogenation of ether to form an ethyl vinyl ether hydride platinum complex (65).

It is clear from the selectivity for 1-pentene that primary C–H bond activation is favored when linear alkanes are

© 2008 NRC Canada

used, but this is not the case for the reaction with ethers. Reaction with THF results in dehydrogenation to yield the 2,3-dihydrofuran complex selectively; the double bond forms adjacent to the oxygen atom. Dehydrogenation of the partially deuterated ether reagent, $CH_3CD_2OCH_2CH_3$, produces both (nacnac)Pt(H)(CH_2=CDOEt) and (nacnac)Pt(H)(CH_2=CHOCD_2CH_3), as well as CH_4 and CH_3D. The absence of Pt-D products confirms that the initial site of C–H activation is the C–H bond α to oxygen (65).

Addition of alkene to these complexes results in rapid olefin exchange at room temperature; indeed, removal of the ortho substituents from the nacnac *N*-aryl groups exposes the metal and allows rapid associative ligand exchange. Given that olefin exchange is facile in these complexes, we attempted to catalyze transfer dehydrogenation with (nacnac)Pt(H)(neohexene). The reaction was quite slow, but we were able to observe about two turnovers in the dehydrogenation of either diethyl ether or tetrahydrofuran. This limited activity is a small step in the right direction.

Conclusions

The flexibility of the Tp′ ligand has allowed us to isolate Pt(IV) intermediates and to study C–H bond activation processes. Building from our knowledge of C–H bond tranformations, we have achieved reductive H–H bond formation from Tp′PtRH_2. We have also seen encouraging results relevant to functionalization of hydrocarbons. Arylation of olefins proceeds under surprisingly mild conditions. Moving to the bidentate nacnac ligand bound to platinum provides the potential for catalytic transfer dehydrogenation of hydrocarbons with some functional group tolerance.

Bonding and structures of copper-aminopyridine complexes — High-resolution electron spectroscopy and ab initio calculations[1]

Xu Wang and Dong-Sheng Yang

Abstract: Copper complexes of *x*-aminopyridine (*x* = 2, 3, 4) were prepared in a laser vaporization supersonic molecular beam source and identified using laser photoionization time-of-flight mass spectrometry. These complexes were studied by pulsed-field ionization zero electron kinetic energy (ZEKE) spectroscopy and second-order Møller-Plesset perturbation theory. Three structures formed by Cu binding to the pyridine nitrogen (σ_α), the amino nitrogen (σ_β), and the pyridine ring (π) were considered by the theoretical calculations, but only the σ_α structures with Cu binding to the pyridine nitrogen were confirmed by the spectroscopic measurements. Adiabatic ionization energies and metal-ligand and ligand-based vibrational frequencies of the σ_α complexes were measured from the ZEKE spectra, and the metal-ligand bond energies of the neutral and ionized complexes were predicted by the theory. The ionization energies of the Cu complexes are about 20 000 cm^{-1} lower than that of bare Cu atom. This ionization energy shift is the result of the stronger Cu^+-ligand bonding because of the additional charge-dipole interaction in the ion. Although the three complexes are formed by Cu coordination to the pyridine nitrogen atom, the position of the amino group affects the metal-ligand bonding strengths in both neutral and ionized species. These effects include the structural resonance and hydrogen bonding in the neutral complexes and the electric dipole moment and bidentate bonding in the ions.

Key words: photoelectron, PFI-ZEKE, ab initio, copper aminopyridine.

Résumé : On a préparé les complexes de cuivre de x-aminopyridine (x = 2, 3, 4) dans une source de faisceau moléculaire supersonique à vaporisation laser et on les a identifiés par spectrométrie de masse en temps de vol avec photoionisation au laser. On a étudié ces complexes par spectroscopie d'énergie cinétique électronique zéro (« ZEKE ») avec ionisation à champ pulsé ainsi que par la théorie de perturbation de Møller-Plesset du deuxième ordre. Pour les calculs théoriques, on a considéré trois structures formées par du cuivre se liant à l'azote de la pyridine (σ_α), l'azote de l'amine (σ_β) et le noyau pyridine (π); seules les structures σ_α du cuivre se liant à l'azote de la pyridine ont pu être confirmées par des mesures spectroscopiques. On a mesuré les énergies d'ionisation adiabatique et les fréquences de vibration métal-ligand ainsi que celles de vibrations basées sur le ligand des complexes σ_α à partir des spectres « ZEKE » alors que les énergies de liaison métal-ligand des complexes neutres et ionisés ont été calculés sur une base théorique. Les énergies d'ionisation des complexes du cuivre sont environ 20 000 cm^{-1} plus faibles que celles de l'atome de cuivre nu. Ce déplacement de l'énergie d'ionisation résulte d'une liaison Cu^+-ligand plus forte causée par l'interaction supplémentaire charge-dipôle dans l'ion. Même si les trois complexes se forment par une coordination du cuivre à l'atome d'azote de la pyridine, les positions différentes du groupe amino affecte les forces de liaison métal-ligand tant dans les espèces neutres qu'ionisées. Ces effets incluent la résonance structurale et la liaison hydrogène dans les complexes neutres et le moment électrique dipolaire ainsi que la liaison bidentate dans les ions.

Mots-clés : photoélectronique, « PFI-ZEKE », ab initio, cuivre-aminopyridine.

[Traduit par la Rédaction]

Introduction

Copper is a bioessential element in biology, whereas nitrogen is the fourth most common element in living systems, after carbon, hydrogen, and oxygen. Thus, the chemistry and biochemistry of the copper–nitrogen interaction have attracted considerable interest over the past decades (1–3). To probe fundamental interactions between a copper atom or ion and nitrogen-containing organic molecules, we have recently studied the bonding and structures of a series of coordinately unsaturated, transient copper complexes of amines (4–7) and aromatic nitrogen systems (8–10). In Cu-

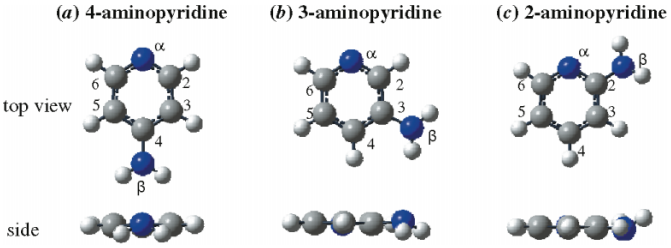
methylamine complexes, the N atom binds to Cu through the lone-pair electrons in the N sp^3 hybrid orbital (6). Although ethylenediamine possesses two N binding sites, the structure of Cu-ethylenediamine was determined to be in a hydrogen-bond stabilized monodentate configuration (5). Interestingly, single methyl substitution of the amino hydrogen atom leads to a bidentate structure, with Cu binding to both N atoms (4). The change from the monodentate to the bidentate mode arises from the competition between copper coordination and hydrogen bonding. The pyridine molecule contains a nitrogen atom and an aromatic ring, thus it can function as a σ donor, a π acceptor, or a π donor. However, only the σ structure was predicted by MP2 theory and confirmed by pulsed-field ionization zero electron kinetic energy (ZEKE) spectroscopy (8). By introducing another nitrogen atom into different mutual positions of the aromatic ring, we predicted a π bonding structure for the neutral Cu-pyrimidine complex and three Cu^+-diazine ions using the MP2 calculations (10). However, our ZEKE measurements have only observed the σ structure for both neutral and ionic Cu-diazine complexes (10).

In this work, we have extended the ZEKE study to the Cu complexes with aminopyridines. These ligands have two types of nitrogen atoms for σ bonding: one is in the pyridine ring with lone-pair electrons in the sp^2 hybrid orbital and the other is in the amino group with lone-pair electrons in the sp^3 hybrid orbital (Figure 1). In addition to the two σ bonding sites, the aromatic pyridine ring in these ligands may offer π binding sites as well. It would be interesting to examine how these binding sites compete with each other to form stable Cu complexes. Previously, bond energies of alkali ion-aminopyridines were measured by threshold collision-induced dissociation, and the σ bonding structures of these ions were predicted by the MP2 method (11). Vibrational spectra of M^{2+}-aminopyridine complexes (M = Mn, Co, Ni, Cu, or Cd) in condensed phases were measured by nujol mulls or KBr FT-IR spectroscopy and analyzed in terms of σ bonding structures (12–15). On the other hand, the π bonding mode was identified for 2-aminopyridine·Ar_n van der Waals complexes by resonance-enhanced multiphoton ionization and ZEKE–mass-analyzed threshold ionization spectroscopy and ab initio calculations (16, 17). In this paper, we report the ZEKE spectra of Cu complexes with 4-aminopyridine (4-AP), 3-aminopyridine (3-AP), and 2-aminopyridine (2-AP). Adiabatic ionization energies (AIEs) and metal-ligand and ligand-based vibrational frequencies were measured from the ZEKE spectra. The structures of these complexes were determined by comparing the spectra with the MP2 calculations and spectral simulations.

Experimental and computational methods

The experimental setup has been described in a previous publication (18). The Cu complexes were prepared by reactions of Cu atoms with the *x*-AP ligands (*x* = 2, 3, and 4) (Sigma-Aldrich, 98%–99%) in molecular beams. The metal atoms were produced by pulsed laser vaporization of a Cu rod (Alfa Aesar, 99.9%) with the second harmonic output of a Nd:YAG laser (Quanta-Ray GCR-3, 532 nm, ~3 mJ) in the presence of He or Ar gas (Scott-Gross, ultra high purity) at ~50 psi (6.894 757 kPa). The carrier gas was delivered by a piezoelectric pulsed valve (19). The metal rod was translated and rotated by a motor-driven mechanism to ensure each laser pulse ablated a fresh surface. Since 4-AP is a solid (mp 155–158 °C) and has a low vapor pressure at room temperature, a Cu oven installed inside the molecular beam chamber was used to obtain sufficient ligand vapor. Although 3-AP and 2-AP are also solids (mp 65 and 57–60 °C, respectively), they have sufficient vapor pressures at ambient temperature. Therefore, these two ligands were placed in a glass bulb without heating, which was also installed inside the molecular beam chamber.

Fig. 1. Structural isomers of aminopyridines.



The Cu-(*x*-AP) complexes in the molecular beams were identified by photoionization time-of-flight mass spectrometry. Ionization was carried out by a frequency-doubled dye laser (Lumonics, HD-500), pumped by a XeCl excimer laser (Lumonics, PM-884) or the third harmonic output of a Nd:YAG laser (Continuum, Surelite III). The production of the 1:1 metal-ligand complexes was maximized by optimizing the timing and power of the vaporization and photoionization lasers, the amount of the ligand vapor, and the reservoir pressure of the carrier gas. Prior to ZEKE experiments, ionization thresholds of these complexes were measured by recording the ion signals as a function of the laser wavelength. ZEKE electrons were produced by phototexcitation of the neutral complexes to high-lying Rydberg states, followed by a 3 μs delayed, 1.2 V cm^{-1}, and 100 ns pulsed-electric-field ionization of these Rydberg states. A small dc field of ~0.08 V cm^{-1} was applied to help separate ZEKE from kinetic electrons produced by direct photoionization. The pulsed electric field was generated by a delay pulse generator (Stanford Research System, DG535). The ion and electron signals were detected by a dual microchannel plate detector (Galileo), amplified by a preamplifier (Stanford Research System, SR445), averaged by a gated integrator (Stanford Research System, SR250), and recorded in a laboratory computer. Laser wavelengths were calibrated against vanadium atomic transitions in regions of the ZEKE spectra (20). The field dependence of the ZEKE signal was not measured because of the limited size of the ZEKE signal. However, the energy shift from the small electric field has been shown to be smaller than the spectral linewidth (21).

Calculations of molecular geometries and vibrational frequencies were carried out by using the MP2/6-311+G(d,p) method, implemented in the GAUSSIAN 03 program (22). Multidimensional Franck–Condon (FC) factors were computed from the equilibrium geometries, harmonic frequencies, and normal modes of the neutral and ionic complexes (23, 24). The Duschinsky effect (25) was considered to account for normal mode differences between the neutral molecule and ion in the FC calculations. Spectral broadening

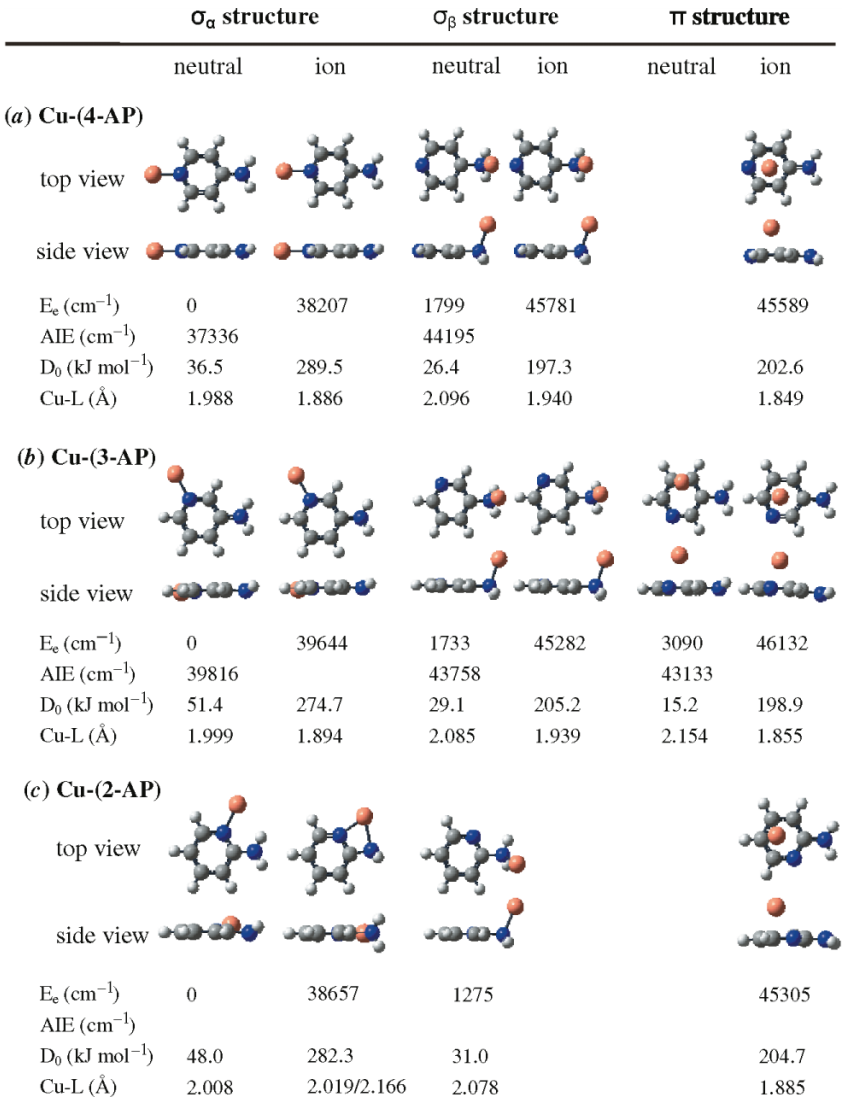
Fig. 2. Structural isomers, relative electronic energies, adiabatic ionization energies (AIE), and bond dissociation energies (D_0) of (*a*) Cu-(4-aminopyridine), (*b*) Cu-(3-aminopyridine), and (*c*) Cu-(2-aminopyridine) from MP2/6-311+G(d,p) calculations. The bond distances are in angstroms. Cu–N distances are given for the σ structures, and Cu-ring vertical distances are given for the π structures.



was simulated by giving each line a Lorentzian line shape with the linewidth of the experimental spectrum. Boltzmann distributions were used to simulate spectra at specific vibrational temperatures.

Equilibrium structures

In our computational survey of the minimum energy structures for the Cu-(*x*-AP) complexes, a π and two σ (σ_α and σ_β) configurations were considered for both neutral and ionic species. The π complex is formed by Cu binding atop of the pyridine ring, whereas the σ_α and σ_β complexes are formed by Cu binding to the pyridine nitrogen (N_α) or the amino nitrogen (N_β). These structures are presented in Figure 2, along with predicted electronic, ionization, and dissociation energies.

Cu-(4-AP)

The σ_α structure of Cu-(4-AP) has C_s symmetry, where the Cu and amino N_β atoms are nearly coplanar to the pyridine ring, and the two N_β–H bonds slightly bend out of the pyridine plane. This out-of-plane bending has also been found in the free ligand, and it is due to the sp^3 hybridized nature of the N_β atom, which tends to remain a tetrahedral configuration. The Cu–N_α distance is calculated to be 1.988 Å by the MP2 theory, which is slightly shorter than that in Cu-pyridine (2.005 Å) predicted previously at the same level of theory (8). However, the bond energy of this Cu–N_α bond is about 10.9 kJ mol^{-1} smaller than that of Cu-pyridine (47.4 kJ mol) (8).

The σ_β structure also belongs to the C_s point group and is ~1800 cm^{-1} less stable than the σ_α structure. This structure has a more distorted amino group because of Cu coordination to the N_β atom. The Cu–N_β bond has a longer distance (2.096 Å) and smaller dissociation energy than the Cu–N_α bond. It is also weaker than the Cu–N bond in the Cu-NH_3 complex (26), because of the larger steric repulsion from the pyridine ring. Like the σ_α structure, the pyridine-ring geometry remains virtually the same as that in the free ligand. This small perturbation on the ligand geometry has been found in other heterocyclic Cu complexes (8, 10).

© 2008 NRC Canada

Upon ionization, the Cu–N distance shrinks by 0.102 Å in the σ_α structure and 0.156 Å in the σ_β structure, respectively. The smaller Cu–N distances in the ionic complexes are due to the reduced repulsion between Cu $4s^1$ and N lone-pair electrons and the additional charge-dipole attraction. Interestingly, although the σ_α structure undergoes a smaller reduction in the Cu–N bond length, it has a larger increase in the C–N bond energy than the σ_β structure upon ionization. The larger increase of the bond energy from the neutral species to the ion leads to a lower AIE for the σ_α structure (38 270 cm^{-1}) than for the σ_β structure (45 781 cm^{-1}). Moreover, the Cu^+–N_α bond in the σ_α ion is predicted to be 30.8 kJ mol^{-1} stronger than that in Cu^+-pyridine, but the Cu–N bond energies in the corresponding neutral species have the opposite order (8). This difference is due to a so-called π resonance delocalization effect, which induces more negative charge on the N_α atom in 4-AP than the nitrogen atom in pyridine. The larger negative charge on N_α leads to an increased repulsion towards the Cu $4s^1$ electron but an enhanced attraction towards the Cu^+ ion. On the other hand, the Cu^+–N σ_β bond in the σ_β structure is much weaker than that in Cu^+-NH_3, indicating that the electron withdrawing and steric effects from the pyridine ring play an important role in this ion bonding. Therefore, the metal-ligand bonding strengths in these σ structures are determined by π resonance delocalization, electron withdrawing, and steric effects.

Like Cu-pyridine (8), a computational search for a stable π structure of the neutral Cu-(4-AP) complex is not successful. However, a π ion is located about 7400 cm^{-1} above the σ_α ion. The vertical distance between Cu^+ and pyridine ring is calculated to be 1.849 Å. The Cu^+-(4-AP) dissociation energy in this π structure (202.6 kJ mol^{-1}) is slightly larger than the Cu^+–N_β bond in the σ_β structure (197.3 kJ mol^{-1}) but much smaller than the Cu^+–N_α bond in the σ_α structure (289.5 kJ mol^{-1}).

Cu-(3-AP)

The σ_α structure of Cu-(3-AP) has a slightly longer Cu–N_α distance but a stronger bond compared with the Cu-(4-AP) σ_α complex. Similar to Cu-(4-AP), both the Cu and N_β atoms in the Cu-(3-AP) σ_α structure are nearly coplanar to the pyridine ring, the amino group is slightly tilted from this plane, and the local geometry of the amino group is almost identical to that in the free ligand. The σ_β structure of Cu-(3-AP) has a higher energy, a longer Cu–N distance, and a more distorted amino group than its σ_α structure. As in Cu-(4-AP), ionization reduces the Cu–N distances and thus increases the bond energies for both the σ_α and σ_β structures.

Unlike 4-AP, the 3-AP ligand forms a stable π structure with a Cu atom. This π structure is located 3090 cm^{-1} above the lowest-energy σ_α structure. The Cu atom is closest to the two carbon atoms that are bound to N_α, and the vertical Cu-ring distance is calculated to be 2.154 Å. The longer Cu-ring distance in the π structure than the Cu–N bonds in the σ structures suggests a weaker metal-ligand π interaction. Ionization of the π structure moves the Cu^+ ion towards the pyridine-ring center and reduces the vertical Cu^+-ring distance to 1.855 Å. The decrease of the Cu^+-ring distance is the result of the additional electrostatic interaction between the Cu^+ ion and the π surface of the ligand. Consequently, the resultant π ion is much more strongly bonded (198.9 kJ mol^{-1}) than the corresponding neutral structure (15.2 kJ mol^{-1}). The bond dissociation energy of the Cu^+-(3-AP) π ion is comparable to that of the Cu^+-(4-AP) counterpart.

The existence of the stable π structure in the neutral Cu-(3-AP) indicates that π electrons in the 3-AP ring are more delocalized and the ligand has higher aromaticity than 4-AP and 2-AP. This finding echoes our previous study of Cu-diazine complexes, where only pyrimidine (1,3-diazine) forms a stable π structure with a Cu atom (10).

Cu-(2-AP)

Due to the close proximity of the two nitrogen atoms, 2-AP may exhibit bonding capabilities different from the other two aminopyridines. In our computational search, we considered two σ configurations for both neutral and ionized forms: (*i*) Cu binding to the N_α atom with the amino group fixed in the same orientation as that in the free ligand and (*ii*) Cu binding to both N_α and N_β atoms, where the amino group is rotated by 90° so that the N_β lone-electron pair orbital points to the N_α atom. For the neutral complexes, only the geometry optimization of initial guess (*i*) is converged to a local minimum-energy σ_α structure. The geometry optimization of initial guess (*ii*) results in a transition-state energy structure, with an imaginary frequency of 330*i* cm^{-1}. In the σ_α structure, the Cu atom binds to the N_α atom, the N_β atom is nearly coplanar to the pyridine ring, and each N_β–H bond is slightly tilted out of the plane. Moreover, the Cu atom bends out of the ring plane by about 10° to minimize the repulsion from the amino group. The Cu–Nα distance is slightly longer than those of the Cu-(4-AP) and Cu-(3-AP) σ_α structures, whereas the bond energies are in the order of Cu-(4-AP) < Cu-(2-AP) < Cu-(3-AP). The monodentate Cu-(2-AP) σ_β structure is predicted to be 1275 cm^{-1} higher in energy than the σ_α structure. This σ_β structure has a similar Cu–N distance and bond dissociation energy to those of the Cu-(4-AP) and Cu-(3-AP) σ_β structures. For the ionized species, only the bidentate configuration is converged, where the Cu^+ ion binds to both N_α and N_β atoms. No monodentate structure was predicted for the ion. The bidentate ion has C_s symmetry, with Cu^+ being coplanar to the pyridine ring. In spite of the bidentate binding, the bond energy of Cu^+-(2-AP) is 7 kJ mol^{-1} smaller than that of the monodentate Cu^+-(4-AP) σ_α structure, possibly because of ample strain on the Cu^+-N_α-C-N_β four-membered ring. This ring strain also explains the longer Cu^+–N distances in the bidentate Cu^+-(2-AP) ion than those in the monodentate neutral Cu-(2-AP) or the Cu-(4-AP) and Cu-(3-AP) σ_α ions.

A π ion of Cu^+-(2-AP) is located, where the Cu^+ ion is closest to the C_5 atom. The vertical Cu^+-ring distance and bond dissociation energy are predicted to be nearly the same as those in the Cu^+-(4-AP) and Cu^+-(3-AP) π ions. Thus, the mutual position between the N_β atom in the amino group and the N_α atom in the pyridine ring has no significant effect on the π bonding of these substituted pyridines.

ZEKE spectra and vibrational analysis

Cu-(4-AP)

Figure 3*a* shows the ZEKE spectrum of Cu-(4-AP) seeded in He carrier gas. The first strong peak at 41 377 (5) cm^{-1} has a linewidth of 6 cm^{-1} and is assigned to the 0-0 transi-

© 2008 NRC Canada

tion between the ground vibronic levels of the neutral and ionic complexes. Above the 0-0 transition, the spectrum displays a main progression (ν^n_0) of 260 cm^{-1} intervals with up to four vibrational quanta. Superimposed on the 260 cm^{-1} progression are a number of satellite peaks separated by 15 and 36 cm^{-1} intervals from the respective ν^n_0 bands and an additional progression formed by the combination of 210 and 260 cm^{-1} intervals ($\nu^n_0\omega^j_i\delta^t_s$). Below the 0-0 transition, the spectrum displays a strong band at 193 cm^{-1} with two small bands on the higher energy side ($\nu^0_l\omega^n_n\delta^m_m$). To identify the transitions from excited vibrational levels of the neutral complex, ZEKE measurements were carried out with Ar carrier, and the spectrum is presented in Figure 4*a*. In this spectrum, the intensities of the $\nu^n_0\omega^j_i\delta^t_s$ and $\nu^0_l\omega^n_n\delta^m_m$ bands are largely diminished because of lower vibrational temperatures of the Ar-seeded Cu-(4-AP) complex; the spectral linewidth is reduced from 6 to 4 cm^{-1} because of lower rotational temperatures, and several additional cold bands that overlapped with hot bands in Figure 3*a* are now resolved. These include the peak at 565 cm^{-1} above the band origin (τ^1_{b0}), the combination of the 260 cm^{-1} spacing with a 514 cm^{-1} interval ($\tau^1_{a0}\nu^n_0$), and the combination of 260 and 790 cm^{-1} intervals ($\rho^1_0\nu^n_0$).

To assign the observed vibrations in the ZEKE spectra of Cu-(4-AP), we first compare the measured frequencies with those of Cu-alkylamines (4–7, 26), -pyridines (8), and -diazines (10). The metal-ligand stretching frequencies are in the range of 430–470 cm^{-1} for Cu^+-alkylamines and 265–275 cm^{-1} for Cu^+-pyridines and –diazines. Thus, the 260 cm^{-1} progression in the Cu-(4-AP) ZEKE spectra can be assigned to the Cu^+-(4-AP) stretching vibration of the σ_α structure. This progression should not be due to the Cu^+-(4-AP) stretch of the σ_β structure, because the Cu^+-N stretch of the σ_β structure would have a frequency similar to those in Cu^+-alkylamines (i.e., ≥400 cm^{-1}). Moreover, the spectral profile of Cu-(4-AP) seeded in He is very similar to those of the Cu-pyridine and -diazine complexes seeded in the same carrier. For the Cu-pyridine and -diazine complexes, satellite bands around the metal-ligand stretching progression have been assigned to the sequence transitions of the Cu-ring in-plane and (or) out-of-plane bends and the neutral Cu-ring stretch. Thus, the sequence peaks labeled by $\nu^n_o\omega^j_i\delta^t_s$ and $\nu^o_l\omega^n_n\delta^m_m$ in Figure 3*a* may be assigned to such bending and stretching modes as well. On the other hand, in comparison with the FT-IR spectroscopic measurement of Cu^{2+}-(4- AP)$_2$Ni(CN)$_4$ (13), the 514, 565, and 790 cm^{-1} intervals in the ZEKE spectra may arise from a C–H out-of-plane bend and two ligand-based out-of-plane distortions.

To analyze the ZEKE spectra in more detail, we compare the measurements with theoretical calculations. In our MP2 calculations, both σ_α and σ_β structures are predicted to be local minima for the neutral and ionized Cu-(4-AP) complexes, but only a π ion is found. Since the energy difference between σ_α and σ_β is small, both structures may have been produced in the molecular beam. In our spectral analysis, we thus consider both σ isomers by comparing the measured and calculated AIEs, vibrational frequencies, and FC intensities. Transitions between two different isomers are excluded, because such transitions are expected to have a very different FC intensity profile from the experimental spectra. The AIEs of the σ_α and σ_β complexes are calculated to be 37 336

Fig. 3. Experimental ZEKE spectrum of Cu-(4-aminopyridine) seeded in (*a*) He carrier and simulations of the (*b*) σ_α, and (*c*) σ_β structures at 50 (for vibrational mode smaller than 100 cm^{-1}) and 150 K (for those 200 cm^{-1} or greater).

© 2008 NRC Canada

and 44 195 cm^{-1}. Our previous studies have shown that MP2 calculations typically underestimate the AIEs of Cu-molecule complexes by about 3000 cm^{-1} (4, 6, 8–10). If the 3000 cm^{-1} correction is employed, the AIEs are estimated to be 40 336 cm^{-1} for the σ_α structure and 47 195 cm^{-1} for the σ_β structure, respectively. It is clear that the corrected theoretical AIE value of the σ_α structure matches better the measured value of 41 377 cm^{-1}, and the σ_α structure is most likely the ZEKE carrier.

Figures 3 and 4 compare the experimental ZEKE spectra to the spectral simulations of the σ_α and σ_β structures. Since the thermal population of excited vibrational levels depends on vibrational frequencies, simulations of hot band intensities may require different temperatures for various vibrational modes. We have found that the best temperatures for simulating the hot band intensities of the ZEKE spectrum with He carrier (Fig. 3*a*) are 50 K for vibrational modes smaller than 100 cm^{-1} and 150 K for those 200 cm^{-1} or larger. For the ZEKE spectrum with Ar carrier (Fig. 4a), since no vibrational hot bands are clearly observed, a very low temperature (10 K) is used in our simulations. The simulation of the σ_α structure (Fig. 4*b*) shows a main progression of 256 cm^{-1} intervals, which matches well to the observed 260 cm^{-1} progression. On the other hand, the simulation of the σ_β structure (Fig. 4*c*) displays three progressions with 67, 201, and 422 cm^{-1} intervals, none of which match the experimental observations. Moreover, the hot band positions and intensities in the simulation of the σ_α structure (Fig. 3*b*) exhibit better agreement with the experimental observation (Fig. 3*a*) than those of the σ_β structure (Fig. 3*c*). Thus, these comparisons in vibrational frequencies and intensities suggest again that the σ_α structure is the carrier of the ZEKE spectra.

Based on the overall good agreement between the experimental spectra and simulations of the σ_α structure, the 260 cm^{-1} major progression is attributed to the transitions from the ground vibrational level of the Cu-(4-AP) σ_α neutral complex to symmetric stretching levels of the Cu^+-(4-AP) σ_α ion. The stretching frequency in the neutral Cu-(4-AP) is measured to be 193 cm^{-1}. A least-squares fit of the peak positions of ν^n_0 to $G(\nu) = \omega^+_S(\nu^+ + 1/2) + x^+_{SS}(\nu^+ + 1/2)^2$ yields a harmonic frequency of 261.1(5) cm^{-1} and an anharmonicity of –0.6 (1) cm^{-1} for the Cu^+–N_α stretching mode. The 15 and 36 cm^{-1} intervals arise from $\Delta v = 0$ sequence transitions of the Cu-ring out-of-plane and in-plane bending vibrations, respectively, and the 210 cm^{-1} interval is from the $v^+ = 3 \leftarrow v = 1$ transition of the Cu-ring in-plane bend. The neutral and ionic Cu-ring in-plane bending frequencies are derived to be 56 and 89 cm^{-1}, respectively. Moreover, the 514, 565, and 790 cm^{-1} intervals are assigned to the vibrational frequencies of a C–H out-of-plane bend (ρ^+) and two ligand out-of-plane distortions (τ_a^+ and τ_b^+) in the ion, which have nearly the same frequencies as those of Cu^{2+}-$(4Apy)_2Ni(CN)_4$ (13). The complete assignment for each peak is listed in Table 1.

Cu-(3-AP)

The ZEKE spectra of Cu-(3-AP) seeded in He and Ar carriers are presented in Figs. 5*a* and 6*a*, respectively. Both spectra have a similar spectral profile to and slightly narrower linewidths (5 cm^{-1} in He and 4 cm^{-1} in Ar) than those of Cu-(4-AP). The 0-0 band is located at 42 541(5) cm^{-1}, 1164 cm^{-1} higher in energy than that of Cu-(4-AP). The main progression labeled ν^n_0 has an interval of 268 cm^{-1}. Superimposed on the main progression are sequence transitions with at 29 cm^{-1} separations. Additionally, the spectrum shows a small peak at 131 cm^{-1} above the band origin and its combinations with 268 cm^{-1} intervals ($w^1_0\nu^n_0$). The ZEKE spectrum of the helium-seeded complex shows a fairly strong hot band at 194 cm^{-1} below the 0-0 transition and a small peak 29 cm^{-1} above the 194 cm^{-1} transition ($\nu^n_1 w^m_m$). In the spectrum with Ar carrier, none of these hot bands is observed. From these two spectra, two progressions consisting of 268 cm^{-1} intervals combined with 482 ($\tau^1_{ao}\nu^n_0$) or 564 cm^{-1} ($\tau^1_{bo}\nu^n_0$) spacing are found to be overlapped with some of the sequence transitions. In comparison with the spectra of Cu-(4-AP), the 268 and 194 cm^{-1} intervals are assigned to the Cu^+-(3-AP) and Cu-(3-AP) stretching modes, the 484 and 564 cm^{-1} intervals to ligand-based vibrations, and the sequence bands to Cu-(3-AP) bends.

The spectral simulations of the Cu-(3-AP) σ_α, σ_β, and π structures at 60/150 and 10 K are presented in Figs. 5*b*, 5*c*, 5*d* and 6*b*, 6*c*, 6*d*), respectively. Similar to Cu-(4-AP), the temperature of 50 K is used to simulate hot bands for vibrational modes smaller than 100 cm^{-1} and 150 K is used for those 200 cm^{-1} or larger. A comparison of the experimental and calculated spectra excludes the contributions from both σ_β and π structures to the observed spectrum. On the other hand, the simulation from the σ_α structure matches the experimental spectrum quite well. Moreover, the AIE values of σ_α, σ_β and π structures are predicted to be 42 816, 46 758, and 46 133 cm^{-1}, respectively, by the MP2 method (after the 3000 cm^{-1} correction). The AIE of the σ_α structure (42 816 cm^{-1}) has the best match with the experimental value of 42 541 cm^{-1}. Therefore, the observed spectrum is attributed to the σ_α structure of the Cu-(3-AP) complex. The 268 and 194 cm^{-1} intervals are attributed to the ionic (ν^+) and neutral (ν) metal-ligand stretching frequencies. A least-squares fit of the peak positions of ν^n_0 to $G(\nu) = \omega^+_S(\nu^+ + 1/2) + x^+_{SS}(\nu^+ + 1/2)^2$ yields a harmonic frequency of 271.6 (11) cm^{-1} and an anharmonicity of –1.1 (2) cm^{-1} for the ion stretching mode. The 482 and 564 cm^{-1} intervals are attributed to two (3-AP) out-of-plane distortions (τ_a^+ and τ_b^+), whereas the 131 cm^{-1} interval is assigned to the Cu^+-(3-AP) out-of-plane bending excitation (ω^+). One of the ligand out-of-plane distortions (τ_b^+) is mixed with an NH_2 wagging motion. Due to the limited size of the ZEKE signal, these peaks were not observed in the ZEKE spectrum with Ar carrier gas. From the calculated FC factors, the sequence bands are attributed to both Cu-(3-AP) in-plane (δ) and out-of-plane bending (ω) vibrations. These hot bands overlap each other because the calculated differences between the neutral and ionic in-plane bending vibrations ($\delta^+ - \delta = 30$ cm^{-1}) and between the neutral and ionic out-of-plane bending vibrations ($\omega^+ - \omega = 28$ cm^{-1}) are very close to each other. The experimental frequency difference is 29 cm^{-1} between these ionic and neutral bending vibrations. Thus, the frequency of the neutral Cu-(3-AP) out-of-plane bend is estimated to be 102 cm^{-1}.

[a] Transitions from excited vibrational levels are observed only with He carrier.

broader linewidth (~20 cm^{-1}) and a lower signal/noise ratio compared with the spectra of Cu-(4-AP) and Cu-(3-AP). The spectrum displays a 0-0 transition at 43 745 (5) cm^{-1}, a major vibrational progression of 261 cm^{-1} (ν^n_0) with three quanta, a progression of 446 cm^{-1} (τ_a) with two quanta, an interval of 658 cm^{-1} (τ_b), and a few combinational bands of the 261 and 446 cm^{-1} intervals. In addition, it exhibits a partially resolved sequence transition at about 51 cm^{-1} to the higher energy side of the 0-0 and ν^1_0 peaks. In comparison with the spectra of the other two Cu-aminopyridine complexes discussed above, the 261 cm^{-1} progression is easily assigned to the Cu^+-(2-AP) stretching vibrations; the 446 and 658 cm^{-1} intervals are attributed to the (2-AP) out-of-plan distortions (τ_a^+ and τ_b^+) and the 51 cm^{-1} sequence bands are ascribed to transitions between the first vibrational levels of the Cu^+/Cu-(2-AP) out-of-plane bending mode (ω^+ – ω). In addition, the peak labeled with an asterisk is a Cu atomic transition, while two small peaks labeled with question marks remain to be assigned.

Although both nitrogen atoms in 2-AP may bind with a Cu atom to form a bidentate complex, the observation of vibrational modes similar to those in Cu-(4-AP) and Cu-(3-AP) indicates that the Cu-(2-AP) complex has monodentate binding as well. This observation is consistent with our MP2 prediction of the σ_α structure for the neutral complex. However, the bidentate ion structure predicted by the MP2 calculations is not observed in our ZEKE experiment. This is because a change from the neutral monodentate structure to the ion bidentate structure would give a spectrum with a much longer FC profile than what is observed in the experiment. Furthermore, if the ion is a bidentate σ structure, the ionization energy of the Cu-(2-AP) complex should be sig-

nificantly lower than those of Cu-(4-AP) or Cu-(3-AP) (4). Therefore, both AIE and FC profiles observed in the ZEKE spectrum indicate that the ion should have a σ_α structure as its corresponding neutral complex. Unfortunately, such a monodentate ion was not predicted by our theoretical calculations.

Ionization and bond energies

Table 2 summarizes the AIEs, metal-ligand bond energies, and vibrational frequencies from the ZEKE spectra and MP2/6-311+G(*d,p*) calculations of the σ_α Cu-aminopyridine complexes. The MP2 method predicts well the Cu-(*x*-AP) stretching and (*x*-AP)-based vibrational frequencies, but suffers relative large errors for the low-frequency Cu-(*x*-AP) bending modes. With the +3000 cm^{-1} correction, the theory also produces nicely the AIE values for these complexes. Since our MP2 calculations failed to locate a σ_α structure for Cu^+-(2-AP), no comparisons between the theory and experiment can be made for the ionization energy of Cu-(2-AP) and vibrational frequencies of Cu^+-(2-AP).

The measured AIEs of Cu-(*x*-AP) are 43 745, 42 541, and 41 377 cm^{-1}, with x = 2, 3 and 4, respectively. These values are 20 000 cm^{-1} (~240 kJ mol^{-1}) lower than the ionization energy of bare Cu atom [IE(Cu) = 62 317 cm^{-1}] (27). The large AIE shift arises from much stronger metal-ligand binding in the ion than in the neutral species, and the stronger ion bonding is due to the additional charge-dipole interaction. Because the metal-ligand bond energy in the neutral complex (36–51 kJ mol^{-1}) is only a small fraction of that in the corresponding ion (Table 2), the electrostatic interaction must be the major bonding force in these Cu-aminopyridine ions. The measured AIEs are in the order Cu-(4-AP) < Cu-(3-AP) < Cu-(2-AP), with an increment of ~1200 cm^{-1}. This small increment is consistent with the similar σ_α bonding in all these complexes. On the other hand, these AIE variations reveal subtle differences among the three aminopyridines. Although their polarizabilities are expected to be similar, the

electric dipole moments are rather different and in the order of 4-AP (3.72 D) > 3-AP (3.18 D) > 2-AP (2.13 D), as predicted by our MP2 calculations. However, the dipole-induced interaction does not appear to play a major role in the metal-ligand bonding of the neutral complexes, because the Cu-(*x*-AP) bond energies are in a different order, i.e., D_0 [Cu-(3-AP) = 51.4 kJ mol^{-1}] > D_0 [Cu-(2-AP) = 48.0 kJ mol^{-1}] > D_0 [(Cu-(4-AP) = 36.5 kJ mol^{-1}]. Thus, beside the dipole moment of the molecule, the binding variations may be attributed to other possible factors, such as resonance, chelation, and steric effects. Among these factors, the resonance effect in 4- and 2-AP leads to resonance structures with an additional negative charge on the pyridine N_α atom and thus increases repulsion to the Cu $4s^1$ electron in the Cu-(4-AP) and Cu-(2-AP) σ_α structures. Unlike 4- and 2-AP, no such resonance structures exist in 3-AP, and thus the electron repulsion should be smaller in the neutral Cu-(3-AP) σ_α structure. Our MP2 calculations predict more negative charged N_α atoms and smaller metal-ligand bond dissociation energies in Cu-(4-AP) and Cu-(2-AP) than that of Cu-(3-AP), suggesting that the resonance effect plays a large role in the bonding of the neutral complexes. Between Cu-(4-AP) and Cu-(2-AP), the ortho-substituted complex is more strongly bound than the para-substituted one. The stronger bonding of Cu-(2-AP) is surprising at first glance. However, a careful examination of the predicted σ_α structures reveals that the distance (2.53 Å) of the Cu atom to one of the H atoms in the amino group of Cu-(2-AP) is much shorter than that (2.95 Å) to the closet H atom in the pyridine ring of Cu-(4-AP). Since the 2.53 Å distance is smaller than the sum of the Cu and H van der Waals radii (2.60 Å) (28), interaction must exist between the two atoms. Therefore, the stronger Cu-(2-AP) bond may be the result of the additional hydrogen bonding. This Cu···H bonding in Cu-(2-AP) is also evident from the predicted opposite charges on Cu (–0.01) and H (+0.27). On the other hand, the calculated charges on the Cu and H atoms are 0.03 and 0.14 in Cu-(4-AP).

For the σ_α ions, the bond energy of Cu^+-(4-AP) is predicted to be larger than that of Cu^+-(3-AP), which is consistent with the stronger charge-dipole interaction and resonance effect in the para-substituted complex. For Cu^+-(2-AP), our MP2 calculations were not able to locate a minimum energy σ_α structure. Instead, the calculations predict a bidentate structure with Cu^+ coordination to both pyridine and amino nitrogen atoms. The Cu^+-ligand bond energy of this bidentate structure is slightly lower than that of Cu^+-(4-AP) but larger than that of Cu^+-(3-AP).

Conclusion

Vibrationally resolved ZEKE spectra and minimum energy structures are reported for the three Cu-(*x*-aminopyridine) complexes, where *x* = 2, 3, and 4. The ionization energies of these complexes are much lower than that of bare Cu atom and in the order of the decreasing energy for the 2-, 3-, and 4-aminopyridines. These energy shifts indicate much stronger metal-ligand bonding in the ion than that in the neutral species, and the increased ion bonding is largely due to the charge-dipole interaction. The most stable

© 2008 NRC Canada

structures of these complexes are formed by Cu coordination to the nitrogen atom in the pyridine ring. The major metal-ligand binding force is the σ Cu-N interaction in the neutral complexes and the charge-dipole interaction in the ions. The binding differences among the three neutral complexes arise from the resonance effect in the ortho- and para-substituted complexes and the additional Cu··H hydrogen bonding in the ortho-substituted species. The small differences among the ions are due to different dipole moments and chelation effects of these ligands.

A mechanistic study of the addition of alkynes to Brook silenes[1]

Kaarina K. Milnes and Kim M. Baines

Abstract: The addition of the alkyne-containing mechanistic probes (*trans*-2-phenylcyclopropyl)ethyne, (*trans,trans*-2-methoxy-3-phenylcyclopropyl)ethyne, and (*trans,trans*-2-methoxy-1-methyl-3-phenylcyclopropyl)ethyne (**1a**–**1c**) to a Brook silene 2-(1-adamantyl)-2-trimethylsiloxy-1,1-bis(trimethylsilyl)-1-silene (**14**) was examined. When alkyne **1a** was added to the silene, an ene adduct was observed; however, addition of alkyne **1c** to **14** gave a mixture of silacyclobutenes and silacycloheptenes. The regiochemistry of the phenyl and methoxy substituents on the seven-membered ring of the silacycloheptenes provides convincing evidence for the formation of a biradical intermediate along the reaction pathway.

Key words: Brook silene, alkyne, cycloaddition, reaction mechanism, mechanistic probe.

Résumé : On a étudié l'addition d'alcynes contenant des sondes mécanistiques, le (*trans*-2-phénylcyclopropyl)éthyne, le (*trans,trans*-2-méthoxy-3-phénylcyclopropyl)éthyne et le (*trans,trans*-2-méthoxy-1-méthyl-3-phénylcyclopropyl)éthyne (**1a**–**1c**) à un silène de Brook, le 2-(1-adamantyl)-2-triméthylsiloxy-1,1-bis(triméthylsilyl)-1-silène (**14**). Lorsque l'alcyne **1a** est additionné au silène, on observe la formation d'un adduit ène; toutefois, l'addition de l'alcyne **1c** au silène **14** conduit à la formation d'un mélange de silacyclobutènes et de silacycloheptènes. La régiochimie des substituants phényle et méthoxy sur le cycle à sept chaînons des silacycloheptènes fournit des données convaincantes de la formation d'un intermédiaire biradicalaire au cours de la voie réactionnelle.

Mots-clés : silène de Brook, alcyne, cycloaddition, mécanisme réactionnel, sonde mécanistique.

[Traduit par la Rédaction]

Introduction

There has been recent interest in the use of silenes as reagents in organic synthesis because of their highly regioselective cycloaddition reactions and the variety of transformations that the silicon can subsequently facilitate (1). In addition to their potential use in organic synthesis, the cycloaddition reactions of silenes have been critical for the synthesis of many new silacycles that have not been readily available by any other route (2). Furthermore, the cycloaddition reactions of silenes have played a central role in the development of silene chemistry, as they usually occur cleanly and in high yield, and thus these reactions have been used to provide indirect evidence for transient silenes (2). To fully exploit these important transformations, it is necessary to increase our understanding of their mechanisms.

In this work, we investigate the mechanism of the cycloaddition of alkynes to Brook silenes $(Me_3Si)_2Si{=}C(R)(OSiMe_3)$ (Scheme 1) (2). Brook silenes are a special class of relatively nonpolar silenes, which are important since they are one of the few stable silenes that can be easily synthesized (2). The products derived from the reactions of Brook silenes are, in general, the same as those derived from polar silenes; however, the rate constants for the reactions of Brook silenes appear to be less (2*c*). As with polarized silenes, the products formed from the addition of alkynes to Brook silenes are silacyclobutenes or, possibly, ene adducts if the silene or the alkyne contain an α-hydrogen (2). In an attempt to probe the mechanism of alkyne addition to silenes, Brook and co-workers (3) examined the addition of phenylacetylene and trimethylsilylacetylene to a mixture of the *E*- and *Z*-isomers of $(Me_3Si)(R)Si{=}C(1\text{-}Ad)(OSiMe_3)$, R = Mes (2,4,6-trimethylphenyl) or Tip (2,4,6-triisopropylphenyl); the E/Z ratio of the silene isomers was known but not assigned. In all cases, the ratio of the two isomeric silacyclobutenes produced was found to be identical to the E/Z ratio of the starting silene mixture. It was concluded that these results were, therefore, only consistent with a concerted mechanism of addition of the alkyne to the silene. Ishikawa and co-workers (4) have also examined the addition of alkynes to Brook silenes, both experimentally and theoretically, and in several cases implicate the involvement of biradical intermediates; however, unambiguous evidence for the intermediacy of biradicals was never obtained.

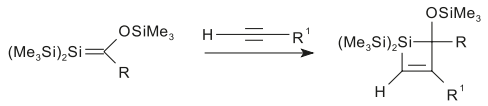
Scheme 1.

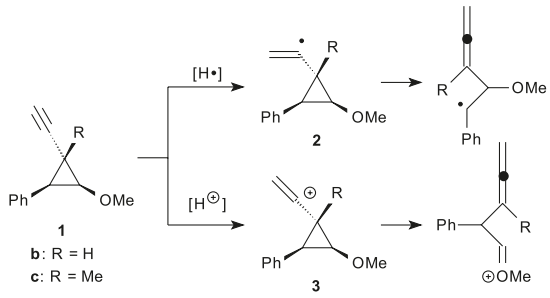


In the past few years, our group has investigated the use of molecular probes as a means of examining the mechanism of alkyne addition to group 14 (di)metallenes (5). We have developed alkynes **1b** and **1c** as mechanistic probes designed to undergo regiochemically distinct rearrangements to differentiate between the formation of α-cyclopropylvinyl radical and ionic intermediates (6). To exemplify, the α-cyclopropylvinyl radical (**2**), derived from alkyne **1b** or **1c**, rapidly ring opens toward the phenyl substituent yielding a benzyl radical. In contrast, the corresponding α-cyclopropylvinyl cation (**3**) undergoes ring-opening rearrangement selectively toward the methoxy substituent (Scheme 2). The analogous anion, as modeled by α-(*trans*-2-phenylcyclopropyl)vinyllithium (**4**) is stable towards ring opening (6*a*). Thus, an efficient method for distinguishing between the formation of all plausible intermediates has been established. (*trans*-2-Phenylcyclopropyl)ethyne **1a**, which does not contain a methoxy substituent on the cyclopropyl ring, undergoes ring-opening rearrangement toward the phenyl substituent when either a radical or a cation is generated at the α-cyclopropylvinyl position (6). Thus, alkyne **1a** is able to detect the formation of a reactive intermediate; however, there will be no structural differentiation observed in the products that are formed.

To examine the mechanism of the addition of alkynes to Brook silenes, we added cyclopropyl alkynes **1a**–**1c** to the Brook silene $(Me_3Si)_2Si{=}C(t\text{-}Bu)(OSiMe_3)$ (**5**) (7). When alkyne **1a** is added to silene **5**, the only products formed are two diastereomers of allene **6** (R^1 = H) (Scheme 3); however, when alkynes **1b** and **1c** are added to silene **5**, either allene **7** (R^1 = OMe), silacyclobutene **8** (R = H), and silacycloheptene **10**, or silacyclobutene **9** (R = Me) and silacycloheptenes **11** and **12** are formed, respectively. The products **6**–**12** have at least two stereocentres, and thus, two or more diastereomers of the products are typically observed, as indicated by the lower case letters following the compound numbers. Presumably, silacycloheptenes **10**, **11**, and **12** are formed by the reaction of intermediate silacyclohepta-1,2-dienes **13a** and **13b** (R = H or Me) with silene **5**.

In silacycloheptenes **10**, **11**, and **12**, the cyclopropyl ring has clearly undergone ring expansion. Using a variety of spectroscopic techniques, the phenyl substituent was found to be α and the methoxy group was found to be β to the former silenic carbon in all the silacycloheptenes. Because of the placement of the phenyl substituents on the 7-membered ring of silacycloheptenes **10**, **11**, and **12**, it was concluded that alkynes **1b** and **1c** must add to silene **5** to give an initial 1,4-biradical. The 1,4-biradical intermediate can then cyclize, forming silacyclobutenes **8** and **9** or undergo ring-opening rearrangement toward the phenyl substituent forming a 1,7-biradical intermediate. Cyclization of the 1,7-biradical intermediate yields silacyclohepta-1,2-diene (**13**). The addition of a second equivalent of silene **5** to **13** produces silacycloheptenes **10**, **11**, and **12**. Although these results provide evidence for the nature of the intermediate formed during the addition of alkynes to Brook silenes, it is important to remember that Brook silenes are a special class of relatively nonpolar silenes, and thus a generalization of the mechanism of addition of alkynes to all silenes cannot be based on these results. Nonetheless, we wished to explore the generality of these observations, and we now report on the addition of cyclopropyl alkynes **1a**–**1c** to a second example of a Brook silene, $(Me_3Si)_2Si{=}C(1\text{-}Ad)(OSiMe_3)$ (**14**) (8).

Scheme 2.



Results and discussion

Irradiation of 1-adamantanecarbonyltris(trimethylsilyl)-silane (**15**) in the presence of (*trans*-2-phenylcyclopropyl)-ethyne **1a** produces a diastereomeric mixture of allenes **16a** and **16b** (53:47), as revealed by ^{1}H NMR spectroscopy (Scheme 4). When alkyne **1a** is added to a solution of preformed silene **14** in the dark, the same product mixture was obtained in a similar ratio.

Irradiation of acylsilane **15** in the presence of alkyne **1c** produced a mixture of six diastereomers of silacycloheptene **17a**–**17f** and two diastereomers of silacyclobutene **18a** and **18b** (in ratios of 12:13:32:5:17:2:9:10) as revealed by ^{1}H NMR spectroscopy (Scheme 5). When alkyne **1c** is added to a solution of the preformed silene in the dark, the same product mixture was obtained in a similar ratio. Chromatographic separation of the crude product mixture yielded a mixture of silacycloheptenes **17a**–**17f** (14:17:34:8:24:3) and a mixture of silacyclobutenes **18a** and **18b** (56:44). Further chromatographic separation of the silacycloheptenes **17a**–**17f** yielded silacycloheptenes **17a** and **17b** (58:42) and silacycloheptenes **17c**–**17f** (65:14:19:2). Despite several attempts, no one compound could be isolated from the mixtures.

Allenes **16a** and **16b**, silacycloheptenes **17a**–**17f**, and silacyclobutenes **18a** and **18b** were identified by ^{1}H, ^{13}C, gCOSY, ^{1}H-^{13}C gHSQC and gHMBC, and ^{1}H-^{29}Si gHMBC NMR spectroscopy and mass spectrometry. The spectroscopic features that allowed for the elucidation of the structures of compounds **16a**, **16b**, **17a**–**17f**, **18a**, and **18b** are very similar to those seen for the products derived from the addition of alkynes **1a**–**1c** to silene **5** (7). For **17a**–**17e**, the phenyl substituent was found to be α and the methoxy substituent was found to be β to the former silenic carbon. Silacycloheptene **17f** was only present in a small amount, and as a consequence, not all the diagnostic correlations were evident in the NMR spectral data; however, the ^{1}H NMR spectral data for **17f** is very similar to that of the other

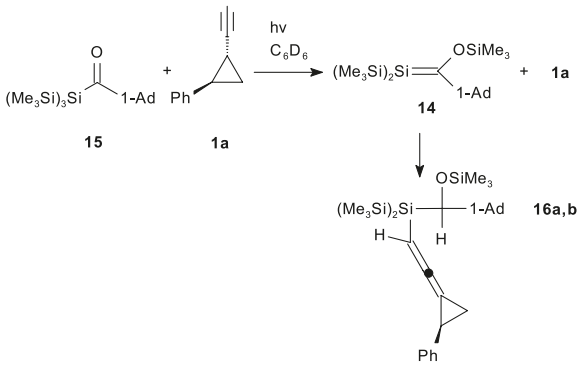
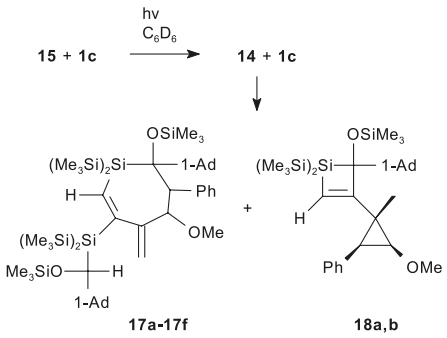


Scheme 5.



diastereomers of **17**, and therefore, its regiochemistry was assumed to be the same as **17a**–**17e**.

The formation of allenes **16a** and **16b** from the addition of alkyne **1a** to silene **14** is best described as a pericyclic ene-addition, as previously reported for the formation of allenes **6** and **7** (Scheme 3, R^1 = H or OMe) from the addition of alkynes **1a** and **1b** to silene **5** (7).

From the structure of silacycloheptenes **17a**–**17f**, it is evident that the cyclopropyl ring has undergone ring expansion. The location of the phenyl substituent on the carbon next to the former silenic carbon is *only* consistent with a mechanism that involves the formation of an α-cyclopropylvinyl *radical* intermediate during the course of the addition of alkyne **1c** to silene **14**: alkyne **1c** must add to the silene to give a 1,4-biradical intermediate that can cyclize forming silacyclobutenes **18a** and **18b** or ring open towards the phenyl substituent to yield a 1,7-biradical intermediate (Scheme 6). Ring closure of the 1,7-biradical intermediate yields silacyclohepta-1,2-diene (**19**), which apparently reacts with a second equivalent of silene via an ene addition to give the observed products **17a**–**17f**. The ene adduct is also likely derived from a biradical intermediate. The addition of alkyne **1c** to silene **14** did not afford a product analogous to **12** (Scheme 3), presumably because of steric effects.

The addition of alkyne **1b** to silene **14** was attempted several times, both by co-irradiation of the alkyne and acylsilane **15** and by addition of the alkyne to the preformed silene; however, a complex mixture of products was formed each time. The addition of alkyne **1b** to the related silene $(Me_3Si)_2Si{=}C(t\text{-Bu})(OSiMe_3)$ **5** yielded the bicycle **10**, where a second equivalent of silene **5** adds to the allene moiety of **13a**, presumably via the biradical intermediate **21a** (Scheme 7) (7). Only one regioisomer of **10** is formed, likely because of steric factors. The addition of silene **14** to the transient silacyclohepta-1,2-diene (**20**) may also form a biradical **21b** (R = 1-Ad) (Scheme 7). Biradical **21b** has no viable reaction pathways; it cannot disproportionate, and the

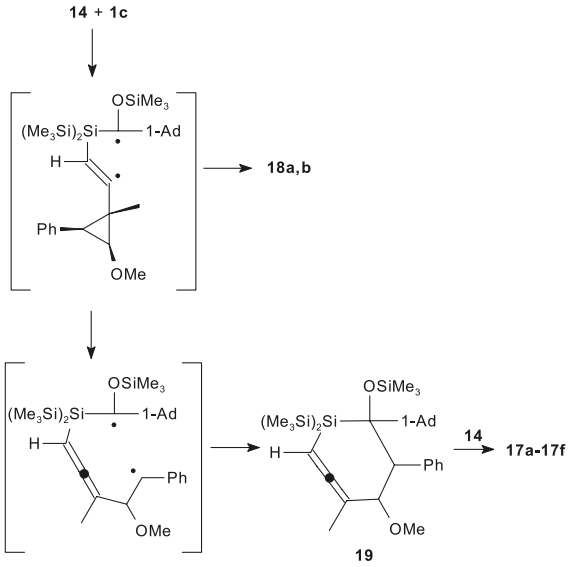
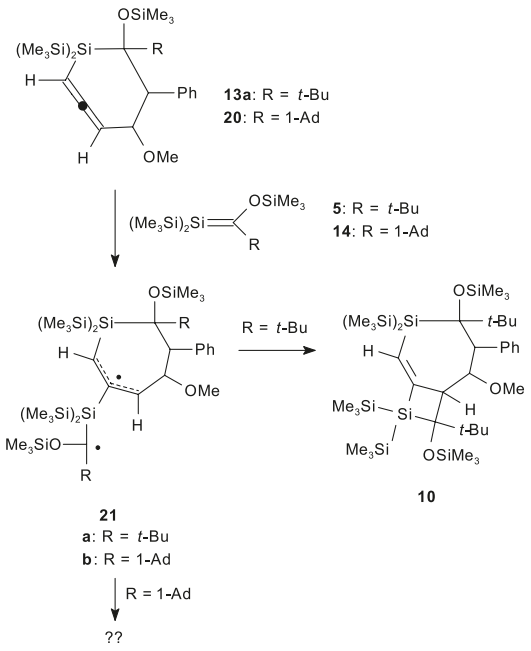


Scheme 7.



bulk of the adamantyl group apparently impedes cyclization to give a fused ring system. Thus, a complicated mixture of products is obtained when alkyne **1b** was added to silene **14**. The separation and characterization of the many products formed was not pursued.

Conclusions

The structure of silacycloheptenes **17a**–**17f**, resulting from the addition of alkyne **1c** to silene **14**, clearly indicates that the cyclopropyl ring has undergone a ring-opening rearrangement. Based on the location of the phenyl and methoxy substituents on the 7-membered ring in silacycloheptenes **17a**–**17f**, it can be concluded that the intermediate formed is an α-cyclopropylvinyl radical.

Table 1. Comparison of the product ratios obtained by the addition of alkynes **1a**–**1c** to $(Me_3Si)_2Si{=}C(R)(OSiMe_3)$.

		Silene	
Reaction	**Product**	**R= 1-Ad**	**R= t-Bu** (7)
Silene + 1a		100	100
Silene + 1b		0	48
		0	35
		0	17
Silene + 1c		81	68
		0	11
		19	21

The results presented in this report are very similar to those obtained previously (7); a summary of the product ratios obtained in the addition of alkynes **1a**–**1c** to the two silenes is presented in Table 1. The most significant difference is seen in the reactivity of silenes **5** and **14** toward alkyne **1b**. The *t*-butyl silene **5** reacts cleanly with the alkyne to form allenes **7a** and **7b**, silacyclobutenes **8a** and **8b**, and silacycloheptenes **10a**–**10g**. In contrast, the adamantyl silene **14** does not react cleanly with alkyne **1b**, and no products were isolated. Both silenes react with alkyne **1a** to give stereoisomers of an allenic silane (i.e., **6a** and **6b** from **5** or **16a** and **16b** from **14**) as the only products. With alkyne **1c**, a silacyclobutene (i.e., **9a** and **9b** from **5** or **18a** and **18b** from **14**) is formed in approximately the same relative amount. The remaining material is converted to the ring-opened silacyclohepta-1,2-diene (i.e., **13a** or **20**), which adds a second equivalent of the silene, most likely via a biradical that can disproportionate to give a silacycloheptene with an exocyclic methylene group (i.e., **11a**–**11f** from **5** or **17a**–**17f** from **14**) or undergo ring closure in the case of silene **5** (i.e.,

© 2008 NRC Canada

10a–**10g**). Interestingly, the additional steric bulk of the adamantyl group does not influence the reactivity of the initially formed 1,4-biradical; the ratio of silacyclobutene to silacycloheptene products remains the same, ~ 20:80. However, the bulky adamantyl group does influence the course of the reaction of the silacyclohepta-1,2-diene with an additional equivalent of silene: no fused ring products are obtained, presumably because of steric effects; only disproportioned products are observed.

Given that the addition of alkynes **1a**–**1c** to Brook silene **5** gave similar results, we are increasingly confident that the addition of the triple bond of alkynes to Brook silenes involves a biradical intermediate. Not surprisingly, the bulk of the alkyl substituent on the carbon of the silene does not alter the mechanism of the reaction. However, if the alkyne has an α-hydrogen, as in the case of alkyne **1a**, allenes such as **16a** and **16b** may be formed. It is likely that these products are formed by a concerted pericyclic ene-addition (7).

Experimental

General details

All reactions were performed in flame-dried Schlenk tubes, or NMR tubes sealed with a septum, under an inert atmosphere of argon. Irradiations were carried out using three 100 W mercury spot lamps (Blak-Ray B-100AP series; λ > 350 nm); the NMR tubes were cooled in a cold water jacket (~6 °C). Benzene-d_6 was distilled from LAH prior to use and stored over 4 Å molecular sieves. Acylsilane **15** (8), silene **14** (8), and alkynes **1a**–**1c** (6*a*) were prepared according to the previously reported procedures.

The NMR standards used are as follows: residual C_6D_5H (7.15 ppm) for ^{1}H NMR spectra and C_6D_6 central transition (128.0 ppm) for ^{13}C NMR spectra; Me_4Si as an external standard, 0 ppm, for ^{1}H-^{29}Si gHMBC spectra. IR spectra were recorded (cm^{-1}) from thin films. Mass spectra were obtained using an ionizing voltage of 70 eV, and the data are reported in mass-to-charge units *m*/*z*.

Irradiation of acylsilane 15 and alkyne 1a

A solution of acylsilane **15** (91 mg, 0.22 mmol) and alkyne **1a** (35 mg, 0.24 mmol) dissolved in C_6D_6 (1.5 mL) was irradiated for 3.5 h. ^{1}H NMR spectroscopic analysis of the crude product revealed a mixture of diastereomeric allenes **16a** and **16b** contaminated with small amounts of impurities and unreacted alkyne **1a**. The crude product was purified by preparative thin layer chromatography (silica gel, hexanes) yielding allenes **16a** and **16b** (53:47, 54 mg) as a pale yellow oil (44% yield). **16a** and **16b**: IR (cm^{-1}) 2945 (s), 2904 (s), 2848 (m), 1987 (s), 1603 (w), 1445 (m), 1240 (s), 1045 (s), 835 (s), 692 (m). **16a**: ^{1}H NMR (C_6D_6) δ: 7.16–7.19 (m, Ph*H*), 7.02–7.07 (m, Ph*H*), 5.60 (q, 1H, *H*C=C=C, *J* = 4.9 Hz), 3.70 (s, 1H, Me_3SiOCH), 2.78 (dt, 1H, PhC*H*, *J* = 8.1, 4.7 Hz), 1.99 (br s, 3H, Ad-C*H*), 1.79–1.90 (m, 1H, CH_2), 1.67–1.69 (br m, 12H, Ad-CH_2), 1.67–1.69 (m, 1H, CH_2) (9), 0.35 (s, 9H, $SiMe_3$), 0.34 (s, 9H, $SiMe_3$), 0.11 (s, 9H, $OSiMe_3$); ^{13}C NMR (C_6D_6) δ: 196.82 (C=*C*=C), 141.54 (*i*-Ph*C*), 128.54 (*m*-Ph*C*), 126.91 (*o*-Ph*C*), 126.44 (*p*-Ph*C*), 84.00 (Me_3OSiCH), 83.83 (H*C*=C=C), 76.06 (HC=C=*C*) (10), 41.24 (Ad-CH_2), 38.07 (4° Ad-*C*), 37.42 (Ad-CH_2), 29.05 (Ad-*C*H), 26.11 (Ph*C*H), 18.12 (CH_2), 1.38 ($OSiMe_3$), 1.30 (2 × $SiMe_3$); ^{29}Si NMR (C_6D_6) δ: 14.5 ($OSiMe_3$), –15.0 (2 × $SiMe_3$), –48.1 ($Si(SiMe_3)_2$). **16b**: ^{1}H NMR (C_6D_6) δ: 7.16–7.19 (m, Ph*H*), 7.02–7.07 (m, Ph*H*), 5.52 (q, 1H, *H*C=C=C, *J* = 4.9 Hz), 3.90 (s, 1H, Me_3SiOCH), 2.82 (dt, 1H, PhC*H*, *J* = 7.6, 4.9 Hz), 1.99 (br s, 3H, Ad-C*H*), 1.79–1.90 (m, 2H, CH_2), 1.67–1.69 (br m, 12H, Ad-CH_2), 0.32 (s, 9H, $SiMe_3$), 0.29 (s, 9H, $OSiMe_3$), 0.18 (s, 9H, $SiMe_3$); ^{13}C NMR (C_6D_6) δ: 196.25 (C=*C*=C), 140.93 (*i*-Ph*C*), 128.53 (*m*-Ph*C*), 127.06 (*o*-Ph*C*), 126.44 (*p*-Ph*C*), 83.77 (H*C*=C=C), 81.76 (Me_3OSiCH), 76.10 (HC=C=*C*) (10), 41.36 (Ad-CH_2), 38.01 (4° Ad-*C*), 37.39 (Ad-CH_2), 29.05 (Ad-*C*H), 26.02 (Ph*C*H), 17.42 (CH_2), 1.59 ($OSiMe_3$), 0.84 ($SiMe_3$), 0.44 ($SiMe_3$); ^{29}Si NMR (C_6D_6) δ 14.2 ($OSiMe_3$), –15.3 ($SiMe_3$), –15.7 ($SiMe_3$), –47.7 ($Si(SiMe_3)_2$). **16a** and **16b**: HR EI-MS for $C_{31}H_{52}OSi_4$ (M^+) (*m*/*z*): calcd. 552.3095; found 552.3102.

Irradiation of acylsilane 15 and alkyne 1c

Two solutions of acylsilane **15** (201 mg, 0.49 mmol; 200 mg, 0.49 mmol) and alkyne **1c** (148 mg, 0.80 mmol; 147 mg, 0.79 mmol) dissolved in C_6D_6 (1.5 mL for each) were simultaneously irradiated. The progress of the reactions was monitored by ^{1}H NMR spectroscopy. After 24 h of irradiation, the two reaction mixtures were combined and the solvent was removed by rotary evaporation (649 mg); a mixture of silacycloheptenes **17a**–**17f** and silacyclobutenes **18a** and **18b** in a ratio of 12:13:32:5:17:2:9:10, respectively, was obtained, as determined by ^{1}H NMR spectroscopy. The ratio of the combined products was the same as the ratio of the individual reaction mixtures. Chromatographic separation of the crude mixture (silica gel, hexanes/CH_2Cl_2 7:3) yielded a mixture of silacycloheptenes **17a**–**17f** (14:17:34:8:24:3, 327 mg, 0.32 mmol) and a mixture of silacyclobutenes **18a** and **18b** (56:44, 41 mg, 0.07 mmol). A portion of the mixture of silacycloheptenes **17a**–**17f** (206 mg, 0.20 mmol) was further separated by chromatography (two preparative plates, silica gel, hexanes/CH_2Cl_2 5:1, hexanes/CH_2Cl_2 9:1) yielding a mixture of silacycloheptenes **17a** and **17b** (58:42, 32 mg, 0.03 mmol), and silacycloheptenes **17c**–**17f** (65:14:19:2, 31 mg, 0.03 mmol). Further separation of silacycloheptenes **17c**–**17f** was attempted with little success. In general, no one compound could be separated from the mixture, and thus the compounds were characterized as mixtures. **17a** and **17b** (colourless crystals): IR (cm^{-1}) 2906 (s), 2850 (m), 1452 (w), 1247 (s), 1109 (w), 1043 (s), 837 (s), 745 (m), 684 (w); **17a**: ^{1}H NMR (C_6D_6) δ: 8.21 (br s), 7.07–7.28 (br m) (all Ph*H*), 6.64 (s, 1H, SiC(*H*) = CSi), 5.39 (s, 1H, C=CH_2), 5.02 (br s, 1H, C=CH_2), 4.48 (br s, 1H, MeOC*H*), 4.36 (s, 1H, Me_3SiOCH), 3.77 (d, 1H, PhC*H*, *J* = 2.4 Hz), 3.15 (s, 3H, MeO), 1.65–2.40 (br m, all Ad-C*H*), 0.62 (s, 9H, $SiMe_{3linear}$), 0.51 (s, 18H, 2 × $SiMe_3$), 0.49 (s, 9H, $SiMe_3$), 0.25 (s, 9H, $OSiMe_{3linear}$), 0.06 (s, 9H, $OSiMe_{3cyclic}$); ^{13}C NMR (C_6D_6) δ: 158.87 (SiC(H) = *C*Si), 151.61 (*C*=CH_2), 142.24 (Si*C*(H) = CSi), 137.11 (br s, *i,o*-Ph*C*), 127.50, 127.43, 126.48 (all Ph*C*), 115.07 (C=*C*H_2), 103.1 (Me_3SiOC_{cyclic}) (11), 81.22 (MeO*C*H), 80.66 (Me_3SiOCH), 66.13 (Ph*C*H), 56.11 (MeO), 42.19 (4° Ad-C_{cyclic}), 41.17, 40.93, 40.15, 37.30, 37.18, 29.22 (all Ad-*C*) (12), 5.53 ($OSiMe_{3cyclic}$), 4.17 ($SiMe_3$), 3.31 ($SiMe_3$), 2.99 ($SiMe_3$), 2.45 ($SiMe_3$), 2.40 ($SiMe_3$) (13); ^{29}Si NMR (C_6D_6) δ: 13.5 ($OSiMe_{3linear}$), 6.2 ($OSiMe_{3cyclic}$), –15.3, –17.0 (2 ×

General procedure for the addition of alkynes to silene 14

Excess alkyne **1a** or **1c** (1.5–4 equiv.) dissolved in hexanes or ether was added to silene **14** dissolved in the same solvent (8). The reaction mixture was left to stir overnight. The solvent was removed and the residue was placed under high vacuum to remove the excess alkyne. The residue was analyzed by ^{1}H NMR spectroscopy.

Synthesis and electrochemistry of new thienyl – Schiff base complexes[1]

A. Pietrangelo, B.N. Boden, M.J. MacLachlan, and M.O. Wolf

Abstract: The synthesis and characterization of nickel(II), copper(II), and vanadyl ($[V=O]^{2+}$) complexes of two new thienyl-substituted Schiff base ligands are reported. Cyclic voltammetry of some of these complexes showed oxidation waves, but none of the complexes formed conductive polymer films upon repeated cycling. UV–vis absorption spectroscopy shows that some of the complexes exhibit enhanced conjugation, and the radical cations formed on these chromophores appear to be too stable to undergo oxidative coupling.

Key words: Schiff base, salphen, conjugated polymer, electrochemistry.

Résumé : On a effectué la synthèse et on a caractérisé les complexes du nickel(II), du cuivre(II) et du vanadyle ($[V=O]^{2+}$) de deux ligands dérivés de bases de Schiff substituées par de groupes thiényles. La voltampérométrie cyclique a permis de montrer que quelques-uns de ces complexes présentent des vagues d'oxydation, mais aucun de ces complexes ne forme de films de polymères conducteurs après des cycles voltampérométriques répétés. La spectroscopie d'absorption UV/vis montre que certains de ces complexes donnent lieu à une conjugaison exaltée et que les cations radicaux qui se forment sur ces chromophores semblent trop stables pour subir des couplages oxydants.

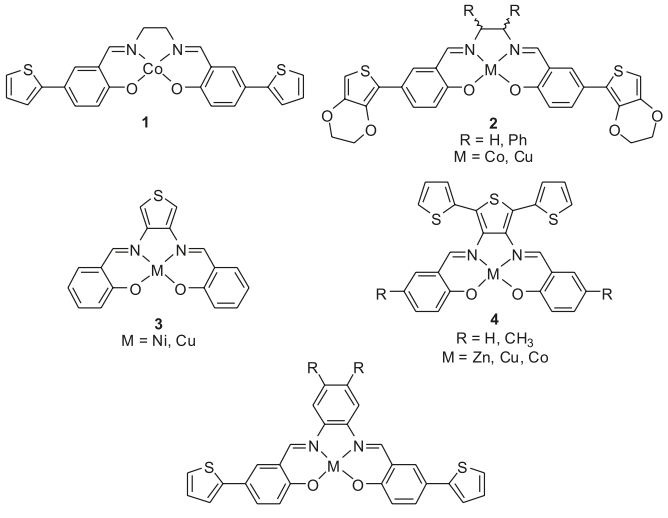
Mots-clés : base de Schiff, salphène, polymère conjugué, électrochimie.

[Traduit par la Rédaction]

Introduction

Conjugated polymers containing metal complexes are of interest because they combine the electronic properties of a highly delocalized π-system with the catalytic, magnetic, and optical properties of a metal (1). Schiff base complexes are a particularly intriguing class of metal complexes because they have large second-order and third-order NLO responses, are stable to over 300 °C, and have electronic or magnetic characteristics that permit additional functionality, such as chemical sensing, catalysis, and supramolecular organization (2–4). Both conjugated and non-conjugated polymers incorporating Schiff base complexes have been reported (5). Schiff base complexes containing a range of transition metals with pendant thiophene units have been electropolymerized to generate conductive polymer films that exhibit catalytic, sensing, and nonlinear optical properties (6).

The groups of both Swager and Reynolds have synthesized thiophene-containing Schiff base monomers and studied their electropolymerization. Oxidative coupling of monomers **1** and **2** (M = Co) gave conductive polymers where the metal does not contribute to conductivity but is necessary for electropolymerization (6*b*). Changing the substituents on **2** from R = H to larger groups such as R = Ph increases interchain spacing resulting in a reduction in conductivity for Cu(II)-containing polymers (6*c*). Reynolds investigated electropolymerization of monomers **3** and **4**, and found that polymerization occurs at the phenylene group for **3** (6*f*, 6*g*). In the case of **4**, polymerization could occur at either the thienyl or phenylene ring, except when R = CH_3, in which case polymerization occurs exclusively through the oligothiophene moiety.



We recently reported the electropolymerization of substituted Schiff base complexes **5**–**7** in microgravity (6*a*). In some cases, improved film order was observed when film

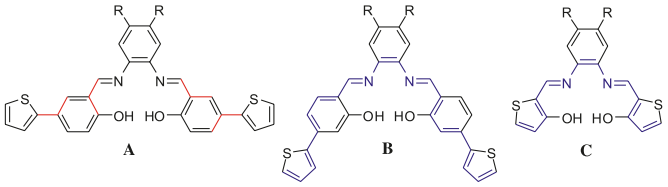
growth occurred in the absence of gravity-driven convection currents as evidenced by higher χ^3 susceptibilities.

While electropolymerization is known for salphen complexes formed from 5-(2-thienyl)salicylaldehyde, such as **5**–**7**, it has not been studied for salphens made from 4-(2-thienyl)salicylaldehyde. In compounds with the general structure **A**, the relative meta arrangement between the thienyl and imine substituents on the phenyl ring leads to less effective conjugation than para arrangements (structure **B**). Visually it may be noted that the π-conjugation pathway between the thienyl substituents for **A** cannot be drawn with alternating single and double bonds in any important resonance structure, whereas in structure **B** the conjugation appears to be improved, inasmuch as this model is an indication of delocalization. Thus, we set out to probe whether 4-substituted structures polymerize and whether the resulting materials show significantly different electronic properties from those made from 5-substituted monomers.



Another possible approach to a fully conjugated monomer involves replacing the terminal phenyl rings with thiophene groups, as in structure **C**. Here, we report a series of new conjugated monomers, along with electrochemistry and electronic absorption data.

Results and discussion

Synthesis

To prepare 4-(2-thienyl)salicylaldehyde **9**, 4-iodosalicylaldehyde **8** was coupled to 2-tributylstannylthiophene via Stille coupling affording **9** as a beige product in 92% yield (Scheme 1). Schiff base condensation of **9** with diamine **10a** gave salphen **11a** as an orange solid. With longer alkoxy chains, a longer reaction time was required for complete conversion to the product (**11b** and **11c**). The ^{1}H NMR spectrum of **11b** shows an imine resonance at δ 8.56 and a hydroxyl resonance at δ 13.34 (Fig. 1).

Heating **11b** at reflux in THF with the appropriate metal salt yielded the salphen metal complexes **12b**–**14b**. All three metal complexes crystallized readily, but the resulting crystals were thin and unsuitable for single crystal X-ray diffraction studies. The ^{1}H NMR spectrum of the diamagnetic Ni(II) complex **12b** was consistent with its structure, and all three complexes gave satisfactory mass spectrometry data and elemental analysis.

Thienolphenylenediimine (thienphen) complexes **19a** and **19b** were prepared by the route shown in Scheme 2. 3-Methoxythiophene **16** was prepared by Cu(I)-catalyzed Ullmann-type coupling of sodium methoxide with 3-bromothiophene **15** (7). Ortho-directed lithiation followed by quenching with DMF yielded 2-formyl-3-methoxythiophene **17** after work-up (8). Deprotection with BBr_3 afforded air-sensitive 2-formyl-3-hydroxythiophene **18** (9). Condensation

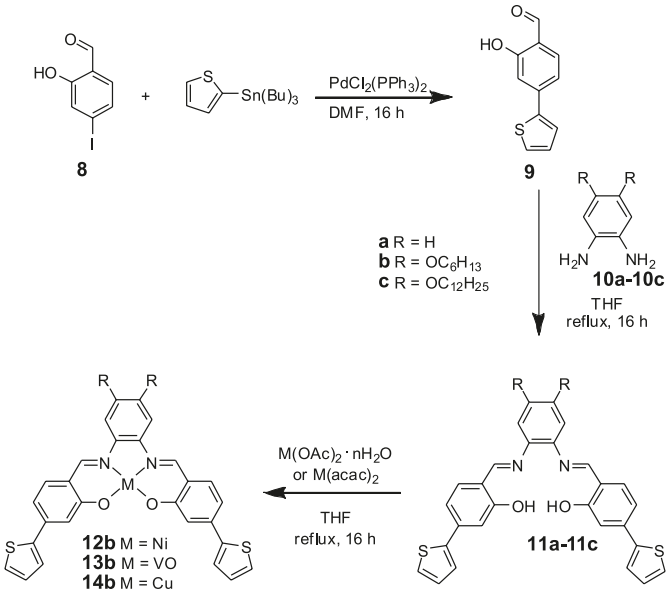

Fig. 1. ^{1}H NMR (300 MHz, $CDCl_3$) spectrum of **11b**.

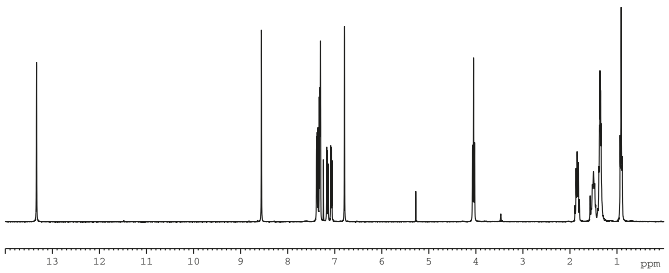
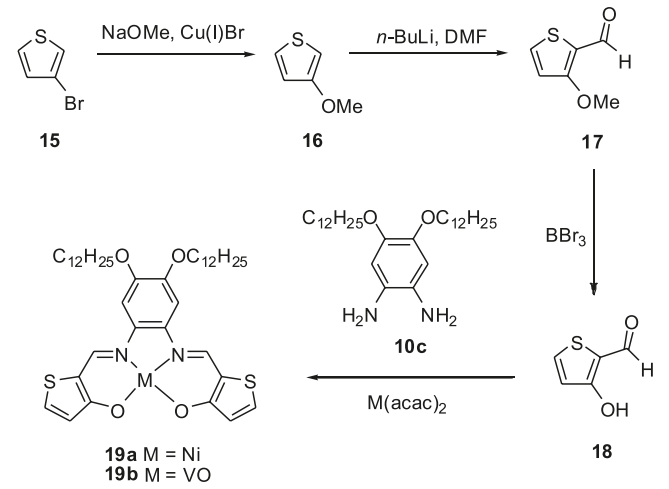


Scheme 2.



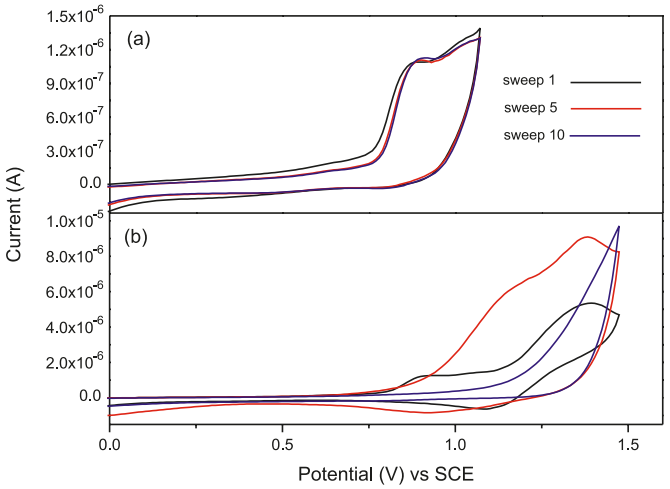
of **18** with diamine **10c** in the presence of a metal salt gave thienphen complexes **19a** and **19b** in 72% yield.

Electrochemistry

Electropolymerization of the three metal complexes **12b**–**14b** was attempted, but only the Ni(II) complex **12b** and Cu(II) complex **14b** showed oxidation waves within the solvent window. Repeated cycling through the first oxidation

© 2008 NRC Canada

Fig. 2. Cyclic voltammetry of **14b**. (*a*) 10 scans to 1.0 V. (*b*) 10 scans to 1.4 V. Only scans 1, 5 and 10 are shown. Pt-disc working electrode, 0.1 mol/L [*n*-Bu_4N]PF_6 in CH_2Cl_2, 100 mV/s scan rate.



wave (~1 V vs. SCE) for both compounds resulted in identical cyclic voltammograms (CVs) on each sweep (Fig. 2*a*). No film growth was visible on either Pt-disc or gold-on-glass working electrodes. Cycling through both the first and second oxidation waves (1.4 V vs. SCE) resulted in significant changes in sequential CVs (Fig. 2*b*). An increase in current and positive shift of the oxidation wave was observed, along with the formation of a red film on the electrode surface. CVs of these films showed no oxidation or reduction features in the solvent window.

To explain these results, we consider the radical cations expected to form upon one electron oxidation of the dithienylsalphen monomers (Fig. 3). The radical cation in the oxidized species $\mathbf{B}^{\cdot+}$ is more delocalized than in the oxidized species $\mathbf{A}^{\cdot+}$; as a result, the radical cation of **B** may be stable enough to prevent polymerization. This explains the lack of polymerization observed when scanning only to the first oxidation wave in **12b** and **14b**. There are no known examples of electropolymerization of thiophene-substituted benzene with an imine para to the thienyl group. Upon scanning to higher potentials, a redox-inactive film is formed. The cyclic voltammetry differs from that observed upon electropolymerization of **5**–**7** where a lower potential feature attributed to reversible oxidation of the polymer backbone is observed. It is possible that at high potentials monomers **12b** and **14b** undergo coupling at the alkoxy substituted phenyl rings as has been observed previously in related species prepared by Reynolds and coworkers (6*f*, 6*g*).

Cyclic voltammetry of **19a** (Fig. 4) shows a quasi-reversible wave at 0.7 V vs. SCE, as well as two higher-potential irreversible waves. These waves are attributed to oxidation of the metal centre as well as ligand-based oxidations. No sign of electropolymerization is observed with repeated scanning to potentials up to 2.0 V. Complex **19b** also does not electropolymerize and shows an anodic wave at 0.9 V vs. SCE with a large associated cathodic wave. It is possible that the oxidized species generated here are also stabilized via resonance stabilization of the radical cations (Fig. 5).

Fig. 3. Formation of the radical cations of **A** and **B**, showing one resonance structure for each monomer.

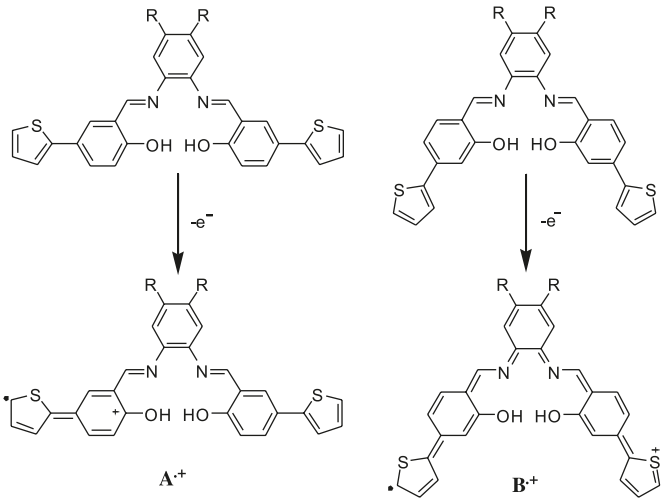


Fig. 4. Cyclic voltammetry of **19a**. The red trace (light trace in print version) shows scan reversal after the first oxidation wave; the black trace (heavy) shows a scan to 2 V. Pt-disc working electrode, 0.1 mol/L [*n*-Bu_4N]PF_6 in CH_2Cl_2, 100 mV/s scan rate.

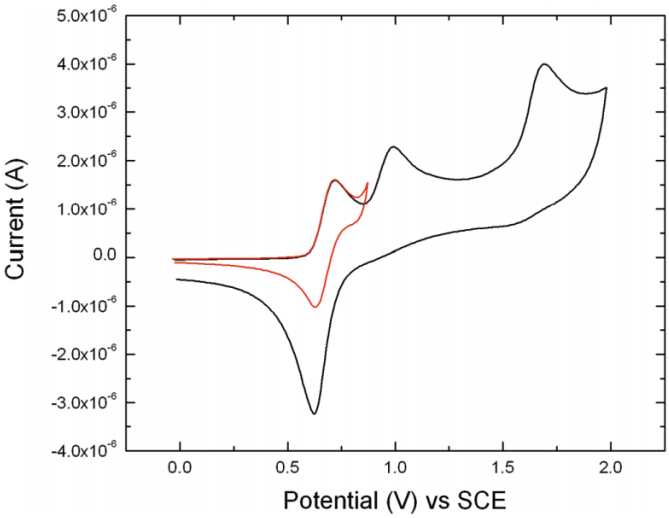

The electronic absorption spectra of the monomers can be used to provide insight into the degree of conjugation, because increased conjugation is expected to result in a bathochromic shift. The spectra for complexes **12b**–**14b** are shown in Fig. 6. At higher energy, the spectrum is dominated by peaks associated with the ligand (e.g., π–π* transitions) whereas the lower energy peaks are attributed to n–π* and metal-based transitions (metal to ligand charge transfer bands, d–d transitions). Comparison of UV–vis spectra of the 5-substituted monomers (**5**–**7**) with the corresponding 4-substituted species (**12b**–**14b**) reveals that, as expected, the low energy charge transfer absorption bands are shifted only slightly. The higher energy bands, on the other hand, are consistently shifted to lower energy in the 4-substituted monomers (cf. 320 nm for **5b** vs 350 nm for **12b**). These bands, attributed to π–π* transitions on the conjugated back-

Fig. 5. Formation of the radical cations of **19** (metal-based oxidation is not considered).

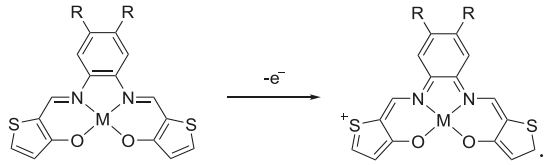

Fig. 6. Normalized absorption spectra of dithienylsalphen monomers in DCM (concentration 4.0 – 5.0 × 10^{-6} mol/L), where (*a*) **5b** (----), **12b** (—); (*b*) **6b** (----), **13b** (—); (*c*) **7b** (----), **14b** (—).

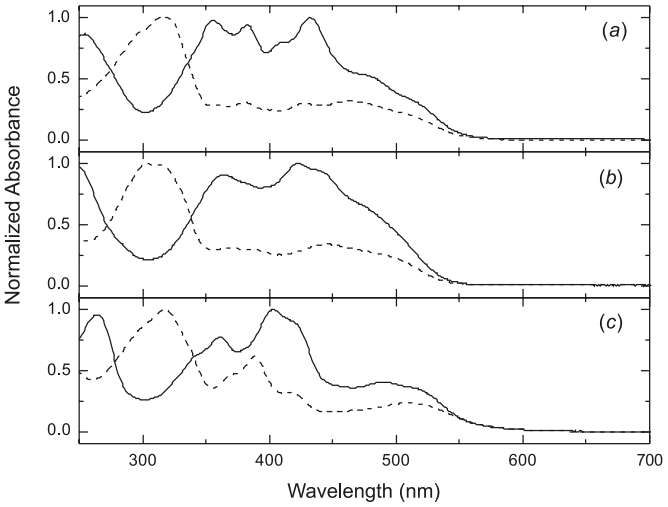


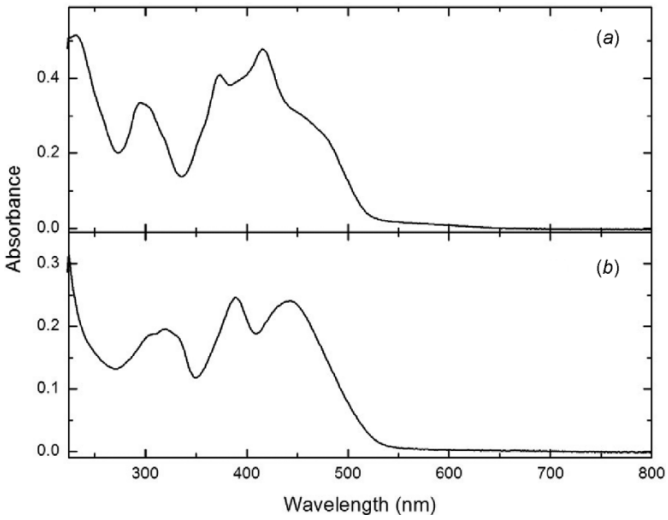
bone, shift in a manner consistent with enhanced conjugation.

The absorption spectra of **19a** and **19b** both have a higher energy band (~300 nm) attributed to the π–π* transition of the conjugated system (Fig. 7). This absorption is close in energy to the π–π* transition in **5b** and **6b** suggesting a similar extent of conjugation in these complexes. It is reasonable to conclude, based on these observations, that the conjugation is localized primarily over the diarylimine unit, regardless of whether the terminal aryl group is a substituted benzene or thiophene. The lower energy transitions in the spectra of **19a** and **19b** are attributed to CT transitions. The intensity of these transitions is comparable to the π–π* transition, possibly owing to an increase in the transition dipole moments as has been previously observed in similar complexes (10).

Conclusions

Two strategies for exploring the factors important in controlling electropolymerization of salphen complexes are reported. Extending the conjugation via substitution of the terminal phenyl ring at the 4-position with a thiophene group leads to a red-shift in the absorption spectrum, but results in species that do not electropolymerize. This is attributed to

Fig. 7. Absorption spectra of monomers in DCM (*a*) **19a** and (*b*) **19b**.



enhanced stabilization of the oxidized species owing to the extended conjugation. Similar observations were made for the thienolphenylenediimine complexes, and were also attributed to enhanced resonance stabilization of the oxidized species. Zotti has previously demonstrated that alkoxy-substituted hexathiophene oligomers do not polymerize well because of stabilization of the radical cation by the substituents (11). These results demonstrate that in order for electropolymerization to occur, the oxidized species cannot be too stable or the desired coupling reaction will not occur. The irreversibility of the oxidation waves associated with the organic groups suggests that other decomposition pathways may be available for the oxidized species. These results will guide future development of polymerizable thienyl – Schiff base complexes.

Experimental[3]

Compounds **8** (12) and **10a**–**10c** (13) were prepared according to literature procedures. Tetrahydrofuran (THF) was distilled over Na and benzophenone under N_2. All other chemicals were purchased from Sigma-Aldrich, TCI, or Fisher and used as received. All reactions were carried out under nitrogen unless otherwise noted. UV–vis spectra were obtained on a Varian Cary 5000 UV–vis NIR spectrometer using a 1 cm cuvette. Infrared spectra were obtained using KBr discs or on NaCl plates with a Bomem MB-100 spectrometer or a Nicolet 4700 FTIR spectrometer. ^{1}H NMR (300 or 400 MHz) and ^{13}C NMR (75.5 or 100.7 MHz) spectra were recorded on Bruker Avance 300 or Bruker Avance 400 spectrometers and were referenced internally to residual protonated solvent. Electrospray ionization (ESI) mass spectra were obtained on a Micromass LCT time-of-flight (TOF) mass spectrometer equipped with an electrospray ion source. Samples were analyzed in methanol–dichloromethane at 1 μmol/L. EI spectra were obtained with a double focusing

mass spectrometer (Kratos MS-50) coupled with a MASPEC data system with EI operating conditions of: source temperatures 120–220 °C and ionization energy 70 eV. Elemental analyses were obtained at the Microanalytical facility at the University of British Columbia. Melting points were recorded on a Fisher John's melting point apparatus.

Synthesis of 4-(2-thienyl)salicylaldehyde 9

A solution of 2-tributylstannylthiophene (8.0 mL, 25.2 mmol) in DMF (40 mL) was added to a mixture of 4-iodosalicylaldehyde **8** (4.095 g, 16.5 mmol) and trans-dichlorobis(triphenylphosphine) palladium (II) (0.606 g, 0.863 mmol). After heating for 16 h, the reaction solution was diluted with ether (100 mL) and washed with aqueous ammonium chloride (3 × 150 mL). The organic layer was filtered through silica and the solvent was removed under vacuum to obtain a beige solid, which was washed with hexanes and filtered to yield 3.088 g (0.794 mmol, 92%) of product; mp 92–94 °C. UV–vis (CH_2Cl_2, nm (L $mol^{-1}cm^{-1}$)): λ_{max} (ε): 331 (2.7×10^4). IR (KBr, cm^{-1}) ν: 3098, 3074, 2834, 2748, 1650, 1625, 1557, 1529, 1492, 1431, 1312, 1235, 1207, 1184, 995, 852, 800, 694. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 11.12 (s, 1H, O*H*), 9.84 (s, 1H, C*H*O), 7.53 (d, 1H, *J* = 8.1 Hz, aromatic C*H*), 7.45 (d, 1H, *J* = 3.9 Hz, aromatic C*H*), 7.40 (d, 1H, *J* = 4.8 Hz, aromatic C*H*), 7.25 (dd, 1H, J_1 = 8.1 Hz, J_2 = 1.5 Hz, aromatic C*H*), 7.21 (s, 1H, aromatic C*H*), 7.11 (dd, 1H, J_1 = 4.8 Hz, J_2 = 3.9 Hz, aromatic C*H*). ^{13}C NMR (75.5 MHz, $CDCl_3$) δ: 195.7, 162.3, 142.7, 142.6, 134.5, 128.7, 127.7, 125.9, 119.8, 117.6, 114.1. ESI–MS *m*/*z*: 227 ($[M + Na]^+$). Anal. calcd. for $C_{11}H_8O_2S$: C 64.69, H 3.95; found C 64.30, H 3.99.

Synthesis of *N,N′*-Phenylenebis(4-(2-thienyl)salicylideneimine 11b

1,2-Dihexyloxy-4,5-diaminobenzene **10b** (0.297 g, 0.962 mmol) and 4-thienylsalicylaldehyde **9** (0.486 g, 2.37 mmol) were combined in a 100 mL Schlenk flask under nitrogen. To this mixture was added 20 mL of dry THF to form an orange solution. The solution was heated to reflux overnight and was cooled to room temperature, after which the volume of solution was reduced. Addition of methanol to the solution caused precipitation of an orange solid, which was collected on a Büchner funnel and washed with additional methanol. Yield: 0.587 g, 0.86 mmol, 89%. Compounds **11a** and **11c** were synthesized in an analogous fashion using **10a** and **10c** with yields of 0.355 g (0.66 mmol, 77%) and 0.525 g (0.61 mmol, 66%), respectively.

Electrochemistry

Cyclic voltammetry experiments were conducted using either a Pine AFCBP1 or Autolab potentiostat. The working electrode was a Pt disk, an indium tin oxide (ITO) thin film on glass, or Au (1000 Å) deposited on Si using a Cr (50 Å) adhesion layer. The counter electrode was a Pt mesh and the reference electrode a silver wire. An internal reference (decamethylferrocene) was added to correct the measured potentials with respect to saturated calomel electrode (SCE). $[(n\text{-}Bu)_4N]PF_6$ was used as a supporting electrolyte and was purified by triple recrystallization from ethanol and dried at 90 °C under vacuum for 3 days. Dichloromethane used for CV was purified by passing the solvent through an activated alumina tower. Polymerizations were carried out in a solution containing 0.1 mol/L electrolyte, and 1 mM monomer. Polymers were grown by cycling a potential between 0 V and the onset of monomer oxidation (= 1.6 V) for a total of 10 cycles, at a scan rate of 100 mV/s.

Acknowledgement

We thank the Canadian Space Agency (CSA) and Natural Sciences and Engineering Research Council of Canada (NSERC) for funding. We thank Dr. Bryan Sih for cyclic voltammetry measurements.

Synthesis and evaluation of the in vitro DNA-binding properties of chiral *cis*-dichloro(pyridyloxazoline)platinum(II) complexes[1]

David W. Dodd, Heather E. Toews, Michael J. Trevail, Michael C. Jennings, Robert H.E. Hudson, and Nathan D. Jones

Abstract: A series of chiral cis-dichloro(pyridyloxazoline)platinum(II) and palladium(II) complexes were synthesized and their reactivity towards a defined sequence of single-stranded and double-stranded DNA was investigated in comparison to cisplatin. The compounds differed in the nature and absolute configuration of the substituent at the *C*4 position of the oxazoline ring. The DNA-binding ability of these compounds was evaluated by HPLC analysis, post metal exposure, of enzymatic digests of an undecamer duplex containing one putative metallation site. Polyacrylamide gel electrophoresis (PAGE) and thermal denaturation confirmed the results of the HPLC analysis, which showed that the stereochemistry and character of the substituent at the *C*4 position of the oxazoline ring had little effect on DNA binding, possibly due to the formation of monofunctional adducts.

Key words: cisplatin, chiral, pyridyloxazoline, DNA-binding studies, platinum, palladium.

Résumé : On a réalisé la synthèse d'une série de complexes chiraux des *cis*-dichloro(pyridyloxazoline)platine(II) et palladium(II) et on a étudié leur réactivité, par comparaison au cisplatine, vis-à-vis une séquence définie d'ADN à un brin et à deux brins. Les composés diffèrent dans la nature et la configuration absolue du substituant dans la position *C*4 du noyau oxazoline. La capacité de liaison à l'ADN de ces composés a été évaluée par une analyse par chromatographie liquide à haute performance (CLHP) à la suite de l'exposition aux métaux, de mélanges obtenus par digestion enzymatique d'un duplex undécamère contenant un site putatif de métallation. Une électrophorèse sur gel de polyacrylamide (EGPA) et une dénaturation thermique ont permis de confirmer les résultats de l'analyse de CLHP qui avait montré que la stéréochimie et le caractère du substituant en position *C*4 du noyau oxazoline n'ont que peu d'effet sur la fixation sur l'ADN, probablement en raison de la formation d'adduits monofonctionnels.

Mots-clés : cisplatine, chiral, pyridyloxazoline, études de fixation d'ADN, platine, palladium.

[Traduit par la Rédaction]

Introduction

The serendipitous discovery of the antiproliferative properties of *cis*-dichlorodiammineplatinum(II) (cisplatin) over 30 years ago led to its eventual use as a chemotherapeutic agent (1). Today, cisplatin remains one of the most widely used drugs for the treatment of solid cell tumours (2). Motivated by cisplatin's effectiveness, similar treatments have been pursued; however, despite vigorous research towards this end, only a handful of successful analogues have been developed (3). While complexes of other metals, such as titanium, rhenium, ruthenium, and gallium, have shown promise as potential antineoplastic agents, the literature of metal anticancer therapeutics is dominated by platinum complexes (4). The efficacy of cisplatin in the treatment of carcinomata is almost universally thought to be due to its ability to form intrastrand adducts between adjacent purines in DNA (2–5).

The design principles of cisplatin analogues were described two years after the first clinical trials: the complexes should be neutral and four-coordinate with two coordination sites occupied by labile leaving ligands and two occupied by inert am(m)ine ligand(s) in a cis geometry (6).

Once cisplatin enters the cell, the lower intracellular chloride concentration permits dissociation of the halides resulting in the formation of an aquated platinum centre. This cationic species reacts predominantly with the *N*7 of guanine or adenine nucleobases (5). The guanine adduct is thought to be stabilized through hydrogen bonding of an ammine proton with the carbonyl oxygen of *C*6 making deoxyguanosine dinucleotide (-dGpdG-) the preferred target sequence (7). Binding to DNA in this fashion causes a kinking of the double helix and a widening of the minor groove; this can inhibit transcription and lead to apoptosis by inducing the

binding of high mobility group (HMG) box proteins (5). Although cisplatin is indeed an effective drug, there are problems associated with prolonged dosages, such as toxicity and acquired resistance. Therefore, the search continues for improved platinum-based therapies.

While several thousand cisplatin analogues have been synthesized and tested for biological activity (8), only a select few have been entered into clinical trials. This has led many in the scientific community to believe that the search for Pt(II) chemotherapeutics is futile. Discovery of a drug suitable for clinical trials is a rare occurrence in every field, yet failure in cisplatin analogue discovery draws inordinate attention. Perhaps the reason for the reluctance to continue in this area is due to the remarkable simplicity of cisplatin itself: even minor substitutions cause drastic changes in efficacy. Although the structure of cisplatin is simple, the mode of action certainly is not, and many questions remain unanswered (5).

Although it is unlikely that a simple substitution of the ammine ligands will yield a complex with activity surpassing that of cisplatin, more elaborate changes, such as variation in the σ-donation character of the ligand and the introduction of chirality, could yield complexes with novel reactivities in vitro and corresponding cytostatic effects in vivo.

As DNA is a chiral molecule, binding of chiral platinum complexes results in diastereomeric adducts. Different binding affinities for enantiomeric complexes have been reported and (of no lesser importance) it has also been found that the diastereomeric adducts may be dealt with by cellular machinery in vastly different ways (9). For example, the *S,S*-enantiomer of (1,2-diaminocyclohexane)oxalatoplatinum(II) (Fig. 1, *S,S*-**I**) is significantly more mutagenic than the *R,R*-enantiomer, and consequently only the latter was entered into clinical trials (9, 10). Other examples of chiral DNA-binding Pt complexes that have been studied in detail include dichloro(*N*-methyl-2-aminomethylpyrrolidine)platinum(II) (Fig. 1, **II**) (10) and complexes involving 1,2-bis(aminomethyl)carbobicyclic ligands (Fig. 1, **III**) (11). Differences in reactivities of enantiomeric complexes towards DNA are rare (12).

Although hydrogen bonding involving coordinated NH groups has been considered necessary for cytostatic activity (13), there are examples of compounds lacking an NH proton that display significant antitumour effects (14, 15).

Pyridyloxazolines, derived from the condensation of a chiral β-amino alcohol with 2-cyanopyridine, are planar, bidentate ligands for platinum(II) and are necessarily bound cis (Fig. 2). The substituent at the α-position of the amino alcohol, *C*4 in the resultant oxazoline ring, can be varied greatly and inexpensively as the alcohols are obtained by the reduction of the corresponding enantiopure amino acids (16, 17).

Pyridyloxazoline Pt(II) complexes have found use in enantioselective enyne cyclizations (18), and the unsubstituted complex **6** has shown some promise as an anticancer therapeutic, displaying significant toxicity towards rat brain tumour cell lines in vitro (19). The palladium analogues have not been used in DNA-binding studies, but have been investigated as asymmetric catalysts for the intermolecular asymmetric Heck reaction (16).

In this work, binding of these complexes to a defined sequence of oligomeric double-stranded (ds) DNA containing one putative metallation site was investigated by HPLC analysis of enzymatic digests. The duplexes that were exposed to the metal complexes were also analyzed by thermal denaturation and polyacrylamide gel electrophoresis (PAGE). The difference in binding abilities between enantiomers and side-chain identity was investigated; the objective being to gain a better understanding of the structure–activity relationship of chiral platinum antineoplastic agents.

Experimental[3]

General

Pyridyloxazoline ligands (17) and the metal precursors $PdCl_2(PhCN)_2$ (20) and *cis*/*trans*-$PtCl_2(SMe_2)_2$ (21) were synthesized according to literature procedures and characterization data matched those of the known compounds. Platinum compounds **1**–**3**, **5**, and **6** were synthesized by a general procedure as outlined for *R*-**1**; spectral data for enantiomeric complexes were identical, as expected. Solution ^{1}H NMR spectra were collected using a Varian 400 spectrometer (400.09 MHz for ^{1}H and 100.61 MHz for ^{13}C) at RT in

$CDCl_3$ (unless otherwise noted) and referenced to residual ^1H or ^{13}C in the deuterated solvent. Coupling constants are given in Hz. Elemental analyses were conducted by Chemisar Laboratories Inc., Guelph, ON. Denaturing polyacrylamide gels were cast and run according to literature procedures (22). The resultant gels were documented by colour digital photography over fluorescent TLC plates illuminated at 258 nm. For clarity, the image presented has been rendered in grayscale, inverted and contrast/brightness adjusted in Adobe Photoshop.

Optical rotations were recorded on an Atago Polax-2L polarimeter at a concentration of 1 g /100 mL at 589 nm in CH_2Cl_2 solution.

Stock solutions of the complexes (40 μmol/L) were prepared by dissolution in a minimum amount of DMF (<0.5 mL) followed by dilution with Milli-Q deionized water to 100 mL and stored at RT in the dark for no longer than 2 weeks. DNA was purchased from the University of Calgary DNA Services and used without further purification.

Syntheses

*Dichloro-2-[(4**R**)-4-**iso**-propyl-4,5-dihydro-1,3-oxazol-2-yl]pyridineplatinum(II) (**R**-1)*

The title complex was synthesized by the addition of *cis*/*trans*-$PtCl_2(SMe_2)_2$ (0.23 g, 0.60 mmol) to 5 mL of 1,2-dichloroethane containing a slight excess of pyridyl-oxazoline ligand (0.14 g, 0.72 mmol). The resultant yellow solution was heated to reflux for 4 h over which time it darkened in colour. The solvent was removed in vacuo and the remaining oil triturated with Et_2O (10 mL). Vacuum filtration gave 0.27 g (94%) of *R*-**1** as an orange/yellow powder. [α] = –65.0°. ^1H NMR δ: 9.51 (m, 1H, py), 8.17 (m, 1H, py), 7.76 (m, 1H, py), 7.63 (m, 1H, py), 5.00 (m, 1H, CH_2), 4.86 (m, 1H, CH), 4.71 (m, 1H, CH_2), 2.99 (m, 1H, CH), 0.98 (d, 3H, CH_3, ^3J = 7.1), 0.83 (d, 3H, CH_3, ^3J = 6.9). $^{13}C\{^1H\}$ NMR δ: 173.2, 149.7, 145.0, 139.4, 129.4, 126.6, 73.3, 68.2, 28.9, 18.9, 14.1. *Dichloro-2-[(4**S**)-4-phenyl-4,5-dihydro-1,3-oxazol-2-yl]pyridineplatinum(II) (**S**-3)*

Yield: 92%. HRMS (ESI) calcd. for (M + Na) $C_{14}H_{12}N_2ONaCl_2Pt$: 511.9872; found: 511.9869. Anal. calcd. for $C_{14}H_{12}N_2Cl_2OPt$: C, 34.30; H, 2.47; N, 5.71%. Found: C, 34.56; H, 2.75; N, 5.73%.

*Dichloro-2-[(4**R**)-4-**iso**-propyl-4,5-dihydro-1,3-oxazol-2-yl]pyridinepalladium(II) (**R**-4)*

The title complex was synthesized as described in the literature. Characterization data matched those of the known compound (17).

*Dichloro-2-[(4**S**)-4-**iso**-propyl-4,5-dihydro-1,3-oxazol-2-yl]pyridinepalladium(II) (**S**-4)*

The title complex was made in the same way as *R*-**4**. Spectroscopic data matched those of the enantiomeric compound.

*Dichloro-2-[(4**S**)-4-**sec**-butyl-4,5-dihydro-1,3-oxazol-2-yl]pyridineplatinum(II) (5)*

Yield: 84%. ^{1}HNMR δ: 9.26 (d, 1H, py, ^3J = 5.5), 7.8 (dd, 1H, py, ^3J = 5.5, ^3J = 7.8), 7.76 (d, 1H, py, ^3J = 7.6), 7.56 (dd, 1H, py, ^3J = 7.8, ^3J = 7.6), 5.13 (m, 1H, CH_2), 4.87 (m, 1H, CH), 4.78 (m, 1H, CH_2), 2.75 (m, 1H, CH), 1.29 (m, 2H, CH_2), 1.00 (t, 3H, CH_3, ^3J = 7.4), 0.78 (d, 3H, CH_3, ^3J = 6.8). $^{13}C\{^1H\}$ NMR δ: 173.2, 149.8, 145.0, 139.3, 129.3, 126.5, 73.3, 66.9, 35.5, 26.5, 18.0, 11.9. HRMS (ESI) calcd. for (M + Na) $C_{12}H_{16}N_2ONaCl_2Pt$: 492.0185; found: 492.0177.

Dichloro-2-[4,5-dihydro-1,3-oxazol-2-yl]pyridineplatinum(II) (6)

The title compound has been previously made by a different route (19). Following the procedure for *R*-**1**, **6** was obtained in 72% yield. The limited solubility of this complex did not allow for the measurement of NMR spectral data. Anal. calcd. for $C_8H_8N_2Cl_2OPt$: C, 23.20; H, 1.95; N, 6.76%. Found: C, 23.50; H, 1.89; N, 6.66%.

Crystallography

An orange plate was cut loose and then mounted on a glass fibre. Data were collected at low temperature (–123 °C) on a Nonius Kappa-CCD area detector diffractometer with COLLECT (Nonius B.V., 1997–2002). The unit cell parameters were calculated and refined from the full data set. Crystal cell refinement and data reduction were carried out using HKL2000 DENZO-SMN (23). The absorption correction was applied using HKL2000 DENZO-SMN (SCALEPACK). The crystal data and refinement parameters of *S*-**1** are listed in Table 1.

The reflection data and systematic absences were consistent with a monoclinic space group: $P2_1$. The SHELXTL/PC V6.14 for Windows NT (Sheldrick, G.M., 2001) suite of programs was used to solve the structure by direct methods. Subsequent difference Fourier syntheses allowed the remaining atoms to be located. There were two independent molecules in the asymmetric unit. For this crystal, twinning was also an issue; it is discussed below. Only the heavy atoms (Pt, Cl) were refined anisotropically, as some of the lighter atoms became non-positive definite when they were allowed to refine freely. The hydrogen atom positions were calculated geometrically and were included as riding on their respective carbon atoms. The largest residue electron density peak (0.877 e/Å^3) was associated with one of platinum atoms. Full-matrix least-squares refinement on F^2 gave R_1 = 3.21 for 2σ data and wR_2 = 6.66 for all data (GooF = 1.021).

The structure was solved readily, but the initial refinement stalled at R = 12.9%. Further, the light atoms did not refine successfully with an anisotropic model. There were signs of non-merohedral twinning in the *E* statistics and the Fobs values were consistently higher than the *F* calculations. WinGX (24) was used to "detwin" the data. ROTAX (25) found the Twin Law, which turned out to be a 180° rotation about the direct lattice direction (100). "Make HKLF5" was used to generate the detwinned file used in further refinement.

The structure refinement improved considerably with better values for R_1, wR_2, GooF, standard uncertainties, and residual electron density. The final R_1 value came down to 3.21%. The final solution, however, could still not be refined completely anisotropically, and the light atoms were left isotropic in the refinement. The constant for the Twin Law refined to a value of 0.47309. All these points served to confirm the correct Twin Law was chosen.

Nuclease digest studies

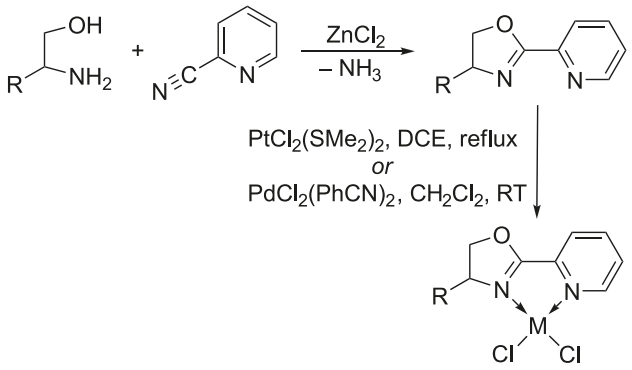
Duplex DNA was prepared by heating a 1:1 mixture of the complementary sequences in 10 mmol/L $NaClO_4$ to 90 °C and allowing the solution to come slowly to RT. The solution was then cooled to 4 °C for 2 h. Both single- and double-stranded DNA (2 μmol/L) were reacted with the complexes in a 1:1 molar ratio in 200 μL of 10 mmol/L $NaClO_4$ for 48 h in the dark. The buffer was then adjusted to 50 mmol/L Tris, 20 mmol/L $MgCl_2$, pH 7.5. Bovine serum albumin (BSA) was added to a final concentration of 0.02 μg/mL, and the DNA was digested sequentially with bovine pancreas DNase I (Sigma, 36 U for 4 h), nuclease P1 (Sigma, 10 U for 18 h), and alkaline phosphatase (Promega, 20 U for 4 h). The samples were then heated to 90 °C for 2 min to denature the enzymes and centrifuged for 10 min at 10 000 g. The supernatant was analyzed at 254 nm by RP–HPLC on a Varian Microsorb 100 Å C18 column using a flow rate of 1 mL min^{-1} and a solvent system of 100:0 0.1 mol/L aqueous [Et_3NH][OAc] (pH 6.5):MeCN from 0–5 min followed by a linear ramp to 90:10 over a period of 20 min. Nucleoside peaks were identified by co-injection of standards. The areas under the peaks were found by integration and analyzed in relation to one another. These digests and the HPLC analyses thereof were carried out in triplicate.

Results and discussion

The modular nature of the pyridyloxazoline ligand scaffold, combined with its brief synthesis from readily available enantiopure starting materials and facile metal coordination, permitted the rapid development of small libraries of enantiomeric Pt(II) and Pd(II) complexes. The pyridyloxazoline ligands were made by the $ZnCl_2$-catalyzed coupling of 2-cyanopyridine with the β-amino alcohols, valinol, phenylalaninol, phenylglycinol, isoleucinol, and ethanolamine, respectively, using the procedure developed by Bolm et al. (Scheme 1) (17). The amino alcohols, except

© 2008 NRC Canada

Scheme 1. Synthesis of dichloro(pyridyloxazoline)metal(II) complexes.



for ethanolamine, were themselves readily made by $NaBH_4/I_2$-reduction of both enantiomers of the corresponding amino acids, during which time no racemization occurs (26). The metal(II) complexes were made in good to excellent yields by the reaction of slight molar excesses of the ligands either with *cis*/*trans*-$PtCl_2(SMe_2)_2$ or *trans*-$PdCl_2(PhCN)_2$ in refluxing 1,2-dichloroethane or CH_2Cl_2 at RT. The complexes were yellow–orange, microcrystalline solids that were freely soluble in polar organic solvents, such as $CHCl_3$ and CH_2Cl_2, and insoluble in Et_2O and hexanes. All complexes were also sufficiently soluble in H_2O to allow DNA-binding studies.

The molecular structure of *S*-**1** is shown in Fig. 3; it is isostructural with the known analogous palladium derivative (16). As expected, the metal adopts an approximately square-planar coordination geometry, and the pyridyloxazoline ligand is roughly planar except for the *iso*-propyl substituent at the 4-position of the oxazoline ring, which projects prominently from one face of the complex and makes a torsion angle with it of ~62 °. The ligand has a "bite angle" of 79.711(4)°, which is nearly identical to that found for the palladium analogue, but unlike in that compound, whose M–oxazoline bond (2.017(5) Å) is significantly shorter than its M–pyridine bond (2.048(6) Å), there is no difference in the two M–N distances, which are both 2.015(11, 12) Å in *S*-**1**. However, there is, as in the palladium analogue, a significant difference in the M–Cl distances: in complexes of both metals, the M–Cl bond trans to the oxazoline ring is longer than that trans to the pyridine ring, which consistently suggests that oxazoline is a stronger field ligand than pyridine, and implies strong contribution from the resonance form that places a formal negative charge on the N atom of the free oxazoline.

The particular undecamer sequence chosen for the present studies (shown below) has been used by Lippard and coworkers to obtain a solution NMR structure of a platinated duplex and is known to adopt the typical B-form of DNA in the absence of platination (27). The putative metallation site is underscored.

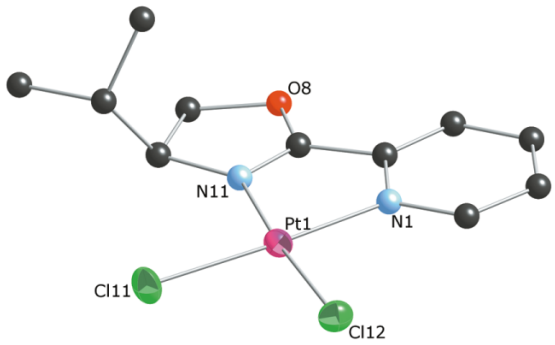
After incubation of the ds DNA test sequence with complexes **1**–**6** and complete digestion of the oligonucleotides,

Fig. 3. Partial ORTEP representation of the molecular structure of *S*-**1**, with H atoms omitted for clarity. Thermal ellipsoids for Pt and Cl atoms are shown at 50 % probablility; all other atoms are refined isotropically (see Experimental section). Selected bond distances (Å) and angles (°), with estimated standard deviations in parentheses: Pt1–N1 2.015(11), Pt1–N11 2.015(12), Pt1–Cl11 2.2869(3), Pt1–Cl12 2.298(4), N1–Pt1–N11 79.711(4), Pt1–N11–C10–C12 61.629(19).



HPLC analyses were carried out. Nucleoside peaks were identified by the coinjection of standards, and integrated peak-area ratios were calculated. The ratios of nucleosides were calculated and analyzed as they are independent of reaction volume and concentration, are not influenced by volume of sample used for HPLC analysis, and eliminate errors associated with pipetting technique. Binding of cisplatin analogues to a ds DNA sequence is consistent with a marked decrease in dG/dC and a slight decrease in dA/dC because dG and dA are known to coordinate metal complexes. This dramatically shifts their retention times in RP–HPLC (28), although for the present work we did not conclusively identify the peaks belonging to metal–nucleoside adducts. The nucleoside peak-area ratios for the control digests conformed to the stoichiometry of the nucleosides within the DNA strands, given their relative absorptivities (extinction coefficients were obtained from ref. 29). The dG/dA ratio can be used as a measure of binding selectivity for dG over dA.

Results are shown in Fig. 4 for 1 equiv. of complex per duplex DNA. From the ratios of dG/dC, it can be seen that the pyridyloxazoline complexes tested are less reactive towards dG than cisplatin. From comparison with the control experiment, the composition of nucleosides is reduced in dG by ~40% and dA by ~8% upon exposure to cisplatin. Higher degrees of platination may be obtained by reaction at elevated temperatures with an excess of platinum salt (28) or through the use of bis-DMF/NO_3^- compounds (27). The low thermal stability of our test sequence precluded us from the use of the former and we avoided the latter as we wished not for complete saturation, but to determine the differences in binding between enantiomeric complexes. In all digests, dC/dT remains approximately constant implying that these bases are not reactive towards the platinum complexes, as expected (data not shown). Enantiomeric complexes showed no discernable patterns in their DNA-binding ability. In the case where R = *i*Pr [*R*-**1**: Δ(dG) = –32%; *S*-**1**: Δ(dG) = –23%], the *S* enantiomer is less reactive towards dG, but in the case where R = Ph [*R*-**2**: Δ(dG) = –16%; *S*-**2**: Δ(dG) = –23%], it is the *R* enantiomer that is less reactive. In the case

Fig. 4. Ratios of peak area for enzymatic digests of the undecamer duplex after exposure to no Pt containing compound (0), cisplatin (cisPt), and compounds **1**–**6**. Error bars are +/– 1 standard deviation.

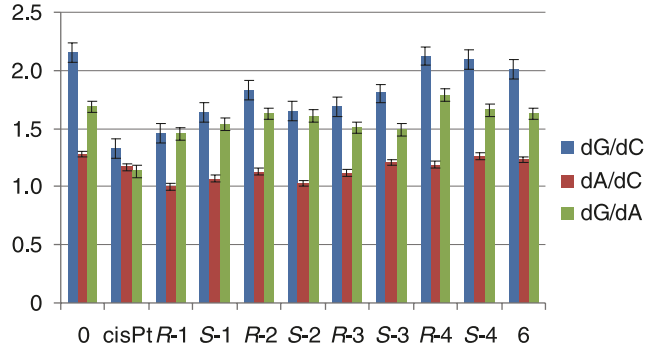

Fig. 5. Ratio of peak areas for the enzymatic digests of the bottom strand undecamer after exposure to no Pt containing compound (0), cisplatin (cisPt), and compounds **1** and **2**. Error bars are +/– 1 standard deviation.

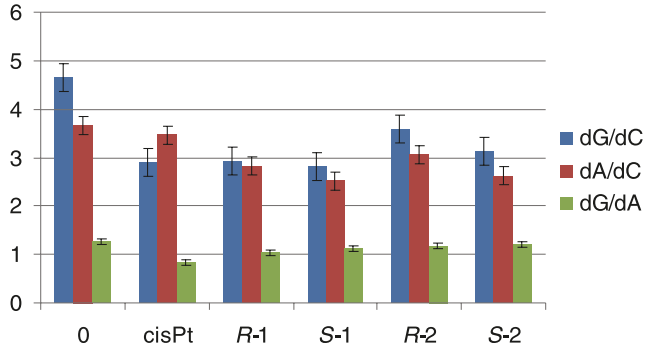
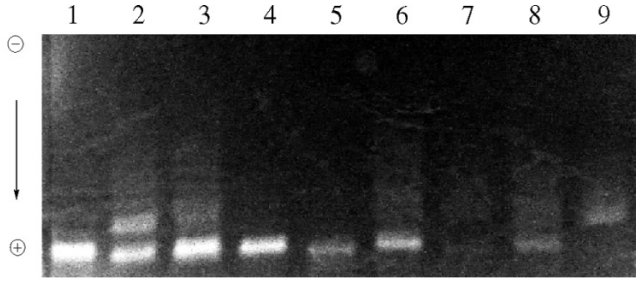


of R = Bn [*R*-**3**: Δ(dG) = –22%, *S*-**3**: Δ(dG) = –16%], there is little difference due to stereochemistry (Fig. 4). The unsubstituted ligand complex **6** (R = H) was the least reactive of the platinum complexes [Δ(dG) = –7%]; this was somewhat surprising as it was thought the decreased steric constraints would allow for greater DNA binding. It has been shown formerly that this compound has antineoplastic effects on cancer cells in vitro (19). The lack of binding in our study implies that this compound may have a different biological target and (or) mode of action. Both palladium complexes tested showed no significant deviations from the negative control [*R*-**4**: Δ(dG) = –1.4%; *S*-**4**: Δ(dG) = –3%]. Palladium complexes in a cis geometry are known to have lower binding affinities towards DNA than *cis*-dichloroplatinum compounds; however, the comparable trans-complexes often offer cytostatic effects surpassing that of cisplatin (30).

With respect to reactivity toward deoxyadenosine nucleosides in the context of duplex DNA, a parallel to the reactivity observed towards dG was found. For compound **1**, the *R*-enantiomer [Δ(dA) = –22%] was more reactive than the *S*-enantiomer [(Δ(dA) = –16%]; whereas for compound **2**, *R*-**2** [(Δ(dA) = –12%] was less reactive than *S*-**2** [(Δ(dA) = –19%]. For compound **3**, the reactivity of the *R*-stereoisomer [(Δ(dA) = –13%] was greater than that of the *S* [(Δ(dA) = –5%]. The loss of dA caused by compounds *R*-**4**, *S*-**4**, and **6** was modest at Δ(dA) = –7%, –1.5%, and –4%, respectively.

In the single-stranded digests, the lack of secondary structure should make the stereochemistry of the complexes less relevant. The complexes exhibited reactivity different from what was observed in the case of the duplex. In the reaction with the bottom strand (5′-GAGACCGAGAG-3′), where the only adjacent purines are dApdG, *R*-**1**, *S*-**1**, and *S*-**2** showed reactivity towards dG comparable to that of cisplatin, Δ(dG) = –37%, –39%, –33%, and –37%, respectively, Fig. 5. All complexes showed greater reactivity towards dA than cisplatin. Whereas cisplatin caused the loss of approximately 5% of dA, compounds *R*-**1**, *S*-**1**, *R*-**2**, and *S*-**2** reacted to a significantly greater extent causing the loss of 23%, 31%, 16%, and 29%, respectively. Decreased selectivity for dG is possibly due to the lack of an available NH proton. Of course, other electronic factors cannot be dismissed. Digests of the top strand (5′-CTCTCGGTCTC-3′) yielded very similar results to the duplex digestions where all compounds bound to dG less efficiently than cisplatin (data not shown).

Fig. 6. Denaturing polyacrylamide gel electrophoresis (PAGE) (negative exposure) of top strand (TS), bottom strand (BS), and double stranded (ds) DNA subjected to 1 equiv. of either *R*-**1**, cisplatin or no Pt. Lanes: 1: ds DNA, negative control; 2: ds DNA + cisplatin; 3: ds DNA + *R*-**1**; 4: BS, negative control; 5: TS, negative control; 6: BS + *R*-**1**; 7: TS + *R*-**1**; 8: BS + cisplatin; 9: TS + cisplatin.



Thermal denaturation of platinated duplexes showed that cisplatin lowered the melting temperature (T_m) of the duplex, which is consistent with the formation of 1,2-intrastrand adducts (the stability of the duplex is compromised to the extent that a ΔT_m of –20 °C can be observed) (2, 31), while the pyridyloxazoline complexes decreased the T_m only very slightly (ΔT_m = 1–3 °C). This indicates that substantial duplex deformation is not occurring and implies that 1,2 adducts are likely not formed.

Denaturing polyacrylamide gel electrophoresis (PAGE) of the platinated ds and ss DNA again confirmed the generally low reactivity of the compounds. However, DNA platination is revealed by electrophoretic analysis of the reaction mixtures employing the most reactive compound used in this study (*R*-**1**), (Fig. 6). The accumulation of positive charge, which occurs after platination of the sequence, results in lower mobility of the oligonucleotide within the gel matrix.

A significant shifting of the bands in the lanes containing cisplatin was observed. The lanes containing the pyridyloxazoline complex *R*-**1** either showed one band identical to the control (no platinum) or two bands, the top band (corresponding to a platinated ss sequence) appearing very faintly.

© 2008 NRC Canada

It is possible that, if left for longer periods of time, the compounds tested may show differences in binding between enantiomers, as the diastereomeric adducts may be resolved towards the thermodynamic product. It was however found that the ratios after 36 h or 48 h of incubation were not substantially different.

In conclusion, the pyridyloxazoline complexes of Pt and Pd tested in this study likely did not form 1,2-adducts with DNA, but had a higher propensity towards the formation of complexes with dA than cisplatin. It was also found that the nature and absolute configuration of the substituent at *C*4 of the oxazoline ring had no systematic or simple and predictable effect on reactivity. The previous work demonstrating the antineoplastic effects of **6** (19) may imply that monofunctional adducts formed are pharmacologically relevant. In vivo or in vitro biological assays may, in turn, highlight whether the chirality of these complexes is pertinent in regards to their efficacy as anticancer agents.

Synthesis and first X-ray structures of cobalt(II) and cobalt(III) complexes bearing 2,4-dioxo-alkanoic acid dialkylamide ligands[1]

Jian Wang, Nicholas A. Morra, Hongda Zhao, Jeffrey S.T. Gorman, Vincent Lynch, Robert McDonald, John F. Reichwein, and Brian L. Pagenkopf

Abstract: The aerobic oxidation of 5-hydroxy pentenes to *trans*-tetrahydrofurans (THFs), the Mukaiyama oxidation, has in recent years emerged as a powerful tool in synthetic chemistry. In this report we describe the first crystal structures of 2,4-dioxo-alkanoic acid dialkylamide complexes for both Co(II) and Co(III) salts. The Co(II) structures show an unprecedented arrangement of atoms, with a central $Co(II)(H_2O)_6$ flanked by two Co(II) atoms each coordinated with three anionic chelating ligands. The dimeric Co(III) structures show two anionic chelating ligands and bridging hydroxyl groups.

Key words: aerobic oxidation, trans-tetrahydrofuran (THF), cobalt, X-ray crystallography, oxidation, coordination.

Résumé : L'oxydation aérobique de 5-hydroxypentènes en *trans*-tétrahydrofuranes (THF), l'oxydation de Mukaiyama, est devenue au cours des années récentes un outil puissant. Dans ce travail, on décrit les structures cristallines de sels complexes de Co(II) et de Co(III) de dialkyamides de l'acide 2,4-dioxoalcanoïque. Les structures des sels du Co(II) présentent un arrangement d'atomes, inconnu jusqu'à maintenant, comportant un groupe central $Co(II)(H_2O)_6$ flanqué de deux atomes de Co(II) qui sont chacun liés à trois ligands chélatants anioniques. Les structures dimères du Co(III) comportent deux ligands chélatants anioniques et des groupes hydroxyles servant de ponts.

Mots-clés : oxydation aérobique, THF, cobalt, diffraction des rayons X, oxydation, coordination.

[Traduit par la Rédaction]

Introduction

Co(III) complexes of 2,4-dioxo-alkanoic acid dialkylamides are useful catalysts for the aerobic oxidation of olefins to peroxides or alcohols (1–5) and for the oxidative cyclization of 5-hydroxy pentenes to tetrahydrofurans (THFs) (6). In recent years, the stereoselective aerobic oxidation of 5-hydroxy pentenes to *trans*-THFs (henceforth the Mukiayama oxidation, Scheme 1) has emerged as a powerful tool in organic synthesis and has been strategically employed in the total synthesis of natural products by the groups of Wang et al. (7), Takahashi et al. (8), Evans et al. (9), and Pagenkopf and co-workers (10). Surprisingly, despite the obvious synthetic importance of these catalysts, there is little structural information available on transition metal 2,4-dioxo amide complexes, and to the best of our knowledge no X-ray structures of these species have been reported. In this paper we describe crystal structures of two Co(II) complexes and one Co(III) complex.

1 mol/L HCl (2×), satd. $NaHCO_3$, and brine and then dried ($MgSO_4$). Concentration in vacuo gave **1** as a white solid or colorless oil in quantitative yield, which was used without further purification.

A solution of *t*-BuOK (23 g, 205 mmol, 2.1 equiv.) in THF (180 mL) was added via cannula to a solution of pinacolone (12 mL, 96 mmol, 1.0 equiv.) and amide **1a** (18 g, 96 mmol, 1.0 equiv.) in THF (40 mL) over 40 min at rt. After 3 h, AcOH (20 mL, 350 mmol, 3.6 equiv.) was added over 5 min and the resulting heterogeneous mixture was filtered and the solids were washed with CH_2Cl_2. The filtrate was washed with $NaHCO_3$ and brine, dried, filtered, and concentrated. Purification of the resulting oil by flash chromatography (SiO_2, 50% EtOAc/hexanes) provided the title compound as a slightly yellow solid (18.1 g, 78%).

To a solution of **2** (7.0 mmol) in hexanes or benzene (**3a**) was added Co(II)(2-ethyl-hexanoate)$_2$ (3.5 mmol) solution in mineral spirits. The reaction mixture was stirred at rt for 8 h and hexane (ca. 70 mL) was added to induce precipitation. The solids were separated by centrifugation or filtration and washed with hexane.

Full characterization of Co(II) complexes by NMR was not possible because the salts are paramagnetic. Combustion analysis is significantly out of range because the number of water molecules within the powder varies and drying generally lead to decomposition. Attempts to record discrete melting points also lead to decomposition. Several of these complexes are known compounds, including **3a**, **3b**, and **3c** (3*a*, 11) (Table 1).

Results and discussion

Cobalt(II) structures

Our initial efforts to employ the Mukaiyama oxidation in synthesis were complicated by fickle oxidation results as a consequence of inconsistent purity of the Co(II) complex. The first reports on Co(II) 2,4-dioxo-alkanoic acid amide complexes utilized $CoCl_2$ under aqueous alkaline conditions, but we found that such conditions caused decomposition of the morpholine amide **2a** (Scheme 2). The result was that the preparation of catalyst **3a** under the aqueous conditions provided a highly contaminated amorphous brown solid and attempts at purification proved fruitless. However, these difficulties were overcome by complexation under neutral conditions in organic solvent. When a solution of the free ligand **2a** in benzene was treated with 0.5 equiv. of Co(II)(2-ethyl hexanoate)$_2$, the initial dark blue color quickly dissipated and the resulting red solution was treated with hexane to precipitate the complex **3a**.

Table 2. Preparation of Co(II) complexes.

Entry	Co(II) Complex	#	Yield[a]

7		**6**	45%
8		**7**	76%
9		**3e**	23%

Note: The compounds shown are representative of the metal to ligand stoichiometry only, and are not meant to imply structure.
[a]Unoptimized yields of complexation.
[b]Poor solubility.

This modified procedure proved effective for the preparation of a variety of 2,4-dioxo amide complexes and these results are summarized in Table 2. Replacement of the morpholine with piperidine (**3b**), diethylamine (**3c**), or dibenzyl amine (**3d**) gave complexes as microcrystalline pink powders unsuitable for single crystal X-ray analysis. Of these, the dibenzyl amide **3d** displayed the most promising crystalline character, and in entries 5–7 of Table 2 the dibenzyl amide portion of the ligand was conserved while substitutions were made in place of the *tert*-butyl group. The methyl (**4**), isopropyl (**5**), and phenyl (**6**) analogs of **3d** were each prepared successfully, but they too failed to give crystals suitable for X-ray analysis.

A more substantial change was made by installing a methyl group at C(3) and, gratifyingly, the complex **7** was obtained as red crystals and the unusual X-ray structure of **7** is shown in Fig. 1.[5] Selected bond lengths and angles are reported in Table 3. There are three cobalt atoms present in the

Fig. 1. (*a*) View of the complex **7**, $[(C_{21}H_{22}NO_3)_3Co]_2$-$Co(H_2O)_6$. The complex resides on a crystallographic inversion center at ½, ½, ½ with $Co(H_2O)_6$ at the center, which bridges a pair of $(C_{21}H_{22}NO_3)_3Co$ complexes via O-H···O hydrogen bonds (12). (*b*) View of **7** showing a single Co-ligand assembly and the central $Co(H_2O)_6$ with selected atoms labeled. Displacement ellipsoids are scaled to the 30% probability level. unit cell, each separated by 4.870 Å. The two outer cobalt atoms are each surrounded by three dioxoamide ligands and their negative charge is balanced by a central $Co(II)(H_2O)_6$. The dihedral angle between the amide carbonyl and the acac-like plane is 118(1)°, which might be expected to minimize A(1,3) strain with the C(3) methyl group. The unfavorable A(1,3) interaction was also evident in the ^1H NMR spectra of the metal-free ligand **8**, which in $CDCl_3$ existed as a 1:1 ratio of both the keto and enol forms (Scheme 3). In contrast, the preceding ligands existed primarily in the enol form. The distinctly different structure and behavior of ligand **8** compared with the others caused concern that the structure of **7** may be unique and not representative of the series.

To address concerns that the C(3) methyl may have lead to a structural anomaly, additional complexes more closely resembling **3d** were prepared. Of these, the biphenyl analog **3e** (Table 2, entry 9) formed crystals suitable for X-ray analysis (Fig. 2). Importantly, the major features of the two structures are conserved, including the arrangement of the three cobalt atoms and the angle of the amide. A minor difference is that the central cobalt in **3e** is surrounded by only

8 **8**

three water molecules, with the coordination sphere being fulfilled by dative bonding from a neighboring ligand. The distance between Co(1) and Co(2) was found to be 4.980 Å, Co(2) and Co(3) are separated by 2.926 Å. Bond lengths and angles of significance are reported in Table 4.

In both X-ray structures there are neutral donors, including water, surrounding the central cobalt atom. The reactions were run under an argon atmosphere using undried bulk solvents and this was presumably the origin of the water. To determine if additional water would facilitate crystallization, several complexation reactions were simply performed open to air. Remarkably, the preparation of **3d** under these conditions gave larger crystals that were easily obtained by filtration (instead of centrifugation). Importantly, no oxidation to Co(III) was observed under these conditions (TLC), whereas the analogous $Co(acac)_2$ species oxidize more readily.

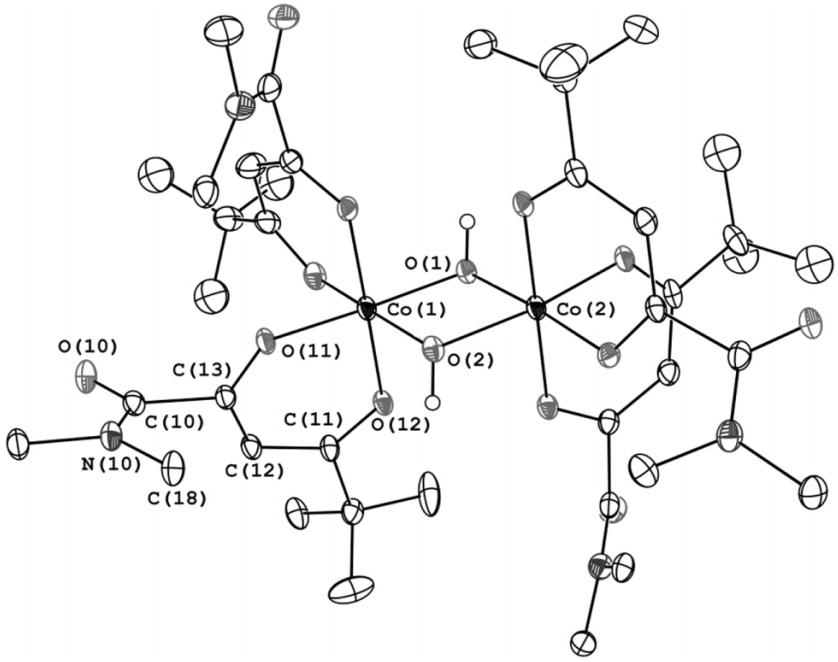
Nonhydrogen atoms are represented by Gaussian ellipsoids at the 30% probability level. Hydroxyl group hydrogen atoms are shown with arbitrarily small thermal parameters; all other hydrogens and aromatic groups have been removed for clarity.



Cobalt(III) structure

Obtaining structural information about the Co(III) complexes (which are generated in situ for the Mukaiyama oxidation) might be more helpful in speculating about the nature of the active catalytic species. However, the Co(III) complexes are generally obtained as green oils or glasses. Efforts to grow crystals at –20 °C were promising, but the resultant crystals were not of suitable quality for X-ray analysis. The Co(III) complexes are stable to flash chromatography on silica gel and the complexes elute as numerous bands, some of which are readily separable while others are overlapping. We speculated one origin of these different bands to be diastereomeric complexation, and when separated the individual diastereomers might crystallize more easily. At rt individually eluted bands isomerize within a day or two to multiple species, as monitored by TLC. However, at –20 °C the isomerization is slowed dramatically and crystals suitable for X-ray crystallography were obtained from one of the more polar bands (R_f = 0.25, 40% EtOAc/hexanes) of compound **9** (the oxidized version of **3d**) (Fig. 3). In this binuclear cluster, the two central cobalt atoms are bridged by two hydroxyl groups and each cobalt is surrounded by two chelating ligands. Significant bond lengths and angles have been summarized in Table 5.

Use of crystals in oxidative cyclizations

All of the new complexes reported in Table 2 possess some catalytic activity for the oxidation of γ-hydroxyl olefins to tetrahydrofurans. The complexes **3a** and **3d** have emerged as particularly useful catalysts and the decision to employ one versus the other is influenced by product polarity and chromatographic characteristics. Crystals of **9** were dissolved in *i*PrOH and appeared as a single spot by TLC. These crystals successfully catalyzed the oxidation shown in Scheme 1 (1 atm O_2, *i*PrOH, 50 °C, 16 h) in yields typically ranging from 70%–90%. Some spots isolated from the Co(III) species via chromatography were found to be inac-

© 2008 NRC Canada

tive under standard Mukaiyama oxidation conditions. Investigations are currently underway to determine the structural differences between the active and inactive Co(III) complexes.

Conclusions

A modified synthesis for the preparation of Co(II) complexes bearing 2,4-dioxo-alkanoic acid dialkylamide ligands has been reported and the resulting complexes are better precatalysts for the Mukaiyama oxidation compared with those prepared under aqueous alkaline conditions. X-ray structures for two of the Co(II) complexes have been solved and they revealed a unique arrangement of cobalt atoms in the unit cell, where two anionic clusters each containing one Co(II) atom surrounded by three negatively charged dioxoamide ligands flank a central Co(II) atom with neutral donors. Oxidation of the Co(II) salts with H_2O_2 gave green oils or glasses. Separation of the slowly equilibrating mixtures by flash chromatography on silica gel resulted in the isolation of a single diastereomer that lead to crystals suitable for X-ray analysis.

Chemical synthesis and structural studies of thiol-capped gold nanoparticles[1]

Peng Zhang, Andy Yuan-Chi Chu, Tsun-Kong Sham, Yun Yao, and Shuit-Tong Lee

Abstract: We report the chemical synthesis and structural studies of thiol-capped Au nanoparticles (NPs) using extended X-ray absorption fine structures (EXAFS) and high-resolution transmission electron microscopy (HRTEM). Synthesis of Au NPs was conducted in one case in a toluene/water two-phase system using alkanethiols with varied hydrocarbon chain length (C6, C12, and C18), resulting in NPs of sizes ranging from 1.6 nm to 5.4 nm. Au L_3-edge EXAFS reveals a systematical trend of the local structure of Au in the NPs when the Au/S ratio and chain-length of thiols are varied. In another synthesis, thiol-capped Au NPs were prepared on the surface of silicon nanowires, which act as both substrates and reducing agents. HRTEM reveals that not only spherical particles but also very small quasi-1D nanostructures of Au were formed. The formation and structure of these Au NPs was discussed in terms of ligand and template effect associated with the silicon nanowire substrates.

Key words: thiol-capped Au nanoparticles, EXAFS, silicon nanowires, electroless deposition, quasi-1D Au nanostructures.

Résumé : On a réalisé la synthèse de nanoparticules (NP) d'or coiffées d'un thiol et on en a fait des études structurales en faisant appel à la méthode des structures fines d'absorption des rayons X étendue(SFAXE) et à la microscopie électronique de transmission à haute résolution (METHR). La synthèse des NP d'or a été réalisé, dans un cas, dans un système binaire toluène/eau et en utilisant des alcanethiols avec des chaînes carbonées de diverses (C6, C12 et C18) conduisant à des NP dont la taille allait de 1,6 à 5,4 nm. Les études de SFAXE à la limite L_3 révèlent la présence d'une tendance systématique de la structure locale de l'or dans les NP avec une variation du rapport Au/S et des longueurs des chaînes des thiols. Dans une autre méthode de synthèse, les NP d'or coiffées de thiol ont été préparées à la surface de nanofils de silicium qui agissent à la fois comme substrats et comme agents réducteurs. La METHR révèle qu'il y a formation non seulement de particules sphériques, mais aussi de très petites nanostructures quasi unidimensionnelles d'or. On discute de la formation et des structures de ces NP d'or en termes de ligand et d'effet de gabarit associé aux substrats nanofils de silicium.

Mots-clés : nanoparticules d'or coiffées d'un thiol, SFAXE, nanofils de silicium, dépôt sans électrode, nanostructures d'or quasi unidimensionnelles.

[Traduit par la Rédaction]

Introduction

During the past decade or so, thiol-capped gold nanoparticle (NP) has emerged as a prototype of nanostructured materials whose important role can be found in a variety of fundamental and applied areas (1). Particularly, because of the very high stability of Au clusters (oxidation-resistant) and strong Au–S bonding, the synthesis of very small thiol-capped has recently been possible (2, 3). The availability of these highly stable small NPs provides important opportunities for studies to understand the structure–property relationship of materials whose dimensions approach the lower limit of nanostructured materials, i.e., in the range of 0.5–2 nm. Meanwhile, rapid advancement in modern instrumental techniques, including a variety of high-resolution microscopic and spectroscopic methods, especially synchrotron-based techniques, opens up new avenues for unveiling the structure and properties of these nanomaterials with considerable details (4–7).

In this article, results from chemical synthesis and structural studies of thiol-capped Au NPs will be presented using synchrotron-based extended X-ray absorption fine structure (EXAFS) and high-resolution transmission electron microscopy (HRTEM). EXAFS studies of dodecanthiol-stabilized Au NPs have been recently reported by a number of groups (8–11). Comparing with the reported results, the new findings in the present work can be found in two areas. Synthetically, we prepared Au NPs with not only the classic

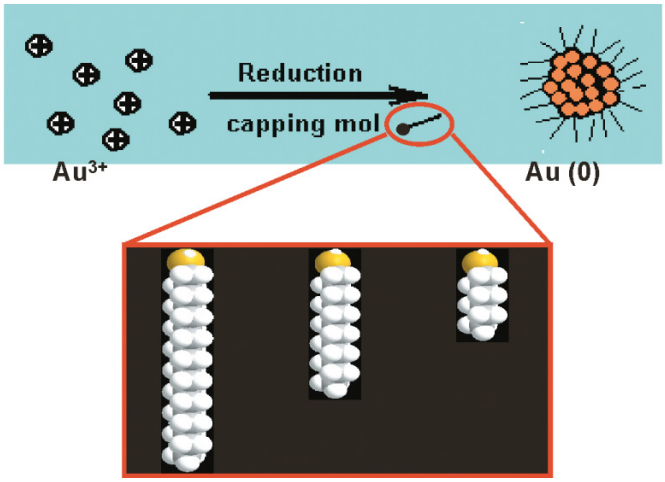
Scheme 1. A schematic illustration of the preparation of Au NPs capped with alkanethiols ($C_{18}SH$, $C_{12}SH$, and C_6SH) in solutions.



two-phase method (12), but also a recently developed strategy using thiol/silicon nanowires as capping ligands/nano-template (13). Particularly, the formation of quasi-1D Au NPs self-aligned on the surface of silicon nanowires was observed. From the perspective of structural analysis, experimental and simulated EXAFS were utilized to probe the structure of Au NPs capped with not only dodecanethiol but also hexanethiol and octadecylthiol. Based on these results, implications for tailoring the structure of Au NPs using wet chemical synthetic methods are discussed.

Experimental methods

The two-phase synthesis of Au NPs was conducted using the Brust method (12), which is schematically illustrated in Scheme 1. Typically, a $HAuCl_4$ aqueous solution (30 mL, 0.03 mol/L) was mixed with a toluene solution of tetraoctylammonium bromide (80 mL, 0.05 mol/L). The two-phase mixture was vigorously stirred until the aqueous phase becomes colourless, indicating that the $HAuCl_4$ compound was all transferred to the toluene phase. Next, the aqueous phase was removed and desired amount of alkanethiol (*n*-hexanethiol, *n*-dodecylthiol, and *n*-octadecylthiol) was added to the toluene phase. With vigorous stirring, freshly prepared aqueous $NaBH_4$ solution (25 mL, 0.4 mol/L) was added slowly to reduce all the Au(III) to Au(0). After further stirring for another 3 h, the toluene phase from the reaction mixture was collected and purified by the alcohol-precipitation method.

The electroless deposition of thiol-capped Au NPs on silicon nanowires (SiNWs) has been described previously (13, 14). Briefly, the SiNWs were prepared by a thermal evaporation method, producing nanowires several micrometers long with diameters of 20–30 nm. Then, stock solutions containing $HAuCl_4$ and thiol derivative (tiopronin) were prepared with the desired Au/S ratio (6:1) and concentrations (1 mmol/L $HAuCl_4$). Next, SiNWs (5% hydrofluoric acid treated for 2 min) were placed into the $HAuCl_4$/organosulfur solution for 5 min. After this, the Au/SiNWs were rinsed with distilled water several times to remove the unreacted chemicals and were allowed to dry in air.

Table 1. The average size and standard size deviation of C_6SH-, $C_{12}SH$-, and $C_{18}SH$-stabilized Au NPs. The results of $C_{12}SH$-stabilized Au NPs were taken from ref. 9.

	Au/S = 1:3	Au/S = 1:1	Au/S = 6:1
C_6SH	1.8±0.3 nm	2.4±0.5 nm	5.4±0.7 nm
$C_{12}SH$	1.6±0.3 nm	2.4±0.5 nm	4.0±0.6 nm
$C_{18}SH$	1.6±0.2 nm	1.9±0.4 nm	3.2±0.5 nm

The Au L_3-edge EXAFS measurements were conducted at the Pacific Northwest Consortium X-ray Operation Research (PNC-XOR) ID-20B beamline of the Advanced Photon Source (APS) at Argonne National Laboratory. The analysis of EXAFS data was performed using the WinXAS program with a standard procedure described previously (15). The FEFF8 (16) simulation was conducted using models of a symmetric Au_{55} cluster with and without 24 sulfur atoms on the three-fold hollow sites on the Au (111) surface of the cluster. High-resolution electron microscope measurements of Au NPs on Si nanowries were carried out using a JEOL 2010F (McMaster University) or a Philips CM200 FEG electron microscopy (City University of Hong Kong) operated at 200 kV.

Results and discussion

Size, morphology, and structure of the Au NPs prepared with two-phase method

For the Au NPs prepared with the two-phase method, the NP size can be controlled by varying either the Au/S ratio or the size of the alkanethiol molecules, or both. The general principle for the size control of Au NPs lies in the effectiveness of thiol-capping ligands in protecting the Au nuclei/clusters from aggregation and the concentration of the capping ligand in the vicinity of the nucleation site. The more effective and concentrated the ligands are, the smaller NPs will result. Therefore, the use of either a lower Au/S ratio in the starting materials or alkanethiols with a longer hydrocarbon chain can often lead to the production of smaller NPs (9).

Table 1 presents the size information of Au NPs synthesized by varying both the Au/S ratio and the chain length of thiols obtained from TEM, and the trend was confirmed by XRD. In Fig. 1, representative TEM images of *n*-dodecylthiol-capped NPs with Au/S ratios of 1:3, 1:1, and 6:1 are also shown. From Table 1, the trend of size dependence on concentration ratio (across the row) and ligand chain length (down the column) is apparent. For example, it can be seen that the use of $C_{18}SH$ or a Au/S ratio of 1:3 can generate the smallest NPs, whereas the use of C_6SH or a Au/S ratio of 6:1 result in the biggest particles. It is also noted that the control of NP size by varying the hydrocarbon chain length of thiols has the widest size range for the series of a Au/S ratio of 6:1. This is understandable in that when the concentration of the capping ligands is low, the size of the NP can grow larger before it is fully capped, and the diffusion rate of the ligand to the nucleation site is a factor. In contrast, when the highest concentration of thiols is used (Au/S = 1:3), the effect of chain length of capping molecules is much less significant, since the S-end of the molecules is

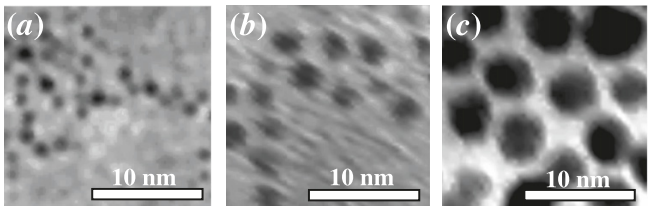

Fig. 2. Normalized FT-EXAFS of $C_{12}SH$-capped Au NPs with Au/S ratios of 1:3, 1:1, and 6:1 and bulk Au. Some baselines are shifted vertically for clarity. k-EXAFS range: 3–12 $Å^{-1}$. The distances are phase-uncorrected.

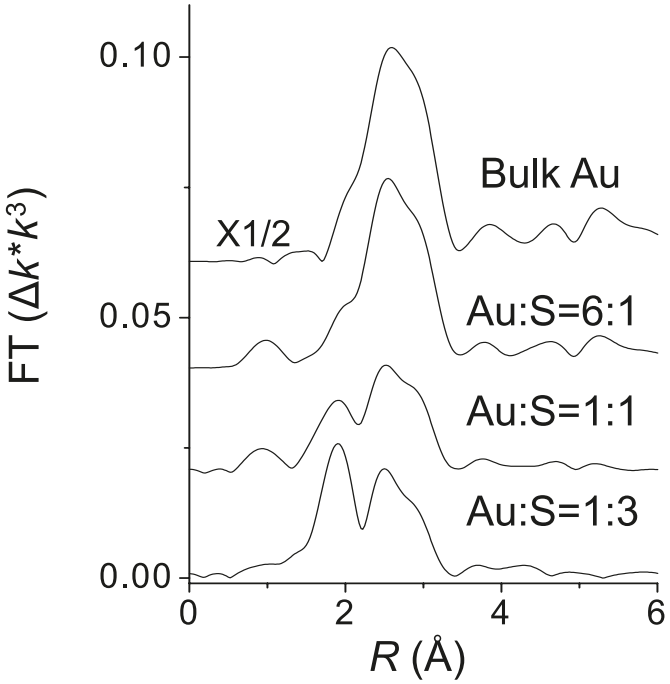
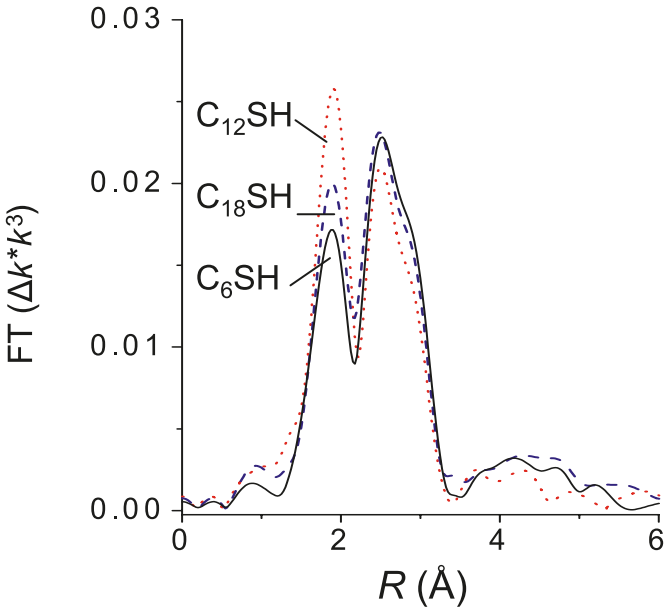


the same and there are abundant ligand molecules in the vicinity of the nucleation site.

To study comparatively the local structure of the NPs, we used EXAFS to investigate two series of samples selected from Table 1 (same ligand, $C_{12}SH$, different ratio and same ratio, 1:3, different ligands). Figure 2 shows the Fourier Transform (FT) of the Au L_3-edge EXAFS (with k^3 weighting) of $C_{12}SH$-capped NPs with Au/S ratios of 1:3, 1:1, and 6:1. Figure 3 depicts the FT-EXAFS of Au NPs with a Au/S ratio of 1:3 and different alkanethiols (C_6SH, $C_{12}SH$, and $C_{18}SH$). It should be noted that the peak position in the radial distribution (FT-EXAFS) is related to the real interatomic distance by a small phase correction. The peak positions are henceforth referred to as "phase uncorrected". The magnitude of the FT is mainly proportional to the coordination number for the same atomic pair. As can be seen in Table 1, the FT-EXAFS in Fig. 2 mainly reflect the NP size effect (same capping ligands), whereas in Fig. 3, the surface capping effect can be revealed as the differently capped NPs are nearly the same size. To assist the analysis, the Au L_3-

Fig. 3. FT-EXAFS of C_6SH, $C_{12}SH$ and $C_{18}SH$-capped Au NPs with a Au/S ratio of 1:3. k-EXAFS range: 3–12 $Å^{-1}$. The distances are phase-uncorrected.



edge EXAFS was also simulated using the FEFF 8 code and the results are shown in Fig. 4. The simulated EXAFS and its FT are used below to interpret the experimental data presented in Figs. 2 and 3.

In Fig. 2, a couple of interesting observations are noted. First, the amplitude of the Au–Au bonding peak in the region of 2.5–3 Å corresponds to the inter-atomic distance of the nearest Au neighbour of the Au absorber in the NP (after a small phase correction). The magnitude of this peak decreases gradually with the size of Au. Second, a new peak at ~2 Å emerges as the NPs become smaller. The first observation is relatively easy to understand. As the NP size decreases, there are less Au neighbour atoms (on average) due to the higher fraction of surface Au atoms. As a result, the EXAFS intensity (amplitude of the FT), which is mainly determined by the Au–Au coordination number, decreases with the NP size (17). The second observation has been reported by a number of groups, and the peak at ~2 Å (phase uncorrected) has been assigned to Au–S bonding on the NP surface (8–11, 15). However, as shown in Fig. 2, this assignment has been challenged by the fact that bulk Au also shows a shoulder in the same region (~2 Å). To provide unambiguous evidence for the origin of the resonance peak at ~2 Å for the thiol-capped Au NPs, we next discuss the simulated EXAFS of three model clusters.

Figure 4*a* shows cross section of the plain Au_{55} model used for the FEFF simulation of FT-EXAFS. Five representative sites (center and 1^{st}–4^{th} shells) were used as the absorber for the simulation. The FT-EXAFS of each site for the model clusters $Au_{55}(SR)_{24}$, $Au_{55}(SR)_8$, and Au_{55} are presented in Figs. 4*b*, 4*c*, and 4*d*, respectively. The final simulated spectra were generated by weight-averaging the EXAFS of Au atoms in each shell of the model clusters. For the average FT-EXAFS shown in Fig. 4*e*, all three model clusters exhibit identical Au–Au bonding peak in the region of 2.5–3 Å. Meanwhile, a peak at ~2 Å is also observed for

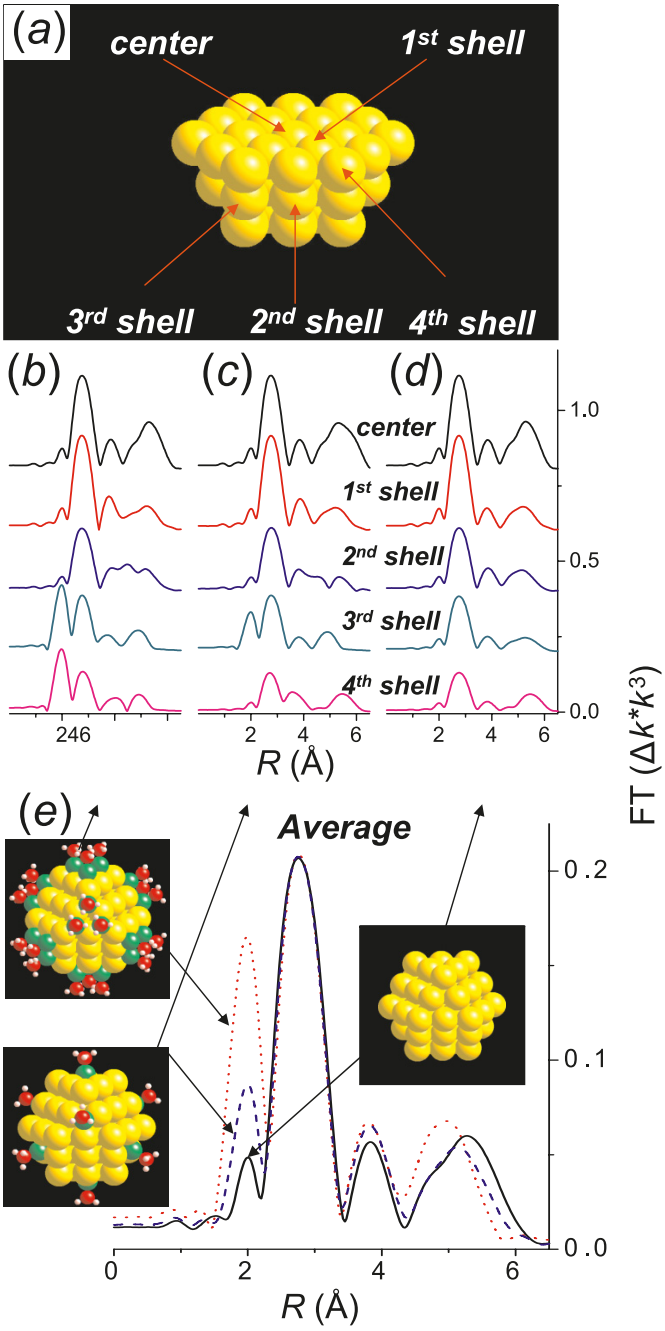
Fig. 4. Simulated FT-EXAFS of $Au_{55}(SR)_{24}$, $Au_{55}(SR)_8$, and Au_{55}. (*a*): Part of a Au_{55} model illustrating the five representative sites for the FEFF simulations. (*b–d*): Site-specific simulations of $Au_{55}(SR)_{24}$ (*b*), $Au_{55}(SR)_8$ (*c*), and Au_{55} (*d*) by selecting each representative site illustrated in (*a*) as the absorber. (*e*): Weight-averaged FT-EXAFS of the three model clusters (for the simulation method, see refs. 18 and 19). The thiolate ligands, represented with $–SCH_3$ groups in the figure, were placed on the Au (111) surface with a Au–S distance of 2.3 Å. In the simulations, only gold and sulfur atoms were included in the input files.



all the three clusters. Specifically, the intensity of this peak is very low for Au_{55} albeit observable. It increases by a factor of ~2 for $Au_{55}S_8$ and a factor of ~4 for $Au_{55}S_{24}$. The results in Fig. 4 indicate that the FT-EXAFS peak at ~2 Å is closely associated with the Au–S bonds of thiol-capped Au NPs and its intensity increases with the number of Au–S bonds on the NP surface. Thus, the intensity of this peak observed in Fig. 2 can be accounted for by the existence of more Au–S bonds on the surface of smaller Au NPs relative to the Au atoms in the core of the NP. Meanwhile, the results in Fig. 4 also suggest that the small but observable peak in this region associated with the Au–Au bonding may also need to be considered. This is particularly true for bigger particles with lower Au/S ratio, such as the largest NPs (Au/S = 6:1) shown in Fig. 2.

Returning to Fig. 3, we see the FT-EXAFS of three smallest Au NPs (1.6–1.8 nm) prepared using the same Au/S ratio (1:3), but capped with different alkanethiol molecules (C_6SH, $C_{12}SH$, and $C_{18}SH$). The sample C_6SH–Au and $C_{18}SH$–Au show Au–Au bonding peaks (in the region of 2.5–3 Å) of essentially the same intensity, which are slightly more intense than that of $C_{12}SH$–Au. The Au–S peak in region of ~2 Å is apparent for all NPs although there is some intensity variation. The EXAFS results suggest that $C_{12}SH$–Au is slightly smaller than the other two. This result, though somewhat different from the TEM results provided in Table 1 (C_6SH–Au = 1.8 nm, $C_{12}SH$–Au = 1.6 nm, $C_{18}SH$–Au = 1.6 nm), is understandable if one considers that TEM-based size information was obtained by counting NPs from a very small area in the sample (<100 nm × 100 nm), whereas EXAFS was collected from an area in the sample of 10^8 times bigger (>1 mm × 1 mm). Therefore, EXAFS can be considered as a measurement of the bulk of the samples, whereas TEM measurement is only sampling an extremely small fraction of the samples. In addition, the small difference of the NP sizes determined by TEM (1.6 nm vs. 1.8 nm) is within the experimental uncertainty of the measurement.

Figure 3 also reveals that the intensity of Au–S peak at ~2 Å decreases in the order of $C_{12}SH$–Au > $C_{18}SH$–Au > C_6SH–Au. The fact that the Au–S peak for $C_{18}SH$–Au is more intense than that of C_6SH–Au suggests a higher packing density of $C_{18}SH$ on the Au NPs than that of C_6SH, as they are of the same size according to EXAFS results. The mechanism for the highest Au–S peak intensity of $C_{12}SH$–Au among the three samples cannot be unambiguously accounted for. It can arise from the slightly smaller NP size (by EXAFS data) or still higher packing density of $C_{12}SH$ on the surface of Au NPs. The chain configuration and its effect on self assembly as well as NP size distribution may also play a role. Further experiment has to be conducted to reach a more satisfactory conclusion.

Morphology of Au NPs prepared on Si nanowires

Now, we report the second synthetic method for the preparation of thiol-capped Au NPs based on a recently developed electroless deposition method using HF-refreshed silicon nanowire (SiNWs) as reducing agent and substrate (13, 14). The mechanism is illustrated in Scheme 2. We have shown that the use of SiNWs in reaction with $HAuCl_4$ in the absence of thiols can lead to the formation of Au NPs of 20–30 nm (13). In comparison, in the presence of thiols, much smaller NPs whose surfaces are chemically functionalized with organic groups can be formed on SiNWs (see

Scheme 2. A schematic illustration of the preparation of Au NPs on silicon nanowires. (*a*) No capping molecules. (*b*) In the presence of capping thiol.

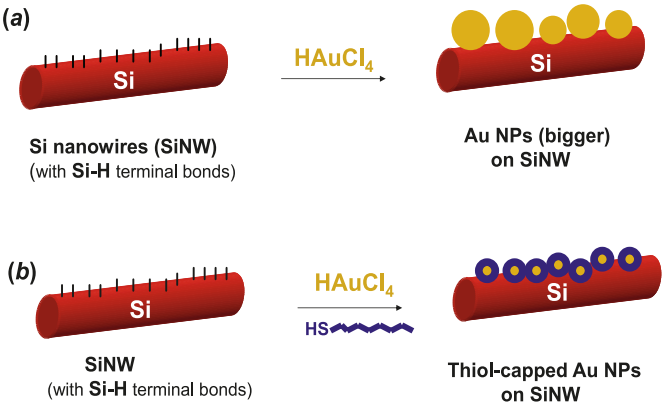

Fig. 5. TEM (*a*) and HRTEM (*b*) images of Au NPs on SiNWs. (*b*) Inset: a lattice-resolved Au NP. Scale bar: 2 nm.

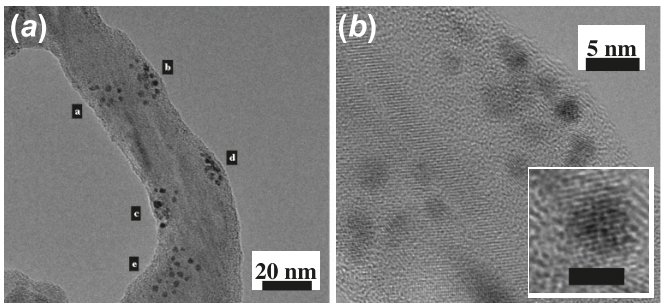
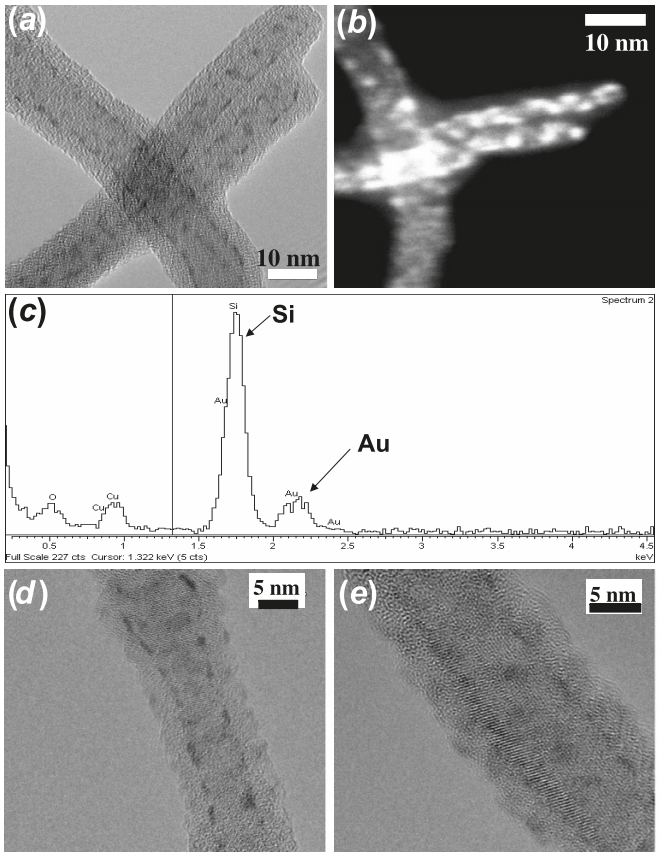


Scheme 2). In Fig. 5, it can be observed that Au NPs of 2–4 nm are formed on the surface of SiNWs. Measurement of lattice spacing of the NPs in Fig. 5*b* yields a value of 0.23 nm, consistent with the value of fcc Au.

Interestingly, we found that in some areas on SiNWs, very small non-spherical NPs were formed, as is shown in Fig. 6*a*. These NPs seem to self-assemble into quasi-1D nanostructure along the SiNW template. The STEM image in Fig. 6*b* and EDX (Energy Dispersive X-ray) spectroscopy data in Fig. 6*c* verify that these quasi-1D nanostructures are gold. Figures 6*d* and 6*e* show the HRTEM images of these quasi-1D Au NPs. The length of each rod-like Au NP is about 3–5 nm long and the width is about 0.8 nm. In the HRTEM image shown in Fig. 6*e*, the lattice fringe of SiNWs can be clearly visualized. However, the atomic structure of Au NPs (darker in colour) cannot be resolved. Instead, only amorphous structure originated from silicon oxide can be seen in the area where the quasi-1D Au NPs were formed. STEM shows similar results. It thus suggests that these very small Au NPs are buried by the oxide layer of SiNWs substrate. The presence of these small self-assemble NPs appears puzzling at first glance but can be understood in terms of the morphology of the SiNW and the HF refreshing process. SiNWs used in these reactions were prepared by the disproportionation of SiO, which usually lead to the formation of SiNW with an oxide sheath and core-shell type morphology (20). HF treatment usually cannot remove the surface oxide completely providing sporadic clean regions along the surface-oxide core-SiNW interface (21). These are

Fig. 6. TEM (*a*), STEM (*b*), EDX (*c*), and HRTEM (*d–e*) of quasi-1D Au nanostructures on SiNWs.



the most active regions for the reductive formation of Au NPs. It should also be noted that in addition to Si–H, clean Si on the surface can participate in the reduction of Au, producing oxide in the process. Thus, Au NPs on SiNW are likely to line up along the silicon oxide and core Si interface and encapsulated by amorphous oxide, which also terminates further growth of Au NPs.

Conclusion

We have used two chemical synthetic methods to prepare thiol-capped Au NPs. The size of Au NPs prepared with the two-phase method can be controlled in the range of 1.6–5.4 nm by varying the chain length of alkanethiols and (or) Au/S molar ratio in the staring materials. EXAFS reveals the trend of how the NP structure changes when these two factors are varied. FEFF8 simulations were used to unambiguously confirm the origin of FT-EXAFS peak of the thiol-capped Au NPs at ~2 Å, which has been assigned to Au–S bonding in the literature. In the second synthesis, both thiols and SiNWs were used to prepare substrate-supported Au NPs. It was found that both spherical and rod-like quasi-1D Au NPs were formed. HRTEM studies verify that these quasi-1D nanostructures are indeed gold. However, the atomic structure of these subnanometer-sized rod-like NPs has not been resolved, since they are buried by the oxide layer associated with the SiNW substrate and the reduction process.

Unusual coordination behaviour of the ferrocenyl-terpyridine ligand with group 11 complexes[1]

Javier E. Aguado, M. Concepción Gimeno, Peter G. Jones, and Antonio Laguna

Abstract: Complexes of the ligand Fcterpy (Fcterpy = 4′-ferrocenyl-2,2′:6′,2′-terpyridine) with group 11 metals display different coordination modes. The reaction with complexes $[Cu(NO_3)(PPh_3)_2]$ or $[M(OTf)(PR_3)]$ (OTf = trifluoromethylsulphonate) gives the species $[M(Fcterpy)(PR_3)]X$ (M = Cu, X = PF_6, PR_3 = PPh_3 (**1**); M = Ag, X = OTf, PR_3 = PPh_3 (**2**), PPh_2Me (**3**); M = Au, X = OTf, PR_3 = PPh_3 (**4**)) in which the ligand is coordinated as a tridentate chelate to the metal. Treatment with $[Cu(NCMe)_4]PF_6$ or Ag(OTf) in 1:1 molar ratio gives the dinuclear complexes $[M_2(Fcterpy)_2]X_2$ (M = Cu (**5**), Ag (**6**)), in which the ligand is tetradentate because the central pyridine group is bonded to two metals. The reaction with the gold(I) complex $[Au(C_6F_5)(tht)]$ (tht = tetrahydrothiophene) leads to the first example of a terpyridine ligand bonded to three metal atoms, $[Au_3(C_6F_5)_3(Fcterpy)]$ (**7**); in the product of the corresponding reaction with the gold(III) derivative $[Au(C_6F_5)_3(OEt_2)]$ to give $[Au(C_6F_5)_3(Fcterpy)]$ (**8**), the ligand is monodentate, which is also unusual for a terpyridine ligand.

Key words: copper, silver, gold, terpyridine, ferrocene derivatives

Résumé : Les complexes du ligand Fcterpy [Fcterpy = 4′-ferrocényl-2,2′:6′,2′-terpyridine] avec les métaux du groupe 11 présentent divers modes de coordination. Les réactions avec des complexes $[Cu(NO_3)(PPh_3)_2]$ ou $[M(OTf)(PR_3)]$ (Otf = trifluorométhylsulfonate) conduisent à des espèces $[M(Fcterpy)(PR_3)]X$ [M = Cu; X = PF_6; PR_3 = PPh_3 (**1**); M = Ag; X = OTf; PR_3 = PPh_3 (**2**); PPh_2R (**3**); M = Au; X = OTf; PR_3 = PPh_3 (**4**)] dans lesquels le ligand est coordiné au métal sous la forme de chélate tridentate. Le traitement avec du $[Cu(NCME)_4]PF_6$ ou du Ag(OTf), dans un rapport molaire de 1:1, conduit à la formation de complexes binucléaires $[Me_2(Fcterpy)_2]X_2$ (M = Cu (**5**); Ag (**6**)] dans lesquels le ligand est tétradentate parce que le groupe pyridine central est lié à deux métaux. La réaction avec le complexe d'or(I) $[Au(C_6F_5)(tht)]$ (tht = tétrahydrothiophène) conduit au premier exemple d'un ligand terpyridine lié à trois atomes métalliques, $[Au_3(C_6F_5)_3(Fcterpy)]$ (**7**); dans le produit de la réaction correspondante avec le dérivé d'or(III) $[Au(C_6F_5)_3(OEt_2)]$ conduisant à la formation de $[Au(C_6F_5)_3Fcterpy)]$ (**8**), le ligand est sous la forme monodentate qui est inhabituelle pour un ligand terpyridine.

Mots-clés : cuivre, argent, or, terpyridine, dérivés du ferrocène.

[Traduit par la Rédaction]

Introduction

The coordination chemistry of terpyridine ligands with various metals has been the subject of numerous studies, inspired by the exciting photophysical properties of metal–polypyridyl complexes (1). In these compounds, the terpyridine generally acts as a chelating planar tridentate ligand; only in some examples does it act as a bidentate ligand with a non-coordinating residue (2). In the last few years, interesting spiral arrays have been prepared with these ligands that, by twisting, can accommodate more than one metal center. Thus, some examples have been prepared with silver in which the terpy is bonded to two different metal centers in a supramolecular structure (3). We have previously communicated another coordination mode in which the three nitrogen atoms are bonded to three different metals in the complex $[Au_3(C_6F_5)_3(Fcterpy)]$ (4). Few terpyridine complexes of gold have been described and these are gold(III) derivatives, such as $[AuX(Rterpy)]^{2+}$ (X = Cl, OH; R = H, SMe, PhOMe) (5–8), or $[Au(CN)_2Br(\eta^2\text{-terpy})]$ (9) (terpy = terpyridine), in which the ligand acts a tridentate or bidentate chelate. For silver and copper, more examples have been described including complexes of the type $[M(PR_3)_2(terpy)]X$ (M = Cu, Ag) (10).

Here we report complexes with the group 11 metals and a substituted terpyridine ligand, 4′-ferrocenyl-2,2′:6′,2′-terpyridine (Fcterpy) (11). Several coordination modes have been achieved, including tridentate chelate in complexes of the type $[M(Fcterpy)(PR_3)]X$ (M = Cu, Ag, Au), tetradentate in the homoleptic species $[M_2(Fcterpy)_2]X_2$ (M = Cu, Ag), which represent the first examples of dinuclear rather than

the usual polymeric derivatives, or monodentate in the gold(III) compound $[Au(C_6F_5)_3(Fcterpy)]$.

Results and discussion

The ligand 4′-ferrocenyl-2,2′:6′,2′-terpyridine (Fcterpy) has been synthesized by aromatization of a 3-ferrocenyl-1-bis(2-pyridyl)pentane-1,5-dione, previously obtained by reaction of ferrocenaldehyde and 2-acetylpyridine, or by aromatization of the corresponding enone with a pyridonium iodide salt (see Scheme 1) as has been previously described (11). The crystal structure of this ligand has been established and the molecule is shown in Fig. 1. A selection of bond lengths and angles are collected in Table 1. The overall bond lengths and angles are within the normal values found in this type of compound (12). The cyclopentadienyl rings are almost eclipsed. In the terpyridine moiety the aromatic rings are almost coplanar themselves, but not with the cyclopentadienyl ring; the dihedral angle formed by the nitrogen atoms and the cyclopentadienyl ring is 161.6°. The nitrogen atoms of the external pyridine rings are pointed in the opposite direction to that of the central one. This configuration changes upon coordination of the ligand.

The reaction of the Fcterpy ligand with $[Cu(NO_3)(PPh_3)_2]$ or $[Ag(OTf)(PR_3)]$ or $[Au(OTf)(PPh_3)]$ affords the complexes $[Cu(PPh_3)(Fcterpy)]NO_3$ (**1**), $[Ag(PR_3)(Fcterpy)]OTf$ (PR_3 = PPh_3 (**2**), PPh_2Me (**3**)), or $[Au(PPh_3)(Fcterpy)]OTf$ (**4**) (see Scheme 2). The IR spectra for these compounds show the absorptions of the ferrocenyl terpyridine unit as those arising from the aromatic pyridine and cyclopentadienyl rings around 1607 (s), 1586 (s), 1104 (s), and 820 (s) cm^{-1}. In addition, complex **1** shows the absorptions of the nitrate group at 1725 (w), 1090 (m), 1026 (m), 1000 (w), and 827 (m) cm^{-1} and complexes **2**–**4** show the bands arising from the ionic trifluoromethylsulfonate anion at around 1262 (vs), 1223 (m), 1147 (vs), and 1030 (vs) cm^{-1}. Because the ^1H NMR spectra of all complexes show the presence of the ligand Fcterpy, it is useful to compare the resonances with those present in the free ligand. The ligand shows two multiplets for the α and β protons of the substituted cyclopentadienyl group and a singlet for the unsubstituted cyclopentadienyl unit; the proton signals for the terpyridine are a doublet of doublets for the pair 5–5″, a doublet of triplets for the pair 4–4″, a singlet for 3′–5′, and doublets for the pairs 3–3″ and 6–6″. The resonances for the coordinated ligand in complexes **1**–**4** resemble those in the free ligand but with a different chemical shift and not so well defined, and in some cases the resonances overlap with those of the phenylic protons. For complex **3**, a doublet at 1.91 ppm for the methyl protons coupled to the phosphorus atom is observed. The $^{31}P\{^1H\}$ NMR spectra shows a singlet for complexes **1** and **4**, whereas for compounds **2** and **3** a broad resonance appears at room temperature and splits into two doublets at –55 °C, because of the coupling of the phosphorus atom with the two silver nuclei with spin 1/2, ^{109}Ag (48.17%) and ^{107}Ag (51.83%). The mass spectra show in all the complexes the cationic molecular peak $[M(PR_3)(Fcterpy)]^+$ at *m/z* = 742 (18%, **1**), 786 (34%, **2**), 724 (36%, **3**), and 876 (45%, **4**), although for the copper and silver complexes the most abundant peaks correspond to the species $[M(Fcterpy)]^+$.

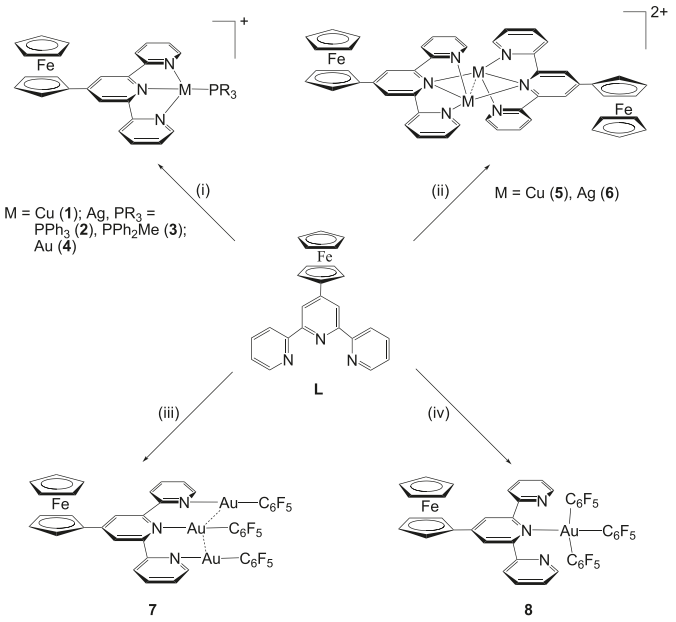
Scheme 2. (*i*) $[Cu(NO_3)(PPh_3)_2]$ or $[Ag(OTf)(PR_3)]$ or $[Au(OTf)(PPh_3)]$; (*ii*) $[Cu(NCMe)_4]PF_6$ or Ag(OTf); (*iii*) 3 $[Au(C_6F_5)(tht)]$; (*iv*) $[Au(C_6F_5)_3(OEt_2)]$.



The silver complexes have been structurally characterized, showing that the metal center is bonded to the three nitrogen atoms of the terpyridine unit, although the shortest bond is with the central nitrogen atom; we assume analogous structures for the copper and gold complexes. However in the gold complex the metal could be far more strongly bonded to the central nitrogen atom and make only very short contacts with the others, given the high tendency of gold to form two-coordinate derivatives. No crystal structure for gold(I) complexes with terpyridine ligands has been carried out, with the exception of the trinuclear complex **7**. The structures of complexes **2** and **3** have been established by X-ray diffraction and are shown in Figs. 2 and 3, respectively. A selection of bond lengths and angles are collected in Tables 2 and 3. The structure for complex **2** shows that the silver center coordinates to the three nitrogen atoms of the terpyridine moiety and to the triphenylphosphine, and although it is tetra-coordinated, the geometry is far from tetrahedral. The silver atom is located 0.11 Å out of the plane formed by the four donor atoms, P, N11, N21, and N31, and only 0.057 Å out of the trigonal plane of the P, N21, and N31 atoms. The Ag–N distances are 2.302(4), 2.435(4), and 2.492(4) Å, the shortest being to the central nitrogen atom. The angles N–Ag–P are 117.53(9) and 109.91(11)°, which corresponds to normal values found in trigonal planar complexes (13); consequently the N–Ag–N angles are very narrow, 68.98(13) and 68.35(14)°. Two of the phenyl rings are disordered in mutually perpendicular positions, although this disorder is not shown in Fig. 2. The structure of complex **3** is similar, with Ag–N distances 2.332(4), 2.421(4), and 2.488(5) Å, again with the shortest to the central pyridine ring. The geometry around the silver center is more distorted than in complex **2**; the Ag atom lies 0.27 Å out of the plane formed by the four coordinated atoms and 0.11 Å out of the plane of the N1, N3, and P atoms. The phosphorus atom is located further from the plane formed by the terpyridine and

Fig. 2. Structure of the cation of compound **2** showing the atom numbering scheme. Displacement parameter ellipsoids represent 30% probability surfaces. Radii are arbitrary; H atoms are omitted for clarity.

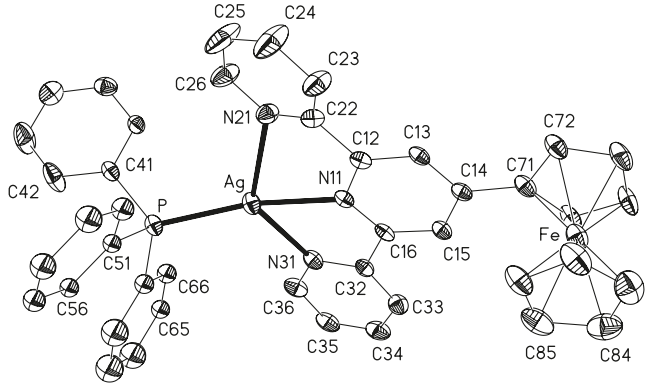


Fig. 3. Structure of the cation of compound **3** showing the atom numbering scheme. Displacement parameter ellipsoids represent 30% probability surfaces. Radii are arbitrary; H atoms are omitted for clarity.

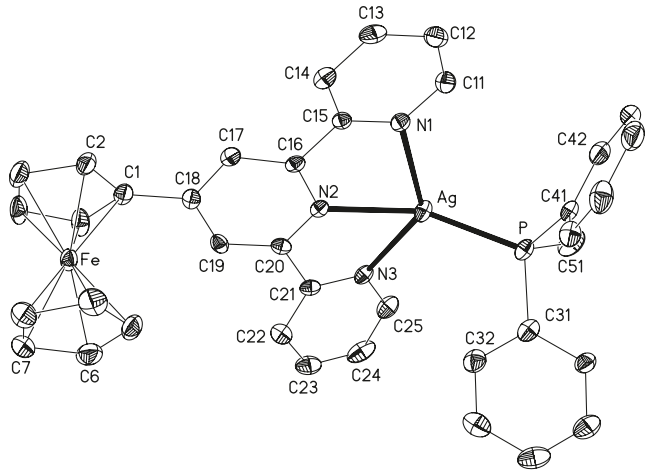

the silver atom than in complex **2**, with an N2–Ag–P angle of 152.06(11)° compared to 158.65(9)° in **2**. These structures are different from the previously reported complexes of stoichiometry $[M(terpy)(PPh_3)_2]^+$, which consist of discrete monomers of distorted trigonal-bipyramidal geometry, with the metal atoms coordinated to the distal terpyridine pyridyl rings [Cu-N 2.386(3), 2.535(4); Ag–N 2.614(2), 2.561 (2)Å] in axial sites (10). The coordination spheres are completed by the binding of the central pyridyl nitrogen atoms [Cu-N(2) 2.102(3), Ag–N(2) 2.457(2)Å] and two PPh_3 phosphorus atoms, which together define the equatorial planes.

The reaction of the ligand with an equimolar amount of $[Cu(NCMe)_4]PF_6$ or Ag(OTf) gives compounds with the stoichiometry [M(Fcterpy)]X (M = Cu, X = PF_6 (**5**); M = Ag, X = OTf (**6**)). The IR spectra show the typical absorptions of the Fcterpy ligand; the copper species show the absorption of the hexafluorophosphate at 640 (s) cm^{-1}, whereas the silver derivative presents the absorptions for the trifluoromethylsulfonate at 1259 (vs), 1223 (m), 1115 (vs),

N(1)-Ag-N(3)	134.47(14)

and 1029 (vs) cm^{-1}. The ^1H NMR spectra also exhibit different ligand chemical shifts for the silver and copper derivatives; the copper species shows a broad resonance at 8.2 ppm for all the protons of the Fcterpy ligand. In the mass spectrum of complex **5** the peaks arising from $[Cu(Fcterpy)]^+$, $[Cu_2(Fcterpy)_2]^{2+}$, and $[Cu_2(Fcterpy)](PF_6)^+$ appear at m/z = 480 (100%), 960 (9%), and 1129 (15%); for complex **6** similar peaks at m/z = 524 ($[Ag(Fcterpy)]^+$, 100%), 941 ($[Ag(Fcterpy)_2]^+$, 12%), and 1119 ($[Ag_2(OTf)(Fcterpy)_2]^+$, 4%) are observed. These data could imply a dinuclear structure with two metal atoms and two ferrocenyl-terpyridine ligands. The previously reported complexes that contain a terpyridine ligand and silver atoms are usually polymeric species in which the silver center bonds asymmetrically to the terpyridine units, giving a polymeric chain structure or a helical structure for the ligand *t*-BuPh-terpy (14). In our ligand the presence of a more bulky group, the ferrocenyl unit, makes the structure different. Several crystals of complex **6** proved to be of low quality, small and poorly diffracting, but the molecule can be recognised in the structure solution and corresponds to a dinuclear derivative in which the ferrocenyl-terpyridine ligand has an unusual role; central pyridine is bonded to the two silver atoms, in a coordination mode described as "crevice" (see Scheme 1) that has only recently been reported for silver (10). We assume a similar structure for the copper species although we can not rule out other possibilities.

The reaction of the ferrocenyl-terpyridine ligand with three equivalents of $[Au(C_6F_5)(tht)]$ in dichloromethane leads to the synthesis of the compound $[Au_3(C_6F_5)_3(\eta^3\text{-Fcterpy})]$ (**7**), which has been previously communicated and represents the first example of a terpyridine ligand bonded to three metal atoms (4) The treatment of the ligand with the gold(III) derivative, $[Au(C_6F_5)_3(OEt_2)]$, gives an orange solid $[Au(C_6F_5)_3(Fcterpy)]$ (**8**). The IR spectrum shows the typical absorptions arising from the pentafluorophenyl groups bonded to gold(III) at 1509 (vs), 965 (vs), 821 (m), and 794 (vs) cm^{-1}. The ^{19}F NMR spectrum also confirms the presence of an $Au(C_6F_5)_3$ moiety because six resonances appear, three for the pentafluorophenyl rings in a mutually *trans* position and the other three for the other pentafluorophenyl ring (ratio 2:1). The ^1H NMR spectrum presents the resonances for the ferrocenyl-terpyridine, shifted compared to the free ligand. The protons of the ferrocenyl and terpyridine unit have the same pattern as in the free ligand and, consequently, we assume a symmetrical coordination. Furthermore, since gold(III) is mainly square planar and pentacoordination is not easily achieved, we propose a coordination of the gold(III) center to the central pyridine group.

Electrochemistry

The electrochemical behaviour of the ligand Fcterpy and some of these complexes has been studied by cyclic voltammetry at a platinum electrode in CH_2Cl_2. The ligand Fcterpy undergoes a reversible one-electron oxidation process at 0.64 eV; this is based on the ferrocene unit although at higher potential than the ferrocene itself. The cyclic voltammogram of the gold derivative **8**, at a scan rate of 100 mV s^{-1}, shows an essentially reversible wave arising from the oxidation-reduction of the ferrocene moiety at slightly lower potential than the free ligand, 0.61 eV. The copper(I) and silver(I) compounds $[M(PPh_3)(Fcterpy)]^+$ show, in addition to the wave from the ferrocene oxidation at 0.54 and 0.59 eV, respectively, a more anodic irreversible wave that can be assigned to the one electron oxidation of Cu^+ to Cu^{2+} and Ag^+ to Ag^{2+} at 0.70 and 1.12 eV. The dinuclear silver derivative $[Ag_2(Fcterpy)_2](OTf)_2$ also shows a quasi reversible wave for the oxidation-reduction of the ferrocene moieties at 0.60 eV and it is possible to distinguish two oxidation waves at 1.08 and 1.17 eV for the two Ag^+ atoms.

Experimental section[3]

Reagents and general procedures

Infrared spectra were recorded in the range 4000–200 cm^{-1} on a PerkinElmer 883 spectrophotometer using Nujol mulls

between polyethylene sheets. C, H, N, and S analyses were carried out with a PerkinElmer 2400 microanalyzer. Mass spectra were recorded on a VG Autospec, with the liquid secondary-ion mass spectra (LSIMS) technique, using nitrobenzyl alcohol as matrix. NMR spectra were recorded on a Varian Unity 300 spectrometer and a Bruker ARX 300 spectrometer in $CDCl_3$, unless otherwise stated. Chemical shifts are cited relative to $SiMe_4$ (^1H, external), $CFCl_3$ (^{19}F, external), and 85% H_3PO_4 (^{31}P, external). Cyclic voltammetric experiments were performed by employing an EG&G PARC Model 273 potentiostat. A three-electrode system was used, consisting of a platinum disk working electrode, a platinum wire auxiliary electrode, and a saturated calomel reference electrode. The measurements were carried out in CH_2Cl_2 solutions with 0.1 mol/L Bu_4NPF_6 as a supporting electrolyte. Under the present experimental conditions, the ferrocenium–ferrocene couple was located at 0.47 V vs. SCE. The starting materials Fcterpy (11), $[Au(C_6F_5)(tht)]$ (15), $[Ag(OTf)(PR_3)]$ (16), $[Cu(NO_3)(PPh_3)_2]$ (17), $[Cu(NCMe)_4]PF_6$ (17), and $[Au(C_6F_5)_3(OEt_2)]$ (18) were prepared according to published procedures. $[Au(OTf)(PPh_3)]$ was obtained by reaction of $[AuCl(PPh_3)]$ (19) with Ag(OTf) in dichloromethane and used in situ. All other reagents were commercially available.

Preparation of $[Cu(PPh_3)(Fcterpy)]NO_3$ (1)

To a solution of Fcterpy (0.041 g, 0.1 mmol) in 20 mL of dichloromethane was added $[Cu(NO_3)(PPh_3)_2]$ (0.063 g, 0.1 mmol) under an argon atmosphere, and the mixture was left to react for 40 min. Evaporation of the solvent to ca. 2 mL and addition of hexane gave a deep red solid of complex **1**; yield 53%. ^1H NMR δ: 4.09 (s, 5H, C_5H_5), 4.63 (m, 2H, C_5H_4), 5.0 (m, 2H, C_5H_4), 6.9–7.5 (m, 15H + 4H, Ph + H5,H5″ + H6,H6″), 7.66 (t, 2H, *J*(HH) = 7.45 Hz, H4,H4′), 7.97 (d, 2H, *J*(HH) = 8.06 Hz, H3,H3″), 8.01 (s, 2H, H3′,H5′). ^{31}P NMR {^1H} δ: 1.2 (s, 1 P, PPh_3). MS *m*/*z*: 742 (18%, $[Cu(PR_3)(Fcterpy)]^+$), 480 (100%, $[Cu(Fcterpy)]^+$). Anal.calcd.. for $C_{43}H_{34}CuFeN_4O_3P$: C 64.14, H 4.25, N 6.95; found: C 64.53, H 4.62, N 6.74.

Preparation of $[Ag(PR_3)(Fcterpy)]OTf$ (PR_3 = PPh_3 (2) and PPh_2Me (3))

To a solution of Fcterpy (0.041 g, 0.1 mmol) in 20 mL of dichloromethane was added $[Ag(OTf)(PPh_3)]$ (0.051 g, 0.1 mmol) or $[Ag(OTf)(PPh_2Me)]$ (0.045 g, 0.1 mmol) and the mixture was left to react for 40 min. Evaporation of the solvent to ca. 2 mL and addition of hexane gave deep red solids of complex **2** or **3**. Complex **2**: yield, 92%. ^1H NMR δ: 4.10 (s, 5H, C_5H_5), 4.54 (m, 2H, C_5H_4), 5.08 (m, 2H, C_5H_4), 7.2–7.4 (m, 15H, Ph), 7.45 (d, 2H, *J*(HH) = 7.33 Hz, H5,H5″), 7.97 (t, 2H, *J*(HH) = 7.69 Hz, H4,H4′), 8.17 (d, 2H, *J*(HH) = 4.17 H6,H6″), 8.21 (s, 2H, H3′,H5′), 8.45 (d, 2 H, *J*(HH) = 7.92 Hz, H3,H3″). ^{31}P NMR {^1H, –55 °C} δ: 12.3 (2d, 1 P, *J*(^{109}AgP) = 707, *J*(^{107}AgP) = 615 Hz, PPh_3). MS *m*/*z*: 786 (34%, $[Ag(PPh_3)(Fcterpy)]^+$), 524 (100%, $[Ag(Fcterpy)]^+$). Anal. calcd. for $C_{44}H_{34}AgF_3FeN_3O_3PS$: C 56.43, H 3.65, N 4.48, S 3.42; found: C 56.57, H 3.70, N 4.72,S 3.20. Complex **3**; yield 80%. ^1H NMR δ: 1.91 (d, 3H, *J*(HP) = 6 Hz, Me), 4.45 (s, 5H, C_5H_5), 4.84 (m, 2H, C_5H_4), 5.35 (m, 2H, C_5H_4), 7.2–7.4 (m, 10H, Ph), 7.41 (2H, H5,H5″), 7.89 (t, 2H, *J*(HH) = 7.57 Hz, H4,H4′), 7.98 (s, 2H, H3′,H5′), 7.98 (s, 2H, H3′,H5′), 8.37 (d, 2H, *J*(HH) = 3.91 Hz, H6,H6″). ^{31}P NMR {^1H, –55 °C) δ: –6.7 (2d, 1 P, *J*(^{109}AgP) = 733 Hz, *J*(^{107}AgP) = 631 Hz, PPh_2Me). MS *m*/*z*: 724 (36%, $[Ag(PPh_2Me)(Fcterpy)]^+$), 524 (100%, $[Ag(Fcterpy)]^+$). Anal.calcd. for $C_{39}H_{32}AgF_3FeN_3O_3PS$: C 53.56, H 3.68, N 4.80, S 3.66; found: C 53.69, H 3.71, N 5.12, S 3.83.

Preparation of $[Au(PPh_3)(Fcterpy)]OTf$ (4)

To a solution of Fcterpy (0.041 g, 0.1 mmol) in 20 mL of dichloromethane was added $[Au(OTf)(PPh_3)]$ (0.060 g, 0.1 mmol) and the mixture was left to react for 40 min. Evaporation of the solvent to ca. 2 mL and addition of hexane gave a deep red solid of complex **4**; yield 65%. ^1H NMR δ: 4.31 (s, 5H, C_5H_5), 4.67 (m, 2H, C_5H_4), 5.30 (m, 2H, C_5H_4), 7.2–7.5 (m, 15H + 2H, Ph + H5,H5″), 7.89 (m, 2H, H4,H4′), 8.59 (m, 2H, H6,H6″), 8.32 (m, 2 H, H3,H3″), 8.71 (s, 2H, H3′,H5′). ^{31}P NMR{^1H} δ: 33.6 (s, 1P, PPh_3). MS *m*/z: 876 (45%, $[Au(PPh_3)(Fcterpy)]^+$). Anal. calcd. for $C_{44}H_{34}AuF_3FeN_3O_3PS$: C 51.52, H 3.34, N 4.09, S 3.12; found: C 51.74, H 3.44, N 4.10, S 3.31.

Preparation of $[M_2(Fcterpy)_2]X_2$ (M = Cu, X = PF_6 (5) and M = Ag, X = OTf = (6))

To a solution of Fcterpy (0.041 g, 0.1 mmol) in 20 mL of dichloromethane was added $[Cu(NCMe)_4]PF_6$ (0.038 g, 0.1 mmol), at 0 °C and under an argon atmosphere, or Ag(OTf) (0.025 g, 0.1 mmol), and the mixture was left to react for 30 min. Evaporation of the solvent to ca. 2 mL and addition of hexane gave deep red solids of complexes **5** or **6**. Complex **5**: yield 53%. ^1H NMR δ: 4.10 (s, 5H, C_5H_5), 5.06 (m, 2H, C_5H_4), 4.52 (m, 2H, C_5H_4), 8.2 (m, 10H, terpy). MS *m*/*z*: 1129 (15%, $[Cu_2(Fcterpy)_2](PF_6)^+$), 960 (9%, $[Cu_2(Fcterpy)_2]^+$), 480 (100%, $[Cu(Fcterpy)]^+$). Anal. calcd. for $C_{50}H_{38}Cu_2F_{12}Fe_2N_6P_2$: C 47.98, H 3.06, N 6.71; found: C 47.97, H 3.27, N 7.03. Complex **6**: yield 61%. ^1H NMR δ: 4.19 (s, 5H, C_5H_5), 4.65 (m, 2H, C_5H_4), 5.32 (m, 2H, C_5H_4), 7.43 (dq, 2H, *J*(HH) = 5.0, 1.1 Hz, H5,H5″), 8.06 (dt, 2H, *J*(HH) = 7.69, 1.71 Hz, H4,H4′), 8.31 (d, 2H, *J*(HH) = 5.0 Hz, H6,H6″), 8.48 (d, 2 H, *J*(HH) = 8.05 Hz, H3,H3″), 8.51 (s, 2H, H3′,H5′). MS *m*/*z*: 1119 (4%, $[Ag_2(OTf)(Fcterpy)_2]^+$), 941 (12%, $[Ag_2(Fcterpy)_2]^+$), 524 (100%, $[Ag(Fcterpy)]^+$). Anal. calcd. for $C_{52}H_{38}Ag_2F_6Fe_2N_6O_6S_2$: C 46.31, H 2.84, N 6.23, S 4.75; found: C 46.55, H 3.02, N 6.37, S 4.66.

Preparation of $[Au(C_6F_5)_3(Fcterpy)]$ (8)

To a solution of Fcterpy (0.041 g, 0.1 mmol) in 20 mL of dichloromethane was added $[Au(C_6F_5)_3(OEt_2)]$ (0.077 g, 0.1 mmol) at 0 °C and under an argon atmosphere, and the mixture was left to react for 40 min. Evaporation of the solvent to ca. 2 mL and addition of hexane gave a deep red solid of complex **8**; yield 63%. ^1H NMR δ: 4.15 (s, 5H, C_5H_5), 4.57 (m, 4H, C_5H_4), 5.04 (m, 4H, C_5H_4), 7.51 (m, 2H, H5,H5″), 8.01 (s, 2H, H3′,H5′), 8.03 (m, 2H, H3,H3″), 8.40 (m, 2H, H4, H4′), 8.69 (d, 2H, *J*(HH) = 5.13, H6,H6″). ^{19}F NMR δ: –121.6 (m, 6F, *m*-F), –156.4 (t, 2F, *p*-F, *J*(FF) = 21.12 Hz), –156.7 (t, 1F, *p*-F, *J*(FF) = 21.33 Hz), –160.8 (m, 4F, *o*-F), –161.9 (m, 2F, *o*-F). Anal. calcd. for $C_{43}H_{19}AuF_{15}FeN_3$: C 46.30, H 1.71, N 3.76; found: C 46.25, H 1.54, N 3.49.

Crystal structure determinations

Crystals were mounted in inert oil on glass fibers and transferred to the cold gas stream of a Bruker Smart 1000 CCD (Fcterpy) or Siemens P4 (**2**, **3**) diffractometer equipped with a low-temperature attachment. Data were collected using monochromated Mo Kα radiation (λ = 0.710 73 Å) and scan type ω, or ω and ϕ. Absorption corrections based on psi-scans (**2**, **3**) or multiple scans with the program SADABS (20) (Fcterpy), were applied. The structures were refined on F^2 using the program SHELXL-97 (21). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included using a riding model. A special refinement was required for **2**: Two rings of the PPh_3 ligand are disordered over two positions and were refined isotropically. A peak of ca. 3 e/Å^3 was interpreted as a partially occupied water site. It is also involved in a contact of ca. 2.9 Å to itself, which could represent an H bond. Further details of the data collection and refinement are given in Table 4.

Probing solid iminobis(diorganophosphine chalcogenide) systems with multinuclear magnetic resonance[1]

Bryan A. Demko and Roderick E. Wasylishen

Abstract: A ^{31}P and ^{77}Se solid-state NMR investigation of the iminobis(diorganophosphine chalcogenide) HN(R_2PE)$_2$ (R = Ph, ^{i}Pr; E = O, S, Se) systems is presented. The NMR results are discussed in terms of the known HN(R_2PE)$_2$ structures available from X-ray crystallography. The phosphorus chemical shift tensors are found to be sensitive to the nature of the alkyl and chalcogen substituents. The nature of the R group also influences the selenium chemical shift tensors of HN(R_2PSe)$_2$ (R = Ph, ^{i}Pr), which are shown to be sensitive to hydrogen bonding in the dimer structure of HN(Ph$_2$PSe)$_2$ and to the presence of disorder in the case of HN(^{i}Pr$_2$PSe)$_2$. Scalar relativistic ZORA DFT nuclear magnetic shielding tensor calculations were performed yielding the orientations of the corresponding chemical shift tensors. A theoretical investigation into the effect of the E-P···P-E "torsion" angle on the phosphorus and selenium chemical shift tensors of a truncated HN(Me$_2$PSe)$_2$ system indicates that the electronic effect of the alkyl group on the respective nuclear magnetic shielding tensors are more important than the steric effect of the E-P···P-E torsion angle.

Key words: iminobis(diorganophosphine chalcogenide), solid-state NMR, ^{31}P NMR, ^{77}Se NMR, ZORA DFT.

Résumé : On a effectué une étude basée sur les RMN du ^{31}P et du ^{77}Se à l'état solide d'iminobis(chalcogénure de diorganophosphine) HN(R_2PE)$_2$ (R = Ph, ^{i}Pr; E = O, S, Se). On discute des résultats de la RMN en fonction de structures HN(R_2PE)$_2$ connues, disponibles à partir de la diffraction des rayons X. On a trouvé que les tenseurs du déplacement chimique du phosphore sont sensibles à la nature du groupe alkyle et des substituants chalcogènes. La nature du groupe R influence aussi les tenseurs du déplacement chimique du sélénium de HN(R_2PSe)$_2$ (R = Ph, ^{i}Pr) et on a démontré qu'ils sont aussi sensibles à la liaison hydrogène dans la structure dimère du HN(Ph$_2$PSe)$_2$ et à la présence de désordre dans le cas du HN(^{i}Pr$_2$PSe)$_2$. On a effectué des calculs de théorie de la fonctionnelle de densité ZORA scalaires relativistiques du tenseur de blindage magnétique qui ont permis d'obtenir les orientations correspondantes des tenseurs de déplacements chimiques. Une investigation théorique de l'effet de l'angle de torsion E-P···P-E sur les tenseurs du déplacement chimique du phosphore et du sélénium d'un système HN(Me$_2$PSe)$_2$ tronqué indique que l'effet électronique du groupe alkyle sur les tenseurs respectifs de blindage magnétique nucléaire sont plus importants que l'effet stérique de l'angle de torsion E-P···P-E.

Mots-clés : iminobis(chalcogénure de diorganophosphine), RMN à l'état solide, RMN du ^{31}P, RMN du ^{77}Se, calculs de théorie de la fonctionnelle de densité ZORA.

[Traduit par la Rédaction]

Introduction

The coordination of monoanionic bidentate ligands with metal and non-metal centers continues to provide a vast area of research interest. Acetylacetonate (acac) and its β-diketonate derivatives represent the ideological figurehead of monoanionic bidentate coordination chemistry (1). Recently, β-diketonate precursors have been utilized in the fabrication of metal oxide thin films (2) and other chemical vapor deposition applications (3). Interest in related metal chalcogenide materials has spurred the investigation of monoanionic bidentate ligands possessing the corresponding elements of Group 16. Some sulfur- and selenium-containing ligands such as dialkyldichalcogenophosphates, dialkyldichalcogenophosphinates, and dialkyldichalcogenocarbamates have appeared in the literature (4–6); however, their small chalcogen–chalcogen interatomic distances result in the formation of complexes primarily in an anisobidentate fashion (*7*). The iminobis(diorganophosphine chalcogenide) compounds, the so-called non-carbon (main group) analogues of acetylacetone, offer the opportunity to vary the donor chalcogen atom. Also, variation of the alkyl group in these ligands is more easily accessible than for the organic

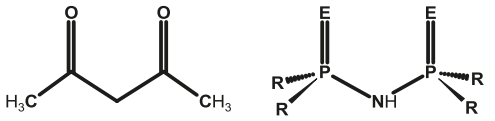
Scheme 1. Similarities between the structures of acetylacetone and the iminobis(diorganophosphine chalcogenide) systems.



analogues (8). The fine-tuning available for specific metal complexation permits comparisons between the bonding in organic and inorganic analogues, knowledge widely sought throughout the chemistry community (9). While not isoelectronic, acac and dichalcogenoimidodiphosphinate systems are closely related (Scheme 1). An early example of the Group 10 complexes of $[N(Ph_2PSe)_2]^-$ contained heterocyclic MSe_2P_2N rings that were puckered (10), unlike those of acetylacetonate that contain planar six-membered rings (11, 12). This difference has been attributed to the ability of the dichalcogenoimidodiphosphinate ligands to form delocalized systems utilizing low lying d orbitals (10, 13, 14). The structures of these complexes are known to depend on the choice of chalcogen, alkyl group, and metal (13, 15–19). Often, the complexes exhibit symmetrical coordination patterns with the donor chalcogen atoms (8, 20).

Numerous reviews of the versatile dichalcogenoimidodiphosphinate ligands exist in the literature (15, 21–23). In addition to applications as single-source precursors for solid-state metal chalcogenide materials (4–6, 20, 24–29), these bidentate ligands have found uses in the search for stereochemically active lone pairs (10, 19, 30–32), in catalysis (33–35), and in metal extraction processes (15, 36–39), as lanthanide shift reagents (40, 41), luminescent materials (42), and as enzyme mimetics (43–45).

Despite the considerable interest in the properties and chemistry of the complexes of dichalcogenoimidodiphosphinate ligands, relatively little is known about the neutral iminobis(diorganophosphine chalcogenide) $HN(R_2PE)_2$ derivatives (46). Characterization of these systems has predominantly been performed by X-ray crystallography (10, 31, 47–53), often accompanied by IR (31, 54–57), Raman (56, 57), and (or) solution NMR spectroscopy (10, 31, 47, 54, 58). Solid-state NMR, being potentially more informative than solution NMR spectroscopy, would appear to be an appropriate technique for characterizing the $HN(R_2PE)_2$ ligands. Recently, we have demonstrated the use of solid-state NMR spectroscopy in the characterization of the metal(II) complexes of the $[N(^iPr_2PSe)_2]^-$ ligand (59, 60). Herein we present a solid-state ^{31}P and ^{77}Se NMR investigation of the $HN(R_2PE)_2$ (E = O, S, Se; R = Ph, ^{i}Pr) systems representing the first solid-state NMR investigation of the iminobis(diorganophosphine chalcogenides). Comparisons of the solid-state NMR results obtained herein with those of the $M[N(^iPr_2PSe)_2]_2$ complexes previously investigated are made, where appropriate (59, 60).

Experimental

Sample preparation

The phenyl and isopropyl variants of bis(diorganophosphino)amine $HN(R_2P)_2$ were prepared via the condensation reaction between hexamethyldisilazane $HN(SiMe_3)_2$ and the appropriate chlorodiorganophosphine R_2PCl (Sigma-Aldrich) (55, 61). Briefly, R_2PCl in toluene is added dropwise to a hot toluene solution of $HN(SiMe_3)_2$ and is maintained above 80 °C for at least two hours to remove the chlorotrimethylsilane by-product by distillation. Oxidation to the corresponding iminobis(diorganophosphine chalcogenide) was achieved from the subsequent reaction with hydrogen peroxide in an ice bath (55, 62) and via reflux with either elemental sulfur (55) or elemental selenium (10, 20). X-ray crystal structures from the literature, for each of the investigated iminobis(diorganophosphine chalcogenide) systems, $HN(R_2PE)_2$ (E = O; R = Ph (*50*) and ^{i}Pr (31), E = S; R = Ph (50–52) and ^{i}Pr (47), E = Se; R = Ph (10) and ^{i}Pr (31)), have been previously reported.

NMR experiments

Solid-state NMR investigations of powdered samples of $HN(R_2PE)_2]_2$ (E = O, S, Se; R = Ph, ^{i}Pr) were obtained using 4.70 T, 7.05 T, and 11.75 T NMR spectrometers. The samples were packed in 4 mm (7.05 T and 11.75 T) and 7.5 mm (4.70 T) o.d. zirconium oxide rotors and were placed within probes suitable for magic angle spinning, MAS, NMR experiments. A ramped amplitude cross polarization (RACP) pulse sequence was used to acquire all spectra (63). Two-pulse phase-modulation (TPPM) (64) and proton decoupling fields of approximately 60 kHz were utilized. The ^{31}P NMR spectra were referenced with respect to 85% aq. H_3PO_4 by setting the isotropic ^{31}P NMR peak of solid $(NH_4)H_2PO_4$ to 0.81 ppm (65). Selenium-77 NMR spectra were referenced to Me_2Se (l) by setting the isotropic peak of solid ammonium selenate $(NH_4)_2SeO_4$ to 1040.2 ppm (65, 66).

Solid-state ^{31}P NMR experiments were performed at Larmor frequencies of 81.0, 121.6, and 202.5 MHz, and at spinning frequencies ranging from 3.0 to 7.2 kHz. A total of between 64 and 128 scans were acquired per spectrum. Contact times between 1.5 and 6.5 ms, and pulse delays between 600 and 840 s for $HN(Ph_2PE)_2$ systems and between 7 and 18 s for the $HN(^iPr_2PE)_2$ systems were employed.

Solid-state ^{77}Se NMR measurements were performed at Larmor frequencies of 38.2, 57.3, and 95.4 MHz, and at spinning frequencies ranging from 2.0 to 14.0 kHz. A total of between 384 and 16 384 scans were acquired per spectrum. Contact times between 6.5 and 10.0 ms, and pulse delays between 600 and 840 s for $HN(Ph_2PE)_2$ species and between 5 and 14 s for the $HN(^iPr_2PE)_2$ systems were employed.

The principal components of the respective phosphorus and selenium chemical shift tensors, $\delta_{11} \geq \delta_{22} \geq \delta_{33}$, were determined from the experimental spectra using the procedure of Herzfeld and Berger (67, 68). All experimental solid-state NMR spectra were simulated using the determined values with the program WSOLIDS (69) to assess the quality of the obtained parameters. This procedure results in errors of ±0.2 ppm in the isotropic chemical shift, $\delta_{iso} = (1/3)(\delta_{11} + \delta_{22} + \delta_{33})$, and errors in the principal components of approximately 1%–3% of the span, $\Omega = \delta_{11} - \delta_{33}$, of the respective chemical shift tensors. Another useful quantity for describing the appearance of chemical shift powder patterns is the skew, $\kappa = 3(\delta_{22} - \delta_{iso})/\Omega$, where axial symmetry is described by $\kappa = +1$ or -1 (70).

© 2008 NRC Canada

DFT computations

Theoretical calculations of NMR parameters were performed on isolated molecules. Cartesian coordinates of the atoms were generated from the reported crystal structures placing hydrogen atoms at idealized locations (r_{CH} = 1.08 Å (R = Ph), 1.09 Å (R = ^{i}Pr)). Magnetic shielding tensors σ were calculated using the NMR module (71–73) of the Amsterdam density functional (ADF) program package (74–78). The Vosko–Wilk–Nusair (79) local density approximation with the Becke88–Perdew86 (80–82) generalized gradient approximation were used for the exchange-correlation functional. Scalar relativistic corrections were carried out based on the implementation of the zero-order regular approximation (ZORA) formalism (83–86). Triple-ζ doubly polarized (TZ2P) Slater-type ZORA basis sets were used for all atoms except for hydrogen, where double-ζ quality (DZ) basis functions were utilized. The corresponding phosphorus and selenium chemical shift tensors were obtained from the magnetic shielding tensors using the relationship,

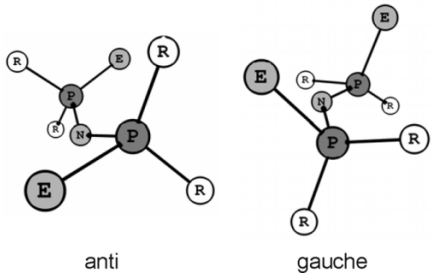
$$[1] \qquad \delta_{ii}(\text{sample}) = \frac{\sigma_{\text{iso}}\ (\text{ref}) - \sigma_{ii}(\text{sample})}{1 - \sigma_{\text{iso}}\ (\text{ref})}$$

where σ_{iso}(ref) is the isotropic shielding of a standard reference. The absolute shielding scale for ^{31}P has been determined, and the value of σ_{iso} (85% aq. H_3PO_4) has been established to be 328.35 ppm (87). We have previously investigated the selenium chemical shift tensors in a wide range of selenium-containing compounds and used the value of 1580 ppm determined therein for the isotropic reference shielding of a neat liquid of dimethyl selenide at 23 °C (*88*).

Results and discussion

A common difference between the R = Ph and R = ^{i}Pr structures of the HN(R_2PE)$_2$ systems is that while the EPNPE backbones in iminobis(diphenylphosphine chalcogenide) species are oriented *anti*, the HN(^{i}Pr$_2$PE)$_2$ (E = O, S, Se) molecules all possess *gauche* conformations (Fig. 1). X-ray diffraction studies of each of the iminobis(diorganophosphine chalcogenides) investigated here indicate that the crystals contain one molecule in the asymmetric unit. The reported structure for HN(Ph_2PO)$_2$ contains an inversion center providing chemical equivalence between the two phosphorus atoms such that only a single phosphorus chemical shift tensor is expected for this sample. The remaining samples investigated, HN(Ph_2PE)$_2$ (E = S, Se) and HN(^{i}Pr$_2$PE)$_2$ (E = O, S, Se), do not possess any symmetry elements within their respective molecular structures providing chemical equivalence between the two phosphorus (or two selenium) atoms, thus two distinct phosphorus (or selenium) chemical shift tensors are expected in the experimental NMR spectra. The obtained phosphorus chemical shift tensors for the iminobis(diorganophosphine chalcogenide) systems are presented first, followed by the results of a solid-state ^{77}Se NMR study on HN(R_2PSe)$_2$ (R = Ph, ^{i}Pr). As the syntheses of the phenyl-derivatized species were reported prior to the isopropyl variants, the results for HN(Ph_2PE)$_2$ will precede those for HN(^{i}Pr$_2$PE)$_2$. The extracted NMR parameters are discussed in terms of the known molecular structures, highlighting the impact in the choice of R group and (or) chalcogen where applicable. DFT computations are used to provide the orientations of the phosphorus and selenium nuclear magnetic shielding tensors.

Fig. 1. Common conformations encountered in iminobis(diorganophosphine chalcogenide), HN(R_2PE)$_2$ (E = O, S, Se), systems.



Solid-state ^{31}P NMR

The ^{31}P NMR parameters obtained for each of the HN(R_2PE)$_2$ (E = O, S, Se; R = Ph, ^{i}Pr) samples investigated are given in Table 1, along with theoretical calculations of the corresponding phosphorus chemical shift tensors. Experimental solid-state ^{31}P NMR spectra for HN(R_2PO)$_2$, HN(R_2PS)$_2$, and HN(R_2PSe)$_2$ are given in Figs. 2, 5, and 6, respectively.

HN(R_2PO)$_2$ (R = Ph, ^{i}Pr)

For the phenyl derivative, the imidodiphosphinic acid tautomer $Ph_2P(OH)NP(O)Ph_2$ (50) was found instead of the initially hypothesized HN(Ph_2PO)$_2$ structure (48, 49), which possesses an acidic N-H proton. As a result, $Ph_2P(OH)NP(O)Ph_2$ has a considerably different structure from the other iminobis(diorganophosphine chalcogenide) systems investigated that all display acidic N-H protons. Similar to the HN(Ph_2PE)$_2$ (E = S, Se) molecules that possess a solid-state structure in which the EPNPE backbone adopts an *anti* conformation, $Ph_2P(OH)NP(O)Ph_2$ is *trans* with an O-P···P-O "torsion" angle of 180° (50). However, unique to the $Ph_2P(OH)NP(O)Ph_2$ system is a linear P-N-P angle of 180° (50). The solid-state ^{31}P NMR spectrum is given, along with its simulation, in Fig. 2*a*. Contrary to the single phosphorus environment expected from the crystal structure of $Ph_2P(OH)NP(O)Ph_2$ (50), two phosphorus chemical shift tensors were extracted (Table 1), which possess isotropic chemical shifts and spans that differ by more than 20 ppm despite the two tensors possessing similar skews. As the ^{31}P NMR spectrum (not shown) of a chloroform solution of $Ph_2P(OH)NP(O)Ph_2$ displays only a single peak, the solid sample investigated, as obtained from a methylene chloride – hexanes recrystallization, must be of a different polymorph of $Ph_2P(OH)NP(O)Ph_2$ than the reported structure from a crystal grown in glacial acetic acid (50).

Phosphorus chemical shift tensors from the DFT computations of a single $Ph_2P(OH)NP(O)Ph_2$ unit from the reported crystal structure (50) (Table 1) produce comparable values of δ_{iso}, δ_{ii}, Ω, and κ with the experimentally determined parameters; however, they do not predict an equally large difference between the two respective isotropic chemical shifts. This discrepancy is likely a result of using the geometry from the reported crystal structure, which is not entirely representative of the actual solid-state structure of the solid

[a]For directly bonded selenium-77 and phosphorus-31 spin pairs; signs of $^1J(^{77}Se,^{31}P)_{iso}$ are known to be negative for numerous analogous systems (95, 96).

sample investigated, as well as the neglect of intermolecular effects including potential hydrogen bonding between $Ph_2P(OH)NP(O)Ph_2$ molecules. Additionally, the computations indicate that the phosphorus bearing the hydroxyl group is more shielded than the P=O phosphorus in $Ph_2P(OH)NP(O)Ph_2$. The calculated orientations of the two phosphorus chemical shift tensors are also different, as shown in Fig. 3*a*. The computed P-OH phosphorus chemical shift tensor is oriented with δ_{11} perpendicular to the local O-P-N plane, and δ_{33} approximately parallel to the P-N vector with δ_{22} within the O-P-N plane and perpendicular to P-N. The calculated P=O phosphorus chemical shift tensor places δ_{11} perpendicular to the local O-P-N plane, while in contrast δ_{33} is oriented nearly parallel to the P-O vector with δ_{22} within the O-P-N plane and perpendicular to P-O. The orientation of the P=O phosphorus chemical shift tensor is similar to what is consistently found for tris-organophosphine oxides (89).

One of the largest differences between HN(^{i}Pr$_2$PO)$_2$ and $Ph_2P(OH)NP(O)Ph_2$ is that iminobis(diisopropylphosphine oxide) possesses an acidic N-H proton leading to a P-N-P angle of 130° (31). The *gauche* conformation of HN(^{i}Pr$_2$PO)$_2$, reflected in a 52° O-P···P-O "torsion" angle, yields a chain-like arrangement of HN(^{i}Pr$_2$PO)$_2$ units in its solid state structure (31). The X-ray structure of HN(^{i}Pr$_2$PO)$_2$ displays some disorder in that one methyl carbon on one isopropyl group possesses two 50% occupancy sites (31). There exists three spinning sideband manifolds corresponding to three discernable signals in the ^{31}P MAS spectrum of HN(^{i}Pr$_2$PO)$_2$ given in Fig. 2*b*; however, as one of the three signals is significantly less intense than the other two it is considered to be a minor impurity in the sample rather than resulting from disorder in the structure. The impurity can be readily identified in Fig. 2*b* by comparison of the experimental with the simulated spectrum. The two isotropic phosphorus chemical shifts obtained (Table 1) are in good agreement with the ^{31}P NMR value from a chloroform solution of HN(^{i}Pr$_2$PO)$_2$, i.e., 55.5 ppm (31). The phosphorus environments are deshielded with respect to those of $Ph_2P(OH)NP(O)Ph_2$ and possess slightly smaller spans and larger positive skews. The steric or electronic source of this difference will be discussed later. One phosphorus environment indicates an axially symmetric chemical shift tensor despite there being no symmetry reasons for attaining this axial symmetry. Methods for obtaining accurate principal components of the chemical shift tensor from spectra of MAS samples are known to have the greatest difficulty with axially or near axially symmetric species (90).

Calculated phosphorus chemical shift tensors were obtained for both of the 50% occupancy structures (31), labeled "a" and "b" in the Table 1. Both phosphorus chemical shift tensors computed for each of the two structures are in

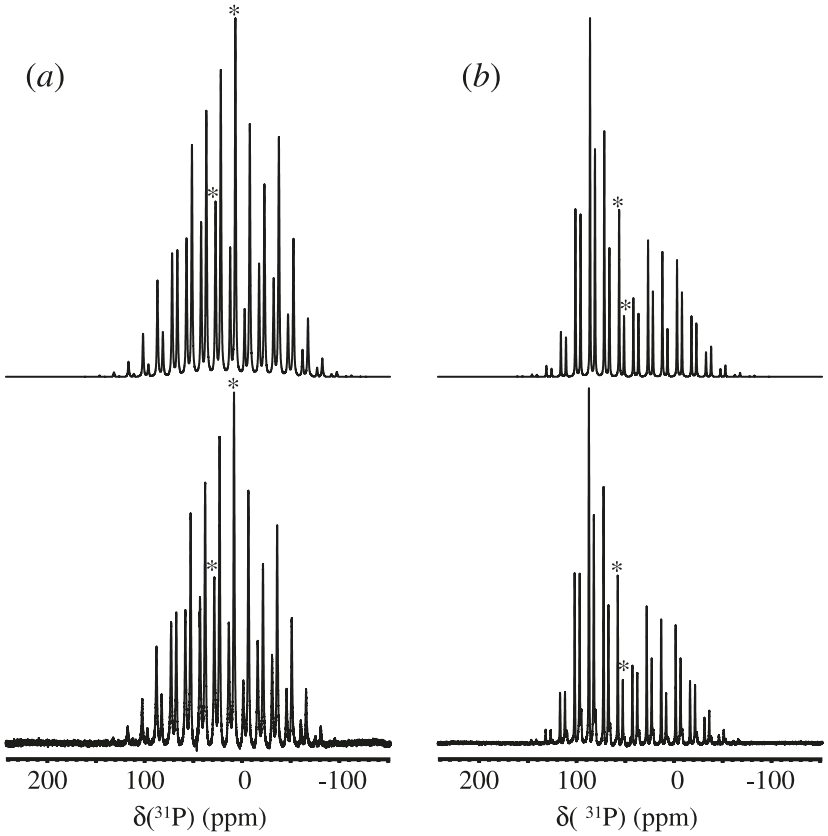
Fig. 2. (*a*) RACP MAS ^{31}P NMR spectrum (lower trace) for $Ph_2P(OH)NP(O)Ph_2$ and its simulation (upper trace). Experimental conditions: 11.75 T, 64 scans, MAS at 3.0 kHz, 10 Hz of line broadening, 3.0 ms contact time, and 900 s recycle delay. (*b*) RACP MAS ^{31}P NMR spectrum (lower trace) for $HN(^iPr_2PO)_2$ and its simulation (upper trace). Experimental conditions: 11.75 T, 128 scans, MAS at 3.0 kHz, 10 Hz of line broadening, 3.0 ms contact time, and 18 s recycle delay. The isotropic peaks are marked with an asterisk (*).



reasonable agreement with the experimental values. The values of δ_{ii}(calcd.) are quite similar for structures "a" and "b", suggesting that the presence of disorder in the methyl group does not significantly affect the phosphorus shielding in $HN(^iPr_2PO)_2$. This is consistent with the solid-state ^{31}P NMR spectrum (Fig. 2*b*) where no discernable difference in the obtained line widths or line shapes of the two phosphorus environments was detected. In contrast to the calculated orientations of the phosphorus chemical shift tensors in $Ph_2P(OH)NP(O)Ph_2$, all phosphorus tensors for $HN(^iPr_2PO)_2$ are oriented similarly (Fig. 3*b*). The computations place δ_{33} approximately along the O-P vector, and δ_{22} perpendicular to the local O-P-N plane, with δ_{11} perpendicular to O-P within the O-P-N plane.

$HN(R_2PS)_2$ (R = Ph, ^{i}Pr)

The *anti* conformation of $HN(Ph_2PS)_2$, with a S-P···P-S torsion angle of 156° is similar to that of $Ph_2P(OH)NP(O)Ph_2$, while the P-N-P angle of 133° is consistent with a PNP backbone that possesses a protonated nitrogen (50–52). The solid state structure consists of two $HN(Ph_2PS)_2$ molecules hydrogen bonded to form dimer pairs (Fig. 4) (50–52). The ^{31}P NMR parameters obtained from the RACP MAS spectrum for $HN(Ph_2PS)_2$ (Fig. 5*a*) are given in Table 1. The isotropic chemical shifts obtained are in good agreement with the solution ^{31}P NMR values of 55.1 ppm in THF (54) and 58.2 ppm in $CDCl_3$ (58). The phosphorus chemical shift tensors of $HN(Ph_2PS)_2$ describe phosphorus nuclei that are more deshielded, possess larger spans, and have slightly more positive values of κ than those obtained for $Ph_2P(OH)NP(O)Ph_2$.

The DFT computations were performed on a dimer of $HN(Ph_2PS)_2$ units. The calculated principal components of the respective phosphorus chemical shift tensors slightly overestimate the corresponding experimental values. The orientations of the two calculated phosphorus chemical shift tensors (Fig. 3*c*) are nearly identical and most closely resemble those calculated for the P=O phosphorus of $Ph_2P(OH)NP(O)Ph_2$, with δ_{33} approximately parallel to the P-S vector, δ_{11} perpendicular to the local S-P-N plane, and δ_{22} nearly within the S-P-N plane perpendicular to P-S. These orientations are consistent with those obtained for tris-organophosphine sulfide systems (89) and similar to those found in tetramethyldiphosphine disulfide (91).

Similar to that of $HN(^iPr_2PO)_2$, the structure of $HN(^iPr_2PS)_2$ contains a 132° P-N-P angle; however, the S-P···P-S torsion angle is slightly larger at 79° and the X-ray structure reports no evidence of disorder (47). The solid-state ^{31}P NMR spectrum of $HN(^iPr_2PS)_2$ is given in Fig. 5*b*. The isotropic chemical shifts for the two phosphorus environments are in good agreement with the value of 91.2 ppm reported for $HN(^iPr_2PS)_2$ in $CDCl_3$ (47). Similar to the chemical shift tensors describing the phosphorus shielding of $HN(Ph_2PS)_2$ and $Ph_2P(OH)NP(O)Ph_2$, the two phosphorus

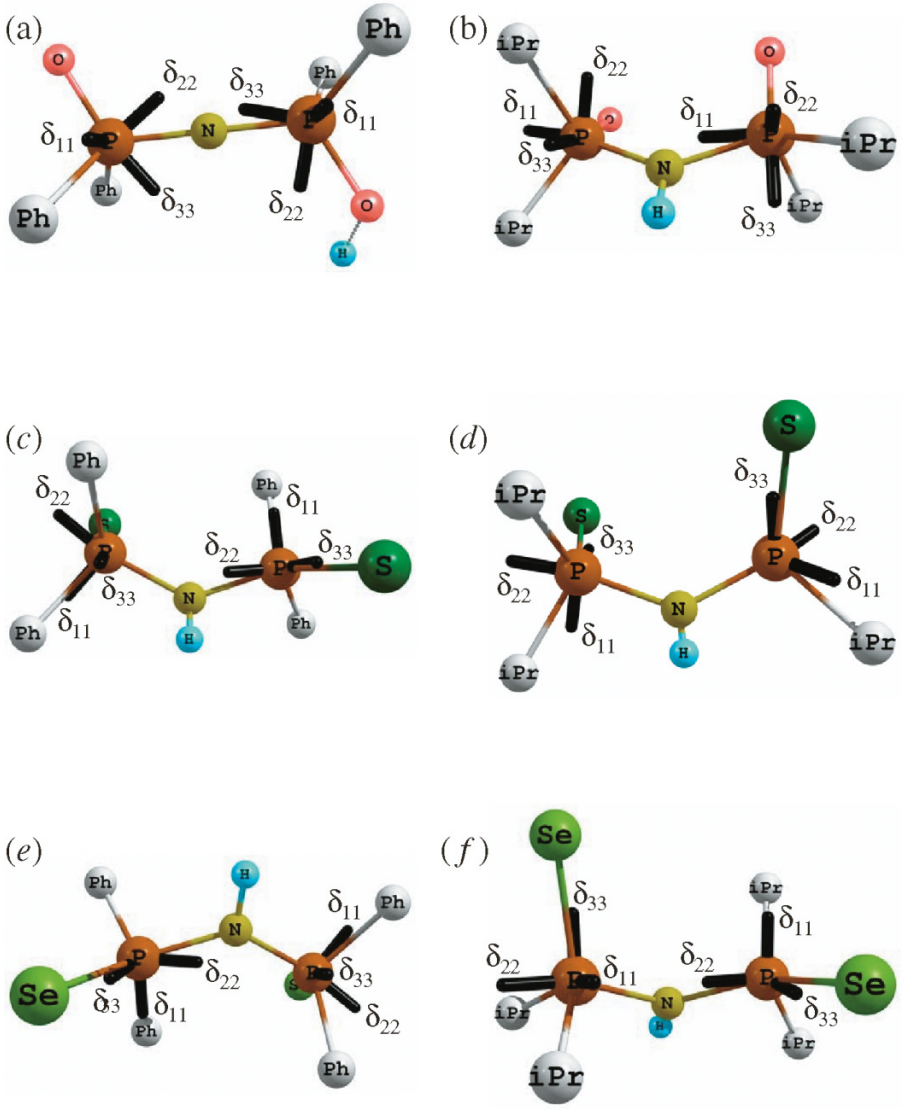

Fig. 4. Dimer structure of $HN(Ph_2PE)_2$ (E = S, Se).

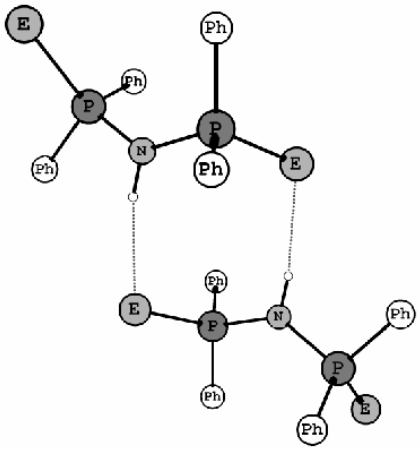

environments of $HN(^iPr_2PS)_2$ are more deshielded and possess larger spans than those for $HN(^iPr_2PO)_2$. Solution ^{31}P NMR for the mixed chalcogen system $^iPr_2P(O)NHP(S)^iPr_2$ displays a comparable difference in the values of $\delta_{iso}(^{31}P)$, 54.8 and 90.9 ppm (31). Additionally, as with the E = O compounds, the phosphorus sites in $HN(^iPr_2PS)_2$ are more deshielded and have larger positive skews than the phenyl derivative.

Calculated phosphorus chemical shift tensors for $HN(^iPr_2PS)_2$ are given in Table 1. The computed values of δ_{iso}, δ_{ii}, Ω, and κ are in reasonable agreement with the experimentally obtained parameters. As observed with the calculated orientation of the tensors in $HN(^iPr_2PO)_2$, the two phosphorus chemical shift tensors for $HN(^iPr_2PS)_2$ (Fig. 3*d*) are approximately identical and place δ_{33} nearly parallel to the E-P vector; however, the directions of δ_{11} and δ_{22} are essentially reversed in $HN(^iPr_2PS)_2$ with respect to $HN(^iPr_2PO)_2$, with δ_{11} perpendicular to the local S-P-N plane and δ_{22} within the S-P-N plane perpendicular to S-P.

$HN(R_2PSe)_2$ (R = Ph, ^{i}Pr)

Isomorphous with $HN(Ph_2PS)_2$, the dimer structure of $HN(Ph_2PSe)_2$ possesses an *anti* conformation with a Se-P···P-Se torsion angle of 154° and a P-N-P angle of 132° (10). The phosphorus chemical shift parameters, along with an estimation of the one-bond selenium–phosphorus indirect spin–spin coupling constant $^1J(^{77}Se,^{31}P)_{iso}$ from the MAS ^{31}P NMR spectrum (Fig. 6*a*) are reported in Table 1. The values of $\delta_{iso}(^{31}P)$ and $^1J(^{77}Se,^{31}P)_{iso}$ obtained are in good agreement with those from ^{31}P NMR of methylene chloride and chloroform solutions of $HN(Ph_2PSe)_2$, 53.0 ppm and (–)793 Hz (10), and 53.2 ppm (58), respectively. The principal components of the phosphorus chemical shift tensors are very similar to those found for $HN(Ph_2PS)_2$ (Table 1) indicating that the impact of exchanging oxygen for sulfur in $HN(Ph_2PE)_2$ is larger than exchanging sulfur for selenium.

The phosphorus chemical shift tensors were calculated for a dimer of $HN(Ph_2PSe)_2$ molecules (10). The calculations overestimate the values of δ_{iso} and Ω, indicating that scalar relativistic effects may not be sufficient to accurately describe the shielding environment for $HN(Ph_2PSe)_2$, and that spin–orbit relativistic effects may be important. Similar to those of $HN(Ph_2PS)_2$, the calculated orientations of the phosphorus chemical shift tensors in $HN(Ph_2PSe)_2$ (Fig. 3*e*) place δ_{11} perpendicular to the local Se-P-N plane, δ_{33} approximately along the P-Se vector, and δ_{22} within the Se-P-N plane perpendicular to P-Se. This orientation is similar to that found for tris-organophosphine selenides (89).

The structure of $HN(^iPr_2PSe)_2$ more closely resembles that of $HN(^iPr_2PS)_2$ with an 80° Se-P···P-Se torsion angle and a P-N-P angle of 131° (31). However, similar to the structure of $HN(^iPr_2PO)_2$, the selenium analogue was refined where the location of one methyl carbon on one isopropyl group contained two 50% occupancy locations (31). The isotropic chemical shifts and $^1J(^{77}Se,^{31}P)_{iso}$ values extracted (Table 1) from the simulation of the solid-state ^{31}P NMR spectrum of $HN(^iPr_2PSe)_2$ (Fig. 6*b*) are in good agreement with those from a chloroform solution ^{31}P NMR study, 89.5 ppm and (–)757 Hz (31). Similar to the solid-state ^{31}P NMR spectrum of $HN(^iPr_2PO)_2$ (Fig. 2*b*), no evidence for the disorder in the methyl group was detected in the corresponding spectrum for iminobis(diisopropylphosphine selenide). As with the phosphorus chemical shift tensors of $HN(Ph_2PE)_2$ (E = S, Se), the two tensors for $HN(^iPr_2PSe)_2$ are comparable to those found for $HN(^iPr_2PS)_2$ (Table 1). The isotropic phosphorus chemical shifts of the mixed chalcogen compound $^iPr_2P(S)NHP(Se)^iPr_2$ from a chloroform solution ^{31}P NMR study are also very similar at 89.2 and 92.1ppm (31).

Phosphorus chemical shift tensors were calculated for both of the 50% occupancy structures (31), labeled "a" and "b" in Table 1. The scalar relativistic calculated phosphorus

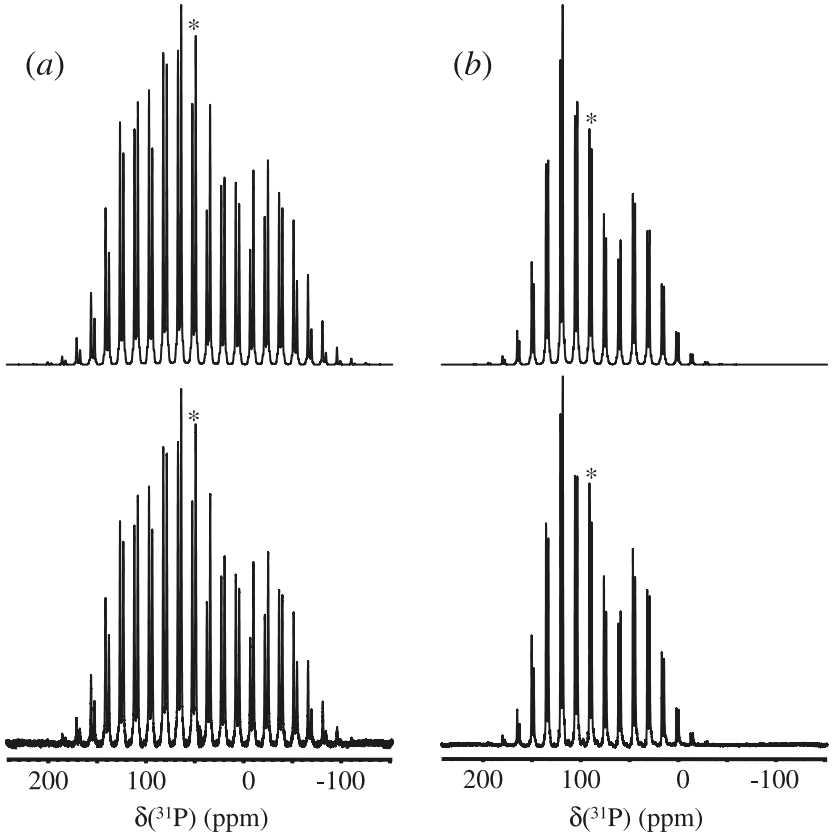
Fig. 6. (*a*) RACP MAS ^{31}P NMR spectrum (lower trace) for $HN(Ph_2PSe)_2$ and its simulation (upper trace). Experimental conditions: 11.75 T, 64 scans, MAS at 3.0 kHz, 10 Hz of line broadening, 3.0 ms contact time, and 900 s recycle delay. (*b*) RACP MAS ^{31}P NMR spectrum (lower trace) for $HN(^iPr_2PSe)_2$ and its simulation (upper trace). Experimental conditions: 11.75 T, 128 scans, MAS at 3.0 kHz, 10 Hz of line broadening, 3.0 ms contact time, and 18 s recycle delay. The isotropic peaks are marked with an asterisk (*).



chemical shift tensors for $HN(^iPr_2PSe)_2$, as with those for $HN(Ph_2PSe)_2$, overestimate the experimental values. Analogous to those for $HN(^iPr_2PO)_2$, the calculated phosphorus chemical shift tensors for $HN(^iPr_2PSe)_2$ structures "a" and "b" are nearly identical and suggest that evidence for the disorder is unlikely to come from the solid-state ^{31}P NMR spectrum. As with the calculated orientations of the phosphorus chemical shift tensors in $HN(^iPr_2PO)_2$, all four tensors for iminobis(diisopropylphosphine selenide) are identical, as shown in Fig. 3*f*. They are all oriented similarly to those of $HN(^iPr_2PS)_2$ with δ_{33} near the P-Se vector, δ_{11} perpendicular to the local Se-P-N plane, and δ_{22} within the Se-P-N plane perpendicular to the P-Se vector.

Solid-state ^{77}Se NMR

The solid-state ^{77}Se NMR spectrum for $HN(Ph_2PSe)_2$ is given in Fig. 7*a* and the ^{77}Se NMR parameters extracted from its simulation are reported in Table 2. The values of $^1J(^{77}Se,^{31}P)_{iso}$ obtained are in agreement with those from solution ^{31}P NMR (10) and with our solid-state ^{31}P NMR values (Table 1) above. Similar to the large difference in isotropic phosphorus chemical shifts observed for $Ph_2P(OH)NP(O)Ph_2$, there is a significant difference between the two values of δ_{iso}(Se) in $HN(Ph_2PSe)_2$. The spans of the selenium chemical shift tensors are both larger than any of the phosphorus chemical shift tensors, which is consistent with the less symmetric environment of selenium in the iminobis(diorganophosphine chalcogenide) systems and the larger chemical shift range of selenium with respect to that of phosphorus (92, 93).

The dimer structure of $HN(Ph_2PSe)_2$ (Fig. 4) was used to calculate the selenium chemical shift tensors. The computed principal components are in good agreement with the experimental values, particularly in the difference in shielding between the two chemical shift tensors. The calculations indicate that the selenium that participates in hydrogen bonding between the two $HN(Ph_2PSe)_2$ molecules is less shielded than the selenium that is not involved in hydrogen bonding. The calculated orientations of the two selenium chemical shift tensors are also different (Fig. 8*a*). For the selenium involved in hydrogen bonding between the dimers, δ_{33} is nearly parallel to the Se-P vector, δ_{11} is perpendicular to the local Se-P-N plane, and δ_{22} is within the Se-P-N plane perpendicular to Se-P. The selenium that is not involved in hydrogen bonding possesses a chemical shift tensor that orients δ_{22} approximately along Se-P, with δ_{11} perpendicular to the local Se-P-N plane, and δ_{33} within the Se-P-N plane perpendicular to Se-P.

The ^{77}Se NMR parameters obtained from the solid-state ^{77}Se NMR spectrum for $HN(^iPr_2PSe)_2$ (Fig. 7*b*) are given in Table 2. The two $^1J(^{77}Se,^{31}P)_{iso}$ obtained are in good agreement with the reported values from solution (31) and solid-

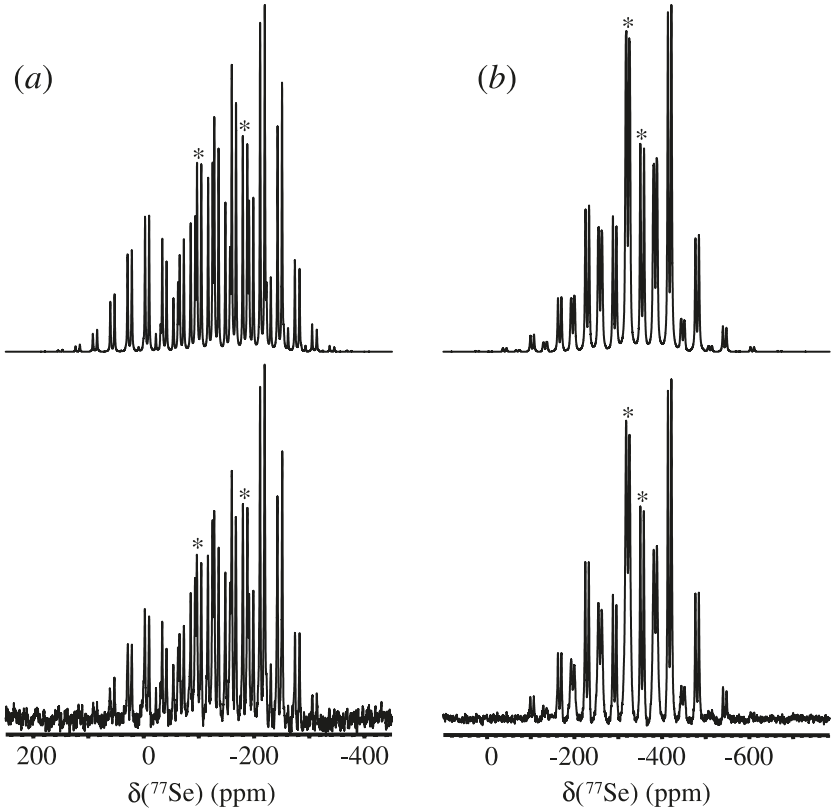
Fig. 7. (*a*) RACP MAS ^{77}Se NMR spectrum (lower trace) for HN($Ph_2PSe)_2$ and its simulation (upper trace). Experimental conditions: 11.75 T, 384 scans, MAS at 3.0 kHz, 50 Hz of line broadening, 10.0 ms contact time, and 840 s recycle delay. (*b*) RACP MAS ^{77}Se NMR spectrum (lower trace) for HN($^i Pr_2PSe)_2$ and its simulation (upper trace). Experimental conditions: 11.75 T, 5288 scans, MAS at 6.0 kHz, 50 Hz of line broadening, 6.5 ms contact time, and 14 s recycle delay. The isotropic peaks are marked with an asterisk (*).



state (above) ^{31}P NMR. Unlike those for HN($Ph_2PSe)_2$, the two isotropic selenium chemical shifts for iminobis(diisopropylphosphine selenide) are more shielded and significantly closer together. In contrast to the solid-state ^{31}P NMR spectra for HN($^i Pr_2PE)_2$ (E = O, Se), the solid-state ^{77}Se NMR spectrum for HN($^i Pr_2PSe)_2$ appears to be sensitive to the disorder of the methyl group in the structure (31). Figure 9 displays the isotropic region of the solid-state ^{77}Se NMR spectra for HN($R_2PSe)_2$ (R = Ph, ^{i}Pr), where one of the two J-coupled isotropic peaks for HN($^i Pr_2PSe)_2$ is visibly broader than the other.

The two calculated selenium chemical shift tensors for each of the two 50% occupancy structures also suggest that the impact of the disorder of the methyl group should be more pronounced in the solid-state ^{77}Se NMR spectrum; however, the calculations indicate that both selenium environments should be influenced by the disorder. The calculations predict that the selenium environment that is furthest from the methyl group should be affected more than the proximal selenium. The calculated orientations of the selenium chemical shift tensors (Fig. 8*b*) are identical for structures "a" and "b", yet distinct. The chemical shift tensor for the selenium distal to the methyl disorder is oriented such that δ_{33} is nearly along the Se-P vector, δ_{11} is perpendicular to the local Se-P-N plane, while δ_{22} lies within the Se-P-N plane perpendicular to Se-P. The selenium nearest the methyl disorder possesses a calculated chemical shift tensor that also places δ_{11} approximately perpendicular to the local Se-P-N plane; however, the P-Se vector nearly bisects the δ_{22}-Se-δ_{33} angle within the Se-P-N plane.

Iminobis(diorganophosphine selenide) vs. diselenoimidodiphosphinato complexes

Upon comparison with the phosphorus and selenium chemical shift tensors of the M[N($^i Pr_2PSe)_2]_2$ complexes previously investigated (59, 60), there are some consistent changes in the calculated orientations of the phosphorus and selenium chemical shift tensors of HN($^i Pr_2PSe)_2$ upon deprotonation and complexation with a cationic center. The phosphorus chemical shift tensors in the diselenoimidodiphosphinato complexes are all oriented similarly, with δ_{33} nearly parallel to the P-N bond vector, δ_{11} perpendicular to the local Se-P-N vector, and δ_{22} within the Se-P-N plane perpendicular to the P-N vector (59, 60). This is in contrast to the majority of the phosphorus chemical shift tensors where δ_{33} is nearly parallel to the P-E vector, and most closely resembles the orientation of the phosphorus chemical shift tensor for the P-OH environment in $Ph_2P(OH)NP(O)Ph_2$. The change in the orientation of the selenium chemical shift tensor upon complexation is not quite as predictable. When [N($^i Pr_2PSe)_2]^-$ is coordinated with a Group 10 (Pd or Pt) or 12 (Zn, Cd or Hg) metal center, the orientation of the selenium chemical shift tensor remains essentially identical to that found in HN($^i Pr_2PSe)_2$ with δ_{33} nearly parallel to the P-Se vector, δ_{11} perpendicular to the local Se-P-N plane, and δ_{22} perpendicular to the P-Se vector (59, 60). However, when

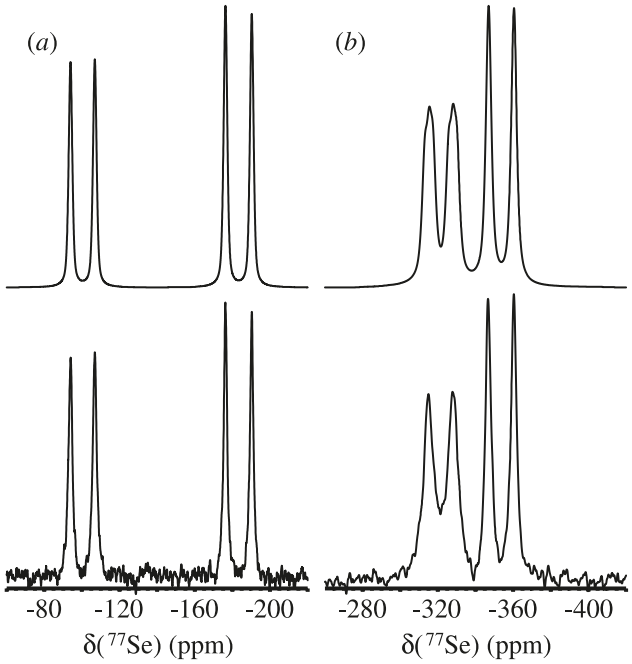
coordinated to a Group 16 (Se or Te) center, the orientation of the selenium chemical is significantly different in that δ_{33} is directed nearly parallel to the Se-Se or Te-Se vector, δ_{11} nearly parallel to the Se-P vector, and δ_{22} perpendicular to the Se-Se-P/Te-Se-P plane (60).

The influence of the *E*-P···P-*E* torsion angle on ^{31}P and ^{77}Se NMR parameters

From Table 1, it is clear that the phosphorus environments in the HN($Ph_2PE)_2$ (E = O, S, Se) systems, which all possess

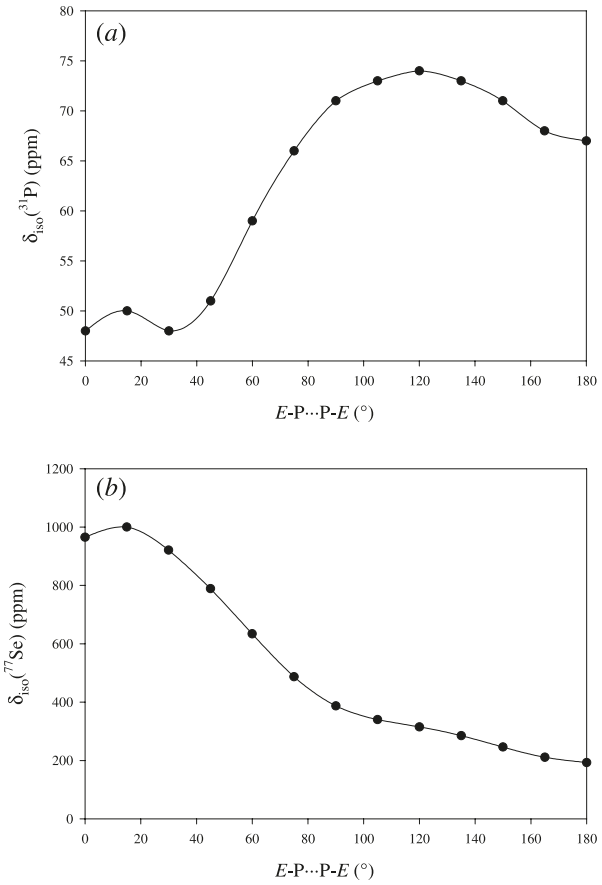
Fig. 9. Isotropic region of the ^{77}Se NMR spectrum for (*a*) HN($Ph_2PSe)_2$ and (*b*) HN($^iPr_2PSe)_2$ (lower traces) and their simulations (upper traces).



anti *E*-P···P-*E* torsion angles, are all more shielded than their HN($^iPr_2PE)_2$ counterparts that have *gauche* torsion angles. Conversely, in Table 2 the selenium nuclei of HN($Ph_2PSe)_2$ are both less shielded than those of HN($^iPr_2PSe)_2$. The consistent differences observed in the isotropic chemical shifts between the phenyl and isopropyl variants of HN($R_2PE)_2$ (E = O, S, Se) are likely to arise from a combination of the electronic effects of the chosen R group and the common steric differences between the structures. To probe the nature of these differences, nuclear magnetic shielding calculations were performed on a truncated system, HN($Me_2PSe)_2$. The HN($Me_2PSe)_2$ structure was achieved by replacing the isopropyl groups of one of the two 50% occupancy structures of HN($^iPr_2PSe)_2$ with methyl groups. Figure 10 displays the effect of rotation about the *E*-P···P-*E* torsion angle from an eclipsed orientation of 0° to a *trans* conformation of 180° in 15° increments. For both the computed phosphorus

© 2008 NRC Canada

Fig. 10. Effect of rotation about the *E*-P···P-*E* torsion angle for $HN(Me_2PSe)_2$ on (*a*) $\delta_{iso}(^{31}P)$ and (*b*) $\delta_{iso}(^{77}Se)$.



and selenium chemical shifts, the calculations predict the opposite effect to what was observed experimentally; that is, the *anti* structures of $HN(Me_2PSe)_2$ possess less shielded phosphorus and more shielded selenium environments than any of the *gauche* structures. The outcome of these calculations suggest that the electronic effect of the chosen *R* group dominates the impact of the *E*-P···P-*E* torsion angle, which is supported by the solution ^{31}P NMR reported for the mixed alkyl system $Ph_2P(S)NHP(S)^iPr_2$ (94). The isotropic phosphorus chemical shifts of $Ph_2P(S)NHP(S)^iPr_2$, 100.0 and 51.5 ppm, display an even larger separation than those found between the phenyl and isopropyl compounds studied herein, $HN(R_2PE)_2$ (*E* = O, S, Se) (Table 1). Rotation of the S-P···P-S angle in solution may effectively average the conformational impact on the phosphorus chemical shift present in the solid state. Thus, the electronic effect of *R* groups on the phosphorus shielding is not opposed to the same extent by the conformation of the *E*PNP*E* backbone and the isotropic phosphorus chemical shifts are found to be further apart.

Conclusions

The iminobis(diorganophosphine chalcogenide) systems, $HN(R_2PE)_2$ (*E* = O, S, Se; *R* = Ph, ^{i}Pr), have been investigated by solid-state ^{31}P and ^{77}Se NMR spectroscopy and DFT computational chemistry. The phosphorus environments of the $HN(Ph_2PE)_2$ (*E* = O, S, Se) systems are all more shielded, with larger spans and smaller skews than the corresponding $HN(^iPr_2PE)_2$ systems. Aside from $Ph_2P(OH)NP(O)Ph_2$, the calculated orientations of the two phosphorus chemical shift tensors in each $HN(R_2PE)_2$ system are essentially identical with δ_{33} oriented nearly parallel to the P-*E* vector as expected from tris-organophosphine chalcogenide systems (89). The experimental and theoretical selenium chemical shift tensors in $HN(Ph_2PSe)_2$ were found to be sensitive to the presence of hydrogen bonding in its solid state dimer structure, while those of $HN(^iPr_2PSe)_2$ were susceptible to the disorder found in its structure. The impact of the conformation of the *E*PNP*E* backbone via the *E*-P···P-*E* torsion angle was studied by DFT nuclear magnetic shielding calculations on a truncated system, $HN(Me_2PSe)_2$. The steric impact of the Se-P···P-Se angle on the computed phosphorus and selenium isotropic chemical shifts was found to have the opposite effect to what was observed experimentally, suggesting that the choice of phenyl or isopropyl group is more important than the conformational contributions to the phosphorus and selenium shielding in these systems.

Finally, this study further demonstrates the feasibility of the measurement of phosphorus and selenium chemical shift tensors for these important ligands. Furthermore, the sensitivity of these tensors to subtle structural effects is apparent.

Dissecting out the effect of Ru-OAr bonding in a five-coordinate complex of ruthenium (II)[1]

Sebastien Monfette, João A. Duarte Silva, Serge I. Gorelsky, Scott J. Dalgarno, Eduardo N. dos Santos, Maria H. Araujo, and Deryn E. Fogg

Abstract: Blue Ru(*o*-cat)(PPh_3)$_3$ (**5**; *o*-cat = *ortho*-catecholate), obtained in 94% yield by reaction of $RuCl_2(PPh_3)_3$ (**4**) with dithallium catecholate, was characterized by NMR, MALDI-MS, IR, and single crystal X-ray analysis, and by a combined electronic spectroscopy and time-dependent density functional theory (TD-DFT) study. The frontier orbitals in **5** participate in a low-energy charge transfer excitation involving donation from the Ru-catecholate π bond (largely localized on catecholate) to a low-lying σ* orbital on Ru-$PPh_{3(apical)}$. The energy of this transition increases on binding a pyridine ligand in the sixth site.

Key words: ruthenium aryloxide, catecholate, phosphine, electronic spectroscopy, time-dependent DFT.

Résumé : Le Ru(*o*-cat)(PPh_3) bleu (**5**; *o*-cat = *ortho*-catécholate) qui est obtenu avec un rendement de 94% par réaction du $RuCl_2(PPh_3)_3$ (**4**) avec le catécholate de dithallium a été caractérisé par RMN, spectrométrie de masse "MALDI", spectroscopie IR et par diffraction des rayons X par un cristal unique ainsi que par une combinaison de spectroscopie électronique et d'une étude de théorie de la fonctionnelle de densité en fonction du temps. Les orbitales frontières du produit **5** participent dans une excitation par transfert de charge de basse énergie impliquant le don d'électron à partir de la liaison π du catécholate de ruthénium (principalement localisée sur le catécholate) vers une orbitale σ* de basse énergie du Ru-$PPh_{3(apical)}$. L'énergie de cette transition augmente lors de la fixation d'un ligand pyridine sur le sixième site.

Mots-clés : aryloxyde de ruthénium, catécholate, phosphine, spectroscopie électronique, théorie de la fonctionnelle de densité en fonction du temps.

[Traduit par la Rédaction]

Introduction

Olefin metathesis is now one of the most powerful methods in use for the construction of C=C bonds (1). Of the many well-defined catalysts developed for this versatile reaction, the Grubbs-class catalysts, $RuCl_2LL'$(=CHPh), have had the greatest impact in organic synthesis owing to their relative robustness and ease of handling. We have been engaged in a program of study focusing on the largely neglected (2) potential of the anionic sites to expand the modularity, tunability, and lifetime of the Ru-NHC catalysts (3) (NHC = *N*-heterocyclic carbene). Particular success has emerged for derivatives containing monodentate or κ^2-chelating aryloxide ligands (Fig. 1). These exhibit, inter alia, increased lifetime (for **1**), enhanced efficiency (**2** and **3**), and a high kinetic selectivity for cyclic vs. oligomeric products in macrocycle RCM (**2**, **3**; RCM = ring-closing metathesis) (3).

Emerging findings from our laboratory have focused our attention on the importance of the Ru-aryloxide electronic interactions in determining not merely catalyst activity, but also the kinetic bias toward RCM products. In the present work, we wished to evaluate the electronic interactions specific to the basal Ru-aryloxide moiety within the square pyramidal coordination geometry, unperturbed by the variety of additional bonding interactions present in the alkylidene complexes of Fig. 1. While five-coordinate Ru complexes containing monodentate phosphine and phenoxide ligands (e.g., $RuX(OPh)(PPh_3)_3$) would be suitable candidates for study, such species are unstable with respect to isomerization to piano-stool structures (Scheme 1) (4), unless the aryloxide ligand is stabilized by electron-withdrawing substituents that add to the complexity of our intended electronic analysis.

In earlier work, we established that σ–π isomerization of aryloxide donors in these labile, coordinatively unsaturated

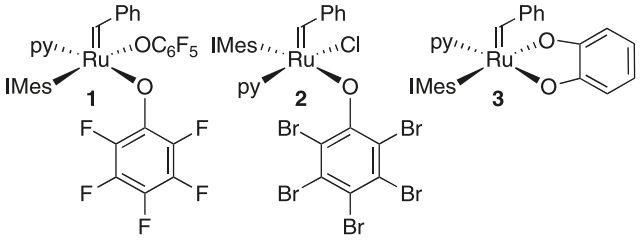
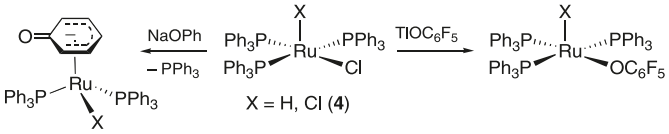


Scheme 1.



species is not inhibited by chelation within large (seven-membered) chelate rings (4*a*). The stability of the catecholate ligand in **3**, however, suggested that a smaller chelate might stabilize our target systems. We therefore sought to examine an alternative model complex, Ru(*o*-cat)(PPh_3)$_3$ (**5**, *o*-cat = *ortho*-catecholate). Here we describe the synthesis and structural characterization of **5** and an analysis of its frontier orbital interactions by electronic spectroscopy and time-dependent density functional theory (TD-DFT) calculations.

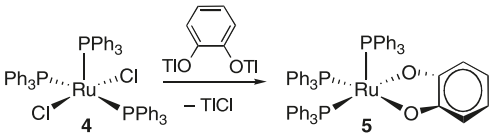
Results and discussion

Synthesis of Ru(*o*-cat)(PPh_3)$_3$ (5)

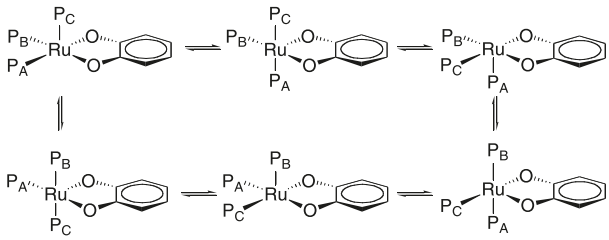
The addition of solid thallium catecholate to a homogeneous solution of $RuCl_2(PPh_3)_3$ **4** in THF caused a colour change from brown to deep blue within 1 h at room temperature, accompanied by precipitation of TlCl. ^{31}P NMR analysis of the crude reaction mixture indicated clean formation of a single Ru product, without liberation of PPh_3. The suspension was filtered through Celite, and the Ru product was isolated in 94% yield by precipitation from THF–hexanes. It was identified as Ru(κ^2-$O_2C_6H_4$)(PPh_3)$_3$ **5** (Scheme 2) on the basis of spectroscopic, crystallographic, and combustion analysis. This complex exhibits high air-sensitivity even in the solid state (possibly a function of the high-lying HOMO in this system; vide infra).

The anaerobic MALDI-TOF mass spectrum (5) of **5** revealed a well-defined isotope pattern for [M–PPh_3]$^{+\cdot}$ at *m*/*z* 734.4 Da. The facile elimination of one triphenylphosphine group in the gas phase probably reflects the steric pressure within the three approximately facial PPh_3 ligands. Retention of all three of these ligands in the solid state is confirmed by X-ray analysis, as discussed below; their retention in solution can be inferred from the ^{1}H NMR integration values as well as the absence of a signal for free PPh_3 in the ^{31}P NMR spectrum of the crude reaction mixture. Unexpectedly, however, a sharp ^{31}P{^{1}H} NMR *singlet* was observed at 55.1 ppm, rather than the A_2X pattern predicted on the basis of the square pyramidal geometry of Scheme 2. This singlet undergoes no change in multiplicity even on cooling to –90 °C. We confirmed that the square pyramidal

Scheme 2.



Scheme 3.



coordination geometry represents the energetic minimum by DFT optimization. The steric constraints in **5** may thus cause averaging of the ^{31}P environments in solution, via a series of equilibria such as those depicted in Scheme 3. Notably, no loss of PPh_3 in solution is evident by NMR analysis, despite this steric pressure, and in contrast to the behaviour of the corresponding dichloride complex **4** (6). This point is examined in more detail below.

Blocky blue crystals of **5** suitable for X-ray analysis were obtained by slow evaporation of a benzene solution. An ORTEP diagram is shown in Fig. 2 with crystal data in Table 1. Only one five-coordinate Ru-catecholate complex, Ru(o-cat)$_2$(≡N) **6** (7), has previously been structurally characterized. In contrast with the slightly distorted square pyramidal geometry of **6**, in which the nitrido ligand is only 0.6 Å above the basal plane, the structure of **5** exhibits significant deviations, though it remains closer to square pyramidal than trigonal bipyramidal at Ru. Two "basal" PPh_3 ligands lie trans to the catecholate oxygen donors (P(1)-Ru(1)-O(1) = 144.61(4)°; P(2)-Ru(1)-O(2) = 158.53(4)°), with the third phosphine approximately apical (P(3)-Ru(1)-P(1) = 97.766(17)°; P(3)-Ru(1)-P(2) = 99.561(17)°; P(3)-Ru(1)-O(1) = 116.13(4)°; P(3)-Ru(1)-O(2) = 98.45(4)°), trans to the vacant site. The extent of distortion is also evident from the 0.05 Å difference in length between the two Ru–P bonds in the basal plane (Ru(1)–P(1) 2.2954(5) Å; Ru(1)–P(2) 2.3496(5) Å). The apical Ru–P bond (Ru(1)–P(3) 2.2527(5) Å) is shorter by 0.04–0.09 Å. This is *not* due to population of the Ru-P(3) σ*-orbital (LUFO+1 of [$Ru(PPh_3)_3$]$^{2+}$): while there is indeed a 19% population of this orbital, the basal Ru–P bonds are likewise populated and to a greater extent (22% for LUFO; 11% for LUFO+2). Instead, the decreased bond length is due to the apical position of the phosphine ligand involved, and the consequent absence of a trans ligand that would give rise to a competing donor–acceptor interaction. A similar effect was found for the apical Ru–P bond in the dichloride analogue **4** (6).

The distorted geometry of **5** is unsurprising, given the rigidity and small bite angle of the catecholate ligand and the unfavourable steric interaction between the three cis-PPh_3 ligands. In comparison, the crystal structure of **4**, containing a meridional arrangement of these ligands, shows little distortion in the bond angles about ruthenium (6). Similarly,

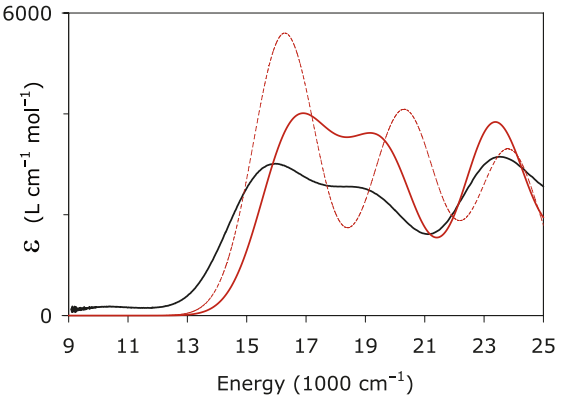
six-coordinate Ru(II)-catecholate complexes containing smaller neutral ligands such as PMe_3 (8) or pyridine (9) form reasonably regular octahedral complexes. The C–O bond

Fig. 3. Experimental and calculated electronic spectra for **5** (solid black and red lines, respectively) and calculated spectrum for **7** (dashed red line).



lengths within **5** (1.350(2) and 1.345(2) Å for C(1)–O(1) and C(6)–O(2), respectively) are within the range of 1.34–1.47 Å usual for Ru-catecholate complexes; benzoquinone complexes exhibit shorter C–O bond lengths (1.27–1.31 Å (10)). The magnitude and uniformity of C–C bond lengths within the $O_2C_6H_4^{2-}$ ligand (1.372(4)–1.407(4) Å) likewise support formulation of **5** as a Ru-catecholate complex, as does the presence of an IR band for $\nu_{C\text{-}O}$ at 1270 cm^{-1}, which is not observed for starting **4**, but is present in the IR spectra of the catecholate salts.

The electronic structure of **5** was analyzed experimentally by UV–vis spectroscopy and theoretically by use of TD-DFT calculations (11–13) to establish the key metal-ligand bonding contributions. Our interest was stimulated further by the unusual blue color of **5**, rare in Ru(II) complexes (for examples see refs. 14–21), which could provide added insight into its properties. A fragment molecular orbital (FMO) analysis enabled the quantification of charge donation. Orbital interactions were considered in terms of dative bonds between the lowest unoccupied fragment orbitals (LUFOs) of the metal fragment $[Ru(PPh_3)_3]^{2+}$ and the highest occupied fragment orbitals (HOFOs) of the $O_2C_6H_4^{2-}$ ligand.

The calculated electronic spectrum is in very good agreement with the experimental spectrum (Fig. 3). The latter, measured in THF, is comprised of three absorption maxima of near-identical intensity (16 000, 18 400, and 23 500 cm^{-1}), whereas TD-DFT predicts three principal bands (16 500, 19 700, and 23 200 cm^{-1}), of which the latter two overlap with two weaker bands at 18 000 and 23 600 cm^{-1}. The band energies thus correspond within ca. 500 cm^{-1} vs. the more typical agreement of 2 000 cm^{-1} (11–13, 22); a minor difference in intensity is also evident. The level of theory was therefore deemed appropriate for the analysis of the electronic transitions. Electron excitations contributing to each band are summarized in Table 2.

The FMO analysis indicates that the formation of **5** involves a significant (>2%) change in the electronic population for only three orbitals on the Ru fragment. We therefore confine our discussion of the metal-based orbital interactions to these three acceptor orbitals. Contributions from Ru are cited as the composite of s, p, and d contributions; those from PPh_3 are largely p in character (for individual constitu-

Note: Atomic contributions evaluated by Mulliken population analysis.

ents see Fig. 4). The LUFO is 62% Ru and 38% PPh_3 (of which 21% is contributed from the P atoms) in character; cf. relative contributions of 58% Ru + 42% PPh_3 for LUFO+1, and 59% Ru + 40% PPh_3 for LUFO+2. The population of each of these orbitals increases from its null value in the non-interacting fragment to 22%, 19%, and 11%, respectively, in **5**. LUFO and LUFO+2 participate in forming the two σ bonds with the ligand, while LUFO+1 forms a π bond (19% × 2 = 0.38 e^-). For the catecholate FMOs, turning on the bonding interaction with Ru results in a significant change in population for six occupied and one unoccupied orbital. These are the HOFO (–21%, i.e., 21% depopulation), HOFO–1 (–14%), HOFO–2 (–7%), HOFO–3 (–3%), HOFO–6 (–5%), HOFO–7 (–4%), and LUFO (+5% population). Thus, in addition to strong ligand-to-metal charge donation (0.94 e^-), formation of the complex involves significant polarization of the electron density on the catecholate ligand through 5% population of the LUFO. This charge distribution description is consistent with the Mulliken population analysis (23–26) and the NPA-derived charges assessed for the catecholate ligand in the complex (–1.06 and –1.20 au, respectively; NPA = natural population analysis).

The molecular orbitals that contribute to the visible spectrum of **5** are summarized in Table 3; visual depictions of all of these are given in the supporting information.[4] The LUMO is a σ* orbital for the apical Ru-PPh_3 bond (Fig. 5), while LUMO+1 consists principally of the aromatic π* orbitals of PPh_3 with a 7% contribution from the Ru 4d orbitals. The low energy of the LUMO of **5** derives from the contribution of a single (apical) phosphine ligand to this σ* orbital (p_z(P)–d_{z2}(Ru)); the other σ* orbital involves both basal PPh_3 ligands. The HOMO is a π bonding orbital between the catecholate and Ru. HOMO-1, HOMO-2, and HOMO-3 are also dominated by Ru-catecholate contributions: these are a largely non-bonding π orbital, a largely σ nonbonding orbital, and a σ–π hybrid, respectively. Finally, HOMO-4 is nonbonding, being composed of a Ru d orbital and the catecholate π orbital.

For four of the five visible bands calculated for **5**, the LUMO (σ* orbital of the apical Ru-PPh_3 bond) participates

[4]Supplementary data contains molecular orbitals implicated in the visible spectrum of **5**; tables of crystal data collection and refinement parameters, atomic coordinates, bond lengths, and angles, anisotropic displacement parameters and hydrogen coordinates, and NMR spectra for **5**. Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 3854. For more information on obtaining material refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml. CCDC 689209 contains the crystallographic data for this manuscript. These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (Or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

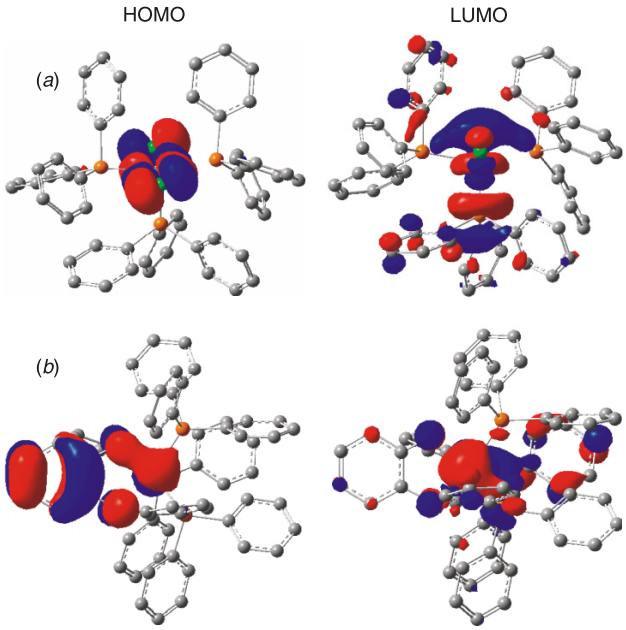
Fig. 5. Frontier orbitals for (*a*) **4** and (*b*) **5**. Isosurface contour value for orbital images = 0.03 au.



in the electronic excitations. However, the LUMO+1, composed of the π* orbitals of the aromatic rings of the PPh_3 ligands (Table 3), is also implicated in the absorption bands at 23 200 and 23 600 cm^{-1}. To determine whether this orbital plays a significant role in the electronic spectrum, we calculated the electronic spectrum of Ru(*o*-cat)$(PMe_3)_3$ (**7**), which contains no π*(Ph) orbitals. The calculated spectra for **5** and **7** are very similar, as shown in Fig. 3 (**7**: three absorption maxima at 16 300, 20 400, and 23 800 cm^{-1}; cf. the values for **5** noted above). We conclude that the LUMO is more critical to the spectroscopic features in the visible region than is LUMO+1. The intense blue colour of **5** (ε 3000 L $mol^{-1}cm^{-1}$) is thus due to charge transfer from the Ru-catecholate π bond (localized mostly on catecholate) to the low-lying σ* orbital on the apical Ru-PPh_3 bond.

Replacing the two chloride ligands in **4** by catecholate reduces the magnitude of the HOMO–LUMO gap, as evidenced by the change in colour from brown to blue. Consistent with this, the calculated values drop from –3.06 eV for **4** to –2.81 eV for **5**. The coordination number also affects the energy of the relevant electronic transitions, as noted above; Ru(*o*-cat)$(PMe_3)_4$ (8) and Ru(*o*-cat)$(py)_4$ (9), for example, are yellow in colour. While crystallographic analysis has demonstrated that a phenyl ring blocks the sixth coordination site in the solid state for **4**, the Ru–H distance (2.82 Å, corresponding to a bond order of 0.03) precludes the presence of an agostic C–H bond (27). We therefore exclude octahedral coordination as a potential explanation for the higher-energy visible transition for **4**. The smaller HOMO–LUMO gap in **5** is thus due principally to the higher energy of the HOMO, the Ru-P_{apical} σ* LUMO interaction being less affected, as shown in Fig. 5 and Table 3.

While the smaller HOMO–LUMO gap present in **5** might be expected to heighten reactivity, the resistance of this complex to loss of PPh_3 is in striking contrast to the behaviour of **4** (phosphine dissociation being the stepping-stone to the rich coordination chemistry of this classic ruthenium precursor (28)). The low lability of the PPh_3 ligand in **5**, evident by NMR analysis, is further supported by the unreactivity of the complex toward terminal alkynes, a facile, high-yield route to cumulenylidene products for **4** (29). The difference in behaviour lies in the stronger donation and back-donation involving the basal PPh_3 ligands in **5**, which result in a larger binding energy for Ru-$P_{(basal)}$ (–16.0 kcal mol^{-1} in **5** and –10.6 kcal mol^{-1} in **4**) (1 cal = 4.184 J). The weaker donation from the catechol ligand, relative to chloride, is anticipated on the basis of the higher electronegativity of oxygen vs. chlorine, reinforced by the capacity of the catecholate phenyl ring to delocalize negative charge. Consistent with this view, the NPA-derived charge for the catecholate ligand is –1.20 au, while for the chloride ligands the corresponding sum charge is –1.11 au.

Summary

The foregoing demonstrates that replacing chloride by catecholate in the simple model system $RuCl_2(PPh_3)_3$ raises the energy of the X-based HOMO. By analogy, replacing chloride by catecholate in Ru metathesis catalysts is expected to raise the energy of the corresponding Ru-X occupied molecular orbital(s). While the nature and energy of the frontier molecular orbitals in Ru metathesis catalysts has been surprisingly little examined (30), it is clear that the higher energy of the Ru-OAr HOMO will facilitate interaction with any LUMOs of appropriate symmetry present (which may include those for the alkylidene and bound olefin as well as the neutral donor that serves as a proxy for incoming olefin). These amplified interactions enhance the potential for modulating reactivity and selectivity by tuning the electronic properties of the anionic donors. Important steps in the catalytic cycle for olefin metathesis that may be affected range from dissociation of the neutral donor (in **3**, the pyridine ligand), to olefin binding and activation, and potentially, the key 2+2 cycloaddition step. Of additional interest is the extent to which the energy of the Ru-X (catecholate) HOMO is affected by the constrained bond geometry of the catecholate ligand. Future work will explore the specifics of these interactions, and their impact on the energy profile for metathesis in the $RuX_2(IMes)(py)(=CH_2)$ family of catalysts (X = Cl, *o*-cat, OC_6F_5).

Experimental

General procedures

Synthesis of **5** was carried out at room temperature (RT) (23 °C) under N_2 using standard drybox techniques. Dry, oxygen-free solvents, obtained using a Glass Contour solvent purification system, were stored over Linde 4 Å molecular sieves. Thallium catecholate (3*d*) and $RuCl_2(PPh_3)_3$ (31) were prepared by the methods reported.

^1H NMR (500 MHz), ^{13}C (125 MHz), and ^{31}P (121 MHz) spectra were recorded on a Bruker Avance-500 spectrometer. Chemical shifts are reported relative to TMS (^1H, ^{13}C) or 85% H_3PO_4 (^{31}P) at 0 ppm. X-ray data were collected on a Bruker SMART 1000 CCD diffractometer. IR spectra were measured on a Bomem MB100 IR spectrometer. Inert-atmosphere MALDI-MS analyses were carried out using a

© 2008 NRC Canada

Bruker OmniFlex MALDI-TOF mass spectrometer equipped with an N_2 laser (337 nm), interfaced to an MBraun glovebox (5). Data were collected in positive reflectron mode, with the accelerating voltage held at 20 kV. Matrix (pyrene) and analyte solutions were prepared in CH_2Cl_2 at concentrations of 20 and 1 mg/mL, respectively. Samples were mixed in a matrix/analyte ratio of 20:1. UV–vis spectra were measured on a Varian Cary-50 spectrophotometer at a scan rate of 600 nm/min. Samples were prepared under N_2 by filling a Hellma screw-top optical glass cell with 2 mL of a 0.24 mmol/L solution of **5** in THF and sealing prior to analysis. Microanalyses were carried out by Guelph Chemical Laboratories Ltd., Guelph, Ontario, Canada.

Note: The toxicity of thallium (particularly in the +1 oxidation state) is well-established (32). Care must be taken to prevent introduction into the body by inhalation, ingestion, or through the skin. All thallium reagents and wastes, including contaminated solvents, were handled using double-glove and secondary containment procedures, with separate disposal of all wastes in accordance with government regulations.

Synthesis of Ru(κ^2-*O,O′*-$O_2C_6H_4$)(PPh_3)$_3$ 5

Solid thallium catecholate (296 mg, 0.573 mmol) was added to a stirred solution of **4** (500 mg, 0.521 mmol) in 10 mL THF at RT. A colour change from brown to blue took place over 1 h, and the solution became cloudy. The suspension was filtered through Celite to remove TlCl, and the filtrate stripped to dryness. Precipitation from THF–hexanes and washing with hexanes (3 × 5 mL) afforded deep blue **5**. Yield 486 mg (94%). ^{1}H NMR (C_6D_6, 500 MHz) δ: 7.39 (m, 2H, catechol CO-C*H*), 7.30 (m, 18H, *o*-C*H* of PPh_3), 7.02 (m, 2H, catechol C*H*), 6.90 (m, 9H, *p*-C*H* of PPh_3), 6.74 (m, 18H, *m*-C*H* of PPh_3). ^{13}C{^{1}H} NMR (C_6D_6, 125 MHz) δ: 163.3 (s, catechol *C*-O), 137.4–137.1 (m, *i-C* of PPh_3), 135.3–135.2 (m, *o-C*H of PPh_3), 128.9 (s, *p-C*H of PPh_3), 127.5–127.4 (m, *m-C*H of PPh_3), 117.6 (s, catechol *C*H), 117.5 (s, catechol *C*H). ^{31}P{^{1}H} NMR (C_6D_6, 121 MHz) δ: 55.1 ppm (s); multiplicity unchanged down to –90 °C. IR (Nujol, cm^{-1}): $\nu_{C\text{-}O}$ 1270. Anal. calcd. for $C_{60}H_{49}O_2P_3Ru$: C 72.35, H 4.96%; found C 72.08, H 4.85%. MALDI-MS, *m/z* (pyrene matrix): calcd. for $[M\text{-}PPh_3]^{+\cdot}$: 734.1; found, 734.4.

Representative reaction of 5 and 3,3-dimethylbutyne

To a blue solution of **5** (14 mg, 0.014 mmol) in C_6D_6 (1 mL) was added 3,3-dimethylbutyne (10 μL, 0.084 mmol, 6 equiv). The reaction vessel was sealed and heated to 60 °C in an aluminum block for up to 72 h, after which NMR analysis showed only unreacted **5**.

Representative reaction of 5 with 1,1-diphenylprop-2-yn-1-ol

To a blue solution of **5** (25 mg, 0.025 mmol) in THF (2 mL) was added solid 1,1-diphenylprop-2-yn-1-ol (6 mg, 0.029 mmol, 1.2 equiv). No reaction was evident by NMR analysis at RT over a period of 24 h. Only the ^{31}P NMR signal for **5** was present after heating for 1 h in an oil bath set at 70 °C. Complex **5** remains a major species after heating for 17 h, but it is accompanied by multiple products, suggesting sample decomposition. Similar results were found on use of up to 5 equiv of the alkyne.

Structural determination

Blue, blocky crystals of **5** were grown by slow evaporation of a saturated benzene solution. Data were collected on a Bruker SMART 1000 CCD diffractometer with Mo Ka radiation using the ω-scan mode. A single crystal (0.6 mm × 0.44 mm × 0.42 mm) was mounted on a thin glass fiber using paraffin oil and cooled to the data collection temperature (173 K). Data were corrected using the SADABS program (Bruker). Structure solution in the space group $P2_1/c$ was performed with Patterson methods, completed with difference Fourier syntheses, and refined by full-matrix least-squares procedures based on F^2 using the SHELX-97 software package. All non-hydrogen atoms were refined anisotropically; hydrogen atoms were placed at geometrically calculated positions and allowed to ride on their parent atoms. Although the crystals were weakly diffracting, a satisfactory structural solution was obtained.

Computational details

DFT calculations were carried out using the Gaussian 03 package (33). The X-ray structures of **4** (27*b*) and **5** were used for these calculations, after adjusting all C–H distances to 1.08 Å, as only aromatic C–H bonds are present in the structure. All other interatomic distances were left unperturbed. That the square pyramidal structure represents a true energy minimum for **5** was confirmed by geometry optimization. DFT calculations utilized the B3LYP (34) exchange-correlation functional with the DZVP basis set (35) for all atoms. Tight SCF convergence criteria (10^{-8} au) were used for all calculations. The converged wave functions were tested to confirm that they correspond to the ground-state surface. Bond orders and the compositions and populations of molecular orbitals were calculated using the AOMix program (36). The energies and intensities of the lowest 30 singlet-singlet transitions were calculated by TD-DFT. Absorption profiles were calculated from TD-DFT bands by the method reported (22), assuming for all electronic transitions a bandwidth at half-height of 2500 cm^{-1} (a typical value for complexes of the type described). Pseudo-Voigt functions with 50% weights for contributing Gaussian and Lorentzian functions were used to simulate the absorption bands.

Zinc halide oxazoline complexes — The quest for structural diversity[1]

Robert A. Gossage, Paras N. Yadav, Timothy D. MacInnis, J. Wilson Quail, and Andreas Decken

Abstract: The synthesis and characterization of 14 ZnX_2 (X = Cl or Br) complexes containing aryl-oxazoline (ox) ligands is reported. Eleven of these derivatives have been structurally elucidated in the solid state by single crystal X-ray diffraction methods. The ligands used are 2-(3-R-phenyl)-2-oxazoline (R = Cl or Me), 2-(4-R-phenyl)-2-oxazoline (R = Cl, F, Me or –OMe), and 2-(anisol-2-yl)-4,4-dimethyl-2-oxazoline (**7a**). All oxazolines, with the exception of **7a**, lead to the formation of materials identified as $ZnX_2(ox)_2$ upon reaction with ZnX_2. A distorted tetrahedral coordination motif around the Zn metal centre is displayed in nine examples that have been characterized by single crystal X-ray diffraction methods. In the case of ligand **7a**, an unusual dimeric species (X-ray) of formula $[ZnCl_2(\mathbf{7a})]_2$ (**7b**) is formed upon reaction with $ZnCl_2$. Compound **7b** displays a rare (formally neutral) μ-$(Cl)_2$-$(Zn[L]Cl)_2$ (L = neutral donor ligand) unit in addition to secondary bonding interactions between the Zn centres and the *O*-atom of the –OMe group (Zn···O distance of ~2.56 Å). In contrast, reactions of **7a** with $ZnBr_2$ lead to the formation of a monomeric species containing a chelating molecule of **7a** with binding through the oxazoline *N*-atom and the methoxy (Zn–O distance of ~2.14 Å) group, i.e., $ZnBr_2(\mathbf{7a}\text{-}\kappa^2 N,O_{OMe})$. These complexes are discussed in terms of structurally related Zn species and some comment is made as to the direction to be explored within this series of materials that may lead to further unusual structural diversity.

Key words: oxazoline, oxazole, zinc, X-ray crystal structure, coordination complex, Zn(II) halide.

Résumé : On rapporte la synthèse et la caractérisation de quatorze complexes de ZnX_2 (X = Cl ou Br) contenant des ligands aryloxazoline (ox). On a élucidé les structures de onze de ces dérivés en faisant appel à des méthodes de diffraction des rayons X à l'état solide. Les ligands utilisés comprennent des 2-(3-R-phényl)-2-oxazolines (R = Cl ou Me), des 2-(3-4-phényl)-2-oxazolines (R = Cl, F, Me ou OMe) et la 2-(anisoly-2-yl)-4,4-diméthyl-2-oxazoline (**7a**). Par réaction avec du ZnX_2, toutes les oxazolines, à l'exception du composé **7a**, conduisent à la formation de produits identifiés par la formule générale $ZnX_2(ox)_2$. Dans neuf exemples caractérisés par des méthodes de diffraction des rayons-X par un cristal unique présentent un motif de coordination de tétraèdre déformé autour du centre métallique Zn. Dans le cas du ligand **7a**, il se forme une espèce dimère inhabituelle (aux rayons X) de formule $[ZnCl_2(\mathbf{7a})]_2$ (**7b**). Le composé **7b** comporte une unité rare (formellement neutre) μ-(Cl_2)-$(Zn[L]Cl)_2$ (L = ligand donneur neutre) en plus des interactions de liaisons secondaires entre les centres Zn et l'atome d'oxygène du groupe –OMe (distance Zn···O de ~2,56 Å). Par opposition, les réactions du composé **7a** avec le $ZnBr_2$ conduit à la formation d'espèces monomères contenant une molécule chélatante de **7a** qui donne des liaisons par le biais de l'atome d'azote de l'oxazoline et du groupe méthoxy (distance Zn–O de ~2,14 Å), c'est-à-dire $ZnBr_2(\mathbf{7a}\text{-}\kappa^2 N,O_{OMe})$. On discute de ces complexes en fonction d'espèces de Zn reliées d'un point de vue structural et on fait quelques commentaires concernant la direction qui devrait être explorer dans cette série de produits qui pourrait conduire à une plus grande diversité structurale.

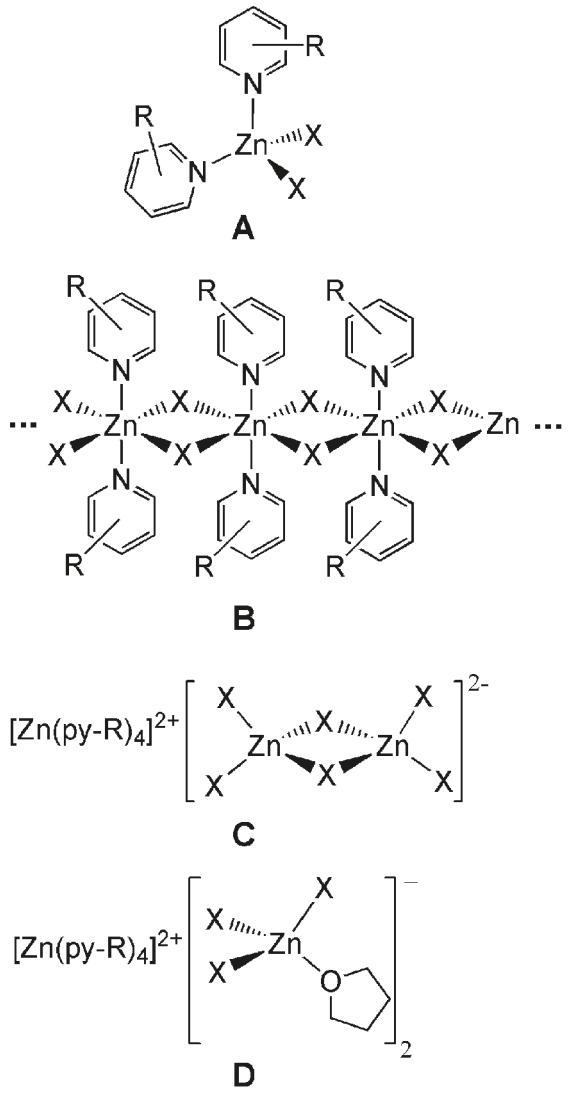
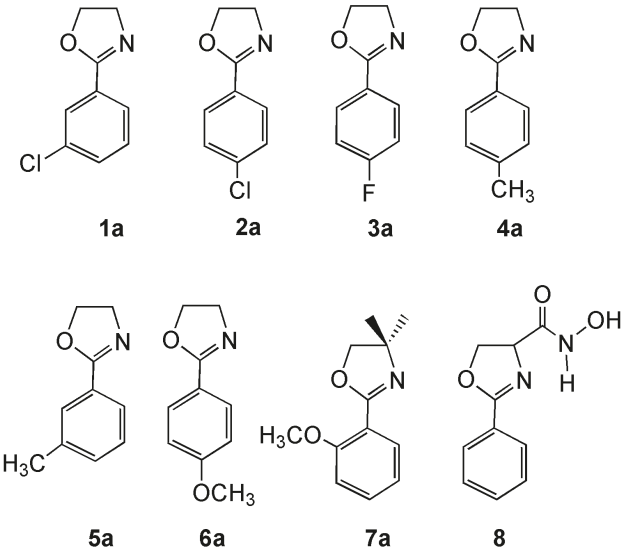
Fig. 1. Some of the known structural motifs for $(ZnX_2[py–R]_n)_m$ complexes.



Introduction

Despite the stability of only a single cationic oxidation state, zinc displays rich and diverse coordination chemistry in both the natural and artificial (i.e., synthetic) settings (1). The formal Zn^{2+} ion binds with a large variety of ligands (1) including alkyl and aryl anions, halides, P-donor, O-donor, and N-donor fragments, etc. Many Zn materials have been isolated with heterocyclic ligands, with substituted pyridines (py–R) being a particularly noteworthy example. Several years ago, we reported our initial investigations into the coordination chemistry of the zinc(II) halides (i.e., ZnX_2) with heterocyclic bases containing a single oxazoline (i.e., 4,5-dihydro-1,3-oxazole) group. In this earlier work, we observed that the only structural motif observed (X-ray) was that of a neutral four-coordinate Zn species with a distorted tetrahedral coordination mode around the metal centre (2). Ligation to zinc in our case invariably consisted of two metal-bound halide atoms and two oxazolines, the latter of which was shown to bind through the N-atom, as expected (3). This is in sharp contrast to the complimentary py–R donor series (Fig. 1), in which tetrahedra4l (**A**), polymeric octahedral (**B**), Magnus type salts (**C**), multi-component salts (**D**), and a variety of five-coordinate structures have all been structurally characterized (4).

Fig. 2. Ligands employed in this study (**1a**–**7a**) and the structure of L-573,655 (**8**).



A secondary underlying theme of our research is the focus on biologically relevant metal complexes (5). In this regard, the lead drug candidate L-573,655 (**8**: Fig. 2) has been shown to inhibit *Lipid A* biosynthesis by selective binding to an enzyme-bound Zn^{2+} ion (6). This result emphasises the biological relevance and importance of the structure and variability in Zn-oxazoline complexes. In this report, we expand our fundamental investigations of the solid-state structure of Zn halide aryl-oxazoline complexes. This study reveals that although the tetrahedral coordination motif seems to dominate the coordination chemistry of ZnX_2 with oxazolines, unusual species can be produced from a simple ortho-substituted aryl oxazoline.

Results and discussion

Syntheses and spectroscopic characterization

The synthesis of the materials discussed here is quite straightforward. Treatment of diethylether solutions of ZnX_2 with an excess of oxazoline (ox) ligand (Fig. 2, **1a**–**7a**) typically leads to the rapid precipitation of a white coloured ma-

© 2008 NRC Canada

terial. This is essentially pure $(ZnX_2[ox]_n)_m$, which can then be readily recrystallized from a variety of organic solvents (e.g., CH_2Cl_2/petroleum ether mixtures, MeOH/Et_2O mixtures). Although most of the complexes reported here have quite low solubility in deuterochloroform, solubility is sufficient to obtain ^{1}H NMR spectra; attempts to obtain spectra in DMSO-d_6 or MeOH-d_4 resulted in ligand displacement by these solvents. These properties precluded ^{13}C NMR studies of these compounds. The observed spectroscopic properties (^{1}H NMR, IR, etc., see Experimental section) of these materials display the expected behaviour with respect to the free ligand form (2, 7, 8). Specifically, these data are characterized by a lowering of the IR stretching frequency assigned to the ν(C=N) absorption of the oxazoline ring system and the appearance of lower frequency bands attributed to Zn-ligand bonding vibrations (see Experimental section and refs. 8*d* and 8*e*). Other spectroscopic trends of this ligand class upon coordination to ZnX_2 have been discussed previously in some detail (2, 8*e*).

Examination of these materials by elemental analysis strongly suggests that chlorido compounds **1b**–**6b** and the bromo-containing **1c**–**6c** are characterized by the presence of two oxazolines per [ZnX_2] unit. Hence, a likely structural motif is that of the distorted tetrahedral array around the Zn atom, although polymeric materials (Fig. 1, cf., **B**) cannot be ruled out by these data. Compounds 7b and **7c**, however, analyse for a 1:1 ratio of the zinc halide unit per oxazoline. This is a situation that we did not encounter in our previous investigations (2). Thus, an examination of a number of these materials by X-ray diffraction methods was obviously in order (vide infra).

Solid-state crystal structures

Despite the widespread use of oxazolines (9) and their transition metal complexes (3*h*), there is surprisingly little structural information on Group 12 species containing mono-oxazolines (2, 3*a*, 3*h*). As stated earlier, our previous work (2) had revealed only mononuclear formally Zn^{2+} halide complexes with both alkyl- and aryl-oxazolines, all with similar bonding motifs. Unfortunately during this study, crystals suitable for X-ray diffraction of compounds **6b** and **1c** could not be obtained and therefore one can only assign a 2:1 ratio of the oxazolines to the ZnX_2 unit based on their respective elemental analyses. The rest of the compounds reported here yielded crystalline material from CH_2Cl_2 or $CHCl_3$ solutions that had been layered with excess Et_2O and (or) petroleum ether.

ZnX_2 Complexes possessing a 2:1 oxazoline/Zn ratio

The lack of suitable crystals of compounds **6b** and **1c** means that we are unable to comment any further with regards to the overall structural nature of these two complexes (Scheme 1). The crystalline material obtained of compound **5c** was invariably of only very poor quality in terms of the suitability of the crystals for X-ray diffraction analysis. As a result, the diffraction data could only be used to confirm the *global* structure of the molecule(s) in the unit cell. Although one can discern the general aspects of the atom connectivity, exact data on bond lengths, bond angles, etc. could not be obtained within acceptable experimental error. However, a mononuclear structure of this material was established that contains a Zn atom with a distorted tetrahedral array of bonded groups (comprising of two bromide atoms and two N-bonded oxazoline ligands: Fig.1, cf. **A**). This is similar to that observed (2) for ZnX_2(2-phenyl-2-oxazoline-κ$^1N)_2$ (X = Cl: **9** or Br: **10**). The other nine compounds of 2:1 oxazoline-to-metal stoichiometry reported herein (i.e., **1b**–**5b**, **2c**–**4c**, and **6c**) have all been fully characterized by single crystal X-ray diffraction. Tables 1 and 3 contain the data on the $ZnCl_2$ derivatives and Tables 2 and 3 report the results for the $ZnBr_2$ complexes. ORTEP representations of a molecule within the unit cell of each of complexes **1b**–**5b**, **2c**–**4c**, and **6c** appear in Figs. 3 to 11. Of this group, all are structural analogues of the previously reported parent materials **9** or **10** (2). This bonding motif involves two metal-bound halide atoms and two N-bound oxazolines forming a distorted tetrahedral coordination motif around the zinc atom (Scheme 1). There is little variability in the Zn–N bond lengths (Table 3), which all lie in the range of 2.03–2.08 Å and can be compared with similar bond distances of 2.026(2) and 2.050(2) Å reported for **9**, and 2.025(3) and 2.053(3) Å for **10** (2). In five of the nine novel complexes, the narrowest bond angle containing the Zn atom is the N-Zn-N angle, and perhaps not surprisingly, the larger halide atoms (vs. that of N) occupy the fragment with the larger E-Zn-E (E = donor atom) angle (Table 3 and Supplementary Data).[7] The exceptions to this trend are found with complexes **5b**, **2c**, and **3c**. All three of these compounds contain at least one N-Zn-X angle that is identical in magnitude (within experimental error) to that of the X-Zn-X angle. In contrast, compound **6c** displays an N-Zn-N angle that is larger than that of the Br-Zn-Br grouping (Table 3). This is similar to that observed in the complex $ZnBr_2$(4,4-dimethyl-2-phenyl-2-oxazoline-κ$^1N)_2$ reported previously (2). Further details on the structure of these materials can be found in the Supplementary Data.[7]

ZnX_2 Complexes possessing a 1:1 oxazoline/Zn ratio (ZnX_2 derivatives of 7a)

The analytical data of complexes **7b** and **7c** present the first examples of stoichiometric diversity within the $(ZnX_2[ox]_n)_m$ series thus far investigated. Both of these materials contain oxazoline **7a**. In terms of the ligand itself, the primary difference between this compound and other oxazolines (ref. 2 and this work) is the presence of a potentially donating substituent located on the ortho-position of the aromatic ring.[8] This leads to the formation of 1:1 complexes in both cases, regardless of the use of excess **7a** in the

synthetic protocol. The chlorido case, complex **7b**, reveals itself (X-ray) to be a dinuclear species in which two Zn atoms are connected via two symmetry-related chloride bridges (Fig. 12). The residual coordination polyhedron around the Zn atom contains a second, albeit terminal, chloride atom. The terminal Zn–Cl bond is distinctly shorter than that found in the complimentary bridging halide (Table 3, ~2.22 vs. ~2.32 Å). In addition, a single N-bonded oxazoline is coordinated to each Zn atom. This latter ligand also displays secondary bonding interactions between the metal nucleus and the O-atom of the –OMe group contained on the aromatic ring. The Zn···O bond distance is a respectable 2.56 Å. Of particular interest in the structure of **7b** is the presence of a μ-$(X)_2$-$(M[L]X)_2$ unit (M = Group 12 element, X = halogen, L = neutral donor ligand).

Although this dimeric structure is well-known in the case of M = Cd or Hg, zinc derivatives with such a bridging motif are surprisingly rare.[9] Structurally characterized examples include the phosphine or arsine compounds μ-$(I)_2$-

[9] See the Cambridge structural database (CSD) at http://www.ccdc.cam.ac.uk/products/csd. Further information on Cd and Hg compounds containing the μ-$(X)_2$-$(M[L]X)_2$ structural unit can be found in Comprehensive coordination chemistry. Vol. 5. *Edited by* G. Wilkinson. Elsevier, Toronto, Ont., Canada, 1987. Chaps. 56.1–56.2 and Comprehensive coordination chemistry II. Vol. 6. *Edited by* J.A. McCleverty and T.J. Meyer. Elsevier, Toronto, Ont., Canada, 2003.

$(ZnI[P\{NMe_2\}_3])_2$ (10*a*), μ-$(I)_2$-$(ZnI[PEt_3])_2$ (10*b*), and μ-$(I)_2$-$(ZnI[AsEt_3])_2$ (10*c*), in addition to the tetranuclear nitrido complex **11** (10*d*), bridged oxo compound **12** (10*e*), tin-containing **13** (10*f*), the unusual iron carbonyl (10*g*) species **14** (Fig. 13), amongst others (10*h*, 10*i*). Hence, our material **7b** is the first oxazoline (and, in fact, imine) example of this structural motif in Zn chemistry.

The bromide analogue of complex **7b** (viz., complex **7c**) is not a structural relative of the chlorido congener (Fig. 14). With the heavier halogen, a mononuclear complex is revealed and as expected it contains only a single oxazoline ligand. This organic group is found to chelate to the $ZnBr_2$ fragment via bonding of the oxazoline N-atom and the O-atom of the –OMe group (i.e., a $\kappa^2 N,O_{OMe}$ bonding pattern). This is the only member of the series with a distinct chelate (Zn–O distance = ~2.14 Å) and the only one with an NOX_2 atomic composition of the Zn-binding set. Not surprisingly, compound **7c** displays a narrow N-Zn-O bond angle (~85°) to accommodate the chelating ligand; this is accompanied by a slightly shorter (with respect to **1b**–**5b**, **2c**–**4c**, **6c**, **9**, and **10**) Zn–N bond length (~1.99 Å). The Zn–Br bond lengths are also the shortest in this series (~2.33 Å). These data can be compared with another $ZnBr_2$ species with the NOX_2 Zn-

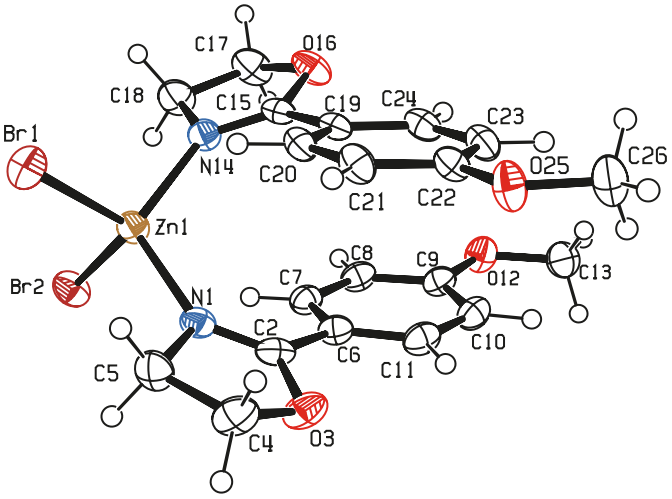

Fig. 12. ORTEP representation of a molecule of complex **7b**.

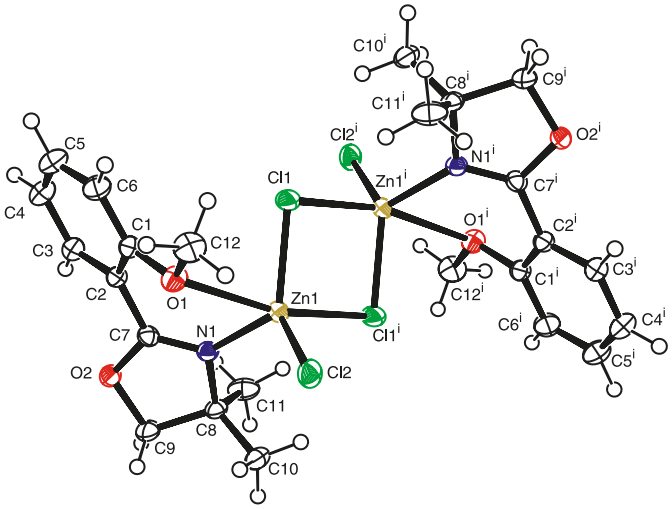

binding set, viz. 2-picoline-6-carbaldehyde-κ^2N,O zinc(II) bromide (**15**). As observed for **7c**, complex **15** (11) contains a six-membered chelate ring with a similarly narrow N-Zn-O bond angle (80.3(6)°) and similar metal-ligand bond lengths (Zn–N: 2.05(2) Å, Zn–O: 2.10(1) Å; Zn–Br: 2.314(3) and 2.334(4) Å).

In terms of potential future work in relation to the above investigations, the presence of a sterically bulky group on oxazoline ring position-2 seems to be a potential gateway for the discovery of other structural classes of Zn materials. Our intentions are to survey ligands such as 2-*t*-butyl-2-oxazoline in this regard. In terms of other bulky 2-aryl-2-oxazolines, the use of ortho-substituted aromatic groups may also lead to novel structural forms, especially if such substitution contains groups that are unlikely to form a stabilization interaction with Zn (e.g., Me, Ph, *t*-Bu, etc.). As a variety of nucleophiles are known to readily replace the –OMe group from **7a** (12), this is an obvious avenue for our continued investigations into ligand design strategies and coordination chemistry in general (13). Two further aspects that we have yet to vary are the effect of solvent(s) and the replacement of

Fig. 13. Some previously characterized relatives of complex **7b**

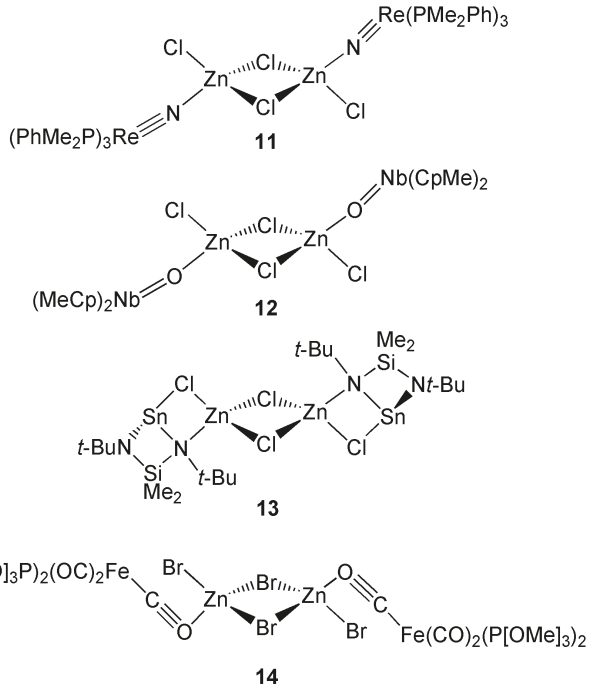

Fig. 14. ORTEP representation of a molecule of complex **7c**.

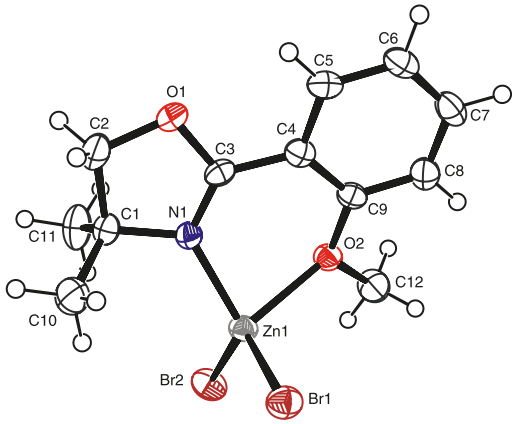

the halides for other anionic sources (e.g., NO_3^-, ClO_4^-, etc.) on the structural nature of the resulting products (Fig. 1, cf., **D**). These facets will also be included in some of our future synthetic endeavours.

Conclusions

The results reported herein greatly expand the number of structurally characterized ZnX_2 oxazoline complexes, although unfortunately the structural elucidation of compounds **6b** and **1c** has thus far eluded us. Generally speaking, 2-aryl-2-oxazoline ligands have demonstrated little structural diversity with the Zn(II) halides, regardless of the presence of electron-withdrawing (**1a**, **2a**, and (or) **3a**) or electron-donating groups (**4a**, **5a**, and (or) **6a**) located meta or para within the arene framework (Scheme 1). Although admittedly only represented here by ligand **7a**, the formation of novel binuclear Zn-imine complex **7b** or ligand chelation

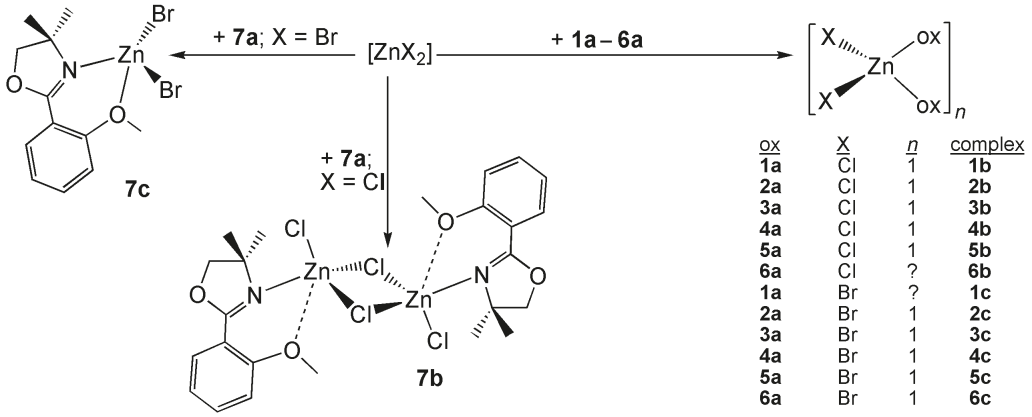
Scheme 1. A summary of the products synthesized herein.



(**7c**) has been realised with an appropriately basic ortho-functionality (Scheme 1).

Experimental

General

All reactions were carried out using standard bench top techniques employing commercially available, reagent grade solvents. Zinc bromide and **7a** (Fig. 2) were purchased and used as received. Commercial zinc chloride was purified as detailed previously (2). Ligands **1a**–**6a** (Fig. 2) were synthesized using published protocols (7, 8, 14), and their purity checked by a combination of mp and ^{1}H NMR spectroscopy (7, 8). The ^{1}H NMR spectra (300 MHz) were recorded at room temperature (RT) using a Bruker Avance 300 NMR spectrometer using $CHCl_3$-*d* as solvent (except where noted); chemical shifts are reported vs. that of external $SiMe_4$ (δ_H = 0.00 ppm), which is, in turn, referenced to residual non-deuterated solvent resonance. IR data (CsCl or CsI plates) was recorded using a PerkinElmer 283B IR spectrometer and (or) a Nicolet Avatar 300 FT-IR spectrometer. Elemental analyses were carried out by the Analyst Centre (University of Toronto, Canada), the Analytical Services Department of the University of Saskatchewan, and by Lakehead University Centre for Analytical Services (Thunder Bay, Canada).

Synthesis of bis-(2-[*m*-chlorophenyl]-2-oxazoline-κ^1*N*) zinc(II) chloride (1b)

A sample of $ZnCl_2$ (0.068 g, 0.50 mmol) was dissolved in Et_2O (10 mL) and stirred at RT for 20 min. The mixture was filtered and a solution (10 mL of Et_2O) of **1a** (0.218 g, 1.20 mmol) was added. The product began to precipitate almost immediately. Stirring was continued for 24 h (RT) and the resulting solid was isolated by filtration and washed with Et_2O (15 mL) and then allowed to dry in open air. The yield of cream coloured product was 0.26 g (95%), mp 217–220 °C (decomp). IR (cm^{-1}): 1631 (s, ν[C=N]), Zn–L (L = ligand) vibrations: 295 (m) 230 (w). ^{1}H NMR δ: 4.39 (m, 2H, NCH_2), 4.57 (m, 2H, OCH_2), 7.33 (m, 1H, Ar*H*), 7.55 (m, 1H, Ar*H*), 7.62 (m, 1H, Ar*H*), 7.77 (s, 1H, Ar*H*). Synthesis of bis-(2-[*p*-chlorophenyl]-2-oxazoline-κ^1*N*) zinc chloride (2b)

Complex **2b** was produced in a manner similar to that of **1b** using of $ZnCl_2$ (0.068 g, 0.50 mmol) and oxazoline **2a** (0.218 g, 1.20 mmol). The yield of cream coloured product was 0.28 g (96%), mp 198–200 °C (decomp). IR (cm^{-1}): 1635 (s, ν[C=N]), Zn–L vibrations: 300 (s), 285 (s), 232 (m). ^{1}H NMR δ: 4.30 (t, *J* = 9.0 Hz, 2H, NCH_2), 4.50 (t, *J* = 9.0 Hz, 2H, OCH_2), 7.40 (d, *J* = 8.4 Hz, 2H, Ar*H*), 7.83 (d, 2H, Ar*H*). Synthesis of bis-(2-[*p*-fluorophenyl]-2-oxazoline-κ^1*N*) zinc(II) chloride (3b)

Complex **3b** was produced in a manner similar to that of **1b** using of $ZnCl_2$ (0.068 g, 0.50 mmol) and oxazoline **3a** (0.198 g, 1.20 mmol). The yield of cream coloured product was 0.18 g (78%), mp 229–231 °C (decomp). IR (cm^{-1}): 1633 (s, ν[C=N]), Zn–L vibrations: 296 (s), 286 (s), 232 (w). ^{1}H NMR δ: 4.33 (m, 2H, NCH_2), 4.48 (m, 2H, OCH_2), 7.10 (m, 2H, Ar*H*), 7.91 (m, 2H, Ar*H*). Anal. calcd. for $C_{18}H_{16}N_2F_2O_2Cl_2Zn$ (%): C 46.33, H 3.46, N 6.00; found: C 46.01, H 3.48, N 5.67.

Synthesis of bis-(2-[*p*-tolyl]-2-oxazoline-κ^1*N*) zinc(II) chloride (4b)

Complex **4b** was produced in a manner similar to that of **1b** using of $ZnCl_2$ (0.068 g, 0.50 mmol) and oxazoline **4a** (0.193 g, 1.20 mmol). The yield of cream coloured product was 0.18 g (79%), mp 206–209 °C (decomp). IR (cm^{-1}): 1628 (s, ν[C=N]), Zn–L vibrations: 296 (s), 288 (s). ^{1}H NMR δ: 2.44 (s, 3H, CH_3), 4.30 (m, 4H, CH_2CH_2), 7.21 (d, *J* = 8.1, 2H, Ar*H*), 7.71 (d, *J* = 8.1, 2H, Ar*H*). Anal. calcd. for $C_{20}H_{22}N_2O_2Cl_2Zn$ (%): C 52.37, H 4.83, N 6.11; found: C 51.94, H 4.88, N 6.06.

Synthesis of bis-(2-[*m*-tolyl]-2-oxazoline-κ^1*N*) zinc(II) chloride (5b)

Complex **5b** was produced in a manner similar to that of **1b** using of $ZnCl_2$ (0.068 g, 0.50 mmol) and oxazoline **5a** (0.193 g, 1.20 mmol). The yield of cream coloured product was 0.19 g (85%), mp 175–177 °C (decomp). IR (cm^{-1}): 1634 (s, ν[C=N]), Zn–L vibrations: 295 (m), 230 (w). ^{1}H

NMR δ: 2.41 (s, 3H, CH_3), 4.31 (m, 4H, NCH_2), 4.50 (t, J = 8.9, 2H, OCH_2), 7.28 (m, 1H, ArH), 7.31 (m, 1H, ArH), 7.57 (m, 2H, ArH). Anal. calcd. for $C_{20}H_{22}N_2O_2Cl_2Zn$ (%): C 52.37, H 4.83, N 6.11; found: C 51.67, H 4.82, N 6.03.

Synthesis of bis-(2-[*p*-anisolyl]-2-oxazoline-κ^1*N*) zinc(II) chloride (6b)

Complex **6b** was produced in a manner similar to that of **1b** using of $ZnCl_2$ (0.068 g, 0.50 mmol) and oxazoline **6a** (0.212 g, 1.20 mmol). The yield of cream coloured product was 0.24 g (99%), mp 230–232 °C (decomp). IR (cm^{-1}): 1626 (s, ν[C=N]), Zn–L vibrations: 300 (s), 284 (s), 234 (w). ^{1}H NMR δ: 3.89 (s, 3H, CH_3), 4.32 (m, 4H, CH_2CH_2), 6.89 (d, J = 8.7 Hz, 2H, ArH), 7.82 (d, J = 8.7 Hz, 2H, ArH). Anal. calcd. for $C_{20}H_{22}N_2O_4Cl_2Zn$ (%): C 48.96, H 4.52, N 5.71; found: C 48.21, H 4.39, N 5.52.

Synthesis of bis-(2-[*m*-chlorophenyl]-2-oxazoline-κ^1*N*) zinc(II) bromide (1c)

A sample of $ZnBr_2$ (0.112 g, 0.497 mmol) was dissolved in Et_2O and treated with **1a** (0.218 g, 1.20 mmol) dissolved in 10 mL of Et_2O. The cream coloured product (0.21 g, 82%) was isolated as for compound **1b**, mp 217–219 °C (decomp). IR (cm^{-1}): 1630 (s, ν[C=N]), Zn–L vibrations: 286 (s), 274 (m), 240 (m), 232 (m). ^{1}H NMR δ: 4.47 (m, 2H, NCH_2), 4.61 (m, 2H, OCH_2), 7.32 (m, 1H, ArH), 7.57 (m, 2H, ArH), 7.77 (s, 1H, ArH). Anal. calcd. for $C_{18}H_{16}N_2O_2Cl_2ZnBr_2$ (%): C 36.74, H 2.74, N 4.76; found: C 36.82, H 2.74, N 4.98.

Synthesis of bis-(2-[*p*-chlorophenyl]-2-oxazoline-κ^1*N*) zinc(II) bromide (2c)

Complex **2c** was produced in a manner similar to that of **1c**, using of $ZnBr_2$ (0.112 g, 0.497 mmol) and oxazoline **2a** (0.218 g, 1.20 mmol). The yield was 0.20 g (67%) of a cream coloured solid, mp 215–217 °C (decomp). IR (cm^{-1}): 1632 (s, ν[C=N]), Zn–L vibrations: 286 (m), 268 (m), 258 (m). ^{1}H NMR δ: 4.37 (t, J = 8.7 Hz; 2H, NCH_2), 4.49 (t, 2H, OCH_2), 7.39 (d, J = 8.4 Hz, 2H, ArH), 7.81 (d, 2H, ArH). Anal. calcd. for $C_{18}H_{16}N_2O_2Cl_2ZnBr_2$ (%): C 36.74, H 2.74, N 4.76; found: C 36.31, H 2.67, N 4.43.

Synthesis of bis-(2-[*p*-fluorophenyl]-2-oxazoline-κ^1*N*) zinc(II) bromide (3c)

Complex **3c** was produced in a manner similar to that of **1c**, using of $ZnBr_2$ (0.112 g, 0.497 mmol) and oxazoline **3a** (0.198 g, 1.20 mmol). The yield was 0.28 g (99%) of a cream coloured solid, mp 235–237 °C (decomp). IR (cm^{-1}): 1630 (s, ν[C=N]), Zn–L vibrations: 304 (m), 275 (w), 260 (w), 232 (w). ^{1}H NMR δ: 4.34 (m, 2H, NCH_2), 4.49 (m, 2H, OCH_2), 7.10 (m, 2H, ArH), 7.89 (m, 2H, ArH). Anal. calcd. for $C_{18}H_{16}N_2F_2O_2ZnBr_2$ (%): C 38.92, H 2.90, N 5.04; found: C 38.92, H 3.02, N 5.32.

Synthesis of bis-(2-[*p*-tolyl]-2-oxazoline-κ^1*N*) zinc(II) bromide (4c)

Complex **4c** was produced in a manner similar to that of **1c**, using of $ZnBr_2$ (0.112 g, 0.497 mmol) and oxazoline **4a** (0.193 g, 1.20 mmol). The yield was 0.27 g (99%) of a cream coloured solid, mp 224–226 °C (decomp). IR (cm^{-1}): 1624 (s, ν[C=N]), Zn–L vibrations: 304 (m), 282 (w), 270 (w). ^{1}H NMR δ: 2.44 (s, 3H, CH_3), 4.33 (m, 4H, CH_2CH_2), 7.19 (d, J = 8.1, 2H, ArH), 7.70 (d, J = 8.1, 2H, ArH). Anal. calcd. for $C_{20}H_{22}N_2O_2ZnBr_2$ (%): C 43.87, H 4.05, N 5.12; found: C 43.50, H 3.98, N 5.10.

Synthesis of bis-(2-[*m*-tolyl]-2-oxazoline-κ^1*N*) zinc(II) bromide (5c)

Complex **5c** was produced in a manner similar to that of **1c**, using of $ZnBr_2$ (0.112 g, 0.497 mmol) and oxazoline **5a** (0.193 g, 1.20 mmol). The yield was 0.22g (81%) of a cream coloured solid, mp 173–175 °C (decomp). IR (cm^{-1}): 1631 (s, ν[C=N]), Zn–L vibrations: 324 (w), 310 (w), 262 (m). ^{1}H NMR δ: 2.39 (s, 3H, CH_3), 4.36 (m, 4H, CH_2CH_2), 7.28 (m, 1H, ArH), 7.38 (m, 1H, ArH), 7.58 (m, 2H, ArH). Anal. calcd. for $C_{20}H_{22}N_2O_2ZnBr_2$ (%): C 43.87, H 4.05, N 5.12; found: C 43.24, H 3.88, N 5.02.

Synthesis of bis-(2-[*p*-anisolyl]-2-oxazoline-κ^{1}N) zinc(II) bromide (6c)

Complex **6c** was produced in a manner similar to that of **1c**, using of $ZnBr_2$ (0.112 g, 0.497 mmol) and oxazoline **6a** (0.212 g, 1.20 mmol). The yield was 0.20 g (69%) of a cream coloured solid, mp 222–224 °C (decomp). IR (cm^{-1}): 1621 (s, ν[C=N]), Zn–L vibrations: 296 (w), 286 (w), 270 (w), 232 (w). ^{1}H NMR δ: 3.89 (s, 3H, OCH_3), 4.37 (m, 4H, CH_2CH_2), 6.88 (d, J = 9.0 Hz, 2H, ArH), 7.82 (d, J = 9.0 Hz, 2H, ArH). Anal. calcd. for $C_{20}H_{22}N_2O_4ZnBr_2$ (%): C 41.45, H 3.83, N 4.83; found: C 41.81, H 3.56, N 4.76.

Synthesis of μ-bis-chloro-bis-([4,4-dimethyl-2-{*o*-anisolyl}-2-oxazoline-κ^1*N*]zinc monochloride) (7*b*)[10]

A 1.0 g sample of $ZnCl_2$ (7.3 mmol) was added to Et_2O (100 mL), and the mixture was stirred until virtually all of the zinc materials had dissolved. The mixture was then filtered and 1.52 g of **7a** (7.41 mmol) was added at RT with stirring. Within a few seconds, a white solid had precipitated from the solution. Stirring was continued for 1 h, and then the product was isolated by filtration and then washed with Et_2O (2 × 50 mL). The yield was 2.18 g (87%). IR (cm^{-1}): 1624 (s, ν[C=N]). ^{1}H NMR (acetone-d_6) δ: 1.49 (s, 6H, CH_3), 4.03 (s, 3H, OCH_3), 4.29 (s, 2H, OCH_2), 7.06 (m, 1H, ArH), 7.25 (d, 1H, J = 8.4 Hz, ArH)), 7.59 (m, 1H, ArH), 7.80 (m, 1H, ArH). Anal. calcd. for $C_{24}H_{30}N_2O_4Cl_4Zn_2$ (%): C 42.20, H 4.43, N 4.10; found: C 42.29, H 4.50, N 3.96.

Synthesis of 4,4-dimethyl-2-(*o*-anisolyl)-2-oxazoline-κ^2*N*,*O*$_{OMe}$ zinc(II) bromide (7*c*)[10]

To a sample of $ZnBr_2$ (1.0 g, 4.4 mmol) was added Et_2O (75 mL), and the mixture was stirred at RT until the Zn material had dissolved. This mixture was then filtered and oxazoline **7a** (1.13 g, 5.51 mmol) was added in a single portion. A white solid began to precipitate almost immediately. This material was isolated by filtration after 1 h of stirring at RT, and the product was then washed with Et_2O (50 mL). The yield was 1.75 g (92%). IR (cm^{-1}): 1626 (s, ν[C=N]). ^{1}H NMR δ: 1.69 (s, 6H, CH_3), 4.00 (s, 3H, OCH_3), 4.35 (*AB*-pattern, 2H, OCH_2), 7.25 (m, 2H, ArH), 7.69 (m, 1H,

[10]Optimized reaction conditions based on product stoichiometry.

Ar*H*), 7.99 (dd, J = 7.8; 1.8, 1H, Ar*H*). Anal. calcd. for $C_{12}H_{15}NO_2ZnBr_2$ (%): C 33.48, H 3.51, N 3.25; found C 33.53, H 2.96, N 3.15.

Single crystal X-ray structure determinations

X-ray structures of 1b–5b, 2c–4c, and 6c

Suitable crystals of complexes **1b**-**5b**, **2c**–**4c**, and **6c** were obtained from a CH_2Cl_2 solution of the compounds that had been layered with an equal volume of Et_2O or petroleum ether and then set aside for several days at RT. Single crystals were coated with Paratone-N oil, mounted using a glass fibre, and frozen in the cold nitrogen stream of the goniometer. A hemisphere of data was collected on a Bruker AXS P4/SMART 1000 diffractometer using ω and θ scans with a scan width of 0.3° and 10 s exposure times. The detector distance was 5 cm. The data were reduced (SAINT) (15) and corrected for absorption (SADABS) (16). The structure was solved by direct methods and refined by full-matrix least-squares on F^2 (SHELXTL). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were found in Fourier difference maps and refined isotropically (n.b., thermal ellipsoid plots are at the 30% probability level and pictorial representations are drawn at the 50% probability level) (17–20).

X-ray structures of 7b and 7c

Suitable crystals of complexes **7b** and **7c** were obtained from a CH_2Cl_2 solution of the compounds that had been layered with an equal volume of Et_2O, sealed with a rubber septum, and then set aside for several days at RT. Data was collected at –100 °C on a Nonius Kappa CCD diffractometer, using the COLLECT program (21). Cell refinement and data reductions used the programs DENZO and SCALEPACK (22). SIR97 (23) was used to solve the structure and SHELXL-97 (24) was used to refine the structure. ORTEP-3 for Windows (25) was used for molecular graphics, and PLATON (26) was used to prepare material for publication. H atoms were placed in calculated positions with U_{iso} constrained to be 1.5 times U_{eq} of the carrier atom for methyl protons and 1.2 times U_{eq} of the carrier atom for all other H atoms.

For complex **7b**, the only checkCIF ALERT is for a high Hirschfeld test (6.59 s.u.) for Zn1 Cl1A. The Cl1 atom is a bridge Cl, and this behaviour is commonly found for such atoms. For complex **7c**, the only checkCIF ALERT is at the C level. The centre of gravity of the molecule is claimed to be outside the unit cell. To us it appears inside the unit cell and PLATON does not give a new set of coordinates.

For the molecular representations found in Figs. 12 and 14, a general ORTEP (25) view of the molecule of the title compound is displayed with non-hydrogen displacement ellipsoids drawn at the 50% probability level.

Phenylene-1,4- and biphenylene-4,4′-diselenolate bridged complexes of gold(I)[1]

Deeb Taher, Nicholas J. Taylor, and John F. Corrigan

Abstract: Homobimetallic gold-selenolate complexes of the type [(Ph_2R)PAuSe(C_6H_4)$_n$SeAuP(Ph_2R)] (**3a**, *R* = Et, *n* = 1; **3b**, *R* = Et, *n* = 2; **5a**, *R* = Ph, *n* = 1; **5b**, *R* = Ph, *n* = 2) are obtained by the reaction of [Ph_2RPAuCl] (**1**, *R* = Et; **4**, *R* = Ph) with 0.5 equiv. of $Me_3SiSe(C_6H_4)_nSeSiMe_3$ (**2a**, *n* = 1; **2b**, *n* = 2) in good yield. Complex [(Pr_3P)AuSe(C_6H_4)$_2$SeAu(PPr_3)] **7b** can be prepared in a two-step synthesis procedure: treatment of [AuCl(SMe_2)] **6** with 0.5 equiv. of $Me_3SiSe(C_6H_4)_2SeSiMe$**3 2b** gives [(Me_2S)AuSe(C_6H_4)$_2$SeAu(SMe_2)], which further reacts with PPr_3 to afford **7b**. The new gold-selenolate complexes have been characterized by multinuclear NMR (^{1}H, ^{31}P, ^{77}Se) and elemental analysis. The solid state structures of **3b**, **5a**, and **7b** were determined by single X-ray structure analysis.

Key words: gold, dimer, selenolate, biphenylene, phenylene.

Résumé : La réaction des produits de formule générale [Ph_2RPAuCl] (**1**, *R* = Et; **4**, *R* = Ph) avec 0,5 équivalents de $Me_3SiSe(C_6H_4)_nSeSiMe_3$ (**2a**, n = 1; **2b**, n = 2) conduit à la formation de complexes homobimétalliques sélénolate d'or du type [(Ph_2R)PAuSe(C_6H_4)$_n$SeAuP(Ph_2R)] (**3a**, *R* = Et, *n* = 1; **3b**, *R* = Et, *n* = 2; **5a**, *R* = Ph, *n* = 1; **5b**, *R* = Ph, *n* = 2) avec de bons rendements. On peut préparer le complexe [(Pr_3P)AuSe(C_6H_4)$_2$Au(PPr_3)] (**7b**) par une méthode de synthèse en deux étapes dans laquelle le traitement du [AuCl(SMe_2)] (**6**) avec 0,5 équivalents de $Me_3SiSe(C_6H_4)_2SeSiMe_3$ (**2b**) conduit à la formation du [(Me_2S)AuSe(C_6H_4)$_2$SeAu(SMe_2)] qui, par réaction subséquente avec du PPr_3, fournit le produit **7b**. Les nouveaux complexes sélénolates d'or ont été caractérisés par la RMN multinucléaire (^{1}H, ^{31}P et ^{77}Se) et par analyse élémentaire. Faisant appel à la diffraction des rayons X, on a déterminé les structures des produits **3b**, **5a** et **7b** à l'état solide.

Mots-clés : or, dimère, sélénolate, biphénylène, phénylène.

[Traduit par la Rédaction]

Introduction

The coordination chemistry of Au(I) is a most important branch of inorganic chemistry (1), and in particular there has been considerable interest in the study of gold(I) phosphine complexes of the type R_3PAuL (L = anionic ligand) in part because of the successful use of auranofin (a second-line, orally administered gold drug) for the treatment of rheumatoid arthritis (2, 3). Recent reviews by McKeage et al. (4) and Tiekink (5) also highlight that Et_3PAuCl and other gold(I) phosphine complexes can act as potential anti-tumor agents. With the rapid explosion of the ligand chemistry of the heavier chalcogen elements, it is somewhat surprising that the chemistry of gold selenolates has been the focus of less attention, despite the great possibilities that the compounds can offer regarding their structures (6). Gold(I) selenolates, including mononuclear gold(I) complexes of the type [Au(Se*R*)(PR_3)] (7, 8), have been prepared by the reaction of gold(I) chloride with selenols (9), or alkali metal selenolate salts (10, 11, 12), the coupling of stannyl diselenolate (13), the reaction with $PhSeSiMe_3$ (14, 15), as well as reactions between gold(I) chloride with organic selenolate ligands in the presence of $AgSbF_6$ (15). They have also been prepared by the reaction $Ph_3PAuN(SiMe_3)_2$ with selenols (16).

As part of our continued interest in developing the structural chemistry of metal–selenium interactions with conjugated diselenolate ligands (17), we report here a simple and efficient method for the synthesis and characterization of a small series of dimeric gold(I) selenolate complexes incorporating phosphines as ligands. These represent the first structures for gold selenolates of this type.

Results and discussion

When RPh_2PAuCl (**1**, *R* = Et; **4**, *R* = Ph) was reacted with 0.5 equimolar amounts of 1,4-bis(trimethylsilylseleno)-phenylene (**2a**) or biphenylene-4,4′-bis(trimethylsilylselenium)

β′	173.47(7)	175.26(9)	178.4(1)

(**2b**), the digold(I) selenolate complexes [(*R*Ph_2P)AuSe-(C_6H_4)$_n$SeAu(PPh_2*R*)] (**3a**, *R* = Et, *n* = 1; **3b**, *R* = Et, *n* = 2; **5a**, *R* = Ph, *n* = 1; **5b**, *R* = Ph, *n* = 2) are formed, with the elimination of Me_3SiCl (Scheme 1). After appropriate work-up, **3a**, **3b**, **5a**, and **5b** can be isolated in yields between 71% and 75% as pale yellow solids.

Air stable **3a**, **3b**, **5a**, and **5b** are soluble in common organic solvents, including dichloromethane and chloroform. They were characterized by ^1H, $^{31}P\{^1H\}$, and $^{77}Se\{^1H\}$ NMR spectroscopy. The results are summarized in Table 1.

The ^1H NMR spectrum of [($EtPh_2P$)AuSeC_6H_4SeAu(PPh_2Et)] **3a** displays, in addition to the aromatic and aliphatic resonances from the phosphine ligands, a singlet for the aryl protons of the 1,4-phenylene moiety at 7.41 ppm. The $^{31}P\{^1H\}$ NMR spectra of solutions of **3a** display one singlet for the two equivalent phosphorus atoms at 38.9 ppm with no evidence for satellites arising from $^2J_{PSe}$ coupling. The $^{77}Se\{^1H\}$ NMR spectrum consists of a singlet for the two equivalent selenium atoms at 148.6 ppm. Reactions with triphenylphosphine gold(I) chloride proceeded under similar conditions to yield 1,4-[(Ph_3P)AuSeC_6H_4SeAu(PPh_3)] **5a**. Small, single crystals of **5a** were obtained by diffusing *n*-pentane onto CH_2Cl_2 solutions, isolated as the CH_2Cl_2 solvate. The structural parameters are summarized in Table 2, and the crystallographic details are provided in the Experimental section (Table 3). The structure of **5a** (Fig. 1) confirms the expected, near liner coordination about the Au(I) centres (P-Au-Se = 178.95(8)° for Au1 and 175.26(9)° for Au2). The two Ph_3PAuSe units are nearly parallel (deviation = 1.1°), with each rotated out of the plane defined by the C_6 phenylene spacer by 99°.

Schmidbaur and co-workers (18) reported recently that treatment of phenylene-1,4-diol with [{(*p*-$CH_3C_6H_4$)$_3$PAu}$_3$O][BF_4] in a 1:1 ratio leads to the formation of the tetragold dicationic complex 1,4-[{(*p*-$CH_3C_6H_4$)$_3$PAu}$_2$$SC_6H_4$S{Au(P-*p*-$C_6H_4CH_3$)$_3$}$_2$][$BF_4$]$_2$. This also leads to short intramolecular (3.16–3.21 Å) and intermolecular (2.97–3.16 Å) Au–Au interactions and an infinite chain-like arrangement of the 1,4-[$(Au)_2SC_6H_4S(Au)_2]^{2+}$ repeat units (18). In **5a**, no significant Au···Au interactions are present, with distances (4.45 Å) significantly longer than the sum of the van der Waals radii (3.6 Å). A "head-to-tail" arrangement of adjacent Ph_3P-Au fragments leads to the crystallographic repeat observed in **5a**, with only weak interactions between adjacent 1,4-[(Ph_3P)AuSeC_6H_4SeAu(PPh_3)] (Au···Se = 3.37 and 3.54 Å) (Fig. 2).

The ^1H NMR spectra of biphenylene bridged 4,4′-[($EtPh_2P$)AuSe(C_6H_4)$_2$SeAu(PPh_2Et)] **3b** and 4,4′-[(Ph_3P)AuSe(C_6H_4)$_2$SeAu(PPh_3)] **5b** display two doublets at 7.68 and 7.24 ppm, and 7.73 and 7.24 ppm, respectively, for the equivalent protons of the biphenylene rings. Consistent with the proposed structures, the $^{31}P\{^1H\}$ NMR spectrum displays one signal for the equivalent phosphorus atoms (41.4 ppm for **3b** and 39.6 for **5b**), and the $^{77}Se\{^1H\}$ NMR spectrum shows the expected equivalence of the AuSe(C_6H_4)$_2$SeAu groups with one signal for each complex

Fig. 1. A perspective view of the molecular structure of 1,4-[$(Ph_3P)AuSeC_6H_4SeAu(PPh_3)$] **5a**. Thermal ellipsoids are drawn at the 40% probability level.

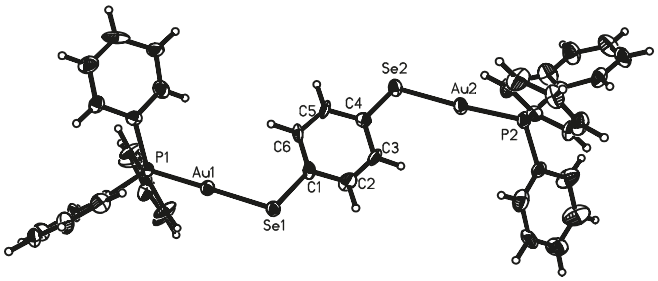

Fig. 2. The packing of 1,4-[$(Ph_3P)AuSeC_6H_4SeAu(PPh_3)$] **5a** in the crystal (hydrogen atoms omitted).

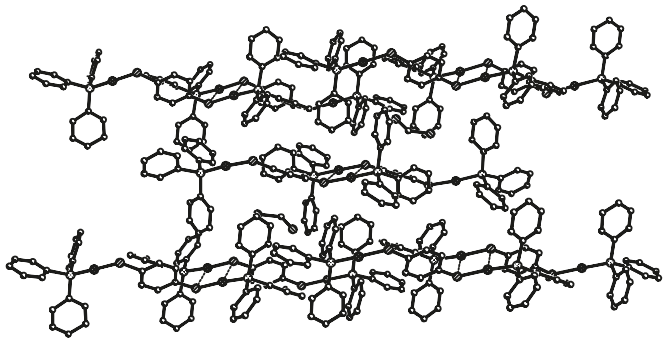

(**3b**: 157.0; **5b**: 156.6 ppm). The $^{31}P\{^1H\}$ NMR data are similar to those reported for related (triphenylphosphine)gold(I) thiolate and selenolate complexes (12, 19, 20, 21). The ^{77}Se NMR shifts of the biphenylene linked **3b** and **5b** resonate at higher field than their 1,4-phenylene linked counterparts **3a** and **5a**.

Crystals of 4,4′-[$(EtPh_2P)AuSe(C_6H_4)_2SeAu(PPh_2Et)$] **3b** were obtained from layering CH_2Cl_2 solutions with pentane. A summary of bond lengths and angles is provided in Table 2. Molecular **3b** resides about a crystallographic inversion centre (monoclinic space group $P2_1/n$), which bisects the atoms labelled C4-C4A (Fig. 3). The two C_6 rings are thus crystallographically co-planar and thus similar to the reported 4,4′-[$Cl(Bu_3P)_2PdSe(C_6H_4)_2SePd(PBu_3)_2Cl$] (17) and 4,4′-[$(Cy_3P)AuS(C_6H_4)_2SAu(PCy_3)$] (18). The Au centres in **3b** deviate from linearity (173.47(7)) sightly more than was oberved in **5a**. There are no significant intermolecular interactions.

Treatment of $(Me_2S)AuCl$ in THF solution with $Me_3SiSe(C_6H_4)_2SeSiMe_3$ (**2b**) at –78 °C produced an insoluble material ("$(Me_2S)AuSe(C_6H_4)_2SeAu(SMe_2)$") which can be used without isolation for the preparation of trialkylphosphine stabilized $(R_3P)AuSe(C_6H_4)_2SeAu(PR_3)$. The addition of two equivalents of PPr_3 to a suspension of $(Me_2S)AuSe(C_6H_4)_2SeAu(SMe_2)$ (at –78 °C) resulted in a clear solution from which weakly diffracting single crystals

Fig. 3. A perspective view of the molecular structure of 4,4′-[$(EtPh_2P)AuSe(C_6H_4)_2SeAu(PPh_2Et)$] **3b**. Thermal ellipsoids are drawn at the 40% probability level.

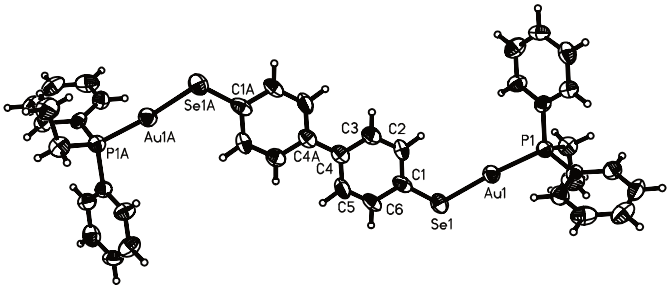

Fig. 4. The molecular structure of 4,4′-[$(Pr_3P)AuSe(C_6H_4)_2SeAu(PPr_3)$] **7b**. Thermal ellipsoids are drawn at the 40% probability level.

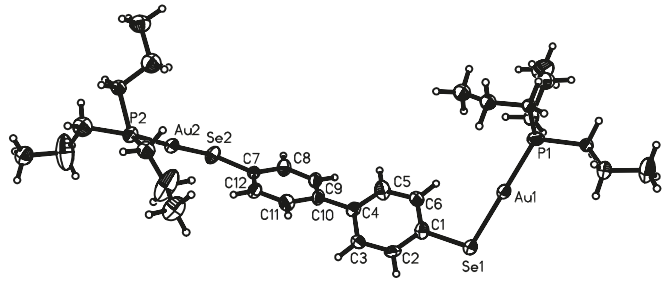
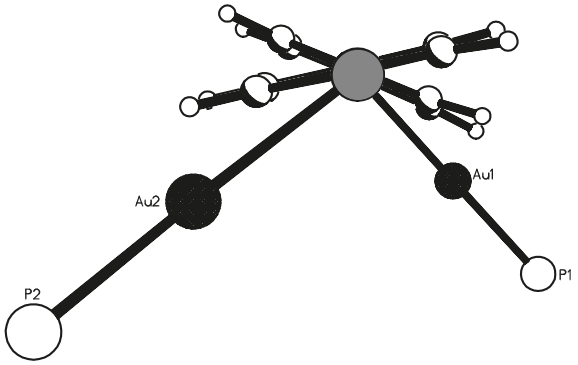


of 4,4′-[$(Pr_3P)AuSe(C_6H_4)_2SeAu(PPr_3)$] **7b** could be isolated. ^1H NMR spectra for **7b** display the expected signals for the equivalent propyl groups at 1.80, 1.58, 1.02 ppm with the aromatic resonances at 7.65 and 7.28 ppm, and in the $^{31}P\{^1H\}$ NMR spectrum the equivalent phosphorus units gives rise to single signal at 32.5 ppm. The $^{77}Se\{^1H\}$ shows a singlet at 143.7 ppm. Attempts to prepare 4,4′-[$(EtPh_2PAuSe(C_6H_4)_2SeAu(PPh_2Et)]$ **3b** and 4,4′-[$(Ph_3PAuSe(C_6H_4)_2SeAu(PPh_3)]$ **5b** from ("$(Me_2S)AuSe(C_6H_4)_2SeAu(SMe_2)$") via the addition of PPh_2Et were unsuccessful, as the suspended precipitate did not dissolve with the addition of the larger, less basic phosphine ligand in a variety of common organic solvents. Similarly, attempts to prepare 4,4′-[$(Pr_3P)AuSe(C_6H_4)_2SeAu(PPr_3)$] **7b** from 4,4′-$Me_3SiSe(C_6H_4)_2SeSiMe_3$ **2b** Pr_3PAu-Cl led to only poor yields of **7b**.

X-ray diffraction analysis of single crystals of **7b** illustrate that the molecular geometry in the solid state is markedly different than that oberved for **3b** (Fig. 4). Unlike the planar C_6-C_6 structure observed in **3b**, the two phenylene rings in **7b** are rotated such that there is a 35.9° angle between them, similar to what was reported in 4,4′-[{$(p$-$CH_3C_6H_4)_3PAuS(C_6H_4)_2S\{Au(P$-$p$-$C_6H_4CH_3)_3\}_2]^+$ (40.3°). Unlike in **3b**, the P-Au-Se moieties asymmetrically lie on the same side of the biphenylene spacer, with a 42.4° angle between the two Se-Au-P vectors (Fig. 5). The Au-Se and Au-P distances are, however, similar to those oberved in **3b** and **5a** (Table 2).

In summary, the facile preparation of **3**, **5**, and **7b** from ligated Au-Cl and silylated selenium reagents has led to the first examples of dinuclear AuSe-spacer-SeAu. The strategies employed herein lend themselves to facile adaptation using didentate ligands (e.g., [$ClAuPPh_2(CH_2)_xPh_2PAuCl$]),

Fig. 5. A projection along the inter-ring C–C bond in 4,4′-[$(Pr_3P)AuSe(C_6H_4)_2SeAu(PPr_3)$] **7b** illlustrating the orientation of the phenylene rings and the Au-Se-P moeities (propyl chains omitted).



which would allow for the preparation of coordination polymers (23) of the type $[AuPPh_2(CH_2)_xPh_2PAuSe(C_6H_4)_2Se]_n$. We are currently developing these avenues of research.

Experimental section

All syntheses were carried out under an atmosphere of high-purity dried nitrogen using standard double-manifold Schlenk line techniques and nitrogen-filled gloveboxes. Solvents were dried and collected using an MBraun MB-SP Series solvent purification system. Chloroform-*d* was dried and distilled over P_2O_5. NMR spectra [^1H (399.763 MHz), $^{13}C\{^1H\}$ (100.522 MHz), $^{77}Se\{^1H\}$ (76.217 MHz)] were recorded on a Varian Inova 400 NMR spectrometer. ^1H and ^{13}C NMR chemical shifts were referenced internally to $SiMe_4$ using the residual proton and carbon signal of the deuterated solvent, respectively. ^{77}Se $\{^1H\}$ spectra were referenced to external standards $C_6H_5SeSiMe_3$ at +85.6 ppm, relative to Me_2Se at 0 ppm. Elemental analyses were performed by Guelph Chemical Laboratories (Guelph, Canada). Crystals of **3b** and **7b** were mounted immersed in cooled mineral oil and placed in a cold stream of N_2 during data collection. X-ray structural analyses were carried out on Bruker AXS (**3b**) and Enraf-Nonius Kappa CCD (**5a** and **7b**) single-crystal X-ray diffractometers. Data were corrected for Lorentz and polarization effects. The SHELXTL (G.M. Sheldrick, Madison, Wisconsin, USA) program package was used to solve (direct methods, Au, Se, and P) and refine the structures. The weighting scheme employed was of the form $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ (a, b = refined variables, $P = 1/3\ \max(F_o^2, 0) + 2/3\ F_c^2$). All non-hydrogen atoms, with the exception of disordered carbon centers, were refined with anisotropic thermal parameters. Hydrogen atoms were included as riding on their respective carbon atoms. The structures solved and refined without complications, with the following exceptions: In **3b**, a solvent moleceule of crystallization (CH_2Cl_2) was refined as disordered over two sites with restrained geometries; in **7b**, many of the carbon atoms of the propyl chains were disordered over two sites. A satisfactory model with 50:50 occupancy was refined using mild restraints (SADI command). All non-hydrogen atoms, with the exception of disordered carbon centres, were refined with anisotropic thermal parameters.

Hydrogen atoms were included as riding on their respective carbon atoms.[4]

Materials

Phenylene-1,4-bis(trimethylsilylselenium) and biphenylene-4,4′-bis(trimethylsilylselenium) (17), [AuCl(SMe_2)] (22), and R_3PAuCl (23) were synthesized according to literature procedures.

Synthesis of $EtPh_2PAuSeC_6H_4SeAuPPh_2Et$ (3a)

$EtPh_2PAuCl$ (220.7 mg, 0.494 mmol) was added in one portion to 1,4-$C_6H_4(SeSiMe_3)_2$ (94.0 mg, 0.247 mmol) in tetrahydrofuran (30 mL) at –78 °C and warmed to room temperature (RT) after 15 min. After 2 h of stirring at RT, all volatiles were removed in vacuo, and the residue obtained was washed with *n*-pentane. Crystallization from *n*-pentane/dichloromethane (8:1) gave yellow crystals of **3a** in 72% yield (188 mg, 0.178 mmol). ^{1}H NMR ($CDCl_3$) δ: 7.65 (m, 12 H, C_5H_4), 7.46 (m, 8 H, C_5H_4), 7.41 (s, 4 H,, C_6H_4), 2.44 (dq, 4 H, J_{HH} = 8 Hz, J_{HP} = 16 Hz, CH_2), 1.23 (dt, 6 H, J_{HH} = 8 Hz, J_{HP} = 20 Hz, CH_2). ^{131}P{^{1}H} δ: 38.9. ^{77}Se{^{1}H} δ: 148.6. Anal. for $C_{34}H_{34}Au_2P_2Se_2$ (1056.43): found: C 37.75, H 3.43; calcd.: C 38.65, H 3.24.

Synthesis of $EtPh_2PAuSe(C_6H_4)_2SeAuPPh_2Et$ (3b)

One hundred mg of 4,4′-$(C_6H_4SeSiMe_3)_2$ (0.219 mmol) was reacted with 196 mg (0.438 mmol) of $EtPh_2PAuCl$ as described for the preparation of **3a** (above). After appropriate work-up, **3b** was isolated as yellow crystals in 75% yield (186 mg, 0.164 mmol). ^{1}H NMR ($CDCl_3$) δ: 7.68 (d, 4 H, J_{HH} = 8 Hz, C_6H_4), 7.65 (m, 12 H, C_5H_4), 7.45 (m, 8 H, C_5H_4), 7.24 (d, 4 H, J_{HH} = 8 Hz, C_6H_4), 2.45 (dq, 4 H, J_{HH} = 8 Hz, J_{HP} = 20 Hz, CH_2), 1.23 (dt, 6 H, J_{HH} = 8 Hz, J_{HP} = 20 Hz, CH_2). ^{131}P{^{1}H} δ: 41.4. ^{77}Se{^{1}H} δ: 157.0. Anal. for $C_{40}H_{38}Au_2P_2Se_2$ (1132.52): found: C 42.18, H 3.36; calcd.: C 42.42, H 3.38.

Synthesis of $Ph_3PAuSeC_6H_4SeAuPPh_3$ (5a)

One hundred mg of 1,4-$C_6H_4(SeSiMe_3)_2$ (0.263 mmol) was reacted with 260 mg (0.526 mmol) of Ph_3PAuCl as described for the preparation of **3a** (above). After appropriate work-up, **3b** was isolated as a yellow solid in 71% yield (216 mg, 0.187 mmol). ^{1}H NMR ($CDCl_3$) δ: 7.47 (m, 30 H, C_6H_5), 7.42 (s, 4 H, C_6H_4). ^{131}P{^{1}H} δ: 39.9. ^{77}Se{^{1}H} δ: 148.2. Anal. for $C_{42}H_{34}Au_2P_2Se_2$ (1152.52): found: C 43.49, H 2.93; calcd.: C 43.77, H 2.97.

Synthesis of $Ph_3PAuSe(C_6H_4)_2SeAuPPh_3$ (5b)

One hundred mg of 4,4′-$(C_6H_4SeSiMe_3)_2$ (0.219 mmol) was reacted with 217 mg (0.438 mmol) of Ph_3PAuCl as described for the preparation of **3a** (above). After appropriate work-up, **3b** was isolated as yellow solid in 73% yield (196 mg, 0.160 mmol). ^{1}H NMR ($CDCl_3$) δ: 7.73 (d, 4 H, J_{HH} = 8 Hz, C_6H_4), 7.53 (m, 18 H, C_6H_5), 7.43 (m, 12 H, C_6H_5), 7.24 (d, 4 H, J_{HH} = 8 Hz, C_6H_4). ^{131}P{^{1}H} δ: 39.6. ^{77}Se{^{1}H} δ: 156.6. Anal. for $C_{48}H_{38}Au_2P_2Se_2$ (1228.62): found: C 46.54, H 2.99; calcd.: C 46.92, H 3.12.

Synthesis of $Pr_3PAuSe(C_6H_4)_2SeAuPPr_3$ (7b)

[AuCl(SMe_2)] (65 mg, 0.221 mmol) was added in one portion to 4,4′-$(C_6H_4SeSiMe_3)_2$ (51 mg, 0.111 mmol) in tetrahydrofuran (30 mL) at –78 °C and warmed to RT after 15 min. After 2 h of stirring at RT, a yellow suspension formed. The reaction mixture was again cooled to –78 °C, and 0.43 mL of PPr_3 (35.4 mg, 0.221 mol) was added in one portion to the reaction mixture. After 2 h of stirring at RT, all volatiles were removed in vacuo from the clear yellow solution, and the residue obtained was washed with *n*-pentane. Crystallization from *n*-pentane/dichloromethane (8:1) gave colorless crystals of **7b** in 75% yield (79 mg, 0.083 mmol). ^{1}H NMR ($CDCl_3$) δ: 7.65 (d, 4 H, J_{HH} = 8 Hz, C_6H_4), 7.23 (d, 4 H, J_{HH} = 8 Hz, C_6H_4), 1.80 (m, 12 H, $CH_2CH_2CH_3$), 1.58 (m, 12 H, $CH_2CH_2CH_3$), 1.02 (m, 18H, $CH_2CH_2CH_3$). ^{131}P{^{1}H} δ: 32.5. ^{77}Se{^{1}H} δ: 143.7.

Tunable electrogenerated chemiluminescence from CdSe nanocrystals[1]

Jigang Zhou, Jun Zhu, Jack Brzezinski, and Zhifeng Ding

Abstract: Electrochemical behavior and related optoelectronic properties of CdSe nanocrystals (NCs) in aprotic solutions have been investigated. NCs of 2.50 ± 0.50 nm diameter were synthesized using a modified procedure in which the temperatures at the time of Se precursor injection and NC growth were controlled. The electrochemical band gap was found to agree with those determined by UV–vis absorption spectroscopy and by the tunneling current-voltage spectrum in the literature. Electrogenerated chemiluminescence of the NCs with peak maxima at 1.90 eV (red, 653 nm) and 2.55 eV (blue, 486 nm) can be generated and altered by scanning the voltage between –1.60 and –1.80 V and between –2.00 and –2.20 V, respectively. The results demonstrate the potential capability of the NCs for light emission tuned by the applied potential.

Key words: CdSe nanocrystals, electrochemistry, electrogenerated chemiluminescence, UV–vis spectroscopy, photoluminescence.

Résumé : On a étudié le comportement électrochimique et les propriétés optoélectroniques apparentés de nanocristaux (NC) de CdSe dans des solutions aprotiques. On a effectué la synthèse des NC d'un diamètre de 2,50 ± 0,50 nm en utilisant une méthode modifiée dans laquelle les températures sont contrôlées tant au moment de l'injection du Se précurseur que de la croissance du NC. On a trouvé que l'intervalle de la bande électrochimique est en accord avec ceux déterminés dans la littérature par la spectroscopie d'absorption UV–visible et par les spectres de l'effet tunnel courant/voltage. La chimiluminescence électrogénérée de NC avec un pic maximal à 1,90 eV (rouge, 653 nm) et 2,55 eV (bleu, 486 nm) peut être générée et modifiée par un balayage du voltage respectivement entre –1,60 et –1,80 V et entre –2,00 et –2,20 V. Les résultats démontrent la capacité potentielle des NC d'émettre de la lumière de longueur d'onde modifiée par le potentiel appliqué.

Mots-clés : nanocristaux de CdSe, électrochimie, chimiluminescence électrogénérée, spectroscopie UV–visible, photoluminescence.

Introduction

Semiconductor nanocrystals (NCs), which have a direct band gap structure, strongly exhibit size dependent electronic, optical, and electrochemical properties (1) when their dimensions are smaller than 10 nm. Recently, active devices have been exploited that combine the diversity of organic materials with the high-performance electronic and optical properties of semiconductor NCs (2, 3). Any desired color emission can be varied by changing the NC size or the luminescent organic materials (4). However, reports concerning the optoelectronic properties of semiconductor NCs remain scarce (5, 6) because of limited investigation methods. Electrogenerated chemiluminescence (ECL) (7–9) of semiconductor NCs (10–15) can reveal information about their structure and about the electroluminescence mechanisms of the future devices.

Because of their photon-emitting properties, CdSe NCs are beginning to make an impact in light-emitting diode and photonics technology (2–4). However, light emission is known to be sensitive to the nature of the particle surface due to the large surface area and the possible presence of surface states caused by uncoordinated atoms (14). For instance, the peak position in the ECL spectrum of CdSe NCs capped with trioctyl phosphine oxide (TOPO) was red-shifted by hundreds of nanometers compared with the PL spectrum (11), while the ECL spectrum of CdSe NCs passivated with a shell of the wider band gap material, ZnSe, is similar to the PL spectrum (12).

Here we describe the ECL of small size CdSe NCs (2.50 ± 0.50 nm) capped with TOPO. Two colours of light emission (blue and red) were observed and could be altered by tuning the applied potential. This new observation may lead to potential tuned LEDs fabricated with the NCs.

Experimental section

Synthesis of CdSe NCs

CdSe NCs capped with TOPO were synthesized according to procedures reported by Peng's group (16) and Bard's group (12), with modifications to the temperatures at the time of the Se precursor injection and NC growth (17). Briefly, a Se solution was prepared by mixing 0.16 g of Se powder, 4 g of trioctylphosphine (TOP), and 80 μL of toluene. Approximately 12 g of technical grade trioctylphosphineoxide (TOPO) and 0.1 g of cadmium acetate hydrate were placed into a 3-neck round-bottomed flask and heated to ~140 °C. After degassing with argon for 1 hour at this temperature, the solution in the flask was heated to 280 °C. At this temperature, the heating mantle was removed immediately, and a cold Se solution was quickly injected into the reaction vessel through a rubber septum. The temperature decreased to 250 °C after the injection was done. With continuous stirring, the temperature further decreased to 180 °C. At this point, the flask was reheated to about 220 °C, and the first aliquot, the sample under investigation in this report, was removed from the flask. The sample solution was cooled to ~50 °C with cold tap water. After addition of 10 mL of $CHCl_3$, the solution was kept in the dark.

The NCs were precipitated with a copious amount of methanol and collected by centrifugation and decantation. The collected precipitate was dissolved in $CHCl_3$ and precipitated again with methanol. This cycle was repeated three times. The final product was dissolved in $CHCl_3$. NCs were obtained by evaporating the solvent and drying under vacuum. The resulting NCs were used for the electrochemistry and ECL experiments.

All chemicals were purchased from Sigma-Aldrich and used with no further purification.

Physical methods

A JEOL 2010F high-resolution transmission electron microscope (HRTEM), a Varian Cary 100 UV–vis absorption spectrometer, and a Spex Fluorolog 3–11 fluorimeter were employed to characterize the morphology, electronic structure, and photo-induced luminescence (PL) of the prepared NCs.

A specially designed photoelectrochemical cell was used for all the electrochemical and ECL measurements. The cell consisted of a Pt disk working electrode (0.07 cm^2), a Pt wire counter electrode, and an Ag wire quasi-reference electrode. CdSe NC solutions were prepared with 0.1 mol/L tetrabutylammonium perchlorate (TBAP) as the supporting electrolyte and with 2 mL CH_2Cl_2 as the solvent, freshly treated by a solvent purification system. The bottom of the cell has a flat Pyrex window for detection of the light generated from the working electrode (7, 18). The loaded cell was degassed with Ar and sealed with an air-tightening Teflon cap.

Differential pulse voltammograms (DPVs) were obtained using an electrochemical workstation, CHI 610A (CH instruments, Austin, Texas). The experimental parameters for DPVs were as follows: 0.05 V pulse height, 60 ms pulse width, 200 ms period, and 0.02 V/s scan rate. Voltammetric ECL curves were obtained using the electrochemical workstation coupled with a photomultiplier tube (PMT, R928, Hamamatsu, Japan) held at –750 V with a high-voltage power supply (7, 18). The ECL generated at the working electrode was collected by the PMT under the flat Pyrex window at the bottom of the cell. The photocurrent from the PMT was transformed into a voltage signal by an electrometer (Model 6517, Keithley, Cleveland, Ohio). This signal, along with the potential and current signals from the electrochemical workstation. was sent through a DAQ board (DAQ 6052E, National Instruments, Austin, Texas) to the computer where the dada acquisition system was controlled by a homemade LabVIEW (National Instruments, Austin, Texas) program.

ECL spectra (7, 18) were measured by employing a potential program with the electrochemical workstation. By collecting the ECL light through the Pyrex window of the cell in a spectrograph (Spectra Physics, Cornerstone 260M) and dispersing the emission with a grating, the output was recorded on a back-illuminated charge coupled device (CCD) camera (Andor 420BU), which was electrothermally cooled to below –56 °C.

The electrochemical potential was calibrated at the end of each experiment by the addition of ferrocene as an internal standard with the formal potential of Fc^+/Fc 0.400 V vs. SHE (19). ECL quantum yields were calculated by comparing the integrated ECL intensities and the current values (charge) of the NCs with the reference $Ru(bpy)_3^{2+}$ (Φ_{ECL} = 5%) (20). The quantum yield was calculated using the following equation:

$$[1] \qquad \Phi_{NC} = 100 \times \left(\frac{\int_a^b \mathrm{ECL}\, dt}{\int_a^b \mathrm{Current}\, dt} \right)_{NC} \Bigg/ \left(\frac{\int_a^b \mathrm{ECL}\, dt}{\int_a^b \mathrm{Current}\, dt} \right)_{St}$$

where Φ_{NC} is the quantum yield (%) relative to $Ru(bpy)_3^{2+}$, ECL is the ECL intensity, Current is the electrochemical current value, St is the standard, and NC is the nanocrystal sample.

Results and discussions

The temperature effect on NC growth

We believe that precursor concentration and temperature for injection and NC growth are two important factors that manipulate NC size in general. The NC growth was fast, and it was difficult to obtain desired NC sizes under reported temperature conditions (16). Temperature was therefore chosen as our major parameter to optimize. We decreased the reaction temperature of the Cd precursor solution in a flask by using a cold Se precursor solution and a fast injection speed, as well as by removing the heat mantle under the reaction flask before injection. Growth solution was cooled quickly with an ice bath once the desired size was achieved, which was monitored via absorption wavelength. With this method, we were able to control NC sizes undergoing different growth times. The emission colours of the obtained NCs covered almost the entire visible spectrum when excited by a UV lamp.

Characterization of CdSe NCs

One batch of small size NCs was selected for study, with the focus on probing their electronic structure by electrochemistry and ECL. As shown in Fig. 1, the NCs were characterized by TEM, high-resolution TEM, UV–vis absorption, and PL spectra (Fig. 1). TEM experiments showed a narrow size distribution, and NC size was determined to be 2.50 ± 0.50 nm, as demonstrated in Fig. 1*b*. According to the UV–vis absorption spectrum, the diameter of the NCs was estimated at about 2.0 nm (21, 22), and the sharp peak illustrated that the size distribution was narrow. From the PL spectrum, one sharp peak at 2.55 eV and a second broad peak at 2.03 eV were observed. The narrow absorption peak diminishes the possibility of wide size distribution, thus we can attribute the sharp PL peak to the core structure emission and the broad peak to the surface state emission. The NCs in question may produce strong PL emission from both core excitons and surface traps, as depicted by the energy diagram in Scheme 1*a*.

Electrochemistry

NC reduction (electron injection, whose mechanism is illustrated in Scheme 1*b*) in the negative bias region, as shown by the DPV in Fig. 2, was characterized by a doublet followed by a continuous increase in current, with the applied potential becoming more negative. This is indicative of two discrete charge transfers followed by multiple charge transfers. The various peak spacings in the DPV can be attributed to Coulomb charging into higher energy levels (10). The DPV responses in this region reveal information about the conduction levels and look very similar to the tunneling current-voltage spectrum (TCVS) of a similar size CdSe NC at 4.2 K, obtained by Alperson et al. (23). The doublet was attributed to the two consecutive electron injections to the first conduction band, $1S_e$ (s character) in the case of electrochemically prepared NCs (23). The energy difference between the first two peaks, i.e., the Coulomb charging, was 0.37 eV in DPV, which agrees well with the value in the TCVS (0.34 eV). Broader peaks were observed in DPV than those observed in the TCVS. While the CdSe NCs were monodisperse in size, the broadness of the peaks might be due to the surface states, which increased the complexity of the electronic structure. Furthermore, a continuous increase in current, instead of a Coulomb staircase for the electron injections to the second conduction band, was observed in DPV. However, up to six peaks spaced by values close to the Coulomb charging energy in TCVS for a single InAs dot were reported by Banin et al. (24). This might be caused by an overlap of core and shell (surface) electronic structures as well as an interplay between level spacing and single electron tunneling. Alternatively, two oxidation (hole injection) peaks were seen in the positive bias side of the DPV in Fig. 2. These peaks were broader, and the Coulomb charging energy was larger (0.48 eV) than that of the negative side. These results were expected because of the higher density of valence levels and the close proximity between Coulomb charging and level spacing as well as the multiplicity of electronic structures.

The electrochemical gap was determined to be 2.34 eV from the separation of the first oxidation and reduction peaks in the DPV (Fig. 2). This is in good agreement with the optical band gaps, 2.50 and 2.06 eV, estimated from the absorption onset and the broad PL peak of the NC, respectively (25). The zero current gap in TCVS, 2.88 to 3.13 eV, also provided a qualitative description of the band gap (23). The electrochemical gap is strongly affected by the presence

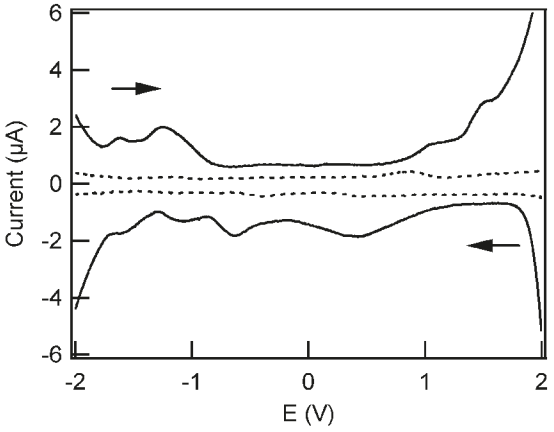
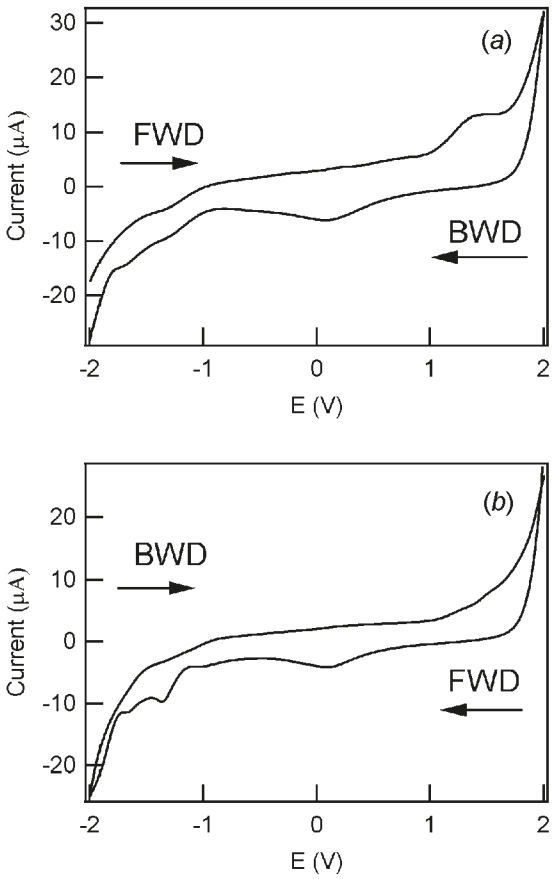
Fig. 2. Differential pulse voltammograms (DPVs) of a dichloromethane solution containing 0.1 mol/L tetrabutylammonium perchlorate (TBAP) as supporting electrolyte (dotted line) and 2.50 nm CdSe NCs (40 μmol/L) dispersed in the same solution (solid line) at a 0.07 cm^2 Pt disk working electrode. The lower lines are DPVs with a potential scan from positive to negative, while the upper lines from negative to positive. A potential increment of 4 mV, a sample width of 0.0167 s, a pulse period of 0.2 s, a pulse width of 0.05 s, and a pulse amplitude of 50 mV were used.



of surface states that can act as local traps for electrons and holes. Considering the small size of NCs studied here, a large part of the CdSe should be on the surface of the NCs (14, 17), which may be capped with TOPO or possibly a small amount of oxide. Very recently, Bard's group reported an electrochemical study of CdTe NCs (13). In comparison to CdTe NCs, CdSe NCs were assumed to be less passivated by TOPO in similar preparation conditions (11, 13). The CdSe NCs in question had even richer surface states than those reported previously (11). This is observed in an intense photoluminescence peak at a longer wavelength, i.e., surface state emission. Such evidence suggests that the above observed oxidation and reduction may reflect the properties of the NC surface. Electron and hole injections may first occur on the $1S_e$ and 1VB bands of surface CdSe, respectively (23). However, it is not clear from the DPV where further charge injections occur. In addition, forward and reverse DPV scans are relatively less symmetric than those of Si NCs (10), indicating that charge transfers are not very reversible.

Cyclic voltammograms (CVs) of the CdSe NCs dispersed in the same dichloromethane electrolyte solution are demonstrated in Fig. 3. As shown by the DPVs, the redox behavior of the NCs is dependent on the scan direction of the applied potential. The NC anions are more stable than the cations as illustrated by the CV in Fig. 3*a*: the anions generated at the negative potential can be re-oxidized in the forward scan, while the cations produced at the positive potential can barely be re-reduced in the backward scan. A new peak also appears at 0.11 V, probably due to the new species from the decomposed cations. In addition, the CV in the reversed order of forward and backward scans as above does not show evident reduction peaks and the following oxidation reaction due to the depletion of the NCs in the vicinity of the electrode (Fig. 3*b*).

Fig. 3. Cyclic voltammograms (CVs) of a dichloromethane solution containing 0.1 mol/L tetrabutylammonium perchlorate (TBAP) as supporting electrolyte (dotted line) and 2.50 nm CdSe NCs (40 μmol/L) dispersed in the same solution (solid line) at a 0.07 cm^2 Pt disk working electrode. (*a*) CV with a potential scan from –2.000 to 2.000 and back to –2.000 V. (*b*) CV with a potential scan from 2.000 to –2.000 and back to 2.000 V. A scan rate of 100 mV/s was used.



Electrogenerated chemiluminescence (ECL)

ECL of the same electrolyte solution used for electrochemical experiments was first investigated by recording voltammetric photocurrent with a photomultiplier tube (PMT) (10). ECL was observed under various stimulus conditions. We found that emission was produced in both negative and positive sides when the applied potential was swept between –2.30 and 2.30 V, though the ECL intensity is rather weak. An annihilation mechanism, i.e., electron transfer between reduced and oxidized NCs, was assumed in this light emission process (10, 11). More interestingly, a significant ECL signal was detected as the potential was scanned from 0.00 to –3.00 V, as shown in Fig. 4. The ECL-potential curve showed two overlapping peaks, which may correspond to two emission processes. ECL turn-on potential was at –1.30 V, which is slightly more negative than the first reduction peak in DPV. Stable ECL could be obtained even at pesudo constant potentials on the negative side, e.g., slowly scanning from –1.60 to –1.80 V or from –2.00 to –2.20 V. The second peak on the ECL-potential curve appeared at –2.12 V. Note that in these cases, only the reduced species

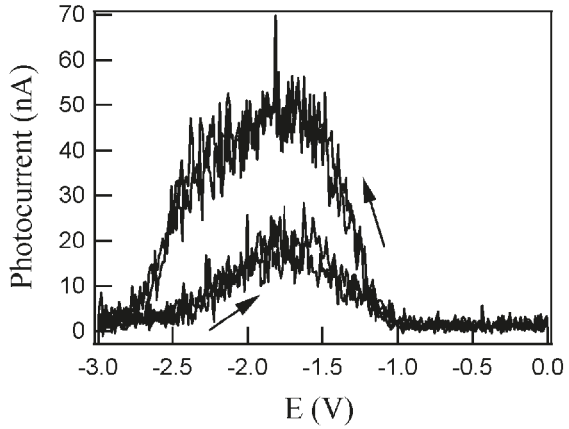
Fig. 4. Voltammetric ECL curves of at a 0.07 cm^2 Pt disk working electrode immersed in 0.1 mol/L TBAP CH_2Cl_2 electrolyte solution containing 2.50 nm CdSe NCs (40 μmol/L). Scan rate was at 0.5 V/s. Two cycles are overlapped in the figure.



existed in the solution, and the above electrochemical study showed a higher stability of anions than that of cations. The annihilation leading to light emission in this situation could not occur. Therefore, there must be another oxidant that accepted an electron from the valance band of anion NC radicals to form excited states. Bard and co-workers (13) suggested that similar emission from CdTe NCs might occur through an electron transfer reaction between anion CdTe radicals and electrogenerated oxidant radicals, $CH_2Cl^{\bullet}$, from the dichloromethane used as the solvent. This is the so-called co-reactant emission mechanism (26). This mechanism explains well the ECL signal at more negative potential and is depicted in Scheme 1*b*, according to our observation. This mechanism is illustrated in Scheme 2. However, our ECL "turn-on voltage" of –1.30 V is not negative enough to generate the oxidant, and similar ECL was observed in dimethylformide (DMF) solution. Nevertheless, it was found that ECL was enhanced several times by introducing air to the electrolyte solution. Similar to the chemiluminescence of certain linear hydrazides, aldehydes, and ketones in dimethyl sulfoxide with potassium tert-butoxide and oxygen (27, 28), ECL might be emitted from the excited states formed by the reaction of the anion radicals with oxygen molecules,

$$(CdSe)_{NC} + e^- \rightarrow (CdSe)^{\bullet -}_{NC}$$

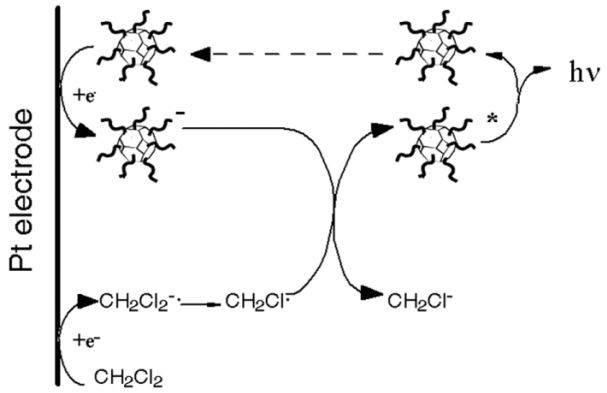
$$(CdSe)^{\bullet -}_{NC} \xrightarrow{O_2} (CdSe)^{*}_{NC}$$

$$(CdSe)^{*}_{NC} \rightarrow (CdSe)_{NC} + h\nu$$

It is unlikely that an oxygen molecule accepts an electron to form a superoxide ion ($O_2^{-\bullet}$), as in the case of hydrazides, aldehydes, and ketones, since the redox potential of O_2/O_2^- (–0.33 V) is too negative. Indeed, this redox couple acted as an electron donor in an alkaline solution to the CdSe NC packed film (6).

As demonstrated in Scheme 2, CdSe NCs were recycled with dichloromethane or oxygen molecules acting as a scavenger in this emission mechanism. ECL was therefore very stable with repetitive potential cycling over a long time period. Nearly constant ECL intensity was also measured periodically over several weeks. The ECL efficiency was found to be half that of $Ru(bpy)_3^{2+}$ under the same experimental conditions.

Scheme 2. Schematic mechanisms for ECL of the CdSe NCs with CH_2Cl_2 as the co-reactant.



ECL spectra are presented in Fig. 5. The integration time for the spectra is 6 min. As the potential was scanned from 0 to –2.20 V, the ECL spectrum, consisting two peaks at 1.90 and 2.55 eV, was very broad and weak. However, strong ECL at 1.90 eV (red, 653 nm) was observed at potentials slowly scanned between –1.60 and –1.80 V. Even stronger ECL consisting of two peaks at 1.90 and 2.55 eV (blue, 486 nm) was emitted at more negative potentials (–2.00 to –2.20 V). We assume that ECL at 1.90 and 2.55 eV correspond to the surface state and core structure emission, respectively. These energies are in good agreement with band gaps from surface and core electronic structures as analyzed from our electrochemical and spectroscopic study above. Illustrative ECL mechanisms for the core and the surface are summarized in Scheme 1*b*. Emission at 2.55 eV implies that the current rise at very negative potentials in DPV resulted from the electron injections to the core conduction bands. Quantitatively, however, it is not clear why the NCs luminesced at 1.90 eV simultaneously when stimulated with higher energy. It is even more difficult to understand at this point why ECL was only observed at longer wavelength (1.70 eV) for 3.2 nm diameter CdSe NCs prepared using similar methods in a previous report (11). We can speculate that ECL from the core was not favorable in the absence of oxygen molecules in an airtight electrochemical cell. Another speculation is that we might obtain the NCs with different crystallinity from that of the NCs in the previous report (11), which lead to different crystal band structures. Bawendi and co-workers (21) found that simulated X-ray powder diffraction spectra for 3.5 nm diameter spherical nanocrystallites such as zincbende, wurtzite, and wurtzite with one stacking fault are very different. However, more detailed studies are needed to understand the relationship between the nanocrystallinity and the ECL.

Conclusion

In addition to size-tunable character, light emission is also potentially tunable for the CdSe NCs under investigation. This new phenomenon is rather remarkable as it provides a

new avenue to tune colours of light emission from CdSe NCs simply by switching applied potentials. An impact to optoelectronics technology such as light-emitting diodes and color-display screens is anticipated.

TRIBUTE/HOMMAGE

A Tribute to a Complete Academic: Dick Puddephatt

It is a privilege to be able to provide this biographical sketch of my colleague Richard J. (Dick) Puddephatt. It is well-known that Dick is a world-class organometallic and coordination chemist. Perhaps less appreciated are his immense contributions to teaching and service at the University of Western Ontario and beyond. His sustained record of excellence in all areas of university life allows me to state with complete conviction that Dick is the complete academic.

Dick was educated at University College, London, where he received his B.Sc. in 1965 and Ph.D. in 1968, working with A.G. Davies and R.J.H. Clark. He did postdoctoral research with H.C. Clark at the University of Western Ontario, took up a position as lecturer and then senior lecturer at the University of Liverpool, before coming back to the University of Western Ontario as a Professor in 1978. He currently holds the rank of Distinguished University Professor, Western's highest academic honour. He also held a Tier 1 Canada Research Chair in Materials Chemistry.

Dick's research has encompassed studies of reactivity and mechanism in organometallic chemistry related to catalysis, especially involving activation of normally inert bonds, in metallacyclobutane chemistry, the chemistry of binuclear and trinuclear complexes as models for reactions on metal surfaces, and the structure, bonding, and spectroscopy of organometallic compounds. In organometallic and coordination chemistry related to materials science, he has designed new precursors for chemical vapor deposition of thin films of metals and metal oxides, used dynamic coordination chemistry to make macrocycles, catenanes, polymers, and network materials, defined elegant examples of dynamic ring-opening polymerization, and shown how secondary bonding forces can be used to organize the higher-order structures of functional molecular materials. He has been particularly enamored with the chemistry of platinum and gold.

To date he has published over 550 papers, 3 books, and several reviews. The impact of his work can be gauged by a number of factors. With an h-index of 56, Dick is one of the top cited chemists in the world. The esteem in which Dick's work is held can be measured in part by the numerous awards he has received including the Florence Bucke Science Prize, a Distinguished Research Professorship, and the Hellmuth Research Award from the University of Western Ontario, the Alcan and Steacie Awards of the Canadian Society for Chemistry, the Noble Metal Chemistry award and Nyholm Lecture Award from the Royal Society of Chemistry, and the CIC Medal of the Canadian Institute of Chemistry. He is a Fellow of the Royal Society of Canada (FRSC) and the Royal Society, U.K. (FRS). The citation on his election as Officer of the Order of Canada in 2007 read, "For his contributions to the advancement of organometallic chemistry, as well as for his inspirational leadership of generations of researchers".

On research alone, Dick would be an obvious and worthy candidate for this special issue of the Canadian Journal of Chemistry. However, his talents and contributions don't end there. Dick is a gifted teacher. As a long time departmental Teaching Coordinator for Inorganic Chemistry at Western, Dick has been a leading advocate for, and developer and instructor of an inorganic curriculum that is both rigorous and innovative. Dick's record in graduate teaching is equally impressive. His average graduate teaching evaluations are among the highest in the department.

What is particularly noteworthy at the graduate level is Dick's record of graduate supervision. He has successfully supervised 52 Ph.D. students, 13 M.Sc. students and over 30 postdoctoral fellows during his career. Over the years, his group size was routinely 10–15 graduate students and postdocs. Visiting faculty members from around the world have also been guests in his research group while on sabbatical leave. I name below a list of some of his students and where they have ended up as an indicator of Dick's role as a mentor. This list is not meant to be exhaustive or exclusive. All of Dick's students have benefited from working in his group because as a supervisor Dick encourages students to work and think independently, creatively, and rigorously, and to take a broad view of science.

Some of his former students have made academic careers in Canada: Ross Hill, Patrick Monaghan, Brian Lloyd, Lucio Gelmini, Hilary Jenkins, Greg Spivak, Ernie Prokopchuk, Brian Sterenberg; USA: Craig Anderson, Chris Levy; UK: Jon Rourke, Jianliang Xiao; Germany: Fabian Mohr; Spain: Margarita Crespo; Australia: Lou Rendina; Hong Kong: Guochen Jia; Poland: Wanda Radecka-Paryzek; India: Sujit Roy; Bangladesh: Mohammed Quyser, Kazi Azam; Iraq: Jaafar Jawad; Iran: Mehdi Rashidi. They have made independent careers in diverse areas, using their training in organometallic chemistry but also applying their creativity to address new problems. For example, Ross Hill (Professor, Simon Fraser University) is expert in photochemical processing of materials for microelectronics and has successful patents as well as distinguished publications in that area. Jianliang Xiao (Reader, University of Liverpool) has built an independent reputation in environmental catalysis, especially using supercritical carbon dioxide or ionic liquids as recyclable, non-polluting solvents. Lou Rendina (Reader, University of Sydney) is a leading researcher in the developing field of bio-organometallic chemistry. Guochen Jia (Professor, Hong Kong University of Science and Technology) has made major contributions to dihydrogen chemistry and the chemistry of metal–carbon multiple bonds. Chris Levy (Assistant Professor, University of Kansas) is expert in metal complex catalysis and self-assembly of molecular materials.

Many former students have made successful careers in research and development and management in industry. For example, in Canada, senior R&D positions are held by Marie-Claude Brandys and Mike Irwin (3M Canada), John Scott (3M, Barrday), Gilles Arsenault (Wellington Laboratories, Bayer), Ian Jobe (Nova, Bayer), Geoff Hill (Bowater Canada), Tom Burton (ICI Canada). Sudhir Achar has been director of paint research for ICI India and food research for Unilever India, Zheng Yuan is a senior materials chemist in the microelectronics industry in the USA, and Guy Schoettel is a senior pharmaceutical chemist in Switzerland. Many have made the transition from R&D to management. For example, Ilse Treurnicht is CEO of MaRS (Toronto), and John Laws is Director of Sales for Proctor and Gamble in the USA.

Students who have flourished in government or professional careers include Paul Makin (scientific publishing, U.N.), Peter Hall (forensic scientist, UK), Maria Stalteri (medical research, UK), Sam Choi (environmental science, Hong Kong), Dave Elliot (research institute, Australia), Jan Hux (COO, Institute for

© 2009 NRC Canada

Clinical Evaluative Sciences and medical doctor, Canada), Mary-Ann MacDonald (dentist, Canada).

It was only fitting, given Dick's record in teaching and graduate supervision, that he was awarded Western's highest teaching accolade, the Edward G. Pleva Award for Excellence in Teaching in 2003-04.

Dick's service record is equally outstanding. He has been served on many NSERC committees including those for Discovery Grants, Collaborative Grants, Steacie Fellows, and the Gold Medal, the Polanyi Prize selection committee (including as its Chair), and on the Rutherford award selection committee of the Royal Society of Canada (including as its Chair). He is the past President of the Chemical Institute of Canada and the Canadian Society for Chemistry. He has also served on various subcommittees of these organizations. He is a past Senior Editor of the Canadian Journal of Chemistry and currently an Editor of Inorganica Chimica Acta. He is a member of several editorial advisory boards of other chemistry journals. His contributions to the Chemistry community were recognized by the Montreal Medal of the Chemical Institute of Canada in 2006.

On a personal note, Dick is a true gentleman. His experience and altruistic nature makes his opinions highly sought. I cannot recall a single instance where he had to raise his voice to get his point across, and that point is rarely ignored. He has been a leader in building up the Chemistry department at Western. On a further personal note, I will always be grateful for Dick's support and advice when I took over from him as Senior Editor of the Canadian Journal of Chemistry. The quality and quantity of the papers in this issue and the response of the community to this special issue shows that my thoughts regarding Dick are not unique. I congratulate him on this distinction and wish him all the best for the future.

HOMMAGE/TRIBUTE

Hommage à un universitaire remarquable : Dick Puddephatt

C'est pour moi un privilège de pouvoir fournir un aperçu biographique de mon collègue Richard J. (Dick) Puddephatt. Reconnu mondialement en chimie organométallique et en chimie de coordination, Dick est peut-être moins bien reconnu pour sa remarquable contribution à l'enseignement et aux services à l'Université Western Ontario (UWO) et ailleurs. Ses grandes réalisations dans tous les domaines de la vie universitaire me permettent d'affirmer avec conviction que Dick est vraiment le parfait universitaire.

Formé à l'University College de Londres, Dick a obtenu un baccalauréat ès sciences en 1965 et un doctorat en 1968, en travaillant avec A.G. Davies et R.J.H. Clark. Chercheur postdoctoral sous la direction de H.C. Clark à l'UWO, Dick a par la suite accepté un poste de chargé de cours à l'Université de Liverpool, puis de chargé de cours principal, avant de revenir à l'UWO comme professeur en 1978. Il occupe maintenant le rang de professeur émérite à l'UWO. Ce rang constitue la plus haute distinction de cette institution. Enfin, il a été titulaire de la chaire de recherche du Canada sur la chimie des matériaux (niveau 1).

Les travaux de Dick ont porté sur l'étude de la réactivité et des mécanismes en chimie organométallique sur le plan de la catalyse, surtout en ce qui touche l'activation de liaisons normalement inertes en chimie des métallocyclobutanes, la chimie des complexes binucléaires et trinucléaires comme modèles de réaction sur des surfaces métalliques, ainsi que la structure, les liaisons et la spectroscopie des composés organométalliques. Dans le domaine de la science des matériaux lié à la chimie organométallique et à la chimie de coordination, Dick a conçu de nouveaux précurseurs pour le dépôt chimique en phase vapeur de feuils de métaux et d'oxydes métalliques, il a utilisé la chimie de coordination dynamique pour produire des macrocycles, des caténanes, des polymères et des matériaux de réseaux, il a décrit des exemples élégants de polymérisation dynamique par ouverture de cycle et il a montré comment les forces de liaison secondaire peuvent être utilisées pour organiser les structures d'ordre supérieur des matériaux moléculaires fonctionnels. Il était particulièrement friand de la chimie du platine et de l'or.

À ce jour, il a publié plus de 550 articles, trois livres et plusieurs synthèses. De nombreux facteurs permettent de mesurer l'impact de ses travaux. Avec un indice h de 56, Dick est un des chimistes les plus cités dans le monde. La considération pour les travaux des Dick se mesure en partie par les nombreux prix qu'il a reçus, dont le Florence Bucke Science Prize, le Distinguished Research Professorship et le prix Hellmuth de l'UWO, les prix Alcan et Steacie de la Société canadienne de chimie, les prix Noble Metal Chemistry et Nyholm Lecture de la Royal Society of Chemistry, et la médaille de l'Institut de chimie du Canada. Il est membre de la Société royale du Canada et de la Royal Society de Londres. La citation de sa nomination comme officier de l'Ordre du Canada en 2007 se lisait comme suit : « Pour sa contribution à l'avancement de la chimie organométallique, ainsi que pour son leadership qui est une source d'inspiration auprès de plusieurs générations de chercheurs. »

Les recherches de Dick suffisent amplement à faire de lui le candidat tout désigné pour ce numéro spécial de la *Revue canadienne de chimie*. Toutefois, ses talents et ses contributions ne se limitent pas à ses recherches. Dick est un enseignant doué. Sa longue expérience en qualité de coordonnateur de l'enseignement de la chimie inorganique à l'UWO a fait de lui un acteur de premier plan de la promotion, de l'établissement et de l'enseignement d'un programme de chimie inorganique rigoureux et novateur. Le bilan de Dick aux cycles supérieurs est tout aussi impressionnant, et les évaluations de son enseignement sont parmi les meilleures du département.

Ce qui est particulièrement remarquable en ce qui concerne les études de cycles supérieurs, c'est l'expérience de Dick en matière de supervision. Durant sa carrière, Dick a dirigé 52 étudiants de doctorat, 13 étudiants de maîtrise et plus de 30 boursiers postdoctoraux. Au fil des ans, il a dirigé des groupes de 10 à 15 étudiants des cycles supérieurs et boursiers postdoctoraux. Des professeurs des quatre coins du monde ont aussi été invités à se joindre à son groupe de recherche durant leur congé sabbatique. Vous trouverez ci-dessous une liste non exhaustive de certains des étudiants de Dick et de l'endroit où ils sont maintenant, laquelle liste illustre son rôle de mentor. Tous les étudiants ont bien profité de leur collaboration avec le groupe de Dick puisque ce dernier supervise ses étudiants en les incitant à travailler et à penser de façon indépendante, créative et rigoureuse, et à voir la science dans une vaste perspective.

Certains de ses anciens étudiants ont eu une carrière universitaire au Canada (Ross Hill, Patrick Monaghan, Brian Lloyd, Lucio Gelmini, Hilary Jenkins, Greg Spivak, Ernie Prokopchuk, Brian Sterenberg), aux États-Unis (Craig Anderson, Chris Levy), au Royaume-Uni (Jon Rourke, Jianliang Xiao), en Allemagne (Fabian Mohr), en Espagne (Margarita Crespo), en Australie (Lou Rendina), à Hong Kong (Guochen Jia), en Pologne (Wanda Radecka-Paryzek), en Inde (Sujit Roy), au Bangladesh (Mohammed Quyser, Kazi Azam), en Iraq (Jaafar Jawad) et en Iran (Mehdi Rashidi). Ils ont fait carrière indépendamment dans divers domaines, en utilisant leur formation en chimie organométallique, mais aussi en mettant leur créativité au service de la résolution de nouveaux problèmes. Par exemple, Ross Hill (professeur à l'Université Simon Fraser) est expert du traitement photochimique des matériaux en microélectronique. Il est détenteur de brevets fructueux dans ce domaine et auteur de publications reconnues. Jianliang Xiao (chargé de cours à l' Université de Liverpool) a forgé sa réputation dans le domaine de la catalyse écologique, particulièrement en utilisant du dioxyde de carbone supercritique ou des liquides ioniques comme solvants recyclables et non polluants. Lou Rendina (chargé de cours à l'Université de Sydney) est un éminent chercheur dans le domaine de la chimie bioorganométallique, en plein développement. Guochen Jia (professeur à l'Université de science et technologie de Hong Kong) a contribué de façon significative à la chimie du dihydrogène et des liaisons multiples métal-carbone. Chris Levy (professeur adjoint à l'Université du Kansas) est expert de la catalyse des complexes métalliques et de l'autoassemblage des matériaux moléculaires.

De nombreux anciens étudiants ont connu une brillante carrière en recherche et développement (R-D) et en gestion dans l'industrie. À titre d'exemple, au Canada, les personnes suivantes occupent des postes supérieurs en R-D : Marie-Claude Brandys et Mike Irwin (3M Canada), John Scott (3M, Barrday), Gilles Arsenault (Wellington Laboratories, Bayer), Ian Jobe (Nova, Bayer), Geoff Hill (Bowater Canada), Tom Burton (ICI Canada). Sudhir Achar a été directeur de la recherche sur la

© 2009 NRC Canada

peinture à Peintures ICI et directeur de la recherche sur les aliments à Unilever en Inde. Zheng Yuan est chimiste supérieur en microélectronique aux États-Unis. Guy Schoettel est pharmacochimiste supérieur en Suisse. De nombreux autres sont passés de la R-D à la gestion, notamment Ilse Treurnicht, directrice générale à MaRS (Toronto), et John Laws, directeur des ventes chez Proctor and Gamble aux États-Unis.

Parmi ceux et celles qui travaillent comme fonctionnaires ou qui exercent une profession libérale, mentionnons Paul Makin (édition scientifique, ONU), Peter Hall (expert judiciaire, R.-U.), Sam Choi (science de l'environnement, Hong Kong), Dave Elliot (institut de recherche, Australie), Jan Hux (directeur de l'exploitation à l'Institute for Clinical Evaluative Sciences et médecin, Canada) et Mary-Ann MacDonald (dentiste, Canada).

Compte tenu de ce bilan en enseignement et à la direction d'études supérieures, il n'est pas surprenant que l'UWO lui décerne sa plus haute récompense, le prix Edward G. Pleva pour l'excellence en enseignement en 2003-2004.

Le dossier de Dick est tout aussi exceptionnel sur le plan des services. Il a siégé à de nombreux comités du CRSNG, dont ceux des subventions à la découverte, des subventions de recherche et développement coopérative et des bourses Steacie, ainsi qu'aux comités de sélection de la médaille d'or et du prix Polanyi (y compris à titre de président). Il a aussi siégé au comité de sélection du prix Rutherford de la Société royale du Canada (y compris à titre de président). Il a présidé l'Institut de chimie du Canada et la Société canadienne de chimie, et siégé à divers sous-comités de ces organismes. Ancien rédacteur en chef de la *Revue canadienne de chimie*, il est maintenant corédacteur en chef d'*Inorganica Chimica Acta* et membre du comité de rédaction de plusieurs autres revues en chimie. En 2006, l'Institut de chimie du Canada lui a remis la médaille de Montréal pour souligner ses contributions au milieu de la chimie.

Sur un plan personnel, Dick est un vrai gentleman. Son opinion est très recherchée en raison de son expérience et de sa nature altruiste. Je ne peux me souvenir d'une seule occasion où il aurait élevé la voix pour convaincre ses interlocuteurs; ses arguments son généralement très convaincants. Il a été un des ténors de la création du Département de chimie à l'UWO. Pour ma part, je serai toujours reconnaissant envers Dick pour son appui et ses conseils quand je l'ai remplacé au poste de rédacteur en chef de la *Revue canadienne de chimie*. La qualité des articles publiés dans ce numéro spécial, leur quantité et la réponse du milieu de la chimie montrent bien que je ne suis pas seul à tenir Dick en très haute estime. Je le félicite pour cette distinction et lui souhaite bonne chance pour l'avenir.

A mild and efficient chemoselective *N*-benzyloxycarbonylation of amines using TBAB as a catalyst under solvent-free conditions

Kothamasu Suresh Babu, Vidadala Rama Subba Rao, Ravu Ranga Rao, Sakhamuri Sivaram Babu, and Janaswami Madhusudana Rao

Abstract: We describe a mild and efficient method for the chemoselective *N*-benzyloxycarbonylation of amines by treatment of amines and aminoesters with benzyloxycarbonyl chloride (Cbz-Cl) in the presence of TBAB under solvent-free conditions in excellent yields. The method is general for the preparation of a wide variety of *N*-Cbz derivatives of aliphatic, aromatic amines, and aminoesters.

Key words: amines, green chemistry, benzyloxycarbonyl chloride, TBAB, solvent-free conditions.

Résumé : On décrit une méthode douce et efficace de *N*-benzyloxycarbonylation chimio-sélective des amines par traitement des amines ou des aminoesters par du chlorure de benzyl-oxy-carbonyle (Cbz-Cl), en présence de TBAB, dans des conditions sans solvant et avec d'excellents rendements. La méthode est générale et elle s'applique à une grande variété de dérivés d'amines ou d'aminoesters aliphatiques ou aromatiques portant un groupe benzyloxycarbonyle (CBZ).

Mots-clés : amines, chimie verte, chlorure de benzyloxycarbonyle, TBAB, conditions sans solvant.

[Traduit par la Rédaction]

Introduction

The protection and deprotection of amines is a common event in multistep organic syntheses. Among protecting groups of amines, the *N*-benzyloxycarbonyl (Cbz) group is very important and provides a useful functionality for the protection of amines because *N*-Cbz is stable in the presence of a wide range of nucleophiles in alkaline and also in aqueous acidic conditions. It is easily removable by catalytic hydrogenation, without any side reactions, to get the parent amine. In addition, it also serves as a stable protecting group in peptide chemistry.[1] There are several methods available for the protection of amino groups as *N*-Cbz derivatives, with aryl and (or) alkyl amine and benzyloxycarbonyl chloride (Cbz-Cl) in the presence of 4-(dimethylamino)pyridine (DMAP) being the most commonly employed method.[1] Recently, LiHMDS in THF-HMPA[2] and β-cyclodextrin in aqueous medium have been reported for this transformation.[3,4] However, the utility of a catalyst having quaternaryammonium salt for the preparation of *N*-Cbz derivatives has not been thoroughly investigated.

Organic reactions using mild water tolerant catalysts have received much attention in recent years, as they can conveniently be handled and removed from the reaction mixture, making the experimental procedure simple and ecofriendly.[5] On the other hand, organic reactions carried out in the absence of solvent are also attracting the attention of chemists because of their ease of processing and environmentally friendly nature. Tetra-alkylammonium bromides $(NR_4)^+Br^-$ have a molecular structure similar to that of the cationic surfactants previously employed,[6] the main difference being the absence of the long hydrophobic tail that prevents the formation of any organised structure (micelle) and thereby the partition of the substrate. These salts are promising additives, as different alkyl residues in the $(R_4N)^+$ ammonium cation lead to different charge density and hydrophobicity. In continuation of our work to develop new organic transformations,[7] we have observed the *N*-benzyloxycarbonylation of amines and (or) aminoesters with Cbz-Cl using TBAB as a mild and efficient catalyst under solvent-free conditions at room temperature (RT) (Scheme 1).

Scheme 1.

Results and discussion

In the present method, we describe a mild, efficient, and high yielding protocol for the *N*-benzyloxycarbonylation of amines and (or) aminoesters. In general, all the reactions were carried out by the addition of amines and (or) aminoesters (1 mmol) to Cbz-Cl (1.2 mmol) in the presence of TBAB under solvent-free conditions at RT to give the corresponding *N*-benzyloxycarbamates in excellent yields (Table 1, 75%–99%). The times required for derivatization were comparatively very short (5–35 min). This method

was compatible with various amines including aliphatic, aromatic, heteroaromatic, and some aminoesters. Amino groups with different chemical natures further demonstrated the chemoselectivity of the reaction. Similarly, in the cases of an amino phenol (Table 1, entry 14) and an amino alcohol (Table 1, entry 15), only the amino groups were protected. In the case of a mixture of aliphatic and aromatic amines (1 mmol), only the aliphatic amine was derivatized in the reaction with Cbz-Cl (1 mmol) in the presence of TBAB. Aromatic amines containing electron-withdrawing groups also gave the desired derivatives in good yields. Chiral substrates were resistant to racemization and labile functionalities, such as esters, were compatible in this conversion. The protocol is highly chemoselective, involves simple experimental procedures, mild reaction conditions, and gives excellent yields of Cbz-protected amines.

In conclusion, we have described a mild and efficient method for the protection of amines and (or) aminoesters as their *N*-benzyloxycarbonyl derivatives in the presence of catalytic amount of TBAB under solvent-free conditions at RT in excellent yields of the corresponding products. In the absence of TBAB, the reaction takes more time to complete and leads to a laborious process. The advantages of the method are reduced reaction times, simple experimental work-up procedures, and high product yields, making it a useful addition to the existing methodologies.

Experimental

IR spectra were recorded on a PerkinElmer FT-IR 240-c spectrometer using KBr optics. ^{1}H NMR spectra were recorded on a Gemini-200 spectrometer in $CDCl_3$ using TMS as internal standard. Mass spectra were recorded on an Agilent 1200 spectrometer. Starting materials were obtained commercially from Sigma-Aldrich and Lancaster, and were used without purification.

Typical experimental procedure

To a mixture of amine and (or) aminoesters (1 mmol) and benzyloxycarbonyl chloride (Cbz-Cl) (1.2 mmol) was added TBAB (5 mol %), and the reaction was stirred under solvent-free conditions at RT for an appropriate amount of time (Table 1). After completion of the reaction as monitored by TLC, saturated sodium bicarbonate was added to the reaction mixture, and the product was extracted into ethyl acetate (3 × 20 mL). The combined organic layer was washed with brine, dried over anhydrous sodium sulphate, and concentrated under reduced pressure to give a crude product that was purified by silica gel column chromatography to afford the corresponding *N*-benzyloxycarbonyl-protected amines or aminoesters. Spectral data for selected compounds are given below.

Chemical constituents from the bark of *Anisopus mannii*

Apollinaire Tsopmo, Pierre Kamnaing, Jean Watchueng, Jin-Ming Gao, Yasuo Konishi, and Olov Sterner

Abstract: A minor novel 1,7-naphthyridine alkaloid with an unprecedented skeleton, named anisopusine (**1**), was isolated from the CH_2Cl_2 soluble materials of an acetone extract of the bark of *Anisopus mannii* (Asclepiadaceae) together with four known compounds 5α-hydroxy-lup-20(29)-en-3β-yl eicosanoate (**2**), [6]-gingerdione (**3**), [6]-dehydrogingerdione (**4**), and ferulic acid (**5**). Their structures were determined on the basis of spectroscopic data, including 1D and 2D NMR, HR-EI-MS. Compounds (**2–5**) were characterized for the first time from this genus.

Key words: Asclepiadaceae, *Anisopus mannii*, 1,7-naphthyridine alkaloid, anisopusine, gingerdione, 5α-hydroxy-lup-20(29)-en-3β-yl eicosanoate.

Résumé : Dans les matériaux solubles dans le CH_2Cl_2, obtenus à partir des produits solides obtenus par extraction de l'écorce d'*Anisopus mannii* (asclépiadacée) avec de l'acétone, on a isolé un nouvel alcaloïde mineur dont la structure comporte un squelette inconnu jusqu'à maintenant, une 1,7-naphtypyridine, et qui a été dénommé anisopusine (**1**); à ses côtés, on a aussi retrouvé quatre produits connus, l'eiconinate de 5α-hydroxylup-20(29)-én-3β-yle (**2**), la [6]-gingerdione (**3**), la [6]-déhydrogingerdione (**4**) et l'acide férulique (**5**). Les structures ont été déterminées sur la base de données spectroscopiques, dont la RMN en 1D et 2D et la spectrométrie de masse à ionisation électronique à haute résolution (SM-IE-HR). La caractérisation des composés **2** à **5** dans ce gène est une première.

Mots-clés : Asclépiadacée, *Anisopus mannii*, 1,7-naphtypyridine, alcaloïde, anisopusine, gingerdione, eiconinate de 5α-hydroxylup-20(29)-én-3β-yle.

[Traduit par la Rédaction]

Introduction

It is well-established that plant species, belonging to the botanical family of Asclepiadaceae contain cardenolides[1] and pregnane glycosides,[2–4] as well as pyrroloisoquinoline and phenanthroindolizidine alkaloids.[5,6] 7-Demethoxytylophorine from *Cynanchum komarovii*[5] inhibited tobacco mosaic virus (TMV) while cryptolepine, an indoloquinoline alkaloid from *Cryptolepis sanguinolenta*, showed antimalarial properties.[7,8] Several cytotoxic and antiviral activities have been reported for some glycosides.[9–11]

Some species within the Asclepiadaceae family have been used to prepare arrow poisons for fishing,[12] and some have been used traditionally to treat diseases like fevers,[13] rheumatism, and urinary diseases.[14] The genus *Anisopus* belongs to this important family with about six species and subspecies in Africa. Little is known about its chemistry and biology. A report of the use of *Anisopus larvae* to treat intestinal and urino-genital myiasis was published in 1966.[15] In Cameroon, *Anisopus mannii* N. E. Br. is a shrub indigenous to the Southwest province where it is used as a fish poisoning agent.[12] In our continuous search for secondary metabolites from the Cameroon medicinal plants,[16,17] an acetone extract of the bark of *A. mannii* was investigated, and we herein report the isolation and structure elucidation of a novel naphthyridine alkaloid with an unprecedented skeleton, named anisopusine (**1**), as well as four previously reported compounds (**2–5**).

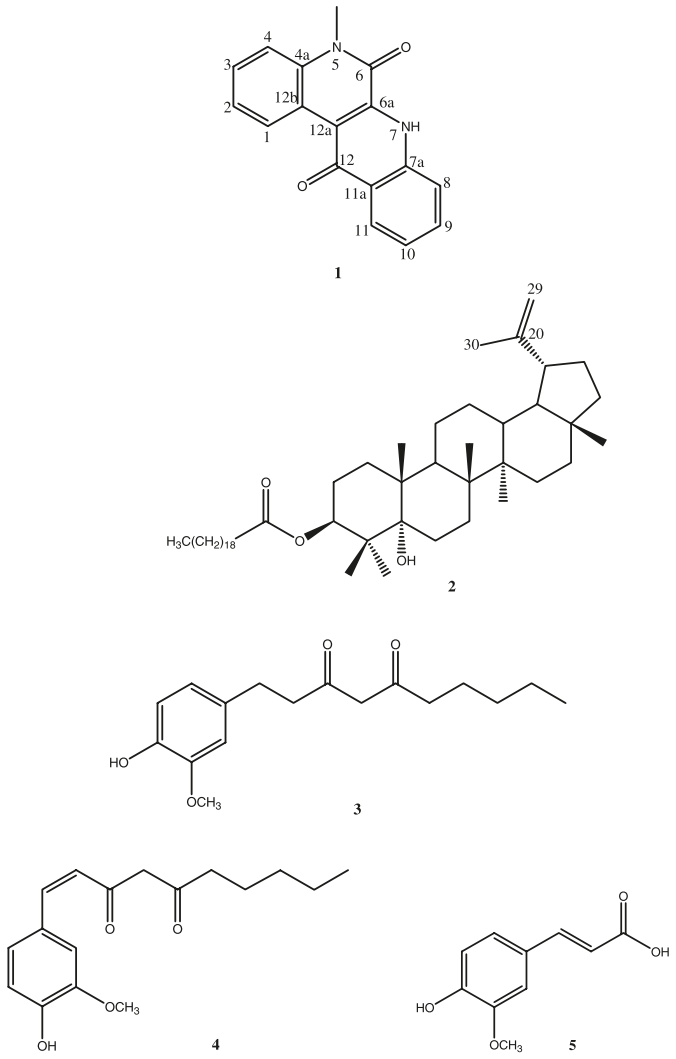
Results and discussion

The CH_2Cl_2 -soluble materials of an acetone extract of the ground parts of *A. mannii* was subjected to repeated column chromatography on silica gel to afford a novel alkaloid (**1**) together with four known compounds (**2–5**) (Fig. 1). Their structures were elucidated by 1D and 2D NMR, HR-EI-MS, and by comparison with published data.

Compound **1** was obtained as red needles (yield: 0.0001% on dry wt. basis), and named anisopusine. The high resolution (HR) EI-MS of **1** showed a molecular ion peak at *m/z* 276.0910, corresponding to the molecular formula $C_{17}H_{12}N_2O_2$, with thirteen degrees of unsaturation. The IR spectrum of this molecule displayed absorption bands for a secondary amine group at 3308 cm^{-1}, two conjugated car-

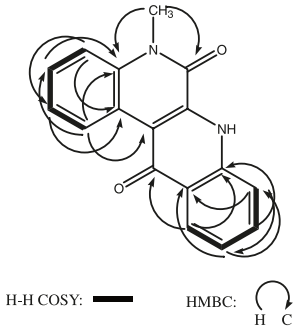
Fig. 1. Molecular structures of compounds (**1–5**) from *A. mannii*.



bonyl functionalities at 1692 and 1657 cm^{-1}, and a benzene ring backbone (s) at 1608, 1585, and 1481 cm^{-1}. This molecule could encompass a tertiary amide, since strong absorption bands are typically observed for tertiary amides between 1700 and 1650 cm^{-1}.[7] The ^1H and ^{13}C NMR data of **1** in $CDCl_3$ analyzed in conjunction with the HMQC spectrum showed the presence of 17 carbon signals attributed to an amide carbonyl, a ketone carbonyl, six sp^2 quaternary carbons, eight sp^2 methines, and one sp^3 methyl. Because 11 out of 13 unsaturation degrees were accounted for, **1** was inferred to possess two rings in the molecule.

The ^1H NMR spectrum of **1** exhibited eight aromatic proton signals in the downfield region of δ 6.8–9.0 and one nitrogen methyl group at δ 3.36. The ^1H NMR and ^1H–^1H COSY spectra of **1** showed two aromatic spin systems: δ 8.90 (d, J = 7.8 Hz, H-1), 7.16 (dt, J = 1.0, 7.8 Hz, H-2), 7.34 (dt, J = 1.0, 7.8 Hz, H-3), and 6.89 (d, J = 7.8 Hz, H-4), and δ 7.00 (d, J = 7.6 Hz, H-8), 7.52 (dt, J = 1.2, 7.6 Hz, H-9), 7.02 (t, J = 7.6 Hz, H-10), and 7.75 (d, J = 7.9 Hz, H-11). Two proton–proton connectivities from H-1 through H-4 and from H-8 through H-11 were revealed from the ^1H–^1H COSY spectrum (Fig. 2). This suggested the presence of two ortho-substituted aromatic rings in this molecule. The ^{13}C NMR spectrum showed two carbonyl carbon signals at δ 170.7 and 188.2; the former being characteristic of a tertiary amide function. This amide group was further confirmed on the basis of 2D NMR. Pertinent HMBC correlations were observed from the N-methyl group (δ 3.36) to an aromatic quaternary carbon C-4a (δ 142.9) and a carbonyl carbon C-6 (δ 170.7), indicating that it was linked to a nitrogen atom of the amide moiety. Further HMBC correlations were observed from H-8 to C-7a (δ 151.8), C-10 (δ 121.5), and C-11a (δ 120.0), as well as from H-11 to C-7a (δ 151.8), C-9 (δ 136.9), and C-12 (δ 188.2), which in turn suggested that the ketone carbon C-12 is attached to an aromatic quaternary carbon C-11a. The remaining amino group (–NH–) was connected between C-6a (δ 139.3) and C-7a (δ 151.8), since their chemical shifts appeared at lower field. Inspection of the HMBC spectrum (Fig. 2) enabled us to construct the skeleton of **1**, as depicted in Fig. 1. As a consequence, based on the above spectroscopic analysis, compound **1** was unambiguously characterized as a novel naphthyridine alkaloid, 7-methyl-5,7-dihydrodibenzo[b,*f*]-1,7-naphthyridine-4,8-dione, which has an unprecedented skeleton.

Fig. 2. H–H COSY and important HMBC correlations in anisopusine (**1**).



The four other known compounds obtained in the present investigation were identified as lup-20(29)-en-3-ol-3,5-dihydroxyeicosanoate,[18] [6]-gingerdione,[19] [6]-dehydrogingerdione[19], and ferulic acid[20] by comparison of their spectroscopic data with those reported in the literature.

It is worthwhile to point out that two pungent flavouring gingerdione derivatives, [6]-gingerdione (**3**) and [6]-dehydrogingerdione (**4**), are the major active components from the rhizomes of the spice and oriental herbal medicine ginger, *Zingiber officinale* Rosc (Zingiberaceae). These two products have been reported to possess many properties, such as anti-inflammatory and analgesic,[21–23] inhibition of cell proliferation in HL-60 cells,[24] and anti-feedant activities.[25,26] In this work, from the bark of *A. mannii*, we have isolated these two compounds in addition to a naphthyridine alkaloid anisopusine (**1**), which is a new secondary metabolite. This is the first reported occurrence of an alkaloid based on a 1,7-naphthyridine skeleton from plants. To the best of our knowledge, this is the first characterization of compounds (**2–5**) from this genus. Biogenetically, this existing alkaloid (**1**) may be formed from anthranilic acids and acetic acids via a sequence of condensation, decarboxylation, N-methylation, and oxidation coupling reactions.

Experimental

General

Melting points were measured with a Reichter microscope and are uncorrected. IR spectra were recorded with an FTIR Shimazu Hyper 1.51 spectrophotometer. ^{1}H NMR (500 MHz) and ^{13}C NMR (125 MHz) were taken in $CDCl_3$ using a Brucker ARX500 spectrometer with an inverse multinuclear 5 mm probe head equipped with a shielded gradient coil. The chemical shifts (δ) are reported in parts per million (ppm) relative to chloroform (7.26 ppm for $CHCl_3$ and 77.0 ppm for $CDCl_3$), while the coupling constants (*J*) are given in Hz. COSY, HMQC, and HMBC experiments were recorded with gradient enhancements using sine-shaped gradient pulses. For 2D heteronuclear correlation spectroscopy, the refocusing delays were optimized for $^1J_{CH}$ = 145 Hz and $^nJ_{CH}$ = 10 Hz. The raw data were transformed, and the spectra were evaluated with the standard Bruker UXNMR software. HR-EI-MS and EI-MS spectra (direct inlet at 70 eV) were recorded with a JEOL SX102 spectrometer. Column chromatography was run on Merck silica gel 60. TLC analyses were carried out on silica gel GF_{254} precoated plates with detection accomplished by spraying with 15% H_2SO_4 followed by heating at 100 °C or by visualizing under a UV lamp at 254 nm.

Plant material

The bark of *A. mannii* N. E. Br. was collected from the Southwest Province, Cameroon, in December 2006. Authentification was done at the Limbe botanic garden, and the voucher specimen (CM 0611068) was deposited at its Herbarium.

Extraction and isolation

The air-dried and powdered bark of *A. mannii* (3 kg) was extracted by percolation with acetone to yield a crude extract (79 g). The crude extract was dissolved in a mixture of 500 mL of MeOH/H_2O (1:1, *v*/*v*), and then extracted with CH_2Cl_2 (3 × 400 mL) to afford on evaporation 21 g of the CH_2Cl_2 soluble residue. The resulting residue was subjected to vacuum liquid chromatography on silica gel using hexane/EtOAc of increasing polarity (1:0–0:1) to provide three fractions (A–C). Fraction A (3 g) contained most fats and was not further investigated. Fraction B (2.5 g) was separated by flash chromatography on silica gel using hexane/ethyl acetate (85:15) to give 5α-hydroxy-lup-20(29)-en-3β-yl eicosanoate (500 mg, **2**) and a crude product containing **1**. The crude product was purified by flash chromatography on silica gel using hexane/EtOAc (85:15) to afford anisopusine (3 mg, yield: 0.0001% on dry wt. basis, **1**). Fraction C (3.7 g) after two successive flash chromatography columns using hexane/EtOAc gradient system gave five fraction Ca–e. Fraction Cb was subjected to flash chromatography on silica gel using hexane/acetone (90:10, 80:20, and 70:30) to afford [6]-gingerdione (15 mg, **3**) as a yellow oil and [6]-dehydrogingerdione (21 mg, **4**) as yellow needles. Fraction Cd was repeatedly separated by flash chromatography on silica gel using $CHCl_3$/MeOH (80:20) to give ferulic acid (150 mg, **5**).

7-Methyl-5,7-dihydrodibenzo[*b*,*f*]-1,7- naphthyridine-4,8-dione (anisopusine)

Red needles; mp 231–233 °C (acetone). IR ($CHCl_3$) ν_{max}: 3308 (NH), 1692 (ArC=O), 1657(ArNC=O), 1609, 1585, 1481, 1382, 1319, 1103, 1082, 939 cm^{-1}. ^{1}H NMR (500 MHz, $CDCl_3$) δ_H: 8.90 (1H, d, *J* = 7.8 Hz, H-1), 7.16 (1H, dt, *J* = 1.0, 7.8 Hz, H-2), 7.34 (1H, dt, *J* = 1.0, 7.8 Hz, H-3), 6.89 d (1H, d, *J* = 7.8 Hz, H-4), 7.00 (1H, d, *J* = 7.6 Hz, H-8), 7.52 (1H, dt, *J* = 1.2, 7.6 Hz, H-9), 7.02 t (1H, t, *J* = 7.6 Hz, H-10), 7.75 (1H, d, *J* = 7.9 Hz, H-11), 3.36 (3H, s, N–CH_3), 10.55 (1H, br s, NH). ^{13}C NMR (125 MHz, $CDCl_3$) δ_C: 125.5 (C-1), 122.7 (C-2), 129.2 (C-3), 107.9 (C-4), 142.9 (C-4a), 170.7 (C-6), 139.3 (C-6a), 151.8 (C-7a), 111.9 (C-8), 136.9 (C-9), 121.5 (C-10), 125.2 (C-11), 120.0 (C-11a), 188.2 (C-12), 106.8 (C-12a), 121.0 (C-12b), 26.0 (N–CH_3). EI-MS *m*/*z*: 276 $[M]^+$ (100), 248 [M – CO](22), 247(51), 220(11), 219(19), 205(15), 172(15), 143(15), 117(14), 104(9), 76(16). HR-EI-MS *m*/*z*: 276.0910 $[M]^+$ (calcd. for $C_{17}H_{12}N_2O_2$: 276.0899).

One-pot synthesis of β-amido ketones using Brønsted acidic ionic liquid as an efficient and reusable catalyst

Krishna M. Deshmukh, Ziyauddin S. Qureshi, Nitin S. Nandurkar, and Bhalchandra M. Bhanage

Abstract: An efficient protocol was developed for one-pot condensation of an aldehyde, ketone, acetyl chloride, and nitriles catalyzed by a stable and reusable 1-methyl-imidazolium hydrogen sulfate ([Hmim][HSO_4]) as a Brønsted acidic ionic liquid. The system tolerated a variety of functional groups affording the corresponding β-amido ketones in moderate to good yields under milder operating conditions.

Key words: ionic liquids, multicomponent reactions, β-amido ketones, one-pot synthesis.

Résumé : On a développé un protocole efficace pour la condensation monotope d'un aldéhyde, d'une cétone, du chlorure d'acétyle et de nitriles, catalysée par un liquide ionique stable et réutilisable, le sulfate acide de 1-méthyl-imidazolium [Hmim][HSO_4] qui agit comme acide de Brønsted. Le système tolère une grande variété de groupements fonctionnels conduisant à la formation des β-amidocétones correspondantes avec des rendements allant de modérés à bons, dans les conditions d'opération les plus douces.

Mots-clés : liquides ioniques, réactions à plusieurs composantes, β-amidocétones, synthèse monotope.

[Traduit par la Rédaction]

Introduction

β-Amido ketones constitute an important class of compounds having biological and medicinal properties.[1,2] They are used as precursors for the synthesis of 1,3-amino alcohol present in antibiotic drug such as nikkomycines or neopolyoxines.[3,4] Traditionally, these compounds are synthesized by a Dakin–West reaction, which involves the condensation of an α-amino acid with acetic anhydride in the presence of a base.[5] Iqbal and co-workers proposed a multicomponent route for the synthesis of β-acetamido ketones via condensation of an aldehyde, enolizable ketones, acetyl chloride, and acetonitrile using $CoCl_2$[6] and Montmorillonite K10[7] as the catalysts. Subsequently, other groups extended these methodologies by exploring various Lewis or Brønsted acid catalysts such as $FeCl_3 \cdot 6H_2O$,[8] $ZrOCl_2 \cdot 8H_2O$,[9] silica sulfuric acid,[10,11] $SiCl_4$-$ZnCl_2$,[12] heteropoly acid,[13] ZnO,[14] and $BiCl_3$ generated from BiOCl.[15] Inspite of their potential applications, these methodologies face disadvantages like the requirement of harsh reaction conditions, use of expensive and moisture sensitive Lewis acid catalysts, and elevated temperatures.

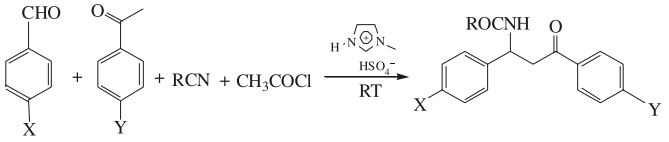
In recent years, application of ionic liquids have gained considerable interest in the context of green synthesis. Although ionic liquids were initially introduced as an alternative green reaction media, today they have marched far beyond this border for their significant role in controlling the reaction as a catalyst. Among various ionic liquids developed to date, Brønsted acidic ionic liquids have emerged as a most promising alternative for a wide variety of acid catalyzed reactions.[16–24]

Results and discussion

We herein report an efficient protocol for one-pot condensation of an aldehyde, ketone, acetyl chloride, and nitriles catalyzed by a stable and reusable Brønsted acidic ionic liquid, 1-methyl-imidazolium hydrogen sulfate ([Hmim][HSO_4]). The system tolerated a variety of functional groups affording corresponding β-amido ketones in moderate to good yields under milder operation conditions (Scheme 1).

Initially, condensation of benzaldehyde, acetophenone, acetyl chloride, and acetonitrile were chosen as model reaction and the role of the different ionic liquids as a catalyst and it's loading on the reaction system was investigated (Table 1, entries 1–4). The influence of various 1-methyl-imidazolium based ionic liquids, such as 1-butyl-3-methyl-imidazolium hydrogen sulfate ([C_4mim][HSO_4]), 1-methyl-imidazolium hydrogen sulfate ([Hmim][HSO_4]), 1-methyl-imidazolium tetraflouroacetate ([Hmim][Tfa]), and 1-methyl-imidazolium nitrate ([Hmim][NO_3]), were studied. Out of various ionic liquids screened, the [Hmim][HSO_4] ionic liquid was found to be the most effective, providing good yield of the desired product. The effect of catalyst

Scheme 1. Synthesis of β-amido ketones using ionic liquid as catalyst.



loading on the reaction system was also investigated and 40 mol% [Hmim][HSO_4] was found to be the most effective in providing a higher yield. (Table 1, entries 5–10).

Since [Hmim][HSO_4] was one of the most effective functional ionic liquids, it was selected to investigate the possibility of recyclability. After the completion of the reaction, the reaction mixture was evaporated under reduced pressure to obtain a residue. The residue was dissolved in ethyl acetate to obtain two phases; the ionic liquid phase was separated by decantation of ethyl acetate. The ionic liquid phase was then washed with diethyl ether (3 × 5 mL) and was evaporated under reduced pressure at 80 °C for 1 h to remove the redundant mixed solvent and it was then used for further recyclability test.

It can be seen from Table 1, entry 2, that there was no obvious change on the recovered catalyst (88%–95%) and excellent yield was obtained. After recycling three times, [Hmim][HSO_4] was still stable enough and had less impact on the catalytic activity. The purity of the recycled ionic liquid was confirmed using ^{1}H NMR and it was the same as that used for the first run. This indicated that [Hmim][HSO_4] was a highly efficient and recyclable catalyst for synthesis of β-amido ketones.

Thus, using [Hmim][HSO_4] as the best catalyst, the condensation of various aldehydes, ketones, and nitriles with different steric and electronic properties were investigated (Table 2, entries 1–22). The condensation of benzaldehyde, acetophenone, acetyl chloride, and nitriles provided a 75% yield of the desired product. Aldehydes with electron-donating (CH_3, OCH_3) and electron-withdrawing substituents (NO_2, Cl, Br, F) were also investigated and found to provide good yields (50%–84%) under the present conditions. Substituted acetophenones having activating and deactivating groups were found to be compatible and provided good yields of the desired products (Table 2, entries 2–4, 10–13, 16, 17, 21, 22). To show the generality of the protocol, the effect of aliphatic and aromatic nitriles, such as acetonitrile, benzonitrile, and phenylacetonitrile were also investigated. The reaction of benzonitrile require longer reaction times, up to 24 h and the probable reason for this may be the steric factor as well as low nucleophilicity of benzonitrile (Table 2, entries 14–17).

The reaction of acetonitrile and phenylacetonitrile were found to proceed smoothly under the present conditions, providing good yields of the desired products. Thus, the protocol is general in nature and tolerates a wide range of functional groups. A plausible reaction mechanism for the present reaction may proceed as depicted in Scheme 2. The yield of β-amido ketones depends upon the ionic liquid chosen, as shown in Table 1. It can be seen that [Hmim][NO_3] gives a lower yield of the product as compared to [Hmim][HSO_4] and [C_4mim][HSO_4], which suggests that the counter anion also plays a catalytic role in the reaction (Scheme 2). The counter anion protonates the ketone by a donating proton.

Table 1. Effect of catalysts and catalyst loading on the condensation of benzaldehyde, acetophenone, acetyl chloride, and acetonitrile.

Entry	Catalyst	Catalyst loading (mol %)	Yield (%)[a]
1	[C_4mim][HSO_4]	40	60
2[b]	[Hmim][HSO_4]	40	75, 73, 71
3	[Hmim][Tfa]	40	66
4	[Hmim][NO_3]	40	36
5	[Hmim][HSO_4]	10	50
6	[Hmim][HSO_4]	20	54
7	[Hmim]HSO_4]	30	63
8	[Hmim][HSO_4]	50	72
9	[Hmim][HSO_4]	60	70
10	[Hmim][HSO_4]	100	62

Note: Reaction conditions: benzaldehyde (1 mmol); acetophenone (1 mmol); acetyl chloride (0.3 mL); acetonitrile (4 mL); reaction time: 10 h at RT.

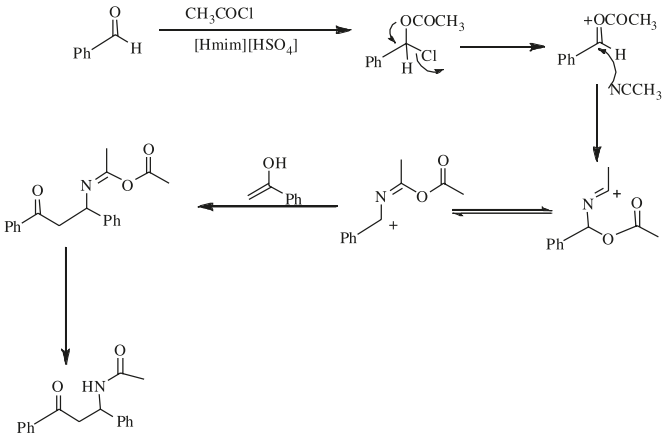
[b]Recyclability of the catalyst tested up to three cycles.

Scheme 2. Mechanism for the synthesis of β-amido ketones.



In summary, [Hmim][HSO_4] is a reusable and moisture stable Brønsted acidic ionic liquid, reported as an efficient catalyst for the synthesis of a wide range of β-amido ketone under mild operating conditions. The system tolerates a wide range of functional groups affording the desired products in good to excellent yields. Further work is in progress to broaden the scope of ionic liquids to various other organic transformations.

Experimental section

The chemicals and solvents were supplied by Sigma-Aldrich, Fluka, and S.D. Fine-chem Ltd. companies and used without further purification

Synthesis of ionic liquids

In this study, the ionic liquids used were synthesized according to the procedure reported in the literature[22–24] and were characterized by ^{1}H NMR.

Synthesis of β-amido ketones using [Hmim][HSO_4] as the catalyst

To a stirred suspension of [Hmim] [HSO_4] (40 mol %) in acetonitrile (4 mL) were added benzaldehyde (1 mmol), acetophenone (1 mmol), and acetyl chloride (0.3 mL). The reaction mixture was stirred at ambient temperature for 10 h. After the completion of the reaction, crushed ice (30 mL) was added to the reaction mixture and stirred thoroughly. On solidification, the products were filtered off and dried to get the corresponding β-amido ketone. The solid product obtained was recrystallized from the mixture of solvents (ethyl acetate–hexane) to get the pure product. All compounds are known compounds and were characterized by using IR and ^{1}H NMR.

A DFT study of thymine and its tautomers

Dongsheng Jiao, Hongyan Wang, Yanlan Zhang, and Yu Tang

Abstract: The structures and the relative energies of six possible tautomers of the thymine base have been studied by density functional theory (DFT) using the B3LYP and BP86 functionals. The keto-thymine (T1) is predicted to be the most stable thymine tautomer, which is consistent with the other theoretical results and experimental data. The corresponding thymine cations and anions are studied using the same level of theory with double-ζ plus polarization and diffuse functions (DZP++) basis sets. The ionization potentials (IPs), the electron affinities (EAs), and proton affinities (PAs) for different protonation sites in thymine base are obtained. T1 has the largest ionization potential and the lowest proton affinity among all the considered thymine tautomers.

Key words: thymine, DFT, tautomer, IP, EA, PA.

Résumé : Faisant appel à la théorie de la fonctionnelle de la densité et utilisant des fonctions B3LP et BP86, on a étudié les structures et les énergies relatives de six tautomères potentiels de la thymine à l'été de base. Sur la base de ces calculs, il est prédit que la cétothymine (T1) est le tautomère le plus stable de la thymine; cette conclusion est en accord avec les autres calculs théoriques et avec les résultats expérimentaux. Les cations et anions correspondants à la thymine ont aussi été étudiés aux même niveaux de la théorie en utilisant comme ensembles de base des fonctions de polarisation double ζ plus et des fonctions diffuses (DZP++). On en a extrait les potentiels d'ionisation (PI), les affinités électroniques (AE) et les affinités protoniques (AP) pour les différents sites de protonation de la thymine. La cétothymine (T1) possède le potentiel d'ionisation le plus élevé et l'affinité protonique la plus faible parmi tous les tautomères considérés de la thymine.

Mots-clés : thymine, théorie de la fonctionnelle de la densité (TFD), tautomère, potentiel d'ionisation (PI), affinité électronique (AE), affinité protonique (AP).

Introduction

Recently, there has been increasing interest in the damage of DNA, which may cause various diseases such as cancer.[1–5] DNA is made of thymine (T), cytosine (C), guanine (G), and adenine (A). The nucleic-acid bases store the genetic information for cell replication and synthesis of proteins. Their physical chemistry has been extensively studied both experimentally and theoretically. In these bases, the thymine is the simplest pyrimidine base and only exists in DNA, not in RNA. It has been a highly frequent subject of theoretical studies because of its biochemical importance.[6,7] One of the possible molecular mechanisms for the formation of spontaneous mutations is conditioned by the tautomerism of DNA bases.[8–10]

Theoretically, M.J. Scanlan and I.H. Hillier researched the relative energies of the six tautomers of thymine using a 3–21G basis at an ab initio study in 1984.[11] J. Gu and J. Leszczynski studied the molecular geometries, energy properties, H-bonding patterns, and electrostatic potential characters of the thymine (T) and the role of the potassium cation in the formation of the T tetrad at the B3LYP/6–311G(d, p) and the HF/6–311G(d, p) levels of theory in 2001.[12] The tautomerism of the N_1-methylated derivatives of uracil, thymine, and 5-bromouracil has been studied to analyze its implications in the mutagenicity of 5-bromouridine by Michal Hanus in 2004.[7] The protonated keto-thymine (T1) have been predicted by A.K. Chandra et al.,[13] who predicted the interaction between thymine and water, compared with uracil. Their result indicates that O_8 is the preferred protonation site.

S.K. Kim et al. explored the gas-phase hydration of adenine, cytosine, thymine, and uracil in supersonic molecular beams by mass spectra and ionization potential measurements in 1996.[14] They researched the IP of hydrated thymine and obtained the IP of T1 (9.15 eV). S.L. Zhang et al. reported the vibration spectra and experiment assignments of thymine and nine of its isomers.[15] The IR and Raman spectra have been presented in their study. D.M. Close and coworkers studied the IPs of the DNA bases in gas phase and in aqueous solution in 2004.[16,17] The goal of their work is to explore methods to performe the IP calculations with DFT, and compare with the experiment and PMP2 method.

Recently, S. Yarasi et al. calculated the vibration properties of uracil and three of its isomers, thymine and nine of its isomers using DFT method at the B3LYP/6–311G(d, p) level.[18] In 2006, K. Mazurkiewicz et al. studied the thymine tautomers using MP2, CCSD, and B3LYP methods.[19] In their work, the energy ordering of thymine tautomers are

Fig. 1. Geometries of thymine tautomers.

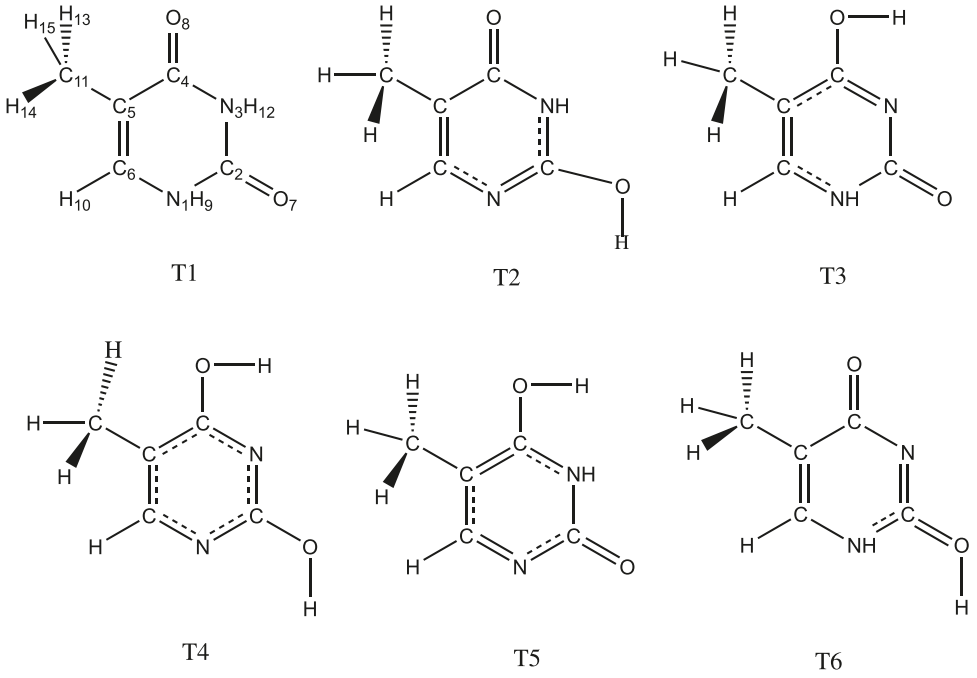

Table 1. Relative energies (kcal/mol) of neutral thymine tautomers.

	Relative energies (kcal/mol)		ZPE corrected relative energies (kcal/mol)	
Tautomers	B3LYP	BP86	B3LYP	BP86
T1	0	0	0	0
T2	10.6	10.7	10.4	10.3
T3	12.5	12.1	12.3	11.9
T4	12.7	13.2	12.5	13.0
T5	25.6	24.8	24.4	23.6
T6	29.0	28.8	27.8	27.5

predicted by different methods, and the anionic states of thymine are characterized using different methods.

The purpose of the research is to carry out a comprehensive theoretical investigation of all possible thymine tautomers using different DFT methods. All the anions and cations are considered to compare with K. Mazurkiewicz's paper.
