The introduction of the a block in the QM region greatly favours (by –7.05 or –5.56 kcal/mol, depending on the estimation method) the transition state going to the R product. Inspection of the geometries in Fig. 2 shows no obvious steric differences associated to these particular phenyl substituents, so the difference is likely of an electronic nature. Bond distances around rhodium provide key information on the nature of these electronic effects. The Rh–P distances corresponding to the phosphinite side are 2.33 and 2.42 Å in **ONIOM-RMolH$_2$-TS** and **ONIOM-SMolH$_2$-TS**, respectively. The distance is 0.09 Å shorter for the structure leading to the R product because of the different trans influence of the substrate regions across the rhodium centre. In the R isomer, the position trans to phosphinite is occupied by the weakly coordinating carbonyl group, while it is occupied by the more strongly binding olefin group in the S isomer. The

Table 1. Effect of the partitioning system on the relative R and S oxidative-addition transition-state energies. Systems are labelled according to which UFF regions (see Fig. 3) are added to DFT.

Partitioning system	ΔEp(R–S) (ONIOM)	ΔEp(R–S) (DFT only)	ΔEp(R–S) (UFF only)
Original	–1.88	–6.45	+4.58
a	–8.93	–4.80	–4.13
b	+4.10	–5.11	+9.21
c	–0.69	–5.13	+4.44
d	–3.77	–7.93	+4.16
ab	–3.71	–3.57	–0.14

abcd	–4.15	–4.15	—

introduction of the phenyl substituents in the QM region has an important effect on phosphorous basicity, because they are represented by hydrogen atoms in the QM part of the ONIOM calculation. This increase of basicity is much more stabilizing when a weaker ligand is in the trans position, which is the case for the transition state going to the R product. This is further confirmed by geometrical changes observed in the full DFT optimizations, also shown in Fig. 2. The corresponding Rh–P distances are reduced by 0.03 Å (from 2.33 to 2.30) when going from **ONIOM-RMolH$_2$-TS** to **DFT-RMolH$_2$-TS**, but are lengthened by 0.01 Å (from 2.42 to 2.43) when going from **ONIOM-SMolH$_2$-TS** to **DFT-SMolH$_2$-TS**. Therefore, use of the DFT description for the a region stabilizes the transition state leading to the R product, heavily favouring the formation of this product.

In view of the results for the a block, it is not surprising that introduction of the b block, the phenyl substituents on the phosphine side, to the QM region has an opposite effect, increasing the stability of the transition state going to the S product. The weakly coordinating carbonyl ligand is in a position trans to the phosphine in **SMolH$_2$-TS**, whereas the olefin is trans to the phosphine in **RMolH$_2$-TS**. Comparing the ONIOM- and DFT-optimized geometries, the Rh–P distances are unchanged (2.50 Å) going from **ONIOM-RMolH$_2$-TS** to **DFT-RMolH$_2$-TS**, but decrease by 0.01 Å (from 2.35 to 2.34) when going from **ONIOM-SMolH$_2$-TS** to **DFT-SMolH$_2$-TS**. Additionally in the S-transition states, the Rh–O distance increases by 0.02 Å (from 2.14 to 2.16) when comparing the respective ONIOM and DFT geometries. Thus, a DFT description of the phosphine stabilizes the S transition state and results in an increase of the amount of predicted S product.

A chemically relevant conclusion of this analysis is that the enantiomeric excess can be affected by modification of the electronic properties of the phosphorous donor groups, for instance by placing electron-releasing or electron-withdrawing substituents on the phenyl rings. Substituent electronic effects in asymmetric catalysis have recently been reviewed by Flanagan and Guiry.[26] Moreover, our results suggest that the electronic effects of the phosphorous donors on the enantiomeric excess should be opposite, depending on whether the modification is performed on the phosphinite phenyls or on the phosphine phenyls.

Effect of substituents on the backbone

The use of an MM or a QM representation of the backbone substituents (phenyl and methoxymethyl) has a smaller effect than that of the phosphorous phenyl substituents, but it is still large enough to have an important effect on the computed enantiomeric excess. In fact the difference can be as large as 1.89 kcal/mol between the original and the d partition schemes, which differ only in the QM or MM representation of the methoxymethyl group.

Again, inspection of the structures in Fig. 2 shows no obvious steric difference. The presence of direct electronic effects is in this case also hard to justify, because of the relative distance in terms of single bonds from the rhodium centre. The c group, a phenyl, is bound to an sp^3 carbon, which is bound to a phosphorous, which is only afterwards bound to rhodium. Also, the methoxymethyl group d is one single bond farther away from the metal. The key in this case seems to be in the conformational flexibility of the six-membered ring defined by the metal and the phosphine–phosphinite chelating ligand.

The ring has a clear boat conformation in **ONIOM-RMolH$_2$-TS**, but it is distorted towards a chair arrangement in **ONIOM-SMolH$_2$-TS**. The reasons for this behaviour are probably related to non-trivial steric interactions between the phosphorous phenyls and the substrate, but the relevant outcome for this discussion is that the backbone substituents occupy different positions. Phenyl c has a more axial-like arrangement in the structure going to the S product. The methoxymethyl group d is always equatorial, but points upwards (in Fig. 2 orientation) in **ONIOM-RMolH$_2$-TS,** and downwards in **ONIOM-RMolH$_2$-TS**. The electronic preference of the phenyl and methoxymethyl substituents for this different placements in the six-membered ring seems to be different from that of the hydrogen atoms used in the DFT/

MM calculation, and because of this, it is necessary to consider a full DFT description for a proper reproduction of the experimental results.

The analysis of the role of the backbone substituents is less conclusive than that of the phosphorous substituents because the interactions at play seem more subtle. However, there is also a chemically relevant message in the sense that, because of the conformational flexibility of the ligand, it is possible to affect the enantiomeric excess through modifications in the electronic effects of substituents that are relatively far away from the metal reaction centre.

Concluding remarks

The computational study of the addition of dihydrogen to methyl-(*N*)-acetylaminoacrylate catalyzed by a bidentate phosphine–phosphinite rhodium catalyst shows that the experimentally reported enantiomeric excess cannot be properly reproduced by hybrid QM/MM calculations. The degree of conformational flexibility in the system and the differing electronic nature of the two phosphorous donor groups are not well-described by MM methods, resulting in poor description of the experimental enantiomeric excess. A full DFT description must instead be applied in this case. Another option would be to use a method such as Q2MM, developed by Wiest, Norrby, and co-workers,[27] to generate a custom molecular mechanics force-field with all the MM parameters required to accurately describe this system. However, generation of accurate MM parameters via this method requires the creation of a representative training data set based on DFT optimizations of the rate-determining transition states in similar flexible systems with non-identical phosphorous donors, which is also not a trivial task. Moreover, we suspect that one of the reasons why force fields work better in other systems is because of their superior symmetry. With C_2, or C_s, chelating phosphines, the electronic effects on both phosphorus centers are compensated, which is not the case for intrinsically C_1 systems as the one discussed here.

Whilst the results of the DFT/MM methods are disappointing, the critical analysis of these results is highly informative on the chemical role of the different regions of the catalyst. The performance of a series of single-point calculations with different DFT/MM partitions leads to an explanation as to why each of the regions considered requires a QM description, and to a better understanding of its role on the overall chemistry of the system. In particular, we have characterized the following effects: (*a*) the presence of substituents increasing the basicity of the phosphinite centre favours the formation of the R product, (*b*) substituents increasing the basicity of the phosphine centre favour the formation of the S product, although by a lesser extent, and (*c*) substituents in the backbone have a smaller yet relevant role on selectivity, although their effect is not easy to predict a priori. These qualitative observations will guide us in the design of modifications of the catalytic system that will be studied in the near future by full DFT and experimental methods.

Aromaticity in pericondensed cyclopenta-fused polycyclic aromatic hydrocarbons determined by density functional theory nucleus-independent chemical shifts and the Y-rule — Implications in oil asphaltene stability

Yosadara Ruiz-Morales

Abstract: The characterization of the stability of the fused aromatic region (FAR) in oil asphaltenes in terms of kinetic and thermodynamic stability is primary. Such an understanding is important if we are to get the optimal use from the heavy fraction of any crude oil. The FAR region is composed of pericondensed cyclopenta-fused polycyclic aromatic hydrocarbon compounds (CPPAHs) with N, S, and O heteroatoms. The Clar model, which states that the most important representation of a PAH is one having the maximum number of disjoint π-sextets, depicted by inscribed circles, and a minimum number of fixed double bonds, captures the essence of the kinetic and thermodynamic stability arguments. This model is readily employed for complex aromatics of the sort to be considered for asphaltenes. In the present research we prove that the aromaticity of CPPAHs can be assessed by using the qualitative easy-to-apply Y-rule. In the literature, it is proven that the Y-rule is applicable to elucidate the aromaticity of benzenoid PAHs and it has been validated for pericondensed benzenoid PAHs but not for pericondensed CPPAHs. Here, we verify that it is applicable for CPPAHs. The applicability of the Y-rule has been theoretically proven by comparing the π-electronic distribution obtained with it with the one obtained from nucleus-independent chemical shift (NICS) calculations at the density functional theory (DFT) level. The importance of doing this is that due to the polydispersity in the composition of the oil asphaltenes, and to understand their aromatic core structure, it is necessary to be able to asses the aromaticity of many cyclopenta-fused PAHs (possibly more than 500), of different sizes (up to 15 rings between hexagons and pentagons), and different spatial rearrangements in a quick but realistic and effective way. To try to do this with NICS will be very time consuming and computationally expensive, especially in the case of big systems.

Key words: aromaticity, nucleus-independent chemical shifts (NICS), Y-rule, cyclopenta-fused PAHs, asphaltenes.

Résumé : En termes de stabilité cinétique et thermodynamique, la caractérisation de la stabilité de la région aromatique condensée (RAC) des asphaltènes d'huile est primaire. Une telle compréhension est important si on veut pouvoir faire un usage optimal de la fraction lourde des huiles brutes. La région aromatique condensée est formée d'hydrocarbures aromatiques polycycliques cyclopentaniques péri-condensés (HAP-CP) dans lesquels on retrouve des atomes d'azote, de soufre ou d'oxygène comme hétéroatomes. Le modèle de Clar qui spécifie que la représentation la plus importante d'un HAP est de posséder un nombre maximal de sextets π décrits par des cercles insérés et un nombre minimal de doubles liaisons fixes décrit l'essence des arguments de stabilité cinétique et thermodynamique. Ce modèle est facilement utilisable pour les produits aromatiques complexes de la sorte retrouvée dans les asphaltènes. Dans le présent travail, on montre que l'aromaticité des HAP-CP peut être évaluée en utilisant la règle-Y qui est facile à appliquer d'un point de vue qualitatif. Dans la littérature, il est prouvé que la règle-Y peut être utilisée pour élucider l'aromaticité de HAP benzénoïdes et elle a aussi été validée pour les HAP benzénoïdes péricondensés, mais pas pour les HAP-CP péricondensés. On vérifie donc ici qu'elle est aussi applicable à ces dérivés. L'applicabilité de la règle-Y a été démontrée d'une façon théorique en comparant la distribution électronique obtenue grâce à elle avec celle obtenue à partir de calculs de déplacements chimiques indépendants des noyaux (DCIN) au niveau de la théorie de la fonctionnelle de la densité. L'importance de cette démarche est que, en raison de la polydispersité dans la composition des asphaltènes de l'huile et afin de mieux comprendre leur structure aromatique fondamentale, il est nécessaire d'être capable d'évaluer l'aromaticité de plusieurs HAP-CP (possible plus de cinq cents), de tailles différentes (allant jusqu'à 15 noyaux hexagonaux ou pentagonaux) et d'arrangement spatial différent d'une façon rapide, mais réaliste et efficace. Il serait très long et d'un point de vue de temps de calcul très coûteux d'essayer de faire ces évaluations à l'aide de calculs DCIN.

Introduction

Polycyclic aromatic hydrocarbons (PAHs) containing, by periannulation, at least one unsaturated five-membered ring, cyclopenta (CP) moiety, and fused to six-membered ring perimeters (CPPAHs) are important in several contexts.[1,2] CPPAHs are of considerable chemical importance and biological relevance. This stems from their identity as substructures of fullerenes and carbon nanotubes[3,4] and their potential to show unusual (photo)physical properties, e.g., facile (consecutive) one-electron reduction processes,[5] anomalous fluorescence,[6] and deviant aromatic character,[7] and, their presence, in charged form, in the interstellar medium.[8] UV–vis spectra are strongly modulated by the distribution and number of pentagons,[9,10] high electron affinities,[11,12] and characteristic up-field shifted ^{1}H NMR chemical shifts.[9,10,13] Theoretical interest follows from the role of CPPAHs as probes for the magnetic criteria of aromaticity, and they have been extensively investigated from this point of view.[14–18] In addition, CPPAHs were found to possess bioactivity.[19] This is of interest since CPPAHs have been identified as prevalent environmental pollutants that are invariably generated during incomplete combustion processes.[20]

Due to their biological activity, there is a need to assess the importance of CPPAHs as products of the incomplete combustion of hydrocarbon fuels.[21] CPPAHs have been observed as pyrolysis products of anthracene[22,23] and pyrene[24] and as combustion products of benzene,[25] ethylene flames,[26] and ethylenenaphthalene mixtures.[27] Wornat et al.[28] reported the identification of CPPAHs as products of the rapid pyrolysis of an Australian brown coal.

CPPAHs are also present in the fused aromatic ring region (FAR region) of oil asphaltenes. The asphaltenes[29] are a very important class of petroleum, impacting virtually all aspects of resource use. Optimization of production and processing of crude oils behooves proper chemical understanding of the asphaltenes. The vision of petroleomics, including establishment of structure–function relationships of crude oils and asphaltenes, mandates determination of asphaltene molecular structure. Nevertheless, many basic features of the molecular architecture of asphaltenes have been the subject of long debate.[29] The presence of asphaltenes have a negative impact on both the physical and chemical properties of heavy oils and increase the difficulties of crude oil utilization by impacting the processability of these heavy hydrocarbons. In catalytic processes, asphaltenes cause severe catalyst deactivaton.[30–35] Asphaltenes are defined in terms of a solubility classification, not by chemical structure, due to the difficulty of defining their structure experimentally. A widely used definition of petroleum asphaltenes is that they are the petroleum component that is insoluble in *n*-heptane and soluble in toluene.[30–35]

Asphaltenes are polycyclic aromatic compounds similar to the polycyclic aromatic hydrocarbons (PAHs) but containing heteroatoms (N, O, S), some in cyclopentafused rings, and alkyl side chains in their structure.[36] To understand the chemistry and aggregation of asphaltenes, it is essential to know the size and structure of their fused aromatic ring (FAR) region. The characterization of the stability of the FAR region in asphaltenes in terms of kinetic and thermodynamic stability is primary. The defining terms of pericondensed and catacondensed are subordinate to the stability considerations. Regarding geometry, the terms pericondensed versus catacondensed are generally used where pericondesation refers to single bridgehead carbons attached to three rings, while catacondensation refers to aromatic carbons shared by at most two rings. PAHs can be investigated by their characteristic electronic absorption and fluorescence emission spectra. The relation of these PAHs to crude oils and asphaltenes can be established. In particular, systematic rules governing the optical absorption spectra of PAHs in terms of the number of fused rings, their geometry, and their heteroatom content have been developed[37–40] but not in terms of the number of cyclopenta-fused rings.

To understand the optical properties of asphaltene PAHs, it is essential to determine their molecular geometry by measurement. This has been accomplished in part by carbon X-ray Raman spectroscopy.[41–43] It has been established that aromatic sextet carbon dominates asphaltene PAHs; this is most likely due to the significantly enhanced stability of sextet carbon over that of isolated double bond carbon (within the Clar representation).[37–40] The Clar model,[44,45] which states that the most important representation of a PAH is one having the maximum number of disjoint π-sextets (depicted by inscribed circles) and a minimum number of fixed double bonds, captures the essence of the kinetic and thermodynamic stability arguments enabling a simple heuristic for assessing stability. FARs with more sextet carbon are more aromatic and more kinetically and thermodynamically stable; that is, they gain in stability due to delocalization of π-electrons within the resonant sextets. FARs with increased isolated double bond carbon are much more reactive and unstable; that is, they are kinetically and thermodynamically less stable.

With asphaltene PAH geometry completely understood, it will be possible to decipher the known optical properties[46] of crude oils and asphaltenes. It has been shown that the major characteristics of the optical absorption and fluorescence emission spectra of asphaltenes are understandable in terms of PAHs with, most probably, seven fused rings and a distribution with four to ten rings.[46,47] Recently, the results of molecular orbital (MO) calculations on 523 selected benzenoid PAHs have been used to create an ensemble of possible asphaltene molecular structures.[48] These PAHs are selected in terms of having acceptable ratios of isolated double bond carbon to sextet carbon. However, it is still necessary to conclude on the distribution and size of the CPPAHs present in the FAR region of asphaltenes. For this, it is essential to be able to know the aromaticity of the CPPAH systems. For the

case of the benzenoid PAHs, the Clar representation or model is readily employed for complex aromatics of the sort to be considered for asphaltenes. We extended these concepts using a methodology with the simple sobriquet "the Y-rule".[37–39] The Y-rule establishes the most important and most kinetically and thermodynamically stable representation, in terms of π-sextets and double bonds, for any pericondensed *benzenoid* PAH. Regarding reactivity, it is well-known that a PAH is attacked at the position of the double bonds because it requires less energy to break these bonds than to break a π-sextet. Thus, the Clar structures found with the Y-rule also give information about where it is most likely that chemical reactivity would take place. These simple methods are tied to stability arguments and shown to yield asphaltene structures found experimentally.[46–48]

Previously, we verified theoretically the performance of a proposed modification of the basic postulates of the Clar aromatic sextet theory, called the Y-rule,[37–39] which determines the relative aromaticity of each hexagonal ring in pericondensed benzenoid polycyclic aromatic hydrocarbons (peri-PAHs). The Y-rule for constructing Clar-type aromatic sextet formulas for benzenoid peri-PAHs was also examined, and the limits of its applicability were established.[40] The π-electronic distribution obtained by the Clar sextet principle (or model) as determined by the Y-rule was compared with the π-electronic distribution obtained from nucleus-independent chemical shift (NICS) calculations for various series of benzenoid peri-PAHs.[39] The NICS values were used to assess the relative aromaticities of the individual rings in the peri-PAH compounds. It was found that the simple heuristic Y-rule predicts for all the calculated systems the same relative aromaticities given by the NICS calculations, and for the case of peri-systems with very high symmetry (like the compact peri-PAHs) it reinforces the picture derived from the NICS calculations. In these cases, the NICS results can be complex due to symmetry. The advantages of the qualitative Y-rule are that it is of particular importance for the case of large peri-PAHs, as it takes few minutes to be applied following a very easy methodology, and it provides a quick answer about the aromaticity and location of the resonant sextets in peri-PAH compounds without having to carry out theoretical chemistry calculations that take time and that can be costly depending on the size of the system.

The aromaticity of benzenoid PAHs has been highly studied. The widely used notion of the aromatic sextet is usually attributed to Armit and Robinson,[49] but was originally introduced in 1922 by Crocker.[50] Clar[44,45] employed the notion of the aromatic sextet to account for the aromaticity of PAHs by studying their reactivity, NMR properties, and UV spectra and combining the experimental facts with his intuition. The quantitative criteria commonly used to assess the aromaticity of molecules are based on energetic, geometric, and magnetic properties.[51–61] Energetic criteria are based on homodesmotic,[62] isodesmic,[63] or isomerization reactions.[64] Greater bond-length alternation is assumed to be associated with a decrease in aromatic character. Geometric treatments such as HOMA[54–56] (harmonic oscillator model of aromaticity) are typically used to deduce the degree of aromaticity from bond distances. Magnetic criteria also are quite effective in discerning aromaticity, as the ability to sustain a diatropic ring current is the defining characteristic of aromatic species.[57–59] The use of NICS, "nucleus-independent chemical shift," as a measure of aromaticity is straightforward and well-established.[50,51,65] It has already been demonstrated in the literature[39,66–72] that the NICS values represent strong theoretical support for Clar's picture of aromatic π-sextets.

If one considers that asphaltenes are essentially stable for geologic time, then unstable aromatic structures are ruled out. The optical absorption spectra of asphaltenes exhibit an exponential decrease in the neighborhood of 650 nm, showing that large graphitic structures with very low energy electronic absorption do not constitute a significant component of the asphaltene fraction. Likewise, asphaltene fluorescence emission spectra, which exhibit significant intensity in the range of 400–650 nm, reflect the nature and type of FAR structures present in asphaltenes. However, this optical absorption and emission data when considered alone has limited use in particular for the determination of aromatic structures. The utility of this data is greatly expanded when comparing it with the aromaticity for the many possible candidates, pericondensed CPPAHs, for asphaltenes. Understanding the implications of different ring geometries and sizes on stability also provides essential information about governing heuristics for the asphaltene aromatics.[37,38]

To understand the number of rings (in terms of the ratio of five-member rings and six-member rings), size, and geometry of the cyclopenta-PAHs present in the aromatic region of the asphaltenes it is necessary to understand their stability, which is directly related to their aromaticity and in turn to the observed optical properties of asphaltenes. In previous studies,[37,38,46–48] we found that the stability and reactivity of asphaltene molecules is closely associated to the stability and reactivity of their benzenoid polycyclic aromatic hydrocarbon core. We systematically analyzed the relationship between the structure of PAH isomers and the number of resonant sextets present. The number of resonant sextets in the structure is closely related to the HOMO–LUMO gap magnitude and thus to the observed optical properties of asphaltenes. Due to the polydispersity in the composition of the oil asphaltenes it is important to be able to assess the aromaticity of many cyclopenta-PAHs, of different sizes and spatial rearrangements, in a quick but realistic and effective way.

The goal of the present work is to verify the applicability of the Y-rule to pericondensed cyclopenta-fused polycyclic aromatic hydrocarbons by comparing the π-electronic distribution obtained with it with the one obtained from nucleus-independent chemical shift (NICS) calculations for various neutral CPPAHs. The advantages of the qualitative Y-rule are that it is of particular importance for the case of large peri-PAHs, it takes few minutes to be applied following a very easy methodology, and it provides a quick answer about the aromaticity and location of the resonant sextets in peri-PAH compounds without having to carry out theoretical chemistry calculations that take time and that can be costly depending on the size of the system. Therefore, if the Y-rule is applicable to CPPAHs then it will be used in a following investigation to asses the aromaticity of more than 500 CPPAHs from four to fifteen rings and to withdraw conclu-

sions of the size and stability of the CPPAHs in asphaltenes by comparing with the optical properties of asphaltenes.

In the section named "Results and discussion" a detail discussion on the Y-rule and its application and on the definition of NICS will be provided.

Computational details

We studied 25 neutral pericondensed cyclopenta-fused polycyclic aromatic hydrocarbons (peri-CPPAHs). The structure optimization of the CPPAH systems was done by performing quantum density functional theory (DFT) calculations. The self-consistent generalized gradient GGA with the exchange-correlation potential of Perdew–Wang 91[73] was used along with the DNP basis set (triple ζ numerical basis set)[74] with a radial cut off of 3.7 Å; as implemented in the DMol3 code.[74–76] The DNP basis uses double-numeric quality basis set; approximately two atomic orbitals for each one occupied in free atom, with polarization functions, i.e., functions with an angular momentum of one higher than that of the highest occupied orbital in the free atom. The size of the DNP basis sets are comparable to 6-31G** sets.[77] However, the numerical basis set is much more accurate than a Gaussian basis set of the same size.

The nucleus-independent chemical shift (NICS) calculations were carried out using the GIAO-DFT[78,79] method as implemented in the Gaussian 98[77] package using the optimized structures. A dummy atom was located on the molecular plane at the geometrical center of each hexagon in the CPPAH structures to calculate the NICS(0). The Becke's 1988 functional,[80] which includes the Slater exchange along with corrections involving the gradient of the density was used together with the correlation functional of Lee, Yang, and Parr,[81] which includes both local and nonlocal terms, i.e., B3LYP functional was used. It is well-known that the shielding tensor and NICS are very sensitive to the quality and size of the basis set used.[82,83] Schleyer and co-workers[60,61,68,71] recommend the use of the 6-31G(d) basis. However, a sufficiently large basis is needed for an accurate description of the chemical shift. Therefore, we used a basis set that is augmented with two sets of polarization functions, i.e., the 6-31G(d, p) or 6-31G** basis set.[77]

In some figures we use a combination of an Arabic number with a Roman number. The Arabic number corresponds to the number of the structure and the Arabic number corresponds to the several Clar-type structures of that CPPAH.

Results and discussion

Nucleus-independent chemical shift (NICS)

The nucleus-independent chemical shift (NICS) was introduced by Schleyer et al.[60] in 1996 as a new aromatic index, which is defined as the negative value of the absolute isotropic magnetic shielding at some selected point in space, e.g., at the center of a ring that is being probed, NICS(0), or one angstrom above the geometrical center of the ring that is being probed, NICS(1). The NICS data are reported with the reverse signs to conform to the NMR chemical shift signs conventions (negative upfield and positive downfield). Significant negative (i.e., magnetically shielded) NICS values in interior positions of rings or cages indicated the presence of induced diatropic ring currents or "aromaticity" whereas positive values (i.e., deshielded) at each position denote paratropic ring currents and "antiaromaticity".[60] The NICS criterion is now widely applied[65,69] in many ab initio and density functional studies, which have demonstrated that NICS is a useful indicator of aromaticity and generally correlates well with the energetic, geometric, and magnetic criteria for aromaticity.[65,70]

The diamagnetic contribution, which is negative in the NICS convention, stems from the circulation of ground state density (diatropic or diamagnetic current) originated from the coupling of occupied CC(π) and CH molecular orbitals by the applied magnetic field. On the other hand, the paramagnetic contribution, which is positive in the NICS convention, stems from the circulation of current density (paratropic or paramagnetic current) originated from the coupling of occupied and virtual CC(σ) molecular orbitals by the applied magnetic field.[39]

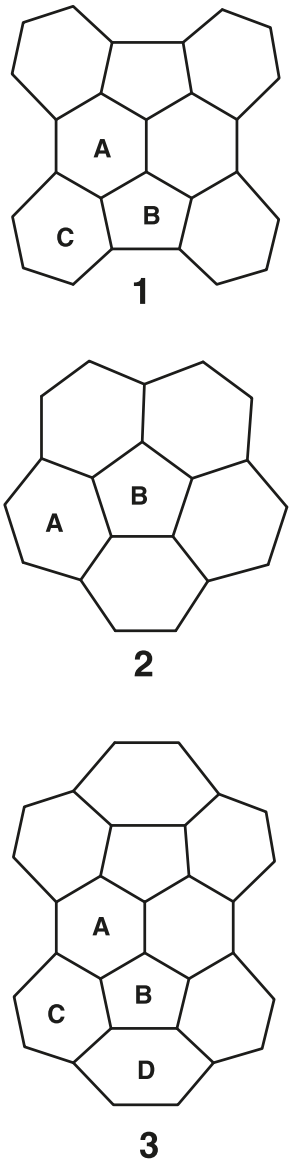

Fig. 2. Studied planar pericondensed cyclopenta-fused polycyclic aromatic hydrocarbons (planar CPPAHs).

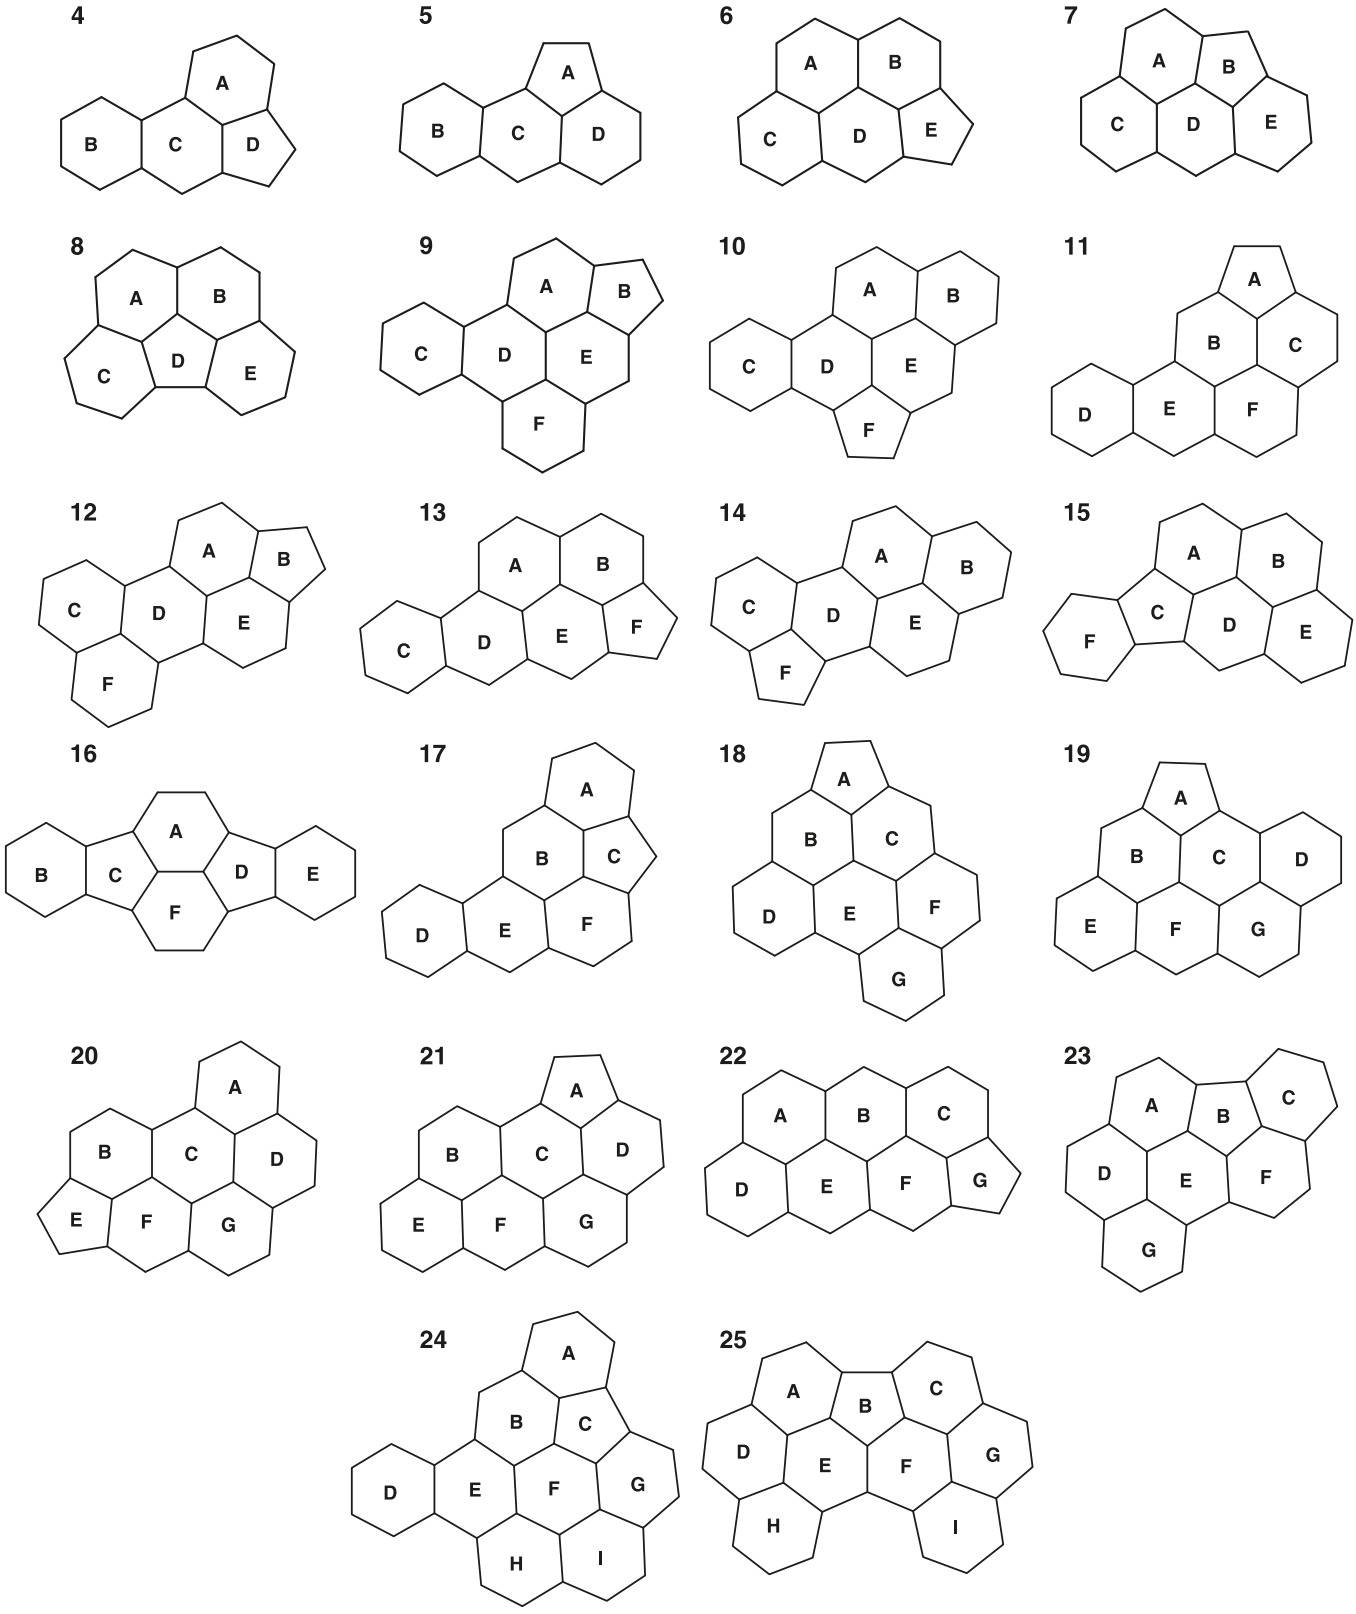

The Y-rule in identifying Clar-type structures

Recently, a modified version of the Clar theory has been proposed.[37–39] The new approach was applied to numerous benzenoid PAHs and its surprisingly good agreement with other, more sophisticated, theoretical assessments of local aromaticity (in particular, the Schleyer's NICS values, cf. refs. 60, 65, 68, and 84) was extensively discussed. On the other hand, some general features of the new method, in-

Table 1. Calculated NICS(0) for the bowl-shaped or curved CPPAHs presented in Fig. 1.

CPPAH number	*n*FAR[a]	Formula	Name	NICS(0) in each ring			
				A	**B**	**C**	**D**
1	8FAR	$C_{26}H_{12}$		–5.6[b]	+3.9b[b]	–10.0[b]	
2	6FAR	$C_{20}H_{10}$	Dibenzo[*ghi,mno*]fluoranthene or corannulene	–7.3 (–8.6)[b]	+9.6 (+7.6)[b]		
3	10FAR	$C_{30}H_{12}$		–6.5[b]	+6.8[b]	–9.4[b]	–8.1[b]

[a]Number of total fused aromatic rings (*n*FAR).

[b]Reference 86.

cluding the limits of its applicability, have been established.[40] The new version of the Clar theory is named "the Y-rule". The Y-rule applies to benzenoid PAHs possessing carbon atoms that simultaneously belong to three hexagons. Such carbon atoms are usually referred to as "internal" or also "Y-carbons". Benzenoid PAHs containing internal carbon atoms are classified as perifusenes or pericondensed (in contrast to catafusenes or catacondensed that, by definition, do not possess internal carbon atoms).

In both the original formulation of the Clar theory and its several later variants, sextets of π-electrons are located in particular hexagons of the benzenoid molecule, indicating domains of increased π-electron contents and (or) local aromaticity. The Y-rule offers a new, original, and easy-to-apply criterion for locating aromatic sextets in pericondensed benzenoids.

The Y-rule is formulated as follows:

> (*a*) The aromatic sextets are to be located so as to cover all internal carbon atoms. If not all Y-carbon atoms can be covered by aromatic sextets, then the highest possible Y-carbons must be covered.
>
> (*b*) Provided condition (*a*) is obeyed, the number of aromatic sextets must be as large as possible.
>
> (*c*) If several Clar-type structures satisfy conditions (*a*) and (*b*), then the one with the highest symmetry, provided such exists, is chosen, i.e., considered as most important.
>
> (*d*) If the Clar-type structure obtained by means of requirements (*a*), (*b*), and (*c*) is unique, then it is expected to represent the basic features of the π-electron distribution, and local aromaticity.
>
> (*e*) If there are several Clar-type structures obeying the requirements (*a*), (*b*), and (*c*), then the conclusions about π-electron distribution, and local aromaticity are drawn from their superposition.

The details and many examples on the application of the Y-rule are exemplified in ref. 39 and will not be discussed here in great detail.

The π-electronic distribution for CPPAHs obtained by the Clar sextet principle as determined by the Y-rule and NICS(0) calculations

In Fig. 1 and Fig. 2 the studied pericondensed cyclopentafused polycyclic aromatic hydrocarbons (CPPAHs) are presented. The letters in the structures in these figures are for identifying each ring and refer to the information given in Table 1 and Table 2. Table 1 lists the values of the calculated NICS(0) for bowl-shaped or curved CPPAHs, presented in Fig. 1, while Table 2 lists the values of the calculated NICS(0) for planar CPPAHs, presented in Fig. 2. A total of 25 CPPAHs are studied.

As mentioned in the "Computational details" section, the geometry optimization structure of the CPPAH systems was done by performing quantum density functional theory (DFT) calculations. In Fig. 3 the comparison between the calculated and the experimental X-ray structure for compound **2** is displayed. As it can be seen in Fig. 3, there is a good agreement between the calculated bond distances and the experimental data. The differences in bond lengths are not greater than 0.022 Å.

The π-electronic distribution for bowl-shaped or curved CPPAHs obtained by the Clar sextet principle as determined by the Y-rule and NICS(0) calculations

Table 1 lists the values of the calculated NICS(0) for bowl-shaped or curved CPPAHs, presented in Fig. 1. We calculated the NICS(0) for corannulene, **2**, but the data for compounds **1** and **3** were obtained from the literature.[86] Also, for compound **2** we obtained NICS(0) data from the literature,[86] and compared it with our calculated data. Two different NICS(0) values are obtained for corannulene, **2**, that correspond to the rings labeled A and the rings labeled B. The calculated NICS(0) compares well with the reported data for **2**, see Table 1, and the differences stem from the fact that the optimization of the structures in ref. 86 for compounds **1**, **2**, and **3** were calculated with the semiempirical AM1 method and the basis set used for the NICS calculation was less accurate, 6-31G*.[86] However, the general tendency and conclusion on the aromaticity for compound **2** is the same.

From the total NICS values presented in Table 1, and as proposed by Schleyer et al.,[60] see the section titled "Nucleus-independent chemical shift (NICS)" and in ref. 39, we consider that the highest negative NICS(0) in each structure corresponds to the presence of a sextet in that given ring. Therefore, for compound **1,** which contains 26 π-electrons and a total of eight fused rings (8FAR), the sextets are located in the rings labeled as C, NICS(0)= –10.0, giving a total of four resonant sextets that comprise 24 π-electrons, see Fig. 1 and Fig. 4. Thus, the remaining two π-electrons are located in the rings A and no density is presented in rings B, which have a positive NICS(0) value, +3.9, see Table 1. When distributing the double bonds, taking care of not exceeding the valence of any of the carbon atoms, it is only possible to locate one double bond in the A-hexagons. Therefore, the π-density in the A-hexagons involves a double bond that is right at the junction of the A-rings, see Fig. 4.

Table 2. Calculated NICS(0) for the planar CPPAHs presented in Fig. 2.

CPPAH number	*n*FAR[a]	Formula	Name	NICS(0) in each ring

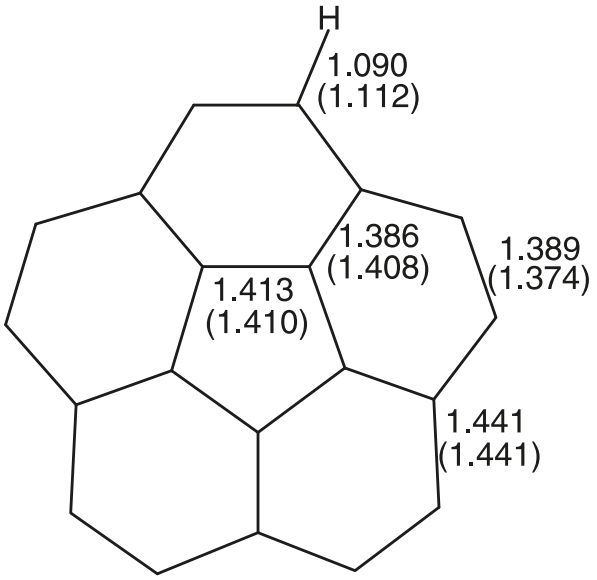
Fig. 3. Comparison between the calculated and the experimental X-ray structure (values in parenthesis are from ref. 85) for corannulene, compound **2**.

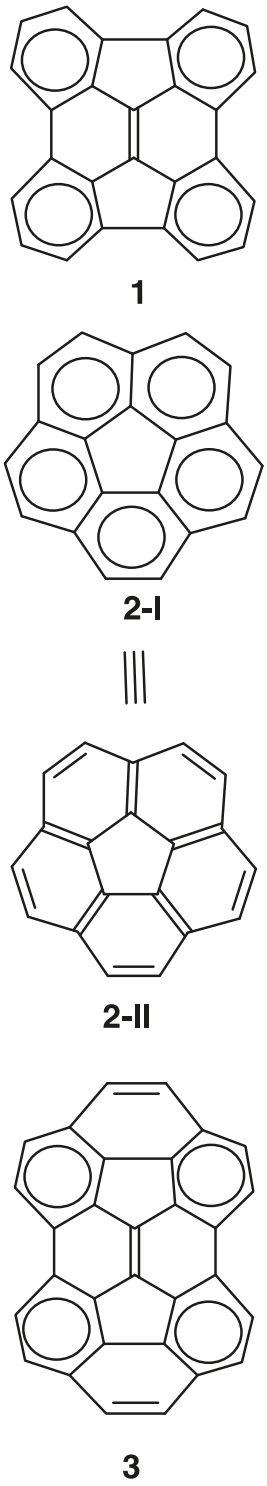


The application of the Y-rule to compound **1** is presented in Fig. 5. The CPPAH **1** presents a total of six Y-carbons or internal carbons, which are highlighted in bold in Fig. 5. There are two possibilities to accommodate as many as possible π-electrons in sextets covering all the Y-carbons and without overcoming the carbon atoms valence. These two possibilities are shown in Fig. 5 and are labeled as **1**-**I** and **1**-**II**. The solid circles and the open circles represent aromatic resonant sextets in both cases. Following the Y-rule enunciate (e), see above, the pictorial superposition of both distributions, **1**-**I** and **1**-**II**, shown as **1**-**III** is equivalent to the distribution **1**-**IV**. Because it cannot be possible to have simultaneous adjacent sextets without overcoming carbon atoms valences, then there is a double bond right at the junction of the A-hexagons, as shown in structure **1**-**IV**. The π-electronic distribution given by the NICS(0), Fig. 4, for compound **1** agrees with the distribution obtained with the Y-rule and presented as **1**-**IV** in Fig. 5.

Compound **2** has a total of 20 π-electrons and a total of six fused aromatic rings (6FAR), and according to the NICS(0) results, see Table 1 and Fig. 1, the sextets are located in all the external hexagonal rings, as shown in **2**-**I** in Fig. 4. However, there cannot be simultaneously adjacent sextets without overcoming the carbon atoms valence. Therefore, the structure **2**-**II**, in Fig. 4, where there is a double bond right at the junction of the external hexagons, is more appropriate and explains the obtained NICS(0).

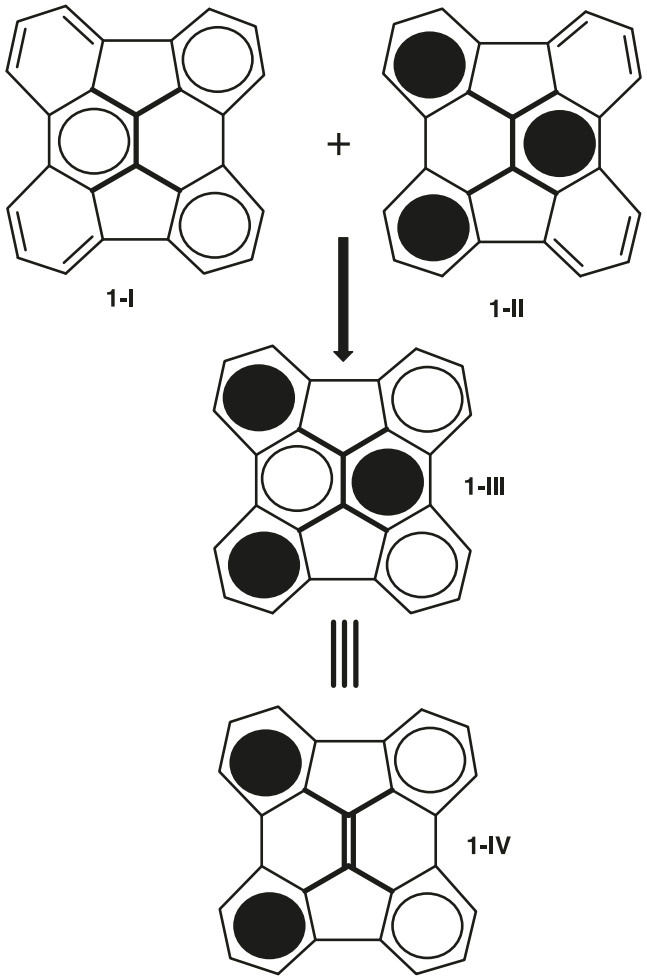
Four different Clar-type structures are found for compound **2** by applying the Y-rule, which are presented in Fig. 6, named **2**-**I**, **2**-**II**, **2**-**III**, and **2**-**IV**. Compound **2** has a total of five Y-carbons or internal carbons that are highlighted in bold in Fig. 6. For CPPAH **2** it is not possible to cover all the Y-carbons with resonant sextets without exceeding the carbon atoms valence. In each of the four Clar-type structures there is one Y-carbon atom that is not covered by sextet. The pictorial superposition of the four Clar-type structures provides structure **2**-**V,** which is equivalent to the structure **2**-**VI**, see Fig. 6. The π-electronic distribution given by the NICS(0), Fig. 4, for compound **2** agrees with the distribution obtained with the Y-rule and presented as **2**-**VI** in Fig. 6.

Fig. 4. π-Electronic distribution obtained with NICS(0) for bowl-shaped CPPAHs.



The CPPAH **3** has a total of thirty π-electrons and a total of ten fused aromatic rings (10FAR). According to the

Fig. 5. π-Electronic distribution obtained with the Y-rule for the bowl-shaped CPPAH compound **1**.

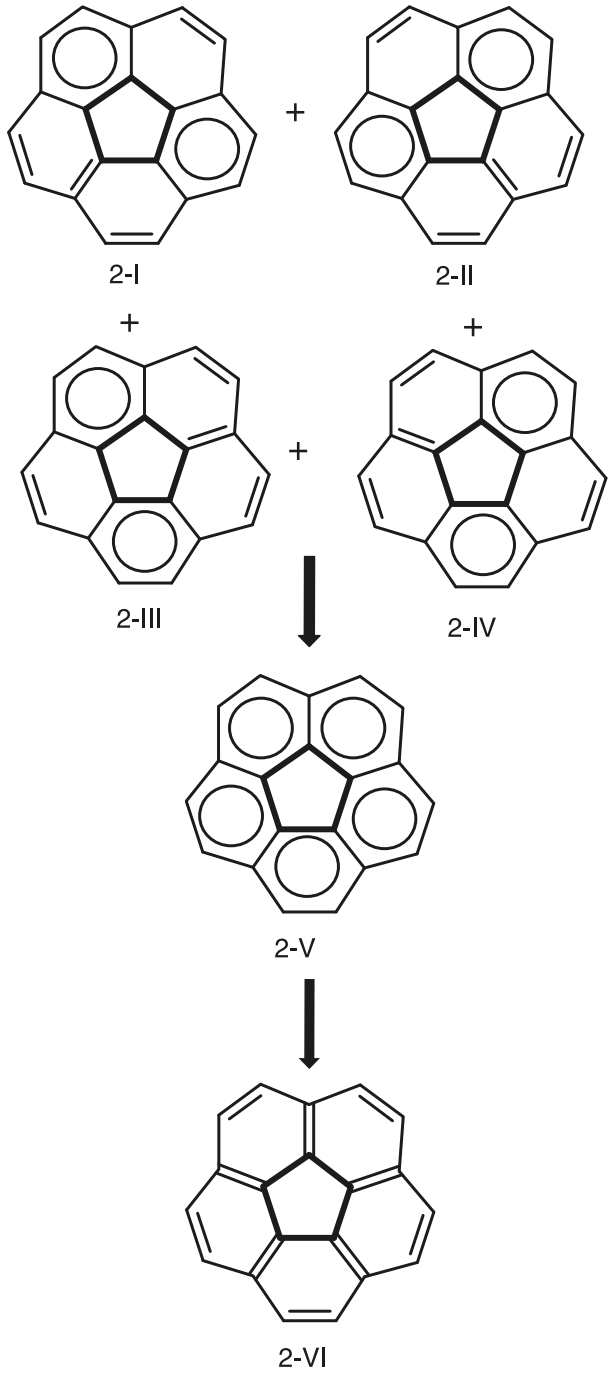


NICS(0) results, see Table 1 and Fig. 1, the sextets are located in the C-hexagons, which have the highest NICS(0) value, –9.4, giving a total of four resonant sextets. The remaining six π-electrons are located in rings A and D, see Fig. 1 and Fig. 4. The B-rings have a positive NICS(0) value, +6.8; thus, they have no electron density.

The π-electronic distribution obtained by the Y-rule for CPPAH **3** is presented in Fig. 7. Compound **3** has a total of ten Y-carbons highlighted in bold in Fig. 7. For this compound it is not possible to cover all the Y-carbons with resonant sextets without overcoming carbon atoms valence. Two Y-carbons are not covered by sextets. In Fig. 7 several Clar-type structures with three resonant sextets each are presented as **3-1** to **3-VIII**, however, the only one structure that covers all the Y-carbons, except two, and presents the highest possible number of resonant sextets is the Clar-type structure **3-IX**, thus, this is the π-electronic distribution obtained with the Y-rule. Again, the π-electronic distribution obtained with the Y-rule agrees with the one obtained with the NICS calculation, see Fig. 4 and Fig. 7.

For the case of all the studied bowl-shaped CPPAHs, the π-electronic distribution obtained with the Y-rule agrees with the π-electronic distribution obtained with the NICS(0) calculation.

Fig. 6. π-Electronic distribution obtained with the Y-rule for the bowl-shaped CPPAH compound **2**, corannulene.

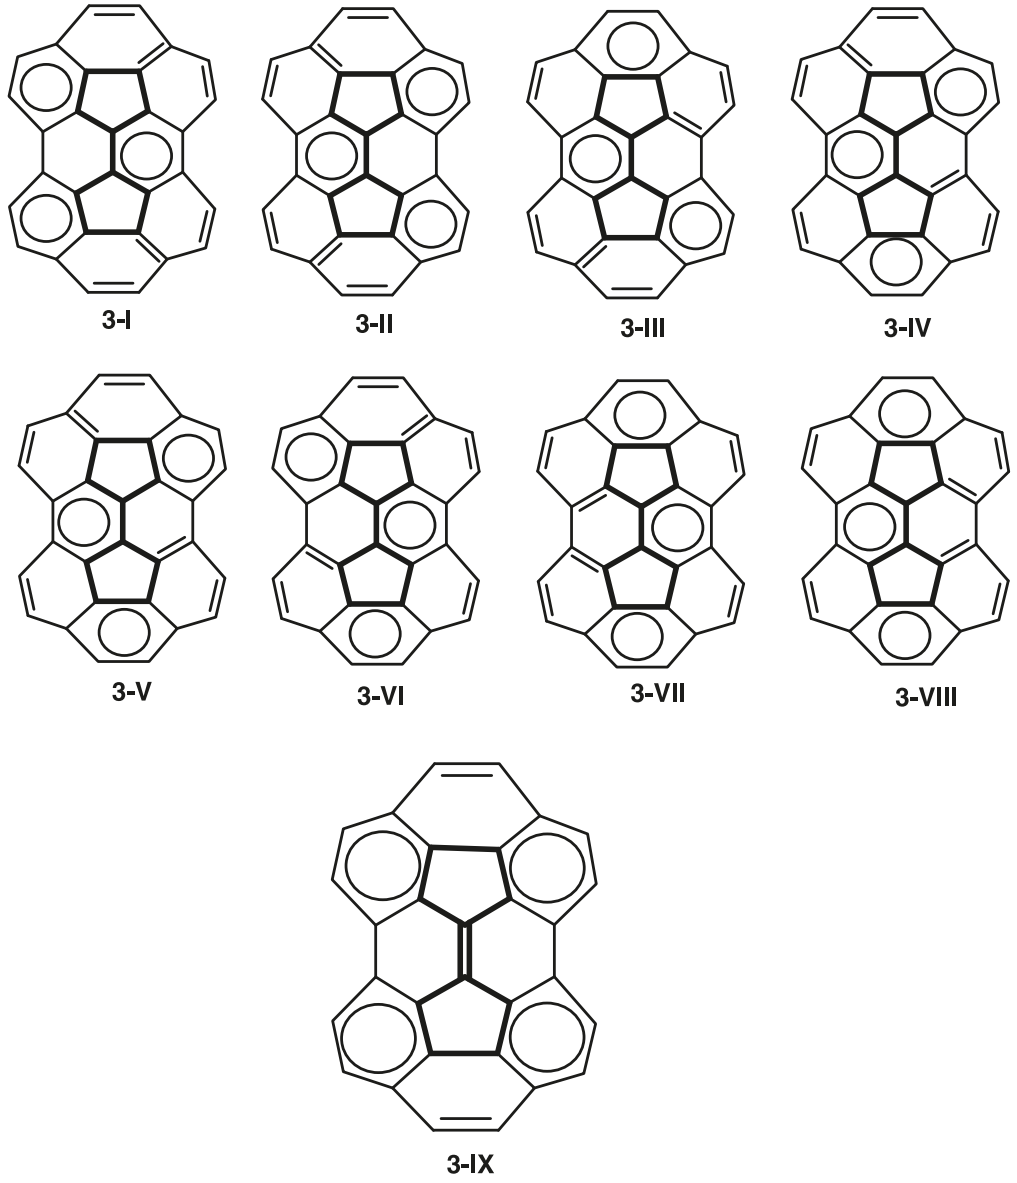


The π-electronic distribution for planar CPPAHs obtained by the Clar sextet principle as determined by the Y-rule and NICS(0) calculations

In this section, the π-electronic distribution in planar CPPAHs with a total of fused rings from 4FAR to 9FAR, and with 16–30 π-electrons, is presented. This section follows the same principles as those explained in the former sections, therefore, in this section we will discuss only some particular cases in detail but not all cases.

In Table 2, the calculated NICS(0) values for the planar CPPAHs shown in Fig. 2 are presented. In general, it is ob-

Fig. 7. π-Electronic distribution obtained with the Y-rule for the bowl-shaped CPPAH compound **3**.



served that six-membered rings vicinal to a five-member ring are less aromatic than those not directly connected to a five-member ring, which is in agreement with data reported in the literature,[7,86] see, for example, data for compounds **12** and **15**. An analysis of the NICS values given in Table 2, as done in the former section, provides the Clar-type structures shown in Fig. 8 (for labels, see Fig. 2).

The arrow shown in Fig. 8, see structures **10**–**13**, means that there is sextet migration[39,45] between the signaled hexagons because their NICS(0) values are too close or are too close to the highest NICS(0) in the molecule to discern where the sextet is located. In the case of structures **8**, **12**, **16**, **19**, **21**–**23**, and **25**, see Fig. 8, the double bonds right at the junction of hexagons stem from the fact that the NICS(0) are too close but far from the highest value in the molecule.

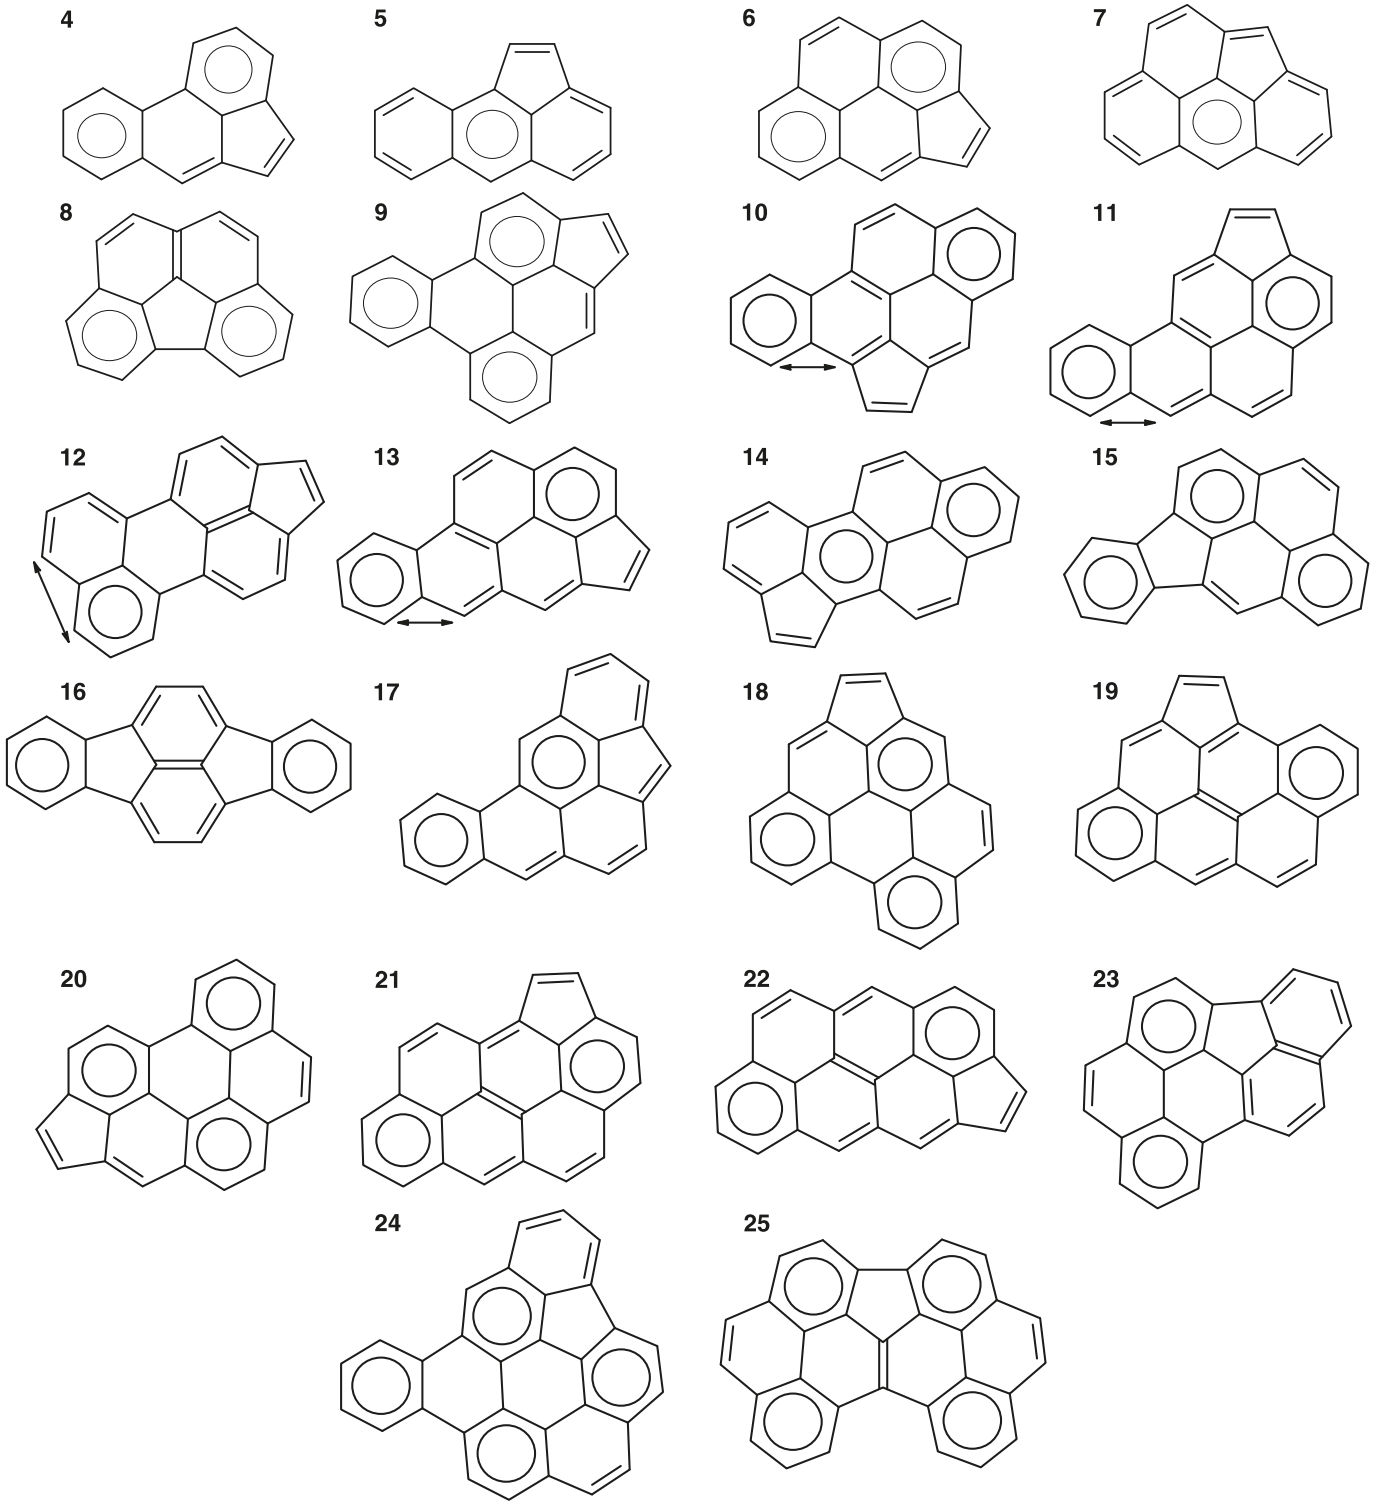
In Fig. 9 the π-electronic distribution obtained with the Y-rule for the planar CPPAHs is presented. In all the cases the Y-carbon are highlighted in bold. The 4FAR systems (**4** and **5**) have one Y-carbon, see Fig. 9. The 5FAR systems (**6**, **7**, and **8**) have three Y-carbons. The 6FAR systems (**9**–**17**) have three Y-carbons, except for the system **16** that has two Y-carbons. The 7FAR systems (**18**–**23**) have five Y-carbons. Finally, the 9FAR systems (**24** and **25**) have seven Y-carbons. As it can be seen, the number of Y-carbons in CPPAHs is given by odd numbers while it is given by even numbers in benzenoid PAHs.[39]

As it can be seen by comparing Fig. 8 and Fig. 9, there is a good agreement between the π-electronic distribution obtained with the Y-rule and the NICS(0) values. The application of the Y-rule for some of the planar CPPAHs is given in Fig. 10. The application of the Y-rule for these examples is carried out as explained in the former section.

Implications in oil asphaltenes stability

Under high-temperature pyrolysis conditions, CPPAH appear to be more stable than their benzenoid counterparts,[87]

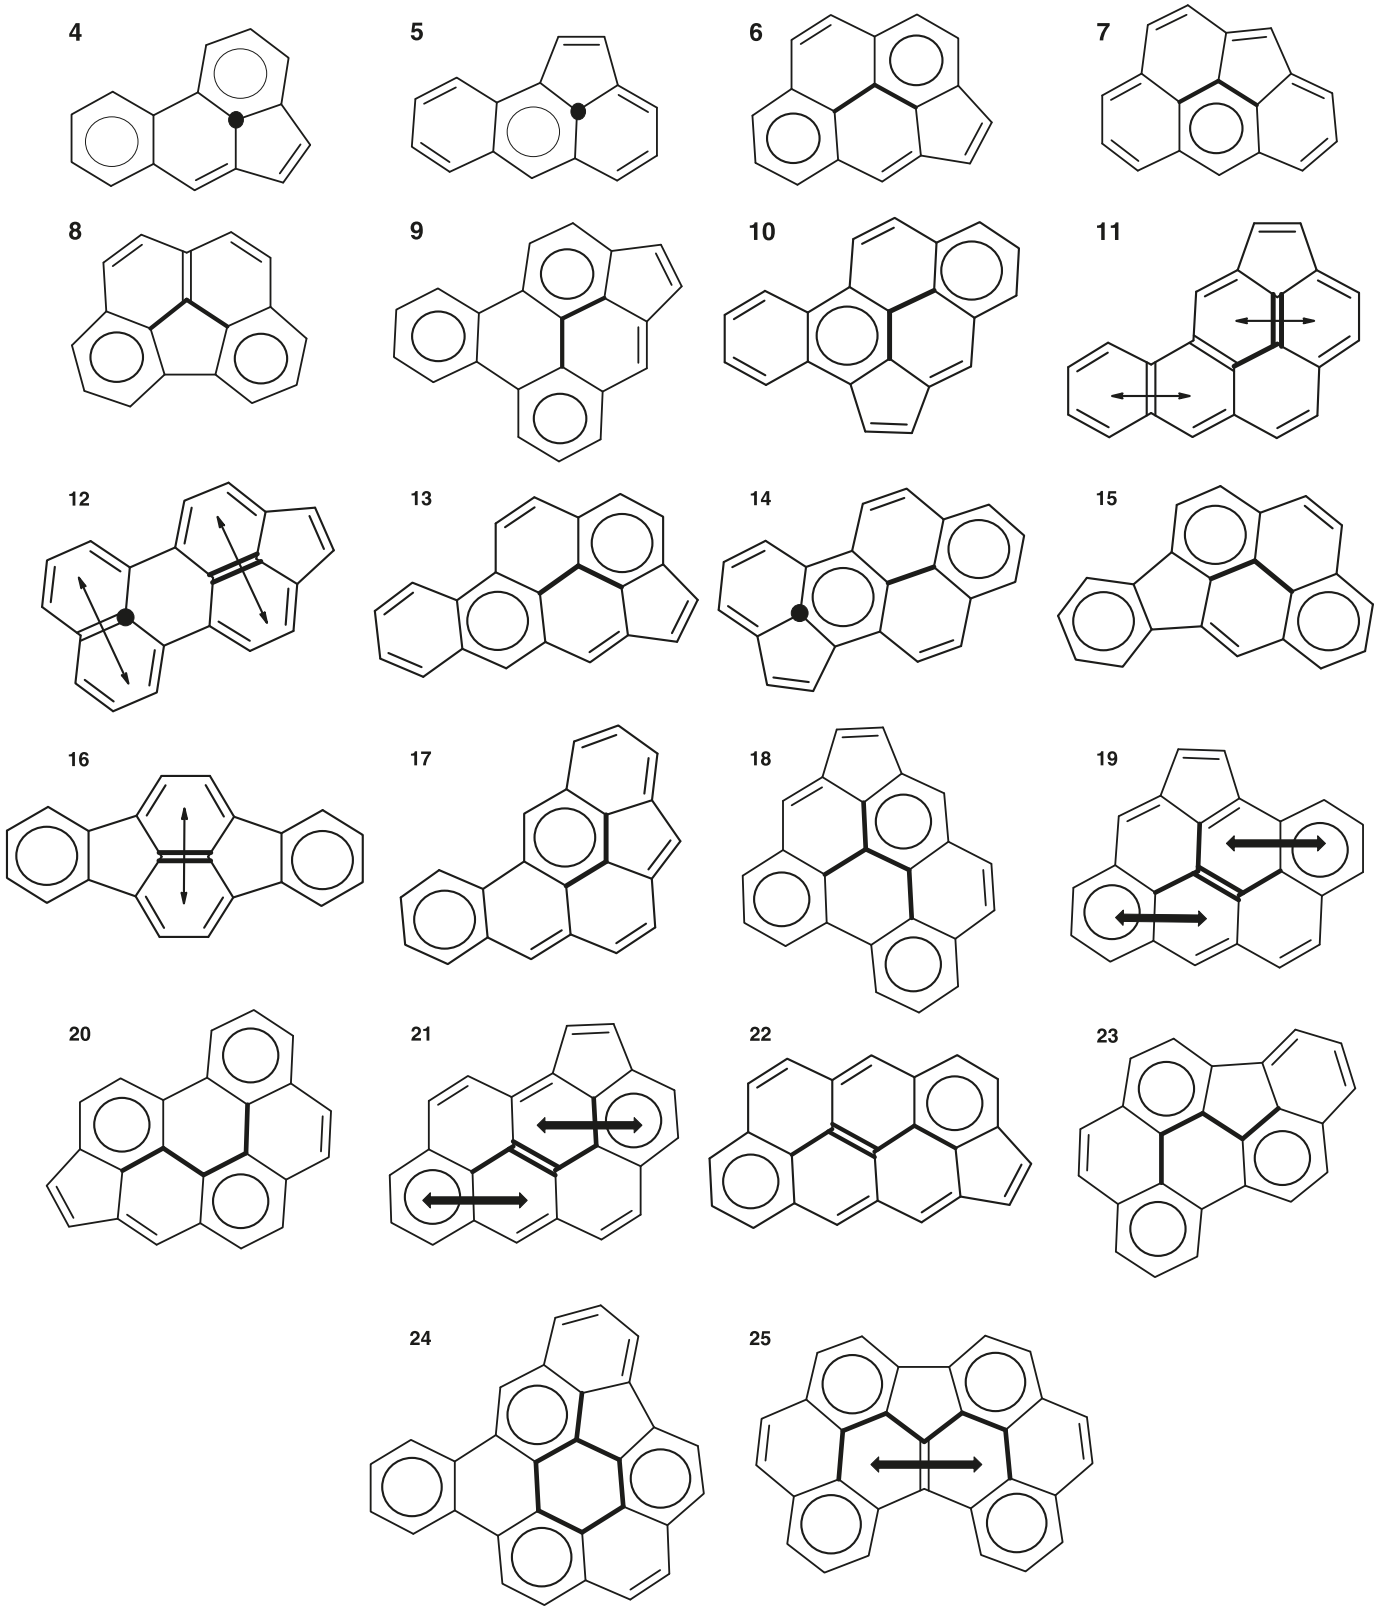
Fig. 8. π-Electronic distribution obtained with the NICS(0) calculations for the planar CPPAHs.



which suggests that CPPAH may survive in combustion regimes where more common PAH are known to break down. This stability is associated with the aromaticity of the CPPAHs, as proven for the case of PAHs.[37,38] The addition of pentagonal ring(s) to the benzenoid PAHs might form new Y-carbons that will lead to more possibilities for carbon sextet. However, due to the fact that asphaltenes present a very specific stability, it is important to find out how many sextets in CPPAHs are present in asphaltenes. As proven here this is going to be possible by using the Y-rule to elucidate the aromaticity of many CPPAHs candidates with the same optical properties as asphaltenes.

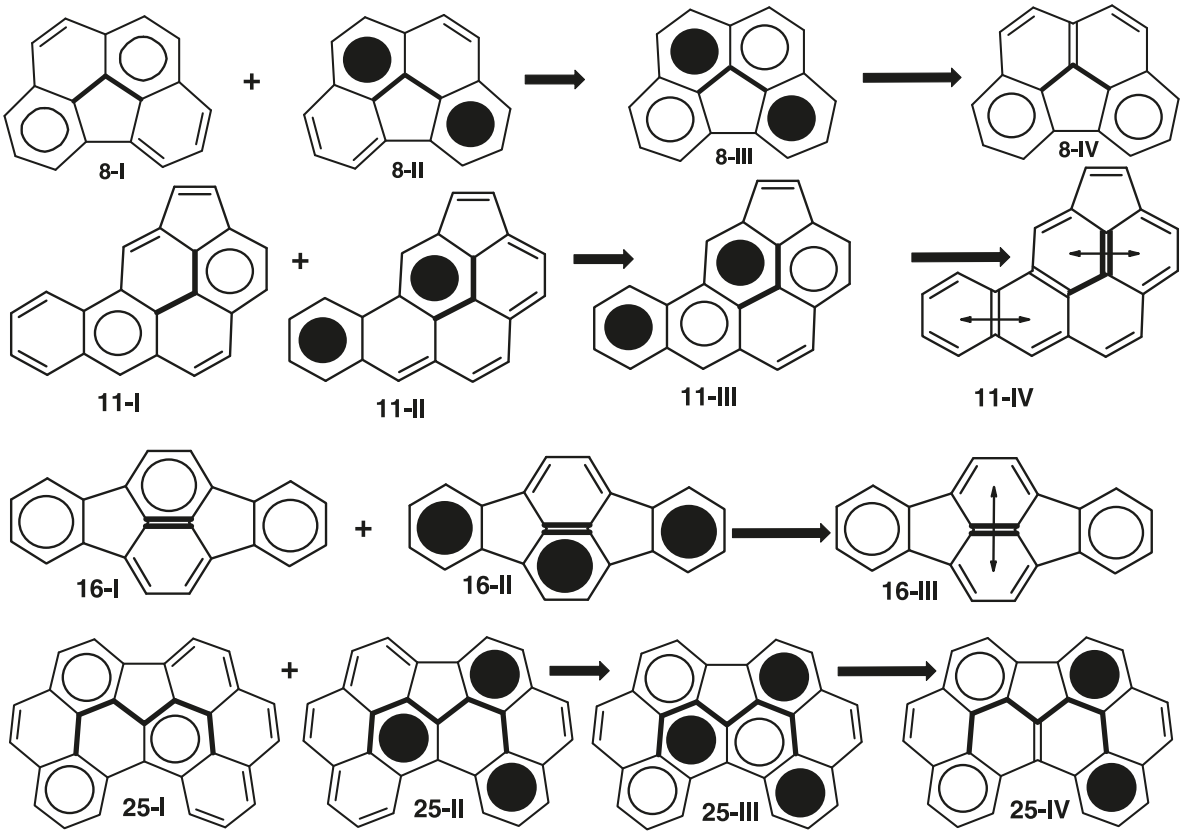
Andreatta et al.[88] have used high-Q high-resolution ultrasonic spectroscopy to detect the onset of aggregation in asphaltene solutions and micelle formation with standard surfactants. These authors have shown that the molecular

Fig. 9. π-Electronic distribution obtained with the Y-rule for the planar CPPAHs.



size and molecular architecture of asphaltenes can be used to understand primary aggregate formation of asphaltenes. Therefore, to establish structure–function relationships for the case of aspaltenes, in particular to relate molecular structure with solubility, it is necessary to understand the asphaltenes molecular architecture, stability, as well as their polydispersity. Thus, the importance of the present work in establishing the asphaltene molecular architecture.

Fig. 10. π-Electronic distribution obtained with the Y-rule for the planar CPPAHs compounds **8**, **11**, **16**, and **25**.



There are potentially different stages of aggregation in asphaltenes, for instance, as proposed in the Yen model, which consists of a hierarchy of aggregation for asphaltene solutions.[88,89] Different hierarchies of aggregation correspond to different energies of interaction. Andreatta et al.[88] have shown that the growth and its termination of nanoaggregates can be understood directly from molecular structural considerations.[88] The polydispersity in a standard asphaltene sample ensures nanoaggregate initiation from the least soluble molecular fraction and nanoaggregate termination from the most soluble fraction, thereby creating a stable (nano)colloidal suspension. The resulting nanoaggregates resembles a "hairy tennis ball" with alkanes surrounding the outside. The governing chemical principles of asphaltenes that determine solubility and thus define asphaltenes have shown to be van der Waals (and polar) attraction of their aromatic ring systems versus steric repulsion of their alkane chains. Asphaltene molecules are relatively small having mean molecular weights of 750 g/mol. This restriction on molecular structure enables identification of key dynamics of asphaltene behavior, thereby extending the Yen model. This "modified Yen model" or equivalently the "Yen–Mullins model" includes: (1) the restriction of small molecular size of asphaltene molecules and (2) showing the effect of asphaltene intermolecular interactions on the dynamics of aggregate formation. Therefore, the determination or elucidation of the aromatic penta-fused PAH aromatic core in asphaltenes and their polydispersity is necessary to understand asphaltene nanoaggregation. As proven in the present work the Y-rule is a necessary tool to determine the stability of the CPPAHs structural candidates that show similar optical properties as the asphaltene chromophores.

Conclusions

One of the main interests in the oil industry is to understand the aggregation process of oil asphaltenes to be able to come up with methods, either chemical or physicochemical, as inhibitors, for example, to avoid the economical losses, during the extraction, transportation, and refining of petroleum, and to get the optimal use from the heavy fraction of any crude oil. To do this it is necessary to know the structure of asphaltenes. Asphaltenes are defined operationally, due to the many difficulties to elucidate their structure from experimental results. Asphaltenes present polydispersity because they are actually mixtures of cyclopenta-fused polycyclic aromatic compounds (CPPAHs) with N, S, and O atoms in their structure and aliphatic chains. The structure of the oil asphaltenes is ruled by stability. They present a very particular stability, which has been measured experimentally by their optical properties. This stability is closely related to their aromaticity. Therefore, to elucidate the complete structure of asphaltenes their aromaticity has to be known. Because asphaltenes are mixtures there may be thousand of possibilities of CPPAHs, of different size (in terms of number of fused rings) and structure, that compose their aromatic core. Thus, the necessity to be able to asses the aromaticity of CPPAHs in a quick and easy way arises. CPPAHs with an aromaticity close to the one presented by asphaltenes will be good structural candidates but hundreds of CPPAHs will have to be analyzed to be able to get to conclusions on the

asphaltenes structure that is close to reality. The need of finding a proper method that allows us to predict the aromaticity, in an easy way, of CPPAHs is required.

In this work, we have studied the local aromaticity of cyclopenta-fused polycyclic aromatic compounds (CPPAHs) by means of the qualitative Y-rule method and the well-accepted quantitative theoretical method NICS (nucleus-independent chemical shift). The quick and easy to apply Y-rule has been proven in the literature[37,39] to compare well with NICS results for the case of benzenoid PAHs but its capabilities for CPPAHs had not been proven. This last point is addressed in the present work.

A comparison of the π-electronic distribution obtained by the Clar sextet principle, or model, as determined by the Y-rule and the π-electronic distribution obtained from nucleus-independent chemical shift (NICS) calculations show that both methodologies agree. Therefore, the aromaticitity in CPPAHs may be calculated with both methodologies. The advantages of the qualitative Y-rule are that it is of particular importance for the case of large CPPAHs, it takes few minutes to be applied following a very easy methodology, and it provides a quick answer about the aromaticity and location of the resonant sextets without having to carry out theoretical calculations that take time and that can be costly depending on the size of the system. We have found that the five-member ring in the CPPAHs presents a low electron density, it is not aromatic, and presents a NICS value that is positive. This conclusion is also reached with the Y-rule.

We suggest that the use of drawing circles in each hexagon of the σ-frame in CPPAHs, to represent the distribution of the π-density, must be discouraged. This practice has been done due to the fact that it was not possible to know, in an easy way, where the resonant sextets and the double bonds are located.

We can now continue our investigations on the structure of oil asphaltenes and we will be able to apply the Y-rule to asses the stability of hundreds of CPPAHs and choose those, as possible asphaltene candidates, with the carbon ratio (ratio between carbon atoms in sextets and carbon atoms in double bonds) close to the measured asphaltene ratio.[38,41–43,46–48] Also, the effect on the stability by the introduction of heteroatoms in the CPPAH core will be studied. However, it is known experimentally that the replacement of carbon in PAH compounds with heteroatoms typically results in red-shift (higher wavelength) of the fluorescence maximum if there is any spectral effect.[90]

The Yen–Mullins model, which enables identification of key dynamics of asphaltene behavior requires the elucidation of the molecular architecture of the aromatic penta-fused PAH aromatic core in asphaltenes and their polydispersity to understand asphaltene nanoaggregation. As proven in the present work the Y-rule is a helpful tool in determining the stability of the CPPAHs structural candidates that show similar optical properties as the asphaltene chromophores.

Towards a computational treatment of polyoxometalates in solution using QM methods and explicit solvent molecules

Pere Miró, Josep M. Poblet, Josep Bonet Ávalos, and Carles Bo

Abstract: This study is aimed at developing an explicit solvent model for highly charged species such as polyoxometalates. The model includes solvent molecules in the first solvation shell explicitly, and long-range bulk effects and counterions as a set of single point charges. The model strongly stabilizes the electronic structure of the Keggin anion. The energies of the Kohn–Sham orbitals obtained using our model lie very close to those computed using the COSMO continuum solvent model; moreover, the total solvation energy evaluated with our model compares well to the value calculated by COSMO.

Key words: polyoxometalates, solvation, DFT, MD, discrete models.

Résumé : Cette étude a été réalisée dans le but de développer un modèle de solvant explicite pour les espèces fortement chargées, tels les polyoxométalates. Le modèle comprend explicitement des molécules de solvant dans la première couche de solvatation et les effets globaux à longue distance ainsi que les contre-ions sous la forme de charges ponctuelles. Le modèle stabilise fortement la structure électronique de l'anion Keggin. Les énergies des orbitales Kohn–Sham obtenues à l'aide de notre modèle sont très proches de celles calculées à l'aide du modèle de solvant continu COSMO; de plus, l'énergie totale de solvatation évaluée à l'aide de notre modèle se compare bien avec celle calculé à l'aide du modèle COSMO.

Mots-clés : polyoxométalates, solvatation, théorie de la fonctionnelle de la densité, modèles discrets, MD.

[Traduit par la Rédaction]

Introduction

The introduction of solvent effects in quantum chemical studies is nowadays an almost standard procedure thanks to the development of several continuum solvent models, which efficiently introduce the effect of solvent molecules by treating the solvent as a structureless continuum.[1–20] Although these solvation methods for uncharged molecules experienced notable advances in the last years, for charged species the models implicitly assume that no ion-pairing occurs and neglect the direct effects of counter ions and of other species in the liquid media. However, in the field of polyoxometalates (POMs), experiments demonstrate the dramatic influence of the environment on the electronic properties of POMs in solution. For instance, Weinstock et al.[21] reported that the redox potentials of Keggin anions strongly depend on the counter-ion and on the ionic force of the solution. Our group has been pioneering the theoretical study of the electronic structure of POMs during the last two decades[22–24] (by using mainly ADF), and realized that computational assessment of the redox properties of these species has to somehow include solvent effects. However, continuum solvent models are not able to introduce in their formulations the explicit nature of the counter-ion (such as Li^+, Na^+, or K^+), nor the ionic force of the solution. Therefore, there is a need to go one step further, and introduce those effects for reproducing such experimental results.

The conductor-like Screening Model (COSMO) developed by Klamt[2–4] as implemented in the ADF program package by Pye and Ziegler[1] is of common use in the polyoxometalate field. The present study makes use of COSMO as reference. Note that for a neutral species, continuum solvent models include the electrostatic effect of a polarized dielectric (with total charge equal to zero) onto the electron density of the solute. This mimics the interactions of solvent molecules with the solute. However, for a charged species,

since the total charge of the dielectric is not zero but equal to the charge of the species with opposite sign, in addition to the solvent effects, the continuum model must include the effects of the counter-ions too.

In recent papers, we described how classical molecular dynamics simulations applied to Keggin anions (see Fig. 1, $[XW_{12}O_{40}]^{n-}$, X = P, Si, Al; n = 3, 4, 5) in liquid water enabled the study of the structure of solvent water molecules around the polyoxometalates, and the effect of cations in the dynamic properties of POMs.[25] Also, the likely formation of ion pairs was discussed. Moreover, the same techniques have been applied to investigate the structure of water encapsulated in the giant Mo_{132} nanocapsule.[26] Other groups also demonstrated the usefulness of classical MD in the study of ion aggregation in concentrated solutions of Keggin anions in aqueous and methanol solvents.[27] Given that we had at hand snapshots of instant configurations of the solvent water molecules and the counter-ions around the Keggin anion, we decided to use this data to develop an explicit solvation model and investigate the effects of solvent water molecules, long-range solvent effects, and counter-ion effects on the electronic structure of POMs. In this paper, we report the results of such a study, and discuss how this microscopic model of the solvent compares to the COSMO continuum solvent model. The final goal is to develop a cheap and standard protocol that would include the effect of additional species in solution and simulate as closely as possible the nature of the liquid media that is used in the real-life laboratory.

Computational details

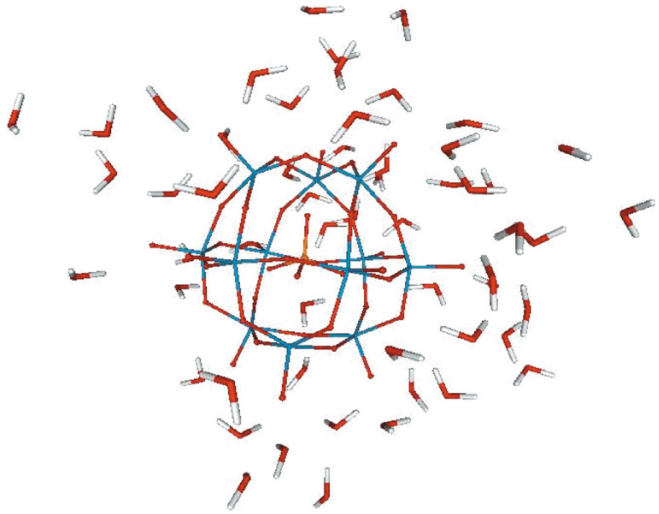
Classical molecular dynamics simulations were carried out using the GROMACS 3.2 program.[28] Two water models were considered, the SPC/E[29] and the TIP3P.[30,31] Lennard-Jones parameters and atomic charges for the polyoxometalate were developed previously in our group[32] and used here also. The polyoxometalate was kept rigid during the simulation. For Na^+ cations, the parameters developed by Lee et al.[33] were used. Quantum mechanical calculations were carried out using DFT-based methods implemented in the ADF2004 program[34–37] The local spin density approximation characterized by the electron gas exchange was used with Vosko–Wilk–Nusair[38] (VWN) parameterization for correlation and Becke and Perdew[39–42] nonlocal corrections were added to the exchange and correlation energy, respectively. The basis set was composed of triple ξ+ polarization (TZP) Slater basis sets extracted from the ADF library. The quasirelativistic scalar ZORA formalism with corrected core potentials was used.[43–47]

First solvation shell

Modeling the first solvation shell properly was our first goal, since in many cases (metal ions, highly charged species, proteins, etc.) specific interactions operate between the solute and the solvent molecules. These interactions originate with hydrogen bonds and van der Waals forces, which are poorly described with continuum models. Solvent molecules may be highly structured around the solute; thus the treatment of solvent in such species often uses an explicit model.

The Keggin anion has a high negative charge and polarizes the surrounding water molecules, which form multiple hydrogen bonds with the external oxygens of the polyoxometalate. To describe these interactions as accurately as possible, we decided to include the first solvation shell explicitly in the DFT calculation.

Fig. 1. A Keggin anion $[PW_{12}O_{40}]^{3-}$ surrounded by some water molecules.



Several configurations of the solvent around the polyoxometalate were chosen from molecular dynamics simulations with two different water models, the SPC/E and the TIP3P. A preliminary study was carried out with a system that included the polyoxometalate and the first 24 neighboring water molecules. For both types of water the variations in binding energy, energies of the frontier orbitals HOMO and LUMO, and their gap, are rather similar, but in TIP3P the variations in HOMO and LUMO energies are slighly lower than in SPC/E model (see Supplementary data). Also the convergence of the SCF process was better in TIP3P than in SPC/E, probably because the H–O–H angle in SPC/E (109.47°) is larger than in a real water molecule. The H–O–H angle in TIP3P water molecules is 105.52°. As a result of this previous study all the configurations were taken from simulations that used TIP3P model.

The next question to answer was how many water molecules the first solvation shell has to contain. To answer this question, a set of calculations was carried out increasing the size of the first solvation shell (24, 49, 74, 99), and the interactions between water molecules and the POM. and water molecules with themselves were analyzed. Following Goddard's protocol,[48] we estimated the energy of the hydrogen bond between water molecules by using the same set of water clusters $(H_2O)_n$ (n = 1 to 16) (see Supplementary data). Using the DFT method described above, we obtained a value of 5.13 kcal mol^{-1}, which is only 0.55 kcal mol^{-1} smaller than the value obtained using the X3LYP functional.[48] Then, we assessed the number of hydrogen bonds between water molecules in the solvation shell and the number of hydrogen bonds between the polyoxometalate and the solvent by performing a series of single point fragment calculations. This assumption was made because our interest was to see whether the number of hydrogen bonds between the solvent and the polyoxometalate converges or not when the number of solvent molecules in the solvation shell increases.

Fig. 2. Number of hydrogen bonds between water molecules and between water and polyoxometalate in different systems.

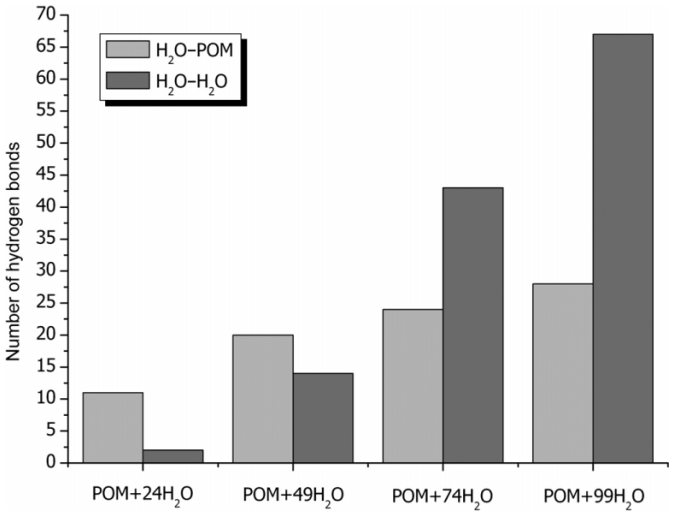


Figure 2 shows the number of hydrogen bonds between water molecules and between water and the polyoxometalate, in systems with different numbers of water molecules in the first solvation shell. The number of hydrogen bonds between water molecules increased with the size of the solvation shell; the number of hydrogen bonds with the polyoxometalate increased significantly from a shell of 24 water molecules to a shell of 49, but above 49, the increase remains nearly constant. Above 49 water molecules in the first solvation shell, the increase in the number of hydrogen bonds can be explained as an increase in interaction between water bulk and the polyoxometalate, and not to a true increase in the number of hydrogen bonds since the POM surface is already fully covered by solvent molecules. Since the computational cost strongly depends on the number of water molecules, we considered that 49 molecules in the solvation shell was a suitable number.

By introducing explicit water molecules in the DFT calculation, the Kohn–Sham molecular orbitals suffered a strong stabilization, as shown in Fig. 3. The effect is stronger when 24 and 49 water molecules are included, and seems to converge afterward. This stabilization is directly related to the addition of extra water molecules, but it is worth noting that it affects all the orbitals equally. In Fig. 3, HOMO and LUMO energies and the HOMO–LUMO gaps are shown, and it is clearly seen that the addition of water molecules in the first solvation shell shift both the HOMO and the LUMO down, while the HOMO–LUMO gap remains nearly constant (standard deviation 0.07 eV) in all cases. The addition of 99 water molecules is not enough to reach the effect of COSMO, since the levels still appear about 4 eV above.

Long-range electrostatic solvent effects

The second effect that one has to take into account is the long-range electrostatic interactions with the bulk of the solvent. This effect is also present in solids and well known as the Madelung field. Following the same approach as above, we prepared a set of calculations for a unique solvent configuration, with an increasing number of solvent molecules represented as point charges (using the TIP3P parameters,

Fig. 3. Energies of the HOMO and the LUMO (lines and left scale), and energy gap (dots and right scale).

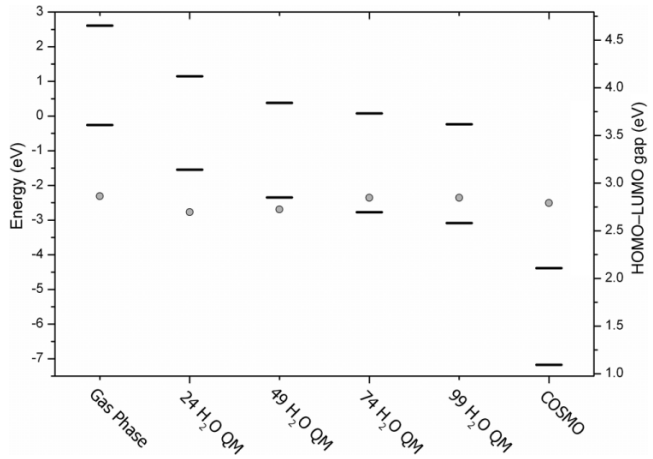

Fig. 4. Energies of HOMO (black line) and LUMO (red line) as function of the number of water molecules included as point charges.

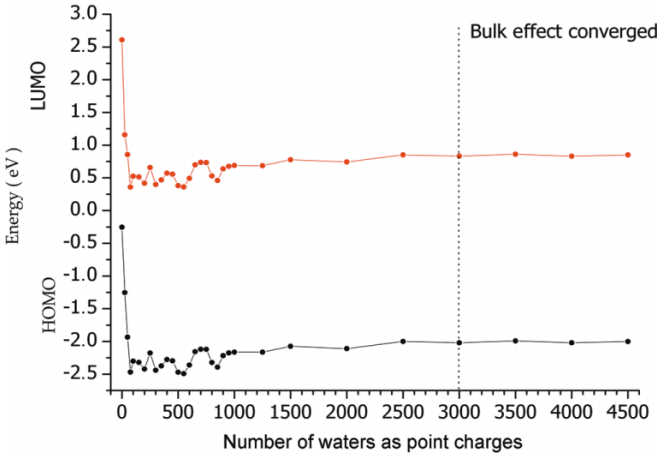
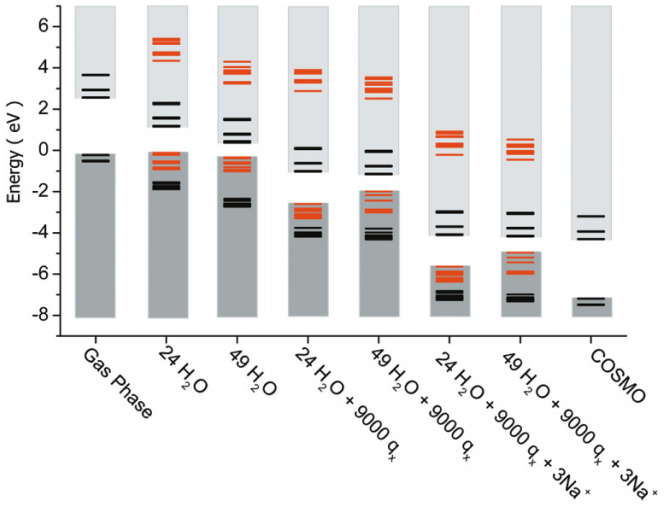


i.e., 3 point charges per molecule) in spherical shells, and performed a single point calculation to explore how many solvent shells should be included until reaching convergence. As before, we recorded the energies of the HOMO and the LUMO levels. Figure 4 plots the HOMO and LUMO energies as a function of the number of water molecules. Note that when few water molecules were included, the orbitals were strongly stabilized by more than 2 eV, and that after the first 150 water molecules a fluctuation in the energies was observed. After including 3000 water molecules, the HOMO and LUMO energies remained constant; therefore we considered that the electrostatic field converged at this point. Note also that the HOMO–LUMO gap remained constant, since the electrostatic field created by the set of point charges is isotropic.

Counter-ion effects

In addition to the specific interactions between the first solvation shell and the POM, and the long-range electrostatic field created by the bulk solvent, the remaining term is the effect associated with the counter-ions. In this case, since the POM is $[PW_{12}O_{40}]^{3-}$, three Na^+ cations must be included.

Fig. 5. Energies for the eight highest occupied and lowest empty levels for the different models. (Black: levels belonging to the POM; red: levels of water molecules; dark grey: occupied levels; light grey: empty levels).



At this point we identified two approaches for including the counter-ions in our model, either as three single point charges at locations extracted from a snapshot, or as a spherical distribution at a given radius. Since we had access to the radial distribution function, g(r), of the sodium cations computed from the simulation, we used that information to determine a reasonable value for the radius of a spherical charge distribution. A plot of g(r) of Na^+ is included in the Supplementary data. By using the intensity (I_n) of g(r) at each distance form the center of the anion (r_n), we defined a weighted-averaged radius <r> of the distribution as:

$$[1] \qquad \langle r \rangle = \frac{\sum_n I_n r_n}{n}$$

Thus, we computed <r> = 14.28 Å, and created a spherical distribution of 1446 point charges, with a total charge equal to the charge of the polyoxometalate with opposite sign, i.e., –3. By including this additional set of point charges, we obtained energies for the HOMO (–6.988 eV) and for the LUMO (–4.172 eV) that were quite close to the values produced by a continuum solvent model such as COSMO (–7.183 and –4.308 eV, respectively).

In Fig. 5, the reader can observe the progressive stabilization of the electronic structure of the POM in the different models. The first system in the left hand side corresponds to a gas phase calculation without any solvent effect. Moving to the right, the effect of the first solvation shell with 24 or 49 water molecules, the effect of the bulk as a set of 9000 point charges, and finally the effect of the three sodium cations are included step by step. As a reference, the energies for HOMOs and LUMOs obtained in a COSMO calculation are shown on the right hand side. Note the nice agreement between the largest model and COSMO.

Discussion

The model, including the first solvent shell explicitly, the solvent bulk, and the counter-ions as point charges, is able to achieve the same stabilization of the electronic structure of a Keggin $[PW_{12}O_{40}]^{3-}$ anion as the COSMO continuum solvent model. As we mentioned in the introduction, COSMO includes two effects of different types, one arising from the solvent and the other one due to the neutralization of the charge by the counter-ions. Our model includes both these effects, and enables us to quantify and analyze them separately. By increasing the complexity of the solvation model step by step, it allow us to evaluate different terms, namely, the stabilization energies due to the counter-ions (E^c), due to the first solvation shell (E^{ss}), and due to the bulk (E^{bulk}). This task is easily carried out by selecting a suitable fragment and by evaluating its energy. To accomplish this, we selected different models as shown in Table 1, and defined E^c, E^{ss}, and E^{bulk} as follows: The stabilization energy due to the counter-ions is $E^c = (E_1 - E_2)$, that due to the first solvation shell is $E^{ss} = (E_3 - E_4 - E_5)$, and that due to the bulk as $E^{bulk} = ((E_2 - E_3) - (E_6 - E_5))$.

Table 1. Models and the corresponding labels and binding energies.

Label	System	Energy (ev)
E_1	POM + 49 H_2O + 9000q_x + counter-ions	–1168.25
E_2	POM + 49 H_2O + 9000q_x	–1164.66
E_3	POM + 49 H_2O	–1136.8
E_4	POM	–442.97
E_5	49 H_2O	–689.90
E_6	49 H_2O + 9000q_x	–713.50

Table 2. Solvation Energy terms (values in eV).

	COSMO	Our model
E^{solv}	–10.88	–11.78
E^{ss}	—	–3.51
E^{bulk}	—	–4.68
E^c	—	–3.59

Therefore, we can also evaluate the total solvation energy as the sum of the three terms, E^c, E^{ss}, and E^{bulk} . This total solvation energy, computed by using our microscopic solvent model, can be directly compared with solvation energy computed using the COSMO continuum model. The comparison in Table 2 shows the almost perfect agreement between the two models. The three distinct terms are quite similar in value, indicating that hey contribute to stabilizing the solute in a similar way.

Conclusions

We presented a study aimed at developing an explicit solvation model and applied it to highly charged species, a Keggin polyoxometalate. The model makes use of DFT-based methods as implemented in the ADF program, and of instant configurations of the solvent molecules extracted from classical molecular dynamics simulations. The model includes, step by step, the specific effects of the first solvation shell, since solvent molecules in this shell are explicitly introduced in the DFT calculation. The long-range electrostatic effects created by the bulk of the solvent and by the

counter-ions are introduced in the model through the use of point charges.

The model strongly stabilizes the molecular orbitals of the Keggin anion, and reaches a degree of stabilization fully comparable to COSMO, which was used as a reference. This stabilization is progressive, and increases with the complexity of the model. In addition, the model enables quantifying the effects of the solvent and the counter-ions by splitting the total solvation energy into three terms. The sum of these terms directly compares and nicely agrees with the solvation energy computed by COSMO.

The main limitation of the results presented here is the lack of sampling. All the results were obtained using just one solvent configuration. We think that by increasing the number of configurations a better model could be developed. On the other hand, the model presented here is a first step towards the computational modeling of complex polyoxometalate systems, which should explicitly include additional electrolytes used in the experiments to fix the ionic force. We think that this challenge could be achieved in the near future.

Kohn–Sham DFT and ligand-field theory — Is there a synergy?

Claus E. Schäffer and Jesper Bendix

Abstract: In forming electronic states of the partially filled shell of transition-metal atomic and molecular systems, real, symmetry-based, fixed, Kohn–Sham eigenorbitals can be used to bridge KS-states with strong-field, ligand-field states. Thereby, DFT computations, restrained by the use of these frozen orbitals of the so-called average-of-configuration type, allow a central-field modeling of the partially filled shell whose Hamiltonian matrix consists of mutually orthogonal diagonal and non-diagonal parts, of which only the former can be computed. Mutually orthogonal operators of ligand-field theory are particularly suited to parameterize the energy "data" obtained from the bridges between molecular Kohn–Sham DFT states and ligand-field states. With the d^2 configuration as the simplest example encompassing both ligand-field and interelectronic repulsion, each one-electron parameter, though defined by energy differences of perturbed d orbitals, is associated with a 45×45, diagonal, theoretical, strong-field-type coefficient matrix of the ligand field repulsion model (LFR), which is mapped in a one-to-one fashion onto a likewise diagonal KS-DFT computational energy matrix. For sets of mutually orthogonal operators, the mapping determines the value of any such ligand-field parameter as a scalar product between the DFT matrix and the coefficient matrix of the associated ligand-field operator. Each and every two-electron parameter of LFR is in the same strong-field function basis associated with a 45×45 coefficient matrix that includes a non-diagonal part. This matrix, nevertheless, by the formation of a scalar product with the appropriate diagonal, computational DFT matrix, provides the value of the two-electron parameter. In spite of the lacking non-diagonal DFT information, its non-diagonal elements of the two-electron interelectronic repulsion matrices are indirectly accessible through the parameterization based upon the computed diagonal DFT matrices combined with the mapping of the DFT energy results onto the parametric LFR. In this way, LFR delivers back to DFT a quantification of the deviation of the systems' eigenbasis from the DFT-computed states, which are defined by having unit occupation numbers. This work focuses firstly on using the LFR model for forming a full DFT energy matrix and dissecting it into mutually orthogonal one- and two-electron parts and secondly on the use of the two-electron parts to obtain a complete ligand-field image of a nephelauxetic, molecular atom, intrinsic of the chemical system.

Key words: Kohn–Sham DFT, average-of-configuration, ligand-field theory, interelectronic repulsion, mutually orthogonal operators.

Résumé : Dans la formation des états électroniques de la couche partiellement remplie des systèmes atomiques et moléculaires d'un métal de transition, on peut utiliser les orbitales propres de Kohn-Sham DFT, réelles, fixes et basées sur la symétrie pour faire le pont avec des états de champ de ligand dans la formulation de champ fort. Il est donc possible que des calculs selon la théorie de la fonctionnelle de la densité (TFD) restreints par l'utilisation de ces orbitales fixes du type connu sous le nom de configuration moyenne puisse permettre d'utiliser un modèle à champ central d'une couche partiellement remplie dont la matrice de l'hamiltonien serait formée de parties mutuellement orthogonales diagonales et non diagonales desquelles on ne calculerait que les premières. Les opérateurs mutuellement orthogonaux de la théorie du champ de ligand sont particulièrement appropriés pour déterminer les paramètres des données d'énergie obtenues à partir des ponts entre des états moléculaires de la TFD selon Kohn–Sham et les états du champ de ligand. Avec la configuration d^2 comme exemple le plus simple recouvrant le champ de ligand ainsi que la répulsion interélectronique, chaque paramètre pour un électron, même s'il a été défini par des différences d'énergie d'orbitales d perturbées, est associé à une matrice 45×45, diagonale, théorique avec un coefficient du type champ fort du modèle de la répulsion du champ de ligand (RCL) qui peut être décrit d'une façon un à un sur une diagonale apparentée d'une matrice d'énergie calculée de la théorie de la fonctionnelle de la densité selon Kohn–Sham (TFD-KS). Pour les ensembles d'opérateurs mutuellement orthogonaux, la représentation permet

d'attribuer une valeur pour chacun des paramètres de champ de ligand sous la forme du produit scalaire entre la matrice de la TFD et le coefficient de la matrice du l'opérateur du champ de ligand qui lui est associé. Tous et chacun des paramètres à deux électrons du coefficient du type champ fort du modèle de la RCL fait partie de la même fonction de base du champ fort associé avec le coefficient d'une matrice 45×45 qui inclut une partie non diagonale. En raison de sa formation par un produit scalaire impliquant une matrice TFD diagonale calculée appropriée, cette matrice fournit le paramètre à deux électrons, malgré tout. Même s'il manque l'information TFD non diagonale, ses éléments non diagonaux des matrices de répulsion interélectroniques à deux électrons sont indirectement accessibles par le biais de la paramétrisation basée sur les matrices diagonales TFD calculées combinées avec la représentation de l'énergie TFD conduit à l'obtention de la RCL paramétrisée. De cette façon, la RCL fournit à la TFD une quantification de la déviation des bases propres du système à partir d'états calculés par la TFD qui sont définies par des nombres d'occupation d'unités. Ce travail est principalement orienté vers l'usage du modèle de la RCL pour créer une matrice complète d'énergie TFD et sur sa dissection en parties à un et à deux électrons mutuellement orthogonales et ensuite vers l'utilisation des parties à deux électrons pour obtenir une image à champ de ligand complète d'un atome moléculaire néphélauxétique, intrinsèque du système chimique.

Mots-clés : théorie de la fonctionnelle de densité de Kohn–Sham (TFD-KS), moyenne de configuration, théorie du champ de ligand, répulsion interélectronique, opérateurs mutuellement orthogonaux.

[Traduit par la Rédaction]

Introduction

A paper by Ziegler at al.[1] implied that Kohn–Sham DFT was capable of providing an energy that corresponds to an expectation value of a Hamiltonian of a wave-function description of a molecule. This capability has been used in recent years to illuminate and revive ligand-field theory. Tom told us in Danish, after having been elected a member of the Danish Royal Society of Humanities and Sciences, that he, 40 years ago, had attended a course on ligand-field theory, given by one of us at our university. He added with a smile that he had not appreciated it. Then, last August in Vålådalen, Sweden, at the 50th anniversary of the Löwdin summer schools on quantum chemistry, he expressed that he had come to appreciate it. We therefore thought it would be appropriate for this Special Issue of the *Canadian Journal of Chemistry* to illustrate some of the possible synergies between KS-DFT and ligand-field theory as we see them.[2–6]

At first, we emphasize that the novelty here is a more thorough discussion of the consequences of using KS-DFT as a tool replacing spectroscopic results. Our eyes are those of experimentalists and ligand-field theoreticians. We summarize that the ligand-field repulsion model (LFR), whose Hamiltonian does not contain the spin, is the sum of a ligand-field part and an interelectronic repulsion part, both acting on a d^q configuration. For half a century, it has been known that two apparently rather different formulations of this "quantitative LFR", the weak-field and the strong-field formulation, are mathematically equivalent. The weak field is diagonal in the interelectronic repulsion (R), the strong field in the ligand-field (LF) parameters. The number of LF parameters is determined by the symmetry of the ligand field and the particular choice of parameters may also be made on the basis of symmetry. The most famous LF parameter is the so-called spectrochemical parameter or cubic-field splitting parameter Δ, which for a metal complex of T_d symmetry is defined as the one-electron energy difference between the $e(T_d)$ and the $t_2(T_d)$ set of "d" orbitals, where the quotation marks refer to the fact that the orbitals of the molecular situation have a d orbital parentage. Once the one-electron parameters have been defined, the concept of the strong-field function basis is defined physically. In conventional LFR, all d^q functions are naturally chosen to be eigenfunctions of $\hat{S}^2$, as the Hamiltonian of LFR commutes with this operator.

Recent developments based upon a KS-DFT model have focused on the requirements of this model. The fact that the energies, which in our context are obtainable by the use of KS-DFT as a computational model, correspond to d^q functions that are single Slater determinants[2] means that the computed energies in wave-function theory are expectation values, rather than eigenvalues, of the Hamiltonian, and the associated KS state functions must be conceived as eigenfunctions of $\hat{S}_z$ rather than $\hat{S}^2$. Nevertheless, the energies directly obtained from KS-DFT belong to a strong-field situation of LFR, but the energies are different from those of the conventional situation. In LFR, the energy matrix based upon single Slater determinants is much further away from being diagonal than is the case in the conventional strong-field description. Thus, a major part of the effect of the exchange integrals is contained in the non-diagonal elements of this single-determinant basis, which we shall call for short the DFT-basis. This partial loss of the exchange-information from the DFT computations would seem to be a fatal problem and is of course a problem in a general sense. However, LFR operates by its determination of energy parameters that allow the eigenfunctions to be determined through the model, and from the eigenfunctions, all the other properties, which are consequences of the model. Here, the KS-DFT mimicking of LFR has up until now[2–6] been extremely useful because its computational results have agreed well with the empirical data on which ligand-field theory built its well-known successes in inorganic chemistry as well as its pedagogical successes.[7] Therefore, KS-DFT already has the status of being a valuable supplement or, even to a certain extent, a replacement of spectroscopic experiments.

This story also seems like a little miracle in view of the fact that ligand-field theory is so horribly simple that no one would ever have thought that it could be supported computationally in such a fundamental way. Moreover, in our previous work, our main focus was the interelectronic

repulsion (R) of ligand-field theory rather than the ligand field, LF, itself. However, our analyses cast light upon the combined model, LFR, and left the result that the model Hamiltonian matrix of LFR, after having been associated with computed KS-DFT energies, contained more information[6] regarding the partially filled shell than was extractable from KS-DFT without LFR.

Here, we focus upon the extraction of this additional information from the bridging between DFT and LFR in the hope that LFR can deliver some credit back to DFT, which has the deficiency of partially hiding the two-electron interaction energies.

The KS-DFT description

An unusual property of Kohn–Sham DFT: fractional occupation numbers

The one-electron density is introduced into KS-DFT by means of KS-orbitals. This feature of KS-DFT allows non-integer occupation numbers to be associated with well-defined computed energies. Thus, when the issue is a mimicking of LFR, the ten d spin-orbitals may be all occupied evenly so as to define the eigenorbitals of a totally symmetrical atomic or molecular system. This particular choice of occupation numbers, named the average-of-configuration, AOC,[2,3,8,9,10] has been suggested as the first step of these kinds of computations. The fact that the energy associated with the AOC is not the average energy of the configuration was at the same time pointed out.[8] If KS-DFT is constrained by the use of "average-of-configuration" frozen orbitals, an additional one-to-one relationship between unit occupation number pairs of KS spin orbitals and d^2 Slater determinants based upon real d orbitals can be established.[2,3] This means that KS-DFT molecular "d^2" energies can be equated with d^2-parameterized energies of the ligand-field theory. These energies may comprise effective two-electron operator contributions.

Many years ago, Ziegler et al. argued[1] that unit (combined with zero) occupation numbers were the key to bridging from the Hartree–Fock–Slater model to wave function theory in the form of Slater determinants. Unit occupation numbers of the AOC spin-orbitals make the basis for the mimicking of LFR, the AOC being the basis for the KS-DFT definition of the fixed (frozen) orbitals.

The ligand-field repulsion description

Quantitative ligand-field theory and the orthogonal operators formalism

LFR is a sum of operators: a sum of one-electron operators representing LF and of two-electron operators representing R. Both kinds of operators act on the configuration d^q (or p^q or f^q) and when the chemical system is molecular and the l value of the orbitals becomes subclassifiable (for example, for d orbitals in tetrahedral symmetry as $t_2(T_d)$ and $e(T_d)$), the R part of LFR causes this model to include a subconfiguration interaction, for example, the interaction[3] between the $^3T_1$ states of the subconfigurations et_2 and t_2^2 is a part of LFR. By the inclusion of this type of correlation, LFR reaches in this special respect beyond Hartree–Fock.

LFR is often formulated on a symmetry basis. Then, an inherent heterogeneity is revealed by the fact that the LF operators, which are defined upon a d^1 function space, have the symmetry assumed for the molecular system, while the R part, which is defined on a d^2 function space, is parameterized by the Slater–Condon–Shortley (SCS) parameters or equivalent sets, or even sets richer in parameters, such as the parametric multiplet term (PMT) sets. These parameterizations imply spherical symmetry. The consequence of these essentially different definitions is that the LF and R operators are mutually orthogonal on d^2 (vide infra) and remain so for the other d^q configurations (see ref. 22 and refs. cited therein). Another consequence is that quantitative LFR encompasses a central-field view on ligand-field theory (LFT) by parameterizing the R part as if the chemical system were spherical and by using basis orbitals that are eigenfunctions of the angular momentum operator $\hat{l}^2$. Moreover, by letting the LF part be defined solely by the symmetry of the chemical system, the theoretical part of LFR lies to 100% in the angular factors.

In the last two decades, we have used the SCS model in terms of the parameters D and E,[11] whose associated coefficient operators are mutually orthogonal alternatives to the conventionally used non-orthogonal operators of the Racah B and C parameters. D is Jørgensen's 50 year old spin-pairing energy parameter,[12] which we have analyzed to have a spin as well as a seniority origin, and E is the supplementary parameter of the SCS model, which, in addition, is connected with D by its associated coefficient operator being orthonormal to that of D. The orthogonality means that the parameter value can be obtained as a scalar product between the LFR Hamiltonian operator and the coefficient operators of the parameters; the normality means that the values of D and E are directly comparable in the following sense: for an atomic system, the sum of the squares of the barycentered eigenvalues, $<\hat{H}_R|\hat{H}_R>$, is a sum of the following two contributions from the parameters

$$[1] \qquad <\hat{H}_R|\hat{H}_R> = D^2 <\hat{Q}[D]|\hat{Q}[D]> + E^2 <\hat{Q}[E]|\hat{Q}[E]>$$

The important point here being that no cross terms occur, contrary to the case with the conventional parameterizations of the SCS model.

About 30 years ago, it became the custom among atomic spectroscopists to embody their observations in a quantum mechanical modeling, which gradually became more and more refined and provided with more and more well-defined parameters that were able to accurately reproduce their data sets. We used one of these models, which had a Lie-group history among theoretical physicists[13] and which encompassed all d^q configurations under one symmetry roof, and another one developed by the atomic spectroscopists,[14] which we slightly modified for our purposes, namely the determinations of spin-orbit parameters as accurately as possible from the spectroscopic J-level data.[15] We named our model the parametrical multiplet term model (PMT) because it used the energies of the multiplet terms as its major parameters. These multiplet term parameters are not directly determinable from spectroscopy, whereas their spin-orbital components, their levels are. Thus, by optimizing the energies of the multiplet terms, the standard deviations on the spin-orbit coupling constants based upon the full spectro-

scopic information, that is, the complete set of experimental energy data for all the levels of the d^q configuration, became minimized.

In our DFT work on atomic systems,[2,4] the PMT model was used in the first place to obtain a maximally flexible repulsion description intended to mimick the experimental data tightly.[4] However, when comparing the results of the computed PMT energies with those of the SCS model by confronting these two sets of "data" with experimental energy data, it turned out that the SCS model gave the better agreement.

For d^2 systems, the extension of the SCS model to the PMT model is particularly simple and instructive. Thus, the PMT model has a Hamiltonian acting on the full d^2 function space just as the SCS model does. Moreover, the four parameters, which the PMT model requires for obtaining a 100% fitting of the energy differences between the five multiplet terms of d^2, can be chosen in such a way that a contraction[4,6] by discarding two of the parameters results in the SCS model.

The superstructure of the ligand-field repulsion model: weak-field and strong-field limits

The weak-field and strong-field representations of LFR are equivalent representations connected by a unitary transformation. The former one is diagonal in R, the latter one in LF. If real functions are used as the orbital basis and the two-electron functions are chosen to be eigenfunctions of $\widehat{S}^2$, the transformation matrix is equal to a permutationally symmetrized Racah-lemma matrix,[16] which means that it is purely symmetry-determined. The concepts of the weak-field and strong-field limits refer to the energy expressions of the diagonal elements of the corresponding matrices. We shall refer to the special strong-field diagonal whose functions are single Slater determinants, and therefore eigenfunctions of $\widehat{S}_z$, but not necessarily also eigenfunctions of $\widehat{S}^2$, as DFT-based (vide infra).

By attaching unit occupation numbers to the frozen "d" spin orbitals that are molecular orbital eigenorbitals of KS-DFT, chemical situations arise, which translate to Slater determinants of WFT and LFR. These Slater determinants are diagonal in LF, and therefore belong to the class normally associated with the limiting strong-ligand field. It should be emphasized that this never means that R is not present. Therefore, although the concepts of the weak- and the strong-ligand-field limits are mathematically symmetrical concepts, this symmetry does not hold chemically because in the weak-field limit, the LF is actually not present and its radial parameters therefore cannot avoid being vanishing.

The fact that the conventional LFR model is semi-empirical in the sense that the angular factors make up all its theory while the radial factors are purely empirical is responsible for the success of the model. That is not to say that this fact ever provided an understanding of why it furnished the model with such a width within the chemistries of systems with partially filled shells of atomic parentage. However, the new fact that the empirical parameters of LFR have now become so satisfactorily computationally available came as a complete surprise because of the extreme simplicity of the model. We chose to emphasize this by using the term "data" for the set of energy expectation values obtained by the computational DFT model.

The AOC computation is unique in a chemical sense and from the point of view of WFT; chemically, because it is used to define the complete orbital basis so that it is adapted to the symmetry of the chemical system, and from a WFT point of view, because it is defined by fractional occupation numbers. Last but not least, the AOC computation is also unique within our approach by being the only restricted computation for any given chemical system that involves an SCF computation.

The fact that this SCF computation consists of a series of consecutive steps furnishes a quantification of the conventional qualitative superstructure of ligand-field theory: For a molecular system, the starting point of the iterative SCF procedure is the completely ionic situation as far as orbital occupation numbers are concerned. Then, the atomic orbitals, while keeping their occupation numbers unchanged, are gradually modified so as to end up being Kohn–Sham molecular orbitals, which are quantitatively specified. In this way, the qualitative superstructure of semi-empirical LFT has become quantitatively illustrated by the AOC computation.

Sets of mutually orthogonal conglomerate operators for describing LFR

The Hamiltonian of LFR acting on a d^q configuration can, for a cubic system using the SCS model, be written in the simple form

$$[2]\qquad \widehat{H}_{LFR} = E_{av}\widehat{1} + \Delta\widehat{Q}[\Delta] + R\widehat{Q}[R] = E_{av}\widehat{1} + \Delta\widehat{Q}[\Delta] + D\widehat{Q}[D] + E\widehat{Q}[E]$$

where E_{av} is the average energy of d^q, D is Jørgensen's spin-pairing energy parameter, and E is the spatial energy parameter. In the first term, $\widehat{1}$ is the scalar operator whose matrix in all function bases is a unit matrix, $\Delta\widehat{Q}[\Delta]$ is the ligand-field operator, and $\widehat{Q}[D]$ and $\widehat{Q}[E]$ are mutually orthogonal coefficient operators, which are diagonal when the ligand field is vanishing so that the symmetry is spherical. Moreover, all the coefficient operators are orthogonal to $\widehat{1}$ by being barycentered.

Mutual orthogonality of two operators $\widehat{A}$ and $\widehat{B}$ is, when the function bases are real, defined by the scalar product relationship

$$[3]\qquad \langle \widehat{A} \mid \widehat{B} \rangle = \sum_{i,j} \mathbf{A}_{ij}\mathbf{B}_{ij} = 0$$

and this operator overlap[16] is accordingly independent of the function basis. A useful corollary to eq. [3] is that it also defines the scalar product of the matrices.

The value of an energy parameter can be found by forming the overlap (or scalar product) between the Hamiltonian operator and the coefficient operator associated with the parameter. We have, for example, using eq. [2]

$$[4]\qquad < \widehat{H}_{LFR}|\widehat{Q}[D] >= D < \widehat{Q}[D]|\widehat{Q}[D] >$$

as a consequence of the orthogonality between, on one hand, the LF and R operators, and on the other hand, between $\widehat{Q}[D]$ and $\widehat{Q}[E]$.

If H_{LFR} is replaced by H_{obs}, where H_{obs} is hypothetically

assumed to be an exact observation of the complete H_{LFR} matrix referring to a known function basis, then the value obtained for D is identical to the value obtained by a least-squares procedure, and the fitting will be 100%. An analogous description applies to a non-exact observation except that there will now be a residual diagonal matrix, which by the very procedure is orthogonal to the matrix of $\widehat{Q}[D]$. When all the three barycentered parameters of eq. [2] have been determined, the self overlap or norm square of the residual matrix is the total variance of the fitting. The norm squares of the operators depend on the function space (but not on the function basis). However, the concept of the diagonal norm square is useful provided the basis is defined and interesting. Then, the ratio between the diagonal norm square and the full norm square is the degree of diagonality, which is always of interest if the elements of the diagonal are the observations. For d^2, the norm square of $\widehat{1}$ equals 45, and the same is true for the diagonal norm square. The norm squares of the SCS coefficient operators, $\widehat{Q}[D]$ and $\widehat{Q}[E]$,[4,11] are by their definition equal to 400/7 with the consequence that the Landé-like formula applies

$$[5] \qquad E_{av}[S{=}0] - E_{av}[S{=}1] = 2D$$

For the norm square, area, of $\widehat{H}_R$ the equation

$$[6] \qquad < \widehat{H}_R|\widehat{H}_R >= 45(E_{av})^2 + (400/7)D^2 + (400/7)E^2$$

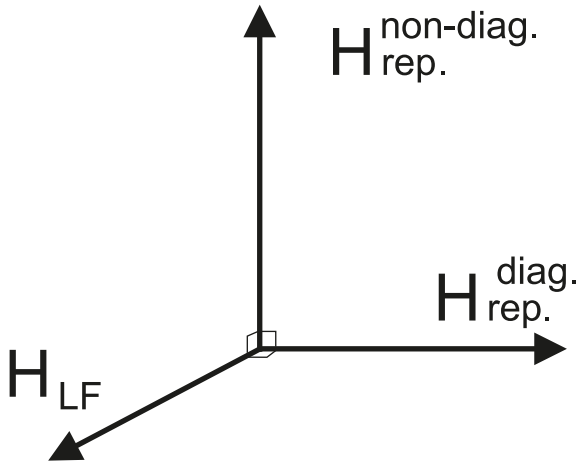
tells that the area of the model Hamiltonian is equal to the sum of the squares of the normalized parameters, which is an expression of extended Pythagorean form that we use when the associated coefficient operators are normalized to unity over the full function space, here d^2. For the sum of the squares of the observed Hamiltonian matrix minus the total variance, the expression in eq. [6] applies as well.

The norm square has a further use based upon the following statement: Because two operators $\widehat{Q}[D]$ and $\widehat{Q}[E]$ say, have the same norm squares, then if $D > E$, the contributions of D to the area of LFR is also larger than that of E. This statement has, of course, a quantitative corollary.

The experimental information is, in practice, never complete. The most common situation for the semi-empirical LFR is that a limited number of eigenvalue differences are the observed quantities and the problem is to use the model to find the eigenbasis corresponding to the parameter values that diagonalize the parametric energy matrix. By using KS-DFT, we obtain the special LFR situation that the number of "observations" is mathematically maximal but the kind of observation is far from being perfect because the "experimental" method, that is, computation of the DFT energies dictates the DFT-basis in which the R operators are not diagonal and for some operators far from diagonal. The orthogonal operator's formalism is especially effective for analyzing this situation when it is applied to the complete function basis in which case the scalar product procedure is available for determining the individual parameters. However, since we have no "observations" relating to the non-diagonal elements of LFR in the DFT-basis, only the diagonal part of this matrix contributes to the scalar products.

For the chemical system being a molecular d^q system of lower symmetry than cubic, the ligand-field terms of the same form and in the same basis as that contained in eq. [2] must be chosen hierarchically and added. These terms are then mutually orthogonal one-electron terms, which automatically are orthogonal also to the two-electron terms, and they are favored by being diagonal in the DFT-basis,[13,17] which means that the one- and two-electron operators are also diagonally orthogonal in this basis. Looking back at the atomic chemical system, one has to remember that here the curious feature applies that the DFT computation model nevertheless requires the DFT strong-field basis even though the radial parameters of LF are zero.

Fig. 1. Illustration of three mutually orthogonal components of LFR in the DFT-basis. With the basis fixed, mutual operator orthogonality and mutual matrix orthogonality become synonymous (cf. eq. [3]). Only the two horizontal parts can be DFT-computed. Once the R parameters have been computed, the non-diagonal component of LFR is also known.



In any given function basis, a simple operator or a composite operator such as $\widehat{Q}[R]$ of eq. [2] can be divided into diagonal and non-diagonal parts, which by their very structure (eq. [3]) are mutually orthogonal. This situation is illustrated in Fig. 1.

Classification of the Slater determinantal functions of the DFT basis

In our study of atomic d^q ions,[2] we considered the use of orbitals that were characterized by m_l values and thus were complex linear combinations of real d orbitals. With just one example, this choice was demonstrated to be an impossible one. Thus, the Slater determinant |(2)(1)| with M_S = 1 is clearly a pure ^{3}F function. On the other hand, the determinant |(3)(–1)|, likewise with M_S = 1, corresponds to the same one-electron density and thus the same DFT energy, but consists of 60% ^{3}F and 40% ^{3}P, as can be read from the Wigner coefficients for coupling the two d functions to obtain F and P symmetries. This kind of problem is avoided if real orbitals are used. Thus, our problem is to find parametric expressions for the LFR energies of Slater determinants built upon real orbitals. These are linear spherical harmonics for which a lot of symmetry information has accumulated[18] during the LFT era. The LF energy contribution of our strong-field determinants is just the sum of the one-electron energies. So, we are left with the R terms, expressed in a

real Slater-determinant basis, using for instance some parameterization of the SCS model.

The symmetry analysis turned out to be simple, but extraordinary (Table 1). The obvious properties of the Slater determinants are their being eigenfunctions of the spin component operator $\widehat{S}_z$ and their two-electron energy expectation values accordingly expressible in terms of Coulomb integrals (J) and exchange integrals (K). When d^2 Slater determinants are eigenfunctions of $\widehat{S}_z$ with M_S values of 1 or –1, this implies that they are also eigenfunctions of $\widehat{S}^2$ with energies of the form J–K. However, when such single Slater determinants have $M_S = 0$, they cannot simultaneously be eigenfunctions of $\widehat{S}^2$ unless the orbitals are doubly occupied, in which case they belong to class 0 of Table 1 with energy J_0. For these reasons, the 45 Slater determinants of d^2 can immediately be separated into three classes whose expectation values of the coefficient operator $\widehat{Q}[D]$ are tabulated in Table 1.

Class 0 encompasses the doubly occupied class consisting of five determinants, all with the Coulomb energy J_0. Class 1 has the singly occupied orbitals with $M_S = 0$ with an energy equal to a specific Coulomb energy, for example $J(xy,zx)$ referring to the two Slater determinants $|(xy)(zx)|$ with the columns $m_s = 1/2$ and $m_s = -1/2$ and vice versa. There are 20 members in this class. Finally, class 2 also has singly occupied orbitals, but in this case, the Slater determinants have $|M_S| = 1$. Again, there are 20 members whose energy expressions are J–K, where K refers to the exchange integral, for example $K(xy,zx)$. Altogether, there are 45 Slater determinants as required by the Pauli principle for two equivalent d electrons. The three classes are separated in energy in the SCS model solely by Jørgensen's spin-pairing energy parameter D.

Table 1. Symmetry analysis.

	Strong-field labeled repulsion integral	Degeneracy	$\widehat{Q}[D]$	$\widehat{Q}[E]$
Class 0	J_0	5	40/21	0
Class 1	$J_{\delta\delta}$	2	4/21	20/21
	$J_{\sigma\pi}$	4	4/21	12/21
	$J_{\pi\pi}$ and $J_{\pi\delta}$	10	4/21	–4/21
	$J_{\sigma\delta}$	4	4/21	–12/21
Class 2	$J_{\delta\delta}$–$K_{\delta\delta}$	2	–14/21	30/21
	$J_{\sigma\pi}$–$K_{\sigma\pi}$	4	–14/21	18/21
	$J_{\pi\pi}$–$K_{\pi\pi}$ and $J_{\pi\delta}$–$K_{\pi\delta}$	10	–14/21	–6/21
	$J_{\sigma\delta}$–$K_{\sigma\delta}$	4	–14/21	–18/21

The five Slater determinants of class 0 can be illustrated by just one of the d orbitals; for example, $|(xy)(xy)|$, of course with $M_S = 0$. The functions of this class are degenerate for atomic systems. The class 1 and class 2 Slater determinants are both divided into energy subclasses, which in the SCS model are separated by another energy parameter,[9] denoted by E. This parameter is proportional to the historically extremely important energy difference between ^3P and ^3F (and in particular between ^4P and ^4F of the configuration d^3, which has provided a dominant part of all the information we have about nephelauxetism) and thereby also to the Racah parameter B when this is combined with the other Racah parameter C.[4] A symmetry property of the spatial part of the real d orbitals[4] is responsible for the pair-interaction subclasses of the SCS model as well as the PMT model.

The coefficients to the parameter E of the SCS model are given in Table 1 in terms of matrix elements of the associated coefficient operator $\widehat{Q}[E]$. In order of decreasing repulsion energy, the spatial part of the subclasses may be labeled by

[7]

			Number of determinants
Subclass 1	δ−δ	$e2t_23(T_d)$	1
Subclass 2	σ−π	$e1t_22$, $e1t_21$	2
Subclass 3	π−π	t_21t_23, t_22t_23, t_21t_22, $e2t_21$, $e2t_22$	5
Subclass 4	σ−δ	e1e2	2

where the individual subclasses are defined by the lambda values of the real linear spherical harmonics[18b–18d] combined with the components of the symmetry species of T_d. It should be noted that the π–π subclass of Slater determinants (for reasons of spatial symmetry)[4] includes the π–δ subclass, as for example $|(zx)(yz)|$, which clearly has the same repulsion energy as $|(zx)(xy)|$.

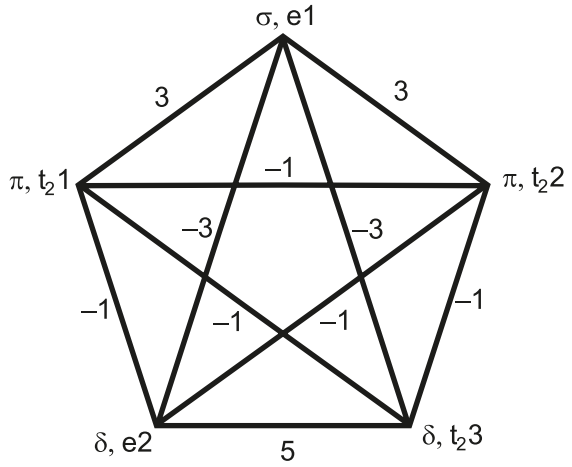
Common to class 1 and class 2 are the relative expectation energy differences between the subclasses,[4] cf. Table 1. Thus, while the energy difference between subclass 1 and subclass 2 equals that between subclasses 3 and 4, the energy difference between subclass 2 and subclass 3 is twice that. Explicit details have been tabulated in ref. 4 (Chapter 4) and are illustrated in Fig. 2.

It should be noted that an approximate adherence to these parametric expressions for the KS-DFT energies could be observed immediately on inspection of the computed AOC-KS-DFT Slater-determinant energies; at first for our atomic computations[2] and then for the molecular ones.[3,4] From an intuitive point of view, this agreement, even if approximate, is surprising, since the KS-DFT fundamentally is one-electron density-based and yet here provides remarkable results concerning two-electron interaction energies, even for the Slater determinants built up from molecular orbitals.

Partial quenching of the total spin operator in the strong-field, single-determinant bases — The spin symmetry problem of the class 1 Slater determinants, its analysis, and solution

The class 1 Slater determinants (Table 1) consist of pairs that are related to each other by a permutation of their columns. With the first functions associated with $m_s = 1/2$ and the second one with $m_s = -1/2$, $|(xy)(zx)|$ and $|(zx)(xy)|$ make

Fig. 2. The relative, symmetry-determined interlectronic repulsion interactions within the d-shell, cf. eq. [7] and the surrounding text. The figure illustrates particularly the symmetry obtained by linear adapatation of the basis functions, where detailed specification of the components is unnecessary.



up an example of such a pair. In WFT, these two determinants, which are eigenfunctions of $\widehat{S}_z$ with eigenvalue zero, both have the diagonal elements J_3 and are connected by a non-diagonal element equal to the exchange integral K_3, where the subindices refer to the subclass 3 of eq. [7] (see also Table 1 and Fig. 2). Diagonalization of the corresponding two-by-two matrix

$$[8] \qquad \begin{bmatrix} J_3 & K_3 \\ K_3 & J_3 \end{bmatrix}$$

provides us with the eigenfunctions of $\widehat{S}^2$, and this use of WFT for all the orbital pairs was implemented in two previous papers[4,6] to adapt the directly obtained KS-DFT energies so as to obtain the singlet eigenenergies J_3+K_3 and triplet eigenenergies J_3-K_3. The function basis implied in this energy adaptation was called the spin basis (sb, eigenfunctions of $\widehat{S}^2$) as opposed to the DFT-basis, which was called the Slater-determinant basis (db, eigenfunctions of $\widehat{S}_z$).

An alternative way of bridging between LFR and KS-DFT is to adapt the conventional basis of LFR (the sb) to the DFT-basis (db). This can be accomplished by transforming the appropriate pairs of $\widehat{S}^2$ eigenstates with $M_S = 0$, which are those occurring in a standard strong-field LFR calculation, into the corresponding eigenstates of $\widehat{S}_z$.

Illustration of the PMT model by use of the definition of its spin and seniority operators' diagonal parts in the KS-DFT basis

Certain fundamental observations are necessary before the spin and seniority separators can be defined in strong-field bases in general and in the DFT-basis in particular:

(*i*) The ^{1}S term is the only state among the 45 states of d^2, which has the pure seniority equal to *zero*. The meaning of this concept is that if ^{1}S of d^2 is viewed mathematically as a member of the d^q group of configurations incorporating all q, then another ^{1}S term has already occurred at $q = 0$. This q value of the first ^{1}S term is the seniority number v of the second one.

(*ii*) The ^{1}S state of d^2 is an equally weighted linear combination of the five states of class 0 of Table 1, each of which consists of doubly occupied d orbitals. This means that these five states are distinguished from the remaining 40 states of d^2 by seniority. This fact combined with the operator barycentration suffices to define the operator $\widehat{Q}[D_v^{DFT}]$ (up to a constant of proportionality).

(*iii*) Denoting the class expectation values of $\widehat{S}^2$ by $<\widehat{S}^2>$, these remaining 40 states fall by virtue of $\widehat{S}^2$ into two classes, each containing 20 functions. These classes are characterized by $<\widehat{S}^2> = 1$ when $M_S = 0$ and by $<\widehat{S}^2> = S(S+1) = 2$ when $M_S = |1|$. Thereby, the operator $\widehat{Q}[D_v^{DFT}]$ has been defined (up to a constant of proportionality).

For the operators $\widehat{Q}[D_v^{DFT}]$ and $\widehat{Q}[D_s^{DFT}]$, which separate by seniority and spin, respectively, a comparison with Table 1 is illustrative. The top right suffix marks the function basis that has been chosen for the definition of the mutually orthogonal operators.

The spatial separators are subspace separators, one applying to the $<\widehat{S}^2> = 1$ subspace and the other one to the $<\widehat{S}^2> = 2$ subspace of functions. Thereby, the diagonal matrix elements of the spatial operators, $\widehat{Q}[E_1^{DFT}]$ and $\widehat{Q}[E_2^{DFT}]$, respectively, are obtained from the pentagon numbers of Fig. 2 (again up to a constant of proportionality). The diagonal elements of the matrices of all the four operators in the DFT-basis appear in Table 2.

The use of KS-DFT in mimicking LFR: the treatment of "data"

We take the sum of the squares of the barycentered computed energies in the DFT-basis as a measure of the magnitude, "area", of the "data" information available for fitting KS-DFT energies to the diagonal elements of LFR in the DFT-basis. These energies are elements of a diagonal matrix $H_{?obs"}$ to be treated as a genuine H_{obs} and correspond to H_{LFR} when this is also expressed in the DFT-basis. Then, the diagonal part of the overlaps, which is analogous to eq. [4], provides us with all the radial parameters, LF as well as R parts, and when all the parametrical terms are subtracted from $H_{?obs"}$, we are left with a diagonal matrix whose norm square is equal to the total variance of a linear least-squares fitting.

There is, however, something rotten in the state of Denmark: KS-DFT is unable to provide the non-diagonal elements of this modeling, which are symmetry required by the 1:1 relationship in the DFT-basis between the states of LFR and the corresponding ones of KS-DFT.[4,6] Thus, we are lacking the non-diagonal DFT matrix elements to proceed directly to the diagonalization of a hypothetical full DFT energy matrix.

However, by virtue of the parametrical nature of LFR, we are able to use the diagonal of the LFR only, obtain the R parameter values, and then proceed indirectly by means of these parameter values to obtain the non-diagonal elements.

Table 2. DFT-computed energies for Cr^{4+} and CrF_4 (outer columns, in μm^{-1}) for all strong-field DFT-based functions of the d^2 configuration. The single Slater-determinant functions are specified by the symmetries of their rows, named by components of symmetry species of T_d (cf. eq. [7]. Column headings are named after the associated parameters. The middle columns of single-digit numbers are the matrix elements of the PMT coefficient operators, which were defined by their diagonal elements in the DFT-basis . The remaining columns are the terms that add up to scalar products (involving either of the outer columns). For example, the second column to the left refers to the overlap $\hat{H}^{DFT}[Cr^{4+}]|\hat{Q}[D_v^{DFT}]$.

This situation is a little bit curious and it therefore triggers the imagination enough to ask the question: Can a method be found to squeeze this additional "area" of information out of KS-DFT computations?

Comparison of a set of atomic and a set of molecular DFT "data"

Tables 2 and 3 illustrate how the DFT computations of the atomic ligand-field system, Cr^{4+}, and the molecular one, CrF_4, can be compared by taking advantage of the present formalism of mutual orthogonalities among all the model operators. In particular, the effective two-electron operators, which in LFR are described as interelectronic repulsion operators, are used to define and characterize the atomic part of CrF_4.

Intrinsic molecular atoms and nephelauxetism

Tables 2 and 3 illustrated the well-defined concept of a weak-field complex by the naked Cr^{4+} system, which is atomic and which, in LFR, is characterized by having a vanishing ligand field. A strong-field complex can, strictly speaking, not be exemplified because this would, for symmetry reasons, require the R parameters by analogy to be vanishing, a situation which for physical reasons cannot be realized. However, the tables illustrate by their quantitative contents that CrF_4 is not too far from being a so-called strong-field complex because its degree of diagonality in the DFT-basis is not too far from unity, in fact it is equal to $20.82/26.49 \approx 0.79$, that is, the ratio between the magnitudes of the information contribution of LF relative to that of LFR (Table 3).

Another aspect of Tables 2 and 3 is that if the ligand-field contribution to the analysis of CrF_4 is discarded, we are, for each R parameter, left with two LFR-parametric pictures that are identical, one for Cr^{4+} and one for CrF_4. And, since one of these pictures an atom, both do. We shall emphasize this property of LFR by considering the atomic R image associated with CrF_4, that of a molecular atom. There is one such 45×45 matrix picture for each R coefficient operator, and it is the same for all molecules of the same symmetry. Interestingly, for this purpose, the symmetry of Cr^{4+} has T_d symmetry, which is undeniable. The individuality appears when these matrices are weighted by their associated parameters, and the ratio between these weight factors for CrF_4 relative to that for Cr^{4+} exemplifies a so-called nephelauxetic ratio,[19–23] β, of which there are four in Table 3, one for each PMT parameter. A cumulative nephelauxetic ratio can be obtained from the square root of the ratio between the two values for $< \hat{H}_R | \hat{H}_R >$

$$[9] \qquad \beta^{\text{global}} = \sqrt{\frac{\langle \hat{H}_R(CrF_4) | \hat{H}_R(CrF_4) \rangle}{\langle \hat{H}_R(Cr^{4+}) | \hat{H}_R(Cr^{4+}) \rangle}} = 0.525$$

Thereby, we have obtained a global, multiparameter-based expression of nephelauxetism. This word refers to an expansion of the electronic cloud of the partially filled shell. It originated in the discovery, empirical or semi-empirical, of a phenomenon that manifests itself in reduced values for

Table 3. Parameter values resulting from the analysis of barycentered DFT calculated (ADF 2003, LDA)[24] data (Table 2) by use of orthogonal set of (LF)R operators. The first five lines give the parameter values extracted by the scalar product method. The following five lines list the contributions to the total area of the (LF)R Hamiltonian from each of the contributing conglomerate operator terms. In the following two lines, the sums corresponding to the cumulated contribution from, respectively, the R and the LFR are given. When the small residuals (variances) in the penultimate line are added to the LFR area, the total area of the DFT data is (re)covered.

all the R parameters for all molecular systems with a partially filled shell.

A final remark brings us back to the extent of the coverage of the KS-DFT computations at this time. The DFT energies contribute only to the diagonal of all these R matrices, whereas the non-diagonal elements are derivations due to the complete LFR formalism.

Conclusion

Kohn–Sham DFT is a useful tool for supplementing our data bank on the spectroscopy of transition-metal atoms and molecules with a partially filled shell. The approach to obtaining the one-electron and two-electron parameters of ligand-field theory is, in principle, objective. The only remaining degrees of freedom, which are unimportant in the present context, and for which standards exist, are the choice of functionals, the KS-DFT function basis, and the implementation.

The energy information extractable from KS-DFT is not, however, very straightforward, even after the DFT sets of functionals have been chosen. Two extraordinary features of the mimicking of the ligand-field repulsion model, LFR, by KS-DFT computation of its radial parameters have been illuminated.

First, only the values of the diagonal elements of a certain so-called strong-field energy matrix can be DFT-computed. The consequence of this fact is that the one-electron parameters of the ligand field itself often dominate in the extraction of information from the computed energies. Even for the computation on atoms, where only the interelectronic repulsion operators are in play, the low degree of diagonality of these operators in the DFT-basis reduces the accuracy by which the associated parameters can be obtained. However, once values of these parameters have been obtained, the non-diagonal elements that are necessary to obtain eigenvalues must be delivered by the simple ligand-field formalism. The question is: Can something be done about this status of KS-DFT? The present situation seems rather unfortunate from a more general point of view. Another way of asking the same question is: Can eigenenergies be obtained by DFT without taking advantage of ligand-field theory?

Second, unit occupation numbers of the KS-DFT spin eigenorbitals define system states that are eigenfunctions of $\hat{S}_z$, rather than $\hat{S}^2$, and whose computed energies can be interpreted and parameterized. Translated into a wave-function formulation, these states are single Slater determinants. From the point of view of ligand-field theory, they are strong-field functions, some of which are different from conventional strong-field functions by not being eigenfunctions of $\hat{S}^2$. This happens in d^2 for 20 out of the 45 state functions with the consequence that the exchange is moved out of the diagonal relative to the situation of the usual ligand-field, strong-field functions, which are eigenfunctions of $\hat{S}^2$. This curious situation may have more general stratifications.

This paper's main contribution has been to unravel the intertwining of the contributions from the one-electron and two-electron effective operators of the LFR by the method of mutually orthogonal operators. Moreover, this method allows the separation of the spin and seniority parts of the repulsion from the spatial parts. These results have been illustrated by the LFR concept of the molecular atom as the central atom inside the complex. This molecular atom was illustrated quantitatively by a common matrix expression for a given two-electron coefficient operator for all chemical members of a general class of complexes with the symmetry and number of electrons in the partially filled shell in common and an individual matrix for the conglomerate operators for each specific complex. These statements include the ma-

trices of the central ion because its symmetry covers that of any complex.

Finally, the conventional LFR Hamiltonian matrix has been modified to the DFT-adapted function basis, which is an eigenbasis of $\widehat{S}_z$, rather than $\widehat{S}^2$.

Comprehensive study of some well-known molecular numerical integration methods

Aisha El-Sherbiny and Raymond A. Poirier

Abstract: In a previous study, we compared, both in terms of accuracy and efficiency, the performance of some of the well-known grids, which use the Becke partitioning scheme for molecular numerical integration. We concluded, based on the number of electrons only, that the MultiExp grid performed well compared with the grids proposed by Becke, Gill et al., and Treutler and Ahlrichs. In this work, we re-examine the performance of the same set of grids in addition to the SG-0 grid and a benchmark grid. These grids are evaluated by integrating the Hartree–Fock electron density to calculate the number of electrons, dipole moment, potential energy, and Coulomb repulsion energy. Our results show that, except for the large benchmark grid, none of these grids were completely satisfactory.

Key words: numerical integration, radial quadrature, ab initio, electron density.

Résumé : Dans une étude antérieure, on a comparé en termes d'exactitude et d'efficacité, la performance de quelques grilles bien connues qui font appel au schéma de partition de Becke pour l'intégration numérique. On a conclu, sur la base uniquement du nombre d'électrons, que la grille MultiExp donne de bonnes performances par comparaison avec les grilles proposées par Becke, Gill et al. et Treutler et Ahlrichs. Dans ce travail, on réexamine la performance du même ensemble de grilles, plus la grilles SG-0 et une autre grille reconnue. On a évalué ces grilles en intégrant la densité électronique de Hartree–Fock pour calculer le nombre d'électrons, le moment dipolaire, l'énergie potentielle et l'énergie de répulsion coulombienne. Les résultats obtenus montrent que, à l'exception de la grosse grille bien connue, aucune des autres grilles ne donne des résultats complètement satisfaisants.

Mots-clés : intégration numérique, quadrature radiale, ab initio, densité électronique.

[Traduit par la Rédaction]

Introduction

The use of numerical integration in quantum chemistry has become routine, especially in density functional theory (DFT). Grid-based numerical solutions of the Hartree–Fock (HF) equations of polyatomic molecules have also been considered.[1] In general, the accuracies of numerical quadrature methods are evaluated by integrating the electron density for the total number of electrons, for the total DFT energy, or specifically, for the exchange-correlation energy, which are compared to a larger grid as in refs. 2, 3, and 4–6. In this paper, we use an approach similar to Pérez-Jordá et al.,[7] where we use numerical quadrature methods to integrate properties for which the exact analytical results are known, namely, the Hartree–Fock wave function. In addition to calculating the total number of electrons N_{el}, we also calculate the electron–nuclear potential energy V_{ne}, dipole moment, μ, and Coulomb potential energy V_{ee} using the Hartree–Fock wave function and calculate these properties numerically using the HF density. Therefore, the values of V_{ne}, μ, and V_{ee} calculated using the HF wave function serve as exact values to compare with those calculated by numerical integration. We also compare our results to a benchmark grid, a large version of the SG-1 grid[2] with 100 radial points and 1202 angular points for a total of 12 200 angular points. In this work, we examine our implementation of six standard grids: the MultiExp grid by Gill and Chien,[8] the Becke grid,[9] the Treutler and Ahlrichs (TA) grid,[3] our modified version of TA,[10] TAnew, the SG-1 grid by Gill et al.,[2] and the more recent SG-0 MultiExp grid by Chien and Gill.[11] The radial quadrature formulas for these grids are given in Table 1. The accuracy of the quadrature depends on a number of factors: the function being integrated, the choice of the radial grid, the angular grid used, the radial scale factor R (See Table 1), on which it is quite dependent, the radial mapping, and ultimately on the total number of grid points used. Although other efficient types of grids exist,[6,12,13] all the grids investigated in this work use the Becke partitioning scheme.[9] In addition, we investigate how the accuracy of these grids vary with the size of the system. To our knowledge, the "size consistency" of these grids has not been investigated. It is important that grids perform equally well for different systems. For that reason, the grids are tested using a total of 89 different molecules (Table 2), including ground states, ions, complexes, and transition states. The molecules are divided into seven sets. The first three sets represent molecules containing first-, second-, and third-row atoms. The other four sets represent transition states, ions, complexes, and peptides. The peptides consist of one to five glycine amino acids (1G to 5G).

Method

All calculations were performed with program MUNgauss.[14] The different grids along with the total number of grid points associated with each grid are given in Table 3. For the MultiExp grids, the atomic space is divided into three regions (core, middle, and outer). For the 20, 25, and 30 radial grids, the space is divided into (6,6,8), (6,8,11), and, (6,10,14), respectively. For each radial region, a spherical grid of six angular points was used for the core and 86 for the middle region. For the outer region, three different spherical grids of 110, 194, and 302 angular points were used. The largest grid gives 5124 [(6 × 6) + (10 × 86) + (14 × 302)] grid points. The notations 20(110), 20(194), 20(302), 25(110), 25(194), 25(302), 30(110), 30(194), and 30(302) denote the MultiExp grids with 20, 25, or 30 radial points with 6–86–110, 6–86–194, or 6–86–302 angular grids. All calculations were performed using the 6–31G(d) basis set and HF/6–31G(d) optimized structures. For each set of molecules listed in Table 2, the mean absolute error, MAE, is calculated as

$$[1] \qquad \mathrm{MAE} = \sum_i |P^i_{\mathrm{NI}} - P^i_{\mathrm{HF}}|/N$$

where P^i_{NI} is the value of the molecular property, N_{el}, V_{ne}, V_{ee}, or μ calculated using numerical integration for a molecule *i*, and P^i_{HF} is the corresponding molecular property calculated using HF. *N* is the number of molecules in each set. The radial scale factor *R* (see Table 1) was optimized[9] for Ge, As, Se, and Br in the molecules CH_3GeH_3, CH_3AsH_2, CH_3SeH, and CH_2Br_2, respectively. For SG-0 and SG-1, values of *R* are only available for elements up to argon, whereas for TA and TAnew, *R* values are available for up to krypton.

Results and discussion

Number of electrons

The total number of electrons is calculated by integrating the HF electron density using the equation:

$$[2] \qquad N_{\mathrm{el}} = \int \rho(\boldsymbol{r})\mathrm{d}\boldsymbol{r}$$

Table 4 gives the MAE of the integration of the electron density for the seven sets of molecules described above with the 15 grids mentioned previously. The MAEs range from 1.2×10^{-2} (TA) to 2.5×10^{-8} (benchmark). For molecules containing first-row atoms, the accuracy of the integration of the electron density using the MultiExp grid with 20 radial points improves slightly as the angular grid for the outermost region increases from 110 angular points to 194, but it does not improve by further increasing the number of angular points to 302. The accuracy improves slightly by increasing the size of the outermost grid using the MultiExp grid with 25 radial points. The 30(302) grid is the most accurate,

[a]Transition states.

[b]Only 1G and 2G peptides are calculated.

while 25(302) and 30(194) are almost of the same accuracy. The SG-0 and Becke grids are of comparable accuracies to our implementation of the MultiExp grid with 20 radial points. The least accurate grid is TA. Our new implementation of the TA grid, TAnew,[10] is almost an order of magnitude more accurate than the original TA grid. The SG-1 and TAnew grids give almost the same accuracy. For molecules containing first- and second-row atoms, third column of Table 4, a similar trend is found for the MultiExp grids. The worst accuracy is given by the TA grid. The TAnew grid is the most accurate grid and is more accurate than TA by more than an order of magnitude. For molecules containing third-row atoms, TA is again the least accurate and the best accuracy is given by TAnew, while Becke and the nine MultiExp grids give nearly the same accuracy. For the transition states, 30(194) is the most accurate and TA is the least accurate. The performance of the MultiExp grids improves slightly by increasing the number of angular points in the outermost region. For complexes, 30(194), 30(302), TAnew, and SG-1 grids give better accuracies than the rest of the grids. The TA grid is the least accurate, almost two orders of magnitude less accurate than TAnew. For ions, 25(302) and 30(302) are the most accurate and TA is the least accurate. TAnew and SG-1 grids are of comparable accuracies. Performance of the smaller SG-0 grid is similar to our implementation of the MultiExp grid. For peptides, the

[a]Transition states.

[b]Only 1G and 2G peptides are calculated.

30(302) grid is the most accurate, while TA is the least accurate. The small 20(110) grid and the large Becke grid are of similar accuracy and generally of lower accuracy than the other grids. The 25(194), 25(302), 30(194), TAnew, and SG-1 grids have similar MAEs of around 2.0×10^{-4}, an order of magnitude less than that of the most accurate 30(302) grid. The MAEs for the benchmark grid are in the range of 1.2×10^{-7} to 2.5×10^{-8}, which is extremely accurate. For all of the seven sets, the best accuracies are for the 30(194), 30(302), TAnew, and SG-1 grids, while the performance of the 25(194) is reasonable.

Dipole moment

The electronic component of the dipole moment is calculated numerically using

$$[3] \qquad \mu = \int \rho(\boldsymbol{r})\boldsymbol{r}\mathrm{d}\boldsymbol{r}$$

The dipole moment (scalar) is calculated for all the molecules in Table 2, including those possessing a zero dipole by symmetry. Table 5 gives MAEs for the different test sets with the15 grids. The MAEs range from 4.6×10^{-2} au (TA) to 4.2×10^{-8} au (benchmark). For molecules containing first-row atoms, except for the TA grid, which gave an MAE of 4.6×10^{-3} au, the MAEs for the rest of the 13 grids are in the range of 9.0×10^{-4} au [20(110)] to 1.5×10^{-4} au [30(302)]. However, an improvement can be noticed as the number of angular points is increased in the outermost region from 110 to 194, and almost no improvement is observed by increasing to 302 angular points for 20, 25, or 30 radial points. The same observation can be made for molecules containing second-row atoms. Table 5 shows that, for molecules containing atoms from the second and third rows, the TA grid was the least accurate. TAnew is more accurate than TA and of the same accuracy as SG-1. It also shows that the SG-0 grid performed as well as the 20(110) MultiExp grid. For molecules containing third-row atoms, the MAE is almost the same and in the range of 3.7×10^{-2} au to 1.3×10^{-2} au for the nine MultiExp grids, Becke, and TA grids, while the MAE of TAnew is 3.5×10^{-4} au, two orders of magnitude less than all of the other grids. For transition states, the error in calculating the dipole moment using 20(194) MultiExp grid is less than using 20(110). However, the error does not decrease by using the larger 20(302) grid. The same pattern is also observed with the MultiExp grids of 25 radial points. The accuracy does not improve by increasing the grid size from 25(194) to 25(302), but the error decreases by increasing the grid from 25(110) to 25(194). The same trend can be also observed in the dipole moment calculated using the MultiExp grids of 30 radial points. For complexes, the accuracies of 20(110), Becke, TA, and SG-0 are of the same order of magnitude (10^{-3} au), and these grids are less accurate than the rest of the grids. It also shows that TAnew and SG-1 are almost of the same accuracy. For ions, 20(110), 25(110), and 30(110) grids give almost the same accuracy, which is less than the rest of the grids. The grid 25(302) gave the best accuracy, even better than 30(302). TAnew is as accurate as SG-1, while SG-0 is almost as accurate as 20(194). For peptides, the Becke and TA grids were the least accurate grids, while 30(302) was the most accurate. Again, TAnew and SG-1 have the same accuracy. The general trend amongst the MultiExp grids is also clear. An angular grid of 194 angular points gives better accuracy than 110, while 302 does not offer an improvement over the 194 grid. The benchmark grid is again excellent for all sets with an MAE of around 1.0×10^{-7} au. As in the case of number of electrons, the best performance for all sets was obtained by using 30(194), 30(302), TAnew, and SG-1. Of those, the 30(194) grid is the most economical.

Potential energy

The electron–nuclear potential energy is calculated numerically using

$$[4] \qquad V_{\mathrm{ne}} = \sum_{\mathrm{A}} Z_{\mathrm{A}} \int \frac{\rho(\boldsymbol{r})}{|\boldsymbol{r} - \boldsymbol{R}_{\mathrm{A}}|}\mathrm{d}\boldsymbol{r}$$

where $\boldsymbol{R}_{\mathrm{A}}$ is the position of the atom A of atomic charge Z_{A}. Table 6 gives the MAEs for the potential energy. For V_{ne},

Table 6. Mean absolute errors of the potential energy, V_{ne} (μH), eq. [4].

[a]Transition states.

[b]Only 1G and 2G peptides are calculated.

the errors are significantly larger than the other two properties and can be as high as 10^8 μH. For molecules containing first-row atoms, the highest MAE is given by the MultiExp grid of 20 radial points (7.9×10^5 μH), while the lowest is given by SG-1 (1.5×10^3 μH). The nine MultiExp grids from 20(110) to 30(302) give MAEs around 10^5 μH. For TAnew, the MAE is very close to that of SG-1 (10^3 μH). For molecules containing second-row atoms, the 20(110), 20(194), and 20(302) grids gave MAEs of about 10^7 μH, while the MAEs for the rest of the MultiExp grids are around 10^6 μH. The most accurate grid is TAnew, followed by SG-1. For molecules containing third-row atoms, the nine MultiExp grids gave similar accuracies, while TA is slightly more accurate than TAnew. For transition states, the MultiExp grid of 20 radial points is the least accurate. Increasing the size of the outermost grid for the MultiExp grid of 20 radial points did not change the accuracy significantly, which is the same for MultiExp grids of 25 and 30 radial points. The most accurate grid for transition states is SG-1, followed by TAnew. For complexes, the MultiExp grid of 20 radial points was the least accurate grid, while SG-1 is the most accurate. For complexes and ions, performance of the nine MultiExp grids is similar to the transition states. The most accurate grid for complexes is SG-1, while TAnew is the most accurate grid for ions. For peptides, SG-1 is the most accurate grid, followed by TAnew. The error in calculating the potential energy drops significantly when the benchmark grid is used, but is still relatively high. This huge error in potential energy suggests that the grids currently used for numerical integration are not suitable for the calculation of potential energy ($1/r$ type functions) and that numerical integration is very dependent on the form of the function to be integrated. Although the errors in calculating the potential energy using all of the 14 grids are large, the TAnew and SG-1 grids performed relatively better than the rest of the grids. Although the potential energy need not be

[c]p-Nitrobenzylchloride.

calculated using numerical integration, our results do clearly show that all grids except perhaps the benchmark grid are not sufficiently large to accurately integrate such a function.

Coulomb repulsion energy V_{ee}

Although we investigated the double numerical integration to calculate the Coulomb energy,

$$[5] \qquad V_{ee} = \int\int \frac{\rho(\boldsymbol{r}_1)\rho(\boldsymbol{r}_2)}{|\boldsymbol{r}_{12}|} d\boldsymbol{r}_1 d\boldsymbol{r}_2$$

like V_{ne}, the errors are quite large and in the order of 10^5 to10^7 μH. Even with the benchmark grid, the error is still extremely high and in the range of 9.1×10^4 to 3.1×10^5 μH. In Table 7, we report the MAEs in the Coulomb energy using a more realistic approach.

$$[6] \qquad V_{ee} = \int \rho(\boldsymbol{r}_2) \left[\sum_{\mu\nu} P_{\mu\nu} \int \frac{\Phi_\mu(\boldsymbol{r}_1)\Phi_\nu(\boldsymbol{r}_1) d\boldsymbol{r}_1}{|\boldsymbol{r}_{12}|} \right] d\boldsymbol{r}_2$$

$P_{\mu\nu}$is a density matrix element, ρ is the charge density, and Φ_μ and Φ_ν are basis functions. The first integral, in the brackets, was performed analytically, while the second integral was performed numerically. Table 7 shows that in some cases, the larger MultExp grids give larger errors than the smaller grids. A likely explanation for this apparently odd behaviour may be due to the values used for radial scale factors. Since R is optimized to give the best accuracy in the integration of the electron density, by re-optimizing R to give the most accurate Coulomb energy, these grids may perform in a more reliable fashion. From Table 7, for molecules containing first-row atoms, the most accurate grid is 30(302) and the second most accurate is 30(194), and both of them are slightly more accurate than TAnew and SG-1. Compared with the rest of the grids, SG-0 is of an average accuracy. The least accurate grid is the 25(110) MultiExp grid. While the error for the 14 grids was in the range of 239 to 8960 μH, the error for the benchmark grid was incredibly small (0.38 μH). For molecules containing second-row atoms, TAnew is by far the most accurate and its MAE is almost 30 times less than that of TA. SG-1 follows TAnew in accuracy. Of the nine MultiExp grids, the least accurate grid is the 25(110) grid, which is less accurate than the

smaller grids 20(110) and SG-0. The error varied from 675 μH (TAnew) to 11133 μH [25(110)]. The 20(194), 20(302), 30(110), and Becke grids are of similar accuracy, although they differ in size. The benchmark grid is extremely accurate with an MAE of only1.81 μH. For molecules containing atoms from the third-row, TAnew is the most accurate grid. The largest error is for the MultiExp grid 25(302), which is a relatively large grid. Again, the large errors for molecules containing third-row atoms, 445 333 μH for 25(302), points to a serious problem either with the optimization of the radial scale factor *R* or the MultiExp grid size. However, since the radial scale factor for the third-row atoms was optimized using the same technique used for the first- and second-row atoms (see ref. 10) we expect that the 20, 25, or 30 radial-points grids are not large enough to calculate the Coulomb repulsion energy. Both Becke and TA grids are more accurate than the nine MultiExp grids. For transition states, the MultiExp grids performance is reasonable. For the 20, 25, and 30 radial MultiExp grids, the MAE decreases slightly as the outermost angular grid increases from 110 to 194 angular points. However, the accuracy does not increase much as the size increases from 194 to 302 angular points. The 30(194) grid is the most accurate, followed by TAnew. SG-0 has an MAE almost equivalent to that of the 20(110), 25(110), and 30(110) grids. The MAE for the benchmark grid is only 1.63 μH. For complexes, TAnew continued to be the most accurate, followed by the 30(194) grid, while TA is the least accurate. For ions, 30(302) is the most accurate, followed by TAnew. Again, TA is by far the least accurate grid. For peptides, 30(302) is the most accurate, while 30(194) is the second most accurate. In general, the accuracy of SG-0 was consistent with that of 20(110). The overall performance of the TAnew and SG-1 grids for the seven sets was the best. In general, the 30(194) and 30(302) gave relatively small MAEs; however, their poor performance for molecules containing third-row atoms makes them unreliable.

Some interesting observations

Table 8 gives the error in the Coulomb repulsion energy using the Becke, TA, TAnew, SG-1, SG-0, and benchmark grids for a series of five peptides ranging in size from one to five glycine amino acids (1G to 5G). It is obvious from the table that the Coulomb repulsion energy is in some cases underestimated, while in other cases it is overestimated and that the error changes randomly as the size of the peptide increases. This is true even with some of the larger and more accurate grids, TAnew and SG-1. For example, SG-1 predicts the error for the 3G peptide to be smaller than the error for the 2G peptide and the error with TAnew jumps from –3 960 μH for the 4G peptide to +5 890 μH for the 5G peptide. The error in V_{ee} increases consistently with the size of the peptide only when the benchmark grid is used. Using the benchmark grid, the error increased from 0.6 μH for 1G peptide to 24.9 μH for 5G peptide, which is a relatively large error, given the size of the benchmark grid. Since the benchmark grid is very time-consuming, one can only wonder how big the error would be for much larger peptides and just how reliable the numerical integration would be using smaller grids. These results suggest that comparing systems of different sizes could lead to serious errors due to the inconsistency in the results even for the larger grids.

The effect of the radial scale factor (*R*) on the integration

In our previous paper,[10] the radial scale factors for the MultiExp grid were optimized to give the best accuracy in the number of electrons. Here, we investigate the possibility of optimizing the *R* values to give the best accuracy in V_{ee} for molecules containing first- and second-row atoms. Table 9

gives the new R values for the MultiExp 20(110) grid along with the accuracy defined as

$$[7] \qquad \text{accuracy} = -\log_{10}\left|\frac{\text{approx}}{\text{exact}} - 1\right|$$

where approx is the value of the Coulomb energy calculated using numerical integration, and exact is the HF value. Table 10 shows the error in the Coulomb potential V_{ee} calculated using the previous set of R values, R_1, and the new set of R values, R_2. The overall MAE decreased only slightly from 8 280 μH to 7 231 μH. However, from Table 10, we notice that the error for the set of molecules containing chlorine did not change systematically. The error did not change for $p$$NO_2$BzCl, but changed in sign for HOCl and CH_2Cl_2, and decreased slightly for Cl_2, and dramatically changed in both sign and magnitude for NaCl, CH_3Cl, CCl_4, and ClF. The same pattern can be observed for the set of molecules containing phosphorous, P_2, PF_5, PH, CH_3PH_2, and CH_2 PH_2 PH_2 as well as the set containing sulfur SO, SO_2, CH_3SH, and CH_2SHSH. Of special interest is the comparison of the molecules SO and SO_2. The error changed sign for SO, while it changed sign and increased more than an order of magnitude for SO_2. This analysis shows that the accuracy of the numerical integration using MultiExp grid is highly sensitive to the change in the radial scale factor. This dependence on R could explain the odd behaviour of MultiExp grid where a larger grid, 25(110), gave an overall MAE larger than that of the smaller grid 20(110) (see the third column of Table 7). To test whether further improvements are possible, we have performed simultaneous optimization of both the radial scale factors for oxygen and sulfur in SO and SO_2 using an optimization algorithm described in ref. 15, in which the gradients are calculated numerically. The radial scale factors are chosen to minimize the error, $|V_{ee}(\text{NI}) - V_{ee}(\text{HF})|$, and since the optimized values depend on the initial R values used, several optimized values are reported. In Table 11, we report the error in the Coulomb repulsion energy using different radial scale factors. It is

obvious from these results that the error in Coulomb repulsion energy is quite sensitive to the radial scale factors. Although it is possible to substantially reduce the error in V_{ee} by optimizing R values for SO or SO_2, no values of R can reduce errors in V_{ee} equally for both SO and SO_2.

Numerical integration efficiency

Number of points of the atomic grid

Table 3 gives the number of points for the atomic grids. The number of grid points for SG-0 from hydrogen to chlorine is in the range of 1328 to 1496, which makes it one of the smallest grids and comparable in size to the 20(110) grid. Table 3 shows that, except for H and He, the largest grid is the Becke grid followed by the TA grid. Also Table 3 shows that, except for H and He, the TAnew grid is larger than the SG-1 grid, the 30(194) grid is comparable in size to the SG-1 grid, and the 25(194) grid is medium in size between the SG-0 and SG-1 grids. To better measure grid convergence, errors for the five properties studied are reported in Tables 12 and 13 for CH_3CONH_2 and CH_3SiH_3, respectively. In both Table 12 and Table 13, the grids are arranged in increasing grid size. From the smallest (SG-0) to the largest [30(302)], the MultiExp grids generally perform equally. It can be seen that the larger grids are not necessarily the most accurate grids and that the mapping and the radial quadrature play a crucial rule in determining the accuracy of the numerical integration.

Conclusions

The performance for a number of well-known grids, including the most recently developed SG-0 grid, and a large benchmark grid, was examined. We used numerical integration to calculate the number of electrons, dipole moment, potential energy, and Coulomb repulsion energy. In general, the most accurate grids are our new implementation of the Trutler and Alhrichs grid, TAnew, and the standard grid, SG-1. Increasing the size of the outermost grid of the MultiExp grid from 110 to 194 angular points improved the accuracy, but increasing it further to 302 angular points did not. All the grids were very inaccurate in calculating the potential energy. The Coulomb energy calculations showed the inconsistency of the performance of the MultiExp grid. Also, the inconsistent behaviour of the numerical integration, specifically with calculating Coulomb energy, was noticed with some of the larger grids such as SG-1 and TAnew. For compounds containing third-row elements, it is interesting to note that when using the MultiExp grids, the errors are very insensitive to the angular grid used in the outer region. This would suggest that the error is mainly arising from the core or middle regions.

Finite-temperature effects in enzymatic reactions — Insights from QM/MM free-energy simulations

Hans Martin Senn, Johannes Kästner, Jürgen Breidung, and Walter Thiel

Abstract: We report potential-energy and free-energy data for three enzymatic reactions: carbon–halogen bond formation in fluorinase, hydrogen abstraction from camphor in cytochrome P450cam, and chorismate-to-prephenate Claisen rearrangement in chorismate mutase. The results were obtained by combined quantum mechanics/molecular mechanics (QM/MM) optimizations and two types of QM/MM free-energy simulations (free-energy perturbation and umbrella sampling) using semi-empirical or density-functional QM methods. Based on these results and our previously published free-energy data on electrophilic substitution in *para*-hydroxybenzoate hydroxylase, we discuss the importance of finite-temperature effects in the chemical step of enzyme reactions. We find that the entropic contribution to the activation barrier is generally rather small, usually of the order of 5 kJ mol^{-1} or less, consistent with the notion that enzymes bind and pre-organize the reactants in the active site. A somewhat larger entropic contribution is encountered in the case of chorismate mutase where the pericyclic transition state is intrinsically more rigid than the chorismate reactant (also in the enzyme). The present results suggest that barriers from QM/MM geometry optimization may often be close to free-energy barriers for the chemical step in enzymatic reactions.

Key words: QM/MM, combined quantum mechanics/molecular mechanics, free-energy methods, free-energy perturbation, enzyme reactions.

Résumé : On rapporte les données d'énergie potentielle et d'énergie libre pour trois réactions enzymatiques, soit la formation d'une liaison carbone-halogène avec la fluorinase, l'enlèvement d'un hydrogène à partir du camphre avec le cytochrome P450cam et un réarrangement de Claisen chorismate à préphénate avec une chorismate mutase. Les résultats ont été obtenus par des optimisations MQ/MM semi-empiriques ou de la théorie de la fonctionnelle de la densité (TFD) et deux types de simulations d'énergie libre MQ/MM (perturbation de l'énergie libre et échantillonnage parapluie). Sur la base de ces résultats et des résultats d'énergie libre publiés antérieurement pour la substitution électrophile avec l'hydroxylase de *p*-hydroxybenzoate, on discute de l'importance d'effets de température finie sur l'étape chimique des réactions enzymatiques. Il a été observé que la contribution entropique à la barrière d'activation est relativement faible, généralement inférieure à 5 kJ mol^{-1}, en accord avec la notion que les enzymes se lient et organisent les réactifs dans le site actif. On rencontre une contribution entropique un peu plus importante dans le cas de la chorismate mutase pour laquelle l'état de transition péricyclique est intrinsèquement plus rigide que le réactif chorismate, aussi dans l'enzyme. Les résultats présentés ici suggèrent que les barrières obtenues à partir de l'optimisation MQ/MM de la géométrie se rapprochent souvent des barrières d'énergie libre pour l'étape chimique des réactions enzymatiques.

Mots-clés : MQ/MM, combinaison de mécanique quantique et de mécanique moléculaire, méthodes de l'énergie libre, perturbation de l'énergie libre, réactions enzymatiques.

[Traduit par la Rédaction]

Introduction

Combined quantum mechanics/molecular mechanics (QM/MM) approaches are the method of choice for treating chemical reactions in enzymes,[1–4] providing an efficient and accurate description of complex biomolecular systems. They allow detailed insights into the mechanisms of enzyme reactions; see, e.g., refs. 3–5 for recent overviews. The QM/MM method is essentially a potential-energy method. However, the key quantity to characterize chemical systems and proc-

esses is the free energy. The free-energy difference between two states is directly related to the probability of finding the system in one state or the other. For an *NVT* system with constant number of particles, *N*, constant volume, *V*, and constant temperature, *T*, the relevant free energy is the Helmholtz free energy, *A*,

$$[1] \qquad A = U - TS$$

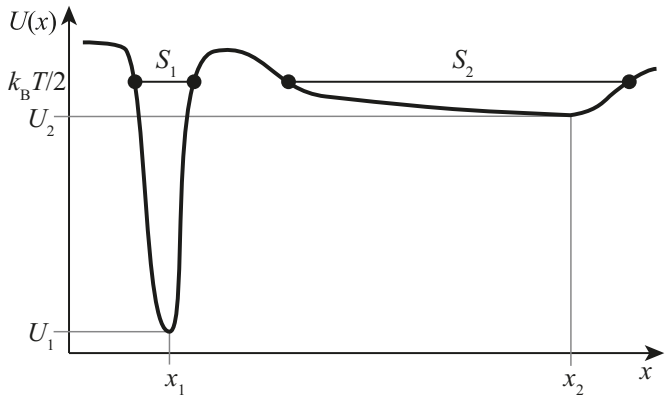
The free energy is composed of the internal energy, *U* (which is the potential energy plus the zero-point vibrational energy plus finite-temperature corrections, which are usually small), and the entropic contribution, –*TS*. At temperatures $T > 0$ K, knowledge of the energy alone is therefore not sufficient to determine the free energy. A higher-energy state with high entropy may be more favourable (that is, have a lower free energy) than a low-energy state with low entropy (see Fig. 1). The entropy can be related, loosely speaking, to the size of the configuration space available to the system at a given temperature.

In quantum chemistry, the conventional approach to computing the free energy of a molecule is based on the rigid-rotor/harmonic-oscillator (RRHO) approximation,[7] where the partition function is formulated under the assumptions that the molecule as a whole rotates as a rigid body and that all intramolecular motions can be treated as harmonic vibrations. However, when applied to large biomacromolecular systems, the RRHO treatment is problematic for several reasons: (*i*) A full vibrational analysis is computationally very costly or even prohibitive for systems typically encountered when modeling enzymatic reactions (several 1000 to 10 000 atoms). (*ii*) There are many "soft", anharmonic degrees of freedom in a (solvated) biomolecule for which the harmonic-oscillator approximation is inadequate. (*iii*) Even if the above points could be resolved, there remains a major issue: The RRHO approach is applied at a stationary point (minimum or transition state) obtained from a potential-energy minimization procedure. However, for large systems, this configuration will be just one of very many of similar energy, and one cannot assume it to be *the* representative structure.[8]

A more appropriate approach for biomolecular systems is therefore to calculate free energies from some type of sampling procedure at finite temperature that is able to explore, at least locally, the configuration space available to the system. The sampling can be done either with Monte Carlo or molecular-dynamics (MD) simulation techniques; we will restrict ourselves here to MD-based methods. The general idea is to express the free-energy difference between two states as a statistical-thermodynamical average that can be evaluated by sampling the appropriate ensemble (e.g., the canonical, or *NVT*, ensemble or the isothermal–isobaric, or *NPT*, ensemble).

Over the last few years, numerous studies have been reported that combine QM/MM methods with a variety of sampling techniques to calculate reaction and activation free energies of enzymatic processes; see refs. 3, 4, and 9 for recent reviews. In the present contribution, we have used QM/MM free-energy perturbation (FEP) as well as umbrella sampling (US) to investigate several enzyme reactions, namely, the halogenation step in fluorinase, the hydrogen-abstraction step in cytochrome P450cam, and the Claisen rearrangement in chorismate mutase. We will incorporate into the discussion previously reported free-energy results on other systems and obtained by other methods. From the combined body of data, we will attempt to draw more general conclusions on the effect of finite temperature on the chemical step of these, and perhaps other, enzymatic reactions.

Fig. 1. The high-energy state x_2 has a lower (more favourable) free energy than x_1 because of its higher entropy, indicated by the larger width of the potential well (adapted from ref. 6).



We will begin by briefly outlining our QM/MM method and discuss the QM/MM free-energy perturbation method, with which the majority of results herein were obtained. We will then introduce the three enzymatic reactions studied and provide computational details. The Results section will present potential-energy and free-energy data for the reactions, which will subsequently be discussed with a view on the importance of finite-temperature effects in the chemical step of enzyme reactions. We will finish with some conclusions.

Theoretical background

The QM/MM energy

Here, we outline our QM/MM scheme to facilitate the following discussion and introduce some notation. In brief, we use an additive scheme with hydrogen link atoms and electrostatic embedding with charge shifting.[3,10–13] The total (potential) energy of the entire system is written as

$$[2] \qquad E_{\mathrm{QM/MM}}(\mathbf{R}_{\mathrm{QM}},\mathbf{R}_{\mathrm{MM}}) = E_{\mathrm{QM}}(\mathbf{R}_{\mathrm{QM}};\mathbf{R}_{\mathrm{MM}}) + E_{\mathrm{MM}}(\mathbf{R}_{\mathrm{MM}}) + E_{\mathrm{QM-MM}}(\mathbf{R}_{\mathrm{QM}},\mathbf{R}_{\mathrm{MM}})$$

where $\mathbf{R}_{\mathrm{QM}}$ and $\mathbf{R}_{\mathrm{MM}}$ are the coordinates of the QM and the MM atoms, respectively; link atoms are included in $\mathbf{R}_{\mathrm{QM}}$ to simplify the notation. $E_{\mathrm{QM}}(\mathbf{R}_{\mathrm{QM}};\mathbf{R}_{\mathrm{MM}})$ is the electronic energy of the QM system in the presence of the MM point charges, but *without* accounting for the electrostatic interaction with the surrounding MM atoms (see below). $E_{\mathrm{MM}}(\mathbf{R}_{\mathrm{MM}})$ is the energy of the MM atoms as calculated by the classical force field. All QM–MM interactions are collected in $E_{\mathrm{QM-MM}}(\mathbf{R}_{\mathrm{QM}},\mathbf{R}_{\mathrm{MM}})$:

$$[3] \qquad E_{\mathrm{QM-MM}} = E^{\mathrm{b}}_{\mathrm{QM-MM}} + E^{\mathrm{vdW}}_{\mathrm{QM-MM}} + E^{\mathrm{el}}_{\mathrm{QM-MM}}$$

$E^{\mathrm{b}}_{\mathrm{QM-MM}}$ and $E^{\mathrm{vdW}}_{\mathrm{QM-MM}}$ contain the bonded (typically bond stretching, angle bending, torsion) and van der Waals interactions between the QM and the MM atoms, respectively. These terms are calculated at the force-field level. The elec-

trostatic QM–MM interaction, E^{el}_{QM-MM}, is treated within the electrostatic embedding scheme, that is, the QM electron density is polarized by the MM charges. This is achieved by including the point charges into the QM Hamiltonian, which amounts to solving the SCF equations in the presence of the point-charge field. The corresponding electronic Hamiltonian thus reads (in atomic units)

$$\begin{aligned}\widehat{H}_{SCF} &= \widehat{H}_0 + \widehat{H}^{el}_{QM-MM} \\ &= \widehat{H}_0 - \sum_i^{\text{electrons}} \sum_k^{\text{point charges}} \frac{q_k}{|\,\mathbf{r}_i - \mathbf{R}_k\,|} \\ &\quad + \sum_\alpha^{\text{QM nuclei}} \sum_k^{\text{point charges}} \frac{Z_\alpha q_k}{|\,\mathbf{R}_\alpha - \mathbf{R}_k\,|}\end{aligned} \quad [4]$$

where $\widehat{H}_0$ designates the gas-phase Hamiltonian of the QM system. The converged SCF energy obtained by the QM program therefore includes *both* the energy of the QM system alone *and* its interaction with the point charges, that is

$$\begin{aligned}E_{SCF} &= \langle \Psi_{QM/MM} | \widehat{H}_0 + \widehat{H}^{el}_{QM-MM} | \Psi_{QM/MM} \rangle \\ &= E_{QM} + E^{el}_{QM-MM}\end{aligned} \quad [5]$$

With the corresponding polarized wave function $\Psi_{QM/MM}$, we can write the energy of the QM system in its environment (but *without* the interaction with the environment) as

$$E_{QM}(\mathbf{R}_{QM};\mathbf{R}_{MM}) = \langle \Psi_{QM/MM} | \widehat{H}_0 | \Psi_{QM/MM} \rangle \quad [6]$$

To evaluate E_{QM} with a standard QM program, we can perform one single SCF cycle using $\widehat{H}_0$ and the polarized wave function.

Free energies from QM/MM molecular-dynamics simulations

Various free-energy methods (such as thermodynamic integration, slow growth, fast growth, free-energy perturbation, or umbrella sampling) have long been developed and used within the framework of classical MD simulations.[14–19] In principle, all these approaches can be applied with a QM/MM, rather than an MM, potential-energy function. An excellent overview of ab initio QM/MM free-energy calculations has recently been given by Hu and Yang.[9] Most commonly, QM/MM free-energy calculations are used to compute the potential of mean force (PMF) along a distinguished coordinate. Usually, the system is driven along this one-dimensional reaction coordinate (RC) from the initial to the final state using constraints (thermodynamic integration, slow growth, fast growth) or restraints (umbrella sampling). The free-energy difference is then obtained by integrating the mean force of constraint or by reconstructing the probability distribution along the reaction coordinate, respectively.

Although feasible in principle, the extended sampling required to produce converged free energies makes these approaches rather expensive when implemented with a QM/MM potential. With a semi-empirical QM method, full QM/MM sampling is well-affordable, as shown here for the chorismate mutase case or in other work from our laboratory.[20–23] However, when a first-principles (ab initio or density functional theory) QM method is required to accurately treat the reactive process, full QM/MM MD simulations become highly computationally demanding, if not prohibitive, even by modern standards (but see, e.g., ref. 24 for an ab initio QM/MM MD study). To alleviate the computational cost of such simulations, methods have been devised that avoid the sampling of the QM region; among them, QM/MM FEP has been widely used. Recent free-energy techniques even allow the computation of the minimum free-energy path and the optimization of stationary points on the free-energy surface.[25–28] QM/MM has also been combined with metadynamics[29–31] as a sampling technique.[32]

QM/MM free-energy perturbation

Here, we first summarize our implementation of the QM/MM FEP method[23] and discuss related schemes thereafter. QM/MM FEP is based on Zwanzig's perturbation formula[33] that expresses the free-energy difference between two states a and b as the exponential average of the potential-energy change between a and b, the (canonical ensemble) average being taken over configurations representative of state a

$$\Delta A^{a\to b} = -k_B T \ln\langle \exp\{-\Delta E^{a\to b}/(k_B T)\}\rangle^a \quad [7]$$

where k_B is Boltzmann's constant and T the temperature. Note that this is not a perturbation treatment in the usual sense; in the limit of complete sampling, eq. [7] is exact. By exchanging the labels of the states, one obtains a "backward" perturbation $\Delta A^{b\to a} = -\Delta A^{a\to b}$.

The basic idea in QM/MM FEP is to use a sequence of QM/MM-optimized structures, typically along a reaction coordinate, as the states and to keep the QM part fixed in each state. The free-energy difference between two states (a, b) along the reaction coordinate is then evaluated by sampling, at the MM level, the energy difference between the QM part being in configuration a to being in configuration b

$$\Delta A^{a\to b}_{env} = -k_B T \ln\langle \exp\{-\Delta E^{a\to b}_{pert}/(k_B T)\}\rangle^a_{MM} \quad [8]$$

with

$$\begin{aligned}\Delta E^{a\to b}_{pert} &= E_{QM-MM}\left(\mathbf{R}^b_{QM}, \mathbf{R}_{MM}(t)\right) \\ &\quad - E_{QM-MM}\left(\mathbf{R}^a_{QM}, \mathbf{R}_{MM}(t)\right)\end{aligned} \quad [9]$$

E_{QM-MM} is the QM–MM interaction energy as defined in eq. [3]; $\mathbf{R}_{MM}(t)$ is the instantaneous configuration of the MM atoms; $\mathbf{R}^a_{QM}$ and $\mathbf{R}^b_{QM}$ are the configurations of the QM atoms fixed in state a and b, respectively.

The subscript "env" in eq. [8] is a reminder that the free-energy difference thus obtained only accounts for the environment and the QM–MM coupling. The free-energy change due to the fixed QM part can simply be approximated in a first step by the corresponding potential-energy difference

$$\Delta A_{QM} \approx \Delta E_{QM} \quad [10]$$

where the QM energy is as defined in eq. [6]. If the two states are stationary points, one can apply the harmonic-oscillator approximation to the QM part to calculate the zero-point vibrational energy, ΔE^{ZPE}_{QM}; the thermal contributions to the internal energy, ΔU^{th}_{QM}; and the entropy contribution, $-T\Delta S_{QM}$:

$$[11] \qquad \Delta A_{QM} = \Delta E_{QM} + \Delta E_{QM}^{ZPE} + \Delta U_{QM}^{th} - T\Delta S_{QM}$$

The final free-energy difference between two stationary points thus becomes

$$[12] \qquad \Delta A = \Delta A_{env} + \Delta A_{QM}$$

Keeping the QM part fixed during the sampling is the first crucial approximation that makes QM/MM FEP computationally viable. The second key approximation is made when calculating the electrostatic QM–MM term. Within the electrostatic embedding scheme, where the QM–MM electrostatic interaction is calculated at the QM level, each change in the configuration of the MM atoms in principle triggers a QM calculation (i.e., a full SCF) to adapt the QM electron density to the new MM positions. We can eliminate the need for these QM calculations in two steps: Firstly, we introduce the approximation that the density will not change when the MM atoms move (frozen-density approximation). The QM–MM electrostatic interaction is then still calculated at the QM level but requires only one SCF cycle. Secondly, we approximate the (frozen) QM density by a point-charge model. Specifically, at each point along the reaction coordinate, we fit a set of point charges, placed on the QM atoms, to reproduce the electrostatic potential of the true density in the vicinity of the QM region (ESP charges). The QM–MM electrostatic interaction, E_{QM-MM}^{el}, during the sampling is thus approximated by the interaction of the ESP charges with the surrounding MM charges, $E_{QM-MM}^{el,ESP}$.

Note that we apply the ESP charge model not only in the calculation of $\Delta E_{pert}^{a\to b}$ but also to evaluate E_{QM} as

$$[13] \qquad E_{QM} = E_{SCF} - E_{QM-MM}^{el,ESP}$$

(cf. eqs. [5] and [6]). This not only eliminates the need for additional SCF cycles altogether but also leads to a consistent description of the QM–MM electrostatic interaction throughout the procedure.

Using the ESP charges, all terms in $\Delta E_{pert}^{a\to b}$ can therefore be evaluated at the classical level, which makes the sampling highly computationally efficient. The computational bottleneck of the procedure is shifted from the sampling to the QM/MM optimizations required to determine the points along the reaction coordinate. In our present implementation, we calculate $\Delta E_{pert}^{a\to b}$ in each MD step (i.e., typically every 1 fs). However, because MD data are correlated, it would actually be sufficient to evaluate $\Delta E_{pert}^{a\to b}$ less frequently as it is done in the related QTCP approach, e.g., every 100 to 1000 MD steps (0.1 to 1 ps).

We validated the different approximations involved in QM/MM FEP using the activation energy of the OH transfer in the enzyme *p*-hydroxybenzoate hydroxylase (PHBH) at the AM1/GROMOS level.[23] As shown in Table 1, the two methods using full QM/MM MD sampling, thermodynamic integration, and umbrella sampling, agree with each other very well and can therefore be considered as a reference. FEP with a full SCF in each sampling step to evaluate E_{QM-MM}^{el} provides a free-energy barrier that is 4–5 kJ mol^{-1} higher. This difference is statistically significant and reflects the approximations introduced by keeping the QM atoms fixed:[1] The dynamics of the environment is decoupled from the dynamics of the QM region.[2] The QM region is not treated dynamically but within the harmonic approximation. The further approximations of the QM/MM FEP approach that make the evaluation of E_{QM-MM}^{el} viable (the frozen-density approximation and the representation of the density by ESP charges) have almost no effect on the result, which differs from FEP with full SCF by 2 kJ mol^{-1}, which is barely statistically significant. We can therefore conclude that the approximations of the QM/MM FEP method lead to deviations in the computed free energies from the fully sampled reference in the order of a few kJ mol^{-1}, which is very acceptable given the massive reduction in computational effort. The major contribution to the deviation stems from keeping the QM region frozen; representing the density by point-charges does not significantly affect the result.

Table 1. Activation free energy of the OH transfer in the enzyme PHBH calculated at the AM1/GROMOS level using different free-energy methods.

Method	$\Delta^{\ddagger}A$ (kJ mol^{-1})[b]	Reference
Thermodynamic integration	101	20
Umbrella sampling	102	23
FEP (full SCF)[a]	106	23
FEP (frozen density)[a]	108	23
FEP (ESP charges)[a]	108	23

[a]The $\Delta^{\ddagger}A$ values from FEP include the QM thermal and entropic terms ($\Delta U_{QM}^{th} - T\Delta S_{QM}$) obtained within the harmonic approximation for the QM part, but are *exclusive* of the zero-point vibrational energy (ΔE_{QM}^{ZPE}) to make them comparable to the thermodynamic-integration and umbrella-sampling results.

[b]The statistical uncertainty of $\Delta^{\ddagger}A$ is 1–2 kJ mol^{-1}.

We also implemented and tested different schemes for handling the link atoms in the FEP approach and found that their effect on the results is small.[23] Moreover, we verified the validity of the ESP fit for densities described by extended basis sets.

Related FEP methods

The QM/MM FEP method described in the previous section is essentially an implementation of the QM/MM-FE method introduced by Zhang et al.,[34] with which it shares all its key features. Rod and Ryde[35,36] presented a closely related approach called QTCP (quantum thermodynamic-cycle perturbation). However, they derived it from slightly different assumptions. They start from a subtractive QM/MM scheme with mechanical embedding, where the QM atoms bear some type of point charges to begin with and the QM–MM electrostatic interaction is described at the classical level. To improve upon this, they introduce two additional FEP calculations (the vertical legs of their thermodynamic cycle) at the initial and final states that recover the free-energy difference due to changing the charge model of the QM region from point charges to a polarizable density. That is, they additionally sample perturbations, in our notation, of the type

$$[14] \qquad \begin{aligned} \Delta E_{pert}^{MM\to QM/MM} &= E_{SCF}\left(\mathbf{R}_{QM}^{a}, \mathbf{R}_{MM}(t)\right) \\ &\quad - E_{QM-MM}^{el,classical}\left(\mathbf{R}_{QM}^{a}, \mathbf{R}_{MM}(t)\right) \end{aligned}$$

(see eq. [16] in ref. 36). $E_{QM-MM}^{el,classical}$ is the QM–MM electro-

static interaction calculated using any kind of point-charge model, not necessarily ESP charges, for the QM region.

This full QTCP scheme is obviously rather costly because of the QM sampling required to evaluate the vertical legs of the cycle. Rod and Ryde therefore introduce approximations akin to the ones used in the QM/MM FEP approach, which eliminate the sampling for the vertical legs: The QM density is kept frozen during the sampling, and the density is represented by ESP charges derived from a QM/MM calculation of the initial state. With these approximations, QTCP essentially becomes equivalent to QM/MM FEP or QM/MM-FE, respectively.

The idea of the QTCP approach to use the FEP formalism to calculate the free-energy due to a change in computational level at the same configuration, rather than between two configurations, was previously exploited by Warshel and co-workers[37] and has been applied also by others.[38–40]

System setups and computational details

Fluorinase

System overview

The enzyme 5′-fluoro-5′-deoxyadenosine synthase (FDAS or fluorinase for short) from the soil bacterium *Streptomyces cattleya* is the only native enzyme known to date to catalyze the formation of C–F bonds.[41] It uses fluoride and *S*-adenosine-L-methionine (SAM) as substrates to produce 5′-fluoro-5′-deoxyadenosine (FDA); see Scheme 1. The enzyme is a hexamer in solution, consisting of a dimer of tightly bound C_3-symmetric homotrimers; each monomer is a chain of 299 amino-acid residues. The trimer unit features three equivalent active sites at the monomer interfaces.

We have previously investigated the C–F bond formation in fluorinase in detail using QM/MM optimization methods at the DFT/CHARMM level.[42] The active site with bound SAM and fluoride is shown in Fig. 2. The position of the fluoride, which is not present in the experimental structure, was determined from classical MD simulations and QM/MM optimizations. In agreement with experimental evidence,[43] we found that the attack of the fluoride at the C5′ position of SAM follows an S_N2-type mechanism. Our study revealed interesting details about the involvement of active-site residues in fluoride binding and produced reaction and activation energies.

Herein, we will report reaction and activation energies for the reaction with the other halides (Cl^-, Br^-, I^-) and free reaction and activation energies for the complete halide series.

System setup

The preparation and setup of fluorinase system was described in detail in ref. 42. In summary, we used a complete trimer unit and hydrated one of the three equivalent active sites with a sphere of water of 25 Å radius centered on the sulfur atom of SAM, which amounts to a total of 17 596 atoms. Inside the hydrated sphere, we defined an active region in which the atoms were free to move while the remaining atoms were kept frozen. To be consistent with previous work,[42] the active region for the optimization of reactant, transition, and product states for the other halides was a shell of 8 Å around SAM and the halide (1394 atoms). For the reaction-profile optimizations and the FEP simulations, the active region was a sphere of 17 Å radius containing 2947 atoms.

Scheme 1. C–F bond formation catalyzed by fluorinase.

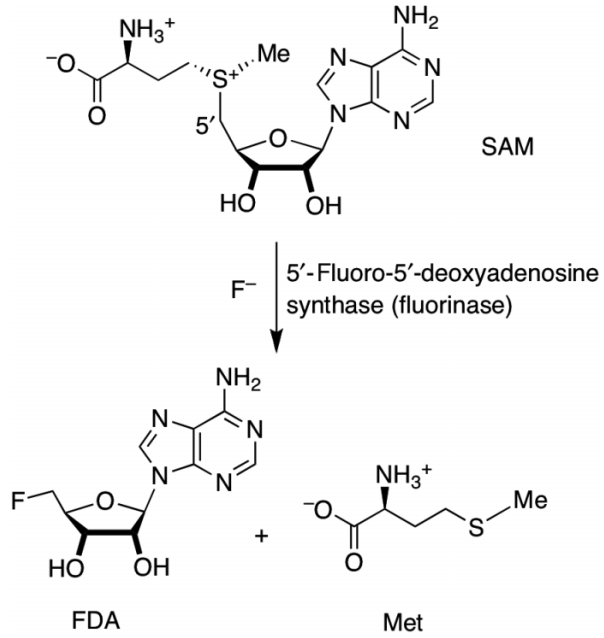


Fig. 2. QM/MM optimized structure of the active site of fluorinase. SAM is shown in ball-and-stick representation; fluoride as a green ball; selected active site residues as sticks; and hydrogen bonds are indicated in orange. The protein chains of the two monomers that form the active site are sketched in grey and yellow, respectively.

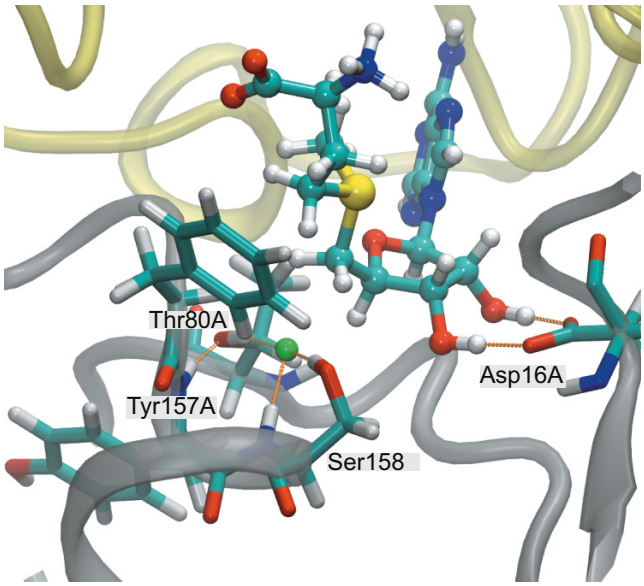


The QM/MM calculations were carried out at the DFT(BP86)/CHARMM level with the modular program package ChemShell.[13,44] QM energy and gradient were provided by TURBOMOLE,[45–49] interfaced to ChemShell. The resolution of the identity (RI) approximation[50–53] was employed with the BP86 functional.[54–57] The def2-TZVP[58,59] basis set was used, augmented with one diffuse function on all atoms (TZVP+; see Supplementary data);[41] the core

electrons of iodine were described by an effective core potential (def2-ecp)[60]. MM energy and gradient were evaluated by ChemShell's internal force-field driver using the CHARMM22[61] all-atom topology and parameter data; the MM electrostatic interactions were fully calculated. The QM electron density was electrostatically embedded into the field of the rigid MM point charges by including them into the QM Hamiltonian. The charge-shift scheme was applied at the QM/MM boundary,[13] and no electrostatic QM/MM cutoff was employed. The QM part contained SAM without the 2-ammoniopropanoate moiety, that is, 5′-(*S*,*S*-dimethylsulfonio)-5′-deoxyadenosine, the covalent bond across the QM/MM boundary being saturated with a H link atom (39 QM atoms).

QM/MM geometry optimizations were performed with a linearly scaling algorithm in hybrid delocalized coordinates (HDLCOpt)[62] as implemented in ChemShell. The residues for the optimization algorithm were the standard amino-acid residues. In microiterative transition-state searches, the core region, for which the Hessean is calculated, included the halide, C(5′)H_2, and S; full details can be found in the Supporting Information to ref. 42.

Structure optimizations with other halides

Starting from the reactant, transition, and product states obtained for the native fluoride,[42] we optimized the respective states for chloride, bromide, and iodide by replacing the halide and re-optimizing the active region. This procedure allowed the local environment to adjust to the different sizes and charge distributions of the halides, but it does not account for longer-range effects.

QM/MM reaction profile and harmonic frequencies

The reaction coordinate was defined as the difference between the bond being broken and the bond being formed, $\xi = d(\text{S–C5}) - d(\text{C5′–X})$, where X = F, Cl, Br, I. The reaction profiles were calculated by QM/MM optimizations from $\xi = -1.0$ to 2.2 Å (full profile, for F) or $\xi = -1.4$ to 0.4 Å (profiles from reactant to transition state only, for Cl, Br, I) initially in steps of 0.2 Å. If the FEP forward and backward simulations at a given RC step showed convergence problems, the step size was reduced by inserting additional optimization points. This was only necessary in certain parts of the profile between the transition and the product state. In this region of the RC, the fluoride anion gradually becomes a fluoro substituent bearing a much smaller charge, which leads to a rearrangement of the hydrogen bonding around the fluorine.

To calculate the QM contribution to the free energy at the stationary points from the harmonic approximation, numerical second derivatives were calculated at these points for the QM region (partial Hessean including the QM atoms and the MM boundary atom, consistent with link-atom method 4)[23] using ChemShell. Two displacements of 0.01 au were done per degree of freedom; the SCF convergence was tightened for the Hessean calculations (scfconv 10, grid m4).

Free-energy perturbations

For each QM/MM-optimized structure along the RC, a set of ESP charges for the QM atoms was derived by fitting to the electrostatic potential at the positions of the 200 MM atoms nearest to the QM region. With the QM region (plus the MM boundary atom) held fixed, the active region of the system was then equilibrated by QM/MM MD at 300 K under *NVT* conditions. The QM–MM electrostatic interaction in all simulations was evaluated at the classical level using the ESP charges. The MD time step was 1 fs. The Berendsen thermostat[63] ($\tau_T = 0.1$ ps) was used during the first 10 ps of the equilibration phase; the Nosé–Hoover chain thermostat[64–67] (with a chain length of 4; $\tau_{NHC} = 0.02$ ps, corresponding to $\tilde{\nu}_{NHC} = 375$ cm^{-1}) thereafter. The total equilibration time was 50 ps at each RC point.

The FEP simulations were then carried out; both forward and backward perturbations were done. The sampling time per step was 20 ps, of which the first ps was always discarded. The data of the remaining 19 ps were subjected to coarse-graining and statistical tests as described in ref. 20. Additional data were discarded as necessary to obtain a series with trend-free mean and variance. Note that the sampling length effectively used to calculate the average therefore varies between steps. The maximum deviation between forward and backward perturbation at a given RC step was about 3 kJ mol^{-1}; typical deviations were <1 kJ mol^{-1} (Fig. 3).

The discontinuities in the sampled free-energy increments in Fig. 3 are caused by non-continuous changes between the optimized structures along the reaction path that are not explicitly included in the RC. For example, the dip at $\xi = 0.7$ Å is related to the breaking of a hydrogen bond and the formation of a new one in the vicinity of the fluoride ion in the MM part. This hydrogen-bond rearrangement causes the decrease in A_{env} (plotted in Fig. 3), which is, however, counterbalanced by an increase in E_{QM}. Therefore, the sum $A(\xi) = E_{QM} + A_{env}$ is smooth (see Fig. 7). Such discontinuous changes in the environment free energy that arise from shifts between the QM energy and the environment energy due to structural rearrangements in the MM region do not disappear with longer sampling or smaller steps in ξ; note that the associated error bars are not larger than those for other points along the reaction coordinate.

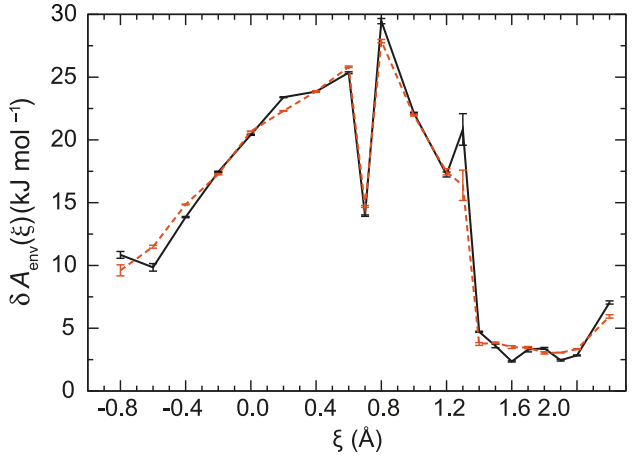
On the other hand, there are features like the one at $\xi = 1.3$ Å (with a larger sampling error and a larger difference between forward and backward perturbation relative to other points) that are related to structural rearrangements in the QM part. Their error bars would be reduced by adding more steps in ξ. In the present case, this was not done at $\xi = 1.3$ Å because the error bar was still deemed acceptable and because the point does not contribute to the barrier, which is of primary interest here.

P450cam

System overview

The cytochrome P450 enzymes constitute a superfamily of haem monooxygenases that perform a variety of essential functions, such as detoxification and biosynthesis, in nearly all living species. They catalyze a variety of oxidation processes, including aliphatic and aromatic hydroxylation, epoxidation, and heteroatom oxidation. The extensive theoretical work on these enzymes has been reviewed.[68] QM/MM studies in our laboratory[69–84] (see ref. 4 for a summary) have focused on P450cam from the bacterium *Pseudomonas putida*, which catalyzes the selective hydroxylation of camphor at

Fig. 3. FEP-sampled environment free-energy increments, $\delta A_{env}(\xi_i \rightarrow \xi_{i+1})$ and $\delta A_{env}(\xi_{i+1} \rightarrow \xi_i)$ for the forward and backward perturbations, respectively, along the reaction coordinate for the fluorination reaction in fluorinase. The increments are plotted at ξ_{i+1} for both sampling directions; hence, there is no value at $\xi_1 = -1.0$ Å. The error bars show the statistical uncertainty (standard deviation of sampled mean). Black line: Forward perturbations; red dashed line: backward perturbations.



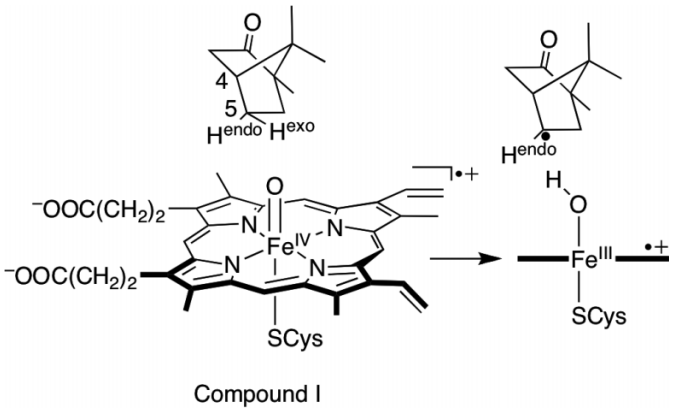
C5 to the exo alcohol (Scheme 2). The crucial reactive intermediate is an iron(IV)-oxo species (Compound I) with three unpaired electrons that give rise to almost degenerate doublet and quartet states. Compound I is able to abstract an aliphatic hydrogen from the substrate. Subsequently, the substrate radical thus generated recombines with the iron(III) hydroxo ligand to form the hydroxylated product.

We have previously studied the hydrogen-abstraction step in P450cam at the DFT(B3LYP)/CHARMM level by QM/MM optimizations.[71,77,78,80] Herein, we report on FEP simulations of this step.

System setup

We started from an optimized hydrogen-abstraction transition state obtained previously. The details of preparing and setting up the system have been published previously.[71,77,78,80] The procedures used were conceptually and technically very similar to the ones described above for fluorinase. We only highlight system-specific differences from here on. The enzyme was fully hydrated by enclosing it into a water shell of 15 Å, the outer 10 Å of which were kept fixed; the total system size is about 24 000 atoms. The active region contained 444 atoms in optimizations and 7439 atoms for the FEP simulations. The QM region included 51 atoms (region R1):[71,77,78,80] the oxy-haem without the side chains; the thiolate S of the distal cysteine; and the $C(4)HC(5)H_2C(6)H_2$ fragment of camphor. Twelve hydrogen link atoms were used to saturate the bonds across the QM–MM boundary; the QM region therefore was [FeO(porphine)(SH)] + propane. The electronic structure was described by the B3LYP functional[54,55,85–88] as implemented in TURBOMOLE. The basis set of double-ζ quality denoted B1[71,77,78,80] was used. All calculations were done in the quartet state ($S = 3/2$). The MM region was described by the CHARMM22[61] force field. All QM/MM calculations were done with ChemShell.

Scheme 2. Hydrogen abstraction from camphor by Compound I of P450cam.



QM/MM reaction profile and FEP simulations

The reaction coordinate was defined as the difference between the bond being broken and the bond being formed, $\xi = d(C5–H^{exo}) - d(H^{exo}–O)$. Starting from the optimized transition state, the reaction profile was produced initially from $\xi = -1.2$ to 1.4 Å in steps of 0.2 Å and subsequently refined to a step size of 0.1 Å. Frequency calculations at the stationary points were not performed for this case.

At the transition state, the system was equilibrated for 30 ps at 300 K (time step of 1 fs) with the QM part and MM boundary atoms being frozen in addition to the outer water layer (7388 active atoms). For the other points along the RC, the QM region of the equilibrated TS was replaced by the QM/MM-optimized QM region of the respective point and then re-equilibrated for 20 ps. A cutoff of 15.9 Å was used for the non-bonded MM–MM interactions with a pair-list updated every 25 steps. No QM/MM cut-off was applied.

For the FEP simulations, both forward and backward perturbations were performed. The sampling time at each RC point was 20 ps. Only the trend-free[20] part (no less than 8 ps) of the data was used to calculate the average. The P450cam system is particular in that it has rather many link atoms.[12] The impact of different link-atom treatments is therefore more pronounced. With steps of 0.2 Å and link-atom method 4,[23] where both QM and MM boundary atoms and the link atoms are perturbed, the sampled free-energy differences deviated between the forward and backward perturbation by 19 kJ mol^{-1} on average, which was considered unacceptable. Applying link-atom method 2,[23] where the MM boundary atoms remain unperturbed, the average deviation between the forward and backward perturbation was still 15 kJ mol^{-1}. Only by reducing the step size to 0.1 Å and using link-atom method 4, we obtained an acceptable agreement (maximum deviation of 7 kJ mol^{-1}) between forward and backward perturbations. Only these results will be discussed below.

Chorismate mutase

System overview

The enzyme chorismate mutase catalyzes the Claisen rearrangement of chorismate to prephenate, without covalent-

bond formation between the substrate and the enzyme (Scheme 3). The reaction, a rare example of a pericyclic reaction in biochemistry, is a key step of the shikimate pathway for the synthesis of aromatic amino acids in plants, fungi, and bacteria. It has been the subject of numerous theoretical studies devoted to the structure of the enzyme–substrate complex, reaction pathways, and the role of specific residues in transition-state stabilization. It has also served as an important case for testing and developing theories on the origin of enzymatic catalysis. A summary of recent theoretical work is provided in ref. 4. Here, we have investigated the Claisen rearrangement in the *Bacillus subtilis* chorismate mutase (BsCM) by means of umbrella-sampling free-energy simulations at the semi-empirical QM/MM level.

Preparation and setup

Full details about system preparation and setup, methods, and programs can be found in the Supplementary data. All simulations were performed with the program CHARMM[89,90] using the self-consistent-charge density-functional tight-binding (SCC-DFTB) method[91,92] for the QM region (substrate, 24 atoms) and the CHARMM22[61] all-atom force field for the MM region (protein and solvent atoms, 13 397 atoms). No electrostatic QM/MM cut-off was employed; MM electrostatic interactions were treated with the extended electrostatics method.[90,93]

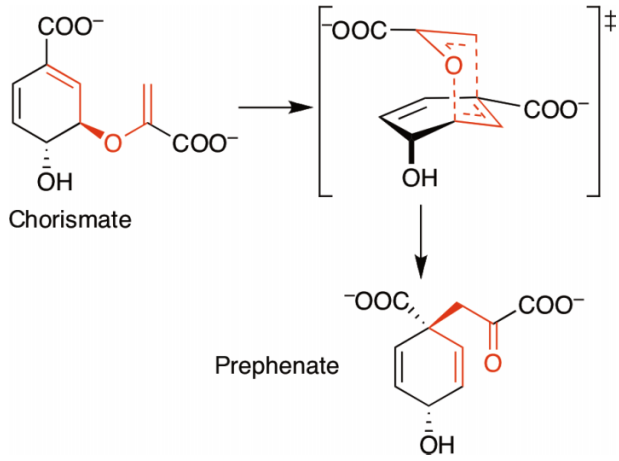
The initial coordinates of BsCM bound to a transition-state analogue (TSA) were obtained from the Protein Data Bank (PDB code 2CHT). The crystal structure[94] consists of four trimers in the asymmetric unit; only the first one was retained. The TSA in the active site at the interface between chains A and B was converted to chorismate; the other two TSA molecules were removed. The BsCM–chorismate complex was hydrated with a 30 Å sphere of water. Protein and substrate atoms within 17 Å from the origin of the sphere and all (crystallographic and added) water molecules within 30 Å were free to move (active region). The system was then subjected to QM/MM MD simulations under *NVT* conditions (time step 1 fs). After 200 ps of equilibration, 10 snapshots were taken every 10 ps as initial configurations for the subsequent QM/MM simulations. Depending on the snapshot, the active region included about 9850 atoms.

Umbrella-sampling simulations

The free energy of activation and the free energy of reaction of chorismate to prephenate in the active site of BsCM were obtained from umbrella-sampling[95] simulations along a reaction coordinate defined as the difference between the lengths of the breaking C–O and the forming C–C bond. The biased MD simulations consisted of two parts: First, the snapshots were equilibrated in the reactant state (ξ = –2.5 Å) at 300 K for 20 ps. Then, the RC was sequentially changed from –2.5 Å to 2.5 Å in steps of 0.1 Å (51 windows). In each window, the system was sampled for 10 ps, and RC data were collected in every time step. Only the data of the last 9 ps were used for the analysis. The sampling was then repeated in the backward direction starting from ξ = 2.5 Å.

We used umbrella integration (UI)[21,22] as well as the weighted histogram analysis method (WHAM)[96] to combine the windows of the US simulations. The number of bins was always chosen to be 500. Using 1000 bins left the free-energy results virtually unchanged for either UI or WHAM. UI and WHAM yielded essentially identical results, differing by no more than 0.8 kJ mol^{-1}. The root-mean-square deviation (RMSD) between UI and WHAM results was 0.4 kJ mol^{-1} for the activation free energies and 0.2 kJ mol^{-1} for the reaction free energies. The values reported below were obtained using UI.

Scheme 3. Claisen (allyl vinyl ether to 4,5-unsaturated ketone) rearrangement of chorismate to prephenate in chorismate mutase.



Potential-energy profiles

Complementary to the free-energy reaction profiles obtained from US, we also calculated potential-energy profiles for all the snapshots. The structures were energy-minimized and then subjected to reaction-path calculations using the same RC definition as for the US simulations. The reaction pathways were calculated in both the forward and backward direction. To precisely locate minima and maxima in the reaction profiles, the energy curves were fitted by cubic splines.

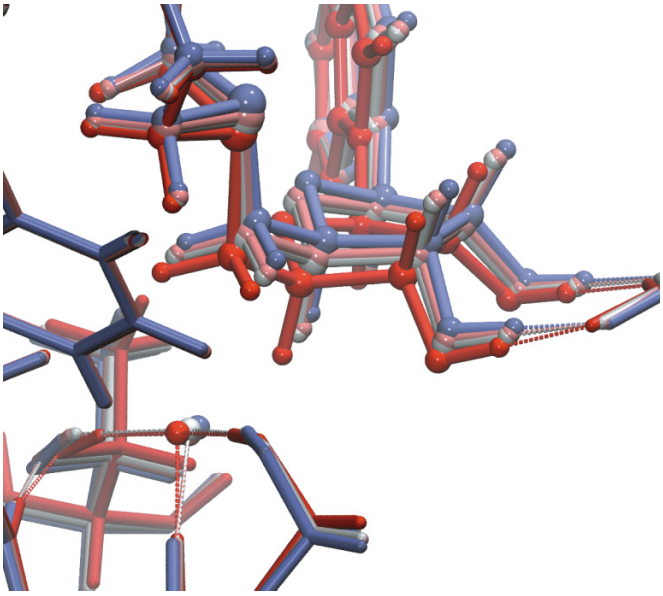
Results

Fluorinase

Optimizations with halides other than fluoride

The QM/MM-optimized reactant states with bound SAM and halide for all four halides are shown in Fig. 4. It can be seen that the structures are largely superimposable and only minor adjustments have taken place (here and below, structure were superimposed by aligning all fixed atoms). The structures with Cl^- and Br^- in particular are nearly identical. While the chosen optimization procedure does not allow for larger rearrangements, the stable binding position of SAM is explained by the highly specific recognition in the binding site through multiple hydrogen bonds with the adenine part and salt bridges and hydrogen bonds to the zwitterionic amino acid of the methionyl part. Additionally, the ribose part is held in position by the double hydrogen bond to Asp 16A. The halide binding site is in all cases formed by hydrogen bonds from the side-chain OH and the backbone NH of Ser 158A and the side-chain OH of Thr 80A. Selected structural parameters of the reactant states are collected in Table 2. The trends seen along the halide series follow the expected pattern. With increasing size of the halide, and

Fig. 4. Superimposed optimized reactant states for the complete halide series in the fluorinase: F (red), Cl (white), Br (salmon), and I (blue); for clarity, the halides are all represented by a sphere of the same size.



thus decreasing charge density, the hydrogen-bonding distances to the halide become monotonically longer. The biggest changes are seen from F to Cl and then from Br to I, while the Cl and Br systems are very similar. The distance between the halide and the attacked C5′ also increases along the series. However, only the change from F to Cl is larger than the other two. The slightly lengthened C5′–S bond for F compared with the other halides suggests an increased degree of activation towards nucleophilic attack.

The optimized transition states are presented in Table 3 and Fig. 5. The pertinent changes between reactant and transition state have already been discussed for fluoride[42] and apply also to the other halides, i.e., the C5′–S bond is essentially broken, the X–C5′ bond is partially formed, and the coordination around C5′ is trigonal-planar; in brief, it is a nearly ideal S_N2 transition state. As the reaction progresses, the attacking halide's negative charge is increasingly delocalized over the substrate as the interaction between halide and substrate increases. This is reflected in weakened hydrogen bonds to the halide, especially the Thr 80A OH···X bond is starting to break at the transition state. The hydrogen bonds from Ser 158A, however, are only slightly lengthened at this stage, somewhat more for F than for the other halides. In the product states (Table 4 and Fig. 6), the X–C5′ bond is fully formed and the methionine leaving group is well-separated from the halogenated deoxynucleoside. Only the hydrogen bond from the Ser 158 amide NH to the halogen is retained. Remarkably, the halogen position does not differ very much along the series, despite the differences in C5′–X bond lengths (the C–I bond is 0.7 Å longer than the C–F bond). The RMSD from F is between 0.1 Å (Br) and 0.4 Å (I); the ribose unit as a whole is displaced relative to the F system by 0.3 Å (Cl, Br) to 0.5 Å (I). To accommodate the longer C5′–X bonds for the heavier halogens, while keeping the halogen itself almost at the same position, the exocyclic torsion about C4′–C5′ needs to adjust. There are

experimental structures available of the fluoro-[41] and the chloro-product.[97] Essentially, they agree perfectly with the QM/MM-optimized structures, which validates our approach.

The energetic data from the optimizations of the stationary points are summarized in Table 5. They reveal three main results: (*i*) The reaction is exothermic only with fluoride, while it is endothermic with the other halides; (*ii*) the forward barrier is lowest for fluoride; (*iii*) therefore, the backward barriers for the other halides are significantly

lower than the backward barrier for fluoride. Fluorinase thus has a clear preference in the C–X bond-forming step for fluorination over other halogenations. This is also reflected in the extent to which the C–X bond has formed in the transition state (Table 5), which, in agreement with the Hammond postulate, shows an earlier transition state for fluoride than for the other halides.

The calculated preference for fluoride over chloride is in agreement with the experimental data:[97] Fluorinase was found to act also as a chlorinase, however, with the equilibrium of the reaction being shifted to the reactant side and with much lower activity, as expected from the calculated reaction and activation energies. The measured ratio of effective rate constants of the forward reactions with fluoride and chloride corresponds to a difference in activation energy ($\Delta\Delta^{\ddagger}G$ at 298 K) of 12 kJ mol^{-1}. The excellent agreement with the calculated difference of 10 kJ mol^{-1} is certainly fortuitous; however, it again provides support for the validity of our approach in the present case.

Experimentally, no activity has been observed with bromide or iodide. Our results would not suggest such a discrimination between, e.g., chloride and bromide, although the reaction with bromide is more endothermic and has a somewhat higher barrier. However, it should be kept in mind that we have investigated only the C–X bond-forming step, while the halide selectivity may well be determined earlier in the mechanism. For instance, the halide-binding step, which will involve the (partial) replacement of the halide's hydration water by interactions with the protein, may well be decisive for the halide selectivity.[98,99] It is interesting to note that the recently reported SAM chlorinase SalL,[100] which is structurally, and thus presumably also mechanistically, similar to fluorinase, accepts chloride, bromide, and iodide, but not fluoride, as halide substrate.

Table 5. Reaction and activation energies (in kJ mol^{-1}) as well as relative lengths of the forming and breaking bonds in the TS for C–X bond formation in fluorinase. Data from QM/MM optimizations of stationary points (at BP86/def2-TZVP+/CHARMM level).

Free energies

The forward activation free energies obtained from the FEP simulations for C–X bond formation in fluorinase with X = F, Cl, Br, and I are collected in Table 6. We also provide the contributions of the individual components that sum up to the total free-energy difference according to eqs. [11] and [12]. With fluoride only, we determined the complete free-energy profile from reactants to products (Fig. 7), which allowed us to calculate also the reaction free energy: $\Delta_r A$ = –19.5 ± 0.6 kJ mol^{-1} (composed of $\Delta_r A_{env}$ = 261.9 ± 0.6 kJ mol^{-1}, $\Delta_r E_{QM}$ = –275.1 kJ mol^{-1}, $\Delta_r E_{QM}^{ZPE}$ = 0.0 kJ mol^{-1}, and $\Delta_r U_{QM}^{th} - T\Delta_r S_{QM}$ = –6.3 kJ mol^{-1}).

Comparing the free energies (excluding ΔE_{QM}^{ZPE}) with the corresponding potential energies from Table 5, the main conclusion is that the effect of finite temperature on the reaction and activation energies investigated is small (<3 kJ mol^{-1}) in this case. Without the ZPE and finite-temperature contributions to the free energy from to the QM part, the potential-energy and free-energy profiles are essentially identical from the reactant up to the transition state (shown for fluoride in Fig. 7). Also the values of the reaction coordinate at the stationary points of the free-energy curve differ only insignificantly from their potential-energy counterparts.

An explanation for this small difference between potential and free energies in the reactive step can be found in the high degree of pre-organization and pre-orientation provided by the active site. The reactants are ideally set up and held in place for the S_N2 process by their various interactions with the protein throughout the reaction. Moreover, only minimal adjustments to the active-site structure are necessary to accommodate either the reactants or the products. There is therefore not much room for thermal and entropic contributions to the free energy.

Cytochrome P450cam

The results for the hydrogen abstraction from camphor by Compound I of cytochrome P450cam are summarized in Table 7. Like for fluorinase, the differences between poten-

Table 6. Activation free energy (for the forward reaction, $\Delta^{\ddagger}A$(fw), in kJ mol^{-1}) and its components according to eqs. [11] and [12] from QM/MM FEP for C–X bond formation in fluorinase. Also given are the values of the reaction coordinate (in Å) at the stationary points of the free-energy profile.

	F	Cl	Br	I
$\Delta^{\ddagger}A$(fw)	53.5±0.6	64.5±1.7	71.2±0.3	61.5±1.0

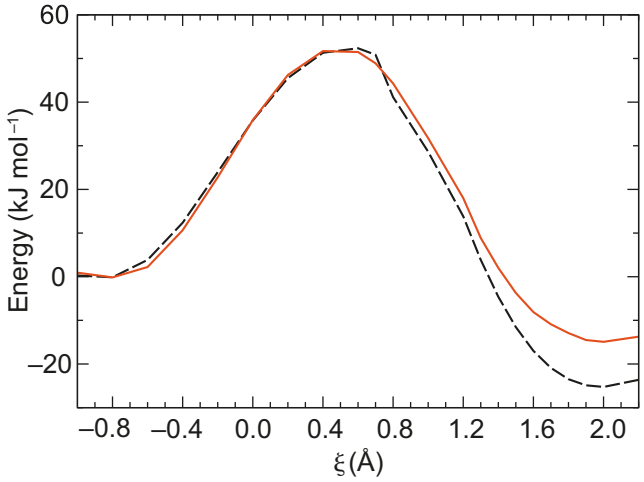
ξ_{TS} (FEP)	0.51	0.28	0.23	0.02

Fig. 7. Reaction profile of the C–F bond formation in fluorinase. Dashed line: Potential-energy profile; solid line: free-energy profile. Note that the free-energy curve only includes $\Delta A_{env} + \Delta E_{QM}$ because the harmonic approximation for the calculation of the QM ZPE and finite-temperature terms is valid only at stationary points.



tial and free energies are small (see Fig. 8), although we note that the free-energy values here were calculated as $\Delta A_{env} + \Delta E_{QM}$ only (i.e., not including the ZPE and finite-temperature contributions from the QM part). Previous gas-phase model calculations at the B3LYP level[66] gave ZPE and enthalpic finite-temperature corrections to the QM barrier of –18 and +2 kJ mol^{-1}, respectively. Thus, the overall finite-temperature contribution remains small (nominally 4 kJ mol^{-1}, ignoring $\Delta^{\ddagger}S_{QM}$), while the ZPE correction to the barrier is significant for hydrogen transfer and should be applied to both ΔE and ΔA. The values of the reaction coordinate at the stationary points differ only slightly between the potential-energy and free-energy profiles, respectively: ξ_{RS} = –0.99/–1.03 Å (opt/FEP); ξ_{TS} = 0.17/0.18 Å; ξ_{PS} = 1.10/1.07 Å. Again, the small effect of finite temperature on structure and energetics of the hydrogen-abstraction reaction can be attributed to the pre-orientation of the bound reactants. Figure 9 shows the optimized TS; camphor is seen to be hydrogen-bonded to an active-site Tyr residue.

Chorismate mutase

Table 8 reports the activation and reaction energies obtained by optimizations for the conversion of chorismate to

Table 7. Activation and reaction energies (in kJ mol^{-1}) for the hydrogen abstraction in P450cam. Both potential energies and free energies are given.

	Forward barrier	Reaction energy

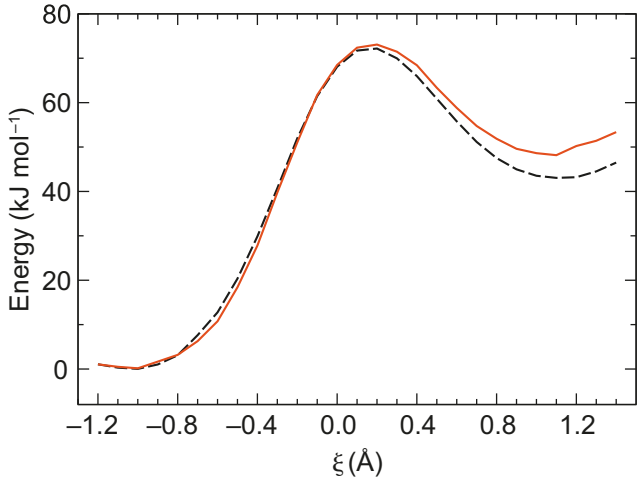
ΔA(FEP)	73±2	48±2
ΔA_{env}	–15±2	–19±2
ΔE_{QM}	88	67

Note: Free energies do not include the QM ZPE and finite-temperature terms.

Fig. 8. Reaction profile of the H-abstraction in P450cam. Dashed line: Potential-energy profile; solid line: free-energy profile. Note that the free-energy curve only includes $\Delta A_{env} + \Delta E_{QM}$.



prephenate in *B. subtilis* chorismate mutase. The values for the barrier range from 21.8 to 38.7 kJ mol^{-1} across the forward and backward scans of the 10 snapshots, with a mean of $\Delta^{\ddagger}E$ = 27.5 ± 1.2 kJ mol^{-1} (the error bar indicated is the single standard deviation of the mean over the 20 values, corresponding to a confidence level of 68%). The reaction energies cover the interval from –68.5 to –98.4 kJ mol^{-1}; the mean is $\Delta_r E$ = –83.5 ± 1.9 kJ mol^{-1}. The standard deviations of the individual energy values are 5.3 kJ mol^{-1} and 8.3 kJ mol^{-1}, respectively. The difference between forward and backward scan for a given snapshot is at most 1.0 and 0.5 kJ mol^{-1} for $\Delta^{\ddagger}E$ and $\Delta_r E$, respectively. The associated RMSD (forward vs. backward) is 0.3 kJ mol^{-1} for the barriers and 0.2 kJ mol^{-1} for the reaction energies.

Multiple potential-energy profiles for the reaction of interest were previously calculated with hybrid DFT QM/MM methods (B3LYP/6–31G(d)/CHARMM27).[101] From 16 different reaction pathways, an average reaction barrier of 50.2 kJ mol^{-1} was obtained, with a standard deviation of 7.1 kJ mol^{-1}. Like in the present work, a large spread of the calculated barriers from 37.7 to 62.8 kJ mol^{-1} was reported. The differences in barrier height between the 16 QM/MM reaction profiles were explained by differences in the microstructure of the active site. Another research group[102] performed reaction-path calculations for the rearrangement of chorismate to prephenate in BsCM at various QM/MM levels of theory. At the B3LYP/6–31+G(d)/CHARMM22 level, they calculated $\Delta^{\ddagger}E$ = 37.4 kJ mol^{-1} and $\Delta_r E$ = –81.6 kJ

Fig. 9. Transition-state structure for the hydrogen abstraction from camphor in cytochrome P450cam. Camphor and haem are represented as all-atom ball-and-stick models. The residues of the binding pocket are shown as sticks; only hydrogen atoms involved in hydrophobic interactions or H-bonds (Tyr) with camphor are shown. mol^{-1}, while their best estimates (34.3 and –96.7 kJ mol^{-1}, respectively) were obtained using MP2 instead of B3LYP. We also refer to ref. 102 for an overview of previous theoretical results. The experimental value[103] for the activation enthalpy is $\Delta^{\ddagger}H$ = 53.1 ± 1.7 kJ mol^{-1} (at 298 K). Comparing the calculated value for $\Delta^{\ddagger}E$ to the experimental result for $\Delta^{\ddagger}H$, as is usually done in the literature,[101] the experimental barrier is clearly underestimated by the present value of $\Delta^{\ddagger}E$ = 27.5 ± 1.2 kJ mol^{-1}; the relative error is –48%.

The Helmholtz free energies of activation and reaction for the Claisen rearrangement of chorismate to prephenate in BsCM calculated with US for the 10 snapshots are shown in Table 9. It should be noted that free energies from US (and other techniques where the full system is sampled by classical mechanics) do not include any ZPE contributions. The $\Delta^{\ddagger}A$ values from forward and backward runs range from 30.8 to 46.1 kJ mol^{-1}, with a mean of 36.5 ± 0.8 kJ mol^{-1}, which is thus our best estimate for the activation free energy. The $\Delta_r A$ values lie within a range of –67.6 to –88.6 kJ mol^{-1}; the mean is –75.2 ± 1.3 kJ mol^{-1}. The standard deviation of the individual values amounts to 3.5 and 5.7 kJ mol^{-1} for the $\Delta^{\ddagger}A$ and $\Delta_r A$ data, respectively. We note that propagating the statistical sampling errors reported in Table 9 would produce smaller error bars for the mean (0.3 and 0.5 kJ mol^{-1}, respectively). However, these would not properly represent the distribution of the individual values.

The free-energy barriers obtained from the forward and backward runs on a given snapshot agree within 5 kJ mol^{-1}; the RMSD is 4.4 kJ mol^{-1}. The 30 ps and 40 ps snapshots are exceptions where the deviation is larger (6.7 and 9.4 kJ mol^{-1} in absolute value, respectively). For the reaction free energies, four snapshots (10 ps, 40 ps, 80 ps, and 90 ps) have a forward-versus-backward difference of >5 kJ mol^{-1} in absolute value (9.5, 7.7, 13.5, and 11.6 kJ mol^{-1}, respectively). The RMSD is 7.0 kJ mol^{-1}. The variability of values between sampling directions for the same snapshot as well as between different snapshots may be explained as a consequence of yet incomplete sampling. The distribution could be narrowed by equilibrating more extensively in each window and (or) additional sampling.[20]

Note: US free energies do not include ZPE contributions.

The present result for the free energy of activation of 36.5 ± 0.8 kJ mol^{-1} agrees well with the value of 33.5 kJ mol^{-1} obtained from multiple-steering MD simulations employing a DFT QM/MM Hamiltonian.[104] In the same study, the reaction free energy was calculated to be about –88 kJ mol^{-1}, which lies at the lower end of the present range of $\Delta_r A$ values. Recently,[105] the free-energy profile was calculated by ab initio QM/MM combined with constrained MD-FEP simulations, yielding 41.4 kJ mol^{-1} for the free-energy barrier and about –84 kJ mol^{-1} for the reaction free energy. The experimental value[103] for the Gibbs free energy of activation is 64.4 kJ mol^{-1} (298 K). All the calculations above thus clearly underestimate the barrier. The relative error for the present free-energy barrier (–43%) is similar to the one of the activation enthalpy (–48%).

The overall finite-temperature effect on the barrier, calculated from our best estimates for $\Delta^{\ddagger}A$ and $\Delta^{\ddagger}E$ (see above), is $T\Delta^{\ddagger}S - \Delta^{\ddagger}U_{th}$ = –9.0 ± 1.4 kJ mol^{-1} at T = 300 K. It is dominated by the entropic contribution, since the change of the thermal contribution to the internal energy, $\Delta^{\ddagger}U_{th}$, is

generally very small. Alternatively, we can calculate individual values for the finite-temperature effect on the barrier for all the snapshots (forward and backward direction) reported in Tables 8 and 9. The corresponding 20 values range from –18.7 to +2.0 kJ mol^{-1}, with a mean of –8.9 ± 1.2 kJ mol^{-1} and a standard deviation of 5.6 kJ mol^{-1}. Obviously, both estimates for the finite-temperature effect on the barrier are close to each other (–9.0 ± 1.4 vs. –8.9 ± 1.2 kJ mol^{-1}) and in good agreement with the experimental[103] value of $T\Delta^{\ddagger}S$ = –11.4 ± 1.5 kJ mol^{-1} at T = 298 K. The difference between free and potential energy is thus larger in this case than for the two systems discussed above.

The finite-temperature effect on the reaction energy can be computed analogously either from our best estimates for $\Delta_r A$ and $\Delta_r E$ (see above) or from the corresponding individual snapshot values, which yields –8.3 ± 2.3 and –8.3 ± 2.6 kJ mol^{-1}, respectively. The 20 snapshot values range from –25.1 to +20.0 kJ mol^{-1}, with a standard deviation of 11.6 kJ mol^{-1} (indicating a larger scatter than in the case of the barriers).

Discussion

In this paper, we have presented potential-energy and free-energy data from QM/MM optimizations and MD-based simulations for the carbon–halide bond formation in fluorinase, the hydrogen abstraction from camphor by Compound I in cytochrome P450cam, and the chorismate-to-prephenate rearrangement in *B. subtilis* chorismate mutase. For the purpose of discussion, we complement these results with similar data obtained for the OH transfer in *para*-hydroxybenzoate hydroxylase (PHBH). The free energy of activation in PHBH at the AM1/GROMOS level is 101 kJ mol^{-1} (average from thermodynamic-integration runs on 10 snapshots; individual values range from 95 to 106 kJ mol^{-1}).[20] The potential-energy barriers obtained from geometry optimizations of the corresponding snapshots at the same level vary between 90 and 109 kJ mol^{-1} (avg. 100 kJ mol^{-1}). The finite-temperature contribution to the barrier is thus small for PHBH; nominally (judging from the average values) of the order of 1 kJ mol^{-1}, which is well within the statistical uncertainty of the thermodynamic-integration simulations and the RMS deviation of the results for the different snapshots.

For chorismate mutase, the availability of data from ten different snapshots (with a forward and a backward value each; Tables 8 and 9) enables us to assess the uncertainty of "single-snapshot" results. Statistically, a measurement falls within an interval of ±2σ around the mean with 95% probability, where σ is the sample standard deviation. Treating the 20 data points as statistically independent, one obtains 2σ error bars of 10.6 and 7.0 kJ mol^{-1} for $\Delta^{\ddagger}E$ and $\Delta^{\ddagger}A$, respectively, and of 16.6 and 11.4 kJ mol^{-1} for $\Delta_r E$ and $\Delta_r A$, respectively. Alternatively, one may consider the maximum deviations from the mean, which are 11.2 ($\Delta^{\ddagger}E$), 9.6 ($\Delta^{\ddagger}A$), 15.0 ($\Delta_r E$), and 13.4 ($\Delta_r A$) kJ mol^{-1}. Combining these values with the PHBH snapshot data,[20] we can assign a rather approximate, but practically useful, error bar of about 10 kJ mol^{-1} for (free) energy differences obtained on a single snapshot of a biomolecular system. The errors tend to be smaller for free energies than for potential energies because the former involve sampling. Also, they appear to be somewhat smaller for barriers than for reaction energies.

If one wants to improve on the accuracy of a "single-snapshot" value, be it a free-energy difference obtained from some kind of sampling technique or, even more so, a potential-energy difference obtained by optimizations, it is necessary to perform calculations for several independent snapshots extracted from extended MD simulations. Such a protocol is arguably the most practical way to include effects due to the variability of the wider environment into QM/MM results.

Leaving reaction energies aside, we now focus on activation barriers, in particular on the entropic contributions to barriers. Strictly speaking, the results obtained from umbrella sampling or thermodynamic integration represent $T\Delta S - \Delta U_{th}$, but since ΔU_{th} is generally small (of the order of 1 kJ mol^{-1}), we shall use the term "entropic contribution" for these quantities (as well as for $T\Delta^{\ddagger}S$ itself). We find the calculated entropic contribution (at 300 K unless noted otherwise) to be small for fluorinase, P450cam, and PHBH (between 1 and 4 kJ mol^{-1} in absolute value); only for BsCM, it is somewhat higher (9 kJ mol^{-1}). To put these values into perspective, we have compared to gas-phase data. The Claisen rearrangement in BsCM lends itself particularly well to such a comparison because the reaction is intramolecular, which makes the choice of gas-phase model obvious, and is experimentally known to have a sizeable entropic contribution to the barrier also in the enzyme.

We have calculated the activation free-energy for the rearrangement of chorismate to prephenate in the gas phase at SCC-DFTB level and obtained (at 300 K) $T\Delta^{\ddagger}S$ = –13.6 kJ mol^{-1} ($\Delta^{\ddagger}G$ = 94.0 kJ mol^{-1}; the chorismate reactant was taken to be in the reactive conformation). Compared with our value in the enzyme of –9.0 kJ mol^{-1}, the activation entropy is therefore 50% higher in the gas phase. This substantial reduction of the entropic contribution in the enzyme is attributed to the pre-organization of the reactant in the active site that is found to be significant even for an intramolecular process like the Claisen rearrangement. The reduced, but still fairly large, negative activation entropy in the enzyme is rationalized by considering the tight, rather rigid pericyclic TS. In the chorismate reactant, even when enzyme-bound, the interaction between the two reacting carbon atoms is only weakly preformed and leaves sufficient motional freedom to the fragments, which are only connected by the C–O bond. In the TS, however, both the forming C–C and the breaking C–O interactions are partial covalent bonds, with correspondingly low flexibility with respect to distance and orientation. So, in a case like this, where the reaction has a high (negative) activation entropy related to the intrinsic structure of the TS, the pre-organization of the reactant by the enzyme can only partially compensate for it.

The situation is rather different for the other enzymatic reactions studied herein. They are bimolecular processes and as such inherently entropically disfavoured in the gas phase because of the loss of translational degrees of freedom. For the H-abstraction from camphor by Compound I, $T\Delta^{\ddagger}S$ = –43 kJ mol^{-1} in the gas phase at the B3LYP level.[68] This high entropy contribution is essentially annihilated in the chemical step in the enzyme (to –2 kJ mol^{-1}) owing to the binding and pre-organization of the reactants in the ac-

tive site. The dominating influence of the pre-orientation of the reactants in intermolecular reactions is also illustrated in PHBH. Gas-phase calculations of the barrier with respect to a pre-reactant complex, where the translational degrees of freedom have already been lost, yield $T\Delta^{\ddagger}S$ = –5 kJ mol^{-1} at the AM1 level. In the enzyme, the entropic contribution is further reduced to –1 kJ mol^{-1}, which can again be explained by motionally restricting interactions of the reactants with the protein; in this case, the hydrogen bond of the transferring OH to a proline residue in the TS plays a special role.[20]

For fluorinase, finally, we do not have suitable gas-phase reference data. However, for an intermolecular S_N2 substitution, $T\Delta^{\ddagger}S$ in the gas phase is expected to be strongly negative relative to separated reactants. In the enzyme, most of the entropic contribution should be quenched, which we find indeed to be the case (–0.9 to 2.5 kJ mol^{-1}).

Conclusions

In this contribution, we have reported potential-energy and free-energy data for three enzymatic reactions: carbon–halogen bond formation in fluorinase, hydrogen abstraction from camphor in cytochrome P450cam, and chorismate-to-prephenate Claisen rearrangement in chorismate mutase. The results were obtained by semi-empirical or DFT QM/MM optimizations and two types of QM/MM free-energy simulations (free-energy perturbation and umbrella sampling). On the basis of these results and our previously published free-energy data for PHBH, we have discussed the importance of finite-temperature effects in the chemical step of enzyme reactions. Consistent with the notion that enzymes bind and pre-organize the reactants in the active site, we find that the entropic contribution to the activation barrier tends to be small, particularly when compared with an intermolecular process in the gas phase. In the latter case, the enzyme will "quench" the part of the entropic contribution that is related to the association of the reactants. If a reaction has a transition state that is intrinsically tight (compared with the reactant) due to the specific type of bond-making and -breaking, there may still be a sizeable entropic contribution to the barrier of the reaction in the enzyme, as seen in the chorismate mutase case. Furthermore, it should be emphasized that there will undoubtedly be considerable finite-temperature effects associated with the binding of the reactants preceding the chemical step that are well worth investigating by free-energy techniques. On the other hand, when focusing on localized chemical events in the catalytic cycle of an enzyme, the present evidence suggests that QM/MM optimization studies may often provide barriers that are close to the corresponding free-energy barriers. Our results also highlight the importance of performing biomolecular QM/MM optimizations or free-energy simulations on several snapshots taken from MD simulations if one wants to improve the accuracy of energy differences beyond about 10 kJ mol^{-1}.

Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. NMR line shapes from AB spin systems in solids — The role of antisymmetric spin–spin coupling

Kristopher J. Harris, David L. Bryce, and Roderick E. Wasylishen

Abstract: NMR parameters such as indirect nuclear spin–spin coupling (**J**), nuclear magnetic shielding ($\boldsymbol{\sigma}$), direct dipolar coupling (**D**), and electric field gradient (**V**) are properly described by second-rank tensors. Each may be decomposed into isotropic, symmetric, and antisymmetric components; the number of these three components which may be nonzero is a distinguishing attribute of each interaction tensor. The rank-1 antisymmetric portion of **J** ($\mathbf{J}^{anti}$) holds the distinction of remaining the only nonzero part of these fundamental NMR interaction tensors which has never been observed experimentally. Accordingly, effects from $\mathbf{J}^{anti}$ are usually ignored, but it is important to consider when this is valid. An experimental strategy for observing $\mathbf{J}^{anti}$ in powdered samples of tightly coupled homonuclear spin pairs, based on ideas originally presented by Andrew and Farnell (*Mol. Phys.* 1968, **15**, 157), is described. The theory of Andrew and Farnell is extended to powder samples, and methods for analyzing NMR spectra from powdered samples are presented. It is found that, in certain rare cases, $\mathbf{J}^{anti}$ has the potential to affect the NMR line shapes from AB spin systems, but that even in these systems, the most intense features of the spectra are not affected and may be analyzed independently of $\mathbf{J}^{anti}$. Furthermore, $\mathbf{J}^{anti}$ will only have an observable effect on the NMR spectra when its magnitude is comparable with that of J_{iso} and with the difference in chemical shifts (in Hz) between the two sites. Finally, the first experimental attempts to measure $\mathbf{J}^{anti}$ are reported, and experimental proof that no elements of $\mathbf{J}^{anti}(^{119}Sn,^{119}Sn)$ in hexa(*p*-tolyl)ditin are larger than 2900 Hz is given. The benefits of modern double-quantum filtering NMR pulse sequences in isolating effects from $\mathbf{J}^{anti}$ are also illustrated.

Key words: J coupling, solid-state NMR spectroscopy, indirect nuclear spin–spin coupling, ^{119}Sn NMR, symmetry, NMR relaxation, antisymmetric tensor.

Résumé : Les interactions de RMN, tel le couplage spin-spin nucléaire indirect (**J**), le blindage magnétique nucléaire ($\boldsymbol{\sigma}$), le couplage dipolaire direct (**D**) et le gradient du champ électrique (**V**) peuvent être décrits correctement par des tenseurs de deuxième rang. Chacune peut être décomposée en composants isotropes, symétriques et antisymétriques; le nombre de ces trois composants qui peut être différente de zéro est un attribut caractéristique de chaque tenseur d'interaction. La portion antisymétrique de rang 1 de **J** ($\mathbf{J}^{anti}$) se distingue par le fait qu'il s'agit de la seule partie de ces tenseurs fondamentaux d'interaction RMN dont la valeur est différente de zéro qui n'a pas encore été observée expérimentalement. Il en découle qu'on ignore généralement les effets attribuables à $\mathbf{J}^{anti}$, mais il est important de considérer quand cela est valide. On décrit une stratégie expérimentale basée sur les idées proposées originalement par Andrew et Farnell (*Mol. Phys.* 1968, **15**, 157) pour observer $\mathbf{J}^{anti}$ dans des échantillons en poudre de paires de spin homonucléaires fortement couplés. La théorie de Andrew et Farnell a été étendue aux échantillons en poudre et on présente des méthodes qui permettent d'analyser les spectres RMN des échantillons en poudre. On a trouvé que dans certains rares cas, le couplage $\mathbf{J}^{anti}$ a le pouvoir d'affecter les formes des raies RMN des systèmes de spin AB, mais que même avec ces systèmes, les caractéristiques les plus intenses des spectres ne sont pas affectées et elles peuvent être analysées indépendamment de $\mathbf{J}^{anti}$. De plus, $\mathbf{J}^{anti}$ n'aura un effet observable sur les spectres RMN que lorsque son amplitude sera comparable à celle de J_{iso} et à la différence dans les déplacements chimiques (en Hz) entre les deux sites. Finalement, on rapporte les premiers efforts experimentaux à mesurer $\mathbf{J}^{anti}$, et on démontre experimentallement qu'il n'y a pas d'éléments de $\mathbf{J}^{anti}(^{119}Sn, ^{119}Sn)$ plus grand que 2900 Hz dans l'hexa(*p*-tolyl)di-étain. On illustre aussi les bénéfices des séquences modernes d'impulsions RMN avec filtrage à double quantum pour isoler les effets de $\mathbf{J}^{anti}$.

Mots-clés : couplage *J*, spectroscopie RMN à l'état solide, couplage spin-spin nucléaire indirect, RMN du ^{119}Sn, relaxation RMN, tenseur antisymmétrique.

Introduction

One of the most useful aspects of NMR spectroscopy for relating spectroscopic observables to molecular structure and dynamics is the inherent orientation dependence of the fundamental NMR interactions.[1] This orientation dependence is routinely taken advantage of in solid-state NMR spectroscopy to determine, for example, internuclear coupling tensors, magnetic shielding tensors, and electric field gradient tensors. Over the last decade, this orientation dependence has also been exploited in solution NMR spectroscopy by employing dilute liquid crystalline solvents which introduce a small degree of molecular alignment, thereby preventing complete isotropic averaging of direct dipolar coupling tensors and magnetic shielding tensors.[2–7] Clearly, an improved understanding of the tensor nature of NMR interactions is desirable.

The most important fundamental NMR parameters in diamagnetic molecules include the electric field gradient (**V**) and nuclear magnetic shielding ($\boldsymbol{\sigma}$), as well as the direct dipolar (**D**), and indirect nuclear spin–spin (**J**) coupling, and are properly represented by second-rank tensors.[8] The **J** tensor may be written in Cartesian form as follows, with up to nine elements[9]

$$[1] \qquad \mathbf{J} = \begin{bmatrix} J_{xx} & J_{xy} & J_{xz} \\ J_{yx} & J_{yy} & J_{yz} \\ J_{zx} & J_{zy} & J_{zz} \end{bmatrix}$$

In general, any second-rank tensor may be decomposed into three contributions. The rank-0 contribution is independent of orientation, and is given by (for **J**)

$$[2] \qquad J_{iso} = \frac{1}{3}\mathrm{Tr}(\mathbf{J}) = \frac{1}{3}(J_{xx} + J_{yy} + J_{zz})$$

This term is also commonly known as the "scalar" coupling constant in the NMR spectroscopy literature of both solids and solutions. The isotropic portions of the **V** and **D** tensors are zero, while the isotropic part of $\boldsymbol{\sigma}$ is simply the nuclear magnetic shielding constant, σ_{iso}. The shielding tensor and the isotropic shielding constant are directly related to the experimentally observable chemical shift tensor ($\boldsymbol{\delta}$) and isotropic chemical shift (δ_{iso}). Thus, the nonzero isotropic portions of NMR interaction tensors (J_{iso}, δ_{iso}) are routinely measured.

The rank-2 symmetric part of **J** is given by

$$[3] \qquad \mathbf{J}^{sym} = \frac{1}{2}(\mathbf{J} + \mathbf{J}^{t}) - J_{iso}\mathbf{1} \xrightarrow{\text{to PAS}} \mathbf{J}^{sym,PAS} = \begin{bmatrix} J_{11} - J_{iso} & 0 & 0 \\ 0 & J_{22} - J_{iso} & 0 \\ 0 & 0 & J_{33} - J_{iso} \end{bmatrix}$$

where $\mathbf{J}^{t}$ is the transpose of **J,** and "symmetric" refers to the fact that $J_{ij}^{sym} = J_{ji}^{sym}$ in any axis system. As shown in eq. [3], when $\mathbf{J}^{sym}$ is represented in its principal axis system (PAS) there are no off-diagonal elements and the diagonal elements are referred to as the principal components. Note that, although there are three principal components, their sum is zero and $\mathbf{J}^{sym,PAS}$ therefore contains only two independent elements. However, it should be noted that $\mathbf{J}^{sym}$ is only fully described if its eigenvectors, i.e., the vectors that form its PAS, are known in addition to the two independent elements of $\mathbf{J}^{sym,PAS}$. Because the PAS can be specified via three Euler angles that relate it to some reference frame in the molecule, $\mathbf{J}^{sym}$ is generally described as containing five independent parameters. By definition, the principal components are ordered $|J_{33} - J_{iso}| \geq |J_{11} - J_{iso}| \geq |J_{22} - J_{iso}|$.[10,11] The **V**, **D**, and $\boldsymbol{\sigma}$ tensors can all have nonzero rank-2 symmetric contributions, but of course this depends on symmetry for **V** and $\boldsymbol{\sigma}$. For example, the nuclear quadrupolar coupling constant (C_Q) and asymmetry parameter (η_Q) are characteristic of $\mathbf{V}^{sym}$; the direct dipolar coupling constant used to extract internuclear distances from NMR measurements is characteristic of $\mathbf{D}^{sym}$; anisotropy and asymmetry parameters describing nuclear magnetic shielding and chemical shift tensors are representations of $\boldsymbol{\sigma}^{sym}$. Thus, experimental measurements of the symmetric parts of **V**, **D**, and $\boldsymbol{\sigma}$ (or $\boldsymbol{\delta}$), are routinely made. Measurements of the principal components of $\mathbf{J}^{sym}$ are not nearly as straightforward;[11,12] nevertheless, much effort has been directed at making such measurements in the gas phase, in liquid crystal solutions, and in the solid state so that a body of reliable data now exists.[13,14] Quantum chemical calculation of **J** tensors is an important tool in the interpretation of experimental results,[15–25] and advances in this area are reviewed regularly.[13,26–28]

The rank-1 antisymmetric contribution to the NMR interaction tensors is zero for **V** and **D**, but not for $\boldsymbol{\sigma}$ or **J**. For the **J** tensor, this contribution is given by[10,11]

$$[4] \qquad \mathbf{J}^{anti} = \frac{1}{2}(\mathbf{J} - \mathbf{J}^{t}) = \frac{1}{2}\begin{bmatrix} 0 & J_{xy} - J_{yx} & J_{xz} - J_{zx} \\ J_{yx} - J_{xy} & 0 & J_{yz} - J_{zy} \\ J_{zx} - J_{xz} & J_{zy} - J_{yz} & 0 \end{bmatrix} \equiv \begin{bmatrix} 0 & J_{yx}^{anti} & J_{zx}^{anti} \\ -J_{yx}^{anti} & 0 & J_{zy}^{anti} \\ -J_{zx}^{anti} & -J_{zy}^{anti} & 0 \end{bmatrix}$$

This component of **J** is designated antisymmetric because of the obvious form of the matrix in eq. [4]. While $\mathbf{J}^{sym}$ can be diagonalized through a change of basis, $\mathbf{J}^{anti}$ remains in the form shown in eq. [4] under any choice of coordinate system. Because there is no obvious reference frame for $\mathbf{J}^{anti}$, the simplest method is to report $\mathbf{J}^{anti}$ in the PAS of $\mathbf{J}^{sym}$; however, it should be noted that symmetry may require one or more elements of $\mathbf{J}^{anti}$ to be zero in a particular coordinate system, in which case the tensor will still appear to have 6 entries (three unique) in other coordinate systems (compare with $\mathbf{J}^{sym}$ versus $\mathbf{J}^{sym,PAS}$). In summary, the rank-0 portion of **J** contains one independent parameter, the rank-2 symmetric portion contains five, and the rank-1 antisymmetric portion contains three. Any **J** tensor can therefore be represented in an arbitrary coordinate system using the six independent elements of J_{iso} + $\mathbf{J}^{sym}$ + $\mathbf{J}^{anti}$, and three Euler angles relating the coordinate system to the PAS of $\mathbf{J}^{sym}$.

It has been shown that the antisymmetric components of $\boldsymbol{\sigma}$ affect the spectrum in second order only, causing small peak shifts and (or) subtle pattern changes.[10,29,30] While direct effects on the spectra would generally be very small and thus difficult to detect, the components of $\boldsymbol{\sigma}^{anti}$ can contribute to nuclear spin relaxation, but only two reports of their influ-

ence on relaxation have been published.[31,32] Wi and Frydman have shown that cross-correlations with the quadrupolar Hamiltonian can make direct detection of $\boldsymbol{\sigma}^{anti}$ more tenable, and have reported the antisymmetric components of the ^{59}Co chemical shift tensor in cobalt(III) tris(acetylacetonate), referenced to 1M $K_3[Co(CN)_6]_{(aq)}$, as $\delta_{zx}^{anti} = 1000 \pm 500$ ppm, $\delta_{zy}^{anti} = -1000 \pm 500$ ppm, $\delta_{xy}^{anti} = 1000 \pm 1000$ ppm.[33] Nuclear spin relaxation measurements, similar to those used for $\boldsymbol{\sigma}^{anti}$, could provide a method to detect the antisymmetric part of $\mathbf{J}$,[34,35] while another experimental strategy may arise from the symmetry-based pulse-sequence design methodology developed by Levitt and co-workers.[36]

The rank-1 antisymmetric part of the $\mathbf{J}$ tensor remains as the only contribution to the four fundamental NMR interactions which has yet to be measured experimentally. In 1968, Andrew and Farnell tackled this problem by considering a pair of spin-1/2 nuclei in a single crystal, taking into account the full second-rank tensor nature of the chemical shift, the direct dipolar coupling tensor, and the indirect nuclear spin–spin coupling tensor.[37] Under rapid MAS, the chemical shift tensors are averaged to their isotropic values for each of the two nuclei involved; the direct dipolar coupling tensor is averaged to its isotropic value (zero); the isotropic *J*-coupling constant manifests itself in a fashion analogous to the situation observed in solution, and the anisotropic rank-2 part of the $\mathbf{J}$ tensor is averaged to zero. The most interesting aspect of their analysis, however, is with regards to the antisymmetric rank-1 part of $\mathbf{J}$, which is averaged to zero in solution, but *not under MAS conditions*.[37,38] The theory laid out by Andrew and Farnell alone does not provide much insight into what types of chemical systems may actually lead to an experimental observation of $\mathbf{J}^{anti}$, and a discussion of such considerations is presented here. Additionally, the theory is extended to include averaging over the orientations of a micro-crystalline powdered sample, and methods for analyzing the resultant line shapes are presented. In the present paper, the discussion describes one strategy for the measurement of $\mathbf{J}^{anti}$ and details some initial experimental attempts at its characterization.

Theory

The theory for describing NMR spectra from a pair of non-equivalent spin-1/2 nuclei in solution or in the solid state without effects from $\mathbf{J}^{anti}$ is well established.[39–41] The full Hamiltonian operator for a homonuclear pair of spin-1/2 nuclei in a stationary sample is

$$[5] \quad h^{-1}\widehat{H} = -(2\pi)^{-1}\gamma\widehat{\mathbf{I}}(1-\boldsymbol{\sigma}_I)\mathbf{B}_0 - (2\pi)^{-1}\gamma\widehat{\mathbf{S}}(1-\boldsymbol{\sigma}_s)\mathbf{B}_0 + \widehat{\mathbf{I}}\cdot\mathbf{J}\cdot\widehat{\mathbf{S}} + \widehat{\mathbf{I}}\cdot\mathbf{D}\cdot\widehat{\mathbf{S}}$$

After breaking the interaction tensors into their isotropic, symmetric, and antisymmetric components, and dropping nonsecular[42] terms, the effects of MAS in averaging orientation dependencies can be included. It is well known that all terms in the secular Hamiltonian containing $\mathbf{J}^{sym}$ and $\mathbf{D}$ average to zero, and also that the secular part of $\hat{\mathbf{I}}\cdot\boldsymbol{\sigma}_I\cdot\mathbf{B}_0$ is averaged to $\sigma_I\hat{I}_Z$ when $\mathbf{B}_0$ is along the laboratory *Z* axis;[37] this last result uses σ_I as notation for the isotropic shielding (i.e., 1/3 the trace of $\boldsymbol{\sigma}_I$). Therefore, the secular Hamiltonian under MAS can be defined as

$$[6] \quad h^{-1}\widehat{H}_0^{MAS} = -\nu_L[(1-\sigma_I)\widehat{I}_Z + (1-\sigma_S)\widehat{S}_Z] + J_{iso}\widehat{I}_Z\widehat{S}_Z + \frac{1}{2}J_{iso}(\widehat{I}_+\widehat{S}_- + \widehat{I}_-\widehat{S}_+) + \widehat{\mathbf{I}}\cdot\mathbf{J}^{anti,MAS}\cdot\widehat{\mathbf{S}}$$

where $\nu_L = (2\pi)^{-1}\gamma B_0$, and $\mathbf{J}^{anti,MAS}$ is the MAS average of $\mathbf{J}^{anti}$, and an infinitely fast MAS rate is assumed. Line-shape simulations for solid samples generally neglect the term containing $\mathbf{J}^{anti,MAS}$; however, Andrew and Farnell have presented a theory including effects from the antisymmetric portion of $\mathbf{J}$ on solid-state NMR spectra from a pair of spin-1/2 nuclei in a single crystal undergoing MAS.[37] We first review Andrew and Farnell's results for NMR spectra from a single crystal, and then extend the theory to include the orientational distribution of a powder sample. Methods for analyzing the resultant powder pattern in terms of the components of $\mathbf{J}^{anti}$ are then discussed.

The Antisymmetric J-coupling Hamiltonian

Returning to a stationary single crystal in the lab frame, the only secular terms in the antisymmetric *J*-coupling Hamiltonian between spins *I* and *S* are the two involving $J_{YX}^{anti,L}$:

$$[7] \quad \begin{aligned} h^{-1}\widehat{H}^{anti} &= \widehat{\mathbf{I}}\cdot\mathbf{J}^{anti,L}\cdot\widehat{\mathbf{S}} \\ h^{-1}\widehat{H}_0^{anti} &= J_{YX}^{anti,L}(\widehat{I}_X\widehat{S}_Y - \widehat{I}_Y\widehat{S}_X) \\ &= i\frac{1}{2}J_{YX}^{anti,L}(\widehat{I}_+\widehat{S}_- - \widehat{I}_-\widehat{S}_+) \end{aligned}$$

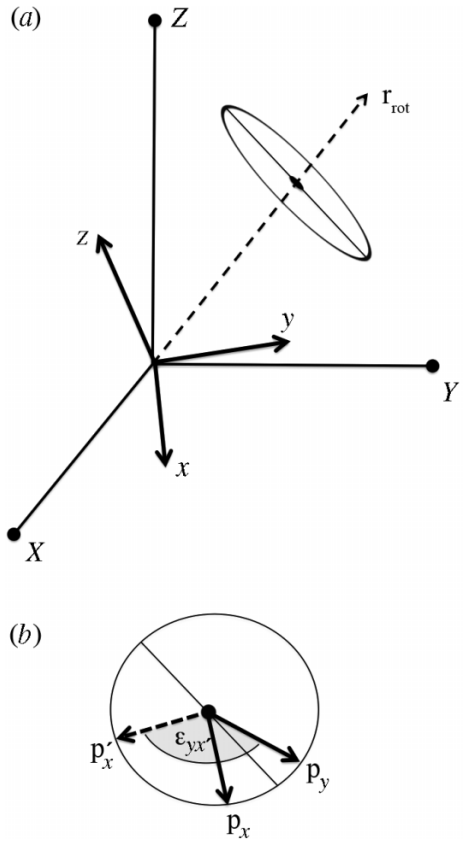
Because $\widehat{H}_0^{anti}$ contains only the flip-flop operator involving spins *I* and *S*, it has a negligible effect on the energy levels unless the spins *I* and *S* have nearly equal chemically shifted Zeeman interactions; accordingly, $\mathbf{J}^{anti}$ only affects NMR spectra from AB spin systems. The only step remaining before we can predict spectra using the Hamiltonian in eq. [6] is determination of the MAS average of $J_{YX}^{anti,L}$.

Under MAS, the orientation of each crystallite will become time-dependent, so it is convenient to consider the tensor in the lab frame, $\mathbf{J}^{anti,L}$, as being derived from its representation in the crystallite axis system depicted in Fig. 1*a*, $\mathbf{J}^{anti,C}$, using direction cosines:[43]

$$[8] \quad J_{YX}^{anti,L} = \begin{bmatrix} (a_{Yx}a_{Xy} - a_{Yy}a_{Xx})J_{yx}^{anti,C} \\ +(a_{Yx}a_{Xz} - a_{Yz}a_{Xx})J_{zx}^{anti,C} \\ +(a_{Yy}a_{Xz} - a_{Yz}a_{Xy})J_{zy}^{anti,C} \end{bmatrix}$$

In eq. [8], each a_{Uv} is the cosine of the angle between lab-frame axis U and crystallite axis v. If some external motion causes the molecular orientation to change, each direction cosine will be time-dependent. After including expressions for the time dependence of each a_{Uv}, the average value of $J_{YX}^{anti,L}$ under external motion can be derived (see ref. 44 for an instructive example where U is the laboratory Z axis and the external motion is MAS). Under isotropic tumbling, the time average of $J_{YX}^{anti,L}$ is zero, but not for a solid undergoing MAS.[37] It is convenient to use the notation $A(\Theta)$ for the average value of $J_{YX}^{anti,L}$ under MAS, because it acts as an effective antisymmetric coupling constant which differs for each orientation, Θ, of the crystallite.[37] The effect of $\mathbf{J}^{anti}$ is therefore to add the following term to the secular Hamiltonian for an AB spin system under MAS:

Fig. 1. (*a*) Coordinate system and conventions used in the expressions for the $A(\Theta)$ distribution. The lab frame is defined by the axes X, Y, Z; the axis of sample rotation is r_{rot}, which is at the "magic angle" of $\cos^{-1}(1/\sqrt{3})$ relative to the Z axis; and the crystallite axis system in which **J** is represented is described with the vectors x, y, z. Angles given as ξ_a are those between axis *a* of the crystallite frame and r_{rot}. (*b*) Normalized projections of the crystallite axes x, y, z on the plane perpendicular to r_{rot} shown in (*a*) are labelled p_x, p_y, p_z. Rotation of these projected vectors by –90° about r_{rot} are annotated as the corresponding primed vectors p'_x, p'_y, p'_z, and angles given as $\varepsilon_{ab'}$ are those between p_a and p'_b ($\varepsilon_{yx'}$ is shown as an example).



$$[9] \qquad h^{-1}\widehat{H}_0^{\text{anti,MAS}} = i\frac{1}{2}A(\Theta)(\widehat{I}_+\widehat{S}_- - \widehat{I}_-\widehat{S}_+)$$

Andrew and Farnell have provided an expression for the effective antisymmetric coupling constant for a crystallite undergoing MAS, see eq. [39] of reference 37. Application of a few algebraic manipulations produces an analogous, but slightly simpler, form for $A(\Theta)$:

$$[10] \qquad A(\Theta) = 1/\sqrt{3}\begin{bmatrix} (\sin\xi_y \sin\xi_x \cos\varepsilon_{yx'})J_{yx}^{\text{anti,C}} \\ +(\sin\xi_z \sin\xi_x \cos\varepsilon_{zx'})J_{zx}^{\text{anti,C}} \\ +(\sin\xi_z \sin\xi_y \cos\varepsilon_{zy'})J_{zy}^{\text{anti,C}} \end{bmatrix}$$

Equation [10] makes use of the coordinate system and definitions shown in Fig. 1. As described in the previous section, the components of $\mathbf{J}^{\text{anti,C}}$ are those in the crystallite reference frame shown in Fig. 1, which could be, for example, the PAS of $\mathbf{J}^{\text{sym}}$. While the depiction in Fig. 1 is for the crystallite axis system at time zero, all angles in eq. [10] are constant during the motion of the rotor, reflecting the fact that the value of $A(\Theta)$ for each crystallite is independent of time. Furthermore, the rotational independence of the expression requires that any crystallites whose initial orientations are related to each other by rotation around the sample's spinning axis are characterized by the same value of $A(\Theta)$. However, any crystallites whose orientations do not become superimposed by the motion of the rotor will exhibit a different value of $A(\Theta)$, and a powder will therefore be characterized by a distribution of these effective coupling constants.

It is interesting to contrast the effects of MAS on $\mathbf{J}^{\text{anti}}$ with its effect on the other anisotropic terms in the secular Hamiltonian. By defining $\boldsymbol{\sigma}^{\text{sym}}$ analogously to the definition of $\mathbf{J}^{\text{sym}}$ in eq. [3], the only orientation dependence, discounting $J_{YX}^{\text{anti,L}}$, is contained in terms involving $\boldsymbol{\sigma}^{\text{sym}}$, $\mathbf{J}^{\text{sym}}$, and **D**. For these more familiar terms, the secular Hamiltonian's dependence on crystallite orientation is encoded in direction cosines between the applied magnetic field and the principal component axes of the involved tensor, i.e., terms of the form a_{Zv}.[37] Because the average squared value under MAS (or in solution) for this form of direction cosine, $\langle a_{Zv}^2 \rangle$, is 1/3 for any crystallite orientation, the average of each secular Hamiltonian term involving $\boldsymbol{\sigma}^{\text{sym}}$, $\mathbf{J}^{\text{sym}}$, and **D** is zero.[37,44] This averaging explains why these three terms need not be included in the Hamiltonian, and do not affect spectra of samples undergoing MAS (at a sufficiently rapid rate). All of the orientation-dependent terms in the secular Hamiltonian other than $\widehat{H}_0^{\text{anti}}$ depend on the angles between each crystallite axis and the lab-frame Z axis, while $\widehat{H}_0^{\text{anti}}$ instead depends on the angles between each crystallite axis system and the lab-frame X and Y axes. Because the direction cosines describing the value of $J_{YX}^{\text{anti,L}}$ are of a different form, the effect of MAS on $\mathbf{J}^{\text{anti}}$ differs from its effect on $\boldsymbol{\sigma}^{\text{sym}}$, $\mathbf{J}^{\text{sym}}$, and **D**; accordingly, the average value of $J_{YX}^{\text{anti,L}}$ under MAS is not zero, but a constant, $A(\Theta)$, that differs for each nondegenerate crystallite orientation.

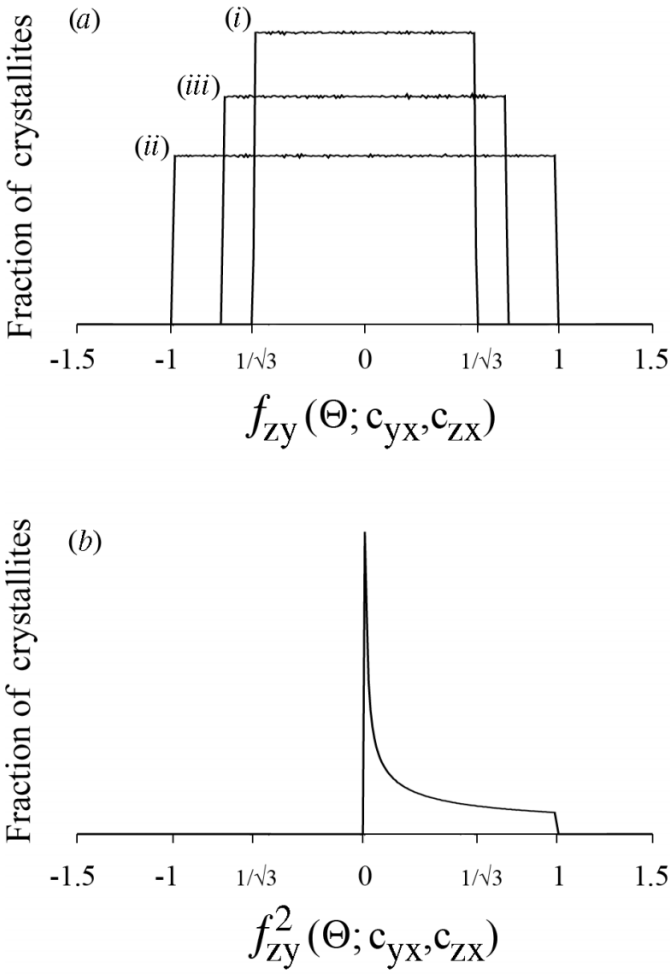
The $A(\Theta)$ distribution

To predict NMR spectra using the above Hamiltonian operator it is necessary to determine the shape of the $A(\Theta)$ distribution, and this was investigated here using numerical powder averaging. To investigate the behaviour of $A(\Theta)$ independent of the magnitude of the $\mathbf{J}^{\text{anti,C}}$ components, it is convenient to scale eq. [10] by the largest component of $\mathbf{J}^{\text{anti,C}}$. Considering first the case when J_{zy}^{anti} is the largest element,

$$[11] \qquad A(\Theta) = J_{zy}^{\text{anti,C}}(1/\sqrt{3})\begin{bmatrix} (\sin\xi_y \sin\xi_x \cos\varepsilon_{yx'})c_{yx} \\ +(\sin\xi_z \sin\xi_x \cos\varepsilon_{zx'})c_{zx} \\ +(\sin\xi_z \sin\xi_y \cos\varepsilon_{zy'}) \end{bmatrix}$$
$$= J_{zy}^{\text{anti,C}} \times f_{zy}(\Theta; c_{yx}, c_{zx})$$

where $f_{zy}(\Theta; c_{yx}, c_{zx})$ is a function of the crystallite orientation, which is again denoted by Θ. The function $f_{zy}(\Theta; c_{yx}, c_{zx})$ involves only the ratio of elements in $\mathbf{J}^{\text{anti,C}}$ through the parameters $c_{ij} = J_{ij}^{\text{anti,C}}/J_{zy}^{\text{anti,C}}$; note that while the theoretical range for these parameters is $-1 \le c_{ij} \le 1$, all results were found to be independent of the sign of the c_{ij} constants. See the Experimental section for specific details on the numeri-

Fig. 2. (*a*) Numerically generated plots of $f_{zy}(\Theta; c_{yx}, c_{zx})$ versus fraction of crystallites displaying that value; (*i*) The smallest range of the f_{zy} distribution, $\pm 1/\sqrt{3}$, is found with the parameters $c_{yx} = c_{zx} = 0$; (*ii*) The largest range of the f_{zy} distribution, ±1, occurs when $c_{yx} = c_{zx} = 1$; (*iii*) Example of the range found for the f_{zy} distribution with intermediate values of the c_{ij} constants, in this plot, $c_{yx} = 0$ and $c_{zx} = 0.8$. (*b*) Plot of $f_{zy}^2(\Theta; c_{yx}, c_{zx})$, with parameters $c_{yx} = c_{zx} = 1$, the same as in (*a*) (*ii*).



cal calculations. As shown in Fig. 2*a*, all values of f_{zy} between $\pm 1/\sqrt{3}$ are equally probable when $J_{zy}^{anti,C}$ is the only component of $\mathbf{J}^{anti,C}$, while all values in the range ±1 are populated equally when $J_{yx}^{anti,C} = J_{zx}^{anti,C} = J_{zy}^{anti,C}$. For all other values of the c_{ij} constants, the upper and lower limits of f_{zy} were found to be intermediate between the extremes of $\pm 1/\sqrt{3}$ and ±1 mentioned above, and all values of the distribution were also found equally probable. There appears to be no obvious connection between the specific limits of f_{zy} and the c_{ij} constants, except in the two cases of $c_{yx} = c_{zx} = 0$ or 1. Results obtained under the assumption that either $J_{yx}^{anti,C}$ or $J_{zx}^{anti,C}$ are the largest component of $\mathbf{J}^{anti,C}$ are entirely analogous. In summary, a powdered sample is populated equally by crystallites displaying all values of $A(\Theta)$ between $-A_{max}$ and $+A_{max}$, where A_{max} is between 1 and $1/\sqrt{3}$ of the largest component of $\mathbf{J}^{anti,C}$.

As will be shown below, values for the transition frequencies depend on $A^2(\Theta)$ rather than on $A(\Theta)$. The $f_{zy}^2(\Theta; c_{yx}, c_{zx})$ distribution is displayed in Fig. 2*b*, where the increasing probability towards zero is apparent. Interestingly, there is a striking similarity between $f_{zy}^2(\Theta; c_{yx}, c_{zx})$ and the powder pattern for an isolated spin-1/2 nucleus with an axially symmetric magnetic shielding tensor. From the shape of the distribution in Fig. 2*b*, and the range of A_{max} noted above, it may be seen that the most probable value of A^2 is zero, and the observed values of $A^2(\Theta)$ will cover the range between 0 and A_{max}^2, where A_{max}^2 is between 1 (when $J_{yx}^{anti,C} = J_{zx}^{anti,C} = J_{zy}^{anti,C}$) and 1/3 (when two components of $\mathbf{J}^{anti}$ are zero) of the largest squared component of $\mathbf{J}^{anti,C}$.

NMR spectra from a single crystal

From the above considerations, the secular Hamiltonian for one crystallite containing an "isolated" AB spin pair under fast MAS averaging must incorporate the usual terms involving isotropic nuclear magnetic shieldings for both nuclei and the isotropic *J*-coupling, and, additionally, must include the antisymmetric *J*-coupling term defined above

$$[12]\quad h^{-1}\widehat{H}_0^{MAS} = -\nu_L[(1-\sigma_I)\widehat{I}_Z + (1-\sigma_S)\widehat{S}_Z] + J_{iso}\widehat{I}_Z\widehat{S}_Z + \frac{1}{2}J_{iso}(\widehat{I}_+\widehat{S}_- + \widehat{I}_-\widehat{S}_+) + i\frac{1}{2}A(\Theta)(\widehat{I}_+\widehat{S}_- - \widehat{I}_-\widehat{S}_+)$$

To predict the NMR spectrum resulting from this Hamiltonian, one must first find the energy levels. For spin-1/2 nuclei, taking the Zeeman states as basis functions, the nonzero elements of the Hamiltonian matrix are the diagonal ones,

$$[13]\quad \begin{aligned} \langle\alpha\alpha|h^{-1}\widehat{H}_0^{MAS}|\alpha\alpha\rangle &= -\nu_L\left[1-\frac{1}{2}(\sigma_I+\sigma_S)\right]+\frac{1}{4}J_{iso} \\ \langle\alpha\beta|h^{-1}\widehat{H}_0^{MAS}|\alpha\beta\rangle &= +\nu_L\left[\frac{1}{2}(\sigma_I-\sigma_S)\right]-\frac{1}{4}J_{iso} \\ \langle\beta\alpha|h^{-1}\widehat{H}_0^{MAS}|\beta\alpha\rangle &= -\nu_L\left[\frac{1}{2}(\sigma_I-\sigma_S)\right]-\frac{1}{4}J_{iso} \\ \langle\beta\beta|h^{-1}\widehat{H}_0^{MAS}|\beta\beta\rangle &= +\nu_L\left[1-\frac{1}{2}(\sigma_I+\sigma_S)\right]+\frac{1}{4}J_{iso} \end{aligned}$$

and two off-diagonal entries which contain contributions from J_{iso} and $A(\Theta)$:

$$[14]\quad \begin{aligned} \langle\beta\alpha|h^{-1}\widehat{H}_0^{MAS}|\alpha\beta\rangle &= \frac{1}{2}[J_{iso} - iA(\Theta)] \\ \langle\alpha\beta|h^{-1}\widehat{H}_0^{MAS}|\beta\alpha\rangle &= \frac{1}{2}[J_{iso} + iA(\Theta)] \end{aligned}$$

Both $|\alpha\alpha\rangle$ and $|\beta\beta\rangle$ are eigenfunctions of $\widehat{H}_0^{MAS}$, and their eigenvalues are simply given by the first and last expressions of eq. [13]. The two remaining eigenfunctions can be obtained in the usual way by diagonalizing the 2×2 submatrix containing the four remaining nonzero matrix elements.[41] Resulting from this diagonalization is the set of energy levels and wave functions given in Table 1, where

Table 1. Energy levels and wave functions for an AB spin system under MAS, including the effects of $\mathbf{J}^{anti}$.

Wave function[a]	Energy level[a]	m_T[a]
$\psi_1 = \|\alpha\alpha\rangle$	$E_1 = -\nu_L\left[1 - \frac{1}{2}(\sigma_I + \sigma_S)\right] + \frac{1}{4}J_{iso}$	+1
$\psi_2 = Q^{-1}\{[J_{iso} + iA(\Theta)]\|\alpha\beta\rangle + [C - \Delta_S]\|\beta\alpha\rangle\}$	$E_2 = -\frac{1}{4}J_{iso} + \frac{1}{2}C$	0
$\psi_3 = Q^{-1}\{[C - \Delta_S]\|\alpha\beta\rangle - [J_{iso} - iA(\Theta)]\|\beta\alpha\rangle\}$	$E_3 = -\frac{1}{4}J_{iso} - \frac{1}{2}C$	0
$\psi_4 = \|\beta\beta\rangle$	$E_4 = +\nu_L\left[1 - \frac{1}{2}(\sigma_I + \sigma_S)\right] + \frac{1}{4}J_{iso}$	–1

Note: See ref. 37 for analogous expressions.

[a]See text for definitions of constants.

Table 2. Transition frequencies and intensities for an AB spectrum, incorporating isotropic chemical shifts and the full **J** tensor.

Transition	Frequency	Relative intensity[a]
$\nu_{3,4}$	$\nu_L\left[1 - \frac{1}{2}(\sigma_I + \sigma_S)\right] + \frac{1}{2}C + \frac{1}{2}J_{iso}$	$1 - \frac{J_{iso}}{C}$
$\nu_{1,2}$	$\nu_L\left[1 - \frac{1}{2}(\sigma_I + \sigma_S)\right] + \frac{1}{2}C - \frac{1}{2}J_{iso}$	$1 + \frac{J_{iso}}{C}$
$\nu_{2,4}$	$\nu_L\left[1 - \frac{1}{2}(\sigma_I + \sigma_S)\right] - \frac{1}{2}C + \frac{1}{2}J_{iso}$	$1 + \frac{J_{iso}}{C}$
$\nu_{1,3}$	$\nu_L\left[1 - \frac{1}{2}(\sigma_I + \sigma_S)\right] - \frac{1}{2}C - \frac{1}{2}J_{iso}$	$1 - \frac{J_{iso}}{C}$

[a]See text for definitions of constants.

the following definitions have been used to simplify the expressions:

$$[15] \qquad \Delta_S = \nu_L(\sigma_I - \sigma_S)$$

$$[16] \qquad C = \sqrt{J_{iso}^2 + A^2(\Theta) + \Delta_s^2}$$

$$[17] \qquad Q = \sqrt{2C(C - \Delta_S)}$$

Here, Δ_S is the difference between the magnetic shieldings of the two sites, measured in Hz. All results reduce to match those of the classic expressions for an AB spin system in the limit of $A^2(\Theta) = 0$.

The allowed transitions are those where m_T, the eigenvalue of the operator for the z-component of total spin angular momentum $(\hat{I}_Z + \hat{S}_Z)$ changes by ±1,[41] and values of m_T for each wave function are reported in Table 1. Frequencies for each allowed transition are given in Table 2. Relative intensities for each transition may be determined from the absolute squares of the matrix elements of $\hat{F}_- = \hat{I}_- + \hat{S}_-$ between the involved wave functions,[41] and are also reported in Table 2. The spectrum expected from a single crystal undergoing MAS is presented in Fig. 3*a*, and is analogous to the textbook example of an AB spectrum in solution (where $\mathbf{J}^{anti}$ has no effect); however, for a solid sample under MAS, the splitting between the two central lines is increased when $A(\Theta)$ is nonzero. It is interesting to note that when $A(\Theta)$ is of substantial magnitude compared with J_{iso}, the relative intensities of the outer two transitions increase relative to the case when $A(\Theta)$ is negligible (for the same ratio of J_{iso} to the chemical shift difference between the two sites).

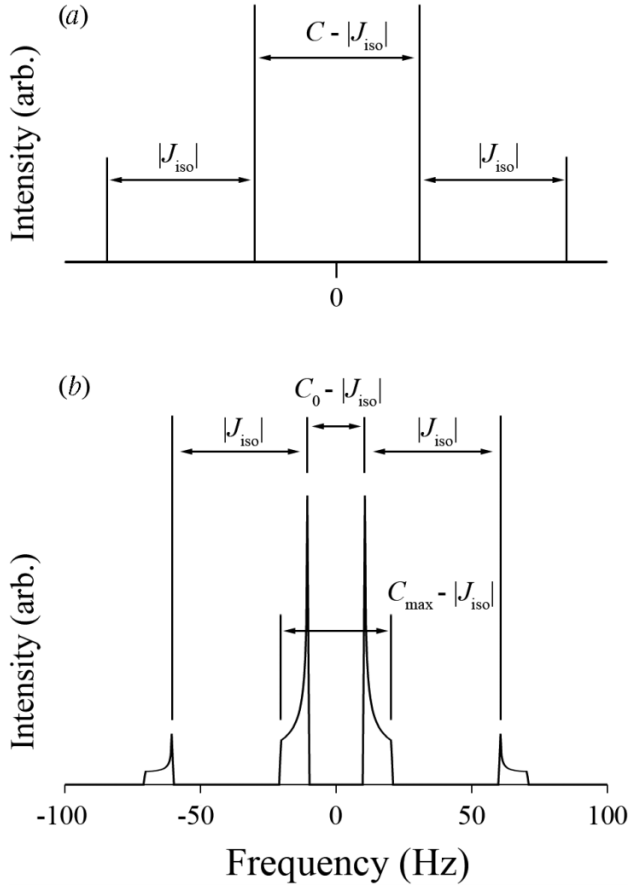
NMR spectra from powdered samples

Because each crystallite of a powder has a different value of $A(\Theta)$, each will produce a different four-line NMR spectrum. The separation between the two inner peaks is $C - |J_{iso}|$, and because C is a function of A^2, the inner peaks will form powder patterns. The outer two peaks will also have a line shape because, in every crystallite, each is separated by J_{iso} from the respective inner peak. The smallest separation between the inner two peaks occurs for crystallites with $A^2(\Theta) = 0$, designated as $C = C_0$ in Fig. 3*b*, and this will also be the most intense portion of the line shape as it is the most probable value of $A^2(\Theta)$. Crystallites with increasing values of $A^2(\Theta)$ will produce NMR spectra with an increasing separation between the inner peaks, but with decreasing intensity because of the smaller probability of $A^2(\Theta)$; see Fig. 3*b*. The two outer peaks of the spectrum of each crystallite will mimic that of the inner two, producing the total NMR spectrum given in Fig. 3*b*.

The form of the spectrum in Fig. 3*b* illustrates the information that can be derived from it. The spacings between the most intense parts of the four line shapes are independent of the antisymmetric components of **J**, so these can be analyzed according to the methods used for AB NMR spectra of solution samples.[41,45,46] Because the intensity of the outer two peaks is generally too small to measure, it is usually necessary to obtain NMR spectra at two applied magnetic field strengths (or from two isotopomers) to separate the value of J_{iso} from that of Δ_S. The largest splitting observed between the inner two transitions of Fig. 3*b* occurs for crystallites where $C = C_{max}$, from which eq. [16] can be solved for A_{max}. And, as noted above, the absolute value of the largest of the three components of $\mathbf{J}^{anti,C}$ is between $1A_{max}$ and $\sqrt{3}A_{max}$. Interestingly, it is not necessary to fit the entire line shape, because all of the information comes from the breadth of the peak. Analysis of the NMR line shape from an AB spin system under MAS therefore provides the values of J_{iso} and Δ_S, and a measure of the largest component of $\mathbf{J}^{anti,C}$.

It is worth noting that symmetry requirements on the number of components in $\mathbf{J}^{anti,C}$, see below, may make it possible to fix the values of the c_{ij} constants and thereby reduce the noted range of $1A_{max}$ to $\sqrt{3}A_{max}$ that experiments can place on the largest component of $\mathbf{J}^{anti,C}$. We also note

Fig. 3. (*a*) General four-line NMR spectrum for a homonuclear AB spin pair in a single crystal undergoing fast MAS, taking into account isotropic chemical shifts, isotropic *J* coupling, and antisymmetric *J* coupling. Adapted from reference 37. Note that for a tightly coupled spin pair, the two outer lines will be much less intense than the two central lines. (*b*) NMR spectrum corresponding to part (*a*), but for a powdered sample; C_0 is the value of C when $A^2 = 0$, and C_{max} is the value of C when $A^2 = A^2_{max}$. Specific data used for this example are $\Delta_S = J_{iso} = 50$ Hz, $J^{anti}_{zy} = 100$ Hz, and $J^{anti}_{yx} = J^{anti}_{zx} = 0$. The zero frequency in both spectra is $\nu_L[1–1/2(\sigma_I + \sigma_S)]$.

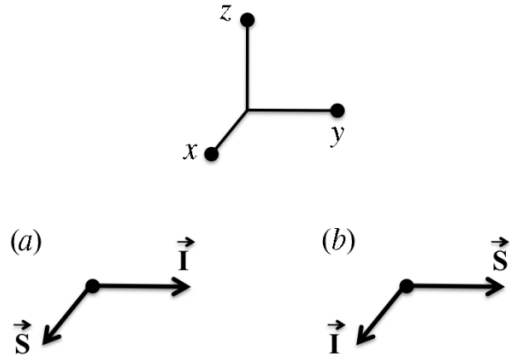


that the above results are independent of the choice used for the crystallite axis system. The PAS of $\mathbf{J}^{sym}$ can be used, but any crystallite axis system related by a set of three Euler angles could be chosen; accordingly, the experiment would provide an upper limit on the largest component of $\mathbf{J}^{anti}$ transformed to the new coordinate system. As the conclusions must remain valid under a change of the crystallite coordinate system, the final result is an upper limit of $\sqrt{3}A_{max}$ on the largest component of $\mathbf{J}^{anti}$ as represented in any coordinate system. No orientation information regarding $\mathbf{J}^{anti}$ is produced by the experiment.

Geometric interpretation of the antisymmetric component

The above discussion is focussed on deriving the effect of $\mathbf{J}^{anti}$ on the NMR spectrum. It is possible to gain some insight into the character of the antisymmetric component by using some simple geometric arguments. Consider a system

Fig. 4. Depiction of the geometry used in the classical mechanics example. In the coordinate system shown, the example angular momentum vectors are shifted to the same origin; (*a*) $\vec{S}$ along the *x* axis, and $\vec{I}$ along the *y* axis; (*b*) the vectors are interchanged, with $\vec{I}$ now along the *x* axis and $\vec{S}$ along the *y* axis.



in classical mechanics whose energy is governed by the analogous equation $E^{classical} = \vec{\mathbf{I}} \cdot \mathbf{J}^{trial} \cdot \vec{\mathbf{S}}$, where

$$[18] \qquad \mathbf{J}^{trial} = \begin{bmatrix} 0 & J_{xy} & 0 \\ J_{yx} & 0 & 0 \\ 0 & 0 & 0 \end{bmatrix}$$

In this example, only the J_{xy} and J_{yx} elements (the only terms that affect the quantum energy levels) are nonzero. In the example orientations shown in Fig. 4, the classical energy, $E^{classical} = J_{xy}I_xS_y + J_{yx}I_yS_x$, is unaltered when the orientations of the two vectors are interchanged if $\mathbf{J}^{trial}$ is symmetric, but is reversed if $\mathbf{J}^{trial}$ is antisymmetric. In general, an indirect coupling tensor will have both symmetric and antisymmetric components; the symmetric portion encodes the contribution to the energy that is the same when the two angular momentum vectors are interchanged, and the antisymmetric component represents a contribution to the energy that is equal and opposite. Linear combination of the two components allows the equation to represent any difference in the energetics when the orientation of the two angular momentum vectors is interchanged. A similar geometric description of $\mathbf{J}^{anti}$ has been given by Robert and Weisenfeld.[38]

This geometric picture provides an interesting way to interpret $\mathbf{J}^{anti}$; however, it is important to consider which part of the picture is quantum mechanically relevant. For there to be an antisymmetric component in $\mathbf{J}$, there does have to be a difference in energy when the directions of the nuclear spins are interchanged in the fashion shown in Fig. 4. However, one does not measure $\mathbf{J}^{anti}$ by placing the spins in the two orientations shown in the Figure; instead, the difference in the total energy (Hamiltonian operator) terms describing these orientations causes an extra flip-flop type operator to be active. Because it is represented by such an operator, $\mathbf{J}^{anti}$ affects the energy levels of a tightly coupled AB spin system by mixing the $|\alpha\beta\rangle$ and $|\beta\alpha\rangle$ levels.

Selection of appropriate spin systems and compounds

In this section, we seek to establish some practical requirements for the observation of spectral features induced by $\mathbf{J}^{anti}$. There are several requirements which must be satis-

fied to ensure the feasibility of measuring $\mathbf{J}^{anti}$. Even if all the requirements are satisfied, there is no guarantee that $\mathbf{J}^{anti}$ will be of significant magnitude to be measured unambiguously. The requirements may be divided into those which concern the nuclear spin interactions of the nucleus to be observed, and those that describe the structural and symmetry properties of the molecule to be studied. The following discussion aims to demonstrate that after consideration of all requirements, only a small fraction of molecules are likely to provide an observation of $\mathbf{J}^{anti}$. The discussion is focussed on powdered samples; however, measurement of $\mathbf{J}^{anti}$ from a single crystal has many of the same general requirements.

The first requirement is that a chemical system must be found for which the two nuclei are strongly J coupled and for which their isotropic chemical shift difference is as small as possible. This requirement may be understood by considering the Hamiltonian, eq. [12], where it may be seen that the only occurrence of A is as the coefficient of a flip-flop type operator. And, in the usual fashion, a flip-flop operator only affects the energy levels when the two involved spins have Larmor frequencies which don't differ by much more than the magnitude of its coefficient. This behaviour is also encoded in the energy-level expressions through the value of C, eq. [16], where it may be seen that the influence of A on the spectrum increases as the magnitude of A increases relative to the chemical shift difference. Because of the necessity of a small difference in chemical shifts, a homonuclear spin pair will be required. A pair of magnetically equivalent nuclei, which constitute an A_2 spin pair and give rise to identical chemical shifts, is not a suitable spin pair since J coupling between these nuclei will not manifest itself in the NMR spectrum. Hence, what is required is an isolated pair of bonded nuclei which are nearly (but not exactly) crystallographically equivalent, so they will have very similar isotropic chemical shifts, but are likely to have a large indirect nuclear spin–spin coupling interaction. Since the chemical shift difference is smaller in Hz at lower applied magnetic field strengths, in some cases the observation of $\mathbf{J}^{anti}$ will only be possible at low applied magnetic field strengths. Measurement of $\mathbf{J}^{anti}$ is therefore one of the unusual cases where it is advisable to use the lowest possible external magnetic field strength.

The second requirement within the present strategy is that one must have a chemical system for which there is an effectively isolated pair of spin-1/2 nuclei. Quadrupolar nuclei are not feasible candidates due to the typically dominant quadrupolar interaction; however, it is possible that another method for measuring antisymmetric J coupling may involve quadrupolar nuclei as the quadrupolar interaction was used by Wi and Frydman to estimate the antisymmetric part of the chemical shift tensor.[33] Isotopes such as ^{1}H, ^{19}F, and possibly $^{203/205}$Tl will likely not be suitable due to strong homonuclear dipolar couplings preventing them from forming isolated spin pairs. Lastly, because of the fact that spin *pairs* must be observed, the spectral intensity will scale with natural abundance squared, and as such, natural abundance will play an important role in selecting a nucleus (unless isotopic labelling is available).

Although Abragam states that the components of $\mathbf{J}^{anti}$ are expected to be negligible relative to the symmetric part of $\mathbf{J}$,[47,48] multiconfigurational self-consistent field calculations on ClF_3 and OF_2 have indicated that the magnitudes of the components of the $\mathbf{J}^{anti}$ tensor are comparable to those of the principal components of the $\mathbf{J}^{sym}$ tensor in these compounds.[49] Thus, a spin pair with a large value of J_{iso} favours the likelihood of there being an antisymmetric component of substantial magnitude. This requirement rules out certain spin pairs including ^{13}C and ^{15}N because in a magnetic field of 4.7 T, e.g., the value of $^{1}J_{iso}(^{13}C,^{13}C)$ would have to be well in excess of 50 Hz for a spin pair with a chemical shift difference of 1 ppm. Such a situation is not likely given that one-bond carbon–carbon coupling constants are typically on the order of 50 Hz.[50] Because J_{iso} values generally become larger moving down any group in the periodic table, the heavier elements present the best chance of possessing observable $\mathbf{J}^{anti}$ components.

Table 3. Number of independent components of $\mathbf{J}^{anti}$ for each point group, assuming the two nuclei are not exchanged by a symmetry operation.[38,53]

Point group symmetry about the two coupled nuclei	Number of unique antisymmetric components
C_1	3
C_s, C_n ($n > 2$)	1
All others	0

Practically, one must be concerned with the chemical shift anisotropy of the nuclei in the AB pair. Heavier nuclei such as ^{199}Hg and ^{207}Pb tend to have substantial CS tensor spans.[51,52] When carrying out a MAS NMR experiment on a powdered sample, this fact introduces the additional complication that the spectral intensity is distributed over a large spectral width in the form of spinning sidebands. Thus, not only would a large span reduce the effective signal-to-noise ratio of the NMR spectrum, but it would also complicate the appearance and interpretation of the spectrum. Hence it is preferable to find a system for which the nuclei have relatively small CS tensor spans. This requirement is not critical, especially if a single-crystal NMR experiment is to be performed. However, this discussion is focussed on measurements made using powdered samples.

The molecule under study must be of sufficiently low symmetry about the bond axis of the coupled nuclei to ensure that the antisymmetric component of $\mathbf{J}$ is not forced to be zero by symmetry. The number of symmetry-allowed components in $\mathbf{J}^{anti}$ under various point groups is presented in Table 3 (see also references 38 and 53).

While the anisotropy of the symmetric part of the $\boldsymbol{\sigma}$ tensor may pose a challenge in the acquisition of high-quality NMR spectra of the AB spin pair, we do not expect the antisymmetric component of $\boldsymbol{\sigma}$ to hamper or influence the measurement of $\mathbf{J}^{anti}$ by this method. The effect of $\boldsymbol{\sigma}^{anti}$ on NMR line shapes is generally expected to be very small.[10,29,30] However, in some cases it is possible for the inclusion of extra terms in the Hamiltonian to magnify effects from the typically nonsecular terms involving $\boldsymbol{\sigma}^{anti}$, e.g., a strong quadrupolar interaction is known to have such an effect.[33] Inspection of the wave functions in Table 1 shows that this is not the case with $\widehat{H}^{anti,MAS}$, as terms in the Hamiltonian containing $\boldsymbol{\sigma}^{anti}$ remain nonsecular. Accordingly, we do not expect the predicted effects of $\mathbf{J}^{anti}$ to be obscured by the presence of $\boldsymbol{\sigma}^{anti}$ terms.

In the present work, the nuclei deemed most suitable for a definitive measurement of $\mathbf{J}^{anti}$ are ^{29}Si, ^{31}P, ^{77}Se, $^{111/113}$Cd, $^{115/117/119}$Sn, $^{123/125}$Te, and ^{129}Xe. There is also a possibility that some heavier nuclei could provide valuable results, particularly if single crystal spectra are investigated using MAS.

Data collection and analysis

Now that the most promising candidates for the observation of homonuclear antisymmetric *J* coupling have been narrowed down, suitable compounds must be identified. Tin seems to be the most promising element due to the high receptivities of the ^{119}Sn and ^{117}Sn isotopes, in addition to moderate chemical shift anisotropies and well-developed synthetic chemistry. Tellurium is another promising element, and some tellurium systems are also discussed.

Tellurium-125 solid-state NMR spectroscopy of diaryl ditellurium compounds

Tellurium-125 CP MAS NMR spectra were acquired from *p*,*p*′-dimethoxydiphenyl ditelluride, **I**; *p*,*p*′-ditolyl ditelluride, **II**; 1-naphthyl ditelluride, **III**; and diphenyl ditelluride, **IV**. One-bond ^{125}Te–^{125}Te coupling constants are generally of significant magnitude, e.g., $^1J_{iso}(^{125}Te, ^{125}Te)$ in $(Me_4N)_2Te_2$ is ±3568 Hz in the solid state,[54] making these promising samples for investigations of $\mathbf{J}^{anti}$. However, measurement of antisymmetric *J* coupling in the present case is hampered in several ways. First, there is a large tellurium chemical shift anisotropy[55] which distributes the powder pattern across ~1200 ppm. Second, the chemical shift difference between the tellurium sites, e.g., 74.4 ppm or 4698 Hz at 4.7 T for **II**, is of the same order of magnitude as the expected value of J_{iso}, thereby reducing the "AB" character of the spin system. The situation is even less promising in the case of **I**, for which there are two molecules in the asymmetric unit.[56] This distributes the desired ^{125}Te NMR signal over twice as many sites, thereby reducing the signal-to-noise ratio. In summary, ^{125}Te NMR spectra of these compounds were of such poor quality that the resonances from the AB spin pairs could not be resolved at 4.7 T (spectra not shown), and there was therefore no opportunity for detecting whether the components of the AB spectrum possessed a line shape.

Tin-119 solid-state NMR spectroscopy of hexa(*p*-tolyl)ditin

Many ditin compounds of the type $R_3Sn–SnR_3$ possess magnetically equivalent tin atoms which are related by an inversion centre. Others have C_{3v} symmetry, which by symmetry requires all elements of $\mathbf{J}^{anti}$ to be zero.[38,53] One candidate that satisfies the stringent requirements is hexa(*p*-tolyl)ditin (**V**), which has two crystallographically nonequivalent tin atoms[57] (Fig. 5). Solution ^{119}Sn NMR in $CDCl_3$ has provided a value of δ_{iso} = –141.9 ppm for the then chemically equivalent tin atoms, and a value of $^1J_{iso}(^{119}Sn,^{119}Sn)$ of 4570 Hz.[57]

The ^{119}Sn CP MAS NMR spectrum of solid powdered **V** acquired at 7.05 T is presented in Fig. 6*a*; ^{119}Sn and ^{117}Sn CP MAS spectra were also obtained at 4.70 T (not shown). The form of the spectrum, which appears more complicated than the four-line ideal spectrum presented in Fig. 3, is due to the fact that the ^{119}Sn isotope is not 100% abundant. We also note that nearly all of the spectral intensity is concentrated in the centrebands, as ^{119}Sn CP NMR spectra of a stationary sample of **V** indicate a CS tensor span for tin of less than 200 ppm. Values for the NMR parameters derived from these spectra are presented in Table 4. The isotropic chemical shifts of the two Sn sites in **V** are easily determined as –142.5 and –154.2 ppm from the peaks of the uncoupled ^{119}Sn nuclei, providing a value for Δ_S of 1310 ± 20 Hz. In Fig. 6*a*, the splittings (i) and (ii) between the outer two pairs of lines reflect the couplings of sites 1 and 2 to ^{117}Sn nuclei. These two couplings are found to be the same (as expected), and the spectra yield a final value of 4175 ± 20 Hz for $^1J_{iso}(^{119}Sn,^{117}Sn)$ in **V**. Because isotope effects are expected to be insubstantial here,[58] a value for $^1J_{iso}(^{119}Sn,^{119}Sn)$ of

Fig. 5. Structure of hexa(*p*-tolyl)ditin. (*a*) View along the tin–tin bond; (*b*) side view. Hydrogen atoms are omitted for clarity.

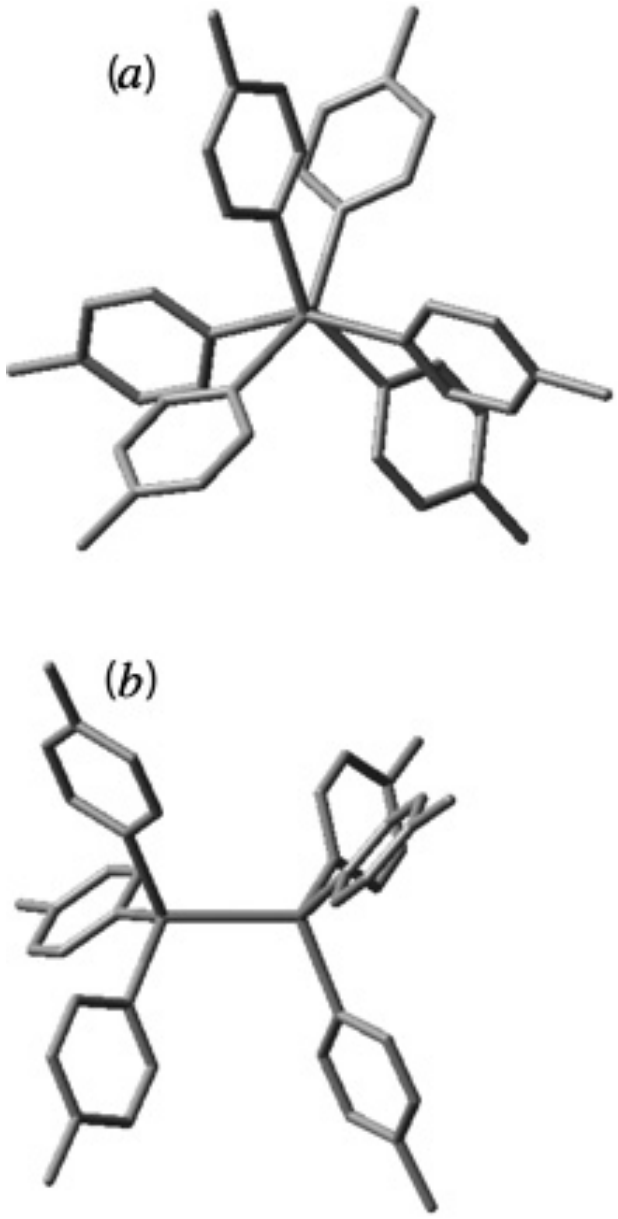


Fig. 6. (*a*) Tin-119 VACP MAS spectrum of hexa(*p*-tolyl)ditin obtained at 7.05 T. The two dominant peaks result from the uncoupled nuclei, and are therefore far more intense than peaks from the coupled isotopomers. The splitting (*i*) is equal to $^1J_{iso}(^{119}Sn, ^{117}Sn)$ for site 1 and the splitting (ii) is $^1J_{iso}(^{119}Sn, ^{117}Sn)$ for site 2. The splitting corresponding to $C_0 - |J_{iso}(^{119}Sn, ^{119}Sn)|$ is also marked in the figure. (*b*) Tin-119 POST-C7 spectrum of hexa(*p*-tolyl)ditin also obtained at 7.05 T, where the double-quantum pulse sequence filters out all but homonuclear spin pairs, leaving only the central part of the AB pattern. The edges of the line shape provide a maximum value for $C_{max} - |J_{iso}(^{119}Sn, ^{119}Sn)|$, and therefore of the largest component of $\mathbf{J}^{anti}$.

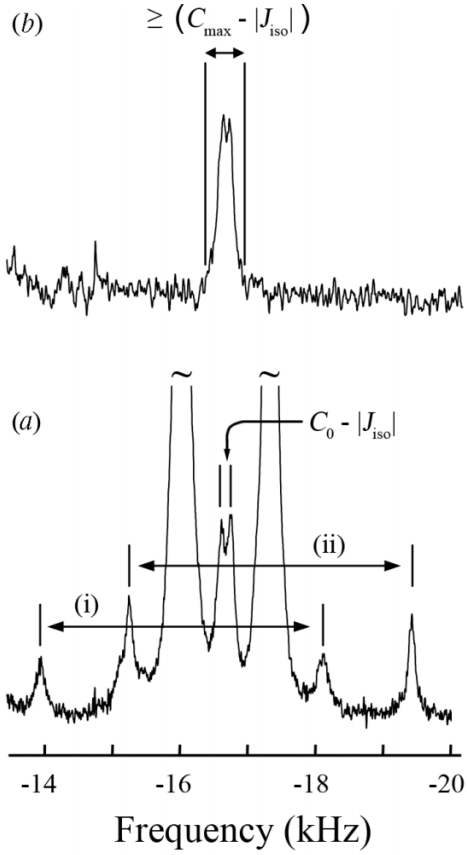


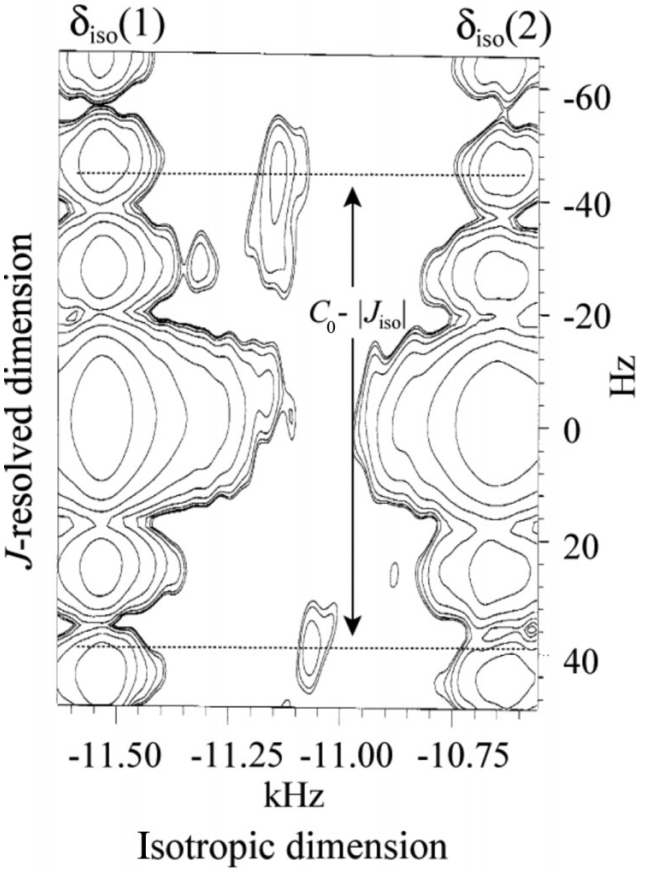
4368 Hz may be obtained through multiplication by the ratio of the magnetogyric ratios, $\gamma(^{119}Sn)/\gamma(^{117}Sn)$.[9] The splitting $C_0 - |J_{iso}|$, see Fig. 6*a*, is 140 ± 50 Hz, which agrees within error with the splitting of 192 ± 7 Hz expected from the above values of J_{iso} and Δ_S. Note that for molecules containing two ^{119}Sn nuclei, the two outer transitions are not observed in the ^{119}Sn NMR spectrum shown in Fig. 6*a*. Because the integrated intensity of each of the transitions is approximately 2.2% of each of the inner transitions, it would be extremely difficult to observe them. It would be possible to observe effects of $\mathbf{J}^{anti}$ solely from the inner transitions; however, spectral crowding by peaks from the other isotopomers prevents observation of the entire line shape and could be responsible for obscuring the effects of $\mathbf{J}^{anti}$.

In an effort to determine some line shape for the inner two peaks, a two-dimensional *J*-resolved ^{119}Sn NMR spectrum was obtained at 4.70 T.[59,60] In the *J*-resolved experiment, heteronuclear dipolar interactions as well as anisotropic chemical shifts are refocused at the top of the echo, thereby providing better resolution in the indirect (F_1) dimension.[59] Furthermore, because the peaks from the AB pattern are separated along the F_1 dimension, this experiment presents the opportunity to observe some anisotropic line shape that could be obscured in the one-dimensional spectrum. Shown in Fig. 7 is a 2D *J*-resolved ^{119}Sn CP MAS NMR spectrum of hexa(*p*-tolyl)ditin. The projection of this spectrum onto the isotropic dimension corresponds to the one-dimensional CP MAS spectrum. In the indirect *J*-resolved dimension, the splitting $C_0 - |J_{iso}(^{119}Sn,^{119}Sn)|$ is much better resolved than it is in the isotropic dimension, and therefore provides a more accurate measurement. The precision of the measurement in the indirect dimension is limited by the number of points which define the spectrum. In the spectrum shown in Fig. 7, 16 points define the 200 Hz spectral window in the indirect dimension, thereby providing one data point every 12.5 Hz. The splitting $C_0 - |J_{iso}(^{119}Sn,^{119}Sn)|$ is 85.0 ±

Table 4. Tin-119 NMR parameters determined for hexa(*p*-tolyl)ditin.

Parameter	Value
δ_{iso}(site 1)	–142.5±0.2 ppm
δ_{iso}(site 2)	–154.2±0.2 ppm
$J_{iso}(^{119}Sn,^{119}Sn)$	4368±20 Hz
$\mathbf{J}^{anti}(^{119}Sn,^{119}Sn)$ elements	<2900 Hz

Fig. 7. 2D *J*-resolved ^{119}Sn CP MAS NMR spectrum of hexa(*p*-tolyl)ditin obtained at 4.70 T. The isotropic chemical shifts of the uncoupled nuclei in sites 1 and 2 are indicated. The splitting $C_0 - |J_{iso}(^{119}Sn,^{119}Sn)|$ is easily resolved in the second dimension.



12.5 Hz, which compares favourably with the splitting of 87 ± 5 Hz expected from J_{iso} and the Δ_S = 875 ± 20 Hz measured from the 1D spectrum. Unfortunately, when the signal is spread out into two dimensions, the signal-to-noise ratio of the inner two peaks of the AB spectrum is reduced such that any line shape present was not detected.

Another method of decongesting the spectral overlap seen in Fig. 6*a* is to use a double-quantum filter, DQF, to remove any peaks that do not arise from a homonuclear spin pair. The spectrum shown in Fig. 6*b* is an example of this method where we have used the POST-C7 experiment which leaves only peaks from ^{119}Sn nuclei that are relatively strongly dipolar coupled to one another.[61,62] The spectrum in Fig. 6*b* therefore corresponds to that of Fig. 6*a*, except that only the inner two peaks from the AB spin system remain. Before providing a concrete evaluation, we note that A_{max} only produces a significant effect on the spectrum when its magnitude is comparable to both J_{iso} and Δ_S. For example, the breadth of the each of the inner peaks of Fig. 3*b*, $C_{max} - C_0$, would only be 11 Hz if A_{max} were 450 Hz (10% of J_{iso}). Comparing the DQF spectrum to the theoretical form of Fig. 3*b* shows that the edges of the peaks in the DQF spectrum provide an upper limit to C_{max}, and therefore an upper limit on the largest element of $\mathbf{J}^{anti}$. The breadth of the AB doublet is 500 Hz, which translates into a value of 1700 Hz for A_{max}, and A_{max} is from 1 to $1/\sqrt{3}$ of the largest element of $\mathbf{J}^{anti}$. The DQF spectrum therefore provides an upper limit of 2900 Hz for the largest element of $\mathbf{J}^{anti}$ in compound **V**.

In cases where a peak shoulder is directly observed, an exact value of A_{max} can be extracted; however, only the peak width can be determined from the presented spectrum of hexa(*p*-tolyl)ditin, and therefore only an upper limit on A_{max} can be reported. It should also be noted that line broadening from other sources acts to increase the upper limit provided by this analysis. For example, the sample calculation presented in the preceding paragraph shows that even if A_{max} were zero in this compound, line broadening causing an apparent increase in $C_{max} - C_0$ of only 11 Hz would lead to an upper limit of 450 Hz for A_{max}. Because of interference from line-broadening effects, the actual value of $\mathbf{J}^{anti}$ elements may be anywhere between 0 and the upper limit of 2900 Hz. Despite the limitations of analyzing a spectrum for which the theoretically expected shoulder is not observed, it is interesting that we can place a definite upper limit on $\mathbf{J}^{anti}$ elements.

Experimental and theoretical implications

Given that quantum chemical calculations have shown that the magnitudes of $\mathbf{J}^{anti}$ elements have the potential to be comparable to those of $\mathbf{J}^{sym}$,[49] it is important to consider their effect on NMR spectra. Effects from $\mathbf{J}^{anti}$ have generally been ignored in spectral analysis, despite the fact that Andrew and Farnell have predicted measureable effects on AB spectra from single crystals spinning at the magic angle.[37] Aside from interest in $\mathbf{J}^{anti}$ itself, it is important to consider whether the presence of large elements in $\mathbf{J}^{anti}$ could lead to errors when analyzing AB spectra of powders undergoing MAS. While an observable difference in peak position is predicted for each crystallite, it is found here that the most probable frequency, i.e., the highest part of each peak, is independent of $\mathbf{J}^{anti}$. Therefore, one need not worry about $\mathbf{J}^{anti}$ introducing errors in determinations of the other NMR observables.

While the above theory shows that it is possible to analyze spectra independently of $\mathbf{J}^{anti}$, the discussion also presents a strategy for its measurement. The fundamental reason for measuring the antisymmetric parts of NMR interaction tensors, and indeed for measuring the anisotropic symmetric parts, is to make use of the fact that up to nine independent elements are available for a given interaction tensor (see eq. [1]). Routine use is made of the isotropic portions of the chemical shift and *J*-coupling tensors; the availability of up to eight more parameters to describe a given interaction signifies the opportunity to provide much more complete descriptions of the nuclear environment.

The potential existence of sizable antisymmetric contributions to **J** also has other important implications. For example, the different mechanisms which contribute to *J* coupling are listed in Table 5, where it may be seen that each mechanism possesses different symmetry properties.[63] Because $\mathbf{J}^{anti}$ contains no contribution from the Fermi-contact (FC) coupling mechanism, measurement of a nonzero antisymmetric coupling constant would represent some of the most convincing experimental evidence for non-FC contributions to **J**. Furthermore, it is noted that in principle the antisymmetric part of **J** contributes to nuclear spin relaxation although its effect has never been observed experimentally.[34,35] While the experimental strategy described herein is applicable to tightly coupled homonuclear spin pairs, antisymmetric *J* coupling is a general phenomenon which will in principle affect nuclear spin relaxation even in situations where it cannot be measured directly. That heteronuclear *J* couplings may contain important antisymmetric contributions has been demonstrated by high-level quantum chemical calculations on selected systems.[49]

Conclusions

The present work has described an experimental strategy for measuring the antisymmetric part of indirect nuclear spin–spin coupling tensors for tightly coupled (AB) homonuclear spin pairs in solid samples undergoing MAS. Considerations for identifying appropriate spin systems and chemical compounds have been developed, and we also note that modern quantum-chemical calculations would likely be helpful in selecting suitable candidate molecules. Analysis of spectra from samples undergoing MAS, which averages all interactions other than $\mathbf{J}^{anti}$ to their isotropic values, appears to be an ideal strategy. $\mathbf{J}^{anti}$ would affect

spectra from stationary samples, but it would be difficult to separate $\mathbf{J}^{anti}$ from the orientationally dependent $\mathbf{J}^{sym}$ and **D** interactions (even with single crystal data). The effect of $\mathbf{J}^{anti}$ components on NMR line shapes from powdered samples undergoing MAS is derived, and the method of spectral analysis discussed. The main finding is that NMR peak shapes from AB spin systems will be affected, but that the most intense portion of the spectra may be analyzed independent of $\mathbf{J}^{anti}$. It is also found that $\mathbf{J}^{anti}$ must be comparable in magnitude to J_{iso} and the difference in chemical shifts between the two sites to affect the NMR spectra. In particular, the method of analysis allows one to determine a measure of the largest element of $\mathbf{J}^{anti}$. Using this approach, the ^{119}Sn NMR spectrum of hexa(*p*-tolyl)ditin was analyzed to show that all elements of $\mathbf{J}^{anti}$ in this compound must be smaller than 2900 Hz.

Experimental details

p,*p*′-Dimethoxydiphenyl ditelluride, **I**, (dark red powder), *p*,*p*′-ditolyl ditelluride, **II**, (orange powder), 1-naphthyl ditelluride, **III**, (light orange powder), and diphenyl ditelluride, **IV**, (orange powder) were obtained from Sigma-Aldrich. Tellurium-125 one-dimensional VACP MAS NMR spectra of compounds **I**-**IV** were acquired on a Chemagnetics CMX Infinity 200 spectrometer operating at a frequency of 63.16 MHz. MAS rates of at least 10 kHz were found to be essential to resolve spinning sidebands satisfactorily; a double-resonance 4 mm MAS probe was used for all experiments. Telluric acid, $Te(OH)_6$, was used as a cross-polarization setup sample.[64] Typical experimental parameters were: 10–20 s recycle delay, 2.50 μs π/2 pulse, 10.0 ms contact time, 76.8 ms acquisition time, 4k–8k scans recorded. High-power proton decoupling was used for all experiments. For compounds **I**, **II**, and **IV**, the temperature around the sample was kept below room temperature, typically ≈ 10 °C, to prevent melting of the samples.

Hexa-(*p*-tolyl)ditin, **V**, (white powder) was synthesized following a procedure adapted from references 65 and 66. The compound was recrystallized from benzene, which apparently affords the type-B polymorph.[57] Tin-119 VACP MAS NMR spectra of powdered samples of hexa(*p*-tolyl)ditin were acquired at a frequency of 74.63 MHz using a Chemagnetics CMX Infinity 200 spectrometer, or at 112.01 MHz with a Bruker Avance 300 spectrometer. Tin-117 VACP MAS NMR spectra were acquired at 71.31 MHz using a Chemagnetics CMX Infinity 200 spectrometer. A 4 mm DR MAS probe was used for all experiments. Tetracyclohexyltin was used as a setup sample and secondary chemical shift reference, δ_{iso} = –97.35 ppm, with respect to a solution of $SnMe_4$ at 0 ppm.[67,68] All ^{119}Sn and ^{117}Sn CP/MAS experiments used a 40 s recycle delay, 5–6 ms contact times, and either 2.40 μs (at 4.70 T) or 4.00 μs π/2 pulses. High-power proton decoupling ($\gamma B_1/2\pi$ > 60 kHz) was used for all experiments. The POST-C7 pulse sequence[61,62] was used to provide a double-quantum filtered ^{119}Sn spectrum; an MAS rate of 8.929 kHz and an experimentally optimized ^{119}Sn B_1 field near the theoretical maximum of 62.5 kHz was applied. The DQ conversion efficiency of the POST-C7 sequence was found to be approximately half the theoretical value of 47% for the 895.96 μs DQ excitation block used.[69] Heteronuclear decoupling was applied only during the acquisition period of the POST-C7 experiment.[70] Two-dimensional *J*-resolved ^{119}Sn MAS NMR spectra[59,60] were acquired using similar parameters, with 16 points acquired in the indirect dimension, a spectral window of 200 Hz in the indirect dimension, and 128 scans per increment.

Numerical calculations of the $A(\Theta)$ distribution and its effect on NMR spectra were performed with purpose-built C code. The powder distribution was generated by calculating the value of $f_{zy}(\Theta;c_{yx},c_{zx})$, see eq. [11], for a large set of crystallite orientations;[71] orientations were generated in the rotor frame, to take advantage of the above-noted rotational symmetry of $f_{zy}(\Theta;c_{yx},c_{zx})$ about the axis of sample rotation. Specifically, crystallites were initially aligned with z along r_{rot}, then rotated about r_{rot} through the angle α ($0 < \alpha < 2\pi$), and then about the initial *y* axis through the angle β ($0 < \beta < \pi$). A total of 832039 crystallite orientations were used, where the α and β Euler angles were sampled according to the Zaremba–Conroy–Wolfsberg, ZCW, distribution.[72–74] Each ξ_a and ε_{ab} angle in eq. [11] was then calculated using standard linear algebra, and used to create plots of $f_{zy}(\Theta;c_{yx},c_{zx})$, $f_{zy}^2(\Theta;c_{yx},c_{zx})$, or the NMR spectral frequencies.

Jones and magnetoelectric birefringence of pure substances — A computational study

Antonio Rizzo, Dmitry Shcherbin, and Kenneth Ruud

Abstract: We present the first investigation of condensed-phase effects on the Jones (and magnetoelectric) birefringence of a set of nondipolar (CCl_4 and CS_2) and dipolar (nitro- and chloro-benzene) molecules using a recent implementation of the polarizable continuum model for cubic response functions at the time-dependent density-functional level of theory. The condensed-phase calculations have been performed on the neat liquids of the sample molecules using a nonequilibrium solvation scheme to properly account for the solute–solvent interactions in the presence of a frequency-dependent electromagnetic field. It is demonstrated that the condensed-phase effects as modelled by the polarizable continuum model can be substantial, increasing the observable birefringence by more than sixty percent in the case of CCl_4, and by a factor of more than three for CS_2. Solvent effects are also substantial for the dipolar molecules, leading to an enhancement by a factor of roughly five for nitrobenzene and by a bit less than 30% for chlorobenzene. Comparison is made with the results of experiment. Our calculated anisotropies confirm that the effect is below current experimental detection limits for CCl_4 and CS_2. We compute Jones constants of the same order of magnitude as the upper limits given in experiment for nitro- and chlorobenzene.

Key words: birefringences, non linear optical properties, computational chemistry, density functional theory, polarizable continuum method.

Résumé : Faisant appel à une récente implantation du modèle du continuum polarisable des fonctions cubiques de réponse au niveau dépendant du temps de la théorie de la fonctionnelle de densité, on a réalisé la première étude des effets d'une phase condensée sur la biréfringence de Jones (et magnétoélectrique) d'un ensemble de molécules dipolaires (nitro- et chlorobenzène) et d'autres qui ne le sont pas (CCl_4 et CS_2). Les calculs de phase condensée ont été effectués sur des liquides purs des molécules échantillonnées en utilisant un schéma de solvatation qui n'est pas en équilibre pour bien tenir compte des interactions soluté–solvant en présence d'un champ électromagnétique dépendant de la fréquence. On a démontré que les effets de phase condensée, tels que représentés par le modèle du continuum polarisable, peuvent être substantiels et augmenter la biréfringence observable par plus de soixante pour-cent dans le cas du tétrachlorure de carbone et par un facteur supérieur à trois pour le disulfure de carbone. Les effets de solvant sont aussi substantiels pour les molécules dipolaires; ils conduisent à des augmentations qui correspondent à un facteur pratiquement égal à cinq dans le cas du nitrobenzène et d'un peu moins de 30 % pour le chlorobenzène. Une comparaison est faite avec les résultats expérimentaux. Les anisotropies calculées confirment que, pour le CCl_4 et le CS_2 l'effet est inférieur aux limites actuelles de détection expérimentale. On a aussi calculé les constantes de Jones du même ordre de grandeur que les limites supérieures expérimentales pour le nitro- et le chlorobenzène.

Mots-clés : biréfringence, propriétés optiques non linéaires, chimie théorique, théorie de la fonctionnelle de densité, méthode du continuum polarisable.

[Traduit par la Rédaction]

Introduction

Jones linear birefringence (JB) is the anisotropy of the refractive index observed when linearly polarized monochromatic light interacts with matter in the presence of external uniform electric and magnetic induction fields applied parallel to each other and perpendicular to the direction of propagation of the light beam.

The theory of the effect, predicted by Jones as early as 1948,[1] was laid down by Graham and Raab;[2] see also ref. 3. The birefringence is bilinear in the electric and magnetic induction field strengths, relating the observable to relevant

Received 6 January 2009. Accepted 24 March 2009. Published on the NRC Research Press Web site at canjchem.nrc.ca on 16 September 2009.

This article is part of a Special Issue dedicated to Professor T. Ziegler. It is a great pleasure for us to dedicate this work to one of the masters in understanding the origins of electric and magnetic responses of molecules, Prof. Tom Ziegler, on the occasion of his 65th birthday.

molecular optical property tensors. It is characterized by a pair of axes bisecting those of the two traditional birefringences, the Kerr[4,5] and Cotton–Mouton[6,7] birefringences. Rikken and co-workers have been able to detect and measure JB in liquids.[8–10] These studies have been extended also to the analysis of the so-called "Magneto-electric birefringence" (MEB),[11,12] a different (from the experimental point of view) type of birefringence also bilinear in the strength of the electric and magnetic induction field strengths and which appears when the three directions (propagation, electric field, and magnetic induction field) are mutually orthogonal.[13] The optical axes of MEB are the same as for Kerr and Cotton–Mouton. The molecular expression for the corresponding anisotropy in fluids turns out to be identical to that for the JB,[14] and from now on we will only refer to the latter, with the understanding that the results presented below will apply to both experiments, JB and MEB.

Linear birefringences such as Jones and magnetoelectric birefringence are in principle powerful tools for polarization–optical studies which can have applications in the field of crystals, of biology, and of polymer science. Experimental interest stems also from the challenges that the measurement of tiny ellipticities poses, and which in recent years have led to the development of ever more sophisticated optics and detection hardware. These measurements are moreover often performed to calibrate optical apparatus designed for the detection of such elusive and fundamental properties as vacuum polarization. Indeed quantum electrodynamics predicts that vacuum should exhibit yet undetected Cotton–Mouton, Kerr, Jones, and magnetoelectric birefringences.[15,16] Magnetoelectric Jones dichroism has also been discussed.[17–19]

Rizzo and Coriani have identified the relevant response functions entering the expression for the birefringence.[20] The authors determined ab initio estimates of the observable, the anisotropy of the refractive index for the light polarized at +45 and –45 degrees with respect to the direction of polarization of the light in JB, in some atomic systems (He, Ne, Ar, Kr) and in a few linear molecules (H_2, N_2, C_2H_2, and CO). These estimates were obtained using the techniques provided by modern response theory, in particular the coupled cluster singles and doubles (CCSD) model.[21–23] The study involved the determination of mixed electric dipole – magnetic dipole – electric quadrupole linear, quadratic, and cubic response functions,[24–32] and it was later extended to benzene[33] and hexafluorobenzene,[34] where the relevant quantities were obtained using Density Functional Theory (DFT) approaches.[35,36] For a discussion of the subject, see also refs. 37 and 38, whereas issues arising when studying birefringences in condensed phase are analyzed in ref. 39.

In this paper we extend the study of Jones birefringence to include the effects of the condensed phase to estimate the optical anisotropy induced by mixed static electric and magnetic fields in some of the pure liquids which were the subject of the experimental study of Roth and Rikken in ref. 9. In particular, we focus on two non-dipolar (CCl_4 and CS_2) and two dipolar (nitro- and chlorobenzene) molecules. The effect of the environment is included via a polarizable continuum model (PCM)[40,41] in its integral equation formulation (IEF–PCM),[41–44] taking advantage of recent developments of linear,[45] quadratic[46], and cubic[47,48] frequency-dependent PCM response theory at the time-dependent DFT level of theory. A nonequilibrium solvation scheme is adopted, as this allows us to properly take into account the solute–solvent interactions in the presence of a frequency-dependent electromagnetic field.

Experiments were performed on a series of eleven samples, including molecular liquids and solutions of varying structural complexity, and it involved the measurements of Jones birefringence together with the Cotton–Mouton and Kerr effects.[9] Of the eleven molecules analyzed experimentally, it was only possible to measure the absolute values of Jones birefringence for three of the samples, and these three species were all metal complexes containing manganese, iron, or titanium, which have low-lying strong charge-transfer transitions of approximately octupolar symmetry and which also possess a permanent electric dipole moment. Although it is clearly of interest to explore the Jones birefringence of these metal complexes, the challenges faced in providing accurate DFT results for charge-transfer states of transition metal complexes would make it difficult to assess the quality of the calculated results. For this reason we here focus instead on somewhat simpler molecular liquids, for which experiment could only establish upper limits for the birefringence.[9,10]

In the following, we will briefly define the important quantities determining the JB, connecting these molecular quantities to the experimental observables, and outline the computational approach utilized in this work. A section will be devoted to the details on the calculations performed here. The results obtained for pure liquid CCl_4, CS_2, and chloro- and nitrobenzene are then presented and discussed. We end the paper by a brief summary of our most important findings.

Theory

Graham and Raab[2] obtained the following general expression for the anisotropy of the refractive index, indicated as $n_{-45^\circ} - n_{+45^\circ}$, in Jones birefringence

$$[1]\qquad n_{-45^\circ} - n_{+45^\circ} = \frac{NE_xB_x}{30\varepsilon_0 c_0} \times\left\{ \mathcal{G}^{(3)}_{para} + \mathcal{G}^{(3)}_{dia} + \mathcal{A}'^{,(3)} + \frac{1}{kT}[\mathcal{G}^{(2)}_{para} + \mathcal{G}^{(2)}_{dia} + \mathcal{A}'^{,(2)}]\right\}$$

where, using the Einstein summation convention for repeated Greek indices,

$$[2]\qquad \mathcal{G}^{(3)}_{para} = 3G^{para}_{\alpha\beta\alpha\beta} + 3G^{para}_{\alpha\beta\beta\alpha} - 2G^{para}_{\alpha\alpha\beta\beta}$$

$$[3]\qquad \mathcal{G}^{(3)}_{dia} = 3G^{dia}_{\alpha\beta\alpha\beta} + 3G^{dia}_{\alpha\beta\beta\alpha} - 2G^{dia}_{\alpha\alpha\beta\beta}$$

$$[4]\qquad \mathcal{A}'^{,(3)} = -\frac{\omega}{2}\varepsilon_{\alpha\beta\gamma}(a'_{\alpha\beta\delta\delta\gamma} + a'_{\alpha\beta\delta\gamma\delta})$$

$$[5]\qquad \mathcal{G}^{(2)}_{para} = \mu_\alpha(3G^{para}_{\alpha\beta\beta} + 3G^{para}_{\beta\alpha\beta} - 2G^{para}_{\beta\beta\alpha})$$

$$[6]\qquad \mathcal{G}^{(2)}_{dia} = \mu_\alpha(3G^{dia}_{\alpha\beta\beta} + 3G^{dia}_{\beta\alpha\beta} - 2G^{dia}_{\beta\beta\alpha})$$

$$[7]\qquad \mathcal{A}'^{,(2)} = -\frac{\omega}{2}\varepsilon_{\alpha\beta\gamma}(\mu_\gamma a'_{\alpha\beta\delta\delta} + \mu_\delta a'_{\alpha\beta\delta\gamma})$$

In the equations above, N is the number density, ε_0 is the electric constant, c_0 is the speed of light in vacuo, k is Boltz-

mann's constant, T is the temperature, and ω is the circular frequency of the radiation. E_x and B_x represent the x components of the electric E and magnetic B fields, respectively, and μ_α is the α component of the permanent electric dipole moment. We have thus assumed that the radiation propagates along the z axis, whereas the fields are applied along the x axis. In eqs. [4] and [7], $\varepsilon_{\alpha\beta\gamma}$ represents the Levi-Civita alternating tensor.

The remaining tensors in eqs. [2]–[7] were identified in terms of frequency-dependent response functions in ref. 20 as

$$[8]\quad a'_{\alpha\beta\gamma\delta}(-\omega;\omega,0) = a'_{\alpha\gamma\beta\delta}(-\omega;\omega,0) = -\Im\langle\langle\mu_\alpha;q_{\beta\gamma},m_\delta\rangle\rangle_{\omega,0} = i\langle\langle\mu_\alpha;q_{\beta\gamma},m_\delta\rangle\rangle_{\omega,0}$$

$$[9]\quad a'_{\alpha\beta\gamma\delta\varepsilon}(-\omega;\omega,0,0) = a'_{\alpha\gamma\beta\delta\varepsilon}(-\omega;\omega,0,0) = \Im\langle\langle\mu_\alpha;q_{\beta\gamma},m_\delta,\mu_\varepsilon\rangle\rangle_{\omega,0,0} = -i\langle\langle\mu_\alpha;q_{\beta\gamma},m_\delta,\mu_\varepsilon\rangle\rangle_{\omega,0,0}$$

$$[10]\quad G^{para}_{\alpha\beta\gamma}(-\omega;\omega,0) = \Re\langle\langle\mu_\alpha;m_\beta,m_\gamma\rangle\rangle_{\omega,0} = \langle\langle\mu_\alpha;m_\beta,m_\gamma\rangle\rangle_{\omega,0}$$

$$[11]\quad G^{para}_{\alpha\beta\gamma\delta}(-\omega;\omega,0,0) = -\Re\langle\langle\mu_\alpha;m_\beta,m_\gamma,\mu_\delta\rangle\rangle_{\omega,0,0} = -\langle\langle\mu_\alpha;m_\beta,m_\gamma,\mu_\delta\rangle\rangle_{\omega,0,0}$$

$$[12]\quad G^{dia}_{\alpha\beta\gamma}(-\omega;\omega) = -\Re\langle\langle\mu_\alpha;\xi^{dia}_{\beta\gamma}\rangle\rangle_\omega = -\langle\langle\mu_\alpha;\xi^{dia}_{\beta\gamma}\rangle\rangle_\omega$$

$$[13]\quad G^{dia}_{\alpha\beta\gamma\delta}(-\omega;\omega,0) = \Re\langle\langle\mu_\alpha;\xi^{dia}_{\beta\gamma},\mu_\delta\rangle\rangle_{\omega,0} = \langle\langle\mu_\alpha;\xi^{dia}_{\beta\gamma},\mu_\delta\rangle\rangle_{\omega,0}$$

The last equalities hold for real electronic wave functions. The operators involved in the definitions of the response functions are the electric dipole (μ), magnetic dipole (m), traced electric quadrupole (q), and diamagnetic susceptibility (ξ^{dia}) operators

$$[14]\quad \mu_\alpha = -\sum_i r_{ia}$$

$$[15]\quad m_\alpha = -\frac{1}{2}\sum_i (r_i \times p_i)_\alpha = -\frac{1}{2}\sum_i \varepsilon_{\alpha\beta\gamma} r_{i\beta} p_{i\gamma} = -\frac{1}{2}\sum_i l_{i\alpha}$$

$$[16]\quad q_{\alpha\beta} = -\sum_i r_{i\alpha} r_{i\beta}$$

$$[17]\quad \xi^{dia}_{\beta\gamma} = \frac{1}{4}\sum_i (r_{i\beta} r_{i\gamma} - r_{i\delta} r_{i\delta}\delta_{\beta\gamma})$$

where the sum runs only over the electrons and the standard notation for cartesian components of the position ($r_{i\alpha}$), angular momentum ($l_{i\alpha}$), and linear momentum ($p_{i\alpha}$) operators of electron i is used. The traced form of the electric quadrupole moment operator was adopted, following the derivation of Graham and Raab.[2] Gauge invariance of the observable anisotropy of the refractive index, eq. [1], was proven in ref. 20.

We will report the birefringence per unit density (ρ), unit electric and unit magnetic fields, $[\Delta n]$, given as

$$[18]\quad [\Delta n] = \frac{n_{-45^\circ} - n_{+45^\circ}}{\rho E_x B_x} = \frac{N_a}{30\varepsilon_0 c_0 M}\times\left\{J_0 + \frac{J_T}{T}\right\} = [\Delta n^{(0)}] + \frac{[\Delta n^{(T)}]}{T}$$

where N_a is Avogadro's number and M is the molar mass. If the latter is given in g mol^{-1}, and the quantity in graph parentheses is computed in atomic units, $[\Delta n]$ is obtained in units of cm^4 g^{-1} V^{-1} T^{-1}, using the following expression

$$[19]\quad [\Delta n] \approx 2.25681\times 10^{-19}\times\frac{1}{M[\mathrm{g\ mol^{-1}}]}\times\left\{J_0 + \frac{J_T}{T}\right\}[\mathrm{au}]$$

The quantities J_0 and J_T are easily identified as, see above,

$$[20]\quad J_0 = \mathcal{G}^{(3)}_{para} + \mathcal{G}^{(3)}_{dia} + \mathcal{A}'^{,(3)}$$

$$[21]\quad J_T = \frac{1}{k}[\mathcal{G}^{(2)}_{para} + \mathcal{G}^{(2)}_{dia} + \mathcal{A}'^{,(2)}]$$

Note that in the case of a gas with molar volume V_m, eq. [18] can be employed upon substitution of ρ with $\frac{M}{V_m}$. In the case of a perfect gas at pressure P, $\rho = \frac{MP}{N_a kT}$. Below we will refer to $[\Delta n]$ as the "specific" birefringence.

In experiment, the measurements are analyzed using a definition of the Jones birefringence that involves a Jones constant K_J,[9] defined through the relationship

$$[22]\quad \Delta n = n_{-45^\circ} - n_{+45^\circ} = k_J \lambda \boldsymbol{E}\cdot\boldsymbol{B}$$

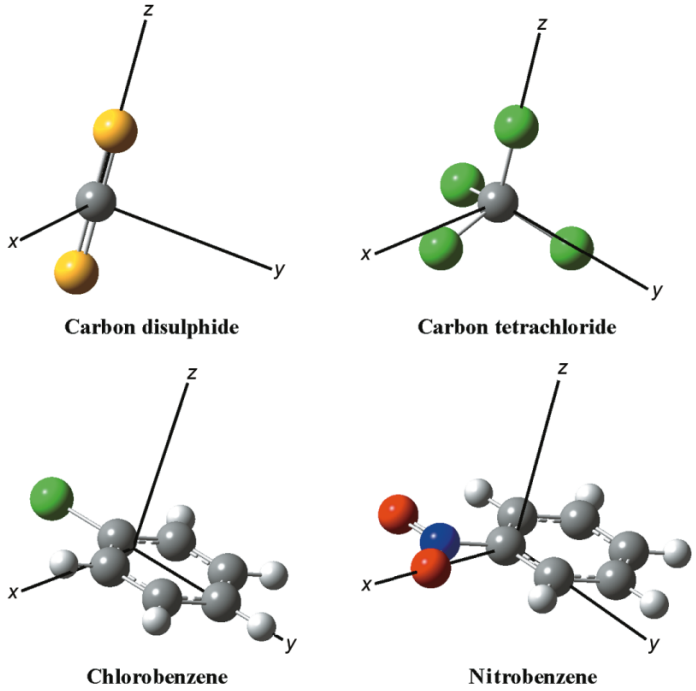
and involving explicitly the wavelength of the radiation, λ. It is easy to show that

$$[23]\quad k_J = \frac{N_a\rho}{30\varepsilon_0 c_0 M\lambda}\times\left\{J_0 + \frac{J_T}{T}\right\} \approx 2.25681\times 10^{-12}\times\frac{\rho[\mathrm{g\ cm^{-3}}]}{\lambda[\mathrm{nm}]\times M[\mathrm{g\ mol^{-1}}]}\times\left\{J_0 + \frac{J_T}{T}\right\}[\mathrm{au}]$$

with the resulting value of the Jones constant being given in units of V^{-1} T^{-1} when the density, molar mass, and wavelength are given in the SI units specified above in square parentheses, whereas again the quantity in graph parentheses is computed in atomic units.

In the polarizable continuum model, pioneered by Tomasi and co-workers,[40,41] and exploited here in the particular formulation given by the integral-equation formalism (IEF),[43,49,50] the solvent is described as a homogeneous, polarizable dielectric medium characterized by a set of di-

Fig. 1. A sketch of the geometry arrangement for the four molecule studied here.



electric constants, normally restricted to a static and an optical dielectric constant, whereas the solvated molecule is placed in a cavity within the dielectric medium. The cavity can be given any arbitrary shape, and it is built from a set of interlocking spheres. As also done in this work, it is customary to center the spheres on the heavy atoms of the solvated molecules, with radii determined by the functional nature of the heavy atom and optimized against experimental solvation energies. A nonequilibrium solvation scheme is adopted, to properly account for the solute–solvent interactions in the presence of a frequency-dependent electromagnetic field.

We have developed a second-quantization formalism for the PCM[44] at the Hartree–Fock and multiconfigurational level of theory, later extended to DFT.[51] In the present work we will utilize the DFT formulation of the PCM model in combination with linear, quadratic, and cubic response functions. Indeed, building on the original implementation of linear,[24,52] quadratic,[25,35] and cubic[26,36] response theory at the Hartree–Fock, multiconfigurational Hartree–Fock and DFT levels of theory, in recent years we have been extending the PCM to the linear,[45] quadratic,[46,53,54] and recently also cubic[48] response theory levels. In the latter case, work is in progress to extend the formalism from the Hartree–Fock / density functional level of theory also to multiconfigurational self-consistent field wave functions.[55] Indeed, the present study is only the second analytic study of fourth-order, frequency-dependent molecular properties using PCM, though we note that PCM studies of fourth-order molecular properties have been carried out using mixed analytic and numerical methods.[56,57] Since the present work is an application of the method development mentioned above, we do not give further details on the implementation of the response function within the PCM framework, referring the interested reader instead to the original references.

Computational details

Calculations have been carried out for CCl_4, CS_2, chlorobenzene (C_5H_5Cl) and nitrobenzene ($C_5H_5NO_2$), four of the systems analyzed experimentally by Roth and Rikken.[9] A sketch of the geometry arrangement for the four systems in our calculations is given in Fig. 1. For each of these systems we have performed three sets of calculations of the property:

(1) in the one labelled below as "gas", the molecules are treated as being in the gas phase, and no solvent model is included;
(2) in the one labelled as "pcm", both the geometry optimization and the calculation of the properties are made with the introduction of the IEF polarizable continuum model;
(3) in the one labelled "pcm/gas", the geometry optimization is carried out on the isolated molecule, and the PCM is employed only for the calculation of the properties.

This sequence of calculations allows us to assess the extent to which the condensed phase affects the observable both through the change of geometry and through the change in the electromagnetic response.

All geometries were optimized at the DFT level of theory, using the 3-parameter exchange functional of Becke[58] in combination with the Lee–Yang–Parr correlation functional,[59] commonly referred to as the B3LYP functional.[60] For the geometry optimizations, both in gas phase and in the liquids, we have used Dunning's correlation-consistent basis set of triple-zeta quality (cc-pVTZ).[61] The cavities surrounding the solvated molecules have been created by adding spheres around all the heavy atoms in the molecules. These radii have been determined according to the United Atom Topological Model.[62] The parameters employed in the PCM calculations are given in Table 1.

Table 1. The parameters of the PCM calculations, cavity radii (R_{cav}, Å) and permittivities (ε and ε_∞).

Molecule	ε	ε_∞	Atom	R_{cav}
CCl_4	2.129	2.228	C	1.7
			Cl	1.81
CS_2	2.632	2.663	C	1.7
			S	1.85

			C (Cl)[a]	1.7
			Cl	1.8

[a]In parenthesis the atom to which carbon is bound.

For a higher-order molecular property such as Jones birefringence, the choice of basis set is important to obtain reliable results. In many of our earlier studies of nonlinear birefringences, the strength of the augmented correlation-consistent basis sets[63] have been demonstrated. A detailed investigation of the basis set convergence of the different contributions to the Jones birefringence is beyond the scope of the present work, and will be presented in a forthcoming publication in which we will also consider the effects of using London orbitals on the basis set convergence of the property.[64] However, the dependence of the different cubic response function contributions to the temperature-independent contribution of the Jones birefringence is illustrated for CCl_4 in the gas phase in Table 2. From the data in Table 2, the importance of diffuse functions can be easily appreciated. The data also indicates that the daug-cc-pVTZ basis set[63] represents a good compromise between accuracy and computational feasibility, and this basis set has thus been used for all the subsequent data presented in this paper. The wavelength λ = 632.8 nm, as used in experiment, was selected. The calculations were carried out using a parallel version[48,65,66] of the Dalton 2.0 program.[67]

Results and discussion

In Table 3 we have collected the results obtained for the isolated molecules and for the neat liquids of the four molecules investigated here. In addition to presenting the results for the isolated molecules at their optimized geometries in the gas phase, and the corresponding values obtained for the liquid phase optimized geometries using PCM, we also report the results obtained when the gas-phase optimized structures were used in PCM property calculations. Comparison of the change in the calculated properties when going from the gas to the liquid phase, keeping the geometry fixed, gives us an indication of the importance of the direct solvation effects as described by the PCM, whereas the changes induced going from the properties calculated in the liquid phase at the gas-phase optimized structure to the liquid-phase optimized structure, gives us a feeling for the indirect condensed phase effects due to the relaxation of the molecular geometry occurring in the presence of the surrounding molecules. When presenting data for the specific birefringence $[\Delta n]$ or for the Jones constant k_J, a temperature of 294.15 K, the room temperature at which the experiment was performed, is assumed.

$$\mathcal{G}^{(3)} = G^{(3)}_{para} + G^{(3)}_{dia}$$
$$\mathcal{A}'^{,(3)} = -\frac{\omega}{2}\varepsilon_{\alpha\beta\gamma}(a'_{\alpha\beta\delta\delta\gamma} + a'_{\alpha\beta\delta\gamma\delta})$$

The change from the gas phase to the pure liquid, as modelled by PCM, is remarkable, leading to a general increase in the magnitude of the birefringence, with a change ranging at room temperature from around 25% for chlorobenzene to a notable factor of about five, for nitrobenzene. The anisotropy increases by ≈60% for CCl_4, and by ≈250% for CS_2. We also note that the effect of the condensed phase is larger for the temperature-independent contribution, see J_0 or $[\Delta n^{(0)}]$ in Table 3, than for the temperature-dependent one, see J_T or $[\Delta n^{(T)}]$, for chlorobenzene, whereas the reverse happens for nitrobenzene. Note that $[\Delta n^{(0)}]$ and $[\Delta n^{(T)}]$ are referred to as temperature-independent and temperature-dependent contributions, respectively, due to the explicit dependence on the temperature of the right-hand side term in eq. [18]. This separation into a temperature-independent and a temperature-dependent contribution is rigorous only for ideal gases at constant pressure. In the case of solutions, the dependence on T is implicit in both $[\Delta n^{(0)}]$ and $[\Delta n^{(T)}]$ through the temperature dependence of the density ρ.

Almost all of the notable influence of the condensed phase on the property is due to the effect on the linear and nonlinear response properties, in particular for the two non-dipolar molecular liquids. For the latter, the modifications induced on the geometry of the molecule yield negligible changes in the property: the difference between the "pcm/gas" and "pcm" results is less than 0.1% for CCl_4 and CS_2. For chlorobenzene, the same difference is about 3.2%. In nitrobenzene, the pcm/gas results for the specific birefringence are approximately 7.5% larger than those obtained in the pcm approximation. In the case of polar molecules, the solvent-induced geometry changes are therefore of some relevance, although still somewhat limited, when compared to the changes induced directly by the solvent on the molecular properties. The influence of the introduction of a condensed phase model in the geometry optimization is in general larger on the temperature-dependent than on the temperature-independent contribution, with J_0 in chlorobenzene being remarkably insensitive to the change of geometry. Due to the general predominance of the T-dependent contribution (J_T) over the T-independent one (J_0) on the observable $[\Delta n]$, the dependence of the latter on both direct (through changes in the molecular properties) and indirect

(through changes in the molecular geometry) condensed-phase effects reflects roughly that observed for J_T.

It is interesting to go into a somewhat more detailed analysis of the effect of the PCM in the study of JB. In particular, the extent to which changes induced on the different response functions provide some insight into the mechanisms that govern the remarkable effect of the solvent, as modeled by the dielectric continuum model. In Table 4, the $\mathcal{G}^{(3)}_{para}$, $\mathcal{G}^{(3)}_{dia}$, $\mathcal{A}'^{,(3)}$, $\mathcal{G}^{(2)}_{para}$, $\mathcal{G}^{(2)}_{dia}$, and $\mathcal{A}'^{,(2)}$ contributions, defined in eqs. [2]–[7], are given for the different calculations carried out in the present study.

The condensed-phase effect on the temperature-independent contributions is larger for the mixed electric field – magnetic field hyperpolarizabilities, $\mathcal{G}^{(3)} = \mathcal{G}^{(3)}_{para} + \mathcal{G}^{(3)}_{dia}$, than for the one originating from the interaction of electric dipole, electric quadrupole , and magnetic dipole, $\mathcal{A}'^{,(3)}$. For all contributions to J_0 (or $[\Delta n^{(0)}]$), the dielectric medium leads to a positive increase in the value of the individual mixed hyperpolarizabilities. The condensed-phase effects are substantial on both $\mathcal{G}^{(3)}$ and $\mathcal{A}'^{,(3)}$, the solvent shift being often larger than the gas phase value itself. However, since $\mathcal{A}'^{,(3)}$ is at most $\approx$17% (in the "gas" calculation on CS_2) and in general less than about 8% of the whole $\mathcal{G}^{(3)} + \mathcal{A}'^{,(3)}$ T-independent term, J_0 is dominated by $\mathcal{G}^{(3)}$ and the condensed-phase shift on J_0 is thus mainly determined by the shift of the $\mathcal{G}^{(3)}$ contribution. $\mathcal{G}^{(3)}_{para}$ and $\mathcal{G}^{(3)}_{dia}$ have opposite sign, and the percentage change between "pcm" and "gas" results is a factor of 2–3 larger for the former than for the latter. This percentage is magnified to some extent by the partial cancellation occurring when the two contribution are summed up.

For the two dipolar substituted benzenes, switching from gas to liquid phase induces an increase in J_0 by roughly a factor of two and four for Cl^- and NO_2^- benzene, respectively. This increase results from a combination of the changes in all quadratic and cubic response functions, being possibly slightly larger for $\mathcal{A}'^{,(3)}$ than for $\mathcal{G}^{(3)}_{para}$ or $\mathcal{G}^{(3)}_{dia}$, when the latter two contributions are considered separately. Once again, the partial cancellation occurring between $\mathcal{G}^{(3)}_{para}$ and $\mathcal{G}^{(3)}_{dia}$ when they are combined magnifies the effect for the overall $\mathcal{G}^{(3)}$ combination.

For chlorobenzene, the effect of the change of phase from gas to liquid on the temperature-dependent J_T term, is larger for the contribution involving the quadrupolar interaction, $\mathcal{A}'^{,(2)}$, than for the electric dipole – magnetic dipole contribution, $\mathcal{G}^{(2)}$, in contrast to the behavior noted above for J_0. The former increases roughly by 105%, the latter by about 45%, in absolute value, going from the gas to the liquid. The cancellation between "para" and "dia" contributions to $\mathcal{G}^{(2)}$ has therefore, relatively speaking, a contained effect. Since the electric dipole – magnetic dipole linear and quadratic response functions give the dominant (more than 90%) contribution to J_T through $\mathcal{G}^{(2)}$, the effect of moving from gas to liquid phase is essentially determined by the change in this contribution.

For nitrobenzene, we first note that a quite efficient cancellation between $\mathcal{G}^{(2)}_{para}$ and $\mathcal{G}^{(2)}_{dia}$ in the "gas" calculation yields a relatively small value of $\mathcal{G}^{(2)}$, a bit more than half

$$\mathcal{G}^{(2)}_{para} = \mu_\alpha(3\mathcal{G}^{para}_{\alpha\beta\beta} + 3\mathcal{G}^{para}_{\beta\alpha\beta} - 2\mathcal{G}^{para}_{\beta\beta\alpha})$$
$$\mathcal{G}^{(2)}_{dia} = \mu_\alpha(3\mathcal{G}^{dia}_{\alpha\beta\beta} + 3\mathcal{G}^{dia}_{\beta\alpha\beta} - 2\mathcal{G}^{dia}_{\beta\beta\alpha})$$
$$\mathcal{G}^{(2)} = \mathcal{G}^{(2)}_{para} + \mathcal{G}^{(2)}_{dia}$$
$$\mathcal{A}'^{,(2)} = -\frac{\omega}{2}\varepsilon_{\alpha\beta\gamma}(\mu_\gamma a'_{\alpha\beta\delta\delta} + \mu_\delta a'_{\alpha\beta\delta\gamma})$$

the size of the corresponding $\mathcal{A}'^{,(2)}$ contribution, see Table 4. Nitrobenzene in the gas phase is therefore the only occurrence in this work of Jones birefringence where a major part is played by one of the two quadrupolar contributions, specifically by $\mathcal{A}'^{,(2)}$. Moving to the "pcm" calculation, we note that although the "para" and "dia" contributions to $\mathcal{G}^{(2)}$ increase (in absolute value) *only* by 60 to roughly 80%, their combination increases by as much as about 1000%. This more than compensates for a corresponding increase of $\approx$130% in $\mathcal{A}'^{,(2)}$, and therefore the whole T-dependent contribution J_T, and consequently the whole observable, show a remarkable increase in the specific anisotropy by more than one order of magnitude.

For the nonpolar molecules, CCl_4 and CS_2, only the temperature-independent contribution survives in eq. [18]. Our calculations for the Jones constant yield k_J values of 0.68×10^{-12} and 0.51×10^{-12} V^{-1} T^{-1}, for CCl_4 and CS_2, respectively. These ab initio estimates are well below the upper limits given by Roth and Rikken,[9] of 3×10^{-12} and 2×10^{-12} V^{-1} T^{-1}, respectively. The relative magnitude of the effect is predicted correctly, with the birefringence, still too weak to be seen by the apparatus used in ref. 9, being apparently slightly stronger for CCl_4 than for CS_2.

In the case of the two dipolar monosubstituted benzenes, we first note that the temperature-dependent contribution has the same sign with respect to its temperature-independent counterpart for nitrobenzene, the former being from four times (gas phase) to about six times (liquid phase) larger than the latter at room temperature. For chlorobenzene under the same conditions, J_T, which carries a negative sign, ranges from ten times (gas phase) to about five times (liquid phase) larger than J_0 (which is instead positive). At room temperature, $[\Delta n^{(0)}]$ therefore yields a substantial contribution to the Jones birefringence of the two substituted benzenes studied here, more for the nitro- than for the chloro-substituted benzene. This evidence for Jones (and magnetoelectric) birefringence is roughly in line with the behavior of more "traditional" linear birefringences such as the Kerr, Cotton–Mouton, or Buckingham[68–70] birefringences. On the other hand, for these birefringences, very often the dominating importance of the temperature-dependent contribution at room temperature, invariably associated with lower-order, often linear, response functions and being due to the reorientation of the molecular multipoles in the presence of the external perturbations, is indeed very notable.[37–39]

At 294.15 K, the predicted Jones constant is $k_J = 10.2 \times 10^{-12}$ and $k_J = -3.23 \times 10^{-12}$ V^{-1} T^{-1}, for nitro- and chlorobenzene, respectively. The ab initio estimates are therefore of the same order of magnitude as the upper limits given by Roth and Rikken,[9] again 3×10^{-12} and 2×10^{-12} V^{-1} T^{-1}, for the two systems, respectively. The relative order of magnitude is again reproduced. We also note that the sign of the birefringence of chlorobenzene is opposite to that predicted for the other three systems studied here. Our results allow us to predict that minor improvements in the efficiency of the detection system should permit the observation of an ellipticity induced by crossed electric and magnetic induction fields, in the classical experimental setup of Jones and magnetoelectric birefringences, for liquid chloro-, and even better, for liquid nitrobenzene.

Summary

We have presented the result of an ab initio Time Dependent Density Functional Theory (TD–DFT) study of Jones birefringence in the liquid phase for four systems (CCl_4, CS_2, and nitro- and chlorobenzene) which were part of the set of eleven substances analyzed in an experimental study by Roth and Rikken.[9] The calculations, performed using the B3LYP functional with correlation-consistent basis sets of d-aug-cc-pVTZ quality, exploit the recently developed linear, quadratic, and cubic formulations of analytical response theory within a nonequilibrium, IEF polarizable continuum model. The effects of the interactions appearing in the liquid phase on both the frequency-dependent mixed electric and magnetic linear and nonlinear responses and on the geometry have been analyzed.

The effect of the condensed phase on the birefringence is remarkable. The response changes dramatically for all four systems studied here, in all cases increasing, albeit to a different extent. At room temperature, the specific anisotropy [Δn] almost doubles for CCl_4, and it is more than three times larger for CS_2 because of the interactions occurring in the liquid, as mimicked by the polarizable continuum model. Nitrobenzene, where the change in phase yields an increase of the JB by a factor of about five, is the liquid exhibiting the strongest response, whereas in chlorobenzene the changes induced by the introduction of the PCM are limited to an increase of the birefringence by 25% at room temperature.

Almost the whole enhancement arises from the effect of the dielectric medium on the response functions, more so for the higher-order (quadratic and especially cubic) response functions, contributing to the so-called temperature-independent contribution to [Δn], than for the linear and quadratic response functions entering the temperature-dependent contribution. Nitrobenzene is an exception to this general trend, where a near cancellation between the "para" and "dia" contributions arising due to the electric dipole – magnetic dipole interactions in the T-dependent term is responsible for the remarkable enhancement of the birefringence observed in the liquid-phase calculations. The changes in the geometry induced by the solvent is essentially negligible for CCl_4 and CS_2, and it has a minor effect in the case of nitrobenzene and (to a lesser extent) chlorobenzene.

The temperature-dependent contribution to the observable is, where present and as usually observed in other classical linear birefringence, stronger than the temperature-independent contribution. We predict birefringences of decreasing intensities in the order nitrobenzene > chlorobenzene > CCl_4 > CS_2, with the Jones constants k_J ranging (in absolute value) from a maximum of 10.2×10^{-12} to a minimum of 0.51×10^{-12} V^{-1} T^{-1} in this sequence. The sign of the anisotropy is opposite (negative) in chlorobenzene with respect to the other three molecules. With a resolution limited to $\Delta n_J \approx 2 \times 10^{-12}$, in an applied magnetic field of 17 T and an applied electric field of 2.5×10^5 V m^{-1}, and with a path length of 25 mm, the upper limits coming from experiment are 3×10^{-12} for nitrobenzene and CCl_4 and 2×10^{-12} for chlorobenzene and CS_2.[9] In the case of CCl_4 and CS_2, our study confirms that the birefringence cannot be measured with the apparatus used by Roth and Rikken.[9] Theory, at our level of approximation, predicts that the JB of chloro- and (even more) nitrobenzene are at the edge of the current detection limits at room temperature, and they might be measured with minor improvements in the detection limits of the apparatus employed by the authors of ref. 9.

A discussion on the level of confidence of our results, taking all approximations into account, has been done in several other instances in the past. This study is carried out at roughly the same computational level as some recent studies on other linear birefringences, as for example the studies in the gas phase of benzene and hexafluorobenzene,[33,34] or, even more to the point, the study[71] of condensed phase effects on magnetochiral birefringence.[72–76] The reader should refer to those papers, or to refs. 37, 38, and 39, for an in-depth analysis.

Mechanism of dihydride formation and hydrogen/deuterium exchange in a cationic iridium(III) complex

Luigi Cavallo, Steven P. Nolan, and Heiko Jacobsen

Abstract: In this manuscript, we provide a theoretical rationalization of the mechanisms that control double H_2 addition to an unsaturated 14 e cationic Ir(III) complex to yield a dihydride Ir(III) complex. Further, we also present two mechanisms that can explain the experimentally observed incorporation of deuterium into the *tert*-Butyl (^{t}Bu) groups of the *N*-heterocyclic I^{t}Bu ligands.

Key words: homogeneous catalysis, hydrogenation, deuteration, *N*-heterocyclic carbene, density functional calculations.

Résumé : Dans ce travail, on rapporte une rationalisation théorique des mécanismes qui contrôlent la double addition de H_2 sur le complexe cationique insaturé de Ir(III) conduisant à la formation d'un dihydrure complexe de Ir(III). De plus, on présente deux mécanismes qui pourraient expliquer l'incorporation observée expérimentalement de deutérium dans les groupes *tert*-butyles des ligands I^{t}Bu de l'hétérocycle azoté.

Mots-clés : catalyse homogène, hydrogénation, deutération, carbène *N*-hétérocyclique, calculs de la fonctionnelle de la densité.

[Traduit par la Rédaction]

Introduction

Coordinatively unsaturated transition-metal complexes containing hydride ligands are of remarkable interest because of their potential role in catalysis.[1–6] Due to their unsaturated nature, the structural characterization and a detailed understanding of the chemical mechanics of these complexes are often difficult. A few years ago, we reported a detailed characterization of an unsaturated 14 e cationic iridium(III) complex, $[Ir(I^tBu')_2]^+$, **1** in Chart 1, presenting a double cyclometalated structure.[7]

We suggested that **1** is remarkably stabilized by the two *N*-heterocyclic carbene (NHC) ligands that act as π-electron donors into empty d orbitals of the metals. The highly unsaturated nature of **1** prompted us to examine its reactivity with dihydrogen.[8] Exposure of **1** to H_2 gas resulted in the formation of the dihydride cationic complex **2**, whose X-ray structure evidenced strong agostic interaction with CH_3 groups of the I^{t}Bu NHC ligands. Interestingly, extended exposure of **1** to D_2 resulted in expected D atoms in the hydride position, but also in the unexpected complete deuteration of *tert*-Butyl (^{t}Bu) groups. Finally, undeuterated **2** can be regenerated by extended exposure to H_2, while the cyclometalated complex can be regenerated by exposure of **2** to CO, to yield **3**, which indicates that all the reactivity described above is reversible.

While the overall chemical scenario is already provided by the experiments, the details of the mechanisms behind this interesting chemical behavior are unknown. To shed light on this point, we decided to carry out density functional calculations (DFT) on the interaction of the bare, cationic iridium complex **1** $[Ir(I^tBu')_2]^+$ with molecular hydrogen. The goal of the present investigation is twofold: (*i*) to clarify the mechanism of formation of the iridium dihydride complex **2** $[Ir(H)_2(I^tBu)_2]^+$, assumed to occur as depicted in Scheme 1, and (*ii*) to elucidate possible pathways for hydrogen exchange and intramolecular C–H activation.

Computational details

For the sake of computational efficiency, the I^{t}Bu ligand has been replaced by an IEt ligand; this simplification only restricts the proper description of the steric properties of the carbene ligand, whereas it can be expected that electronic and bonding properties are rather well-reproduced. We further note that the IEt ligand is a suitable model ligand when agostic interactions are to be considered.

Our nomenclature is such that Et refers to a free ethyl group of an NHC ligand, whereas Et′ describes an ethyl group involved in cyclometalation.

The DFT calculations were carried out with the Gaussian03 program suite[9] and utilized the pure BP86 functional.[10–12] The basis set employed for the main-group elements is the split-valence plus one polarization function basis set of Ahlrichs and co-workers (SVP keyword in G03),[13] while for iridium, we used the Stuttgard–Dresden

basis set, and a pseudopotential representation of the sixty innermost core electrons has been selected (SDD keyword in G03).[14] H atoms in special bonding situations, such as hydride ligands, have been described by the enlarged triple-ζ plus one polarization function basis set of Ahlrichs (TZVP keyword in G03).[15] All calculations refer to the gaseous phase and are not corrected for solvation. All stationary points have been characterized by frequency analysis, and transition states were checked to have one imaginary frequency for which the vibrational displacement vector corresponds to a molecular motion along the assumed reaction coordinate. The free energies discussed in the text are derived by standard analysis at 298 and 200 K.

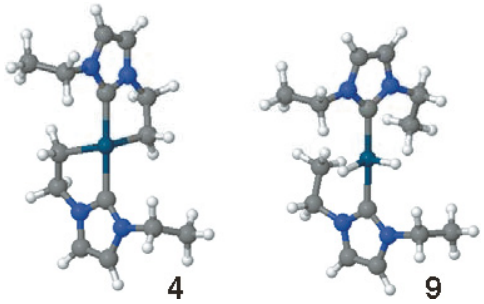
Results and discussion

Hydrogenation of $[Ir(IEt')_2]^+$

The molecular geometry of the optimized complex $[Ir(IEt')_2]^+$ **4** is displayed in Fig. 1. The structure of the C_2-symmetric complex $[Ir(I^tBu')_2]^+$ **1** has been determined by X-ray crystallography, and was described as highly distorted, divacant octahedral. The bond angles around the transition-metal center amount to 79°, 98°, 111°, and 175°. The optimized geometry of the model system **4** compares well with that of the real system **1**, both in terms of symmetry and distorted coordination geometry. In particular, neither the crystal structure nor the DFT geometry indicates the presence of any agostic interactions that stabilize the electron-deficient transition-metal center.

Complex **4** reacts with two molecules of hydrogen to form the iridium dihydride complex $[Ir(H)_2(IEt)_2]^+$ **9**. The optimized geometry of complex **9** is also displayed in Fig. 1. Complex **9** is of C_2 symmetry; the Ir–H bond length is 156 pm, which is in the expected range for a transition-metal hydride bond. Characteristic for **9** are the agostic interactions in trans position to the hydride ligands; the presence of the agostic bonds together with the coordination geometry around the transition-metal center suggest that complex **9** is indeed best-described as an octahedral complex.

Fig. 1. Optimized geometry of complexes **4** and **9**. Selected bond lengths (in pm) in **4**: Ir—C_{Im}: 205; Ir—C_{Et} = 203; selected bond angles in **4**: C_{Im}–Ir–C_{Et}: 80°, 99°; C_{Im}–Ir–C_{Im}: 176°; C_{Et}–Ir–C_{Et}: 119°. Selected bond lengths (in pm) in **9**: Ir—C_{Im}: 206; Ir—H = 156; Ir···H = 203; selected bond angles in **9**: C_{Im}–Ir–C_{Im}: 179°; H–Ir–H: 84°.



While structure **9** is stabilized by a double agostic interaction, structure **4** is not. The reason is in the constraint imposed by the five-membered metallacyle structure that pulls the Et groups of the IEt′ ligands away from the metal center (the Ir–C_{Im}–N(Et′) and Ir–C_{Im}–N(Et) angles are equal to 115° and 140°, respectively).

We have estimated the strength of the agostic interaction by optimizing a geometry **9′** in which one of the ethyl groups was rotated away from the iridium center; and the value of $\Delta E_{agostic}$ = 13 kJ/mol suggests that cleavage of the agostic bond does not account for a sizeable energetic barrier for formation of a dihydrogen complex of compound **9**. This fact will be of importance at a later point of our discussion.

The addition of the first molecule of hydrogen to complex **4** that eventually yields the monohydride complex $[Ir(H)(IEt')(IEt)]]^+$ **7** is a three-step process (see Scheme 1). First, complex **4** loosely binds a hydrogen molecule, and forms the dihydrogen complex $[Ir(H_2)(IEt')_2]^+$ **5**. We have calculated the energetics for formation of complex **5**, eq. [1].

$$[1] \qquad [Ir(IEt')_2]^+ + H_2 \rightarrow [Ir(H_2)(IEt')_2]^+$$

For the process shown in eq. [1], the value of ΔG (298 K) amounts to +18 kJ/mol, and decreases with decreasing temperature, ΔG (200 K) = 6 kJ/mol. Thus, the first step of hydrogen addition is a slightly endoergonic step.

Once dihydrogen is coordinated to the iridium center, the addition of hydrogen proceeds via a dihydride intermediate **6** to the monohydride **7**. The formation of complexes **6** and **7** occur through the respective transition states [**5**–**6**] and [**6**–**7**]. The energy profile for the addition of the first H_2 molecule corresponds to the first part of the conversion pathway **4** → **9**, as displayed in Fig. 2.

The first transition state [**5**–**6**] is reached with an activation energy of 88 kJ/mol and corresponds to the step of cleavage of the H–H bond of the coordinated hydrogen molecule. The intermediate **6** is 79 kJ/mol higher in energy than the H_2 adduct **5**. The second transition state [**6**–**7**] requires an activation energy of only 4 kJ/mol and corresponds to the

Fig. 2. Energy profile for the conversion reaction **4** → **9**.

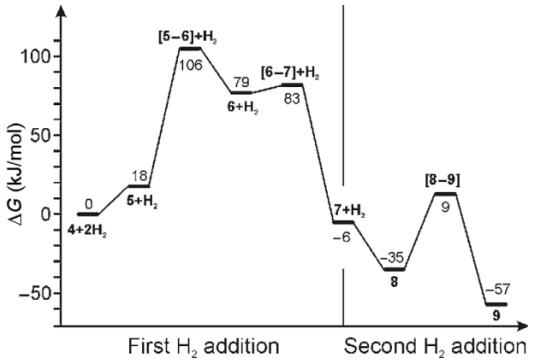


Fig. 3. Optimized geometries of the complexes relevant for the first H_2 addition.

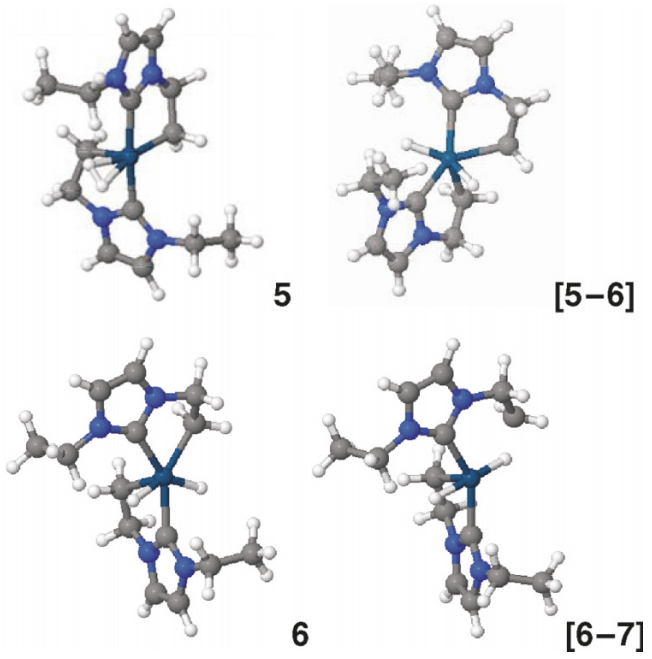
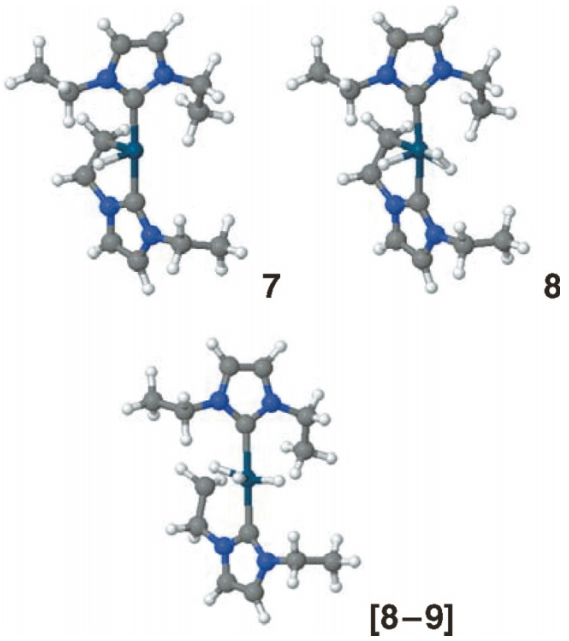


formation of the H–C bond. Transition state [**6**–**7**] collapses into intermediate **7** that is 24 kJ/mol more stable than the H_2 adduct **5**. Formation of the monohydride complex **7** represents an exoergonic process with ΔG (298 K) = –6 kJ/mol and ΔG (200 K) = –16 kJ/mol, respectively.

Optimized geometries of species relevant for the first H_2 addition are displayed in Fig. 3, and we will briefly discuss relevant geometric parameters for the complexes involved in the first hydrogen-addition process. Compared with the bare cation **4**, the dihydrogen adduct **5** shows elongated Ir–C bonds of d(Ir–C_{Im}) = 206 pm and 207 pm, and d(Ir–C_{Et}) = 209 pm and 210 pm, respectively. The bond angle ∠(C_{Et}–Ir–C_{Et}) decreases to 95°. This indicates that H_2 coordination has an influence on the coordination geometry around the Ir center, which changes from highly distorted divacant octahedral to monovacant octahedral. The Ir–H bond lengths amount to d(Ir–H) = 178 pm. The H–H bond with d(H–H) = 87 pm is slightly elongated, compared with the free ligand, d(H–H) = 74 pm, indicating that H–H bond cleavage is initiated by simple coordination to the metal center.

Fig. 4. Optimized geometry of complexes relevant for the second H_2 addition.



The first transition state [**5**–**6**] shows short Ir–H contacts of 157 pm and 165 pm, respectively, and a long H–H separation of 290 pm. These geometric parameters suggest that the first transition state has to be classified as late transition state, with the H–H bond being broken and the Ir–H bonds being almost completely formed.

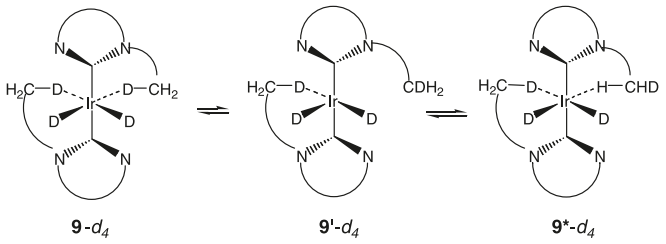
Intermediate **6** displays pentagonal-pyramidal coordination around the transition-metal center. The two H atoms, the two C_{Im} atoms, and one of the C_{Et} atoms span the pentagonal coordination plane around Ir. The respective X_1–Ir–X_2 angles (X_1, X_2 = H, C_{Im}, C_{Et}) amount to 75°, 69°, 69°, 72°, and 74°, summing up to 359°. The two Ir–H distances remain at 157 pm and 165 pm. The hydride ligand with the shorter Ir–H separation is positioned cis to the C_{Et} atom with a H–C_{Et} separation of 229 pm, and will eventually be transferred to the adjacent ethyl group.

In the second transition state [**6**–**7**], the respective Ir–C_{Et} is already broken, d(Ir–C_{Et}) = 265 pm, and the relevant distances for the H atom that is transferred from the transition metal to the ethyl group are d(H–Ir) = 166 pm and d(H–C_{Et}) = 158 pm, respectively. With respect to the migrating H-atom, transition state [**6**–**7**] is best classified as early transition state, consistent with the fact that only a small energetic barrier separates transition state [**6**–**7**] from intermediate **7**.

The optimized geometry of complex **7** is displayed in Fig. 4 together with structures relevant for H_2 addition. Important bond distances, and especially the Ir–H separation compare well with those calculated for the dihydride **9**. One short Ir–H contact with one of the hydrogen atoms of an ethyl group suggests the presence of an agostic interaction in trans position to the hydride ligand, and complex **7** is again best-described as monovacant octahedral.

Complex **7** binds dihydrogen stronger than complex **4**, and forms the dihydrogen complex $[Ir(H)(H_2)(IEt')(IEt)]^+$ **8**. We have calculated the energetics for the formation of complex **8**, eq. [2].

Scheme 2. Proposed mechanism for deuterium incorporation into the I^{t}Bu C–H bonds.



$$[2] \qquad [\mathrm{Ir(H)(IEt')(IEt)}]^+ + \mathrm{H_2} \rightarrow [\mathrm{Ir(H)(H_2)(IEt')(IEt)}]^+$$

For the process shown in eq. [2], the values of ΔG (298 K) = –29 kJ/mol and ΔG (200 K) = –51 kJ/mol were calculated, demonstrating that the monohydride **7** binds dihydrogen about 30 kJ/mol stronger than complex **4**. Thus, the first step of addition of a second hydrogen molecule is now an exoergonic step.

Optimized geometries of species relevant for the second H_2 addition are displayed in Fig. 4. The dihydrogen ligand in complex **8** binds to the transition-metal center with Ir–H distances of 177 pm, and shows an elongated H–H bond of 88 pm. The H_2 coordination geometry in complex **8** is similar to that found for complex **5**. Since the H_2 coordinates in trans position to the IEt′ group, it is the hydride ligand of complex **7** that will be transferred to the ethyl group. The incoming H_2 ligand is cleaved under coordination to the transition-metal center and will transform into the two hydride ligands of complex **9**. Geometric parameters calculated for transition state [**8**–**9**] corroborate this mechanistic proposal. In [**8**–**9**], the H_2 is almost completely transformed into two hydride ligands, which is indicated by the Ir–H bond lengths of 164 pm and a H–H separation of 158 pm. The Ir–C_{Et} bond is broken in transition state [**8**–**9**], indicated by the long Ir–C_{Et} separation of 253 pm. The hydride ligand of the transition-state complex now shows a short Ir–H bond distance of 139 pm, but is also in close contact to the C atom of the separating IEt′ group, with a H–C separation of 186 pm

The dihydride complex **9** is reached by addition of H_2 via transition state [**8**–**9**], which requires an activation energy $\Delta G^{\ddagger}$ (298 K) of 44 kJ/mol. Compared with the H_2 adduct **8**, the dihydride complex **9** is favored by 22 kJ/mol in terms of total energy. The energy profile for the second H_2 addition is also displayed in Fig. 2.

Deuterium incorporation into the I^{t}Bu C–H bonds

In this section, we discuss a possible mechanism that leads to deuterium incorporation into the ^{t}Bu groups. Complex **4** is an important intermediate in the process of incorporating external hydrogen or deuterium into hydride positions and possibly into I^{t}Bu or IEt positions. During the reaction of **1** with D_2, rapid incorporation of D into other I^{t}Bu positions is also observed, leading to complete deuteration on both the hydride and I^{t}Bu positions upon extended exposure to D_2 gas. One reaction that is of relevance for multiple D incorporation into ^{t}Bu positions is illustrated for the model complex **9**-d_4 in Scheme 2.

We briefly commented on the energetics of the agostic interaction, and we now will consider the reaction shown in Scheme 2 in terms of free-energy values. The release of the agostic interaction, which leads from complex **9**-d_4 to **9**′-d_4, proceeds with ΔG (298 K) = –2 kJ/mol and ΔG (200 K) = 2 kJ/mol. In terms of free energy, the agostic interaction is a weak interaction, and as to be expected is upset by the effect of higher temperature. Thus, the release and reformation of the agostic interaction is a facile process in solution. Under the assumption that the rotation of the deutero-methyl group in **9**′-d_4 is essentially free, the agostic interaction might be re-established to give complex **9***-d_4. This complex serves as a precursor from which incorporation of additional deuterium atoms into the I^{t}But or IEt groups might occur. We further note that the effect of deuteration affects the energetics of the agostic bond by about 0.5 kJ/mol.

Scheme 3. Proposed mechanism for H/D exchange.

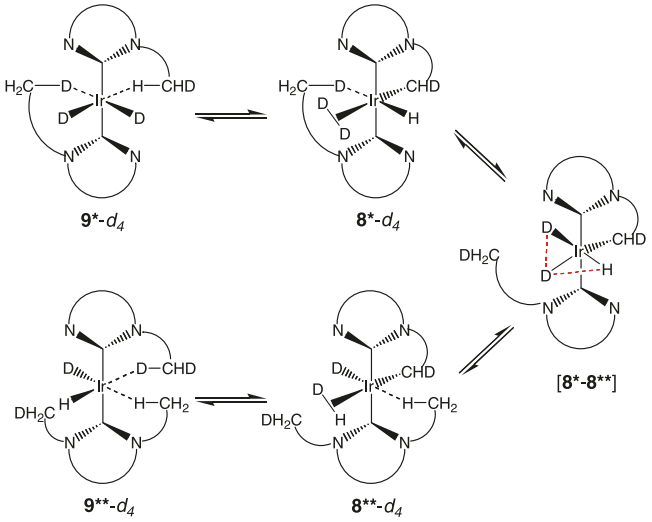


Fig. 5. Optimized geometry of the transition state [**8***–**8****] for intramolecular deuterium/hydrogen scrambling.

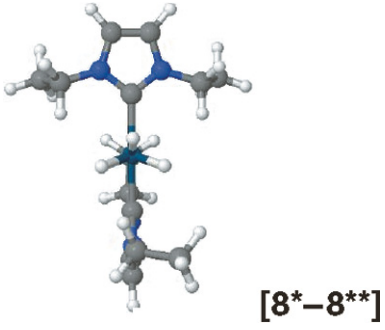
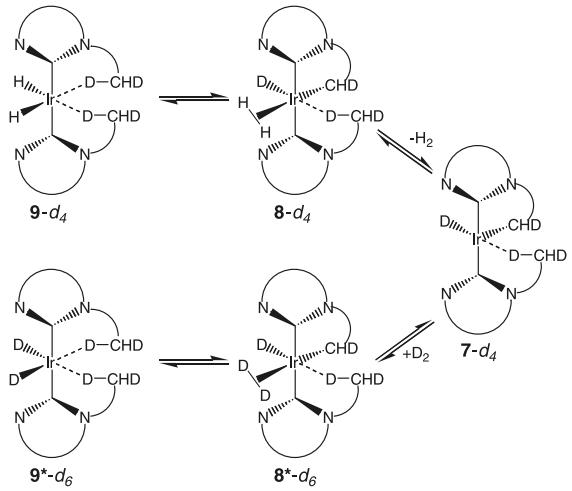


A possible mechanism for incorporation of additional deuterium atoms into the IEt position of complex **9***-d_4 is outlined in Scheme 3.

Complex **9***-d_4 undergoes a step of oxidative addition of the agostic C–H bond that leads to formation of the dideuterium hydride complex **8***-d_4. Intramolecular deuterium/hydrogen scrambling leads to the formation of complex **8****-d_4 possessing a deuteride ligand and a coordinated HD molecule. Addition of the HD ligand then furnishes complex **9****-d_4 in which one of the IEt groups is now doubly deuterated. Repeatedly running through this reaction sequence will eventually furnish the deuterated compound.

Scheme 4. Proposed mechanism to explain full deuteration of the I^{t}Bu C–H bonds.



Scheme 5. Reaction profile for intramolecular deuterium/hydrogen scrambling through intermediate **10**.

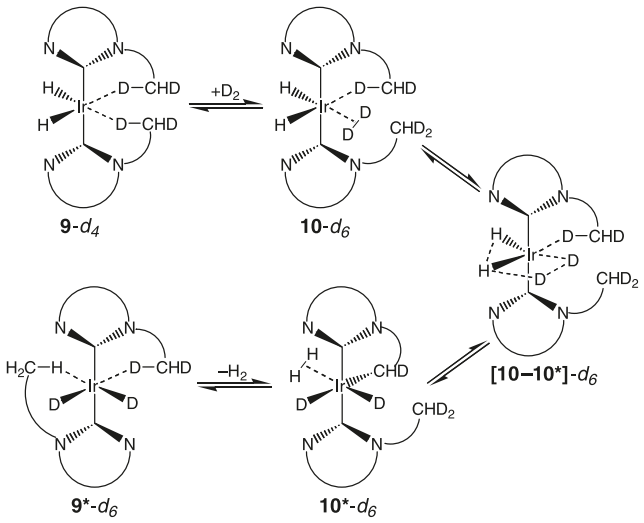


Fig. 6. Reaction profiles for intramolecular deuterium/hydrogen scrambling.

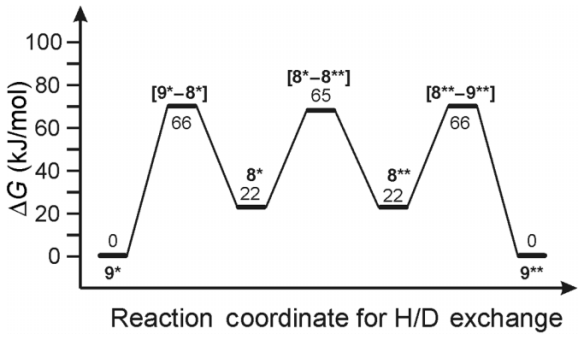

Fig. 7. Optimized geometries of dihydride–dihydrogen complexes **10** and **10a** and of the transition state [**10**–**10a**] for their interconversion.

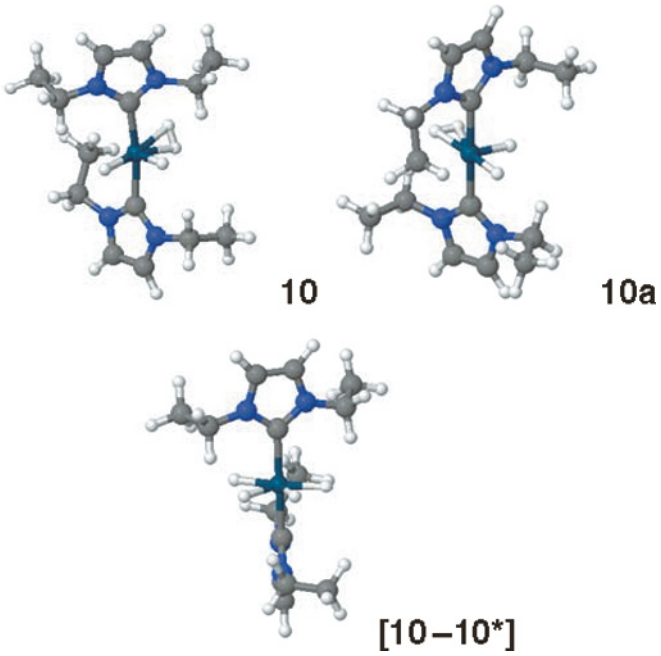


The optimized geometry of the hydrogen analogue of the transition state [**8***–**8****] is presented in Fig. 5.

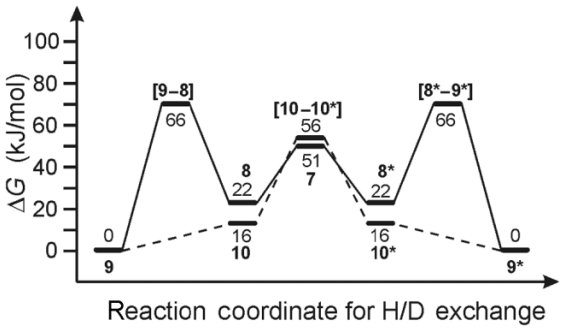
The Ir–H bond lengths amount to 157, 164, and 157 pm, respectively, and are slightly elongated compared with the Ir–H distances optimized for local minimum geometries (vide supra). The longest Ir–H(D) separation is associated with a H(D)–ligand in central position, one H(D) atom of the former hydrogen(deuterium) molecule being transferred to the hydride ligand to form a new H_2(DH) molecule. Compared with complex **8**, the transition state [**8***–**8****] is reached with an activation energy of 43 kJ/mol. The complete energy profile from **9*** to **9**** is sketched in Fig. 6. The activation energy is comparable to the activation energy for addition of H_2 via transition state [**8**–**9**], which transforms the hydride–dihydrogen complex **8** into the dihydride **9**. This suggests that during the process of hydrogenation, a complex such as **8****-d_4 is accessible in terms of energetic requirements.

After complex **9**-d_4 has exchanged two H atoms on the I^{t}Bu arms with the two deuteride ligands of Ir to form a **9**-d_4 complex with the four D atoms incorporated into the ^{t}Bu groups as C–D bonds, the most intuitive mechanism to explain complete deuteration of the I^{t}Bu C–H bonds is a reductive elimination of H_2 from the two Ir–H bonds (i.e., the reverse of step **8** → **9** in Fig. 2), followed by substitution of the coordinated H_2 molecule by a D_2 molecule (i.e., the reverse of step **7** → **8** in Fig. 2 through a dissociative or associative pathway), as shown in Scheme 4.

Nevertheless, considering that **9** possesses a vacant coordination site, we explored its reactivity toward H_2 or D_2. This mechanism is based on a scenario in which the dihydride $[Ir(H)_2(IEt)_2]^+$ **9** itself forms a complex with molecular hydrogen, $[Ir(H)_2(H_2)(IEt)_2]^+$, from which further deuterium incorporation into the Et groups can proceed as shown in Scheme 5.

For the molecular hydrogen adduct to **9**, we have calculated two possible structures, referred to as **10** and **10a**, respectively. Optimized geometries are displayed in Fig. 7. In complex **10**, the dihydrogen ligand is oriented perpendicular to the $H_{Hydride}$–Ir–$H_{Hydride}$ plane, whereas in complex **10a**, all

Fig. 8. Energy profiles to account for full deuteration of the Et groups, see Schemes 4 and 5.



four hydrogen atoms connected to Ir are to be found within the same plane. Complex **10a** is 4 kJ/mol higher in energy than complex **10**, which indicates that the dihydrogen ligand can freely rotate without a substantial barrier. The bond distances of the dihydrogen ligand to the transition-metal center, d(Ir–H) = 181 pm and 182 pm, are slightly longer than those of the dihydrogen complexes **5** and **8** (vide supra).

To estimate the likelihood that a dihydrogen–dihydride complex might be a possible intermediate in a hydride exchange/incorporation, we have calculated the energetics for formation of complex **10**, eq. [3].

$$[3] \qquad [Ir(H)_2(IET)_2]^+ + H_2 \rightarrow [Ir(H)_2(H_2)(IEt)_2]^+$$

For the process shown in eq. [3], values of ΔG (298 K) = +16 kJ/mol and ΔG (200 K) = 6 kJ/mol were calculated, similar to the values found for H_2 binding to complex **4**. Although the formation of complex **10** represents an endoergonic reaction, it requires less of an energetic barrier than the reductive elimination **9** → **8**, see also Fig. 6. At this point, hydride/hydrogen exchange process can proceed through transition state [**10–10***], displayed in Fig. 7. Transition state [**10–10***], which is 40 kJ/mol higher in energy than complex **10** at 298 K, represents a tetrahydride coordination, with Ir–H distances between 158 pm and 167 pm and the terminal H atoms forming the longer bonds. We note that, in [**10–10***], all four hydride ligands are located in a coordination plane around Ir.

It is interesting to note that, in transition state [**10–10***], all hydride ligands are separated from each other at least by 160 pm. Structures **10**, **10a**, and transition state [**10–10***] readily explain the hydrogen/deuterium exchange in complex **9**. When complex $[Ir(H)_2(IEt)_2]^+$ **9***-d_4 is exposed to an atmosphere of deuterium, a deuterium dihydride $[Ir(H)_2(D_2)(IEt)_2]^+$ **10**-d_6 can be formed, from which the Icorresponding transition state **[10–10*]** can be reached. Transition state **[10–10*]** leads to the formation of the hydrogen dideuteride $[Ir(D)_2(H_2)(IEt)_2]^+$ **10***-d_6, which can dissociate H_2 to form the dideuteride complex $[Ir(D)_2(IEt)_2]^+$ **9-**d_6. According to the mechanism discussed in Scheme 4, complex **9**-d_6 then allows for incorporation of deuterium into the I^{t}Bu or IEt positions to form the dihydride complex $[Ir(H)_2(IEt)_2]^+$ **9***-d_6.

As for a comparison between the two possible mechanisms for complete deuteration of the NHC ligands from **9***-d_4, our calculations suggest that the **9** → **10** pathway is lower in energy that the **9** → **8** → **7** pathway, see Fig. 8.

Conclusions

In this manuscript, we provided a detailed characterization of the mechanisms that control the reactivity of an unsaturated 14 e cationic Ir(III) complex toward molecular hydrogen. Specifically, our calculations indicate the following:

(*i*) Double H_2 addition to the starting unsaturated complex **4** to give the dihydride complex **9** is a relatively easy process, with the second H_2 addition proceeding easier than the first H_2 addition.

(*ii*) Incorporation of deuterium into the ^{t}Bu groups can be rationalized by a reductive elimination of H_2 from two Ir–H bonds from **9**, followed by substitution of the coordinated H_2 molecule by a D_2 molecule. However, an alternative mechanism that starts with H_2 binding to **9**, with successive formation of an intermediate that resembles a tetrahydride intermediate, is also possible.

Tests of an exact-exchange-based density-functional theory on transition-metal complexes

Erin R. Johnson and Axel D. Becke

Abstract: We have compiled a benchmark set of mean ligand-removal enthalpies for 32 transition-metal complexes of relevance in organometallic and catalysis chemistry. Our recent exact-exchange-based density-functional model, DF07 (*J. Chem. Phys.* **2007**, *127* (12), 124108), is assessed on this benchmark set along with other representative GGA, meta-GGA, and hybrid functionals. DF07 performs remarkably well, despite its exact-exchange foundation, indicating that it properly describes nondynamical correlation in transition-metal–ligand bonds.

Key words: density-functional theory, electronic structure methods, computational chemistry.

Résumé : On a compilé un ensemble de référence des enthalpies moyennes d'enlèvement d'un ligand à partir de trente-deux complexes pertinents à la catalyse et la chimie organométallique. On a évalué le modèle de fonctionnelle de densité à base d'échange exact proposé récemment, DF07 (*J. Chem. Phys.* **2007**, *127* (12), 124108), sur cet ensemble de référence ainsi que sur l'autre GCA, la méta-GCA, ainsi que d'autres fonctionnelles hybrides. La performance du modèle DF07 est remarquablement bonne malgré sa fondation d'échange exact, ce qui indique qu'elle décrit correctement la corrélation non dynamique des liaisons entre un ligand et un métal de transition.

Mots-clés : théorie de la fonctionnelle de densité, méthodes de la structure électronique, chimie des calculs théoriques.

[Traduit par la Rédaction]

Introduction

Density-functional theory (DFT) has achieved widespread popularity in computational chemistry thanks to its balance between computational cost and accuracy. DFT results now approach chemical accuracy for heats of formation and bond-dissociation enthalpies in main-group chemistry. However, recent benchmarking studies have revealed that approximate density functionals are susceptible to much larger errors in transition-metal chemistry,[1–3] in the order of 10 kcal/mol per bond. This is far from the level of accuracy needed for chemical applications. These recent results are at odds with the good agreement between DFT and experiment seen in earlier organometallic and catalysis applications by, e.g., Ziegler, Woo, and co-workers.[4]

We have recently introduced an exact-exchange-based density functional,[5] DF07, which explicitly models all three distinct correlation types in chemistry: dynamical, nondynamical, and dispersion. DF07 performs very well on a variety of main-group benchmark sets, giving excellent thermochemical properties and barrier heights.[6] However, this does not necessarily translate into good performance in transitional-metal chemistry. Indeed, DF07 might be expected to suffer even larger errors in transitional-metal chemistry than conventional DFTs, since it is based on exact (Hartree–Fock) exchange.

Transition-metal chemistry is notoriously problematic for Hartree–Fock-based theories due to the importance of both dynamical and nondynamical correlation. Veillard[7] states that the HF orbitals tend to be too localized on the metal atom or the ligands due to the small spatial extent of the d orbitals. Consequently, HF predicts the metal–ligand bonds to be too ionic. Inclusion of nondynamical correlation remedies this problem by increasing the covalent character of the metal–ligand bonds. MP2 theory, the simplest ab initio approach to incorporate electronic correlation, does not fully capture the effects of correlation in transition-metal–ligand bonds. In transition-metal carbonyls,[8] MP2 overestimates the bond energies with errors in the order of 20 kcal/mol per bond. Even basis-set-extrapolated CCSD(T) theory may yield large errors in some transition-metal systems (e.g., in TiF_2, the error is 16.6 kcal/mol per bond[9]). For the atomization energies of a set of 10 transition-metal halides and oxides, CCSD(T) gives overall results much closer to experiment than HF or MP2, with a mean absolute error (MAE) of 3.4 kcal/mol per bond.[9]

In this work, the performance of DF07[5] is assessed on a benchmark set consisting of mean ligand-removal standard enthalpies of 32 3d-transition-metal complexes. Our benchmark set differs from those of recent studies[1–3] in that we focus on closed-shell complexes of relevance in organometallic and catalysis chemistry. The exact-exchange character of DF07 is tested by comparing with several pure and hybrid density functionals.

The benchmark set

Recent DFT benchmarking studies on dissociation enthalpies of transition-metal compounds have focused primarily on diatomics and triatomics[1–3] due to the availability of accurate reference data. These are frequently open-shell systems, with very high multiplicity in some cases. Our aim in this work is to assess the performance of density functionals on a benchmark set that better represents systems of interest to transition-metal chemists. Our set consists of mean ligand-removal standard enthalpies for 32 closed-shell molecules. The set is restricted to 3d transition metals to minimize relativistic effects inherent in the experimental data.[10] Reference data with large error bars are excluded as well. Mean ligand-removal enthalpies were obtained using experimental heats of formation to determine total fragmentation enthalpies of the transition-metal complex into free transition-metal atom(s) and neutral ligands, and dividing by the total number of metal–ligand bonds (and metal–metal bonds where applicable). The experimental heats of formation are from NIST[11] for all species except the cyclopentadienyl radical.[12]

Note that one molecule in the benchmark set, $Fe(CO)_4$, has a triplet ground state, which lies approximately 2 kcal/mol lower in energy than the singlet.[13] The dissociation enthalpy of $Fe(CO)_4$ is computed for the singlet state because the triplet energy is highly sensitive to the level of theory.[13] Since the energy difference between the triplet and singlet states is small, this has minimal effect on the resultant error statistics.

Computational methods

All geometry optimizations and frequency calculations were performed with B3LYP/6–31G(2df,p)[14,15] as in the G3X procedure,[16] using the Gaussian 03 program.[17] The quality of B3LYP/6–31G(2df,p) geometries in transition-metal complexes such as these is assessed in the Appendix. Single-point energy calculations were then performed with the 6–311++G(3df,3pd) basis set and a selection of eight popular functionals: BLYP,[15,18] B3LYP,[14,15] BP86,[18,19] B3P86,[14,19] PBE,[20] PBE0,[21] TPSS,[22] and TPSSh.[23] Single-point post-LSDA[24] calculations were also carried out on all species with the basis-set-free NUMOL program[25] to obtain DF07 electronic energies.

The various exchange and correlation terms in the DF07 functional are thoroughly reviewed in ref. 5. The DF07 functional has the form:[5]

$$[1]\qquad E_{XC}^{DF07} = E_X^{exact} + a_{NDC}^{opp}U_{NDC}^{opp} + a_{NDC}^{par}U_{NDC}^{par} + a_{DC}^{opp}E_{DC}^{opp} + a_{DC}^{par}E_{DC}^{par} + E_{disp}^{BR}(a_1,a_2) + a_{RC}(E_X^{B86} - E_X^{B88})$$

where E_X^{exact} is the exact exchange energy, U_{NDC} is the potential energy of nondynamical correlation,[26] and E_{DC} is the dynamical correlation energy,[27] with the superscripts indicating opposite or parallel electron spins. E_{disp}^{BR} is the BR variant of our dispersion energy (see ref. 5) dependent on two universal cutoff parameters a_1 and a_2, and $(E_X^{B86} - E_X^{B88})$ is a Pauli repulsion correction. The seven parameters were fit simultaneously to 222 main-group atomization energies and to binding energies of 45 van der Waals complexes.[5] Each parameter in DF07 is related to a well-defined physical effect, and the value of each parameter concurs with physical intuition.

To illustrate the importance of the nondynamical correlation terms in DF07, we also performed calculations with Hartree–Fock exchange corrected for dynamical correlation only. This functional, which we call HFBR, has the form:

$$[2]\qquad E_{XC}^{HFBR} = E_X^{exact} + E_{DC}^{opp} + E_{DC}^{par}$$

where E_{DC}[27] is the same dynamical correlation energy as in DF07. There are no empirical fit parameters in HFBR.

Since we are computing ligand-removal enthalpies, calculations must also be performed on free transition-metal atoms. This has been the source of great vexation in previous density-functional benchmark studies.[2,3] The treatment of degenerate states in atomic systems is a long-standing fundamental problem in DFT.[28] Density-functional calculations on transition-metal atoms are particularly problematic due to the numerous possible ways, having inequivalent densities, of occupying the d orbitals. The problem is compounded by the issue of real orbitals versus complex orbitals. We have recently demonstrated[29] that all possible single-determinantal angular-momentum eigenstates in the ground-state terms of the open-shell 3d and 4d transition-metal atoms are nearly degenerate, as they should be, in the current-density-corrected DFT of Becke and Roussel.[30,31] None of the five possible density-distinct occupation schemes of the *real* atomic orbitals in d^2-type configurations is an angular-momentum eigenstate. However, we found[29] that the current-density-corrected ground-state energies are well-reproduced in d^2-type configurations if the two electrons/holes occupy the d_{z^2} and the d_{xy} or the $d_{x^2-y^2}$ real orbitals (the e orbitals in tetrahedral or octahedral symmetry groups). In d^1-type configurations, occupancy of the d_{z^2} orbital is the preferred choice, giving a proper angular-momentum eigenstate. Since not all density functionals can be easily corrected for current-density dependence, these simple rules provide a convenient real-orbital occupation formula for calculations on free transition-metal atoms. In the present work, experimental ground-state electronic configurations were used for the free transition-metal atoms, and the above real-orbital occupancies were used throughout.

Results and discussion

The calculated and experimental mean ligand-removal enthalpies are shown in Table 1. DF07 gives an MAE of 2.3 kcal/mol, a mean error (ME) of 0.2 kcal/mol, and a maximum error (MaxE) of 7.1 kcal/mol for TiF_2O. These errors are only slightly worse than for the set of 76 main-group bond-dissociation enthalpies in ref. 32 (MAE of 1.7 kcal/mol, ME of –0.4 kcal/mol, and MaxE of 6.8 kcal/mol for the C–C bond in cyanomethane[6]). On the present transition-metal set, HFBR gives an MAE of 30.2 kcal/mol, an ME of –28.5 kcal/mol, and a MaxE of –91.5 kcal/mol for TiO_2. This demonstrates that the post-HF correlation terms in DF07 recover essentially all of the nondynamical correlation energy in these transition-metal complexes.

The other density functionals considered also perform reasonably well on our transition-metal set. The pure DFTs

Table 1. Mean ligand-removal enthalpies of benchmark transition-metal complexes, in kcal/mol.

give MAEs of 6.3–10.9 kcal/mol and tend to over-bind, as we would expect. The hybrid DFTs give MAEs of 2.7–4.5 kcal/mol. In general, the performance of the various functionals on this transition-metal benchmark set mirrors their performance for main-group atomization energies.[5,33] We conclude that there is little qualitative difference in the ability of density functionals to predict accurate thermochemistry for main-group or transition-metal complexes. This explains the transferability of DFTs to organometallic and catalysis applications despite their relatively poor performance for small transition-metal molecules.[1–3]

We note that all of the DFTs considered will have problems with the dissociation energies of metal–metal multiple bonds, as observed by Furche and Perdew.[2] These problems arise because approximate functionals cannot describe near-degeneracies, as occur in the stretching of chemical bonds.[34,35] Transition-metal dimers, with their weakly interacting 3d atomic orbitals, have near-degeneracies even at equilibrium geometries. In these cases, DF07 will give even larger errors than pure DFTs and hybrid functionals, since it is based on Hartree–Fock exchange.

Conclusions

In this work, we have compiled a new thermochemical benchmark set consisting of mean ligand-removal enthalpies of transition-metal complexes. This set is more representative of inorganic chemistry than other recent data sets consisting primarily of small transition-metal molecules.[1–3] We have assessed the performance of our recently published exact-exchange-based density functional, DF07,[5] and several popular pure and hybrid DFTs. DF07 gives the best agreement with experiment of the functionals considered, with results approaching chemical accuracy. DF07 nicely recovers the nondynamical correlation effects that are important in metal–ligand bonds. We also observe that, for the present set of closed-shell transition-metal complexes, the errors of the selected density functionals are similar to the errors typically seen in main-group thermochemistry.

Appendix: Assessment of geometries

In this work, B3LYP/6–31G(2df,p) was used for geometry optimizations and zero-point energy calculations. This is the theory/basis-set combination recommended in the G3X thermochemical procedure[16] for geometry and frequency calculations. Since B3LYP/6–31G(2df,p) is not commonly used in transition-metal chemistry, we assess its performance in computing bond lengths in organometallic complexes in this Appendix (note that the basis-set polarization designation 2df actually means 2fg on a transition-metal atom).

In Table A1, we compare 18 optimized B3LYP/6–31G(2df,p) bond lengths for complexes in our benchmark set with available experimental data from refs. 2 and 36. The mean absolute error in these 18 bond lengths is 0.02 Å. The largest errors, 0.08 and 0.09 Å, occur in the late transition-metal systems $Co_2(CO)_8$ and CuF, respectively, in agreement with the findings of others.[37] This level of accuracy in geometries is quite adequate for thermochemical benchmarking purposes.

Table A1. Calculated B3LYP/6–31G(2df,p) bond lengths for benchmark transition-metal complexes in Å.

Compound	Bond	B3LYP	Experimental
TiF_4	Ti—F	1.74	1.75[a]
$TiCl_4$	Ti—Cl	2.17	2.17[b]

A comparative study on the LDA + *U* and hybrid functional methods on the description of the electronic structure of $YTiO_3$ under high pressure

Z. Song, J.J. Yang, and J.S. Tse

Abstract: The electronic structures of $YTiO_3$ under pressure have been studied with LDA + *U* (local density approximation + Hubbard parameter) and hybrid functional methods. From matching the experimental band gaps, the Hubbard *U* and hybrid functional mixing parameters were determined. It is found that both parameters vary with the pressure. Analysis of the electronic structures indicates that the description of the chemical bonding is also dependent on the method of choice.

Key words: density functional theory, Hubbard Model, hybrid function, electronic structure, high pressure.

Résumé : On a étudié les structures électroniques du $YTiO_3$ sous pression en faisant appel aux méthodes LDA + *U* et de la fonction hybride. En utilisant les séparations de bandes, on a déterminé les paramètres de mélange Hubbard *U* et de la fonction hybride. On a trouvé que les deux paramètres varient avec la pression. L'analyse des structures électroniques indique que la description de la liaison chimique dépend aussi du choix de la méthode.

Mots-clés : théorie de la fonctionnelle de la densité, modèle de Hubbard, fonction hybride, structure électronique, pression élevée.

Introduction

The field of electronic structure calculation is at a momentous stage, with rapid advances in basic theory, new algorithms, computational methods, and new computer architectures. There are basically two numerical approaches based on the Hartree–Fock (HF) and the density functional theory (DFT),[1] respectively. Within the independent particle approximation, both methods have several known shortcomings for a correct description of the electronic structure of highly correlated systems. The HF method, which neglects electron correlation effects, often overestimates the energy gap between the occupied and conduction band of solids. Although the DFT is formally exact, but with many approximations, for example, the local spin density approximation (LSDA), it tends to symmetrically underestimate the band gap. Well-known examples are the transition-metal oxides, FeO, MnO, and NiO.[2,3] This shortcoming has led to the erroneous prediction of a metallic ground state for FeO and very small band gaps in MnO and NiO.[4–6] The deficiency of these methods in the prediction of excited-state properties can be amended by advanced treatments of the electron correlation effect. For example, through configuration interaction (CI) methods in the HF-based theory and the extension of the LSDA to include nonlocal interactions through perturbative theory, such as the *GW* method.[7] However, the extension of these methods are rather computationally demanding and expensive to apply in the study of the electronic structure of highly correlated solids.

Recent studies have shown that the HF-based methods[2,8] can be improved substantially with the so-called hybrid functional approach. In essence, the HF Hamiltonian is augmented by introducing an exchange-correlation function computed from the DFT method. On the other hand, DFT tends to emphasize delocalization of the valence electrons and yields a smaller gap between occupied and unoccupied states. To amend this problem, an ad hoc scheme with a semi-empirical correction to the DFT energy functional is introduced to include a model Hamiltonian depending on *U*, which is the "on-site" electron–electron (Coulomb) repulsion. This method is known as the LDA + *U* (local density approximation + Hubbard parameter) method.[9,10]

The goal of this investigation is to compare the results on the electronic properties obtained from the LDA + *U* and hybrid functional methods and to obtain the description of chemical bonding in $YTiO_3$ at ambient and high pressure. $YTiO_3$ was chosen as a prototype of transition-metal oxides due to the considerable experimental and theoretical work already reported. Most importantly, the band gap of $YTiO_3$ as a function of external pressure has been determined recently from synchrotron infrared experiments.[11] This experi-

mental data is very useful as it offers an opportunity to evaluate the pressure dependence of the electron correlation effects and band gap energies over a wide pressure range.

The ground-state electronic structure of $YTiO_3$ under ambient pressure has previously been studied by a variety of theoretical calculations. A calculation using the full-potential linear augmented plane wave method within the LSDA reproduced the experimentally observed ferromagnetism, but erroneously predicted a metallic ground state.[6] The insulating behaviour was attributed to unfounded lattice distortions.[12] Later, the electronic structure of $YTiO_3$ was studied using the generalized gradient approximation (GGA), but the calculation failed to reproduce its insulating nature.[13] The band gap only appeared with the introduction of the LDA + U model. A calculation on the orbital ordering in $YTiO_3$ at ambient pressure using LSDA had been reported.[14] The orbital ordering was found to be in good agreement with the experiment and the HF results. The relationship between lattice distortion and the magnetic behaviour has also been reported recently.[15] Lately, dynamical mean-field theory (DMFT) calculations[16,17] demonstrated the importance of the interplay between correlation effects and cation covalency in suppressing the orbital fluctuations leading to an insulating state.[18] The DMFT[16,17] maps a model Hamiltonian involving highly correlated d electrons (e.g., the Hubbard model) onto a self-consistent quantum impurity model and then solved exactly (e.g., numerically by the Monte Carlo method), is the current method of choice for the treatment of highly correlated systems. However, the computational expenditure is significantly more demanding than that of the standard LDA + U[9,10] and hybrid functional methods.[19–21] In the LDA + U method, the atom-centered Hubbard parameter, U, can be estimated theoretically from atomic[22–24] or cluster models[25] and recently, self-consistently from band calculations using the linear response method.[26] However, the application of the LDA + U method becomes more complicated for high pressure solids where atoms are compressed against each other since it is not certain whether a unique choice of U is possible over a large pressure range. In previous studies of electronic structure of transition-metal oxides at high pressure employing LDA + U, a constant U parameter was always assumed. The validity of this assumption has yet to be tested.

The purpose of this study is to understand the pressure dependence of the on-site Coulomb parameter, U, in the LDA + U theory and the amount of mixing (mixing parameter A) used in the hybrid density functional theory. This can be achieved by treating U and A as empirical parameters and optimize their values by matching the calculated with the experimental band gap at select pressures. The questions to be addressed are (*i*) if there were any discernible trends in these parameters with pressure and (*ii*) did the calculated electronic structure depend on the theoretical model? The present study is a prelude for future work on the nonempirical determination of the U parameters[26] at high pressure.

This paper is organized as follows. First, a brief description of the methods and essential computational details will be given. This is followed by the presentation of the results obtained from LDA + U and hybrid functional methods. Finally, the electronic structures of $YTiO_3$ obtained from both methods will be compared and discussed.

Theoretical and computational details

The LDA + U theory

The LDA + U method is designed to account for strong electron correlation in LDA theory by an additional Hubbard-like Hamiltonian including on-site interactions,[9,10] E_U, which depends on the electron occupancy (n). To first order, the total Hamiltonian becomes[9,10]

$$[1] \qquad E_{\mathrm{DFT}+U} = E_{\mathrm{DFT}}[\rho^\sigma] + E_U[\{n^\sigma_{jj'}\}]$$

where ρ^σ is the charge density for spin-σ electrons and $n^\sigma_{jj'}$ is the density matrix for correlated electrons (σ is the spin index, j and j' are the orbital indices). A simple rotationally invariant LDA + U Hamiltonian of the form,[27]

$$[2] \qquad E_{\mathrm{DFT}+U} = E[\rho^\sigma] + \frac{(U-J)}{2}\sum_\sigma \left[\left(\sum_j n^\sigma_{jj}\right) - \left(\sum_{jl} n^\sigma_{jl} n^\sigma_{lj}\right)\right]$$

is employed in the present calculations. J is the intra-atomic exchange interaction. The corresponding potential V^σ_{ij} is given by

$$[3] \qquad V^\sigma_{ij} = \frac{\delta E[\rho^\sigma]}{\delta n^\sigma_{ij}} + (U-J)\left[\frac{1}{2}\delta_{jl} - \delta^\sigma_{jl}\right]$$

In this study, the U parameter is treated as an empirical parameter and evaluated from a comparison of the calculated and experimental band gaps. A fixed value of J = 0.64 eV was used throughout.

Computational details

The program VASP (Vienna ab initio simulation package)[29] was employed in this study. VASP is a software package for performing ab initio electronic calculations using pseudopotentials method with a plane wave basis set.[1] The approach implemented in VASP is based on the local density approximation (LDA) with an extension to the LDA + U approximation. The interaction between ions and electrons is described by pseudopotentials and allows a considerable reduction of the number of plane waves for transition metals and first row elements like C and O. Projector-augmented wave (PAW) potentials[30,31] for Ti, Y, and O were taken from the pseudopotential library distributed with the VASP code. The Perdew–Burke–Ernzonhof (PBE) exchange-correlation functional[32] was used. A Monkhorst–Pack[33] 8 × 6 × 8 k-mesh was used for the energy sampling of the first Brillouin zone (BZ). $YTiO_3$ is an open-shell system, all calculations were performed in the spin-unrestricted (spin-polarized) formalism.[34] Since only the Ti 3d orbitals are occupied at the top of the valence band (vide infra), the on-site Coulomb correction, U, is applied to the Ti atom only. Full geometry optimization was performed at selected pressure points.

Hybrid functional method

Since the HF theory neglects the correlation effects, an empirical extension to improve the accuracy is to include some form of correlation energy. The hybrid functional theory is based on the adiabatic connection between the HF and DFT. Applying the adiabatic connection, the exchange-correlation (XC) energy is given as

$$[4] \qquad E_{XC} = \int_0^1 U_{XC}^{\lambda} \, d\lambda$$

where λ "connects" the noninteracting Kohn–Sham reference system (λ = 0) to the fully-interacting systems (λ = 1) through a continuum of partially interacting systems ($0 \leq \lambda \leq 1$), all of which have the same density $n(r)$.[20] The advantage of the hybrid method is that for a given system, if an optimal coupling parameter, λ, can be found, it will balance the deficiency inherent in both the HF and DFT methods. The mixing of the DFT functional helps to introduce correlation effects into the Hamiltonian.

A practical "hybrid" scheme was introduced by Becke.[21] In this method, the exchange-correlation energy is expressed as the arithmetic average of the exact Kohn–Sham exchange of the local spin density approximation (LSDA) exchange-correlation potential,

$$[5] \qquad E_{XC} = 0.5E_X + 0.5U_{XC}^{LSDA}$$

Test calculations on atomic systems gave promising results on atomic exchange-correlation energies, atomization energies, and ionization potentials. This method was later extended to the hybrid functional formalism employing a three-parameter exchange-correlation (B3LYP) expression with the parameters obtained in a semi-empirical manner.[21] Using this hybrid functional, excellent results on the atomization energies of molecules in good accordance with experimental values were obtained. For isolated molecules, the accuracy of this method rivals that of the more sophisticated HF-based correlation methods but at a fraction of the computational expense.

In this study, a simplified form of the hybrid functional is employed with the exchange-correlation energy given by Ref. 8,

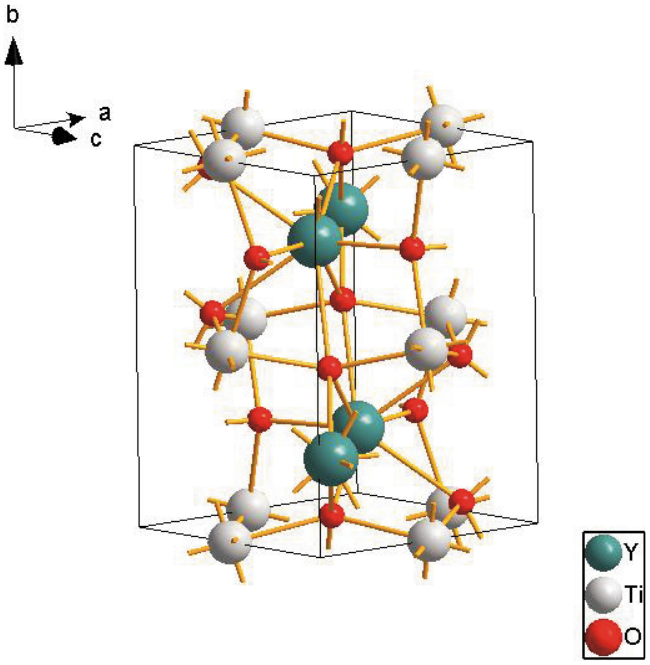
$$[6] \qquad E_{XC} = (1 - A)E_X^{LSA} + AE_X^{HF} + E_C^{VWM}$$

The E_{XC} potential is then a simple sum of the individual energy components, the local density approximation (LDA) exchange (E_X^{LDA}), the Hartree–Fock (E_X^{HF}), and the correlation energy functional of Vosko–Wilk–Nusair (VWM, E_C^{VWM}). By tuning the mixing parameter A between 0 and 1, the progression from pure LDA to pure HF exchange can be followed. This approximate hybrid functional has been applied to calculate the band gap on a number of solid semiconductors with good results.

Computational details

The localized basis set program CRYSTAL for periodic systems[35] was used for the hybrid functional calculations. Atomic double zeta valence basis sets augmented with diffuse functions for Y, Ti, and O atoms were taken from the tabulation found at http://www.tcm.phy.cam.ac.uk/~mdt26/crystal.html. In view of the large amount of computational resources required, the electronic structures at four selected pressures were computed using the optimized structures determined from the LDA + U calculations. This protocol was verified on $YTiO_3$ at ambient pressure via the calculation of the forces acting on the atoms in the crystal using the hybrid functional method. Even without full geometry optimization, the residual forces were found to be acceptably small.

Fig. 1. A perspective view of the crystal structure of $YTiO_3$.



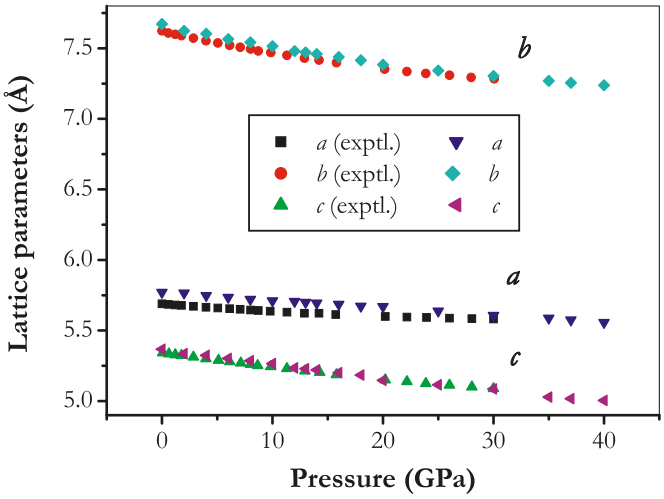
Results

$YTiO_3$ crystallized in the tetragonal space group *Pnma*[11,36] and the structure is depicted in Fig. 1. The Y atom has three valence electrons ($4d^15s^2$) and the Ti atom has four valence electrons ($3d^25s^2$). Formally, each oxygen atom can accommodate two more electrons forming an O^{2-} anion. If the charge transfer was completed, all of the electrons in the Y atom will be removed and only one electron will be left in the Ti 3d orbitals. According to the crystal field theory, in an ideal octahedral environment, this single electron will occupy the t_{2g} orbital. Moreover, it is expected that the valence bands consist mostly of Y–O and Ti–O bonding levels with the singly occupied electron in the Ti 3d orbitals at the top of the valence bands. In reality, although each Ti atom in the crystal structure is surrounded by six O atoms, there are three distinct Ti–O bonds of 2.0161, 2.0232, and 2.0769 Å.[11,36] The O–Ti–O angles range from 87°–90°. Therefore, the local environment of the Ti atom is distorted from the ideal octahedral environment, thus lifting the degeneracy of the t_{2g} orbitals. The single Ti 3d electron then occupies the lowest band and the spin multiplicity of the ground state wave function is a doublet. In the ensuing discussion, we simply refer to the singly filled band as "lower t_{2g}" and the lowest empty band as "higher t_{2g}". The empty e_g band is located at a higher energy.

LDA + *U* method

Before embarking on a detailed analysis of the electronic structure, the reliability of the LDA + U method and the choice of computational parameters used in the present calculations are examined from the comparison of calculated and experimental unit cell parameters. The theoretical predicted lattice constants at zero pressure of a = 5.7705 Å, b = 7.6719 Å, and c = 5.3675 Å, using an optimal U parameter of 2.7 eV (see below) are in exceedingly good agreement with the experimental[11] values of a = 5.6790 Å, b =

Fig. 2. Comparison of experimental and calculated lattice constants for $YTiO_3$.



7.6110 Å, and c = 5.3160 Å. The atomic coordinates (theoretical values in parentheses): Y (0.07294(0.0749), 1/2, 0.97925(0.9764)), O1(0.4580 (0.4544), 1/2, 0.1213(0.1260)), and O2 (0.3095(0.3101), 0.0579(0.0585), 0.6909(0.6904)) are also in good accord with observed values. Over the pressure range from 0 to 25 GPa where experimental data is available, the agreement between the calculated and observed lattice parameters is consistently good (Fig. 2).

Since the observed maximum band gap energy of $YTiO_3$ is ~0.652 eV or ~5300 cm^{-1},[11] it can be measured conveniently with midinfrared optical absorption under pressure at ambient temperature. Quasi-hydrostatic conditions were ensured by the use of two different pressure transmission media: solid N_2 and KCl. The experimental results show that the band gap decreases almost linearly with increasing pressure. From 1.6 to 16 GPa,[11] the band gap energy reduces by ~2000 cm^{-1} (or 0.25 eV). No closure of the band gap is observed in the experiment up to 16 GPa. The band gap energies, ΔE, for pressures > 16 GPa were obtained from the extrapolation of a linear fit to experimental data,

$$[7] \qquad \Delta E(P)\,(\mathrm{cm}^{-1}) = 5300 - 145 \times P\,(\mathrm{GPa})$$

The derived optimal U parameters are summarized in Fig. 3. The U parameter obtained at zero pressure of 2.70 eV with a fixed J of 0.64 eV is consistent with the theoretically calculated U and J parameters of 2.75 eV and 0.81 eV, respectively[15] (converted from the Kanamori definition, see ref. 15). A general trend emerges on the pressure dependence of the optimal U parameters. At low pressure, from 0 to 4 GPa, the U parameter is not sensitive to the change in pressure and remains constant at 2.70 eV. This observation helps to understand the apparent success on the assumption of a constant U parameter in previous applications to mineral oxide systems at low pressure. It is likely that the change in electron correlation effects at low pressure is quite small and does not affect the electronic structure to a significant extent. This assumption, however, is certainly not valid over a broader range of pressures. The U parameter shows a slow steady decrease from 4 to 12 GPa and drops more rapidly for pressures above 12 GPa.

Fig. 3. Variation of calculated U parameter with pressure. The curve is a polynomial fit of the calculated data using eq. [7] (see text).

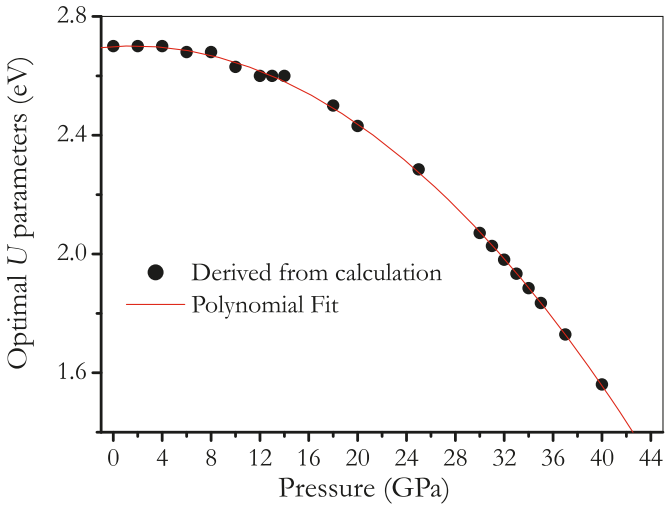


Fig. 4. Comparison of hybrid functional calculated and experimental band gaps for $YTiO_3$. Note that the band closure is predicted at 32 GPa from the extrapolation of the polynomial fit to the experimental data (see text).

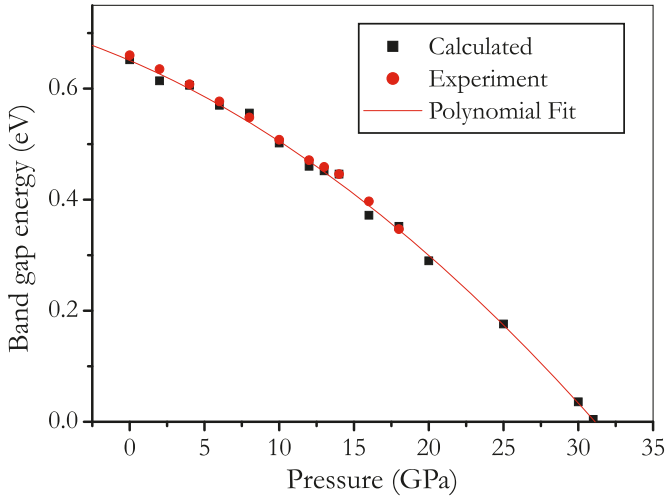
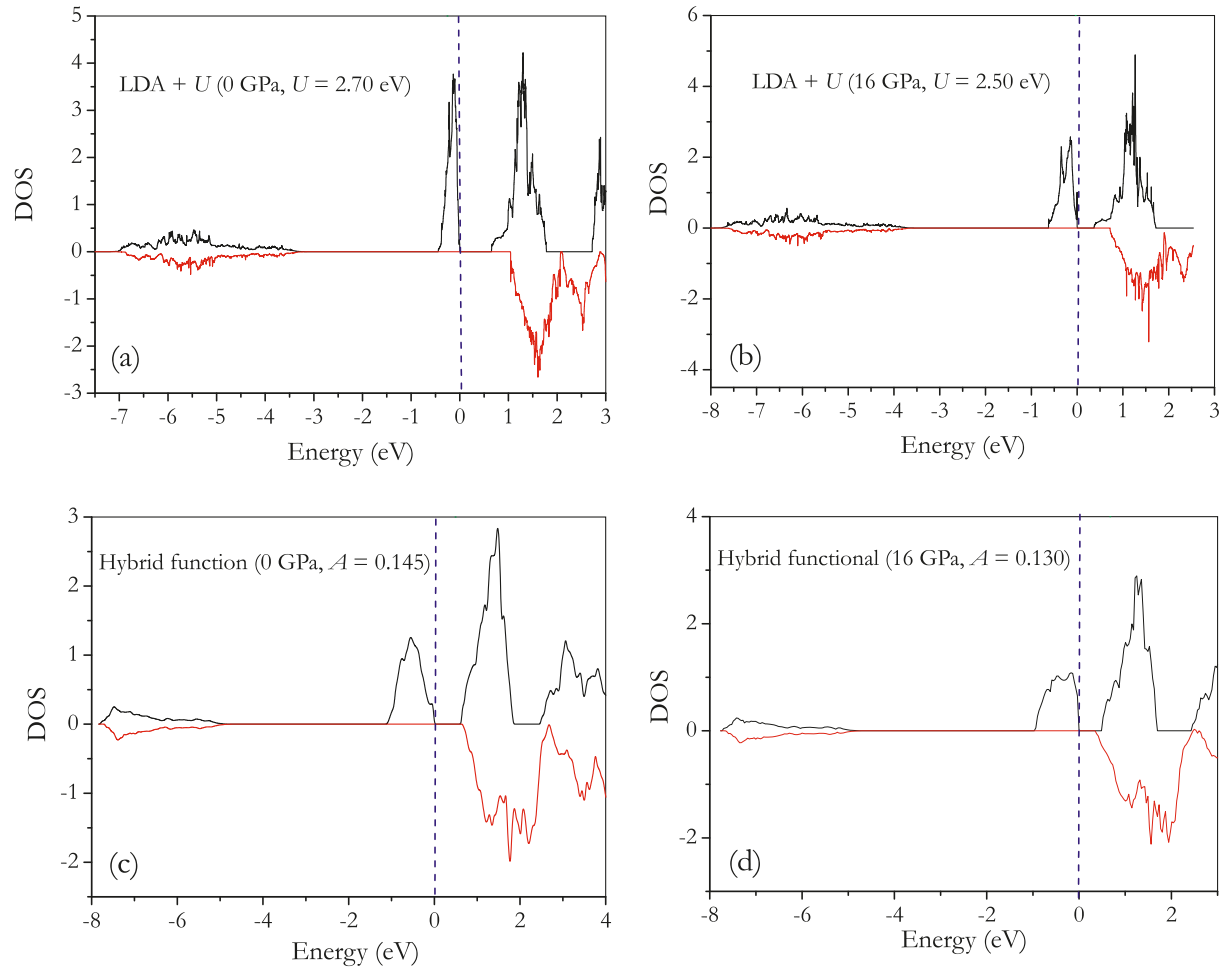


The experimental and calculated band gaps for $YTiO_3$ from 0 to 40 GPa are shown in Fig. 4. From LDA + U calculations, it is shown that $YTiO_3$ will become metallic at 32 GPa. This value is consistent with the estimation from the extrapolation of the experimental band gap energies.[11] The result, however, disagrees with a recent theoretical calculation where the electronic gap closure was suggested to occur at ~100 GPa,[37] which is almost three times that of the present estimated pressure. It should be noted that in this earlier calculation, a constant U parameter was employed throughout the entire pressure range.[37] As shown here, this assumption is invalid and therefore the pressure of the closure of the band gap would be seriously overestimated. It is noteworthy that at 32 GPa, the pressure at which $YTiO_3$ was predicted to become metallic, the derived U parameter is 1.98 eV, which is 33% smaller than the ambient value of 2.70 eV. Using a polynomial fit to the calculated results (Fig. 3), the extrapolated pressure where U = 0 is

Fig. 5. Total and projected density of state (DOS) of Ti in $YTiO_3$ calculated using LDA + U and hybrid functional methods at (a) 0 GPa (U = 2.70 eV), (b) 16 GPa (U = 2.50 eV), (c) 0 GPa (A = 0.145), and (d) 16 GPa (A = 0.13). U is the Hubbard parameter and A is the mixing parameter (see text).



60 GPa. This value is significantly higher than the metallization pressure. This result suggests that even in the metallic state, the effect of on-site repulsion of the Ti 3d electron is not negligible (i.e., $U \neq 0$). This raises the question as to whether the standard LDA method should be used in highly correlated metallic systems.

The calculated trend of the dependence of the U parameter with pressure provides an insight into the behaviour of the electron repulsive interactions in $YTiO_3$. Since the U parameter is added to the Ti atoms to alleviate the problem of overestimated delocalization of valence electrons, a smaller U at high pressure indicates that the effect of delocalization becomes more dominant. It is consistent with the expectation that the overlap between Ti and the surrounding oxygen atoms will become more significant with decreasing Ti–O distances at high pressure. Consequently, the valence electrons should be more delocalized. As a result, the importance of the on-site Coulomb repulsion becomes less significant.

To understand the electronic structure of the occupied Ti 3d band, situated at the top of the valence band, the density of electronic state (DOS) and the projection (PDOS) into the individual components, i.e., d_{xy}, d_{yz}, d_{z^2}, d_{xz}, and $d_{x^2-y^2}$, will be used to assist the characterization and interpretation of the electron orbitals. The coordinate frame for the orbital projection is the orthorhombic crystal frame. It should be noted that although the local Cartesian coordinate frame of the TiO_6 unit does not coincide precisely with the crystal system, the principal (z) axis of the TiO_6 unit is tilted only about 14° from the crystallographic c axis. Thus, the projected d orbital DOS are convenient and useful guides to elucidate the electronic structure, in particular, for later comparison with the hybrid functional calculations. The total DOS of the dominant valence bands of Ti at 0 and 16 GPa are shown in Figs. 5a and 5b, respectively. For convenience, the energy scale is set to zero (E = 0) at the top of the valence band.

As discussed above, the degeneracy of the t_{2g} band is lifted by the local symmetry and the t_{2g} band is further decomposed into a singly filled band and an empty band. As shown in the DOS, the band width of lower t_{2g} band is very narrow ($\sim$0.5 eV). There is a "pseudo" band gap of 2–3 eV between the lower t_{2g} band and the broad band ranging from –3 to –8 eV. This broad band is mostly oxygen, which is in character with the contribution from both Ti–O and Y–O bonding. The large band width indicates strong dispersion, i.e., strong bonding interactions. Since this study is fo-

cussed on the Ti atom, in ensuing discussions, this low energy band is simply referred as the "Ti–O" band. At all pressures, the DOS of spin-up and spin-down Ti–O bands are nearly identical and, therefore, electrons in this band are perfectly paired. Close to the top of the valence, there is a predominantly Ti 3d t_{2g} spin-up band occupied by a single electron, which resulted in the doublet ground state of $YTiO_3$. In Fig. 5, it is observed that, except for d_{z^2} and d_{xz} orbitals, the highest energy electronic band at the top of the valence level shows a clear dip. This can be attributed to the splitting of the Ti t_{2g} orbitals due to deviation of the local symmetry from the ideal octahedron environment.

The population of the Ti 3d t_{2g} orbitals can be calculated from integrating the DOS in an energy window comprising only the uppermost Ti 3d valence band. The results are summarized in Table 1. At zero pressure, the population of the t_{2g} orbitals is 0.723 e. As describe above, crystal field theory analysis of the formal charges in $YTiO_3$ expected only one electron to reside in the Ti 3d orbitals. The theoretical results confirm this analysis. It is also clear that the orbitals d_{xy}, d_{yz}, and $d_{x^2-y^2}$ are main contributors to the electron occupancies of Ti 3d states. Also, the electron occupancies of the orbitals d_{xy} and $d_{x^2-y^2}$ decrease with increasing pressure. Conversely, the electron occupancy of orbital d_{yz} increases with increasing pressure. In passing, it should be mentioned that the total DOS at zero pressure obtained here compares very well with that from a previous LDA + U calculation, which employed a slightly different U parameter of 3 eV.[23] It is reassuring that, although not totally unexpected, the calculated total DOS are almost identical.

Hybrid functional method

The procedure in finding the "optimal" mixing parameter, A, in eq. [6] at a given pressure is similar to the LDA + U calculations. For example, to reproduce the experimental band gap energy at zero pressure, trial calculations are performed with mixing parameters in the range 0.13–0.80. It was found that when $A = 0.145$, the hybrid functional calculation reproduced the observed band gap energy of 0.66 eV. Similar calculations were repeated at 8, 16, and 25 GPa and the optimal A values are summarized in Table 2. It is shown that the optimal mixing parameter decreases with increasing pressure. Therefore, the Hartree exchange term becomes less important with increasing pressure. This observation is not unexpected. Similar to the case of the LDA + U method, the on-site Coulomb parameter, U, becomes smaller as the pressure is increased. Again, the reason is due to the increase in orbital overlap and the system becomes more metallic at high pressure. Incidentally, extrapolation of the mixing parameter to $A = 0$ gives a pressure of 31 GPa, which is in agreement with the predicted metallization pressure from experiment and from LDA + U calculations (vide supra). There appears to be no single mixing parameter that is appropriate to reproduce the electronic structure for the entire pressure range.

Analyses of the total and projected density of states on the results obtained from hybrid functional calculations were performed. Figures 5c and 5d show the total density of states of the Ti 3d orbitals at 0 and 16 GPa, respectively. Two electronic bands are found below the Fermi level (0 eV). The Ti–O band is located between –8 and –5 eV.

Table 1. Electron occupancy of Ti 3d t_{2g} below the top of valence band calculated with the LDFA + U method at different pressures.

	0 GPa	8 GPa	12 GPa	16 GPa	25 GPa	32 GPa
d_{xy}	0.197	0.159	0.139	0.132	0.119	0.112
d_{yz}	0.208	0.220	0.230	0.234	0.245	0.255
d_{z^2}	0.073	0.085	0.090	0.093	0.099	0.106
d_{xz}	0.020	0.027	0.033	0.036	0.042	0.048
$d_{x^2-y^2}$	0.227	0.227	0.223	0.219	0.209	0.191
Sum	0.723	0.718	0.714	0.714	0.714	0.712

Table 2. Optimal mixing parameters (A) using hybrid functional method for $YTiO_3$ at selected pressures.

Pressure (GPa)	Optimal mixing parameter (A)
0	0.145
8	0.140
16	0.130
25	0.085

Table 3. Electron occupancy of Ti 3d states in $YTiO_3$ predicted from hybrid functional calculations at selected pressures.

	0 GPa	8 GPa	16 GPa	25 GPa
d_{xy}	0.263	0.218	0.209	0.153
d_{yz}	0.160	0.177	0.187	0.214
d_{z^2}	0.104	0.107	0.112	0.125
d_{xz}	0.043	0.029	0.046	0.060
$d_{x^2-y^2}$	0.208	0.221	0.212	0.195
Sum	0.778	0.752	0.766	0.747

The lower Ti 3d t_{2g} band extends from –1.3 eV to the top of the valence band (0 eV). In the Ti–O bonding band, the occupancies of the spin-up and spin-down bands are also identical. The isolated spin-up bands are entirely due to spin-polarized lower Ti 3d t_{2g} states.

The total and projected density of state (PDOS) profiles of the Ti atom obtained by the hybrid functional method are similar to the LDA + U method. There are, however, subtle differences, which will be discussed in the next section when the results obtained by both methods are compared. It is suffice to say that the Ti 3d valence band is relatively narrow (band width is $\sim$1 eV) and is well separated from the Ti–O band by 3 eV. The band width of the Ti–O and Y–O bonding band extends from –5 to –8 eV. This is about 1 eV smaller than the LDA + U prediction. Integrating the PDOS of the isolated lower Ti 3d t_{2g} spin-up band in the energy window from –2 to 0 eV gives the electron occupancies of the individual d orbitals. The results at different pressures are reported in Table 3. From Table 3, it is again shown that d_{xy}, d_{yz}, d_{z^2}, and $d_{x^2-y^2}$ orbitals are main contributors to the electron occupancies of Ti d bands. The electron occupancy of the d_{xy} orbital decreases with increasing pressure, whereas, the electron occupancies of d_{yz} and d_{z^2} orbitals increase with increasing pressure. The trends obtained here are in broad agreement with the LDA + U results (see Table 1), although the details are somewhat different.

Table 4. Band widths of Ti–O, occupied Ti 3d t_{2g}, and pseudo-gap below the top of the valence band.

	0 GPa		8 GPa		16 GPa		25 GPa	
Width (eV)	LDA + *U*	Hybrid	LDA + *U*	Hybrid	LDA + *U*	Hybrid	LDA + *U*	Hybrid
Ti–O	3.8	3	3.6	3	4.1	3	4.2	3
Ti 3d t_{2g}	0.5	1	0.5	1	0.6	1	0.7	1
Pseudo-gap	2.7	3.6	3	3.7	3	3.7	3	3.6

Discussions

The results reported above show that both the LDA + *U* and hybrid functional methods can reproduce the observed band gap energies of $YTiO_3$ at different pressures by adjusting the relevant *U* and *A* parameters. The electronic structures from the analysis of the density of states were presented. In the ensuing discussion, details on the electronic structures predicted by the two methods are compared.

First, the occupied valence band at zero pressure computed with both approaches is discussed. For convenience, the energy at the top of the valence band is set arbitrarily to 0 eV. As shown in the DOS (Fig. 5), there are two distinct bands within the energy window from 0 to –8 eV corresponding to Ti 3d t_{2g} orbitals and "Ti–O" bonding orbitals (vide supra). However, widths of the valence bands calculated from the two methods are obviously very different. In the LDA + *U* scheme, the width of the Ti–O band is 3.8 eV. In comparison, the Ti–O width calculated using the hybrid functional method is 3 eV which is 0.8 eV smaller. A broader band width indicates that the "covalency" of Ti–O bonding predicted by the LDA + *U* method is more dominant than from the hybrid functional method. In contrast, the calculated Ti 3d t_{2g} band width of 0.5 eV by LDA + *U* is much smaller than the 1 eV width obtained by the hybrid functional method. The larger calculated band width by the latter method may be due to the inclusion of nonlocal exchange.[39] The widening of the valence band width has also been reported in a recent application of the hybrid functional method to the adsorption of CO on metal surfaces.[40]

It is also noted that the "pseudo-gap" energies, the energy difference from the top of the Ti–O band to the bottom of the Ti 3d band, are also different between the two approaches. The calculated pseudo-gap by LDA + *U* is about 2.7 eV, which is 0.9 eV smaller than that obtained from the hybrid functional method of 3.6 eV. A larger band width indicates that stronger Ti–O interactions were predicted by the hybrid functional method. Taken in all, there are quantitative differences in the description of chemical bonding between the LDA + *U* and hybrid functional methods. The results indicate that the hybrid functional method tends to prefer more ionic Ti–O interactions. This interpretation is consistent with the smaller Ti–O band width and larger Ti 3d to Ti–O pseudo-gap energy as compared to the LDA + *U*. At the same time, the Ti 3d t_{2g} band obtained from the hybrid functional method seems to experience a larger crystal field since that band width is almost double that predicted by the LDA + *U* method.

We now proceed to analyze the occupied Ti 3d t_{2g} band at high pressure in more detail. As indicated in the calculation of the DOS, the Ti 3d t_{2g} band is nearly 100% spin-polarized by both methods. The DOS calculated with the LDA + *U* method (Fig. 5) also showed that the occupied Ti 3d t_{2g} are split into two subbands. The splitting, however, is not as clear in the hybrid functional results. The lifting of the Ti 3d t_{2g} degeneracy is due to the local oxygen environment around the Ti atom not being perfectly octahedral. The magnitude of the splitting is related to interactions with the oxygen atoms. A comparison of the calculated band widths at different pressures is given in Table 4. At 8, 16, and 25 GPa, widths of Ti 3d t_{2g} bands are calculated to be almost constant at 1 eV by hybrid functional method. In comparison, widths of the corresponding bands obtained from LDA + *U* of 0.5, 0.6, and 0.7 eV at 8, 16, and 25 GPa, respectively, are slightly dependent on the pressure. A similar trend is also observed in the Ti–O band width. While the band widths were predicted to be constant at 3 eV by hybrid functional calculations, the LDA + *U* calculated widths at 8, 16, and 25 GPa of 3.6, 4.1, and 4.2 eV, respectively, show an increase of the band width with pressure. Both methods, however, predicted that the "pseudo band gap" between the Ti–O and Ti 3d t_{2g} bands is relatively insensitive to the pressure. The pseudo-gaps at 8, 16, and 25 GPa predicted by LDA + *U* are 3 eV compared with the 3.7 eV by the hybrid functional. Thus, the hybrid functional method gave a smaller Ti–O band and a larger pseudo-gap. This observation is consistent with the suggestion that the latter method tends to predict a more ionic Ti–O interaction.

Tables 1 and 3 summarize the Ti 3d occupancies in $YTiO_3$. The general trend is very similar between LDA + *U* and hybrid functional methods with a total Ti 3d occupancy close to 0.7 e. The difference in the absolute values calculated from LDA + *U* and hybrid functional methods is small and may be attributed to different *k*-point sets and integration schemes used. In LDA + *U* calculations, the tetrahedron integration method[41] was used for Brilluoin zone integration whilst the Fourier–Legendre interpolation scheme was employed in the hybrid functional calculations.[35]

The theoretical results reported here show that the details of the electronic structure predicted by LDA + *U* and hybrid functional methods are quite different. Consequently, the nature of the chemical bonding on $YTiO_3$ reflected by the two methods is also different. Results from this investigation inevitably lead to the following question: since the description of the chemical bonding is dependent on the method of calculation, which method is more reliable? So far we have only limited experimental results, with the measured band gap energies as a reference. There is no sufficient experimental evidence in the literature on $YTiO_3$ and, as a matter of fact, on other systems to make a judicial choice of either method.

It is noteworthy that the LDA + *U* calculations very well reproduced the experimental cell parameters over the entire pressure range (Fig. 2). The agreement in the calculated and

observed atomic positions is equally excellent up to 13 GPa. Based on Rietveld analysis of the powder diffraction patterns, a sudden change in the shortening trend of the Ti–O bond lengths was reported at 13 GPa.[11] The change has led to the conclusion that the orbital ordering, the occupancy of the singly occupied orbital, has changed to Ti $3d_{xy}$. The experimental observation was not reproduced by the calculations in which no discontinuity in the Ti–O bond lengths was revealed. It is tempting to attribute this discrepancy to possible artefacts in the structural refinement of high pressure powder patterns. However, failure of the LDA + *U* calculations at this pressure cannot be ruled out. Further experimental study (e.g., measurement of magnetic properties) at high pressure is needed to confirm the change in the orbital ordering.

Conclusions

In this study, using $YTiO_3$ as an example, it is found that the experimental band gap can be reproduced by varying the appropriate *U* and *A* parameters in LDA + *U* and hybrid functional methods, respectively. However, analysis of the electronic structure shows that the details of the electronic structure are quite different between the two methods indicating there are significant differences in the description of the nature of the chemical bonding. A conclusive evaluation on the reliability of the LDA + *U* and hybrid functional methods cannot be reached in this investigation, mainly due to a lack of experimental information for direct comparison. This investigation, however, invites future experimental studies on the electronic properties of $YTiO_3$ and other related systems. For example, the recent advance in charge-compensation detection of photoelectrons from insulating systems enable accurate measurements of the valence band from X-ray photoelectron spectra.[42] These spectra are invaluable for the direct comparison with the calculated electronic density of states of the occupied bands. For the characterization of empty states, X-ray photoemission experiments will be most useful. On the theoretical aspect, a future direction is to explore new methods for the ab initio prediction of the *U* parameter. Higher level approximations such as the DMFT[16,17] may be a good model to treat correlation effects. This method is under active development and there are issues still needed to be understood before the method can be employed for general computation.

The analog of Koopmans' theorem for virtual Kohn–Sham orbital energies

Oleg Gritsenko and Evert Jan Baerends

Abstract: An analog of Koopmans' theorem is formulated for the energies, ε_a, of virtual Kohn–Sham (KS) molecular orbitals (MOs) from the requirement that the KS theory provides, in principle, not only the exact electron density, but also its exact response. The starting point is the Kohn–Sham analog of Koopmans' theorem, relating the vertical ionization energies, I_i, to the energies, ε_i, of the occupied MOs (Chong, D.P.; Gritsenko, O.V.; Baerends, E.J. *J. Chem. Phys.* **2002,** *116,* 1760). Combining this with the coupled-perturbed equations of time-dependent density functional theory (TDDFT), exact relations between the energies, ε_a, of virtual KS MOs and the excitation energies, ω_{ia}, and vertical ionization energies (VIPs), I_i, are obtained. In the small matrix approximation for the coupling matrix **K** of TDDFT, two limiting cases of these relations are considered. In the limit of a negligible matrix element, $K_{ia,ia}$, the energy, ε_a, can be interpreted as (minus) the energy of ionization from the $\phi_i \rightarrow \phi_a$ excited state, $\varepsilon_a \approx -I_a$, where $-I_a$ is defined from the relation $I_i = \omega_{ia} + I_a$. This relation breaks down in special cases, such as charge-transfer transitions and the HOMO–LUMO (highest occupied molecular orbital – lowest unoccupied molecular orbital) transition of a dissociating electron-pair bond (also of charge-transfer character). The present results highlight the important difference between virtual orbital energies in the Kohn–Sham model ($\varepsilon_a \approx -I_a$) and in the Hartree–Fock model ($\varepsilon_a \approx -A_a$). Kohn–Sham differences $\varepsilon_a - \varepsilon_i$ approximate the excitation energy, ω_{ia}, while Hartree–Fock differences $\varepsilon_a^{\mathrm{HF}} - \varepsilon_i^{\mathrm{HF}}$ do not approximate excitation energies but approximate the difference of an ionization energy and an electron affinity, $I_i - A_a$.

Key words: Koopmans' theorem, density functional theory, Kohn–Sham, orbital energies.

Résumé : On formule un théorème analogue à celui de Koopmans pour les énergies ε_a des orbitales moléculaires (OM) de Kohn–Sham (KS) à partir de la condition selon laquelle la théorie de KS fournit, en principe, non seulement la densité électronique exacte, mais aussi sa réponse exacte. Le point de départ l'analogue de Kohn–Sham du théorème de Koopmans qui relie les énergies d'ionisation verticale, I_i, aux énergies ε_i des OM occupées (Chong, D.P.; Gritsenko, O.V.; Baerends, E.J. *J. Chem. Phys.* **2002,** *116,* 1760). En combinant ceci avec les équations couplées-perturbées de la théorie de la fonctionnelle de densité dépendante du temps (TFDDT), on a pu obtenir les relations exactes entre les énergies ε_a des OM virtuelles de KS et les énergies d'excitation, ω_{ia}, et les énergies d'ionisation verticale (EIV), I_i. Dans l'approximation de la petite matrice pour la matrice couplante de TFDDT, on considère deux cas limites de ces relations. Dans la limite d'un élément de matrice négligeable, $K_{ia,ia}$, on peut interpréter l'énergie ε_a comme étant la valeur négative de l'énergie d'ionisation à partir de l'état excité $\phi_i \rightarrow \phi_a$, $\varepsilon_a \approx -I_a$, dans laquelle $-I_a$ est défini par la relation $I_i = \omega_{ia} + I_a$. Cette relation ne tient pas dans certains cas, tel celui des transitions de transfert de charge et celui de la transition des OM HO à BV d'une paire d'électrons d'une liaison qui se dissocie (qui comporte aussi un caractère de transfert de charge). Les résultats obtenus dans ce travail mettent en évidence l'importante différence entre les énergies des orbitales virtuelles dans le modèle de Kohn–Sham ($\varepsilon_a \approx -I_a$) et dans le modèle de Hartree–Fock ($\varepsilon_a \approx -A_a$). Les différences $\varepsilon_a - \varepsilon_i$ de Kohn–Sham correspondent à une approximation de l'énergie d'excitation ω_{ia} alors que les différences de Hartree–Fock, $\varepsilon_a^{\mathrm{HF}} - \varepsilon_i^{\mathrm{HF}}$ ne correspondent pas à une approximation des énergies d'excitation, mais à une approximation de la différence d'une énergie d'ionisation et d'une affinité électronique, $I_i - A_a$.

Mots-clés : théorème de Koopmans, théorie de la fonctionnelle de la densité, Kohn–Sham, énergie des orbitales.

1. Introduction

The requirement that the occupied Kohn–Sham (KS) molecular orbitals (MOs), ϕ_i, of density functional theory (DFT)[1,2] yield the exact (fully correlated) electron density, ρ,

$$[1.1] \qquad \rho_{\mathrm{s}}(\mathbf{r}_1) = \sum_i^H |\phi_{\mathrm{i}}(\mathbf{r}_1)|^2 = \rho^{\mathrm{exact}}(\mathbf{r}_1)$$

can be shown to lend physical meaning to the energies ε_i.[3–6] The latter appear in the one-electron KS equations

$$[1.2] \qquad \left\{-\frac{1}{2}\nabla^2 + v_s(\mathbf{r})\right\}\phi_\mu(\mathbf{r}) = \varepsilon_\mu\phi_\mu(\mathbf{r})$$

in which the local potential, v_s, is unique (fully determined by the requirement that ρ_s is exact). Equation [1.2] has the doubly occupied orbitals ($\mu \leq H = N/2$), for which we use indices $i, j, \ldots$, as the lowest solutions, but also leads to virtual ($\mu = a, b, \ldots$) MOs (throughout the paper atomic units are used and closed-shell systems are considered).

The analog of Koopmans' theorem for Kohn–Sham DFT formulated in refs. 3–6 provides the interpretation of ε_i as approximate vertical ionization potentials (VIPs):

$$[1.3] \qquad \varepsilon_i \approx -I_i$$

The quality of this approximation depends on the strength of satellite ionizations accompanying the considered primary ionization[5] in the photoemission spectrum; the KS one-electron energy is a weighted average over the primary ionization potential and its satellites, so the relation $\varepsilon_i \approx -I_i$ is more closely obeyed for MOs with ionizations that have little satellite structure, i.e., in particular for outer valence MOs.[3] Earlier, the exact identity, $\varepsilon_H \approx -I_H$, was established for the highest occupied MO (HOMO), ϕ_H, from the analysis of the long-range asymptotics of the KS equations (eq. [1.2]).[7–12] Indeed, there are no satellites to the first ionization potential. For the upper valence orbitals with generally weak satelites, the exact Kohn–Sham ε_i differ from the I_i by only ~0.1 eV, while the deviation of Hartree–Fock (HF) orbital energies from the I_i typically exceeds 1 eV. Formulated initially for closed-shell systems,[3] the identification of the Kohn–Sham orbital energies as approximate ionization energies was extended later to open-shell systems.[4,6] We continue to call this identification the analog of Koopmans' theorem in DFT, although it should be kept in mind that Koopmans' theorem in Hartree–Fock invokes, apart from the Hartree–Fock approximation, the frozen orbital approximation for the ion, while in Kohn–Sham DFT the identification is with vertical ionization to electronically relaxed and correlated ions, the approximation stemming from the averaging in the Kohn–Sham case over the primary ionization and its satellites (with weights according to the intensities). The deviations are much smaller than in the Hartree–Fock case.

While the orbital energies of both the occupied KS MOs and the occupied Hartree–Fock MOs can both be related to vertical ionization energies, the interpretation of the energies, ε_a, of virtual MOs in these theories must be different. Indeed, according to the canonical Koopmans' theorem,[13] the energies of virtual HF MOs are interpreted as approximate electron affinities (in the frozen orbital Hartree–Fock approximation). This agrees with the nature of the nonlocal one-electron HF potential which, for virtual HF MOs, describes an electron interacting with all N electrons of the system (an added electron). Unlike this, in the KS theory both occupied and virtual MOs are solutions in the same potential v_s describing interaction with $(N-1)$ electrons. Because of this, ε_a represents an "excited" electron interacting with $(N-1)$ electrons, rather than an "extra" electron interacting with N electrons. In particular, as was concluded in ref. 14 from the analysis of the long-range asymptotics of the KS equations, the energy differences between exact (not local density approximation (LDA) or generalized gradient approximation (GGA)) Rydberg type KS MO energies and HOMO energy should be good approximations to the energies of the corresponding Rydberg type excitations because the diffuseness of the Rydberg orbitals leads to a vanishing contribution from the coupling matrix (see below). In ref. 15 excited-state ensemble DFT was employed to express the difference of a virtual orbital energy and the HOMO energy, $\varepsilon_k - \varepsilon_H$, as the difference of the expectation values of the $\phi_H \rightarrow \phi_k$ excited KS determinant, Φ^k_{ES}, and ground state Kohn–Sham determinants for the full (interacting) Hamiltonian, $\langle\Phi^k_{ES}|\hat{H}|\Phi^k_{ES}\rangle - \langle\Phi_s|\hat{H}|\Phi_s\rangle$, plus the ϕ_k matrix element of the, unfortunately unknown, difference between the KS potentials for the excited state ensemble and the ground state.

More general energy differences $(\varepsilon_a - \varepsilon_i)$ between virtual and occupied orbitals obtained with standard DFT local density generalized gradient approximations (GGA) appear to be fair zero-order estimates of the valence excitation energies, ω_α ($\alpha = i \rightarrow a$), as obtained in time-dependent density functional theory (TDDFT),[16–27] at least for excitations in compact molecules or for intrafragment excitations in larger systems. To extend this agreement between ω_α and approximate $(\varepsilon_a - \varepsilon_i)$ to the abovementioned case of Rydberg excitations, model potentials that are improved with respect to those of the LDA or GGA models so that they have the qualitatively correct shape, have been proposed.[28–33] The Kohn–Sham orbital energy differences appear naturally as zero-order estimates of the excitation energies in Görling's[34] perturbation treatment of excited state DFT, which takes the Kohn–Sham system as zero order, but it is not clear in that approach if these zero-order estimates would be any more accurate than Hartree–Fock orbital energy differences.

In this paper, an analog of Koopmans' theorem is formulated for the energies, ε_a, of virtual KS MOs. In section 2 the exact KS potential, v_s, is considered under two requirements; first, that it produces the exact density ρ via eqs. [1.1], [1.2], and second, that it exhibits the proper change $\delta v_s(\omega)$ to yield the exact density response, $\delta\rho(\omega)$, to a frequency-dependent change, $\delta v_{ext}(\omega)$, of the external potential. With these requirements in section 3, the analog of Koopmans' theorem for the energies of the occupied MOs is combined with the coupled-perturbed equations of TDDFT to obtain exact relations between the energies, ε_a, of virtual KS MOs and the VIPs, I_i, as well as the excitation energies, ω_α. We analyze these relations in the small matrix approximation for the coupling matrix $\mathbf{K}$ of TDDFT, which neglects coupling of the $i \rightarrow a$ excitation with $j \rightarrow b$ excitations. Two limiting cases are considered. In the limit of a negligible matrix element, $K_{ia,ia}$, the energy, ε_a, can be interpreted as (minus) the energy of ionization of the corresponding excited state, $\varepsilon_a \approx -I_a$. Of course there may be several excited states corresponding to $i \rightarrow a$ when i and (or) a belong to a degenerate level, and for a given a there are many choices for the occupied orbital, i. The condition of negligible $K_{ia,ia}$ leads to a unique I_a that is the same for all excited states $i \rightarrow a$ to which this condition applies. We will consider the consequences of small but nonnegligible $K_{ia,ia}$ for the definition of I_a in section 3. The opposite limit of a large $K_{ia,ia}$, which is known to occur when the occupied bonding and empty antibonding orbitals of a chemical bond become nearly degenerate upon bond dissociation, leads to $\varepsilon_a \approx -I_i$.

In this particular case, the orbital energy difference, $\varepsilon_a - \varepsilon_i$ (≈ 0 in the homonuclear case), is not a good approximation of the excitation energy, ω_{ia}, which can still be quite large, at least for the singlet excited state (many eVs). So, no longer does $\varepsilon_a \approx -I_i + \omega_{ia}$, and in general when $K_{ia,ia}$ is not negligible, the association $\varepsilon_a \approx -I_a$ is not valid; $-I_i + \omega_{ia}$ for an $i \rightarrow a$ excitation with large $K_{ia,ia}$ will be rather different from the $-I_j + \omega_{ja} \approx -I_a$ values of excitations $j \rightarrow a$ for which the condition that $K_{ja,ja}$ is small does hold. In section 4 the implications of the present "Koopmans' theorem" for the virtual orbital energies, ε_a, for DFT and TDDFT are drawn, and the difference with Hartree–Fock is stressed.

2. Conditions on the KS potential

By definition, the KS potential, v_s, is that unique local potential that yields the exact density, ρ, with eqs. [1.1] and [1.2] and the correct change, $\delta v_s(\omega)$, produces the exact density response, $\delta\rho(\omega)$, to a change of the external potential, $\delta v_{ext}(\omega)$. From an analysis of the "response" part of $v_s(\mathbf{r}) = v_{xc}^{hole}(\mathbf{r}) + v_{c,kin}(\mathbf{r}) + v^{resp}(\mathbf{r})$,[35] one can establish the analog of Koopmans' theorem for the energies, ε_i, of the $H = N/2$ occupied KS MOs, starting from the exact relations between ε_i and VIPs, I_j, which have been derived in ref. 3.

$$[2.1] \qquad \varepsilon_i = T_i[\{I_j\}]$$

where

$$[2.2] \qquad T_i = \sum_k^H M_{ik}^{-1} \left(\sum_j^\infty P_{kj} I_j + \varepsilon_k^{resp} \right)$$

In eq. [2.2], $\mathbf{M}^{-1}$ is the inverse matrix of the $H \times H$ matrix of $1/\rho$ weighted overlap integrals, M_{ik}, between the occupied KS MO densities, $|\phi_i|^2$ and $|\phi_k|^2$,

$$[2.3] \qquad M_{ik} = 2 \int \frac{|\phi_i(\mathbf{r}_1)|^2 |\phi_k(\mathbf{r}_1)|^2}{\rho(\mathbf{r}_1)} d\mathbf{r}_1$$

and P_{kj} is the $H \times \infty$ matrix of $1/\rho$ weighted overlap integrals between the MO densities, $|\phi_k|^2$, and the densities, $|d_j|^2$, of the Dyson orbitals, d_j, associated with the vertical ionizations from ground state, $\Psi_0^N(x_1, x_2, \ldots, x_N)$, to ion states, $\Psi_j^{N-1}(x_2, x_3, \ldots, x_N)$,

$$[2.4] \qquad \begin{aligned} d_j(x_1) &= \sqrt{N} \int \Psi_j^{N-1}(x_2, x_3, \ldots, x_N) * \Psi_0^N(x_1, x_2, \ldots, x_N) dx_2, \ \ldots, dx_N \\ P_{kj} &= 2 \int \frac{|\phi_k(\mathbf{r}_1)|^2 |d_j(\mathbf{r}_1)|^2}{\rho(\mathbf{r}_1)} d\mathbf{r}_1 \end{aligned}$$

ε_k^{resp} is the orbital expectation value of the response part, v_{resp},[35] of v_s

$$[2.5] \qquad \varepsilon_k^{resp} = \int |\phi_k(\mathbf{r}_1)|^2 v_{resp}(\mathbf{r}_1) \, d\mathbf{r}_1$$

Furthermore, with its change, $\delta v_s(\omega)$, in response to the external change, $\delta v_{ext}(\omega)$, the potential, v_s, yields the correct density response, $\delta\rho(\omega)$,[36]

$$[2.6] \qquad \delta\rho(\mathbf{r}_1, \omega) = \int \chi_s(\mathbf{r}_1, \mathbf{r}_2, \omega) \delta v_s(\mathbf{r}_2, \omega) d\mathbf{r}_2$$

where χ_s is the non-interacting KS density response function (here and in the rest of the paper we consider real MOs):

$$[2.7] \qquad \chi_s(\mathbf{r}_1, \mathbf{r}_2, \omega) = \sum_i^H \sum_{a>H} \frac{4(\varepsilon_a - \varepsilon_i)}{\omega^2 - (\varepsilon_a - \varepsilon_i)^2} \phi_i(\mathbf{r}_1) \phi_a(\mathbf{r}_1) \phi_a(\mathbf{r}_2) \phi_i(\mathbf{r}_2)$$

Subdividing $\delta v_s(\omega)$ into the external perturbing potential, $\delta v_{ext}(\omega)$ and the "coupling" part representing the response of the electronic part (Hartree-exchange-correlation, Hxc) of the potential due to the induced density change, $\delta v_{Hxc}(\omega)$, one can re-write eq. [2.6] as follows:

$$[2.8] \qquad \delta\rho(\mathbf{r}_1, \omega) = \int \chi_s(\mathbf{r}_1, \mathbf{r}_2, \omega) [\delta v_{ext}(\mathbf{r}_2, \omega) + \delta v_{Hxc}(\mathbf{r}_2, \omega)] \, d\mathbf{r}_2$$

where $\delta v_{Hxc}(\omega)$ is obtained with the Hartree-xc kernel, $f_{Hxc}(\omega)$,

$$[2.9] \qquad \delta v_{Hxc}(\mathbf{r}_2, \omega) = \int f_{Hxc}(\mathbf{r}_2, \mathbf{r}_3, \omega) \delta\rho(\mathbf{r}_3, \omega) \, d\mathbf{r}_3$$

From eqs. [2.8], [2.9], and the alternative representation of $\delta\rho(\omega)$

$$[2.10] \qquad \delta\rho(\mathbf{r}_1, \omega) = \int \chi(\mathbf{r}_1, \mathbf{r}_2, \omega)\delta v_{\text{ext}}(\mathbf{r}_2)\, \mathrm{d}\mathbf{r}_2$$

follows the expression for $f_{\text{Hxc}}(\omega)$

$$[2.11] \qquad f_{\text{Hxc}}(\mathbf{r}_1, \mathbf{r}_2, \omega) = \chi_s^{-1}(\mathbf{r}_1, \mathbf{r}_2, \omega) - \chi^{-1}(\mathbf{r}_1, \mathbf{r}_2, \omega)$$

In eq. [2.11], $\chi^{-1}(\omega)$ is the inverse of the interacting density–density response function, χ, in eq. [2.10]

$$[2.12] \qquad \chi(\mathbf{r}_1, \mathbf{r}_2, \omega) = \sum_\alpha \frac{2\omega_\alpha}{\omega^2 - \omega_\alpha^2} \langle\Psi_0|\widehat{\rho}(\mathbf{r}_1)|\Psi_\alpha\rangle\langle\Psi_\alpha|\widehat{\rho}(\mathbf{r}_2)|\Psi_0\rangle$$

where $\widehat{\rho}$ is the density operator, Ψ_0 and Ψ_α are the ground and the excited state wave functions, and $\omega_\alpha = E_\alpha - E_0$ are the corresponding excitation energies. Using the orbital expansion of $\delta\rho(\omega)$ in eqs. [2.8] and [2.9], one arrives at the following eigenvalue equations of TDDFT:[16]

$$[2.13] \qquad (\varepsilon_a - \varepsilon_i)^2 F_{ia}^\alpha + 2\sum_{jb} \sqrt{\varepsilon_a - \varepsilon_i} K_{ia,jb}(\omega_\alpha) \sqrt{\varepsilon_b - \varepsilon_j} F_{jb}^\alpha = \omega_\alpha^2 F_{ia}^\alpha$$

In eq. [2.13] the (super)vector, F_{ia}^α, yields the oscillator strength, q_α, of the corresponding excitation with the energy, ω_α, while the coupling (super)matrix, $\mathbf{K}(\omega)$, contains the integrals of the Hxc kernel, $f_{\text{Hxc}}(\omega)$,

$$[2.14] \qquad K_{ia,jb}(\omega) = 2\int \mathrm{d}\mathbf{r}_1 \mathrm{d}\mathbf{r}_2 \phi_i(\mathbf{r}_1)\phi_a(\mathbf{r}_1)\phi_j(\mathbf{r}_2)\phi_b(\mathbf{r}_2) f_{\text{Hxc}}(\mathbf{r}_1, \mathbf{r}_2, \omega)$$

Equations [2.1], [2.2], and [2.13] represent a set of relations obeyed by the eigenvalues of the exact KS potential. From this set, exact relations between ε_a, ω_α, and I_i will be derived in the next section.

3. Relations between ε_a, ω_α, and I_i

We combine the analog of Koopmans' theorem (eqs. [2.1] and [2.2] for the energies of the occupied MOs) with the coupled-perturbed equations of TDDFT by inserting eq. [2.1] in eq. [2.13] to obtain

$$[3.1] \qquad \Big(\varepsilon_a - T_i(\mathbf{I})\Big)^2 F_{ia}^\alpha + 2\sum_{jb} \sqrt{\Big(\varepsilon_a - T_i(\mathbf{I})\Big)\Big(\varepsilon_b - T_j(\mathbf{I})\Big)} K_{ia,jb}(\boldsymbol{\varepsilon}, \mathbf{I}; \omega_\alpha) F_{jb}^\alpha = \omega_\alpha^2 F_{ia}^\alpha$$

where we have collected the set of ionization energies in the vector $\mathbf{I}$, and the set of orbital energies in the vector $\boldsymbol{\varepsilon}$. The coupling matrix $\mathbf{K}$ is denoted as a function of $\boldsymbol{\varepsilon}$ and $\mathbf{I}$ as follows from eqs. [2.7], [2.11], [2.12], and [2.14]. Summing eq. [3.1] over the indices i and α, and separating the terms, which contain ε_a explicitly, we obtain, for all a, the following coupled equations:

$$[3.2] \qquad A_a\varepsilon_a^2 + B_a\varepsilon_a + \sum_{i,j\neq i}^{H} \sqrt{\Big(\varepsilon_a - T_i(\mathbf{I})\Big)\Big(\varepsilon_a - T_j(\mathbf{I})\Big)} C_{iaja} + \sum_{ij}^{H} \sum_{b\neq a} \sqrt{\Big(\varepsilon_a - T_i(\mathbf{I})\Big)\Big(\varepsilon_b - T_j(\mathbf{I})\Big)} D_{iajb} + G_a = 0$$

where

$$[3.3] \qquad A_a = \sum_i^H \sum_\alpha F_{ia}^\alpha$$

$$[3.4] \qquad B_a = 2\sum_i^H \sum_\alpha \{-T_i(\mathbf{I}) + K_{ia,ia}(\boldsymbol{\varepsilon}, \mathbf{I}; \omega_\alpha)\} F_{ia}^\alpha$$

$$[3.5] \qquad C_{iaja} = 2\sum_\alpha K_{ia,ja}(\boldsymbol{\varepsilon}, \mathbf{I}; \omega_\alpha) F_{ja}^\alpha$$

$$[3.6] \qquad D_{iajb} = 2\sum_\alpha K_{ia,jb}(\boldsymbol{\varepsilon}, \mathbf{I}; \omega_\alpha) F_{jb}^\alpha$$

$$[3.7] \qquad G_a = \sum_i^H \sum_\alpha \{T_i^2(\mathbf{I}) - 2T_i(\mathbf{I}) K_{ia,ia}(\boldsymbol{\varepsilon}, \mathbf{I}; \omega_\alpha) - \omega_\alpha^2\} F_{ia}^\alpha$$

These equations represent exact relations between ε_a on the one hand, and I_i and ω_α on the other hand. The energies of the virtual KS MOs, ε_a, and the excitation energies, ω_α, appear in eqs. [3.2]–[3.7] explicitly, and implicitly in the coupling matrix

K. In turn, VIPs, I_i, appear in the functional dependence eqs. [2.1] and [2.2] of the energies, ε_i, of occupied KS MOs on the $\{I_j\}$. Taken together, eqs. [2.1], [2.2], [3.2], and [3.3] constitute a set of exact relations connecting both occupied (eqs. [2.1] and [2.2]) and virtual (eqs. [3.1] and [3.2]) KS MOs with the VIPs.

The equations for the virtual KS orbital energies simplify very much in case that the approximation $T_i(\mathbf{I}) \approx -I_i$ is valid. As discussed in ref. 5, this is a reasonable approximation when $\varepsilon_i^{\text{resp}}$ is negligible and when the $H \times \infty$ matrix $\mathbf{M}^{-1}\mathbf{P}$ consists of a leading $H \times H$ unit matrix and contains negligible matrix elements in its remaining columns. These conditions are met when ϕ_i is an upper valence orbital, in which case the satellite structure to the main peak representing the "orbital ionization", $(\phi_i)^{-1}$, in the photoelectron spectrum, is weak (it is absent for the HOMO); the absence of satellite structure is equivalent with negligible columns $j > H$ of $\mathbf{M}^{-1}\mathbf{P}$. Applying in addition the small matrix approximation, which means that effectively the off-diagonal elements, $K_{ia,jb}$, connecting the $i \rightarrow a$ excitation with $j \rightarrow b$ excitations are neglected, one obtains a simple "pseudoquadratic" equation for $(\varepsilon_a + I_i)$:

$$[3.8] \qquad (\varepsilon_a + I_i)^2 + 2(\varepsilon_a + I_i)K_{ia,ia}(\boldsymbol{\varepsilon}, \mathbf{I}; \omega_\alpha) - \omega_\alpha^2 = 0$$

where α denotes the excited state corresponding to the $i \rightarrow a$ orbital excitation. We have here assumed that both i and a are nondegenerate; degeneracy will be considered below. From eq. [3.8], it follows that the relation between ε_a, I_i and ω_α depends essentially on the magnitude of the coupling matrix element, $K_{ia,ia}$. We consider two limiting cases.

In the first place, when $K_{ia,ia}$ is small, and using as definition of the ionization energy, I_a, of the excited state the difference between the ground state ionization energy from orbital, ϕ_i, minus the excitation energy, ω_α,

$$[3.9] \qquad I_a = I_i - \omega_\alpha$$

we obtain approximately (writing $K = K_{ia,ia}$),

$$[3.10] \qquad \varepsilon_a \approx -I_i + \omega_\alpha - K + \frac{1}{2}\frac{K^2}{\omega} = -I_a - K + \frac{1}{2}\frac{K^2}{\omega}$$

With negligible $K_{ia,ia}$, eq. [3.10] leads immediately to the interpretation of the energy, ε_a, of the virtual orbital, ϕ_a, as (minus) the energy of ionization, I_a, of the corresponding excited state, which by definition is the difference between the ground state ionization energy from orbital ϕ_i, minus the excitation energy ω_α, $I_a = I_i - \omega_\alpha$. The condition of negligible $K_{ia,ia}$ is rather strong. For instance, it implies that the difference between the $K_{ia,ia}$ matrix element for the singlet and the triplet excited states corresponding to the $i \rightarrow a$ orbital excitation is also negligible, i.e., $\omega_{ia}^S = \omega_{ia}^T$, and $I_a = I_i - \omega_{ia}^{S,T}$ is defined. In general, we should expect $-\varepsilon_a$ to be in-between the ionization energies from the excited triplet and singlet states, and the average ionization energy could be defined as I_a, i.e., $-\varepsilon_a \approx I_i - (\omega_{ia}^S + \omega_{ia}^T)/2 \equiv I_a$.

Of course ϕ_i and (or) ϕ_a may belong to a symmetry–degenerate set of levels. The ionization energy, I_i, will still be unique: if ϕ_i belongs to the nth set of levels $(n\gamma)$ of irrep symmetry, Γ, of the point group, ionization from any of the degenerate $\phi_j \in n\Gamma$ leads to one of the degenerate states of the manifold of doublet states, $^2\Gamma$, of the ionized system. If ϕ_a belongs to irrep Δ, orbital excitations from the manifold of orbitals, $\{\phi_i\}$, belonging to the nth level of Γ symmetry, $\{\phi_i\} \in n\Gamma$, to the manifold of orbitals, $\{\phi_a\} \in m\Delta$, will lead to excited states belonging to the irreps contained in $\Gamma \times \Delta$. In the small matrix approximation one retains the coupling amongst the *ia* pairs, but neglects all coupling of the *ia* pairs to *jb* pairs with $\{\phi_j\} \notin n\Gamma$ and (or) $\{\phi_b\} \notin m\Delta$. Diagonalization of the small matrix results in a diagonal matrix, where the ω_α^2 will be on the diagonal. Of course, each ω_α appears as many times as the order of the irrep to which the α excited state belongs. The diagonalization is essentially a diagonalization of the **K** matrix, because ε_a and I_i are the same in the whole small matrix. We label the eigenvectors with $\alpha,\beta,\ldots$ Suppose α is an eigenvector belonging to irrep $\Lambda \in \Gamma \times \Delta$, then we obtain again equations of the form of eq. [3.8] (as many identical equations as the order of Λ),

$$[3.11] \qquad (\varepsilon_a + I_i)^2 + 2(\varepsilon_a + I_i)K_{\alpha\alpha}(\boldsymbol{\varepsilon}, \mathbf{I}; \omega_\alpha) - \omega_\alpha^2 = 0$$

where it should be understood that the **K** matrix in the $\{\alpha\}$ basis is diagonal. We would now obtain equations like eq. [3.10] for the relation of ε_a with each of the ω_α, α being one of the excited states of the $\Gamma \times \Delta$ manifold. It is natural to define I_a as the average ionization energy from these excited states,

$$[3.12] \qquad I_a = -I_i + \frac{1}{d}\sum_{\alpha \in \Gamma \times \Delta} \omega_\alpha$$

and average eq. [3.10] like the equations for ε_a that can be obtained from eq. [3.11] to obtain

$$[3.13] \qquad \varepsilon_a \approx -I_i + \frac{1}{d}\sum_{\alpha \in \Gamma \times \Delta} \omega_\alpha - \frac{1}{d}\sum_{\alpha \in \Gamma \times \Delta} K_\alpha + O(K^2) = I_a - \frac{1}{d}\sum_{\alpha \in \Gamma \times \Delta} K_\alpha + O(K^2)$$

Here, d is the total number of excited states resulting from $n\Gamma \rightarrow m\Delta$ excitations. Equation [3.13] yields the interpretation of the virtual orbital energy, ε_a, as the average ionization energy from the excited state manifold of the $n\Gamma \rightarrow m\Delta$ excitations. The "error" is of first order in the diagonal elements, $K_{\alpha\alpha}$, which in practice are usually small, see the examples below. A typical case where this approximation breaks down (the charge-transfer excitation) will be discussed below.

Finally, we have to realize that the orbital, i, or the manifold, $n\Gamma$, that we have chosen to consider in the definition of I_a, is not unique. A further averaging would involve all the occupied orbital levels from which excitations to ϕ_a can be carried out:

$$[3.14] \qquad I_a = \sum_i^H \left[-I_i + \frac{1}{d} \sum_{\alpha \in \Gamma_i \times \Delta} \omega_\alpha \right]$$

Altogether, we obtain the approximate identification

$$[3.15] \qquad \varepsilon_a \approx -I_a$$

where I_a is either the ionization energy from a specific excited state (eq. [3.9]), or from an average over excited states belonging to a particular manifold defined by a degenerate occupied level and (or) degenerate virtual level (eq. [3.13]), or finally an average over the excitations from all occupied orbitals to the virtual orbital, ϕ_a. The important point is that ε_a is such an ionization energy, not an electron affinity, see below.

Equations [3.10], [3.13], and [3.14] can be considered as an analog of Koopmans' theorem for the energies of virtual KS MOs. Conversely, of course, they tell us that the excitation energy, ω_α, is approximately equal to a virtual-occupied orbital energy difference when we apply the KS Koopmans theorem, $\varepsilon_i \approx -I_i$,

$$[3.16] \qquad \varepsilon_a - \varepsilon_i \approx I_i - I_a \approx \omega_\alpha$$

We emphasize that this is a radically different approximate interpretation of the Kohn–Sham than of the Hartree–Fock virtual orbital energy. It is easily seen that the Koopmans frozen orbital assumption for the negative ion with an added electron in the virtual orbital, ϕ_a, results in $\varepsilon_a^{\mathrm{HF}}$ being approximately minus the electron affinity, A_a, for addition of an electron to orbital ϕ_a, which creates an excited negative ion state (and the negative ion ground state if ϕ_a is the lowest unoccupied molecular orbital, LUMO),

$$\varepsilon_a^{\mathrm{HF}} = E_{\mathrm{froz}}^{\mathrm{HF}}[M^-(\phi_a)^1] - E^{\mathrm{HF}}[M] \approx -A_a$$

Using the frozen orbital and Hartree–Fock approximations for the ionization energy out of an occupied orbital, the standard Koopmans' theorem is obtained

$$-\varepsilon_i^{\mathrm{HF}} = E_{\mathrm{froz}}^{\mathrm{HF}}[M^+(\phi_i)^{-1}] - E^{\mathrm{HF}}[M] \approx I_i$$

It is observed that the virtual-occupied orbital energy difference in the Hartree–Fock case is approximately

$$\varepsilon_a^{\mathrm{HF}} - \varepsilon_i^{\mathrm{HF}} = I_i - A_a$$

In the Hartree–Fock model, the virtual-occupied orbital energy difference is totally different from an excitation energy, it is the difference of an ionization energy and an electron affinity. This very important difference between KS and HF models of course reflects the fact that the virtual orbital energy in the Kohn–Sham model represents an excited electron in the *same* potential as the electrons in the occupied orbitals, whereas in the Hartree–Fock model the virtual orbital energy represents an *added* electron that sees a more repulsive potential (repulsion with N electrons) than the electrons in the occupied orbitals (repulsion with $N-1$ electrons).

Let us now consider the opposite limit of large $K_{ia,ia}$, still in the small matrix approximation. It is well known that in charge-transfer transitions, where in the long distance limit the transition density, $\phi_i(\mathbf{r})\phi_a(\mathbf{r})$, goes to zero, the exchange-correlation kernel, f_{xc}, has to diverge,[37] so that the total contribution of the coupling matrix term, $\sqrt{\varepsilon_a - \varepsilon_i}K_{ia,ia}\sqrt{\varepsilon_a - \varepsilon_i}F_{ia}^{\alpha}$, in eq. [2.13] remains finite and the excitation energy, ω_{ia}, differs from the simple orbital energy difference, $\varepsilon_a - \varepsilon_i$. In that case, it is clear that eq. [3.8] will no longer afford the approximation $\varepsilon_a \approx -I_i + \omega_{ia}$. In other words, for excitations to a virtual orbital, ϕ_a, from an orbital, ϕ_i, which is in a different spatial region (no differential overlap with ϕ_a), the excitation energy, ω_{ia}, no longer leads to a quantity, $-I_i + \omega_{ia}$, which is approximately equal to the quantities, $-I_j + \omega_{ja} = -I_a$, we obtained for the small $K_{ja,ja}$ cases ("normal" excitations where ϕ_j is in the same spatial region as ϕ_a). In the extreme case that $K_{ia,ia}$ would diverge, $K_{ia,ia} \to \infty$, a finite excitation energy, ω_{ia}, would only be obtained in eq. [3.8] if the energy, ε_a, would tend to $-I_i$,

$$[3.17] \qquad \varepsilon_a \approx -I_i$$

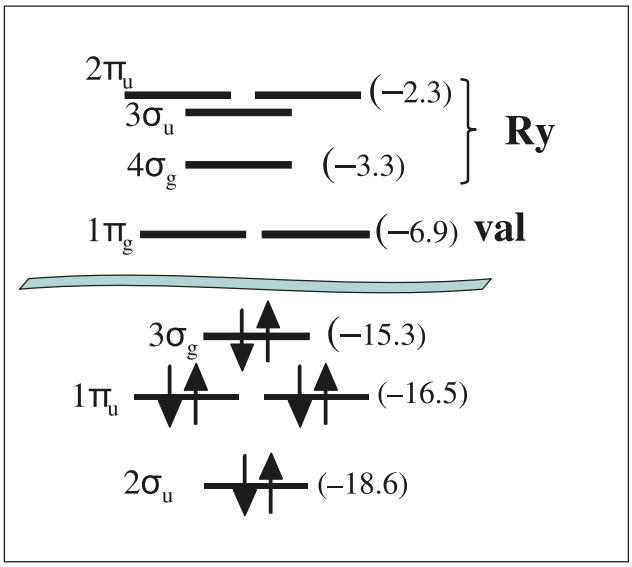
There is a case where it is known that $K_{ia,ia}$ diverges. This happens for the HOMO (bonding orbital) → LUMO (antibonding orbital) transition in the case of a dissociating electron pair bond.[38] In that particular case the orbital energies of the HOMO and LUMO become degenerate, so the difference, $\varepsilon_a - \varepsilon_i$, tends to zero. Nevertheless, it is known that the excitation energy does not go to zero, and will in the homonuclear case even go to rather high energy as the excited state is a mixture of the ionic states A^+-A^- and A^--A^+. The excitation energy, ω_{ia}, is not zero and therefore is not approximately equal to $\varepsilon_a - \varepsilon_i \approx 0$, which according to eq. [2.13] implies that the contribution of the coupling matrix term is significant. The term with the coupling matrix is not negligible because the divergence of $K_{ia,ia}$ leads to a significant contribution in spite of the small $(\varepsilon_a - \varepsilon_i)$ factor. We conclude that in the case of large or even diverging $K_{ia,ia}$, the relation $\varepsilon_a \approx -I_i + \omega_{ia}$ does not hold, and the quantity I_a we have defined should only relate to the difference $-I_i + \omega_{ia}$ for ionization/excitation from an orbital, ϕ_i, for which $\phi_i \to \phi_a$ is not a charge transfer transition.

4. Energies of virtual orbitals and excitations — An illustration with the N_2 molecule

To illustrate numerically the interpretation of the KS virtual orbital energies, ε_a, given in the previous section and their relation to the excitation energies, ω_{ia}, we consider in this section the example of the prototype N_2 molecule.[33] Figure 1 presents the energy levels of the frontier KS MOs of N_2. They are calculated with the approximate exchange-correlation (xc) potential obtained with the statistical average of (different) orbital potentials (SAOP),[31,39] which reproduces closely the features of the KS xc potential for small prototype systems, see Fig. 1 in ref. 33.

According to the SAOP calculation, the highest occupied MO (HOMO) is the $3\sigma_g$ MO of the σ bond N–N, while the $1\pi_u$ level of the π bonds lies somewhat lower (see Fig. 1). This corresponds to the experimental assignment of the lowest ionization of N_2. Unlike this, the HF theory incorrectly

Fig. 1. Orbital energy diagram for the occupied and virtual orbitals of N_2 according to a Kohn–Sham calculation (SAOP potential). Orbital energies in eV.



predicts $1\pi_u$ as the HOMO. Another characteristic feature of the KS spectrum are the negative energies of the virtual MOs (see Fig. 1). They reflect the binding nature of the KS potential, which, as was mentioned above, is a shared potential for both occupied and virtual KS MOs. The lowest unoccupied MOs (LUMO) are the valence antibonding $1\pi_g$ MOs of the π bonds, the next is the Rydberg-type $4\sigma_g$ MO, while the antibonding $3\sigma_u$ MO (which also has significant Rydberg character) and the Rydberg type $2\pi_u$ MOs lie at higher energies (see Fig. 1).

Table 1 compares the experimental and TDDFT energies, ω_{ia}, of the $3\sigma_g \rightarrow 3\sigma_u$ and $3\sigma_g \rightarrow 2\pi_u$ excitations as well as the corresponding oscillator strengths, f. According to the percentages of single excitation character given in Table 1, there is indeed rather little admixture of other single excitations. The theoretical quantities are calculated within the adiabatic local density approximation (ALDA) for the Hxc kernel, $f_{Hxc}(\omega)$, with the SAOP and LDA potentials as well as with the Becke–Perdew generalized gradient approximation (GGA) for the potential. We note that the calculated $3\sigma_g \rightarrow 2\pi_u$ excitation should, according to the analysis of ref. 40, be associated with the experimental $c^1\Pi_u$ band, and not with $o^1\Pi_u$ as surmised in ref. 33. One can see from Table 1 that the SAOP ω_{ia} value for $3\sigma_g \rightarrow 3\sigma_u$ is very close to experiment, while for the $3\sigma_g \rightarrow 2\pi_u$ excitation it makes a small error of ~0.2 eV. In contrast, the LDA/GGA excitation energies are much too low (several eV) compared to the experimental ones. The trend observed reflects the incorrect shape of the LDA/GGA xc potentials, which are not attractive enough in the bulk molecular region, see Fig. 1 of ref. 33. This produces orbital energies for these potentials that are typically too high by ~5 eV, at least for the valence orbitals (such as $3\sigma_g$), which have large amplitude in the molecular region. Since the orbital energies of the diffuse Rydberg orbitals do not only, or not primarily, probe the molecular region but rather the outer and large distance regions, where all potentials are close to zero anyway, the orbital energies of the Rydberg states are not so different between the approximate LDA/GGA potentials and the SAOP (or highly accurate Kohn–Sham) potentials. This holds for the diffuse $3\sigma_u$ and $2\pi_u$ orbitals. For LDA/GGA therefore, the orbital energy gap, $\varepsilon_a - \varepsilon_i$, is much too small, which leads to much too small calculated excitation energies. The deficiency of the LDA/GGA potentials masks the simple relations we are discussing in this paper of the true Kohn–Sham system between orbital energies and ionization energies (from both the occupied and the virtual orbitals) as well as excitation energies.

Table 1. The excitation energies, ω (in eV), oscillator strengths, f, and the assigned orbital transitions for two excitations of N_2. The percentages refer to the percentage character that the specific single excitation has in the eigenvector of the TDDFT calculation. The $1\pi_u \rightarrow 1\pi_g$ excitation leads to the states $^{1,3}\Sigma_u^+$, $^{1,3}\Sigma_u^-$, $^{1,3}\Delta_u$. The $\Delta\varepsilon = \varepsilon_{1\pi g} - \varepsilon_{1\pi u}$ is compared in this case to the average calculated and experimental excitation energies for these states.

	$\Delta\varepsilon$	SAOP	BP	LDA	Experimental
$3\sigma_g \rightarrow 3\sigma_u$		98%	100%	100%	$c'^1\Sigma_u^+$
ω	13.0	12.9	10.4	10.5	12.9
f		0.219	0.003	0.003	0.279
$3\sigma_g \rightarrow 2\pi_u$		99%	100%	100%	$c^1\Pi_u$
ω	13.0	12.95	10.36	10.51	13.2
f		0.122	0.004	0.006	0.145
$1\pi_u \rightarrow 1\pi_g$					
ω^{av}	9.6	9.9	10.0	10.0	10.0

The deficient LDA/GGA potentials may not affect the diffuse (Rydberg) orbital energies so much, but they do distort the shapes of these orbitals. We note that the calculated oscillator strengths in the SAOP model potential correspond well with the experimental f values (the oscillator strengths are notoriously difficult quantities, and order of magnitude agreement is already quite good). However, as the LDA/GGA potentials lack the correct Coulombic $-1/r$ behavior, but decay to zero much more rapidly (exponentially), they do not support the extended Rydberg-type MOs. The latter are too much contracted in LDA/GGA, which leads to much too low oscillator strengths, f. By its construction, the SAOP xc potential is free from the abovementioned drawbacks, which results in the observed excellent agreement between the SAOP and experimental quantities (see Table 1).

A remarkable feature of the present results is that the experimental/SAOP ω_{ia} of Table 1 nearly coincide with the corresponding orbital energy differences of Fig. 1. Indeed, the energy difference of 13.0 eV between the $3\sigma_g$ and $3\sigma_u$ MOs (see Fig. 1) is only 0.1 eV higher than the experimental/SAOP ω_{ia} of 12.9 eV (see Table 1). Furthermore, the energy difference of 13.0 eV between the $3\sigma_u$ and $2\pi_u$ MOs differs from the SAOP ω_{ia} by only 0.2 eV (see Table 1). This indicates, in the considered cases, a negligible contribution of the coupling matrix **K** to the calculated TDDFT excitation energies, ω_{ia}, with the latter being reproduced rather accurately with the virtual-occupied orbital energy differences. Then, the analog of Koopmans' theorem for the energies of virtual KS MOs of the previous section can be applied, so that the energies, ε_a, of the virtual orbitals $3\sigma_u$ and $2\pi_u$ can be interpreted as (minus) the energies of ionization, I_a, of the corresponding excited states.

Table 1 also includes the experimental and TDDFT data on the valence $1\pi_u \rightarrow 1\pi_g$ excitations in the N_2 molecule. In this case, the degenerate $1\pi_u \rightarrow 1\pi_g$ KS orbital transitions (bonding π to antibonding π^*) correspond to a manifold of excited states ($^{1,3}\Sigma_u^+$, $^{1,3}\Sigma_u^-$,$^{1,3}\Delta_u$) ranging from 7.75 to 14.2 eV. In contrast to the other excitations it is also a genuine valence transition, without Rydberg character. According to eq. [3.12] and [3.13], ε_a ($a = 1\pi_g$) is interpreted as the averaged ionization energy from these excited states, so that the orbital energy difference, $\Delta\varepsilon = \varepsilon_a$ ($a = 1\pi_g$) $- \varepsilon_i$ ($i = 1\pi_u$), is to be compared with the average energy of the $1\pi_u \rightarrow 1\pi_g$ excitations. Table 1 presents the experimental as well as the SAOP, BP, and LDA energies, ω^{av}, averaged over the six excited states. It has been observed that for valence excitations, in contrast to Rydberg excitations, SAOP, BP, and LDA all have good performance, since all valence orbitals, both the occupied and unoccupied ones, have their main amplitude in the molecular region and are all shifted in the same way by the deficient LDA and GGA potentials. In this case, all models perfectly reproduce the experimental average excitation energy of 10.0 eV. It is to be noted that the $\Delta\varepsilon$ value of 9.6 eV is also fairly close to this average (see Table 1). This provides further numerical support to our interpretation (3.15) of $-\varepsilon_a$ as the (average) ionization energy of the relevant excited state(s). It has to be cautioned that the excited states in this case correspond to a valence excitation and so are not of purely single excitation type, there is considerable mixing with other single excitations. This mixing is different for different states. Such mixing is neglected in the approximate Koopmans' theorem for the virtual orbital energies. Moreover, the diagonal $K_{\alpha\alpha}$ matrix elements are not negligible here, since they account for the spread of the energies of the excited states resulting from the $1\pi_u \rightarrow 1\pi_g$ excitation. The average of the $K_{\alpha\alpha}$ is apparently still fairly small. But it is clear, of course, that the relation of orbital energy differences to (average) excitation energies remains a qualitative correspondence rather than a quantitative equality.

5. Conclusions

In this paper, from the requirement that the KS system delivers not only the exact density, but also its response, the exact relations between the orbital energies of virtual KS orbitals, vertical ionization potentials, and excitation energies are obtained. To establish these ε_a, I_a and ($\varepsilon_a - \varepsilon_i$), ω_{ia} relations, the eigenvalue equations of time-dependent density functional theory are combined with the relations between the energies of the occupied KS MOs and VIPs, which have been derived earlier.[3–5]

We consider approximations to these exact relations in order to establish the DFT analog of Koopmans' theorem. Within the small matrix approximation of TDDFT and in the limit of small coupling matrix **K**, the energy, ε_a, of a virtual orbital is interpreted as (minus) the energy of ionization, I_a, of the corresponding excited state. This holds for the predominantly single electronic excitations in compact molecules or for intrafragmental excitations in larger systems. The opposite limit of large **K** is much more special. It occurs for charge-transfer transitions, and an example of very large (diverging) $K_{ia,ia}$ is the case of near-degenerate HOMO, ϕ_i, and LUMO, ϕ_a, occurring in the dissociating electron pair bond (with the excitation $\phi_i \rightarrow \phi_a$ also leading to a charge-transfer excited-state). In these cases, one does not have the relation $\varepsilon_a \approx -I_a$, but in the latter case the relation $\varepsilon_a \approx -I_i$ holds.

The present results are related to the previous ones of ref. 14 in a similar way as the analog of the Koopmans' theorem for the occupied KS MOs[3] is related to the previous work.[11] Indeed, in ref. 11 the long-range asymptotics of the KS equations were analyzed to provide the physical meaning of the HOMO, while in ref. 3 the exact relations between the energy, ε_i, of an arbitrary occupied MO and the manifold of VIPs, $\{I_k\}$, were obtained, from which the physical meaning of ε_i was derived. Analogously, the long-range asymptotics of the KS equations were analyzed in ref. 14 to consider the energy differences between Rydberg type KS MOs and HOMO as good approximations to the energies of the corresponding Rydberg type excitations. And in the present paper, the exact relations between the energy, ε_a, of an arbitrary virtual orbital and the manifold of VIPs, $\{I_k\}$, and excitation energies, $\{\omega_\alpha\}$, are obtained, with which a physical meaning is attributed to ε_a for small coupling matrix **K**.

The present results show the important qualitative difference between virtual MOs of the KS and HF theories; in the latter theory, according to the canonical Koopmans' theorem, the energies of virtual orbitals are interpreted as the affinities, $-A_a$, to an extra electron. This implies that the orbital energy difference, $\varepsilon_a^{HF} - \varepsilon_i^{HF}$, is not close to an excitation energy, but to the difference of an ionization energy and an electron affinity, $I_i - A_a$. In contrast, in the KS theory the energy of a virtual orbital, ε_a, can be interpreted, under certain conditions, as the ionization energy, $-I_a$, from the corresponding excited state. Moreover, the virtual-occupied orbital energy differences were shown to approximate the excitation energies, $\varepsilon_a - \varepsilon_i \approx \omega_{ia}$. Since the Kohn–Sham occupied orbital energies have already received the interpretation of approximate ionization energies, $\varepsilon_i \approx -I_i$, one obtains $\varepsilon_a \approx -I_i + \omega_{ia}$, which is by definition $-I_a$, consistent with the interpretation of ε_a noted above.

Mechanistic insight into the selective trans-1,4-polymerization of butadiene by terpyridine–iron(II) complexes — A computational study

Sven Tobisch

Abstract: The density functional theory (DFT) method has been employed to unravel mechanistic intricacies of the 1,4-polymerization of 1,3-butadiene mediated by the $[(\eta^3\text{-}RC_3H_4)Fe^{II}(C_{15}H_{11}N_3)(\eta^2\text{-}C_4H_6)]^+$ terpyridine–iron(II) active catalyst species. The π-allyl-insertion mechanism is operative for chain growth, whilst the alternative σ-allyl-insertion mechanism has been explicitly demonstrated as being inoperable. This study elucidates the mechanism of cis–trans regulation and unveils the factors that govern the observed high trans-1,4 stereoselectivity, in particular, the discriminative role of allylic isomerization. An atactic *trans*-1,4-polydiene is expected from polymerization of a terminally monosubstituted butadiene, the experimental results of which have not been reported thus far.

Key words: 1,3-diene polymerization, reaction mechanisms, structure–reactivity relationships, iron complexes, density functional calculations.

Résumé : La méthode DFT a été employée afin d'éclaircir les subtilités de la 1,4-polymérisation du 1,3-butadiène assistée par les espèces terpyridine–fer(II) ($[(\eta^3\text{-}RC_3H_4)Fe^{II}(C_{15}H_{11}N_3)(\eta^2\text{-}C_4H_6)]^+$) catalytiquement actives. Le mécanisme selon l'insertion π-allylique se déroule pour la croissance de chaine tandis que le mécanisme alternatif selon l'insertion σ-allylique a été explicitement démontré comme inopérable. Cette étude élucide le mécanisme de la régulation cis–trans et dévoile les facteurs gouvernant la haute stéréoselectivité trans-1,4 observée, en particulier le rôle discriminatoire de l'isomérisation allylique. Un *trans*-1,4-polydiène atactique est attendu à partir de la polymérisation d'un butadiène monosubstitué en position terminale. Ces résultats expérimentaux n'ont pas été reportés jusque-là.

Introduction

The metal-catalyzed polymerization of 1,3-dienes is a key process in the chemical industry and as such has triggered considerable research efforts in both academia and industry.[1–5] Structurally defined allyl-transition-metal complexes and Ziegler–Natta systems have been established as being competent in catalysing the stereoselective polymerization of 1,3-dienes.[6] These catalyst systems are superior to other initiators due to their ability to effect the C–C bond formation in a highly chemo-, regio- and stereo-selective fashion.[7] 1,3-Diene polymerization mediated by various catalyst systems has furthermore been the subject of computational mechanistic examination.[8–10]

Recently, the group of Yasuda[11] has reported a set of iron compounds based on the motif of the 2,2′:6′,2″-terpyridine (terpy) tridentate N_3 ligand, which upon activation with modified methylaluminoxane (MMAO) are capable of effecting homo- and co-polymerization of 1,3-butadiene and isoprene. The substituents on the terpy's phenyl rings have been found to regulate catalytic performance and stereoselectivity.[11] Aryl groups in 6,6′ positions bearing sterically demanding substituents inhibit the catalysis completely, presumably because these ligands block the iron centre against diene attack, which prevents any insertion event. Conversely, Fe(terpy) compounds in which the 6,6′ positions are unsubstituted, thereby ensuring sufficient openness around the metal centre, display good polymerization performance.[11]

The $FeCl_3$(terpy) **0**/MMAO system with an unsubstituted terpy ligand is unique among all the reported systems. It leads to a highly active catalyst that affords a polybutadiene of predominant trans-1,4 structure (96% trans-1,4, 0% cis-1,4, and 4% 1,2-enchainment, Chart 1).[11] This observation prompted a mechanistic exploration of the title process by employing the density functional theory (DFT) method as an established and predictive means to aid in mechanistic

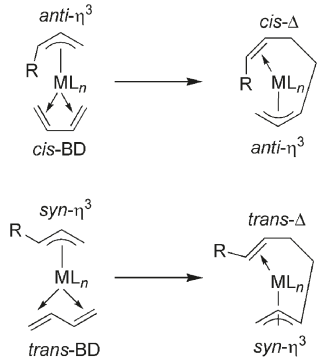
understanding. The objective of the present study is twofold, first, to elucidate the mechanism behind the catalytic performance of this catalyst system and secondly, to unveil the factors that govern the high trans-1,4 stereoselectivity. Moreover, the present mechanistic investigation enables one to predict what type of 1,4-polydiene to expect for terminally monosubstituted butadienes, the result of which has not been reported thus far by experiment.

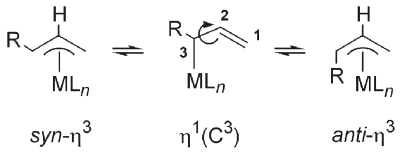
General aspects of the polymerization cycle

The catalyst precursor **0** requires activation by MMAO,[11] which likely effects halide abstraction, methylation, and methyl anion abstraction at the iron centre together with its reduction due to the presence of the strong organylating and reducing MMAO agent. These steps have precedence in organo-iron chemistry. As an example, Yamamoto and co-workers[12] reported that $Fe^{III}(acac)_3$ transforms into $Fe^{II}Me_2(PPh_3)_3$ upon treatment with triphenylphosphine in the presence of trimethylaluminium. It is thus reasonable to assume that upon activation with MMAO the cationic $[(Me)Fe^{II}(terpy)]^+$ species, **1**, with two vacant coordination sites, is formed (Scheme 1). Butadiene insertion into the Fe–Me linkage of **1** then initiates polymer chain growth to give rise to the cationic $[(C_5H_9)Fe^{II}(terpy)]^+$ species, **2**, bearing one empty coordination site (Scheme 1).

Scheme 3. Anti–cis and syn–trans correlation of the transition-metal-mediated 1,4-polymerization of 1,3-butadiene exemplified for η^4-butadiene insertion into the η^3-butenyl–metal linkage (R denotes the polybutadienyl chain).



Scheme 4. Interconversion of syn and anti forms of the η^3-butenyl–metal linkage through an $\eta^1(C^3)$-σ intermediate (R denotes the polybutadienyl chain).

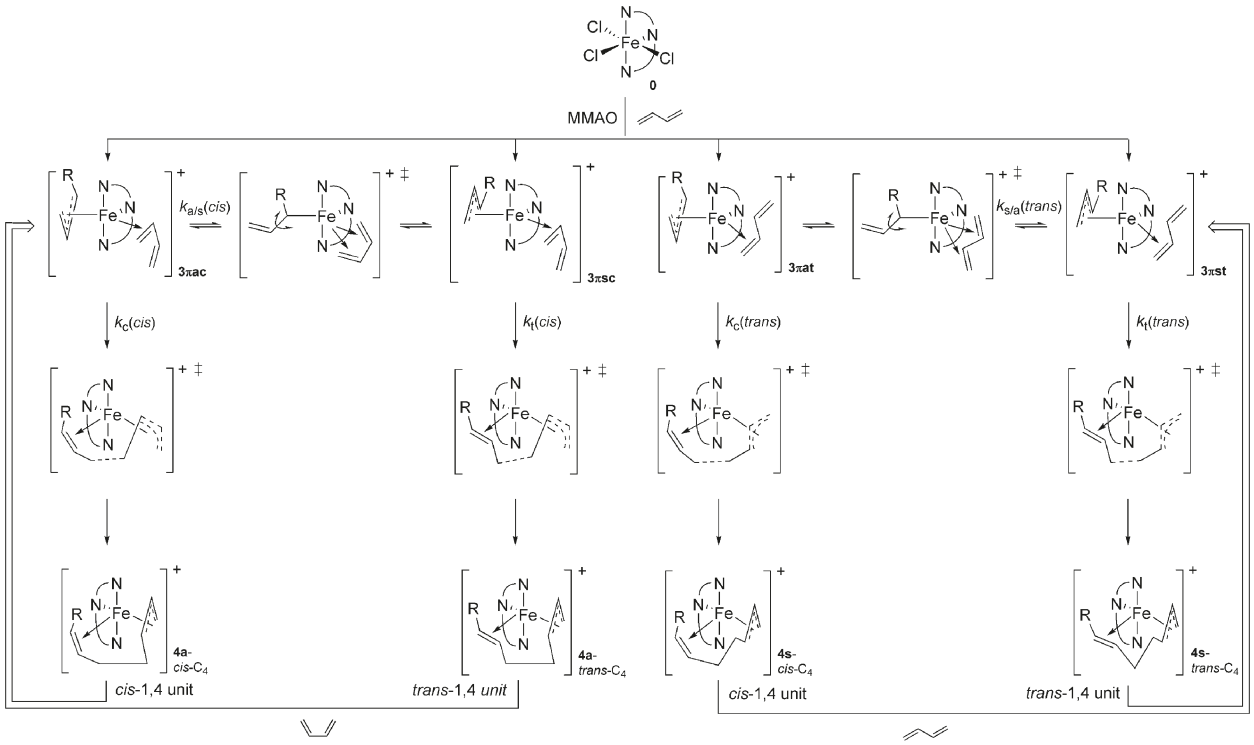


Polymer chain growth does proceed through repeated monomer insertion into the pentenyl–iron linkage of **2**. Hence, $[(RC_3H_4)Fe^{II}(terpy)(C_4H_6)]^+$ represents the catalytically active species in the productive enchainment cycle. Two mechanisms have been proposed for the chain growth step (Scheme 2). Firstly, Cossee and Arlmann[13] assumed, in their so-called σ-allyl-insertion mechanism, the η^1-σ-allyl-metal form in reactive intermediates. Taube and co-workers,[2,14] on the other hand, suggested that butadiene inserts into the η^3-π-allyl-metal bond, which is the so-called π-allyl-insertion mechanism. Detailed computational examination has identified the π-allyl-insertion mechanism as being operative for a variety of early and late transition metal-based catalysts.[8]

In contrast to olefin polymerization, enchainment of 1,3-butadiene is characterized by a greater diversity as the reactive butadiene and allylic units can adopt various forms. Butadiene can coordinate at the metal centre in monodentate (η^2) or bidentate (η^4) mode, from either the s-trans or s-cis configuration. The terminal reactive butyl group of the growing polybutadienyl chain, on the other hand, can be bound to the metal centre in η^3-π or η^1-σ mode and can adopt syn and anti configurations, which are interconvertible. According to the generally accepted anti–cis and syn–trans correlation,[6e] the configuration of the butenyl–metal linkage in the kinetic insertion product is determined by the configuration of the inserting monomer (Scheme 3). An *anti*- or *syn*-butenyl group is generated if butadiene inserts from its s-cis (anti insertion) or s-trans (syn insertion) configuration, respectively. Moreover, the polymer chain is extended by a C_4-unit with a cis or trans double bound, for butadiene to insert into the *anti*- or *syn*-butenyl group, respectively.

As mentioned before, interconversion of the syn and anti forms of the butenyl–metal linkage is another important elementary step, which can play a decisive role in cis–trans

Scheme 5. Catalytic reaction cycle for 1,4-polymerization of 1,3-butadiene with $[(\eta^3\text{-}RC_3H_4)Fe^{II}(C_{15}H_{11}N_3)(\eta^2\text{-}C_4H_6)]^+$ (**3π**) as the active catalyst species. Rival pathways for insertion of *cis*- and *trans*-butadiene into the *anti*-butenyl–Fe^{II} linkage (via k_c(cis) and k_c(trans)) affording a cis-1,4 polymer unit and into the *syn*-butenyl–Fe^{II} linkage (via k_t(cis) and k_t(trans)) affording a trans-1,4 polymer unit, together with the isomerization of the η^3-butenyl–Fe^{II} terminal group of the polymer chain (via $k_{a/s}$, $k_{s/a}$) are shown. The conformations of the key species (for notation, see the text) participating at the various pathways are schematically depicted. The *anti*- and *syn*-butenyl forms for **3** and **4** are labelled by **a** and **s**, respectively, whilst an additional **c** and **t** is used to distinguish between species that are involved in the routes for *cis*-butadiene and *trans*-butadiene insertion, respectively.



stereoregulation of the polymerization process (see below). Scheme 4 displays schematically the process for complexes with ligand architectures that allow η^3-π-butenyl–metal ligation. The isomerization of *syn*- and *anti*-η^3-butenyl forms preferably proceed by means of a η^3-π ⇄ $\eta^1(C^3)$-σ transformation of the butenyl group, followed by internal rotation of the vinyl group around the formal C^2–C^3 single bond. This has been supported by evidence provided by both experimental[15,16] and computational[17] studies.

Results and discussion

The computational exploration of butadiene polymerization is divided into two parts. The first part investigates elementary events of the tentative catalytic cycle for chain growth (Scheme 5) and also the initiation of the polymer growth commencing from **1**. The various conceivable stereochemical pathways for C–C bond formation have been thoroughly examined for both of the proposed mechanisms (Scheme 2). Special attention has been attributed to determining the spin state preferably adopted by the Fe^{II}(terpy) species when traversing the most accessible pathways. Hence, the whole account of possible singlet, triplet, and quintet states has been comprehensively examined. The free-energy profile of the productive enchainment cycle is presented in the second part. Further sections elucidate the mechanism of cis–trans stereoregulation and discuss the implications for the tacticity control of the 1,4-polymerization process.

Table 1. Gibbs free-energy profile (singlet PES) for insertion of butadiene (BD) into the Fe^{II}–Me bond of $[(Me)Fe^{II}(C_{15}H_{11}N_3)]^+$ (**1**).

Insertion path	**1**-**BD**	TS[**1**-**BD**–**2**]	**2**
trans-Butadiene	–17.3 (**1**-*t*BD)	1.5	–30.3 (**2s**)
cis-Butadiene	–16.1 (**1**-*c*BD)	3.1	–26.6 (**2a**)

Note: The free energies of activation ($\Delta G^{\ddagger}$) and reaction (ΔG) are given relative to {**1** + *trans*-C_4H_6} (singlet PES), in kilocalories per mole.

DFT calculations employed the Tao–Perdew–Staroverov–Scuseria (TPSS) functional[18] in conjunction with flexible basis sets of triple-ζ quality (TZVP[19]) for optimization of key stationary points. The good to excellent performance of the TPSS functional for a wide range of applications, with transition metal complexes in particular, has been demonstrated previously.[20] The final energies were obtained from single-point calculations at the TPSSh level[18,20a,21] using the same basis sets. This DFT method has recently been reported to accurately describe spin-states energetics for first row transition metal complexes.[22] The influence of the solvent (toluene)[11] was taken into explicit consideration by making use of a continuum model. All the key stationary points were fully located with inclusion of solvation by using the conductor-like screening model (COSMO) method.[23] The effect of the counteranion was neglected. Although its influence cannot be excluded a priori, the cationic catalyst model employed herein is likely to provide a realistic description of the studied proc-

Table 2. Gibbs free-energy profile (singlet PES) for the butadiene insertion step of the 1,4-polymerization of 1,3-butadiene with $[(\eta^3\text{-}C_4H_7)Fe^{II}(C_{15}H_{11}N_3)(\eta^2\text{-}C_4H_6)]^+$ (**3π**) as the active catalyst species.

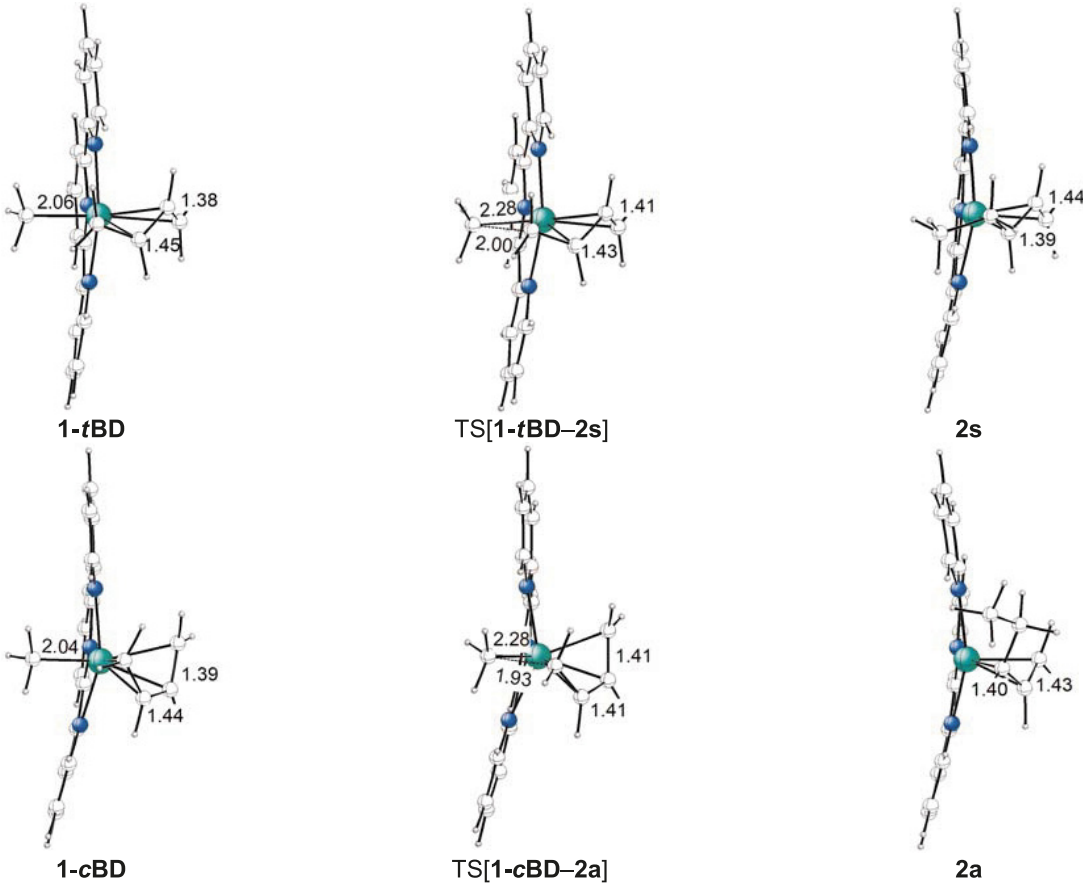
[a]Rotational isomerization via inward/outward trajectories has been examined; see Scheme 7.

ess: the Fe^{II} centre always adopts a six coordinate geometry in all the formally cationic key stationary structures.

The mechanistic conclusions drawn in this study were based on the computed free-energy profiles for relevant elementary steps of the chain growth process (see Scheme 5). Table 1 summarizes the energy profile for chain initiation, while the energetics of chain growth events are collated in Tables 2–4 for the favourable singlet potential energy sur-

Fig. 1. Selected structural parameters (Å) of the optimized structures of key stationary points (singlet PES) for insertion of *trans*-butadiene (top) and *cis*-butadiene (bottom) into the Fe^{II}–Me bond of $[(Me)Fe^{II}(terpy)]^+$ (**1**).



face (PES). The full account of investigated singlet, triplet, and quintet spin states for all the steps is included in the Supplementary data.

Initiation of polymer chain growth

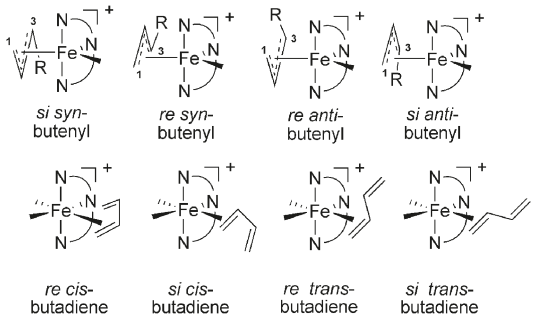
Chain propagation is initiated by capture of a butadiene unit by the methyl precursor (**1**) to form the π-complex (**1**-BD). It comes as no surprise that butadiene binds preferably in a bidentate mode (Fig. 1), hence, occupying the two empty sites available in **1** in a process that is strongly exergonic and proceeding in an essentially barrierless fashion (Table 1).[24] Remarkably, *trans*-butadiene binds somewhat stronger (ΔG = –17.3 kcal mol^{-1}, Table 1) than *cis*-butadiene in the π-complex. The favourable of the two initiation routes commences from **1**-*t*BD and features the insertion of *trans*-η^4-butadiene into the Fe–Me bond to furnish $[(syn\text{-}\eta^3\text{-}C_5H_9)Fe^{II}(terpy)]^+$ (**2s**). This step has a free energy of activation that amounts to 18.8 kcal mol^{-1} and is driven by a thermodynamic force of 13.0 kcal mol^{-1} (Table 1). The generation of the *anti*-η^3-pentenyl species (**2a**) via the rival *cis*-η^4-butadiene insertion route is found to be also viable, but somewhat disfavoured on both kinetic and thermodynamic grounds. Overall, chain initiation is predicted to be a relatively rapid, irreversible transformation with an activation energy that is of similar magnitude as the turnover-limiting barrier for the dominant trans-1,4 enchainment (see below). This leads to the conclusion that chain initialisation is unlikely to cause an induction period.

Elementary events of the chain growth process

General reaction course

Based on the general features of 1,3-diene polymerization discussed before, Scheme 5 shows a plausible catalytic cycle for 1,4-polymerization of butadiene with the cationic $[(\eta^3\text{-}RC_3H_4)Fe^{II}(C_{15}H_{11}N_3)(\eta^2\text{-}C_4H_6)]^+$ (**3π**) as the active catalyst compound. It comprises various possible enchainment paths. After **0** → **1** activation of the catalyst precursor and subsequent **1** → **2** chain initiation, butadiene uptake onto **2** affords **3π** representing the active species of the productive enchainment cycle. Generation of a new C_4-unit can proceed via alternative routes for *cis*-butadiene or *trans*-butadiene insertion. Each of the two routes has two rival pathways for butadiene to insert into the *anti*- or *syn*-butenyl–Fe^{II} bond, thereby giving rise to a cis-1,4 (k_c) or trans-1,4 (k_t) polymer unit, respectively. Traversing the *cis*-butadiene insertion route (via k_c(cis) or k_t(cis), left side in Scheme 5), an *anti*-butenyl group is regenerated as the reactive chain end in the η^3,η^2-polybutadienyl–Fe^{II} insertion produces **4a**. *Cis*-butadiene capture by **4a** to initially afford **3πac** starts a new loop through the chain-growth cycle. Intermediate **4s** with a *syn*-η^3-butenyl-terminated polybutadienyl chain is generated along the route for *trans*-butadiene insertion (via k_c(trans) or k_t(trans), right hand side in Scheme 5), giving rise to **3πst** after *trans*-butadiene uptake to continue chain growth. For each of the insertion routes, the anti and syn forms of **3π** and **4** are interconvertible and presumably in equilibrium.

Scheme 6. Enantiomeric forms of the η^3-butenyl–metal (syn and anti configurations) and the η^2-butadiene–metal (s-cis and s-trans configurations) coordination (R denotes the polybutadienyl chain).



This is indicated in Scheme 5 for butenyl isomerization in **3π** through $k_{a/s}$(cis) and $k_{s/a}$(trans). It becomes evident from Scheme 5 that isomerization is indispensable for the generation of trans-1,4 polymer units along the *cis*-butadiene insertion route (via k_t(cis)) and likewise for the production of a cis-1,4 polybutadiene (via k_c(trans)) for the case that *trans*-butadiene insertion is favourable.

Butadiene π-complex

An octahedral configuration is expected for a six-coordinated d^6-metal centre such as Fe^{II} from orbital interaction considerations.[25] Hence, $[(\eta^3\text{-butenyl})Fe^{II}(terpy)(\eta^2\text{-butadiene})]^+$ (**3π**) and $[(\eta^1\text{-butenyl})Fe^{II}(terpy)(\eta^4\text{-butadiene})]^+$ (**3σ**) are conceivable forms of the π-complex. The configurations of the reactive butadiene (s-cis and s-trans) and butenyl (anti and syn) units and also their enantioface involved in chain propagation are of importance for the stereocontrol of the polymerization process. Scheme 6 depicts the stereoisomers (in *re*/*si* terminology)[26] of η^2-butadiene–Fe^{II} and η^3-butenyl–Fe^{II} ligations.[27] All the possible isomers of key stationary points, which participate in the various stereochemical pathways for chain propagation, have been carefully explored (Tables 2, 3). The $[(RC_3H_4)Fe^{II}(C_{15}H_{11}N_3)(C_4H_6)]^+$ complex, with R = CH_3 as an adequate representation of the growing polybutadienyl chain,[8b,8d,8e,8g] was used as a catalyst model.

For all the various forms of the butadiene π-complex, the singlet spin state represents the ground state. Alternative triplet and quintet spin states are well-separated from the singlet state and are found at higher energies (cf. Table S2a–S3b in the Supplementary data). The most stable form is characterized by a η^3-butenyl–Fe^{II} ligation with butadiene bound in a monodentate mode (Table 2, Fig. 2). The σ-butenyl form (**3σ**), on the other hand, is seen to be distinctly less favourable by about 17 kcal mol^{-1} (Table 3, Fig. 3). Hence, $[(\eta^3\text{-butenyl})Fe^{II}(terpy)(\eta^2\text{-butadiene})]^+$ (**3π**) is the dominant form of the active catalyst complex. For the coordinatively, relatively open terpyridine–iron architecture, which provides sufficient space around the iron centre for η^3-butenyl–Fe^{II} ligation and to capture a butadiene unit, sterics are found to play a minor role in determining the stability of **3π**. Instead, electronic factors prevail. Owing to the mainly covalent character of the butenyl–Fe^{II} interaction, the syn-η^3 form is more stable than the anti-η^3 form by about 3.5 kcal mol^{-1} (Table 2). This is similar to the findings for the several Ni^{II}-based polymerization catalysts,[8a–8f] but contrasts sharply with the situation for highly ionic crotyl-Li complexes,[28] where the anti form is predominant. Interestingly, the syn–anti gap ($\Delta G \sim 1.3$ kcal mol^{-1}, Table 3) is significantly reduced by more than half in **3σ**, but the syn-η^1 form is nevertheless more stable. With regard to butadiene coordination, the η^2-trans form is generally found to be more stable than its η^2-*cis* analogues. Because the electronic stabilization is of comparable magnitude for the two forms, the diversity in stability can simply be traced back to the higher stability of s-trans butadiene relative to its s-cis form (ΔG = 3.6 kcal mol^{-1}),[29] an amount that agrees roughly with the assessed gap between *trans*-η^2- and *cis*-η^2-butadiene forms of **3π**. As anticipated for the open terpy-Fe architecture, the enantioface of the reacting units (i.e., *re*/*re* vs *re*/*si* stereoisomers, see Table 2 and Scheme 6) influences the stability of **3π** to a marginal extent only, thereby reflecting that sterics is of minor importance.

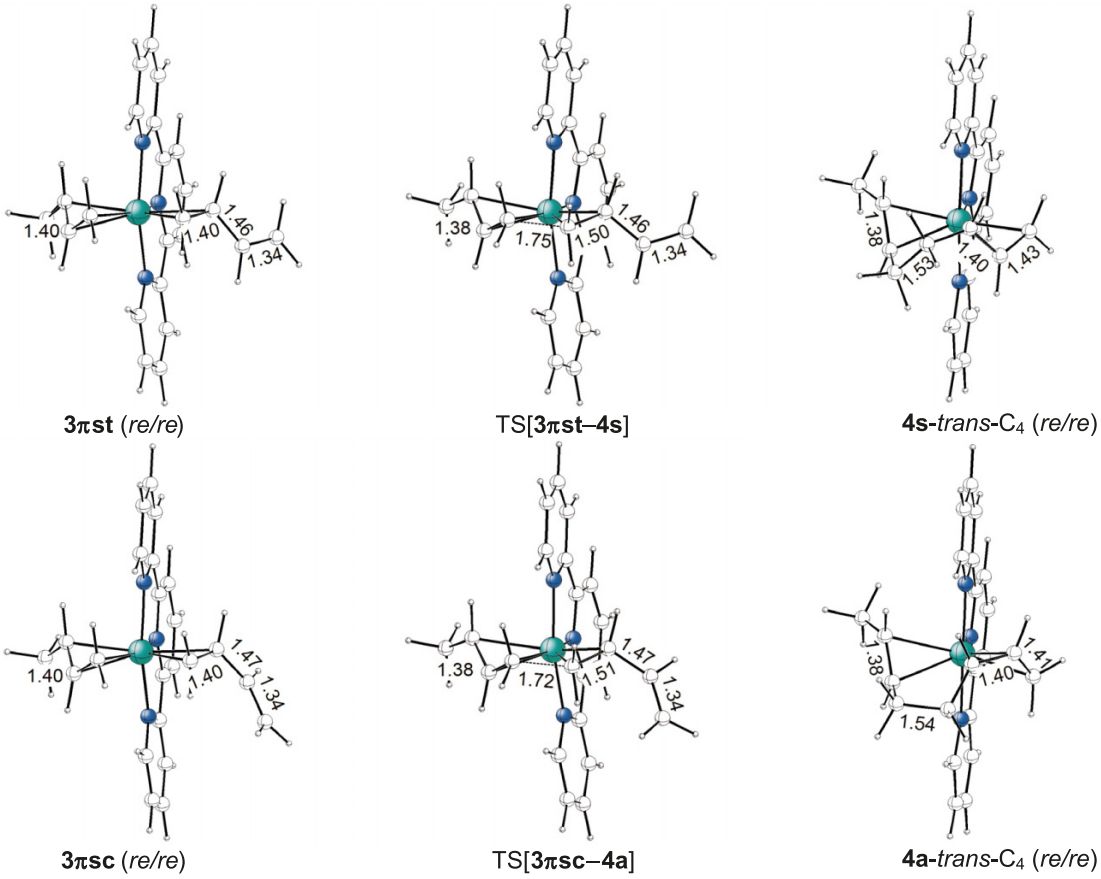
Overall, $[(\eta^3\text{-butenyl})Fe^{II}(terpy)(\eta^2\text{-butadiene})]^+$ (**3π**) is the dominant form of the active catalyst species. Its various isomers, with the *syn*-η^3-butenyl/*trans*-η^2-butadiene isomer (**3πst**) being the most stable, are separated by a few kcal mol^{-1} only. Hence, all the isomers are present in certain concentrations that are determined by their relative stability, provided that isomerization is facile. In contrast, the σ-form (**3σ**) is predicted to be highly unfavourable energetically. Although stabilized by a chelating η^4- butadiene, **3σ** is separated by $\sim$17 kcal mol^{-1} from **3π**.

Butadiene insertion into the Fe^{II}–butenyl linkage

Similar to what has been found for precursor **3**, the transition state for C–C bond formation and also the polybutadienyl–Fe^{II} insertion product **4**, preferably adopts the singlet spin state whilst traversing the most accessible pathways. Hence, chain propagation proceeds at the singlet PES and does not involve any spin-state crossing. For all key stationary points the triplet and quintet states are found at higher energies, well-separated from the low-spin singlet ground state (see the Supplementary data). This also holds true for the two alternative insertion mechanisms (see Scheme 2)

Chain propagation proceeding via butadiene insertion into the η^3-butenyl–Fe^{II} and $\eta^1(C^1)$-butenyl–Fe^{II} linkages has been probed explicitly. The key stationary points participating in these processes are characterized structurally in Figs. 2 and 3, whereas the energy profiles are collated in Tables 2 and 3, respectively. Inspection of key stationary points for the π-butenyl insertion (Fig. 2) reveals that chain growth commences from **3π** and takes place via TS[**3π-4**] that constitutes the insertion of (*cis* or *trans*)-η^2-butadiene into a somewhat distorted (*syn* or *anti*)-η^3-butenyl–Fe^{II} linkage. The TS[**3π-4**] appears at a distance of $\sim$1.75–1.85 Å of the emerging C–C σ-bond and is characterized by a quasi-planar four-membered cis arrangement of the butadiene's double bond that is inserted, the terminal butenyl-C^1 and the iron centre. Decay of the transition state leads to the η^3, η^2-polybutadienyl–Fe^{II} compound (**4**) where the growing polybutadienyl chain is ligated to iron by its terminal η^3-butenyl group and its first double bond. Along the alternative process that starts from **3σ**, the C–C bond formation takes place at $\sim$2.0–2.1 Å in the quasi-planar four-membered TS[**3σ–4**] featuring the (*trans* or *cis*)- η^4-butadiene insertion into an elongated (*syn* or *anti*)-η^1-butenyl–Fe^{II} bond (Fig. 3). Fol-

Fig. 2. Selected structural parameters (Å) of the optimized structures of key stationary points (singlet PES) for insertion of *trans*-butadiene (top) and *cis*-butadiene (bottom) into the *syn*-η^3-butenyl–Fe^{II} bond in $[(\eta^3\text{-}C_4H_7)Fe^{II}(terpy)(\eta^2\text{-}C_4H_6)]^+$ (**3π**) along the most accessible stereochemical pathway.



lowing the reaction path further, the η^3-butenyl terminal group is readily regenerated from the former η^4-butadiene unit together with a recoordinating polybutadienyl chain, hence the insertion product (**4**) that is formed along the alternative insertion processes are identical. The next loop through the cycle would first require an $\eta^3 \rightarrow \eta^1(C^1)$ conversion of the terminal butenyl group prior to η^4-butadiene insertion via TS[**3σ-4**]. The comparison of the energy profile for the most feasible pathways of the alternative insertion mechanisms (i.e., *trans*-butadiene insertion into the *syn*-butenyl–Fe^{II} bond, Tables 2, 3) reveals that insertion into the η^3-butenyl–Fe^{II} bond is distinctly preferred kinetically ($\Delta G^{\ddagger}$ = 17.4 kcal mol^{-1}) against the σ-butenyl insertion ($\Delta G^{\ddagger}$ = 33.9 kcal mol^{-1}). The substantial kinetic gap of 16.5 kcal mol^{-1} ($\Delta\Delta G^{\ddagger}$) between the two mechanisms indicates that insertion into the barely reactive σ-butenyl form is almost entirely precluded kinetically. This leads to the following conclusions: (*i*) The thermodynamically favourable η^3-butenyl form is also preferably involved in C–C bond formation; (*ii*) conversely, $\eta^1(C^1)$-butenyl species are predicted to be at high energy, well-separated from η^3-butenyl congeners and hence do not participate along the most accessible pathway for chain growth; (*iii*) the π-allyl insertion mechanism is operative, whilst the σ-allyl mechanism is clearly rendered inoperable.

Focusing now exclusively on the π-allyl insertion mechanism (Table 2, Fig. 2), careful analysis of the located TS[**3π-4**] structures reveals that the unsubstituted terpy ligand provokes a rather modest congestion around the iron centre. As a result, unfavourable interactions of the reactive units with the ligand backbone are of minor importance, such that the propensity of the various stereoisomers of **3π** to undergo C–C bond formation is predominantly dictated by electronic factors. The higher stability of η^2-*trans*-butadiene isomers (**3π(s/a)t**) relative to η^2-*cis*-butadiene isomers (**3π(s/a)c**) is paralleled in the TS structures. Leaving the possible discriminating role of allylic isomerization in the enchainment cycle out of consideration, by assuming facile isomerization events, DFT predicts that η^2-*trans*-butadiene insertion into the *syn*-η^3- (k_t(trans) with $\Delta G^{\ddagger}$ = 17.4 kcal mol^{-1}) and *anti*-η^3-butenyl–Fe^{II} linkage (k_c(trans) with $\Delta G^{\ddagger}$ = 23.1 kcal mol^{-1}) are the more accessible pathways to furnish a new 1,4-trans and 1,4-cis polymer unit, respectively. Of particular note, the trans–cis gap of 3.7–4.0 kcal mol^{-1} for **3πs** and **3πa** remains almost unchanged in the TS structures, thereby indicating that traversing the alternative k_t(cis) and k_c(cis) pathways is less probable. The assessed trans–cis gap coincides nicely with the disparity in stability between s-trans and s-cis butadiene (ΔG = 3.6 kcal mol^{-1}).[29] This is quite understandable for butadiene to insert in η^2-mode, i.e., formally as a vinylethylene, because of the lack of extra stabilization by a chelating η^4-butadiene, which may lead to differentiation between trans and cis isomers. The higher reactivity of the *syn*-η^3-butenyl form together

Fig. 3. Selected structural parameters (Å) of the optimized structures of key stationary points (singlet PES) for insertion of *trans*-butadiene (top) and *cis*-butadiene (bottom) into the *syn*-$\eta^1(C^1)$-butenyl–Fe^{II} bond in $[(\eta^1\text{-}C_4H_7)Fe^{II}(terpy)(\eta^4\text{-}C_4H_6)]^+$ (**3σ**) along the most accessible stereochemical pathway.

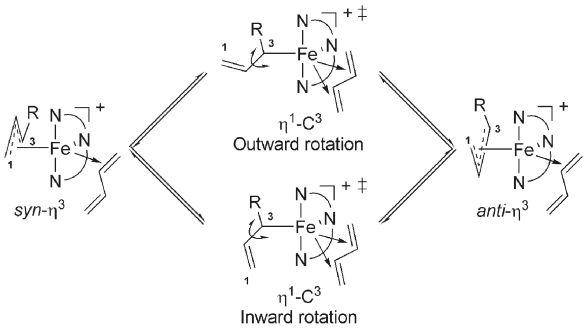
Scheme 7.

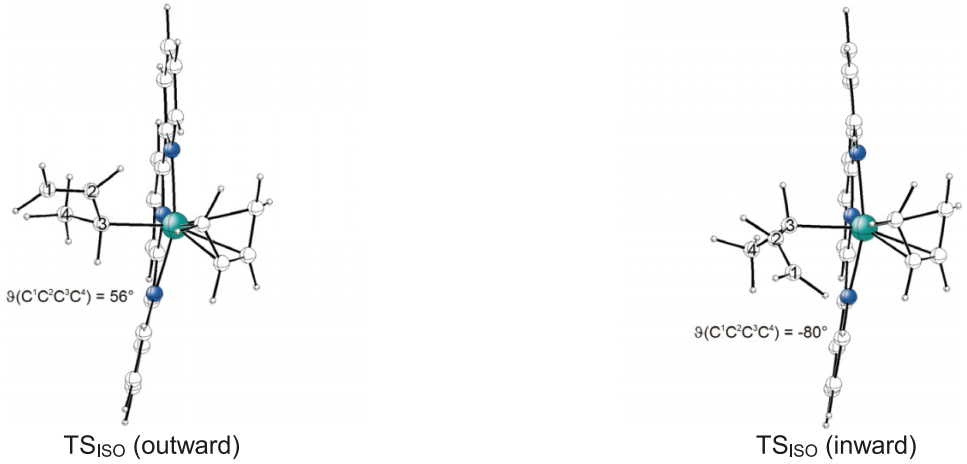


with the higher stability of s-trans butadiene are seen to dictate the propensity of the various stereoisomers of **3π** for C–C bond formation. Although it is of no mechanistic relevance for the studied catalyst system, it is worth mentioning that the gap in reactivity for *anti*- and *syn*-$\eta^1(C^1)$-butenyl isomers is significantly reduced to ~2.0–2.5 kcal mol^{-1} ($\Delta\Delta G^{\ddagger}$, Table 3) when compared to ~5.7–6.0 kcal mol^{-1} for η^3-butenyl–Fe^{II} forms

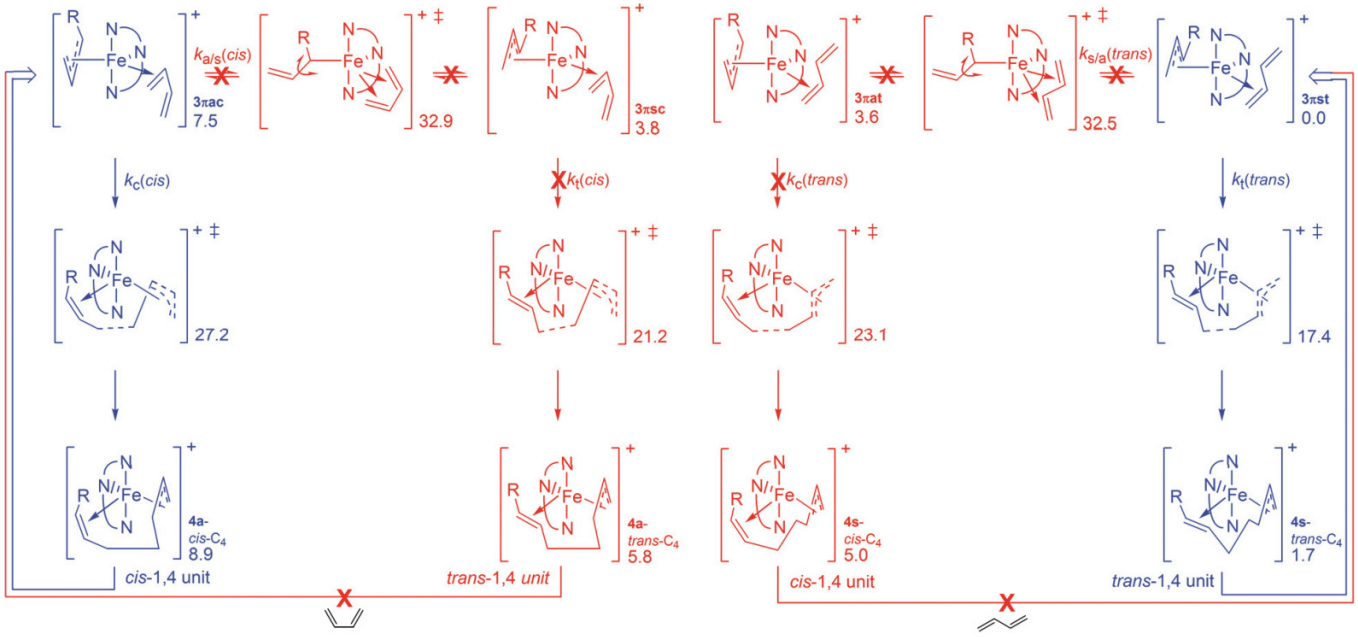
Allylic isomerization

The interconversion of the syn and anti forms of the terminal reactive η^3-polybutadienyl group is investigated next. Two trajectories are conceivable (Scheme 7)[17,30] for allylic isomerization to proceed by inward and outward rotation of the vinyl group around the formal C^2–C^3 single bond. This is exemplified in Scheme 7 for the butadiene-assisted process. Rotational isomerization taking place in **3π** or **4** has been examined. The most accessible pathway does evolve through a $\eta^1(C^3)$-butenyl-TS structure that benefits from a stabilizing η^4-butadiene complexation. The alternatively imaginable coordination of the polybutadienyl chain by its double bonds of the ultimate and (or) penultimate polymer units, however, is found to be less effective in stabilizing the TS structure. Hence, allylic isomerization preferably takes place in the butadiene π-complex (**3π**). Figure 4 shows rotational TS structures for isomerization via the *cis*-butadiene insertion route ($k_{a/s}$(cis), see Scheme 5) proceeding through inward and outward trajectories, whilst the energetics for both $k_{a/s}$(cis) and $k_{s/a}$(trans) events is collected in Table 4. *Cis*-butadiene insertion leads exclusively to anti-η^3 **4a**, from which **3πac** is readily regenerated by capture of a new butadiene unit. The most accessible isomerization pathway encounters first the anti-η^3 → anti-$\eta^1(C^3)$ butenyl conversion to be followed by rotational isomerization through the $\eta^1(C^3)$-butenyl TS_{ISO}, giving rise initially to a syn-$\eta^1(C^3)$ transient species, which transforms readily thereafter into the energetically preferred syn-η^3 species (**3πsc**). Careful inspection of the reaction path indicated that $\eta^3 \rightleftarrows \eta^1(C^3)$ butenyl transformation is a smooth process proceeding in an almost barrierless fashion,[31] which is essentially driven by the thermodynamic gap between the two

Fig. 4. Selected structural parameters (Å) of the optimized TS structures (singlet PES) for rotational isomerization of the terminal η^3-butenyl–Fe^{II} linkage via $k_{a/s}$(cis) proceeding through inward and outward trajectories.



Scheme 8. Free-energy profile (singlet PES) for 1,4-polymerization of 1,3-butadiene with $[(\eta^3\text{-}RC_3H_4)Fe^{II}(C_{15}H_{11}N_3)(\eta^2\text{-}C_4H_6)]^+$ (**3π**) as the active catalyst species proceeding through competing routes for insertion of *cis*-butadiene (left) and *trans*-butadiene (right).Viable pathways are drawn in blue colour, whilst pathways that are inaccessible are indicated in red colour. The assessed reaction heat for *trans*-1,4 enchainment (ΔG = 9.2 kcal mol^{-1}) has been subtracted from polybutadienyl–Fe^{II} compounds (**4s** and **4a**). R = CH_3.



forms. Hence, TS_{ISO} is the highest point to be traversed along the most accessible pathways.

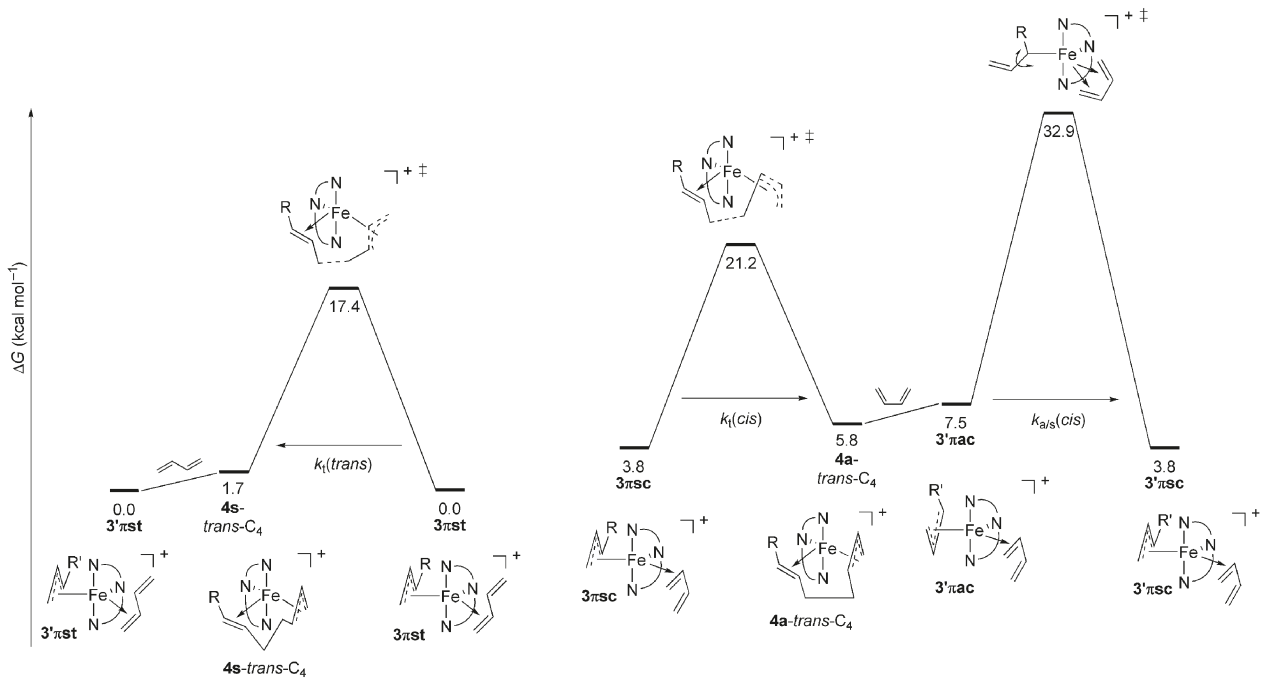
Although TS_{ISO} features a chelating η^4-butadiene (Fig. 4), a substantial activation energy is associated with rotational isomerization. The total barrier[32] for $k_{s/a}$(trans) occurring along the *trans*-butadiene insertion route and for $k_{a/s}$(cis) encountered along the *cis*-butadiene insertion route is predicted to be almost identical and amounts to 32.5–32.9 kcal mol^{-1} (Table 4). The outward rotation of the vinyl group is the more accessible pathway. Conversely, unfavourable interactions between the vinyl group and the terpy-Fe backbone are seen to disfavour the transition state of the inward trajectory. Overall, butenyl group isomerization (Table 4) is predicted to be considerably more demanding kinetically when compared with butadiene insertion (Table 2), thereby indicating that isomerization is slower than C–C bond formation ($k_{ins} >> k_{iso}$).

Productive chain growth cycle

Free-energy profile

The condensed Gibbs free-energy profile for relevant steps of the tentative catalytic cycle (Scheme 5) is displayed in Scheme 8. It is comprised of various pathways for each of these steps to follow the operative mechanistic route; viz. the η^2-butadiene insertion into the η^3-butenyl–Fe^{II} linkage proceeding through rival pathways for trans-1,4 enchainment (k_t(trans), k_t(cis)) and cis-1,4 enchainment (k_c(cis), k_c(trans)), the butadiene-assisted isomerization of the η^3-butenyl–Fe^{II}

Scheme 9. Reaction energy profile (singlet PES) for trans-1,4 enchainment of butadiene by the $[Fe^{II}(C_{15}H_{11}N_3)(RC_3H_4)(C_4H_6)]^+$ catalyst species via alternative routes for *trans*-butadiene insertion (left) and *cis*-butadiene insertion (right). The assessed reaction heat for trans-1,4 enchainment (ΔG = 9.2 kcal mol^{-1}) has been subtracted from polybutadienyl–Fe^{II} products (**4s** and **4a**), respectively. R = CH_3, R′ = $C_4H_6CH_3$.



functionality of the growing polybutadienyl chain, and the facile butadiene capture of the polybutadienyl–Fe^{II} compound (**4**) to readily regenerate the active catalyst species (**3π**). The reaction heat for regular trans-1,4 enchainment has been excluded from Scheme 8. Viable pathways for trans-1,4 and cis-1,4 enchainment are drawn in blue, whilst inaccessible pathways are indicated in red. The likelihood of the various pathways to be traversed in the productive enchainment cycle is discussed in the next section. Of all the various steps, allylic isomerization is connected with the overall highest activation barrier, whilst butadiene insertion is considerably more favourable kinetically. DFT predicts that $[(syn\text{-}\eta^3\text{-}RC_3H_4)Fe^{II}(C_{15}H_{11}N_3)(trans\text{-}\eta^2\text{-}C_4H_6)]^+$ (**3πst**) is the most stable species in the productive cycle for trans-1,4 enchainment and is therefore likely to represent the catalyst resting state.

Mechanism of cis–trans regulation

As shown before, insertion of *trans*-η^2-butadiene into the *syn*-η^3- and *anti*-η^3-butenyl–Fe^{II} bond are the more accessible of the rival pathways for generation of a trans-1,4 and cis-1,4 polymer unit, respectively (see the Butadiene π-complex section). Accordingly, trans-1,4 and cis-1,4 enchainment should proceed through k_t(trans) and k_c(trans), respectively. For k_c(trans) to become accessible, however, a sufficiently facile syn–anti isomerization (k_{sa}(trans)) is required. DFT predicts that allylic isomerization is significantly more kinetically demanding than butadiene insertion, and the gap amounts to 5.7–15.1 kcal mol^{-1} ($\Delta\Delta G^{\ddagger}$).[33] This leads to the conclusion that isomerization is kinetically disabled relative to C–C bond formation and, as such, *syn*- and *anti*-butenyl forms of **3π** and **4** are not in rapid equilibrium. As a consequence, the configuration of the terminal butenyl group and also the mode of enchainment is entirely dictated by the configuration of the inserting butadiene. Hence, trans-1,4 enchainment exclusively proceeds via k_t(trans) through repeated *trans*-η^2-butadiene insertion into the *syn*-η^3-butenyl–Fe^{II} linkage and a regular cis-1,4 polymer is produced via k_c(cis) by repeated insertion of *cis*-η^2-butadiene into the *anti*-η^3-butenyl–Fe^{II} bond (cf. Scheme 8). The alternative k_t(cis) and k_c(trans) pathways for trans-1,4 and cis-1,4 enchainment, which necessitates a sufficiently fast $k_{a/s}$(cis) anti–syn and $k_{s/a}$(trans) syn–anti isomerization, respectively, cannot be traversed because of the slow isomerization (i.e., k_c(cis) >> $k_{a/s}$(cis) and k_t(trans) >> $k_{s/a}$(trans)). This is illustrated in Scheme 9 for rival trans-1,4 enchainment paths.

The trans-1,4 enchainment via k_t(trans) has a total activation barrier[32] of 17.4 kcal mol^{-1}, whilst the transition state encountered along k_c(cis) to generate a regular *cis*-1,4 polybutadiene is 9.8 kcal mol^{-1} ($\Delta\Delta G^{\ddagger}$) higher in free energy. Considering the magnitude of the assessed kinetic gap,[34] cis-1,4 enchainment appears to be kinetically prevented. Hence, DFT predicts that k_t(trans) is almost exclusively traversed in the productive enchainment cycle, thereby giving rise to a polybutadiene of predominantly trans-1,4 structure, which is in accordance with observed selectivity (Chart 1).[11] Moreover, the predicted turnover-limiting barrier of 17.4 kcal mol^{-1} compares favourably with reported performance data.[11] Although no data are available for polymerization of butadiene,[11] an effective barrier of 18.3 kcal mol^{-1} can be estimated from the reported activity for isoprene polymerization.[35] The good agreement of effective kinetics obtained by theory and experiment, although appearing somewhat fortuitous, can serve as an example for demonstrating the substantial predictive values that computational mechanistic studies can nowadays accomplish.

Generation of tactic trans-*1,4-polydienes*

The polymerization of a chiral butadiene with an asymmetrically substituted methylene group leads to the generation of a tactic 1,4-polydiene. An isotactic, syndiotactic, or atactic polymer is formed, dependent on whether the chiral centres possess an identical, alternating, or random configuration in subsequent chain growth events. It is generally agreed that the chirality of the two carbon centres that generate the C–C bond determines the tacticity of 1,4-polydienes.[6e] Hence, the enantiofaces of the reactive butenyl and butadiene units in the TS for chain propagation is of crucial importance. As an example, multiple insertion events to involve identical enantiofaces would give rise to an isotactic 1,4-polydiene.

The structure of a polymer obtained from polymerising a terminally monosubstituted butadiene by $FeCl_3$(terpy) **0**/MMAO has not been reported thus far by experiment.[11] However, the precise insight into the enchainment process detailed by the present study, brings us to a position to predict its structure. As analysed in the Butadiene π-complex section, steric interactions between the butenyl and butadiene units and the Fe(terpy) backbone are small in the TS structure and also in **3π** and **4**. As a result, the assessed energy profiles for *re*/*re* and *re*/*si* stereochemical pathways (cf. Scheme 6 and Table 2 for further details) of an individual insertion path (viz. k_t(trans), k_c(trans), k_t(cis), and k_c(cis)) are virtually congruent (Table 2). The TS structures of syn-*re*/*re* ($\Delta G^{\ddagger}$ = 17.4 kcal mol^{-1}) and syn-*re*/*si* ($\Delta G^{\ddagger}$ = 17.5 kcal mol^{-1}) pathways for trans-1,4 enchainment via k_t(trans) are almost energetically degenerate. Hence, DFT predicts an equal likelihood for the two pathways to be traversed in trans-1,4 enchainment. As a consequence, an atactic *trans*-1,4-polydiene, which lacks any stereoregularity within the methylene groups, is generated in polymerization of a terminally monosubstituted butadiene by the sterically relatively open **0**/MMAO catalyst system.

Concluding remarks

Presented herein is a computational study of the 1,4-polymerization of 1,3-butadiene mediated by a recently developed, highly active, trans-1,4 regulating terpyridine–iron catalyst. The [$Fe^{III}Cl_3$(terpy)] catalyst precursor is likely to be converted into [(Me)Fe^{II}(terpy)]$^+$ in the presence of MMAO. Subsequent butadiene insertion into the Fe–Me linkage then initiates polymer chain growth, where [$Fe^{II}(C_{15}H_{11}N_3)(\eta^3\text{-}RC_3H_4)(\eta^2\text{-}C_4H_6)]^+$ (**3π**) represents the catalytically active species in the productive enchainment cycle. Alternative mechanistic routes and pathways of all crucial elementary steps have been carefully explored for the various conceivable spin states by means of a reliable DFT method. All the studied chain initiation, chain propagation, and allylic isomerization events are found to preferably proceed at the singlet PES. Chain growth employs the π-allyl-insertion mechanism and takes place preferably by η^2-butadiene insertion into the η^3-butenyl terminal group. Conversely, the alternative suggested mechanism via $\eta^1(C^1)$-butenyl–Fe^{II} species (**3σ**) is seen to be inoperable. The likelihood of traversing rival insertion pathways is predominantly determined on electronic grounds, whilst steric factors have a small influence only for the sterically relatively open catalyst studied. The *syn*-η^3-butenyl–Fe^{II} form of **3π** is more stable than its anti counterpart and displays a higher propensity to undergo C–C bond formation, whilst η^2-butadiene preferably inserts from prevalent s-trans configuration. Isomerization of the η^3-butenyl–Fe^{II} group, to preferably proceed via a rotational $\eta^1(C^3)$-butenyl–Fe^{II} TS structure that is stabilized by a chelating η^4-butadiene, is found to exert a profound influence on cis–trans regulation. DFT predicts that isomerization is disabled kinetically relative to butadiene insertion, thereby indicating that syn and anti forms of **3π** and **4** are not in rapid equilibrium. Hence, all enchainment pathways that involve an isomerization event, are rendered inaccessible due to slow isomerization. Trans-1,4 enchainment does proceed through repeated *trans*-η^2-butadiene insertion into the *syn*-η^3-butenyl–Fe^{II} linkage with an effective barrier of 17.4 kcal mol^{-1}. This pathway is almost exclusively traversed, thereby giving rise to a polybutadiene of a predominantly 1,4-trans structure, since the competing cis-1,4-generating pathway is kinetically disabled. All these aspects match with experimental observations and rationalise them. For polymerization of a terminally monosubstituted butadiene, an atactic *trans*-1,4-polydiene is predicted, the structure of the generated polymer structure has, however, not been reported thus far by experiment.

Computational details

All DFT calculations were performed with the program package TURBOMOLE.[36] The nonempirical meta-GGA functional developed by Tao, Perdew, Staroverov, and Scuseria,[18] which is usually termed TPSS in the literature, was utilized together with the RI-*J* approximation[37] for the optimization of key stationary points. All elements were represented by Ahlrich's valence triple-ζ TZVP basis set[19a] with polarization functions on all atoms. For Fe, the TZVP set[19a] supplemented by two diffuse p functions[19b] contracted to (842111/63111/411) was used. The good to excellent performance of the TPSS functional for a wide range of applications including transition metal complexes has been demonstrated previously.[20] All the Fe^{II}(terpy) key stationary points were located for the singlet, triplet, and quintet spin states. Unrestricted calculations were performed in all cases to avoid singlet instabilities. It is well-known that pure functionals favour low-spin configurations, whilst conversely, the exact exchange contribution in hybrid functionals leads to a bias towards high-spin states. With regard to relative spin-state energetics, a version of B3LYP with 15% exact exchange has been reported to perform better for $Fe^{II}(phen)_2(NCS)_2$ complexes,[38a] and a version of BP86 with 10% exchange was found to provide the best results for some {FeNO} and {FeO2} compounds.[38b] Hence, refined energies were obtained from single-point calculations at the hybrid TPSS level, i.e., TPSSh with 10% exchange,[21] for TPSS(COSMO)-optimized geometries by using the same basis set. This DFT method has recently been reported to provide accurate spin-state energetics for first row transition metal complexes.[22] The reaction paths were explored by the growing string method,[39] in which two string fragments (commencing from reactant and product side, respectively) are grown until the two fragments join. As this was performed in mass-weighted coordinates, an approximate to the minimum energy path (MEP) was obtained. This identified the reactant and product states to be linked to the associated

transition state. The approximate saddle point connected with the MEP was subjected to an exact localization of the TS structure. All stationary points were located by utilizing analytical/numerical gradients/Hessians according to standard algorithms and were identified exactly by the curvature of the potential-energy surface at these points corresponding to the eigenvalues of the Hessian. All reported transition-state structures possess exactly one negative Hessian eigenvalue, whilst all other stationary points exhibit exclusively positive eigenvalues. The reaction and activation enthalpies and free energies (ΔH, $\Delta H^{\ddagger}$ and ΔG, $\Delta G^{\ddagger}$ at 298 K and 1 atm) were evaluated according to standard textbook procedures[40] using computed harmonic frequencies. The frequency analysis was conducted for stationary points that were located with an alternative basis set, consisting of the aforementioned basis set for Fe and Ahlrich's split-valence SV(P) basis set[41] with polarisation functions on main group atoms, but not on hydrogen. This level of basis-set quality has been reported as a reliable tool for the assessment of structural parameters and vibrational frequencies;[42] hence, this protocol allows an affordable and accurate determination of thermodynamic state functions. Enthalpies were reported as ΔE + zero point energy corrections at 0 K + thermal motion corrections at 298 K and Gibbs free energies were obtained as $\Delta G = \Delta H - T\Delta S$ at 298 K. The influence of the solvent was taken into explicit consideration by making use of a continuum model. The experimentally used toluene solvent[11] was described as a homogeneous, isotropic dielectric medium (characterized by its relative static dielectric permittivity, ε = 2.379 at 298 K)[43] within the conductor-like screening model (COSMO) due to Klamt and Schüürmann[23] as implemented in TURBOMOLE.[44] Nonelectrostatic contributions to solvation were not included. The solvation effects were included self-consistently, and all the key species were fully located including solvation. The fitted atomic COSMO radii (r_H = 1.3 Å, r_C = 2.0 Å, r_N = 1.83 Å)[45a] have been used in combination with a radius of 2.22 Å[45b] for Fe. The mechanistic conclusions drawn in this study were based on the computed Gibbs free-energy profile of the overall reaction for experimental condensed phase conditions. All the drawings were prepared by employing the StrukEd program.[46]

Supplementary data

Supplementary data (Tables S2a–S4ab giving the energetics for triplet and quintet spin states for all the investigated species) for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 5265. For more information on obtaining material, refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml.

(31) All attempts to precisely localise the TS for $\eta^3 \rightleftarrows \eta^1(C^3)$ butenyl conversion were unsuccessful because the PES is rather flat in this region.

(32) Total activation barriers are given relative to the most abundant isomer of **3π**, viz. [(*syn*-η^3-C_4H_7)Fe^{II}(terpy)(*trans*-η^2-C_4H_6)]$^+$ (**3πst**).

(33) The disparity in free energy between k_c(cis) and $k_{a/s}$(cis) of 5.7 kcal mol^{-1} and between k_t(trans) and $k_{s/a}$(trans) of 15.1 kcal mol^{-1} represent the lower and upper limits of the kinetic gap for insertion and isomerisation events (cf. Tables 2 and 4).

(34) The assessed kinetic gap of 9.8 kcal mol^{-1} ($\Delta\Delta G^{\ddagger}$) between k_c(trans) and k_t(trans) pathways transforms into a relative likelihood of $\sim 6.5 \times 10^{-7}$: 100 (298.15 K) for cis-1,4 and trans-1,4 enchainment events on application of Stefan–Boltzmann statistics.

(35) The effective free energy of activation for the polymerization of 1,3-butadiene with the studied terpyridine–iron(II) catalyst has been estimated from available experimental data (ref. 11) by the following somewhat crude approximation: with an activity of 6 kg of isoprene (mol of Fe)$^{-1}$ h^{-1} at 298 K, one obtains an effective rate constant of $k_{eff} \sim 0.0245$ s^{-1}. Low temperature (253 K) measurements indicate that polymerization of butadiene is about 10 times faster then isoprene polymerization. The so adapted $k_{eff} \sim 0.245$ s^{-1} corresponds to $\Delta G^{\ddagger} \sim 18.3$ kcal mol^{-1} upon application of the Eyring equation with $k = (2.08 \times 10^{10}) \times T \times \exp(-\Delta G^{\ddagger}/RT)$].

Bis(cyclopentadienyl)dihydrido Mo and W complexes as Lewis bases — A computational study about their adducts with BX_3 (X = F, Cl) and $Al(CH_3)_3$

Mario Amati and Francesco Lelj

Abstract: A computational investigation about the Lewis acid–base adducts between bases Cp_2MH_2 (M = Mo, W) and acids BX_3 (X = F, Cl) and $Al(CH_3)_3$ is presented. Density functional methods based on pure and hybrid correlation-exchange functionals and relativistic corrections based on the zero order relativistic approximation (ZORA) have been applied. A comparison with experimental data has been addressed to give insights about the nature of the acid–base interaction with the aim to evaluate the role of the transition metal in charge donation toward the acid centre. In this respect, the likelihood of proposed criteria for recognizing the presence of transition-metal direct charge donation has been discussed.

Key words: metallocenes, Lewis basicity, density functional theory (DFT), atoms in molecules (AIM), zero order relativistic approximation (ZORA).

Résumé : On a effectué une étude théorique des adduits acide–base de Lewis entre les bases Cp_2MH_2 (M = Mo, W) et les acides BX_3 (X = F, Cl) et $Al(CH_3)_3$. On a utilisé les méthodes de la fonctionnelle de la densité en faisant appel à des fonctionnelles de corrélation-échange pures ainsi qu'hybrides et on a appliqué des corrections relativistes basées sur l'approximation relativiste d'ordre zéro (AROZ). Une comparaison avec les données expérimentales a été réalisée afin d'obtenir des informations sur la nature de l'interaction acide–base qui permettraient d'évaluer le rôle du métal de transition dans le transfert de charge vers le centre acide. Dans cette optique, on discute du potentiel d'utilité des critères proposés pour reconnaître la présence d'un transfert de charge direct de la part du métal de transition.

Mots-clés : métallocènes, basicité de Lewis, théorie de la fonctionnelle de la densité (TFD), atomes dans une molécule « AIM », approximation relativiste d'ordre zéro (AROZ).

[Traduit par la Rédaction]

Introduction

The acid–base adduct between bis(cyclopentadienyl)dihydridotungsten (Cp_2WH_2) and BF_3 was firstly communicated by Shriver[1] in 1963. It represented one of the first (and representative) examples of Lewis base behaviour of a transition-metal centre. The adduct formation was reported as a fast process in toluene and benzene solutions in an inert atmosphere. The resulting solid was insoluble in common solvents, limiting its characterization to nujol dispersion IR spectroscopy. The substantial invariance of the W–H stretching frequency in comparison to the free complex was used as proof of the direct interaction of the BF_3 moiety with the central metal without assistance from the hydride ligands.

A more complete successive investigation extended the study to BCl_3 and B_2H_6 as acid compounds and Cp_2MoH_2 (other than Cp_2ReH and cyclopentadielylmetal carbonyl complexes) as Lewis basic metal centres in addition to Cp_2WH_2.[2] BF_3 was reported to form adducts with both W and Mo complexes, whereas BCl_3 only reacted with the W complex. The reported adducts were prepared in an inert atmosphere and temperatures lower than 0 °C when the reaction was performed in solution. In all the cases, insoluble solids are quickly produced and IR analyses substantially confirmed the little effect of the acid–base interaction on the M–H stretching band (particularly in the case of BF_3). This observation seemed to confirm the direct metal–boron interaction, which has been paralleled in the protonated forms, $[Cp_2MH_3]^+$, and often proposed in inorganic chemistry text books as an example of Lewis acidity of transition metals.[3]

The ability of Cp_2MoH_2 and Cp_2WH_2 to bind group-13 acids was confirmed by Storr and Thomas[4] who clearly demonstrated the adduct formation with $AlMe_3$ in solution by NMR analysis. Interestingly, these adducts were evidenced as precursors of chemical reactions with the evolution of methane and production of metal clusters with bridging aluminium atoms.[5] On the other hand, the existence of a direct metal–aluminum bond was not corroborated by

the X-ray analysis.[6] The Cp_2WH_2–$AlMe_3$ Lewis adduct structure was compared with the free Cp_2MoH_2 neutron diffraction structure.[7] From this study, the acid–base interaction led to a reduction of the H–W–H angle and (possibly) loss of symmetry in the two W–H bond distances. Furthermore, the metal–aluminum distance was considered too long for a direct donation from the transition metal. On this basis, hydride ligands were considered as bridging donors in a $Cp_2W(\mu\text{–}H)_2AlMe_3$ dinuclear complex. A different conclusion was proposed for the adduct between $Cp^*(PMe_3)IrH_2$ ($Cp^* = \eta^5$-pentametylcyclopentadienyl) and $AlPh_3$.[8] In this case, the H–Ir–H angle widened in comparison to the free complex and the Ir–Al distance was reported as much shorter than the W–Al one (2.68 vs. 3.11 Å, respectively). As for Cp_2WH_2, the Lewis adduct is the starting step for further (rather slow) reactions leading to metal clusters.

More recently, the existence of the Cp_2WH_2–BF_3 adduct has been excluded on the basis of the work of Braunschweig and Wagner.[9] The ionic solid $[Cp_2WH_3][BF_4]$ has been recognised by NMR analysis as the reaction product rather than the insoluble compound described by Shriver[1] and Johnson and Shriver.[2] In these same papers, a similar conclusion has been claimed for the reaction between Cp_2WH_2 and BCl_3 (the salt $[Cp_2WH_3][BCl_4]$). The scarce likelihood of the Lewis adducts proposed by Shriver[1,2] was successively stressed by Braunschweig[10] and Braunschweig and Colling[11] in review works and, to our knowledge, has never been more deeply investigated to date.

A comparison of the works of Shriver[1] and co-worker[2] and Braunschweig and co-workers[9–11] pushes us to think that different products have been obtained by these two authors. Shriver[1] and co-worker[2] reported that their compounds were insoluble in common solvents, so that no NMR analysis was possible. This fact does not agree with Braunschweig and his co-workers'[9–11] observations, whose compounds were soluble. Johnson and Shriver[2] reported a dark-yellow adduct, Cp_2WH_2–BF_3, and a yellow adduct, Cp_2WH_2–BCl_3. Braunschweig and co-workers[9–11] reported colourless solids. Charge-transfer bands in the visible region are indicative of adduct formation between Cp_2MH_2 (M = W and Mo) and several olefins.[12] Furthermore, Shriver[1] and co-worker[2] excluded the formation of $[Cp_2MH_3]^+$ ions on the basis of their supposed different IR behaviour. Braunschweig and co-workers[9–11] reported a Cp_2WH_2–BF_3 W–H stretching frequency, which is blue-shifted by more than 30 cm^{-1} in comparison to the one by Shriver[1] and co-worker.[2] These facts would suggest that Shriver[1] and co-worker[2] were able to quench the reaction at the stage of the Lewis adduct, whereas Braunschweig and co-workers[9–11] reported what evolved from this initial stage.

In this paper, we present a comparative study on Lewis adducts between Cp_2MH_2 (M = Mo, W) and group 13 acids BX_3 (X = F and Cl) and $AlMe_3$. Computational techniques have been primarily tested on the well-characterized Cp_2WH_2–$AlMe_3$ adduct[4,6] with the further aim to verify the stability of the adducts with boron halogenides. Furthermore, a computational description of the bond between complex and acid fragments has been directed to quantify the direct metal–aluminium or metal–boron interactions. IR spectrum has been computed to verify if the M–H stretching band can be considered a valuable tool for identifying bridging hydrides. An attempt to reconcile Shriver[1] and co-worker's[2] and Braunschweig and co-workers'[9–11] reports is proposed.

Methods

Density functional theory (DFT) calculations have been performed with the ADF2007[13] and Gaussian03[14] packages. The fragment-oriented approach of the ADF2007[13] program was particularly useful in this work. Furthermore, the ADF2007[13] program allowed us to consider relativistic effects by means of the ZORA (zero order regular approximation) approach.[15] This variationally stable scheme is based on a regular-potential expansion and produces a Hamiltonian that in zeroth order reproduces all important relativistic effects including the spin–orbit interaction.

A valence triple-zeta STO (Slater-type orbital) basis set with one polarization function (ZORA/TZP (triple-ζ plus polarization) without frozen cores) has been used for the relativistic calculations. Gradient-corrected exchange-correlation (XC) functionals have been used: the 1988 Becke[16] functional for the exchange and the 1986 Perdew[17] functional for the correlation. The local part of the XC functionals has been the default VWN (Vosko, Wilk, and Nusair[18]). The integrals accuracy has been increased to 10^{-8} (keyword "INTEGRATION 8.0") and the self-consistent field (SCF) convergence criterium has been set to 10^{-9} (keyword "SCF", subkey "converge 1e–9"). The structures have been optimized without using symmetry constraints and applying default convergence criteria apart from the maximum gradient, which has been set to 1.0×10^{-4} hartree/bohr. Delocalized coordinates have been used ("delocal" option). Similar levels of approximation have been shown to be reliable in analogue computations performed for 15th and 16th group complexes with ICF_3.[19]

Analytical computation of the Hessian (the matrix containing the energy second-derivatives with respect to the cartesian coordinates) has been performed to confirm the nature of minima of the found stationary points.

The interaction between the acid and base fragments have been analyzed by using the fragment analysis proposed by Ziegler and Rauk,[20] as better detailed in the Acid–base interaction section.

The Gaussian03[14] computations have been performed by using the hybrid XC functional of Adamo and Barone[21] known as MPW1PW91. Geometry optimizations were performed by applying the Stuttgart–Dresden ECP (effective core potentials) and basis set[22] ("SDD" keyword) on Mo and W atoms, and the 6-31G(d,p) basis set[23] on C, B, Al, F, and H atoms. Default gradient and displacement thresholds were used for the geometry optimization convergence criteria. All the reported geometries are relative minima of the potential energy surface (electronic energy in the Born–Oppenheimer approximation), as confirmed by the analytical computation of the Hessian matrix at the same level of approximation.

In the rest of the paper, "ADF computations" refers to the ZORA-based methods detailed above, whereas "Gaussian computations" refers to the MPW1PW91-based computations.

The AIM (atoms in molecules)-based study (see the AIM analysis section) has been performed on the electron density produced by ADF computations. The Xaim[24] program

Results and discussion

Structures

Table 1 lists the acid–base adducts of this paper and relative relevant geometric parameters resulting from geometry optimizations and literature experimental works.

All the computed adducts show an asymmetric disposition of the acid moiety relative to the MH_2 fragment. As shown in Fig. 1, this asymmetry is particularly evident for the boron halogenide adducts, where the boron atom clearly points toward one hydride and is external to the WH_2 group.

In Cp_2WH_2–$Al(CH_3)_3$, the aluminium centre is closer to one of the hydride atoms, but now it is internal to the WH_2 group and appears not too far from the second hydride atom to exclude some interaction with it (see the following paragraph for details). This description is in line with the reported X-ray structure,[6] whose parameters are listed in Table 1. Because of the asymmetric disposition of the aluminium atom, the two W–H distances are different. As expected, the H1 hydride (the one closer to the acid centre shown in Fig. 1) is farther from the central transition metal, possibly due to higher charge donation toward the acid. As a consequence, the second hydride ligand slightly approaches the central transition metal. A comparison of computed and experimental hydride–aluminium distances would suggest that the computations overestimate the asymmetric character

of the hydride–aluminium interactions. However, the use of W–H distances would lead to the opposite conclusion. Furthermore, the experimental W–H2 distance of 1.22(17) Å, although subject to a higher measure error, appears particularly poorly reproduced by the computations, especially if we consider that the computed W–H1 and Al–H1 distances are in the experimental error and that the W–Al distance inaccuracy amounts to less than 4%. Indeed, the possibility to apply X-ray analysis to accurately determine the hydride positions in this class of complexes has been questioned.[7] The fact that the more reliable neutron diffraction data are in good agreement with the computations (Cp_2MoH_2 as a free complex in Table 1) seems to suggest that the reported position of H2 (the closest to the central metal) in Cp_2WH_2–$Al(CH_3)_3$ is not accurate. As a consequence, the H–W–H angle also appears neatly overestimated by our computations in this compound, but not in the W and Mo free complexes obtained by gas-phase microwave spectroscopy[27] and neutron diffraction data,[7] respectively.

The possible error on the experimental measure of the H–W–H angle could have important implications. In fact, as said above, the presence of a direct metal–acid interaction has been excluded for Cp_2WH_2–$Al(CH_3)_3$ on the basis of H–W–H angle reduction induced by adduct formation.[6] In truth, the authors compared the reported H–Mo–H angle of the free Cp_2MoH_2 complex with the H–W–H angle in the adduct (both in Table 1) because no experimental structures of free Cp_2WH_2 have been previously reported. Contrarily, our computations describe a 6.0° angle opening from ADF computations and 6.1° from Gaussian computations on passing from the free Cp_2WH_2 to the acid–base adduct. An identical change is predicted for the Mo complex with $Al(CH_3)_3$ in the case of ADF computations (6.6° from Gaussian computations). In all the adducts with BF_3 and BCl_3, we noted lower changes in the H–M–H angle in comparison to the free complexes (both Mo and W complexes). Furthermore, the angle closes in all the cases, apart from Cp_2MoH_2–BF_3 where it opens slightly (1.7° from ADF computations). From above, if we base our study only on a structural analysis, we would conclude that in the case of $Al(CH_3)_3$ a certain metal–acid direct interaction is present, which induces the Al centre to lay internally to the MH_2 group. BF_3 and BCl_3, in contrast, do not seem to be able to significantly interact with the transition metal. In the following paragraph we will deeply discuss this point.

A final point to be discussed is the computational evaluation of the energy barrier associated with the acid fragment jump from one hydride atom to the other one. It has been computed that such a barrier amounts to 3.1 kcal/mol in Cp_2WH_2–BF_3 and 2.7 kcal/mol in Cp_2WH_2–$Al(CH_3)_3$ (Gaussian computations). Such values suggest a very fast exchange of the acid fragment between the two hydride atoms. Proton NMR spectra of Cp_2WH_2–$Al(CH_3)_3$ shows a single peak associated with the WH_2 group[4] possibly for this reason. We think that a similar behaviour is to be expected for boron halogenide adducts in solution at room temperature.

Acid–base interaction

Table 2 collects computed data about the complex–acid interaction. The whole energy variation from free relaxed fragments to the adduct (ΔE_{TOT} or formation energy) has been decomposed as

$$\Delta E_{TOT} = \Delta E_{def} + \Delta E_{bond}$$

where ΔE_{def} is the energy change from relaxed (free) fragments to fragments in the distorted structure assumed in the acid–base adduct. This term is always positive and it is reported for both the acid and base fragments in Table 2. The ΔE_{bond} is the negative energy term due to both steric interaction of the fragments in the adduct, which includes electrostatic interaction, and the charge transfer from one fragment to the other one (covalence). In the case of ADF computations, the two contributions are computed according to the Ziegler–Rauk's decomposition scheme[20] and have been written as

$$\Delta E_{bond} = \Delta E_s + \Delta E_o$$

where ΔE_S and ΔE_o are the steric term (sum of Pauli repulsion and electrostatic interaction) and the orbital term (charge donation from the base to the acid), respectively.

From Table 2, it is possible to note that none of the adducts seem particularly stable in comparison to its free fragments, although all the adduct formation energies are negative. In all the reported syntheses of the studied adducts,[2,4] a solid separation from solution has been used to obtain the compound. On this basis, we can suggest that a relevant part of the favourable Gibbs reaction energy could be associated with the crystallization process. However, returning to the computational study, we can note that the most stable adducts have been obtained with boron halogenides rather than $Al(CH_3)_3$. This fact is mainly due to lower charge donation, as evidenced by the lower ΔE_o term and the consequently lower ΔE_{bond} (Table 2). On the other hand, the neatly more stabilizing ΔE_o terms in boron halogenides are counterbalanced by higher steric repulsions, which reduce the adduct stability gap with $Al(CH_3)_3$ adducts.

Table 2. Interaction energies from ADF computations. The deformation energy of $Al(CH_3)_3$ is computed on relaxed dimeric $Al_2(CH_3)_6$.

Compound	ΔE_{def} [a]	ΔE_{bond} [a]	ΔE_{TOT} [a]
Cp_2WH_2–$Al(CH_3)_3$	$Al(CH_3)_3$: 14.9	ΔE_S = +10.7	–2.4
	Cp_2WH_2: 1.0	ΔE_o = –29.0	–2.4
	Total: 15.9	ΔE_{bond} = –18.3	–2.4
Cp_2WH_2–BF_3	BF_3: 17.4	ΔE_S = +30.1	–4.2
	Cp_2WH_2: 1.6	ΔE_o = –53.3	–4.2
	Total: 19.0	ΔE_{bond} = –23.3	–4.2
Cp_2WH_2–BCl_3	BCl_3: 20.9	ΔE_S = +58.4	–2.6
	Cp_2WH_2: 4.4	ΔE_o = –86.4	–2.6
	Total: 25.4	ΔE_{bond} = –28.0	–2.6
Cp_2MoH_2–$Al(CH_3)_3$	$Al(CH_3)_3$: 15.0	ΔE_S = +11.7	–2.2
	Cp_2MoH_2: 1.2	ΔE_o = –30.1	–2.2
	Total: 16.2	ΔE_{bond} = –18.4	–2.2
Cp_2MoH_2–BF_{3l}	BF_3: 21.6	ΔE_S = +36.8	–4.2
	Cp_2MoH_2: 2.2	ΔEo = –64.9	–4.2
	Total: 23.8	ΔE_{bond} = –28.1	–4.2
Cp_2MoH_2–BCl_3	BCl_3: 22.0	ΔE_S = +61.4	–4.3
	Cp_2MoH_2: 5.2	ΔE_o = –92.9	–4.3

[a]Electronic energy in the Born–Oppenheimer approximation (kcal/mol).

Table 3. Computed Hirshfeld[28] charges of the acid fragment in each studied compound.

Compound	Charge (e)[a]
Cp_2WH_2–$Al(CH_3)_3$	–0.140
Cp_2WH_2–BF_3	–0.204
Cp_2WH_2–BCl_3	–0.321
Cp_2MoH_2–$Al(CH_3)_3$	–0.138
Cp_2MoH_2–BF_3	–0.231
Cp_2MoH_2–BCl_3	–0.337

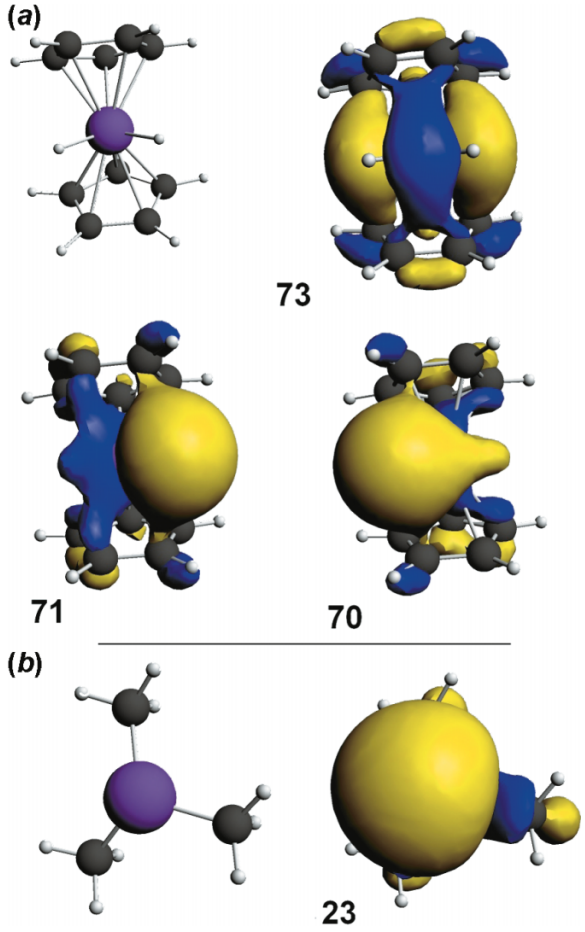
[a]ADF computations.

The lower charge donation in $Al(CH_3)_3$ adducts is evidenced by the more positive fragment charge computed on the basis of Hirshfeld's method[28] and listed in Table 3. In Cp_2WH_2–$Al(CH_3)_3$ and Cp_2MoH_2–$Al(CH_3)_3$ the acid fragment charge is clearly more positive in comparison to BF_3 and BCl_3 adducts. BCl_3 is able to accept more electronic charge than BF_3.

In all the studied compounds, the acid fragment is able to receive electronic charge by using its LUMO (lowest-in-energy unoccupied molecular orbital). Figure 2 shows the $Al(CH_3)_3$ fragment LUMO in Cp_2MoH_2–$Al(CH_3)_3$. It is labelled as 21 (because 20 orbitals are doubly occupied in the free fragment), and, not surprisingly, it is an empty sp^3-like orbital (according to ADF computations, p-type orbitals contribute a 69.5% weight with s-type orbitals for the remaining part). Its gross population in the adduct amounts to 0.23 e (e = electron charge) and no other virtual orbitals seem to be interested by charge donation (gross population lower than 0.01 e). Interestingly, the acceptor orbital mainly receives charge from three Cp_2WH_2 fragment orbitals (Fig. 2*a*). Orbital 73 is the HOMO (highest occupied molecular orbital) in the free complex. In agreement with previous computational studies about bent metallocenes,[29] it is a metal localized d-type orbital whose gross population is reduced to 1.95 e due to adduct formation. Orbitals 71 and 70 are mainly localized on the hydride ligands. They are more effective in donating charge toward the acid fragment. Orbital 71 is localized on the hydride atom, which is closer to the aluminium centre (H1 in Fig. 1). Its gross population in the adduct is 1.87 e, lower than orbital 70 (1.94 e), which is mostly localized on the farther hydride atom (H2). We can conclude that the base behaviour of Cp_2WH_2 is mainly due to the hydride ligands, particularly the hydride atom closer to the aluminium centre. However, the central metal is able to donate charge. This fact can be associated with the previously discussed H–W–H angle opening (Table 1) in comparison to the free complex.

In Cp_2MoH_2–BF_3, we find again that the LUMO fragment orbital on BF_3 is the principal acceptor orbital of the charge transfer process. It is similar, in terms of shape, to orbital 23 of Fig. 2. In this case, the stronger covalent interaction is reflected by a higher gross population of this orbital, which now amounts to 0.43 e. In spite of this fact, however, in this adduct only the hydride ligands are able to donate. The complex fragment orbital 73 (still the HOMO in the free complex) now maintains the 2.00 e gross population in the adduct and no other metal-localized orbitals are involved in charge donation. Thus, the central metal Lewis behaviour is not present in this complex. This implies that the H–W–H angle is less affected by adduct formation in comparison to Cp_2MoH_2–$Al(CH_3)_3$. Hydride-localized orbitals (very similar to orbitals 70 and 71 in Fig. 2*a*) are the main ones responsible for charge donation.

Fig. 2. Relevant fragment orbitals in the charge donation process of Cp_2WH_2–$Al(CH_3)_3$. (*a*) The most important Cp_2WH_2 donor orbitals and (*b*) the main $Al(CH_3)_3$ acceptor orbital are reported.



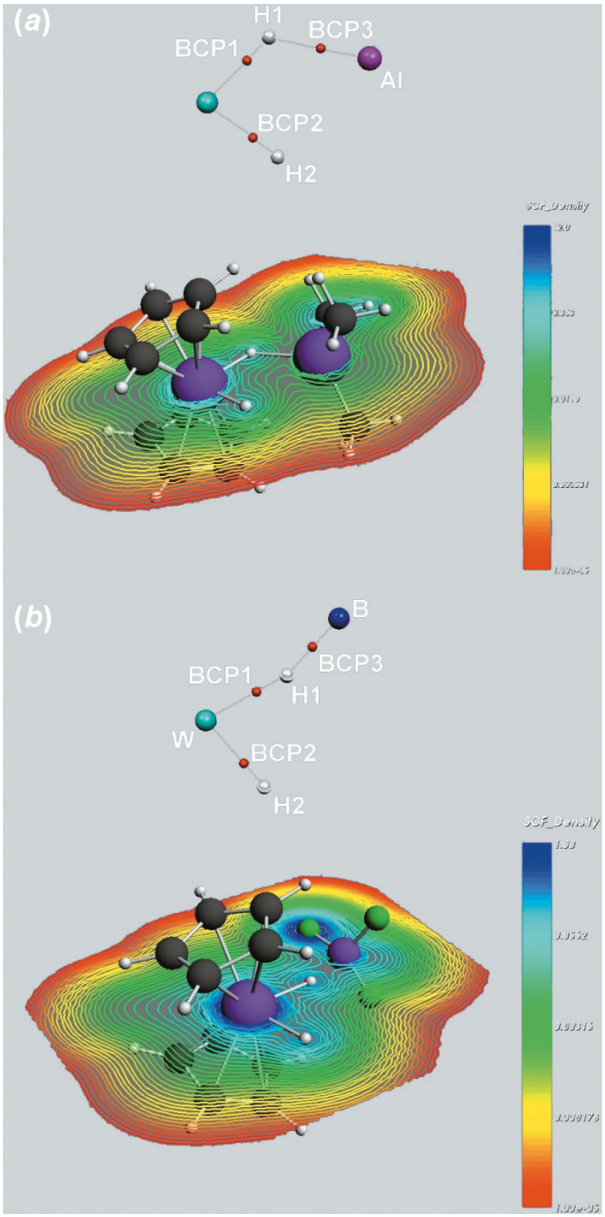
The same conclusions can be applied to Cp_2WH_2–BCl_3. In this case, however, we evidence a higher charge donation toward the sp^3-like acid fragment LUMO (0.63 e gross population). This is in line with the more negative Hirshfeld charge of BCl_3 in the acid–base adduct (Table 3) and higher ΔE_o in Table 2. Donation from the central metal can also be excluded in this case.

In the case of Mo complexes, we have substantially comparable results. Boron halogenide adducts are characterized by somewhat higher charge donations as evidenced in Table 2 (more negative ΔE_o) and Table 3 (more negative charges). The $Al(CH_3)_3$ adduct characteristics are in line with the W complex. In this case, a direct donation from the central metal is present. The Cp_2MoH_2 fragment HOMO donates a 0.04 e charge and the H–Mo–H angle opens by 6° (ADF computations) by virtue of adduct formation as in Cp_2WH_2.

AIM analysis

According to the AIM (atoms in molecules) model, it is possible to define an atom inside a molecule and recognize connections between them (bond paths) from the analysis of

Fig. 3. Bond critical points (BCPs) describing the metal–hydride and hydride–acid interactions and cut plane level curves of the electron density in (*a*) Cp_2WH_2–$Al(CH_3)_3$ and (*b*) Cp_2WH_2–BF_3. The plane is defined by the WH_2 group. A logarithmic scale has been used.



the electron density (ρ) and its gradient field (▽ρ).[30] From the detection of bond critical points (BCPs) as the points where ▽ρ vanishes, and from the determination of the eigenvalues of the electron density Hessian (second derivatives matrix of ρ) in the BCPs, it is possible to recover the bond patterns within a system of interacting particles defined, according to this view, as atoms in a molecule.

This approach has given interesting results in molecules and in the description of supramolecular systems generated by low intensity interactions as in the case of van der Walls and hydrogen bonds[31] and in the case of halogen bonds.[32]

Organometallic compounds, in particular π-acid–metal complexes, frequently show unusual interaction schemes that are difficult to describe in terms of elementary bond theories. We believe that the AIM approach can also be a useful tool in discussing the bond pattern in the case we are examining and can help to shed some light on what the bond pattern is in the case of these molecules.

Table 4. Characterization of the bond critical points (BCPs) from the AIM study. See Fig. 3 for the definition of the three BCPs. The electron density (ρ) has bee computed by the ADF program (see the Methods section).

[a]Electron density.
[b]Lapacian of the electron density.
[c]Eigenvalues of the electron density Hessian matrix.
[d]Ellipticity.

The cut plane plots of the Cp_2WH_2–$Al(CH_3)_3$ and Cp_2WH_2–BF_3 ρ are reported in Fig. 3 (the cut plane contains the WH_2 group). Figure 3 also shows a plot of the same molecules where (3, –1) critical points (two negative eigenvalues of the electron density Hessian) are indicated by red dots (BCP in Fig. 3). Table 4 collects information about the found BCPs. No (3, –1) critical points are present between Al (or B) and W atoms, a fact that seems to exclude direct transition-metal – acid interaction. Furthermore, no (3, –1) BCPs can be located between H2 (the farther atom) and acid centre. Similar results have been found in the case of BCl_3 complexes (both W and Mo ones).

This suggests that the studied acid–base adducts can be seen as μ-hydrido complexes and not as μ-dihydrogen ones. This view is further supported by the absence of (3, +1) ring critical points (two positive eigenvalues of the electron density Hessian) inside the W–H1–Al–H2 ring (and in the cases of a boron acid centre) as required by the Poincaré–Hopf's relation.[33]

IR spectra

IR spectra represented the principal tool used by Johnson and Shriver[2] to demonstrate that boron halogenides accept charge directly from the transition metal without relevant contributions from the hydride ligands. A similar approach with similar conclusions has been used for Cp_2MH_2–AlR_3 adducts,[4] but successive X-ray investigations demonstrated that, in the last adduct, the aluminium centre mostly interacts with the hydride ligands,[7] as confirmed by our computational work.

The IR suggestion was based on the substantial invariance of the W–H stretching band frequency passing from the free complex to the acid–base adducts.

Table 5 contains experimental data about the W–H stretching frequencies collected in different environments and the computational results from our work. The reported computed frequencies have not been scaled. We can note a much better agreement between ADF computations and experimental data in Cp_2MoH_2 and Cp_2WH_2 free complexes. From our computations, two bands with similar intensity are predicted, which are the asymmetric and symmetric stretching modes. The lowest frequency is always associated with the asymmetric stretching. In all the experimental works, a single band is reported, allowing us to think that the two computed bands merge or that the computed intensities are not reliable.

When the acid–base adducts are considered, our computations predict relatively low influences on the W–H stretching frequency due to adduct formation with $Al(CH_3)_2$. This seems particularly evident in the case of the Mo complex, where the computed most intense band shifts of 10 cm^{-1}, in agreement with the reported, scarce change due to adduct formation.[4] Also, BF_3 is described to have a low influence on the stretching frequency in the case of the W complex, in agreement with the data reported by Johnson and Shriver.[2] In contrast, when Mo complexes are considered, BF_3 is computed to induce a very strong shift, which does not seem to be justified by experimental data. A relatively large error is associated with the BCl_3 adduct with Cp_2WH_2.

The fact that the free complexes are much better described than the acid–base adducts can be explained on the basis of the scarce directionality of the acid–base interaction. As said above, the acid fragment is predicted to easily jump from the hydride ligand to the other one. In truth, the energy surface associated with the movement of the acid fragment appears flat. In our study, we have noted that small changes in the acid fragment position can lead to significant changes in the W–H stretching frequency. As an example, a relative minimum in Cp_2WH_2–BF_3 is 0.5 kcal/mol higher in energy with respect to the absolute minimum that has been described in this paper (Fig. 1*b* and Fig. 3*b*). It only differs for the BF_3 group position, that is slightly internal to the WH_2 group rather than being slightly external. This small structural change leads to a blue shift of the W–H stretching frequency of more than 20 cm^{-1}. A flat energy surface means great changes in the molecular structure induced by the environment that cannot be easily modelled by computational studies and that can lead to relatively poor predictions.

However, from the above results and an analysis of the experimental data, it is hard to claim that the W–H stretching frequency is a reliable tool for distinguishing between direct metal donation and hydride donation.

Table 5. Computed M–H stretching frequencies (cm^{-1}) and intensities (in parenthesis; km/mol) of the studied complexes.

Conclusions

According to our computations, Cp_2WH_2 and Cp_2MoH_2 can act as Lewis bases mainly by virtue of their hydride ligands. BX_3 acids show a stronger preference for the coordination with a single hydride ligand, a fact that excludes direct metal donation toward the acid centre. In this light, the supposed direct metal–boron interaction does not seem to be likely. In the case of $Al(CH_3)_3$ adducts, the central metal shows a significant ability to donate charge to the aluminum centre. This fact leads to a more central, although still asymmetric, disposition of the aluminium atom with respect to the WH_2 group.

Two criteria have been suggested to evaluate the entity of the charge donation from the central transition metal. The first one is the H–M–H angle, which should widen when such a charge donation occurs. The second one is the W–H stretching frequencies, which should be unaffected by adduct formation when the central metal is the only one responsible for the Lewis behaviour.

The first criterion is confirmed by our computations. The relatively low metal charge donation in Cp_2MH_2–$Al(CH_3)_3$ adducts induces an angle opening of about 6°, which has not been observed in the case of the BX_3 acid fragments.

The second criterion seems less reliable and does not seem to be confirmed by our computations. A possible explanation could be the relatively high dependence of the W–H stretching frequency on the position assumed by the acid fragment and the relatively flat energy surface associated with the acid fragment movement in proximity to the WH_2 group.

According to our computations, the adducts with BX_3 are stronger than the $Al(CH_3)_3$ ones. In this light, since the last ones have been isolated and characterized, we cannot exclude the existence of Cp_2MH_2–BX_3 adducts, at least as precursors of successive reactions. The fact that Braunschweig and co-workers[9–11] excluded the presence of these adducts could be induced by slight changes in the reaction conditions in comparison to the Shriver[1] and co-worker's[2] experiments. These could lead to further reactions. For instance, the presence of water could catalyze further reactions toward the $[Cp_2WH_3][BX_4]$ ionic solid obtained by Braunschweig and co-workers.[9–11] According to us, further experimental investigations could be fruitfully addressed in this field, with the aim to confirm or confute the existence of the Shriver[1] and co-worker's[2] adducts.

Theoretical prediction of O–H, Si–H, and Si–C σ-bond activation reactions by titanium(IV)–imido complex

Noriaki Ochi, Yoshihide Nakao, Hirofumi Sato, and Shigeyoshi Sakaki

Abstract: The O–H σ-bond activation of methanol, the Si–H σ-bond activation of silane, and the Si–C σ-bond activation of methylsilane by titanium(IV)–imido complex $(Me_3SiO)_2Ti(NSiMe_3)$ were theoretically investigated with DFT and MP2 to MP4(SDQ) methods. The O–H σ-bond activation of methanol occurs with small activation barrier (E_a) of 7.1 (14.6) kcal/mol and large exothermicity (E_{exo}) of 65.8 (61.4) kcal/mol to afford $(Me_3SiO)_2Ti(OCH_3)[NH(SiMe_3)]$, indicating that the O–H σ-bond activation occurs easier than the C–H σ-bond activation (E_a = 14.6 (21.5) kcal/mol and E_{exo} = 22.7 (16.5) kcal/mol), where DFT- and MP4(SDQ)-calculated values are presented without and in parenthesis hereafter. Though the OCH_3 group becomes anionic and the H atom becomes proton-like in this activation reaction, population changes more moderately occur than those of the C–H σ-bond activation. This is because the H–OCH_3 bond is already polarized in methanol. In the Si–H σ-bond activation, two reaction courses were investigated; in one course, the product is $(Me_3SiO)_2Ti(SiH_3)[NH(SiMe_3)]$ in which the H atom and the SiH_3 group are bound to the N atom and the Ti center, respectively, while in the other course the product is $(Me_3SiO)_2Ti(H)[N(SiH_3)(SiMe_3)]$ in which the H atom and the SiH_3 group are bound to the Ti center and the imido N atom, respectively. Though the former reaction occurs with small E_a value and large exothermicity, the latter reaction occurs easier with further smaller E_a value of 2.6 (4.3) kcal/mol and larger E_{exo} value of 32.5 (34.1) kcal/mol than those of the former reaction. This is because the Ti–H bond energy is much larger than the Ti–SiH_3 one. The Si–C σ-bond activation occurs with moderate activation barrier of 19.1 (18.6) kcal/mol and considerably large exothermicity of 33.9 (37.7) kcal/mol. Based on these results, we wish to propose the theoretical prediction that the titanium(IV)–imido complex is useful for O–H, Si–H, and Si–C σ-bond activation reactions.

Key words: σ-bond activation, titanium(IV)–imido complex, heterolytic σ-bond activation, density functional theory (DFT), bond energy.

Résumé : Faisant appel aux méthode de la théorie de la fonctionnelle de la densité (TFD) et aux méthodes MP2 et MP4(SDQ), on a étudié d'une façon théorique l'activation de la liaison σ du O–H du méthanol, lactivation de la liaison σ du Si–H du silane et l'activation de la liaison σ Si–C du méthylsilane par le complexe titane(IV)–imido $(Me_3Si)_2Ti(NSiMe_3)$. L'activation de la liaison σ du OH du méthanol donne lieu à une faible barrière d'activation (E_a) de 7,1 (14,6) kcal/mol et une grande exothermicité (E_{exo}) de 65,8 (61,4) kcal/mol qui conduit à la formation de $(Me_3Si)_2Ti(OCH_3)[NH(SiMe_3)]$ indiquant que l'activation de la liaison σ du O–H se produit plus facilement que celle de la liaison σ C–H [(E_a) de 14,6 (21,5) kcal/mol et (E_{exo}) de 22,7 (16,5) kcal/mol] dans lesquelles les valeurs obtenues par la méthode TFD sont rapportées sans parenthèses alors que celles calculées par la méthode MP4(SDQ) sont rapportées entre parenthèses. Même si le groupe OCH_3 devient ionique et que l'atome H prend une forme semblable à celle d'un proton dans cette réaction d'activation, les changements de population sont plus modérés que ceux observés lors de l'activation σ de la liaison C–H. Ceci résulte du fait que la liaison H–OCH_3 est déjà polarisée dans le méthanol. Dans la réaction d'activation σ de la liaison Si–H, on a étudié deux voies réactionnelles; dans l'une, le produit est $(Me_3Si)_2Ti(SiH_3)[NH(SiMe_3)]$ dans lequel l'atome H et le groupe SiH_3 sont liés respectivement à l'atome N et au centre Ti alors que dans l'autre voie réactionnelle le produit est $(Me_3Si)_2Ti(H)[NH(SiCH_3)(SiMe_3)]$ dans lequel l'atome H et le groupe SiH_3 sont liés respectivement au centre Ti et à l'atome N imido. Même si la première réaction se produit avec une valeur de E_a faible et une grande exothermicité, la dernière réaction se produit plus facilement avec une valeur de E_a encore plus faible 2,6 (4,3) kcal/mol et une valeur de E_{exo} plus élevée de 32,5 (34,1) kcal/mol que celle de la réaction précédente. Ceci résulte du fait que l'énergie de liaison du Ti–H est beaucoup plus élevée que celle de la liaison Ti–SiH_3. L'activation σ de la liaison Si–C se produit avec une barrière d'activation modérée de 19,1 (18,6) kcal/mol et une exothermicité beaucoup plus élevée de 33,9 (37,7) kcal/mol. Sur la base de ces résultats, on désire proposer une prédiction théorique que le complexe titane(IV)–imido $(Me_3Si)_2Ti(NSiMe_3)$ s'avérera utile pour l'activation des liaisons σ O–H, Si–H et Si–C.

Introduction

The σ-bond activation of a saturated molecule by a transition-metal complex is one of the important reactions in organometallic chemistry, inorganic chemistry, and catalytic chemistry, because active species is produced by this reaction in many cases.[1] There are several categories of σ-bond activation: (*i*) The first is the σ-bond activation via oxidative addition reaction by late transition-metal complexes. This reaction has been theoretically investigated well by many groups.[2–15] (*ii*) The second is the σ-bond activation via metathesis by lanthanide and actinide complexes, which was theoretically investigated by Eisenstein and her coworkers.[16] (*iii*) The third is the σ-bond activation by metal–ligand single bond such as the platinum(II)–chloride, palladium(II)–acetate, and iridium(III)–acetate bonds,[17–19] which were theoretically investigated by Siegbahn et al.,[20] Sakaki et al.,[21] Ziegler et al.,[22] Goddard et al.,[23] and Schwarz et al.[24] (*iv*) The last is the σ-bond activation via addition of C–H σ-bond across M=N multiple bond by early to middle transition-metal complexes.[25] This σ-bond activation was theoretically investigated by Cundari and his collaborators in the last decade.[26] Recently, the C–H σ-bond activation of benzene by the titanium(IV)–alkylidyne complex was experimentally succeeded and theoretically investigated with the DFT method by Mindiola group.[27] We also theoretically investigated the C–H σ-bond activation of methane by the titanium(IV)–imido complex recently, and clearly showed that not only the charge transfer (CT) from the Ti=N moiety to the σ*-anti-bonding orbital but also the reverse CT from the C–H σ-bonding orbital to the Ti empty d orbital plays important role in this σ-bond activation.[28]

In our previous work,[28] we presented theoretical prediction that N–H σ-bond activation of ammonia can be achieved by the titatnium(IV)–imido and titanium(IV)–alkylidyne complexes. Though one successful N–H σ-bond activation of ammonia has been reported recently,[29] it is still difficult. Considering that the titanium(IV)–imido complex is useful for the C–H and N–H σ-bond activations, one can expect that this complex can be also applied to other σ-bond activations of O–H, Si–H, and Si–C bonds. Because the O–H bond is strong like the N–H bond, its activation is interesting. Also, the Si–H σ-bond activation is important because it is involved in many catalytic reactions producing organosilicon compounds. The Si–C σ-bond activation is challenging, because it is difficult as well-known.

In this theoretical work, we investigated the O–H σ-bond activation of methanol, the Si–H σ-bond activation of silane, and the Si–C σ-bond activation of methylsilane with titanium(IV)–imido complex, $(Me_3SiO)_2Ti(NSiMe_3)$, by DFT and MP2 to MP4(SDQ) methods. This complex was used for many experimental works by Wolczanski group.[25] Our purposes here are to show the differences of the O–H, Si–H, and Si–C σ-bond activations from the C–H σ-bond activation, to present theoretical prediction if the titanium(IV)–imido complex can be utilized for these σ-bond activations, and to clarify what factor is important in these σ-bond activations.

Computational details

Geometries were optimized by the DFT method with the B3LYP functional.[30–32] We ascertained that each equilibrium geometry has no imaginary frequency and each transition state has only one imaginary frequency. Two kinds of basis set systems were used. The smaller system (BS1) was used for geometry optimization. In this BS1, core electrons of Ti (up to 2p) were replaced with effective core potentials (ECPs),[33] and their valence electrons were represented with (311111/2111/411/1) basis set.[33] For H, C, N, O, and Si, 6–31G* basis sets[34] were employed, where a p-polarization function[35] was added to the active H atom that reacts with the Ti complex to form either Ti–H or N–H bond. The better basis set system (BS2) was used for evaluation of energy changes. In this BS2, (311111/2111/411/11) basis set was employed for Ti,[33,36] where the same ECPs as those of BS1 were employed for core electrons. For H, C, N, O, and Si, the 6–311G* basis sets were employed,[37–39] where a p-polarization function was added to the active H atom and a diffuse function was added to the imido N atom. Zero-point energy was evaluated with the DFT/BS1 method under assumption of harmonic oscillator. The energy changes are presented here after correction of zero-point energy.

The Gaussian 03 program package[40] was used for all calculations. Population analysis was carried out with the method of Weinhold and co-workers.[41] Molecular orbitals were drawn with the MOLEKEL program package.[42]

Results and discussion

Geometry and energy changes in the O–H σ-bond activation of methanol by titanium(IV)–imido complex, $[(Me_3SiO)_2Ti(NSiMe_3)]$ (R)

The O–H σ-bond activation of methanol by $(Me_3SiO)_2Ti(NSiMe_3)$ **R** occurs through precursor complex (**PC1**) and transition state (**TS1**) to afford product complex (**PRD1**), as shown in Fig. 1. The optimized geometry of **R** agrees well with the experimental one[43,44] except for the moderate discrepancies in the Ti–N and N–Si bond distances, as reported previously.[26,28] We stop to discuss the moderate discrepancies here because we presented the discussion in our recent work.[28] In **PC1**, the O atom of methanol approaches the Ti center, where the Ti–O distance is 2.109 Å, but the H atom is considerably distant from the N atom. The O–H bond little lengthens in **PC1**, which is different from the moderately elongated C–H bond in the precursor complex of the C–H σ-bond activation of methane. This difference will be discussed below in more detail. In **TS1**, the Ti–O distance becomes shorter to 2.034 Å, which is moderately longer than that of **PRD1**. The O–H distance is moderately elongated to

Fig. 1. Geometry changes in O–H σ-bond activation of methanol by $(Me_3SiO)_2Ti(NSiMe_3)$ **R**. Bond lengths are in angstroms, and bond angles are in degrees. In parenthesis is relative energy calculated by DFT(B3LYP)/BS2 method.

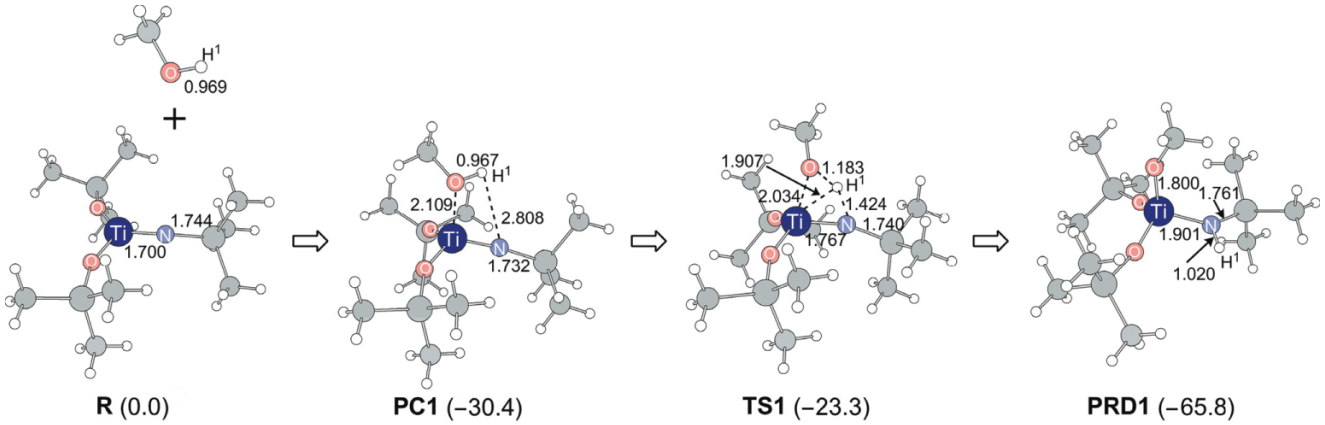

Table 1. Binding energy (BE), activation barrier (E_a), and reaction energy (ΔE) of the Si–H σ-bond activation of silane, O–H σ-bond activation of methanol, and C–Si σ-bond activation of methylsilane by $(Me_3SiO)_2Ti(NSiMe_3)$ **R** (in kcal/mol unit).

[a]BE = E(precursor complex) – E(sum of reactants).
[b]E_a = E(transition state) – E(precursor complex).
[c]ΔE = E(product) – E(sum of reactants).
[d]Reference 28.

1.183 Å, and the N–H distance (1.424 Å) is still considerably long. The moderate elongation of the O–H distance in **TS1** is in contrast to the considerable elongation of the C–H bond in the transition state of the C–H σ-bond activation of methane.[28] The product **PRD1** takes pseudo-tetrahedral structure, as expected from the d^0 electron configuration of Ti(IV).

Binding energy (BE), activation barrier (E_a), and reaction energy (ΔE) are defined as the energy differences between **PC1** and the sum of reactants, between **PC1** and **TS1**, and between **PRD1** and the sum of reactants, respectively. Negative ΔE value means that the σ-bond activation is exothermic, and vice versa. The BE value is –30.4 (–36.6) kcal/mol, as shown in Table 1, where DFT- and MP4(SDQ)-calculated values are presented without and in parenthesis hereafter, respectively. This large BE value indicates that methanol strongly coordinates with the Ti center to afford **PC1** unlike the methane complex.[28] This difference is interpreted as follows: Because methanol has the lone-pair orbital on the O atom, the charge-transfer (CT) occurs from the lone-pair orbital to the Ti empty d orbital. Also, the O atom forms considerably strong electrostatic interaction with the positively charged Ti(IV) center, because the O atom is much negatively charged. In the precursor complex of methane, the CT occurs from the C–H bonding orbital to the Ti empty d orbital like agostic interaction,[28] but the CT is weak because the C–H bonding-orbital energy is much lower than the O lone pair of CH_3OH. Because the CT occurs from the O lone pair to the Ti empty d orbital in **PC1**, the O–H σ-bonding orbital little participates in the CT, which induces little elongation of the O–H bond; remember that the C–H bond is moderately elongated in the precursor complex of the C–H σ-bond activation, because the CT occurs from the C–H bonding orbital to the Ti empty d orbital.[28] It is also noted that the DFT-calculated BE value is similar to the MP4(SDQ)-calculated one here, though the MP4(SDQ)-calculated BE value is much larger than the DFT-calculated one in the C–H σ-bond activation of methane (see Table 1). This difference would arise from the fact that van der Waals interaction, as well as the CT, also participates in the weak interaction between the C–H bond and the metal center.

In the O–H σ-bond activation, the E_a value is 7.1 (14.6) kcal/mol, which is much smaller than that of the C–H σ-bond activation of methane, as shown in Table 1. The ΔE value is much more negative than in the C–H σ-bond activation of methane. These results suggest that the titanium(IV)–imido complex can be utilized for the O–H σ-bond activation of alcohol.

Geometry and energy changes in the Si–H σ-bond activation of silane SiH_4 by titanium(IV)–imido complex, $[(Me_3SiO)_2Ti(NSiMe_3)]$ (R)

In the reaction, we need to consider two possibilities; in one reaction course (course A), the H atom and the SiH_3 group are bound to the N atom and the Ti center, respectively,

Fig. 2. Geometry changes in Si–H σ-bond activation of silane by $(Me_3SiO)_2Ti(NSiMe_3)$ **R** (reaction course A). In this reaction course, Ti–SiH_3 and N–H bonds were formed. Bond lengths are in angstroms, and bond angles are in degrees. In parenthesis is relative energy calculated by DFT(B3LYP)/BS2 method.

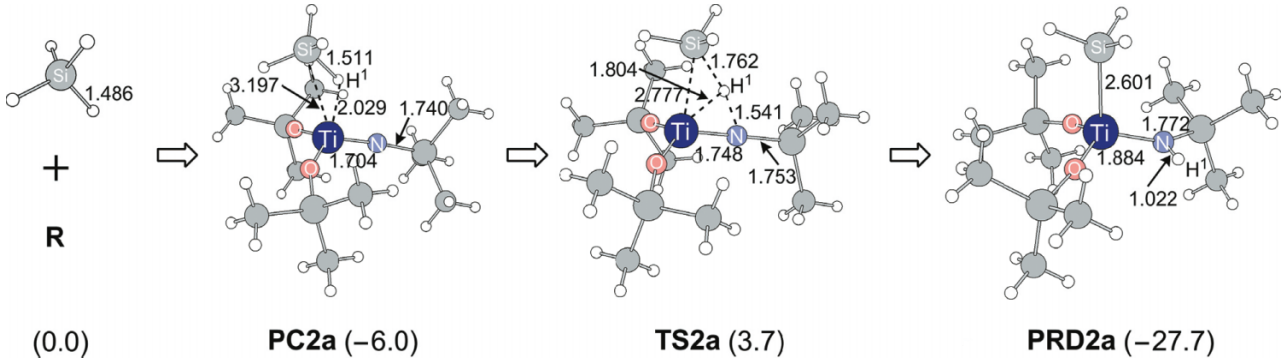

Fig. 3. Geometry changes in Si–H σ-bond activation of silane by $(Me_3SiO)_2Ti(NSiMe_3)$ **R** (reaction course B). In this reaction course, Ti–H and N–SiH_3 bonds were formed. Bond lengths are in angstroms, and bond angles are in degrees. In parenthesis is relative energy calculated by DFT(B3LYP)/BS2 method.

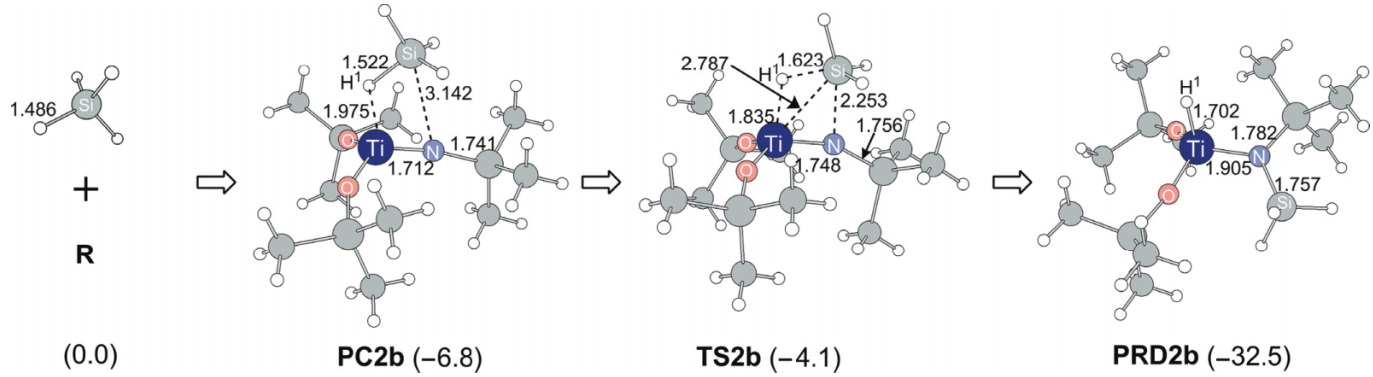
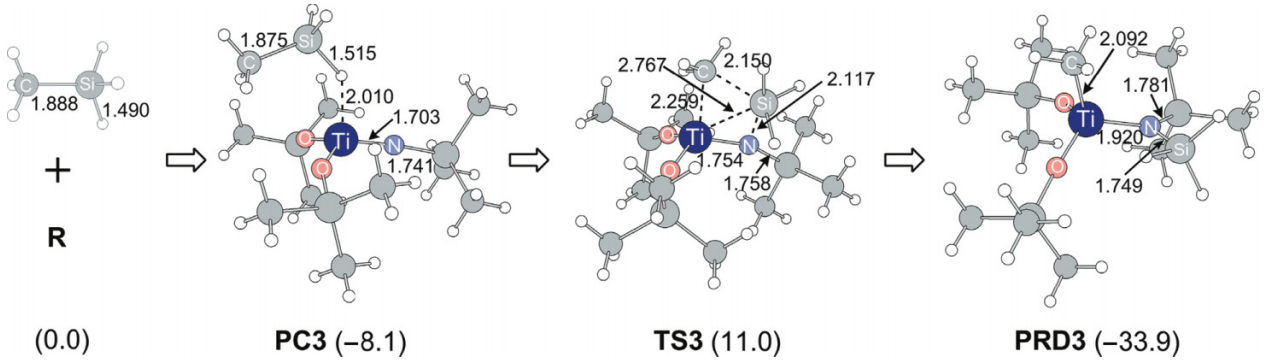


in the product like the C–H σ-bond activation, while in the other course (course B) the H atom and the SiH_3 group are bound to the Ti center and the N atom, respectively, in the product unlike the C–H σ-bond activation. The former reaction occurs through precursor complex **PC2a** and transition state **TS2a** to afford product $(Me_3SiO)_2Ti(SiH_3)[NH(SiMe_3)]$ **PRD2a**, as shown in Fig. 2. In **PC2a**, the Ti–H distance is 2.029 Å, which is shorter than that of the precursor complex in the C–H σ-bond activation of methane. Also, the Si–H distance is moderately elongated to 1.511 Å. These results indicate that the agostic interaction of the Si–H σ-bond with the Ti center more contributes to the stabilization of **PC2a** than does the C–H σ-bond. This is because the Si–H σ-bonding orbital exists at higher energy than the C–H σ-bonding orbital. In **TS2a**, the Si–H bond is moderately elongated to 1.762 Å, and the Ti–Si distance becomes shorter to 2.777 Å, which is slightly longer than that of **PRD2a**. But, the N–H distance is still long. These geometrical features indicate that **TS2a** is more reactant-like than the transition state of the C–H σ-bond activation. **PRD2a** is four-coordinate pseudo-tetrahedral titanium(IV)–alkyl amino complex, as expected.

In the course B, the precursor complex **PC2b** is formed. As shown in Fig. 3, its Si–H distance is moderately elongated to 1.522 Å like that of **PC2a**. The Ti–H distance is 1.975 Å and the Si–N distance is very long. In the transition state **TS2b**, the Si–H distance is moderately elongated to 1.623 Å, and the Ti–H and N–Si distances become shorter to 1.835 Å and 2.253 Å, respectively. The Ti–H distance is somewhat and the N–Si distance is considerably longer than those of the product $(Me_3SiO)_2Ti(H)[N(SiH_3)(SiMe_3)]$ **PRD2b**, indicating that **TS2b** is reactant-like, too. **PRD2b** is a four-coordinate titanium(IV)–hydride disilylamino complex, the geometry of which is pseudo-tetrahedral.

In the reaction course A, the BE value is –6.0 (–13.9) kcal/mol, which is somewhat larger than that of the precursor complex of the C–H σ-bond activation. This is because the CT from the Si–H σ-bonding orbital to the Ti empty d orbital is stronger than that from the C–H σ-bonding orbital to the Ti empty d orbital; remember that the Si–H σ-bonding orbital exists at higher energy than the C–H σ-bonding orbital. The E_a value is 9.7 (15.0) kcal/mol and the ΔE value is –27.7 (–26.4) kcal/mol. This E_a value is much smaller than that of the C–H σ-bond activation, but moderately larger than that of the O–H σ-bond activation. In the reaction course B, the BE value is similar to that of the course A. However, the E_a value (2.7 (4.3) kcal/mol) is much smaller and the ΔE value (–32.5 (–34.1) kcal/mol) is much more negative than those of the course A. These results clearly show that the course B is easier than the course A and the titanium(IV)–hydride disilylamino complex $(Me_3SiO)_2Ti(H)[N(SiH_3)(SiMe_3)]$ **PRD2b** is a product of the Si–H σ-bond activation. It is noted that the E_a value is much smaller than those of the C–H and O–H σ-bond activations, and that the ΔE value is much more negative than that of the C–H σ-bond activation but much less negative than that of the O–H σ-bond activation. The reasons will be discussed below in detail.

Fig. 4. Geometry changes in Si–C σ-bond activation of methylsilane by $(Me_3SiO)_2Ti(NSiMe_3)$ **R**. Bond lengths are in angstroms, and bond angles are in degrees. In parenthesis is relative energy calculated by DFT(B3LYP)/BS2 method.



Geometry and energy changes in the Si–C σ-bond activation of methylsilane SiH_3–CH_3 by titanium(IV)–imido complex, $[(Me_3SiO)_2Ti(NSiMe_3)]$ (R)

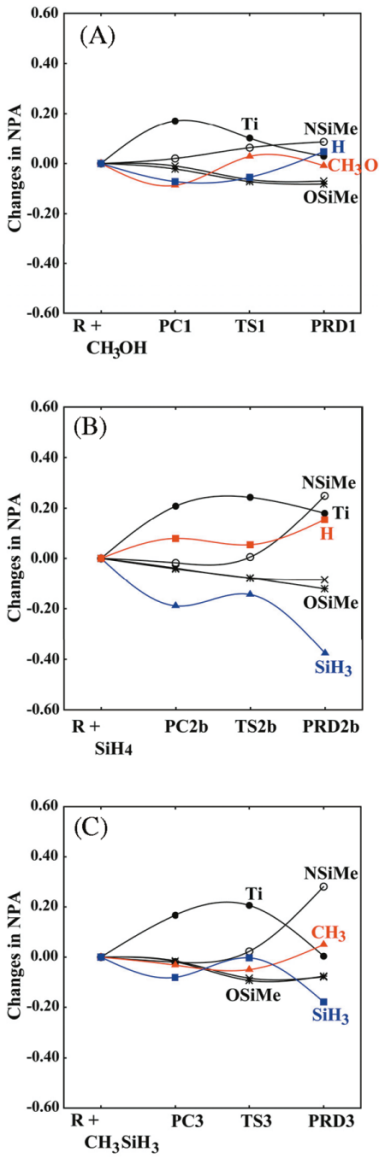
The precursor complex **PC3** is formed by the CT interaction of the Si–H σ-bond with the Ti empty d orbital like **PC2b**, as shown in Fig. 4. In the transition sate **TS3**, the Ti–C distance is 2.259 Å and the N–Si distance is 2.117 Å, which are not very much longer than those of the product **PRD3**. Also, the Si–C distance is moderately elongated to 2.150 Å. These geometrical features suggest that **TS3** is understood to be more product-like than **TS1** and **TS2b** but more reactant-like than the transition state of the C–H σ-bond activation. The product **PRD3** is a titanium(IV)–methyl disilylamino complex $(Me_3SiO)_2Ti(CH_3)[N(SiH_3)(SiMe_3)]$, the geometry of which is pseudo-tetrahedral, as expected.

The BE value is similar to that of **PC2b**. The E_a value is 19.1 (18.6) kcal/mol and the ΔE value is –33.9 (–37.7) kcal/mol. The E_a value is similar to and the ΔE value is much larger than those of the C–H σ-bond activation reaction. Considering that the C–H σ-bond activation by the titanium(IV)–imido complex was reported experimentally,[25] these E_a and ΔE values suggest that the Si–C σ-bond activation can be achieved by the titanium(IV)–imido complex.

Comparisons of the population changes among O–H, Si–H, and Si–C σ-bond activations

In the O–H σ-bond activation, the H atomic population little decreases and the electron population of the OCH_3 group little increases in the reaction, as shown in Fig. 5. On the other hand, the Ti atomic population increases in **PC1** because of the CT from the O lone pair to the Ti empty d orbital, while it moderately decreases upon going from **PC1** to **PRD1**. These population changes are quite different from those of the C–H σ-bond activation, in which the H atomic population considerably decreases and the electron population of the CH_3 moiety considerably increases. The moderate population changes by the O–H σ-bond activation are easily interpreted in terms of the highly polarized O–H bond of CH_3OH; actually, the positive charge of the H atom and the negative charge of the OCH_3 group are considerably large in CH_3OH. In the product, the H atom is bound to the N atom, the electronegativity of which is not different very much from that of the O atom. The OCH_3 group is anionic in the product because it is bound to the Ti center. Because the OCH_3 group is sufficiently anionic in CH_3OH,

Fig. 5. Population changes in (A) O–H σ-bond activation of methanol, (B) Si–H σ-bond activation of silane (course B), and (C) Si–C σ-bond activation of methylsilane by $(Me_3SiO)_2Ti(NSiMe_3)$ **R**. The positive value represents the increase in electron population, and vice versa. The DFT(B3LYP)/BS2 method was employed.



as discussed above, the electron redistribution does not considerably occur in the O–H σ-bond activation.

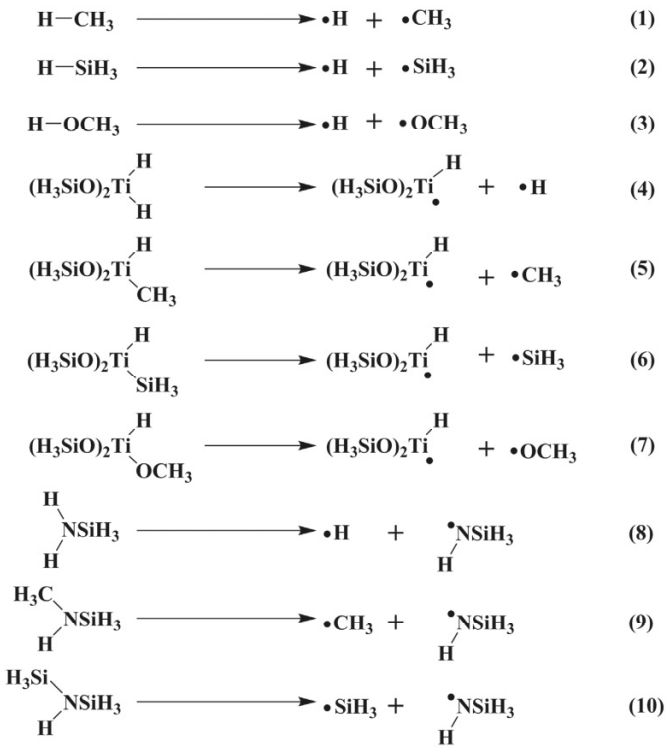
In the Si–H σ-bond activation via the course B, the total electron population of H–SiH_3 moderately decreases by 0.113 e and the electron population of the Ti–imido complex moderately increases by 0.113 e upon going to **PC2b** from **R**. Also, the Ti atomic population increases. These population changes arise from the fact that the net CT occurs from the Si–H bond to the Ti empty d orbital in **PC2b**, as discussed above. Interestingly, the H atomic population increases and the electron population of SiH_3 decreases upon going to **PC2b** from **R**, as shown in Fig. 5B. The increase in the H atomic population and the decrease in the SiH_3 electron population are interpreted in terms of the polarization, as follows: Because the H atom and the SiH_3 moiety approach the positively charged Ti center and the negatively charged N atom, respectively, in **PC2b**, the polarization occurs so as to increase the H atomic population and decrease the electron population of the SiH_3 moiety. Little population change occurs upon going from **PC2b** to **TS2b**, because **TS2b** is reactant-like; remember that the Si–H distance is elongated by only 0.1 Å upon going to **TS2b** from **PC2b**. However, the populations considerably change upon going to **PRD2b** from **TS2b**, in which the H atomic population considerably increases and the electron population of SiH_3 considerably decreases. These population changes indicate that the Si–H σ-bond cleavage occurs via heterolytic σ-bond activation. It is noted that the increase in the H atomic population and the decrease in the SiH_3 electron population contrast with those of the C–H σ-bond activation of methane in which the H atomic population considerably decreases but the CH_3 electron population considerably increases. The reason is easily interpreted in terms of the polarized Si–H bond; because of the very small electronegativity of the Si element, the H atom is negatively charged and the Si atom is positively charged in SiH_4. As a result, the H atomic population does not need to increase but rather decreases and the SiH_3 electron population does not need to decrease but rather increases.

In the Si–C σ-bond activation, the populations moderately change too, as shown in Fig. 5C. The reason is the same as those of the O–H and Si–H σ-bond activations, as follows: Because the SiH_3 group is bound to the N atom and the CH_3 group is bound to the Ti center in **PRD3**, the SiH_3 group is positively charged and the CH_3 group is negatively charged in **PRD3**. In CH_3–SiH_3, the CH_3 group is negatively charged and the SiH_3 group is positively charged, due to the electronegativity difference between C and Si atoms. As a result, the large population changes do not necessarily occur in the reaction too.

Comparisons of the reactivity among O–H, Si–H, Si–C, and C–H σ-bond activations

First, we wish to discuss the reason why the course B is easier than the course A in the Si–H σ-bond activation. In the course A, the Ti–SiH_3 and N–H bonds are formed, while the Ti–H and N–SiH_3 bonds are formed in the course B. We evaluated these bond energies, considering assumed reactions shown in Scheme 1. Though the DFT-computed bond energies are moderately smaller than the CCSD(T)-computed values, as shown in Table 2, the trends are the same

Scheme 1.



in both computational values. Apparently, the N–H bond energy is moderately larger than the N–SiH_3 bond energy by 11.3 kcal/mol at the DFT level and by 6.1 kcal/mol at the CCSD(T) level. However, the Ti–H bond is much stronger than the Ti–SiH_3 bond by 19.5 kcal/mol and 13.3 kcal/mol at the DFT and CCSD(T) levels, respectively. As a result, the course B is easier than the course A.

The O–H σ-bond activation is more exothermic than the Si–H σ-bond activation. In the O–H σ-bond activation, the Ti–OCH_3 and N–H bonds are formed. Though the O–H bond is much stronger than the Si–H bond, the difference (12.4 kcal/mol) is much smaller than the difference between the sum of Ti–OCH_3 and N–H bond energies and that of the Ti–H and N–SiH_3 bond energies, because the Ti–OCH_3 bond is much stronger than the Ti–H bond. This is the reason why the H–OCH_3 σ-bond activation is more exothermic than the Si–H σ-bond activation. However, the O–H σ-bond activation needs larger E_a value than the Si–H σ-bond activation unexpectedly from the above-described exothermicity. One of the important factors to determine the E_a value is the strength of the σ-bond to be broken. The O–H bond is considerably stronger than the Si–H bond. In the transition state, the O–H bond should be cleaved, while the Ti–OCH_3 bond is not completely formed yet. Actually, the elongation of the O–H bond to 1.183 Å gives rise to larger destabilization energy than that of the Si–H bond to 1.623 Å, as shown in Table 3; remember the O–H distance is 1.183 Å and the Si–H distance is 1.623 Å in the transition state. The difference in the destabilization energy between CH_3OH and SiH_4 is similar to the difference in E_a value. Thus, it is concluded that the O–H σ-bond activation needs larger E_a value than the Si–H σ-bond activation because the strong O–H bond should be broken.

Table 2. Bond energies calculated with DFT(B3LYP), MP2-MP4(SDQ), and CCSD(T)/BS2 methods (in kcal/mol unit).

	DFT(B3LYP)	MP2	MP3	MP4(DQ)	MP4(SDQ)	CCSD(T)
Ti–H	65.4	69.9	62.0	64.4	70.1	67.5
Ti–SiH_3	45.9	59.4	47.4	49.0	55.9	54.2
Ti–OCH_3	108.7	130.5	105.6	109.5	119.5	116.8
Ti–CH_3	68.4	83.0	69.0	69.3	75.2	74.5
N–H	115.9	116.9	114.0	114.2	114.2	114.5
N–SiH_3	104.6	114.4	107.9	107.5	107.8	108.4
N–CH_3	100.3	108.4	101.0	100.4	100.8	102.1
C–H	118.4	114.5	115.0	114.9	115.1	115.5
Si–H	94.8	90.6	92.9	93.2	93.3	93.4
O–H	107.2	111.0	106.5	107.1	107.0	107.3
Si–C	96.1	99.0	96.7	95.6	95.9	96.5

Table 3. Distortion energies of CH_3OH and SiH_4 in **TS1** and **TS2b**, respectively (in kcal/mol unit).

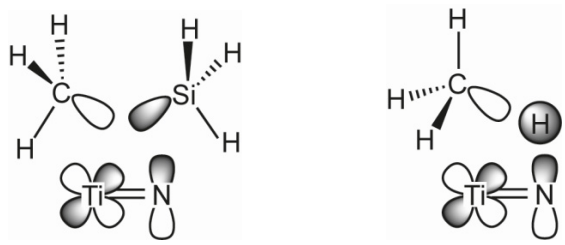
	CH_3OH	SiH_4
DFT(B3LYP)	21.3	16.6
MP2	23.2	18.8
MP3	24.2	18.5
MP4(DQ)	23.6	18.4
MP4(SDQ)	23.3	18.3
CCSD(T)	22.6	17.9

Then, we will compare the O–H σ-bond activation with the C–H σ-bond activation. In the C–H σ-bond activation, the Ti–CH_3 and N–H bonds are formed. Though the C–H bond is moderately stronger than the O–H bond, the Ti–CH_3 bond is much weaker than the Ti–OCH_3 bond. Thus, the O–H σ-bond activation occurs much easier than the C–H σ-bond activation.

The difference between the Si–H and C–H σ-bond activations is easily interpreted in terms of bond energy too, as follows: In the Si–H σ-bond activation, the Ti–H and N–SiH_3 bonds are formed. Though the N–SiH_3 bond is somewhat weaker than the N–H bond and the Ti–H bond is as strong as the Ti–CH_3 bond, the Si–H bond is much weaker than the C–H bond. As a result, the Si–H σ-bond activation occurs easier than the C–H σ-bond activation.

It is worth investigating the reason why the C–H σ-bond activation occurs via the course A, which leads to the formation of the Ti–CH_3 and N–H bonds,[28] but the Si–H σ-bond activation occurs via the course B, leading to the formation of the Ti–H and N–SiH_3 bonds. One of the reasons is that the N–SiH_3 bond is stronger than the N–CH_3 bond. Another reason is that the Ti–SiH_3 bond is much weaker than the Ti–CH_3 bond. This is because the electropositive Si element tends to form a strong bond with the electronegative N atom but a weak bond with the electropositive Ti atom. Also, the electronegative C element tends to form a strong bond with the electropositive Ti center. Because of the formation of this strong N–SiH_3 bond and the weak Ti–SiH_3 bond, the Si–H σ-bond activation occurs via the course B. On the other hand, because the Ti–CH_3 and N–H bonds are stronger than the Ti–H and N–CH_3 bonds, respectively, the C–H σ-bond activation occurs via the course A.

Scheme 2.



(A) Si–C σ-bond activation (B) C–H σ-bond activation

In the Si–C σ-bond activation, the MP4(SDQ)-calculated E_a value is similar to and the DFT-calculated value is moderately larger than those of the C–H σ-bond activation, while the former reaction is more exothermic than the latter one. In the Si–C σ-bond activation, not the bond energy but another factor plays an important role to determine the E_a value. This is the same as the difference between the C–H and C–C σ-bond activations.[8a] In general, the C–C σ-bond activation of ethane is much more difficult than the C–H σ-bond activation, though the exothermicity is similar between them. The difference between the C–H and C–C σ-bond activations was interpreted in terms of the distortion of valence orbital.[4,5a,45] The difference here is interpreted in the same way, as follows: In the Si–C σ-bond activation, the CH_3 and SiH_3 groups must change their directions toward the Ti center and the N atom, respectively, to form Ti–CH_3 and N–SiH_3 bonds, as shown in Scheme 2, because the valence orbitals of CH_3 and SiH_3 are sp^3-like. Such direction changes give rise to considerably large distortion energy. On the other hand, the C–H σ-bond activation, only the CH_3 group must change its direction toward the Ti center but the H atom can interact with both CH_3 and imido groups because of the spherical 1s orbital. As a result, the Si–C σ-bond activation needs larger E_a value than the C–H σ-bond activation.

Reasons why bond energy increases in the order $Ti–SiH_3 < Ti–H < Ti–CH_3 < Ti–OCH_3$

Because these bond energies are important factor to determine the reactivity of the σ-bond activation, it is worthy investigating the reason why bond energy increases in the

Table 4. Orbital energies of $^{\bullet}TiH(OSiH_3)_2$, $^{\bullet}CH_3$, $^{\bullet}SiH_3$, $^{\bullet}OCH_3$, $^{\bullet}NH(SiH_3)$, and $^{\bullet}H$ calculated with DFT(B3LYP)/BS2 and HF/BS2 (in eV).

	$^{\bullet}TiH(OSiH_3)_2$	$^{\bullet}CH_3$	$^{\bullet}SiH_3$	$^{\bullet}OCH_3$	$^{\bullet}NH(SiH_3)$	$^{\bullet}H$
SOMO (Kohn–Sham)	–5.56	–7.23	–6.24	–9.33	–9.18	–8.75
SOMO (Hartree–Fock)	–10.68	–11.63	–9.29	–14.38	–12.93	–13.60

above order. The covalent bond energy ΔE_{cov} is approximately represented by eq. [1],[46] as follows:

If the $|\varepsilon_A - \varepsilon_B|$ value is much larger than the $|\beta_{AB}|$ value, eq. [1] can be further simplified to eq. [2]. In the above equations, ε_A and ε_B are valence orbital energies of A and B, respectively, and β_{AB} is resonance integral between valence orbitals of A and B. As shown in Table 4, the valence orbital energy of $^{\bullet}TiH(OSiH_3)_2$ is calculated to be –5.56 eV, where we employ Kohn–Sham orbital energy. This is much higher than those of $^{\bullet}CH_3$, $^{\bullet}SiH_3$, and $^{\bullet}OCH_3$. Because the valence orbital energy becomes lower in the order $^{\bullet}SiH_3 > {}^{\bullet}CH_3 > {}^{\bullet}OCH_3$, as expected from their electronegativities, the $|\varepsilon_A - \varepsilon_B|$ value increases in the order $^{\bullet}SiH_3 < {}^{\bullet}CH_3 < {}^{\bullet}OCH_3$. Thus, the Ti–$SiH_3$ bond is the weakest and the Ti–OCH_3 is the strongest in these three bonds.[47] In other words, the electronegative group forms strong bond with the Ti center. Also, the Ti–H bond is much stronger than the Ti–SiH_3 bond, because the H 1s orbital is at lower energy (–8.75 eV) than the $^{\bullet}SiH_3$ valence orbital and the $|\varepsilon_A - \varepsilon_B|$ value for the H 1s orbital is considerably larger than that for the $^{\bullet}SiH_3$ valence orbital. Though the H 1s orbital energy is lower than the $^{\bullet}CH_3$ valence orbital, the Ti–H bond is moderately weaker than the Ti–CH_3 bond. This is probably because the $|\beta_{AB}|$ value is larger for the Ti–CH_3 pair than that for the Ti–H pair. It is likely that the CH_3 sp^3 orbital more expands toward the Ti center than the H 1s orbital to provide the larger $|\beta_{AB}|$ value for the Ti–CH_3 pair. Though Hatree–Fock orbital energies are much different from Kohn–Sham orbital energies, the trend is the same between them (see Table 4).

$$[1] \qquad \Delta E_{cov} = \sqrt{(\varepsilon_A - \varepsilon_B)^2 + 4\beta_{AB}^2}$$

$$[2] \qquad \Delta E_{cov} \approx |\varepsilon_A - \varepsilon_B| + \frac{2\beta_{AB}^2}{|\varepsilon_A - \varepsilon_B|}$$

The same explanation can be presented on the N–X bond energy except for the N–H bond energy. The valence orbital energy of $^{\bullet}NH(SiH_3)$ is calculated at –9.18 eV, which is lower than the valence orbital of $^{\bullet}H$, $^{\bullet}CH_3$, and $^{\bullet}SiH_3$. Because the difference in orbital energy between $^{\bullet}CH_3$ and $^{\bullet}NH(SiH_3)$ is the smallest, the N–CH_3 bond is the weakest in these three bonds, as seen in Table 2. Because the energy difference between valence orbitals of $^{\bullet}NH(SiH_3)$ and $^{\bullet}SiH_3$ is the largest, the N–SiH_3 bond is strongest. Though the valence orbitals of $^{\bullet}SiH_3$ and $^{\bullet}CH_3$ are higher than that of the H atom, the N–H bond is stronger than the N–SiH_3 and N–CH_3 bonds. It is likely that this result arises from the larger $|\beta_{AB}|$ value for the N–H pair because the N–H distance is much shorter than the N–C and N–Si distances due to the small size of H atom.

From these results, we wish to present theoretical prediction that the X–H σ-bond activation by the titanium(IV)–imido complex becomes easier as the X group becomes electronegative, when the X and H are bound to the Ti and N atoms, respectively, in the product. However, the X–H σ-bond activation becomes easier as the X group becomes electropositive, when the X and H are bound to the N and Ti atoms, respectively, in the product.

Conclusions

The O–H σ-bond activation of methanol, the Si–H σ-bond activation of silane, and the Si–C σ-bond activation of methysilane by $(Me_3SiO)_2Ti(NSiMe_3)$ **R** were theoretically investigated with the DFT and MP2 to MP4(SDQ) methods. The σ-bond activations of methanol and silane (course B) occur much easier than the C–H σ-bond activation to afford the products $(Me_3SiO)_2Ti(OCH_3)[NH(SiMe_3)]$ and $(Me_3SiO)_2Ti(H)[N(SiH_3)(SiMe_3)]$, respectively. Their activation barriers (E_a) are 7.1 (14.6) kcal/mol and 2.7 (4.3) kcal/mol, respectively, and their exothermicities are 65.8 (61.4) kcal/mol and 32.5 (34.1) kcal/mol. The very large exothermicity and moderate E_a value of the O–H σ-bond activation arise from the formation of the very strong Ti–OCH_3 bond. The very small E_a value and the considerably large exothermicity of the Si–H σ-bond activation arise from the weak Si–H bond.

The Si–C σ-bond activation, which is in general considered to be difficult, occurs with moderate activation barrier and considerably large exothermicity. These results arise from the formations of considerably strong Ti–CH_3 and N–SiH_3 bonds.

In the Si–H σ-bond activation, the other reaction course (course A) leading to the formation of $(Me_3SiO)_2Ti(SiH_3)[NH(SiMe_3)]$ was also investigated. However, the activation barrier is larger and the exothermicity is smaller than those of the course B leading to $(Me_3SiO)_2Ti(H)[N(SiH_3)(SiMe_3)]$. This result is understood in terms of the bond energy; the Ti–SiH_3 bond is considerably weaker than the Ti–H bond, while the N–SiH_3 bond is moderately stronger than the N–H bond. These results of the weak Ti–SiH_3 bond and the strong N–SiH_3 bond arise from the fact that the Si element is considerably electropositive.

From these results, we wish to theoretically propose that the titanium(IV)–imido complex can be utilized for the O–H, Si–H, and Si–C σ-bond activation reactions. In the X–H σ-bond activation (X = CH_3, OCH_3, and so forth), the reaction becomes easier as the electronegativity of X increases, when the X and H are bound to the Ti center and the N atom, respectively, in the product. However, the X–H σ-bond activation becomes easier as the X becomes electropositive, when the X and H are bound to the N atom and the Ti center, respectively, in the product. Considering these results, one can construct the reaction system leading to the formation of the Ti–X species through the σ-bond activation of H–X.

The flattening phase transition in systems of trapped ions

Taunia L. L. Closson and Marc R. Roussel

Abstract: When the anisotropy of a harmonic ion trap is increased, the ions eventually collapse into a two-dimensional structure consisting of concentric shells of ions. This collapse generally behaves like a second-order phase transition. A graph of the critical value of the anisotropy parameter vs. the number of ions displays substructure closely related to the inner-shell configurations of the clusters. The critical exponent for the order parameter of this phase transition (maximum extent in the z direction) was found computationally to have the value $\beta = 1/2$. A second critical exponent related to displacements perpendicular to the z axis was found to have the value $\delta = 1$. Using these estimates of the critical exponents, we derive an equation that relates the amplitudes of the displacements of the ions parallel to the x–y plane to the amplitudes along the z axis during the flattening process.

Key words: ion trap, flattening, phase transition, critical exponent.

Résumé : Quand on augmente l'anisotropie d'un piège ionique, les ions adoptent tôt ou tard une structure aplatie formée de couches concentriques d'ions. Cet aplatissement se comporte comme une transition de phase du deuxième ordre. Un graphe de l'anisotropie critique contre le nombre d'ions démontre une organisation reliée à la configuration de la couche interne de l'amas. Nos calculs numériques démontrent que l'exposant critique associé au paramètre d'ordre de cette transition de phase (l'étendue maximale le long de l'axe z) a la valeur $\beta = 1/2$. Un deuxième exposant critique associé aux déplacements des ions perpendiculairement à l'axe z a la valeur $\delta = 1$. Ces estimations numériques des exposants critiques nous permettent d'obtenir une équation qui relie les amplitudes des déplacements des ions parallèles au plan x–y aux déplacements parallèles à l'axe z durant l'aplatissement.

Mots-clés : piège ionique, aplatissement, transition de phase, exposant critique.

Introduction

The potential energy of a system of N identically charged ions in a harmonic trap, expressed in dimensionless form, is[1,2]

$$[1] \qquad u = \sum_{i=1}^{N-1} \sum_{j=i+1}^{N} \frac{1}{r_{ij}} + \frac{1}{2} \sum_{i=1}^{N} [x_i^2 + y_i^2 + \alpha z_i^2]$$

where r_{ij} is the distance between ions i and j, (x_i,y_i,z_i) is the position of particle i, and α is the anisotropy parameter of the trap. Ion traps have a number of applications in chemistry, notably in mass spectroscopy, chemical dynamics, and high-resolution spectroscopy.[3] The ions can be cooled to temperatures down to the milliKelvin range, leading to Wigner crystallization.[4–6]

The anisotropy is experimentally controllable in many ion trap designs. At sufficiently low temperatures and large anisotropies, the ions undergo a structural phase transition, collapsing onto the x–y plane.[1,2] Dahm and Vinen have argued that the study of two-dimensional systems enhances our understanding of surfaces, interfaces, and anisotropic solids.[7] We concur, and point out that because of the flattening phase transition, ion traps afford us the possibility of studying two-dimensional "crystals" involving from two to several thousand ions. Ion traps specifically designed to study two-dimensional clusters have been devised, particularly for the closely related dusty plasma problem.[8–10] There has also been considerable interest in the confinement of charged particles in two dimensions in condensed matter physics for a number of reasons. First, these systems may give us some insight into the poorly understood phenomenon of superconductivity in two-dimensional electron systems at low temperatures.[11] Second, they may be used as models of contact phenomena at semiconductor boundaries,[12] of electron dimples on liquid helium,[13] or of quantum dots.[14] Third, there has been a suggestion that ions trapped in a two-dimensional geometry could be used in quantum computing.[15,16] And finally, problems of this class are of historical interest since Thomson's "plum pudding" model of the atom led him to study the closely related problem of stabilization by rotation of planar arrangements of point charges in a neutralizing background.[17] Given the importance of two-dimensional systems, understanding the conditions under which a three-dimensional system can be flattened is clearly of interest.

There have been a number of studies of structural phase transitions in trapped-ion clusters.[1,2,18–20] Early studies of the flattening phase transition in particular have focused on the large-N regime.[1,2] Cornellissens and co-workers have studied the sequence of phase transitions that occur in both small and large clusters as the anisotropy of the trap is increased, the flattening transition being the final phase transition in this sequence.[18] Calvo and Yurtsever have obtained a phase diagram showing the regions in the (N,α) parameter plane where one-, two-, and three-dimensional structures can be observed.[19] Here, we focus specifically on the final collapse to a two-dimensional structure in smaller clusters, which we show to be a second-order structural phase transition. We characterize both the critical anisotropy and a pair of critical exponents of the collapse process. The computed values of the critical exponents then allow us to derive a very interesting connection between the displacements of the ions along the z axis and perpendicular to this axis during the flattening process.

Computing methods

We study structural phase transitions of cold clusters as α is varied, i.e., qualitative changes in the equilibrium structures. Our approach is closely related to that described by Schweigert and Peeters[21] and since applied by the Peeters group to structural phase transitions in trapped-ion clusters.[18,20] Specifically, we use a gradient optimizer to locate minimum energy structures, as described elsewhere.[22] As pointed out by Schweigert and Peeters, this greatly speeds convergence, and typically avoids locking into saddle points on the potential energy surface (PES) when combined with a method to explore the local vicinity of a critical point.[21] Our program takes a previously discovered equilibrium structure, adds or deletes particles or changes the value of α, and reminimizes the potential energy (eq. [1]) using a fast gradient optimizer. The program allows other operations used to probe the stability and accuracy of determined structures, including "jiggling" (adding small random numbers to all coordinates prior to energy minimization as a probe of stability), and "squashing" (replacing all z coordinates by small random numbers). The latter operation was particularly useful near the flattening phase transition to test whether a given flattened structure was higher or lower in energy than the corresponding completely flat structure. To avoid trapping in unstable states, Schweigert and Peeters used molecular dynamics steps.[21] Our jiggling operation, implemented by adding uniformly distributed random numbers in the range [–0.005,0.005] to each of the x, y, and z coordinates of the ions, plays the same role. To put the random amplitudes of the jiggling operation in perspective, note that in our scaling, the equilibrium coordinates for the small clusters studied here are of unit magnitude. Moreover, for the small values of α studied in this paper, jiggling typically results in a relative increase of the energy of the order of one part in 10^5. Empirically, we find that the small random displacements used here are not generally sufficient to displace a stable equilibrium structure out of its potential well when two equilibria coexist, although they are often sufficient to avoid trapping at saddle points. Additionally, note that the isotropic displacements in space used here are not isotropic in potential energy due to the anisotropy of the trapping potential.

As in our previous work,[22] we used the balancing condition between the Coulomb and trapping contributions to the energy[23] to estimate the errors in the computed energies. We thus determined that the energies computed by our programs are always accurate to at least six decimal places.

We also computed some key global minima, particularly the global minima of the two-dimensional problem corresponding to the large-α limit of the potential, eq. [1], using simulated annealing.[24]

Our main computations involved repeated gradient optimizations after small changes in α, sometimes in combination with other operations such as jiggling or squashing. These calculations are roughly equivalent to an experiment where the trap anisotropy is changed very slowly while maintaining the laser cooling so that at any time, the cluster is in quasi-equilibrium at the instantaneous value of α. In cases where there were questions about the nature of the critical points computed (which mainly occurred when jiggling was not used), we calculated the eigenvalues of the Hessian matrix of u (the matrix of second partial derivatives of u with respect to the $3N$ particle coordinates) to eliminate structures that are saddle points on the potential energy surface.

To study the dependence of the equilibrium geometries on α, we used two different sampling strategies. In one strategy, we scanned the value of α using a large number of small steps (often in steps of 0.01, but verifying results in key regions with smaller step sizes), either with or without jiggling. Jiggling generally had little effect on the results, except very near the phase transition, although it typically resulted in slightly more accurate energies. In this variation, we used the statistics (energies, coordinates, etc.) from a single scan in further analyses (e.g., determination of critical parameters). In the second strategy, we computed an ensemble of minima for each value of α starting from a variety of different initial configurations (e.g., structures obtained at nearby values of α) and using different program options (jiggling, squashing, etc.), with the difference in α values between adjacent points adapted to study the region of the phase transition particularly finely. When we used this procedure, we typically extracted statistics only from the best structure in an ensemble at a given value of α for further analysis. The best structure was taken to be the one that simultaneously had the lowest energy and smallest error in the energy as determined by the balancing criterion. Occasionally, several structures had identical energies and errors. In these cases, the median structural statistics from this set of structures were used. Both strategies produced estimates of the parameters studied that are within error of each other.

The critical parameters (β and α_c from eqs. [2] and [3] below) were obtained using the Marquardt–Levenberg non-linear least-squares algorithm[25] as implemented in OCTAVE 2.9.9.[26] Error bars were calculated by a simple Monte Carlo method based on the analysis of ensembles of structures generated for each value of α. This generated a range of values of ζ (maximum absolute value of z) for each α. The fitting procedure was repeated 1000 times, each time choosing random values of ζ uniformly within the range identified from the ensemble of structures. The standard deviations of β and α_c obtained from these fits are the uncertainties in our

estimates of these parameters. Note that the average values of β and α_c from the Monte Carlo procedure were always within error of the values obtained from the best structures.

Results and discussion

Computational results

When $\alpha \rightarrow \infty$, minimizing the potential (eq. [1]) becomes equivalent to finding minimum-energy structures of the two-dimensional problem where all particles have a z coordinate of zero. We computed the global minima of this two-dimensional problem by simulated annealing. These calculations were useful to determine the global minimum-energy structure for each value of N. Our results agree with previously published global minima[27,28] and are thus not reproduced here. Note that these authors found minimum-energy structures that improve on those presented earlier by Bedanov and Peeters[29] for $N = 29$, 39, and 49, as did our own calculations. Also note that both of these groups use a somewhat different scaling of the energy than we do: Energies in our scaling can be converted to theirs by multiplying by $2^{1/3}$.

Our main calculations follow the fate of particular local minima on the PES as α is varied. As we increase α, we observe qualitative changes in the cluster structures. These changes are associated with discontinuities in the derivatives of u with respect to α, i.e., to structural phase transitions, which are classified according by the order of the discontinuity in the derivatives of the energy.

In most cases, the last phase transition observed as we increase α is a second-order flattening phase transition, i.e., a phase transition in which the second derivative of u with respect to α is discontinuous at the critical value of this parameter, α_c. Figure 1 illustrates the behavior of the energy and of its first and second derivatives in a typical example of the flattening phase transition. Since u is constant above the critical anisotropy and the first derivative is continuous, the first derivative must converge to zero as α approaches α_c, as observed in Fig. 1. Moreover, the second derivative of u with respect to α must be negative below the phase transition since the energy increases with increasing anisotropy, but the rate of change of the energy must decrease to zero as $\alpha \rightarrow \alpha_c$ from below. Again, our numerical results are consistent with this argument. Interestingly, $d^2u/d\alpha^2$ appears to be constant, and $du/d\alpha$ decreases linearly with α near the phase transition, implying that the linear coefficient of a Taylor series of $u(\alpha)$ expanded about $\alpha = \alpha_c$ for $\alpha < \alpha_c$ is identically zero, a fact that will feature prominently in our later analysis of this phase transition.

It is useful to define an order parameter for the flattening phase transition, i.e., a quantity that decreases to zero at the critical value of α.[30] We chose the maximum absolute value of z of the configuration, a quantity we will denote by ζ. Near the flattening phase transition, an order parameter should behave as

$$[2] \qquad \zeta(\varepsilon) \sim (-\varepsilon)^{\beta}$$

where

$$[3] \qquad \varepsilon = \frac{\alpha - \alpha_c}{\alpha_c}$$

Fig. 1. Second-order flattening phase transition for $N = 18$. The energy of the fully flattened structure, $u_{flat} = 104.408\ 542\ 872\ 30 \pm 0.000\ 000\ 000\ 15$, is subtracted from the energy of the minimum-energy structure for each value of α in panel (*a*). While the result is shown as a continuous curve, this graph is in fact the result of a set of calculations in which the value of α was increased in steps of 0.001 and the energy reminimized at each step. In panels (*b*) and (*c*), we see a kink in $du/d\alpha$ and a corresponding jump discontinuity in $d^2u/d\alpha^2$ near $\alpha = 4.926$, characteristic of a second-order phase transition. The derivatives in these panels were calculated by finite differences of adjacent points and the computed points are shown, along with the trend lines in each region.

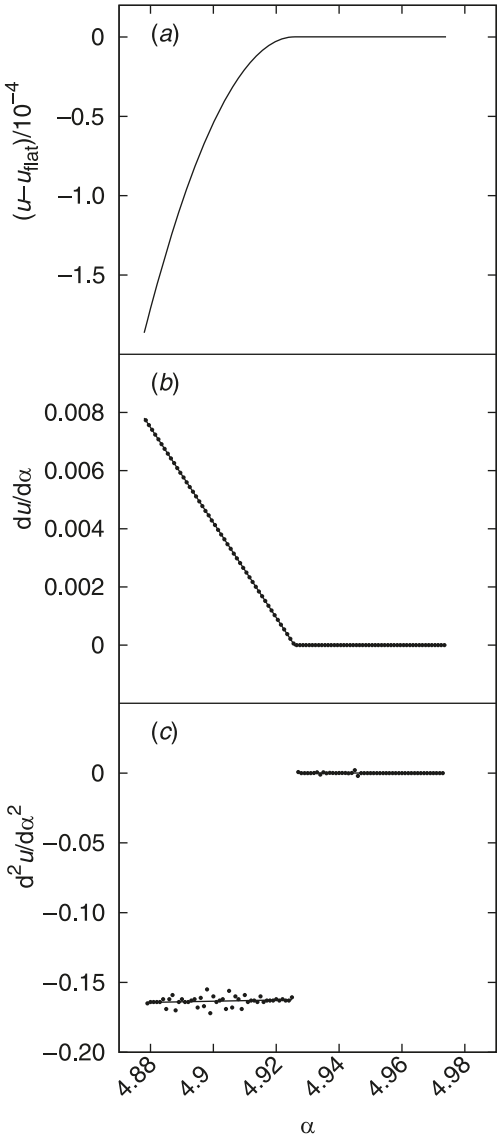

Figure 2 shows the behavior of the order parameter near the critical point for $N = 18$. The inset confirms that the behavior is consistent with eq. [2] over several orders of magnitude in −ε. Note the larger error bars near the critical point. During flattening, deformation of the cluster follows the two "softest" eigenmodes of the Hessian matrix, i.e., the two modes with the smallest eigenvalues, not counting the trivial zero eigenvalue associated with rigid rotation of the whole cluster around the z axis. The first of these ei-

Fig. 2. Behavior of the order parameter ζ near the critical value of α for $N = 18$. For this structure, $\alpha_c = 4.925\,800 \pm 0.000\,009$ and the critical exponent $\beta = 0.5000 \pm 0.0022$. The error bars show the spread of values obtained by computing the minimum-energy structure at a given value of α from several different initial configurations. Configurations in which the Hessian matrix has a negative eigenvalue, i.e., those that are not stable equilibria, were discarded from each of these sets. The spread of values is only significant for points near the critical α. The inset shows that the analytic form eq. [2] is a good fit to the data (The error bars are not shown in the inset for clarity).

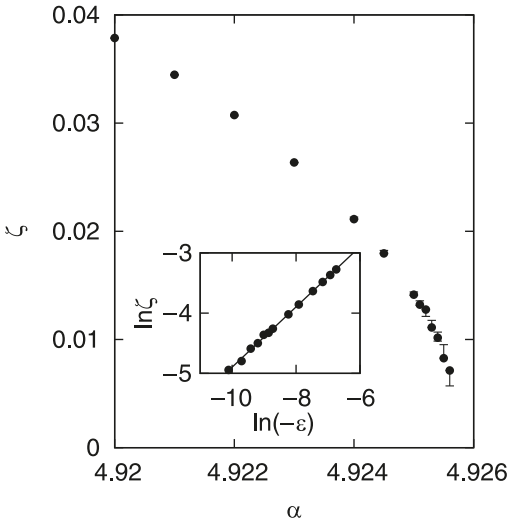

Fig. 3. Second nontrivial eigenvalue of the Hessian matrix (λ_2) vs. α near the critical anisotropy for $N = 18$. In this case, the eigenvalues were recovered from a succession of structures obtained by scanning α with jiggling. The first nontrivial eigenvalue is associated with deformation of the structure parallel to the *x*–*y* plane during flattening. The eigenvalue plotted here is associated with deformation along the *z* axis during flattening. Note the decrease in λ_2 by a factor of more than 20 over this range of α.

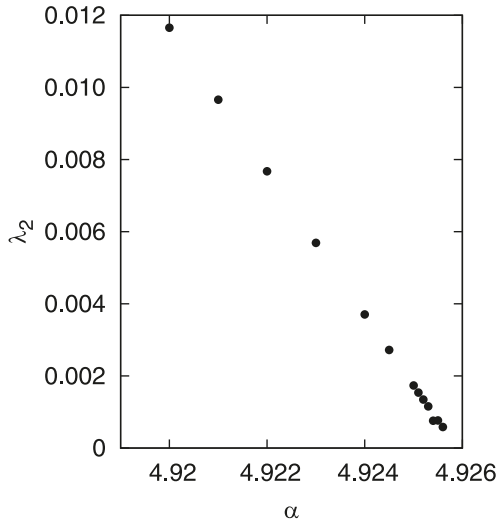


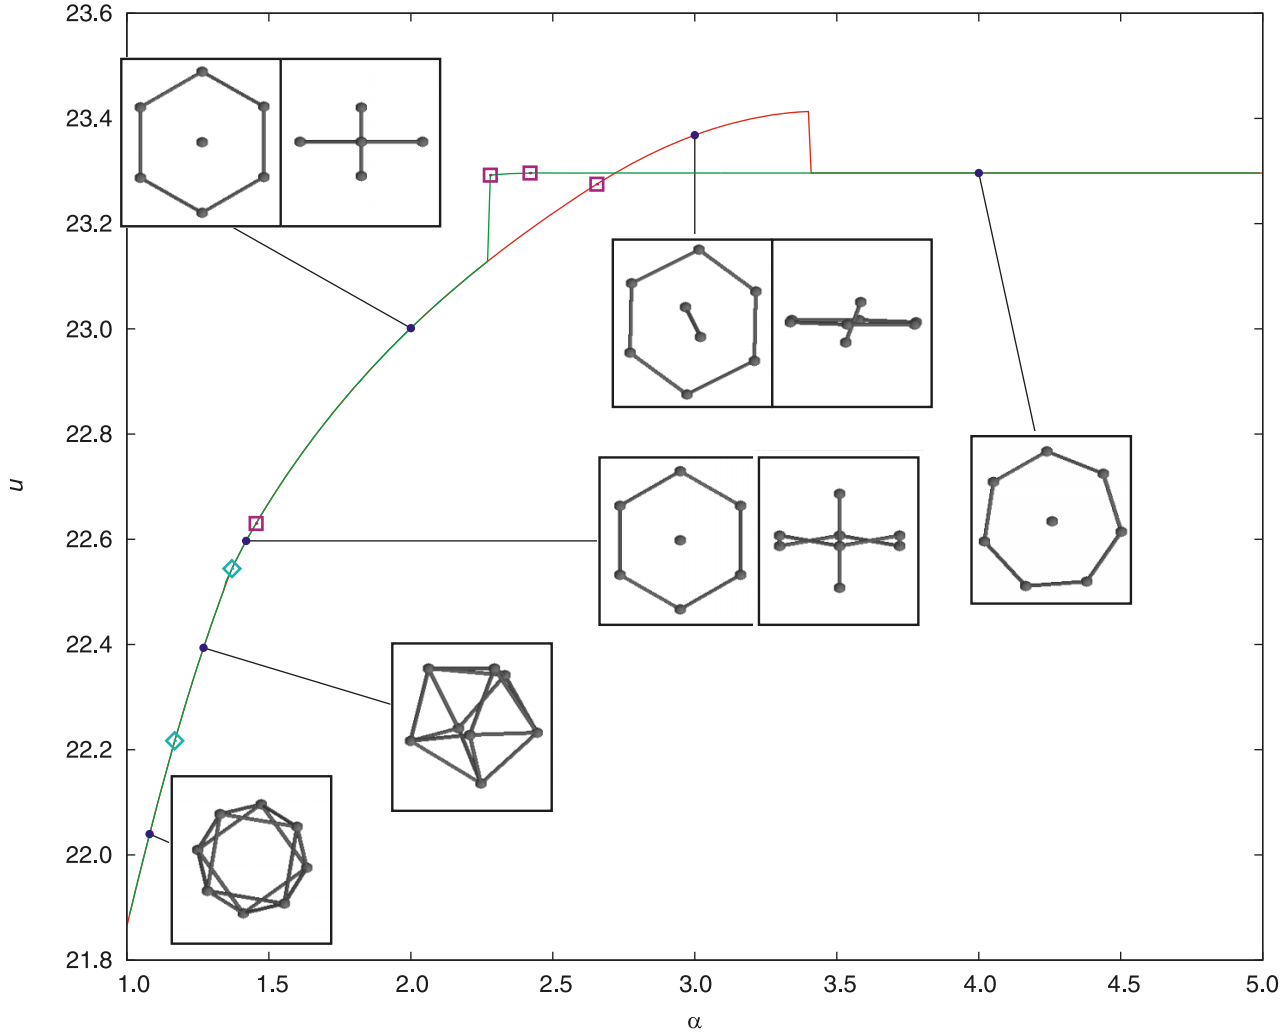
genmodes corresponds to the deformation of the structure parallel to the *x*–*y* plane. The second eigenmode largely involves deformation along the *z* axis. The eigenvalue corresponding to the latter mode (λ_2) decreases significantly as we approach the phase transition (Fig. 3), indicating an effective softening of the potential in this direction. The eigenvalue for the first eigenmode varies much less dramatically (it increases by about 11% over the same range of α), and the other eigenvalues hardly vary at all with α. Accordingly, it becomes harder for numerical methods to converge to the minimum along the second eigenvector, and we typically find a wider dispersion in values of ζ near $\alpha = \alpha_c$. This complicates the computation of critical data for this phase transition, which is why we generally found it necessary to retain only the lowest energy structure at a given value of α for high-resolution studies of the vicinity of the critical point.

As a rule, the minimum-energy structures in both the two-dimensional and three-dimensional versions of this and related problems can be thought of as having ions organized in shells.[6,17,22,23,29,31–38] Each ion within a shell is at a similar distance from the centre of the trap as other ions in the same shell, and the distance between shells is much larger than the variability of the distance from centre within a shell. It is convenient to have a shorthand notation for the shell structure of a cluster. We denote a configuration by a set of indices (*n*,*m*,...), where *n* is the number of ions in the outermost shell, *m* is the number of ions in the next shell, and so on, all the way to the centre.

The description of the phase transitions in this system is complicated by the coexistence of multiple equilibria. For example, for $N = 5$ and $1 < \alpha < 1.76412$, the global minimum-energy structure is a square pyramid. (The base of the pyramid becomes nonplanar for values of α approaching 1 from above, the overall structure converging on a trigonal bipyramid as α tends to 1.) Above $\alpha = 1.76412$, a planar pentagon is the global minimum-energy structure. The planar pentagon results from the flattening of a nonplanar ring (with all atoms roughly equidistant from the centre of the trap) at $\alpha_c = 1.76394$, while the pyramid becomes a centered square at $\alpha_c = 2.55482$. Thus, it is not only the number of particles that matters in determining the critical value of α, but also the geometry of the structure being flattened. We did not attempt to build an exhaustive catalog of metastable two-dimensional structures. Rather, we started from our set of $\alpha = 1$ three-dimensional structures[22] and studied how these structures flatten. In many cases, different initial structures flattened to the same two-dimensional structure. Nevertheless, when the opportunity presented itself, we did study the flattening transition for multiple structures for a given *N*. Additional data points could be added to this study using the catalog of metastable states of the two-dimensional problem compiled by Kong, Partoens, and Peeters.[27]

In other cases, a region of bistability and hysteresis is observed, complicating the observation of the flattening phase transition. We use hysteresis here in the sense it is used in dynamical systems theory, namely that a different equilibrium is followed when we vary a parameter forward and backward through a region sufficiently slowly (equivalently, using sufficiently small steps in the parameter scanned). This is the case, for example, for $N = 8$, where, in addition to the sequence of first- and second-order phase transitions reported by Cornelissens and co-workers,[18] two different examples of hysteresis are observed. Our results for this value of *N* are summarized in Fig. 4. The red curve in this figure

Fig. 4. Cluster energy vs. α during forward and reverse scans of the anisotropy for $N = 8$. Red curve: forward scan; green curve: reverse scan; diamonds: first-order phase transitions; squares: second-order phase transitions. Typical structures at various points along the $u(\alpha)$ curve are shown. Each structure is illustrated from a perspective looking down the z axis; where a second image is shown, the illustration on the right shows a perpendicular view of the same cluster. The "bonds" connecting the ions have no particular interpretation and are only there to guide the eye. Due to the order in which the curves were plotted, the green (reverse) curve overlies the red (forward) curve for $\alpha > 3.4$ and $\alpha < 2.28$. Note the discontinuous jumps due to sudden loss of stability of, respectively, the (6,2) structure above $\alpha = 3.4$ and the (7,1) structure below $\alpha = 2.28$, and the consequent region of hysteresis.



was obtained by increasing α in steps of 0.01, adding small random increments to all the coordinates (jiggling), and re-minimizing. The same procedure was followed along the reverse path (green curve). Phase transitions were located by numerical differentiation of the energy and identification of discontinuities in the derivatives. In some regions, scans were carried out at higher resolution to confirm the existence and location of a phase transition. The jiggling amplitudes used (see Computing methods) are only large enough to avoid converging to a saddle point, but are not usually large enough to jump out of a local minimum well on the PES. This empirical observation of course depends on the height of the barrier between the structures. These barriers decrease in magnitude along the upper branch of a hysteresis loop. It is the eventual vanishing of the barrier, leaving a downhill path to the lower-energy structure, that is responsible for the loss of stability of the upper branch of a hysteresis loop. Near the jump points, we therefore cannot be sure that jiggling, even at very low amplitudes, will not displace a structure out of its well on the PES. To verify whether this was a problem, we scanned through the regions where the jumps occur using very small increments in α without jiggling. One of two situations was always observed: either a branch of equilibria in a high-resolution scan ended between the two endpoints of the jump identified in the lower resolution calculations, or the high-resolution scan followed an unstable branch of equilibria, as verified by computing the eigenvalues of the Hessian matrix. In the latter case, the first value of α at which the equilibrium became unstable was always between the two endpoints identified in the lower resolution scan with jiggling. We therefore have a high degree of confidence that, at least to the resolution of Fig. 4, we have fully mapped out each branch of equilibria.

For $N = 8$ at $\alpha = 1$, the equilibrium structure can be described as a pair of squares rotated 45° with respect to each other (Fig. 4). For α just slightly larger than 1, the square

faces are orthogonal to the z axis. The structure compresses smoothly in the z direction as α increases until approximately $\alpha = 1.17$ where a first-order phase transition occurs in which the structure reorients with respect to the z axis, with some distortion of the structure as the ions are no longer in symmetry-equivalent positions with respect to the trapping field. At $\alpha = 1.37$, another first-order phase transition occurs, yielding a (6,2) structure consisting of a six-membered ring in a chair conformation (a hexagon with one vertex tipped up out of the plane and the directly opposite vertex tipped down) and a pair of ions lying along the z axis. If we decrease α through this region, we find that the phase transition is slightly delayed, to $\alpha = 1.35$. This is a true example of hysteresis as the relevant structures are both stable in the region indicated, as determined by computing the eigenvalues of the Hessian matrix. As we continue to increase α, we pass through two second-order phase transitions, the first of which flattens the ring while the second results in the central pair of ions tilting away from the z axis. This latter structure suddenly loses stability (i.e., the PES undergoes a catastrophe[39]) above $\alpha = 3.4$ (approximately). The lone stable structure at higher values of α is the planar (7,1) structure. If we now decrease α starting from the planar (7,1) structure, we do not retrace our steps. Rather, there is a region of coexistence of the (7,1) and (6,2) structures, i.e., hysteresis is again observed. The planar (7,1) structure is stable down to $\alpha_c = 2.421$. A second-order phase transition then occurs which is associated with a displacement of the central ion along the z axis, with some slight displacements of the ring ions along this coordinate axis as well. This is of course the reverse process of a flattening phase transition. If we start a forward scan from this branch with α between 2.28 and 2.421, we do observe a normal flattening transition. Another second-order phase transition occurs near $\alpha = 2.28$ where the central ion starts to slide away from the z axis, i.e., it acquires nonzero x and y components, with corresponding deformation of the outer ring. (These last two structures, which are easily imagined, are not shown in Fig. 4, both due to space constraints and to the relatively subtle nature of the deformations.) Then, near $\alpha = 2.273$, the (7,1) structure suddenly loses stability and the (6,2) hexagon+vertical-stick structure reappears. Thereafter, the sequence of phase transitions described for the forward scan is followed in reverse, give or take the narrow region of hysteresis already noted for the first-order phase transition near $\alpha = 1.37$. Whether we would observe the two examples of hysteresis seen here either in molecular dynamics simulations or in experiments would depend a great deal on the barriers between the two conformations and on the temperature of the simulation. Since we deliberately avoided saddle points, for the moment we can say nothing with certainty about this subject, although the significant structural differences between the planar (7,1) structure and the (6,2) structure are at least suggestive of a significant activation barrier.

Figure 5 shows how the structure deforms during some selected flattening sequences, using color coding for the z displacements and arrows to show the x–y displacements of the ions. These displacements were computed directly from our structure optimizations at different values of α, although they could also have been recovered from the eigenvectors of the Hessian, as described above. We can make several observations: First, the outer-shell ions typically approach the x–y plane earlier in the flattening sequence than the inner-shell ions as we increase α, no doubt because the latter have more neighbors and are closer to each other on average. Flattening thus often occurs in distinct phases corresponding to the progressive flattening of shells, starting from the outside. The one exception to this trend in Fig. 5 is the $N = 21$ (12,8,1) cluster where the middle-shell ions approach the x–y plane later than the central ion. Second, as one might expect, the increased Coulomb repulsion as ions are pushed into the x–y plane causes the cluster to expand radially (on average). However, there is an energetic cost to this expansion because of the trapping field. As a result, the outer-shell ions typically have smaller displacement amplitudes parallel to the x–y plane than ions in inner shells.

Figure 6 shows the critical value of α as a function of N. The observations here are compatible with those we made of the displacements of the ions in the last paragraph. Typically, the critical anisotropy changes little for clusters that have the same number of ions in their inner shells, with the notable exception of the $N = 16$ and $N = 21$ (n,m,1) configurations. In other words, the force required to push the ions down into a plane is relatively insensitive to the number of ions in the outer shell(s) because the flattening phase transition typically involves only modest displacements of the outer-shell ions. On the other hand, going from 1 to 2 ions in the inner shell, or from 3 to 4 ions, tends to cause the critical anisotropy to increase significantly. Contrast in particular the large differences in α_c between configurations with the same number of ions but different inner-shell configurations for $N = 12$, 21, and 26 to the very small difference in α_c for the (8,2) and (7,3) configurations for $N = 10$, or the (12,6,1) and (11,7,1) configurations for $N = 19$. Again, this occurs because inner-shell ions have more neighbors, so that the increase in the Coulomb repulsion energy is larger when one of these is pushed down into the x–y plane than when an outer-shell ion undergoes a similar displacement. When there is more than one ion in the inner shell, this effect will be particularly large. The largest exception to these trends, the large jump in α_c between the $N = 20$ and 21 (n,m,1) configurations, is related to the peculiar flattening sequence of the $N = 21$ (12,8,1) cluster where the central ion collapses onto the x–y plane earlier than the eight middle-shell ions (Fig. 5). The reason for the other major exception, the anomalously large value of α_c for the $N = 16$ (10,5,1) cluster, is the high symmetry of this configuration which requires an outward displacement of middle-shell ions directly towards outer-shell ions as the central ion is pushed down (Fig. 5). Note that the critical anisotropies for the $N = 16$ (10,5,1) and $N = 19$ (12,6,1) clusters, both of which have the same symmetry-induced restraint of the middle-shell by the outer-shell ions (Fig. 5), are similar ($\alpha_c = 5.078\ 125 \pm 0.000\ 026$ for the former and $4.995\ 054 \pm 0.000\ 018$ for the latter). Finally, we can understand why there is essentially no difference in α_c for clusters with either two or three inner-shell ions by considering the example of the $N = 25$ (13,9,3) cluster: One of the inner-shell ions of a three-ion inner shell approaches the x–y plane much earlier than the other two as α increases, so that the final flattening process in these cases is not very different from the case of a two-ion inner shell.

Fig. 5. Structural deformations during some flattening sequences. The number of ions and shell structures of the clusters are indicated in the top left-hand corner of each panel. The value of the critical anisotropy, α_c, and the value of the normalized distance from the phase transition at which these snapshots were taken, ε, is given in the top right corner. The arrows indicate the displacements of the ions parallel to the x–y plane. These displacements are greatly exaggerated, these clusters all being close to their final fully flattened configurations. Note also that the arrows are scaled independently in each of the panels for ease of visualization. Only the relative sizes of the arrows within a panel are significant. The colors of the ions indicate their positions relative to the x–y plane, and thus the direction of change of their z coordinates during the flattening process: Red indicates an ion above the x–y plane for which $dz/d\varepsilon < 0$, and blue indicates an ion situated below the plane for which $dz/d\varepsilon > 0$. The intensity of the color is proportional to the distance of the ion from the plane, again with each panel scaled independently. The relative sizes of the z displacements and of the displacements parallel to the x–y plane are maintained throughout the final stages of the flattening process, i.e., they do not depend on the value of ε provided this value is not too large.

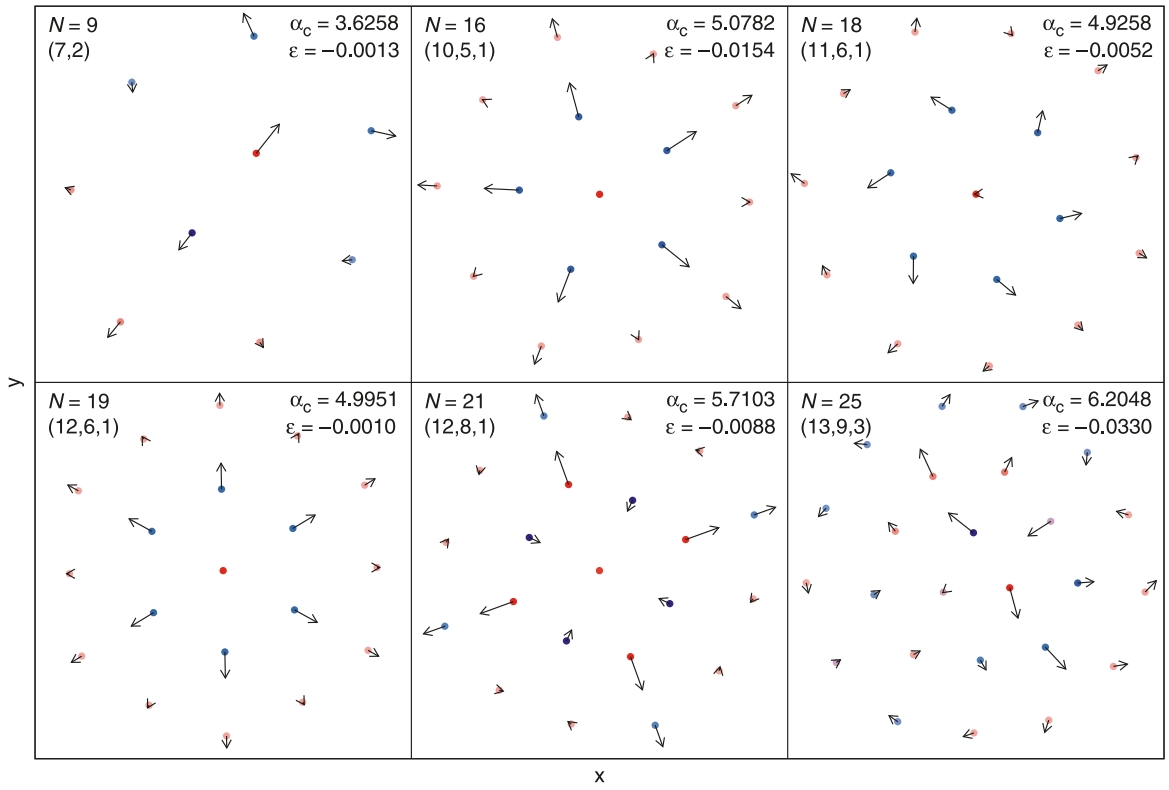


Fig. 6. Critical value of α vs. N. The line segments connect configurations with a common inner-shell configuration. In the three-shell configurations, n and m are both variable. The isolated points are the $N = 15$ (10,5) and $N = 30$ (15,10,5) clusters. Error bars are negligible on this scale and are not plotted.

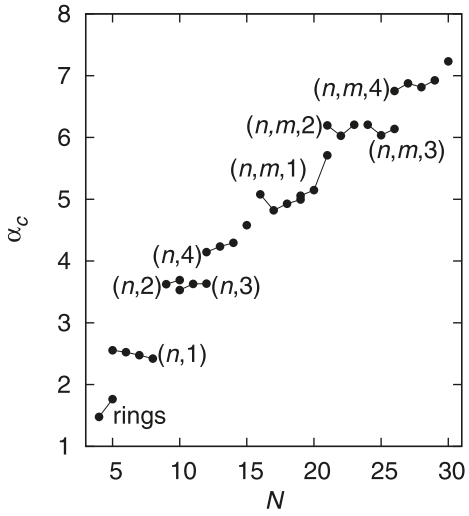

Figure 6 may be compared to Fig. 8 in Calvo and Yurtsever .[19] The latter reports the critical anisotropy as a function of N on a log–log plot, for N between 10 and 1000. This presentation disguises a great deal of the substructure identified here. In fact, the roughly $N^{1/2}$ scaling originally predicted by Dubin[2] and confirmed by Calvo and Yurtsever does not seem to set in until larger values of N are reached than those studied here, where we find a scaling exponent significantly greater than 1/2 (results not shown).

Figure 7 shows the values of the critical exponent β calculated for each of the flattening phase transitions observed in this study. In each case, the estimated value of β is within error of 1/2.

Of course, we expect that all the z coordinates, and not just the largest one, will follow a law similar to eq. [2]. Specifically, we can write

$$[4] \qquad z_i = c_i(-\varepsilon)^{\beta}$$

Figure 8 shows a typical set of z coordinates as we approach the phase transition. Most of the z coordinates behave as shown, with a value of β within error of 1/2. Occasionally, one finds an ion that sits at a small finite distance from the x–y plane for all values of α near (but below)

Fig. 7. Critical exponent β vs. *N*. The error bars are statistical fitting errors, i.e., standard deviations of the parameter estimates, reported only for some typical cases to avoid visual clutter. Where two points are seen for a given value of *N*, the flattening of two different structures was studied.

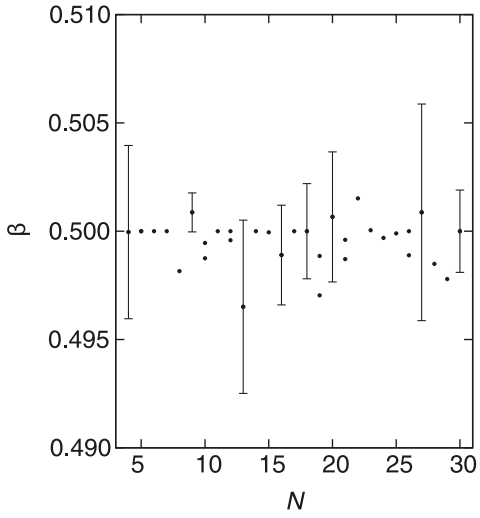

Fig. 8. Fits to eq. [4] of some representative *z* coordinates for the flattening transition of the nine-ion cluster. ε was calculated using eq. [3] and the estimate of α_c obtained from the nonlinear fit of the ζ(α) data (procedure of Fig. 2 with results in Fig. 6). In each case, a critical exponent of approximately 1/2 is obtained.

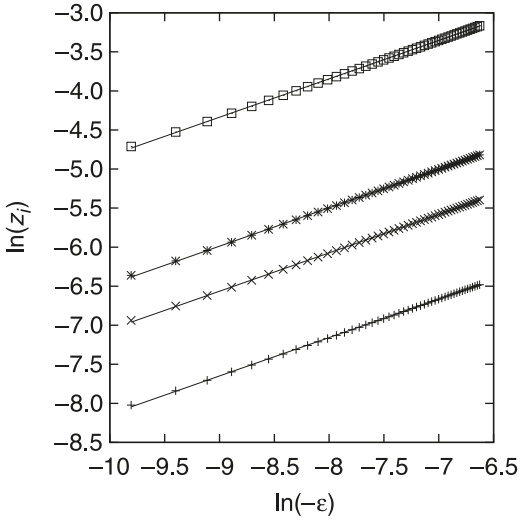
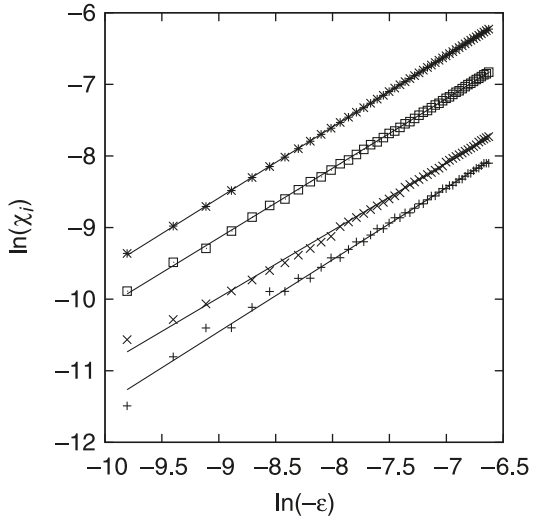


α_c, and whose approach to $z_i = 0$ does not fit eq. [4] particularly well. It is likely that the poor fits in these cases are due to the limited numerical precision of our calculations. Even if this is not the case, the low displacement amplitudes of these ions in the *z* direction makes the precise functional form of their approach to $z_i = 0$ relatively unimportant.

We now analyze the deformation of the structure parallel to the *x*–*y* plane. We can study the changes in the *x* and *y* coordinates individually, but because there is no constraint keeping the cluster from rotating around the *z* axis, energy minimization sometimes results in an incidental twisting component which somewhat obscures the true behavior. Rather, we define the radial coordinate

Fig. 9. Behavior of χ_i near the flattening phase transition for several representative ions for the same process as in Fig. 8. The critical exponent for this coordinate is found to be approximately δ = 1.



$$[5] \qquad \rho_i = \sqrt{x_i^2 + y_i^2}$$

which is invariant with respect to rotations around the *z* axis. Let ρ_i^∞ be the value of ρ_i beyond the phase transition, i.e., in the fully flattened cluster. Define also

$$[6] \qquad \chi_i = |\rho_i - \rho_i^\infty|$$

Clearly, $\chi_i \to 0$ as $\varepsilon \to 0^-$. We assume that, below the phase transition,

$$[7] \qquad \chi_i \sim (-\varepsilon)^\delta$$

Again, with the exception of ions with very small displacement amplitudes parallel to the *x*–*y* plane during the phase transition, we find that eq. [7] is generally a good fit to the displacements (Fig. 9). Moreover, we find that the exponent δ is generally within error of 1.

Coupling of expansion and flattening

We can use our computational results to motivate a theoretical treatment that will determine the coupling of the radial expansion (parallel to the *x*–y plane) to the flattening in the *z* direction. We begin by assuming that eq. [4] holds and that the behavior found for χ_i also holds for x_i and y_i. With the caveats mentioned above regarding the rotational freedom around the *z* axis, this appears to be true except perhaps for ions whose displacement amplitudes parallel to the *x*–*y* plane are vanishingly small. Thus we write

$$[8] \qquad x_i = x_i^\infty - a_i(-\varepsilon)^\delta$$

and

$$[9] \qquad y_i = y_i^\infty - b_i(-\varepsilon)^\delta$$

In these equations, x_i^∞ and y_i^∞ are the coordinates of the ion in the fully flattened structure. The geometric interpretation of the vector (a_i,b_i) is that it points in the direction of displacement for an ion parallel to the *x*–*y* plane as the ion approaches its final coordinates (x_i^∞, y_i^∞). Note that

eqs. [4], [8], and [9] define the trajectory of an individual ion in three-dimensional space during the flattening process. If we substitute these equations into the potential (eq. [1]) and use eq. [3] to eliminate α, we obtain an equation for the variation of u with ε as we approach the phase transition, i.e., as $\varepsilon \to 0^-$. In this region, both $(-\varepsilon)^\beta$ and $(-\varepsilon)^\delta$ are small quantities. We can expand the potential in powers of these small quantities, a tedious but straightforward process. To lowest order, and assuming that $1 + 2\beta > \delta$, we get

$$[10] \quad u(\varepsilon) \approx u(0) + \sum_{i=1}^{N-1}\sum_{j=i+1}^{N}[p_{ij}(-\varepsilon)^\delta - q_{ij}(-\varepsilon)^{2\beta}] + \frac{1}{2}\sum_{i=1}^{N}[-2(a_i x_i^\infty + b_i y_i^\infty)(-\varepsilon)^\delta + \alpha_c c_i^2(-\varepsilon)^{2\beta}]$$

where

$$[11] \quad p_{ij} = \frac{(x_i^\infty - x_j^\infty)(a_i - a_j) + (y_i^\infty - y_j^\infty)(b_i - b_j)}{(r_{ij}^\infty)^3}$$

$$[12] \quad q_{ij} = \frac{(c_i - c_j)^2}{2(r_{ij}^\infty)^3}$$

r_{ij}^∞ is the distance between ions i and j in the fully flattened structure, and $u(0)$ is the corresponding energy (a well-defined quantity due to the continuity of the energy in a second-order phase transition). Note that we can immediately rule out cases where either δ or 2β is less than one since, for a second-order phase transition, the first derivative is continuous through the phase transition, whereas, according to eq. [10], it diverges for $\delta < 1$ or $2\beta < 1$. We can also rule out the possibility that both δ and 2β are greater than 2 since, in this case, both $u'(\varepsilon)$ and $u''(\varepsilon)$ would tend to zero as $\varepsilon \to 0^-$. As we saw earlier (Fig. 1 and associated discussion), this is the correct behavior for $u'(\varepsilon)$ but not for $u''(\varepsilon)$, which must be negative for $\varepsilon < 0$. We can go a little further, and state that the leading coefficient cannot have an exponent between 1 and 2, or $u''(\varepsilon)$ would diverge as $\varepsilon \to 0^-$, which is not observed in our numerical results (Fig. 1). Accordingly, we can conclude that $\delta \geq 1$, $2\beta \geq 1$, and min $(\delta, 2\beta) \in \{1,2\}$.

Our computational results support the values $\delta = 2\beta = 1$ for the critical exponents. Assume that this is the case. Then we have

$$[13] \quad u'(\varepsilon) \approx -\sum_{i=1}^{N-1}\sum_{j=i+1}^{N}[p_{ij} - q_{ij}] - \frac{1}{2}\sum_{i=1}^{N}[-2(a_i x_i^\infty + b_i y_i^\infty) + \alpha_c c_i^2]$$

where again this result is valid only for $\varepsilon < 0$. As noted above, we must have $u'(\varepsilon) \to 0$ as $\varepsilon \to 0^-$. Thus, the constant expression given in eq. [13] must be identically zero. The first nonzero term in the expansion of $u(\varepsilon)$ would therefore be the quadratic term, which is consistent with our computational results, as discussed earlier.

We also know that at every critical point, $u_{\text{Coulomb}} = 2u_{\text{trap}}$, where u_{Coulomb} is the Coulomb repulsion energy, and u_{trap} is the energy due to the harmonic trapping potential.[23] If we separate eq. [10] into Coulomb and trapping terms and apply the balancing relationship, the corresponding terms of $u(0)$ automatically satisfy the balancing relationship since they are critical points of the large-α problem. This leaves

$$[14] \quad \sum_{i=1}^{N-1}\sum_{j=i+1}^{N}[p_{ij} - q_{ij}] = \sum_{i=1}^{N}[-2(a_i x_i^\infty + b_i y_i^\infty) + \alpha_c c_i^2]$$

If we now set eq. [13] to zero and use eq. [14] to eliminate the double sum, we conclude that each of the two contributions to $u'(\varepsilon)$ must individually be equal to zero. In particular,

$$[15] \quad 2\sum_{i=1}^{N}(a_i x_i^\infty + b_i y_i^\infty) \approx \alpha_c \sum_{i=1}^{N} c_i^2$$

Numerically, we find that eq. [15] is approximately obeyed, typically to a few parts in 10^3, and always within 2%. The small deviations observed are due to a number of factors: the precision of the estimate of α_c, which also affects our estimates of the vectors (a_i,b_i) and of the amplitudes c_i through eqs. [3], [4], [8], and [9]; the loss of precision in the subtraction necessary to obtain the vectors (a_i,b_i) using eqs. [8] and [9]; the possibility of slight rotations of the whole cluster during optimization; and of course the fact that we derived eq. [15] through a theory that only examines the lowest-order terms.

We can obtain a great deal of qualitative insight from eq. [15]. For instance, since the right-hand side of this equation is strictly positive, the sum of dot products on the left must also be a positive quantity. This confirms the intuition that, on average, displacements of the ions must be directed outward during flattening. Moreover, since the left-hand side involves the dot product of the vectors (a_i,b_i) and (x_i^∞, y_i^∞), we would typically expect that ions in the outer shells would have smaller displacements during flattening, which is again confirmed by our numerical results (Fig. 5).

Given the numerical confirmation of eq. [15], which implies that the double sum on the left-hand side of eq. [14] is also zero, we can then ask whether these equalities impose any further conditions on the critical exponents. Suppose that $\delta = 2\beta = 2$. Then the limit as $\varepsilon \to 0^-$ of $u'(\varepsilon)$ is automatically zero. However, $u''(\varepsilon)$ is then also identically zero for $\varepsilon < 0$, which is contrary both to our data (Fig. 1) and to the argument presented above that the second derivative of u should be negative. Thus, if we take both [14] and [15] as premises along with our earlier reasoning about the critical exponents, we conclude that at least one of δ or 2β must have the value 1.

Conclusions

We have studied the flattening phase transition in systems of ions held in a harmonic trap. The critical exponent corresponding to the order parameter ζ was found by computational experiment to have the value 1/2. The critical value of the trap anisotropy, α_c, was shown to display jumps where the inner-shell configuration changes. A second critical exponent related to the amplitude of displacements parallel to the x–y plane was found to have the value $\delta = 1$. Using these estimates of the critical exponents, we derived

eq. [15], which gives an explicit coupling between the amplitudes of displacements toward the *x*–*y* plane and the radial expansion of the cluster during the flattening process. Using a combination of numerical results and analysis, we were also able to place some constraints on the values of the critical exponents, specifically that $\delta \geq 1$, $2\beta \geq 1$, and $\min(\delta,2\beta) = 1$. It would be gratifying to prove from first principles that β and δ must have the values obtained in our computations. Notwithstanding, our analysis does provide a useful consistency check on our computational results.

There are several ways in which this study could be extended. One of the more interesting variations would be to examine what happens if either the interatomic potential or the trapping potential were different in form. For the interatomic potential, the shielded Coulomb potential would be particularly interesting since it describes, among other systems, dusty plasmas.[9,40] Are the critical exponents found here universal exponents for flattening processes, or are they particular to the interatomic and trapping potentials in eq. [1]? We have focused here on the final flattening, which is the easiest phase transition to define and the only one that occurs for almost every flattening sequence. Since we often find phase transitions associated with the flattening of parts of the structure (e.g., the flattening of the outer ring for $N = 8$ illustrated in Fig. 4), it would also be of some interest to study the behavior of a suitably constructed order parameter for these transitions. Does the corresponding critical exponent have a value of 1/2 as for the final flattening?

Complementary information could also be gathered using other techniques. We have focused here on the equilibrium structures on the PES and the manner in which they change as α is varied. We have not attempted to search for saddle points (i.e., transition states) connecting coexisting equilibria found, for instance, in the $N = 8$ system. These could be found using constrained optimization methods, and would yield valuable information on the expected rate of transitions between coexisting structures. Information on the transition rates could also be obtained from molecular dynamics (MD) simulations. MD simulations of these systems would yield a wealth of additional information, notably on the response of these systems to fluctuations in the trap parameters, especially in the vicinity of phase transitions or in regions displaying hysteresis.

Neptunium(VII) in high-ionic-strength alkaline solutions — $[NpO_2(OH)_4]^{1-}$ or $[NpO_4(OH)_2]^{3-}$?

John E. C. Wren and Georg Schreckenbach

Abstract: Relativistic density functional theory (ZORA-PBE, COSMO solvation) is used to address the title question, based on comparison with recent experimental data (1). Structural data (bond lengths), vibrational frequencies, and ^{17}O NMR chemical shifts are used to prove that $[NpO_4(OH)_2]^{3-}$ is the predominant species in high-ionic-strength alkaline solutions of Np^{VII}. Neptunium(VII) complexes have stronger bonds than their formally isoelectronic uranium(VI) analogues. The experimentally observed 300 ppm shift in ^{17}O chemical shifts between the known $[UO_2(OH)_4]^{2-}$ and Np^{VII} solution is shown to be partly a function of the central metal (Np^{VII} vs. U^{VI}) and not of the coordination environment (tetraoxo vs. dioxo). Comparing, for a given An (U^{VI} or Np^{VII}), actinyl complexes $[AnO_2X_4]^{2-/1-}$, X = Cl, F, OH, a decreasing strength of the axial actinyl bond is observed that is traced to electronic factors (equatorial π-competition).

Key words: neptunium, density functional theory, relativity, NMR chemical shifts, alkaline solution.

Résumé : En se basant sur une comparaison avec des données expérimentales récentes (1), on a utilisé la théorie de la fonctionnelle de la densité relativiste « ZORA-PBE, solvatation COSMO » pour étudier la question mentionnée dans le titre. On a utilisé les données de structure (longueurs de liaison), les fréquences de vibration et les déplacements chimiques en RMN du ^{17}O pour prouver que le cation $[NpO_4(OH)_2]^{3-}$ est l'espèce prédominante dans les solutions alcalines de force ionique élevée du Np^{VII}. Les complexes du Np^{VII} possèdent des liaisons plus fortes que leurs analogues formellement isoélectroniques de l'uranium(VI). On a démontré que les déplacements chimiques de 300 ppm observés expérimentalement pour les ^{17}O du cation connu $[UO_2(OH)_4]^{2-}$ et de la solution de Np^{VII} sont partiellement fonction de l'atome métallique central [Np^{VII} vs. U^{VI}] et non pas de l'environnement de coordination (tétraoxo vs. dioxo). Pour un actinyle, An, donné, lorsqu'on compare des complexes d'actinyle d'uranium(VI) et de neptunium(VII) de formule générale $[AnO_2X_4]^{2-/1-}$ dans lesquels X = Cl, F, OH, on observe une diminution de la force de la liaison axiale de l'actinyle qui peut être attribuée à des facteurs électroniques (compétition équatoriale/π).

Mots-clés : neptunium, théorie de la fonctionnelle de la densité, relativité, déplacements chimiques en RMN, solution alcaline.

[Traduit par la Rédaction]

Introduction

The purpose of this paper is to provide a definite answer to the title question: Is neptunium(VII) in high-ionic-strength alkaline solution present as $[NpO_2(OH)_4]^{1-}$ or as $[NpO_4(OH)_2]^{3-}$? We address this question by applying the tools of computational quantum chemistry to calculate a variety of spectroscopic properties that can be compared directly to the available experiment, particularly the new data from Clark and co-workers published in 2004.[1]

Neptunium is the first transuranic element, and the lowest of the artificially produced actinides in the periodic table. Because of its relatively long half-life of 2.1×10^6 years, the isotope ^{237}Np, when part of high-level nuclear wastes, is of great environmental concern.[2] Hence, besides fundamental interest, there is immediate practical interest in understanding the aqueous chemistry of the element.

The identity of neptunium(VII) in alkaline solutions has been discussed controversially in the literature.[1,3–7] Although originally the dominant ion was thought to be $[NpO_2(OH)_4]^{1-}$, i.e., a neptunyl structure similar to that of most early actinides in high oxidation states (including the isoelectronic uranyl(VI) hydroxide, $[UO_2(OH)_4]^{2-}$[8,9]), in recent years, this has been contested. Appelman et al.[3] proposed a coordination environment of four oxo ligands, i.e., the $[NpO_4(OH)_2]^{3-}$ version of the molecule. This has been disputed by Clark and co-workers[4] who interpreted their solution X-ray data (XAFS) as pointing towards the neptunyl species, $[NpO_2(OH)_4]^{1-}$. Williams et al.,[5] however, confirmed the original tetraoxo proposal of Appelman et al., based on solution X-ray measurements (XANES, EXAFS). Simple gas-phase density functional theory (DFT) calculations were also performed, though they suffer from imaginary frequencies.

Bolvin and co-workers[6,7] picked up the discussion using both DFT calculations with small-core effective core poten-

tials (SCECP) and X-ray measurements (EXAFS). They, too, interpret their data as pointing toward the tetraoxo species. This conclusion is chiefly based on comparing experimental EXAFS results (mostly bond lengths) and DFT calculations with and without continuum solvation (CPCM). Bolvin et al. also provide a discussion of the bonding modes in tetraoxo actinide complexes.

The most recent experimental paper came again from the Clark group.[1] In this paper, the authors revise their earlier conclusion and find strong support for the tetraoxo species, $[NpO_4(OH)_2]^{3-}$. This new work clearly goes beyond any of the earlier studies that had relied on bond-length information, both on the experimental (various solution X-ray techniques, with their associated need for fitting the data and resulting uncertainties) and theoretical sides. Indeed, Clark et al. provide evidence from ^{17}O NMR shifts of the oxo ligands (viz. a shift of some 300 ppm as compared with the known uranyl(VI) hydroxide complexes in basic solution). Furthermore, additional evidence comes from Raman spectroscopy (where we note, however, that the expected B_{1g} Raman frequency was not present in their analysis of the structure, although the expected A_{1g} frequency was), as well as from solution X-ray studies.

In light of this new data, we feel that it is timely to computationally reexamine the nature of neptunium(VII) in basic solutions, and to include *all* of the available spectroscopic data (i.e., ^{17}O NMR chemical shifts and vibrational spectroscopy, in addition to the bond-length data of the previous studies). Specifically, we make use of the ability of theory to examine hypothetical species such as, for example, a hypothetical $[UO_4(OH)_2]^{4-}$, and to differentiate between the various effects. Likewise, while Clark et al.[1] had to *assume* that the observed 300 ppm difference in ^{17}O chemical shifts is a function of the ligand environment (tetraoxo vs. dioxo) and not the central metal (Np^{VII} vs. the isoelectronic U^{VI}), we can address that question directly.

For this study, we undertook calculations on eight different actinide complexes, namely $[UO_2(OH)_4]^{2-}$, $[NpO_2(OH)_4]^{1-}$, $[UO_4(OH)_2]^{4-}$, $[NpO_4(OH)_2]^{3-}$, $[UO_2Cl_4]^{2-}$, $[NpO_2Cl_4]^{1-}$, $[UO_2F_4]^{2-}$, and $[NpO_2F_4]^{1-}$. All species were chosen to be in either the U^{VI} or Np^{VII} oxidation state, creating essentially isoelectric species. Although not all of these species have been found experimentally, the three uranyl(VI) complexes have been well-explored computationally.[10] These species were therefore used as a guide along which the neptunyl(VII) ions could be compared, providing confirmation of the correct methodology, particularly for the NMR calculations.

Computational details

Currently, density functional theory (DFT)[11–13] is the almost sole practical method for calculations on actinide molecules.[14–17] This is due to the size of typical molecules, combined with the central importance of electron correlation effects that are included in DFT in an approximate and efficient manner. In this study, we have applied DFT with the PBE exchange-correlation functional.[18] Generalized gradient approximation (GGA) functionals such as PBE have been shown to provide reasonably accurate geometries and vibrational frequencies for actinide molecules.[19–22] All calculations were performed with the ADF program.[23–25]

Relativistic effects are essential for even a qualitative description of heavy-element chemistry.[26] Relativity has been included by applying the zeroth order regular approximation (ZORA) for relativistic effects.[27–32] ZORA has been shown to give accurate results that are comparable to other modern relativistic methods such as, for instance, all-electron four-component calculations.[19–22] Spin-orbit effects have been neglected for the computation of structures and frequencies. This is a generally thought to be a good approximation, particularly since the molecules at hand are formally closed-shell, f^0 species. For NMR calculations, however, spin-orbit cannot be neglected.[10,33–35]

The ADF code uses accurate numerical integration for all integrals.[25,36] A numerical integration parameter of ACCINT = 5.5 was applied. All structures were optimized either in the gas phase or in continuum solvation (see below) without any symmetry constraints, using standard convergence criteria as implemented in ADF. The optimized structures of $[NpO_4(OH)_2]^{3-}$ and $[NpO_2(OH)_4]^{1-}$ are shown in Fig. 1. Frequency calculations were then performed to verify that true minima had been achieved. In the gas phase, the hypothetical $[UO_4(OH)_2]^{4-}$ complex did not converge to a true minimum state with real frequencies, despite numerous attempts. This is likely related to the significant charge of this ion that leads to the molecule being unstable without the stabilizing effect of a polarizable solvent (as, e.g., in the COSMO model).

Following our earlier work on NMR shielding (chemical shift) calculations in diamagnetic (f^0) compounds of actinide elements,[10,33,34,37] we applied the GIAO-NMR methods as implemented in ADF.[38–42]

All-electron Slater-type basis sets of triple- and quadruple-ζ polarized quality (ZORA-TZ2P, ZORA-QZ4P) were used, since NMR chemical shifts tend to place higher requirements on basis set convergence than, for instance, geometries. For reduced computational cost, quadruple-ζ basis sets were reserved solely for the metal centers, while the ligands were calculated using the triple-ζ basis sets.

Solvation effects might be crucial for the electronic structure (and consequently for the spectroscopic observables) of the highly charged molecules of interest. In our previous studies on NMR parameters of actinide molecules,[10,33,34,37] we had not been able to include such effects, since, at the time, no code had both, relativistic NMR and a continuum solvation model implemented. This has changed since, and we have modeled bulk solvation with the COSMO model[43] as implemented in ADF.[44] ADF requires that radii be assigned to the individual atoms to set up the COSMO surfaces. These radii were taken from Klamt's paper on the COSMO surfaces (see ref. 45), where parameters are provided for all of the necessary elements.[45,46] Test calculations with a different set of atomic radii (having smaller values) resulted in minor changes of the spectroscopic observables only. Although Klamt did not publish radii for the actinide elements, it has been shown that, due to their central position in the complex, the central atom is essentially solvated by the overlap of the ligands; therefore, the actinide radius was set to a relatively small value of 1.70 Å. The effects of central-metal-atom radii for COSMO surfaces has

Fig. 1. Optimized structures of $[NpO_4(OH)_2]^{3-}$ and $[NpO_2(OH)_4]^{1-}$.

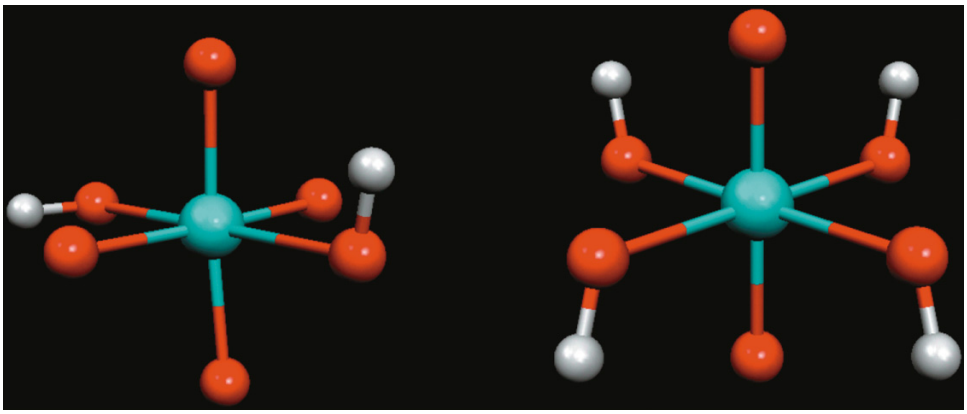

Table 1. Calculated and observed ^{17}O absolute NMR shieldings for the oxo ligands of diamagnetic actinide complexes (ppm).

					Gas phase			
Np^{VII} complexes	Gas phase	COSMO	Experimental	U^{VI} complexes	Reference 10	This work	COSMO	Experimental
$[NpO_2F_4]^-$	–997. 5	–991.1		$[UO_2F_4]^{2-}$	–768.0	–815.6	–891.3

$[NpO_4(OH)_2]^{3-}$	–1041.1	–1022.1	–1179.1±8[a]	$[UO_4(OH)_2]^{4-}$		Dissociative	–1005.2	

Note: These values represent the average of all formally equivalent oxo ligands within the complex. The experimental values have been converted to absolute shieldings.

[a]Reference 1; assigned to $[NpO_4(OH)_2]^{3-}$ (see the text).

[b]Reference 8; cited as absolute shielding as per ref. 10. It is likely that this particular experimental value refers to the pentahydroxide, $[UO_2(OH)_5]^{3-}$, or a mixture of $[UO_2(OH)_4]^{2-}$ and $[UO_2(OH)_5]^{3-}$; see the discussion in our earlier paper.[10]

been shown to have little effect on results, noting that the central atom is indeed mostly buried. Hence, the current choice of metal radius is considered reasonable.[47,48]

Results

^{17}O NMR shieldings (chemical shifts) in U^{VI} and Np^{VII} complexes

As discussed in the introduction, Clark et al.[1] have taken their new ^{17}O NMR data as the strongest evidence for the tetraoxo complex to be the dominant species in highly alkaline solutions of neptunium(VII). Hence, we have calculated ^{17}O NMR shieldings for the pertinent Np^{VII} complexes, the analogous isoelectronic U^{VI} complexes, as well as four other diamagnetic (f^0) actinyl compounds. This series of compounds allows us to verify our computational protocol and to distinguish between effects of the central metal and the ligand environment.

In our earlier paper,[10] we had studied ^{17}O NMR shieldings for a few uranyl(VI) complexes. Comparison with the available experimental data (converted to absolute shieldings) yielded modest agreement between theory and experiment. Importantly, though, the qualitative experimental trend within a series of three compounds was reproduced correctly. Since our current computational protocol differs from the earlier one (basis sets, the particular choice of GGA functional, and, perhaps most importantly, the inclusion of COSMO solvation), we have reexamined some of these compounds, specifically $[UO_2Cl_4]^{2-}$, $[UO_2F_4]^{2-}$, and $[UO_2(OH)_4]^{2-}$, Table 1. This was done to verify the current computational protocol and to provide reference data for the formally isoelectronic Np^{VII} compounds that are the target of our study. We have also included the hypothetical uranium(VI) complex $[UO_4(OH)_2]^{4-}$, as well as the corresponding neptunium(VII) complexes.

Comparing first our gas-phase calculations on uranium(VI) complexes to the older results from ref. 10, we note that there is reasonable agreement between the two sets of data, giving confidence in the current protocol. Most importantly, the relative chemical shift between the three compounds is similar between the two methods, and the current calculations are slightly (though not dramatically) closer to the experimental value for the uranyl hydroxide. The overall agreement with experiment is modest, similar in quality to our earlier studies. However, it is sufficient to draw conclusions regarding the neptunium(VII) complexes, see below.

Bulk solvation effects (COSMO), not covered in the earlier studies, are seen to have a modest, relatively constant influence on the shieldings in the uranium(VI) complexes, Table 1 (solvation shifts of –53 to –74 ppm). The solvation influence on the isoelectronic neptunium(VII) species is generally much smaller. This can be understood from the smaller charge in the neptunium case, noting that the free energy of solvation is to first order proportional to the charge squared. The only exception to this statement is the (hypothetical) $[NpO_2(OH)_4]^{1-}$ complex where the solvation shift is –68 ppm. This is larger than for the other Np species, though still modest. The reason for this difference is not clear. We note that trends in calculated shieldings (chemical shifts) depend on a variety of factors that can all

be influenced by continuum solvation, particularly structural parameters, molecular orbital (MO) compositions (polarization of the electronic structure), and MO energies.

The data in Table 1 allow for a direct comparison between the two actinide metals U^{VI} and Np^{VII}, as well as between different ligand environments. Inspection of the data demonstrates that the effect of the central metal atom within each of the studied complexes on the absolute shift of the oxo ligands is variable. In the fluorine complexes, we note a shift of about 100 ppm between the neptunium(VII) species and the corresponding uranium(VI) species, while in the less electronegative chlorine complexes, the shift is only in the order of 60 ppm (for COSMO solvated species).

The neptunium(VII) data allow for a comparison between the two target species of this paper, viz. $[NpO_2(OH)_4]^-$ and $[NpO_4(OH)_2]^{3-}$. It is noteworthy that the difference in the shift between the tetraoxo and and dioxo hydroxide species is only a meager 43 ppm for neptunium(VII) (solvated complexes; the gas-phase difference is still relatively small at 130 ppm), but in uranium(VI), the shift is a significant ~270 ppm. While we do reproduce the experimentally observed shift of some 300 ppm between $[NpO_4(OH)_2]^{3-}$ and $[UO_2(OH)_4]^{2-}$, a large part of that difference appears to be a function of the central metal and *not* the ligand environment. Below, we will further discuss this data in comparison with the available experiment.

Vibrational frequencies

Vibrational frequencies (Raman) provide another set of data to help assign the coordination environment of neptunium(VII). Calculated vibrational frequencies for the symmetric and antisymmetric actinyl stretches in Np^{VII} and U^{VI} complexes are collected in Table 2. From the data in Table 2, we can see that of the standard actinyl ($[AnO_2L_4]^n$) species the stretching frequencies are strongest for the chlorine complexes, and weakest for the hydroxide species. This can be related to the equatorial bonding mode in these complexes, with the hydroxide complexes having the strongest equatorial bond that contains partial π-character. The ensuing π-competition weakens the axial bond, as is directly evident from the frequencies, see also below.[15]

For the tetraoxo complexes, there are four stretching modes in total. They can either be classified by symmetry labels within the approximate D_{4h} point group of the $[AnO_4]^{-/2-}$ ion or they can be viewed as linear combinations of the two sets of AnO_2 stretches along the x and y axes, respectively. We have chosen the latter classification, since the optimized structures have no symmetry. Moreover, this approach allows for a direct comparison with the dioxo complexes (Table 2).

When the tetraoxo species are compared with the others, it is notable that the stretching modes incorporate all four ligands moving together in unison. The frequencies are lower than those in the dioxo complexes, which is indicative of much weaker bonds.[6,7] Whereas, for the various actinyl complexes, the range in frequencies did not exceed 100 cm^{-1}, the tetraoxo species have stretching frequencies that are ~200 cm^{-1} lower then those of the other complexes. As mentioned, in the tetraoxo complexes, the antisymmetric stretches occur over two frequencies, each involving a different pair of oxo ligands. Also, the trend seen in the other complexes is for the symmetric stretch of the oxo ligands to be at lower frequency over the antisymmetric stretch, but in the tetraoxo species, the two symmetric stretches bracket the antisymmetric ones, with the totally symmetric four-oxo-ligand stretch being at higher frequency as compared with the two antisymmetric stretches.

It is also instructive to compare the calculated frequencies for corresponding isoelectronic complexes of uranium(VI) and neptunium(VII). We note that, in each case, the latter metal has stronger bonds, evident from higher stretching frequencies. The difference is particularly pronounced for the antisymmetric stretches but is consistently present in the symmetric stretches also. This is in contrast to periodic trends when the actinide metal oxidation state stays the same along the series, e.g., comparing U^{VI} with Np^{VI} and Pu^{VI}. In these cases, we generally see weaker bonds as we go along the series.[19,49] Along the series, the 5f orbitals gradually decrease in size and energy, leading to this trend. However, the higher positive charge of Np^{VII} as compared with Np^{VI} offsets the trend.

Geometries

Calculated metal–oxo-ligand bond distances have been collected in Table 3. The data show a strong indication that as the electronegativity increases in the equatorial ligands, the bond distances grow shorter for the actinide–oxygen double bond. This can be related to the differing degree of equatorial π-competition, as discussed above.

Neptunium(VII) bond lengths are significantly shorter than the corresponding uranium(VI) bond lengths. We relate this to the stronger bonds in the former case (see the frequency discussion above), as well as to the actinide contraction, which results in 5f orbitals that become more contracted and lower in energy towards the right of the actinide series. This can be compared to trends for compounds in the same oxidation state. In these cases, the bonds are generally getting shorter *and* weaker along the series, which has been traced solely to the actinide contraction.[19,49]

Regarding the title question of the paper, we note that the AnO_4 species have a much greater average bond length than the corresponding AnO_2 species. This suggests much weaker overall bond strengths and a more diffuse electronic structure, similar to what was already suggested in the discussion of the frequencies. A further comparison of some of the neptunium(VII) bond lengths with experiment will be provided below.

Discussion

Within their 2004 paper,[1] Clark et al. make three specific arguments for the preferential state of Np^{VII} in high-ionic-strength alkaline solutions. One argument is based on geometry, a second one on vibrational frequencies, and finally a third argument on the observed ^{17}O NMR chemical shift. From our results, we are able to add further insight into these arguments.

Geometries / bond lengths

Table 4 contains a comparison between Clark's 2004 solution XAFS data,[1] Bolvin's 2001 EXAFS, and computational results (both gas phase and CPCM solvated[6,7]), and

Table 2. Vibrational frequencies for oxo-ligand symmetric and antisymmetric stretches in Np^{VII} and U^{VI} complexes (cm^{-1}).

	$[NpO_2(OH)_4]^-$		$[UO_2(OH)_4]^{2-}$		$[NpO_4(OH)_2]^{3-}$		$[UO_4(OH)_2]^{4-}$

[a]Cited from Clark et al., ref. 1. The numbers cited for $[NpO_2(OH)_4]^-$ correspond to an *expected* range for neptunyl(VII) in general, based on literature data, whereas those listed under $[NpO_4(OH)_2]^{3-}$ are the actually *observed* Raman frequencies. In this case, the two numbers refer to alkaline solution and crystal structure, respectively.

Table 3. Calculated metal–oxo-ligand bond distances for Np^{VII} and U^{VI} complexes (average; Å).

Complex	Gas phase	COSMO
Np^{VII} complexes		
$[NpO_2F_4]^-$	1.792	1.789
$[NpO_2Cl_4]^-$	1.769	1.768

$[UO_4(OH)_2]^{4-}$	Dissociative	2.006

our own computational data in both gas-phase and solvated COSMO models. Our results agree reasonably well with those of Bolvin et al., particularly if we keep in mind that the B3LYP hybrid DFT functional used by these authors has a tendency for overbinding in actinide complexes, i.e., bond lengths that are too short and frequencies that are too high[20] (even in cases where the best choice of DFT functional might not be as clear cut that the designation of "overbinding" would be justified, one can still confidently state that B3LYP bond lengths are shorter than those from GGA functionals, which tend to be too long as compared with experiment; all of this is borne out clearly in the data in Table 4).

As mentioned already, the bond lengths for the actinide-to-oxygen bonds in the $[AnO_2(OH)_4]^{-/2-}$ species (where they are partial triple bonds) are always in the order of 10–15 pm shorter than for the corresponding $[AnO_4(OH)_2]^{3-/4-}$ species. This would confirm that the long oxo-ligand bond lengths observed by Clark et al.[1] within their Np^{VII} solution sample (XAFS) are likely those of $[NpO_4(OH)_2]^{3-}$. This conclusion is further strengthened with the comparison between their observed neptunium–hydroxide bond lengths and our calculated bond lengths, which are within the experimental error of the crystal X-ray data for $[NpO_4(OH)_2]^{3-}$, with the solution data leaning heavily towards the tetraoxo Np^{VII} species (particularly when keeping in mind that GGA bond lengths would be expected to be slightly too long, as mentioned above).[20] We note in passing the strong influence of solvation on the Np–O(H) distance. This is consistent with earlier results.[19]

Vibrational frequencies

The next argument of Clark et al.[1] was based on the observation of the Raman spectra of both crystal and solutions of Np^{VII} complexes. Specifically, they note that the expected symmetric and antisymmetric oxo-ligand stretching modes should be observed with, respectively, A_{1g} and B_{1g} symmetry. Although they were unable to observe the antisymmetric stretch for some unknown reason, they were able to observe a symmetric stretch with a frequency of 716 cm^{-1} in the crystal and 735 cm^{-1} in 2.2 mol/L LiOH solution.

Table 2 provides a comparison of these data with our calculated data for the two neptunium(VII) structures. From a qualitative view point, we can say that in both Clark's experimental and our calculated data, we observe a strong decrease in frequency between the dioxo and tetraoxo complexes. This reduction in frequency provides further confirmation that, within Clark's sample, there appears to be a tendency towards the formation of the tetraoxo neptunium complex over the dioxo complex. We should also note that GGA functionals tend to yield frequencies that are slightly too low (in accordance with the mentioned overestimation of bond lengths). Hence, it is logical to assign the observed frequency to a calculated value that is lower (as in the tetraoxide) rather than higher (in the dioxo complex).

^{17}O NMR

Finally, the Np^{VII} complexes were investigated by ^{17}O NMR, both by Clark et al. through experimentation and by us using relativistic density functional theory. Clark's team was able to observe an ^{17}O NMR chemical shift of 1470 ppm for Np^{VII} in a high-ionic-strength alkaline solution, which, if referenced against water at 290.9 ppm, gives an absolute shielding of –1179.1 ppm, Table 1. It is their reasoning that since the commonly observed ^{17}O chemical shift for UO_2^{2+} is only about 1125 ppm, or –834.1 ppm in absolute shieldings, the greater NMR shift for Np^{VII} must indicate a greater electron density on the oxygen atoms and therefore implies a weaker bond, which would coincide with the expected electronic structure of the $[NpO_4(OH)_2]^{3-}$ complex over the dioxo species.

In our calculations, we notice an error within this argument; it essentially ignores the contributions of the central metal to the NMR shifts of the oxo ligands, which appears to be more significant than expected. By calculating the NMR shifts for both the dioxo and tetraoxo complexes for both

[a]Clark et al. reference various known dioxo-Np^{VII} species as having average oxo-ligand bond lengths of 1.75 Å.

[b]The discussion in the paper of Bolvin et al. left the identity of the Np^{VII} species within solution as an unknown; therefore, their EXAFS results could be applied to either. However, in light of the current discussion, it appears as though they were likely observing $[NpO_4(OH)_2]^{3-}$.

neptunium and uranium, we can see that the metal has a large influence on the shift behavior, Table 1. It is noteworthy that there appears to be a difference between the literature values and the calculated values of about 90–150 ppm, depending on whether the COSMO data are considered over the gas-phase calculations and whether the comparison is between the experimental values for the dioxo uranyl or the tetraoxo neptunyl complexes and their respective calculated shifts. It could also be argued that the COSMO model is not entirely accurate for this system, since it was optimized for representing a solvent shell of water, not a high-ionic-strength alkaline solution such as the one Clark's samples are in. However, it was established in our practice that the COSMO surfaces allowed for easier convergence for the highly charged species such as the tetraoxo uranium complex.

Looking at the data collected in Table 1, we observe that the differences between the di- and tetra-oxo species is seen to be fairly significant between the two uranyl species, with a difference in the order of 274 ppm. Meanwhile, the difference between the Np^{VII} dioxo and tetraoxo species is only in the order of 43 ppm, much less significant than that of uranium(VI). This observation dictates that these NMR shifts are not solely a factor of the conformation of the ligands or their bonding structure but also depend on the nature of the central contributing metal. Still, the comparison of computed and experimental shieldings allows again for an unequivocal assignment of the observed complex to be $[NpO_4(OH)_2]^{3-}$, Table 1.

Axial and equatorial bond strengths in actinyl complexes

In addition to addressing the title question, the data (particularly the data in Tables 2 and 3) allow for a comparitive discussion of actinyl complexes $[UO_2X_4]^{2-}$ and $[NpO_2X_4]^{1-}$ along the series of ligands X = Cl, F, and OH,. Along the series, we notice a clear trend of increasing axial (actinyl) bond lengths and decreasing bond strengths, the latter inferred from the calculated vibrational frequencies, Table 2. We had found the same trend in our earlier study of the uranyl complexes, at the time using inferior relativistic methods.[15] It is reassuring, then, that these trends are confirmed by the current, more accurate calculations.

The three complexes in each series have the same charge (2– and 1–, respectively, for U^{VI} and Np^{VII}) and the same coordination environment, octahedral coordination of two axial oxo ligands and four equatorial X^{-} ligands. Moreover, none of the ligands is sterically demanding. The trend in axial actinyl bond strengths must therefore be traced to electronic factors. Earlier, we had argued that partial π-bonding of the equatorial bonds in the hydroxy and, to a lesser degree, fluoride complexes is responsible for weakening the corresponding axial bonds.[15]

Conclusion

Quantum-chemical methods (relativistic DFT) have been used to investigate and answer the title question, i.e., the identity of neptunium(VII) in high-ionic-strength alkaline solutions. Based on various spectroscopic observables, we conclude that the most likely candidate for the dominant ion is the $[NpO_4(OH)_2]^{3-}$ complex, at least in the kind of high-ionic strength, highly-alkaline environment that was used in the experiments. This conclusion is in agreement with the majority of the literature studies, particularly the more recent ones.[1,3,5–7] However, we feel that the combination of modern computational chemistry and three qualitatively different types of data (structural data, vibrational frequencies, and ^{17}O NMR) makes this conclusion stronger then before. Indeed, any single one of the previous experimental techniques could be critiqued in one way or another: First, solution X-ray experiments such as EXAFS depend heavily on fitting, and therefore, on some structural model that the fitting procedure is based upon from the outset. As a consequence, coordination numbers are notoriously difficult to obtain accurately.[50] Second, Clark's vibrational Raman data is not fully conclusive by and of itself, since

the expected B_{1g} Raman frequency was not observed.[1] Third, as mentioned in the introduction, Clark et al.[1] *assumed* that the observed 300 ppm shift in the oxo-ligand ^{17}O NMR between U^{VI} and Np^{VII} should be assigned to the difference in ligand environment (di- vs. tetra-oxo), but had no direct proof for this assumption. Indeed, as discussed above, our calculations show clearly that this argument is not entirely correct.

In discussing each of these points and combing the computational and experimental data, we can confidently assign the identity of neptunium(VII) in high-ionic-strengths alkaline solutions as being $[NpO_4(OH)_2]^{3-}$.

A number of other, secondary conclusions are as follows:

Regarding NMR, the identity of the central metal has a strong influence on the (ligand) ^{17}O NMR shieldings and chemical shifts. This can be understood by noting that the paramagnetic parts of the calculated shieldings are inversely proportional to the gap between occupied and virtual molecular orbitals with significant f contributions,[10] and this gap is expected to be smaller for neptunium than for uranium. Therefore, conclusions that are solely based on comparisons between formally isoelectronic uranium(VI) and neptunium(VII) complexes are not necessarily fully conclusive.

Comparing oxo-ligand stretching frequencies for U^{VI} and Np^{VII}, we find that the latter are consistently higher than the former, indicating stronger bonds. This is also borne out by shorter bond lengths but is on contrast with series of compounds that have the same metal oxidation state along the actinide series.

Comparing, for a given metal (An = U^{VI} or Np^{VII}), the respective actinyl complexes $[AnO_2X_4]^{2-/1-}$ with X = Cl, F, OH, we observe a decreasing strength of the axial actinyl bond. This must be traced to electronic factors, and should be due to increasing amounts of π-competition from the equatorial ligands.[15]

Acknowledgements

We gratefully acknowledge financial support from the Natural Sciences and Engineering Research Council of Canada (NSERC). GS would like to thank Tom Ziegler for giving him the opportunity to come to Canada almost twenty years ago, for his example and insight in scientific matters and elsewhere, and, most importantly, for his ongoing support over all those years.

Charge density reconstitution from approximate exchange-correlation holes

Paola Gori-Giorgi, János G. Ángyán, and Andreas Savin

Abstract: The electronic charge density and the expectation of any monoelectronic operator can be reconstructed by a density-weighted integral of the exchange-correlation hole. This property can be used to test and improve approximate holes that are not spherically averaged. As an example, we test the Becke–Roussel exhange-hole model in its nonspherical formulation on small atoms, finding that it accurately reproduces the density in the core region, while missing some of the features of the valence and core-valence regions. The same test on the local-density approximation shows poor results, as expected.

Key words: electronic structure theory, density functional theory, electronic correlations, exchange-correlation functionals, pair-correlation functions.

Résumé : On peut reconstruire la densité de charge électronique et la valeur moyenne des opérateurs monoélectroniques sous forme d'une intégrale du trou d'échange-corrélation pondérée par la densité. Cette propriété peut être utilisée pour tester et améliorer les trous approximatifs qui ne sont pas moyennés selon les directions dans l'espace. Comme exemple, opérant sur de petits atomes, on peut tester le modèle d'échange de trou de Becke–Roussel dans sa formulation non sphérique et on trouve qu'elle reproduit d'une façon precise la densité dans la région de coeur même si l'accord est moins bon dans les régions de valence et de coeur-valence. Tel que prévu, le même test effectué en utilisant l'approximation de densité locale produit des résultats assez médiocres.

Mots-clés : théorie de la structure électronique, théorie de la fonctionnelle de la densité, corrélations électroniques, fonctionnelles d'échange-corrélation, fonctions de corrélation de paires.

Introduction

Density functional theory (DFT)[1,2] in its Kohn–Sham (KS)[3] formulation is nowadays a widely used method in quantum chemistry and solid-state physics, thanks to its unique combination of low computational cost and reasonable accuracy.[4] In the Kohn–Sham formalism, the total energy of a many-electron system in the external electron-nuclei potential, $\widehat{V}_{\rm ne} = \sum_i v_{\rm ne}(\mathbf{r}_i)$, is rewritten as a functional of the one-electron density, $\rho(\mathbf{r})$,

$$[1] \qquad E[\rho] = T_{\rm s}[\rho] + U[\rho] + E_{\rm xc}[\rho] + \int {\rm d}\mathbf{r}\, v_{\rm ne}(\mathbf{r})\, \rho(\mathbf{r})$$

In eq. [1], $T_{\rm s}[\rho]$ is the kinetic energy of a non-interacting system of fermions (usually called the KS system) having the same one-electron density, ρ, of the physical, interacting system. The Hartree energy, $U[\rho]$, is the classical repulsion energy, $U[\rho] = \frac{1}{2}\int {\rm d}\mathbf{r} \int {\rm d}\mathbf{r}' \rho(\mathbf{r})\rho(\mathbf{r}')|\mathbf{r} - \mathbf{r}'|^{-1}$, and the exchange-correlation functional, $E_{\rm xc}[\rho]$, must be approximated.

Despite its success, to which can be ascribed the description of a variety of systems, from bulk materials to proteins, KS DFT is still plagued by several unsolved problems. For example, approximate KS DFT has well known problems in handling near-degeneracy effects (rearrangement of electrons within partially filled shells) and in the description of long-range dispersion forces. The quest for better approximations for the exchange-correlation functional, $E_{\rm xc}[\rho]$, is thus a very active research field (for recent reviews see, e.g., refs. 5–9).

The exchange-correlation (xc) hole has always played a special role in this quest, as a powerful tool to understand[10–18] and build (see, e.g., refs. 19–27) approximations. In particular, the exact properties of the xc hole have been extensively used to construct nonempirical $E_{\rm xc}[\rho]$. As we shall review later, to compute the exchange-correlation energy one only needs knowledge of the system- and spheri-

cally averaged xc hole. Usually, most of the approximations try to construct a model for the spherically averaged hole in each point of space, neglecting those exact properties that do not affect the final system-averaged result (i.e., the final integration over all space). In real systems of nonuniform density, the xc hole can be highly nonspherical (an elegant discussion based on the shape of localized orbitals was given in ref. 11), and one can expect that somehow taking into account this anisotropy would improve the resulting $E_{xc}[\rho]$ and other properties that can be calculated from the xc hole. For example, an interesting recent model for describing van der Waals interactions is precisely based on the anisotropy of the exchange hole.[28–32]

In this paper, we focus on an exact property (the "charge density reconstitution") of the (nonspherically averaged) xc hole that is often overlooked (since it does not affect system- and spherically averaged models), by testing some approximate holes on small atoms. After giving the basic definitions in the next section, we analyze the charge density reconstitution in the "charge reconstitution" section, discussing its generalization to one-electron properties. In the "Becke–Roussel exchange hole before spherical average" and "local density approximation" sections, we give two examples of charge density reconstitution for small atoms from the Becke–Roussel[23] exchange hole and the local-density approximation (LDA) xc hole, respectively.

Definitions

Although KS DFT was first formulated as a method "without wavefunction", writing an expression for the xc functional, $E_{xc}[\rho]$, in terms of wave functions is a useful step to define the xc hole. This can be done via the adiabatic connection formalism.[10,33–36] In its simplest version,[10,33,34] the electron–electron repulsion operator, $\widehat{W}_{ee} = \sum_{i=1}^{N}\sum_{j=i+1}^{N} 1/|\mathbf{r}_i - \mathbf{r}_j|$, in the N-electron hamiltonian is multiplied by a real parameter, λ, which varies between 0 and 1. At the same time, the physical external potential, $v_{ne}(\mathbf{r})$, is replaced by another local potential, $v^{\lambda}(\mathbf{r})$, determined by the condition that the one-electron density, $\rho(\mathbf{r})$, does not change with λ. If Ψ^{λ} denotes the ground state of these λ-dependent hamiltonians, we have the exact formula[10,34]

$$[2] \qquad E_{xc}[\rho] = \int_0^1 \langle \Psi^{\lambda} | \widehat{W}_{ee} | \Psi^{\lambda} \rangle \mathrm{d}\lambda - U[\rho]$$

This decomposition of $E_{xc}[\rho]$ is by no means unique: for example, one can consider different ways of turning on the electron-electron interaction[35,36] or a formula that only involves the expectation of the kinetic energy.[37,38] The simple adiabatic connection that leads to eq. [2] is by far the most used to build approximations.

Introducing the spin-summed pair density, $P_2(\mathbf{r}, \mathbf{r}')$, associated with a given N-electron wave function, Ψ,

$$[3] \qquad P_2(\mathbf{r}, \mathbf{r}') = N(N-1) \times \sum_{\sigma_1,\ldots,\sigma_N} \int |\Psi(\mathbf{r}\sigma_1, \mathbf{r}'\sigma_2, \mathbf{r}_3\sigma_3, \ldots, \mathbf{r}_N\sigma_N)|^2 \mathrm{d}\mathbf{r}_3, \ldots, \mathrm{d}\mathbf{r}_N$$

we can rewrite eq. [2] as

$$[4] \qquad E_{xc}[\rho] = \frac{1}{2} \int \mathrm{d}\mathbf{r} \int \mathrm{d}\mathbf{r}' \frac{\bar{P}_2(\mathbf{r}, \mathbf{r}') - \rho(\mathbf{r})\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|}$$

where

$$[5] \qquad \bar{P}_2(\mathbf{r}, \mathbf{r}') = \int_0^1 \mathrm{d}\lambda \, P_2^{\lambda}(\mathbf{r}, \mathbf{r}')$$

is the coupling-constant-averaged pair density, and P_2^{λ} is obtained by putting Ψ^{λ} in eq. [3]. The interaction-averaged xc hole, $h_{xc}(\mathbf{r}, \mathbf{r}')$, is then usually defined as

$$[6] \qquad h_{xc}(\mathbf{r}, \mathbf{r}') = \frac{\bar{P}_2(\mathbf{r}, \mathbf{r}')}{\rho(\mathbf{r})} - \rho(\mathbf{r}')$$

so that

$$[7] \qquad E_{xc}[\rho] = \frac{1}{2} \int \mathrm{d}\mathbf{r} \, \rho(\mathbf{r}) \int \mathrm{d}\mathbf{r}' \frac{h_{xc}(\mathbf{r}, \mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|}$$

Since the xc hole is simply related to the pair density, all its properties come from exact conditions satisfied by the pair density itself.[39] The xc hole is often divided into exchange (x) and correlation (c),

$$[8] \qquad h_x(\mathbf{r}, \mathbf{r}') = \frac{P_2^{KS}(\mathbf{r}, \mathbf{r}')}{\rho(\mathbf{r})} - \rho(\mathbf{r}')$$

$$[9] \qquad h_c(\mathbf{r}, \mathbf{r}') = h_{xc}(\mathbf{r}, \mathbf{r}') - h_x(\mathbf{r}, \mathbf{r}')$$

where $P_2^{KS}(\mathbf{r}, \mathbf{r}')$ is the pair density of the Kohn–Sham system, obtained by putting the Kohn–Sham Slater determinant (i.e., $\Psi^{\lambda=0}$) into eq. [3]. Notice that, because of its definition (eq. [6]), the xc hole is not symmetric in its variables, $h_{xc}(\mathbf{r}, \mathbf{r}') \neq h_{xc}(\mathbf{r}', \mathbf{r})$, but satisfies $\rho(\mathbf{r})h_{xc}(\mathbf{r}, \mathbf{r}') = \rho(\mathbf{r}')h_{xc}(\mathbf{r}', \mathbf{r})$.

Because the Coulomb interaction, $1/|\mathbf{r} - \mathbf{r}'|$, only depends on the electron–electron distance, to compute $E_{xc}[\rho]$ of eq. [7] we only need the spherical average, $h^s_{xc}(\mathbf{r}, u)$, of the xc hole with respect to the direction of $\mathbf{u} = \mathbf{r} - \mathbf{r}'$,

$$[10] \qquad h^s_{xc}(\mathbf{r}, u) = \int h_{xc}(\mathbf{r}, \mathbf{r} + \mathbf{u}) \frac{d\Omega_{\mathbf{u}}}{4\pi}$$

so that

$$[11] \qquad E_{xc}[\rho] = \frac{1}{2} \int d\mathbf{r}\, \rho(\mathbf{r}) \int_0^\infty du\, 4\pi u^2 \frac{h^s_{xc}(\mathbf{r}, u)}{u}$$

We can go one step further, and realize that to compute $E_{xc}[\rho]$ we actually only need the system- and spherically averaged hole,

$$[12] \qquad \langle h^s_{xc}(u) \rangle = \int d\mathbf{r}\, \rho(\mathbf{r}) h^s_{xc}(\mathbf{r}, u)$$

$$[13] \qquad E_{xc}[\rho] = \frac{1}{2} \int_0^\infty du\, 4\pi u^2 \frac{\langle h^s_{xc}(u) \rangle}{u}$$

The most common practice when constructing approximations in DFT is somehow in between eqs. [10] and [12]: most models prefer to build $h^s_{xc}(\mathbf{r}, u)$ (e.g., refs. 23, 26, 40–44), but with the idea in mind that only $\langle h^s_{xc}(u) \rangle$ matters for the exchange-correlation energy, so that exact properties of $h^s_{xc}(\mathbf{r}, u)$ that do not affect $\langle h^s_{xc}(u) \rangle$ can be neglected. One of the reasons to follow this practice is that an approximation defined locally is believed to be automatically size consistent, even if this might not be true in the case of systems with a degenerate ground state.[45,46]

As we integrate information out, passing from $h_{xc}(\mathbf{r}, \mathbf{r}')$ to $h^s_{xc}(\mathbf{r}, u)$ and then to $\langle h^s_{xc}(u) \rangle$, there are exact properties that do not hold anymore (i.e., they can either be hidden in a very complicated way in the integrated quantities, or may just not be important anymore). For instance, the symmetry property, $\rho(\mathbf{r}) h_{xc}(\mathbf{r}, \mathbf{r}') = \rho(\mathbf{r}') h_{xc}(\mathbf{r}', \mathbf{r})$, does not translate into a simple condition for the spherically averaged hole, $h^s_{xc}(\mathbf{r}, u = |\mathbf{r}' - \mathbf{r}|)$, so that, in general, even for the exact hole we have $\rho(\mathbf{r}) h^s_{xc}(\mathbf{r}, |\mathbf{r}' - \mathbf{r}|) \neq \rho(\mathbf{r}') h^s_{xc}(\mathbf{r}', |\mathbf{r} - \mathbf{r}'|)$. When targeting only the spherically and system-averaged hole, $\langle h^s_{xc}(u) \rangle$, the original symmetry in $\mathbf{r}$, $\mathbf{r}'$ does not play a role anyhow: even if we start from a model hole that does not respect it, the integration over all space cancels the contribution from its antisymmetric part.

Besides the possibility of constructing $E_{xc}[\rho]$, the xc holes, $h_{xc}(\mathbf{r}, \mathbf{r}')$ and $h^s_{xc}(\mathbf{r}, u)$, are interesting quantities per se: they contain chemical information, they can be used to estimate the expectation of two-electron properties, and they define a gauge for the exchange-correlation energy density, $\epsilon_{xc}(\mathbf{r})$,

$$[14] \qquad \epsilon_{xc}(\mathbf{r}) = \frac{1}{2} \int_0^\infty du\, 4\pi u^2 \frac{h^s_{xc}(\mathbf{r}, u)}{u}$$

$$[15] \qquad E_{xc}[\rho] = \int d\mathbf{r}\, \rho(\mathbf{r})\, \epsilon_{xc}(\mathbf{r})$$

The exchange-correlation energy density, $\epsilon_{xc}(\mathbf{r})$, is often used as a starting point to refine approximations.

Charge reconstitution

From the definition of the exchange-correlation hole (eq. [6]) and of the one-electron density,

$$\rho(\mathbf{r}) = \frac{1}{N-1} \int d\mathbf{r}' P_2(\mathbf{r}, \mathbf{r}')$$

one obtains the two sum rules

$$[16] \qquad \int d\mathbf{r}'\, h_{xc}(\mathbf{r}, \mathbf{r}') = -1$$

$$[17] \qquad \int d\mathbf{r}\, \rho(\mathbf{r})\, h_{xc}(\mathbf{r}, \mathbf{r}') = -\rho(\mathbf{r}')$$

Equation [16] is the usual xc hole sum rule, satisfied by almost all models. It leads to a corresponding sum rule for the spherically averaged hole,

$$[18] \qquad \int_0^\infty 4\pi u^2\, h^s_{xc}(\mathbf{r}, u)\, du = -1$$

The second sum rule, eq. [17], is a simple consequence of the symmetry property, $\rho(\mathbf{r}) h_{xc}(\mathbf{r}, \mathbf{r}') = \rho(\mathbf{r}') h_{xc}(\mathbf{r}', \mathbf{r})$, and shows that the electronic charge density can be reconstructed by a density-weighted integral of the exchange-correlation hole (charge reconstitution). Like the symmetry property from which it is derived, this second sum rule does not translate into a simple condition for the spherically averaged hole, because its information is partially averaged out in the integration over the direction of $\mathbf{u} = \mathbf{r}' - \mathbf{r}$ in eq. [10]. Since most of the approximate holes only try to model $h^s_{xc}(\mathbf{r}, u)$, eq. [17] is often neglected in the literature. Notice that if we consider exchange and correlation separately, we obtain

$$[19] \qquad \int d\mathbf{r}\, \rho(\mathbf{r})\, h_x(\mathbf{r}, \mathbf{r}') = -\rho(\mathbf{r}')$$

$$[20] \qquad \int d\mathbf{r}\, \rho(\mathbf{r})\, h_c(\mathbf{r}, \mathbf{r}') = 0$$

We can define, for any monoelectronic local operator, $\hat{O} = \sum_i o(\mathbf{r}_i)$, an associated exchange-correlation hole projected property

$$[21] \qquad o_{xc}(\mathbf{r}) = -\int d\mathbf{r}'\, o(\mathbf{r}')\, h_{xc}(\mathbf{r}, \mathbf{r}')$$

By the virtue of eq. [17], the exchange-correlation hole projected property, $o_{xc}(\mathbf{r})$, weighted by the charge density, $\rho(\mathbf{r})$, leads to the same value as the expectation value of the operator, $\hat{O}$,

$$[22] \qquad \langle \Psi | \hat{O} | \Psi \rangle = \int d\mathbf{r}\, \rho(\mathbf{r})\, o(\mathbf{r}) = \int d\mathbf{r}\, \rho(\mathbf{r})\, o_{xc}(\mathbf{r})$$

Another way to look at it is that, for any local monoelectronic operator, $\hat{O}$, there exist an associated "exchange-correlation-hole weighted" operator, $\hat{O}_{xc} = \sum_i o_{xc}(\mathbf{r}_i)$, with $o_{xc}(\mathbf{r})$, given by eq. [21], with the same ground-state expectation value.

For instance, $o(\mathbf{r})$ can be a multipole moment function. In the case of the monopole, i.e., $o(\mathbf{r}) = 1$, one obtains the total number of electrons. For the first order moment, $o(\mathbf{r}) = r_\alpha$, where α denotes a cartesian component, x, y, or z, one has

$$[23] \qquad \mu_\alpha = -\int d\mathbf{r}\rho(\mathbf{r}) \int d\mathbf{r}' h_{xc}(\mathbf{r},\mathbf{r}') r'_\alpha$$

where μ_α denotes a cartesian component of the electronic dipole moment. The corresponding characteristic exchange-correlation weighted function, $D_\alpha(\mathbf{r})$,

$$[24] \qquad D_\alpha(\mathbf{r}) = -\int d\mathbf{r}' h_{xc}(\mathbf{r},\mathbf{r}') r'_\alpha$$

provides the coordinates of the xc hole barycenter (center of charge) belonging to the point $\mathbf{r}$.[30] Thus, eq. [23] tells us that the total electronic dipole moment can be obtained as the weighted sum of the xc hole barycenters. This result can be regarded as a generalization of the Wannier-center decomposition of the polarization,[47] widely used in the solid-state physics community: the Wannier-center, which is a Dirac-like distribution placed in the barycenters of the localized orbitals, is replaced by a fuzzy distribution of xc hole barycenters.[48] Similar analysis can be carried out for higher-order multipole moments. Notice that if we consider exchange and correlation separately, we see that eqs. [19]–[20] imply that eqs. [21]–[22] hold as well for the exchange hole alone.

Becke and Johnson[28,31] have constructed a heuristic model to take into account van der Waals interactions between two subsystems using the square, $d_x^2(\mathbf{r}) = \mathbf{d}_x(\mathbf{r}) \cdot \mathbf{d}_x(\mathbf{r})$, of the dipole moment of the exchange hole plus its reference electron on each subsystem,

$$[25] \qquad \mathbf{d}_x(\mathbf{r}) = -\int d\mathbf{r}' h_x(\mathbf{r},\mathbf{r}')\mathbf{r}' - \mathbf{r} = \mathbf{D}(\mathbf{r}) - \mathbf{r}$$

where here the subscript x stands for exchange hole.

Because of the charge density reconstitution sum rule of eq. [17], the exact $\mathbf{d}_x(\mathbf{r})$ has zero expectation,[30]

$$[26] \qquad \int \rho(\mathbf{r})\, \mathbf{d}_x(\mathbf{r})\, d\mathbf{r} = 0$$

A density functional approximation for $d_x^2(\mathbf{r})$ has been constructed by Becke and Johnson[29] using the Becke–Roussel (BR)[23] exchange-hole model. As briefly reviewed in the next section, the BR exchange-hole model is based on the spherical average of an anisotropic hole. Thus, even if its final outcome is a spherically averaged hole, it is based on the idea that the real hole is nonspherical, and for this reason it can be used to estimate the exchange-hole dipole moment. In this context, it is interesting to check how well the BR model before spherical average satisfies eq. [19]. This is the object of the next section.

The Becke–Roussel exchange hole before spherical average

The BR exchange-hole model[23] is inspired by the exact exchange hole of the hydrogen atom: it places a normalized exponential at a distance $b(\mathbf{r})$ from the position $\mathbf{r}$ of the σ-spin reference electron (the total exchange hole considered in the previous sections is the sum over the two σ-spin holes, $h_x = h_{x,\uparrow} + h_{x,\downarrow}$),

$$[27] \qquad h_{x,\sigma}^{BR}(\mathbf{r},\mathbf{r}') = -\frac{a^3(\mathbf{r})}{8\pi} e^{-a(\mathbf{r})|\mathbf{r}'-\mathbf{r}+\mathbf{b}(\mathbf{r})|}$$

The dipole moment of this hole plus its reference electron, evaluated with eq. [25], is simply $\mathbf{b}(\mathbf{r})$.

The final form of the BR model is obtained by taking the spherically averaged with respect to the direction of $\mathbf{u} = \mathbf{r}' - \mathbf{r}$ of eq. [27]. This way, the BR spherically averaged hole only depends on the magnitude $b(\mathbf{r})$ of $\mathbf{b}(\mathbf{r})$. The two parameters $a(\mathbf{r})$ and $b(\mathbf{r})$ are fixed by imposing the exact on-top ($\mathbf{r} \to \mathbf{r}'$ or $u \to 0$) depth and curvature,

$$[28] \qquad h_{x,\sigma}(\mathbf{r}, u) = -\rho_\sigma + \frac{u^2}{6}\left(2\tau_\sigma - \frac{|\nabla\rho_\sigma|^2}{2} - \nabla^2\rho_\sigma\right) + O(u^4)$$

where $\rho_\sigma(\mathbf{r})$ is the density of spin-σ electrons and $\tau_\sigma = \sum_i |\nabla\phi_{i,\sigma}|^2$ ($\phi_{i,\sigma}$ are the Kohn–Sham orbitals). The model, thus, provides the magnitude of $\mathbf{b}(\mathbf{r})$ but not its direction, since it is not needed either in the spherically averaged hole or in the Becke–Johnson dispersion model,[29] which only uses $b^2(r)$.

In an atom, however, with the BR ingredients, the only possible choice is having $\mathbf{b}(\mathbf{r})$ pointing towards the nucleus. In this case we can thus test without ambiguity how well the BR hole model *before* spherical average satisfies eq. [19]. In a spherical atom, the charge density reconstitution of eq. [19] from the BR hole would read

$$[29] \qquad \int d\mathbf{r}\ \rho(r)\ \frac{a^3(r)}{8\pi} e^{-a(r)|(b(r)/r-1)\mathbf{r}+\mathbf{r}'|} = \rho(r')$$

where we now have to check how well this equality is actually satisfied. In the left-hand side of eq. [29], the integration over the angular part of $\mathbf{r}$ is analytical, so that we are left with a one-dimensional integral, which is evaluated numerically on a grid.

In Figs. 1–3, we show our results for the He, Be, and Ne atoms, respectively, using highly accurate input ingredients to avoid any bias (using almost "exact" input quantities allows us to focus on the results of the model, without introducing any other source of error). For the He atom we have used the density coming from the variational wave function of ref. 49, while for Be and Ne we have used the density and the Kohn–Sham orbitals from the accurate Kohn–Sham potentials of refs. 50 and 51. We see that eq. [29] is almost satisfied for the He atom, and for the core region of Be and Ne, which are dominated by 1s-type orbitals qualitatively similar to eq. [27]. The valence region of Be, instead, is poorly reproduced, with the BR hole yielding results of similar quality to the LDA (see the next section). Some of the features of the core-valence region of the Ne atom are also missed by the BR hole.

Local density approximation

The local density approximation (LDA) to the exchange-correlation hole consists in taking the xc hole of a uniform

Fig. 1. Charge density reconstitution from approximate holes for the He atom. We tested the Becke–Roussel (BR) exchange hole before spherical average, and the LDA exchange and exchange-correlation hole at full coupling strength.

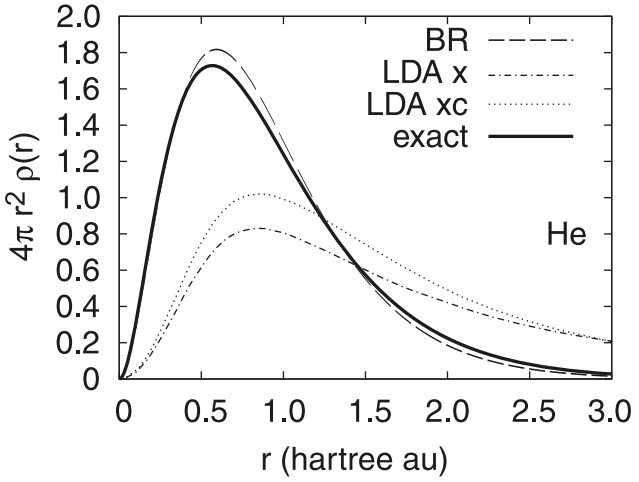

Fig. 2. Charge density reconstitution from approximate holes for the Be atom. We tested the Becke–Roussel (BR) exchange hole before spherical average, and the LDA exchange and exchange-correlation hole at full coupling strength.

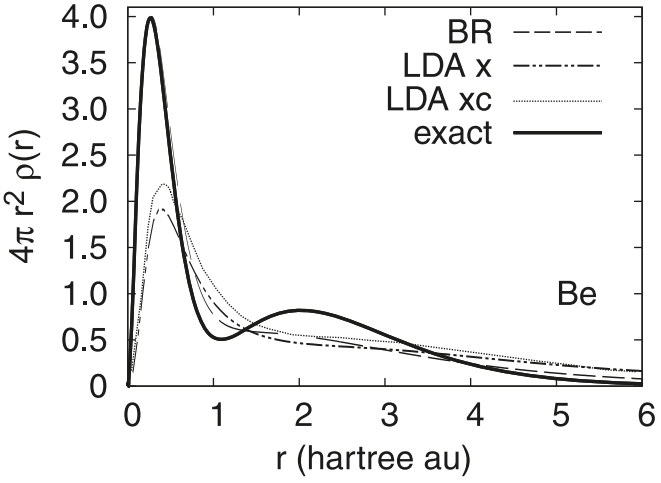


electron gas with density $\rho(\mathbf{r})$ from around the reference electron at position $\mathbf{r}$,

$$[30] \qquad h_{xc}^{LDA}(\mathbf{r},\mathbf{r}') = \rho(\mathbf{r}) g_{xc}^{UEG}(|\mathbf{r}' - \mathbf{r}|; \rho(\mathbf{r}))$$

where $g_{xc}^{UEG}(u;\rho)$ is the exchange-correlation pair-distribution function (see, e.g., ref. 52). Being that the uniform electron gas is an isotropic system, the LDA xc hole is spherical, and it has been shown to be a surprisingly good approximation for the short-range part (small $u = |\mathbf{r}' - \mathbf{r}|$) of the spherically averaged xc hole of systems of nonuniform density.[13–15]

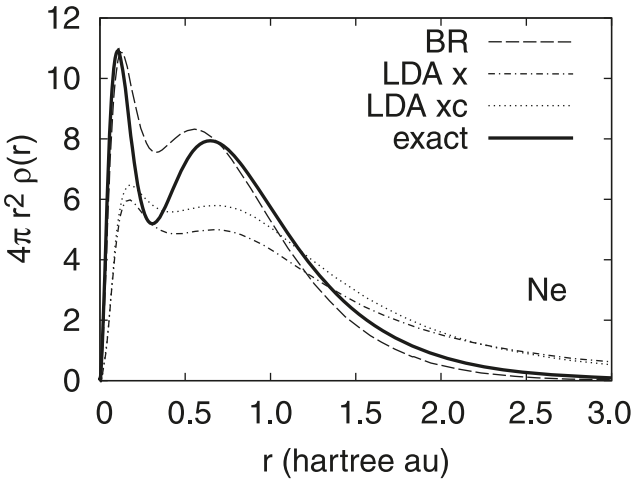
As explained in the charge reconstitution section, the sum rule of eq. [17] does not translate into a simple condition on the spherically averaged hole. Thus, if we want to consider LDA as a good approximation for the spherically averaged hole, there is no space for checking eq. [17]. However, since the LDA hole is intrinsically spherical, we can also consider eq. [30] as an approximation for the nonspherically averaged hole. In this case, the charge density reconstitution of eq. [17] for spherical atoms reduces to the condition

$$[31] \qquad \rho(r') = 2\pi \int_0^\infty \mathrm{d}r\, r^2\, \rho^2(r) \times \int_{-1}^{1} \mathrm{d}y\, g_{xc}^{UEG}\left(\sqrt{r^2 + r'^2 - 2rr'y}; \rho(r)\right)$$

where again the point is to check whether this equality is actually satisfied. Notice also that other widely used models such as PBE[40,41] and TPSS[42] only approximate the spherically averaged hole, so that we cannot carry out similar tests for those models.

Using the same densities of the previous section, we have numerically evaluated the right-hand side of eq. [31] for He, Be, and Ne. We have considered the case of the exchange-only hole and of the exchange-correlation hole at full coupling strength (i.e., with $P_2^{\lambda=1}$ in eq. [6] instead of the coupling-constant averaged $\bar{P}_2$), using the parametrization of $g_{xc}^{UEG}(u;\rho)$ of ref. 52. We see from Figs. 1–3 that, as expected, LDA does not satisfy eq. [31], which should actually be fulfilled at the exchange-only level, meaning that adding the correlation part should not change the result. Notice that the curve corresponding to the coupling-constant-averaged xc hole will always lie between the exchange-only result and the full-coupling strength xc result.

Fig. 3. Charge density reconstitution from approximate holes for the Ne atom. We tested the Becke–Roussel (BR) exchange hole before spherical average, and the LDA exchange and exchange-correlation hole at full coupling strength.



This failure of LDA to fulfill eq. [17] should not be considered as a flaw of the model, if we regard LDA as an approximation to the spherically averaged hole, $h_{xc}^{s}(\mathbf{r}, u)$. As said, the exact spherically averaged hole, $h_{xc}^{s}(\mathbf{r}, u = |\mathbf{r}' - \mathbf{r}|)$, in fact, is not supposed to satisfy eq. [17] (only the nonspherically averaged hole does). So, if LDA is a reasonable approximation (even if only at short range) for the spherically averaged hole, it should not fulfill eq. [17]. This point is somehow philosophical, since the LDA hole model is exactly the same for the nonspherically averaged $h_{xc}(\mathbf{r}, \mathbf{r}')$ and the spherically averaged $h_{xc}(\mathbf{r}, u)$.

Conclusions and perspectives

We have discussed a sum rule concerning the (nonspherically averaged) exchange-correlation hole, in which different monoelectronic local operators can be used. Even if, eventually, only the system- and spherically averaged hole is needed to obtain the exchange-correlation energy, a given model for the spherically averaged hole (which is interesting by itself to compute different properties and to define energy densities) could be improved by taking into account, in some approximate way, the sum rule of eq. [17]. If the whole eq. [17] may be too hard to impose, a selection of local operators $o(\mathbf{r})$ in eq. [22] might be simpler to handle. For example, the Becke–Roussel[23] hole could be improved by adding some parameters that are adjusted to fulfill, at least approximately, eq. [22] for the case of the dipole moment. This may give a more accurate estimate of the exchange-hole dipole moment needed in the Becke–Johnson model[29] for dispersion forces.

Another important point to consider is the following. When dealing with open systems or with systems with strong nondynamical correlation, a better local model for the exchange hole can be obtained by relaxing[18,27] the sum rule of eq. [16], and thus also, by symmetry, the sum rule of eq. [17] considered here. Again, taking this symmetry into account in some approximate way before the spherical average could also improve a given model for nondynamical correlation.

Density functional theory analyses of bis(bipyridine)ruthenium noninnocent quinonoid and thiolosulfinato complexes containing ligands formally in the semiquinone oxidation state

A.B.P. Lever

Abstract: Density functional theory and the polarized continuum model are used to derive the electronic structures of some open-shell, bis(bipyridine)ruthenium complexes bound to noninnocent quinonoid or thiolosulfinato ligands formally in the semiquinone oxidation state. The noninnocent properties of the *o*-thiolosulfinato ligand are explored and compared with those of the more conventional *o*-semiquinones with nitrogen, oxygen, and sulfur donor atoms. Spin densities are shown to be fairly localized in the metallocycle ring. It is demonstrated that oxidation of the parent $[Ru^{II}(bpy)_2$ (1,2-(S,SO_2)–$C_6H_4]$ species occurs primarily in the metallocycle ring and is localized in the Ru–S^0 bond.

Key words: ruthenium, sulfenate, sulfinate, thiol, optical spectrum, density functional theory (DFT), infrared, noninnocent ligand.

Résumé : On a fait appel à la théorie de la fonctionnelle de densité et du modèle du continuum polarisé pour dériver les structures électroniques de quelques complexes à couches ouvertes du bis(bipyridine)ruthénium lié à des ligands quinonoïdes ou thiolosulfinato non innocents formellement dans l'état d'oxydation semiquinone. On a étudié les propriétés non innocentes du ligand *o*-thiolosulfinato et on les a comparées avec celles de *o*-semiquinones plus conventionnelles portant des atomes d'azote, d'oxygène et de soufre donneurs. On a montré que les densités de spin sont assez localisées dans le noyau métallocyclique. On démontre que l'oxydation de l'espèce parente $[Ru^{II}(bpy)_2(1,2\text{-}(S,SO_2)\text{–}C_6H_4)]$ se produit principalement dans le noyau métallocyclique et qu'elle est localisée dans la liaison Ru–S^0.

Mots-clés : ruthénium, sulfénate, sulfinate, thiol, spectre optique, théorie de la fonctionnelle de la densité (TFD), infrarouge, ligand non innocent.

[Traduit par la Rédaction]

Introduction

We have recently reported[1] the physical properties and electronic structures of bis(bipyridine)ruthenium complexes of *o*-thiolosulfinatobenzene **1** $[Ru(bpy)_2(1,2\text{-}(S,SO_2)\text{–}C_6H_4)]$ and *o*-disulfinatobenzene **2** $[Ru(bpy)_2(1,2\text{-}(SO_2,SO_2)\text{–}C_6H_4)]$, which are of interest, in part, because of the biological involvement of ligating systems of this type in nitrile hydratase.[2–5] Species **1** contains sulfur in oxidation states S^0 and S^{IV}, while in species **2**, both S are S^{IV}. A detailed analysis of the binding of these ligands was presented[1] revealing extensive metal–ligand covalency. In the isolated complexes, these sulfinato ligands were doubly negatively charged and attached to a ruthenium(II) center. Species **1** is henceforth written as $[Ru(bpy)_2(S,SO_2)]$ where (S,SO_2) in the following text will signify the 1,2-(S,SO_2)–C_6H_4 ligand.

Electrochemically, in acetonitrile, these species show reduction of the bipyridine ligands and an oxidation process, in the commonly explored potential range. In complexes of the general class $Ru(bpy)_2(X,Y)$, the first reduction potential at bipyridine spans a considerable range[6,7] depending on the donor and acceptor properties of the ligands X,Y. In general, the more negative the first reduction potential, the less positive is the $Ru^{III/II}$ oxidation potential and indeed, there is a linear relationship[7] between these two potentials involving the electrochemical parameter values (E_L(L))[8] of ligands X,Y. Based upon this relationship, the observed first oxidation potential of species **2** lay at a potential reasonably expected for oxidation of Ru^{II} to Ru^{III} but in species **1** the first oxidation potential was insufficiently positive to be simply associated with the $Ru^{III/II}$ process. This suggests that oxidation of the sulfinato^{2-} ligand may be occurring and hence that this ligand, like the quinonoid ligands, is also noninnocent.[9–12] In this paper, we explore the electronic properties of this oxidized species, $\mathbf{1}^+$, and use this as an opportunity to compare the properties of a series of complexes, $[Ru(bpy)_2(o\text{-}X,Y\text{–}C_6H_4)]^+$, formally in the semiquinone oxidation state, for comparative purposes, and hitherto not studied computationally in great detail.

Experimental

Synthesis

The synthesis of complex **1** was carried out according to the literature.[1] Spectroelectrochemical oxidation was carried out in acetonitrile using a gold foil working electrode and

silver/silver chloride quasi-reference electrode. Optical data were collected using an Ocean Optics HR4000 high-resolution, fibre-optic spectrometer.

Calculations

Density functional theory (DFT) calculations were performed using the Gaussian 03 (Revision C.02) program.[13] Optimized geometries were calculated using the B3LYP exchange-correlation functional[14] with the TZVP basis set[15,16] for all elements except ruthenium for which the DGDZVP basis set[17,18] was used. Tight self-consistent field (SCF) convergence criteria (10^{-8} au) were used for all calculations. Vibrational frequency calculations were performed to ensure that the stationary points were minima. Wave functions were checked for stability.

Molecular orbital (MO) compositions and the overlap populations between molecular fragments were calculated using the AOMix-CDA program[19,20] using the Mulliken scheme.[21–24] Atomic charges were calculated using the Mulliken[21–24] and natural population analysis[25] methods (MPA and NPA, respectively) as implemented in Gaussian 03.[13] The analysis of the MO compositions, and the charge decomposition analysis was performed using AOMix-CDA.[20,26] The PCM model[27,28] was used to model solvation assuming acetonitrile as the solvent.

Time-dependent DFT (TDDFT)[29–32] was used to calculate the energies and intensities of the 60 lowest-energy electronic transitions of complex $\mathbf{1}^+$. These were converted with the SWizard program[33] into simulated spectra as described before,[34] using Gaussian functions.

Results and discussion

Experimental characterization of species $\mathbf{1}^+$

Species **1** displays the first $E_{1/2}$[bpy/bpy$^-$] potential at –1.58 V versus a saturated calomel electrode (SCE) and an oxidation potential at 0.18 V versus SCE.[1] Using the correlation[7]

$$[1] \qquad E_{1/2}[Ru^{III}/Ru^{II}] = 4.5[E_{1/2}(bpy/bpy^-) + 1.69] \quad (V, \text{ vs. SCE})$$

then $E_{1/2}$[Ru^{III}/Ru^{II}] should lie at ~ +0.5 V rather than +0.18 V versus SCE. The correlation (eq. [1]) was rather scattered, i.e., the statistics are imprecise, but the discrepancy between observed and predicted potential, especially the experimental value being observed as significantly negative of that predicted, is sufficiently large to give one cause to argue that oxidation does not occur primarily at ruthenium.

Although species $\mathbf{1}^+$ was not isolated, its visible region optical spectrum was obtained using spectroelectrochemical oxidation of species **1** in acetonitrile (Fig. 1).

The two visible region bands in the electronic spectrum of **1** are replaced in $\mathbf{1}^+$ by one stronger band at a lower energy with at least two weaker transitions, in the visible region, to the blue of the strong band, as shown in Fig. 1 (see legend for energy values). To assign the spectrum, a molecular orbital analysis was carried out using density functional theory. Good agreement between the observed and DFT predicted UV–vis and IR spectra of the precursor species **1** was obtained[1] using the popular B3LYP functional[14] and the triple zeta basis set, TZVP, for all atoms except ruthenium (for which the TZVP bases are not yet available); thus, a double zeta DGDZVP was used for ruthenium, in a spin unrestricted calculation. The solvent was included, using the polarizable continuum model (PCM).[27,35] We therefore use the same procedure here.

Fig. 1. Spectroelectrochemical oxidation of $Ru^{II}(bpy)_2(S,SO_2)$ (**1**) to species $\mathbf{1}^+$ in acetonitrile/tetrabutylammonium hexafluorophosphate, at ~0.3 V vs. SCE. Initial species **1**: bold black line, and subsequent timed spectra (bold lines) changing to species $\mathbf{1}^+$: bold hatched line. Experimental band maximum at 14 600 cm^{-1} (ε = 2900 L mol^{-1} cm^{-1}) with weak shoulders at ~16 200 and 21 000 cm^{-1}. The time dependent DFT predicted spectrum is shown as a long hatched line. Transitions are shown as vertical lines scaled to their oscillator strengths.

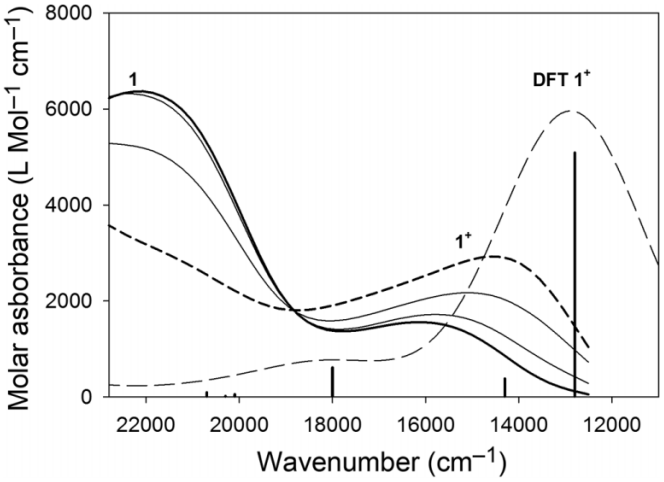

Table 1 shows the percent contributions of (S,SO_2) ligand; Ru s, p, and d; bipyridine; individual S^0 and S^{IV} orbital; and the contribution of the C_2S_2Ru metallocycle ring to the frontier molecular orbitals of species $\mathbf{1}^+$. The two visible region bands shown in Fig. 1 for species **1** are assigned as ligand to ligand charge transfer (LLCT) transitions from the S^0 ligator to π^*-bpy.[1] Based on the calculation, the new, strong, red-shifted band in the spectrum of $\mathbf{1}^+$ (exptl. 14 600 cm^{-1}, predicted 12 900 cm^{-1}) is primarily 146β,147β → 148β, which comprises an internal π–π* type of transition largely associated with the metallocycle ring with some d–d component since the d orbitals involved in these three orbitals are not all the same. There are two weaker transitions predicted in the visible region that may be associated with the two shoulders. The weak predicted band at 14 300 cm^{-1} (exptl. ~16 200 cm^{-1}) is mainly 144β → 148β, which is also metallocycle localized. The transition at 18 000 cm^{-1} (exptl. ~21 000 cm^{-1}) is mainly 143β → 148β, which is best described as a π–π* from the benzenoid fragment of the sulfinato ligand to the metallocycle but with a ligand to metal charge transfer (LMCT) component to the β-hole on ruthenium (see Table 1).

The unpaired (α) electron resides in #148H and is localized primarily in the metallocycle ring and with significant involvement of the ruthenium atom and the S^0 ligand but not the S^{IV} ligand. It mainly involves the overlap of highest occupied MO (HOMO; #45α) (see Fig. 2) of the sulfinato-ligand fragment (formal 1– oxidation state) with several

tional data for a series of related derivatives formally in the semiquinone oxidation state and described as $[Ru(bpy)_2(1,2\text{-}X,Y\text{–}C_6H_4)]^+$ with (X,Y) = (O,O), (O,NH), (S,NH), and (NH,NH). Since the oxidation of species **1** reveals that the (S,SO_2) ligand is noninnocent, then the sulfinato-ligand complexes might be described as members of this series, with X = S and Y = SO_2. It is of interest to explore whether this is the case, and if not, just how they differ.

We also include $[Ru(acac)_2(1,2\text{-}NH,NH\text{–}C_6H_4)]^-$ (acac = 2,4-pentanedionate) because of our earlier work with this species[36] and to provide a direct connection with the work of Remenyi and Kaupp.[37] For ease of discussion, we henceforth abbreviate these species as $[Ru(bpy)_2(X,Y)]^+$ and $[Ru(acac)_2(NH,NH)]^-$.

Remenyi and Kaupp[37] have discussed in great depth the electronic and geometric structures of several $[Ru(acac)_2(1,2\text{-}X,Y\text{–}C_6H_4)]^-$ species. Although we use a different basis set from that study, the bond distances in our optimized geometry of $[Ru(acac)_2(NH,NH)]^-$ (see selected distances in Table 3) are essentially identical to theirs. Our discussion of the $[Ru(bpy)_2(X,Y)]^-$ species follows similar arguments to those presented by Remenyi and Kaupp[37] and is therefore kept rather brief. The fully reduced species, $[Ru^{II}(bpy)_2\ (X,Y)]^0$, are regarded as ruthenium(II) complexes of the doubly reduced quinone, i.e., generically called a catecholate, which we write as $[Ru^{II}(bpy)_2(cat.X,Y)]^0$. The ambiguity arises when an electron is removed by oxidation. Is the product now a ruthenium(III) catecholate^{2-}, i.e., $[Ru^{III}(bpy)_2(cat.X,Y)]^+$, or a ruthenium(II) semiquinonate^{1-}, $[Ru^{II}(bpy)_2(sq.X,Y)]^+$? The general conclusion reached by Remenyi and Kaupp[37] for the acetylacetonate series was that they were best represented by a resonance hybrid between the Ru^{II} and Ru^{III} representations. Clearly, individual species may be closer to the Ru^{II} or to the Ru^{III} formulations.

We have recently reported[36] that the $[Ru^{II}(acac)_2(q.X,Y)]^0$ formally quinone oxidation state complexes reveal extensive π-back donation into the Ru–X,Y metallocycle ring. The very covalent Ru–X,Y interaction confers aromatic properties on this metallocycle ring.[38–40] Thus, another way to view the 'semiquinone' species is to regard it as being formed by the oxidation of the $[Ru^{II}(bpy)_2(cat.X,Y)]$ complex by the removal of an electron from this metallocycle.

Based on this background, we can now discuss the electronic and geometric properties of all of these semiquinone X,Y species, leaving aside for now the (S,SO_2) species, which we defer for later comparison below. Figure 3 (left) shows the bond distances in the DFT optimized $[Ru(bpy)_2((O,NH)\text{–}C_6H_4)]^+$ structure, which is typical (Table 3). The benzene ring C–C distances alternate in length (Table 3) but to a much smaller degree than observed experimentally in quinone complexes and to a similar degree to those observed in semiquinone species. Bond alternation in these quinonoid species has been discussed elsewhere.[11,41]

The bond order data in Table 4 provide greater insight. The Ru–NH and Ru–O bond orders in $[Ru(bpy)_2(NH,NH)]^+$ and analogous (O,NH) and (O,O) species have rather similar values. Those of $[Ru(acac)_2(NH,NH)]^-$ are substantially larger. The (S,NH) species displays a very strong Ru–S bond, evidently highly covalent. This covalency extends to the Ru–NH bond whose bond order is significantly higher than the Ru–NH bonds of the previous complexes. The metallocycle C=N and C=O bond orders do not change a great deal in this series except that the values for $[Ru(acac)_2(NH,NH)]^-$ are larger. Table 4 also provides the Mayer bond orders[42,43] between the $[RuL_2]$ and [X,Y] fragments for the α- and β-electrons. There is one more α-electron than β, and it resides in an orbital (148α) that is antibonding between these fragments explaining why the α-bond order is always less than the β-bond order. Not unexpectedly, the β-bond orders are again substantially larger for the (S,NH) and acac(NH,NH) species.

In Table 2, we report natural bond orbital[25,44] charges, and Mulliken charge decomposition analysis (CDA) charges[20,26,45–47] in an extended method, ECDA, developed by Gorelsky and co-workers[45,48] on the fragments and on the donor atoms. Spin densities are also provided. The natural bond orbital (NBO) and CDA charges differ somewhat

but have the same relative values. An ionic semiquinone would obviously carry a net unit negative charge. All these species have charges less than –1 but are generally more negative than those reported previously[36] for the quinone oxidation state species. The net charge on the (X,Y) ligand decreases to small negative values in the sequence acac(NH,NH) > (O,O) > (O,NH) > (NH,NH) > (NH.S). Predictably, the net positive charge on ruthenium decreases in the same sequence.

The spin density on the ruthenium atom in the (NH,NH), (O,NH), and (O,O) species is small (Table 2), while that on the (X,Y) ligand is greater than 0.8. They also all have roughly the same net negative charge on the (X,Y) ligand (and net positive charge on Ru). Thus, these three derivatives are most reasonably defined as $[Ru^{II}(bpy)_2(sq.X,Y)]^+$. The (S,NH) derivative has a somewhat larger positive charge on Ru and a larger spin density on Ru; thus, one may argue for a greater $[Ru^{III}(bpy)_2(cat.X,Y)]^+$ contribution than for the aforementioned three derivatives. Clearly, the bond orders cited in Table 4 convey arguments for much stronger covalent bonds in this complex.

The $[Ru(acac)_2(NH,NH)]^-$ species is evidently quite different from $[Ru^{II}(bpy)_2(NH,NH)]^+$ with a substantially larger Mayer β-electron bond order (Table 4), significantly larger net negative charge on the (NH,NH) ligand, and a larger positive charge on Ru, and the C–C benzene ring bond distances are similar to those of a catecholate (Table 3). It also has a significantly larger spin density on Ru and a smaller spin density on (NH,NH) (data are similar to those reported by Remenyi and Kaupp[37]). It therefore appears to have a significantly greater degree of Ru^{III}(cat.NH,NH) character than the bipyridine analog.

It is of interest to explore in more depth why replacing the neutral bipyridine with the mono-anionic acetylacetonate

Table 5. Net σ donation and net back donation in selected species as a function of spin. (CDA analysis; au).

	α-Electrons		β-Electrons		
	σ Donation[a]	Back donation[b]	σ Donation[a]	Back donation[b]	Net charge on bpy/acac

$[Ru(acac)_2(NH,NH)]^-$	0.38	0.03	0.41	0.40	–1.38
$[Ru(bpy)_2(S,SO_2)]^+$	0.73	0.07	0.75	0.50	+0.81

[a]σ Donation to fragment A $[RuL_2]^{n+}$ (L = bpy, n = 2; $acac^{1-}$, n = 0).

[b]π Back donation to fragment B $(1,2\text{-}(NH,NH)\text{–}C_6H_4)^{1-}$ or $(1,2\text{-}(S,SO_2)\text{–}C_6H_4)^{1-}$.

has such an effect. Net charge transfer between $[RuL_2]^{n+}$ (L = bpy, n = 2; L = $acac^{1-}$, n = 0) (fragment A) and $(1,2(NH,NH)\text{–}C_6H_4{}^{1-})$ (fragment B) depends on the net contribution of the empty orbitals of each fragment to the filled orbitals of the final complex, which are subject to changes in polarization (ECDA method[26,36,45]). Using the CDA method, one can factor the charge σ donated from fragment B to fragment A and the charge returned by back donation from fragment A to fragment B.

The major difference between the first two species in Table 5 is clearly the much greater β-electron back donation in the acac species; otherwise, the electron distributions are rather similar. This back donation arises through mixing of the lowest unoccupied MO (LUMO) and some higher virtual orbitals of fragment B into filled orbitals of the acac complex. The dominant contribution, by far, is mixing of the β-LUMO (#29, fragment B) into the HOMO-2 of the complex. Obviously, a major factor is the dinegative charge of the acac ligands, which softens the metal atom and makes it a stronger π donor. Nevertheless, the net positive charge on Ru is larger for the acac ligand than for the bpy ligand complex reflecting an increased resonance contribution of Ru^{III}(cat.NH,NH). Evidently, negative charge is transferred from acac to (NH,NH) (rendering it the most negative (X,Y) ligand of our comparative group), and 'bypassing' the ruthenium center!

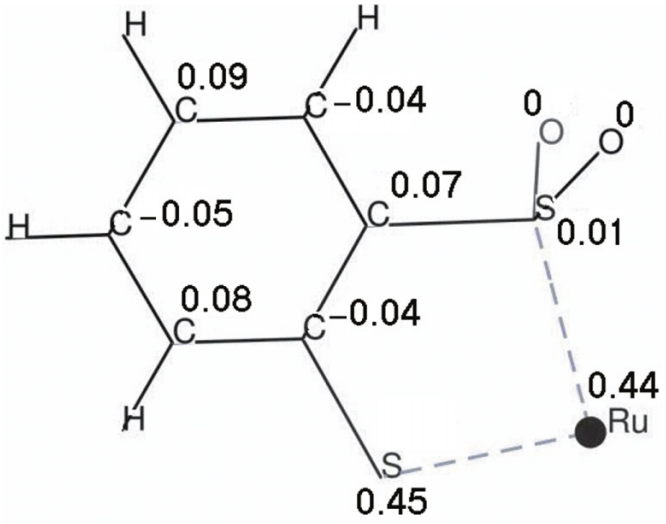
Electronic structure of $[Ru(bpy)_2(S,SO_2)]^-$

We are now in a position to discuss the electronic structure of this species. We note previous studies on the structures of sulfinato species by Grapperhaus et al.[49,50] while Wieghardt and co-workers,[11,51–55] and other groups,[56–58] have extensively studied thiolato species in comparison with other noninnocent ligands. These studies provide a theoretical background but do mostly deal with first row transition metal ions, which offer a rather different perspective than does ruthenium. However, a mixed thiolato-sulfinato ruthenium(II) species, which can be oxidized to its Ru^{III} oxidation product, is relevant to this study.[50]

Clearly (Table 4), there is a much stronger interaction of ruthenium with this ligand than for any of the other species discussed, with substantially larger Ru–S and Mayer fragment bond orders. The C=S bond order is substantially smaller than the corresponding value for the (S,NH) species (Table 4) and the NBO charges on Ru and on the (S,SO_2) ligand are the smallest of the group (Table 2). The C–C bond distances (Table 3) in the benzenoid ring are similar to those found in the catecholate oxidation state.

Table 2 is displayed in order of spin density on ruthenium, and it is seen that the largest spin density on ruthenium is observed with this (S,SO_2) complex; indeed, the spin densities on Ru and the (S,SO_2) ligand are similar and approach 50:50. Clearly, the complex is very covalent as indicated by the large (Ru,X,Y) bond orders and by the fact that the charge separation between Ru and (S,SO_2) ligand is

Fig. 4. Upper: Spin density diagram in the $Ru(S,SO_2)$ fragment. Lower: Kohn–Sham HOMO (#45α) of the free oxidation state^{1-} ligand $(S,SO_2)^-$. THe ligand is in the same relative orientation. The β-LUMO, #45β, has almost an identical appearance to #45α.



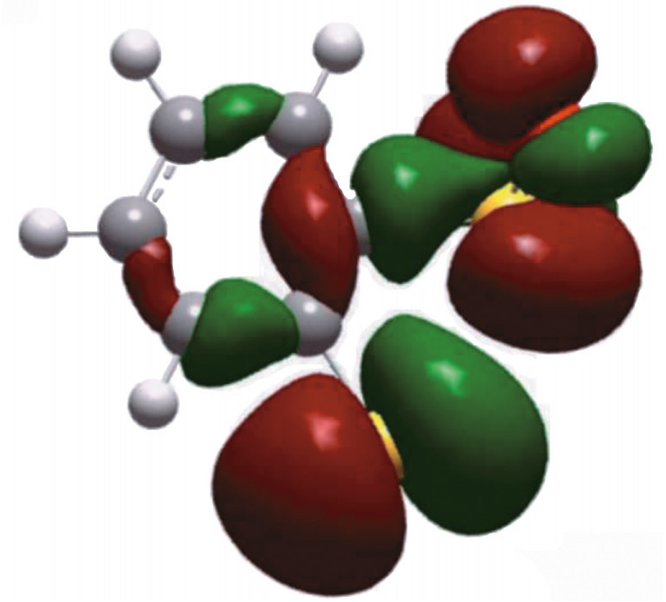


Fig. 5. Left: C—S, C—S(O_2), and S—O bond distances in the free ligands $(S,SO_2)^{n-}$ cited from top to bottom n = 2–, 1–, 0. (DFT optimized (not PCM), see text). Right: C—S, Ru—S, and S—O DFT computed bond distances in species $\mathbf{1}^+$. The benzene C—C distances are all about 1.39 Å in the complex and in the ligand, independent of the oxidation state.

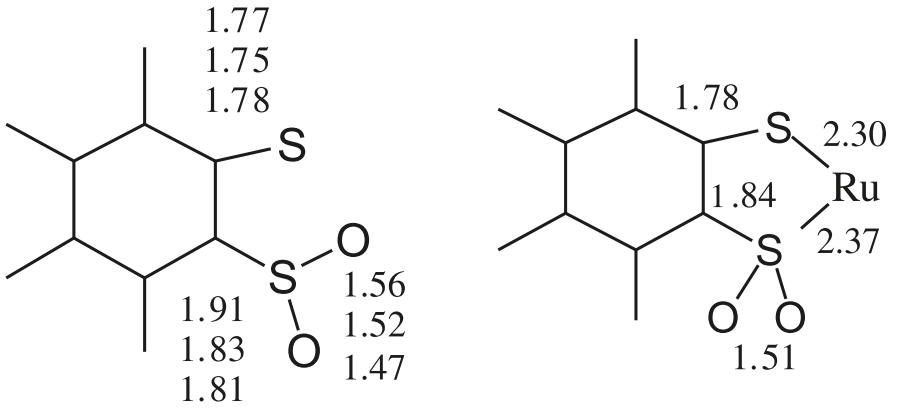

mitigated, i.e., charges are smaller on both fragments than is the case with the other species.

As noted above, many of these species in the quinonoid oxidation contain an aromatic metallocycle ring and, at least for the Ru(acac)$_2$ group, back donation occurs primarily into this ring rather than to the ligand overall.[36] It was suggested above that the current group of semiquinone species might arise through removal of an electron from this ring (from the 2– oxidation state), rather than from the ligand overall. Indeed, based on the spin density distribution (Fig. 3, Table 2) much of the spin density does lie inside the metallocycle with relatively little in the phenyl ring. This distribution would clearly have an influence on the reactivity of the species.

The spin distribution for the (O,NH) derivative is shown in Fig. 3. By considering the data in Table 2, comparing total spin on the X,Y ligand with those on X and Y alone, it is clear that the spin does tend to lie mostly in the metallocycle ring, for all the species, and this is most obvious for the (S,NH) and especially (S,SO_2) species (Fig. 4). In the asymmetric species, (O,NH) and (S,NH), the spin density is predominantly on the NH ligator because the HOMO of the complex has very little Ru–O(S) character (e.g., see Fig. 3).

Clearly, in the case of the (S,SO_2) species where the HOMO very definitively involves the Ru–S^0 and has little contribution from the Ru–S^{IV} bond (Fig. 2), the spin resides mostly within the Ru–S^0 bond. Indeed, the HOMO of the free ligand (S,SO_2) in the 1– oxidation state shows electron density primarily on the S ligators and not in the benzene ring (Fig. 4 (lower)).

Figure 5 reveals the variation in free ligand sulfur related bond distances as a function of the net oxidation state of the free ligand. The C–C (benzene) and C–S^0 bond lengths are essentially independent of oxidation state but the C–S^{IV} and S–O distances are fairly sensitive to the oxidation state. Thus, changing the oxidation state alters the electron density in what will become the metallocycle ring but has little influence on the benzene ring. Comparison with the bond distances in the [Ru(bpy)$_2$(S,SO_2)]$^+$ complex (Fig. 5 (right)) shows reasonable agreement with the 1– ligand oxidation state. The Ru–S^0 and Ru–S^{IV} bond distances have been reported (X-ray) for a so-called Ru^{III} species[50] containing Ru–S^0 (2.14 Å), Ru–S^{IV} (2.30–2.35 Å), and Ru–P bonds. Our calculated Ru–S^0 is substantially shorter in agreement with the strong covalent interaction, while our Ru–S^{IV} is slightly longer.

Given the spin density on both the ruthenium atom and S^0 atoms, then the best description is $[Ru^{II0.5}(bpy)_2(S,SO_2)^{I0.5-}]^+$. Thus, it is evident that the actual oxidation process from species **1** is best described neither as ruthenium oxidation nor as ligand oxidation, but as oxidation of the metallocycle ring. Over 90% of the spin density lies inside this ring (Fig. 4). The electron that is 'removed' is in an antibonding orbital largely localized along the Ru–S^0 vector and we note, indeed, that the Ru–S^0 bond order jumps from 0.86 in species **1** to 1.31 in species $\mathbf{1}^+$ (Table 4), which is a dramatic increase.

The net negative charge on the (S,SO_2) fragment is the smallest of the group and it is evident from the data in Table 5 that this is because the sulfinato ligand is a much stronger donor than the other quinonoid ligands. Nevertheless, there is a quite significant back donation contribution from the β-electrons from fragment A to the sulfinato^{1-} ligand. How does this occur? Several β-virtual orbitals of the (S,SO_2) ligand (fragment B) contribute to filled orbitals of the complex, but by far the dominant contributor is the β-LUMO (#45β). This is the counterpart to the HOMO (#45α) and indeed appears almost identical to it (Fig. 4). It is localized within the S,SO_2 groups (Fig. 4). In effect, therefore, β back donation involves back donation primarily to the metallocycle ring (and hence reduces the C=S^0 bond order), and very little back donated charge reaches the phenyl ring. One needs to be cautious in describing this situation. We might have chosen the fragments to be $[Ru^{III}(bpy)_2\ ]^{3+}$ and $(1,2(S,SO_2)–C_6H_4)^{2-}$ in which case there is an extra electron on the (S,SO_2) ligand and ligand orbital #45β is now occupied. The overall description of the complex, of course, remains the same.

Referring to Table 2, as one passes from species **1** to species $\mathbf{1}^+$ the net charge on the (S,SO_2) ligand decreases, the net positive charge on Ru increases, the charge on the S^0 donor becomes positive but that of S^{IV} remains unchanged (positive). The dramatic change in the charge on S^0 from a negative to positive value is consistent with the removal of an electron from the Ru–S^0 bond.

Thus, in summary, oxidation of species **1** to $\mathbf{1}^+$ involves loss of an electron from the metallocycle ring

generating a highly covalent species best represented as $[Ru^{II0.5}(bpy)_2(S,SO_2)^{I0.5-}]^+$. There is very little change in the geometry and electronic structure of the phenyl ring component of the (S,SO_2) ligand in species **1** and $\mathbf{1}^+$.

The $[Ru(bpy)_2(S,NH)]^+$ species is significantly more covalently bound than the other nonsulfur species. Both sulfur species have a larger 4d Ru population (Table 2) than the other complexes, due to this covalency.

The other formally Ru^{II} semiquinone species described here are similar species with a spin density largely associated with the metallocycle ring but with a greater relative contribution from the (X,Y) benzenoid ring. As noted by Remenyi and Kaupp:[37] "The anionic (acac) complexes turn out to be approximately halfway between a d^6-Ru^{II}/semiquinone and a d^5-Ru^{III}/catecholate formulation, ..." but the important involvement of the metallocycle ring makes such labels rather incomplete.

Carbon–hydrogen vs. carbon–halogen oxidative addition of chlorobenzene to a cationic iridium(I) system — A density functional theory study

Hong Wu and Michael B. Hall

Abstract: Density functional theory (DFT) is used to explore the competitive C–H and C–Cl oxidative additions (OA) of chlorobenzene to the cationic Ir(I) complex: $[(PNP^*)Ir^I]^+$ [PNP* = 2,6-bis((dimethylphosphino)methyl)pyridine]. Consistent with experimental results, the calculated activation barrier for C–H OA ($\Delta G^{\ddagger}$ = 10.7 kcal mol^{-1}) is lower than that for C–Cl OA ($\Delta G^{\ddagger}$ = 19.7 kcal mol^{-1}). However, the C–Cl OA product is calculated to be thermodynamically preferred as its ΔG^{o} is 14.3 kcal mol^{-1} below that for the most stable C–H OA product.

Key words: iridium, catalysis, density functional, bond activation, oxidative addition, reaction mechanism, thermochemistry.

Résumé : On a utilisé la théorie de la fonctionnelle de la densité (TFD) pour étudier les réactions d'additions oxydantes (AO) C–H et C–Cl du chlorobenzène sur le complexe cationique de l'iridium(I), $[(PNP^*)Ir^I]^+$ [PNP* = 2,6-bis{(diméthylphosphino)méthyl}pyridine]. En accord avec les résultats expérimentaux, la barrière d'activation calculée pour la réaction d'addition oxydante du C–H ($\Delta G^{\ddagger}$ = 10,7 kcal·mol^{-1}) est inférieure à celle pour la réaction d'addition oxydante du C–Cl ($\Delta G^{\ddagger}$ = 19,7 kcal·mol^{-1}). Toutefois, on a calculé que le produit de la réaction d'addition oxydante du C–Cl est thermodynamiquement privilégié puisque son ΔG^{o} est 14,3 kcal·mol^{-1} inférieur au produit le plus stable de l'addition oxydante d'un C–H.

Mots-clés : iridium, catalyse, fonctionnelle de la densité, activation d'une liaison, addition oxydante, mécanisme réactionnel, thermochimie.

[Traduit par la Rédaction]

Introduction

Carbon–hydrogen bond activation by transition-metal complexes, an extremely important process because of its widespread use in functionalizing arenes, alkanes, and other organic molecules, has been studied extensively by experimental and theoretical investigations[1] since the pioneering studies of Crabtree,[2] Chatt and co-workers,[3] Shilov,[4] Bergman and co-workers,[5] Jones and co-workers,[6] and Graham and co-workers.[7] Group-9 metal complexes[8] have played a central role in the expansion of this challenging field, especially those of iridium.[9]

The ability to selectively and catalytically activate C–H bonds has tremendous utility in organic synthesis. Because of their strength, C–X bonds in haloarenes, commonly used organic substrates,[10] are expected to be less likely to undergo oxidative additions (OA) to transition-metal species than the C–H bonds. However, because of their higher polarity, C–X bonds may have stronger initial binding tendencies compared with C–H bonds in forming σ-complexes, precursors to OA reactions. Due to steric effects, C–H bond activation in haloarenes usually takes place at less hindered positions, forming predominantly mixtures of meta- and para-activated complexes. In a recent work, Milstein and co-workers described an unprecedented ortho C–H activation preference (at ≤60 °C) in chloro- and bromo-benzene via oxidative addition to the cationic $[(PNP^*)Ir^I]^+$ [PNP* = 2,6-bis((di-*tert*-butylphosphino)methyl)pyridine] where the halogen apparently acts as a directing group (Scheme 1).[11] No C–X activation products were observed in this study. On the other hand, Ozerov and co-workers reported that $(PNP)Ir(H)_2$ [PNP = bis(2-(diisopropylphosphino)-4-methylphenyl)amino] activates the ortho C–H bond at 70 °C but forms C–X OA products above 100 °C.[12] Further, the PNP Rh system exclusively activates the C–X bond.[13] Clearly, the strongly electron-donating and bulky tridentate PNP ligands generate a variety of unusual transition-metal chemistry.[14] All studies suggest that the OA reactions proceed via a 14-electron three-coordinated intermediates, such as $[(PNP^*)Ir^I]^+$.

Although there have been extensive theoretical studies of C–H bond addition in group-9 metals, there has been only one recent report of the thermodynamic vs. kinetic preference of C–X bonds vs. C–H bonds, respectively, and that was for a simple $Ir(PH_3)_2(H)$ model compound.[15] Here, we report a theoretical study to explore the kinetic and thermodynamic parameters in OA reactions of aromatic C–H and C–X bonds for the $[(PNP)(Me)Ir^I]^+$ system (Scheme 2).

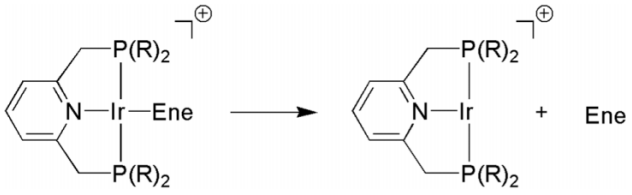
Computational details

All geometry optimizations and frequency determinations were carried out with the Gaussian 03 package of programs[16] at the B3LYP computational level.[17] Transition states were located with the use of synchronous transit-guided quasi-Newton method.[18] The basis set used for Ir is the extended valence double-zeta LANL2DZ[19] basis in which the 6s and 6p functions are replaced by the functions reoptimized by Couty and Hall,[20] and sets of diffuse f functions (exponent = 0.938(Ir)) were added.[21] The LANL2DZdp basis sets were employed for phosphorus and chlorine.[22] The 6–31G(d′) basis sets were used for all carbon, nitrogen, and hydrogen atoms.[23] Our computational models have methyl groups attached to the phosphorus atoms (i.e., $P(CH_3)_2$), a compromise between the use of hydrogen atoms and the bulky ^{t}Bu groups actually employed in the experiment.[11]

All computed structural data are documented in the Supplementary data, and we show models only of the most relevant conformations of the reactants, intermediates, and products and of the transition-state structures between them. Total electronic energies E, zero-point energies ZPE, E_0, ΔH, and ΔG, are reported as part of the Supplementary data (Table S1). Here, we report and discuss ΔH and ΔG data unless noted otherwise.

No basis set superposition error corrections were made for ligand-dissociation or substrate-association energy, since we are mainly interested in C–Cl vs. C–H OA in the current study. Following a reviewer's suggestion, we would like to note that the B3LYP functional sometimes predicts absolute dissociation energies that are too small, but this problem should not affect our main results, which depend on the relative energies. Solvent effects were considered only for dissociation-energy calculations with single-point calculations based on gas-phase geometries using the polarizable conductor calculation model (CPCM).[24] Chlorobenzene was the chosen solvent as employed in the experiments.

Scheme 3.



Throughout this paper, bond lengths are given in Ångstroms, bond angles in degrees, and relative reaction energies in kcal mol^{-1}.

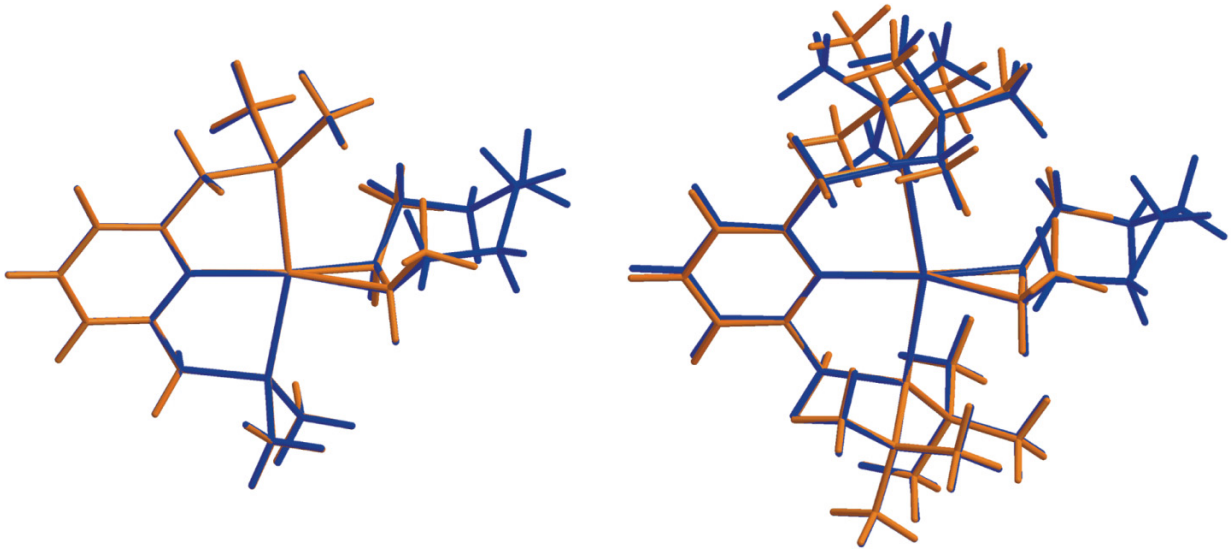
Results and discussion

Complex **1** is used to model the reactant [(PNP*)Ir^{I}(cyclooctene)]$^+$ of the related experimental study.[11] In the solvent chlorobenzene (**4**), the unsaturated 14-electron [(PNP*)Ir^{I}]$^+$ species **3** is generated via the release of cyclooctene (**2**) from **1,** and species **3** undergoes either C–H OA to **5** or C–Cl OA to **6** (Scheme 2). Fourteen-electron ML_2L' fragments, like species **3** could have T- or Y-shaped struc-

Table 1. Dissociation energies and structural parameters.

R	Ene	ΔH_{gas}	ΔG_{gas}	$\Delta G_{solvent}$	Ir–C_1	Ir–C_2	C_1–Ir–C_2	P_1–Ir–C_1	P_2–Ir–C_2
Methyl	*Z*-2-butene	42.14	27.89	24.84	2.168	2.174	38.2	100.0	94.0
Methyl	Cyclooctene	35.93	22.68	16.90	2.161	2.180	38.1	98.6	92.2
^{t}Butyl	*Z*-2-butene	21.71	6.22	2.42	2.188	2.195	37.7	102.1	90.2
^{t}Butyl	Cyclooctene	17.54	2.80	–6.08	2.171	2.190	37.9	99.7	90.1

Fig. 1. Superimposed optimized geometries for the two olefins, Ene = *Z*-2-butene (orange) and Ene = cyclooctene (blue), when R = methyl (left) and R = ^{t}butyl (right).



tures,[25] but the tridentate PNP* ligand enforces a T-shaped structure on $[(PNP^*)Ir^I]^+$, **3**, with Ir, P, P, and N approximately lying in a plane.

Loss of Ene

The steric and electronic effects in the olefin dissociation process (Scheme 3) are explored by the comparison of different R groups (methyl and ^{t}butyl) on P and different Enes (*Z*-2-butene and cyclooctene) on Ir.

The predominance of steric over electronic effects is seen in the dissociation energies when R and Ene groups are varied. Replacing the *Z*-2-butene with cyclooctene only reduces the gas-phase endoergicity of the dissociation process by 5.2 and 3.4 kcal mol^{-1}, respectively, but replacing the methyl groups attached to the phosphorus atoms with ^{t}butyl groups reduces this endoergicity by 21.6 and 19.8 kcal mol^{-1}, respectively. Thus, in the experimental system, R = ^{t}butyl and Ene = cyclooctene, the endoergicity of the dissociation process reduces dramatically in the gas phase to 2.8 kcal mol^{-1}, and the process is even exoergonic ($\Delta G_{solvent}$ = –6.1 kcal mol^{-1}) when the solvent effects are included (Table 1). Therefore, consistent with the experimental observation, the cyclooctene dissociation is facile, and the formation of the 14 e$^-$ $[(PNP^*)Ir]^+$ intermediate is energetically favored.

Examination of the structural difference for these four systems reveals the origin of the larger energy difference. There are strong structural similarities for the two olefins (*Z*-2-butene or cyclooctene) bonding to the $[(PNP^*)Ir^I]^+$ center in both cases of R = methyl (left) and R = ^{t}butyl (right) (Fig. 1). When R = methyl (left), except for the additional atoms in cyclooctene, the two geometries perfectly match each other, while there is some deviation on the $[(PNP^*)Ir^I]^+$ part when R = ^{t}butyl (right). The steric effects are more apparent when different R groups are structurally compared (Fig. 2). Unlike Fig. 1, in which structures overlay to each other fairly well, when the R group is changed from methyl to ^{t}butyl, there are strong deviations for the olefin functionality and also some for PR_2 group. Hence, the steric effect dominates the favorable loss of cyclooctene from $[(PNP^*)IrL]^+$.

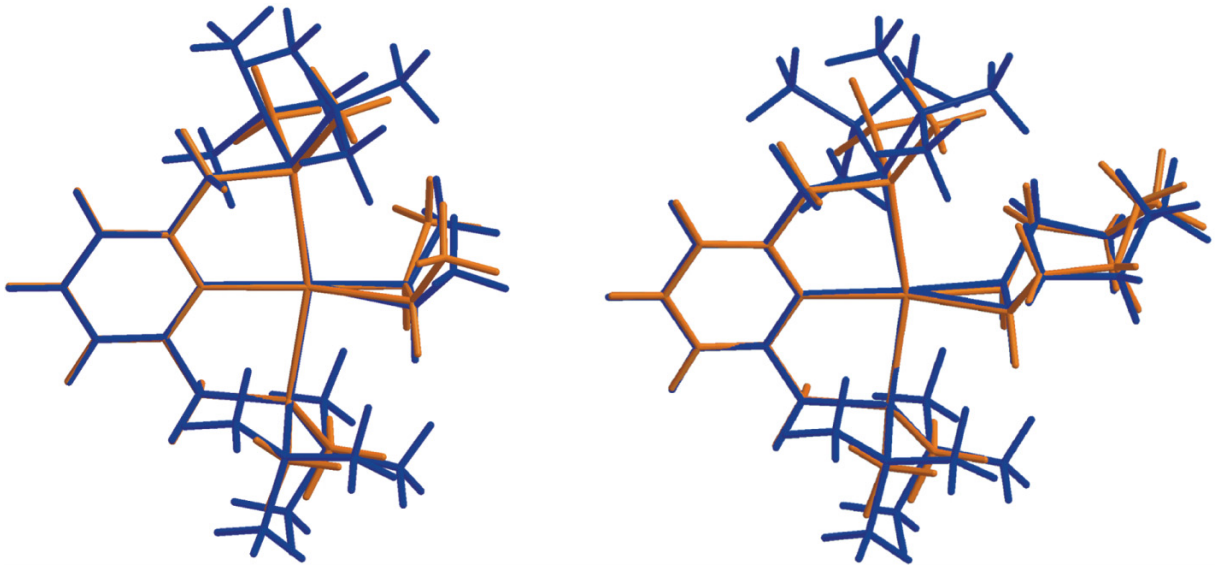
Attachment of C_6H_5Cl to $[(PNP^*)Ir^I]^+$, 3

Transition-metal complexes with three-coordinate d^8 configurations are typically highly active.[26] Oxidative addition (OA) of chlorobenzene, **4**, to the unsaturated 14-electron $[(PNP^*)Ir^I]^+$ complex **3** leads to the formation of 16-electron five-coordinate adducts from C–H OA, $[(PNP^*)Ir^{III}(H)(C_6H_4Cl)]^+$ (**5**) or from C–Cl OA, $[(PNP^*)Ir^{III}(Cl)(C_6H_5)]^+$ (**6**). Initially, Ir binds weakly to the chlorobenzene forming either a σ-adduct, through a C–H (agostic), or a C–Cl bond, or a π-arene adduct. These three intermediates may be in rapid equilibria with the 14 e$^-$ complex (**3**) and solvent (**4**). We discuss the results of these initial adducts next.

(*i*) "Agostic" C–H σ-adducts, IM1-a – IM1-e

Prior to C–H OA, **3** reacts with **4** to form the C–H σ-adducts as intermediates **IM1**. With respect to the positions between the activated C–H bond and the Cl atom, five inter-

Fig. 2. Superimposed optimized geometries for the two R groups, R = methyl (orange) and R = ^{t}butyl (blue) when Ene = *Z*-2-butene (left) and Ene = cyclooctene (right).



mediates are found: **IM1-a** and **IM1-b** are two intermediates for the ortho C–H OA, **IM1-c** and **IM1-d** are the two for the meta C–H OA, and **IM1-e** is the one for the para C–H OA (Fig. 3). In all structures, the H atom is closer to the Ir, but each one also has a close contact to the corresponding C atom.

All of the calculated energetic quantities are given in the Supplementary data (Table S2). We will discuss the most important quantities in the text. The attachment of chlorobenzene to $[(PNP^*)Ir^I]^+$ in C–H bond is strongly exothermic (ΔH = –15.2, –17.1, –16.7, –16.9, and –16.5 kcal mol^{-1}) and slightly exergonic (ΔG = –3.4, –4.6, –5.0, –5.1, and –4.9 kcal mol^{-1}) for all five pathways, respectively.

(*ii*) C–Cl σ-adduct, IM2

Prior to the C–Cl OA reaction, $[(PNP^*)Ir^I]^+$ binds **4** via the adduct Ir···Cl–C **IM2**. The optimized geometry of intermediate **IM2** is shown in Fig. 3. The attachment of chlorobenzene to $[(PNP^*)Ir^I]^+$ (**IM2**) is strongly exothermic (ΔH = –20.7 kcal mol^{-1}) and exergonic (ΔG = –10.5 kcal mol^{-1}).

(*iii*) η^2-Arene adduct, (PNP*)Ir(η^2-C_6H_5Cl), IM3

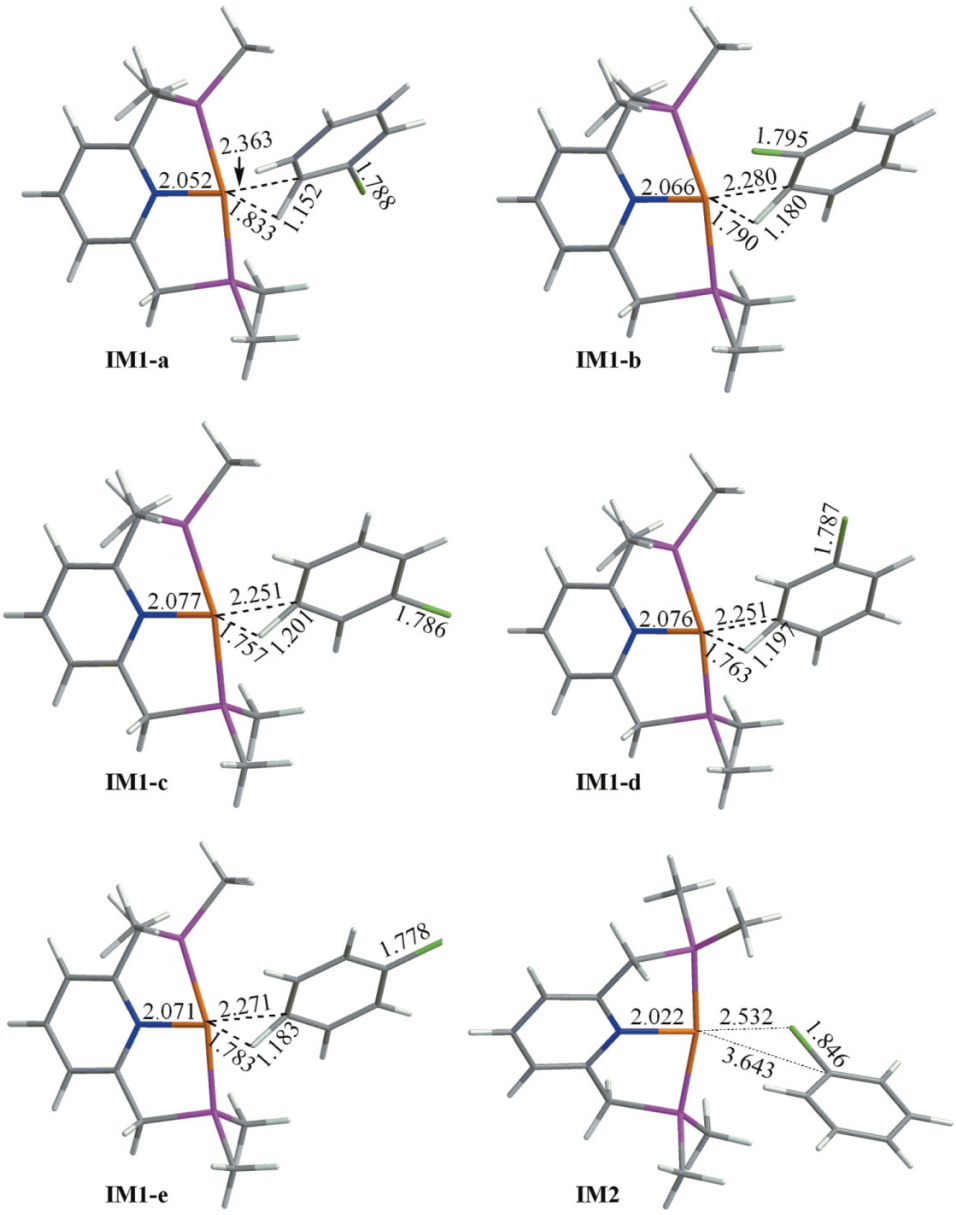
Six isomers of the η^2-C_6H_5Cl, complex with the C=C double bond perpendicular to the pyridine plane (Fig. 4) are also considered, since this partial coordination of arene to transition metals has often been suggested as a step prior to oxidative additions.[27] Because the PNP ligand is not completely planar, the six isomers correspond to two orientations of the three different C–C arene bonds. The pairs of isomers with respect to the twist of the PNP ligand are denoted as unprimed and primed isomers (Fig. 4). The energetic differences between the unprimed and primed relatives are less than 0.5 kcal mol^{-1} (Table S2), and we focus on the unprimed **IM3** isomers. When incoming chlorobenzene binds in an η^2 fashion, the 2,3-position (site **a**) is the most preferred site for η^2-coordination to **3** because the double bond character is highest between C(2) and C(3) (high population in π and low population in π*) as a result of the conjugation with the π donor Cl. The Cl-substituted double bond (site **c**) is the least favored site by 2.7 (unprimed) and 4.2 (primed) kcal mol^{-1} due to the decreased olefinic character at the C=C bonds carrying Cl. Furthermore, the dislocation at the two coordinated C atoms will disfavor the Cl substitution from being on one of these C atoms. Because of its similar electronic structure, coordination to 3,4-position (site **b**) is only 0.9 kcal mol^{-1} less stable than site **a**. In spite of some loss in resonance energy in the aromatic ring induced by the η^2-coordination of C_6H_5Cl to **3**,[28] the addition of chlorobenzene to $[(PNP^*)Ir^I]^+$ to the most stable η^2-intermediate, **IM3-a**, is strongly exothermic (ΔH = –25.8 kcal mol^{-1}) and exergonic (ΔG = –13.2 kcal mol^{-1}). **IM3-a** is 9.8 and 2.8 kcal mol^{-1} lower in free energy than **IM1-a** and **IM2**, respectively.

C–H and C–X oxidative addition products

Before discussing the transition states and reaction paths, we will discuss the structures and energetics of the OA products. Addition of chlorobenzene, **4**, to the unsaturated 14-electron $[(PNP^*)Ir^I]^+$ complex **3** leads to the C–H OA product, $[(PNP^*)Ir^{III}(H)(C_6H_4Cl)]^+$ (**5**), or C–Cl OA product, $[(PNP^*)Ir^{III}(Cl)(C_6H_5)]^+$ (**6**). For the C–H OA reaction, five isomers of product **5** (Fig. 5) have been calculated: ortho C–H bond activation produces isomers **5a** and **5b**, meta C–H bond activation produces isomers **5c** and **5d**, and para C–H bond activation produces isomer **5e**. The isomer **5a** is the most stable one by ~10 kcal mol^{-1}, as the chlorophenyl ring is oriented such that the Cl is weakly bound to the sixth coordination site, anti to the H. (Fig. 5) For isomers **5b**–**5e**, the Ir(III) metal center has a five-coordinate square-pyramidal geometry where the hydride occupies the apical site.

For the (**5a**, **5b**) and (**5c**, **5d**) rotamer pairs, transition states **TS(5a, 5b)** and **TS(5c, 5d)** for rotation about the Ir–C bond show that the Ir(III) center maintains the square-pyramidal geometry and the TSs have the chlorophenyl ring nearly coplanar with the pyridine. Our calculations also show much higher rotational barrier required for ortho-sub-

Fig. 3. Optimized geometries of agostic C–H σ-adducts, **IM1-a** – **IM1-e**, and the C–Cl adduct, **IM2**.



stituted **5a** → **5b** ($\Delta H^{\ddagger}$ = 23.8 kcal mol^{-1}) than for meta-substituted **5c** → **5d** ($\Delta H^{\ddagger}$ = 4.1 kcal mol^{-1}) (Table S2). **5c** and **5d** are nearly isoenergetic and interconvert too fast to be detected separately by NMR. Hence, only one meta-C–H activated complex will be detected. However, the rotation between **5a** and **5b** is relatively slow on the NMR time scale, and thus both **5a** and **5b** will be observed easily. Experimental observations show that, for (PNP)Ir(aryl)(H) system, the rotation about the Ir–C bond is restricted only for the ortho-substituted aryls.[29] The para-C–H activated complex **5e** is the fourth isomer that will be observed. The higher thermodynamic stability of **5a** than **5b**–**5e** can be explained by its additional intramolecular coordination of Cl to the Ir center (Cl → Ir donation).

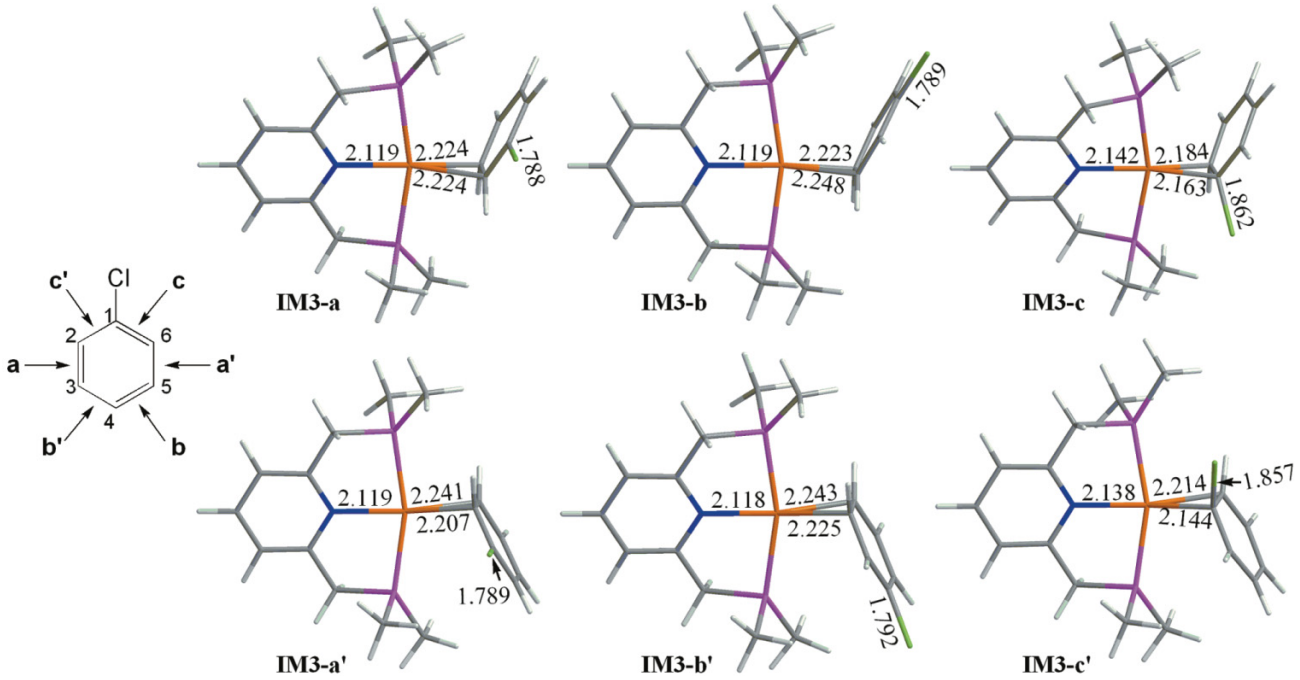
For the C–Cl OA reaction, two approximately square-pyramidal isomers of product **6** were optimized (Fig. 6). Only isomer **6a**, which has the phenyl group occupying the apical site, was observed in the related experimental study, and no isomerization of **6a** was detected.[12] Consistent with this observation, our calculations show that **6b** is 18 kcal mol^{-1} higher in energy than **6a**.

Among the various isomeric stationary points (intermediates and products) for C–H and C–X activations, the C–Cl OA product **6a** is the global minimum. The lowest energy C–H OA product **5a** is 14.3 kcal mol^{-1} higher in enthalpy than the C–Cl OA product, **6a**. Hence, under equilibrium conditions we would expect to see the formation of C–Cl OA product, but the authors did not observe any in their experiments[11] at 60 °C.

Transition states for C–H OA reaction

Since both the η^2-C_6H_5Cl and the agostic Ir···H–C adducts are possible precursors/intermediates prior to C–H OA, we searched for C–H OA transition states starting from both ad-

Fig. 4. Optimized geometries of isomers of η^2-C_6H_5Cl complexes, **IM3-a – IM3-c′.**



ducts. The same transition states, **TS1-a** – **TS1-e** (Fig. 6), were obtained from both starting points. In all these TS, the Ir–H and Ir–C bonds are nearly formed as indicated by their short distances. Overall, the geometries of the transition states correspond to a highly distorted trigonal-bipyrimidal metal center (Y-shaped) with relatively small H–Ir–C angles.

The η^2-C_6H_5Cl adducts are more stable than the agostic Ir···H–C adducts (i.e., **IM3-a** is 9.8 kcal mol^{-1} lower in free energy than **IM1-a**); hence, **IM3-a** is taken as the intermediate for the formation of **5a**–**5d**, and **IM3-b** is taken as the one for the formation of **5e**. The five C–H OA reactions are all exothermic and exergonic. The activation barriers ($\Delta G^{\ddagger}$) for all reaction pathways are fairly small ($\Delta G^{\ddagger}$ = 10.6 (**a**), 8.4 (**b**), 8.0 (**c**), 7.9 (**d**), and 7.1 (**e**) kcal mol^{-1}). The calculations, therefore, predict that the C–H bond activation by [(PNP*)Ir^{I}]$^{+}$ upon the addition of chlorobenzene is quite facile. The formation of the thermodynamically most stable C–H OA product **5a** requires a somewhat higher barrier (~2.2–3.5 kcal mol^{-1}) than the formation of other products. Therefore, **5a** is observed together with other isomers by experiments at 50 °C and becomes the dominant C–H OA product at higher temperatures due to its thermodynamic stability.

Transition state for C–Cl OA reaction

Similarly, since both the η^2-C_6H_5Cl and C–Cl σ-adducts are possible precursors/intermediates prior to C–Cl OA, we searched for C–Cl OA transition states starting from both adducts. The same transition state, **TS2** (Fig. 6), was found in both attempts.

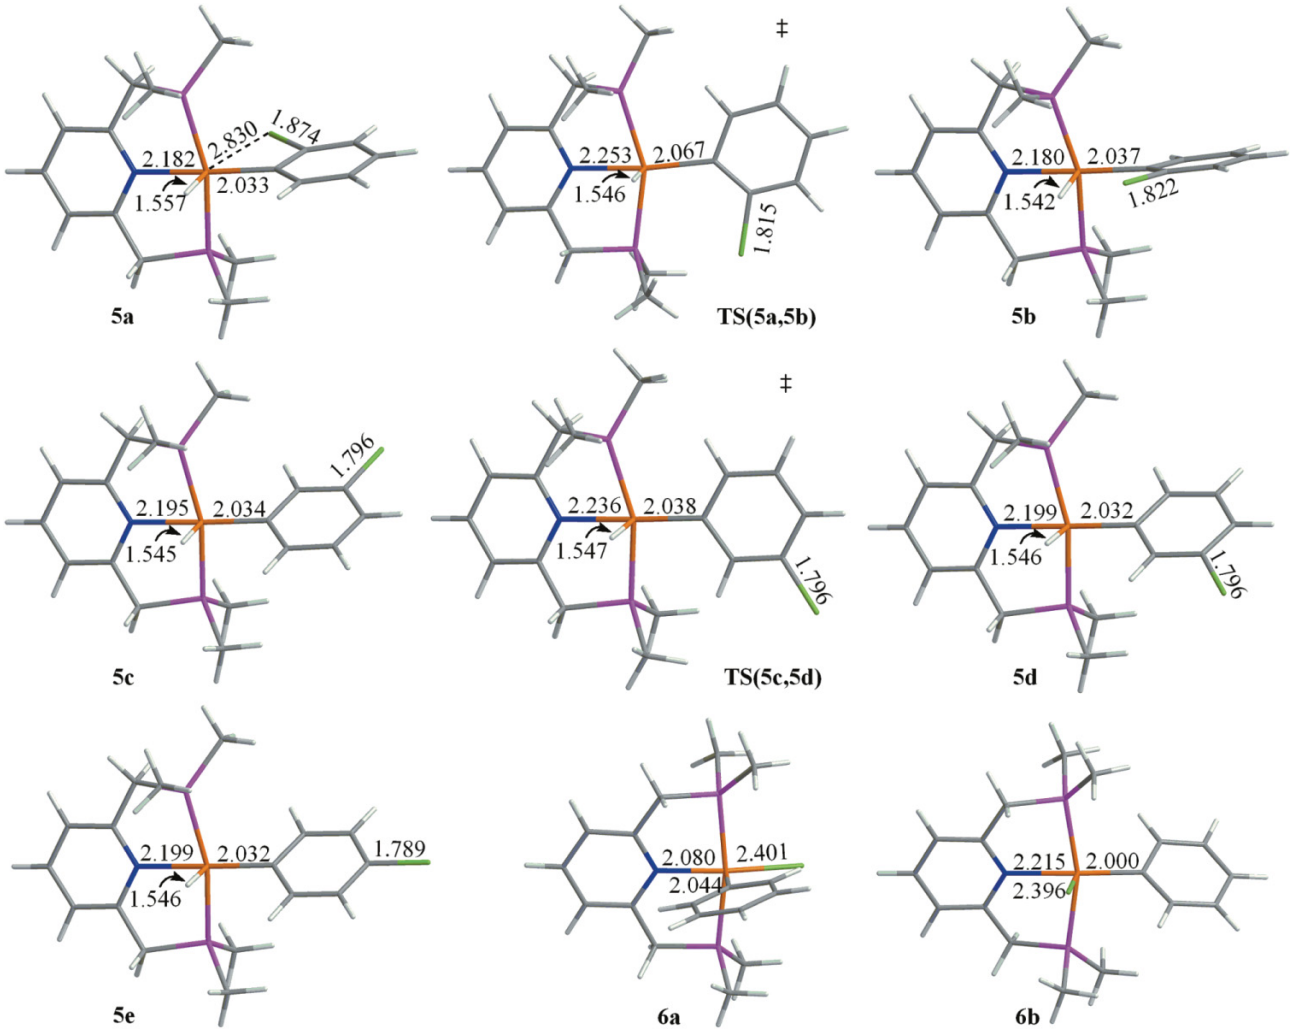
Again, since the η^2-C_6H_5Cl complex **IM3-a** is more stable than the **IM2** by 2.7 kcal mol^{-1}, **IM3-a** is taken as the intermediate for the formation of **6a**. In contrast to the C–H OA reactions, which require fairly small activation barriers, C–Cl bond activation requires an activation free energy of 19.7 kcal mol^{-1}. Because of the large kinetic preference for C–H OA, those products are not observed[11] in spite of the thermodynamic preference for product **6a**, which is the global minimum.

Isomerization of 5a to 6a

Although Milstein and co-workers did not observe any C–Cl OA product,[11] other experimental work[12] shows that the yield of the C–X (X = F, Cl, and Br) activation product increases at higher temperature as the kinetically favored C–H activation products undergo isomerization to the thermodynamically favored C–Cl OA product. Hence, it is critical to understand the isomerization path from the most stable C–H OA product **5a** to the most stable C–Cl OA product **6a**. The calculations show a low-energy route involving simultaneous cleavage of Ir–H and C–Cl bonds in **5a** and formation of C–H and Ir–Cl bonds via **TS3.** The product is intermediate **6b**, an isomer of the most stable C–Cl OA product, **6a**, with Cl occupying the apical site of Ir center, which then undergoes isomerization to **6a** via transition state **TS4** (Scheme 2). The optimized geometries of the two transition states involved in this isomerization, **TS3** and **TS4**, are shown in Fig. 7.

The activation free energy ($\Delta G^{\ddagger}$) for **5a** → **6b** is 16.7 kcal mol^{-1}, which is lower than that for **5a** → **5b** ($\Delta G^{\ddagger}$ = 25.6 kcal mol^{-1}) and for **5a** → **IM3-a** ($\Delta G^{\ddagger}$ = 27.1 kcal mol^{-1}). Thus, a direct route will be preferred over routes leading back to the reactants. Therefore, after formation of **5a**, increasing the reaction temperature converts **5a** directly to **6b** through **TS3** and then through **TS4** to the thermodynamically favored product **6a**. The activation barrier ($\Delta G^{\ddagger}$) for the latter step **6b** → **6a** is only 6.0 kcal mol^{-1}, while that for its reverse reaction (**6a** → **6b**) is 23.9 kcal mol^{-1}. Thus, the entire process of **5a** → **6a** is likely to proceed irreversibly.

Fig. 5. Optimized geometries of **5a**-**5e**, **TS(5a, 5b)**, **TS(5c, 5d)**, **6a**, and **6b**.



Conclusions

The energetic data for the reaction of the 14 e$^-$ intermediate [(PNP*)Ir^I]$^+$ (**3**) with chlorobenzene (**4**) are summarized by the ΔG potential-energy surface diagram (Fig. 8). All the energies are relative to the starting materials. Both C–H OA and C–Cl OA reactions are exothermic and exoergonic. Although **5a** is the most stable C–H OA product, it and the other C–H OA products (**5b**–**5e**) are formed through their own TS such as **TS1-a** (**TS1-b** – **TS1-e**). Additionally, some C–H OA products may be formed from the common intermediate **IM3-a**, but the interconvertion of these isomers (**5a**–**5e**) occurs only as higher temperatures are reached. The C–Cl OA product **6a** is the globe minimum; it is likely formed by the irreversible conversion from **5a** via intermediate **6b**; the higher energy direct C–Cl activation is a less likely route.

C–H activations are more competitive kinetically. The formation of the most stable C–H OA product, **5a,** only requires 10.6 kcal mol^{-1} activation free energy from **IM3-a** and much less from **IM1-a**, but the formation of C–Cl OA product, **6a**, requires 19.6 kcal mol^{-1} activation free energy for the direct C–Cl OA. In all cases, C–H OA is kinetically favored over C–Cl OA by at least 9.0 kcal mol^{-1}; therefore, only C–H OA reactions proceed at lower temperatures. This prediction is consistent with the experimental results that show no C–Cl OA product even at 60 °C.[11] However, as the temperature increases, **5a** becomes the only C–H OA product, and it isomerizes to **6b** and finally to **6a**. **6a** is thermodynamically much more stable than any of the intermediates or other products and its formation from the isomerization of **5a** requires 16.7 kcal mol^{-1} of activation energy, which is much less than that needed for **5a** converting back to either **5b** (25.6 kcal mol^{-1}) or **IM3-a** (27.1 kcal mol^{-1}). Hence, the isomerization of **5a** to **6a** is the exclusive pathway for the formation of **6a**, the thermodynamically most favored product. Even though the experimental workers did not report the results at temperatures higher than 60 °C,[11] we would expect that the C–Cl OA product, **6a**, be observed at higher temperatures.

In summary, the density functional calculations of the OA reactions of chlorobenzene with the cationic Ir^I complex [(PNP*)Ir^I]$^+$ (**3**) [PNP* = 2,6-bis((dimethylphosphino)methyl)pyridine] show that the PNP*-based Ir^I system exhibits high kinetic selectivity for the aromatic C–H activations. Lower-energy transition states in C–H activation and lower-energy products in C–Cl activation support the conclusion that C–H activation is more competitive kinetically, whereas

C–Cl activation is more favorable thermodynamically. We expect that a similar energetic scenario may appear to other transition-metal systems that are capable of OA reactions upon the addition of haloarenes (X = Cl, Br, and I).[30]

The Dewar–Chatt–Duncanson model reversed — Bonding analysis of group-10 complexes $[(PMe_3)_2M–EX_3]$ (M = Ni, Pd, Pt; E = B, Al, Ga, In, Tl; X = H, F, Cl, Br, I)

Catharina Goedecke, Pierre Hillebrecht, Till Uhlemann, Robin Haunschild, and Gernot Frenking

Abstract: Quantum chemical calculations using BP86 with TZ2P basis sets were carried out to elucidate the structures and the bond–bond dissociation energies of the donor–acceptor complexes $[(PMe_3)_2M–EX_3]$ with X = H, F, Cl, Br, I; E = B, Al, Ga, In, Tl; and M = Ni, Pd, Pt. The nature of the metal–ligand bond was investigated with an energy decomposition analysis. The geometry optimizations gave for most compounds T-shaped structures with nearly linear P–M–P angles where the EX_3 ligand has either a staggered or eclipsed conformation with respect to the PMP plane. The energy differences between the conformations are very small which means that there is nearly free rotation about the M–EX_3 axis. The equilibrium structures of eight nickel compounds have a distorted geometry where one E–X bond is engaged in attractive interactions with the metal atom which yields a distorted square-planar arrangement of the metal atom. The complex $[(PMe_3)_2Ni–TlI_3]$ exhibits two attractive interactions between Tl–I bonds and the metal which features a five-coordinated metal atom. The calculated bond dissociation energies show that the boron complexes exhibit a different trend for the D_e values than the heavier group-13 homologues. The results for the Pd and Pt complexes suggest that the $[(PMe_3)_2M–BX_3]$ bond strength increases with F < Cl < Br < I < H which means that the BH_3 ligands are the most strongly bonded Lewis acids and BF_3 is the most weakly bonded species . The trend for the heavier group-13 complexes $[(PMe_3)_2M–EX_3]$ where E = Al, Ga, In, Tl follows the opposite order F > Cl > Br > I > H. The energy decomposition analysis of the M–EX_3 bonds indicates a substantial π contribution of between 12.7% and 30.3% to the total orbital interactions. There is no direct correlation between the strength of the orbital interactions or any of the other energy terms ΔE_{elstat} or ΔE_{Pauli} which correlates with the total interaction energy. The bond dissociation energy of the EX_3 ligands after breaking the M–EX_3 bonds is quite large. It is shown that the intrinsic strength of the M–EX_3 bonds is much larger than the BDEs and that the trends of ΔE_{int} and D_e are not always the same. The EX_3 ligands in $[(PMe_3)_2M–BX_3]$ always carry a large negative charge.

Key words: density functional calculations, bonding analysis, Lewis acids, transition metal complexes, reversed DCD model.

Résumé : On a effectué des calculs de mécanique quantique BP86 à l'aide d'ensembles de base TZ2P dans le but d'élucider les structures et les énergies de dissociation de liaison des complexes donneur–accepteur $[(PMe_3)_2M–EX_3]$ dans lesquels X = H, F, Cl, Br, et I; E = B, Al, et Ga, In, Tl; et M = Ni, Pd, et Pt. On a étudié la nature de la liaison métal–ligand par le biais d'une analyse de l'énergie de décomposition. Les optimisations de la géométrie conduisent, pour la plupart des composés, à des structures en forme de T avec des angles P–M–P pratiquement linéaires, dans lesquels le ligand EX_3 se trouve dans une conformation décalée ou éclipsée par rapport au plan PMP. Les différences d'énergie entre les conformations sont très faibles, ce qui implique qu'il existe une rotation pratiquement libre autour de l'axe M–EX_3. Les structures à l'équilibre dans les neuf composés du nickel comportent toutes une géométrie déformée dans laquelle une liaison E–X est engagée dans des interactions attractives avec l'atome métallique ce qui conduit à un arrangement plan carré déformé de l'atome métallique. Le complexe $[(PMe_3)_2Ni–TlI_3]$ présente même deux interactions attractives entre les liaisons Tl–I et le métal qui comporte un atome de métal pentacoordonné. Les énergies de dissociation de liaison calculées montrent que les complexes de bore présentent une tendance différente pour les valeurs D_e que les homologues plus lourds du groupe 13. Les résultats pour les complexes du Pd et du Pt suggèrent que la force de la liaison $[(PMe_3)_2M–EX_3]$ augmente avec F < Cl < Br < I < H, ce qui signifie que les ligands BH_3 sont les acides de Lewis les plus fortement liés et que les espèces BF_3 participent aux liaisons les plus faibles. La tendance pour les complexes plus lourds du groupe 13 $[(PMe_3)_2M–EX_3]$ dans lesquels E = Al, Ga, In et Tl conduit à l'ordre inverse F > Cl > Br > I > H. L'analyse de l'énergie de décomposition des liaisons M–EX_3 met en évidence la présence d'une contribution π importante, allant de 12,7 % à 30,3 % des interactions or-

bitalaires totales. Il n'existe aucune corrélation directe entre la force des interactions orbitalaires ou l'un des autres termes d'énergie, tel ΔE_{elstat} ou ΔE_{Pauli} et l'énergie totale d'interaction. L'énergie de dissociation de la liaison des ligands EX_3 après le bris des liaisons M–EX_3 est très élevée. On a démontré que la force intrinsèque des liaisons M–EX_3 est beaucoup plus élevée que les BDE et que les tendances des ΔE_{int} et D_e ne sont pas toujours les mêmes. Les ligands EX_3 dans les complexes [$(PMe_3)_2$M–EX_3] portent toujours une forte charge négative.

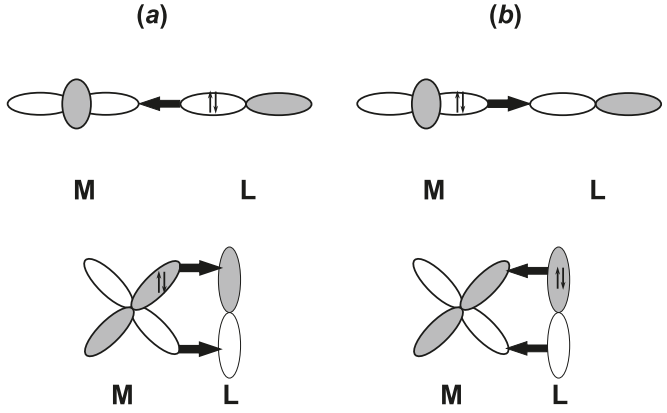
Introduction

The chemical bonds in donor–acceptor complexes of transition metals with main-group ligands are usually described using the Dewar–Chatt–Duncanson (DCD) model[1] where the ligand, being a Lewis base, serves as a σ-donor and π-acceptor and the metal, being a Lewis acid, is a σ-acceptor and π-donor (Scheme 1*a*). Quantum chemical investigations using charge and energy decomposition analyses have shown that the DCD model is a very useful description of the metal–ligand interactions.[2] It is conceivable that electron deficient ligands which are Lewis acids bind to electron rich (late) transition metals in a reversed fashion where the metal, which behaves as a Lewis base, becomes a σ-donor whereas the Lewis acidic ligand is a σ-acceptor (Scheme 1*b*). This could be possible when a group-13 Lewis acid EX_3 (E = B, Al, Ga, In, Tl) is bonded to a d^{10} metal fragment. Note that the main difference between the DCD model shown in Fig. 1 (A) and the reverse DCD model shown in Fig. 1 (B) lies in the direction of the σ donation. The M–L π interaction between a Lewis base ligand and a metal may also take place through donation from occupied π orbitals of L to empty d(π) orbitals of the metal. This was recently suggested for *N*-heterocyclic carbenes which may serve not only as (weak) π acceptors but also as (weak) π donors.[3] Ligands which serve as σ donors *and* as π donors are carbodiphosphoranes $C(PR_3)_2$[4] because the divalent carbon(0) atom has two electron lone pairs with σ and π symmetry.[5] In the present case it is conceivable that the π interaction between the metal and the EX_3 ligands takes place not only via back–donation from the ligand to the metal but also through donation from the occupied d(π) orbitals to the vacant (antibonding) E–X orbitals which have π symmetry. This question is discussed below.

There have been early reports on the synthesis of donor–acceptor complexes of BF_3, BCl_3, $AlBr_3$, and $AlMe_3$ with group 6–8 transition metals[6] but none of the compounds was structurally characterized. Recent work by Braunschweig[7] and co-workers question the alleged syntheses of complexes [M]–EX_3. Several borane complexes of transition metals have been synthesized in recent years but the bonding of the BR_3 ligand was only made possible with the use of chelating ligands.[8] A qualitative description of the possible bonding modes in transition metal borane complexes was given recently.[9] The first neutral donor–acceptor complex with a non-chelating EX_3 ligand of a group-13 element E which was identified by X-ray structure analysis was only reported in 2005 by R.A. Fischer and co-workers.[10] The authors succeeded in isolating the complex [$Cp^*Rh(GaCp^*)_2(GaCl_3)$]. Later Braunschweig reported the syntheses and X-ray analyses of [$(Cy_3P)_2Pt$–$AlCl_3$][11a] and [$(Cy_3P)_2Pt$–$GaCl_3$].[11b] A review on the coordination chemistry of aluminum, gallium, and indium with transition metals shows that it is very difficult to prepare neutral complexes [M]–EX_3 which have a non-chelating group-13 ligand EX_3.[12]

Scheme 1. Schematic representation of (*a*) the Dewar–Chatt–Duncanson model and (*b*) the reversed Dewar–Chatt–Duncanson model.



To the best of our knowledge there is no publication which reports a theoretical analysis of the metal–ligand interactions in transition metal complexes with "reversed" DCD bonding using modern quantum chemical methods. In this work we describe a charge and energy decomposition analysis of the metal–ligand bonding in the complexes [$(Me_3P)_2$M–X_3] for M = Ni, Pd, Pt; E = B through Tl; X = H, F through I. We also give the equilibrium structures and bond dissociation energies which should be helpful as a guideline in the search for further examples of stable complexes with EX_3 ligands.

Computational methods

The presented structures have been preoptimized with C_S symmetry constraints in Gaussian 03.[13] For the energy, gradient and frequency calculations, gradient-corrected density functional theory was employed using the gradient-corrected density functional BP86[14] with the resolution of the identity (RI) approximation[15] as implemented in TURBOMOLE[16] in conjunction with the def2-SVP basis sets by Weigend and Ahlrichs.[17] The analytically calculated harmonic vibrational frequencies showed that all but two complexes ([$(PMe_3)_2Pt$–$InCl_3$] and ([$(PMe_3)_2Pt$–$TlCl_3$] are local minima. The latter compounds each exhibit an imaginary mode whose magnitude is smaller than 10 cm^{-1}, which can

be neglected because they refer to the rotation of the methyl groups. The atomic partial charges have been estimated by the NBO method of Weinhold and co-workers.[18]

The analysis of the chemical bond between the ER_3 and the $M(PMe_3)_2$ closed-shell fragments was carried out using the program ADF 2006.01[19] employing the energy decomposition analysis (EDA) suggested by Morokuma[20] and Ziegler.[21] For the EDA calculations the geometries were optimized under C_S symmetry constraints at the BP86 level of theory using triple-*zeta* valence basis sets consisting of uncontracted Slater-type orbitals (TZ2P)[22] as implemented in ADF 2006.01 with the notation "TZ2P+" for nickel and "TZ2P" for all other elements used in this study. The differences in the RI-BP86/def2-SVP and BP86/TZ2P geometries

[b]Not calculated because the energy minimum has a bridged geometry.

are very small. Relativistic effects were considered by the zeroth-order regular approximation (ZORA).[23] The density fitting procedure has been used to represent coulomb and exchange potentials accurately in each SCF cycle.[24] Additional information to the ADF calculations are given in the Supplementary data.

The focus of the bonding analysis is the instantaneous interaction energy, ΔE_{int}, of the bond, which is the energy difference between the molecule and the fragments in the electronic reference state and frozen geometry of the compound. The interaction energy can be divided into three main components:

$$[1] \qquad \Delta E_{int} = \Delta E_{elstat} + \Delta E_{Pauli} + \Delta E_{orb}$$

ΔE_{elstat} gives the electrostatic interaction energy between the fragments, which are calculated using the frozen electron density distribution of the fragments in the geometry of the complex. It can be considered as an estimate of the *electrostatic contribution* of the bonding interaction. The second term in eq. [1] ΔE_{Pauli} refers to the repulsive interactions between the fragments, which are caused by the fact that two electrons with the same spin cannot occupy the same region in space. ΔE_{Pauli} is calculated by enforcing the Kohn–Sham determinant on the superimposed fragments to obey the Pauli principle by antisymmetrization and renormalization. The stabilizing orbital interaction term, ΔE_{orb}, is calculated in the final step of the energy decomposition analysis when the Kohn–Sham orbitals relax to their optimal form. The ΔE_{orb} term can be considered as the *covalent contribution* to the bonding interaction. Thus, the ratio $\Delta E_{orb}/\Delta E_{elstat}$ indicates the *covalent/electrostatic* character of the investigated bond. The orbital interaction can be further partitioned into contributions by the orbitals belonging to different irreducible representations of the point group of the interacting system. The EDA calculations of the present molecules have been carried out using C_S symmetry which means that the irreducible representation a′ contains σ and π contributions. Assuming that both orthogonal π interactions are equally strong, the following partitioning scheme is possible:

$$[2] \qquad \Delta E_{orb} + \Delta E_{\sigma} + \Delta E_{\pi} = \Delta E_{a'} - \Delta E_{a''} + 2\Delta E_{a''}$$

where $\Delta E_{\sigma} = \Delta E_{a'} - \Delta E_{a''}$ and $\Delta E_{\pi} = 2\ \Delta E_{a''}$. Finally, the negative value of the bond dissociation energy ($-D_e = \Delta E$) is given by the sum of the interaction energy and the preparation energy:

$$[3] \qquad \Delta E = \Delta E_{int} + \Delta E_{prep}$$

The latter term is the energy necessary to promote the fragments from their equilibrium geometry and electronic ground state to the geometry and electronic state they have in the optimized structure of the complex. Technical details about the EDA method can be found in the literature.[19e,19f] The performance of the EDA for analyzing donor–acceptor bonds has been published in recent reviews.[24]

Results and discussion

The geometry optimizations of the complexes $[(PMe_3)_2M–EX_3]$ gave for most compounds T-shaped structures with nearly linear P–M–P angles where the EX_3 ligand has a staggered conformation (structure type A; Fig. 1) For one molecule $[(PMe_3)_2Pt–TlF_3]$, an eclipsed conformation

[a]Not calculated because the energy minimum has a bridged geometry.

[b]The values in parentheses give the percentage contribution to the total attractive interactions $\Delta E_{elstat} + \Delta E_{orb}$.

[c]The values in parentheses give the percentage contribution of the σ-type orbital interaction to the total orbital interactions. The σ-type orbital interaction was calculated by $\Delta E_{\sigma} = \Delta E_{a'} - \Delta E_{a''}$.

[d]The values in parentheses give the percentage contribution of the π-type orbital interaction to the total orbital interactions. The π-type orbital interaction was calculated by $\Delta E_{\pi} = 2\Delta E_{a''}$.

with respect to the PMP plane (structure type B) was found as the equilibrium structure. The energy differences between the conformations A and B which have C_s symmetry are very small (<0.5 kcal/mol for all compounds) which means that there is nearly free rotation about the M–EX_3 axis. The equilibrium structures of eight nickel compounds $[(PMe_3)_2Ni–EX_3]$ have a distorted geometry where one E–X bond is engaged in bonding interactions with the metal atom which yields a distorted square-planar arrangement of the metal atom (Fig. 2). The P–Ni–P angle in the latter complexes is significantly smaller than 180°. The complex $[(PMe_3)_2Ni–TlI_3]$ exhibits two attractive interactions between Tl–I bonds and the metal which features a five-coordinated metal atom.

Table 1 gives the calculated M–EX_3 bond lengths and bond dissociation energies D_e for the structure types A and B of $[(PMe_3)_2M–EX_3]$. There are only a few experimental geometries and no experimentally derived BDE which may be used for comparison with the calculated values. The calculated bond length for $[(PMe_3)_2Pt–GaCl_3]$ (2.456 Å) is in good agreement with the experimental value for $[(PCyc_3)_2Pt–GaCl_3]$ (2.402 Å)[11b] and the theoretical value for the aluminum homologue $[(PMe_3)_2Pt–AlCl_3]$ (2.439 Å) concurs with the experimental result for $[(PCyc_3)_2Pt–AlCl_3]$ (2.386 Å).[11a] Please note that the experimental values for the bond lengths come from X-ray analyses of the compounds in the solid states which are always shorter than for the free molecules.[25]

The theoretically predicted bond dissociation energies show (Table 1) that the boron complexes exhibit a different trend for the D_e values than the heavier group-13 homologues. The results for the Pd and Pt complexes suggest that the $[(PMe_3)_2M–BX_3]$ bond strength increases with F < Cl < Br < I < H which means that the BH_3 ligands are the most strongly bonded Lewis acids and BF_3 is the most weakly bonded species . The trend for the heavier group-13 complexes $[(PMe_3)_2M–EX_3]$ where E = Al, Ga, In, Tl follows

Table 3. EDA results of the $[(Me_3P)_2MEF_3]$ compounds for E = B, Al, Ga, In, Tl, M = Ni, Pd, Pt at BP86/TZ2P. Energy values are given in kcal/mol.

[a]Structure type B.

[b]The values in parentheses give the percentage contribution to the total attractive interactions $\Delta E_{elstat} + \Delta E_{orb}$.

[c]The values in parentheses give the percentage contribution of the σ-type orbital interaction to the total orbital interactions. The σ-type orbital interaction was calculated by $\Delta E_{\sigma} = \Delta E_{a'} - \Delta E_{a''}$.

[d]The values in parentheses give the percentage contribution of the π-type orbital interaction to the total orbital interactions. The π-type orbital interaction was calculated by $\Delta E_{\pi} = 2\Delta E_{a''}$.

the opposite order F > Cl > Br > I > H. It is interesting to note that, in the latter complexes, EF_3 is the strongest bonded ligand while EH_3 is the most weakly bonded moiety. We considered only the C_s symmetric structures A and B to compare the intrinsic strength of the M–EX_3 bonds. The trend for the bond strength of $[(PMe_3)_2M–EX_3]$ for the elements E depends somewhat on the nature of X and also on the metal M. The strongest bonds for the trifluorides and trichlorides are calculated for the indium and thallium complexes while the EI_3 complexes show a maximum for E = Al. The BX_3 ligands are always significantly more weakly bonded than the heavier group-13 homologues except for X = H. The calculated values should be helpful for future experimental studies aimed at isolating further examples of the rare $[(PMe_3)_2M–EX_3]$ species.

Table 2 presents the results of the energy decomposition analysis of the $[(PMe_3)_2M–EH_3]$ complexes. Tables 3 and 4 show the EDA values for the compounds $[(PMe_3)_2M–EX_3]$ for X = F, Cl. The EDA results for X = Br, I give no further insight into the bonding situation of the molecules. Therefore, they are given in the Tables SI-1 and SI-2 in the Supplementary data and are not discussed in the text.

The calculated data for the interaction energies ΔE_{int} give the intrinsic strength of the metal–ligand bonding in $[(PMe_3)_2M–EX_3]$, while the ΔE_{prep} values give the relaxation of the fragments after breaking the bonds. The results in Tables 2–4 show that ΔE_{prep} values are are not negligible and that they become quite large for the complexes with EF_3 and ECl_3 ligands particularly for E = B. The data show that the rather low bond dissociation energies D_e of the BF_3 and BCl_3 ligands do not come from the weak metal–boron attraction but from the large energy differences between the planar equilibrium geometries of BX_3 and the pyramidal structures of the ligands in the complex. The intrinsic bond strength of the halogenide ligands EF_3 and ECl_3 in $[(PMe_3)_2M–EX_3]$ which is given by the ΔE_{int} values is sig-

[a]Not calculated because the energy minimum has a bridged geometry.

[b]The values in parentheses give the percentage contribution to the total attractive interactions $\Delta E_{elstat} + \Delta E_{orb}$.

[c]The values in parentheses give the percentage contribution of the σ -type orbital interaction to the total orbital interactions. The σ-type orbital interaction was calculated by $\Delta E_{\sigma} = \Delta E_{a'} - \Delta E_{a''}$.

[d]The values in parentheses give the percentage contribution of the π-type orbital interaction to the total orbital interactions. The π-type orbital interaction was calculated by $\Delta E_{\pi} = 2\Delta E_{a''}$.

nificantly higher than that of $[(PMe_3)_2M–EH_3]$. The differences between the D_e values of the two classes of compounds are smaller because of the larger ΔE_{prep} values of the former species. The results show that bond dissociation energies may not be faithful probes for the intrinsic strength of a chemical bond.

The breakdown of the ΔE_{int} values into the attractive components ΔE_{elstat} and ΔE_{orb} shows that the two terms contribute nearly equally to the chemical bonds in most $[(PMe_3)_2M–EX_3]$ compounds. The electrostatic attraction is somewhat larger than the orbital term in some complexes (up to 62.3% of the total attraction in $[(PMe_3)_2Pt–TlH_3]$) while it is smaller in others (down to 39.1% in $[(PMe_3)_2Pd–BH_3]$). The most interesting EDA result concerns the breakdown of the orbital interactions into σ and π type bonding. The ΔE_{π} term gives the strength of the intrinsic π orbital interactions of the M–EX_3 bonds. Tables 2–4 show that the π orbital interactions contribute between 12.7% $[(PMe_3)_2Pd–BH_3]$) and 29.8% ($[(PMe_3)_2Ni–AlF_3]$). The π orbital interactions of the trifluoride and trichloride ligands are in most cases slightly larger than the π bonding of the BH_3 ligands but the differences are not very large.

The calculated values for the π orbital interactions may come from M←EX_3 π-back-donation as shown in the reversed DCD model (Scheme 1) but they may also come from M→EX_3 π-donation because the group-10 metals have a d^{10} electron configuration. To distinguish between the two types of π orbital interactions we carried out EDA calculations on some complexes where the a″ orbitals of EX_3 or the $(PMe_3)_2M$ fragments are deleted. The results showed that both components contribute with comparable strength when $EX_3 = BH_3$, BF_3, AlH_3, and AlF_3. For the fluorides, the M→EX_3 π-donation is a little stronger than the M←EX_3 π-back-donation while the reversed trend is found for the hydrides, a result which could be expected.

Does the trend of the interaction energies ΔE_{int} correlate

Table 5. NBO partial charges of the EX_3 fragments and the metal atoms M in parentheses of the $(Me_3P)_2MEX_3$ compounds for M = Ni, Pd, Pt; E = B, Al, Ga, In, Tl; and X = H, F, Cl, Br, I at the RI-BP86/def2-SVP level of theory.

[a]Structure type B.
[b]Bridged equilibrium structure.

with any of the contributing terms which could be singled out as a crucial factor for determining the change in the metal–ligand interactions? Table 2 shows that AlH_3 has the largest ΔE_{int} value in the $[(PMe_3)_2M–EH_3]$) complexes of all EH_3 ligands. Inspection of the attractive terms ΔE_{elstat} and ΔE_{orb} shows that neither term has a maximum value for AlH_3 but also that the repulsive term ΔE_{Pauli} of the latter ligand exhibits a minimum value. It is the combination of the three terms which makes AlH_3 the strongest bonded EH_3 ligand. Note that BH_3 has a much stronger orbital attraction than AlH_3 but the weaker electrostatic attraction and the significantly stronger Pauli repulsion makes BH_3 more weakly bonded than AlH_3. This is a warning against the ubiquitious use of orbital interactions as a sole indicator for the trend in bonding interactions. A pertinent example has been reported before.[26] A similar situation is found for the trend of the bond strength of the trifluorides and trichlorides in $[(PMe_3)_2M–EX_3]$ (Tables 3, 4). None of the terms ΔE_{elstat}, ΔE_{orb}, or ΔE_{Pauli} corelates with the trend of ΔE_{int}.

The NBO partial charges given in Table 5 provide further details about the electronic structure of the complexes. The partial charge of EX_3 is always negative which means that the donation from the metal fragment to the Lewis acid dominates the metal–ligand interactions which agrees with the relative contributions of the σ and π interactions to the ΔE_{orb} term of the EDA. Note that the PMe_3 ligands carry always a positive partial charge which is clearly smaller in the nickel compounds than in the Pd and Pt homologues, whereas the negative partial charges of EX_3 in the latter species are smaller than in the former. The NBO charges thus predict that Ni carries positive partial charge while Pd and Pt are negatively charged in $[(PMe_3)_2M–EX_3]$ except $[(PMe_3)_2Pd–TlCl_3]$ where Pd is predicted to have a small positive partial charge.

Summary

The geometry optimizations of $[(PMe_3)_2M–EX_3]$ for most compounds gave T-shaped structures with nearly linear P–M–P angles where the EX_3 ligand has either a staggered or eclipsed conformation with respect to the PMP plane. The energy differences between the conformations are very small which means that there is nearly free rotation about the M–EX_3 axis. The equilibrium structures of eight nickel compounds have a distorted geometry where one E–X bond is engaged in attractive interactions with the metal atom which yields a distorted square-planar arrangement of the metal atom. The complex $[(PMe_3)_2Ni–TlI_3]$ even exhibits two attractive interactions between Tl–I bonds and the metal which features a five-coordinated metal atom. The calculated bond dissociation energies show that the boron complexes exhibit a different trend for the D_e values than the heavier group-13 homologues. The results for the Pd and Pt complexes suggest that the $[(PMe_3)_2M–BX_3]$ bond strength increases with F < Cl < Br < I < H which means that the BH_3 ligands are the most strongly bonded Lewis acids and BF_3 is the most weakly bonded species . The trend for the heavier group-13 complexes $[(PMe_3)_2M–EX_3]$ where E = Al, Ga, In, Tl follows the opposite order F > Cl > Br > I > H. The energy decomposition analysis of the M–EX_3 bonds indicates a substantial π contribution of between 12.7% and 30.3% to the total orbital interactions. There is no direct correlation between the strength of the orbital interactions or any of the other energy terms ΔE_{elstat} or ΔE_{Pauli}

and the total interaction energy. The bond dissociation energy of the EX_3 ligands after breaking the M–EX_3 bonds is quite large. It is shown that the intinsic strength of the M–EX_3 bonds are much larger than the BDEs and that the trends of ΔE_{int} and D_e are not always the same. The EX_3 ligands in $[(PMe_3)_2M–BX_3]$ carry always a large negative charge.

Supplementary data

Table SI-1 gives the EDA results for the $[(Me_3P)_2MEBr_3]$ compounds. Table SI-2 gives the EDA results for the $[(Me_3P)_2MEI_3]$ compounds. Table SI-3 gives the Cartesian coordinates of the optimized geometries at the RI-BP86/def2-SVP level of theory. A quantum mechanical approach to ligand binding — Calculation of ligand–protein binding affinities for stromelysin-1 (MMP-3) inhibitors

Jian Li and Charles. H. Reynolds

Abstract: Linear-scaling quantum mechanical method was applied to calculate binding affinities of six stromelysin-1 (MMP-3) inhibitors with two different zinc binding groups (ZBGs). The entire protein and ligand–protein complexes were calculated using PM5 Hamiltonian, which enables the treatment of metal ion coordination, bond forming/breaking, and proton/charge transfers associated with the ligand binding process by the self-consistent field method. The calculated binding energies reproduce the binding-affinity trend observed experimentally.

Key words: ligand–protein binding affinities, stromelysin-1 inhibitors, matrix metalloproteinase, linear-scaling quantum calculation.

Résumé : On a appliqué la méthode de mécanique quantique de mise l'échelle pour calculer les affinités de fixation de six inhibiteurs de la stromélysine-1 (MMP-3) avec deux groupes différents fixés au zinc (GFZ). On a effectué des calculs pour la protéine complète et pour les complexes ligand-protéine à l'aide de l'hamiltonien PM5 qui permet de traiter la coordination de l'ion métallique, la formation et le bris d'une liaison et les transferts de proton et de charge associés au processus de fixation de ligand par la méthode du champ autocohérent. Les énergies de fixation calculées permettent de reproduire la tendance dans les affinités de fixation observées expérimentalement.

Mots-clés : affinités de fixation ligand–protéine, inhibiteurs de la stromélysine-1, matrice de métalloprotéinase, calcul de mécanique quantique de mise l'échelle.

[Traduit par la Rédaction]

Introduction

Accurate prediction of ligand–protein binding affinity is of fundamental importance to all aspects of structure-based drug design and virtual screening. Many computational approaches have been developed to tackle this problem. These methods include thermodynamic integration (TI), free-energy perturbation (FEP), linear interaction energy (LIE), and molecular mechanics/Possion–Boltzmann surface area (MM/PBSA).[1] Although many aspects of these methods vary, they all rely on classical force-field energies.[2] This is severely limiting in cases where the ligand binding process involves bond breaking/forming, proton/charge transfer, or metal ion coordination. In these cases, a quantum mechanical (QM) description of the system becomes indispensable.

Traditionally, QM calculations have been limited to relatively small molecules due to their scaling of N^3 with respect to the number of basis functions even for semi-empirical methods. Any QM calculation for a protein was impractical even with the fastest computers. This has changed with the introduction of linear-scaling quantum mechanical methods. Divide-and-conquer (D&C)[3] and localized molecular orbital methods[4] allow for QM calculations that scale linearly with respect to size rather than exponentially. This makes calculations for very large systems, even proteins, practical. Linear-scaling QM calculations have been used to study hydration effects,[5] charge transfer,[6] reaction mechanisms,[7] and enzyme dynamics.[8] Recently, a quantum-mechanics-based scoring function was reported, along with specific applications to zinc-ion-mediated carbonic anhydrases and carboxypeptidases.[9]

Matrix metalloproteinases (MMPs) are a family of zinc-containing endoproteinases that mediate degradation and remodeling of the extracellular matrix. The Zn ion in the active site of MMPs plays a central role in the catalytic function of these enzymes and inhibitor binding. Therefore, almost all MMP inhibitors contain some type of zinc binding group (ZBG) such as hydroxamate or carboxylate.[10] The zinc center presents a long-standing challenge to efforts to model the binding affinity of zinc-containing proteins. Using classical methods, one must assume either a bonded or non-bonded structure for the zinc ion (i.e., either the ZBG has a valence bond to Zn or it does not).[11] The calculation results are strongly affected by this ad hoc assumption, and it is virtually impossible to compare results for inhibitors containing different ZBGs. In addition, the protonation states of some acidic residues in the active site also change upon ligand

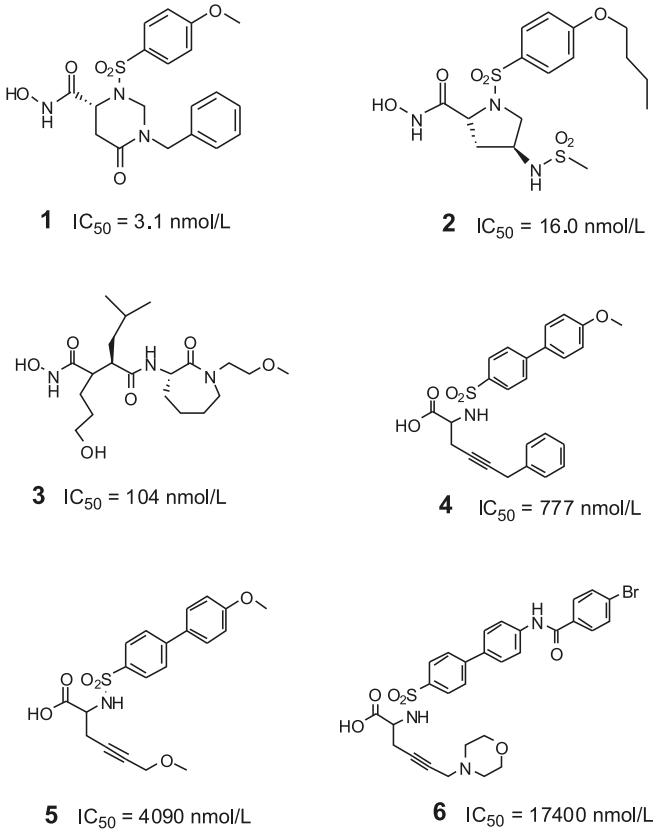
Chart 1. Six stromelysin-1 inhibitors with binding affinities.



binding. This further complicates selection of the relevant classical representation. These complications can be readily addressed by QM methods.

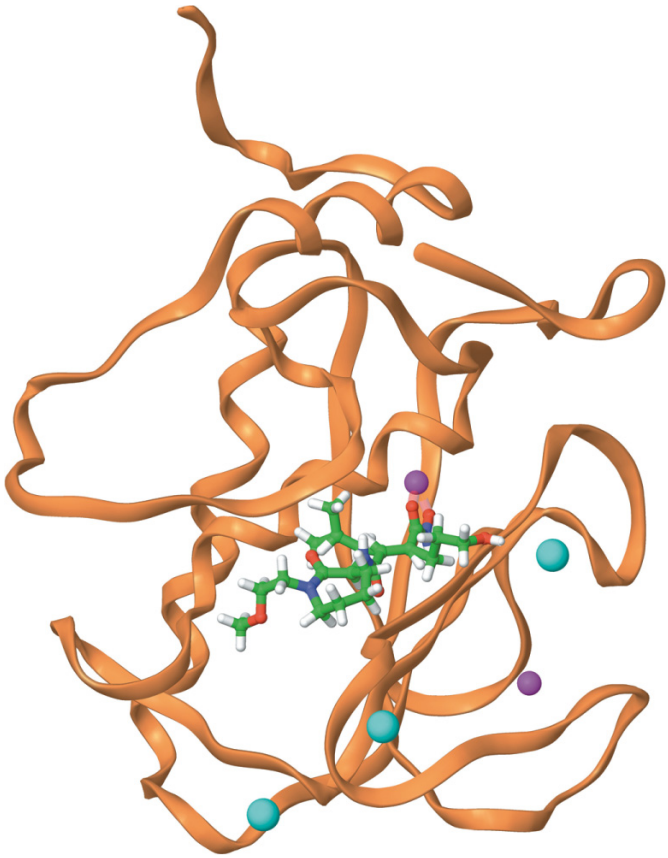
We have used linear-scaling quantum calculations to study the binding affinities of six inhibitors for stromelysin-1 (MMP-3). The entire protein and ligand–protein complexes were treated quantum-mechanically. This allowed the binding characteristics of the zinc center and the protonation states to be determined automatically by the QM wave function.

Computational method

All calculations were carried out using MOZYME as implemented in MOPAC2002/BioMedCACHe 6.0.[12] The PM5 Hamiltonian[13] was employed for all atoms including Zn^{2+} and Ca^{2+}. Protein backbone atoms were fixed, but all side chain atoms and the inhibitors were optimized. Following gas-phase geometry optimization, the solvation energy was calculated by a continuum COSMO model using the water dielectric constant of 78.[14] The non-polar contribution to the solvation term was calculated by using the solvent accessible surface area (SASA) as 0.00542 × SASA + 0.92 kcal/mol. The entropic contribution was omitted in the calculation.

The binding affinity in this calculation is defined as the energy difference between the ligand–protein complex and the free protein plus free ligand. The total ΔE_{ba} then can be divided into QM and solvation contributions, ΔE_{qm} and ΔE_{sol}, respectively .

Fig. 1. Structure of inhibitor **3** and stromelysin-1 complex. The magenta balls are Zn^{2+} ions and blue balls are Ca^{2+} ions.



$$\begin{aligned}\Delta E_{ba} &= E(\text{complex}) - E(\text{protein}) \\ &= E_{qm}(\text{complex}) + E_{sol}(\text{complex}) - E_{qm}(\text{protein}) \\ &\quad - E_{sol}(\text{protein}) - E_{qm}(\text{ligand}) - E_{sol}(\text{ligand}) \\ &= \Delta E_{qm} + \Delta E_{sol}\end{aligned} \quad [1]$$

Results and discussion

Chart 1 shows six stromelysin-1 (MMP-3) inhibitors with hydroxamate and carboxylate ZBGs.[12] The potencies of these compounds span a wide range from IC_{50} = 3 nmol/L to 17 μmol/L.[15] The crystal structures of four inhibitors (**1**, **2**, **3**, and **4**) bound to truncated stromelysin-1 (MMP-3) were downloaded from Protein Data Bank (PDB codes: 1G05, 1G49, 1BIW, and 1HY7, respectively).[15] The calculations were carried out for the MMP-3 monomer, which consists of 172 residues and 2686 atoms. All crystalline waters were removed except three within the Ca^{2+} coordination spheres. Protonation states were assigned and hydrogen atoms were added using the Schrödinger/Maestro protein-preparation procedure.[16] Figure 1 demonstrates the structure of compound **3** complexed in stromelysin-1 (PDB code: 1BIW). The binding modes of inhibitors **5** and **6** were assigned by docking the ligands to 1HY7, using inhibitor **4** as a reference template. The docking calculation was done using Schrödinger/Glide package.[17] The free protein was obtained by removing the ligand from 1BIW structure, and no zinc-bound water was added. This approximation will not affect the calculation of relative binding energies.

Table 1. Calculated and experimental energies (kcal/mol).

Inhibitor	ΔE_{qm}	ΔE_{sol}	ΔE_{ba}	pIC_{50}	ΔG^a	$\Delta G_{pred}{}^b$
1	–24.2	30.0	3.1	8.5	–12.1	–11.0
2	–27.2	31.4	1.2	7.8	–11.1	–11.3

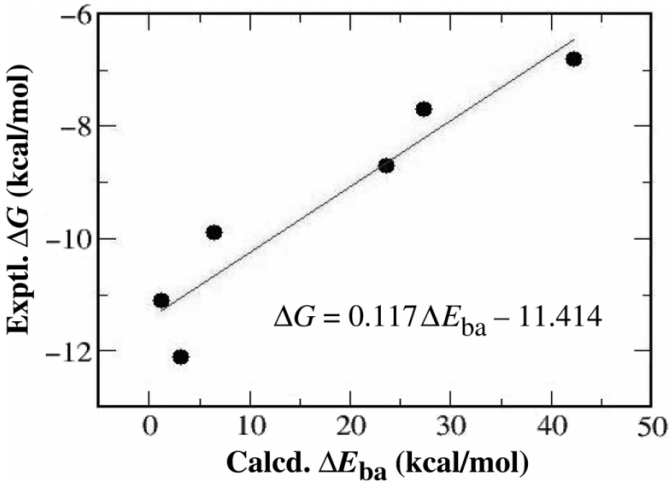
5	–30.9	61.4	27.4	5.4	–7.7	–8.2
6	–38.9	85.7	42.3	4.8	–6.8	–6.5

[a]Experimental binding energies are estimated according to $\Delta G \approx -2.303RT\ pIC_{50}$.
[b]Calculated according to $\Delta G_{pred} = 0.117\Delta E_{ba} - 11.414$, see Fig. 2.

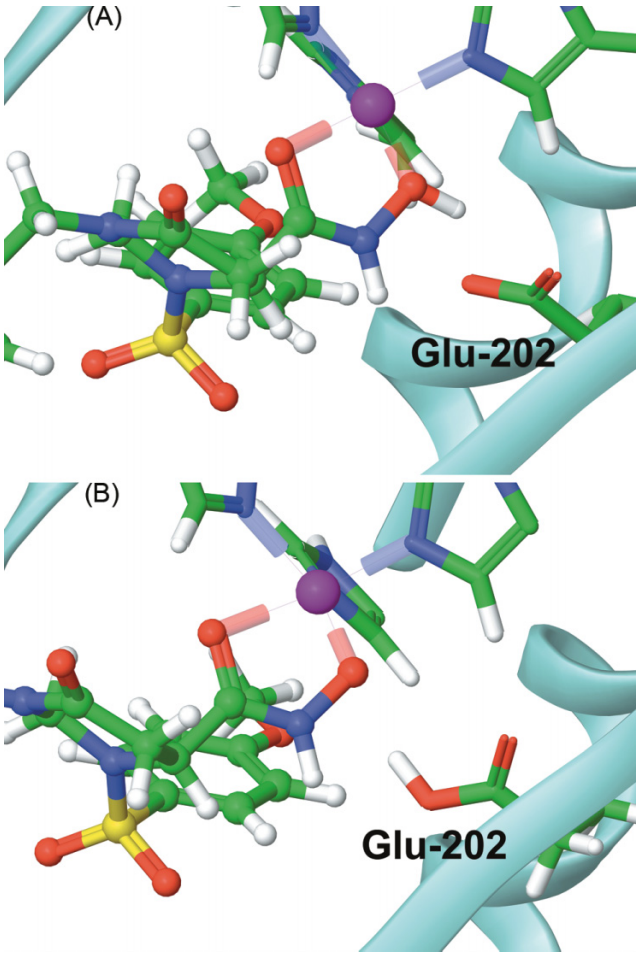
Fig. 2. Plot of calculated vs. experimental relative binding energies for six stromelysin-1 inhibitors.



The experimental binding free energies ΔG and computed energy terms are summarized in Table 1. The ΔG values were estimated based on pIC_{50} ($-\log IC_{50}$) and therefore are relative binding free energies. For all six inhibitors, the QM terms ΔE_{qm} are negative, indicating a stabilizing interaction between the ligand and the protein in the gas phase. The positive ΔE_{sol} terms correspond to a large desolvation penalty to the formation of the ligand–protein complex. Due to underestimation of the van der Waals interaction by semi-empirical QM methods, the overall calculated ΔE_{ba} terms are positive. However, they show an excellent correlation to experimental binding energies ($r^2 = 0.95$). Figure 2 shows the correlation between the relative experimental binding energies and the calculated binding energies for six inhibitors. While a relatively small set of inhibitors, this correlation is remarkable given that two different ZBGs are involved. The calculated $\Delta\Delta E_{ba}$ correctly predict that inhibitors with hydroxamate ZBG bind more tightly to stromelysin-1 than those with carboxylate ZBG. Except for the two most potent binders, **1** and **2**, the model ranks the inhibitor affinities correctly.

The gas-phase geometry optimization of the protein–ligand complexes starts with the protonated state where the ligand is neutral and Glu-202 is deprotonated. During the course of geometry optimization, the ligand spontaneously donates a proton to Glu-202 and binds to zinc as a bidentate ligand (Fig. 3). This would be impossible with a classical force-field representation. This indicates that binding to the zinc ion decreases the pK_a of the ligand's ZBG, a result that

Fig. 3. Proton transfer from hydroxamate group in inhibitor **1** to Glu-202 in stromelysin-1: (A) before the gas-phase geometry optimization; (B) after the gas-phase geometry optimization.



is consistent with experimental evidence that zinc-bound water exhibits a lower pK_a value.[18] Meanwhile, the electrostatic and hydrogen-bonding environment of Glu-202 causes it to be mostly protonated at physiological pH.[19]

Mulliken charge analysis on the free and bound inhibitors reveal a non-negligible charge transfer accompanying ligand binding. As shown in Table 2, the net charges for Zn in free protein and in the complex are +0.88 and +0.83, respectively. This is significantly lower than the formal +2 charge commonly assigned to Zn ion in force-field-based calculations. The most dramatic change in charge is on the oxygen atoms of the ZBG hydroxyl group. The charge changes

Table 2. Mulliken atomic charges.

		Free form			Complex		
Inhibitor	Δ|e|[a]	Zn	O_1	O_2	Zn	O_1	O_2
1	–0.21	+0.88	–0.40	–0.31	+0.83	–0.48	–0.59
2	–0.11	+0.88	–0.43	–0.31	+0.83	–0.48	–0.56
3	–0.20	+0.88	–0.43	–0.31	+0.82	–0.50	–0.62
4	–0.27	+0.88	–0.43	–0.38	+0.83	–0.53	–0.58
5	–0.25	+0.88	–0.37	–0.38	+0.82	–0.51	–0.57
6	–0.27	+0.88	–0.42	–0.38	+0.83	–0.52	–0.59

[a]Charge transferred from protein to ligand.

from –0.3 to –0.6 and from –0.4 to –0.6 in carboxylate and hydroxamate, respectively. Overall, the protein transfers 0.2|e| to the hydroxamate ligand and 0.3|e| to the carboxylate ligand.

Conclusion

In summary, these calculations show that QM methods can be applied to the ligand–protein binding problem, even when metals are involved. Although dynamic and entropy contributions were not considered, the calculated binding energies reproduce the experimental trend in binding potency. This is true even though two very different ZBGs were modeled together, i.e., hydroxamate and carboxylate. This methodology can treat metal ions such as Zn, bond forming and breaking processes, proton transfer, and charge transfer in a consistent way that cannot be achieved by classical forcefield approaches.

Non-empirical derivation of the parameter in the B88 exchange functional

Peter Elliott and Kieron Burke

Abstract: The B88 exchange energy density functional (created by Becke in 1988) is a crucial part of the most popular density functional in use today, B3LYP. B88 contains one empirical parameter which was fitted to Hartree–Fock exchange energies for the noble gas atoms. We show how local approximations to exchange become relatively exact under a very specific approach to the limit of large numbers, but the usual gradient expansion does not. The leading corrections can be captured by generalized gradient approximations, producing a non-empirical derivation of the parameter in B88.

Key words: density functional theory (DFT), exchange functional, B88, potential scaling.

Résumé : La fonctionnelle de la densité d'énergie d'échange B88 (développée par Becke en 1988) est une partie cruciale de la fonctionnelle de densité B3LYP, la plus populaire parmi les bases en usage aujourd'hui. La fonction B88 comprend un paramètre empirique qui a été ajusté aux énergies d'échange d'Hartree–Fock des atomes des gaz rares. On démontre comment des approximations locales des échanges deviennent relativement exactes dans une approche très spécifique à la limite des grands nombres, ce que l'expansion habituelle des gradients ne permet pas. Les corrections principales peuvent être capturées par les approximations de gradients généralisées et produire une dérivation non empirique du paramètre dans la fonction B88.

Mots-clés : théorie de la fonctionnelle de densité (TFD), fonctionnelle d'échange, B88, mise à l'échelle du potentiel.

[Traduit par la Rédaction]

I. Introduction

Density functional theory (DFT) has become the method of choice for many electronic structure calculations in quantum chemistry.[1] It balances the demands of accuracy and computation time, making it advantageous to other available methods. Although DFT is a formally rigorous theory, in practice, it requires an approximation to the exchange-correlation (XC) energy, E_{xc}, as a functional of the density. In the late 1980s and early 1990s, approximations, such as B88, were developed which proved accurate enough for their application in many areas of both chemistry and physics. The explosion in the use of DFT, driven by newly available computational power, could not have succeeded without the development of such functionals.

Modern DFT began with the Hohenberg–Kohn theorem of 1964[2] and the Kohn–Sham scheme of 1965.[3] The first approximation to the XC energy was the local density approximation (LDA), which uses only the density at a given point to determine the energy density at that point. This is exact for a uniform gas, since it is the known energy density of the uniform gas that is used to define LDA. The natural successor to LDA is a semi-local (or gradient-corrected) approximation which adds information about the derivative of the density at that point. In fact, in the same paper in which LDA is introduced, so too is the gradient expansion approximation (GEA) for XC. The coefficients of the GEA are determined by the energy of a slowly varying gas.[4–6] However, it was found that the GEA often worsened LDA results, and two decades passed before substantial improvements were made.

Generalized gradient approximations (GGAs) effectively resum the gradient expansion, but using only $|\nabla n|$. The B88 functional[7] is the most used GGA for exchange overall (as part of B3LYP[8,9]), but the most popular GGA in solid-state applications is PBE.[10] Neither reduces to the GEA in the limit of small gradients. In this paper, we explain the reason why this must be the case. Asymptotic expressions for the energy components as functionals of N, the number of electrons, display "unreasonable accuracy"[11] even for low N. To give good energies for finite systems, any approximate XC functional must have accurate coefficients in its large-N expansion. LDA gives the dominant contribution, but the GEA does not yield an accurate leading correction for atoms. Popular GGAs such as B88 and PBE do get this correction right.

In ref. 12, the underlying ideas behind this work were developed; however, the reasoning was based upon scaling the density and not on the potential scaling discussed below. We refine these ideas and explicitly show how they can be used for functional development, and in particular, we show how the parameter in B88 may be derived in a non-empirical manner.

II. Background theory

In this section, we review the theory behind asymptotic expansions of the energy, including the expression for the exchange energy. A demonstration of the usefulness of this asymptotic expansion for exchange is also given, where the constant in LDA is found without referring to the electron gas. We also show the form of the gradient correction to LDA exchange, as well as discussing the form of the GGAs, B88, and PBE.

A. Asymptotic expansion in *N*

Begin with any system (atom, molecule, cluster, or solid) containing N electrons. We then imagine changing the number of electrons to N'. Since we usually begin from a neutral system, usually we consider only $N' > N$. Thus, we define a scaling parameter $\zeta = N'/N > 1$. As we change the particle number, we simultaneously change the one-body potential $v_{\text{ext}}(\mathbf{r})$ in such a way as to retain overall charge neutrality, which means

$$[1] \qquad v_{\text{ext}}^{\zeta}(\mathbf{r}) = \zeta^{4/3} v_{\text{ext}}(\zeta^{1/3}\mathbf{r}), \qquad N \to \zeta N$$

We refer to this as charge–neutral (CN) scaling. For an isolated atom, $Z \to \zeta Z$ under this scaling, so it remains neutral as the electron number grows. For molecules with nuclear positions R_α and charges Z_α, $Z_\alpha \to \zeta Z_\alpha$, and $R_\alpha \to \zeta^{-1/3} R_\alpha$. In the special case of neutral atoms, the resulting series for the energy is well-known:

$$[2] \qquad E = -a_0 N^{7/3} - a_1 N^2 - a_2 N^{5/3} - \ldots$$

where $a_0 = 0.768745$, $a_1 = -1/2$, and $a_2 = 0.269900$.[11,13] We say an approximation is large-N *asymptotically exact* to the pth degree (AEp) if it recovers exactly the first $p + 1$ coefficients for a given quantity under the potential scaling of eq. [1]. Lieb and Simon[14,15] showed that Thomas–Fermi (TF) theory becomes *exact* in the limit $\zeta \to \infty$ for *all* systems. TF is exact in a statistical sense, in that TF gives the correct first term of eq. [2], but not the other terms. We say TF is AE0 for the total energy.

A similar expression exists for the exchange component of the energy alone

$$[3] \qquad E_{\text{x}} = -c_0 N^{5/3} - c_1 N - \ldots$$

where $c_0 = 0.2208 = 9a_2/11$, and c_1 will be the main topic of this paper. In a similar fashion, Schwinger demonstrated that the local approximation for exchange is AE0, and this coefficient is given exactly by local exchange evaluated on the TF density.[11,13,16] However, to give atomic exchange energies needed for chemical accuracy, any exchange approximation should be at least AE1.

Now, suppose we want to make a local approximation for E_{x} but know nothing about the uniform gas. Dimensional analysis (coordinate scaling[17]) tells us that it must be of the form:

$$[4] \qquad E_{\text{x}}^{\text{LDA}}[n] = A_{\text{x}} I, \quad I = \int \mathrm{d}^3 r n^{4/3}(\mathbf{r})$$

Requiring that this gives the leading contribution to eq. [3] then fixes the value of the constant A_{x}. Using any (all-electron) Hartree–Fock atomic code, such as were already available in the 1960s,[18] one calculates I for densities running down a particular column of the periodic table and then deduces its dependence on $Z^{5/3}$. A modern alternative is to use the fully numerical OPMKS code[19] using the OEP exact exchange functional to find densities for neutral atoms from $Z = 1$ to $Z = 88$. By fitting, one finds $I = 0.2965 Z^{5/3}$ and hence $A_{\text{x}} = -0.7446$. This is remarkably close to the derived result of

$$[5] \qquad A_{\text{x}} = -\frac{3}{4}\left[\frac{3}{\pi}\right]^{1/3} = -0.7386$$

Thus, without any recourse to the uniform electron gas, we have derived the correct local approximation to $E_{\text{x}}[n]$. This demonstrates that, via asymptotic exactness, the local approximation to exchange is a universal feature of all systems as $N \to \infty$, when scaled appropriately. (In fact, Schwinger only proved this for atoms,[11] we know of no proof for arbitrary systems).

B. Gradient expansions

The next step up the ladder of increasingly sophisticated density-functional approximations[20] is a semi-local approximation for $E_{\text{x}}[n]$, i.e., one which includes information about the gradient of the density. We introduce the dimensionless measure of the gradient:

$$[6] \qquad s(\mathbf{r}) = \frac{|\nabla n(\mathbf{r})|}{2k_{\text{F}}(\mathbf{r}) n(\mathbf{r})}$$

where $k_{\text{F}}(\mathbf{r}) = (3\pi^2 n(\mathbf{r}))^{1/3}$ is the local Fermi wave vector. This is often written in terms of $x = |\nabla n|/n^{4/3}$, which is simply proportional to s. Assuming smoothness in s and no preferred spatial direction, we know any sensible approximation depends only on s^2. The gradient expansion is defined as the expansion of the energy as a functional of the density around the uniform limit. The leading correction for exchange is

$$[7] \qquad E_{\text{x}}^{(2)}[n] = \mu \int \mathrm{d}^3 r s^2(\mathbf{r}) \epsilon_{\text{x}}^{\text{LDA}}(n(\mathbf{r}))$$

where $\varepsilon_{\text{x}} = A_{\text{x}} n^{4/3}$ and μ is a constant. Alternatively, we may write

$$[8] \qquad E_{\text{x}}^{(2)}[n] = -\beta \int \mathrm{d}^3 r n^{4/3}(\mathbf{r}) x^2$$

with

$$[9] \qquad \beta = \frac{3}{16\pi}\left[\frac{1}{3\pi^2}\right]^{1/3} \mu$$

In a very slowly-varying electron gas, the gradient is very small, and the exchange energy will be accurately given by $E_{\text{x}}^{\text{LDA}} + E_{\text{x}}^{(2)}$. For such systems, the constant $\mu = 10/81$,[4] so that $\beta \approx 0.0024$.

The gradient expansion approximation (GEA) means applying this form to a finite system, using the value of μ from the slowly-varying gas. The GEA for exchange typically reduces the LDA error by about 50%. However, it's counterpart for correlation worsens the LDA error, as its en-

ergy density is not even always negative. In many cases, GEA strongly overcorrects LDA leading to positive correlation energies and giving poor total energies.[5]

A generalized gradient approximation (GGA) seeks to include the information contained in $s(\mathbf{r})$ while improving on the success of LDA. The B88 exchange functional was designed to reduce to the GEA form when s is small, but also recover the correct $-n(r)/2r$ decay of the exchange energy density for large r in atoms. Thus, it interpolates between two known limits, and has the form:

$$[10] \qquad \Delta E_{\mathrm{x}}^{\mathrm{B88}}[n] = -\beta^{\mathrm{B88}} \int \mathrm{d}^3 r n^{4/3}(\mathbf{r}) \frac{x^2}{1 + 6x\beta^{\mathrm{B88}} \sinh^{-1}[2^{1/3}x]}$$

where ΔE_{x} denotes the correction to LDA. Thus, the B88 functional[7] contains one unknown parameter, β^{B88}. In 1988, Becke found this parameter by fitting to the Hartree–Fock exchange energies of the noble gases, finding a value of 0.0053. In fact, Becke notes that this value is consistent with the observation of a high-Z asymptote for β. In ref. 21, B86, Becke calculates what value of β in eq. [8] is required to give the HF exchange energy for each atom in the first two rows of the periodic table along with the noble gas atoms. Thus, β is treated as a function of Z, and he observes that it converges for high-Z. Thanks to the previous section on asymptotic series, we can now understand why this convergence occurs. Although the B88 form reduces to that of the gradient expansion for small gradients, the value for β is about twice as large as that predicted from the slowly varying gas.

Another common GGA for exchange is the Perdew–Burke–Ernzerhof (PBE) approximation,[10] usually written in terms of an enhancement factor, $F_{\mathrm{x}}(s)$, to the LDA exchange energy density

$$[11] \qquad E_{\mathrm{x}}^{\mathrm{PBE}}[n] = \int \mathrm{d}^3 r F_{\mathrm{x}}^{\mathrm{PBE}}(s) \epsilon_{\mathrm{x}}^{\mathrm{LDA}}[n]$$

where

$$[12] \qquad F_{\mathrm{x}}^{\mathrm{PBE}}(s) = 1 + \kappa - \frac{\kappa}{1 + \mu s^2/\kappa'}$$

and $\mu = 0.2195$ and $\kappa = 0.8040$. This form for the enhancement factor is chosen so that it reduces to LDA for $s = 0$ and again recovers the form of the gradient expansion for small s. For large s, it becomes a constant determined by the parameter κ. Both κ and μ are determined via satisfaction of various exact conditions. The value of μ was chosen to preserve the good linear response of LDA for the uniform electron gas under a weak perturbation,[22,23] while κ is set by the Lieb–Oxford bound[24] on the exchange-correlation energy. (That condition is obviously violated by B88, while PBE does not accurately recover the X energy density in the tails of Coulombic systems).

III. Theory

LDA yields the dominant term in *either* the asymptotic charge–neutral expansion ($\zeta \to \infty$) *or* the gradient expansion for the slowly varying electron gas, $s \to 0$. We next show that, contrary to popular myth, the important expansion is the charge–neutral expansion, *not* the gradient expansion.

The charge–neutral expansion can be applied to any type of matter, be it molecule or extended solid. For any finite system, the density decays exponentially far from the nuclei. This is a key distinction between finite systems and bulk matter, treated with periodic boundary conditions. Bulk matter has no such regions.

But, for slowly varying gases, or more generally when there are no classical turning points at the Fermi surface, the charge–neutral scaling and the gradient expansion become identical, i.e., the gradient expansion for the slowly varying gas is simply a *special case* of charge–neutral scaling. To see that this is so, consider just the kinetic energy as a density-functional. Here, the gradient expansion is known out to 6th order,[25] and eventually, the integrated quantity itself diverges for atomic densities due to the evanescent tail. But no such divergence occurs for extended systems with finite density everywhere.[25,26]

Thus, CN scaling applies to all systems, but only becomes identical to the gradient expansion for slowly varying bulk systems. For the dominant contribution, effectively the local Fermi wavelength becomes short on the length scale on which the density is changing, so that the local approximation applies and yields the exact answer for this term. Hence, LDA reproduces the AE0 terms, but GEA does *not* produce the leading corrections. All this has been amply demonstrated for simple 1D model systems[16] and for the Kohn–Sham kinetic energy for atoms.[27]

Here, we apply the same reasoning for exchange. The local approximation becomes relatively exact as $\zeta \to \infty$, but the gradient expansion does not reproduce the leading correction in the CN expansion. Below, we use the simple reasoning of ref. 12 to recover this leading correction. We perform a much more extensive calculation of the asymptotic behavior, using methods developed in ref. 27. We find, in agreement with ref. 12, that the leading correction for atoms is about double that given by the gradient expansion, matching quite closely that of B88 and of PBE. Reversing this logic for B88, we show that B88 may be more or less derived non-empirically via the constraint that the approximation be AE1. If we enforce AE1 exactly, we find a slightly different value for β, and discuss the properties of the resulting functional, excogitated B88.

IV. Extracting asymptotic coefficients

Under the potential scaling of eq. [1], any approximation for the exchange energy that reduces to LDA in the uniform limit has an expansion in N like eq. [3], with the same value for c_0. However, the coefficient c_1 depends on the particular approximation. Below, we explain the procedure used to extract these coefficients.

As mentioned in the previous section, the OPMKS[19] electronic structure code is a fully numerical electronic structure code that has the ability to perform optimized effective potential (OEP) calculations. We evaluate the various approximations using atomic densities found with the OEP exact exchange (EXX) method. The densities found using this method will be extremely close to the exact densities despite the fact that correlation is missing. Moreover, the effect of correlation will contribute at higher orders in the asymptotic expansions of the energy than those we are interested in.

Fig. 1. The OEP exact exchange energies E_x for neutral atoms from $Z = 1$ to 88, divided by $Z^{5/3}$ to pick out the leading term in its asymptotic series. The leading corrections are proportional to powers of $Z^{-1/3}$. The values for the noble gas atoms are given as the circle symbols.

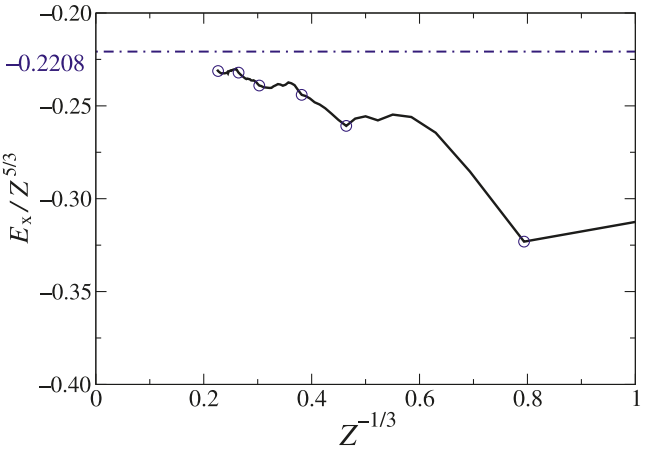

Fig. 2. We add to Fig. 1 the results for the LDA functional evaluated on the OEP densities (dashed-line) keeping the EXX values (solid line). As in Fig. 1, the noble gas atoms are highlighted with circle and square symbols for EXX and LDA, respectively.

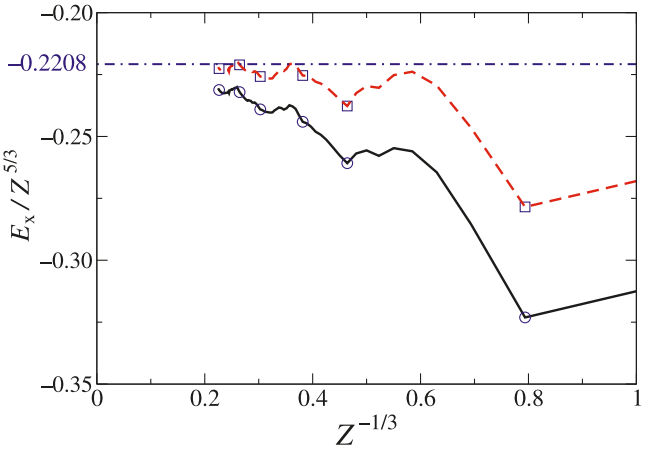


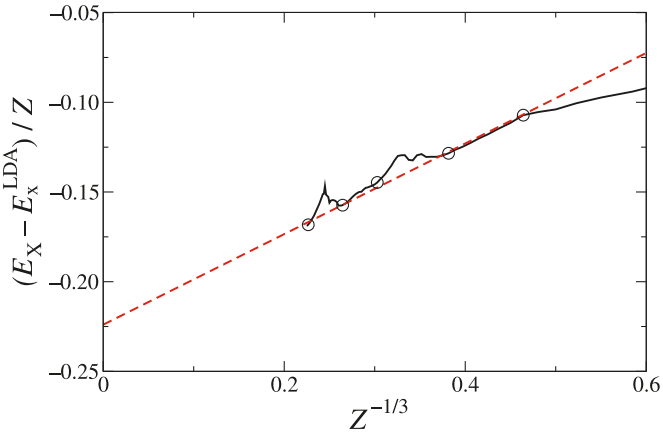
Thus, EXX calculations are in principle sufficient for extracting the coefficient we seek.

In Fig. 1, we plot $E_x/Z^{5/3}$ vs. $Z^{-1/3}$ where E_x is the exchange energy from the exact exchange calculation. Since the leading term in the asymptotic expansion of eq. [3] is $Z^{5/3}$, this procedure picks out the c_0 coefficient as a constant while all other terms are functions of $Z^{-1/3}$. One can see that the curve in Fig. 1 is heading towards the exact value of $c_0 = -0.2208$, but it is difficult to extract higher coefficients due to oscillation of the curve due to the shell structure.

To overcome this difficulty, in Fig. 2, we add the LDA curve to Fig. 1. It can be seen that it too recovers the exact c_0 coefficient, but also clearly differs in higher orders in the asymptotic expansion. More usefully, we see that the LDA curve mimics the oscillations shown by exact exchange, so subtracting LDA from EXX will minimize this effect and make the extraction of asymptotic coefficients more accurate.

In Fig. 3, we plot $(E_x - E_x^{LDA})/Z$ vs. $Z^{-1/3}$ and find that it behaves close to linearly. There appears to be no $Z^{4/3}$ term

Fig. 3. We now find the next coefficient in the exchange asymptotic series. To minimize the error due to shell structure oscillations, the LDA exchange energy is subtracted from the exact exchange for each atom. As both give the leading correction, their difference will then have ΔcZ, $\Delta c = c_1 - c_1^{LDA}$, as the leading term in its asymptotic expansion. The dashed line is the result of fitting to the noble gas atoms (circle symbols).



in E_x. Such a contribution was argued not to exist in ref. 12, but this was based on CN scaling of the density and studying the behavior of the terms in the gradient expansion. That reasoning is insufficient, as the expansion should be performed in terms of the potential, as described in section II. But since the Scott correction (the Z^2 contribution to the total energy) comes from the core region, there is no reason to expect an analogous contribution for exchange. To show this and also to precisely determine the c_1 coefficient, one should use the techniques developed by Schwinger for deriving the Scott correction to the total energy,[11] but apply them to exchange.

To further reduce the remaining uncertainty due to shell structure oscillations, we choose simply to use the noble gas atoms (excluding helium) for our fit. The strongest deviations from linearity come from the transition metals and lanthanides and actinides. We fit the difference $(E_x - E_x^{LDA})/Z$ with a straight line in $Z^{-1/3}$, and extrapolate to $Z \to \infty$, finding $\Delta c = -0.2240$, where $\Delta c = c_1 - c_1^{LDA}$, and

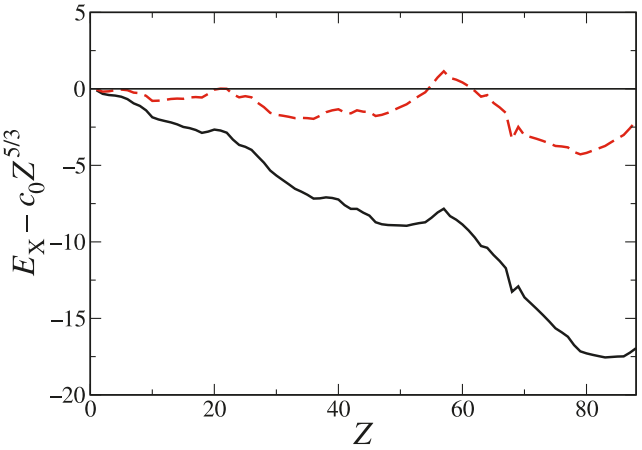
$$[13] \qquad E_x \approx E_x^{LDA} - 0.2240\,Z + 0.2467\,Z^{2/3}$$

The coefficient of the last term is given by the slope of the dashed line in Fig. 3, although the meaning of this term is unclear in the presence of such strong oscillating contributions.

If instead we used the alkaline earth atoms (excluding beryllium), we find an almost identical value, $\Delta c = -0.2236$. If we use all elements with $Z > 10$, we find a similar value, $\Delta c = -0.2164$. If all elements from $Z = 1$ to 88 are used, we find $\Delta c = -0.1982$. In ref. 12, Δc was found using noble gas atoms, except with the helium value included, and that method gave a value of $\Delta c = -0.1978$. In our analysis, atoms with $Z < 10$ are not used as they are not necessarily dominated by the asymptotic series.

Since LDA displays the shell oscillations that prevented us from fitting EXX directly, the value of the LDA c_1 coefficient cannot be found exactly. But we estimate

Fig. 4. To see that LDA does not significantly contribute to the higher orders of the exchange asymptotic series, we plot the difference between LDA and the leading term $c_0 Z^{5/3}$ (dashed line), as a function of Z. The exact exchange value is also shown (solid line).



$0 \geq c_1^{\mathrm{LDA}} \geq -0.04$, i.e., at least five times smaller in magnitude than Δc. In Fig. 4, we show $E_x - c_0 Z^{5/3}$ as a function of Z for both the exact values and within LDA, demonstrating that the linear contribution comes almost entirely from the beyond-LDA terms.

Finally, we determine Δc for GEA. In Fig. 5, we plot $(E_x^{\mathrm{GEA}} - E_x^{\mathrm{LDA}})/Z$ vs. $Z^{-1/3}$ to find $\Delta c = c_1^{\mathrm{GEA}} - c_1^{\mathrm{LDA}}$, finding $\Delta c = -0.1062$. This plot is much closer to linear than the previous one. The leading corrections to LDA in the asymptotic expansion produce corrections to the shell structure *beyond* those captured by LDA evaluated on the exact density.[16,27] Although the smooth contribution can be partially captured by GEA, there is almost no correction to the shell structure. Just as for the kinetic energy,[27] GEA yields a correction to the smooth part that is about half of the accurate value.

To understand the power of these asymptotic expansions, we add the corrections of eq. [13] to the LDA energies, and in Fig. 6, plot the percentage error relative to exact exchange, as a function of Z. For all but the second row of the periodic table, the resulting error is below 0.5% in magnitude, and typically of the order 0.2%.

V. Generalized gradient approximations

Generalized gradient expansions were designed to improve energetics over LDA for electron systems of interest and relevance. Early versions, such as PW91,[28,29] were tortured into reducing to the gradient expansion when the density is slowly varying. But this was later given up, in both B88 and PBE exchange, which both reduce to the gradient expansion form for slow variations, but with coefficients much larger than that of the gradient expansion.

Our analysis explains why this must be so. Regardless of its derivation, any modern GGA for exchange is tested against the neutral atoms. Any approximation that cannot recover the right c_1 will be generally inaccurate for these energies, and so discarded. Thus, any that become popular have already passed this test.

In Table 1, we give the results for Δc for several different functionals. The same methodology was used in all extractions. Both popular GGAs recover (at least approximately) the accurate value. B88, designed specifically for molecular systems, is very close to the accurate value. PBE exchange is less so, but is also designed to bridge molecular and solid-state systems. The PBE value is between that of GEA and B88, but much closer to the latter than the former. Taking advantage of this insight, a new variation on PBE, called PBEsol,[30] restores the original gradient expansion, thereby worsening atomization energies (total energy differences), but improving many lattice constants of solids over PBE and LDA.

Fig. 5. We use the same procedure as in Fig. 3 to find the Δc coefficient for the gradient correction to LDA, $E_x^{(2)}[n]$, as defined in eq. [7]. The dashed line was fitted to the noble gas atoms (circle symbols).

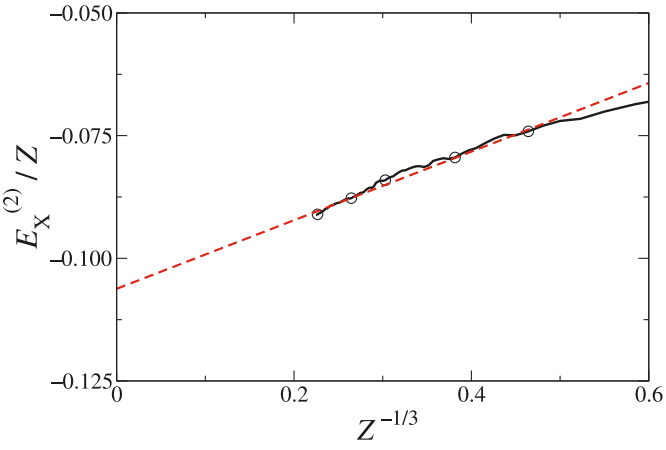


Fig. 6. The percentage error of the approximate asymptotic series given in eq. [13] is plotted as a function of Z. The error is remarkably low and demonstrates the power of these asymptotic series.

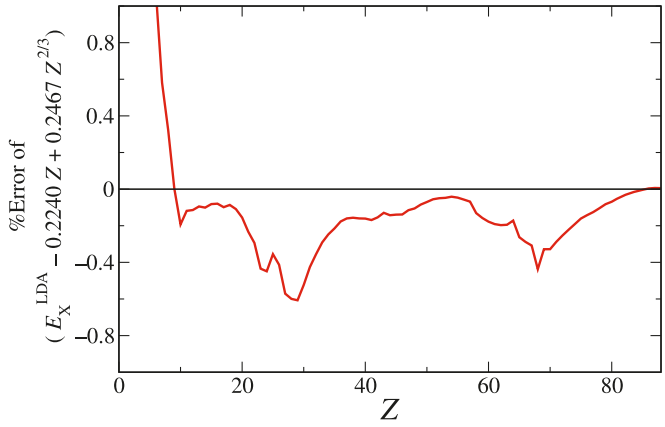

Deriving the β in B88

When designing a good GGA, one first chooses the functional form in terms of the dimensionless gradient s. This is usually based upon satisfying various constraints that the designer feels are important, e.g., reduce to LDA for $s = 0$, give correct asymptotic behavior for large r, prevent divergence for large s, and so forth. This is the most important step, and we do not discuss it in this paper, although work is ongoing in this direction.[16] After picking a functional form, there is usually still some freedom to choose any pa-

Table 1. $\Delta c = c_1 - c_1^{LDA}$ values for several different functionals.

	E_x	LDA	GEA	B88	PBE
Δc	–0.2240	—	–0.1062	–0.2216	–0.1946

Fig. 7. The percentage error for LDA, GEA and the modified GEA (MGEA) exchange functionals for $Z > 10$. The coefficient of $E_X^{(2)}$ is multiplied by 2.109 to make the MGEA AE1 asymptotically exact.

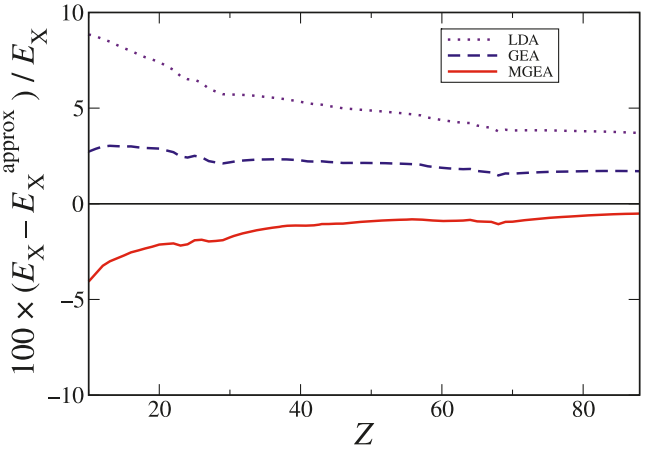

Fig. 8. We add to Fig. 7 the results for B88, PBE, and the excogitated B88 functional, all evaluated on the OEP exact exchange densities.

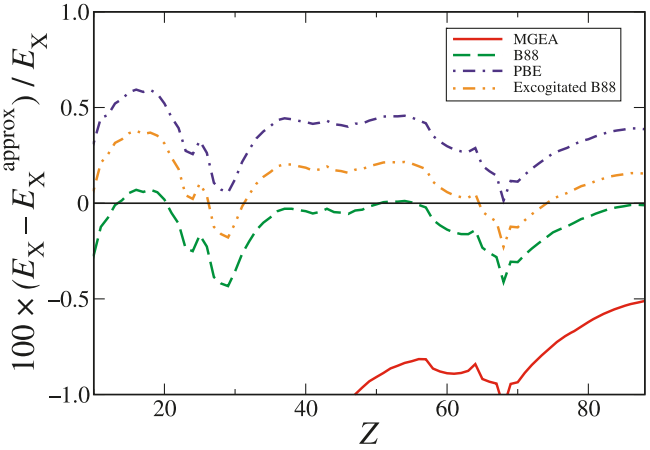

rameters (hopefully a small number) that may be left. These can be fixed by satisfying different exact constraints or by fitting to a set of experimental or computational data. The former is considered more favorable by some,[31] as it makes a functional more trustworthy for application to many different classes of systems, while the latter generally gives better properties for systems close to the fitting set. In the case of B88, we now show that the previously empirical parameter can be derived by requiring the exact condition that it be AE1. This explains why B88 was so successful when applied to different types of system.

The exchange energies found using GGAs such as B88 or PBE are generally dominated by their gradient expansion components for most chemically relevant densities (see Table 2 in ref. 12). Thus, to make B88 AE1, it is sufficient to impose this exact condition on just the $E_x^{(2)}[n]$ functional form. Since both B88 and the GEA are built on top of LDA, we can simply look at the Δc values calculated above. If we set $\mu = 2.109\mu_{AK}$ in eq. [7], we multiply the c_1 coefficient of GEA by a factor of 2.109, making it AE1. In Fig. 7, we name this functional MGEA for modified GEA and plot its percentage errors. The values for LDA and GEA are also shown. It can be seen that modifying GEA to be AE1 has greatly reduced the error.

We now require that the B88 functional form, eq. [10], reduce to this MGEA for small values of x. Using eq. [9], this corresponds to using a value of $\beta = 0.0050$. Thus, we have derived an excogitated B88 that is free of any empirical parameters. The actual value used in B88 is $\beta^{B88} = 0.0053$ (for spin-polarized systems, this becomes 0.0042, which is the value given in ref. 7), so the values are very close. This is not surprising as fitting to Hartree–Fock exchange energies is an approximate way of demanding asymptotic exactness. Interestingly, the value quoted as the high-Z asymptote in ref. 7 and found using ref. 21 is essentially the same as our value, but was evidently rejected in favor of a better fit. In Fig. 8, we plot the percentage errors for B88, PBE, and the excogitated B88. As is typical for empirically fitted functionals, B88 performs very well for systems close to the data set used in the fitted procedure. Although the error for PBE is higher than both B88 and the excogitated B88, it is systematic in its overestimation. As noted, PBE was designed to perform reasonably well for a wide range of systems, so again, its behavior is not surprising. On this data set, the excogitated B88 was never going to do better than B88, although it remains to be seen how it performs for more complicated systems.

VI. Conclusion

We have carefully and systematically extracted the leading large-Z correction to the exchange energy of atoms. Our results differ slightly from those of ref. 12 but yield the same qualitative conclusion, i.e., that the gradient expansion yields an error of a factor of 2 or more for this coefficient. We have clarified some of the reasoning, and applied it more generally to any atom, molecule, or cluster. By looking in detail at the exchange energy asymptotic series for neutral atoms, we have demonstrated the power of using such series for functional development. Requiring that the small gradient expansion of B88 capture the two leading coefficients of the asymptotic expansion is a method by which the unknown coefficient β can be found. This gives a coefficient very close to the one actually used in B88, and thus is an *ex post facto* "derivation" of B88. Inserting our most accurate estimate for β into the B88 form yields an excogitated B88.

DFT studies of complexes between ethylenediamine tetraacetate and alkali and alkaline earth cations

Melissa Gajewski and Mariusz Klobukowski

Abstract: Density functional theory (DFT) calculations for M–($C_{10}H_{12}N_2O_8^{4-}$) and M–($(H_2O)_6$, where M = Na^+, K^+, Rb^+, Mg^{2+}, Ca^{2+}, and Sr^{2+}, and ($C_{10}H_{12}N_2O_8^{4-}$) = $EDTA^{4-}$, were carried out at both all-electron and pseudopotential levels. Results from these four methods were compared, and it was found that the ions bind to $EDTA^{4-}$ with selectivity of $Mg^{2+} > Ca^{2+} > Sr^{2+} > Na^+ > K^+ > Rb^+$.

Key words: ethylenediamine tetraacetic acid (EDTA), alkali metal ions, alkaline earth metal ions, binding affinity.

Résumé : Faisant appel à la théorie de la fonctionnelle de la densité et opérant aux niveaux de tous les électrons ainsi que du pseudopotentiel, on a effectué des calculs sur les cations M–($C_{10}H_{12}N_2O_8^{4-}$) et M–($(H_2O)_6$ dans lesquels M = Na^+, K^+, Rb^+, Mg^{2+}, Ca^{2+}, et Sr^{2+} et $C_{10}H_{12}N_2O_8^{4-} = EDTA^{4-}$. Les résultats obtenus avec ces méthodes ont été comparés entre eux et on a trouvé que les ions se lient avec $EDTA^{4-}$ avec la sélectivité suivante : $Mg^{2+} > Ca^{2+} > Sr^{2+} > Na^+ > K^+ > Rb^+$.

Mots-clés : acide éthylènediaminetétraacétique, ions de métaux alcalins, ions de métaux alcalinoterreux, affinité de fixation.

[Traduit par la Rédaction]

Introduction

Ethylenediamine tetraacetic acid (H_4EDTA) is a polyprotic acid that has been widely used, together with its associated anion ethylenediamine tetraacetate ($EDTA^{4-}$), since the pioneering work on H_4EDTA was done by Schwarzenbach in the 1940s.[1] One of the most useful properties of $EDTA^{4-}$ is its ability to form exceptionally strong complexes with Mn^{2+}, Cu^{2+}, Fe^{3+}, and Co^{3+};[2] $EDTA^{4-}$ will also form complexes with many other cations. For this reason, $EDTA^{4-}$ can be used in sequestering heavy metal ions, buffering solutions, and many forms of titration.[3] Also, some of the properties of $EDTA^{4-}$ allow it to be used in the pulp and paper industry,[4] and as an industrial cleaner,[2] as a food preservative,[5] as a drug,[6] and as a detergent to complex with Ca^{2+} and Mg^{2+} to reduce the hardness of water.[7]

H_4EDTA is a polyprotic acid with $pK_{a1} = 1.99$, $pK_{a2} = 2.67$, $pK_{a3} = 6.16$, and $pK_{a4} = 10.26$.[8] This can allow for different ion selectivity based on the pH of the solution; one can adjust the pH of the solution and influence the order in which the ions forms complexes with H_nEDTA^{n-4} (n = 0, 1, 2, 3, 4). Crystal structures of $EDTA^{4-}$ complexed with Na^+, Mg^{2+}, and Ca^{2+} are available[9–11] and may be used to compare with calculated geometries.

One computational approach that can be taken to establish the order with which cations bind to $EDTA^{4-}$ is to calculate the energy difference between reactants and products. Based on this energy difference (ΔE_{rxn}), the binding affinities of cations to $EDTA^{4-}$ could be determined by comparing the energy of complexation. Equation [1] illustrates the calculation of ΔE_{rxn}, or the stabilization energy (SE), for cation–$EDTA^{4-}$ and the cation–$(H_2O)_6$ complexes:

$$[1] \qquad \begin{aligned} EDTA^{4-} + M^{n+} &\rightleftharpoons [MEDTA]^{n-4} \\ 6H_2O + M^{n+} &\rightleftharpoons [M(H_2O)_6]^{n+} \end{aligned}$$

where M $\in$ {Na^+, K^+, Rb^+, Mg^{2+}, Ca^{2+}, Sr^{2+}}.

Density functional theory (DFT) calculations that were performed in the present work were carried out for the gas phase; in such a case, eq. [1] introduces errors because solvation effects have not been taken into account. Thompson et. al.[12] and Glendening et. al.[13] suggested that an alternative approach may be used to assess the binding affinity of cations to a ligand in aqueous solution. Their method is shown in eq. [2] and depicted in Fig. 1,

$$[2] \qquad [M_1EDTA]^{n_1-4} + [M_2(H_2O)_6]^{n_2+} \rightleftharpoons [M_2EDTA]^{n_2-4} + [M_1(H_2O)_6]^{n_1+}$$

where $M_1 \neq M_2$, and $M_i \in$ {Na^+, K^+, Rb^+, Mg^{2+}, Ca^{2+}, Sr^{2+}}. This method is based on an exchange reaction of two cations, which are enclosed in six water molecules, and the host ligand, in the present case the $EDTA^{4-}$ anion.

Glendening et al.[13] demonstrated that this approach will mimic some of the solvation effect that influence the binding affinity of cations to ligands. Their work on crown-ether complexes[13] showed that using eq. [2] changed the ordering

of the gas phase calculations on the binding affinity of cations to 18-crown-6 to match experimental results obtained in aqueous solution. Using eq. [2] may also lead to a reduction in errors which are due to inadequate basis set representation because it may be expected that these errors would be approximately equivalent on both sides of eq. [2]. In the present work, corrections for basis set superposition errors (BSSE) were calculated and it was found that these BSSE corrections were approximately equal for all the cation–EDTA^{4-} complexes. Therefore the BSSE corrections need not be included as they cancel out when using eq. [2]. It is for these reasons that eq. [2] was used to determine the order of selectivity of selected alkali and alkaline earth cations.

Glendening et. al.[14,15] carried out extensive studies to determine the lowest energy structure for different configurations of water clusters with various cations. The different structures of water complexes are shown in Fig. 2. Alkali cations have lower energies for the first two geometries depicted in Fig. 2, with the first structure possessing S_6 symmetry (left image) and the second C_{2v} symmetry (centre image). The results from the calculations show that the energy difference between these two water complex conformations either is negligible or slightly favors the C_{2v} geometry. Therefore the C_{2v} geometry was chosen for all of the alkali cations. Alkaline earth cations all prefer the T_h geometry that is shown in the right image of Fig. 2. As seen in Fig. 2, the lowest energy structures of the alkali cations are very different from the lowest-energy structures of the alkaline earth cations.

The structures of free EDTA^{4-} and the cation–EDTA^{4-} complexes are quite different and are shown in Fig. 3. The free EDTA^{4-} has all four carboxylate groups pointing away from the central N–C–C–N dihedral angle, as shown in the left image of Fig. 3. As the cations are sequestered, three or four oxygen atoms envelope the cation (one oxygen atom from each of the carboxylate groups). The case of three oxygen atoms from three carboxylate groups sequestering a cation is shown in the centre image of Fig. 3 and the case of four oxygen atoms from four carboxylate groups sequestering a cation is shown in the right image of Fig. 3. It is interesting to note that the carboxylate groups do not lose their resonance structure upon complexation with a cation: all of the carbon–oxygen bond lengths are approximately 1.26 ± 0.03 Å in all of the calculated geometries and the crystal structure geometries.[9–11] There is little change (±0.02 Å) in the carbon–oxygen bond lengths between the free EDTA^{4-} and the cation–EDTA^{4-} complex.

Method of calculations

DFT with two different functionals was used to calculate the cation–EDTA^{4-} and the cation–$(H_2O)_6$ complexes. The

DFT calculations in the first set were carried out using Gill 1996 exchange[16] and Perdew 1986 correlation functional[17] (GP86) while in the second set the commonly used B3LYP functional[18,19] was employed. Furthermore, two different methods were used to describe electron distribution: the all-electron (AE) and a pseudopotential method, more specifically the model core potential (MCP). For all the studied systems, geometry optimization was performed, followed by a Hessian calculation and harmonic vibrational analysis. The Hessian calculation was done to ensure that the stationary points found in the geometry optimization were minima rather than saddle points.

For the AE calculations, the following composite basis set was used: 6–31G* basis set on carbon, magnesium, calcium, sodium, potassium;[20,21] 6–31+G* on oxygen, nitrogen, hydrogen;[20,21] and a split-valence all-electron basis set (SVPall) on rubidium and strontium;[22] the SVPall basis is roughly equivalent to 6–31G*.[23] The AE DFT calculations are denoted by B3LYP/AE and GP86/AE.

To reduce computational effort as well as to calibrate the pseudopotential method, the MCP method[24] and basis sets were used in the second set of DFT calculations. The MCP method approximates the core electrons by a potential and explicitly treats only the valence electrons and thus offers an effective manner of reducing the basis set size, leading to reduction of CPU time. The recently prepared MCP-DZP parameters and basis sets[25] were used. The MCP DFT calculations are referred to as B3LYP/MCP and GP86/MCP.

All of the computations for the complexes were done for systems in gas phase. Computer programs GAMESS-US[26] and Gaussian03[27] were used, running concurrently on computer clusters at the University of Alberta. The GP86 DFT functional is implemented equivalently in both GAMESS and Gaussian03 for the AE calculations, which allowed for both GAMESS and Gaussian03 to be used for the AE/GP86 calculations. Visualization of molecular structures, vibrational modes, and molecular orbitals were done using Molden[28] and MacMolPlt.[29]

Results, discussion, and conclusions

The two functionals, GP86 and B3LYP, were employed to ensure that the results were independent of the DFT functional used. In the present calculations, the cations were surrounded by six water molecules to mimic some of the solvent effects[12,14] and reduce the significance of the errors that may be introduced due to inadequate basis set representation.

Glendening et al.,[14] who carried out calculations on the 18-crown-6 molecule and calculated the binding affinities to the alkali cations, showed that by using an equation equivalent to eq. [1] the ordering of binding affinities matched experimental results that were obtained using a kinetics method in a collision-induced dissociation, liquid secondary ion mass spectrometry study of mixed crown ether – alkali halide complexes which was done by Maleknia and Brodbelt.[30] The calculations that best describe this type of experimental measurement are gas phase calculations. The gas phase calculations done by Glendening et al. and the experimental results given by Maleknia et al. both gave the same order of binding affinities for the crown ether – alkali cation complexes.

As mentioned earlier, in order to calculate the binding affinities with some of the solvation effects being represented in the calculations, eq. [2] can be used, as demonstrated by Glendening et al.[14] It is for this reason that eq. [2] was used in the present work to determine the binding affinities that selected alkali and alkaline earth cations have with $EDTA^{4-}$, since $EDTA^{4-}$ is typically used in the aqueous phase. Equations below show how the $\Delta\Delta E$ is derived using the equations for the stabilization energies of individual complexes:

$$[\Delta E_1] \qquad EDTA^{4-} + M_1{}^{n+} \rightleftharpoons [M_1EDTA]^{n-4}$$

$$[\Delta E_2] \qquad EDTA^{4-} + M_2{}^{n+} \rightleftharpoons [M_2EDTA]^{n-4}$$

$$[\Delta E_3] \qquad 6H_2O + M_1{}^{n+} \rightleftharpoons [M_1(H_2O)_6]^{n_2+}$$

$$[\Delta E_4] \qquad 6H_2O + M_2{}^{n+} \rightleftharpoons [M_2(H_2O)_6]^{n_2+}$$

Suitable combination of these equations cancels out $EDTA^{4-}$ and six H_2O molecules, leaving only cation–$EDTA^{4-}$ or cation–$(H_2O)_6$ complexes, with the energy change given by

$$[3] \qquad \Delta\Delta E_{rxn} = (\Delta E_2 + \Delta E_3) - (\Delta E_1 + \Delta E_4)$$

for the reaction

$$[M_1EDTA]^{n_1-4} + [M_2(H_2O)_6]^{n_2+} \rightleftharpoons [M_2EDTA]^{n_2-4} + [M_1(H_2O)_6]^{n_1+}$$

that is equivalent to eq. [2]. Thus, the specific equation that was used to calculate the binding affinities of the cation to $EDTA^{4-}$ is based on eq. [2]:

$$[4] \qquad \Delta\Delta E_{rxn} = \left(E_{[M_2EDTA]^{n_2-4}} + E_{[M_1(H_2O)_6]^{n_1+}}\right) - \left(E_{[M_1EDTA]^{n_1-4}} + E_{[M_2(H_2O)_6]^{n_2+}}\right)$$

A negative value of $\Delta\Delta E$ indicates that M_2 binds with greater affinity to $EDTA^{4-}$ than M_1. The results for the calculated order of selectivity for some of the alkali and alkaline earth cations are summarized in Tables 1 and 2.

The data shown in Tables 1 and 2 show that the relative difference between the $\Delta\Delta E$ for the two different functionals is smaller when using the AE DFT method. More importantly, it is apparent from these tables that the same selectivity of cations to $EDTA^{4-}$ was obtained for all four methods used, B3LYP/AE, GP86/AE, B3LYP/MCP, and GP86/MCP, namely, $Mg^{2+} > Ca^{2+} > Sr^{2+} > Na^{+} > K^{+} > Rb^{+}$, which matches experimental results except for the reverse ordering of Ca^{2+} and Mg^{2+}.[31] To understand this discrepancy, it must be noticed that at the high *p*H required for the existence of $EDTA^{4-}$ in aqueous solution, Mg^{2+} would have precipitated out of solution forming $Mg(OH)_2$. The magnesium cation would more likely bind to $HEDTA^{3-}$ according to the reaction

$$[5] \qquad HEDTA^{3-} + Mg^{2+} \rightleftharpoons Mg[HEDTA]^{-}$$

unlike the calcium cation which reacts with $EDTA^{4-}$ as shown in the generic $EDTA^{4-}$ reaction in eq. [1]. To address the inconsistency in the binding order, the stabilization en-

Table 1. Binding affinity (in kcal/mol) for cation–$EDTA^{4-}$ complexes results from B3LYP/AE calculations (GP86/AE values in parentheses); PCM values in italics.

ergy for the $Mg[HEDTA]^-$ complex in eq. [5] was calculated and compared to the stabilization energy from the $Ca[EDTA]^{2-}$ complex using the B3LYP/MCP method. It was found that the stabilization energy of the calcium–EDTA complex was approximately 18 kcal/mol lower than that of the magnesium–HEDTA complex. It may be assumed that if analogous calculations were performed with the replacement of $EDTA^{4-}$ with $HEDTA^{3-}$, the reversal of the Mg^{2+} and Ca^{2+} binding affinities for the complexes would remain consistent across all of the DFT calculations and a correct matching of calculated binding affinities to experimental results would be obtained.

To assess whether the same trend in the binding affinities would be seen in the presence of implicit solvent, single point calculations were done using the polarizable continuum model (PCM)[32] in GAMESS.[26] The previously described B3LYP/AE DFT method was employed at the geometry optimized in B3LYP/AE calculations. The uncorrected energies from the PCM calculations were corrected using the ZPE (zero-point energy) energy corrections from the B3LYP/AE calculations and the results were analyzed using eq. [4] to determine the binding affinity for the cation–$EDTA^{4-}$ complexes. The same trend, $Mg^{2+} > Ca^{2+} > Sr^{2+} > Na^+ > K^+ > Rb^+$, was observed for the PCM results as for the gas-phase ones. It can be conjectured that, if similar calculations were performed using the other DFT methods described in this paper, the same binding affinity order would be obtained. It should be noted that compared to gas-phase results, all PCM calculations led to more stable, lower energy metal–ligand systems. The alkali cation – $EDTA^{4-}$ complexes are all more stable by approximately 330 kcal/mol, whereas the alkaline earth cation – $EDTA^{4-}$ complexes are all more stable by approximately 190 kcal/mol. A similar trend is seen for the cation–$(H_2O)_6$ complexes with the increase in stability of 60 kcal/mol and 190 kcal/mol for the alkali and alkaline earth cation complexes, respectively.

Experimental data for cation–$EDTA^{4-}$ complexes are available for all of the cation–$EDTA^{4-}$ complexes that were studied in this paper except for Rb^+.[31] The experimental results show that on the basis of the logarithms of the stability constants (log K), the binding affinities for the cation–$EDTA^{4-}$ complexes is $Ca^{2+} > Mg^{2+} > Sr^{2+} > Na^+ > K^+$. The log K values are 1.7, 0.8, 8.8, 10.7, and 8.7 for the reaction:

$$EDTA^{4-} + M^{n+} \rightleftharpoons [MEDTA]^{n-4}$$

for Na^+, K^+, Mg^{2+}, Ca^{2+}, and Sr^{2+}, respectively. Using these values of log K, the stability constant for the exchange reaction were calculated using the following equations (in aqueous solution),

$$[K_1] \qquad EDTA^{4-} + M_1{}^{n+} + \rightleftharpoons [M_1EDTA]^{n-4}$$

$$[K_2] \qquad EDTA^{4-} + M_2{}^{n+} \rightleftharpoons [M_2EDTA]^{n-4}$$

$$[K_3] \qquad [M_2EDTA]^{n-4} + M_1{}^{n+} \rightleftharpoons [M_1EDTA]^{n-4} + M_2{}^{n+}$$

where $K_3 = K_1/K_2$. These values of K_3 inserted into the formula for Gibbs free energy, $\Delta G = -RT \ln K$, allowed for the experimental ΔG_{rxn} values to be calculated for the reaction shown in eq. [2], with the exception of Rb^+. These values are summarized in Table 3 along with the values of ΔG obtained from the PCM calculations. The calculated values for ΔG_{rxn} were obtained from the PCM results by using the uncorrected energies ($E_{o(PCM)}$) from the AE B3LYP PCM single-point calculations and adding the thermodynamic Gibbs

free energy correction ($G_{corr(GAS)}$) from the Hessian calculations of AE B3LYP.

$$G_{[M_nEDTA]^{n_2-4}} = E_{o(PCM)} + G_{corr(GAS)}$$
$$G_{[M_n(H_2O)_6]^{n_1+}} = E_{o(PCM)} + G_{corr(GAS)}$$

The values of the ΔG_{rxn} that were obtained for the PCM calculations using eq. [6],

$$[6] \qquad \Delta G_{rxn} = \left(G_{[M_2EDTA]^{n_2-4}} + G_{[M_1(H_2O)_6]^{n_1+}}\right) - \left(G_{[M_1EDTA]^{n_1-4}} + G_{[M_2(H_2O)_6]^{n_2+}}\right)$$

are summarized in Table 3. It is apparent from Table 3 that the calculated and experimental trends of ΔG_{rxn} match except for Mg^{2+}. This is again due to the discrepancy between these calculated binding affinities and the experimental binding affinities, i.e., the reversal of the Mg^{2+} and Ca^{2+} ordering, which was discussed earlier.

The ZPE-corrected energies are shown in Tables 4 and 5. In these tables ΔE_0 denotes the stabilization energy, calculated using eq. [1]. The energies were taken at the optimized geometry (minimum, as confirmed by Hessian calculation). ΔZPE is the ZPE correction which, when added to ΔE_0, gives the ZPE-corrected energy ΔE_{corr}. It is interesting to note that the magnitude of the ΔZPE correction is much larger for the water complexes than it is for the $EDTA^{4-}$ complexes. This difference is due to the way ZPE was evaluated: the ZPE correction is calculated by summing over all normal modes (3N-6 for non-linear molecules). In the cation–water complexation reaction, there is an increase of 33 normal modes when going from reactants to products, while there is an increase of only 3 normal modes in the cation–$EDTA^{4-}$ complexation reaction. This 11-fold increase in the number of normal modes between the two different reactions is the reason that the cation–$(H_2O)_6$ complexation reaction has a much greater ΔZPE correction. The ΔZPE is fairly consistent across the two functionals (B3LYP and GP86) and the basis sets (AE and MCP).

The two different DFT functionals (B3LYP and GP86) provide similar results for the AE and MCP calculations. The corrected stabilization energies (ΔE_{corr}) that are shown in Table 4 for B3LYP/AE and GP86/AE and in Table 5 for B3LYP/MCP and GP86/MCP, are summarized in Fig. 4. In addition to revealing that the four methods give the same trend in the corrected stabilization energies, this figure also shows that the MCP calculations for the cation-$(H_2O)_6$ and cation-$EDTA^{4-}$ complexes give a lower stabilization energy.

Selected bond lengths and the C–N–N–C dihedral angle for the optimized structures of ligands and complexes for the four sets of calculations are shown in Table 6. The calculated B3LYP/AE, GP86/AE, B3LYP/MCP, and GP86/MCP geometries exhibit great similarity. The bond lengths and dihedral angles are also given for the crystal structures that were available. However, it is difficult to compare the calculated gas phase structural parameters to the crystal structure data, because in all crystal structures there are other cations, water molecules, or other complexes present. The presence of these extra atoms and molecules as well as the crystal packing effects will affect not only the dihedral angle but also the bond lengths. However, Durand et al.[33] showed in molecular dynamics simulations that the cation–oxygen and cation–nitrogen bond distances are comparable with calculated geometries in the present work. Specifically, Durand et al. found that the cation–oxygen distances are 2.3 Å and 2.5 Å for Ca^{2+} and Sr^{2+}, respectively, and the cation–nitrogen distances are 2.5 Å and 2.6 Å for Ca^{2+} and Sr^{2+}, respectively, which is within 0.1 Å of the calculated values in the present work, which are shown in Table 6.

The natural bond orbital analysis (NBO)[34,35] was carried out for both cation–$(H_2O)_6$ and cation–$EDTA^{4-}$ complexes, and the obtained atomic charges are summarized in Table 7. It may be noticed that cationic charge was reduced by approximately 10% for all cations in both cation–$(H_2O)_6$ and cation–$EDTA^{4-}$ complexes. This indicates that there is little transfer of charge between the ligand and the cation and thus the bonding is mainly electrostatic.

Acknowledgments

This research was funded in part by Natural Sciences and Engineering Research Council (NSERC) research grant to MK. Results presented in this work were obtained using computing resources of the Department of Academic Information and Communication Technologies of University of Alberta as well as two Beowulf clusters maintained by the Department of Chemistry, University of Alberta.

Explorations of many-body relativistic wave equations within a one-dimensional model

Marcel Nooijen

Abstract: A one-dimensional analog that reflects many of the features of the many-body Dirac equation is considered. The model can be solved numerically using a convenient finite basis discrete variable representation. Both an (unbound) harmonic oscillator potential and a (bound) inverse Gaussian one-particle potential are discussed for interacting particles. In a second thread in the paper, the mass term is neglected in the model many-body Dirac equation, and it is shown that the original equation, which has 2^N coupled components for N particles can then be reduced to 2^N decoupled one-component equations, which can be solved "analytically" for arbitrary many particles interacting through central two-body potentials.

Key words: many-body, Dirac equation, relativity, one-dimensional model, exact solutions, massless neutrino.

Résumé : On étudie un analogue unidimensionnel de l'équation de Dirac à plusieurs composants qui est un reflet de plusieurs caractéristiques de cette équation. Le modèle peut être résolu numériquement en utilisant une représentation variable commode avec base finie individuelle. Pour les particules qui interagissent, on discute d'un potentiel d'oscillateur harmonique non lié ainsi que d'un potentiel gaussien inverse et non lié à une particule. Dans la seconde partie de ce travail, on néglige le terme de masse dans le modèle de l'équation de Dirac à plusieurs composants et on montre que l'équation originale qui comporte 2^N composants couplés pour N particules peut être réduite à 2^N équations découplées à un composant et qu'elle peut être résolue d'une façon analytique pour plusieurs particules arbitraires interagissant par le biais de potentiels à deux composants centraux.

Mots-clés : plusieurs composants, équation de Dirac, relativité, modèle unidimensionnel, solutions exactes, neutrino sans masse.

[Traduit par la Rédaction]

I. Introduction

The Dirac equation[1] is the basis for relativistic quantum chemistry, and results from accurate computations based on the Dirac equation in general agree well with experiment, e.g., refs. 2 and 3. However, there are significant difficulties with the theoretical framework.[4–11] In particular, the many-body Dirac–Coulomb equation is not Lorentz-covariant,[5] while in addition, the no-pair approximation[6–8] is typically invoked to obtain a discrete low-energy spectrum[4] for many-body problems. Some of these fundamental difficulties disappear if the techniques of quantum field theory, e.g., ref. 12, are invoked, but in practice, bound-state quantum field theoretical calculations, e.g., refs. 13–15, are cumbersome, and there are few prospects that methods rooted in such methodologies can become routinely applicable. Even within a quantum field theoretical conception, it is not entirely clear if Lorentz covariance can be strictly maintained.[16,17]

To discuss the difficulties with solving the Dirac equation for many-particle systems, let us first recall the standard no-pair Dirac–Coulomb procedure, e.g., ref. 7. The first step consists of solving the four-component Dirac–Fock one-particle problem, in which the Dirac–Fock operator is given by

$$[1] \qquad \widehat{f} = \begin{pmatrix} (\widehat{U} + mc^2)\mathbf{1}_2 & c\sigma \cdot \mathbf{p} \\ c\sigma \cdot \mathbf{p} & (\widehat{U} - mc^2)\mathbf{1}_2 \end{pmatrix}$$

in which each entry in $\widehat{f}$ is a 2×2 matrix operator, in particular σ_i, $i = x, y, z$ denote the Pauli spin matrices. The effective potential operator $\hat{U}$ contains a nuclear attraction Coulomb potential $\widehat{V}_{\mathrm{Ne}}$ in addition to a mean field Coulomb-exchange repulsion, which is calculated self-consistently. To define the no-pair many-body problem, the one-particle Dirac–Fock equation is solved and the many-particle no-pair Dirac–Hamiltonian operator is expressed in second quantization, where only matrix elements over positive energy orbitals are included, i.e.,

This article is part of a Special Issue dedicated to Professor T. Ziegler. It is my pleasure to contribute this paper to the Festschrift honoring Tom Ziegler. Over the years, I have enjoyed many discussions with Tom ever since he spent a sabbatical year in Amsterdam in the mid 1980s, when I was a starting graduate student. I have always felt it was easy to discuss things with Tom, even as the volume might rise during our (sometimes) passionate arguments, as it was always clear this did not affect feelings of mutual appreciation and respect. For some reason, many of our discussions have touched upon fundamental aspects of our science, and the topic of this paper reflects this common interest.

$$[2] \qquad \hat{H} = \sum_{i,j} \langle i|\hat{f} + \hat{V}_{\mathrm{Ne}} - \hat{U}|j\rangle \hat{a}_i^{\dagger}\hat{a}_{\mathrm{j}} + \frac{1}{4}\sum_{i,j,k,l} \langle ij|\frac{1}{r_{12}}|kl\rangle \hat{a}_i^{\dagger}\hat{a}_j^{\dagger}\hat{a}_l\hat{a}_k$$

This Hamiltonian is mathematically similar to the usual non-relativistic Hamiltonian, and can be solved using more or less conventional techniques. The main issue is the different spin-symmetry, as the Hamiltonian explicitly includes spin-orbit coupling, while in addition, the matrix elements are complex. The Coulomb–Breit interaction, e.g., ref. 18, is sometimes used rather than the Coulomb interaction to include additional relativistic effects. However, irrespective of the potential used, the resulting approach is not Lorentz covariant. Moreover, the projection on positive energy solutions is not unique. In principle, one could use different potentials in the one-particle Dirac–Fock operator, e.g., including electron-correlation using a DFT approach, or solving the one-particle problem for inividual atoms first and using the positive energy solutions to create a molecular Hamiltonian, as advocated by Liu et al.[19,20] It hence transpires that the no-pair Dirac–Coulomb problem has some intrinsic arbitrariness, and it is disconcerting that the most accurate, still practical, formulation in relativistic quantum chemistry is not rigorously defined. Other groups, e.g., refs. 9, 10, argue that the no-pair approximation is not needed, but then the (low-energy) spectrum for a many-body system will consist of discrete energies embedded in a continuum. The physical meaning of this continuum is not clear, in particular one might ask if this continuum should then be included in the calculation of properties using statistical mechanics.

This paper is just a small step in a wider ranging investigation, and it may be good to try to put it in perspective. On the long term, we are pursuing a strictly Lorentz-covariant many-body quantum mechanics in which each particle would be described by four spacetime coordinates and the many-body wave function in addition depends on a universal time-evolution parameter denoted u. In prior work, a suitable Lorentz-covariant framework is developed for a many-body classical relativistic mechanics, in which each particle is described by its own spacetime coordinates,[21–24] and which appears to be a suitable candidate for quantization.[25–30] Not surprisingly, interpretation is easier for quantities defined in a computer simulation than interpreting, e.g., spacetime coordinates and a universal time in the real world. Partly for this reason, we have become interested in what we call "physics for a computable universe".[23] This also might become the basis for simulations of a virtual reality, and the requirements are primarily ease of computation and a semblance of the (perhaps very complicated) computed virtual reality with real world phenomena. To illustrate further what I have in mind, the "physics for a computable universe" might be the theoretical foundation for sophisticated 3D computer games. Obviously, there is no reason to insist on quantitative agreement with real world phenomena, but efficient computation would have very high priority. In the context of this paper, an intriguing possibility arises because momentum occurs linearly in the Dirac equation, and for this reason, it may be possible to find exact analytical solutions to the many-body problem, at least after some modification of the equation. Even if such an exactly solvable wave equation does not describe physical reality, it may provide new insights, for example, regarding the somewhat troublesome relation between quantum mechanics and statistical mechanics, and it might be useful in simulations of virtual reality, or perhaps even in classical renditions of a quantum computer. On the one hand, this type of consideration entails the danger of taking us far a field. On the other hand, this point of view allows us to explore possibilities freely, constrained by the requirement of mathematical consistency, but less by the harness of physical reality. Of course, there is always the (perhaps remote) possibility that we might arrive at an improved description of physical reality that avoids the mathematical problems of the many-particle Dirac equation.

To make some progress and to guide the thoughts, I will analyze here a simple model for a many-particle wave equation in one spatial dimension. In Section II, the model is described in detail, as well as the techniques used to find solutions to the many-body problem. In Section III, numerical solutions are presented for a small number of selected model Hamiltonians. In particular, it will be shown that numerically stable solutions exist that correspond to positive energy components, but in case of the many-body problem, these stable solutions are embedded in what is likely a continuum of solutions. There is substantial literature on the treatment of relativistic Dirac-like problems in one dimension, e.g., refs. 31–34. Our results, obtained for both a harmonic oscillator and an inverted Gaussian potential, confirm the phenomena reported in the literature, and qualitatively agree with results for the two-body Dirac–Coulomb problem, see e.g., ref. 11. I will not attempt to be complete or systematic in the simulations, but merely discuss selected examples. Neither is a more sophisticated mathematical analysis pursued, e.g., based on complex scaling to investigate the precise nature of the continuum, see e.g., ref. 11. The model captures the somewhat strange features of the many-body Dirac equation (if the no-pair approximation is *not* invoked), and in this respect, the model serves its purpose. The simplicity of the model allows easy access, I think, to understanding these issues.

When I started this investigation, the idea was to use the computer program to investigate whether solutions to the many-particle Dirac equation could be constructed directly from numerical solutions to the two-body problem. This amounted to a construction of exact many-body wave functions from two-body geminals, which superficially seemed possible due to the occurrence of linear momentum in the Dirac Hamiltonian. On closer examination, the many-component form of the Dirac solution poses a problem, and the original purpose of the program was to understand this aspect better by pursuing numerical simulations. While the idea of using geminals for this purpose did not come to fruition, pondering the problem led me into another direction, towards a quest for an exactly solvable quantum many-body problem. This is discussed in Section IV where we switch gears and discuss a modification of the 1D problem that allows an analytical solution for the eigenfunctions of the many-body problem for arbitrarily many interacting particles, for essentially arbitrary two-body central potentials in one dimension. The spectrum of solutions is found to be

continuous, and the linearity of the momentum operator is crucial. However, let me mention immediately here that the modification is not innocent, and the physical relevance of the resulting equation is not at all clear. Nonetheless, future work is planned to find suitable generalizations to design a solvable many-body relativistic wave equation in three and possibly four (spacetime) dimensions. While it is doubtful perhaps that such equations would have an immediate relevance to problems in chemistry, they may have applications in other fields like mathematics or computer science, and they may potentially serve as a starting point for creating the physics underlying a virtual reality that can be rapidly computed and trivially propagated in time. At this point in time, we can only speculate.

II. Description of the one-dimensional model

The basic model contains a one-particle Hamiltonian

$$[3]\qquad \widehat{h} = \begin{pmatrix} U(x)+mc^2 & -ic\widehat{p} \\ ic\widehat{p} & U(x)-mc^2 \end{pmatrix} = \begin{pmatrix} U(x)+mc^2 & -c\dfrac{\mathrm{d}}{\mathrm{d}x} \\ c\dfrac{\mathrm{d}}{\mathrm{d}x} & U(x)-mc^2 \end{pmatrix}$$

in which the choice is made to use

$$[4]\qquad \sigma_y\widehat{p} = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}\left(-i\frac{\mathrm{d}}{\mathrm{d}x}\right) = \begin{pmatrix} 0 & -\dfrac{\mathrm{d}}{\mathrm{d}x} \\ \dfrac{\mathrm{d}}{\mathrm{d}x} & 0 \end{pmatrix}$$

to represent the kinetic energy operator. Alternatively, one could use $\sigma_x\widehat{p}$ leading to identical energy spectra, but the actual operator, using σ_y has the advantage that all matrix elements are real. For the one-particle potential operator, we choose a harmonic potential $U(x) = \frac{1}{2}x^2$, although later on, an inverted Gaussian potential will be considered also. To describe the many-particle system, a repulsive two-particle interaction is introduced of the form $G(x_{12}) = qe^{-\mu(x_1-x_2)^2}$, in which q and μ are parameters, which we take to be q = 0.1and μ = 1.0. This potential has the advantage that it provides a smooth interaction without singularities and is easy to use in our employed numerical procedure, discussed next.

To numerically diagonalize the resulting one- or many-body Hamiltonian, a non-relativistic harmonic oscillator basis is used in a discrete variable representation (DVR), e.g., ref. 35. Specifically, the momentum operator and position operator can be expressed in second quantization

$$[5]\qquad \begin{aligned} \widehat{x} &= \frac{1}{\sqrt{2}}(\widehat{a}^\dagger + \widehat{a}) \\ -i\widehat{p} &= \frac{1}{\sqrt{2}}(\widehat{a}^\dagger - \widehat{a}) \end{aligned}$$

such that matrix elements over these operators are easily evaluated over the basis

$$[6]\qquad |n\rangle = \frac{1}{\sqrt{n!}}(a^\dagger)^n|0\rangle$$

The orthonormal DVR basis is defined by diagonalizing the operator $\widehat{x}$ in a finite Harmonic oscillator basis of dimension M (maximum degree M – 1). This provides the DVR basis $|\lambda_i\rangle$, which satisfies

$$[7]\qquad \begin{aligned} \langle\lambda_i|\widehat{x}|\lambda_j\rangle &= \lambda_j\delta_{ij} \\ \langle\lambda_i|\widehat{U}|\lambda_j\rangle &= U(\lambda_j)\delta_{ij} \end{aligned}$$

for any one-particle potential $U(x)$. Hence, the DVR basis allows us to conveniently evaluate matrix elements of arbitrary potentials. Even more conveniently, the evaluation of two-particle matrix elements is straightforward, and importantly, the two-particle integrals are diagonal in the DVR basis:

$$[8]\qquad \begin{aligned} \langle\lambda_k\lambda_l|\mathrm{G}(\mathrm{x}_{12})|\lambda_\mathrm{i}\lambda_\mathrm{j}\rangle &= G(|\lambda_\mathrm{i}-\lambda_\mathrm{j}|)\delta_{ik}\delta_{jl} \\ &= \delta_{ik}\delta_{jl}q\mathrm{e}^{-\mu(\lambda_i-\lambda_j)^2} \end{aligned}$$

The numerical diagonalization procedure converges smoothly with the size M of the one-particle basis set, provided fairly smooth potentials are chosen, such that the integrations are accurate using the DVR "grid" points λ_i. The described procedure is not accurate for rapidly varying potentials, e.g., of the Coulombic type. In that case, one would need to explicitly evaluate the Coulombic two-particle integrals analytically, and this would destroy the sparsity of the integrals. For this reason, we simplify things and use the Gaussian repulsion potential. The DVR procedure was tested first for non-relativistic problems in which there is no issue with continuum states. In that case, the operator $\widehat{p}^2 = -\frac{\mathrm{d}^2}{\mathrm{d}x^2}$ is required also. The exact harmonic oscillator energies $(n+\frac{1}{2})\omega$ are obtained in the non-relativistic DVR calculation, provided that the matrix elements of $\widehat{p}^2$ are obtained from a resolution of the identity $\langle n|\widehat{p}^2|m\rangle \approx -\sum_{k=0}^{M-1}\langle n|\frac{\mathrm{d}}{\mathrm{d}x}|k\rangle\langle k|\frac{\mathrm{d}}{\mathrm{d}x}|m\rangle$.

For a relativistic one-particle system, one would need to diagonalize a matrix of dimension $2M$, if we assume equal basis set dimensions for the two components of the wave function. In electronic structure calculations, one often invokes kinetic balance for the basis set. In the present case, this would mean that one uses one more basis function for the second component. For the current model, this does not seem very important (judging from our simulations), and we restrict ourselves here to discussing results using equal basis expansions for the first and second components.

For a two-particle system, a multi-component product basis of the form $|\lambda_i, \lambda_j, a\rangle$ is used in which the index a, a = $\{(s_1,s_2)\}$ = {(1,1), (1,2), (2,1), (2,2)}, refers to one of the possible four components of the two-body wave function. The two-body Hamiltonian can be represented as

$$[9]\qquad \widehat{H}_2 = \begin{pmatrix} V+2mc^2 & -ic\widehat{p}_2 & -ic\widehat{p}_1 & 0 \\ ic\widehat{p}_2 & V & 0 & -ic\widehat{p}_1 \\ ic\widehat{p}_1 & 0 & V & -ic\widehat{p}_2 \\ 0 & ic\widehat{p}_1 & ic\widehat{p}_2 & V-2mc^2 \end{pmatrix}$$

The momentum operators are assigned based on the component labels (s_1,s_2) of the columns and row in the matrix. The mass term only enters on the diagonal and is the sum

of $\pm mc^2$ contributions for each particle. The plus sign applies for the first component, and the minus sign for the second component. The second and third diagonal elements hence have no mass dependence as they consist of mixed entries, and the sum of the mass terms vanishes for the two-body hamiltonian. The total potential V for two particles is given by

$$[10] \qquad V = U(x_1) + U(x_2) + G(x_{12})$$
$$\langle \lambda_k \lambda_l b|V|\lambda_i \lambda_j a\rangle = \delta_{ab}\delta_{ij}\delta_{kl}(U(\lambda_i) + U(\lambda_j) + G(|\lambda_i - \lambda_j|)$$

and is completely diagonal due to the choice of DVR basis. The momentum operators are also readily evaluated, e.g.,

$$[11] \qquad \langle \lambda_k \lambda_l 1| - ic\hat{p}_2|\lambda_i \lambda_j 2\rangle = -c\delta_{ik}\left\langle \lambda_l \left| \frac{\mathrm{d}}{\mathrm{d}x} \right| \lambda_j \right\rangle$$

The structure of the Hamiltonian is quite similar to a vibronic Hamiltonian, in which the various components are analogous to electronic states, while the one-particle basis states are analogous to quanta along the vibrational normal modes. We use a Davidson type of diagonalization procedure to obtain eigenstates of the many-particle Hamiltonian, and we built the current relativistic code from modified subroutines in VIBRON, our Waterloo package for vibronic simulations.[36] The procedure of multiplying H by an arbitrary vector was checked against explicit construction of one- and two-particle Hamiltonians. It is easily seen that using M basis functions for n particles, the full dimension of the diagonalization problem is $2Mn$. To reach convergence, a typical size of the one-particle basis set is around 20. Hence, for two-particle problems, 1600 basis functions would be used; for three particles, one would already require 64 000 many-body basis functions; and for four particles, 2 560 000. It is readily seen that the dimension of the problem grows very rapidly, and even for this simple one-dimensional problem, a direct diagonalization technique is required beyond two-particle problems. The direct diagonalization procedure used here has some special features to calculate high lying (i.e., positive energy) states, which may be embedded in a continuum. In particular, after some initial iterations using the shifted Hamiltonian ($H - n\ mc^2$), (for n particles), which allows us to converge the energy to, say, 10^{-3}, we switch to diagonalizing the operator $(H - n\ mc^2)^2$, (applying the finite basis operator twice), and calculate the final energy as the square root of the eigenvalue from this operator. The squared operator has the advantage that the sought for eigenvalues are the lowest eigenvalues of the operator, and the energies satisfy a variational lower bound. As a result, the energies in the direct diagonalization procedure steadily decrease, and this improves the convergence behavior. In addition, we do not use an energy denominator to find the next iteration vector, which would be usual in the Davidson procedure used in electronic structure theory. The relativistic many-body problem may require a large number of iterations (in the order of 100s for difficult cases), which is in stark contrast to the non-relativistic case, for which the analogous many-body problem is solved using typically 10s of iterations. This reflects the additional complication of the presence of close-lying pseudo-continuum states. Two types of solutions to the many-body problem are considered. In what I refer to as the fermion problem, the wave function is taken to by fully antisymmetric upon permutation of one-particle basis states, while in the boson problem the states are fully symmetric. In three dimensions, the Dirac equation describes spin-1/2 particles, which is reflected by the full angular momentum symmetry, which has both orbital and spin contributions. For spin-0 particles, the Klein–Gordon equation would be appropriate, e.g., ref. 12. This, however, does not imply by itself that many-body wave functions describing spin-1/2 particles are antisymmetric. The notion of fermions and bosons refers to statistics, or equivalently the symmetry of the many-body wave function. The argument that spin-1/2 particles are fermions and particles with integer spin are bosons and the spin-statistics theorem are rooted in quantum field theory.[37,38] From a mathematical perspective, there is no problem to impose either antisymmetry or symmetry on the many-body wave function, even for the Dirac Hamiltonian. Likewise, there are solutions with yet different permutational symmetries, transforming to yet different irreducible representations of the permutation group. Here, I will consider both antisymmetric solutions (denoted as fermionic) and symmetric solutions (denoted as bosonic). It is found to be advantageous to explicitly (anti)symmetrize every state in the iterative diagonalization procedure, as numerical noise can easily destroy the symmetry, further exacerbating convergence issues. In the next section, we will investigate the behavior of the numerical solutions as we vary the speed of light in the problem and the nature of the one-particle potential.

III. Numerical results

(*a*) The one-particle relativistic harmonic oscillator

The one-particle one-dimensional Dirac harmonic oscillator is a classic problem in relativity theory. It was first studied in the 1930s,[31,32] and it continues to be a topic of research even today. [39] The spectrum consists of (very) sharp resonances in the continuum, and formally there are no square integrable eigenfunctions. This is different from the Hydrogenic 3D Dirac–Coulomb problem, for which bound square integrable eigenstates do exist. From a numerical point of view, it is still possible to study the 1D Dirac harmonic oscillator using a finite non-relativistic square integrable harmonic oscillator basis set, and in this way, the convergence of the eigenvalues representing the sharp resonances can be examined. Undoubtedly, the use of finite basis sets is a very convenient way to obtain approximate solutions in quantum chemistry, in particular for many-body problems, and here, we will elucidate some of the subtleties involved for the Dirac equation, without striving for rigor.

In the first set of test cases, we use a harmonic one-particle potential, $U(x_i) = \frac{1}{2}x_i^2$, the speed of light is set to 10.0 au, rather than the physical value of 137 au to enhance relativistic effects. In Table 1, the lowest positive energy eigenvalues, shifted by $-mc^2$, are listed. The largest basis set used has 30 one-particle basis functions, and in the Table also, the energy difference is reported between the largest ($M = 30$) results and the results for calculations with $M = 10$ and $M = 20$ basis functions. The results in Table 1 suggest that the diagonalization problem is well-behaved. Convergence of the positive energy levels with the size of the

basis set is smooth, and there is no indication of so-called Brown–Ravenhall disease, meaning the presence of positive energy continuum solutions. This does not mean these do not exist however, as the basis set is simply not large enough to show their presence. This will be discussed below.

Despite the seemingly smooth convergence, it is illuminating to monitor the one-particle spectrum for the harmonic oscillator potential. In Fig. 1, the resulting energies are drawn for the M = 30 calculations. The x-axis labels the energies, while the y-axis indicates the fraction of the first component: $f_1(\lambda) = \sum_{i \in S_1} |c_{i\lambda}|^2$ for an overall normalized state. For the negative energy states, this fraction would become very small, and instead, we use $f_2(\lambda) = -(1 - f_1(\lambda))$. It follows that positive fractions indicate states dominated by the first component, while negative fractions indicate states dominated by the second component. In all figures below, we shift to the negative fraction representation when $f_1(\lambda) <$ 0.25. There is no physical significance to this convention. It is simply used to clarify the pictures. In Fig. 2, we focus on the positive energy solutions, and it is seen that they more or less follow the equidistant spectrum of the non-relativistic harmonic oscillator. The doubling of the level near 23 au in Fig. 2 occurs because of the lack of kinetic balance in the calculations.

In Fig. 1, obtained for M = 30, it is seen that there are many negative energy states that fall in the gap between $-2mc^2 = -200$ and 0. As the size of the basis set increases, the number of such states and their energies keeps growing, and there is no reason for them not to become larger than 0, such that the states with large second components have similar energies as the "true" positive energy states, having large first components.

Rather than through an increase of the basis set, this issue can be investigated by reducing the speed of light. In Fig. 3, the one-particle spectrum is shown for the case c = 3 au and 40 basis functions. It is seen that indeed positive energy levels with large first components are interspersed with positive energy levels that are dominated by the second component of the wave functions (having negative fractions in the figure). Moreover, in numerical experiments, we were not able to converge the eigenvalues with respect to the basis set for these positive energy second-component states (using up to 300 basis states). These levels therefore are the finite basis

Fig. 1. One-particle energies for harmonic oscillator potential, c = 10, 30 basis functions included. Negative fractions of first components equal $-(1 - f_1)$, for small f_1. They indicate states dominated by the second component.

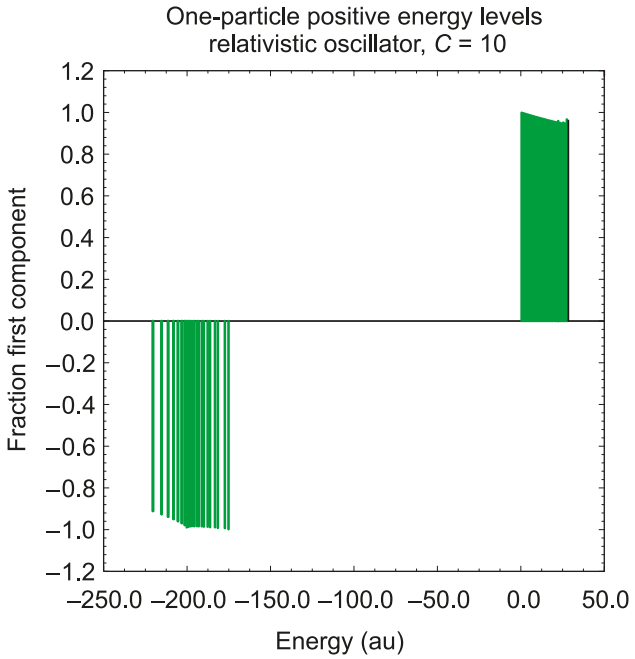

Fig. 2. One-particle energies for harmonic oscillator potential, c = 10, 30 basis functions included. Focus on positive energy spectrum. Energy levels are essentially equidistant, except for relativistic corrections. The double energy level around 23 au reflects a lack of kinetic balance in the basis.

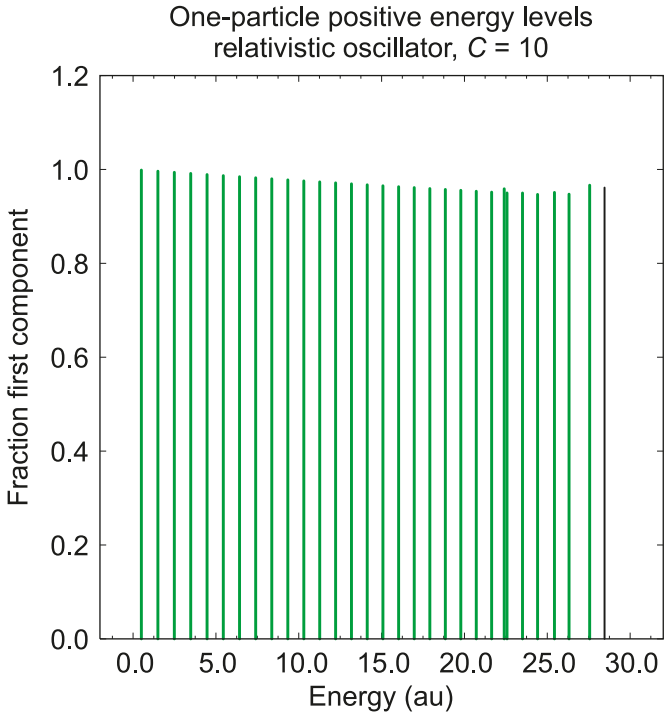

representation of a continuum using the harmonic oscillator potential that extends from $-2mc^2$ upwards. It is intriguing that the first-component positive energy levels converge rea-

sonably well with the size of the basis. These states can be interpreted therefore as sharp resonances embedded in a continuum, in accordance with the discussion of results in the literature for the harmonic oscillator.[31,32] This is also in accord with the two-body Dirac–Coulomb problem, when negative energy one-particle states are included.[11]

While we will use basis set convergence studies below to study many-particle problems in one dimension, it is clear that this is a somewhat crude vehicle to understand the subtle issue of sharp resonances in a continuum. For the one-dimensional Harmonic oscillator, we can pursue another analysis and calculate the energy dispersion in the approximate energy state $|\Psi_\lambda\rangle$

$$[12] \qquad \Delta H_\lambda = \langle\Psi_\lambda|(\widehat{H} - E_\lambda)^2|\Psi_\lambda\rangle = \langle\widehat{H}^2\rangle_\lambda - \langle\widehat{H}\rangle_\lambda^2$$

For the one-body Dirac equation, the square of the Hamiltonian operator is given by

$$[13] \qquad \widehat{H}^2 = \begin{pmatrix} (V+mc^2)^2 - c^2\dfrac{\mathrm{d}^2}{\mathrm{d}x^2} & -c\left(V\dfrac{\mathrm{d}}{\mathrm{d}x} + \dfrac{\mathrm{d}}{\mathrm{d}x}V\right) \\ c\left(V\dfrac{\mathrm{d}}{\mathrm{d}x} + \dfrac{\mathrm{d}}{\mathrm{d}x}V\right) & (V-mc^2)^2 - c^2\dfrac{\mathrm{d}^2}{\mathrm{d}x^2} \end{pmatrix}$$

For the case that $V = \frac{1}{2}kx^2$, $\widehat{H}^2$ is easily expressed in second quantization, and hence, we can evaluate the dispersion explicitly for any state expressed in a finite harmonic oscillator basis. Let me note that the full integral representation of the operators is used here (or equivalently the second quantized matrix elements), *not* the DVR diagonal basis to evaluate the potential, which was discussed in the previous section. The DVR representation will continue to be used for the many-body problems discussed below, but never to calculate ΔH. In Fig. 4, $\log(\Delta H_\lambda)$ is plotted vs. the energy E_λ for the case $c = 3$, $M = 40$. Sharp resonances in Fig. 4 are characterized by relatively small dispersions ($< 10^{-4}$ say), or negative values for $\log(\Delta H_\lambda)$. The values of the energies can be improved for these states with increasing size of the basis set (up to a limit, see below). In contrast, states with negative energies all have large dispersion ($\log(\Delta H_\lambda) > 0$). They represent continuum states and they do not converge at all with the basis set. In addition, positive energy states occur with large values for the dispersion, which also represent continuum states, and whose energies show no convergence with the basis set. In Table 2, we list positive energies for the cases $c = 3$, $M = 100$, and the energy difference with calculations using $M = 20$, 30, 40, and 60. Table 2 also includes the dispersion at $M = 40$ and $M = 100$. The identification of the sharp resonances using the dispersion criterion or alternatively the convergence of their energies with respect to the basis set is unambiguous. However, Table 2 also suggests that the sharp resonances do not strictly correspond to square integrable wave functions. The dispersion is often lower for $M = 40$ than for $M = 100$, which would be unexpected for true bound states. Moreover the energies are not strictly variational, as revealed by negative errors, e.g., certain entries in the $E(30) - E(100)$ column in Table 2. Interestingly, for the $M = 40$ case, the level around 2.39 au is poorly converged, and this can be attributed to the presence of a close lying

Fig. 3. One-particle energies for harmonic oscillator potential, $c = 3$, 40 basis functions. For this value of c, the "continuum" part of the levels dominated by the second-component overlaps the positive energy first-component levels.

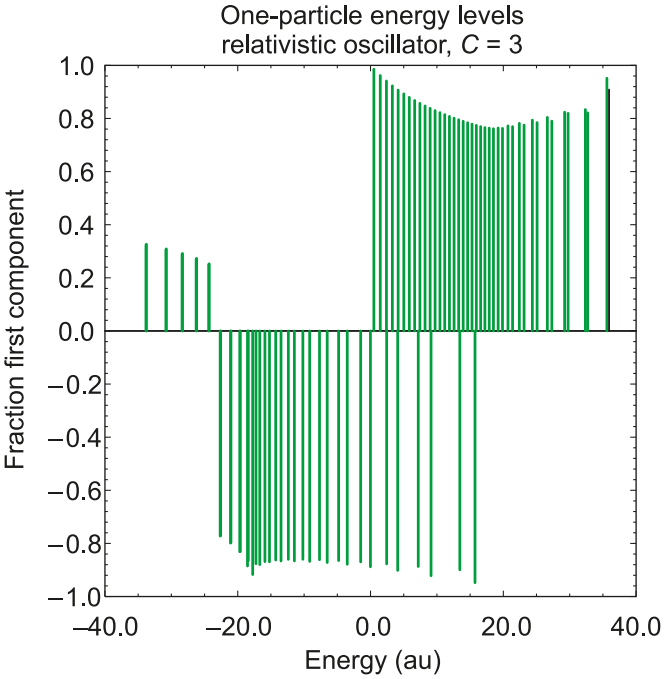

Fig. 4. Dispersion vs. energy for one-particle harmonic oscillator using 40 basis functions and $c = 3$.

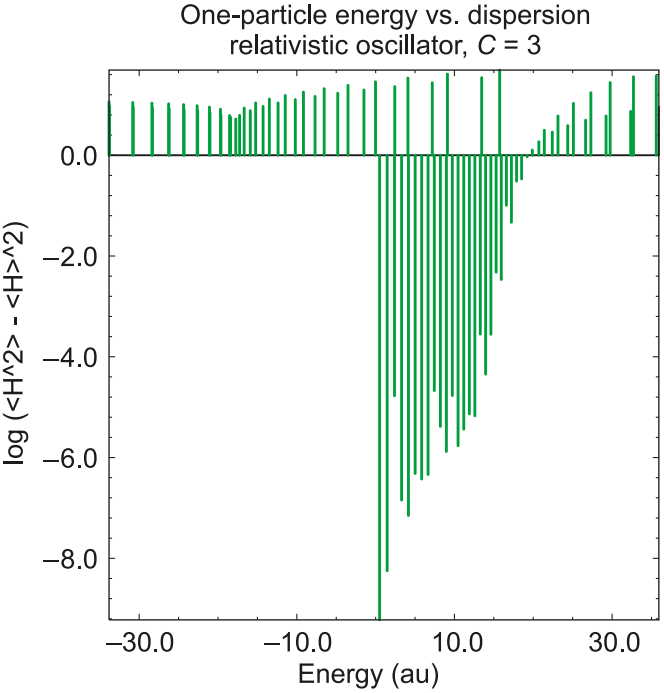

continuum level for this basis set, around 2.43 au. A similar conclusion can be drawn from calculations with different values for the speed of light. From numerical results (not shown) the dispersion for $c = 10$ is typically 10^{-10}, while for $c = 3$, one obtains values around 10^{-8} for "converged" levels. These numbers do not improve with an increasing size

Table 2. Relativistic one-particle energies: $c = 3$, Harmonic oscillator potential, total energies for 100 basis functions, and energy differences between nominally converged $E(100)$ and calculations with 60 and 40 and 30 and 20 basis functions for the bound states. Absolute energies are given for the continuum states. In addition, log(dispersion) is tabulated for $M = 100$ and $M = 40$.

of the basis set. If the speed of light is lowered even further to $c = 1$ (not shown), all states are found to have rather high values for $\log(\Delta H_\lambda)$, and none of the energies converge well with the basis set size. For this value of c then, the resonances have lost most of their sharpness, and the finite basis set approach very clearly shows its deficiencies. The behavior clearly seen for $c = 1$, in principle is present for all values of c. The exact eigenstates are not square integrable, but have continuum tails that may have a very small relative magnitude (or ratio) compared with the bound part of the wave function. For most values of the speed of light, the finite basis set approach can be expected to yield very good approximations to the energy of the sharp resonance and to the wave function in the bound state region. The continuum part of the wave function extends to infinity, however, and for very large basis sets, the continuum region would dominate the matrix elements, and the finite basis approach would break down. I think that it is justified to conclude from this (brief) investigation that one can meaningfully diagonalize finite basis Hamiltonians for the harmonic Dirac problem in basis sets that are not too large. One can monitor convergence with the size of the basis set, and the results agree with results based on monitoring the dispersion, which can be done using a single basis set. It should be kept in mind, however, that rigorous convergence is not possible. Very large basis sets would introduce the problem with continuum states. Below, we will use the convergence with basis set criterion to study many-body problems.

(*b*) Many-body relativistic problems in one dimension in harmonic confinement

In a first set of many-body test cases, we use a harmonic one-particle potential as above, the speed of light is set to 10.0 au, while for all models, the two-body potential is the Gaussian form discussed in section II. In Tables 3 and 4, the lowest positive energy solutions (from diagonalizing $(H - n{\cdot}mc^2)$, where n indicates the number of particles) are listed for the two- and three-particle problems. The largest basis set used has 30 one-particle basis functions, and in Tables 3 and 4, the energy difference is reported between the largest ($M = 30$) results and the results for calculations with $M = 10$ and $M = 20$ basis functions.

I also attempted to converge the two-particle and three-particle problems for the $c = 3$ harmonic model with Gaussian interparticle interactions, using direct diagonalization techniques. The current implementation is not powerful enough to extract converged eigenvalues for this problem, however. For the two-body problem, the size of the matrix is small enough to resort to an in-core diagonalization procedure. The spectrum then has similar features as the one-particle problem (not shown). Solutions dominated by the first-component ($s_1 = s_2 = 1$) appear stable with respect to variations in the basis set, and they are embedded in a continuum of solutions, which have smaller first components, and which do not show a semblance of convergence with respect to the size of the one-particle basis set.

(*c*) Results for an inverted Gaussian potential

The harmonic oscillator potential is somewhat pathological perhaps. It is unusual to see a continuum positive energy contribution for a one-particle problem arising from wave functions dominated by the second component. This does not happen in the one-electron Dirac–Coulomb problem. As another example, we therefore consider a potential that is bound both from above and from below, namely, an inverted Gaussian of the form $V(x) = B(1 - \mathrm{e}^{-\lambda x^2})$, $B = 5.0$, $\lambda = 0.1$, in which the parameters are chosen such that near the minimum, the potential has the harmonic oscillator form $\frac{1}{2}x^2$, indicating that the usual harmonic oscillator basis functions are a suitable expansion set. The non-relativistic Hamiltonian supports a number of bound levels below $E = B$, and has a continuous spectrum above the asymptote of the potential, B. In Fig. 5, the relativistic one-particle spectrum is shown, for $c = 3$, and it can be seen that the spectrum is

qualitatively different from the harmonic oscillator case. There are a few stable negative energy states with energy above $E = -2mc^2$ (analogous to the positive energy states), and then there is a continuum extending to $-\infty$. There are no energy levels in the gap between the highest discrete negative energy state (at about –12.2 au in Fig. 5) and $E = 0$, and we assume this continues to hold for any size of the one-particle basis set (up to 300 basis functions were used to check). However, the two-particle spectrum is qualitatively similar to the case discussed before. There are continuum states of mixed component character that increase in energy with an increase of the basis set.

The above calculations illustrate the delicate nature of the solutions of the many-particle Dirac equation, even for simple problems like interacting particles in one dimension. From a numerical point of view, it is not easy to demonstrate convergence. Nevertheless, our calculations seem to indicate that the many-body solutions consist of isolated sharp resonances, well-described in a square integrable basis set, embedded in a continuum that is represented by energy levels that do not converge with the size of the basis set. This lack of convergence for the continuum states is analogous to diagonalizing the operator x, which we use to define the DVR basis set. The eigenvalues of the operator x (or DVR points) are different for every finite basis, and do not show convergence.

I also conclude it is not trivial to converge the relativistic many-body problem using direct diagonalization techniques, and moreover, the presence of the continuum seems to be in conflict with physical reality. The same phenomena occur for the two-particle Dirac–Coulomb problem, e.g., for Helium, as discussed for example in ref. 11. It is not clear what the presence of the low-energy continuum solutions would imply for the specific heat of Helium. It certainly seems less controversial to restrict the many-particle basis set to determinants built from one-particle positive energy solutions, as advocated for example by Sucher,[7] as then the continuum disappears. However, as mentioned in the introduction, the choice of (effective) one-particle operator used to define the manifold of positive energy one-particle states is ambiguous, and we are left with the undesirable situation that the most accurate model in quantum chemistry is mathematically not well-defined. It is not clear to me to what extent the problem is resolved in quantum field theory for bound-state systems, as these calculations are so difficult and invariably have their basis in perturbation theory.

IV. Alternative approaches: an analytically solvable many-body problem

Let us first discuss some alternate forms of the one-particle Hamiltonian, which would provide exactly the same eigenvalues as presented in section III. Previously, the kinetic energy part of the Hamiltonian was represented as

$$[14] \qquad \widehat{T} = mc^2\sigma_z + c\sigma_y\widehat{p}$$

Let us note that we used $\sigma_y\widehat{p}$ to create a suitable momentum operator, but we could as well have used $\sigma_x\widehat{p}$. The reason to use $\sigma_y\widehat{p}$ was that all matrix-elements and diagonalization steps then can use real numbers. However, there are more substantially different representations. One might equally well use

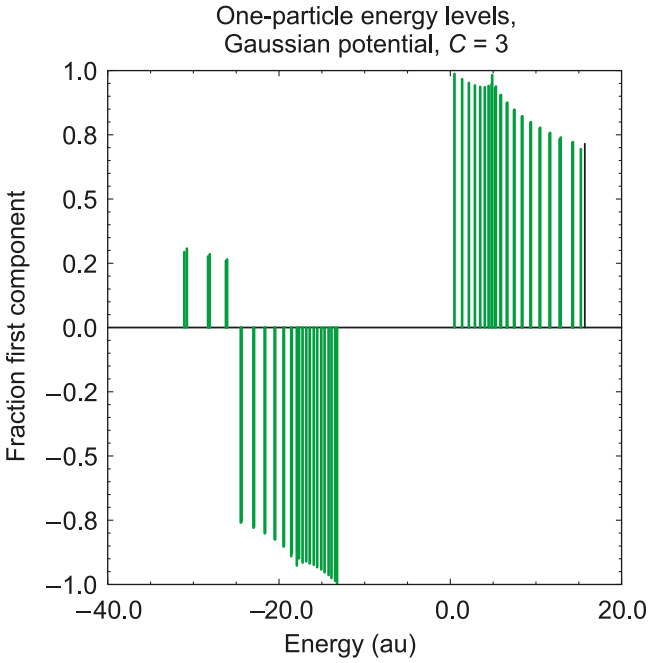
$$[15] \qquad \widehat{T} = mc^2\sigma_x + c\sigma_y\widehat{p} = \begin{pmatrix} 0 & mc^2 - c\dfrac{\mathrm{d}}{\mathrm{d}x} \\ mc^2 + c\dfrac{\mathrm{d}}{\mathrm{d}x} & 0 \end{pmatrix}$$

where the mass is transferred to the off-diagonal, which in the literature (for the 3D case) is known as the Weyl representation.[12] If one follows the reasoning by Dirac in his derivation of the Dirac eq. [1], the essential element is to find a representation of the classical relativistic square-root kinetic energy operator

$$[16] \qquad T = \sqrt{c^2p^2 + m^2c^4}$$

Using $\widehat{T} = mc^2\sigma_i + cp\sigma_j$ for any two of the Pauli matrices, which satisfy the Clifford algebra relation $\sigma_i\sigma_j + \sigma_j\sigma_i = 2\delta_{ij}\mathbf{1}$, then satisfies the fundamental relation $\widehat{T}^2 = (m^2c^4 + c^2p^2)\mathbf{1}$. Additional freedom arises as the Pauli matrices might be subject to an overall similarity transformation which preserves the Clifford algebra relations. A convenient proof that the above forms of Hamiltonian are equivalent is to demonstrate that they are related by simple similarity transformations. Let us simply demonstrate by some examples, without striving for full generality.

Fig. 5. One-particle energy levels for inverse Gaussian potential, c = 3, 30 basis functions. The negative energy states dominated by the second component do not overlap with the positive energy first-component solutions.



$$[17] \qquad \frac{1}{2}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix}\begin{pmatrix} V+m & p \\ p & V-m \end{pmatrix}\begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} = \begin{pmatrix} V+p & m \\ m & V-p \end{pmatrix}$$

where we have set the speed of light to unity for notational convenience. Alternatively,

$$[18] \qquad \frac{1}{2}\begin{pmatrix} 1 & -i \\ -i & 1 \end{pmatrix}\begin{pmatrix} V & m-ip \\ m+ip & V \end{pmatrix}\begin{pmatrix} 1 & i \\ i & 1 \end{pmatrix} = \begin{pmatrix} V+p & m \\ m & V-p \end{pmatrix}$$

Any similarity transformation of the Hamiltonian preserves the eigenvalues, while the eigenvectors would be related by a corresponding transformation. In this fashion, we can essentially use any two of the Pauli matrices to represent the mass and momentum terms. It was verified numerically that the real forms

$$[19] \qquad \begin{pmatrix} V+mc^2 & -icp \\ icp & V-mc^2 \end{pmatrix}, \begin{pmatrix} V & mc^2-icp \\ mc^2+icp & V \end{pmatrix}$$

yield indeed identical eigenvalues, both for the single particle and the many-particle (i.e., two- and three-body) problems.

For the sequel, the representation in which

$$[20] \qquad \widehat{h} = V\mathbf{1} + mc^2\sigma_x + c\sigma_z\widehat{p} = \begin{pmatrix} V+c\widehat{p} & mc^2 \\ mc^2 & V-c\widehat{p} \end{pmatrix} = \begin{pmatrix} V - ic\dfrac{\mathrm{d}}{\mathrm{d}x} & mc^2 \\ mc^2 & V + ic\dfrac{\mathrm{d}}{\mathrm{d}x} \end{pmatrix}$$

is most convenient to use. The two-particle Hamiltonian in this representation reads

$$[21]\qquad \widehat{H}_2 = \begin{pmatrix} V + c\widehat{p}_1 + c\widehat{p}_2 & m_2c^2 & m_1c^2 & 0 \\ m_2c^2 & V + c\widehat{p}_1 - c\widehat{p}_2 & 0 & m_1c^2 \\ m_1c^2 & 0 & V - c\widehat{p}_1 + c\widehat{p}_2 & m_2c^2 \\ 0 & m_1c^2 & m_2c^2 & V - c\widehat{p}_1 - c\widehat{p}_2 \end{pmatrix}$$

and likewise for higher-particle Hamiltonians.

An interesting observation can be made if the mass terms of the particles are neglected. This is of course not a small modification, and it greatly changes the physics of the problem. In the literature, this model (in the 3D case) is known as the two-component model for the neutrino,[12] although as far as I am aware, it is not often used with many-body interations. Let us however treat this as a mathematical exercise and first consider the 1D one-body problem without mass and a harmonic potential. It is easily confirmed that the analytical solutions to the corresponding equation are given by

$$[22]\qquad \begin{pmatrix} e^{ik_1x+if(x)} \\ 0 \end{pmatrix}, \begin{pmatrix} 0 \\ e^{-ik_1x-if(x)} \end{pmatrix}$$

where the function $f(x)$ satisfies $\frac{1}{2}kx^2 + c\frac{\mathrm{d}f}{\mathrm{d}x} = 0 \rightarrow f(x) = -\frac{k}{6c}x^3$, and the energy eigenvalues are continuous and are given by $E = ck_1 = c\hbar k_1$, in units in which $\hbar = 1$. Also, the two-body problem can be solved, and the solutions would be one-component functions (if the mass term is neglected). Solutions corresponding to the first component read

$$\Psi_1(x_1, x_2) = \exp\left(i\left[k_1x_1 + k_2x_2 - \frac{k}{6c}(x_1^3 + x_2^3) - \frac{1}{2c}(x_1 + x_2)v(x_{12})\right]\right)$$

$$[23]\qquad \left[V - ic\left(\frac{\partial}{\partial x_1} + \frac{\partial}{\partial x_2}\right)\right]\Psi_1(x_1, x_2) = \left[V + c(k_1 + k_2) - \frac{1}{2}kx_1^2 - \frac{1}{2}kx_2^2 - v(x_{12})\right]\Psi_1(x_1, x_2)$$
$$= c(k_1 + k_2)\Psi_1(x_1, x_2)$$

where it is used that for central potentials

$$[24]\qquad \left(\frac{\partial}{\partial x_1} + \frac{\partial}{\partial x_2}\right)v(|x_1 - x_2|) = \frac{\partial v}{\partial x_{12}}\left(\frac{\partial x_{12}}{\partial x_1} + \frac{\partial x_{12}}{\partial x_2}\right) = 0$$

Following these simple examples, it is straightforward to obtain the general analytical solution to the one-component many-body problem defined by the Hamiltonian

$$[25]\qquad \widehat{H} = \sum_\alpha S_\alpha cp_\alpha + \sum_\alpha U(r_\alpha) + \frac{1}{2}\sum_{\alpha\neq\beta} v(r_{\alpha\beta})$$

where the signs $S_\alpha = \pm 1$. The general solution has the form

$$[26]\qquad \Psi = \exp\left[i\sum_\mu S_\mu x_\mu(k_\mu + f(r_\mu)) + \frac{1}{2}i\sum_{\mu\neq\nu}(S_\mu x_\mu + S_\nu x_\nu)g_{\mu\nu}(r_{\mu\nu})\right]$$

with energy $c\sum_\mu k_\mu$, provided the functions f,g satisfy the radial first-order differential equations

$$[27]\qquad f(r) + r\frac{\mathrm{d}f}{\mathrm{d}r} = -\frac{U(r)}{c}$$

and

$$[28]\qquad g_{\mu\nu}(r) = -\frac{v}{2c},\ (S_\mu = S_\nu)$$
$$g_{\mu\nu}(r) + r\frac{\mathrm{d}g_{\mu\nu}}{\mathrm{d}r} = -\frac{v(r)}{2c},\ (S_\mu = -S_\nu)$$

The geminal function $g_{\mu\nu}$ hence depends on the relative signs of the momentum operators. The verification that the above function satisfies the differential equation is elementary and is given in the appendix. Also, the solution of the inhomogenous differential equations for the radial functions f and g for essentially arbitrary potentials is straightforward, and a series expansion of the solution is given in the appendix. In a very simple way, we hence obtain exact, analytical, continuum solutions to the one-dimensional mass-less Dirac equation for arbitrary many particles and (essentially) arbitrary central force potentials.

The solution is particularly simple if the diagonal representation for the momentum operators is used, but if a one-particle Hamiltonian is related by a similarity transformation to the diagonal representation, one can construct continuum multicomponent eigenfunctions using an overall similarity transformation. It may be instructive to discuss this by example. If a mass-less two-body Hamiltonian would be given by

$$[29]\qquad \widehat{H}_2 = \begin{pmatrix} V & c\widehat{p}_2 & c\widehat{p}_1 & 0 \\ c\widehat{p}_2 & V & 0 & c\widehat{p}_1 \\ c\widehat{p}_1 & 0 & V & c\widehat{p}_2 \\ 0 & c\widehat{p}_1 & c\widehat{p}_2 & V \end{pmatrix}$$

then the corresponding *one-body* problem can be transformed into a diagonal form by the transformation $\frac{1}{\sqrt{2}}\begin{bmatrix} 1 & 1 \\ 1 & -1 \end{bmatrix}$. The corresponding transformation for the two-body problem would be given by the direct product of the transformation matrices, denoted symbolically as

$$[30]\qquad \frac{1}{2}\begin{bmatrix}1 & 1\\ 1 & -1\end{bmatrix}\otimes\begin{bmatrix}1 & 1\\ 1 & -1\end{bmatrix}=\frac{1}{2}\begin{bmatrix}1 & 1 & 1 & 1\\ 1 & -1 & 1 & -1\\ 1 & 1 & -1 & -1\\ 1 & -1 & -1 & 1\end{bmatrix}=U=U^{\dagger}$$

Transforming the Hamiltonian, $U^{\dagger}HU$ then brings the Hamiltonian to diagonal form, with the momentum operator in the (s_1,s_2)-sectors given by the linear combination $S_1p_1 + S_2p_2$. This example shows more clearly that in the absence of a mass term, the 2^N coupled differential equation can be reduced to 2^N uncoupled differential equations, of the form shown in relation to eq. [25].

Let me discuss one more intriguing perspective. Let us focus on a particular component for the block-diagonal Dirac problem $H = c\sum_{\alpha} S_{\alpha}p_{\alpha} + V(\{\mathbf{x}\})$. The solutions to this mass-less one-component Dirac problem are plane waves $e^{\mathbf{ik}\cdot\mathbf{x}}$ times a solution to the zero energy problem, which might be written $\Psi_0 = \mathrm{e}^{ig(\mathbf{x})}$, and which satisfies $\widehat{H}\Psi_0 = 0$. The function $\Psi_0(\{\mathbf{x}\})$ can be associated with a transformation $\hat{U}$, such that the transformed Hamiltonian $\widehat{G} = \widehat{U}^{\dagger}\widehat{H}\widehat{U} = \widehat{T}$ is reduced to purely the momentum operators, and the potential is eliminated. The solutions of the transformed Hamiltonian are plane waves. From the above considerations, it follows that for the mass-less Dirac equation it is easy to find what amounts to a gauge transformation, *analytically*, that eliminates the potential completely, and reduces the problem of interacting particles to a free-particle problem under a suitable transformation. It then follows that solutions to the time-dependent mass-less Dirac equation are wave packets propagating analogously to plane waves, times an overall (time-independent) gauge factor. If one considers the full multi-component block diagonal Hamiltonian, each many-body component would consist of a wave packet of the form $\Psi_0(\{\mathbf{x}\})\int \mathrm{d}\mathbf{k}\mathrm{e}^{i(\mathbf{k}\cdot\mathbf{x}-E_{\mathbf{k}}t)}a(\mathbf{k})$. The function $\Psi_0 = \mathrm{e}^{ig(\mathbf{x})}$, and the coefficients $a(\mathbf{k})$ would be different for each component of the wave function.

I find this a fascinatingly simple picture for the many-body problem, but let me emphasize it only works if we first remove the mass from the equation. To make this aspect explicit, let us transform the simplest one-particle Hamiltonian, including masses

$$[31]\qquad \begin{bmatrix}e^{-ig(x)} & 0\\ 0 & e^{ig(x)}\end{bmatrix}\begin{bmatrix}V+cp & mc^2\\ mc^2 & V-cp\end{bmatrix}\begin{bmatrix}e^{ig(x)} & 0\\ 0 & e^{-ig(x)}\end{bmatrix}=\begin{bmatrix}cp & 0\\ 0 & -cp\end{bmatrix}+mc^2\begin{bmatrix}e^{-ig(x)} & 0\\ 0 & e^{ig(x)}\end{bmatrix}\begin{bmatrix}0 & e^{-ig(x)}\\ e^{ig(x)} & 0\end{bmatrix}$$
$$=\begin{bmatrix}cp & mc^2e^{-2ig(x)}\\ mc^2e^{2ig(x)} & -cp\end{bmatrix}$$

It is seen that this leads to a complicated transformed Hamiltonian, as the phase factor in the mass term can be a rapidly oscillating function. I conclude there is a simplifying feature to the one-dimensional many-body Dirac problem only if the mass term is discarded. Similar simplifications are expected to be possible for the mass-less many-body problem in three and perhaps four dimensions. These issues will be discussed in future work.

V. Concluding remarks

In this paper, a one-dimensional relativistic Hamiltonian is considered, and it was found useful to illustrate some of the pathological behavior of the many-body Dirac equation. The model employs a finite basis set, but all of the necessary integrals are conveniently obtained using second quantization techniques that are familiar from the harmonic oscillator and a DVR representation for the potentials. In particular, we find very sharp resonances that can be described quite well using finite basis set expansions, even if one can argue that such solutions are formally not correct.

The use of the dispersion relation $\Delta H = \langle H^2\rangle - \langle H\rangle^2$ in combination with finite basis sets seems to provide a powerful tool for analysis of this kind of problem. This requires evaluating $\langle H^2\rangle$ analytically over a finite basis set, and in particular for many-body problems, this leads to elaborate integrals. The DVR idea is not applicable to calculate the dispersion, e.g., for the one-body harmonic problem, the use of the DVR such that $\mathbf{V}^2 = \mathbf{V}$ for the matrices yields 0 dispersion for all states, and does not provide useful information regarding the continuum nature of the solutions, or the sharpness of the resonances.

The second part of the paper (section IV), in which we discuss analytical solutions to the many-body problem, is perhaps most interesting. We took the drastic measure to discard the mass from the equations, and this will clearly affect the physics. However, a number of observations are likely more generally applicable. For example, the reduction of the (mass-less) many-body Dirac equation in three dimensions from 4^N to a two- or four-component form. Moreover, there might be possibilities to identify mass with the time component of momentum in a spacetime formulation, and in this way, retain the analyticity of the solutions for problems that effectively include mass. The analytical solution discussed above can be essentially viewed as a gauge transformation that eliminates the potential and transforms the (mass-less) Dirac equation to a free-particle problem. This may be an interesting viewpoint to discuss dynamical equations between interacting particles. The ideas presented in section IV are clearly still in their infancy and require further development.

Appendix: Form of exact many-body wave function for one-component Hamiltonian

Consider the many-body Hamiltonian in one dimension

$$[A.1] \qquad \widehat{H} = \sum_{\alpha} S_\alpha c p_\alpha + \sum_{\alpha} U(r_\alpha) + \frac{1}{2}\sum_{\alpha\neq\beta} v(r_{\alpha\beta})$$

Then, if we assume a wave function of the following form:

$$[A.2] \qquad \Psi = \exp[i\sum_{\mu} S_\mu x_\mu (f(r_\mu) + k_\mu) + \frac{1}{2} i \sum_{\mu\neq\nu} (S_\mu x_\mu + S_\nu x_\nu) g_{\mu\nu}(r_{\mu\nu})]$$

we can find differential equations for the functions $f(r_\mu)$, $g_{\mu\nu}(r_{\mu\nu})$

$$[A.3] \qquad E = \frac{1}{\Psi} H\Psi = \sum_{\alpha} [c S_\alpha^2 (k_\alpha + f(r_\alpha)) + \sum_{\mu} S_\alpha S_\mu x_\mu \frac{\partial f}{\partial r_\mu}\frac{\partial r_\mu}{\partial x_\alpha} + U(r_\alpha)] + \frac{1}{2}\sum_{\alpha,\mu\neq\nu} (c S_\alpha S_\mu \delta_{\alpha\mu} + c S_\alpha S_\nu \delta_{\alpha\nu}) g_{\mu\nu}(r_{\mu\nu})$$
$$+ \frac{1}{2}\sum_{\mu\neq\nu} v(r_{\mu\nu}) + \frac{1}{2}\sum_{\alpha,\mu\neq\nu} (c S_\alpha (S_\mu x_\mu + S_\nu x_\nu) \frac{\partial g_{\mu\nu}(r_{\mu\nu})}{\partial r_{\mu\nu}}\frac{\partial r_{\mu\nu}}{\partial x_\alpha}$$

Using

$$[A.4]\qquad \frac{\partial r_\mu}{\partial x_\alpha} = \frac{\partial}{\partial x_\alpha}(x_\mu^2)^{1/2} = \frac{x_\alpha}{r_\alpha}\delta_{\alpha\mu}$$
$$\frac{\partial r_{\mu\nu}}{\partial x_\alpha} = \frac{\partial}{\partial x_\alpha}[(x_\mu - x_\nu)^2]^{1/2} = \frac{(x_\mu - x_\nu)(\delta_{\alpha\mu} - \delta_{\alpha\nu})}{r_{\mu\nu}}$$

such that

$$[A.5]\qquad \begin{aligned}\frac{1}{2}\sum_\alpha (cS_\alpha(S_\mu x_\mu + S_\nu x_\nu)\frac{\partial g_{\mu\nu}(r_{\mu\nu})}{\partial r_{\mu\nu}}\frac{(x_\mu - x_\nu)(\delta_{\alpha\mu} - \delta_{\alpha\nu})}{r_{\mu\nu}} &= \frac{c}{2r_{\mu\nu}}\frac{\partial g_{\mu\nu}(r_{\mu\nu})}{\partial r_{\mu\nu}}(S_\mu x_\mu + S_\nu x_\nu)(x_\mu - x_\nu)(S_\mu - S_\nu)\\ &= \begin{cases} 0, S_\nu = +S_\mu \\ \dfrac{c}{2r_{\mu\nu}}\dfrac{\partial g_{\mu\nu}(r_{\mu\nu})}{\partial r_{\mu\nu}}(x_\mu - x_\nu)^2(2S_\mu^2), & S_\nu = -S_\mu \end{cases}\\ &= \begin{cases} 0, S_\mu = S_\nu \\ cr_{\mu\nu}\dfrac{\partial g_{\mu\nu}(r_{\mu\nu})}{\partial r_{\mu\nu}}, S_\nu = -S_\mu \end{cases}\end{aligned}$$

Equation [A.3] simplifies to

$$[[A.6]]\qquad E = \frac{1}{\Psi}H\Psi = c\sum_\alpha k_\alpha + \sum_\alpha [cf(r_\alpha) + cr_\alpha\frac{\partial f}{\partial r_\alpha} + U(r_\alpha)] + \frac{1}{2}\sum_{\mu\neq\nu}[2cg_{\mu\nu}(r_{\mu\nu}) + v(r_{\mu\nu}) + 2cr_{\mu\nu}\frac{\partial g_{\mu\nu}(r_{\mu\nu})}{\partial r_{\mu\nu}}\delta(S_\mu, -S_\nu)]$$

If we equate the above equation to a constant, $E = c\sum_\alpha k_\alpha$, we obtain differential equations for the functions f, g

$$[A.7]\qquad \begin{aligned} f(r) + r\frac{\mathrm{d}f}{\mathrm{d}r} &= -\frac{U(r)}{c}\\ g_{\mu\nu}(r) + r\frac{\mathrm{d}g_{\mu\nu}}{\mathrm{d}r} &= -\frac{v(r)}{2c}, (S_\mu = -S_\nu)\\ g_{\mu\nu}(r) &= -\frac{v(r)}{2c}, (S_\mu = S_\nu)\end{aligned}$$

It is seen that the one- and the "opposite S" two-body differential equations are essentially the same. It is easily verified that a particular solution of the differential equation

$$[A.8]\qquad f(r) + r\frac{\mathrm{d}f}{\mathrm{d}r} = y(r) \equiv \sum_{k=-\infty}^{k=+\infty} a_k r^k$$

is given by

$$[A.9]\qquad f(r) = a_{-1}\frac{\ln r}{r} + \sum_{k\neq -1}\frac{1}{(1+k)}a_k r^k$$

The verification is elementary. For the series in eq. [A.9],

$$[A.10]\qquad \begin{aligned} f(r) + r\frac{\mathrm{d}f}{\mathrm{d}r} &= a_{-1}\frac{\ln r}{r} + ra_{-1}\frac{1}{r^2} - ra_{-1}\frac{\ln r}{r^2}\\ &+ \sum_{k\neq -1}\frac{a_k r^k + ka_k r r^{k-1}}{(1+k)} = a_{-1}\frac{1}{r} + \sum_{k\neq -1} a_k r^k = y(r)\end{aligned}$$

The solution to the homogenous differential equation

$$[A.11]\qquad f(r) + r\frac{\mathrm{d}f}{\mathrm{d}r} = 0$$

is given by $f(r) = \frac{\lambda}{r}$, and this solution can be added to the particular solution in eq. [A.9]. The effect of including this arbitrary term amounts to a phase factor in the overall wave function: $\lambda x\alpha/r\alpha = \pm\lambda$ for f, and $\lambda(x_\mu - x_\nu)/r_{\mu\nu} = \pm\lambda$ for g. The phase factor would change sign discontinuously for each coincidence of the particles, and this pathological behavior does not seem desirable. For this reason, it seems best to take $\lambda = 0$, as was assumed in eq. [26] in the body of the text.

In conclusion, for any potential expressed as a power series expansion, it is easy to obtain the exact solution of the one-component many-body differential equation.

Catalyzed β scission of a carbenium ion III — Scission observed in ab initio molecular dynamics simulations

Greg M. Berner and Allan L. L. East

Abstract: The β scission (cracking) of branched carbenium ions have been observed in molecular dynamics simulations, possibly for the first time. Simulations were performed with molecular dynamics based on PW91 density functional theory, and which included three-dimensional periodic boundary replication of the unit cell to mimic long-range bulk effects. A rising-temperature algorithm was used to encourage reaction within the narrow time windows ($\sim$10 ps) of the simulations. Twenty-eight simulations were performed, featuring alkyl ions in three different catalytic systems: the ionic liquid, $[(C_5H_5NH^+)_5(Al_2Cl_7^-)_6]^-$, the chabazite zeolite, $[AlSi_{23}O_{48}]^-$, and the chabazite zeolite, $[Al_4Si_{20}O_{45}(OH)_3]^-$. Twenty-four runs began with unbranched *sec-n*-alkyl ions, but only one exhibited β scission, and only after branching to a tertiary ion and under extreme heating. In contrast, the four simulations that began with branched alkyl ions were all successful in demonstrating β scission at lower temperatures: 2,4,4-trimethyl-2-pentyl ion and 2,4-dimethyl-2-hexyl ion in each of the first two catalysts. The lifetimes of desorbed alkyl ions in the chabazite models were < 5 ps at 1000–1500 K. The β scission results support the classical Weitkamp et al. (*Appl. Catal.* **1983,** *8,* 123) mechanism over the nonclassical Sie (*Ind. Eng. Chem. Res.* **1992,** *31,* 1881) and the chemisorping Kazansky et al. (*J. Catal.* **1989,** *119,* 108) mechanisms.

Key words: C–C bond fission, cationic β scission, carbenium ions, alkyl ions, protonated cyclopropane (PCP^+), catalysis, chloroaluminate, catalytic cracking mechanism.

Résumé : On a observé, peut être pour la première fois, une scission β (craquage) d'ions carbénium ramifiés dans des simulations de dynamique moléculaire. Les simulations ont été effectuées à l'aide de la dynamique moléculaire basée sur la théorie de la fonctionnelle de densité PW91 qui inclut une réplication tridimensionnelle de la frontière périodique de la cellule unitaire pour représenter les effets globaux à long terme. On a utilisé un algorithme avec température croissante pour encourager la réaction vers des fenêtres étroites de temps ($\sim$10 ps) des simulations. On a effectué vingt-huit simulations mettant en évidence des ions alkyles dans trois systèmes catalytiques différents, un liquide ionique, $[C_5H_5NH^+)_5(Al_2Cl_7^-)_6]^-$, la chabazite zéolithe, $[AlSi_{23}O_{48}]^-$ et la zéolithe chabazite, $[Al_4Si_{20}O_{45}(OH)_3]^-$. Vingt-quatre de ces simulations commençaient avec des ions linéaires alkyles secondaires, mais seulement un a présenté une scission β et uniquement après avoir ramifié la chaîne vers un ion tertiaire, avec un chauffage intense. Par ailleurs, les quatre simulations lancées avec des ions ramifiés ont toutes conduit à des scissions β, à des températures plus basses, dont l'ion 2,4,4-triméthylpent-2-yle et l'ion 2,4-diméthylhex-2-yle dans chacun des deux premiers catalyseurs. Les temps de vie des ions alkyles désorbés dans les modèles de la chabazite sont de < 5 ps à 1000–1500 K. Les résultats de scission β sont en accord avec le mécanisme classique de Weitkamp et al. (*Appl. Catal.* **1983,** *8,* 123) concernant le mécanisme non classique de Sie (*Ind. Eng. Chem. Res.* **1992,** *31,* 1881) et celui de chimisorption de Kazansky et al. (*J. Catal.* **1989,** *119,* 108).

Mots-clés : fission d'une liaison C–C, scission cationique β, ions carbénium, ions alkyles, PCP^+, catalyse, chloroaluminate, mécanisme de craquage catalytique.

Introduction

In petroleum cracking of aliphatic hydrocarbon feedstock, the dominant C–C-bond scission step is β scission of carbocations (carbenium ions). The 1949 mechanisms of Thomas[1] and Greensfelder et al.[2] assumed classical alkyl ions with a three-coordinate charged carbon atom and viewed primary carbocations as acceptable primary products of the scission. In the ensuing 60 years, primary carbocations have proven to be impossibly recalcitrant to observation, and in response to this "primary carbocation dilemma", several modern versions of the β scission mechanism have been proposed. Review articles in 2001[3] and 2007[4] have expressed chagrin that the proper mechanism has still not been resolved. In this paper, we address this problem by reporting the results of ab initio molecular dynamics simulations, which shed light on which of these proposals is most likely to be correct.

In 1983, Weitkamp, Jacobs, and Martens (WJM)[5] proposed a mechanism variation (Fig. 1, top) that kept the concept of classical carbocations, but avoided the formation of

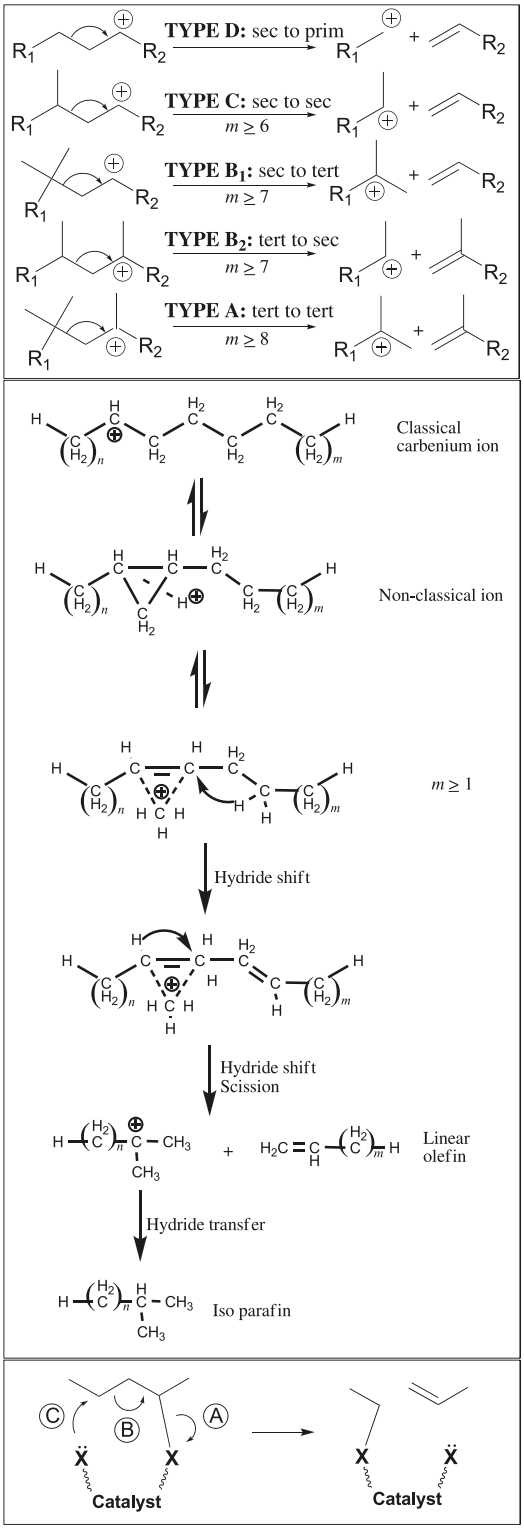
Fig. 1. Three commonly cited mechanisms for catalytic β scission. Upper: Weitkamp, Jacobs, and Martens classical mechanism,[5] where *m* is the minimum number of carbons needed in the alkyl ion. Middle: Sie PCP$^+$ mechanism.[6] Lower: Li and East's version[14] of Kazansky and Senchenya[10] and van Santen and co-workers[11] chemisorption mechanism, where A, B, and C are the electron rearrangement steps, which could be stepwise or concerted. The extra final step of hydride transfer in the Sie mechanism,[6] presumably from another alkane in a chain reaction, would be common to all three mechanisms.



primary carbocations by requiring *n*-alkyl ions to undergo skeletal branching first, so that β scission could begin with secondary or tertiary ions and lead directly to secondary or tertiary ions. Their scheme categorized the reactions by ion type, and helped to explain the absence of two-carbon fragments in cracking experiments. Although the classical mechanism for skeletal branching was also at odds with the primary carbocation dilemma, by 1983 there was a newer branching mechanism proposed by others that involved a nonclassical protonated cyclopropane (PCP$^+$) structure (see the Discussion section).

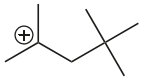
In 1992–1993, Sie published a series of three papers,[6–8] which criticized the WJM[5] classical scheme, suggesting that if PCP$^+$ structures exist for the branching step, then they should exist for the β scission step as well. The mechanism of the 1992 Sie paper[6] is the most detailed (Fig. 1, middle), with hydrogen–atom rearrangement steps, and features the product double bond forming outside of the PCP$^+$ structure. Far less steps are presented in the 1993 papers.[7,8] The Sie[6–8] mechanism has been quoted often.[3,4,9]

The third prominent variation has been the chemisorption hypothesis, put forward by Kazansky and Senchenya[10] and popularized by van Santen and co-workers.[11] In this hypothesis, the carbocations are thought to exist not as classical or nonclassical ions, but as alkyl substituents chemisorbed to the catalyst (typically an oxygen atom in an aluminosilicate zeolite). Such alkoxide or silyl-ether structures are the only forms of nonresonant alkyl ions observed in in situ NMR experiments.[12] This variation can avoid the primary carbocation dilemma because, shortly after desorption, β scission can proceed as an S_N2 reaction (Fig. 1, bottom): instead of β scission resulting in a primary alkyl fragment containing the gamma carbon atom, a nucleophilic site on the catalyst attacks the gamma carbon first, causing the β scission while preventing the formation of a primary alkyl fragment.

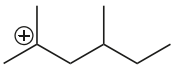
In the first two papers of this series,[13,14] we examined this third variation, because we recognized that all previous computational studies[15] were adversely affected by the computational expense required to calculate transition states correctly, and hence made unfortunate compromises. Our work entailed computational geometry-optimization studies of secondary carbenium ions ($C_5H_{11}^+$, $C_6H_{13}^+$) on aluminum-containing molecular fragments of varying sizes, thoroughly exploring the potential energy surfaces and using accurate transition-state algorithms. One of the major conclusions was that the mechanism tended to be two-step, with the initial step being desorption and the rate-limiting second step being S_N2 β scission. This conclusion opens the possibility that desorption might lead to the Sie[6–8] or WJM[5] mechanisms, instead of the S_N2 second step of the chemisorption mechanism.

Faced with multiple possibilities, we have switched tactics and turned to rising-temperature molecular dynamics (MD) simulations[16] based on PW91 density functional theory. The simulation should, in principle, reveal which of the three β-scission variations is most likely to occur. Use of ab initio MD simulation to explore mechanisms was promoted by Dupuis and co-workers.[17] The rising-temperature technique is a means of increasing the probability of observing a chemical "rare event" in the narrow molecular times of the simulation (typically 10 ps from a week of simulation).

Fig. 2. Octyl ions studied.



2,4,4-trimethylpent-2-yl cation



2,4-dimethylhex-2-yl cation

oct-4-yl cation

Although the simulated temperatures did get artificially high (sometimes over 2000 K), potentially opening up alternative high-barrier reaction possibilities, the processes with lower barriers remain orders of magnitude more probable. Furthermore, our simulations are incapable of producing homolytic C–C bond cleavage, because all electrons are required to be paired and hence unable to create radical products.

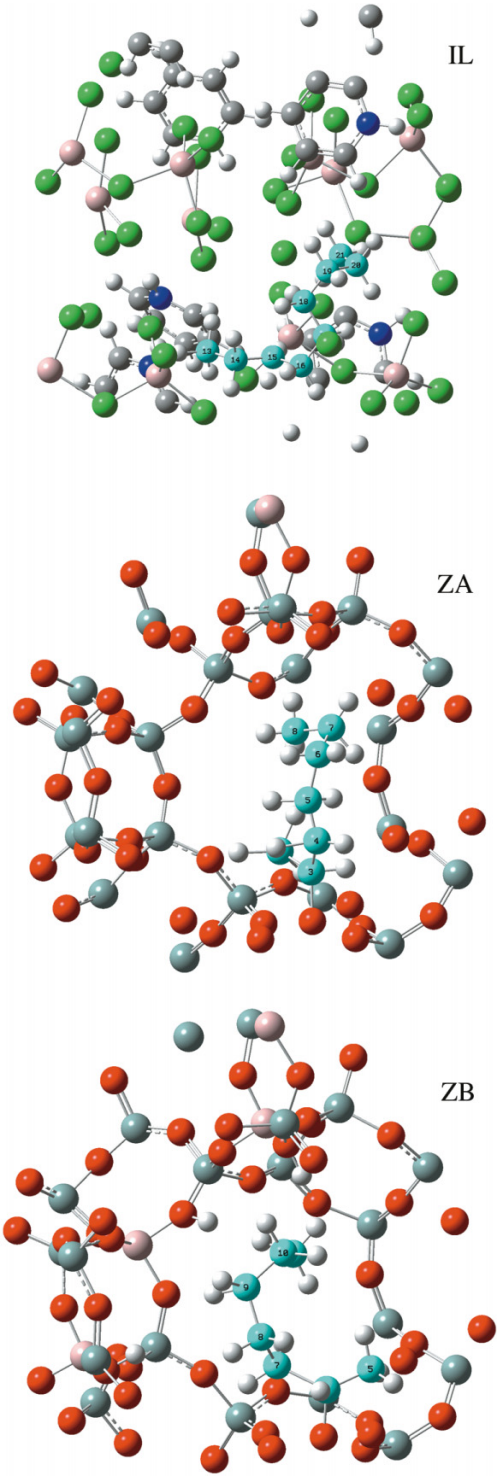
In this paper, we report the results of several simulations: five of *sec*-*n*-nonyl in the ionic liquid, $[(C_5H_5NH^+)_5(Al_2Cl_7^-)_6]^-$,[18] fifteen of *sec*-*n*-heptyl in chabazite, $[AlSi_{23}O_{48}]^-$,[19] two of *sec*-*n*-heptyl in chabazite, $[Al_4Si_{20}O_{45}(OH)_3]^-$, and a set of six from combining each of three octyl ion isomers (Fig. 2) with each of the first two catalysts. This final set of six include branched isomers to better test the WJM[5] mechanism. The ionic liquid simulations were motivated by the experiments of Johnson and co-workers,[18] who demonstrated that this particular liquid could crack nonane.

Methods

The ab initio molecular dynamics (AIMD) simulations were performed with the Vienna ab initio simulation package (VASP).[20] The level of theory was PW91, a gradient-corrected density functional theory (GGA DFT).[21] The calculations used Blöchl's[22] projector augmented wave technique,[23] applied to pseudopotentials appropriate for GGA DFT,[24,25] and a plane-wave basis set with various choices of the energy cutoff parameter ENMAX (350–500 eV). Simulations were performed with the NVT (canonical) ensemble, using a Nosé[26] thermostat set for a thermal oscillation every 40 timesteps (SMASS = 0), and a Verlet velocity algorithm[27] with a timestep of 1 fs. These condensed-phase calculations employed periodic replication of a unit cell, and calculations were restricted to the gamma point. The unit cell contained catalysts of an overall –1 charge, to counterbalance the positive charge of the alkyl ion. Each atom had an isotope-averaged mass (e.g., 35.453 amu for Cl), except for H (mass 1.000 amu).

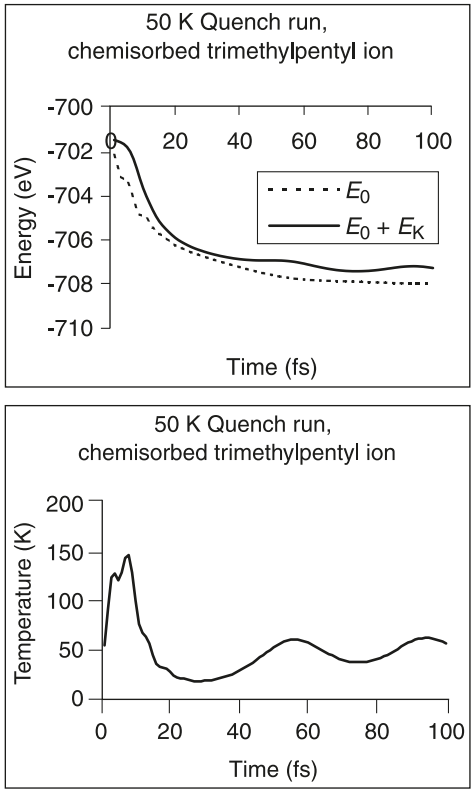
Simulations were performed of various C_7–C_9 alkyl ions in three different condensed-phase catalytic environments (Fig. 3). System IL was an ionic liquid, consisting of five pyridinium cations ($C_5H_5NH^+$) and six $Al_2Cl_7^-$ ions. Sys-

Fig. 3. Snapshot of parent geometries (within the replicated cell) used for simulations. Atom colour scheme: C atoms of alkyl ion, light blue; C atoms of pyridinium ions, light grey; N atoms of pyridinium ions, dark blue; Cl atoms, green; H atoms, white; O atoms, red; Si atoms, dark grey; Al atoms, pink.



tems ZA and ZB were based on chabazite zeolite; our unit cell contains $Si_{24}O_{48}$ (twice the true unit cell of chabazite). System ZA had an Al^- substituted in the place of one Si atom. System ZB was derived from system ZA by the sub-

Fig. 4. Energy (upper plot) and temperature (lower plot) vs. time for the 50 K quench run of trimethylpentyl ion on chabazite ZA. E_0: potential energy for nuclear motion. $E_0 + E_K$: total internal energy. Regular nuclear speeds (temperature plot) are achieved after ~50 fs.



stitution of three Si–O diatom units with Al–O–H units. The purpose of system ZB was to increase the number of Brønsted acid sites, because simulations with system ZA tended to quickly result in deactivation of the carbocation to an alkene, thereby requiring reactivation by a Brønsted site. Details on the initial structures can be found in Appendices A–C.

Results

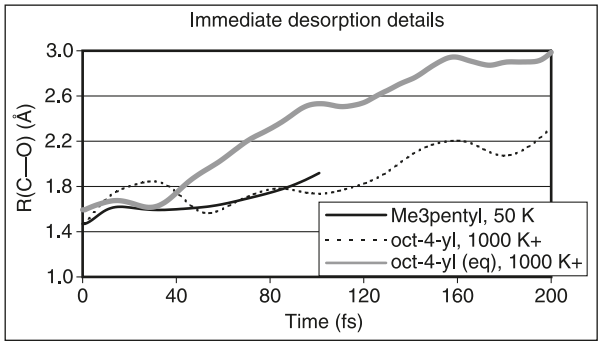
Preparatory runs

Equilibration runs were performed as described in Appendices A–C. For the zeolite simulations, attempts at equilibrating chemisorbed alkyl ions normally resulted in immediate desorption. We present some results from our preparatory runs to reassure the reader that we did ensure that immediate desorption was not the result of poor initial geometries.

For the tertiary 2,4,4-trimethylpent-2-yl ion, in system ZA, a quick quench run was performed at 50 K for only 100 fs. The choice of initial chemisorbed structure did not produce unreasonable velocities at the start (Fig. 4), but desorption began regardless, after only one C–O vibrational period (Fig. 5). Hence, one cannot equilibrate tertiary carbocations chemisorbed to chabazite with PW91-based simulations.

For *n*-alkyl secondary ions, which should bind more strongly than tertiary ions, we could maintain chemisorption at temperatures below ~1000 K, but above 1000 K desorption would occur within 1 ps. For instance, when our simulation of *n*-4-octyl chemisorbed on system ZA showed rapid desorption upon simulation above 1000 K, we tried a 4000 fs chemisorption-maintaining pseudo-equilibration run, rising in temperature from 200 to 600 K, before relaunching the production run from 1000 K. This relaunched production run produced desorption at t = 50 fs, earlier than in the original, nonequilibrated run (Fig. 5).

Fig. 5. Plot of chemisorption bond lengths to chabazite ZA vs. time: an equilibrated run (dashed line), a pre-equilibrated run (thick line), and the 50 K quench run for the tertiary trimethylpentyl ion (black line), demonstrating rapid desorption in each case.



Production runs: unbranched alkyl ions

Twenty four of our 28 production runs began with *sec-n*-alkyl ions: six with desorbed ions in ionic liquid (IL) (Table 1, run 1, and Table 2) and 18 with chemisorbed ions on chabazite systems ZA and ZB (Tables 3 and 4, and Table 1, run 2). Of these 24 runs, β scission was observed in only the very first one: the ion branched first[17] and then, after taken to a very high temperature, performed a very rare tertiary-to-primary β scission. Although the other 23 runs did not produce β scission, there is useful information to be gleaned from them. One general observation from these other 23 runs was that the ultimate fate of the ions was deactivation: the loss of H^+ back to the catalyst to generate an alkene. On longer timescales, these C_7–C_9 alkenes could be reactivated by the Brønsted catalyst, but such a reactivation was not observed in the small (10^{-11} s) timescales of the simulations, even in system ZB, presumably because reactivation is a neutral–neutral bimolecular reaction requiring a specific low-probability collision.

Of the six runs in system IL, three resulted in branching before deactivation occurred. Several 1,2-H-shifts were observed, as were episodes of short-lived (~100 fs) PCP^+ structures, particularly at temperatures above 1000 K. Secondary carbocations tended to live for 1–4 ps in these rising-temperature simulations, until temperatures reached 1800–2000 K. Branching occurred between 1300 and 2000 K, after which the tertiary carbocations tended to live another 1–4 ps, until temperatures reached ~2500 K. The stability of these ions in system IL at constant temperatures was not tested: at experimental temperatures (~373 K) these ions would be expected to live longer, although not indefinitely, as carbocations would undergo oligomerization and cracking cycles until they either reach their most stable form (*t*-butyl ions) or become deactivated hydrocarbons that would settle into an organic layer.

Table 1. The results of simulations of various octyl ions.

Run	Baseline temperature (K)	Time (fs)	Event description
1. Oct-4-yl cation, system IL	1000 + 0.25/fs (to 2000)	1225	1,2-Propyl-shift, sec → prim
		1250	1,3-H-shift, prim → sec
		1695	1,2-Methyl-shift, sec → sec
		3590	1,2-H-shift, sec → prim
		3650	1,2-Hexyl-shift, prim → prim
		3730	1,6 H-shift (ene + pentavalent C)
		3830	Loss of H_2 (3-methylhept-6-en-2-yl)
		4010	Deactivation
2. Oct-4-yl cation, system ZA	1000 + 0.25/fs (to 2000)	135	Desorption
		3045	Deactivation
3. 2,4-Dimethylhex-2-yl cation, system IL	1000 + 0.25/fs (to 2000)	2250	1,2-H-shift, tert → sec
		2380	1,2-H-shift, sec → tert
		2790	1,2-H-shift, tert → sec
		2850	1,2-Ethyl-shift, sec → sec
		3468	***β Scission, sec → sec***
		3858	Deactivation
4. 2,4-Dimethylhex-2-yl cation, system ZA	1000 + 0.25/fs (to 2000)	20	Desorption
		365–546	Attempted β scission
		875–1005	Attempted β scission
		1905	***β Scission, tert → sec***
		3735	H transfer, sec → tert
5. 2,4,4-Trimethylpent-2-yl cation, system IL	600 + 0.2/fs (to 2200)	6880	***β Scission, tert → tert***
		7060	Deactivation
6. 2,4,4-Trimethylpent-2-yl cation, system ZA	300 + 0.25/fs (to 1300)	1	Desorption
		2317	***β Scission, tert → tert***
		3000	H transfer, tert → tert

Note: In each run, ENMAX = 350 eV. Deactivation refers to the loss of H^+ to the catalyst. H transfer refers to the transfer between hydrocarbon fragments. The numerous 1,2-H-shifts that did not result in a change of ion type were not reported.

Table 2. The results of simulations of non-3-yl ion in system IL (ionic liquid).

Run	Baseline temperature (K)	Time (fs)	Event description[a]
1	973 + 0.2/fs	5000	Branched, sec → tert
		7705	***β Scission, tert → prim***
		7775	Deactivated
2	973 + 0.2/fs	4248	Deactivated
3	1773 + 0.1/fs	145	Branched, sec → tert
		5583	Deactivated
4	1773 + 0.2/fs	1630	Deactivated
5	1773 + 0.2/fs	1380	Deactivated

Note: Each run was continued until deactivation occurred, and ENMAX = 400 eV except for runs 1 and 5 (500 eV).

[a]At these elevated temperatures, H-shifts were too numerous to report.

The 18 runs with the model zeolite systems, ZA and ZB, were begun with the alkyl ions in the chemisorbed state, to test the chemisorption hypothesis (Fig. 1), but the ion either stayed chemisorbed (three runs) or desorbed without performing the S_N2 β scission step (15 runs). Deactivation generally occurred at lower temperatures (1000–1800 K) than with the ionic liquid catalyst (>1700 K), because the zeolite is a stronger conjugate base than the ionic liquid, and this early deactivation is likely why neither cracking nor branching was observed in any of these 18 runs. In Table 3, several constant-temperature runs were performed to lengthen times before deactivation, but these longer times were not long enough to witness any branching or β scission events. The longest lifetime observed for a desorbed alkyl ion inside chabazite was 4.7 ps (Table 3, runs 3e and 4a).

Production runs: branched alkyl ions

In contrast to the 24 *sec-n*-alkyl runs, all four of the branched-alkyl runs succeeded in performing β scission, and are reported as the last four runs of Table 1. We make some minor remarks first. In Table 1, run 3, the starting tertiary ion spent some time as a secondary ion, during which an ethyl shift occurred before the β scission event. In Table 1, run 4 there were two unsuccessful attempts at β scission before the successful one occurred; this is demonstrated in Fig. 6 as a plot of the β C–C bond distance vs. time. In Table 1, runs 4 and 6, there were hydrogen transfers between the two product fragments, after β scission, the probability of which was likely enhanced by the solid pore structure of the zeolite, which kept the two fragments in close proximity.

Most importantly, in all four cases, the β scission mechanisms observed were classical WJM[5] ones from desorbed ions. No attempts at chemisorption-style S_N2 β scission were observed. Although occasional PCP^+ structures were observed for secondary alkyl ions during the simulations, none existed during the β scission events: in Fig. 7 we plot the critical C–C–C angle during the C–C bond scission events in these four runs, and the angle is never near the $\sim 80^\circ$ expected for a PCP^+ structure. The observed β-scission reactions are summarized in Table 5.

Table 3. The results of simulations of chemisorbed hept-2-yl ion in system ZA (zeolite).

Run	Baseline temperature (K)	Event description
Set I		
1	298	Stayed chemisorbed
2	300 + 0.2/fs (to 1100)	Stayed chemisorbed
3 (from 2)	1100 + 0.2/fs	Desorbed 770 fs, 3,2-H-shift 1600 fs, deactivated 1990 fs
3b (from 2)	1100 + 0.2/fs	Desorbed 50 fs, deactivated 500 fs
3c (from 2)	1000	Stayed chemisorbed
Set II (from 3c)		
3d[a]	1000	Desorbed 535 fs, deactivated 1670 fs
3f[a]	1100	Desorbed 500 fs, 3,2-H-shift 2035 fs, 2,3-H-shift 2065 fs, deactivated 2790 fs, reactivated 2920 fs, 3,2-H-shift 2935 fs, re-chemisorbed 3320 fs
3g[a]	1200	Desorbed 510 fs, 3,2-H-shift 1110 fs, 4,3-H-shift 1375 fs, deactivated 1465 fs
3e[a]	1300	Desorbed 500 fs, 3,2-H-shift 1220 fs, 5,3-H-shift 2340 fs, 6,5-H-shift 3440 fs
Set III (from 3c)		
4d[b]	1000	Desorbed 3150 fs, deactivated 3340 fs
4f[b]	1100	Desorbed 1200 fs, deactivated 1630 fs
4g[b]	1200	Desorbed 2080 fs, deactivated 2200 fs
4e[b]	1300	Desorbed 430 fs, deactivated 660 fs
Set IV (from 3e)		
4a[c]	1300	Deactivated 1250 fs
4b[d]	1300	Deactivated 2170 fs

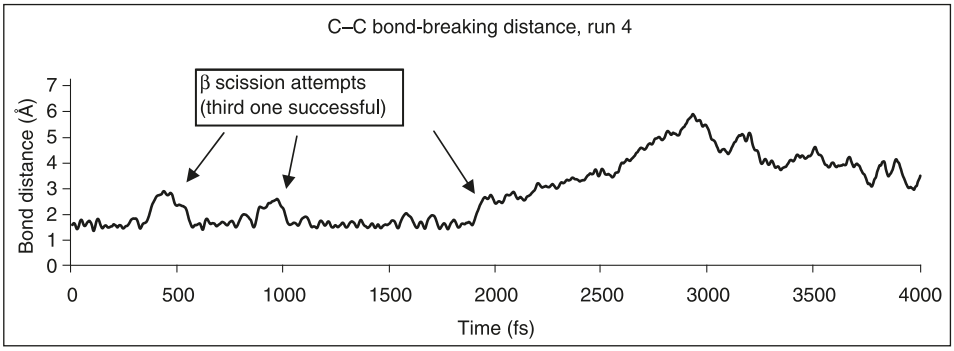
Note: In each run, ENMAX = 350 eV and the length of the runs were 4000 fs.
[a]Set II runs began with the last positions and velocities of run 3c.
[b]Set III runs began with the last positions of run 3c, but with fresh Boltzmann velocities each run.
[c]Run 4a began with the last positions and velocities of run 3e.
[d]Run 4b began with the last positions of run 3e, but with fresh Boltzmann velocities.

Table 4. Results of simulations of chemisorbed hept-2-yl ion in system ZB (zeolite).

Run	Baseline temperature (K)	Length of simulation (fs)	Event description
1	1500	12000	Desorbed 140 fs, 3,2-H-shift 510 fs, deactivated 520 fs
1b	1900	4000	Desorbed 120 fs, 1,2-H-shift 250 fs, deactivated 267 fs, reactivated 285 fs, deactivated 380 fs

Note: In each run, ENMAX = 350 eV.

Fig. 6. A plot of the rupturing C–C bond distance vs. time, Table 1, run 4 (dimethylhexyl ion, chabazite catalyst).

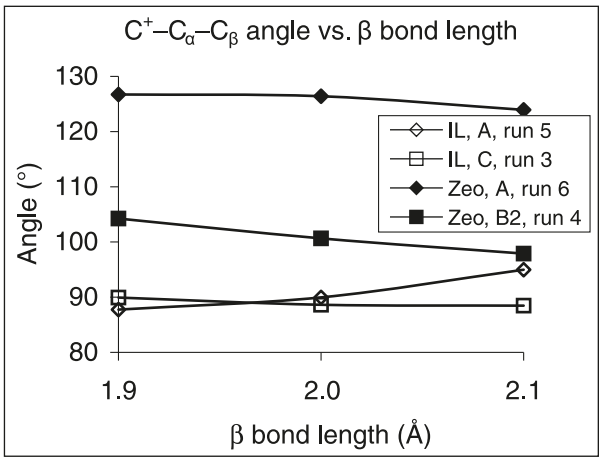


The use of artificially high temperatures does not bias the simulations against producing PCP^+ structures and Sie's[6–8] nonclassical mechanism; in fact, it produces more of these high-energy structures, but no β scissions resulted from them. The use of artificially high temperatures may bias the simulations against the chemisorption hypothesis, if it promotes desorption over S_N2 reaction, but our previous potential-energy-surface work[13,14] has already indicated that partial desorption is a commonly required step even at 0 K. Indeed, all the simulations are in accord with the WJM[5] scheme, in which desorbed and branched classical carbocations are the ones that undergo β scission.

Discussion

PCP^+ as an intermediate in *isomerizations* was proposed long ago, perhaps first by Nevell, de Salas, and Wilson,[28] who in 1939 described the possibility of an intermediate

Fig. 7. $C^+–C_\alpha–C_\beta$ bond angles during the four β scission events of Table 1. An expected angle for a β scission from a PCP^+ intermediate would be 80°, which was not observed.



"mesomeric" between the two classical carbocation intermediates that Meerwein and van Emster[29] had postulated for the Wagner–Meerwein rearrangement. In the Wagner–Meerwein rearrangement, the PCP^+ ring has four alkyl substituents (2,1,1 distribution). In 1943, in a general article on organic reaction rates, Eyring, Hulbert, and Harman[30] speculated that "triangular configurations" for carbocations should have low enough energies to explain 1,2-alkyl rearrangements, quoting the early calculations on H_3^+ by Hirschfelder,[31] which revealed a triangular minimum-energy structure. These two suggestions, plus knowledge of triangular Ag^+-bridged alkenes,[32] led Winstein and Trifan[33] in 1949 to draw a symmetric "alkyl-bridged" norbornyl carbocation intermediate to account for racemization of its substituted exo enantiomers. In this racemization, the PCP^+ ring has only three substituents (1,1,1 distribution). Brown[34] would later famously contest the symmetric PCP^+ structure in Winstein and Trifan's[33] case, arguing that it is a transition state but not an intermediate. However, quantum chemistry calculations since 1983[35,36] have demonstrated that the bare ion does indeed have the (symmetric) PCP^+ structure, and not a classical one as Meerwein[29] would have thought.

In the Wagner–Meerwein and norbornyl rearrangements, the three participating carbons in the PCP^+ ring are tethered in a tricyclic structure. In 1952, Stevenson et al.[37] extended the PCP^+ idea for acyclic alkyl ions, proposing such structures as intermediates for alkyl shifts that change the amount of branching in the ion. This required a 1,2-H-shift to take place "concomitantly" with the PCP^+ branching mechanism. McCaulay,[38] in 1959, published a rate study demonstrating much slower rates of rearrangements for those that change the extent of branching, and explained this with PCP^+ arguments, arguing that PCP^+ allows partial, but not complete, avoidance of primary carbenium ion structures in the branching cases. The role of the hydrogens during branching was correctly postulated by Edwards and Lesage[39] in 1963, with the mechanism determined to be two-step in 1996 calculations by Corma and co-workers[40] and verified in recent simulations.[17] A seminal demonstration of the importance of PCP^+ structures for nontethered alkyl ions was provided by the thorough ab initio study of $C_4H_9^+$ conformers by Sieber et al.[41]

Table 5. Summary of β-scission events observed in our simulations.

Type	Reaction	Catalyst system
tert→tert (A)		Ionic liquid Zeolite
tert→sec (B_2)		Zeolite
sec→sec (C)		Ionic liquid
tert→prim		Ionic liquid

In contrast, there is no such long history of PCP^+ as an intermediate in *β scission*. Sie[6] proposed this mechanism in 1992. We could not find any significant challenges to this proposal in the literature, but there are in fact three criticisms that can be made. First, the Sie[6–8] mechanism is faulty on theoretical grounds because, in the last structure leading to β scission (Fig. 1, middle panel, fourth structure down), there are two carbon atoms each sharing 10 electrons (third and fourth carbons from the right), a disastrous violation of the octet rule. Second, this mechanism describes not β scission, but γ scission, and is thus clearly contrary to experimental evidence. Third, Sie[6–8] had originally criticized the WJM[5] mechanism because it implied that cracking rates should be independent of the original extent of branching (WJM[5] assumed that branching occurs before cracking), in contrast to experiments such as those by Nace,[42] which appeared to show otherwise. However, the Nace[42] experiments that Sie[6–8] quoted were two-minute experiments on alkanes with a zeolite catalyst, and can be explained (as Nace[42] himself did) by realizing that the overall cracking rate is determined by the initiation step, not the branching or cracking steps. The two probable reasons why Nace's[42] heptamethylnonane cracked more slowly than *n*-hexadecane are that (*i*) each heptamethylnonane molecule had only seven attackable hydrogens (six secondary and one tertiary), while each *n*-hexadecane has 28 (all secondary), and (*ii*) the heptamethylnonane possessed three quaternary carbon atoms, giving the molecule sufficient bulk that it may have had difficulty fitting into the zeolite pores.

Since the current study demonstrates that simulations biased towards PCP^+ structures (due to elevated temperatures) do not use PCP^+ structures during β scission, it would seem appropriate to retire the Sie[6–8] mechanism altogether. Since the WJM[5] mechanism only applies to hexyl ions and larger, there may be a role for PCP^+ structures in the extreme high-temperature monomolecular cracking of pentyl and butyl ions, but certainly not with 10-valence-electron carbon atoms as Sie[6] had envisaged.

The chemisorption hypothesis, while unimportant for ionic liquids, cannot yet be ruled out for zeolites. The simulations employed here used elevated temperatures, which are biased toward desorption. There might also be possible bias against the chemisorption hypothesis due to the PW91 DFT approximation, which might underestimate desorption ener-

gies and overestimate S_N2-scission barriers due to omission of dispersion interactions; future research should test these possibilities. However, since computed activation enthalpy barriers[13,14] for the chemisorption mechanism are not much lower than those for full desorption, since entropy would favour desorption, and since our simulations gave four instances of unimolecular scission and none of bimolecular-S_N2 scission, it would seem to us that the S_N2-chemisorbed mechanism in Fig. 1 is on shakier ground than unimolecular WJM[5] mechanisms. We are now inclined to think that the chemisorbed state is a storage state for alkyl ions, but that β scission likely occurs in the desorbed state. Although in situ NMR experiments have failed to identify desorbed carbocations inside zeolites, the simulations offer the explanation that the desorbed alkyl ions simply have short (10^{-9} to 10^{-12} s) lifetimes relative to deactivation to alkenes (or chemisorption), and that cracking must occur during these brief but periodic lifetimes.

Conclusions

In 28 simulations of branched and unbranched alkyl (carbenium) carbocations in the presence of catalysts, only the branched alkyl ions performed β scission within simulation timescales, and all five performed straightforward bond breaking without involving chemisorbed or PCP^+ structures. Formation of a primary carbocation, which would have been produced by β scission of *sec-n*-alkyl ions, is simply not energetically favourable, and only occurred in one simulation at a very high temperature (>2500 K). Desorption was common to all simulations that began in the chemisorbed state, and the lifetimes of desorbed carbocations (relative to deprotonation by the zeolite) was <5 ps at 1000–2000 K. These new simulations give support for the WJM[5] classical mechanism, and not for the Sie[6–8] PCP^+ mechanism, which has several theoretical problems. The S_N2-chemisorbed and alternative PCP^+ mechanisms cannot yet be ruled out, but they should be considered targets for further scrutiny.

Acknowledgements

Grants were made available by the Natural Sciences and Engineering Research Council of Canada (NSERC) and the Canada Foundation for Innovation (CFI). All simulations were performed on a Parallel Quantum Solutions computer (56 processors) housed in the Laboratory of Computational Discovery at the University of Regina. J. Hafner and T. Bučko (University of Vienna) are thanked for for valuable advice, and T. Bučko for providing the chabazite input deck.

Appendix A. Starting geometries: system IL

An ionic liquid starting geometry was meticulously built by hand, with six $[C_5H_5NH]^+$ ions and six $[Al_2Cl_7]^-$ ions, in a cubic unit cell of width 13.72 Å to match the experimental density of 1.476 g/mL.[18] This was equilibrated at 373 K with a Nosé[26] thermostat for 1004 fs. Initially, the temperature rose to 1700 K due to the initial forces caused by the artificial geometry, but the thermostat quenched this within 50 fs, and the cell energy was steady from 200 fs onward. The velocities of all 126 atoms were plotted vs. time to ensure that no lingering "hot modes" existed after 1004 fs.

Table 2 runs: the structure from the first equilibration was taken, the cell width was expanded from 13.72 to 13.90 Å (a 4% volume expansion), and one $C_5H_5NH^+$ was replaced with a non-3-yl ion (Fig. 3, top). This corresponds to a nonyl ion concentration of 5% by weight; although the experiment of interest[18] used 25% nonane by weight, the nonane is insoluble in an ionic liquid until it is ionized, so that 5% nonyl ion concentration may be a reasonable estimate of reality. Four copies of this geometry file were made. The first copy was further equilibrated, for 3000 fs at 773 K followed by another 3000 fs at 973 K, and then split into two copies for trials 1 and 2, each starting at 973 K. Trials 3, 4, and 5 ignored the further 6 ps of equilibration and began from the three other original copies.

Table 1 runs: the structure from the first equilibration was taken, the cell width was expanded from 13.72 to 13.90 Å (a 4% volume expansion), one $C_5H_5NH^+$ was replaced with a 2,6-H-bridged $C_9H_{19}^+$ ion (originally intended for a different study), and this mixture was further equilibrated at 300 K for another 1000 fs (the $C_9H_{19}^+$ ion began and ended with the 2,6-H-bridge). The resulting structure was split into three copies, and in each the $C_9H_{19}^+$ ion was replaced with one of the three starting $C_8H_{17}^+$ ions of the current study. No further equilibration was performed, as the liquid quickly adjusted to the new ion in the first $\sim$100 fs of each of the rising-temperature runs in this study.

Appendix B. Starting geometries: system ZA

The chabazite structure, $[AlSi_{23}O_{48}]^-$, contains two unit cells of chabazite, with an Al atom substituted for a Si one, as described previously.[19] We received a pre-equilibrated one (containing a desorbed $C_4H_{11}^+$ ion) from Tomas Bučko (Vienna).

Table 3 runs: the desorbed $C_4H_{11}^+$ ion was replaced with a hept-2-yl ion chemisorbed to an oxygen atom neighbouring an Al atom of a replicated cell (Fig. 3, centre). The first run reported in Table 3 served as the equilibration run, but it possessed a continually rotating methyl group, so the second run was begun from the first but with velocities removed to reset the methyl rotation. All remaining runs in Table 3 are descendants of this second run.

Table 1 runs: the desorbed $C_4H_{11}^+$ ion was replaced with one of the three $C_8H_{17}^+$ ions of this study, chemisorbed to the same oxygen atom. Attempts at equilibrating the chemisorbed *sec*- and *tert*-alkyl ions failed to prevent immediate desorption (see text), so the rising-temperature production runs were run from the structures built.

Appendix C. Starting geometries: system ZB

Table 4 runs: the final heptyl ion/chabazite chemisorbed complex from run 3c of Table 3 was copied to a new input file, three Si atoms were replaced with Al atoms, and three H atoms were then added to O atoms bonded to these new Al atoms, creating three Brønsted AlOH sites within the same pore as the alkyl ion (Fig. 3, bottom). This structure was used as the starting structure for both runs in Table 4.

Validation of broken-symmetry density functional methods for the calculation of electron paramagnetic resonance parameters of dinuclear mixed-valence $Mn^{IV}Mn^{III}$ complexes

Sandra Schinzel and Martin Kaupp

Abstract: . The EPR parameters of a series of dinuclear manganese(III,IV) complexes with mono(μ-oxo), bis(μ-oxo), (μ-oxo)(μ-carboxylato), bis(μ-oxo)(μ-carboxylato), and (μ-oxo)bis(μ-carboxylato) bridges were studied by broken-symmetry density functional (DFT) methods. The influence of the exchange-correlation functional on the agreement with experiment has been evaluated systematically for **g** tensors; ^{55}Mn, ^{14}N, and ^{1}H hyperfine coupling tensors; and Heisenberg exchange couplings. ^{14}N and ^{1}H hyperfine couplings, ^{55}Mn hyperfine anisotropies, **g** tensors, and exchange couplings are well described by hybrid functionals with moderate exact-exchange admixtures such as B3LYP. The isotropic ^{55}Mn hyperfine couplings require larger exact-exchange admixtures. However, the errors of the B3LYP calculations are systematic and may be corrected by a constant scaling factor, providing good predictive power for a wide range of EPR parameters with broken-symmetry DFT and standard functionals. The influence of terminal and bridging ligands on structure, spin-density distributions, and EPR parameters are evaluated systematically. Computed hyperfine and **g** tensors are not covariant to each other. This may have consequences for spectra simulations. The nature of the broken-symmetry state and the origin of its spin contamination were analyzed by an expansion into restricted determinants, based on paired orbitals.

Key words: broken-symmetry density functional theory, electron paramagnetic resonance, **g** tensor, Heisenberg exchange coupling constant, hyperfine tensor, dinuclear manganese complex, paired orbital analysis.

Résumé : Faisant appel aux méthodes de la théorie de la fonctionnelle de la densité (TFD) à symétrie brisée, on a étudié les paramètres de résonance paramagnétique électronique (RPE) d'une série de complexes dinucléaires du manganèse(III,IV) comportant des ponts mono(μ-oxo), bis(μ-oxo), (μ-oxo)(μ-carboxylato), bis(μ-oxo)(μ-carboxylato) et (μ-oxo)bis(μ-carboxylato). On a évalué d'une façon systématique l'influence de la fonctionnelle d'échange de corrélation sur l'accord entre les valeurs expérimentales et calculées des tenseurs-**g**, des tenseurs de couplage hyperfin du ^{55}Mn, du ^{14}N, et du ^{1}H ainsi que des couplages d'échange d'Heisenberg. Les couplages hyperfins du ^{14}N et du ^{1}H hyperfine, les anisotropies hyperfines du ^{55}Mn, les tenseurs-**g** et les couplages d'échange sont bien décrits par les fonctionnelles hybrides avec un mélange d'échange exact modéré du type B3LYP. Les couplages hyperfins isotrope du ^{55}Mn nécessitent des mélanges d'échange exact plus importants. Toutefois les erreurs découlant d'une utilisation de calculs B3LYP sont systématiques et peuvent être corrigées par un facteur d'échelle constant, ce qui permet de profiter de bons pouvoirs de prédiction pour une grande variété de paramètres RPE avec la TFD à symétrie brisées et des fonctionnelles standard. On a évalué d'une façon systématique l'influence des ligands terminaux et ceux agissant comme pont sur la structure, les distributions de la densité de spin et les paramètres RPE. Les valeurs calculées pour les tenseurs-**g** et les propriétés hyperfines ne sont pas covariantes l'une par rapport à l'autre. Cette situation peut avoir des conséquences pour les simulations de spectres. On a analysé la nature de l'état de la symétrie brisée et l'origine de sa contamination du spin par une expansion dans des déterminants restreints, basée sur des orbitales en paires.

Mots-clés : théorie de la fonctionnelle de densité à symétrie brisée, résonance paramagnétique électronique, tenseur-**g**, constante de couplage d'échange d'Heisenberg, tenseur hyperfin, complexe dinucléaire du manganese, analyse d'orbitales par paires.

Introduction

The structure and electronic properties of multinuclear manganese complexes are of substantial importance in such diverse fields as molecular magnetism[1] and bioinorganic chemistry. Prominent examples for the latter area are the active sites of metalloenzymes,[2] in particular, the oxygen-evolving complex (OEC) of photosystem II.[3,4] The oxidation of two water molecules to provide the molecular oxygen of Earth's atmosphere is driven by sunlight and catalyzed by a tetranuclear manganese complex. Structure, protein environment, and function of the OEC have been at the focus of a

tremendous amount of research over the past 25 years. The methodology applied ranges from biochemical studies via X-ray diffraction,[5–7] X-ray absorption spectroscopies,[8,9] and IR and optical spectroscopies[10,11] to electron paramagnetic resonance (EPR) spectroscopy.[12,13] Significant progress has been made, yet many questions remain open, e.g., the precise position of the manganese atoms, the ligand sphere, or the nature of the bridging ligands. For many steps along the catalytic cycle of the OEC (and for dinuclear enzyme sites like catalase), EPR provides important information. Optimal use of EPR for structure elucidation should benefit greatly from the quantum chemical computation of EPR parameters for the evaluation of the validity of proposed molecular models. The development of suitable methodology applicable to such multinuclear mixed-valence manganese sites is thus highly desirable.

A main challenge for spin-coupled multinuclear transition metal systems is their energetically close-lying electronic levels. To correctly describe the antiferromagnetic couplings present in ground and excited statess would require a multideterminant based treatment for very accurate calculations. For the systems of interest, their size typically prohibits such a multideterminantal treatment at present. This holds in particular for the OEC. A cost-efficient approximate alternative in widespread use is broken-symmetry density functional theory (BS-DFT)[14,15] technique, where single-determinantal unrestricted Kohn–Sham (KS) wave functions are appropriately spin-projected[16,17] to simulate energy levels and spin-density distributions of the true antiferromagnetically coupled states. The main area of application of BS-DFT has been in the computation of Heisenberg exchange coupling constants that describe the spin couplings of the system. Yet, EPR parameters like hyperfine coupling constants (HFCs) or electronic **g** tensors also have been the focus of interest early on[18] (also see ref. 19).[19] Recently, Sinnecker et al.[20,21] have carried out BS-DFT based EPR parameter calculations (for **g** tensors and ^{55}Mn, ^{14}N, and ^{1}H HFCs) for the dinuclear Mn^{III}–Mn^{IV} complexes $[(dtne)Mn(\mu\text{-}O)_2(\mu\text{-}OAc)Mn]^{2+}$ and for a model of the superoxidized state of dimanganese catalase (**Mn-cat**). Here, we extend these important studies to a larger set of mixed-valence dinuclear Mn^{IV}–Mn^{III} complexes with different bridging and terminal ligand sets and to a wider selection of functionals, with the aim of validating the BS-DFT approaches for application to the OEC. In particular, we are interested in examining the effect of an exact-exchange (EXX) admixture in hybrid exchange-correlation functionals. This point has not yet been addressed in detail for BS-DFT calculations of EPR parameters, but it is deemed crucial for accurate predictions. Calculations on mononuclear Mn complexes suggest, for example,[22] that Mn HFCs and certain ligand HFCs require substantially larger EXX admixtures than provided by standard hybrid functionals like B3LYP. As we will also provide results for Heisenberg exchange coupling constants, we note in passing, in addition to the above-mentioned work of Sinnecker et al., the BS-DFT studies on the exchange couplings of dinuclear Mn^{III}–Mn^{IV} [23] and Mn^{IV}–Mn^{IV}[24] complexes (the vast literature on BS-DFT calculations of exchange couplings of di- and multi-nuclear transition metal complexes in general is outside the scope of this Introduction; some references will be given later in the paper). We compare different functionals and different spin-projection schemes[15,25] in this context and we also study the influence of bridging and terminal ligand sets.

Theoretical formalism and computational details

The theoretical background of EPR parameters and spin-projection techniques for simulations of spectra of multinuclear complexes are covered in detail in various text books.[17,26–31] Here, we summarize only the most relevant points.

g-Tensor calculations

The **g** tensor is provided as a correction to the free-electron value g_e (in ppt, i.e., in units of 1×10^{-3})

$$[1] \qquad \mathbf{g} = g_e 1 + \Delta g$$

with $g_e = 2.002\,319$. Up to the level of second-order perturbation theory based on the Breit–Pauli Hamiltonian, the g-shift Δg consists of three terms:

$$[2] \qquad \Delta g = \Delta g^{SO/OZ} + \Delta g^{RMC} + \Delta g^{GC}$$

of which the "paramagnetic" second-order spin-orbit/orbital Zeeman cross term, $\Delta g^{SO/OZ}$, dominates (except for extremely small Δg values).[31] The relativistic mass correction term Δg^{RMC} and the one-electron part of the gauge correction term Δg^{GC} are also included in our implementation[32,33] (also see refs. 34 and 35 for related implementations).

Hyperfine tensor calculations

In the usual nonrelativistic first-order approximation, isotropic hyperfine splittings $\mathbf{A}_{iso}(N)$ correspond to the Fermi-contact term $\mathbf{A}^{FC}$:

$$[3] \qquad \mathbf{A}_{iso}(N) = \mathbf{A}^{FC} = \frac{4\pi}{3}\beta_e\beta_N g_e g_N \langle S_Z\rangle^{-1} \sum_{\mu,\nu} P^{\alpha-\beta}_{\mu,\nu} \langle \varphi_\mu | \delta(\mathbf{R}_N) | \varphi_\nu \rangle$$

β_e is the Bohr magneton, β_N the nuclear magneton, g_N is the g value of nucleus N, $\langle S_Z\rangle$ is the expectation value of the z component of the total electronic spin, $P^{\alpha-\beta}_{\mu,\nu}$ is the spin density matrix, φ_μ and φ_ν are basis functions, $\mathbf{R}_N$ is the position vector of nucleus N, and the summation runs over all occupied molecular orbitals. The components $\mathbf{A}^{dip}_{ij}$ of the anisotropic tensor are given by

$$[4] \qquad \mathbf{A}^{dip}_{ij}(N) = \frac{1}{2}\beta_e\beta_N g_e g_N \langle S_Z\rangle^{-1} \times \sum_{\mu,\nu} P^{\alpha-\beta}_{\mu,\nu} \langle \varphi_\mu | \mathbf{r}_N^{-5} (\mathbf{r}_N^2 \delta_{ij} - 3\mathbf{r}_{N,i}\mathbf{r}_{N,j}) | \varphi_\nu \rangle$$

where $\mathbf{r}_N = r - \mathbf{R}_N$. In the rest of this section, we will refer to the metal hyperfine interaction and omit subscript N. The second-order perturbation treatment of refs. 36 and 37[36,37] is used to compute spin-orbit (SO) corrections to the hyperfine tensor (in this work, the corrections are only relevant for the metal HFC). At the coupled-perturbed KS level, the dominant SO correction term arises as a second-order cross term between the one- and two-electron SO Hamiltonian $\mathscr{H}^{SO}$ and the perturbed Fock operator F'

$$[5]\qquad \mathbf{A}^{\mathrm{SO}-I}_{K,uv} = \frac{1}{2}\alpha^4 g_e \gamma_K \frac{1}{2\langle S_Z\rangle}\left[\sum_k^{\mathrm{occ}(\alpha)}\sum_a^{\mathrm{virt}(\alpha)} \frac{\langle\psi_k^\alpha|h_u^{\mathrm{SO}}|\psi_a^\alpha\rangle\langle\psi_a^\alpha|F_v'|\psi_k^\alpha\rangle}{\varepsilon_k^\alpha - \varepsilon_a^\alpha} - \sum_k^{\mathrm{occ}(\beta)}\sum_a^{\mathrm{virt}(\beta)} \frac{\langle\psi_k^\beta|h_u^{\mathrm{SO}}|\psi_a^\beta\rangle\langle\psi_a^\beta|F_v'|\psi_k^\beta\rangle}{\varepsilon_k^\beta - \varepsilon_a^\beta}\right]$$

where α is the fine-structure constant; γ_K is the gyromagnetic ratio of the nucleus; h_u^{SO} are matrix elements of the spatial part of the spin-orbit Hamiltonian; $F_v' = (\ell_v/r^3) - \frac{2}{\alpha}a_0\sum_{k=1}^{n/2} K_v'$, where (ℓ_v/r^3) is the paramagnetic nuclear-spin electron-orbit (PSO) operator, K_v' is a component of the response exchange operator, and a_0 is the weight of HF exchange depending on the specific hybrid functional used (see ref. 38 for a related simultaneous CPKS implementation and also refs. 36 and 37 for references to earlier work); ψ^σ and ε^σ are spin-polarized KS orbitals and orbital energies, respectively. GGA or LDA functionals lead to an uncoupled DFT (UDFT) treatment for this second-order term ($a_0 = 0$).

Spin-projection techniques

The Heisenberg exchange coupling constant J describes the magnetic coupling between localized spins in the Heisenberg Hamiltonian

$$[6]\qquad \widehat{H}_{HDvV} = -2J\boldsymbol{S}_A\boldsymbol{S}_B$$

where $\boldsymbol{S}_A$ and $\boldsymbol{S}_B$ are spins localized on centers A and B, respectively.

Next, we compare two different spin-projection schemes: Noodleman's[15] broken-symmetry expression for weakly coupled centers provides J as

$$[7]\qquad J = -\frac{E_{hs} - E_{bs}}{4S_AS_B}$$

where E_{hs} and E_{bS} are the energies of the high-spin and broken-symmetry spin states, respectively, and S_A and S_B are the individual spins. Yamaguchi and co-workers[25] suggested using

$$[8]\qquad J = -\frac{E_{hs} - E_{bs}}{\langle\widehat{S}^2\rangle_{hs} - \langle\widehat{S}^2\rangle_{bs}}$$

where $\langle\widehat{S}^2\rangle_{hs}$ and $\langle\widehat{S}^2\rangle_{bs}$ are the computed total spin angular momentum expectation values for the high-spin and broken-symmetry spin states, respectively. This scheme is supposed to be independent of the bonding situation and hence usable for any coupling strength.

For the evaluation of the **g** tensor, two separate DFT calculations were carried out, from which the **g** tensors of the high-spin state ($\mathbf{g}_{hs}$) and of the broken-symmetry doublet configuration ($\mathbf{g}_{bs}$) are obtained. Spin-projection schemes give access to the **g** tensor site values ($\mathbf{g}_i$) of the exchange-coupled Mn^{III}–Mn^{IV} complex ($M_S^{hs} = S_A + S_B$, $M_S^{bs} = S_A - S_B$)[17]

$$[9]\qquad \mathbf{g}_1 = \frac{1}{2S_1}(\mathbf{g}_{hs}M_S^{hs} + \mathbf{g}_{bs}M_S^{bs})$$

and

$$[10]\qquad \mathbf{g}_2 = \frac{1}{2S_2}(\mathbf{g}_{hs}M_S^{hs} + \mathbf{g}_{bs}M_S^{bs})$$

Following this approach, the effective **g** is given by[39]

$$[11]\qquad \mathbf{g} = c_1\mathbf{g}_1 + c_2\mathbf{g}_2 \frac{c_1c_2}{5J}(\mathbf{g}_1 - \mathbf{g}_2)[(3c_1+1)\cdot\mathbf{D}_1 - (3c_2+1)\cdot\mathbf{D}_2]$$

where c_i is the spin projection coefficient, $\mathbf{D}_1$ and $\mathbf{D}_2$ are site zero-field splitting tensors.

In eq. [11] the spin projection coefficient is

$$[12]\qquad c_i = \frac{S(S+1) + S_i(S_i+1) - S_j(S_j+1)}{2S(S+1)}$$

For dinuclear Mn^{III}–Mn^{IV} complexes this gives $c_1 = 2$ (Mn^{III}, d^4) and $c_2 = -1$ (Mn^{IV}, d^3). In view of the large exchange coupling ($J > 100$ cm^{-1}) and relatively small zero-field splitting (<5 cm^{-1}),[39,40], the ZFS contributions may be neglected,[20] and eq. [11] then reduces to

$$[13]\qquad \mathbf{g} = c_1\mathbf{g}_1 + c_2\mathbf{g}_2$$

The hyperfine site values A_i^{eff} for a dinuclear Mn^{III}–Mn^{IV} complex are given as[39]

$$[14]\qquad A_1^{\mathrm{eff}} = c_1\mathbf{a}_1 - \frac{\mathbf{a}_1}{5J}c_1c_2[(3c_1+1)\cdot\mathbf{D}_1 - (3c_2+1)\cdot\mathbf{D}_2]$$

$$[15]\qquad A_2^{\mathrm{eff}} = c_2\mathbf{a}_2 - \frac{\mathbf{a}_2}{5J}c_1c_2[(3c_1+1)\cdot\mathbf{D}_1 - (3c_2+1)\cdot\mathbf{D}_2]$$

where $\boldsymbol{a}_i$ are intrinsic hyperfine tensors (site tensors).

Again, neglecting the ZFS contributions, eqs. [14] and [15] can be simplified to

$$[16]\qquad A_1^{\mathrm{eff}} = c_1\mathbf{a}_1$$

and

$$[17]\qquad A_2^{\mathrm{eff}} = c_2\mathbf{a}_2$$

In our analysis, we have not considered double-exchange interactions within the effective spin Hamiltonian. While these can, in principle, affect the EPR parameters of mixed-valence complexes mainly via vibronic coupling,[41,42] the necessary computations are outside the scope of the present work (see ref. 43 for a computational study of double exchange for energies of a smaller Mn^{III}–Mn^{IV} model system). In the analyses of the experimental EPR spectra for the present type of Mn^{III}–Mn^{IV} systems, double exchange has also generally been neglected. This is justified by the rather large antiferromagnetic couplings, which suggest relatively large energy differences between the lowest excited states and the ground state.[44]

Paired-orbital analysis of the BS-state KS wave functions

Based on the paired-orbital (PO) transformation,[45] it is possible to analyze the nature of the BS-KS wave function more closely. The magnetically active orbitals may already

be identified by computing the natural orbitals (NOs) of the system. These orthogonal NOs may be subsequently transformed to POs, where corresponding magnetic pairs are identified by their small finite (non-integer) overlap. In particular, the origin of the spin contamination may be traced back to a limited number of PO pairs, following an expansion of the unrestricted wave function ψ^{U} into quasi-restricted determinants in the PO basis:[46,47]

$$[18] \qquad \Psi^{U} = C^0 D^0 + \sum_{i=1}^{k} C_i^1 D_i^1 + \sum_{i<j}^{k} C_{ij}^2 D_{ij}^2 + \ldots + C^k D^k$$

where C_i is the expansion coefficient, k is the number of corresponding orbitals, and D is the set of restricted determinants obtained by substitutions of "occupied" by "virtual" POs.[46]

Computational details

Structure optimizations and KS wave function computations were done with the Turbomole code (revisions 5.8 and 5.9.1, the latter locally modified to allow the use of custom-made hybrid functionals).[48] For catalase, initial coordinates were taken from crystallographic studies of ref. 49. To construct the model **Mn-cat**,[21] histidine residues were substituted by methyl imidazole and glutamates by acetate. Structure optimizations were done at the B3LYP/SVP level,[50–52] using unrestricted KS wave functions. Structures of both BS and HS solutions have been fully optimized.

Subsequent unrestricted KS single-point calculations used a 9s7p4d all-electron manganese basis set (designed for hyperfine calculations[50,52–54]) and flexible IGLO-II[55,56] basis sets for the ligand atoms. Different exchange-correlation functionals were compared (*i*) the BLYP[50,51] GGA functional; the hybrid functionals (*ii*) B3LYP[50,51] with 20% exact exchange and (*iii*) BHLYP[50,57] with 50% exact exchange; as well as the custom-made hybrid functionals (*iv*) B-XXLYP with XX = 60%, 70%, 80%, or 90% exact exchange (100% – XX% E_X^{Slater}, 100% – XX% ΔE_x^{B88}, and E_c^{LYP}). Mulliken spin densities were used to characterize the broken-symmetry and high-spin states.

The unrestricted KS orbitals were transferred to the MAG-Respect property package[58] by suitable interface routines. The atomic mean-field approximation (AMFI)[59,60] was used to compute the matrix elements of the Breit–Pauli SO operator for **g** tensors and SO corrections to the Mn hyperfine tensors.

The PO analyses were done with the UHF decomposition code of Zilberberg and Ruzankin[46] and Zilberberg et al.[47] based on a Gaussian03[61] single-point calculation at the B3LYP[50,51] DFT level with the extended basis set described earlier.

Figure 1 shows the labels of the core atoms (Mn, O) of the investigated model systems $[LMn(\mu\text{-}O)MnL]^{3+}$ (**1-(μ-O)**, L = *N*,*N*-bis(2-pyridylmethyl)-*N*′-salicyliden-1,2-diaminoethane); $[(bipy)_2Mn(\mu\text{-}O)_2Mn(bipy)_2]^{3+}$ (**2-(μ-O)$_2$**, bipy = 2,2′-bipyridine); $[(phen)_2Mn(\mu\text{-}O)_2Mn(phen)_2]^{3+}$ (**3-(μ-O)$_2$**, phen = 1,10-phenanthroline); $[(dtne)Mn(\mu\text{-}O)_2(\mu\text{-}OAc)Mn]^{2+}$ (**4-(μ-O)$_2$(μ-OAc)**, dtne = 1,2-bis(1,4,7-triazacyclonon-1-yl)ethane); $[(tacn)Mn_2(\mu\text{-}O)_2(\mu\text{-}OAc)(tacn)]^{2+}$ (**5-(μ-O)$_2$(μ-OAc)**, tacn = 1,4,7-triazacyclononane); $[(tacn)Mn(\mu\text{-}O)(\mu\text{-}OAc)_2Mn(tacn)]^{3+}$ (**6-(μ-O)(μ-OAc)$_2$**); and **Mn-cat** (a previously studied model[21] for the superoxidized state of dimanganese catalase). The two systems **4-(μ-O)$_2$(μ-OAc)**[20] and **Mn-cat**[21] are those investigated in previous computational studies by Sinnecker, Neese, and co-workers.

Results and discussion

For all seven dinuclear Mn^{IV}–Mn^{III} complexes (Fig. 1), we compare the results of structure optimization in the HS and BS states. For each parameter (Heisenberg exchange coupling, **g** tensors, and ^{55}Mn, ^{14}N, and ^{1}H HFC constants) the dependence on an exact-exchange admixture are discussed. The influence of terminal ligand size and of the bridging ligand sets are studied for Heisenberg exchange couplings and for the ^{55}Mn HFC constants.

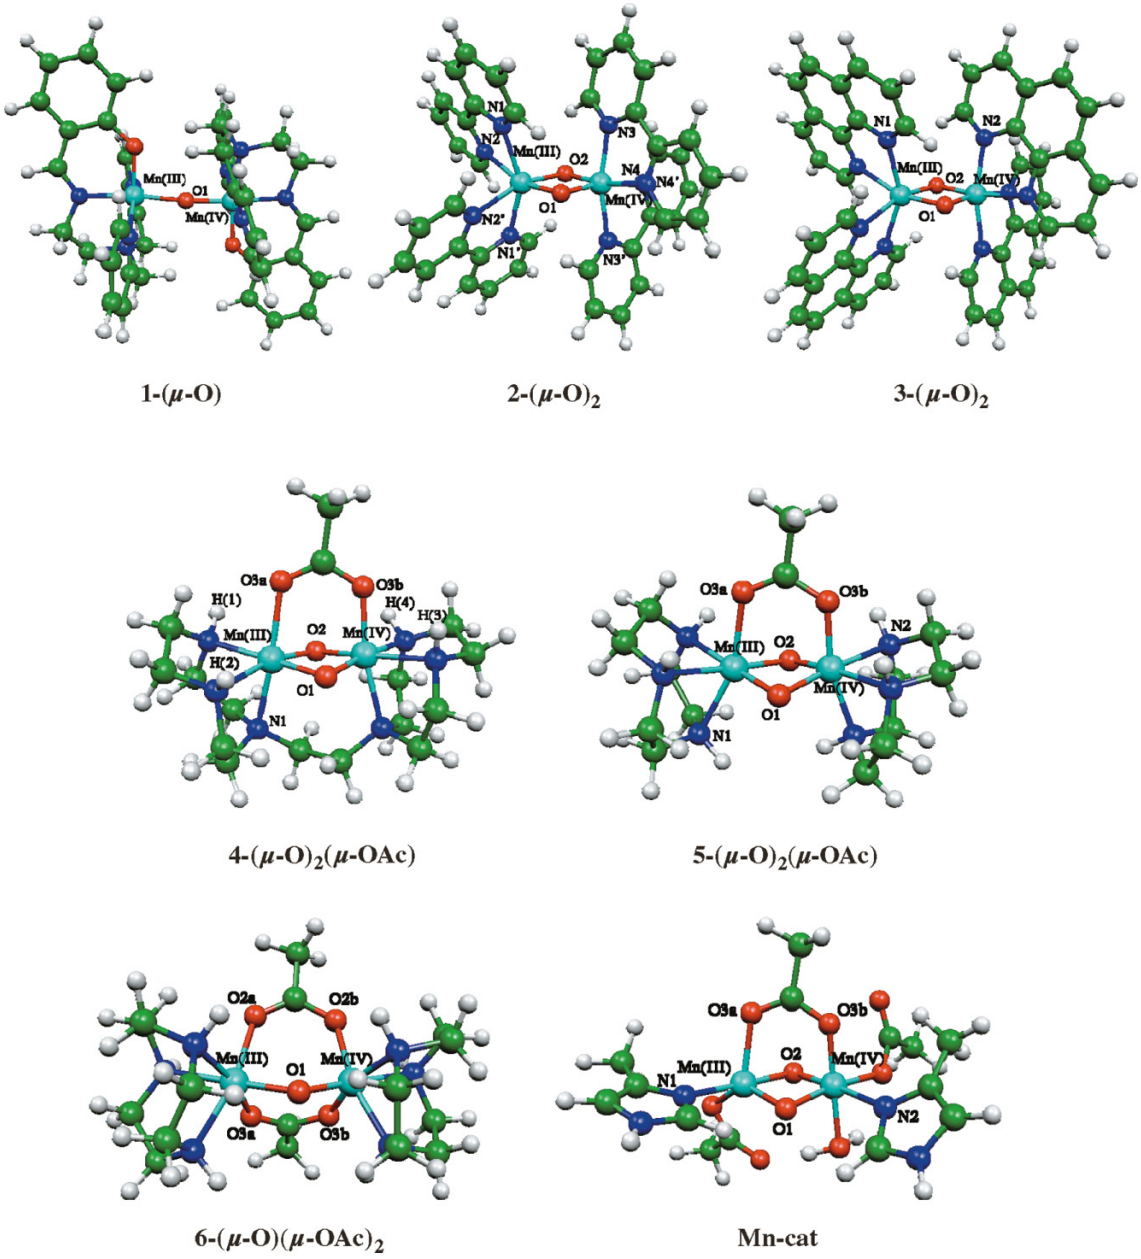
Structures

For the OEC, one usually assumes[62–65] that the differences between the optimization in the HS and the BS states are rather small (but cf. refs. 20 and 21).[20,21] The comparison of central distances of the optimized HS and BS states with experimental data in Table 1 (**Mn-cat** was not analyzed, as no experimental data for the superoxidized state was available), indicates first of all the distinctly different coordination environment of the two Mn centers in all cases, consistent with localized ("trapped") mixed-valent complexes. Generally, the distorted octahedral Mn^{III} ion exhibits larger distances to the ligand atoms than the Mn^{IV} center.

The optimized BS structure (S = 1/2) exhibits generally better agreement with the experimental X-ray data than the optimized HS structure (S = 7/2). The largest differences between BS and HS structure (Table 1) by far are found for **1-(μ-O)**, where the single (μ-O) bridge provides relatively high flexibility of the core region. Here, the HS calculation gives significantly larger Mn–Mn and Mn^{III}–O1 distances than the BS optimization. In the other cases, the differences tend to be <0.03 Å. The deviations of the BS results from experimental are <0.05 Å for Mn–Mn distances and <0.07 Å for Mn–O distances. The largest discrepancy is again found for **1-(μ-O)**. Comparison with the experimental for **5-(μ-O)$_2$(μ-OAc)** should be made only after averaging the two sides in the computations, as the reported experimental C_2 symmetry is due to statistical disorder.[70] This is a common problem in the structural characterization of such trapped mixed-valence systems.[70]

Based on the BS optimizations, we note the following points: clearly different Mn–Mn distances occur for the different cores. The largest Mn–Mn distance is obtained for the mono-μ-oxo bridged core owing to its almost linear arrangement. The di-μ-oxo bridged complexes **2-(μ-O)$_2$** and **3-(μ-O)$_2$** exhibit Mn–Mn distances of 2.76 Å with very similar planar central units. That is, bipy and phen ligands provide very similar frameworks for the central bridge. Even smaller model complexes $[(dab)_2Mn(\mu\text{-}O)_2Mn(dab)_2]^{3+}$ and $[(NH_3)_4Mn(\mu\text{-}O)_2Mn(NH_3)_4]^{3+}$ differ in the core region by <0.02 Å from the larger systems (see Supplementary data). The di-μ-oxo-mono-μ-acetato bridged complexes **4-**

Fig. 1. Structures and atom labels of model systems **1**–**6** and **Mn-cat**.



(μ-O)$_2$(μ-OAc) and **5-(μ-O)$_2$(μ-OAc)** have even lower Mn–Mn distances (Table 1). In contrast, a significantly larger distance is obtained for the mono-μ-oxo-di-μ-acetato bridged complex **6-(μ-O)(μ-OAc)$_2$**.

Table 2 provides the BS-optimized core distances for Mn^{III}–Mn^{IV} complexes with similar terminal ligand sets (one tacn and sometimes additionally one water ligand) but with different bridges. For the modified model systems, similar trends are found as for the experimentally studied complexes, indicating the importance of the bridging ligands and the limited influence of the terminal ligands.

Mulliken spin densities

Mulliken atomic spin densities (Table 3) provide a simple check of the unrestricted KS wave function obtained, regarding both the oxidation states of the individual Mn centers and the spin-coupling pattern. For all systems, the HS state is well represented by a ferromagnetic coupling between a Mn^{III} and a Mn^{IV} center. The BS state exhibits the expected antiferromagnetic coupling. The S^2 expectation values of the HS solutions are close to the nominal value for an $S = 7/2$ state, whereas the broken-symmetry nature of the BS solution is apparent from the fact that values around 3.7–4.0 are found (at the given computational level) instead of the 0.75 expected for a pure $S = 1/2$ state (see the PO analysis section). The spin densities on the Mn^{III} center are close to the ideal d^4 configuration (the somewhat lower value for the HS state in **1-(μ-O)** reflects the larger delocalization across the linear bridge in this case). More notable deviations from the ideal d^3 configuration for the Mn^{IV} center are seen for the BS states of the first three complexes (and again for the HS state of **1-(μ-O)**). Interestingly, the spin density on the Mn^{IV}

center depends notably on the bridging ligand, reflecting the more pronounced covalency of the Mn^{IV}–O bonds and an associated larger spin polarization. Acetate bridges tend to diminish this effect and provide somewhat larger absolute spin densities on the Mn^{IV} centers. In the BS states, spin polarization of the bridge oxygen atoms is particularly pronounced for the single bridge in **1-(μ-O)** but is also large for the di-μ-oxo bridges and still notable for the other oxo bridges. Slightly positive spin density on the bridging acetate oxygen atoms points more to spin delocalization than to spin polarization. Interestingly, the HS state of **1-(μ-O)** exhibits large positive spin density on the bridging oxygen, in accordance with substantial spin delocalization (this is made possible by the parallel orientation of the unpaired spins). Smaller positive spin densities are visible on the other oxo bridges in the HS states. Curiously, in the HS states small negative spin densities are found on bridging acetate oxygen atoms.

The influence of the exact-exchange admixture on the atomic spin densities of the BS state of **2-(μ-O)$_2$** is studied in Table 4. As also found for mononuclear complexes,[53,54,71] a larger exact-exchange admixture enhances the spin density on the Mn centers, because of the more ionic metal-ligand bonding and partly because of increased spin polarization. GGA functionals tend to overestimate metal–ligand covalency, and this is compensated for by some exact exchange. However, for very large admixtures (>50%), a counteracting effect is visible, which leads to a slight decrease of the spin density on the Mn^{III} center, likely because of the effects of spin polarization. The spin densities on the bridging oxygen atoms depend in a striking manner on the functional: starting from appreciably negative values at the GGA level, they go through 0 between a 50% and 60% exact exchange

Table 3. Mulliken atomic spin densities and $\langle S^2 \rangle$ expectation values of HS and BS states.

and then turn significantly positive at a 70%–80% exact exchange. As enhanced spin polarization with more exact exchange would be expected to lead to more negative values overall, apparently, the more ionic Mn–O bonding at a larger exact exchange counteracts this effect. At 90% exact exchange, pronounced symmetry breaking renders the two oxygen atoms strongly nonequivalent, indicating this KS wave function to be unphysical.

Paired-orbital analysis of spin contamination in the BS state

The S^2 expectation value tends to be near 3.75 for all systems at the B3LYP level (cf. Table 3), lower at the GGA level, and higher at larger exact-exchange admixtures (Table 4). The value may be analyzed within the formalism of an expansion of the BS determinant into quasi-restricted determinants in the basis of the POs (see the Theory section).[45–47] The magnetic NOs for **2-(μ-O)$_2$** obtained at the B3LYP level are shown in Fig. 2 and also look similar to other functionals (data not shown). The occupation numbers of the NOs (see Table 5 for **2-(μ-O)$_2$**) generally give the expected picture of seven magnetic orbitals: this includes the "true" SOMO of the $S = 1/2$ system (occupation 1.00) and three pairs of corresponding orbitals, indicated by complementary deviations of the NO occupation numbers from 1.0. These deviations may be translated[45–47] into overlaps of the corresponding POs, also shown in Table 5 (numbers in parentheses). As has been discussed in refs. 45–47,[45–47] all spin contamination (i.e., deviation of $\langle S^2 \rangle$ from the nominal value of 0.75 for $S = 1/2$) may be traced back to those active pairs. Indeed, three magnetic pairs with small overlap should give rise to an increase of $\langle S^2 \rangle$ by three units.[46,47] This situation is almost ideally represented by the B3LYP results (cf. Tables 3 and 4). The BLYP GGA calculations are known to overestimate delocalization. This may be seen from the larger overlaps of ca. 0.4 for the three corresponding magnetic POs (or from the larger deviations of the NO occupation numbers from 1.0; Table 5). The B3LYP PO overlaps are close to 0.2 and the BHLYP ones are close to 0.1. Whereas the larger overlap for BLYP decreases the spin contamination compared with the B3LYP results, the small overlap for BHLYP enhances it. Moreover, the spin

polarization of formally inactive NOs and (or) POs increases with increasing exact-exchange admixture. This is visible in Table 5 from the deviations of formally doubly occupied NOs 190, 191, and 192 from 2.0 (and from the non-zero occupations of the corresponding NOs 200, 201, and 202). Further analyses based on the PO-based expansion into quasi-restricted determinants in eq. [18][46,47] are provided in Table S5 in the Supplementary data. The spin contamination of the BS–KS determinant arises from single, double, and triple substitutions of the leading restricted determinant of the expansion (some contributions arise also from the spin polarization of the formally doubly occupied set — POs 190, 191, and 192).

Exchange coupling constants

As knowledge of spin-coupling patterns in multinuclear systems is essential for an understanding of the spectroscopic properties, we have also computed the Heisenberg exchange couplings, using the above-mentioned spin projection schemes of Noodleman et al. and Yamaguchi et al. The vast literature[72–82] on broken-symmetry DFT calculations of exchange couplings for multinuclear transition metal complexes cannot be described here in detail. The small energy differences involved, the intrinsically multideterminantal nature of the lower spin states, and the necessity of mapping the electronic structure onto the Heisenberg spin Hamiltonian make this a challenge for quantum chemistry. BS-DFT with standard hybrid functionals like B3LYP tends to work surprisingly well when spin projection is used.[24] This is con-

firmed for the present title systems. Figure 3 illustrates the example of **2-(μ-O)$_2$**, the large dependence of J on the exact-exchange admixture in the functional, and the good performance of B3LYP (likely related to the physically well-defined structure of the BS–KS determinant at this level, see the above). The Noodleman[15] and the Yamaguchi[25] mapping schemes perform similarly, confirming the weak interaction between the spins for the complexes studied here. The pure GGA BLYP functional exhibits larger spin delocalization[83] and thus more negative J values. In contrast, the larger exact-exchange admixture overcorrects and gives absolute values for J that are too low. The unprojected BS-DFT formula of Ruiz et al.[73,75,84] gives generally lower values (see Table S6 in the Supplementary data) and provides poorer agreement with the experimental when used with B3LYP (but reasonable agreement with BLYP).

††A lower bound of –175 cm^{-1} has been estimated.[86]

B3LYP results for the entire series of complexes are provided in Table 6. Differences between data obtained with the moderate-basis SVP and data obtained with extended basis sets are very small. Obviously, the energy differences between HS and BS states are not very basis-set dependent.[24] In all cases, the Noodleman (eq. [7] and Yamaguchi (eq. [8] projection schemes provide very similar results. For complexes with di-μ-oxo or di-μ-oxo-μ-carboxylato cores, agreement with the experimental is excellent (for **Mn-cat** no truly reliable estimate is available). For the remaining two compounds **1-(μ-O)** and **6-(μ-O)(μ-OAc)$_2$**, the calculations underestimate the experimental absolute values by factors of 3–4. Presumably,[24] OAc bridges give rise to some spin delocalization between the centers in the HS state, thus partly invalidating the basis for the spin projection. In the case of **1-(μ-O)**, the question of the accuracy of the structure optimization may come into play (cf. Table 1). The calculated distances are, especially for the HS state, much larger than distances derived from X-ray experiments (Mn–Mn: HS, 3.67 Å; X-ray[66], 3.52 Å). Computation of J for the X-ray structure of **1-(μ-O)**[66] gives –185 cm^{-1}, i.e., a value closer to the experimental.

The di-μ-oxo bridged complexes exhibit larger antiferromagnetic coupling than the di-μ-oxo-μ-carboxylato bridged ones, in spite of the longer Mn–Mn distances. The magnetic interactions are more efficient in the planar di-μ-oxo structures than in a tilted Mn_2O_2 core,[78] as present in the (μ-O)$_2$(μ-OAc) bridged systems. In general, O^{2-} is a strong donor, leading to strong Mn – oxo π interactions, which are responsible for the strong, super exchange-mediated[79,85] antiferromagnetic interactions.

To evaluate the influence of the terminal ligand sets, we computed J for smaller models of **3-(μ-O)$_2$**, where the phen ligands were replaced by simpler ligands. Even for the simplest model $[(NH_3)_4Mn(\mu\text{-}O)_2Mn(NH_3)_4]^{3+}$ (–132 cm^{-1}) are obtained (Noodleman projection, SVP basis), in good agreement with the experimental (see Table S7 in the Supplementary data).

In the opposite type of computational experiment, we kept the terminal ligand framework similar (tacn and H_2O; see also the above) and changed the bridges. As expected,[78] this had a larger effect on J (see Table 6). The influence of the bridge depends on the various super exchange pathways provided by the bridging oxo and acetato ligands.[20,21] Overall, smaller Mn–Mn distances and a planar Mn_2O_2 core give rise to larger antiferromagnetic couplings. These effects work into opposite directions for $[(tacn)(H_2O)Mn(\mu\text{-}O)_2Mn(tacn)]^{3+}$ and $[(tacn)Mn(\mu\text{-}O)_2(\mu\text{-}OAc)Mn(tacn)]^{2+}$, leading to rather similar couplings. Complexes with a di-μ-oxo bridge have J couplings in the range of –110 to –150 cm^{-1} (Tables 6 and 7). A similar range is covered by di-μ-oxo-μ-carboxylato bridged complexes (–108 to –127 cm^{-1}). A small antiferromagnetic coupling was computed for **6-(μ-O)(μ-OAc)$_2$**. A small ferromagnetic coupling was obtained for $[(tacn)Mn(\mu\text{-}O)(\mu\text{-}OAc)Mn(tacn)]^{4+}$ (Table 7). Because of the OAc bridge, a delocalization of the unpaired electrons in the high-spin state occured,[24] reducing the antiferromagnetic coupling. This effect was also be observed in complexes $[(tacn)Mn(\mu\text{-}O)_2(\mu\text{-}OAc)Mn(tacn)]^{2+}$ and $[(tacn)Mn(\mu\text{-}O)(\mu\text{-}OAc)_2Mn(tacn)]^{3+}$. The more μ-carboxylato bridges, the lower the antiferromagnetic coupling. The spin-density distributions of these complexes are given in Fig. 4.

g Tensors

Computed effective **g** tensors (eq. [13]) tend to agree reasonably well with the experimental (Table 8). The **g** anisotropy is generally small for all title complexes, and the isotropic **g** value is close to the free-electron value. Dependence on the functional is small, and for **2-(μ-O)$_2$** even the BLYP GGA functional provides reasonable results for $\mathbf{g}_{iso}$. At very large exact-exchange admixtures, agreement with the experimental values may be improved further (also see the results for **Mn-cat** in Fig. S1 in the Supplementary data). Comparing our B3LYP results with those of Sinnecker et al. for **4-(μ-O)$_2$(μ-OAc)**[20] and **Mn-cat**,[21] we see

Table 7. Dependence of J (in cm^{-1}) on the bridging ligand set.

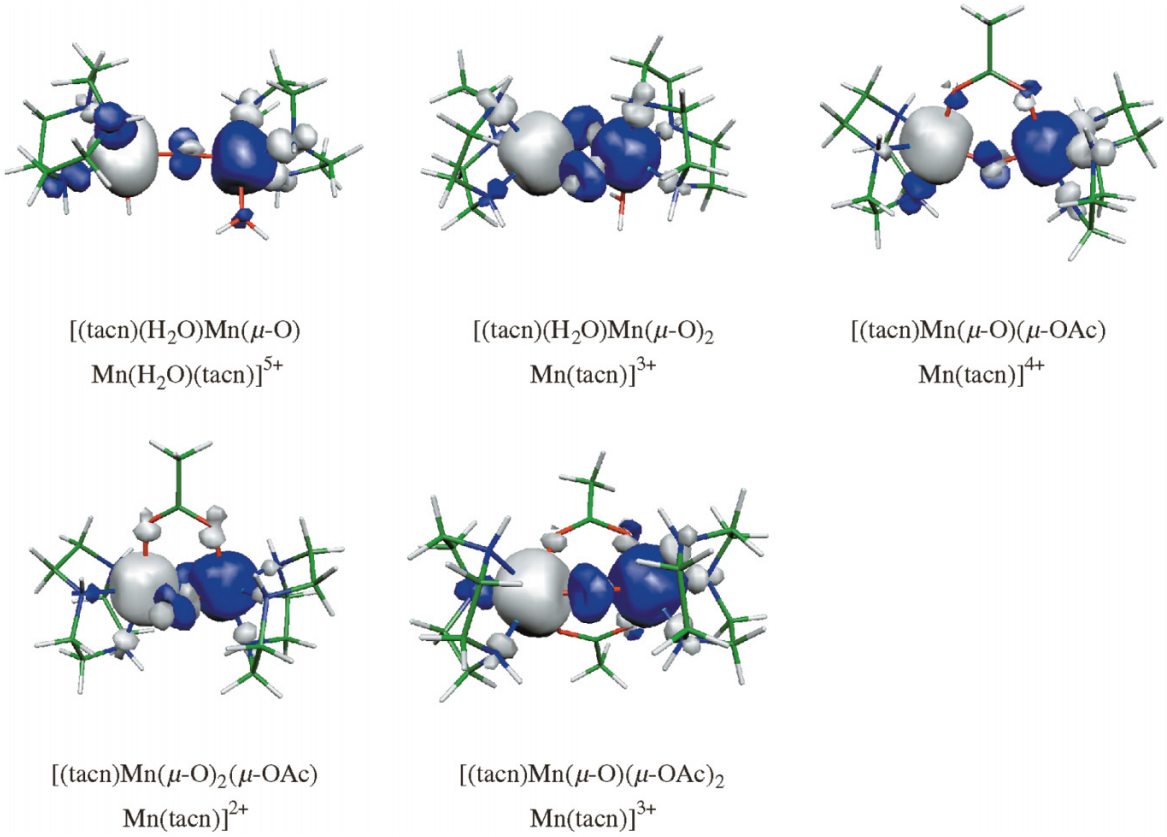
§Experimental value taken from Wieghardt et al.[70]

Fig. 4. Spin-density isosurfaces (±0.005 au) for tacn complexes with different bridging ligands.



some moderate discrepancies (data not shown) in that their overall effective g-shift components are all somewhat below g_e, whereas in our calculations, $\boldsymbol{g}_{22}$ and $\boldsymbol{g}_{33}$ are above g_e and $\boldsymbol{g}_{11}$ is below (Table 8). This brings their data closer to the experiment value for **4-(μ-O)$_2$(μ-OAc)**[20] (in fact, most of the complexes in Table 8), whereas our positive $\boldsymbol{g}_{22}$ and $\boldsymbol{g}_{33}$ values agree better for **Mn-cat**. Differences between the two sets of calculations could arise from (*i*) different spin-orbit operators (atomic-meanfield operators in this work vs. semi-empirical operators in refs. 20 and 21), (*ii*) different structures (we used optimized structures individually for HS and BS states, whereas Sinnecker and Neese and co-workers used the HS structures for both calculations), (*iii*) general differences between the optimized structures and basis sets used, or (*iv*) the gauge origin of the magnetic vector potential (placed at the center of charge density in our calculations). Yet, our evaluations of all of these points did not reveal the origin: Our use of the same semi-empirical spin-orbit operators used by Sinnecker et al. actually increased $\boldsymbol{g}_{22}$ and $\boldsymbol{g}_{33}$ further in all cases, and the dependencies on structures, basis sets, or gauge origin turned out to be too small to account for the differences. Therefore, we do not have a good explanation for the (moderate) discrepancies in the computed effective **g** tensors, but hyperfine couplings computed from the same Kohn–Sham wave functions agree very well.

Overall, the **g** tensors for different systems tend in to be too similar to have much diagnostic value for structural details. **g** Tensor orientations will be discussed further in the following section together with those of the ^{55}Mn hyperfine tensors.

^{55}Mn hyperfine coupling tensors

The ^{55}Mn hyperfine couplings exhibit much more sensitivity to bonding and structural details. Isotropic HFCs of transition metal nuclei are known to also depend sensitively on the exchange-correlation functional employed.[53] This includes manganese HFCs and has recently been confirmed for the mononuclear manganese binding site of concanavalin A.[22] Table 9 evaluates the ^{55}Mn tensors for **2-(μ-O)$_2$** with different functionals. Tensors after spin projection (eqs. [16] and [17])) and isotropic site values are provided.

Because of the distorted coordination of high-spin d^4, Mn^{III} exhibits appreciable HFC anisotropy (and a nearly axial tensor). An almost isotropic HFC is found for the high-spin d^3 Mn^{IV} center. The dependence on the functional is as found before,[22] for both Mn centers: The isotropic Fermi-contact term A_{FC} becomes more negative with increasing EXX admixture because of the enhancement of (overall negative) core-shell spin polarization contributions to the spin density at the nucleus.[53,54,71] Agreement with experimental values is thus improved even up to rather large admixtures of exact exchange. SO contributions are on the order of about 5%–10% of the nonrelativistic values. This value is less than the values for some complexes of other 3d transition metals,[36,38,89] yet not negligible.[20,21] The HFC anisotropy of the Mn^{III} ions depends less on the functional. It is already reproduced reasonably well at the B3LYP level and tends to be overshot somewhat at higher EXX admixtures. Notably, at EXX admixtures >60%, the HFC anisotropies of the Mn^{IV} centers start to increase notably. This is likely an unphysical artefact of the increased spin contamination[53,54] (cf. S^2 expectation values in Table 4 and the PO analysis section). Another observation in this context is the faster increase of the a_{iso} site values with exact exchange for the Mn^{IV} compared with the Mn^{III} centers (Table 9). We note, in passing, that the differences between the BLYP GGA functional and the B3LYP hybrid functional are clear-cut and consistent with the above-mentioned dependence on EXX admixture. Somewhat more similar results obtained by Sinnecker et al.[20] with BP86 vs. B3LYP functionals may be attributed to the compensating effects of exchange and correlation contributions to the functional (see Munarová and Kaupp[53]).

In the long run, improved exchange-correlation functionals will be needed that will allow optimum agreement with the experimental values for a wide range of spectroscopic parameters with one given functional. A possible route towards this goal are local hybrid functionals with position-dependent EXX admixtures[90–94] (as self interaction errors may be particularly relevant for mixed-valence systems, functionals that effectively decrease self interaction yet still provide a good simulation of static correlation are of interest). For the moment, we are content with more approximate short-term solutions. As the exchange couplings (see above) and several ligand HFCs (see the following) are reproduced well with B3LYP, it would be desirable to be able to scale the computed A_{iso} at this level, as suggested recently,[20] to provide essentially quantitative predictions for the entire tensor. This requires that the errors owing to the incorrect description of the core-shell spin polarization are systematic and apply similarly to both Mn^{III} and Mn^{IV} centers, as well as to different coordination environments. The latter is

Table 9. Dependence of ^{55}Mn hyperfine tensors (in MHz) for **2-(μ-O)$_2$** on the exchange-correlation functional.

Note: Site values were obtained with an extended basis set (see Computational details). a_{iso} (site) is the intrinsic site isotropic hyperfine coupling constant. A_{iso} is the total isotropic value, T_i represents the traceless part of the full **A** tensor, A_{FC} and A_{PC} denote the isotropic first-order Fermi-contact and second-order pseudo-contact (spin-orbit) contributions to the full total **A** tensor, respectively. $\mathbf{A}_i^{dip}$ and $\mathbf{A}_i^{dip,2}$ denote, respectively, the first-order nonrelativistic and second-order spin-orbit anisotropic tensors. EPR, electron paramagnetic resonance.

*HF-EPR studies from ref. 87.

clearly the case, as the B3LYP results for A_{iso} in **2-(μ-O)$_2$** have to be scaled by 1.44 for Mn^{III} and by 1.45 for Mn^{IV} (Table 9) to agree with the experimental values.

The validity of the former condition for a range of the present dinuclear systems is explored in Table 10. Spin-projected B3LYP results are compared with ^{55}Mn HFC tensors from several EPR studies.[39,66,87] The behavior is as previously delineated for **2-(μ-O)$_2$**: significant anisotropy for Mn^{III} centers and essentially isotropic HFCs for Mn^{IV} centers. Scaling the total computed A_{iso} by a factor of ca. 1.45 provides excellent agreement with the experimental value (A_{iso}*, Table 10), independent of terminal and bridging ligand sets. Similar scaling factors were found from a somewhat more limited set of complexes by Sinnecker et al.[20,21] The anisotropies of the Mn^{III} centers are generally reproduced more or less reasonably without scaling. The small anisotropies of the Mn^{IV} centers are less well reproduced.

Turning our magnifying glass on the a_{iso} site values (Table 10), we see that the relative magnitudes for the Mn^{III} vs. Mn^{IV} centers are, in most cases, reproduced, but not always; for **1-(μ-O)** and **4-(μ-O)$_2$(μ-OAc)**, the experimental values would suggest slightly larger absolute values for the Mn^{III} center, whereas the calculations give the opposite behavior (but the differences are tiny). The switch from larger absolute a_{iso} site values for Mn^{III} in **2-(μ-O)$_2$** and **3-(μ-O)$_2$** to larger values for Mn^{IV} in **5-(μ-O)$_2$(μ-OAc)** and **Mn-cat** is well reproduced. The latter two cases are the most clear-cut ones. These results show that, overall, the intrinsic isotropic site values for Mn^{III} and Mn^{IV} are surprisingly similar and translate into rather different projected A_{iso} values owing to the factor two in the Mn^{III} projection. This will have to be kept in mind in studies on, e.g., the OEC.

In Table 11, the ^{55}Mn HFC tensors are provided for **3-(μ-O)$_2$** and for models in which the phen ligands have been replaced by smaller units. Even for the smallest model system, $[(NH_3)_4Mn(\mu\text{-}O)_2Mn(NH_3)_4]^{3+}$, the isotropic ^{55}Mn HFC of the Mn^{IV} center is essentially the same as for the full system with phen ligands. In the case of NH_3 or dab ligands, the value for the Mn^{III} center is 7% too small in absolute value compared with the phen complex (note the switch in relative magnitude of the Mn^{III} and Mn^{IV} a_{iso} site values). Slight structural differences for the dab complex and the bipy and phen complexes might explain this deviation (see Table S1 in the Supplementary data). For NH_3, its nonaromatic nature and different donor character come into play. The bipy complex is an almost perfect model of phen in this context. These findings suggest that similar simplifications of the terminal ligand sets may be cautiously applied to models of the OEC, where full modelling of the protein and co-factor environment is computationally demanding.

Table 12 keeps the terminal ligand set more or less constant (tacn and possibly terminal H_2O) and varies the bridges. Surprisingly, at first sight $[(tacn)(H_2O)Mn(\mu\text{-}O)Mn(H_2O)(tacn)]^{5+}$ and $[(tacn)Mn(\mu\text{-}O)(\mu\text{-}OAc)\ Mn(tacn)]^{4+}$ exhibit unusually small A_{iso} valuesfor the Mn^{IV} center. This can be traced back clearly to a five coordination at this center, suggesting a diagnostic value of the Mn HFC in this context. This is interesting for the OEC, as the coordination number of the different centers is currently far from settled. The other variations of the Mn^{IV} HFC are much smaller, with the $(\mu\text{-}O)(\mu\text{-}OAc)_2$-bridged system having the lowest

A_{iso}. Stronger ligation appears to lead to larger HFCs. This agrees with results for mononuclear complexes. For example, at the same computational level we obtain an A_{iso} value of –147.8 MHz for $[Mn(H_2O)_6]^{4+}$, a value of –227.6 MHz for $[Mn(H_2O)_5(OH)]^{3+}$, and a value of –303.3 MHz for $[Mn(H_2O)_5(O)]^{2+}$. On the Mn^{III} side, the observed variations in Table 12 are smaller but suggest the largest A_{iso} for the triply bridged systems and the lowest value for the (μ-O)$_2$-bridged system. The mono-μ-O and (μ-O)(μ-OAc) bridged systems feature fivefold coordination for the Mn^{III} center and are therefore more difficult to compare. Interestingly, however, the Mn^{III} HFCs appear to be changed less when going from six- to five-fold coordination. Insight from mononuclear complexes would suggest a similar trend as for Mn^{IV}, namely increasing A_{iso} with stronger coordination: a $[Mn(H_2O)_6]^{3+}$ value of –171.4 MHz compared with a $[Mn(H_2O)_5(OH)]^{2+}$ value of –226.4 MHz, as well as a $[Mn(H_2O)_5]^{3+}$ value of –135.6 MHz compared with a $[Mn(H_2O)_4(OH)]^{2+}$ value of –158.0 MHz.

Orientation of g and ^{55}Mn hyperfine tensors

The orientation of the **g** and hyperfine tensors with respect to the molecular framework and, in particular, with respect to each other, is crucial in the simulation of the EPR spectra. Often assumptions about co-axiality or of axial symmetry of tensors are made to reduce the degrees of freedom in a simulation. The known ability of modern DFT methods to typically provide the tensor orientations reliably is thus of interest to validate or invalidate these assumptions. The orientations of the computed HS, BS, and site **g** tensors and of the **A** tensors relative to the effective **g** tensor have been thus evaluated (see Table 13 for two of the complexes). Figure 5 shows the orientations for **2-(μ-O)$_2$** (orientations for **4-(μ-O)$_2$(μ-OAc)** are given in Fig. S3 in the Supplementary data). The computed **g**tensor orientation for **2-(μ-O)$_2$** agrees with the experimental assignment.[39] The $\mathbf{g}_{11}$ vector lies perpendicular to the Mn_2O_2 plane. The $\mathbf{g}_{22}$ axis is parallel to the Mn–Mn connection line, and the $\mathbf{g}_{33}$ axis is parallel to the connection between the bridging oxygen atoms. The Euler angles between the principal axes of the HS and BS **g** tensors are small, between 11.7° and 17.8°, as expected for a planar Mn_2O_2 core. Spin-projection results in an effective **g** tensor orientation intermediate between those of $\mathbf{g}_{HS}$ and $\mathbf{g}_{BS}$ (slightly closer to $\mathbf{g}_{HS}$ owing to the larger mass of the HS tensor after spin projection; eqs. [9]–[13]). As expected, the orientation of the site **g** tensor of the distorted Mn^{III} center ($\mathbf{g}_1$) dominates the effective **g** tensor orientation, as indicated by the smaller absolute values of the Euler angles relative to the effective **g** tensor.

The often assumed covariance between HFC and **g** tensors is clearly not fulfilled for **2-(μ-O)$_2$** (Fig. 5 and Table 13); whereas $\mathbf{A}_3$ of the Mn^{III} HFC tensors coincides with $\mathbf{g}_{11}$, the $\mathbf{A}_2$ and $\mathbf{A}_1$ orientations are rotated significantly relative to $\mathbf{g}_{22}$ and $\mathbf{g}_{33}$, respectively. The HFC tensor orientation of the Mn^{IV} center is also not covariant to **g** or the Mn^{III} HFC tensor ($\mathbf{A}_2$ is covariant with $\mathbf{g}_{22}$). But this is of lesser importance owing to the small HFC anisotropy on this center (see above).

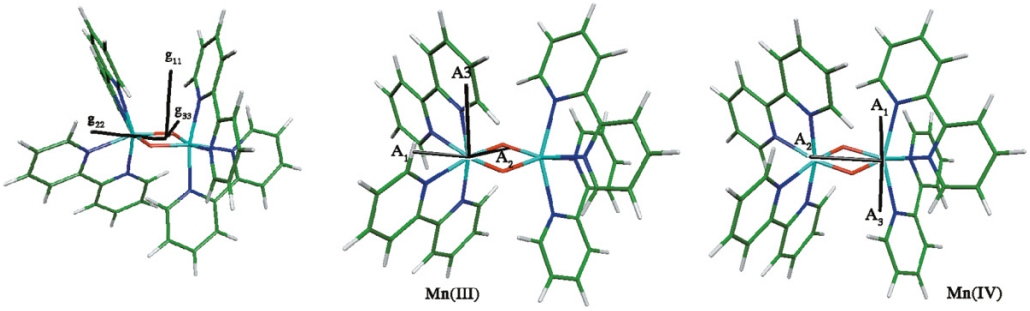
Fig. 5. Orientation of **g** tensor and manganese hyperfine tensors for **2-(μ-O)$_2$** (B3LYP results).



For the di-μ-oxo-μ-carboxylato bridged complex **4-(μ-O)$_2$(μ-OAc)** with its nonplanar core, **g** tensor orientations are similar as for **2-(μ-O)$_2$**: $\mathbf{g}_{22}$ is again parallel to the Mn–Mn connection line, $\mathbf{g}_{33}$ is parallel to the O–O connection line, and $\mathbf{g}_{11}$ is perpendicular to the $\mathbf{g}_{22}$–$\mathbf{g}_{33}$ plane, which does not contain all four atoms of the core. Yet, the differences between the orientations of $\mathbf{g}_{HS}$ and $\mathbf{g}_{BS}$ are more pronounced (Table 13). Again, $\mathbf{g}_1$ dominates the effective **g** tensor orientation. As for **2-(μ-O)$_2$**, we find the Mn^{III} **A** tensor not to be covariant with the **g** tensor, as shown by the large Euler angles for $\mathbf{A}_1$ than for $\mathbf{g}_{11}$ and for $\mathbf{A}_2$ than for $\mathbf{g}_{33}$. The Mn^{IV} HFC tensor orientation is close to that of the **g** tensor but again likely to be less important for spectra simulations.

*Electron spin echo envelope modulation (ESEEM) data for catalase are from Ivancich et al.[97]

^{14}N Hyperfine coupling and nuclear quadrupole coupling tensors

Nitrogen donor ligands are present in several of the model systems studied, including catalase, and also in the OEC. In catalase, histidine imidazole nitrogens are coordinated to the two manganese centers (cf. Fig. 1), and in the OEC, a histidine is known to coordinate to one of the manganese centers.[95,96] Nitrogen HFCs and (given the quadrupolar nature of the ^{14}N nucleus) nuclear quadrupole coupling tensors are thus spectroscopic parameters with potential value for structure elucidation. Table 14 evaluates the dependence of the parameters for the two distinguishable ligand nitrogen atoms for **Mn-cat** on the exchange-correlation functional. Increased EXX admixture makes the isotropic ^{14}N HFC of N1 (bound to the Mn^{III} center) more negative. For the N2 atom bound to the Mn^{IV} center, the BLYP GGA functional gives a positive value, whereas increasing EXX admixture moves A_{iso} first towards small positive values (e.g., BHLYP or B60LYP) before turning it increasingly negative. No sign information is available from the experimental, but the good agreement of the B3LYP results with both the absolute value of A_{iso} and with the nuclear quadrupole coupling and asymmetry (Table 14) suggests this level (and the positive sign of A_{iso}) to be more reliable than large EXX admixtures >60%. Only one nitrogen atom was seen[97] in the ESEEM experiment, and its assignment[98] to N2–Mn^{IV} is consistent with our calculations and with those of Sinnecker et al.[21] The larger ^{14}N HFC of N1 is outside the range detectable by ESEEM, but it might be detected by ENDOR spectroscopy. For both N1 and N2, the calculations suggest small hyperfine anisotropy, with a somewhat larger dependence on the functional on the Mn^{IV} side (N2). For both nuclei, the nuclear quadrupole couplings increase with EXX admixture. Already, BLYP and B3LYP perform almost identically compared with the experimental. The asymmetry parameter behaves differently on the two nuclei. Again, the B3LYP results agree well with the experimental.

The second dinuclear system, for which the ^{14}N HFCs have previously been computed, is **4-(μ-O)$_2$(μ-OAc)**[20] (cf. Table 15). Our results for N1 (ligand to Mn^{III} along the Jahn–Teller axis) agree well with those of Sinnecker and Neese and co-workers and with the experimental. In the closely related **5-(μ-O)$_2$(μ-OAc)**, ESEEM has provided a second, smaller splitting assigned to N2 (equatorial ligand to Mn^{IV}; cf. Fig. 1 for atom labels). This relatively small splitting is underestimated somewhat by the computations. Notably, however, the smaller nuclear quadrupole coupling on N2 is better reproduced than the larger one on N1, which is overestimated. The asymmetry parameter is too low. Possible error sources are inaccuracies in the computed Mn–N distances along the Jahn–Teller axes of the Mn^{III} centers. The hyperfine tensors of these nitrogen nuclei at the Mn^{III} centers have nearly axial symmetry and are highly anisotropic, which is rather difficult to observe with either ESEEM or ENDOR.[98]

Table 15 shows only results for those nitrogen atoms for which an experimental assignment is available (see Table S9 in the Supplementary data for the remaining nitrogen nuclei). In addition to **Mn-cat**, **4-(μ-O)$_2$(μ-OAc)**, and **5-(μ-O)$_2$(μ-OAc)** discussed previously, experimental data are also available for **2-(μ-O)$_2$** and **3-(μ-O)$_2$**. Agreement with experimental values is similar as for the other complexes. Taking **2-(μ-O)$_2$** as an example, all ligating nitrogen atoms may be differentiated, based on the computed nitrogen HFCs and nuclear quadrupole tensors. The nitrogen atoms on the Jahn–Teller axes of the Mn^{III} center (N1, N1′) exhibit particularly large A_{iso}, whereas the equatorial N2 and N2′ have small values (0.6 MHz). The four nitrogen atoms bonded to Mn^{IV} exhibit similar, intermediate values (N3, N3′, 2.5 MHz; N4, N4', 1.9 MHz). These results suggest that similar evaluations may help in structure elucidation in more complex cases, provided nitrogen parameters are available from ESEEM and (or) ENDOR.

^{1}H hyperfine coupling tensors

Finally, we evaluate the dependence of the ligand proton HFCs on the functional. For this, we have chosen **4-(μ-O)$_2$(μ-OAc)**, which was studied previously by Sinnecker and Neese and co-workers at the BP86 and B3LYP levels.[20] Only the hydrogen atoms directly attached to the nitrogen nuclei in the first coordination sphere of the manganese atoms were experimentally accessible.[39] Moreover, H(1) vs. H(2) and H(3) vs. H(4) are in a too similar environment (cf. Fig. 1) and could not be distinguished experimentally. They

*DFT study using ORCA (B3LYP//B3LYP) from Sinnecker et al.[20]

†Experimental data for [MnMn(μ-O)$_2$(μ-OAc)(CH$_3$)$_4$DTNE](BPh)$_4$.[39]

have been averaged computationally. Our B3LYP results (Table 16) are similar to those of Sinnecker et al.,[20] small differences likely arising from the different basis sets employed. As found already for mononuclear Mn complexes like the divalent site in concanavalin A or simple aqua complexes,[22] the isotropic HFC decreases somewhat with increasing EXX admixture. Yet, even at very high admixtures, the absolute value at the Mn^{III} site is still overestimated compared with the experimental value. In the case of the Mn^{IV} site, the values for H3 and H4 start to diverge for large EXX admixtures, suggesting artificial symmetry breaking because of unphysical spin contamination (see above). The HFC anisotropies are already reproduced well at B3LYP level (somewhat better than with BLYP) and cannot be improved significantly by enhanced EXX admixture.

Conclusions

The detailed interpretation of EPR spectra for di- and multi-nuclear manganese complexes, such as the oxygen-

evolving complex of photosystem II, could be improved considerably if we could assist the experimentalists by providing reliable quantum chemical calculations and analyses. Building on important recent computational work by Sinnecker et al. on a synthetically available dinuclear model complex and on a model for dimanganese catalase, we provide a systematic study of various EPR parameters of a wider set of dinuclear $Mn^{III}Mn^{IV}$ complexes, using broken-symmetry DFT approaches. A main focus has been the evaluation of the influence of exact-exchange admixture in hybrid functionals on the computed spin-density distributions and spectroscopic parameters.

Spin-projected **g** tensors are generally almost isotropic and exhibit only relatively small deviations from the free-electron value. Whereas the **g** tensors are reproduced well by the standard B3LYP functional, their diagnostic value remains low at this point. Computations on the ^{55}Mn hyperfine tensors confirm that (*i*) the isotropic hyperfine couplings are underestimated by standard functionals, but (*ii*) this systematic error may be remedied to a good approximation by an empirical scaling factor (~1.45 at B3LYP level). The hyperfine anisotropies are already well reproduced by standard functionals. The same holds for the ligand ^{14}N and ^{1}H hyperfine tensors. Ongoing work in our lab concentrates on also finding suitable spin-projection schemes for bridging ligand sets. We find the Mn^{III} hyperfine tensors not to be generally covariant to the **g** tensors. This information is of importance for spectra simulations and will possibly affect simulation results for the OEC.

The spin contamination of the BS–KS determinants has been analyzed using NO occupations, PO overlaps, and an expansion into quasi-restricted determinants in the PO basis. It turns out that the S^2 expectation values near 3.75 obtained at B3LYP level are well in line with the expected seven active orbitals, which include the truly unpaired "SOMO" and three pairs of corresponding magnetic orbitals. The lower $\langle S^2 \rangle$ for the BLYP functional arises from a larger overlap between the POs, in line with an overestimation of delocalization by GGA functionals. The increased $\langle S^2 \rangle$ at higher exact-exchange admixtures arises partly from an increased active PO space, related to the spin polarization of nominally double-occupied orbitals. This additional spin contamination and the partly deteriorated results for other quantities somewhat restrict the amount of exact exchange one may use to improve the isotropic ^{55}Mn HFCs. Fortunately, the insufficiently negative intrinsic isotropic Mn HFCs at the B3LYP level may be easily corrected by scaling (see above). Standard hybdrid functionals such as B3LYP with ~20% exact exchange thus may be used with predictive power also for more complicated systems such as the oxygen-evolving complex of photosystem II. In the long run, improved generations of functionals are desirable, which will allow a well-balanced description of core- and valence-shell spin polarization. Work along these lines is in progress in our laboratory.

Out of one, many — Using moment expansions of the virial relation to deduce universal density functionals from a single system

Paul W. Ayers and Juan I. Rodriguez

Abstract: Moment expansions for density functionals are revisited. This allows for a simple proof of the equivalence between the integrodifferential virial relation and the coordinate-scaling equation. The virial relation is then used to show how, starting from an exact and explicit form of a functional for one system, one may deduce the exact functional for other systems with the same number of electrons.

Key words: density functional theory, coordinate scaling, electron density moments.

Résumé : On a réexaminé les expansions de moments pour les fonctionnelles de densité. Cet exercice permet de présenter une preuve simple de l'équivalence entre la relation virielle intégrodifférentielle et l'équation d'ajustement des coordonnées. On utilise ensuite la relation virielle pour montrer comment, en partant d'une forme exacte et explicite d'une fonctionnelle pour un système, on peut déduire une fonctionnelle exacte pour d'autres systèmes avec le même nombre d'électrons.

Mots-clés : théorie de la fonctionnelle de la densité, ajustement des coordonnées, moments de la densité électronique.

[Traduit par la Rédaction]

I. Introduction

When the present authors began working with density functional theory (DFT) in the mid-1990s, it was clear that the rich vein of "generalized gradient approximation" functionals (GGAs) was essentially depleted:[1] it seemed impossible to build GGAs that were significantly better than the old standbys.[2–9] Reasoning that the next generation of density functionals would be nonlocal, some researchers explored the idea of building functionals from the moments of the electron density,[10–16] e.g., the Cartesian moments

$$[1] \qquad m_{ijk}[\rho] = \int x^i y^j z^k \rho(\mathbf{r}) \mathrm{d}\mathbf{r}$$

(however, for reasons that will soon be clear, most of this work used different sets of moments). The moments are manifestly nonlocal functionals of the electron density and have a clear physical interpretation in terms of multipoles, but, in retrospect, this idea failed. For example, it is difficult to design moment functionals that are size-consistent[17] and invariant to rotations and translations of the density. While moment functionals may not be useful computationally, we believe that moments are useful as a *theoretical* tool. In particular, it is sometimes useful to express *functionals* of the electron density as *functions* of the density moments,

$$[2] \qquad Q[\rho] \leftrightarrow Q(\{m_{ijk}\})$$

if only because most theoreticians find functions easier to manipulate and understand than functionals.

Equation [1] presumes that for a given set of moments, there is only one and only one electron density. This is not always true, and discovering sufficient conditions for a set of moments to uniquely specify a probability distribution function (p.d.f.) is called the "problem of moments." For one-dimensional systems, the problem of moments is well-characterized[18–20] and Stieltjes's sufficient condition establishes that any p.d.f. that decays asymptotically faster than $r^{\beta}\mathrm{e}^{-\alpha r^{\lambda}}$ for some $\alpha,\beta > 0$ and some $\lambda \geq 1/2$ is uniquely determined by its moments.[21] For spherically symmetric systems with positive ionization potentials, $\rho(r) \sim \mathrm{e}^{-r\sqrt{8IP}}$,[22–26] and so the set of moments $\left\{\int_0^{\infty} r^k \rho(\mathbf{r})\mathrm{d}\mathbf{r}\right\}_{k=0}^{\infty}$ is complete. By contrast, the multi-dimensional moment problem is related to Hilbert's 17th problem, and is still being studied by mathematicians.[27] The extension of the Stieltjes condition to the multi-dimensional case,[28] however, establishes that the electron density is uniquely determined by the set of Cartesian moments,[1] as long as it decays exponentially fast. So, the densities of finite electronic systems with positive ionization potentials are determined by their moments. Additional infor-

This article is part of a Special Issue dedicated to Professor T. Ziegler. PWA recalls meeting Prof. Tom Ziegler for the first time in 2003, at breakfast in the Hotel Melia at the 10th International Conference on the Applications of Density Functional Theory in Chemistry and Physics (in Brussels, Belgium). Starting then, and to the present time, he has admired Prof. Zieglers ability to balance openness and skepticism, utility and rigor, humility and confidence, courtesy and candor.

P.W. Ayers[1] and J.I. Rodriguez. Department of Chemistry, McMaster University, Hamilton, ON L8S 4M1, Canada.

[1]Corresponding author (e-mail: ayers@mcmaster.ca).

mation about sufficient sets of moments can be found in ref. 13.

Not all electron densities are determined by their moments. In particular, one cannot represent an infinite system (like the uniform electron gas) in terms of its moments. In fact, only a tiny fraction of the p.d.f.s in the commonly considered spaces of electron densities, $\mathbb{L}^1 \cap \mathbb{L}^3$ or $\mathbb{L}^1 \cap \mathbb{L}^\infty$,[29,30] are determined by their moments.[31] However, for realistic systems of chemical and physical interest, the electron density is determined by its moments. In this way, mathematical arguments based on moments sacrifice universality for convenience. This is similar to current work on studying functionals that are "subuniversal" but still exact for molecules.[32–34] The mathematics of subuniversal density functional theories is complicated because functional derivatives on restricted sets of densities are sometimes ill-defined.[35–38] Because the set of densities that are determined by their moments is a dense subset of the full space of densities, the functionals and functional derivatives used in the following are well-defined, and equal to their values in conventional density functional theory.

In this paper, we will present two results that follow from the method of moments. In Section II, we will show how moments provide a short and lucid proof for the equivalence between the coordinate-scaling condition of a functional,[39–42]

$$[3] \qquad Q[\rho_\alpha] = \alpha^k Q[\rho]$$

$$[4] \qquad \rho_\alpha(x, y, z) = \alpha^3 \rho(\alpha x, \alpha y, \alpha z)$$

and its virial relation,[40,43–45]

$$[5] \qquad Q[\rho] = \frac{-1}{k} \int \rho(\mathbf{r}) \mathbf{r} \cdot \nabla \frac{\delta Q[\rho]}{\delta \rho(\mathbf{r})} \mathrm{d}\mathbf{r}$$

Generalizing and extending the argument in ref. 13, in Section III, we will show how, given the exact and explicit form of a density functional for a single reference system, one may obtain the exact functional for any other density that is determined by its moments and has the same number of electrons as the reference system.

II. Equivalence between scaling and the virial relation

The coordinate-scaling conditions for density functionals and the relationship between coordinate scaling and the adiabatic connection were first established by Levy and Perdew in their classic 1985 paper.[40] Almost all of the coordinate-scaling conditions of interest here are either contained in that paper[40] or easily derived from equations contained therein.[46,47] The general coordinate-scaling equalities in density functional theory can be summarized in a single formula,

$$[6] \qquad Q[\rho_\alpha; \alpha\lambda] = \alpha^n Q[\rho; \lambda]$$

Here, $\alpha = 1$ for potential-like quantities (Coulomb energy, J; exchange energy, E_x; correlation energy, E_c; exchange-correlation energy, $E_{xc} = E_x + E_c$; correlation potential energy, V_c; electron–electron repulsion energy, $V_{ee} = J + E_x + V_c$) and $\alpha = 2$ for kinetic-like quantities (noninteracting kinetic energy, T_s; correlation-kinetic energy, T_c; total kinetic energy, $T = T_s + T_c$). For functionals that do not change over the adiabatic connection path (J, E_x, and T_s), the λ index is superfluous, and the generalized coordinate-scaling conditions reduce to the simpler form in eq. [3]. Notice that even though the exchange-correlation energy and the correlation energy have both kinetic-energy and potential-energy components, they satisfy the potential-like coordinate-scaling relation because they can be computed as the integral of a potential-like quantity over the adiabatic connection path.

The first people to write coordinate-scaling relations in this general form were Levy, Yang, and Parr, who wrote down the special cases of eq. [6] appropriate to the kinetic energy and the electron–electron repulsion energy in this form.[42] More inclusive forms of this equation play an important role in Wang's work on coordinate scaling.[41]

To derive virial equations that are equivalent to eq. [6], it is helpful to use a set of moments with uniform coordinate scaling. For atoms, such a set was proposed by Nagy, Liu, and Parr[11]; generalizing their result to arbitrary systems gives

$$[7] \qquad m_{ijk}^{(NLP)}[\rho] = (m_{ijk}[\rho])^{\left(\frac{-1}{i+j+k}\right)} = \left(\int x^i y^j z^k \rho(\mathbf{r}) \mathrm{d}\mathbf{r}\right)^{\left(\frac{-1}{i+j+k}\right)} \quad \begin{matrix} i,j,k \geq 0 \\ \\ \\ i+j+k > 0 \end{matrix}$$

The Nagy–Liu–Parr moments are homogeneous of degree one with respect to coordinate scaling,

$$[8] \qquad m_{ijk}^{(NLP)}[\rho_\alpha] = \left(\iiint \left[\frac{(\alpha x)^i (\alpha y)^j (\alpha z)^k}{\alpha^{(i+j+k)}} \rho(\alpha x, \alpha y, \alpha z) \mathrm{d}(\alpha x) \mathrm{d}(\alpha y) \mathrm{d}(\alpha z) \right] \right)^{\left(\frac{-1}{i+j+k}\right)} = \alpha m_{ijk}^{(NLP)}[\rho]$$

Notice that the zeroth Nagy–Liu–Parr moment is undefined; for this reason, all of our subsequent arguments assume that the number of electrons does not change. This is clearly true in this context, because the normalization of the density is not changed upon coordinate scaling.

Consider the Euler equation,

$$[9] \qquad nQ[\{m_{ijk}^{(NLP)}\}, \lambda] = \lambda \frac{\partial Q}{\partial \lambda} + \sum_{\substack{i+j+k>0 \\ i,j,k \geq 0}}^{\infty} m_{ijk}^{(NLP)} \frac{\partial Q}{\partial m_{ijk}^{(NLP)}}$$

If this equation is valid, then the function Q is homogeneous of degree n with respect to scaling of its variables:[48]

$$[10] \qquad Q\left(\{\alpha m_{ijk}^{(NLP)}[\rho]\}, \alpha\lambda\right) = \alpha^n Q\left(\{m_{ijk}^{(NLP)}[\rho]\}, \lambda\right)$$

From the scaling of the Nagy–Liu–Parr moments (cf. Equation [8]), we have

$$[11] \qquad Q\left(\{m_{ijk}^{(NLP)}[\rho_\alpha]\}, \alpha\lambda\right) = \alpha^n Q[\{m_{ijk}^{(NLP)}[\rho]\}, \lambda]$$

which is equivalent to eq. [6].

So, eq. [9] is equivalent to the coordinate-scaling condition, eq. [6]. Now, it follows from the chain rule for functional derivatives,

$$[12] \qquad \int \rho(\mathbf{r})\mathbf{r}\cdot\nabla\left(\frac{\delta Q[\rho]}{\delta\rho(\mathbf{r})}\right)d\mathbf{r} = \int \rho(\mathbf{r})\mathbf{r}\cdot\nabla \sum_{\substack{i,j,k=0\\ i+j+k>0}}^{\infty}\left(\frac{\partial Q[\{m_{ijk}^{(NLP)}\}]}{\partial m_{ijk}^{(NLP)}}\frac{\delta m_{ijk}^{(NLP)}}{\delta\rho(\mathbf{r})}\right)d\mathbf{r}$$

$$= \sum_{\substack{i,j,k=0\\ i+j+k>0}}^{\infty}\left(\frac{\partial Q[\{m_{ijk}^{(NLP)}\}]}{\partial m_{ijk}^{(NLP)}}\left[\frac{-\left[\int x^i y^j z^k \rho(\mathbf{r}')d\mathbf{r}'\right]^{\left(\frac{-1}{i+j+k}-1\right)}}{i+j+k}\right]\int \rho(\mathbf{r})\mathbf{r}\cdot\nabla(x^i y^j z^k)d\mathbf{r}\right)$$

that

$$[13] \qquad \sum_{i,j,k=0}^{\infty} m_{ijk}^{(NLP)}\frac{\partial Q}{\partial m_{ijk}^{(NLP)}} = -\int \rho(\mathbf{r})\mathbf{r}\cdot\nabla\left(\frac{\delta Q[\rho]}{\delta\rho(\mathbf{r})}\right)d\mathbf{r}$$

Inserting eq. [13] into eq. [9] allows us to rewrite the coordinate-scaling condition, eq. [6], in its virial form,

$$[14] \qquad nQ[\rho;\lambda] = \lambda\frac{\partial Q[\rho;\lambda]}{\partial\lambda} - \int \rho(\mathbf{r})\mathbf{r}\cdot\nabla\left(\frac{\delta Q[\rho;\lambda]}{\delta\rho(\mathbf{r})}\right)d\mathbf{r}$$

Many special cases of eq. [14] are known in the literature.[40,49] When Q does not depend on λ, the first term on the right-hand-side of eq. [14] vanishes and eq. [5] is obtained.

The original derivation of eq. [5] from eq. [3] requires that $\rho(\mathbf{r})\delta Q[\rho]/\delta\rho(\mathbf{r})$ decay faster that r^{-3} as $r \to \infty$.[43] The present derivation clarifies the situation by showing that the DFT virial theorem is equivalent to the Eulerian virial theorem for simple functions. The moment-based derivation requires only that the moments determine the density, which imposes a different condition, albeit one that is often more stringent than the restriction on the asymptotic decay of $\rho(\mathbf{r})\delta Q[\rho]/\delta\rho(\mathbf{r})$. However, given the recent realization that the asymptotic decay of $\delta T_s/\delta\rho(\mathbf{r})$, $\delta E_x/\delta\rho(\mathbf{r})$, and $\delta E_{xc}/\delta\rho(\mathbf{r})$ is nonuniform,[50–53] there is merit in a derivation that does not depend in any way on the asymptotic decay of the functional derivative.

III. Deducing "universal" functionals from a single system

Equation [9] is a first-order partial differential equation that can be solved by the method of characteristics.[13] Suppose, then, that the *exact and explicit* expression for $Q\left(\{m_{ijk}^{(NLP)}\}, \lambda\right)$ is known for a specific N-electron system. Notice that we are not merely assuming that the value of the functional is known; we require that the exact *functional form* is known. The values of λ and the moments for this system are the initial values from which the differential equation will be solved. To simplify the notation, it is helpful to introduce a new set of coordinates, $\{x_p\}$, where $x_0 = \lambda$ and $x_{p>0}$ denote the various Nagy–Liu–Parr moments. The values of these variables for the known system are denoted $\{x_p^{(0)}\}$ and, in terms of these coordinates, eq. [9] (equivalently, eq. [14]) has the form

$$[15] \qquad nQ(\{x_p\}) = \sum_{p=0}^{\infty} x_p\frac{\partial Q}{\partial x_p}$$

We define a variable, τ, that parameterizes the characteristics through the equations

$$[16] \qquad \frac{dQ}{d\tau} = nQ \qquad \frac{dx_p}{d\tau} = x_p$$

Note that inserting these formulae into eq. [15] yields the identity

$$[17] \qquad \frac{\partial Q}{\partial\tau} = \sum_{p=0}^{\infty}\frac{\partial x_p}{\partial\tau}\frac{\partial Q}{\partial x_p}$$

Equation [16] can be solved by inspection, giving

$$[18] \qquad Q = C_Q e^{n\tau} \qquad x_p = C_p e^{\tau}$$

The Cs are constants of integration and can be determined based on the functional form of the known system

$$[19]\qquad \begin{aligned} C_Q &= Q\left(\{x_p^{(0)}\}\right)\mathrm{e}^{-n\tau^{(0)}} \\ C_p &= x_p^{(0)}\mathrm{e}^{-\tau^{(0)}} \end{aligned}$$

Substituting back into eq. [18] gives

$$[20]\qquad \begin{aligned} Q &= Q\left(\{x_p^{(0)}\}\right)\mathrm{e}^{n\left(\tau-\tau^{(0)}\right)} \\ x_p &= x_p^{(0)}\mathrm{e}^{\tau-\tau^{(0)}} \end{aligned}$$

To eliminate most of the explicit dependence on the initial conditions, we will express all of the other variables in terms of a specific variable, q,

$$[21]\qquad \mathrm{e}^{\tau-\tau^{(0)}} = \frac{x_q}{x_q^{(0)}}$$

$$[22]\qquad x_p^{(0)} = \frac{x_{p\neq q}x_q^{(0)}}{x_p}$$

giving the "final" form

$$[23]\qquad \begin{aligned} Q(\{x_p\}_{p=0}^{\infty}) = &\left(\frac{x_q}{x_q^{(0)}}\right)^n \\ &\times Q\left(\frac{x_0x_q^{(0)}}{x_q}, \frac{x_1x_q^{(0)}}{x_q}, \ldots, \frac{x_{q-1}x_q^{(0)}}{x_q}, x_q^0, \frac{x_{q+1}x_q^{(0)}}{x_q}, \ldots\right) \end{aligned}$$

This functional can be used for any system with the same number of electrons as the reference system, so long as both that system and the reference system are determined by their moments. The key to using this formula, however, and the reason this formula is not computationally facile, is that it requires that one know the *exact* functional form of $Q(\{x_p\}) = Q[\rho;\lambda]$. If the exact functional form were known for some $\{\rho_0(\mathbf{r}),\lambda_0\}$, however, then all of the derivatives of Q would also be known, and one could evaluate $Q[\rho;\lambda]$ from perturbation theory or, somewhat more elegantly, through the Parr–Liu–Kugler–Nagy expansion.[54,55] So, the reader should not be too surprised that full knowledge of a functional for a single system is generally sufficient to determine it for other systems also. For example, the work of Ludeña and his colleagues on local scaling transformations is also based on using extending functionals from a single known system to the general case.[56–61] Equation [23] is still important, however, as a constraint on the functional form of exact functionals.

IV. Specific cases and extensions

If the exact functional is known for an intermediate point on the adiabatic connection path, $0 < \lambda_0 < \infty$, then the exact functional can be determined at any other value of λ. Recalling that $x_0 = \lambda$, eq. [23] becomes

$$[24]\qquad \begin{aligned} Q(\lambda, \{x_p\}_{p=1}^{\infty}) &= \left(\frac{\lambda}{\lambda_0}\right)^n Q\left(\lambda_0, \frac{x_1\lambda_0}{\lambda}, \frac{x_2\lambda_0}{\lambda}, \ldots\right) \\ Q[\rho;\lambda] &= \left(\frac{\lambda}{\lambda_0}\right)^n Q\left[\rho_{\lambda_0/\lambda};\lambda_0\right] \end{aligned}$$

The scaling of the Nagy–Liu–Parr moments was used to derive the second line. This equation is obviously equivalent to eq. [6] with $\alpha = \frac{\lambda_0}{\lambda}$. Levy has presented several specific cases of eq. [24], including the electron–electron repulsion potential case. He has also described the "out of one, many" nature of this formula, by which knowledge of a functional at a specific point on the adiabatic connection curve suffices to determine that functional at all other points.[62]

The analysis in Sections II and III can be extended to other sets of density functionals that fully specify the electron density and scale homogeneously, $g_{ijk}[\rho_\alpha] = \alpha g_{ijk}[\rho]$. For any such functional, eq. [5] implies that

$$[25]\qquad g_{ijk}[\rho] = -\int \rho(\mathbf{r})\mathbf{r}\cdot\nabla\frac{\delta g_{ijk}[\rho]}{\delta\rho(\mathbf{r})}\mathrm{d}\mathbf{r}$$

so there is an analogue to eq. [13], namely

$$[26]\qquad \begin{aligned} g_{ijk}\frac{\partial Q}{\partial g_{ijk}} &= -\int \rho(\mathbf{r})\mathbf{r}\cdot\nabla\frac{\partial Q}{\partial g_{ijk}}\frac{\delta g_{ijk}}{\delta\rho(\mathbf{r})}\mathrm{d}\mathbf{r} \\ \sum_{i,j,k} g_{ijk}\frac{\partial Q}{\partial g_{ijk}} &= -\sum_{i,j,k}\int \rho(\mathbf{r})\mathbf{r}\cdot\nabla\frac{\partial Q}{\partial g_{ijk}}\frac{\delta g_{ijk}}{\delta\rho(\mathbf{r})}\mathrm{d}\mathbf{r} \\ &= \int \rho(\mathbf{r})\mathbf{r}\cdot\nabla\frac{\delta Q}{\delta\rho(\mathbf{r})}\mathrm{d}\mathbf{r} \end{aligned}$$

Then, from the generalized scaling relation, eq. [6],

$$[27]\qquad nQ[\{g_{ijk}\},\lambda] = \lambda\frac{\partial Q}{\partial\lambda} + \sum_{\substack{i+j+k>0 \\ i,j,k\geq 0}}^{\infty} g_{ijk}\frac{\partial Q}{\partial g_{ijk}}$$

From this equation and eq. [26], the generalized virial relation (eq. [14]) follows. Equation [27] can be solved by the method of characteristics to obtain a solution in the form of eq. [23]. This means that were the exact functional form known for *any value* of *any* homogeneously scaling functional, $g_{ijk}[\rho] = g_{ijk}^{(0)}$, then a "universal" functional for other systems with the same numbers of electrons could be written using eq. [23]. This suggests considering alternative sets of homogeneous functionals, e.g.,

$$[28]\qquad g_k[\rho] = \left(\int (\rho(\mathbf{r}))^{1+\frac{k}{3}}\mathrm{d}\mathbf{r}\right)^{\frac{1}{k}},\quad k = 1, 2, \ldots$$

$$[29]\qquad g_{ijk}[\rho] = \left(\int \frac{\partial^{i+j+k}\rho(\mathbf{r})}{\partial x^i\partial y^j\partial z^k}\mathrm{d}\mathbf{r}\right)^{\frac{1}{i+j+k}}$$

The former set of functionals may be argued to be (over)-complete,[13] but the latter set of functionals is probably incomplete.

V. Summary

The purpose of this paper is to demonstrate that using the moments of the electron density, instead of the electron density itself, in density functional theory is a useful theoretical trick. Part of this is because the mathematical tools for working with functions of moments are more familiar than the tools for working with functionals of the density. Part of this is because moment-based density functionals are subu-

niversal in useful ways. Most notably, the moment-based techniques are not necessarily applicable to systems with "strange" nonexponentially decaying electron densities. Second, the convenient Nagy–Liu–Parr set of moments excludes the number of electrons; using a different moment functional for each number of electrons avoids difficulties associated with the derivative discontinuity,[63–65] though it introduces size-consistency problems.

To demonstrate the power of moment-based reasoning, we first derived the equivalence of the the generalized coordinate-scaling condition (eq. [6]) and its virial form (eq. [14]). One advantage of this derivation is that it clarifies the link between density scaling in DFT and variable scaling in real analysis. In fact, the DFT virial equation is exactly equivalent to the Euler differential equation for functions that scale homogeneously with respect to their coordinates, eq. [9]. The Euler differential equation can then be solved, provided a suitable initial condition is known. This means that for any quantity (e.g., the kinetic energy, the electron–electron repulsion energy, or the exchange-correlation energy) that satisfies a generalized coordinate-scaling condition, if one knows the exact functional (not just its value, but its functional form) for *one N*-electron density, then one can determine the value of the functional for all other *N*-electron densities that are determined uniquely by their moments. We hope that results of this type may guide the use of special cases (e.g., the strongly interacting limit[66–70]) in the development of density functionals.

Experimental and theoretical investigations of selenium nuclear magnetic shielding tensors in Se–N heterocycles

Andre Sutrisno, Andy Y.H. Lo, Joel A. Tang, Jason L. Dutton, Gregg J. Farrar, Paul J. Ragogna, Shaohui Zheng, Jochen Autschbach, and Robert W. Schurko

Abstract: A preliminary study involving solid-state ^{77}Se NMR spectroscopy and first principles calculations of ^{77}Se NMR parameters in Se–N heterocycles is reported. ^{77}Se CP/MAS NMR spectra of the ring systems reveal expansive selenium chemical shift (CS) tensors, which are extremely sensitive to molecular geometry, symmetry, ligand substitution, and intermolecular contacts. For systems with known crystal structures, hybrid density functional theory (DFT) calculations of selenium nuclear magnetic shielding (NMS) tensors were carried out, and tensor orientations in the molecular frames examined. Additional DFT calculations of selenium NMS tensors are presented, along with a detailed analysis of pairs of occupied and virtual molecular orbitals that give rise to the Se NMS tensors. A new naturalized local molecular orbital (NLMO) analysis under the same DFT framework is also discussed. Collectively, the NMR data and first principles calculations provide understanding of the influences of electronic structure, bonding, and intermolecular interactions on the selenium NMS tensors, allowing for (*i*) prediction of unknown molecular structures and (*ii*) insight into the positions of the stereochemically active selenium lone pairs.

Key words: solid-state NMR, ^{77}Se NMR, ab initio calculations, chemical shielding, main-group inorganic chemistry, heterocycles, DFT calculations, MO analysis, Gaussian 03, ADF.

Résumé : On rapporte les résultats d'une étude préliminaire de spectroscopie RMN du ^{77}Se à l'état solide et de calculs à partir de principes fondamentaux des paramètres RMN du ^{77}Se dans des hétérocycles Se–N. Les spectres RMN des systèmes cycliques par la technique de la rotation à l'angle magique avec polarisation croisée (RAMPC) mettent en évidence l'existence d'un large éventail de tenseurs du déplacement chimique (DC) du sélénium qui sont extrêmement sensibles à la géométrie moléculaire, à la substitution par des ligands et aux contacts intermoléculaires. Pour les systèmes dont on connaît les structures cristallines, on a effectué des calculs des tenseurs de blindage magnétique nucléaire (BMN) du sélénium avec la théorie de la fonctionnelle de la densité (TFD) hybride et on a examiné les orientations des tenseurs dans des cadres moléculaires. On rapporte les résultats de calculs effectués sur la base de la TFD des tenseurs de blindage magnétique nucléaire ainsi qu'une analyse détaillée des paires d'orbitales moléculaires occupées et virtuelles qui donnent lieu aux tenseurs de blindage magnétique nucléaire du sélénium. On discute aussi d'une nouvelle analyse de l'orbitale moléculaire naturalisée (OMLN) dans le même cadre de la TFD. Pris collectivement, les données de la RMN et les calculs à partir de principes fondamentaux permettent de comprendre les influences de la structure électronique, des liaisons et des interactions intermoléculaires sur les tenseurs de BMN et aussi (*i*) de faire des prédictions pour 15 structures moléculaires inconnues et (*ii*) de se faire une idée sur les positions des paires d'électrons libres du sélénium qui sont actives d'un point de vue stéréochimique.

Mots-clés : RMN à l'état solide, RMN du ^{77}Se, calculs ab initio, blindage chimique, chimie inorganique du groupe principal, hétérocycles, calculs TFD, analyse des OM, gaussienne 03, fonctionnelle de la densité d'Amsterdam (FDA).

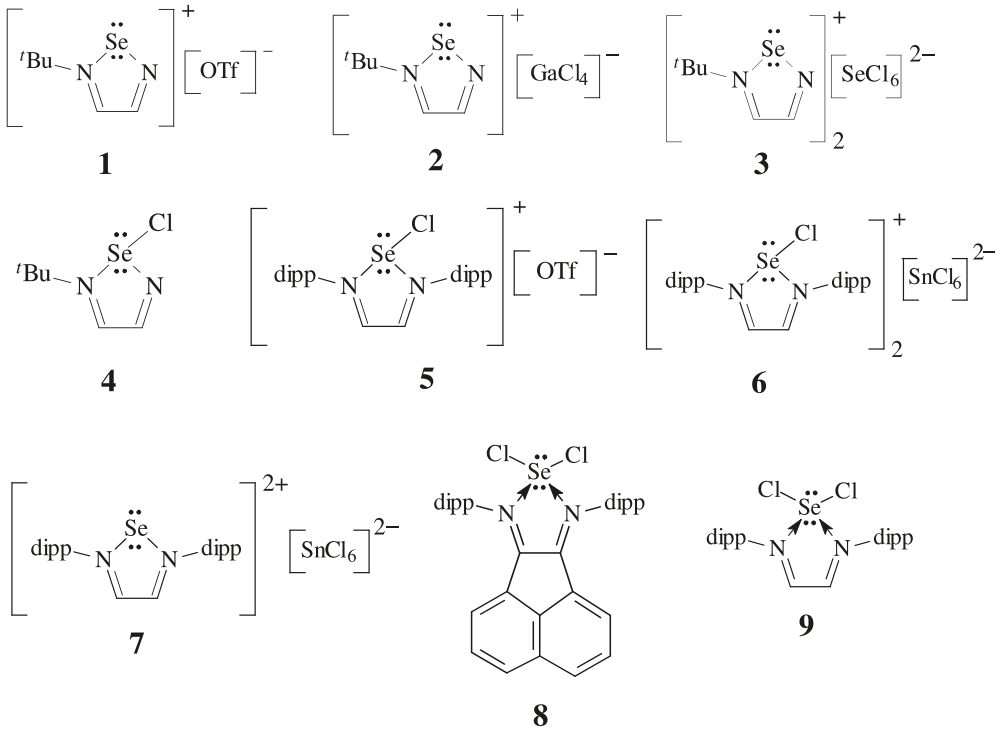
Introduction

Carbenes are known to be important reaction intermediates, and there is an enormous amount of literature reporting their syntheses, structures, and reactivities.[1–7] Since the first report of the synthesis of stable crystalline *N*-heterocyclic carbenes by Arduengo,[8] there have been a substantial number of papers discussing the isovalent p-block analogues known as the *N*-heterocyclic carbenoids.[4,5,9–11] In these carbenoids, the main-group element is bi-coordinate and bears a lone pair. *N*-heterocyclic carbenoids have been successfully synthesized and characterized for group 13 (B^-, Al^-, Ga^-, In^-, Tl^-), group 14 (Si, Ge, Sn), group 15 (N^+, P^+, As^+, Sb^+), and group 16 (S^{2+}), with main-group elements being formally understood as anionic, neutral, cationic, and dicationic, respectively.[12–20] The recent synthesis of dicationic

Chart 1. Schematic drawings of selenium carbenoid compounds **1–9**.



N-heterocyclic selenium carbenoids has extended the series into group 16, and the distinct formal charge at the Se atom (+2) has a significant impact on the reactivity of these carbenoids.[21–23]

^{77}Se solid-state NMR (SSNMR) spectroscopy should prove to be valuable for the study of molecular structure and reactivity for a wide array of organometallic selenium heterocycles,[13,24,25] including the *N*-heterocyclic selenium carbenoids and derivative structures. Selenium has only one NMR-active isotope, ^{77}Se, which has a spin quantum number $I = 1/2$, 7.58% natural abundance, and a gyromagnetic ratio of 5.1214×10^7 rad T^{-1} s^{-1} (relative receptivity of 2.9 in comparison to ^{13}C). Selenium chemical shifts (CS or δ) are very sensitive to the local electronic environment of the selenium atom and are presently known to span a range of about 5800 ppm,[26–43] with the extreme isotropic chemical shifts, δ_{iso}, being marked by values of 3691 and 4531 ppm for Se sites in Mo_6Se_8,[44] to –1274 ppm for Se^{2-} sites in Ag_7PSe_6.[45,46] Solution ^{77}Se NMR and ab initio calculations have been applied to many selenium containing compounds;[34,35,38,39,42,43,47–55] however, there have been fewer reports of ^{77}Se SSNMR experiments,[26–30,40,41,56,57] despite the significant number of selenium-containing solid materials that could benefit from such characterization. There have also been a number of recent studies detailing ab initio calculations of selenium shielding tensors and their relationships to molecular electronic structure for systems such as aryl selenides,[58] square-planar metal complexes of the diselenoimidodiphosphinate anion,[59] and a variety of organic, inorganic and organometallic selenium containing compounds.[30] In particular, the careful examination of which molecular orbitals make dominant contributions to nuclear magnetic shielding (NMS) tensors, and the effects of alteration of molecular structure, have been studied in great detail.[58]

Herein, a preliminary ^{77}Se SSNMR study of selenium heterocyclic compounds is reported. The aims of this study are to experimentally measure the selenium CS tensors in these heterocycles (Chart 1) using ^{77}Se SSNMR spectroscopy, and to investigate the relationships between the selenium NMS tensor parameters and the molecular structure, bonding, and symmetry in these systems using first-principles calculations. Density functional theory (DFT) calculations using the Amsterdam density functional (ADF) software package[60] are applied to a series of model systems to examine the origin of the selenium NMS tensors from the perspective of contributions of single and pairs of molecular orbitals (MOs), under the formalism developed by Ziegler and coworkers.[52,61–63] A natural localized molecular orbital (NLMO)[64] analysis of MOs contributing to selenium shielding is also presented,[65,66] which classifies these MOs according to "chemically intuitive" orbitals, such as bonding, core, and lone pairs. By applying this methodology and developing an understanding of relationships between shielding tensors and molecular structure for a series of well-characterized Se heterocycles, we will demonstrate that ^{77}Se NMR is useful for (*i*) predicting unknown heterocyclic structures for which crystal structure data are not available and (*ii*) confirming the orientation and nature of the selenium lone pairs, which will be of great importance for understanding the reactivity and stability of these systems.

Experimental methods

Sample preparation

Samples of 1,2,5-selenadiazolium trifluoromethane sulfonate ([*t*-Bu-N_2C_2Se][OTf]) (**1**), 1,2,5-selenadiazolium gallium(III) tetrachloride ([*t*-Bu-N_2C_2Se][$GaCl_4$]) (**2**), bis(1,2,5-selenadiazolium) selenium(IV) hexachloride ([*t*-Bu-N_2C_2Se]$_2$[$SeCl_6$]) (**3**), 1,2,5-selenadiazolium chlorine ([*t*-Bu-N_2C_2Se–Cl]) (**4**),

2-chloro-1,2,5-selenadiazole trifluoromethane sulfonate ($[SeN_2C_{26}H_{36}Cl][OTf]$) (**5**), 2-chloro-1,2,5-selenadiazole tin(IV) hexachloride ($[SeN_2C_{26}H_{36}Cl]_2[SnCl_6]$) (**6**), selenium "carbenoid" 1,2,5-selenadiazole tin(IV) hexachloride ($[SeN_2C_{26}H_{36}]_2[SnCl_6]$) (**7**), $SeCl_2$-BIAN (bis(imino)acenapthene) ($[SeN_2C_{36}H_{40}Cl_2]$) (**8**), and selenium carbene analogue $SeCl_2$-dipp ($[SeN_2C_{26}H_{36}Cl_2]$) (**9**) were synthesized using previously reported procedures,[21,22] with some modifications which will be discussed in a forthcoming publication.

Sample purity

^{13}C CP/MAS NMR and powder X-ray diffraction experiments were performed to confirm sample purity (Table S1 and Figs. S1–S12 in Supplementary data).

Solid-state NMR spectroscopy

Solid-state NMR experiments were conducted on a Varian Infinity Plus spectrometer with an Oxford 9.4 T (ν_0 (^1H) = 400 MHz) wide-bore magnet, operating at resonance frequencies of ν_0 (^{77}Se) = 76.28 MHz and ν_0 (^{13}C) = 100.52 MHz. A Varian/Chemagnetics 4 mm double resonance HX magic-angle spinning (MAS) probe was used for all experiments. All samples were finely ground and packed into 4 mm o.d. zirconia rotors and sealed with airtight caps under a dry N_2 atmosphere. Selenium chemical shifts were referenced to a solution of Me_2Se in $CDCl_3$ (60% *v/v*) at 0.0 ppm, using solid $(NH_4)_2SeO_4$ as a secondary standard (δ_{iso} = 1040.2 ppm).[31] Carbon chemical shifts were referenced to tetramethylsilane (TMS) at 0.0 ppm, by using the high-frequency peak of solid adamantane as a secondary standard (δ_{iso} = 38.57 ppm).[67]

^{77}Se VACP/MAS NMR

Proton-decoupled ^{77}Se variable-amplitude cross-polarization magic-angle spinning (VACP/MAS)[68,69] NMR spectra were acquired with spinning speeds ranging from 4.5 to 12.0 kHz (a minimum of two spinning speeds were utilized to isolate peaks corresponding to isotropic shifts). Calibrated recycle delays from 1.0 to 5.0 s were used. The ^{77}Se radio-frequency (rf) frequencies, $\nu_1(^{77}Se)$, were calibrated at various power levels using a solution of 1.0 mol/L $(NH_4)_2SeO_4$. The Hartmann–Hahn matching condition was optimized using a sample of solid $(NH_4)_2SeO_4$. The proton $\pi/2$ pulse widths were between 1.6 and 4.0 μs, and optimized contact times of 15 to 17 ms were used, with spectral widths of 200 to 300 kHz (see Table S2 for detailed experimental parameters). TPPM ^1H decoupling[70] was used in all experiments, with decoupling fields of 62.5 kHz or greater.

Spectral simulations

Selenium chemical shift tensor parameters, δ_{iso}, Ω, and κ (see tables for definitions) were extracted using Herzfeld–Berger (HB)[71] analysis and analytical simulations of ^{77}Se SSNMR spectra were performed using the WSOLIDS package.[72]

Theoretical Methods: G03 and ADF

Hybrid DFT and Hartree–Fock calculations were conducted using Gaussian 03[73] running on a dual-2.8 GHz Xenon Dell Precision 650 workstation or a dual-3.6 GHz Xenon Dell Precision 670n workstation, as well as quad-2.2 and 2.4 GHz Opteron HP workstations on SHARCNET. Selenium nuclear magnetic shielding tensors were calculated using the GIAO method[74,75] with the B3LYP (Becke's three-parameter hybrid density functional[76] with the Lee, Yang, and Parr correlation functional[77,78]) and RHF (Restricted Hartree–Fock) techniques. The 6–31G**, 6–311G**, and 6–311++G** basis sets were used on the Se atoms, as well as the 13s10p4d, 14s10p5d, 17s13p6d, and 24s20p10d all-electron Huzinaga basis sets.[79] Basis sets for the lighter atoms are listed in the Supplementary data. Selenium chemical shifts were referenced to Me_2Se by comparing calculated shielding values to the absolute shielding value of Me_2Se.[31,52] The ADF software package[61] was applied to several model systems; contributions from individual MO pairs to the NMS tensors were analyzed using the NMR–EPR module.[63] The BLYP[77,78] and VWN-BP (Vosko–Wilk–Nusair[80] local density approximation with the Becke–Perdew[76,77] generalized gradient approximation) exchange-correlation functionals were applied for non-relativistic (NR) calculations, and all-electron gauge including atomic orbitals (GIAO)[74,75] double-ζ (DZ) or triple-ζ doubly polarized (TZ2P) basis sets were used on all atoms. Full sets of crystal structure coordinates with optimized proton positions were used for Gaussian 03 calculations, while symmetry-constrained geometry-optimized structures were used for ADF calculations.

NLMO analyses

For the natural bond orbital (NBO) / natural localized molecular orbital (NLMO) analysis of the Se shielding, a locally modified version of the ADF package was used. The modifications include an interface program "adfnbo" integrating the DFT computations with a generic version of the NBO 5.0 version by Glendening et al.[64] Details of the NBO/NLMO analysis of shielding constants are published elsewhere.[65,66] The approach taken is a relativistic generalization of the NBO shielding analysis of Bohmann et al.[81] The zeroth-order regular approximation (ZORA)[82] in its spin-free (scalar relativistic) form was applied to treat relativistic effects. The triple-ζ doubly polarized (TZ2P) all-electron Slater-type basis sets from the ADF basis set library was used for the shielding calculation and the accompanying NBO/NLMO analyses. The calculations employed the VWN-BP functional.

Results and discussion

Prior to the detailed discussion of our results, it is important to differentiate between the chemical shift (CS) and nuclear magnetic shielding (NMS). Nuclear magnetic shielding, σ, describes the degree of magnetic shielding of a nucleus in an atom or molecule with respect to a bare nucleus. The nuclear magnetic shielding is related to the chemical shift, δ, which is measured experimentally with respect to a reference compound, via the equation:

$$[1] \qquad \delta = \frac{\sigma_{ref} - \sigma}{1 - \sigma_{ref}} \approx \sigma_{ref} - \sigma$$

where σ_{ref} is the nuclear magnetic shielding of the reference compound. The approximation in eq. [1] generally holds for most nuclei with small to moderate chemical shift ranges

Table 1. Summary of observed ^{77}Se CS tensor parameters for compounds **1**–**9**.

Compound	δ_{11} (ppm)[a]	δ_{22} (ppm)	δ_{33} (ppm)	δ_{iso} (ppm)[b]	Ω (ppm)[c]	κ[d]
1 (site 1)	2005	1520	1275	1600 (10)[e]	730 (10)	–0.33 (3)

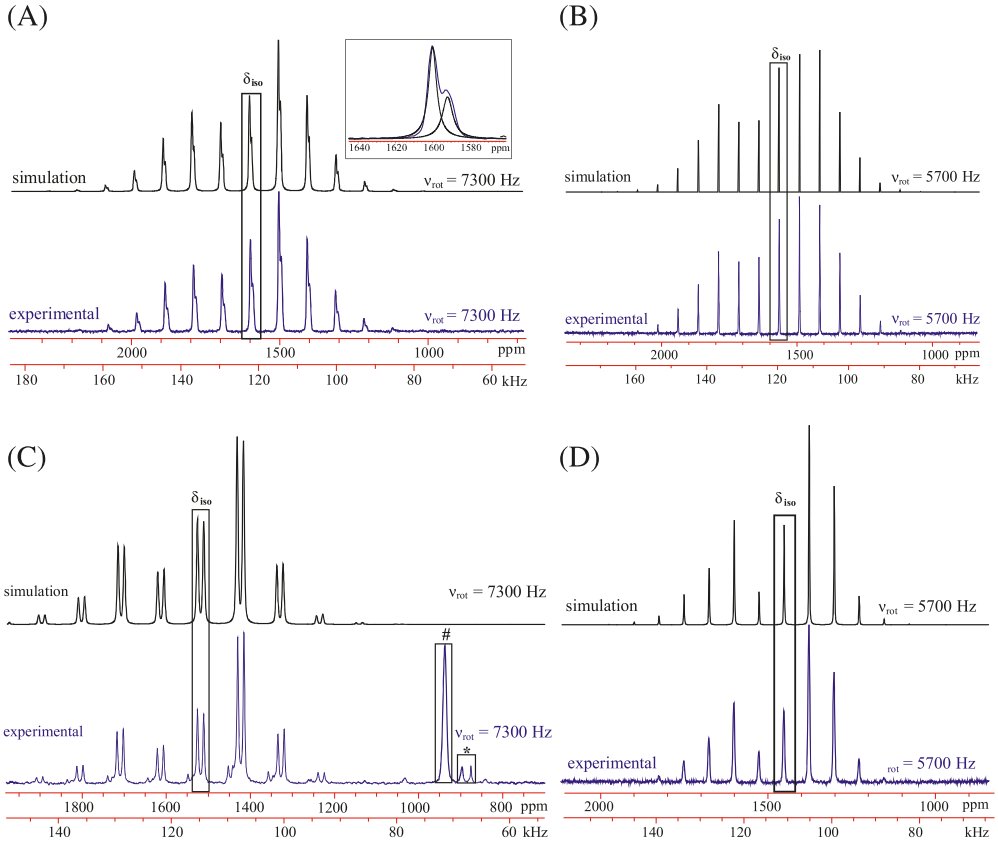
[a]No calculations are done on compounds **1** and **9** due to the unavailability of the single crystal X-ray structures.
[b]The chemical shielding tensor is described by three principal components, ordered such that $\sigma_{11} \leq \sigma_{22} \leq \sigma_{33}$.
[c]$\sigma_{iso} = (\sigma_{11} + \sigma_{22} + \sigma_{33})/3$.
[d]The chemical shift values were referenced to Me_2Se by comparing the calculated shielding values of all compounds to the absolute shielding value of Me_2Se (see eq. [1] in main text).
[e]$\Omega = \sigma_{33} - \sigma_{11}$.
[f]$\kappa = 3(\sigma_{iso} - \sigma_{22})/\Omega$.
[g]These particular methods and basis sets were used to generate the CS tensor orientations in Fig. 4.

(exceptions include nuclei with enormous chemical shift ranges like ^{59}Co, ^{195}Pt, ^{207}Pb, etc.). Hence, theoretically calculated shielding parameters can be easily compared to experimentally measured chemical shifts by calculating the absolute shielding for both the system under investigation and the reference system or compound. In this work, CS tensors will refer to experimentally measured data, and NMS tensors (or shielding tensors) will refer to theoretically calculated data. The two can easily be compared via eq. [1]. Definitions of the CS and NMS tensor parameters are found in Tables 1 and 2, respectively. More details on the relations between chemical shifts and nuclear magnetic shielding, as well as conventions utilized for describing these parameters, can be found elsewhere.[83,84]

Fig. 1. Experimental ^{77}Se VACP/MAS and simulated spectra for (A) **1**, (B) **2**, (C) **3,** and (D) **4** at 9.4 T. (A) Inset: the deconvolution of the isotropic peak. (C) Note: # denotes the isotropic shift for the $SeCl_6^{2-}$ anion, and * denotes impurities in the sample.



In the first part of this section, the acquisition and interpretation of solid-state ^{77}Se VACP/MAS NMR spectra of all of the heterocycles are discussed (the compounds are grouped according to common structural features in Chart 1). Second, a discussion of hybrid DFT and Hartree–Fock calculations of selenium NMS tensors is presented. Finally, we examine the application of DFT calculations to model systems to ascertain which molecular orbitals (MOs) are key in determining the nature of the selenium NMS tensor. A summary of the experimentally observed ^{77}Se NMR parameters is shown in Table 1.

[*t*-Bu–N_2C_2Se][OTf] (1) and [*t*-Bu–N_2C_2Se][$GaCl_4$] (2)

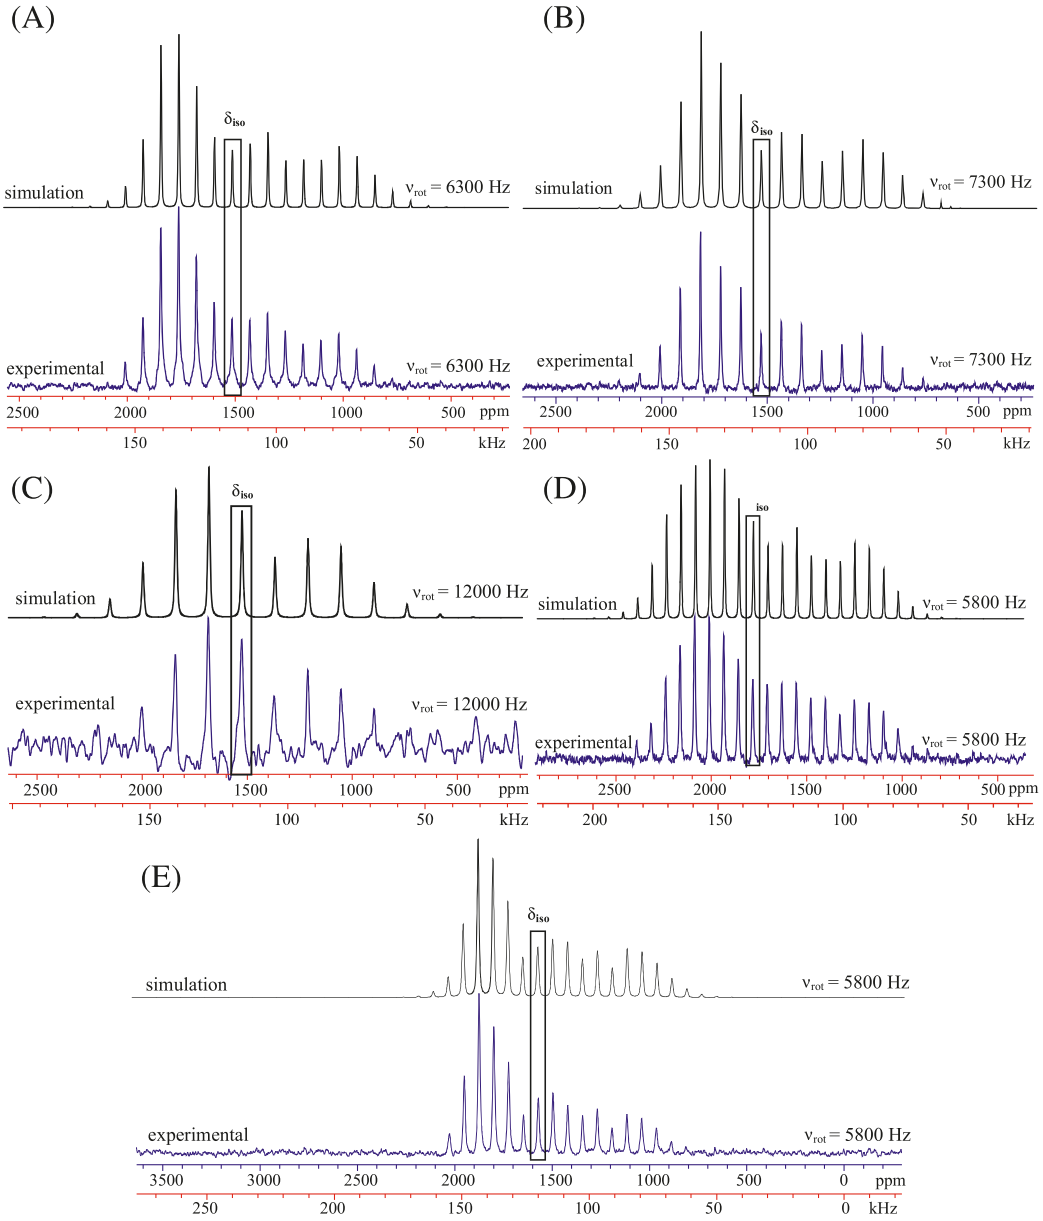
Complexes **1** and **2** are isostructural 1,2,5-selenadiazolium heterocyclic cations which are singly substituted by a *t*-butyl group at one nitrogen position. Furthermore, atoms in the counteranions of these species are not expected to make any distant contacts or formal bonds with the Se atoms. The crystal structure has been determined for **2**,[21] revealing a dimeric structure featuring an inversion centre at the heart of a four-membered Se_2N_2 ring and inter-ring Se···N contacts of 2.605 Å. The ^{77}Se VACP/MAS NMR spectra of **1** and **2** (Figs. 1A and 1B) are very similar in appearance, except for the two separate resonances in the spectrum of **1**. There are two isotropic chemical shifts observed for **1** at 1600 and 1593 ppm, corresponding to two magnetically distinct sites. The NMS tensor parameters for these sites are almost identical, and the total powder patterns have equal integrated intensities, indicating that there are two crystallographically distinct Se sites whose environments differ only slightly. For **2**, there is only one isotropic chemical shift observed at 1565 ppm, which is consistent with the unique crystallographic Se site.

Although the crystal structure is unknown for **1**, the similarity of the NMR parameters suggest that the local Se environment is very similar to that of **2**; however, the crystallographic space group must be different, because of the appearance of two distinct peaks in the spectrum of **1**. The low frequency peak is broader than the high frequency peak, with full-widths at half-height (FWHH) of 550 and 400 Hz, respectively (Fig. 1A, inset). The differential broadening might be caused by distinct dipolar or *J*-coupling interactions, likely resulting from distinct Se–N bond distances, though no effects of residual dipolar coupling are observed. The large spans and non-axial skews are not surprising given the planar structure of these molecules.[30] In both cases, the skew is negative, indicating that δ_{11} is the distinct component of the NMS tensor. Since these types of molecules are known to have significant aromatic character, and a π-system delocalized over the five-membered ring, the δ_{33} component is likely directed perpendicular to the plane of the heterocycle. NMS tensor orientations will be further discussed in the theoretical section below.

[*t*-Bu–N_2C_2Se]$_2$[$SeCl_6$] (3) and [*t*-Bu–N_2C_2Se–Cl] (4)

Complexes **3** and **4** have the same heterocyclic structures as **1** and **2**; however, the counteranions are positioned such

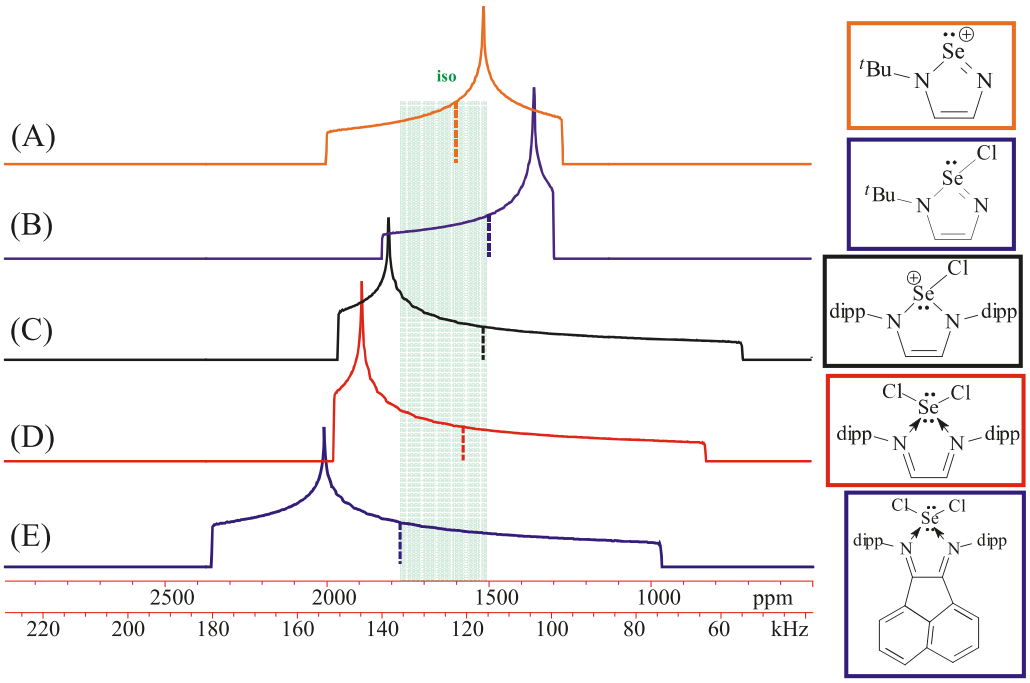
Fig. 2. Experimental ^{77}Se VACP/MAS and simulated spectra for (A) **5**, (B) **6**, (C) **7**, (D) **8** and (E) **9** at 9.4 T.



that one chlorine atom makes a distant contact with the Se atom (we define a "distant contact" as a weak bonding interaction with energy significantly less than a formal covalent bond). Formal Se–Cl bonds are best described in the range of 2.2 to 2.5 Å, while distant Se···Cl contacts fall in the range of 2.6 to 2.9 Å. The distances between Se and Cl (2.850 Å for **3** and 2.605 Å for **4**)[21] are significantly shorter than that in **2** (3.510 Å). Solid-state structures of **3** and **4** also reveal different types of N–Se–N bonding arrangements: **3** has a much longer Se···N inter-ring contact (4.147 Å) than **2**, which falls outside of the sum of the van der Waals radii for Se and N (3.54 Å). However, for **4**, the presence of the Cl atom on Se prevents the creation of a four-membered Se_2N_2 ring, as observed for **2**.

^{77}Se VACP/MAS NMR spectra of **3** and **4** are presented in Figs. 1C and 1D, respectively. Three isotropic chemical shifts were observed in the spectrum of **3**, two of which are assigned to the two [*t*-Bu-N_2C_2Se]$^+$ cations (1522 and 1507 ppm), and one to the $SeCl_6^{2-}$ anion (935 ppm). The former two isotropic chemical shifts correspond to the two distinct crystallographic cations, which are structurally similar enough that the Se NMS tensor parameters are comparable. For **4**, there is only one isotropic chemical shift observed at 1452 ppm, consistent with a single crystallographic site. Compared to **1** and **2**, the spans of **3** and **4** are reduced by about 200 ppm, and the skews are more negative (i.e., δ_{11} is increasingly distinct), suggesting that the Cl atoms play a role in reducing the span and moving the isotropic chemical shift to lower frequency (δ_{iso} becomes more negative). The ^{77}Se nuclei are more shielded with respect to **1** and **2**; since the Cl is in the plane of the heterocycles, it is likely that changes in δ_{11} and δ_{22} are influencing the overall value of δ_{iso}, consistent with δ_{33} being oriented perpendicular to the ring plane; further comments are made in the theoretical section.

Fig. 3. Summary of the observed ^{77}Se NMR parameters for selected structural motifs: A (**1**, **2**), B (**3**, **4**), C (**5**, **6**), D (**7**, **8**), and E (**9**). The shaded region indicates the range of isotropic chemical shifts, δ_{iso}.



$[SeN_2C_{26}H_{36}Cl][OTf]$ (5) and $[SeN_2C_{26}H_{36}Cl]_2[SnCl_6]$ (6)

Complexes **5** and **6** are planar 2-chloro-1,2,5-selenadiazolium heterocyclic cations which are substituted by dipp (2,6-di(isopropyl)phenyl) groups at each nitrogen position, and have formal Se–Cl bonds of 2.323 and 2.458 Å, respectively. The N–Se–Cl bond angles are 92.3° and 93.1° for **5** (owing to the presence of a disorder with an occupancy of 80:20), while it is approximately 92.8° for **6**. ^{77}Se VACP/MAS NMR spectra of **5** and **6** (Figs. 2A and 2B) reveal isotropic shifts of 1514 and 1527 ppm, respectively, which are similar to those of **1** through **4**. However, the anisotropic selenium NMS tensors are quite different from those of earlier complexes: first, the spans of **5** and **6** are more than double those of **3** and **4**, and secondly, the skews are positive, meaning that the δ_{33}s are now the distinct components (the change in κ is especially noticeable, since the discontinuous portion of the pattern corresponding to δ_{22} is now located to high frequency of δ_{iso}). Clearly, the addition of a ligand to the second nitrogen position alters the selenium NMS tensor, although it does not necessarily mean that the selenium nucleus becomes more or less shielded. The second nitrogen substituent undoubtedly results in a significant change in the electronic environment at the Se atom, serving to increase the magnetic shielding along the direction of δ_{33}.

$[SeN_2C_{26}H_{36}]_2[SnCl_6]$ (7), $[SeN_2C_{36}H_{40}Cl_2]$ (8), and $[SeN_2C_{26}H_{36}Cl_2]$ (9)

Complexes **7**, **8**, and **9** are 2,2-dichloro-1,2,5-selenadiazolium complexes with a dipp group at each of the nitrogen positions. The crystal structure of **7** reveals short Se···Cl contacts from the counteranion which are approximately in the same range as that in **3** (~ 2.74 Å), while in **8**, the Se–Cl bond distances are similar to those in **5** and **6** (~ 2.29 to 2.32 Å). A comparison of ^{77}Se VACP/MAS NMR spectra of **7**, **8**, and **9** (Figs. 2C, 2D, and 2E, respectively) reveals values of δ_{iso} ranging from 1526 to 1782 ppm, along with large spans and positive skews (Table 1). Unfortunately, the VACP/MAS spectra of **7** have very poor S/N, increasing the errors associated with the selenium NMS tensor parameters for this sample. A large reduction in CP efficiency was observed for this sample, the reason for which is unknown at this time; however, it is recognized that the poor spectral quality does not arise from sample size, quality, or crystallinity (see Figure S7 for ^{13}C solid-state NMR spectra).

For **7** and **8**, the spans are increased and the skews are less positive than those of **5** and **6**, undoubtedly due to the additional Se···Cl contacts in the former. It is also interesting to note that the δ_{iso} for **8** is significantly higher than for all other species, perhaps suggesting that the presence of an extended aromatic system plays a role in deshielding the ^{77}Se nucleus. The structure of **9** is unknown; however, ^{77}Se NMR spectra are useful in helping to elucidate the structures of these systems: a comparison of the NMS tensor parameters of **9** with those of **5** through **8** suggest that the structure of **9** is akin to that of **5** and **6**, which have single Se···Cl contacts.

Summary of the observed ^{77}Se NMR parameters

^{77}Se SSNMR spectra are very sensitive to the local bonding environment of the selenium atom and serve as a powerful probe of changes in molecular structure as well as intermolecular interactions.[28,29] Several trends in the selenium NMS tensors for this series of the *N*-heterocyclic compounds (**1** to **9**) are observed (Table 1, Fig. 3). First, a single Se···Cl contact results in a reduction of the span (compare **1** and **2** vs. **3** and **4**), whereas two Se···Cl contacts increase the span and reduce the axial symmetry of the tensor (**5** and **6** vs. **7** and **8**). Second, the addition of a substituent to the second N atom of the ring (compare **5**–**9** vs. **1**–**4**), increases the span of the NMS tensor significantly and changes the sign

Fig. 4. Selenium NMS tensor orientations obtained by the B3LYP functional. σ_{33} is directed $\perp$ to the page for all molecules.

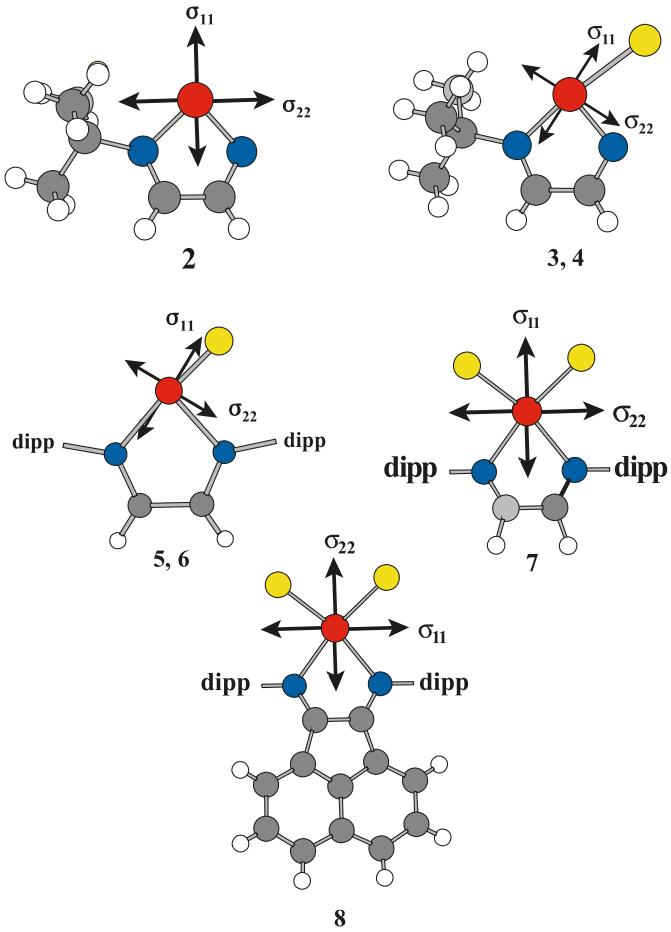


Fig. 5. Model systems and Se NMS tensor orientations from VWN-BP calculations. Note that **B** is the analogue of **1** and **2**, **B′** for **3** and **4**, **A′** for **5** and **6**, and **A″** for **7**, **8**, and **9**. of the skew from negative to positive, mainly via a large increase in shielding along the direction of δ_{33}. Finally, interactions between the cation and anion (e.g., **3** and **7**) and the relative Se–Cl bond distances have a significant influence on the NMR parameters.

Theoretical selenium nuclear magnetic shielding tensors

A subset of the density functional calculations of selenium NMS tensor parameters and their orientations in the molecular frames were performed with the Gaussian 03 software package with the aim of correlating molecular structure, symmetry, and the experimental NMR parameters. Calculated NMS tensor parameters having the best agreement with the experimental results are presented in Table 2 (See Tables S3–S9 for a summary of all of the calculations). Since there are no solid-state structures for **1** and **9**, calculations are not reported for these molecules.

Selenium NMS tensors calculated with the B3LYP functional were generally superior to those from RHF calculations, with the former resulting in NMS tensor parameters that are reasonably close to the experimental values (about 5 to 15% error), and the latter not correctly predicting NMS tensor parameters in most cases (except for **7** and **8**). In general, Huzinaga's basis set (14s10p5d and 17s13p6d) seems to be the most appropriate for predicting selenium NMS tensor parameters. For **3** and **7**, intermolecular interactions between the cation and the anion have a large influence on the magnitudes of the NMR parameters. Calculations that were performed without the $SeCl_6^{2-}$ and $SnCl_6^{2-}$ anions overestimate the magnitudes of the spans, while those performed with the anions yielded a better agreement with the experimental results (e.g., refer to Table S4 for **3**). For the doubly-substituted compounds (**5**–**8**), the calculations do predict larger spans, as observed experimentally. The only major discrepancy is observed from calculations on **5** and **6**, where negative skews are consistently predicted, regardless of the chosen structural model (vide infra).

For all of the systems, DFT calculations predict that σ_{33}, the most shielded component, is directed perpendicular to the plane of the heterocyclic ring, along the direction of a presumed Se lone pair. The orientation of σ_{33} is the same as those predicted for the analogous ^{13}C NMS tensors in carbenes; however, in carbenes, the lone pair is in the plane of the ring along the direction of σ_{22}.[85,86] The σ_{11} and σ_{22} components of the Se NMS tensor are always in the plane of the heterocycle, and vary in magnitude and position depending on the presence of intermolecular Se···Cl contacts and the nature of the N-substituents (Fig. 4). For **2**, it is predicted that σ_{11}, the most deshielded component of the NMS tensor, is oriented towards the centroid of the five-membered ring. Similar tensor orientations are observed for **7** and **8**, which have local, two-fold symmetry at the Se atom; however, for

[a]The chemical shielding tensor is described by three principal components, ordered such that $\sigma_{11} \leq \sigma_{22} \leq \sigma_{33}$.

[b]$\sigma_{iso} = (\sigma_{11} + \sigma_{22} + \sigma_{33})/3$.

[c]The chemical shift values were referenced to Me_2Se by comparing the calculated shielding values of all compounds to the absolute shielding value of Me_2Se (see eq. [1] in main text).

[d]$\Omega = \sigma_{33} - \sigma_{11}$.

[e]$\kappa = 3(\sigma_{iso} - \sigma_{22})/\Omega$.

[f]DZ is double-ζ and TZ2P is triple-ζ doubly polarized.

[g]These particular methods and basis sets were used to generate the occupied and virtual MOs in Figs. 6, 7, and S13–S16.

8, σ_{22} is oriented towards the ring centroid rather than σ_{11}. In **3** and **4**, the Se···Cl contact results in σ_{11} being oriented away from the ring centroid and closer to the direction of the Se–Cl bond. For **5** and **6**, despite the disagreement between experiment and theory, the tensor orientations resemble those in **3** and **4**, with σ_{11} oriented nearly along the direction of the Se–Cl bond. Some of the resonance structures of the Se carbenoids are often drawn with two lone pairs at the Se atom; however, there is no implicit suggestion from the NMR data of a second lone pair localized on the Se atom (vide infra).

Calculations on model systems

To analyze the influences of electronic structure and bonding on the Se NMS tensors, we have conducted calculations using ADF on several model systems (Fig. 5), including detailed analyses of contributing molecular orbitals (vide infra). A summary of NR ADF calculations of ^{77}Se NMS tensor parameters is shown in Table 3. Given that these are geometry-optimized model systems, the agreement between these calculations and the experimental data is poor relative to the benchmarks of the previous section; however, selenium NMS tensor orientations from the NR calculations are almost identical to the Gaussian 03 results (Fig. 5).

Nuclear magnetic shielding at a nucleus, or *nuclear shielding*, is arbitrarily decomposed into two components according to the formalism of Ramsey,[87–89] which are known as the diamagnetic and paramagnetic contributions, such that $\boldsymbol{\sigma}_{tot} = \boldsymbol{\sigma}_d + \boldsymbol{\sigma}_p$. This division of contributions persists in modern descriptions of the origins of nuclear shielding.[74,75,90–93] The diamagnetic shielding arises from the field-induced electron circulation in the ground electronic state which creates a local field anti-parallel to the applied field; hence, it is responsible for shielding the nucleus and gives rise to a negative frequency shift (neglecting the sign of the Larmor frequency). The paramagnetic shielding arises from symmetry-allowed magnetic-field induced mixing of MOs, which in most cases gives rise to a local field that is parallel to the applied magnetic field, thereby deshielding the nucleus and causing a positive frequency shift. The DFT–GIAO formalism developed by Ziegler and co-workers describes diamagnetic and paramagnetic shielding contributions in a manner distinct from that of Ramsey, in the sense that the basis set incompleteness is taken into account.[62,63] As a consequence, the paramagnetic shielding contribution is further partitioned into contributions arising from the mixing of occupied MOs ($\boldsymbol{\sigma}_P^{occ-occ}$) and mixing of the occupied (occ) and virtual (vir) MOs ($\boldsymbol{\sigma}_P^{occ-vir}$). The NMR–EPR module of the ADF program outputs paramagnetic shielding contributions associated with each MO pair (Table 4). Despite the fact that the NR calculations are not in good quantitative agreement with the experimental results, they are still useful in understanding the origin of selenium nuclear magnetic shielding in these systems.

Model complex **A** (Fig. 5) has been chosen as the focus of discussion for this section, due to its high symmetry (C_{2v}). Paramagnetic shielding contributions account for approximately 90% of the total isotropic shielding and occ-

Table 4. ADF calculations: contributions to paramagnetic shielding from mixing of occ-vir MOs in model compounds.

[a]The asterisk (*) sign indicates a virtual MO.

[b]Signifies the total contribution to the isotropic chemical shielding.

[c]The point group of the molecule is given in parentheses. All systems are pictured in Fig. 5.

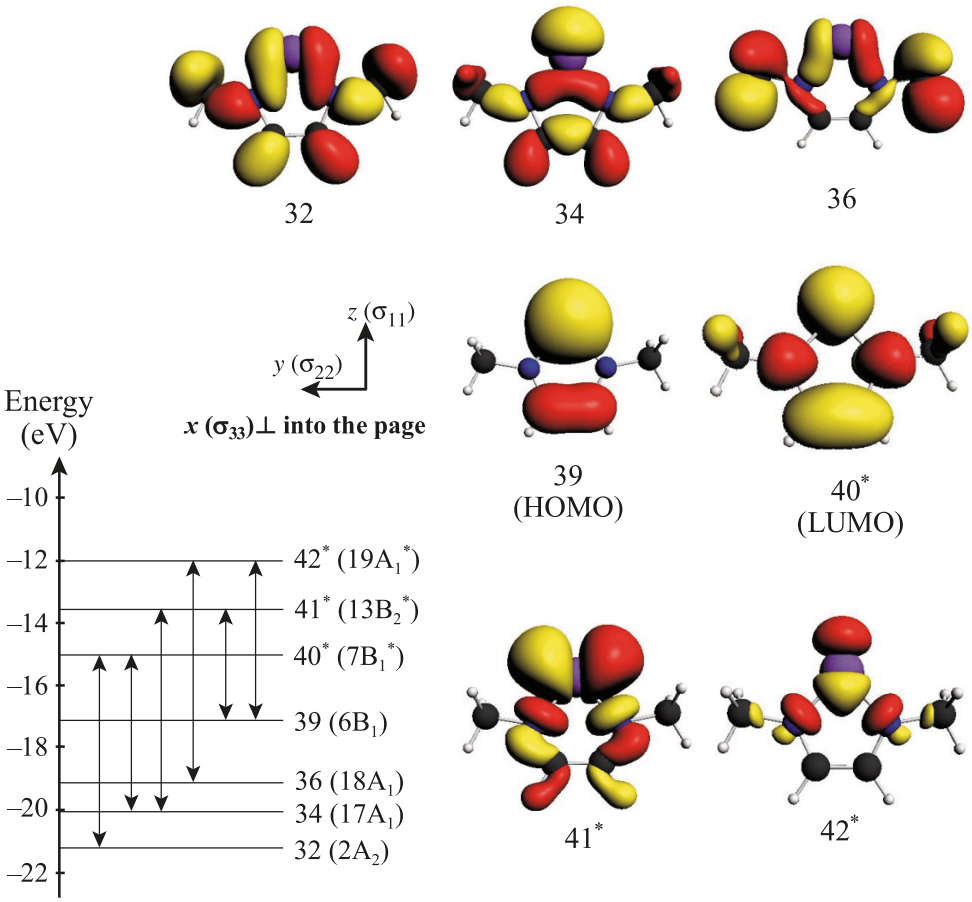
[d]All shielding values in bold correspond to the highest contribution for each tensor component. Blank spaces indicate no contribution to these tensor components.

vir MO mixing is the dominant contribution to the anisotropy of the NMS tensor; therefore, occ-occ mixing will not be considered here. Due to the large number of MO pairs, only those that contribute to greater than 5% (~200 ppm) of the total isotropic shielding arising from occ-vir MO mixing (–3909.8 ppm) are listed. This focuses the analysis on a few crucial MOs that are near the HOMO and (or) involved in the bonding.

In **A,** the occupied-virtual MO pairs 34–41*, 39–41*, and 39–42* make the largest contributions to deshielding along the directions of σ_{33}, σ_{11}, and σ_{22}, respectively (Fig. 6, Table 4). The mixing of the occupied MO 34 (HOMO–5) with virtual MO 41* (LUMO+1) results in deshielding along the direction of σ_{33} and contributes –636.8 ppm to the total paramagnetic shielding ($\boldsymbol{\sigma}_p$) of –3721.2 ppm; however, the mixing of the HOMO, MO 39, with energetically proximate MOs 41* and 42*, causes even greater deshielding along the directions of σ_{11} and σ_{22}, respectively. We also note that the LUMO, MO 40*, plays a role in creating additional deshielding along σ_{11} and σ_{22}.

The analysis of contributions of individual MOs to paramagnetic shielding combined with the calculation of gross AO populations of each MO (Table 5) can provide some insights into the origin of nuclear magnetic shielding at a nucleus. The HOMO, MO 39, has a relatively high Se $4p_x$-orbital character (71.0%) and smaller contributions from the C1 and C2 $2p_x$-orbitals (12.9% each) on the aromatic rings. The stereochemically active lone pair of selenium is best described by MO 39, and is oriented along the direction of the σ_{33} component (perpendicular to the plane of the ring). The

Fig. 6. The occupied and virtual MOs of **A** that make significant contributions to the paramagnetic shielding term. A partial MO diagram indicating the magnetic-dipole allowed transition between the occupied and virtual MOs shown above. An isosurface of ±0.04 is used for the diagrams above.



LUMO, MO 40*, is largely delocalized over the heterocyclic ring, while MOs 41* and 42* have high Se $4p_y$ (75.0%) and $4p_z$ (58.9%) orbital characters, respectively, oriented for convenient mixing with the HOMO.

To qualitatively understand why these particular MO pairs make important contributions to the selenium nuclear magnetic shielding tensor, it is useful to consider the point group symmetry representations for both the MOs and the angular momentum operators (i.e., from Ramsey's equations).[94] Ramsey's equations and various modern modifications feature three-centre integrands which can describe the magnetically-induced mixing of MOs[95]

$$[2] \qquad \langle \psi_m | \hat{L}_i | \psi_n \rangle$$

where ψ_m and ψ_n are the occupied and virtual MOs, respectively, and $\hat{L}_i$ (i = x,y,z) is an angular momentum operator. The integrand above is only nonzero if the direct product of the irreducible representations (IRs) of the MOs and angular momentum operators (which have the same IRs as the rotational operators, $\hat{R}_i$, listed in the point group tables) is equal to or contains the totally symmetric representation of the point group (for this case of C_{2v}, it is A_1):

$$[3] \qquad \Gamma(\psi_n) \otimes \Gamma(\hat{R}_i) \otimes \Gamma(\psi_m) \supseteq A_1$$

The symmetry representations of the rotational operators $\hat{R}_x$, $\hat{R}_y$, and $\hat{R}_z$ are B_2, B_1, and A_2, respectively. Hence, the 34–41*, 39–41*, and 39–42* MO pairs, which contribute to paramagnetic shielding along σ_{33}, σ_{11}, and σ_{22}, respectively, are all nonzero,

$$[4] \qquad \Gamma(\psi_n) \otimes \Gamma(\hat{R}_x) \otimes \Gamma(\psi_m) = B_2 \otimes B_2 \otimes A_1 = A_1$$

$$[5] \qquad \Gamma(\psi_n) \otimes \Gamma(\hat{R}_z) \otimes \Gamma(\psi_m) = B_2 \otimes A_2 \otimes B_1 = A_1$$

$$[6] \qquad \Gamma(\psi_n) \otimes \Gamma(\hat{R}_y) \otimes \Gamma(\psi_m) = A_1 \otimes B_1 \otimes B_1 = A_1$$

and make symmetry-allowed contributions to the selenium NMS tensor.

Simple visualization, often referred to as "charge rotation",[63,66,96,97] can also be used to understand how MO pairs make paramagnetic shielding contributions. MOs which contribute to the shielding along the direction of a particular principal component must be relatively close in energy and have the correct symmetry to overlap or mix with one another when rotated about the direction of the tensor component. An arbitrary convention of a right-handed ninety degree rotation of the virtual MOs about their nuclear origins (i.e., rotating the contributing AOs about their own origins) is utilized. The three MO pairs which make the largest contributions to the three different NMS tensor components are

Table 5. ADF calculations: composition of the MOs in **A** from NR calculations (see Supplementary data for other model compounds).

[a]Occ stands for occupancy.

[b]SFO stands for symmetrized fragment orbitals.

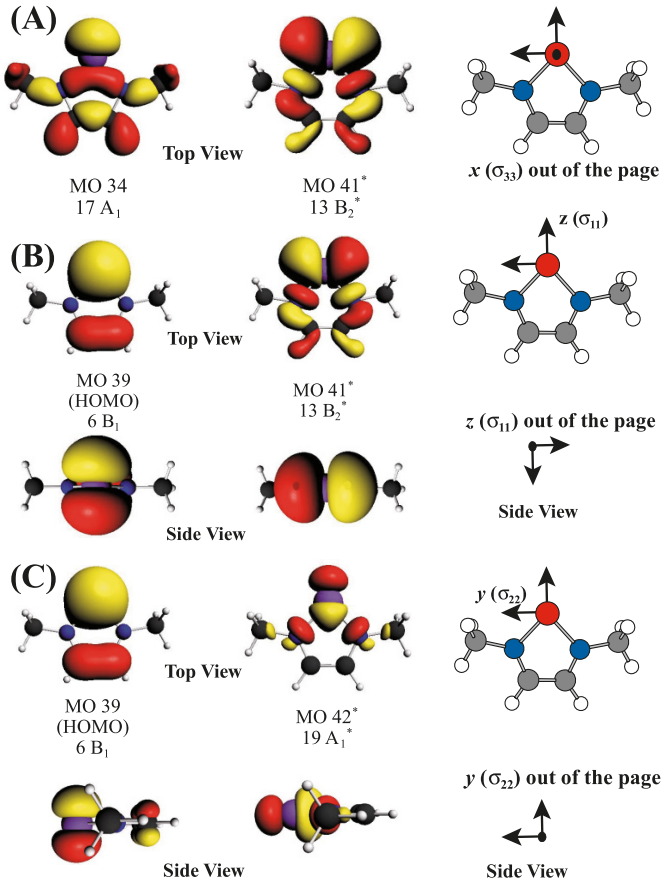
[c]MO 39 is the best representation of the Se "lone pair" MO, and is the HOMO in this case. All MOs following with asterisks are virtual (unoccupied).

discussed (Figs. 7A–7C): 34–41* for σ_{33}, 39–41* for σ_{11}, and 39–42* for σ_{22}. A right-handed 90° rotation of MO 41* about σ_{33} (out of the page), which is coincident to the *x*-axis, gives a constructive overlap (i.e., lobes of the same phase overlap) with MO 34. Similarly, a right-handed rotation of MO 41* about σ_{11} (pointing away from the direction of the centroid of the five-membered ring) results in a large constructive orbital overlap with MO 39, accounting for the largest deshielding contribution. Finally, a right-handed rotation of MO 42* about σ_{22} (pointing to the direction of the methyl group) leads to a constructive overlap with MO 39 as well, but to a lesser extent. All of the other paramagnetic contributions can be visualized in this manner as well (see Table 4 and Fig. 6 for the MO pairs). Such visualizations, of course, do not provide any sort of formally quantitative measure of nuclear magnetic shielding (this is left to the calculations).

An understanding of how individual MOs play roles in determining the selenium NMS tensor characteristics can be extended to describe experimentally observed variations in NMS tensors. Of all of the NR ADF calculations that we performed, the VWN-BP/DZ method best reproduces some of the experimental trends (Table 3): specifically, (1) a single Se···Cl contact reduces the span and (2) an extra substituent at a heterocyclic nitrogen position increases the span.

First, let us consider how Se···Cl interactions reduce the span of the Se NMS tensor by comparing **A** and **B** with their chlorinated analogs **A′** and **B′**. For both **A′** and **B′**, calculations indicate that the HOMO is no longer associated with the lone pair on Se, but rather, is described by an MO which is largely localized on the Cl atom (Table S10). For example, in **B′**, the HOMO, MO 44, is largely comprised of the $3p_x$ AO (96.7%) of the Cl atom, whereas the HOMO-3, MO 41, describes the Se lone pair (major contribution from the $4p_z$ AO of Se atom (59.7%)), which is oriented perpendicular to the plane of the ring. Similar changes in relative MO energies are observed when comparing **A** and **A′**. The effects of the Se···Cl interactions of the selenium NMS tensor are seen by comparing **B** and **B′** (Table 4, Figs. S13, S15): in the former, the 35–37*, 35–38*, and 34–37* MO pairs

Fig. 7. A representation of (A) 34–41* MO pair, in which their mixing contributes to paramagnetic deshielding along σ_{33}, (B) 39–41* MO pair (σ_{11}), and (C) 39–42* MO pair (σ_{22}).



are responsible for the largest contributions to deshielding along σ_{11}, σ_{22}, and σ_{33}, respectively; however, in the latter, the analogous 41–46*, 41–49*, and 40–46* pairs make significantly smaller contributions. This is largely due to both the increased energy spacings and decreased induced MO overlaps in **B**′. With very few exceptions, almost all of the valence MOs in **B** have analogues in **B**′, featuring similar AO compositions and energies (e.g., there is an additional MO 42 in **B**′ because of the Cl atom). The difference in the composition of MO 37* in **B** (57.7% of $4p_y$ and 16.5% of $4p_x$ of Se atom) compared to MO 46* in **B**′ (27.6% of $4p_x$ and 19.6% of $4p_y$ of Se atom) has a major influence on shielding along the σ_{11} and σ_{33} directions, serving to reduce the span in the latter.

Now, let us consider how the selenium NMS tensor is affected by the presence of a second substituent at a heterocyclic nitrogen position. In accordance with experimental observations, comparison of theoretical Se NMS tensors of **A** and **B** reveal an increased span and an increasingly positive skew in the former (Table 3). This is the result of reduced shielding along σ_{11} and increased shielding along σ_{33} in **A**. The source of the reduced shielding in **A** is the 39–41* MO pair (Table 4), which serves to deshield the ^{77}Se nucleus by a significantly higher degree than the corresponding 35–37* MO pair in **B** (Table 6). The second substituent serves to increase the symmetry of the molecule, thereby increasing the MO mixing in **A**, and resulting in greater deshielding. Deshielding along σ_{33} is similarly described by the 34–41* MO pair for **A** and the 34–37* MO pair for **B**. However, MO 37* in **B** also mixes efficiently with MOs 30 and 32, which serves to increase deshielding along σ_{33} in general.

It is important to note that there is a general difficulty with both sets of DFT calculations in the prediction of positive skews for heterocycles with two substituents and a single chlorine contact (e.g., complexes **5** and **6** and model system **A**′); though, in every case an increasingly positive skew is calculated with respect to systems with a single substituent (e.g., complexes **3** and **4** and model system **B**′). Gaussian 03 calculations were performed on the isolated monomeric cations, the combined cations and anions, and the full dimeric structures for both **5** and **6**; however, in all cases, negative skews are predicted. ADF calculations on model complex **A**′ involved calculations on heterocyclic rings with methyl, *t*-butyl, and dipp substituents, all of which yielded negative skews. The reason for this disagreement between experiment and theory in these particular systems is unknown at this time.

NLMO analysis of nuclear magnetic shielding contributions

The classical resonance structures for these Se–N heterocycles are often drawn with two lone pairs at the Se atom, and previous NBO calculations on a variety of main-group heterocycles analogous to those discussed herein indicated that there are indeed two lone pairs[98] (see below for analysis of this situation). However, the MO analysis of the nuclear shielding tensor contributions reveals only one MO which might be considered as describing a lone pair, along with other significant MOs which are difficult to describe as traditional, "chemically intuitive," Lewis-type orbitals. A more intuitive understanding of the contributions of individual MOs can be accomplished via a natural localized molecular orbital (NLMO) analysis; hence, we have employed a set of NLMOs to analyze the shielding tensor in terms of these orbitals. In this section, we describe the results of such analyses for model systems **A** and **A**′. In the NBO algorithm, each NLMO is constructed from a strongly localized "parent" NBO and a delocalization tail that may or may not be large, depending upon how delocalized the molecule really is. The parent NBOs are classified as "chemically intuitive" orbital types, such as bonding, core, or lone pair orbitals. Besides the delocalization tail of the NLMOs, another useful criterion revealing information about delocalization or other non-Lewis type behavior is the NBO occupancy number: values less than 2.0 indicate a departure from Lewis structure descriptions. In the data tables, we report the type and occupancy of the parent NBO for each NLMO of interest, as well as the composition of the NLMOs in terms of the weighted coefficients of the atomic orbitals (AOs). Finally, the contributions of each NLMO to the isotropic nuclear magnetic shielding are presented, in terms of its main localized part ("Lewis" contribution, from the parent NBO) and from its delocalization tail (the "non-Lewis" contribution).

Characteristics and compositions for various key NLMOs, with most contributing more than ~ ±200 ppm to the isotropic nuclear magnetic shielding, are summarized for **A** and **A**′ in Tables 6 and 7, respectively (full listings of NLMO

Table 6. Analysis of major NLMO Contributions to isotropic chemical shift for model compound **A**.

[a]This is the index number assigned by the NBO program.

[b]This is the label assigned by the NBO program. BD denotes a bonding electron pair, core to a non-bonding pair in the sub-shell below the valence shell, and LP to a lone pair.

[c]Occ refers to the occupancy of the parent NBO of the NLMO, the analysis data is for the NLMO itself. Occupancies less than 2 indicate deviation away from an ideal Lewis structure.

[d]The number before the atom symbol indicates the percentage composition of each NLMO in terms of atomic orbitals from the given atom(s). The contribution of each atom is then broken down by percentage orbital type (e.g., s, p, *d*).

[e]A full listing for all of the contributing NLMOs is provided in the Supplementary data.

contributions are in the Supplementary data). In system **A**, two major deshielding contributions come from MOs 1 and 2, which are well localized, and describe bonding (BD) between the Se and neighbouring N atoms (Fig. 8). Interestingly, there is also a significant non-Lewis deshielding contribution from the remaining bonding MOs,[3–17] with some of the key contributors describing the C–H bonds in the five-membered ring. The majority of the core MOs on Se are responsible for shielding the ^{77}Se nucleus; notably, the NLMOs that describe the core 1s, 2s, and 2p Se AOs. Finally, there are two key NLMOs which were also identified as important in the MO analysis in the previous section. NLMOs 38 and 39 are classified as being Se lone pairs (LP) which make significant deshielding contributions. The former is a typical Lewis-type LP with a small deshielding contribution, while the latter departs significantly from such an LP classification. The Se π-lone pair NLMO 39 is strongly delocalized over the five-membered ring, and makes the most significant deshielding contribution of all of the NLMOs.

In system **A**′, the presence of the weakly coordinated Cl atom breaks the molecular symmetry and influences the Se shielding characteristics. Two major deshielding contributions from bonding NLMOs now arise from Se–N and Se–Cl bonds instead of two Se–N bonds; however, their net contribution is similar to that of system **A**. Similarly, the contributions from the core orbitals are very close in magnitude and character for **A** and **A**′. The difference between the isotropic shielding for **A** and **A**′ seems to arise in this analysis from the NLMOs which are formally classified as Se LPs. Indeed, NLMOs 43 and 44 are very similar to their counterparts in **A** (NLMOs 38 and 39) in both their composition and contributions to the nuclear shielding (though the former pair makes a smaller net deshielding contribution). NLMO 45, which is unique to **A**′, is classified as a LP, is largely localized on the N3 atom (the side opposite to the Se–Cl bond), and forms a weak σ-type bond with Se. NLMO 45 does not make a large Lewis contribution to shielding; rather, it makes a non-Lewis contribution of ~ –192 ppm, which is comparable to the net non-Lewis contribution from all of the other bonding NLMOs. This, in combination with additional non-Lewis shielding from the three Cl LPs, results in a net deshielding at the ^{77}Se nucleus in **A**′ with respect to that in **A**, inferring that the presence of a single Cl atom in these species should decrease the isotropic selenium chemical shift, or at least dramatically impact the character of the Se NMS tensor.

To test whether the delocalization of the Se π lone pair orbital is to some extent created by the specific nature of the NLMO localization method, we have additionally carried out the Boys localization[99] of the occupied orbitals. Unlike the occupation-driven localization by the NBO algorithm, the Boys method minimizes directly the spatial extent of the orbitals around their center of gravity, i.e., it minimizes

$$[7] \qquad \sum_i (\Delta r)_i^2 = \sum_i \langle \psi_i | r^2 | \psi_i \rangle - \langle \psi_i | \mathbf{r} | \psi_i \rangle^2$$

for the set of orbitals $\{\psi_i\}$. The Boys criterion tends to yield "banana bond" orbitals for double bonds instead of the

[a]This is the index number assigned by the NBO program.

[b]This is the label assigned by the NBO program. BD denotes a bonding electron pair, core to a non-bonding pair in the sub-shell below the valence shell, and LP to a lone pair.

[c]Occ refers to the occupancy of the parent NBO of the NLMO, the analysis data is for the NLMO itself. Occupancies less than 2 indicate deviation away from an ideal Lewis structure.

[d]The number before the atom symbol indicates the percentage composition of each NLMO in terms of atomic orbitals from the given atom(s). The contribution of each atom is then broken down by percentage orbital type (e.g., s, p, *d*).

[e]A full listing for all of the contributing NLMOs is provided in the Supplementary data.

more commonly chosen set of orbitals with local σ and π symmetry. This is easily remedied, however, by taking positive and negative linear combinations of pairs of such banana bond orbitals. Figure 9 shows the Boys localized orbital corresponding to the Se π lone pair alongside the corresponding NLMO, using the same plot plane roughly 1 a.u. above the ring. It is apparent that the high degree of delocalization is very similar in both cases; hence, the delocalized nature of the Se π lone pair orbital is not a matter of which orbital localization method is chosen.

To investigate the nature of the Se lone pairs further, we performed a search for resonance structures for model system **A** using the "natural resonance theory" (NRT) algorithm implemented in the NBO 5 code.[100–102] This method decomposes the density matrix of the molecule into contributions from idealized resonance structures utilizing a given NBO set. Five types of main natural resonance structures, along with the weights they contribute to the overall electron density matrix according to the NRT procedure, are shown in Fig. 10. The resonance structure with two lone pairs has the greatest overall weight of about 1/3. The following two pairs of resonance structures with combined weights of 19% and 14% both involve delocalization of the Se π lone pair over the five-membered ring. This analysis agrees with the strong delocalization seen for the Se π lone pair NLMO, and with the rather strong delocalization of the corresponding Boys localized orbital.

Conclusions

^{77}Se VACP/MAS NMR spectra of selenium-containing heterocycles reveal expansive Se chemical shift tensors which are extremely sensitive to molecular geometry, symmetry, and ligand substitution. A single Se···Cl contact results in a reduction of the CSA, whereas a second substituent at the N atom in the heterocycles increases the span of the CS tensor significantly, and changes the sign of the skew from negative to positive. Cation–anion interactions and variation in Se–Cl bond distances both have significant influence on the NMR parameters. The experimental measurement of selenium CS tensors via SSNMR is especially useful for series of complexes like these, since solution NMR would only yield isotropic shifts over a very narrow shift range that may only provide ambiguous identification of structural variation; this is clearly not the case for the data obtained from SSNMR.

Hybrid DFT is capable of reproducing experimental Se NMS tensors in most cases, as well as predicting their orientations with respect to the molecular frames. The σ_{33} component, which is oriented perpendicular to the heterocycle

Fig. 8. NLMOs with major contributions to the Se nuclear magnetic shielding for model systems **A** (top, isosurfaces) and **A′** (bottom, contour plots). **A**: NLMO 1 (and 2, not shown) are bonding MOs with large deshielding contributions. NLMO 38 describes a lone pair localized at Se, while 39 describes delocalization of the MO into the ring system. Both make deshielding contributions. **A′**: NLMOs 1, 43 and 44 in **A′** are counterparts to 1, 38 and 39 in **A**. NLMO 45, which is largely localized on N3, makes a major contribution to the selenium shielding.

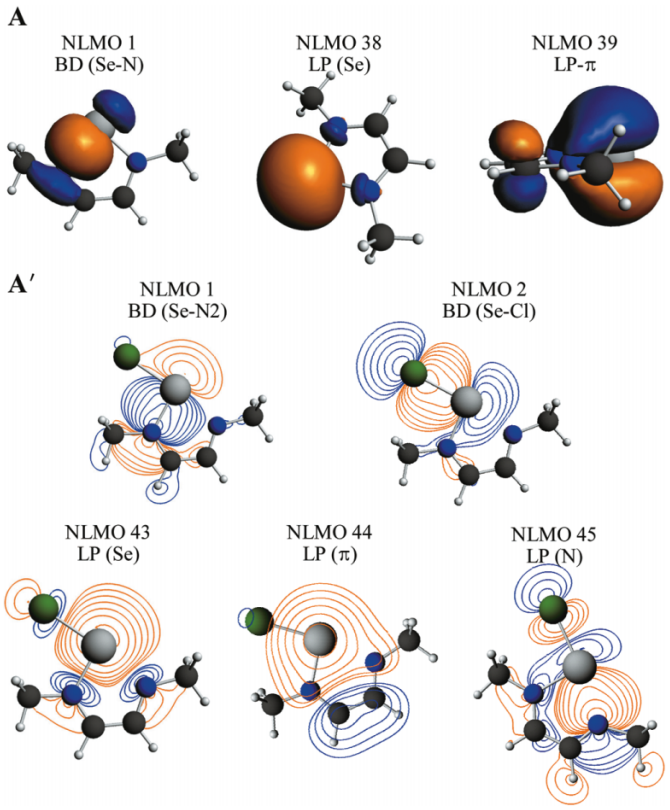

Fig. 9. *Left*: Se π "lone pair" orbital of model system **A** from a Boys localization (after generating the σ–π linear combination from two σ–π mixed Boys orbitals). *Right*: The corresponding Se π "lone pair" NLMO 39. Contour values: ±0.01, ±0.02, ±0.04,...

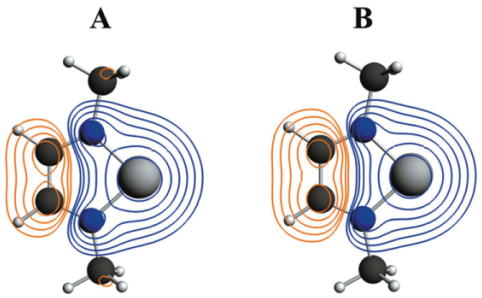
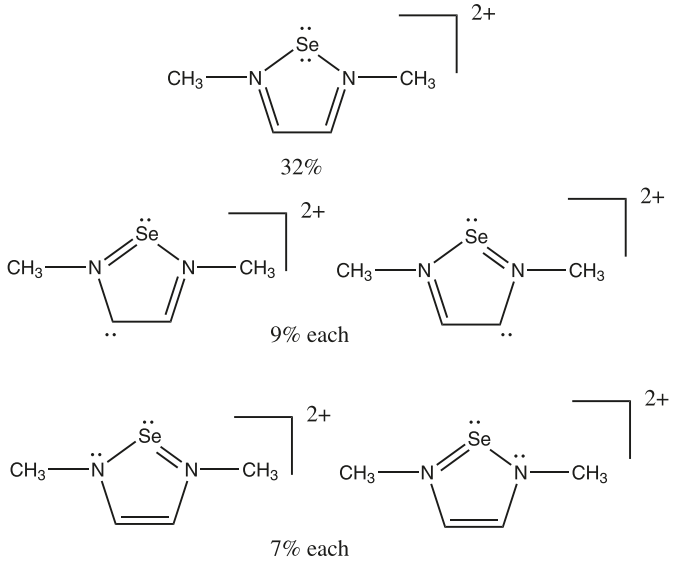


plane, is a good indicator of the direction of the lone pair localized on the Se atom. DFT calculations on model systems explain the origin of the selenium NMS tensors from the perspective of paramagnetic shielding arising from induced mixing of occupied and virtual MOs, and confirm the presumed orientation of the stereochemically active lone pair of selenium. Se···Cl interactions are predicted to shift the MO describing the Se lone pair to a lower energy, which

Fig. 10. Most important resonance structures contributing to the electronic structure of model system A, as calculated using the natural resonance theory (NRT) module in the NBO 5.0 code, with resonance structure weights in percent. A large number of resonance structures with small weights are not shown.



results in both increased energy spacings and decreased induced MO overlaps, leading to a reduction in the span of the Se NMS tensor. The second substituent at nitrogen increases the symmetry of the molecule, thereby increasing MO overlap, and producing greater deshielding along σ_{11}. The NLMO analysis of two of the model systems demonstrates how the presence of the weakly coordinated Cl atom results in increased nuclear shielding. As well, these analyses confirm that there are two lone pairs on the Se atom, one localized and one delocalized, and both of which play an important role in determining the nuclear shielding characteristics.

A precise understanding of the origins of the variations in Se NMS tensors with subtle structural changes should lead to a deeper understanding of the electronic structure of these systems, and possibly even further rational design of heterocycles with specific reactivities, stabilities, and other properties.

Supplementary data

Supplementary data for this article (sample preparation, ^{77}Se CP/MAS NMR experimental parameters, ^{13}C solid-state NMR data, ^{13}C CP/MAS NMR experimental parameters, powder X-ray diffraction patterns, ab initio calculations, and ADF calculations) are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 5264. For more information on obtaining material, refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml.

Acknowledgments

RWS gratefully acknowledges the Natural Sciences and Engineering Research Council of Canada (NSERC), the Canadian Foundation for Innovation (CFI), and the Ontario

Innovation Trust (OIT) for financial support. RWS and AS also acknowledge the Centre for Catalysis and Materials Research (CCMR) at the University of Windsor for funding. Mr. Cory M. Widdifield and Mr. Aaron J. Rossini are thanked for the assistance with ADF calculations. PJR and JLD thank NSERC, CFI, and the University of Western Ontario for their generous financial support. RWS and PJR acknowledge the Ontario Ministry of Research and Innovation for Early Research Awards. JA and SZ acknowledge financial support from the National Science Foundation (CHE-0447321). This work was made possible in part by the facilities of the Shared Hierarchical Academic Research Computing Network (SHARCNET: http://www.sharcnet.ca).

REVIEW / SYNTHÈSE

Naturally occurring and synthetic polyyne glycosides

Yanqing Pan, Todd L. Lowary, and Rik R. Tykwinski

Abstract: Polyyne glycosides are a class of natural products that have been found in terrestrial plants, fungi, and marine algae. Many display interesting and potentially useful biological activities, which in some cases has initiated synthetic efforts toward their formation. This review provides a comprehensive report of polyyne glycosides isolated from natural sources, as well as the synthesis of these molecules and their analogues.

Key words: polyynes, polyacetylenes, carbohydrates, natural products.

Résumé : Les glycosides de polyyne correspondent à une classe de produits naturels qu'on retrouve dans les plantes terrestres, les champignons et les algues marines. Plusieurs présentent des activités biologiques intéressantes et potentiellement utiles qui, dans certains cas, ont conduit à l'initiation d'efforts de synthèse orientés vers leur formation. Cette revue fournit un rapport approfondi sur les glycosides de polyyne isolés de sources naturelles et sur les efforts de synthèse de ces molécules et de leurs analogues.

Mots-clés : polyynes, polyacétylènes, hydrates de carbone, produits naturels.

[Traduit par la Rédaction]

Introduction

Polyynes[1] have long been known to exist in natural sources, and thousands have been isolated in the past century from a wide range of terrestrial plant species, fungi, sponges, corals, and bacteria. Many of these compounds have interesting biological activities, such as antibacterial, antimicrobial, anticancer, anti-HIV, antifeedant, and pesticidal properties.[2] Despite their widespread distribution in nature, the number of polyynes pales in comparison to the diversity of carbohydrates, one of the most abundant families of natural products. Carbohydrates are involved in a wide range of biological processes, including energy storage and transport, modulation of protein function, cell–cell adhesion, and signal transduction.[3–5] Consequently, carbohydrate-containing molecules have attracted attention as novel pharmaceuticals; indeed, many drugs in common use (e.g., erythromycin, doxorubicin) are functionalized with sugars. Over the past few years we have developed an interest in molecules that posses both a polyyne and a carbohydrate moiety. Polyyne glycosides, which consist of a carbohydrate group attached to a polyyne alcohol via an acetal linkage, are one such class of molecules.

In 1959, the first natural polyyne glycoside was found in the metabolites of the wood destroying fungus Basidiomycete B-841.[6] Since then, about fifty polyyne glycosides have been isolated from natural sources. Similar to polyynes lacking a carbohydrate group, several polyyne glycoside natural products display biological properties, including antibacterial activity,[7] the ability to inhibit nitric oxide production,[8] and the capacity to modulate blood glucose levels.[9] The majority of polyyne glycosides have been isolated from plants, and they are particularly common in species such as *Panax* and *Bidens*, which have been used for centuries as traditional medicines in many countries. Although biological testing has often not been reported in conjunction with their isolation, in those studies in which this work has been performed, interesting bioactivity profiles have been obtained. It is therefore likely that most (if not all) polyyne glycosides possess useful biological activities.

Synthetic analogues of polyyne glycosides might also have significant biological activity, yet virtually no efforts in this direction have been undertaken.[10,11] The isolation, biological activity, and synthesis of polyyne glycosides are the subject of this review. The first section offers a compilation of polyyne glycosides that have been isolated from plants,

fungi and algae; where possible, information on the biological activity of these compounds is provided. The second section documents syntheses of naturally occurring polyyne glycosides, natural products analogues, and several molecules that, while strictly speaking are not polyyne glycosides, are composed of polyyne and carbohydrate moieties.

Polyyne glycosides isolated from plants

Family Araliaceae — Ginseng family

Red ginseng, the steamed and dried root of *P. ginseng* C. A. Meyer, has been used extensively in Asian traditional medicine.[12] From this plant and other ginseng species,[13,14] a host of polyynes have been identified, and this class of compounds has received substantial synthetic attention.[2] To date, however, only two polyyne glycosides have been isolated from *P. ginseng*, as well as one related species, the oleanolic acid-derived saponin ginsenoside-Ro, **1** (Fig. 1). Studies on the natural product **1** showed that it inhibited the replication of human immunodeficiency virus type 1 (HIV-1) with an IC_{50} value of 13.4 μg/mL (11.1 μmol/L).[15] It should be mentioned that the carbohydrate ester functionality of **1** contains the natural polyyne panaxytriol, one of the most studied of all known naturally occurring polyynes.[2]

More recently, guided by the hepatoprotecting activity of fractions extracted from the dried root of *P. notoginseng*, Yoshikawa et al.[16] isolated and characterized notoginsenic acid β-sophoroside (**2**, Fig. 1) as fine, colorless crystals. Unfortunately, nothing further has been reported on the bioactivity of this compound.

Finally, two structurally intriguing polyyne glycosides have been identified from *P. ginseng*, the trans and cis isomers panaxfurayne A and B, **3a** and **3b** (Fig. 1), respectively.[17] To date, no studies of biological activity have been reported for these tetrahyrofuranic[18] derivatives.

Family Asteraceae — Aster family

Polyynes are widely distributed in the plant family Asteraceae,[19–23] and they are particularly prevalent in the species of the genus *Bidens*, commonly referred to as beggarticks in North America.[24] Species of the genus *Bidens* have long been used as traditional medicinal plants in numerous countries, and many of them have afforded polyyne natural products.[25–27] In 1970, Romussi and Pagani[28] isolated a polyyne

Fig. 2. Polyyne glycoside from the species *Bidens frondosa* (devil's beggarticks).

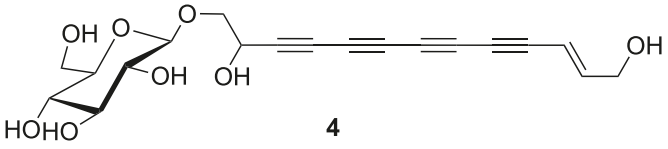

Fig. 3. Polyyne glycosides from the species *Bidens campylotheca* (viper beggarticks).

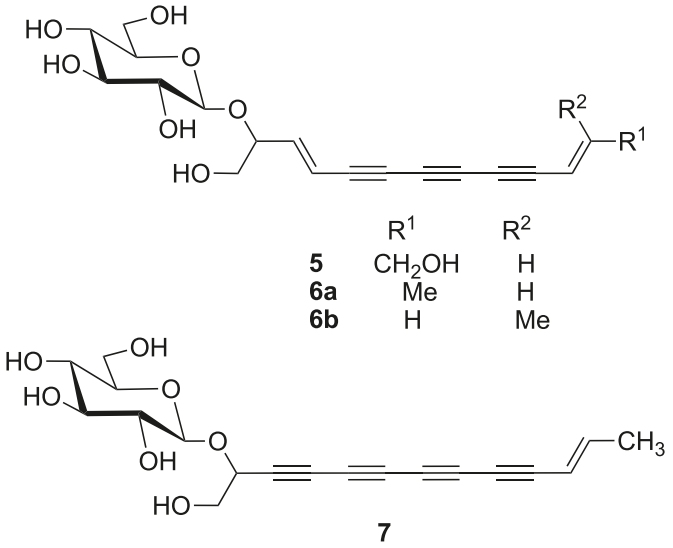
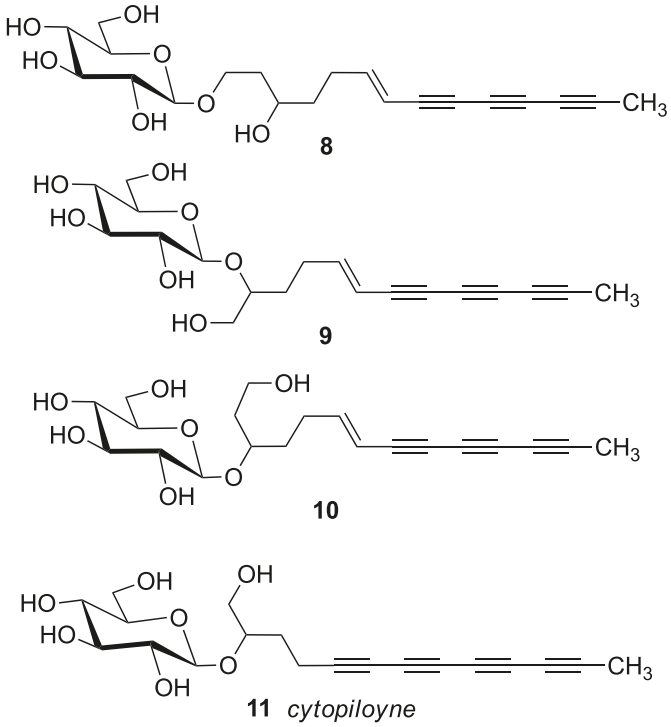


glycoside from the species devil's beggarticks, *B. frondosa*, and the structure was initially determined to be a D-glycoside of trideca-4,6,8,10-tetrayn-2-en-1,12,13-triol, although neither the attachment point of the sugar moiety, nor the stereochemistry of the glycosidic linkage was established (the aglycone was also isolated). In subsequent papers, the authors reported their efforts to confirm the structure of this natural product as **4** (Fig. 2), but they did not provide any information about its biological activity.[29,30]

More than two decades later, in 1992, Davis and co-workers[31] reported the isolation of four polyyne glucosides, **5**–**7**, from polar extracts of the dried aerial parts of viper beggarticks, *B. campylotheca* (Fig. 3). This herb is found only on the Hawaiian islands and has been used in traditional Hawaiian folk medicine as an appetite stimulant, as well as a treatment of general debility, throat and stomach afflictions, and severe cases of asthma.[32] There was no reported study of the bioactivity of **5**–**7** at the time of isolation. It was suggested, however, that glycosylation of the polyyne may facilitate the transportation of the typically lipophilic polyynes that are commonly isolated from the many members of this genus.[33] Subsequently, safynol, the aglycone of **6a**, was isolated from the same species, and this compound showed a weak inhibitory affect on prostaglandin biosynthesis.[34] In 1999, de Moraes and co-workers[35] reported that tetrayne **7** was also present in the methanolic extract of hairy beggarticks (*B. pilosa*) and also examined its bioactivity. Their investigations showed that both the methanolic extract and polyyne glycoside **7** suppressed human lymphocyte proliferation, with the pure compound **7** being 10-fold more potent than the crude extract.

Fig. 4. Polyyne glycosides from *Bidens pilosa* (hairy beggarticks).



Bidens pilosa is a widely distributed weed in tropical and subtropical regions, and its leaves and flowers are commonly used as a traditional medicine. In Cuba, for example, it is used for treating renal and respiratory problems, as well as inflammation,[26] while it is used in China to treat inflammation,[36] in South Africa for diarrhea,[37] and in Brazil to combat malaria.[38] Alvarez et al.[39] have isolated triyne glucoside, **8**, from the methanolic extract of the whole plants of *B. pilosa* in 1996 (Fig. 4). Although **8** did not show activity against a range of bacterial and fungal species including *Staphylococcus aureus*, *Salmonella typhimurium*, *Escherichia coli*, *Pseudomonas aeruginosa*, *Microspoum gypseum*, and *Candida albicans*, it did have moderate activity against *Trichophyton mentagrophytes* (MIC = 100 μg/mL), a fungus that causes scalp infections in children.[40] The cytotoxicity of **8**, and the parent polyyne, were also evaluated against several cancer cell lines, including HCT-15 (colon carcinoma), UISO (uterine–cervix cancer), KB (nasopharyngeal carcinoma), and W138 (lung embryonic fibroblasts), and in all cases the ED_{50} was greater than 4 μg/mL, indicating moderate potency. Interestingly, however, was that **8** enhanced the growth of cells, particularly the W138 cells. It was suggested that this proliferative activity might be related to cocarcinogenic action found for dried leaves of *B. pilosa* for esophageal tumors induced in rats.[41]

Two polyyne glucosides, **9** and **10**, were isolated from the African shrub *Microglossa pyrifolia* by Rücker et al.[7a] in 1992. The same compounds were obtained as a 3:2 mixture from *B. pilosa* in 2000 by Fort and co-workers[9] (Fig. 4), but the individual compounds (**9** and **10**) were neither separated nor tested individually because of their instability during purification. When administered as a mixture (250 mg/kg, twice daily) to genetically altered obese diabetic mice, a significant drop in blood glucose levels was observed on the

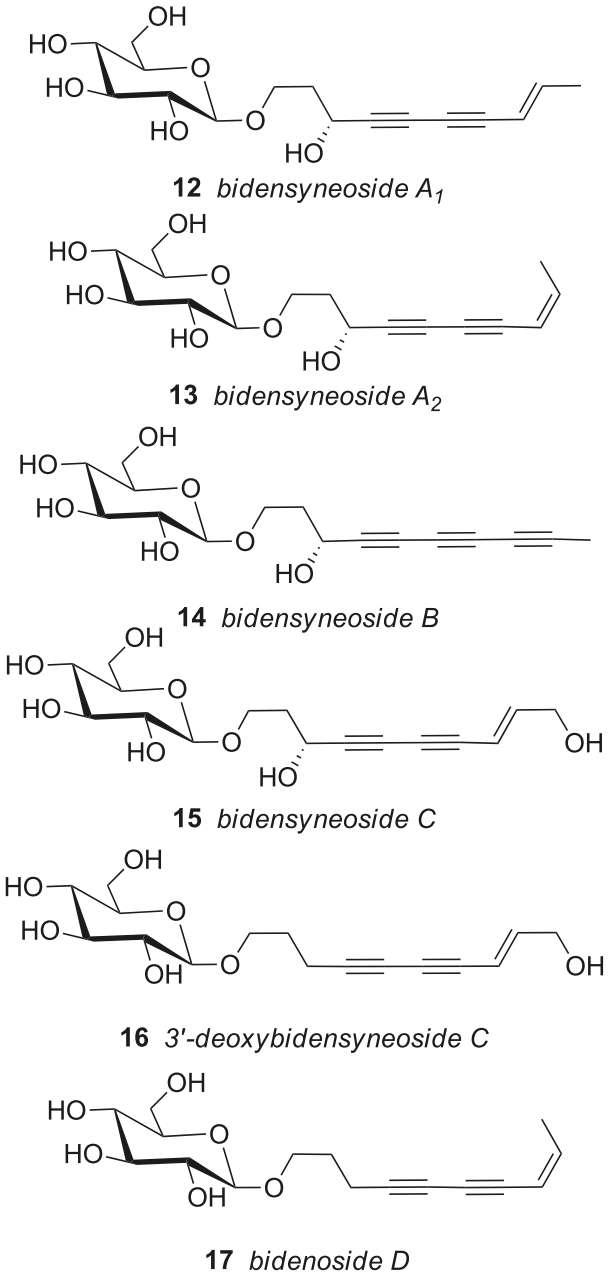
second day, along with a noticeable reduction in food intake. In another investigation, Chang et al.[42] have explored the bioactivity of **9** and **10** and found that both prevent diabetes development in nonobese diabetic mice.

Tetrayne **11** (cytopiloyne, Fig. 4) was recently isolated from the methanolic extract of *B. pilosa*, together with the known triyne glucosides **9** and **10**.[43,44] Similar to the triyne glucosides **8**–**10**, it was found that cytopiloyne was able to control or prevent type I diabetes in nonobese diabetic mice. More detailed investigations on cytopiloyne revealed that it was capable of inducing the selective differentiation of T helper (Th0) cells into type II T helper (Th2) cells, over type I T helper (Th1) cells. Cytopiloyne also suppressed IFN-γ expression and promoted IL-4 expression. These studies, therefore, demonstrated that cytopiloyne is a T cell modulator, and this function may explain, in part, why *B. pilosa* extracts prevent diabetes. Very recently, cytopiloyne was also found to suppress the maturation of human dendritic cells.[45] The corresponding triyne glycosides were not, however, evaluated in this study and thus the immunomodulatory potential of these compounds is unknown.

In addition to *B. frondosa*, *B. campylotheca*, and *B. pilosa*, two other *Bidens* species have afforded polyyne glucosides, *B. parviflora* and *B. bipinnata*. Both species have been used in traditional Chinese medicine for treatment of, for example, inflammation and rheumatism.[46] In 2001, polyyne glucosides **12**–**16** (Fig. 5), the bidensyneosides, were isolated from *B. parviflora*. These molecules were characterized as part of a study designed to identify antiallergic agents,[8] and all five were shown to inhibit both histamine release and nitric oxide production. Subsequently, in 2004, Okuyama and co-workers[47] reported the isolation of bidensyneoside C (**15**) from *B. bipinnata* (Spanish needles), as well as a new polyyne glycoside, bidenoside D (**17**), through extraction of the aerial parts with hot ethanol. To date, the biological activity of **17** remains unexplored.

The isolation of polyyne glycosides from other genera of the Asteraceae family, such as *M. pyrifolia*, has also been reported. Parts of this shrub are used as a traditional medicine in Ghana for treating fever and impotence,[25] while hunters in the Ivory Coast have used the leaf extract as an arrow poison.[48] In 1992, Rücker et al.[7a] reported the isolation of acetylenic glucosides from the leaves of this species, including triynes **9** and **10** (Fig. 4), as well as a tetrayne **18** and, remarkably, the pentayne **19** (Fig. 6). All of these molecules are β-glucopyranosides and were characterized spectroscopically through comparisons to their aglycones, which were generated via enzymatic hydrolysis. These four polyyne glycosides were then evaluated for their antimicrobial properties against five bacterial stains, and it was determined that only pentayne **19** possessed any substantial activity, in particular against *P. aeruginosa* and *S. aureus*.[7a] Pentayne **19** and its aglycone have most recently been isolated from *B. pilosa*.[7b] It was suggested by the authors that the successful isolation of these unstable pentaynes was a result of following the Fijian tradition of using the fresh plant for extraction rather than using the dried root, as prescribed by Asian tradition. The aglycone of **19** showed highly potent antimalarial and antibacterial properties in vitro. Furthermore, the aglycone also showed significant antimalarial activity in vivo, based on intravenous injection of the drug in mice infected with the *Plasmodium berghei* NK-65 strain.[7b]

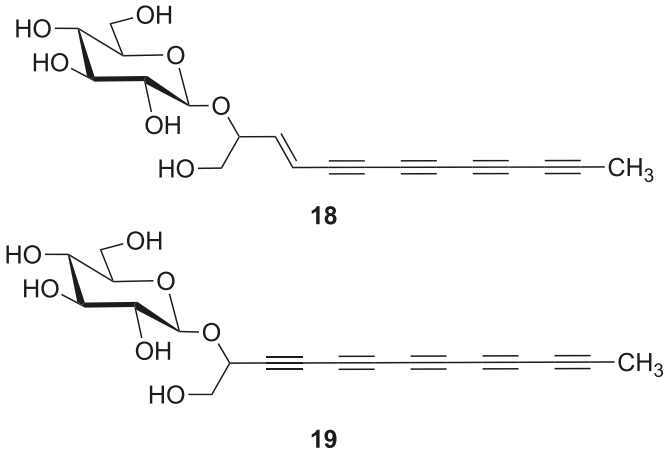
Fig. 5. Polyyne glycosides from *Bidens parviflora* and *B. bipinnata*.



In 1993, Yoshihara, and co-workers[49] isolated two new methyl β-D-glucopyranosyl helianthenates, **20** and **21**, from the ethyl acetate soluble portion of the 70% aqueous ethanol extract of the leaves of Jerusalem artichoke (*Helianthus tuberosus*), which, despite its name, is a species of sunflower (Fig. 7).[22] Both **20** and **21** showed tuber-forming activity in potatoes. This same group has reported four additional methyl β-D-glucopyranosyl helianthenates, **22**–**25**, which were isolated from the same plant species.[50] It is worth noting that the helianthenates A–E share a similar substructure with falcarinol and falcarindiol, two of the most widely studied, naturally occurring polyynes.[2,13,51]

Members of the *Aster* genus have been used in traditional

Fig. 6. Polyyne glycosides from *Microglossa pyrifolia*.



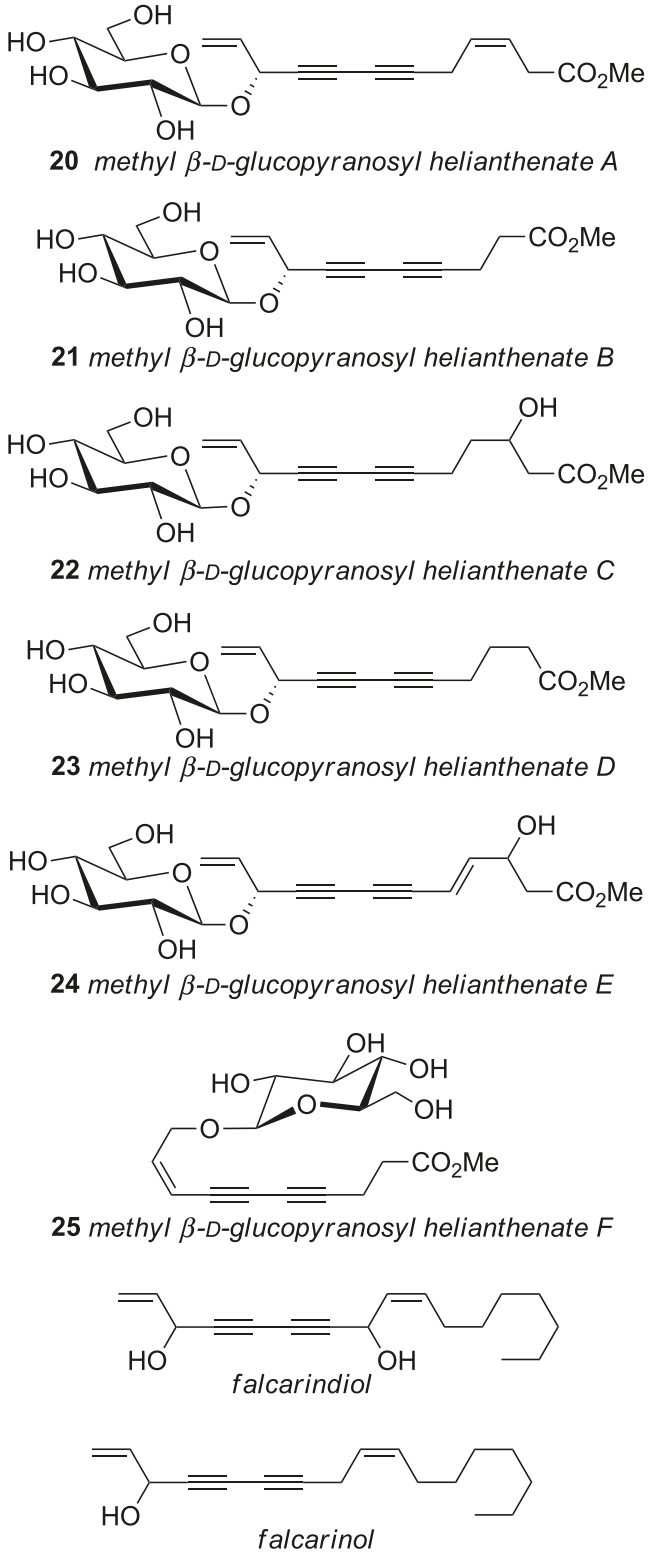
medicine for the treatment of, for example, fever, colds, snakebites, and bee stings.[52] As part of their study of *Aster* species as sources of bioactive compounds, Zhou and co-workers[53] have isolated asteryunnanoside I, **26** (Fig. 8) from the *n*-butanol soluble portion of a 70% ethanol extract of *A. yunnanensis* roots.

In a similar investigation, Wang and Yu[54] isolated four glycosidic constituents, **27**–**30**, from the 70% ethanol extract of the roots of the species *A. auriculatus*. Compounds **27** and **28** are both disaccharides that possess the same aglycone, but differ in the structure of the carbohydrate moiety. In contrast, compounds **29** and **30** are both β-D-glucopyranosides, but differ in the position of the double bond in their aglycone. Compound **29** resembles bidensyneoside D (**17**, Fig. 5), which was isolated by Okuyama and co-workers[47] from *B. bipinnata*, except that the configuration of the olefin at the distal end of the aglycone is *E*, rather than *Z*.

Another member of the aster family recently studied is *Gymnaster koraiensis*, a common Korean plant. From this species, a series of polyyne natural products was recently isolated, including gymnasterkoreaynes A–G (not shown).[55,56] Because gymnasterkoreaynes A–G showed significant cytotoxicity against L1210 tumor cells (ED values of 0.12–3.3 μg/mL),[55] Bae and co-workers[57] continued their work toward identifying pharmacologically active constituents from this species. This ultimately led to the isolation of two polyyne glycosides, gymnasterkoreasides A (**12**, Fig. 5) and B (**31**, Fig. 9) from the root extracts (butanol soluble fraction). Compound **12** had been previously isolated from *B. parviflora* by Wang et al.,[8] who christened it bidensyneoside A_1, while compound **31** (which like **28** (Fig. 8) possesses a β-D-apiofuranosyl-(1→6)-β-D-glucopyranosyl moiety) represented a new polyyne disaccharide.

The rhizomes of another genus of the aster family, *Atractylodes*, have long been used in Japanese traditional medicine.[58] A number of polyyne natural products have been discovered in this genus, including glucoside derivative **32** (Fig. 10) identified from *A. lancea* by Kitajima et al.[59] It is worth noting that the aglycone of **32** has also been isolated from the aerial parts of the ornamental knapweed (*Centaurea ruthenica*) by Bohlmann and co-workers.[60] From a related species, *A. ovata*, the same group isolated and identified the polyyne glycoside **33**.[61] While there are no reports

Fig. 7. Polyyne glycosides **20**–**25** from *Helianthus tuberosus*.



on the biological activity of either **32** or **33** to date, it is interesting to note the structural similarity of these two compounds to 3′-deoxybidensyneoside C and bidensyneoside C (**16** and **15**, respectively, Fig. 5), respectively, both of which inhibit histamine release and nitric oxide production.[8]

The aster family species *Artemisia monosperma* is a des-

Fig. 8. Polyyne glycosides from *Aster yunnanensis* and *A. auriculatus*.

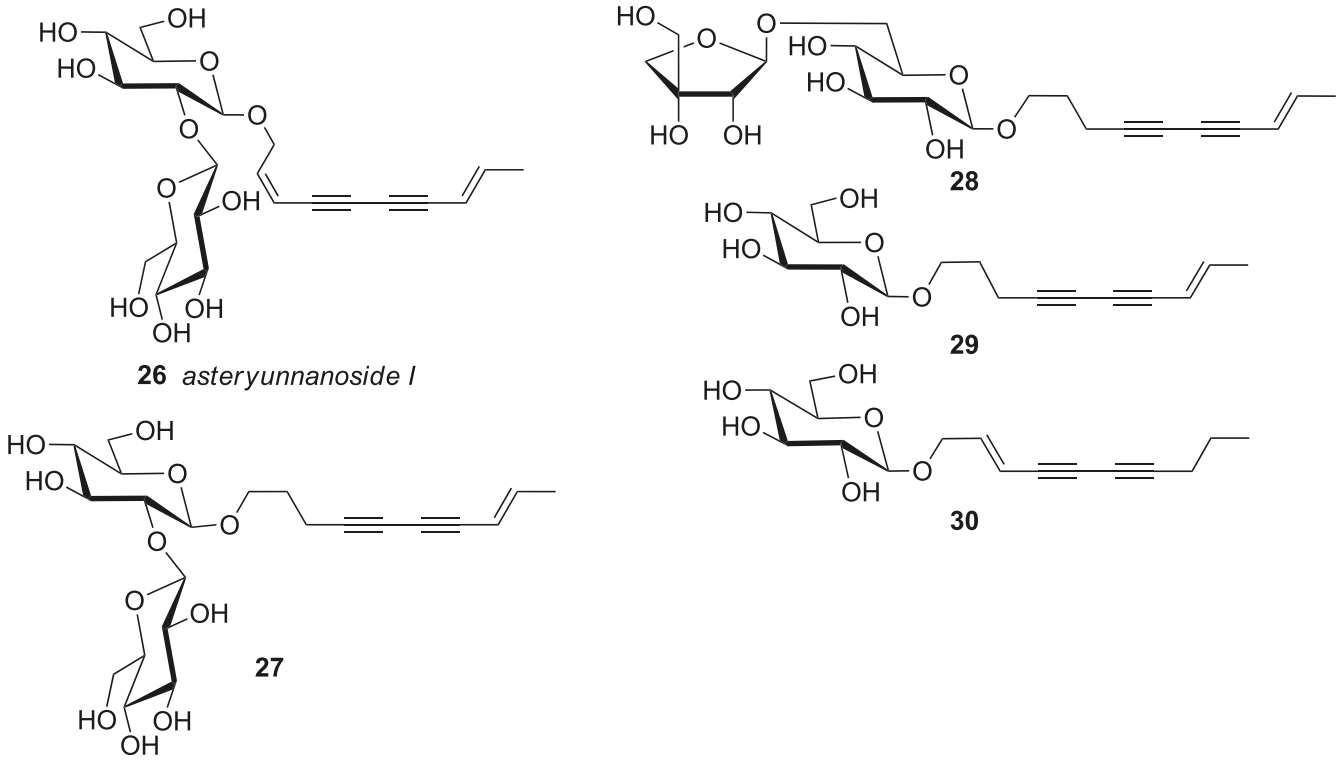


Fig. 9. Polyyne glycoside from *Gymnaster koraiensis*.

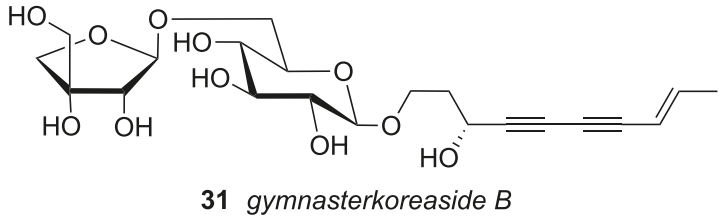

Fig. 10. Polyyne glycosides from *Atractylodes lancea* and *A. ovata*.

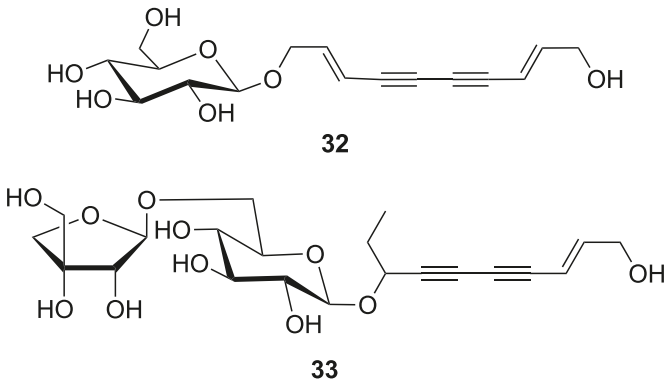
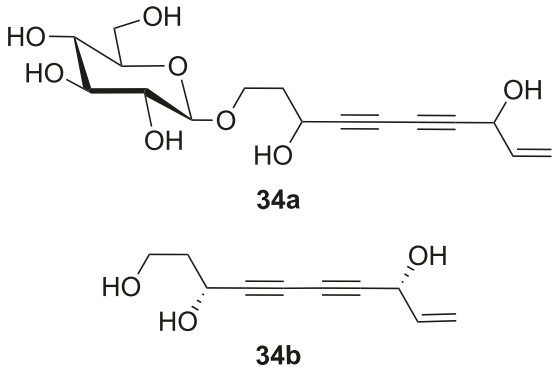


ert shrub native to a number of countries in the Middle East, for example, Egypt, Libya, Israel, Jordan, and Lebanon. Phytochemical studies on this species have resulted in the isolation of polyyne, sesquiterpene, and acetophenone natural products.[62,63] In 2005, Gibbons and co-workers[64] reported the isolation of additional bioactive constituents from *A. monosperma*, including a new polyyne glucoside **34a** and its aglycone **34b** (Fig. 11). Diol **34b** had been isolated previously from the same plant[62] and it was proposed, but not established, that the stereochemistry of the aglycone of **34a** was the same. These two compounds were tested for their ability to inhibit the enzyme 12-lipoxygenase, and both exhibited moderate activity against the enzyme at 30 μg/mL.

In addition to cultivation for its seed oil, the dried flower petals of the safflower plant (*Carthamus tinctorius*) are widely used in traditional Chinese medicine to, for example, promote blood circulation.[65] Two new compounds, carthamoside A_1 (**35**) and A_2 (**36**, Fig. 12), were isolated from *C. tinctorius*, as well as **17** (bidenoside D, Fig. 5).[66] It should be noted that compound carthamoside A_2 has an unusual 4,6-*O*-isoproylidene glucopyranosyl moiety, a rare structural motif in a natural product. Similar to bidenoside D, whose biological activity has not been reported, the ability of neither **35** nor **36** to modulate biological processes has seemingly been investigated.

Pluchea indica (Indian fleabane or Indian camphorweed) is a native plant of India, South China, Malaysia, and Australia, and recently it has been classified as an invasive species in the Hawaiian Islands.[67] The species has been used traditionally to remedy a variety of ailments; for example, in

Fig. 11. Polyyne glycoside from *Artemisia monosperma* and the aglycone **34b**.



Thailand and Java the chopped stem bark is smoked as cigarettes to relieve the pain of sinusitis.[68] From the aerial parts of this plant, the thiophene based polyyne glycoside **37** has been isolated, together with several other polyynes including the aglycone (Fig. 13).[69] The antimicrobial properties of these derivatives have been explored, and, using a standard disk diffusion assay, it was shown that **37** was active against *S. aureus* and *Bacillus subtilis*. By way of comparison, the aglycone of **37** was active against not only *S. aureus* and *B. subtilis*, but also *Saccharomyces cerevisiae*. Neither was active against *E. coli* or *B. thuringiensis*. The aglycone of **37** has been previously identified from several sources, including *Pterocaulon allopecuroides* (blackroot),[70] *Onoseris alata*,[71] and *P. suaveolens* (wingstem camphorweed).[72]

Family Campanulaceae — Bellflower family

Of the known polyyne glycosides from the bellflower family of plants, two have been particularly well-studied: lobetyolin (**38**) and lobetyolinin (**39**, Fig. 14). The aglycone of both glycosides, lobetyol (**40**), has also been included in these investigations. In 1990, Tanaka and co-workers[73] first identified lobetyolin (**38**), along with a number of other glucosides, from the herb *Codonopsis tangshen*, a very common drug plant in China (known as dangshen) whose root is widely used as a substitute for ginseng.[74] In 1994, Nörr and Wagner[75] also reported the isolation of lobetyolin from *C. pilosula*, a related species that is sometimes called "poor man's ginseng".

In 1991, Ishimaru et al.[76] isolated lobetyolin (**38**) and lobetyol (**40**) from *Lobelia inflata*, a common North American plant, typically called Indian tobacco or puke weed. In the following year, lobetyolinin (**39**), was isolated from this same species.[77] Ishimaru and co-workers also isolated lobetyol, lobetyolin, and lobetyolinin from hairy root cultures of *L. sessilifolia*, *L. chinensis*, and *L. cardinalis*.[78–80] More recently, Bálványos et al.[81] analyzed these three compounds in hairy root cultures of *L. inflata* cultivated in a bioreactor by direct infection of the sterile plants with *rhizogenes* strain R1601.

In 1995, Ishimaru and co-workers[82] infected the cultured hairy roots of *Platycodon grandiflorum* with *A. rhizogenes* to produce lobetyol, lobetyolin, and lobetyolinin. Over the next few years, this group reported the use of the same method to culture hairy roots of *P. grandiflorum* (Korean balloon flower) and *Trachelium caeruleum* with the goal of

Fig. 12. Polyyne glycosides from *Carthamus tinctorius*.

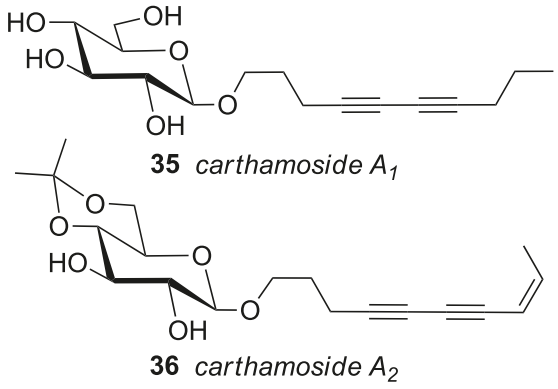


Fig. 13. Polyyne glycoside from *Pluchea indica*.

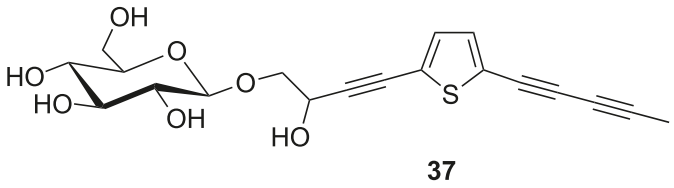

obtaining larger amounts of the polyyne glycosides.[83,84] The isolation of **38**–**40** from hairy root cultures of *Campanula medium*,[85] *C. glomerata*,[86] *Wahlenbergia marginata*,[87,88] and *Dialypetalum floribundum*[89] has also been reported.

Interestingly, despite the significant amount of work directed at producing and isolating lobetyolin, lobetyolinin, or lobetyol from various sources, in none of these studies has their biological activity been reported. Indeed, the only report on the biological activity of these compounds comes from Dumlu et al.[90] who isolated five known compounds, including lobetyol and lobetyolin, from the methanolic extract of the ivory bellflower (*C. alliariifolia*) and studied their antioxidant (free radical scavenging) activity. These investigations revealed that lobetyolin (**38**) and lobetyol (**40**) showed similar antioxidant activity.

In 2008, another plant species used in Chinese herbal remedies, *C. cordifolioidea*, was shown to produce three polyyne glycosides, cordifolioidynes A–C (**41**–**43**, Fig. 15), as well as lobetyolin (**38**).[91] Using the agar dilution method, the antibacterial activity of these compounds was assessed against eight microbial strains, and none exhibited antibacterial effects at concentrations up to 100 μg/mL.[91]

Pratia nummularia is a perennial plant found at high altitudes in China, India, Malaysia, Thailand, Myanmar, Australia, and South America. The whole plant has been commonly used as a traditional medicine for the treatment of contusions, cough, and inflammation.[92] From the hairy root cultures of *P. nummularia*, Ishimaru et al.[93] isolated two unique glycosides (Fig. 16), pratialin-A (**44**) and pratialin-B (**45**), as well as lobetyolin and lobetyolinin. Their report did not include any biological testing of these complex glycolipids.

Polyyne glycosides isolated from fungi

While polyynes are rather commonly found in fungi,[94–96] only two reports describe polyyne glycosides isolated from

Fig. 14. Polyyne glycosides lobetyolin (**38**), lobetyolinin (**39**), and lobetyol (**40**).

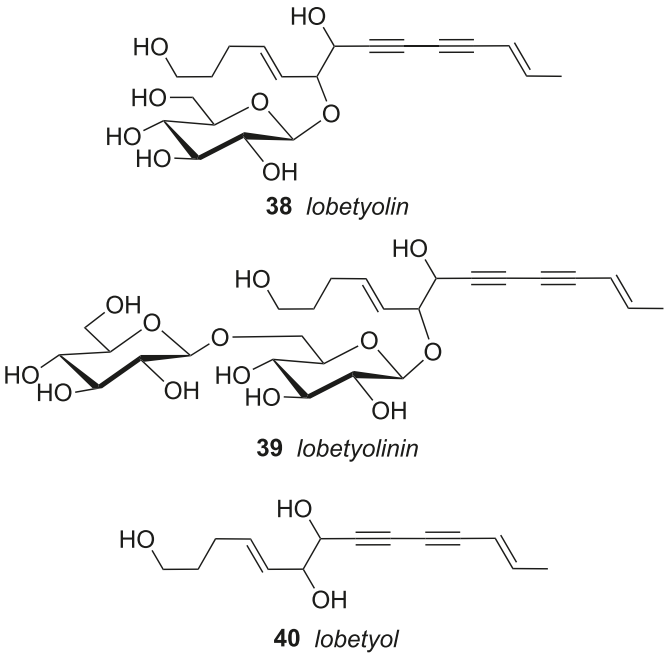

Fig. 15. Polyyne glycosides from *Codonopsis cordifolioidea*.

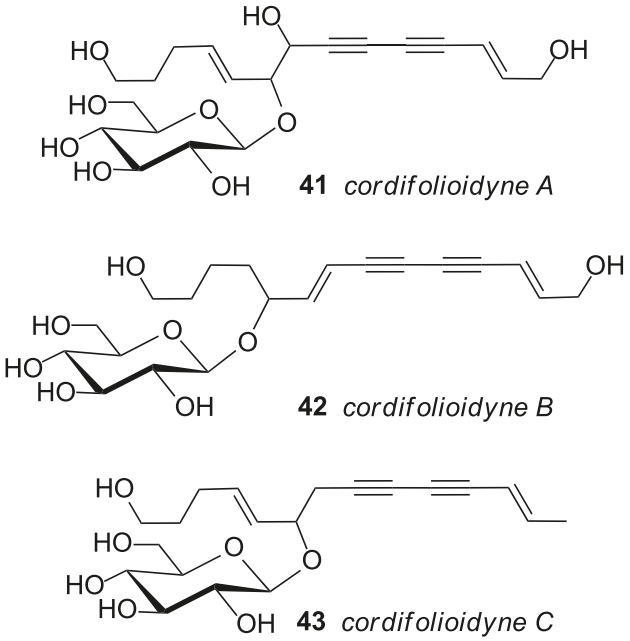

this class of organisms. The first comes from species of the fungus *Fistulina*, which are known to produce polyynes both in mycelia cultures[97] and in fruiting bodies in the field.[98] In 1974, it was demonstrated that extracts from the culture fluids of the pale beefsteak fungus (*F. pallida*) grown in surface cultures produced small amounts of several triyne products, including a polyyne glucoside and the corresponding aglycone. Unfortunately, this glucoside could not be isolated in a pure state, but on the basis of their analyses on the impure materials, the compound was determined to be one of two isomeric structures, triyne **46** or **47** (Fig. 17).[99] No biological activity of these compounds was reported.

In 1950, research at the New York Botanical Gardens identified the isolation and characterization of two highly unsaturated molecules in extracts of the fungi *Poria cortical* and *P. tenuis*, as well as in an unidentified Basidiomycete.[100] It was noted that the liquid cultures of these compounds showed antibiotic activity against a number of microorganisms, including *Mycobacterium tuberculosis*.[101] Spectral evidence suggested that the new molecules, christened nemotinic acid and nemotin, contained a polyyne framework. It was not until 1955, however, that the structures were elucidated as the allene-diynes **48a** and **48b** (Fig. 18), respectively, by Bu'Lock, Jones, and Leeming,[102] using cultures of Basidiomycete B-841.[103] In their subsequent investigation of the polyyne metabolites from Basidiomycete B-841, the β-D-xylopyranoside of nemotinic acid (**49**) was identified (Fig. 18).[6,104] While the configuration of the allene group remains unknown, the identification of **48** and **49** is very impressive given that structural assignment was achieved prior to 1960 through chemical analysis and degradation, rather than NMR spectroscopic analysis.

These early studies of **48** and **49** also provide some of the only experimental insight into the mechanism of polyyne glycoside biosynthesis.[6,104] When [1-^{14}C]-acetate (15%–20%) is added to Basidiomycete B-841, under conditions in which glucose is the only nutrient, the label is efficiently incorporated into the polyyne, but not the monosaccharide. This result suggests that, under these conditions, the source of the carbohydrate moiety is glucose, not acetate. Basidiomycete B-841 will also grow using ethanol as only nutrient and when 15%–20% of [1-^{14}C]-acetate is added under these conditions, both the polyyne and sugar segments of **48** are labeled. From these results it was concluded that in the ethanol cultures, where all metabolic intermediates are synthesized from two-carbon units, the xylose moiety is produced by a pathway similar to glucose.

Polyyne glycosides isolated from algae

The unicellular alga *Prymnesium parvum* is one of the most damaging red tide species,[105,106] and its bloom has been responsible for devastating fish kills.[107] It has been known for over three decades that the organism produces a potent ichthyotoxin named prymnesin, although the structure of this toxin was unknown at the time this discovery was made.[108] In 1996, 10 mg of prymnesin-1 (**50**) and 15 mg of prymnesin-2 (**51**, Fig. 19) were isolated by Yasumoto and co-workers from 400 L of *P. parvum* cultures.[109] Initially, only the structure of the major component, prymnesin-2, was reported, albeit without the stereochemistry established; the structure of prymnesin-1 remained unknown.[109] However, in 1999, Yasumoto and co-workers[110] reported, on the basis of extensive NMR spectroscopic analyses, the structural elucidation of both prymnesins, including stereochemical assignments. The relative configuration of two stereogenic centers of these initial structures (at the E/F ring junction) have subsequently been reassigned.[111] The toxicity of both molecules is quite impressive: both are toxic to fish at concentrations less than 10 nmol/L, and they also lead to complete lysis of mouse cells at a concentration of 3 nmol/L.[112]

Synthesis of polyyne glycosides

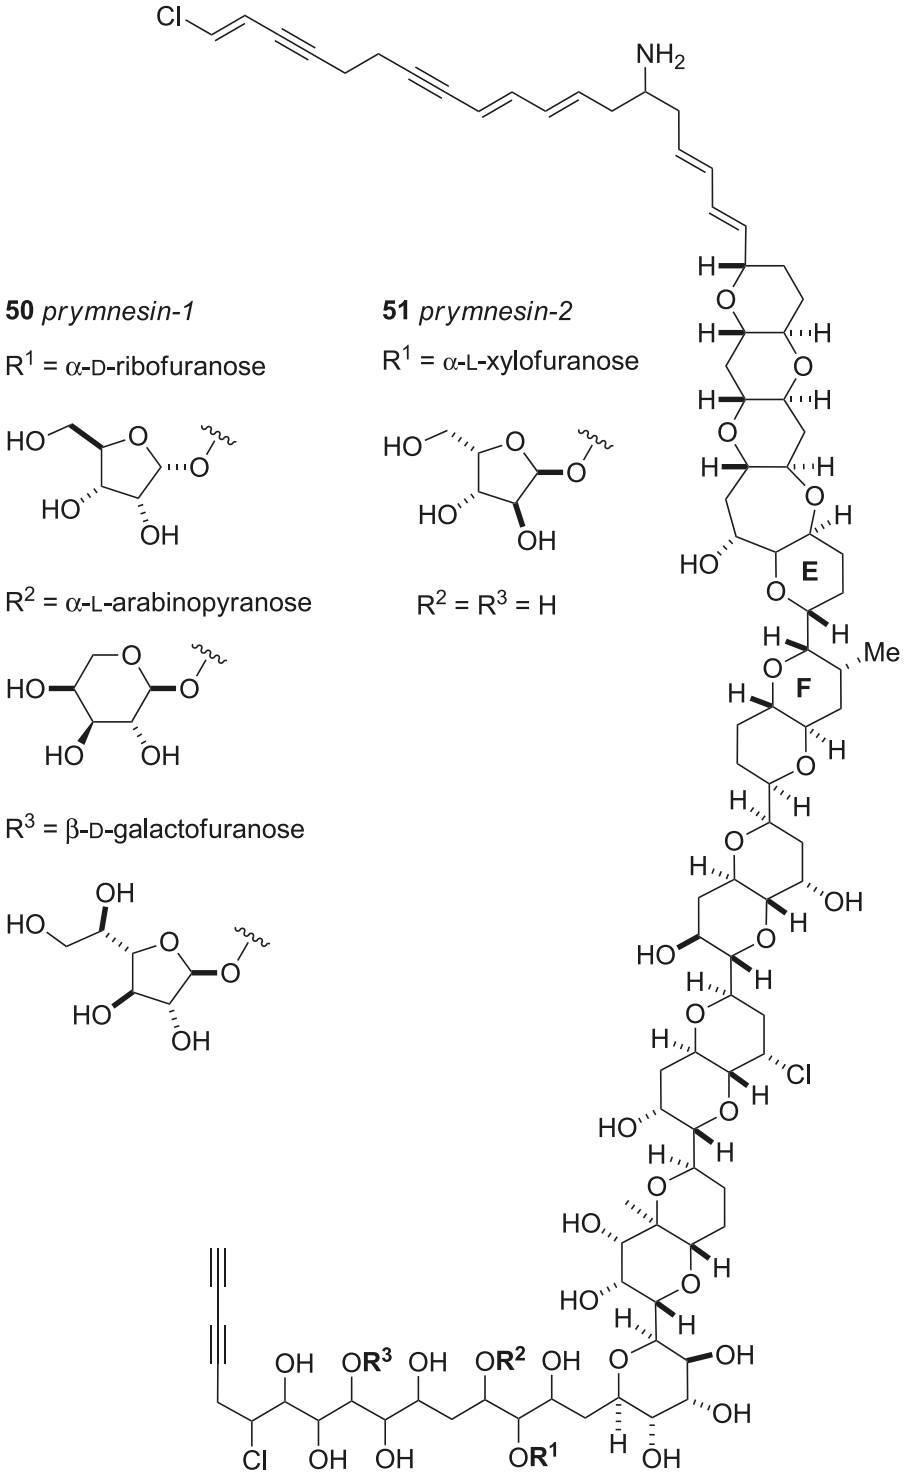
Synthesis of natural products

Although many polyyne glycosides have been isolated from natural sources, and some of them have been shown to possess a range of biological activities, there has been surprisingly little interest in their synthesis.[11] To date, only two studies have described the synthesis of naturally occurring polyyne glycosides. Gung and co-workers[113,114] have reported the syntheses of bidensyneosides A_1, A_2, B, and C (**12**–**15**, respectively), and an analogue bidensyneoside C (**16**, Scheme 1). Although the protecting group strategy employed for the sugar moiety varied among the individual syntheses, the general approach for construction of the polyyne segment remained constant. In each case, the di- or triyne segment of the bidensyneoside was completed with a Cadiot–Chodkiewicz coupling between a glycosyl bromoacetylene derivative and a mono- or diyne. Depending on the coupling partners, yields between 31% and 91% were realized. Global deprotection, in one or two steps, then afforded the desired products. It should be mentioned that the synthesis of these glycosides also allowed for the confirmation of the stereochemistry at C3 of the aglycone of **12**–**15**, which had not yet been established.

Synthesis of natural product analogues

As is the case described above for naturally occurring polyyne glycosides, there has also been surprisingly little effort amongst synthetic chemists toward the assembly of natural product analogues. The synthesis of polyyne glycosides, particularly derivatives with a tri-, tetra-, or pentayne skeleton can be challenging, in part due to the inherently unstable nature of these longer polyynes.[2] Presumably this instability,

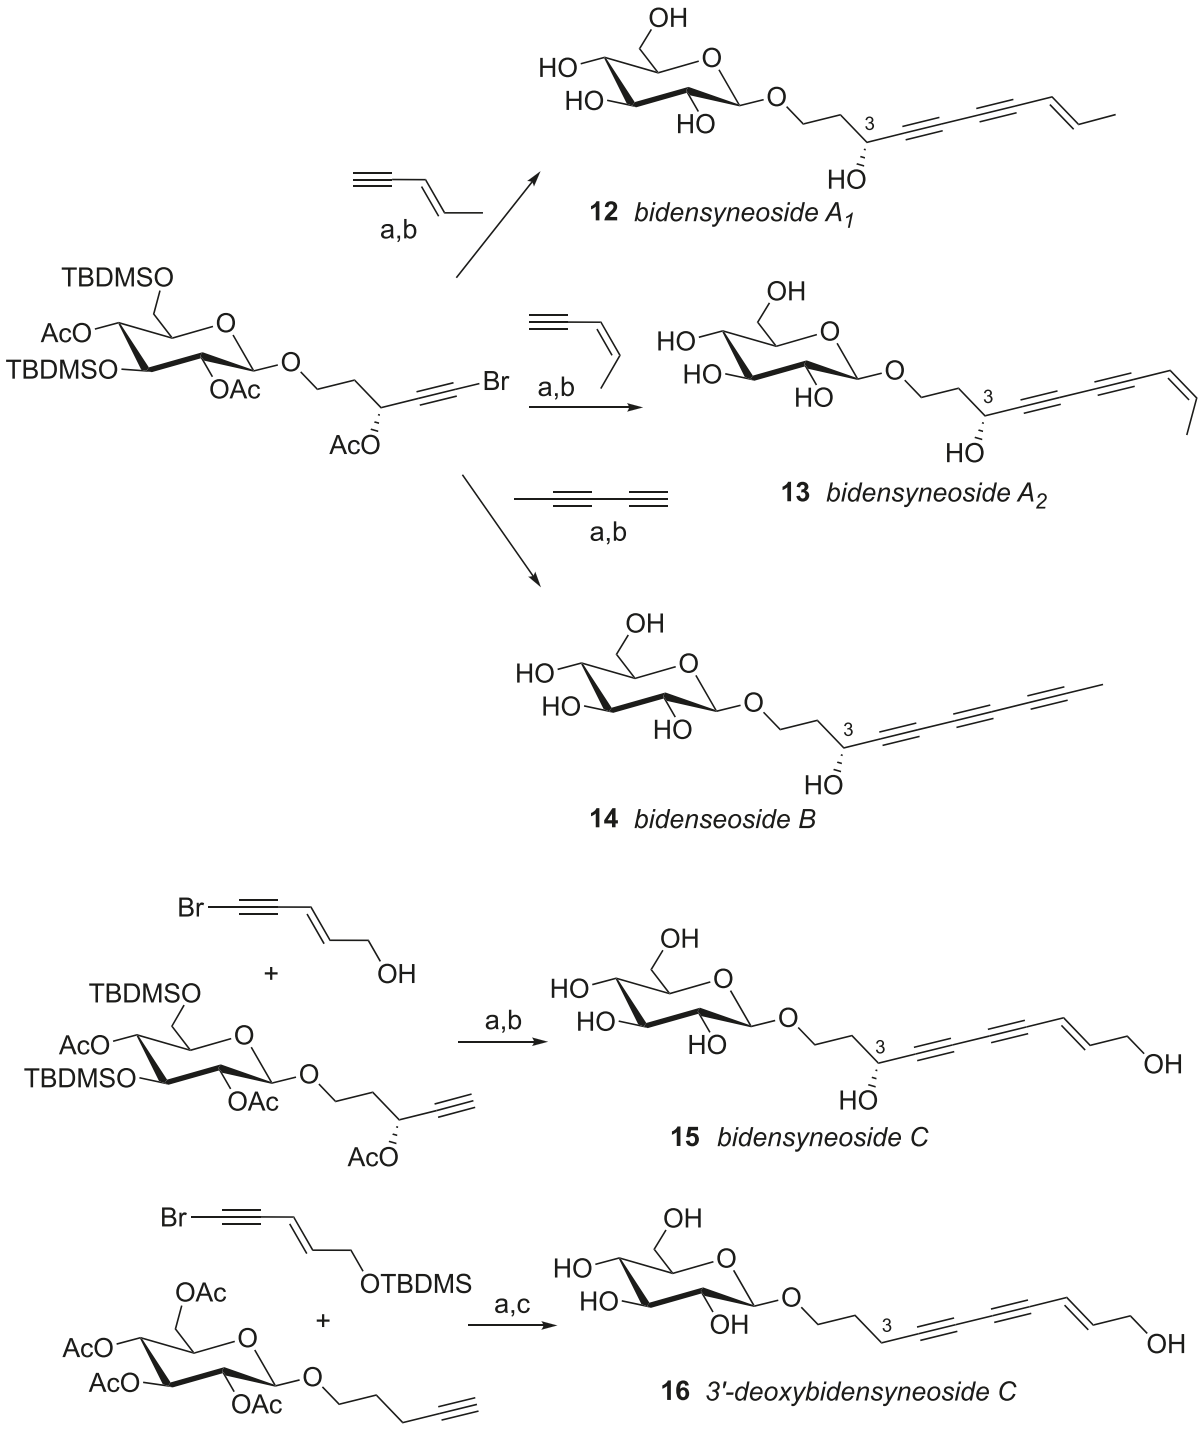
Fig. 19. Polyyne glycosides prymnesin-1 (**50**) and prymnesin-2 (**51**) from alga *Prymnesium parvum.*



and the dearth of effective methods for making polyynes, are factors that have limited synthesis of compounds in this class of molecules. To date, there has been a single report that has specifically targeted the synthesis of natural product analogues of polyyne glycosides.

In 2005, Tykwinski and co-workers[115] described the first syntheses of triyne glycosides using triynol **52** that, together with its acetate derivative **53** (Scheme 2), has been isolated from several species of *Bidens* (beggarticks), including *B. pilosa* and *B. leucanthus*.[116] The synthesis of **52** and **53** started from 1,4-butynediol.[115] Monoprotection of this diol as *tert*-butyldiphenylsilyl (TBDPS) ether followed by oxidation gave the corresponding aldehyde, which was then reacted with lithium phenylacetylide to provide alcohol **54**. A sequence of oxidation, dibromoolefination, and Fritsch–Buttenberg–Wiechell rearrangement gave the triyne core **55**. Fi-

Scheme 1. Bidensyneoside syntheses from Gung and co-workers.[113,114] (a) CuCl, Et_2NH, $NH_2OH{\cdot}HCl$, MeOH, H_2O, 0 °C, 91% (**12**), 86% (**13**), 46% (**14**), 56% (**15**), 31% (**16**); (b) (*i*) HF–pyr, THF, 0 °C; (*ii*) MeOH, K_2CO_3, RT, 87% (**12**), 85% (**13**), 53% (**14**), 50% (**15**) over the two steps; (c) HF–pyr, THF, 0 °C, 51%.



nally, liberation of the alcohol with TBAF gave a 90% yield of triynol **52**, which was then acetylated affording an 81% yield of **53**.

In theory, coupling triynol **52** to different sugar moieties could be achieved through the use of a number of different glycosylation protocols. In this study, three standard methods, each employing a different class of glycosylating agent (glycosyl acetates, glycosyl halides, and glycosyl imidates) were investigated. The reaction rate and yields were both low when glycosyl bromides were used as donors, while the coupling reactions using trichloroacetimidates as donors led to multiple products. In contrast, using glycosyl acetates as donors gave the desired products **56**–**58** in modest to good (61%–78%) yields. Deacetylation of the protected sugars afforded the triynol glycosides **59**–**61** (Scheme 3).[115]

In addition to the natural product analogues just described,

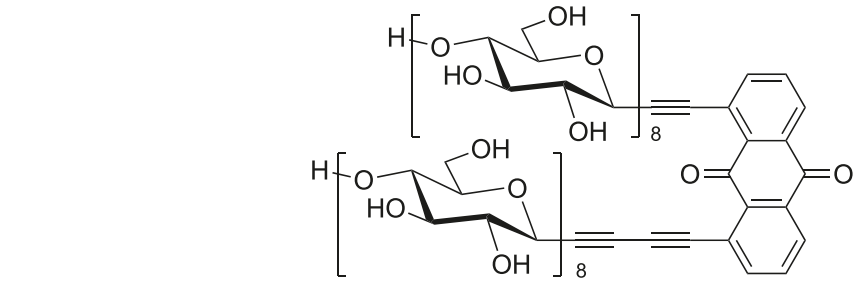
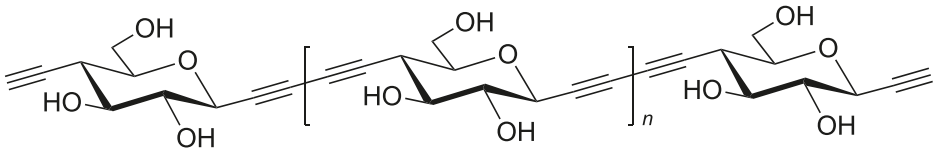
there have been several forays into combining the conjugated framework of a polyyne with that of a carbohydrate. Although these studies have not always targeted natural products or their analogues (indeed most are not, strictly speaking, polyyne glycosides) several are mentioned here to show the broad and evolving scope of this area of chemistry.[10]

Vasella and co-workers[117] have explored a number of potential mimics of cellulose, such as **62**, which possesses two cellooctaosyl chains with a C-glycosidic mono- or diyne linkage between the "reducing" end of the oligosaccharide and an anthraquinone core (Fig. 20). The anthraquinone template was used to ensure a parallel orientation of the oligosaccharide chains, and the distance between the two chains was designed to correspond to that determined crystallographically for the two independent chains of cellulose I. The ethynyl and butadiynyl linker units enforced an appropriate phase shift between the two chains. Key steps in the synthesis of these compounds involved the formation of a carbon-linked

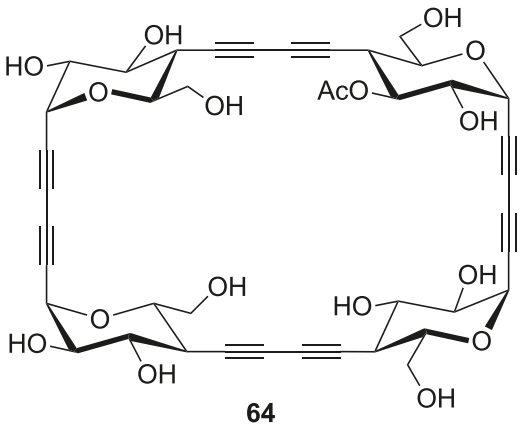
Fig. 20. Polyyne glycoside oligomers synthesized by Vasella and co-workers.[118–126]



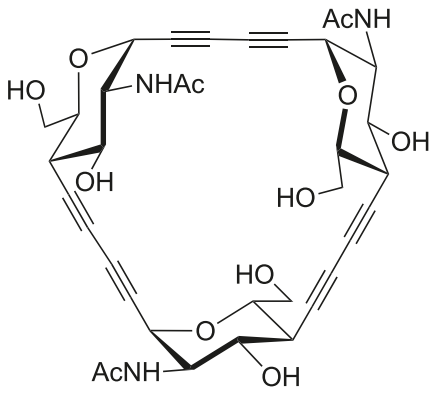
62



63 n = 0, 2, 6, 14



64

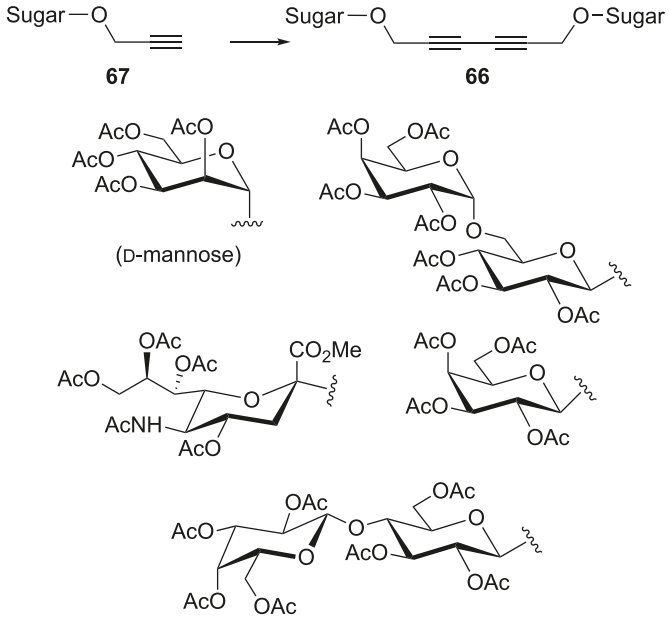


65

glycosyl acetylene or diacetylene derivative, which was then coupled via a Sonagashira coupling to anthraquinone triflates. The use of a selective protection–deprotection sequence on 1,8-dihydroxyanthraquinone facilitated the introduction of two different carbohydrate substitutents. The Vasella group has also used butadiyne-linked saccharide oligomers as cellulose analogues in which intrachain–interresidue hydrogen bonding can be avoided. This has led to the development of efficient methodology for the formation of monodisperse oligomers such as **63**, which relies on palladium-catalyzed coupling of carbohydrate building blocks functionalized at C1 and C4 (or C4′) with ethynyl fragments to form the diyne linkers.[118–123]

4-Ethynyl-α-D-glucopyranosylacetylenes have also been used by the Vasella group[124–126] for the preparation of cyclodextrin analogues free of inter-residue hydrogen bonds (**64**, **65**). In the synthesis of these compounds, a series of sequential Cadiot–Chodkiewicz cross-couplings was used to form

Fig. 21. Glycoside dimers by Roy et al.[129]



linear oligomers, which were then cyclized via an intramolecular Cadiot–Chodkiewicz or Glaser coupling to provide tri-, tetra-, penta-, and hexamers.[124–126] In other cases, oxidative homocoupling has been used to assemble the cyclic acetylenosaccharides.[127] One example involves the formation of **65** via reaction of a 4-ethynyl-α-D-pyranosylacetylene monomer under Eglinton conditions.[128] In addition to their synthesis, the host-guest properties of these cyclic structures were investigated and they have indeed been shown to act as hosts for small molecules. For example, the D2-symmetric tetramer **64** forms complexes of approximately the same strength with D- or L-adenosine in D_2O, albeit with rather low affinity (K_a = 40 mol/L^{-1}).[124,125]

Roy et al.[129] have explored the use of butadiyne moieties to connect carbohydrate residues. Their procedure is based on a mild Pd-catalyzed homocoupling method for the formation of conjugated carbohydrate diynes **66** based from the corresponding monomer **67** (Fig. 21). Five derivatives were reported, with yields ranging from 65%–85%. The mannose terminated dimer was subsequently deacylated and its ability to cross-link the tetrameric plant lectin concanavalin (Con A) was examined.

Conjugates of carbohydrates and polyynes have also been synthesized as potential biological sensors. An example are diynes **68** and **69**, which were synthesized and then incorporated into self-assembled monolayer of polydiacetylenes by Charych et al.[130] (Fig. 22). The sialic acid component of **68** acts as a ligand for molecular recognition for the influenza virus, while the photochromic conjugated polymer backbone serves to signal the binding event, which is visible to the naked eye as a blue to red color change. The lactose analogue **69** was also prepared and used to test for nonspecific binding.

In work related to that of Charych et al.,[130] Nie and Wang[131] have synthesized a series of 24 diacetylene-containing sugar lipids, **70**, that incorporated a range of different chain lengths, substituents, as well as varied positioning of diyne moiety (Fig. 23). The self-assembling properties of these diynes were then explored in several solvents including hexane, ethanol, and ethanol–water mixtures. Many of these derivatives exhibited excellent gelation properties in ethanol or ethanol–water mixtures, and this behavior was dependent both on the position of the diyne on the carbohydrate and the chain length. The production of new materials, via diacetylene polymerization of the resulting gels, was also explored.

Most recently, Hoheisel and Frauenrath,[132] have expanded on the concept of polyyne tethered saccharides through the construction of two derivatives, a hexayne and octayne (**71**, Fig. 24). The formation of these extended molecules relied on a newly devised cross-coupling method using the combination of a zinc acetylide and a bromoacetylene in the presence of $Pd(Cl_2)$dppf. Despite their highly unsaturated polyyne skeleton, both molecules were stable for days under ambient conditions.[133]

Conclusion

Polyyne glycosides are a structurally interesting class of compounds with important biological activities including antibacterial and anti-inflammatory properties, as well as the ability to modulate blood glucose levels. To date, about fifty polyyne glycoside natural products have been isolated. Although biological data exists for some of these compounds, it is absent for many others and a systematic study of their biological activity will require multimilligram amounts of these glycoconjugates. Such quantities are most realistically available by chemical synthesis. However, with the exception of the seminal work of Gung and co-workers,[11,113,114] the synthesis of naturally occurring polyyne glycosides has not received significant attention, although analogs of these compounds have been prepared.[115] This is clearly an area that is ripe for further investigation and future studies in this area should include both methodological investigations as well as total synthesis followed by the measurement of biological activity.

One significant and currently unanswered question is the role that the carbohydrate residue plays on the bioactivity of these molecules. It should be noted that in those species isolated from plants, the sugar moiety directly attached to the polyyne is always glucopyranose. Occasionally, this carbohydrate residue is further glycosylated, and most often the identity of the additional sugar residues is another glucopyranose moiety (e.g., lobetyolinin, **39**, Fig. 14). Less commonly, apiofuranose (gymnasterkoreaside B, **31**, Fig. 9) or rhamnopyranose (pratialin-A, **44**, Fig. 16) moieties are found attached to the core glucopyranose residue. Polyyne glycosides isolated from fungi incorporate a broader range of carbohydrate residues including xylopyranose, xylofuranose, arabinopyranose, galactofuranose, and ribofuranose (see Figs. 18 and 19).

The relative lack of diversity of sugars present in these compounds may suggest that the carbohydrate serves either to solubilize the typically hydrophobic polyyne, or facilitates the delivery of these molecules to certain cell types (e.g., through binding to a glucose transporter that tolerates substitutions at the anomeric carbon).[33] It is also possible that the

Fig. 22. Glycoside diynes from Charych et al.[130]

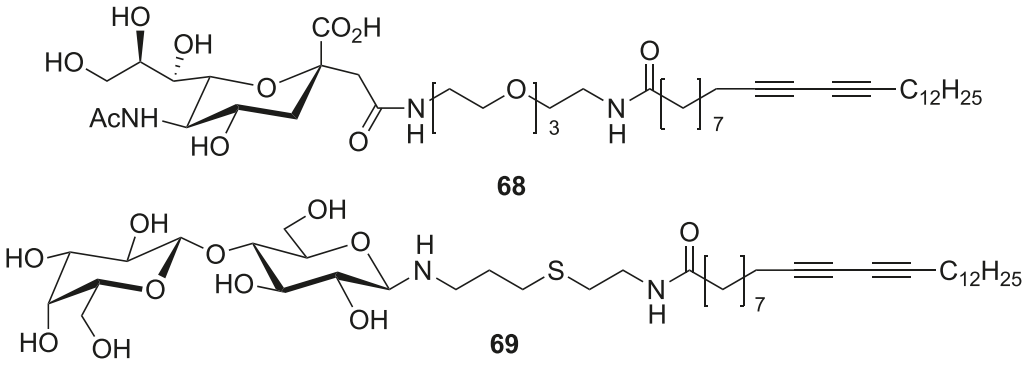


Fig. 23. Glycoside dimers synthesized by Nie and Wang.[131]

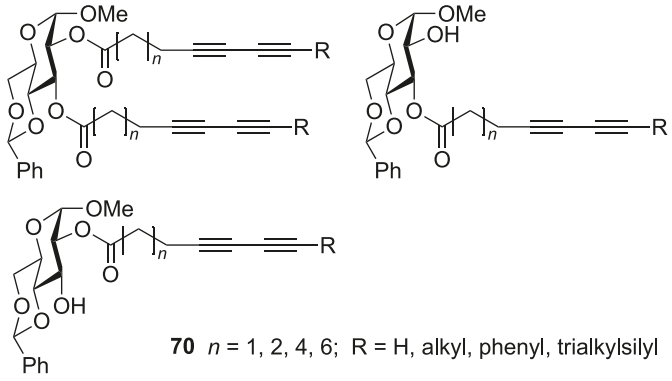

Fig. 24. Glycoside polyynes prepared by Hoheisel and Frauenrath.[132,133]

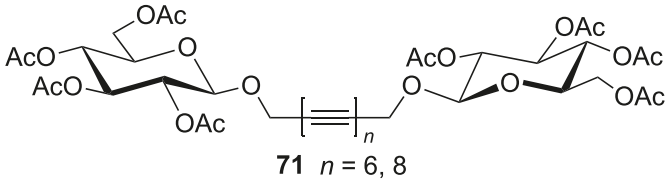

carbohydrate plays a "protecting" role in either stabilizing the polyyne moiety, or in masking its biological activity until cleavage of the carbohydrate moiety by a glycosidase. The latter mechanism is intriguing, and is a strategy used by some plants as protection against herbivores.[134] However, given the lack of detailed structure activity relationships on polyyne glycosides, proposals of this type must at this point be regarded only as speculation. Without question, developing a deeper understanding of the bioactivity of these fascinating molecules justifies more intense future study, from both a chemical and biological perspective.

(1) The term polyyne is meant to denote compounds with a structural sequence of two or more consecutive (conjugated) acetylene units. The term polyacetylene has often been used in this context as well, but can be ambiguous because of its more common use in reference to polymerized acetylene, –[CH=CH]*n*–.

Energy additivity in branched and cyclic hydrocarbons

Hongwei Gao, Richard F. W. Bader, and Fernando Cortés-Guzmán

Abstract: This paper considers the degree to which branched hydrocarbons obey a group additivity scheme for energy and population, extending the study of the known experimental and theoretical transferability of the methyl and methylene groups of the linear hydrocarbons. The chemical groups are defined and their properties are determined using the quantum theory of atoms in molecules (QTAIM). The calculations are carried out with a large basis set at the restricted Hartree–Fock and MP2(full) levels of theory. The deviations from additivity, noted for small ring hydrocarbons leading to the definition of strain energy, are also investigated, showing that the QTAIM energies recover the experimental values. The particular delocalization of the electron density over the surface of the cyclopropane ring, responsible for its "homoaromatic" properties, is discussed in some detail. The calculations reported here satisfy the virial theorem as required for the atomic definition of energy. The problems associated with the use of DFT theory arising from its failure to satisfy the virial theorem are discussed with reference to the study of group transferability.

Key words: atoms in molecules, group additivity, transferability, strain energy.

Résumé : Dans ce travail, on considère le degré auquel des hydrocarbures ramifiés obéissent à un schéma d'additivité de groupe pour l'énergie et la population, étendant ainsi l'étude de la transférabilité expérimentale et théorique connue des groupes méthyle et méthylène des hydrocarbures linéaires. Les groupes chimiques sont définis et leurs propriétés sont déterminées en faisant appel à la théorie quantique des atomes dans les molécules (TQADM). Les calculs sont effectués avec un grand ensemble de base aux niveaux de Hartree–Fock et MP2(complet) de la théorie. On a aussi examiné les déviations par rapport à l'additivité notés pour les petits cycles hydrocarbonés, ce qui a conduit à la définition de l'énergie de tension et qui a permis de montrer que les énergies de la TQADM récupèrent les valeurs expérimentales. On discute en détail de la délocalisation particulière de la densité électronique sur la surface du noyau cyclopropane, responsable de ses propriétés homoaromatiques. Les calculs rapportés ici satisfont le théorème du viriel, tel que requis pour la définition atomique de l'énergie. En référence avec l'étude sur la transférabilité de groupe, on discute aussi des problèmes associés avec l'utilisation de la théorie de la fonctionnelle de la densité découlent de son incapacité à satisfaire le théorème du viriel.

Mots-clés : atomes dans les molécules, additivité de groupe, transférabilité, énergie de tension.

Experimental additivity schemes

It is nearly 80 years since Rossini and co-workers demonstrated that the heats of formation of the homologous series of linear saturated hydrocarbons obey a group additivity relationship of the form indicated in eq. [1]

$$[1] \qquad E(C_nH_{2n+2}) = 2E^o(CH_3) + (n-2)E^o(CH_2)$$

where $E^o(CH_3)$ is the standard additive energy for the methyl group and $E^o(CH_2)$ is the same for the methylene group.[1–3] The compilations of the additive group contributions to thermodynamic properties by Benson and co-workers demonstrate the remarkable degree to which the heat of formation may be equated to a sum of group contributions, those for the methyl and methylene groups exhibiting an average deviation of less than 0.1 kcal/mol for data up to and including $n = 12$ for the homologous series of linear hydrocarbons.[4]

The relationship in eq. [1] has been shown to apply not only to the measured heats under standard conditions, but also to the energies referenced to the vibrationless states at 0 K, energies that can be estimated in theoretical calculations.[5] In 1987, it was shown that the RHF (the acronym used here for single determinant SCF calculation) obeyed the same linear relationship using basis sets ranging from 6–31G* to 6–311++G(2d,2p), with the linear regression analyses yielding $R^2 = 1.00000$.[6] The same goodness of fit is obtained at the MP2(full) level of theory determined by a linear scaling of the methylene group.[7]

This paper considers the degree to which branched hydrocarbons obey a group additivity scheme for energy and populations, using the quantum theory of atoms in molecules (QTAIM) to define the properties of the groups.[8] Previous studies have demonstrated that the QTAIM group properties recover the experimentally determined values for the linear hydrocarbons.[6,7,9] A closely related property is "ring strain",

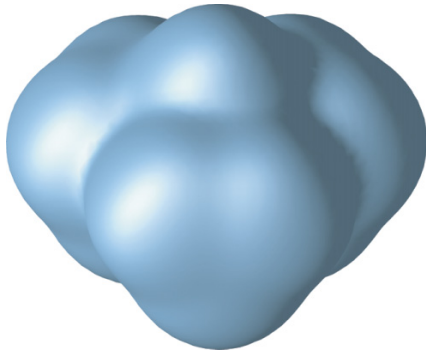
defined as the difference in the calculated or measured energy of cyclic hydrocarbon $(CH_2)_n$ with that predicted by n times the energy of the standard methylene group as defined in eq. [1], $E^o(CH_2)$.[10] While measured ring strain has also been shown to be recovered by QTAIM,[6] the present paper presents the first study of this property using the group energies of QTAIM determined in MP2(full) calculations from wave functions that satisfy the virial theorem.

The recently proposed theorem,[11] stating that the electron density of an atom or functional grouping of atoms in a molecule determines its contributions to the properties of the total system, had its origin in studies that focused on the degree of retention of an atom's properties during its transfer between molecules. The atoms of QTAIM are "proper open systems" whose properties are defined by quantum mechanics. They have been shown to recover all measurable atomic and group properties, including second-order field-induced response properties along with those resulting from exposure to electromagnetic radiation and atomic charges and moments measured in the atomic polar tensors governing infrared intensities.[12,13] Someone unfamiliar with the mathematics necessary to follow the derivation of the physics of an open system from Schwinger's principle of stationary action[14,15] may derive QATIM heuristically. This requires only knowledge of Schrödinger's equation together with rudimentary mathematics using Gauss' theorem to relate the volume integral of the divergence of a vector to a surface integral of its flux, coupled with an appeal to experiment to demonstrate the validity of the "zero-flux" boundary condition.[16]

The physics of an open system demonstrates that transferability of an atom's energy and density is paralleled by the transferability in its virial field, the total potential-energy density, a transferability that can be maintained in spite of gross changes in its external potential, the quantity that according to the theorem of Hohenberg and Kohn, determines a molecule's electron density.[17] There is no conflict here, as the theorem of Hohenberg and Kohn refers to a closed isolated molecule, while chemical transferability is concerned with the physics of an open system that governs the transfer of groups between different molecules. Figure 1 shows the 0.001 au density envelope of the *iso*-butane molecule. The methyl groups and the H at the top of the CH group are clearly defined by the intersections of the zero-flux interatomic surfaces with the density envelope. The properties of these groups determine the properties of the molecule, their properties being determined by their charge distributions.[11] The extent to which that the density of a methyl group in this molecule differs from the density of a methyl group in a linear hydrocarbon determines the extent to which its properties differ from those of the standard transferable methyl group. The methyl group in *iso*-butane is found to be 14 kcal/mol more stable than the standard group, though they may come from molecules that differ in many thousands of kcal/mol in their external potentials.

A recent study extended these observations to determine the atomic transferability encountered in chemical change through a study of the changes in an atom's virial, energy, and population engendered by the formation of the hydrogen-bonded interactions that underlie DNA base-pairing.[18] The present paper provides further examples of how the transferability of a group's energy mirrors the changes in its density.

Fig. 1. The 0.001 au isodensity surface of the *iso*-butane molecule that contains over 99% of the total electron density. The methyl groups and the hydrogen atom of the interior CH group are clearly defined by the intersections of the ClC zero-flux interatomic surfaces with the density envelope. The contributions of each group to the total properties of the molecule are determined by its electron density distribution.



Perfect and compensatory transferability of group properties

The linear additivity scheme observed for the hydrocarbon heats of formation was the first experimental property demonstrated to result from functional group contributions defined by QTAIM.[6] Later studies demonstrated that the molecular values for the electric polarizability[19] and magnetic susceptibility[20] of the hydrocarbons are also recovered in terms of the additive methyl and methylene group contributions defined by QTAIM, with the physics of an open system equating all measurable molecular properties to the sum of their atomic contributions. While all properties are additive, groups and their properties are in general not completely transferable between molecules, as would seem to be required for an experimental additivity scheme, as represented by eq. [1].

While QTAIM does indeed predict the occurrence of such essentially "perfect transferability" of groups and their properties, this is not the sole mechanism underlying the observation of experimental additivity schemes. The extensive tabulations of thermodynamic properties by Benson et al. demonstrate that group additivity must in many cases be only apparent, as it is found in cases where a group is unavoidably perturbed by a change in its environment.[4] The additivity scheme in these cases is a result of compensatory transferability, with the change in all properties experienced by one group being equal and opposite to those experienced by the second group. Charge is of course, necessarily conserved, but to have the energy and all other properties conserved as well is nothing short of remarkable and is a phenomenon neither predicted nor understood and found to apply even in complex systems. Thus, Benson et al. proposed a rule of the arithmetic mean to account for the observation that many examples can be found wherein the energy of AGGB is the mean of the energies of AGGA and BGGB. As an example where the rule of the mean applies to molecules with delocalized charge distributions, one finds that the experimental heat of formation of pyridine is the mean of the energies of benzene and pyrazine to within 0.1 kcal/mol.[9]

The observed additivity in the linear hydrocarbons is the result of both perfect and compensatory transferabilities. The standard methyl group energy $E^o(CH_3)$ necessarily equals one-half of the molecular energy for ethane, but the methyl group in the succeeding members of the series must differ from this, as they are bonded to a methylene group from which they withdraw electronic charge with $\Delta N(CH_3)$ = +0.016 e and undergo a corresponding energy decrease with $\Delta E(CH_3)$ = –9 kcal/mol, referring to RHF/SCVS values. These values remain unchanged as n increases, and this perturbed methyl group exhibits perfect transferability in all members past ethane to within computational accuracy. The methylene groups bonded to methyl groups undergo compensating changes in N and E from the values for the standard group: zero net charge and an energy equal to $E^o(CH_2)$. The group bonded to two methyls in propane exhibits twice the changes for methyl with ΔN = –0.32 e and ΔE = +19 kcal/mol. Those bonded to a single methyl have ΔN and ΔE values equal and opposite to those for the bonded methyl group. This is the transferable methylene group bonded to a single methyl. The remaining methylene groups must necessarily exhibit perfect transferability with an energy equal to the standard energy $E^o(CH_2)$ and a zero net charge. For example, the six innermost "standard" methylene groups in n = 12 have energy and population changes relative to the standard values within computational accuracy, with $\Delta N(CH_2)$ = 0.2 e and $\Delta E(CH_2)$ = 0.001 kcal/mol. Once removed from methyl, the population of a methylene group is slightly perturbed relative to the standard methylene group with an average $\Delta N(CH_2)$ value of –0.001 e.

The same pattern of perfect and compensatory transferability applies to the polysilanes Si_nH_{2n+2}.[9] Mosquera et al. have demonstrated linear fittings of the RHF energies for a wide range of molecules of the form $X(CH_2)_nCH_3$ for X = F, for aldehydes and ketones, for nitriles and alkanols, all for extended chains of up to 30 carbon atoms.[21–23] The contribution of the methylene group, $E^o(CH_2)$, is the same for all X and equal to the energy of the repeating $|CH_2|$ group of QTAIM, the vertical bars denoting its defining zero-flux interatomic surfaces. Their results for X = F have been repeated using both RHF and MP2 in SCVS calculations to demonstrate that their findings of apparent deviations in the transferability of group energies are artefacts arising from the failure of their calculations to satisfy the virial theorem.[7]

Transferability of group properties in branched hydrocarbons

Total molecular energies

All calculations were done using the 6–311++(2d,2p) basis in RHF/SCVS and MP2(full)/SCVS calculations, where SCVS denotes a self-consistent scaling of the electronic coordinates so that the virial theorem is satisfied.[24] Table 1 lists the RHF and MP2 total energies of the branched hydrocarbons studied in this paper along with the virial ratio $\gamma = -V/T$, which should equal 2 for satisfaction of the virial theorem, which is seen to be the case to computational accuracy. The symmetries of the molecules are also given and are in agreement with those previously reported for *neo*-pentane[25] and for *iso*-butane.[26,27] The errors in the summation of the integrated atomic populations $N(\Omega)$ and energies $E(\Omega)$ are all acceptably small, the magnitudes of the largest differences being 0.007 e for N and 1.4 kcal/mole for E. The total energies are denoted by E_n, where n denotes the number of carbon atoms. The iso- molecules, *iso*-butane, *iso*-heptane, and *iso*-dodecane are given first, followed by the neo- forms of pentane and nonane.

Table 2 lists the difference Δ between the calculated energy and that predicted by the linear relationship given in eq. [1], $\Delta = E_n - E_n^o$, where $E_n^o = E(C_nH_{2n+2})$ for the same level of theory, with the RHF results given in bold. It should be noted that the energies of the corresponding linear molecules agree with the predictions of eq. [1] to within 0.02 kcal/mol or less for both levels of theory. In two cases, C4 and C5, the difference Δ is of smallest magnitude for the RHF result and so close to zero as to fall within the limits of the integration error. In the remaining three cases, C7, C10, and C9, the RHF result exhibits Δ values lying between 7 and 11 kcal/mol.

The MP2 energies predict the branched hydrocarbons to be more stable than their linear isomers by 1 to 5 kcal/mol with the exception of C10 where the difference is approaching computational uncertainties. The differences fluctuate in a manner that does not appear to be related to the degree of branching. The differences in the experimental heats of formation between the linear and branched molecule are available for butane/*iso*-butane and pentane/*neo*-pentane pairs[28] and are listed in Table 2 and are in excellent agreement with the MP2 results.

The results do indicate that the inclusion of electron correlation beyond the Fermi correlation of RHF causes the

branched isomer to be more stable than its linear isomer, a result that might have its origin in an increased electron delocalization among the neighboring groups, which is possible in the branched molecules. This is something that can be determined by a comparison of the RHF and MP2 delocalization indices, which have been shown to be accurate indicators of the effective range of the stabilizing contributions from the exchange energy.[11] Rafat and Popelier give more direct confirmation of this correspondence by demonstrating that the delocalization index between atoms A and B is proportional to the negative of the exchange energy multiplied by their internuclear separation if the expansion of the exchange energy is restricted to the harmonics $L = 1$.[29] Overall, the percentage delocalization is greater for linear octane than for branched C7, $CH(CH_2CH_3)_3$, at both RHF and MP2, and greater at RHF than at MP2. However, the delocalization indices between the hydrogen atoms of different methyl and methylene groups in C7 at MP2 exceed those at RHF, and it is these interactions that specifically contribute to a lowering of the energy as a result of the "crowding" in the branched hydrocarbons.

Group contributions

Although there is no a priori reason to expect the energies of the branched molecules to follow those predicted by the relationship for their linear isomers, it is instructive to compare the methyl and methylene group contributions with those determined by the linear relationship. This comparison is given in Tables 3 and 4. It should be recalled that the transferable methyl group in a linear hydrocarbon is found for all cases with $n > 2$, wherein the group is bonded to a methylene from which it withdraws electrons, giving it a $\Delta N(CH_3)$ = +0.016 e and a $\Delta E(CH_3)$ = –9 kcal/mol at RHF and $\Delta N(CH_3)$ = +0.011 e and $\Delta E(CH_3)$ = –5.0 kcal/mol at MP2. The deviations of the energies of the methyl groups from the standard value $E^o(CH_3)$ are given in Table 3 in order of decreasing magnitude.

Considering first the RHF results, the increase in stability of the methyl group, measured by $\Delta E(CH_3)$, parallels the increase in its population $\Delta N(CH_3)$, with the methyl group withdrawing an increasing number of electrons as the number of hydrogens on the group it is bonded to decreases. Thus, it is most stable and withdraws the most electrons from the C group, next most from CH and least from CH_2, determining the order of electron withdrawing ability as $CH_3 > CH_2 > CH > C$. The extent of electron withdrawal and the accompanying decrease in energy approach the deviations found for the transferable methyl group in the linear hydrocarbons: +0.016 e and –9 kcal/mol observed for a methyl bonded in the extended chain $CH_2CH_2CH_3$ found in C10. The MP2 results parallel those for RHF, with the values of $\Delta N(CH_3)$ being slightly reduced, and the values of $\Delta E(CH_3)$ slightly less negative. As for the RHF results, one finds that the values for the methyl group bonded to the extended chain in C10 approach the values found for the transferable methyl group, with $\Delta N(CH_3)$ = 0.011 e and $\Delta E(CH_3)$ = –4 kcal/mol.

Table 4 lists the deviations of the populations and energies of the methylene groups in the branched hydrocarbons from their standard values in the linear molecules. A meth-

ylene group bonded to the transferable methyl in a linear molecule transfers density equal to the amount the methyl groups gain, $\Delta N(CH_2)$ = –0.16 e, and is destabilized by an amount opposite to the stabilization of the methyl group, $\Delta E(CH_2)$ = +9 kcal/mol. Only in the case of the methylene bonded to a methyl in the extended chain found in C10 are these values approached. The groups bonded to either a C or a CH group have population changes close to zero and are either stabilized, as in C9 and C10, or only slightly destabilized as in C7. Again, the same pattern in population and energy changes is found for the MP2 results. While there is no significant transfer of charge from either C or CH to a bonded methylene, the methylene gains in stability unless it is sandwiched between a methyl group and the end group in question, when it is slightly destabilized.

The CH group contributions are listed in Table 5, where they are referenced to the CH group in *iso*-butane, C4. To put the results on an absolute scale, the energies of the C and H atoms of the CH group in $CH(CH_3)_3$ are compared with the energies of the C and the H atoms in the standard methyl group, $E^o(CH_3)$, i.e., the energy of methyl group in ethane. Both atoms gain in electronic charge and decrease in energy compared with the corresponding atoms in the standard methyl group; the C atom gains 0.020 e and undergoes a decrease of 20 kcal/mol, while the H atom gains 0.028 e and undergoes a decease in energy of 13 kcal/mol at the RHF level, which is illustrative of MP2 as well. Thus, the atoms of the CH group of $CH(CH_3)_3$ are more stable than their counterparts in standard methyl, and these stabilities increase with increasing length of the linear group at MP2.

The contributions of the C atom to C5 and C9 are listed in Table 6, again referenced to the C atom in the CH group of C4, $CH(CH_3)_3$. The C atom is more stable than the C atom in the CH group in C4, and the results determine the relative stabilities of the energies of the C atoms in the acyclic hydrocarbons: the stability of C increases as the number of bonded hydrogens decreases. Thus, E(C) in the group C < E(C) in CH < E(C) in CH_2 < E(C) in CH_3. The populations of the C atoms decrease in the same order from 5.87 e in the group C to 5.82 e in methyl, and it is the transfer of density from C to H that results in a decrease in the stability of C.

Summary

The energies of the branched hydrocarbons do not differ significantly from those predicted by the linear relationship, eq. [1], with the differences decreasing with the inclusion of electron correlation. This is found in spite of deviations in the methyl and methylene group energies from their standard transferable values. The deviations parallel the increasing transfer of electron density from C to H, a transfer that results in an increasing stability of the group. Thus, the order of electron withdrawing ability $CH_3 > CH_2 > CH > C$ parallels the increasing stability of the methyl group. Start-

ing from the other end of hydrogen substitution, the most stable carbon atom is the one not bonded to any hydrogens, resulting in the energy order: E(C) in the group C < E(C) in CH < E(C) in CH_2 < E(C) in CH_3. Thus, the methylene group is least stable when bonded to either methyl as in $CH(CH_2CH_2CH_3)_3$ or to a C group as in $C(CH_2CH_3)_4$. Thus, the direction of charge transfer appears to be the dominating feature in determining the relative group energies.

Dependence of results on theoretical method

This summary brings into question a possible dependence of the direction of charge transfer of the group properties on q(H) and thus with the method of calculation. DFT calculations can predict a transfer of density from C to H in saturated hydrocarbons, but this direction is reversed with the inclusion of diffuse functions on the hydrogen atoms. Thus, q(H) = +0.0094 e in ethane for a B3PW91/6–311+G(2d,p) DFT calculation, a value that decreases to –0.0149 e for the same calculation with an extra diffuse function on H, that is with G(2d,2p). The direction of negative-charge transfer is C → H in RHF and all post-HF calculations, and this direction is maintained in all DFT calculations that employ a basis set with a diffuse function on H, results that are made clear in Fig. 2. The energies of the H atoms parallel the populations with the most negative energies associated with the diffuse basis set that gives the largest H populations, Fig. 2. An investigation of the changes in populations and energies of the linear hydrocarbons at B3PW91/6–311+G(2d,2p) DFT shows a transfer of electronic charge from methyl to its bonded methylene, with the charge transfer being reduced to zero for the interior methylene groups in pentane and octane. These results are in agreement with those found in the SCF calculations. The group energies only partially emulate the SCF results, with methyl being stabilized in comparison with its standard value in the linear molecules, but by a decreasing amount with increasing n, one that is not balanced by an energy increase of the bonded methylene group. In addition, the changes in energies of the interior methylene groups referenced to their standard linear values do not reduce to zero, the change for a central methylene in octane for example equalling –2.7 kcal/mol. These results are, however, anticipated, as a DFT calculation is incapable of satisfying the virial theorem, unlike the SCVS results reported here for the RHF and MP2 calculations. The kinetic energy used in a DFT calculation in the determination of the atomic energies is T_s, the kinetic energy of a set of non-interacting electrons and is in error by the omission of T_c, the "correlation" kinetic energy. This problem is discussed at some length in an appendix to the paper by Mata et al.[30] and treated in more detail in a forthcoming paper by Rodríguez et al.[31]

Cyclic hydrocarbons and strain energy

Total molecular energies

Table 7 gives the RHF and MP2 total energies of the cyclic hydrocarbons $(CH_2)_n$ with n = 3, 4,5, and 6, along with the virial ratio $\gamma = -V/T$, which should equal 2 for satisfaction of the virial theorem. The symmetries of the molecules are also indicated. The errors in the summation of the integrated atomic populations $N(\Omega)$ and energies $E(\Omega)$ are all acceptably small, with the magnitudes of the largest differences being 0.008 e for N and 1.6 kcal/mole for E.

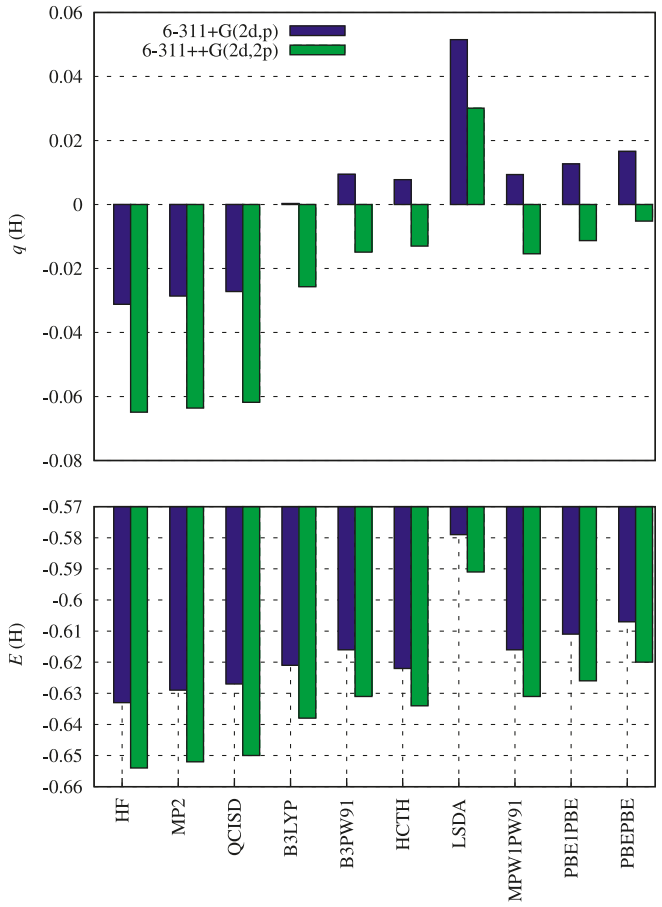

Fig. 2. Bar graphs of the atomic charges q(H) and energies E(H) of a hydrogen atom in ethane, showing their variation with the mode of calculation and basis-set dependence. The first three are RHF and post HF, and the remaining seven are DFT results for differing functionals.

Table 8 gives the integrated populations and energies of a methylene group in each molecule and the difference between the group energy and that of the standard methylene group, $E^o(CH_2)$ of eq. [1]. The strain energy is given by n times this difference in the column entitled "Strain energy". The "experimental" value for the strain energy is given as a bracketed value in the same column. The experimental value is from a recent compilation of the known heats of formation of alkanes and cycloalkanes by Cohen and Benson,[10] values that are almost unchanged from the Franklin equivalents[32] used in the first determination of strain energies using QTAIM.[6] As anticipated, the value of $\Delta E(CH_2)$ decreases as n increases, giving a zero value for the strain energy in cyclohexane, in essential agreement with experiment.

Overall, the agreement with experiment is seen to be better at RHF than at the correlated level MP2, although MP2 does recover the small observed ring strain in cyclohexane. In fact, RHF frequently does better than MP2 at reproducing experimental energies for the saturated hydrocarbons, a consequence of the C and H atoms possessing almost equal electronegativities and thus possessing similar density-based

Table 7. Total energies in atomic units and related energy quantities for cyclic hydrocarbons.

Molecule	Method	Molecular energy	$\gamma = -V/T$	$\Sigma N(\Omega) - N$	$\Sigma E(\Omega) - E_n$
Cyclopropane	RHF/SCVS	–117.09541	2.0000001	0.0001	–0.1

Table 8. Populations and energies of CH_2 groups and their differences from the standard energy E^o(CH2) defining the strain energy for cyclic hydrocarbons.

Method	Molecule	$N(CH_2)$	$E(CH_2)$	$\Delta E(CH_2)$	Strain energy (experimental)
RHF/SCVS	Cyclopropane	8.000	–39.03172	9.2	27.6 (27.7)
	Cyclobutane	8.000	–39.03605	6.5	26.0 (26.8)
	Cyclopentane[a]	8.000	–39.04417	1.3	6.3 (7.1)
	Cyclohexane	7.999	–39.04644	0.0	0.0(0.7)
MP2/SCVS	Cyclopropane	8.000	–39.21077	10.6	31.8 (27.7)
	Cyclobutane	8.000	–39.21576	7.5	30.0 (26.8)
	Cyclopentane	8.002	–39.22457	1.9	9.7 (7.1)
	Cyclohexane	7.999	–39.22750	0.1	0.6 (0.7)

Note: RHF/SCVS: $E^o(CH_2)$ = –39.04634 au. MP2/SCVS: $E^o(CH_2)$ = –39.22766 au.

[a]These are average values for N, E, and ΔE. At RHF, the unique CH_2 has N and E values of 8.003 e and –39.03659 au, methylenes bonded to it have $N(CH_2)$ = 8.000 e and $E(CH_2)$ = –39 04282 au, and the remaining methylenes have $N(CH_2)$ = 7.998 e and $E(CH_2)$ = –39.04982 au. At MP2, the corresponding sets of values are 8.003 e, –39.21672 au; 8.001 e, –39.22315 au; 7.998 e, –3922992 au.

energy contributions. In density functional theory, the correlation energy is expressed as a functional of the density. Thus, when the density remains unchanged for a given group in different molecules, the group's contribution to the correlation energy should also remain unchanged. If transferability is maintained with the addition of correlation, as it appears to be since transferability is an observed property, this should result in contributions to the correlation energy that parallel the uncorrelated results. This is borne out by calculation of the correlation energy of the methyl and methylene groups at RHF in 6–31G**/6–31G* calculations[33] using the functional of Langreth et al.[34] As anticipated, the correlation energies for the transferable methyl and methylene groups from propane to hexane were separately conserved to 1 to 2 kcal/mol.

The introduction of limited electron correlation as done in MP2 appears to upset this balance in some properties.Thus, RHF using the smaller basis set 6–31G** recovers the experimental strain energies to an almost equal extent to that found here with the larger basis set; 28.7, 26.8, 7.1, and 0.6 kcal/mol for n = 3, 4, 5, and 6, respectively.[6] It has also been demonstrated that the strain energies in branched and bicyclic hydrocarbons, such as the propellanes, are also recovered at this level of theory.[6,35] In any event, the agreement with experiment leaves no doubt that QTAIM recovers the essential features of strain energy, approaching quantitative agreement at the RHF level of theory, a conclusion borne out by the following discussion of QTAIM's accounting for the origin of strain energy.

The unique ability of RHF with relatively simple basis sets to recover experimental heats of formation of hydrocarbons has been amply illustrated by Herndon[28] wherein he demonstrated that a multilinear regression analysis using the calculated HF 6–31G*//STO-3G energies enabled the fitting of the measured heats of formation of hydrocarbons with only two parameters (the number of carbon atoms and the number of hydrogen atoms) for structures ranging from acyclic to planar and nonplanar polycyclic aromatics, alkyl substituted benzenes, and highly strained alkenes, alkanes, and alkynes, with a mean deviation in ΔH_f^o (g) of 1.1 kcal/mol and with a correlation coefficient of 0.9998.

Origin of strain energy in cyclic hydrocarbons

Within the orbital model, the angle strain in a 3-MR causes an increase in the p character of the C–C bonds, thereby increasing the s character of the bonds to H and increasing the electronegativity of C relative to H, which results in the carbon atoms approaching ethylenic carbons in electronegativity. Coulson and Moffitt emphasize this point in their classic study of strain in cyclopropane by noting that the bond lengths and bond angles of the methylene group in cyclopropane resemble those for ethylene.[36] The limit of sp hybridization of C in ethyne results in H possessing a net positive charge in this molecule, thus accounting for this molecule's acidic properties. The effective sp^2 hybridization in cyclopropane increases the stability of its carbons relative to their unstrained analogue, and ring strain is not a result of a "repulsive" destabilization of the carbon atoms. Rather, it is a result of the destabilization of the bonded hydrogens following their loss of electron density to the carbons. Thus, the atomic populations and energies of the methylene group in cyclopropane are similar to those for the CH_2 group of ethene, with the group being 3 kcal/mol more stable than in ethene. The transfer of density

Table 9. Bond and ring critical-point data for C|C bonded interactions in cyclic hydrocarbons.

Molecule	Method	C—C bond length in au	$\rho_{b(rc)}$ (in au)	$\rho_{r(rc)}$ (in au)	Ellipticity (ε)
Cyclopropane	HF/SCVS	2.827	0.2467	0.1984	0.445
	MP2/SCVS	2.842	0.2339	0.1903	0.442
Cyclobutane	HF/SCVS	2.916	0.2438	0.0891	0.011
	MP2/SCVS	2.920	0.2311	0.0897	0.010
Cyclopentane	HF/SCVS	2.905	0.2473	0.0416	0.004
	MP2/SCVS	2.901	0.2363	0.0432	0.004
Cyclohexane	HF/SCVS	2.888	0.2521	0.0193	0.003
	MP2/SCVS	2.880	0.2413	0.0211	0.003

from H to C results in a decrease in energy of the C atom in the amount of 18.8 kcal/mol while the energies of the two H atoms increase by a greater amount, equal to 28.0 kcal/mol (relative to their value in the standard transferable methylene group) and the CH_2 group of cyclopropane is less stable than the standard methylene group of saturated hydrocarbons by 9.2 kcal/mol, thus reproducing the strain energy of 27.5 kcal/mol. This transfer of density from H to C decreases with the size of the ring and vanishes for cyclohexane, which is consequently predicted to have zero strain energy, in agreement with experiment. The hybridization model is simple and powerful; s electrons are bound more tightly than p electrons, and hybridization is determined primarily by bond angles. Thus, with the increasing bond angles (RHF), from 60.0 in cyclopropane to 88.5, to 103.3, and to 111.5 in cyclohexane, there is a decreasing extent of transfer of density from the hydrogens to the carbon atom; the amount deceasing from 0.047 e in cyclopropane to 0.013 e for $n = 4$, to 0.01 e for $n = 5$, and to zero for cyclohexane. Correspondingly, the energies of the H atoms, in excess of the energy of a H atom in the standard transferable methylene group, decrease in the same order from +14 in $n = 3$ to +5 in $n = 4$, to +2 in $n = 5$, and to zero in cyclohexane, with the energy of the C atom undergoing corresponding increases to yield the tabulated strain energies.

It is important to note that QTAIM energies are in complete accord with the hybridization model.[35,37,38] The carbon atom energies in ethane, ethene, and ethyne for example, yield a near linear relationship with respect to their atomic populations at B3PW91/6–311+G(2d,p) with a regression coefficient of 0.996.[38] The resulting "linear charge/energy relationship" enables one to determine the extent to which a carbon atom is stabilized in a system with electron delocalization. A carbon atom in benzene for example, with a population intermediate between that in ethane and ethene, is more stable than that predicted by the linear charge/energy relationship by 17 kcal/ mol. A comparison of the energy of a |CH group in benzene with that of the corresponding non-conjugated group in cyclohexane, yields a "resonance" energy of 40 kcal/mol in agreement with the generally accepted values.

One should note that this definition of strain energy is not determined by symmetry, that is, determined by the fact that the energy of an *n*-cyclic hydrocarbon is 1/*n* that of the total. The strain energy is instead determined by comparing 1/*n*th of the cyclic energy with the energy of the standard methylene group defined by the linear regression analysis of the energies of the linear hydrocarbons, the quantity $E^o(CH_2)$ of eq. [1]. This energy is determined theoretically by integration of the electronic kinetic energy density over a region of space bounded by the two C|C zero-flux surfaces bounding the $|CH_2|$ group in a linear hydrocarbon, using the virial theorem of an open system. The finding that this energy is given precisely by the slope $E^o(CH_2)$ (to within 0.2 kcal/mol) assigned to the methylenic energy in a linear-regression analysis of the hydrocarbon energies is a striking proof of the physical relevance of the zero-flux surface and of the energies defined by QTAIM.[39]

The physics underlying Winstein's "homoaromaticity"

To account for enhanced solvolysis rates in systems containing a three-membered ring, Winstein postulated that cyclopropane may enter into conjugation with an unsaturated system when the ring surface is properly aligned, giving rise to homoconjugated or homoaromatic interactions.[40] An example of the former is cyclopropyl carbinyl cation $C_4H_7^+$, wherein the ring surface is conjugated with an empty p orbital on a CH_2 group. A recent paper describes in detail examples of homoaromatic behaviour and of how it is accounted for in terms of QTAIM.[38] The paper demonstrates that homoaromaticity is a direct consequence of the unique delocalization of the electron density found over the surface of a three-membered ring of carbon atoms and illustrates the consequences of this delocalization in accounting for the Cope rearrangement in semibullvalene.

The chemistry of cyclopropane emulates that of an unsaturated system. This is accounted for in MO theory by Walsh orbitals, which ascribe π character to orbitals lying in the plane of the ring.[41,42] QTAIM gives physical substance to this model by determining that the C|C bond paths exhibit significant ellipticities whose major axes lie in the ring surface. This is a topological consequence of the proximity of the ring and bond critical points unique to a three-membered ring (3-MR).

The electron density of "bonds", which in an orbital model possesses "π" character, is elliptically disposed about the bond path with the density being preferentially accumulated in a plane that, in ethene for example, is perpendicular to the plane of the nuclei, the plane determined by the major axis of the ellipse. Thus, the presence of π bonding should lead to a measurable distortion of the density from circular symmetry about the bond axis.

This distortion is measured by the bond's "ellipticity". The ellipticity is defined in terms of the two negative eigen-

values of the Hessian of the density at the bond critical point that determine the curvatures of the density perpendicular to the bond path. The ellipticity ε is defined as $\lambda_1/\lambda_2 - 1$, where λ_1 and λ_2 are the negative eigenvalues of the Hessian of the electron density at the bond critical point.[8]

These are the curvatures perpendicular to the bond path with $|\lambda_1| > |\lambda_2|$ whose associated eigenvectors determine the interatomic surface. Thus, λ_2 is the curvature along the major axis of the ellipse, that is, the direction of the "soft" curvature.[43] The ellipticities of the C–C bonds in ethane, benzene, and ethylene are 0.0, 0.18, and 0.30, respectively. What is important is that the ellipticity provides a measure of the distortion of the density away from cylindrical symmetry that is independent of any model, orbital, or otherwise thereby enabling one to determine "π" character in any situation independent of the nominal order of the bond.[38] Thus, in molecules exhibiting homoaromaticity, significant ellipticities are found for bonds with orders less than unity. Because of the accumulation of density within the interior of a three-membered ring, the value of the density at the ring critical point in cyclopropane approaches to within 0.05 au of its value at the C|C bond critical points. The result is a delocalization of the density over the surface of the ring, resulting in the density exhibiting a distinct elliptical distortion relative to the cylindrical distribution found in an isolated C|C bond with the major axis of the ellipticity lying in the ring surface. Table 9 shows that the ellipticity of a C–C bond in cyclopropane is actually greater than that found in ethene. In cyclopropane, the major axes of the C|C ellipticities are perpendicular to the ring axis, the axis associated with the unique positive eigenvalue of the (3,+1) critical points, just the opposite behaviour to that found in an aromatic system such as benzene where the C|C bond ellipticities, as anticipated for bonds with π character, are aligned with the ring axis, perpendicular to the plane of the molecule.

Table 9 also gives the values of the density at the bond and ring critical points in the cyclic hydrocarbons. The data demonstrate that the surface delocalization of the density is unique to a three-membered ring in hydrocarbon chemistry. On the other hand, the stabilities of boranes and carboranes have been shown to be accounted for by the significant delocalization of the density over the surfaces of both three- and four-membered rings.[44] Not only does the ellipticity decrease significantly with increase in ring size in the cyclic hydrocarbons, the soft axis does not lie in the ring surface as found for the delocalization of the density over the surface of cyclopropane. In cyclobutane, the soft curvature is directed 28° above the ring surface, and in cyclohexane, it is parallel to the ring axis, the reverse of the situation found in cyclopropane.

QSPR studies on normal boiling points and molar refractivities of organic compounds by correlation-ranking-based PCR and PC–ANN analyses of new topological indices

Raouf Ghavami, Amir Najafi, and Bahram Hemmateenejad

Abstract: The new topological indices (Sh indices) based on the distance sum and connectivity of a molecular graph, previously developed by our team, were extended to predict the two physicochemical properties, including normal boiling point (NBP) and molar refractivity (MR), of a large set of organic compounds consisting of alkanes, alkenes, ethers, amines, alcohols, alkylbenzenes, and alkylhalides. The sets of molecular descriptors were derived directly from the two-dimensional molecular structure of the compounds based on graph theory. Both linear and nonlinear modelings were implemented by using principal component regression (PCR) and principal component – artificial neural network (PC–ANN) with back-propagation learning algorithm, respectively. Eigenvalue and correlation-ranking procedures were used to rank the principal components and entered them into the models. Principal component analysis of Sh data matrix showed that the respective six and seven PCs could explain 97.49% and 99.22% of variances in the Sh indices. PCR analysis of the NBP and MR data demonstrated that the proposed Sh indices could explain about 97.52% and 99.52% of variations, while the variations explained by the PC–ANN modeling were more than 99.00% and 99.82%, respectively. The predictive ability of the models were evaluated using an external test set for NBP and MR of the molecules with the respective root-mean-square errors lower than 9.69 K and 0.660 cm^3 mol^{-1} for the linear model and 6.17 K and 0.416 cm^3 mol^{-1} for the nonlinear model.

Key words: topological Sh indices, eigenvalue ranking, correlation ranking, normal boiling point, molar refractivity, principal component analysis, principal component regression (PCR), principal component – artificial neural network (PC–ANN).

Résumé : Les nouveaux indices topologiques (indices Sh) basés sur la somme de la distance et la connectivité d'un graphe moléculaire et développés antérieurement par notre équipe ont été étendus afin de pouvoir prédire deux propriétés physico-chimiques, dont le point d'ébullition normal (PEN) et la réfractivité molaire (RM) d'un large ensemble de composés organiques formés d'alcanes, d'alcènes, d'amines, d'alkylbenzènes et d'halogénures d'alkyle. Les ensembles de descripteurs moléculaires ont été dérivés directement de la structure moléculaire bidimensionnelle des composés basée sur la théorie des graphes. On a développé des modèles linéaires et non linéaires en utilisant l'algorithme d'apprentissage en rétropropagation respectivement avec une régression du composant principal (RCP) et avec le réseau neural artificiel du composant principal (RNA–CP). On a fait appel aux méthodes de la valeur de eigen et du classement des corrélations pour classer les composants principaux qui ont ensuite été introduits dans les modèles. L'analyse du composant principal d'une matrice de données Sh a permis de montrer que respectivement six ou sept composants principaux (CP) peuvent expliquer 97,49 % et 99,22 % des variances dans les indices Sh. L'analyse de la RCP des données relatives aux PEN et aux RM a permis de démontrer que les indices Sh peuvent expliquer environ 97,52 % et 99,52 % des variations alors que les variations expliquées par me modèle RNA–CP expliquent respectivement 99,00 % et 99,82 % des variations. On a évalué l'habilité des modèles à faire des prédictions relatives aux PEN et aux RM des molécules en utilisant un ensemble externe et les erreurs quadratiques moyennes respectives étaient inférieures réseau neural artificiel du composant principal (RNA–CP) à 9,69 K et 0,660 cm^3 m^{-1} pour le modèle linéaire et de 6,17 K et 0,416 cm^3 m^{-1} pour le modèle non linéaire.

Mots-clés : indices SH topologiques, classement de valeurs de eigen, classement de corrélation, point d'ébullition normal (PEN), réfractivité moléculaire (RM), analyse du composant principal, régression du composant principal (RCP), réseau neural artificiel du composant principal (RNA–CP).

Introduction

One of the most fundamental ideas of chemistry is that the physicochemical properties, for instance, normal boiling point and molar refractivity, for chemical and chemical engineering substances are determined on the basis of their molecular structures (the term "structure" taken here in its broadest sense to include both geometric and electronic aspects).[1–6] It is necessary to describe the chemical structure of the examined compound as one or more parameters such as various topological indices in developing a quantitative structure–property relationship (QSPR) model. The normal boiling points (NBPs) of liquids reflect the strength of the intermolecular forces that hold them together. The stronger the intermolecular forces, the more tightly atoms will be held together; therefore, it causes higher normal boiling point. However, the boiling points are not always available in tables or other reference materials, while molar refractivity (MR) is a constitutive–additive property. Alternative definitions of MR have been proposed by Lorentz and Lorentz[7,8] (see eq. [1]), Gladston and Dale[9] (see eq. [2]), and Vogel[10] (see eq. [3]).

$$[1] \qquad MR_{LL} = (n^2 - 1)/(n^2 + 1)(M/\rho)$$

$$[2] \qquad MR_{GD} = (n - 1)(M/\rho)$$

$$[3] \qquad MR_{V} = nM$$

where n is the refractive index, M is the molecular mass, and ρ is the density of a molecule. MR is dependent on volume and polarizability. MR can be used for the substituted or for the whole molecule. Although molecular volume aspect of MR is of some interest to chemists and biologists, its relationship to polarizability is also of special interest to drug-design workers. Electronic polarization or molecular polarizability α_E and molar refractivity are related as ($MR = 4/3\pi\alpha_E$). The polarizability α_E of a molecule related to the intermolecular forces is important in drug and receptor reactions. Significantly, the α_E term is a dominant term in the expression for dispersion energy of interactions. The uses of α_E and MR have recently become significant in correlating physical properties with biological actions of drug molecule series.[11] Its ability to predict molar refractivity from a simple chemical graph has significant consequences in gaining insight into the SAR of biological molecules as well as the study of their physical properties such as boiling point. As a result, methods of estimation have increasingly become important and useful for procedures and consumers of many organic chemical compounds.

Quantitative structure–property relationships (QSPR) are mathematical equations relating the chemical structure to a wide variety of physical, chemical, biological, and technological properties.[12–14] The established QSPR models could be used to predict the properties of compounds that have not been measured or even have been unknown. Thus, QSPR approach saves resources and expedites the process of development of new molecules.[15] Because getting the physicochemical parameters for each considerable compound is not always possible, development of capable nonempirical structural representation to give a satisfactory correlation with the studied property would be useful. Several topological, geometric, electronic, and quantum chemical indices have been already used in quantitative structure–property relationship researches.[16,17] Topological indices (TIs) consider the molecule as a mathematical graph; a number of these descriptors simply are various graph invariants or other functions of the molecular graph. TIs are able to provide a more detailed description of molecular shape features such as branching and crowdedness. In this regard, TIs can be easily designed and calculated; however, the correlation of them to present the normal boiling point and molar refractivity properties is in a good way, and their applications in QSPR studies instead of more complicated geometric, electronic, and quantum chemical descriptors are preferred. More than 100 topological indices such as the Wiener index, Hosoya index, Balaban index, and Randic indices were developed, and these structural descriptors have been widely applied in QSPR studies.[18–22] Many investigators have reported a good correlation of both the normal boiling point and molar refractivity with structural characteristics of molecules by using different topological indices as structural descriptors.[6,23–25]

The development of QSPR studies is required for the suitable mathematical technique to make the models. In this regard, there are many available classical multivariate calibration techniques that could be used. These include multivariate linear regression (MLR), principal components regression (PCR), and partial least-squares regression (PLS).[26–28]

As an alternative to the fitting of data to an equation and reporting the coefficients derived from there, a neural net or artificial neural network (ANN) is designed to process input information and generate a hidden model of the relationships. One advantage of neural nets is that they are naturally capable of modeling nonlinear systems.[29] Disadvantages include a tendency to overfit the data, and a significant level of difficulty in ascertaining which descriptors are most significant in the resulting model (a consequence of the interconnected character of a multilayered neural network [30]). Recently, the ANN modeling technique has attracted an increasing interest as a very promising method for classification and multivariate calibration problems.[31–33] The flexibility of ANN enables it to discover more complex relationships in experimental data when it is compared with the traditional statistical models. Hence, the ANNs provide proper analytical alternatives to conventional techniques and interesting approaches to the QSAR/QSPR studies.[34–36] The principal component – artificial neural network (PC–ANN) is another version of the PCR, which models the nonlinear relationships between the PCs and dependent variables, and it was proposed by Gemperline et al. to improve the training speed and decrease the overall calibration error.[37]

The relationship between molar refraction and normal boiling point has been found the literature. Gonzales et al.[38] proposed the use of corrlation weighing of atomic orbitals with extended connectivity of zero- and first-order graphs of atomic orbitals to estimate normal boiling points for a set of 200 organic molecules through the application of QSPR theory. Jäntschi et al. reported the relationship of molecular descriptor familiy to predict the normal boiling points and molar refraction values for 33 504 alkanes and 10 cyclic organophosphorous compounds, respectively.[39,40]

Qian et al.[41] have proposed the use of 3–6–1 back-propagation neural network technique to link the relation between molecular structures and boiling points. The data sets were composed of 73 saturated aliphatic aldehydes and alkanones, with experimental boiling points ranging from 253.7 K to 631.2 K, and the number of carbon atoms ranging from 1 to 20. Balaban et al.[42] predicted 200 carbonyl compounds contained 127 mono- and di-aldehydes and ketones and 73 esters using five topological indices. Toropov and Toropova[43] obtained one-variable models of the normal boiling points of carbonyl compounds by the nearest-neighboring code (NNC). Toropov and co-workers[44] have used simplified molecular input line entry system (SMILES) to model normal boiling points of acyclic carbonyl compounds.

In our previous paper, some new topological indices (Sh_1–Sh_{10} indices) based on the molecular connectivity[22] and Balaban-distance-sum[20,21] approaches were proposed.[45–48] The aim of the present investigation was to extend our previously developed model with an enlarged data set for QSPR characterization of normal boiling points and molar refractivities of a set of 394 diverse organic compounds using the new topological Sh indices. Obviously, these topological indices have been selected for the representation of molecular structure to obtain a prediction model as simple as possible. Besides the PCR model, a three-layered feed-forward PC–ANN has also been employed, as a statistical method, for building the prediction model.

Materials and methods

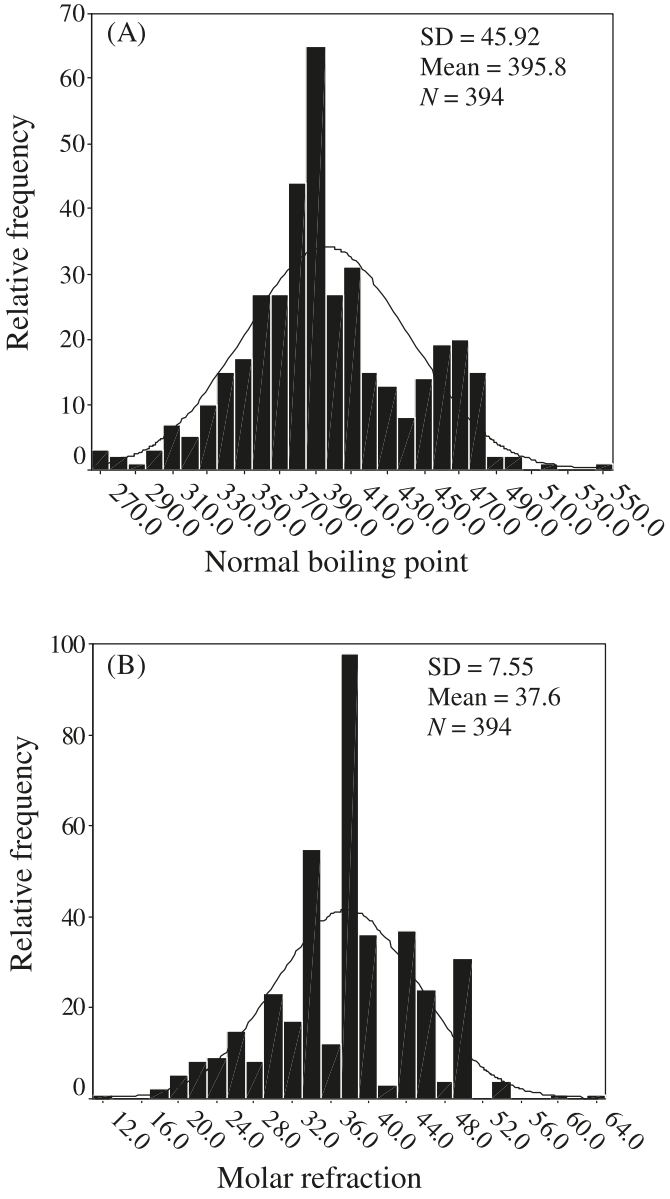
Dataset

The QSPR treatment started with the assembly of the data set. A collection of diverse organic compounds containing 394 compounds having C, H, O, N, and halogen atoms, and moreover, the two physicochemical properties of normal boiling point and their molar refractivity, which were realized experimentally along with the various number of carbon atoms from 2 to 9, which are taken from the scientific resources, have been investigated.[23,25,49,50] The normal boiling points of these compounds range from 266.25 to 545.95 K and their molar refractivities are from 12.9267 to 63.3751 cm^3 mol^{-1}, respectively. The mentioned organic compounds include 52 alcohols, 22 amines, 69 alkanes, 156 monoalkenes, 9 ethers, 69 alkylbenzenes, and 17 alkylhalides. The histogram presenting the experimental values related to the normal boiling points and molar refractivities' distribution for all data collected is depicted in Figs. 1A and 1B), respectively. As it is shown, the average values of NBP and MR belonging to all mentioned compounds are 395.80 and 37.69 along with the standard deviation (SD) of 45.92 and 7.55, respectively. A complete list of the compounds in the data set and their corresponding experimental normal boiling points and molar refractivities has been categorized in Table S1 of the Supplementary data. The range of the molecular masses of the compounds is also extensive and located in the range of 24 to 266 g mol^{-1} for ethanol and 1-iodoheptane, respectively.

Sh and Randic connectivity topological descriptors

Initially, the structure related to the computer design of each of the 394 diverse organic compounds, then for any

Fig. 1. Histogram of the distribution of the experimental NBPs (A) and MRs (B) for the total data set of 394 organic compounds used in this study. The solid curve is the fitting of the NBP and MR data to the normal distribution.



composition, the 10 Sh and Randic connectivity index (χ) topological molecular-structure descriptors were calculated from the combination of connectivity vectors and distance matrices, which were expressed by their computational style in our previous studies.[45–48] These indices were calculated by a home-made program (written in MATLAB environment), then the values of 10 Sh indices were placed inside the matrix with dimensions of 394 × 10. So, any chemical compound was placed inside as a point in the 10-dimensional space, X^{10}. The results are demonstrated in Table S2 (see Supplementary data).

Linear modeling: principal component regression

The $\boldsymbol{b}$ vector of the model equation $\boldsymbol{y} = \mathbf{X}\boldsymbol{b} + e$ was calculated by singular value decomposition (SVD)[51] according to

[a] R^2: correlation coefficient; SE: standard error of estimation; RMS: root-mean-square error; REP: root-mean-square error prediction; *F*: Fisher's criterion at the 95% probability level; R^2_{LOO}: square of the leave-one-out cross-validation correlation coefficient; RMS_{LOO}: leave-one-out cross-validation root-mean-square error.

the procedure of Sutter and Kalivas.[52] The $\mathbf{X}(m \times n)$ matrix, where m and n are the number of molecules and descriptors, respectively, was decomposed by SVD to give three matrices $\mathbf{U}(m \times n)$, $\mathbf{S}(n \times n)$, and $\mathbf{V}(n \times n)$ such that $\mathbf{X} = \mathbf{USV}^{\mathrm{T}}$, where $\mathbf{U}$ and $\mathbf{V}$ are the orthonormal matrices spanning the respective row and column spaces of the data matrix ($\mathbf{X}$) and $\mathbf{S}$ is a diagonal matrix whose diagonal elements are the square roots of the corresponding eigenvalues of the $\mathbf{U}$ and $\mathbf{V}$ eigenvectors. The eigenvalues are denoted by λ_i. The superscript T denotes the matrix transpose. As presented by Sutter and Kalivas,[52] the $\boldsymbol{b}$ vector in PCR can be obtained as

$$[4] \qquad \boldsymbol{b} = \sum_{i \in M} \frac{1}{\lambda_i} \boldsymbol{\upsilon}_i \boldsymbol{\upsilon}_i^{\mathrm{T}} \mathbf{X}^{\mathrm{T}} \boldsymbol{y}$$

where M contains k elements that are a subset of $\{1, 2, \ldots, w\}$ and w is the largest number such that $\lambda_w > 0$. By using this equation, it is possible to select a subset of PCs for building the PCR model. A column vector ($\boldsymbol{y}$) was made by the physicochemical property or activity data. The PCs of the validation ($\mathbf{X}_{\mathrm{v}}$) and test ($\mathbf{X}_{\mathrm{t}}$) sets were calculated by the following equation:

$$[5] \qquad \mathbf{U}_{\mathrm{v/t}} = \mathbf{X}_{\mathrm{v/t}} \mathbf{S}_{\mathrm{c}}^{-1} \mathbf{V}_{\mathrm{c}}$$

Application of the PCA on the Sh indices data matrix resulted in 10 principal components or factors (PC_1–PC_{10}). A linear regression model was built between the NBP and MR with the resulted factors. The best set of PCs was selected by the eigenvalue ranking (EV) and correlation ranking (CR) procedures.[53,54] In the EV–PCR procedure, the PCs were entered to the PCR model consecutively based on their decreasing eigenvalue. Once each new PC was entered to the model, the model performances were evaluated by the leave-one-out cross validation (LOO-CV), twofold out cross validation (2FO-CV), and external validation. In the external validation procedure, we used the method suggested by Hawkins and co-workers.[55,56] So, first, the data were arranged based on the $\boldsymbol{y}$ increase (the physical properties were including NBP and MR), then they were classified into two data sets as odd and even, which makes the same distribution for $\boldsymbol{y}$ values of the two sets. The separate QSPR model was made, for odd and even data sets, and then each of them was used to predict the data belonging to the other method. To compare the estimation abilities of the models, two statistical parameters, RMS error prediction (RMSEP) and R^2, were calculated. These parameters were determined for the same data set (the "calibration set") that was used to fit the models (resubstitution parameters, i.e., $\mathrm{RMSEP_{RS}}$ and R^2_{RS}) and for the other data set that was not involved in the fitting (holdout parameters, i.e., $\mathrm{RMSEP_{HO}}$ and R^2_{HO}). The resubstitution statistical parameters base their predictions on the regression fitted to that sample, and holdout statistical parameters base their prediction on the regression fitted to the other samples. In the CR–PCR, the correlation of each one of the extracted PCs with the NBP and MR data was determined first. The stepwise entrance of the PCs to the PCR model was based on their decreasing correlation with the NBP or MR. Some statistical parameters such as the square of the correlation coefficient (R^2), square of the leave-one-out and twofold out cross-validation correlation coefficient (R^2_{LOO}, R^2_{2FO}), the standard error of estimation (SE), the root-mean-square error (RMS), the leave-one-out and twofold out cross-validation root-mean-square error ($\mathrm{RMS_{LOO}}$, $\mathrm{RMS_{2FO}}$), and the Fisher's criterion at the 95% probability level were calculated to estimate the quality of the resulted models.

Nonlinear modeling: neural networks

The extracted PCs by CR–PCR and EV–PCR were used as the predictor variables (input) for the neural network model.[46,47,53,54] A three-layered feed-forward ANN with back-propagation of an error algorithm was constructed to model the structure–property relationship.[57–60] The 394 compounds were randomly divided to 300 calibration (or training) samples, 54 validation samples, and 40 test samples. The validation set is a subset of compounds used to help find an optimal set of weights and biases during ANN calibrating, and it is also used to avoid overtraining of the ANN. The number of neurons in the input layer is equal to the number of PCs selected for the model. The transformed values are then passed to the hidden layer. The input value of a hidden-layer neuron is the summation of the products of the weights (neuron connections) times the corresponding outputs of the previous input layer plus a bias term. The ANN model is confined to a single hidden layer, because the network with more than one hidden layer would be harder to train. The neuron parameters and architectures were optimized to obtain better performances. The summation is put through a nonlinear transfer function, and then the resulting values are passed to the output layer, which contains a single neuron, which represents the predicted NBP and MR values. The training and validation data sets were used to optimize the network performance. To ensure that the overfitting and underfitting of the ANN models did not occur, for each configuration, the fitness function (η), calculated from both the root-mean-square errors of calibration and validation (RMSEC and RMSEV, respectively), was used to evaluate the performance of each neuron for both physical properties. This fitness function, recently proposed by Depczynski et al.[61] was used in this paper.

$$[6] \qquad \eta = \{[(m_{\mathrm{c}} - n - 1)\mathrm{RMSEC}^2 + m_{\mathrm{v}}\,\mathrm{RMSEV}^2]/(m_{\mathrm{c}} + m_{\mathrm{v}} - n - 1)\}^{1/2}$$

where m_{c} and m_{v} are the number of compounds in the calibration and validation sets, respectively, and n represents the number of selected PCs. The training of each network was stopped after observing no improvement in η for both properties.

Software

Calculations were performed by a Pentium IV (CPU at 2.8 GHz) personal computer equipped with Windows$^{\mathrm{xp}}$ operating system. Calculation of Sh indices, cross validation, and other mathematical operations, such as error calculations, were performed by homemade programs in MATLAB environments (Mathwork Inc., version 7, MA, USA). The PLS toolbox (Eigenvector Research, Inc., 1991–1998) was used for PLS and PCR regressions. The other necessary programs were written in our laboratory. The ANN processing was performed by a homemade program written in MATLAB environment, where all necessary codes were provided by our laboratory.

Results and discussion

Correlation of NBP and MR with Sh and χ indices

At first, the correlation of the Sh indices along with the NBP and MR properties of compounds has been studied. It has been characterized that some of the indices, such as Sh1, revealed good correlation with the mentioned properties of compounds. To control the physicochemical properties for any chemical compounds through molecular mass more than molecular topology, we combined the number of carbon atoms belonging to any organic compounds (as a measure of molecular mass) with some of Sh indices and produced a novel topological index with high correlation ability presented in eq. [7] as

$$[7] \qquad Sh = n + n^{0.5}Sh1$$

To demonstrate the mentioned ability, the correlation of the combinational index of Sh with NBP and MR properties for organic compounds has been studied, and also the linear relationships between them have been computed as the following:

$$[8] \quad \begin{array}{ll} NBP = 253.576(\pm 5.023) + 9.419(\pm 0.321)Sh & R^2 = 0.6866,\ SE = 25.74,\ F = 859 \\ MR = 9.891(\pm 0.273) + 1.838(\pm 0.017)Sh & R^2 = 0.9659,\ SE = 1.40,\ F = 11098 \end{array}$$

Furthermore, for comparison, the correlation of Randic connectivity index (χ) has been validated with these properties, and the obtained relations are the following:

$$[9] \quad \begin{array}{ll} NBP = 233.463(\pm 4.925) + 44.484(\pm 1.311)\chi & R^2 = 0.7459,\ SE = 23.176,\ F = 1150 \\ MR = 7.676(\pm 0.397) + 8.211(\pm 0.106)\chi & R^2 = 0.9391,\ SE = 1.867,\ F = 6042 \end{array}$$

Clearly, the topological index of Sh rather than the topological index of χ presents the best model and statistical parameters for predictiing the MR of organic compounds ($SE_{Sh} = 1.40 < SE_\chi = 1.87$, $R^2_{Sh} = 0.9659 > R^2_\chi = 0.9391$, and $F_{Sh} = 11098 > F_\chi = 6042$), while the Randic index produces the better model and statistical parameters to predict the NBPs ($SE_{Sh} = 1.25.74 < SE_\chi = 23.17$, $R^2_{Sh} = 0.6866 < R^2_\chi = 0.7459$, and $F_{Sh} = 859 < F_\chi = 1150$). Also, the best correlation coefficients and statistical parameters to predict the MR against NBP would be obtained by using both mentioned topological molecular descriptors.

PCR modeling

At first, the eigenvalue ranking procedure was employed to build the PCR-based QSPR model equations of the different types of organic compounds independently, but this procedure did not produce satisfactory results for NBP and MR properties. Using the correlation ranking procedure produced more suitable models, for which the QSPR related to the whole sets of molecules, and their subsets from the correlation ranking procedure are listed in Table 1. Furthermore, a number of statistical parameters, such as R^2, SE, RMS, the relative error of prediction (REP), and F statistics are also shown in Table 1. The obtained QSPR models to predict the MR values have the best results in all cases (i.e., $R^2 > 0.99\%$ and $REP < 2.40\%$) while they only have the high statistical quality to predict the NBPs of alkanes and alkyl halides (i.e., $R^2 > 0.95\%$ and $REP < 2.00\%$). Also, as it is shown in Table 1, for the QSPR produced models for any subset of compounds, the number and type of selected PCs against the correlation ranking procedure vary from two PCs for ethers to six PCs for alkane compounds.

At the next stage, we applied the PCR method, based on the correlation ranking procedure for making the model of NBP and MR properties, to a complete set containing 394 compounds. Two CR–PCR models were obtained as follows

$$[10] \quad \begin{array}{l} NBP = 395.798 + 39188PC_1 + 12.947PC_6 - 11.674PC_4 - 8.522PC_7 + 7.729PC_2 + 4.471PC_3 + 3.532PC_{10} \\ R^2 = 0.9505;\ SE = 10.31;\ REP = 2.58;\ F = 1059;\ R^2_{LOO} = 0.9454;\ RMS_{LOO} = 10.72;\ R^2_{2FO} = 0.9450;\ \text{and}\ RMS_{2FO} = 10.76 \end{array}$$

$$[11] \quad \begin{array}{l} MR = 37.642 + 7.509PC_1 + 1.791PC_3 + 1.017PC_2 + 1.009PC_7 + 0.858PC_{10} - 0.608PC_8 \\ R^2 = 0.9846;\ SE = 0.94;\ REP = 2.49;\ F = 4122;\ R^2_{LOO} = 0.9833;\ RMS_{LOO} = 0.98;\ R^2_{2FO} = 0.9829;\ \text{and}\ RMS_{2FO} = 0.99 \end{array}$$

As it is clear from these equations, to make the NBP model of a complete set of compounds, we used seven PCs, and for the MR modeling of them, six PCs were used. The trend of PCs to decrease their correlation with NBP is PC1 > PC6 > PC4 > PC7 > PC2 > PC3 > PC10, and also for their correlation with MR, the trend is PC1 > PC3 > PC2 > PC7 > PC10 > PC8, which is not parallel to decreasing their eigenvalues ranking, so we avoid showing the results of the modeling based on the eigenvalues ranking. The study of obtained results showed that the mentioned models

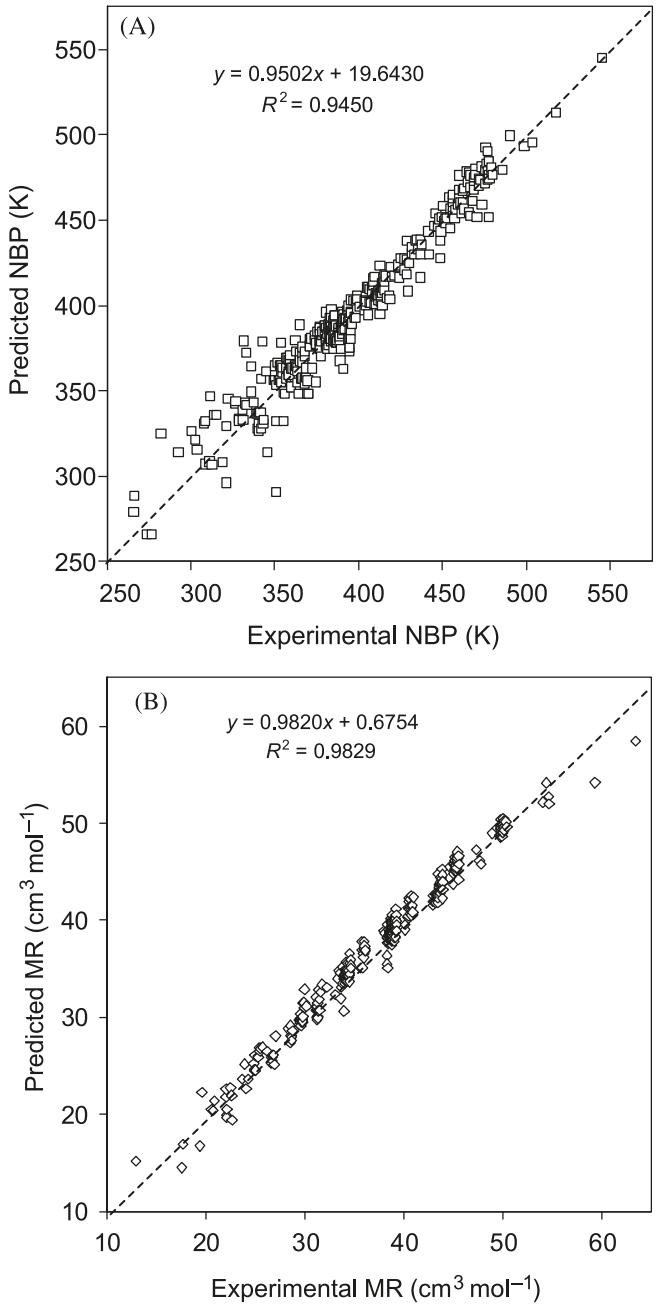

Fig. 3. Plots of the properties predicted: NBP (A) and MR (B) for the odd-number (■) and even-number (□) samples by holdout model against the corresponding experimental values. The dashed lines are the ideal fits to the straight lines.

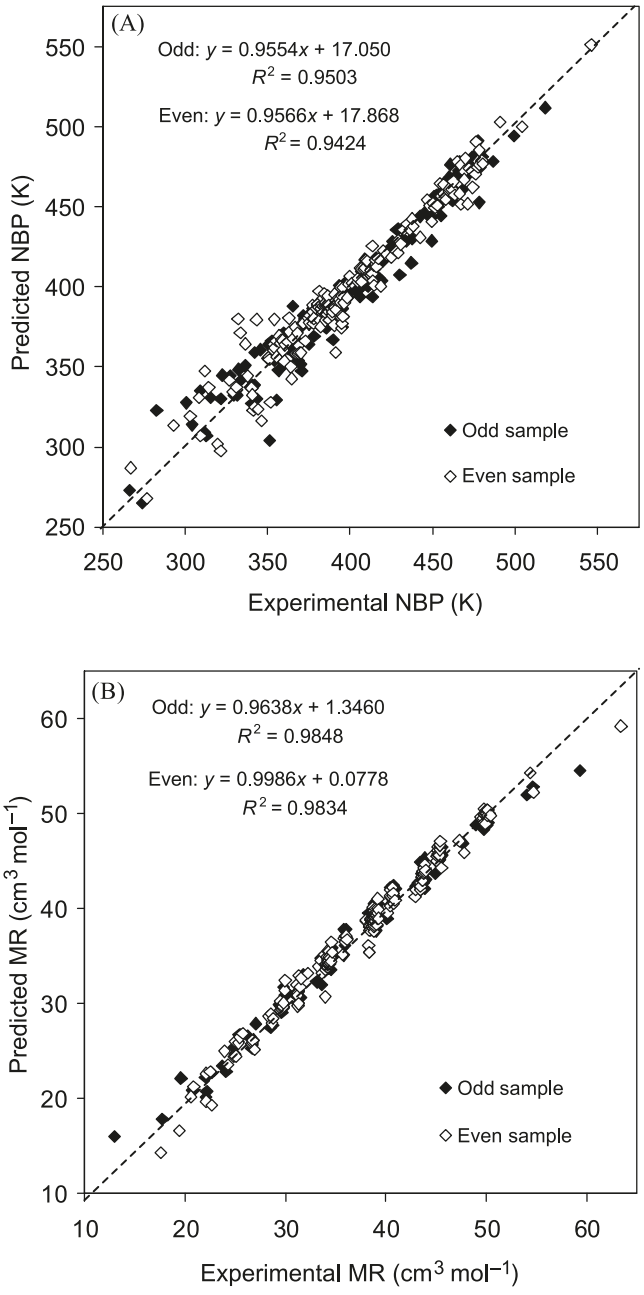

explain more than 97% and 99% variance in the experimental values of NBP and MR with a root-mean-square error of 10.21 K and 0.94 cm^3 mol^{-1}, respectively.

To demonstrate the ability of the obtained models to estimate the properties related to NBP and MR of these organic compounds during this study, the prediction ability was examined for external samples, in which the leave-one-out and twofold cross validation and external validation (EV) have been used for this investigation. The cross-validation results showed R^2 values, for LOO and twofold cross-validation values, greater than 0.94% for NBP and MR in both models. For more investigation, the predicting ability of the models, the EV can also be applied. The NBP and MR properties predicted by the best model against the corresponding experimental values by twofold CV procedure are plotted in Fig. 2 (A and B), respectively. For more checking of the prediction ability of the QSPR models, the external validation was also applied. The results are listed in Table 2. In odd- and even-number samples, the resubstitution and holdout RMS and REP are very similar, which shows that the same-sample and out-of-sample predictions were equally precise. This indicated that the resulting QSPR models had high prediction

ability with low overfitting. The plots of the properties estimated by odd- and even-number QSPR models (holdout prediction) vs. the properties observed experimentally are given in Fig. 3 (A and B) for the NBP and MR, respectively. As seen, the plots show the distribution of the data around a straight line with very low scattering, which confirms that there was good agreement between the predicted and experimental values. Comparison of the results of CV and EV indicated that the resulting QSPR models not only had high CV statistical qualities but there was also a good agreement between the results of the two validation methods. The cross-validation test indicates that the Sh indices can model-ize the properties of NBP and MR of all types of organic

compounds used during these studies perfectly. Other cross-validation parameters also support these results.

On the basis of the obtained results, the QSPR model to MR property has less PC numbers and better statistical results for the MR linear property, while the QSPR model to NBP has more PC numbers, so we can find the nonlinear behavior for NBP property. The latter attempts to test the quality of obtained models produced by dividing the data set into calibration (340 molecules) and validation sets (54 molecules). Also, to produce the CR–PCR model of the calibration set, the same PCs, which were obtained for the complete set of compounds, have been used. In Table 3, the statistical parameters have been presented for the best fitted models related to the NBP and MR. The results show that seven and six selected PCs by correlation ranking method could at least explain 97.52% and 99.66% variances in NBP and MR values for external data, respectively. The graphs of the predicted values against their corresponding experimental values are depicted in Fig. 4 (A and B).

PC–ANN modeling

In another attempt to improve the overall RMS error of the linear models obtained by PCR, we focused on demonstrating if prediction results could be improved by the use of nonlinear artificial neural network modeling methods. A fully connected, three-layered feed-forward ANN model with back-propagation learning algorithm is developed for nonlinear modeling between the selected PCs by the EV–PCR and CR–PCR models.[47,53,54] In this step, the selected PCs of seven and six numbers, respectively, for NBP and MR data were gathered in a new data matrix. To evaluate the network architecture effect on the performance of the PC–ANN models, many networks have been selected with various parameters for all types of properties. In Table 4, the results obtained from different network configurations are presented. Also in Table 4, the network parameters containing the number of presented nodes (n_H) and type of transfer function in the hidden layer (denotes by TF_H), also momentum (Mom) and learning rate (LR), have been demonstrated. In addition, the fitness function (η), based on EMSEC and RMSEV, was calculated for any PC–ANN model and shown for any property. The convergence criterion is the least fitness function according to eq. [6]. The number of iterations for convergence was between 15 000 and 20 000. As it is obvious from the data shown in Table 4, for NBP property, the performance of ANN model to execute architecture run number 13 is better than the others. Moreover, the fitness function of the ANN model configuration number 13 is equal to 14.25. This model has acceptable quality with six nodes in hidden layer, tansig transfer function, learning rate of 0.84, and momentum of 0.26 and is also able to predict the NBP of organic compounds in the test set with low error scale. The optimized PC–ANN model was used for predicting the NBP values of the compounds that have not been used in any step of the ANN modeling procedure (test set). In Table S1, the predicted NBP values using optimized models of EV–PC–ANN and CR–PC–ANN have been demonstrated, and they have also been depicted the against their experimentally determined values in Figs. 5A and 5B. Also, the statistical parameters to take the best-fitted model for EV–PC–ANN and CR–PC–ANN are shown in Table 3.

In the next step, the ANN models were built to predict the molar refraction. To take these models, the same calibration, validation, and test sets of compounds were employed. As it was realized before, the model containing six PCs has the effective performance to predict the MR of these compounds. Table 4 shows that the performance of ANN model having architecture number 7 is better than the other models

Fig. 5. Plots of the predicted NBP by (A) PC–EV–ANN and (B) PC–CR–ANN against the experimental values. The dashed lines are the ideal fits to the straight lines.

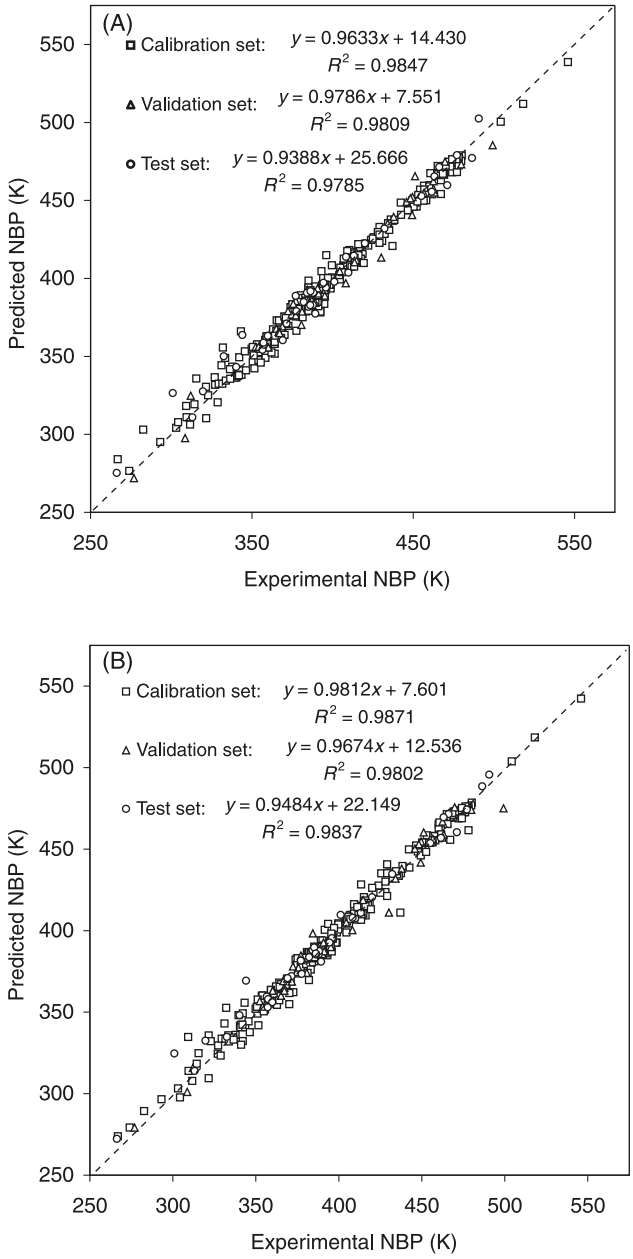

Fig. 6. Plots of the predicted MR by (A) PC–EV–ANN and (B) PC–CR–ANN against the experimental values. The dashed lines are the ideal fits to the straight lines.

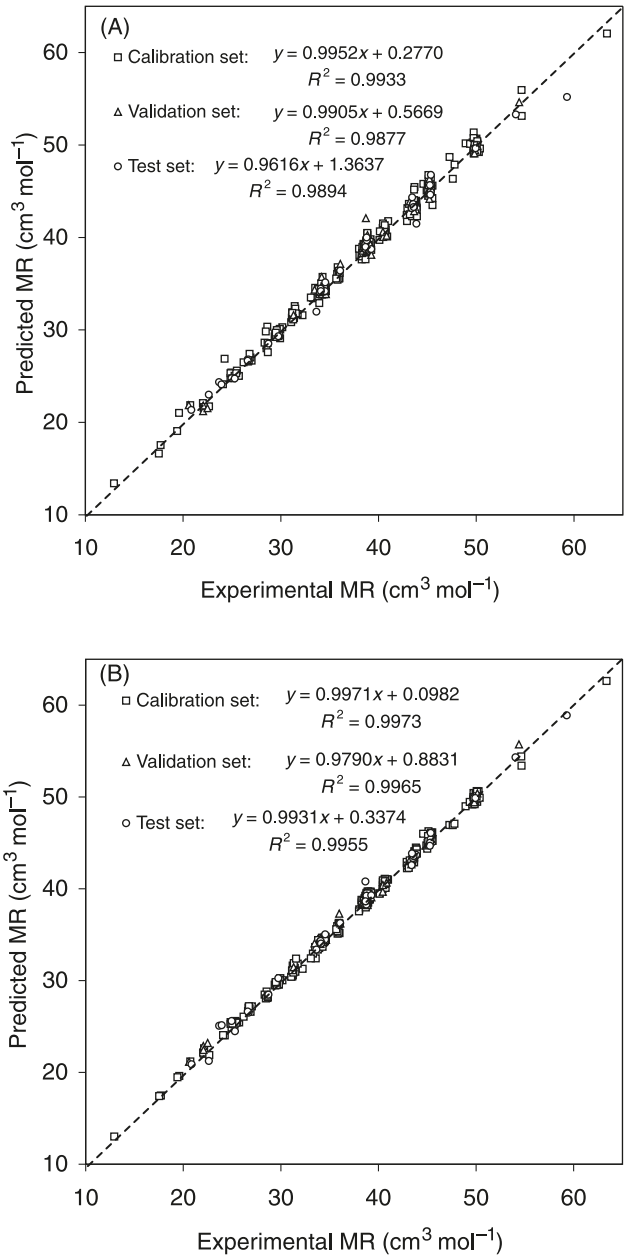

with the fitness function equal to 0.0770. This model with four nodes in the hidden layer, a tansig transfer function, learning rate of 0.74, and momentum of 0.22 has acceptable quality and can predict the MR of the organic compounds of the test set with less error scales, while the optimized PC–ANN model used to predict the MR related compounds that were not utilized in any step of ANN modeling (test set). In Table S1, the values of the predicted MRs were depicted for optimized EV–PC–ANN and CR–PC–ANN models, respectively, and in Figs. 6A and 6B, against their corresponding experimental values have been demonstrated. Also, the statistical parameters to take the best corresponding models are summarized in Table 4.

As it can be observed from Table 3, the obtained models from PC–ANN, compared with PCR models, have relative higher quality for both physical properties. It means that between the suggested topological Sh indices and the studied NBP values of organic compounds during this research, there are nonlinear relationships, while the ANN could not extent the linear models obtained from the linear method studies for MR values of those compounds. Furthermore, the comparison of the results obtained from PC–ANN modeling, according to the eigenvalue ranking and correlation ranking, revealed that the CR–PC–ANN produced more accurate results, which is in accordance with our previous finding.[47,53,54,62]

Conclusion

In this study, it was shown that accurate QSPR models can be developed to predict the normal boiling point and molar refractivity of structurally diverse set of organic compounds having C, H, O, N, and halogen atoms, including some alkanes, alkenes, ethers, amines, alcohols, alkylbenzenes, and alkylhalides, using some newly proposed topological indices (Sh indices) by using principal component regression and principal component – artificial neural network modeling methods. In addition, the performances of two different principal components selection procedures, including eigenvalue ranking and correlation ranking, were evaluated. The PCs were entered to the models based on their decreasing eigenvalue and correlation-ranking coefficients. The obtained results showed that the frequent extraction of PCs based on decreasing the correlation ranking with NBP and MR physical properties presents the better results. These results demonstrated that normal boiling points and molar refractivities for a wide range of organic compounds could be predicted easily and accurately based solely on molecular structure, with no corrective factor for physical state or use of other additional data.

Water-promoted regioselective hydrothiolation of alkynes

Sukalyan Bhadra and Brindaban C. Ranu

Abstract: Water promotes hydrothiolation of unactivated alkynes efficiently without any catalyst or additive. The reaction at room temperature furnishes vinyl sulfides with high regioselectivity via anti-Markovnikov addition. The terminal alkynes provide dithiolanes at 80 °C by bis-addition. The reactions are very clean and high yielding.

Key words: alkynes, hydrothiolation, vinyl sulfides, regioselectivity, water.

Résumé : L'eau favorise l'hydrothiolation des alcynes non activés d'une façon efficace, sans catalyseur ou additif. À la température ambiante, la réaction conduit à la formation de sulfures de vinyle, avec une régiosélectivité par le biais d'une addition anti-Markovnikov. Les additions à 80 °C sur des alcynes terminaux conduisent à des dithiolanes résultant d'une bis-addition. Les réactions sont très propres et les rendements sont élevés.

Mots-clés : alcynes, hydrothiolation, sulfures de vinyle, régiosélectivité, eau.

[Traduit par la Rédaction]

Introduction

The hydrothiolation of alkynes by thiols is a very interesting and challenging reaction being associated with mono- and bis-condensation, Markovnikov and (or) anti-Markovnikov addition, and stereoselectivity. This reaction is also of great importance as it provides an attractive method for the formation of vinyl sulfides, which are valuable synthetic intermediates in total synthesis[1] and serve as precursors to a wide range of functionalized molecules.[2] The conventional procedures for hydrothiolation of alkynes involves transition metal catalysts[3] or a base[4] in organic solvents. Recently, a few procedures using catalytic phenylselenyl bromide,[5a] Al_2O_3–KF,[5b] nickel[5c] under solvent-free conditions, β-cyclodextrin in water–acetone,[5d] and $NaBH_4$–alumina under solvent-free conditions[5e,5f] have been reported.

According to the basic principles of Green Chemistry the use of organic solvents should be avoided wherever possible and use of alternative green solvents such as water are encouraged.[6a] Thus, the reaction in water has attracted considerable interest in the context of Green Chemistry.[6] In addition, water often exhibits unique reactivity and selectivity that cannot be attained in conventional organic solvents.[7] Thus, development of an efficient procedure for an organic reaction using water as a promoter as well as reaction medium has received intense attention in the design of a chemical process. Here, we report an efficient hydrothiolation of alkynes in water without any catalysts or additives, imparting good control on regioselectivity (Scheme 1).

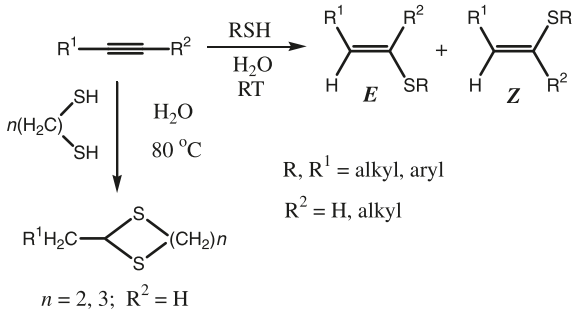
Scheme 1. Reaction of alkynes with thiols in water.



Results and discussion

The experimental procedure is very simple. A mixture of alkyne and thiol in water was stirred at room temperature (or at 80 °C) for a required period of time (TLC). Standard work-up provided the product.

A variety of terminal and internal alkynes underwent hydrothiolation with thiophenol and alkane thiols at room temperature by this procedure to provide the corresponding vinyl sulfides. The results are summarized in Table 1. Aryl- as well as alkyl-substituted alkynes and both aromatic and aliphatic thiols participated in this reaction uniformly. All reactions proceeded through anti-Markovnikov additions. Regarding the stereochemistry of the products, the reaction of terminal alkynes and thiophenols (entries 1–3, 6–8, 10, and 11 in Table 1) provided low to high selectivity with respect to *E*-isomers, whereas alkane thiols (entries 13, 14, 16, and 17 in Table 1) produced *Z*-isomers predominantly. The internal alkynes (entries 5 and 9 in Table 1) provided *Z*-isomers selectively. However, dimethyl acetylene dicarboxylate (entries 4, 12, 15, and 18 in Table 1) furnished *Z*-isomers as the sole product. As a whole, the stereoselectivity is excellent in a few of the reactions, although, in some reactions, no selectivity was observed. The steric distribution of prod-

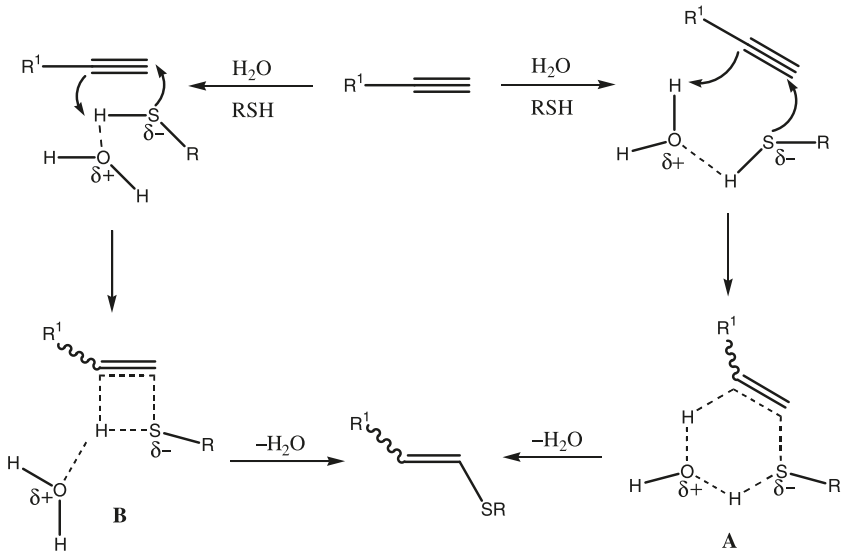
ucts is probably controlled by the steric compulsion of the bulky substituents.

The terminal alkynes produced dithiolanes or dithianes when treated with dithiols at 80 °C, based on the use of ethane or propane dithiol. It has already been mentioned that a similar reaction at room temperature produced only vinyl sulfide (entry 19 in Table 1). The results are summarized in Table 2. However, the use of 2 equiv. of monothiols in the reaction of phenyl acetylene under identical conditions produced only vinyl sulfides and no dithioacetal was obtained. On the other hand, reaction of 0.5 equiv. of ethane dithiol and phenyl acetylene at room temperature produced the corresponding vinyl sulfide associated with the starting material, whereas reaction at 80 °C provided the corresponding dithiolane together with unreacted phenyl acetylene.

The dithianes and dithiolanes are very useful compounds.[19] The standard methods[17] employ aldehydes for dithiolane–dithiane formation using an acid catalyst, whereas this procedure provides an attractive and novel alternative using alkynes through a simple operation in mild and neutral conditions.

Water plays a very significant role in this reaction. Without water the reaction in neat is very slow and low yielding. Possibly, water promotes the reaction through hydrogen bond formation with the sulfhydryl hydrogen of the thiol and thus enhances the nucleophilicity of the thiolate ion to add to the alkyne at the less-hindered carbon atom, giving anti-Markovinkov product. Although we do not have any concrete evidence regarding the exact mechanism, it may be speculated that addition of thiolate anion to the C≡C bond

Scheme 2. Speculative reaction pathway.



takes place either through a six- (**A**) or four-membered (**B**) transition state,[3f] with steric factors controlling the regioselectivity (Scheme 2).

It was found that, with the progress of reaction the product, vinyl sulfide isomerizes to the thermodynamically more stable isomer over time. For example, during the reaction of phenyl acetylene and thiophenol, the 32:68 *E*/*Z* mixture of product after 45 min of reaction ultimately gave rise to a 68:32 *E*/*Z* mixture at the end of the reaction after 3 h. This ratio for this mixture did not change even when the reaction was allowed to proceed past the 3 h time point. To check for the possibility of a radical process, the reaction was carried out in the dark. The progress of the reaction remained undisturbed. It should be mentioned that all the reactions were carried out in water that contained dissolved oxygen without an interference. Thus, a radical pathway is unlikely.

In general, the reactions were very clean. The hydrothiolations were accomplished in water at room temperature much faster (2–3.5 h) and in higher yields (84%–96%) when compared with many of the existing procedures.[3–5] All the products were obtained in high purities. The ratio of stereoisomers was determined by integration of the corresponding peaks in ^{1}H NMR spectra. Although a report[5d] using β-cyclodextrin in water stated that no reaction was observed in the absence of β-cyclodextrin, very interestingly, all the reactions listed in Tables 1 and 2 proceeded in water without any difficulty in the absence of additive. In addition, our water-mediated procedure is more general. The cyclodextrin–water mediated procedure[5d] failed to initiate reactions with alkane thiol, terminal alkyl alkynes, and internal alkynes, whereas our procedure was very successful for all these substrates. However, the stereoselectivity is better in cyclodextrin–water than in water alone by the present procedure. The reason for all these differences is not very clear to us. In general, the transition metal catalyzed reactions led to predominantly Markovnikov products,[3a,3b,3d,3e] whereas nonmetal-catalyzed reactions, including the present procedure, proceeded through anti-Markovnikov addition.[3f,4,5a,5b,5d,5e,5f] Excellent stereoselectivity was observed producing *E*-isomers in all the reactions using β-cyclodextrin,[5d] whereas attainment of high stereoselectivities providing a single isomer is not uniform in reactions using other reagents.[3,4,5a,5b,5c,5e,5f]

In conclusion, we have developed a very simple and efficient methodology for the addition of thiols to unactivated alkynes in water, producing vinyl sulfides and dithiolanes at room temperature and 80 °C, respectively. The additions exhibited high regioselectivity (exclusive anti-Markovnikov addition) and excellent stereoselectivity in several reactions (products obtained as one stereoisomer). Other significant advantages are simple operation, mild conditions (room temperature and neutral reaction media), general applicability to a variety of substituted alkynes and aromatic as well as aliphatic thiols, no catalyst or additive is required, high yields of isolated products, environment-friendly experimental conditions, and cost effectiveness. We believe, being endowed with so many attractive features, that this procedure will make an important addition to the existing methods of hydrothiolation.

Experimental

IR spectra were recorded on a Shimadzu 8300 FT IR spectrometer in neat. ^{1}H NMR and ^{13}C NMR spectra were run on a Bruker DPX-300 instrument at 300 and 75 MHz, respectively. HR-MS were taken on a Microtek Qt of a Micro YA263 spectrometer. All commercial reagents were distilled before use.

General experimental procedure for the synthesis of vinyl sulfides

Representative procedure for the reaction of phenyl acetylene with thiophenol (Table 1, entry 1)

A mixture of phenyl acetylene (102 mg, 1 mmol) and thiophenol (121 mg, 1.1 mmol) was stirred in H_2O (2 mL) at room temperature (30 °C) for 3 h (TLC). The reaction mixture was extracted with Et_2O (3 × 15 mL). The ether extract was washed with H_2O, NaOH (5%) solution, and brine and then dried over Na_2SO_4. Evaporation of solvent gave a crude product that was purified by column chromatography over silica gel (hexane) to provide (*E*)- and (*Z*)-phenyl styryl sulfane (204 mg, 96%) as a colourless liquid (*E*:*Z* = 62:38). IR (neat, cm^{-1}) ν: 3057, 3022, 1598, 1581, 1477, 1438, 1024,

945, 738, 688. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.61 (d, 1H, J = 10.8 Hz), 6.70 (d, 1H, J = 10.8 Hz), 6.85 (d, 1H, J = 15.4 Hz), 6.99 (d, 1H, J = 15.4 Hz), 7.34–7.54 (m, 20H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 123.4, 126.0 (2C), 126.9, 127.2, 127.6, 128.3, 128.7 (2C), 128.8, 129.2 (2C), 129.8 (2C), 130.1, 131.8, 135.3, 136.2, 136.5 (2C). These data are in good agreement with those reported.[5d] This procedure was followed for all the reactions listed in Table 1. The known compounds were identified by comparison of their spectral data with those reported earlier (see refs. in Table 1). The unknown compounds were characterized properly by their spectroscopic data (IR, ^{1}H NMR, ^{13}C NMR, and HRMS), which are reported as follows.

2-Dodecylsulfanyl-but-2-enedioic acid dimethyl ester (Table 1, entry 15)

Pale yellow oil. IR (neat, cm^{-1}) ν: 2925, 2854, 1741, 1716, 1585, 1434, 1338, 1247, 1164, 1035, 723. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.87 (t, 3H, J = 6.02 Hz), 1.25–1.39 (m, 17H), 1.61–1.69 (m, 3H), 2.79 (t, 2H J = 7.34 Hz), 3.69 (s, 3H), 3.87 (s, 3H), 5.70 (s, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 14.2, 22.8, 28.1, 28.9, 29.1, 29.4 (2C), 29.5, 29.6, 29.7, 31.9, 32.0, 51.9, 53.2, 112.4, 150.9, 164.2, 166.2. HRMS *m/z* [M + Na]$^+$ calcd. for $C_{18}H_{32}O_4SNa$: 367.1919; found: 367.1915.

1-(2-Butylsulfanyl-vinyl)-4-chloro-benzene (Table 1, entry 17; Z:E = 70:30)

Colourless oil. IR (neat, cm^{-1}) ν: 2957, 2928, 2871, 1558, 1520, 1489, 1397, 1091. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.69–0.76 (m, 6H), 1,17–1.29 (m, 4H), 1.41–1.50 (m, 4H), 2.55–2.60 (m, 4H), 6.06 (d, 1H, J = 10.9 Hz), 6.13–6.19 (m, 2H), 6.50 (d, 1H, J = 15.6 Hz), 6.96–7.04 (m, 2H), 7.09 (d, 2H, J = 8.5 Hz), 7.20 (d, 2H, J = 8.5 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 13.7 (2C), 21.7 (2C), 32.3 (2C), 35.7 (2C), 124.0 (2C), 125.1, 126.6, 128.6, 128.7, 128.8, 128.9, 129.8 (2C), 130.1 (2C), 132.0 (2C), 135.6 (2C). HRMS *m/z* [M + Na]$^+$ calcd. for $C_{12}H_{15}ClSNa$: 249.0481; found: 249.1879.

2-Styrylsulfanyl-ethanethiol (Table 1, entry 19; Z:E = 89:11)

Colorless oil. IR (neat, cm^{-1}) ν: 2980, 2930, 2865, 2223, 1487, 1462, 1272, 730. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.93–3.00 (m, 4H), 3.04–3.14 (m, 4H), 6.19 (d, 1H, J = 10.8 Hz), 6.48 (d, 1H, J = 10.8 Hz), 6.55 (d, 1H, J = 15.1 Hz), 6.67 (d, 1H, J = 15.1 Hz), 7.19–7.25 (m, 2H), 7.28–7.37 (m, 4H), 7.45 (d, 4H, J = 7.6 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 35.4 (2C), 39.3 (2C), 126.3 (2C), 127.2 (2C), 127.3 (2C), 128.7 (4C), 129.0 (4C), 137.0 (2C). Anal. calcd. for $C_{10}H_{12}S_2$: C 61.18, H 6.16; found: C 61.57, H 6.28.

General procedure for the synthesis of dithiolanes–dithianes

Representative procedure for the reaction of phenyl acetylene and 1,2-ethane dithiol (Table 2, entry 2)

A mixture of phenyl acetylene (102 mg, 1 mmol) and 1,2-ethane dithiol (103 mg, 1.1 mmol) in water (2 mL) was heated at 80 °C for a required period of time (4 h) (TLC). Then the mixture was extracted with Et_2O (3 × 15 mL). The ether extract was washed with brine, dried (Na_2SO_4), and evaporated to get the crude product, which was purified by column chromatography over silica gel (hexane–ether, 95:5) to provide 2-benzyl-[1,3]-dithiolane (159 mg, 81%) as a colorless oil. IR (neat, cm^{-1}) 3060, 3026, 2930, 2894, 1604, 1498, 1453, 1427, 1270, 1240, 1172, 743, 688. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.10 (d, 2H, J = 7.08 Hz), 3.17–3.24 (m, 4H), 4.72 (t, 1H, J = 7.08 Hz), 7.20–7.32 (m, 5H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 38.5 (2C), 45.2, 54.8, 126.7, 127.9 (2C), 129.0 (2C), 139.0. These data are in good agreement with those reported.[17a] This procedure was followed for all the reactions listed in Table 2. The known compounds were identified by comparison of their spectral data with those reported earlier (see refs. in Table 2). The unknown compounds were characterized properly by their spectroscopic data (IR, ^{1}H NMR, ^{13}C NMR, and HRMS), which are reported as follows.

2-(3-Methoxy-benzyl)-[1,3]-dithiolane (Table 2, entry 4)

Yellowish oil. IR (neat, cm^{-1}) ν: 2999, 2922, 2833, 1598, 1583, 1488, 1454, 1434, 1259, 1153, 1049, 769, 694. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 3.09 (d, 2H, J = 7.2 Hz,), 3.12–3.22 (m, 4H), 3.79 (s, 3H), 4.72 (t, 1H, J = 7.2 Hz), 6.73–6.87 (m, 3H), 7.21 (t, 1H, J = 7.68 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 28.0 (2C), 45.1, 54.6, 55.0, 112.0, 114.6, 121.2, 129.2, 140.5, 159.4. HRMS *m/z* [M + Na]$^+$ calcd. for $C_{11}H_{14}OS_2Na$: 249.0384; found: 249.0412.

2-(4-Chloro-benzyl)-[1,3]-dithiolane (Table 2, entry 5)

Colourless oil. IR (neat, cm^{-1}) ν: 2923, 2250, 1712, 1490, 1397, 1222, 909, 732. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.84–2.93 (m, 4H), 2.97–3.04 (m, 2H), 4.59 (t, 1H, J = 6.9 Hz), 7.12–7.29 (m, 4H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 5.0, 38.2, 38.9, 54.6, 129.2 (2C), 129.9 (2C), 132.8, 135.1. HRMS *m/z* [M + H]$^+$ calcd. for $C_{10}H_{11}ClS_2H$: 231.0069; found: 231.1078.

2-(4-Chloro-benzyl)-[1,3]-dithiane (Table 2, Entry 6)

Yellowish oil. IR (neat, cm^{-1}) ν: 3060, 3026, 2898, 2825, 1602, 1494, 1452, 1421, 1274, 1242, 1178, 906, 740, 698, 663. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.98–2.06 (m, 2H), 2.70–2.81 (m, 4H), 2.91 (d, 2H, J = 7.3 Hz), 4.13 (t, 1H, J = 7.3 Hz), 7.08 (d, 2H, J = 7.4 Hz), 7.20 (d, 2H, J = 7.4 Hz). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 25.5, 30.4 (2C), 40.9, 48.3, 128.3 (2C), 130.5 (2C), 130.8, 135.6. HRMS calcd. for [M+Na]$^+$ $C_{11}H_{13}ClS_2Na$: 267.0045; found: 267.010.

A theoretical model study on the cyclic reaction of 4-hydroxybutanal catalyzed by Brønsted acid

Qingyong Meng, Chenggen Zhang, and Ming-Bao Huang

Abstract: For a theoretical model study on the cyclic reaction of 4-hydroxybutanal (4-OH-BL), we have examined five assumed reaction pathways (I–V) by performing the B3LYP calculations in the gas phase and self-consistent isodensity polarized continuum model (SCIPCM)-B3LYP calculations in aqueous solution. Pathways II (4-OH-BL + H^+), III (4-OH-BL + H_3O^+), and IV (4-OH-BL + H_3O^+ + H_2O) represent three models for the cyclic reaction catalyzed by Brønsted acids. The present study leads to the following conclusions concerning the five pathways (mainly on the basis of the calculation results in the solution). The high barrier along pathway I (with no catalyst) implies that the reaction does not occur without a catalyst, and the extremely large stabilization energy of the intermediate implies that pathway II is not a realistic model for the reaction catalyzed by Brønsted acid. Along pathway III, there are two intermediates and a transition state in between, and they are 10–16 kcal/mol lower in energy than the reactants (4-OH-BL + H_3O^+). Along pathway IV, there is only one intermediate, and it is 20.6 kcal/mol lower in energy than the reactants (4-OH-BL + H_3O^+ + H_2O). Pathways III and IV are predicted to be feasible. Energetically, pathway IV is more favourable than pathway III and it is considered as a rational model for the cyclic reaction of 4-OH-BL catalyzed by Brønsted acid. Our calculations for pathway V (catalyzed by H_2O) indicate that the water molecule may also serve as a catalyst for the cyclic reaction. The transition state along pathway V is 20.0 kcal/mol higher in energy than the reactants (4-OH-BL + H_2O), and one can clearly see the "proton wire" in its structure. Our calculations show strong solvent effects on energetics of the charged intermediates along pathways II, III, and IV.

Key words: cyclic reaction of 4-hydroxybutanal, catalyzed by Brønsted acid, B3LYP, self-consistent isodensity polarized continuum model (SCIPCM), model study.

Résumé : Comme modèle théorique pour une étude de la réaction cyclique du 4-hydroxybutanal (4-OH-BL), on a étudié cinq présumées voies réactionnelles (I–V) en effectuant des calculs B3LYP en phase gazeuse et des calculs SCIPCM-B3LYP en solution et les voies réactionnelles II (4-OH-BL + H^+), III (4-OH-BL + H_3O^+) et IV (4-OH-BL + H_3O^+ + H_2O) représentent trois modèles pour la réaction cyclique catalysée par les acides de Brønsted. La présente étude conduit aux conclusions suivantes concernant les cinq voies réactionnelles (principalement sur la base des résultats de calculs en solution). La barrière élevée le long de la voie I (sans catalyseur) implique que la réaction ne se produit pas sans catalyseur et l'énergie de stabilisation extrêmement grande de l'intermédiaire implique que la voie réactionnelle II n'est pas un modèle réaliste pour la réaction catalysée par un acide de Brønsted. Le long de la voie III, on rencontre deux intermédiaires et un état de transition entre les deux et leurs énergies sont de 10 à 16 kcal/mol inférieures à celles des réactifs (4-OH-BL + H_3O^+). Le long de la voie IV, il n'existe qu'un intermédiaire et son énergie est de 20,6 kcal/mol inférieure à l'énergie des réactifs (4-OH-BL + H_3O^+ + H_2O). Les voies réactionnelles III et IV sont donc toutes les deux possibles. D'un point de vue énergétique, la voie IV est plus favorable que la voie III et on la considère comme un modèle rationnel pour la réaction du 4-OH-BL catalysée par un acide de Brønsted. Les calculs pour la voie V (catalysée par l'eau) indiquent que la molécule d'eau peut aussi servir de catalyseur pour la réaction cyclique. L'énergie de transition de l'état de transition le long de la voie V est de 20,0 kcal/mol plus élevée que celles des réactifs (4-OH-BL + H_2O) et on peut voir le « treillis de proton » dans sa structure. Les calculs montrent l'existence d'importants effets de solvant sur les énergies des intermédiaires chargés le long des voies réactionnelles II, III et IV.

Mots-clés : réaction cyclique du 4-hydroxybutanal, catalyse par un acide de Brønsted, B3LYP, SCIPCM, étude modèle.

[Traduit par la Rédaction]

Introduction

Nucleophilic reactions are very important reactions in organic chemistry.[1] There are numerous theoretical studies[2–9] on nucleophilic substitution reactions (S_N2 reactions), but less theoretical studies on nucleophilic addition reactions. The cyclic reaction of 4-hydroxybutanal (4-OH-BL) to form 2-hydroxytetrahydrofuran (2-OH-THF), catalyzed by Brønsted acid, is a simple nucleophilic addition reaction, which generates the ring framework of an α- or β-furanose.

Following the experimentally suggested mechanism,[10–12] we performed theoretical calculations for a model reaction system of (4-OH-BL + H^+) (the H^+ ion being a prototype of Brønsted acid), and the calculations predicted an intermediate with a stabilization energy of around 200 kcal/mol along the path of the cyclic reaction (see the Results and discussion section). The extremely large stabilization energy, which must be the proton affinity energy of 4-OH-BL, indicates that the model reaction system was too simple to lead to a realistic description of the reaction. The experimentally reported cyclic reaction of 4-OH-BL catalyzed by Brønsted acid occurs in aqueous solution.[1,10–12] We realized that the reaction system might include the H_3O^+ ion (a prototype of Brønsted acid) and the H_2O molecule (as catalyst).

For the cyclic reaction of 4-OH-BL, we have assumed five reaction pathways, I, II, III, IV, and V, which correspond to the model reaction systems of (4-OH-BL), (4-OH-BL + H^+), (4-OH-BL + H_3O^+), (4-OH-BL + H_3O^+ + H_2O), and (4-OH-BL + H_2O), respectively. The species, besides 4-OH-BL, in these reaction systems are considered as catalyst(s). Pathways II, III, and IV represent three models for the cyclic reaction of 4-OH-BL catalyzed by Brønsted acids and pathway V represents a model for the cyclic reaction catalyzed by an H_2O molecule. The five reaction pathways were first studied in the gas phase using the density functional theory (DFT) B3LYP (the Becke's three-parameter hybrid function with the nonlocal correlation of Lee–Yang–Parr)[13,14] method. The theoretical study on a ground-state reaction in the gas phase is a kind of routine work: geometry optimization and frequency analysis calculations for stationary points (intermediates and transition states), followed by intrinsic reaction coordinate (IRC) calculations. The gas-B3LYP calculations can give us general pictures (sequences of stationary points) of the five pathways in the gas phase.

Considering that the experimentally reported cyclic reaction occurs in aqueous solution,[1,10–12] we should study the five assumed reaction pathways in aqueous solution. There are several models of the SCRF (self-consistent reaction field) theory to simulate solution effects, and we used the SCIPCM (self-consistent isodensity polarizable continuum model),[15] which is the latest model in the SCRF theory. In our SCIPCM-B3LYP calculations, water is considered as solvent and for some of the assumed pathways the water molecule is also considered as catalyst, which should be included in the model reaction systems. We performed geometry optimization calculations for the stationary points in aqueous solution and obtained the SCIPCM-B3LYP energetic and geometric results, which are quite different from the B3LYP results in the gas phase (see the Results and discussion section). We assume that each of the five pathways has the same sequence of the stationary points in the gas phase and in aqueous solution.

In the present paper, we will report and discuss the B3LYP (in the gas phase) and SCIPCM-B3LYP (in aqueous solution) calculation results for the five pathways. The present study is a model study and it is different from theoretical studies on reactions for which the reaction systems are explicitly known. The main purpose of the present study is to suggest a rational model for the experimentally reported cyclic reaction of 4-OH-BL catalyzed by Brønsted acid in aqueous solution on the basis of the SCIPCM-B3LYP results. We will also discuss the calculation results for pathway V (catalyzed by H_2O). In the present paper, we will show that the results (relative energies and geometries) in the solution, based on the SCIPCM-B3LYP geometry optimization calculations, are quite different from those in the gas phase obtained in the gas-B3LYP calculations, and we will discuss the difficulties in using the SCIPCM model.

Computational details

All the calculations were carried out with the Gaussian 03W suite of programs.[16]

As mentioned above, the five assumed reaction pathways, I, II, III, IV, and V, correspond to the model reaction systems (including catalyst molecules and (or) ions) of (4-OH-BL), (4-OH-BL + H^+), (4-OH-BL + H_3O^+), (4-OH-BL + H_3O^+ + H_2O), and (4-OH-BL + H_2O), respectively, and the calculations were performed on these five reaction systems. In the gas phase, the geometry optimization calculations were performed for the reactants, transition states (TSs), intermediates (IMs), and products along the pathways at the B3LYP/6-31G(d), B3LYP/6-311G(d,p), and B3LYP/6-311++G(d,p) levels. Frequency analysis calculations at the same levels were then performed for all the species to ensure the absence of imaginary frequencies for the intermediates, the presence of the unique imaginary frequencies for the transition states, and the frequency calculations produce the zero-point energies (ZPEs). All the reaction steps along the pathways were checked at the B3LYP/6-31G(d) level: (1) the reaction steps having transition states were checked by the intrinsic reaction coordinate (IRC) calculations[17–19] and (2) the reaction steps having no transition states were checked by partial geometry optimization calculations along "reaction coordinates".

In aqueous solution, the geometry (re)optimization calculations were performed for the reactants, TSs, IMs, and products along the pathways at the SCIPCM-B3LYP/6-311++G(d,p) level, and the calculations predicted the geometries and energies of those species in aqueous solution. In the SCIPCM we used an isodensity value of 0.0004, which was recommended by Wiberg and Rablen.[20] Since the SCIPCM-B3LYP geometry optimization calculations for one IM and one TS along pathway III were not successful (see below), we performed the PCM-B3LYP/6-311++G(d,p) geometry optimization calculations for the stationary species along pathway III (PCM (polarizable continuum model)[21–24] being another model of the SCRF theory) and calculated the SCIPCM-B3LYP/6-311++G(d,p)//PCM-B3LYP/6-311++G(d,p) relative energies.

In the following discussion on the reaction pathways in the gas phase, we use the B3LYP/6-311++G(d,p) geometries ("geometries in the gas phase") and B3LYP/6-311++G(d,p) relative energies corrected with the gas-B3LYP/6-311++G(d,p) ZPEs ("relative energies in the gas phase"). In the following discussion on the reaction pathways in aqueous solution, we use the SCIPCM-B3LYP/6-311++G(d,p) geometries ("geometries in aqueous solution") and SCIPCM-B3LYP/6-311++G(d,p) relative energies corrected with the gas-B3LYP/6-311++G(d,p) ZPEs ("relative energies in aqueous solution"), unless otherwise noted. The reported (Mulliken) charge values on atoms (with hydrogens

summed into the heave atoms) in some of the TSs and IMs are the results of the gas-B3LYP/6-311++G(d,p) calculations.

Results and discussion

Figures 1a and 1b are schematic diagrams of the calculated potential energy curves for pathways I–V in the gas phase and in aqueous solution, respectively. In Fig. 1a, the relative energies in the gas phase for the TSs and IMs to the respective reactants along the pathways are given in parentheses, and in Fig. 1b, the relative energies in aqueous solution for the TSs and IMs to the respective reactants along the pathways are given in parentheses (for the TS and IMs along pathway III, the ZPE-corrected SCIPCM-B3LYP//PCM-B3LYP relative energies are given). Given in Table 1 are the relative energies, without and with the ZPE corrections, of the TSs and IMs along the pathways. Before we describe and discuss the results for the five reaction pathways, we will first report our results for the reactant (4-OH-BL) and product (2-OH-THF).

Reactant and product

The 4-OH-BL molecule has many conformations. In our calculations we located 17 conformations, which have very similar energies. For convenience, we take the conformation (R) shown in Fig. 2a as the reactant of the cyclic reaction, which is less stable than the most stable conformation by only 0.91 and 0.61 kcal/mol in the gas phase and in aqueous solution, respectively. The 2-OH-THF molecule has six conformations.[25–27] In our calculations we located all the conformations. We take the most stable conformation (P) shown in Fig. 2b as the product of the cyclic reaction. Our calculations predict that in the gas phase 2-OH-THF (P) is only 2.0 kcal/mol more stable than 4-OH-BL (R), while in aqueous solution 2-OH-THF (P) is only 0.8 kcal/mol less stable than 4-OH-BL (R). Therefore, the cyclic reaction can thermodynamically occur.

The geometries of R and P (in the gas phase and in aqueous solution) are shown in Figs. 2a and 2b, respectively, and we give only the bond length values in the heavy-atom frameworks. The geometries of R or P in the gas phase and in aqueous solution are very similar. In the geometries of R, the O(10), C(7), C(1), and C(12) atoms are almost in one plane, and the C(4) atom is out of the plane. In the geometries of P, the O(10), C(7), C(4), and C(12) atoms are almost in one plane, and the C(1) atom is out of the plane. The O(10)–C(12) bond length [r(10–12)] values are 2.824 and 2.829 Å in the geometries of R in the gas phase and in aqueous solution and 1.413 and 1.419 Å in the geometries of P in the gas phase and in aqueous solution, respectively. The C(12)–O(14) bond length [r(12–14)] values are 1.207 and 1.213 Å in the geometries of R in the gas phase and in aqueous solution and 1.420 and 1.421 Å in the geometries of P in the gas phase and in aqueous solution, respectively.

Reaction pathway I (R → P)

The assumed pathway I represents a cyclic reaction of 4-OH-BL leading to 2-OH-THF with no catalyst. Our gas-B3LYP calculations indicate that pathway I has only one reaction step and a transition state (denoted as TS1) that is the unique stationary point along the potential energy curve (see Fig. 1). The structure of TS1 is shown in Fig. 3a. Important parameters in the geometries of TS1 in the gas phase and in aqueous solution are given in Table 2. The r(10–12) value (1.653 Å) in aqueous solution is somewhat smaller than the value (1.716 Å) in the gas phase. The r(10–12) values in TS1 are much smaller than those in R and larger than those in P. The r(10–11) and r(11–14) values in TS1 indicate that the H(11) atom is migrating from the hydroxyl oxygen (O(10)) to the carbonyl oxygen (O(14)).

The barrier values (the relative energies of TS1 to R) for pathway I are predicted to be 38.0 and 38.8 kcal/mol in the gas phase and in aqueous solution, respectively. The high barrier along pathway I indicates that the cyclic reaction does not occur without a catalyst.

Fig. 1. Schematic diagrams of the potential energy curves for the five assumed pathways (I–V) of the cyclic reaction of 4-hydroxybutanal in (a) the gas phase and (b) aqueous solution. In part (a), the ZPE-corrected B3LYP/6-311++G(d,p) relative energies (in kcal/mol) for transition states (TSs) and intermediates (IMs) to the respective reactants are given in parentheses. In part (b), the ZPE-corrected SCIPCM-B3LYP/6-311++G(d,p) relative energies for the TSs and IMs are given in parentheses (for the TS and IMs along pathway III the ZPE-corrected SCIPCM-B3LYP/6-311++G(d,p)//PCM-B3LYP/6-311++G(d,p) relative energies are given).

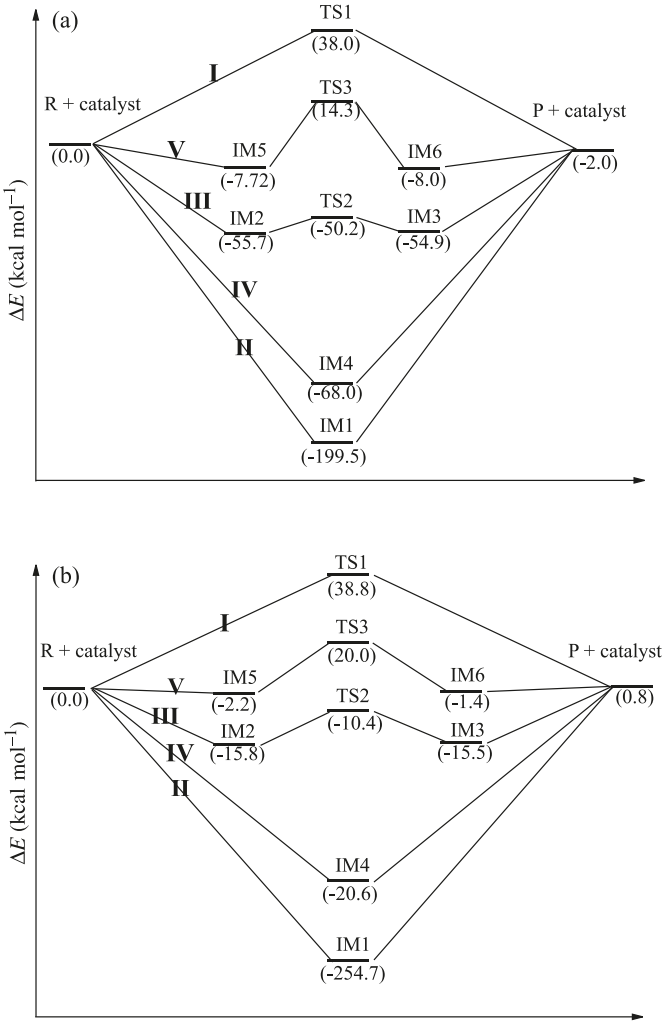

Table 1. B3LYP/6-311++G(d,p) and SCIPCM-B3LYP/6-311++G(d,p) relative energies (to the respective reactants, in kcal/mol) of transition states (TSs) and intermediates (IMs) along the five assumed reaction pathways (I–V) for the cyclic reaction of 4-hydroxybutanal, and values in parentheses are the relative energies corrected with the B3LYP/6-311++G(d,p) zero-point energies.

	B3LYP/6-311++G(d,p)	SCIPCM-B3LYP/6-311++G(d,p)[a]

(a) R (b) P

Reaction pathway II (R + H^+ → P + H^+)

The assumed pathway II represents a cyclic reaction of 4-OH-BL leading to 2-OH-THF with a proton as catalyst (the reactants being (R + H^+)), and it is the simplest model for the reaction catalyzed by Brønsted acid. Our gas-B3LYP calculations indicate that there is only one stationary point along the potential energy curve (see Fig. 1), which is an intermediate (denoted as IM1). The structure of IM1 (H(15) being the catalyst "proton") is shown in Fig. 3b. Important parameters in the geometries of IM1 in the gas phase and in aqueous solution are given in Table 2. The *r*(10–12) value (1.682 Å) in aqueous solution is considerably smaller than the value (1.844 Å) in the gas phase, and the *r*(12–14) value in aqueous solution is larger than the value in the gas phase. The *r*(10–12) values in IM1 are much smaller than those in R and significantly larger than those in P. The *r*(10–11) and *r*(14–15) values of around 0.97 Å indicate that the O(10)–H(11) and O(14)–H(15) bonds in IM1 are two normal O–H bonds, and the calculated charges on the two hydroxyl groups are +0.161 and +0.246 e, respectively. The experimentally suggested mechanism[10–12] for the cyclic reaction catalyzed by Brønsted acid implies that there be two inter-

r(14–15)		0.971 (0.970)	1.018 (1.031)	0.983 (0.985)	
r(15–16)			1.564 (1.508)	1.892 (1.852)	

Note: For IM2, TS2, and IM3 along pathway III, the lower values in parentheses are the parameters in the PCM-B3LYP/6-311++G(d,p) geometries.

mediate species along the reaction path, while our calculations indicate that there is only one intermediate species along pathway II.

The relative energies of IM1 to the reactants (R + H^+) in the gas phase and in aqueous solution are –199.5 and –254.7 kcal/mol, respectively (see Fig. 1). Actually, the value of 199.5 kcal/mol (8.65 eV) is the value of the proton affinity energy[28] for the 4-OH-BL molecule. There are no experimental indications for such extremely large stabilization energies. The assumed reaction pathway II is not a realistic model for the cyclic reaction catalyzed by Brønsted acid.

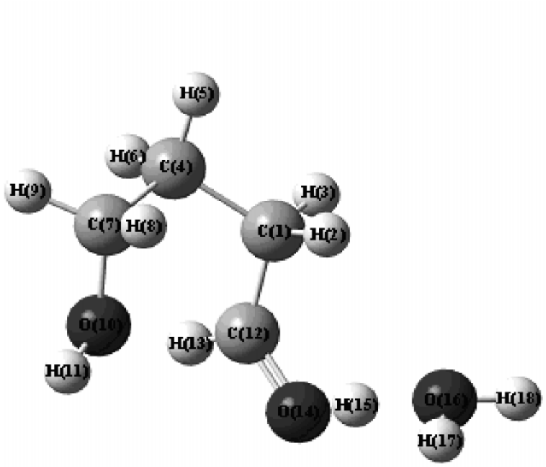
Reaction pathway III (R + H_3O^+ → P + H_3O^+)

The assumed pathway III represents a cyclic reaction of 4-OH-BL leading to 2-OH-THF with an H_3O^+ ion as catalyst (the reactants being (R + H_3O^+)), and it is a second model for the reaction catalyzed by Brønsted acid.

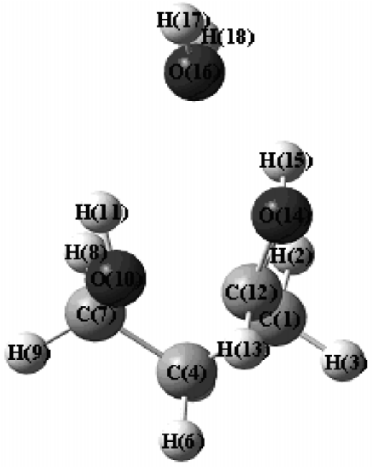
We will first consider pathway III in the gas phase. Our gas-B3LYP calculations indicate that along the potential energy curve (see Fig. 1a) in the gas phase there are two intermediates and a transition state (denoted as TS2) between the two intermediates. The intermediate between the reactants and TS2 is denoted as IM2 and the intermediate between TS2 and the products is denoted as IM3. The structures of IM2 (the H(15)–O(16)–H(17)–H(18) moiety representing the catalyst "H_3O^+"), TS2, and IM3 are shown in Figs. 4a, 4b, and 4c, respectively, and important geometric parameters are given in Table 2. The *r*(14–15) value of 1.018 Å and the *r*(15–16) value of 1.564 Å in IM2 indicate that there is an H-bond between O(14) and O(16) (with the H-atom close to O(14)). The *r*(10–11) value of 1.028 Å and the *r*(11–16) value of 1.516 Å in IM3 indicate that there is an H-bond between O(10) and O(16) (with the H-atom close to O(10)). In the structure of TS2 the *r*(15–16) and *r*(11–16) values are very large and the sum of the calculated charge values on the H(17)–O(16)–H(18) moiety ("the migrating group") is close to zero (0.0315 e). The *r*(10–12) and *r*(12–14) values are 2.277 and 1.264 Å in IM2, 1.867 and 1.300 Å in TS2, and 1.581 and 1.355 Å in IM3, respectively. The relative energies of IM2, TS2, and IM3 to the reactants (R + H_3O^+) in the gas phase are –55.7, –50.2, and –54.9 kcal/mol, respectively (see Fig. 1a). Therefore, the assumed pathway III is feasible in the gas phase.

In aqueous solution the SCIPCM-B3LYP/6-311++G(d,p) geometry optimization calculations were not successful for IM2 and TS2 (successful only for IM3). We performed the PCM-B3LYP/6-311++G(d,p) geometry optimization calculations for the reactants, IM2, TS2, IM3, and products along pathway III and then calculated the SCIPCM-B3LYP/6-311++G(d,p)//PCM-B3LYP/6-311++G(d,p) relative energies of IM2, TS2, IM3, and the products to the reactants. Important parameters in the PCM-B3LYP geometries of IM2, TS2, and IM3 are given in Table 2. The PCM-B3LYP val-

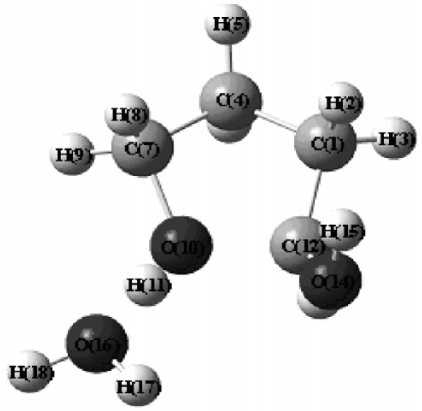
Fig. 4. Structures of (a) IM2, (b) TS2, and (c) IM3 along pathway III (important geometric parameters are given in Table 2).



(a) IM2



(b) TS2



(c) IM3

ues for important geometric parameters in IM3 are similar to the respective SCIPCM-B3LYP values. As shown in Table2, the PCM-B3LYP *r*(10–12) values in IM2, TS2, and IM3 are smaller than the respective gas-B3LYP values, but the PCM-B3LYP *r*(12–14) values in IM2, TS2, and IM3 are very close to the respective gas-B3LYP values. The PCM-B3LYP values for the O(16)–H(15) long distance in IM2 and TS2 and for the O(16)–H(11) long distance in TS2 and IM3 are smaller than the respective gas-B3LYP values. The (ZPE-corrected) SCIPCM-B3LYP//PCM-B3LYP relative energies of IM2, TS2, IM3, and the products to the reactants along pathway III are –15.8, –10.4, –15.5, and 0.8 kcal/mol, respectively (see Fig. 1b). Therefore, the assumed pathway III is feasible in aqueous solution.

Reaction pathway IV ($R + H_2O + H_3O^+ \rightarrow P + H_2O + H_3O^+$)

The assumed pathway IV represents a cyclic reaction of 4-OH-BL leading to 2-OH-THF with H_2O and H_3O^+ as catalysts (the reactants being ($R + H_2O + H_3O^+$)), and it is a third model for the reaction catalyzed by Brønsted acid. Our gas-B3LYP calculations indicate that there is only one stationary point along the potential energy curve (see Fig. 1), which is an intermediate (denoted as IM4). The reaction paths from ($R + H_2O + H_3O^+$) to IM4 and from IM4 to ($P + H_2O + H_3O^+$) were checked by partial geometry optimization calculations at the B3LYP/6-31G(d) level, and no other stationary points were found. The structure of IM4 (the H(15)–O(16)–H(17)–H(18) moiety representing the catalyst H_3O^+ and the H(20)–O(19)–H(21) moiety representing the catalyst "H_2O") is given in Fig. 5a. The geometries of IM4 in the gas phase and in aqueous solution are quite similar, and important geometric parameters are given in Table 3. As in the case of IM1, the *r*(10–12) values in IM4 are much smaller than those in R and significantly larger than those in P. The *r*(10–11) and *r*(11–19) values in IM4 indicate that there is an H-bond between O(10) and O(19) (with the H(11) atom close to the hydroxyl oxygen). The *r*(14–15) and *r*(15–16) values in IM4 indicate that there is another H-bond between O(14) and O(16) (with the H(15) atom close to the carbonyl oxygen).

The relative energies of IM4 to the reactants ($R + H_2O + H_3O^+$) in the gas phase and in aqueous solution are –68.0 and –20.6 kcal/mol, respectively (see Fig. 1). The assumed pathway IV is feasible in the gas phase and in aqueous solution. The relative energy value of –20.6 kcal/mol in aqueous solution is rational.

We also performed the PCM-B3LYP/6-311++G(d,p) geometry optimization calculations for the reactants and IM4

along pathway IV and calculated the SCIPCM-B3LYP/6-311++G(d,p)//PCM-B3LYP/6-311++G(d,p) relative energy of IM4 to the reactants. The (ZPE-corrected) SCIPCM-B3LYP//PCM-B3LYP relative energy of IM4 to the reactants is –20.7 kcal/mol (we will mention this value in the Conclusion section).

Reaction pathway V ($R + H_2O \rightarrow P + H_2O$)

Experimental and theoretical studies[29] suggest that glycolaldehyde in the chain conformation can form complexes with the water molecule by H-bonds. The 4-OH-BL (R) molecule is similar to glycolaldehyde, which also has one hydroxyl and one aldehyde groups, in the chain conformation. Thus, we have considered the role of the water molecule (without the proton) in the cyclic reaction of 4-OH-BL.

The assumed pathway V represents a cyclic reaction of 4-OH-BL leading to 2-OH-THF with a water molecule as catalyst (the reactants being ($R + H_2O$)). Our gas-B3LYP calculations indicate that along the potential energy curve (see Fig. 1) there are two intermediates and a transition state (denoted as TS3) between the two intermediates. The intermediate between the reactants and TS3 is denoted as IM5 and the intermediate between TS3 and the products is denoted as IM6. The structures of IM5 (the H(15)–O(16)–H(17) moiety representing the catalyst H_2O), TS3, and IM6 are shown in Figs. 5b, 5c, and 5d, respectively. Important parameters in the geometries of IM5, TS3, and IM6 in the gas phase and in aqueous solution are given in Table 3, and the geometries in the gas phase and in the solution are similar. IM5 has one H-bond between O(10) and O(16) (with the H(11) atom close to O(10)) and another H-bond between O(14) and O(16) (with the H(15) atom close to O(16)) in its structure, and IM5 is an analogue to the glycolaldehyde–water complex "CC-W-1" or "CC-W-2" shown in Fig. 1 of ref. 29. By checking the bond distance values (see Table 3) in the O(10)–H(11)–O(16) part of IM5, TS3, and IM6, we note that the H(11) atom is migrating from O(10) to O(16). By checking the bond distance values (see Table 3) in the O(16)–H(15)–O(14) part of IM5, TS3, and IM6, we note that the H(15) atom is migrating from O(16) to O(14). Along the O(10)–H(11)–O(16)–H(15)–O(14) chain in TS3, the bond distance values range from 1.15 to 1.28 Å, and this O–H–O–H–O chain serves as a "proton wire".[30]

IM5 and IM6 are predicted to be slightly more stable than the reactants ($R + H_2O$) in the gas phase and in aqueous solution (see Fig. 1). The relative energies of TS3 to the reactants are 14.3 and 20.0 kcal/mol in the gas phase and in aqueous solution, respectively (see Fig. 1), and the barriers in the gas phase and in aqueous solution are not very high. Therefore, the assumed pathway V represents a possible mechanism for the cyclic reaction (catalyzed by H_2O).

The so-called proton wire was discussed by Eigen[31] as a cyclic (cooperative) mechanism in proton transfer processes as early as in 1965. Wolfe and co-workers[32–39] have extensively studied the cooperative mechanism in hydrolysis reactions. In their theoretical study on hydration of a carbonyl group, Wolfe et al.[32] confirmed that the reaction proceeds via a cyclic transition state containing two water molecules. In the structures of their transition state ($(TS)_2$), reactant ($(RC)_2$), and product ($(PC)_2$), one can see an O–H–O–H–O–C ring (the two H's in the ring being the transferring protons). In the structure of TS3 (see Fig. 5c) one can see the O(10)–H(11)–O(16)–H(15)–O(14)–C(12) ring (the O(10)–H(11)–O(16)–H(15)–O(14) part was called a proton wire, see above). One can also see the O–H–O–H–O–C ring in the structures of IM5 and IM6 (see Figs. 5b and 5d). IM5, TS3, and IM6 along pathway V are similar to $(RC)_2$, $(TS)_2$, and $(PC)_2$ (in ref. 32), respectively, if the "H(11)–O(10)–C(7)-" part of IM5, TS3, and IM6 was viewed as the second water molecule. The barrier value for the $(RC)_2 \rightarrow (TS)_2 \rightarrow (PC)_2$ process in aqueous solution was calculated to be 24.6 kcal/mol[32] (at the Onsager-MP2/6-31G(d)//3-21G level), and it is quite close to the relative energy value (20.0 kcal/mol) of TS3 to the reactants (pathway V) in aqueous solution (at the SCIPCM-B3LYP/6-311++G(d,p) level). Pathway V (with one water molecule as catalyst) has a "cooperative mechanism" as the hydrolysis reactions of the carbonyl group.[32]

Conclusions

Since the experimentally reported cyclic reaction of 4-OH-BL occurs in aqueous solution,[1,10–12] discussions leading to conclusions on the reaction mechanisms will be on the basis of the energetic and geometric results calculated in aqueous solution for the five assumed reaction pathways, and the energetic data are given in Fig. 1b and in parentheses in the last column of Table 1.

The high barrier along pathway I (with no catalyst) indicates that the cyclic reaction does not occur without catalyst. Pathways II, III, and IV represent three models for the cyclic reaction catalyzed by Brønsted acids. The extremely large stabilization energy of the intermediate along pathway II (catalyzed by H^+) implies that pathway II is not a realistic model for the cyclic reaction catalyzed by Brønsted acid.

Along pathway III (catalyzed by H_3O^+), there are two intermediates (IM2 and IM3) and one transition state (TS2) between IM2 and IM3. The (ZPE-corrected) SCIPCM-B3LYP//PCM-B3LYP relative energies of IM2, TS2, and IM3 to the reactants ($R + H_3O^+$) are –15.8, –10.4, and –15.5 kcal/mol, respectively. Along pathway IV (catalyzed by H_3O^+ and H_2O) there is only one intermediate (IM4), and the (ZPE-corrected SCIPCM-B3LYP) relative energy of IM4 to the reactants ($R + H_2O + H_3O^+$) is –20.6 kcal/mol. The negative relative energy values indicate that pathways III and IV are both feasible in aqueous solution. For comparison purposes, we calculated the (ZPE-corrected) SCIPCM-B3LYP//PCM-B3LYP relative energy of IM4 to the reactants ($R + H_2O + H_3O^+$) and obtained a value of –20.7 kcal/mol (see the last section), which is lower than the relative energy values of IM2, TS2, and IM3 to the reactants ($R + H_3O^+$) calculated at the same level. Therefore, pathway IV is considered to be more (energetically) favourable than pathway III, and we conclude that pathway IV is a rational model for the cyclic reaction of 4-OH-BL catalyzed by Brønsted acid.

By checking the structures of IM2, TS2, and IM3, we can consider that the process of pathway III consists of three steps: (*i*) the H_3O^+ ion (catalyst) attacks 4-OH-BL at the carbonyl oxygen (see the structure of IM2), and it leaves a proton (H^+) at the carbonyl oxygen and becomes an H_2O moiety; (*ii*) the H_2O moiety (the charge on the moiety being

almost zero, see the last section) migrates from the carbonyl oxygen side of 4-OH-BL to the hydroxyl group side (see the structure of TS2); and (*iii*) the H_2O moiety takes a proton (H^+) from the hydroxyl group and leaves the system (becoming 2-OH-THF) as an H_3O^+ ion. However, steps (*ii*) and (*iii*) are not quite realistic in aqueous solution. One H_2O molecule in the solvent around the hydroxyl group can complete step (*iii*) and the H_2O moiety at the carbonyl oxygen side can leave the system as a H_2O molecule (the migration step, step (*ii*), is not needed). The H_2O molecule in the solvent is a second catalyst, and this realistic process is just that of pathway IV (see the structure of IM4). We do believe that pathway IV is a rational model for the cyclic reaction of 4-OH-BL catalyzed by Brønsted acid.

Our calculations for pathway V indicate that the H_2O molecule may also serve as a catalyst for the cyclic reaction of 4-OH-BL, though the transition state along the pathway is 20.0 kcal/mol higher in energy than the reactants ($R + H_2O$). In the structure of the transition state one can clearly see the proton wire. The H_2O molecule can be considered as a weak Brønsted acid.

We note that, for the neutral reaction systems (pathways I and V), the relative energy values of IMs and TSs in aqueous solution are similar to the values in the gas phase (see the data in Figs. 1a and 1b). However, the situations for the charged reaction systems (pathways II, III, and IV) are different. The stabilization energy values (the negatives of the relative energy values) for IMs along pathways III (IM2 and IM3) and IV (IM4) in aqueous solution are much smaller than those in the gas phase, which can be explained by considering the fact that the positive charges in IMs are more delocalized than in the reactants (($R + H_3O^+$) and ($R + H_2O + H_3O^+$)). The positive charges are mainly located on the O(10), O(14), C(1), and C(7) atoms in IM2, IM3, and IM4. The stabilization energy value for IM1 along pathway II in aqueous solution is much larger than the value (already very large) in the gas phase, for which we have no explanations.

Supplementary data

Copolymerization of sterically demanding phosphine-olefins and 1-hexene

Jenny S.J. McCahill and Douglas W. Stephan

Abstract: The copolymerization of 1-hexene with *t*-$Bu_2P(CH_2)_3CH{=}CH_2$ **(1)** or *t*-$Bu_2P(CH_2)_9CH{=}CH_2$ **(2)** has been achieved using $CpMe_2Ti(NPt\text{-}Bu_3)$ as the precatalyst and $B(C_6F_5)_3$, $[Ph_3C][B(C_6F_5)_4]$, or $[PhNMe_2H][B(C_6F_5)_4]$ as the activator. The resulting polymers are shown to incorporate up to 9% of the phosphine comonomer, albeit with reduced catalyst activity and polymer molecular mass. The cause of the catalyst inhibition is also considered in the light of phosphine–activator interactions.

Key words: titanium phosphinimide, copolymerization, phosphine-containing polymers, phosphine–activator interactions.

Résumé : On a effectué la copolymérisation du hex-1-ène avec le *t*-$Bu_2P(CH_2)_3CH{=}CH_2$ (**1**) ou le *t*-$Bu_2P(CH_2)_9CH{=}CH_2$ (**2**) en utilisant le $CpMe_2Ti(NPt\text{-}Bu_3)$ comme précatalyseur et le $B(C_6F_5)_3$, $[Ph_3C][B(C_6F_5)_4]$, ou $[PhNMe_2H][B(C_6F_5)_4]$ comme activateurs. On a montré que les polymères qui en résultent incorporent jusqu'à 9 % du comonomère phosphine, avec une réduction de l'activité du catalyseur et du poids moléculaire du polymère. On considère la cause de cette inhibition du catalyseur en fonction des interactions entre la phosphine et l'activateur.

Mots-clés : phosphinimide de titane, copolymérisation, polymères contenant une phosphine, interaction entre une phosphine et un activateur.

Introduction

The development of single-site catalysts for the polymerization of ethylene and other α-olefins has been a major area of research for the past quarter of a century. The specific tuning of defined metal complexes allows strict control over the microstructure of polyolefins produced.[1,2] This rational catalyst development, although extensively studied, continues to be a motivating objective in numerous research endeavors. A driving force behind some of these investigations is the expansion of these systems to incorporate functional moieties into the polymer, to enhance or change the polymer properties and range of applications.

There are two main approaches to the synthesis of functional polyolefins: chain-end functionalization and in-chain functionalization.[3–5] Chain-end functionalization is achieved through reactivity on unsaturated chain-ends or via functionalization of polymer terminae. In-chain functionalization is typically achieved through post-polymerization reactivity, the use of groups to protect the functionality during the polymerization, or via direct polymerization. Of these methods of in-chain functionalization, direct polymerization is preferred, since it requires no post-polymerization modification. Therefore, numerous studies have been carried out to incorporate the functional moieties directly during the polymerization process. Furthermore, it is desirable to add these moieties in a controlled manner without compensation of any desirable properties.

The direct polymerization of functionalized monomers using group-IV transition-metal catalysts has been limited, as many polar monomers poison the catalyst by coordination to the electrophilic metal center. Nonetheless, functionalized monomers containing Si,[6,7] halogens,[8] and N[7,9] have been directly polymerized using group-IV catalysts as such groups afford weak donor interactions.

Previous efforts in our group have shown that activation of $CpMe_2Ti(NPt\text{-}Bu_3)$ with borane and borate activators affords highly active catalysts for olefin polymerization. Moreover, the catalytically active cation can be intercepted with phosphine donors affording species of the form $[CpMeTi(NPt\text{-}Bu_3)(PR_3)]^+$. However, with sterically bulky phosphines (R = Cy, *t*-Bu, and *o*-tolyl) there was no evidence of phosphine binding to Ti and the free phosphine was observed in solution by NMR methods.[10,11] In this paper, we exploit this absence of interaction of bulky phosphines to probe the viability of copolymerization of olefins with olefins containing pendant bulky phosphine fragments.

Experimental section

General considerations

All preparations were performed under an atmosphere of dry O_2-free N_2 employing either Schlenk-line techniques or a Vacuum Atmospheres inert atmosphere glovebox. Solvents were purified employing Grubbs-type column systems man-

ufactured by Innovative Technologies. Uninhibited THF purchased from EDM and deuterated benzene, toluene, and methylenechloride purchased from Cambridge Isotopes Laboratories, were dried, distilled, and freeze-pump-thaw degassed (three times) prior to use. ^{1}H and ^{13}C NMR spectra were recorded on Bruker Avance 300 and 500 spectrometers. Trace amounts of protonated solvents were used as references, and ^{1}H and ^{13}C{^{1}H} NMR chemical shifts are reported relative to $SiMe_4$. ^{31}P{^{1}H}, ^{11}B{^{1}H}, and ^{19}F NMR spectra were referenced to external 85% H_3PO_4, $BF_3{\cdot}Et_2O$, and $CFCl_3$, respectively. Combustion analyses were performed at the University of Windsor Chemical Laboratories employing a PerkinElmer CHN Analyzer. Molecular mass determinations were performed using a Waters Breeze system GPC using THF as eluent. The detector used was a Waters model 410 refractive index detector at 35 °C, and molecular masses were calibrated using narrow polystyrene standards (Polymer Laboratories Inc.). High-temperature GPC data were provided by the technical staff at NOVA Chemicals Corporation.

HP*t*-Bu_2, $Br(CH_2)_3CHCH_2$, $Br(CH_2)_4CH_3$, $Br(CH_2)_9CH_3$, and anhydrous MeOH were purchased from Sigma-Aldrich Chemical Company, and $[Me_2PhNH][B(C_6F_5)_4]$ was purchased from Strem Chemical Inc.; all were used as received. 1-Hexene was purchased from Sigma-Aldrich Chemical Company and distilled from Na/benzophenone. $B(C_6F_5)_3$, and $[Ph_3C][B(C_6F_5)_4]$ were generously donated by NOVA Chemicals Corp. $CpTiMe_2(NPt\text{-}Bu_3)$ was prepared via literature methods.[12]

Synthesis of *t*-$Bu_2P(CH_2)_3CH{=}CH_2$ (1), *t*-$Bu_2P(CH_2)_9CH{=}CH_2$ (2), *t*-$Bu_2P(CH_2)_4CH_3$ (3)

These compounds were prepared in a similar fashion, and thus only one preparation is detailed. A solution of $Br(CH_2)_3CH{=}CH_2$ (4.829 g 32.40 mmol) in THF (5 mL) was added to a solution of *t*-Bu_2PLi (4.392g, 28.87 mmol) in THF (50 mL) cooled to 0 °C. The solution was stirred and warmed to room temperature for 12 h. The solvent was removed in vacuo, and hexanes were added to precipitate LiBr. The solution was filtered through Celite and vacuum-distilled (58–62 °C) to yield a clear liquid.

(2): Yield: 2.70 g (66%) ^{1}H NMR (C_6D_6) δ: 5.73–5.87 (m, 1H, C*H*=CH_2), 4.98–5.09 (m, CH=CH_2), 1.99 (q, 2H, CH_2CH=CH_2), 1.29–1.66 (m, 14H, CH_2), 1.16 (d, 18H, $^3J_{H-P}$ = 11 Hz, *t*-Bu). ^{13}C{^{1}H} NMR (C_6D_6) partial δ: 139.59 (s, *C*H=CH_2), 114.86 (s, CH=*C*H_2), 34.57 (s, CH_2), 32.27 (d, $^2J_{C-P}$ = 13 Hz, CH_2), 31.58 (d, $^1J_{C-P}$ = 23 Hz, *t*-Bu), 31.56 (s, *C*H_2), 22.13 (d, $^1J_{C-P}$ = 23 Hz, *t*-Bu). ^{31}P{^{1}H} NMR (C_6D_6) δ:27.82 (s). Anal. calcd. for $C_{19}H_{39}P$: C 76.45, H 13.17; found: C 76.25, H 13.00.

(3): Yield: 0.71 g (51%). ^{1}H NMR (C_6D_6) δ: 1.27–1.54 (m, 8H, CH_2), 1.11 (d, 18H, $^3J_{H-P}$ = 11 Hz, *t*-Bu), 0.97 (t, 3H, $^3J_{H-H}$= 7 Hz, CH_3). ^{13}C{^{1}H} NMR (C_6D_6) δ: 34.41 (d, $^3J_{C-P}$ = 12 Hz, $CH_2CH_2CH_2$), 31.56 (d, $^1J_{C-P}$ = 23 Hz, *t*-Bu), 31.02 (d, $^2J_{C-P}$ = 12 Hz, PCH_2CH_2), 30.19 (d, $^2J_{C-P}$ = 14 Hz, *t*-Bu), 23.26 (s, $CH_2CH_2CH_3$) 22.03 (d, $^1J_{C-P}$ = 22 Hz, P*C*H_2), 14.68 (s, *C*H_3). ^{31}P{^{1}H} NMR (C_6D_6) δ: 27.84 (s). Anal calcd. for $C_{14}H_{39}P$: C 76.45, H 13.17; found: C 76.13, H 13.13.

Synthesis of *t*-$Bu_2P((CH_2)_9CHCH_2)C_6F_4BF(C_6F_5)_2$ (5)

To a solution of $B(C_6F_5)_3$ (0.254 g, 0.50 mmol) in CH_2Cl_2 (10 mL) **2** (0.156 g, 0.52 mmol) was added. The solution was stirred overnight, and the solvent was removed in vacuo. The residue was dissolved in 3 mL of CH_2Cl_2 and hexanes were added to precipitate an off-white solid. The solid was filtered and washed with pentanes several times to give a white solid. Yield: 0.198 g (50%). ^{1}H NMR (CD_2Cl_2) δ: 5.74–5.88 (m, 1H, C*H*=CH_2), 4.89–5.01 (m, 2H, CH=CH_2), 2.51–2.63 (br m, 2H, CH_2), 1.99–2.08 (br m, 2H, CH_2), 1.62–1.79 (br, m, 2H, CH_2), 1.51 (d, 18H, $^3J_{H-P}$ = 13 Hz, *t*-Bu_2), 1.25–1.36 (br, 12H, CH_2). ^{11}B{^{1}H} NMR (CD_2Cl_2) δ: –0.16 (br). ^{13}C{^{1}H} NMR (CD_2Cl_2) partial δ: 148.41 (dm, $^1J_{C-F}$ = 238 Hz, *C*F), 139.77 (s, *C*H=CH_2), 139.53 (dm, $^1J_{C-F}$ = 244 Hz, *C*F), 137.15 (dm, $^1J_{C-F}$ = 244 Hz, *C*F), 114.39 (s, CH=*C*H_2), 38.37 (d, $^1J_{C-P}$ = 32 Hz, *t*-Bu), 34.27 (s, CH=*C*H_2), 32.12 (s, *C*H_2), 31.94 (s, *C*H_2), 29.91 (s, *C*H_2), 29.53 (s, *C*H_2), 29.42 (s, *C*H_2), 29.27 (s, *C*H_2), 27.92 (s, *t*-Bu_2), 20.00 (dd, $^1J_{C-P}$ = 40 Hz, $^3J_{C-F}$ = 13 Hz, *C*H_2). ^{19}F NMR (CD_2Cl_2) δ: –119.93 to –119.73 (m, 1F, C_6F_4), –125.24 (s, 1F, C_6F_4), –125.82 (s, 1F, C_6F_4), –130.28 to –130.06 (m, 1F, C_6F_4), –132.54 (t, 4F, $^3J_{F-F}$ = 12 Hz, *o*-C_6F_5), –158.28 (t, 2F, $^3J_{F-F}$ = 20 Hz , *p*-C_6F_5), –163.78 to –163.22 (m, 4F, *m*-C_6F_5), –190.87 (br s, BF). ^{31}P{^{1}H} NMR (CD_2Cl_2) δ: 54.98 (s). Anal. calcd. for $C_{37}H_{39}BP$: C 54.83, H 4.85; found: C 54.72, H 4.65.

Generation of [*t*-$Bu_2PH((CH_2)_3CH{=}CH_2)][B(C_6F_5)_4]$ (6)

A solution of **1** (0.021 g, 0.100 mmol) in C_6D_5Br (0.5 mL) was added to a solution of $[Me_2PhNH][B(C_6F_5)_4]$ (0.079 g, 0.100 mmol) in C_6D_5Br. Quantitative product formation was observed by NMR. ^{1}H NMR (C_6D_5Br) δ: 7.22 (t, $^3J_{H-H}$ = 7 Hz, 2H, Ph), 6.75 (t, $^3J_{H-H}$ = 7 Hz, 1H, Ph), 6.65 (d, $^3J_{H-H}$ = 8 Hz, 2H, Ph), 5.50–5.54 (m, 1H, C*H*=CH_2), 4.96–5.08 (m, 2H, CH=CH_2), 4.22 (d, $^1J_{H-P}$ = 444 Hz, P*H*), 2.69 (s, 6H, Me_2), 1.93–1.95 (m, 2H, CH_2), 1.29–1.61 (m, 4H, CH_2), 0.87 (d, $^3J_{H-P}$ = 17 Hz, 18H, *t*-Bu). ^{11}B NMR (C_6D_5Br) δ: –16.70 (s). ^{19}F NMR (C_6D_5Br) δ: –132.37 (s, 8F, *o*-C_6F_5), –162.76 (t, 4F, $^3J_{F-F}$ = 19 Hz, *p*-C_6F_5), –166.46 (t, 8F, $^3J_{F-F}$ = 18 Hz, *m*-C_6F_5). ^{31}P NMR (C_6D_5Br) δ: 53.26 (d, $^1J_{P-H}$ = 438 Hz).

Polymerization procedures

A 20 mL vial with a propylene top closure with TFE–silicone septa was equipped with a magnetic stir bar. 0.673 g of 1-hexene (8 mmol), 0.015 g of $CpMe_2Ti(NPt\text{-}Bu_3)$ (0.04 mmol) and 6 mL of toluene were added to the vial. The vial was then immersed in a bath of desired temperature and stirred for 5 min at the polymerization temperature. A syringe containing 0.020 g of $B(C_6F_5)_3$ (0.04 mmol) dissolved in 4 mL of toluene was then brought out of the glovebox,

and its contents were injected into the vial. After a desired time interval, polymerizations were quenched by injection of 1 mL of MeOH. Volatiles were removed in vacuo. 1 mL of toluene was added and 5 mL MeOH was added to precipitate the polymer. Polymer was washed two times with 5 mL MeOH and dried in vacuo.

The % P incorporation is based on the relative integrals of the ^{13}C resonances attributable to methyl groups from the *t*-Bu groups on P and methyl groups of the hexene side chains. While differences in the T_1 relaxation times are expected to be small, a 10 s relaxation delay was employed to record these spectra. This delay was selected based on previously determined T_1 experiments on polyhexene.[13]

Results and discussion

In designing an appropriate phosphine-containing monomer for the polymerization with the $CpTiMe_2(NPt\text{-}Bu_3)$/$B(C_6F_5)_3$ system, we noted the previous studies by Waymouth and co-workers in which polymerization incorporated amine-functionalized olefin.[7,14] It was shown that the steric bulk of amine substituents correlated with the resulting activity of the catalyst. Similar results were also observed by Hakala et al. for the copolymerization of oxygen-functionalized olefins.[15] In addition to the influence of the steric properties of the functional group, the length of the spacer between the functional group and the olefinic residue was also seen to have a profound impact on polymerization. For example, reducing the spacer to two carbons from three carbons to the 4-amino-1-butene, resulted in a decreased polymerization activity.[14] Gianni et al.[16] also observed this trend for the polymerization of amino-functionalized olefins using Ziegler catalysts. Lofgren and co-workers have also reported the increased incorporation of oxygen-functionalized monomers into the polyethylene chain with the increase of the spacer group.[17]

In our efforts to incorporate phosphine residues into polyolefins, these earlier results prompted us to target a sterically encumbered phosphine with the pendant olefinic substituent, $t\text{-}Bu_2P(CH_2)_3CH{=}CH_2$ (**1**). This species was readily prepared via treatment of the corresponding halide derivative with lithium phosphide (Scheme 1). Employing the same methodology, the species $t\text{-}Bu_2P(CH_2)_9CH{=}CH_2$ (**2**) and $t\text{-}Bu_2P(CH_2)_4CH_3$ (**3**) were also prepared.

Initial attempts to effect the homopolymerizations of the phosphine-functionalized monomer were unsuccessful as no polymer was formed. However, copolymerization using 1, 5, and 10 mol% of (**1**) with 1-hexene did yield isolable polymeric products. In the cases where 5 and 10 mol% of the phosphine-functionalized monomer were used (Table 1), this resulted in a marked suppression of yield and molecular mass of the resulting polymers. The PDI of these polymers were typical of the single-site phosphinimide catalyst[12] used, ranging between 1.0 and 4.2. The degree of comonomer incorporation was determined by analysis of the $^{13}C\{^1H\}$ NMR spectra of the polymers. Specifically, the ratio of the integrals of signal attributable to the terminal methyl group of the hexyl residue was compared with that ascribed to the *tert*-butyl fragment (Fig. 1). The level of comonomer incorporation ranges between 3% and 5% with use of 5–10 mol% of comonomer **1**. While these values vary

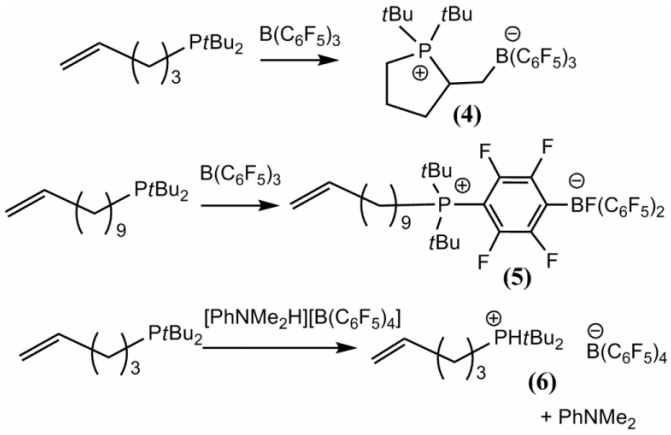
slightly with co-catalyst used, in general the level of incorporation of comonomer into the polymer increase with increased comonomer concentration. Use of 5 mol% comonomer results in less than 5 mol% incorporation, reflecting the differing steric demands of comonomer and hexene. In the case where 10 mol% of **2** is employed, incorporation rises to 9%, reflecting the decreased steric influence of the P*t*-Bu_2 fragment with the increase chain length in **2**. This result is consistent with observations made for N- and O-containing functional monomers where longer spacers between the heteroatom and the olefinic fragment were used.[18]

Competitive reactions

The reduced catalyst activity observed in the presence of the phosphine-olefin comonomers could be attributed to competitive and independent interactions of these species with the activators. For example, the independent reaction of **1** with $B(C_6F_5)_3$ has been previously reported to effect addition of P and B to the olefinic fragment to give the cyclic phosphonium borate *t*-$Bu_2P((CH_2)_4CHCH_2B(C_6F_5)_3$ (**4**). This yields a cyclic phosphonium borate (Scheme 2). In contrast, as a result of the longer chain in **2**, it is unlikely to undergo such cyclization. However, reaction of $B(C_6F_5)_3$ with **2** does proceed to give a new species **5** in 50% isolated yield. This species exhibits a $^{31}P\{^1H\}$ NMR signal at 54.98 ppm. Perhaps most diagnostic, however, is the ^{19}F NMR data. Here signals at –119.8, –125.24, –125.82, and –130.1 ppm are

Scheme 2. Reactions of olefinic phosphines with activators.



consistent with the presence of a C_6F_4 fragment in addition to signals attributable to C_6F_5 rings. As well, the signal at –190.87 ppm is attributable to a B–F residue. These data together with the ^1H and ^{13}C data confirm the formulation of **5** as *t*-$Bu_2P((CH_2)_9CH{=}CH_2)C_6F_4BF(C_6F_5)_2$ (Scheme 2). This species forms by para-attack on a C_6F_5 ring by the sterically encumbered P center. We have previously documented such reactivity of bulky phosphines with $B(C_6F_5)_3$.[19,20]

Such reactions of comonomer with the activator could compete with the precatalyst and thus account for the lesser activity observed. Similarly, in the case of the activator $[Ph_3C][B(C_6F_5)_4]$, interactions of phosphines are known to form traditional acid–base adducts affording the corresponding phosphonium salts. Alternatively, bulky phosphines are also known to effect nucleophilic aromatic substitution of a ring of $[Ph_3C]^+$ yielding cations of the form $[R_3PC_6H_4CH(C_6H_5)_2]^+$.[21] In the case of the activator $[Me_2PhNH]$ $[B(C_6F_5)_4]$, it is operative via protonation of the Ti–Me fragment. Clearly, the basicity of the phosphine centers in **1** or **2** could compete for this proton, affording the corresponding phosphonium salt. Indeed, independent reaction of **1** with $[Me_2PhNH][B(C_6F_5)_4]$ generated [*t*-$Bu_2P(H)((CH_2)_3CH{=}CH_2)][B(C_6F_5)_4]$ (**6**) (Scheme 2) and free amine Me_2PhN as evidenced by the NMR data, and in particular, the ^{31}P NMR signal at 52.5 ppm which exhibits P–H coupling of 438 Hz. Such phosphonium salts have been shown ineffective activators. Thus, such competitive side reactions could also slow catalyst generation.

The yields of polymerizations conducted in the presence of **1** or **3** were also compared. The yield of polymer generated, under otherwise identical conditions was significantly reduced when **1** was employed. This suggests the possibility that an intramolecular interaction of inserted comonomer could inhibit catalyst activity. This proposition is consistent with observations made by Waymouth and co-workers,[18] where the aminopentene, *i*$Pr_2N(CH_2)_3CHCH_2$, was found to be a more potent inhibitor than the amine, *i*$Pr_2N(CH_2)_4CH_3$, which lacks an olefinic group.[18] Nonetheless, the yield was also seen to decrease with increasing concentration of **3**, albeit to a lesser extent, suggesting that intermolecular coordination of the phosphine to the Ti cation could also diminish polymerization to some extent.

Conclusions

Copolymerization of 1-hexene and phosphine functionalized monomers is possible, although the catalyst activity is diminished. The cause of this diminished reactivity could be competitive reactions of the comonomer with the activator or the Ti catalyst. This issue can be mitigated to some extent by increasing the separation of the functional group from the double bond. Presumably, increased steric bulk at the heteroatom and decreased nucleophilicity would also facilitate comonomer incorporation.

Emitting-state properties of square-planar dithiocarbamate complexes of palladium(II) and platinum(II) probed by pressure-dependent luminescence spectroscopy

Caroline Genre, Geneviève Levasseur-Thériault, and Christian Reber

Abstract: Temperature- and pressure-dependent Raman and luminescence spectra of four crystalline complexes of palladium(II) and platinum(II) with chelating diethyldithiocarbamate (EDTC) and pyrrolidine-*N*-dithiocarbamate (PDTC) ligands are reported. The crystal structure of $[Pd(PDTC)_2]$ was resolved at 120 K. Luminescence band maxima are observed at approximately 14 500 cm^{-1} and 16 000 cm^{-1} for the palladium(II) and platinum(II) complexes, respectively. Pressure leads to blue shifts of the band maxima by +9 and +13 cm^{-1}/kbar for $[Pd(EDTC)_2]$ and $[Pd(PDTC)_2]$, and +15 cm^{-1}/kbar for $[Pt(EDTC)_2]$. These spin-forbidden d–d luminescence transitions have lifetimes of approximately 600 μs at temperatures below 20 K. Luminescence intensities at room temperature are low, but they increase significantly with external pressure. The experimental results show that strong increases of luminescence intensities caused by pressure are not limited to complexes with monodentate ligands, a result providing insight on the coordinates with emitting-state distortions responsible for this effect.

Key words: palladium(II) complexes, platinum(II) complexes, high-pressure luminescence spectroscopy, high-pressure Raman spectroscopy.

Résumé : Cet article porte sur les propriétés spectroscopiques d'une série de quatre composés du palladium(II) et du platine(II) avec les ligands chélatants diéthyldithiocarbamate (EDTC) et pyrrolidine-*N*-dithiocarbamate (PDTC). La structure cristalline du complexe $[Pd(PDTC)_2]$ à 120 K a en outre été résolue. Les spectres Raman et de luminescence à température et pression variable ont été mesurés pour les quatre composés. Les maxima des bandes de luminescence se trouvent à environ 14 500 cm^{-1} et 16 000 cm^{-1} pour les complexes de palladium(II) et platine(II). La pression induit un décalage vers le bleu des maxima de luminescence de +9 cm^{-1}/kbar pour $[Pd(EDTC)_2]$, de +13 cm^{-1}/kbar pour $[Pd(PDTC)_2]$ et de +15 cm^{-1}/kbar pour $[Pt(EDTC)_2]$. Ces transitions d–d interdites de spin ont des durées de vie de l'ordre de 600 μs à basse température. Les bandes de luminescence ont une faible intensité à température ambiante, mais celle-ci augmente de manière importante avec la pression. Les résultats expérimentaux montrent que l'augmentation de l'intensité de luminescence à haute pression n'est pas limitée aux complexes avec ligands monodentates.

Mots-clés : complexes du palladium(II), complexes du platine(II), spectroscopie de luminescence à basse température et à haute pression, spectroscopie Raman à haute pression.

Introduction

Square-planar complexes of d^8-configured metal ions such as platinum(II) and palladium(II) have a rich variety of electronic excited states, which has made them attractive systems for studies of electronic structure. They show intriguing and widely variable luminescence properties. Applications as luminescent sensors or organometallic light-emitting devices have been proposed.[1,2]

One recent focus of attention are luminescence properties that show drastic variations as a consequence of small structural changes, such as mechanical grinding, reported recently for a platinum(II) terdentate polypyridyl complex.[3] While the observed variations of spectroscopic properties such as the energies of band maxima are significant, more controlled and preferably reversible structural changes are desirable, as they lead to additional and detailed insight through clear trends. External pressure is one experimental approach to obtain such variations. Recent advances in high-sensitivity detection using CCD cameras for both structural and spectroscopic studies have led to renewed interest in pressure as an attractive probe.[4–7] In addition, theoretical modeling of such effects has also obtained recent attention.[8]

In this study, we present new d–d luminescence spectra for a series of complexes of palladium(II) and platinum(II) with the chelating diethyldithiocarbamate (EDTC) and pyrrolidine-*N*-dithiocarbamate (PDTC) ligands. The temperature-dependent luminescence spectra and lifetimes support the d–d assignment for these transitions. Temperature- and pressure-dependent spectra show quantitative variations that are compared to those

reported for monodentate ligands such as thiocyanate.[5–7] Luminescence intensities increase with pressure for all complexes presented here, but to a lesser extent than for compounds with monodentate ligands, most likely due to the chelating ligands that block excited-state distortions along ligator atom – metal ion – ligator atom bending normal coordinates. Raman spectra show continuous changes of frequencies as a function of pressure, indicative of the absence of structural phase transitions in the pressure range studied. The spectra allow us to identify trends and to characterize differences between structurally very similar compounds.

Experimental

All reagents and solvents were purchased from Sigma-Aldrich and used without further purification.

Synthesis of [Pd(EDTC)$_2$] and [Pt(EDTC)$_2$]

Hydrated $PdCl_2$ was dissolved in a minimum of DMSO. Two equivalents of Na(EDTC) in an ethanol solution were then added, and a pale yellow powder immediately precipitated. It was filtered and washed with diethyl ether. Single crystals were obtained by slow evaporation of an acetone solution of the complex. Elemental analysis calculated for $C_{10}H_{20}N_2S_4Pd$ (402.96): C 29.81, H 5.00, N 6.95, S 31.83; found: C 29.97, H 5.02, N 6.86, S 28.51.

[Pt(EDTC)$_2$] was prepared in an analogous fashion from hydrated $PtCl_2$, orange crystals were obtained. Elemental analysis calculated for $C_{10}H_{20}N_2S_4Pt$ (491.62): C 24.43, H 4.10, N 5.70, S 26.09; found: C 24.54, H 4.07, N 5.63, S 25.89.

Synthesis of [Pd(PDTC)$_2$] and [Pt(PDTC)$_2$]

[Pd(PDTC)$_2$] was prepared from hydrated $PdCl_2$ and NH_4(PDTC) as described above. Pale yellow crystals were grown from an acetone solution of the complex. Elemental analysis calculated for $C_{10}H_{16}N_2S_4Pd$ (398.93): C 30.11, H 4.04, N 7.02, S 32.15; found: C 29.97, H 5.02, N 6.86, S 28.51.

Powdered [Pt(PDTC)$_2$] was prepared with the same method, and orange crystals were grown by slow evaporation of a dichloromethane solution of the complex. Elemental analysis calculated for $C_{10}H_{16}N_2S_4Pt$ (487.57): C 24.63, H 3.31, N 5.75, S 26.31; found: C 24.66, H 3.06, N 5.77, S 25.84.

Single crystal X-ray diffraction

X-ray crystallographic data for [Pd(PDTC)$_2$] were collected from a single crystal sample, which was mounted on a loop fiber. Data were collected using a Bruker Platform diffractometer, equipped with a Bruker SMART 2K Charged-Coupled Device (CCD) Area Detector using the program SMART and normal focus sealed-tube source graphite monochromated Cu K_α radiation. The crystal-to-detector distance was 4.908 cm, and the data collection was carried out in 512×512 pixel mode, utilizing 4×4 pixel binning. The initial unit cell parameters were determined by a least-squares fit of the angular setting of strong reflections, collected by a 9.0° scan in 30 frames over four different parts of the reciprocal space (120 frames total). One complete sphere of data was collected, to better than 0.8 Å resolution. Upon completion of the data collection, the first 101 frames were recollected to improve the decay correction analysis.

Note: Estimated standard deviations on the least-significant digits are given in parentheses.

All non-H atoms were refined by full-matrix least-squares with anisotropic displacement parameters. The H atoms were generated geometrically (C–H 0.97 Å and N–H 0.86 Å) and were included in the refinement in the riding model approximation; their temperature factors were set to 1.2 times those of the equivalent isotropic temperature factors of the parent site. A final verification of possible voids was performed using the VOID routine of the PLATON program.[9]

Spectroscopic measurements

The solution absorption spectra of the complexes were recorded with a double-beam Varian Cary 5E spectrophotometer. The luminescence and Raman spectra of the crystalline samples were measured using a Renishaw 3000 imaging microscope system equipped with a CCD camera. The excitation sources were the 488 and 514.5 nm lines of argon ion lasers for the luminescence experiments and the 785 nm line of a diode laser for the Raman experiments. All spectra are unpolarized and corrected for spectrometer response. Pressure was applied to the solid samples by loading crystals into a gasketed diamond-anvil cell (DAC, High-Pressure Diamond Optics) with paraffin oil as the pressure-transmitting medium. The ruby (R_1) method was used to calibrate the pressure.[10] All pressure effects reported here are reversible: upon gradual release of external pressure, all quantities return to their normal values at ambient pressure. For the temperature-dependent measurements, the samples were cooled in a gas-flow microcryostat system (Janis ST-500) with liquid nitrogen or liquid helium.

Luminescence lifetimes were measured using the 532 nm line of a pulsed Nd:YAG laser, a 0.5 m single monochromator (Spex 500M, 600 lines/mm grating) and a Hamamatsu R928 photomultiplier.[11,12]

Results

Crystal structure of $[Pd(PDTC)_2]$

The single crystal structure of $[Pd(PDTC)_2]$ was determined by X-ray diffraction at 120 K. The compound crystallizes in the $P\bar{1}$ space group, with $Z = 1$. The palladium atom lies at the inversion center of the cell. Table 1 provides further information about the unit cell.

The complex molecule displays a square-planar coordination for palladium(II), with the metal ion situated exactly in the plane of the four S donor atoms, as illustrated in Fig. 1. The Pd–S distances are 2.343(2) and 2.352(2) Å, typical for this kind of complex.[13,14] The S(1)–Pd–S(2) angle is 75.69(8)°, the distortion from a perfect square geometry being imposed by the chelating PDTC ligand, as summarized in Table 2. The C1 and N atoms lie fairly close to the coordination plane, consistent with the double-bond character of the C1–N bond. The complex molecules globally have planar structures, and are packed in parallel sheets, as illustrated in Fig. 2. The shortest intermolecular metal–metal distance is 6.38 Å, indicating that there is no Pd–Pd interaction. The C3 atom of each molecule is situated at a nearly axial position above the Pd atom of the molecule translated by a (0,0,1) vector, the distance between these two atoms being 3.85 Å. The Pd–C3 bond forms a 75.4° angle with the metal-coordination plane.

Although numerous palladium(II) and platinum(II) bis-dithiocarbamato complexes are known, only a few have been structurally characterized.[13–25] All of them have a planar centrosymmetric [MS4] core unit. Due to the shape of the dithiocarbamate ligands, the S–M–S angles are not exactly 90° but have values of approximately 75° for both platinum(II) and palladium(II) complexes. The M–S distances are within a 2.31–2.33 Å range for both metals. Structures for palladium(II) and platinum(II) complexes with identical ligands are isomorphous. None of the structurally characterized palladium(II) or platinum(II) dithiocarbamate complexes report any significant metal–metal interactions. The structural data presented here are in perfect agreement with structures reported for other dithiocarbamate complexes.

It is interesting to note that the complexes with EDTC ligands are packed orthogonally to one another, whereas the structures of the PDTC complexes consist of parallel sheets of molecular units.

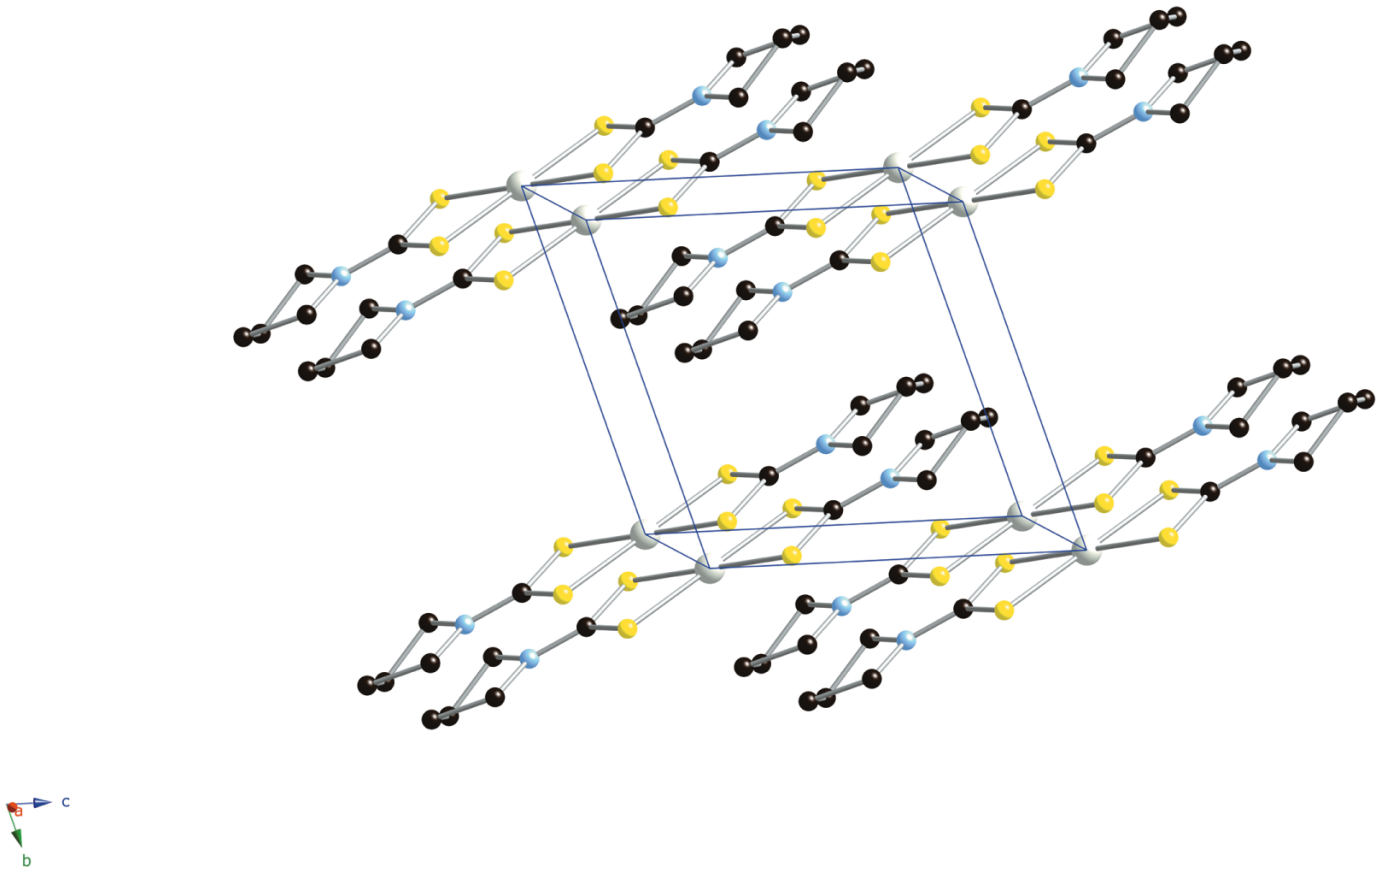
Absorption spectroscopy

The absorption spectra of the title complexes in solution have been recorded and are given as Supplementary data. In the region of the lowest-energy absorption bands, the spin-allowed d–d $^1A_{1g} \rightarrow {}^1E_g$ transition is higher in energy than the spin-forbidden $^1A_{1g} \rightarrow {}^3E_g$ band. For $[Pd(SCN)_4](n\text{-}Bu_4N)_2$,[11] the energy of the spin-forbidden transition is 16 450 cm^{-1} with a molar absorptivity ε of 10 $mol/L^{-1}cm^{-1}$, while the singlet–singlet transition occurs at 18 590 cm^{-1} and has a molar absorptivity ε of approximately 100 $mol/L^{-1}cm^{-1}$. The lowest-energy metal–ligand charge-transfer band has an energy of 29 000 cm^{-1}, significantly higher in energy than the d–d bands. For the platinum(II) complexes, the spin-forbidden $^1A_{1g} \rightarrow {}^3E_g$ transition is not observed due to its weak intensity and possible overlap with the onset of the spin-allowed d–d band. For $[Pt(SCN)_4](n\text{-}Bu_4N)_2$, this transition has an energy of 19 460 cm^{-1} and a molar absorptivity of less than 10 $mol/L^{-1}cm^{-1}$.[11] The spin-allowed d–d band of this complex has a maximum at 21 960 cm^{-1} ($\varepsilon > 100$ $mol/L^{-1}cm^{-1}$), similar to the $^1A_{1g} \rightarrow {}^1E_g$ transitions of both platinum(II) dithiocarbamate complexes. The absorption spectra of the title complexes are very similar to those of other square-planar d^8 complexes with sulfur ligator atoms.

Temperature-dependent luminescence and Raman spectroscopy

The luminescence spectra of crystals of the title compounds are broad, spanning up to 4500 cm^{-1}. The band maxima are at approximately 14 500 cm^{-1} for the palladium(II) complexes and 16 000 cm^{-1} for the platinum(II) complexes, values comparable to those reported in the literature for other square-planar complexes of these two metals.[11,12,26–30] It is commonly observed that the luminescence energies of square-planar platinum(II) complexes are higher than those of their palladium(II) analogs.[11,27]

Fig. 2. View of the crystal packing of $[Pd(PDTC)_2]$. The hydrogen atoms are omitted for clarity.



Figures 3 and 4 display representative temperature-dependent luminescence spectra of the four complexes on identical wavenumber scales. Their luminescence intensities clearly increase as temperature is lowered due to a lower rate of non-radiative relaxation at low temperature. The luminescence lifetimes of $[Pd(PDTC)_2]$ at three wavelengths have been measured at different temperatures as shown in Fig. 5. The luminescence lifetime of $[Pd(PDTC)_2]$ at 8 K is 650 μs, similar to the value of 947 μs observed for $[Pd(SCN)_4](n\text{-}Bu_4N)_2$ at 5 K.[11,12] This indicates that the nature of the luminescence transition is similar, confirming our d–d assignment. Much shorter lifetimes are observed at higher temperature. At 150 K, the lifetime is 0.1 μs for $[Pd(PDTC)_2]$, even shorter than the value of 19 μs for $[Pd(SCN)_4](n\text{-}Bu_4N)_2$ observed at this temperature,[11] a consequence of efficient non-radiative relaxation processes.

The temperature-dependent luminescence spectra of $[Pd(EDTC)_2]$ have been recorded between 20 K and 140 K. In this temperature range, the emission maximum is located at approximately 12 800 cm^{-1}. This is quite different from the value of 14 500 cm^{-1} observed at room temperature. The band at 12 800 cm^{-1} is only observed at low temperature, while another band emerges when the sample is heated above approximately 70 K, as illustrated in Fig. 3*b*, where the onset of the higher energy band is clearly visible in the spectrum measured at 70 K. A possible explanation for this could be the occurrence of a structural phase transition. The luminescence band maximum for $[Pd(PDTC)_2]$ is at approximately 14 100 cm^{-1}. The spectra of both palladium(II) complexes show a decrease in energy of the luminescence band maxima when the sample is heated from 70 K to room temperature, with a similar red shift of about -4 cm^{-1}/K.

Figure 4 displays the temperature-dependent luminescence spectra of $[Pt(EDTC)_2]$ and $[Pt(PDTC)_2]$. The luminescence intensity of those compounds also decreases with temperature. The temperature-dependent emission lifetimes of $[Pt(PDTC)_2]$ have been recorded at 16 667 cm^{-1}, close to the luminescence band maximum. They decrease with increasing temperature, from 700 μs at 77 K to 145 μs at 200 K. These lifetimes are somewhat longer than those for $[Pt(SCN)_4](n\text{-}Bu_4N)_2$, where values of 320 μs at 5 K and 0.3 μs at 200 K have been reported.[11] In contrast to the palladium(II) complexes, the platinum(II) complexes studied here show a blue shift of their luminescence band maxima with increasing temperature. The energy of the band maximum for $[Pt(EDTC)_2]$ changes from approximately 16 300 cm^{-1} at 15 K to approximately 16 600 cm^{-1} at 200 K, a blue shift of $+2.5$ cm^{-1}/K. A similar blue shift of $+3.3$ cm^{-1}/K is observed for $[Pt(PDTC)_2]$, with its emission maxima shifting from 15 800 cm^{-1} at 15 K to 16 500 cm^{-1} at 250 K.

Temperature-dependent Raman spectra of all four complexes have been recorded between 80 K and room temperature, given as Supplementary data. There are no major modifications in the shape of the spectra or major shifts of the Raman peaks for any of the compounds, suggesting that none of them undergoes a phase transition in this temperature range.

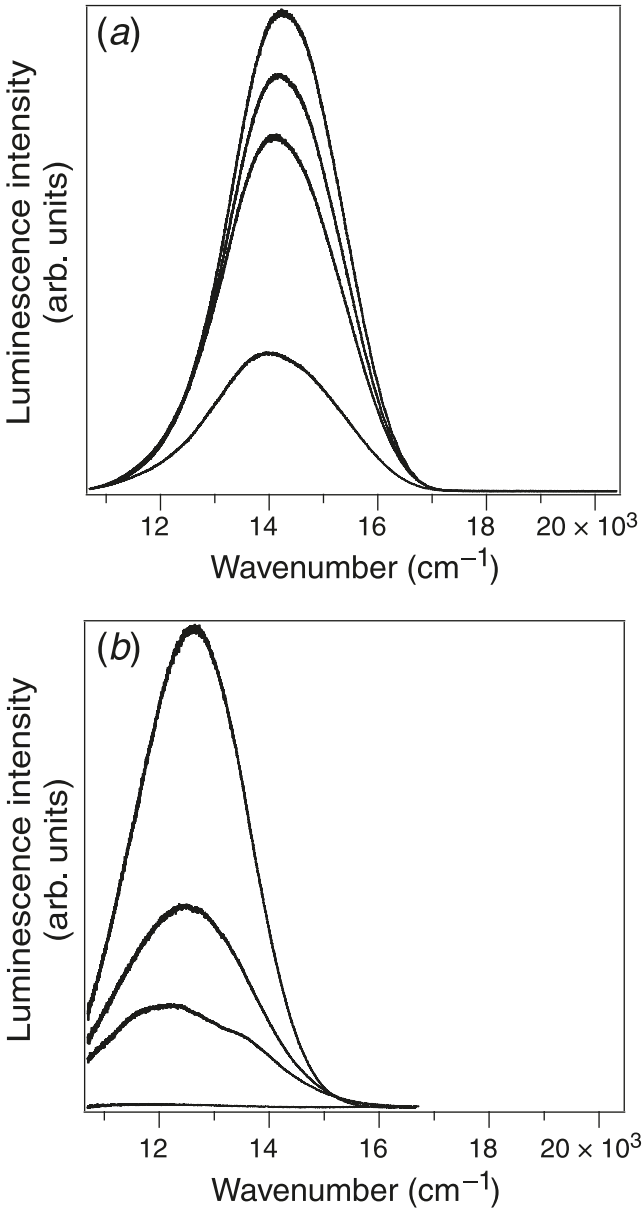

Fig. 4. Representative temperature-dependent luminescence spectra of (*a*) [Pt(PDTC)$_2$] at 78, 125, 200, and 250 K (top to bottom) and (*b*) [Pt(EDTC)$_2$] at 60, 150, and 200 K (top to bottom).

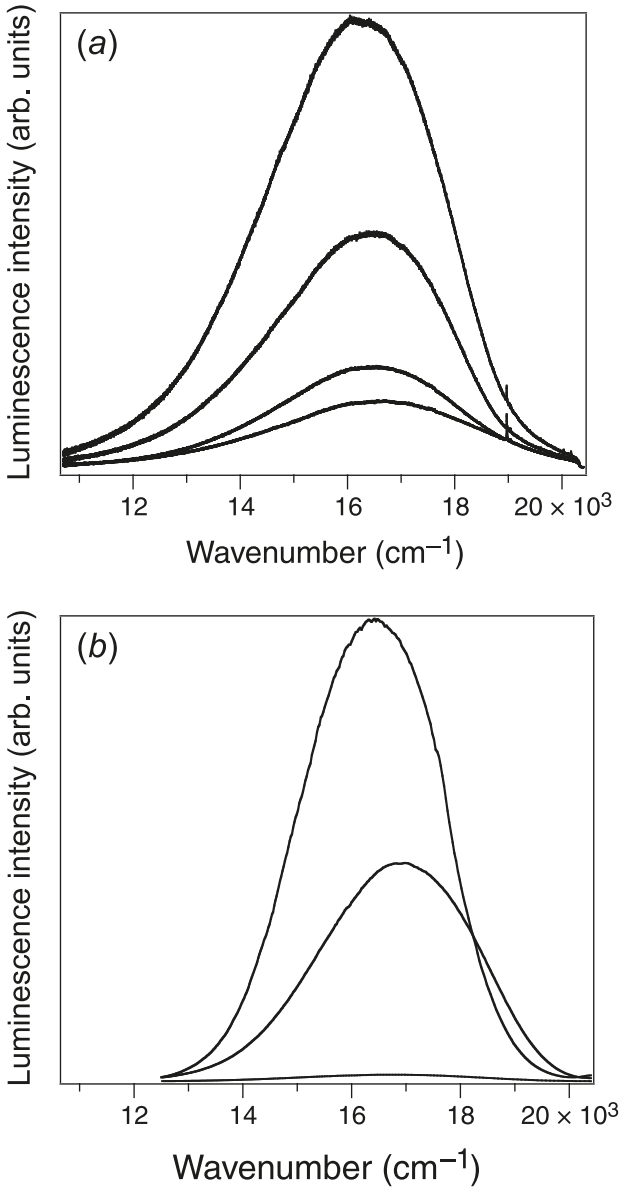
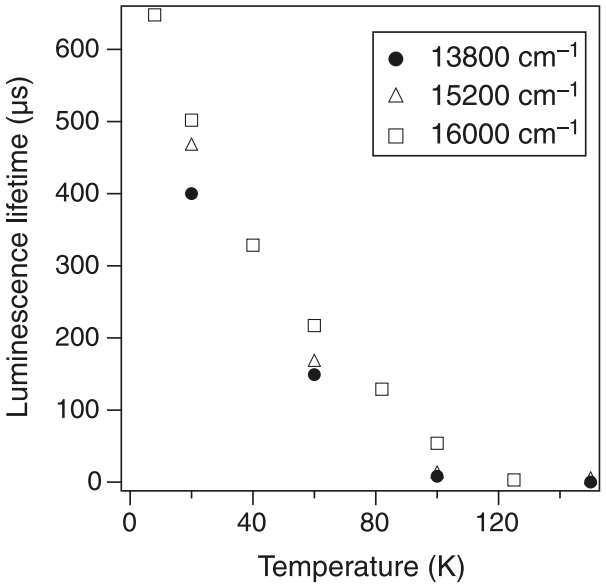


Pressure-dependent luminescence and Raman spectroscopy

Figures 6 and 7 show representative pressure-dependent luminescence spectra of the title compounds. The luminescence intensities show a fast and continuous increase with pressure, followed by a decrease above a threshold pressure. For the palladium(II) complexes, this effect is accompanied by a blue shift of the luminescence band maxima by +9 cm^{-1}/kbar for [Pd(EDTC)$_2$] and +13 cm^{-1}/kbar for [Pd(PDTC)$_2$]. This blue shift is easily seen by comparing the spectra of [Pd(PDTC)$_2$] at 21 kbar and 42 kbar in Fig. 6*a*. The luminescence of [Pt(EDTC)$_2$] displays a blue shift of +15 cm^{-1}/kbar. Although several attempts were made, it was not possible to establish a clear trend for the pressure-induced shift of the emission maximum for [Pt(PDTC)$_2$]. All luminescence maxima and shifts are summarized in Table 3. These blue shifts are comparable to those observed for palladium(II) and platinum(II) tetrathiocyanate and tetraselenocyanate complexes.[11,31] They are clearly different from the red shifts observed for the well-studied tetracyanoplatinate(II) complexes where the metal–metal interaction between the stacked [Pt(CN)$_4$]$^{2-}$ chromophores[32,33] is enhanced by pressure, leading to strong red shifts of the luminescence maxima. No such interactions are present in the dithiocarbamate complexes, as shown by the pressure effects reported here.

Pressure-dependent Raman spectra of the four title complexes are shown in Figs. 8 and 9. The 100–600 cm^{-1} region contains the vibrational modes involving the metal ions and ligator atoms. The ambient-pressure Raman spectra of [Pd(EDTC)$_2$] and [Pt(EDTC)$_2$] and those of [Pd(PDTC)$_2$] and [Pt(PDTC)$_2$] are similar in shape and number of peaks.

Fig. 5. Temperature-dependent luminescence lifetimes for $[Pd(PDTC)_2]$ measured at different wavelengths across the emission spectrum. The excitation wavelength is 532 nm.



Changes of the band shapes and Raman shifts occur as pressure is increased on the crystalline samples. A precise study of the evolution of each Raman band shows that most of them are shifted towards higher energies as pressure is increased, indicative of shorter and stronger chemical bonds at high pressure. The Raman band maxima of all four complexes show linear shifts with pressure. The shape of the peaks is also influenced by pressure. It is interesting to note that the complexes with the two different ligands show a different behavior. The bands at 160–175 cm^{-1} and at 400 cm^{-1} are split and enlarged at high pressure for both EDTC complexes, but not for the PDTC complexes. This difference could indicate a possible structural phase transition in the EDTC complexes, most likely involving slight changes in packing. The pressure-dependent luminescence spectra of the EDTC complexes in Figs. 6*b* and 7*b* do not show evidence for a structural phase transition, as the bands are likely too large to be influenced by small changes in the packing of the chromophores. In general, it appears that the EDTC complexes are more susceptible to structural phase transitions, as illustrated by the pressure-dependent Raman spectra and the temperature-dependent luminescence spectra in Fig. 3*b*.

Discussion

Assignment of the luminescence transitions

The absorption spectra of the title complexes all show bands with molar absorptivities of 2000 $mol/L^{-1}cm^{-1}$ or less, which can be attributed to d–d transitions. $[Pd(EDTC)_2]$ in particular has a very weak band at 16 050 cm^{-1}, corresponding to the symmetry and spin-forbidden $^1A_{1g} \rightarrow {}^3E_g$ transition. This is a strong indication that the observed luminescence bands also are of a d–d nature. The oscillator strength of the corresponding absorption bands in thiocyanate and halide complexes with better resolved bands than observed for the title complexes increases with temperature, again typical for forbidden d–d transitions gaining vibronic intensity.[26,27,34] The comparison of the luminescence spectra of the dithiocarbamate complexes with those of $[Pd(SCN)_4](n\text{-}Bu_4N)_2$ and $[Pt(SCN)_4](n\text{-}Bu_4N)_2$, which also show d–d transitions,[11,26,31] supports this assignment. The observed luminescence lifetimes at low temperatures for the dithiocarbamate complexes are between 300 μs and

1000 μs, similar to those reported for the thiocyanate complexes.[11] The luminescence maxima of both kinds of complexes can also be compared. They are observed between 14 200 cm^{-1} and 14 800 cm^{-1} for all platinum(II) complexes and between 12 400 cm^{-1} and 12 800 cm^{-1} for palladium(II) tetrathiocyanate and tetraselenocyanate complexes, close to the band maxima of the title complexes summarized in Table 3. The width at half height of the luminescence bands of the dithiocarbamate complexes is between 2500 cm^{-1} and 4000 cm^{-1}, again similar to the thiocyanate compounds.

Vibronic structure in low-temperature luminescence spectra

The low-temperature luminescence spectra of [Pd(EDTC)$_2$] and [Pd(PDTC)$_2$] display vibronic progressions. The intensity distributions provide insight on the structural changes which the complex molecules undergo when emitting a photon. The simplest model to analyze vibronic progressions is based on harmonic potential energy curves along a single configurational coordinate with identical vibrational frequencies for the ground and emitting states. The theoretical equations used to calculate spectra have been published and discussed in detail before.[35–37] The energy of the electronic origin of the luminescence band maximum E_{00} and the dimensionless normal coordinate offset Δ are the only adjustable parameters. Vibrational frequencies are known from the Raman spectra, and the width of the vibronic lines Γ is set to a value somewhat lower than observed to better illustrate the progression. The 7 K luminescence spectrum of [Pd(EDTC)$_2$] is displayed in Fig. 10*a*, along with a series of calculated spectra. The average interval between the members of the progression in the experimental spectrum is 390 cm^{-1}, close but not identical to the observed frequency of 381 cm^{-1}, corresponding to the range of the M–S_4 stretching vibrations. This discrepancy is possibly a manifestation of a missing mode effect.[29,37] The consequence of a variation of the offset Δ by ±10% is shown by the dotted calculated spectra in Fig. 10*a*. It is obvious that these spectra do not reproduce the band width and intensities within the progression as well as the best calculated spectrum shown as a solid line. The low value for Δ leads to a calculated spectrum narrower than the experimental spectrum; the high value results in a calculated band larger than the experimental spectrum, indicating that offsets are defined to within better than 10% by the simple model used here. The comparison of the luminescence spectrum of [Pd(PDTC)$_2$] measured at 6 K and a calculated spectrum is shown in Fig. 10*b*. The parameter values obtained for the palladium(II) dithio-

carbamate complexes are summarized in Table 4 and compared to literature values for [Pd(SCN)$_4$](*n*-Bu$_4$N)$_2$.[11] The low-temperature spectrum of [Pd(SCN)$_4$](*n*-Bu$_4$N)$_2$ displays better resolved vibronic structure than the spectra in Fig. 10. Four different vibrational modes contribute to the observed progressions. The normal coordinate offset Δ for the totally symmetric (a_{1g}) mode is lower for [Pd(SCN)$_4$](*n*-Bu$_4$N)$_2$ than for the two palladium(II) dithiocarbamate complexes. This is due to the fact that other vibrational modes are identified in the vibronic structure of [Pd(SCN)$_4$](*n*-Bu$_4$N)$_2$, allowing the emitting-state distortion of the molecule to be distributed on several normal coordinates. In contrast, the low-temperature spectra of the dithiocarbamate complexes in Fig. 10 are not sufficiently resolved to determine multiple offsets, and only a single coordinate is used in our analysis, leading to the results in Table 4.

Pressure effects on luminescence and Raman spectra

A detailed study of the pressure-dependent Raman spectra of the four title complexes shows that a vast majority of the frequencies increase when pressure is imposed on the samples. This is an indication that submitting the crystals to a higher pressure reduces most interatomic distances, as is intuitively expected. The frequencies of the Raman bands vary linearly with pressure, and there is no sign of an abrupt change that would indicate a phase transition in the studied pressure range.

The luminescence spectra of the palladium(II) and platinum(II) dithiocarbamate complexes also show a pressure-dependence. Their luminescence energies are shifted towards higher values with pressure, as is the case for [Pd(SCN)$_4$](*n*-Bu$_4$N)$_2$ and [Pt(SCN)$_4$](*n*-Bu$_4$N)$_2$[11,12] with numerical values given in Table 3. These blue shifts are linear with pressure, and the width of the luminescence bands does not vary significantly over the studied pressure range. The sign of the shift is due to the σ-antibonding $d_{x_2-y_2}$ LUMO whose energy increases sharply with decreasing metal–S distances. The HOMO is π-antibonding, and its energy increases to a lesser extent as bond lengths de-

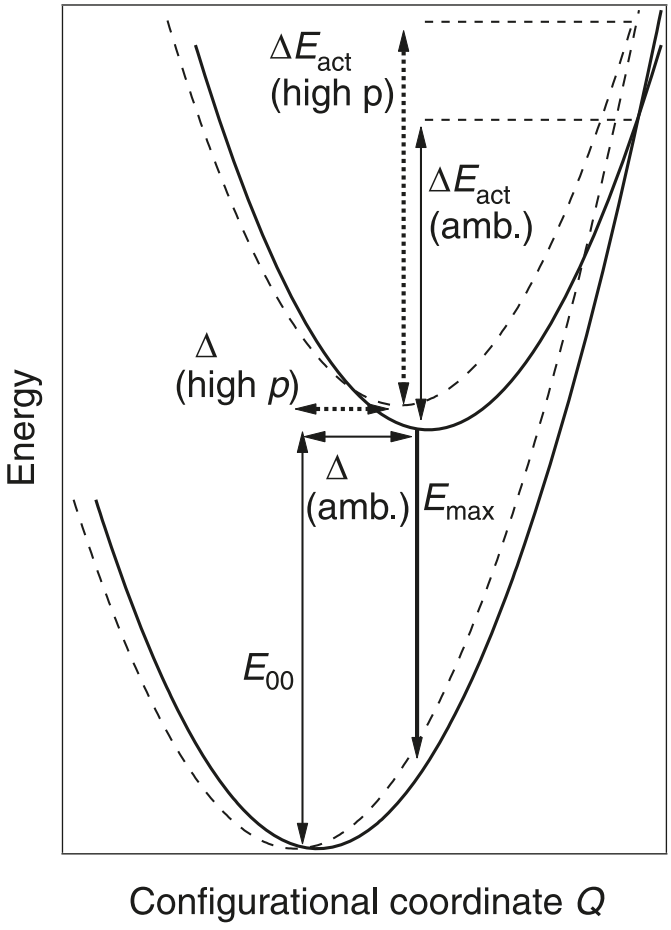
Fig. 11. One-dimensional harmonic potential energy curves of the ground and excited states at atmospheric pressure (solid lines) and high pressure (dotted lines). ΔE_{act} represents the activation energy barrier for non-radiative relaxation in a qualitative model view.



crease. These blue shifts again support the d–d assignment for the luminescence transitions.

At room temperature and ambient pressure, the luminescence of the title complexes is fairly weak, but all four compounds exhibit a pressure-induced enhancement of their luminescence intensities. The same phenomenon takes place, albeit in a more dramatic fashion, with the $[M(SCN)_4](n\text{-}Bu_4N)_2$ (M = Pd(II), Pt(II)) complexes, whose luminescence intensities increase by two to three orders of magnitude between ambient pressure and 30 kbar.[11,12] The enhancement of the luminescence intensity is due to less efficient non-radiative processes at high pressure, as documented by lifetimes for thiocyanate complexes.[11,12] This effect can be qualitatively rationalized with the model shown in Fig. 11, based on the same potential energy curves used for the calculations in Fig. 10. The main effect of high pressure is a decrease of the offset Δ along the coordinate Q, leading to a higher activation energy barrier for non-radiative relaxation, as illustrated by the dotted potential energy curves denoting the ground and emitting states at high pressure. While this model rationalizes the observed luminescence intensity increase, it cannot account quantitatively for the observed behavior, as many factors, such as the different influence of several normal coordinates with nonzero offsets Δ, the change of the potential energy curves with increasing pressure, and all energy-transfer processes are neglected. The effects of multiple modes can be analyzed from the well-resolved luminescence transition of $[M(SCN)_4](n\text{-}Bu_4N)_2$ (M = Pd, Pt),[11] and the offset along some of these modes could be blocked by the rigidity of the chelate ligand, thus not allowing a shift of the wells along this coordinate for the title compounds. Pressure appears to have a smaller effect on the chelate compounds and causes a smaller enhancement of their luminescence intensities. This reasoning is further supported by the values of the luminescence energy shifts of the dithiocarbamate compounds, which are also lower than for the thiocyanate complexes.

The pressure-dependent Raman spectra support this analysis, since the frequency of the totally symmetric metal–ligand stretching mode shifts less in the dithiocarbamate than in the tetrathiocyanate compounds. The precise values of the pressure-induced shifts are +0.17 cm^{-1}/kbar and +0.49 cm^{-1}/kbar for $[Pd(EDTC)_2]$ and $[Pd(PDTC)_2]$, respectively, lower than the value of +0.68 cm^{-1}/kbar for $[Pd(SCN)_4](n\text{-}Bu_4N)_2$.[11,12] For the platinum(II) complexes, the values are +0.29 cm^{-1}/kbar for $[Pt(EDTC)_2]$ and +0.47 cm^{-1}/kbar for $[Pt(PDTC)_2]$, again lower than the value of +0.60 cm^{-1}/kbar for $[Pt(SCN)_4](n\text{-}Bu_4N)_2$.[11] It is interesting to note the different evolution of the Raman spectra of the EDTC and the PDTC complexes of both metal ions with pressure. Both EDTC complexes exhibit a splitting of their 160–175 cm^{-1} band, corresponding to the metal–sulfur bending mode. A band at approximately 400 cm^{-1} also shows a pressure-induced splitting. The frequency of the bending mode shifts by +0.19 cm^{-1}/kbar and +0.17 cm^{-1}/kbar for palladium(II) and platinum(II), respectively, less than in the thiocyanate complexes, where shifts of +0.72 cm^{-1}/kbar and +0.78 cm^{-1}/kbar are observed. In the PDTC complexes, this frequency shifts by +0.83 cm^{-1}/kbar for palladium(II) and by +0.80 cm^{-1}/kbar for platinum(II), closer to the values observed for complexes with monodentate ligands. It can be assumed that the metal–sulfur bending mode is more affected by pressure in the EDTC compounds than in their PDTC

analogues or in $[M(SCN)_4](n\text{-}Bu_4N)_2$ (M = Pd, Pt). The orthogonal structure of the EDTC complexes seems more easily perturbed by pressure than the parallel sheet structure of their PDTC counterparts. The alkyl substituents are also more prone to be disordered than the pyrrolidine cycle. When pressure is increased on the crystal, there is a higher probability of them arranging differently, thus provoking the broadening and splits of certain Raman bands observed for the EDTC compounds.

The spectroscopic comparison of d^8 complexes, with different substituents on otherwise identical chelating ligands shows that even groups located far from the metal core of the complex can have a bearing on the spectroscopic features of the complexes. Pressure-dependent spectroscopic methods as those illustrated here can therefore be valuable tools to probe detailed effects in solid molecular materials.

Cowaxanthone F, a new tetraoxygenated xanthone, and other anti-inflammatory and antioxidant compounds from *Garcinia cowa*

Kanda Panthong, Nongporn Hutadilok-Towatana, and Ampai Panthong

Abstract: A new tetraoxygenated xanthone, cowaxanthone F (**1**), as well as four known compounds, morelloflavone (**2**), volkensiflavone (**3**), morelloflavone-7″-*O*-glucoside (fukugiside, **4**), and 1,6-dihydroxyxanthone (**5**), were isolated from the crude acetone extract of the twigs of *Garcinia cowa* (Guttiferae). All compounds (**1**–**5**) were tested for antioxidant activity against DPPH (diphenylpicrylhydrazyl), hydroxyl, and superoxide radicals; only morelloflavone (**2**) and morelloflavone-7″-*O*-glucoside (**4**) exhibited high potency. Eight tetraoxygenated xanthones from the fruits of *G. cowa*, cowaxanthones A–D (**6**–**9**), cowanin (**15**), α-mangostin (**16**), mangostanin (**17**), and cowanol (**18**), were also investigated for anti-inflammatory activity using ethyl phenylpropiolate (EPP)-induced ear edema. Assessment at 30, 60, and 120 min revealed that cowaxanthones B–D (**7**–**9**), cowanin (**15**), and α-mangostin (**16**) exhibited significant anti-inflammatory activity when compared to phenylbutazone, while cowaxanthone A (**6**), mangostanin (**17**), and cowanol (**18**) showed less activity.

Key words: Guttiferae, *Garcinia cowa*, cowaxanthone F, anti-inflammatory activity, antioxidant activity.

Résumé : On a isolé une nouvelle xanthone tétraoxygénée, la cowaxanthone F (**1**) ainsi que quatre composés connus : morelloflavone (**2**), volkensiflavone (**3**), morellosflavone-7″-*O*-glucoside (fukugiside, **4**), et la 1,6-dihydroxyxanthone (**5**) à partir de l'extrait brut à l'acétone des rameaux de *Garcinia cowa* (Guttiferae). On a testé tous les produits pour leurs propriétés antioxydantes contre les radicaux DPPH, hydroxyles et superoxydes et seuls la morelloflavone (**2**) et le morellosflavone-7″-*O*-glucoside présentent des potentiels élevés. On a aussi examiné huit xanthones tétraoxygénées extraites des fruits de *G. cowa* : cowaxanthones (A–D) (**6**–**9**), cowanine (**15**), α-mangostine (**16**), mangostanine (**17**) et cowanol (**18**) pour déterminer leur activité anti-inflammatoire à l'aide de l'œdème de l'oreille induite par EPP. L'évaluation à 30, 60 et 120 minutes révèle que, par comparaison avec la phénylbutazone, les cowaxanthones (B–D) (**7**–**9**), cowanine (**15**) et α-mangostine (**16**) présentent une activité anti-inflammatoire significative alors que la cowaxanthones (A) (**6**), la mangostanine (**17**) et le cowanol (**18**) en possède moins.

Mots-clés : Guttiferae, *Garcinia cowa*, cowaxanthone F, activité anti-inflammatoire, activité antioxydante.

[Traduit par la Rédaction]

Introduction

Garcinia cowa Roxb. (Guttiferae, Clusiaceae), commonly known as "Cha-muang", is a small to medium sized tree found widely distributed in Thailand. The fruits and leaves are used for the improvement of blood circulation, as an expectorant for the treatment of coughs and indigestion, and as a laxative, while the root is used for fever relief.[1] The bark of *G. cowa* has been used in Thai folk medicine as an antipyretic agent.[2] Xanthones and flavanone glucosides were isolated from *G. cowa* by other groups.[2–7] Our previous phytochemical study of its fruits has led us to the isolation of five new tetraoxygenated xanthones (cowaxanthones A–E, **6**–**10**), and 10 known tetraoxygenated xanthones.[8] In this continuing investigation on its twigs, one new xanthone was identified. We describe herein the isolation and structural elucidation of the new tetraoxygenated xanthone (**1**), named cowaxanthone F, as well as four other known compounds. In a search for bioactive substances from this plant, we also evaluated the antioxidant activity of all compounds isolated from the twigs as well as the anti-inflammatory activity of eight tetraoxygenated xanthones from the fruits.

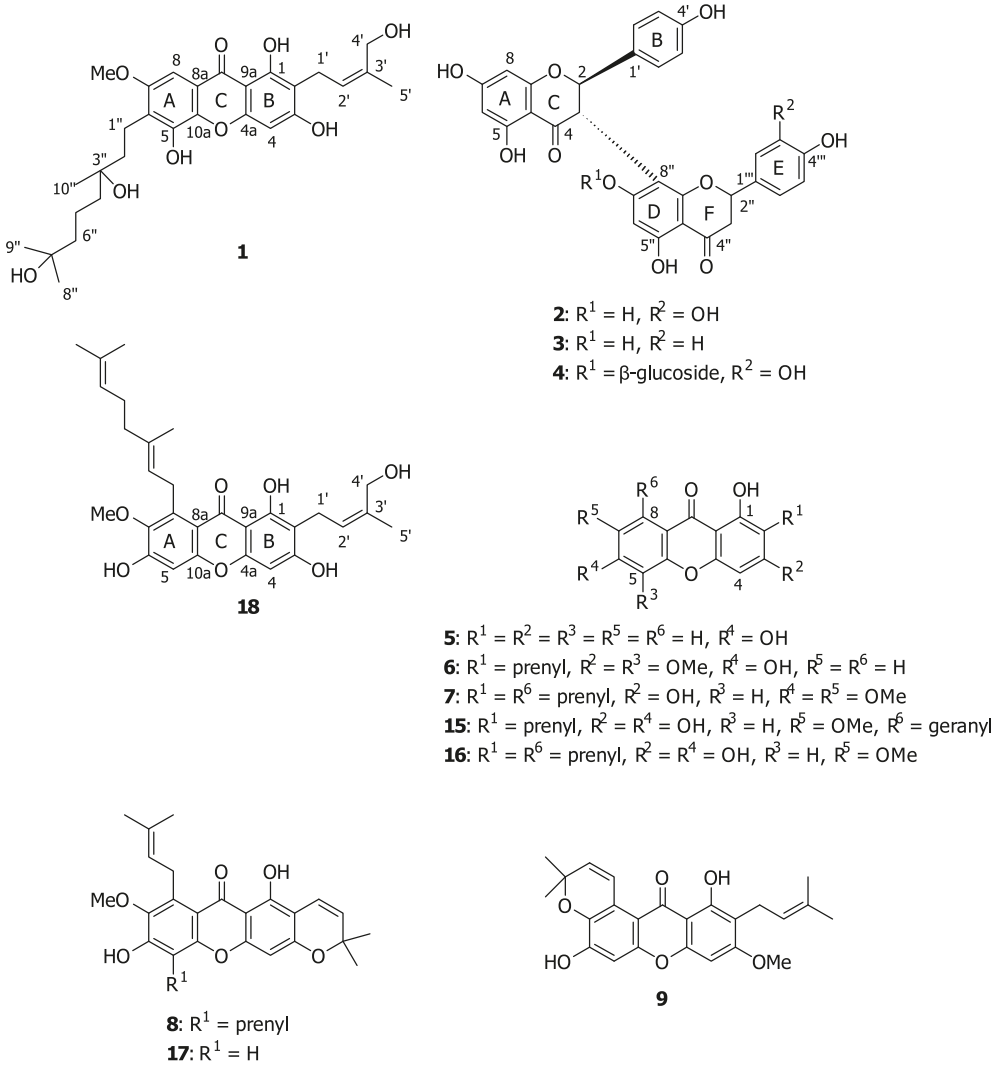
Results and discussion

The acetone extract of the dried twigs of *G. cowa* was subjected to chromatographic purification to yield one new tetraoxygenated xanthone (cowaxanthone F, **1**), together with four known compounds: morelloflavone (**2**),[9–11] volkensiflavone (**3**),[12,13] morelloflavone-7″-*O*-glucoside (fukugiside, **4**),[14,15] and 1,6-dihydroxyxanthone (**5**).[16] The structures of all compounds were elucidated by analysis of 1D and 2D NMR spectroscopic data. The ^{1}H and (or) ^{13}C spectroscopic data of known compounds (see Fig. 1) were also compared with those reported in the literature.

Fig. 1. Structures of isolated compounds.



Cowaxanthone F (**1**) was obtained as a pale yellow solid. Its molecular formula was determined as $C_{29}H_{38}O_9$ by HRTOFMS (atmospheric pressure chemical ionization (APCI) positive) measurement for $C_{29}H_{38}O_9Na$ at *m/z* 553.2366 (calcd. 553.2414). The IR spectrum of compound **1** suggested hydroxyl (3436 cm^{-1}) and carbonyl absorptions (1639 cm^{-1} (conjugated aryl ketone)). The UV spectrum showed absorptions at 243, 257, and 316 nm, which is typical of the xanthone chromophore.[17] The ^1H NMR spectrum (Table 1) was comparable to that of cowanol (**18**).[2,8] The differences were found at position 5, 6, and 8 of ring A. An aromatic proton (δ 6.72, s)[2,8] at position 5 of **18** was replaced, in **1**, by a hydroxyl proton (δ 9.95, br s). The hydroxyl group (not observed)[2, 8] at position 6 of **18** was replaced, in **1**, by a dihydroxy geranyl group (δ 3.44 (2H, m, H-1″), 1.77 (2H, m, H-6″), 1.57 (4H, m, H-2″ and H-5″), 1.30 (6H, s, H-8″ and H-9″), and 1.20 (3H, s, H-10″)). In the HMBC spectrum (Table 1), the methylene protons (δ 3.44, H-1″) of the dihydroxy geranyl unit showed cross peaks with C-5 (δ 160.7), C-6 (δ 139.4), and C-7 (δ 143.6), indicating the attachment of the dihydroxy geranyl side chain at C-6. The geranyl group (δ 5.24 (1H, br t, *J* = 6.0 Hz), 5.01 (1H, br t, *J* = 6.6 Hz), 4.03 (2H, d, *J* = 6.0 Hz), 2.02 (4H, m), 1.83 (3H, s), 1.58 (3H, s), and 1.53 (3H, s)) at position 8 of **18** was replaced, in **1**, by an aromatic proton (δ 6.84, s) whose assignment was confirmed by its HMBC cross peaks with C-7 (δ 143.6), C-8a (δ 110.7), C-9 (δ 181.9), and C-10a (δ 155.5). In addition, the substituents on ring B were located at the same position as those of **18**, indicated by HMBC correlations and comparison of the NMR data of **1** and **18**. Thus, cowaxanthone F was identified as 1,3,5-trihydroxy-7-methoxy-2-(3-methyl-4-hydroxy-2-butenyl)-6-(3,7-dihydroxy-3,7-dimethyloctyl)xanthone (**1**).

When compounds **1** (cowaxanthone F), **2** (morelloflavone), **3** (volkensiflavone), **4** (morelloflavone-7″-*O*-glucoside), and **5** (1,6-dihydroxyxanthone), isolated from the twigs of *G. cowa*, were evaluated for their free radical scavenging activities, only **2** and **4** were effective in the DPPH (diphenylpicrylhydrazyl) assay.[18] Both compounds showed equal potency with an IC_{50} value of 18 μmol/L, whereas the butylated hydroxytoluene (BHT) control had an IC_{50} of 136 μmol/L. These results implied that the crucial parts responsible for the radical scavenging activity should be the ortho dihydroxy of ring E.[19–21] Compounds **2** and **4** also exerted their inhibitory effects on the hydroxyl radical with IC_{50} values of 0.56 and 0.74 mmol/L, respectively, which are rather weaker than

tannin (IC_{50} 0.12 mmol/L). Thus, a substitution of a hydroxyl group at C-7″ of morelloflavone (**2**) by a sugar moiety as in **4** seems to diminish the hydroxyl radical scavenging activity. In the superoxide anion assay, compound **4** (IC_{50} 0.89 mmol/L) was less effective than compound **2** (IC_{50} 0.27 mmol/L), however, both compounds showed better activity than the standard trolox (IC_{50} 1.36 mmol/L). Taken together with the above results, it is likely that a sugar moiety at the C-7″ position of ring D would not only diminish the superoxide dismutase-like activity but also attenuate the potency to scavenge the most reactive hydroxyl radical (comparison of **2** and **4**).

Eight compounds, cowaxanthones A–D (**6**–**9**), cowanin (**15**), α-mangostin (**16**), mangostanin (**17**), and cowanol (**18**), previously isolated from the fruits of *G. cowa*, were investigated for anti-inflammatory activity in a rat ear edema model (Table 2).[22] At 15 min after ethyl phenylpropiolate (EPP) application, cowaxanthones B (**7**) and C (**8**) exhibited the strongest anti-inflammatory activity while cowaxanthone D (**9**), cowanin (**15**), and α-mangostin (**16**) showed moderate activity and the others exhibited less activity. However, at 30, 60, and 120 min after administration of EPP, it was found that most compounds showed similar intensity of anti-inflammatory effect as those of phenylbutazone. Only cowanol (**18**) showed less activity. The results suggested the inhibitory effect of the compounds on synthesis and (or) release of inflammatory mediators involved in this model, especially histamine, kinins, and prostaglandins.

Experimental

General

Melting points were determined on an Electrothermal 9100 melting point apparatus and are uncorrected. IR spectra were obtained using a FTS 165 FTIR spectrometer (PerkinElmer 783). UV spectra were recorded using a UV-160A spectrophotometer (SHIMADZU). ^{1}H and ^{13}C NMR spectra were recorded on a Bruker FTNMR Ultra Shield™ 300 MHz and 500 MHz spectrometer using a $CDCl_3$ solution unless otherwise stated with TMS (tetramethylsilane) as the internal standard. EIMS were measured on a Thermo Finnigan Polaris Q mass spectrometer at 70 eV (probe). The HRMS were recorded on a Micromass model VQ-TOF-2 spectrometer. Optical rotations were measured on a JASCO DIP-370 digital polarimeter by using a 50 mm microcell (1 mL). TLC (thickness 200 μm) and precoated TLC (thickness 250 μm) were performed on silica gel 60 F_{254} (Merck). Quick column chromatography (QCC) and column chromatography (CC) were performed on silica gel (Merck) types 60H and 100 (70–230 mesh ASTM), respectively.

Plant material

The twigs of *G. cowa* Roxb. were collected from Sathingmoo District, Amphur Singhanakhon, Songkhla Province, in the southern part of Thailand, in June 2003. A voucher specimen (WIPAPAN 01) has been deposited at the Herbarium of the Department of Biology, Faculty of Science, Prince of Songkla University, Thailand.

Extraction and isolation

The dried and chopped twigs of *G. cowa* (2 kg) were extracted with acetone (5 L) for 7 d at room temperature three times. Filtration and subsequent evaporation of the combined acetone extracts to dryness in vacuo afforded a dark brown gum (40.48 g). The crude acetone extract (22.56 g) was subjected to QCC, eluting with CH_2Cl_2 and MeOH in a polarity-gradient manner to afford seven fractions.[1–7] Fraction 3 (2.26 g, eluted with 10%–20% MeOH–CH_2Cl_2) was further purified by CC on silica gel and eluted with a gradient of CH_2Cl_2–MeOH to afford **5** (12.0 mg). Fraction 4 (674.7 mg, eluted with 20%–30% MeOH–CH_2Cl_2) was further separated by CC using a gradient of CH_2Cl_2–MeOH to afford **3** (18.04 mg) and **4** (25.6 mg). Fraction 5 (8.10 g, eluted with 30%–50% MeOH–CH_2Cl_2) was fractionated further by QCC using a gradient system (CH_2Cl_2–MeOH) to yield four subfractions (A1–A4). Subfraction A2 (3.26 g, eluted with 5%–8% MeOH–CH_2Cl_2) was further subjected to QCC using CH_2Cl_2–MeOH to yield 8 fractions (B1–B8). Further chromatography of fraction B7 (650 mg) on CC and preparative TLC using 8% MeOH–CH_2Cl_2 as a mobile phase (4 elutions) gave **2** (379.6 mg) and **3** (23.0 mg) as a yellow solid. Subfraction A3 (663.6 mg, eluted with 4%–10% MeOH–CH_2Cl_2) was further subjected to CC using CH_2Cl_2–MeOH as an eluent to give five subfractions (C1–

C5). Further chromatography of subfraction C2 (181.4 mg) on CC and preparative TLC using 10% MeOH–CH_2Cl_2 as a mobile phase (3 elutions) yielded a yellow solid of **1** (5.1 mg) and a yellow solid of **2** (100.9 mg). Subfraction C3 (253.6 mg) was further subjected to CC, followed by preparative TLC using 14% MeOH–CH_2Cl_2 as a mobile phase (4 elutions) to give a yellow solid of **3** (17.3 mg) and a yellow solid of **4** (147.2 mg). Subfraction A4 (1.54 g, eluted with 10%–15% MeOH–CH_2Cl_2) was further purified by CC, followed by preparative TLC using 12% MeOH–CH_2Cl_2 as a mobile phase (7 elutions) to yield a yellow solid of **4** (117.6 mg).

1,3,5-Trihydroxy-7-methoxy-2-(3-methyl-4-hydroxy-2-butenyl)-6-(3,7-dihydroxy-3,7-dimethyloctyl)xanthone (cowaxanthone F, 1)

Animals

Male Sprague-Dawley rats weighing 40–60 g were purchased from the National Laboratory Animal Center, Nakorn Pathom. The animals had free access to water and food and were acclimatized at least one week before starting the experiments. The animal experiment was performed according to the Ethical Principles and Guidelines for the Use of Animals prepared by the National Research Council of Thailand.

Anti-inflammatory activity

The method described by Brattsand et al.,[22] ethyl phenylpropiolate (EPP)-induced ear edema in rat, was performed. Male rats weighing 40–60 g were used. Ear edema was induced by topical application of EPP, dissolved in acetone, at a dose of 1 mg/20 μL per ear to the inner and outer surfaces of both ears by means of an automatic microliter pipet. Each test compound, also dissolved in acetone, was applied topically in a volume of 20 μL just before the EPP. The control group received acetone only. Before and at 15, 30, 60, and 120 min after edema induction, the thickness of each ear was measured by the digital vernier calipers. The percent inhibition of the edema formation of test substances was calculated.

Free radical scavenging activity

In this study, three assays were carried out, as previously described by Hutadilok-Towatana et al.,[18] as follows.

DPPH assay

To different concentrations of a sample in methanol (0.5 mL each) was added 1 mL of a methanolic solution of 0.2 mmol/L DPPH. After mixing thoroughly, the mixture was allowed to stand in the dark for 30 min and the absorbance at 523 nm was measured using methanol for the baseline correction. The results were then compared with that of the control, which was prepared as above but without a test sample. Radical scavenging activity was expressed as a percentage and was calculated using the following formula: %Scavenging = $[(A_{control} - A_{sample}) / A_{control}] \times 100$. For each sample, the result was presented as an IC_{50} (the sample concentration that produced 50% scavenging of the DPPH radical). BHT (butylated hydroxytoluene) was used as a positive control.

Hydroxyl radical scavenging assay

Various amounts of test sample were mixed with 134 μL of 30 mmol/L KH_2PO_4–KOH buffer (pH 7.4), 67 μL of 17 mmol/L deoxyribose, 33 μL of 34 mmol/L H_2O_2, 33 μL of 1.2 mmol/L EDTA (ethylenediaminetetraacetic acid), 67 μL of 300 μmol/L $FeCl_3$, and 67 μL of 600 μmol/L ascorbic acid was then added to start the reaction. After incubation at 37 °C for 1 h, the products of the hydroxyl radical attack on deoxyribose were determined by adding 333 μL of 1% (*w/v*) TBA (thiobarbituric acid) in 50 mmol/L NaOH, followed by 333 μL of 2.8% (*w/v*) TCA (trichloroacetic acid). After further incubation at 80 °C for 20 min, the reaction mixtures were centrifuged. The clear supernatants were then measured for their absorption at 532 nm. A parallel assay omitting the test sample was used as a control whereas that without the addition of deoxyribose was used as a sample blank. The results were expressed as percent inhibition of the deoxyribose attack using the following formula: %In-

hibition = $[(A_{control} - (A_{sample} - A_{sample\ blank}) / A_{control}] \times 100$. For each sample, the result was presented as an IC_{50} (the sample concentration that produced 50% inhibition of hydroxyl radical). Tannin was used as a positive control.

Superoxide anion scavenging assay

Test samples were prepared in methanol and 20 μL of each was added to 1 mL of the reagent composed of 9.9 mmol/L L-methionine, 1.72 mmol/L NBT (nitroblue tetrazolium), 1% (*w*/*v*) Triton X-100, and 117 μmol/L riboflavin in 50 mmol/L K_2HPO_4, with a pH 7.8. After mixing, the reaction mixture was illuminated under a 40 W fluorescent light for 7 min. A control tube in which the test sample was replaced by methanol and a sample blank, which contained no riboflavin, were also run in parallel. The absorbance at 560 nm was then measured. The results were expressed as percent scavenging of the superoxide radical using the following formula: %Scavenging = $[(A_{control} - (A_{sample} - A_{sample\ blank}) / A_{control}] \times 100$. For each sample, the result was presented as an IC_{50} (the sample concentration that produced 50% inhibition of superoxide radical). Trolox was used as a positive control.

Acknowledgements

K.P. would like to thank the Prince of Songkla University for a research grant. The authors are grateful to Associate Professor Dr. Kitichate Sridith from the Herbarium of the Department of Biology, Faculty of Science, Prince of Songkla University for the identification of the plant. We are also grateful to the Commission on Higher Education (CHE-RES-RG), the Center for Innovation in Chemistry (PERCH-CIC), and the Royal Thai Government for their partial support of this work.

Structural control of Au and Au–Pd nanoparticles by selecting capping ligands with varied electronic and steric effects

Patrick B. Murphy, Feng Liu, Stephen C. Cook, Nusrat Jahan, D. Gerrard Marangoni, T. Bruce Grindley, and Peng Zhang

Abstract: Weakly interacting ligands including three Gemini surfactants, didodecyldimethylammonium bromide (DDAB), and amines (RNH_2, R_2NH, and R_3N) were used to prepare Au nanoparticles (NPs). Aqueous Au NPs capped with DDAB and Gemini surfactants showed similar sizes (3–4 nm), whereas toluene-based NPs stabilized with DDAB, amines, and their mixtures range from 2.5 to 9.3 nm. Ligand effect on Au–Pd NP structure was also studied with EXAFS. These findings were consistently accounted for by considering the ligand's electronic/steric effects and mixed ligands coadsorption, and suggest useful ways to control NP structure by manipulating the two effects and using mixed capping ligands.

Key words: metal nanoparticles, capping ligands, electronic effect, steric effect, EXAFS.

Résumé : On a utilisé des ligands interagissant faiblement, dont trois agents de surface Gemini, le bromure de didodécyldiméthylammonium (BDDA) et des amines (RNH_2), R_2NH et R_3N) pour préparer des nanoparticules (NP) d'or (Au). Les tailles des nanoparticules d'or aqueuses, fermées avec du BDDA ou des agents de surfaces Gemini sont assez semblables (3–4 nm) alors que celles des nanoparticules à base de toluène et stabilisées par du BDDA, des amines ou leurs mélanges varient de 2,5 à 9,3 nm. On a aussi examiné l'effet de ligand sur la structure des nanoparticules Au–Pd par la technique de structure fine d'absorption des rayons-X étendue (SFAXE). Les observations peuvent être expliquées d'une façon cohérente en considérant les effets stérique/électronique du ligand et la coadsorption des ligands mixtes et ceci suggère des façons utiles de contrôler la structure des nanoparticules en manipulant les deux effets et en utilisant des ligands mixtes pour les fermer.

Mots-clés : nanoparticules métalliques, ligands de fermeture, effet électronique, effet stérique, structure fine d'absorption des rayons X étendue (SFAXE).

[Traduit par la Rédaction]

Introduction

Selection of capping ligands for the synthesis of metal nanoparticles (NPs) is of fundamental and technological importance.[1–6] Capping the NP surface with alkanethiols and their derivatives has become a widely used method in the past decade.[1] The availability of a large variety of commercial thiol derivatives and the advancement in thiol ligand-exchange reactions for the NPs have made such an approach particularly attractive.[7–9] However, the primary limitation of using thiol derivatives to functionalize NP surface is that the metal–ligand interaction is too strong and this hinders some applications such as catalysis. An alternative route to control the NP surface structure is to use weakly interacting molecules (relative to thiols) such as tetraalkylammonium surfactants. A noteworthy advantage of using weakly binding ligands is that the catalytic activity of NPs can be dramatically improved relative to those of their thiol-stabilized counterparts.[4,10] More significantly, the use of weakly interacting ligands can offer excellent control of NP structures, making possible the synthesis of NPs with flexibly controlled size and shape (e.g., nanorods and nanowires).[3,11] In addition, weakly interacting ligands are easily replaceable/exchangeable if strongly binding ligands are desired to surface-functionalize the NP surface.

Tetraalkylammonium surfactants are among the most widely studied weakly interacting ligands in recent years. Numerous syntheses of NPs have been reported using tetraalkylammonium ligands, such as tetraoctylammonium bromide (TOAB),[12] didodecyldimethylammonium bromide (DDAB),[13] and cetyltrimethylammonium bromide (CTAB).[11] Remarkably, significant progress has also been made in understanding the binding/stabilization mechanism of NP capping ligands, which plays a critically important role in the development of more efficient NP synthetic routes.[2,4,14] However, most of the in-depth studies on the stabilization mechanisms of weakly interacting ligands are based on ionic

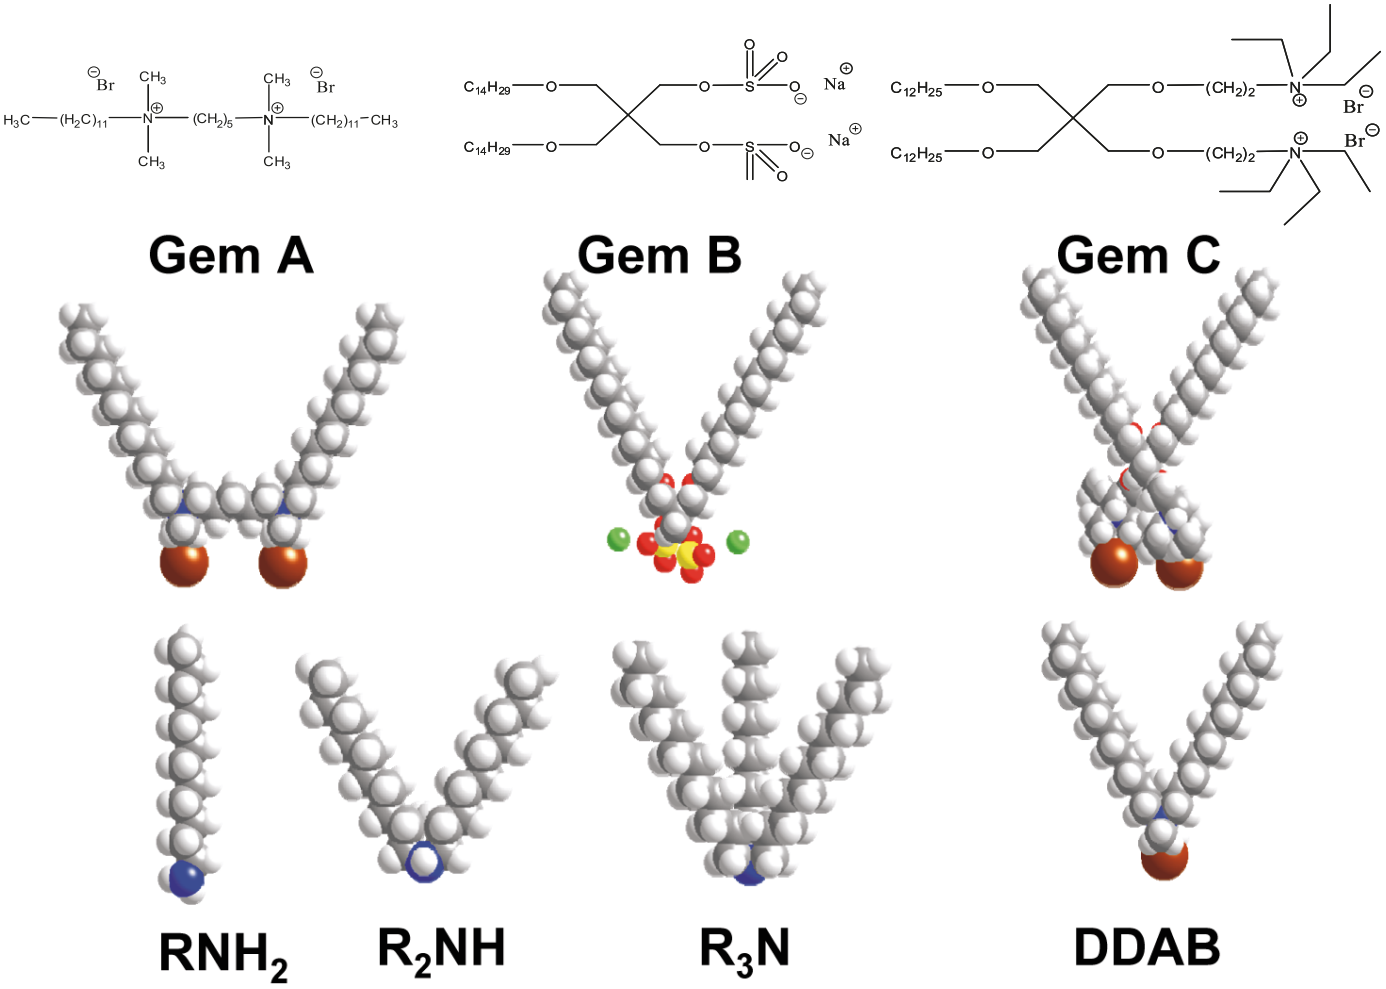
Scheme 1. Molecular structures of three Gemini surfactants, three fatty amines, and DDAB.

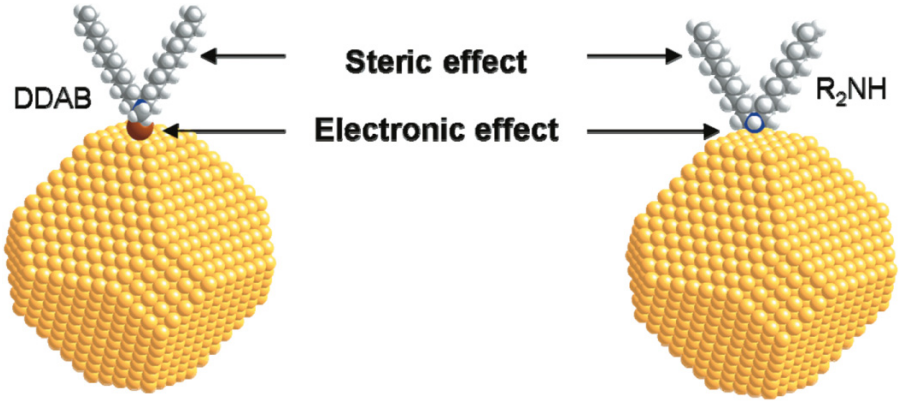


ligands.[4] For instance, one of the widely accepted ligand-stabilization mechanisms used for NP catalysis, proposed by Ott and Finke, mainly consider two effects of the ligands, i.e., the so-called electronic effect (also known as charge or DLVO effect) and the steric effect.[4] Such a mechanism has been found to provide good interpretation of the structural and catalytic properties of high-charge ionic ligands such as $(Bu_4N^+)_9$ $(P_2W_{15}Nb_3O_{62})^{9-}$. In contrast, detailed stabilization mechanisms of other types of ligands, such as neutral weakly interacting ligands, has remained largely under-explored. Such studies are particularly desirable in light of the recent remarkable findings on amine-based nanoelectronic devices.[15–17] Herein, we report the synthesis of Au NPs with a variety of weakly interacting ligands (Scheme 1), including some novel Gemini surfactants, didodecyldimethylammonium bromide (DDAB), dodecylamine, didecylamine, tridodecylamine, and nine mixtures of DDAB/amines (DDAB mixed with three amine ligands, each with three different molar ratios). The purposes of the present work are threefold: (*i*) exploring how Finke's models on ligand's electronic and steric effects can be used/extended to understand the stabilization of Au/Au–Pd NPs with the above-mentioned ligands (particularly the neutral amine ligands); (*ii*) seeking possible ways to controllably synthesize Au NPs by selecting ligands with varied electronic/steric effects or using a mixed capping method, and (*iii*) investigating how the capping ligands influence the local structure (i.e., the bimetal mixing pattern) of Au–Pd NPs.

Experimental section

All the chemicals were obtained commercially from Alfa Aesar or Aldrich except for ligands Gem A, Gem B, and Gem C (Scheme 1). Synthetic details for the preparations of Gemini surfactants will be published elsewhere[18] and can also be found in the Supplementary data. Au nanoparticles (Au NPs) were prepared by reducing $HAuCl_4$ in aqueous solution or $AuCl_3$ in toluene with sodium borohydride. Three amine capping ligands were used singularly or in combination with DDAB. For combination systems, the ratios of amine to DDAB used were 1:4, 1:1, and 4:1. In a typical procedure, 0.03 mmol gold(III) chloride and 0.45 mmol of capping ligands (gold:ligand = 1:15 molar ratio) were dispersed in 30 mL of toluene by sonication. Then, the gold(III) was reduced with sodium borohydride (0.3 mmol) in 20 μL of water, and stirred under argon for 2 h at room temperature. The as-prepared Au NP liquid suspensions were then stored in darkness in a refrigerator without further purification. UV–vis experiments were conducted

Scheme 2. A schematic demonstration of the electronic and steric effect of ionic (DDAB) and neutral (R_2NH) ligands.



right after the NP synthesis, and TEM measurements were done within three days. Although only as-prepared samples (ideally purified samples are preferred) were measured in the present work, the reported TEM and UV–vis results were proved to be valid by time-dependent UV–vis measurements. Indeed, the as-prepared Au NPs were found to be stable for at least one month, as shown by comparing the UV–vis spectra of fresh and one month old samples. The bimetallic Au–Pd NPs capped with DDAB/RNH_2 (80% RNH_2) were synthesized using the same conditions as those reported recently for TOPB/RNH_2–capped Au–Pd NPs.[19] It was assumed that the initial Au-to-Pd molar ratio in the starting materials was maintained after the Au–Pd NPs were formed, which was supported by the XPS composition analysis result reported for similar Au–Pd NPs in our recent publication.[19]

The morphology of the nanoparticles was characterized with a Technai 12 or JEOL 123 transmission electron microscope (TEM), both equipped with a CCD camera and operated at a voltage of 80 keV. One or two drops of the nanoparticle solutions were cast to carbon or formvar-coated Cu grids for the TEM measurements. The particle size information was obtained using a size-measuring program from the TEM by counting at least 100 particles. The Au–Pd NPs were purified using the centrifuge method described in our recent publication[19] to obtain high-quality EXAFS data. The Au L_3-edge EXAFS measurements were conducted at the HXMA beamline at the Canadian Light Source (CLS) operated at 2.9 GeV. Purified Au–Pd NPs were cast onto a Mylar tape to form a uniform film, and the samples were measured at room temperature using a transmission mode. The EXAFS data were normalized and fitted with theoretical phase-shift and amplitude generated from FEFF 8 program[20] using a WinXAS program, following the procedure described in our recent papers.[19,21] The best-fit FT-EXAFS was provided in the Supplementary data.

Results and discussion

The mechanism of nanoparticle stabilization by ligands

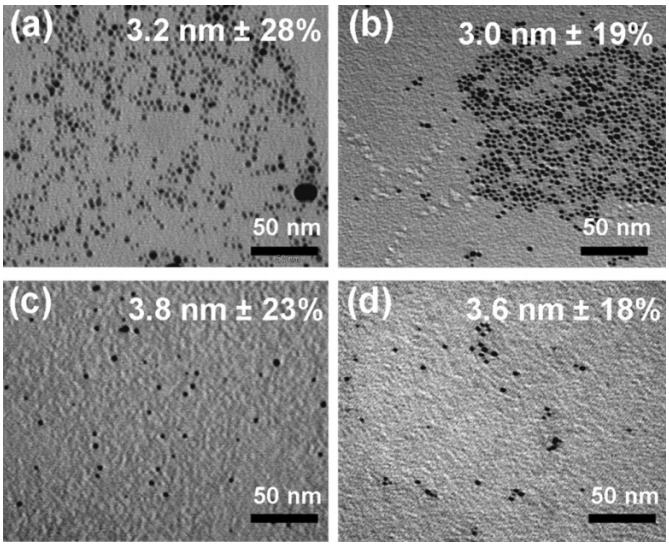
Finke and co-workers have recently reviewed the stabilization modes of catalytic NPs with a particular emphasis on metal NPs capped with anionic ligands.[2,4] Electronic and steric effects are proposed as the main factors influencing ligand stabilization. These two effects are schematically illustrated in Scheme 2 by inspecting the interaction between DDAB and Au NP. The electronic effect in Finke's model can be described as the Coulombic repulsive interaction between NPs due to the binding of Br^- onto Au NP surface, resulting in negatively charged NPs. That is why the electronic effect for these ionic ligands is also called the charge effect. The steric effect, on the other hand, originates from the relatively bulky ammonium groups that stay near the negatively charged NPs as counter cations. For DDAB used In the present work, the two 12-carbon alkyl chains sterically hinder direct contact between Au NPs.

When non-ionic ligands interact with Au NPs, the charge-induced Coulombic effect used for ionic ligands does not directly apply. However, the steric effect alone is not sufficient to account for the stabilities of NPs. For instance, Au NPs stabilized with dodecylamine and dodecylthiol ligands should experience very similar steric effects, but these two types of NPs have significantly different stabilities (amine–Au < thiol–Au). A second important stabilizing effect is apparently related to the metal–ligand electronic bonding (e.g., Au–SR and Au–amine), which can be considered as another type of electronic effect. Such an electronic effect for non-ionic ligands can also play an important role in the stabilization of NPs. In a later section, it will be shown that the electronic and steric effects for non-ionic ligands, which are considered as a simple extension of the models for ionic ligands, can be used to understand the ligand-dependent NP size when Au samples were capped with primary, secondary, tertiary amines, and with amine/DDAB mixtures.

Au NPs in aqueous vs. toluene phase

Recently, it has been reported that Gemini surfactants form a unique category of capping ligands for the preparation of metal nanoparticles in the aqueous phase.[22,23] In addition, the molecular structures of the Gemini surfactants can be altered to a much greater degree than those of the monomers, which may offer new opportunities to control the size and stability of NPs. Herein, two novel Gemini surfactants (Gem B and Gem C) together with a standard Gemini surfactant (Gem A) were used for the synthesis of Au NPs in aqueous solutions. The molecular structures of these Gemini surfactants are displayed in Scheme 1. In addition, DDAB was also used as a reference, since it has been found that DDAB can form a bilayer capping structure similar to those of the Gemini capping ligands.[13] Figure 1 shows the

Fig. 1. TEM images of aqueous Au NPs capped with (a) DDAB, (b) Gem A, (c) Gem B, and (d) Gem C. The average size and standard deviation are also presented in the figure.



TEM images of four Au NP samples prepared with the four ligands in water. It can be seen that all four capping ligands lead to Au NPs of similar sizes (average diameter ranging from 3.0 nm to 3.8 nm), although their molecular structures, including both the binding groups and the steric non-binding moiety, vary. It has been proposed that the double-chained structure of surfactants facilitates the formation of vesicles.[13,23–25] The inner polar heads of the vesicles bind to the metal surface and the outer ones are exposed to the aqueous environment. The hydrophobic alkyl chains exist inside bilayers with quite dense packing through chain–chain interaction. Formation of such densely packed bilayers should significantly enhance the role of the steric effect in the stabilization of NPs and thus make it dominant in controlling the NP size. The dominant role of the steric effect can be more clearly revealed by the identical size of Au NPs capped with Gem B and Gem C (3.8 nm vs. 3.6 nm), whose binding head-groups are different (bromide vs. sulfate, respectively) but have similar steric moieties.

Next, we turn to toluene-phase Au NPs prepared with DDAB and three fatty amines (primary, secondary, and tertiary) under identical synthetic conditions. The use of amines with systematically varied structures in the synthesis of NPs is particularly interesting in light of the recent remarkable findings in amine-based single-molecule circuits. Venkataraman and co-workers reported that amines bind selectively to undercoordinated Au atoms with sufficient angular flexibility for easy junction formation but well-defined electronic coupling of the N lone pair to the Au.[16] It was also found that the variability of observed conductance for diamine–Au junctions is much less than that for dithiol–Au junctions.[16] Therefore, amines can be considered as promising molecules for the construction of single-molecule junctions and circuits. According to recent results from theoretical studies, methyl-substituted primary, secondary, and tertiary amines almost have the same adsorption energy when binding to undercoordinated Au structures such as an adatom.[26] These results suggest that when the three amines stay at the same distance from Au (e.g., amines with small-sized subsituents), the electronic effects are identical. On the other hand, ionic DDAB ligand should have different electronic effects from the neutral amine ligands.

Fig. 2. TEM images of toluene-phase Au NPs capped with (a) RNH_2, (b) R_2NH, (c) R_3N, and (d) DDAB.

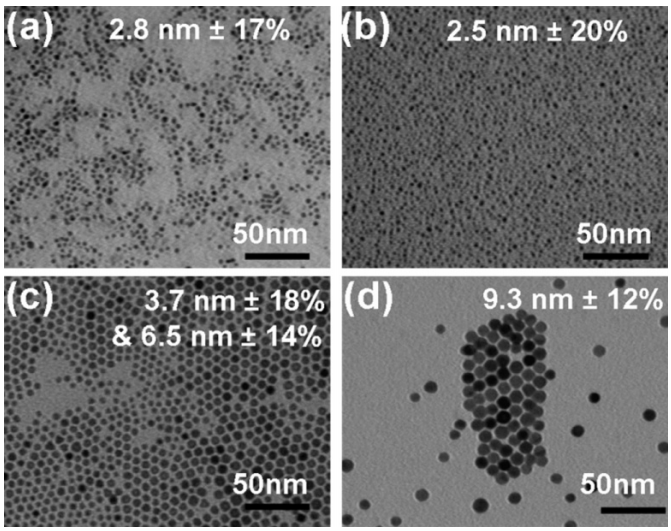


Figure 2 shows the TEM results of Au NPs prepared using DDAB and three amines. The sizes of RNH_2-capped (2.8 nm) and R_2NH-capped (2.5 nm) NPs are very close to each other. Based on the model illustrated in Scheme 2, this observation can be easily understood. For RNH_2- and R_2NH-capped NPs, the electronic effect is dominant; thus, the two NP samples have very similar sizes due to their identical metal–ligand bonding. On the other hand, the steric effect should play a less significant role when going from a primary to a secondary amine.

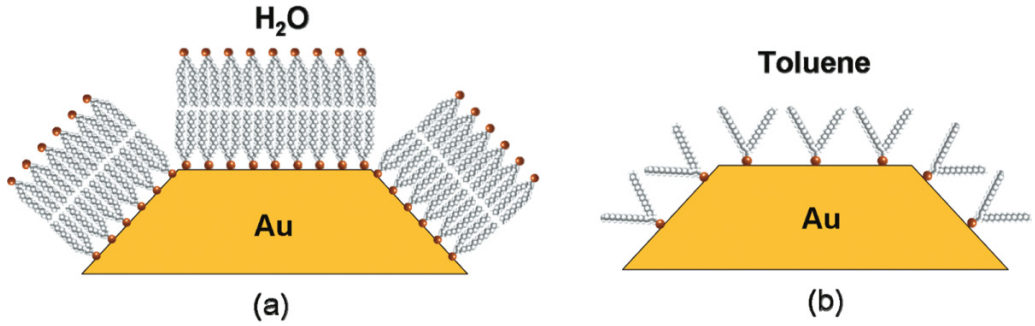
Interestingly, the sizes of R_3N-capped NPs are considerably different from those of primary- and secondary-amine-capped samples. Indeed, as seen in Fig. 2c, there exist two groups of particles for R_3N-capped NPs, one group being 3.7 nm in diameter and the other is 6.5 nm. Similar phenomena were observed from other spots on the same TEM grid. The steric effect for the bulky R_3N ligand should be more significant than the other two amines, favouring the formation of smaller NPs. However, it has been shown that due to steric hindrance, the electronic bonding between Au and amine is significantly weakened for bulky tertiary amines.[15] As a result, the electronic effect for R_3N ligands should be weaker than that for RNH_2 and R_2NH ligands. Indeed, the overall low monodispersity of R_3N-capped NPs also supports the suggestion of a weaker electronic effect for the tertiary ligands.

The DDAB-capped sample has very different particle size (9.3 nm) from those capped with amines, which can be easily attributed to the pronounced difference of its stabilization mechanism from that of the neutral amine ligands. Indeed, it has been reported that amines preferentially bind to low-coordination Au sites (e.g., adatoms and corner atoms), whereas those bound to terrace-type surface atoms are not stable.[15,26] In contrast, tetraalkylammonium bromide molecules were found to be mainly adsorbed to the terrace atoms on Au surface, although the Br^- alone, being separated from the ammo-

Scheme 3. An illustrative presentation of the surface-capping structure of Au NPs in aqueous (a) and toluene phase (b).



nium counterions, can strongly bind to low-coordination Au sites.[27] Therefore, the considerable NP size increase when going from amines to DDAB can be accounted for by considering their different ligand-binding mechanisms. The use of amines resulted in much smaller NPs which contain higher percentage of low-coordination surface atoms (i.e., adatoms, corner, and edge atoms) that can be bound by the ligands; the use of DDAB produced bigger NPs where the terrace-type surface atoms are more abundant.

One may also consider the possibility that the size difference among amine- and DDAB-capped NPs observed in Fig. 2 might be caused by different reduction rates of gold compound in toluene phase by aqueous $NaBH_4$. Since DDAB is a phase-transfer agent, the absence of DDAB in the three amine-capped samples may cause a slower reduction rate. However, the fact that Au NPs capped with 100% RNH_2 and those capped with a mixture of 80% RNH_2 and 20% DDAB (see next section) have very similar sizes (2.8 nm vs. 2.4 nm) suggests that such a possibility can be ruled out. Note that the presence of Cl^- anions from $AuCl_3$ starting materials can also bind to the NP surface. However, the possibility that the chloride anions play an important role in determining the NP size can be ruled out in this work. This argument is supported by the following two facts. First, it is well-known that bromide (from DDAB) can bind to gold surface more strongly than chloride. Therefore, in the presence of DDAB, the anion adsorption effect associated with Br^- should be more significant. Second, even in the absence of bromide, the above argument seems still true as the Au NP size was found to be largely determined by the molecular structure of amines (Fig. 2). It is also noted that different sizes for DDAB-capped Au NPs have been reported in the literature.[28] This could be attributed to differences between the synthetic procedures. Indeed, the stability of weakly bound NPs is largely kinetic in nature, thus causing the NP size to vary in different reports.[29] In the present work, it is still valid to make a comparison between the amine- and DDAB-capped NPs, as they were prepared under identical conditions.

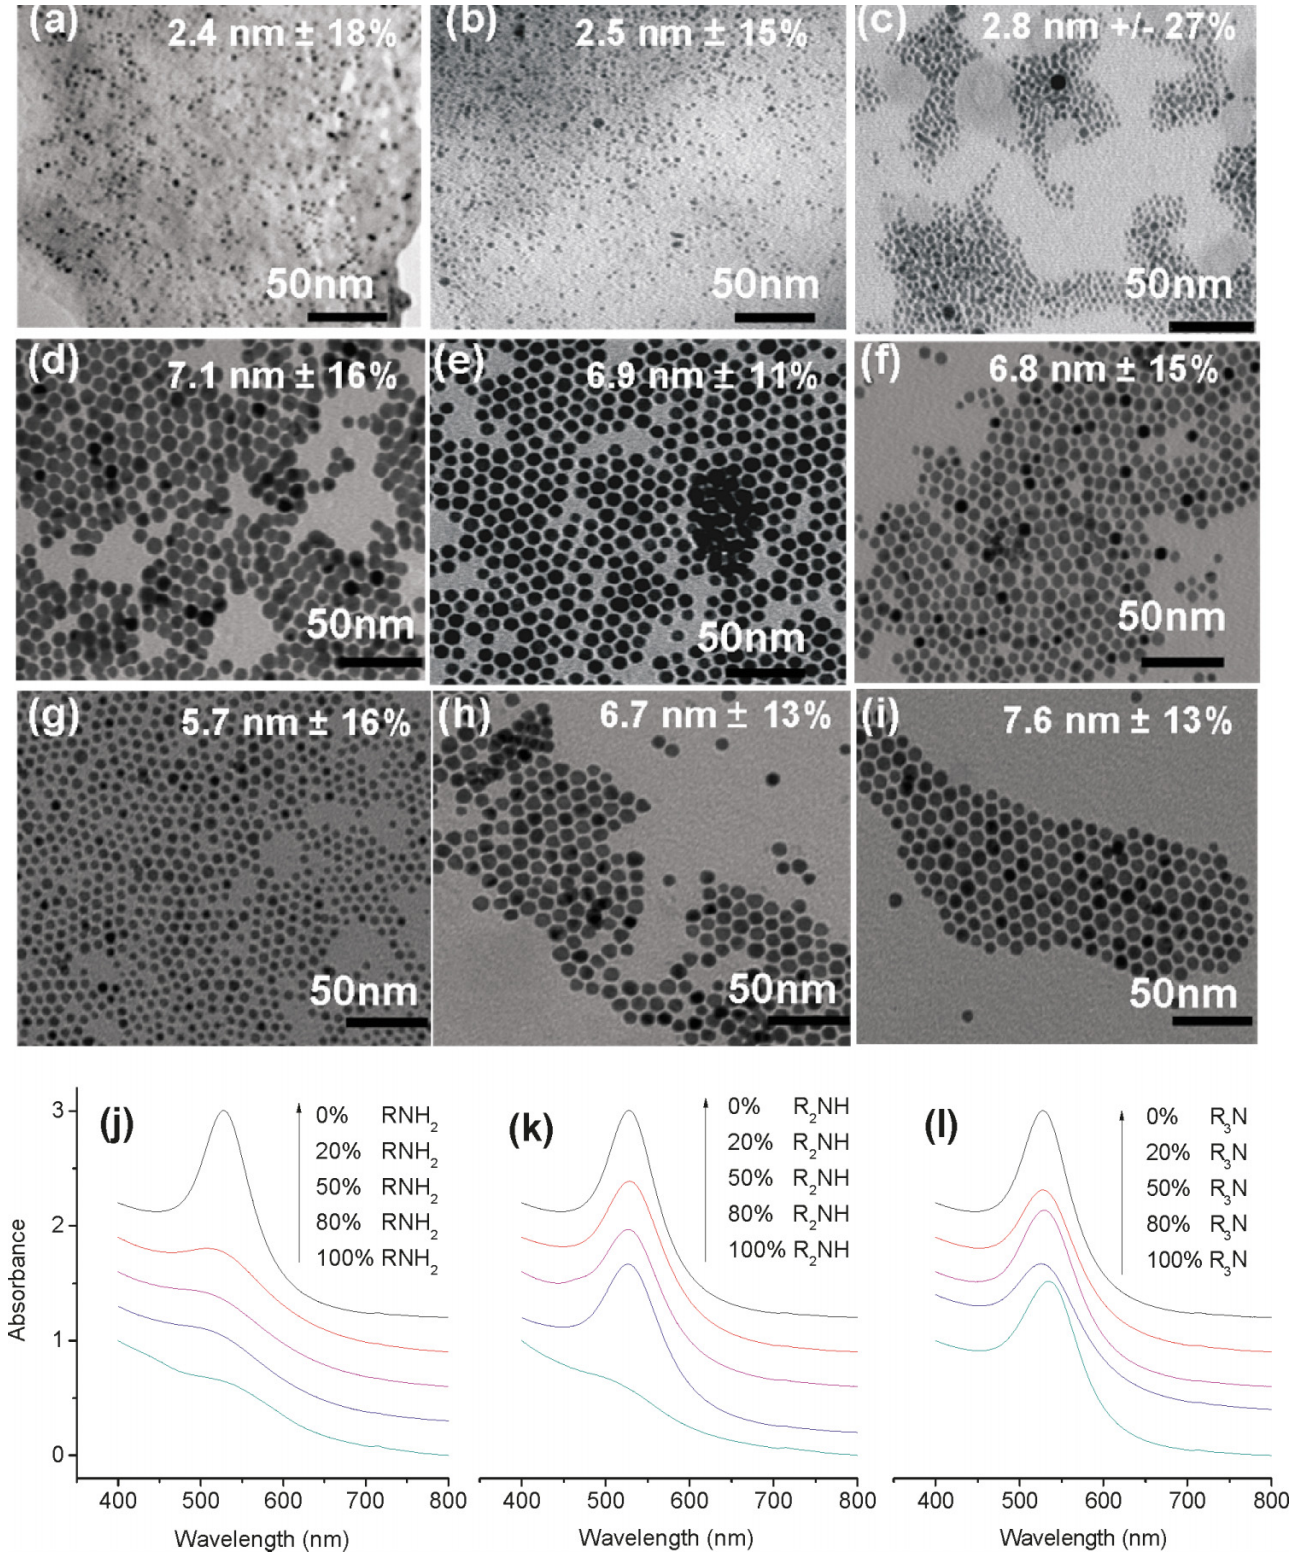
Overall, a comparison of the syntheses of Au NPs in aqueous and toluene phases highlights the very different roles that the steric and electronic effects of the ligands play, which is schematically illustrated in Scheme 3 using DDAB as an example. Due to the existence of densely packed bilayer capping structure in aqueous solutions, the steric effect is dominant, whereas in toluene, the electronic effect is more important than the steric effect.

Au NPs with mixed ligands

To further study the interplay between the electronic and steric effects of the ligands as well as to explore the possibility of manipulating the two effects to control NP size, we next used a combination of amine and DDAB to synthesize Au NPs. Nine NP samples (3×3) were prepared using mixed ligands of RNH_2, R_2NH, or R_3N with DDAB, each series having 20%, 50%, and 80% amines, respectively. Figure 3 shows the TEM images of these nine NP samples. UV–vis results of the three series of Au NPs (i.e., NPs capped with DDAB/RNH_2, DDAB/R_2NH, and DDAB/R_3N) with systematically varied concentration of amines (0%, 20%, 50%, 80%, and 100%) are also displayed in the figure. A few interesting observations are noted. Firstly, the three samples capped with mixed DDAB and RNH_2, shown in Figs. 3a–3c, all have similar sizes (2.4 nm to 2.8 nm in diameter) to that of pure RNH_2-capped NPs (2.8 nm), which are considerably different from that of DDAB-capped samples (9.3 nm). The UV–vis spectra in Fig. 3j show that all the amine-capped NPs exhibit diminishing surface plasmon resonance band, indicating the small sizes for these NPs and consistently supporting the TEM data. Secondly, the DDAB/R_2NH-capped NPs displayed in Figs. 3d–3f exhibit nearly the same particle size (6.8 nm to 7.1 nm in diameter), which are very different from pure R_2NH-capped Au sample (2.5 nm), consistent with the UV–vis results in Fig. 3k. Thirdly, the size of DDAB/R_3N-capped NPs increase gradually with the concentration of DDAB, from 5.7 nm (80% R_3N) to 6.7 nm (50% R_3N) and then to 7.6 nm (20% R_3N). The UV–vis spectra of NPs in this series in Fig. 3l all exhibit fairly intense surface plasmon resonance bands. A close inspection of Fig. 3l reveals that the surface plasmon resonance band of Au shows a noticeable blue shift when DDAB is present, even if the concentration of DDAB is low (20%).

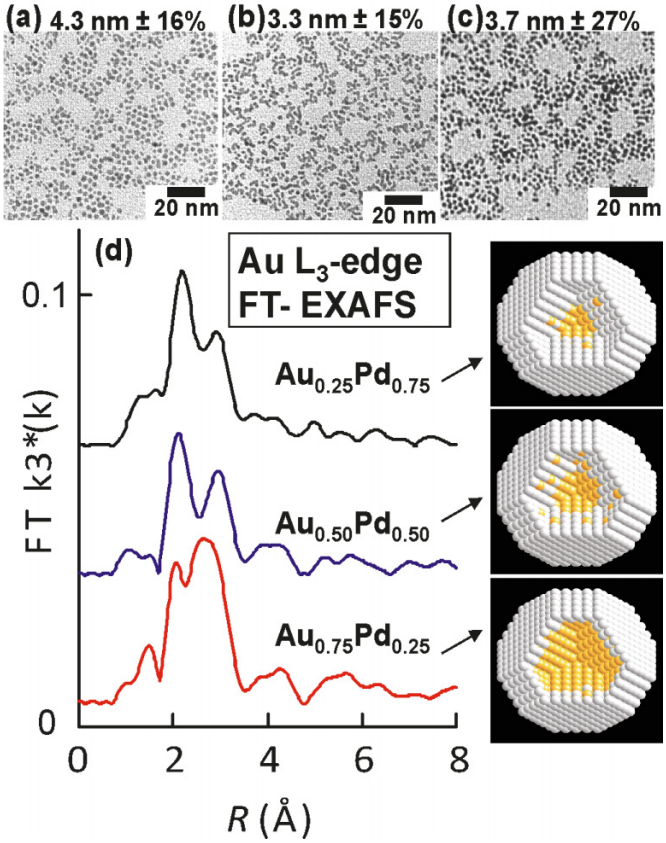
The use of cosurfactants adsorbing onto Au 2D surfaces has been reported.[30] Generally, the existence of a cosurfactant can either reduce the adsorption of the primary surfactant due to a competitive adsorbing mechanism or enhance the adsorption caused by a collaborative adsorption of the two surfactants. The results of DDAB/RNH_2-capped NPs in Figs. 3a–3c suggest a competitive adsorbing process between DDAB and RNH_2 ligands and indicate that stabilization of Au NPs by the latter is dominant. A plausible reason is that RNH_2 is much smaller in size than DDAB, making the former more competitive in the coadsorption process. This is consistent with the reported results in the literature

Fig. 3. TEM images of Au NPs (in toluene) prepared using mixed amines and DDAB: (a) 80% RNH_2, (b) 50% RNH_2, (c) 20% RNH_2, (d) 80% R_2NH, (e) 50% R_2NH, (f) 20% R_2NH, (g) 80% R_3N, (h) 50% R_3N, and (i) 20% R_3N. (j)–(l) are UV–vis spectra of RNH_2 series (j), R_2NH series (k), and R_3N series (l).



on Au 2D surface where cosurfactants of smaller sizes even at low concentration (e.g., 1%–2%) greatly reduced the amount of adsorbed primary surfactants.[30] The results of DDAB/R_2NH-capped NPs, however, seem to be very different from the case of primary amine. The sizes of the three NP samples (~7 nm) shown in Figs. 3d–3f are close to that of pure DDAB-capped NPs (9.3 nm), but quite different from that of pure R_2NH-stabilized sample (2.5 nm). Interest-

Fig. 4. TEM images of (a) $Au_{0.25}Pd_{0.75}$ NPs, (b) $Au_{0.50}Pd_{0.50}$ NPs, and (c) $Au_{0.75}Pd_{0.25}$ NPs. Au L_3-edge FT-EXAFS is presented in (d) using *k*-space EXAFS data of 3–13 $Å^{-1}$. Idealized local structure models of the three NPs are also shown in (d).



ingly, the size of the three DDAB/R_2NH-capped NPs, which are all slightly smaller than that of DDAB-capped ones, does not change as the concentration of DDAB increases. A possible explanation will be discussed in conjunction with the discussion of DDAB/R_3N-capped NPs. The results of DDAB/R_3N-capped NPs clearly indicate that both DDAB and R_3N ligands play an important role in the NP synthesis. As a result, when more DDAB ligands were used, the NP size was closer to that of pure DDAB-capped NPs. As was discussed in a previous section, R_3N has the weakest electronic effect among the three amine ligands. Therefore, it is understandable that the adsorption of DDAB is significant even at low concentration (20%). Supporting evidence is provided by the UV–vis results presented in Fig. 3l. However, the secondary amine (R_2NH), whose electronic effect is stronger than the tertiary amine, seems to be less competitive than R_3N in the coadsorption process with DDAB. Considering their very similar molecular structure (see Scheme 1), we propose that R_2NH and DDAB were collaboratively adsorbed onto the NP surface.[30] Since the NP surfaces mainly consist of terrace atoms, it can be easily understood that DDAB ligands are the ones that mainly determine the NP size, as amines cannot form stable bonds with the terrace Au atoms.[26] This notion can also explain why the particle size of DDAB/R_2NH-capped samples (~7 nm) is close to that of pure DDAB-capped NPs (9.3 nm) and remained almost unchanged when the concentration of DDAB was increased from 20% to 80%.

In summary, the particle-size data of Au NPs capped with mixed amines and DDAB ligands indicate that the coadsorption mechanism of ligands determines the NP size. RNH_2 is more competitive than DDAB in the coadsorption process; thus, the NPs capped with 20%–80% RNH_2 are all very small (<3 nm), similar to that of pure RNH_2-capped NPs. R_2NH may be coadsorbed onto Au in a collaborative way with DDAB, making the NP size close to that of pure DDAB-capped ones. R_3N and DDAB, whose competitive abilities in the coadsorption process are comparable, are similarly important in determining the NP size. Consequently, the NP size increases with the concentration of DDAB. Overall, these results suggest that by selecting ligands with desired molecular structure (and thus the electronic and steric effect), one can possibly control Au NP size with this mixed-capping method. Although further experimentation is needed to rigorously evaluate the effectiveness of this mixed-capping method, the results presented in Fig. 3 do show some promise of more flexible control of NP size than using a single type of ligands.

Au–Pd NPs with mixed ligands

We have recently reported the use of this mixed-capping method to prepare Ag–Pd and Au–Pd NPs.[19,21] Herein, we present results on bimetallic Au–Pd NPs capped with mixed DDAB (20%) and RNH_2 (80%) ligands. These results can be considered as an extension of the work on Au monometallic NPs presented in the above sections. Moreover, the effect of weakly binding ligands on the structure of bimetallic NPs is even more interesting, as not only the particle size but also the bimetal mixing pattern can possibly be influenced by selecting the ligands. We have recently reported EXAFS results on the local structure of Au–Pd NPs capped with a mixture of 20% tetraoctylphosphonium bromide (TOPB) and 80% *n*-dodecylamine, which show alloying-structure-dependent physical and chemical properties.[19] In the present work, we intend to compare the local structure of Au–Pd NPs capped with 20% DDAB and 80% *n*-dodecylamine (RNH_2) with the previous results with an attempt to study the effect of different type of bromide ligands (DDAB vs. TOPB) on the bimetal mixing pattern of Au–Pd NPs.

Figures 4a–4c depict the TEM images of Au–Pd NPs with varied concentrations of Au. The average sizes for $Au_{0.75}Pd_{0.25}$, $Au_{0.50}Pd_{0.50}$, and $Au_{0.25}Pd_{0.75}$ are 4.3 ± 0.7 nm, 3.3 ± 0.5 nm, and 3.7 ± 1.0 nm, respectively. The fact that these NPs are all bigger than their pure Au counterpart (2.4 nm) implies that the metal–ligand binding differed after Pd was introduced. To investigate the ligand effect on the mixing patterns of Au–Pd NPs, Au L_3-edge EXAFS measurements were performed. The FT-EXAFS and fitting results were presented in Fig. 4d and Table 1, respectively. A comparison of the experimental EXAFS data and first-shell best fit is provided in the Supplementary data. The information about Au–Pd mixing pattern can be obtained by analyzing the coordination numbers ($N_{Au–Au}$, $N_{Au–Pd}$, and N_{total}) in the table. It has been established[19,31–33] that if $N_{Au–Au}/N_{Au–Pd}$ is equal to Au/Pd molar ratio, a homogeneous alloy was resulted. If $N_{Au–Au}/N_{Au–Pd}$ is considerably greater than Au/Pd

Table 1. Au L_3-edge EXAFS fitting results for three Au–Pd NP samples.

Sample (% Au)	M–M bond	N^a	N_{total}	R (Å)^b	$\Delta\delta^2$	ΔE (eV)
25	Au–Au	7.4	11.8	2.830	0.0088	0.88
	Au–Pd	4.4		2.804	0.0082	2.28
50	Au–Au	7.8	11.8	2.827	0.0090	–1.14
	Au–Pd	4.0		2.797	0.0093	0.63
75	Au–Au	10.4	12.4	2.810	0.0088	–3.29
	Au–Pd	2.0		2.793	0.0079	3.28

Note: The uncertainty is ~20% for N and ~0.02 Å for R.

[a]Nearest-neighbor coordination number.

[b]First-shell metal–metal bond distance.

molar ratio, then Au-core Pd-shell NPs were formed. Moreover, N_{total} is useful to obtain the information about the location of Au atoms. If N_{total} is 12, which is the first-shell coordination number for a bulk fcc metal, Au atoms cannot be found on the NP surface (i.e., all the neighboring sites for Au are occupied). If N_{total} is less than 12, some Au atoms should be located on the surface, as the surface atoms of a metal with fcc crystalline structure have a coordination number less than 12. The results of $N_{Au–Au}$ and $N_{Au–Pd}$ in Table 1 indicate that all the three Au–Pd NPs have core-shell structures. In addition, all the three N_{total} values are nearly 12, indicating that the particle surfaces are essentially all covered by Pd atoms. Based on the above analysis, the structural models for the three Au–Pd NPs are schematically illustrated in Fig. 4. The core-shell structural models are consistent with the TEM results, which show that Au–Pd NPs are all bigger than pure Au NPs, since the surface metal–ligand bonding in the Au-core Pd-shell NPs is different from that of pure Au NPs. It is interesting to note that the present structural results of Au–Pd NPs capped with DDAB/RNH_2 (80% RNH_2) differ from those capped with TOPB/RNH_2 (80% RNH_2) we recently reported.[19] For the TOPB/RNH_2-capped NPs, core-shell structures were found only for the $Au_{0.50}Pd_{0.50}$ and $Au_{0.75}Pd_{0.25}$ NPs, whereas the $Au_{0.25}Pd_{0.75}$ NPs showed a cluster-on-cluster structure. Therefore, a comparison of the bimetal mixing patterns of these two series of samples indicates that the Au–Pd bimetallic mixing pattern can be modified by varying the type of ligands used in this mixed-capping method. We are in the process of systematically investigating the correlation between the Au–Pd mixing pattern and the structure/concentration of the two types of ligands (e.g., TOPB, DDAB, amines, and so forth) used in the mixed-capping synthesis.

Conclusion

To conclude, we have reported results of Au NP synthesis using a variety of weakly interacting ligands. Aqueous Au NPs capped with DDAB and three Gemini surfactants were found to have very similar sizes (average diameter of 3–4 nm), whereas in toluene, the use of DDAB, amines, and their mixtures as capping ligands led to Au NPs with average sizes ranging from 2.5 nm to 9.3 nm. The ligand effect on the bimetal mixing patterns of Au–Pd NPs was also studied with EXAFS. These results can be accounted for by considering the electronic and steric effects of capping ligands and the ligand coadsorption mechanism when mixed ligands (cosurfactants) were used. The experimental findings presented in this work suggest that manipulation of the electronic and steric effects of weakly interacting ligands and the use of mixed capping ligands can offer useful routes to control NP size and bimetal mixing patterns.

Synthesis and properties of ionic liquids based on 1-methyl-3-(2-phenethyl)imidazolium

Hossein Fakhraian and Azam Gorgi-douze

Abstract: The synthesis and properties of three ionic liquids based on 1-methyl-3-(2-phenethyl)imidazolium cation ([MPIm]) and the chloride, tetrafluoroborate, and hexafluorophosphate anions have been investigated. The proposed quaternization and anion exchange processes afforded quantitative amounts of the three ionic liquids, and very pure [MPIm][BF_4] and [MPIm][PF_6] were obtained after recrystallization from ethanol. [MPIm][BF_4] showed low melting point and high electrical conductivity. These ionic liquids (immiscible with diethyl ether but miscible with water and DMSO) absorb air moisture, increasing their mass and decreasing their viscosity. The results of NMR spectroscopy (^{1}H, ^{13}C, and ^{19}F) and X-ray structure determination confirm the possibility of ion-pair and hydrogen-bond formation in [MPIm][BF_4].

Key words: ionic liquid, 1-methyl-3-(2-phenethylimidazolium), X-ray diffraction, tetrafluoroborate, hexafluorophosphate.

Résumé : La synthèse et les propriétés de trois liquide ioniques basés sur le cation de 1-méthyl-3-(2-phénéthyl)imidazolium ([MPIm]) et des anions comme chlorude, tétrafluoroborate et hexafluorophosphate ont été investigués. Le processus proposé pour les réactions de quaternization et d'échange d'anion a offert les trois liquide ioniques de façon quantitative et très pure [MPIm][BF_4] et [MPIm][PF_6] ont été obtenus après la cristallisation dans l'éthanol. [MPIm][BF_4] a montré le point de fusion bas et la conductivité électrique élevée. Ces liquide ioniques (immiscibles dans l'éther mais miscibles dans l'eau et le DMSO) absorbent l'humidité de l'air qui augmente leur poids et diminue leur viscosité. Les résultats de spectroscopie RMN (^{1}H, ^{13}C et ^{19}F) et la détermination de structure par rayon-X confirment la possibilité de la formation d'une paire d'ion et de la bande hydrogène dans [MPIm][BF_4].

Mots-clés : liquide ionique, 1-méthyl-3-(2-phénéthyl)imidazolium, Diffraction du rayon X, tetrafluoroborate, hexafluorophosphate.

Introduction

Intense research activity in the field of ionic liquids is currently in progress. Because the properties of ionic liquids (miscibility with water and other solvents, solvation ability, polarity, viscosity, density, and so forth) can be adjusted by an appropriate choice of the anion and cation, ionic liquids are often considered designer solvents.[1–5] Some of the applications of ionic liquids include their use as solvents for extraction processes and as electrolytes for batteries, fuel cells, and dye-sensitized solar cells.[6–8]

Functionalized imidazolium salts have applications, such as catalyst recycling, support for organic synthesis, and separation of specific metal ions from aqueous solution.[9–11] Bulky imidazolium cations such as 1-benzyl-3-methylimidazolium have been considered as a new class of stationary phase for gas chromatography.[12] The three ionic liquids 1-benzyl-3-methylimidazolium chloride, tetrafluoroborate, and hexafluorophosphate are commercially available (Sigma-Aldrich) and have mp of 70, 77, and 136 °C, respectively.[13] Asymmetric synthesis of the chiral 1-phenethyl analogue of methylimidazole has attracted attention due to the applications of these liquids in electrochemistry (capillary electrophoresis) and in asymmetric phase transfer catalysis.[14,15]

The formation of hydrogen bonds (CH···F) between the counterions imidazolium cation and $[BF_4]^-$ has been identified by analysis of the ^{13}C dipole–dipole relaxation rate.[16] Hydrogen bonding was found in BMImX (BMIm = butylmethylimidazolium) with X = BF_4 and PF_6, and the latter was recognized as a better hydrogen bond acceptor.[17] On the other hand, [BMIm][BF_4] was found to have dual (ionic polymer – ionic pair) behaviour.[18]

In this study, we have investigated the synthesis of three ionic liquids based on 1-methyl-3-(2-phenethyl)imidazolium cation ([MPIm]) and the chloride, tetrafluoroborate. and hexafluorophosphate anions and have studied their properties such as melting point, solvent miscibility, electrical conductivity (in aqueous solution), water uptake from air, NMR spectra characteristics, and X-ray structure.

Results and discussion

Previous reports on the quaternization of pyridine with 2-phenethylchloride have indicated that it does not take place under reflux conditions and microwave irradiation at normal pressure, but when the reaction is carried out in a closed vessel in a microwave digester (for 1 h at 200 °C and 56 psi), excellent yield of the product can be obtained.[19] This result is therefore extrapolated to apply to 1-methylimidazole without explicit experimental confirmation.

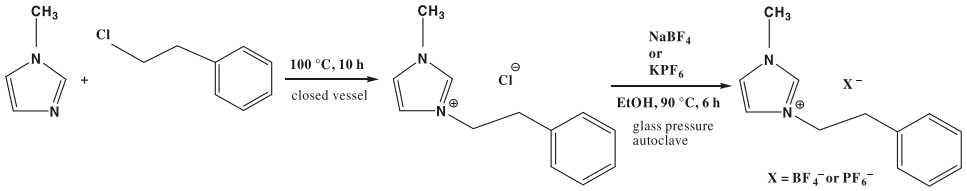
Scheme 1. Reaction conditions for the preparation of [MPIm][X] with X=BF_4 and PF_6.



We have prepared 1-methyl-3-(2-phenethyl)imidazolium chloride ([MPIm][Cl], **1**) quantitatively via a solventless quaternization reaction between equimolar amounts of 1-methyl imidazol and 2-phenethyl chloride in a closed vessel at a temperature of 100 °C for 10 h (Scheme 1).

Anion exchanges of salt **1** with $NaBF_4$ and KPF_6 were performed successfully under soft conditions in ethanol (in a glass pressure autoclave at temperatures of 95 and 85 °C, respectively, for 6 h) and produced pure crystals of 1-methyl-3-(2-phenethyl)imidazolium tetrafluoroborate ([MPIm][BF_4], **2**) and 1-methyl-3-(2-phenethyl)imidazolium hexafluorophosphate ([MPIm][PF_6], **3**) after recrystallization from EtOH (Scheme 1). The purification of ionic liquids (especially the imidazolium salt of BF_4^-) formed by anion exchange presents its own set of problems, but in the cases of salts **2** and **3**, we have found EtOH to be an appropriate solvent for both their preparation and their purification.

The melting points, water uptake from the air, and electrical conductivities of these three ionic liquids are outlined in Table 1, and their solubilities in different solvents are presented in Table 2. [MPIm] contains an aromatic system in which the phenyl ring shows a high electron density including electron donor potential. The main lipophilic parts within this molecule are the methyl group and the phenyl structural element, but some lipophilicity also resides in the aromatic imidazolium ring. Salts **1**, **2**, and **3** are miscible with DMSO but immiscible with ether and $CHCl_3$ (Table 2). Salts **1** and **2** are miscible with water, but salt **3** is immiscible with water, consistent with other ionic liquids based on $[PF_6]^-$ as anion.

The most common impurities in ionic liquids are halide anions or unwanted cations inefficiently separated from the final product. The presence of impurities such as halide anions after anion exchange can be extremely detrimental to the performance of ionic liquids. This problem occurs more frequently in water-soluble ionic liquids. The first requirement for the preparation of colourless ionic liquids is that all starting materials used for the preparation of the cation should be distilled prior to use. Due to the non-volatile nature of ionic liquids, they cannot be purified by distillation. Purification is therefore usually carried out by dissolving the ionic liquid in acetonitrile or tetrahydrofuran (THF), treating it with activated charcoal for at least 24 h, and finally removing the solvent in vacuo.[7]

The miscibility difference of salt **1** with salts **2** and **3** in ethanol, along with the fact that salts **2** and **3** are immiscible with cold EtOH and miscible with hot EtOH, led us to the production of pure crystals of salts **2** and **3** with melting points of 61 and 112 °C, respectively.

Salts **1** and **2** were water miscible, and their aqueous solution showed interesting electrical conductivity compared to an aqueous solution of NaCl (Table 1) and other neat ionic liquids.[1] The lower electrical conductivity of salt **2** compared to salt **1** is consistent with the size of the anion in the two ionic liquids.

Table 1. Melting point, mass gain (Δw), and electrical conductivity of ionic liquids based on 1-methyl-3-(2-phenethyl)imidazolium.

Ionic liquid	Mp (°C)	Δw (%)[a]	Conductivity[b] ms/cm
[MPIm][Cl]	92	21	1.090
[MPIm][BF_4]	61	45	0.783
[MPIm][PF_6]	112	30	Immiscible

[a]Mass gain due to water uptake from air after 24 h.

[b]Electrical conductivities were measured in 0.2 mol/L aqueous solution at 25 °C. Electrical conductivities of distilled H_2O and 0.2 mol/L aqueous solution of NaCl in the same conditions were 0.04 and 1.994 ms/cm, respectively.

The other impurity likely to be present in the largest concentration in most ionic liquids is water. It has been stated that even a water-immiscible ionic liquid based on $[PF_6]^-$ as the anion can absorb up to 2 wt% water on equilibration with the air.[1] Water uptake from air, causing liquefaction and decreasing the viscosity of an ionic liquid at RT, was greater for salt **2** (Table 1). The order of increasing hydrophilicity with respect to the anion is $[BF_4]^- > [PF_6]^- > [Cl]^-$. The hydrophilicity of salt **3** (immiscible with water) is consistent with previous observations.[1]

Elemental analysis of salts **2** and **3** is consistent with calculated values for these salts (see the Experimental section). For salt **1**, elemental analysis is compatible with hydrated salt **1** (calculated for $C_{12}H_{15}N_2Cl$: C 64.72, H 6.74, N 12.58; calculated for $C_{12}H_{15}N_2Cl$ (H_2O): C 59.87, H, 7.07, N 11.64; found: C 59.84, H 7.73, N 11.73). Water uptake from air by salt **1** was so fast that liquefaction was nearly instantaneous (in a few minutes), and we were unable to send salt **1** for elemental analysis before water absorption.

The chemical shifts in both ^1H and ^{13}C NMR spectra of 1-methyl-3-(2-phenethyl)imidazolium salts containing $[Cl]^-$, $[BF_4]^-$ and $[PF_6]^-$ are presented in Tables 3 and 4. Anion exchange of salt **1** by $[BF_4]^-$ and $[PF_6]^-$ decreased the chemical shifts of H_a, H_b, and H_c but this effect is stronger for H_a and H_b. It seems that the interaction of the H_a atom with the relatively small and basic Cl^- is closer than its interaction with the larger and less basic $[BF_4]^-$ and $[PF_6]^-$. This is consistent with the idea of hydrogen bonding between H_a and these anions (as has been previously reported).[17]

The same observations have been made in ^{13}C NMR spectra of salts **1**, **2**, and **3**, in which all chemical shifts are fairly similar except for C_4 and C_9 in salt **2**, which showed $\Delta\delta$ of 0.5 and 0.9 ppm, respectively. The ^{19}F NMR spectra of salt **2** showed two peaks at –148.91 and –148.96 ppm with relative integrals of 20% and 80%, respectively. This situation persists in a threefold diluted solution of salt **2**, and the same multiplicity is observed for $NaBF_4$ in DMSO-d_6 and D_2O. The peak downshifted by 0.05 ppm is due to

Table 2. Miscibility of ionic liquids based on 1-methyl-3-(2-phenethyl)imidazolium in different solvents.

Ionic liquid	H_2O	DMSO	$CHCl_3$	Me_2CO	EtOAc	EtOH	Et_2O
[MPIm][Cl]	+	+	–	–	–	+	–
[MPIm][BF_4]	+	+	–	+	+	–	–
[MPIm][PF_6]	–	+	–	+	–	–	–

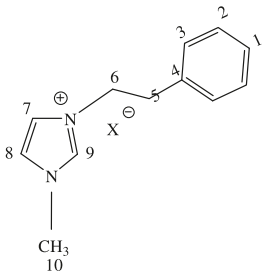
X	CH_3	Ha	Hb	Hc	Phenethyl
$[Cl]^-$	3.86	9.49	7.88	7.79	3.17 (t, J_{H-H} = 7.5 Hz, CH_2), 4.50 (t, J_{H-H}= 7.5 Hz CH_2), 7.23–7.34 (m, C_6H_5)
$[BF_4]^-$	3.87	9.05	7.55	7.71	3.18 (t, J_{H-H} = 7.5 Hz, CH2), 4.47 (t, J_{H-H} = 7.5 Hz CH_2), 7.25–7.38 (m, C_6H_5)
$[PF_6]^-$	3.82	9.01	7.70	7.65	3.14 (t, J_{H-H} = 7.5 Hz CH2), 4.44 (t, J_{H-H} = 7.5 Hz CH_2), 7.21–7.35 (m, C_6H_5)

Table 4. Chemical shifts of carbons in ^{13}C NMR spectrum of ionic liquids based on 1-methyl-3-(2-phenethyl)imidazolium.



X	1	2	3	4	5	6	7	8	9*	10
$[Cl]^-$	127.2	129.3	128.9	137.1	35.9	50.1	123.8	122.8	137.3	36.2
$[BF_4]^-$	127.4	129.4	129.1	137.6	36.1	50.3	124.0	122.9	138.2	36.2
$[PF_6]^-$	127.5	129.3	129.3	137.1	36.0	50.4	124.1	122.9	137.5	36.3

fluorine on boron-10 (with isotopic abundance of 20%), as was previously reported.[20] The chemical shift of fluorine is consistent with the shifts reported for other ionic liquids with $[BF_4]^-$ as anion.[21]

The structure of the crystalline salt **2** was determined by X-ray single diffraction (Table 5, Fig. 1–3). The structural characteristics and ORTEP diagram of salt **2** (Fig. 1) were consistent with those of other imidazolium-based salts containing fluoroanions.[22] It crystallized in the monoclinic space group $P2_1$. Cross-sections of crystal packing (projection along *a* crystal axis) show that C–H···F bonded anion–cation layers are formed (Fig. 2 and 3). The shortened C–H···F contacts for salt **2** are C(2)–H(2)···F(4) (2.47 Å), C(4)–H(4)···F(1) (2.28 Å), C(5)–H(5)···F(2) (2.45 Å),and C(6)–H(6)···F(3) (2.40 Å) with C–H–F angles of 121°, 162°, 140°, and 162°, respectively. Thus it appears that the more acidic proton (H(4)) is engaged in a hydrogen bond with the $[BF_4]^-$ anion. This is also consistent with the ion pair formation model previously suggested for this type of ionic liquid in solution.[18]

Conclusion

In summary, the synthesis and properties of three ionic liquids based on 1-methyl-3-(2-phenethyl)imidazolium cation ($[MPIm]^+$) and chloride ($[Cl]^-$), tetrafluoroborate ($[BF_4]^-$) and hexafluorophosphate ($[PF_6]^-$) anions have been investigated. The neat (solventless) equimolar mixture of 1-methyl imidazole and phenethyl chloride was used for the quaternization reaction at a temperature of 100 °C for 10 h in a glass pressure autoclave, and quantitative amounts of [MPIm][Cl] were obtained. Afterward, anion exchange with $NaBF_4$ and KPF_6

and finally recrystallization from ethanol produced very pure crystals of [MPIm][BF_4] and [MPIm][PF_6]. [MPIm][BF_4] showed a melting point of 60 °C and an electrical conductivity of 0783 ms/cm. These ionic liquids (immiscible with diethyl ether but miscible with water and DMSO) absorb air moisture, increasing their mass and decreasing their viscosity. Crystallographic analysis of [MPIm][BF_4] permitted us to identify the relative positions of the [BF_4]$^-$ anion and the CH–F bonded anion–cation layer in the crystal cell.

Experimental

General

NMR spectra were recorded on a Bruker DPX-250 instrument (250 MHz for ^{1}H, 62.5 MHz for ^{13}C, 100 MHz for ^{31}P, and 235 MHz for ^{19}F); DMSO-d_6 and D_2O were used as solvents; chemical shifts were reported in δ (ppm). Melting points were obtained on a Mettler FP61 apparatus. Conductivities of aqueous solutions of ionic liquids were measured by a Jenway 4060 apparatus at room temperature.

X-ray analysis

X-ray single diffraction analysis was performed on a colorless crystal of salt **2**. It was carried out on a Bruker SMART APEX II CCD area detector diffractometer (Mo-K_α radiation, graphite monochromator, λ = 0.71073) at 100.0(2) K. The structure was solved by a direct method using SHELXTL, V. 6.12.[23] The ORTEP diagram of salt **2** represents the atoms by thermal ellipsoids drawn at 50% probability level. See Supplementary data section for crystallographic data (excluding structure factors) for the structure of salt **2**.

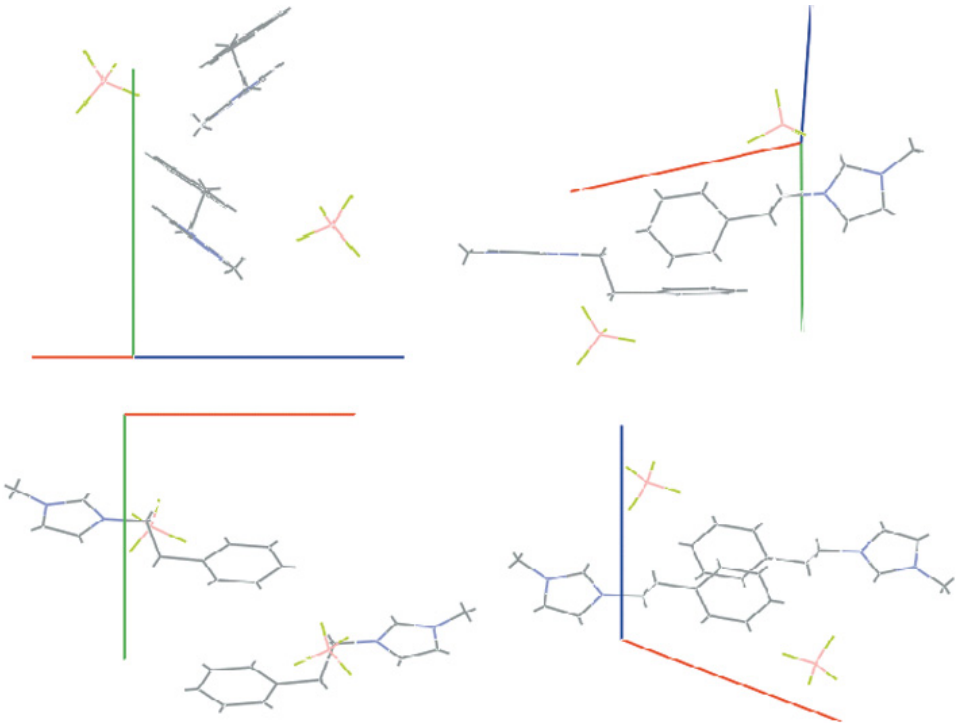
Preparation of 1-methyl-3-(2-phenyl ethyl) imidazolium chloride([MPIm][Cl] (salt 1))

Quantities of 1-methyl imidazole (8.2 g, 8 mL, 0.1 mol) and 2-phenyl ethyl chloride (14.1 g, 13 mL, 0.1 mol) were placed in a 50 mL closed glass vessel equipped with a magnetic stir bar. The mixture was stirred at 100 °C for 10 h. The yellow solid formed was washed with ether (2 × 50 mL) at 100 °C in a glass autoclave to afford pure [MPIm][Cl]; mp 91–92 °C. ^{1}H NMR (DMSO) δ: 3.17 (t, $J_{H–H}$ = 7.5 Hz, CH_2), 3.86 (s, 3H, CH_3), 4.50 (t, $J_{H–H}$ = 7.5 Hz, CH_2), 7.23–7.34 (m, C_6H_5), 7.79 (s, 1H), 7.88 (s, 1H), 9.49 (s, 1H). ^{13}C NMR (DMSO) δ: 35.9, 36.2, 50.1, 122.8, 123.8, 127.2, 128.9, 129.3, 137.1, 137.3.

Preparation of 1-methyl-3-(2-phenyl ethyl) imidazolium tetrafluoroborate ([MPIm][BF_4] (salt 2))

[MPIm][Cl] (22.2 g, 0.1 mol), $NaBF_4$ (10.9 g, 0.1 mol), and ethanol (50 mL) were placed in a 150 mL glass pressure autoclave equipped with a magnetic stirrer. The solution was stirred at 95 °C for 6 h. Hot solution with suspended NaCl was filtered. Cooling the filtrate to RT caused precipitation of [MPIm][BF_4] which was recrystallized from ethanol to afford white crystals; mp 61–62 °C. ^{1}H NMR (DMSO-d_6) δ: 3.18 (t, $J_{H–H}$ = 7.5 Hz, CH_2), 3.87 (s, 3H, CH_3), 4.48 (t, $J_{H–H}$ = 7.5 Hz, CH_2), 7.25–7.38 (m, C_6H_5), 7.55 (s, 1H), 7.71 (s, 1H), 9.05 (s, 1H). ^{13}C NMR (DMSO-d_6) δ: 36.1, 36.2, 50.3, 122.9, 124.0, 127.4, 129.1, 129.4, 137.6, 138.2. ^{19}F NMR (DMSO-d_6) δ: –148.91 (20%, ^{19}F–^{10}B), –148.96 (80%, ^{19}F–^{11}B); (D_2O) δ: –150.74 (20%, ^{19}F–^{10}B), –150.79 (80%, ^{19}F–^{11}B). Anal. calcd. for $C_{12}H_{15}N_2BF_4$: C 52.55, H 5.47, N 10.22; found: C 52.28, H 5.83, N 9.85.

Fig. 3. Crystal packing diagrams of [MPIm][BF_4].



Preparation of 1-methyl-3-(2-phenyl ethyl) imidazolium hexafluorophosphate ([MPIm][PF_6] (salt 3))

[MPIm][Cl] (22.2 g, 0.1 mol), KPF_6 (18.4 g, 0.1 mol), and ethanol (50 mL) were placed in a 150 mL glass pressure autoclave equipped with a magnetic stirrer. The solution was stirred at 85 °C for 6 h. Hot solution with suspended NaCl was filtered. Cooling the filtrate to RT caused precipitation of [MPIm][PF_6] which was recrystallized from ethanol to afford white crystals; mp 112–113 °C. ^{1}H NMR (DMSO-d_6) δ: 3.14 (t, $J_{H–H}$ = 7.5 Hz, CH_2), 3.87 (s, 3H, CH_3), 4.44 (t, $J_{H–H}$ = 7.5 Hz, CH_2), 7.21–7.35(m, C_6H_5), 7.65 (s, 1H), 7.70 (s, 1H), 9.01 (s, 1H). ^{13}C NMR (DMSO-d_6) δ: 36.0, 36.3, 50.4, 122.9, 124.1, 127.5, 129.3, 129.3, 137.1, 137.5. ^{19}F NMR (DMSO-d_6) δ –70.58 (d, $J_{F–P}$ = 710 Hz). ^{31}P NMR (DMSO-d_6) δ: –143.70 (septet, $J_{F–P}$ = 710 Hz). Anal. calcd. for $C_{12}H_{15}N_2PF_6$: C 43.37, H 4.52, N 8.43; found: C 43.07, H 4.46, N 7.69.

Supplementary data

AWARD LECTURE / CONFÉRENCE D'HONNEUR

Design and synthesis of some biologically interesting natural and unnatural products based on organosulfur and selenium chemistry

Thomas G. Back

Abstract: Organosulfur and selenium chemistry has provided fertile ground for the discovery of novel synthetic methodology and for the design of bioactive molecules with potential therapeutic applications. Thus, acetylenic sulfones have been employed in novel strategies for the synthesis of nitrogen heterocycles, including several biologically active alkaloids. The conjugate addition of nitrogen nucleophiles containing ester or chloroalkyl substituents to acetylenic sulfones was followed by base-mediated intramolecular alkylation or acylation to afford variously substituted piperidines, pyrrolizidines, indolizidines, quinolizidines, decahydroquinolines, and 4-quinolones. The products include the dendrobatid alkaloids (–)-pumiliotoxin C, indolizidines (–)-167B, 207A, 209B, and 209D, as well as (–)-(*ent*)-julifloridine, (–)-lasubine II, myrtine, and two recently discovered alkaloids from the medicinal plant *Ruta chalepensis*, which had not been previously synthesized. Acetylenic sulfones were also incorporated on solid supports and employed in the types of cyclizations mentioned above, as well as for Diels–Alder reactions and a large variety of 1,3-dipolar cycloadditions. Conjugate additions of tertiary cyclic α-vinyl amines to acetylenic sulfones generated zwitterions that underwent exceptionally facile formal aza-Cope rearrangements to afford ring-expanded macrocyclic amines. An iterative version was developed and used in the synthesis of motuporamine A and B. With respect to organoselenium chemistry, two classes of compounds are described that function as novel mimetics of the selenoenzyme glutathione peroxidase (GPx), which protects cells from oxidative stress caused by the formation of peroxides during aerobic metabolism. They include cyclic seleninates and spirodioxyselenuranes, both of which efficiently catalyze the reduction of peroxides with thiols and are of potential value in the mitigation of oxidative stress. Their aromatic derivatives are generally less effective catalysts, but substituent effects can be used to modulate their activities. The mechanism of their catalytic cycles has been elucidated and Hammett plots indicate that the oxidation of Se(II) to Se(IV) is the rate-determining step for both classes. A methoxy-substituted aromatic spirodioxyselenurane provided the fastest rate for a small-molecule selenium compound that we have observed to date for the reduction of hydrogen peroxide with benzyl thiol.

Key words: acetylenic sulfones, conjugate addition, intramolecular alkylation and acylation, alkaloid synthesis, aza-Cope reaction, solid-phase organic synthesis, glutathione peroxide mimetics, cyclic seleninates, spirodioxyselenuranes.

Résumé : La chimie des composés organiques du soufre et du sélénium a fourni un champ fertile pour la découverte d'une nouvelle méthodologie de synthèse et de développement de molécules bioactives possédant des applications thérapeutiques potentielles. Ainsi, les sulfones acétyléniques ont été utilisés dans de nouvelles stratégies pour la synthèse d'hétérocycles azotés, dont plusieurs alcaloïdes biologiquement actifs. L'addition conjuguée de nucléophiles azotés comportant des substituants esters ou chloroalkyles sur des sulfones acétyléniques a été suivie par des alkylations ou des acylations intramoléculaires catalysées par des bases qui ont conduit à la formation des diverses pipéridines, pyrrolizidines, indolizidines, quinolizidines, décahydroquinoléines et 4-quinolones. Les produits incluent les alcaloïdes dendrobatides (–)-pumiliotoxine C, indolizidines (–)-176B, 207A, 209B et 209D, ainsi que la (–)-(*ent*)-julifloridine, la (–)-lasubine II, la myrtine et deux alcaloïdes découverts récemment à partir de la plante médicinale *Ruta chalepensis* et qui n'avaient pas été synthétisés antérieurement. Les sulfones acétyléniques ont aussi été incorporées sur des supports solides et utilisés dans les réactions de cyclisations mentionnées plus haut ainsi que dans des réactions de Diels-Alder et une grande variété de réactions de cycloadditions 1,3-dipolaires. Les additions conjuguées d'amines α-vinyliques cycliques tertiaires à des sulfones acétyléniques conduisent à des zwitterions qui subissent des réarrangements formels azo-Cope exceptionnellement faciles qui fournissent des amines macrocycliques avec expansion de cycle. Une version itérative a été développée et utilisée dans la synthèse des motuporamines A et B. Pour ce

qui est de la chimie des composés organiques du sélénium, on décrit deux classes de composés qui fonctionnent comme de nouveaux mimétiques du sélénoenzyme peroxydaze du glutathion « GPx » qui protège les cellules contre la tension oxydante causée par la formation de peroxydes durant le métabolisme aérobie. Elles comprennent les séléninates et les spirodioxysélénuranes cycliques qui catalysent tous les deux la réduction des peroxydes avec des thiols et qui ont une valeur potentielle dans la mitigation de la tension oxydante. Leurs dérivés aromatiques sont généralement moins efficaces comme catalyseurs, mais les effets de substituant peuvent être utilisés pour moduler leurs activités. On a élucidé le mécanisme de leurs cycles catalytiques et les courbes de Hammett indiquent que, pour chacune des deux classes, l'oxydation du Se(II) au Se(IV) correspond à l'étape cinétiquement limitante. Pour la réaction de réduction du peroxyde d'hydrogène à l'aide de benzylthiol, de tous les composés à base de petites molécules contenant du sélénium, la vitesse la plus rapide a été obtenue avec un spirodioxysélénurane aromatique portant un substituant méthoxy.

Mots-clés : sulfones acétyléniques, addition conjuguée, alkylation et acylation intramoléculaire, synthèse d'alcaloïdes, réaction aza-Cope, synthèse organique en phase solide, mimétiques du peroxyde de glutathion, séléninates cycliques, spirodioxysélénuranes.

[Traduit par la Rédaction]

Introduction

Organosulfur and selenium chemistry has played a prominent role in our laboratory, both in the development of new synthetic methodology and in the design of biologically interesting compounds containing these elements. The first part of this article describes several novel protocols based on acetylenic sulfones for the synthesis of a broad range of nitrogen heterocycles. These include various types of alkaloids, some of which display potentially useful medicinal properties. In the latter section, the design and synthesis of several types of small-molecule selenium compounds that emulate the selenoenzyme glutathione peroxidase are described. This enzyme plays a crucial role as a biological antioxidant, which protects cells of living organisms against oxidative stress by catalyzing the reduction of harmful peroxides with the tripeptide glutathione.

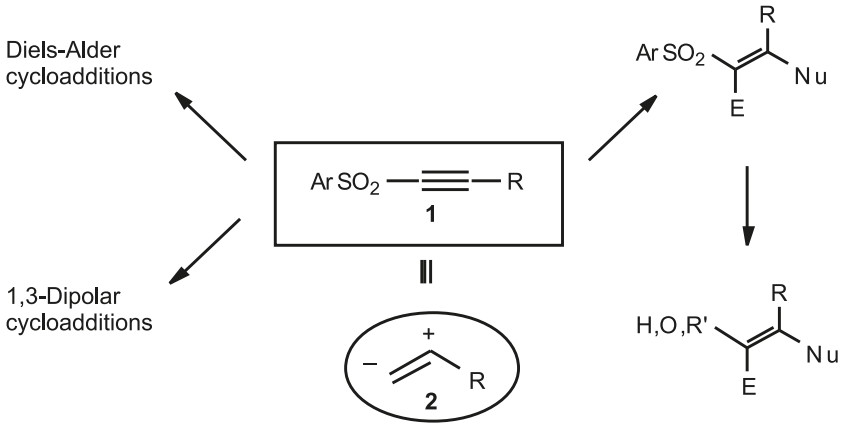
Organosulfur chemistry: synthesis of nitrogen heterocycles using acetylenic sulfones

The electron-withdrawing sulfonyl group in acetylenic sulfones **1**,[1,2] as well as in other types of unsaturated sulfones,[3,4] renders these compounds excellent dienophiles and dipolarophiles. It also promotes the conjugate additions of various types of nucleophiles to the β-position and stabilizes anions at the α-position. In this way, unsaturated sulfones behave in a comparable manner to that of unsaturated carbonyl compounds. However, unlike the latter species, where the presence of the carbonyl moiety is generally desired in the product, the sulfonyl group is typically cleaved at the end of such transformations by a variety of reductive, oxidative, or cross-coupling procedures.[5] The sequence of conjugate addition, α-alkylation or acylation, and desulfonylation therefore renders the acetylenic sulfone the synthetic equivalent of the hypothetical dipole species **2** (Scheme 1). The possibility of performing the conjugate addition in tandem with an intramolecular alkylation or acylation step suggests a variety of novel cyclization protocols.

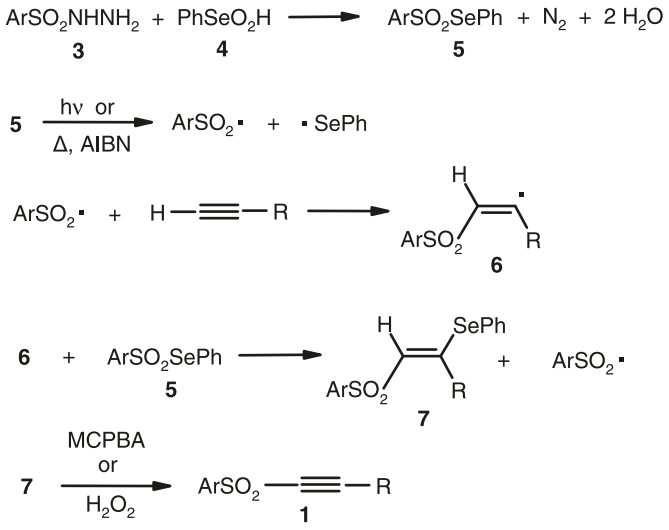
First, however, one requires a reliable source of acetylenic sulfones for such studies and, fortunately, several versatile methods for preparing these compounds are available.[2] We have found the procedure shown in Scheme 2, which we named "selenosulfonation",[6] to be particularly convenient for this purpose. The dropwise addition of a readily available sulfonhydrazide **3** in methanol solution to a stirred methanolic solution of commercially available benzeneseleninic acid (**4**) at 0 °C results in the evolution of nitrogen and the crystallization in high yield of the corresponding selenosulfonate **5** directly from the reaction mixture as an odourless, yellow solid.[7] When the selenosulfonate is heated with an acetylene in the presence of a radical initiator, or subjected to photoinitiation, a highly regio- and stereo-selective 1,2-addition is observed. Homolytic cleavage of the S–Se bond of **5** takes place, followed by addition of the sulfonyl radical to the terminus of the acetylene. The intermediate vinyl radical **6** then undergoes rapid chain transfer with additional **5**, resulting in an overall anti addition to produce **7**, with accompanying generation of a new sulfonyl radical to propagate the chain. The addition product, in which the vinylic hydrogen and the phenylseleno group are cis-oriented, is then subjected to oxidation with MCPBA or hydrogen peroxide, followed by a selenoxide syn-elimination to afford the desired product **1**.[8] There is a strong preference for the formation of the acetylene, instead of the corresponding allene, even when the substituent R is an alkyl group containing available hydrogens for syn-elimination.

Several typical cyclizations via the conjugate addition–intramolecular alkylation/acylation pathway of acetylenic sulfones are shown in Scheme 3. For example, when a primary amine containing a chloroalkyl substituent is employed as the nucleophile, the adduct **8** is obtained in generally excellent yield in a variety of solvents. The product **8** in THF is then typically cooled to –78 °C and excess LDA in THF is added to generate a sulfone-stabilized enamide anion by abstraction of the acidic N–H proton. After ~15–30 min, the reaction is quenched with water to afford the corresponding dehydropiperidine **9**.[9,10] The use of THF in both the conjugate addition and cyclization steps results in a particularly convenient one-pot procedure for obtaining **9**, as the solution of **8** is simply cooled to –78 °C prior to the addition of LDA. The chloroalkylamines can be stored indefinitely, as their hydrochloride salts and the free bases are liberated prior to use. Similarly, amino esters can be cyclized via intramolecular acylation of addition products **10** to produce enaminones **11**. In the case of cyclic secondary amines, the

Scheme 1.



Scheme 2.



addition products **12** lack the acidic N–H proton present in **8** and **10**. However, providing that the substituent R contains a hydrogen atom in the γ-position (relative to the sulfonyl substituent), then cyclization can be effected via the corresponding sulfone-stabilized allyl anion, which reacts with high regioselectivity at its α-position. The ring sizes of the bicyclic products **13** are determined by the size of ring in the starting amine and by the length of the pendant chloroalkyl substituent. To date, we have only investigated *n*, *m* = 1 or 2, but it is entirely possible that other ring sizes could also be prepared in this manner. Intramolecular acylation can be effected similarly, starting with cyclic amines containing ester substituents. It is also worth noting that the precursor amines are typically prepared from amino acids and the stereocenters in the latter are incorporated intact into the cyclized products, where they may be used to control the configurations of new stereocenters developed in subsequent steps. In this way, we have prepared series of pyrrolizidines **14** (*n*, *m* = 1),[9] indolizidines **15** or **16** (*n* = 1, *m* = 2 or *n* = 2, *m* = 1),[9] and quinolizidines **17** (*n*, *m* = 2),[9] as well as decahydroquinolines **18**[11] and 4-quinolones **19**[12] by minor variations of the protocol. These core structures are shown in Fig. 1, after appropriate desulfonylation and reduction, with the part originating from the acetylenic sulfone indicated in bold. Several illustrative examples of the syntheses of natural products containing these ring systems follow.

The dendrobatid alkaloids are found in the toxic skin secretions of certain species of neotropical frogs that are found principally in the rain forests of Central and South America.[13] These compounds serve as a chemical defense against predators, and the skin secretions are employed by indigenous tribes as coatings for blowgun darts and arrows to enhance their effectiveness in hunting. Over 800 dendrobatid alkaloids have been identified,[14] largely through the lifelong efforts of the late John Daly, and many contain the types of ring systems that we envisaged as possible products via Scheme 3. When used individually, and at appropriate doses, some dendrobatid alkaloids display potentially useful pharmacological properties, including cardiotonic, analgesic, and neuroregulatory activity. They are therefore of interest as leads in drug discovery and as biochemical tools. Moreover, many dendrobatid alkaloids occur naturally in but trace amounts, and their structures have only been tentatively identified, often based solely on GC–MS data. Thus, their synthesis has attracted considerable attention because of possible medicinal applications and to verify their assigned structures.

(–)-Pumiliotoxin C (**27**) was first isolated from the frog *Dendrobates pumilio* by Daly et al.[15] Although it is one of the most abundant dendrobatid alkaloids, only 80 mg of **27** were isolated from 2540 frogs collected in Panama,[16] and this compound has therefore been the subject of numerous synthetic efforts.[17] Our approach to pumiliotoxin C is illustrated in Scheme 4. The amino ester **20** is available as a single enantiomer.[11b,18] Conjugate addition of **20** to acetylenic sulfone **21** was effected in the usual manner, and cyclization of **22** by intramolecular acylation occurred without epimerization of the ester substituent via its enolate. Conversion of the product enaminone **23** to the intermediate enol triflate **24** was followed, without isolation of the latter, by stereoselective hydrogenation from the exo face and simultaneous hydrogenolysis of the C–O bond. The major diastereomer, in the form of the easier-to-handle Cbz derivative **26**, was then desulfonylated with sodium amalgam and deprotected to afford (–)-pumiliotoxin C (**27**) as a pure enantiomer.[11b] This

Scheme 3.

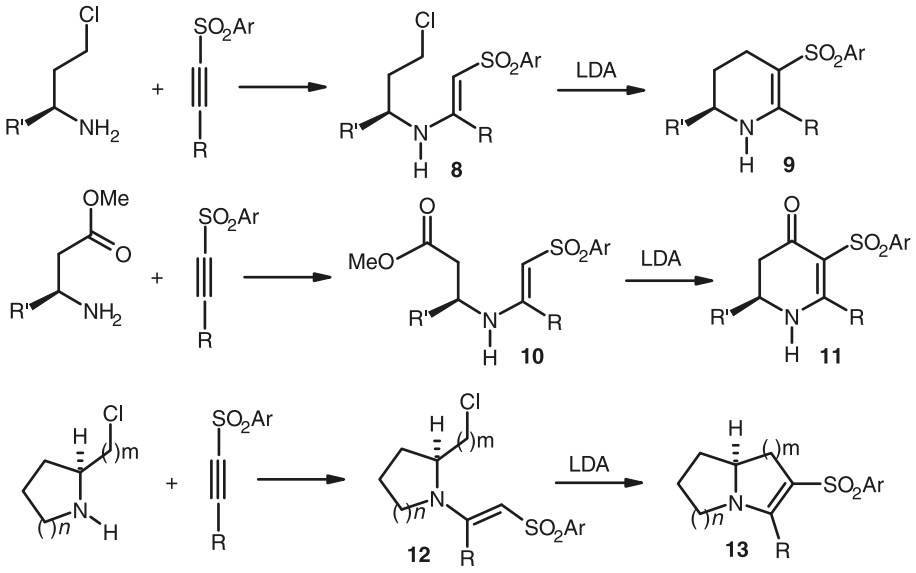


Fig. 1. Bicyclic nitrogen heterocycles produced from acetylenic sulfones.

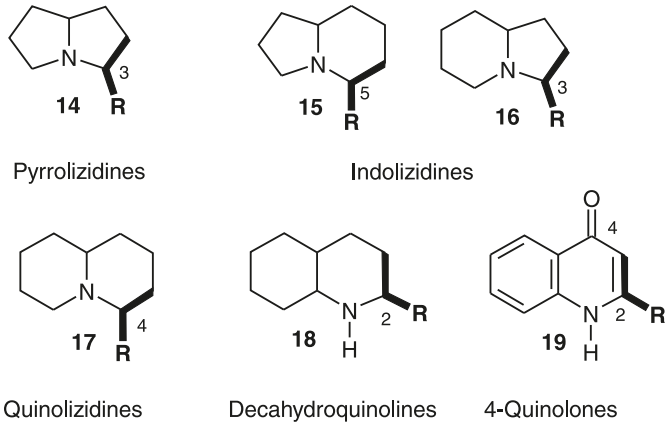


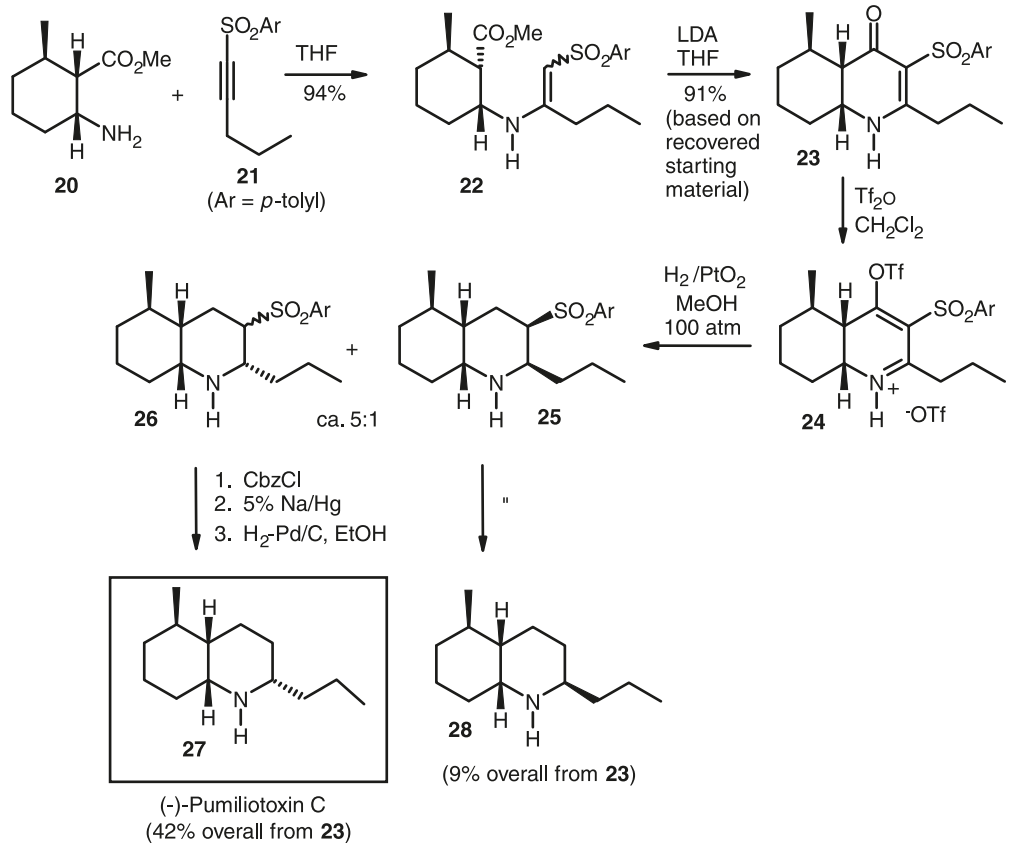
provided a concise and relatively efficient synthesis of the alkaloid from the key intermediates **20** and **21**.

The dendrobatid alkaloid family also includes numerous examples of substituted indolizidines,[14,19] several of which proved amenable to synthesis via cyclizations of acetylenic sulfones. Thus, indolizidines (–)-167B (**33**) and (–)-209D (**34**) were easily prepared from 2-(2-chloroethyl)pyrrolidine (**29**), which was in turn obtained from L-proline (Scheme 5).[9] Thus, conjugate addition of **29** to acetylenic sulfones **21** and **30**, followed by treatment with LDA to effect intramolecular alkylation, afforded dehydroindolizidines **31** and **32**, respectively. Stereoselective reduction of the enamine double bond via the corresponding iminium ion, followed by reductive desulfonylation under Birch conditions, provided the two alkaloids **33** and **34** as pure enantiomers in high overall yield. Similarly, the homologated proline derivative **35** was prepared by the method of Lhommet et al.[20] and converted into chloroalkylamine **36**. The latter compound was then used to obtain the 5,8-disubstituted indolizidines (–)-209B (**39**) and (–)-207A (**43**) via a similar sequence of steps, as shown in Scheme 6.[9]

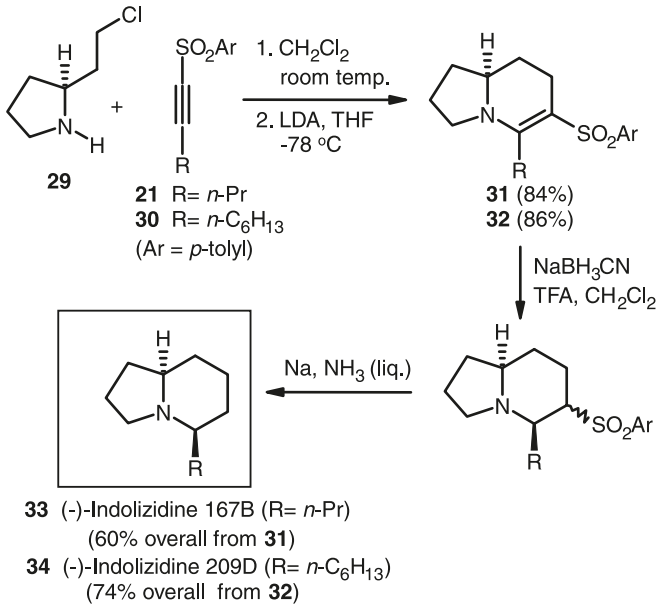
The synthesis of the quinolizidine alkaloid (–)-lasubine II (**50**) from the homologated pipecolic acid derivative **44** and the acetylenic sulfone **45** by this protocol (Scheme 7) posed an additional challenge. As seen earlier, the base-mediated cyclization step proceeds via a sulfone-stabilized enamide anion formed by abstraction of the remaining N–H proton when a primary amine is used (as in **22** in Scheme 4), or via a sulfone-stabilized allyl anion formed by deprotonation of the γ-position of the sulfone in cases where a secondary amine is employed (as in the preparation of the indolizidine products in Schemes 5 and 6). Since amine **44** is secondary and the acetylenic sulfone contains an aromatic substituent, the conjugate addition product **46** lacks both N–H and γ-protons. Cyclization is therefore contingent upon the formation of the corresponding sulfone-stabilized vinyl anion preferentially to that of the ester enolate of **46**, upon treatment with LDA. Fortunately, it appears that the acidity of the vinyl sulfone is at least comparable to that of the ester and the desired cyclization to **47** was achieved, albeit in somewhat lower yield than usual. We hoped that the reduction of the enamine double bond in **47** could be performed simultaneously with stereoselective reduction of the ketone function to the axial alcohol. However, a variety of reducing agents that were investigated failed to provide the desired outcome. The enamine and ketone were therefore reduced with sodium borohydride, which afforded the product as a mixture of inseparable alcohol epimers. These were reoxidized back to the ketone and a more hindered reducing agent, L-selectride, with a stronger preference for equatorial approach, then afforded the axial alcohol required in the final product **50** with high stereoselectivity.[21] A similar approach to the quinolizidine alkaloid myrtine was also successful.[21b]

We next explored the possibility of using anthranilic esters to produce 4-quinolones by conjugate additions to acetylenic sulfones, followed by intramolecular acylation. The 4-quinolone structure comprises the core of numerous compounds that display a remarkable variety of biological activities.[22,23] Perhaps, the best known is the antibacterial agent ciprofloxacin, which inhibits bacterial topoisomerase and is

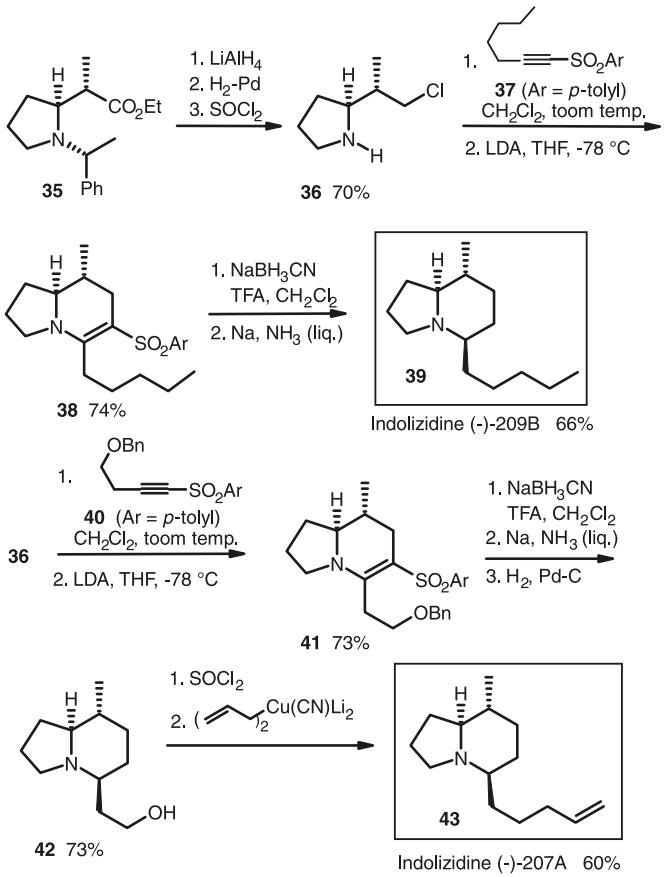
Scheme 4.



Scheme 5.

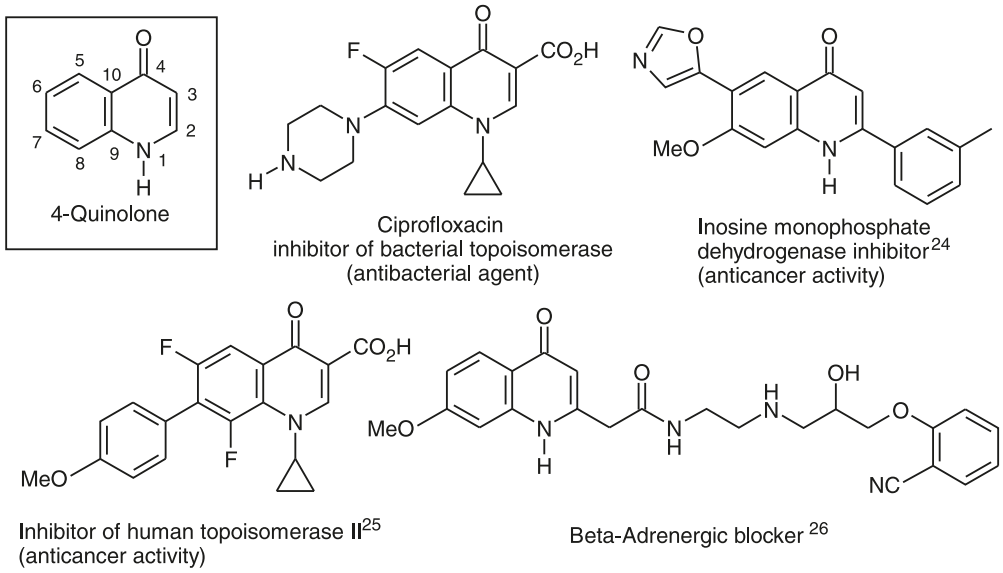


Scheme 6.

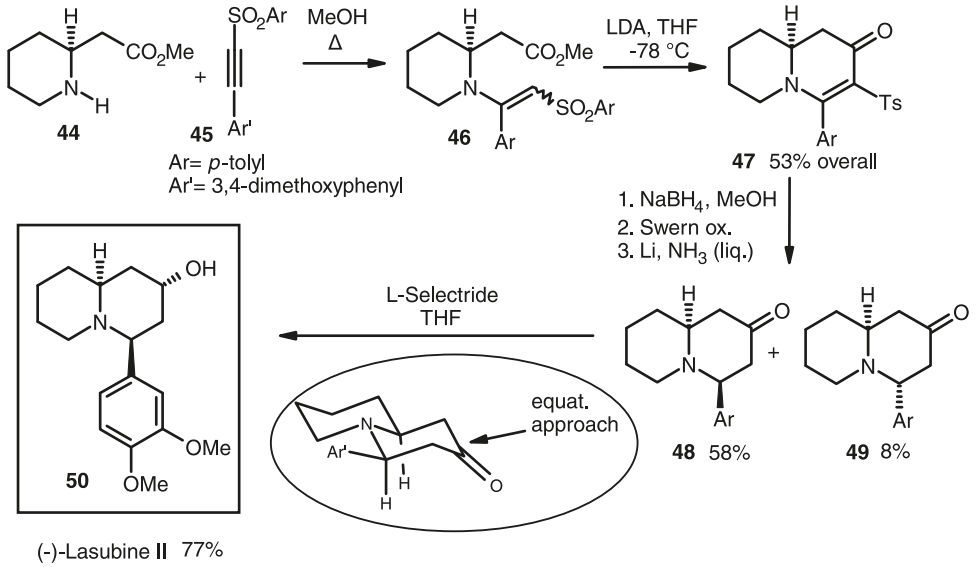


currently among the most widely prescribed antibiotics. A few other representative 4-quinolones and their principal bioactivities are shown in Fig. 2.[24–26] The principal difficulty in our approach to these target molecules lies in the doubly deactivated aniline amino group, where the lone pair is delocalized not only by the aromatic ring, but also by the ester substituent required for the cyclization step. After considerable effort at optimization, it was found that the conjugate

Fig. 2. Examples of bioactive 4-quinolones.



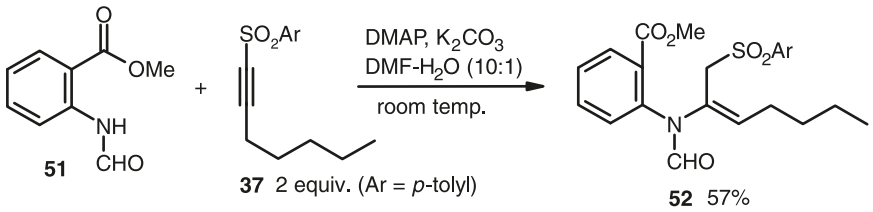
Scheme 7.



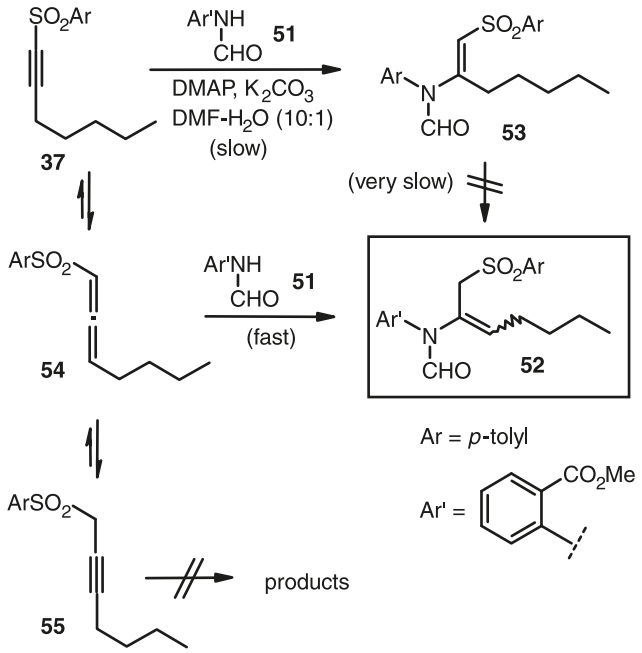
base of the *N*-formyl anthranilate **51** could be added to acetylenic sulfone **37** under the conditions indicated in Scheme 8.[12b] However, the sluggish reaction rate and competing polymerization of the acetylenic sulfone necessitated the use of excess **37**. Furthermore, the presence of DMAP was required, and even under precisely optimized conditions, the best yield of the addition product **52** was only 57%. It was therefore evident that the process in this form would not be of general synthetic utility. Finally, it was also noted that product **52** contained an allyl sulfone moiety instead of being formed as the typically observed vinyl sulfone isomer, which was present in only trace amounts.

While it was tempting to assume that the allyl sulfone **52** was produced by prototropic isomerization of the initially formed, but thermodynamically less stable vinyl sulfone, further investigation revealed that this was not the case.[12b] An authentic sample of the vinyl sulfone **53** was subjected to the same conditions under which **52** had been obtained, and it was observed that the isomerization was too slow to account for the formation of **52** as the main product in Scheme 8. Furthermore, a control experiment with acetylenic sulfone **37** in the absence of amine **51** showed that it isomerized readily to its allenic counterpart **54** under the basic conditions of Scheme 8, followed by further isomerization to the propargylic isomer **55** (Scheme 9). Finally, it was observed that authentic allene **54** reacted with amine **51** considerably faster than did acetylene **37**. Thus, the pathway for the reaction of the poorly nucleophilic aniline derivative **51** with acetylenic sulfone **37** proceeds via the prior isomerization of **37** to its allenic isomer **54**, followed by conjugate addition of **51** to the latter and not by the initial conjugate addition of amine **51** to acetylene **37**, with subsequent isomerization of the vinyl adduct **53** to the observed allyl product **52**. The propargylic sulfone **55** is inert toward conjugate addition, but can slowly regenerate the more reactive allenic sulfone through further equilibration, as shown in Scheme 9.

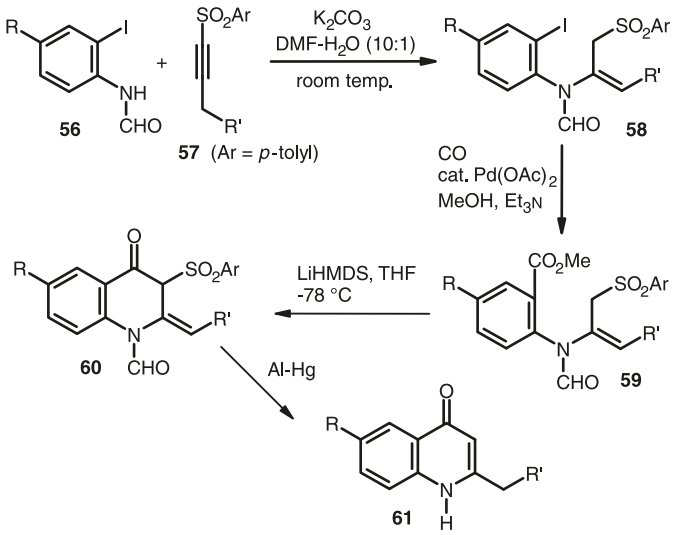
Scheme 8.



Scheme 9.



Scheme 10.



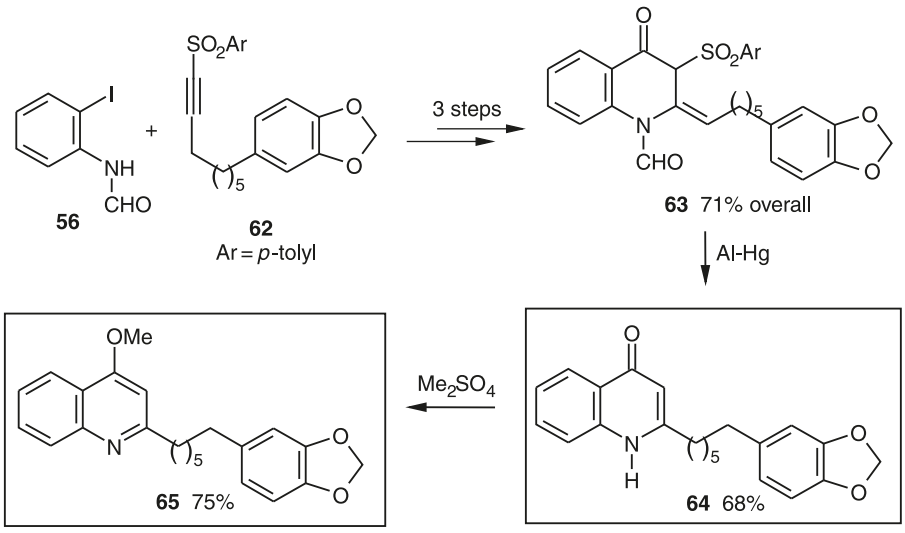
The complexity and limitations of the above method prompted us to develop an improved procedure, based on the enhanced nucleophilicity of the conjugate bases of *N*-formyl-*o*-iodoanilines compared with those of the corresponding anthranilate esters such as **51** in Scheme 8.[12b] For example, iodoaniline **56** (R = H) added smoothly to equimolar amounts of acetylenic sulfone **57** (R = *n*-pentyl), without the need for DMAP, affording the corresponding **58** in the improved yield of 81%. Similar conjugate additions of substituted *o*-iodoanilines **56** with other acetylenic sulfones **57** proved equally effective. The ester moiety required for the subsequent cyclization step was then introduced into **58** by a palladium-catalyzed carbonylation reaction.[27] Cyclization of the latter products **59** to **60** was effected with LiHMDS, while simultaneous desulfonylation, deformylation, and isomerization of the double bond into conjugation with the carbonyl group was carried out in one step with aluminum amalgam. This procedure proved widely applicable to variously substituted *o*-iodoanilines, including one already containing an ester moiety (i.e., **56**, R = CO_2Me), leading to an efficient and concise route to 4-quinolones **61** (Scheme 10). Of special note is the preparation of **61** with R = H and R′ = *n*-Bu from iodoaniline **56** (R = H) and acetylenic sulfone **37** in 40% overall yield.[12b] This compound had been isolated from a marine pseudomonad by Andersen and co-workers[28] and exhibits antibiotic and other bioactivities.[28,29] An X-ray crystal structure confirmed the presence of the 4-quinolone tautomer, as opposed to the corresponding pyridinol.[12b]

In 2000, quinolone **64** and quinoline **65** were isolated from the medicinal plant *Ruta chalepensis* by El-Sayed et al.[30] Extracts of this plant are used in the Middle East as antispasmodic and antirheumatic agents. The synthesis of these natural products was easily completed via the general protocol shown in Scheme 10. Thus, *N*-formyl-*o*-iodoaniline (**56**, R = H) and acetylenic sulfone **62** were converted to **63** in 71% overall yield via the usual three-step sequence of conjugate addition, palladium-catalyzed carbonylation, and base-mediated cyclization. Treatment of **63** with aluminum amalgam then afforded the 4-quinolone alkaloid **64** and O-alkylation produced the corresponding methoxyquinoline **65** in yields of 68% and 75%, respectively (Scheme 11). This represents the first synthesis of these two alkaloids.[12]

The success of the above cyclizations prompted us to explore ways in which acetylenic sulfones could be immobilized on polymer supports, since solid-phase variations of these processes might lend themselves to the production of small libraries of nitrogen heterocycles (Scheme 12).

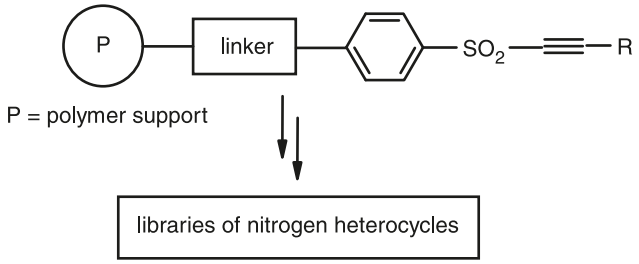
Commercially available Merrifield resin was first converted to the polymer-supported carboxylic acid **66** by a literature method.[31a] The benzylic bromide **67** was then prepared by selenosulfonation (see Scheme 2) of the corresponding acetylene and coupled to the polymer by esterification with the cesium carboxylate of **66**.[31b] Selenoxide syn-elimination was performed on the support rather than prior to the coupling step to avoid competing conjugate addition of the carboxylate to the fully developed acetylenic sulfone. Several representative solid-supported acetylenic sulfones **68** were thus prepared (Scheme 13) and comprise the first such species to be reported.[32]

Scheme 11.



Ruta chalepensis alkaloids

Scheme 12.



We were delighted to discover that a variety of cyclizations with various chloroalkylamines could be effected with solid-supported acetylenic sulfones **68** under similar conditions as in solution phase. Furthermore, various Diels–Alder and 1,3-dipolar cycloadditions could also be performed with **68**. The products were cleaved from the supports in either of two ways. First, hydrolysis of the ester linker afforded cyclized products containing the 4-(hydroxymethyl)phenylsulfonyl moiety intact. Alternatively, if products devoid of the sulfonyl group were desired, cleavage by reductive desulfonylation with sodium amalgam was also feasible. Scheme 14 illustrates a few representative examples.[32]

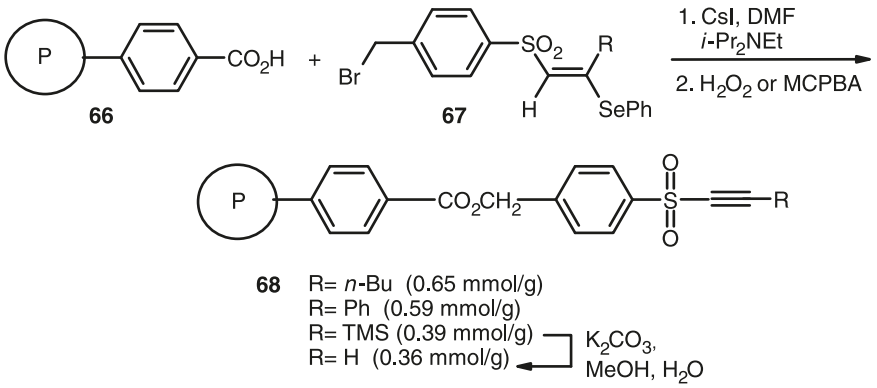
A more extensive investigation of 1,3-dipolar cycloadditions of acetylenic sulfones ensued, both on solid supports and in solution phase.[33] Successful cycloadditions were observed with azides, diazo compounds, nitrile oxides, nitrile imines, nitrile ylides, nitrones, azomethine imines, azomethine ylides, munchnones, and sydnones.

The final applications of acetylenic sulfones that will be described here involve the reactions of acetylenic sulfone **70** with tertiary cyclic amines containing α-vinyl substituents, such as **69**. The expectation was that the usual conjugate addition would occur, producing a zwitterion intermediate **71** that would undergo a formal aza-Cope rearrangement to **72** (Scheme 15).[34] Aza-Cope reactions are generally characterized by high activation energies and so require strongly elevated temperatures. However, it has been reported that quaternization of the nitrogen atom by protonation or complexation with a Lewis acid lowers the activation energy and accelerates the rearrangement considerably.[35] In the case of a dipolar intermediate such as **71**, one might expect an even more facile rearrangement because of the cancellation of charge during the course of the transformation. The overall process would result in the ring expansion of the original starting amine **69** by four carbon atoms and would provide a potentially useful approach to the synthesis of medium- and large-ring cyclic amines such as **72**.

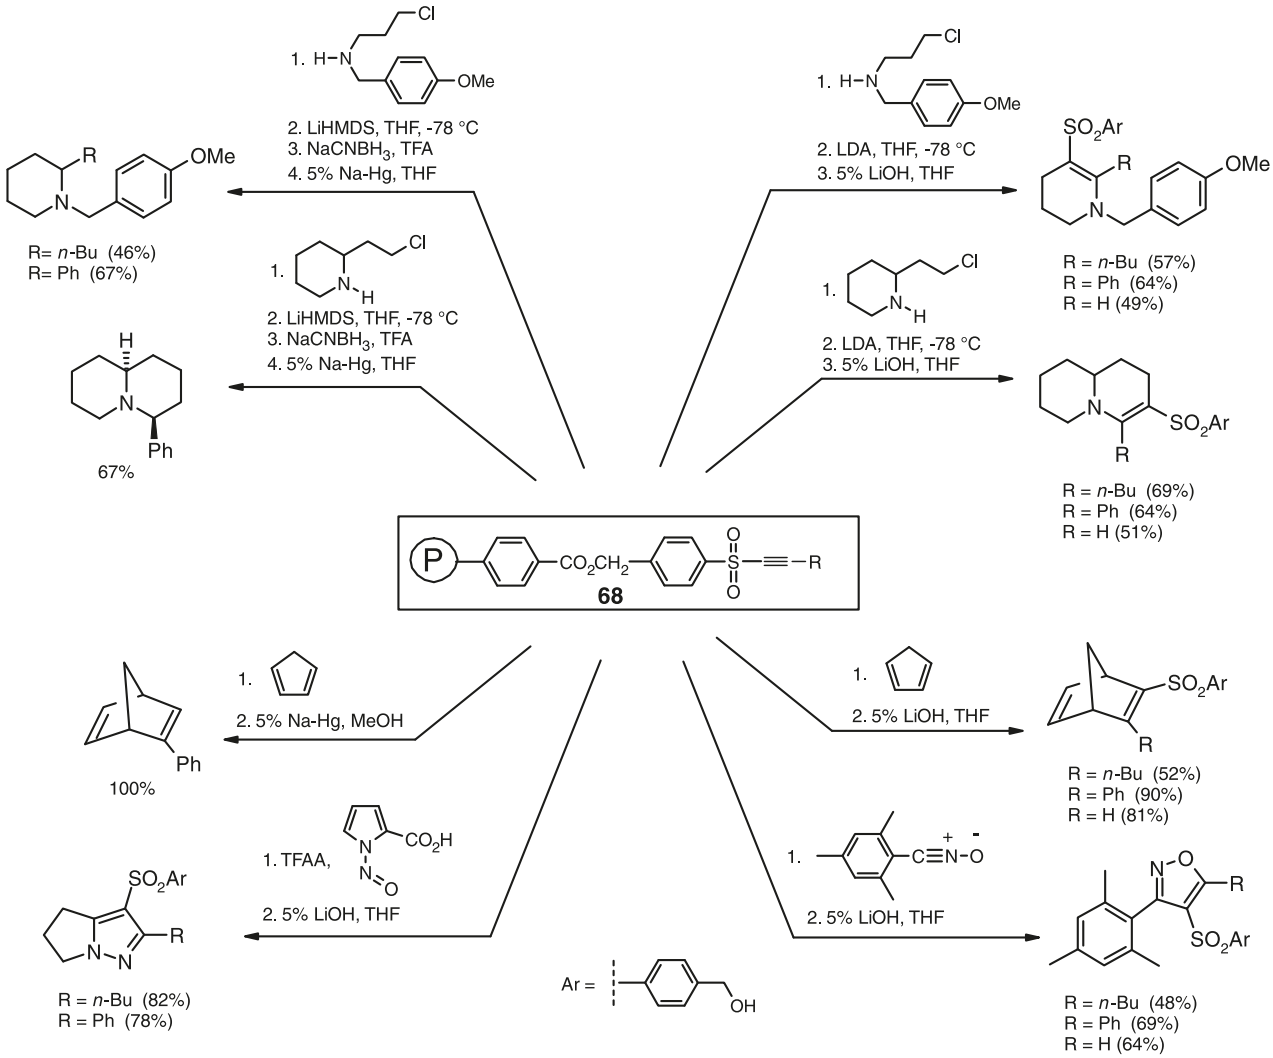
The results of this study are illustrated in Scheme 16.[36] We observed that, as expected, the rearrangement took place under remarkably mild conditions, typically in dichloromethane at temperatures ranging from –78 °C to reflux. In some cases, other solvents, including methanol, acetonitrile, ether, DMF, and THF, were also employed successfully. The products contained from nine- to 17-membered rings and the method tolerated other heteroatoms, as well as substituents at either position of the vinyl group. Selective reduction of either the enamine or isolated double bonds could be effected with sodium borohydride or cyanoborohydride, or by hydrogenation, respectively. Desulfonylation was accomplished with sodium amalgam or under Birch conditions.

While the precise mechanism of the rearrangement is not fully understood, a kinetic investigation indicated that the process is bimolecular (first-order in each reactant) and that it is accelerated by the presence of electron-withdrawing substituents at the para position of the aryl group in the acetylenic sulfones. This supports the formation of the zwitterion **71** as the rate-determining step, as a more strongly electron-withdrawing arylsulfonyl substituent better stabilizes the vinyl anion moiety of **71** and lowers the activation energy leading to its formation.[36a] The rearrangement step may, however, be different from a classical Cope or hetero-Cope reaction, where the new sigma bond is produced from the interaction of p orbitals at the terminal positions of a 1,5-diene or heterodiene system. In the present case, this step could alternatively be envisaged as an intramolecular allylic substitution (S_N') of the quaternary nitrogen atom by a sulfone-stabilized vinyl anion.

Scheme 13.

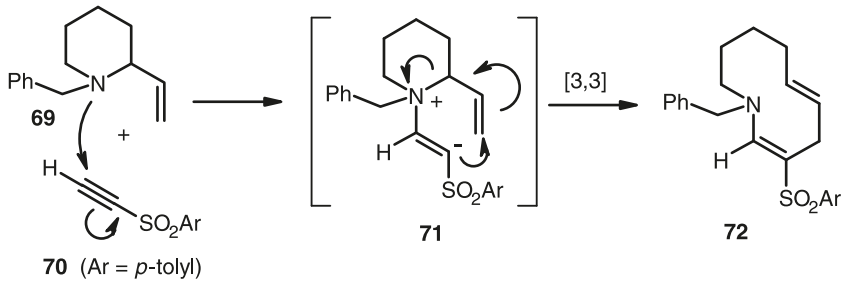


Scheme 14.

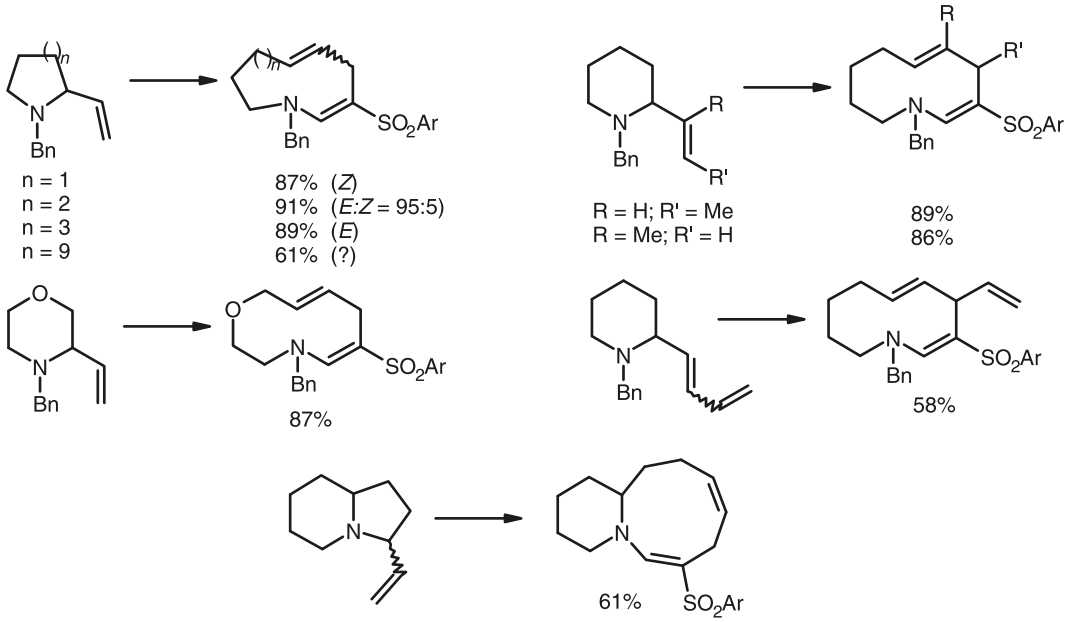


An iterative version of the aza-Cope reaction was also achieved by introducing a new α-vinyl substituent into the sulfonyl-substituted enamine moiety of the initial ring-expanded products **73** and **74**. This was accomplished by treatment of the latter with triflic acid and vinylmagnesium bromide, resulting in incorporation of the desired vinyl group via the corresponding iminium ion. In general, some starting material was also recovered because of competing deprotonation of the iminium intermediate by the Grignard reagent. The iterative ring-expansion was successfully applied to the synthesis of motuporamine A and B (**75** and **76**, respectively; Scheme 17).[36a,37] These compounds are marine natural products that were discovered by the Andersen group.[38a] They exhibit powerful anti-invasive and anti-angiogenic activity which makes them potentially useful as anticancer agents.[38]

Scheme 15.



Scheme 16.



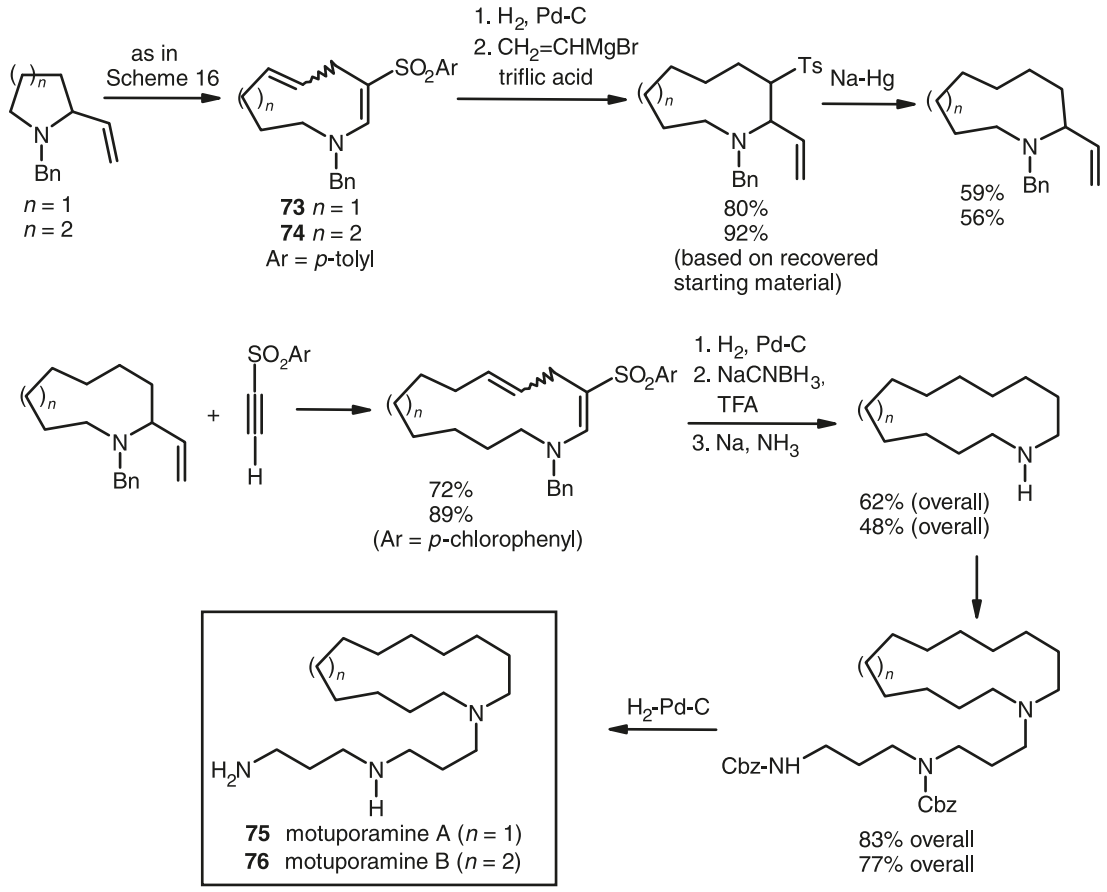
All reactions were performed in CH_2Cl_2 (-78 °C to reflux); Ar = *p*-tolyl

The preceding results indicate that acetylenic sulfones are a very useful and, to date, somewhat overlooked class of compounds in organic synthesis. Among other applications, they readily undergo conjugate additions by primary, secondary, and even tertiary amines, followed by intramolecular alkylations, acylations, or formal aza-Cope rearrangements to afford a variety of nitrogen heterocycles. These include the dendrobatid alkaloids (–)-pumiliotoxin C and indolizidines (–)-167B, (–)-207A, (–)-209B, and (–)-209D, as well as the piperidine alkaloid (–)-*ent*-julifloridine and the quinolizidines (–)-lasubine II and myrtine. Anilines provide access to 4-quinolones, as in the first syntheses of two alkaloids from the medicinal plant *R. chalepensis*, while cyclic tertiary α-vinylamines afford macrocyclic amines such as the motuporamines.

Organoselenium chemistry: design and synthesis of glutathione peroxidase mimetics

The preceding section described some of our studies of organosulfur chemistry during the past 10 years that enabled us to develop new synthetic routes to a host of biologically interesting natural products. During this period, we also investigated applications of selenium in the design and synthesis of unnatural products that would mimic the antioxidant properties of the selenoenzyme glutathione peroxidase (GPx). Harmful peroxides and other reactive oxygen species are produced during normal aerobic metabolism and contribute to a condition generally referred to as oxidative stress.[39] This in turn can lead to a variety of degenerative conditions and disease states, including inflammation, cancer and mutagenesis, cardiovascular and neurological disease, and possibly the aging process. Fortunately, protection from oxidative stress is available from both exogenous and endogenous sources. The former include natural antioxidants present in a variety of foods and beverages,[39b,39c] while several enzymes (e.g., superoxide dismutase, catalase, and a series of peroxidases) afford endogenous protection. In particular, the selenoenzyme GPx catalyzes the destruction of peroxides with the sacrificial reductant glutathione, which is a ubiquitous tripeptide thiol that occurs in high concentration in the cells of higher organisms. X-ray crystallography has established that GPx has a tetrameric structure, in which each subunit contains a selenocysteine residue bearing a redox-active selenol function at its active site.[40] The catalytic cycle of GPx[41] is shown in Scheme 18, where the selenol (EnzSeH) reduces a peroxide molecule to the corresponding

Scheme 17.

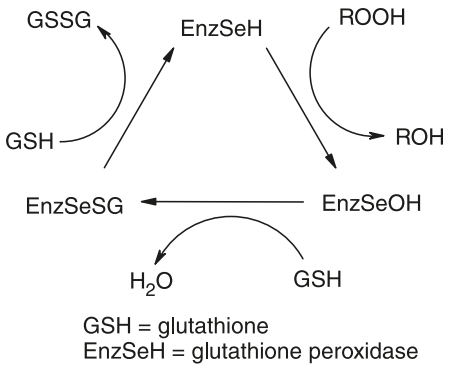


alcohol (or water in the case of hydrogen peroxide) and is in turn oxidized to the selenenic acid EnzSeOH. This reacts successively with two molecules of glutathione (GSH), first producing an intermediate selenenyl sulfide (EnzSeSG), followed by regeneration of the original selenol moiety and oxidation of GSH to its disulfide (GSSG).

Although a diet rich in antioxidants, together with endogenous enzymes such as GPx, help to mitigate the deleterious effects of oxidative stress, there are conditions where such effects overwhelm one's natural defenses. For example, heart attack and stroke patients suffer increased levels of oxidative stress during ischemic reperfusion, resulting in cardiovascular and neurological damage. Consequently, several groups have devised small-molecule selenium compounds designed to emulate the catalytic activity of GPx that could be administered as additional protective measures to such patients.[42] Figure 3 shows a few examples of such compounds that have been reported in the literature.[43–51] Many contain a nitrogen atom that is covalently bonded to selenium, or that can coordinate with it at appropriate stages in the catalytic cycle, which appears to modulate the redox properties of the selenium center. Several tellurium compounds have also been investigated in this context. Two compounds, SYI 2074[52] and ebselen,[53,54] are currently in Phase I and Phase III clinical trials being conducted by Synvista Therapeutics Inc. and Daiichi Sankyo Inc., respectively.

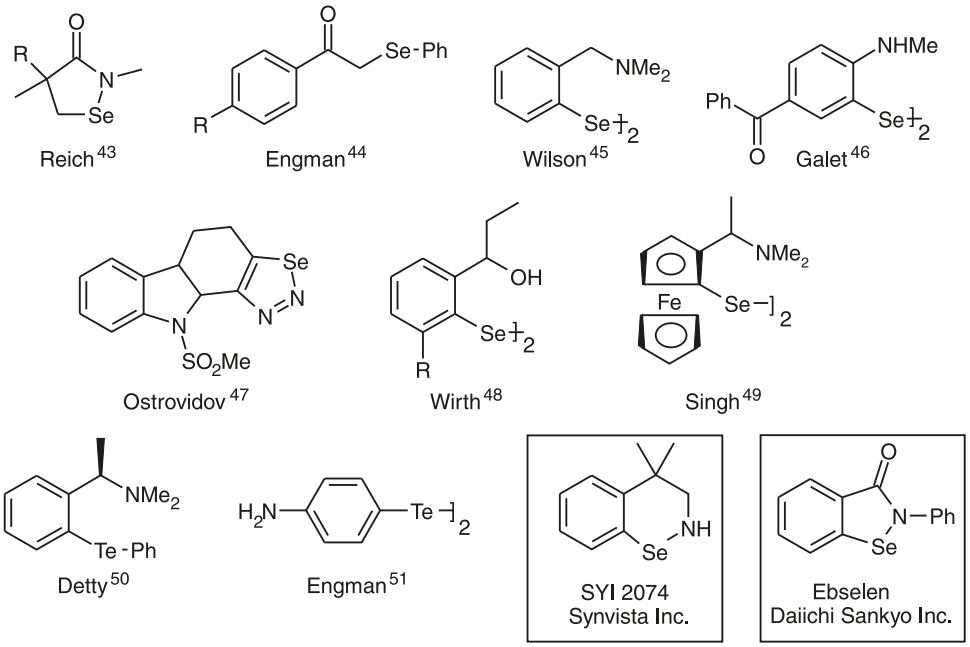
During an investigation of camphor-based chiral auxiliaries for asymmetric electrophilic selenium reactions, we had

Scheme 18.



occasion to prepare cyclic selenenamide **77** (Scheme 19).[55] Since this compound bears a superficial similarity to some of the existing Se–N-containing GPx mimetics in Fig. 4, it seemed opportune to test the compound for GPx-like behaviour in an assay that we developed for this purpose. The assay employed *t*-butyl hydroperoxide as a model peroxide and benzyl thiol as a surrogate for glutathione, which permitted the reaction to be monitored conveniently by HPLC or NMR methods. The catalytic activity of various selenium compounds could then be compared according to the time

Fig. 3. Examples of small-molecule mimetics of GPx.



Scheme 19.

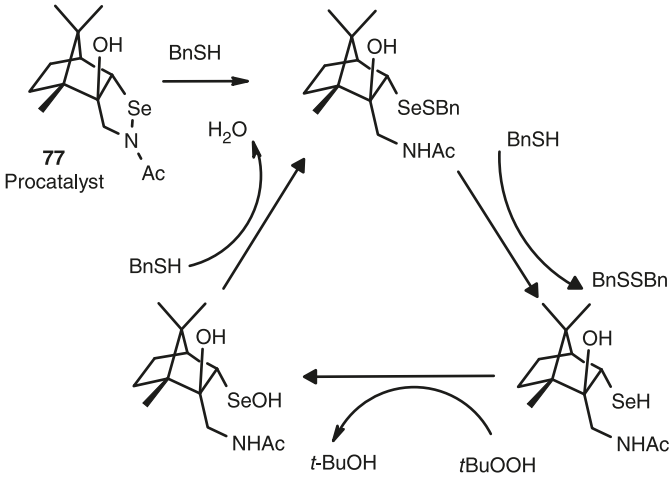


Fig. 4. ORTEP diagram for the X-ray structure of spirodioxyselenurane **88**.

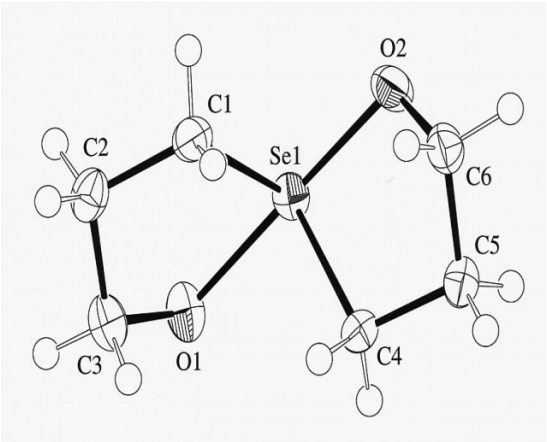
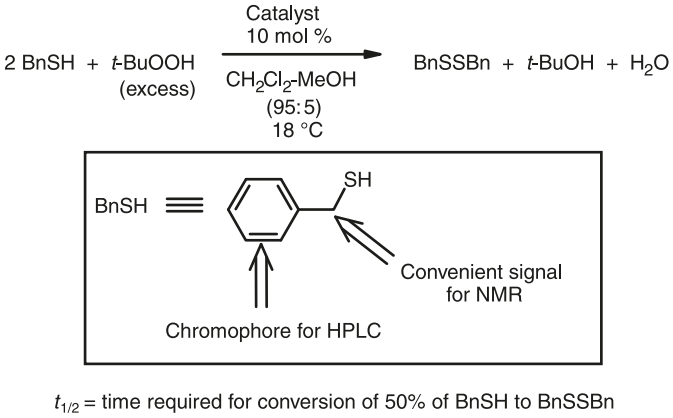


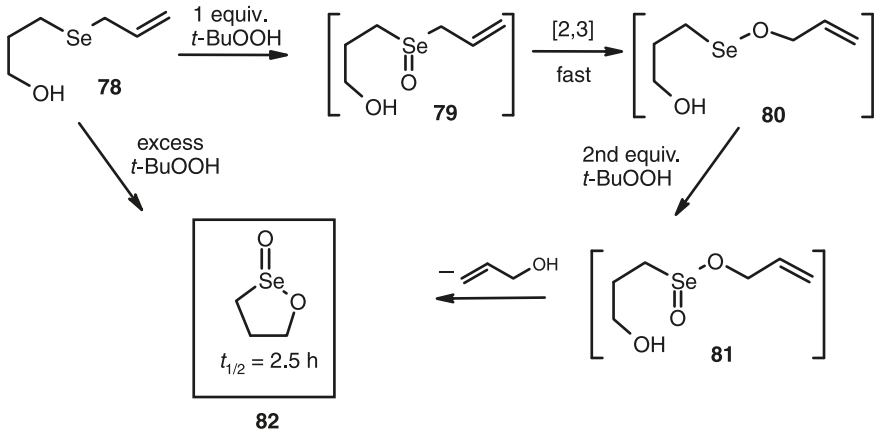
Scheme 20.



($t_{1/2}$) required for the consumption of 50% of the thiol under the conditions indicated in Scheme 20. When **77** was thus tested, it produced a $t_{1/2}$ of 18 h, compared with 42 h for ebselen and >300 h for a control reaction with no catalyst.[55,56] A study of the mechanism revealed that **77** was merely a procatalyst that reacted with the thiol in the initial step to generate a selenenyl sulfide analogous to EnzSeSG in Scheme 18. From there, the catalytic cycle mimicked that of GPx, proceeding via a putative selenol and selenenic acid.[55]

These encouraging results prompted us to investigate many other types of organoselenium compounds for GPx activity in the ensuing years, of which two classes stood out. In the first, we examined a series of allyl ω-hydroxyalkyl selenides (e.g., **78**), reasoning that oxidation with a peroxide would produce the corresponding selenoxide **79**, which would undergo a very rapid [2,3]sigmatropic rearrangement, affording the selenenate ester **80**. This was expected to provide entry into a catalytic cycle similar to those shown in Schemes 18 and 19, where a related selenenic acid is generated and reacts with a thiol to afford the selenenyl sulfide in one of the three key

Scheme 21.

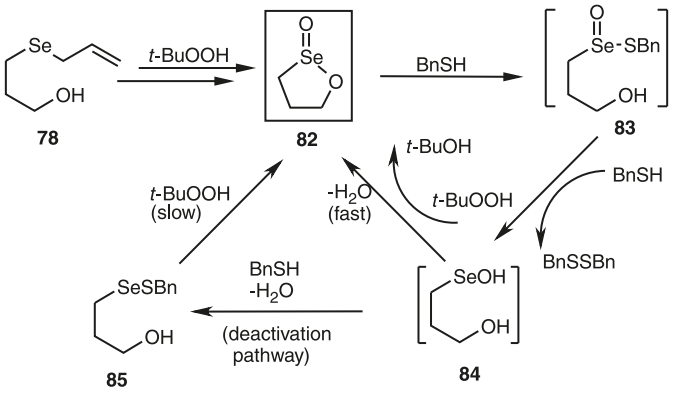


steps. When a control reaction was performed in the absence of thiol, the expected selenenate ester **80** proved unstable, but could be tentatively identified by NMR when only one equivalent of hydroperoxide was added. However, oxidation of selenide **78** with excess hydroperoxide cleanly afforded the cyclic seleninate **82**, presumably via the mechanism shown in Scheme 21.[56] To our surprise, despite its simple structure, **82** proved to be a novel compound, with remarkable catalytic activity ($t_{1/2}$ = 2.5 h; 17 times faster than with ebselen). Moreover, it was a stable, odourless solid that could be conveniently handled and stored. A comparison of selenide **78** with 2-hydroxyethyl and 4-hydroxybutyl analogues indicated that the 3-hydroxypropyl derivative and the corresponding five-membered cyclic seleninate **82** were optimum for catalytic activity. Moreover, a variety of other functionalities (carboxylic acids, amines, amides, and so forth) in place of the hydroxyl group in allyl alkyl selenides also proved inferior.[57] Therefore, it appears that compounds containing Se–O bonds, which have been much less studied than Se–N systems,[58] can also function as highly effective GPx mimetics.

Further studies revealed that **82** reacted very rapidly with benzyl thiol, presumably via intermediates **83** and **84**, which could not be detected. In the presence of excess hydroperoxide, cyclic seleninate **82** was regenerated, as shown in Scheme 22. However, varying amounts of another product, identified as the selenenyl sulfide **85**, were also observed when both thiol and hydroperoxide were present, with increasing amounts formed when the thiol:hydroperoxide ratio was increased. When the reaction was conducted with excess thiol in the absence of the hydroperoxide, **85** was obtained quantitatively. Since selenenyl sulfides were key intermediates in the catalytic cycles of GPx and **77** (Schemes 18 and 19, respectively), selenenyl sulfide **85** was isolated, characterized, and tested for GPx activity independently. We were surprised to discover that although **85** is slowly converted back to the cyclic seleninate **82** by *t*-butyl hydroperoxide, its $t_{1/2}$ in our standard assay was 35 h, which precludes it from playing an active role in the catalytic cycle of **82**, with $t_{1/2}$ = 2.5 h. Thus, in contrast to the key roles of selenenyl sulfides in Schemes 18 and 19, we conclude that the formation of **85** in Scheme 22 actually comprises a deactivation pathway.[57]

The discovery of a second class of GPx mimetics stemmed from an alternative attempt to generate cyclic sele-

Scheme 22.

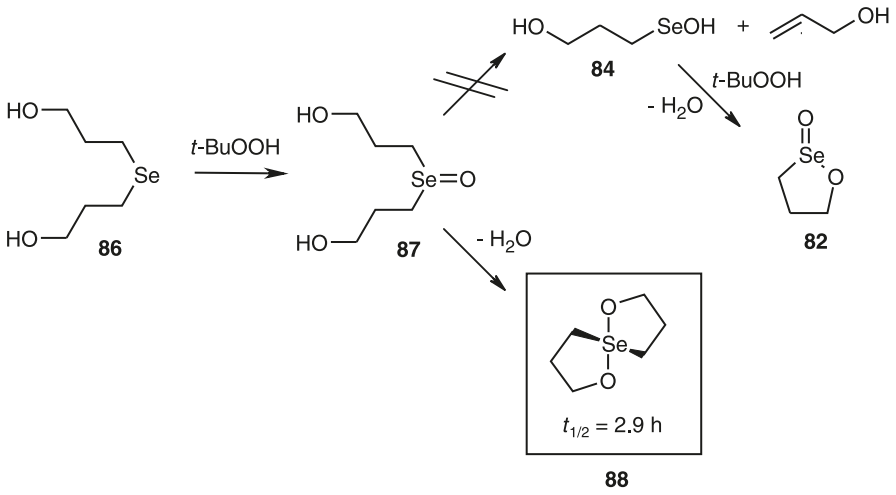


ninate **82** by oxidation and selenoxide elimination of bis(3-hydroxypropyl) selenide **86** (Scheme 23). Instead, the selenoxide **87** underwent an intramolecular condensation to produce the spirodioxyselenurane **88** in essentially quantitative yield.[59] While various other substituted and fused-ring spiroselenuranes have been reported previously, it was again surprising to discover that the parent structure **88** was novel. It was subjected to our standard assay and was also found to possess high catalytic activity, with $t_{1/2}$ = 2.9 h. Like the cyclic seleninate **82**, it too is an odourless, stable, crystalline solid. An X-ray crystal structure was obtained and is shown in Fig. 4.[59] As expected, the geometry of **88** is that of a distorted trigonal bipyramid in which the oxygen atoms occupy apical positions, while the carbon substituents on the central selenium, as well as the lone pair (not shown) define the equatorial plane. The bond angles O(1)–Se(1)–O(2) and C(1)–Se(1)–C(4) were found to be 172.99° and 102.95°, respectively.

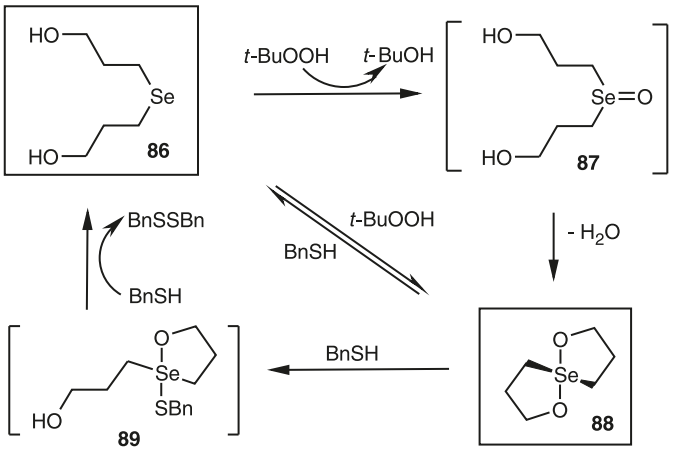
The proposed mechanism for the catalytic activity of **88** is shown in Scheme 24. The selenide **86** is inert to benzyl thiol, but is readily oxidized to selenoxide **87**, which, as described previously, cyclizes spontaneously to the spiro compound **88**. The latter undergoes substitution with one mole of the thiol to form **89** and then, presumably, a reductive elimination with a second mole, regenerating the selenide **86** and producing dibenzyl disulfide as a byproduct.[59]

The discovery of two novel structures, **82** and **88**, that act as GPx mimetics by catalyzing the reduction of a model hy-

Scheme 23.



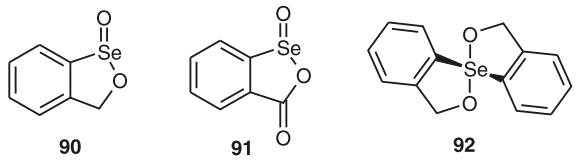
Scheme 24.



droperoxide with a thiol by mechanisms distinct from that of the enzyme itself was encouraging. However, aliphatic organoselenium compounds tend to be more toxic than aromatic ones,[42b,60] possibly a reflection of their weaker C–Se bonds and greater ease of metabolic degradation. We therefore turned our attention to aromatic analogues of **82** and **88** to determine if they too would exhibit desirable catalytic properties. Compounds **90**–**92** were synthesized and tested, but their catalytic activity was greatly diminished compared with that of their aliphatic counterparts for the reduction of *t*-butyl hydroperoxide, while only the spiro compound **92** provided a satisfactory $t_{1/2}$ of 2.9 h when hydrogen peroxide was used as the model peroxide (Fig. 5).[61,62] Attempts to prepare spirodiazaselenuranes afforded unsymmetrical selenonium species that proved relatively ineffective as GPx mimetics.[63] On the other hand, the tellurium analogues of **82** and **88** showed extremely high catalytic activity, with $t_{1/2}$ of ~5 min.[61] A related study of some similar compounds was reported by Singh and co-workers.[64]

Since the reactivity of aromatic systems is often strongly affected by electron-donating or -withdrawing groups, a series of aromatic derivatives of cyclic seleninate **90** and of the spiro compound **92** were prepared with substituents attached para to the selenium atom. These analogues were subjected

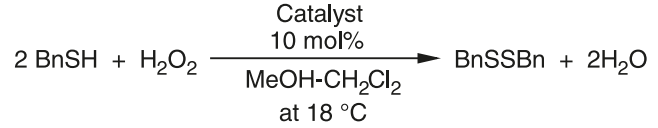
Fig. 5. Aromatic derivatives of GPx mimetics.



t-BuOOH: $t_{1/2}$ = 162 h (61) $t_{1/2}$ = 252 h (61) $t_{1/2}$ = 62 h (61)

H_2O_2: $t_{1/2}$ = 50 h (62) $t_{1/2}$ = 73 h (61) $t_{1/2}$ = 2.9 h (62)

Table 1. Catalytic activities of substituted aromatic derivatives of **90** and **92**.



Catalyst	$t_{1/2}$ (h)
Ebselen	21

R = H	2.9
R = F	22
R = Cl	25
R = Br	31
R = Me	3.6
R = OMe	0.5

to the assay with hydrogen peroxide as the oxidant, and the results are shown in Table 1, where it is clear that electron-donating substituents enhance catalytic activity, while electron-withdrawing groups suppress it. Indeed, the methoxy-substituted spirodioxyselenurane displayed $t_{1/2}$ = 0.5 h, which is the shortest time observed with any of the selenium compounds we have tested to date in this regard.[62]

Fig. 6. Hammett plot for the reduction of hydrogen peroxide with benzyl thiol in the presence of substituted derivatives of **90**.

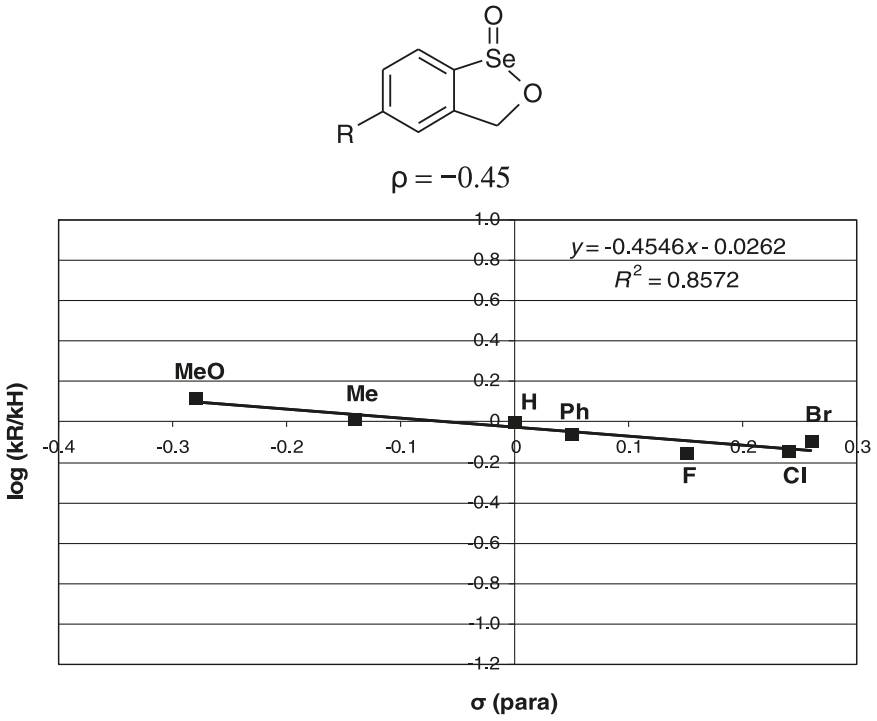

Fig. 7. Hammett plot for the reduction of hydrogen peroxide with benzyl thiol in the presence of substituted derivatives of **92**.

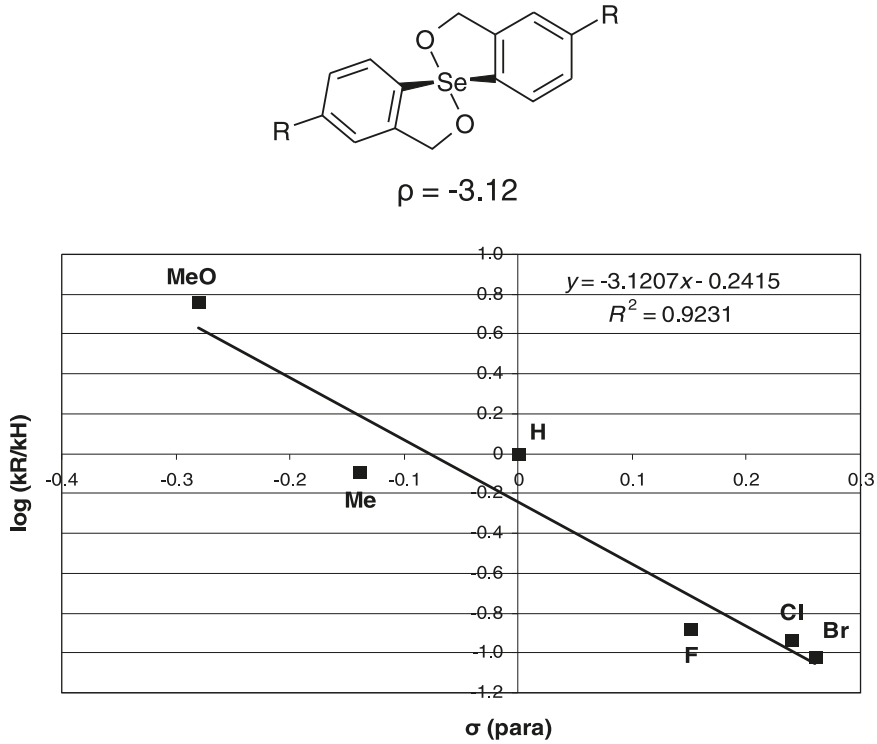

A more detailed kinetic study of the compounds in Table 1 revealed that the reactions are zero-order in thiol, suggesting that the steps in their catalytic cycles that involve oxidation of selenium(II) to selenium(IV) are rate-determining. This was confirmed by means of the corresponding Hammett plots, shown in Figs. 6 and 7. In both the cyclic seleninates and the spirodioxyselenuranes, the Hammett plots show negative slopes, indicating that the transition states of the rate-determining steps are stabilized by electron donation, consistent with an increase in the oxidation state of the selenium. It was also noted that the reaction constant had a considerably greater magnitude in the case of the spiroselenuranes (ρ = –3.12) compared with the corresponding seleninates (ρ = –0.45), indicating that the overall rate of the reaction

was significantly more susceptible to substituent effects in the former series than in the latter.[62] Moreover, the kinetic plots of the assays of the spirodioxyselenuranes showed positive *y*-intercepts, indicating anomalously high rates of formation in the early stages of the reaction. This is consistent with the rapid consumption of the catalyst (10 mol%) and simultaneous conversion of benzyl thiol to its disulfide in the first two steps in Scheme 24, prior to the rate-determining oxidation of Se(II) to Se(IV), and eventual regeneration of the catalyst.

A final point concerns the ability of some GPx mimetics that employ selenol or selenolate intermediates in their catalytic cycles to reduce dioxygen to reactive oxygen species that can then, paradoxically, contribute to oxidative stress instead of suppressing it.[65] Both the cyclic seleninates and spirodioxyselenuranes described above operate through catalytic cycles that do not rely on selenol intermediates. This precludes the possibility of undesired concomitant generation of harmful reduced oxygen species.

In conclusion, various mechanisms for GPx-like activity are possible, not just the one that was established for the enzyme itself. Both the cyclic seleninates and the spirodioxyselenuranes exhibit mechanisms that are different from that of GPx and from each other. Moreover, selenenyl sulfides are not essential intermediates. In fact, in Scheme 22, selenenyl sulfide **85** is part of a deactivation pathway instead of the primary catalytic cycle. As noted earlier, most of the GPx mimetics studied to date focused on the modulation of catalytic activity by means of appropriate amine substituents bonded to or capable of coordinating with the selenium atom. The above work indicates that oxygen substituents can serve equally well in this regard, and the novel aliphatic cyclic seleninate **82** and spirodioxyselenurane **88** proved remarkably effective catalysts in our assay. Aromatic derivatives are expected to be less toxic than the above aliphatic compounds, but they generally display poorer catalytic activity. Fortunately, kinetic studies revealed that oxidation of Se(II) to Se(IV) is the rate-determining step of the process and that catalytic activity can be significantly improved by the inclusion of electron-donating substituents para to the selenium atom. With these insights, it may be possible to devise an improved second generation of GPx mimetics with enhanced catalytic activity and improved therapeutic properties, and such work is ongoing in our laboratory. Indeed, the *p*-methoxy-substituted spirodioxyselenurane compound in Table 1 is a promising candidate for further in vivo studies of antioxidant activity[66] because of its exceptional catalytic activity and absence of selenol or selenolate intermediates in the catalytic cycle.

Acknowledgement

I am honoured and most grateful to the Alfred Bader Award Selection Committee for choosing me as the 2008 recipient of the award. The results described here were obtained through the determination and hard work of numerous talented undergraduate and graduate students, postdoctoral fellows, and colleagues, whose names are listed in the cited references. We also acknowledge the generous financial support for the work described here from the Natural Sciences and Engineering Research Council of Canada (NSERC) and Merck Frosst (Canada) Inc.

Direct halogenation of organic compounds with halides using oxone in water — A green protocol

H. Firouzabadi, N. Iranpoor, and S. Kazemi

Abstract: Direct bromination and iodination of various aromatic compounds with NaBr and NaI using oxone ($2KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$) in water was accomplished successfully in high-to-excellent yields. The main benefit of this protocol is the performance of the reactions in water in the presence of a harmless oxidant without the use of any organic co-solvents. Using NaBr and NaI as the safe sources of halogens is another advantage of the protocol. This method is easily applicable to the large-scale operations. We have also applied this method successfully for the iodocyclization of an unsaturated alcohol and an unsaturated carboxylic acid.

Key words: iodination, bromination, oxone, water.

Résumé : On a effectué avec succès la bromation et l'iodation directe de divers composés aromatiques avec du NaBr et du NaI à l'aide d'oxone ($2KHSO_5 \cdot KHSO_4 \cdot K_2SO_4$) dans l'eau; les rendements vont d'élevés à excellents. Le bénéfice principal de ce protocole réside dans le fait que les réactions sont effectuées dans l'eau, en présence d'un oxydant inoffensif, sans nécessité de solvant organique. L'utilisation de NaBr et de NaI comme source sécuritaire d'halogène est un autre avantage de cette méthode qui peut facilement être appliquée à des opérations d'envergure. On a aussi appliqué avec succès cette méthode à l'iodocyclisation d'un alcool et d'un acide carboxylique insaturés.

Mots-clés : iodation, bromation, oxone, eau.

[Traduit par la Rédaction]

Introduction

Waste prevention rather than its treatment is of great concern for the industry and academia. For this aim, the use of less toxic materials as solvents and reagents is encouraged.[1] However, disposing organic solvents in pharmaceutical industries is their current major problem, as these solvents compose ~80% of their waste.[2,3] Replacement of toxic, flammable, non-recyclable, expensive, and organic solvents with water in organic reactions is a great challenge for academia and chemical industries.[4,5]

Using water is beneficial from different aspects. Water is a cheap, abundant, nontoxic, nonflammable, and green solvent. On the other hand, water with its chemical and physical properties imposes selectivity and reactivity in reactions, which cannot be achieved using organic solvents.[6] In addition, organic compounds are insoluble in water; therefore, phase separation is easier and they can be easily isolated from aqueous media.

Recently, we have paid attention towards using water as a reaction medium. Along this line, Michael addition of amines and thiols to α,β-unsaturated ketones,[7] regioselective iodination of aromatic compounds,[7b] ring opening of epoxides with varieties of nucleophiles,[7c] oxidation of sulfides to their sulfoxides with H_2O_2,[7d] Michael addition of indoles and pyrroles to α,β-unsaturated electron-deficient compounds,[7e] conversion of epoxides to thiiranes and amino alcohols,[7f] C–S bond formation via odorless thia-Michael addition,[7g] C–C bond formation via Heck–Mizoroki reactions in water,[7h] and highly efficient halogenation of organic compounds with halides catalyzed by $CeCl_3 \cdot 7H_2O$ using H_2O_2 as the terminal oxidant in H_2O[7i] are reported.

The aromatic halogenation reaction is an important electrophilic substitution reaction, and haloarenes are useful synthetic intermediates in the pharmaceuticals, pesticides, and agrochemical industries.[8] In addition, haloarenes are useful and important substrates for the preparation of organometallic compounds. The other important uses of haloarenes are in Heck, Stille, Sozuki, and Sonogashira reactions.[9] Halogenation of organic substrates requires using chlorine, bromine, or iodine. This reaction is associated with serious environmental hazards with respect to handling, transportation, and storage of chlorine, bromine, and iodine.[10]

Handling of halide salts is safer and easier than their molecular halogens. They are oxidized to the corresponding positive halogens or hypohalous acids by a variety of oxidants, including peroxo compounds.[8] However, the articles describing the application of peroxo compounds for the oxidative halogenation of arenes include $Ce(OH)_3OH$/SDS-H_2O,[7b] KI/benzyltriphenylphosphoniumperoxo mono-sulfate/MeCN,[11] KI/H_2O_2(30%)/H_2SO_4/MeOH,[12] KI or I_2/PVP-supported $H_2O_2/H_3PW_{12}O_{40}$ in CH_2Cl_2,[13] I_2 or KI /($Na_2CO_3 \cdot 3H_2O_2$),[14] $I_2/[(Bu_4N)_4(S_2O_8)]$/MeCN or CH_2Cl_2,[15] $I_2/[(MePPh_3)_2(S_2O_8)]$/MeCN,[16] I_2/NaS_2O_8/MeCN,[17] and NaI/H_2O_2/organotelluride cat. at pH-6 buffer in Et_2O/H_2O,[18] KBr/benzyltriphenylphosphonium peroxodisulfate/ MeCN,[19] Br_2 or LiBr/tetrabutylammonium peroxydizulfate/MeCN or CH_2Cl_2,[20] I_2/

poly(4-vinylpyridine)-supported peroxodisulfate/MeCN,[21] and NaI/Oxone/CH_3OH.[22] The other methods using hydrogen peroxide include the use of NH_4I/H_2O_2/HOAc,[23] NH_4Br/H_2O_2/HOAc,[24] HX/ $H_2O_2/C_2H_4Cl_2$/MW,[25] H_2O_2/I_2,[26] and NaBr/ H_2O_2/ H_2SO_4/ $CHCl_3$.[27]

Oxone is a ternary composite of $2KHSO_5$, $KHSO_4$, and K_2SO_4 that is a stable peroxo inorganic compound. Oxone has a low order of toxicity when taken internally, based on animal studies. The approximate lethal dose (ALD) for rats is 2250 mg/kg.[28] Iodination of arenes with NH_4I in MeOH in the presence of oxone is recently reported.[29] This procedure encounters limitations such as the following: (*i*) it is applicable to electron-rich aryl compounds, (*ii*) usually long reaction times are required (8–48 h), and (*iii*) moderately deactivated aryl compounds such as bromobenzene remain intact even after 24 h.

In this article, we report a green method for the iodination and bromination of structurally different arenes by NaI and NaBr with oxone in H_2O in the absence of any organic co-solvents with high regioselectivity. In addition, halocyclization of unsaturated alcohols and a carboxylic acid with NaI/oxone system in water is also reported.

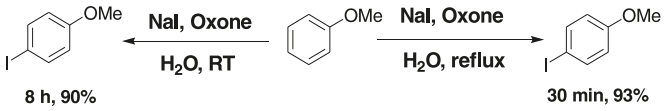
Results and discussion

In this study, we report a green procedure for the halogenation of structurally diverse arenes using NaBr and NaI salts as safe sources of halogens and oxone as a safe solid oxidant in water in the absence of any organic co-solvents. For optimization of the reaction conditions, we studied the reaction of anisole with NaI in the presence of oxone in water at room temperature. We found that the optimized molar ratio of anisole/NaI/Oxone was 1:1:0.5 mmol in 2 mL of water. The reaction proceeded well with excellent para selectivity, and after 8 h (GC or TLC), the *p*-iodoanisole was isolated in 90% yield. The structure of the isolated compound was confirmed by ^1H and ^{13}C NMR and compared with an authentic sample. The reaction was also investigated under reflux conditions. The reaction proceeded to completion faster, and after 30 min (GC or TLC), the para isomer was isolated with excellent selectivity in 93% yield (Scheme 1).

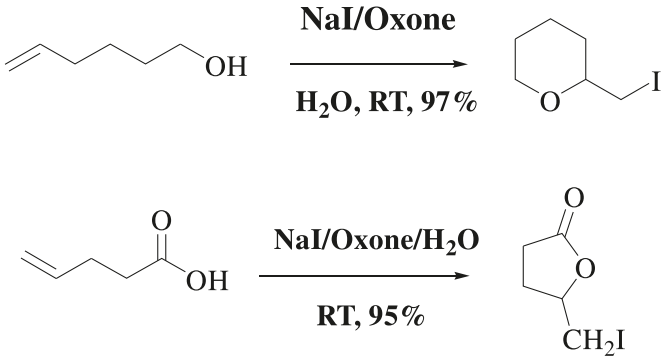
To show the general application of the method, the optimized conditions were applied to structurally different arenes. The results of this investigation are tabulated in Table 1. As it is evident from the results, this protocol is applicable to a broad spectrum of arenes, such as electron-rich aromatic compounds, toluene, benzene, bromo-, and chlorobenzenes. As shown in Table 1, electron-poor compounds like acetophenone and benzonitrile were also subjected to iodination reaction. The reaction of acetophenone proceeded very slowly, and after 48 h, the meta product was isolated in 40% yield. Benzonitrile was isolated intact from the reaction mixture after 48 h.

Bromination of arenes was also investigated by this protocol. For this purpose, we first optimized the reaction conditions for the bromination of anisole with NaBr in the presence of oxone in water as a model reaction. The optimized molar ratio of anisole/NaBr/oxone was 1:1:0.5 mmol in 2 mL of water at room temperature. In contrast to the iodination reaction, bromination proceeded well to completion after 10 min at room temperature, and the *para*-bromo compound was isolated in 93% yield as the sole product. Then, we applied these conditions to electron-rich aromatic compounds, e.g., benzene, toluene, naphthalene, and chlorobenzene. The reactions proceeded well in high isolated yields. All the reactions were performed with high selectivity and only one product was isolated from the reaction mixtures. The structures of the products were also confirmed by ^1H and ^{13}C NMR and were compared with authentic samples. The results are tabulated in Table 2.

Scheme 1.



Scheme 2.



We also easily scaled up the bromination reaction of anisole, xylene, and naphthalene to 20 mmol. All the reactions proceeded well within the reaction times indicated in Table 2, and the mono-brominated compounds were isolated with the same yields as indicated in the table.

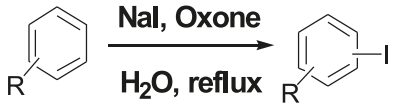
To show the advantage of using water as the reaction medium, we compared the results of the iodination of arenes with some of the reactions that proceeded in methanol,[29] as presented in Table 3.

Iodoetherification and iodolactonization are important and crucial reactions in organic synthesis and also for the structural elucidation of organic molecules.[30,31] Examples include Corey's prostaglandin synthesis,[32] total synthesis of tumor inhibitors, e.g., vernolepin and vernomenin,[33] and in vitamin D_2 and D_3 syntheses.[34]

We were also interested in investigating halocyclization reactions, such as iodoetherification and iodolactonization, by this system. For this purpose, a similar molar ratio to the ratio used for the iodination of arenes was applied to the reaction of 5-hexene-1-ol and 4-pentene-1-oic acid as model compounds. Our preliminary studies show that iodination – ring-closure reaction proceeded immediately, and the corresponding iodocyclic ethers and the iodolactone were isolated in excellent yields as shown in Scheme 2.

Most of the products are known compounds, and their spectral data and physical constants along with their references are given in the Experimental section. The data of the known compounds have been found to be identical with those reported. For the unknown compounds, spectral data along with their elemental analyses are also given in the Experimental section.

Table 1. Mono-iodination of aromatic compounds using NaI/oxone/H_2O under reflux conditions.



Entry	Substrate	product	Time	GC conversion (%)	Isolated yield (%)
1			15 min	100	98
2			30 min	100	93
3			10 min	100	85

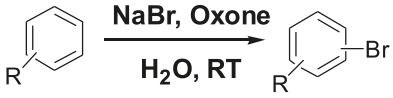
11			48 h	45[a]	40
12			48 h	–	–

[a] *n*-Ocatane was used as an internal standard.

Conclusions

In conclusion, in this article, we have presented a green protocol for the halogenation of organic compounds using NaI or NaBr/oxone/H_2O system. We have modified the previously reported protocol using NaI/oxone system in MeOH for the iodination of activated aromatic compounds with NaI/oxone system in H_2O as a green solvent. As we have shown, similar iodination reactions proceeded more efficiently in H_2O than in MeOH. NaI/oxone/H_2O system

Table 2. Bromination of aromatic compounds using NaBr/Oxone/H_2O at room temperature.



Entry	Substrate	product	Time (min)	GC conversion (%)	Isolated yield (%)
1			5	100	95
2			10	100	93
3			20	100	87
4			25	100	85
5			7	100	80
6			1.5 h	100	88
7			3 h	100	90
8			12 h	–	–

Table 3. A comparison between two procedures using NaI/oxone/MeOH[29] and NaI/oxone/ H_2O for the iodination of different aromatic compounds.

	NaI/Oxone/MeOH		NaI/Oxone/H_2O	
Substrate	Time (h)	Conversion	Time (h)	Conversion
Bromobenzene	24	NR	12	85%
m-Xylene	24	99%	3	90%
Anisole	8	99%	0.5	93%

has been successfully applied to highly efficient and regioselective iodination and bromination of structurally different aromatic compounds. In addition, we have also successfully applied the protocol to highly efficient one-pot iodination/cyclization of unsaturated alcohols and iodination/lactonization of an unsaturated carboxylic acid. The method is also applicable to the large-scale reactions without any difficulties.

Experimental section

Typical procedure for the mono-iodination of 1,3-dimetoxybenzene with NaI/oxone system in H_2O

To a stirring mixture of 1,3-dimetoxybenzene (0.138 g, 1 mmol) and NaI (0.149 g, 1 mmol) in water (3 mL), oxone (0.307 g, 0.5 mmol) was added, and the mixture was refluxed for 15 min. The progress of the reaction was monitored by GC or TLC. The resulting reaction mixture was treated with $Na_2S_2O_4$ solution (10 mol%, 10 mL) and extracted with diethyl ether (2 × 10 mL). The ethereal solution was dried over anhydrous Na_2SO_4 and filtered. Evaporation of the solvent resulted in the desired crude product, which was further purified by plate chromatography technique to produce the pure compound in 98% (Table 1, entry 1).

Typical procedure for the mono-bromination of 1,3-dimetoxybenzene with NaBr/oxone system in H_2O

To a stirring mixture of 1,3-dimetoxybenzene (0.138 g,

1 mmol) and NaBr (0.102 g, 1 mmol) in water (3 mL), oxone (0.307 g, 0.5 mmol) was added. The reaction was completed within 5 min (GC or TLC). The resulting reaction mixture was treated with $Na_2S_2O_4$ solution (5 mol%, 30 mL) and extracted with diethyl ether. The organic layer was separated and dried over anhydrous Na_2SO_4, and after filtration and evaporation of the solvent, the desired mono-brominated crude product was obtained. Further purification was performed by plate chromatography technique to give the pure compound in 95% yield (Table 2, entry 1).

Typical procedure for the iodoetherification of 5-hexene-1-ol with NaI/oxone system in H_2O

To a stirring mixture of 5-hexene-1-ol (0.1 g, 1 mmol) and NaI (0.149 g, 1 mmol) in water (3 mL) was added oxone (0.307 g, 0.5 mmol). An immediate reaction occurred (GC or TLC). To the resulting reaction mixture, $Na_2S_2O_4$ solution (5 mol%, 30 mL) was added, and the mixture was extracted with diethyl ether. The organic layer was separated and dried over anhydrous Na_2SO_4. After filtration and evaporation of the solvent, the resulting crude product was further purified by plate chromatography technique to give the desired iodocyclic ether in 97% yield (Scheme 2). The structure of the product was identified by ^1H and ^{13}C NMR.

Typical procedure for the iodolactonization of 4-pentene-1-oic acid with NaI/oxone system in H_2O

To a stirring mixture of 4-pentene-1-oic acid (0.1 g, 1 mmol) and NaI (0.149 g, 1 mmol) in water (3 mL) was added oxone (0.307 g, 0.5 mmol). An immediate reaction occurred (GC or TLC). To the resulting reaction mixture, $Na_2S_2O_4$ solution (5 mol%, 30 mL) was added, and the mixture was extracted with diethyl ether. The organic layer was separated and dried over anhydrous Na_2SO_4. After filtration and evaporation of the solvent, the resulting crude product was further purified by plate chromatography technique to give the desired iodolactone in 95% yield (Scheme 2). The structure of the product was identified by ^1H and ^{13}C NMR.

Physical constants of known compounds

4-Iodo-1,3-dimethoxy benzene
Mp 39–41 °C (lit.[41] mp 37–41 °C).

4-Iodoanisole
Mp 52–53 °C (lit.[35] mp 48–55 °C).

4-Iodo*-N-*methylaniline
Mp 30–32 °C (lit.[36] mp 31.5).

4-Iodo*-N,N-*dimethylaniline
Mp 75–76 °C (lit.[37] mp 77 °C).

4-Iodo-1,3-dimethylbenzene
Bp 229–230 °C (lit.[35] mp 229 °C).

4-Iodotoluene
Mp (petroleum ether) 33–35 °C (lit.[38] mp 34 °C).

Iodobenzene
Bbp 187–189 °C (lit.[41] mp 188 °C).

4-Bromo-1-iodobenzene
Mp (petroleum ether) 91–93 °C (lit.[39] mp 95–97 °C).

4-Chloro-1-iodobenzene
Mp (diethyl ether) 55–57 °C (lit.[39] mp 54–56 °C).

4-Bromo-1,3-dimethoxy benzene
Mp (petroleum ether) 24–26 °C (lit.[41] mp 25–26 °C).

4-Bromoanisole
Bp 222–224 °C (lit.[41] mp 223 °C).

4-Bromo-1,3-dimethylbenzene
Bp 212–213 °C (lit.[41] mp 214 °C).

4-Bromotoluene
Mp (petroleum ether) 24–26 °C (lit.[40] mp 25–26 °C).

1-Bromonaphthalene
Bp 280–282 °C (lit.[42] mp 279–281 °C).

Bromobenzene
Bp 153–155 °C (lit.[41] mp 156 °C).

4-Chloro-1-bromobenzene
Mp (diethyl ether) 66–68 °C (lit.[40] mp 65–66 °C).

Spectral data and elemental analysis for the unknown compounds

4-Iodo*-N-*ethylaniline
Mp($CHCl_3$/diethyl ether) 79–81 °C. ^1H NMR ($CDCl_3$, 250 MHz) δ (ppm): 1.11 (t, 3 H, J = 7.1 Hz), 2.97 (q, 2 H, J = 7.1 Hz), 3.37 (m, 1 H), 6.27 (d, 1 H, J = 4.9 Hz), 7.30 (d, 1 H, J = 4.8 Hz). ^{13}C NMR ($CDCl_3$, 62.9 MHz) δ (ppm): 13.65, 37.26, 76.55, 113.89, 136.66, 146.84. Anal. calcd.: C, 38.88; H, 4.05; N, 5.67. Found: C, 38.69; H, 4.00; N, 5.38.

5-(Iodomethyl)dihydrofuran-2-one
Liquid. ^{13}C NMR ($CDCl_3$, 62.9 MHz) δ (ppm): 7.39, 27.01, 27.89, 77.42, 175.38. Anal. calcd.: C, 31.85; H, 4.86. Found: C, 31.70; H, 4.07.

2-Iodomethyltetrahydropyran
Liquid. ^1H NMR ($CDCl_3$, 250 MHz) δ (ppm): 1.18–1.80(m, 6 H), 3.10 (d, 2 H, J = 3.5), 3.21–3.40 (m, 1 H), 3.93–4.12 (m, 2 H). ^{13}C NMR ($CDCl_3$, 62.9 MHz) δ (ppm): 9.10, 22.14, 24.56, 30.69, 67.77, 76.61. Anal. calcd.: C, 26.54; H, 3.09. Found: C, 26.22; H, 3.00.

Chemo- and regio-selective functionalization of Morita–Baylis–Hillman bromides with anthranilic acid

Yusuf Zulykama, Ulagamani Uma, Palanisamy Chitra Devi, and Paramasivan T. Perumal

Abstract: Nucleophilic substitution products of Morita–Baylis–Hillman adducts and their derivatives are valuable synthons. In an attempt to ameliorate the functionality of these functionalized motifs, we report the regio- and chemo-selective functionalization of Morita–Baylis–Hillman bromides with anthranilic acid.

Key words: Morita–Baylis–Hillman reaction, Morita–Baylis–Hillman bromides, nucleophilic substitution, anthranilic acid.

Résumé : Les produits de substitution nucléophile des adduits de Morita–Baylis–Hillman et de leurs dérivés sont des synthons très utiles. Afin d'améliorer la fonctionnalité de ces motifs fonctionnalisés, on a réalisé la fonctionnalisation régio- et chimio-sélective des bromures de Morita–Baylis–Hillman avec l'acide anthranilique.

Mots-clés : réaction de Morita–Baylis–Hillman, bromures de Morita–Baylis–Hillman, substitution nucléophile, acide anthranilique.

[Traduit par la Rédaction]

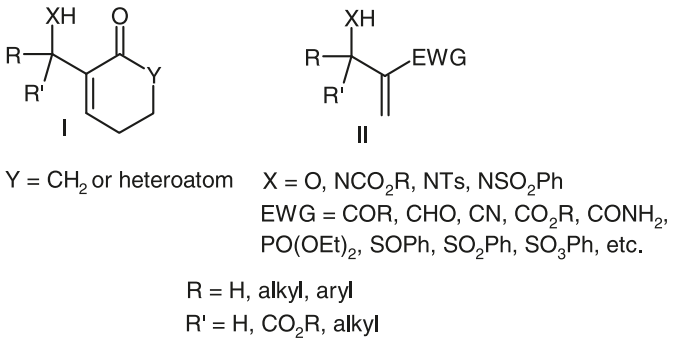
Introduction

The Morita–Baylis–Hillman reaction[1–4] (MBH), a powerful C–C bond forming reaction, has earned overwhelming popularity in recent years. The MBH adduct comprise of a contiguous assembly of three different functionalities and a chiral center. The versatility of the functionality of MBH adducts have made them valuable synthetic intermediates. Efforts of various research groups contributing to the widening of the substrate scope[1] of the MBH reaction have further diversified the functionality of MBH adducts (Fig. 1).

Functionalization of MBH adducts and their derivatives is an active area of research, as it provides valuable synthetic intermediates, which have been successfully translated into various useful synthetic targets, including substituted alkenes,[5] carbocycles,[6] heterocycles,[7] and several biologically relevant molecules.[1e,1g] The repertoire of nucleophiles added to MBH adducts includes carbon,[8] hydrogen,[9] heteroatomic nucleophiles,[10] aromatics,[11] and heteroaromatics.[12] In addition to newer nucleophiles[13] being added to MBH acetates/bromides, the synthetic potential of previously reported nucleophilic substitution products is illustrated by newer applications.[14]

Nucleophilic substitution of MBH adducts and their derivatives with monofunctional aromatics and their further elaboration to several synthetic targets have been extensively studied.[15] Basavaiah et al.[16] synthesized chromones from phenol[16b–16d] substitution products and successfully applied the same strategy to the synthesis of antifungal agents.

Fig. 1. The Morita–Baylis–Hillman adduct.



Aniline substitution products have been elaborated to synthesize indenoquinolinones,[17a] polysubstituted quinolines,[17b] quinolones, quinolinols, indanones and indenoindenones,[17c] and β-lactam.[17d,17e] The fascinating post modifications of nucleophilic substitution products of monofunctional aromatics made the nucleophilic substitution of bifunctional aromatics intriguing. However, literature scanning reveals only a few reports of nucleophilic substitution of MBH derivatives with bifunctional aromatics.[18] Kim et al.[18a] added *o*-phenylenediamine on Baylis–Hillman acetates and subsequently converted to benzodiazepinones and benzoimidazoles. Basavaiah and Satyanarayana[18b] reported one-pot transformation of the Baylis–Hillman acetates to fused pyrimidones via a reaction with 2-aminopyridine in aqueous media. The synthetic utility of dinaphthol substitution products were illustrated in the synthesis of bis-chromones.[18c] In this context, we were prompted to explore this avenue of MBH chemistry, and herein, we wish to report the results of our

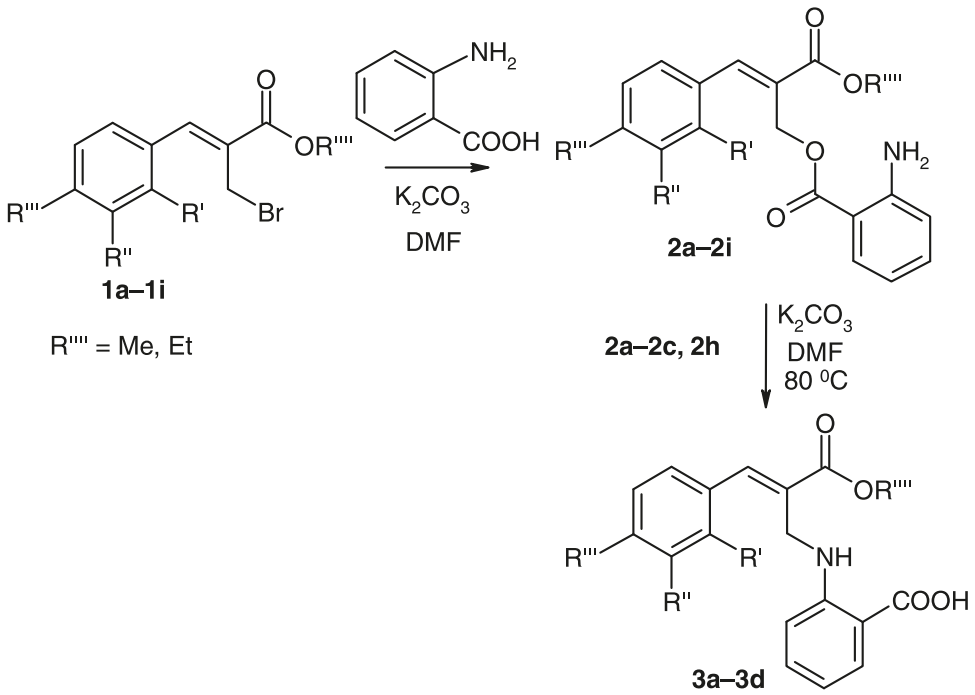
Scheme 1.



investigation of the chemo- and regio-selectivity of nucleophilic substitution of MBH bromides with anthranilic acid.

Results and discussion

Recently, we have reported the functionalization of MBH bromides with symmetric and asymmetric bifunctional aromatics,[19] and in continuation of our interest in this avenue of MBH chemistry, we intended to study the functionalization of MBH bromides with anthranilic acid. Accordingly, a solution of MBH bromide (**1a**) in DMF was treated with anthranilic acid in the presence of potassium carbonate to furnish **2a** in 61% isolated yield (Scheme 1).

The presence of two stretching absorptions in the IR spectrum of **2a** (3266 and 3468 cm^{-1}) indicated that the N-terminal of the anthranilic acid moiety is free. Moreover, the downfield appearance of the allylic protons (δ 5.15 ppm) confirmed the formation of O-linked products. The reaction was then extended to other MBH bromides (**1b**–**1i**), and the results are assembled in Table 1.

The stereochemistry of the products **2a**–**2i** was settled on the basis of difference nuclear Overhauser effect (NOE) experiments on **2f**. Irradiation of the methylene protons at δ 5.0 ppm led to the enhancement of the aromatic signal at δ 7.33 by 5.25%. However, there was comparatively less enhancement in the olefinic signal (0.69%) implying they are spatially far, and thus confirming *E* stereochemistry (Fig. 2). Further irradiation of the ester methyl proton resulted in the enhancement of the olefinic peak, confirming their spatial proximity.

To study the regio- and chemo-selective outcome of the reaction, we further treated MBH bromide with anthranilic acid in the presence of K_2CO_3 in DMF at 80 °C. TLC monitoring revealed the formation of a new minor product in addition to O-linked product. Prolonging the heating did not improve the yield of the minor product. The new product was characterized by IR, NMR, and Mass studies. The IR spectrum of the product exhibited only one stretching absorption, suggesting secondary amine functionality. The allylic protons were observed at δ 4.26 ppm (as compared with the O-linked allylic protons at δ 4.92–5.15 ppm), confirming the formation of N-linked product **3a**. Small coupling was observed in the allylic proton signal due to the NH proton further confirming the formation of N-linked products. However, the carboxyl proton was not detected in the ^1H NMR spectrum, and the presence of the carboxyl group in the product was confirmed through IR and ^{13}C spectral analysis.

Interestingly, on heating O-linked anthranilic acid, substitution products **2a** in DMF with K_2CO_3 at 80 °C, N-linked S_N2 products **3a** was obtained in comparatively good yields (Scheme 1).[20] The generality of the reaction was demonstrated by the successful conversion of O-linked products **2b**, **2c**, and **2h** to **3b**, **3c**, and **3d**, respectively (Table 2).

With the O-linked anthranilic acid products in our hands, we intended to further derivatize these substitution products by treatment with trifluoroacetic anhydride (Scheme 2). Consequently, **2a** was stirred in trifluoroacetic anhydride at ice temperature under nitrogen atmosphere, and we observed solidification of the reaction mixture immediately. TLC profile of the reaction mixture showed two new spots. The major product was assigned the structure **4a** and the minor product was found to be **5a**.[20]

The formation of **5a** can be explained as the result of the reaction of **4a** with **2a**. In the ^1H NMR spectrum of **5a**, the signal for the BH moiety was observed in duplicate, indicating that the bisfunctionalisation[21] of anthranilic moiety with the MBH bromides at both the N- and O-terminal had occurred.

The diastereotropic methylenic protons were observed as four doublets at δ 4.46, 5.02, 5.11, and 5.36 ppm. Further

mass spectral analysis [604 (M^+ + Na)] confirmed the formation of the product. Next, it was our interest to obtain S_N2' anthranilic acid substitution products adopting DABCO-salt strategy.[22] In accordance, the MBH bromide (**1a**) was stirred with an equivalent of DABCO in acetone for 30 min at ambient temperature. After the salt formation as indicated by the TLC, anthranilic acid and potassium carbonate were added and stirring continued for an hour to afford **6a** (Scheme 3).

In the ^{1}H NMR of **6a**, two singlets were obtained for the olefinic protons and were observed at δ 5.63 and 6.39 ppm, confirming the formation of S_N2' products. The signal due to the benzylic proton at δ 5.87 ppm was split into a doublet by the NH proton (J = 6.1 Hz), and also the signal for the NH proton was observed as a doublet at δ 8.11 ppm (J = 6.1 Hz), confirming that the S_N2' product was N-linked. For **6a**–**6h**, the carboxyl proton was not detected in ^{1}H NMR spectra. However, the presence of the carboxyl group in the product was confirmed through IR and ^{13}C spectral analyses. Table 3 reveals the results of S_N2' substitution of MBH bro-

mides with anthranilic acid. Salt formation of anthranilic acid with DABCO explains the formation of N-linked S_N2' product and not the O-linked S_N2' product.

Conclusion

In conclusion, we have demonstrated a simple and practical methodology for the chemo- and regio-selective functionalization of MBH bromides with anthranilic acid. Extension of the same methodology to other bifunctional nucleophiles and their chemical transformation to synthetically important scaffolds are underway.

Experimental section

Melting points were determined in open capillary tubes and are uncorrected. IR measurements were carried out using KBr pellets in PerkinElmer Spectrometer RXI FTIR. Nuclear magnetic resonance spectra were recorded on a Bruker spectrometer or a JEOL spectrometer. ^{1}H NMR spectra were recorded at 300 MHz or 500 MHz in $CDCl_3$ or DMSO-d_6 combination with tetramethylsilane as internal standard. ^{13}C NMR spectra were recorded at 75 MHz or 125 MHz spectrometer in $CDCl_3$ or DMSO-d_6 combination with the same internal standard. The chemical shifts are given in δ in ppm scale. Mass spectra were recorded on a varian VG 70–70H mass spectrometer or on a Thermo Finnigan LCQ Advantage MAX 6000 ESI spectrometer. TLC was performed on silica gel alumina plates. Column chromatography was carried out using 100–200 mesh silica gel.

General procedure for the syntheses of 2a–2i

To a stirred solution of Baylis–Hillman bromide (0.3 g, 1.18 mmol) in DMF (5 mL) was added anthranilic acid (0.16 g, 1.18 mmol) and K_2CO_3 (0.19 g, 1.18 mmol). The reaction mixture was stirred at room temperature. After the disappearance of the starting compound (TLC), reaction mixture was poured into water and extracted with ethyl ace-

General procedure for the syntheses of 4 and 5

2a (0.5 g, 1.6 mmol) was taken in a 50 mL RB flask, and 1 mL of TFAA was added under ice temperature in N_2 atmosphere. The reaction mixture solidified and was extracted with ethyl acetate. The excess solvent was removed and col-

umn purified (25% ethyl acetate in hexane) to obtain **4a** (63%) and **5a** (11%).

Methyl2-(2-trifluoroacetamidophenylcarbonyloxymethyl)-3-phenyl prop-2-enoate (4a)

White solid; mp 108 °C. IR (KBr) ν: 1616, 1635, 1685, 2955, 3332 cm^{-1}. ^1H NMR (500 MHz, $CDCl_3$) δ: 3.86 (s, 3H), 5.24 (s, 2H), 7.21 (t, *J* = 7.65 Hz, 1H), 7.39–7.41 (m, 5H), 7.61 (t, *J* = 8.45 Hz, 1H), 8.06 (d, *J* = 8.45 Hz, 1H), 8.11 (s, 1H), 8.65 (d, *J* = 7.65 Hz, 1H), 12.24 (s, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 52.57, 60.84, 114.63 (q, *J* = 287 Hz), 116.15, 116.93, 120.80, 124.85, 125.81, 128.99, 129.47, 129.97, 131.36, 134.07, 135.20, 139.10, 146.70, 154.92 (q, *J* = 36.9 Hz), 167.14, 167.96. MS *m/z*: 407 (M^+). Anal. calcd. for $C_{20}H_{16}F_3NO_5$: C, 58.97; H, 3.96; N, 3.44. Found: C, 58.85; H, 3.96; N, 3.45.

Methyl2-(2-trifluoroacetamidophenylcarbonyloxymethyl)-3-(2-fluoro-phenyl) prop-2-enoate (4b)

White solid; mp 120 °C. IR (KBr) ν: 1230, 1618, 1620, 1642, 1680, 2958 cm^{-1}. ^1H NMR (500 MHz, $CDCl_3$) δ: 3.86 (s, 3H), 5.18 (s, 2H), 7.10 (t, *J* = 7.65 Hz, 1H), 7.14 (t, *J* = 7.65 Hz, 1H), 7.19 (t, *J* = 7.65 Hz, 1H), 7.32 (t, *J* = 7.65 Hz, 1H), 7.37 (t, *J* = 7.65 Hz, 1H), 7.60 (t, *J* = 8.4 Hz, 1H), 7.98 (d, *J* = 7.65 Hz, 1H), 8.09 (s, 1H), 8.63 (d, *J* = 8.4 Hz, 1H), 12.19 (s, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 52.64, 60.91, 114.63 (q, *J* = 288.5 Hz), 116.02 (d, *J* = 22.7 Hz), 120.78, 122.12 (d, *J* = 11.9 Hz), 122.23, 124.50, 124.81, 128.09, 130.21, 131.30, 131.79 (d, *J* = 7.2 Hz), 131.85, 135.20, 139.03, 139.06, 154.93 (q, *J* = 39.3 Hz), 166.54, 167.80. MS *m/z*: 425 (M^+). Anal. calcd. for $C_{20}H_{15}F_4NO_5$: C, 56.48; H, 3.55; N, 3.29. Found: C, 56.39; H, 3.56; N, 3.30.

2-(Methoxycarbonyl)-3-phenyl-2-propenyl-2-[2-(methoxy carbonyl)-3-phenylpropenyl]trifluoroacetamidobenzene carboxylate (5a)

Yellow oil. IR (neat) ν: 1617, 1620, 1637, 2945, 3340 cm^{-1}. ^1H NMR (500 MHz, $CDCl_3$) δ: 3.61 (s, 3H), 3.80 (s, 3H), 4.46 (d, *J* = 14.5 Hz, 1H), 5.02 (d, *J* = 11.45 Hz, 1H), 5.11 (d, *J* = 11.45 Hz, 1H), 5.36 (d, *J* = 14.5 Hz, 1H), 6.96–6.98 (m, 3H), 7.22–7.23 (m, 3H), 7.32–7.34 (m, 5H), 7.38 (t, *J* = 7.65 Hz, 1H), 7.43 (t, *J* = 7.65 Hz, 1H), 7.76 (s, 1H), 7.94 (d, *J* = 8.4 Hz, 1H), 8.03 (s, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 44.78, 52.23, 52.42, 60.61 115.6 (q, *J* = 282 Hz), 115.30, 117.60, 125.87, 125.98, 128.71, 128.84, 129.0, 129.39, 129.50, 129.66, 129.77, 132.08, 132.12, 132.98, 133.88, 134.10, 136.93, 145.88, 146.25, 155.84 (q, *J* = 34.6 Hz), 167.14, 167.46. MS *m/z*: 604 (M^+ + Na). Anal. calcd. for $C_{31}H_{26}F_3NO_7$: C, 64.03; H, 4.51; N, 2.43. Found: C, 64.14; H, 4.53; N, 2.44.

2-(Methoxycarbonyl)-3-(2-fluorophenyl)-2-propenyl-2-[2-(methoxycarbonyl)-3-(2-fluorophenyl)propenyl] trifluoroacetamidobenzene carboxylate (5b)

Yellow oil. IR (neat) ν: 1225, 1619, 1640, 1689 cm^{-1}. ^1H NMR (500 MHz, $CDCl_3$) δ: 3.68 (s, 3H), 3.85 (s, 3H), 4.34 (d, *J* = 13.75 Hz, 1H), 4.93 (d, *J* = 12.25 Hz, 1H), 5.03 (d, *J* = 11.45 Hz, 1H), 5.35 (d, *J* = 14.5 Hz, 1H), 6.86 (t, *J* = 7.65 Hz, 1H), 6.92 (t, *J* = 9.2 Hz, 1H), 6.98 (t, *J* = 7.65 Hz, 1H), 7.02 (d, *J* = 8.4 Hz, 1H), 7.07–7.11 (m, 2H), 7.23 (t, *J* = 8.4 Hz, 2H), 7.32–7.35 (m, 1H), 7.39 (t, *J* = 7.65 Hz, 1H), 7.48 (t, *J* = 7.65 Hz, 1H), 7.76 (s, 1H), 7.89 ((d, *J* = 6.9 Hz, 1H), 8.05 (s, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 52.38, 52.53, 58.28, 60.65, 115.2 (q, *J* = 291.4 Hz), 115.66 (d, *J* = 21.4 Hz), 115.83 (d, *J* = 29.7 Hz), 121.86 (d, *J* = 13.1 Hz), 122.12 (d, *J* = 14.3 Hz), 128.1, 128.45, 129.62, 129.75, 130.30, 131.14, 131.20, 131.67, 131.74, 132.03, 132.13, 133.09, 135.12, 137.07, 138.66 (d, *J* = 15.5 Hz), 145.59, 156.02 (q, *J* = 35.7 Hz), 163.9, 166.60, 166.97. MS *m/z*: 617 (M^+). Anal. calcd. for $C_{31}H_{24}F_5NO_7$: C, 60.29; H, 3.92; N, 2.27. Found: C, 60.20; H, 3.93; N, 2.28.

General procedure for the syntheses of 6a–6h

To a stirred solution of Baylis–Hillman bromide (0.3 g, 1.18 mmol) in acetone (5 mL), DABCO (0.132 g, 1.18 mmol) was added. The reaction mixture was stirred for 30 min. The salt formation was confirmed by TLC. After the salt formation, anthranilic acid (0.16 g, 1.18 mmol) and K_2CO_3 (0.163 g, 1.18 mmol) were added. The reaction mixture was stirred at room temperature. After the formation of the product, as indicated by TLC, the reaction mixture was poured into water and extracted with ethyl acetate (3 × 30 mL). The organic layers were dried over Na_2SO_4 and evaporated under reduced pressure. Column purification (20% ethyl acetate in hexane) furnished the products.

Methyl 3-(2-carboxylphenylamino)-2-methylene-3-phenyl propanoate (6a)

Yellow solid; mp 150 °C. IR (KBr) ν: 1664, 1716, 2951, 3365 cm^{-1}. ^1H NMR (500 MHz, $CDCl_3$) δ: 3.74 (s, 3H), 5.63 (s, 1H), 5.87 (d, *J* = 6.1 Hz, 1H), 6.39 (s, 1H), 6.60 (d, *J* = 8.5 Hz, 1H), 6.63 (t, *J* = 7.7 Hz, 1H), 7.30 (d, *J* = 7.7 Hz, 1H), 7.34–7.37 (m, 3H), 7.39 (d, *J* = 6.9 Hz, 2H), 7.98 (d, *J* = 7.7 Hz, 1H), 8.11 (d, *J* = 6.1 Hz, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 52.18, 57.61, 109.55, 112.68, 115.70, 126.24, 127.48, 127.96, 128.96, 132.72, 135.72, 140.06, 140.47, 150.19, 166.67, 173.89. MS *m/z*: 311 (M^+). Anal. calcd. for $C_{18}H_{17}NO_4$: C, 69.44; H, 5.50; N, 4.50. Found: C, 69.37; H, 5.51; N, 4.49.

Methyl 3-(2-carboxylphenylamino)-2-methylene-3-(2-methylphenyl) propanoate (6b)

White solid; mp 158 °C. IR (KBr) ν: 1667, 1724, 2955, 3354 cm^{-1}. ^1H NMR (500 MHz, DMSO-d_6) δ: 2.28 (s, 3H), 3.62 (s, 3H), 5.66 (d, *J* = 6.9 Hz, 1H), 5.88 (s, 1H), 6.31 (s, 1H), 6.53 (d, *J* = 8.4 Hz, 1H), 6.58 (t, *J* = 7.65 Hz, 1H), 7.14–7.20 (m, 4H), 7.30 (t, *J* = 8.4 Hz, 1H), 7.79 (d, *J* = 7.65 Hz, 1H), 8.08 (d, *J* = 6.9 Hz, 1H). ^{13}C NMR (125 MHz, DMSO-d_6) δ: 19.15, 52.59, 53.76, 111.28, 112.43, 115.90, 126.44, 126.82, 126.91, 128.31, 131.29, 132.28, 135.18, 136.65, 138.42, 140.06, 149.86, 166.53, 170.52. MS *m/z*: 325 (M^+). Anal. calcd. for $C_{19}H_{19}NO_4$: C, 70.14; H, 5.89; N, 4.31. Found: C, 70.06; H, 5.91; N, 4.32.

Methyl 3-(2-carboxylphenylamino)-2-methylene-3-(3-chlorophenyl) propanoate (6c)

Pale yellow solid; mp 162 °C. IR (KBr) ν: 1035, 1660, 1720, 2955, 3362 cm^{-1}. ^1H NMR (500 MHz, $CDCl_3$) δ: 3.75 (s, 3H), 5.58 (d, *J* = 5.35 Hz, 1H), 5.87 (s, 1H), 6.42 (s, 1H), 6.55 (d, *J* = 8.4 Hz, 1H), 6.65 (t, *J* = 7.6 Hz, 1H), 7.28–7.29 (m, 3H), 7.33 (t, *J* = 7.6 Hz, 1H), 7.37 (s, 1H),

7.99 (d, J = 6.9 Hz, 1H), 8.11 (d, J = 6.15 Hz, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 52.31, 57.17, 109.73, 112.54, 116.02, 125.62, 127.03, 127.68, 128.22, 130.25, 132.78, 134.75, 135.77, 139.97, 142.25, 149.97, 166.38, 173.74. MS *m*/*z*: 346 (M^+), 348 (M^+ + 2). Anal. calcd. for $C_{18}H_{16}ClNO_4$: C, 62.52; H, 4.66; N, 4.05. Found: C, 62.46; H, 4.65; N, 4.04.

Methyl 3-(2-carboxylphenylamino)-2-methylene-3-(2-chlorophenyl) propanoate (6d)

Yellow solid; mp IR (KBr) ν: 1037, 1656, 1723, 2944, 3352 cm^{-1}. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 3.76 (s, 3H), 5.70 (s, 1H), 6.04 (d, J = 6.1 Hz, 1H), 6.44 (s, 1H), 6.56 (d, J = 8.4 Hz, 1H), 6.63 (t, J = 8.4 Hz, 1H), 7.23–7.25 (m, 2H), 7.32 (t, J = 6.9 Hz, 1H), 7.40–7.42 (m, 2H), 7.97 (d, J = 6.9 Hz,1H), 8.01 (d, J = 6.1 Hz, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 52.37, 54.25, 109.67, 112.57, 115.96, 127.34, 128.03, 128.40, 129.24, 130.13, 132.66, 133.97, 135.85, 137.38, 139.50, 150.20, 166.45, 173.91. MS *m*/*z*: 346 (M^+), 348 (M^+ + 2). Anal. calcd. for $C_{18}H_{16}ClNO_4$: C, 62.52; H, 4.66; N, 4.05. Found: C, 62.63; H, 4.67; N, 4.04.

Methyl 3-(2-carboxylphenylamino)-2-methylene-3-(2-fluorophenyl) propanoate (6e)

White solid; mp 130 °C. IR (KBr) ν: 1222, 1672, 1720, 3011, 3357 cm^{-1}. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 3.75 (s, 3H), 5.85 (s, 1H), 5.94 (d, J = 6.1 Hz, 1H), 6.42 (s, 1H), 6.63–6.65 (m, 2H), 7.06–7.10 (m, 1H), 7.11 (t, J = 7.65 Hz, 1H), 7.26–7.29 (m, 1H), 7.34 (q, J = 8.4 Hz, 2H), 7.98 (d, J = 8.4 Hz, 1H), 8.14 (d, J = 6.1 Hz, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 51.20, 52.26, 109.64, 112.46, 115.82 (d, J = 38.15 Hz), 127.03 (d, J = 13.1 Hz), 127.13, 128.67, 129.66 (d, J = 8.35 Hz), 129.73, 132.72, 135.82, 139.39, 150.07, 159.65, 161.61, 166.36, 173.88. MS *m*/*z*: 329 (M^+). Anal. calcd. for $C_{18}H_{16}FNO_4$: C, 65.65; H, 4.90; N, 4.25. Found: C, 65.58; H, 4.88; N, 4.26.

Methyl 3-(2-carboxylphenylamino)-2-methylene-3-(2,4-dichlorophenyl) propanoate (6f)

Brown solid; mp 114 °C. IR (KBr) ν: 1043, 1656, 1722, 2948, 3355 cm^{-1}. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 3.76 (s, 3H), 5.71 (s, 1H), 5.95 (d, J = 5.35 Hz, 1H), 6.45 (s, 1H), 6.51 (d, J = 8.4 Hz, 1H), 6.65 (t, J = 7.65 Hz, 1H), 7.21 (t, J = 8.4 Hz, 1H), 7.34 (t, J = 8.4 Hz, 2H), 7.43 (s, 1H), 7.98 (d, J = 7.65 Hz, 2H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 52.41, 54.02, 109.76, 112.45, 116.23, 127.64, 128.23, 129.35, 129.98, 132.74, 134.37, 134.69, 135.91, 136.14, 139.08, 149.96, 166.22, 173.75. MS *m*/*z*: 380 (M^+), 382 (M^+ + 2), 384 (M^+ + 4). Anal. calcd. for $C_{18}H_{15}Cl_2NO_4$: C, 56.86; H, 3.98; N, 3.68. Found: C, 56.92; H, 3.99; N, 3.69.

Ethyl 3-(2-carboxylphenylamino)-2-methylene-3-phenyl propanoate (6g)

White solid; mp 124 °C. IR (KBr) ν: 1650, 1719, 2982, 3359 cm^{-1}. ^{1}H NMR (500 MHz, DMSO-d_6) δ: 1.08 (d, J = 7.65 Hz, 3H), 4.04 (m, 2H), 5.58 (d, J = 7.6 Hz, 1H), 5.81 (s, 1H), 6.24 (s, 1H), 6.57 (d, J = 7.6 Hz, 1H), 6.59 (d, J = 8.4 Hz,1H), 7.30–7.34 (m, 5H), 7.79 (d, J = 7.65 Hz, 2H), 8.44 (d, J = 7.65 Hz, 1H). ^{13}C NMR (125 MHz, DMSO-d_6) δ: 14.34, 57.42, 61.14, 111.33, 112.69, 115.73, 126.47, 127.66, 128.13, 129.19, 132.25, 135.01, 140.76, 140.91, 149.81, 165.79, 170.54. MS *m*/*z*: 325 (M^+). Anal. calcd. for $C_{19}H_{19}NO_4$: C, 70.14; H, 5.89; N, 4.31. Found: C, 70.0; H, 5.91; N, 4.30.

Ethyl 3-(2-carboxylphenylamino)-2-methylene-3-(2-chlorophenyl) propanoate (6h)

Brown solid; mp 110 °C. IR (KBr) ν: 1038, 1656, 1715, 2984, 3356 cm^{-1}. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.21 (t, J = 6.9 Hz, 3H), 4.19 (m, 2H), 5.68 (s, 1H), 6.02 (d, J = 4.6 Hz, 1H), 6.43 (s, 1H), 6.57 (d, J = 8.4 Hz, 1H), 6.63 (t, J = 7.65 Hz, 1H), 7.23–7.25 (m, 2H), 7.32 (t, J = 7.65 Hz, 1H), 7.39–7.42 (m, 2H), 7.96 (d, J = 7.65 Hz, 2H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 14.13, 54.34, 61.25, 109.59, 112.54, 115.90, 127.31, 127.63, 128.44, 129.19, 130.05, 132.64, 133.97, 135.83, 137.50, 139.74, 150.25, 165.95, 173.75. MS *m*/*z*: 360 (M^+), 362 (M^+ + 2). Anal. calcd. for $C_{19}H_{18}ClNO_4$: C, 63.42; H, 5.04; N, 3.89. Found: C, 63.50; H, 5.05; N, 3.88.

Benzimidazole quinoline derivatives — An effective green fluorescent dye for bacterial imaging

Mahalingam Malathi, Palathurai Subramaniam Mohan, Raymond J. Butcher, and Chidambaram Kulandaisamy Venil

Abstract: A one-pot synthesis of benzimidazoles by condensing naphthyl or quinoline aldehyde with benzene-1,2-diamine has been reported. IR, ^{1}H and ^{13}C NMR, mass spectral, and CHN analyses were used to elucidate the structures of the products. The molecular structural correlation in the optical properties of the quinoline and naphthalene benzimidazoles was explored. The fluorescence quantum yield (ϕ_f) and time-resolved fluorescent lifetime of the quinoline benzimidazoles derivatives were estimated. The influence of solvent polarity and pH on the optical property of quinoline derivatives was illustrated. To explore the bioanalytical applicability, the thermal stability by TG–DTA analysis and the cytogenetic analysis of 3-(1*H*-benzoimidazol-2-yl)-2-chloro-8-methyl-quinoline (**1b**) compound were carried out. The fluorescent staining ability of **1b** was analyzed and also compared with the normal Gram staining in the bacterium.

Key words: benzimidazole quinolines, optical property, fluorescence quantum yield, cytogenetic analysis, fluorescence staining.

Résumé : On a réalisé une synthèse monotope de benzimidazoles par condensation de naphtyl- et de quinoléinealdéhydes avec de la benzène-1,2-diamine. On a fait appel aux analyses CHN et aux spectroscopies IR, RMN ^{1}H et ^{13}C et de masse pour élucider la structure des produits. On a exploré la corrélation de la structure moléculaire dans les propriétés optiques des benzimidazolylquinoléines et des benzimidazolylnaphtalènes. On a évalué le rendement quantique de fluorescence (ϕ_f) et le temps de vie fluorescent résolu en fonction du temps des dérivés benzimidazolylquinoléines. On a aussi illustré l'influence de la polarité du solvant et du pH sur les propriétés optiques de ces dérivés de la quinoléine. Afin de pouvoir évaluer les possibilités de l'utiliser dans le domaine des analyses biologiques, on a aussi effectué une analyse cytogénétique et on a évalué la stabilité thermique de la 3-(1*H*-benzimidazol-2-yl)-2-chloro-8-méthylquinoléine (**1b**) par analyse thermogravimétrique (TG) et analyse thermique différentielle (ATD). On a analysé la capacité du composé 1b à agir comme colorant fluorescent et on a comparé ses propriétés à celles de la coloration Gram normale dans les bactéries.

Mots-clés : benzimidazolylquinoléines, propriété optique, rendement quantique de fluorescence, analyse cytogénétique, coloration de fluorescence.

[Traduit par la Rédaction]

Introduction

Rapid advances in optical technologies have recently led to significant progress in medical diagnostics, drug discovery, and (bio)chemical analysis, in particular for methods that use fluorescence detection in microscopy, for microarrays or single-molecule tracking.[1] These developments have fueled the search for novel fluorophore (stains, labels, and indicators)[2] with high brightness that can be excited and which could emit well within the visible or near-infrared (NIR) region of the spectrum.[3] This is a part of continual shift away from the use of radioactive tracers in the bioanalytical study. Particularly, it eliminates the dangers of handling carcinogenic dyes, radioactive materials, and the cost of their proper disposal such as crystal violet, ethidium bromide, and ^{32}P in DNA staining analysis.

Accordingly, much research has been done to develop one-photon fluorescent (OPF) probes because they are useful tools for know how the functions in biological systems. One of the major drawbacks of such probes is that the excitation wavelengths are in the range of 350–560 nm, which may cause damage to the substrates specifically in the living

cells.[5] A fluorescent probe having higher excitation wavelength[6] overcomes these shortcomings in two ways: (*i*) using lower energy photon can cause less damage to the cells or tissues and (*ii*) lower energy photon has longer wavelength that can penetrate deep inside the tissue. Many applications of such materials have become reality, some of which include optical power limiting,[7] two-photon (TP) upconversion lasing,[8] TP fluorescence excitation microscopy,[9] three-dimensional optical-data storage,[10] and photodynamic therapy.[11] An important addition to such applications would be the development of TP probes for bioanalytical applications. As a result, the design and synthesis of fluorescent probes with higher excitation wavelength have attained the central position of the current research.[12]

A detailed search of structural correlation in the fluorescent probes reveals that the benzimidazole derivatives could act as an effective fluorescent probe.[13] In addition to the biological activity,[14] many of benzimidazole derivatives are studied as luminescent singling sensors for anions.[15] Recently, Zang et al.[16] have reported a Y-shaped TP-active material based on the imidazole core. Consecutively, Iyer et al.[17] have reported that the benzimidazole ring in a heteroaromatic system could exhibit efficient fluorescence-light-emitting property. All the reports reveal that the benzimidazole and its derivatives have different fluorescence efficiencies, depending on the molecular structure. Consequently, the molecular-structure-based designing is one of the convenient tools for the innovation of the new efficient fluorescent probes.

In this connection, quinoline system gains importance due to its recent revolution in optical chemistry.[18] Basically, quinoline derivatives have been synthesized and widely utilized as drugs for antimalarial, anticancer, and also as DNA intercalators.[19] In contrary, there has been a paucity of imperative papers account that the quinoline derivatives could be used as selective fluorescence chemosensors for biologically important metal ions, as fluorescent dopent in OLEDs and electrochemiluminescence,[20] and so forth. This kindles interest to study the optical property of the benzimidazole-substituted quinoline derivatives. Consecutively, the synthesis of benzimidazole naphthalene derivatives also intended to study the role of quinoline system in the optical property of the synthesized quinoline benzimidazole derivatives.[4]

On par with our objective, we propose a conventional synthetic methodology for the synthesis of quinoline and naphthalene benzimidazole derivatives (BIQ, BIN) in high yield (see Scheme 1 for structures). The optical properties of the synthesized compounds were analyzed by using absorption and emission spectral studies. Based on the fluorescence property, the applicability of the compounds in the bioanalytical studies is focused.

Experimental section

Materials and physical measurements

All reagents and chemicals were purchased from Ranchem chemicals. All the solvents were HPLC-grade. Thin-layer chromatography (TLC) was performed using glass plates coated with silica gel-G containing 13% calcium sulphate as binder. Melting points were determined using a Raga melting point apparatus and are uncorrected. The starting quinoline carbaldehyde compounds were synthesized according to the reported procedure.[21] The naphthalene carbaldehyde starting material was purchased from Sigma-Aldrich chemicals and used without further purification. FTIR spectra (4000–400 cm^{-1}) of compounds were recorded as KBr pellets with a Nicolet Avatar Model FTIR spectrophotometer. ^1H and ^{13}C NMR spectra were recorded on a Bruker Avance 400 (400 MHz) spectrometer in $CDCl_3$ as a solvent and tetramethylsilane (TMS) as an internal standard. Mass spectra were recorded on a Trace DSQ mass spectrograph. Microanalyses (C, H, and N) were performed on a Vario EL-III Elementar elemental analyzer. UV–vis absorption spectra (200–800 nm) were recorded using a Shimadzu UV/2501PC spectrophotometer. The fluorescence spectra were recorded using JASCO FP-6600 spectrofluorometer (Xenon lamp). The fluorescence microscopy analysis was done by using Nikon fluorescence microscopes.

1b $R_1 = CH_3$, R_2, and $R_3 = H$
1c R_1, $R_3 = H$, $R_2 = CH_3$
1d R_1, $R_2 = H$, $R_3 = CH_3$

2a $R_1 = H$
2b $R_1 = CH_3$

Synthesis of benzimidazole compounds

Scheme 2 outlines the general procedure for the synthesis of quinoline and naphthalene benzimidazole derivatives. The aldehyde compound (**3** or **4**) in chloroform was stirred with two drops of glacial acetic acid. To this, benzene-1,2-diamine (**5**) was added, and the stirring was continued for about 15 min. The formation of product was confirmed by TLC. Excess $CHCl_3$ was evaporated, and the resulting crude was washed with water. The dried crude was adsorbed for column chromatography using petroleum ether and EtOAc mixture as eluent. The benzimidazole product was isolated in petroleum ether/EtOAc (9:1) medium. The obtained product was characterized by IR, ^1H and ^{13}C NMR, mass, and elemental analyses.

Synthesis of 3-(1H-benzoimidazol-2-yl)-2-chloro-quinoline (1a)

The compound was prepared as described above by the reaction of 2-chloro-quinoline-3-carbaldehyde (10 mmol, 1.73 g) and benzene-1,2-diamine (5 mmol, 0.541 g). Off-white solid (yield: 1.25 g, 89.33%); mp 202 °C. IR (KBr): 3424, 1607, 1405, 1034, 741. ^1H NMR (400 MHz, $CDCl_3$) δ: 7.27 to 7.38 (m, 2H, C6–quinoline–Q–H, C3′–benzo–BE–H), 7.60–7.64 (m, 2H, C2′ and C5′ of BE–H), 7.79–7.83 (m, 2H, C7–Q–H and C4′–BE–H), 7.92–7.94 (d, 1H, J = 8 Hz, C5–Q–H), 8.03–8.05 (d, 1H, J = 8 Hz, C8–Q–H), 9.26 (s, 1H, C4–Q–H), 10.59 (bs, NH–imidazole–IMD–H). ^{13}C NMR δ: 120.22, 122.66, 123.84, 126.31, 127.10, 127.45, 127.81, 130.59, 131.30, 131.80, 136.21, 140.83, 141.11,

*Synthesis of 2-(3-chloro-naphthalen-2-yl)-1*H*-benzoimidazole (2a)*

The compound was prepared as described above by the reaction of 3-chloro-naphthalene-2-carbaldehyde (9 mmol, 1.72 g) and benzene-1,2-diamine (4.5 mmol, 0.4866 g). Yellowish orange solid (yield: 1.125 g, 89.70%); mp 210 °C. IR (KBr): 3470, 1614, 1321, 744. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 7.25–7.34 (m, 4H, C6 and C7–naphthalene–NA, C3′ and C4′–BH–H), 7.65–7.67 (d, 2H, C5 and C8–NA, J = 8 Hz), 7.69–7.75 (m, 3H, C4–NA, C2′ and C5′–BE–H), 7.84 (s, 1H, C1–NA–H), 9.5 (bs, NH–IMD–H). ^{13}C NMR δ: 115.4, 115.5, 122.9, 123.0, 126.1, 126.9, 127.0, 127.1, 127.8, 128.0, 130.1, 132.2, 134.3, 134.7, 137.9, 138.0, 141.5. EI-MS: m/z = [M$^+$] 278, [M + 2]$^+$ 280. Anal. calcd. for $C_{17}H_{11}N_2Cl$: C, 73.26; H, 3.98; N, 10.05. Found: C, 73.15; H, 3.79; N, 9.85.

*Synthesis of 2-(3-chloro-5-methyl-naphthalen-2-yl)-1*H*-benzoimidazole (2b)*

The compound was prepared as described above by the

reaction of 3-chloro-5-methyl-naphthalene-2-carbaldehyde (9 mmol, 1.84 g) and benzene-1,2-diamine (4.5 mmol, 0.4866 g). Yellowish orange solid (yield: 1.132 g, 85.65%); mp 225 °C. IR (KBr): 3456, 1607, 1332, 756. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 2.61 (s, 3H, C6–Q–CH_3–H), 7.20–7.29 (m, 4H, C6 and C7–NA–H, C3′ and C4′–BE–H), 7.59–7.63 (d, 2H, C5 and C8–NA–H, J = 8 Hz), 7.65–7.72 (m, 3H, C4–NA–H, C2′ and C5′–BE–H), 7.82 (s, 1H, C1–NA–H), 9.2 (bs, 1H, NH–IMD–H). ^{13}C NMR δ: 20.63, 114.2, 114.5, 121.9, 122.0, 125.1, 125.9, 127.2, 127.5, 127.9, 128.0, 130.2, 132.2, 134.2, 134.5, 137.5, 138.2, 140.5. EI-MS: m/z = [M$^+$] 292, [M + 2]$^+$ 294. Anal. calcd. for $C_{17}H_{11}N_2Cl$: C, 73.85; H, 4.48; N, 9.57. Found: C, 73.65; H, 4.34; N, 9.47.

Optical measurements

For the absorption analysis, stock solution was prepared by dissolving 10 mg of BIQ derivatives in 100 mL ethanol. The solution was diluted to 10^{-5} mol/L concentration for the absorption and 10^{-7} mol/L for the emission analysis. But in the case of solvent polarity study of **1b**, the compounds in the specified solvent medium were only used for both absorption and emission analysis. The fluorescence intensity vs. pH titration was carried out using 10% aqueous alcoholic solution of the BIQ-**1b** compound. 0.1 mol/L HCL and 0.1 mol/L NaOH were used to adjust the pH of the medium.

Fluorescence decays were recorded using TCSPC method using the following setup. A diode-pumped millena CW laser (Spectra Physics) 532 nm was used to pump the Ti:sapphire rod in Tsunami picosecond mode locked laser system (Spectra Physics). The 750 (80 MHz) was taken from the Ti:sapphire laser and passed through pulse picker (Spectra Physics, 3980 2S) to generate 4 MHz pulses. The seond harmonic output (375 nm) was generated by a flexible harmonic generator (Spectra Physics, GWU 23PS). The vertically polarized 375 nm laser was used to excite the sample. The fluorescence emission at magic angle (54.7°) was dispersed in a monochromator (f/3 aperture), counted by a MCP PMT (Hamamatsu R 3809), and processed through CFD, TAC, and MCA. The instrument response function for this system is ~52 ps. The fluorescence decay was analyzed by using the software provided by IBH (DAS-6) and PTI global analysis software.[22]

Cytogenetic analysis

Cytogenetic analysis was performed for compound **1b** in human peripheral blood lymphocyte culture (PBLC). They were obtained from peripheral blood set-up following the method of Hungerford.[23] Two experiments were carried out using four smoking and non-smoking healthy male donors, aged 23, 24, and 28 years. The testing compound was dissolved in 1% methanol. Its four different concentrations of 0.02, 0.2, 2, and 20 μg mL^{-1} were added to the culture medium (0.1 mL solution of compound **1b** per 8 mL of the medium) after 48 h culture initiation. Duplicate cultures for each dose were maintained for the study of chromosomal aberrations. Then, cultures were incubated at 37 °C for a period of 24 (total 72 h) h. Methanol (1%) was applied to control I and II, respectively.

The cultures were shaken periodically up to three times a day. During the two hours before the culture harvest, the dividing cells were arrested in the metaphase by adding 0.05 mL of colchicine solution (w = 0.01%). The contents in the vial were centrifuged at 1200 rpm for 5 min at the end of the colchicine treatment. The supernatant was discarded, and 5 mL of pre-warmed hypotonic solution (0.075 mol L^{-1} KCl) was added to the cell button. The cells were incubated for 20 min, sedimented after centrifugation at 1200 rpm for 10 min, and then fixed in a freshly prepared fixative (methanol/glacial acetic acid, 3:1, v/v). Two or three changes of the fixative were applied. Slides were prepared by placing a drop of the cell suspension on a clean chilled slide and dried immediately at 40 °C for a few seconds. The slides were routinely stained in a 2% buffered solution of Giemsa.[23] Three-hundred-and-fifty well-banded metaphases were analyzed for each treatment under an oil immersion lens.

Staining analysis in the bacterial microbe

Potent strains of bacteria were isolated from the gut of sulfur butterfly (*Kricogonialyside*). The isolation and culturing experimental procedures of the bacteria were carried out using the reported methods.[24] The confirmed *Serratia marcescens* SB08 was used in the staining process. Initially, the bacterium was heat-fixed in the clean glass slide. Two or three drops of 10% ethanolic solution of **1b** (10^{-9} mol/L) was added to the heat-fixed bacterial smear and allowed to bind for 15–60 s. After that, the slide was rinsed with distilled water and air-dried. Then, the slide was examined under the fluorescence microscopy.

Results and discussion

Synthesis of benzimidazole derivatives

Recent exploration of pyrene- and benzimidazole-based compounds as long-wavelength fluorophores[25] raise our interest to synthesize quinoline and naphthalene derivatives containing benzimidazole unit and study their structural correlation in the optical property. To achieve our objective, the work is started by synthesizing benzimidazole compounds from the derivatives of quinoline and naphthalene aldehydes with 1,2-diaminobenzene (Scheme 2). Such quinoline benzimidazole derivative was first prepared by Bhanumathi et al.[26] in two-stage approach. Their synthetic method was low-yielding, time-consuming, and did not seem amenable for the synthesis of benzimidazole compounds as demanded by the need of their application. Additionally, Kidwai et al.[27] reported a bisquinoline formation in the condensation reaction of quinoline aldehyde with benzene-1,2-diamine. Their reaction conditions and medium are similar to the Bhanumathi et al. synthetic methodology. Recently, Chen reported a one-pot synthetic methodology for the synthesis of 2-benzimidazolyl quinoline by the direct condensation of diamine with quinoline acid.[28] In this sequence, the exploration of reaction conditions and temperature for the synthesis of benzimidazole derivatives from the diamine and aldehydes could be significant. It may give a valuable outlook for the synthesis of complex benzimidazole derivatives.

Initially, the reaction was carried out with the 1:1 molar ratio of reactants in chloroform with catalytic amount of glacial acetic acid. This reaction conditions resulted in the formation of a mixture of products. However, 2:1 molar ratio

[a]NH proton of the benzimidazole ring in the BIQ and BIN (400 MHz, $CDCl_3$).
[b]The 30 μmol/L ethanolic solution of BIQ and BIN compounds were used in the UV–vis absorption analysis.

of the reactants, i.e., aldehyde and diamine, respectively, produced a single product in the same reaction medium after 15 min. The purification of the products from the crude mixture was done by column chromatography using petroleum ether:ethyl acetate (9:1) mixture as eluent. The structure of the products was confirmed by IR, NMR, mass, and elemental analyses. The single-crystal structure of one of the quinoline benzimidazole derivatives (**1b**) was solved by X-ray crystallographic technique and was reported.[29] The characterization analysis supports the formation of benzimidazole derivatives using the 2:1 molar ratio of reactants. The same reaction was carried out smoothly in a beaker without changing the environmental condition, such as the high temperature, inert atmosphere, and expensive catalysts. It is believed that the presence of excess aldehydes might help to stop the backward reaction.

In the characterization analysis, a broad spectral correlation could be observed specifically in the benzimidazole N–H functional group of BIQ and BIN derivatives (Table 1). The IR spectrum of the BIQ and BIN derivatives shows ν_{NH} band in the region of 3420–3445 and 3455–3470 cm^{-1}, respectively. The lower ν_{NH} wavelength for BIQ compounds illustrates the existence of strong hydrogen bonding (Imida–N–H···Cl–Q) in their molecular structure. In addition, the ^{1}H NMR spectra of BIQ and BIN derivatives show a pronounced deshielding effects in the δ value of BIQ–N–H functional group (δ 10.40–10.59 and 8.52–8.55, respectively), which further confirms the existence of strong hydrogen bonding (Imida–N–H···Cl–Q) in the BIQ derivatives. It is concluded that the nitrogen lone-pair electrons in the quinoline ring could facilitate the existence of strong hydrogen bonding in the BIQ derivatives. This specific molecular structural conformation will play a vital role in the optical behavior of BIQ compounds compared with BIN compounds.

Absorption and emission spectral studies

The optical analyses of BIQ and BIN compounds were recorded in ethanol. Figure 1 shows the absorption spectra of compounds **1b** and **2b**. In general, UV–vis absorption spectra of BIQ and BIN ethanolic solutions exhibit peaks with λ_{max} in the range of 340 to 355 nm (Table 1). λ_{max} values of the respective compounds was used to excite the corresponding compound in the spectrofluorimetric analysis. The resulting fluorescence spectra of BIQ and BIN compounds prove the existence of fluorescence property only in BIQ compounds.

The absorption λ_{max} of **1b** is 354 nm in ethanol. This solution, on excitation in the range of λ_{max} 350–355 nm (single excitation), exhibits two fluorescence peaks around λ_{max} 432 and 851 nm (Fig. 2*a*). But the intensity of the first fluorescence peak is 10 times higher compared with the following peak (10:1). The same solution, on excitation in the range of λ_{max} 700–710 nm (double excitation), exhibits a fluorescence peak and a hump (Fig. 2*b*) around λ_{max} 433 and 849 nm, respectively. In this double excitation, the intensity ratio of the fluorescence peak and hump is also found to be 10:1. However, the fluorescence peak intensity in the single excitation (350–355 nm) is five times higher than the doubly excited (700–710 nm) fluorescence peak. This shows the sensitivity of the double excitation process. All the spectrofluorimetric experiments of **1b** were repeated in different solvents, i.e., in CH_2Cl_2, $CHCl_3$, DMF, DMSO, and EtOH. The combined spectral data expose the double-excitation property of **1b** in the above mentioned solvent. Additionally, it illustrates that the intensity of the fluorescent λ_{max} is higher in polar solvents than in non-polar solvents.

All the observed results propose that the BIQ derivatives should have intramolecular charge transfer (ICT) interaction in the solution form. ICT occurs between the quinoline and imidazole ring systems during electronic excitation. It restricts the internal rotation of imidazole unit within the molecule, which creates a self-organized supramolecular architecture. This molecular conformational arrangement of

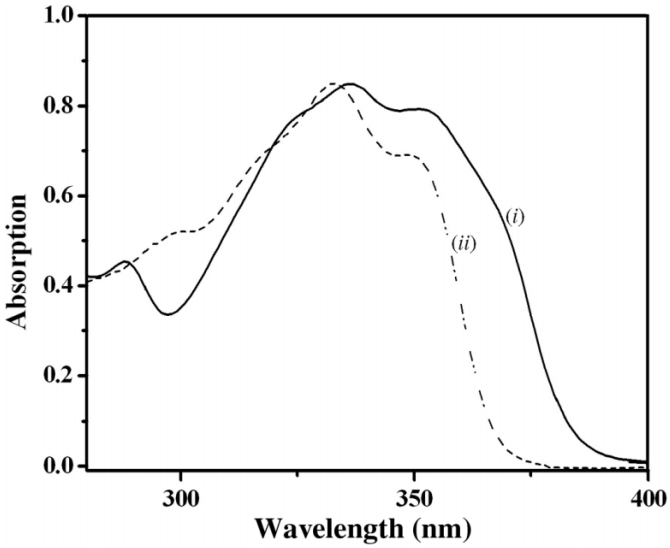

Fig. 2. Fluorescence spectra of ethanolic solution of BIQ-**1b** in 0.3 μmol/L concentration: (*a*) Solid line: emission spectra of **1b** in the excitation wavelength λ_{exc} 354 nm and the resulting emission λ_{emi} = 434 and 852 nm; dashed line: emission spectra of **1b** in the excitation wavelength λ_{exc} = 708 nm and the resulting emission λ_{emi} = 447 nm. (*b*) Expansion form of fluorescence spectra of **2a** from 750 to 1000 nm.

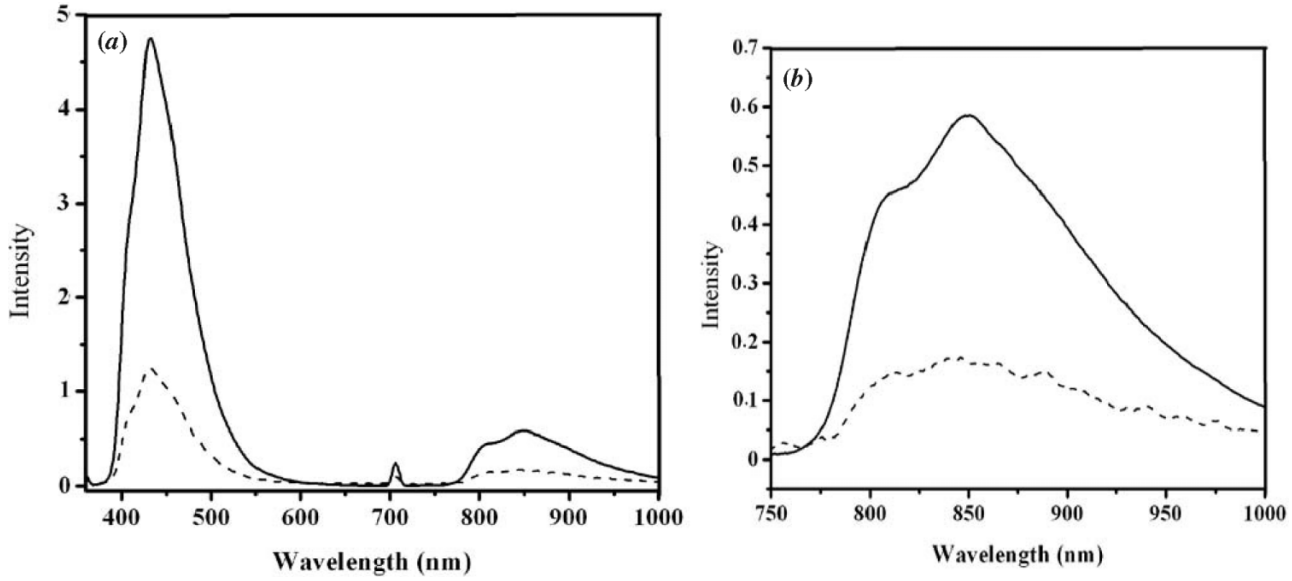


excited molecules can facilitate radiative decay during the electronic relaxation process, while in the case of naphthalene bearing imidazole moiety, the absence of ICT can sustain the internal rotation, thereby the electronic relaxation frequently takes place as non-radiative decay process.[30] Spectrofluorimetric analysis of other derivatives of BIQ (**1a**, **1c**, and **1d**) also exhibits the higher wavelength excitation and fluorescence emission property in solution.

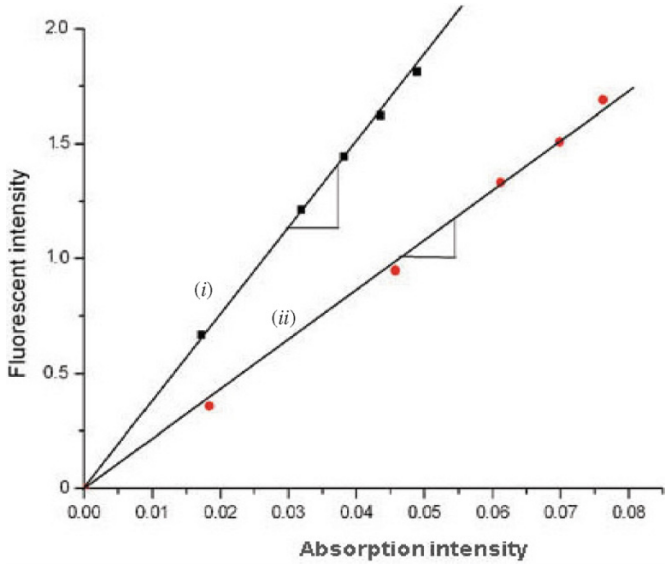
Fluorescence quantum-yield measurement

Fluorescence quantum yield (ϕ_f) of the BIQ derivatives (x) in ethanol was determined using 2-amino pyridine as a standard (std), since both compounds have excitation wavelength in the range of 340–450 nm. 0.1 mol/L H_2SO_4 solution was used in the preparation of 2-amino pyridine solution in different concentrations. For quantum-yield measurement, the absorption and fluorescence spectra of 2-amino pyridine solution were recorded in the following concentrations: 0 (blank), 0.2, 0.4, 0.6, 0.8, and 1 μmol/L. The spectral experimental procedures were repeated in the ethanolic solution of BIQ derivatives in the same concentrations. The integrated fluorescence intensity vs. absorbance was plotted (Fig. 3), and the slope was calculated. The quantum yields of the benzimidazolyl quinoline compounds were calculated by applying the observed experimental data in the following equation:

$$[1] \qquad \phi_x = \phi_{std}\left(\frac{Grad_{std}}{Grad_x}\right)\left(\frac{\eta_x^2}{\eta_{std}^2}\right)$$

Here, ϕ_x and ϕ_{std} denote the fluorescence quantum yields of unknown (BIQ derivatives) and standard (2-amino pyridine) compounds, respectively. The "Grad" and η denote the gradient (slop) of the graph and refractive index of the respective solvent, respectively. The ϕ_{std} of the 2-amino pyridine in 0.1 mol/L H_2SO_4 solution is 0.6. The refractive index of the 0.1 mol/L H_2SO_4 and ethanol is 1.36 and 1.003, respectively. By doing the calculation, the fluorescence quantum yields (ϕ_f) of the BIQ derivatives are determined, and the values are tabulated (Table 2).

Fig. 3. Fluorescence quantum-yield measurement of **1b** (μmol/L concentration range). (*i*) Fluorescent vs. absorption intensities of 2-aminopyridine in 0.1 mol/L H_2SO_4 solution, λ_{exc} = 335 nm and λ_{emi} = 370 nm. (*ii*) Fluorescent vs. absorption intensities of BIQ-**1b** in ethanol, λ_{exc} = 354 nm and λ_{emi} = 434 nm.



Fluorescence lifetime measurement

Time-dependent measurements of receptors have been performed using time-correlated single-photon counting (TCSPC) technique (Fig. 4). The fluorescecent lifetime of

each BIQ derivative was measured in ethanol using the corresponding solution absorption λ_{max} wavelength as the excitation wavelength. The fluorescence lifetimes (τ_f) of the compounds are found to be in the range of 2–3 ns (Table 2).

Fluorescence efficiency

To optimize the fluorescence efficiency of BIQ derivatives, the influence of solvent polarity and pH of the medium on the optical property of **1b** was studied. In this fluorescence-optimizing spectrofluorimetric analysis, the single excitation of **1b** (428–435 nm) is mainly accounted.

Solvent-polarity study

The absorption and emission of **1b** were studied in different solvents with increasing polarity (toluene, CH_2Cl_2, $CHCl_3$, DMSO, DMF, EtOH, and 10% EtOH). Absorption spectra of the quinoline benzimidazole derivatives showed a gradual red shift with the increase in solvent polarity. This shift is much pronounced in the last three solvents in the following order: DMF < EtOH < H_2O (10% ethanol) (Fig. 5). Absorption λ_{max} values of **1b** in different solvents were used to record fluorescence spectra of the corresponding solutions. The recorded fluorescence spectrum shows red shift with the increase in solvent polarity. This illustrates the utility of this compound as a polar fluorescent probe (Fig. 6).[31] The experiment was repeated with double-excitation wavelength λ_{max}. The resulting spectra in the combined form were shown in Fig. 7. Absorbance and fluorescence wavelength λ_{max} of all other BIQ derivatives (**1a**, **1c**, and **1d**) in DMF, EtOH, and water (10% ethanol) were measured and tabulated (Table 2).

Figures 5, 6, and 7 point out that **1b** in the excited state is more polar than in the ground state. For the increase of the polarity of the solvent, the energy level which corresponds to a more polar molecular conformation will be more inten-

Fig. 5. UV–vis absorption spectra of BIQ-**1b** in (*i*) toluene, λ_{max} = 312 nm; (*ii*) DMF, λ_{max} = 326 and 342 nm; (*iii*) EtOH, λ_{max} = 330 and 354 nm; (*iv*) 10% aqueous ethanol, λ_{max} = 354 and 375 nm.

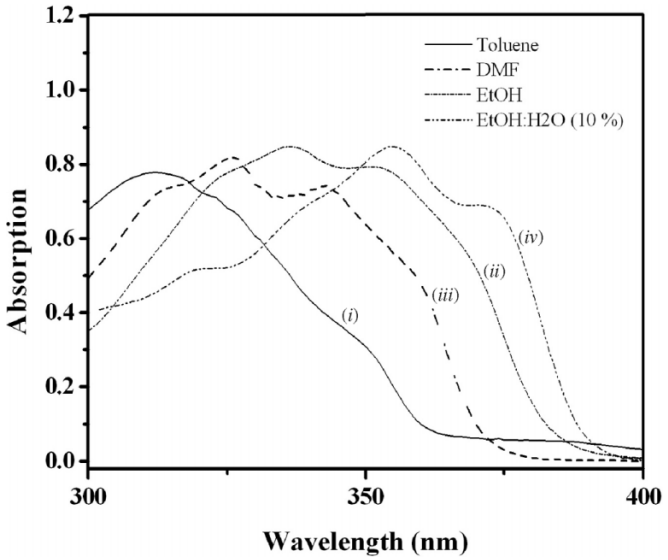

Fig. 6. Emission spectra of **1b** (single excitation) in (*i*) toluene, λ_{exc} = 312 nm and λ_{emi} = 370 nm; (*ii*) DMF, λ_{exc} = 342 and λ_{emi} = 425 nm; (*iii*) EtOH, λ_{exc} = 354 nm and λ_{emi} = 434 nm; (*iv*) 10% aqueous ethanol, λ_{exc} = 375 nm and λ_{emi} = 442 nm.

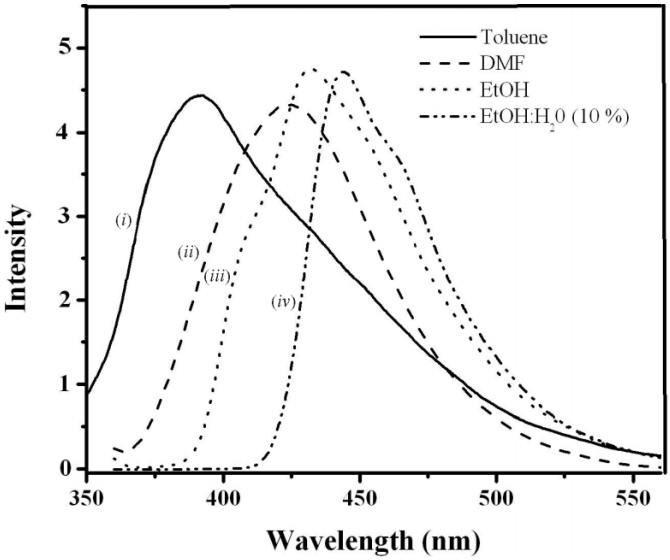


sively lowered.[32] Hence, a red shift of the wavelength is observed in the absorption and emission spectra of **1b** with the increase in solvent polarity.

In addition to the red shift of wavelength, Figs. 6 and 7 illustrate marked difference in the λ_{max} of the solution during double excitation compared with the single excitation. This further confirms the sensitivity of the double-excitation processes. This type of shifting also suggests that the excited geometrical conformation of **1b** may be suitable for the model of twisted intramolecular charge transfer (TICT).[32]

Fluorescence pH titration

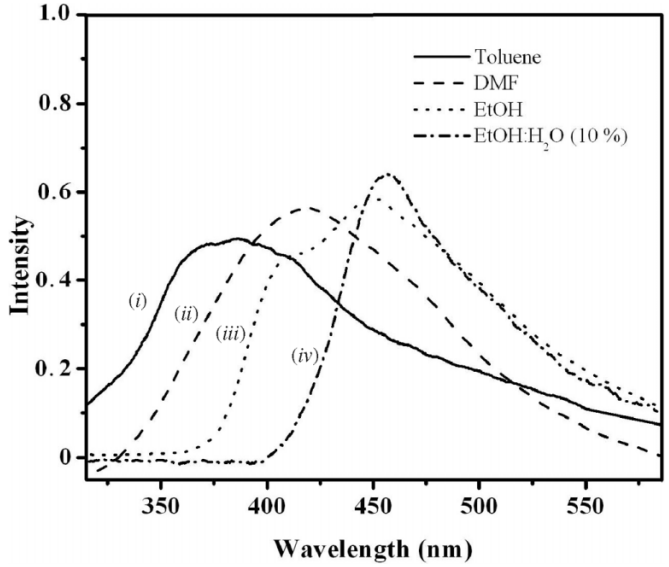
Quantitative pH titration was performed to find the fluorescent efficiencies of BIQ compounds in the wide range of pH. In this analysis, the intensity of first fluorescence peak during the single excitation of **1b** (λ_{exc} = 354 nm and λ_{emi} = 432 nm) was accounted. The fluorescence spectrum of the 3 μmol/L aqueous ethanol solution of **1b** was recorded in the pH range of 2 to 14, and a plot was drawn between the fluorescence intensity and pH. Figure 8 shows the fluorescent intensity vs. pH titration plot of **1b**. From the graph, it is observed that the fluorescent intensity is higher in the lower pH range and continuously decreases in higher pH range, owing to the deprotonation of the N atoms in the basic medium. However, it should be noted that the difference in the fluorescent intensity is very little when the pH is greater than 6.5. The fluorescent stability of **1b** in this pH range might be helpful to avoid the interference of possible pH change induced by biological stimulation.

Bioanalytical study of 1b

Cytogenetic analysis

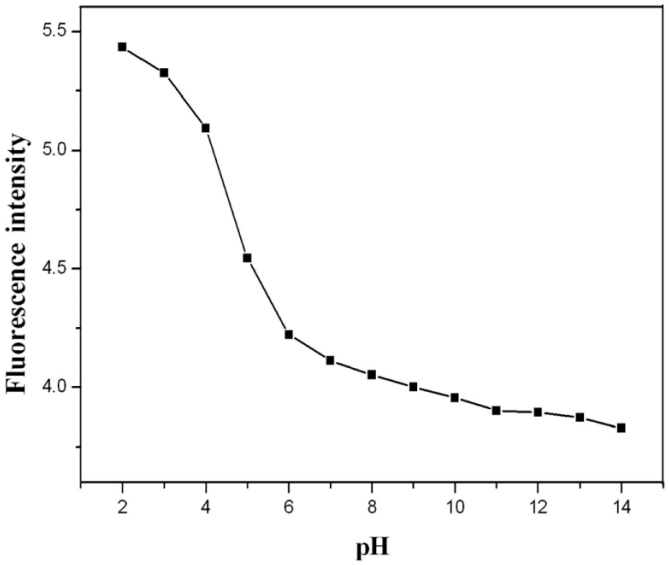
The observed results in the optical measurements support the suitability of BIQ derivatives as efficient polar fluorescent probes for bioanalytical study. But in the case of in vivo analysis, the cytotoxicity of the compound is the main factor which determines the suitability of the compound in cell-line analysis. With this necessity, the cytogenetic analysis was performed by using one of the BIQ compounds **1b** to scale up the utility of the derivatives in living-cells analysis. The preparation of the metaphase plates is detailed in the Experimental section.

Fig. 7. Emission spectra of **1b** (double excitation) in (*i*) toluene, λ_{exc} = 624 nm and λ_{emi} = 385 nm; (*ii*) DMF, λ_{exc} = 684 nm and λ_{emi} = 421 nm; (*iii*) EtOH, λ_{exc} = 708 nm and λ_{emi} = 447 nm; (*iv*) 10% aqueous ethanol, λ_{exc} = 750 nm and λ_{emi} = 456 nm.



All the prepared slides in well metaphase plates were screened for chromosomal aberrations (Table 3). The aberration includes endoreduplication, fragments, chromatid breaks, and chromatid gaps. The clastogenic properties of the compound were studied by investigating the effects of the compounds on human chromosomes through in vitro

Fig. 8. Fluorescence pH titration of BIQ-**1b** (3 μmol/L of 10% aqueous ethanolic solution) with λ_{exc} = 354 nm and λ_{emi} = 432 nm. The pH of the solution was adjusted by using 0.1 mol/L HCl and 0.1 mol/L NaOH to get acidic and basic pH, respectively.



analysis in the lymphocyte cultures. The data of the compound are pooled and shown in Table 3. It was noted that the increase in the chromosomal aberrations is dose-dependent. Chromosomal aberrations like chromatid gaps and chromatid breaks were also observed. Polyploid cells were absent in all examined slides. From Table 3, it is inferred that the compound did not show any aberration up to 10^{-4} mol/L concentration, which is essential for cell-lines in vitro studies.

Thermal analysis

BIQ compounds are remarkably stable towards air. It can be kept under air for a long time without any noticeable decomposition. Figure 9 shows the TG–DTA curves of **1b**. Compound **1b** exhibits two steps of decomposition in TG. The endothermic peak at 200 °C corresponds to the melting point of the compound. The first exothermic peak at 275 °C corresponds to the loss of chlorine. Then, a complete exothermic decomposition of the molecule occurs between 500 and 800 °C. During the decomposition, the masses of the compound, intermediate, and final product are those which best fit with observed mass loss in TG curve. The TG results are in good agreement with the DTA data. From this study, it is inferred that the compound is highly stable up to 250 °C.

Staining study

All the photophysical, cytotoxicity, and thermal analyses of BIQ derivatives support its applicability for bioanalytical studies. This creates an intention to carry out the staining analysis using BIQ compounds as staining dye. The appreciable fluorescence efficiency (high ϕ_f, water solubility, and thermal stability analysis) of **1b** makes it attractive for the staining analysis. For the initial staining analysis, we prefer small microorganism selectively bacteria because they are one of the primary microbes used in the drug discovery. Apart from the pathogenic activity of bacteria, they have significant applications in the industrial biotech processes, such as biocatalysis,[33] bioremediation[34], and so forth, in such a way that leads to the implementation of green chemistry in various industrial processes. Additionally, the enzyme-producing bacteria have promising medicinal activity.[35] In this regard, many enzyme-producing bacteria are analyzed in anticancer studies.[36]

In this margin, *S. marcescens* a Gram-negative bacterium produces L-asparaginase enzyme that has anti-proliferative and anti-tumor activities.[37] Accordingly, its identification, proliferation, and its structural analysis become significant in the bacterial research. Recently, Venil et al.[24] discussed the factors affecting the production of enzyme L-asparaginase from the bacterium *S. marcescens* SB and optimized an effective medium for its production. In this progress, the fluorescence imaging of the bacteria should have significant value. The surface morphological study will reveal many fundamental features of this organism and produce novel tools to study previously inaccessible problems. Additionally, this staining analysis can give a fundamental idea about the affinity of the BIQ compounds in the cell wall and also decides its applicability for further bioanalytical studies, such as optical imaging of living systems, detection of intracellular free metal ions, and so forth. With this intension preliminarily, we concentrate the staining analysis in the Gram-negative bacterium *S. marcescens* SB08.

Bacterial staining analysis

The fluorescent microscopic view shows that **1b** is an excellent green-fluorescence light-emitting material (Fig. 10*a*). The details of the slide preparation are explained in the Experimental section. In addition to the fluorescence staining, normal Gram staining of the bacterium were also done. The normal Gram-stained bacterial smear in the slide was viewed in the microscope (Fig. 10*b*), whereas the BIQ-stained one was viewed in the fluorescence microscope. The clean rod-shape image (Fig. 10*c*) of the bacterium confirms the binding of **1b** to the surface of the bacterium.

Conclusion

A specific molar ratio is implemented for the synthesis of BIQ and BIN compounds at room temperature. This short-reaction-time method offers high yield with reference to the reported procedures. All the synthesized compounds are characterized by various spectral and analytical techniques (IR, ^{1}H, ^{13}C NMR, mass, and CHN analyses).

The preliminary optical analysis confirms the fluorescence property of the BIQ derivatives and also reveals that such property is silent in the BIN derivatives. This optical behavior of BIQ derivatives can be attributed to the quinoline moiety facilitating a strong charge-transfer interaction with the imidazole group during the electronic relaxation. Due to that, its derivatives alone show intense absorption and fluorescence bands with ϕ_f approximately close to 1. In addition to the fluorescence property, the spectrofluorimetric analysis of BIQ derivatives exhibits a higher excitation wavelength (λ_{exc} = 708 nm) and emission property (λ = 434 and 850 nm) in different solvents, since it is also an essential parameter for the recognition of TP fluorescence probes. This low energy excitation and emission photophys-

Table 3. Cytogenetic analysis of the BIQ compound **1b**.

ical property of BIQ compounds is significantly economic in the preliminary bioanalytical study of the living systems.

The fluorescence quantum yield (ϕ_f) and time-resolved fluorescent lifetime (T_f) of the BIQ derivatives were measured to evaluate its fluorescence efficiency. The optical analysis with increasing solvent polarity exposed the polar fluorescent probe nature of the BIQ derivatives. The fluorescence pH-titration measurement confirms the applicability of the BIQ derivatives in a wide range of pH.

In general, the combined optical spectral data of the BIQ and BIN derivatives conclude that the methyl derivatives have better photophysical properties in comparison with the unsubstituted derivatives. In addition to the optical property, a vast difference also exists in the IR and NMR spectral data of the substituted and unsubstituted benzimidazole derivatives. This is mainly due to the extension of conjugation (hyperconjugation)[38] facilitated by the methyl protons.

Based on the optical properties, one of the BIQ deriva-

tives (**1b**) was completely examined to evaluate its applicability in the bioanalytical studies. The TG–DTA analysis of **1b** exhibits that it is stable around the 250 °C and can withstand up to 500 °C with the loss of chlorine atom. The cytogenetic analysis exposed that up to the 10^{-4} mol/L concentration of **1b** can be used in living cells, which is expected to be sufficient for the in vitro analysis.

From the optimization, the bacterial staining applicability of **1b** was attempted. The **1b**-stained bacterial view in the fluorescence microscopy explores its staining ability. It reveals that BIQ derivatives could be good alternative for green beads in fluorescence-imaging studies. Solvent polarity and pH-sensitivity analyses illustrate the promising platform to design TP biomarkers from the BIQ derivatives. The low energy excitation and emission property of the BIQ derivatives in the solid form and its TP analysis are underway.

Multi-component supramolecular synthesis of spirooxindoles catalyzed by β-cyclodextrin in water

Regati Sridhar, Boga Srinivas, Bandaru Madhav, Vutukuri Prakash Reddy, Yadavalli Venkata Durga Nageswar, and Kakulapati Rama Rao

Abstract: A neutral and efficient one-pot three-component aqueous-phase synthesis is developed for various spirooxindole derivatives from isatin, malononitrile, and 1,3-dicarbonyl compounds in high yields by supramolecular catalysis involving β-cyclodextrin. The β-cyclodextrin can be recovered and reused a number of times without any loss of activity.

Key words: spirooxindole, isatin, dimedone, 4-hydroxy coumarin, barbituric acid, biomimetic synthesis, β-cyclodextrin, water.

Résumé : On a mis au point une synthèse monotope neutre et efficace, à trois composants et en milieu neutre qui permet d'obtenir avec des rendements élevés des dérivés spirooxindoles de l'isatine à partir du malononitrile et de composés 1,3-dicarbonylés et faisant appel à une supracatalyse impliquant la β-cyclodextrine. La β-cyclodextrine peut être récupérée et réutilisée un certain nombre de fois sans aucune perte d'activité.

Mots-clés : spirooxindole, isatine, dimédone, 4-hydroxycoumarine, acide barbiturique, synthèse biomimétique, β-cyclodextrine, eau.

[Traduit par la Rédaction]

Introduction

The spirooxindole is an important structure present in a number of natural bioactive compounds, such as coerulescine, elacomine, horsfiline, welwitindolinone A, spirotryprostatin A, alstonisine, and surugatoxin.[1] They display potent cytotoxic activity and are also known as h5-HT6 serotonin receptors, estrogen-receptor modulators, antiproliferative agents, and oxytocin antagonists.[2] In view of their significance, various methodologies have been developed for the construction of spirooxindole frameworks.[2] However, our interest in the synthesis of heterocyclic compounds involving supramolecular chemistry[3] and the growing focus on environment-friendly processes prompted us to revisit the synthesis of spiroxindoles.

It is highly desirable to develop a chemical system that can mimic the action of enzymes and effect organic reactions in water with excellent efficiency and selectivity. Water is a safe, inexpensive, and environment-friendly solvent, which makes its use favorable in both academic laboratories and industry. The pioneering studies of organic reactions in water by Breslow[4] in the early 1980s triggered a more widespread interest in the use of water as a medium for organic synthesis, not only because these reactions eliminate the necessity for vigorously drying solvents and substrates, but also because of the unique reactivity and selectivity often observed in aqueous reactions. However, the synthesis of spirooxindoles described so far by the three-component reaction of isatin, malononitrile or methyl cyanoacetate, and 1,3-dicarbonyl compounds have limited scope because of the use of transition-metal catalysts, microwave irradiation, surfactants, acidic or basic conditions, and hazardous solvents.[5] As a consequence, the development of environmentally benign practical synthetic routes under neutral conditions using a recyclable catalyst in water for accessing these spirooxindole derivatives still remains a major goal.

These aqueous reactions can be made more sophisticated if they can be performed under supramolecular catalysis, such as β-cyclodextrin, overcoming many of the drawbacks observed in the previous methodologies. Cyclodextrins (CDs) are cyclic oligosaccharides possessing hydrophobic cavities which bind substrates and catalyze chemical reactions with high selectivity. They catalyze reactions by supramolecular catalysis involving reversible formation of host-guest complexes by non-covalent bonding as seen in enzymes.

In continuation of our interest in the β-cyclodextrin catalyzed biomimetic synthesis of heterocyclic compounds in aqueous phase,[3] we have explored the aqueous-phase synthesis of spiooxindole derivatives by the three-component reaction of isatin, malononitrile, and dimedone under neutral conditions catalyzed by β-cyclodextrin (Scheme 1).

Results and discussion

In general, the reactions were carried out by forming an in situ β-CD complex of the isatin in water, followed by the

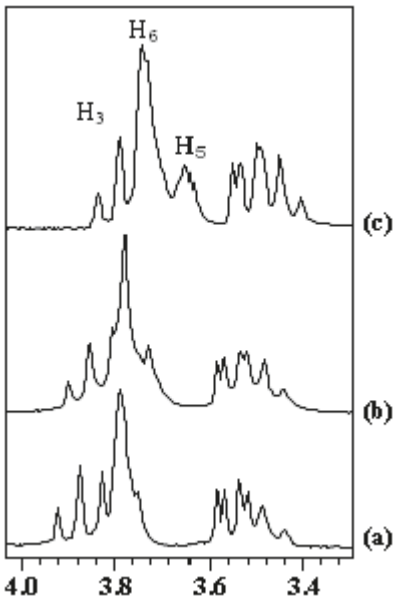
addition of malononitrile and dimedone, and stirring at 60 °C. The corresponding spirooxindole compounds were obtained in impressive yields (84%–91%) after 4–6 h by simple filtration. This methodology is compatible with various substituted isatins having different functionalities such as bromo, methyl, nitro, phenyl, and benzyl groups (Table 1, entries 1–8). It was found that methyl cyanoacetate also underwent condensation with isatin and dimedone to give the desired product in impressive yields (Table 1, entries 9–10, 85%–87%) under similar conditions. These reactions proceeded efficiently under neutral conditions. No byproduct formation was observed. β-Cyclodextrin can be easily recovered and reused.

Further applications of this methodology involve the reactions of 4-hydroxy coumarin and barbituric acid under the above optimized conditions (Scheme 2) to produce spirooxindole derivatives (Table 2, entries 11–16) efficiently in yields ranging from 84–88%.

The complexation of isatin with β-CD was confirmed by the isolation of the β-CD–isatin complex and the study of its ^{1}H NMR spectrum, which shows an upfield shift of H3 and H5 of β-CD as observed by us earlier.[3a] The ^{1}H NMR spectra (D_2O) of β-CD, the β-CD–isatin complex, and the freeze-dried reaction mixture of the β-CD–isatin complex after the addition of malononitrile and dimedone were studied. It was observed from Fig. 1 that there was an upfield shift of H3 (0.02 ppm) and H5 (0.02 ppm) protons of cyclodextrin in the β-CD–isatin complex as compared to β-CD, indicating the formation of an inclusion complex of isa-

Fig. 1. [1]H NMR spectra of (a) β-CD; (b) β-CD–isatin complex; and (c) reaction mixture after 2 h. The spectra were recorded in D_2O at 25 °C.



tin with β-CD from the secondary side of cyclodextrin.[6] In the spectra of the reaction mixture of the β-CD–isatin complex after the addition of malononitrile and dimedone after 2 h, an upfield shift of the CD H6 proton by 0.048 ppm was also observed. This indicated that the reaction proceeded by complexation of malononitrile and dimedone from the primary side of cyclodextrin (Fig. 1). This clearly demonstrates that the isatin is ideally located for the condensation with malononitrile and dimedone in the hydrophobic environment of the β-cyclodextrin cavity.

The catalytic activity of cyclodextrins for these reactions is established by the fact that in the absence of cyclodextrin, the reaction was observed to proceed in very poor yields (20%) even after long reaction times (24 h). The complexation of isatin with β-CD increases the reactivity of the keto group due to intermolecular hydrogen bonding with the CD-hydroxyl groups[7] facilitating the Knoevenagel condensation with malononitrile to form an isatylidene malononitrile derivative. It then undergoes the established sequence of reactions such as Michael addition of dimedone followed by the cycloaddition of hydroxyl group to the cyano moiety to form the spiro compound.[5] Here, β-CD not only forms the inclusion complex with isatin but is also involved in the intermolecular hydrogen bonding with the guest to promote the condensation and cycloaddition of the hydroxyl group to the cyano moiety.

In summary, we have developed a neutral aqueous-phase synthesis of various spirooxindole derivatives by the one-pot three-component reaction of the corresponding isatin, activated methylene reagent, and 1,3-dicarbonyl compounds under biomimetic conditions in the presence of β-cyclodextrin. These cyclodextrin mediated water solvent reactions are very useful from both economical and environmental points of view. β-Cyclodextrin, apart from being nontoxic, is also considered as metabolically safe. This straightforward, environmentally benign methodology may find widespread applications in organic and medicinal chemistry.

Experimental

General

Melting points were recorded on a Buchi R-535 apparatus and are uncorrected. IR spectra were recorded on a PerkinElmer FT-IR 240-c spectrometer using KBr optics. [1]H NMR spectra were recorded on Gemini-200/Avance-300/Inova-400 spectrometer in DMSO or $CDCl_3$ using TMS as internal standard. Mass spectra were recorded on an Agilent 1200 spectrometer. Starting materials were obtained commercially from Sigma-Aldrich or Lancaster and were used without purification.

General procedure for the synthesis of spirooxindole

β-CD (1 mmol) was dissolved in water (15 mL) by warming to 60 °C until a clear solution was formed. Then, isatin (1 mmol) dissolved in methanol (0.5 mL) was added dropwise followed by malononitrile (1.2 mmol) and dimedone (1 mmol), and the mixture was stirred at 60 °C until the reaction was complete (as monitored by TLC) (Table 1). The mixture was cooled to 40 °C and the solid was filtered off, washed with water (10 mL), and recrystallized from EtOH to yield colorless crystals. The filtrate of the reaction mixture was cooled to 5 °C to recover β-CD.

Remarkable high-yielding chemical modification of gold nanoparticles using uncatalyzed click-type 1,3-dipolar cycloaddition chemistry and hyperbaric conditions

Hossein Ismaili, Abdolhamid Alizadeh, Kristen E. Snell, and Mark S. Workentin

Abstract: Azide-terminated alkyl thiolate monolayer-protected gold nanoparticles (**1**-C_{12}MPN) with a core size of 1.8 ± 0.2 nm were prepared. **1**-C_{12}MPN was modified in high yields via an uncatalyzed 1,3-dipolar cycloaddition (click-type reaction) with a variety of terminal acyl–alkynes under hyperbaric conditions at 11 000 atm. The resulting 1,2,3-triazole modified MPNs (**2**-C_{12}MPN) were characterized using ^{1}H NMR spectroscopy and were verified by comparison of the spectra to those obtained for the products of the model reactions of 1-azidododecane with the same alkynes. TEM analysis showed that the high-pressure conditions did not affect the size of the gold core, suggesting that the only effect is to facilitate the chemical reaction on the particles.

Key words: nanoparticles, hyperbaric chemistry, 1,3-dipolar cycloaddition, monolayers.

Résumé : On a préparé des nanoparticules d'or protégées par une monocouche d'alkylthiol (**1**-C_{12}MPN) portant une fonction azide en position terminale et dont le diamètre principal est égal à 1,8 ± 0,2 nm. Le produit **1**-C_{12}MPN a été modifié avec des rendements élevés par le biais d'une cycloaddition 1,3-dipolaire non catalysée (réaction de type par un clic) avec une variété d'acyl–alcynes terminales, dans des conditions hyperbariques, à 11,000 atmosphères. Les nanoparticules d'or modifiées, protégées par une monocouche d'alkylthiol (**2**-C_{12}MPN) et portant un cycle 1,2,3-triazole ont été caractérisées par spectroscopie RMN du ^{1}H et ont été vérifiées par comparaison avec les spectres obtenus pour les produits des réactions modèles du 1-azidodécane avec les mêmes alcynes. Une analyse par microscopie électronique à transmission (MET) a permis de montrer que les conditions de haute pression n'ont pas affecté la taille du diamètre principal de l'or suggérant que le seul effet est de faciliter la réaction chimique sur les particules.

Mots-clés : nanoparticules, chimie hyperbarique, cycloaddition 1,3-dipolaire, monocouches.

[Traduit par la Rédaction]

Introduction

The Cu(I)-catalyzed Huisgen 1,3-dipolar cycloaddition of azides to terminal alkynes to produce a triazole ring, the "click" reaction, is a popular and powerful tool in organic synthesis and combinatorial chemistry.[1] This reaction is also being exploited in material science applications for the modification of metal and silica surfaces,[2] dendrimers,[3] and polymers.[4] Recently, the reaction was extended to monolayer-protected CdSe,[5] iron oxide,[6] and monolayer-protected gold nanoparticles (MPN).[7–12] Because the 1,3-dipolar cycloaddition reaction of an alkyne and azide is slow, this type of reaction is typically done in the presence of a Cu(I) catalyst because it facilitates the rapid, high reaction conversions with little or no byproducts under mild conditions. The later is of key importance for the functionalization of Au-MPN. While the catalyzed reaction is effective for the modification of the CdSe and iron oxide nanoparticles, this approach is not considered as feasible with gold nanoparticles. Gold MPNs (now simply referred to as MPNs) in the presence of the Cu catalyst have been suggested to be unstable, and lead to aggregation or decomposition likely due to the reaction of the Cu catalyst with the gold surface. In another case, Brennan et al. reported using the Cu-catalyzed route to modifiy azide-functionalized 12 nm MPNs with alkyne-appended lipases but a million-fold excess of Cu was required and the yield was less than 1% conversion.[7] More recently, and while this work was in progress, Astruc and co-workers reported specific reaction conditions to circumvent the difficulties of the Cu(I) click reaction on azide-terminated MPNs.[13]

Williams and co-workers reported a thorough study showing that the Huisgen dipolar cycloaddition reaction can be used to modify azide-terminated MPNs with a variety of activated alkynes without a catalyst.[8] However, the yields (extent of conversion of the azide groups) were extremely low (13% and less after 60 h in dioxane, depending on the alkyne) and could only be marginally improved by altering the solvent. In a latter study where they reported on the kinetics of this reaction on the MPN, they stated that these

yields were slightly underestimated because of the method used to follow reaction conversion.[9] However, the yields were still relatively low (22%, or 54% in one specific case) and did not allow the product MPNs to be completely characterized by NMR spectroscopy. Because of the potential of this type of reaction as a general approach to surface modification and to allow the introduction of a variety of functionalities from common starting MPNs, an important goal is to improve the efficiency of this type of reaction on MPN. To this end, and while this work was in progress, Sommer and Weck reported on the microwave-assisted catalyzed 1,3-dipolar cycloaddition of azide-terminated MPNs.[10] The method proved successful and allowed a large variety of terminal alkynes to form triazole-functionalized MPN with near-quantitative yields, but still required very careful control of the microwave conditions because excess heating of the MPN lead to nanoparticle decomposition ascribed to particle aggregation.

Recently, we reported that the inefficient modification of a maleimide-modified MPN by the Diels–Alder reaction at ambient conditions with a series of dienes was improved remarkably using hyperbaric conditions without affecting the particle core.[14] The hyberbaric method for modification of gold MPNs was more general and was further used to accelerate the 1,3-cycloaddition of a large variety of nitrones to the maleimide-modified MPN in quantitative yields.[15] In both these studies, we showed that the reactions carried out on the MPNs at ambient temperature and pressure were significantly slower than the corresponding reactions on model compounds under the same conditions. We attributed this difference in reactivity to the unique steric effects of the environment at the interfacial site of reactivity on the MPN. In the present report, we extend this methodology to study the Huisgen 1,3-dipolar cycloaddition of azide-terminated MPN to terminal alkynes to improve the efficiency of this reaction and to expand the scope of reactions that can be utilized for modification of nanoparticles using hyperbaric conditions. The Huisgen 1,3-dipolar cycloaddition of azides to terminal alkynes is also subject to rate acceleration at elevated pressure, although as far as we are aware, this has only been the subject of one report.[16] Specifically, we report herein that azide-terminated, 1.8 nm core size MPNs prepared to be essentially identical to the original report of Williams and co-workers,[8] will react with activated acyl–alkynes efficiently under high-pressure conditions at ambient temperature to form the 1,2,3-triazoles essentially quantitatively in the absence of a Cu catalyst. This approach eliminates the complications due to the presence of catalysts or higher temperatures.

Experimental

Commercial solvents and reagents used

The compounds dodecanethiol, hydrogen tetrachloroaurate (III), tetraoctylammonium bromide, 1,12-dibromododecane, 11-bromo-1-undecene, azobis(isobutyronitrile) (AIBN), 1-bromododecane, sodium azide, ethynyl magnesium bromide, 1-octyn-3-ol, and ethyl propionate were all purchased from Aldrich and used as received. Deuterated benzene (C_6D_6), deuterated chloroform ($CDCl_3$), and deuterated dichloromethane (CD_2Cl_2) (Cambridge Isotope Laboratories) were also used as received.

General instrumentation

High-pressure reactions were carried out utilizing a LECO Tempres High-Pressure chemical reactor, which operates at 11 000 atm. ^1H and ^{13}C NMR spectra were recorded, as indicated, on either a Varian Inova 600 (^1H: 600 MHz, ^{13}C: 150 MHz) or 400 (^1H: 400 MHz, ^{13}C: 100 MHz) spectrometers and were referenced to the residual protons in the solvent relative to $(CH_3)_4Si$ (δ (ppm): chloroform-*d*, 7.26; dichloromethane-d_2, 5.32; or benzene-d_6, 7.15). Mass spectra and exact mass were recorded on a MAT 8200 Finnigan High resolution Mass Spectrometer. Infrared spectra were recorded on a Bruker Vector 33 FTIR spectrometer and are reported in wavenumbers (cm^{-1}). Melting points were measured using the Electrothermal 9100 melting-point instrument and are uncorrected. High resolution transmission electron microscopy (HRTEM) images were collected on a JEOL 2010F HRTEM.

Synthetic details

Dodecanethiolate MPN (C_{12}MPN)

Following the procedures of Brust–Shiffrin and Murray,[17,18] hydrogen tetrachloroaurate (III) trihydrate (0.30 g, 0.77 mmol) was dissolved in 28 mL distilled water (resulting in a bright yellow solution) and then mixed with tetraoctylammonium bromide (2.30 g, 4.2 mmol) in 70 mL toluene. The contents were stirred for 30 min at room temperature to facilitate the phase transfer of the hydrogen tetrachloroaurate (III) trihydrate into the toluene layer, which resulted in the organic layer turning to a dark orange colour and the aqueous layer becoming clear and colourless. After phase transfer, the aqueous layer was removed and the organic layer was cooled to 0 °C in ice bath. Dodecanethiol (0.468 g, 0.57 mL, 2.31 mmol) was added to the solution via a volumetric pipette and allowed to stir for 10 min. The addition of dodecanethiol resulted in a colour change from brownish-orange to clear and colourless. A fresh solution of sodium borohydride (0.33 g, 8.7 mmol) in 28 mL water was then added to the rapidly stirring toluene solution over 5 s. The solution darkened instantly, eventually becoming dark brown. The mixture was allowed to stir overnight (~18 h) as it warmed to room temperature, after which time, the aqueous layer was removed and the toluene layer was washed with 3 × 20 mL distilled water and dried over $MgSO_4$. The toluene layer was then isolated by gravity filtration and evaporated to dryness. The resulting mixture of C_{12}MPN and tetraoctylammonium bromide was suspended in 200 mL of 95% ethanol and placed in the freezer overnight during which time the C_{12}MPN precipitated from solution. When the MPN had precipitated, the supernatant was decanted and the precipitate was dissolved in benzene and concentrated, resulting in the formation of a film in the round-bottom flask. This film was washed repeatedly with 10 × 15 mL of 95% ethanol, resulting in pure C_{12}MPN as judged by ^1H NMR spectroscopy, which showed no signs of free dodecanethiol, dodecyldisulfide, or tetraoctylammonium bromide. The resulting C_{12}MPN was dark brown.

Synthesis of bromo-terminated C_{12}MPN

Approximately 200 mg of C_{12}MPN was dissolved in 60 mL of benzene and degassed with nitrogen. 290 mg

(1.54 mmol) of 11-bromo-1-undecanethiol was added to the solution and stirred for 2 days at room temperature. The mixture was then concentrated and the resulting film was washed with 95% ethanol and dried. The ^{1}H NMR spectrum of this MPN is shown in Fig. S1. ^{1}H NMR (600 MHz, CD_2Cl_2) δ: 3.4, 1.9, 1.8–1.0, 0.9. The integrated areas of methylene protons alpha to the bromide and terminal methyl group of dodecanethiolate in the ^{1}H NMR spectra reveals that the ratio of ligands on the bromoundecane-thiolate-modified C_{12}MPN was 1:1.2, terminal bromide to terminal methyl.

The required 11-bromo-1-undecanethiol was synthesized by the reported method.[19] 11-Bromo-1-undecene (1.5 g, 6.43 mmol), AIBN (0.6 g, 3.65 mmol), and thioacetic acid (3 mL) were dissolved in toluene and refluxed for 2 h. The reaction mixture was washed with water and then concentrated. The crude product was purified by column chromatography (eluting with 5:1 hexanes/ethyl acetate) to separate. A solution of 11-bromo-1-undecanethioacetate in dry methanol was cooled in an ice bath, then 3 mL acetyl chloride was added dropwise, and the solution was stirred for 6 h at room temperature. The reaction was quenched by adding water and extracted with CH_2Cl_2, and then combined extracts were washed with water. The organic layer was dried over $MgSO_4$ and evaporated to get the pure product: Yellow oil. ^{1}H NMR (600 MHz, $CDCl_3$) δ: 3.40 (t, J = 6.8 Hz, 2H), 2.51 (q, J = 7.3 Hz, 2H), 1.84 (m, 2H), 1.60 (m, 2H), 1.44–1.27 (m, 15H).

Synthesis of azide-terminated MPN: (1-C_{12}MPN)

1-C_{12}MPN was prepared according to the procedure of Fleming et al.[8] A 60 mL solution of 0.25 mol/L NaN_3 in DMSO was added to the mixture of the bromo-terminated MPN (prepared as above) in benzene (~200 mg of bromo-terminated C_{12}MPN in 60 mL of benzene) and the mixture was stirred for 48 h. After which time, the reaction was quenched with water and organic layer was separated and washed with water three times, dried over $MgSO_4$, and then concentrated. The resulting film was rinsed with 95% ethanol and dried. ^{1}H NMR (600 MHz, CD_2Cl_2) δ: 3.4, 3.25, 1.9, 1.85–1.0, 0.9. The ^{1}H NMR spectrum of this **1**-C_{12}MPN is shown in Fig. 1*a*. The integrated areas of the three types of ligands, determined by decomposition of 10 mg of **1**-C_{12}MPN with ~2 mg of iodine, showed that the ratio of terminal azide/bromide/methyl was 3.5:1:5. Additionally, **1**-C_{12}MPN was characterized using IR spectroscopy and TEM. IR (cm^{-1}): 2959, 2921, 2853, 2096, 1467, 1366, 1282, 1089, 1040, 801. The average particle size was determined by analysis of TEM images of numerous samples: 1.8 ± 0.2 nm

Synthesis of 1-azidododecane (3)

A solution of 1-bromododecane (2 g, 8 mmol) and NaN_3 (0.57 g, 8.8 mmol) in DMSO (30 mL) was stirred overnight at room temperature. The reaction mixture was diluted with diethyl ether and washed with water five times to remove DMSO. The ethereal layer was dried over $MgSO_4$ and concentrated. The spectral data are in accord with the literature.[20] Colourless oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 3.25 (t, J = 6.9 Hz, 2H), 1.59 (m, 2H), 1.37–1.26 (broad, 18H), 0.88 (t, J = 6.8 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 51.7, 32.1, 29.8, 29.77, 29.71, 29.5, 29.4, 29.0, 26.9, 22.9, 14.3. IR (cm^{-1}): 2955, 2924, 2854, 2095, 1467, 1366, 1258.

Synthesis of alkynes (4a–4i)

Compounds 1-pyren-1-yl-propyn-1-one (**4a**), 1-anthracen-9-yl-propyn-1-one (**4c**), propynoic acid phenylamide (**4h**),[8] 1-ferrocenyl-2-propyn-1-one (**4b**),[21] and 1-(4-nitrophenyl)-2-propyn-1-one (**4e**)[22] were prepared by their literature method, and their ^{1}H NMR spectra are in accord with those reported. Compounds 1-phenyl-2-propyn-1-one (**4f**), 1-(4-biphenyl)-2-propyn-1-one (**4d**), and 1-octyn-3-one (**4i**),[23] as well as 1-(2-methylphenyl)-2-propyn-1-one (**4g**),[24] were synthesized by the following procedure (except for **4i** where commercial alcohol was oxidized by magnesium(IV) oxide), and their ^{1}H NMR spectra are in accord with those reported: 5 mmol of the corresponding aldehyde was dissolve in 10 mL of THF and cooled in an ice bath. 10 mL of ethynyl magnesium bromide (0.5 mol/L in THF) was added dropwise in 15 min. The mixture was allowed to stir for 3 h as it warmed to room temperature, after which time, the reaction was quenched with saturated NH_4Cl and extracted with ether. Organic layer was dried over $MgSO_4$ and then concentrated. The crude product was purified by column chromatography (eluting with 3:1 hexanes/ethyl acetate).The corresponding alcohol was dissolved in 10 mL CH_2Cl_2 and 5.2 g (60 mmol) of magnesium(IV) oxide was added and the mixture was stirred at room temperature for 1 h. The oxidized reagent was removed by filtration through Celite, the organic layer was washed with water (three times), and the solvent was evaporated.

General procedures for azide–alkyne Huisgen 1,3-dipolar cycloaddition reactions at high-pressure conditions

Preparation of 2-C_{12}MPN

Approximately 10 mg of **1**-C_{12}MPN was dissolved in ~2.0 mL of CH_2Cl_2 then mixed with 15–20 equiv. of the appropriate activated acyl–alkynes (**4a**–**4j**). The mixture was transferred into a brass-clamp-sealed PTFE tube and placed in the LECO Tempres High-Pressure reactor at 11 000 atm for 15–24 h. The product **2a**–**2j**-C_{12}MPNs were purified by washing with 95% ethanol and then CH_3CN to remove any unreacted alkyne. IR and ^{1}H NMR spectroscopy were used to check the completion of the reaction, as described below, and purity of the resulting **2a**–**2j**-C_{12}MPNs. The NMR spectra obtained were compared to those of the products of the model reaction, **5a**–**5j**. These are provided, along with IR spectra in the Supporting information.

2a-C_{12}MPN: ^{1}H NMR (600 MHz, CD_2Cl_2) δ: 8.63–7.73, 4.28, 3.40. IR (cm^{-1}, dropcast on NaCl): 2921, 2851, 1643, 1467, 1225, 923, 849, 805, 716.

2b-C_{12}MPN: ^{1}H NMR (600 MHz, CD_2Cl_2) δ: 8.23, 5.49, 4.95, 4.63, 4.42, 4.14, 3.66, 3.41, 3.25, 1.9–0.88. IR (cm^{-1}, dropcast on NaCl): 2925, 2853, 2096, 1631, 1530, 1453, 1260, 1039, 825, 721.

2c-C_{12}MPN: ^{1}H NMR (600 MHz, CD_2Cl_2) δ: 8.58, 8.04, 7.73, 7.39, 4.16, 3.40, 1.70–0.86 IR (cm^{-1}, dropcast on NaCl): 2962, 2921, 2851, 1678, 1467, 1261, 1095, 1019, 805.

2d-C_{12}MPN: ^{1}H NMR (600 MHz, CD_2Cl_2) δ: 8.45–8.30, 7.67–7.42, 4.41, 3.40, 1.94–0.87. IR (cm^{-1}, dropcast on

NaCl): 2961, 2922, 2851, 1652, 1603, 1458, 1261, 1092, 1056, 906, 801, 749.

2e-C_{12}MPN: ^{1}H NMR (600 MHz, CD_2Cl_2) δ: 8.58, 8.33, 4.45, 3.40, 1.97–0.87. IR (cm^{-1}, dropcast on NaCl): 2960, 2920, 2851, 1653, 1525, 1343, 1261, 1093, 1041, 848, 798.

2f-C_{12}MPN: ^{1}H NMR (600 MHz, CD_2Cl_2) δ: 8.34, 7.59–7.46, 4.40, 3.40, 1.90–0.87. IR (cm^{-1}, dropcast on NaCl): 2964, 2924, 2854, 1653, 1603, 1457, 1261, 1115, 1019, 904, 815, 698.

2g-C_{12}MPN: ^{1}H NMR (600 MHz, CD_2Cl_2) δ: 8.18, 7.67, 7.38–7.26, 4.36, 3.38, 2.38, 1.89–0.87. IR (cm^{-1}, dropcast on NaCl): 2918, 2849, 2075, 1657, 1524, 1457, 1228, 1015, 904, 798, 742.

2h-C_{12}MPN: ^{1}H NMR (600 MHz, CD_2Cl_2) δ: 9.09, 8.24, 7.71, 7.33, 7.13, 4.36, 3.41, 1.86–0.87. IR (cm^{-1}, dropcast on NaCl): 2961, 2921, 2851, 2094, 1678, 1599, 1467, 1260, 1087, 1036, 797.

2i-C_{12}MPN: ^{1}H NMR (600 MHz, CD_2Cl_2) δ: 8.18, 4.33, 3.37, 1.87–0.87. IR (cm^{-1}, dropcast on NaCl): 2955, 2921, 2852, 1739, 1437, 1260, 1224, 1199, 1108, 1039, 800, 721.

2j-C_{12}MPN: ^{1}H NMR (600 MHz, CD_2Cl_2) δ: 8.15, 4.39, 3.40, 3.25, 3.06, 1.92–0.89. IR (cm^{-1}, dropcast on NaCl): 2922, 2852, 2091, 1691, 1468, 1261, 1224, 798, 723.

Preparation of 5a–5j

Alkynes (**4a**–**4j**) (0.15 mmol) and 1-azidododecane (**3**) (0.16 mmol) were dissolved in ~2 mL of CH_2Cl_2 then transferred into a brass-clamp-sealed PTFE tube and placed in the LECO Tempres High-Pressure reactor at 11 000 atm and room temperature for 10 h. The product was removed from unreacted alkyne by preparative TLC plate (3:1 hexanes/ethyl acetate). The resulting products, **5a**–**5j**, were characterized as summarized below.

5a: Yellow solid, mp 81–84 °C. ^{1}H NMR (600 MHz, $CDCl_3$) δ: 8.61 (d, *J* = 9.3 Hz, 1H), 8.32–8.30 (m, 2H), 8.25–8.20 (m, 4H), 8.15–8.10 (m, 2H), 7.81 (s, 1H), 4.93 (t, *J* = 7.4 Hz, 2H), 2.10–2.04 (m, 2H), 1.49–1.37 (m, 4H), 1.32–1.25 (broad, 14 H), 0.87 (t, *J* = 7.0, 3H). ^{13}C NMR ($CDCl_3$) δ: 14.1, 22.7, 26.6, 29.1, 29.3, 29.4, 29.5, 29.6, 30.5, 31.9, 50.9, 123.8, 123.9, 124.1, 124.8, 126.5, 126.6, 126.7, 126.9, 127.1, 127.2, 127.3, 130.0, 130.2, 130.9, 131.1, 132.1, 134.3, 140.4, 186.0. IR (cm^{-1}, dropcast on NaCl): 3240, 2923, 2853, 1650, 1510, 1221, 999, 926, 849, 708. MS (EI): Exact mass ($C_{31}H_{35}N_3O$) calcd.: 465.2780, found: 465.2777.

5b: Maroon oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 8.16 (s, 1H), 5.52–5.51 (m, 2H), 4.65–4.64 (m, 2H), 4.42 (t, *J* = 7.2 Hz, 2H), 4.17 (s, 5H), 2.00–1.93 (m, 2H), 1.35–1.25 (broad, 18H), 0.87 (t, *J* = 6.7 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 14.1, 22.7, 26.4, 28.9, 29.3, 29.4, 29.5, 29.6, 30.1, 31.9, 50.5, 70.2, 71.6, 73.0, 126.3, 149.1, 189.2. IR (cm^{-1}, dropcast on NaCl): 3117, 2925, 2853, 1629, 1528, 1444, 1377, 1260, 1107, 1041, 826, 771. MS (EI): Exact mass ($C_{25}H_{35}N_3FeO$) calcd.: 449.2129, found: 449.2139.

5c: Yellow solid, mp 84–86 °C. ^{1}H NMR (600 MHz, $CDCl_3$) δ: 8.57 (s, 1H), 8.05 (d, *J* = 8.2 Hz, 2H), 7.97 (s, 1H), 7.80 (d, *J* = 8.6 Hz, 2H), 7.47 (t, 2H), 7.42 (t, 2H), 4.35(t, *J* = 7.3 Hz, 2H), 1.92–1.87 (m, 2H), 1.31–1.24 (broad, 18H), 0.88 (t, *J* = 7.0 Hz, 3H). ^{13}C NMR (150 MHz, $CDCl_3$) δ: 14.1, 22.7, 26.4, 28.9, 29.3, 29.4, 29.5, 29.6, 30.1, 31.9, 50.7, 125.0, 125.4.3, 126.6, 127.4, 128.5, 128.7, 129.1, 131.1, 133.4, 149.0, 192.0. IR (cm^{-1}, dropcast on NaCl): 3132, 3056, 2920, 2852, 1653, 1525, 1470, 1180, 884, 841, 729. MS (EI): Exact mass ($C_{29}H_{35}N_3O$) calcd.: 441.2780, found: 441.2783.

5d: Yellow solid, mp 94–98 °C. ^{1}H NMR (600 MHz, $CDCl_3$) δ: 8.55 (d, *J* = 8.2 Hz, 2H), 8.27 (s, 1H), 7.75 (d, *J* = 8.2 Hz, 2H), 7.66 (d, *J* = 7.4 Hz, 2H), 7.48 (t, 2H), 7.40 (t, *J* = 7.3 Hz, 1H), 4.45(t, *J* = 7.2 Hz, 2H), 2.00–1.95 (m, 2H), 1.37–1.25 (broad, 18H), 0.88 (t, *J* = 6.9 Hz, 3H). ^{13}C NMR (150 MHz, $CDCl_3$) δ: 14.1, 22.6, 26.4, 28.9, 29.2, 29.3, 29.4, 29.5, 30.1, 31.9, 50.8, 127.0, 127.3, 128.1, 128.2, 128.9, 131.2, 135.3, 140.0, 145.8, 148.2, 185.2. IR (cm^{-1}, dropcast on NaCl): 3126, 2918, 2848, 1633, 1602, 1523, 1467, 1344, 1255, 909, 876, 851, 746, 692. MS (EI): Exact mass ($C_{27}H_{35}N_3O$) calcd.: 417.2780, found: 417.2787.

5e: Yellow solid, mp 74–76 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 8.64 (d, *J* = 9.0 Hz, 2H), 8.35 (d, *J* = 9.0 Hz, 2H), 8.32 (s, 1H), 4.46 (t, *J* = 7.2 Hz, 2H), 2.01–1.94 (m, 2H), 1.35–1.24 (broad, 18H), 0.86 (t, *J* = 6.8 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 14.0, 22.6, 26.4, 28.9, 29.2, 29.3, 29.4, 29.5, 30.1, 31.8, 50.8, 123.4, 128.5, 131.6, 141.2, 147.4, 150.3, 183.8. IR (cm^{-1}, dropcast on NaCl): 3129, 2915, 2849, 1643, 1599, 1518, 1331, 1237, 1047, 1016, 911, 881, 847, 785, 725, 694. MS (EI): Exact mass ($C_{21}H_{30}N_4O_3$) calcd.: 386.2317; found: 386.2320.

5f: Yellow solid, mp 49–51 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 8.43 (d, *J* = 8.7 Hz, 2H), 8.25(s, 1H), 7.61 (t, 1H), 7.51 (t, 2H), 4.44 (t, *J* = 7.2 Hz, 2H), 1.99–1.92 (m, 2H), 1.34–1.24 (broad, 18H), 0.86 (t, *J* = 6.8 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 14.0, 22.6, 26.4, 28.9, 29.2, 29.3, 29.4, 29.5, 30.1, 31.8, 50.6, 128.1, 128.4, 130.6, 133.2, 136.5, 148.0, 185.7. IR (cm^{-1}, dropcast on NaCl): 3137, 2957, 2853, 1653, 1577, 1260, 1234, 1181, 1045, 1018, 904, 798, 725, 696. MS (EI): Exact mass ($C_{21}H_{31}N_3O$) calcd.: 341.2467; found: 341.2477.

5g: Yellow oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 8.15 (s, 1H), 7.77 (d, *J* = 7.7 Hz, 1H), 7.41 (t, *J* = 7.5 Hz, 1H), 7.31–7.28 (m, 2H), 4.42 (t, *J* = 7.2 Hz, 2H), 2.45(s, 3H), 1.98–1.91 (m, 2H), 1.33–1.25 (broad, 18H), 0.87 (t, *J* = 6.8 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 14.1, 20.3, 22.6, 26.4, 28.9, 29.2, 29.3, 29.4, 29.5, 30.1, 31.8, 50.6, 125.2, 127.5, 130.1, 131.2, 131.3, 137.1, 137.9, 148.3, 189.5. IR (cm^{-1}, dropcast on NaCl): 3135, 2925, 2855, 1658, 1524, 1460, 1440, 1233, 1042, 905, 742 MS (EI): Exact mass ($C_{22}H_{33}N_3O$) calcd.: 355.2623, found: 355.2614.

5h: Yellow solid, mp 128–130 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 8.94 (s, 1H), 8.13 (s, 1H), 7.69 (*J* = 7.6 Hz, 2H), 7.38 (t, 2H), 7.15 (t, *J* = 7.4 Hz, 1H), 4.42 (t, *J* = 7.2 Hz, 2H), 1.98–1.92 (m, 2H), 1.33–1.25 (broad, 18H), 0.87 (t, *J* = 6.9 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 14.1, 22.7, 26.4, 28.9, 29.3, 29.34, 29.5, 29.6, 30.1, 31.9, 50.9, 119.8, 124.5, 125.5, 129.1, 137.5, 143.4, 163.9. IR (cm^{-1}, dropcast on NaCl): 3317, 3139, 2920, 2851, 1664, 1558, 1437, 1047, 800, 749, 689. MS (EI): Exact mass ($C_{21}H_{32}N_4O$) calcd.: 356.2576, found: 356.2589.

5i: Colourless solid, mp 80–82 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 8.02 (s, 1H), 4.39 (t, *J* = 7.2 Hz, 2H), 3.11 (t, *J* = 7.5 Hz, 2H), 1.95–1.88 (m, 2H), 1.78–1.71 (m 2H), 1.40–1.24(broad, 22H), 0.92–0.86 (m, 6H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 13.9, 14.1 22.5, 22.7, 23.7, 26.4, 28.9, 29.31, 29.33, 29.5, 29.6, 30.1, 31.5, 31.9, 39.5, 50.6, 125.1, 148.1,

195.7. IR (cm^{-1}, dropcast on NaCl): 3102, 2915, 2847, 1687, 1469, 1241, 1159, 1055, 970, 887, 719. MS (EI): Exact mass ($C_{20}H_{37}N_3O$) calcd.: 335.2936, found: 335.3001.

5j: Colourless oil. ^1H NMR (400 MHz, $CDCl_3$) δ: 8.11 (s, 1H), 4.70 (t, J = 7.4 Hz, 2H), 4.38 (q, J = 7.1 Hz, 2H), 1.94–1.84 (m, 2H), 1.39 (t, J = 7.1 Hz, 2H), 1.31–1.24 (broad, 18H), 0.87 (t, J = 6.5 Hz, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 14.1, 14. 14, 22.7, 26.4, 29.0, 29.3, 29.4, 29.5, 29.6, 30.3, 31.9, 50.4, 61.7, 127.7, 137.9, 158.5. IR (cm^{-1}, dropcast on NaCl): 2956, 2855, 1731, 1528, 1457, 1311, 1255, 1092, 772. MS (EI): Exact mass ($C_{17}H_{32}N_3O_2$) ($M+H^+$) calcd.: 310.2494, found: 310.2482.

Results and discussion

The azide-terminated MPNs were prepared according to the method recently reported.[8] Starting with 1.8 ± 0.2 nm dodecanethiol-stabilized MPN (C_{12}-MPN), 11-bromoundecanethiol was introduced onto the MPN using the place-exchange method to yield a mixed monolayer containing Br-terminated undecanethiol ligands. Reaction of this MPN with NaN_3 in DMSO introduced the azide functionality onto the MPN. The ratio of terminal azide/bromide/methyl in the newly made mixed MPN was estimated to be roughly 3.5:1:5 by ^1H NMR spectroscopy of I_2-reduced MPNs. This mixed monolayer particle (**1**-C_{12}MPN) was further characterized by IR and UV–vis spectroscopy and TEM. Figure 1*a* shows the ^1H NMR spectrum of **1**-C_{12}MPN. The key diagnostic signals are the characteristically broad signals due to the methylene protons alpha to the azide and bromide functionality at 3.24 and 3.41 ppm, respectively. The IR spectrum of **1**-C_{12}-MPN also shows a strong absorbance at 2096 cm^{-1} due to the antisymmetric –N=N=N stretch in addition to the CH_2/CH_3 stretches at 2959, 2921, and 2852 cm^{-1}.

Compound **1**-C_{12}MPN (~10 mg) was then mixed with each of the activated acyl–alkynes **4a**–**4j**, shown in Scheme 1, in a ratio of 1:15–20 in 2 mL of CH_2Cl_2 and placed in a high-pressure reactor at 11 000 atm at ambient temperature. Model reactions of 1-azidododecane (**3**) with each alkyne were also performed under high-pressure conditions to aid in monitoring the extent of reaction and to provide analogous 1,2,3-triazole products (**5a**–**5j**) to allow for characterization of the reactions on **1**-C_{12}MPN (Scheme 2). The extent of reaction of **1**-C_{12}MPN was followed by ^1H NMR and IR spectroscopy. The reaction was considered complete when there was no evidence of the protons alpha to the azide in the ^1H NMR spectrum and by the disappearance of the azide peak in the IR spectrum. For most cases, this occurred after 15–24 h, depending on the alkyne (Table 1). We note that high temperatures cannot be employed to decrease reaction times for **1**-C_{12}MPN because MPNs are not thermally stable for extended periods. The reaction of **1**-C_{12}MPNs with alkynes **4a**, **4c**, **4d**, **4e**, and **4f**, resulting in the corresponding **2**-C_{12}MPNs, was quantitative after 15 h (perhaps less). Alkynes **4b**, **4g**, **4h**, **4i**, and **4j** had slightly lower 1,3-dipolar cycloaddition reactivity, and their reactions with **1**-C_{12}MPNs was carried out for 24 h. After which time, the azide peak in the IR spectra was completely absent for mixtures containing **4g**, **4h**, and **4j**, indicating near-complete conversion, but only around 80% conversion was observed for the reaction of the **1**-C_{12}MPNs with **4b** and **4i** (Table 1). Presumably, extending the reaction times further would lead to more complete conversion for these two less activated alkynes.

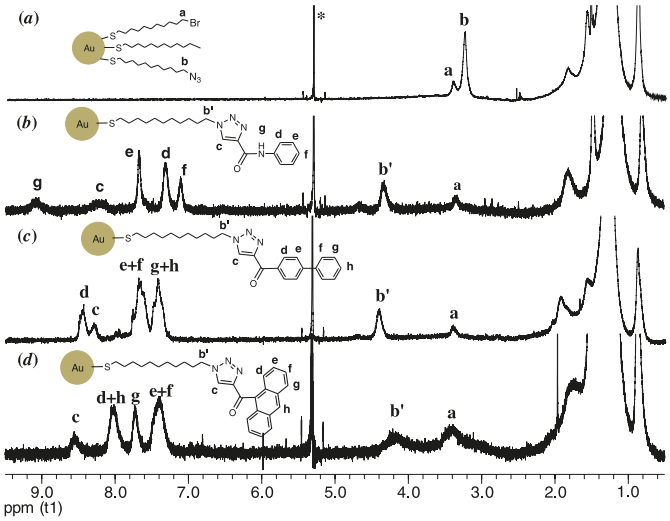

Fig. 1. ^1H NMR spectra of **1**-C_{12}MPN (*a*) and representative product 1,2,3-triazoles **2**-C_{12}MPN formed in click reactions of **1**-C_{12}MPN with acyl alkynes **4h**, **4d**, and **4c**: (*b*) **2h**-C_{12}MPN, (*c*) **2d**-C_{12}MPN, and (*d*) **2c**-C_{12}MPN. Solvent: CD_2Cl_2, residual proton signal is indicated by *.

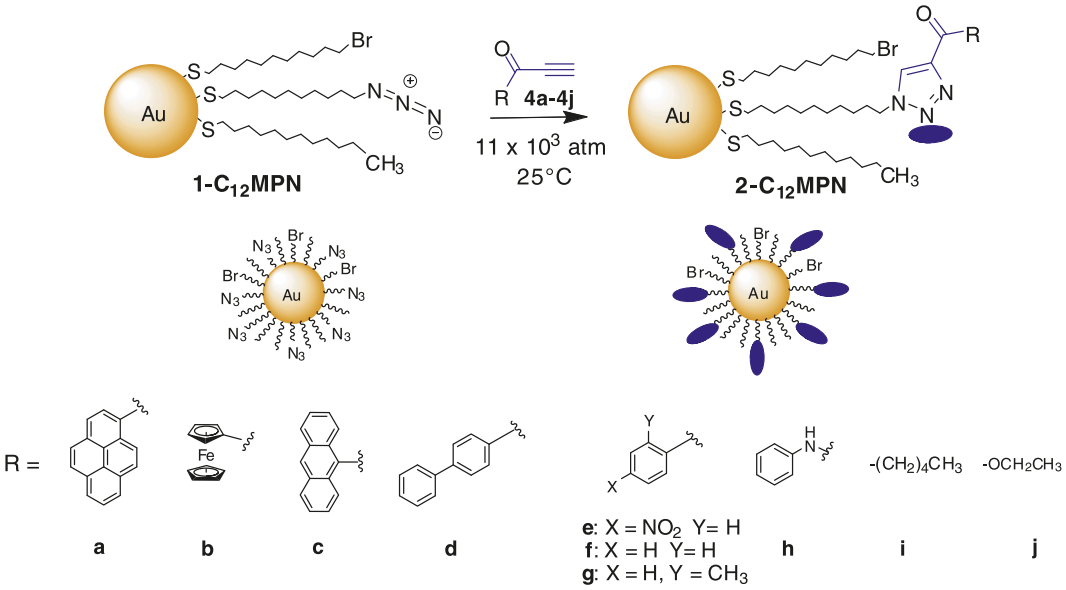
After completion of the reaction and removal of the reaction mixture from the high-pressure reactor, the mixtures were washed several times to remove excess alkyne from the MPN and a ^1H NMR spectrum was recorded. These spectra show that **1**-C_{12}MPN had reacted to form the corresponding 1,2,3-triazole product **2**-C_{12}MPN. Figures 1*b*–1*d* show representative ^1H NMR spectra of the product **2**-C_{12}MPN formed by reaction of **1**-C_{12}MPN with alkynes **4h**, **4d**, and **4c**, respectively. Evidence for the reaction includes the downfield chemical shift of the protons alpha to the nitrogen atom from 3.24 ppm in the azide (labeled b) to ~4.2 ppm (labeled b′), alpha to the triazole ring (Fig. 1). The disappearance of the signal at 3.24 ppm on the **1**-C_{12}MPNs was considered as a sign of complete conversion of the azide. IR spectra of **2a**–**2j**-C_{12}MPN also show loss of the –N=N=N stretch at 2096 cm^{-1}, verifying completion of the reaction, and a new stretch at ~ 1639–1670 cm^{-1} due to the C=O (1734 cm^{-1} for ester **2j**-C_{12}MPN). Common to all spectra is the absence of the signal at 3.24 due to the CH_2 alpha to the azide, and a new signal appears between 7.8–8.6 ppm (chemical shift varies slightly with structure) due to the triazole C–H proton (labeled c in the spectra). Of course, other signals in the NMR spectra due to the functionality introduced with the cycloaddition with the alkyne are assignable easily by comparison to the spectra of the products of the model reactions, **5a**–**5j**. These are provided in the Supporting information. For example, The ^1H NMR spectra of **2h**-C_{12}MPNs (Fig. 1*b*) shows new peaks in the aromatic region attributed to the aromatic ring as well as the triazole C–H proton at 8.25 ppm and the amide proton at 9.15 ppm, verifying the formation of the triazole ring. It is noticeable that the ^1H NMR of the **2a**- and **2c**-C_{12}MPN with a relatively bulky R group (pyrene and anthracene) shows broad-

Scheme 1. The 1,3-dipolar cycloaddition of **1**-C_{12}MPN with a variety of terminal acyl-alkynes (**4a**–**4j**) at 11 000 atm.



Scheme 2. Model reaction of 1-azidododecane (**3**) with alkenes (**4a**–**4j**) to yield 1,2,3-triazoles (**5a**–**5j**).

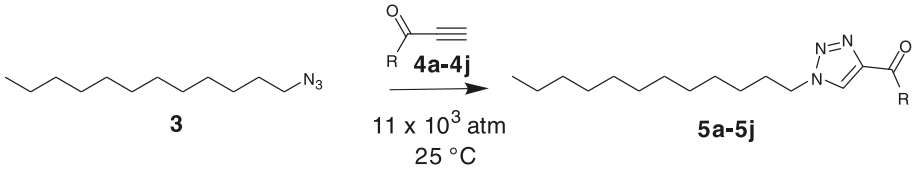


Table 1. Extent of reaction of **1**-C_{12}MPN with alkynes (**4a**–**4j**) via uncatalyzed 1,3-dipolar cycloaddition reaction at atmospheric and hyperbaric pressure conditions.

Alkyne	% Conversion (atmospheric pressure)[a]	% Conversion (11 000 atm)
4a	13	>95[c]
4b	12	>80[d]
4c	6	>95[c]
4d	6	>95[c]
4e	6	>95[c]
4f	NR[b]	>95[c]
4g	NR	>95[d]
4h	NR	>95[d]
4i	NR	>80[d]
4j	NR	>95[d]

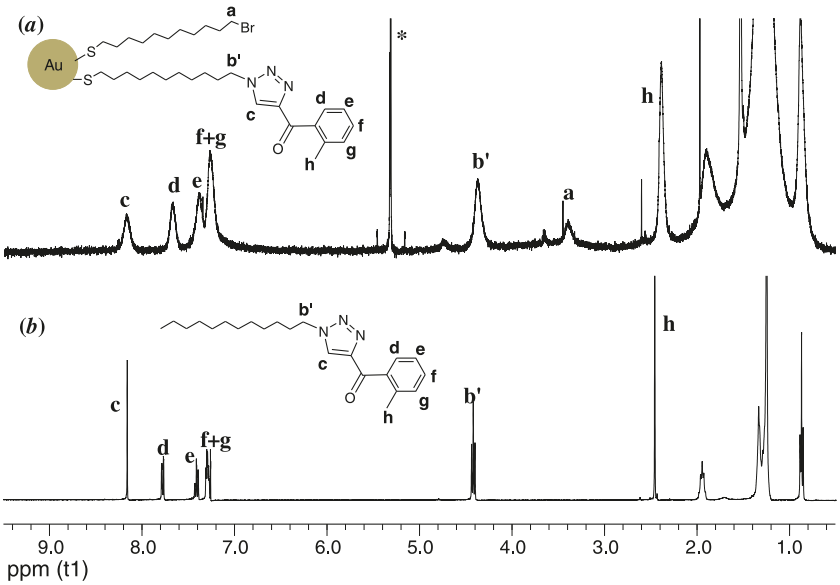
[d]As determined by NMR after 24 h.

ened peaks, especially for the peak assigned to the methylene group (b′) adjacent to the triazole ring, in comparison with the **2**-C_{12}MPNs with less-bulky R groups. This broadness suggests that the bulky group limits the mobility of these groups on the MPNs more than that of the less-bulky R groups. UV–vis spectra and TEM of the particles after reaction verify that there is no measureable change to the Au core size and that the only effect of the high-pressure conditions is the acceleration of the 1,3-dipolar cycloaddition. Although these reactions were only carried out at relatively small scale, they are easily scalable to the gram scale (or more) making the use of the hyperbaric reactor practical for synthetic preparations on MPNs. As mentioned above, to facilitate the assignment of the protons of the ^{1}H NMR spectra of **2**-C_{12}MPNs, the reactions were also carried out using the solution-phase reaction of 1-azidododecane with the same alkynes at high-pressure conditions as a model reaction to yield compounds **5a**–**5j** (Scheme 2). Compounds **5a**–**5j** could be characterized more completely via ^{1}H NMR, ^{13}C NMR, and IR spectroscopy, as well as mass spectrometry (see Experimental). Because the ^{1}H NMR spectra of **5a**–**5j** are not as broad as those of **2**-C_{12}MPN, they are more easily assignable, and hence they provide the confidence in the assignments of the spectra for **2**-C_{12}MPN. For example, Fig. 2 shows the ^{1}H NMR spectra of **2g**-C_{12}MPN and the model compound **5g**, respectively. The signals at 4.4 ppm (b′), alpha to the triazole ring, and 8.18 ppm (c), attributed to the C–H proton of triazole ring, verify the formation of the cycloaddition product on the MPN. The other signals observed for **2g**-C_{12}MPN are also readily assignable because the intensity and chemical shift are comparable to **5g** except the expected broadening of the ^{1}H NMR signals on the MPN. The labeled ^{1}H NMR spectra of **2a**–**2j**-C_{12}MPN and the corresponding model compounds **5a**–**5j** are provided in the Supporting information. In general, the reaction of the 1-azidododecane with the less-electron-deficient dipolarophiles (**4d**, **4f**, and **4h**) provided a higher yield in the same reaction time compared with the more-electron-deficient (**4e** and **4j**) and the sterically hindered (**4a**–**4c**)

Fig. 2. ^{1}H NMR spectra of (*a*) **2g**-C_{12}MPN in CD_2Cl_2* and (*b*) compound **5g** in $CDCl_3$.



alkynes; a result mirrored in the reactivity of **1**-C_{12}MPN with the same alkynes (Table 1).

The Huisgen uncatalyzed 1,3-dipolar cycloaddition of an azide with an alkyne can lead to two possible regioisomers: the 1,4- (anti) and 1,5- (syn) isomers. Only the 1,4 isomer is shown as a product in Schemes 1 and 2. In cases where the alkyne is electron-defficient[25] or when a sterically bulky azide[26] is used, the 1,4-isomer is usually the major product (e.g., 1,3-dipolar cycloadditions of 1-azidoadamantane with ethyl propionates form only 1,4 isomers). The formation and ratio of the 1,4- and 1,5-isomers can be determined by ^{1}H NMR spectroscopy because the C–H triazole protons of the 1,4- and1,5-isomers are different, the latter usually downfield of the former. In this study, the ^{1}H NMR spectra of **2a**–**2j**-C_{12}MPNs show only one peak that can be assigned as a C–H proton of the triazole ring; this indicates that there is one major isomer formed. Because the alkynes used in this study are electron-deficient and the environment around the azide moiety in **1**-C_{12}MPN is sterically hindered, the formation of 1,4-isomer is the regioisomer that is most likely preferred.

The NMR and IR data together indicate the essentially quantitative conversion of the azide-terminated ligand **1**-C_{12}MPN to the corresponding 1,2,3-triazole **2a**–**2j**-C_{12}MPN under hyperbaric conditions. This can be compared to those of the reaction of the similarly azide-terminated MPN with a number of the same alkynes in the absence of a catalyst in dioxane for 60 h: **a** (13%), **b** (12%), **c** (6%), **e** (6%), and **h** (6%).[8] The use of high pressure leads to efficient and high-yielding chemical modification of monolayer-protected gold nanoparticles for this reaction system. We believe that the hyperbaric reaction method described here is general for performing this reaction with activated alkynes in the absence of catalyst. As such, it can be used as a preparative tool in performing these azide–alkyne 1,2-dipolar cycloadditions for the preparation of novel materials where high chemical conversion is desirable, where the use of the copper-based catalysts is problematic, or in applications where the toxicity of the Cu complicates purification.

Supplementary data

Supplementary data (^{1}H NMR spectra of the bromine-terminated-MPN, **1**-C_{12}MPN, ^{1}H NMR and IR spectra **2a**–**2j**-C_{12}MPN, and ^{1}H NMR spectra of **5a**–**5j**) for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 5301. For more information on obtaining material, refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml.

Theoretical investigation of the oxidation pathways of HO•-initiated reactions of acrolein, methacrolein, and *trans*-crotonaldehyde

Sabry El-Taher

Abstract: Ab initio molecular-orbital calculations have been performed to investigate the reaction mechanisms of the HO•-initiated reactions of the α,β-unsaturated aldehydes: acrolein (ACR), methacrolein (MACR), and *trans*-crotonaldehyde (CROT). All geometries were fully optimized at the MP2(Full)/6–31G(d,p) level. The correlation energy corrections were introduced by carrying out single-point calculations using both spin-projected second-order Møller–Plesset perturbation theory (PMP2) and coupled-cluster theory (CCSD(T)) using basis sets of different sizes. All reaction pathways studied proceed via a barrierless formation of a loosely bound pre-reactive complex in the entrance channel. The transition-state structures of the HO• additions to the terminal (β) and to the central (α) carbon atoms of the C=C double bond are found to be reactant-like structures. The lowest-energy barrier pathways are found to be the aldehydic H-atom abstraction. The β-addition pathways are found to be energetically more favored than the α-addition pathways. The HO• addition and aldehydic H-atom abstraction pathways are found to be highly exoergic, with the H-atom abstraction pathway being more exoergic than the addition pathways. Although the methyl substitution at the C=C double bond of methacrolein and crotonaldehyde lowers the energies of the transition-state structures of both α- and β-addition pathways, it destabilizes the energies of the transition-state structures of the corresponding aldehydic H-atom abstraction pathways, compared with that of acrolein.

Key words: ab initio, transition-state structures, acrolein, methacrolein, crotonaldehyde.

Résumé : On a effectué des calculs théoriques d'orbitales moléculaires ab initio afin d'étudier les mécanismes de réactions initiées par le radical HO• d'aldéhydes α,β-insaturées, tel l'acroléine (ACR), la méthacroléine (MACR) et le *trans*-crotonaldéhyde (CROT). Toutes les géométries ont été complètement optimisées au niveau MP2(full)/6–31G(d,p). Des corrections d'énergie de corrélation ont été introduites en effectuant des calculs ponctuels à l'aide de la théorie des perturbations de Møller–Plesset du deuxième ordre en projection de spin (PMP2) ainsi que la théorie des agrégats couplés [CCSD(T)], en faisant appel à des ensembles de bases de diverses tailles. Toutes les voies réactionnelles étudiées procèdent, à l'entrée du tunnel, par la formation sans barrière réactionnelle d'un complexe préréactif à interactions faibles. On a trouvé que les structures des états de transition résultant de l'addition du HO• aux atomes de carbone terminal (β) et central (α) de la double liaison C=C possèdent des structures qui ressemblent aux réactifs. On a trouvé que les voies réactionnelles impliquant la barrière d'énergie la plus faible correspondent à l'enlèvement de l'atome d'hydrogène aldéhydique. On a trouvé que les voies réactionnelles correspondant à l'addition du radical HO•et à l'enlèvement de l'atome d'hydrogène sont fortement exoergiques; la voie impliquant l'enlèvement de l'atome d'hydrogène est plus exoergique que les voies réactionnelles conduisant à une addition α. Même si elle diminue les énergies des structures de transition de chacune des deux voies réactionnelles des additions en α et en β, par comparaison avec celle de l'acroléine, la présence de substituants méthyles sur la double liaison C=C de la méthacroléine et du crotonaldéhyde déstabilise les énergies des structures de l'état de transition des voies réactionnelles correspondantes d'enlèvement de l'atome d'hydrogène aldéhydique.

Mots-clés : ab initio, structure de l'état de transition, acroléine, méthacroléine, crotonaldéhyde.

Introduction

Aldehydes play an important role in the chemistry of the polluted troposphere. They may be emitted as primary pollutants from partial oxidation of hydrocarbon fuels, industrial uses, and from biogenic sources. They may also arise as secondary pollutants from atmospheric oxidation of volatile organic compounds (VOCs).[1–4] The principal unsaturated compounds of atmospheric interest are the α,β-unsaturated carbonyls: acrolein (ACR), methacrolein (MACR), and *trans*-crotonaldehyde (CROT). Acrolein and *trans*-crotonaldehyde are both emitted into the atmosphere through different sources, such as combustion and chemical industries.[5] Acrolein is also generated as a byproduct of the atmospheric oxidation of buta-1,3-diene[6,7] On the other hand, methacrolein has a central importance as a major product in the atmospheric degradation of isoprene.[8]

It is well-established that the main atmospheric degradation processes of α,β-unsaturated carbonyl compounds are controlled by photolysis, reaction with HO•, NO_3, radicals,

and O_3. However, the dominant tropospheric removal pathway for these species is via reactions with HO• radicals during the daytime. The atmospheric lifetimes during the day for acrolein (*trans*-crotonaldehyde) for the reactions with OH, NO_3, and O_3 are estimated to be 7 h (4 h), 14 months (83 days), and 36 days (5 days), respectively.[9] For methacrolein, the atmospheric lifetime for the reaction with HO• during the day is found to be $\approx$ 2–3 h.[10]

The HO•-initiated oxidation reactions of methacrolein have been the subject of numerous experimental studies.[8,11–15] It has been shown[11,12] that about 50%–55% of those reactions occur via electrophilic addition of HO• to the C=C double bond (eqs. [1] and [2]), while about 45%–50% occur via abstraction of the aldehydic hydrogen (eq. [3]).

[1] $CH_2{=}C(CH_3)CHO + HO^{\bullet} \rightarrow CH_2(OH)^{\bullet}C(CH_3)CHO$

[2] $CH_2C(CH_3)CHO + HO^{\bullet} \rightarrow CH_2C(OH)(CH_3)CHO$

[3] $CH_2{=}C(CH_3)CHO + HO^{\bullet} \rightarrow CH_2{=}C(CH_3)^{\bullet}CO + H_2O$

[4] $CH_2{=}CHCHO + HO^{\bullet} \rightarrow CH_2(OH)^{\bullet}CHCHO$

[5] $CH_2{=}CHCHO + HO^{\bullet} \rightarrow CH_2C(OH)HCHO$

[6] $CH_2{=}CHCHO + HO^{\bullet} \rightarrow CH_2{=}CH^{\bullet}CO + H_2O$

[7] $CH(CH_3){=}CHCHO + HO^{\bullet} \rightarrow CH(CH_3)(OH)CHCHO$

[8] $CH(CH_3){=}CHCHO + HO^{\bullet} \rightarrow CH(CH_3)^{\bullet}CH(OH)CHO$

[9] $CH(CH_3){=}CHCHO + HO^{\bullet} \rightarrow CH(CH_3){=}CH^{\bullet}CO + H_2O$

While the kinetics of the reactions of HO• with both acrolein (eqs. [4]–[6]) and crotonaldehyde (eqs. [7]–[9]) are well-established,[16–19] only two recent studies have been reported[9,20] on the corresponding reaction mechanisms. It has been suggested that 20%–25% (56%)[9] and 32% (50%)[20] of the HO• reactions with acrolein (crotonaldehyde) proceed via addition to the double bond (eqs. [4], [5], [7], and [8]), with the remainder occurring via abstraction of the aldehydic hydrogen (eqs. [6] and [9]). For the addition reaction, there is an unresolved question concerning the actual site of the HO• addition. It has been estimated that at least 80% of the addition occurs at the β-carbon (the furthest double-bonded carbon from the carbonyl group) for both acrolein and methacrolein.[20] On the other hand, the experimental data provide a situation which is less clear concerning the favorable site of the HO• addition in the case of crotonaldehyde.[20]

It seems that there is an actual need for a theoretical study to analyze the different pathways in the HO• reactions with ACR, MACR, and CROT. To accomplish this goal, herein, a systematic investigation for the different pathways of HO•-

initiated reactions of acrolein, methacrolein, and *trans*-crotonaldehyde is performed using high levels of ab initio calculations. The results are expected to shed light on the reactivity of HO• radical toward the studied compounds by providing a quantitative estimation of the preferability of the suggested pathways, based on accurate calculations of the electronic energies, enthalpies, and Gibbs free energies of activation of parts of the corresponding energy surfaces. The results will be compared with the available experimental findings[20] as well as with theoretical calculations recently reported during the course of carrying out[21,22] and publishing[23] this work.

Computational methods

All ab initio molecular-orbital calculations were performed using Gaussian 98W series of programs.[24] Unrestricted ab initio methods were used for all open-shell radical species. All geometries were fully optimized at the MP2(Full)/6–31G(d,p) level. The nature of each stationary point was confirmed by calculating the corresponding vibrational frequencies at the same level (scaled by using a factor of 0.9608). Zero-point vibrational energy and thermal corrections at the MP2(Full)/6–31G(d,p) level were used in the estimation of the electronic energies, enthalpies, and Gibbs free energies of activation. The correlation energy corrections were introduced by carrying out single-point calculations using both Møller–Plesset perturbation theory up to second order (MP2)[25] and CCSD(T) coupled cluster method[26] using basis sets of different sizes. Furthermore, intrinsic reaction coordinate (IRC) calculations[27] were performed to confirm the connections of the transition-state structures between the corresponding minima.

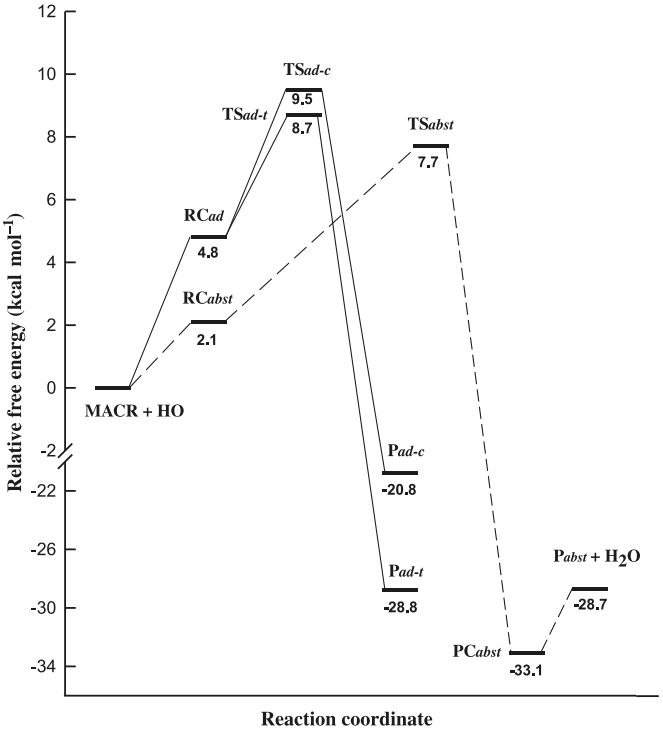
For methacrolein + HO• reaction, single-point calculations at different levels of theory were performed (MP2, MP4(SDTQ), and CCSD(T)) using large basis sets up to the aug-cc-pVTZ, which is Dunning's correlation-consistent triple-ζ basis set,[28] augmented with diffuse functions.

Results and discussion

The internal rotation around the C–C single bond joining the vinyl and the aldehydic moieties of ACR, MACR, and CROT results in two conformers. The more stable conformer is calculated to have an antiperiplanar (ap) conformation for the C=C–C=O chain of atoms, whereas the less stable one has a synperiplanar (sp) conformation for this chain. The MP2(full)/6–31G(d,p)-optimized structures of the two conformers are depicted in Fig. S1 (Supplementary data) for ACR, and those of conformer (ap) for each of MACR and CROT. At the MP2(full)/6–31G(d,p) level, the ap conformer turns out to be 1.41, 2.67, and 1.30 kcal/mol more stable than the sp conformer in terms of Gibbs free energy at 298.15 K for ACR, MACR, and CROT, respectively. These results provide equilibrium constants of 0.092, 0.011, and 0.111, which give ap:sp population ratios of 91.6:8.4, 98.9:1.1, and 90:10 for ACR, MACR, and CROT, respectively. The results show that the ap conformers of the studied aldehydes have significant weights in their reactivity at room temperature, which are in good agreement with available experimental results (97.5:2.5) for MACR.[29] As a result, only the reactions of HO• with the ap conformers of the studied molecules will be considered in this study.

The MP2, MP4(SDTQ), and CCSD(T) methods were used to calculate the energies of the reactants and transition states for the HO•-initiated addition and aldehydic hydrogen abstraction reactions of MACR using different basis sets. The zero-point vibrational energy and thermal corrections to enthalpy and Gibbs free energy were calculated at the MP2/6–31G(d,p) level. Table 1 shows the classical energy barriers ($\Delta U^{\ddagger}$), the ZPE-corrected activation energies at 0 K ($\Delta E^{\ddagger}$(0 K)), the Gibbs free energies ($\Delta G^{\ddagger}$(298 K)), and enthalpies ($\Delta H^{\ddagger}$(298 K)) of activation for the studied reactions calculated at PMP2, PMP4(SDTQ), and CCSD(T) levels of theory. In addition, Fig. 1 displays the free-energy surfaces along the reaction coordinate that connect the reactants, the pre-reactive complexes, the transition states, and the final products for the reaction of HO• with MACR in which the relative free energies are calculated at the PMP2/aug-cc-pVTZ level of theory. Inspection of the results in Table 1 and the free-energy surfaces in Fig. 1 reveals the following: (*i*) The spin-projected MP2 $\Delta E^{\ddagger}$(0 K), $\Delta H^{\ddagger}$(298 K), and $\Delta G^{\ddagger}$(298 K) are considerably lower by about 10 kcal/mol as compared with the UMP2 values for addition reactions, whereas they are lower by only 1.5 kcal/mol for the abstraction reaction (Table 1). This may be due to severe spin contamination in the UMP2 method. (*ii*) The increase of the basis set size decreases the deviation of the calculated Gibbs free energies of activation, from those ($\Delta G^{\ddagger}(298\ \mathrm{K})_{\mathrm{abs}}$ = 5.81 kcal/mol and $\Delta G^{\ddagger}(298\ \mathrm{K})_{\mathrm{add}}$ = 5.77 kcal/mol) estimated from experimental rate coefficients ($k_{\mathrm{abs}} = 1.4 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1} and $k_{\mathrm{add}} = 1.5 \times 10^{-11}$ cm^3 molecule^{-1} s^{-1}, respectively)[20] using the transition-state theory (TST) equation.[30] (*iii*) The use of the large aug-cc-pVTZ basis set gives the best PMP2 energy barriers for the HO• additions to the terminal ($\Delta U^{\ddagger}$(*ad-t*) = –2.76 kcal/mol) and the central ($\Delta U^{\ddagger}$(*ad-c*) = –1.91 kcal/mol) carbons of the C=C double bond, respectively. This result agrees well with the slopes of the experimental Arrhenius plots for MACR + OH system (E_a/R = –(1050/R ± 120) K at 5 torr and 300–420 K),[14] in which the negative activation energy is reported to be due to the negative value of the energy barriers of the corresponding reactions, particularly the addition pathways. On the other hand, the single-point calculations at the CCSD(T)/cc-pDVZ level give $\Delta U^{\ddagger}$(*ad-t*) = 2.09 kcal/mol and $\Delta U^{\ddagger}$(*ad-c*) = 2.6 kcal/mol. Inclusion of ZPE corrections leads to $\Delta E^{\ddagger}$(0 K)(*ad-t*) and $\Delta E^{\ddagger}$(0 K)(*ad-c*) of 5.37 and 5.49 kcal/mol, respectively. In fact, these findings are in agreement with previously reported results,[31] showing that single-point calculations at the PMP2/aug-cc-pVTZ level give the best agreement between theoretical and experimental activation energies for HO• addition reactions, whereas the single-point coupled-cluster method does not give satisfactory results, probably due to the fact that the geometry is not optimized at this level, and hence, spin contamination is not effectively eliminated.[31] (*iv*) Another important reason may be the use of the relatively small cc-pVDZ basis set; it is worth noting that the use of Møller–Plesset perturbation methods (MP2 and MP4(SDTQ)) does not contribute significantly to lowering the activation energy of the hydrogen-atom abstraction reaction even with

Fig. 1. Schematic free-energy profiles for the HO•-initiated addition and aldehydic H-atom abstraction reactions of methacrolein. Relative free energies are calculated at the PMP2/aug-cc-pVTZ level of theory.



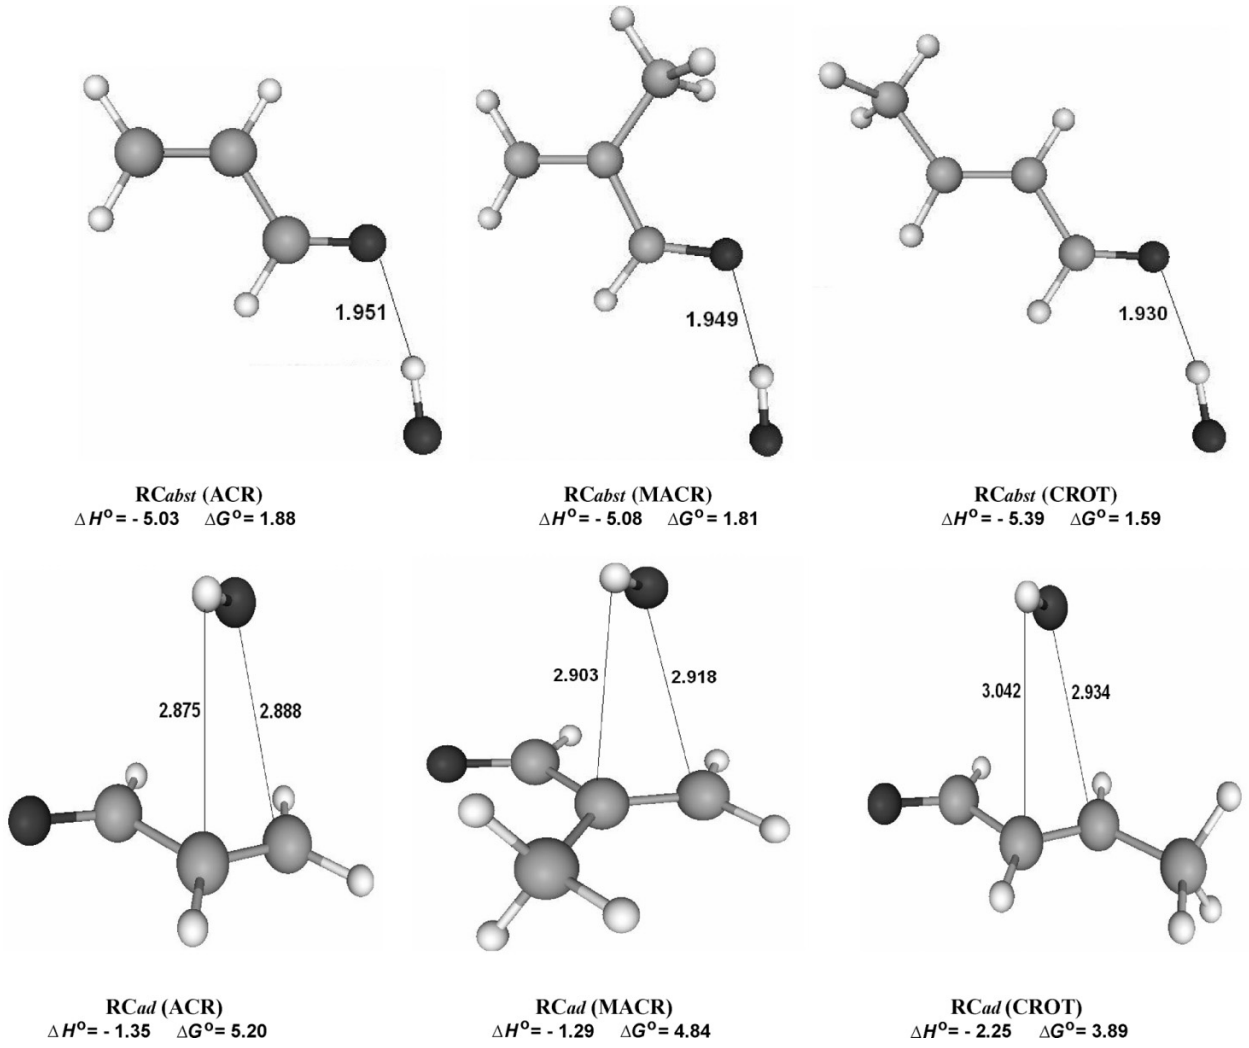
large basis sets (aug-cc-pVTZ and 6–311++G(d,p)). This means that the transition-state structure of the H-atom abstraction reaction should be optimized using highly correlated ab initio method, where the electron correlation provided by the MP2 method is insufficient for quantitative results for these open-shell systems as observed previously.[32] However, the single-point coupled-cluster calculation at the CCSD(T)/cc-pVDZ level, though the basis set cc-pVDZ is relatively small, significantly lowers the energy barrier of the H-atom abstraction reaction, giving activation energy of –1.68 kcal/mol, which is identical to the reported value (–1.70 kcal/mol) at CCSD(T)/cc-pVTZ(Q)//MPW1K/6–31+G(d,p) level.[21] Moreover, the corresponding value of $\Delta G^{\ddagger}$(298 K) at CCSD(T)/cc-pVDZ level is found to be 5.92 kcal/mol, which is in excellent agreement with the experimentally estimated one (5.85 kcal/mol). Considering what was mentioned above, one concludes that the appropriate single-point calculation methods to be adopted in this study for the HO•-initiated addition reactions are the spin-projected MP2 method using the large aug-cc-pVTZ basis set, while for H-atom abstraction reactions, the coupled-cluster CCSD(T) method using the cc-pVDZ basis set may be more appropriate. These methods may be a proper choice for the study of HO•-initiated reactions of relatively large α,β-unsaturated carbonyl compounds in which using large basis sets will be computationally demanding.

HO•-initiated addition reactions

The electrophilic additions of HO• to both terminal (β-addition) and central (α-addition) carbon atoms of ACR, MACR, and CROT proceed via the formation of a barrierless pre-reactive complex (RC*ad*). The MP2(Full)/6–31G(d,p)-optimized structures of RC*ad* are characterized as true local minima on the corresponding potential-energy surfaces (PES) and are depicted in Fig. 2 together with enthalpies and Gibbs free energies, relative to the corresponding reactants. These complexes are in agreement with the ones obtained in recently reported work.[22,23] They may be considered as van der Waals complexes, not hydrogen-bonded ones. The distances between the HO• and the C=C double-bond carbons are very long; they range from 2.875 to 3.042 Å. This is in accord with the distance range calculated at RQCISD(T)/aug-cc-pVTZ level[21] for the acrolein + HO• system (2.830–2.934 Å). On the other hand, the distances between the HO• and ACR (2.612 Å), MACR (2.566 Å), and CROT (2.520 Å) calculated at M05–2X/6–311++G(d,p) level of DFT theory[23] are relatively small as compared with the ones calculated in this work. Starting from the pre-reactive complex RC*ad*, the reaction proceeds via two different pathways. The corresponding transition-state structures for the additions of the HO• to the terminal (TS*ad-t*) and the central (TS*ad-c*) carbon atoms of the C=C double bond are depicted in Fig. 3 for ACR, MACR, and CROT. In general, the C=C double-bond character is almost unperturbed as compared to that of the corresponding reactants, preserving the planarity of the C=C π system. In addition, the distance between the carbon and oxygen atoms (C···O) is rather long and ranges from 2.03 to 2.04 Å. It is slightly longer in TS*ad-c* by 0.004, 0.003, and 0.01 Å in ACR, CROT, and MACR, respectively, than that in TS*ad-t*. These structures are in agreement with the ones obtained in recently reported work,[22,23] except for the C···O distances, which are rather longer by ≈ 0.16 Å than the ones obtained in this work. Therefore, both TS*ad-t* and TS*ad-c* are reactant-like transition structures. The angle of attack, O–C=C, in TS*ad-t* (93.4°) of ACR is smaller by 8° than that in TS*ad-c* (101.3°). This difference is reduced to 3° in MACR and increased to 12° in CROT due to the steric hindrance caused by the methyl group attached to the central (MACR) and the terminal (CROT) carbon atoms of the C=C double bond, respectively.

The MP2(Full)/6–31G(d,p)-optimized structures of the corresponding adducts, P*ad-t* and P*ad-c*, are shown in Fig. S2 (Supplementary data) for ARC, MACR, and CROT. In an attempt to obtain the most stable adduct structures, rotations of the torsion angle, φ(HOCC), were performed. It represents the torsion angle of the HO• hydrogen atom, where the reference carbon atom is the central carbon of the C=C double bond and the aldehydic carbon for P*ad-t* and P*ad-c*, respectively. In the case of P*ad-c*, another torsion angle, φ(OCCO), has been rotated in addition to the φ(HOCC) angle, which describes the rotation of the aldehydic CHO group. The P*ad-c* structures chosen are found to be the most stable conformers due to the hydrogen bonding between the HO• hydrogen and the carbonyl oxygen, where φ(HCCO) = 2.8°, 1.3°, and 2.7° for ACR, MACR, and CROT, respectively. The H···O hydrogen-bonded distances in P*ad-c* adducts of ACR, MACR, and CROT are found to be 2.018, 1.999, and 2.016 Å, respectively. Those P*ad-c* conformers have not been detected in the previously reported work.[21,22] The most stable conformers of P*ad-t* ad-

Fig. 2. Optimized structures of the pre-reactive complexes located in the entrance channels of the HO•-initiated additions (RC*ad*) and aldehydic H-atom abstraction (RC*ad*) reactions of acrolein (ACR), methacrolein (MACR), and crotonaldehyde (CROT) calculated at MP2(Full)/6–31G(d,p) level. Relative enthalpies, Gibbs free energies (kcal/mol), and distances (Å) between HO• and aldehydes are given.

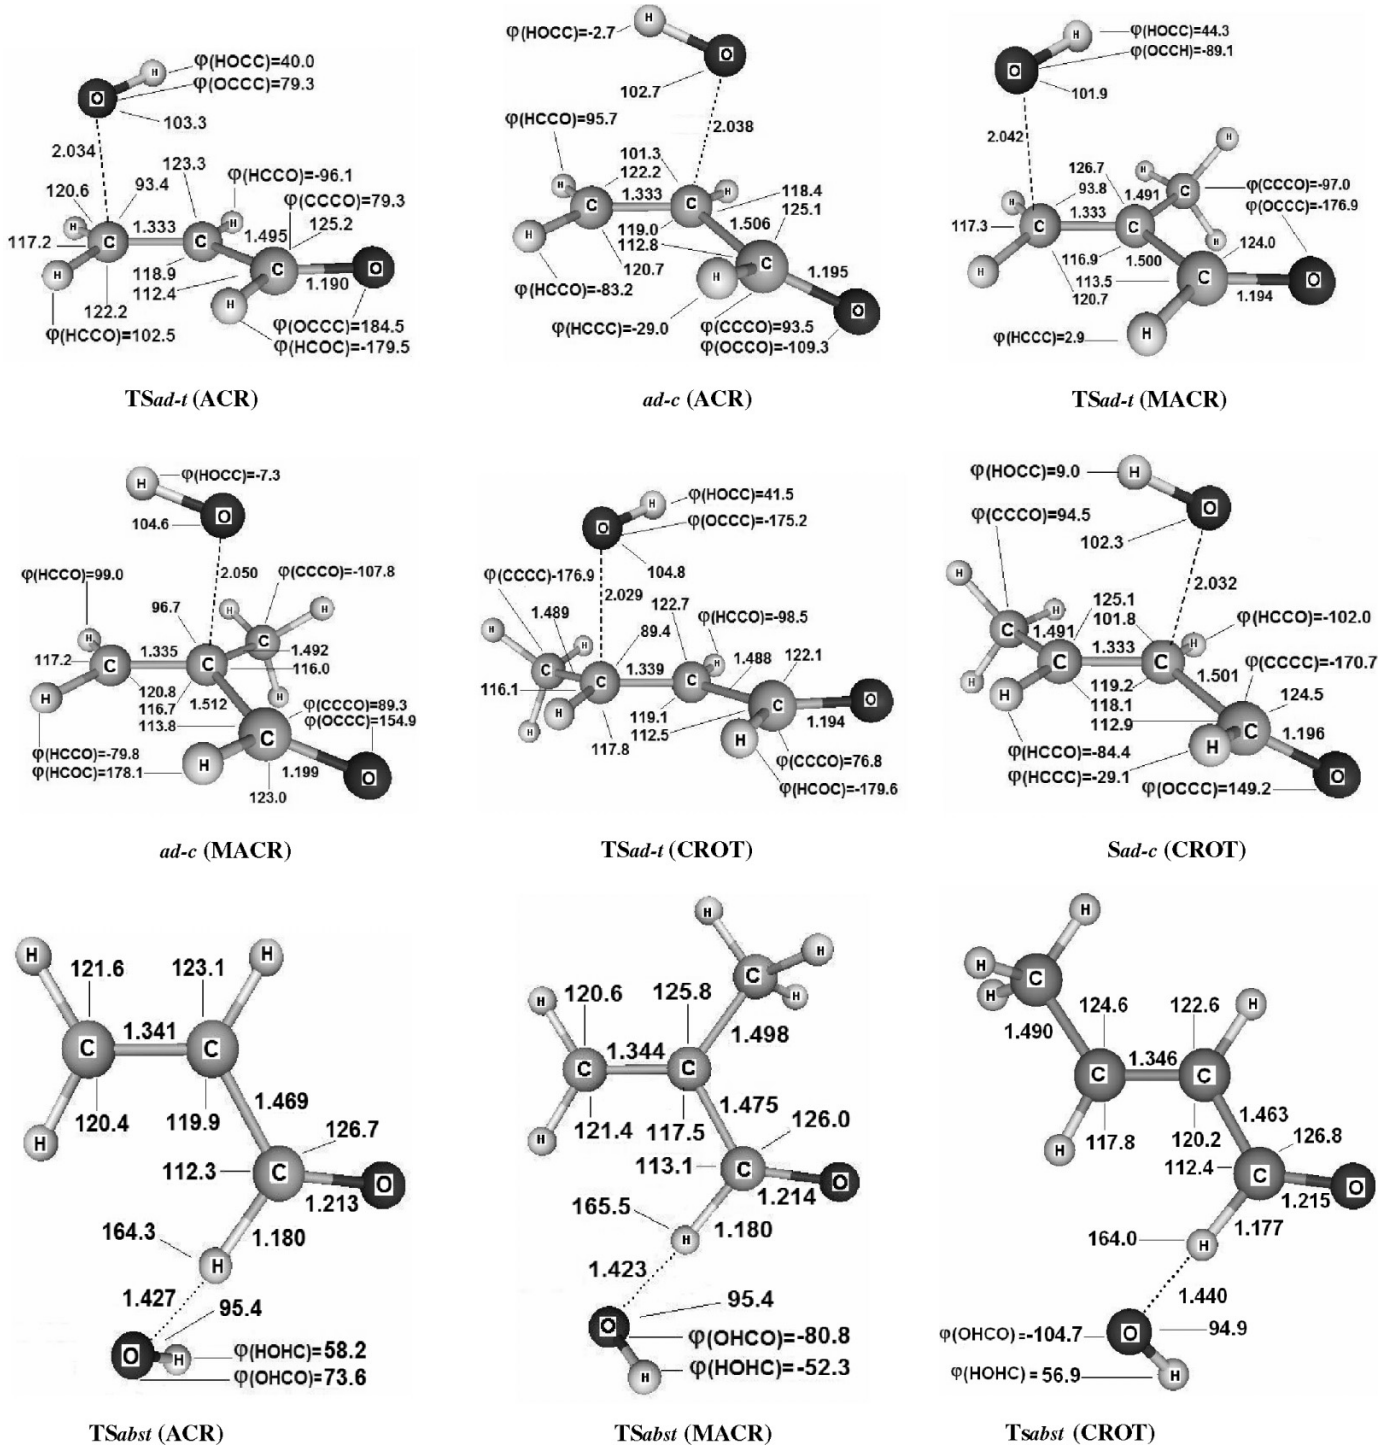


ducts in ACR, MACR, and CROT are found to be the ones that have the angles φ(HOCC) equal to –62.3°, –64.8°, and –59.7°, respectively.

The total electronic energies as well as the corresponding ZPEs, thermal corrections to enthalpy, and Gibbs free energy computed at different levels of theory are collected in Table S1 for reactants, transition-state structures, and products, and in Table S2 for the corresponding pre-reactive (RC*ad* and RC*abst*) and post-reactive (PC*abst*) complexes for all studied reaction pathways. Figure 4 shows schematic energy profiles obtained for the HO• addition pathways of the studied aldehydes using (ZPE-uncorrected) relative energies calculated at PMP2/aug-cc-pVTZ level of theory. Figure 4 shows that the RC*ad* structures lie 2.44, 2.36, and 3.43 kcal/mol below the energies of the isolated reactants for ARC, MACR, and CROT, respectively. This is in accord with a reported value of –2.7 kcal/mol for HO• + ACR system.[22] The corresponding ΔG^{o}(298 K) values are 5.20, 4.84, and 3.89 kcal/mol (see Fig. 1) for the pre-reactive complexes of HO• with ACR, MACR, and CROT, respectively. These ΔG^{o}(298 K) values are in agreement with the reported ones of 4.23, 4.43, and 3.33 kcal/mol, respectively. However, this finding disagrees with the reported results for HO• + MACR reaction[21] that only one pre-reactive complex, in which the hydrogen atom of the HO• moiety is hydrogen-bonded to the aldehydic oxygen atom, is formed in the entrance channel of the HO• addition as well as the H-atom abstraction reactions.

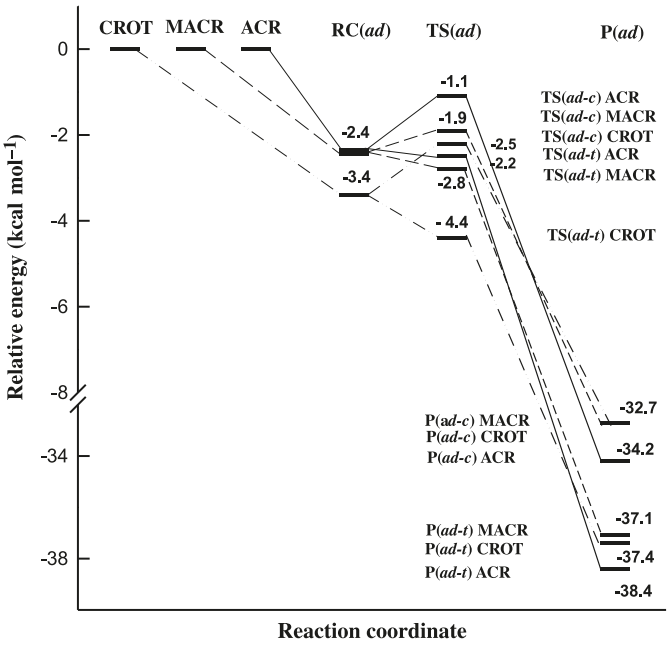
TS*ad-t* (TS*ad-c*) structures of ACR, MACR, and CROT lie 2.5 (1.1), 2.8 (1.9), and 4.4 (2.2) kcal/mol below the energies of the corresponding reactants (Fig. 4). Inclusion of ZPE corrections to energy leads to $\Delta E^{\ddagger}$(0 K) values for the HO• addition to the terminal (central) carbon atom of the C=C double bond of 0.93 (2.03), 0.52 (0.98), and –0.96 (0.88) for ACR, MACR, and CROT, respectively. Inspection of these results reveals that the addition of HO• to the terminal carbon atom of the C=C double bond is energetically more favorable than the addition to the central carbon atom, which may be due to the delocalization of the unpaired electron into the π-bond of the adjacent carbonyl group. This is in agreement with a calculated branching ratio of 95.1:4.9 recently reported for the HO• + ACR[22] and with experimen-

Fig. 3. Optimized structures of the transition states of the HO•-initiated addition (TS*ad-t* and TS*ad-c*) and aldehydic H-atom abstraction (TS*abst*) reactions of ACR, MACR, and CROT calculated at MP2(Full)/6–31G(d,p) level. The Symbol φ refers to dihedral angles.



tal data indicating that at least 80% of the HO• additions to ACR and MACR take place on the terminal carbon atom.[20] Furthermore, the $\Delta G^{\ddagger}$(298 K) values for the HO• addition to the terminal (central) carbon atom are found to be 9.0 (10.2), 8.7 (9.5), and 7.5 (9.1) for ACR, MACR, and CROT, respectively (Tables 1 and 2). The values of $\Delta G^{\ddagger}$(298 K) for the terminal additions are relatively smaller than those of the central ones. This trend is in agreement with recently reported values of $\Delta G^{\ddagger}$(298 K) of 6.04 (8.72), 7.98 (8.76), and 6.09 (8.24) for ACR, MACR, and CROT, respectively.[23] On the other hand, the value of $\Delta E^{\ddagger}$(0 K) decreases by 0.41 (1.05) and 1.89 (1.15) kcal/mol on going from ACR to MACR and CROT, respectively. The presence of the methyl group attached to the double bond may increase the stabilization energy of RC*ad*, resulting in a subsequent lowering in the energies of TS*ad-t* and TS*ad-c* as a

Fig. 4. Schematic energy profiles for the HO• additions to ACR, MACR, and CROT. Relative energies (kcal/mol) are calculated at the PMP2/aug-cc-pVTZ level of theory (ZPE-uncorrected).



result of the inductive and the dipole–dipole effects. This is in agreement with a reported increase in the rate coefficients for the HO• addition to the methyl-substituted species: MACR (1.5×10^{-11} cm^3 molecule^{-1} s^{-1}) and CROT (1.7×10^{-11} cm^3 molecule^{-1} s^{-1}), compared with that of ACR (6×10^{-11} cm^3 molecule^{-1} s^{-1}).[20]

The imaginary frequencies of TS*ad-t* (TS*ad-c*) are found to be 557*i* (530*i* cm^{-1}), 566*i* (521*i* cm^{-1}), and 568*i* (544*i* cm^{-1}) for ACR, MACR, and CROT, respectively. This means that these frequencies decrease when going from ACR to CROT, and thus the curvatures of the calculated energy barriers and their heights are reduced as well. Figure 4 shows that HO• additions to the terminal and central carbons are highly exoergic, where the P*ad-t* (P*ad-c*) structures of ACR, MACR, and CROT are –38.4 (–34.2), 37.1 (32.7), and –37.4 (–32.7) kcal/mol lower in energy than the isolated reactants, respectively. The exoergicity of the HO• addition to the terminal carbon is found to be 4.2, 4.4, and 4.7 kcal/mol, respectively, larger than that to the central carbon. This may be due to the delocalization of the unpaired electron into the π-system of the adjacent carbonyl group.

HO•-initiated H-atom abstraction reactions

The aldehydic H-atom abstraction from ACR, MACR, or CROT by HO• proceeds via a barrierless pre-reactive complex, RC*abst*, in the entrance channel. Figure 5 shows schematic potential-energy profiles obtained for the HO•-initiated aldehydic H-atom abstraction pathways of the studied aldehydes using ZPE-uncorrected CCSD(T)/cc-pVDZ//MP2/6–31G(d,p) relative energies (ΔU). The formation of a stable pre-reactive complex RC*abst* in the entrance channel followed by a transition-state structure TS*abst* whose energy is lower than the energy of the isolated reactants is clearly observed. The MP2(Full)/6–31G(d,p)-optimized structures of these complexes (Fig. 2) are characterized as true local minima on the potential-energy surface. These complexes have been identified as hydrogen-bonded ones[21–23] in which a hydrogen-bonding interaction occurs between the hydrogen atom of HO• and the carbonyl oxygen atom. In addition, the data given in Fig. 2 show that the H···O distance decreases and the stabilization energy (ΔH^o(298 K)) increases from ACR to CROT. This is in good agreement with previously reported trends.[23] Inspection of Fig. 5 reveals that RC*abst* structures are found to be 6.46, 6.50, and 6.83 kcal/mol lower in energy than the isolated reactants, respectively. After the formation of RC*abst*, the aldehydic hydrogen atom is transferred to the HO• moiety through the transition-state structure TS*abst* and then to a product complex, PC*abst*, in which the pre-formed water is loosely bound to the unsaturated aldehydic fragment. Finally, PC*abst* dissociates into the isolated products.

The MP2(Full)/6–31G(d,p)-optimized structures of PC*abst* are given in Fig. S3 (Supplementary data) for ACR, MACR, and CROT. The H···C distance is equal to 2.402, 2.369, and 2.370 Å, respectively. The PC*abst* structures are stabilized by a hydrogen-bonding interaction between the oxygen atom of the pre-formed water molecule and the nearest hydrogen of the methylene group in the unsaturated aldehydic fragment, where the distances between them are 2.339, 2.395, and 2.354 Å, respectively. The PC*abst* structures of ACR, MACR, and CROT lie, respectively, 26.1 (22.5), 25.3 (21.7), and 27.5 (24.0) kcal/mol lower in energy (ZPE-corrected energy) than the isolated reactants, and 3.5 (0.6), 3.5 (0.9), and 4.5 (4.1) kcal/mol lower in energy (ZPE-corrected energy) than the separated products, P*abst* and H_2O (Fig. 5). This means that the aldehydic H-atom abstractions from ACR, MACR, and CROT by HO• are predicted to be exoergic due to the O–H bond strength of water. In addition, the dissociation of PC*abst* to the separated products has insignificant energy barrier, especially in the case of ACR and MACR, and hence it is expected to irreversibly occur as soon as the PC*abst* is formed.

The MP2(full)/6–31G(d,p)-optimized geometries of TS*abst* are shown in Fig. 3 for ACR, MACR, and CROT. The H···C distance slightly increases from ACR (1.181 Å) to CROT (1.177 Å), while the H···O distance slightly decreases from ACR (1.427 Å) to CROT (1.440 Å) . This means that larger energy barrier has to be overcome. This trend is consistent with the increase in $\Delta E^{\ddagger}$(0 K) on going from ACR to CROT, where the results in Tables 1 and 2 show that $\Delta E^{\ddagger}$(0 K) of the H-atom abstraction reactions for ACR, MACR, and CROT has values of –1.82, –1.68, and –0.34 kcal/mol at the CCSD(T)/cc-pVDZ level, respectively. In contrast to the HO• additions, the substitution of the methyl group at the C=C double bond destabilizes the transition-state structures of the aldehydic H-atom abstraction pathways of the HO• reactions with MACR and CROT by 0.14 and 1.48 kcal/mol, respectively, as compared with that of ACR. On the other hand, the results in Table 1 show that the activation energy, $\Delta E^{\ddagger}$(0 K), of the H-atom abstraction reaction of HO• with MACR is 0.04 kcal/mol at the PMP2/aug-cc-pVTZ level, which is lower by 0.48 and 0.94 kcal/mol than that of the terminal and the central additions, respectively. This trend is found to be in agreement with previously reported data for HO• + MACR in which $\Delta E^{\ddagger}$(0 K) of H-abstraction reaction is lower by 1.1 and 1.5 kcal/mol in energy than that of the terminal and central additions at

Table 2. CCSD(T)/cc-pVTZ(Q)//MPW1K/6–31+G(d,p) level, respectively.[21] However, the branching ratio for the HO• addition vs. the H-atom abstraction reaction has been determined to be 50:50[11] and 55:45,[12] respectively. The H-atom abstraction channel for the HO• + MACR reaction has been suggested to dominate the overall rate constant at higher temperatures as the contribution of the pressure-dependent HO• addition channel decreases leading to a weak pressure-dependence of the overall rate constant.[14] For HO• + ACR reaction, the results in Table 2 show that the value of $\Delta E^{\ddagger}$(0 K) for the H-atom abstraction reaction is –0.09 kcal/mol at the PMP2/aug-cc-pVTZ level, which is lower by 1.02 and 2.12 kcal/mol than that of the terminal and the central additions, respectively. This trend is in agreement with recently reported data in which the value of $\Delta E^{\ddagger}$(0 K) for H-abstraction reaction is lower by 1.1 and 1.5 kcal/mol in energy than that of the terminal and central additions at RQCISD(T)/aug-cc-pVTZ//UQCISD/aug-cc-pVDZ level, respectively.[22] In addition, the calculated rate coefficients at 298 K for the three reaction pathways are found to lead to a branching ratio of about 75:4:1,[22] which is in good agreement with the experimental data, which showed that about 68% of the HO• reaction with acrolein proceeds via aldehydic H-atom abstraction.[20] For HO• + CROT reaction, the value of $\Delta E^{\ddagger}$(0 K) for the H-atom abstraction reaction is –1.24 kcal/mol at the PMP2/aug-cc-pVTZ level, which is lower by 0.28 and 2.12 kcal/mol than that of the terminal and the central additions, respectively. This means that the H-atom abstraction pathway is slightly more important than the HO•-addition one, which is inconsistent with the experimental data, which reported that 56% of the reaction proceeds via the HO•-addition pathway, while 46% proceeds via the H-atom abstraction pathway.[9] However, another reported experimental data showed that 50 ± 15% of the reaction proceeds via HO•-addition pathway.[20] On the other hand, inspection of the values of $\Delta G^{\ddagger}$(298 K) calculated at CCSD(T)/cc-pVDZ level (Tables 1 and 2) reveals that, for HO• + MACR, the $\Delta G^{\ddagger}$(298 K) is found to be 5.92 kcal/mol, which is in excellent agreement with the experimentally estimated one (5.85 kcal/mol). Moreover, the values of $\Delta G^{\ddagger}$(298 K) for the hydrogen-atom abstraction reaction of HO• + ACR and HO• + CROT at CCSD(T)/cc-pVDZ level are found to be 5.91 and 5.56 kcal/mol, respectively. These values are in agreement with recently reported values of 5.83 and 5.59 kcal/mol[23] and with values of 5.81 and 5.69 kcal/mol estimated from experimental rate coefficients using the TST eq. [20].

Conclusions

High-level ab initio molecular-orbital calculations have been performed to study the mechanisms of the HO•-initiated reactions of acrolein, methacrolein, and *trans*-crotonaldehyde. The exploration of the corresponding potential-energy surfaces shows the existence of different reaction pathways, with multiple stationary points, which have been located, verified, and connected. From the above discussion, one concludes the following:

The spin-projected MP2 method using the large aug-cc-pVTZ basis set and the coupled-cluster CCSD(T) method using the relatively small cc-pVDZ basis set are found to be appropriate single-point calculation methods for the studied HO•-initiated addition and aldehydic hydrogen-atom abstraction reactions, respectively. These methods may be a proper choice for relatively large α,β-unsaturated carbonyl compounds in which using large basis sets will be computationally demanding.

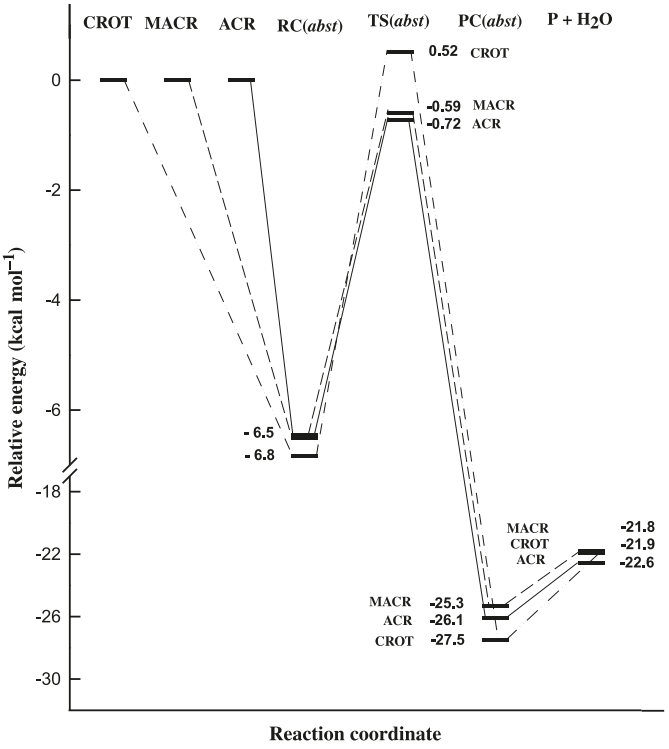
All reaction pathways studied proceed via the barrierless formation of a van der Waals loosely bound pre-reactive complex in the entrance channel of the HO•-addition pathways and a hydrogen-bonded pre-reactive complex in the entrance of the aldehydic H-atom abstraction pathway.

The lowest-energy barrier pathways (ZPE-corrected) at 0 K are found to be the aldehydic H-atom abstraction pathway via a transition-state structure lying 1.82, 1.68, and 0.34 kcal/mol below the energy of the reactants for acrolein, methacrolein, and *trans*-crotonaldehyde, respectively, at the CCSD(T)/cc-pVDZ level.

The transition-state structures of the additions of HO• to the terminal (β) and the central (α) carbon atoms of the C=C double bond are found to be reactant-like structures.

The lowest-energy barrier pathway at 0 K for the HO• addition is found to be the β-addition one, which proceeds via a transition-state structure lying 0.93 and 0.52 kcal/mol above the energy of the reactants for acrolein and methacrolein, respectively, and 0.96 below the energy of the reactants for *trans*-crotonaldehyde.

Fig. 5. Schematic energy profiles for the HO•-initiated aldehydic H-atom abstraction reactions of ACR, MACR, and CROT. Relative energies (kcal/mol) are calculated at the CCSD(T)/cc-pVDZ level of theory (ZPE-uncorrected).



The α-addition pathway proceeds via a transition-state structure lying 2.03, 0.98, and 0.88 kcal/mol above the energy of previously mentioned reactants, respectively, at the PMP2/aug-cc-pVTZ level. This is in agreement with experimental rate coefficients at 298 K, calculated for these HO•-addition reactions, which lead to a branching ratio of about 80:20 for both acrolein and methacrolein and 60:40 for crotonaldehyde.[20]

Both the HO•-initiated additions and aldehydic H-atom abstraction pathways are found to be highly exoergic. The H-atom abstraction pathways are found to be more exoergic than the addition pathways (see Fig. 1 for methacrolein).

The presence of the methyl group attached to the double bond increases the stabilization energy of the pre-reactive complex, resulting in a subsequent lowering in the energies of the transition-state structures of both α- and β-addition pathways, which may be due to an inductive and dipole–dipole effects. This is in agreement with an experimentally reported increase in the rate coefficients for the HO• addition to the methyl-substituted species (methacrolein and crotonaldehyde) as compared with that of acrolein.[20] On the other hand, the methyl substitution destabilizes the transition-state structures of the corresponding aldehydic H-atom abstraction pathways of both methacrolein and crotonaldehyde, compared with that of acrolein.

Development of additive isotropic site potential for exchange-repulsion energy, based on intermolecular perturbation theory

Daisuke Yokogawa, Hirofumi Sato, Sergey Gusarov, and Andriy Kovalenko

Abstract: We have developed an additive spherical site potential for exchange-repulsion energy by applying the local density approximation in Hilbert space, the local-site approximation, and the s-type auxiliary basis set to the equation derived from intermolecular perturbation theory. The method efficiently addresses the decomposition of molecular interactions derived from quantum chemistry into additive spherical site potentials, required as force field input in a statistical-mechanical, reference interaction site model (RISM and 3D-RISM), molecular theory of solvation. The present method reproduces the exchange-repulsion energy between simple molecules obtained from quantum chemical calculations.

Key words: exchange-repulsive potential, intermolecular perturbation theory, quantum chemical calculation, force field, reference interaction site model.

Résumé : On a développé un nouveau potentiel de site sphérique et additif pour l'énergie de répulsion d'échange qui est obtenu en appliquant l'approximation de densité locale de l'espace de Hilbert, l'approximation de site local, ainsi que l'ensemble de base auxiliaire de type s à l'équation dérivée de la théorie de la perturbation intermoléculaire. La méthode tient compte exactement de la décomposition des interactions moléculaires dérivées de la chimie quantique en potentiels de site sphériques additifs requis comme donnée du champ de force en mécanique statistique, le modèle de site d'interaction de référence (MSIR et MSIR-3D), théorie moléculaire de solvatation. La présente méthode reproduit l'énergie de répulsion d'échange entre les molécules simples obtenues à l'aide de calculs de la chimie quantique.

Mots-clés : potentiel de répulsion d'échange, théorie de la perturbation intermoléculaire, calcul de chimie quantique, champ de force, modèle du site d'interaction de référence.

[Traduit par la Rédaction]

Introduction

A large number of studies to develop force fields for predicting the interactions between molecules have been performed over the last three decades.[1] In a standard force field, interactions are split up into terms classified, for example, as electrostatic interaction, dispersion interaction, and exchange interaction. Expressions for these interactions are constructed under the assumption that they can be treated as a sum of additive spherical potentials dependent on the distance R between the constituent atoms or interaction sites but not on the molecular orientations. This type of force field makes it possible to study a large system such as a biosystem by molecular simulation with reasonable computational cost. Nowadays, many parameter sets have been proposed.[2–4]

The most important term in the force field at long range is the electrostatic interaction when a molecule is polarized. This interaction has been widely studied for a long time. Fortunately, this interaction is sufficiently well-approximated with point charges assigned on each atom (point charge model) and described as a sum of additive isotropic, Coulomb potentials $1/R$. Nowadays, atomic charges are easily assessed from quantum chemical calculations.[5,6]

At short range, the exchange interaction becomes important. In a standard force field, this interaction is modelled with additive isotropic potentials as well, such as $1/R^{12}$.

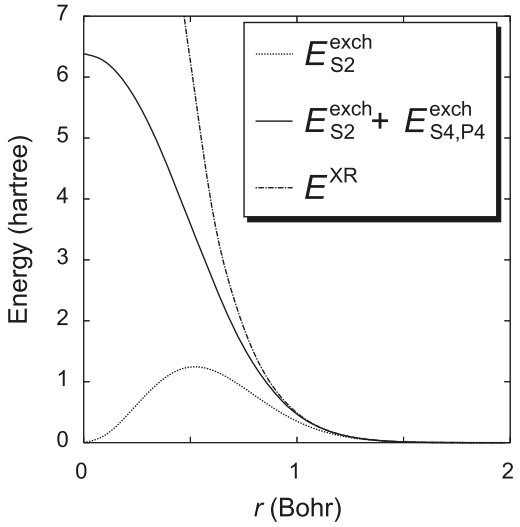
However, determination of its parameters is much more involved than for the electrostatics. One reason is that the interaction originates from the Pauli exclusion principle, which requires an accurate nonlocal, multideterminant representation of the wave function and thus makes it very difficult to derive an additive isotropic potential directly from quantum mechanics. Therefore, parameter sets for exchange interaction are usually empirically adjusted to fit some chemical properties. Although this approach works well for many systems, it is not easy to improve a force field systematically. Theoretical methods to evaluate the exchange potential based on ab initio calculations have also been proposed.[7–11] One of the well established theories is intermolecular perturbation theory (IMPT).[1,7,8] The resulting method can evaluate the energy very accurately.[9,10] However, this is computationally expensive because of the necessity to compute two-electron integrals of the total system.

There have been some approaches to derive the exchange-repulsive potential in a less empirical way, based on ab initio treatment.[12–16] In the effective fragment potential (EFP) method, a very simple equation was derived based on IMPT.[17,18] The potential between molecules is composed of fundamental intermolecular interactions, similar to the SIBFA (sum of interactions between fragments ab initio computed) method.[19] The parameter of each interaction term is generated in a single ab initio calculation; therefore, the integrals required in the calculation are greatly simplified, compared to those in IMPT.

In this work, we derived a simple exchange-repulsion energy potential based on IMPT. This method has the advantage of being fully ab initio, without any semiempirical parameters. The derivation focuses on the following three goals: (1) construct the total potential from additive atomic interaction potentials; (2) have the atomic potentials spherically symmetric; (3) tabulate the site potentials on a spatial grid directly from the matrix elements of the operators projected onto the augmented spherical basis set, rather than calculate the site contributions by brute-force orientational averaging of the six-dimensional intermolecular potential obtained from symmetry-adapted perturbation theory or its derivatives. Such site potentials are typically required in a self-consistent field coupling of quantum chemical methods with statistical-mechanical, molecular theory of solvation,[20] such as KS-DFT/3D-RISM-KH[21,22] and CASSCF/3D-RISM-KH.[23] As classical force fields typically use terms constructed along the lines of requirements (1) and (2), the present strategy will be helpful to systematically improve the classical force field, based on ab initio calculations.

Fig. 1. Exchange-repulsion energy of the model system, calculated at levels E_{S2}^{exch}, $E_{S2}^{exch} + E_{S4,P4}^{exch}$, and E^{XR}. The exponent of ABS is 2.0.

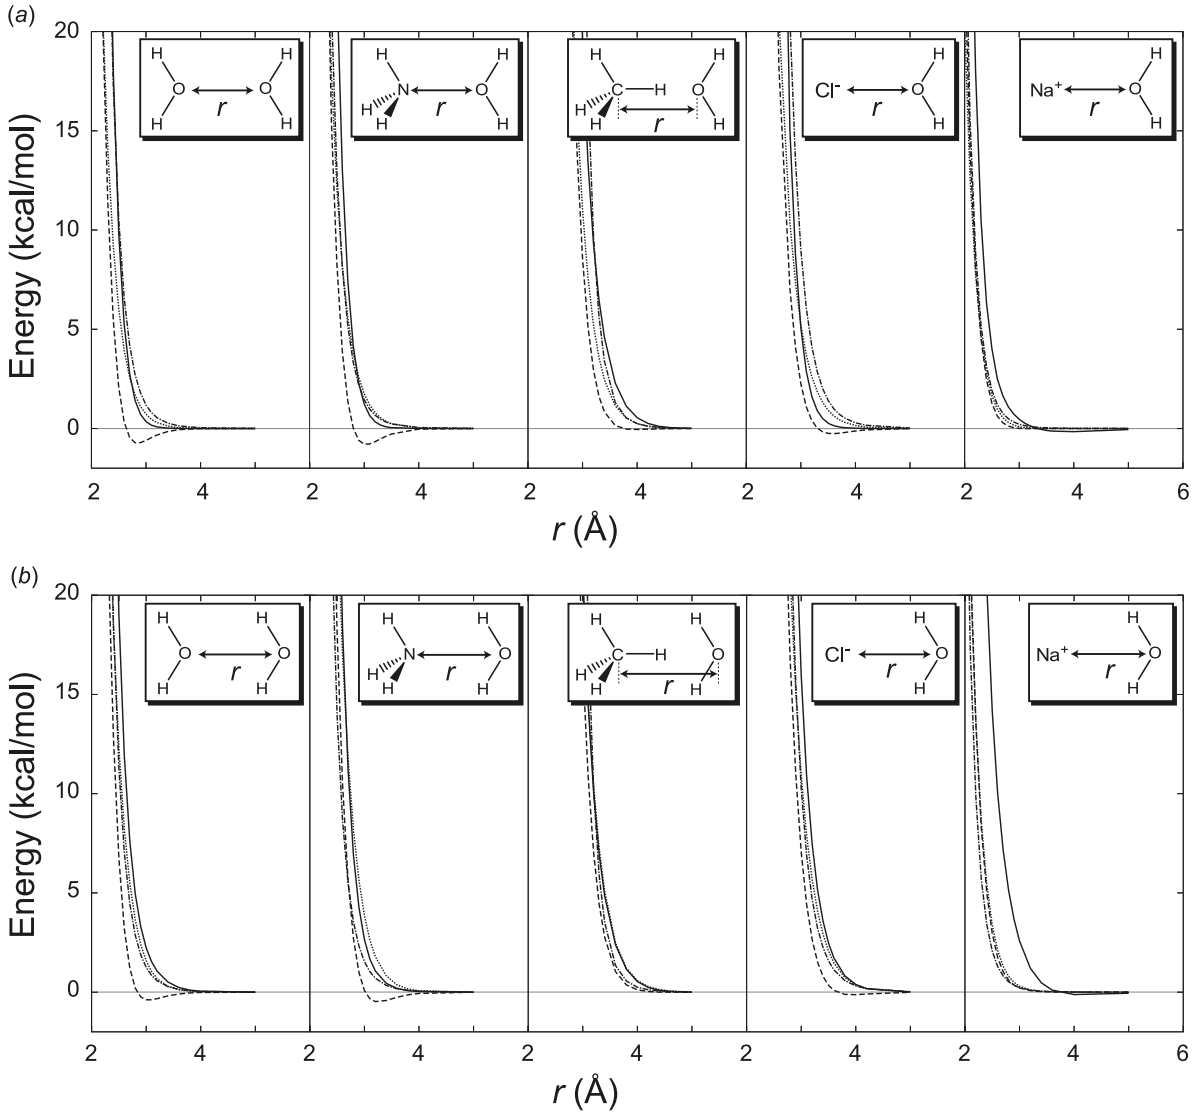


Method

Under the condition of orthogonality of the orbitals inside the isolated molecules A and B, exchange-repulsion energy between the molecules can be expressed with intermolecular overlap integrals of atomic orbitals (AOs),[7,8,18]

$$
\begin{aligned}
E^{\mathrm{exch}} = & -\frac{1}{2}\sum_{\mu\delta}\sum_{\nu\gamma} P^A_{\mu\delta} P^B_{\nu\gamma} \langle \mu\nu|\delta\gamma\rangle - \frac{1}{2}\sum_{\mu\delta}\sum_{\nu\gamma} P^A_{\mu\delta} P^B_{\nu\gamma} \langle \mu|\nu\rangle \left[V^A_{\delta\gamma} + G^A_{\delta\gamma} + V^B_{\delta\gamma} + G^B_{\delta\gamma} \right] \\
& + \frac{1}{4}\sum_{\mu\eta}\sum_{\nu\gamma} P^A_{\mu\eta} P^B_{\nu\gamma} \langle \mu|\nu\rangle \left[\sum_{\delta\theta} P^A_{\delta\theta} \langle \delta|\gamma\rangle (V^B_{\eta\theta} + J^B_{\eta\theta}) + \sum_{\delta\theta} P^B_{\delta\theta} \langle \eta|\delta\rangle (V^A_{\theta\gamma} + J^A_{\theta\gamma}) \right] \\
& - \frac{1}{8}\sum_{\mu\eta}\sum_{\nu\gamma}\sum_{\delta\theta}\sum_{\varepsilon\omega} P^A_{\mu\eta} P^B_{\nu\gamma} P^A_{\delta\theta} P^B_{\varepsilon\omega} \langle \mu|\nu\rangle \langle \delta|\varepsilon\rangle \langle \eta\theta|\omega\gamma\rangle \\
& - \frac{1}{8}\sum_{\mu\delta}\sum_{\gamma\eta} P^A_{\mu\delta} P^B_{\gamma\eta} \langle \delta|\gamma\rangle \left[\sum_{\nu\theta} P^A_{\nu\theta} \langle \eta|\theta\rangle K^B_{\mu\nu} + \sum_{\nu\theta} P^B_{\nu\theta} \langle \mu|\theta\rangle K^A_{\eta\nu} \right] \\
& + \frac{1}{2}\sum_{\mu\eta}\sum_{\nu\theta}\sum_{\gamma\omega}\sum_{\delta\varepsilon} P^A_{\mu\eta} P^B_{\nu\theta} P^A_{\gamma\omega} P^B_{\delta\varepsilon} \langle \eta|\theta\rangle \langle \omega|\varepsilon\rangle \langle \mu\nu|\gamma\delta\rangle \\
= & \; E^{\mathrm{exch}}_{S2} + E^{\mathrm{exch}}_{S4,P4}
\end{aligned}
\qquad [1]
$$

Fig. 2. Exchange-repulsion energies between H_2O and molecule X (X = H_2O, NH_3, CH_4, Cl^-, and Na^+) calculated by the present method (solid line), EFP (dashed line), KM (dotted line), and LJ (dash-dotted line). (*a*) water oxygen site approaching molecule X (approach I); (*b*) water hydrogen sites approaching molecule X (approach II).



where $\mathbf{P}^X$ is the density matrix for molecule X (X = *A* or *B*), $<\mu|\nu>$ is the overlap matrix, $V^X_{\mu\nu}$ is the nucleus attraction integral in the field of molecule X, and $<\mu\nu|\delta\gamma>$ is the electron repulsion integral. $\mathbf{J}^X$ and $\mathbf{K}^X$ are the Coulomb and exchange matrices and $\mathbf{G}^X$ is defined as

$$[2] \qquad G^X_{\mu\nu} = J^X_{\mu\nu} - \frac{1}{2}K^X_{\mu\nu}$$

The exchange-repulsion energy $E^{\text{exch}}_{\text{S2}}$ to the second order of $<\mu|\nu>$ has a familiar form obtained in previous work.[7] $E^{\text{exch}}_{\text{S4,P4}}$ is the exchange-repulsion energy to the fourth order of $<\mu|\nu>$ and to the fourth order of $\mathbf{P}^X$.

Equation [1] can be simplified by density fitting. The electron density is expressed with AOs as follows:

$$[3] \qquad \rho^X(\mathbf{r}) = \sum_{\mu\nu} P^X_{\mu\nu}\phi_\mu(\mathbf{r})\phi_\nu(\mathbf{r})$$

This value is fitted by the auxiliary basis set $\tilde{\phi}$ with coefficients *d*,

$$[4] \qquad \tilde{\rho}^X(\mathbf{r}) = \sum_{\nu} d^X_\nu \tilde{\phi}_\nu(\mathbf{r})\tilde{\phi}_\nu(\mathbf{r})$$

Fitting $\rho(\mathbf{r})$ with $\tilde{\rho}(\mathbf{r})$ using proper auxiliary basis set (ABS) $\tilde{\phi}$ can reproduce the effect of considerable off-diagonal elements of the density matrix. The use of *d* and $\tilde{\phi}$ leads to the following equation:

$$
\begin{aligned}
E^{\mathrm{exch}} = & -\frac{1}{2}\sum_{\mu}\sum_{\nu} d_{\mu}^{A} d_{\nu}^{B} \langle \tilde{\mu}\,\tilde{\nu} \,|\tilde{\mu}\,\tilde{\nu}\rangle - \frac{1}{2}\sum_{\mu}\sum_{\nu} d_{\mu}^{A} d_{\nu}^{B} \langle \tilde{\mu}\,|\tilde{\nu}\rangle \left[V_{\mu\nu}^{A} + \widehat{G}_{\mu\nu}^{A} + V_{\mu\nu}^{B} + \widehat{G}_{\mu\nu}^{B} \right] \\
& + \frac{1}{4}\sum_{\mu}\sum_{\nu} d_{\mu}^{A} d_{\nu}^{B} \langle \tilde{\mu}\,|\tilde{\nu}\rangle \left[\sum_{\delta} d_{\delta}^{A} \langle \tilde{\delta}\,|\tilde{\nu}\rangle (V_{\mu\delta}^{B} + \widehat{J}_{\mu\delta}^{B}) + \sum_{\delta} d_{\delta}^{B} \langle \tilde{\mu}\,|\tilde{\delta}\rangle (V_{\delta\nu}^{A} + \widehat{J}_{\delta\nu}^{A}) \right] \\
& - \frac{1}{8}\sum_{\mu}\sum_{\nu}\sum_{\delta}\sum_{\varepsilon} d_{\mu}^{A} d_{\nu}^{B} d_{\delta}^{A} d_{\varepsilon}^{B} \langle \tilde{\mu}\,|\tilde{\nu}\rangle \langle \tilde{\delta}\,|\tilde{\varepsilon}\rangle \langle \tilde{\mu}\,\tilde{\delta}\,|\tilde{\varepsilon}\,\tilde{\nu}\rangle \\
& - \frac{1}{8}\sum_{\mu}\sum_{\gamma} d_{\mu}^{A} d_{\gamma}^{B} \langle \tilde{\mu}\,|\tilde{\gamma}\rangle \left[\sum_{\nu} d_{\nu}^{A} \langle \tilde{\gamma}\,|\tilde{\nu}\rangle \widehat{K}_{\mu\nu}^{B} + \sum_{\nu} d_{\nu}^{B} \langle \tilde{\mu}\,|\tilde{\nu}\rangle \widehat{K}_{\gamma\nu}^{A} \right] \\
& + \frac{1}{2}\sum_{\mu}\sum_{\nu}\sum_{\gamma}\sum_{\delta} d_{\mu}^{A} d_{\nu}^{B} d_{\gamma}^{A} d_{\delta}^{B} \langle \tilde{\mu}\,|\tilde{\nu}\rangle \langle \tilde{\gamma}\,|\tilde{\delta}\rangle \langle \tilde{\mu}\,\tilde{\nu}\,|\tilde{\gamma}\,\tilde{\delta}\rangle
\end{aligned} \tag{5}
$$

The matrices $\widehat{\mathbf{G}}^{X}$, $\widehat{\mathbf{J}}^{X}$, and $\widehat{\mathbf{K}}^{X}$ are given by

$$\widehat{G}_{\mu\nu}^{X} = \widehat{J}_{\mu\nu}^{X} - \frac{1}{2}\widehat{K}_{\mu\nu}^{X} \tag{6}$$

$$\widehat{J}_{\mu\nu}^{X} = \sum_{\gamma} d_{\gamma}^{X} \langle \tilde{\mu}\,\tilde{\nu}\,|\tilde{\gamma}\,\tilde{\gamma}\rangle \tag{7}$$

$$\widehat{K}_{\mu\nu}^{X} = \sum_{\gamma} d_{\gamma}^{X} \langle \tilde{\mu}\,\tilde{\gamma}\,|\tilde{\gamma}\,\tilde{\nu}\rangle \tag{8}$$

Our first goal is to derive the equation for the decomposition of the exchange-repulsion energy

$$E^{\mathrm{exch}} = \sum_{I\in A}\sum_{J\in B} E_{IJ}^{\mathrm{exch}} \tag{9}$$

where **I** and **J** refer to atoms belonging to molecules *A* and *B*, respectively. Based on eq. [5], the component E_{IJ}^{exch} is defined as

$$
\begin{aligned}
E_{IJ}^{\mathrm{exch}} \equiv & -\frac{1}{2}\sum_{\mu\in I}\sum_{\nu\in J} d_{\mu}^{A} d_{\nu}^{B} \langle \mu\nu|\mu\nu\rangle - \frac{1}{2}\sum_{\mu\in I}\sum_{\nu\in J} d_{\mu}^{A} d_{\nu}^{B} \langle \mu|\nu\rangle \left[V_{\mu\nu}^{(\mu)} + G_{\mu\nu}^{(\mu)} + V_{\mu\nu}^{(\nu)} + G_{\mu\nu}^{(\nu)} \right] \\
& + \frac{1}{4}\sum_{\mu\in I}\sum_{\nu\in J} d_{\mu}^{A} d_{\nu}^{B} \langle \mu|\nu\rangle \left[\sum_{\delta\in I} d_{\delta}^{A} \langle \delta|\nu\rangle (V_{\mu\delta}^{(\nu)} + J_{\mu\delta}^{(\nu)}) + \sum_{\delta\in I} d_{\delta}^{B} \langle \mu|\delta\rangle \left(V_{\delta\nu}^{(\mu)} + J_{\delta\nu}^{(\mu)} \right) \right] \\
& - \frac{1}{8}\sum_{\mu\in I}\sum_{\nu\in J}\sum_{\delta\in I}\sum_{\varepsilon\in J} d_{\mu}^{A} d_{\nu}^{B} d_{\delta}^{A} d_{\varepsilon}^{B} \langle \mu|\nu\rangle \langle \delta|\varepsilon\rangle \langle \mu\delta|\varepsilon\nu\rangle - \frac{1}{8}\sum_{\mu\in I}\sum_{\gamma\in J} d_{\mu}^{A} d_{\gamma}^{B} \langle \mu|\gamma\rangle \left[\sum_{\nu\in I} d_{\nu}^{A} \langle \gamma|\nu\rangle K_{\mu\nu}^{(\gamma)} + \sum_{\nu\in J} d_{\nu}^{B} \langle \mu|\nu\rangle K_{\gamma\nu}^{(\mu)} \right] \\
& + \frac{1}{2}\sum_{\mu\in I}\sum_{\nu\in J}\sum_{\gamma\in I}\sum_{\delta\in J} d_{\mu}^{A} d_{\nu}^{B} d_{\gamma}^{A} d_{\delta}^{B} \langle \mu|\nu\rangle \langle \gamma|\delta\rangle \langle \mu\nu|\gamma\delta\rangle
\end{aligned} \tag{10}
$$

The matrix elements $V_{\mu\gamma}^{(\nu)}$, $G_{\mu\gamma}^{(\nu)}$, $J_{\mu\gamma}^{(\nu)}$, and $K_{\mu\gamma}^{(\nu)}$ are given by

$$V_{\mu\gamma}^{(\nu)} = -Z_{I_\nu} \left\langle \mu \left| \frac{1}{|\mathbf{r} - \mathbf{R}_{I_\nu}|} \right| \nu \right\rangle \tag{11}$$

$$G_{\mu\gamma}^{(\nu)} = J_{\mu\gamma}^{(\nu)} - \frac{1}{2}K_{\mu\gamma}^{(\nu)} \tag{12}$$

$$J_{\mu\gamma}^{(\nu)} = \sum_{\eta} d_{\eta}^{I_\nu} \langle \mu\gamma|\eta\eta\rangle \tag{13}$$

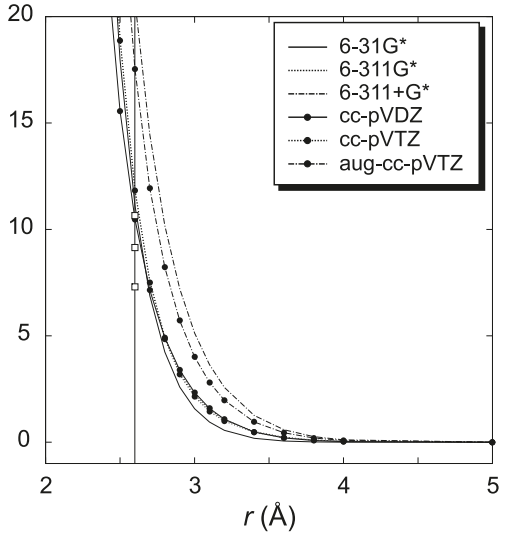
$$K_{\mu\gamma}^{(\nu)} = \sum_{\eta} d_{\eta}^{I_\nu} \langle \mu\eta|\eta\gamma\rangle \tag{14}$$

where $\mathbf{I}_\nu$ is the atom to which AO χ_ν belongs, Z_I is the atomic number of atom **I**, and $\{d_\eta^{I_\nu}\}$ is the density coefficient which is assigned to atom $\mathbf{I}_\nu$.

To achieve our second goal, E_{IJ}^{exch} defined in eq. [10] has to be evaluated only in terms of the distance between atoms **I** and **J**. Applying s-type ABS makes each component in E_{IJ}^{exch} very simple. For example, the two-electron integral $\langle \mu\nu|\gamma\delta\rangle$ in the last term of eq. [10] is expressed as

$$
\begin{aligned}
\langle \mu\nu|\gamma\delta\rangle = & \left[\frac{\sqrt{\alpha_\mu \alpha_\nu}}{\alpha_\mu + \alpha_\nu} \right]^{\frac{3}{2}} \left[\frac{\sqrt{\alpha_\gamma \alpha_\delta}}{\alpha_\gamma + \alpha_\delta} \right]^{\frac{3}{2}} \\
& \times \frac{8}{R_{AB}} \mathrm{erf}\left[\sqrt{\frac{(\alpha_\mu + \alpha_\nu)(\alpha_\gamma + \alpha_\delta)}{\alpha_\mu + \alpha_\nu + \alpha_\gamma + \alpha_\delta}} \right]
\end{aligned} \tag{15}
$$

Fig. 3. Basis set dependence of the exchange-repulsion energy between water molecules in approach II, evaluated by the present method. Also shown are the values of the energy at $r = 2.6$ Å evaluated by MK with cc-pVDZ, cc-pVTZ, and aug-cc-pVTZ, from bottom to top, respectively. The reaction coordinate is the same as in Fig. 2*b* for water molecules.



where orbitals ϕ_ν and ϕ_μ are assigned to atom **I**, ϕ_γ and ϕ_δ to atom **J**, and α_χ ($\chi = \nu$, μ, γ, and δ) is the index of the exponent of ϕ_χ. The strategy for preparing such an ABS and determining the d coefficients was described in detail in the previous work.[24,25]

In statistical-mechanical studies of classical systems, many kinds of empirical potentials for exchange-repulsion energy are employed. Interestingly, even a hard-sphere potential, infinite if atom cores overlap and zero otherwise, can account for some chemical properties of liquid systems.[1,26] This means that the atomic radius (the position where the potential becomes very large) is a very important point in the exchange-repulsion energy. In the following discussion, we focus on the shape and radius evaluated by the present method rather than on the numerical values, and compare them with those obtained from ab initio calculations and empirical potentials.

Application to water and simple molecules and ions

Before applying eq. [9] to the molecular system, the exchange-repulsive potential in a model system is evaluated. In this system, two atoms with $Z = 2$ are prepared and then one Gaussian AO is employed for each atom,

$$[16] \qquad \phi(\mathbf{r}) = \left(\frac{2\alpha}{\pi}\right)^{\frac{3}{4}} \exp(-\alpha(\mathbf{r}-\mathbf{R})^2)$$

where **R** is the position of each atom. The number of electrons for each atom is two (each atom is neutral). With the basis set, eqs. [1] and [9] reduce to the same equation. Figure 1 presents the exchange-repulsive potentials for the component E_{S2}^{exch} and $E_{S2}^{exch} + E_{S4,P4}^{exch}$ versus the interatomic distance r for $\alpha = 2.0$. For comparison, the exchange-repulsion energies without the truncation of the AO overlap (E^{XR}, eq. [13] in [18]) are also calculated and shown in Fig. 1. The exchange-repulsion energy calculated as E_{S2}^{exch} becomes zero at $r = 0$. Because the higher term, larger than the second order of AO overlap, is truncated in E_{S2}^{exch}, it gets far from E^{XR} in the region where the AO overlap is large. However, the component $E_{S4,P4}^{exch}$ improves the potential in that region.

The exchange-repulsion energies between H_2O and molecules H_2O, NH_3, CH_4, Cl^-, and Na^+ were calculated from eq. [9]. The geometry optimization of H_2O, NH_3, and CH_4, and calculation of the exchange-repulsion energy were performed at the HF/6–311G* level. For comparison, the exchange-repulsion energy was also evaluated by using the Kitaura–Morokuma (KM) analysis,[27] the EFP,[12] and the Lennard-Jones potential. The KM analysis is one of the methods used in decomposing the total intermolecular interaction energy into specific energy components. Because the KM analysis is widely employed to analyze intermolecular interactions and its definition is very clear, we took the KM exchange-repulsion energy as a reference. It should be noted that the surfaces evaluated by EFP show some areas of negative values in the panels of water–water and water–NH_3 in Fig. 2. This effect is probably due to the fact that the equation employed in EFP is constructed from many interaction terms,[18] and the values of the exchange-repulsion potential come from a cancellation of the large positive and negative terms. The reasonable balance might have been lost in the regions where the value evaluated by the EFP implementation we used is negative. The repulsive part of the Lennard-Jones potential was calculated using the SPC-like potential,[28] with a correction concerning the Lennard-Jones parameters of the hydrogen sites ($\sigma = 1.0$ Å, $\varepsilon = 0.056$ kcal/mol) for H_2O, and the OPLS-AA all-atom models[29] for NH_3, CH_4, Cl^-, and Na^+. All calculations were performed by using our in-house code implemented in the GAMESS software package.[30]

The exchange-repulsion energy surfaces were calculated for H_2O approaching molecule X in two directions: the oxygen site approaching molecule X (approach I), and the hydrogen site approaching molecule X (approach II). Figures 2*a* and 2*b* present the corresponding energy surfaces; the reaction coordinates for approaches I and II are also depicted in the right upper panel of each figure. Except for $Na^+ \cdot H_2O$ in approach II, the shapes calculated by the present method are close to those evaluated by using quantum chemical calculation and standard classical potentials. The strategy of MK analysis is summarized well by Mo et al.[31] This also shows that the atomic radii evaluated with these methods are almost the same. Although the present method somewhat overestimates the repulsion for $Na^+ \cdot H_2O$ in approach II, this does not lead to severe problems, because the electrostatic interaction between Na^+ and the positively charged H site of H_2O is dominant, compared to the exchange-repulsion energy.

To check the dependence of the results of the present method on the basis set, we calculated the exchange-repulsion energy between water molecules in approach II at the HF/(6–31G*, 6–311+G*, cc-pVDZ, cc-pVTZ, and aug-cc-pVTZ) levels. The resulting energy surfaces are shown in Fig. 3, including the energy at $r = 2.6$ Å evaluated by the

KM analysis with cc-pVDZ, cc-pVTZ, and aug-cc-pVTZ. The calculation using the basis sets without diffuse functions (6–31G*, 6–311G*, cc-pVDZ, and cc-pVTZ) gave almost the same shape for the energy surface. The energies, which become very large (r = 2.6 Å), are very close to those calculated by MK with aug-cc-pVTZ. On the other hand, the energy surfaces evaluated with 6–311+G* and aug-cc-pVTZ are somewhat repulsive. This is because the electron distribution determined by the present density-fitting approach is broad, so the overlap of electrons between two waters becomes large.

Conclusions

We have proposed an ab initio IMPT-based scheme to derive the exchange-repulsive intermolecular energy, broken down into additive spherical-site potentials. This strategy is capable of becoming an important bridge in a multiscale scheme that will produce classical force fields for molecular modeling with high accuracy from ab initio calculations.

A facile method for the preparation of sugar orthoesters promoted by anhydrous sodium bicarbonate

Shanqiao Wei, Jinzhong Zhao, and Huawu Shao

Abstract: A facile and eco-friendly method for the preparation of sugar orthoesters by using anhydrous sodium bicarbonate is described. Various sugar orthoesers, including sugar–sugar orthoesters, were synthesized in good-to-excellent yields by the reaction of a protected glycosyl bromide with an alcohol or sugar.

Key words: sugar orthoesters, anhydrous sodium bicarbonate, protected glycosyl bromide.

Résumé : On a développé une méthode facile et écologique de préparation d'orthoesters de sucres utilisant le bicarbonate de sodium anhydre. On a réalisé la synthèse de divers orthoesters de sucres, y compris des orthoesters de sucre-sucre, avec des rendements allant de bons à excellents en procédant à la réaction d'un bromure de glycosyle protégé avec un alcool ou un sucre.

Mots-clés : orthoesters de sucres, bicarbonate de sodium anhydre, bromure de glycosyle protégé.

[Traduit par la Rédaction]

Introduction

Sugar 1,2-orthoesters are some of the most important intermediates in organic synthesis,[1,2] especially in the oligosaccharide synthesis.[3–7] Sugar 1,2-orthoesters are classic glycosyl donors and can be efficiently converted to the corresponding 1,2-*trans*-glycosides by the action of protonic or Lewis acids, such as TMSOTf,[8] $BF_3{\cdot}Et_2O$,[9a] and TfOH.[9b] Sugar 1,2-orthoesters are also extremely practical for the selective protection of a pyranose ring while the other acetyl groups on the 3, 4, and 6 positions are converted to benzyl groups, and so forth. At present, there are several methods in the literature for the preparation of carbohydrate 1,2-orthoesters.[10,11] The well-known method involves the treatment of peracetylated or perbenzoylated glycosyl bromides with alcohols in the presence of a quaternary ammonium salt[12] or silver triflate[5,13] and an organic base, usually *syn*-collidine or 2,6-lutidine.[14] It is necessary to utilize two kinds of reagents, quaternary ammonium salt and bulky amine compound, for the reaction to occur.[11a,15] Although the method has been extensively used, there is one large disadvantage: the use of a smelly, toxic, and eco-unfriendly organic base. Knowing the broad spectrum of the significant applications of sugar orthoesters, we have focused our interest on improving the synthesis of sugar orthoesters. Herein, a facile, less toxic, and efficient procedure for the synthesis of 1,2-orthoesters, including sugar–sugar orthoesters, by using anhydrous sodium bicarbonate instead of an organic base is reported.[15,16]

Result and discussion

Our studies started with the reaction of peracetylated glucopyranosyl bromide with methanol in the presence of tetrabutylammonium bromide, anhydrous sodium bicarbonate, and a 4 Å molecular sieve in dry acetonitrile solvent (Scheme 1). The reaction was carried out at room temperature for 4 h, affording the glucopyranosyl methyl orthoester in an 86% yield (Table 1, entry 1). To optimize the method, we used toluene, 1,2-dichlorethane, *N*,*N*-dimethylformamide (DMF), and tetrahydrofuran (THF), respectively, as the solvent, and afforded the target product **2** in various yields (Table 1, entries 2–5).

To establish the feasibility of this reaction as a general method for the preparation of 1,2-orthoesters (Scheme 2), we carried out the synthesis of 3,4,6-tri-*O*-acetyl mannose, 3,4,6-tri-*O*-acetyl galactose, 3,4-di-*O*-acetyl rhamnose orthoesters, and 3,4,6-tri-*O*-benzoyl mannose orthoester in good to excellent yields, and the results are shown in Table 2 (entries 1–4). Since 6-*O*-tosyl and 6-*O*-mesyl of these orthoesters can be easily substituted by other groups, the library of sugar orthoesters is greatly expanded. However, the synthesis of 6-*O*-tosyl and 6-*O*-mesyl orthoesters has not been reported in the literature. Herein, with the suitable protocol in hand, 6-*O*-mesyl and 6-*O*-tosyl mannopyranosyl bromide were treated by using various alcohols such as methanol, isopropyl alcohol, and allyl alcohol, and the corresponding orthoesters (Table 2, entries 5–10). 6-*O*-Mesyl orthosters **13** and **14** (Table 2, entries 5 and 6) and 6-*O*-tosyl orthoster **19** (Table 2, entry 11) were obtained in good yields. Whereas 6-*O*-mesyl orthoesters **15–18** (Table 2, entries 7–10) and 6-*O*-tosyl orthoesters **20** and **21** (Table 2, entries 12 and 13) were obtained in modest yields. The

sugar–sugar orthoesters are extremely important intermediates for oligosaccharide synthesis. Comparing simple sugar orthoesters, the reaction pathways of sugar–sugar orthoesters are relatively simplified for oligosaccharide preparation; the consideration is mainly focused on intra- and inter-molecular rearrangement of the alkoxide.[8a] Sugar–sugar orthoesters are usually synthesized by the reaction of a glycosyl bromide donor with a glycosyl acceptor with only one free hydroxyl group in dichloromethane in the presence of silver triflate and 2,4-lutidine.[8a] Although this method is efficient, both silver triflate and 2,4-lutidine are toxic and expensive. We hoped that our newly developed method could be applied to the synthesis of sugar–sugar orthoesters. Hence, **3** and **22** were treated in the presence of tetrabutylammonium bromide and anhydrous sodium bicarbonate, the reaction was completed at room temperature for 12 h, and readily afforded the sugar–sugar orthoester **24** in an excellent yield (90%). Encouraged by the success in synthesizing **24**, we subsequently prepared sugar–sugar orthoesters **25**–**28** in good yields (Table 2, entries 15–18).

In summary, we developed a facile and effective protocol for the synthesis of various sugar 1,2-orthoesters and sugar–sugar orthoesters by using anhydrous sodium bicarbonate as an inexpensive and environmentally friendly base. The approach, in terms of low toxicity of reagents, simplicity, economy, and efficiency, will be a general, useful, and attractive strategy for the synthesis of sugar 1,2-orthoesters.

were recorded in $CDCl_3$. ^1H NMR chemical shifts are reported in ppm (δ) relative to tetramethylsilane (TMS) with the solvent resonance employed as the internal standard ($CDCl_3$, δ 7.26 ppm). Data are reported as follows: chemical shift, multiplicity (s = singlet, d = doublet, t = triplet, m = multiplet), integration, and coupling constants (Hz). ^{13}C NMR chemical shifts are reported in ppm from tetramethylsilane (TMS) with the solvent resonance as the internal standard ($CDCl_3$, δ 77.0 ppm). HR-MS (ESI) spectra were recorded on BioTOF Q. Optical rotations were acquired on a PerkinElmer M341 Digital Polarimeter.

General procedure for the synthesis of 1,2-orthoesters 2, 9–21

The acetobromo glycoside (1 mmol) was dissolved in dry acetonitrile (4 mL), then alcohol (10 mmol), tetrabutylammonium bromide (0.7 mmol), anhydrous sodium bicarbonate (2 mmol), and molecular sieves 4 Å; (400 mg) were added. The reaction mixture was vigorously stirred for 3–7 h at room temperature. TLC indicated when the reaction was complete. The solvent was evaporated to dryness and the residue was purified by silica gel column chromatrography.

General procedure for the synthesis of sugar–sugar orthoesters 24–28

The glycosyl acceptor (1 mmol) and acetobromo glycoside (2 mmol) were dissolved in dry acetonitrile (10 mL), then tetrabutylammonium bromide (1 mmol), anhydrous sodium bicarbonate (4 mmol), and molecular sieves 4 Å; (600 mg) were added. The reaction mixture was vigorously stirred at room temperature for 12–15 h. TLC indicated when the reaction was complete. The solvent was evaporated to dryness and the residue was purified by silica gel column chromatrography.

Characterization data

Compound 2

Yield: 86%. Syrup. $[\alpha]_D^{25}$ +31 (*c* 0.8, EtOAc). ^1H NMR ($CDCl_3$) δ: 5.72 (d, 1H, *J* = 5.1 Hz), 5.19 (dd, 1H, *J* = 2.8, 3.0), 4.90 (dd, 1H, *J* = 2.8, 9.6), 4.32 (m, 1H), 4.20 (m, 2H), 3.95 (m, 1H), 3.29 (s, 3H), 2.11 (s, 3H), 2.10 (s, 3H,), 2.09 (s, 3H), 1.71 (s, 3H).

Compound 9

Yield: 84%. White needle, mp 107–108 °C. $[\alpha]_D^{25}$ –24 (*c* 0.2, EtOAc). ^1H NMR ($CDCl_3$) δ: 5.49 (d, 1H, *J* = 2.5), 5.30 (dd, 1H, *J* = 9.7, 9.8), 5.15 (dd, 1H, *J* = 4.0, 10.0), 4.61 (dd, 1H, *J* = 2.9, 3.5), 4.24 (dd, 1H, *J* = 5.0, 12.2), 4.14 (dd, 1H, *J* = 1.9, 11.7), 3.68 (m, 1H), 3.28 (s, 3H), 2.12 (s, 3H), 2.07 (s, 3H), 2.05 (s, 3H), 1.74 (s, 3H).

Compound 10

Yield: 80%. Syrup. $[\alpha]_D^{25}$ +80 (*c* 0.2, EtOAc). ^1H NMR [$(CD_3)_2CO$] δ: 5.87 (d, 1H, *J* = 4.6), 5.40 (dd, 1H, *J* = 2.9, 3.1), 5.06 (dd, 1H, *J* = 3.4, 6.5), 4.42–4.40 (m, 2H), 4.17 (dd, 1H, *J* = 7.0, 11.3), 4.10 (dd, 1H, *J* = 5.8, 11.3), 3.23 (s, 3H), 2.08 (s, 3H), 2.01 (s, 3H), 2.00 (s, 3H), 1.60 (s, 3H).

Compound 11

Yield: 66%. $[\alpha]_D^{25}$ +20 (*c* 0.4, EtOAc). ^1H NMR ($CDCl_3$) δ: 5.41 (d, 1H, *J* = 2.3), 5.06 (m, 2H), 4.59 (dd, 1H, *J* = 2.3, 3.9), 3.51 (m, 1H), 3.27 (s, 3H), 2.12 (s, 3H), 2.06 (s, 3H), 1.73 (s, 3H), 1.23 (d, 3H, *J* = 6.2).

Compound 12

Yield: 91%. White solid, mp 150–152 °C. $[\alpha]_D^{25}$ –129 (*c* 0.7, EtOAc). ^1H NMR ($CDCl_3$) δ: 8.01 (d, 2H, *J* = 7.6), 7.90–7.89 (m, 4H), 7.71–7.69 (m, 2H), 7.53–7.47 (m, 3H), 7.42–7.32 (m, 6H), 7.30–7.26 (m, 3H), 5.88 (dd, 1H, *J* = 9.5, 9.6), 5.80 (d, 1H, *J* = 2.9), 5.66 (dd, 1H, *J* = 4.1, 10.0), 5.08 (dd, 1H, *J* = 3.3, 3.7), 4.51 (dd, 1H, *J* = 3.1, 11.9), 4.35 (dd, 1H, *J* = 4.7, 12.1), 4.14–4.09 (m, 1H), 3.23 (s, 3H).

Compound 13

Yield: 88%. White solid, mp 128–129 °C. $[\alpha]_D^{25}$ –2.5 (*c* 0.2, EtOAc). ^1H NMR ($CDCl_3$) δ: 5.51 (d, 1H, *J* = 2.5), 5.25 (dd, 1H, *J* = 9.4, 9.8), 5.17 (dd, 1H, *J* = 3.8, 10.0), 4.63 (dd, 1H, *J* = 3.1, 3.1), 4.3 (dd, 1H, *J* = 5.5, 11.1), 4.28 (dd, 1H, *J* = 2.7, 11.1), 3.79 (m, 1H), 3.28 (s, 3H), 3.05 (s, 3H), 2.12 (s, 3H), 2.08 (s, 3H), 1.73 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 170.3, 169.6, 124.3, 97.5, 76.2, 71.6, 70.2, 67.2, 65.5, 50.1, 37.7, 24.0, 20.7, 20.6. HR-MS (ESI) anal. calcd. for $C_{14}H_{22}NaO_{11}S$ [M + Na]: 421.0775; found: 421.0772.

Compound 14

Yield: 83%. White solid, mp 145–146 °C. $[\alpha]_D^{25}$ –1 (*c* 0.2, EtOAc). ^1H NMR ($CDCl_3$) δ: 5.49 (d, 1H, *J* = 2.5), 5.25 (dd, 1H, *J* = 9.5, 9.7), 5.17 (dd, 1H, *J* = 3.9, 9.9), 4.61 (dd, 1H, *J* = 3.1, 3.5), 4.33 (dd, 1H, *J* = 5.5, 11.1), 4.28 (dd, 1H, *J* = 2.7, 11.0), 3.78 (m, 1H), 3.59–3.50 (m, 2H), 3.05 (s, 3H), 2.12 (s, 3H), 2.08 (s, 3H), 1.73 (s, 3H), 1.18 (t, 3H, *J* = 7.0). ^{13}C NMR ($CDCl_3$) δ: 170.3, 169.6, 124.0, 97.5, 76.0, 71.6, 70.2, 67.3, 65.6, 58.4, 37.7, 24.3, 20.7, 20.6, 15.1. HR-MS (ESI) anal. calcd. for $C_{15}H_{24}NaO_{11}S$ [M + Na]: 435.0932; found: 435.0936.

Compound 15

Yield: 77%. White solid, mp 127–129 °C. $[\alpha]_D^{25}$ +11 (*c* 0.1, EtOAc). ^1H NMR ($CDCl_3$) δ: 5.87 (m, 1H), 5.51 (d, 1H, *J* = 2.8), 5.27–5.24 (m, 2H), 5.18–5.14 (m, 2H), 4.62 (dd, 1H, *J* = 3.1, 3.8), 4.33 (dd, 1H, *J* = 5.6, 11.3), 4.28 (dd, 1H, *J* = 3.0, 11.3), 4.06–4.00 (m, 2H), 3.79 (m, 1H), 3.05 (s, 3H), 2.12 (s, 3H), 2.08 (s, 3H), 1.75 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 170.2, 169.6, 133.9, 124.1, 116.8, 97.6, 76.0, 71.7, 70.1, 67.3, 65.5, 64.0, 37.7, 24.4, 20.7, 20.6. HR-MS (ESI) anal. calcd. for $C_{16}H_{24}NaO_{11}S$ [M + Na]: 447.0932; found: 447.0925.

Compound 16

Yield: 70%. White solid, mp 130-132 °C. $[\alpha]_D^{25}$ +1 (*c* 0.2, EtOAc). ^1H NMR ($CDCl_3$) δ: 5.53 (d, 1H, *J* = 2.9), 5.25 (dd, 1H, *J* = 9.4, 9.7), 5.18 (dd, 1H, *J* = 4.0, 10.0), 4.68 (dd, 1H, *J* = 3.2, 3.2), 4.33 (dd, 1H, *J* = 5.6, 11.5), 4.29 (dd, 1H, *J* = 2.8, 11.2), 4.18 (d, 2H, *J* = 2.1), 3.80 (m, 1H), 3.05 (s, 3H), 2.38 (t, 1H, *J* = 1.9), 2.12 (s, 3H), 2.08 (s, 3H), 1.77 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 170.2, 169.6, 123.9, 97.6, 79.4, 76.0, 73.7, 71.8, 69.9, 67.2, 65.4, 51.1, 37.7, 24.0, 20.7. HR-MS (ESI) anal. calcd. for $C_{16}H_{22}NaO_{11}S$ [M + Na]: 445.0775; found: 445.0783.

Compound 17

Yield: 60%. White solid, mp 109–111 °C. $[\alpha]_D^{25}$ +1 (*c* 0.4,

EtOAc). ^{1}H NMR ($CDCl_3$) δ: 5.48 (d, 1H, *J* = 2.7), 5.25 (dd, 1H, *J* = 9.5, 9.5), 5.17 (dd, 1H, *J* = 4.1, 9.9), 4.62 (dd, 1H, *J* = 2.9, 3.7), 4.33 (dd, 1H, *J* = 5.8, 11.3), 4.28 (dd, 1H, *J* = 2.9, 11.2), 3.95 (m, 1H), 3.79 (m, 1H), 3.05 (s, 3H), 2.11 (s, 3H), 2.08 (s, 3H), 1.73 (s, 3H), 1.15 (d, 3H, *J* = 6.2), 1.14 (d, 3H, *J* = 9.1). ^{13}C NMR ($CDCl_3$) δ: 170.2, 169.6, 124.1, 97.4, 75.5, 71.7, 70.1, 67.4, 66.6, 65.6, 37.7, 24.4, 23.7, 20.7. HR-MS (ESI) anal. calcd. for $C_{16}H_{26}NaO_{11}S$ [M + Na]: 449.1088; found: 449.1011.

Compound 18

Yield: 68%. White solid, mp 141–142 °C. $[\alpha]_D^{25}$ +10 (*c* 0.2, EtOAc). ^{1}H NMR ($CDCl_3$) δ: 7.37–7.26 (m, 5H), 5.52 (d, 1H, *J* = 2.7), 5.26 (dd, 1H, *J* = 9.5, 9.7), 5.16 (dd, 1H, *J* = 3.9, 9.9), 4.64–4.54 (m, 3H), 4.35–4.28 (m, 2H), 3.80 (m, 1H), 3.05 (s, 3H), 2.10 (s, 3H), 2.08 (s, 3H), 1.81 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 170.2, 169.6, 137.4, 128.6, 128.4, 127.7, 127.5, 127.0, 124.2, 97.6, 76.0, 71.7, 70.0, 67.3, 65.5, 65.0, 37.7, 24.4, 20.7; HR-MS (ESI) anal. calcd for $C_{20}H_{26}NaO_{11}S$ [M + Na]: 497.1088; found: 497.1079.

Compound 19

Yield: 80%. Syrup. $[\alpha]_D^{25}$ +30.5 (*c* 0.2, EtOAc). ^{1}H NMR ($CDCl_3$) δ: 7.78 (d, 2H, *J* = 8.3), 7.34 (d, 2H, *J* = 7.9), 5.41 (d, 1H, *J* = 2.7), 5.16 (dd, 1H, *J* = 9.2, 9.6), 5.11 (dd, 1H, *J* = 3.8, 9.8), 4.56 (dd, 1H, *J* = 2.9, 3.7), 4.11 (m, 2H), 3.72 (m, 1H), 3.24 (s, 3H), 2.45 (s, 3H), 2.10 (s, 3H), 2.03 (s, 3H), 1.59 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 170.3, 169.5, 145.0, 132.5, 129.8, 128.1, 124.3, 97.4, 76.3, 71.3, 70.2, 67.9, 65.9, 50.0, 24.0, 21.6, 20.7, 20.6; HR-MS (ESI) anal. calcd for $C_{20}H_{26}NaO_{11}S$ [M + Na]: 497.1088; found: 497.1081.

Compound 20

Yield: 78%. Syrup. $[\alpha]_D^{25}$ +19.7 (*c* 0.6, EtOAc). ^{1}H NMR ($CDCl_3$) δ: 7.78 (d, 2H, *J* = 7.3), 7.34 (d, 2H, *J* = 7.7), 5.40 (m, 1H), 5.27–5.11 (m, 2H), 4.55 (m, 1H), 4.13–4.07 (m, 2H), 3.72 (m, 1H), 3.51 (m, 2H), 2.44 (s, 3H), 2.10 (s, 3H), 2.02 (s, 3H), 1.60 (s, 3H), 1.16 (t, 3H, *J* = 6.72). ^{13}C NMR ($CDCl_3$) δ: 170.3, 169.5, 145.0, 132.5, 129.8, 128.1, 124.0, 97.4, 76.1, 71.3, 70.2, 68.0, 65.9, 58.2, 24.3, 21.6, 20.7, 20.6, 15.0 HR-MS (ESI) anal. calcd for $C_{21}H_{28}NaO_{11}S$ [M + Na]: 511.1245; found: 511.1268.

Compound 21

Yield: 71%. Syrup. $[\alpha]_D^{25}$ +23 (*c* 0.2, EtOAc). ^{1}H NMR ($CDCl_3$) δ: 7.78 (d, 2H, *J* = 8.2), 7.34 (d, 2H, *J* = 8.0), 5.43 (d, 1H, *J* = 2.8), 5.18–5.11 (m, 2H), 4.62 (dd, 1H, *J* = 3.2, 3.3), 4.15 (d, 2H, *J* = 1.8), 4.15–4.07 (m, 4H), 3.76 (m, 1H), 2.45 (s, 3H), 2.37 (t, 1H, *J* = 2.3), 2.10 (s, 3H), 2.03 (s, 3H), 1.63 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 170.2, 169.5, 145.1, 132.5, 130.0, 129.8, 128.1, 123.9, 97.5, 79.4, 76.0, 73.7, 71.6, 69.9, 68.0, 65.7, 51.0, 24.0, 21.6, 20.7, 20.6, 14.2; HR-MS (ESI) anal. calcd for $C_{22}H_{26}NaO_{11}S$ [M + Na]: 521.1088; found: 521.1065.

Compound 24

Yield: 90%. White solid, mp 121–123 °C. $[\alpha]_D^{25}$ –27.7 (*c* 0.3, EtOAc). ^{1}H NMR ($CDCl_3$) δ: 5.50 (m, 2H), 5.28 (dd, 1H, *J* = 9.4, 9.8), 5.18 (dd, 1H, *J* = 4.1, 10.0), 4.62 (dd, 1H, *J* = 3.1, 3.5), 4.58 (dd, 1H, *J* = 2.4, 7.9), 4.29 (dd, 1H, *J* = 2.4, 5.1), 4.24–4.22 (m, 2H), 4.15 (dd, 1H, *J* = 2.8, 11.9), 3.91 (dd, 1H, *J* = 5.5, 6.1), 3.74–3.69 (m, 2H), 3.60 (dd, 1H, *J* = 6.2, 9.2), 2.11 (s, 3H), 2.06 (s, 3H), 2.04 (s, 3H), 1.76 (s, 3H), 1.53 (s, 3H), 1.42 (s, 3H), 1.33 (s, 3H), 1.32 (s, 3H).

Compound 25

Yield: 76%. Syrup. $[\alpha]_D^{25}$ –34.3 (*c* 0.3, EtOAc). ^{1}H NMR [$(CD_3)_2CO$)] δ: 5.61 (d, 1H, *J* = 2.2), 5.44 (d, 1H, *J* = 5.0), 5.20 (dd, 1H, *J* = 4.0, 10.0), 4.97 (dd, 1H, *J* = 9.7, 9.8), 4.65 (dd, 1H, *J* = 2.4, 4.0), 4.60 (dd, 1H, *J* = 2.0, 7.9), 4.32 (dd, 1H, *J* = 2.2, 4.9), 4.23 (dd, 1H, *J* = 1.4, 7.9), 3.91 (m, 1H), 3.69 (m, 1H), 3.64 (dd, 1H, *J* = 5.6, 10.1), 3.56 (dd, 1H, *J* = 6.7, 9.8), 2.03 (s, 6H), 1.66 (s, 3H), 1.47 (s, 3H), 1.36 (s, 3H), 1.31 (s, 3H), 1.30 (s, 3H), 1.16 (d, 3H, *J* = 6.2). ^{13}C NMR ($CDCl_3$) δ: 169.6, 169.5, 123.8, 108.7, 108.1, 97.3, 96.3, 77.3, 71.0, 70.7, 70.5, 66.9, 61.4, 25.5, 24.8, 24.3, 23.8, 19.8, 16.9. HR-MS (ESI) anal. calcd. for $C_{24}H_{36}NaO_{13}$ [M + Na]: 555.2048; found: 555.2037.

Compound 26

Yield: 78%. Syrup. $[\alpha]_D^{25}$ –18.5 (*c* 0.2, EtOAc). ^{1}H NMR [$(CD_3)_2CO$] δ: 5.72 (d, 1H, *J* = 5.3), 5.44 (d, 1H, *J* = 4.9), 5.13 (dd, 1H, *J* = 2.8, 2.8), 4.86 (dd, 1H, *J* = 2.0, 9.5), 4.60 (dd, 1H, *J* = 2.4, 7.9), 4.45 (m, 1H), 4.32 (dd, 1H, *J* = 2.4, 5.2), 4.25 (dd, 1H, *J* = 1.8, 7.9), 4.15 (d, 2H, *J* = 4.4), 3.99 (m, 1H), 3.87 (m, 1H), 3.67 (dd, 1H, *J* = 6.3, 9.7), 3.52 (dd, 1H, *J* = 6.5, 9.7), 2.05 (s, 6H), 2.01 (s, 3H), 1.67 (s, 3H, CH_3), 1.45 (s, 3H), 1.37 (s, 3H), 1.31 (s, 3H), 1.30 (s, 3H).

Compound 27

Yield: 78%. Syrup. $[\alpha]_D^{25}$ +9.5 (*c* 0.2, EtOAc). ^{1}H NMR [$(CD_3)_2CO$] δ: 5.87 (d, 1H, *J* = 4.9), 5.45 (dd, 1H, *J* = 4.9), 5.40 (dd, 1H, *J* = 2.5, 2.9), 5.07 (dd, 1H, *J* = 3.5, 6.4), 4.61 (dd, 1H, *J* = 2.2, 7.8), 4.43–4.40 (m, 2H), 4.27 (m, 1H), 4.18 (dd, 1H, *J* = 7.2, 11.5), 4.10 (dd, 1H, *J* = 5.5, 11.3), 4.04 (dd, 1H, *J* = 7.2, 14.1), 3.90 (dd, 1H, *J* = 4.9, 6.7), 3.68 (m, 1H), 3.55 (m, 1H), 2.13–2.01 (m, 9H), 1.63 (s, 3H), 1.46 (s, 3H), 1.37 (s, 3H), 1.31 (s, 3H), 1.30 (s, 3H).

Compound 28

Yield: 80%. Syrup. $[\alpha]_D^{25}$ +10 (*c* 0.3, EtOAc). ^{1}H NMR ($CDCl_3$) δ: 7.34–7.26 (m, 15H), 5.39 (d, 1H, *J* = 2.5), 5.27 (dd, 1H, *J* = 9.6, 9.6), 5.12 (dd, 1H, *J* = 3.9, 9.8), 4.90 (dd, 2H, *J* = 7.8, 10.9), 4.82 (d, 1H, *J* = 11.0), 4.77 (d, 1H, *J* = 11.0), 4.69 (d, 1H, *J* = 11.0), 4.62 (d, 1H, *J* = 10.9), 4.48 (dd, 1H, *J* = 2.9, 3.3), 4.28 (d, 1H, *J* = 7.8), 4.23 (dd, 1H, *J* = 5.1, 12.3), 4.14 (dd, 1H, *J* = 2.6, 12.2), 3.75 (d, 1H, *J* = 8.8), 3.68–3.60 (m, 3H), 3.55 (s, 3H), 3.51 (d, 1H, *J* = 9.2), 3.41 (m, 2H), 2.07 (s, 3H), 2.04 (s, 3H), 2.00 (s, 3H), 1.74 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 170.6, 170.3, 169.4, 138.6, 138.5, 138.3, 128.5, 128.4, 128.1, 128.0, 127.9, 127.8, 127.7, 127.6, 124.2, 104.6, 97.4, 84.6, 82.3, 77.7, 76.4, 75.6, 74.9, 74.7, 73.8, 71.5, 70.3, 65.7, 62.5, 61.8, 57.0, 24.4, 20.7, 20.6. HR-MS (ESI) anal. calcd. for $C_{42}H_{50}NaO_{15}$ [M + Na]: 817.3042; found: 817.3018.

Molecular dynamics simulations of *N*-methylacetamide (NMA) in water by the ABEEM/MM model

Ping Qian, Li-Nan Lu, and Zhong-Zhi Yang

Abstract: The *N*-methylacetamide (NMA) is a very interesting kind of compound and often serves as a model of the peptide bond. The interaction between NMA and water provides a convenient prototype for the solvation of peptides in aqueous solutions. We have carried out molecular dynamics (MD) simulations of a NMA molecule in water under 1 atm and 298 K. The simulations make use of the newly developed NMA–water fluctuating charge ABEEM/MM potential model (Yang, Z. Z.; Qian, P. *J. Chem. Phys.* **2006,** *125,* 064311), which is based on the combination of the atom-bond electronegativity equalization method (ABEEM) and molecular mechanics (MM). This model has been successfully applied to NMA–water gas clusters, $NMA(H_2O)_n$ (n = 1–6), and accurately reproduced many static properties. For the NMA–water ABEEM/MM potential model, two characters must be emphasized in the simulations. Firstly, the model allows the charges in system to fluctuate, responding to the ambient environment. Secondly, for two major types of intermolecular hydrogen bonds, which are the hydrogen bond forming between the lone-pair electron on amide oxygen and the water hydrogen, and the one forming between the lone-pair electron on water oxygen and the amide hydrogen, we take special treatments in describing the electrostatic interaction by the use of the parameters $k_{lpO=,H}$ and $k_{lpO-,HN-}$, respectively, which explicitly describe the short-range interaction of hydrogen bonds in the hydrogen bond interaction region. All sorts of properties have been studied in detail, such as, radial distribution function, energy distribution, ABEEM charge distribution and dipole moment, and so on. These simulation results show that the ABEEM/MM-based NMA–water potential model appears to be robust, giving the solution properties in excellent agreement with other dynamics simulations on similar systems.

Key words: ABEEM/MM model, atom-bond electronegativity equalization method (ABEEM), molecular mechanics (MM), *N*-methylacetamide (NMA) aqueous solution, hydrogen bond.

Résumé : Le *N*-méthylacétamide (NMA) est un type de composé très intéressant qui est souvent utilisé comme modèle pour la liaison peptidique. L'interaction entre le NMA et l'eau fournit un prototype approprié pour la solvatation des peptides en milieu aqueux. On a effectué des simulations à l'aide de calculs de dynamique moléculaire (DM) pour une molécule de NMA dans l'eau sous une atmosphère et à 298 K. Les simulations ont été faites en utilisant le modèle de potentiel MEELA/MM de charge fluctuante développée récemment pour les complexes NMA–eau (Yang, Z. Z.; Qian, P. *J. Chem. Phys.* **2006,** *125,* 064311), qui est basé sur la combinaison de la méthode d'égalisation de l'électronégativité de la liaison atomique (MEELA) et de la mécanique moléculaire (MM). Cette méthode a été appliquée avec succès pour des agrégats gazeux d'eau et de NMA, $NMA(H_2O)_n$ (n = 1–6) et elle a permis de reproduire correctement plusieurs propriétés statiques. Pour le modèle de potentiel MEELA/MM de l'eau et du NMA, on dont tenir particulièrement compte de deux caractères dans les simulations. Premièrement, le modèle permet de faire fluctuer les charges du système afin de correspondre à l'environnement ambiant. Deuxièmement, pour deux types importants de liaisons hydrogènes intermoléculaires, soit la liaison hydrogène reliant la paire d'électrons libre de l'oxygène de l'amide et l'hydrogène de l'eau et celle entre la paire d'électron libre de l'atome d'oxygène de l'eau et l'hydrogène de l'amide, des traitements spéciaux sont appliqués pour décrire l'interaction électrostatique à l'aide, respectivement, des paramètres $k_{lpO=,H}$ et $k_{lpO-,HN-}$, qui décrivent explicitement l'interaction à faible distance de l'atome d'hydrogène dans la région d'interaction de la liaison hydrogène. On a étudié un grand nombre de propriétés en détail, telle la fonction de distribution radiale, la distribution d'énergie la distribution de charge MEELA, le moment dipolaire et autres. Ces résultats de simulation montrent que le modèle de potentiel de l'eau et du NMA à base de MEELA/MM semble approprié pour prédire des propriétés de solutions en excellent accord avec d'autres simulations dynamiques de systèmes semblables.

[Traduit par la Rédaction]

Introduction

The nature of the amide functional group has long been of fundamental interest because of its presence as a repeat unit in proteins and peptides. For understanding the structural properties and biological functions of proteins, it is important to know how they interact with an aqueous environment through hydrogen bonds. *N*-Methylacetamide (NMA), one of the simplest representative models for the main chain of proteins, has been extensively studied in this aspect. So far, a substantial number of experimental investigations[1–8] on the important structural information of NMA have been obtained, such as gas-phase electron diffraction,[1] and X-ray diffraction[2] in a crystal, and so forth.

To the best of our knowledge, the two major types of intermolecular hydrogen bonds[9–11] that occur in amide–water complexes are C=O···H–O–H and N–H···OH_2, respectively. The former forms between the amide oxygen in the NMA molecule and the water hydrogen, the latter forms between the amide hydrogen and the water oxygen. Both are the key to the stabilities of the secondary and tertiary structures of proteins in aqueous phase. These special types of nonbonded interactions have been studied by ab initio[12–20] and molecular mechanics methods.[20–35] Ab initio calculations at different levels and methods have been carried out to investigate the intermolecular interaction of the NMA–water system, and yield theoretical structures and other static properties. Dobbs and co-workers[14] investigated the strengths of the hydrogen bonds between a water molecule and model amide NMA by using ab initio molecule orbital theory, and performed the extensive calculations at the MP2 level with correlation consistent basis sets. Han and Suhai[15] studied the conformations, the hydrogen-bonding effects, and the stabilities of different methyl group orientations of isolated *trans*- and *cis*-NMA and of NMA$(H_2O)_n$ (n = 1–3) complexes, using all kinds of density functional theory (DFT) methods, such as B3LYP, BLYP, and 6-311++G(d,p) basis set. Recently, to fit the hydrogen bonding parameters for the molecular mechanics force field MM4, Langley and Allinger[20] performed the calculations for the amide–water and formamide dimer systems at the MP2/6-311++G(2d,2p) level. Currently, the majority of potential functions for studying amide–water systems employ rigid potential models.[20–30] Studies of combining quantum mechanical and molecular mechanical (QM/MM) simulations of *N*-methylacetamide in aqueous solution have been carried out to investigate the charge polarization of the solute and to explore the feasibility of hybrid QM/MM calculations using ab initio methods by Gao and Freindorf.[31] In addition, the fluctuating charge models in combination with molecular mechanics have been widely developed in the past few years. For example, Rick et al.[32,33] have developed the dynamical fluctuating charge (FQ) force field to study the aqueous solution of amides, and Patel et al.[34,35] have developed the CHARMM fluctuating charge (FQ) force field to research the protein simulations. Lately, based on the atom-bond electronegativity equalization method (ABEEM)[36–42] fused into molecular mechanics (MM), Yang and co-workers[43–50] have reported the ABEEM/MM fluctuating charge model, which has been successfully applied to water clusters,[43] ion–water clusters,[45] and their molecular dynamics simulations,[44,46,47] and have also been engaged in the research on conformations of organic molecules and peptides,[48–50] and so forth.

The purpose of this paper is to carry out a systematic investigation of molecular dynamics simulations on the NMA molecule in liquid water using the previously constructed NMA–water ABEEM/MM potential model. The correlating properties characterizing the NMA–water solution include radial distribution functions, coordination numbers, hydrogen bonds, energy distribution, ABEEM charges, and dipole moments, and so on, and the results are comparable with those obtained from other molecular dynamics simulations.

Theoretical method

The ABEEM/MM model for NMA–water system

Based on the combination of ABEEM and MM, the potential energy, $E_{\mathrm{ABEEM/MM}}$, of an amide–water system is expressed as

$$[1] \qquad E_{\mathrm{ABEEM/MM}} = \sum_{\text{bonds}} E_{\mathrm{b}} + \sum_{\text{angles}} E_{\theta} + \sum_{\text{torsions}} E_{\mathrm{tors}} + \sum_{\text{imptors}} E_{\mathrm{imptors}} + \sum_{\text{nonbonded}} (E_{\mathrm{vdw}} + E_{\mathrm{elec}})$$

where E_{b}, E_{θ}, E_{tors}, E_{imptors}, E_{vdw}, and E_{elec} stand for the energies of individual bond stretching, angle bending, dihedral angle torsion, improper torsion, van der Waals, and electrostatic interaction, respectively. This moment, the cross-terms, like stretch-bend coupling, stretch-torsion coupling, and so forth, are omitted in eq. [1]. The above equation can be concretely expressed as follows:

$$
\begin{aligned}
[2]\quad E = & \sum_{\text{bonds}\in\text{NMA}} k_r (r - r_{eq})^2 + \sum_{\text{bonds}\in \text{H}_2\text{O}} D[e^{-2\alpha(r-r_{eq})} - 2e^{-\alpha(r-r_{eq})}] + \sum_{\text{angles}} f_\theta (\theta - \theta_{eq})^2 \\
& + \frac{1}{2}\sum_{\text{torsions}} \left[v_1(1+\cos\phi) + v_2(1-\cos 2\phi) + v_3(1+\cos 3\phi)\right] + \sum_{\text{improper torsions}} v(1-\cos 2\phi) \\
& + \left[\sum_{\substack{a\\a,b\in\text{NMA}}}\sum_{b} \varepsilon_{a,b}\left[\left(\frac{r_{\min_{a,b}}}{r_{a,b}}\right)^{12} - 2\times\left(\frac{r_{\min_{a,b}}}{r_{a,b}}\right)^{6}\right] f_{a,b} + \sum_{c}\sum_{\substack{d\geq c+6\\c,d\in\text{NMA}}} k\frac{q_c q_d}{R_{c,d}}\right] \\
& + \sum_{i=1}^{N_{mol}}\sum_{j=1(\neq i)}^{N_{mol}}\left\{\sum_a\sum_b \varepsilon_{ia,jb}\left[\left(\frac{r_{\min_{ia,jb}}}{r_{ia,jb}}\right)^{12} - 2\times\left(\frac{r_{\min_{ia,jb}}}{r_{ia,jb}}\right)^{6}\right] + \sum_{H\in i}\sum_{\substack{lp\in j\\H,lp\text{inHBIR}}} k_{H,lp}(R_{iH,j(lp)})\frac{q_{iH}q_{j(lp)}}{R_{iH,j(lp)}}\right. \\
& + k\left(\frac{1}{2}\sum_a\sum_b\frac{q_{ia}q_{jb}}{R_{ia,jb}} + \frac{1}{2}\sum_m\sum_k\frac{q_{im}q_{jk}}{R_{im,jk}} + \frac{1}{2}\sum_{a-b}\sum_{g-h}\frac{q_{i(a-b)}q_{j(g-h)}}{R_{i(a-b),j(g-h)}} + \frac{1}{2}\sum_{\sigma m=n}\sum_{\sigma k=l}\frac{q_{i(\sigma m=n)}q_{j(\sigma k=1)}}{R_{i(\sigma m=n),j(\sigma k=1)}}\right. \\
& + \frac{1}{2}\sum\sum_{\pi m=n\,\pi k=l}\frac{q_{i(\pi m=n)}q_{j(\pi k=1)}}{R_{i(\pi m=n),j(\pi k=1)}} + \frac{1}{2}\sum_{lp}\sum_{lp'}\frac{q_{i(lp)}q_{j(lp')}}{R_{i(lp),j(lp')}} + \sum_a\sum_{g-h}\frac{q_{ia}q_{j(g-h)}}{R_{ia,j(g-h)}} + \sum_a\sum_m\frac{q_{ia}q_{jm}}{R_{ia,jm}} + \sum_a\sum_{\sigma m=n}\frac{q_{ia}q_{j(\sigma m=n)}}{R_{ia,j(\sigma m=n)}} \\
& + \sum_a\sum_{\pi m=n}\frac{q_{ia}q_{j(\pi m=n)}}{R_{ia,j(\pi m=n)}} + \sum_a\sum_{\substack{lp\\(a\neq H,\,H\text{ in HBIR}\\\text{and }lp\text{ not in HBIR})}}\frac{q_{ia}q_{j(lp)}}{R_{ia,j(lp)}} + \sum_m\sum_{a-b}\frac{q_{im}q_{j(a-b)}}{R_{im,j(a-b)}} + \sum_m\sum_{\sigma k=l}\frac{q_{im}q_{j(\sigma k=1)}}{R_{im,j(\sigma k=1)}} + \sum_m\sum_{\pi k=l}\frac{q_{im}q_{j(\pi k=1)}}{R_{im,j(\pi k=1)}} \\
& + \sum_m\sum_{lp}\frac{q_{im}q_{j(lp)}}{R_{im,j(lp)}} + \sum_{a-b}\sum_{\sigma m=n}\frac{q_{i(a-b)}q_{j(\sigma m=n)}}{R_{i(a-b),j(\sigma m=n)}} + \sum_{a-b}\sum_{\pi m=n}\frac{q_{i(a-b)}q_{j(\pi m=n)}}{R_{i(a-b),j(\pi m=n)}} + \sum_{a-b}\sum_{lp}\frac{q_{i(a-b)}q_{j(lp)}}{R_{i(a-b),j(lp)}} \\
& \left.\left. + \sum_{\sigma m=n}\sum_{\pi k=l}\frac{q_{i(\sigma m=n)}q_{j(\pi k=1)}}{R_{i(\sigma m=n),j(\pi k=1)}} + \sum_{\sigma m=n}\sum_{lp}\frac{q_{i(\sigma m=n)}q_{j(lp)}}{R_{i(\sigma m=n),j(lp)}} + \sum_{\pi m=n}\sum_{lp}\frac{q_{i(\pi m=n)}q_{j(lp)}}{R_{i(\pi m=n),j(lp)}}\right)\right\}
\end{aligned}
$$

In eq. [2], the Harmonic and Morse potentials are used to represent the bond stretching energies, E_b, of the NMA molecule and water molecule, respectively, where k_r is the force constant of bond stretching of the NMA molecule, the O–H bond dissociation energy, D, of the water molecule is 529.6 kcal/mol and α is related to the bond force constant ($\alpha = \sqrt{f_b/2D}$, f_b is the bond force constant), and r_{eq} is the equilibrium bond length. The harmonic potential is employed to represent the angle bending, E_θ, where f_θ is the angle force constant and θ_{eq} is the equilibrium bond angle. E_{tors} is almost always expressed as a cosine series expansion, and the energy term $E_{imptors}$ of improper torsion is also applied in this potential model, where v_1, v_2, v_3, and v represent the force constants of the dihedral angle torsion and improper torsion, respectively. r, θ, and ϕ stand for the actual values of bond lengths, bond angles, and dihedral angles.

The nonbonded interactions existing in the amide molecule are represented by a sum of the Lennard–Jones and Coulomb terms, where standard combining rules are used: $\varepsilon_{a,b} = (\varepsilon_{aa}\varepsilon_{bb})^{1/2}$, $r_{\min\,a,b} = \frac{1}{2}(r_{\min\,a-a} + r_{\min\,b-b})$. $\varepsilon_{a,b}$ and $r_{\min\,a,b}$ are the Lennard–Jones well-depth and minimum energy distance for the interaction between atoms a and b belonging to the NMA molecule. Furthermore, among all pairs of atoms ($a < b$) separated by three or more bonds, $f_{a,b}$ = 1.0, except for the intramolecular 1,4 interactions for which $f_{a,b}$ = 0.5. For the intramolecular electrostatic interactions in the NMA molecule, as far as all the site points of the system are concerned, we consider interactions of the site points that have greater than or equal to 1,6 bonding relationships. Then, in eq. [2], q_c and q_d are point charges, which have the above mentioned bonding relationship. $R_{c,d}$ is the distance between the site points c and d in the NMA molecule, k = 0.57, which is an overall optimized correction coefficient.

For the amide–water and water–water intermolecular interactions, the electrostatic interaction is taken from the last term of eq. [A1] in ref. 50, in which the outline of the ABEEM for describing NMA in water are detailed. This is the essence of the ABEEM fused into MM, which is to take the ABEEM charges of all atoms, bonds, and lone-pair electrons in the system to the intermolecular electrostatic interactions term of MM. In eq. [2], q is the charge on every site point of the system and R is the distance between sites. $R_{iH,j(lp)}$ is the distance between the hydrogen atom belonging to molecule i and the lone-pair electron belonging to molecule j in the hydrogen bond interaction region (HBIR), accordingly, the parameter $k_{H,lp}(R_{iH,j(lp)})$ is used to describe the electrostatic interaction between the hydrogen atom and the lone-pair electron in the HBIR. First of all, we use the ABEEM method to compute the charges of all atoms, bonds,

and lone-pair electrons, and then we use eq. [2] to compute the total energy of the system. It is worth noting that the last term of eq. [2] denotes the solute–solvent interaction energy when molecule *i* belongs to NMA and molecule *j* doesn't belong to NMA.

When there is a change of bond length, bond angle, or dihedral angle, or a change of the relative position between the NMA and water molecules, we recalculate the charges by using the ABEEM method from time to time, and then recalculate the total potential energy by eq. [2]. Therefore, the combination of ABEEM and molecular mechanics (MM) cannot only truly reflect the electrostatic polarization by way of the fluctuating charges, but also well-describes the NMA–water interaction explicitly. The detailed information concerning the ABEEM/MM-7P water and ABEEM/MM NMA–water potential models can be found in refs. 43 and 50. The above parameters all derive from the previous studies[43,50] on small water clusters and NMA–water clusters, and are directly transferred to this work without any modification to simulate the correlated dynamics properties of NMA aqueous solution, and further test the reasonableness of this potential model and the correctness and transferability of parameters.

Computational details

All our molecular dynamics (MD) simulation runs were performed on the SGI-3700 Server by using the modified Tinker program in the canonical (constant temperature and volume, NVT) ensemble with Berendsen thermostats and the velocity Verlet integrator. The SETTLE algorithm was used to constrain the water geometry, and the SHAKE algorithm was applied to constrain the bond length of NMA. All the runs used the cubic periodic boundary conditions, one *trans*-NMA molecule and 208 water molecules in a cubic box of size 18.409 Å, and a time step of 1 fs. The density of solvent was set to the experimental value for the temperature 298 K by adjusting the volume of the box. The way to deal with the nonbonded interactions was to use a nonbonded cutoff and to apply the minimum image convention. The cutoff distance was 9.0 Å for all different liquid structures, and the nonbonded interactions were truncated using the force shifting where the calculated forces and energies were smoothly shifted to zero at the cutoff distance. The fact that charges are or are not allowed to transfer between different molecules or just between charged site points on the same molecule makes some difference for the two ABEEM/MM-7P water models.[43] For the computed properties of gas-phase small water clusters, the ABEEM/MM-7P-2 model, which constrains the charge neutrality and electronegativity equalization on each water molecule, gives better results, to some degree, than those by the ABEEM/MM-7P-1 model, which constrains the charge neutrality and electronegativity equalization on the entire water system, especially for the computation of the dimer dipole moment. Therefore, in the present applications, we only considered a charge neutrality constraint on each molecule and there is no charge transfer between molecules and the effective chemical potential of each single bond atom, each double bond atom, each single bond, each σ bond region of double bond, each π bond region of double bond, and each lone-pair electron are to be equal only within a molecule. Rather than solve for the charges exactly at each time step, we recalculated the charges of each site point every picosecond, in consideration of the expensive computational time. Equilibration was performed over 400 ps followed by the evaluation of 600 ps for averaging.

Results and discussions

Radial distribution function

The solute–solvent structures can be well-characterized through radial distribution functions (rdfs) and energy distribution in the following sections.

All rdfs $g_{xy}(r)$ give the probability of finding an atom of type *y* at a distance *r* from an atom of type *x*. Figures 1–4 show the rdfs between water and NMA molecules, indicating the nature of the solvent structure around the amide. These are quite similar to those computed by Rick and Berne[32] using the rigid molecule model with constant intramolecular shielded interactions based on the atom-centered Slater orbital overlaps. The carbonyl oxygen – water oxygen (OO) and carbonyl oxygen – water hydrogen (OH) rdfs are shown in Fig. 1 for the aqueous solution of NMA. The OH rdf has well-defined peaks at 2.2 and 3.4 Å, while the first peak for the OO rdf is at 2.9 Å. This pattern is as expected for hydrogen bonding to the carbonyl oxygen with water molecules acting as the hydrogen bond donors. The hydrogen bonds are not bifurcated in that the two peaks of the OH rdf show that the near and far hydrogens are roughly separated by the H–H distance in a water monomer. The first peaks of OO and OH rdfs can be integrated to obtain estimates of the number of nearest neighbors for the carbonyl oxygen. Integration to the first minima for OO and OH rdfs at 3.8 and 2.7 Å yields 2.1 water neighbors for NMA. On the basis of the shorter O–H distance and further analyses below, the two water molecules may be assigned as hydrogen bonded to the carbonyl oxygen. Of course, this is a very reasonable result.[51,52] Moreover, the OO rdf also has the second peak between 4.0 and 6.4 Å. The water molecules in the second shell around the carbonyl oxygen contribute to this peak as well as the first shell waters near other groups. In particular, the peak near 5.5 Å for the OO rdf corresponds to the expected position for a water molecule hydrogen bonded to the trans NH group.

The hydrogen bonding at the amino end is most clearly represented in amide hydrogen (H_N) – water oxygen and H_N – water hydrogen rdfs (Figs. 2a and 2b). The first peak positions show that the oxygen is closer to the H_N than the hydrogen, so the water molecule is the hydrogen bond acceptor. Integrating the first peak in the HO rdf to the minimum at 3.0 Å reveals 0.9 water oxygen that is in the hydrogen bonding range of the H_N in NMA.

The rdfs involving the carbonyl carbon and the nitrogen in the NMA molecule have less interesting structure and provide little additional insight. Thus, they are not shown here. Rdfs involving the methyl groups in NMA are shown in Figs. 3–4. For NMA, the C_NO and C_CO rdfs are all typical for terminal methyl groups with adjacent secondary atoms as found for *n*-alkanes in water.[53] Integrations to the first minima for the C_NO and C_CO rdfs at 5.0 Å yield 14 and 13 neighboring water molecules, respectively. The difference in solvent structures around hydrophilic and hydrophobic groups is well-contrasted by comparing Figs. 1–2

Fig. 1. Carbonyl oxygen – water oxygen (a) and carbonyl oxygen – water hydrogen (b) rdfs computed for NMA in water using the ABEEM/MM model.

with Figs. 3–4. The sharp peaks of Figs. 1–2 at short range with small areas characterize the geometrical restrictions accompanying hydrogen bonds, while the broad peaks of Figs. 3–4 centered near 3.5 Å with large areas reflect the caging of water molecules around hydrophobic groups.

Energy distribution

Some detail of the solute–solvent energy is revealed in the distribution for total solute–solvent interaction energy (Fig. 5). It can be seen that the solute experiences a continuum of energetic environments covering the range of about –21 kcal/mol. Thus, the instantaneous number of hydrogen bonds to the solute undoubtedly shows substantial variation in the solution at 298 K. At the same time, the result of –21 kcal/mol is larger than the value of –25 kcal/mol from the Monte Carlo simulation by Jorgensen and Swenson.[27]

ABEEM charge distribution and dipole moment

The polarization effects in aqueous solution can be described by the changes of dipole moments of NMA and its neighboring water molecules. The computed average dipole moment for NMA in solution state is 5.49 D (1 D = 1×10^{-18} statC cm), higher than the 3.62 D in gas state[50] with the ABEEM/MM model. This prediction is a little higher than the values obtained from electronic structure calculations using the continuum dielectric model and from an ab initio study using explicit TIP3P water, the former giving 5.33 D[19] and the latter giving 5.18 D,[54] but more reasonable than 7.2 D[35] calculated from the CHARMM fluctuating charge model.

Compared with other potentials, the ABEEM/MM model can fully consider the changes of charge distributions of all atoms, bonds, and lone-pair electrons upon the different ambient environments, and explicitly give the quantitative charges. The average charge distributions of each site point for the NMA molecule in MD simulation are listed in Table 1. At the same time, the table presents a comparison between the gas and aqueous results. The agreement for both the gas-phase and the aqueous charges is very good. The first largest difference takes place in the hydrogen bond interaction regions. For example, the lone-pair electrons (q_{lpO2} and $q_{lp'O2}$) on carbonyl oxygen and water hydrogens can form the hydrogen bonds, which make the charges of lone-pair electrons on the carbonyl oxygen obviously polarized. Therefore, two

Fig. 3. Rdfs involving the methyl on carbon and oxygen (a) and hydrogen of water (b) computed for NMA in water using the ABEEM/MM model.

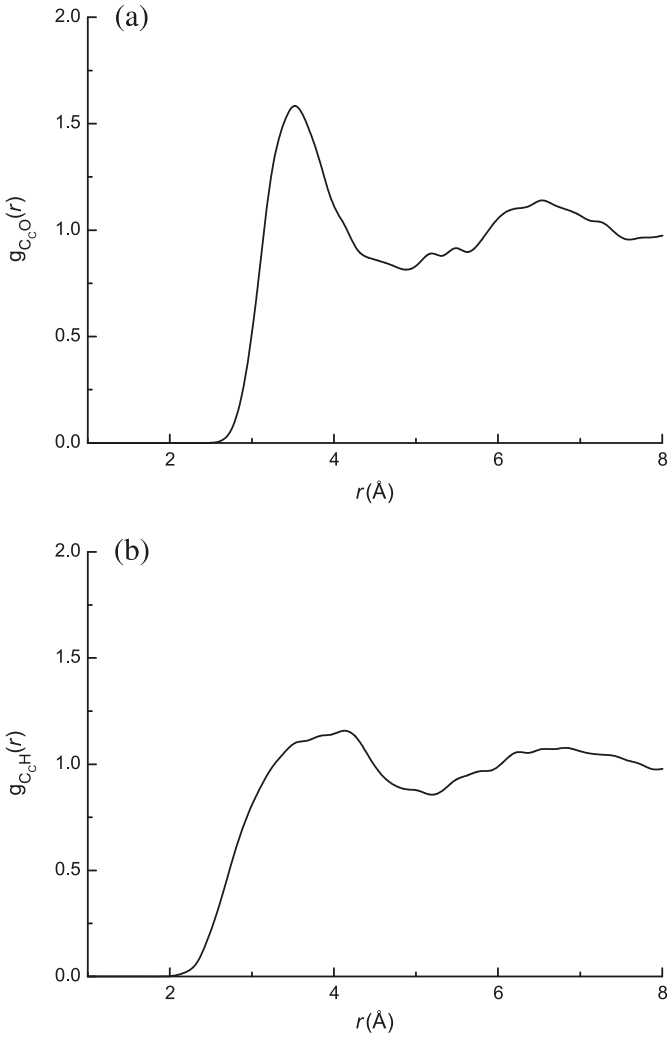

Fig. 4. Rdfs involving the methyl on nitrogen and oxygen (a) and hydrogen of water (b) computed for NMA in water using the ABEEM/MM model.

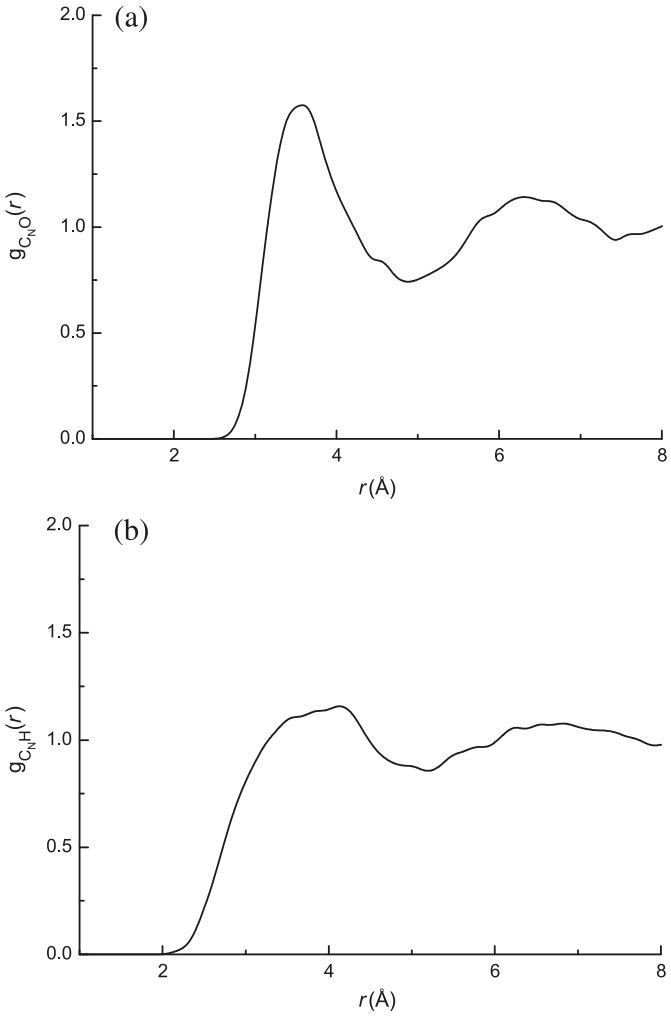

lone-pair electrons ($q_{lp\mathrm{O2}}$ is –0.2075 and $q_{lp'\mathrm{O2}}$ is –0.2053) of the O atom exhibit relatively larger absolute charges than the corresponding values (–0.1704 and –0.1647) of the monomer in the gas phase. Similarly, the amide hydrogen and the lone-pair electron on the water oxygen can also form the hydrogen bond, which also makes the charge of the amide hydrogen obviously polarized. Moreover, the second largest difference is for the charges on the methyl groups. In both the gas phase and aqueous phase, the charges on the methyl hydrogens (q_{H7} and q_{H11}) are about 0.03 $\sim$ 0.04 e larger than the gas results, which indicates that two methyl groups in the NMA molecule are found to have different capabilities in forming weak C–H···O contacts in aqueous solution.[55] In contrast, the fixed-charge models use fixed charges. Thus, the charges used in the simulations based on fixed-charge models must reflect the average or mean field charge values for the particular phase and are not transferable to different thermodynamic states or heterogeneous environments. The aforementioned results show that the ABEEM/MM fluctuating charge model can accurately describe aqueous phase properties, and also correctly reflect the charge redistribution with the changed

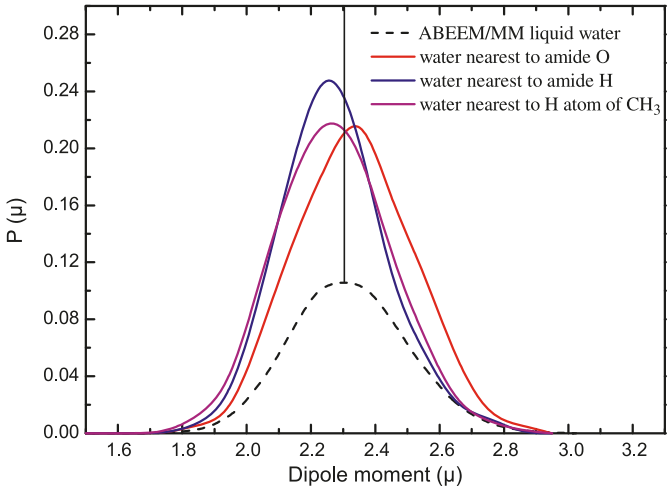
Note: q_{C1}, q_{O2}, q_{N3}, and q_{H4} are the charges on the sites of carbonyl C, carbonyl O, amide N, and amide H of the peptide bond, q_{C5}, q_{H6}, q_{H7}, and q_{H8} are the charges of the atoms on (C)CH_3, q_{C9}, q_{H10}, q_{H11}, and q_{H12} are charges of the atoms on (N)CH_3, $q_{\sigma C=O}$, $q_{\sigma C-N}$, q_{C-C}, q_{C-N}, and q_{H-C} are the bond charges on the sites of the ratio of covalent atomic radii of the directly bonded atoms, q_{lpO} is the charge on the site 0.74 Å from the amide O, $q_{\pi C=}$, $q_{\pi O=}$, and $q_{\pi N\sim}$ are the charges of the π bond region of the double bond atoms C, O, and amide N.

ambient environment and make a compensation for the shortages of the fixed-charge models.

Of particular interest in the application of the polarizable model to peptide simulation is the polarization of the solvent in the vicinity of the solute. That structural and dynamics properties of vicinal water are different from those of the bulk is well-documented. Here, we show the polarization responses for vicinal and bulk water molecules. Figure 6 shows the average dipole moment distributions of water molecules in a shell between 1.0 and 2.9 Å from the center of mass of the solute and in the bulk, respectively. As one would anticipate, the average dipole moment of 2.35 D for water molecules nearest to the carbonyl oxygen is higher than the bulk water value of 2.30 D. By comparison, Rick and Berne[32] reported a higher average dipole moment of 2.72 D for water molecules nearest to the carbonyl oxygen

Fig. 6. Average dipole moment distributions of water molecules using the ABEEM/MM model. The solid curve represents the distribution for molecules near the solute, and the broken curve represents that for the bulk-like water.



relative to the bulk value of 2.62 D, and a shift is higher in magnitude than that observed in the present simulations. It is this mutual enhancement of the dipole moment that leads to the strong amide–water interaction as testified in the relevant radial distribution functions (Fig. 1). Water forms stronger hydrogen bonds with the carbonyl oxygen atom of the solute than it does with other atoms of the solute. In particular, the average dipole moments of water molecules neighboring the other solute atoms are all about 2.27 D, less than the bulk value, indicating that these electrostatic interactions are weak.

Conclusions

This contribution presents the results of our current efforts towards developing and implementing a fluctuating charge ABEEM/MM model for use. The fluctuating charge approach has been applied widely, and is no longer a novelty in some respects. In the present work, several key details of dynamics properties of the NMA molecule in liquid water have been studied by classical MD simulation in terms of the ABEEM/MM-based NMA–water potential model. Based on the ABEEM/MM model, the NMA–water interaction potential and the ABEEM-7P water model parameterized by NMA–water clusters and gas-phase water clusters are tested in the aqueous NMA solution simulations. The simulations have been performed at 298 K with the SETTLE algorithm. Although this investigation is far from being complete, the obtained, systematically simulated results display a few important observations. Simulation results with our own potential model, particularly for the liquid structure and the numbers of hydrogen bonds, are in good agreement with those obtained in other molecular simulations. The computed solute–solvent interaction energy is about –21 kcal/mol. The present model also captures the condensed phase polarization, as testified by the shift in average dipole moment distributions of Fig. 6, although the accuracy of such predicted shifts is difficult to assess at this time. The above results are very important, and could provide the important reference

for studies modeling other biomacromolecular systems based on the ABEEM/MM fluctuating charge model, and also provide the reliable evidence for testing the reasonableness of this model and the correctness and transferability of parameters.

A spectral displacement study of cyclodextrin/naphthenic acids inclusion complexes

Mohamed H. Mohamed, Lee D. Wilson, John V. Headley, and Kerry M. Peru

Abstract: The spectral displacement technique has been used to obtain 1:1 β-cyclodextrin (β-CD)/carboxylate anion equilibrium binding constants (K_2) for some complex mixtures of naphthenic acids (NAs) and some examples of single-component NAs in aqueous solution. Three specific examples of single-component NAs were chosen with variable Z values as follows: 2-hexyldecanoic acid ($Z = 0$; S1), *trans*-4-pentylcyclohexanecarboxylic acid ($Z = -2$; S2), and dicyclohexylacetic acid ($Z = -4$; S3). The estimated K_2 values for S1, S2, and S3 are as follows: 1.42×10^3 M^{-1}, 52.2×10^4 M^{-1}, and 13.1×10^4 M^{-1}, respectively. The corresponding K_2 values are 2.34×10^4 M^{-1} and 1.27×10^4 M^{-1} for commercial (Fluka) and industrial (Syncrude) sourced NAs, respectively. The magnitude of K_2 for 1:1 complexes formed between β-CD and S1, S2, or S3 did not correlate with the degree of hydrogen deficiency (Z-series) but there was a correlation with the size of the guest molecules (n) examined in this study. The correlation between complex stability and the relative size of the lipophilic fragments of the guest molecule are related to the importance of the hydrophobic effect for inclusion of such carboxylic acid guest molecules within β-CD.

Key words: spectral displacement, cyclodextrin, carboxylic acids, naphthenic acids, binding constant, hydrophobic hydration, lipophilic surface area.

Résumé : On a fait appel à la technique du déplacement spectral pour déterminer les constantes d'équilibre de fixation (K_2) du complexe 1 :1 β-cyclodextrine/anion carboxylate pour quelques mélanges complexes d'acides naphténiques (AN) et pour quelques exemples d'acides naphténiques particuliers en solution aqueuse. On a choisi trois exemples spécifiques d'acide naphténique possédant des valeurs de Z variables : acide 2-hexyldécanoïque ($Z = 0$; S1), l'acide *trans*-4-pentylcyclohexanecarboxylique ($Z = -2$; S2) et l'acide dicyclohexylacétique ($Z = -4$; S3). Les valeurs de K_2 évaluées pour les composés S1, S2 et S3 sont respectivement égales à $1{,}42 \times 10^3$ M^{-1}, $52{,}2 \times 10^4$ M^{-1} et $13{,}1 \times 10^4$ M^{-1}. Les valeurs correspondantes de K_2 pour les acides naphténiques de source commerciale (Fluka) et produit industrielle (Syncrude) sont respectivement de $2{,}34 \times 10^4$ M^{-1} et $1{,}27 \times 10^4$ M^{-1}. L'amplitude de la valeur K_2 pour les complexes 1 :1 formées entre la β-cyclodextrine et les produits S1, S2 et S3 ne présentent aucune corrélation avec le degré de déficience en hydrogène (série Z), mais il existe une corrélation entre la taille des molécules hôtes (n) examinées dans cette étude. La corrélation entre la stabilité du complexe et la taille relative de chacun des fragments lipophiles des molécules hôtes est liée à l'importance de l'effet hydrophobe pour l'inclusion de tels acides carboxyliques comme molécules hôtes dans la β-CD.

Mots-clés : déplacement spectral, cyclodextrine, acides carboxyliques, acides naphténiques, constante de fixation, hydration hydrophobe, aire de la surface lipophile.

[Traduit par la Rédaction]

Introduction

Naphthenic acids (NAs) are predominantly complex mixtures of saturated alicyclic and aliphatic carboxylic acids with the general formula $C_nH_{2n+Z}O_2$, where n is the number of carbon atoms and $(2n + Z)$ is the number of hydrogen atoms where Z is the hydrogen deficiency; hydrogen loss due to ring structure. Generally, the carboxyl group is attached to a cyclopentane or cylcohexane ring through a methylene group or an alkyl chain containing five or more methylene groups as shown in Fig. 1. The molecular structure, composition, and concentration of NAs are dependent on the source of crude oil.[1–5]

NAs are non-volatile, chemically stable, and possess surface activity. The acid dissociation constants range between 10^{-5} and 10^{-6} M^{-1} and are comparable to typical carboxylic acids (acetic acid = $10^{-4.8}$ M, propionic acid = $10^{-4.9}$ M, and palmitic acid $10^{-4.9}$ M).[5–7] The presence of NAs in petroleum has led to environmental, health, and industrial concerns. NAs are known to be toxic to aquatic organisms, algae, and mammals.[5–8] NAs are suspected endocrine-disrupting substances; however, the toxicological implications of the various types of NAs are not well-understood. Thus, there is a great need to develop improved methods to sequester NAs leachates from aquatic environments, such as

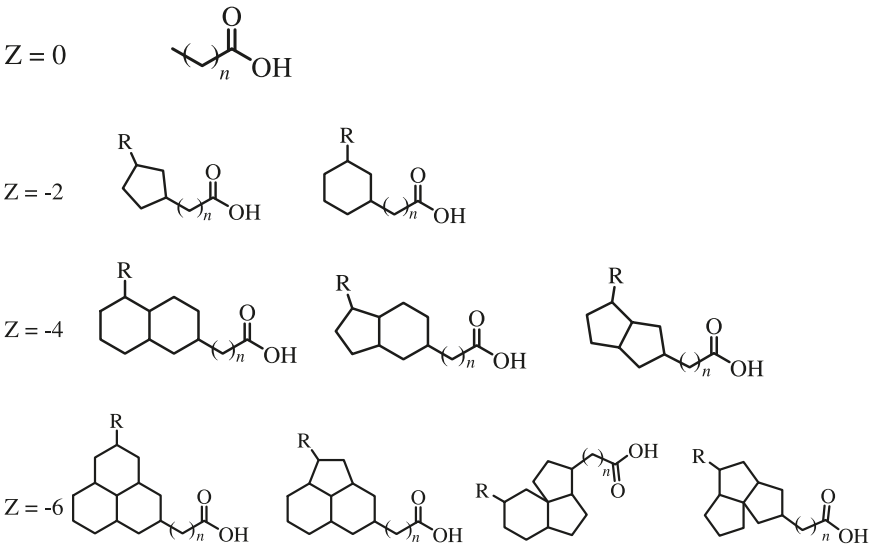
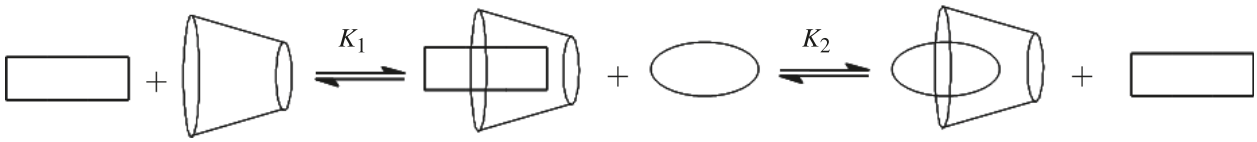


Scheme 1. The formation of a host–guest complex is shown for a β-CD (toroid) and a chromophore guest molecule (rectangle) according to an equilibrium process where K_1 is the equilibrium binding constant. Addition of a non-chromophore guest molecule (oval): the chromophore is replaced and the guest molecule is included into the β-CD according to an equilibrium constant, K_2.



oil-sands tailings ponds, and to alleviate concerns of their deleterious health and environmental effects.

Cylodextrins (CDs) are of interest, in part, because of their ability to form inclusion complexes in aqueous solution. In particular, they are well-known to form relatively stable inclusion complexes with aliphatic and alicyclic carboxylic acids.[9–12] For the latter reason, CDs may display strong binding affinity to NA molecules.

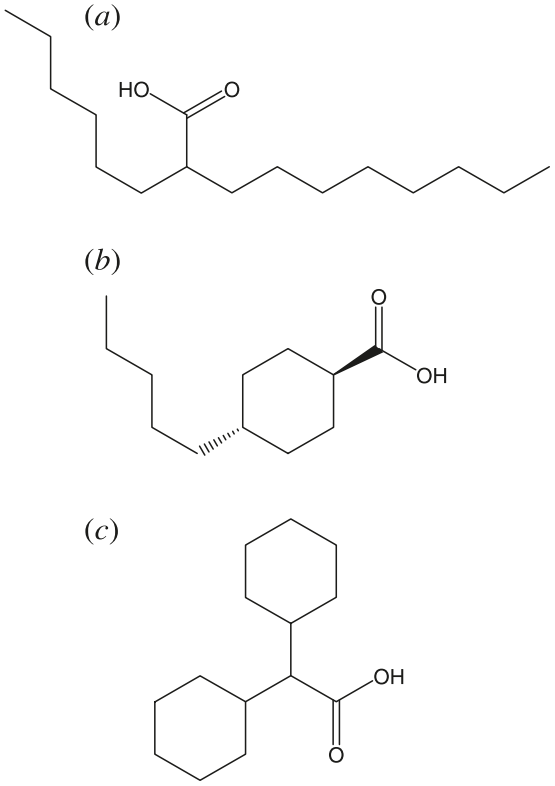
Recently, cyclodextrin-based polymeric materials were used to adsorb NAs from aqueous solutions with considerable success.[13] However, a detailed understanding of the sorption mechanism for polymeric materials requires an understanding of the types of inclusion complexes formed and the magnitude of the binding constants. Thus, this study outlines the use of the spectral displacement technique to study the interaction of β-cyclodextrin (β-CD) with NAs and single-component examples of NAs in aqueous solution, respectively.

Various instrumental methods have been used to examine the nature of the CD/inclusate complexes formed between β-CD and carboxylic acid guest compounds. Among these techniques are ^{1}H NMR,[14] sound velocity,[15] conductivity,[16] surface tension,[17] electrochemical measurements,[18] UV–vis spectrophotometry,[19] and fluorescence measurements.[20] The latter three methods involve direct measurement of bound or free concentrations of inclusates, whereas the other methods involve the measurement of a bulk solution property (time-averaged property consisting of two or more states) that is proportional to some aspect of the complexation process. The apparent discrepancies in the literature between the values of binding constants obtained from different techniques have been attributed to the relative accuracy of the measured variables. However, methods involving the measurement of free or bound inclusate concentration are expected to yield a more accurate estimate of the binding constant.[21]

The spectral displacement technique[22–32] enables determination of the binding constants of spectroscopically transparent compounds, such as NAs, to β-CD. The determination of the binding constants for such complexes involves the measurement of the absorbance changes of a suitable chromophore in the presence of CD and a competing non-chromophoric inclusate. Some examples of the chromophores employed include phenolphthalein (phth),[22–30] methyl orange,[31] and *p*-nitrophenol.[32] Scheme 1 illustrates the two competitive equilibria involved in the spectral displacement technique.

This technique involves certain assumptions and provides good accuracy for the determination of a CD/inclusate binding constant (K_2) values when the relative change in the absorbance of phth between bound and unbound states is large and is directly related to the amount of unbound inclusate. Non-spectroscopic techniques are sometimes susceptible to large errors when K_2 is large ($>10^4$ M^{-1}) because the fraction of unbound species is generally low for this condition and techniques which involve the measurement of macroscopic changes for a total solution property and do not reflect this contribution accurately. Consequently, there are greater uncertainties for the value of K_2 derived from such methods. A further complication arises because of implicit statistical bias in the analysis of the primary data using linearization methods; for example, the inherent assumptions in

Fig. 2. Molecular structures of specific examples of single-component NAs with variable *Z*-values (*Z* = 0, –2, and –4, respectively): (*a*) 2-hexyldecanoic acid (S1), (*b*) *trans*-4-pentylcyclohexanecarboxylic acid (S2), and (*c*) dicyclohexylacetic acid (S3).



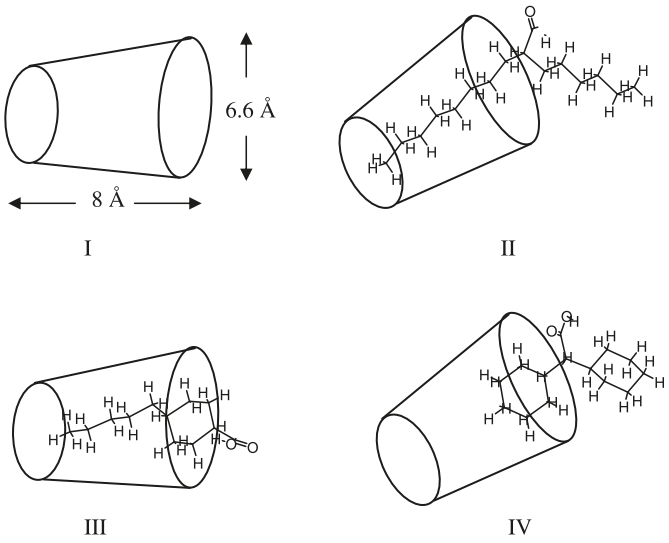
the Benesi–Hildebrand plots are generally not met for strongly bound host–guest systems.[22,33]

This paper presents the results of a determination of the binding constants between β-CD and different types of NAs and some single-component examples of NAs in aqueous solutions at room temperature. The three components chosen to represent examples of NAs with variable *Z* values are 2-hexyldecanoic acid (*Z* = 0; S1), *trans*-4-pentylcyclohexanecarboxylic acid (*Z* = –2; S2), and dicyclohexylacetic acid (*Z* = –4; S3), respectively, as shown in Fig. 2.

Experimental

Absorption measurements were obtained with a double-beam spectrophotometer (Varian CARY 100) at room temperature (295 ± 0.5 K). All solutions were prepared by volume in a 0.1 mol/L sodium hydrogen carbonate buffer adjusted to pH 10.5 with 6 mol/L sodium hydroxide. The concentration of phth (C_{phth}) was maintained at ~ 2×10^{-5} mol/L in all experiments. For the determination of the CD/inclusate binding constants, K_2, the concentration of β-CD ($C_{\beta\text{-CD}}$) was held constant at ~ 3×10^{-4} mol/L, and the concentrations of NAs or single-component NAs (S1, S2, or S3) were varied to exceed the 1:1 molar ratio of the CD/inclusate. A stock solution of phth in ethanol was made and aliquots were utilized to prepare aqueous solutions of phth in buffer. The ethanol/water (0.04%, *v*/*v*)[28] solution was used to increase the solubility of phth. All aqueous solutions were freshly prepared and run within 1.5 h to ensure that the absorbance changes due to any instability of phth at pH 10.5 did not contribute to experimental artefacts. The respective compositions of Fluka and Syncrude NAs were determined using electrospray ionization mass spectrometry (ESI-MS) measurements with a Quattro Ultima mass spectrometer (Micromass, UK) equipped with an electrospray interface operating in the negative-ion mode configuration, as described previously.[13]

Scheme 2. Lipophilic fragments of the guest molecules that are included in β-CD. LSA values are derived from these included fragments. These molecular structures are; β-CD (I), β-CD/S1 (II), β-CD/S2 (III), and β-CD/S3 (IV) complexes, respectively. Note: The relative size of the β-CD torus and the carboxylic acid are not drawn to scale.



β-CD (VWR) was used as received, and the water content was determined using a thermogravimetric analyzer (Q5000, TA Instruments). The water contents were accounted for in the determination of $C_{\beta\text{-CD}}$ where the hydrate content varied from 10.98% to 11.53% (±0.3)% for different samples of β-CD hydrate. 2-Hexyldecanoic acid (S1), *trans*-4-pentylcyclohexanecarboxylic acid (S2), dicyclohexylacetic acid (S3), and Fluka NAs were obtained from Sigma-Aldrich. Syncrude NAs were extracted in bulk from an Athabasca oil-sands tailings pond using a published procedure.[34] Phenolphthalein (phth) (Aldrich) was used as received, since there was no difference in molar absorptivity between the purified and unpurified materials.[28]

A previously described[22] non-linear least-squares (NLLS) fitting procedure was used to determine the 1:1 binding constants, K_1 and K_2, between β-CD and phth and the inclusate, respectively. The method utilizes the Beer–Lambert law and the assumption that the molar absorptivity of the β-CD/phth complex is zero.[24] The following equilibrium and mass-balance relations apply to the competitive equilibrium, as outlined in Scheme 2.

$$[1] \qquad [S]_o = [S] + [CD{-}S] = [S](1 + K_2[CD])$$

$$[2] \qquad [phth]_o = [phth] + [CD{-}phth] = [phth](1 + K_1[CD])$$

$$[3] \qquad [CD]_o = [CD] + [CD{-}S] + [CD{-}phth]$$

The terms $[S]_o$, [S], and [CD–S] refer to the total, unbound, and 1:1 complexed forms of the inclusate, respectively. [CD–S] and [CD–phth] are related to $[S]_o$, $[phth]_o$, K_2, and K_1 as follows:

$$[4] \qquad [CD{-}S] = [S]_o\left(1 + \frac{1}{K_2[CD]}\right)^{-1}$$

$$[5] \qquad [CD{-}phth] = [phth]_o\left(1 + \frac{1}{K_1[CD]}\right)^{-1}$$

Upon substitution into eq. [3] and rearrangement, the following cubic expression in terms of unbound β-CD ([CD]) is obtained in eq. [6].

$$[6] \qquad [CD]^3 + [CD]^2\left(\frac{K_2 + K_1}{K_2K_1} + [phth]_o + [S]_o - [CD]_o\right) + [CD]\left(\frac{1}{K_2K_1} + \frac{[S]_o}{K_1} + \frac{[phth]_o}{K_2} - \frac{[CD]_o}{K_1} - \frac{[CD]_o}{K_2}\right) - \left(\frac{[CD]_o}{K_2K_1}\right) = 0$$

The real solution to the cubic root of eq. [6] was obtained by application of the Newton–Raphson method[35,36] using appropriate boundary values of $[S]_o$, $[phth]_o$, K_2, and K_1. Values for [CD–S], [CD–phth], and [phth] were obtained using Beer–Lambert law for phth and eqs. [1]–[3]. The criterion utilized for the best fit in the NLLS procedure was the minimization of the sums of the squares of the residuals (SSR) according to the relation: $\text{SSR} = \sum_i [(A_{calc})_i - (A_{expt})_i]^2$, where A_{calc} and A_{expt} are the calculated and experimental absorbance values, respectively.

The lipophilic surface area (LSA) of the apolar molecular fragments of the guest molecule included by β-CD was calculated using Spartan 06. The calculations were based on an equilibrium geometry optimization in the ground state with Hartree–Fock 3–21G in vacuum to obtain the minimized molecular structures.

Results and discussion

The low ethanol composition (0.04%, *v*/*v*) was chosen to eliminate possible interferences due to competitive binding by ethanol and undue solvent effects.[28,37–39] A pH of 10.5 was chosen to optimize ε_{phth}, to provide greater sensitivity for absorption measurements, and to minimize the potential for deprotonation of the hydroxyl groups of β-CD (pK_a ~ 12). All absorption measurements were carried out at λ = 552 nm, and no change in the shape of the visible absorption band with $C_{β\text{-CD}}$ was observed at this wavelength.

To obtain valid estimates of the 1:1 binding constant, the following conditions must be met when using the spectral displacement technique: (*i*) competing inclusate must not absorb in the wavelength region of interest or interact with the chromophore and (*ii*) inclusates must bind exclusively in a 1:1 stoichiometry. The first condition has been verified experimentally by measuring the absorbance change as a function of added NAs and the single-component NAs (S1, S2, or S3). *trans*-4-Pentylcyclohexanecarboxylic acid and Fluka NAs showed a small increase in absorbance due to an increased background absorbance, which is attributed to weak interactions between unbound carboxylic anion guests and phth. Appropriate corrections were applied to absorbance data for these conditions. The formation of 1:1 inclusion complexes has been independently verified in these systems from a recent ESI-MS study of the same host–guest systems.[40] A further requirement is that the competing inclusate must fully displace the chromophore from the β-CD cavity and form a well-defined inclusion complex; not as a ternary outersphere complex, since the latter is known to affect the magnitude of K_2.[39] An additional practical consideration is the value of K_1 for β-CD/phth be greater than or equal to the value of K_2 for β-CD/inclusate ($K_1 \geq K_2$).[22] Under these circumstances, it is possible to displace the phth over a suitable concentration range to obtain adequate absorbance changes.

Fig. 3. Absorbance (abs; λ = 552 nm) vs. concentration of β-CD ($C_{β\text{-CD}}$) in 0.1 mol/L $NaHCO_3$ at pH 10.5, [phth] = 2×10^{-5} mol/L and T = 295 K.

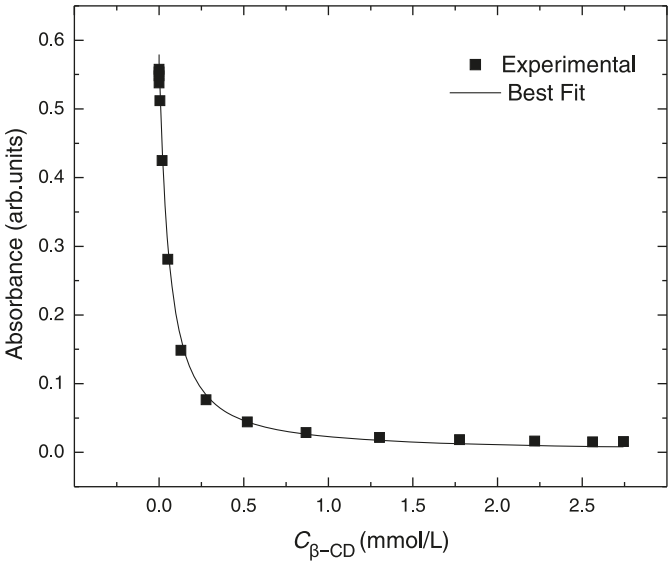


Figure 3 illustrates a typical plot of absorbance vs. $C_{β\text{-CD}}$ at a fixed concentration of phth. The line through the data points represents the calculated absorbance values obtained from the NLLS fitting procedure. The sharp falloff of absorbance as $C_{β\text{-CD}}$ increases represents the formation of the β-CD/phth complex, since the molar absorptivity of the β-CD/phth complex is regarded as zero. Benesi–Hildebrand[41] plots were not utilized to determine values of K_1, since the assumption that the concentration of the complex is lower than the total concentration of β-CD is not usually valid for strongly bound inclusates. As well, such classical double reciprocal plots (1/abs vs. $1/C_{β\text{-CD}}$) improperly weigh the data at lower values of absorbance and higher values of $C_{β\text{-CD}}$. Consequently, an NLLS fitting procedure was employed to obtain values of K_1 and K_2. An average value of the 1:1 β-CD/phth binding constant (K_1 = $2.6 \pm 0.3 \times 10^4$ M^{-1}) was estimated with good agreement with independent literature values.[23–25,27] The conditions employed in this study utilized a relatively low ethanol composi-

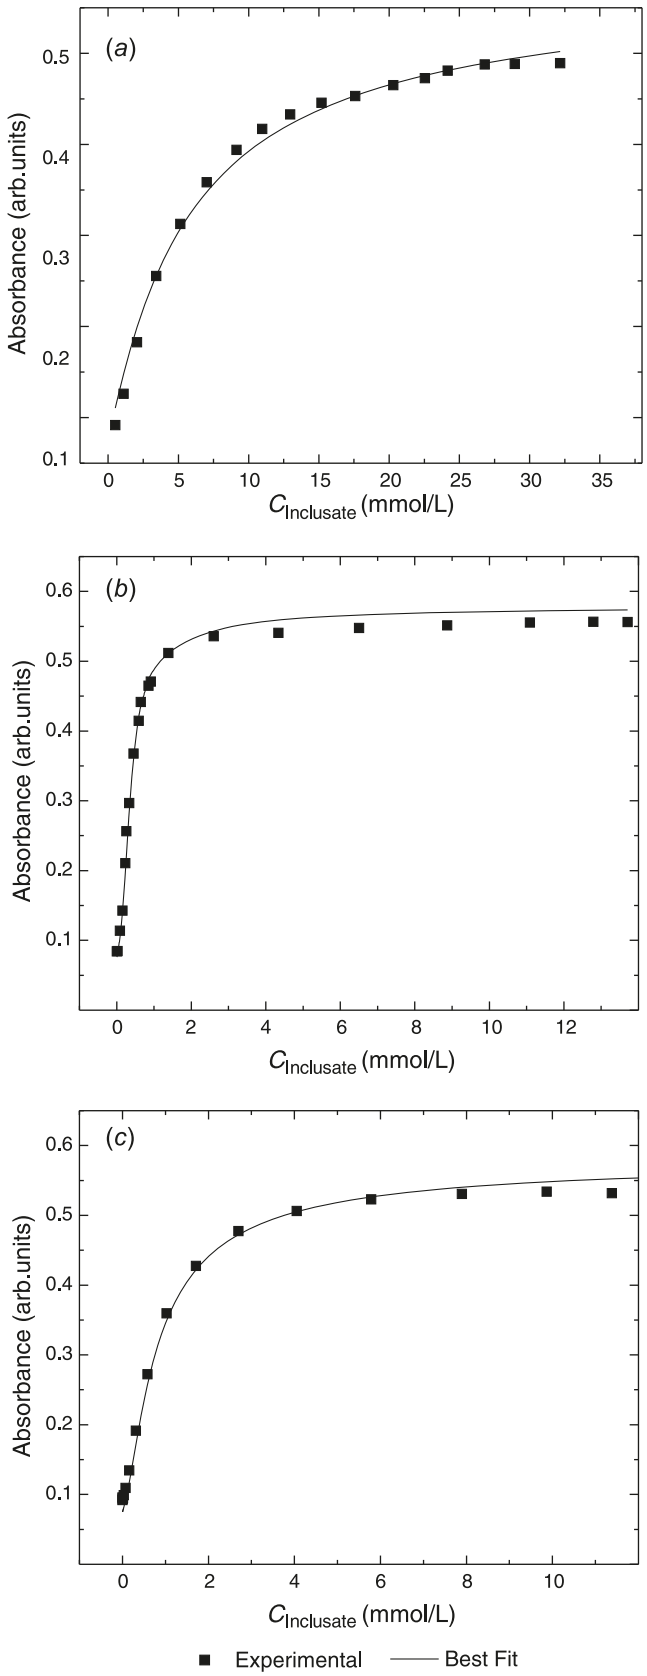

Fig. 4. Absorbance (abs; λ = 552 nm) vs. concentration of specific examples of single-component NAs in 0.1 mol/L $NaHCO_3$ at pH 10.5, [β-CD] = 2 × 10^{-4} mol/L, [phth] = 2 *x* 10^{-5} mol/L, and *T* = 295 K: (*a*) 2-hexyldecanoic acid (S1), (*b*) *trans*-4-pentylcyclohexanecarboxylic acid (S2), and (*c*) dicyclohexylacetic acid (S3).

tion (0.04%, *v*/*v*) as compared with Selvidge and Eftink,[22] and the corresponding value of K_1 obtained is greater.

Figures 4*a*–4*c* are representative plots of the absorbance vs. $C_{Inclusate}$ for the single-component NAs (i.e., S1, S2 and S3). The absorbance values exhibit a smooth monotonic increase with increasing $C_{Inclusate}$, which corresponds to the displacement of phth from the β-CD cavity upon inclusion binding of the single-component molecules. Figure 4*b* represents an example of a strongly bound β-CD/inclusate system where the absorbance changes sharply for S2, the shape of the isotherm becomes increasingly sigmoidal, and the displacement of phth occurs over a narrower range of concentration of guest. S1 displays the weakest binding (cf. Fig. 4*a*) amongst the three examples of single-component NAs examined in Fig. 4. Phenolphthalein (phth) is displaced when $[S1]_o$ reaches ~25 mmol/L, whereas S2 and S3 reach saturation binding ~4 mmol/L and 8 mmol/L, respectively. In Fig. 4*c*, S3 displays a prominent sigmoidal shape as concentration increases but the absorbance changes are more gradual, as compared with S2. These observations indicate that there are differences in the binding affinity of β-CD/inclusate systems as follows: K_2 (S2) > K_2 (S3) > K_2 (S1). Table 1 lists the values of K_2 and ΔG^o for the formation of 1:1 complexes and estimates of lipophilic surface area (LSA) for the single-component NAs. The values of K_2 range between 10^3 and 10^4 M^{-1}, and Gibbs energy change values are negative, indicating the complexation process of β-CD with the inclusates are favourable. There are several factors that govern the formation of CD inclusion complexes.[42] The hydrophobic effect is concluded as very important and is corroborated by the positive correlation between K_2 values and the LSA[43,44] values for the carboxylic acid guest molecules included in the β-CD cavity, as shown in Table 1. β-CD has an approximate cavity length[45] of 8 Å and a diameter of 6.6 Å; thus, β-CD can include ~53 $Å^2$ of an inclusate's LSA. An illustration of the latter is shown for the three single-component NAs as outlined in Scheme 2. Moreover, the cavity volume of β-CD is ~262 $Å^3$ and may include relatively large apolar groups, such as dodecyl alkyl chains,[28] whereas it has been shown that α-CD (less in diameter than β-CD) can include octyl chains.[44,46] Although the LSA of the inclusates were calculated as gas-phase-optimized structures while the experiment was done in aqueous solution, the approach offers a semiquantitative method of relating complex stability to the LSA parameter.[47] The use of LSA values is further corroborated by Connors [45] in his study of CDs with substituted carboxylic acids (cf. Table 1). The binding constants increase as the LSA value increases for a series of cyclohexane carboxylic acids. These results support the important role of the thermodynamics for hydration and dehydration of apolar compounds during complex formation between β-CD and carboxylic acids guests.[28,48–50] The rearrangement of hydrate water includes desolvation of β-CD, dehydration

Table 1. 1:1 Binding constants and Gibbs free energy of complex formation for 1:1 CD/inclusate complexes using the spectral displacement method in 0.1 mol/L $NaHCO_3$ buffer at pH 10.5 and T = 295 K.

of inclusates, and reformation of a hydration shell for the complex. This is outlined by the following contributions to the overall Gibbs energy change of complexation (ΔG°) for a typical 1:1 CD/inclusate complex.[51]

$$[7] \qquad \Delta G^\circ = \Delta G^\circ_{H/W} + \Delta G^\circ_{I/W} + \Delta G^\circ_{H/I/W} + \Delta G^\circ_{W/W}$$

where I, H, and W are inclusate, host, and solvent (water), respectively. The LSA has a large effect on the magnitude of solvent rearrangement, as anticipated for apolar guest compounds and associative processes governed by the hydrophobic effect.

Figures 5*a*–5*b* are representative plots of absorbance vs. $C_{Inclusate}$ for the binding of β-CD/inclusate for Fluka and Syncrude NAs, respectively. Fluka NAs are more strongly bound than Syncrude NAs, as shown by the sigmoidal appearance of the absorbance profile in Fig. 5*a*, as compared with Fig. 5*b*. The former is the more pronounced of the two curves, particularly the change in absorbance at the lower inclusate concentrations. The values of K_2 are shown in Table 1, and the observed differences may be related to the structural variability of the NAs according to the Z value and the carbon number of the respective samples. Fluka NAs have a narrower size distribution and lower average molecular mass, as shown in Figs. 6*a*–6*b* and 7*a*–7*b*. The K_2 values represent an average binding constant, since the NAs studied are mixtures of compounds with similar Z values and carbon number. The molecular mass used in estimates of K_2 utilized the average molecular mass of NAs, since it is not known which specific cogeners are included by β-CD. It is assumed that a random statistical distribution of the NA components are included; however, it is anticipated that high molecular mass components of NAs possessing greater LSA values will be bound more strongly than the lower molecular mass components. The average molecular mass may not represent the fraction of bound species but it is reasonable to report that the K_2 values reported herein reflect the average binding constant for 1:1 complexes of β-CD/NAs. Recent developments in mass spectrometry have also indicated that the Athabasca oil-sands acids may contain co-extractants containing S and N heteratoms along with aromatic and dicarboxylic acids.[52] The interactions of these species with β-CD are indirectly detected in the spectral displacement technique. However, the binding constants reported are representative of the oil-sands acids in the

Fig. 5. Absorbance (abs; λ = 552 nm) vs. concentration of inclusate (Fluka NAs) in 0.1 mol/L $NaHCO_3$ at pH 10.5, [β-CD] = 2 × 10^{-4} mol/L, [phth] = 2 × 10^{-5} mol/L, and T = 295 K: (*a*) Fluka NAs and (*b*) Syncrude NAs.

wider context and not limited to the classical structures (cf. Scheme 1) of naphthenic acids.

Conclusion

The spectral displacement technique provides accurate estimates of the 1:1 binding constants (K_2) for a series of NAs and three examples of single-component NAs (S1, S2, and S3). The values of K_2 for single components ranged from 10^3 to 10^4 M^{-1}, and the NAs (i.e., Fluka and Syncrude) had K_2 values ~10^4 M^{-1}. The K_2 values increased in accordance to their respective LSA values. Fluka NAs have greater K_2

values than Syncrude NAs, and the differences were attributed to the binding of corresponding greater molecular mass components in Fluka NAs vs. Syncrude coextracted oil-sands acids. Although the average molecular mass of Syncrude NAs is higher than Fluka, the former contain impurities which do not appear to bind strongly to the β-CD.

The spectral displacement technique is a versatile method for obtaining accurate estimates of K_2 for carboxylate anions that possess strong binding affinities to β-CD and allows the indirect determination of the concentrations of inclusates in solution. To our knowledge, this is the first quantitative study of the binding constants between NAs and β-CD reported to date. Further thermodynamic studies of complex formation are underway and should provide useful information regarding temperature effects on the stability of these CD/inclusate complexes. The results of this study will contribute toward a further understanding of the sorption mechanism between β-CD-based polymeric materials and carboxylate ions in aqueous solution.

Sommaire
Volume 87, 2009

January / Janvier

This issue is dedicated to Professor R.J. Puddephatt on the occasion of his 65th birthday and to honour his outstanding contributions to Canadian chemistry.
Le présent numéro est dédié à Professor R.J. Puddephatt à l'occasion de son 65e anniversaire de naissance et en reconnaissance de ses contributions exceptionelles à la chimie au Canada.

MINI-REVIEW / MINI-SYNTHÈSE

Wanda Radecka-Paryzek Self-assembly in Schiff base lanthanide complexes — From supramolecular dimers to coordination polymers **1**

REVIEW / SYNTHÈSE

Michael J.D. Bosdet and Warren E. Piers B–N as a C–C substitute in aromatic systems **8**

ARTICLES / ARTICLES

Cuifen Lu, Junqi Nie, Guichun Yang, and Zuxing Chen An improved synthesis of sitophilure **30**

Alicja Haras and Tom Ziegler DFT mechanistic studies on the epoxidation of cyclohexene by non-heme tetraaza manganese complexes **33**

Dana J. Eisler, Stuart D. Robertson, and Tristram Chivers Gold complexes of ditelluridoimidodiphosphinate ligands — Reversible oxidation of Au(I) to Au(III) via insertion of gold into a phosphorus–tellurium bond **39**

Long Chen, Haitao Liu, Keli Yang, Jiankang Wang, and Xiaolai Wang Catalytic synthesis of carbon nanotubes from the decomposition of methane over a Ni–Co/La_2O_3 catalyst **47**

Marco Zimmer De Iuliis, Iain D.G. Watson, Andrei K. Yudin, and Robert H. Morris A DFT investigation into the origin of regioselectivity in palladium-catalyzed allylic amination **54**

Mark A. Fox, Todd B. Marder, and Lars Wesemann DFT studies of the σ-donor/π-acceptor properties of $[SnCB_{10}H_{11}]^-$ and its relationship to $[SnCl_3]^-$, CO, PF_3, $[SnB_{11}H_{11}]^{2-}$, $SnC_2B_9H_{11}$, and related $SnC_2B_nH_{n+2}$ compounds **63**

Dominik Wechsler and Mark Stradiotto Exploring the utility of a new chiral phosphoramidite *P*,*N*-ligand derived from (*R*)-BINOL and 7-azaindole in asymmetric catalysis **72**

Margarita Crespo, Craig M. Anderson, and Joseph M. Tanski Synthesis of platinum(II) cyclometallated compounds derived from imines containing pyridyl or pyrimidyl groups **80**

Malcolm H. Chisholm and Nathan J. Patmore Oxalate bridged heteronuclear compounds containing MM quadruple bonds (M = Mo and W) and their radical cations **88**

Antonio G. De Crisci, Jesse Kleingardner, Alan J. Lough, Anna Larsen, and Ulrich Fekl A weakly coordinating anion as a tripodal "Br_3"-ligand for platinum(IV) — Structure of [(*closo*-$CB_{11}H_6Br_6$)$PtMe_3$] **95**

Cyril Cugnet, Sophie Dal Molin, David Brevet, Dominique Lucas, Yves Mugnier, Pierre D. Harvey, and René T. Boeré Alkyne adducts of paramagnetic and diamagnetic tripalladium clusters supported by dppm ligands **103**

Julia R. Khusnutdinova, Peter Y. Zavalij, and Andrei N. Vedernikov Study of aerobic oxidation of phenyl Pt^{II} complexes (dpms)Pt^{II}Ph(L) (dpms = di(2-pyridyl)methanesulfonate; L = water, methanol, or aniline) **110**

Glen B. Deacon, Winfried Elgersma, Rita Harika, Peter C. Junk, Brian W. Skelton, and Allan H. White The synthesis and X-ray crystal structures of rare earth(III) perfluoroadipate complexes — Novel coordination polymers **121**

Quan Yuan Hu and Guochen Jia Synthesis and electrochemical properties of bimetallic η^5-indenyl ruthenium complexes **134**

Nathan R. Halcovitch, Christopher M. Vogels, Andreas Decken, and Stephen A. Westcott Synthesis, characterization, and reactivity of a novel thallium arylspiroboronate ester **139**

Angela Fleischer, Alexander Roller, Vladimir B. Arion, Bernhard K. Keppler, and Fabian Mohr Synthesis and structures of palladium(II) and platinum(II) complexes containing heterocyclic thiolate ligands formed by cycloaddition reactions of coordinated azides **146**

Hui Huang, N. Raluca Hurubeanu, Cheryl J. Bourgeois, Sue-Mei Cheah, Jian Yuan, Arnold L. Rheingold, and Russell P. Hughes Octahedral perfluoroalkyl complexes of Ir(III) formed by oxidative addition of perfluoroalkyl iodides to $Ir(acac)(CO)_2$ **151**

Graham A. Bowmaker, Narongsak Chaichit, Chaveng Pakawatchai, Brian W. Skelton, and Allan H. White Structural and spectroscopic studies of some adducts of silver(I) salts with ethylenethiourea **161**

Daniele Vinci, Nelson Martins, Ourida Saidi, John Bacsa, Amadeu Brigas, and Jianliang Xiao Ferrocenyl phosphine–oxazaphospholidine oxide ligands for the Suzuki–Miyaura coupling of hindered aryl bromides and chlorides **171**

Nobuyuki Komine, Tomoko Ishiwata, Jun-ya Kasahara, Erino Matsumoto, Masafumi Hirano, and Sanshiro Komiya Synthesis and organic group transfer of organodiplatinum complex with a 1,2-bis(diphenylphosphino)ethane ligand **176**

Joyanta Choudhury, Sanjay Pratihar, Arnab Kumar Maity, and Sujit Roy Reactivity of $IrCl(PPh_3)_3$ with diphenylacetylene — A direct route to 1-iridaindene **183**

Yi Sun, Bryan Ross, Rui-Yao Wang, and Suning Wang $Pt(2,2'\text{-bpy})(O_2CCF_3)_2$ as a terminator for $[Ag(O_2CCF_3)]_n$ aggregates — Syntheses and structures of heterobimetallic $Pt^{II}Ag^{I}$ complexes **188**

Jordan A. Tsui, Timothy M. Bolton, and Brian T. Sterenberg Tungsten coordination chemistry of 1,4-bisdiphenylphosphinobutadiyne — Synthesis of coordination macrocycles and factors controlling diyne cycloaddition **197**

Barry A. Blight, James A. Wisner, and Michael C. Jennings Formation of a [2]rotaxane and [2]catenane based on $PdBr_2L_2$ as a template **205**

Michael G. Crisp and Louis M. Rendina Dinuclear organoplatinum(II) complexes containing *N*-methylbenzamide **212**

Simon Trudel and Ross H. Hill Top-down meets bottom-up — Electron-beam induced metalorganic deposition of amorphous iron oxide nanostructures **217**

Alexander V. Wiznycia, John Desper, and Christopher J. Levy Zinc and iron complexes of a helix-directing (1*R*,2*R*)-cyclohexyl salen ligand with phenanthryl sidearms **224**

Nada Reginato, Laura E. Harrington, Yannick Ortin, and Michael J. McGlinchey Unexpectedly different reactions of $[(arene)Mn(CO)_3]^+$ cations (arene = trindane, indane, tetralin, or dibenzosuberane) with potassium *t*-butoxide — C-H insertions, haptotropic shifts, dimerization, or elimination **232**

Ramanathan Vaidhyanathan, Amir H. Mahmoudkhani, and George K.H. Shimizu A microporous alkaline-earth phosphonate sustained by one-dimensional inorganic and organic units **247**

Francesco Nastasi, Frédérique Loiseau, Sebastiano Campagna, Elaine A. Medlycott, Marie-Pierre Santoni, and Garry S. Hanan Synthesis and photophysical properties of naphthyl-, phenanthryl-, and pyrenyl-appended bis(pyridyl)triazine ligands and their Zn(II) and Ru(II) complexes **254**

Bo-Lin Lin, Jay A. Labinger, and John E. Bercaw Mechanistic investigations of bipyrimidine-promoted palladium-catalyzed allylic acetoxylation of olefins **264**

Tamer A. Elbokl and Christian Detellier Kaolinite–poly(methacrylamide) intercalated nanocomposite via in situ polymerization **272**

Yaofeng Chen and Davit Zargarian Phenylsilane dehydrocoupling and addition to styrene catalyzed by (R-indenyl)Ni(phosphine)(methyl) complexes **280**

Nathan M. West and Joseph L. Templeton Approaches to alkane functionalization with Tp′Pt and (nacnac)Pt reagents **288**

Xu Wang and Dong-Sheng Yang Bonding and structures of copper-aminopyridine complexes — High-resolution electron spectroscopy and ab initio calculations **297**

Kaarina K. Milnes and Kim M. Baines A mechanistic study of the addition of alkynes to Brook silenes **307**

A. Pietrangelo, B.N. Boden, M.J. MacLachlan, and M.O. Wolf Synthesis and electrochemistry of new thienyl – Schiff base complexes **314**

David W. Dodd, Heather E. Toews, Michael J. Trevail, Michael C. Jennings, Robert H.E. Hudson, and Nathan D. Jones Synthesis and evaluation of the in vitro DNA-binding properties of chiral *cis*-dichloro (pyridyloxazoline)platinum(II) complexes **321**

Jian Wang, Nicholas A. Morra, Hongda Zhao, Jeffrey S.T. Gorman, Vincent Lynch, Robert McDonald, John F. Reichwein, and Brian L. Pagenkopf Synthesis and first X-ray structures of cobalt(II) and cobalt(III) complexes bearing 2,4-dioxo-alkanoic acid dialkylamide ligands **328**

Peng Zhang, Andy Yuan-Chi Chu, Tsun-Kong Sham, Yun Yao, and Shuit-Tong Lee Chemical synthesis and structural studies of thiol-capped gold nanoparticles **335**

Javier E. Aguado, M. Concepción Gimeno, Peter G. Jones, and Antonio Laguna Unusual coordination behaviour of the ferrocenyl-terpyridine ligand with group 11 complexes **341**

Bryan A. Demko and Roderick E. Wasylishen Probing solid iminobis(diorganophosphine chalcogenide) systems with multinuclear magnetic resonance **348**

Sebastien Monfette, João A. Duarte Silva, Serge I. Gorelsky, Scott J. Dalgarno, Eduardo N. dos Santos, Maria H. Araujo, and Deryn E. Fogg Dissecting out the effect of Ru-OAr bonding in a five-coordinate complex of ruthenium (II) **361**

Robert A. Gossage, Paras N. Yadav, Timothy D. MacInnis, J. Wilson Quail, and Andreas Decken Zinc halide oxazoline complexes — The quest for structural diversity **368**

Deeb Taher, Nicholas J. Taylor, and John F. Corrigan Phenylene-1,4- and biphenylene-4,4′-diselenolate bridged complexes of gold(I) **380**

Jigang Zhou, Jun Zhu, Jack Brzezinski, and Zhifeng Ding Tunable electrogenerated chemiluminescence from CdSe nanocrystals **386**

Author Index / Index des auteurs **AI-1**

February / Février

ARTICLES / ARTICLES

Kothamasu Suresh Babu, Vidadala Rama Subba Rao, Ravu Ranga Rao, Sakhamuri Sivaram Babu, and Janaswami Madhusudana Rao A mild and efficient chemoselective *N*-benzyloxycarbonylation of amines using TBAB as a catalyst under solvent-free conditions **393**

Apollinaire Tsopmo, Pierre Kamnaing, Jean Watchueng, Jin-Ming Gao, Yasuo Konishi, and Olov Sterner Chemical constituents from the bark of *Anisopus mannii* **397**

Krishna M. Deshmukh, Ziyauddin S. Qureshi, Nitin S. Nandurkar, and Bhalchandra M. Bhanage One-pot synthesis of β-amido ketones using Brønsted acidic ionic liquid as an efficient and reusable catalyst **401**

Dongsheng Jiao, Hongyan Wang, Yanlan Zhang, and Yu Tang A DFT study of thymine and its tautomers **406**

Abdolkarim Zare, Abolfath Parhami, Ahmad Reza Moosavi-Zare, Alireza Hasaninejad, Ali Khalafi-Nezhad, and Mohammad Hassan Beyzavi A catalyst-free protocol for the green and efficient condensation of indoles with aldehydes in ionic liquids **416**

Ramesh C. Kamboj, Urmila Berar, Surinder Berar, Mandeep Thakur, Rita Arora, and Satish C. Gupta Photochemistry of 3-alkoxychromones I — Photocyclisation of 6-chloro-3-alkoxy-2-(furan-3-yl)-4*H*-chromen-4-ones **422**

Robert Britton, Grigori Khaskin, and Gerhard Gries A chromatography-free synthesis of (2*S*,12*Z*)-2-acetoxy-12-heptadecene — The major sex pheromone component of the pistachio twig borer moth (*Kermania pistaciella*) **430**

In Sun Koo, Dildar Ali, Kiyull Yang, Yong Park, Abdelhamid Esbata, Gary W. vanLoon, and Erwin Buncel ^{31}P NMR and ESI-MS studies of metal ion-phosphoruspesticide residue complexes **433**

Eli Zysman-Colman, Karla Arias, and Jay S. Siegel Synthesis of arylbromides from arenes and *N*-bromosuccinimide (NBS) in acetonitrile — A convenient method for aromatic bromination **440**

Patricia G. Boland, Sara J. Accardi, Carrie A. Snow, and Brian D. Wagner Investigations of the supramolecular host properties of a fluorescent bistren cage compound **448**

Justin Renaud, Abdulhrahman M. Alhazmi, and Paul M. Mayer Comparing the fragmentation chemistry of gas-phase adducts of poly(dimethylsiloxane) oligomers with metal and organic ions **453**
