15-*e* intermediates, as illustrated in Fig. 1. The full catalytic cycle was investigated for both S = 3/2 and S = 1/2 states. The S = 3/2 state was consistently preferred by a significant margin (5–25 kcal/mol) for all species within the proposed catalytic cycle.[23] In the remainder of this work we only use the energies for the lowest-energy spin state (S = 3/2 or 1/2) and for the preferred ligand coordination (**3** or **4**) of each intermediate or transition state. The final cycle, including the various excursions and side reactions studied, is shown in Scheme 2. Figure 2 shows the corresponding free energy profile, and Table 1 lists the energies for all relevant species.

As in the cycles proposed earlier for Ta,[6] Ti,[7–9] and Cr[12] we find reductive coupling of two ethenes to a metallacyclopentane, ring expansion to a metallacycloheptane, and direct Cβ → Cα′ hydrogen transfer to form a 1-hexene complex.[25] The initial reductive coupling step (**A** → **B**) is very easy ($\Delta G^{\ddagger}$ = 7.7 kcal/mol, ΔG_{rxn} = –9.9 kcal/mol), reflecting the ease of oxidation of Cr^{I} to Cr^{III}; on the other hand, the final H transfer that reduces Cr^{III} back to Cr^{I} (**D** → **E**) has a high activation free energy of 18.4 kcal/mol.

The results reported by van Rensburg and Steynberg[12] for $Cr^{II/IV}$ [11] imply a somewhat less facile initial step ($\Delta G^{\ddagger}$ = 9.5 kcal/mol, ΔG_{rxn} = –2.1 kcal/mol) and a much easier final H transfer ($\Delta G^{\ddagger}$ = 10.0 kcal/mol).[26] The most common oxidation states of Cr in alkylchromium complexes are Cr^{II} and Cr^{III}. Thus, it makes sense that in a $Cr^{II/IV}$ cycle formation of the unusually *high* oxidation state Cr^{IV} from Cr^{II} is more difficult, and its subsequent reduction back to Cr^{II} is correspondingly easier. In our $Cr^{I/III}$ cycle, on the other hand, Cr starts out in the unusually *low* oxidation state Cr^{I}, so its oxidation to Cr^{III} (**B**) is easier but later reduction back to Cr^{I} (**F**) is more difficult.

However, the rate-limiting step for both types of cycles appears to be the insertion of the third olefin to form metallacycloheptane **D**. In the present system, this is calculated to have an effective free-energy barrier $\Delta G_{eff} = \Delta G$[**TS**(**C** → **D**)] – ΔG[**B**] of 28.1 kcal/mol. The height of this barrier is caused not so much by the insertion itself (which requires only 12.5 kcal/mol) but rather by the strong stabilization of metallacyclopentane **B** through coordination of the Al-bound chloride, which opposes coordination of the incoming ethene molecule.

Interestingly, the coordination of the hemilabile chloride in **D** doesn't assist the reductive Cβ → Cα′ hydrogen transfer, because it selectively stabilizes *high* oxidation states of the metal. Thus, the role of the hemilability in this system appears to be subtly different from that in other trimerization systems studied by DFT. Since the final H transfer is relatively difficult in this $Cr^{I/III}$ system, one might expect easy ring growth beyond the metallacycloheptane intermediate. However, this further ring expansion requires binding of an additional ethene molecule and hence is entropically unfavourable; we find that in terms of free energy, H transfer at the metallacycloheptane (**D** → **E**) is still preferred over ring expansion (**D** → **I** → **J**) by a margin of about 11 kcal/mol.

In any case, neither the $Cr^{I/III}$ cycle (this work) nor the $Cr^{II/IV}$ one[12] appear to involve discrete (hydride)(hexenyl) species analogous to **F**. The transition state **TS**(**F** → **E**) for the final reductive hexene elimination from **F** is simply too high in energy to compete with direct hydrogen transfer through **TS**(**D** → **E**), the difference being about 9 kcal/mol. On the other hand, this difference is not so large that one can confidently exclude this path for all possible chromium systems.

Our results suggest a possible explanation for the observation by Bercaw and co-workers[14b] of methylenecyclopentane and methylcyclopentane side products. The calculated energies of the system are such that, while reductive hydride-alkyl elimination via **TS**(**F** → **E**) is well above **TS**(**D** → **E**), the (hydride)(hexenyl) complex **G** itself is low enough in energy to be accessible. Indeed, intramolecular cyclization via **TS**(**G** → **L**) is calculated to happen *below* the level of **TS**(**F** → **E**), though still above **TS**(**D** → **E**). Thus, it seems likely that depending on the specific catalyst used, there could be systems where formation of cyclopentylmethyl complex **L**

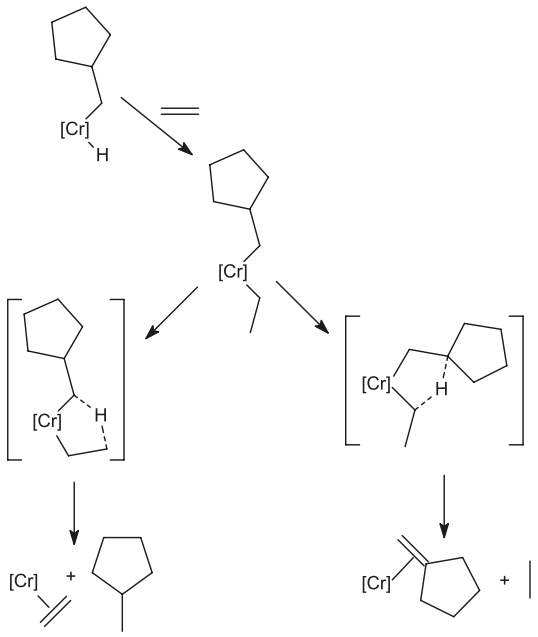
via intramolecular insertion competes with the Cβ → Cα′ hydrogen transfer reaction. Once this (irreversible) cyclization has occurred, the resulting (hydride)(cyclopentylmethyl) complex could insert an olefin in the Cr–H bond[27] and then undergo hydrogen transfer either *from* or *to* the cyclopentylmethyl group to produce the observed side products, as illustrated in Scheme 3.

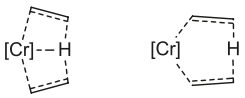
Bercaw and co-workers[14c] have reported kinetic isotope effects (KIE) for trimerization of trans and cis ethylene-d_2 (4.1(1) and 3.1(1), respectively).[14c] These KIE were believed not to have a significant tunnelling component. Our calculated KIE for transfer of a single H versus D in **TS(D → E)** is 4.1, in remarkably good agreement with the experimental value.[28] However, the KIE calculated for the reductive-elimination step is not much higher (5.4), so we cannot draw any definitive conclusions from this fact alone.

Since for our cycle the β-elimination/reductive elimination steps have relatively high barriers, we checked for alternative hydrogen transfer possibilities. In olefin polymerization, chain transfer usually occurs either via β-elimination or via direct transfer of a β-hydrogen to an incoming monomer ("chain transfer to monomer"). The β-elimination path is blocked in **B** by steric constraints, but one could still envisage transfer of a β-hydrogen to an incoming ethene molecule from both **B** and **D**. We located two transition states for each of these reactions, corresponding to the "classical" bis(ole-

Scheme 3. Possible mechanism for formation of methylcyclopentane and methylenecyclopentane side products.



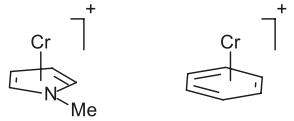
fin)hydride like $\mathbf{TS_A}$ and the "ene" like $\mathbf{TS_B}$ that have been calculated for several polymerization systems.[29] As for most relatively open polymerization catalysts, $\mathbf{TS_A}$ is preferred by a significant margin (about 16 kcal/mol) over $\mathbf{TS_B}$. However, even $\mathbf{TS_A}$ is clearly disfavoured relative to metallacycle growth (from **B**, by 6 kcal/mol) or hydrogen transfer (from **D**, by 14 kcal/mol), so that chain transfer to monomer does not seem to be a relevant side reaction in this system.



$\mathbf{TS_A}$ $\mathbf{TS_B}$

Role of the indolate ligand

For comparison, the same catalytic cycle was studied for model catalysts (*N*-methyl-pyrrole)Cr^+ (**5**) and (benzene)Cr^+ (**6**), which lack the hemilabile $AlMe_2Cl$ group but are otherwise similar to **3** and **4**.



5 **6**

The calculated catalytic cycles are roughly similar, but ethene binding is consistently stronger for both of these models because the incoming ethene monomer does not have to compete with the hemilabile chloride. Nevertheless, the competition between H transfer and further metallacycle growth is very similar for all systems, **3**–**6**, since in the crucial transition states for H transfer and chain growth, chloride coordination does not occur to a significant extent.

These results would suggest that cationic (pyrrole)Cr^+ and (benzene)Cr^+ could be viable trimerization catalysts. They would be even more active than the hemilabile systems **3** and **4** since they lack the additional stabilization at the metallacycle stages **B** and **D** that cause the high effective barriers for these latter systems. We believe, however, that *some* additional form of stabilization of the chromium center is necessary to keep the catalyst alive and prevent it from undergoing unwanted side reactions. Species like **5** and **6** would be so reactive they are unlikely to survive for long.

A cationic (arene)Cr^I species would most plausibly be generated from low-spin 17-*e* (arene)$_2Cr^+$. However, arene dissociation is normally not easy: displacement of one benzene ring of $(C_6H_6)_2Cr^+$ by two molecules of ethene is calculated to be endergonic by about 10 kcal/mol, and is unlikely to happen.[30] Due to the negative charge on the ligand, the arene ring of **4** is a stronger σ-donor and poorer π-acceptor than benzene, resulting in slightly weaker binding of benzene to **4** than to **6**. Also, the chloride ligand may assist in a *stepwise* displacement of an arene from **3/4**, which should be easier than a fully dissociative mechanism. Nevertheless, the use of an arene as solvent should hinder trimerization catalysis at Cr^I, in agreement with experimental results.[14b,16]

Conclusions

Our results indicate that, in addition to the $Cr^{II/IV}$ cycle proposed by van Rensburg and Steynberg[12] a $Cr^{I/III}$ cycle is a reasonable possibility for ethene trimerization at Cr. For the activator-free system described by Gambarotta and coworkers,[16] this $Cr^{I/III}$ cycle seems the more likely one because the starting material contains Cr^I and there is no obvious oxidant present. The observed inhibition by toluene supports this interpretation, since Cr^{II} does not bind arenes strongly enough to result in inhibition of olefin binding. For the commercial Cr-pyrrolyl systems, not enough information is available to assign the oxidation state of the catalyst; both $Cr^{I/III}$ and $Cr^{II/IV}$ cycles should be considered as viable alternatives. It appears that both of these cycles involve direct Cβ → Cα′ hydrogen transfer, avoiding reductive elimination from discrete (hydride)(hexenyl) intermediates. A possible explanation for the formation of methylenecyclopentane and methylcyclopentane side products is given that does not involve a reductive hydride-alkyl elimination step. And finally, the calculated KIE for direct Cβ → Cα′ hydrogen transfer agrees well with the KIEs observed by Bercaw and co-workers[14c] for a PNP catalyst. Taken together, these results make a strong case for the occurrence of direct hydrogen transfer as a "standard" mechanistic step in chromium-catalyzed trimerization.

(22) One could imagine formation of a Al-N-Cr bridge like that in complex **2**. However, we did not examine that possibility in the present study.

(23) The low-spin state is only preferred for 17-*e* complexes such as $(C_6H_6)_2Cr^+$. For all 13-*e* and 15-*e* species, the $S = 1/2$ calculations moreover result in a high spin contamination: typical values of S^2 are 1.7–1.8, whereas the S^2 values for the $S = 3/2$ states are mostly in the range of 3.8–3.9.

(24) The scheme shows single arrows for simplicity; of course, all steps are to some degree reversible.

(25) All attempts to find a separate transition state for hydride-alkyl reductive elimination from **G** led back to the direct Cβ → Cα′ transfer **TS(D → E)**. A discrete reductive elimination TS could only be calculated when the hexenyl C=C bond was first dissociated from the Cr atom, i.e., starting from **F** to give **TS(D → E)**.

(26) Based on data given in ref. 11 for the $ClAlMe_3$ model, using the lowest-energy pyrrolate coordination mode at each stage of the reaction.

(27) Alternatively, and perhaps more likely, olefin could insert in the Cr–H bond of **G** *before* cyclization of the hexenyl group occurs. This would eventually lead to the same products.

(28) KIE calculated from standard thermodynamic free-energy calculations, not including any tunnelling estimates. Calculated secondary isotope effects are also significant, in particular for the Cα′ H having an agostic interaction with the metal (1.14).

(30) Displacement by *three* ethenes was found to be even less favourable, see Table 1.

Pd/X group interchange in the [Pd(Br)(PH_3)(C_6H_5)(C_6H_5X)] system — Theoretical insights from the isolobal analogy perspective[1]

Alain Dedieu and Antonio J. Mota

Abstract: DFT-B3LYP calculations have been carried out to assess the fate of the Pd/X group intermolecular exchange in the [PdBr(PH_3)(C_6H_5)(C_6H_5X)] system, where *X* is either H, an electropositive atom, or a group such as Li, Na, BH_2, AlH_2, BeH or $BeCH_3$, and an electronegative atom, or a group such as F, Cl, Br, CH_3, OH, and SH. The transfer of H is best viewed as involving the migration of a proton between the two phenyls. At variance with this result, the transfer of the more electropositive entities such as X = Li, Na, BH_2, AlH_2, BeH, or $BeCH_3$ is not complete. It stops halfway to yield a stable structure in which *X* can experience interactions with the two phenyl groups that are quite ionic. These stable structures are rationalized through isolobal analogy arguments. In the case of beryllium, the correspondence has been made also with the experimentally known cyclopentadienylberyllium borohydride system, $CpBeH_4$. The results of the DFT geometry optimization call for a re-examination of the gas-phase electron-diffraction structure determination, especially for the bond distances and angles that pertain to the two bridging hydrogens. For the halogen series X = F, Cl, or Br and for the electronegative groups CH_3, OH, or SH, the transfer between the two phenyls takes place via a two-step Pd(II)/Pd(IV) oxidative addition/reductive elimination mechanism. The associated energy barriers are nevertheless quite high, except for Br and SH for which the process might be feasible. The dimerization of the PdBr(PH_3)(C_6H_5) system is also analyzed within the isolobal analogy framework.

Key words: C–X activation, metathesis, group exchange, theoretical study, palladium.

Résumé : On a étudié, à l'aide de calculs DFT-B3LYP l'échange intramoléculaire entre les groupes PdBr(PH_3) et X, lorsque X est soit un atome d'hydrogène, un atome ou un groupe plus électropositif tel que Li, Na, BH_2, AlH_2, BeH or $BeCH_3$, soit un groupe plus électronégatif comme F, Cl, Br, CH_3, OH, SH. Le transfert de H correspond à un transfert de proton entre les deux phényles. Par contre le transfert des atomes ou des groupes plus électropositifs n'est pas complet et s'arrête à mi-chemin pour donner un complexe stable, dans lequel les interactions de X avec les deux groupes phényles ont un fort caractère ionique. On rationalise ce type de structures par des arguments basés sur le concept de l'analogie isolobale. Dans le cas du béryllium la géométrie du système $CpBeBH_4$, qui est aussi un analogue isolobal, a été optimisée. Sur la base des résultats correspondants, on suggère un réexamen de la structure expérimentale obtenue en phase gazeuse par diffraction d'électrons. Pour la série F, Cl, Br, CH_3, OH, SH, le transfert peut se faire via un mécanisme à deux étapes Pd(II)/Pd(IV) impliquant une addition oxydante suivie d'une élimination réductrice. Les barrières d'énergie associées sont cependant très élevées, sauf pour Br et SH, pour lesquels on peut imaginer un tel processus. La dimérisation du système PdBr(PH_3)(C_6H_5) est aussi étudiée sous l'angle de l'analogie isolobale.

Mots-clés : activation C–X, métathèse, échange de groupe, étude théorique, palladium.

Introduction

Synthetic organic reactions catalyzed or mediated by palladium complexes are extraordinarily numerous and different. Among them, the through-space shift of palladium between two sp^2 or an sp^3 and an sp^2 carbon atom, associated to a simultaneous C–H bond activation,[2–18] that has been observed under Heck-type or Suzuki-type conditions, has recently attracted our attention.[19–21] Its intimate mechanism is quite intriguing and still a matter of debate.[17]

Two different "intramolecular" pathways can be envisioned a priori: either an oxidative addition/reductive elimination two-step process in which a hydridopalladium(IV) intermediate is involved, see (i) in Scheme 1, or a one-step process in which the oxidation state +2 of the palladium atom is retained, see (ii) in Scheme 1. In this case, it could be considered either as a metathesis reaction of the C–H σ bond with the Pd–C bond, or as a concomitant 1,*n* shift of both the hydrogen and the palladium atoms, where the hydrogen atom is best viewed as being transferred as a proton. Our investigations also pointed out to the possibility, especially for the 1,4 shift, of an oxidative hydrogen-migration one-step mech-

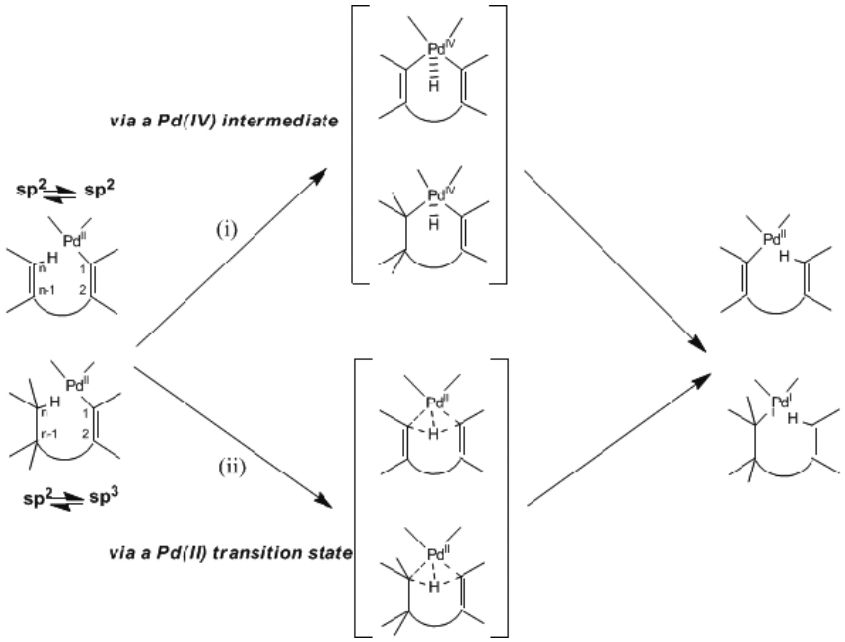

Fig. 1. Optimized structures for the one-step Pd(II) and Pd(IV) rearrangements between $PdBr(PH_3)$ and H in the $PdBr(PH_3)(C_2H_3)(C_2H_4)$ system. The enthalpy values are in kcal mol^{-1} (1 cal = 4.184 J).

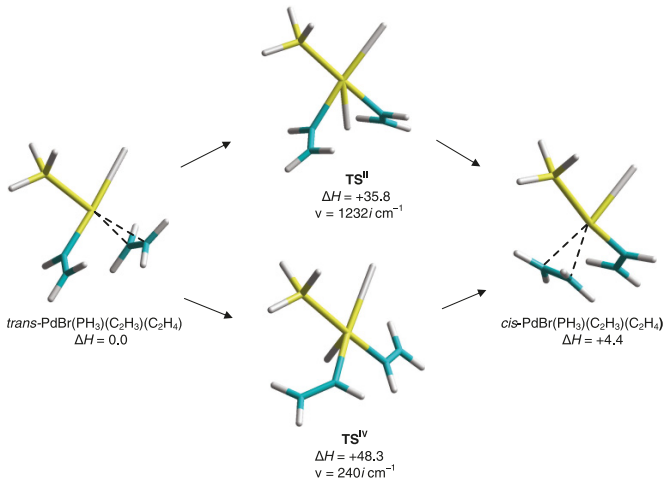

anism, in which the hydrogen is transferred as a hydride.[19–21] In fact, as stressed recently by various authors,[22–25] such clear-cut distinctions are too strict, and there is probably a monotonous evolution from one mechanism to the other, depending on the metal center and its environment. Yet in the palladium PdBr(phosphine)(biaryl) systems that we investigated, we could show that the one-step Pd(II) mechanism was favoured for $n \geq 5$ and unravelled the orbital and geometric factors that account for this feature.[20] This was done by considering the 1,∞ re-arrangement in the unconstrained $PdBr(PH_3)(C_2H_3)(C_2H_4)$ model system, both sides of the system being then allowed to adopt the more adequate position with respect to the Pd atom (see Fig. 1). As shown on Fig. 1, both "one-step" Pd(II) and Pd(IV) mechanisms were found. The one-step Pd(II) transition state is favoured by a clamping arrangement of the two organic moieties around the transferred hydrogen, in contrast to the one-step Pd(IV) transition state, for which a planar arrangement is needed (see Fig. 1) . This Pd(II) transition state $PdBr(PH_3)(C_2H_3)(C_2H_3)(H)$, with its almost linear $C_{vinyl}\cdots H\cdots C_{vinyl}$ unit, involves a proton transfer, and that was, inter alia, rationalized on the basis of the isolobal analogy[26,27] between the d^9 C_{2v} $PdBr(PH_3)$ unit and either CH_2^+ or BH_2. If one also replaces the two groups that are covalently bound to Pd by two hydrogen atoms (their isolobal analogs), one then gets for this transition state a structure that is akin to the one of the C_{2v} transition state for hydrogen scrambling in CH_5^+ or BH_5.[28–30]

Up to now, our mechanistic studies[19–21] and the related studies on sigma-bond metathesis reaction[22–25] have been limited to C–H activation. In an effort to broaden the scope of these interchange processes, we have now considered the Pd/X interchange and related processes (vide infra) in the $Pd(Br)(PH_3)(C_6H_5)(C_6H_5X)$ "model" systems, where the exchanged X group is of cationic character, viz. X = Li, Na, BH_2, AlH_2, BeH, and $BeCH_3$. Our conclusions rely on DFT calculations, but we will use the isolobal analogy as a rationalizing tool. For the sake of completion, we will also briefly report our results for anionic X groups in $Pd(Br)(PH_3)(C_6H_5)(C_6H_5X)$ systems.

Computational details

The calculations were carried out at the DFT-B3LYP level[31–33] with the Gaussian 03 program.[34] The triphenylphosphine ligand PPh_3 was modelled by PH_3. The geometries were fully optimized by the gradient technique with the following basis: For Pd, the LANL2DZ basis set is modified following the prescription of Couty and Hall.[35] In this modified basis, the innermost core electron (up to 3d) are described by the relativistic orbital-adjusted effective core potential of Hay and Wadt,[36] and the remaining outer core and valence electrons by a [341/541/31] basis set where the two outermost 5p functions of the standard LANL2DZ

Fig. 2. (*a*) Optimized structures for the one-step Pd(II) re-arrangement between $PdBr(PH_3)$ and H in the $PdBr(PH_3)(C_6H_5)(C_6H_6)$ system. The enthalpy values are in kcal mol^{-1}; (*b*) structure of the $[CH_2(C_6H_5)(C_6H_5)(H)]^+$ transition state.

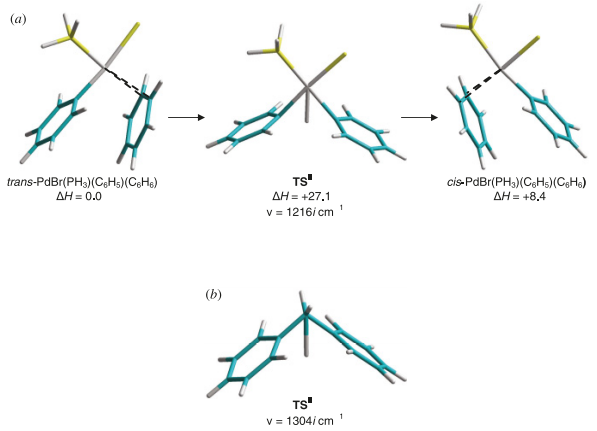

Fig. 3. (*a*) Optimized structures of the $[PdBr(PH_3)(C_6H_5)_2Li]^+$ and $[PdBr(PH_3)(C_6H_5)_2Na]^+$ systems; (*b*) Optimized structures of the $[(CH_2)(C_6H_5)(C_6H_5)(Li)]^+$ and $[(BH_2)(C_6H_5)(C_6H_5)(Li)]$ systems.

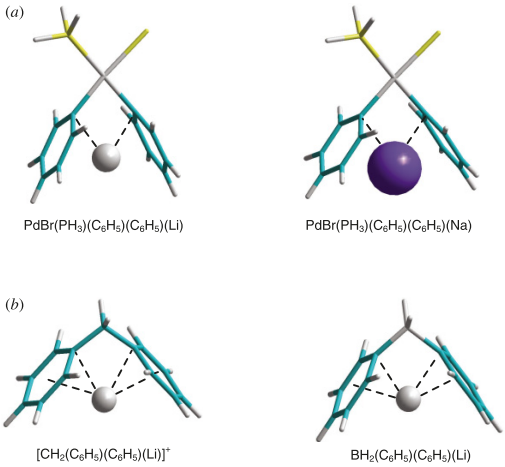


basis set have been replaced by a [41] split of the 5p function optimized by Couty and Hall.[35] For the Br atom, the quasi relativistic energy-adjusted spin-averaged effective core potential was taken from the work of the Stuttgart group, together with their [31/31] basis set,[37] to which s and p diffuse functions (with exponents of 0.0493 and 0.0363, respectively), and a d polarization function (of exponent 0.381) were added, following Radom et al.[38] The other atoms were described by the standard polarized 6–31G* basis set.[39] The cis/trans label that will be used throughout this paper refers to the relative position of the bromine atom and the carbon atom covalently bound to palladium. Note that the transfer will connect a cis structure to a trans structure and vice versa. Since both types of transfer led to similar conclusions, we will focus here on the transfer that starts from the most stable isomer, that is the trans isomer. The nature of the optimized structures, either transition states or intermediates, was assessed through a frequency calculation. Since we are dealing here with intramolecular processes, we will concentrate on enthalpy values, which were obtained by taking into account zero-point energies and the thermal motion at standard conditions (temperature of 298.15 K, pressure of 1 atm) (1 atm = 101.325 kPa). In our first study,[19] we checked that the geometrical parameters obtained with this basis set are in agreement with related experimental structures of bromo-palladium complexes and that the thermodynamic values obtained with this basis set were quite comparable to those obtained with larger basis sets.

Results and discussion

The $PdBr(PH_3)(C_6H_5)(C_6H_6)$ parent system

We will start our study by an analysis of the unsubstituted system $PdBr(PH_3)(C_6H_5)(C_6H_6)$. For this system, the results turned out to be quite similar to the ones obtained previously for $PdBr(PH_3)(C_2H_3)(C_2H_4)$[20] (see Fig. 2*a*). The one-step Pd(II) pathway is the preferred one, with a rather accessible activation barrier of 27.1 kcal mol^{-1} (enthalpy value, 1 cal = 4.184 J). In the transition state, the transferred hydrogen lies halfway between the two ipso carbon atoms and is roughly collinear with them (the C···H···C angle amounting to 166.8°). The value of the imaginary frequency (1216*i* cm^{-1}) compares well with the ones obtained previously for a one-step proton transfer.[19–21] As for $PdBr(PH_3)(C_2H_3)(C_2H_3)(H)$, one can make use of the isolobal analogy of the $PdBr(PH_3)(C_6H_5)(C_6H_5)(H)$ structure with CH_5^+ to account for the protonic character of the transferred hydrogen. The isolobal analogy between $PdBr(PH_3)$ and CH_2^+ is also best exemplified by the results of the geometry optimization that we carried out on the isolobal $[CH_2(C_6H_5)(C_6H_5)(H)]^+$ system. As shown on Fig. 2*b*, the optimized structure is quite similar to the structure of the $PdBr(PH_3)(C_6H_5)(C_6H_5)(H)$ transition state and is characterized by a single imaginary frequency of 1304*i* cm^{-1}, again typical of a through space proton transfer between two aryls.[20]

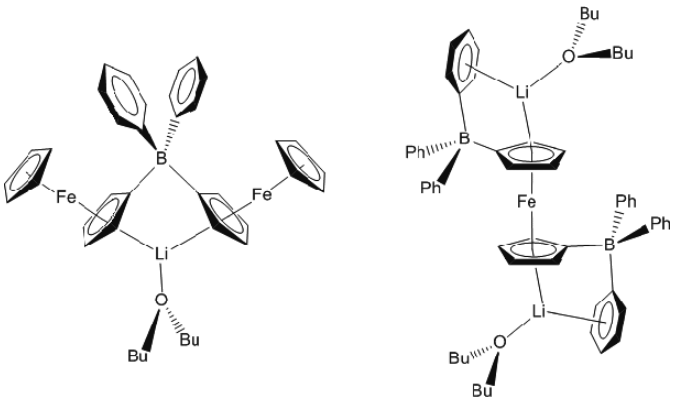
It is also noteworthy that, at variance with the $PdBr(PH_3)(C_2H_3)(C_2H_4)$ system of our previous study,[20] we could not get any one-step Pd(IV) transition state. We stressed in that study that for such a transition state to be operative, a coplanar arrangement of the two organic moieties involved in the transfer is necessary. In the $PdBr(PH_3)(C_6H_5)(C_6H_5)(H)$ system investigated here, a coplanar arrangement of the two mutually cis phenyl ligands is no longer possible due to the steric hindrance that would arise between the phenyl groups. That precludes the existence of a Pd(IV) transition state.

The $PdBr(PH_3)(C_6H_5)(C_6H_5M)$ systems (M = Li, Na)

Replacing the transferred hydrogen atom of Fig. 2*a* by either lithium or sodium led to a totally different situation, i.e., we could not in both cases find any transition state. Instead, the structure with either Li^+ or Na^+ halfway between the two carbon atoms turned out to be an "intermediate" (see Fig. 3*a*). This result is at variance with what has been found in previous computational studies of the isolobal system $[LiCH_4]^+$ [40–44] since they all conclude to the C_{3v} structure (with Li^+ bound in a trihapto fashion to three hydrogen atoms) as being the most stable one. The C_{2v} structure, in which the lithium ion is located along the C_2 axis of CH_4 is a transition structure, as in CH_5^+, although the energy

difference between the two structures, when reported[41–43] is very small (between 1 and 2 kcal mol^{-1} depending on the computational level and on whether basis set superposition error has been taken into account or not). Similar results have also been obtained for $[NaCH_4]^+$.[43] Thus, one might conclude that the isolobal analogy does not work here, since its use would lead to the wrong conclusion that the $PdBr(PH_3)(C_6H_5)(C_6H_5)(Li)$ structure should be a transition state interconnecting *cis*- and *trans*-$PdBr(PH_3)(C_6H_5)(C_6H_5Li)$. In fact this failure of the isolobal analogy is only apparent. It can be traced to the replacement of the two phenyl rings by two hydrogens "and not" to the replacement of $PdBr(PH_3)$ unit by CH_2^+. Unlike the two hydrogens, the two phenyls can experience quite strong cation–π interactions.[45] Compare for instance the affinity of Li^+ for benzene, in an η^6 fashion, with the one for CH_4: 38.3 kcal mol^{-1} instead of 12.6 kcal mol^{-1} according to Ehlers et al.,[43] who have computed both systems at the B3PW91/6–311++G(3d,2p) level. Similar values have been obtained at the B3LYP,[46] MP2 and CCSD(T) level,[47–49] and experimentally in the gas phase.[48] There have also been some reports of X-ray crystal structures of systems in which the lithium atom is η^6 bound to benzene[50] or to a phenyl ring.[51] It is therefore not surprising that the $PdBr(PH_3)(C_6H_5)(C_6H_5Li)$ system will yield a stable structure with Li^+ embedded between the two phenyl groups. Indeed the bond dissociation energy (at 0 K) of a benzene ring from the bis(benzene) $[Li(\eta^6\text{-}C_6H_6)_2]^+$ system is rather high (24.9 ± 1.6 kcal mol^{-1} experimentally, and 25.0 kcal mol^{-1} at the MP2/6–311+G(2d,2p)//MP2/6–311+G(2d,2p) level with BSSE correction).[48] At the B3LYP/6–31G*// B3LYP/6–31G* level (which is our level of calculation), we obtained a value (not BSSE corrected) of 26.2 kcal mol^{-1}.

Thus, to better reconcile our findings with the isolobal analogy concept, one should keep the two phenyl groups and replace only the $PdBr(PH_3)$ moeity by CH_2^+. One can also consider BH_2 instead of CH_2^+. This leads to$[(CH_2)(C_6H_5)(C_6H_5)(Li)]^+$ and $[(BH_2)(C_6H_5)(C_6H_5)(Li)]$ as isolobal analogs of $PdBr(PH_3)(C_6H_5)(C_6H_5)(Li)$. We indeed obtained stable structures for these two systems (see Fig. 3*b*). Note that lithium tetraphenylborate $Li(BPh_4)$ would also be an isolobal analog. $Li(BPh_4)$ is not known experimentally, since organolithium compounds usually occur as oligomers and (or) are stabilized by donor ligands.[52–60] This is in particular the case for the tetraphenylborate salts, such as $[Li(H_2O)_4][BPh_4]$,[61] $[Li(THF)_2(H_2O)_2][BPh_4]$,[62] and $[Li(CH_3OCH_2CH_2OCH_3)(H_2O)_2][BPh_4]$,[63] where the interaction with the tetraphenylborate anion takes place through hydrogen bonding between one water molecule and two phenyl groups. But in potassium and rubidium tetraphenylborate[64,65] the potassium and rubidium cations are embedded between two phenyl rings and experience M^+–π interactions, just like the Li^+ or Na^+ cations in $PdBr(PH_3)(C_6H_5)(C_6H_5)(Li)$ or $PdBr(PH_3)(C_6H_5)(C_6H_5)(Na)$. Quite interesting too is the crystal structure of lithium diferrocenyldiphenylborate·Bu_2O $[Li(OBu_2)][BFc_2Ph_2]$ **1** and of the compound $[(Li(OBu_2))_2][1,1'\text{-}Fc(BPh_3)_2]$,[66] **2,** which are again isolobal analogs of the palladium system. In these systems, Li is bound to only one dibutyl ether molecule and interacts with either two Cp rings, as sketched in **1**, or with one Cp and one phenyl ring, as sketched in **2**. Thus, these results point to the pertinence of the isolobal analogy, when used circumspectly.



1 **2**

The details of the structure of $PdBr(PH_3)(C_6H_5)(C_6H_5)(Li)$ and the energetics of the reaction $PdBr(PH_3)(C_6H_5)$ + C_6H_5Li → $PdBr(PH_3)(C_6H_5)(C_6H_5)(Li)$ also deserve some comments. We may first note that the lithium atom does not lie exactly above the center of the phenyl rings, as in $[Li(C_6H_6)]^+$ and $[Li(C_6H_6)_2]^+$ but is displaced toward the meso carbon atoms: The Li–C_{meso} average bond distance amounts to 2.306 Å, whereas the Li–C_{ortho}, Li–C_{meta}, and Li–C_{para} average bond distances amount to 2.413, 2.611, and 2.695 Å, respectively. The Li–C_{meso} bond distance compares well with the Li–C bond distance computed for $[Li(C_6H_6)_2]^+$,[48] and is somewhat shorter than the Li–C_{meso} bond distance of 2.42 Å in **2**.[66] Note also the relatively acute C_{phenyl}-Pd-C_{phenyl} angle of 81.4°, and the fact that the two phenyl ligands are tilted slightly inward toward the Li (with the Pd-C_{meso}-C_{ortho}-C_{meta} dihedral angle amounting to 163°). This shows clearly how the complex adapts itself to maximize the interaction with lithium. The enthalpy and the Gibbs free energy for the reaction *trans*-$PdBr(PH_3)(C_6H_5)$ + C_6H_5Li → $PdBr(PH_3)(C_6H_5)(C_6H_5)(Li)$ are indeed rather large, –61.2 kcal mol^{-1} and –47.2 kcal mol^{-1}, respectively. The ΔH value is much larger than the value computed for the reaction $[(C_6H_6)Li]^+ + C_6H_6 \rightarrow [(C_6H_6)_2Li]^+$.[47] One may therefore tentatively propose the synthesis of such embedded lithium complexes through the reaction of phenyl lithium with an appropriate palladium complex. We are of course well aware that one should take into account the fact that phenyl lithium interacts with solvation molecules and that the interaction of such molecules in the first coordination sphere of lithium would reduce the magnitude of the interaction with the phenyl group, as shown theoretically by Sastry et al. for $[(C_6H_6)Li^+(H_2O)_n]$.[67] But the fact that the synthesis of **2** could be successfully achieved strengthens our present proposal.

We can finally analyze briefly the results for the Na system. Here too, the sodium atom is embedded between the two phenyl rings (see Fig. 3*a*). The Na–C_{phenyl} distances are longer than the Li–C_{phenyl} distances by 0.2–0.3 Å. A similar lengthening has been obtained in $(C_6H_6)M^+$ and $[(C_6H_6)_2]M^+$, when M is changed from Li to Na.[46–49] In line with this lengthening, one notes that the C_{phenyl}-Pd-C_{phenyl} angle is less acute (84.2°) and that the phenyl rings are also less tilted inward toward the alkali metal (the Pd-C_{meso}-C_{ortho}-C_{meta} dihedral angle value of 171° being now closer to 180°). Yet, the enthalpy and the Gibbs free en-

ergy of the *trans*-$PdBr(PH_3)(C_6H_5)$ + C_6H_5Na → $PdBr(PH_3)(C_6H_5)(C_6H_5)(Na)$ reaction hardly change, with values of –62.0 and –48.0 kcal mol^{-1}, respectively.

The $PdBr(PH_3)(C_6H_5)(C_6H_5AH_2)$ systems (A = B, Al)

In phenylboron dihydride, which can be considered as a model for phenylboron dihalides, the BH_2 group is of cationic character. This is also true for the AlH_2 group in $(C_6H_5)AlH_2$. We therefore investigated the fate of the reaction between $PdBr(PH_3)(C_6H_5)$ and either $(C_6H_5)BH_2$ or $(C_6H_5)AlH_2$. As in the previous paragraph, we will use the isolobal analogy to analyze the corresponding results.

The replacement of the $PdBr(PH_3)$ moiety in $PdBr(PH_3)(C_6H_5)_2BH_2$ by its isolobal analogs CH_2^+ or BH_2, and of the two phenyl groups by H, leads to the BCH_6^+ cation and to the well-known (experimentally and theoretically) diborane molecule B_2H_6. It is therefore not surprising to find as a stable structure the one shown in Fig. 4*a*, with the BH_2 group lying halfway between the two phenyl groups and the BH_2 plane perpendicular to the PdBrP plane. The BCH_6^+ cation has been theoretically studied[68–70] and found to adopt a structure somewhat analog to the one of B_2H_6, i.e., of the form $[H_2C(\mu\text{-}H)_2BH_2]^+$. Quite noticeably, the AIM analysis and the natural orbital analysis performed at the MP2/cc-pVTZ level by Zeng and Davico[70] suggest that the bonding pattern is best described as involving CH_4 in interaction with a BH_2^+ fragment. The optimized structure of Fig. 4*a* is consistent with this bonding pattern: In $PdBr(PH_3)(C_6H_5)_2BH_2$, the $[BH_2(C_6H_5)_2]$ fragment adopts a structure, which is the one of $[BH_2(C_6H_5)_2]^-$ (see Fig. 4*b*). The $PdBr(PH_3)(C_6H_5)_2BH_2$ system is therefore best described as being made of a $[BH_2(C_6H_5)_2]^-$ fragment, which is isolobal to CH_4, in interaction with $[PdBr(PH_3)]^+$, which is isolobal toBH_2^+.

If one now compares the optimized structure of $PdBr(PH_3)(C_6H_5)_2BH_2$ with the one of $PdBr(PH_3)(C_6H_5)_2AlH_2$ (see Figs. 4*a* and 5*a*), one will immediately notice that they differ primarily by the orientation of the two phenyl groups. In $PdBr(PH_3)(C_6H_5)_2BH_2$, the phenyl groups bend away from the boron atom, as in $[BH_2(C_6H_5)_2]^-$, whereas in $PdBr(PH_3)(C_6H_5)_2AlH_2$, they bend away from the palladium atom, as in $[PdBr(PH_3)(C_6H_5)_2]^-$ (see Fig. 5*b*). Thus, the $PdBr(PH_3)(C_6H_5)_2AlH_2$ system now best corresponds to the interaction of a $[PdBr(PH_3)(C_6H_5)_2]^-$ anionic fragment with the AlH_2^+ moiety. This is again consistent with the picture that one can draw from the isolobal analogy. All calculations carried out on the $H_2B(\mu\text{-}H)_2AlH_2$ system by several groups conclude to an electronic structure of the $(BH_4)^-(AlH_2)^+$ type.[71–74] Another structural feature also deserves some comments. In contrast to $PdBr(PH_3)(C_6H_5)_2BH_2$ the Pd-C-Al-C, central ring of the $PdBr(PH_3)(C_6H_5)_2AlH_2$ system is no longer planar, but folded about the Pd···Al line (by 39.3°), see the view along this line in Fig. 5*a*. Al_2H_6,[75] Al_2Me_6,[76] $[Me_2AlH]_2$,[77] and $H_2B(\mu\text{-}H)_2AlMe_2$[78] have a planar central ring, as B_2H_6 (see Scheme 2). The same holds true for $Ph_2Al(\mu\text{-}Ph)_2AlPh_2$.[79] But the X-ray crystal structure of $Me_2Al(\mu\text{-}Ph)_2AlMe_2$, which is isolobal to $PdBr(PH_3)(C_6H_5)_2AlH_2$, shows two kinds of molecules, one with a central planar ring and one with a folded central ring

Scheme 3. Structures obtained through the coupling of $Pd(Br)(C_6H_5)(PH_3)$ and $(C_6H_5)BH_2$. The enthalpies, in kcal mol^{-1}, are relative to the separated *trans*-$PdBr(PH_3)(C_6H_5)$ + $(C_6H_5)BH_2$ reactants. Relative free energy values are in italic.

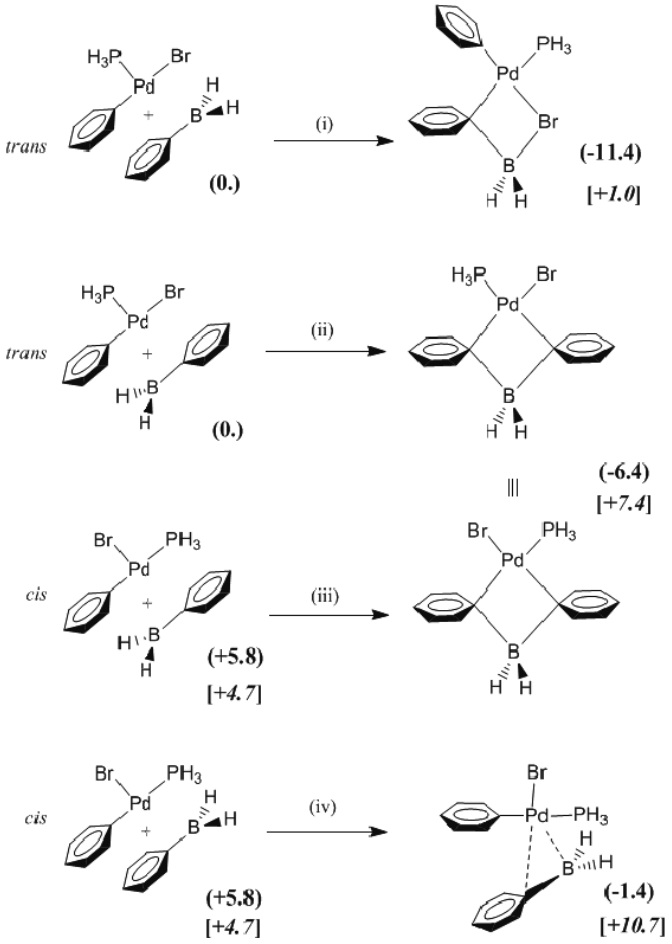

Fig. 6. Optimized structures for the reaction of $(C_6H_5)BH_2$ with *trans*-$PdBr(PH_3)(C_6H_5)$ to yield $PdBr(PH_3)(\mu\text{-}C_6H_5)_2BH_2$. The enthalpy values are in kcal mol^{-1}.

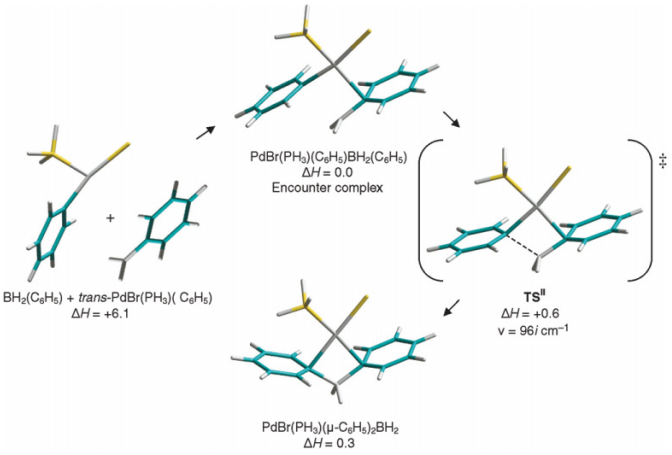

(by 13.7°).[80] In our case, the conformer with a planar central ring turned out to be the transition state for the flipping between the two folded conformers (imaginary frequency of

24*i* cm^{-1}). The computed energy barrier for this flipping is very low, only 1.1 kcal mol^{-1}.

The $PdBr(PH_3)(\mu\text{-}C_6H_5)_2BH_2$ and $PdBr(PH_3)(\mu\text{-}C_6H_5)_2AlH_2$ systems of Figs. 4*a* and 5*a* also differ by their stabilization with respect to the separated reactants, $PdBr(PH_3)(C_6H_5)$ and $(C_6H_5)BH_2$ on one hand for boron, and $PdBr(PH_3)(C_6H_5)$ and $(C_6H_5)AlH_2$ on the other hand for aluminium. For *trans*-$PdBr(PH_3)(C_6H_5)$, we computed a stabilization enthalpy of 6.4 kcal mol^{-1} in the former case and of 22.0 kcal mol^{-1} in the latter one (values not BSSE corrected). This is in line with the greater propensity of aluminum organyls to dimerize.[81] For *cis*-$PdBr(PH_3)(C_6H_5)$, the stabilization enthalpy is 5.8 kcal mol^{-1} larger, a value that corresponds to the destabilization of *cis*-$PdBr(PH_3)(C_6H_5)$ with respect to its isomer *trans*-$PdBr(PH_3)(C_6H_5)$.

We have investigated the reaction of $PdBr(PH_3)(C_6H_5)$ with $(C_6H_5)BH_2$ with some depth. As indicated in the Scheme 3, four modes of approach, (i) to (iv), can be de-

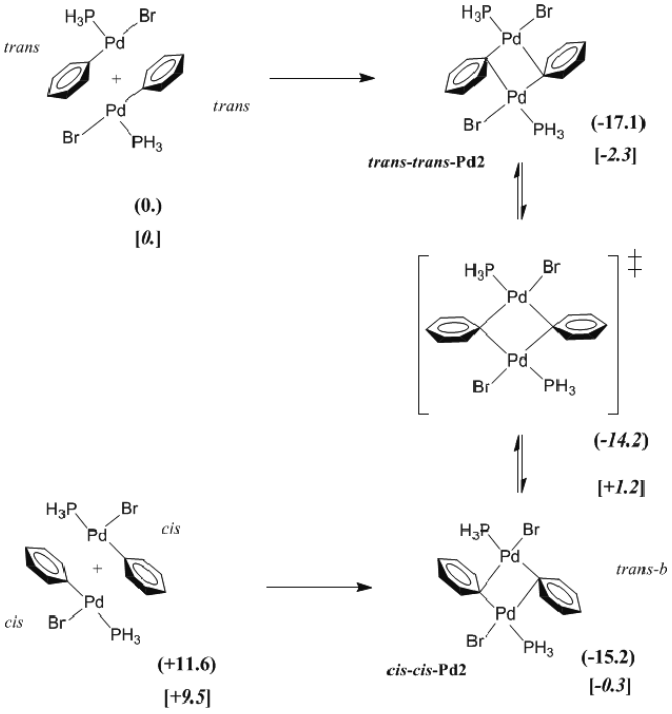
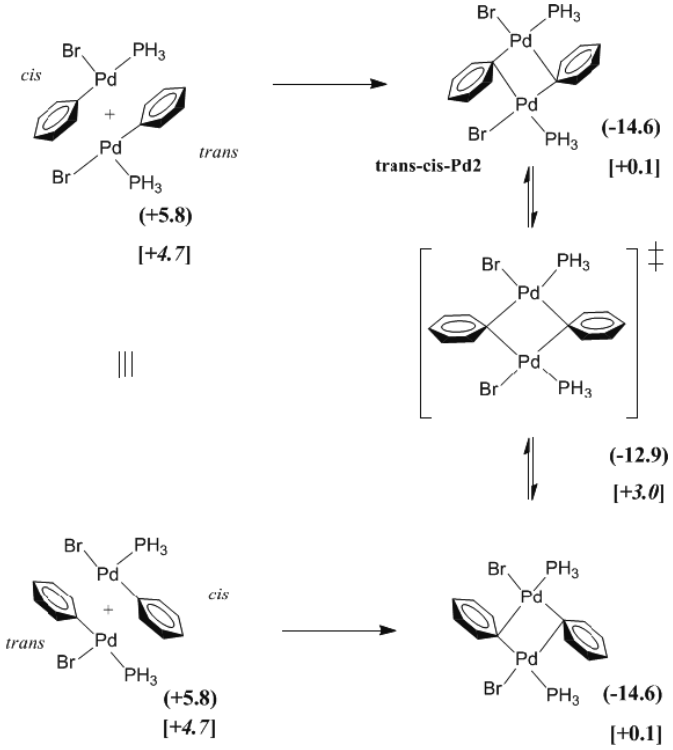
Scheme 4*a*. Phenyl-bridged structures obtained through the homo coupling of $Pd(Br)(C_6H_5)(PH_3)$. The enthalpies, in kcal mol^{-1}, are relative to the separated *trans*-$PdBr(PH_3)(C_6H_5)$ + *trans*-$PdBr(PH_3)(C_6H_5)$ reactants. Relative free energy values are in italic.



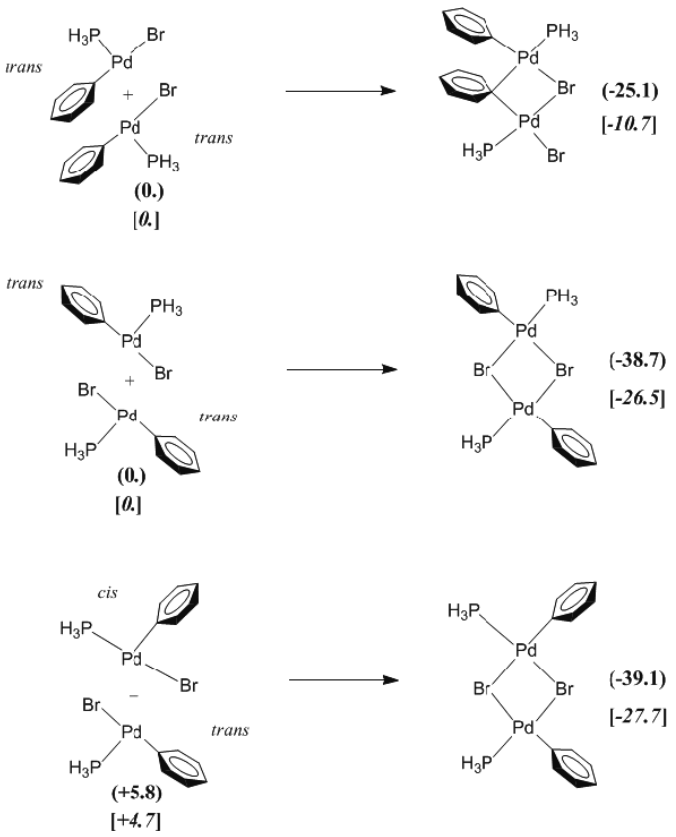
Scheme 4*b*. Phenyl-bridged structures obtained through the hetero coupling of $Pd(Br)(C_6H_5)(PH_3)$. The enthalpies, in kcal mol^{-1}, are relative to the separated *trans*-$PdBr(PH_3)(C_6H_5)$ + *trans*-$PdBr(PH_3)(C_6H_5)$ reactants. Relative free energy values are in italic.



lineated, depending on whether the *cis*- or the *trans*-$PdBr(PH_3)(C_6H_5)$ complex is considered and on whether in the approach the two phenyl groups are facing each other or not. Note that (ii) and (iii) lead in fact to two identical structures. We were able to locate a transition state for the addition of $(C_6H_5)BH_2$ to *trans*-$PdBr(PH_3)(C_6H_5)$ that leads to $PdBr(PH_3)(\mu\text{-}C_6H_5)_2BH_2$ (pathway (ii), see Fig. 6). As shown in this figure, it lies 0.6 kcal mol^{-1} above an encounter complex that correspond to an η^1 coordination of the phenyl group of $(C_6H_5)BH_2$, and 0.9 kcal mol^{-1} above the product $PdBr(PH_3)(\mu\text{-}C_6H_5)_2BH_2$.

We could not find a similar reaction path for the addition of $(C_6H_5)BH_2$ to *cis*-$PdBr(PH_3)(C_6H_5)$, whatever disposition $(C_6H_5)BH_2$ may adopt. The only species that could be unambiguously characterized was a weak interaction complex schematically shown in the Scheme 3 as the outcome of pathway (iv). Finally, one should stress that $PdBr(PH_3)(\mu\text{-}C_6H_5)_2BH_2$ is not the most stable structure, the $Pd(PH_3)(C_6H_5)(\mu\text{-}Br)(\mu\text{-}C_6H_5)BH_2$ structure with one bridging phenyl and one bridging bromine, see Fig. 7, being more stable than $PdBr(PH_3)(\mu\text{-}C_6H_5)_2BH_2$ by 5 kcal mol^{-1}. We have no clear-cut explanation for this greater stability. Phenylhaloboranes Ph_nBX_{3-n} (n = 1, 2; X = F, Cl, Br, or I) are usually monomeric.[82] On the other hand, in the case of haloalanes,[81] halogens are known to be better bridging ligands than phenyls. The Br-bridged structure may be helped also by the disposition of the two phenyl rings in a π-stacking arrangement, see Fig. 7, with the closest carbon···carbon distances of about 3.5 Å.[83] As shown on Scheme 3, it may be obtained via the pathway (i). Alternatively, since the transition state and the encounter complex of pathway (*ii*) are very close in energy from *trans*-$PdBr(PH_3)(\mu\text{-}C_6H_5)_2BH_2$, it

Scheme 4*c*. Bromo-bridged structures obtained through the homo and hetero coupling of $Pd(Br)(PH_3)(C_6H_5)$. The enthalpies, in kcal mol^{-1}, are relative to the separated *trans*-$PdBr(PH_3)(C_6H_5)$ + *trans*-



could be obtained from *trans*-$PdBr(PH_3)(\mu\text{-}C_6H_5)_2BH_2$ via a pathway that would comprise first a partial dissociation of $(C_6H_5)BH_2$, followed by a rotation of $(C_6H_5)BH_2$ around the Pd–C bond in the encounter complex, and a final recombination of the two entities to yield the μ-bromo structure.

The $PdBr(PH_3)(C_6H_5)(C_6H_5BeR)$ systems (R = H, CH_3)

The optimized structures of $PdBr(PH_3)(C_6H_5)(C_6H_5BeH)$ and $PdBr(PH_3)(C_6H_5)$ $(C_6H_5BeCH_3)$ are shown on Fig. 8*a*. As for $PdBr(PH_3)(C_6H_5)(C_6H_5AlH_2)$, we found, for each of these systems, a stable structure with a folded central ring and a transition state with a planar central ring associated to the flipping movement of this central ring. The values of the fold angle are quite similar to the one obtained in the case of AlH_2, 39.0° and 39.9° for $PdBr(PH_3)(C_6H_5)(C_6H_5BeH)$ and $PdBr(PH_3)(C_6H_5)(C_6H_5BeCH_3)$, respectively. The energy barriers are also quite low, 2.2 and 2.3 kcal mol^{-1}, respectively.

We can try to push the isolobal analogy further. Since $PdBr(PH_3)$ is isolobal to BH_2, the $PdBr(PH_3)(\mu\text{-}C_6H_5)_2BeH$ system is isolobal to $H_2B(C_6H_5)_2BeH$. If one replaces the two phenyl groups by two hydrogens, one gets the H_4BBeH system, for which the $HB(\mu\text{-}H)_3BeH$ triply bridged structure, which corresponds to the folded structure of $PdBr(PH_3)(C_6H_5)(C_6H_5BeH)$, has been found to be more stable than the $H_2B(\mu\text{-}H)_2BeH$ double-bridged structure at both the SCF and MP2 levels.[84,85] Moreover, the MP2 calculations indicated that the double-bridged structure is a transition state rather than a stable structure.[84] This is again in line with our results of the previous paragraph for $PdBr(PH_3)(C_6H_5)(C_6H_5BeH)$.

Finally, replacing H (or CH_3) by a cyclopentadienyl group leads to cyclopentadienylberyllium borohydride $CpBeBH_4$ for which the double-bridged structure $H_2B(\mu\text{-}H)_2BeCp$ has been inferred on the basis of gas-phase electron-diffraction measurements supplemented by an infrared and Raman spectra analysis.[86,87] The electron-diffraction study could not distinguish between a double- or a triple-bridged borohydride linkage. Accordingly, the bridging hydrogens were characterized by very large standard deviations (e.g., up to 0.09 Å for the $Be–H_b$ bond distance).[86] Although this system was considered in a theoretical study that dealt with the determination of ^{9}Be NMR chemical shifts,[88] its structure was not optimized. We have therefore carried out such a geometry optimization, using basis sets of increasing quality, viz. 6–31G*, 6–31G**, and 6–311++G**. All basis sets led to the double-bridged structure $H_2B(\mu\text{-}H)_2BeCp$ (Fig. 8*b*), as one could have anticipated from the isolobal analogy and in agreement with the results of the vibrational spectra.[87] Note, however, that with this example, one reaches again the limits of the concept, since the $H_2B(\mu\text{-}H)_2BeCp$ most stable structure is not folded, in contrast to the most stable structure of $PdBr(PH_3)(\mu\text{-}C_6H_5)_2(BeCH_3)$. We checked whether this might be due to the replacement of the two phenyls by two hydrogens by considering the $H_2B(C_6H_5)_2BeCp$ system. But the geometry optimization starting from a $H_2B(\mu\text{-}C_6H_5)_2BeCp$ geometry with two bridging phenyls led to the $(H)(C_6H_5)B(\mu\text{-}H)(\mu\text{-}C_6H_5)BeCp$ structure, with one bridging hydrogen and one bridging phenyl only. This structure is folded, however, with a fold angle of 21.6°. The $H_2B(\mu\text{-}C_6H_5)_2BeCp$ structure was not obtained, and that can be traced to the steric repulsion that would be experienced between the Cp ring and the two phenyl groups. In fact, the $(C_6H_5)_2B(\mu\text{-}H)_2BeCp$ structure, with two bridging hydrogens and two terminal phenyl groups turned out to be more stable by 8.3 kcal mol^{-1}, but planar. The folding of these systems seems therefore to be linked to the presence of bridging phenyls.

The values computed (at the B3LYP/6–31G* and 6–311++G** levels) for selected structural parameters of the $H_2B(\mu\text{-}H)_2BeCp$ system are reported in Table 1 together with the values deduced experimentally from the gas-phase electron-diffraction data. They generally agree, with the exception of the bridging-hydrogen values, for which large discrepancies are found: 0.22 Å for the $Be–H_b$ bond distance, 11° for the $Be\text{-}B\text{-}H_b$ angle, and 15° for the $H_t\text{-}B\text{-}H_b$ angle, whatever the basis set is. We have already mentioned the large experimental standard deviation for these parameters. Thus, we think, on the basis of our results, that the $H_2B(\mu\text{-}H)_2BeCp$ system warrants a re-investigation of its molecular structure.

The $[PdBr(PH_3)(C_6H_5)]_2$ dimer

We can use again the isolobal analogy of $PdBr(PH_3)$ with BH_2 to obtain the $[PdBr(PH_3)(\mu\text{-}C_6H_5)]_2$ dimer as the isolobal analog of the $PdBr(PH_3)(\mu\text{-}C_6H_5)_2BH_2$ system. Similarly, the dimerization reaction of $PdBr(PH_3)(C_6H_5)$ and the reaction of $PdBr(PH_3)(C_6H_5)$ with $(C_6H_5)BH_2$ should bear some resemblance. We indeed found three stable dimeric

Fig. 10. Optimized structures for the two-step Pd(IV) re-arrangement between $PdBr(PH_3)$ and Br in the $PdBr(PH_3)(C_6H_5)(C_6H_5Br)$ system. The enthalpy values are in kcal mol^{-1}. The distances are in Å.

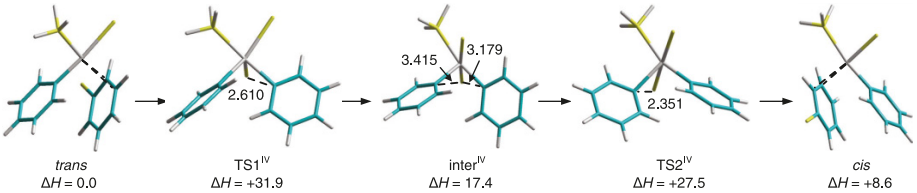


Table 2. Calculated energies for the Pd(IV) pathway in the trans–cis transformation of structures $PdBr(PH_3)(C_6H_5)(C_6H_5Y)$ (Y = F, Cl, Br, CH_3, OH, SH).

Note: The values are in kcal mol^{-1}; the zero of energy for the Pd migration in $PdBr(PH_3)(C_6H_5)(C_6H_5Y)$ refers, respectively, to the corresponding trans isomers. The B3LYP total energies (in a.u.) for Y = F are E = –1046.453680, H = –1046.221620, and G = –1046.291008; for Y = Cl: E = –1406.811765, H = –1406.580727, and G = –1406.651583; for Y = Br: E = –960.001520, H = –959.770805, and G = –959.842577; for Y = CH_3: E = –986.538760, H = –986.269756, and G = –986.340732; for Y = OH: E = –1022.438885, H = –1022.194120, and G = –1022.263903; and for Y = SH: E = –1345.348696, H = –1345.111128, and G = –1345.180185.

[a]In cm^{-1}; refers to the unique imaginary frequency of the calculated transition state.

structures for $[PdBr(PH_3)(\mu\text{-}C_6H_5)]_2$ with the two phenyl rings as bridging ligands, that are denoted ***trans-trans*-Pd2**, ***cis-cis*-Pd2**, and ***trans-cis*-Pd2** in Fig. 9. ***Trans-trans*-Pd2** corresponds to the coupling of *trans*-$PdBr(PH_3)(C_6H_5)$ with another *trans*-$PdBr(PH_3)(C_6H_5)$, ***cis-cis*-Pd2** to the coupling of *cis*-$PdBr(PH_3)(C_6H_5)$ with *cis*-$PdBr(PH_3)(C_6H_5)$, and ***trans-cis*-Pd2** to the coupling of *trans*-$PdBr(PH_3)(C_6H_5)$ with *cis*-$PdBr(PH_3)(C_6H_5)$ (see Schemes 4*a* and 4*b*). Note that the ***trans-trans*-Pd2** and ***cis-cis*-Pd2** structures differ only by a flipping of the two phenyl rings (see Scheme 4*a*). They are rather close in energy, the ***trans-trans*-Pd2** structure being more stable than the ***cis-cis*-Pd2** structure by 1.9 kcal mol^{-1} (enthalpy value) only. The transition state for this synchronous flipping movement is also quite low, only 1 kcal mol^{-1} above ***cis-cis*-Pd2**. On the other hand, the ***trans-trans*-Pd2** and ***cis-cis*-Pd2** phenyl-bridged structures

are well stabilized with respect to the separated monomers, by –17.1 and –15.2 kcal mol^{-1}, respectively. Of course, entropy will work against this stabilization. When the entropy penalty is taken into account, one gets Gibbs free energy stabilization values of –2.3 kcal mol^{-1} and –0.3 kcal mol^{-1} only, the free energy barrier between the two structures amounting to 1.5 kcal mol^{-1} (from ***cis-cis*-Pd2**). We are well aware that the present entropy corrections, which assume that all molecules are an ideal gas, are probably too large.[89–93] Yet, an interesting feature may be inferred from this rather flat free energy profile, viz. that the process sketched in Scheme 4*a* provides a route for exchanging the non aromatic ligands in the three coordinated Pd(II) phenyl complex. Note that this route will be operative if there is no other dimeric structure of large thermodynamic stability. For the present "model" system, structures with one or two bridging bromines are, as expected,[94,95] much more stable than the phenyl-bridged structures (see Scheme 4*c*). But, similarly to what has been found for the existence of monomeric arylpalladium(II) halide complexes, which can be stabilized by agostic interactions,[94,96–99] there might be steric factors that favour the phenyl-bridged dimeric structure when real phosphine ligands are considered.

The $PdBr(PH_3)(C_6H_5)(C_6H_5Y)$ systems (Y = F, Cl, Br, CH_3, OH, SH)

As said in the introduction, we also considered substituents of anionic nature, namely Y = F, Cl, Br, CH_3, OH, and SH. The process that exchanges Y with $PdBr(PH_3)$ is shown in Fig. 10 for Y = Br. Not unexpectedly, it involves a classical two-step oxidative addition/reductive elimination pathway between the +2 and +4 oxidation states of Palladium. We are not aware of such a systematic theoretical study for Pd(II) systems. There have been two studies of the oxidative addition of C_6H_5I to three-coordinate Pd(II) complexes.[100,101] In contrast, for Pd(0) systems, the oxidative addition of CH_3Y to Pd and $PdCl^-$, with Y being either F, Cl, Br, or I, has been thoroughly analyzed.[102] There is also a very recent report of the oxidative addition of C_6H_5Y (with Y = Cl, Br, or I) to a PdL_2 complex, where L_2 is a pyridylpyrazol ligand.[103] Our results for the three-coordinate $PdBr(PH_3)(C_6H_5)$ substrate are reported in Table 2. As for the Pd(0) systems, the energy barrier for the oxidative addition decreases in the order F > Cl > Br. It is very high for CH_3 and OH. The lowest barriers are found for Br and SH, of the order of 30 kcal mol^{-1}. The literature values for iodine are smaller, between 10 and 15 kcal mol^{-1}.[100,101] This points to a similar reactivity order for Pd(0) and Pd(II) systems. Thus, the factors that govern the reactivity pattern (see ref. [102]) are probably similar in both oxidation states.

Conclusion

Our calculations have shown that the Pd/X group intermolecular exchange in the $[PdBr(PH_3)(C_6H_5)(C_6H_5X)]$ system is a relatively easy process when X = H, and can be viewed in this case as involving the migration of a proton between the two phenyls. At variance with this result, the transfer of entities, which are more electropositive, such as X = Li, Na, BH_2, AlH_2, BeH, or $BeCH_3$ cannot take place. Instead, one gets stable structures that correspond to an arrested transfer in which X lies halfway between the two phenyl groups and experiences interactions that are quite ionic. These stable structures can be rationalized through isolobal analogy arguments. In the case of beryllium, the correspondence has been made also with the experimentally known cyclopentadienylberyllium borohydride system, $CpBeH_4$. The results of the DFT geometry optimization call for a re-examination of the gas-phase electron-diffraction structure determination, especially for the bond distances and angles that pertain to the two bridging hydrogens. As far as the halogen series, X = F, Cl, or Br and the electronegative groups X = CH_3, OH, or SH are concerned, the transfer between the two phenyls can take place via a Pd(II)/Pd(IV) two-step oxidative addition/reductive elimination mechanism. Yet, the associated energy barriers are very high, except for Br and SH for which the process might be feasible. We have also considered the $[PdBr(PH_3)(C_6H_5)]$ dimer and analyzed its structure with μ-phenyl ligands on the basis of the isolobal analogy with the previous systems. We hope that this study will be an incentive for the synthesis of systems related to some of the models that have been analyzed here.

Glycosidic bond cleavage in deoxynucleotides — A density functional study[1]

Andrea L. Millen and Stacey D. Wetmore

Abstract: Density functional theory was used to study the glycosidic bond cleavage in deoxynucleotides with the main goal to determine the effects of the nucleobase, hydrogen bonding with the nucleobase, and the (bulk) environment on the reaction energetics. Since direct glycosidic bond cleavage is a high-energy process, two nucleophile models were considered ($HCOO^{-}\cdots H_2O$ and HO^{-}), which represent different stages of activation of a water nucleophile. The glycosidic bond cleavage barriers were found to decrease, while the reaction exothermicity increases, with an increase in the nucleobase acidity. The gas-phase barriers and reaction energies for bond cleavage in all deoxynucleotides were found to be significantly affected by hydrogen-bonding interactions with the nucleobase (by up to 30 kJ mol^{-1} depending on the nucleophile). Although the barriers increase and reaction energies become less exothermic in enzymatic and aqueous environments, the effects of the bulk environment are similar in the presence and absence of small molecules bound to the nucleobase. Therefore, the effects of hydrogen bonding with the bases are approximately the same in all environments. Our results suggest that hydrogen bonding with the nucleobase may play an important role in the glycosidic bond cleavage in both pyrimidine and purine nucleotides in a variety of environments.

Key words: hydrogen bond, density functional theory (DFT), DNA, glycosidic bond cleavage, solvation.

Résumé : On a fait appel à la théorie de la fonctionnelle de la densité pour étudier le clivage de la liaison glycosidique de désoxynucléotides dans le but principal de déterminer les effets de la nucléobase, de la liaison hydrogène avec la nucléobase et l'environnement global sur les énergies impliquées dans la réaction. Puisque le clivage direct de la liaison glycosidique est un processus impliquant une énergie élevée, on a considéré deux processus nucléophiles modèles ($HCOO^{-}\cdots H_2O$ et HO^{-}) qui représentent des stages différents de l'activation de l'eau agissant comme nucléophile. On a trouvé que, avec une augmentation de l'acidité de la nucléobase, les barrières au clivage de la liaison glycosidique diminuent avec une augmentation du caractère exothermique de la réaction. On a aussi trouvé que les barrières en phase gazeuse et les énergies réactionnelles pour le clivage de la liaison de tous les désoxynucléotides sont significativement affectées par les interactions de barrières hydrogènes avec la nucléobase (jusqu'à 30 kJ mol^{-1} suivant le nucléophile). Même si les barrières augmentent et que les énergies réactionnelles deviennent moins exothermiques dans des environnements aqueux ou enzymatiques, les effets de l'environnement global sont semblables en présence ou en l'absence de petites molécules liées à la nucléobase. Les effets des liaisons hydrogènes avec les bases sont donc approximativement les mêmes dans tous les environnements. Les résultats obtenus suggèrent que les liaisons hydrogènes avec la nucléobase peuvent jouer un ţle important sur le clivage de la liaison glycosidique dans les nucléotides tant de pyrimidines que de purines, dans une grande variété d'environnements.

Mots-clés : liaison hydrogène, théorie de la fonctionnelle de densité (TFD), clivage de liaison glycosidique, solvatation, ADN.

Introduction

The sequence of nucleobases within DNA double helices contains the genetic make-up of living organisms. To preserve this important information, the bond between the base and the deoxyribose sugar moiety is very stable.[2–8] Indeed, even some modified DNA nucleotides, which can be formed during cell damage processes or studied for applications in biotechnology or medicine, are stable. Because of the high energy associated with cleavage of the glycosidic bond, this process requires enzymes[9] such as nucleotide hydrolases[10] or phosphorylases,[11] which are involved in nucleotide salvage pathways, or DNA glycosylases,[12,13] which are involved in DNA repair pathways.

The proposed mechanisms of action of enzymes that catalyze DNA glycosidic bond cleavages generally involve attack of a nucleophile (for example, water in the case of hydrolases,[10,14–19] ricin toxin A-chain,[19,20] and some DNA glycosylases (UDG[12,13,21–24] or MutY[12,13,25]), an active site (amine) amino acid in some DNA glycosylases (hOGG1[12,13,26–28] or FPG[12,13,29–32]), and hydrogen phosphate in phosphorylases[11,33–38]). Furthermore, important roles for active site amino acids other than nucleophilic attack, including activation of the nucleophile[10,21,24] or stabilization of the departing nucleobase through proton transfer[12,13,17] or hydrogen-bonding interactions,[12,13,21,24,36] have been suggested. Unfortunately, however, the order and importance of the proposed steps vary from enzyme to enzyme, and it is

not clear whether these differences are correlated with the properties of the nucleophile, the nucleobase, and (or) active site residues.

To shed light on the glycosidic bond cleavage process, previous work in our laboratory used techniques in computational chemistry to study the kinetics and thermodynamics of the glycosidic bond cleavage in 2′-deoxyuridine.[39] The goal was to understand the fundamentals of this reaction for the smallest nucleotide, independent of specific active site interactions for a particular enzyme, and thereby complement previous computational studies in the literature that have typically focused on only one feature of the glycosidic bond cleavage catalyzed by a certain enzyme (see, for example, refs. 24, 25, 28, 32, 34, and 38). Water was chosen as a nucleophile because of its importance in nature and its anticipated role in the glycosidic bond cleavage catalyzed by several enzymes.[10,12–24] The effects of hydrogen-bonding interactions between the nucleophile and (or) nucleobase and several small molecules that span a large acidity range were also considered. Our calculations revealed important information about the effects of the nucleophile, activation of the nucleophile, and interactions with the (uracil) nucleobase on this reaction.

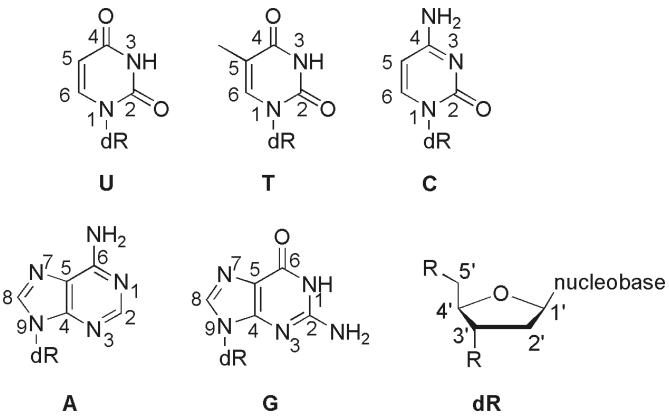
In the present work, we extend our study to all natural nucleotides (Chart 1, R = PO_4H^-) using a truncated model (Chart 1, R = OCH_3). Understanding the effects of different factors (nucleophile activation, hydrogen bonding) on the glycosidic bond cleavage in all DNA nucleotides is important to elucidate how the nature of the nucleobase affects the reaction. Indeed, proposed mechanisms for enzymatic glycosidic bond cleavage are dependent on the nucleobase.[9–13] For example, the bond cleavage in 2′-deoxyuridine by uracil DNA glycosylase has been proposed to proceed via a base anion,[21–24] while bond cleavage in 2′-deoxyadenosine by MutY[25] or dAMP[19] has been proposed to proceed via base protonation. We also complement our previous work by considering the effects of the (bulk) environment on this important reaction for all nucleosides, including 2′-deoxyuridine.

Computational details

Previous work in our laboratory revealed that nucleotide model systems where the phosphodiester backbone at C3′ and C5′ is replaced by hydroxyl groups are inadequate for modeling the glycosidic bond cleavage within DNA because of interactions between the hydroxyl groups and the nucleophile and (or) nucleobase that cannot occur within DNA duplexes.[39] Instead, methoxyl groups were shown to be more accurate, and we use similar models in the present work (Chart 1, R = OCH_3). We note that although a smaller model (Chart 1, R = H) was found to yield similar results, previous computational studies of glycosidic bond cleavage reactions have pointed to the potentially important role of the C5′ hydroxyl group in terms of increasing base acidity, [18] and therefore we use the larger model in the present work.

Relative energies were obtained from B3LYP/6-311+G(2d,p) single-point calculations on geometries optimized at the B3LYP/6-31G(d) level, where previous work in our lab shows that 6-31G(d) geometries yield final relative energies in excellent agreement with geometries obtained using a larger (6-31+G(d,p)) basis set.[39] Scaled (0.9806) zero-point energy corrections are included in all relative energies, and basis set superposition error (BSSE) corrections are included in total energies of hydrogen-bonded complexes. Intrinsic reaction coordinate (IRC) calculations were used to confirm that transition states connect reported reactant and product complexes. Environmental effects were taken into account by performing polarizable continuum (PCM) single-point calculations on gas-phase geometries in both water (ε = 78), due to its abundance in biological systems, and ether (ε = 4), which describes an enzymatic environment between aqueous solution and an active site sequestered from water.[40] All calculations were performed with Gaussian 03.[41]

Chart 1. The natural DNA and RNA (uracil (U), thymine (T), cytosine (C), adenine (A), and guanine (G)) deoxynucleotides (R = PO_4H^-) and truncated nucleotide models (R = OCH_3) used in the present study.



Results and discussion

As mentioned in the Introduction, the glycosidic bonds within DNA are very stable,[2–8] which means direct cleavage of the base-sugar bond is not feasible. Indeed, experimental evidence suggests that nonenzymatic bond cleavage occurs via hydrolysis.[2–8] Furthermore, previous work in our lab indicates that a sole water molecule cannot efficiently cleave the glycosidic bond in deoxyuridine,[39] which emphasizes the important catalytic role of enzymes that facilitate these bond cleavages. Since water activation through (at least partial) proton abstraction prior to nucleophilic attack has been proposed in mechanistic steps for several enzymes that cleave glycosidic bonds,[10,12–24] we previously considered the effects of different stages of water activation on the barrier to deglycosylation in 2′-deoxyuridine.[39] We found that a series of barriers is obtained by considering nucleophiles ranging from water (direct hydrolysis) to the hydroxyl anion. Since the barriers for direct hydrolysis are very large, the present work focuses on two nucleophiles, namely the hydroxyl anion (HO^-), which represents full water activation (deprotonation), and (partial) water activation by a formate ion ($HCOO^-\cdots H_2O$). Using these model nucleophiles, we consider the effects of the nature of the nucleobase, hydrogen bonding with the nucleobase, and the (bulk) environment on the kinetics and thermodynamics of the glycosidic bond cleavage in deoxynucleotides.

Fig. 1. Selected B3LYP/6-31G(*d*) bond lengths (Å) and dihedral angles (°, where χ = ∠(O1′C1′N1C2) in the pyrimidines and ∠(O1′C1′N9C4) in the purines) in reactant (RC), transition state (TS), and product (PC) complexes for glycosidic bond cleavage in deoxynucleotides involving the hydroxyl anion (HO^-) as the nucleophile.

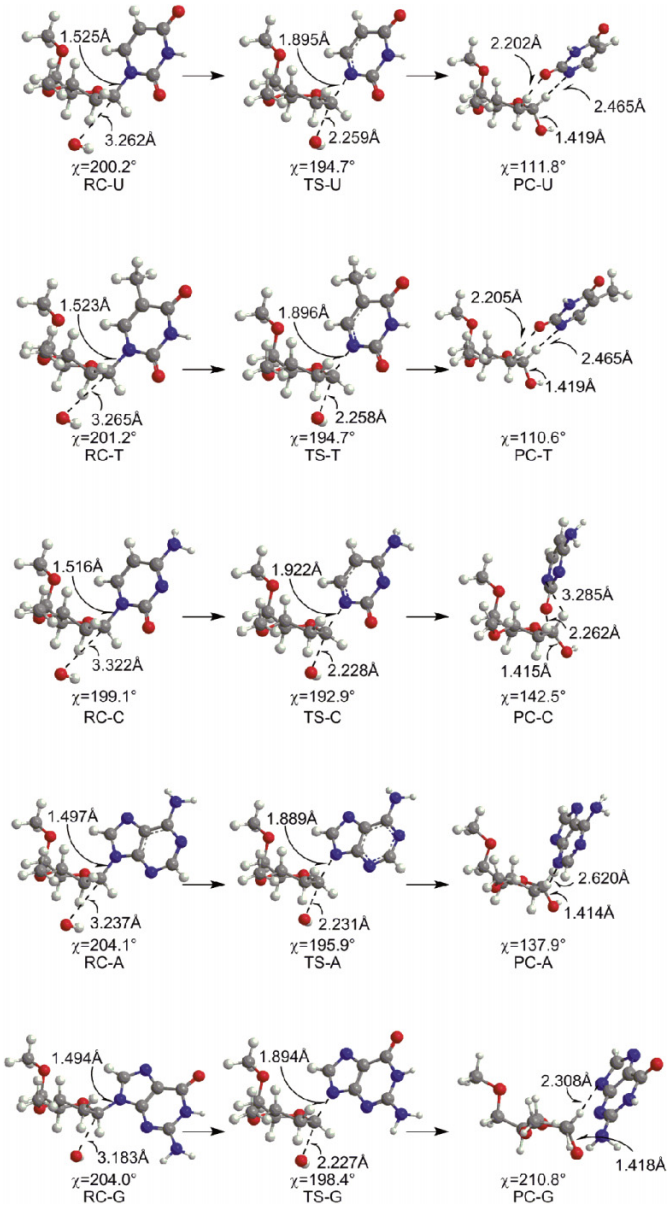


Fig. 2. Selected B3LYP/6-31G(*d*) bond lengths (Å) and dihedral angles (°, where χ = ∠(O1′C1′N1C2) in the pyrimidines and ∠(O1′C1′N9C4) in the purines) in reactant (RC), transition state (TS), and product (PC) complexes for glycosidic bond cleavage in deoxynucleotides involving formate activated water ($HCOO^-\cdots H_2O$) as the nucleophile.

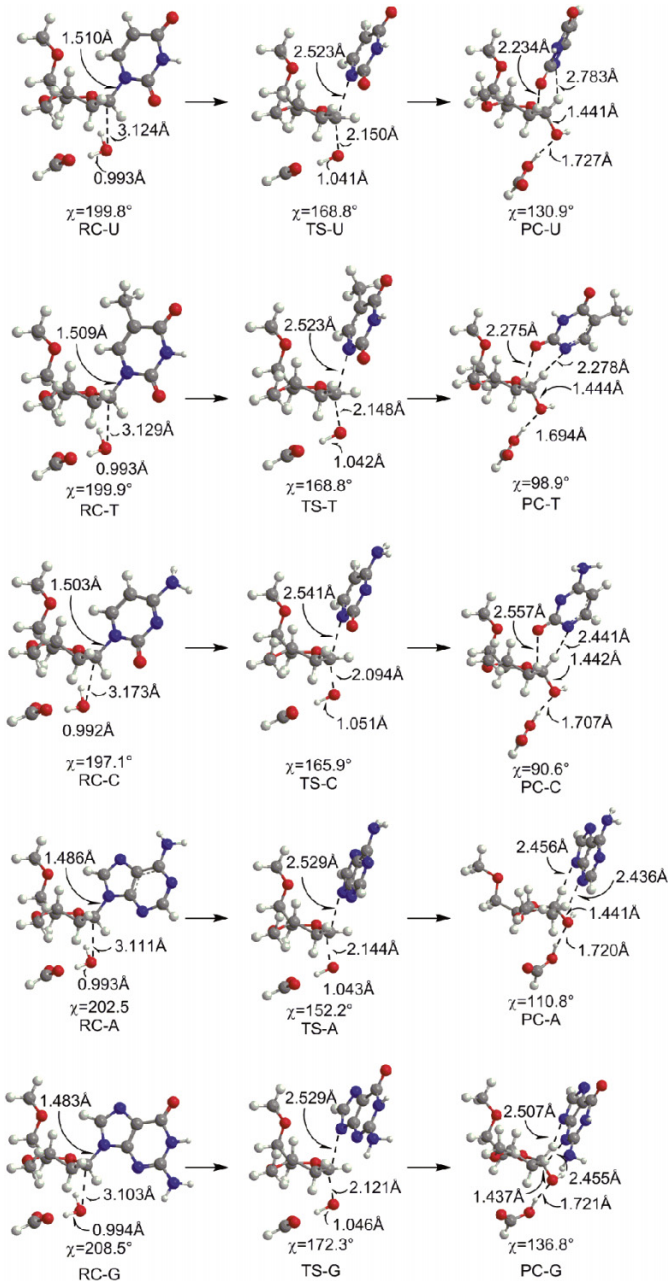

Effects of the nucleobase

The reactant, transition state, and product complexes for glycosidic bond cleavage in the natural DNA nucleotides involving the hydroxyl anion and $HCOO^-$ activated water are compared with those previously reported for uracil[39] in Figs. 1 and 2, respectively. As all transition states are formed, the nucleophile moves from a position under the sugar ring, which benefits from hydrogen-bonding interactions between the nucleophile and sugar moiety, to a position closer to C1′, while the sugar puckering changes from C3′-endo to C3′-endo-C4′-exo twist. In the transition state, the (partial) formation of a sugar cation is stabilized by charges on both the nucleophile and the departing nucleobase. In the product complex, although the final sugar puckering varies with the nucleophile and nucleobase, a bond is fully formed between the sugar and the nucleophile and the departed base is positioned above the sugar where it forms at least two (albeit weak) hydrogen bonds with sugar hydrogens. For all nucleobases, one of these hydrogen bonds involves the nucleobase ring nitrogen that previously formed the glycosidic bond (N1 for the pyrimidines and N9 for the purines, see Chart 1 for atomic numbering in the nucleobases).

Table 1. Barriers and reaction energies (kJ mol^{-1}) for the glycosidic bond cleavage in deoxynucleotides facilitated by $HCOO^{-}\cdots H_2O$ or HO^{-} nucleophiles, as well as nucleobase acidities at the glycosidic bond site (N1 in the pyrimidines and N9 in the purines).

	$HCOO^{-}\cdots H_2O$		HO^{-}

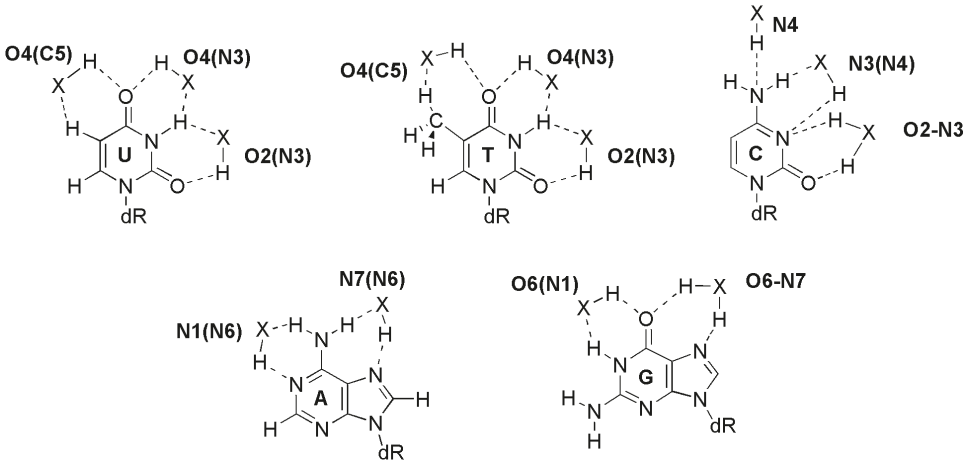
[a]Ref. 39.

[b]Refs. 42–45, where the acidity is calculated as the enthalpy of deprotonation and therefore a decrease in the deprotonation enthalpy represents an increase in the acidity.

Chart 2. Structure and nomenclature for small molecule (XH = HF, H_2O, and NH_3) hydrogen-bonding sites in the natural nucleotides.



In the reaction pathway involving the $HCOO^{-}\cdots H_2O$ nucleophile (Fig. 2), water retains the proton in the transition state, although the O–H bond interacting with the formate ion is lengthened by 0.05–0.06 Å, and the proton is transferred to the formate ion upon product formation. As a result, the nucleophile cannot provide as much stabilization to the developing positive charge on the sugar moiety in this transition state compared with bond cleavage in the presence of the hydroxyl anion. Therefore, the $HCOO^{-}\cdots H_2O$ nucleophile is associated with later transition states as indicated by approximately 0.6 Å longer C1′–N distances and approximately 0.1 Å shorter distances between the nucleophile and C1′ (see Figs. 1 and 2). The end result is that the barrier for the reaction facilitated by the $HCOO^{-}\cdots H_2O$ nucleophile is larger (by a factor of approximately 2), and the reaction is less exothermic (by up to 180 kJ mol^{-1}), compared with the reaction facilitated by the hydroxyl anion for all nucleobases (Table 1).

For both nucleophile models, the magnitude of the transition barrier decreases as C > G ≈ A > T ≈ U, while the overall exothermicity of the reaction generally decreases according to U ≈ T > A ≈ G > C for $HCOO^{-}\cdots H_2O$ and as U ≈ T > A > G > C for HO^{-}. These trends follow the trend in the nucleobase acidity at the glycosidic bond site (Table 1).[42–45] Specifically, the greater the nucleobase acidity, the lower the barrier and the more exothermic the overall reaction. However, despite an approximate 50 kJ mol^{-1} difference in the acidity of the nucleobases, the barriers for glycosidic bond cleavage deviate by only 22 and 15 kJ mol^{-1} when catalyzed by $HCOO^{-}\cdots H_2O$ and HO^{-}, respectively.

The difference between the glycosidic bond cleavage barriers for the natural nucleobases as a function of the nucleophile can be understood by considering the charge on the nucleobase. Specifically, the reaction facilitated by the hydroxyl anion has the earliest transition states with the shortest C1′–N bond lengths, and therefore the nucleobases in these transition states have smaller net charges compared with the corresponding $HCOO^{-}\cdots H_2O$ reaction. As a result, the transition barrier is much less dependent on the ability of the nucleobase to stabilize the charge (or in other words, on the nucleobase acidity), and therefore the smallest range in barriers is observed for the HO^{-} nucleophile. Similarly, the amount of charge on the nucleobase in the transition states for the reaction catalyzed by activated water is less than that on the isolated uracil anion, which does not benefit from interactions with the (cationic) sugar moiety, and therefore the dependence of the barrier on the nucleobase is less than the dependence of the acidity.

In summary, although the barriers for glycosidic bond cleavage for different nucleobases follow the trend in nucleobase acidity, there is a relatively small difference between

the barriers. This suggests that factors other than the acidity likely also play an important role in promoting different mechanisms for cleavage of the glycosidic bonds in the pyrimidine compared with the purine nucleotides.

Effects of hydrogen bonding with the nucleobase

As mentioned in the Introduction, the proposed mechanisms for many enzymes that catalyze DNA glycosidic bond cleavage reactions involve proton transfer reactions or hydrogen-bonding interactions between the nucleobase substrate and active site amino acid residues. Due to the proposed formation of base anions in the mechanisms of action of some enzymes, previous work in our group considered the effects of hydrogen-bonding interactions with small molecules (HF, H_2O, and NH_3) on the (N1 or N9) acidity of the natural (and selected damaged) nucleobases.[42–45] We found that the acidity can be increased by up to 60 kJ mol^{-1}, where the magnitude of the enhancement decreases with the acidity of the small molecule bound ($HF > H_2O > NH_3$) and is more dependent on the nature of the small molecule than the nucleobase binding site (see Chart 2 for binding sites considered). Since the previous section suggests that there is a correlation between glycosidic bond cleavage barriers and nucleobase acidity, we consider the effects of various hydrogen-bonding interactions with the nucleobase on the glycosidic bond cleavage reaction in all natural deoxynucleotides.

Tables 2–6 display the effects of hydrogen bonding between the nucleobase and small molecules (XH = HF, H_2O, or NH_3) for glycosidic bond cleavage in the presence of the formate activated water and hydroxyl anion nucleophiles. Specifically, changes to the barriers ($\Delta^{\ddagger}$) and reaction energies (Δ(energy)) are reported as well as the corresponding changes in the nucleobase acidity (Δ(acidity)). Each small molecule binds to both a nucleobase proton donor and acceptor at a variety of sites, where our notation uses brackets to identify the nucleobase proton donor as defined in Chart 2.

In general, hydrogen bonding with the nucleobase decreases the barrier heights ($\Delta^{\ddagger} < 0$) and increases the reaction exothermicity (Δ(energy) < 0). The magnitude of the effect follows the same trends with respect to the small molecule bound for each nucleobase–nucleophile combination and matches the previously reported trends in the effects on the acidity. Specifically, the effect increases with the relative acidity of the small molecule bound.[42–45] Therefore, ammonia sometimes leads to a small increase in the barrier (reaction energy), while hydrogen fluoride leads to the largest decrease. The trends with respect to the binding site also follow those previously reported for the effects on the acidity,[42–45] which is dictated by the relative magnitude of the proton affinity and acidity of the nucleobase sites involved in each bidentate binding arrangement.

Although decreases in the barriers for glycosidic bond cleavage were anticipated, based on calculated increases in the nucleobase acidity due to hydrogen bonding,[42–45] we find that the results are more dependent on the nature of the small molecule interacting with the nucleobase than the identity of the nucleobase. Specifically, although there is a range in the effect of each small molecule according to the nucleobase identity and binding site, there is little overlap in the effects of different small molecules. For example, the range in the effect of hydrogen fluoride on the barrier ($\Delta^{\ddagger}$) for the reaction involving the $HCOO^{-}\cdots H_2O$ nucleophile is 13–32 kJ mol^{-1}, while the range in the effect of water is 4–15 kJ mol^{-1}. The decrease in the barrier (and increase in reaction exothermicity) found for all nucleobases suggests that hydrogen-bonding interactions can facilitate the glycosidic bond cleavage in all natural nucleotides.

We also find that the effect of hydrogen bonding with the base on the barrier height is highly dependent on the nucleophile involved in the reaction. For example, the effects of hydrogen bonding with HF on the barrier range from approximately 13 to 32 kJ mol^{-1} for the reaction involving $HCOO^{-}\cdots H_2O$ and from 8 to 15 kJ mol^{-1} for the reaction involving HO^{-}. For comparison, the effects of the same HF interactions on the nucleobase acidity range from 39 to 58 kJ mol^{-1}. Thus, in this example, the effects of hydrogen bonding on the nucleobase acidity are approximately double the effects on the barrier for the $HCOO^{-}\cdots H_2O$ nucleophile and approximately four times the effects on the barrier for the HO^{-} nucleophile. Once again, these differences can be understood in terms of the net charge on the nucleobase, where the smaller the net charge on the base (TS for hydroxyl anion < TS for activated water < isolated base anion), the smaller the effect of the hydrogen bonds on the barrier (or acidity).

In contrast, the effects of hydrogen bonding with the base on the reaction energy are generally the same for both nucleophiles (approximately 14 to 38 kJ mol^{-1}), which are approximately half the effects on the acidity. The effects on the reaction energies are independent of the nucleophile due to the similarities in the geometries of the product complexes (see Figs. 1 and 2), where the base anion receives comparable stabilization through interactions with the sugar moiety regardless of the nucleophile. Furthermore, the effects are smaller than those previously reported for the acidity since some stabilization is provided to the base by the sugar cation in the product complexes.

Although the trend in the effects of hydrogen-bonding interactions on the barriers, reaction energies, and acidities can be easily justified, the differences in the magnitudes of these effects are initially surprising. Nevertheless, the deviations can be understood by considering differences in the binding strengths of the small molecules to the neutral nucleobases compared with the reactant complexes or the anionic nucleobases compared with the transition states or product complexes. Specifically, the effect of hydrogen bonding on the acidity arises because of stronger binding to the base anion compared with the neutral base.[42–45] Similarly, the effects of hydrogen bonding on the reaction energy (barrier) can be defined as the difference between the binding strengths in the reactant and product (transition state) complexes.[39] Therefore, when binding is stronger to the reactant complex than the isolated base, the effect of hydrogen bonding on the reaction energy (barrier) is less than the effect on the acidity. Alternatively, when binding is stronger to the product (transition state) complex than the base anion, the effect of hydrogen bonding on the reaction energy (barrier) is greater than the effect on the acidity.

In summary, hydrogen bonding with the nucleobase decreases the barrier height for glycosidic bond cleavage and increases the reaction exothermicity regardless of the identity of the nucleobase or nucleophile. However, although the effect of hydrogen bonding with the base on the reaction

[c]Ref. 45, where a positive Δ(acidity) represents an increase in acidity.

energies is independent of the nucleophile, the effect on the barrier is highly dependent due to differences in transition state geometries that dictate the net charge on the base. Indeed, since the magnitude of the effect can be directly correlated with the net charge on the base, the effects of hydrogen bonds on the reaction energetics are much less than those previously reported for the nucleobase acidity.[42–45] Nevertheless, the effects are still significant (up to approximately 40 kJ mol^{-1}). Furthermore, our previous study of the bond cleavage in deoxyuridine provides evidence that the glycosidic bond cleavage barrier can be further reduced by simultaneously involving more than one hydrogen-bonding interaction with the nucleobase.[39]

Environmental effects

The previous section has shown that hydrogen-bonding interactions between the nucleobase and small molecules can decrease the barrier height and increase the exothermicity of the reaction in the gas phase but to a smaller extent than the same interactions can increase the acidity of the (isolated) nucleobase. Previous work in our lab considered (bulk) environmental effects on the magnitude of the increase in acidity of natural (and damaged) nucleobases due to discrete hydrogen bonds through the implementation of continuum (PCM) solvation methods. We found that although the maximum increase in the gas-phase acidity is 60 kJ mol^{-1}, the maximum increase in enzymatic environments reduces to approximately 40 kJ mol^{-1}, and reduces further to approximately 30 kJ mol^{-1} in water. Since the present work suggests that the effects of discrete hydrogen bonds are also decreased when the reaction kinetics and thermodynamics are considered rather than the base acidity, it is of interest to evaluate the synergy between this outcome and the (bulk) environmental effects on the reaction energetics. Specifically, we must consider whether solvation further decreases the effects of hydrogen bonds on the reaction kinetics and thermodynamics reported in the present work, which may therefore make these interactions negligible to the overall reaction energetics.

Tables 2–6 compare the effects of hydrogen bonds on the kinetics and thermodynamics for glycosidic bond cleavage in the gas phase to those calculated in ether and water. As mentioned in the Computational details section, water was chosen because of its abundance in biological systems, while ether was chosen to represent enzymatic environments as a compromise between an aqueous solution and an active site sequestered from water. Furthermore, our previous work on the effects of hydrogen bonding on the nucleobase acidity shows that the results obtained in the gas phase, ether, and water span the results obtained in a wider range of solvents,[46] and therefore these dielectrics will provide representative examples of the environmental effects of interest.

The glycosidic bond cleavage barriers in the absence of small molecules interacting with the nucleobase in ether or water are only slightly larger (by less than 8 kJ mol^{-1}) than the corresponding gas phase barriers for the $HCOO^-\cdots H_2O$ nucleophile, but up to 30 kJ mol^{-1} larger for the HO^- nucleophile. The reaction energies, on the other hand, are more significantly affected due to the presence of solvent, where the $HCOO^-\cdots H_2O$ and HO^- reaction energies become less exothermic by up to approximately 15 and 90 kJ mol^{-1}, respectively.

The barriers and reaction energies for the glycosidic bond cleavage in the presence of hydrogen-bonding interactions with the nucleobase for the $HCOO^-\cdots H_2O$ nucleophile are larger and more endothermic in ether and water compared with the gas phase, where environmental effects on the barriers and reaction energies are up to approximately 26 and 32 kJ mol^{-1}, respectively. Additionally, there is no clear trend in the relative magnitude of the effects of ether or water, which suggests that there is a plateau in the (bulk) solvent effects for this nucleophile. Alternatively, the barriers systematically increase, and the reaction energies systematically become less exothermic, according to gas < ether < water for the reaction in the presence of the hydroxyl anion nucleophile, where the barriers generally increase by up to approximately 30 kJ mol^{-1} and the reaction energies generally increase by up to 100 kJ mol^{-1}.

The increases in the barriers and decreases in the reaction exothermicities in the absence and presence of hydrogen-bonding interactions with the nucleobases upon inclusion of solvation effects can be correlated with the stabilization of the nucleophile by the (bulk) solvent in the reactant complexes. Specifically, the degree of additional stabilization increases with both the charge on the nucleophile (HO^- > $HCOO^-\cdots H_2O$) and the polarity of the solvent (water > ether), and the net effect of ground state (reactant) stabilization is to increase the relative energies of the transition states and product complexes. For example, a greater degree of stabilization is provided to the hydroxyl anion nucleophile by (bulk) water than ether, which reduces the nucleophilicity in water to a greater extent and leads to larger increases in the reaction barriers. On the other hand, the formate activated water nucleophile is not affected as much as the hydroxyl anion by the bulk solvent and therefore there are smaller barrier increases for $HCOO^-\cdots H_2O$ compared with HO^-. These general conclusions for the effects of the bulk environment are supported by our previous results that considered the effects of interacting discrete molecules with the water nucleophile for the bond cleavage in deoxyuridine.[39] Specifically, the greater the stabilization provided to the hydroxyl anion (fully activated water) nucleophile though discrete hydrogen bonds, the larger the reaction barriers.

The most important finding upon consideration of environmental effects is that the changes in the gas-phase barriers and overall reaction energies upon solvation are essentially the same in the presence and absence of hydrogen-bonding interactions with the nucleobases. Therefore, the effects of hydrogen bonds with the nucleobase on the reaction barriers ($\Delta^{\ddagger}$) and energies (Δ(energy)) are approximately the same in the gas phase, ether, and water. Specifically, for both the HO^- and $HCOO^-\cdots H_2O$ nucleophiles, the deviations between the effects on the barriers in gas and ether or water are typically less than 5 kJ mol^{-1}, while the deviations in the reaction energies are generally less than 10 kJ mol^{-1}. This is a very important finding since the effects of the hydrogen bonds on the kinetics of the glycosidic bond cleavage are less than the effect on the acidity, and the effects on the acidity are further reduced upon solvation. These results emphasize the important role of discrete hydrogen-bonding interactions with the nucleobase in the glycosidic bond cleavage reaction for all deoxynucleotides.

Conclusions

The present work used computational chemistry to study the effects of the nature of the nucleobase, hydrogen bonding with the nucleobase, and the (bulk) environment on the kinetics and thermodynamics of the glycosidic bond cleavage in deoxynucleotides. Two nucleophiles were considered (HO^- and $HCOO^-\cdots H_2O$), which represent different stages of activation of a water nucleophile. In the absence of small molecules interacting with the nucleobase, the trend in the barriers and reaction energies for glycosidic bond cleavage follows the trend in the nucleobase acidities, where the greater the acidity, the smaller the barrier, and the more exothermic the reaction energy. However, the range in the reaction barriers is much less than the range in the base acidity and decreases with an increase in the charge on the nucleophile due to the promotion of earlier transition states with shorter glycosidic bond distances (and less charge on the nucleobase).

Discrete hydrogen-bonding interactions with all nucleobases decrease the barrier to glycosidic bond cleavage and increase the reaction exothermicity, but not to the same extent previous work indicates that these hydrogen bonds increase the base acidity. The magnitude of the effects depends on the small molecule bound, where the most acidic small molecules lead to the greatest effects. Although the effects on the reaction energies are the same for both nucleophiles considered in the present work, the effects on the barriers increase with a decrease in the charge on the nucleophile due to the formation of later transition states with greater charge on the nucleobase.

Environmental effects are found to increase the reaction barriers and decrease the reaction exothermicity due to stabilization of the nucleophile in reactant complexes. Since the ground state stabilization is similar regardless of whether small molecules are bound to the nucleobase, the effects of hydrogen bonding to the nucleobase are not significantly affected by the (bulk) environment and the reduction in barrier heights due to hydrogen bonding is up to approximately 30 kJ mol^{-1} in enzymatic environments depending on the nucleophile.

In summary, the most important conclusion from our work is that the effects of discrete hydrogen bonds with the nucleobase on the glycosidic bond cleavage are significant for all DNA bases in a variety of environments. Thus, although different proposed mechanisms exist for cleavage of the glycosidic bond in purine versus pyrimidine nucleotides, hydrogen bonding to the nucleobase will significantly decrease the reaction barrier regardless of the nucleotide. Future work must consider the implications of this finding for specific enzyme-catalyzed reactions since the magnitude of the effect of hydrogen bonds is dependent on the nucleophile, where different nucleophiles are often involved in cleavage of the glycosidic bond in pyrimidine versus purine nucleotides.

An improved neural network method for solving the Schrödinger equation[1]

Sergei Manzhos and Tucker Carrington, Jr.

Abstract: We propose a neural network (NN) based algorithm for calculating vibrational energies and wave functions and apply it to problems in 2-, 4-, and 6-dimensions. By using neurons as basis functions and methods of nonlinear optimization, we are able to compute three states of a 6-D Hamiltonian using only 50 basis functions. In a standard direct product basis, thousands of basis functions would be necessary. Previous NN methods for solving the Schrödinger equation computed one level at a time and optimized all of the parameters using expensive nonlinear optimization methods. Using our approach, linear coefficients in the NN representation of wave functions are determined with methods of linear algebra and many levels are computed at the same time from one set of nonlinear NN parameters. In addition, we use radial basis function neurons to ensure the correct boundary conditions. The use of linear algebra methods makes it possible to treat systems of higher dimensionality.

Key words: neural networks, vibrational spectroscopy, numerical methods.

Résumé : On propose un algorithme basé sur un réseau neuronal (RN) pour calculer les énergies de vibration et les fonctions d'onde et on l'applique à des problèmes en 2, 4 et 6 dimensions. L'utilisation de neurones comme fonctions de base et de méthodes d'optimisation non-linéaires permettent de calculer trois états d'un hamiltonien 6-D, en n'utilisant que 50 fonctions de base. Dans une base standarde produit direct, des milliers de fonctions de base seraient nécessaires. Les méthodes antérieures de RN utilisées pour résoudre l'équation de Schrödinger calculaient un niveau à la fois et optimisaient tous les paramètres en utilisant des méthodes coûteuses d'optimisation non linéaire. Dans l'approche présentée ici, les coefficients linéaires nécessaires pour représenter des fonctions d'onde sont déterminés par une méthode de l'algèbre linéaire et il est possible de calculer plusieurs niveaux en même temps, à partir d'un seul ensemble de paramètres neuronales nonlinéaires. En plus, nous utilisons des fonctions de base radiale afin d'assurer des conditions de limite correctes. L'utilisation de méthodes de l'algèbre linéaire permet de traiter des systèmes de dimension plus élevée.

I. Introduction

Using a perturbative normal mode approach, it is frequently possible to understand spectral patterns associated with low-lying energy levels of semirigid molecules, and to extract from them information about potential energy surfaces.[2,3] These methods enable one to disentangle the spectrum of a molecule to extract, for example, its equilibrium geometry and some information about its Born–Oppenheimer potential. However, to calculate high-lying levels of semirigid molecules or even low-lying levels of floppy molecules, it is necessary to calculate eigenvalues and eigenvectors of a matrix **H**, representing the nuclear Hamiltonian operator in a chosen basis.[4–7] This variational method has been successfully used to compute both high-lying vibrational states of semirigid molecules and low-lying states of weakly-bound complexes.[4–8] The principal impediment to applying it to compute spectra of small molecules, for which detailed experimental results are available, is the size of the Hamiltonian matrix. The most straightforward way to compute eigenvalues and eigenvectors is using a direct eigensolver (usually Householder transformations and the QR method).[9] The cost of such a calculation scales as N^3, where N is the size of the matrix. In many cases, the cost can be reduced by using the Lanczos algorithm.[10–14]

The basis functions used to make the calculations in refs. 4–8 and 10–14 are either products of functions of a single variable or contracted functions obtained from product basis functions. Contraction greatly reduces the size of the basis required to obtain a converged spectrum,[4–8,12,14–17] but for difficult problems, the matrices for which one must compute eigenvalues and eigenvectors are nonetheless huge. This is due to the fact that a linear variation is used: the only parameters are the coefficients of a basis set expansion. The matrix size can be reduced considerably by using flexible basis functions, which depend on parameters that are optimized. In this paper, we explore this strategy. Owing to the fact that most methods for solving the Schrödinger equation are limited by the amount of memory they require, the advantages of an approach that greatly reduces the basis size (and hence the size of the matrices or vectors one must

store) are compelling. Some questions to be explored: Is it possible to use functions that are flexible enough that they make a good basis for computing many energy levels? Is the cost of the parameter optimization prohibitive?

In this paper, we use neural network (NN) basis functions. Other scientists have also used NNs to solve the Schrödinger equation[18–20] but they have not used NN basis functions and have computed levels one at a time. NNs are attractive tools for solving the Schrödinger equation, because it is known that they are universal approximators,[21–24] and thought to scale favourably with dimensionality.[25–30] These advantages stem from the fact that NNs represent multidimensional functions with univariate functions but not with sums of products of functions. The difficulty of the multidimensional NN-parameter optimization problem has so far limited the application of NN-based methods to 1-, 2-, and 3-dimensional problems for which vibrational levels are obtained one at a time. We give a brief overview of NN methods for solving the Schrödinger equation in Section II.

In Section III, we present an improved NN method for solving the vibrational Schrödinger equation. Our method is better in four respects. (*i*) We simultaneously determine several energy levels and wave functions. This is done by optimizing a set of neurons for all the computed levels, i.e., the same NN hidden layer of neurons is used to make several outputs, one for each desired state. (*ii*) The linear NN parameters are determined using tools from linear algebra instead of standard minimization methods. This reduces the number of parameters one must optimize using expensive nonlinear methods. It involves finding eigenvalues and eigenvectors of "rectangular matrix pencils": recent progress[31] makes this approach feasible. (*iii*) In contrast to previous work, we use radial basis neural networks (RBFNN) and not sigmoid neural networks, in line with the argument that RBFNNs are better suited for approximating band-limited functions.[32] (*iv*) We pretrain the NN to avoid local minima.

II. Neural networks for wave functions

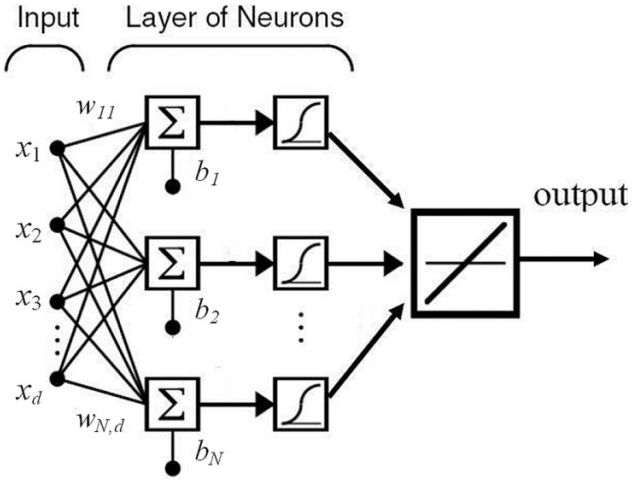
NNs[33–36] are flexible functions of the form

$$[1] \qquad f(y_1,\ldots,y_d)=\sum_{q=1}^{N} c_q \sigma\left(\sum_{p=1}^{d} w_{qp}y_p + b_q\right) + h$$

The one-dimensional function, σ, is called a neuron. The argument of σ is a linear combination of the coordinates; see Fig. 1, where a commonly used single hidden layer NN is shown. The final output of the NN is a linear combination of the outputs of the hidden layer. The key NN parameters are the input weights, $\boldsymbol{w}$, biases, $\boldsymbol{b}$, and output weights, $\boldsymbol{c}$. The most common choice for σ is the sigmoid function, $\sigma(x) = (1 + e^{x})^{-1}$.[24,37] It is well-known that the parameters can be adjusted to fit any function.[21–24] Mathematicians have also argued that the number of neurons required to obtain a good fit scales well with dimensionality.[25–30] Note that eq. [1] has the form of a basis expansion with neuron basis functions. The neurons should be good basis functions because they depend on many optimizable parameters. By varying the parameters, one changes the location, orientation, and extent of the basis functions.

How does one use NNs to solve the Schrödinger equation? One way to proceed[18–20] is to represent a wave function as an NN and to adjust the parameters to make the square of the norm of the residual

Fig. 1. The architecture of the commonly used single hidden layer neural network. *N* neuron inputs are formed from *d* components of the input vector. A weighted sum of the neuron outputs is the NN output. Here, neurons are labeled for the case of the most commonly used sigmoid NN: the neurons inputs are weighted *sums* of the coordinates (Σ) and the transfer function is sigmoid.



$$[2] \qquad R=\frac{\langle\psi|(\widehat{H}-E)^2|\psi\rangle}{\langle\psi|\psi\rangle} \approx \frac{\sum_{i=1}^{M}|(\widehat{H}-E)\psi({}^{i}\mathbf{y})|^2}{\sum_{i=1}^{M}|\psi({}^{i}\mathbf{y})|^2}$$

as small as possible. The ${}^{i}\mathbf{y}$ quadrature points on the right are chosen in the region where the wave function is expected to be non-negligible. If the wave function is represented as an NN, the kinetic energy operator (KEO) can be applied to the wave function analytically. In previous NN methods, NN parameters and E[19,20] or only NN parameters[18] (E being computed from the wave function) were fit to reduce R (or maximize e^{-R}) for a single state. For one-dimensional (1-D) problems, the best values of $\sqrt{R}$ were typically 2.3%–19% of the corresponding energies.[19,20] For a two-dimensional Henon–Heiles potential, the first four wave functions and levels were reported in ref. 18 with a relative error of the order of 10^{-5}. For a three-dimensional case, only the ground state for a Hamiltonian representing three coupled anharmonic oscillators was reported.[18]

III. Multilevel radial neuron matrix method

Our method is based on these ideas but improves on them in four ways; see the last paragraph of section I. Previous NN methods use general optimization techniques to determine the best values of all the NN parameters. These methods are computationally intensive because there are many parameters. Increasing the dimensionality exacerbates the problem. This is certainly one reason that previous calculations did not get beyond 3-D. All previous NN methods also use one NN per wave function. In section III.A, we outline a method that uses the same NN for a whole set of wave func-

tions and exploits a linear algebra technique to reduce the cost of the parameter optimization. In section III.B, we explain why radial basis function neurons are advantageous.

A. Combining linear and nonlinear optimization to determine several wave functions

To reduce the number of parameters that must be determined using general optimization techniques and at the same time to make it possible to compute a group of wave functions from one set of neurons, we think of the neurons as optimizable basis functions. To do so we must use a single hidden layer NN (see Eq. [1]). The simplicity of this architecture allows us to obtain a matrix equation from which we can easily determine the linear coefficients. It also greatly facilitates applying the kinetic energy operator to the NN. For example, applying the KEO of section III.E

$$[3] \qquad \widehat{T}(\boldsymbol{y}) = -\sum_{j,k=1}^{d} \gamma_{jk} \frac{\partial^2}{\partial y_j \partial y_k}$$

to the simple NN of eq. [1], one obtains

$$[4] \qquad \begin{cases} \widehat{T}\psi_k(\boldsymbol{y}) = -\sum_{i=1}^{d} c_{ik} \widetilde{\gamma}_i \sigma''(q_i) \\ \widetilde{\gamma}_i \equiv \sum_{m,n} \gamma_{mn} w_{im} w_{in} \\ q_i \equiv \sum_{j=1}^{d} w_{ij} y_j + b_i \end{cases}$$

Rather than representing each wave function with eq. [1] and optimizing a set of c_q, w_{qp}, and b_p parameters for each wave function, we optimize a single set of w_{qp} and b_p parameters to represent several wave functions and choose different c_q for each wave function, i.e.,

$$[5] \qquad \psi_k(\boldsymbol{y}) = \sum_{i=1}^{N} c_{ik} \sigma(\boldsymbol{w}_i, b_i, \boldsymbol{y}) + h_k$$

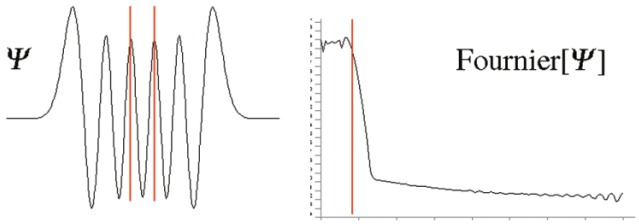
where $\psi_k(\boldsymbol{y})$ is the k^{th} wave function, and $\boldsymbol{w}_i$ is the ith row of the input weight matrix $\boldsymbol{w}$. In NN language, the network has several outputs, one for each wave function. All previous methods extract one vibrational level per neural network: to obtain many levels it is necessary to do many NN fits. As all wave functions are determined by the same potential, it is reasonable to hope that one set of NN hidden layer neurons can be used for many of them.

It is not necessary to optimize the w_{qp}, b_p, and c_q with the same method. We can use tools of linear algebra for the linear coefficients. For a given set of w_{qp} and b_p, we optimize the c_{qk} by solving a matrix equation. It is obtained by replacing the wave function in the Schrödinger equation with the NN, applying the Hamiltonian, and requiring that the Schrödinger equation be satisfied at a set of M points. One finds a generalized rectangular eigenvalue problem for the parameters c and h (see Appendix)

$$[6] \qquad (\mathbf{M} - E_k \mathbf{S})\widetilde{\boldsymbol{c}}_k = 0$$

where $\widetilde{\boldsymbol{c}}_k \equiv \begin{pmatrix} \boldsymbol{c}_k \\ h_k \end{pmatrix}$. Here $\mathbf{M}$ and $\mathbf{S}$ are rectangular matrices (of the dimension $M \times N$) depending on values of the potential and of the neurons at different points in the configuration space. This equation is somewhat analogous to the square matrix equation obtained using the collocation approach.[38] In our case, the matrices are rectangular because the number of basis functions is much smaller than the number of points used to optimize the parameters.

Fig. 2. An illustration of the band-limited character of vibrational wave functions. A vibrational wave function of a harmonic oscillator is shown along with its Fourier transform. The Fourier transform decays sharply above the frequency corresponding to the period of oscillation of the wave function (both shown by vertical lines).



B. RBFNN wave function

When devising a NN method for computing vibrational bound state solutions of the Schrödinger equation, it is important to do something to ensure that wave functions approach zero when the molecule is pulled apart. Previous NN methods used either an amplitude-phase decomposition[19,20] or multiplied the neural network by a function that satisfies the boundary condition by construction.[18] Both these approaches, however, make the application of the KEO cumbersome for a multidimensional problem and are incompatible with the use of linear optimization for some of the NN parameters. Instead, we use so-called radial basis function (RBF) neurons as opposed to the traditional sigmoid neurons. The NN is

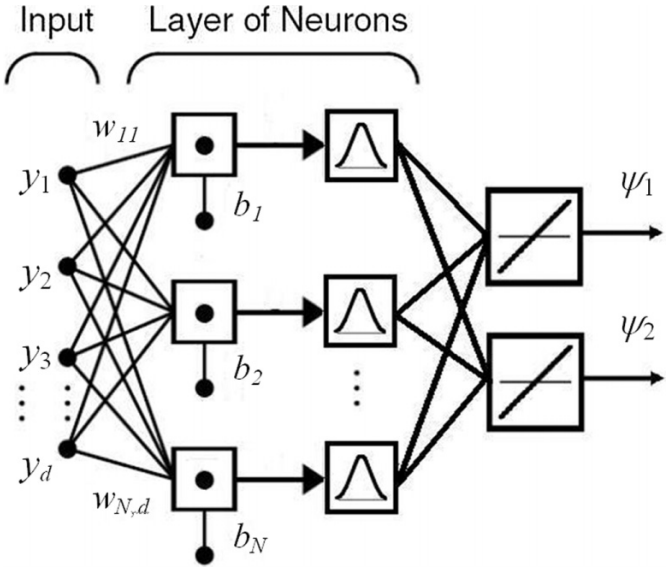
$$[7] \qquad \psi_k(\boldsymbol{y}) = \sum_{i=1}^{N} c_{ik} \exp\Big(- b_i^2 \sum_{j=1}^{d} (w_{ij} - y_j)^2 \Big) + h_k$$

RBFNNs have also been shown to be universal approximators.[39,40] It has recently been suggested that RBF or Gaussian neurons should be good for representing band-limited functions.[32] As vibrational wave functions are band limited, RB neurons should be a good choice for a NN Schrödinger method. Figure 2 shows, as an example, a harmonic wave function and its Fourier spectrum that decays quickly. There is also evidence that a RBF representation of a band limited function should be "free of the curse of dimensionality".[32] The RBFs we use are similar to the distributed Gaussian basis proposed in refs. 41–43. The key difference is that we optimize the parameters numerically to find the best possible basis. The parameters c_{ik} and h_k are determined with linear algebra and the other parameters with nonlinear optimization.

C. Solving the rectangular eigenvalue problem

To solve the rectangular eigenvalue problem we use an approach closely based on that of ref. 31. Note that an exact solution is not possible because the matrices are rectangular. The algorithm minimizes

Fig. 3. The architecture of the multiple output radial basis NN corresponding to eq. [7] and used in this paper.



$$[8] \qquad \min \|(\mathbf{M} - E_k\mathbf{S})\tilde{c}_k\|^2/(1 + |E_k|^2)$$

It requires a guess for E_k. According to the algorithm, an approximate right eigenvector is the eigenvector corresponding to the smallest eigenvalue of $(\mathbf{M} - E_k\mathbf{S})^{\mathrm{H}}$ $(\mathbf{M} - E_k\mathbf{S})$). In ref. 31 energies are updated at each iteration by solving $\tilde{c}^H(\mathbf{S}^{\mathrm{H}} + E_k\mathbf{M}^{\mathrm{H}})(\mathbf{M} - E_k\mathbf{S})\tilde{c} = 0$ for E. We obtain somewhat better results when, instead, we update the energy by fitting the E_k together with the $\boldsymbol{w}$ and $\boldsymbol{b}$ parameters. Here superscript "H" stands for the Hermitian conjugate. See ref. 31 for more details.

We combine the Levenberg–Marquadt algorithm and solutions of the rectangular eigenvalue problem as follows. For a particular set of w_{qp}, b_p, and E_k we solve the rectangular problem to determine eigenvectors and hence approximate wave functions. From the E_k and the approximate wave functions we compute a total residual, $R_{\mathrm{T}} = \sum_k R_k^2$, where R_k is the residual of eq. [2] for the kth eigenpair. We use a nonlinear optimization method to minimize

$$[9] \qquad R_{\mathrm{T}} + \sum_k (E_k - E_k^{\mathrm{int}})^2, \text{ where } E_k^{\mathrm{int}} \equiv \frac{\int \psi_k \hat{\boldsymbol{H}} \psi_k d\boldsymbol{r}}{\int |\psi_k|^2 d\boldsymbol{r}}$$

to find the best values of w_{qp}, b_p, and E_k. Only the w_{qp}, b_p, and E_k are determined by nonlinear optimization. This reduces the cost of finding the best parameters and makes it possible to treat higher-dimensional systems. For each set of w_{qp}, b_p, and E_k values, the rectangular eigenvalue problem must be solved. Figure 3 shows schematically the architecture of the NN, the coordinates that are input, and one layer of neurons whose weighted outputs are used to construct several wave functions.

D. Avoiding local minima

When optimizing the parameters, it is critical to avoid getting stuck in a local minimum. As the dimensionality of the calculation increases, the local minimum problem becomes more severe. We propose starting with parameter values that are close to those required to represent the desired wave functions. If we know good approximate wave functions, we find these values by pretraining the NN so that it reproduces them. If we do not have good approximate wave functions, we pretrain using wave functions obtained from a separable approximation to the potential and then turn on the coupling adiabatically, drawing the parameters to the correct minimum as the coupling strength is increased. (See section III.E).

E. Test Hamiltonians and results

We tested the new NN Schrödinger solver on quadratic potentials. As the NN basis is not based on a zeroth-order approximation it is expected to work about equally well for all potentials. In the original coordinates, the potential, KEO, and energy levels are

$$[10] \qquad \begin{aligned} V(\boldsymbol{x}) &= \sum_{i=1}^{d} x_i^2 \\ \hat{T}(\boldsymbol{x}) &= -\sum_{i=1}^{d} \frac{\partial^2}{\partial x_i^2} \end{aligned}$$

$$[11] \qquad E = 2\sum_{i=1}^{d}\left(n_i + \frac{1}{2}\right)$$

The calculations are done in a new set of coordinates, $\boldsymbol{y}$, obtained from, $\boldsymbol{y} = \boldsymbol{M}\boldsymbol{x}$, where the matrix of $\boldsymbol{M}$ is used to introduce coupling. Although we compute energy levels and wave functions of a coupled Hamiltonian, the exact levels and wave function are known and can be used to assess the quality of the NN solutions. This idea has been used to test other methods for solving the Schrödinger equation.[44,45] In our tests, we used

$$[12] \qquad y = \begin{pmatrix} 1 & 0 & \cdots & 0 \\ 0.2/d & 1 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0.2/d & 0.2/d & \cdots & 1 \end{pmatrix} x$$

In the new coordinates

$$[13] \qquad \begin{aligned} V(\boldsymbol{y}) &= \sum_{i,j=1}^{d} a_{ij} y_i y_j \\ \hat{T}(\boldsymbol{y}) &= -\sum_{j,k=1}^{d} \gamma_{jk} \frac{\partial^2}{\partial y_j \partial y_k} \end{aligned}$$

Configuration space is randomly sampled in the region in which the potential is below twice the energy of the highest level we wish to compute. There is no need to sample on a uniform grid, it is only necessary to have points where the wave functions are nonzero. The point distribution could be used to emphasize specific regions of space. We used the following point selection scheme: a random point, ${}^n\boldsymbol{y}$, is selected within a range of y_i, large enough to include all points for which $V({}^n y) \leq V_{\max} \equiv 2E_{\max}$, where $E_{\max}$ is the energy

of the largest desirable level. The point is accepted into the dataset if

$$[14] \qquad \frac{V_{\max} - V({}^{n}\boldsymbol{y})}{V_{\max}} > rand - PdfBias$$

where *rand* is a uniformly distributed random number in the range [0, 1], and *PdfBias* is a constant also in the range [0, 1]. *PdfBias* = 1 corresponds to a uniform point distribution, while *PdfBias* = 0 results in the "inverted potential" type of distribution with more points put in low-energy regions.[46] We find that it is better to use *PdfBias* < 1 when many levels are computed, as otherwise the lower level wave functions are undersampled. Obviously, computing high-lying levels requires using both more points and more NN parameters. More points are needed because wave functions associated with higher levels span a larger region of space, and a larger NN is needed because these wave functions are more structured. We first computed seven vibrational levels in two-dimensions using one NN with 70 Gaussian neurons and with 2 500 points up to $2E_{\max}$ ($E_{\max}$ = 14.0).

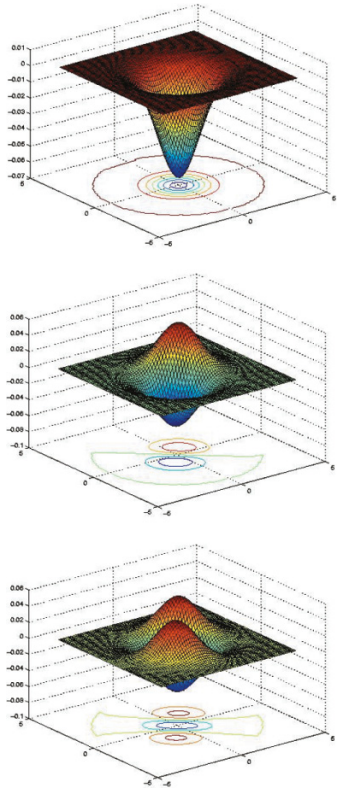
The RBFNN scheme described in section III.B was programmed in Matlab.[47] The neural network architecture was programmed using the Neural Network Toolbox[48] of Matlab. The more time-consuming parts of the code are programmed in Fortran and called from the Matlab code using mex-files.[47] The parameters $\boldsymbol{w}$, $\boldsymbol{b}$, and E_k were fitted with the Levenberg–Marquardt algorithm of Matlab. The parameters $\boldsymbol{c}$ and $\boldsymbol{h}$ were determined with the method described in section III.A. Parameter values can be obtained from the authors by request. The average, over all computed levels, of the residual norm

$$[15] \qquad \langle R_k \rangle = \left\langle \frac{\sum_{i=1}^{Np} |(\hat{H} - E_k)\psi_k({}^{i}\boldsymbol{x})|^2}{\sum_{i=1}^{Np} |\psi_k({}^{i}\boldsymbol{x})|^2} \right\rangle = 0.014$$

The ratio $\sqrt{R_k}/E_k$ is small compared to what was achieved previously for a 1-D problem.[19,20] Differences between exact and computed energies, ΔE_k, are about 0.022, which is also good compared to errors of previous calculations, despite the fact that all previous calculations compute only one level at time.[18–20] The R_k and ΔE_k for different levels have similar magnitudes.

There is, to the best of our knowledge, only one published result (the ground state) for a three-dimensional coupled harmonic oscillator[18] and *no* results for a four-dimensional Schrödinger equation. Therefore, we next performed a four-dimensional calculation for the system specified by eqs. [10] – [13]. For this 4-D test, we used 5 000 randomly sampled points, 70 neuron basis functions, and achieved an average R_k of about 0.007 over the first three levels. A direct product basis would have about 10^4 functions. Figure 4 shows two-dimensional slices of the wave functions for the first three vibrational levels. A similar fit of the three lowest vibrational levels in 6-D at 5 000 points and using 50 neurons yields an average error $<R_k>$ of 0.073. For reference purposes, the E_k we determine in the 6-D fit are

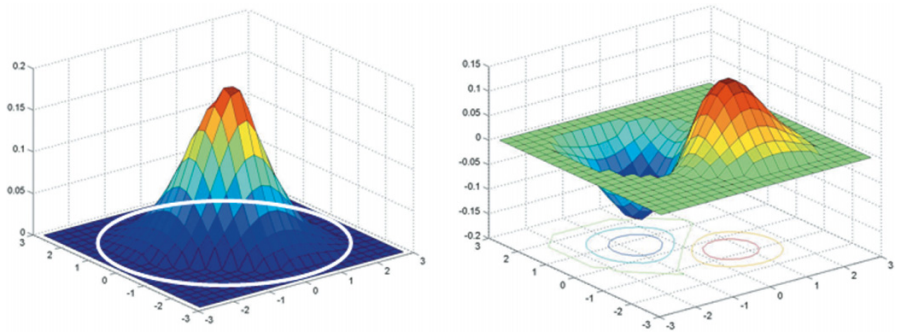
Fig. 4. Two-dimensional cross-sections of wave functions for three levels of the four-dimensional Hamiltonian in transformed coordinates (y).



5.9638, 7.9745, and 10.1388, and the corresponding R_k are 0.0814, 0.0618, and 0.0757. The energies obtained by integrating $\int \psi_k H \psi_k dr$ are 5.9524, 7.9708, and 10.1424, and the exact energies are 6.0, 8.0, and 10.0 (see eq. [11]). This proves that with the modifications we introduced, the new scheme surpasses the previous NN Schrödinger solvers.[18–20]

Finally, we discuss how we choose initial values of the E_k and the $\boldsymbol{w}$ and $\boldsymbol{b}$ parameters. If the initial values are far from optimal, the fit is difficult. Initial values of E_k were randomly chosen in a window $E_{\text{ini}} = E_{\text{exact}} \pm 0.2$. In general, good initial values for the $\boldsymbol{w}$ and $\boldsymbol{b}$ can be determined by pretraining a RBFNN on (fitting it to) wave functions calculated on a potential reasonably close in shape to the real one. The results presented above were all obtained by pretraining to exact wave functions (which we know in the x coordinates and hence can obtain in the y coordinates). The RBFNN we use to pretrain is not fully optimized. The Gaussian widths are not varied, and Gaussians are simply added consecutively and centered at data points where the error is largest. The fit is done with the RBFNN algorithm of Matlab. R_k values obtained from the pretrained NN are typically at least two orders of magnitude larger than their post-fit counterparts. For a real problem, exact wave functions are not known. In this case, we propose starting from known wave functions for a model potential surface (e.g., an uncoupled approximation) and slowly adding the coupling or distortion to "walk" the RBFNN wave functions to the solutions for the potential of interest. To test the procedure for

Fig. 5. Wave functions for the first two vibrational levels of a 2-D version of the eq. [16] potential. They are calculated by pretraining a NN on a harmonic potential and retraining it while progressively increasing α. The circled part of the ground state wave function is very different from the Gaussian shape used in the initial stage of the pretraining.



"walking" the RBFNN wave functions into a deep minimum on the parameter surface, we computed two solutions of the 2-D problem without using the exact wave functions to choose initial parameter values. A RBFNN is pretrained on the first two wave functions of an uncoupled approximation to the Hamiltonian and then the coupling strength is progressively increased by increasing α

$$[16] \qquad V(\boldsymbol{x}) = \sum_{i=1}^{d} x_i^2 + \alpha \left(\sum_{i=1}^{d} x_i \right)^2$$

where α = 0.0, 0.05, …, 1.0. At each value of α, the NN method is used to solve the Schrödinger equation and the solutions obtained are used to pretrain for the next value of α. Figure 5 shows neural network wave functions with α = 1.0: for the ground state one can clearly see that the wave function is not a Gaussian. This procedure does walk the RBF-NN wave functions into a deep minimum on the parameter surface.

IV. Conclusion

Despite recent progress, computational methods for solving the Schrödinger equation are hobbled by the basis size problem. Even if one uses contracted basis functions, the size of the basis required to compute a spectrum increases dramatically with the dimensionality of the Hamiltonian. Neuron basis functions may vitiate the basis size problem. Because they are extremely flexible, very few functions are necessary, and basis size may not increase quickly with dimension. It is encouraging that only 50 basis functions are required to solve a 6-D problem. The NN Schrödinger solver reported in this article is certainly better than previous NN solvers. It obviates the need to compute levels one by one. It uses nonlinear optimization methods only for some of the NN parameters and uses linear algebra tools for the others. Using the NN Schrödinger solver, one can obtain solutions without a potential surface: it is only necessary to know values of the potential at points.

We view a neural network representation of a wave function as an expansion in a small adaptable basis. The location, and, to some extent, shape, of the neuron basis functions are adjusted to achieve the best possible solutions for a given basis size. We have improved four aspects of previous NN Schrödinger solvers. (*i*) We compute several levels at a time from one shared layer of neurons. (*ii*) We use RBF neurons for the first time. RBF neurons automatically incorporate the correct boundary conditions. The application of the KEO to the NN is therefore clean and straightforward as no extra functions are required to impose those conditions. Other scientists have also used Gaussian basis functions,[41,42] but ours are more general and more fully optimized. (*iii*) We determine some of the NN parameters with methods of linear algebra thereby reducing the dimensionality of the parameter space in which nonlinear optimization needs to be done. (*iv*) We developed a systematic scheme for guiding the parameter optimization into the right minimum. This is done by pretraining the NN and adiabatically increasing the coupling strength.

These ideas make it possible to increase the difficulty of problems that can be solved. NN methods for solving the Schrödinger equation are at an early stage of development. The small size of the NN basis is very promising, but the optimization problem remains formidable. The method we have developed could certainly be applied to higher dimensional Hamiltonians. The largest molecules for which a spectrum has been computed using matrix methods are the protonated water dimer and CH_5^+.[49,50] To go even larger would require a huge amount of memory due to the ballooning basis size. In contrast, the NN Schrödinger solver requires only a modest basis. The NN Schrödinger solver might also be useful for computing levels in a high-lying window. The basis functions could be adapted to a particular spectral window. Other methods for computing levels in a window require storing large vectors.[51–53] NN methods for solving the Schrödinger equation are new and still being developed, but the ameliorations suggested in this paper address essential problems and advance the state of the art.

VII. Appendix

Herein, we derive eq. [6]. Applying the KEO of eq. [13] to the NN wave function of eq. [7] we obtain

$$[A1] \qquad T({}^n y)\psi_k({}^n y) = -4\sum_{i=1}\widehat{N}\, c_{ik} b_i^4 \widetilde{\gamma}_{in} \exp\Big(- b_i^2 \sum_{j=1}^{d} (w_{ij} - {}^n y_j)^2 \Big) + 2\gamma_0 \sum_{i=1}^{N} c_{ik} b_i^2 \exp\Big(- b_i^2 \sum_{j=1}^{d} (w_{ij} - {}^n y_j)^2 \Big)$$

with

$$[A2] \qquad \widetilde{\gamma}_{ik} \equiv \sum_{m,n} \gamma_{mn} (w_{in} - {}^k y_n)(w_{im} - {}^k y_m)$$

$$\gamma_0 \equiv \sum_n \gamma_{nn}$$

where the left superscript indexes the point at which the potential surface is evaluated. We then define a matrix $\mathbf{S}$ with elements $S_{ni} \equiv \exp\Big(- b_i^2 \sum_{j=1}^{d} (w_{ij} - {}^n y_j)^2 \Big)$, $\widetilde{\boldsymbol{S}} \equiv (\mathbf{S}|1)$, a matrix $\mathbf{S}''$ with elements $\boldsymbol{S}''_{ni} \equiv b_i^4 \widetilde{\gamma}_{in} S_{ni} - 2\gamma_0 b_i^2 S_{ni}$ and $\widetilde{\boldsymbol{S}}'' \equiv 4(\widetilde{\boldsymbol{S}}''_{ni}|0)$, where 1 and 0 are column vectors of size M with all elements equal to 1 or 0, respectively (the matrix represented by $(\mathbf{A}|\boldsymbol{v})$ is obtained by adding the column $\boldsymbol{v}$ to the matrix $\mathbf{A}$). Then, the Schrödinger equation becomes, at each point n ($V({}^n y) \equiv V_n$):

$$[A3] \qquad -\widetilde{\boldsymbol{S}}''_{ni}\widetilde{c}_{ik} + V_n \widetilde{S}_{ni}\widetilde{c}_{ik} = E_k \widetilde{S}_{ni}\widetilde{c}_{ik}$$

which has the form of eq. [6].

The application of the ONIOM hybrid method to the cycloaddition reactions of bromo-substituted 2(*H*)-pyran-2-ones[1]

Susan M. Larkin, Thom Vreven, Michael J. Bearpark, and Keiji Morokuma

Abstract: We investigate the performance of Our own N-layered Integrated molecular Orbital and molecular Mechanics (ONIOM) hybrid computational method applied to Diels–Alder reactions of bromo-2(*H*)-pyran-2-ones, combining the B3LYP/6–31G(d) method with a variety of low-level methods. We show that ONIOM is able to reproduce full B3LYP calculations, including the prediction of the stereoselectivity, which requires accurate potentials. We focus on the various ways in which the performance and potential errors of ONIOM can be analyzed, and show that the best method combination depends on the property one is interested in.

Key words: ONIOM, hybrid methods, transition structures, transition state, Diels–Alder.

Résumé : On a étudié la performance de la méthode de calcul hybride « ONIOM » appliquée aux réactions de Diels–Alder des bromo-2(*H*)-pyran-2-ones en combinant la méthode B3LYP/6-31G(d) avec une variété de méthodes de niveaux plus faibles. On a démontré que la méthode « ONIOM » permet de reproduire les calculs complets B3LYP, y compris les prédictions relatives à la stéréosélectivité qui demandent des potentiels précis. On a porté une attention particulière aux diverses façons par lesquelles on peut analyser la performance et les erreurs potentielles de la méthode « ONIOM » et on montre que la meilleure méthode de combinaison dépend de la propriété qu'on veut analyser.

Mots-clés : « ONIOM », méthodes hybrides, structures de transition, état de transition, Diels–Alder.

[Traduit par la Rédaction]

Introduction

Diels–Alder reactions of bromo-2(*H*)-pyran-2-ones are extremely useful in the synthesis of substituted ring structures, since their reactions are highly stereoselective.[2,3] These reactions are often governed by subtle features on the potential surface, which affect the relative barrier heights for competing reaction paths, and accurate methods are needed in the computational study of the stereoselectivity. The computation time needed for such methods scales unfavourably with the size of the system, and can quickly become the limiting factor in the studies, especially since one typically considers a large number of reactants and possible cycloadducts. In this paper, we investigate the applicability of Our own N-layered Integrated molecular Orbital and molecular Mechanics (ONIOM) hybrid method to such reactions. ONIOM treats different parts of the system at different levels of theory, and can reduce the computational cost dramatically compared with conventional methods.[4–10] We apply the ONIOM scheme to the cycloadditions of bromo-2(*H*)-pyran-2-ones with strongly electron-deficient and electron-rich dienophiles, methyl acrylate (MA) and methyl vinyl ether (MVE), respectively. Previously, we studied these systems with conventional (i.e., single non-hybrid) B3LYP and the 6–31G(d) basis set, which reproduced experimental results well.[11,12] This level of theory will therefore serve as "benchmark" in the assessment of the ONIOM scheme in the current work.

The focus in this work is on ways to reduce the computational cost of accurate calculations, and to give better scaling for much larger calculations. There are two traditional approaches to reduce the calculation time in computational chemistry. First, one can simply use a lower level of theory to treat the entire system. Second, when the chemical process takes place in a distinct part of the system, high-level calculations can be performed on truncated model systems. These two approximations have their obvious and severe limitations; the former may not treat the reactive center at a sufficiently high level of theory, while the latter excludes any electronic and steric effects from the part of the molecule that is not included in the truncated model.

Over the past decade, a third approach has become popular, which combines the two traditional approaches. In this hybrid approach, the full system is divided into a reactive part, which is treated at an appropriately high level of theory, while the remainder of the system is included at a less expensive level of theory. This ensures a sufficiently

high level of accuracy for the different regions of the system, while reducing the computational cost by only calculating a small part of the system with the expensive method.

A well-known class of hybrid methods is formed by the quantum mechanics / molecular mechanics (QM/MM) schemes, which combine a QM method with a MM method.[13–15] QM/MM methods have been successful in diverse areas, such as the study of enzyme mechanisms, catalysis, solvated systems, and materials.

Somewhat different from QM/MM methods is the ONIOM hybrid method. ONIOM is a generalized scheme for layered calculations. QM/MM methods can only combine a QM method with an MM method, whereas ONIOM can combine QM methods with QM methods as well as QM methods with MM methods. Transition structures can be calculated with ONIOM in general as for a conventional QM method. Furthermore, ONIOM can in principle combine any number of methods, although our current implementation is limited to three. ONIOM has been used for a wide variety of chemical problems, and has been the subject of several reviews.[16–20] In contrast to QM/MM methods, the ability of ONIOM to combine multiple QM methods allows it to include electronic interactions between the reactive and surrounding regions, which is essential for the reactions studied in the work. Besides ONIOM, there are several other methods that can combine QM methods with QM methods. The frozen and constrained DFT methods (FDFT and CDFT) embed the model in the potential from the outer-layer DFT calculation.[21–23] FDFT keeps the density fixed, whereas CDFT relaxes the density iteratively, and is somewhat similar to Yang's divide and conquer method.[24] QM/QM schemes specifically designed for semi-empirical methods in the low level, including electrostatic embedding, were presented by Cui,[25] as well as Merz.[26] Most of these schemes embed the model calculation in the potential generated by the environment, which is not explicit in our ONIOM(QM:QM) scheme. However, as will be outlined in the Computational methods, through the low-level QM calculation on the entire system, we do incorporate polarization effects, as well as electronic effects that can "cross the border". The latter, combined with the ability to use any electronic structure method, form the main strengths of ONIOM. Recently, we did present potential embedding in the ONIOM scheme, using Mulliken charges, including the calculation of gradients.[27]

Computational methods

The ONIOM energy is written as an extrapolation

$$[1] \qquad E^{\mathrm{ONIOM}} = E^{\mathrm{high}}_{\mathrm{model}} + E^{\mathrm{low}}_{\mathrm{real}} - E^{\mathrm{low}}_{\mathrm{model}}$$

"High" and "low" refer to the levels of theory. "Real" refers refer to the full system, and "model" to the part of the system that is treated at the high level of theory. The "model" system is calculated at both levels of theory, while the "real" system is calculated only at the low level of theory. All three terms involve chemically realistic systems, which allows the low level to be either QM or MM, thus forming ONIOM(QM:QM′) or ONIOM(QM:MM). This is in contrast with most other hybrid methods, which allow only QM methods to be combined with MM methods. ONIOM(QM:QM′) schemes include quantum mechanical effects between the regions, albeit at the lower of the two QM methods. This is essential for the accurate modelling of the reactions presented here, since the primary effect of the substituents is electronic.

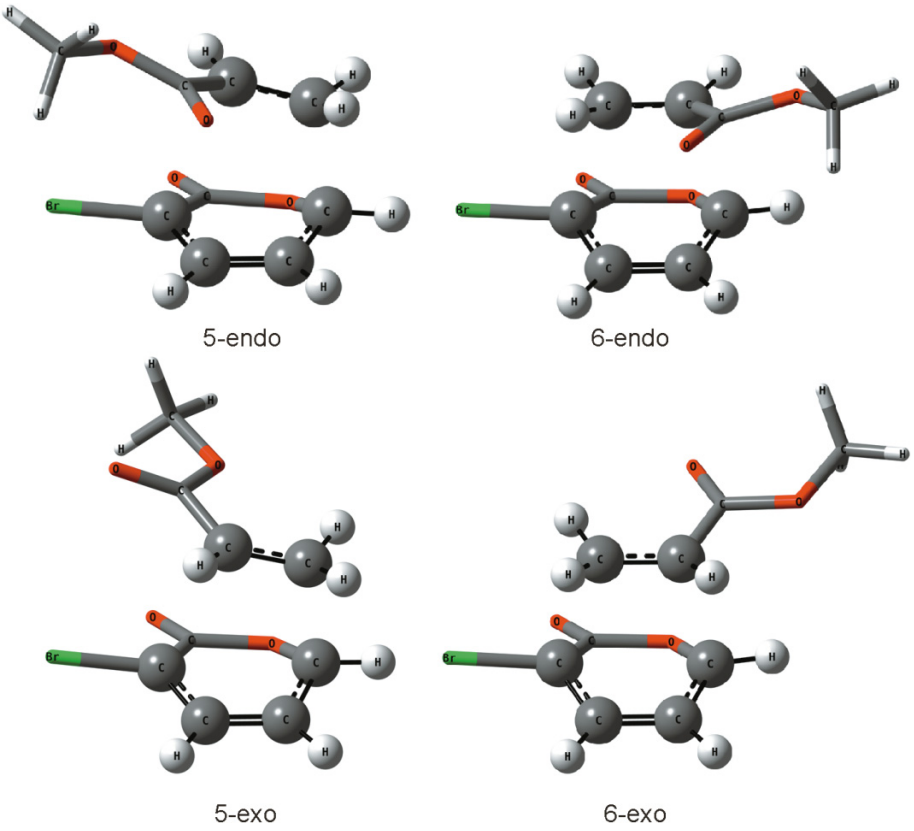
Covalent bonding between the two regions would result in open valencies in the model system if this were just "cut out" from the full molecule. Because the model system would then no longer be representative of the real system we are investigating, we saturate these dangling bonds with hydrogen "link atoms". The gradients and higher derivatives are well-defined, and can be obtained with expressions similar to that of the energy.[8] Because of this, force constants can be calculated and transition structures characterized, which is essential for this work.

We use the level of theory of our previous study,[11,12] B3LYP with the 6–31G(d) basis set, as the benchmark or "Target", to which we compare our ONIOM results. As such, we also use B3LYP/6–31G(d) as the high-level method in our ONIOM calculations. We investigated a variety of low-level methods: the semi-empirical methods AM1 and PM3, the Hartree–Fock (HF) method with the STO-3G and 3–21G basis sets, and B3LYP with the STO-3G, 3–21G, and 6–31G basis sets. For readability, we abbreviate the STO-3G, 3–21G, and 6–31G basis sets as I, II, and III, respectively. These methods cover a wide range of computational costs and accuracies, and have all proven to be valuable in the study of organic reaction mechanisms. We do not consider ONIOM combinations with MM methods in the low level, since ONIOM(QM:MM) is not well-defined when there is bond breaking and formation within three bonds from the MM region, as cancellation of errors is incomplete.[28] Partitioning the system so that there is a three-bond separation would make the QM region too large to yield reasonable time-savings for the systems studied in this work. Instead, we used the "minimal model" of butadiene + ethene in our ONIOM calculations (Figs. 1 and 2). This implies that the effects of the substituents are entirely described by the low level of theory. All the reported energies are obtained for geometries optimized at the specific level of theory (thus using the ONIOM gradients). The calculations were carried out with a development version of the Gaussian package.[29]

Results and discussion

Each reactant pair can generate four unique products, which are denoted as 5-endo, 6-endo, 5-exo, and 6-exo. Each product is reached via a unique transition structure. In Fig. 1, we show the four transition states for 3-bromo-2(*H*)-pyran-2-ones with methyl acrylate, and in Fig. 2, we show those for 3-bromo-2(*H*)-pyran-2-ones with methyl vinyl ether. Since the rate of the reaction depends on the height of the transition-state barrier, and the energy of the separated reactants is the same for each of the four products, the stereoselectivity of the reaction depends on the "relative" energies of the four transition states. In our previous work, we saw that the differences involved are often only several kcal/mol. Therefore, the prediction of the stereoselectivity requires computational levels of theory that can accurately describe such small differences, and B3LYP/6–31G(d) is able to do so.[11,12,30] The "absolute" barrier heights are less

Fig. 1. The four possible transition structures of the cycloadditions of 3-bromo-2(*H*)-pyran-2-ones with methyl acrylate. The high-level region is rendered by ball and bond, and the remainder of the system as tube.



critical for the prediction of the stereoselectivity, which is in contrast with the requirements of computational methods in most other reactivity studies. Also, we are not concerned with free-energy corrections (i.e., we approximate these to be the same in each case).

We calculated the reactant energy and the barriers for all the reaction paths, at the Target and ONIOM levels of theory. As indicated in the previous paragraph, we can assess the performance of ONIOM in two ways. First, we can assess how well ONIOM is able to reproduce the absolute barriers, thus $\Delta E = E^{TS} - E^{reactant}$. This will yield the best ONIOM combination for describing reaction kinetics. Second, we can focus on the ability of ONIOM to describe the relative barriers, thus $\Delta E' = E^{TS} - E^{TS'}$. This will yield the best ONIOM combination for describing the stereoselectivity. Although it is likely that a method combination that performs well for rates also performs well for stereoselectivity, this is not necessarily the case. We will therefore test the performance in both ways, starting with the absolute barriers.

In Table 1, we show the energy barriers calculated at the ONIOM levels of theory, as well as the Target B3LYP/6–31G(d). In Table 2, we show the errors of the ONIOM barriers compared with the Target, and the root-mean-square (RMS) error values for various combinations of barriers. For a quartet of TS configurations (5-exo, 5-endo, 6-exo, and 6-endo, the RMS value is obtained from

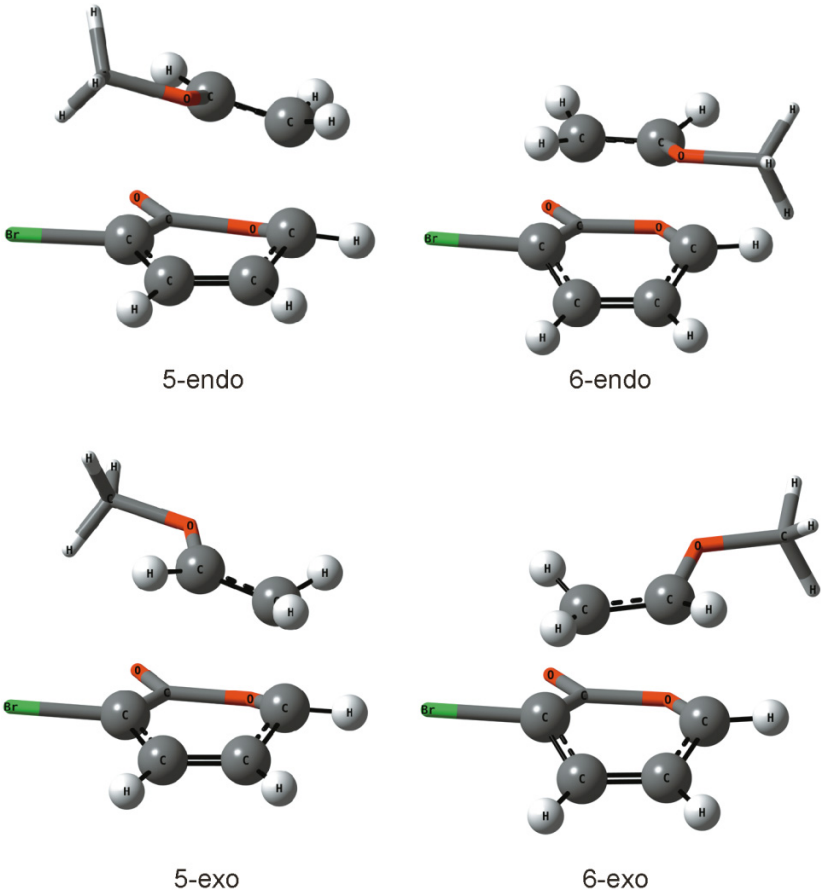
$$[2] \qquad \mathrm{RMS}^{\mathrm{abs}} = \frac{1}{2}\sqrt{\sum_{i}^{4}[(E^{\mathrm{TS}_i}_{\mathrm{ONIOM}} - E^{\mathrm{reactant}}_{\mathrm{ONIOM}}) - (E^{\mathrm{TS}_i}_{\mathrm{Target}} - E^{\mathrm{reactant}}_{\mathrm{Target}})]^2}$$

where i refers to the four configurations, which we sum over.

First, we will look at the total MA + MVE RMS value, which is calculated from the errors of all barriers. Both the semi-empirical methods and HF/I give a value of around 3 kcal/mol, and B3LYP/II and B3LYP/III around 1 kcal/mol. HF/II is somewhat higher, about 4 kcal/mol. Looking at the MVE and MA RMS values separately, we see that they are similar, which indicates that the total RMS value is quite "stable" and not biased by a single or few large individual errors (inspection of all the individual values confirms this). The total mean error is similar to the RMS error, except for AM1 and PM3, in which case it is much lower.

Since HF/II has a total RMS error larger than HF/I, we suspect that the latter is fortuitous due to cancellation of errors, and can therefore not be considered reliable. Unlike almost all of the other methods, the AM1 and PM3 mean errors (Table 2) are much smaller than their respective RMS errors. This indicates that, on average, they perform

Fig. 2. The four possible transition structures of the cycloadditions of 3-bromo-2(*H*)-pyran-2-ones with methyl vinyl ether. The high-level region is rendered by ball and bond, and the remainder of the system as tube.



very well as low level, similar to their small mean errors as stand-alone method,[31] but the errors are less systematic. The mean error being similar to that with B3LYP methods in the low level can be explained by AM1 and PM3 being parameterized to include electron correlation. However, the form of the wave function is much simpler and not similar to that in DFT methods, which causes the error cancellation in the ONIOM extrapolation to be less systematic, and increases the total RMS error relative to the mean error.

Since B3LYP/II and B3LYP/III have very similar total RMS errors, we can consider the basis set of the former (3–21G) to be converged. On the basis of these results, we consider B3LYP/II the best choice when accurate barriers are required and AM1 or PM3 the best choice when more approximate results are sufficient.

We will now assess the ability of ONIOM to reproduce the "relative" barriers of each quartet of transition states. To do this, we need to correct for the systematic overestimation or underestimation from a low-level method for each quartet. We do this by shifting the four transition-state energies with a constant factor, *X*, so that the RMS deviation is minimized:

$$[3] \qquad \mathrm{RMS}^{\mathrm{rel}} = \frac{1}{2}\sqrt{\sum_{i}^{4}[(E^{\mathrm{TS}_i}_{\mathrm{ONIOM}} + X - E^{\mathrm{reactant}}_{\mathrm{ONIOM}}) - (E^{\mathrm{TS}_i}_{\mathrm{Target}} - E^{\mathrm{reactant}}_{\mathrm{Target}})]^2}$$

X is specific for each quartet and low-level method. Note that eq. [3] can be expressed without the reactant energies, which indicates that indeed only the transition-state energies determine the resulting RMS value, and not the barriers, thus

$$[4] \qquad \mathrm{RMS}^{\mathrm{rel}} = \frac{1}{2}\sqrt{\sum_{i}^{4}[E^{\mathrm{TS}_i}_{\mathrm{ONIOM}} - E^{\mathrm{TS}_i}_{\mathrm{Target}} + X']^2}$$

The resulting RMS value indicates how well ONIOM reproduces the Target pattern of four transition states, and is unrelated to the ability of the ONIOM combination to reproduce the absolute barriers. We show these values in Table 3, for each quartet separately, again combined for the MVE quartets and the MA quartets, and combined for all the quartets. In addition,we calculated the spread of each quartet at the Target level of theory, the minimum of

Table 1. Calculated ONIOM and Target barrier heights (kcal/mol) of the reactions of 3-bromo-, 4-bromo-, and 5-bromo-substituted 2(*H*)-pyran-2-ones with methyl acrylate (MA) and methyl vinyl ether (MVE). For low-level methods, HF denotes the Hartree–Fock method, and B3 denotes the B3LYP method. I, II, and III denote the STO-3G, 3–21G, and 6–31G basis sets, respectively.

$\frac{1}{2}\sqrt{\sum_i^4 [E_{\text{Target}}^{\text{TS}_i} + X'']^2}$, which can be compared to the RMS values of the ONIOM calculation.

We first observe from Table 3 that the Target spread is different from the transition states with MA (about 1.5 kcal/mol) and the transition states with MVE (about 3.5 kcal/mol), which indicates that the four MA transition states are closer together than those for MVE. This spread serves as a measure for the required accuracy of the ONIOM potentials, i.e., if the RMS error in the ONIOM results is larger or comparable to the spread, the error is larger than the effect we are attempting to predict. This is indeed the case for AM1 and PM3 as the low level for the MA transition states, which are therefore not recommended for comparing energetics.

Related to the Target spread (Table 3), we need to comment on the basis set superposition error (BSSE) as a source of error in the ONIOM calculations. The BSSE for the high-level region is always included at the Target level of theory. But the BSSE in the low-level region will be different for the various ONIOM combinations that we consider, i.e., it depends on the basis set employed and is zero for the semi-empirical methods. If we assume that the BSSE is the same for all four structures in a quartet, the shift factor X (eq. [3] will take care of it. To test this assumption, we calculated the BSSE in the low-level region (defined as the BSSE difference between the model- and real-system calculations) for the transition states of the 3-bromo compound with MA. Of all the adducts, this quartet has the largest expected interaction in the low-level region, and will provide an upper bound for the BSSE. For the Target, however, we find that the BSSE values for the 5-endo and 5-exo structures are about 1 kcal/mol larger than the 6-endo and 6-exo structures. This clearly is related to the vicinity of the bromine to the oxygen centers in MA. Significant BSSE that affected the endo/exo ratio was observed previously.[32,33] We did not observe the same pattern using ONIOM with smaller basis sets in the low level. Since the semi-empirical methods do not include this error, we cannot expect these to provide a resolution better than 1 kcal/mol compared with the Target. However, this estimate is an upper bound, and we expect transitions states with MVE, 4-bromo, or 5-bromo compounds to have a smaller error. Indeed, we see that for all the low-level methods, MA with 3-bromo in Table 3 has the largest error of all three MA adducts.

We see that again HF/I is somewhat better than HF/II, indicating cancellation of errors. However, contrary to the results in Table 2, HF performs significantly better than the semi-empirical methods. This is most likely the result of all four transition states in a quartet having similar electron-correlation contributions to the barriers. The (systematic) errors in these contributions are then compensated for through the shift factor X in eq. [3]. The good performance of AM1 and PM3 relative to HF for the "absolute" barriers (Table 2) is mostly due to the inclusion of these correlation effects in the semi-empirical parameterization. This is not an important contribution to the "relative" barriers (Table 3), hence the swap in performance of HF and the semi-empirical methods.

Table 2. Errors of the calculated ONIOM barrier heights (kcal/mol, relative to Target) of the reactions of 3-bromo-, 4-bromo-, and 5-bromo-substituted 2(*H*)-pyran-2-ones with methyl acrylate (MA) and methyl vinyl ether (MVE), including the root-mean-square (RMS) value for each quartet of configurations, the RMS value for all the MA and all the MVE barriers and for all 24 barriers combined, and the Mean value for all barriers combined. For the low-level methods, see the caption of Table 1.

B3LYP performs again better than HF in the low level. For the MA reactant, only B3LYP/II and B3LYP/III are able to predict the splitting of the transition-state energies. However, the energy differences are very small, and for MVE, which has a larger splitting, all methods give results better than the target spread. On the basis of these results, it appears that B3LYP/III is needed for an accurate prediction of the stereoselectivity, while the semi-empirical methods are not accurate enough.

Discussion and conclusions

We showed that ONIOM is able to predict barriers as well as relative barriers for the stereoselective reactions presented in this work. In all cases, a level of theory close to the Target, such as B3LYP with the 3–21G or 6–31G basis sets, ensures reliable results. In case of the absolute barriers, the semi-empirical methods AM1 and PM3 in the low level also produce reasonable results, especially when the very low cost is taken into consideration. However, due to the small splitting of the transition states in some cases, the prediction of stereoselectivity requires very accurate potentials, and only B3LYP with the larger basis sets performs consistently well. It is clear that when benchmarking ONIOM, the low level (and partitioning) must be chosen based on the type of problem that one is interested in. However, our conclusion that B3LYP is required as low level for the stereoselectivity is directly related to the difficulty of the problem. Such small differences in TS energies are perhaps not very common or meaningful, and even the Target level of theory in this work may not be the most appropriate for predicting experimental results. When the differences are larger, as in case of MVE in the current work, HF or perhaps even the semi-empirical methods in the low level will be sufficient.

It is interesting to see that for the absolute barriers, the semi-empirical methods perform as well or better than HF, while this is reversed when the relative barriers are considered. This shows that the low level of theory in the ONIOM scheme is not only determined by the required accuracy, but also by the nature of the problem under investigation. It must be noted that the parameterization of semi-empirical methods may not be as good for bromo-containing compounds as it is for species that include only multi-valent non-hydrogen atoms. For non-bromo compounds, the performance of semi-empirical methods in ONIOM may therefore be better than what was concluded from the current work.

Since the goal of ONIOM is to reduce the overall computational cost, we will now comment on the computational times required for the various method combinations we have tested. For an energy and gradient calculation on the transition state of a bromo-substituded 2(*H*)-pyran-2-one with MA, ONIOM with AM1 or PM3 in the low level takes about one-seventh of the CPU time needed for the same calculation at the Target level of theory. This clearly makes the semi-empirical methods attractive choices for many purposes, especially since the accuracy was remarkably good for the prediction of the absolute barriers (much better than the accuracy we would expect when using the semi-empirical method on its own). Of the other promising combinations, HF/II takes about one-third of the CPU time, while B3LYP/II and B3LYP/III need just under half and just over half of the time, respectively. Although the latter reduction in computational cost may not seem very significant, it must be noted that for larger systems, the relative savings will be much larger for these combinations, particularly for carrying out frequency calculations. Savings will be further increased if a more accurate computational level of theory is used as the Target.[34]

To conclude, we have shown that ONIOM is able to reliably describe transition states in Diels–Alder cycloadditions. We envision several ways in which the proposed schemes can be useful. First, we can assume that the methods are transferable to larger systems, which cannot be benchmarked directly. In those cases, the computational savings will be more substantial than in the current work. Second, we can assume that the methods are transferable to other reactants. Having carefully benchmarked for a relatively small set will allow the quick scanning of many different reactant pairs and possible cycloadducts. Third, after benchmarking only the critical points on the potential surface, ONIOM can be used to map other parts of the surface, for example, as needed in transition-state theory (TST).

Mapping approach for quantum-classical time correlation functions[1]

Ali Nassimi and Raymond Kapral

Abstract: The calculation of quantum canonical time correlation functions is considered in this paper. Transport properties, such as diffusion and reaction rate coefficients, can be determined from time integrals of these correlation functions. Approximate quantum-classical expressions for correlation functions, which are amenable to simulation, are derived. These expressions incorporate the full quantum equilibrium structure of the system but approximate the dynamics by quantum-classical evolution where a quantum subsystem is coupled to a classical environment. The main feature of the formulation is the use of a mapping basis where the subsystem quantum states are represented by fictitious harmonic oscillator states. This leads to a full phase space representation of the dynamics that can be simulated without appeal to surface-hopping methods. The results in this paper form the basis for new simulation algorithms for the computation of quantum transport properties of large many-body systems.

Key words: mapping basis, quantum-classical dynamics, quantum correlation functions.

Résumé : Dans ce travail, on s'applique à calculer les fonctions de corrélation du temps quantique canonique. Il est possible de déterminer les propriétés de transport, tels les coefficients des vitesses de diffusion et de réaction, à partir des intégrales de temps de ces fonctions de corrélation. On a dérivé des expressions quantiques classiques approximatives pour les fonctions de corrélation qui peuvent éventuellement être utilisées en simulation. Ces expressions incorporent la structure d'équilibre quantique complète du système, mais ne donne qu'une approximation de la dynamique par le biais d'une évolution quantique classique dans lequel un sous système quantique est couplé à un environnement classique. La caractéristique principale de la formulation est l'utilisation d'une base de cartographie dans laquelle les états quantiques du sous système sont représentés par des états d'oscillateurs harmoniques fictifs. Ce traitement conduit à une représentation spatiale complète de l'espace de la dynamique qui peut être simulée sans faire appel aux méthodes de sauts de surface. Les résultats obtenus dans ce travail forment la base de nouveaux algorithmes de simulation pour le calcul des propriétés de transport de systèmes à plusieurs composantes.

Mots-clés : base de représentation, dynamique quantique classique, fonctions de corrélation quantique.

1. Introduction

In the investigation of condensed-phase systems, one is usually interested in the average value of some observable or in a time correlation function from which a transport coefficient can be computed. Since the basic description of matter is quantum mechanical, we are interested in the average value of a quantum-mechanical operator, which is given by $\overline{B(t)} = \mathrm{Tr}\widehat{B}(t)\widehat{\rho}(0)$, where, for a system with Hamiltonian $\widehat{H}$, the time-dependent operator satisfies the Heisenberg equation of motion,

$$[1] \qquad \frac{\mathrm{d}}{\mathrm{d}t}\widehat{B}(t) = \frac{i}{\hbar}[\widehat{H}, \widehat{B}]$$

and $\widehat{\rho}(0)$ is the initial value of the density matrix. Quantum time correlation functions of two operators $\widehat{A}$ and $\widehat{B}$ have the form,[2] $C_{\mathrm{AB}}(t) = \mathrm{Tr}(\widehat{\rho}_{\mathrm{eq}}\widehat{A}\widehat{B}(t))$, where $\widehat{\rho}_{\mathrm{eq}}$ is the quantum canonical equilibrium density matrix. Either of these quantum expressions requires a knowledge of the time evolution of a quantum operator in a many-body system that is often very large. Consequently, these general expressions are not computationally tractable, and appeal must be made to approximations if they are to be evaluated for problems of physical interest.

The approximate dynamical description we consider in this paper is quantum-classical Liouville dynamics.[4] In this formulation, the system is partitioned into two subsystems, which we call quantum subsystem and bath or environment. The partition is dictated by physical principles. For example, in electron or proton transfer problems, the electron or proton may constitute the quantum subsystem, while the environment in which the transfer takes place, a molecular group or biomolecule dissolved in a solvent, forms the bath. In quantum-classical Liouville dynamics, the bath is treated classically while retaining the full quantum character of the

quantum subsystem. In this theory, the analog of the Heisenberg equation of motion for an operator is[4,5]

$$[2] \qquad \frac{\mathrm{d}}{\mathrm{d}t}\widehat{B}_{\mathrm{W}}(X,t) = \frac{i}{\hbar}\left[\widehat{H}_{\mathrm{W}},,\widehat{B}_{\mathrm{W}}\right] - \frac{1}{2}\left(\left\{\widehat{H}_{\mathrm{W}},\widehat{B}_{\mathrm{W}}\right\} - \left\{\widehat{B}_{\mathrm{W}},\widehat{H}_{\mathrm{W}}\right\}\right)$$

where $X = (R,P)$ are the positions and momenta of the bath degrees of freedom. The subscript W indicates that operators are expressed in a partial Wigner representation, defined below. In addition to the usual quantum commutator, the equation of motion also involves a Poissson bracket denoted by { , }. While this equation is far more tractable than the full quantum equations of motion, its numerical simulation presents challenges and a number of different schemes have been constructed for this purpose.[6,7] These include Trotter-based methods that use an adiabatic basis,[8] as well as trajectory methods that use the diabatic[9] and force bases,[10] schemes based on the multiple threads algorithm,[11] and a method that utilizes the mapping basis.[12] The mapping method has proved to be especially promising for the evaluation of expectation values of operators, as shown by calculations of population relaxation in the spin-boson model, one of the standard test cases for quantum dynamics.[12] In this paper, we show how the mapping method can be extended to the computation of time correlation functions within the quantum-classical Liouville framework.

In the next section, we present the explicit expression for the quantum correlation function that forms the basis of our calculations. Section 3 outlines the mapping formulation, where subsystem quantum states are replaced by fictitious harmonic oscillator states. Section 4 reformulates the quantum correlation function in the mapping basis. This fully quantum description is exact and the dynamics is embodied in the spectral density function. A quantum-classical approximation for the spectral density dynamics is derived in Section 5. The details of this derivation are presented in the Appendix. This result is used in Section 6 to obtain the final result for the quantum-classical correlation function in the mapping basis. The conclusions of the study are presented in Section 7.

2. Correlation function

Before considering quantum-classical approximations to the dynamics, we first rewrite the exact quantum correlation function in a form that is suitable for the introduction of the mapping basis and passage to the quantum-classical limit. Suppose the quantum subsystem and bath have N_{s} and N_{b} degrees of freedom with characteristic masses m and M, respectively. To introduce a phase space description of the bath, we first introduce a coordinate representation of the bath so that the correlation function takes the form

$$\begin{aligned}
C_{AB}(t) &= \mathrm{Tr}\left(\widehat{\rho}_{eq}\widehat{A}\widehat{B}(t)\right) = \left(\mathrm{Tr}\widehat{\rho}_{eq}\widehat{A}e^{i\widehat{H}t/\hbar}\widehat{B}e^{-i\widehat{H}t/\hbar}\right) \\
&= \mathrm{Tr}'\int \mathrm{d}Q_1\mathrm{d}Q_2\mathrm{d}Q_3\mathrm{d}Q_4 \left\langle Q_1\left|\widehat{\rho}_{eq}\widehat{A}\right|Q_2\right\rangle\left\langle Q_2\left|e^{i\widehat{H}t/\hbar}\right|Q_3\right\rangle\left\langle Q_3\left|\widehat{B}\right|Q_4\right\rangle\left\langle Q_4\left|e^{-i\widehat{H}t/\hbar}\right|Q_1\right\rangle \\
&= \mathrm{Tr}'\int \mathrm{d}R_1\mathrm{d}R_2\mathrm{d}Z_1\mathrm{d}Z_2 \left\langle R_1 - \frac{Z_1}{2}\left|\widehat{\rho}_{eq}\widehat{A}\right|R_1 + \frac{Z_1}{2}\right\rangle\left\langle R_1 + \frac{Z_1}{2}\left|e^{i\widehat{H}t/\hbar}\right|R_2 - \frac{Z_2}{2}\right\rangle \\
&\qquad \times \left\langle R_2 - \frac{Z_2}{2}\left|\widehat{B}\right|R_2 + \frac{Z_2}{2}\right\rangle\left\langle R_2 + \frac{Z_2}{2}\left|e^{-i\widehat{H}t/\hbar}\right|R_1 - \frac{Z_1}{2}\right\rangle
\end{aligned} \qquad [3]$$

In these equations, Tr′ stands for a trace over the quantum subsystem degrees of freedom, and in the fourth equality above, we have made a change of variables $Q_1 = R_1 - Z_1/2$, $Q_2 = R_1 + Z_1/2$, etc.

Two further manipulations are required to cast the correlation function into a form that is suitable for the calculations using the mapping basis described below. The coordinate space matrix elements may be replaced with bath phase space functions by introducing the partial[5] Wigner transforms[13–15] of an operator and density matrix

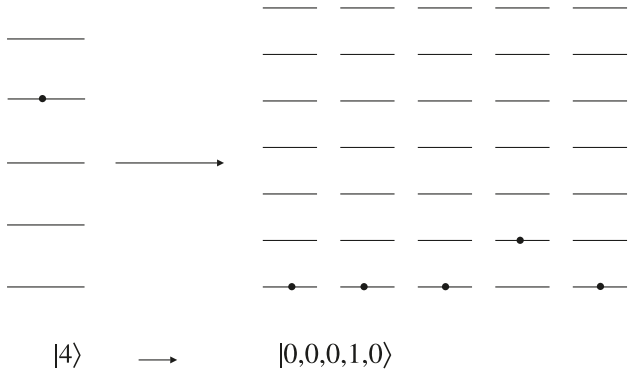
$$[4] \qquad \left\langle R - \frac{Z}{2}\left|\widehat{B}\right|R + \frac{Z}{2}\right\rangle = \frac{1}{(2\pi\hbar)^{N_{\mathrm{b}}}}\int \mathrm{d}P\widehat{B}_W(R,P)e^{-iP\cdot Z/\hbar}, \qquad \left\langle R - \frac{Z}{2}\left|\widehat{\rho}_{\mathrm{eq}}\widehat{A}\right|R + \frac{Z}{2}\right\rangle = \int \mathrm{d}P(\widehat{\rho}_{\mathrm{eq}}\widehat{A})_{\mathrm{W}}(R,P)e^{-iP\cdot Z/\hbar}$$

Note that the partially Wigner-transformed quantities are still operators in the quantum subsystem Hilbert space. In addition, Tr′ may be written explicitly using the eigenfunctions of the Hamiltonian of the quantum subsystem. The Hamiltonian for the entire system is given by

$$[5] \qquad \widehat{H} = \frac{\widehat{P}^2}{2M} + \widehat{V}_{\mathrm{b}}(\widehat{R}) + \frac{\widehat{p}^2}{2m} + \widehat{V}_{\mathrm{s}}(\widehat{q}) + \widehat{V}_{\mathrm{c}}(\widehat{R},\widehat{q})$$

where $\widehat{P}$ and $\widehat{p}$ are momentum operators of the bath and subsystem, and $\widehat{V}_{\mathrm{b}}$, $\widehat{V}_{\mathrm{s}}$, and $\widehat{V}_{\mathrm{c}}$ are, respectively, the bath, subsystem, and coupling potentials. The coordinate operators for the subsystem and bath are $\widehat{q}$ and $\widehat{R}$, respectively. Equation [5] can be written as $\widehat{H} = \frac{\widehat{P}^2}{2M} + \widehat{V}_{\mathrm{b}} + \widehat{V}_{\mathrm{c}} + \widehat{h}_{\mathrm{s}}$, where $\widehat{h}_{\mathrm{s}} = \frac{\widehat{p}^2}{2m} + \widehat{V}_{\mathrm{s}}$ is the subsystem Hamiltonian. The eigenstates of $\widehat{h}_{\mathrm{s}}$ are defined by the eigenvalue problem $\widehat{h}_{\mathrm{s}}|\lambda\rangle = \varepsilon_\lambda|\lambda\rangle$. We suppose that there are N quantum subsystem states. Making use of subsystem

Fig. 1. Schematic representation of the mapping for a five-level system. Subsystem states are on the left and the mapping states are on the right.



energy eigenstates as a basis and introducing the Wigner-transformed forms of $\widehat{\rho}_{eq}\widehat{A}$ and $\widehat{B}$ given in eq. [4] we have

$$[6]\qquad C_{AB}(t) = \frac{1}{(2\pi\hbar)^{N_b}} \sum_{\lambda,\lambda',\mu,\mu'=1}^{N} \int dX_1 dX_2 dZ_1 dZ_2 \left\langle \lambda \middle| (\widehat{\rho}_{eq}\widehat{A})_W(X_1) \middle| \lambda' \right\rangle \times \left\langle \lambda' \middle| \left\langle R_1 + \frac{Z_1}{2} \middle| e^{i\widehat{H}t/\hbar} \middle| R_2 - \frac{Z_2}{2} \right\rangle \middle| \mu \right\rangle \left\langle \mu \middle| \widehat{B}_W(X_2) \middle| \mu' \right\rangle \left\langle \mu' \middle| \left\langle R_2 + \frac{Z_2}{2} \middle| e^{-i\widehat{H}t/\hbar} \middle| R_1 - \frac{Z_1}{2} \right\rangle \middle| \lambda \right\rangle e^{-\frac{i}{\hbar}(P_1\cdot Z_1 + P_2\cdot Z_2)}$$

The spectral density function in the subsystem basis may be defined as

$$[7]\qquad W^{\lambda'\lambda\mu'\mu}(X_1, X_2, t) = \int dZ_1 dZ_2 \left\langle \lambda' \middle| \left\langle R_1 + \frac{Z_1}{2} \middle| e^{i\widehat{H}t/\hbar} \middle| R_2 - \frac{Z_2}{2} \right\rangle \middle| \mu \right\rangle \left\langle \mu' \middle| \left\langle R_2 + \frac{Z_2}{2} \middle| e^{-i\widehat{H}t/\hbar} \middle| R_1 - \frac{Z_1}{2} \right\rangle \middle| \lambda \right\rangle e^{-\frac{i}{\hbar}(P_1\cdot Z_1 + P_2\cdot Z_2)}$$

and contains all information needed to compute the quantum time evolution contribution to the correlation function. The spectral density defined via full Wigner transform was used by Filinov et al.[16–18] in a reformulation of the quantum correlation function. In terms of the spectral density function in the subsystem basis, the correlation function takes the form

$$[8]\qquad C_{AB}(t) = \frac{1}{(2\pi\hbar)^{N_b}} \sum_{\lambda,\lambda',\mu,\mu'}^{N} \int dX_1 dX_2 \left\langle \lambda \middle| (\widehat{\rho}_{eq}\widehat{A})_W(X_1) |\lambda'\right\rangle \langle \mu | \widehat{B}_W(X_2) | \mu' \rangle W^{\lambda'\lambda\mu'\mu}(X_1, X_2, t)$$

This expression for the quantum correlation function is exact. To compute it, the matrix elements of the forward and backward propagators must be evaluated to solve for the time dependence of the spectral density function. This is the most difficult part of the problem. A similar expression utilizing the adiabatic basis in place of the subsystem basis was derived earlier.[19] In addition to the time-dependent spectral density function, the time-independent matrix elements of the quantum operators and quantum equilibrium density matrix must also be computed to evaluate the ensemble average appearing in the definition of the correlation function. While these equilibrium quantities may be difficult to evaluate for complex systems, they are far easier to compute than the quantum time dependence, and algorithms have been developed for this purpose.[20,21]

3. Mapping basis

To construct a useful simulation algorithm for the quantum correlation function, it is convenient to use an alternative but equivalent mapping form for the quantum subsystem matrix elements of the operators that enter in its definition. A well-known mapping approach was introduced by Schwinger.[22] In his scheme, the eigenstates of the angular momentum operator are mapped onto eigenfunctions of two bosonic oscillators, and the angular momentum operators are mapped onto combinations of creation, $\hat{a}_\lambda^\dagger$, and annihilation, $\hat{a}_{\lambda'}$, operators ($\lambda,\lambda' = 1$ or 2). Such a mapping yields a simple treatment of the angular momentum problem in quantum mechanics. In this formalism, the resolution of identity is mapped to $\hat{a}_1^\dagger\hat{a}_1 + \hat{a}_2^\dagger\hat{a}_2 = 1$. This equality is used in the Holstein–Primakoff mapping scheme to eliminate one bosonic oscillator and represent angular momentum states by a single oscillator.[23] An extension of these mapping schemes was used to map discreet states of a quantum system onto fictitious harmonic oscillators, so that all degrees of freedom in the system can be treated with semiclassical approximations.[24–30] The mapping approach has also been used in other closely related contexts.[31–33]

In the mapping scheme used in this work, an N level quantum system is mapped onto N harmonic oscillators. The wave function of the system in a given quantum state is mapped onto a product of harmonic oscillator wave functions where all oscillators are in their ground state, except for one oscillator corresponding to the given quantum state, which is in its first excited state. This mapping is schematically represented in Fig. 1. Therefore, we have a physical space with a cardinality N, which is much lower than the cardinality of the Hilbert space of the N harmonic oscillators, which is infinite. More specifically, the subsystem quantum states are mapped through the relations,

$$[9] \qquad |\lambda\rangle \rightarrow |m_\lambda\rangle = |0_1, \ldots, 1_\lambda, \ldots, 0_N\rangle$$

where

$$\langle q|m_\lambda\rangle = \langle q_1, q_2, \ldots, q_N|0_1, \ldots, 1_\lambda, \ldots, 0_N\rangle = \phi_0(q_1)\ldots\phi_0(q_{\lambda-1})\phi_1(q_\lambda)\ldots\phi_0(q_N)$$

with ϕ_0 and ϕ_1, respectively, being the ground and the first excited state wave functions of an harmonic oscillator. The creation and annihilation operators on the mapping states act in the following ways[34]

$$[10] \qquad \widehat{a}_\lambda^\dagger|0\rangle = |0_1, \ldots, 1_\lambda, \ldots, 0_N\rangle = |m_\lambda\rangle \quad \text{and} \quad \widehat{a}_\lambda|m_\lambda\rangle = |0_1, \ldots, 0_N\rangle = |0\rangle$$

where

$$[11] \qquad \widehat{a}_\lambda = \sqrt{\frac{m\omega}{2\hbar}}\left(\widehat{q}_\lambda + \frac{i}{m\omega}\widehat{p}_\lambda\right), \qquad \widehat{a}_\lambda^\dagger = \sqrt{\frac{m\omega}{2\hbar}}\left(\widehat{q}_\lambda - \frac{i}{m\omega}\widehat{p}_\lambda\right), \quad \text{and} \quad [\widehat{q}_\lambda, \widehat{p}_\lambda] = i\hbar$$

We may then introduce the mapping representation of an operator $\widehat{A}$ as

$$[12] \qquad \widehat{A}_m = \sum_{\lambda\lambda'} A_{\lambda\lambda'}\widehat{a}_\lambda^\dagger\widehat{a}_{\lambda'}$$

For example, the mapping form of the Hamiltonian in eq. [5] is

$$[13] \qquad \begin{aligned}\widehat{H}_m &= \sum_{\lambda\lambda'}\left[\frac{\widehat{P}^2}{2M}\delta_{\lambda\lambda'} + \widehat{V}_{\mathrm{B}}(\widehat{R})\delta_{\lambda\lambda'} + h_{\lambda\lambda'}(\widehat{R})\right]\widehat{a}_\lambda^\dagger\widehat{a}_{\lambda'} \\ &= \frac{\widehat{P}^2}{2M} + \widehat{V}_B(\widehat{R}) + \frac{m\omega}{2\hbar}\sum_{\lambda\lambda'}h_{\lambda\lambda'}(\widehat{R})(\widehat{r}_\lambda\widehat{r}_{\lambda'} + \frac{\widehat{p}_\lambda\widehat{p}_{\lambda'}}{m^2\omega^2} - \frac{\hbar}{m\omega}\delta_{\lambda\lambda'})\end{aligned}$$

where $\widehat{h} = \frac{\widehat{p}^2}{2m} + \widehat{V}_{\mathrm{s}}(\widehat{q}) + \widehat{V}_{\mathrm{c}}(R, \widehat{q})$, and $h_{\lambda\lambda'}$ is its matrix element. We used the fact that $h_{\lambda\lambda'} = h_{\lambda'\lambda}$ in writing this expression. Note that unlike eq. [5], where $\widehat{q}$ and $\widehat{p}$ are the subsystem coordinates and momenta, in eq. [13] $\widehat{r}$ and $\widehat{p}$ are the mapping space coordinates and momenta. These quantities have dimensions equal to the number of subsystem quantum states.

From the definition in eq. [12] it is clear that the matrix elements of $\widehat{A}$ in the subsystem basis are identical to those of $\widehat{A}_m$ in the mapping basis: $\langle\lambda|\widehat{A}|\lambda'\rangle = A_{\lambda\lambda'} = \langle m_\lambda|\widehat{A}_m|m_{\lambda'}\rangle$. Consequently, any matrix element in the quantum subsystem basis can be substituted by its equivalent form in the mapping basis. We show that this substitution leads to computational advantages when simulating quantum correlation functions.

4. Correlation function in mapping basis

The matrix elements in the correlation function expression (eq. [6]) can be replaced by their mapping equivalent forms to yield

$$[14] \qquad \begin{aligned}C_{AB}(t) = \frac{1}{(2\pi\hbar)^{N_{\mathrm{b}}}}\sum_{\lambda\lambda'\mu\mu'=1}^{N}\int \mathrm{d}X_1\mathrm{d}X_2\mathrm{d}Z_1\mathrm{d}Z_2 \left\langle m_\lambda\middle|(\widehat{\rho}_{\mathrm{eq}}\widehat{A})_{Wm}(X_1)\middle|m_{\lambda'}\right\rangle \\ \times\left\langle m_{\lambda'}\middle|\left\langle R_1 + \frac{Z_1}{2}\middle|e^{i\widehat{H}_m t/\hbar}\middle|R_2 - \frac{Z_2}{2}\right\rangle\middle|m_\mu\right\rangle\left\langle m_\mu\middle|\widehat{B}_{Wm}(X_2)\middle|m_{\mu'}\right\rangle \\ \times\left\langle m_{\mu'}\middle|\left\langle R_2 + \frac{Z_2}{2}\middle|e^{-i\widehat{H}_m t/\hbar}\middle|R_1 - \frac{Z_1}{2}\right\rangle\middle|m_\lambda\right\rangle e^{-\frac{i}{\hbar}(P_1\cdot Z_1 + P_2\cdot Z_2)}\end{aligned}$$

The next step in the analysis of this correlation function is to introduce a coordinate space representation of the abstract mapping eigenfuctions. Inserting resolutions of the identity, $\int \mathrm{d}q\ |q\rangle\langle q| = 1$, and making use of the closure relation for mapping states, $\sum_\lambda \langle q'|m_\lambda\rangle\langle m_\lambda|q\rangle = \delta(q - q')$, the correlation function takes the form

$$[15] \qquad \begin{aligned}C_{AB}(t) = \frac{1}{(2\pi\hbar)^{N_{\mathrm{b}}}}\int \mathrm{d}X_1\mathrm{d}X_2\mathrm{d}Z_1\mathrm{d}Z_2\mathrm{d}q_1\mathrm{d}q_2\mathrm{d}q_4\mathrm{d}q_6 \left\langle q_1\middle|\left(\widehat{\rho}_{\mathrm{eq}}\widehat{A}\right)_{Wm}(X_1)\middle|q_2\right\rangle \\ \times\left\langle q_2\middle|\left\langle R_1 + \frac{Z_1}{2}\middle|e^{i\widehat{H}_m t/\hbar}\middle|R_2 - \frac{Z_2}{2}\right\rangle\middle|q_4\right\rangle\left\langle q_4\middle|\widehat{B}_{Wm}(X_2)\middle|q_6\right\rangle\left\langle q_6\middle|\left\langle R_2 + \frac{Z_2}{2}\middle|e^{-i\widehat{H}_m t/\hbar}\middle|R_1 - \frac{Z_1}{2}\right\rangle\middle|q_1\right\rangle e^{-\frac{i}{\hbar}(P_1\cdot Z_1 + P_2\cdot Z_2)}\end{aligned}$$

It is important to note that the dimensionality of the mapping coordinate space representation is fixed by the number of quantum states.

A phase space description of this coordinate representation can be obtained by introducing Wigner transforms of the matrix elements. Making the change of variables, $q_1 = r_1 - z_1/2$, $q_2 = r_1 + z_1/2$, etc., and using the analog of eq. [4] for the mapping coordinates, we find

$$[16] \qquad C_{AB}(t) = \frac{1}{(2\pi\hbar)^{(N_b+N)}} \int dX_1 dX_2 dx_1 dx_2 \left(\widehat{\rho}_{eq}\widehat{A}\right)_{Wm}(X_1, x_1) B_{Wm}(X_2, x_2) W(X_1, X_2, x_1, x_2, t)$$

where in analogy with the bath phase space terminology, $x = (r, p)$. The full Wigner representation of the mapping spectral density W is defined as

$$[17] \qquad W(X_1, X_2, x_1, x_2, t) = \int dZ_1 dZ_2 dz_1 dz_2 \left\langle r_1 + \frac{z_1}{2}\middle|\left\langle R_1 + \frac{Z_1}{2}\middle|e^{i\widehat{H}_m t/\hbar}\middle|R_2 - \frac{Z_2}{2}\right\rangle\middle|r_2 - \frac{z_2}{2}\right\rangle \times \left\langle r_2 + \frac{z_2}{2}\middle|\left\langle R_2 + \frac{Z_2}{2}\middle|e^{-i\widehat{H}_m t/\hbar}\middle|R_1 - \frac{Z_1}{2}\right\rangle\middle|r_1 - \frac{z_1}{2}\right\rangle e^{-\frac{i}{\hbar}(P_1\cdot Z_1 + P_2\cdot Z_2 + p_1\cdot z_1 + p_2\cdot z_2)}$$

All of these manipulations have served simply to cast the exact expression for the quantum correlation function into an equivalent exact form involving a phase-space-like representation for both the bath and the mapping version of the quantum subsystem degrees of freedom. There are advantages to defining W and deriving its dynamics rather than directly considering the dynamics of the correlation function. Not only are the algebraic manipulations simplified, but also all correlation functions for a specific system share the same spectral density. This fully quantum problem is still intractable for complex many-body systems. We now turn to the evaluation of the spectral density function in the quantum-classical limit that will provide the basis for simulation algorithms of the dynamics.

5. Quantum-classical dynamics for *W*

Given the development presented above, the dynamical problem consists in finding a tractable equation of motion for the spectral density function $W(X_1,X_2,x_1,x_2,t)$ and constructing an algorithm for its solution. The equation of motion can be derived by differentiating W with respect to time. However, to derive the quantum-classical equation for W we must introduce approximations. For this purpose we make use of an expansion in the small mass ratio $\mu = (m/M)^{1/2}$, where it is assumed that the characteristic mass M of the bath particles is much larger than m for the quantum subsystem particles. The manner in which this expansion is carried out is analogous to that discussed earlier for the quantum-classical Liouville equation (eq. [2]). More specifically, given the energy ε_0, time $t_0 = \hbar/\varepsilon_0$, and length $\lambda_m = (\hbar^2/m\varepsilon_0)^{1/2}$ units, we scale the light and heavy particle momenta, respectively, with $p_m = (m\lambda_m/t_0) = (m\varepsilon_0)^{1/2}$ and $P_M = (M\varepsilon_0)^{1/2}$. Note that the only difference between subsystem and bath particles is scaling their momenta with different factors. As the subsystem and bath are in thermal equilibrium, their average kinetic energies are equal, and therefore, on average, $p/P = \mu$, so that after scaling both subsystem and bath momenta have the same order of magnitude. After scaling variables, we obtain

$$[18] \qquad W'(R'_1, P'_1, R'_2, P'_2, r'_1, p'_1, r'_2, p'_2; t') = \int dZ'_1 dZ'_2 dz'_1 dz'_2 \left\langle r'_1 + \frac{z'_1}{2}\middle|\left\langle R'_1 + \frac{Z'_1}{2}\middle|e^{i\widehat{H}'_m t'}\middle|R'_2 - \frac{Z'_2}{2}\right\rangle\middle|r'_2 - \frac{z'_2}{2}\right\rangle \times \left\langle r'_2 + \frac{z'_2}{2}\middle|\left\langle R'_2 + \frac{Z'_2}{2}\middle|e^{-i\widehat{H}'_m t'}\middle|R'_1 - \frac{Z'_1}{2}\right\rangle\middle|r'_1 - \frac{z'_1}{2}\right\rangle e^{-i\mu^{-1}(P'_1\cdot Z'_1 + P'_2\cdot Z'_2)} e^{-i(p'_1\cdot z'_1 + p'_2\cdot z'_2)}$$

where a prime means that the variable is divided by the corresponding scaling factor. To avoid cumbersome notation, we drop the primes in the following relations. Differentiation of the scaled form of W yields the equation of motion

$$[19] \qquad \frac{\partial W(t)}{\partial t} = i\int dZ_1 dZ_2 dz_1 dz_2 dQ dq \left[\left\langle r_1 + \frac{z_1}{2}\middle|\left\langle R_1 + \frac{Z_1}{2}\middle|\widehat{H}_m\middle|Q\right\rangle\middle|q\right\rangle \times \left\langle q\middle|\left\langle Q\middle|e^{i\widehat{H}_m t}\middle|R_2 - \frac{Z_2}{2}\right\rangle\middle|r_2 - \frac{z_2}{2}\right\rangle \times \left\langle r_2 + \frac{z_2}{2}\middle|\left\langle R_2 + \frac{Z_2}{2}\middle|e^{-i\widehat{H}_m t}\middle|R_1 - \frac{Z_1}{2}\right\rangle\middle|r_1 - \frac{z_1}{2}\right\rangle - \left\langle r_1 + \frac{z_1}{2}\middle|\left\langle R_1 + \frac{Z_1}{2}\middle|e^{i\widehat{H}_m t}\middle|R_2 - \frac{Z_2}{2}\right\rangle\middle|r_2 - \frac{z_2}{2}\right\rangle \times \left\langle r_2 + \frac{z_2}{2}\middle|\left\langle R_2 + \frac{Z_2}{2}\middle|e^{-i\widehat{H}_m t}\middle|Q\right\rangle\middle|q\right\rangle\left\langle Q\middle|\left\langle q\middle|\widehat{H}_m\middle|R_1 - \frac{Z_1}{2}\right\rangle\middle|r_1 - \frac{z_1}{2}\right\rangle\right] e^{-i\mu^{-1}(P_1\cdot Z_1 + P_2\cdot Z_2)} e^{-i(p_1\cdot z_1 + p_2\cdot z_2)}$$

The mapping Hamiltonian (eq. [13] in scaled variables is $\widehat{H}_m = \frac{\widehat{P}^2}{2} + \widehat{V}_B(\widehat{R}) + \sum_{\lambda\lambda'} \frac{h_{\lambda\lambda'}(\widehat{R})}{2}(\widehat{r}_\lambda\widehat{r}_{\lambda'} + \widehat{p}_\lambda\widehat{p}_{\lambda'} - \delta_{\lambda\lambda'})$, while the scaled quantum mechanical momentum operators are $\widehat{P} = \frac{\mu}{i}\frac{\partial}{\partial Q}$ and $\widehat{p} = -i\frac{\partial}{\partial q}$. Substituting the Hamiltonian and momentum operators into eq. [19] yields

$$[20]\quad \frac{\partial W(t)}{\partial t} = i\mu^{2N_b}\int d\tilde{Z}_1 d\tilde{Z}_2 dQ dz_1 dz_2 dq e^{-i(P_1\cdot\tilde{Z}_1+P_2\cdot\tilde{Z}_2)}e^{-i(p_1\cdot z_1+p_2\cdot z_2)}$$
$$\times\left\{\left\{\left[\frac{-\mu^2}{2}\frac{\partial^2}{\partial Q^2}+V_B(Q)+\frac{1}{2}\sum_{\lambda\lambda'}h_{\lambda\lambda'}(Q)\left(q_\lambda q_{\lambda'}-\frac{\partial}{\partial q_\lambda}\frac{\partial}{\partial q_{\lambda'}}-\delta_{\lambda\lambda'}\right)\right]\right.\right.$$
$$\left.\left.\times\,\delta\left(Q-R_1-\frac{\mu\tilde{Z}_1}{2}\right)\delta\left(q-r_1-\frac{z_1}{2}\right)\right\}\left\langle q\left|\left\langle Q\left|e^{i\widehat{H}_m t}\right|R_2-\frac{\mu\tilde{Z}_2}{2}\right\rangle\right|r_2-\frac{z_2}{2}\right\rangle\right.$$
$$\times\left\langle r_2+\frac{z_2}{2}\left|\left\langle R_2+\frac{\mu\tilde{Z}_2}{2}\left|e^{-i\widehat{H}_m t}\right|R_1-\frac{\mu\tilde{Z}_1}{2}\right\rangle\right|r_1-\frac{z_1}{2}\right\rangle\right.$$
$$-\left\{\left[\frac{-\mu^2}{2}\frac{\partial^2}{\partial Q^2}+V_B(Q)+\frac{1}{2}\sum_{\lambda\lambda'}h_{\lambda\lambda'}(Q)\left(q_\lambda q_{\lambda'}-\frac{\partial}{\partial q_\lambda}\frac{\partial}{\partial q_{\lambda'}}-\delta_{\lambda\lambda'}\right)\right]\right.$$
$$\left.\times\,\delta\left(Q-R_1+\frac{\mu\tilde{Z}_1}{2}\right)\delta\left(q-r_1+\frac{z_1}{2}\right)\right\}\left\langle r_1+\frac{z_1}{2}\left|\left\langle R_1+\frac{\mu\tilde{Z}_1}{2}\left|e^{i\widehat{H}_m t}\right|R_2-\frac{\mu\tilde{Z}_2}{2}\right\rangle\right|r_2-\frac{z_2}{2}\right\rangle$$
$$\left.\times\left\langle r_2+\frac{z_2}{2}\left|\left\langle R_2+\frac{\mu\tilde{Z}_2}{2}\left|e^{-i\widehat{H}_m t}\right|Q\right\rangle\right|q\right\rangle\right\}$$

where the change of variable $\tilde{Z}_1 = Z_1/\mu$ was performed to transfer the μ dependence from the exponential to the argument of the potential energy terms, after integrations over Q and q have been performed. It is more convenient to expand a potential energy term around a small parameter rather than to deal with an oscillatory exponential.

We begin the calculation by performing the integrals over q and Q, followed by Taylor expansion of the potential energy terms around μ = 0, keeping terms up to the first order in μ. Finally, we introduce the definition of W into the resulting expression. The algebra is lengthy so it is presented in the Appendix. While the algebra leading to the result is lengthy, the final equation of motion is relatively simple. In unscaled coordinates it takes the form

$$[21]\quad \frac{\partial W(t)}{\partial t} = -\frac{1}{\hbar}\sum_{\lambda\lambda'}h_{\lambda\lambda'}(R_1)\left[r_{1\lambda}\frac{\partial}{\partial p_{1\lambda'}}-p_{1\lambda}\frac{\partial}{\partial r_{1\lambda'}}\right]W(t)+\left(\frac{P_1}{M}\cdot\frac{\partial}{\partial R_1}-\frac{\partial H_{\rm m}}{\partial R_1}\cdot\frac{\partial}{\partial P_1}\right)W(t)$$
$$+\;\frac{\hbar}{8}\sum_{\lambda\lambda'}\frac{\partial h_{\lambda\lambda'}(R_1)}{\partial R_1}\cdot\left(\frac{\partial}{\partial r_{1\lambda}}\frac{\partial}{\partial r_{1\lambda'}}+\frac{\partial}{\partial p_{1\lambda'}}\frac{\partial}{\partial p_{1\lambda}}\right)\frac{\partial}{\partial P_1}W(t)$$
$$\equiv\; i\mathscr{L}_{\rm m}(x_1,X_1)W(t)$$

Here, the Wigner transform of the Hamiltonian[15] is given by

$$[22]\quad H_{\rm m} = \frac{P^2}{2M}+V_{\rm B}(R)+\sum_{\lambda\lambda'}\frac{h_{\lambda\lambda'}(R)}{2}(r_\lambda r_{\lambda'}+p_\lambda p_{\lambda'}-\delta_{\lambda\lambda'})$$

This equation of motion is one of the principal results of this paper. It results from an expansion of the evolution operator for W to order μ and is equivalent to quantum-classical Liouville dynamics for the spectral density function.[19] The first term in eq. [21] represents the subsystem dynamics of the spectral density in the mapping phase space. The second term is the dynamics of the spectral density due to classical evolution of the bath degrees of freedom and the third term is a higher order correlation between the quantum mapping and classical degrees of freedom. The last equality defines the quantum-classical Liouville operator in the mapping basis. This equation must be solved subject to the initial condition

$$[23]\quad W(\theta) = (2\pi\hbar)^{(N_{\rm b}+N)}\delta\left(r_1-r_2\right)\delta\left(R_1-R_2\right)\delta\left(p_1-p_2\right)\delta\left(P_1-P_2\right)$$

In eq. [19], since $\widehat{H}_m$ commutes with propagator $e^{i\widehat{H}_m t}$ when differentiating with respect to time, $\widehat{H}_m$ could be placed on either side of the propagator. In this derivation, we chose to put it to the left of the propagator in the first term in eq. [19] and to the right of the propagator in the second term. If instead one places $\widehat{H}_m$ to the right of the propagator in the first term and to the left of the propagator in the second term, we can obtain an alternate form of the equation of motion[35]. The manipulations are similar to those described above and in the Appendix and are not repeated her. The resulting equation of motion is

$$[24]\quad \frac{\partial W(t)}{\partial t} = +\frac{1}{\hbar}\sum_{\lambda\lambda'}h_{\lambda\lambda'}(R_2)\left[r_{2\lambda}\frac{\partial}{\partial p_{2\lambda'}}-p_{2\lambda}\frac{\partial}{\partial r_{2\lambda'}}\right]W(t)-\left(\frac{P_2}{M}\cdot\frac{\partial}{\partial R_2}-\frac{\partial H_{\rm m}}{\partial R_2}\cdot\frac{\partial}{\partial P_2}\right)W(t)$$
$$-\frac{\hbar}{8}\sum_{\lambda\lambda'}\frac{\partial h_{\lambda\lambda'}(R_2)}{\partial R_2}\cdot\left(\frac{\partial}{\partial r_{2\lambda}}\frac{\partial}{\partial r_{2\lambda'}}+\frac{\partial}{\partial p_{2\lambda'}}\frac{\partial}{\partial p_{2\lambda}}\right)\frac{\partial}{\partial P_2}W(t)$$
$$\equiv -i\mathscr{L}_m(x_2,X_2)W(t)$$

This alternate form of the dynamics not only shows the symmetry of the dynamics of W in its variables but also allows us to move the time evolution from W to the observable B_{Wm} in the correlation function expression. The formal solution of eq. [24] is

$$[25] \qquad W(X_1, X_2, x_1, x_2, t) = e^{-i\mathscr{L}_m(x_2,X_2)t} W(X_1, X_2, x_1, x_2, 0)$$

These results will be used in the next section to derive a quantum-classical approximation to the time correlation function.

6. Quantum-classical correlation function

We can now employ the results of the last two sections to find an expression for the quantum-classical approximation to the correlation function in the mapping basis. Using eq. [25] in eq. [16], we have

$$[26] \qquad C_{AB}(t) = \frac{1}{(2\pi\hbar)^{(N_b+N)}} \int dX_1 dX_2 dx_1 dx_2 \left(\widehat{\rho}_{eq}\widehat{A}\right)_{Wm}(X_1, x_1) B_{Wm}(X_2, x_2) e^{-i\mathscr{L}_m(x_2,X_2)t} W(X_1, X_2, x_1, x_2, 0)$$

Performing an integration by parts to move the evolution operator onto the B_{Wm} and integrating over the coordinates with subscript 1, making use of the delta functions in the initial value of W, yields

$$[27] \qquad C_{AB}(t) = \int dX dx (\widehat{\rho}_{eq}\widehat{A})_{W_m}(X, x) B_{W_m}(X, x, t)$$

where $B_{Wm}(X, x, t) = e^{i\mathscr{L}_m(x,X)t} B_{Wm}(X, x)$. (We have dropped the subscripts on the phase space coordinates since this notation is no longer needed.) This expression contains the full quantum equilibrium structure of the subsystem and bath and the quantum-classical Liouville evolution of the operator $\widehat{B}$ in the mapping representation.

The evolution equation for $B_{Wm}(X,x,t)$ that one obtains in this derivation is identical to that found earlier in the calculation of the average value of an observable.[12] This evolution equation can be written in the form,

$$[28] \qquad \frac{d}{dt} B_{Wm}(x, X, t) = i\mathscr{L}_m B_{Wm}(t) = -\{H_m, B_{Wm}(t)\}_{x,X} + \frac{\hbar}{8} \sum_{\lambda\lambda'} \frac{\partial h_{\lambda\lambda'}}{\partial R} \cdot \left(\frac{\partial}{\partial r_{\lambda'}} \frac{\partial}{\partial r_\lambda} + \frac{\partial}{\partial p_{\lambda'}} \frac{\partial}{\partial p_\lambda} \right) \frac{\partial}{\partial P} B_{Wm}(t)$$

where $\{\ ,\ \}_{x,X}$ denotes a Poisson bracket in the full mapping-bath phase space of the system. The quantum-classical Liouville operator in the mapping basis can be decomposed into two terms, $i\mathscr{L}_m = i\mathscr{L}^0_m + i\mathscr{L}'_m$, where

$$[29] \qquad \begin{aligned} i\mathscr{L}^0_m &= -\{H_m, \quad\}_{x,X} \\ i\mathscr{L}'_m &= \frac{\hbar}{8} \sum_{\lambda\lambda'} \frac{\partial h_{\lambda\lambda'}}{\partial R} \cdot \left(\frac{\partial}{\partial r_{\lambda'}} \frac{\partial}{\partial r_\lambda} + \frac{\partial}{\partial p_{\lambda'}} \frac{\partial}{\partial p_\lambda} \right) \frac{\partial}{\partial P} \end{aligned}$$

The $i\mathscr{L}^0_m$ evolution operator, corresponding to the Poisson bracket in eq. [28], leads to a classical-like evolution of the coupled dynamics of the quantum mapping and classical bath phase space variables that can be simulated by Newtonian trajectories. The force field that the classical variables feel varies with time as a result of the dependence of the forces on the mapping phase space variables. If $i\mathscr{L}'_m$ is dropped in the evolution equation, $B_{Wm}(t)$ has a solution in terms of characteristics. The set of ordinary differential equations that determines its solution is

$$[30] \qquad \begin{aligned} \frac{dr_\lambda(t)}{dt} &= \frac{1}{\hbar} \sum_{\lambda'} h_{\lambda\lambda'}(R(t)) p_{\lambda'}(t) \\ \frac{dp_\lambda(t)}{dt} &= -\frac{1}{\hbar} \sum_{\lambda'} h_{\lambda\lambda'}(R(t)) r_{\lambda'}(t) \\ \frac{dR(t)}{dt} &= \frac{P(t)}{M}, \frac{dP(t)}{dt} = -\frac{\partial H_m}{\partial R(t)} \end{aligned}$$

The utility of this approximation to eq. [28] is a topic of current research. Tests of its accuracy have been carried out on the spin-boson model where eq. [28] is equivalent to full quantum dynamics and are being carried out on other model systems with nonlinear coupling between the quantum and classical degrees of freedom where eq. [28] is not exact. For the spin-boson model, eq. [30] yields results that are indistinguishable from the known exact quantum results for this system.[12] Tests being carried out on other model systems show that while the results are often in close accord with exact quantum results, sometimes discrepancies are observed that cannot be ascribed to approximations in eq. [28] for these more general interactions, and must be attributed to the use of eq. [30] for the dynamics. Consequently, further research is underway to fully characterize the contributions arising from $i\mathscr{L}'_m$ and construct algorithms that account for its action.

7. Conclusion

In the adiabatic basis, the correlation function may be evaluated in terms of an ensemble of surface-hopping trajectories.[5,7] While this simulation scheme has been used in a number of applications it is difficult to obtain accurate results for long times because of the presence of oscillating terms in the Monte Carlo sampling. In this paper, we show that it is possible to reformulate the calculation of the correlation function in the mapping basis. Simulation schemes based on this formulation do not suffer from some of the problems that arise in the implementation of surface-hopping schemes.

To evaluate the expression for the correlation function obtained in this paper, two ingredients are required. The expression involves an average over the full quantum equilibrium structure. As briefly discussed above, the computation of quantum equilibrium structure is a more tractable problem than the calculation of quantum dynamics. Nevertheless, approximations are usually required to evaluate the equilibrium structure. In the high-temperature limit it is possible to derive analytical expressions that are useful in many applications.[36–38]

The main result of this paper is the quantum-classical expression for the correlation function that involves time evolution of the quantum subsystem in the mapping basis. Provided the quantum-classical evolution is approximated by $i\mathscr{L}_m \simeq i\mathscr{L}_m^0$, the time evolution of the dynamical variable in the correlation function can be computed easily by solving a set of Newtonian-like equations. Thus, difficulties associated with the accumulation of Monte Carlo weights in the evaluation of an oscillatory function that arise in the surface-hopping solution of the quantum-classical Liouville equation in the adiabatic basis are by-passed. Of course, this simple scheme relies on the ability to neglect $i\mathscr{L}_m'$, which accounts for higher-order correlations in the dynamics. Thus, the focus of future research is on the characterization of the nature of the dynamics generated by $i\mathscr{L}_m'$ and the construction of simulation algorithms that account for its presence. The results in this paper form the basis for future applications to the calculation of transport properties, such as rate constants for nonadiabtic chemical reactions.

Appendix: Derivation of the dynamics

In this appendix, we give the details of the calculations needed to obtain the quantum-classical evolution equation for the spectral density function. There are ten terms in eq. [20], and because of the symmetry of the expression, it is convenient to group term i with term $i + 5$ and evaluate the contributions group by group. First, we perform the integrals over Q and q. The first and sixth terms contain $\frac{\partial^2}{\partial \tilde{Z}_1^2}$ and $\frac{\partial^2}{\partial \tilde{Z}_2^2}$, respectively, after this integration. Integration by parts with respect to $\tilde{Z}_1$ and $\tilde{Z}_2$ and summation of the results yield $\mu P_1 \cdot \frac{\partial W}{\partial R_1}$. The second and seventh terms involve bath potentials. After expansion of $V_B(R_1 \pm \frac{\mu \tilde{Z}_1}{2})$ in μ, the first and third terms in the series, which are proportional to μ^0 and μ^2, cancel, and the second terms, which are proportional to μ, yield $-\mu \frac{\partial V_B(R_1)}{\partial R_1} \cdot \frac{\partial W}{\partial P_1}$. The contribution from the fifth and tenth terms is derived similarly to yield $\frac{\mu}{2} \frac{\partial \mathrm{Tr}(h)}{\partial R_1} \cdot \frac{\partial W}{\partial P_1}$. The derivations of the third and eighth and also the fourth and fifth groups of terms are more complicated and are presented in the following two subsections.

Third and eighth terms

The sum of the third and eighth contributions to the time derivative of W is

$$[A1] \quad \left(\frac{\partial W}{\partial t}\right)_{3+8} = \frac{i\mu^{2N_b}}{2} \sum_{\lambda\lambda'} \int d\tilde{Z}_1 d\tilde{Z}_2 dz_1 dz_2 e^{-i(P_1\cdot\tilde{Z}_1 + P_2\cdot\tilde{Z}_2 + p_1\cdot z_1 + p_2\cdot z_2)}$$
$$\times \left\{ \left[h_{\lambda\lambda'}(R_1) + \frac{\partial h_{\lambda\lambda'}(R_1)}{\partial R_1} \cdot \frac{\mu\tilde{Z}_1}{2} \right] \left[r_{1\lambda} r_{1\lambda'} + r_{1\lambda} z_{1\lambda'}/2 + z_{1\lambda} r_{1\lambda'}/2 + z_{1\lambda} z_{1\lambda'}/4 \right] \right.$$
$$\left. - \left[h_{\lambda\lambda'}(R_1) - \frac{\partial h_{\lambda\lambda'}(R_1)}{\partial R_1} \cdot \frac{\mu\tilde{Z}_1}{2} \right] \left[r_{1\lambda} r_{1\lambda'} - r_{1\lambda} z_{1\lambda'}/2 - z_{1\lambda} r_{1\lambda'}/2 + z_{1\lambda} z_{1\lambda'}/4 \right] \right\}$$
$$\times \left\langle r_1 + \frac{z_1}{2} \middle| \left\langle R_1 + \frac{\mu\tilde{Z}_1}{2} \middle| e^{i\widehat{H}_m t} \middle| R_2 - \frac{\mu\tilde{Z}_2}{2} \right\rangle \middle| r_2 - \frac{z_2}{2} \right\rangle$$
$$\times \left\langle r_2 + \frac{z_2}{2} \middle| \left\langle R_2 + \frac{\mu\tilde{Z}_2}{2} \middle| e^{-i\widehat{H}_m t} \middle| R_1 - \frac{\mu\tilde{Z}_1}{2} \right\rangle \middle| r_1 - \frac{z_1}{2} \right\rangle$$

where we have performed a McLauren expansion of $h_{\lambda\lambda'}$ in the small parameter μ, and retained the first two terms. Finally, using the fact that a partial differential with respect to momentum acting on the exponential term has the same effect as multiplication by the variable z_1 or $\tilde{Z}_1$ that results from the expansion, we have

$$[A2] \quad \left(\frac{\partial W}{\partial t}\right)_{3+8} = \frac{i\mu^{2N_b}}{2} \sum_{\lambda\lambda'} \int d\tilde{Z}_1 d\tilde{Z}_2 dz_1 dz_2 \left\{ ih_{\lambda\lambda'}(R_1) \left[r_{1\lambda} \frac{\partial}{\partial p_{1\lambda'}} + r_{1\lambda'} \frac{\partial}{\partial p_{1\lambda}} \right] \right.$$
$$\left. + \frac{\mu}{2} \frac{\partial h_{\lambda\lambda'}(R_1)}{\partial R_1} \cdot \left(i \frac{\partial}{\partial P_1} \right) \left[2 r_{1\lambda} r_{1\lambda'} - \frac{1}{2} \frac{\partial}{\partial p_{1\lambda}} \frac{\partial}{\partial p_{1\lambda'}} \right] \right\} e^{-i(P_1\cdot\tilde{Z}_1 + P_2\cdot\tilde{Z}_2 + p_1\cdot z_1 + p_2\cdot z_2)}$$
$$\times \left\langle r_1 + \frac{z_1}{2} \middle| \left\langle R_1 + \frac{\mu\tilde{Z}_1}{2} \middle| e^{i\widehat{H}_m t} \middle| R_2 - \frac{\mu\tilde{Z}_2}{2} \right\rangle \middle| r_2 - \frac{z_2}{2} \right\rangle$$
$$\times \left\langle r_2 + \frac{z_2}{2} \middle| \left\langle R_2 + \frac{\mu\tilde{Z}_2}{2} \middle| e^{-i\widehat{H}_m t} \middle| R_1 - \frac{\mu\tilde{Z}_1}{2} \right\rangle \middle| r_1 - \frac{z_1}{2} \right\rangle$$
$$= -\frac{1}{2} \sum_{\lambda\lambda'} h_{\lambda\lambda'}(R_1) \left[r_{1\lambda} \frac{\partial}{\partial p_{1\lambda'}} + r_{1\lambda'} \frac{\partial}{\partial p_{1\lambda}} \right] W$$
$$- \frac{\mu}{4} \sum_{\lambda\lambda'} \frac{\partial h_{\lambda\lambda'}(R_1)}{\partial R_1} \cdot \left[2 r_{1\lambda} r_{1\lambda'} - \frac{1}{2} \frac{\partial}{\partial p_{1\lambda}} \frac{\partial}{\partial p_{1\lambda'}} \right] \frac{\partial}{\partial P_1} W$$

where in the last equality the expression for the scaled W is inserted.

Fourth and ninth terms

The sum of the fourth and ninth terms in eq. [20] is

$$
\begin{aligned}
[A3]\qquad \left(\frac{\partial W}{\partial t}\right)_{4+9} = &-\frac{i\mu^{2N_b}}{2}\int d\tilde{Z}_1 d\tilde{Z}_2 dz_1 dz_2 \sum_{\lambda\lambda'}\Bigg\{\Bigg[h_{\lambda\lambda'}\left(R_1+\frac{\mu\tilde{Z}_1}{2}\right)\frac{\partial}{\partial\left(r_1+\frac{z_1}{2}\right)_\lambda}\frac{\partial}{\partial\left(r_1+\frac{z_1}{2}\right)_{\lambda'}}\\
&\times\left\langle r_1+\frac{z_1}{2}\middle|\left\langle R_1+\frac{\mu\tilde{Z}_1}{2}\middle|e^{i\widehat{H}_m t}\middle|R_2-\frac{\mu\tilde{Z}_2}{2}\right\rangle\middle|r_2-\frac{z_2}{2}\right\rangle\Bigg]\\
&\times\left\langle r_2+\frac{z_2}{2}\middle|\left\langle R_2+\frac{\mu\tilde{Z}_2}{2}\middle|e^{-i\widehat{H}_m t}\middle|R_1-\frac{\mu\tilde{Z}_1}{2}\right\rangle\middle|r_1-\frac{z_1}{2}\right\rangle\\
&-\Bigg\{h_{\lambda\lambda'}\left(R_1-\frac{\mu\tilde{Z}_1}{2}\right)\frac{\partial}{\partial\left(r_1-\frac{z_1}{2}\right)_\lambda}\frac{\partial}{\partial\left(r_1-\frac{z_1}{2}\right)_{\lambda'}}\\
&\times\left\langle r_2+\frac{z_2}{2}\middle|\left\langle R_2+\frac{\mu\tilde{Z}_2}{2}\middle|e^{-i\widehat{H}_m t}\middle|R_1-\frac{\mu\tilde{Z}_1}{2}\right\rangle\middle|r_1-\frac{z_1}{2}\right\rangle\Bigg]\\
&\times\left\langle r_1+\frac{z_1}{2}\middle|\left\langle R_1+\frac{\mu\tilde{Z}_1}{2}\middle|e^{i\widehat{H}_m t}\middle|R_2-\frac{\mu\tilde{Z}_2}{2}\right\rangle\middle|r_2-\frac{z_2}{2}\right\rangle\Bigg\}e^{-i(P_1\cdot\tilde{Z}_1+P_2\cdot\tilde{Z}_2+p_1\cdot z_1+p_2\cdot z_2)}\\
=&-\frac{i\mu^{2N_b}}{2}\sum_{\lambda\lambda'}\int d\tilde{Z}_1 d\tilde{Z}_2 dz_1 dz_2\Bigg\{\Bigg[\left(h_{\lambda\lambda'}(R_1)+\frac{\partial h_{\lambda\lambda'}(R_1)}{\partial R_1}\frac{\mu\tilde{Z}_1}{2}\right)\\
&\times\frac{\partial}{\partial r_{1\lambda}}\frac{\partial}{\partial r_{1\lambda'}}\left\langle r_1+\frac{z_1}{2}\middle|\left\langle R_1+\frac{\mu\tilde{Z}_1}{2}\middle|e^{i\widehat{H}_m t}\middle|R_2-\frac{\mu\tilde{Z}_2}{2}\right\rangle\middle|r_2-\frac{z_2}{2}\right\rangle\Bigg]\\
&\times\left\langle r_2+\frac{z_2}{2}\middle|\left\langle R_2+\frac{\mu\tilde{Z}_2}{2}\middle|e^{-i\widehat{H}_m t}\middle|R_1-\frac{\mu\tilde{Z}_1}{2}\right\rangle\middle|r_1-\frac{z_1}{2}\right\rangle\\
&-\Bigg[\left(h_{\lambda\lambda'}(R_1)-\frac{\partial h_{\lambda\lambda'}(R_1)}{\partial R_1}\frac{\mu\tilde{Z}_1}{2}\right)\frac{\partial}{\partial r_{1\lambda}}\frac{\partial}{\partial r_{1\lambda'}}\left\langle r_2+\frac{z_2}{2}\middle|\left\langle R_2+\frac{\mu\tilde{Z}_2}{2}\middle|e^{-i\widehat{H}_m t}\middle|R_1-\frac{\mu\tilde{Z}_1}{2}\right\rangle\middle|r_1-\frac{z_1}{2}\right\rangle\Bigg]\\
&\times\left\langle r_1+\frac{z_1}{2}\middle|\left\langle R_1+\frac{\mu\tilde{Z}_1}{2}\middle|e^{i\widehat{H}_m t}\middle|R_2-\frac{\mu\tilde{Z}_2}{2}\right\rangle\middle|r_2-\frac{z_2}{2}\right\rangle\Bigg\}e^{-i(P_1\cdot\tilde{Z}_1+P_2\cdot\tilde{Z}_2+p_1\cdot z_1+p_2\cdot z_2)}
\end{aligned}
$$

Again, in the second equality we have carried out a McLauren expansion of $h_{\lambda\lambda'}$ to first order in μ. Equation [A3] itself has four terms. In the sum of the first and third subcontributions, one of the partial derivatives over r may be replaced by a partial derivative over z, and an integration by parts may be carried out. We find

$$
\begin{aligned}
[A4]\qquad &\frac{i\mu^{2N_b}}{2}\sum_{\lambda\lambda'}h_{\lambda\lambda'}(R_1)\int d\tilde{Z}_1 d\tilde{Z}_2 dz_1 dz_2 e^{-i(P_1\cdot\tilde{Z}_1+P_2\cdot\tilde{Z}_2+p_1\cdot z_1+p_2\cdot z_2)}\\
&\times\Bigg\{\Bigg[2\frac{\partial}{\partial r_{1\lambda'}}\left\langle r_1+\frac{z_1}{2}\middle|\left\langle R_1+\frac{\mu\tilde{Z}_1}{2}\middle|e^{i\widehat{H}_m t}\middle|R_2-\frac{\mu\tilde{Z}_2}{2}\right\rangle\middle|r_2-\frac{z_2}{2}\right\rangle\\
&\times\left(\frac{\partial}{\partial z_{1\lambda}}-ip_{1\lambda}\right)\left\langle r_2+\frac{z_2}{2}\middle|\left\langle R_2+\frac{\mu\tilde{Z}_2}{2}\middle|e^{-i\widehat{H}_m t}\middle|R_1-\frac{\mu\tilde{Z}_1}{2}\right\rangle\middle|r_1-\frac{z_1}{2}\right\rangle\Bigg]\\
&-\Bigg[(-2)\frac{\partial}{\partial r_{1\lambda'}}\left\langle r_2+\frac{z_2}{2}\middle|\left\langle R_2+\frac{\mu\tilde{Z}_2}{2}\middle|e^{-i\widehat{H}_m t}\middle|R_1-\frac{\mu\tilde{Z}_1}{2}\right\rangle\middle|r_1-\frac{z_1}{2}\right\rangle\\
&\times\left(\frac{\partial}{\partial z_{1\lambda}}-ip_{1\lambda}\right)\left\langle r_1+\frac{z_1}{2}\middle|\left\langle R_1+\frac{\mu\tilde{Z}_1}{2}\middle|e^{i\widehat{H}_m t}\middle|R_2-\frac{\mu\tilde{Z}_2}{2}\right\rangle\middle|r_2-\frac{z_2}{2}\right\rangle\Bigg]\Bigg\}\\
&=\sum_{\lambda\lambda'}h_{\lambda\lambda'}(R_1)p_{1\lambda}\frac{\partial}{\partial r_{1\lambda'}}W
\end{aligned}
$$

Here, we see that the two terms with a momentum multiplier are added together, while the other terms cancel each other.

The second and fourth subcontributions in eq. [A3] are treated in the following way: We replace multiplication by the variable $\tilde{Z}$ with a partial differentiation with respect to the momentum. Furthermore, the sum of these contributions is written as one half the sum of two equal contributions, the expressions appearing in eq. [A3] and the same expression but with the differentials over r replaced with those over z. Thus, the sum of the second and fourth contributions can be written as

$$
\begin{aligned}
[A5]\qquad & \frac{i\mu^{2N_b}}{2}\sum_{\lambda\lambda'}h_{\lambda\lambda'}(R_1)\int \mathrm{d}\tilde{Z}_1\mathrm{d}\tilde{Z}_2\mathrm{d}z_1\mathrm{d}z_2 e^{-i(P_1\cdot\tilde{Z}_1+P_2\cdot\tilde{Z}_2+p_1\cdot z_1+p_2\cdot z_2)} \\
& \times\left\{\left[2\frac{\partial}{\partial r_{1\lambda'}}\left\langle r_1+\frac{z_1}{2}\middle|\left\langle R_1+\frac{\mu\tilde{Z}_1}{2}\middle|e^{i\widehat{H}_m t}\middle|R_2-\frac{\mu\tilde{Z}_2}{2}\right\rangle\middle|r_2-\frac{z_2}{2}\right\rangle\right.\right. \\
& \times\left(\frac{\partial}{\partial z_{1\lambda}}-ip_{1\lambda}\right)\left\langle r_2+\frac{z_2}{2}\middle|\left\langle R_2+\frac{\mu\tilde{Z}_2}{2}\middle|e^{-i\widehat{H}_m t}\middle|R_1-\frac{\mu\tilde{Z}_1}{2}\right\rangle\middle|r_1-\frac{z_1}{2}\right\rangle\Bigg] \\
& -\left[(-2)\frac{\partial}{\partial r_{1\lambda'}}\left\langle r_2+\frac{z_2}{2}\middle|\left\langle R_2+\frac{\mu\tilde{Z}_2}{2}\middle|e^{-i\widehat{H}_m t}\middle|R_1-\frac{\mu\tilde{Z}_1}{2}\right\rangle\middle|r_1-\frac{z_1}{2}\right\rangle\right. \\
& \left.\left.\times\left(\frac{\partial}{\partial z_{1\lambda}}-ip_{1\lambda}\right)\left\langle r_1+\frac{z_1}{2}\middle|\left\langle R_1+\frac{\mu\tilde{Z}_1}{2}\middle|e^{i\widehat{H}_m t}\middle|R_2-\frac{\mu\tilde{Z}_2}{2}\right\rangle\middle|r_2-\frac{z_2}{2}\right\rangle\right]\right\} \\
& =\sum_{\lambda\lambda'}h_{\lambda\lambda'}(R_1)p_{1\lambda}\frac{\partial}{\partial r_{1\lambda'}}W
\end{aligned}
$$

If in both expressions we replace $\frac{\partial^2 A}{\partial x\partial y}B+A\frac{\partial^2 B}{\partial x\partial y}$ with $\frac{\partial^2(AB)}{\partial x\partial y}-\frac{\partial A}{\partial x}\frac{\partial B}{\partial y}-\frac{\partial A}{\partial y}\frac{\partial B}{\partial x}$, the cross terms cancel. Finally, integrating by parts over $z_{1\lambda}$ and $z_{1\lambda'}$, we obtain

$$
[A6]\qquad \frac{\mu}{8}\sum_{\lambda\lambda'}\frac{\partial h_{\lambda\lambda'}(R_1)}{\partial R_1}\cdot\left(\frac{\partial}{\partial r_{1\lambda}}\frac{\partial}{\partial r_{1\lambda'}}-4p_{1\lambda}p_{1\lambda'}\right)\frac{\partial}{\partial P_1}W
$$

Summing all the contributions from the above calculations, we find the comparatively simple result

$$
\begin{aligned}
[A7]\qquad \frac{\partial W}{\partial t} &= -\sum_{\lambda\lambda'}h_{\lambda\lambda'}(R_1)\left[r_{1\lambda}\frac{\partial}{\partial p_{1\lambda'}}-p_{1\lambda}\frac{\partial}{\partial r_{1\lambda'}}\right]W \\
&+\ \mu P_1\cdot\frac{\partial W}{\partial R_1}-\mu\frac{\partial V_B(R_1)}{\partial R_1}\cdot\frac{\partial W}{\partial P_1}-\frac{\mu}{2}\sum_{\lambda\lambda'}\frac{\partial h_{\lambda\lambda'}(R_1)}{\partial R_1}\cdot\left(r_{1\lambda}r_{1\lambda'}+p_{1\lambda}p_{1\lambda'}-\delta_{\lambda\lambda'}\right)\frac{\partial}{\partial P_1}W \\
&+\ \frac{\mu}{8}\sum_{\lambda\lambda'}\frac{\partial h_{\lambda\lambda'}(R_1)}{\partial R_1}\cdot\left(\frac{\partial}{\partial r_{1\lambda}}\frac{\partial}{\partial r_{1\lambda'}}+\frac{\partial}{\partial p_{1\lambda}}\frac{\partial}{\partial p_{1\lambda'}}\right)\frac{\partial}{\partial P_1}W
\end{aligned}
$$

Restoring unscaled coordinates, we have eq. [21] in the text.

Mechanisms for anionic butadiene polymerization with alkyl lithium species[1]

Peter Margl

Abstract: Anionic butadiene polymerization by means of [Li-polybutadienyl]$_x$ species (x = 1–6, 8) without polar agents was investigated by means of density functional theory (DFT) under conditions relevant to industrial application, namely in a low-dielectric hydrocarbon solvent and at room temperature. The calculations indicate that the dimeric and tetrameric catalyst species together account for the bulk of Li-polybutadienyl species in the polymerization mixture under typical conditions. It is likely that each type of oligomer produces its own "fingerprint" signature polymer microstructure, as there is a systematic variation in the amounts of 1,2- and 1,4-insertions as well as in the preference of *cis*- and *trans*-butadiene. According to the calculations, higher aggregated Li species tend to produce more 1,2-insertions and prefer *trans*- over *cis*-butadiene insertion, while the dimer prefers *trans*-butadiene and 1,4-insertions. The dimer closely reproduces the experimentally observed polybutadiene microstructure (5%–10% 1,2-insertion, approximately equal ratios of cis and trans units with a slight predominance of trans). The monomeric catalyst species shows a clear preference for insertion of *cis*-butadiene over *trans*-butadiene. Thus, the monomer species is predicted to be present in the polymerization mixture in very small concentrations under normal conditions and the overall polymerization is predicted to be mainly carried out by the dimeric catalyst species.

Key words: anionic polymerization, density functional theory, polymer microstructure.

Résumé : On a étudié la polymérisation anionique du butadiène à l'aide d'espèces [Li-polybutadiényle]$_x$ (x = 1–6, 8), sans agents polaires en faisant appel à la théorie de la fonctionnelle de densité, dans des conditions intéressantes pour une application industrielle, telle celle en solution dans un solvant hydrocarboné de faible coefficient diélectrique et à la température ambiante. Les calculs indiquent que les espèces dimères et tétramères du catalyseur prises ensemble correspondent à pratiquement l'ensemble des espèces Li-polybutadiényles dans le mélange de polymérisation, dans des conditions typiques. Il est probable que chaque type d'oligomère conduit à une microstructure de polymère qui lui est propre puisqu'on observe des variations systématiques dans les quantités d'insertions 1,2- et 1,4- ainsi que dans la formation préférentielle des *cis*- et *trans*-butadiènes. D'après les calculs, les espèces lithiées plus agrégées ont tendance à produire plus d'insertions 1,2 ainsi qu'une formation préférentielle *trans*-butadiènes par rapport aux *cis*- alors que les espèces dimères ont tendance à produire plus d'insertions 1,4. Le dimère permet de bien reproduire la microstructure observée expérimentalement pour le polybutadiène (5 % à 10 % d'insertion-1,2, des rapports approximativement égaux d'unités *cis*- et *trans*- avec une légère prédominance pour le trans). Les espèces du catalyseur monomère présentent une préférence marquée pour l'insertion de *cis*-butadiène par rapport au *trans*-butadiène. On peut donc prédire que l'espèce monomère n'est présente dans le mélange de polymérisation qu'à de très faibles concentrations, dans les conditions normales, et que la polymérisation globale est effectuée par les espèces du catalyseur dimère.

Mots-clés : polymérisation anionique, théorie de la fonctionnelle de la densité, microstructure d'un polymère.

[Traduit par la Rédaction]

Introduction

Living anionic polymerization is a powerful tool to produce tailor made polymers.[2] The anionic polymerization of butadiene and butadiene/styrene copolymerization is commonly initiated by alkyl lithium compounds. Such processes are commercially used to obtain polybutadiene products for high-impact plastic modification, random styrene butadiene rubber for tire tread compounds, and thermoplastic block copolymers. The area of application depends strongly on the structure of the polymer and its resulting performance characteristics. In these processes, the polymerization is generally performed in nonpolar hydrocarbon solvents. The microstructure (trans-, cis-,[3] 1,2-, and 1,4-incorporation of butadiene and sequence distribution of the styrene monomer) can be varied by the addition of polar compounds, e.g., diglyme, THF, or diethylether.

Industrial demand for ever more sophisticated polymer applications requires manufacturers of butadiene and butadiene/styrene polymers to be able to control the polymer microstructure more effectively. The research and development process for meeting this demand is generally heuristic, and modifications to alkyl-lithium-initiated polymerization towards a particular polymer microstructure are often made by using a trial-and-error method, which is expensive in terms of time and resources. Few, if any, quantitative methods exist to relate a polymer microstructure to the agents involved in the polymerization. Hence, new approaches are required to modulate and predict the micro-

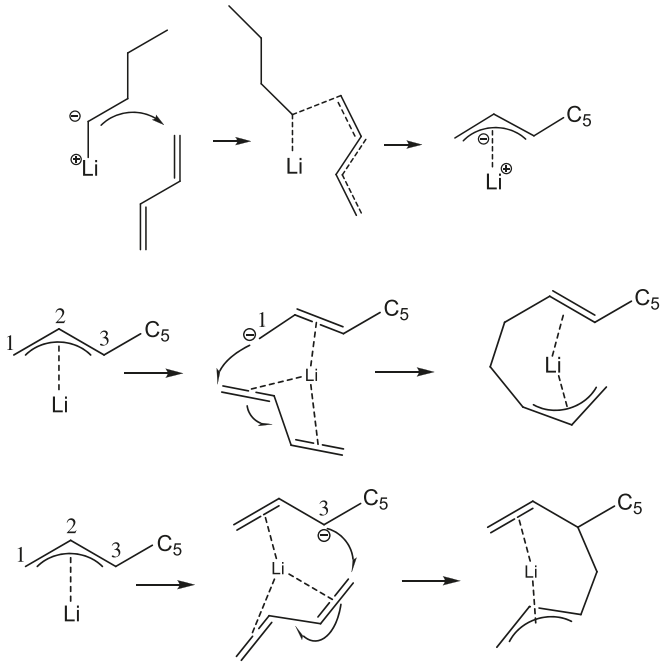
Fig. 1. Mechanism for butadiene (BD) polymerization. Top: initiation leading from butyl lithium to allyl lithium. Middle: 1-carbon attack leading to a linear polymer. Bottom: 3-carbon attack leading to formation of a pendant vinyl chain. Only the trans isomers are shown for simplicity.



structure of the final polymer and to investigate the possibility of obtaining new products. For true microstructure engineering, a mechanism-based simulation method is desirable to assess and eventually predict the impact and effectiveness of a particular agent upon the anionic polymerization and the resulting microstructure of the polymer. A detailed understanding of the species occurring in the living polymerization mixture and their reactivities towards each other is the necessary first step towards such a predictive model.

Alkyl lithium compounds are believed to initiate butadiene polymerization by an anionic mechanism, whereby the anionic alkyl moiety acts as a nucleophile towards an olefinic monomer (Fig. 1, top). The alkyl chain attaches itself to the monomer, which then forms the new active chain end that continues the polymerization by nucleophilic attack upon the next monomer (propagation; Fig. 1, middle and bottom). The propagation step may proceed by nucleophilic attack from either the 1-carbon or the 3-carbon of the allyl chain upon the 1-carbon of the butadiene monomer. In the former case, this results in a so-called 1,4-insertion and formation of a straight chain polymer (Fig. 1, middle), whereas the latter process results in 1,2-insertion and formation of a pendant vinyl chain (Fig. 1, bottom).

The alkyl lithium chain initiators are known to exist as oligomeric or polymeric clusters in the solid state[4–8] as well as in solution.[9–13] In the postinitiation phase, all or most of the alkyl Li initiator has been converted to the allyl Li propagator species and the Li species is thought to exist in a variety of oligomeric or polymeric states.[14–17,18] The degree of aggregation, x, for polybutadienyl lithium is usually put at $x = 4$ for a wide range of concentrations.[19] Stellbrink and co-workers[14] were able to assemble a relationship between the aggregation number and the degree of butadiene polymerization in which x decays exponentially with the degree of polymerization and levels off at at a tetrameric ($x = 4$) aggregation for high monomer conversions. Throughout polymerization, giant aggregates with $x >> 1000$ were also observed, but decayed with increasing butadiene conversion.

Since the chain initiation event itself, to a first approximation, does not determine microstructure, we will review it here only insofar as it is necessary to form a basis for the understanding of the propagation reaction. However, we find it useful to establish a common baseline with prior research by applying our simulation method to the speciation of *n*-butyl lithium, which is a commonly used initiation agent. Despite its industrial importance and widespread use, anionic butadiene polymerization by alkyl lithium initiators has garnered comparatively little attention from the theoretical community. The complex, oligomeric nature of both the alkyl lithium initiator and the propagator species make molecular simulations difficult. For alkyl lithium initiator species, Verstraete et al.[20] have recently given an excellent computational description of various geometries and energetics in the gas phase. For very small aggregation numbers of the allyl lithium propagator species, Schleyer and coworkers[21] have undertaken investigations by means of Møller–Plesset theory, as have Pratt and Khan[22] by means of density functional theory (DFT). More recently, Klein and co-workers[23] have investigated the initiation and propagation steps for isoprene in the presence of monomeric ethyl lithium by first-principles molecular dynamics. Frischknecht and Milner[18] have investigated small and medium-sized aggregates of allyl lithium using the PM3 and DFT methods, with allyl lithium clusters ranging up to $x = 12$. To the best knowledge of the authors, no study to date has attempted to systematically investigate the chain propagation kinetics of relevant allyl lithium clusters for anionic butadiene polymerization by means of mechanistic, first-principles simulations. As a necessary first step towards a comprehensive, mechanistic understanding of anionic styrene/butadiene polymerization by allyl lithium, we are presenting here first-principles simulations of the chain propagation process for alkyl lithium initiated polymerization of butadiene in a nonpolar hydrocarbon solvent in the absence of any polar additives.

As our primary tool, we are using density functional theory[24] (DFT), which has consistently yielded valuable insights in a number of areas in chemistry and catalysis. The density functional calculations are performed in solution phase using the COSMO method.[25] Details of computations and their parameters can be found in the Computational section.

The present work is divided into three logical parts: In the first part, we establish a common baseline with preceding research. In the second part, we discuss various modes of chain propagation for anionic polymerization of butadiene. In the third and last part, we compare our findings with experimental data.

Results and discussion

§Binding energy in kJ/mol relative to separate (allyl)Li units.

ation energies, we calculated the ground state geometries and energies of $(n\text{-BuLi})_x$ (x = 1–6, 8) clusters, where x is the degree of agglomeration. The resulting geometry types are very similar to the ones obtained by Verstraete et al.[20] The total energies obtained in the gas phase as well as in the solution phase are shown in Table 1.

The gas-phase binding energies, E_B, for clusters composed of x monomers were computed according to eq. [1], and agree very well with the binding energies presented by Verstraete et al.,[20] although these authors used a different density functional.

$$[1] \qquad E_B[x] = (E_x - x \cdot E_{monomer})/x$$

Here, E_x is the density functional total energy of oligomer of the degree of agglomeration, x. It appears that E_B reaches a minimum at x = 6, although the binding energy differences between x = 4, 6, and 8 are relatively small. On introducing a nonpolar solvent (ε = 2), a steep decrease in binding energy occurs. The binding energy is decreased by 40%–50% in going from the gas phase to solution phase. This steep drop in binding energy indicates that a large fraction of the binding energy is electrostatic. For a pure electrostatic bond, the interaction energy scales with 1/ε, and thus is expected to decrease by 50% if the dielectric contant changes from vacuum (ε = 1) to a solution with ε = 2. However, no relative structural changes are observed between the structures of the individual clusters. The most stable structure (x = 6) calculated in the gas phase is also the most stable structure in solution, and also the one detected in the X-ray analysis of the solid.[26] These results indicate that our method adequately reproduces the data given by prior calculation, but that inclusion of solvent effects, even for low dielectric solvents, is essential to the description of the system, as it substantially decreases the driving force to agglomeration.

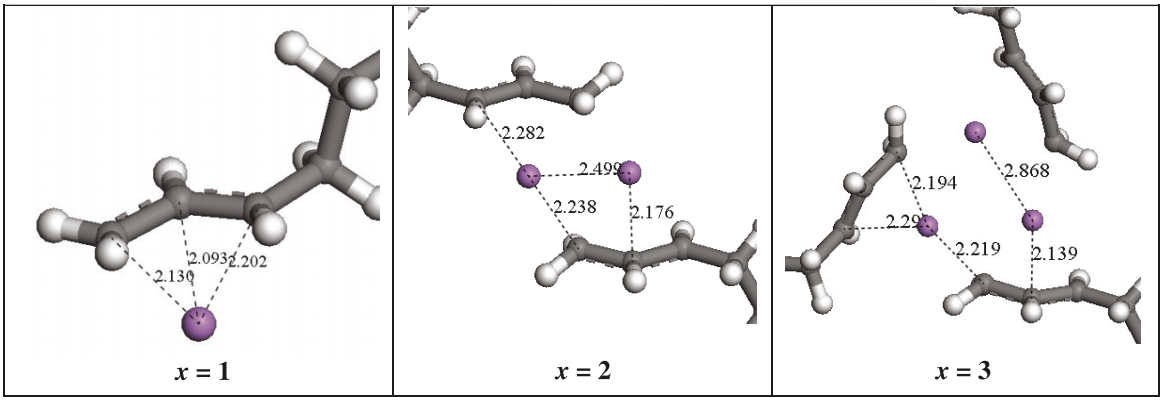
Chain propagation

Propagator species

Having found good agreement between our description of *n*-butyl lithium aggregation and data from the literature,[2,20] we performed calculations on the allyl lithium chain propa-

Fig. 3. $[(\text{Allyl})\text{Li}]_x$ structures for $x = 1$, 2, and 3.



gator to obtain the nature of the active propagating species. In the same manner as above, we calculated the ground state geometries and energies of $[(n\text{-oct-2-en-1-yl})\text{Li}]_x$ (x = 1–6, 8) clusters. The *n*-oct-2-en-1-yl group was chosen since it naturally arises as the allyl species formed after the first insertion of butadiene into the Li–*n*-butyl bond. In the following, we will refer to the *n*-oct-2-en-1-yl group simply as "allyl".

From a comparison of the binding-energy columns, E_B, for solution phase ($\varepsilon = 2$) in Table 1 and Table 2 it is immediately apparent that the allyl intermediates oligomerize with substantially less driving force than the *n*-alkyl intermediates. This is due to the interaction of the allyl π system with the Li ions. The π-allyl group occupies more of the available space around each metal and thus imposes steric hindrance to further oligomerization. Further examination of Table 2 and Fig. 2 shows that the strongest per monomer binding energy occurs for $x = 4$ and 6 for the allyl system, similar to what is observed for the *n*-alkyl system (Table 1). *Free* energies of oligomerization in solution, G_B, (Table 2), which determine the amount of agglomeration in the system, may be derived from vibrational analyses of the oligomers in the gas phase according to the expression

$$[2] \quad G_B[x] = \{[E_x + \Delta H(g)_x - T\Delta S(s)_x] - x \cdot [E_{monomer} + \Delta H(g)_{monomer} - T\Delta S(s)_{monomer}]\}/x$$

In this expression, $\Delta H(g)_x$ is a thermodynamic correction applied to E_x, consisting of the zero-point energy and statistical-mechanic contributions to the enthalpy, as computed in the gase phase. $\Delta S(s)$ is the entropy of oligomer x as computed in the gas phase, corrected for the loss of entropy that accompanies transfer of a gas-phase species to solution.[27–29] This is achieved by scaling the computed gas-phase entropies $\Delta S(g)$ by a factor of 0.75 to arrive at the expression for the solution phase entropy, $\Delta S(s) = 0.75 \cdot \Delta S(g)$. This factor is approximated from data given in Abraham's paper,[29] which shows an approximate reduction of the gas-phase entropy of 20%–30% upon transfer to cyclohexane solution for polyatomic molecules.

Figure 2 shows the free energies of oligomerization G_B derived using eq. [2] at 298.15 K. It is apparent that the dimer ($x = 2$) and the tetramer ($x = 4$) are the species with the lowest free energy; the dimer being slightly favored over the tetramer. The trimer is less stable than the tetramer by a small amount (3 kJ/mol on a per Li basis). The energies of oligomerization, E_B, computed from the raw density functional energetics according to eq. [1] are also given.

Experimentally, the aggregation state of polybutadienyl lithium appears to be a complicated equilibrium of dimers, tetramers, and higher aggregation states up to giant agglomerates of $x >> 1000$.[14–19,30] Niu et al.[14] have found that the observed value of x decreases as the degree of polymerization increases, and levels off at $x \sim 4$, which agrees with our finding that the tetramer is among the most stable species. Experiment did not clarify completely whether the large aggregates consist of mixed initiator/propagator species.[14] Also, it is not entirely clear from experiment which of the oligomeric or polymeric states of polybutadienyl lithium are responsible for chain propagation.

In light of the fact that the experimental determination of the species distribution of the Li polybutadienyl system is approximate and considering that the computed free energy difference between dimer (–25 kJ/mol), trimer (–20 kJ/mol), and tetramer species (–23 kJ/mol) is close to the expected accuracy of our computations (see Computational section), we will assume throughout the remainder of this work that both the dimer, trimer, and tetramer are available for chain propagation to a similar extent.

The allyl-Li monomer (Fig. 3; left) has a well-expressed π-allyl structure, with carbons 1–3 bound tightly. It is important to note that the 1-carbon has a somewhat closer bond to Li than the 3-carbon, which will become important in the subsequent discussion of chain propagation transition states. The corresponding lowest-energy dimer (Fig. 3; middle) has C_i symmetry. In this dimer, the 1-carbon binds approximately to the midpoint of the Li–Li vector, while carbons 2 and 3 bind in π-fashion to one of the Li atoms. The Li–Li distance is shorter (2.5 Å) than in the higher oligomers. The C_3-symmetric trimer (Fig. 3; right) has the Li atoms arranged in an equilateral triangle with Li–Li distances of 2.87 Å. As in the dimer, the 1-carbon binds to the midpoint of the Li–Li vector while carbons 2 and 3 π-bond one of the Li atoms.

As shown in Fig. 4, the $[(\text{allyl})\text{Li}]_x$ structures with $x = 4$, 5, 6, and 8 have a nonplanar arrangement of Li atoms. The Li atoms in the tetramer form an irregular tetrahedron, whereas the Li atoms in the hexamer and octamer form tri-

angular and square antiprisms. The allyl chains can conveniently be considered to be connected through the 1-carbon atom to the midpoint of the isosceles triangles that form the sides of the antiprisms (x = 6, 8) or the faces of the tetrahedron (x = 4). With increasing x, the 1-carbon of the allyl chain becomes bound more closely to the midpoint of the triangle formed by the Li atoms (tetramer: 1.76 Å; hexamer: 1.66 Å; octamer: 1.56 Å). However, the π-bond distances between carbons 2 and 3 and Li stay approximately the same at 2.2–2.4 Å. The three lowest-energy $[(allyl)Li]_x$ (x = 4, 6, 8) structures have S_x symmetry. The pentamer is a somewhat special case in that the lowest energy isomer found here is of C_1 symmetry. The Li atoms in the pentamer are arranged in a distorted trigonal bipyramid, with three of the allyl chains bound to the midpoints of the triangles formed by the Li atoms of the "upper" pyramid, and the remaining two allyl chains bound to the "lower" pyramid, whereby one of the latter is bound to an edge as opposed to a surface.

Propagation from the monomer

The cis and trans isomers[31] of (allyl)Li are schematically shown in Fig. 5, together with their total and relative energies. The cis isomer is less stable by only 2 kJ/mol than the trans isomer.

Insertion may proceed by attack of either the 1-carbon or the 3-carbon of the allyl terminus of the growing chain, as shown in Fig. 1. Attack of the 1-carbon on the 1-position of butadiene (BD) leads to linear chain extension (1,4-insertion; Fig. 1, middle), whereas attack of the 3-carbon leads to formation of a pendant vinyl chain (1,2-insertion; Fig. 1, bottom). The allyl terminus of the growing chain may either have cis or trans geometry (Fig. 5). Taking into account these two factors (insertion mode and terminal isomer) as well as the fact that the inserting butadiene may either be the cis or trans isomer leads to eight (2 × 2 × 2) different insertion pathways for chain propagation from a single (allyl)Li unit.

Table 3 presents the activation energies for these eight propagation pathways, classified by the chain end isomer, the isomer of butadiene, and the insertion mode. The barriers ($E^\dagger$) are calculated relative to free *trans*- or *cis*-(allyl)Li and free *trans*-butadiene.

Examination of Table 3 shows that the barriers for insertion as measured from the isolated reactants are rather low, with the largest barrier just 26 kJ/mol above the dissociation limit of the reactants.[32] There is little difference between insertions into a trans chain end and a cis chain end. Except in one case, insertion of *cis*-butadiene into a particular chain end for a particular insertion mode is faster than insertion of *trans*-butadiene. 1,4-Insertions of *cis*-butadiene are fastest, and 1,4-insertions of *trans*-butadiene are slowest.

2 kJ/mol

These differences between insertion paths are explained by Fig. 6, which shows the transition-state geometries for insertion into a growing chain terminated by *trans*-allyl. During insertion of *cis*-butadiene (Figs. 6*c* and 6*d*), all carbon atoms of the butadiene moiety maintain close contact to the Li atom, thus stabilizing the *cis*-BD transition state relative to the *trans*-BD one, in which the monomer cannot maintain the same degree of contact. This generally favors insertion of *cis*-BD over insertion of *trans*-BD.

1,2-Insertion of *trans*-BD ($E^\dagger$ = 16 kJ/mol) is faster than 1,4-insertion of *trans*-BD (21 kJ/mol < $E^\dagger$ < 26 kJ/mol). This is because the transition state for 1,2-insertion allows the Li atom to move towards the 1-carbon of the growing allyl chain, which is able to bind Li more strongly than the 3-carbon atom, as outlined in Fig. 3, left.

Propagation from the dimer

As shown by Table 2, the lowest energy $[(allyl)Li]_2$ species is formed from the monomer in a reaction that is 86 kJ/mol exothermic (–43 kJ/mol per monomer). Thus, a significant amount of energy would be needed to create the monomer species. However, the significantly more stable dimer species is also able to propagate the chain as outlined in Fig. 1. The dimer species that are considered for chain propagation are shown in Fig. 7, which shows the three lowest-energy $[(allyl)Li]_2$ structures with all-trans, cis/trans, and cis/cis chain ends, respectively. For simulating the insertion process into cis and trans chain ends, the all-trans and cis/trans isomers were used as they were lowest in energy.

Table 4 summarizes the insertion energetics derived with these models. A comparison with the corresponding Li monomer energetics shown in Table 3 shows that insertion of butadiene into a chain growing from an (allyl)Li dimer has a higher activation barrier (46 kJ/mol < $E^\dagger$ < 60 kJ/mol) than insertion into the corresponding (allyl)Li monomer bound chain (7 kJ/mol < $E^\dagger$ < 26 kJ/mol). The difference in the insertion barriers of *cis*- and *trans*-butadiene is less pronounced than for the (allyl)Li monomer based pathways. Cis insertion barriers are consistently higher than trans insertion barriers by 2–6 kJ/mol. 1,2-Insertions have consistently

higher barriers than 1,4-insertions by approximately 5–10 kJ/mol.

The reasons for these trends can be rationalized by examining the three-dimensional structures for the (allyl)Li dimer based transition states as shown in Fig. 8 and drawn out schematically in Fig. 9.

Of the two allyl chain ends in the dimer, one partakes in the insertion process, whereas the other forms a spectator. Both lithium atoms, however, are intimately involved in stabilizing the reacting organic fragments during the transition state. The spectator ligand effectively reduces the binding surface available to the incoming butadiene and thus forces the transition state to a higher energy as compared to the monomer-based transition states in Table 3. However, due to the relatively large binding area that the Li dimer exposes towards allylic chain ends and incoming monomer, both the butadiene moiety and the chain end can maintain effective contact to Li at the transition state. This is especially apparent for 1,4-insertions (Figs. 8*a* and 8*c*).

Propagation from the trimer

The insertion energetics for two trimer species (Fig. 10), namely all-*trans*-[(*n*-oct-2-en-1-yl)Li][(*n*-pent-2-en-1-yl)Li]$_2$ and [(*cis*-*n*-oct-2-en-1-yl)Li][(*trans*-*n*-pent-2-en-1-yl)Li]$_2$, are given in Table 5. We chose to use pentenyl chains for the spectator allyl ligands as they significantly reduce computational overhead and do not significantly impact our results.

First, one notices that the barriers to 1,4-insertion into trimer-borne allyl chains are higher than for dimer- and monomer-borne allyl species. Barriers to 1,2-insertion are similar to 1,2-insertion barriers observed for dimer-borne chains. Secondly, it appears that 1,4-insertions have consistently higher barriers than 1,2-insertions, which is a reversal of the behavior observed for monomer- and dimer-based behavior. 1,2-Insertions are favored by 1–15 kJ/mol over the analogous 1,4-insertions. Also, insertion of *trans*-BD tends to have lower barriers than insertion of *cis*-BD.

Figure 11 schematically depicts the two different insertion pathways (1,4- and 1,2-insertion) occurring at a trimeric Li-allyl propagator. Both pathways are analogous to the pathways for the dimeric propagators shown in Fig. 9, in that they involve two lithium ions for stabilizing the organic fragments during the transition state. The difference between the trimer- and dimer-facilitated insertions lies in the fact that the lithium atoms in the trimer are more sterically

Fig. 8. Transition-state geometries for insertion of *trans*- ((*a*) and (*b*)) and *cis*-butadiene ((*c*) and (*d*)) into a chain growing from an all-*trans*-[(allyl)Li]$_2$. (*a*) and (*c*) show 1,4-insertions, (*b*) and (*d*) shown 1,2-insertions.

shielded, which makes it less straightforward to stabilize the transition state. This especially causes a rise in the activation barriers to 1,4-insertion, which is sterically more demanding than 1,2-insertion, because the 1-carbon that provides binding for the chain end during 1,2-insertion binds more strongly to Li than the 3-carbon atom that anchors the chain during 1,4-insertion (as seen in Fig. 6*b*). This results in a kinetic preference for 1,2-insertion.

Propagation from the tetramer

Figure 12 shows the two model systems used for simulation of butadiene insertion barriers into a butadienyl chain growing from an (allyl)Li tetramer.

As seen in Fig. 4, the lithium atoms in the tetramer are effectively shielded. This makes it harder for the incoming butadiene to stabilize itself during the transition state, and leads to comparatively high butadiene insertion barriers both during 1-carbon attack and 3-carbon attack (Table 6). Barriers range from 86 to 104 kJ/mol, which is at least 20 kJ/mol higher than what was computed for the trimer. Barriers related to 1,4-insertion are consistently higher than barriers related to 1,2-insertion by approximately 10 kJ/mol.

The reason for this becomes apparent on examination of the reaction schematics in Fig. 13. Both 1- and 3-carbon attacks can be regarded as occurring on a Li tetrahedron, three of whose faces are covered with allyl groups (oriented towards the bottom of Fig. 13). The fourth face (oriented towards the top) provides the reaction site. The incoming butadiene attacks the allyl group at the top, and partially displaces it. Throughout the transition state, both 1- and 3-carbon attack pathways derive stabilization from a close interaction of the organic moieties with the Li cluster. For the 1-carbon attack (1,4-insertion), the arrangement of spectator allyl groups around the central Li tetrahedron crowds the top face so strongly that approach of the butadiene towards the 1-carbon is only possible from the top, leading to an energetically unfavorable transition-state energy for 1,4-insertion. For 3-carbon attack (1,2-insertion), the incoming butadiene monomer is able to approach the top allyl from the side, allowing both the 1-carbon as well as the monomer to keep tight contact with the Li atoms of the cluster. Hence, 1,2-insertion is favored for the tetramer.

Propagation from the higher oligomers (x = 5, 6, 8)

Propagation from the higher oligomers with aggregation numbers of 5 and above was investigated only in a cursory manner. For $x = 5$, our calculations indicated that the pentamer was simply too unstable to be considered a serious candidate for polymerization, and no insertion transition-state calculations were attempted. For $x = 6$, insertion transition-state calculations with some amount of conformational sampling were done and showed that insertion of butadiene into chains growing off a hexamer would have prohibitively high barriers (>110 kJ/mol) in addition to a relatively small population of the hexamer itself. Hence, no detailed conformational sampling was done on these preliminary transition states and propagation from the hexamer is not deemed feasible. For $x = 8$, it was clear that the octamer was not present in significant amounts under the most favorable conditions imaginable in the present context, as its per monomer binding free energy is –9 kJ/mol (Table 2). The progression of insertion barriers from monomer to tetramer (Table 3–5) also did not make it likely that propagation from the octamer would be kinetically feasible. Thus, propagation from the octamer was excluded.

Comparison of polymerization kinetics

Figures 14*a*–14*d* compares butadiene insertion energetics for species with $x = 1$–4, using the thermodynamically most stable dimer species as a reference point. In this figure, the recombination energetics of relevant (allyl)Li oligomers are combined with butadiene insertion barriers to give a simple, yet meaningful impression of the accessibility of insertion transition states based on different oligomers. Figure 14 uses a relative free energy *y*-axis. For the relative thermodynamics of different oligomers, we use the free energy values as tabulated in Table 2. For free energy barriers of insertion, which we have not calculated explicitly, we use the approximation that the free energy barrier of insertion is composed according to $\Delta G^\dagger = \Delta E^\dagger - T\Delta S^\dagger$, where $\Delta E^\dagger$ is taken directly from Tables 3–6 and $T\Delta S^\dagger$ is approximated as

–40 kJ/mol at 298.15 K. The value of –40 kJ/mol is an approximation of the entropy loss occurring on bringing two molecules together into one and may therefore be regarded as constant over a series of similar reactions.[27,33] Although a value for $T\Delta S^{\dagger}$ of –40 kJ/mol for a bimolecular reaction appears typical from the literature, further support can be obtained by calculating the entropic correction for association between (allyl)Li and butadiene to form the corresponding insertion transition state. For this reaction, a $T\Delta S^{\dagger}_{(298.15)}$ correction of –60 kJ/mol is obtained. Applying the correction factor of 0.75 introduced above, one arrives at 45 kJ/mol for $T\Delta S^{\dagger}_{(298.15)}$ in solution, which agrees well with our standard value of –40 kJ/mol. The $T\Delta S^{\dagger}$ contributions to the insertion barrier are shown in grey, on top of the $\Delta E^{\dagger}$ values.

The monomer (Fig. 14*a*) is most efficiently created by dissociation of a dimer unit. This process is uphill in terms of free energy by 25 kJ/mol on a per monomer basis, and involves an activation barrier of 86 kJ/mol. The monomer created by this process can then insert butadiene with activation energies as low as $\Delta E^{\dagger}$ = 7 kJ/mol (Table 3). Although the propagation step from the monomer is kinetically favorable, we believe that production of the monomer itself is slow, with an effective barrier of approximately 86 kJ/mol.

The thermodynamically most efficient route to create a trimer is by recombination of three dimer units into two trimer units (Fig. 14*c*). This process is uphill by only 13 kJ/mol free energy on a per trimer basis (1.5 dimer → trimer). However, the lowest-energy butadiene insertion barrier is $\Delta E^{\dagger}$ = 48 kJ/mol above the separated trimer and butadiene reactants. This makes the total barrier relative to the (allyl)Li dimer over 100 kJ/mol in terms of free energy.

The tetramer is most efficiently created by dimerization of two dimers (Fig. 14*d*). This process is marginally endoergic (+8 kJ/mol). However, the lowest-energy butadiene insertion barrier is $\Delta E^{\dagger}$ = 86 kJ/mol high, which brings the barrier relative to the dimer up to $\Delta G^{\dagger}$ = 134 kJ/mol.

Compared to the barrier for insertion into the (resting state) dimer ($\Delta E^{\dagger}$ = 46 kJ/mol; $\Delta G^{\dagger}$ = 86 kJ/mol; Fig. 14*b*), trimer- and tetramer-based insertion transition states are not accessible from a mere thermodynamic standpoint. However, insertion into a monomer-borne allyl chain appears competitive, having an approximate barrier of 86 kJ/mol. Thus, the activation energies of monomer- and dimer-based insertions are sufficiently close that the evidence of the present calculations alone cannot rule out one in favor of the other.

We are now in a position to compare the computed butadiene polymerization behavior with the experimentally ob-

Fig. 14. From left to right: Free-energy reaction profiles for butadiene insertion into monomer, dimer, trimer, and tetramer species. All values in kJ/mol, at 298.15 K.

served polymerization behavior. In the absence of polar modifier agents such as THF, the alkyl lithium initiator produces predominantly straight-chain polybutadiene with only a minimal (around 5%–10%) admixture of 1,2-insertions. *Cis*- and *trans*-butadiene insertions occur with approximately equal frequency, with a slight predominance of trans insertions.

This agrees best with our results computed for the dimeric (allyl)Li species, which indicate that 3-carbon attacks (leading to 1,2-insertions) have slightly higher barriers than the corresponding 1-carbon attacks (leading to 1,4-insertions). Also, it would best agree with the computational results that $[(allyl)Li]_2$ species would produce a slight predominance of *trans*-butadiene units (see Table 4).

As stated above, butadiene insertions into a monomer-borne butadienyl chain have similar barriers. Polybutadiene produced by the monomeric (allyl)Li species would show a predominance of *cis*-BD units. This is clearly not what is observed in experiment. Realistically, we have to admit that the insertion paths for monomic and dimeric (allyl)Li species are so close in energy that even a relatively small systematic error in our simulations (e.g., 10 kJ/mol) may be responsible for skewing our results one way or the other. However, based on the mismatch between experimentally observed polymer microstructure and the microstructure computed for the (allyl)Li monomer, we conclude that the (allyl)Li monomer species is probably not the species responsible for the majority of the polymer produced.

Conclusion

Our computational results indicate that the anionic polymerization of butadiene likely proceeds from an equilibrium of propagating species and that each individual propagating species produces its own signature polymer microstructure. Within the limits of accuracy inherent in our computational approach, we have identified the dimer, trimer, and tetramer species of (allyl)Li as the most prevalent oligomers in nonpolar ($\varepsilon = 2$) solvent at room temperature. The monomeric (allyl)Li species is not present to a significant extent under the conditions investigated in this paper. The dimer is computed as being the most stable species on a per Li basis. The trimer, having uneven x, is less stable than both the dimer and tetramer. However, the relative stabilities of the species with $x = 2$, 3, and 4 are so close at the present level of calculations (G_B = 25, 20, and 23 kJ/mol, respectively) that their relative populations are difficult to predict. The clusters with even agglomeration numbers of $x > 2$ are highly symmetrical antiprisms. Higher order oligomers greater than tetramers are not present in significant amounts to affect the product distributions that are produced with this system.

The chain propagation barriers increase with increasing degree of agglomeration, x. The lowest calculated butadiene insertion barriers for each of the oligomeric species was found to be 7, 46, 48, and 86 kJ/mol for $x = 1$, 2, 3, and 4, respectively. No insertion barriers were calculated for the pentamer, which is rather unstable, as well as the hexamer and octamer, for which our calculations predict negligible populations. Computed barriers for insertion into a dimer-bound butadienyl chain would reproduce the experimentally obtained polymer microstructure closely, whereas our results for monomer-, trimer-, and tetramer-derived microstructures would not. Thus, we conclude that the dimer is the dominant propagating species at least under the commonly practiced experimental conditions.

The polybutadiene microstructures produced by different oligomers change systematically with the degree of agglomeration, *x*. For the monomer, insertion of *cis*-butadiene is significantly faster than insertion of *trans*-butadiene, which would lead to an all-*cis*-butadiene if the monomer were responsible for a significant portion of insertions. For the Li-allyl dimer, insertions of *cis*- and *trans*-butadiene occur at comparable rates, with insertion of *trans*-butadiene being slightly faster. 1-Carbon attack (leading to 1,4-insertion) is faster than 3-carbon attack (leading to 1,2-insertion) by 5–8 kJ/mol, which corresponds to a vinyl fraction of roughly 5%–10%, which is in good agreement with experiment.[2] However, given the inherent limits of accuracy of our calculations, this level of agreement may be fortuitous.

Computational

Methods

All computations in this work were performed with the DMol[3] program developed by Delley.[34] The double numeric with polarization functions (DNP) basis set and the Becke–Perdew gradient-corrected density functional[35] were used. All computations, except where noted, were performed in solution phase, using the COSMO method developed by Klamt and Schüürmann[25] as adapted by Delley for DMol,[3,36] using a dielectric constant of 2.0 to approximate a low dielectric hydrocarbon solvent that is commonly used for anionic butadiene/styrene polymerization. Geometry optimizations for locating ground state intermediates were performed until a threshold gradient of at most 10^{-3} hartree/bohr was reached. Transition-state optimizations were done by computing a Hessian from finite differences and a subsequent eigenvector following search until a threshold of at most 10^{-3} hartree/bohr was reached. Limited conformational sampling was done on both ground state intermediates and transition-state geometries. All calculations were done under C_1 symmetry except where explicitly mentioned. Free energies were calculated from vibrational frequecies using the standard thermodynamics methods.[37] Due to system size restrictions, the vibrational analyses for thermodynamic property calculations were produced on model systems with C_5 (pentenyl) chains instead of C_8 (octenyl) chains using the Gaussian 03 program,[38] the BP86 functional,[35a,39] and a 6-31G basis set.

Accuracy

From experience, we expect reaction energies or barriers for organometallic systems to carry an absolute error of approximately ±20 kJ/mol. When comparing a set of barriers for which some degree of error cancellation can be expected, such as a series of analogous reaction barriers as discussed in the present work, the error decreases sharply. We estimate the relative errors in reaction barriers to be of the order of 5 kJ/mol.

Organoplatinum(IV) complexes with functional alkyl groups and their use in supramolecular chemistry[1]

Richard H.W. Au, Lisa J. Findlay-Shirras, Neil M. Woody, Michael C. Jennings, and Richard J. Puddephatt

Abstract: The oxidative addition of alkyl bromides RCH_2Br (R = C_5H_4N, C_6H_4CN, $CH_2C_6H_4CO_2H$, or $CH_2C_6H_4CH_2CO_2H$) to dimethylplatinum(II) complexes [$PtMe_2(LL)$] (LL = diimine ligand) gives the corresponding organoplatinum(IV) complexes [$PtBrMe_2(CH_2R)(LL)$] containing functionality in the alkyl group RCH_2. The pyridyl derivatives can be protonated, while abstraction of the bromide ligand from [$PtBrMe_2(CH_2R)(LL)$] can form cationic complexes, which can react with water or form oligomers by self-assembly.

Key words: platinum, organometallic, hydrogen bond, supramolecular.

Résumé : L'addition oxydante de bromures d'alkyle, RCH_2Br [R = C_5H_4N, C_6H_4CN, $CH_2C_6H_4COOH$ ou $CH_2C_6H_4CH_2COOH$] sur des complexes de diméthylplatine(II) [$PtMe_2(LL)$] [LL = ligand diimine], conduit à la formation de complexes organoplatine(IV) [$PtBrMe_2(CH_2R)(LL)$] comportant une fonctionnalité dans le groupe alkyle RCH_2. Les dérivés pyridyles peuvent être protonés alors que l'enlèvement du ligand bromure à partir de [$PtBrMe_2(CH_2R)(LL)$] peut conduire à la formation de complexes cationiques qui peuvent réagir avec de l'eau ou former des oligomères par autoassemblage.

Mots-clés : platine, organométallique, liaison hydrogène, supramoléculaire.

[Traduit par la Rédaction]

Introduction

The oxidative addition of small molecules to platinum(II) complexes to form organoplatinum(IV) complexes can be a key step in catalysis, and so this type of reaction has been studied in great detail.[2–6] The oxidative addition can also be a key step in the synthesis of binuclear or even polymeric organoplatinum(IV) complexes, which are of interest as molecular materials.[4–8] The building up of complex structures from simple building blocks is a feature of supramolecular chemistry,[9] and organoplatinum(IV) complexes have proved to be very versatile in the development of supramolecular organometallic chemistry of the transition metals.[10–14] The stability of organoplatinum(IV) complexes towards reactions of protic reagents, oxidants, and other functional groups is an important property in allowing this chemistry to be developed.[15] This paper describes chemistry of new organoplatinum(IV) complexes in which one of the alkyl groups carries a cyanide, a pyridine, or a carboxylic acid group.

Results

Formation of organoplatinum(IV) complexes through oxidative addition reactions

The oxidative addition of 3-cyanobenzyl bromide to complexes [$PtMe_2(LL)$], **1** or **2**, where LL = 4,4′-di-*t*-butyl-2,2′-bipyridine (bu_2bipy) or di-2-pyridyl ketone (DPK), respectively, gave the products of trans oxidative addition [$PtBrMe_2(CH_2C_6H_4$-3-CN)(LL)], **3** or **4** (Scheme 1).

The complexes were readily characterized by their ^{1}H NMR spectra. For example, complex **3** gave a single methylplatinum resonance at δ = 1.51 with coupling constant ^2J(PtH) = 69 Hz, and a single Pt-CH_2 resonance at δ = 2.79 with coupling constant ^2J(PtH) = 96 Hz, indicating formation of a single symmetrical isomer. Complex **3** was also characterized by X-ray structure determination (Fig. 1). The platinum(IV) centre has octahedral stereochemistry and the cyanophenyl group lies over one of the pyridyl groups of the bu_2bipy ligand.

The reactions of complex **1** with the three isomers of bromomethylpyridine are shown in Scheme 2. The organic reagents are available only as the hydrobromide salts, because the neutral compound self-react, but the simple reaction of the bromomethylpyridinium bromides were complex. They evidently act as a source of HBr, which reacts with **1** to give methane and [$PtBrMe(bu_2bipy)$], which can itself react with bromomethylpyridine. To obtain the products of Scheme 2, the pyridinium salts were neutralized with triethylamine to generate the neutral bromomethylpyridine in situ, and this solution was then used to react with complex **1**. Each of the complexes [$PtBrMe_2(CH_2py)(bu_2bipy)$], **5**–**7**

Scheme 1.

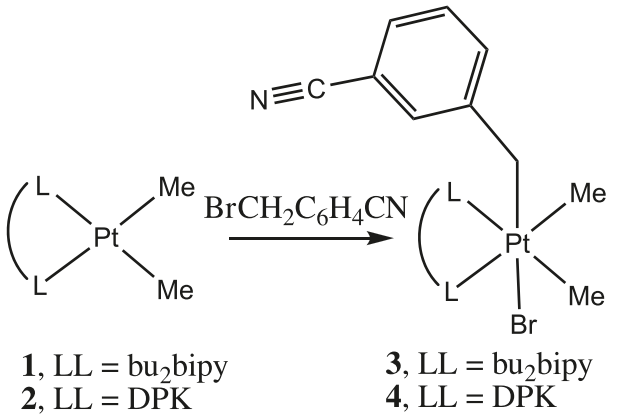

Fig. 1. Structure of [$PtBrMe_2(CH_2C_6H_4$-3-CN)(bu_2bipy)], **3**. Selected bond parameters: Pt–C(1) 2.06(1), Pt–C(2) 2.04(1), Pt–C(31) 2.10(1), Pt–N(11) 2.17(1), Pt–N(22) 2.13(1), Pt–Br 2.582(1), C(38)–N(39) 1.15(2) Å.

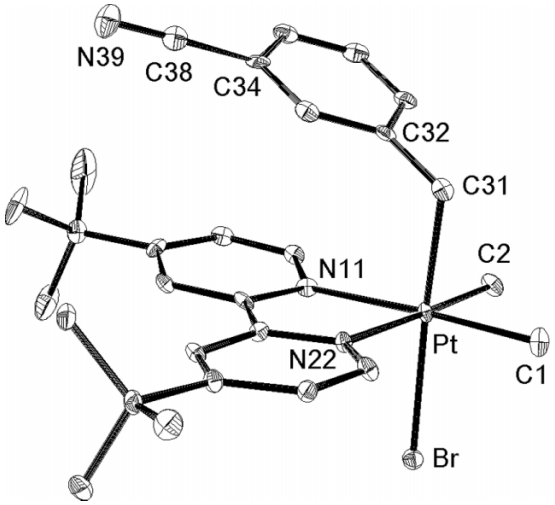

(py = 2-, 3-, or 4-C_5H_4N, respectively), gave a single methylplatinum resonance and a single $PtCH_2$ resonance in the ^{1}H NMR spectra, thus confirming that selective trans oxidative addition of the C–Br bond had occurred. The structure of complex **5** was confirmed by X-ray structure determination and is shown in Fig. 2. There are two independent molecules in the asymmetric unit, but they have similar structures and so only one is shown in Fig. 2. As in complex **3** (Fig. 1), the platinum(IV) centre has octahedral stereochemistry and the 2-pyridyl unit of the $PtCH_2$py group is π-stacked with one of the pyridyl groups of the bu_2bipy ligand.

The oxidative addition reactions of some bromomethyl derivatives of carboxylic acids are shown in Scheme 3. In all cases, *trans* oxidative addition was observed to give the products **8**–**11**. However, the DPK complexes also gave some cis isomer. Complexes **8** and **10** have been reported previously but the structures were not determined.[10]

The structure of complex **8** is shown in Fig. 3. The complex forms a hydrogen bonded dimer in the solid state with a distance of O(39)···O(40A) = O(40)···O(39A) = 2.61(1) Å. The structure of complex **10** is more complex and is illustrated in Figs. 4 and 5. The molecular structure is similar to that of complex **8** (Figs. 3 and 4), but there is disorder of the $CH_2C_6H_4CH_2CO_2H$ groups with roughly 50:50 occupation of the **A** [containing O(40) and O(41)] and **B** [containing O(60) and O(61)] forms. The supramolecular structure of **10** is more complex than for **8** (compare Figs. 3 and 5). The head-to-head dimerization of the type seen for **8** is not observed for complex **10**. Instead, the molecules of the form **A** and **B** alternate in forming hydrogen bonds O(61)=C(R)–O(60)H···O(41)=C(R)–O(40)H···Br. Molecule **A** acts as a hydrogen bond donor to the Br–Pt group of molecule **B**, and a hydrogen bond acceptor through its carbonyl oxygen atom. Molecule **B** acts as a hydrogen bond donor to the carbonyl group of molecule **A** and an acceptor through its Br–Pt group. The overall result is to form a hydrogen-bonded supramolecular polymer.

Scheme 2.

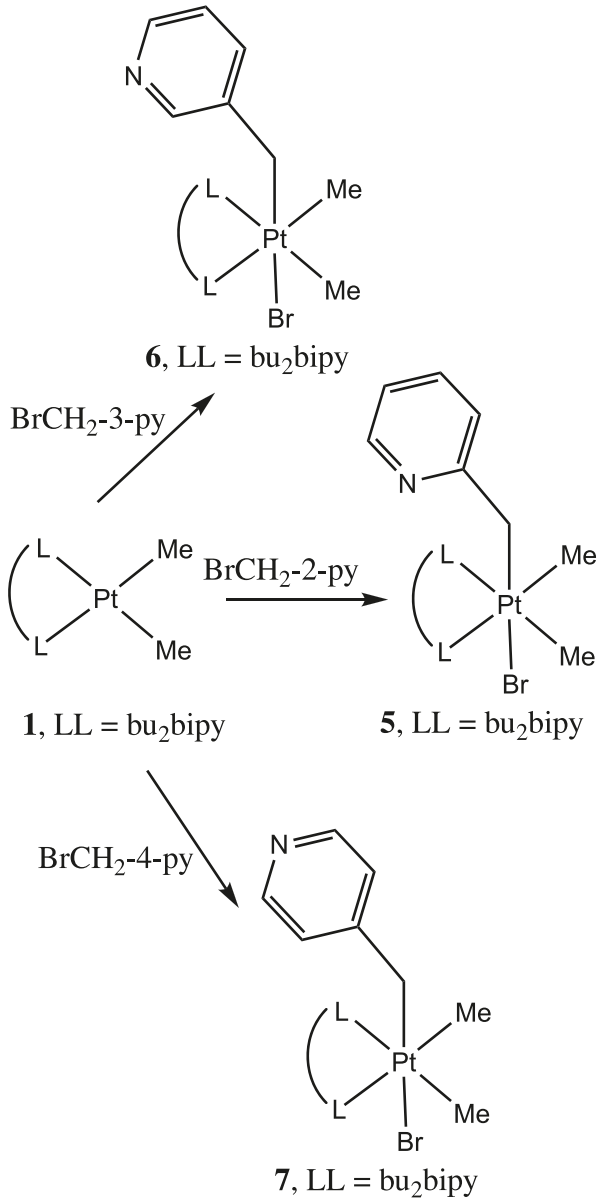

Fig. 2. The structure of [$PtBrMe_2(CH_2$-2-py)(bu_2bipy)], **5**. Selected bond distances: Pt(1)–C(1) 2.04(1), Pt(1)–C(3) 2.08(1), Pt(1)–C(31) 2.10(1), Pt(1)–N(11) 2.136(9), Pt(1)–N(22) 2.166(9), Pt(1)–Br(1) 2.5618(15) Å.

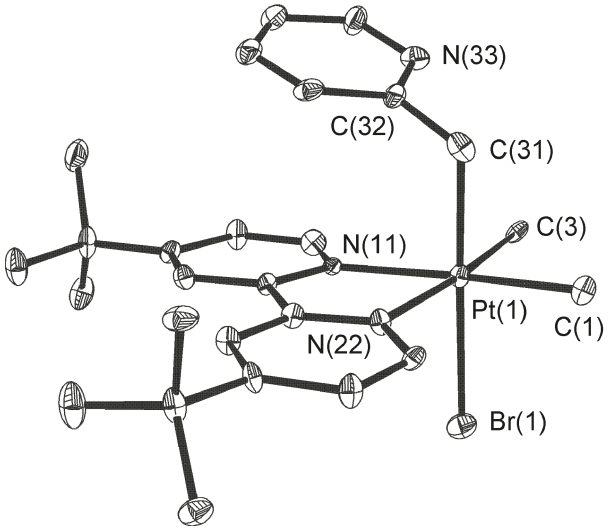
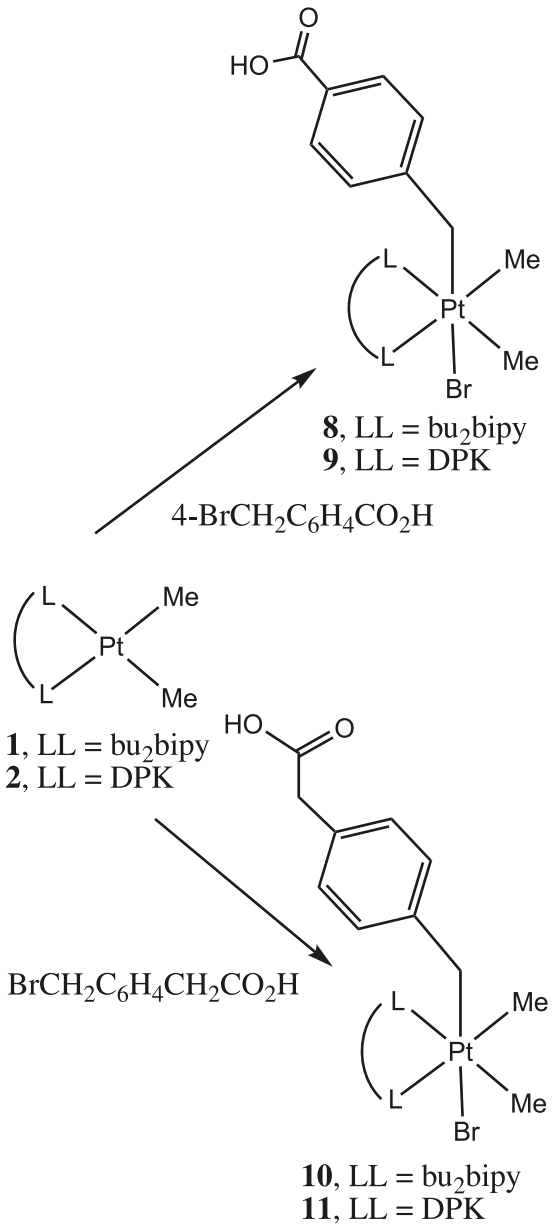


Scheme 3.

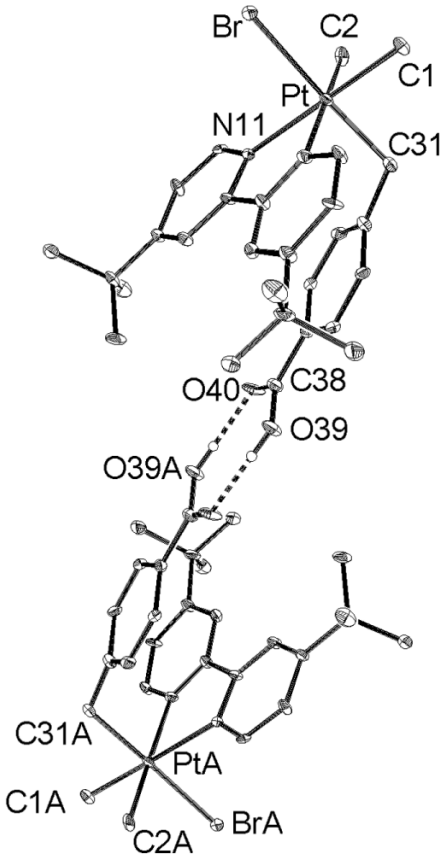


Further derivatization of the platinum(IV) complexes

The pyridyl complexes **5**–**7** could be protonated by addition of acid, as shown for the protonation of 4-pyridylmethylplatinum(IV) derivative (**7**) to give **12** in Scheme 4. The main effect on the ^{1}H NMR spectra was a shift of the $PtCH_2$ resonance on protonation. This shift defined as $\Delta(\delta) = \delta$(protonated complex) – δ(parent complex) = 1.78, 0.52, and 0.32 for the 2-, 3-, and 4-pyridylmethyl derivative, respectively. Two complications were observed in these reactions. Firstly, the reversible isomerization of **12** to the overall product of cis oxidative addition (**13**, in Scheme 4) was catalyzed by acid. It was not possible to isolate the cis isomers such as **13**, but these compounds could be identified by their NMR spectra. For example, the low symmetry of **13** leads to nonequivalent MePt resonances [δ(PtMe, axial) = 0.76, ^2J(PtH) = 72 Hz; δ(PtMe, equatorial) = 1.05, ^2J(PtH) = 68 Hz] and $PtCH^aH^b$py protons [$\delta(PtH^a) = 3.54$, ^2J(HH) = 7 Hz, ^2J(PtH) = 105 Hz; $\delta(PtH^b) = 4.41$, ^2J(HH) = 7 Hz, ^2J(PtH) = 110 Hz] in the ^{1}H NMR spectrum. The isomerization is expected to occur after bromide dissociation to give a five-coordinate intermediate [$PtMe_2(CH_2$-4-py)(bu_2bipy)]$^+$, and this reversible step is catalyzed by H^+.[16] At equilibrium, the ratio of **12**:**13** was ca. 3:1 when X = triflate. A similar isomerization occurred on protonation of the 3-pyridylmethylplatinum(IV) complex (**6**), but no cis isomer was detected on protonation of the 2-pyridylmethylplatinum(IV) complex (**5**). The second complication is that, if the group X in the acid HX can act as a ligand for platinum(IV), then partial exchange of the bromide ligand for X^- can occur. For example, crystallization of complex **7** in the presence of HCl gave complex **12** (X = Cl), but crystallographic characterization of the product showed partial displacement of the PtBr by the PtCl group to give **14** (Scheme 4, X = Cl). The structure of **12** (X = Cl) is shown in Fig. 6, showing only the Pt-Br component. The ratio of disorder components **12**:**14** (X = Cl) was refined as 0.36:0.64. The possibility of supramolecular association between the pyridyl base **7** and the acidic complexes **8** or **10** was investigated, but no such acid–base adducts could be crystallized.

The reactions of the pyridyl complexes **5**–**7** with silver salts of weakly coordinating anions were expected to occur by bromide abstraction followed by intramolecular or intermolecular coordination of the pyridine nitrogen atom to platinum(IV), as illustrated in Scheme 5.[17] The reaction of complex **5** with silver triflate occurred according to Scheme 5, and the product **15**(OTf) was isolated in analytically pure form, though single crystals could not be obtained. The ^{1}H NMR spectrum of **15** was broad at room temperature but, at –20 °C, it clearly showed two methylplatinum resonances and an [**AB**] multiplet for the $PtCH^aH^b$ protons. However, the ^{1}H NMR spectra of compounds obtained by treating the cyanobenzyl complex **3**, or the 3- or 4-pyridylmethyl complexes (**6** or **7**) with silver triflate were very complex, indicating that the self-assembly was nonse-

Fig. 3. The structure of complex **8**, showing the dimer formed by H-bonding. Selected parameters: Pt–C(31) 2.04(2), Pt–C(1) 2.08(1), Pt–C(2) 2.09(1), Pt–N(22) 2.16(1), Pt–N(11) 2.167(9), Pt–Br 2.563(2) Å. Hydrogen bond distance: O(39)···O(40A) = O(40)···O(39A) = 2.61(1) Å.



lective and gave a mixture of oligomers rather than a single product such as **16**. The unique behavior of the 2-pyridylmethyl complex (**5**) was also reflected in the ESI-MS of a solution in dichloromethane. The 2-pyridylmethyl complex (**15**), as the triflate salt, gave a molecular ion at m/z = 585, whereas the corresponding products with 3- or 4-pyridylmethyl groups gave the same envelope of peaks at m/z = 585 but also significant peaks at m/z = 1319 due to the dimer ion $[\{PtMe_2(CH_2py)(bu_2bipy)\}_2(OTf)]^+$ and, for the 4-pyridylmethyl complex only, trimer peaks.

Reaction of the toluic acid derivative (**8**) with silver tetrafluoroborate in moist solvent acetone occurred according to Scheme 6, to give the cationic aqua complex **17**, whose structure is shown in Fig. 7. The stereochemistry at the octahedral platinum(IV) centre is not changed in this reaction and so the effect is to substitute the bromide ligand by the aqua ligand. The carboxylic acid group hydrogen bonds to an acetone molecule, while one hydrogen atom of the aqua group hydrogen bonds to a second acetone molecule and the other hydrogen bonds to the tetrafluoroborate anion. It was anticipated that addition of base to complex **17** would give the carboxylate anion and that this would in turn displace the aqua ligand from a neighbouring molecule to give a dimer or, by repletion of these steps, an oligomer or polymer. However, the reaction gave only a mixture of complexes that could not be characterized.

Fig. 4. The 50:50 disordered structure of complex **10**. Selected parameters: Pt–C(1) 2.09(2), Pt–C(2) 2.07(2), Pt–C(31) 2.10(3), Pt–C(51) 2.11(3), Pt–N(11) 2.16(1), Pt–N(22) 2.18(1), Pt–Br 2.601(2) Å.

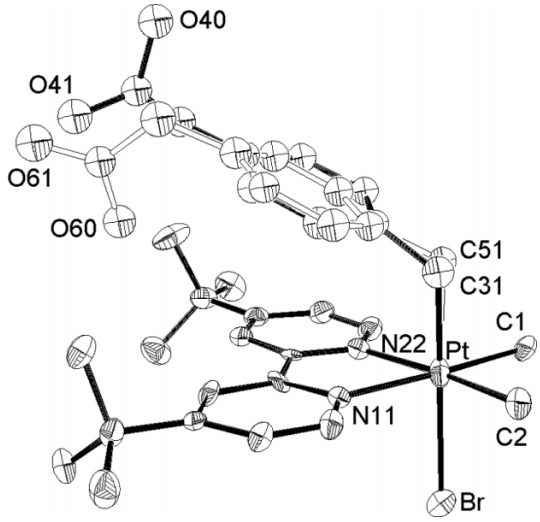


Fig. 5. The supramolecular structure of complex **10**, with alternating conformers **A** (red) and **B** (blue). Hydrogen-bonding parameters: O(40)···Br 3.26(4), O(41)···O(60) 2.67(5) Å. Other sequences, such as $(\mathbf{AABB})_n$ can be ruled out because they lead to unreasonably short contacts.

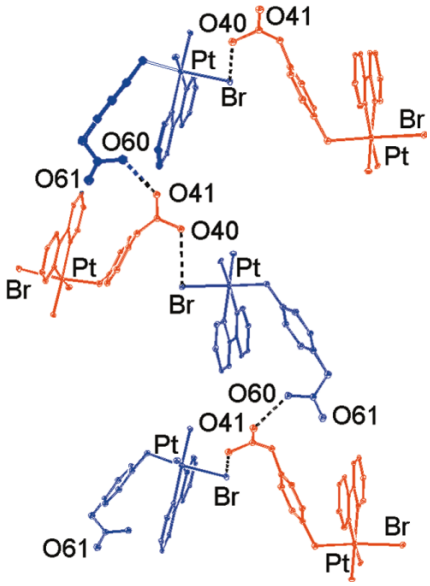
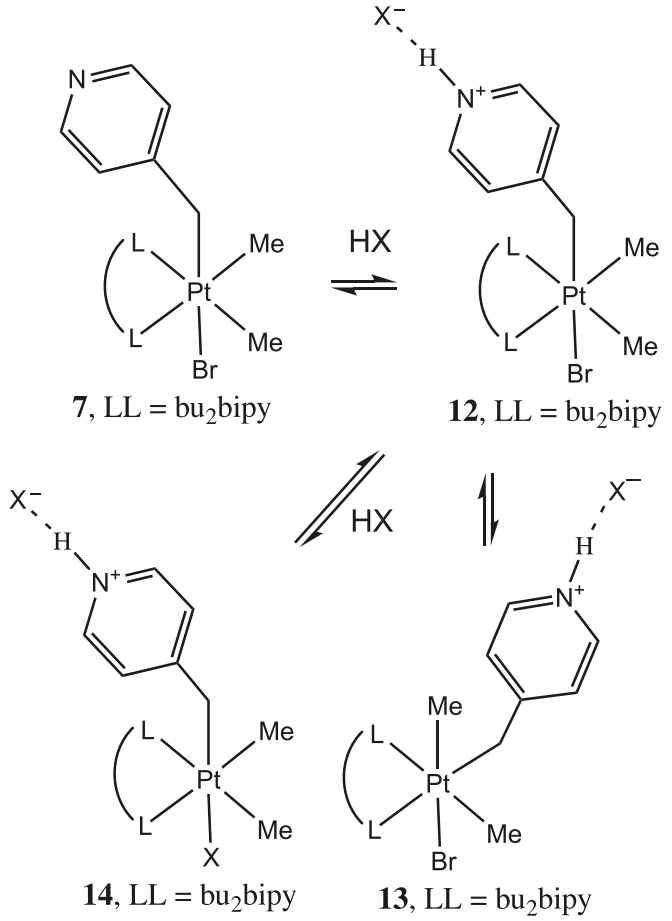


In some reactions of the platinum(IV) complexes with DPK ligands with silver salts, the carbonyl group of the DPK ligand was shown to be involved. The reaction of complex **4** with silver triflate gave the cationic complex **18**, as the triflate salt, according to Scheme 7. The two key features of complex **18** are the change in stereochemistry at platinum(IV) and the hydration of the DPK ligand to give the tridentate DPK-OH_2 ligand. None of the more symmetrical isomer, with the cyanobenzyl group trans to oxygen, was detected. In the ^{1}H NMR spectrum, complex **18** gave two methylplatinum resonances [δ = 1.18, ^2J(PtH) = 72 Hz and δ = 1.48, ^2J(PtH) = 81 Hz], and the $PtCH_2$ group gave an [AB] multiplet [δ = 3.03, ^2J(PtH) = 73 Hz; δ = 3.55,

Scheme 4.



Scheme 5.

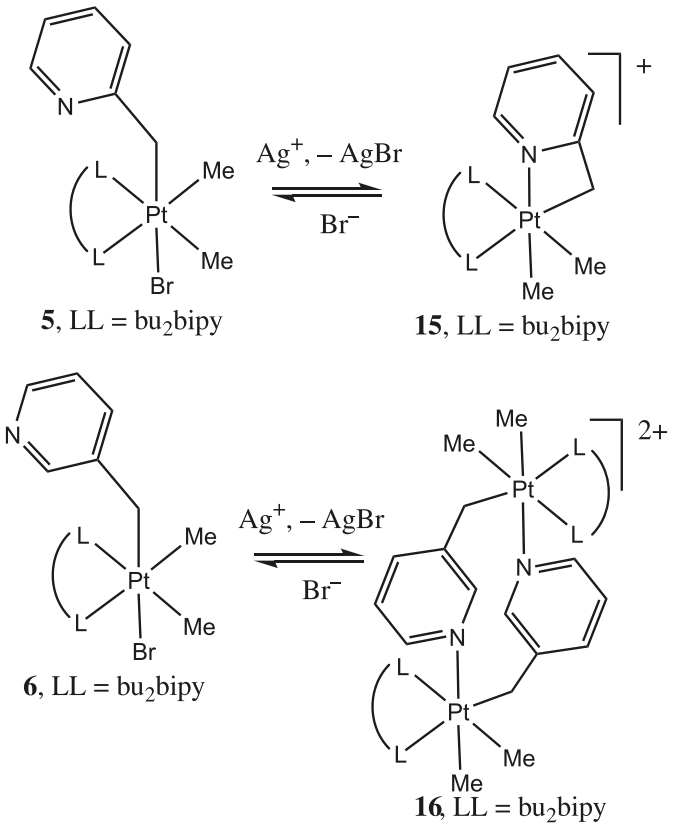


Fig. 6. The structure of disordered complex **12/14** (X = Cl), showing only component **12**. Selected bond parameters: Pt–C(1) 2.09(2), Pt–C(2) 1.99(3), Pt–C(31) 2.06(2), Pt–N(11) 2.15(2), Pt–N(22) 2.10(2), Pt–Br 2.55(2) Å. Hydrogen bond distance: N(35)···Cl(1) 3.61(3) Å.

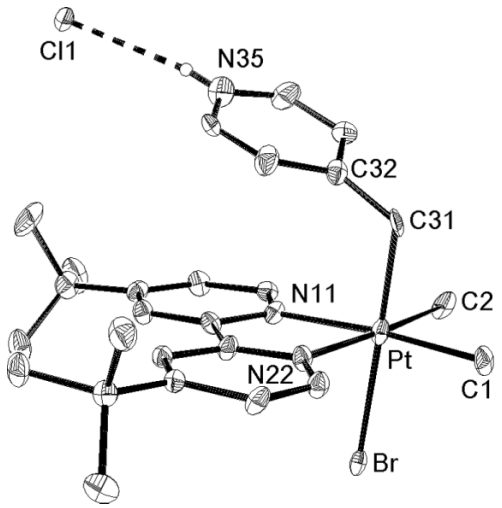
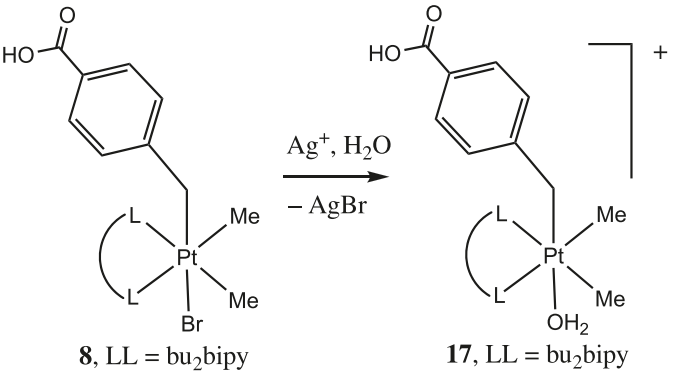
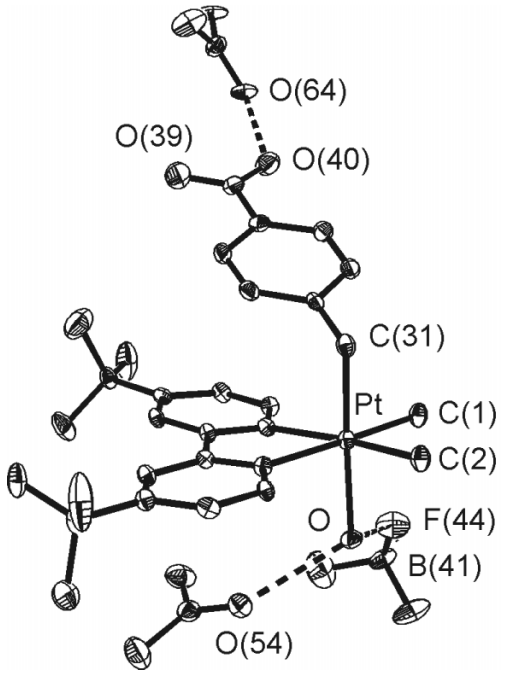


Scheme 6.



^2J(PtH) = 103 Hz; ^2J(HH) = 10 Hz], and there were two sets of pyridyl resonances. The ESI-MS gave a parent ion for **18** at *m*/*z* = 543 as well as a peak corresponding to a cation formed by loss of water at *m*/*z* = 525. In the IR spectrum, the carbonyl peak, found at 1677 cm^{-1} in **4** was absent in **18**. Hydrogen bonding between at least one of the OH groups in **18** to the cyano group was indicated by a shift in the value of ν(CN) from 2226 cm^{-1} in **4** to 2250 cm^{-1} in **18**. The peak assigned to ν(OH) was broad and centred at 3250 cm^{-1}, indicating that both OH groups are involved in hydrogen bonding. The data are most consistent with hydrogen bonding to the nitrogen atom only of the cyano group, because hydrogen bonding to the π-bond should lead to a decrease in ν(CN) whereas end-on hydrogen bonding leads to an increase,[18,19] but it is not clear if both OH groups hydrogen bond to the nitrogen atom or if one of them hydrogen bonds to the triflate anion. The stereochemical change at platinum(IV) in converting **4** to **18** (Scheme 7) is presumably in part to allow maximum hydrogen bonding. Intermolecular OH···NC hydrogen bonding could form a dimer,

Fig. 7. Structure of the aqua complex **17**[BF_4]·2acetone·hexane. Selected bond parameters: Pt–C(1) 2.049(7), Pt–C(2) 2.048(8), Pt–C(31) 2.085(8), Pt–N(11) 2.154(6), Pt–N(22) 2.171(6), Pt–O 2.224(5) Å. Hydrogen bond distances: O···F(44) 2.703(9), O···O(54) 2.43(1), O(40)···O(64) 2.729(9) Å.



oligomer, or polymer. In the ESI-MS, an intense peak was at *m/z* = 543, corresponding to the cation **18**, and a less intense peak assigned to a dimer was observed at *m/z* = 1235 [(2 × **18**) + OTf]. No trimer or higher mass peaks were detected. There are several precedents for the hydration of the DPK ligand and for participation in hydrogen bonding of the DPK-OH_2 ligand.[20]

The reaction of complex **11** with siver trifluoroacetate occurred to give the cationic complex **19** according to Scheme 7. The reaction to give **19** occurred with a change in stereochemistry at platinum(IV) but this reaction was less selective and some trans isomer was also present. The ^{1}H NMR spectrum of the cis isomer **19** contained two methylplatinum resonances and two resonances for the $PtCH^aH^b$ protons, indicating the absence of a mirror plane of symmetry. The structure of complex **19** as the trifluoroacetate salt is shown in Fig. 8. There are two independent but similar molecules in the unit cell, and they are connected by hydrogen bonding between the carboxylic acid groups. In addition, the two OH groups of the ketone hydrate are hydrogen bonded to the trifluoroacetate anions. The hydrogen bond distances O··O are in the range of 2.59–2.65 Å. In the ESI-MS, the most intense envelope of peaks was at *m/z* = 576, corresponding to the cation **19**, with the second most intense peak at *m/z* = 558, corresponding to loss of H_2O. However, intense dimer peaks were also observed at *m/z* = 1151 [(2 × **19**) – H^+], 1133 [(2 × **19**) – H^+ – H_2O], and 1115 [(2 × **19**) – H^+ – 2H_2O]. The trifluoroacetate groups were not present in any observed fragments. These data indicate that the dimer units persist in solution, and that loss of water from the DPK-OH_2 groups occurs easily in the MS. Reactions of complex **11** with silver salts of weakly coordinating anions, such as Ag[BF_4] or Ag[PF_6], gave products that contained the cationic complex **19** but with unidentified side products. We suggest that the hydrogen bonding by the anion (Fig. 8) is significant in stabilizing **19** as the trifluoroacetate salt.

Fig. 8. Structure of the dimer of **19**·CF_3CO_2. Selected bond distances: Pt(1)–C(16) 2.05(1), Pt(1)–C(17) 2.06(1), Pt(1)–C(21) 2.08(1), Pt(1)–N(1) 2.16(1), Pt(1)–N(13) 2.17(1), Pt(1)–O(15) 2.188(9) Å. Discussion

The oxidative addition reactions to give alkyl platinum(IV) complexes tolerate a range of functional groups.[4–8,10–16] In particular, it is possible to incorporate either basic or acidic groups into the organoplatinum(IV) products.[8,10] The reactions of [$PtMe_2$(LL)] with RCH_2Br usually occur by kinetic control to give the product of trans oxidative addition, [$PtBrMe_2(CH_2R)$(LL)], by way of an ionic intermediate, [$PtMe_2(CH_2R)(LL)]^+Br^-$.[4] However, if the ionic intermediate is long-lived, or if the bromide ligand can dissociate easily, the cis isomer may also be formed.[4,16] Several cases of isomerization were observed in this work, and some insight into the reasons for this were sought by computations using density functional theory (DFT).

For the complexes [$PtBrMe_2(CH_2R)$(bipy)] or [$PtBrMe_2(CH_2R)$(DPK)], the trans isomer is calculated to be more stable than the cis isomer in all cases. The example with R = 2-pyridyl is illustrated in Figs. 9*a* and 9*b*. The trans isomer has a preferred conformation with the 2-pyridyl

Scheme 7.

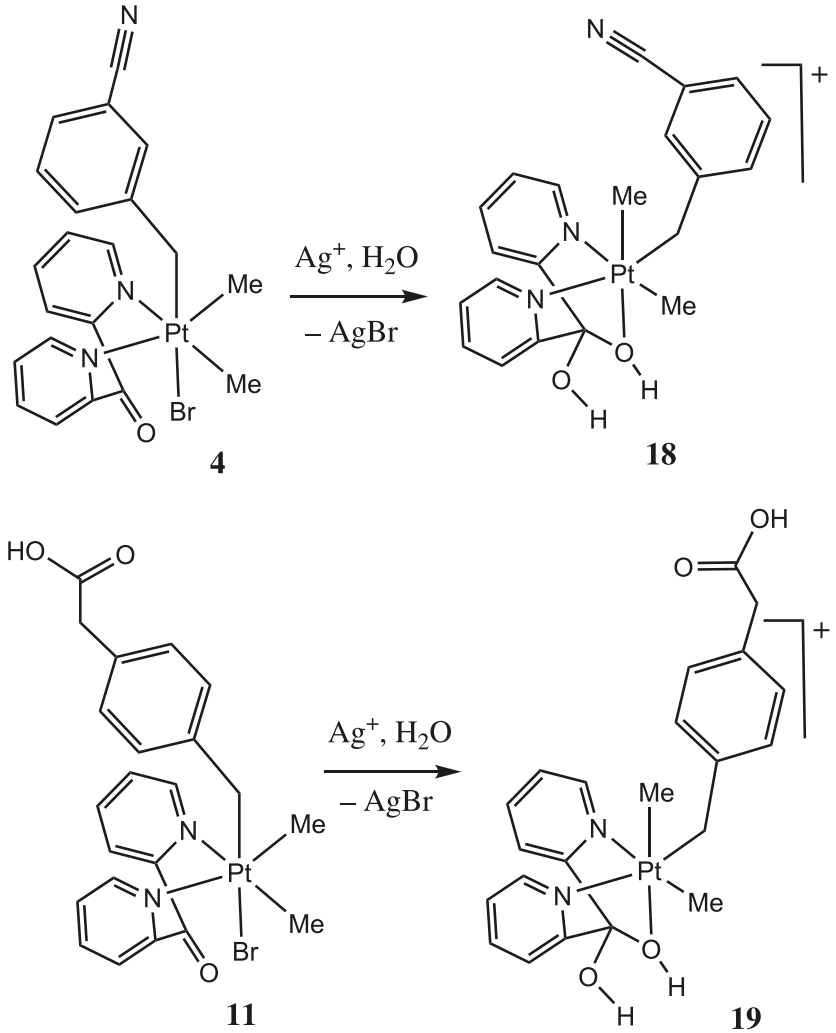

Fig. 9. Optimized structures and calculated relative energies (kJ mol^{-1}) of trans and cis isomers, respectively: (*a*), (*b*) [$PtBrMe_2(CH_2$-2-py)(bipy)]; (*c*), (*d*) [$PtMe_2(CH_2$-2-py)(OH_2)(bipy)]$^+$; (*e*), (*f*) [$PtMe_2(CH_2$-2-py)(bipy)]$^+$.

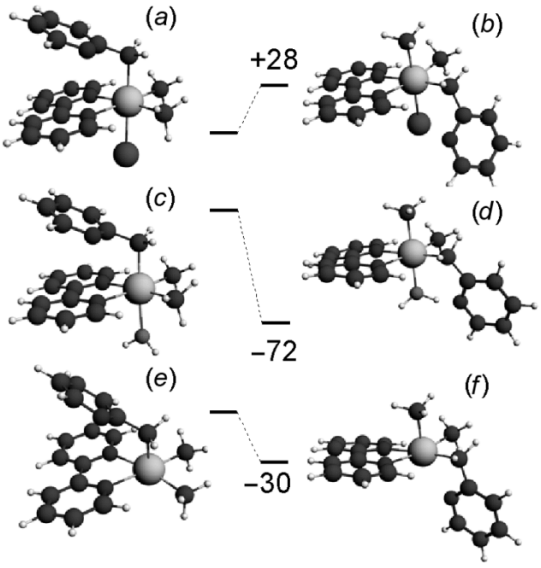
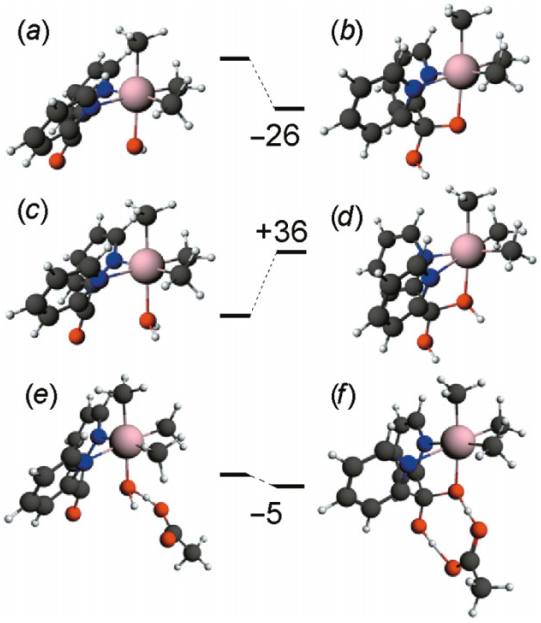


group π-stacked with the 2,2′-bipyridine ligand (Fig. 9*a*) but there is little barrier to rotation about the Pt–CH_2R bond for the cis isomer. The cis isomer can be more stable if there is a specific bonding effect in its favour. For example, the hypothetical aqua complex, [$PtMe_2(CH_2$-2-py)(OH_2)(bipy)]$^+$, is more stable as the cis isomer because an intramolecular hydrogen bond OH···N can exist between the aqua ligand and the 2-pyridyl group (Figs. 9*c*, 9*d*). Similarly, the intermediate five-coordinate complex [$PtMe_2(CH_2$-2-py)(bipy)]$^+$ is more stable as the cis isomer because the pyridylmethyl group can chelate to platinum (Figs. 9*e*, 9*f*). Ring strain in the $PtCH_2$-2-py chelate unit allows easy dissociation of the Pt–N bond. Thus, a conformation with d(Pt–N) increased from the optimized value of 2.23 Å (Fig. 9*f*) to 2.66 Å, with corresponding opening of the angle Pt–C–C(py) from 93° to 104°, was only 18 kJ mol^{-1} higher in energy. Easy reversible access to the coordinatively unsaturated square pyramidal intermediate accounts for the easy fluxionality in complex **15**.

A further complication in the chemistry of the DPK complexes arose from the ease of hydration of the ketone group. Some trimethylplatinum(IV) model complexes, used to avoid complications from cis and trans isomers in the actual complexes studied, are shown in Fig. 10. The ketone addi-

Fig. 10. Optimized structures and calculated relative energies (kJ mol^{-1}) of (*a*) [Pt(OH)Me$_3$(DPK)], (*b*) [PtMe$_3$(DPK-OH)]; (*c*) [PtMe$_3$(OH$_2$)(DPK)]$^+$, (*d*) [PtMe$_3$(DPK-OH$_2$)]$^+$; (*e*) [PtMe$_3$(OH$_2$)(DPK)][MeCO$_2$], (*f*) [PtMe$_3$(DPK-OH$_2$)][MeCO$_2$].

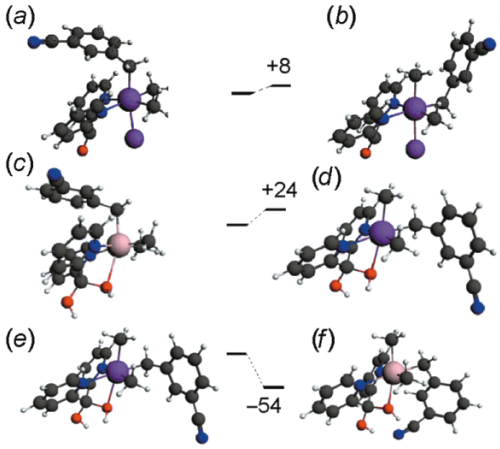


tion step is calculated to be favorable for conversion of neutral complex [Pt(OH)Me$_3$(DPK)] to [PtMe$_3$(DPK-OH)] (Figs. 10*a*, 10*b*). However, for the protonated cationic complexes [PtMe$_3$(OH$_2$)(DPK)]$^+$ and [PtMe$_3$(DPK-OH$_2$)]$^+$, the ketone addition step is unfavorable (Figs. 10*c*, 10*d*). Addition of an acetate anion, which can form a hydrogen bond with the aqua or DPK-OH$_2$ ligand, is enough to make the ketone addition step favorable, as illustrated in Figs. 10*e* and 10*f*. These calculations rationalize the observation that, in all known complexes of the DPK-OH$_2$ ligand, including complex **19**, the OH groups are involved in hydrogen bonding and that hydration is easily reversible.[20,21] The ligand DPK can form a hydrate in hydrochloric acid solution, under conditions where both pyridyl groups are protonated and there is hydrogen bonding between the C–OH groups and chloride anions, but the neutral ketone DPK is not hydrated.[22]

A feature of the complexes **18** and **19** with the DPK-OH$_2$ ligand is that the cis isomer is preferred. Calculations indicate that the trans isomer is expected to be more stable in the absence of hydrogen bonding, for both the ligand DPK and DPK-OH$_2$, as seen in Figs. 11*a*, 11*b* and Figs. 11*c*, 11*d*, respectively. For the cis isomer of the 3-cyanobenzyl derivative (**18**), intramolecular hydrogen bonding is possible and this greatly stabilizes this isomer, as illustrated in Figs. 11*e* and 11*f*. For complex **19**, intramolecular hydrogen bonding is not possible and the carboxylic acid group is involved in intermolecular hydrogen bonding (Fig. 9). In this case, the intermolecular hydrogen bonding is less favored for the trans isomer because of steric effects in the conformation with the aryl group lying over the DPK-OH$_2$ ligand and so the cis isomer is preferred.

Overall, this work has significantly expanded the range of known organoplatinum complexes containing functional alkyl groups. Some of the strengths and limitations in the use of these compounds in supramolecular chemistry are also

Fig. 11. Optimized structures and calculated relative energies (kJ mol^{-1}) of (*a*), (*b*) *trans*- and *cis*-[PtBrMe$_2$(CH$_2$-3-C$_6$H$_4$CN)(DPK)]; (*c*), (*d*) *trans*- and *cis*-[PtMe$_2$(CH$_2$-3-C$_6$H$_4$CN)(DPK-OH$_2$)]$^+$; (*e*), (*f*) *cis*-[PtMe$_2$(CH$_2$-3-C$_6$H$_4$CN)(DPK-OH$_2$)]$^+$ in conformations without and with OH···NC hydrogen bonding, respectively.



defined. The easy trans and cis isomerism and the easy hydration of the DPK ligand makes crystal engineering in these compounds challenging, and the relatively slow rate of ligand substitution at platinum(IV) limits the use of dynamic coordination chemistry for self-assembly. However, the use of hydrogen bonding for self-assembly has given interesting supramolecular dimers and a polymer, which have been structurally characterized.

Experimental

All reactions were performed under a nitrogen atmosphere using standard Schlenk techniques. The complexes [Pt$_2$Me$_4$(μ-SMe$_2$)$_2$], [PtMe$_2$(bu$_2$bipy)], [PtMe$_2$(DPK)], [PtBrMe$_2$(bu$_2$bipy)(CH$_2$-4-C$_6$H$_4$CO$_2$H)], **8**, and [PtBrMe$_2$(bu$_2$bipy)(CH$_2$-4-C$_6$H$_4$CH$_2$CO$_2$H)], **10**, were prepared using the literature methods.[10,23,21] 1-D and 2-D ^{1}H NMR spectra were recorded using a Varian Mercury 400 NMR or a Varian Inova 400 NMR spectrometer at room temperature unless specified otherwise. ESI-MS were recorded using a Micromass LCT spectrometer. DFT calculations were carried out using the Becke–Perdew exchange-correlation functional in the Amsterdam Density Functional program,[24] including first-order scalar relativistic corrections and standard parameters used in previous studies of organoplatinum compounds.[2,25]

[PtBrMe$_2$(3-CH$_2$C$_6$H$_4$CN)(bu$_2$bipy)], 3

To a solution of [PtMe$_2$(bu$_2$bipy)] (0.1096 g, 0.22 mmol) in CH$_2$Cl$_2$ (5 mL) was added a solution of α-bromo-*m*-tolunitrile (0.0463 g, 0.24 mmol) in CH$_2$Cl$_2$ (5 mL). The solution was stirred for 30 min, the volume of solvent was reduced under vacuum, and the product was precipitated by addition of pentane (10 mL) and recrystallized from CH$_2$Cl$_2$/pentane. Yield: 0.085 g (0.12 mmol). ^{1}H NMR (CD$_2$Cl$_2$) δ: 1.43 [s, 18H, *t*-Bu], 1.51 [s, 6H, ^2J(PtH) = 69 Hz, *Me*Pt], 2.79 [s, 2H, ^2J(PtH) = 96 Hz, *CH*$_2$Pt], 6.19 [t, 1H, ^4J(HH) = 2 Hz, C$_6$H$_4$-H^2], 6.76 [d, 1H, ^3J(HH) = 7 Hz, C$_6$H$_4$-H^5], 6.79 [m, 1H, ^3J(HH) = 7 Hz, ^4J(HH) = 2 Hz, C$_6$H$_4$-H^6], 6.95 [m,

1H, ^3J(HH) = 7 Hz, ^4J(HH) = 2 Hz, C_6H_4-H^4], 7.93 [dd, 2H, ^3J(HH) = 6 Hz, ^4J(HH) = 2 Hz, bipy-H^5], 7.95 [d, 2H, ^4J(HH) = 2 Hz, bipy-H^3], 8.58 [d, 2H, ^3J(HH) = 6 Hz, bipy-H^6]. This was prepared similarly from [$PtBrMe_2$(4-CH_2py)(bu_2bipy)] (0.0498 g, 0.075 mmol) and AgOTf (0.040 g, 0.16 mmol). Yield: 0.030 g. ESI-MS *m*/*z*: 585 (100) [$PtMe_2$(bu_2bipy)(4-CH_2py)]$^+$, 1319 (4) [$PtMe_2$(bu_2bipy)(4-CH_2py)]$^+{}_2OTf^-]^+$, 1027 (5) [$PtMe_2$(bu_2bipy)(4-CH_2py)]$^+{}_3OTf^-]^{2+}$. Anal. ca1cd. for $C_{27}H_{36}F_3N_3O_3PtS$ (%): C 44.14, H 4.94, N 5.72; found: C 43.90, H 5.13, N 5.30.

[PtMe$_2$(CH$_2$-4-C$_6$H$_4$COOH)(bu$_2$bipy)(OH$_2$)][BF$_4$], 17·BF$_4$

A solution of $AgBF_4$ (10.5 mg, 0.054 mmol) in acetone (5 mL) was added dropwise to complex **11** (38.5 mg, 0.054 mmol) in acetone (10 mL) and allowed to stir for 1 h. AgBr began to precipitate and the mixture was filtered through Celite. After 2 h of stirring at room temperature, the solvent was evaporated. The product was washed with pentane to give a white solid. Yield: 35.0 mg (88%). ^{1}H NMR (acetone-d_6) δ: 1.33 [s, br, 6H, ^2J(PtH) = 64 Hz, *Me*Pt], 1.41 [s, 18H, *t*-Bu], 2.38 [s, 2H, ^2J(PtH) = 94 Hz, *CH*$_2$Pt], 3.19 [s, br, 2H, $PtOH_2$], 6.52 [br, 2H, C_6H_4(H^2, H^6)], 7.26 [br, 2H, C_6H_4(H^3, H^5)], 7.79 [br, 2H, bipy(H^5, $H^{5'}$)], 8.55 [br, 2H, bipy(H^3, $H^{3'}$)], 8.74 [br, 2H, bipy(H^6, $H^{6'}$)]. Anal calcd. for $C_{28}H_{39}BF_4N_2O_3Pt{\cdot}Me_2CO$ (%): C 47.04, H 5.73, N 3.54; found: C 47.11, H 5.76, N 3.42.

[PtMe$_2$(3-CH$_2$C$_6$H$_4$CN)(DPK-OH$_2$)]OTf, 18·OTf

To a solution of [$PtBrMe_2$(DPK)(3-$CH_2C_6H_4CN$)] (0.056 g, 0.09 mmol) in CH_2Cl_2 (6 mL) was added a solution of AgOTf (0.026 g, 0.1 mmol) in acetone (2 mL). The mixture was stirred for 20 min, decolorizing charcoal was added, the solution was filtered, and the solvent was removed under vacuum to give a pale yellow solid, which was recrystallized from CH_2Cl_2/pentane. Yield: 0.033 g. IR (cm^{-1}): ν(OH) 3250, ν(CN) 2250, ν(C=O) absent. ^{1}H NMR (CD_2Cl_2) δ: 1.18 [s, 3H, ^2J(PtH) = 72 Hz, *Me*Pt], 1.48 [s, 3H, ^2J(PtH) = 81 Hz, *Me*Pt], 3.03 [d, 1H, ^2J(PtH) = 73 Hz, ^2J(HH) = 10 Hz, *CH*$_2$Pt], 3.55 [d, 1H, ^2J(PtH) = 103 Hz, ^2J(HH) = 10 Hz, *CH*$_2$Pt], 7.08 [t, 1H, ^3J(HH) = 8 Hz, C_6H_4-H^5], 7.24 [d, 1H, ^3J(HH) = 6 Hz, C_6H_4-H^4], 7.25 [s, 1H, C_6H_4-H^2], 7.30 [m, 1H, ^3J(HH) = 6 Hz, bipy-$H^{5'}$], 7.34 [d, 1H, ^3J(HH) = 8 Hz, C_6H_4-H^6], 7.57 [t, 1H, ^3J(HH) = 7 Hz, bipy-H^5], 7.78 [d, 1H, ^3J(HH) = 5 Hz, bipy-$H^{3'}$], 8.02 [m, 1H, ^3J(HH) = 7 Hz, bipy-H^3], 8.03 [m, 1H, ^3J(HH) = 5 Hz, bipy-$H^{4'}$], 8.05 [m, 1H, bipy-H^4], 8.08 [d, 1H, ^3J(HH) = 8 Hz bipy-$H^{6'}$], 8.44 [d, 1H, ^3J(HH) = 6 Hz bipy-H^6]. ESI-MS *m*/*z*: 495 (100) [Pt(DPK)(3-$CH_2C_6H_4CN$)]$^+$, 525 (66) [$PtMe_2$(DPK)(3-$CH_2C_6H_4CN$)]$^+$, 543 (16) [$PtMe_2$(DPK)(3-$CH_2C_6H_4CN$) + H_2O]$^+$. Anal. calcd. for $C_{22}H_{22}F_3N_3O_5PtS$ (%): C 38.15, H 3.20, N 6.07; found: C 37.90, H 3.29, N 5.77.

[PtMe$_2$(4-CH$_2$C$_6$H$_4$CH$_2$CO$_2$H)(DPK-OH$_2$)][CF$_3$CO$_2$], 19·O$_2$CCF$_3$

To a solution of [$PtBrMe_2$(4-$CH_2C_6H_4CH_2CO_2H$)(DPK)] (0.050 g, 0.0783 mmol) in Et_2O (15 mL) was added a solution of AgO_2CCF_3 (0.018 g, 0.0815 mmol) in THF (2 mL). The mixture was stirred for 30 min, decolorizing charcoal was added, the mixture was filtered, and the solvent was evaporated to give a yellow solid, which was recrystallized from ether/pentane. ^{1}H NMR (CD_2Cl_2) δ: 1.05 [s, 3H, ^2J(PtH) = 71 Hz, *Me*^{a}Pt], 1.34 [s, 3H, ^2J(PtH) = 71 Hz, *Me*^{b}Pt], 2.80 [d, lH, ^2J(H^{a}H^b) = 10 Hz, ^2J(PtH^a) = 88 Hz, *CH*^{a}Pt], 3.44, 3.47 [m, 2H, CCH_2], 3.65 [d, lH, ^2J(H^{a}H^b) = 10 Hz, ^2J(PtH^b) = 95 Hz, *CH*^{b}Pt], 6.74 [d, 2H, ^3J(HH) = 8 Hz, C_6H_4-H^3], 6.92 [d, 2H, C_6H_4-H^2], 7.20–8.33 [m, 8H, DPK]. ESI-MS (M = [$PtMe_2$(4-$CH_2C_6H_4CH_2CO_2H$)(DPK-OH_2)][CF_3CO_2]) *m*/*z*: 1151 (5) [2M-2CF_3CO_2-H_3O]$^+$, 1133 (7) [2M-2CF_3CO_2-H_3O]$^+$, 1115 (5) [2M-2CF_3CO_2-2H_2O-H)]$^+$, 576 (100) [M-CF_3CO_2]$^+$, 558 (94) [M-CF_3CO_2-H_2O]$^+$. The trans isomer was identified by its ^{1}H NMR spectrum δ: 1.13 [s, 6H, ^2J(PtH) = 71 Hz, *Me*Pt], 3.39 [s, 2H, ^2J(PtH) = 91 Hz, *CH*$_2$Pt], 3.51 [s, 2H, CCH_2]. Anal. calcd. for $C_{24}H_{25}F_3N_2O_6Pt$ (%): C 41.80, H 3.65, N 4.06; found: C 41.56, H 3.87, N 3.81.

X-ray structure determinations

A crystal was mounted on a glass fibre and data were collected using a Nonius Kappa CCD diffractometer. Details of the data collection, absorption correction, and structure refinement are given in Table 1 and in the Supplementary data. Nonhydrogen atoms were refined with anisotropic thermal parameters, except in cases of disorder. The hydrogen atom positions were calculated geometrically and were included as riding on their respective heavy atoms. Brief comments on unusual features of individual structures are given below. The accuracy of bond distances was low in some cases as a result of disorder, but the structures are all well-defined.

[PtBrMe$_2$(3-CH$_2$C$_6$H$_4$CN)(bu$_2$bipy)], 3

There was minor unresolved disorder of the *t*-butyl groups.

[PtBrMe$_2$(2-CH$_2$C$_5$H$_4$N)(bu$_2$bipy)], 5

There were two independent molecules in the asymmetric unit.

[PtBrMe$_2$(CH$_2$-4-C$_6$H$_4$CO$_2$H)(bu$_2$bipy)], 8

The crystal was twinned and the twinning was successfully modelled.

[PtBrMe$_2$(CH$_2$-4-C$_6$H$_4$CH$_2$CO$_2$H)(bu$_2$bipy)], 10

The CH$_2$-4-C$_6$H$_4$CH$_2$CO$_2$H groups were disordered. The disordered atoms were modeled isotropically at a 0.50/0.50 ratio.

[PtBr$_{0.36}$(Cl$_{0.64}$)Me$_2$(4-CH$_2$C$_5$H$_4$NH)(bu$_2$bipy)]Cl·CHCl$_3$, 12/14

The crystal was twinned, with evidence for a multiple twin. The twinning was not modeled successfully, and so the agreement factors are large, but the structure is clearly defined.

[PtMe$_2$(CH$_2$-4-C$_6$H$_4$CO$_2$H)(OH$_2$)(bu$_2$bipy)][BF$_4$]·1.5Me$_2$CO·0.5C$_6$H$_{14}$, 17

There was 50:50 disorder of the carboxylic acid group. In one component form, there was a hydrogen bond to an acetone molecule while, in the other component, that void contained a disordered hexane molecule, which was refined isotropically. The hexane molecule was not well-defined.

[PtMe$_2$(4-CH$_2$C$_6$H$_4$CH$_2$CO$_2$H)(DPK-OH$_2$)][CF$_3$CO$_2$], 19·O$_2$CCF$_3$

There were two independent molecules in the asymmetric unit, and they were connected through hydrogen bonds. The crystal was twinned and the twinning was successfully modeled.

Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 3933. For more information on obtaining material, refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml. CCDC 711234–711240 contain the X-ray data in CIF format for seven complexes for this manuscript. These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (Or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

The affinity of HGGG, GHGG, GGHG, and GGGH peptides for copper(II) and the structures of their complexes — An ab initio study[1]

Stephen D. Barry, Gail A. Rickard, M. Jake Pushie, and Arvi Rauk

Abstract: The structures and relative free energies in aqueous solution of the Cu(II) complexes of the "histidine walk" peptides, $AcHGGGNH_2$, $AcGHGGNH_2$, $AcGGHGNH_2$, and $AcGGGHNH_2$, were determined as a function of pH. Numerous structures of each species were found by gaseous- and solution-phase geometry optimization at the B3LYP/6–31G(d) level, and the effect of solvation estimated by the IEFPCM continuum solvation model. Free energies of solvation of the ionic species are large and favour structures with an extended peptide chain. In all Cu(II)–peptide complexes, deprotonation of two amide groups occurs readily at or below pH 7. In each system, the most abundant species at pH 7 is a neutral 1:1 complex with N3O1 coordination pattern. Binding in the forward direction toward the C terminus is preferred. The results are compared to recent experimental spectroscopic and potentiometric studies on related systems. Alternative explanations are offered for some of the experimental observations.

Key words: copper–peptides, theoretical, DFT, prion, binding affinities, CD spectra.

Résumé : On a déterminé les structures et les énergies libres, en solutions aqueuses et en fonction du pH, des complexes de Cu(II) des peptides de la série histidine, $AcHGGGNH_2$, $ACGHGGNH_2$, $AcGGHGNH_2$ et $ACGGGHNH_2$. On a déterminé les diverses structures de chacune des espèces, en phase gazeuse et en solution, par une optimisation de la géométrie au niveau B3LYP/6-31G(d) et on a évalué l'effet de solvatation par le modèle de solvatation continue IEEPCM. Les énergies libres de solvatation des espèces ioniques sont importantes et elles favorisent les structures avec une chaîne peptidique étendue. Dans tous les complexes Cu(II)–peptide, la déprotonation de deux groupes amides se produit facilement à des pH égal ou inférieurs à 7. Dans chaque système, l'espèce la plus abondante au pH 7 est un complexe 1:1 neutre comportant un patron de coordination N3O1. La fixation est favorisée dans la direction allant vers la position C-terminale. On compare les résultats obtenus ici avec ceux rapportés récemment pour des études expérimentales spectroscopiques et potentiométriques sur des systèmes apparentés. Des explications alternatives sont proposées pour un certain nombre d'observations expérimentales.

Mots-clés : complexes cuivre–peptides, théorique, théorie de la fonctionnelle de densité (TFD), affinités de fixation, spectres de dichroïsme circulaire (DC).

[Traduit par la Rédaction]

Introduction

The pathology of many neurodegenerative diseases involves the disruption of normal trafficking of a metal ion which is ultimately related to its binding to a biologically prevalent protein or peptide. These include Alzheimer's, Parkinson's, and Huntington's diseases, as well as the prion diseases, also known as transmissible spongiform encephalopathies (TSEs), which result in the deterioration of neurons.[2,3] The misfolding of these proteins/peptides, which in some instances may involve metal binding, is believed to cause the observed neurotoxicity of these species.[2,4,5] Especially in the case of TSEs and Alzheimer's disease (AD), copper is involved in peptide–protein binding, and has been shown to be a contributor to the neurotoxicity of the beta amyloid peptide of AD.[6–9]

The prion protein, PrP, a 231 amino acid protein, is a normal component of body tissues and is found at high concentrations in the central nervous systems of humans, as well as various other species, including mammals, avians, and yeast. Prion diseases occur when the cellular form of the protein (PrP^C) is converted into its scrapie form (PrP^{Sc}), which readily aggregates. PrP selectively binds Cu(II) over other bioavailable metal ions.[10] The first Cu(II)-binding region of PrP is termed the octarepeat region, which has four or more tandem repeats of the same 8 amino acids, PHGGGWGQ, beginning at Pro60 (human numbering) and repeating at Pro68, Pro76, and Pro84 in the N-terminal domain. The link between this region and the pathology of Creutzfeldt–Jakob disease (CJD) is apparent, since individuals with extra octarepeats are more prone to developing CJD.[11,12] The association constants of Cu(II) binding to the octarepeat region are varied, but are generally accepted to be between 10^9 M^{-1} [13] and 10^6 M^{-1}.[14]

As in the case of the prion protein, and the beta amyloid peptide of AD, virtually all physiological copper is bound to

one or more His residues in tetracoordinated square-planar complexes. Experimentally, tetragonal coordination is preferred to pentacoordination.[15] Comparison of the affinity of Cu(II) for biologically available ligands, modeled theoretically with small compounds, has shown that the imidazole group of His is a better ligand than any other,[16,17] with the exception of a thiolate group (i.e., cysteine).[16] However, it is well known that Cu(II) has a considerable acidifying effect on the amide N–H bond with the consequence that one or more deprotonated amide groups may be ligands to the Cu(II) ion even at physiological pH 7.[18–21]

Detailed information about the structures of some Cu(II)–peptide complexes is available from crystallography, but information about structures in solution comes from electron paramagnetic resonance (EPR), circular dichroism (CD), and infrared (IR) and UV–vis spectroscopies, and is much less detailed. Millhauser and co-workers were able to partially clarify the binding of Cu(II) to PrP from their use of X-ray crystallography, circular dichroism, and electron paramagnetic resonance spectroscopy studies.[22–24] They determined the prominent binding modes in both solid and solvated forms at various pH values. At pH 7.4, two binding modes existed, called component 1 and component 2. The major component, component 1, has a square-planar binding environment about the Cu center consisting of three N ligands and an oxygen atom (i.e., N3O1). It was established that one of the N atoms is N_π of His and the other two are deprotonated amides of the adjacent two Gly residues. The oxygen is the carbonyl oxygen of the second Gly. In the absence of the Trp residue, i.e., HGGG or HGG, component 2 is dominant. Its binding stoichiometry was tentatively identified as N2O2. These results supported previous experimentally determined binding environments at varied pH values.[25,26] It was found that the minimum peptide sequence required to model the observed N3O1 and N2O2 environments of the full length Cu(II)-bound octarepeat region is the fragment "HGGG".[22,24]

Pushie and Rauk originally analyzed the binding of Cu to PrP at a high theoretical level,[27] using a truncated model of the "HGGG" fragment in which the N- and C-terminal groups were replaced by hydrogen atoms. Nevertheless, the analysis provided some interesting insights into the interaction between Cu and PrP, including confirming the stability of the structure and binding modes determined by Millhauser and co-workers.[22–24] This included identifying both component 1 and component 2, which were the most stable neutral and cationic structures, respectively.

Several recent theoretical[28–30] studies of models of the octarepeat region of the prion protein have appeared since this paper was in preparation. Marino et al.[28] carried out gaseous-phase calculations of the pentapeptide, Cu–HGGGW with and without an additional water molecule, on structures adapted from the crystal structure of Millhauser and coworkers (tetragonal Cu with N3O1 coordination).[23] They found that the water would not occupy a fifth site in the coordination sphere of the metal but additional stabilization ensued if the Trp residue adopted a position over the square plane. Furlan et al.[29] also adopted the crystal structure as a starting geometry and carried out 1 ps ab initio molecular dynamics simulations of Cu–HGGG and Cu–HGGGW surrounded by water. They found that a water molecule would not occupy the fifth coordination site even in the presence of the Trp residue. Riihimäki et al. carried out MD simulations with an empirical forcefield on copper bound to the full octarepeat unit, PHGGGWGQ, also adopting the crystal structure for the tetragonal copper binding environment. With an empirical forcefield, additional coordination to copper could only arise due to electrostatic attraction. A carbonyl group was able to occupy the fifth coordination site.

In the truncated HGGG model, and in the PrP octarepeats, the peptide wraps around the Cu(II) in the forward direction. This was attributed in part to the presence of the Pro residue which precludes full binding in the reverse direction. Mammalian PrP also has two additional His residues capable of Cu(II) binding within the N-terminal domain, located between the octarepeat region and the structured C-terminal domain — these are His96 and His111. The most recent reevaluation of Cu(II) coordination with this region of PrP by Jones et al. supports binding of Cu(II) at His96 and His111 in a noncooperative manner.[31] At physiological pH, the Cu(II) is bound within an N3O1 or N4 coordination environment. Binding at His96 or His111 proceeds in the reverse direction — from the anchoring His residue toward the N-terminus.

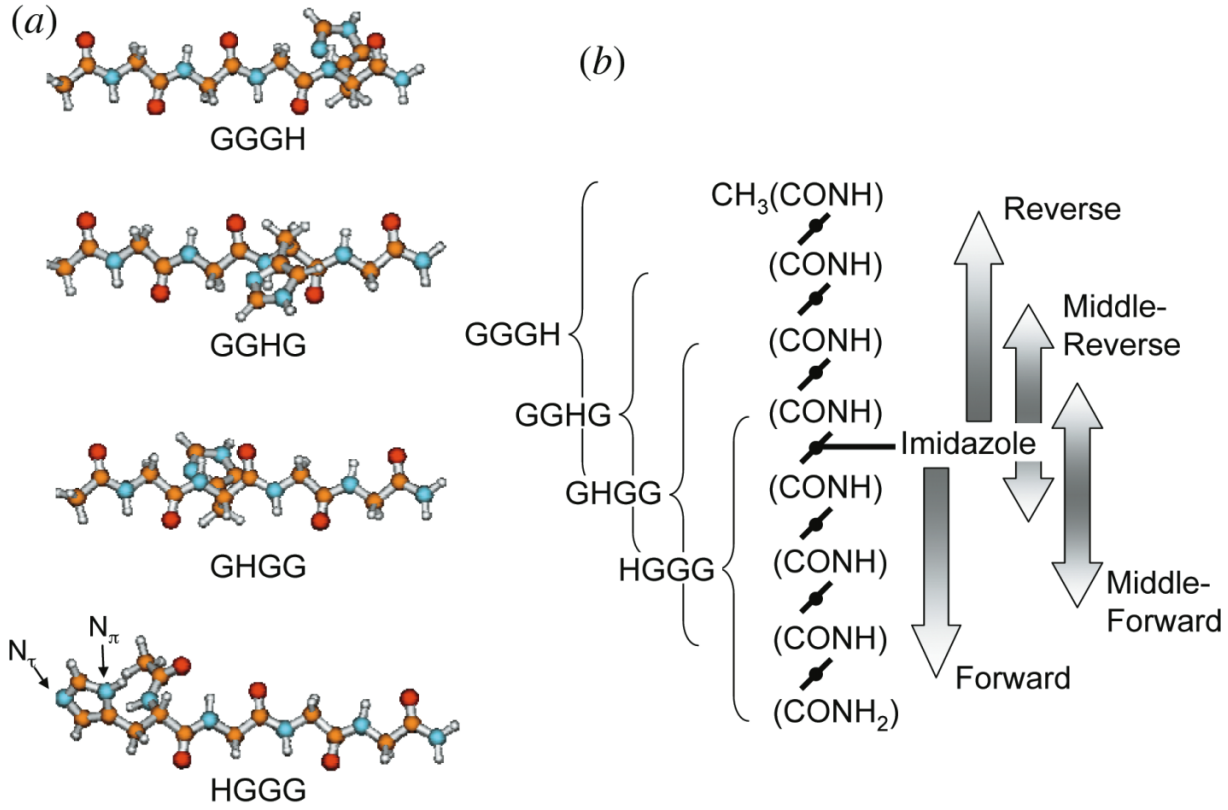
The objectives of this work are threefold: (1) determine the structures of the most stable species in which Cu(II) is bound to a peptide fragment containing an anchoring His residue, as a function of pH; (2) estimate the binding affinities of the structures; and (3) establish the propensity of the Cu(II) to coordinate in a forward or reverse direction relative to the His residue in the absence of specific interactions with side chains.

We adopt as models, the four tetrapeptides, $AcHGGGNH_2$ (**a**), $AcGHGGNH_2$ (**b**), $AcGGHGNH_2$ (**c**), and $AcGGGHNH_2$ (**d**), to which we refer simply as HGGG (**a**), GHGG (**b**), GGHG (**c**), and GGGH (**d**), respectively. These are shown in Fig. 1*a*. The overlapping nature of the models affords comparison of four distinct binding modes as illustrated in Fig. 1*b*. In each case, the Cu(II) can bind to the His residue and may coordinate an oxygen atom or an N atom from one or more of the flanking amide groups. The amide may be protonated or deprotonated. The binding may be in the forward (toward the C terminus) or reverse (toward the N terminus) direction, and may potentially bracket the His residue (middle-forward or middle-reverse). In Fig. 1 and the following figures, all structures are shown with the N-terminal acetyl group to the left.

Methods

Calculations were performed using the Gaussian 03 suite of electronic structure codes.[32] With several exceptions, all optimizations were performed in vacuo without using geometry or symmetry constraints, using the B3LYP hybrid functional method[33] and the 6–31G(d) basis set. Harmonic frequency analysis was performed at the B3LYP/6–31G(d) level, to ensure that a minimum energy stationary point was located on the potential energy surface (no imaginary frequencies). The harmonic frequency data was used to obtain enthalpies, entropies, and zero-point energies for each structure. The zero-point energies were scaled by a factor of

Fig. 1. (*a*) The most stable structures of the four peptide models in water. (*b*) An extended polyGly peptide chain with a central His residue, residues spanned by the four modes of Cu-binding, and the relationship to the four peptide models.



0.9806. Single point energies were calculated from optimized geometries at the B3LYP/6–311+G(2df,2p) level. These energies were used to provide more accurate relative enthalpies at 0 K.

The gaseous- and solution-phase entropies were calculated including the factor, $R\ln(n)$,[34] where R is the normal gas constant and n is an estimate of the number of conformational degrees of freedom, based on allowing 6 conformers for a free His residue, and 5 conformers for each uncoordinated Gly residue. Values of n range from $n = 1$ for some tricyclic, strongly H-bonded structures, to a maximum of $n = 1500$ for a copper-free peptide. It is important to include an estimate of n to take into account loss of conformational degrees of freedom in the formation of cyclic structures. It should be noted that an error of a factor of 2 in the estimate of n corresponds to an error of less than 2 kJ mol^{-1} in the free-energy change at 298 K, but neglect of it altogether may incur an error of as much as 18 kJ mol^{-1} (= $RT\ln(1500)$ at $T = 298$ K). We count only cyclic structures formed by coordination to the copper. Intramolecular hydrogen bonds are considered not to be stable in water. Values of n are given in the Supplementary data.

Aqueous solvation effects were modeled by using the B3LYP/6–31G(d) wave function and the self-consistent integral equation formalism of the polarizable continuum model,[35,36] as implemented in Gaussian 03 software (SCRF=IEFPCM), on the gaseous-phase-optimized geometries. The default scale factor 1.2 was used for the "united atom Hartree–Fock" (UAHF) radii of all neutral species. Selective scaling of UAHF radii was applied to charged species as follows: in cationic species, the radii of the Cu(II) ion and all atoms directly attached to it were scaled by 1.1; in anionic species, the radii of the Cu(II) ion and all formally neutral atoms directly attached to it were scaled by 1.1; the radii of atoms bearing a formal negative charge were unscaled (scale factor = 1.0). In the case of a deprotonated amide group, both the N and O atoms were unscaled. It is our experience that the selective scaling as described yields reasonably accurate absolute free energies of solvation of small charged species and the calculation of pK_a values usually to within two units.

Time-dependent (TD)[37] B3LYP with the 6–31G(d) basis, in the presence of the solvent reaction field as described above, were carried out to estimate the circular dichroism (CD)[38] spectrum for some of the species studied.

Experimental values were adopted for the free energy of solvation of the proton and water: $\Delta G_{solv}(H^+)$ = –1107 kJ mol^{-1} [39]; $\Delta G_{solv}(H_2O)$ = –16.4 kJ mol^{-1}. The value for water corresponds to the transfer of a water molecule from the gaseous phase at a concentration of 1 mol/L into aqueous medium at 55 mol/L.[40]

pK_a values reported in the text and figures were calculated from the aqueous free-energy change of the acid ionization reaction, $AH_{(aq)}{}^{m+} \rightarrow A_{(aq)}{}^{(m-1)+} + H_{(aq)}{}^{+}$. We expect that for the large systems, at the level of theoretical treatment described above, the residual errors in aqueous free-energy changes are likely to be approximately ±15 kJ mol^{-1}. This range corresponds to about ±2 pK_a units. Thus we will place emphasis only on differences that are larger than these amounts.

Table S1 of Supplementary data contains all primary calculated data for all species discussed below. Table S2 contains calculated CD data. The Cartesian coordinates of all species are also provided in the Supplementary data.

Results and discussion

Many conformations of each system were examined to find the most stable in solution. In most cases, the most stable conformation in the gaseous phase involved collapsed structures with a maximum number of intramolecular hydrogen bonds. However, these were often not the most stable structures in solution after addition of ΔG_{solv}; the solvent reaction field strongly favoured extended structures with a maximum exposure of the amide groups to the solvent. In the case of **1b** and **2b** (Fig. 2), there were no local minima corresponding to extended conformations in the gaseous phase, but in each case, geometry optimization with the solvent reaction field yielded a more stable conformation in solution. For these, the zero-point energy and thermal corrections were taken from the nearest gaseous-phase minimum.

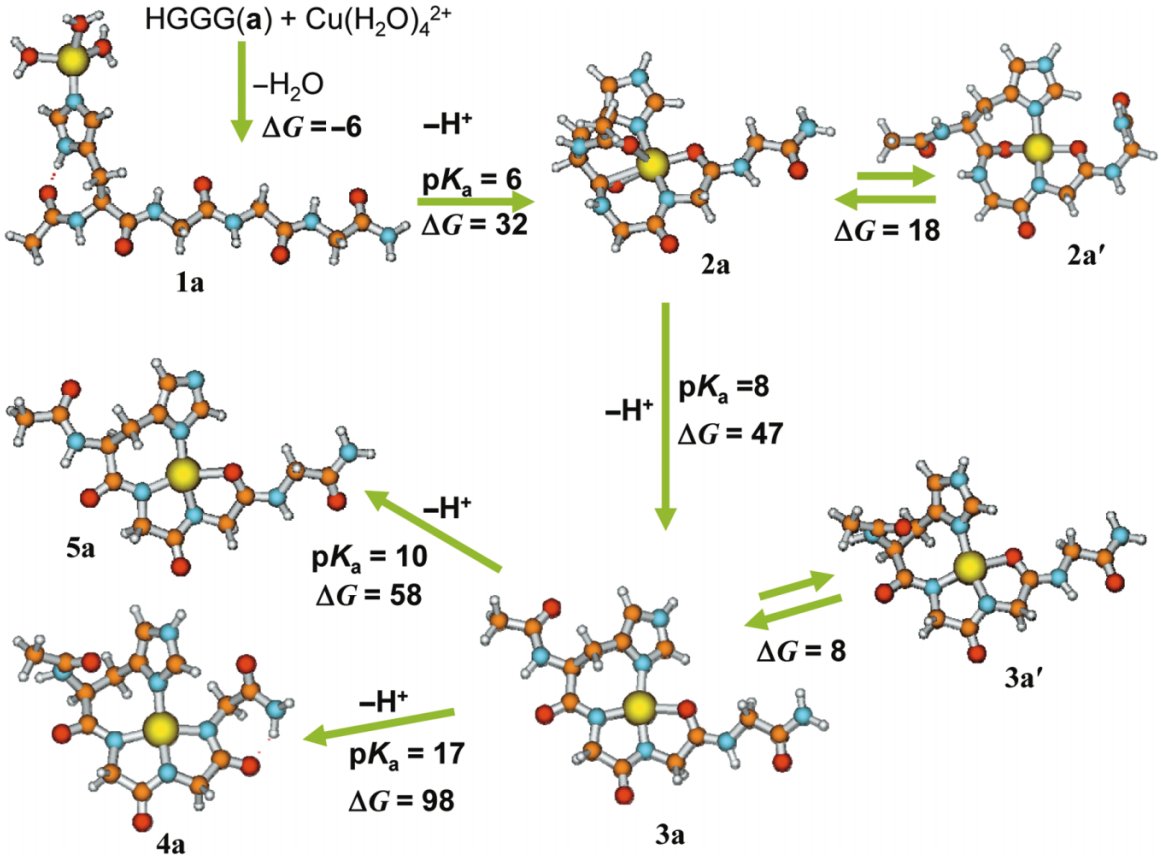
The binding of Cu(II) to the peptides is strongly dependent on pH. The pK_a of a protonated His residue is approximately 7 for loss of proton from either side chain N atom. At pH < 7, both N atoms of the imidazole group are protonated, and the Cu(II) ion must compete with a proton for binding to one of the N atoms. At the present level of theory, the complexes of copper ion with water and other simple ligands are best described as tetracoordinated, having a distorted square-planar coordination sphere.[16] Since an amide carbonyl oxygen will probably not displace water from the coordination sphere, initial binding of the copper will be to one of the imidazole N atoms provided the free-energy penalty for deprotonating the N atom (= $-RT(\ln(K_a) - \ln[H^+])$ is not greater than the free energy of binding. The structures of the most stable complexes of Cu(II) with each peptide, according to the reaction,

$$[1] \quad Cu^{2+}(H_2O)_{4(aq)} + L_{(aq)} \rightarrow Cu^{2+}(H_2O)_3L_{(aq)} + H_2O_{(aq)}$$

are designated **1a**, **1b**, **1c**, and **1d**, and are shown in Figs. 3 or 4, 2, 5, and 6, respectively. In each case, the coordination is through N_τ yielding a tetracoordinated metal center. It is of interest to note that structures that are substantially more stable than **1a**, **1b**, **1c**, and **1d** *in the gaseous phase* were found by attaching the copper ion to N_π. In these cases (not shown), the copper ion is pentacoordinated. Although not part of the starting structure, the His carbonyl O atom moved into the fifth coordination site upon geometry optimization, and short H-bonds were formed between two coordinated water molecules and other carbonyl O atoms. However, the N_π-coordinated structures had significantly lower free energy of solvation, with the result that, for all systems, the most stable structures *in water*, where a *single* water is displaced, involved coordination of the aqueous copper ion through N_τ. with the peptide backbone in an extended configuration.

Since the structures are isomeric, it is possible to compare their energies. The relative $\Delta G_{(aq)}$ of **1a**, **1b**, **1c**, and **1d**, are

Fig. 3. HGGG(**a**)–Cu structures. Ball colours: green = Cu^{2+}; orange = C; blue = N; red = O. Free-energy changes, ΔG, are in units of kJ mol^{-1} in aqueous solution.



0, 5, 23, and 11 kJ mol^{-1}, respectively. We return to a discussion of the low-pH attachment of Cu(II) below when we compare the results with experiment.

The remainder of the structures discussed here are those expected to exist at higher pH. In all of these, the Cu(II) is bound to the histidine via the N_π atom of the imidazole group. The N_π atom is close enough to the peptide backbone to allow easy access to the Cu centre by amide groups that lie adjacent to the C_α of the histidine residue and in forward and reverse directions down the chain. The sequence of models permits evaluation of the energetics of chelation of the Cu in both the forward direction (toward the C terminus) and the backward direction (toward the N terminus) as illustrated in Fig. 1. We consider structures in which the Cu–peptide complex has lost a single proton (structures **2x**), two protons (structures **3x**), and three protons, either from three amide groups (**4x**), or from two amide groups and N_τ of the imidazole (**5x**). Here **x** is one of **a** (HGGG series), **b** (GHGG series), **c** (GGHG series), or **d** (GGGH series). For convenience, all of the structures in all of the figures are oriented with the N-terminus to the left and the C- terminus to the right. We briefly discuss each of the tetrapeptides separately, and then compare them.

HGGG structures

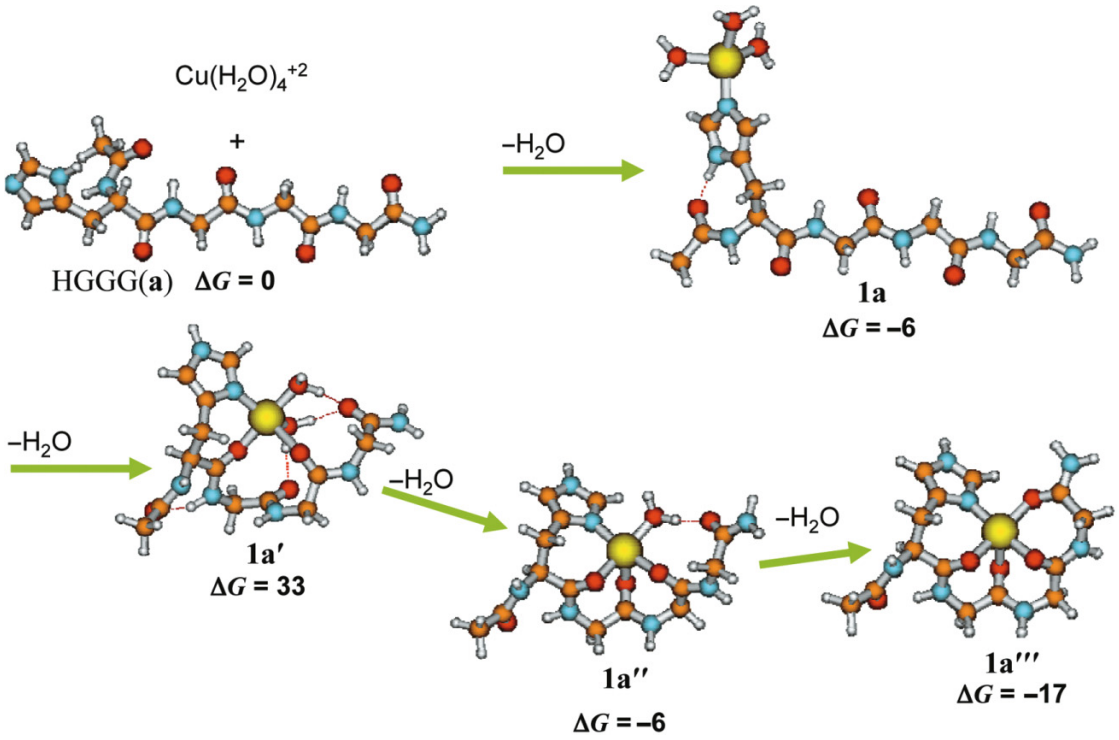
The sequence of the most stable structures of each type in the HGGG series resulting from successive proton loss, namely **1a**, **2a**, **3a**, **4a**, and **5a**, is shown in Fig. 3. Several conformations of the copper-free HGGG peptide, HGGG(**a**), were found. The most stable of these in solution, the N_π-protonated tautomer, is shown in Fig. 4. It attaches to $Cu_{(aq)}^{2+}$ with low affinity, $\Delta G_{(2)}$ = –6 ± 12 kJ /mol^{-1} to yield structure **1a** in which the Cu(II) is tetracoordinated and bound to N_τ of the imidazole.

$$[2] \quad Cu(H_2O)_4^{2+} + HGGG(\mathbf{a}) \rightarrow \mathbf{1a}/Cu(H_2O)_3^{2+} + H_2O$$

Successive loss of water leads to the other structures shown in Fig. 4. The most stable structure in which two waters of coordination remain, **1a**′, is unstable relative to the separated species (left hand side of eq. [2]) by 33 kJ mol^{-1}. Successive loss of the remaining two waters of coordination yields **1a**″ and **1a**‴, that are bound relative to the separated species by $\Delta G_{(aq)}$ = –6 kJ mol^{-1} and –17 kJ mol^{-1}, respectively. In each of **1a**′, **1a**″, and **1a**‴, the Cu(II) is pentacoordinated, with a tetragonal pyramidal geometry.

Structure **2a** (Fig. 3) is the most stable singly-deprotonated species. Of the many structures examined here, **2a** is unusual in that it has a "middle-forward" bonding configuration (see Fig. 1*b*). The pentacoordination in **2a** is probably weak. The average distance for a Cu–O bond at this level of theory is 2.00 ± 0.02 Å. The length of the fifth bond (to the O=C of His) is 2.49 Å, indicating that it is considerably weaker and may not survive in aqueous solution. Structure **2a** has nominally an N2O2 coordination pattern. It can be identified with structure II of Bonomo et al.,[21] and "component 2" of

Fig. 4. Attachment of aqueous Cu(II) to HGGG(**a**) with successive loss of water. The most stable structures of each type are shown. Ball colours: green = Cu^{2+}; orange = C; blue = N; red = O. Free-energy changes, ΔG, are in units of kJ mol^{-1} in aqueous solution.



Millhauser and co-workers, and confirms their tentative N2O2 assignment.[41] The second most stable singly deprotonated structure, **2a**′ (Fig. 3), also has N2O2 coordination and is predicted to be less stable by 18 kJ mol^{-1}. As is evident from both structures **2a** and **2a**′, the first loss of a proton is predicted to occur from the N–H bond of the second Gly residue, since this permits the two strong electron pair donors, the amide group and the imidazole group, to be trans to each other in the Cu coordination shell.

Structure **2a** is predicted to have $pK_a = 8 \pm 2$, corresponding to ionization of the N–H bond of the first Gly residue, yielding **3a**. Species **3a** has N3O1 coordination in the "forward" direction, with two five-membered rings involving the two deprotonated amide groups and a coordinating carbonyl O atom, and a seven-membered ring involving the His residue. A second structure, **3a**′ (Fig. 3) with the same coordination pattern as **3a**, but with the seven-membered ring inverted, is predicted to be slightly less stable. In **3a**′, the oxygen atom of the N-acetyl group almost makes a fifth ligand to the copper ion. Either or both of **3a** and **3a**′ are candidates for structure III of Bonomo et al.,[21] and "component 1" of Millhauser and co-workers.[41]

Structure **3a** has four remaining sites for deprotonation, three from backbone N–H bonds and the N_τ–H bond of the imidazole. The latter is calculated to be the most acidic, with $pK_a = 10 \pm 2$, yielding structure **5a**. We could find no backbone N–H bond with $pK_a < 17$, i.e., corresponding to structure **4a**. Thus our results suggest that the third deprotonation is from the imidazole group rather than from the backbone. We return to this apparent disagreement with the experimental observations by Bonomo et al.[21] in the "Relationship to experimental studies" section below.

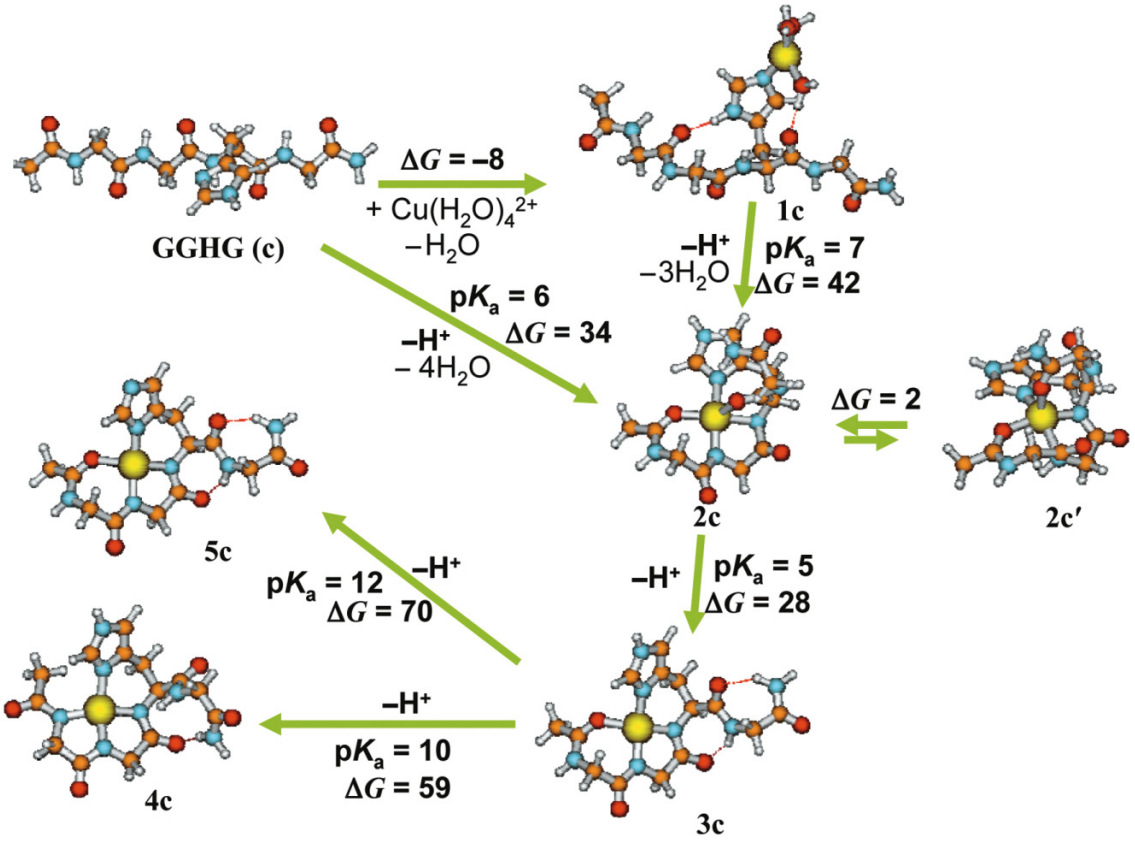
GHGG structures

In a fashion analogous to the HGGG (**a**) system, the pH-dependent origin of GHGG (**b**) structures is displayed in Fig. 2. The first attachment to the copper ion yields **1b** with binding affinity, –23 kJ mol^{-1}. Despite the availability of two amide groups preceding the His residue, the most stable coordination pattern, after loss of a single proton and three water molecules, is in the "forward" direction, yielding **2b** with N2O2 coordination. As in the case of **2a**, loss of the proton has occurred from the "i + 2" Gly residue, affording a trans orientation of the two N ligands. Loss of the proton from the "i + 1" Gly residue of **2b**, yielding **3b**, is predicted to occur more easily than in the case of **2a**, with $pK_a = 6 \pm 2$. Structure **3b** is predicted to deprotonate from N_τ–H of the imidazole with $pK_a = 12 \pm 2$, yielding **5b**. Of the structures that could be derived by further deprotonation of a backbone N–H bond, the most stable is **4b**, which has an N3O pattern of coordination and three five-membered rings. The coordination direction of **4b** is "middle-reverse" and the His residue is not involved. Structure **4b** is predicted to be 94 ± 10 kJ mol^{-1} less stable than **3b** (at pH = 7, $\Delta G_{(aq)}$(**3b** → **4b** + H^+) = 54 ± 10 kJ mol^{-1}) and 27 kJ mol^{-1} less stable than **5b**.

GGHG structures

The pH-dependent origin of GGHG(**c**) structures is displayed in Fig. 5. As was the case with **2a**, the most stable coordination pattern, after loss of a single proton and three water molecules from **1c**, is a pentacoordinated "middle" structure, **2c**. However, **2c** differs in detail from **2a**. In **2c**, the deprotonated amide N–H bond is that of the preceding (i.e., i – 1) Gly residue, again leaving the two strong N donors

Fig. 5. GGHG(**c**)–Cu structures. Ball colours: green = Cu^{2+}; orange = C; blue = N; red = O. Free-energy changes, ΔG, are in units of kJ mol^{-1} in aqueous solution.



in a trans orientation in the copper coordination shell. Cis to the imidazole group is a neutral N atom of the His residue. The two remaining ligands are O atoms of the $i - 2$ Gly residue and of the His residue. The Cu–O bond lengths are 1.99 Å and 2.30 Å, respectively, indicating that the latter ligand is less strongly held and would probably be released in solution. Within 2 kJ mol^{-1} of **2c** is a second pentacoordinated structure, **2c′**, that differs in that the protonation states of the His and $i - 1$ Gly residues are reversed and the fifth coordinating O ligand is from the amidated C-terminus (formally the O atom of the $i + 2$ residue).

Loss of the proton from the N atom of the His residue of **2c** (or the $i - 1$ Gly residue of **2c′**) yields the neutral structure, **3c**, which also has the strong amide donor opposite the imidazole group and four-coordination with N3O1 ligand distribution in the reverse direction. Loss of the proton from **2c** or **2c′**, yielding **3c**, is predicted to occur very easily, with $pK_a = 5 \pm 2$. Structure **3c** is predicted to deprotonate primarily from the $i - 2$ Gly residue ($pK_a = 10 \pm 2$), yielding **4c**, and secondarily from N_τ–H of the imidazole ($pK_a = 12 \pm 2$), yielding **5c**. Structure **4c** has an N4 pattern of coordination with two five-membered rings and a six-membered ring.

GGGH structures

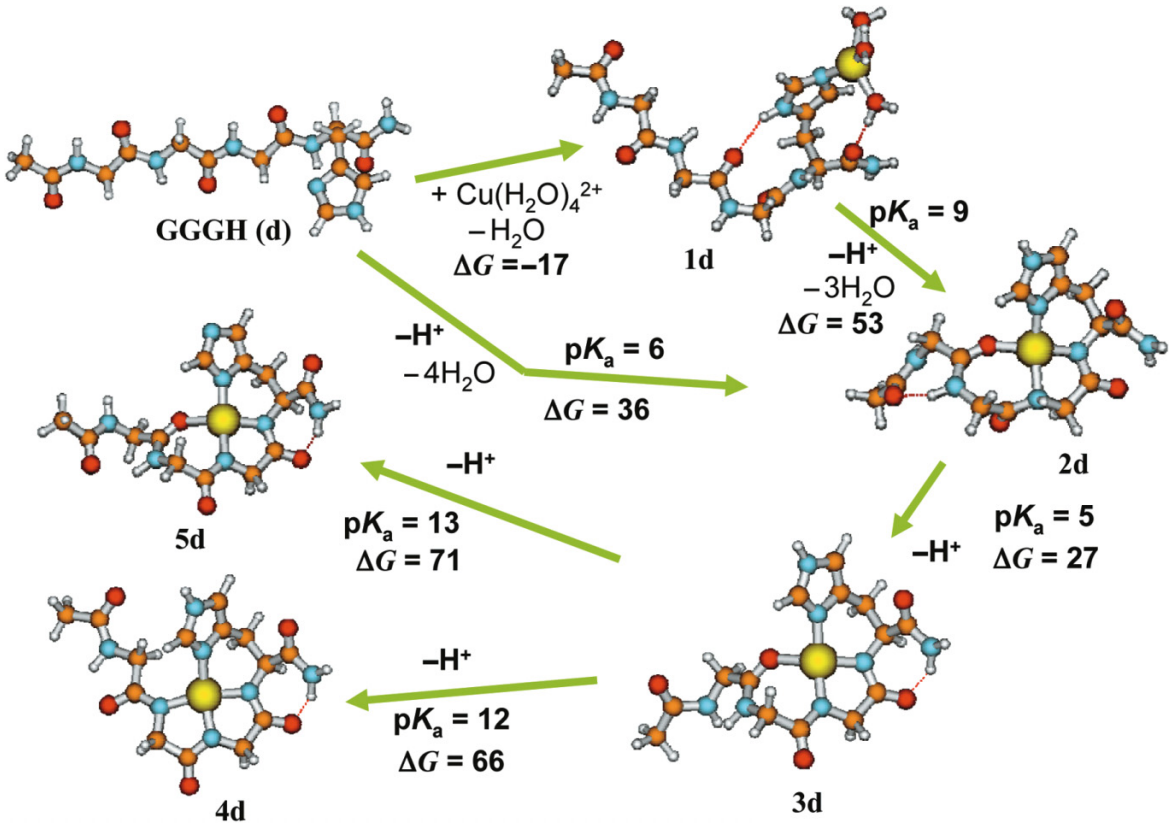
The pH-dependent origin of GGGH(**d**) structures is displayed in Fig. 6. The singly deprotonated structure **2d** is entirely analogous to **2c′**, except that it is four-coordinated in the reverse direction, rather than five-coordinated in the "middle-reverse" direction. In this case, the shorter C-terminus does not provide a weak fifth-coordinating ligand. Deprotonation of **2d** occurs with $pK_a = 5 \pm 2$ to yield **3d**, which has the same bonding characteristics as **3c**, namely coordination in the reverse direction with ligand pattern N3O1. Further deprotonation of **3d** is also entirely analogous to **3c**, with almost equal probability for proton loss from N_τ–H and $i - 2$ Gly residue, with the similar pK_a values, $pK_a = 12 \pm 2$, and $pK_a = 13 \pm 2$,yielding **4d** and **5d**, respectively. Like **4c**, structure **4d** has an N4 pattern of coordination with two five-membered rings and a six-membered ring.

Structural comparisons

Isomeric structures may be compared to each other. The relative aqueous free energies $\Delta G_{(aq)}$ of the most stable singly deprotonated species described above are (in kJ mol^{-1}): **2a**, 1; **2b**, 0; **2c**, 34; and **2d**, 33. The first two represent binding in the forward direction with configuration N2O2. The last two structures are bound in the reverse direction. Thus, in the case of singly deprotonated structures, binding in the forward direction is preferred.

The relative aqueous free energies $\Delta G_{(aq)}$ of the most stable doubly deprotonated species described above are (in kJ mol^{-1}): **3a**, 15; **3b**, 0; **3c**, 29; and **3d**, 27. Again, the first two represent binding in the forward direction, but with configuration N3O1. The last two structures are bound in the reverse direction, also with configuration N3O1. Thus, the neutral doubly deprotonated structures also prefer to bind in

Fig. 6. GGGH(**d**)–Cu structures. Ball colours: green = Cu^{2+}; orange = C; blue = N; red = O. Free-energy changes, ΔG, are in units of kJ mol^{-1} in aqueous solution.



the forward direction. The difference is most pronounced in the cases of GHGG(**b**) and GGHG(**c**), which could bind in either direction. The more stable structure **3b** has a five, five, seven ring system while the less stable structure **3c** has a six, five, seven ring system. The calculated difference in the enthalpies of the two ring systems is ΔH_{298} = 14 kJ mol^{-1}. The remaining 15 kJ mol^{-1} of the difference originates primarily from the higher entropy ($-T\Delta S$ = 10 kJ mol^{-1}) and slightly more favourable solvation ($\Delta\Delta G_{solv}$ = 5 kJ mol^{-1}) of **3b**, both contributions of which are due to the longer free peptide chain in the reverse direction.

The relative aqueous free energies $\Delta G_{(aq)}$ of the most stable anionic triply backbone-deprotonated species described above are (in kJ mol^{-1}): **4a**, 25; **4b**, 5; **4c**, 0; and **4d**, 5. There is no significant difference in stability among the last three structures. Structures **4c** and **4d** exemplify reverse binding and have an N4 coordination pattern. Both structures are favoured by enthalpy over structure **4a**, ΔH_{298} = –18 kJ mol^{-1} and ΔH_{298} = –24 kJ mol^{-1}, respectively. Structure **4b** is technically a middle-reverse binding pattern that has lost the imidazole as a ligand. It is the least stable by enthalpy in the gaseous phase, but a significantly higher free energy of solvation brings it into the same range as the reverse binding structures. Thus, the calculations suggest that at high pH there is a clear preference for backbone deprotonation in the reverse direction, which yields a five, five, six ring pattern as opposed to the five, five, seven ring pattern of forward binding.[18]

Relationship to experimental studies

Protonated imidazoles of His residues have pK_a values in the range 6–7.[42] The calculated pK_as of the present systems are: HGGG(**a**)H^+, 7.5; GHGG(**b**)H^+, 12; GGHG(**c**)H^+, 6;. GGGH(**d**)H^+, 5. Thus, the values of three of the His residues lie within the error in pK_a values (±2) expected due to uncertainties in relative aqueous free energies, but the His residue of GHGG(**b**)H^+ is outside of these bounds. The reason for this is unclear.

The capping at both ends of the peptide models permits direct comparison with previous spectroscopic and potentiometric titration studies on $AcHGGGNH_2$.[21] Similar studies have also been carried out on the related systems, AcHGGG, AcGHGG, AcGGHG, and AcGGGH, in which the C-terminus was a free carboxylate group.[20] The calculated free energies of binding (eq. [1], $\Delta G_{(1)}$ are (kJ mol^{-1}): **1a**, –6; **1b**, –23; **1c**, –8; **1d**, –17. The binding free energy of the first and third is close to zero; **1b** and **1d** are predicted to be bound in water.

An experimental value, –23 kJ mol^{-1}, is available[21] for the first coordination of Cu(II) to HGGG (**a**) yielding a 1:1 complex with +2 charge. The number of waters of coordination is unknown from the experiment. In the case of the HGGG(**a**) system, we examined the successive loss of water for the Cu(II)-bound system at low pH (i.e., with net charge = +2). The results are displayed in Fig. 4. The binding affinity of the most stable structure, **1a**‴, ΔG = –17 ± 10 kJ mol^{-1}, is in satisfactory agreement with ex-

periment, but is also within the overlapping error bars of **1a**. We conclude that it is not possible to determine computationally the degree of hydration of the species arising from the first attachment of the Cu(II) ion to HGGG(**a**) with the present level of theory. Consequently, we have not pursued this course with any of the other three systems, but rather take the N_τ-bound $Cu(II)(H_2O)_3$ species **1b**, **1c**, and **1d**, as being representative. For two of these, the calculated binding affinity **1b**, ΔG = –23 kJ mol^{-1}and **1d**, ΔG = –17 kJ mol^{-1}, agree well with the experimental values based on the stability constant reported for the 1:1 complex of Cu(II) with AcGHGG and AcGGGH.[20]

In the pH range 6.5–8.5, two Cu–$AcHGGGNH_2$ complexes, corresponding to singly and doubly deprotonated species, were observed potentiometrically and spectroscopically.[21] The relative abundance of the former was always less than 15% . These may be identified with **2a** and **3a**, respectively (Fig. 3). The pK_a for loss of the second proton, 6.25, is in satisfactory agreement with that calculated for **2a** → **3a** + H^+, 8 ± 2. ESI-MS revealed a signal corresponding to protonated and sodiated forms of a neutral 1:1 Cu–$AcHGGGNH_2$ complex that notably did not contain any coordinated water molecules. A recent ESI-MS study by one of us confirmed this observation.[43] Two structures consistent with EPR and MS data were proposed for the neutral species, both of N3O1 square-planar coordination in the tetragonal plane, but differing by which terminal carbonyl oxygen atom formed the fifth coordination site.[21] The present results suggest that the neutral complex corresponds to **3a**, which has a square-planar N3O1 coordination geometry, but does not have involvement of either terminal carbonyl oxygen in the coordination sphere of the copper. In solution, this site would be transiently occupied by a water molecule.

Similar potentiometric measurements were carried out on the free terminal carboxylate system, Cu–AcHGGG, by Orfei et al.,[20] with very similar results. In that case, pK_a = 6.96 was assigned for the loss of the second proton. These authors carried out gaseous-phase modeling using the semiempirical PM3 method on the "neutral" species (actually negatively charged because of the carboxylate group) and obtained the same square-planar N3O1 coordination geometry as in **3a**, with coordinating water ligands above and below the plane.[20] In our high-level ab initio study, the fifth and sixth ligands to Cu are not stable to exchange in solution.

Both Bonomo et al.[21] and Orfei et al.[20] detected a third ionization with pK_a = 8.9, yielding a species with a negative charge (ignoring the charge of the carboxylate group). Both groups interpreted the EPR spectra as consistent with N4 coordination, in which three deprotonated amide nitrogen atoms, as well as imidazole N atom were coordinated to copper in a square-planar arrangement. ESI-MS signals collected in negative mode proved the absence of water.[21] As shown in Fig. 3, we could find no species with N4 coordination in an accessible pH range. The lowest pK_a for loss of a third amide proton from **3a** is calculated to be pK_a = 17, yielding **4a**. The lowest energy negatively charged species originates from loss of the remaining proton of the imidazole group, namely **5a**, which is formed from **3a** with pK_a = 10 ± 2. The calculated pK_a is essentially equal to the observed pK_a. Thus our data suggest that it is the imidazole that is the source of the third deprotonation, rather than a third amide group. As we show below, this conclusion is also supported by CD data. We have no explanation for the discrepancy with the EPR results.

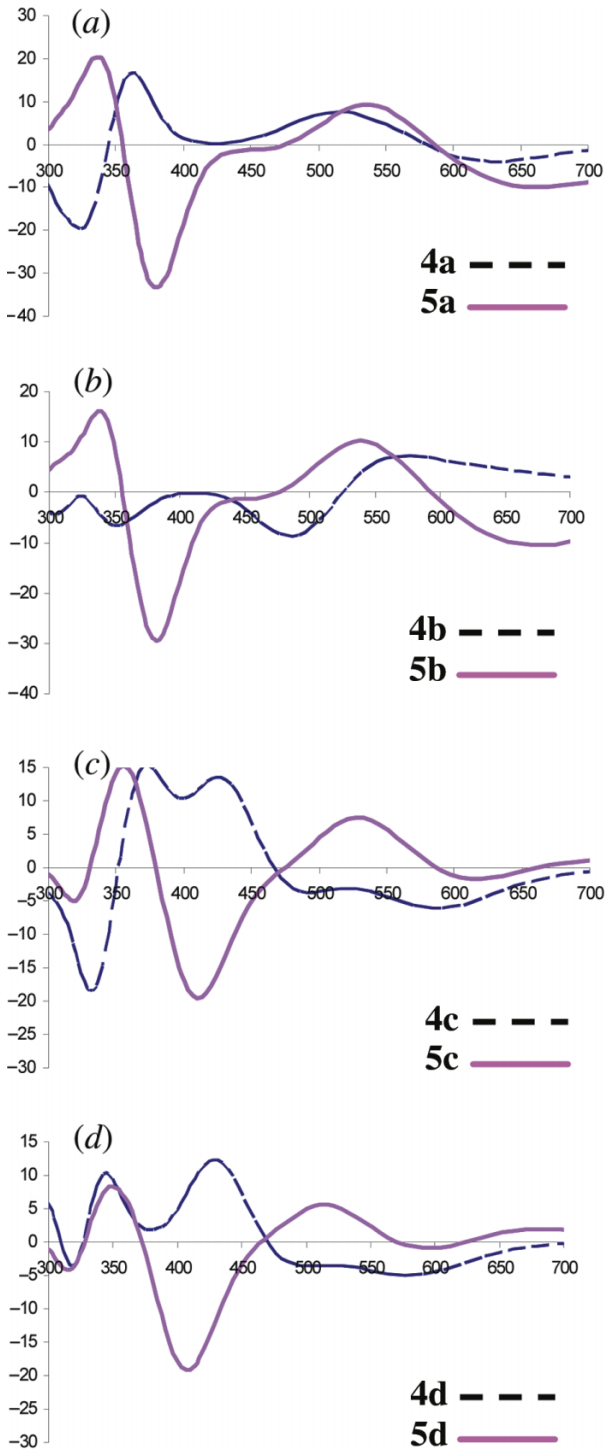
As well as AcHGGG, Orfei et al., also examined the pH-dependent evolution of structures of Cu(II) complexes with AcGHGG, AcGGHG, and AcGGGH.[20] The stability constants for formation of a putative 1:1 Cu–peptide complex without loss of any protons were similar among all of the species, and correspond to free-energy changes in the narrow range –25 kJ mol^{-1} to –27 kJ mol^{-1}, as mentioned above. For each of these, the loss of the first proton produced a species in minor abundance compared to that derived from loss of two protons. pK_a values for both processes for all systems were in the narrow range of 6–7. We would assign structures **2b**, **2c**, and **2d** to the former and **3b**, **3c**, and **3d**, to the latter. However, we find some variability in the energetic parameters among the three systems, and the calculated data for the Cu(II)–GHGG(**b**) system, shown in Fig. 2, does not fit the observed pattern for the free terminal carboxylate systems. Experimentally, the third ionization in the case of the Cu–AcGHGG system was anomalous but the first two were not. In the case of Cu–AcGGHG and Cu–AcGGGH, as for Cu–AcHGGG, the third ionization occurred with a pK_a below 9 units, but the third ionization in the AcGHGG system had an apparent pK_a 2 units higher, and was attributed either to ionization of a bound water molecule or the imidazole.[20] An N4-coordinated pattern was not seen by EPR. In our study, the Cu–GHGG(**b**) system is unusual in several respects. Single and double deprotonation, yielding **2b** and **3b**, respectively, is predicted to occur at pH < 6. The most acidic proton of **3b** is found to be the imidazole proton, as it was in the case of **3a** but 2 pK_a units higher. The lowest energy structure that has three amide groups deprotonated is **4b**, in which the imidazole group is not coordinated to the Cu(II). This complex is 27 kJ mol^{-1} higher in energy than **5b**. By way of contrast, in both the Cu–GGHG(**c**) (Fig. 5) and Cu–GGGH(**d**) (Fig. 6) systems, the third ionization occurs with slightly higher probability from a third amide than from the imidazole group, and with very similar acidity constants.

Circular dichroism data

Orfei et al.[20] found that the high-pH CD spectra of the Cu–AcGGHG and Cu–AcGGGH systems displayed evidence of an identical chromophore. The spectra are dominated by a pair of oppositely signed bands of nearly equal intensity: Cu–AcGGHG, 600 nm (–), 500 nm (+); Cu–AcGGGH, 600 nm (–), 500 nm (+). Distinctly different chromophores were observed in the CD spectra at high pH of Cu–AcHGGG and Cu–AcGHGG. These both showed negative rotatory strength above 700 nm, a positive band near 600 nm, and a negative band near 520 nm.

To seek an explanation for the different CD spectra at high pH, we applied TD-B3LYP/6–31G(d) methodology to calculate and simulate the aqueous CD spectra of the triply deprotonated amide structures, **4a**, **4c**, and **4d**, as well as the imidazole deprotonated forms, **5a**, **5b**, **5c**, and **5d**, and the imidazole-released form, **4b**, in the spectral range studied by Orfei et al. The simulated CD spectra are displayed in Fig. 7, using Gaussian lineshapes with a half width of 0.37 eV (100 nm for a peak centred at 600 nm). Seven to

Fig. 7. Simulated CD spectra by TD-B3LYP/6–31G(*d*) in the presence of solvent reaction field: (*a*) HGGG structures **4a** and **5a**; (*b*) GHGG structures **4b** and **5b**; (*c*) GGHG structures **4c** and **5c**; (*d*) GGGH structures **4d** and **5d**.



ten electronic transitions are predicted to occur on the spectral range 300–700 nm. The simulated CD spectra of the N4 species **4c** and **4d** are very similar to each other, but are qualitatively different from **4a**. The former have negative rotatory strength in the range 450–700 nm, while **4a** has a bisignate feature in the range with positive rotatory strength near 500 nm. **4b** is different again, with a negative CD band at 490 nm and positive intensity above 520 nm. The imidazole-deprotonated systems are distinct from the N4 systems. The spectra of **5c** and **5d** are almost identical to each other with CD pattern (right to left) weak (+), weak (–), medium (+), strong (–), and medium (+). The parallel systems **5a** and **5d** also have a similar pattern but have larger CD intensity in the 450–700 nm range.

Because of the limitations of the theoretical method and the fact that the systems are different, we do not expect a perfect match between our simulated spectra and the experimental spectra of Orfei et al. Nevertheless, *some* of the computed spectra reproduce the main spectral features of the experimental ones very well. For the N4 systems, **4c**, and **4d** (dashed lines in Figs. 7*c* and 7*d*), the dominant characteristic is bisignate, as are the experimental high-pH CD spectra of Cu–AcGGHG and Cu–AcGGGH, with positive rotatory strength to short wavelength and negative to longer. The calculated spectra are more complex in appearance than the experimental spectra, but reveal the multiple-transition origin of the deceptively simple spectra. The calculated spectra for the imidazole-deprotonated species **5c** and **5d** do not match the experimental spectra, thereby confirming the N4 coordination pattern for the high-pH species of the GGHG and GGGH species.

In the case of the GHGG system, the simulated CD spectrum of **5b** exactly matches the sign sequence of the experimental high-pH spectrum of Cu–AcGHGG although all the peaks are shifted to shorter wavelength. The spectrum of **4b** is very different. Thus the spectroscopic as well as energetic calculations are consistent with an imidazole-deprotonated structure for this system.

The most troublesome system is HGGG at high pH. Both Bonomo et al.[21] and Orfei et al.[20] found clear indications of N4 coordination in Cu–AcHGGGNH$_2$ and Cu–AcHGGG, respectively, by EPR. However, our calculations suggest that the most stable N4 system, **4a**, is energetically disfavoured compared to the imidazole-deprotonated species, **5a**, which has N3O1 coordination. Also the CD data of Orfei et al.[20] are quantitatively different from Cu–AcGGHG and Cu–AcGGGH which were clearly assigned as N4 above. The simulated CD spectrum of **4a** is also quantitatively different from that of **4c** and **4d**. The difference is probably due to the different direction of coordination, forward, as apposed to reverse. In our opinion, there is a better match between the experimental CD spectrum of Cu–AcHGGG obtained by Orfei et al and our simulated spectrum of **5a**. Thus, our energetic and spectroscopic calculations both point to an imidazole-deprotonated structure, **5a**, for both Cu–AcHGGG and Cu–AcHGGGNH2 at pH > 11. The discrepancy between the EPR and CD data could be resolved if the different spectroscopic techniques were sensitive to different species in solution. However, we have been unable to find an N4 species analogous to **4a** in an accessible energy range.

Summary and conclusions

The structures and relative free energies in aqueous solution of the Cu(II) complexes of the peptides, AcHGGGNH$_2$ (HGGG(**a**)), AcGHGGNH$_2$ (GHGG(**b**)), AcGGHGNH$_2$ (GGHG(**c**)), and AcGGGHNH$_2$ (GGGH(**d**)) were deter-

mined as a function of pH. Numerous structures of each species were found by gaseous phase geometry optimization and the effect of solvation estimated by the IEFPCM continuum solvation model. Free energies of solvation of the ionic species are large and favour structures with an extended peptide chain. It is rare that the most stable gaseous-phase structure is also the most stable in the aqueous phase. The solvation procedure gives satisfactory results for neutral and cationic species, but undersolvates anionic species, as judged against experimental observations at pH ≥ 8.

At low pH, the tetraaquo Cu(II) ion attaches to a single N atom of the imidazole group with the expulsion of one or more waters of coordination. In Cu–HGGG(**a**), for which all possible levels of hydration were examined, the most stable structure, **1a**‴, had no waters in the copper coordination shell, a result consistent with ESI-MS.[21,43]

In all Cu(II)–peptide complexes, deprotonation of two amide groups occurs readily at or even below physiological pH = 7. The first N–H bond to ionize is that which places the amide N atom in a trans orientation to the imidazole N atom, in the forward direction in the case of HGGG(**a**) and GHGG(**b**) (the i + 2 Gly), and in the reverse direction in the case of GGHG(**c**) and GGGH(**d**) (the i – 1 Gly). The intervening amide group in protonated form and the carbonyl of the i ± 2 Gly complete the coordination sphere of the Cu(II). The second ionization then occurs from the intervening amide group to yield a neutral 1:1 complex with N3O1 coordination pattern as the most abundant species at pH = 7.

In the case of both singly and doubly deprotonated structures, binding in the forward direction is preferred. The observation of forward binding in the crystal structure of the octarepeat region of the prion protein was tentatively attributed to the blocking effect of the proline residue immediately preceding the His. The present results suggest that forward binding would be the preferred mode in any case. It should be noted however, that it is not possible to determine the effect of side-chain interactions on the direction of binding from the present models.

The computed relative free energies of the various ionized species in the Cu–HGGG(**a**) system are in good agreement with the experimental potentiometric studies of Bonomo et al.,[21] with the exception that ionization of the third proton, which was attributed to a third amide group and observed at pH ≈ 9, is calculated to come from the imidazole at similar pH (pK_a = 10). Simulated CD spectra of the candidate high-pH species support this result.

Supplementary data

Supplementary data for this article (Table S1: Primary computed data for all species: energies, zero-point energies, thermal corrections to the enthalpy, entropies, numbers of conformations and free energies of solvation; Table S2: CD spectral data for **4a**, **5a**, **4b**, **5b**, **4c**, **5c**, **4d**, and **5d**) are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 3933. For more information on obtaining material, refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml. Geometries are available upon request.

^{1}H chemical shifts in nonaxial, paramagnetic chromium(III) complexes — Application of novel pNMR shift theory[1]

Helmi Liimatainen, Teemu O. Pennanen, and Juha Vaara

Abstract: We present the first chemical application of the recent, general theory of the nuclear magnetic resonance shielding and chemical shift in paramagnetic compounds, to a set of nonaxial high-spin metallo-organic complexes. The theory is for the first time rigorous for systems of arbitrary spatial and spin symmetry, and introduces new structure to the isotropic, anisotropic but symmetric, and anisotropic and antisymmetric parts of the shielding tensor. We apply the theory using density functional calculations of the proton chemical shift in a family of nonaxial chromium(III) complexes possessing a quartet ground electronic spin state. We discuss the various contributions to the isotropic chemical shift, and compare the full theory to approximate forms appropriate to the doublet case on the one hand, and to the doublet case at the nonrelativistic limit, on the other hand. The performance of various exchange-correlation functionals in reproducing the recently measured experimental chemical shifts is evaluated.

Key words: paramagnetic NMR, chemical-shift calculation, nonaxial, high spin, density functional theory.

Résumé : La récente théorie générale du blindage et du déplacement chimique, en résonance magnétique nucléaire, des composés paramagnétiques a été appliquée pour la première fois à un ensemble de complexes organométalliques de spin élevé et non axiaux. La théorie est la pour la première fois rigoureuse pour des systèmes de symétrie spatiale et de spin arbitraire et elle introduit une nouvelle structure pour les portions isotropes, anisotropes mais symétriques et anisotropes et antisymétriques du tenseur de blindage. On a appliqué la théorie dans des calculs de fonctionnelle de la densité du déplacement chimique du proton dans une famille de complexes non axiaux du chrome(III) possédant un état de spin électronique fondamental quadruplet. On discute des diverses contributions au déplacement chimique isotrope et on les résultats obtenus avec la théorie complète avec ceux obtenus avec des versions approximatives appropriées, d'une part, au cas des doublets et, d'autre part, au cas des doublets à la limite non relativiste. On évalue la performance des diverses fonctionnelles d'échange de corrélation pour reproduire les déplacements chimiques expérimentaux mesurés récemment.

Mots-clés : RMN paramagnétique, calcul du déplacement chimique, non axial, spin élevé, théorie de la fonctionnelle de densité.

Introduction

Nuclear magnetic resonance (NMR) of paramagnetic substances possessing unpaired electrons (pNMR) is gaining importance in studies of magnetic matter ranging from bioinorganic chemistry[2] to materials science.[3] From the point of view of modern electronic structure theory, the field of calculation of the spectral parameters of pNMR is still in its infancy, as compared to the extensive knowledge on diamagnetic systems.[4–6]

Theory and methods of systematic quantum chemical calculation of the pNMR chemical shift, δ, have emerged during the last few years, starting from the nonrelativistic (NR) approach for doublet systems with one unpaired electron.[7] This level involves the orbital shielding, $\boldsymbol{\sigma}_{\mathrm{orb}}$, that is analogous to the closed-shell nuclear shielding, as well as the explicitly temperature-dependent, fully isotropic contact and fully anisotropic dipolar shielding contributions, $\sigma_{\mathrm{con}}\mathbf{1}$ and $\boldsymbol{\sigma}_{\mathrm{dip}}$, respectively. The latter terms arise from the hyperfine interaction of nuclei with thermally averaged electron spin density.[8] Moon and Patchkovskii[9] presented a framework for systematic extension of the theory to higher-order spin-orbit (SO) interaction-induced effects. These arise from the deviation $\Delta\mathbf{g} = \mathbf{g} - g_{\mathrm{e}}\mathbf{1}$ of the $\mathbf{g}$ tensor, used to parameterize the electronic Zeeman interaction, from the isotropic free-electron factor, g_{e}. Two more experimentally relevant terms arising from the anisotropic part of $\Delta\mathbf{g}$ were captured by the approach, namely the anisotropic contact shielding, $\boldsymbol{\sigma}_{\mathrm{c,aniso}}$, and the pseudocontact shielding, $\boldsymbol{\sigma}_{\mathrm{pc}}$, which also contributes to the isotropic shielding constant, σ.[10,11] Two of the present authors added SO corrections to the hyperfine coupling, $\mathbf{A}$, with the result that systematic light-atom shieldings in heavy-element-containing doublet systems became accessible.[12]

Extension of the pNMR shift theory to systems with more than one unpaired electron requires the incorporation of the effect of zero-field splitting (ZFS) on the spin-Zeeman sub-

levels.[13] The first, approximate attempt in this direction was made by Hrobárik et al.[14] who applied a posteriori corrections to the calculated contact and dipolar shifts, formulated using the spin susceptibility tensor as an intermediate physical quantity. These authors were limited to systems possessing cylindrical spatial symmetry in their approach.

Recently, Pennanen and Vaara[15] modified the approach of Moon and Patchkovskii[9] and obtained a general expression for the pNMR shielding tensor for an arbitrary number of unpaired electrons and for an arbitrary spatial symmetry. The theory, which can be viewed as the extension of the Ramsey theory of nuclear shielding[16,17] to the open-shell situation, generalizes the symmetry of all the hyperfine shielding terms present in the doublet case.[9,12,14] In particular, several new contributions to the isotropic chemical shifts arise.[15]

In this paper we present the first chemical applications of the new theory of pNMR chemical shift, and calculate using density functional theory (DFT) the ^{1}H shifts in a family of quinolyl-functionalized Cp chromium(III) complexes, which was recently investigated experimentally by Enders and coworkers.[18] The studied complexes are illustrated in Chart 1. These $S = 3/2$ systems are of interest in studies of olefin polymerization catalysts. In ref. 18, DFT results at the B3LYP/6-311G(d) level[19–21] for the spin densities at the ^{1}H nuclei were related to the experimental hyperfine shifts. Such an approach is based on the, as such, rather realistic assumption that the contact shielding, σ_{con}, dominates the hyperfine contributions to σ.

Due to the theory presented in ref. 15, chemical shifts in such nondoublet, nonaxial open-shell molecules have now for the first time become accessible to systematic quantum chemical investigation, in which a more complete analysis in terms of the various physical contributions can be carried out. Here we present such an analysis based on a DFT implementation of the new theory,[15] and discuss the results in terms of the errors made assuming the doublet (neglecting ZFS)[12] and NR[7] theories. Furthermore, we investigate the dependence of the calculated shifts on various computational factors: selection of the basis set and exchange-correlation functional, as well as the choice between experimental X-ray[18,22] and computationally optimized molecular structures. Finally, we present linear regression fits correlating the experimental ^{1}H shifts[18] based on this more complete theoretical level than applied previously.[18]

Theory

The analysis of ref. 15 resulted in the following expression for the magnetic field independent part of the nuclear shielding tensor in open-shell, paramagnetic molecules:

$$\boldsymbol{\sigma} = \boldsymbol{\sigma}_{\mathrm{orb}} - \frac{\mu_{\mathrm{B}}}{\gamma k T}\mathbf{g}\cdot\langle\mathbf{SS}\rangle_0\cdot\mathbf{A}$$

$$\langle\mathbf{SS}\rangle_0 = \frac{\sum_n \langle n|\mathbf{SS}|n\rangle \exp\left(-E_n(0)/kT\right)}{\sum_n \exp\left(-E_n(0)/kT\right)}$$

where μ_{B}, γ, and k in the hyperfine part of the shielding (the second term on the right-hand side of the first line) are the Bohr magneton, gyromagnetic ratio of the investigated nucleus, and the Boltzmann constant, respectively. **S** is the effective spin operator used in the analysis of electron spin resonance (ESR) spectra, and the product **SS** is on the second line Boltzmann-averaged in the manifold of states, $|n\rangle$, consisting of the ground-state spin multiplet. Any excited states that are thermally accessible from the ground state would also have to be included in the averaging. In a $S = 3/2$ system, such as the present Cr(III) complexes, and neglecting electronically excited states, there are four states, $|n\rangle$, and energies, $E_n(0)$, that can be obtained by diagonalizing the ZFS part of the ESR Hamiltonian:

$$H_{\mathrm{ESR}}(0) = \mathbf{S}\cdot\mathbf{D}\cdot\mathbf{S}$$

g, **A**, and the ZFS tensor, **D**, are obtained from quantum chemical calculations, and the states, $|n\rangle$, are easily obtained in the basis of the eigenfunctions of S_z. The zero argument refers both to the absence of strong hyperfine couplings and considering the limit of vanishing magnetic field, $\mathbf{B}_0 = \mathbf{0}$. The isotropic shielding constant and chemical shift are obtained in the usual fashion as

$$\sigma = (\sigma_{xx} + \sigma_{yy} + \sigma_{zz})/3$$
$$\delta = \sigma_{\mathrm{ref}} - \sigma$$

where σ_{ref} is the shielding constant of a suitable, closed-shell reference compound.

Chart 1. Studied chromium complexes.

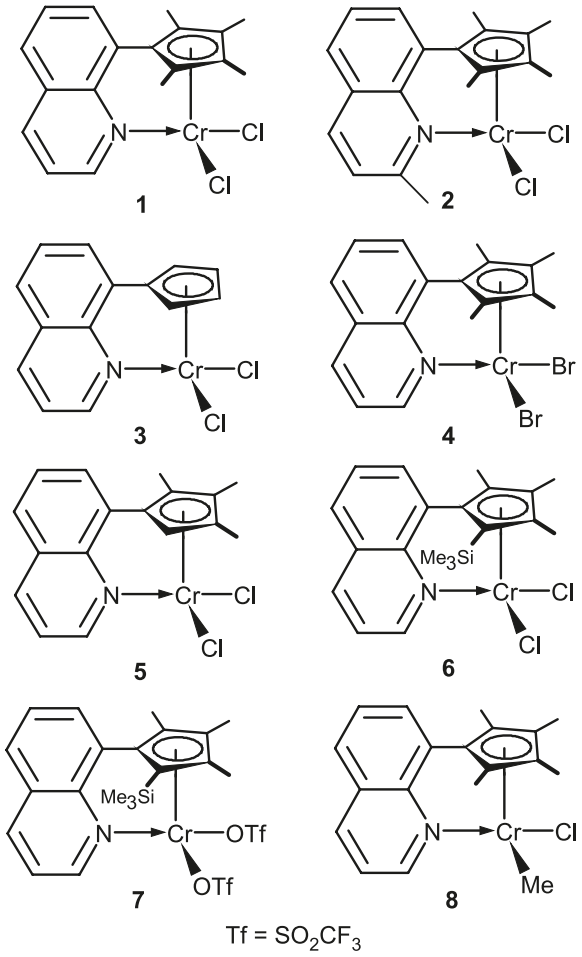

Table 1. Decomposition of the paramagnetic nuclear shielding to isotropic chemical-shift contributions.

Shift symbol	Term in $\sigma_{\varepsilon\tau}$[a]	Isotropic shift contribution		
		Full theory[b]	Doublet theory[c]	NR theory[d]
δ_{orb}	$\sigma_{\varepsilon\tau}^{orb}$	Yes	Yes	Yes
δ_{con}	$g_e\langle S_\varepsilon S_\tau\rangle_0 A_{con}$	Yes	Yes	Yes
δ_{dip}	$g_e\Sigma_b\langle S_\varepsilon S_b\rangle_0 A_{b\tau}^{dip}$	Yes	0	0
$\delta_{con,2}$	$g_e\langle S_\varepsilon S_\tau\rangle_0 A_{PC}$	Yes	Yes	—
$\delta_{dip,2}$	$g_e\Sigma_b\langle S_\varepsilon S_b\rangle_0 A_{b\tau}^{dip,2}$	Yes	0	—
δ_{ac}	$g_e\Sigma_b\langle S_\varepsilon S_b\rangle_0 A_{b\tau}^{as}$	0	0	—
$\delta_{con,3}$	$\Delta g_{iso}\langle S_\varepsilon S_\tau\rangle_0 A_{con}$	Yes	Yes	—
$\delta_{dip,3}$	$\Delta g_{iso}\Sigma_b\langle S_\varepsilon S_b\rangle A_{b\tau}^{dip}$	Yes	0	—
$\delta_{c,aniso}$	$\Sigma_a\Delta\tilde{g}_{\varepsilon a}\langle S_a S_\tau\rangle_0 A_{con}$	Yes	0	—
δ_{pc}	$\Sigma_{ab}\Delta\tilde{g}_{\varepsilon a}\langle S_a S_b\rangle A_{b\tau}^{dip}$	Yes	Yes	—

Note: The entry "yes" means that a nonvanishing contribution to δ arises from the term in question at the level considered, "0" denotes that the contribution is rigorously zero, and "–" indicates that the shielding term does not appear at all in the shielding tensor at this level.

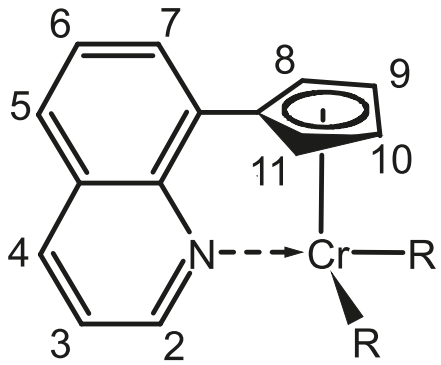
[a]For the hyperfine terms, the contribution to the product $\mathbf{g}\cdot\langle\mathbf{SS}\rangle_0\cdot\mathbf{A}$ is indicated.

[b]General theory for arbitrary spin state,[15] neglecting hyperfine terms beyond the fourth order in the fine structure constant, $O(\alpha^4)$.

[c]Terms resulting from the doublet theory[12] where the symmetric $\langle\mathbf{SS}\rangle_0$ matrix reduces to the isotropic diagonal matrix $S(S+1)\mathbf{1}/3$.

[d]Nonrelativistic terms,[7] neglecting any terms beyond $O(\alpha^2)$.

Chart 2. Numbering of the ^{1}H nuclei in molecules **1**–**8**.



For light NMR nuclei in the presence of heavy-element or transition-metal compounds, it is convenient to analyze the hyperfine part of the shielding expression by performing a breakdown of **g** and **A** to the leading-order parts and the first-order corrections arising from the SO interaction.[9,12,14,15] For the Zeeman interaction, the **g** tensor can be decomposed as

$$\mathbf{g} = g_e\mathbf{1} + \Delta g_{iso}\mathbf{1} + \Delta\tilde{\mathbf{g}}$$

into the isotropic free-electron contribution (the first term) and the *g* shift. It is advantageous to consider the latter in separate isotropic and anisotropic parts, Δg_{iso} and $\Delta\tilde{\mathbf{g}}$, respectively. The hyperfine coupling tensor can be analogously analyzed as

$$\mathbf{A} = A_{con}\mathbf{1} + \mathbf{A}_{dip} + A_{PC}\mathbf{1} + \mathbf{A}_{dip,2} + \mathbf{A}_{as}$$

where the first two terms on the right-hand side are the nonrelativistic, isotropic contact and anisotropic dipolar couplings, respectively. The remaining terms are the isotropic (PC: "pseudocontact", not to be confused with the pseudocontact shift of pNMR), anisotropic but symmetric (dip,2), and antisymmetric (as) contributions that arise due to the relativistic SO correction.[23] Table 1 lists the contributions to the isotropic chemical shift after performing the breakdown. Besides the terms present in the full theory,[15] we also show the shift contributions resulting from an application of the doublet theory[12] as well as the result of limiting ourselves to the NR terms.[7]

Experimentally, δ_{orb} is often approximately eliminated by using a corresponding diamagnetic compound as a secondary shift reference. The true leading-order contact shift, δ_{con}, cannot be experimentally distinguished from the mathematically similar $\delta_{con,2}$ and $\delta_{con,3}$ arising from SO corrections to **A** and **g**, respectively. The pseudocontact term, δ_{pc}, arises from the interplay of anisotropic *g*-shift ($\Delta\tilde{\mathbf{g}}$) and dipolar hyperfine interaction and is useful in structure determination due to the dependence of $\mathbf{A}_{dip}$ on the molecular geometry.[2] Besides these contributions, the general shift theory[15] predicts a number of terms, the isotropic parts of which can be intermixed with δ_{pc}:δ_{dip} (the leading-order dipolar term), $\delta_{dip,2}$ and $\delta_{dip,3}$ (SO-corrections to **A** and **g**, respectively), and $\delta_{c,aniso}$ that is misleadingly termed the "anisotropic" contact term due to the property of this contribution for doublet systems. Consequently, the experimental analysis of chemical shifts based on

$$\delta = \delta_{orb} + \delta_{con} + \delta_{pc}$$

unavoidably hides interesting details that affect the quantitative, potentially also qualitative, results of, e.g., structural studies. With quantum chemical calculations it is possible to unearth the full structure of the contributions. In this con-

text, the errors arising from analyzing either computational or experimental data for $S > 1/2$ systems in terms of the doublet theory, are also of interest.

Computational details

The starting geometries for molecules **1** and **4**–**8** were obtained from the X-ray studies reported in refs. 18 and 22. Structures for molecules **2** and **3** were generated using the molecular modeling program Maestro.[24] Geometry optimization was carried out with the BP86 exchange-correlation functional[25,26] with the def2-TZVP basis set.[27] We used the Turbomole program,[28] except for partial optimizations where only hydrogen positions were optimized. In the latter calculations, GAUSSIAN 03[29] was used. The optimized structures are available in the Supplementary data.

For calculating the pNMR chemical shift corresponding to the new theory, we used two different quantum chemical programs and combined the results and completed calculations with the independent stand-alone code by Pennanen.[15] DFT in the unrestricted Kohn–Sham formulation was applied to **g**, **A**, and **D** using the ORCA package[30] as described in refs. 31– 33, respectively. The orbital shielding was obtained using similar methods in GAUSSIAN 03.[29] The calculated shieldings were averaged between the experimentally equivalent nuclei in the methyl groups on the one hand and in the Cp ring on the other hand. The individual ^{1}H nuclei, particularly in the methyl rings, have different spin densities and, hence, different shifts at the optimized molecular structure. These minimum-energy positions can be viewed as instantaneous locations of the hydrogens in the rotational trajectory of the methyl groups, and averaging them represents an approximation to a full rotational analysis of the ^{1}H shift.

Various basis sets were tested for molecules **1** and **4** with the PBE[34] exchange-correlation functional. The Huzinaga–Kutzelnigg HII-HIV (also known as IGLO II-IV) basis sets[35] were used for the main group elements. For Br we used the primitive set by Fægri and Almlöf,[36] contracted and polarized in the same spirit as the Huzinaga–Kutzelnigg sets. For chromium we used (in the [primitive/contracted] notation) the [15s11p6d/9s7p4d] basis by Munzarová and Kaupp,[37] when the main group elements were represented with the HII or HIII basis sets. The HII sets are [5s1p/3s1p] for H, [9s5p1d/5s4p1d] for C, N, and O, [11s7p2d/7s6p2d] for Si, S, and Cl, and [16s13p10d/11s10p10d] for Br. At the HIII level the basis sets are, in the corresponding order, H: [6s2p/4s2p], C–O: [11s7p2d/7s6p2d], Si–Cl: [12s8p3d/8s7p2d], and Br: [16s13p11d/12s11p11d]. We constructed a larger [15s11p6d3f1g/11s9p6d3f1g] basis for chromium for use with the HIV basis for main group elements. This was done by uncontracting the most diffuse functions and introducing three new f-type functions and one g-type function. The new exponents were obtained from the cc-pVTZ and cc-pVQZ[38] basis sets. The HIV basis sets are H: [6s3p1d/5s3p1d], C–O: [11s7p3d1f/8s7p3d1f], and Si–Cl: [12s8p4d2f/9s8p4d2f].

Chemical shifts were calculated for molecules **1** and **4** with different exchange-correlation functionals to find out about the sensitivity of the results for this choice. HII basis was used. The tested functionals contained two generalized gradient approximation (GGA) functionals, PBE and BLYP,[26,39] and three hybrid functionals, PBE0,[34] B3LYP, and BHandHLYP.[19]

For the chemical shifts we used tetramethylsilane (TMS) as the diamagnetic reference molecule, for which orbital shieldings were calculated with GAUSSIAN 03 using the different exchange-correlation functionals and basis sets. The optimized BP86/def2-TZVP structure was employed. The calculated shielding constants at PBE/HII, PBE/HIII, and B3LYP/HII levels are 31.61, 31.36, and 31.84 ppm, respectively.

Results and discussion

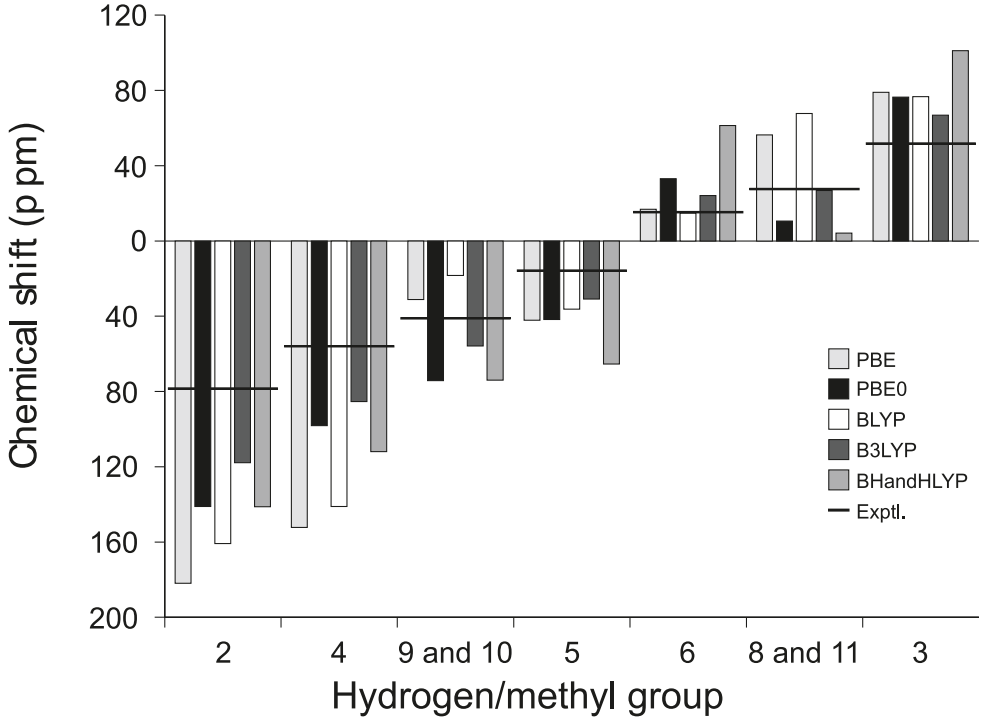
The hydrogen sites are numbered in Chart 2.

Selection of basis set

The choice of the basis set must be made between accuracy and cost. Basis sets were tested for molecules **1** and **4** at the PBE level. The results are listed for molecule **1** in Table 2 (similar observations apply for molecule **4**). Mainly the valence region is improved by changing the basis between the HII, HIII, and HIV levels. The t1–t4 specification indicates the addition of 1–4 sets of tight s- and p-type primitives to the hydrogen basis to improve the description of the spin density around these centers. The tested basis sets imply that the smallest basis set, HII, gives values as accurate as the largest basis sets, due to error cancellation. The best results as compared to the experimental data[18] are obtained with the HIII basis set. For molecule **1**, and the shift at site 4, a result improved by 17.4 ppm is obtained with HIII as compared to the HII level. A reduction of the absolute value of the shift occurs between the HII and HIII sets, amounting on average to 6.7 ppm for molecule **1**.

We will mainly use the compact HII set in the following discussion, but return to the semi-empirical best choice of the HIII basis in our final results.

Fig. 1. [1]H chemical shift in molecule **1** calculated with different exchange-correlation functionals using the HII basis set.



Selection of functional

Different exchange-correlation functionals have a larger impact on our results than the basis set. The comparison of shifts with different functionals is presented for molecules **1** and **4** in Figs. 1 and 2, respectively, with the HII basis. These molecules were selected because all the other molecules behave similarly to molecule **1**, whereas the Br atoms in molecule **4** affect the spin density distribution significantly. From Figs. 1 and 2 we can see that, in comparison to experiment, the best agreement is obtained with the B3LYP hybrid functional. In general, the computations exaggerate the [1]H shift range and the performance of the hybrid functionals (PBE0 and B3LYP) is better than that of the corresponding GGAs (PBE and BLYP). On the other hand, BHandHLYP is seen to fail completely for molecule **4**.

The principal values of the **g** and **D** tensors are listed for molecule 4 in Table 3. Changes between the functionals occur particularly in **D**. We see that the principal values of **D** change very much from the 20%–25% admixture of exact exchange in B3LYP and PBE0 to the 50% fraction in BHandHLYP. The last functional gives an unrealistically large anisotropy of **D**. The spin contamination was not found to change alarmingly between the functionals. The value of S^2 deviated only slightly from the formal value of 3.75.

Impact of geometry on chemical shift

Calculations were carried out for molecules 1 and 4 with three kinds of geometries. We used a fully computationally optimized structure, a structure where only the hydrogens were optimized while the other nuclei retained the X-ray positions, and the experimental X-ray structure for all nuclei. The last one was also used as the starting geometry of the optimizations. The results are listed in Table 4. For most shifts the best results are obtained with hydrogen-optimized structures, although no clear trends for a general improvement of the results can be distinguished.

Among the computational parameters that we vary in the present paper, exchange-correlation functional, basis set, and geometry, by far the greatest sensitivity of the calculated shifts is noted with respect to the choice of the functional. Besides these sources of deviation from the experimental data, solvation effects and rovibrational dynamics are expected to contribute. We do not presently model either of these effects.

Breakdown into chemical-shift terms

The different physical contributions to the chemical shifts (listed in Table 1) are broken down for molecules **1** and **4** in Tables 5 and 6, respectively. The δ_{ac} term is omitted from the tables because its contribution to the isotropic shift is zero. The largest contributions are expectedly the NR contact and orbital terms, which are numerically correctly taken into account also in the doublet theory. By far the dominating new term is δ_{dip} whose magnitude varies from 0.03 ppm to over 16 ppm. For most chemical shifts in molecules **1** and **4**, this contribution clearly exceeds the magnitude of the pseudocontact shift. It is noteworthy that in the presence of zero-field splitting, the δ_{dip} term encodes structural information of the paramagnetic molecule in a manner analogous to the δ_{pc} contribution in the more conventional analysis of pNMR spectra. Both cases share the same spin-dipole hyperfine interaction depending on the length and orientation of the vector joining the resonant NMR nucleus to the center of the electron spin density distribution. However, the role of the spin susceptibility tensor of the analysis of the pseudocontact term[2] is acquired by **D** in the novel δ_{dip} term, for $S \geq 1$ systems.

The other novel dipolar terms, $\delta_{dip,2}$ and $\delta_{dip,3}$, as well as the anisotropic contact term, $\delta_{c,aniso}$, are negligible for [1]H in the present systems. In contrast, the contact terms arising from the SO corrections to the hyperfine and Zeeman interactions, $\delta_{con,2}$ and $\delta_{con,3}$, respectively, both obtain significant values, comparable to the pseudocontact contribution. The con,2 and con,3 contributions are already present in the doublet theory of ref.12.

The overall difference between molecule **4** and the other systems appear to be the enhancement of hyperfine shift terms other than the NR contact term, brought about by the Br centers of molecule **4**. This is reflected in a dramatic order of magnitude increase of the anisotropy of the ZFS tensor, e.g., from molecule **1** to molecule **4**, originating in the spin-orbit contribution to **D**. In contrast, the **g** tensor is much less influenced by the replacement of Cl by Br.

Full theory and approximations

The effect of the choice of the theoretical level was estimated by comparing the calculated chemical shifts for molecules **1** and **4** at the level of the full theory,[15] limiting the treatment to the doublet formulation (keeping, however, the correct $S(S + 1)$ factors appropriate to the quartet state), and the NR theory.[7] The results are shown in Table 7. There are cases, such as site 2 in molecule **4**, where the difference between the theories reaches up to 16 ppm due to the δ_{dip} term (vide supra). A general finding is that the difference be-

tween the shift obtained with the approximate theories and the full theory normally is within 0–3 ppm. The biggest changes occur for hydrogens in positions 2 and 4, and in the methyl groups bonded to the Cp ring. The deviations arise mainly from the terms that do not contribute to the isotropic shift at the approximate levels, especially the δ_{dip} term. Changes also occur in the pseudocontact term δ_{pc} when calculated at different levels of theory.

When comparing to δ_{pc}, which is often the target quantity in experimental investigations, one can see that the error is of a magnitude comparable to or larger than δ_{pc}, which ranges between 0 and 2 ppm in all molecules.

Final results

All the ^{1}H shifts of the eight molecules are reported at the B3LYP/HII level and at the extrapolated B3LYP/HIII* as well as B3LYP/HIII*//H-opt* levels in Table 8. Figure 3 visualizes the B3LYP/HII data and gives linear regression fits for that and the two extrapolated approximations. The first extrapolation, B3LYP/HIII* takes into account the effect of basis set improvement from the HII to the HIII level, evaluated using the PBE functional and added on top of the B3LYP/HII result (all at the fully BP86/def2-TZVP-optimized geometry):

$$\text{B3LYP/HIII}^* = \text{B3LYP/HII} + (\text{PBE/HIII} - \text{PBE/HII})$$

The reason for carrying out this extrapolation is that direct B3LYP/HIII calculations would be rather expensive due to the hybrid functional. Whereas it is evident that extrapolations of the present kind should be used with caution, the change of δ_{con} for the ^{1}H nuclei between the HII and HIII basis set levels is typically a decrease by 10% (PBE calculations for molecule **1**). The B3LYP and PBE functionals give, in general, different results for hyperfine properties. However, a common finding is that their basis set dependence is relatively independent of the choice of the functional. Consequently, the basis set effect represents only a quantitative modification of the shifts and the extrapolation procedure should be safe in the present case. The other extrapolation scheme additionally takes into account the

[a]Including both the orbital and hyperfine shift contributions.

[b]Extrapolated result as follows: B3LYP/HII + ΔBasis + ΔStructure.

[c]Extrapolated result as follows: B3LYP/HII + ΔBasis.

[d]Change induced by adopting the experimental X-ray structure for the heavy-atom framework and computationally optimized hydrogen positions: ΔStructure = PBE/HII//H-optimized – PBE/HII//fully optimized.

[e]Change induced by improving the basis set from HII to HIII: ΔBasis = PBE/HIII – PBE/HII, both at the fully optimized structure.

change of the results (for molecules other than **2**, **3**, and **5**) due to adopting the experimental X-ray structure for the heavy-atom framework, and computationally optimized hydrogen positions:

$$\text{B3LYP/HIII}^*\text{//H-opt}^* = \text{B3LYP/HIII}^* + (\text{PBE/HIII//H-opt} - \text{PBE/HII//fully opt})$$

The linear regression parameters of the three sets of data are given in Table 9. The fit parameters are noted to improve in the succession of approximations from the calculated B3LYP/HII data to the extrapolated B3LYP/HIII* and B3LYP/HIII*//H-opt* versions. That is visible in the k coefficients obtaining values closer to unity and the intercepts, b, becoming smaller. This underlines the role of the basis set as well as the experimental heavy-atom geometry for reproducing the experiment.

Despite the fact that the extrapolations improve the results on average, significant deviations from the experimental values remain. In some cases, the H-opt* step, in particular, introduces outliers that are not present in the earlier approximations. All three approximations feature the largest deviations occurring at the ends of the chemical-shift range. Signals with experimental values at around –80 ppm arise from the aromatic hydrogen atoms at site 2, which is nearest to the chromium center. The shifts experimentally at 220 and 260 ppm are due to molecule **3**, sites 8–11. These signals differ from all the other molecules because the H atoms of the Cp ring in molecule **3** are aromatic, i.e., there are no methyl groups. Other major deviations arise in the methyl groups of the Cp ring in the different molecules. It is thinkable that intramolecular dynamics, in particular the relative movement of the quinolyl and Cp ring structures with respect to each other, can affect the ^{1}H shifts of the Cp rings and the attached methyl groups.

Much of the error is expected to arise from the incompleteness of the B3LYP functional used, despite it being the best performing among the currently tried ones. The omitted solvation and rovibrational effects are likely to constitute other important error sources in our results. With the rigorous theory of pNMR shielding now at hand, it is motivating to pursue studying improved functionals and dynamic solvation effects in the context of the ^{1}H pNMR shifts in $S \geq 1$ transition metal systems.

Conclusions

A novel and general first-principles theory of pNMR nuclear shielding and chemical shift[15] was applied to molecules possessing nonaxial spatial symmetry and quartet spin state. This theory, for the first time, rigorously takes into account the effect of zero-field splitting of the ground-state electronic Zeeman manifold of $S \geq 1$ systems. The isotropic ^{1}H chemical shifts of a family of quinolyl-functionalized Cp chromium(III) complexes were calculated using DFT methods and compared to recent experimental pNMR data.[18] In particular, the selection of the exchange-correlation functional was found to be a crucial factor determining the accuracy of the predicted shifts. Overall, the B3LYP hybrid functional was found to perform best in comparison with a few GGA and other hybrid functionals. Linear regression fits of the calculated B3LYP shifts indicate improved agreement with experiment when extrapolating the data to a larger basis set and furthermore, when experimental X-ray structure is adopted for the heavy-atom framework, instead of the fully computationally optimized geometry. The remaining errors are mainly attributed to the deficiency of the B3LYP exchange-correlation functional and the fact that we did not model solvation or rovibrational effects that affect the experimental shifts.

Fig. 3. [1]H chemical shifts at the B3LYP/HII level as compared to experimental data. Linear regression lines indicate the best fits of the B3LYP/HII as well as the extrapolated B3LYP/HIII*//H-opt* and B3LYP/HIII* results (see text).

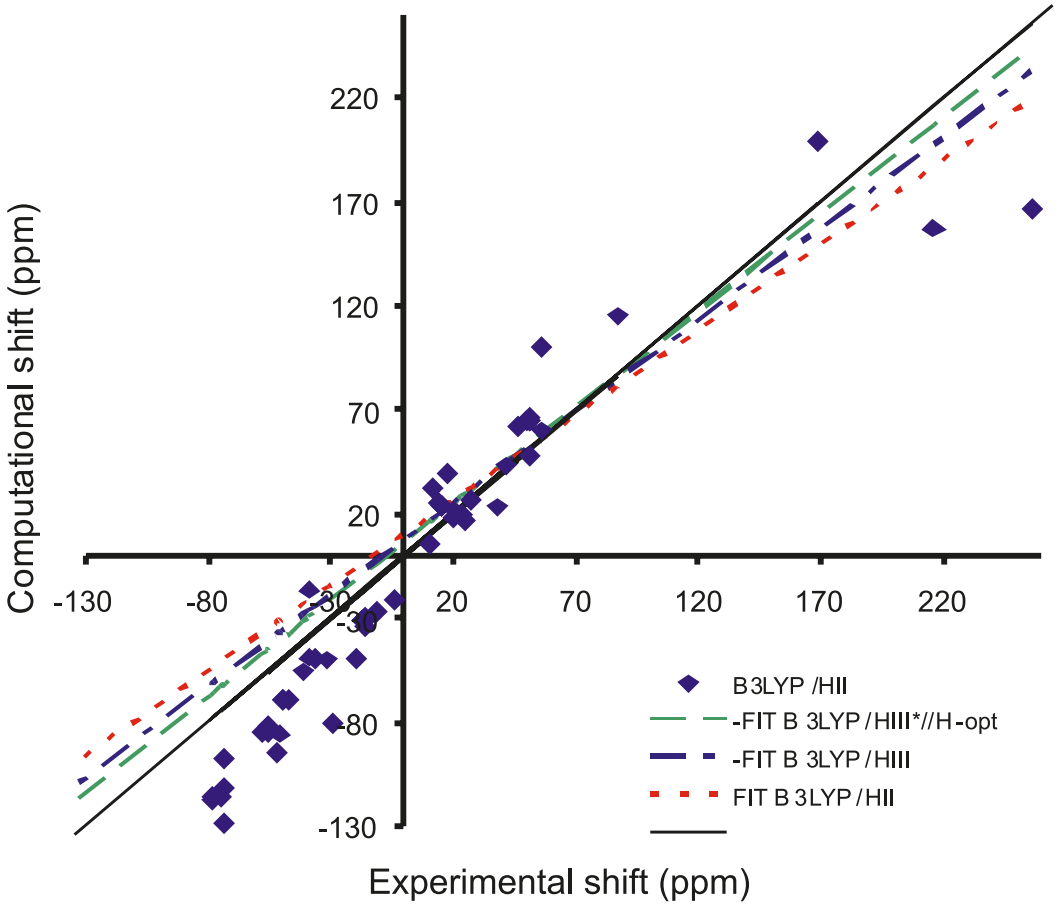

Table 9. Parameters of the linear fit of calculated [1]H chemical shifts with different approximations (see text) to the experimental data.

Approximation	*k*	*b* (ppm)
B3LYP/HII	0.82	10.4
B3LYP/HIII*	0.88	7.9
B3LYP/HIII*//H-opt*	0.93	6.6

Note: Fit to equation Exp = *k* Calc + *b*.

The calculated chemical shifts were broken down into physical contributions according to the new theory of ref. 15. The different terms arise from the expansion of the hyperfine coupling and electronic Zeeman interaction in orders α^2 of the fine structure constant, α, in the presence of the ZFS. The nonrelativistic orbital and contact shift terms, which are already correctly obtained in the approximate, earlier forms of the theory, were found to dominate the [1]H shifts. However, some of the novel isotropic shift contributions due to the ZFS effect are found to obtain significant magnitude. In particular, the nonrelativistic dipolar term, δ_{dip}, that does not enter the isotropic shift at all in the theory appropriate to doublet systems, systematically exceeds in magnitude the isotropic part of the so-called pseudocontact shift, in the present quartet molecules. The latter is traditionally used in the structure determination of paramagnetic molecules due to the spatial structure of the spin-dipole hyperfine Hamiltonian. It is argued that δ_{dip}, which features the same operator, could find similar use in $S \geq 1$ molecules.

Localized-orbital locator (LOL) profiles of transition-metal hydride and dihydrogen complexes[1,2]

Heiko Jacobsen

Abstract: A bond descriptor based on the kinetic-energy density, the localized-orbital locator (LOL), is used to characterize the nature of the chemical bond in transition-metal hydride and dihydrogen complexes. Cationic complexes of the iron triad $[MH_3(PMe_3)_4]^+$ (M = Fe, Ru, Os) serve as model compounds for transition-metal hydrogen bonding, since these complexes not only present examples for hydride as well as dihydrogen complexes, but for certain representatives, the two different types of metal–hydrogen bonds are realized within the same molecule. Both types of ligands show characteristic LOL profiles: (3,–3) Γ attractors in close vicinity to the H-atom for hydride ligands, and (3,–3) Γ attractors located between the two atoms for a dihydrogen ligand with ν_Γ-values of 0.8 and 0.9, respectively. In-between structures combine elements of the hydride and dihydrogen ligands. Relativistic effects on the relative stability of various isomers for the set of model compounds have been evaluated.

Key words: dihydrogen complexes, hydride complexes, localized-orbital locator, transition-metal complexes.

Résumé : On fait appel à un descripteur de liaison basé sur la densité de l'énergie cinétique, le localisateur d'orbitales localisées (LOL), pour caractériser la nature de la liaison chimique de l'hydrure d'un métal de transition et de ses complexes de dihydrogène. On a utilisé les complexes cationiques de la triade du fer $[MH_3(PMe_3)_4]^+$ (M = Fe, Ru, Os) comme composés modèles pour la liaison d'un hydrogène avec un métal de transition puisque ces complexes ne présentent pas uniquement des exemples pour l'hydrure et les complexes de dihydrogène, mais aussi pour certains produits représentatifs, les deux types différents de liaisons métal–hydrogène peuvent se retrouver dans la même molécule. Les deux types de ligands présentent de profils LOL caractéristiques : attracteurs (3,–3) Γ dans le proche voisinage de l'atome d'hydrogène avec les ligands hydrures et des attracteurs (3,–3) Γ situés entre les deux atomes pour un ligand dihydrogène, avec des valeurs de ν_Γ de 0,8 et 0,9 respectivement. Des structures intermédiaires combinent des éléments des ligands hydrure et dihydrogène. On a évalué les effets relativistes sur la stabilité relative de divers isomères pour l'ensemble des composés modèles de l'ensemble.

Mots-clés : complexes de dihydrogène, complexes d'hydrure, localisateur d'orbitales localisées, complexes de métaux de transition.

[Traduit par la Rédaction]

Introduction

Since Werner's work, which explored the nature of complexes between transition-metal ions and ligand entities around the beginning of the 20th century,[3] the nature of the chemical bond in transition-metal complexes continues to be an area of ongoing research activities. In particular, the coordination chemistry of saturated molecules has progressed steadily into a well-established and well-understood structural paradigm,[4] and holds the promise to be an integral player in the quest for "holy grails in chemistry", such as the solar splitting of water to hydrogen and oxygen, and carbon–hydrogen bond activation by synthetic metal complexes.[5] Since dihydrogen complexes constitute prototypes for the coordination chemistry of saturated molecules,[6] transition metal – hydrogen compounds are central to the investigation of bonding and reactivity of this class of compounds.

The discovery of transition-metal complexes with a side-on bonded H_2 ligand[7] has expanded the coordination chemistry of hydrogen from *classical* hydride ligands to *non-classical* dihydrogen complexes: they are part of an important class of compounds, in which an electron pair in a σ-bond of a ligand donates part of its electron density to the transition-metal center,[8] a bonding motif quintessential for the coordination chemistry of saturated molecules. Dihydrogen can in addition act as a σ*-acceptor through its antibonding and vacant σ* orbital. It is the fine balance between the donor and acceptor properties of the transition-metal center that determines the valence tautomerism of the H_2 ligand ranging from non-classical $M–H_2$ dihydrogen complexes to classical H–M–H bishydrides, resulting from an oxidative addition of the hydrogen molecule to the transition-metal center. In the first decade after their initial discovery, the coordination chemistry[9] as well as the reactivity[10] of dihydrogen complexes have already become subjects of extensive review articles; a fact which underlines the importance of this class of

compounds. Dihydrogen complexes are best-viewed as a subclass of transition-metal hydrides,[11] which continue to be the focus of much research activities.[12]

With the recognition of density functional theory (DFT) as a practical tool in molecular energetics and dynamics,[13] computational chemistry began to develop into a reliable companion method to experimental investigations. DFT provides an easy and straightforward computational access to areas that were excessively difficult to tackle with conventional ab initio methodology, such as transition-metal chemistry.[14] Elementary reaction steps in organometallic chemistry have been the subject of DFT investigations early on,[15] and DFT progresses on the way of modeling chemical reactions "from balls and sticks to HOMO's and LUMO's".[16]

Chemical reactions are characterized by processes of bond breakage and bond formation, and central questions that seek for an understanding of chemical reactivity are intimately related to a detailed description of the chemical bond (its strength and its characteristics). The pool of theoretical methods of potential use for studies of inorganic reaction mechanisms is constantly expanding,[17] and so is the number of approaches that explore the nature of the chemical bond. The quantum theory of atoms in molecules (QTAIM)[18] carries the description of a chemical bond from an orbital-based approach to a definition based on the electron density of a molecular system. However, not only the charge density, but also the kinetic-energy density contains valuable information about the chemical bond. Descriptors based on the kinetic-energy density, such as the electron localization function (ELF)[19] and the localized-orbital locator (LOL),[20] provide answers to the problem of electron localization and delocalization (one of the main aspects of the nature of the chemical bond). A recent study of LOL profiles of prototypical chemical bonds demonstrates that LOL represents a conceptually simple but efficient tool in characterizing a chemical bond.[21]

In the present paper, we set out to establish LOL profiles of transition-metal hydrides and dihydrogen complexes. Molecular geometries and electron densities obtained from DFT calculations represent the basis of our analysis. We hope to establish characteristic LOL features that might be useful in characterizing the true nature of the M–H bond.

Results and discussion

We chose cationic complexes of the iron triad $[MH_3(PMe_3)_4]^+$ (M = Fe, Ru, Os) as model compounds for transition metal – hydrogen bonding. These complexes not only present examples for hydride as well as dihydrogen complexes, but for certain representatives, the two different types of metal–hydrogen bonds are realized within the same molecule, allowing for a direct comparison of different hydrogen bonding modes. Like many transition metal – hydride complexes, $[MH_3(PMe_3)_4]^+$ compounds are stereochemically nonrigid in solution, and their structures and dynamics have been investigated by X-ray diffraction studies and detailed NMR experiments.[22]

The possible coordination geometries of $[MH_3(PMe_3)_4]^+$ molecules can be classified as *P*-, *C*-, and *T*-type structures, where the nomenclature is derived from the coordination sphere of the phosphine ligands based on a square-planar, C_{2v}-butterfly, and tetrahedral arrangement, respectively. Further, one has to differentiate between classical trihydride complexes and non-classical hydride–dihydrogen systems, and we designate these types as P_c and C_c (classical), or P_n and C_n(non-classical). Chart 1 depicts the various geometries of $[MH_3(PMe_3)_4]^+$ complexes.

We note that the geometries and relative energies of various $[MH_3(PMe_3)_4]^+$ complexes have been previously studied by DFT calculations;[23,24] what we will add in the present work is a more detailed analysis of the nature of the transition metal – hydrogen bond.

Geometries of transition metal – hydride and transition metal – dihydrogen bonds

A first assessment of the nature of a HH-ligand is usually based on the distance of separation of the two hydrogen atoms, d(H–H). Most of the structural information of dihydrogen complexes is derived from their NMR properties in solution, and Morris has recently analyzed the structures and characteristic NMR properties of 17 Fe-, 98 Ru-, and 70 Os-complexes that contain a HH-ligand.[25] The question then arises of whether the HH-ligand represents a dihydrogen, bishydride, or something in between. Kubas has defined a practical, but qualitative, criterion for categorizing M–(HH) complexes. In comparison to free dihydrogen, d(H–H) = 74 pm, a complex where the H separation falls in the distance range 80 pm < d(H–H) < 100 pm represents a true dihydrogen complex, a complex with 100 pm < d(H–H) < 130 pm is a representative of an elongated dihydrogen complex, and when the HH separation falls into the range 130 pm < d(H–H) < 160 pm, we talk about a compressed bishydride, whereas the true bishydride possesses a H–H separation with d(H–H) > 160 pm.[6]

We note that there is no definite transition from one form to another in this continuum of structures, and so these definitions are somewhat arbitrary. It might be therefore helpful to develop a criterion for characterizing the nature of the M–(HH) bond that goes beyond this rather capricious criterion. Before we address this problem, we will look at the M–(HHH) geometries of our set of model compounds $[MH_3(PMe_3)_4]^+$ (M = Fe, Ru, Os).

For all model complexes, we have optimized *P*-, *C*-, and *T*-type structures without any geometric constraints that define the hydrogen atoms of the HH-ligand as classical hydride H^c or non-classical dihydrogen H^n ligands. Characteristic distances and angles of M–(HHH) coordination geometries are collected in Table 1.

The *T*-isomers contain three true classical hydride ligands H^c; the structural requirement of the pseudotetrahedral arrangement places the H^c ligands at distances between 240 pm and 270 pm from each other. As the data of Table 1 indicate, all the H^c ligands are equivalent in terms of metal to hydrogen separation. The geometries of the *T*-isomers therefore define typical Fe–H^c, Ru–H^c, and Os–H^c bond lengths. It becomes apparent from the slight deviations between the distances d(H^c–H^c) and bond angles (H^c–M–H^c) that the geometry of the *T*-isomers is best described as pseudoterahedral. However, these deviations are only minor and do not invalidate the notion of three equivalent hydride ligands.

The *P*-isomers contain two groups of hydrogen ligands, one consisting of one H and the other consists of two H

[a]For *T* -isomers, H^x refers to H^c; for *P*- and *C*-type complexes of Fe and Ru, H^x refers to H^n; for *P*- and *C*-type complexes of Os, H^x refers to H^c.

atoms. These two groups are well-separated from each other, since they are positioned on opposite sides of the square-planar framework defined by the phosphine ligand. Whereas the single H atom naturally represents a hydride ligand, the question arises of whether the HH-entity represents a bishydride or a dihydrogen ligand. Kubas' geometric criterion characterizes the HH group in the *P*-isomers of complexes of Fe and Ru as a true H_2-complex, whereas the osmium complex contains three true hydride ligands H^c. The sum of the bond angles (H^c–M–H^c) indicates that the three H^c ligands in the Os-complex are located in the same coordination plane.

On the basis of their coordination geometries, we refer to these complexes as P_n–Fe, P_n–Ru, and P_c–Os, respectively. We were also able to locate P_c–Fe, P_c–Ru, and P_n–Os structures, which however are substantially higher in energy. We will only briefly return to these structures in the last section of our discussion, and we refer the interested reader to the Supplementary data for details. To conclude the discussion of *P*-isomers, we note that M–H^c distances for all complexes compare quite well with the standard reference values established for *T*-isomers.

The *C*-isomers possess three H-atoms in a cis arrangement, and offer various possibilities for forming hydride and dihydrogen ligands, or in between bonding situations. For the Fe- and Ru-complexes, we find two HH distances designative of the presence of a true dihydrogen ligand for one pair of neighboring H-atoms, and that indicates that there is no HH-bonding interaction for the other pair of neighboring H-atoms. The *C*-isomers of Fe and Ru compounds are to be classified as hydride–dihydrogen C_n-type complexes. The *C*-isomer of the Os complex displays H–H separations that exceed values for elongated dihydrogen and compressed dihydride complexes, and is to be classified as trishydride, a C_c-type complex. All three H^c ligands display essentially the same d(M–H^c) separation, which compares well with the value of the other trishydride, *T*-Os. The same observation holds true for the single hydride ligands in *C*-type complexes of Fe and Ru.

The geometry optimization of the cationic $[MH_3(PMe_3)_4]^+$ complexes offered no surprises; the values for M–(HHH) coordination geometries compare well with previous studies.[24] The optimized geometries however set the stage for a detailed LOL analysis, which provides insights into the nature of transition metal – hydride and transition metal – dihydrogen bonds.

LOL profiles of transition metal – hydride and transition metal – dihydrogen bonds

Before we engage in a more detailed discussion, a few remarks on LOL are in order. LOL (referred to as ν) is a measure of the relative value of the local kinetic energy τ in a mapping onto the finite range [0,1]. A value of $\nu = 1/2$ indicates that the kinetic-,energy content of the corresponding region is what would be expected from a spin-neutral electron gas of that density, and values of $\nu > 1/2$ indicate regions where electrons are localized. Ideas borrowed from the topological analysis of electron charge density[18] allow one to locate critical points and in particular (3,–3) attractors Γ in the gradient vector field of LOL.[21] Each nucleus position is associated with one attractor Γ, but LOL also features attractors between bonded atoms and in molecular regions associated with lone pairs. It is the Γ topology of LOL and its associated ν_Γ-values that serve as a guide in describing the nature of chemical bonding in molecular systems.

The chemical content of LOL is similar to that of ELF, which is also dependent on the kinetic-energy density τ. However, ELF is founded on considerations of the electron pair density, whereas LOL simply recognizes that gradients of localized orbitals are maximized when localized orbitals overlap. Moreover, LOL offers a simpler interpretation in terms of fast and slow electrons, and always falls to zero asymptotically, whereas ELF sometimes does not.[26] It appears that LOL represents a simpler function than ELF, and is more easily linked to intuitive concepts of chemical bonding.

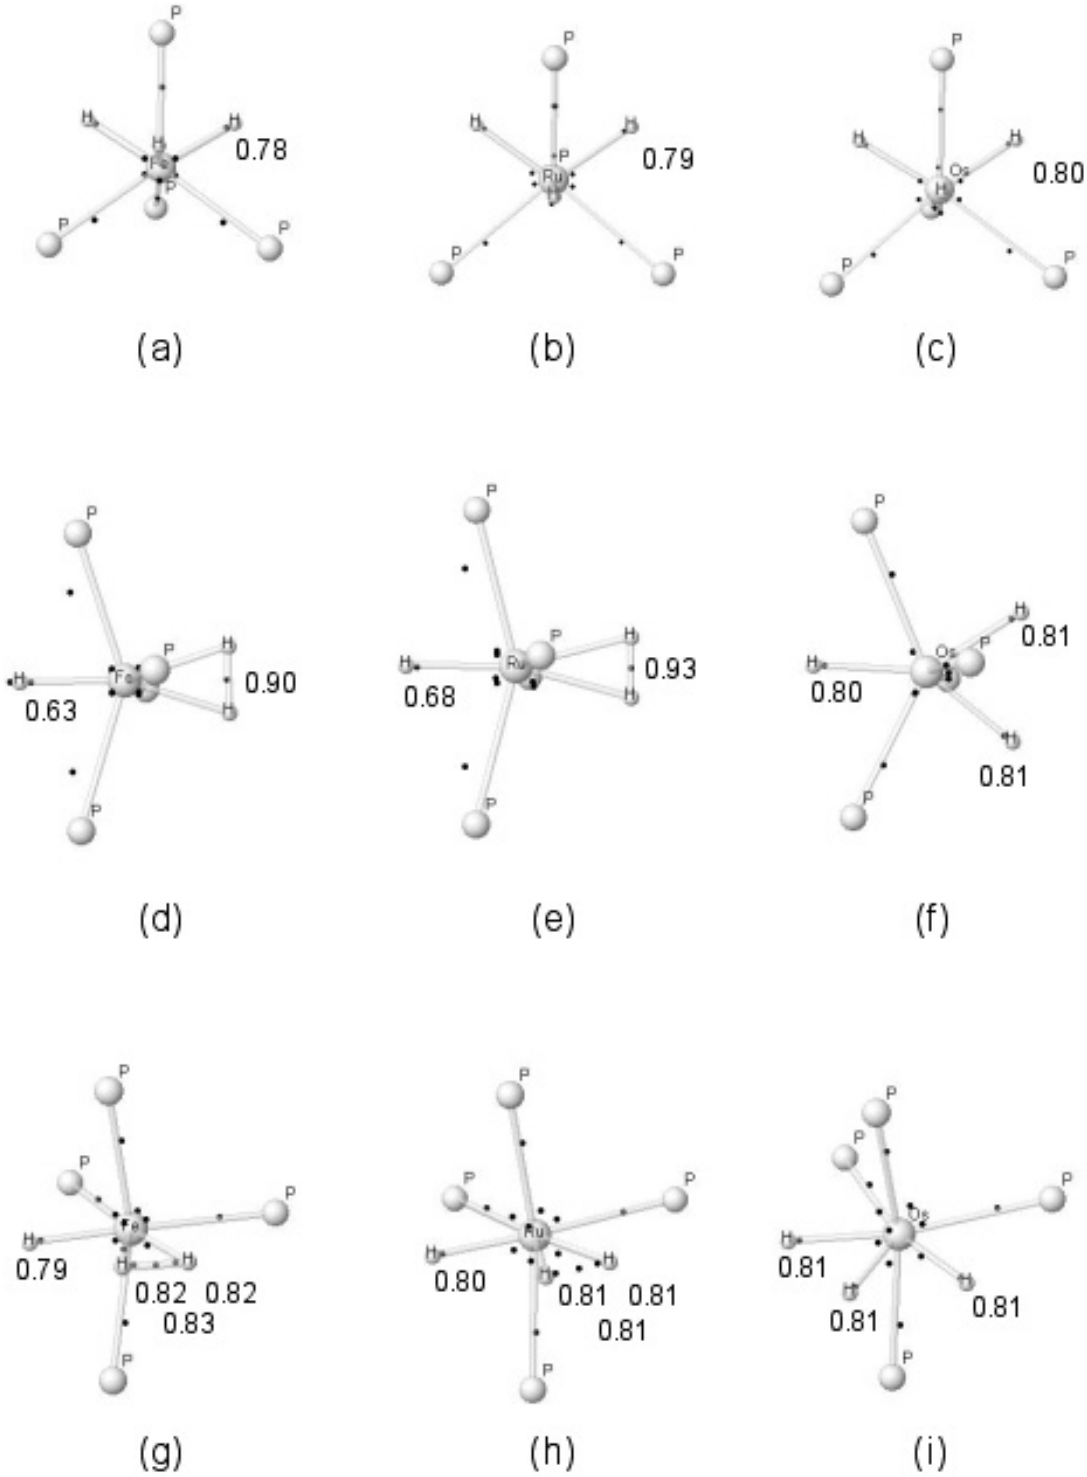
The LOL analysis of hydrogen is a special case due to the lack of an electronic core; similar observations have been made for ELF as well.[27] The kinetic-energy density contains pertinent information in the description of Pauli repulsion,[28] and thus the region of the nucleus is not excluded for valence electrons. For element–hydrogen bonds, E–H, the hydrogen nucleus is within region of the slow moving electrons that form a covalent bond.[20] The (3,–3) attractor Γ is not found at equal distance to the E and H nuclei, but is displaced toward the hydrogen atom. For example, for the prototypical C–H covalent single bond in ethane, a Γ attractor with a ν_Γ-value of 0.92 is found, and the distance ratio between the LOL attractor and the C and H nuclei amounts to $d(\Gamma–C)/d(\Gamma–H) = 4.2$.[21] For the H–H bond in dihydrogen, no (3,–3) attractor Γ is to be found in the LOL gradient vector field because of the absence of core electrons. We will keep these two points in mind when we interpret LOL profiles of transition metal – hydride and transition metal – dihydrogen bonds.

We have analyzed the valence electron kinetic-energy density of various $[MH_3(PMe_3)]^+$ complexes, and located (3,–3) attractors Γ in the gradient vector field of LOL. Here, we restrict ourselves to the analysis of metal–ligand bonds, and the LOL profiles of ligands within the first coordination sphere around the transition-metal center for *T*-, *P*-, and *C*-type isomers are depicted in Fig. 1.

For the *T*-type trishydride complexes, we find that the classical hydride ligand is characterized by the presence of one Γ attractor located between the transition metal and the hydride with a ν_Γ-value around 0.80. This value is about 0.1 units smaller than the ν_Γ-value for the prototypical covalent C–H bond in ethane. The attractor is found in close vicinity to the H^c-ligand, with $d(\Gamma–M)/d(\Gamma–H^c)$ ratios of 8.4 for iron, 8.6 for ruthenum, and 8.8 for osmium. These ratios are about twice as large as for the covalent C–H bond in ethane. We associate the decrease in ν_Γ together with the stronger displacement of the Γ attractor toward the hydride ligand with an increased ionic character of the M–H^c bond.

For the hydride–dihydrogen P_n-isomers of Fe and Ru, the HH ligand is characterized by a Γ attractor located between the two H-atoms of the coordinated dihydrogen molecule. We recall that no Γ attractor exists in the LOL gradient vector field of free dihydrogen, and the existence of the Γ attractor indicates the presence of a σ-bond between the HH ligand and the transition-metal center. The hydride ligand again displays a Γ attractor in close vicinity to the H nu-

Fig. 1. Γ attractors and associated ν_Γ-values of *T*-, *P*-, and *C*-type isomers of cationic $[MH_3(PMe_3)]^+$ complexes (M = Fe, Ru, Os): (a) *T*–Fe, (b) *T*–Ru, (c) *T*–Os, (d) P_n–Fe, (e) P_n–Ru, (f) P_c–Os, (g) C_n–Fe, (h) C_n–Ru, and (i) C_c–Os.



cleus; we note that the ν_Γ-value is about 0.1 to 0.15 units smaller when compared with the *T*-type trihydride compounds. Proceeding to the P_c-type isomer of Os, we find three hydride ligands characterized by Γ attractors in close vicinity to the hydrogen nuclei. The ν_Γ-values are essentially the same as found for *T*–Os, and we conclude that *T*–Os and *P*–Os constitute true structural isomers.

When we proceed to the *C*-type structures, we notice the presence of a dihydrogen ligand for the Fe- and Ru-complex, while Fig. 1 displays a Γ attractor located between the two H-atoms at close distance to each other. This feature characterizes the HH ligand as a dihydrogen ligand, bonded by σ-donation to the transition-metal center. However, whereas for the *P*-type isomers of Fe and Ru, the attractor

located between the two H-atoms was the only attractor to be found in relation to the HH ligand, whereas the HH ligand in C_n–Fe and C_n–Ru displays additional attractors in close vicinity to the H-atom, similar to those observed for hydride ligands. It appears that the HH ligand in *C*-type structures displays characteristic features of both a dihydrogen and a bishydride ligand. Although not obvious from its coordination geometry, the HH ligand in these structures represents an in-between situation between the two extremes, σ-bonded dihydrogen and ionic bishydride. The third H-ligand in C_n–Fe and C_n–Ru is clearly an independent hydride ligand, with attractor ν_Γ-values comparable to those of the related *T*-type structures. When we proceed to the *C*-type structure of osmium, no Γ attractor located between two adjacent H-atoms is to be found; the osmium isomer is a true trishydride, to be classified as C_c–Os, in accord with the assessment based on structural parameters.

LOL profiles might further be helpful in elucidating mechanistic aspects related to the afore-mentioned stereochemical non-rigidity. In particular, hydride fluxionality in transition-metal complexes has played a key role in developing mechanistic concepts, and the possible interchange of a hydrogen atom in hydride–dihydrogen complexes serves as the simplest model for σ-bond activation reactions.[29] The first ab initio studies of the model complex $[Fe(PH_3)_4H(H_2)]^+$ lead to the conclusion that the favoured mechanism for intramolecular atom exchange between the hydride and the dihydrogen moiety within the C_n-isomer is the so-called open direct transfer.[30] This exchange pathway consists of a single-step transfer of the hydrogen atom between the two ligands. In the transition state of this mechanism, the central hydrogen atom is bound to the metal center as well as to the other two hydrogen atoms, forming a trihydrogen ligand. A mechanism following an addition–elimination reaction, which would involve a true transition-metal trishydride, has been excluded on the basis of an extraordinarily high activation energy.

Since the initial investigations employ geometry constrains, the problem has been revaluated using DFT methodologies,[31] and the nature of the transition state – trishydride vs. – trihydrogen has been addressed in a QTAIM study. It turned out that qualitative differences appeared in the topological description of the chemical bonding in the transition state for the hydrogen exchange process and depends on the chosen density functional approach. From results of pure density functional calculations, the transition state had to be classified as a trishydride complex, whereas computations employing hybrid methodologies produced a transition state that, according to its bond critical points and bond paths, represents a trihydrogen situation.

It has been found that in situations where a QTAIM analysis leaves open questions and seems to be dependent of the underlying computational methodology, an LOL analysis provides a more consistent picture, independent of the theoretical method employed.[32] In the context of the present work, we analyze the transition state for hydrogen exchange within the C_n–Fe complex $[FeH_3(PMe_3)_4]^+$ as a representative example. The LOL profile for the transition state is depicted in Fig. 2.

Inspection of Fig. 2 provides an immediate answer to the question of whether the hydrogen exchange in C_n–$[FeH_3(PMe_3)]^+$ follows an open direct transfer or an addition–elimination pathway. No Γ attractors are to be found between two adjacent H-atoms, but three Γ attractors are located in close vicinity to each of the H-atoms. The ν_Γ-values are indicative of a hydride ligand (compare *T*–Fe), and according to its LOL profile, the transition state has to be classified as trishydride rather than a trihydrogen complex.

Fig. 2. Γ attractors and associated ν_Γ-values of the transition state for hydrogen exchange in C_n–$[FeH_3(PMe_3)]^+$.

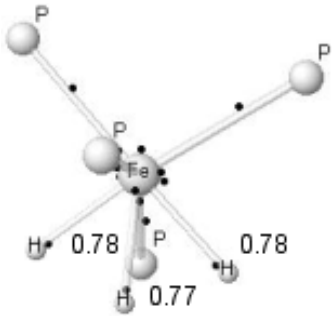


Chart 2. Relativistic influence on the d_π donor and d_σ acceptor orbitals of transition-metal fragments.

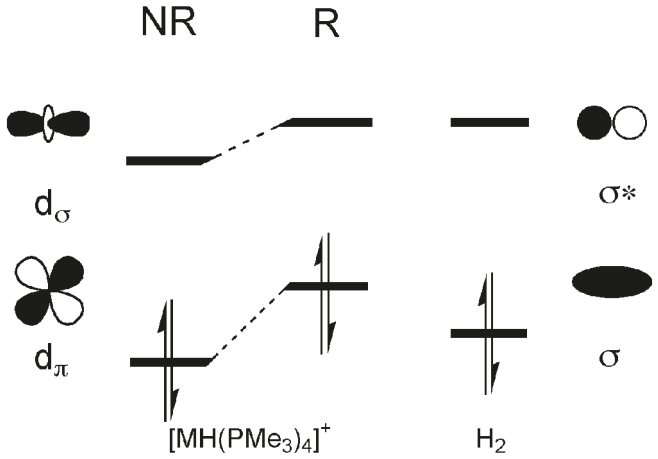
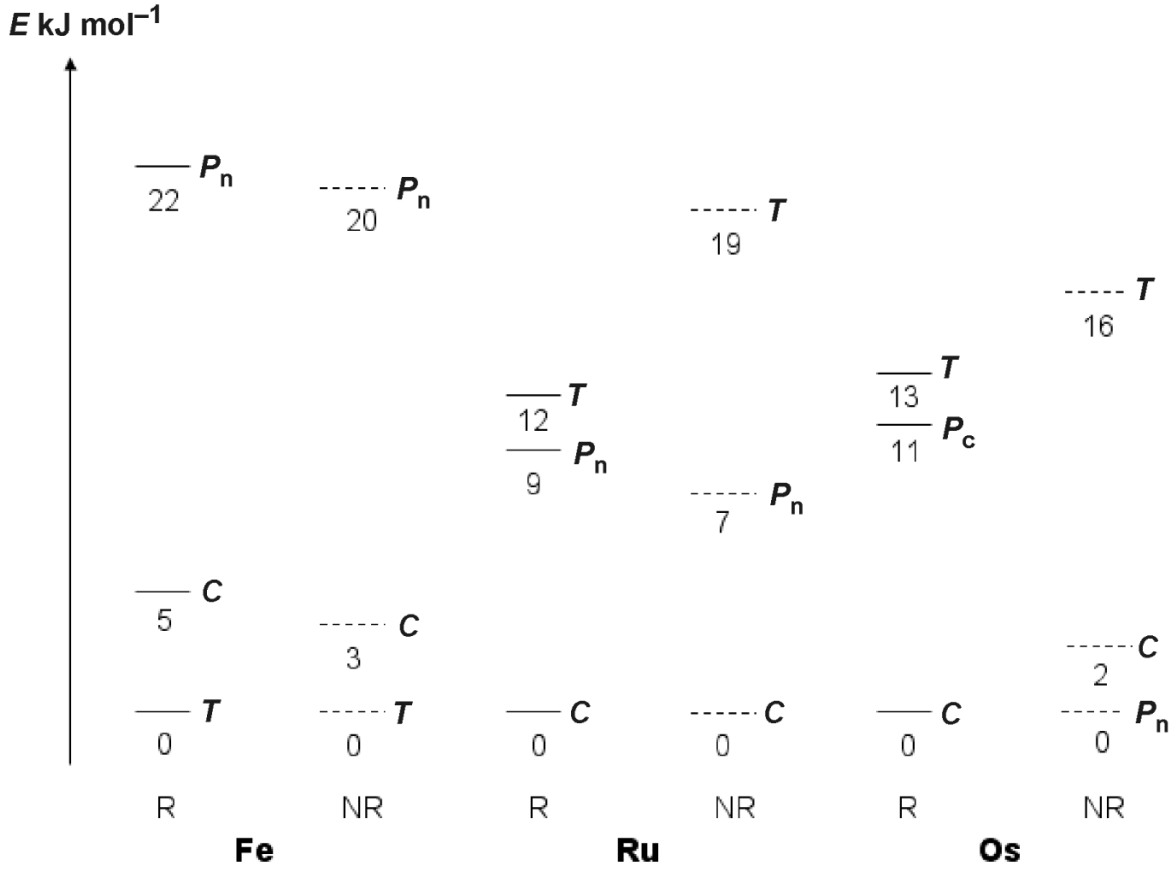


While LOL profiles obtained from the valence electron density are helpful in characterizing the nature of the M–H bond in cationic $[MH_3(PMe_3)]^+$ complexes, they do not answer questions related to different preferences for *C*-, *P*-, and *T*-isomers for classical or non-classical coordination of a HH-ligand when proceeding down group 4 from iron to osmium. There apparently exists a major influence of the core electrons on the relative stability of the various isomers. This problem has been analyzed in detail in the literature, and we conclude our discussion with a brief assessment of relative energies of some of the possible isomers.

Preference for classical or non-classical bonding of a dihydrogen ligand

A seminal paper by Ziegler analyzes the origin of the preference for bishydride complexes as opposed to dihydrogen bonding within a series of related compounds.[33] He chose transition-metal complexes of group 8 metals as representative examples, and the observed preference for a bishydride complex in the case of the heavier congener osmium was explained by a relativistic effect. Chart 2 displays this

Fig. 3. Relative energies (in kJ/mol) of *T*-, *P*-, and *C*-type isomers of cationic $[MH_3(PMe_3)]^+$ complexes (M = Fe, Ru, Os), obtained from relativistic R and non-relativistic NR calculations.



relativistic effect in terms of orbital interactions related to donation and back-donation.

Both d-based orbitals of a transition-metal fragment that are responsible for ligand bonding are raised in energy by relativity. The energy increase for d_π will enhance back-donation, since this orbital now is closer in energy to a σ* accepting orbital of a HH-ligand. On the other hand, the energy increase for d_σ will reduce donation, since the energy gap to a σ donor orbital is enlarged. The relativistic increase in the energy of the osmium d orbitals is the result of a relativistic contraction of the s and p core orbitals, which in turn reduces the effective nuclear charge experienced by electrons in the d-valence shell on osmium.[33] As a consequence of enhanced back-donation, the electron density in the σ* orbital of a HH-ligand is increased, which induces a transformation of the ligand from dihydrogen to bishydride.

This concept has been explored for other systems as well,[34] including the complexes that are the subject of the present investigation.[24] We therefore conclude with only a few remarks on the energetic preferences of different isomers, including and excluding relativistic contributions. These energy rankings are displayed in Fig. 3.

We begin with results obtained from relativistic calculations. For the iron complex, the *T*-isomer represents the most stable isomer, whereas for ruthenium and osmium complexes, this isomer is the least stable, and *C*-isomers are to be found at lowest energy values. The *T*-isomer preference for iron has been observed before,[23] and is explained by the strong donor capabilities of the trimethyl phosphine ligand together with the absence of a d-electron core. While for iron and ruthenium, the *C*- and *P*-type isomers represent non-classical structures, the osmium isomers are classical without any dihydrogen ligands. We also note that the P_n-type isomers are higher in energy than the *C*-type isomers; the reduced ν_Γ-value of the hydride ligand in Fe–P_n and Ru–P_n might be interpreted as a first indication of this fact.

When we turn to non-relativistic calculations, we observe that for iron complexes, the influence of relativistic effects is only marginal, and that the qualitative picture is not affected. For osmium on the other hand, exclusion of relativistic effects turns the classical P_c-isomer into its non-classical P_n counterpart. At the same time, we notice a decrease of the *C*–P_n energy gap when proceeding down group 8. As a consequence, without the inclusion of relativistic effects, a P_n-isomer is predicted to represent the lowest energy isomer for osmium systems.

Conclusion

We have shown how an LOL analysis might provide answers to the question at the heart of many investigations of transition-metal dihydrogen complexes: does a HH-ligand represent a dihydrogen ligand, a bishydride, or something in between? Both the hydride and the dihydrogen ligand pos-

sess their characteristic LOL profiles, and the HH-ligand of in-between structures features LOL characteristics of extremes.

The distinction between classical and non-classical bonding situation is not restricted to transition-metal hydrides, but is applied in other areas of coordinaion chemistry as well, for example, non-classical interligand interactions involving silicon-based ligands.[35] An LOL analysis might provide alternative explanations and place the discussion on firmer grounds, shifting the emphasis away from arguments that are frequently concerned with the idea of hypervalency, a concept that is often misunderstood.[36]

Computational details

Geometries have been optimized in density functional calculations carried out with the Gaussian03 system of programs,[37] which also furnished molecular valence densities used in topology analyses. The pure density functional calculations employed the PBE functional proposed by Perdew, Burke, and Ernzerhof.[38] Transition metals were modeled by a small-core,[39] as quasi-relativistic effective core potential together with a corresponding valence basis set.[40] Atoms bonded to the transition-metal center have been described by contracted Gaussian basis sets of triple zeta valence quality augmented by polarization functions (TZVP).[41] The remaining elements were described by contracted Gaussian split-valence basis sets with polarization (SVP).[42]

For optimized geometries, relative energies with and without the explicit consideration of relativistic effects have been evaluated using the ADF2006.01 program package,[43] The calculations employed the frozen-core approximation. The transition metals and atoms bonded to them have been described by a triple-ζ basis with polarization, the remaining elements were modeled by a double-ζ basis with polarization (ADF basis sets TZP and DZP, respectively). Relativistic effects have been incorporated by the zero-order regular approximation.[44]

Topological analyses of molecular electron densities employed a modified version of the program MORPHY.[45] 3D pictures were generated using the graphical package Jmol.[46]

Supplementary data

Supplementary data (Cartesian coordinates, total bond energies, zero-point energies, entropic terms, and lowest frequencies for all optimized structures and Cartesian coordinates and ν_Γ-values of (3,–3) Γ attractors) for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 3950. For more information on obtaining material, refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml.

Homolytic bond-dissociation enthalpies of tin bonds and tin–ligand bond strengths — A computational study[1]

Sarah R. Whittleton, Russell J. Boyd, and T. Bruce Grindley

Abstract: Density functional theory and second-order Møller–Plesset perturbation theory with effective core potentials have been used to calculate homolytic bond-dissociation enthalpies, *D*(Sn–X), of organotin compounds, and their performance has been assessed by comparison with available experimental bond enthalpies. The SDB-aug-cc-pVTZ basis set with its effective core potential was used to calculate the *D*(Sn–X) of a series of trimethyltin(IV) species, Me_3Sn–X, where X = H, CH_3, CH_2CH_3, NH_2, OH, Cl, and F. This is the most comprehensive report to date of homolytic Sn–X bond-dissociation enthalpies (BDEs). Effective core potentials are then used to calculate thermodynamic parameters including donor–acceptor bond enthalpies, $\overline{D}(\mathrm{Sn-X})$, for a series of tin-ligand complexes, L_2SnX_4 (X = Br or Cl, L = py, dmf, or dmtf), which are compared with previous experimental and nonrelativistic computational results. Based on computational efficiency and accuracy, it is concluded that effective core potentials are appropriate computational methods to examine bonding in organotin systems.

Key words: bond-dissociation enthalpy, trimethyltin bond-dissociation enthalpies, donor–acceptor bond enthalpy, density functional theory, effective core potential, tetrahalotin complexes.

Résumé : On a fait appel à la théorie de la fonctionnelle de la densité et à la théorie des perturbations du deuxième ordre de Møller–Plesset avec des potentiels de coeur effectifs pour calculer les enthalpies de dissociation homolytique des liaisons, *D*(Sn–X), de composés organiques de l'étain et on a évalué leurs performances par comparaison avec les enthalpies expérimentales de liaison disponibles. On a utilisé l'ensemble de base SDB-aug-cc-pVTZ avec son potentiel de coeur effectif pour calculer les valeurs des *D*(Sn–X) d'une série d'espèces organiques de l'étain, Me_3Sn–X dans lequel X = H, CH_3, CH_2CH_3, NH_2, OH, Cl et F. Il s'agit de l'étude la plus complète à date sur les enthalpies de dissociation homolytique de liaisons Sn–X (ENL). On a ensuite utilisé les potentiels de coeur effectifs pour calculer des paramètres thermodynamiques, dont les enthalpies de liaison donneur–accepteur, $\overline{D}(\mathrm{Sn-X})$, pour une série de complexes de l'étain, L_2SnX_4 (X = Br ou Cl, L = py, dmf ou dmtf), qui ont été comparées avec les résultats antérieurs obtenus d'une façon expérimentale ou par des calculs non relativistes. En se basant sur l'efficacité des calculs et leur exactitude, on peut conclure que les potentiels de coeurs sont des méthodes appropriées de calcul pour examiner les systèmes organiques de l'étain.

Mots-clés : enthalpie de dissociation de liaison, enthalpies de dissociation de liaison du triméthylétain, enthalpie de liaison donneur accepteur, théorie de la fonctionnelle de densité, potentiel de coeur efficace, complexes tétrahalogénés de l'étain.

[Traduit par la Rédaction]

Introduction

The importance of tin chemistry is attributed to the prevalence of organotin compounds in organic synthesis and materials science, as well as the industrial, agricultural, and biological applications of tin species. Our specific interests in tin chemistry focus on the use of dialkyltin(IV) intermediates (dialkylstannylene acetals) to obtain regioselective reactions of diols and polyols.[2–7] Reliable estimates of tin bond strengths in organotin compounds allow one to understand their chemistry, including bond breaking, bond making, and chemical reactivity. For organotin species, bond strengths can be reported as homolytic bond-dissociation enthalpies (BDEs) and coordinate donor–acceptor tin bond energies. Both of these bond types are involved in the chemistry of dialkylstannylene acetals and, therefore, an understanding of the nature of covalent and donor–acceptor tin bonds is essential for explaining the complex chemistry of these compounds.

The experimentally determined bond strengths of light elements are well-documented, but bond strengths involving heavier elements such as tin are harder to determine and are surprisingly sparse.[8,9] In fact, there is a lack of reliable experimental bond-dissociation enthalpy, *D*(Sn–X), values in the literature. Several studies have used thermochemical calculations to estimate the bond strengths of various Sn–X bonds[10–13] from fairly old reference values that may be unreliable.[8] In addition, some experimental studies do not yield directly determined homolytic bond-dissociation enthalpies for particular bonds, but rather report average BDEs.[14] The challenges of obtaining absolute values of experimental bond energies have

led some workers to emphasize the use of relative values.[15] Computational methods have been employed to calculate tin bonds strengths,[16–26] by use of a variety of effective core potentials (ECPs). The earlier studies did not validate the results by comparison with experimental data.

The first goal of this two part study was to identify a computational method to obtain reliable estimates of the homolytic Sn–X bond-dissociation enthalpies (BDEs) for a variety of organotin species. An appropriate basis set and effective core potential used for tin was selected by comparing calculated and experimental[8,27] bond-dissociation enthalpies, D(Sn–H), for three different organotin compounds, Me_3SnH, Ph_3SnH, and Bu_3SnH (eqs. [1] and [2]). A more comprehensive study of Sn bonds (Sn–O, Sn–C, Sn–N) was precluded by the lack of reliable gas-phase bond-dissociation enthalpies for tin species.[8,9]

$$[1] \quad Y_3Sn{-}H \rightarrow Y_3Sn^{\cdot} + H^{\cdot}, \text{ where Y} = \text{Me, Bu, and Ph}$$

$$[2] \quad \text{BDE} = D(\text{Sn}{-}\text{H}) = \Delta_f H^o(Y_3Sn^{\cdot}) + \Delta_f H^o(H^{\cdot}) - \Delta_f H^o(Y_3Sn{-}H)$$

The ECP that yields the best agreement with the experimental bond-dissociation enthalpies was used subsequently to predict the D(Sn–X) of a series of trimethyltin(IV) species, Me_3Sn–X (eqs. [3] and [4]). It should be emphasized that this is not a methodological study, but instead uses the limited available experimental BDEs to verify that these ECPs are appropriate for further calculation of tin bond strengths, Me_3Sn–X. The X substituents were chosen on the basis of the prevalence of Sn–X bonds in the current experimental and computational tin literature, where typically X substituents are small, main-group elements.

$$[3] \quad Me_3Sn{-}X \rightarrow Me_3Sn^{\cdot} + X^{\cdot}, \text{ where X} = \text{H, } CH_3, \text{ } CH_2CH_3, \text{ } NH_2, \text{ OH, Cl, and F}$$

$$[4] \quad \text{BDE} = D(\text{Sn}{-}\text{X}) = \Delta_f H^o(Me_3Sn^{\cdot}) + \Delta_f H^o(X^{\cdot}) - \Delta_f H^o(Me_3Sn{-}X)$$

The second goal of this study was to examine bond strengths of donor–acceptor tin bonds, where tin(IV) acts as an acceptor to the donor ligand. These donor–acceptor, or coordinate, bonds are ubiquitous in the chemistry of tin, including catalysis,[28–30] carbohydrate chemistry,[5,7] anti-fungal agents,[31] potential antitumor drugs,[32–35] and biological systems.[36,37] In these types of coordinate systems, donor ligands bind to tin creating new Sn–L bonds, where L = N, O, S, Br, Cl, and Se. Dissociation enthalpies, reorganization energies, basis set superposition error corrections, and bond strengths were calculated using the two different effective core potentials. These thermodynamic parameters were compared to corresponding values obtained from available experimental[38–43] and nonrelativistic all-electron computational studies.[20] One of these effective core potentials will be used in further studies involving donor–acceptor tin bonds.

The complexes examined in this study (eq. [5]) are tin(IV) chlorides or bromides bound to the ligands (L) pyridine (py), *N*,*N*-dimethylformamide (dmf), or *N*,*N*-dimethylthioformamide (dmtf), with two Sn–N, Sn–O, or Sn–S bonds in each L_2SnX_4 complex. These bond strengths are defined as the mean tin(IV)-ligand coordinate bond energies, $\overline{D}$(Sn–L). The approach used to calculate $\overline{D}$(Sn–L) for the L_2SnX_4 coordinate complexes considered reorganization effects of the donor–acceptor complexes (eq. [6]).[20,44,45] Reorganization effects are caused by the increase in the tin coordination number. In L_2SnX_4 systems, the tin coordination number decreases from six to four upon dissociation, changing the geometry of the tin center from octahedral to tetrahedral. The dissociation enthalpy (ΔH^{diss}) differs from the coordinate bond energy (ΔH^{DA}) because it does not include the energies associated with the reorganization of individual donor and acceptor fragments from their geometries in the coordinate complex, ΔH^{reorg}(L) and $\Delta H^{reorg}(SnX_4)$.[20,44,45] Previous researchers have calculated reorganization energies involved in the formation of similar group-14 coordination complexes[20,44] as part of the calculation of ΔH^{DA}.

$$[5] \quad L_2SnX_4 \rightarrow SnX_4 + 2L, \text{ where X} = \text{Br or Cl; L} = \text{py, dmf, or dmtf}$$

$$[6] \quad \overline{D}(\text{Sn}{-}\text{L}) = \Delta H^{DA} = 0.5[\Delta H^{diss} + \Delta H^{reorg}(SnX_4) + 2\Delta H^{reorg}(L) + \Delta H^{BSSE}(L_2SnX_4)]$$

Computational methods

Gas-phase calculations were performed using the B3LYP density functional implemented in Gaussian 03[46] with Becke's three-parameter hybrid exchange functional (B3)[47,48] and the correlation functional of Lee, Yang, and Parr.[49] For geometry optimizations and frequency calculations, unrestricted B3LYP was used for radical species while restricted B3LYP was employed for all other compounds. MP2 single point calculations were preformed on optimized species. The D(Sn–X) and $\overline{D}$(Sn–L) values include basis set superposition error (BSSE) corrections[50] and the enthalpies include the zero point vibrational energy corrections (ZPVE). Frequency analyses were performed on the optimized geometries of the compounds and no imaginary frequencies were observed.

Previous work has shown that a variety of basis sets and effective core potentials can be used to predict the geometries of organotin compounds, $Cl_nSn(CH_3)_{4-n}$, n = 0–4, accurately.[51] However, the abilities of these ECPs to predict the thermochemistry of organotin compounds was not examined, due to a lack of thermochemical data for $Cl_nSn(CH_3)_{4-n}$. Two of these effective core potentials were shown to be appropriate for the prediction of organotin tin geometries and in this study have been evaluated for their applicability for the calculation of bond-dissociation enthalpies.[51] The first method uses the Los Alamos National Laboratory double-zeta basis set (LANL2DZdp) with diffuse and polarization functions[52] and the associated LANL2 ECP developed by Wadt and Hay.[53] The second method uses a correlation consistent, triple-zeta basis set developed by Martin and Sundermann[54] that includes diffuse and polarization functions (SDB-aug-cc-pVTZ) and was used in conjunction with the Stuttgart–Dresden–Bonn (SDB) ECP developed by Dolg and co-workers.[55] Both LANL2 and SDB are 46-electron core ECPs. It should be noted that all

nontin atoms in this study (H, C, N, O, F, S, Cl, and Br) were treated at the MP2/6-311G(2d,p)//B3LYP/6-31G(d,p) level. The BSSE calculations were performed at same level as the MP2 single point calculations, using 6-311G(2d,p) for nontin atoms and LANL2DZdp or SDB-aug-cc-pVTZ for tin. The ZPVE corrections were obtained at the same level as B3LYP geometry optimizations, using 6-31G(d,p) for nontin atoms and LANL2DZdp or SDB-aug-cc-pVTZ for tin.

Results and discussion

Comparison with experimental results — D(Sn–X)

Table 1 lists the experimental bond-dissociation enthalpies, the corresponding calculated enthalpies, and the standard deviations of Y_3Sn–H, Y = Me, Bu, and Ph. The standard deviation in bond-dissociation enthalpies (s_D), defined in eq. [7], compares the calculated bond-dissociation enthalpies (D_{ci}) to the experimental values (D_e).

$$[7] \qquad s_D = \sqrt{\frac{\sum_{i=1}^{n} (D_{ci} - D_e)^2}{(n_D - 1)}}$$

The SDB-aug-cc-pVTZ basis set and ECP yields an s_D value for Y_3Sn–H of 23.3 kJ mol^{-1}, 5 kJ mol^{-1} less than that calculated using LANL2DZdp. Both methods consistently underestimate the bond-dissociation enthalpies of the three organotin molecules, by –32.5 to –3.6 kJ mol^{-1}. The experimental D(Sn–H) values increase as Y changes from Ph to Me to Bu, which is the same order found for D(Ge–H) for the respective germanium species.[9] Both ECPs predict the D(Sn–H) values for H-$SnBu_3$ to be slightly smaller than for H-$SnMe_3$, contrary to observation. Therefore, on the basis of Table 1, the effective core potential paired with the larger basis set, SDB-aug-cc-pVTZ, slightly outperforms the LANL2DZdp.

It would be ideal to compare the results from theory with experimental results for a more diverse sample of tin bonds, but this is prevented by a lack of reliable experimental data. In addition, it is unlikely that larger basis sets (QDZ) would substantially decrease the s_D values because the much larger, augmented, triple-zeta SDB basis set with polarization functions calculates Y_3Sn–H within 5 kJ mol^{-1} of LANL2DZdp. Therefore, it was decided that the SDB-aug-cc-pVTZ and its ECP would be used to calculate the Sn–X bond-dissociation enthalpies of the Me_3Sn–X compounds in the following section.

Table 2. Calculated bond-dissociation enthalpies, D(Sn–X), of Me_3Sn–X, where X = H, CH_3, CH_2CH_3, NH_2, OH, Cl, and F (kJ mol^{-1}).

X	D(Sn–X)
H	301.2
CH_3	284.8
CH_2CH_3	267.5
NH_2	324.7
OH	409.3
F	531.3
Cl	411.3

Homolytic bond-dissociation enthalpies for Me_3Sn–X

Using the SDB-aug-cc-pVTZ basis set and SDB ECP, D(Sn–X) values were calculated for a series of trimethyltin(IV) species, Me_3Sn–X, where X = H, CH_3, CH_2CH_3, NH_2, OH, Cl, and F. The results are shown in Table 2.

The calculated D(Sn–X) increase in the order of X = CH_2CH_3 < CH_3 < H < NH_2 < OH < Cl < F, as observed in other BDE studies.[25,56] This generally agrees with the trend of increasing electronegativity, confirming the strong correlation between electronegativity and bond dissociation.[18,21,57,58] Fluorine is the most electronegative substituent, resulting in a large Sn–F bond-dissociation enthalpy. One apparent discrepancy in this trend occurs for hydrogen, which has a lower electronegativity but a larger D(Sn–X) than the nitrogen and carbon species. However, this trend is seen for other series of group-14 compounds, namely for C, Si, and Ge.[59]

Experimental bond-dissociation energies of X bound to other group-14 atoms (M), reported in Table 3, can be compared to the calculated D(Sn–X) values in Table 2. The trends in D(C–X) values are in general agreement with those of the D(Sn–X) values. The experimental D(C–X) values for X = R and NH_2 are 34–103 kJ mol^{-1} larger than their respective calculated D(Sn–X) values. For X = F, OH, and Cl, the D(Sn–X) values are greater than the D(C–X) values. Fluorine, oxygen, and chlorine are electronegative atoms that draw electron density away from the polarizable tin atom, creating strong electrostatic attractions (high ionic character) that explain these larger bond-dissociation enthalpies. The largest D(Sn–X) and D(C–X) values are observed with X = F. The experimental D(Si–X) and D(Ge–X) values are also larger than their respective calculated D(Sn–X) val-

Table 3. Experimental bond-dissociation enthalpies D(M–X) of Me_3M–X, where M= C, Si, Ge and X= H, CH_3, CH_2CH_3, NH_2, OH, Cl, and F (kJ mol^{-1}).

X	D(C–X)	D(Si–X)	D(Ge–X)
H	403.9[a]	378.0[b]	343.3[c]
CH_3	366.3[a]	374.2[b]	340.0[d]
CH_2CH_3	358.3[a]	—	—
NH_2	358.7[a]	—	—
OH	401.0[a]	535.8[b]	—
F	484.7[e]	—	—
Cl	355.4[a]	473.0[b]	485.6[f]

Note: Available D(M–X) are reported and are considered only relative values in the context of this study; they are used solely to compare trends with D(Sn–X).

ues. Although many D(Si–X) and D(Ge–X) values are not available, the general trends agree with the other group-IV species, linking electronegativity with bond dissociation.

L_2SnX_4 complex geometries

For L_2SnX_4, the ligands can be cis or trans in the octahedral geometry (Fig. 1), and each trans isomer can exist as two possible conformers. If a ligand, such as pyridine, has a C_2 axis of symmetry, the trans conformers have D_{2h} and D_{2d} symmetry. Unsymmetric ligands, such as *N,N*-dimethylformamide (dmf) and *N,N*-dimethylthioformamide (dmtf), can exist as trans isomers with C_{2h} or C_{2v} symmetry.

The relative energies calculated for the different L_2SnX_4 complexes are significant because experimental $\overline{D}$(Sn–L) values are reported[38–43] as single values that are the summation of population-weighted contributions from all complexes formed. Trends in energy are generally consistent regardless of ECP and are discussed below.

For the $(dmf)_2SnCl_4$ complex, the relative energies are similar for three structural complexes, with the C_{2h}, C_{2v}, and cis geometries differing by less than 6.3 kJ mol^{-1}. Similarly, the energies of three unique $(dmtf)_2SnCl_4$ complexes differ by less than 3.4 kJ mol^{-1}. However, while the energies of the D_{2h} and D_{2d} $(py)_2SnCl_4$ complexes differ by less than 2 kJ mol^{-1}, the cis complexes are 13–15 kJ mol^{-1} less stable. These relative energies are consistent with those calculated previously for the $(py)_2SnX_4$ complexes.[20,63] The relative instabilities of the *cis*-$(py)_2SnCl_4$ complexes may be attributed to the greater steric repulsions between the larger py ligands than between the dmf and dmtf ligands (see Fig. 2). The steric interactions present in the *cis*-$(py)_2SnCl_4$ complex are not present in the *trans*-$(py)_2SnCl_4$ complexes where the ligands are 180° apart (Fig. 1); resulting in lower relative energies for trans species. Because the magnitudes of ligand–ligand steric interactions in *cis*-$(dmf)_2SnCl_4$ and $(dmf)_2SnCl_4$ are small, these complexes were calculated to have energies similar to those of their trans counterparts.

These relative energy trends are also found for L_2SnBr_4, where the three structural complexes yield relative energies differing by less than 8 and 6 kJ mol^{-1} for $(dmf)_2SnBr_4$ and $(dmtf)_2SnBr_4$, respectively. In these cis complexes the dmf–dmf and dmtf–dmtf interactions do not appear to be larger than the Br–Br interactions; however, the *cis*-$(py)_2SnBr_4$ complexes are calculated to be 13–15 kJ mol^{-1} less stable than the D_{2h} and D_{2d} complexes, indicating that there are significantly larger steric interactions between cis py ligands.

The calculated mean tin–ligand bond lengths (r) of L_2SnX_4, L = py, dmf, and dmtf and X = Cl and Br, using the LANL2DZdp basis set with the LANL2 ECP are reported in Table 4. The two trans complexes yield similar r(Sn–L) while cis complexes contain longer Sn–L bond lengths. The bond strengths increase in the order of r(Sn–O) < r(Sn–N) < r(Sn–S) for both L_2SnCl_4 and L_2SnBr_4, however, the r(Sn–L) bonds in bromine species are longer than the respective chlorine complexes.

Thermodynamic parameters for L_2SnX_4 complexes

The thermodynamic parameters for the L_2SnX_4 complexes shown in Table 5 include gas-phase dissociation enthalpies (ΔH^{diss}), reorganization energies ($\Delta H^{reorg}(SnX_4)$), and BSSE corrections ($\Delta H^{BSSE}(L_2SnX_4)$). These three contributions and the reorganization energies of the donor ligands ($\Delta H^{reorg}(L)$) define the tin(IV)–ligand coordinate bond energies, $\overline{D}$(Sn−L) (eq. [6]). Although the $\Delta H^{reorg}(L)$ values are included in the calculation of $\overline{D}$(Sn–L), they are not reported in Table 5 because they are almost identical regardless of the type of isomer, the identity of X, or the computational method. The ligands' reorganization energies are very small compared to those for SnX_4; $\Delta H^{reorg}(L)$ for py, dmf, and dmtf are less than 3, 10, and 1 kJ mol^{-1}, respectively.

Results in Table 5 show that the calculated values for ΔH^{diss}, $\Delta H^{reorg}(SnX_4)$, $\Delta H^{BSSE}(L_2SnX_4)$, and $\overline{D}$(Sn − L) are unique for each molecule. The BSSE correction is the smallest contribution to the total bond strength, which seems to be ruled by dissociation and reorganization energies. This is consistent with the results of the previous computational study of L_2SnX_4,[18] which are further discussed in the final section titled "comparison with previous all-electron theoretical results". However, it should be noted that to obtain the average bond strengths, $\overline{D}$(Sn−L), all enthalpies and corrections are included and the total divided by the number of bonds formed (eq. [6]). Therefore, the dissociation enthalpies and reorganization energies can be greater or less than the bond strength because of the BSSE correction and final division by two. Some interesting trends in Table 5 are discussed in the following sections.

Comparing cis and trans isomers

Trends for ΔH^{diss} mirror those seen for the relative energies of cis and trans isomers. The trans isomers for $(dmf)_2SnX_4$ and $(dmtf)_2SnX_4$ complexes have ΔH^{diss} similar in magnitude to those of the cis complexes. However, for $(py)_2SnX_4$, ΔH^{diss} for the trans isomers are approximately equal while the cis complex has a smaller dissociation enthalpy. Furthermore, for each L_2SnX_4, BSSE corrections are similar for cis and trans complexes, while calculated reorganization energies for cis complexes are much lower than for trans species. Compared to the square planar SnX_4 in

	C_{2v}	2.160
	Cis	2.193
$(Dmf)_2SnBr_4$	D_{2d}	2.180
	D_{2h}	2.176
	Cis	2.208
$(Dmtf)_2SnCl_4$	C_{2h}	2.658
	C_{2v}	2.660
	Cis	2.740
$(Dmtf)_2SnBr_4$	C_{2h}	2.675
	C_{2v}	2.676
	Cis	2.758

Note: Bond length r(Sn–L) refers to r(Sn–N), r(Sn–O), and r(Sn–S) in py, dmf, and dmtf complexes, respectively.

the trans complex, the distorted-tetrahedral geometry of SnX_4 in cis complexes is closer in energy to the tetrahedral SnX_4 that exists upon dissociation, resulting in smaller $\Delta H^{reorg}(SnX_4)$ values. The $\Delta H^{reorg}(SnX_4)$ influences $\overline{D}$(Sn–L), as cis complexes contain weaker tin–ligand bonds than their respective trans counterparts, by as much as 26 and 27 kJ mol^{-1} in L_2SnCl_4 and L_2SnBr_4, respectively. This reflects geometric trends (Table 4), with tin–ligand bonds longer in cis complexes.

Effects of ligand choice in L_2SnX_4 complexes

The enthalpies of dissociation are affected by the choice of ligand as the magnitude of ΔH^{diss} increases from dmtf to dmf to py. BSSE energies are comparable for $(py)_2SnX_4$ and $(dmf)_2SnX_4$, and are up to 22 kJ mol^{-1} greater than $(dmtf)_2SnX_4$ complexes. The $\Delta H^{reorg}(SnX_4)$ values are consistent for every ligand because every trans geometry has the square planar tin center while cis complexes have the distorted-tetrahedral tin center. Like ΔH^{diss}, tin–ligand bonds increase in strength from $\overline{D}$(Sn–S) to $\overline{D}$(Sn–O) to $\overline{D}$(Sn–N).

Effect of X in L_2SnX_4 complex

As shown in Table 5, the choice of X affects the thermodynamic parameters of the L_2SnX_4 complexes. While BSSE corrections and the enthalpies of reorganization are comparable, the enthalpies of dissociation are generally larger in magnitude for L_2SnCl_4 than L_2SnBr_4. This affects the strength of the tin–ligand bonds, which are stronger for L_2SnCl_4 by as much as 13 kJ mol^{-1}.

Effect of computational method on L_2SnX_4 thermodynamic parameters

The foregoing discussion of the results in Table 5 focused on trends that are consistent for both effective core potentials; the choice of ECP does affect the quantitative values of dissociation, reorganization, BSSE, and bond enthalpy. Specifically, the ΔH^{diss} values from LANL2DZdp are up to 18 kJ mol^{-1} larger than those calculated using the SDB basis set. Conversely, the large SDB-aug-cc-pVTZ basis set produces BSSE and $\Delta H^{reorg}(SnX_4)$ values 9 and 13 kJ mol^{-1} larger than those with LANL2DZdp. All these values, along with reorganization energies of the ligands, contribute to the calculated bond strengths, $\overline{D}$(Sn–L), that differ by less than 9 kJ mol^{-1} between the two effective core potentials.

Computational efficiency should also be considered to determine which method is best for calculations on organotin compounds. The augmented, triple-zeta SDB-aug-cc-pVTZ basis set is larger than the double-zeta LANL2DZdp basis set. The smaller basis set requires less CPU time for geometry optimizations, and CPU times of both methods show significant time savings with LANL2DZdp (25%–90%) compared to the SDB-aug-cc-pVTZ basis set. Although these time savings are not substantial for the small organotin compounds in the present study, obtaining results with similar accuracy while using a fraction of the CPU time will be valuable in future studies of large dialkylstannylene acetal systems of interest. Therefore, based on computational accuracy and efficiency, we conclude that the LANL2DZdp basis set and ECP is an appropriate method and should be employed for further bond strength calculations of large donor-ligand tin complexes.

Comparison with previous experimental results

Table 5 includes the experimental dissociation enthalpies, calculated as the standard enthalpies for the Lewis acid/base reaction obtained for the gaseous phase using thermodynamic cycles.[38–43] For all L_2SnX_4 complexes, the $\Delta H^{diss} > 0$ indicated dissociation is not favored. However, there are noticeable discrepancies in the magnitudes of experimental and calculated dissociations. While this discrepancy may be attributed to an improper evaluation of complex energies by computational methods, other factors such possible uncertainties within the thermodynamics cycles employed in experiment may be the cause. Specifically, within these cycles the enthalpies of sublimation for the L_2SnX_4 are unknown, as the adducts decompose upon heating. Therefore, to complete the thermodynamic cycles, these enthalpies of sublimation were assumed to equal the enthalpies of vaporizations of the respective donor ligands. These assumptions may be the cause of the substantial difference between calculated and experimental dissociation enthalpies.

Comparison with previous all-electron theoretical results

The thermodynamic parameters of D_{2h} and *cis*-$(py)_2SnX_4$ complexes have been previously calculated using nonrelativistic, all-electron computational calculations employing B3LYP and basis sets of DZP quality on both tin and nontin atoms. Table 6 compares these with calculated theoretical parameters from the present study.

The effective core potentials in the present study yield dissociation energies up to 99 kJ mol^{-1} larger than the non-

relativistic, all-electron computational results. This trend occurs for $\Delta H^{reorg}(SnX_4)$ and $\Delta H^{BSSE}(L_2SnX_4)$, where ECPs values are greater by as much as 29 kJ mol^{-1}. However, these large deviations are created because of the different basis sets and levels of theory employed in each computational study. Previous results[20] show that for Si and Ge adducts of pyridine, ΔH^{diss} values calculated using MP2 are up to 50 kJ mol^{-1} larger than those using B3LYP. Therefore, including relativistic effects using ECPs, larger basis sets, and MP2 single-point calculations leads to large discrepancies between previous computational results and those in the present study. All of these thermodynamic contributions are included in the final bond strengths listed in Table 6, where large BSSE values using MP2 leads to better agreement between computational studies. However, MP2 calculations with ECPs still lead to $\overline{D}$(Sn–N) values larger than the previous all-electron B3LYP results.

The discrepancies between our thermodynamic values and those in the literature may be, in part, due to differences in geometries. The r(Sn–N) calculated with nonrelativistic, all-electron methods are up to 0.024 Å longer than those in the present study. The previous computational study used all-electron basis sets of DZP quality and neglected relativistic effects, which results in longer bonds.[64] It should also be

[a]Ref. 20.

[b]Although previous studies[20,44] have included half of the BSSE correction in eq. [6], the present study includes the entire $\Delta H^{BSSE}(L_2SnX_4)$ in calculation of $\overline{D}(Sn-X)$. Therefore, we compare values calculated in the present study to BSSE corrections and bond strengths that contain the entire $\Delta H^{BSSE}(L_2SnX_4)$, which are estimated from previous work.

noted that the values obtained from the present study are closer to all-electron calculations[20] than previous studies that employed effective core potentials.[16,17]

Conclusions

Effective core potentials were used to calculate homolytic bond-dissociation enthalpies, D(Sn–X), and donor–acceptor bond enthalpies, $\overline{D}$(Sn–L), of organotin compounds. Comparing calculated to experimental values showed that ECPs are suitable computational methods to examine bond in organotin systems. The large SDB-aug-cc-pVTZ basis set and ECP was used to calculate the D(Sn–X) of a series of trimethyltin(IV) species, Me_3Sn–X. However, it was concluded, based on computational efficiency and accuracy, that the LANL2DZdp basis set and effective core potential on tin and nontin atoms described by the 6-31G(d,p) basis set is also an appropriate method for calculation of tin bond strengths. Therefore, in larger organotin systems, including the dialkylstannylene acetals of interest, the LANL2DZdp basis set and effective core potential will be employed to calculate tin bond strengths in organotin compounds.

Supplementary data

Supplementary data (archive entries for the geometry optimizations of the molecules and the radical species and the geometry optimizations for the L_2SnX_4 series of donor–acceptor complexes) for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 3938. For more information on obtaining material, refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml.

Acknowledgements

We thank the Natural Sciences and Engineering Research Council (NSERC) for financial support. We gratefully acknowledge WestGrid for use of computer resources, and in turn the Canada Foundation for Innovation, Alberta Innovation and Science, BC Advanced Education. WestGrid equipment is provided by IBM, Hewlett Packard, and SGI. Additional computational facilities were provided in part by ACEnet, the regional high performance computing consortium for universities in Atlantic Canada. ACEnet is funded by the Canada Foundation for Innovation (CFI), the Atlantic Canada Opportunities Agency (ACOA), and the Provinces of Newfoundland & Labrador, Nova Scotia, and New Brunswick.

The response of extended systems to electrostatic fields[1]

Michael Springborg and Bernard Kirtman

Abstract: The response to electrostatic fields by finite systems, which contain a large central region of chemically identical building blocks, is shown not to depend on the boundaries of the system. Consequently, we can determine this response from that of the corresponding infinite periodic system and a vector potential theoretical–computational approach is presented for doing so. Both the electronic and structural response can be obtained with our approach. In many cases, neglecting the structural response is a poor approximation. To illustrate the performance of our treatment, extensive calculations have been carried out for simple model systems. Selected results are reported.

Key words: polarization, extended systems, electrostatic fields, structural properties, electronic properties.

Résumé : On démontre que, pour des systèmes finis contenant une grande région de blocs chimiquement identiques, la réponse à des champs électrostatiques ne dépend pas des limites du système. En conséquence, on peut déterminer cette réponse à partir des systèmes infinis correspondants et on présente une approche par calculs théoriques des potentiels vectoriels qui permet d'y arriver. Avec notre approche, il est possible d'obtenir aussi bien la réponse électronique que structurelle. Dans plusieurs cas, si on néglige la réponse structurelle, on obtient une mauvaise approximation. Afin d'illustrer la performance de notre traitement, on a effectué des calculs extensifs de systèmes modèles simples. On rapporte des résultats choisis.

Mots-clés : polarisation, systèmes étendus, champs électrostatiques, propriétés structurelles, propriétés électroniques.

Introduction

With this contribution, we want to honor Tom Ziegler on the occasion of his 65th birthday. It happens that Tom Ziegler shares a number of life experiences with one of the present authors (MS). Both grew up and studied in Denmark, but followed a scientific career outside of Denmark. Moreover, some of their first scientific footsteps were taken under the supervision of the same person, Jens Peder Dahl.

A significant part of Tom Ziegler's research has been devoted to calculating the electronic structure properties, including experimental observables, of large systems. These properties can be interpreted as the response of the system to external perturbations. In the spirit of Tom Ziegler's work, we discuss in this contribution, the response of large systems to electrostatic fields. The systems considered contain a large inner part consisting of a repetition of the same building block. On the boundaries other groups of atoms may be found. For the sake of simplicity, we shall concentrate on quasi-one-dimensional systems, i.e., polymers or chain compounds, but our treatment can be generalized to 2D and 3D systems as well.

The response of a material to spatially uniform electric fields can be described through its dipole moment, which may be expanded (in the perturbation regime) as

$$[1]\quad \mu_i(\omega) = \mu_i^{(0)}(\omega) + \sum_j \sum_{\omega_1} \alpha_{ij}(\omega;\omega_1)\cdot E_j(\omega_1) + 1/2 \sum_{jk} \sum_{\omega_1,\omega_2} \beta_{ijk}(\omega;\omega_1,\omega_2)\cdot E_j(\omega_1)E_k(\omega_2) + 1/6 \sum_{jkl} \sum_{\omega_1,\omega_2,\omega_3} \gamma_{ijkl}(\omega;\omega_1,\omega_2,\omega_3) \cdot E_j(\omega_1)E_k(\omega_2)E_l(\omega_3) + \ldots$$

Here the external field is given by

$$[2]\quad \vec{E} = \sum_j \sum_{\omega_n} E_j(\omega_n)\vec{1}_j$$

where $\vec{1}_j$ is a unit vector along the j direction (i.e., x, y, or z), and ω_n is its frequency. Furthermore, $\omega = \pm\omega_1 \pm \omega_2 \pm \ldots$ is the frequency of the molecular response[2] and $\mu_i^{(0)}(\omega)$ is the dipole moment in the absence of the field, which vanishes for $\omega \neq 0$. The quantity $\alpha_{ij}(\omega;\omega_1)$ is the linear polarizability, while $\beta_{ijk}(\omega;\omega_1,\omega_2)$, $\gamma_{ijkl}(\omega;\omega_1,\omega_2,\omega_3)$, ... are the first, second, ... hyperpolarizabilities. The fact that the non-linear responses of a material can result in frequencies different from those of the external field is very important for a number of future applications in non-linear optics (see, e.g., refs. 2–4).

In the present contribution we shall focus on the low-frequency case, where setting $\omega = \omega_1 = \omega_2 = \ldots = 0$ is a good approximation. In that case, both structural and electronic degrees of freedom will respond to the external field. From a practical point of view, the relevant property is the re-

sponse per unit volume, which in our case translates into the dipole moment, per unit,

$$[3] \qquad P = \lim_{N\to\infty} [\mu_i(N+1,\omega) - \mu_i(N,\omega)]$$

where N is the number of units in our system and P is the polarization.

A number of earlier theoretical studies, devoted to identifying the polarization of extended systems, have been based on applying eq. [3] (see, e.g., ref. 6 and references therein). As a general conclusion, it has been found that wave-function-based methods give significantly more accurate results for chain-length dependence than those that are found with density-based methods, at least as far as conventional density functionals are concerned.[7,8] There is an on-going search for more adequate functionals as discussed, for example, in refs. 9 and 10. However, that pertains to short and medium-size chains. To the knowledge of the present authors, there has been no attempt to characterize the $N \to \infty$ limit directly. Although it is not the scope of the present work, we suggest use of the methods presented here to obtain further insight into the problems of density functionals in describing responses of extended systems to electric fields.

Theoretical studies of the properties of a material exposed to an external electrostatic field face a number of challenges. Even for an isolated atom, the external field changes a bound state into a resonance. In a practical calculation, runaway solutions can be avoided by using a basis set of functions that are localized on the atom. For molecules, a second problem may occur: electrons may tunnel from one end to the other (the analogue of Zener tunneling in periodic systems). To avoid this, one may consider external fields that are not too strong. But for large systems the fields may have to be so weak that numerical accuracy will suffer.

Here we shall first demonstrate that the response of finite chains containing a long central region of repeat units is independent of how the chain is terminated. Thus, one may study infinite, periodic chains instead. It turns out to be non-trivial to formulate the polarization calculation for the periodic chain, or periodic systems in general. However, once that has been done, the resulting computational procedure can be more efficient and reliable than that of considering a large finite system.

In the past we have found it extremely useful to analyse computational performance and obtain illustrative insights through model calculations, and we shall do the same here. Our formulation for infinite periodic systems has been discussed in detail elsewhere,[11–13] but a brief review with illustrative calculations for the structural response will be provided below. Additional results for long finite chains have been presented previously.[6] For technical details, the reader is referred to those papers. Finally, we offer some concluding remarks.

Long finite chains

In this section, we shall study the responses of finite chains consisting of a long sequence of identical units plus some terminations. It will also be assumed that the chain can be split into three different parts, i.e., a central region (C) where the effects of the terminations are not felt (criteria to be specified later), and the two terminal left and right (L and R) regions. The fact that such a split can be made defines what we mean by a 'long' chain.

General considerations

When the system can be split into three segments as in Fig. 1 it can be shown that any accumulated charge, Q, is localized to the terminations. This follows from the fact that, for fixed terminations, increasing the length of the chain increases the number of units (N_C) in the central region. If there were extra charge, $\widetilde{Q}$, not localized to the terminations, then the charge per central unit (i.e., $\widetilde{Q}/N_C$) would change (unless $\widetilde{Q}$ were zero). This conflicts with being able to identify a central region with given properties.

Next we relate the dipole moment to the charge transfer between the L and R terminal regions. We assume that the chain is placed along the z axis, with $z = 0$ determined by the average of the nuclear positions in the z direction. Then, for the z component of the dipole moment, we may write

$$\begin{aligned}[4] \qquad \mu_z &= \int \rho(\vec{r}) z d\vec{r} \\ &= \int_L \rho(\vec{r}) z d\vec{r} + \int_C \rho(\vec{r}) z d\vec{r} + \int_R \rho(\vec{r}) z d\vec{r} \\ &= N_C \mu_C + \left[Z_R \int_R \rho(\vec{r}) d\vec{r} + Z_L \int_L \rho(\vec{r}) d\vec{r} \right] \\ &\quad + \left[\int_L \rho(\vec{r})(z - Z_L) d\vec{r} + \int_R \rho(\vec{r})(z - Z_R) d\vec{r} \right]\end{aligned}$$

This expression is valid whether or not an external electrostatic field is included and whether or not the structure has been relaxed accordingly. In eq. [4], $\rho(\vec{r})$ is the total density, including nuclear and electronic charges, and μ_C is the z component of the dipole moment of one of the central units. Z_R and Z_L describe the centers of the nuclear positions in the R and L regions, respectively.

To analyse eq. [4], we make a similar separation of the total charge of the system, which leads to

$$\begin{aligned}[5] \qquad Q &= \int \rho(\vec{r}) d\vec{r} \\ &= \int_L \rho(\vec{r}) d\vec{r} + \int_C \rho(\vec{r}) d\vec{r} + \int_R \rho(\vec{r}) d\vec{r} \\ &= \int_L \rho(\vec{r}) d\vec{r} + \int_R \rho(\vec{r}) d\vec{r}\end{aligned}$$

since the central units are neutral as shown above. From this equation,

$$\begin{aligned}[6] \qquad Z_R \int_R \rho(\vec{r}) d\vec{r} + Z_L \int_L \rho(\vec{r}) d\vec{r} &= (Z_R - Z_L)/2 \left[\int_R \rho(\vec{r}) d\vec{r} - \int_L \rho(\vec{r}) d\vec{r} \right] \\ &\quad + \frac{(Z_R + Z_L)}{2} Q\end{aligned}$$

Thus, we see that in eq. [4] the first term in square brackets is the dipole moment due to electron transfer from one end to the other plus a term that is non-vanishing only for a charged system. It is important to note that the last term in square brackets in eq. [4] describes local dipole moments

that arise from the charge distribution within the two terminal regions. Thus, for fixed terminations, it is the only term in this equation that does not increase with increasing chain length and, therefore, does not contribute to the dipole moment per unit as defined in eq. [3].

Instead of partitioning physical space into rigorously nonoverlapping regions, it is convenient at this point to use a different partitioning based on localized orbitals, which are confined primarily, but not exclusively, to one of the regions and are orthogonal when integrated over all space. Let us assume, then, that we have solved the electronic single-particle (Hartree–Fock or Kohn–Sham) equation,

$$[7] \qquad \hat{h}\psi_i(\vec{r}) = \epsilon_i\psi_i(\vec{r})$$

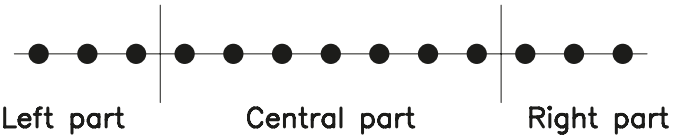
with or without the external field and with or without allowing the structure to relax in response to the field. Using an approach related to one that has been presented by Vanderbilt and King-Smith[14] (see also ref. 15), we now prove that the dipole moment per unit is independent of the terminations, except for terms that result from the transfer of an integral number of electrons from one end to the other. This result is independent of the presence of an external electrostatic field with or without structural relaxation. Therefore, the linear and nonlinear responses of the extended chain (i.e., dipole derivatives with respect to the field) are independent of the terminations.

The first step is to transform the occupied orbitals into a set of maximally localized orthogonal functions, $\{w_{np}(\vec{r})\}$ which in C will approach Wannier functions as the system becomes larger. Here, w_{np} is the pth function localized primarily to the nth cell (in the terminal regions the division into cells is arbitrary) which, however, may have tails sticking out into other cells. We can, then, write μ_z as

$$\begin{aligned}[8] \qquad \mu_z &= \sum_n \left[-\sum_p \int |w_{np}(\vec{r})|^2 z d\vec{r} + \sum_m z_{nm} Q_m \right] \\ &= \sum_{n\in C} \left[-\sum_p \int |w_{np}(\vec{r})|^2 z d\vec{r} + \sum_m z_{nm} Q_m \right] \\ &\quad + Z_L \sum_{n\in L} \left[-\sum_p \int |w_{np}(\vec{r})|^2 d\vec{r} + \sum_m Q_m \right] \\ &\quad + \sum_{n\in L} \left[-\sum_p \int |w_{np}(\vec{r})|^2 (z - Z_L) d\vec{r} \right. \\ &\qquad \left. + \sum_m Q_m (z_{nm} - Z_L) \right] \\ &\quad + Z_R \sum_{n\in R} \left[-\sum_p \int |w_{np}(\vec{r})|^2 d\vec{r} + \sum_m Q_m \right] \\ &\quad + \sum_{n\in R} \left[-\sum_p \int |w_{np}(\vec{r})|^2 (z - Z_R) d\vec{r} \right. \\ &\qquad \left. + \sum_m Q_m (z_{nm} - Z_R) \right] \end{aligned}$$

where Q_m is the charge of the mth nucleus (independent of n) and z_{nm} is the z coordinate for the position of the mth nucleus in the nth cell. In contrast to eq. [4], where the integrals are over different regions of space but the (electron) densities are completely delocalized, all integrals in eq. [8] are over the complete space, but the orbital densities are localized to different regions of space,. In eq. [8] only the 1st, 2nd, and 4th terms depend (linearly) on the size of the system and therefore only these terms will contribute to the long chain limit of the dipole moment per unit (i.e., the polarization), cf. eq [3].

Fig. 1. Schematic representation of a long finite chain separated into a central region and two terminal regions. Each dot represents a group of atoms.



Using the w functions, the density matrix can be written in block form,

$$[9] \qquad \underline{\underline{D}} = \begin{pmatrix} \underline{\underline{D}}_L & \underline{\underline{0}} & \underline{\underline{0}} \\ \underline{\underline{0}} & \underline{\underline{D}}_C & \underline{\underline{0}} \\ \underline{\underline{0}} & \underline{\underline{0}} & \underline{\underline{D}}_R \end{pmatrix}$$

where each block $\underline{\underline{D}}_X$ is the density matrix for the region X and the submatrices $\underline{\underline{0}}$ contain elements that are exponentially vanishing as a function of the distance from the boundary between regions. As the w functions become closer to Wannier functions in C, $\underline{\underline{D}}_C$ will approach a diagonal matrix. The full density matrix is idempotent, so that each block $\underline{\underline{D}}_X$ is idempotent as well. Therefore, in the formulation of eq. [8] the w functions centered in the terminal regions are associated with an integral number of electrons.

In the formulation of eq. [4], any non-integral electron transfer between the two terminations is determined by tails of the w functions in C that extend into either R or L. To maintain neutrality there must be an exactly equal transfer of electronic charge into C from the other termination. Since the w functions of C are, by definition, independent of the termination, so is the amount of charge transfer from one end to the other, $\int_R \rho(\vec{r}) d\vec{r} - \int_L \rho(\vec{r}) d\vec{r}$. Therefore, the contribution of the first term on the rhs of eq. [6] to the dipole moment per unit is independent of the terminations. The same is true of the second term on the rhs of eq. [6] due to the fact that $Z_R + Z_L$ is unchanged by adding a unit at the center of the chain. Finally, as argued above, the last term in square brackets on the rhs of eq. [4] does not grow with chain length. Hence, its contribution to the dipole moment per unit becomes increasingly negligible as N_c increases. This completes our demonstration that the dipole moment per unit is a bulk property for sufficiently long chains.

Illustrative calculations

To illustrate the result of the preceding sub-section, calculations were carried out using a simple Hückel-like model for long finite $(AB)_{2M+1}$ chains placed along the z axis. We employed a basis set of orthonormal atomic orbitals (AOs) with one AO per atom. The system has one electron per

atom and the nuclei have charges of +1. With χ_n being the AO of the nth atom, we assume that $\langle\chi_n|\widehat{h}_0|\chi_m\rangle$ is non-vanishing only for $m = n$, $n \pm 1$, or $n \pm 2$. For $m = n$ this matrix element oscillates between $\pm\epsilon_0$ as a function of n, and in the other cases it is a linear function of the interatomic distance. The quantity $\widehat{h}_0$ is that part of the single-particle Fock (or Kohn–Sham) operator, $\widehat{h}$, that does not depend explicitly on the electrostatic field. Thus, we have

$$
\begin{aligned}
&\langle\chi_{2p+1}|\widehat{h}|\chi_{2p+1}\rangle = \epsilon_0 - E_{\mathrm{DC}}\cdot z_{2p+1}\\
&\langle\chi_{2p}|\widehat{h}|\chi_{2p}\rangle = -\epsilon_0 - E_{\mathrm{DC}}\cdot z_{2p}\\
&\langle\chi_{p}|\widehat{h}|\chi_{p+1}\rangle = -[t_1 - \alpha_1(z_{p+1} - z_p)]\\
&\langle\chi_{p}|\widehat{h}|\chi_{p+2}\rangle = -[t_2 - \alpha_2(z_{p+2} - z_p)]
\end{aligned}
\qquad [10]
$$

with z_j being the position of the jth atom and E_{DC} the external electrostatic field in the z direction. To study the dependence of the results on the the terminations, we modify the on-site energies of the terminal atoms and (or) the terminal hopping integrals:

$$
\begin{aligned}
&\langle\chi_{1}|\widehat{h}|\chi_{1}\rangle = \epsilon_0 + \epsilon_L - E_{\mathrm{DC}}\cdot z_1\\
&\langle\chi_{4M+2}|\widehat{h}|\chi_{4M+2}\rangle = -\epsilon_0 + \epsilon_R - E_{\mathrm{DC}}\cdot z_{4M+2}\\
&\langle\chi_{1}|\widehat{h}|\chi_{2}\rangle = -[t_1 - \alpha_1(z_2 - z_1)] + t_L\\
&\langle\chi_{4M+1}|\widehat{h}|\chi_{4M+2}\rangle = -[t_1 - \alpha_1(z_{4M+2} - z_{4M+1})] + t_R
\end{aligned}
\qquad [11]
$$

In eqs. [10] and [11] ϵ_0, t_1, t_2, α_1, α_2, ϵ_L, ϵ_R, t_L, and t_R are parameters whose values have been varied over a large range. Here, we shall just report typical results. The total energy is written as a sum over the energies of the occupied orbitals augmented by elastic terms and a contribution from the DC field acting on the nuclear charges, i.e.

$$
\begin{aligned}
\mathscr{E}_{\mathrm{tot}} = 2\sum_{i=1}^{\mathrm{occ}}\epsilon_i + k_1/2\sum_{p=1}^{4M+1}(z_{p+1} - z_p)^2\\
+ k_2/2\sum_{p=1}^{4M}(z_{p+2} - z_p)^2 + E_{\mathrm{DC}}\sum_{p=1}^{4M+2} z_p
\end{aligned}
\qquad [12]
$$

where the parameters k_1 and k_2 are defined so that, for the infinite periodic chain without an external field, the minimum total energy corresponds to the atomic positions

$$
z_n = [n\cdot a/2 - (4M+3)\cdot a/4] + (-1)^{n+1}u_0 \qquad [13]
$$

Here, a is the lattice constant and u_0 is a bond length alternation parameter that describes a displacement of the atoms leading to alternating shorter and longer bonds.

We set $\epsilon_0 = 0.5$, $t_1 = 2.5$, $\alpha_1 = 4.5$, $t_2 = 0.5$, and $\alpha_2 = 0.2$. Moreover, k_1 and k_2 are chosen so that the optimized structure for a vanishing field and an infinite periodic chain has $a = 2.1$ and $u_0 = 0.05$. Finally, we consider the six different terminations obtained by setting (ϵ_L, ϵ_R, t_L, t_R) equal to (0, 0, 0, 0), (0, 0.5, 0, 0), (0.5, 0, 0, 0), (0, 0, 0, 0.8), (0, 0, 0.8, 0), and (0.5, 0.5, 0.8, 0.8), respectively. Results of the calculations are shown in Fig. 2 for both the relaxed and unrelaxed geometries of a long neutral chain with $N = 2M + 1 = 81$ units. To analyse the results we define the charge transfer

$$
q = 1/2\left[\int_L \rho(\vec{r})d\vec{r} - \int_R \rho(\vec{r})d\vec{r}\right] \qquad [14]
$$

Since we employ a set of orthonormal AOs

$$
\begin{aligned}
q = 1/2\left[\sum_{n=1}^{2M}\left(1 - 2\sum_{i=1}^{2M+1}|C_{ni}|^2\right)\right.\\
\left. - \sum_{n=2M+3}^{4M+2}\left(1 - 2\sum_{i=1}^{2M+1}|C_{ni}|^2\right)\right]
\end{aligned}
\qquad [15]
$$

where C_{ni} is the coefficient of the nth AO in the ith molecular orbital. The figure shows clearly that q is independent of the termination, i.e., all six curves lie on top of each other except that for certain field strengths this quantity changes by an integer. The precise value of the field at which the jump occurs depends on the termination. Figure 2 (bottom two panels) also shows that for different terminations the dipole moment per unit, μ_z/N, follows parallel curves when plotted vs. the field. The differences between the curves are due to the charge distributions within the terminations, i.e., the last term in square brackets in eq. [4]. The fact that all curves are parallel implies that the linear and non-linear responses are independent of the termination. This is a consequence of the fact that, for these responses, the terminal regions make a negligible contribution to the total property for the entire system (cf. the discussion following eq. [6]). For the unrelaxed chains, the calculations were done using the unrelaxed geometry of the infinite, periodic chain. Although this is an approximation, we note that an optimization of the finite chain geometry would only alter the structure of the terminal regions and, accordingly, would result in rigid shifts of the curves shown in the figure. When the structure is allowed to relax correctly, the responses increase significantly as seen in the right hand panels.

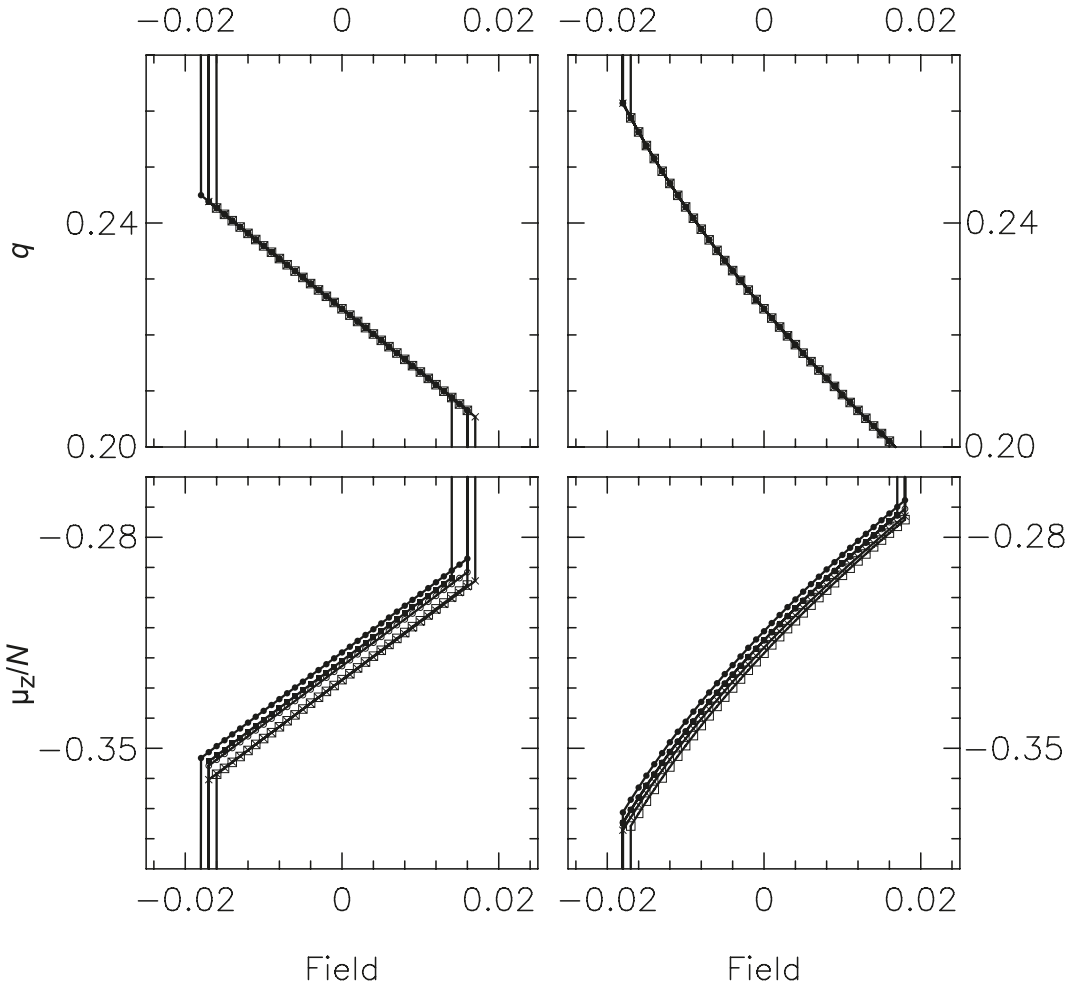
Infinite periodic chains

In the preceding section we demonstrated that, for a long chain with a central region of repeating units and arbitrary terminations, the dipole moment induced by an electrostatic field is unaffected by the terminations. This means that the responses are properties of the central region. The only possible exception is associated with transfer of an integral number of electrons from one end to the other. Thus, treating an infinite periodic chain might provide a convenient alternative procedure for calculating (hyper)polarizabilities of ordinary neutral systems. In that way the terminations are removed and the various band-structure approaches that have been developed in solid state physics can be applied. However, there are theoretical problems with this alternative because the external (scalar) potential destroys the periodicity and, in addition, is unbounded. One solution is to introduce the external field through the vector potential as described below (see, e.g., refs. 16 and 17).

Calculation of the electronic energy using the vector potential approach

In this subsection we discuss our vector potential approach (VPA) for calculating the total electronic energy of a given infinite periodic structure. In the second subsection we present our procedure for optimizing the structure automatically. Within the VPA, the external electrostatic field is described by a vector potential, in contrast to the more conventional scalar potential. It has the advantage that the ex-

Fig. 2. Charge transfer, q, and dipole moment per unit, μ_z/N, as a function of applied external field, for a model chain containing 81 units. The panels on the left show the results for the field-free structure of the infinite periodic chain while the panels on the right show the results after the structure has been allowed to relax. Vertical lines indicate the field at which an integral number of electrons is transferred from one end to the other. The details of the model are described in the text and the different curves in each panel are for different terminations.



tension to time-dependent fields is trivial. Moreover, as we have shown elsewhere[13] the two approaches can be formulated identically in the static field case.

In a conventional band-structure calculation, without an electrostatic field, translational symmetry is used in writing the electronic orbitals as

$$[16] \qquad \psi_j(k, \vec{r}) = e^{ikz} u_j(k, \vec{r})$$

with j being a band index and $u_j(k, \vec{r})$ a periodic unit cell function. In a typical calculation, a finite set of K equidistant k points in the interval $[-\frac{\pi}{a}; \frac{\pi}{a}]$ is employed. Here $a = |\vec{a}|$ is the lattice constant, and the k spacing is

$$[17] \qquad \Delta k = \frac{2\pi}{Ka}$$

Thus, the Born–von Kármán (BvK) zone consists of K unit cells. For a system with B doubly filled bands, and a gap between the occupied and unoccupied orbitals, the electronic part of the polarization can, then, be expressed as[11,16,18,19]

$$[18] \qquad P_e = \frac{2i}{K} \sum_{k=1}^{K} \sum_{j=1}^{B} \langle u_j(k) | \frac{\partial}{\partial k} u_j(k) \rangle$$

in the Hartree–Fock or Kohn–Sham approach.

If we write the orbitals as a linear combination of Bloch functions formed from atom-centered basis functions, i.e.

$$[19] \qquad \psi_j(k, \vec{r}) = \sum_p C_{pj}(k) \chi_p(k, \vec{r})$$

$$\chi_p(k, \vec{r}) = \frac{1}{\sqrt{K}} \sum_m e^{ikam} \chi_{pm}(\vec{r})$$

(χ_{pm} is the pth basis function of the mth unit cell), then[16,18]

$$[20] \qquad P_e = \frac{2}{K} \sum_{j=1}^{B} \sum_{k=1}^{K} \sum_m e^{ikma} \sum_{pq} C^*_{qj}(k) \left(\underbrace{\langle \chi_{q0} | z - ma | \chi_{pm} \rangle}_{\text{charge}} + \underbrace{i \langle \chi_{q0} | \chi_{pm} \rangle \frac{d}{dk}}_{\text{current}} \right) C_{pj}(k)$$

This relation expresses the polarization as a sum of charge and current contributions. The former can be interpreted as being the expectation value of a potential that is piecewise linear and has the periodicity of the lattice. On the other hand, the latter is not the expectation value of a potential since it involves the $\frac{d}{dk}$ operator. The charge term is identical to μ_C of eq. [4], implying that the current term replaces the contributions associated with the terminations in eq. [4]. Numerical calculations for a simple model confirm this analysis.[11]

In an actual calculation of P_e the current term can easily be the source of both numerical and conceptual difficulties. The reason is that the coefficients $C_{qj}(k)$ contain a band-dependent phase factor, which is arbitrary except that it must satisfy

$$[21] \qquad C_{qj}(-\pi/a) = C_{qj}(\pi/a)$$

Because $\frac{dC_{qj}(k)}{dk}$ has to be calculated numerically in determining the response to a finite field, this arbitrariness can very easily result in severe numerical problems. We have demonstrated that a smoothing procedure which makes $C_{qj}(k)$ maximally similar to the coefficients at the neighboring k points provides an optimal solution.[12]

A more fundamental problem occurs as follows. When introducing a phase factor so that

$$[22] \qquad \widetilde{C}_{qj}(k) = C_{qj}(k)e^{i\phi_j(k)}$$

the phase angle is required to satisfy

$$[23] \qquad \phi_j(\pi/a) = \phi_j(-\pi/a) + \widetilde{n}_j \cdot 2\pi$$

However, that still leaves $\widetilde{n}_j$ as an unknown integer. Adding the contribution from all bands the polarization and the total energy will change according to

$$[24] \qquad \begin{aligned} P_e &\rightarrow P_e - a \cdot \widetilde{n} \\ \mathscr{E}_{\text{tot}} &\rightarrow \mathscr{E}_{\text{tot}} + E_{\text{DC}} \cdot a \cdot \widetilde{n} \end{aligned}$$

where $\widetilde{n} = \sum_j \widetilde{n}_j$. Thus, the total energy depends upon the product of the lattice constant a, the field E_{DC}, and an unknown integer. Despite appearing to be physically irrelevant, different values of $\widetilde{n}$ will lead to different values of a piezoelectric coefficient, defined as

$$[25] \qquad \eta = \left.\frac{da}{dE_{\text{DC}}}\right|_{E_{\text{DC}}=0}$$

which quantifies how the material changes length (or, in 3D, volume) under the influence of an external electrostatic field. Although a practical procedure is available for obtaining the value of the unknown integer, at the moment of writing we have not come up with a final prescription.

Having defined the polarization, we can write the total electronic energy for one BvK zone as

$$[26] \qquad \mathscr{E}_e(E_{\text{DC}}) = \mathscr{E}_e(0) - E_{\text{DC}} \cdot K \cdot P_e$$

where $\mathscr{E}_e(0)$ is the field-free electronic energy and P_e is defined in eq. [18]. The corresponding Hartree–Fock equation (see, e.g., refs. 12 and 13) for the crystal orbitals is

$$[27] \qquad \left\{\underline{\underline{F}}(k) - E_{\text{DC}} \cdot \left[\underline{\underline{M}}(k) + i\underline{\underline{S}}(k)\frac{\partial}{\partial k}\right]\right\} \cdot \underline{C}_j(k) = \epsilon_j(k) \cdot \underline{\underline{S}}(k) \cdot \underline{C}_j(k)$$

where $\underline{C}_j(k)$ is the (field-dependent) jth column of the matrix $\underline{\underline{C}}(k)$, and

$$[28] \qquad \begin{aligned} S_{qp}(k) &= \sum_l e^{ikal}\langle\chi_{0q}|\chi_{1p}\rangle \\ M_{qp}(k) &= \sum_l e^{ikal}\langle\chi_{0q}|z - la|\chi_{1p}\rangle \\ &= \sum_l e^{-ikal}\langle\chi_{1q}|z|\chi_{0p}\rangle \\ F_{qp}(k) &= \sum_l e^{ikal}\langle\chi_{0q}|\widehat{F}|\chi_{1p}\rangle \end{aligned}$$

are the overlap, unit cell dipole, and Fock matrix elements, respectively. Here $\widehat{F}$ is the usual Fock operator which depends on the field through the orbital coefficients (see later).

Equation [27] deserves some discussion. First, note that the quantity in square brackets replaces the dipole moment operator that would occur in a molecular treatment based on the scalar potential. This quantity preserves the translational symmetry, i.e., k remains a good quantum number even though the derivative with respect to k now appears. Second, because of this derivative, eq. [30] is not a standard matrix-eigenvalue problem. However, by using the normalization condition

$$[29] \qquad \underline{\underline{1}} = \underline{\underline{C}}^{\dagger}(k) \cdot \underline{\underline{S}}(k) \cdot \underline{\underline{C}}(k)$$

which gives

$$[30] \qquad \underline{\underline{S}}(k)\frac{\partial}{\partial k}\underline{\underline{C}}(k) = \left[\underline{\underline{S}}(k)\left(\frac{\partial}{\partial k}\underline{\underline{C}}(k)\right)\underline{\underline{C}}^{\dagger}(k)\underline{\underline{S}}(k)\right]\underline{\underline{C}}(k)$$

equation [27] can be cast into the standard form. In that event, the term in square brackets in eq. [30] (as well as the Fock matrix) has to be treated self-consistently. Third, as mentioned above, the coefficients $\underline{C}_j(k)$contain arbitrary phase factors (eq. [22]). Since $\frac{\partial}{\partial k}\overline{C}(k)$ has to be calculated numerically, in general, the occurrence of these arbitrary phase factors can cause severe numerical problems. This makes the previously described smoothing procedure of paramount importance. Due to the arbitrariness of the phase factors there is an arbitrariness in the orbital energies. Thus, upon making the substitution of eq. [22], $\epsilon_j(k)$ changes according to

$$[31] \qquad \epsilon_j(k) \rightarrow \epsilon_j(k) + E_{\text{DC}}\frac{\partial}{\partial k}\phi_j(k)$$

Although the integral of the second term over the entire band will vanish, except for possible contributions from the undetermined $\widetilde{n}_j$ in eq. [23], the field-dependent orbital energies will vary in a somewhat arbitrary fashion as one goes across the band. Thus, the usual interpretation of the orbital energies as ionization potentials or electron affinities, based on Koopmans' (Hartree–Fock) / Janak's (DFT) theorem, must be reconsidered.

Our experience has shown that it is not possible to solve eq. [27] self-consistently to arbitrary accuracy. In the itera-

tive process a convergence parameter may be defined using, for example, the magnitude of the differences between output and input coefficients $\{C_{qj}\}$. That parameter reaches a minimum and then increases. Furthermore, its value at the minimum grows as a function of the strength of the external field, $|E_{DC}|$. This numerical instability is associated with the oscillations in the band structures described by eq. [31]. In physical terms it is undoubtedly related to the onset of Zener tunneling. However a full understanding has not yet been reached.

Optimization of the structure

The total energy, at a given geometry, is the sum of the electronic and the nuclear energy,

$$[32] \qquad \mathscr{E}_{tot} = \mathscr{E}_e + \mathscr{E}_n$$

The nuclear energy contains the (classical) electrostatic interaction between the nuclei as well as the (classical) interaction between the external electrostatic field and the nuclear charges. To optimize the structure automatically, the forces, $\frac{\partial \mathscr{E}_{tot}}{\partial x}$ are normally used. Here x is a general structural coordinate such as a lattice constant or an internal parameter, whose variation does not destroy the translational symmetry. Analytical formulas for evaluation of the forces are especially helpful in this regard. For the $\frac{\partial \mathscr{E}_n}{\partial x}$ term they are easily found, whereas for $\frac{\partial \mathscr{E}_e}{\partial x}$ they are more difficult to obtain.

In our recent work,[13] we have shown how an approach of Zerner[20] for finite, molecular systems can be generalized to the present case. As usual, the field-free Hamiltonian operator is written as a sum of one- and two-electron terms,

$$[33] \qquad \widehat{H}_e = \sum_i \widehat{h}_0(\vec{r}_i) + 1/2 \sum_{i \neq j} \widehat{v}(\vec{r}_i, \vec{r}_j)$$

for which the matrix elements are

$$[34] \qquad h_{0qp}(k) = \sum_l e^{ikal} \langle \chi_{0q} | \widehat{h}_0 | \chi_{lp} \rangle$$

$$v_{q_1q_2p_1p_2}(k_1, k_2) = \frac{1}{K} \sum_{l_1, l_2, m_2} e^{ia(k_1 l_1 + k_2 l_2 - k_2 m_2)} (\langle \chi_{0q_1} \chi_{m_2 q_2} | \widehat{v} | \chi_{l_1 p_1} \chi_{l_2 p_2} \rangle - \langle \chi_{0q_1} \chi_{m_2 q_2} | \widehat{v} | \chi_{l_2 p_2} \chi_{l_1 p_1} \rangle)$$

The total electronic energy in the presence of an electrostatic field may then be written as

$$[35] \qquad \mathscr{E}_e = \sum_k \sum_{pq} D_{qp}(k) h_{0qp}(k) + \frac{1}{2} \sum_{k_1 k_2} \sum_{p_1 p_2 q_1 q_2} D_{q_1 p_1}(k_1) D_{q_2 p_2}(k_2) v_{q_1 q_2 p_1 p_2}(k_1, k_2) - E_{DC} K P_e$$

where $D_{qp}(k)$ is the (k-dependent) density matrix,

$$[36] \qquad D_{qp}(k) = \sum_j C_{qj}(k) C^*_{pj}(k)$$

constructed from the coefficients that satisfy eq. [27] with

$$[37] \qquad F_{qp}(k) = h_{0qp}(k) + \sum_{k_1} \sum_{q_1 p_1} D_{q_1 p_1}(k_1) v_{q_1 q p_1 p}(k_1, k)$$

Note that $D_{qp}(k)$ depends upon E_{DC} since the expansion coefficients C_{qj} are field-dependent. After several steps where we use the facts that (1) the polarization is real, (2) the coefficients $C_{qj}(k)$ satisfy the single-particle eq. [27], (3) the overlap matrices are Hermitian, and (4)

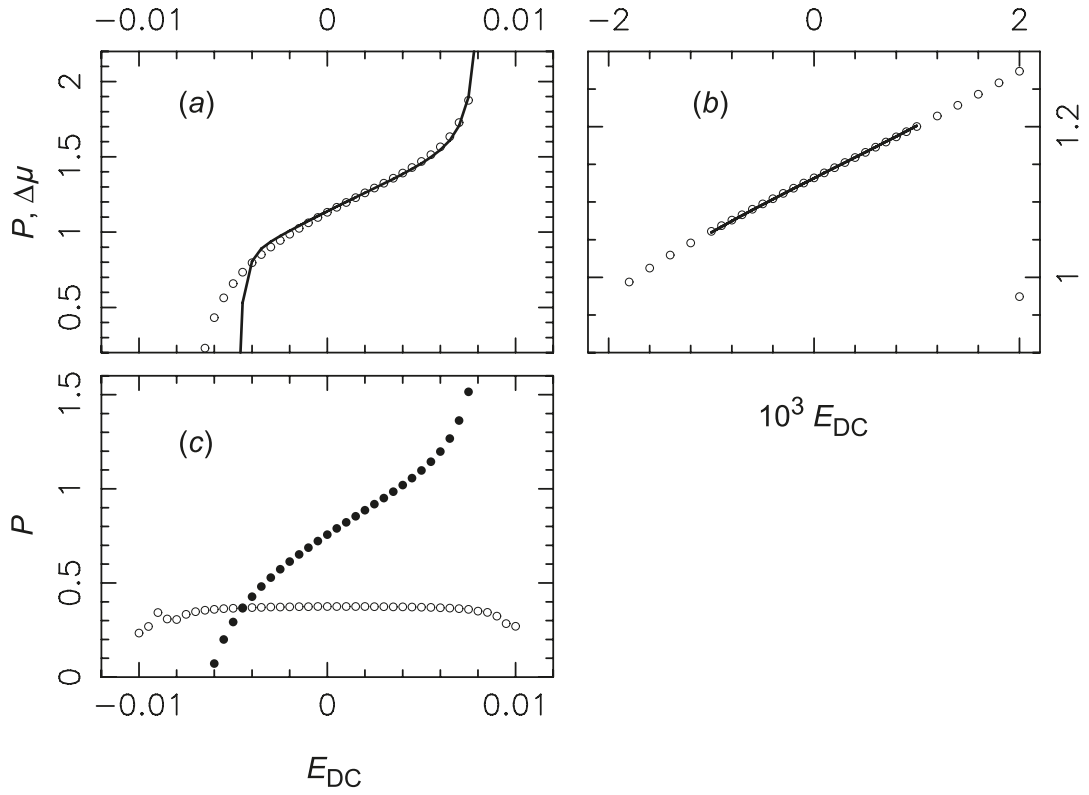
$$[38] \qquad \frac{\partial S_{qp}(k)}{\partial k} = -i[M_{qp}(k) - M^*_{pq}(k)]$$

we obtain

$$[39] \qquad \frac{\partial \mathscr{E}_e}{\partial x} = \sum_k \sum_{pq} D_{qp}(k) \frac{\partial h_{0qp}(k)}{\partial x} + \frac{1}{2} \sum_{k_1 k_2} \sum_{p_1 p_2 q_1 q_2} D_{q_1 p_1}(k_1) D_{q_2 p_2}(k_2) \frac{\partial v_{q_1 q_2 p_1 p_2}(k_1, k_2)}{\partial x}$$
$$- \sum_k \sum_{pq} Q_{pq}(k) \frac{\partial S_{qp}(k)}{\partial x} - \frac{\mathscr{E}_{DC}}{2} i \sum_k \sum_{pq} [R_{qp}(k) - R^*_{pq}(k)] \frac{\partial S_{qp}(k)}{\partial x}$$
$$- \frac{E_{DC}}{2} \sum_k \sum_{pq} D_{qp}(k) \left(\frac{\partial M_{qp}(k)}{\partial x} + \frac{\partial M^*_{pq}(k)}{\partial x} \right)$$

in which

Fig. 3. Comparison of the total polarization, P, for a periodic chain (open circles) with $\Delta\mu$ for a finite chain (full curve) as a function of field strength for: (*a*) field-free geometry ($N = 25$); (*b*) relaxed geometry ($N = 51$). In (*c*) the periodic chain results of (*a*) have been separated into the charge term (open circles) and the current term (full circles). All periodic chain calculations were done with $K = 60$ units in the BvK zone. For further details see the text.



$$[40] \qquad R_{qp}(k) = \sum_j C^*_{qj}(k)\frac{\partial C_{pj}(k)}{\partial k}$$

$$Q_{qp}(k) = \sum_j \epsilon_j(k) C^*_{qj}(k) C_{pj}(k)$$

have been introduced.

Illustrative calculations

The model in the above section was extended in the following ways:[13] Instead of only one, two (orthonormal) basis functions per atom were considered and the functions of neighboring atoms were allowed to overlap. In the nearest-neighbor one-electron matrix elements $\langle \chi_{n(i)}|\hat{h}_0|\chi_{n\pm1(j)}\rangle$, with $\chi_{m(k)}$ being the kth basis function of the mth atom, (k = 1,2) were assumed to depend linearly on the distance between the atoms, whereas the next-nearest neighbor terms were set equal to zero. Moreover, $\langle \chi_{n(i)}|\hat{h}_0|\chi_{n(i)}\rangle$ was assumed to depend only on i and the (A or B) atom type. Of the (parameterized) two-electron matrix elements, only $\langle \chi_{n(i)}\chi_{n(i)}|\hat{v}|\chi_{n(i)}\chi_{n(i)}\rangle$ were assumed to be nonzero. The parameters entering into the overlap matrix and P_e were calculated from basis functions whose rectangular shape was chosen to simplify the evaluation; i.e.

$$[41] \qquad \chi_{m(1)} = \begin{cases} 1/\sqrt{w_{X1}} \text{ for } |z - z_m| \le w_{X1}/2 \\ 0 \text{ otherwise} \end{cases}$$

$$\chi_{m(2)} = \begin{cases} 1/\sqrt{w_{X2}} \text{ for } w_{X2}/4 \le |z - z_m| \le w_{X2}/2 \\ -1/\sqrt{w_{X2}} \text{ for } |z - z_m| \le w_{X2}/4 \\ 0 \text{ otherwise} \end{cases}$$

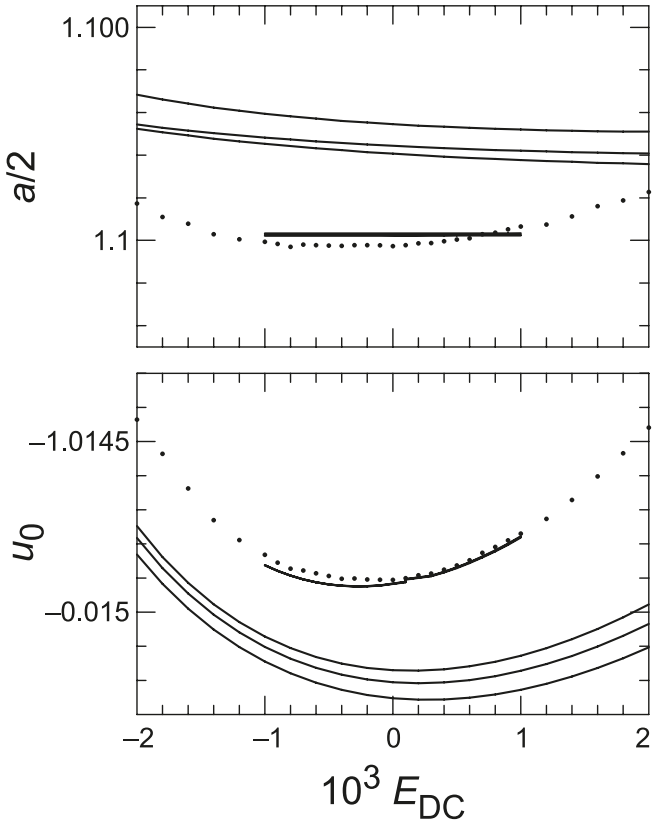
Here, X denotes whether the mth atom is of type A or B. We considered the case of four electrons per AB unit and the nuclei were each given a charge of +2 a.u.

In total, the model includes more than 20 parameters. By varying their values over a considerable range, the validity of our approach could be verified. We shall not give details of our results or values of the parameters but instead present typical calculations. More details, including values of the parameters, are available from the authors upon request.

Two different cases were studied: (1) a long finite chain of N units, for which the polarization was calculated using eq. [3], and (2) an infinite periodic chain with the electronic polarization given by eq. [20] and the nuclear polarization by the standard classical expression. Finally, we have adjusted the unknown integer $\tilde{n}$ of eq. [24] to obtain the best agreement between the finite and infinite chains.

In Fig. 3, we show typical results of our calculations. The number of k points, which is the same as the number of unit

Fig. 4. Optimized values of (top panel) the average bond length, $\frac{a}{2}$, and (bottom panel) the displacement of the atoms away from the equidistant positions, u_0 [see eq. [13], as a function of the field strength. Solid curves are for finite chains with N = 25, 26, 27, 50, 51, and 52 units, whereas the infinite chain results (dots) are for K = 60. The finite chain results for $N \simeq 25$ are those that differ most from the infinite chain results.



cells in the BvK zone, was set equal to K = 60 (cf. eq. [17]). According to our previous experience, this is sufficient to provide good accuracy. For the field-free structure, satisfactory agreement between the finite and infinite chains was found for N = 25, but when the structure is optimized, N = 51 was needed. Even with our simple model, the finite chain calculations for N = 51 are quite demanding, thereby providing support for the infinite periodic chain approach outlined here.

The figure clearly demonstrates that our approach for infinite periodic chains is able to reproduce the results for finite chains, when the latter are sufficiently long. When separating the polarization into the charge and current contributions [cf. Fig. 3*c*] we see that the variation in the polarization as a function of field strength is dominated by the current term, at least for this model system. Thus, the current term cannot generally be neglected.

In the present model the infinite periodic system has only two structural variables, which may be taken as the average bond length $\frac{a}{2}$ and the bond length alternation parameter u_0. Using the force expression of eq. [39] the relaxed structure was determined as a function of field strength. For comparison purposes we used the positions of the atoms in the middle of the finite chain to estimate $\frac{a}{2}$ and u_0.

The resulting parameters are shown in Fig. 4. As already observed the finite chains with 25 units are too short to allow for an accurate estimate of the infinite chain limit; at least 50 units are needed. In the latter case, the two sets of calculations yield good agreement. We believe that the small remaining differences are due to self-consistent field (SCF) convergence difficulties for the finite chains. In addition, we emphasize that the calculations for the latter are several orders of magnitude slower than those for the infinite periodic chains.

Concluding remarks

In this presentation we have demonstrated that finite chains consisting of a long sequence of identical building blocks with arbitrary terminations can be treated as if they were infinite and periodic. However, the correct procedure for determining the polarization (the dipole moment per unit) of an infinite periodic chain in an electrostatic field is not obvious. We have outlined how this problem can be solved by using the vector potential to describe the field. The resulting Hartree–Fock single particle equation has been formulated as eq. [27]. Although not presented, the analogous equation can be set up within Kohn–Sham density functional theory as well. Solving the single particle equation entails some non-trivial numerical difficulties. We have utilized a numerically stable procedure for obtaining a solution, but have also indicated some numerical and conceptual issues that remain open. Our approach allows for automatic structure optimization, with eq. [39] being the central result; again, a similar expression can be derived within the Kohn–Sham density functional theory formalism.

We have defined what is meant by a "long" chain, as used here, only in general terms, i.e., a chain for which maximally localized orbitals in the central region are unaffected by the terminations. When the property of interest is the polarization in the absence of an external field, also known as the "spontaneous" polarization, then the long chain limit will usually be reached for chains that contain on the order of 10 diatomic units. On the other hand, when higher-order responses and (or) structural relaxations are sought, we also require that contributions from the terminal regions be negligible compared to those from the central region. Then, considerably longer chains will often be required. Furthermore, when a field is turned on, our numerical results indicate that the size of the central region is reduced. This means that even larger systems are necessary before reaching the long chain limit.

Another method used to determine some of the responses to electrostatic fields is based on the application of a periodic, piecewise linear potential,

$$[42] \qquad V(z) = E_{DC} \cdot \begin{cases} z + L/4 \text{ for } -L/2 \le z \le 0 \\ -z + L/4 \text{ for } 0 \le z \le L/2 \end{cases}$$

where L is the size of the periodic repetition (which could be the size of the BvK zone). This approach has been employed, for example, by Darrigan et al.[21] Naturally, the length L must be sufficiently large to obtain accurate results. Although convergence with increasing L can be improved by taking differences, preliminary model calculations suggest that L values have to be so large that this procedure is

not useful compared to the one we have presented here. A more detailed analysis, which is beyond the scope of the present work, will be presented elsewhere.[22]

Our focus here has been on quasi-one-dimensional systems as studied by simple models. However, the treatment presented can be extended relatively easily to higher dimensions and can be implemented into parameter-free electronic structure programs. Work along these lines has already been initiated.[23] Nevertheless, by focusing on simple model systems, it has been possible to carry out extensive calculations which enabled our numerical methodology to be fully developed and tested. This would not have been possible had we solely considered accurate ab initio methods.

A time-dependent density functional theory (TDDFT) interpretation of the optical spectra of zinc phthalocyanine π-cation and π-anion radicals[1]

Angela Rosa and Giampaolo Ricciardi

Abstract: The UV–visible and near-IR spectra of the zinc phthalocyanine π-cation and π-anion radicals, $[ZnPc(-1)]^{\bullet+}$ and $[ZnPc(-3)]^{\bullet-}$, are investigated by time-dependent density functional theory (TDDFT) calculations using the pure, asymptotically correct, statistical average of (model) orbital potentials (SAOP) functional. The nature and intensity of the main spectral features are highlighted and interpreted on the basis of the ground-state electronic structure of the complexes. Similarities and differences with previous TDDFT/B3LYP results are discussed. TDDFT/SAOP results for the π-anion radical prove to be in excellent agreement with the solution spectra and generally in line with deconvolution analyses of solution absorption and magnetic circular dichroism (MCD) spectra. On the basis of these results a novel interpretation of the Q-band system is proposed. For the π-cation radical TDDFT/SAOP calculations provide a satisfactory description of the UV region of the spectrum. However, they do not reproduce accurately the energy and intensity of the Q band observed at 825 nm. The description of the Q-band region appears to be complicated by the presence of spurious non-Gouterman transitions. Furthermore, the calculations, either in the gas phase or in solution, do not account for the broad absorption near 500 nm that has been suggested to arise from a nondegenerate, *z*-polarized $^2A_{2g}$ excited state. Theory and experiment can be reconciled if the presence of an axial ligand such as CN^- is explicitly considered in the calculations. TDDFT/SAOP results for the axially ligated $[ZnPc(-1)(CN)]^{\bullet}$ species indicate that the 500 nm feature is related to the axial ligation induced symmetry lowering of the π-cation radical and this band is assigned to a *z*-polarized transition associated with the hole in the $2a_{1u}$.

Key words: metallophthalocyanine π-radicals, optical and magnetic circular dichroism (MCD) spectra, density functional theory (DFT) calculations, time-dependent density functional theory (TDDFT) calculations.

Résumé : On a étudié d'une façon théorique les spectres UV–visible et proche infrarouge des radicaux π-cationiques et π-anioniques de la phtalocyanine de zinc, $[ZnPc(-1)]^{\bullet-}$ et $[ZnPc(-3)]^{\bullet+}$, en faisant appel à la théorie de la fonctionnelle de la densité en fonction du temps (TFDFT) et une fonctionnelle pure et asymptotiquement correcte, SAOP. La nature et l'intensité des caractéristiques spectrales principales sont signalées et interprétées sur la base de la structure électronique de l'état fondamental des complexes. On discute des similarités et des différences observées avec les résultats rapportées antérieurement sur la base de calculs au niveau TFDFT/B3LYP. Les résultats obtenus pour radical π-anionique sont en excellent accord avec le spectre en solution et il est généralement en accord avec les analyses de déconvolutoin des spectres d'absorption de dichroïsme circulaire moléculaire (DCM). Sur la base de ces résultats, on propose une nouvelle interprétation pour la bande Q. Pour le radical π-cationique, les calculs au niveau TFDFT/SAOP fournissent une description satisfaisante de la région de l'UV du spectre. Toutefois, ils ne reproduisent pas d'une façon satisfaisante l'énergie et l'intensité de la bande Q observée à 825 nm. La description de la région de la bande Q semble compliquée par la présence de fausses transitions de Gouterman. De plus, les calculs, en phase gazeuse ou en solution, n'expliquent pas l'absorption large près de 500 nm pour laquelle il a été suggéré qu'elle découle d'un état excité $^2A_{2g}$ polarisé suivant l'axe *z* et qui ne serait pas dégénéré. On peut réconcilier les résultats théoriques et expérimentaux si la présence d'un ligand axial, tel un CN^-, est explicitement considérée dans les calculs. Les résultats de calculs au niveau TFDFT/SAOP pour l'espèce portant un ligand axial $[ZnPc-1)(CN)]^{\bullet}$ indiquent que l'absorption à 500 nm est reliée au fait que le ligand axial induit une réduction de la symétrie du radical π-cationique et ils attribuent cette bande à une transition polarisée selon l'axe des *z* qui serait associé avec le trou dans la $2a_{1u}$.

Mots-clés : radicaux π de métallophtalocyanines, spectres optiques et de dichroîsme circulaire moléculaire (DCM), calculs selon la théorie de la fonctionnelle de densité (TFD), calculs selon la théorie de la fonctionnelle de la densité en fonction du temps (TFDFT).

Introduction

The electronic and spectroscopic properties of oxidized and reduced metallophthalocyanines (MPcs) have been studied since the middle of the past century because of their involvement in photocatalysis and photoinduced redox chemistry and because of their similarity with the tetrapyrrolic species (porphyrins, chlorins, bacteriochlorins) formed as principal intermediates in a number of key biological processes, such as the primary charge-separation reactions of photosynthesis and the catalytic processes of naturally occurring hemes in catalase and peroxidase enzymes.[2–13] Oxidized and reduced MPcs have also shown potential as building blocks of photovoltaic devices. For instance, incorporating MPcs into donor–acceptor systems together with fullerenes,[14] perylenes,[15] anthraquinones,[16] carbon nanotubes,[17] or related metallomacrocycles,[18] gives rise to long-lived and highly emissive charge-separated states. MPcs may be reduced or oxidized chemically or electrochemically to give a series of negative or positive ions. For MPcs with redox nonactive metal ions, such as Mg^{2+} and Zn^{2+}, electron addition or removal is confined to the π orbitals of the Pc macrocycle. Up to four electrons can be reversibly added to the lowest unoccupied molecular orbitals (LUMOs), the twofold degenerate e_g* MOs in the D_{4h} molecular structure of MPcs, and up to two can be reversibly removed from the highest occupied molecular orbital (HOMO) of the Pc ring, the a_{1u} MO. Although spectral data concerning oxidized and reduced metallophthalocyanines have been available in the literature since the early seventies, the first band assignment was provided only in 1985 by Minor et al.[6] These authors have proposed a general assignment of the bands in the electronic absorption spectra of the cationic and anionic species for a number of MPcs based on a semiquantitative theoretical approach. Subsequently, through a combination of band deconvolution analysis of solution absorption and magnetic circular dichroism (MCD) spectra and semiempirical intermediate neglect of differential overlap (INDO) calculations, Stillman and co-workers[7–11,13,19,20] were able to provide an assignment of the optical spectra of the $[MPc(-1)]^{\bullet+}$ (M = Zn, Mg), $[MgPc(-3)]^{\bullet-}$, and $[ZnPc(-(2 + n)]^{n-}$ (n = 1–4) species as well as a general band assignment scheme for both main group and transition metal phthalocyanine anions. A band assignment for $[MgPc(-3)]^{\bullet-}$ based on INDO calculations has also been reported by Cory et al.,[12] who have also investigated the effects of Jahn–Teller (JT) distortions on the computed excitation energies. Recently, band deconvolution analyses of the absorption and MCD spectra have been used in combination with INDO calculations to interpret the optical absorption spectra of the radical anion of an electron-deficient zinc phthalocyanine.[21] Although spectral band deconvolution analyses of the absorption and MCD spectra give indications on the energy, number, and magnetic moment of the excited states contributing to each spectral region, a full characterization of the excited states requires accurate quantum mechanical calculations. Time-dependent density functional theory (TDDFT) is one of the most popular approaches for the calculation of excitation energies in quantum chemistry due to its efficiency and accuracy. It has already been used to study electron spectra for a wide range of molecules, including metallotetrapyrroles.[22] Except for special cases, such as long-range charge-transfer (CT) transitions,[23–26] TDDFT shows great promise in studies of excited states and its accuracy can be compared with the much more expensive correlated ab initio methods. In the last few years TDDFT has also been successfully applied to the calculation of the excitation energies of open-shell transition metal compounds.[27–32] Worth mentioning in this context is the recent TDDFT study by Stillman and co-workers[33] of the optical spectra of the zinc phthalocyanine π-cation and π-anion radicals, $[ZnPc(-1)]^{\bullet+}$ and $[ZnPc(-3)]^{\bullet-}$. Using the hybrid B3LYP functional, these authors came to a satisfactory description of the optical spectra of these compounds, although the assignments of several key spectral features remained problematic.

In this work, the optical spectra of $[ZnPc(-1)]^{\bullet+}$ and $[ZnPc(-3)]^{\bullet-}$ are revisited using TDDFT methods in conjunction with the sophisticated, asymptotically correct non-hybrid functional, SAOP (statistical average of orbital potentials).[34,35]This functional has been shown to provide an accurate description of the UV–visible spectra of tetrapyrrole complexes,[22,31,36,37] and in several cases, including ZnPc, proved to perform better than B3LYP[22] and other hybrid functionals.[38]

Since the compounds studied in this work are charged, we have also investigated the effect of the solvent on both the ground-state geometries and the excitation energies.

Computational details

All calculations have been performed with the program package ADF (Amsterdam Density Functional).[39–42] The geometry optimizations were carried out using the local density approximation (LDA) functional of Vosko–Wilk–Nusair (VWN),[43] plus the generalized gradient approximation (GGA), employing Becke's[44] gradient approximation for exchange and Perdew's[45] for correlation (BP86). Because this work is concerned with open-shell complexes, the spin-unrestricted density functional theory (DFT) formalism was employed. The calculated structures were verified to represent local minima by calculation of harmonic frequencies. Spin contamination, monitored by the $\langle S^2 \rangle$ expectation value, was found to be negligible in all cases. Electronic vertical excitation energies and oscillator strengths were computed using spin-unrestricted TDDFT, as implemented in ADF.[30]

Ground- and excited-state property calculations at the optimized geometries were performed using the pure, asymptotically correct, SAOP functional.[34,35] In the DFT and TDDFT calculations the all electron ADF TZ2P basis set, which is an uncontracted triple-ζ STO basis set with two polarization functions, was used.

Since the compounds studied in this work are charged, we have also carried out the calculations in solution by using the conductor-like screening model (COSMO)[46,47] as implemented in ADF.[48] The effects on the predicted geometries proved, however, to be negligible. Therefore, the excited-state properties were computed at the gas phase optimized geometries. Concerning the effect of the solvent on the excited state energies, it should be pointed out that in the ADF implementation[48] the COSMO surface charges are not explicitly considered in the TDDFT procedure other than through their influence on the ground-state density. This effectively amounts to using the ground-state surface charges

for both the ground and excited states as a first approximation to simulate the solvent effect on the excitation energies. The high-frequency component of the solvent electric susceptibility accounting for changes of the electronic structure of the solvent upon electronic excitations within the solute is not considered.

Results and discussion

Molecular structure

The interpretation of the optical and MCD spectra of MPc π-cation radicals reported so far has been based on the assumption that these species retain the D_{4h} symmetry of the parent neutral complexes.[6–9,13,19,33] Indeed, it is commonly accepted that formation of MPc π-cation radicals invariably involves removal of one electron from the $1a_{1u}$ HOMO of the Pc ring resulting in a $^2A_{1u}$ ground state. The situation is different in MPs (P = porphyrin). MPs have two nearly degenerate highest occupied MOs of a_{1u} and a_{2u} symmetry in the D_{4h} molecular framework, and removal of one electron can lead to a π-cation radical with a $^2A_{1u}$ or $^2A_{2u}$ ground state.[49–52] Neither of these pure state species, however, is stable under the D_{4h} symmetry, and both radical cation types are subject to *pseudo*-JT distortion that leads to structures with lower symmetry and states with mixed A_{1u} and A_{2u} character.[52]

Our DFT/BP86 calculations on the zinc phthalocyanine π-cation radical fully confirm the previously assumed D_{4h} structure. Geometry optimization of $[ZnPc(-1)]^{\bullet+}$ under D_{4h} symmetry constraint indeed led to a stable minimum with a $^2A_{1u}$ electronic ground state. In an attempt to capture out-of-plane distortions, unconstrained geometry optimizations of ad hoc distorted structures were also performed. However, these invariably converged to the D_{4h} structure.

Table 1 collects the most relevant bond parameters calculated for $[ZnPc(-1)]^{\bullet+}$ and $[ZnPc(-3)]^{\bullet-}$ and, for the sake of comparison, those previously reported for the neutral complex, ZnPc.[36] The orientation of the molecules and the atom labeling are shown in Fig. 1. According to the data in Table 1, removal of one electron from the $2a_{1u}$ HOMO causes a shortening of the Zn–N_p bond. A recent theoretical analysis of the structural and electronic properties of metalloporphyrin π-cation radicals also points to a contraction of the M–N_p bond length upon formation of π-cation radicals of A_{1u} type.[52] The decrease of the macrocycle core size is accompanied by changes in other geometric parameters. The largest bond lengthening is observed for the C_o–C_m bond, due to a loss of π-bonding interaction between the C_o and C_β atoms. On the other hand, significant contraction is observed for the C_m–C_m, C_β–C_o, and C_β–C_β bonds, owing to the relief of π-antibonding interaction between the involved atoms. All these changes in the bond lengths reflect the nodal pattern of the $2a_{1u}$ MO (see the plot of this orbital in Fig. 2).

Concerning the MPc π-anion radicals, the addition of one electron to the e_g* LUMOs of the neutral MPc results in the twofold degenerate ^2E_g state. Therefore, a JT distortion will take place to remove this electronic degeneracy. According to the general theory,[53,54] JT-active coordinates are of either B_{1g} or B_{2g} symmetry resulting in D_{2h} configurations of a *rhombus* or *rectangle*, respectively. Geometry optimization of $[ZnPc(-3)]^{\bullet-}$ led to a *rectangular* D_{2h} structure (the elongation is along the *y* axis) with a $^2B_{3g}$ electronic ground state. The D_{2h} *rhombic* structure, which is only 0.5 kJ/mol less stable, has an imaginary frequency (350 cm^{-1}) of B_{1g} symmetry. A JT distorted rectangular D_{2h} structure was also predicted for $[MgPc(-3)]^{\bullet-}$ by Cory et al.,[12] using both ab initio and semiempirical (INDO/1) self-consistent field approaches.

The bond parameters obtained for the equilibrium rectangular D_{2h} structure of $[ZnPc(-3)]^{\bullet-}$ indicate that the Zn–N_p bond shortens along the *y* axis and elongates along the perpendicular axis (see Table 1). The changes of the other

[b]The data in the column refer to the indole moieties bisected by the *y*/*x* axes.

Fig. 1. Atom labeling scheme for ZnPc. The elongation for the π-anion radical is along the *y* axis.

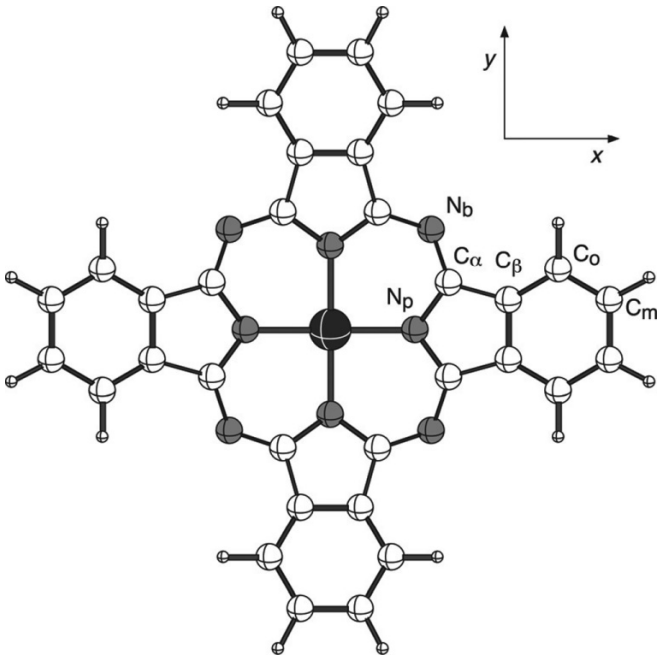

Fig. 2. DFT/SAOP ground-state molecular-orbital description of ZnPc. Double occupancy is indicated for the HOMO only. All lower lying levels are also doubly occupied. The Gouterman's four orbitals are indicated with red lines. For the sake of clarity, the N lone pairs of b_{1g}, b_{2g}, and e_u symmetry are reported in a separate column.

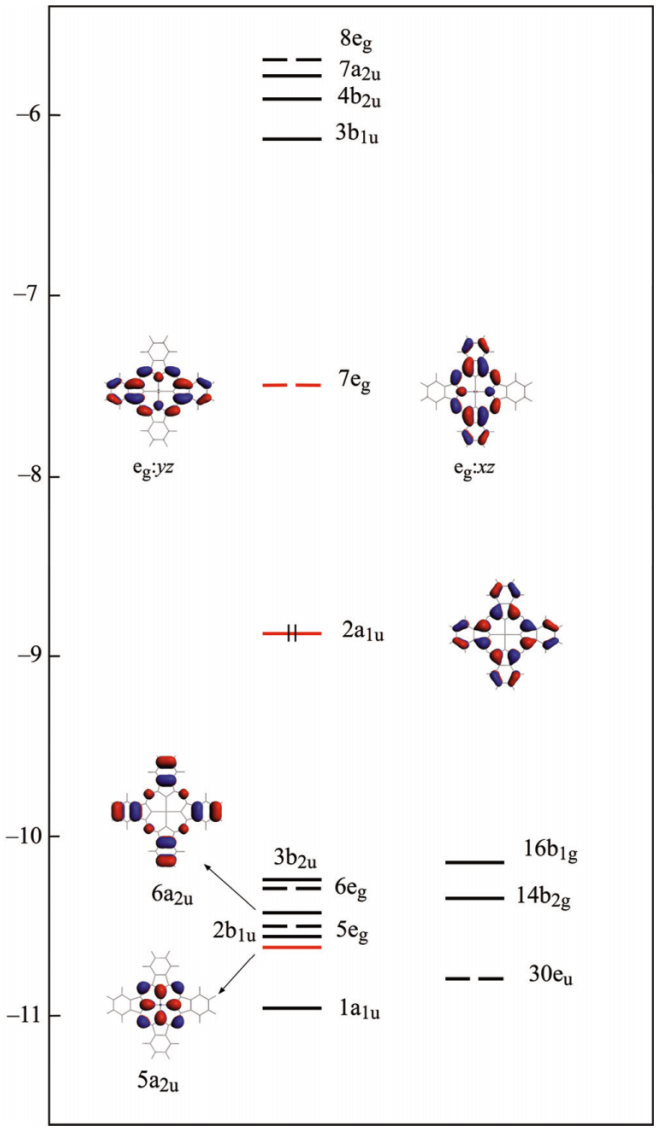


bond parameters are consistent with the nodal pattern of the *yz* component of the $7e_g$ MOs (see plots in Fig. 2), the b_{3g} SOMO (singly occupied MO) in the distorted D_{2h} structure. For instance, the C_α–N_p bond of the pyrroles bisected by the *y* axis elongates significantly on account of the increased π-antibonding interaction between the C_α and N_p atoms. In contrast, the C_α–N_p bond of the pyrroles bisected by the *x* axis remains unperturbed, which is consistent with the b_{3g} having no amplitude on the N_p atoms lying on the *x* axis.

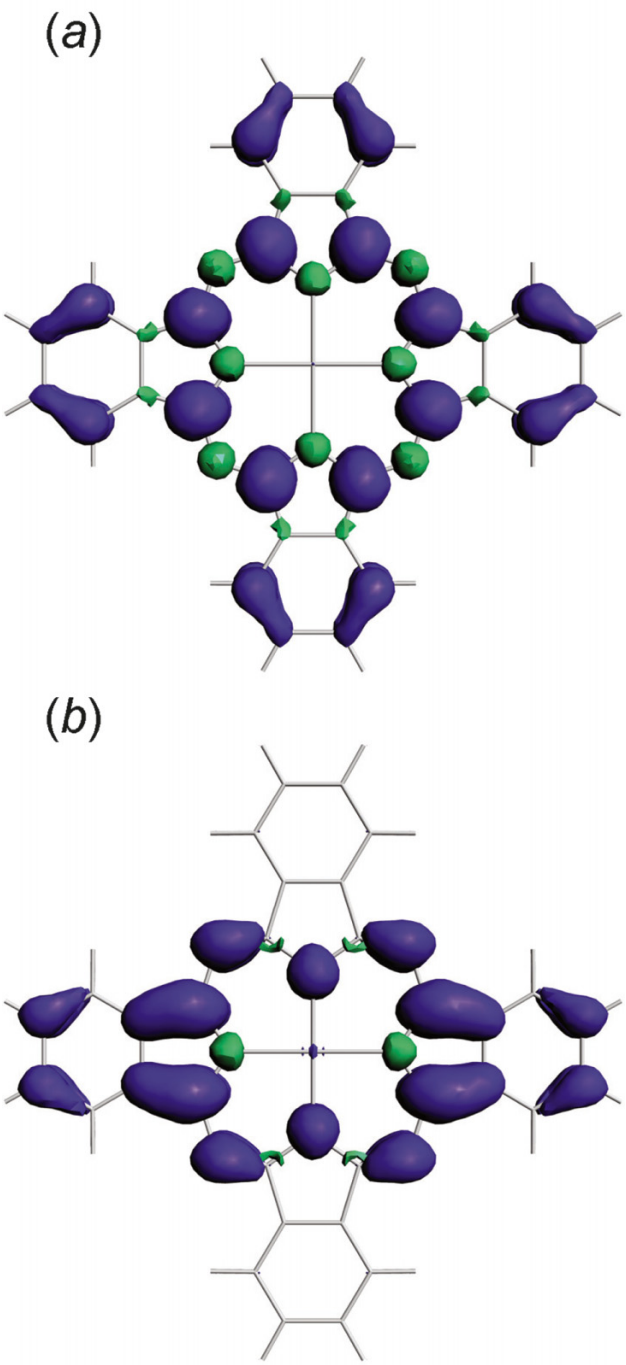
Electronic structure

Before dealing with the excited states of $[ZnPc(-1)]^{\bullet+}$ and $[ZnPc(-3)]^{\bullet-}$, we analyze the ground-state electronic structure of these species. Our analysis is based on the Kohn–Sham (KS) MOs of DFT. The KS orbital model is very suitable for the interpretation of the electronic structure and elucidation of the character of the excitations.[55] The use of KS orbitals affords a direct connection with the linear combination of atomic orbitals (LCAO)–MO treatments based on semiempirical or Hartree–Fock (HF) orbitals that have been used so far to interpret the main spectral features of oxidized and reduced MPcs,[6,11–13,19] while having at the same time the advantage of the high accuracy of the TDDFT treatment of the excitation energies.

To discuss the ground-state electronic structure of $[ZnPc(-1)]^{\bullet+}$ and $[ZnPc(-3)]^{\bullet-}$, it is useful to take the neutral complex as the reference point. Since an extensive DFT analysis of the electronic structure of ZnPc has been previously reported,[36] only the most salient features are recalled here. The highest occupied and lowest unoccupied levels of ZnPc are shown in Fig. 2. The Gouterman MOs, i.e., the occupied $5a_{2u}$ and $2a_{1u}$ (HOMO) and the unoccupied $7e_g$ (LUMOs), are indicated with red lines. For the sake of clarity, the highest N lone pair levels are given in the right column of the level scheme of Fig. 2. Of these in-plane levels, the $16b_{1g}$ is a N_p lone pair MO, which is pushed up by antibonding with the Zn-$3d_{x^2-y^2}$ and ends up just above the set of the occupied π orbitals, but is still well below (~1.1 eV) the HOMO. The $16b_{1g}$ is actually the HOMO-1 of the molecule. The lower lying N lone pair levels shown in Fig. 2, the $14b_{2g}$ and $30e_u$, are basically N_b lone pair MOs. Of the occupied π levels, the two MOs of A_{2u} symmetry, the $6a_{2u}$ and $5a_{2u}$, have received special attention in view of their relevance to the interpretation of the absorption spectrum of ZnPc.[36] As it will be shown herein, they also play an important role in the absorption spectra of the zinc phthalocyanine π-cation and π-anion radicals. According to the level scheme of Fig. 2, quite a large energy gap separates the LUMOs from a set of closely spaced π* levels, which have large amplitude on the benzo rings. These MOs have been shown to be involved in the excitations accounting for the UV features (N, L, and C bands) of the optical spectra of ZnPc.[36]

As mentioned above, one electron oxidation of ZnPc affords a π-cation radical having a D_{4h} molecular structure and a $^2A_{1u}$ electronic ground state, with the unpaired electron residing on the $2a_{1u}\uparrow$. Consistent with the nature of the SOMO, the spin density is almost entirely localized in the p_z orbitals of the carbon atoms of the indole moieties, as inferred from Fig. 3*a* where a plot of the spin density distribution in $[ZnPc(-1)]^{\bullet+}$ is displayed. The plot of Fig. 3*a* also shows that, besides the spin density coming from the SOMO, there exists some p_z spin density on the N_p and N_b atoms. This negative spin density at the nitrogen atoms is due to a polarization effect produced by the SOMO on the double occupied π MOs having amplitude on N_p and (or) N_b atoms. When comparing the level schemes of Fig. 2 and Fig. 4 it is apparent that the outstanding difference between ZnPc and $[ZnPc(-1)]^{\bullet+}$ is the generalized, although not uniform, stabilization of occupied and virtual levels. The downward shift of the spin orbitals with N lone pair character, i.e., the $16b_{1g}$, $14b_{2g}$, and $30e_u$, is particularly large so that the ordering of the occupied orbitals is in the π-cation radical, slightly altered relative to the neutral complex. The splitting between the spin-up and spin-down levels is in general quite modest, which is in line with the delocalized character of these spin orbitals.

Fig. 3. Spin density distribution in (*a*) $[ZnPc(-1)]^{\bullet+}$ and (*b*) $[ZnPc(-3)]^{\bullet-}$.



Coming now to the π-anion radical, this species has a $^2B_{3g}$ electronic ground state in the equilibrium JT distorted rectangular D_{2h} structure. The ground-state spin density distribution in $[ZnPc(-3)]^{\bullet-}$ (see Fig. 3*b*) reflects the atomic orbital composition of the SOMO, the $7b_{3g}\uparrow$, although a small amount (–0.030) of negative spin density resides on the p_z orbitals of the N_p atoms lying on the *x* axis. An energy level scheme showing the highest-occupied and lowest-unoccupied KS spin orbitals of $[ZnPc(-3)]^{\bullet-}$ is displayed in Fig. 5. When comparing the level schemes of $[ZnPc(-3)]^{\bullet-}$ and ZnPc, it is apparent that the negative charge induces a generalized destabilization of the levels. The JT splitting of the e_g and e_u levels is small, particularly in the case of the $7e_g$. The spin-down components of the JT split $7b_{3g}$ and $7b_{2g}$ MOs are actually nearly degenerate (see the level scheme of Fig. 5), with the splitting of the spin-up components being merely related to occupation of the $7b_{3g}\uparrow$.

Excited states and optical spectra

[ZnPc(–1)]$^{\bullet+}$

Figure 6 displays the absorption and MCD spectra of $[ZnPc(-1)]^{\bullet+}$ recorded after controlled potential oxidation of ZnPc(Im) (Im = imidazole) dissolved in dichloromethane solution at room temperature.[8] Figure 6 also shows the absorption and MCD spectra of ZnPc(Im) before controlled coulometry oxidation. The optical spectrum of the neutral complex is characterized by an intense Q band at ~670 nm showing vibrational structure, and by a broad envelope peaking at ~330 nm followed by a weaker feature at ~270 nm, denoted as B and N bands, respectively. Band envelope deconvolution analyses of the room temperature solution absorption and MCD spectra of ZnPc(L) complexes, where L is

Fig. 5. Energy-level scheme for $[ZnPc(-3)]^{\bullet-}$ obtained from spin-unrestricted DFT/SAOP calculations.

an axially coordinate cyanide, imidazole, or pyridine ligand, identified, within the B band envelope, at least two components associated to MCD *A* terms.[7] In the case of zinc phthalocyanine with cyanide, the two components of the B band, denoted as B1 and B2, were located at 386 and 331 nm, respectively. When comparing the absorption spectrum of the neutral complex with that of the π-cation radical in Fig. 6, it is apparent that upon oxidation dramatic spectral changes occur in the visible and near-IR region. The intense Q band of the neutral complex and its vibrational progression disappear, while broad and weaker bands appear at around 500, 720, and 825 nm. Less dramatic changes occur in the UV region ($\lambda < 400$ nm). These mainly consist in a blue shift and weakening of the B band envelope. Spectral deconvolution analyses of the absorption and MCD spectra of $[ZnPc(-1)]^{\bullet+}$ assigned the bands at 825 and 720 nm to transitions to ^2E_g (*x*/*y* polarized) excited states, since they are accounted for by MCD *A* terms.[7,8] More recent studies by Stillman and coworkers[33] have demonstrated that the 720 nm band arises from an electron paramagnetic resonance (EPR) silent dimeric species in equilibrium with the monomer. As for the broad band at 500 nm, it was assigned to a transition of a nondegenerate excited state since it is an intense *z*-polarized Faraday *B* term.[7] The absorption spectrum in Fig. 6 clearly indicates that the 440–250 nm region comprises several bands. Actually, a sum of 11 bands was used by Stillman and co-workers[7] to fill most of the intensity in both the absorption and MCD spectra. Of these, the bands at 424, 370, 317, and 278 nm were associated to MCD *A* terms.

The excitation energies and oscillator strengths calculated for the optically allowed ^2E_g and $^2A_{2g}$ excited states of $[ZnPc(-1)]^{\bullet+}$ up to 4.0 eV are gathered in Table 2. The TDDFT calculations were performed both in the gas phase and dichloromethane solution (the solvent used to record the absorption and MCD spectra) using the gas-phase optimized geometry of the complex. The theoretical results in the gas phase will be considered first, and then the solvent effects will be examined. As inferred from the data in Table 2, only three doubly degenerate excited states are predicted in the 860–560 nm spectral region. Of these, the 2^2E_g and 3^2E_g computed at 1.50 eV (827 nm) and 1.82 eV (681 nm), respectively, consist of the same one-electron transitions, the $2a_{1u}\uparrow \rightarrow 7e_g\uparrow$ and the $5e_g\downarrow \rightarrow 2a_{1u}\downarrow$, with approximately reversed weights. The large transition dipoles of

[a]The numbering and composition of the excited states refer to TDDFT calculations in the gas phase.

[b]Band maxima corresponding to positive MCD *A* terms obtained trough deconvolution analyses of the absorption and MCD spectra of $[ZnPc(-1)]^{\bullet+}$ in CH_2Cl_2, from refs. 7 and 33.

these transitions reinforce in the 3^2E_g and cancel in the 2^2E_g to the result that the former is by far more intense than the latter. It is evident from the data in Table 2 that neither of these excited states properly account for the energy and intensity of the band observed at 825 nm. The discrepancy between theory and experiment can be traced to the well-known failure of TDDFT to correctly calculate the energy of CT transitions.[23–26] The description of the Q-band region appears to be complicated by the presence of spurious non-Gouterman transitions out of MOs mostly localized on the benzo rings, the $5e_g$, to the highly delocalized Gouterman SOMO, the $2a_{1u}$. As these transitions have significant CT character, they are calculated at an energy that is somewhat too low and accidentally mix with the Gouterman $2a_{1u} \rightarrow 7e_g$ transitions. One way of counterbalancing this observed shortcoming of TDDFT is the admixture of a portion of "exact" HF exchange (hybrid-GGA functionals). The optimum percentage of HF exchange may vary from molecule to molecule and state to state.[56,57] However, the more exact exchange is included in the treatment, the less electron correlation is considered, again leading to wrong excitation energies. It is instructive in this respect to look at the TDDFT/B3LYP/6-31G(d) results by Stillman and co-workers[33] showing that the introduction of a 20% HF exchange is sufficient to avoid the mixing between the $2a_{1u}\uparrow \rightarrow 7e_g\uparrow$ and the $5e_g\downarrow \rightarrow 2a_{1u}\downarrow$ transitions, but at the expense of the accuracy. In the Q-band region they indeed compute only an intense ($f = 0.23$) ^2E_g excited state, which is a nearly pure (93%) $2a_{1u} \rightarrow 7e_g$ state. The calculated energy is, however, far too low compared to the experiment (950 vs 825 nm).

As for the lowest ^2E_g state, the 1^2E_g, it is a nearly pure $6e_g\downarrow \rightarrow 2a_{1u}\downarrow \pi \rightarrow \pi$ state. This state, computed at 843 nm and with a very low oscillator strength ($f = 0.002$), is likely to contribute to the broadening of the 825 nm band.

As inferred from the calculated excitation energies, a large energy gap separates the 3^2E_g from the next excited state, the 4^2E_g, which is computed at 2.56 eV (485 nm). Thus, TDDFT results confirm the vibronic origin of the weak and broad absorption to the blue of the band at 825 nm, as suggested by Stillman and co-workers.[7] They do not account, however, for the broad absorption near 500 nm. According to the absorption and MCD deconvolution analysis by Stillman and co-workers,[7,33] this band should be accounted for by a nondegenerate, z-polarized $^2A_{2g}$ excited state. However, TDDFT/SAOP calculations predict the lowest $^2A_{2g}$ state at a much higher energy, 3.17 eV (391 nm). Inclusion of the solvent effects (vide infra) does not reconcile theory and experiment.

In the region of the observed spectrum between 480 and 300 nm, TDDFT/SAOP calculations predict 12 doubly degenerate excited states, four of which, the 9^2E_g, 13^2E_g, 14^2E_g, and 15^2E_g, with sufficient intensity to be easily observed. Taking into account the near degeneracy of the 13^2E_g and 14^2E_g states, there is an excellent correspondence between the energies of the three bands of the deconvolution of Stillman and co-workers[7] and the calculated excitation energies. The bands located by the deconvolution analysis at 424, 370, and 317 nm are indeed nicely accounted for by the 9^2E_g, the two nearly degenerate 13 and 14^2E_g, and the 15^2E_g states, respectively. Comparing the present TDDFT/

Note: Only states with $f \geq 0.001$ are reported.

[a]The numbering and composition of the excited states refer to TDDFT calculations in the gas phase.

[b]Band maxima observed in the absorption spectrum of $[ZnPc(-3)]^{\bullet-}$ in DMF at 77 K, from ref. 11.

SAOP results for $[ZnPc(-1)]^{\bullet+}$ with the previous ones for ZnPc[36] we note that the 9^2E_g has approximately the same energy, intensity, and composition as the excited state accounting for the B1 band of ZnPc, the 4^1E_u (see Table 3 in ref. 36). The same holds true for the 15^2E_g state of the π-cation radical and the excited state accounting for the B2 band in ZnPc, the 7^1E_u (see Table 3 in ref. 36). Thus, the bands located at 424 and 417 nm in the absorption and MCD spectra of $[ZnPc(-1)]^{\bullet+}$ correspond to the B1 and B2 bands of ZnPc, respectively. The B1 and B2 bands are located by TDDFT/B3LYP/6-31G(d) calculations[33] at a much higher energy, 321 and 295 nm, respectively.

The TDDFT/SAOP results in dichloromethane show that the vertical absorption energies of the excited states are scarcely (if at all) affected by solvation. As previously pointed out (see Computational details section), since the COSMO surface charges are not explicitly considered in the TDDFT procedure other than through their influence on the ground-state density, changes in vertical excitation energies upon solvation only reflect changes in the energies of the ground-state MOs. In dichloromethane, both the occupied and virtual spin orbitals are destabilized by 2.2–2.4 eV. The destabilization of the levels is not uniform, however, which causes small changes in the composition, excitation energies, and oscillator strengths of the excited states, the most relevant example being the inversion of the 13^2E_g and 14^2E_g excited states. As for the assignment of the band at 500 nm to the lowest $^2A_{2g}$ state, as suggested by Stillman and co-workers,[7] on the basis of the absorption and MCD spectra deconvolution analyses, the disagreement between theory and experiment about the location of this state still holds when solvent effects are taken into account. As a matter of fact, the lowest $^2A_{2g}$ state is calculated in dichloromethane at an even higher energy than in the gas phase (383 nm vs 391 nm), with the discrepancy between theory and experiment amounting to more than 0.7 eV (117 nm). Such a large error is unlikely, however, for TDDFT excitation energies on tetrapyrrole complexes.[22] Rather, this discrepancy might be related to the fact that the calculations have been performed for the bare $[ZnPc(-1)]^{\bullet+}$ complex, while the absorption and MCD spectra have been recorded for the axially ligated $[ZnPc(-1)L]^{\bullet+}$ (L = CN^-, Im, py) species. Although the axial ligand is not expected to significantly alter the main features of the spectra –the fitting of the absorption and MCD spectra was successfully obtained assuming a D_{4h} symmetry for the π-cation radical[7–9]– the symmetry lowering following axial ligation might allow for additional transitions, which are forbidden in the D_{4h} symmetry of the unligated π-cation radical. To verify if this is indeed the case, we have examined the ground and excited states of an axially ligated π-cation radical, $[ZnPc(-1)(CN)]^{\bullet}$. According to DFT/BP86 calculations, in $[ZnPc(-1)(CN)]^{\bullet}$ the metal center is C bound, the N bound species being 29.2 kJ/mol less stable. The complex shows a saucer-like structure of C_{4v} symmetry in the $^2A_2$ electronic ground state (see Fig. 7). As indicated by the short (1.980 Å) Zn–C(CN) distance, the interaction with the axial ligand is quite strong. Accordingly, there is a considerable displacement (0.767 Å) of the metal out of the $(N_p)_4$ plane and a significant elongation of the Zn–N_p distance relative to the unligated complex (2.125 Å vs 1.995 Å).

Fig. 7. DFT-calculated structure of [ZnPc(–1)(CN)]•. Selected bond distances (Å) are also shown.

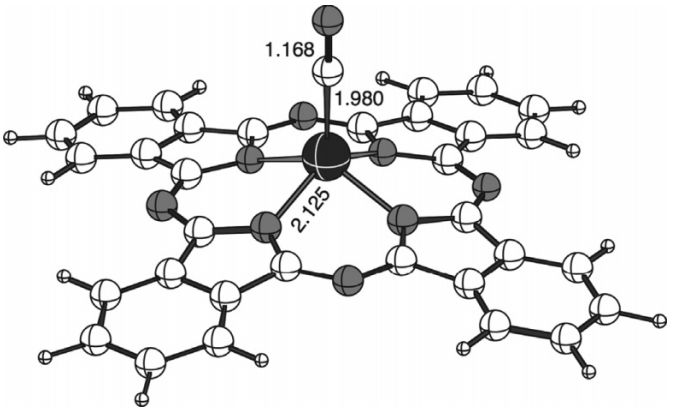

Fig. 8. Absorption and MCD spectra of [ZnPc(–3)]•– recorded in DMF, at cryogenic temperatures. Reprinted with permission from ref. 11.

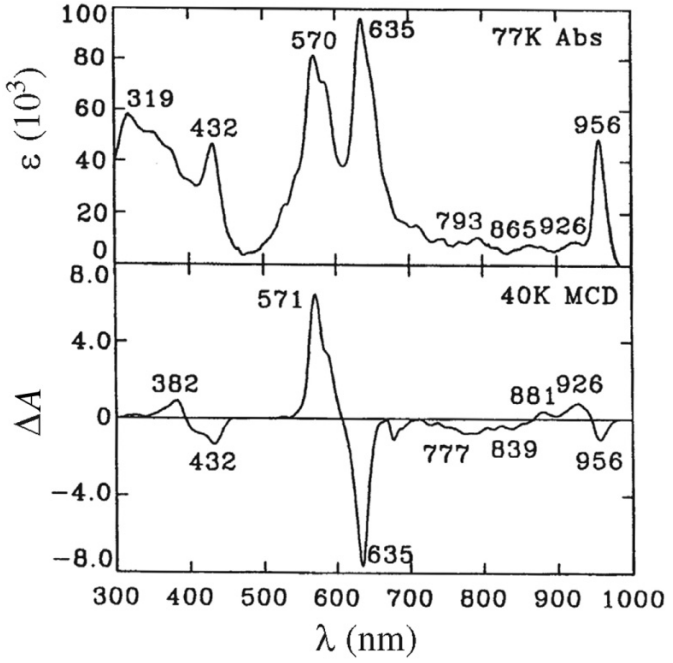

TDDFT/SAOP results in dichloromethane for the [ZnPc(–1)(CN)]• species show that axial coordination of CN^- has, as expected, very little impact on the excitation energies and oscillator strengths of the doubly degenerate ^2E excited states accounting for the salient spectral features. In the region where deconvolution analyses of the absorption and MCD spectra locate a nondegenerate transition,[7] TDDFT calculations now predict a nondegenerate excited state, the 1^2A_2, that is a plausible candidate for assignment to the broad feature at ~500 nm. This state computed at 2.25 eV (550 nm) and with oscillator strength of 0.001, is largely (96%) described by the *z*-polarized $12a_2\downarrow \rightarrow 13a_2\downarrow$ transition, which corresponds in the D_{4h} symmetry of the bare [ZnPc(–1)]•+ complex to the optically forbidden $1a_{1u}\downarrow \rightarrow 2a_{1u}\downarrow$ transition. What we find suggests that the feature appearing in the solution absorption spectra of [MPc(–1)L]•+ (M = Mg, Zn; L = CN^-, Im, py) species at ~500 originates from the axial ligation induced symmetry lowering. Notably, TDDFT calculations assign this band to a transition associated with the hole in the $2a_{1u}$, which is in line with this feature being observed in the spectra of virtually all phthalocyanine π-cation radicals,[6] but not in those of the parent neutral complexes. TDDFT/B3LYP/6-31G(d) calculations by Stillman and co-workers[33] for the chloride anion ligated π-cation radical, [ZnPc(–1)Cl]•, also locate a very weak π → π *z*-polarized excited state in the region of the 500 nm band, at 589 nm.

[ZnPc(–3)]•–

Figure 8 displays the absorption and MCD spectra of [ZnPc(–3)]•– recorded in DMF at cryogenic temperatures.[11] The absorption spectrum of the π-anion radical shows three prominent clusters of bands, centered on 960, 600, and 400 nm. Spectral deconvolution analyses of the MCD and absorption spectra of [ZnPc(–3)]•– recorded at cryogenic temperatures identified three distinct sets of coupled, oppositely signed *B* terms observed in the MCD spectrum of the complex, at 958/925, 635/569, and 434/383 nm.[11] Mack and Stillman[11] observed that the alternating – and + signs of the *B* terms (pseudo *A* terms[58,59]) that comprise the MCD envelope in the three spectral regions of the anion radical are the same as the sign alternation of the *A* terms in the parent neutral complex. These authors also pointed out that this behavior is typical of *x*- and *y*-polarized transitions to close lying, coupled excited states, and the MCD spectral features observed for [ZnPc(–3)]•–, especially the band at 958 nm, are characteristic marker bands for ring-reduced phthalocyanine radical anions.[11]

To provide an assignment of the main spectral features of [ZnPc(–3)]•–, we have computed the excitation energies and oscillator strengths of the dipole and spin allowed ^2A_u, $^2B_{1u}$, and $^2B_{3u}$ excited states of the complex, in both the gas phase and DMF solution (DMF is the solvent used to record the absorption and MCD spectra of the π-anion radical). With our choice of coordinates these states are *x*, *y*, and *z* allowed, respectively. The TDDFT results are reported in Table 3. The excited states of B_{3u} symmetry are not listed in Table 3 since they have oscillator strengths smaller than 0.001 and are therefore not relevant for the interpretation of the main spectral features. According to the TDDFT results, the lowest dipole allowed excited state is the *y*-polarized 1^2B_{1u}, computed in both the gas phase and DMF solution at 1.31 eV (948 nm) and with an oscillator strength of 0.001. The 1^2B_{1u} is a pure $4a_u \rightarrow 7b_{2g}$ π → π* state. The $4a_u \rightarrow 7b_{2g}$ transition would in the neutral species be the $2a_{1u} \rightarrow 7e_g$:*xz*, which describes the *y*-polarized component of the 1^1E_u excited state accounting for the intense Q band.[36] As inferred from the composition of the excited states given in Table 3, the higher lying, intense, 4^2B_{1u} state computed at 2.06 eV (602 nm) and 2.09 eV (594 nm) in the gas phase and DMF solution, respectively, also originates from the $4a_u \rightarrow 7b_{2g}$ transition.[60] On the basis of the calculated excitation energies and oscillator strengths, the 1^2B_{1u} and 4^2B_{1u} states can be unambiguously assigned to the bands appearing in the absorption spectrum of the π-anion radical at 956 and 570 nm, respectively. As these spectral features share with the Q band of the parent neutral complex a common electronic origin and are *y* polarized, they can be denoted as Q'_y and Q''_y. Immediately above the 1^2B_{1u} state, TDDFT calcula-

tions predict another weak dipole-allowed excited state, the *x*-polarized 1^2A_u. This state, which is computed at 1.32 eV (932 nm) in the gas phase and at slightly higher energy in DMF, is a nearly 50:50 mixture of the $7b_{3g}\uparrow \rightarrow 5a_u\uparrow$ and $4a_u\downarrow \rightarrow 7b_{3g}\downarrow$ one-electron transitions. This configuration mixing generates another excited state, the 2^2A_u, which is computed at 1.86 eV (667 nm) in the gas phase and at 1.90 (650 nm) in DMF solution. In the 1^2A_u and 2^2A_u states the mixing coefficients of the $7b_{3g}\uparrow \rightarrow 5a_u\uparrow$ and $4a_u\downarrow \rightarrow 7b_{3g}\downarrow$ transitions are such that their large transition dipole moments cancel each other in the former and add up in the latter. The energy and intensity computed for the 1^2A_u and 2^2A_u states leaves little doubt on their assignment to the features appearing in the absorption spectrum of the π-anion radical at 925 and 635 nm, respectively. As one of the transitions contributing to the 1^2A_u and 2^2A_u states, the $4a_u\downarrow \rightarrow 7b_{3g}\downarrow$, would in the neutral species be the $2a_{1u} \rightarrow 7e_g$:*yz*, which describes the *x*-polarized component of the 1^1E_u excited state accounting for the Q band,[36] the features appearing in the absorption spectrum of the π-anion radical at 925 and 635 nm can be denoted as Q'_x and Q''_x. In sum, TDDFT results indicate that the features appearing in the absorption spectrum of $[ZnPc(-3)]^{\bullet-}$ at 956, 925, 635, and 570 nm can be interpreted as deriving from the splitting of the Q(0,0) band of the neutral species into two pairs of bands, one pair (Q'_y, Q'_x) with low intensity and shifted to red, and the other pair (Q''_y, Q''_x) with high intensity and shifted to the blue. This interpretation fits in with the two pairs of bands just described being a spectral signature of virtually all phthalocyanine π-anion radicals.[6] Previous TDDFT/B3LYP results by Stillman and co-workers[33] basically provide the same description of the visible and near-IR region of the spectrum in terms of energy and composition of the excited states. These authors, however, come to a different interpretation of the four key features characterizing this spectral region.

In the spectral region comprised between the two pairs of Q bands, we compute two excited states, the 2^2B_{1u} and 3^2B_{1u}, which are dominated by the SOMO → LUMO+2 and SOMO → LUMO+4 transition, respectively. TDDFT results in the gas phase place the 2^2B_{1u} in the energy regime of the weak band appearing in the absorption spectrum of $[ZnPc(-3)]^{\bullet-}$ at ~793 nm and the 3^2B_{1u} in the red tail of the intense Q''_y band. In DMF these states shift to higher energy by some 60–80 nm (solvation stabilizes the SOMO more than the LUMO+2 and LUMO+4) to the effect that both end up in the red tail of the Q''_y band. Thus, TDDFT calculations in DMF strongly support the conclusion by Mack and Stillman[11] that the two peaks observed at 865 and 793 nm are vibrational overtones of the 956 nm and 925 nm band pair.

In the region of the observed spectrum between 450 nm and 300 nm, we compute 11^2A_u and 9^2B_{1u} excited states. The energy, composition, and intensity of some of these excited states change appreciably on going from the gas phase to the DMF solution, due to a differential stabilization in DMF of the occupied and virtual MOs involved in the pertinent one-electron transitions. In the energy regime of the band centered at 432 nm in the absorption spectrum of $[ZnPc(-3)]^{\bullet-}$ we compute, in the gas phase, two excited states with sufficient intensity to be observed, the 8^2A_u and 7^2B_{1u}. The former has a multitransitional character involving transitions from the HOMO and SOMO to MOs of the set of π* levels, which have large amplitude on the benzo rings, such as the $8b_{3g}$ and $6a_u$ (see level scheme of Fig. 5). The latter is largely described by a transition from the $8b_{1u}$ (the $6a_{2u}$ in the D_{4h} symmetry of the neutral complex) into the SOMO. The assignment of the 8^2A_u and 7^2B_{1u} states to the 432 nm band is consistent with the MCD spectra showing in correspondence of this feature a couple of oppositely signed *B* terms at 434 and 383 nm.[11] In DMF the states corresponding to the 8^2A_u and 7^2B_{1u} are the 11^2A_u and 9^2B_{1u} computed at 3.26 eV (380 nm) and 3.17 eV (391 nm), respectively. At a higher energy we compute four excited states with considerable intensity, the 11^2B_{1u}, 12^2A_u, 14^2A_u, and 15^2B_{1u}. The excitation energies and oscillator strengths computed for these states are scarcely affected by solvation. However, the composition of the lowest two, the 11^2B_{1u} and 12^2A_u, changes to some extent going from the gas phase to DMF. According to the TDDFT results in solution, the 11^2B_{1u} is a nearly 50:50 mixture of the $3a_u \rightarrow 7b_{2g}$ and $4a_u \rightarrow 8b_{2g}$ transitions and the 12^2A_u is described by the $7b_{1u}\uparrow \rightarrow 7b_{2g}\uparrow$ (30%), $2a_u\downarrow \rightarrow 7b_{3g}\downarrow$ (30%), and $8b_{1u}\downarrow \rightarrow 7b_{2g}\downarrow$ (20%) transitions. On the basis of the calculated energies and oscillator strengths, the 11^2B_{1u} and 12^2A_u are assigned to the features appearing in the UV region of the spectrum of the π-anion radical at 383 and 364 nm, respectively. As for the nearly degenerate 14^2A_u and 15^2B_{1u} excited states, they account well for the prominent peak at 319 nm. It is worth noting that these excited states are π* → π* states since they are dominated by transitions out of the SOMO into MOs of the set of π* levels, which have large amplitude on the benzo rings, viz. the $7a_u$ and $12b_{1u}$. The assignment of the intense band at 319 nm to π* → π* states is consistent with this feature being missing in the absorption spectra of the parent neutral complex.

Conclusions

An accurate description of the UV–visible and near-IR spectra of the zinc phthalocyanine π-cation and π-anion radicals, $[ZnPc(-1)]^{\bullet+}$ and $[ZnPc(-3)]^{\bullet-}$, has been provided by TDDFT calculations of the excited states of these molecules, in both the gas phase and solution. The theoretical results are in good agreement with the solution spectra and generally in line with deconvolution analyses of the solution absorption and MCD spectra. The nature and intensities of the main spectral features have been highlighted and interpreted on the basis of the ground-state electronic structure of the complexes.

For the π-cation radical, DFT calculations predict a D_{4h} molecular structure and a $^2A_{1u}$ electronic ground state, with the unpaired electron residing on the $2a_{1u}\uparrow$. TDDFT/SAOP calculations of the dipole and spin allowed ^2E_g and $^2A_{2g}$ excited states locate, in the Q-band region, two excited states, the 2^2E_g at 827/802 nm (gas phase/CH_2Cl_2) and the 3^2E_g at 681/664 nm, consisting of the same one-electron transitions, the $2a_{1u}\uparrow \rightarrow 7e_g\uparrow$ and the $5e_g\downarrow \rightarrow 2a_{1u}\downarrow$, with approximately reversed weights. The large transition dipoles of these transitions reinforce in the 3^2E_g and cancel in the 2^2E_g to the result that the former is by far more intense than the latter. Neither of these excited states properly account for the energy and

intensity of the band observed at 825 nm. The discrepancy between theory and experiment can be traced to the well-known failure of TDDFT to correctly calculate the energy of CT transitions.[23–26] The description of the Q-band region appears to be complicated by the presence of spurious non-Gouterman transitions out of MOs mostly localized on the benzo rings, such as the $5e_g$, to the highly delocalized Gouterman SOMO, the $2a_{1u}$. As these transitions have significant CT character, they are calculated at an energy that is somewhat too low and accidentally mix with the Gouterman $2a_{1u} \rightarrow 7e_g$ transitions. According to the TDDFT/B3LYP/6-31G(d) results by Stillman and co-workers,[33] the introduction of a 20% HF exchange is sufficient to avoid the mixing between the $2a_{1u}\uparrow \rightarrow 7e_g\uparrow$ and the $5e_g\downarrow \rightarrow 2a_{1u}\downarrow$ transitions, but at the expense of the accuracy. In the Q-band region they indeed compute only an intense ($f = 0.23$) ^2E_g excited state, which is a nearly pure (93%) $2a_{1u} \rightarrow 7e_g$ state. The calculated energy is, however, far too low compared to the experiment (950 vs 825 nm). In the 480–300 nm spectral region, TDDFT/SAOP calculations predict four doubly degenerate excited states with sufficient intensity to be easily observed, the 9^2E_g, 13^2E_g, 14^2E_g, and 15^2E_g. Taking into account the near degeneracy of the 13^2E_g and 14^2E_g states, there is an excellent correspondence between the calculated excitation energies and the energies of the three bands located by the deconvolution analysis of Stillman and co-workers[7] at 424, 370, and 317 nm. Analysis of the composition of the pertinent excited states reveals that the features in the absorption and MCD spectra of $[ZnPc(-1)]^{\bullet+}$ at 424 and 417 nm correspond to the B1 and B2 bands of ZnPc, respectively.

TDDFT/SAOP calculations, either in the gas phase or in solution, do not account for the broad absorption near 500 nm assigned by Stillman and co-workers[7] to a nondegenerate, *z*-polarized $^2A_{2g}$ excited state. Theory and experiment can be reconciled only if the presence of an axial ligand such as CN^- is explicitly considered in the calculations. TDDFT calculations for the axially ligated $[ZnPc(-1)(CN)]^{\bullet}$ species indicate that the 500 nm feature originates from axial ligation induced symmetry lowering and assign this band to a *z*-polarized transition associated with the hole in the $2a_{1u}$, which is in line with this feature being observed in the spectra of virtually all phthalocyanine π-cation radicals[6] but not in those of the parent neutral complexes.

Concerning the π-anion radical, this species has a $^2B_{3g}$ electronic ground state in the JT distorted rectangular D_{2h} structure. TDDFT calculations of the dipole and spin allowed ^2A_u, $^2B_{1u}$, and $^2B_{3u}$ excited states of the complex, in both the gas phase and DMF solution, indicate that the features appearing in the absorption spectrum of $[ZnPc(-3)]^{\bullet-}$ at 956, 925, 635, and 570 nm can be interpreted as derived from the splitting of the Q(0,0) band of the neutral species into two pairs of bands, one pair (Q'_y, Q'_x) with low intensity and shifted to red, and the other pair (Q''_y, Q''_x) with high intensity and shifted to the blue. This interpretation fits in with the two pairs of bands being a spectral signature of virtually all phthalocyanine π-anion radicals.[6] Previous TDDFT/B3LYP results by Stillman and co-workers[33] basically provide the same description of the visible and near-IR region of the spectrum in terms of energy and composition of the excited states. These authors, however, come to a different interpretation of the four key features characterizing this spectral region.

In the region of the observed spectrum between 450 nm and 300 nm we compute several excited states, the most intense of which nicely account for the most intense features located at 432, 383, 364, and 319 nm. In particular, the assignement of the prominent peak at 319 nm to the nearly degenerate 14^2A_u and 15^2B_{1u} $\pi^* \rightarrow \pi^*$ excited states, is consistent with this feature being missing in the absorption spectra of the parent neutral complex.

Spin–orbit ab initio investigation of the UV photoinduced bond cleavage in iodotrimethylstannane[1]

N. Ben Amor and C. Daniel

Abstract: The photoinduced homolytic cleavage of the Sn–I bond in iodotrimethylstannane $(CH_3)_3SnI$, observed after UV irradiation, is investigated by means of spin–orbit ab initio calculations based on CASSCF (complete active space self-consistent field) and MS-CASPT2 (multi-state complete active space 2nd order perturbation theory) methods. The absorption electronic spectrum is characterized by ten low-lying $^{1,3}A'$ and $^{1,3}A''$ spin eigenstates corresponding to $p_y(I),p_x(I) \rightarrow \sigma^*_{SnI}$; $\sigma_{SnI} \rightarrow \sigma^*_{SnI}$ and $p_y(Sn)$, $p_x(Sn) \rightarrow \sigma^*_{SnI}$, where σ_{SnI} and σ^*_{SnI} are the bonding and anti-bonding orbitals of the Sn–I bond along the p_z axis. From the $^1A'$ electronic ground state and these ten spin eigenstates, 21 spin–orbit states are generated leading to various deactivation channels of $(CH_3)_3SnI$, corresponding to the formation of radicals $(CH_3)_3Sn^{\bullet}$ and $^{\bullet}I$ and to the ionic species $(CH_3)_3Sn^+$ and I^-. Irradiation into the upper band at 175 nm should lead to the heterolytic cleavage of the Sn–I bond to form the ionic primary products exclusively, whereas absorption into the shoulder at 250 nm induces the homolytic breaking with formation of the radical products.

Key words: ab initio, spin–orbit, UV spectroscopy, iodostannane, photodissociation.

Résumé : Faisant appel à des calculs ab initio spin-orbite basés sur des méthodes de champ autocohérent avec espace actif complet « CASSCF » et de la théorie des perturbations du second ordre, à espace actif complet et à états multiples « MS-CASPT2 », on a étudié le clivage homolytique photoinduit de la liaison Sn–I de l'iodotriméthylstannane, $(CH_3)_3SnI$, observé après une irradiation UV. Le spectre d'absorption électronique est caractérisé par dix états de spin de basses intensités, $^{1,3}A'$ et $^{1,3}A''$ qui correspondent aux transitions $p_y(I)$, $p_x(I) \rightarrow \sigma^*_{SnI}$; $\sigma_{SnI} \rightarrow \sigma^*_{SnI}$ et $p_y(Sn)$, $p_x(Sn) \rightarrow \sigma^*_{SnI}$ dans lesquelles σ_{Sn1} et σ^*_{SnI} sont les orbitales liantes et antiliantes de la liaison Sn–I le long des axes p_z. De l'état électronique fondamental $^1A'$ à ces états de spin, on peut obtenir vingt états spin–orbite qui génèrent divers canaux de désactivation du $(CH_3)_3SnI$ qui correspondent à la formation des radicaux $(CH_3)_3Sn^{\bullet}$ et $^{\bullet}I$ et aux espèces ioniques $(CH_3)_3Sn^+$ et I^-. L'irradiation dans la bande supérieure, à 175 nm, devrait conduire à un clivage hétérolytique de la liaison Sn–I avec une formation exclusive de produits primaires ioniques alors qu'une absorption dans l'épaulement à 250 nm devrait induire une scission homolytique avec formation de produits radicalaires.

Mots-clés : ab initio, spin–orbite, spectroscopie UV, iodostannane, photodissociation.

[Traduit par la Rédaction]

Introduction

In contrast to the extensive literature on the photochemistry of transition-metal complexes, and despite of the numerous potential applications of main-group metal molecules, little is known on their photoreactivity. Oxides derived from main-group compounds are characterized by large band gaps leading to high transparency in the visible–UV spectral domains. Experiments based on $(CH_3)_3SnI$, used as a precursor, confirm changes in refractive index in porous Vycor glass (PVG),[2] comparable to those obtained with Fe(CO). UV photolysis of $(CH_3)_3SnI$ adsorbed onto PVG or porous glassy matrixes enhances the refractive index relative to the bulk glass.[3–13] Subsequent heating drives the unexposed complex from the glass and, at 1200 °C, consolidates the glass, entrapping a photogenerated gradient index pattern in the glass.[12] Several experiments were undertaken to improve the optical performance of these gradient-index structures by establishing the nature of the precursor on the glass surface and identifying the photoactive excited states. Photochemistry of $(CH_3)_3SnI$ in hydrocarbon solution indicates homolytic cleavage of the Sn–I bond following 254 nm irradiation leading to $((CH_3)_3Sn)_2$ and I_2 primary products.[14] However, both products desorb from the glass during subsequent heating, thereby precluding their involvement in gradient index formation. Furthermore, UV photolysis of $(CH_3)_3SnI$ adsorbed onto PVG yields I_3^-, suggesting heterolytic cleavage of the molecule in the glass matrix. It has been pointed out that the quantum yield of the radical channel depends on the solvent medium. In nonpolar solvents, excitation leads to homolytic

cleavage, while in solvent capable of acting as Lewis bases, formation of a solvent adduct switches the reactivity to heterolytic rupture of the Sn–I bond.[14] In hexane, $(CH_3)_3SnI$ exists as a four-coordinate tetrahedron, but adsorbed onto PVG, and in ethanol, the complex exists as a five-coordinate adduct with the oxygen of the surface silanol, or the alcohol, occupying the fifth coordination site. A preliminary theoretical study of the tetrahedral compound based on CASSCF/CASPT2 calculations of the low-lying singlet excited states and associated potential-energy curves (PECs) has enabled us to assign the experimental absorption spectrum and to determine two dissociative channels leading to the radical and ionic primary products $(CH_3)_3Sn^{\bullet}$ and $^{\bullet}I$ and $(CH_3)_3Sn^+ + I^-$, respectively.[15] In a more recent article, the photodissociation dynamics of this compound has been investigated in the semi-classical approximation and in the quasi-resonant approximation.[16]

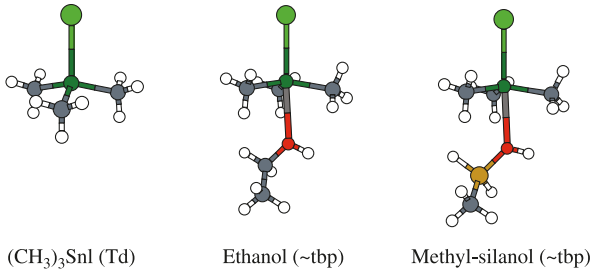
The present theoretical study reports partly the quantum chemical calculations underlying this dynamical study based on wavepacket propagations on one-dim potential-energy functions obtained by nonlinear fit of the SO-MS-CASPT2 eigenvalues. This work differs from the quantum chemical study reported in ref. 15 by considering the low-lying triplet states as well as their spin–orbit interactions with the singlet excited states. Moreover, an additional state, perturbing significantly the SO-states and corresponding to the ($p_y Sn \rightarrow \sigma^*_{SnI}$) excitation, is included. To contribute to a better understanding of the complex experimental behavior described above, we aim at determining the photoactive states and the various dissociation channels accessible after UV, far-UV irradiation of tetrahedral $(CH_3)_3SnI$. In a first step, a preliminary investigation of the structural aspects related to the tin-compounds coordination lability is undertaken by means of DFT calculations. In a second step, the electronic absorption spectrum including all the singlet and triplet states between 273 nm and 176 nm is modelized in vacuum by means of spin–orbit (SO) MS-CASPT2 calculations. The PECs describing the Sn–I bond dissociation have been calculated at the same level of theory.

Methods and computational details

The geometries of $(CH_3)_3Sn^{\bullet}$, $(CH_3)_3Sn^+$, $(CH_3)_3SnI$, $(CH_3)_3SnI–OHC_2H_5$, and $(CH_3)_3SnI–OHSiH_2CH_3$ have been optimized at the DFT level of theory using the B3LYP[17] functional within the quasi-relativistic pseudopotential[18] with the associated valence basis sets for the tin centre a (4s4p) set contracted to [2s2p], for the iodine a (4s5p) set contracted to [2s3p] while all electrons split-valence basis sets[19] were used for the carbon and hydrogen atoms, respectively (9s5p) contracted to [3s2p] and (4s) contracted to [2s]. The geometry optimizations have been performed without any constraint in the C_1 symmetry group. The electronic ground state of all species is described by a singlet configuration, except for the radical, which is a doublet.

The photodissociation of $(CH_3)_3SnI$ has been modeled within a one-dimensional scheme described by the Sn–I bond elongation, without relaxation of the whole molecule with the C_s symmetry constraint. Scalar relativistic effects were included within the Douglas–Kroll Hamiltonian. The calculations are based on atomic natural orbitals-relativistic

Fig. 1. DFT-optimized geometries.



correlation consistent (ANO-RCC)[20] basis sets with the following contraction scheme: for Sn atom, a (22s19p13d5f) set contracted to [6s5p3d1f]; for I atom, a (22s19p13d5f) set contracted to [6s5p3d1f]; for C, a (14s9p4d) set contracted to [3s2p1d]; and for H, a (8s4p) set contracted to [2s1p]. To determine the potential presence of Rydberg states in the domain of energy investigated here (UV, far-UV), one more calculation has been performed, at the equilibrium geometry, with the following extended basis set: for Sn and I atoms, (22s19p13d5f3g) sets contracted to [10s9p5d3f1g]; for C, a (14s9p4d3f) set contracted to [5s4p3d1f]; and for H, a (8s4p3d) set contracted to [4s3p2d]. Since the ten first singlet or triplet states of A′ and A″ symmetries have mainly a valence character, the first contraction scheme is well-adapted to this study. The electronic ground state is described by the following electronic configuration $(\sigma_{SnC})^2\ (\sigma_{SnI})^2\ (5p_yI)^2\ (\sigma_{SnC})^2\ (5p_xI)^2$.

The electronic excited states and associated PECs have been calculated by means of complete active space self-consistent field (CASSCF) method,[21] with ten electrons correlated in ten active orbitals in coherence with our first study.[15] This active space includes the σ_{SnC} and σ_{SnI} bonding orbitals and their anti-bonding counterparts, the $5p_xI$, $5p_yI$, and virtual orbitals mainly located on methyl groups and Sn atom to keep a stable active space along the dissociation path. Ten singlet and ten triplet excited states of A′ and A″ symmetries are calculated. These rather large active space and number of states are necessary to get all the states of interest along the dissociation path. Dynamic correlation is included in subsequent multi-state complete active space 2nd order perturbation theory[22] (MS-CASPT2) calculations based on state average CASSCF reference wave functions. The multi-state approach has been preferred to the state specific approach for two reasons: (*i*) to take into account the mixing at the level of avoided crossings occurring along the Sn–I coordinate; (*ii*) to use 2nd Order energies coherent with the zero-order multi-state CASSCF wave function in SO-RASSI. To avoid intruder states, we used a level shift of 0.2. For each symmetry and spin, eight roots are coupled at second order via an effective Hamiltonian approach. The core electrons are frozen in the CASSCF as well as in the CASPT2 calculations.

The spin–orbit coupling between the different electronic states is determined by the restricted active space state interaction approach (RASSI-SO).[23] Although, the method has been conceived in the basis of RASSCF wave functions, recent works use the MS-CASPT2 results[24–26]: the diagonal elements are the correlated MS-CASPT2 energies and the off-

diagonal SOC elements are evaluated on the basis of first-order MS-CASPT2 wave functions (i.e., mixed CASSCF states). To take into account the interaction between the low-lying SO states involved in the absorption spectroscopy with the upper states, the SO states have been determined over spin-components of 32 MS-CASPT2 eigenstates (spin eigenstates).

The calculations have been performed either with GAUSSIAN[27] (DFT) or MOLCAS 6.2[28] (transition energies and spin–orbit coupling) quantum chemistry software.

Results and discussion

Structures

The DFT (B3LYP) equilibrium geometries of the ground state of $(CH_3)_3SnI$ and of the penta-coordinated $(CH_3)_3SnI–OHC_2H_5$ and $(CH_3)_3SnI–OHSiH_2CH_3$ are depicted in Fig. 1. Some optimized relevant distances and bond angles are reported in Table 1 for the five complexes.

As expected with the valence shell electron pair repulsion method (VSEPR),[29] the radical $(CH_3)_3Sn^{\bullet}$ and $(CH_3)_3SnI$ have very similar geometries, nearly tetrahedral (Td) and the ionic compound $(CH_3)_3Sn^{+}$ is planar.

The C–Sn–C angle in the radical $(CH_3)_3Sn^{\bullet}$ is slightly smaller than the 109.5° associated to the pure tetrahedral structure. Similarly, the C–Sn–I angle in $(CH_3)_3SnI$ is smaller than the C–Sn–C angle. In the $(CH_3)_3SnI–OHC_2H_5$ and $(CH_3)_3SnI–OHSiH_2CH_3$ complexes, the oxygen is bound to the tin, leading to nearly trigonal bipyramidal (TBP) structure of the tin, with the three methyl groups in the trigonal plan. These results confirm the experimental hypothesis,[13] namely the significant change of the structure of the trimethyltin iodine complex in a five-coordinate system when it is adsorbed on a PVG or when ethanol is added to hexane trimethyltin iodine solution.

In the present study, related to the experiment reported in hexane (poorly polar solvent), the calculations reported below have been performed for the isolated molecule in vacuum. Obviously, in a more realistic theoretical study, dedicated to environment effects on the absorption spectroscopy and photoreactivity, the calculations should be performed on the solvated structures, $(CH_3)_3SnI–OHC_2H_5$ and $(CH_3)_3SnI–OHSiH_2CH_3$ (Fig. 1), in addition to the standard solvent correction (discrete or polarized continuum models). This will be the purpose of further investigations.

Electronic absorption spectroscopy of $(CH_3)_3SnI$

The transition energies to the low-lying singlet and triplet excited states of $(CH_3)_3SnI$ have been obtained by means of CASSCF/ MS-CASPT2 calculations based on the DFT tetrahedral optimized geometry with a Sn–I equilibrium distance of 2.7 Å in the $^1A'$ electronic ground state. This value re-

Table 3. SO states and the corresponding transition energies (in cm^{-1}) of $(CH_3)_3SnI$. Oscillator strengths are in parenthesis.

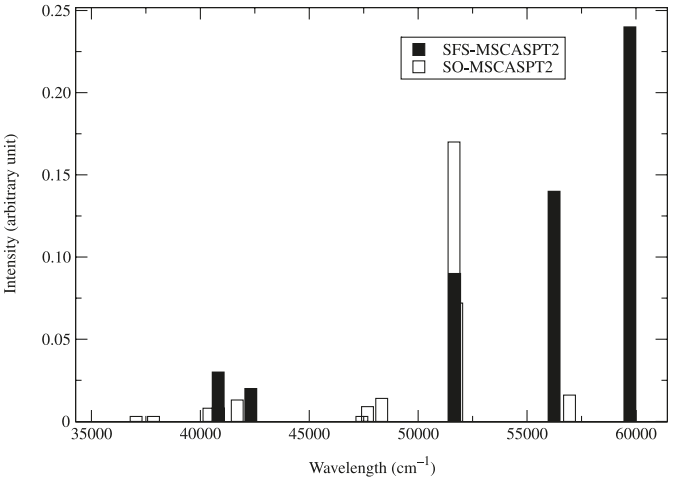
mained unchanged when adding SO effects. The low-lying excited states are generated by excitations from the valence-occupied orbitals of the tin and iodine to the antibonding orbital σ^*_{SnI}. The MS-CASPT2 calculated electronic Franck–Condon transitions of the complex are reported in Table 2 with the previous results obtained with Cowan–Griffin relativistic core ab initio model potential (CG-AIMP).[30]

The two studies differ by the following features: (*i*) In the present work, the scalar relativistic effects are taken into account by the Douglas–Kroll Hamiltonian, whereas they were included in the pseudopotentials in the previous study; (*ii*) the Sn–I equilibrium distance was shortened: 2.70 Å in the present study compared with 2.73 Å in the previous one. There is a good qualitative agreement between the transition energies obtained in the present work and the previous published values. The two first excited states correspond to an excitation from the iodine to the antibonding orbital σ^*_{SnI} and are followed by singlet state arising from p_xSn to σ^*_{SnI} excitation. However, an additional singlet state appeared in the Franck–Condon region, corresponding to the $p_ySn \rightarrow \sigma^*_{SnI}$ excitation. This state was found to have quite important oscillator strength. The transition energies differ by less than 1600 cm^{-1} except for the $\sigma_{SnI} \rightarrow \sigma^*_{SnI}$ state, which is calculated at 59 720 cm^{-1} vs. 55 610 cm^{-1} with the AIMP. The oscillator strengths are qualitatively equivalent, with a maximum value for the $\sigma_{SnI} \rightarrow \sigma^*_{SnI}$ ionic state in the two studies.

Spin–orbit coupling

Spin–orbit coupling (SOC) effects have been determined for all singlet and triplet states of both symmetries (32 spin eigenstates). The SO states and the corresponding transition energies of $(CH_3)_3$ SnI are presented in Table 3. The treatment of spin–orbit coupling is very sensitive to the size of

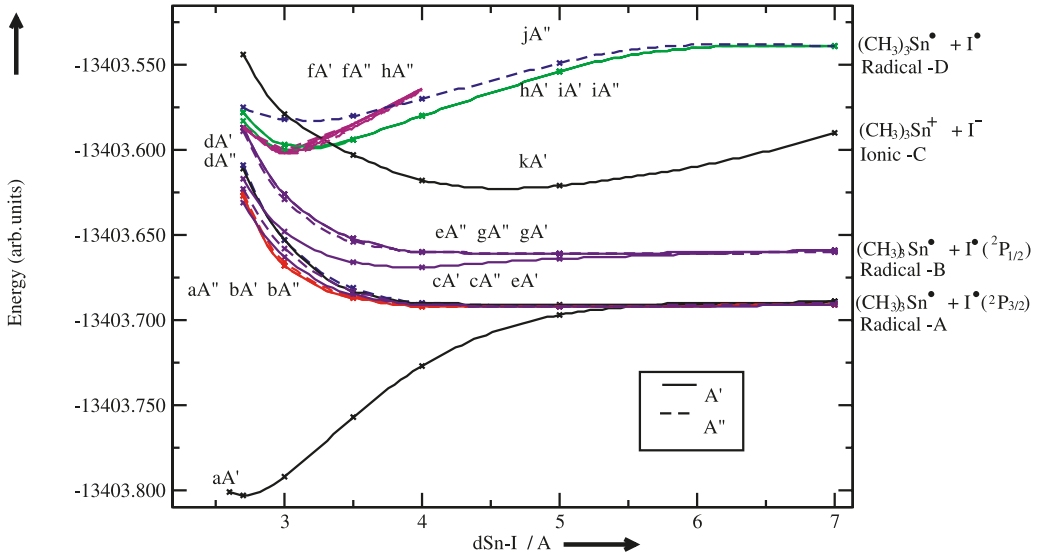
Fig. 2. Comparison between the theoretical absorption spectra of $(CH_3)_3SnI$ from MSCASPT2 and spin–orbit (SO) MSCASPT2 states.



the spin eigenstates basis. In ref. 16, the SO A′ state, arising mainly from the $p_{ySn} \rightarrow \sigma^*_{SnI}$ state, has not been calculated, while it is included in the present study. Although this state has a high energy, the results are affected as a whole. For instance, the bA′ SO state with an electronic term value of 38 590 cm^{-1} in ref. 16 is now calculated at 36 670 cm^{-1} at the equilibrium distance of 2.7 Å. A greater effect is found for the ionic state, higher by more than 5000 cm^{-1}, while the $p_{ySn} \rightarrow \sigma^*_{SnI}$ state takes its place at 51645 cm^{-1}.

According to the double-group symmetry rules, the $^3A'$ states are split into two A″ and one A′ components, whereas the $^3A''$ states are split into two A′ and one A″ components. By interaction with the A′ components of the triplet spin eigenstates, the $^1A'$ electronic ground state is shifted down by

Fig. 3. SO-MSCASPT2 potential-energy curves of $(CH3)_3SnI$ as a function of the Sn–I bond distance.



245 cm^{-1}. The $^3A'$ and $^3A''$ electronic states split into several spin–orbit states. The SO splittings of the low-lying $^3A'$ and $^3A''$ amount to 390 cm^{-1}, 500 cm^{-1}, and 530 cm^{-1} for the a^3A', b^3A', and c^3A', respectively, and are larger for the a^3A'' and b^3A'' states with values of 2970 cm^{-1} and 730 cm^{-1}, respectively.

In the Franck–Condon region, apart from the aA′ electronic ground state and the jA″ (b^1A'') state, the SO states are strongly mixed. The singlet states gain significant contributions of the triplet spin eigenstates (~20%), whereas the SO states that originate from the triplet states are nearly exclusively composed by contributions of the triplet spin eigenstates. By inclusion of the SO, transition energies increase by more than 1800 cm^{-1} for the b^3A' and a^3A'', while they decrease by 1000 cm^{-1}, 1880 cm^{-1}, 1110 cm^{-1}, and 2770 cm^{-1} for the b^3A'', a^3A', a^3A'', and d^1A', respectively.

As illustrated by Fig. 2, the theoretical absorption spectrum is broadened and less intense when SO effects are included. The decrease of the oscillator strength is a general trend also observed for $H_2M(CO)_4$.[31] This may be explained by the large contributions of the SO states arising from the triplet states in the absorbing states.

Potential-energy curves

The 1D PECs, corresponding to ten of the 11 low-lying post-SO A′-levels and ten low-lying post-SO A″-levels, are depicted in Fig. 3 as a function of the Sn–I bond distance. The post-SO-adiabatic A′-levels originate from the a^1A' electronic ground state and from the ten low-lying $^{1,3}A'$ and $^{1,3}A''$ states corresponding to p_yI, $p_xI \rightarrow \sigma^*_{SnI}$, $\sigma_{SnI} \rightarrow \sigma^*_{SnI}$ and p_ySn, $p_xSn \rightarrow \sigma^*_{SnI}$ excitations. From these 11 spin eigen states (four $^1A'$, three $^3A'$, two $^1A''$, and two $^3A''$), one may generate 11 SO A′-states and ten SO A″-states. These 21 SO states lead to various deactivation channels of $(CH_3)_3SnI$. The lowest channel radical A, which leads to $(CH_3)_3Sn^\bullet$ (J = 1/2) + $^\bullet I$ (J = 3/2), is an eightfold degenerate at infinite separation, while the next channel radical B, fourfold degenerate, gives $(CH_3)_3Sn^\bullet$ (J = 1/2) + $^\bullet I$ (J = 1/2). The third channel is nondegenerate and corresponds to the ionic channel leading to $(CH_3)_3$ $Sn^+ + I^-$ (channel ionic C). The fourth channel, radical D eightfold degenerate, leads to $(CH_3)_3Sn^\bullet + {}^\bullet I$.

The SO splitting of 6930 cm^{-1} between the radical-A and radical-B species at the asymptote corresponds roughly to the energy gap between I (J = 3/2) and I (J = 1/2) of 7600 cm^{-1} (experimental value[32]: 7595 cm^{-1}). It is worth noting that the six spin eigenstates leading to radical A and radical B by SO splitting are degenerate at the asymptote. The PECs connected to radical A (bA′, cA′, dA′, eA′, aA″, bA″, cA″, and dA″) and the upper PECs connected to radical B (eA″ and gA″) are dissociative. The gA′ SO state has bounded PECs, due to an important mixing of the b^3A' with the a^3A'' SFS in the range of 3.0–5.0 Å. The single post-SO adiabatic kA′ curve leading to the ionic species is characterized by a minimum between 4 Å and 5 Å in agreement with the PEC shown in ref.15. The upper PECs are bound along the Sn–I bond elongation. The jA′ SO state, which has the larger oscillator strength in the Franck–Condon region, becomes higher in energy, and its oscillator strength decreases (from 0.17 at d_{SnI} = 2.7 Å to 0.11 at d_{SnI} = 3.0 Å), while the ionic state kA′ has an increasing oscillator strength (0.016 to 0.61) within the same range. It was not possible to follow the jA′ state along the dissociation path. According to the shape of the PECs depicted in Fig. 3 and to the theoretical absorption spectrum represented in Fig. 2, photoinduced bond cleavage in $(CH_3)_3SnI$ may occur following three distinct mechanisms. Whereas irradiation in the upper intense band at about 52 000 cm^{-1} (195 nm) will produce radical primary products, irradiation in the shoulder at 57 000 cm^{-1} (175 nm) will lead to the formation of ionic primary products. Another shoulder, between 40 000 cm^{-1} and 42 500 cm^{-1} (250 and 235 nm), will produce radical primary products. This last mechanism explains the homolytic cleavage of the Sn–I bond observed after irradiation at 254 nm in hydrocarbon solution leading to $((CH_3)_3Sn)_2$ and I_2 primary products.[14] The branching ratio between the radical and ionic channels will depend on the solvent conditions, as suggested by the experiments reported in various media. Indeed,

the relative position and the shape of the "ionic" and "radicals" PECs should be very sensitive to the polarity of the solvents.

Conclusion

The theoretical electronic absorption spectrum of $(CH_3)_3SnI$, representative of organotin compounds, has been calculated and analyzed by means of spin–orbit accurate ab initio calculations. It has been shown that it is characterized by an intense band centered at 51 700 cm^{-1} (or 195 nm) assigned to transitions composed essentially of $p_xSn/p_ySn \rightarrow \sigma^*_{SnI}$ excitations. A shoulder starting at 40 000 cm^{-1} (or 250 nm) is attributed to A′ and A″ states corresponding to $p_xI/p_yI \rightarrow \sigma^*_{SnI}$ excitations. Irradiation in the upper band, at 175 nm, will lead to the heterolytic cleavage of the Sn–I bond, leading exclusively to the ionic primary products observed under certain experimental conditions ($(CH_3)_3SnI$ adsorbed on PVG or in polar solvents). In contrast, irradiation into the shoulder at 250 nm should induce homolytic rupture of the Sn–I bond with formation of the radicals primary products.

A preliminary study of the quantum dynamics of the photodissociation of $(CH_3)_3SnI$ suggests that population of the ionic channel in a limited range around 207 nm leads to a quantum yield of ionic products higher than 50% vs. 10% for the radical product.[16] Further work will consider other degrees of freedom, such as the umbrella angle and the environment effects, which may modify drastically the mechanism by controlling the relative position of the ionic and radical channels. Another aspect of the quantum dynamics concerns the control of the ionic/radical branching ratio. This will be the subject of new simulations based on the potentials presented here.

Competition between mixing and segregation in bimetallic Ag_nRb_n clusters (n = 2–10)[1,2]

René Fournier, Shaima Zamiruddin, and Min Zhang

Abstract: We found the minimum-energy structures of Ag_nRb_n (n = 2–10) clusters by a combination of density functional theory (DFT) and taboo search global optimization. The global minimum geometry is mixed for $n \leq 4$ and segregated, with a core-shell arrangement, for $n > 4$. There is a change in the nature of the bonding, from ionic to metallic, between $n = 4$ and $n = 5$. Although metallic bonding dominates at $n > 4$, large atomic charges (in the order of ±0.5) persist. These atomic charges (negative on the interior Ag atoms, positive on the surface Rb atoms) make Ag_nRb_n clusters analogous to Zintl compounds and could prevent them from coalescing. This makes them intriguing potential building blocks for cluster-assembled materials. Ag_4Rb_4 is relatively stable compared with other Ag_nRb_n clusters; it has a nearly cubic shape, a large HOMO–LUMO gap (2 eV), and a highly ionic character with atomic charges equal to roughly ±1 au.

Key words: bimetallic clusters, nanostructured materials, global energy minima, segregation, Zintl compounds.

Résumé : Nous avons déterminé les structures d'énergie minimum d'agrégats Ag_nRb_n (n = 2–10) par une méthode qui combine la théorie de la fonctionelle de la densité avec une recherche de minima par optimisation globale (recherche tabou). Les minima globaux que nous obtenons sont des structures mixtes d'alliages pour $n \leq 4$, et des structures ségrégationnée de topologie concentrique $Ag_n@Rb_n$, pour $n > 4$. La nature des liens évolue en fonction de n, avec de fortes interactions ioniques pour $n \leq 4$ et des liens de type métallique pour $n > 4$. Cependant, des charge atomiques appréciables subsistent à $n > 4$ (charges négatives sur les atomes de Ag qui sont à l'intérieur, et charges positives sur les atomes de Rb en surface). La séparation radiale des charges rend les agrégats de Ag_nRb_n analogues aux composés Zintl, et les rend probablement stables vis-à-vis la coalescence. Cette propriété ferait des agrégats de Ag_nRb_n des unités de base intéressantes pour d'éventuels matériaux. Ag_4Rb_4 est relativement stable comparé aux autres agrégats de Ag_nRb_n et possède une structure cubique ainsi qu'une forte séparation des niveaux d'énergie des orbitales frontières (2 eV) et un fort caractère ionique avec des charges atomiques de l'ordre de ±1 au.

Mots-clés : agrégats bimétalliques, matériaux à l'échelle du nanomètre, minima globaux d'énergie, ségrégation, composés Zintl.

Introduction

The structure of small metal clusters, and particularly "bimetallic" clusters, are not well-known. The phase diagrams of bulk alloys do not give reliable predictions about possible mixing in the corresponding small bimetallic clusters.[3] For alloying, as for many other things, clusters are often very different from the bulk. Many simple questions about bimetallics A_nB_p are still open. Generally, one would like to know if A and B segregate, or if they mix to form a nanoalloy. Experimentally, the structures of bimetallic clusters A_nB_p often fall into one of these three categories: mixed, core-shell, or onion-layered.[4] There is also a fourth category, "left-right segregated", that often occurs in the bulk limit because it minimizes the A–B interfacial area. A recent computational study showed that Pd–Pt clusters described by a Gupta potential adopt different types of segregated structures depending on the value of A–B interaction parameters used in the potential.[5] One could also distinguish between various mixed structures, some of them ordered, others, random. In fact, the details of A–B ordering can be intricate even in simple theoretical models of coinage (Cu, Ag, Au) bimetallic clusters.[6]

We chose to study the series of clusters Ag_nRb_n (n = 2–10) as a model to test computational methods and tackle general questions about AB order in bimetallic clusters because (*a*) it is simple (Ag and Rb atoms have only s valence electrons), (*b*) the big difference in absolute electronegativity $\chi = (I + A)/2$ (I is the ionization energy, A is the electron affinity, χ = 4.44 eV for Ag, and χ = 2.33 eV for Rb) favors mixing but, (*c*) the big difference in cohesive energies (2.95 eV for Ag, 0.85 eV for Rb) and atomic radii (1.45 Å for Ag, 2.42 Å for Rb) favor core-shell segregation. We expect (*c*) to dominate and control the structure at large n. But small clusters, where there are few or no interior atoms, could be very different, and the size evolution of structure is non-trivial. The nature of the bonding in these small clusters is also unclear a priori. Ag and Rb both have a very low ionization energy, and many aspects of Ag_n[7] and Rb_n[8] clusters are reasonably

well-described in the jellium model.[9] So, in a way, Ag and Rb are ideal metals. But in Ag_nRb_n, ionic interactions could be important, and maybe small clusters of Ag_nRb_n are not even metallic, after all. Clusters like Ag_nRb_n are interesting for another reason. Their presumed core-shell structure, combined to large surface charges, should prevent them from coalescing. This is important for making cluster-assembed materials. For instance, size-selected metastable $Ag_n@Rb_n$ or $Ag_n@Na_n$ clusters (the @ symbol denotes a core-shell structure with the Ag atoms inside) could be relatively stable intermediates on the way to making uniform size silver clusters embedded in ionic solids (e.g., RbCl, NaCl). In fact, one can view $Ag_n@Rb_n$ as a metal cluster analog of Zintl compounds, with a true metal (Ag) in the interior instead of a semimetal (Ge, Sn, Pb, Sb, and so forth) like in the known Zintl compounds,[10] so there is a slight possibility that it could be stable in itself.

Methods

We performed global optimization by the taboo search in descriptor space (TSDS) method.[11] All energies were calculated by density functional theory (DFT) with the Perdew–Burke–Ernzerhof (PBE)[12] generalized gradient approximation to exchange-correlation and a LANL2 double-zeta (LANL2DZ) basis set as implemented in the Gaussian 03 software package.[13] The number of possibles isomers (local minima) for elemental clusters X_n is quite large; for a 13-atom cluster, it is in the order of 1000, and the number of isomers roughly triples for every additional atom.[14] However, the number of isomers for a bimetallic cluster A_nB_n is much greater than for an elemental cluster X_{2n}. Ignoring symmetry, there are $(2n)!/(n!)^2$ ways to substitute n atoms of X by atoms of A (and the rest by atoms of B). The $(2n)!/(n!)^2$ isomers of A_nB_n that result from these different ways to occupy sites with atoms of type A or B are often called "homotops".[15] For $Ag_{10}Rb_{10}$, then, an order of magnitude estimate for the number of isomers is 10^{11}. Fortunately, the optimization problem is not as difficult as it seems because the vast majority of isomers are very high in energy, *and the low-energy isomers fall into one or a few categories that share common geometric characteristics*. The TSDS algorithm exploits these resemblences among low-energy structures to quickly identify regions of configuration space where the search is likely to succeed, and it finds GMs, or good approximations to them, with very few energy evaluations even in difficult cases.[16,17] The TSDS runs for this study consisted of $(12n^2 + 30)$ iterations, where $2n$ is the number of atoms. At every iteration, TSDS produces a structure of Ag_nRb_n with predefined nearest-neighbour (NN) distances. A few preliminary runs of local optimization on arbitrary trial geometries of small Ag_nRb_n clusters show what distances are appropriate, and they were set at 2.82 Å for Ag–Ag, 4.70 Å for Rb–Rb, and 3.65 Å for Ag–Rb. For comparison, the bulk experimental interatomic distances are 2.89 Å for Ag–Ag and 4.84 Å for Rb–Rb. Other control parameters in TSDS ensure that the majority of the $(12n^2 + 30)$ structures generated in this way are topologically distinct, but a fraction of them are "distorted copies" of previous structures. These $(12n^2 + 30)$ geometries are not local minima of the potential surface, but are near local minima. For this reason, our optimization algorithm can be viewed as having an additional approximation compared to basin hopping (BH) methods,[18] but having the advantage of being much more economical (by roughly a factor of 50) compared to BH in terms of the number of energy evaluations required. The last point is, of course, crucial for doing global optimization directly on a first-principles DFT energy surface. After the TSDS iterations are complete, the $(12n^2 + 30)$ structures are ordered according to their energy and their similarity to higher ranked structures, i.e., similar structures get pushed down the ranks. The 10 to 20 top in this order constitute the lowest energy-distinct structures: we take them as initial geometries for local optimization with Gaussian 03 PBE/LANL2DZ.

To analyze trends in the final optimized structures, we use a number of geometric descriptors. Note that these are, generally speaking, different from the descriptors used during TSDS optimization. The three basic descriptors that we use for characterizing AB order are the number of A–B NN pairs m, and two variables, c and ℓ, that quantify core-shell segregation (CSS) and left–right segregation (LRS), respectively. In the following equations, a and b are indices that label atoms of type A and B, respectively, d_{ab} is the distance between a A–B pair of atoms, R_A and R_B are the atomic radii for elements A and B, $R_{AB} = R_A \pm R_B$, $\vec{P}_a$ and $\vec{P}_b$ are position vectors of the nuclei, and $\vec{C}$ is the center of mass of the cluster calculated with fictitious masses of one for all atoms. We use a simple cut-off function of interatomic distance $f(d_{ab})$ to decide if two atoms are neighbours, and add up to get the number of AB neighbour pairs.

$$\begin{aligned} f(d_{ab}) &= 1 \text{ if } d_{ab} < 1.1R_{AB} \\ &= [1.3R_{AB} - d_{ab}]/0.2R_{AB} \text{ if } 1.1 \le d_{ab}/R_{AB} \le 1.3 \\ &= 0 \text{ if } 1.3R_{AB} < d_{ab} \\ m &= 1/2\sum_{a=1}^{n}\sum_{b=1}^{n} f(d_{ab}) \end{aligned} \quad [1]$$

The two segregation variables are simple relations between centers of mass of different types of atoms.

$$\ell = \frac{1}{n}\left|\sum_{a=1}^{n}\vec{P}_a - \sum_{b=1}^{n}\vec{P}_b\right| \quad [2]$$

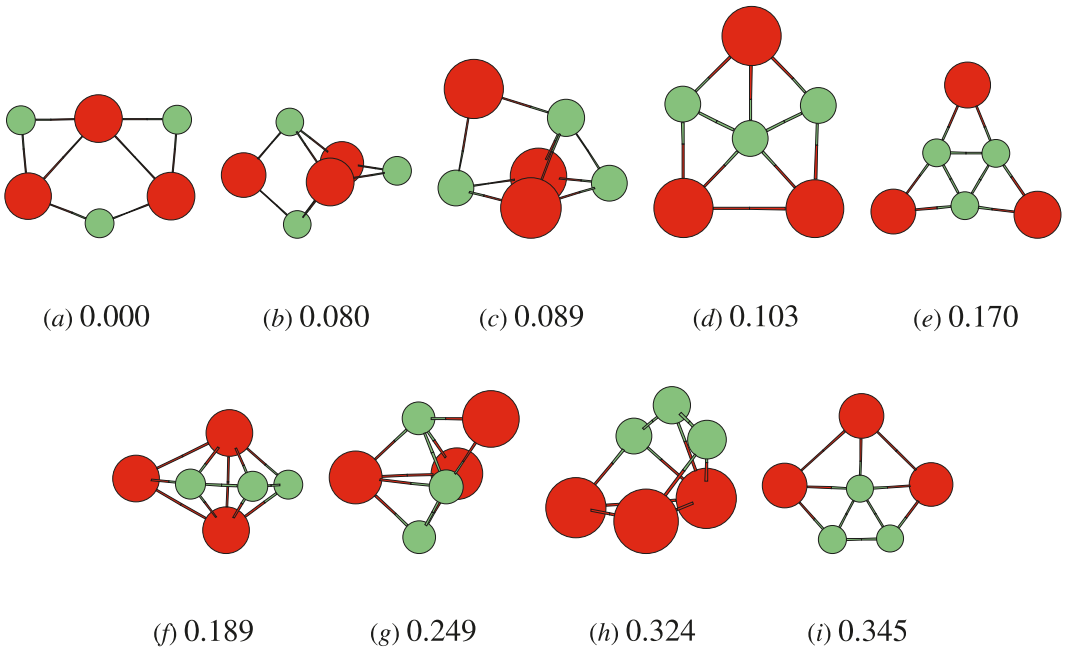
$$c = \frac{1}{n}\left[\sum_{a=1}^{n}|\vec{P}_a - \vec{C}| - \sum_{b=1}^{n}|\vec{P}_b - \vec{C}|\right] \quad [3]$$

We normally do not use m, ℓ, or c directly. Instead, we calculate m, ℓ, and c for all the homotops of a given structure, or a large sample of those homotops, and estimate the average "Avg" and standard deviation "SD" of m, ℓ, and c over the sample set of homotops. We sample homotops by doing a long sequence of random A–B position interchanges, calculating m, ℓ, and c each time. We denote the values of the variables for the structure itself (parent homotop) m_0, ℓ_0, and c_0, and define relative descriptors like this:

$$M = \frac{m_0 - \text{Avg}(m)}{\text{SD}(m)} \quad [4]$$

$$L = \frac{\ell_0 - \text{Avg}(\ell)}{\text{SD}(\ell)} \quad [5]$$

Fig. 1. Isomers of Ag_3Rb_3 and their relative energies (eV).



$$[6] \qquad C = \frac{c_0 - \mathrm{Avg}(c)}{\mathrm{SD}(c)}$$

So, for instance, an M value of +2.00 means that this structure has a number of A–B nearest neighbours that is larger than the average value for all of its homotops by two standard deviations; a value of zero for ℓ means that the structure has a degree of left–right segregation that is average relative to the set of all homotops to which it belongs, and so forth. Another variable that we use to quantify core-shell separation is the number of interior atoms N_i defined as follows: First, we calculate the asphericity ζ_j around each atom j by

$$[7] \qquad \zeta_j = \frac{(I_a - I_b)^2 + (I_b - I_c)^2 + (I_c - I_a)^2}{I_a^2 + I_b^2 + I_c^2}$$

where I_a, I_b, and I_c are the moments of inertia of the *neighbours* of atom j. We assign, to atom j, a number $n_j = \exp(-(\zeta_j/\zeta_0)^2)$, which tends to be close to one for interior atoms and close to zero for surface atoms, and get an effective number of interior atoms, N_i, by adding up the n_j's.

$$[8] \qquad N_i = \sum_j n_j = \sum_j \exp\left(-(\zeta_j/\zeta_0)^2\right)$$

With these definitions and $\zeta_0 = 0.0601$, we almost always get $n_j > 0.9$ for atoms that we would have classified as "interior atoms" upon visual inspection and $n_j < 10^{-5}$ for typical surface atoms. Another descriptor of geometry that we use is F_{90}, the number of 90° angles per atom. It is defined by

$$[9] \qquad F_{90} = \frac{1}{2n}\sum_j \sum_{k>\ell} \cos(\theta_{kjl} - 90°)^{100}$$

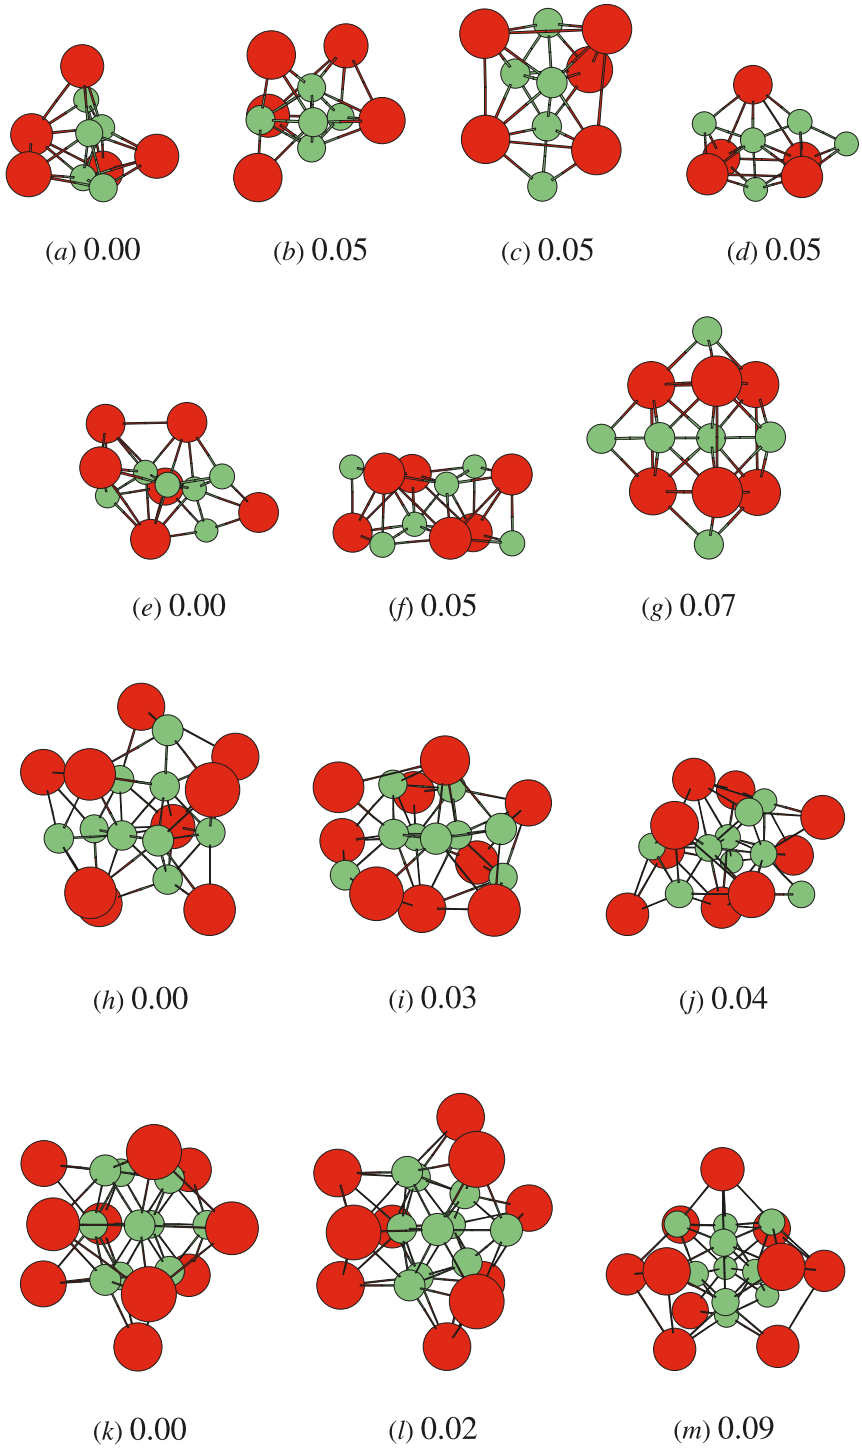
where k and ℓ index the neighbours of atom j. The exponent 100 in that formula is arbitrary, but it produces an intuitively correct count of the number of right angles.

Results and discussion

A taboo search explicitly encourages diverse solutions; therefore, it not only has a good chance of finding the global minimum (GM), but it is also likely to find many of the lowest-energy isomers. This is illustrated in Fig. 1, which shows the nine isomers found for Ag_3Rb_3 (another structure found by TSDS turned out to be a repeat of the 0.080 eV isomer). We should say a few words to put our results in perspective. We estimate that DFT-PBE gives errors of roughly 0.1 eV to 0.2 eV on relative cluster isomer energies for elements with low cohesive energy like Ag and Rb, and we believe that it is unlikely that TSDS would miss the GM but it is more likely that it would miss some (and maybe many) of the low-energy isomers. That said, there is clearly a lot of diversity among the lowest-energy structures of Ag_3Rb_3 some flat and some tridimensional, some well-mixed (e.g., 0.000 eV) and some segregated (e.g., 0.324 eV). The same is true for Ag_5Rb_5 (four very different isomers found within 0.1 eV, see Fig. 2) and Ag_6Rb_6 (three very different isomers found within 0.1 eV). The Ag_9Rb_9 and $Ag_{10}Rb_{10}$ clusters also have many isomers within 0.1 eV of the GM, but those isomers are similar, all of them have a silver core and an incomplete rubidium shell. In Fig. 3, we show the distribution of isomer energies as a function of n, and the cohesive energies of GM as a function of $N^{-1/3}$ ($N = 2n$). The number of isomers within a small energy range of the GM varies a lot. We did not find any isomer within 0.2 eV of the GM at n = 2, 4, and 8 but found five for n = 3, six for n = 5, four for n = 6, one for n = 7, four for n = 9, and six for n = 10 (some of them are indistinguishable in Fig. 3*a*).

Notwithstanding the uncertainty about the identity of the GM, it is convenient to focus on the structures and properties of the putative GM to see how they evolve with size (Figs. 3 and 4). Cohesive energies $E(N)$ of the GM (Fig. 3*b*) follow a typical trend for metal clusters; they are well-fitted by the function $E(N) = E_{bulk} + bN^{-1/3}$, with a

Fig. 2. Isomers of Ag_nRb_n ($n > 3$) within 0.10 eV of the GM and their relative energies.



correlation coefficient of –0.9918. The intercept E_{bulk} is 1.75 eV/atom, which is 8% smaller than the average of experimental cohesive energies for Ag (2.95) and Rb (0.85). The negative of the slope (1.26) is related to surface energy: it is much smaller than the negative of the slope (3.48) that we got by fitting the Ag_n cohesive energies obtained years ago in another series of DFT calculations.[7] This is not surprising considering that the surfaces of Ag_nRb_n clusters are enriched in Rb atoms. Generally, for elemental solids and clusters, surface energy is roughly proportional to (E_c/R^2), where E_c is the cohesive energy and R is the bulk interatomic distance. So, we can get a *rough* estimate of what the slope would be for pure Rb clusters by taking $3.48 \times (0.85/2.95) \times (2.89/4.837)^2$, which is 0.36. So, the slope of 1.26 for the mixed Ag–Rb clusters must surely be very different from the pure Rb_n case also. Looking at N_i for $n = 5$ to 10, we see that it is roughly $n/4$ on average, i.e., a quarter of Ag atoms are "interior atoms" in that size interval. The weighted average $(3/4 \cdot 3.48 + 0.36)/1.75 = 1.70$ is reasonably close to 1.26, so the slope of the fit line in Fig. 3*b*

Fig. 3. Relative isomer energies, and cohesive energies of the GMs.

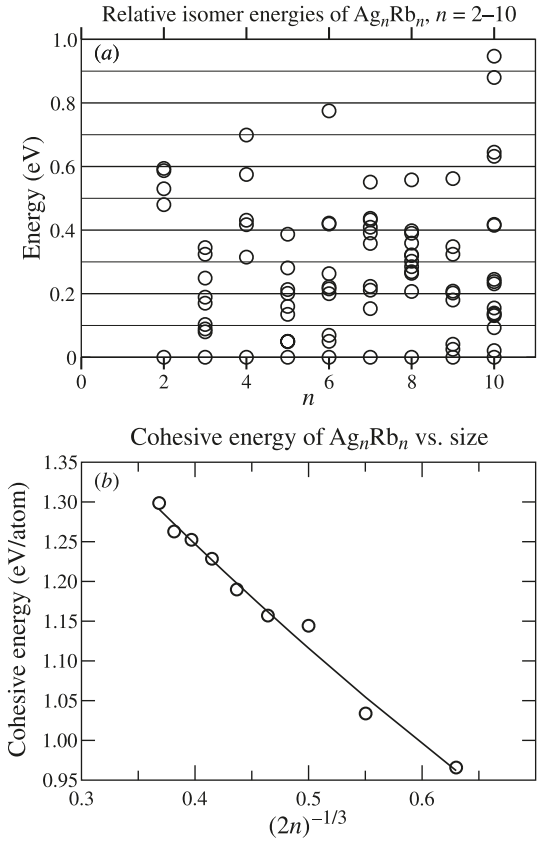


Fig. 4. Global minima.

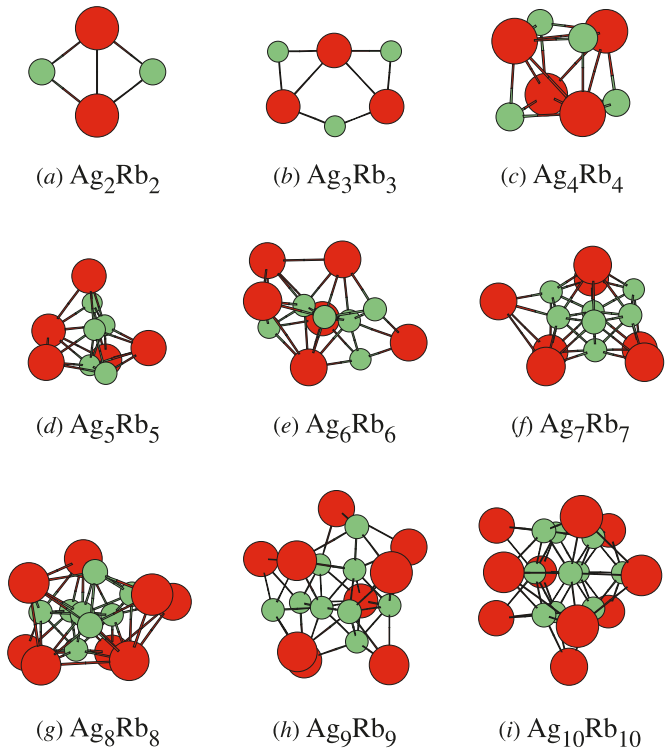
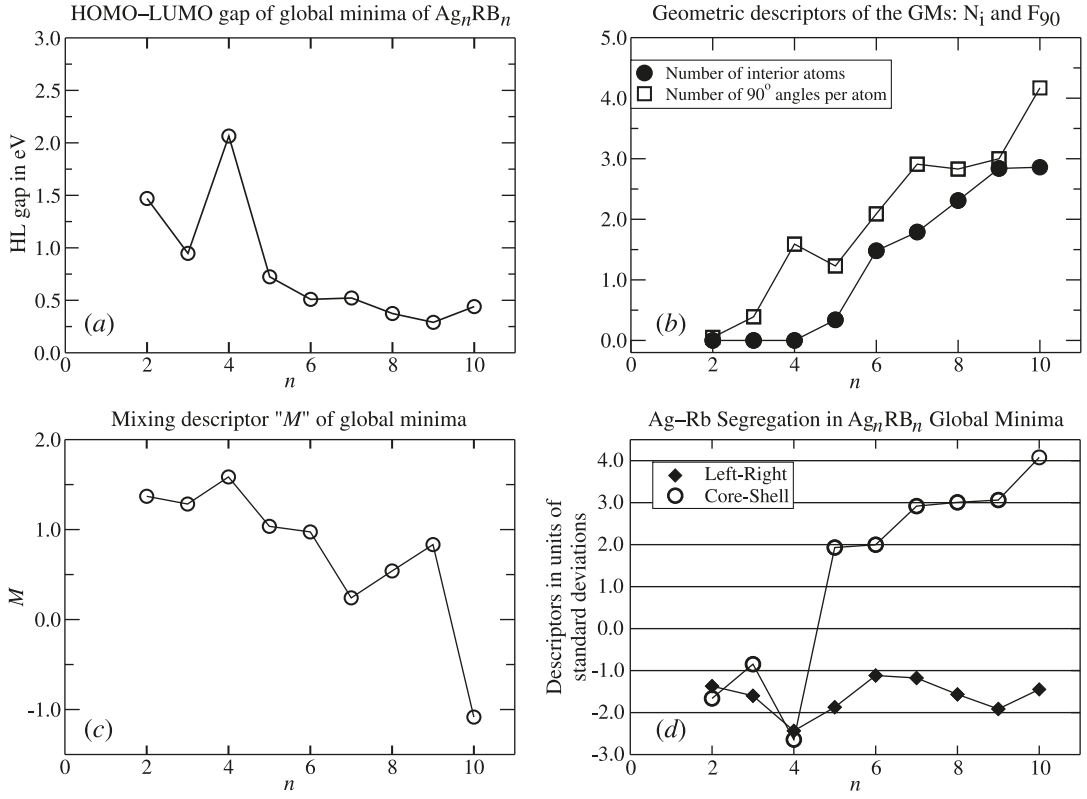


can be understood as a sort of weighted average of the surface energies of Ag and Rb. At very large n, the surface should consist entirely of Rb atoms, and the slope of a straight line fit would have to be close to –0.36, not –1.26. So, clearly, a linear function of $N^{-1/3}$ cannot fit accurately the cohesive energies of Ag_nRb_n over the entire range of n.

The n = 2–4 GM structures are very well-mixed (Figs. 4*a*–4*c*). A natural bond orbital (NBO) analysis reveals atomic charges of nearly ±0.75 in all three cases and shows that bonding is predominantly ionic. The structures in bigger clusters show a strong tendency for Ag atoms to be near the center, and by n = 8, the silver core is already fairly compact and tridimensional. The NBO analysis for $n > 4$ shows that charges are smaller (~ ± 0.50) and that a larger fraction of the valence electrons are delocalized, both of which indicate a transition from ionic to metallic bonding at around n = 5.

We also calculated atomic charges using the self-consistent charge equalization (SC QEq) method,[6,19] which is an improved version of QEq,[20] to gain more insight. In SC QEq, an electronegativity parameter χ is assigned to each element (Ag, Rb), along with parameters for the first, second, and third derivatives of χ with respect to atomic charge. These derivatives also depend on an atom's position, through its screened Coulomb interactions to other atoms, so, for instance, the Ag atoms in a given cluster do not necessarily all end up with the same charge. Atomic charges, and charge-dependent atomic electronegativities, are calculated iteratively until they satisfy the principle of electronegativity equalization.[21,22] An approximate electrostatic energy is then calculated by summing pairwise-screened Coulomb interactions. Details of the method can be found in the literature.[19] For the GM of Ag_nRb_n (n = 2, 3, and 4), the average SC QEq charges on Rb atoms are 0.76, 0.91, and 1.12, respectively. For the GM at n = 5–9, the average SC QEq charges on Rb atoms vary between 0.40 and 0.53 and have no simple relation to n, and for n = 10, it is 0.27. These SC QEq charges are not very different from the NBO charges. The SC QEq electrostatic energy per atom is strongly correlated to the average magnitude of SC QEq charges. So, the different geometric AB ordering of the GMs as a function of n, along with a simple electrostatic model that ignores quantum mechanical effects (SC QEq), are sufficient to explain some qualitative differences in bonding seen in a more rigorous (NBO) analysis. Other interesting things emerge from the SC QEq analysis. First, at $n > 4$, the average magnitudes of SC QEq charges in the GM are neither small or big compared to those in other structures found in our TSDS search. But for $n \leq 4$, the average magnitudes of SC QEq charges in the GMs are much bigger than in the other structures, which indicates ionic bonding in the GMs, and they increase as a function of size (from n = 2 to n = 4), whereas other structures show no clear trend with size. Second, the SC QEq electrostatic energies of the different isomers for a given cluster size vary over a big range: 1.1 eV (n = 2), 2.1 eV (n = 3), 3.5 eV (n = 4), 1.8 eV (n = 5), and for $n > 5$, a typical range is n/2 eV. At $n > 4$, the GMs have SC QEq electrostatic energies that are typically 2–3 eV less negative (less stable) than for the structure with most negative SC QEq electrostatic energy for that size. Third, there is a big drop in the SC QEq average Rb charge between n = 9 (0.47) and n = 10 (0.27) and, linked to that, a big drop in the mixing parameter M (Fig. 5*c*). One could say that Ag_nRb_n clusters ($n \leq 10$) are an example of a frustrated sys-

Fig. 5. Size evolution of structure and properties in the GM of Ag_nRb_n.



tem. Their lowest-energy structures do not necessarily minimize electrostatic energy, or surface energy (i.e., do not maximize the number of nearest neighbours). Instead, the GM structures are normally the best compromise between these two things, and evolve with size from mixed ($n \leq 4$) to "mostly core-shell segregated" ($n = 10$). We wanted to see how much difference there is between the GM of Ag_nRb_n ($n > 4$) and ideal CSS structures. To do that, we calculated the mean coordination "x" in hypothetical Ag_n clusters that consist of the n Ag atoms at their positions in the GM of Ag_nRb_n, $x(Ag;Ag_nRb_n)$; and for comparison, we calculated the mean coordinations of Ag atoms in the GM of Ag_n clusters that we had previously obtained,[7] $x(Ag;Ag_n)$. In either case, x is the mean number of Ag atom neighbours around a Ag atom. An ideal Ag_nRb_n CSS structure would have a central compact Ag_n subunit with a structure comparable to, and roughly as compact as, that of a pure Ag_n cluster. What we find, going in order from $n = 2$ to $n = 10$, is $x(Ag;Ag_nRb_n)$ = 0.0, 0.0, 0.0, 2.4, 2.3, 3.4, 3.5, 3.3, and 4.6. These values are much smaller than the corresponding $x(Ag;Ag_n)$; going again in order from $n = 2$ to $n = 10$, we have $x(Ag;Ag_n)$ = 1.0, 2.0, 2.5, 2.8, 3.0, 4.6, 4.5, 4.7, and 5.2. We see that the Ag_n subunits in Ag_nRb_n are a lot less compact than Ag_n clusters, except maybe for $n = 5$ and $n = 10$. This again shows that the GM of Ag_nRb_n ($n > 4$) represent a compromise between minimizing surface energy and maximizing ionic energy (mixing).

The size evolution of the HOMO–LUMO gap and some geometric descriptors of the GMs are shown in Fig. 5. The peak in HOMO–LUMO gap at $n = 4$ is remarkable. Two other things indicate special stability for Ag_4Rb_4: the $E(n = 4)$ point is well above the fit line of cohesive energies (Fig. 3*b*), and the second most stable isomer found for Ag_4Rb_4 is much higher (0.3 eV) than the GM (Fig. 3*a*). It is tempting to ascribe that to the eight-electron count, which is a closed shell in the jellium model. However, the difference in bulk electron densities of Ag and Rb, 0.0087 – 0.0017 = 0.0070 au, is very close to the critical value (0.0080 au) beyond which one normally sees inversion of the 2s and 1d jellium levels and magic numbers of 2, 10 (instead of 8), and 20.[3, 23] Also, the large atomic charges (NBO and SC QEq) in Ag_4Rb_4 indicate that ionic bonding is more important than delocalized metallic bonding. The SC QEq electrostatic energy, which is admittedly very approximate, amounts to 60% of the KS-DFT-PBE atomization energy of Ag_4Rb_4. Aside from the anomaly at $n = 4$, and maybe $n = 10$, HOMO–LUMO gaps decrease smoothly from $n = 2$ to $n = 10$, suggesting a gradual transition from ionic to metallic bonding.

There is a rationale for why the transition from mixed to CSS structure should occur near $n = 5$. Ionic bonding favors mixed structures at any size. On the other hand, the difference in surface energies between Ag and Rb, which is *roughly* $E_s(Ag) - E_s(Rb) \approx 0.4 \times (2.95 - 0.85) = 2.1$ eV per surface atom, favors CSS structures, i.e., it disfavors mixing, but only provided that the number of interior atoms (N_i) is not zero of course. Generally speaking, for metal clusters, one expects that N_i becomes nonzero for clusters with more than roughly 12 atoms because the 13-atom icosahedron is the smallest cluster in the polytetrahedral growth sequence with one interior atom. For structures other than polytetrahedral, N_i can become nonzero at slightly smaller or slightly bigger size. In mixed A_nB_n clusters where the el-

ement with lowest cohesive energy has a bigger atomic radius, like Ag_nRb_n, the smallest cluster size with one interior atom can occur at a smaller size, 10 atoms ($n = 5$) in our case (see Fig. 5*b*). As soon as clusters are big enough to accommodate one interior atom, the maximally mixed structure is no longer automatically favored, and the GM are generally "structures of compromise". Using a crude model (see Appendix 1), we estimate that the surface energy of a CSS structure is lower than that of a mixed (ionic) structure by an amount ΔU_s that is roughly $(2n - 8) \times 0.43$ eV in Ag_nRb_n clusters ($n > 4$). On the other hand, as we said earlier, the range in calculated SC QEq electrostatic energies among different isomers of Ag_nRb_n is roughly $0.5n$ eV. So, these two contributions to energy differences between mixed and segregated structures have comparable magnitudes, and they both scale roughly as n, which gives a rationale for why, starting with $n = 5$, the structures of GM are neither of the mixed nor the ideal (compact) core-shell type.

There remains a strong ionic character (charges of ±0.5) even in the largest clusters. This has an effect on the preferred geometries of Ag_nRb_n clusters. In particular, the number of 90° bond angles (F_{90}) per atom is large compared with other metal clusters: F_{90} varies between 1 and 4 for Ag_nRb_n ($n > 3$), and it is 2.1 for $n = 6$ (12-atom cluster) and 2.9 for $n = 7$ (14-atom cluster). The average of 2.1 and 2.9, 2.5, can be compared to the F_{90} value we found for the calculated GM of 26 different 13-atom metal clusters.[17] Of those 26 cases, only six (Tc_{13}, Ru_{13}, Rh_{13}, Re_{13}, Os_{13}, Ir_{13}) had $F_{90} > 2.5$. The large F_{90} values in those six cases were explained by the participation of d orbitals in bonding; but this explanation obviously cannot apply to Ag_nRb_n. The largest F_{90} we calculated[17] for 13-atom clusters of group 1, 2, 11, or 12 in the periodic table was 1.5 (for Zn_{13}), much smaller than 2.5. We think that the large F_{90} in Ag_nRb_n is a consequence of the large ionic contribution to bonding and the effect this has on A–B ordering, since cubic packing (as in NaCl) would minimize the electrostatic energy. The tendency to adopt structures with large F_{90} is not limited to the GM of Ag_nRb_n; several isomers (some of them not shown here) have prismatic or square arrangements of Rb atoms, e.g., Fig. 2*g* and 2*k*. It is also interesting to track the number of interior atoms, N_i, as a function of n (see Fig. 5*b*), but we are unable to predict accurately the size where $N_i = n$, i.e., the smallest cluster with n interior Ag atoms covered by a "monolayer" of n Rb atoms (this would correspond to the closure of an atomic shell in the core-shell growth sequence and could give enhanced stability). A simple geometric model leads us to predict that, within the Ag_nRb_n sequence, the Rb shell of the atoms becomes complete only at $n = 30$, *roughly*.

The mixing descriptor M and core-shell segregation parameter C (Figs. 4*j* and 4*k*) both undergo a sudden change between $n = 4$ and $n = 5$. The value of M starts off very large (at $n = 2$) and goes down but remains above zero until $n = 10$. As expected, the large electronegativity difference between Ag and Rb favors mixing. The drop of M at $n = 10$ shows that the driving force for having Ag atoms inside (difference in surface energies of Ag and Rb) is bigger than the driving force for mixing (difference in electronegativities of Ag and Rb). There is no special significance to M becoming negative at precisely $n = 10$. It happens partly because, with increasing number of atoms, there are many more ways to make highly mixed homotops, which makes the CSS structures appear poorly mixed in a relative sense (see eq. [4]). The C values get very large at $n > 4$ (+2.0 to +4.0) while L always stays negative; this shows that Ag_nRb_n has indeed a strong tendency to form core-shell structures, even for n values as small as 5.

The shape descriptor, $\eta = (2I_b - I_a - I_c)/I_a$, of the GMs of Ag_nRb_n is negative for $2n = 4$, 6, 14, 16, and 18, positive for $2n = 10$ and 12, and very nearly zero for $2n = 8$ and 20. These predictions of oblate, prolate, and spherical shapes agree with the ellipsoidal jellium model in every case except Ag_2Rb_2. The peaks in the HOMO–LUMO gap at $2n = 8$ and 20 also agree with the jellium model, but this is partly coincidental. For instance, the structure of Ag_4Rb_4 is optimal for ionic bonding (it is cubic), and also for accomodating a spherical closed-shell of eight electrons ($I_a = I_b = I_c$) as per the jellium model, but bonding in Ag_4Rb_4 is predominantly ionic. However, the agreement of DFT and EJM cluster shapes for all cases at $n \geq 5$ is probably not entirely accidental either. The EJM may be a crude model of electronic structure, but it gives a qualitatively correct relation between cluster shape and orbital symmetry and energies. These effects of shape and orbital symmetry are implicitly included in a more complete theory like DFT and may well give a small energetic preference (maybe in the order of a few tenths of eV) to structures that conform to the EJM.

In conclusion, the structures and nature of chemical bonding in Ag_nRb_n clusters evolve from mixed AB structures having ionic bonding for $n \leq 4$ to CSS structures where metallic bonding dominates but where ionic bonding is still important for $n = 5$ to 10. The Ag_4Rb_4 clusters are special for their relative stabilities and large HOMO–LUMO gaps. The geometric structures of Ag_nRb_n ($n = 5$ to 10) have a Ag core and an incomplete Rb shell, but the Ag core is not very compact. These structures are the result of a compromise between metallic and ionic contributions to bonding. Atomic charges on the Rb outer-shell atoms in $Ag_{10}Rb_{10}$ are calculated to be +0.3; this may be large enough to prevent coalescence of larger $Ag_n@Rb_n$ clusters having a complete Rb outer shell.

Appendix I. Model of surface energy in mixed and core-shell A_nB_n clusters

We want to estimate the energy difference, ΔU_s, arising from the different surface area, structure, and composition at the surface of two qualitatively different types of A_nB_n cluster structures (ionic and maximally mixed (IMM), and core-shell (CS)). A model like SC QEq could be used to estimate energy differences due to electrostatics, ΔU_e. The sign of $\Delta U_s + \Delta U_e$ could then be used to make qualitative predictions of cluster structure in A_nB_n mixed clusters.

We assume that IMM clusters have a packing similar to the simple cubic crystal structure and have a cubic shape, whereas the CS clusters are spherical with atoms packed in a way similar to fcc. These assumptions clearly cannot be exact for small clusters, but they hopefully capture an essential difference in the surface-to-volume ratio for the two types. So, the volume V and surface area A of the two structure types are estimated to be

$$[A1] \qquad \begin{array}{ll} \text{IMM} & \left\{ \begin{array}{l} V = Nv\sqrt{2} \\ A = 6V^{2/3} = 7.560(Nv)^{2/3} \end{array} \right\} \\ \text{CS} & \left\{ \begin{array}{l} V = Nv \\ A = 4.836V^{2/3} = 4.836(Nv)^{2/3} \end{array} \right\} \end{array}$$

where $N = 2n$ is the number of atoms and v is the average of the bulk atomic volumes for elements A and B. The surface of an IMM cluster is assumed to have A–B composition of 50%:50%, so the surface energy for IMM can be estimated as

$$[A2] \qquad U_s = (A_{IMM}/a)E_c \times 0.4$$

where E_c is the average of the two cohesive energies ((0.85 + 2.95)/2 = 1.90 eV for Ag–Rb) and a is the square of the average of bulk A–A and B–B distances (14.9 Å^2 for Ag–Rb); a is a rough estimate of surface area per atom in a mixed ordered A–B surface. The factor 0.4 is empirical; a factor of 0.16 would be appropriate for surface atoms of macroscopic particles,[24] but the cohesive energy of very small metal clusters (those with $N_i = 0$) is often close to 60% of the bulk cohesive energy, which motivates the choice of 0.4. The composition of the surface of a CS cluster depends on the number N_i of interior atoms. If N_i is large enough, the surface of CS clusters have only atoms of type "B" (the one with lowest surface energy), and in this particular case, the surface energy of the CS cluster would be

$$[A3] \qquad U_s = (A_{CS}/R_B^2)E_{c,B} \times 0.4$$

Let us define $f_m = 7.56E_c/a$ and $f_c = 4.836E_{c,B}/R_B^2$. Then, the surface energy for IMM is $f_m \times 0.4 \times (Nv)^{2/3}$, and the surface energy of a very large CS cluster is $f_c \times 0.4 \times (Nv)^{2/3}$. For the Ag–Rb case, $0.4 \times v^{2/3} = 4.78$ Å^2. When a CS cluster is not too large, there are $N_i < n$ interior atoms, and the surface composition is not 100% B. Instead, it is closer to $(N/2 - N_i)$ atoms of A and $N/2$ atoms of B, or alter-

natively, $(N - 2N_i)$ of AB, and N_i of B. So, we calculate a factor f_x for intermediate size CS cluster like this:

[A4] $$f_x = [(N - 2N_i)f_m + N_i f_c]/(N - N_i)$$

and estimate the surface energy of the CS cluster as

[A5] $$\begin{aligned} U_s &= f_x \times 0.4 \times (Nv)^{2/3} \\ &= f_x \times 4.78 \times N^{2/3} \text{ for Ag}-\text{Rb} \end{aligned}$$

From our calculated N_i values (Fig. 5*b*), we can propose a simplified approximate relation between N_i and N, $N_i \approx (N - 4)/2$. Using this relation and the equations above, we can estimate the contribution ΔU_s to the energy difference between IMM- and CS-type structures that is specifically due to surface structure and composition. We find ΔU_s = 0, 1.8, 3.4, and 4.9 eV for N = 8, 12, 16, and 20, respectively.

Ab initio electronic structure and direct dynamics simulations of CH_3OCl[1]

Stephanie Y. Y. Wong, Pierre-Nicholas Roy, and Alex Brown

Abstract: The ground (X^1A') and two lowest lying excited singlet states ($1^1A''$ and $2^1A'$) of methyl hypochlorite have been examined using ab initio electronic structure techniques to validate computationally efficient methods, upon which direct dynamics can be based, versus high-level ones, for which direct dynamics would be intractable. Ground-state equilibrium geometries and vibrational frequencies determined using density functional theory (DFT) with the 6-31G(d) basis set are tested against coupled-cluster theory (CCSD(T)) results from the literature. Vertical excitation energies and transition dipole moments calculated at the complete active space self-consistent field CASSCF/6-31+G(d) level of theory are benchmarked against multireference configuration interaction (MRCI) results with the aug-cc-pV*X*Z (*X* = D, T, Q) family of basis sets. The excited-state gradients that will govern the classical dynamics are compared for CASSCF/6-31+G(d) versus MRCI/aug-cc-pV*X*Z (*X* = D, T). To carry out the ab initio molecular dynamics (AIMD), existing electronic structure codes have been interfaced with the molecular modelling toolkit (MMTK), an open-source program library for molecular simulation applications. We use two examples to demonstrate the use of direct dynamics in MMTK: a canonical ground-state trajectory to sample positions and momenta, and an excited-state microcanonical trajectory based on CASSCF. The work presented here forms the basis for future study of the photodissociation of CH_3OCl. As well, the implementation of AIMD within MMTK provides a useful tool for examining a variety of other research problems.

Key words: ab initio molecular dynamics, excited states, atmospheric chemistry, electronic spectroscopy.

Résumé : Faisant appel à une technique de structure électronique ab initio, on a étudié l'état fondamental (X^1A') et les deux états singulets excités de plus basse énergie ($1^1A''$ and $2^1A'$) de l'hypochlorite de méthyle afin de valider les méthodes de calcul numériques sur lesquelles des dynamiques directes pourraient être basées par opposition aux méthodes de haut niveau dont le coût serait prohibitif. Les géométries d'équilibre de l'état fondamental et les fréquences de vibration déterminées à l'aide de la théorie de la fonctionnelle de la densité (TFD) avec un ensemble de base 6-31G(d) ont été comparées avec les résultats obtenus avec la méthode CCSD(T) et rapportés dans la littérature. Les énergies d'excitation verticale et les moments dipolaires de transition calculés au niveau (CASSCF)/6-31+G(d) de la théorie avec champ autocohérent de l'espace actif complet sont utilisées comme référence et comparées aux résultats de l'interaction de configuration multiréférence (MRCI) avec des familles d'ensembles de base aug-cc-pV*X*Z (*X* = D, T, Q). Les gradients de l'état excité qui gouverneront les dynamiques classiques obtenus au niveau (CASSCF)/6-31+G(d) sont comparés avec ceux obtenus au niveau MRCI/aug-cc-pV*X*Z (*X* = D, T). Dans le but d'effectuer des calculs ab initio de dynamiques moléculaires (AIDM), on a établi une interface entre les codes existants de structure électronique et le « molecular modelling toolkit (MMTK) », une source ouverte de programmes pour des applications de simulation moléculaire. On a examiné deux exemples pour démontrer l'utilisation des dynamiques directes dans MMTK: positions et impulsions de la trajectoire d'un état fondamental canonique et une trajectoire macrocanonique d'un état excité basée sur CASSCF. Les résultats présentés ici forment la base d'une étude future sur la photodissociation du CH_3OCl. De plus, l'implantation d'AIMD dans MMTK fournit un outil utile pour étudier une variété d'autres problèmes de recherche.

Mots-clés : dynamique moléculaire ab initio, états excités, chimie de l'atmosphère, spectroscopie électronique.

I. Introduction

The stratospheric molecule CH_3OCl has been shown to be important in ozone chemistry through its role as a reservoir for Cl.[2] Therefore, it is important to understand the loss mechanisms for CH_3OCl, including its UV absorption and subsequent decomposition. Gas-phase experiments have shown there to be two CH_3OCl absorption peaks between the range of 200–400 nm. The absorption peak at 236 nm is strong and narrow while the one at 310 nm is weaker and broader.[3] Due to its structural and spectral similarities to HOCl,[4,5] it has been predicted that CH_3O and Cl would be the photolysis products.[2,5] The dominant reaction upon photolysis via either absorption peak was confirmed experimentally[6,7] as

$$[1] \qquad CH_3OCl + h\nu \rightarrow CH_3O(X^2E) + Cl(^2P)$$

where the chlorine atom could be produced in either its spin–orbit ground ($^2P_{3/2}$) or excited ($^2P_{1/2}$) state. Theoretical

determination of the excited states[8] demonstrated their highly repulsive nature along the Cl–O coordinate. Butler and co-workers[6] measured the velocity distributions of the photofragments resulting from photodissociation at 248 nm. All their data could be fit assuming Cl and CH_3O as the only photoproducts. They determined that the CH_3O fragments had a narrow range of internal energies (vibration and primarily rotation). Schindler et al.[7] used resonantly enhanced multiphoton ionization time-of-flight mass spectrometry to measure the Cl atom fragments produced following excitation at 308 nm and 235 or 237 nm; different wavelengths were used to detect $Cl(^2P_{3/2})$ versus $Cl(^2P_{1/2})$. The chlorine atoms were formed with nearly unity probability at both wavelengths. Interestingly, the ratio of spin-orbit excited to ground-state chlorine atoms, $Cl(^2P_{1/2})/Cl(^2P_{3/2})$, was strongly wavelength dependent with a value of 0.31 ± 0.02 at 308 nm and 1.45 ± 0.05 at 235 nm. Clearly, the photodissociation dynamics of CH_3OCl is quite rich, and thus, it is a useful model molecule for our study.

Francisco[9] completed an equilibrium structure and vibrational frequency study of CH_3OCl with density functional theory B3LYP/6-31++G(3df,3pd) and coupled-cluster theory CCSD(T)/6-311G(2df,2p) where the results show a structure similar to that of methanol. Li and Francisco[8] have determined energetics for low-lying singlet and triplet excited electronic states using complete active space self-consistent field (CASSCF) followed by internally-contracted multireference configuration interaction (MRCI) with cc-pVTZ and (or) cc-pVTZ+sp basis sets. Peyerimhoff and co-workers[10,11] have examined similar properties for CH_3OCl using CCSD(T)/cc-pVTZ (equilibrium structure and vibrational frequencies) and MRCI/cc-pVTZ+sp (vertical excitation energies). The goal of the present study is not to reproduce these results, but to demonstrate that a computationally efficient method will provide an energetically correct characterization of CH_3OCl, consistent with the previously reported findings above. The necessity for a merely "sufficient" method is to be able to conduct direct dynamics simulations. To this effect, single-point calculations along the O–Cl bond coordinate are demonstrated to semiquantitatively provide the potential-energy surface and energy gradients of the first three singlet states. In the present study, we neglect the roles that low-lying triplet states and spin-orbit coupling play in the dissociation process. In the Franck–Condon region, the singlet ground-to-triplet excited-state transitions are essentially forbidden, and, thus, the triplet states play no role in the initial excitation process. As the molecule dissociates, coupling between the singlet and triplet states becomes important as the states approach the asymptote and are energetically similar. The coupling manifests itself in the production of both $Cl(^2P_{3/2})$ and $Cl(^2P_{1/2})$ fragments. Therefore, if one wants to interpret the experimental measure-

Fig. 1. Energies at the CASSCF/6-31+G(d) level of the first three singlet states of CH_3OCl as a function of the r_{OCl} bond length. All other bond parameters fixed at those of the B3LYP/6-31G(d) ground-state equilibrium geometry. Calculations are carried out in C_1 symmetry and, therefore, the states (along with their C_s symmetries) illustrated are $1^1A = X^1A'$ (solid line + circles), $2^1A = 1^1A''$ (dashed line + squares), and $3^1A = 2^1A'$ (dotted line + diamonds).

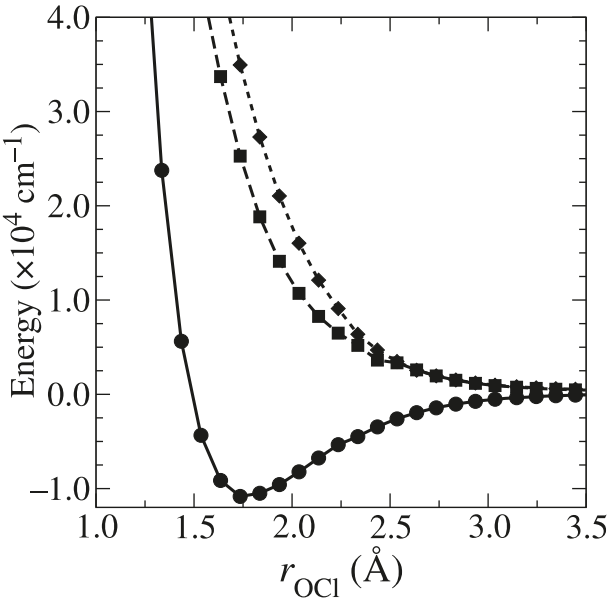

Fig. 2. Gradient projections of the first excited state ($2^1A = 1^1A''$) onto the O–Cl bond vector as a function of the r_{OCl} bond length: CASSCF/6-31+G(d) (circles), MRCI/aug-cc-pVDZ (squares), and MRCI/aug-cc-pVTZ (triangles). Other coordinates are fixed at the B3LYP/6-31G(d) optimized geometry.

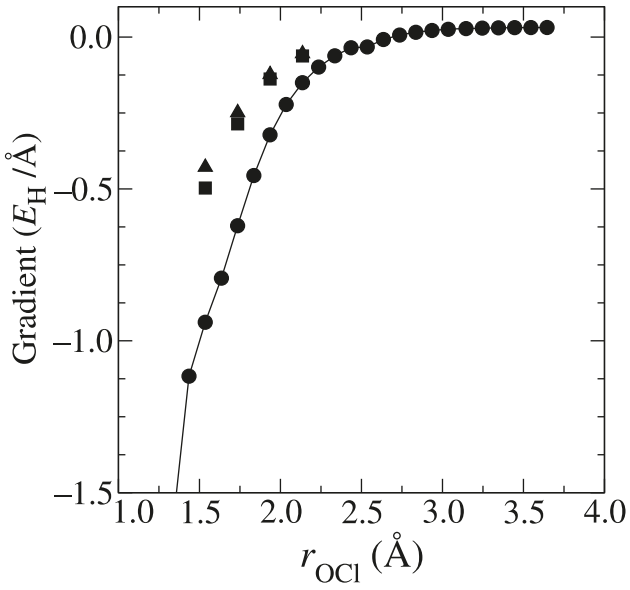

ments[7] of the branching ratio for these photoproducts, the spin-orbit coupling will have to be taken into account. This is not, however, the purpose of the present study.

In this paper, excited-state energies, gradients, and transition dipole moments for the CH_3OCl molecule determined using computational methods tractable for ab initio molecular dynamics, i.e., density functional theory (DFT) for the ground state and CASSCF for the excited states, are validated against high-level internally-contracted MRCI results. These lay the groundwork for future studies of the photodissociation of CH_3OCl. This article also reports the first implementation of ab initio molecular dynamics (AIMD) using

Fig. 3. Gradient projections of the second excited state ($3^1A = 2^1A'$) onto the O–Cl bond vector as a function of the r_{OCl} bond length: CASSCF/6-31+G(d) (circles), MRCI/aug-cc-pVDZ (squares), and MRCI/aug-cc-pVQZ (triangles). Other coordinates are fixed at the B3LYP/6-31G(d) optimized geometry.

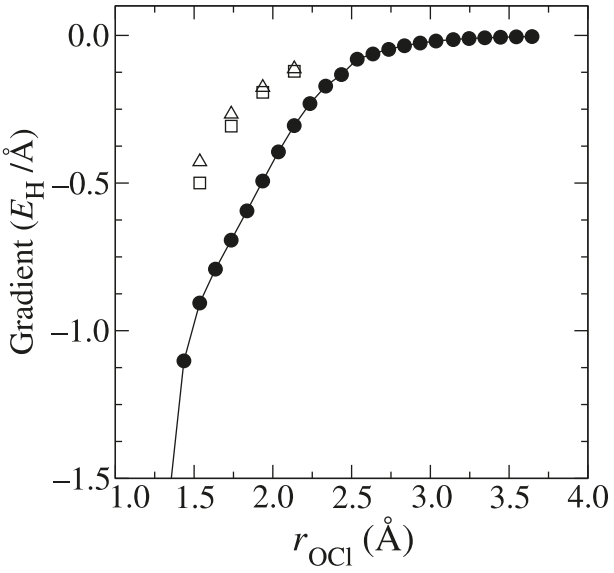

Fig. 4. The canonical distribution of C–O bond lengths (r_{CO}) for unconstrained and constrained (with C–H bond lengths fixed at their equilibrium values) dynamics. Both trajectories are at the B3LYP/6-31G(d) level of theory. Trajectory length is 9.6 ps for both unconstrained (dt = 2 fs) and constrained (dt = 4 fs) dynamics. The vertical line represents the equilibrium value.

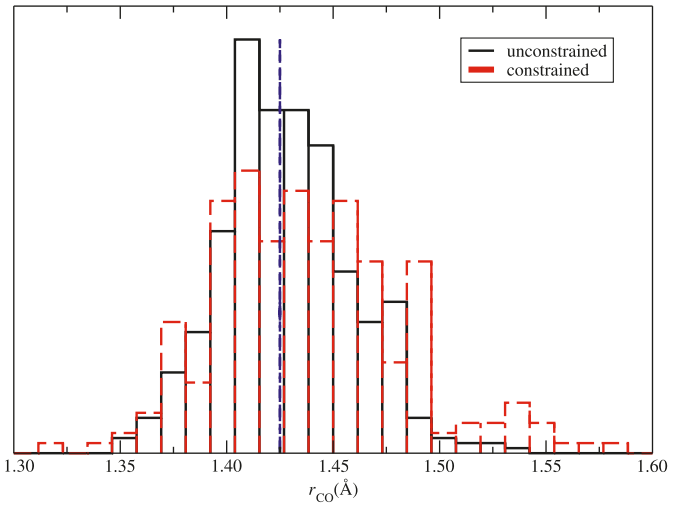

Fig. 5. The canonical distribution of O–Cl bond lengths (r_{OCl}) for unconstrained and constrained (with C–H bond lengths fixed at their equilibrium values) dynamics. Both trajectories are at the B3LYP/6-31G(d) level of theory. Trajectory length is 9.6 ps for both unconstrained (dt = 2 fs) and constrained (dt = 4 fs) dynamics. The vertical line represents the equilibrium value.

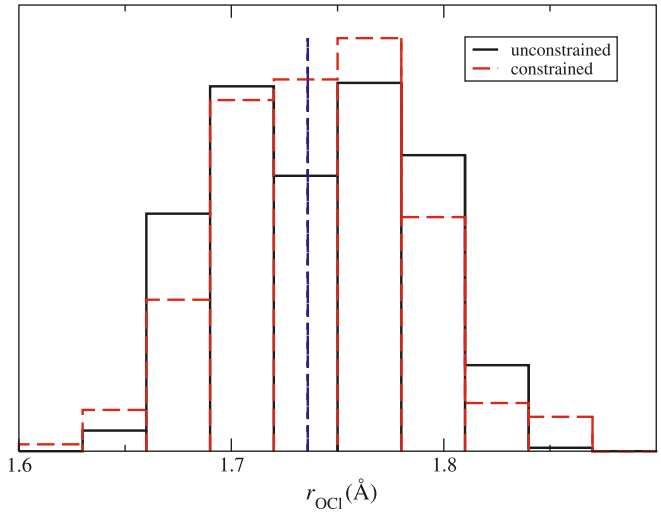

Fig. 6. The canonical distribution of the C–O–Cl bond angle (θ_{COCl}) for unconstrained and constrained (with C–H bond lengths fixed at their equilibrium values) dynamics. Both trajectories are at the B3LYP/6-31G(d) level of theory. Trajectory length is 9.6 ps for both unconstrained (dt = 2 fs) and constrained (dt = 4 fs) dynamics. The vertical line represents the equilibrium value.

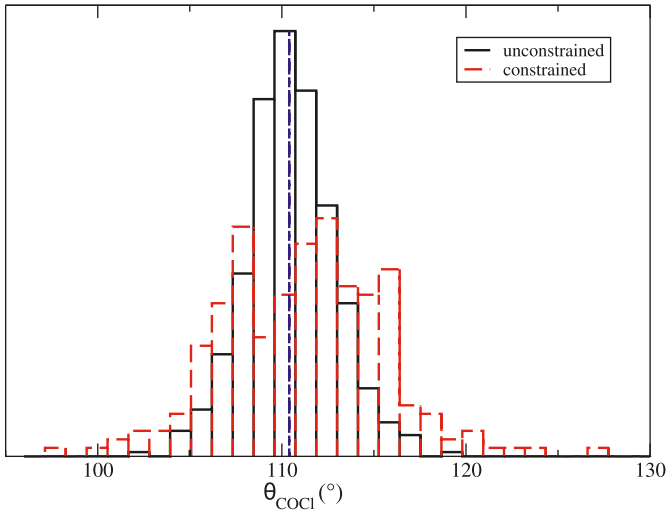


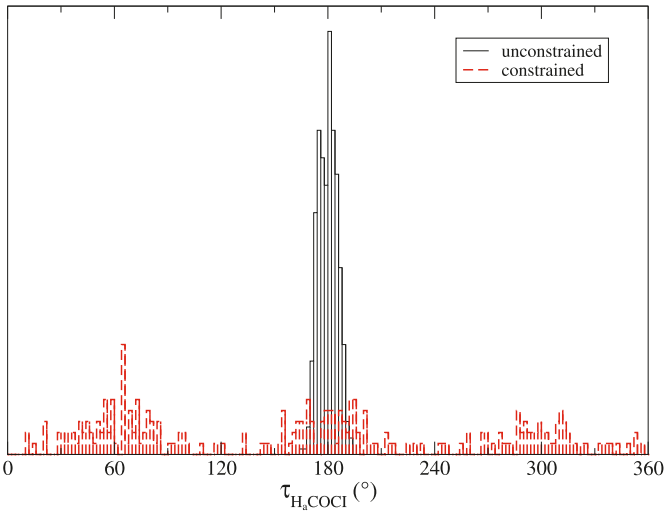
the molecular modelling toolkit (MMTK) and illustrates its use with both ground- and excited-state dynamics for CH_3OCl. Section II.A details the present and previous ab initio methods used to explore the electronic structure of CH_3OCl. The AIMD techniques are discussed in Section II.B. The static electronic structure properties are reported in Section III.A and a comparison is made between those from methods viable for AIMD and high-level benchmark results. Ground electronic state configurational sampling from AIMD for unconstrained and constrained dynamics is discussed in Section III.B. Section III.B also contains a brief discussion of AIMD for excited states of CH_3OCl. Finally, some conclusions and an outlook on future uses of AIMD with MMTK are presented in Section IV.

II. Computational methods

A. Electronic structure

There have been several previous theoretical studies of the ground-state structure and vibrational frequencies of CH_3OCl.[9,11–13] In particular, there have been two benchmark studies by Francisco[9] and by Peyerimhoff and co-workers[11]

Fig. 7. The canonical distribution of the H_a–C–O–Cl dihedral angle (τ_{H_aCOCl}) for unconstrained and constrained (with C–H bond lengths fixed at their equilibrium values) dynamics. Both trajectories are at the B3LYP/6-31G(d) level of theory. Trajectory length is 9.6 ps for both unconstrained (dt = 2 fs) and constrained (dt = 4 fs) dynamics.



at the CCSD(T)/6-311G(2df,2p) and at the CCSD(T)/cc-pVTZ levels of theory, respectively. Unless otherwise specified, all single-point calculations reported in this article have been carried out at the equilibrium geometry determined by Francisco (see Table 1) using C_s symmetry. Since the CCSD(T) methodology is too computationally expensive for dynamics calculations, a B3LYP/6-31G(d) geometry optimization and vibrational frequency analysis were performed to assess the suitability of this level of theory for ground-state configurational sampling (see the discussion in Section II.B). The B3LYP/6-31G(d) ground-state structure (Table 1) and vibrational frequencies (Table 2) as compared to the benchmark CCSD(T) results indicate that this method and basis set provide a suitable representation for the ground-state potential-energy surface, including the equilibrium structure. For example, and as expected, the bond lengths differ by less than 0.05 Å and the angles by less than 1.3°. Importantly, the frequencies also differ by a maximum of 5% and, in most cases, are within 1% of the benchmark results.

There have only been two theoretical studies focused on surveying the lowest-lying singlet and triplet excited states for CH_3OCl.[8,10] In these studies, they have determined the energies for the lowest six singlet and triplet states (three A′ and three A″ for each spin multiplicity). From these works, the two lowest energy absorptions observed experimentally at 310 nm and 236 nm[5] are identified with excitation to the $1^1A'$ and $2^1A''$ states, respectively. These two low-lying electronic states are the focus of this work. Benchmark calculations of both vertical excitation energies and transition dipole moments have been carried out using the augmented correlation consistent family of basis sets (aug-cc-pV*X*Z, *X* = D, T, and Q).[14–16] To determine the energies and transition dipole moments, state-averaged complete active space self-consistent field (SA-CASSCF) calculations[17,18] were carried out including two A′ and one A″ states. Following the work of Li and Francisco,[8] the active space consisted of 14 electrons in 10 active orbitals (seven and three active molecular orbitals in A′ and A″ symmetry, respectively). The resulting CASSCF orbitals and wave functions were then used for internally-contracted MRCI[19,20] calculations. For the MRCI calculations, the effect of higher-order excitations on the energies was estimated using the Davidson correction.[21] All electronic structure calculations reported in this article were carried out using the MOLPRO ab initio electronic structure program.[22]

The MRCI method is suitable for single-point calculations (or even potential-energy scans) but it is far too computationally intensive to be utilized for a direct dynamics study. The benchmark calculations discussed above were used to gauge the accuracy of SA-CASSCF calculations using the same (14,10) active space as described above but with the much more modest 6-31+G(d) basis set.[23–26] The major difference was that these calculations were carried out with C_1 symmetry as they will form the basis for future excited-state dynamics studies, where the planar symmetry of the molecule will be broken. We would like to use a moderate level of theory since efficiency (speed) is of critical importance for dynamics but we would like to retain a quantitative description of the excited states. Therefore, the vertical excitation energies were determined as they provide information on the energetic accessibility of the two excited states. The transition dipoles were determined as they provide information about the relative probability of accessing either state. Finally, and perhaps most importantly, the energy gradients must be determined since they govern the classical dynamics. To assess the accuracy of the SA-CASSCF/6-31+G(d) gradients, they are compared with numerical MRCI gradients at a small number of geometries (note that analytic MRCI gradients are not available in MOLPRO). The comparison of the gradients we make involves a projection onto the O—Cl bond vector, i.e., the primary "reaction" channel, defined by

$$[2] \qquad g_{OCl} = \frac{(\vec{g}_O - \vec{g}_{Cl}) \cdot (\vec{r}_O - \vec{r}_{Cl})}{\| \vec{r}_{OCl} \|}$$

where $\vec{g}_i$ and $\vec{r}_i$ are atom Cartesian vectors of the gradient and position, respectively. The numerical MRCI gradients are computed by four-point finite difference using a displacement length of 0.01 bohr along the r_{OCl} bond coordinate.

B. Molecular dynamics

Ab initio molecular dynamics simulations on the ground electronic state were carried out using MMTK.[27] MMTK is a simulation and modelling program library written in Python and C, which has been proven to be useful for atomic systems to large biomolecules. Most of the procedures needed in conducting the dynamics is self-contained in program classes that can be called from a main code. Significantly for us, MMTK allows the ready implementation of constrained dynamics, where the bond lengths can be fixed. A proper choice of constraints can "freeze out" high-frequency vibrations, permitting the use of larger integration timesteps. To perform AIMD using MMTK, an ab initio force field class that obtains energies and gradients directly from electronic structure calculations was implemented. The electronic structure calculations were performed using the MOLPRO package.[22] The present implementation allows the use of Hartree–Fock (HF), Møller–Plesset second-order

perturbation theory (MP2), DFT, and CASSCF classical trajectories, which are methods where analytic gradients are available in MOLPRO. An ab initio force field determined using GAMESS[28] has also been developed for HF and DFT trajectories (results are not presented here). The computer code for interfacing these ab initio electronic structure packages with MMTK is available upon request from the authors.

To generate initial conditions for examining the excited-state dynamics, one requires a sampling of geometries and initial velocities from the ground electronic state. One can do this by Monte Carlo sampling or by running a canonical NVT (where N, V, and T refer to the number of particles, volume, and temperature in the system, respectively) classical trajectory on the ground-state potential-energy surface to sample both positions and momenta. In this paper, we chose the latter to demonstrate our implementation of AIMD in MMTK. A single long NVT ground-state trajectory was generated at the B3LYP/6-31G(d) level of theory and can serve as a sampling of initial conditions of the molecule prior to photoabsorption. The initial conditions of the trajectory consisted of the equilibrium geometry determined at the B3LYP/6-31G(d) level of theory (see Table 1) and velocities obtained from a Boltzmann distribution at 300 K. Dynamics were conducted using the Velocity Verlet integrator.[29] To maintain the temperature, a Nosé thermostat[30] with a time constant of 0.2 ps was used. The proper timestep was determined from NVE (where E refers to the total energy of the system) dynamics and the length of simulation determined from proper phase space coverage. These NVT trajectories were determined for both unconstrained and constrained systems. In the constrained dynamics, the r_{CH} distances were fixed at their equilibrium values. The excited-state dynamics at the CASSCF/6-31+G(d) level of theory is briefly discussed. A more detailed study of the photodissociation process is beyond the scope of this paper.

III. Results and discussion

A. Static electronic structure

The important properties for photodissociation are the vertical excitation energies from the ground state ($1^1A'$) to the low-lying excited states ($1^1A''$ and $2^1A'$) and the corresponding transition dipole moments. Our results (CASSCF and MRCI) along with previous calculations for CH_3OCl[8,10] are presented in Table 3. All the present results are determined at the CCSD(T)/6-311G(2df,2p) equilibrium geometry.[9] Examining the MRCI vertical excitation energies as a function of increasing basis set size (aug-cc-pV*X*Z, X = D, T, Q), it is clear that they are converging to the values of 4.13 eV and 5.27 eV for the $1^1A'' \leftarrow X^1A'$ and $2^1A' \leftarrow X^1A'$ excitations, respectively. The present CASSCF and MRCI excitation energies are consistent with those determined previously[8,10] and with the experimentally-determined absorption spectrum[2,5] that exhibits maxima at 4.00 eV (310 nm) and 5.25 eV (236 nm). Importantly, the CASSCF/6-31+G(d) energies, upon which we plan to base the direct dynamics, are within 0.180 eV and 0.513 eV of the MRCI/aug-cc-pVQZ results.

The square of the magnitudes of the transition dipole moments can be used to determine the probability of a transition to each excited state; presently, the transition dipole moments are treated as scalars rather than as vectors. Examining the CASSCF versus MRCI transition dipole moments for a given basis set (see Table 3), it is clear that the inclusion of dynamic correlation plays a significant role in determining their magnitudes. For example, the CASSCF/6-31+G(d) transition dipoles as compared to the MRCI/aug-cc-pVQZ results are reduced from 0.282 D ($1^1A'' \leftarrow X^1A'$) and 0.331 D ($2^1A' \leftarrow X^1A'$) to 0.089 D and 0.270 D, respectively. More importantly, the ratio of the square of the dipole moments, which is proportional to the absorption cross section, changes significantly, e.g., for the aug-cc-pVQZ basis set, $(\mu_2/\mu_1)^2 = 1.38$ for CASSCF and 9.30 for MRCI. To assess the reliability of the computed transition dipole moments, we can compare as a first-order approximation to the ratio of the experimentally determined maximum-absorption cross sections,[2,5] where $\sigma_{236}/\sigma_{310} = 9.99$. Clearly, the ratios predicted by the CASSCF calculations are incorrect while the MRCI results for the triple- and quadruple-zeta basis sets agree fairly well with experiment. For future excited-state direct dynamics work, the CASSCF results will be unable to predict correctly the relative populations of the $1^1A''$ and $2^1A'$ states. Therefore, a geometry-independent dipole will be assumed and the populations in the states will be weighted 1:9 if both states are energetically accessible.

The CASSCF/6-31+G(d) energies also need to be considered away from the ground-state equilibrium geometry as the eventual goal of the research is to examine the photodissociation dynamics, where the molecule will access geometries far from equilibrium. Figure 1 shows the potential-energy curves for the first three singlet states of CH_3OCl as determined using the CASSCF/6-31+G(d) level of theory. As expected from previous investigations,[8,10] the excited states are highly repulsive in the r_{OCl} coordinate. Since the dynamics will break the C_s symmetry of the molecule, the CASSCF calculations have been performed using C_1 symmetry, i.e., no symmetry. One difficulty with carrying out the calculations in C_1 symmetry is that root-flipping problems can occur in the asymptotic region of the potentials.

Gradients serve the purpose of providing the acceleration term in the Velocity Verlet integration scheme. Therefore, obtaining accurate forces is more important than the potential-energy curves (relative energetics), although, they are, of course, intimately related. The gradients for the first excited state ($1^1A''$ in C_s symmetry = 2^1A in C_1 symmetry) as a function of the r_{OCl} bond length (all other coordinates are fixed at the B3LYP/6-31G(d) optimized geometry) are shown in Fig. 2. The CASSCF/6-31+G(d) gradients are compared to those from MRCI/aug-cc-pVDZ and MRCI/aug-cc-pVTZ determinations at four bond lengths (r_{OCl} = 1.536, 1.736, 1.936, and 2.136 Å). The MRCI results are noticeably smaller in magnitude than the corresponding CASSCF results; the ratio of the MRCI/aug-cc-pVTZ to the CASSCF results is approximately 0.4 for all four r_{OCl} bond lengths considered. The gradients for the second excited state ([$2^1A'$ in C_s symmetry = 3^1A in C_1 symmetry], see Fig. 3) are qualitatively similar to those of Fig. 2, where now the MRCI/aug-cc-pVTZ to CASSCF ratio is approximately 0.5. Hence, we conclude that the CASSCF/6-31+G(d) gradients provide a qualitative picture for guiding the excited-state dynamics; a semiquantitative picture could be obtained through simple

scaling of the CASSCF/6-31+G(d) gradients. Importantly, the CASSCF/6-31+G(d) energy and analytic gradient calculations are reasonable in computational time (approximately 2 min per geometry) for performing AIMD while those using MRCI/aug-cc-pV*X*Z are prohibitive. Note that for $r_{OCl} > 2.5$ Å, there is a problem with root flippping as the $2^1A'$ (3^1A) state becomes lower in energy than $^1A''$ (2^1A); this is obvious due to the observation of a discontinuity in the original gradient calculations. Therefore, the potentials, Fig. 1, and gradients, Figs. 2 and 3, present results where the root flipping has been accounted for "by hand". When AIMD is determined in the excited states, the root flipping must be accounted for automatically or trajectories must be terminated before $r_{OCl} > 2.5$ Å.

B. Ground- and excited-state dynamics

Presented here are NVT ground-state trajectories at the B3LYP/6-31G(d) level of theory. In the first case, motion in all $3N - 6$ internal degrees of freedom is allowed. In the second case, to remove high frequency vibrational motions, all three C–H bonds are fixed at their equilibrium bond lengths. To determine an appropriate timestep, equivalent NVE simulations with various timesteps (dt) are run. Equilibration occurs within a few femtoseconds. By applying constraints, we are able to increase the timestep about threefold (from $\sim$2 fs in unconstrained dynamics to $\sim$5 fs with constrained dynamics) before energy conservation is violated or SCF nonconvergence occurs in the electronic structure calculation, when large timesteps lead to significant geometric and, hence, electronic, changes. The latter point is of particular importance in AIMD simulations. Therefore, the energy convergence tests are merely to show the general upper limit on dt for the unconstrained and constrained systems. As a prescription, we suggest that actual production runs should be performed at smaller timesteps.

Figures 4, 5, 6, and 7 present histograms of the r_{CO} and r_{OCl} bond lengths, the C–O–Cl bond angle, θ_{COCl}, and the torsional angle, τ_{H_aCOCl}, respectively, from 9.6 ps unconstrained and constrained NVT trajectories (dt = 2 fs and dt = 4 fs, respectively). As expected, in the ground state at this temperature, the harmonic-like C–O bond exhibits a Gaussian distribution centered about the equilibrium bond length. Similarly, the O–Cl bond, C–O–Cl bond angle and torsional angle exhibit canonical behaviour. The Cl fragment neither diverges too far from its equilibrium distance to the O nor changes exceedingly from its orientation with respect to the C–O. For the constrained simulation, note that the methyl group isomerizes and H_a occupies equivalent minima at 60°, 180°, and 300°. Taking all the above into consideration, the use of a canonical NVT trajectory to sample initial ground-state distributions is certainly feasible, although it should be implemented with care. A small enough timestep needs to be taken to prevent integrator problems, which can adversely affect ab initio calculations. Yet, the simulation must be long enough for all modes to reach the canonical limit. The use of a Monte Carlo sampling scheme may allow us to circumvent such difficulties.

Positions and momenta sampled from the constrained ground-state trajectory will serve as initial conditions for future excited-state dynamics studies. To test AIMD for excited electronic states, a short 20 fs constant energy excited-state trajectory is determined on the first excited electronic state (2^1A in C_1 symmetry) at the CASSCF/6-31+G(d) level of theory. The trajectory starts at the ground-state equilibrium geometry with no initial kinetic energy (in practice, NVT ground-state initial conditions would be used). The molecule quickly reaches the asymptotic dissociation limit ($r_{OCl} > 2.5$ Å) in about 100 timesteps (dt = 0.2 fs). Thus, a single trajectory would take only (approximately) 300 min pointing to the computational feasibility of exploring ensembles of trajectories on the excited electronic states. The entire ensemble of excited-state trajectories can then be easily parallelized.

IV. Conclusions

The three lowest-lying singlet states of methyl hypochlorite have been examined using electronic structure methods for which direct dynamics studies would be computationally feasible, i.e., B3LYP/6-31G(d) for the ground state and CASSCF/6-31+G(d) for the excited states. From this, potential-energy scans and energy gradients along the O–Cl bond were obtained with an accuracy compared to that of MRCI with the aug-cc-pV*X*Z (*X* = D, T, Q) family of basis sets. In particular, the CASSCF gradients are related to the MRCI gradients by only a factor, allowing for appropriate dynamics. Thus, this moderate method is capable of semiquantitatively representing the benchmark calculations of the CH_3OCl system at a fraction of the computational cost. We have successfully implemented direct dynamics into MMTK using the electronic structure packages MOLPRO (results presented here) and also GAMESS (results not presented here). The power of using an ab initio "on the fly" method is that any system, provided electronic structure calculations are feasible, can be studied. Implementing this method with a modular molecular dynamics package lends to portability, generalization, and great potential. Note, however, careful analysis of the single-point calculations must be done. In our case, we encountered root-flipping problems and the potential for electronic structure nonconvergence of systems far from equilibrium. We have also shown that constrained dynamics can markedly decrease simulation time.

A full dynamical study of CH_3OCl dissociation is currently underway. In theory, a large set of trajectories generated from a Boltzmann distribution of initial states can be used to produce the sampling pool of ground-state configurations from which photoexcitation (vertical excitation) can occur. However, a Monte Carlo sampling approach may be more practical. One could, for instance, sample the ground-state NVT distribution in the harmonic approximation, yielding a Monte Carlo sampling scheme where no rejection step is required. In this case, the Monte Carlo sampling would be more efficient than the molecular dynamics sampling. The dissociative nature of CH_3OCl in its excited states was demonstrated with our AIMD algorithm, and for this type of process, is highly computationally practical at this level of theory. Further investigations will involve calculating ensemble averages and other structural properties. Quantum dynamical properties are also currently being investigated based on the present tool along with semiclassical initial value representation (SC-IVR) techniques.[31–34] The present work opens the door to the development of semiclassical dy-

namics with constraints using ab initio force fields. This is an advancement over earlier work where the quantum dynamics of rigid water clusters[35,36] was studied using model potentials. Very recent work has shown the practicality of on-the-fly AIMD based semiclassical calculations[37] and the aforementioned inclusion of constraints is therefore quite timely.

V. Acknowledgment

The authors thank the Natural Sciences and Engineering Research Council of Canada (NSERC), the Canadian Foundation for Innovation and the University of Alberta for financial support. AB thanks Chen Liang for performing preliminary calculations for CH_3OCl.

Computational design of ruthenium hydride olefin-hydrogenation catalysts containing hemilabile ligands[1,2]

Christopher N. Rowley and Tom K. Woo

Abstract: Three ruthenium hydridocarbonyl complexes containing bidentate hemilabile ligands have been evaluated as possible catalysts for the H_2 hydrogenation of olefins. Our previous investigations of the mainstay hydridoruthenium catalyst, $RuHCl(CO)(PR_3)_2$ (**1**), indicated that the rate-limiting olefin-insertion barrier was increased by the need for an H_2 molecule to act as a stabilizing two-electron donor. Using density functional theory (DFT) calculations, we have determined that a P,N phosphane-oxazoline would be suitable for stabilizing the metal center of the complex $RuHCl(CO)(P^iPr_3)(DZ)$, where DZ is a neutral bidentate hemilable ligand. In the reaction catalyzed by this complex, the olefin insertion occurs before the coordination of H_2, avoiding the entropic penalty of coordinating H_2. We predict that the phosphane-oxazoline containing catalyst will have higher activity than **1** and a different rate-law, zero-order in $[H_2]$. The oxazoline increases the strength of coordination of the ethylene due to stronger back-donation from destabilized Ru d-orbitals to the ethylene π^* molecular orbital.

Key words: catalyst design, catalysis, olefin, hydrogenation, DFT, hemilabile, phosphine, oxazoline.

Résumé : On a évalué la possibilité d'utiliser trois complexes hydridocarbonyle du ruthénium contenant des ligands bidentates hémilabiles comme catalyseurs pour l'hydrogénation d'oléfines. Les études antérieures effectuées avec le catalyseur traditionnel de l'hydridoruthénium, $RuHCl(CO)(PR_3)_2$, **1**, ont permis de déterminer que l'étape cinétiquement limitante à l'insertion de l'oléfine est rehaussée par la nécessité qu'une molécule d'hydrogène agisse comme donneur stabilisant de deux électrons. Se basant sur des calculs de la théorie de la fonctionnelle de la densité, on a pu déterminer qu'un ligand phosphane-oxazoline contenant un atome d'azote et un atome de phosphore devrait être approprié pour stabiliser le centre métallique du complexe $RuHCl(CO)(isoPr_3)(DZ)$ dans lequel le groupe DZ est un ligand bidentate hémilabile neutre. Dans la réaction catalysée par ce complexe, l'insertion de l'oléfine se produit avant la coordination du H_2 ce qui a pour effet d'éviter la pénalité entropique de la coordination du H_2. Sur la base des calculs, il est prédit que l'activité d'un catalyseur contenant un ligand phosphane-oxazoline sera plus élevée que celle du composé **1** et sera régit par une loi de vitesse différente, d'ordre zéro en $[H_2]$. L'oxazoline augmente la force de la coordination de l'éthylène en raison d'un pouvoir de rétrocession plus important à partir des orbitales d déstabilisée du ruthénium vers l'orbitale moléculaire π^* de l'éthylène.

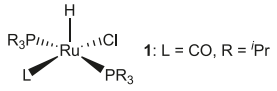
Introduction

The homogeneous H_2 hydrogenation of olefins is of considerable importance in organic synthesis, fine chemical production, and polymer chemistry.[3–5] Among homogeneous catalysts, hydridoruthenium complexes of the class $RuHCl(L)(PR_3)$ are of notable use in the reduction of challenging substrates[6–12] or within a tandem ROMP-hydrogenation (ring-opening metathesis polymerization) process.[13–19]

The first example of this type of catalyst was the arylphosphine complex $RuHCl(PPh_3)_3$, reported 40 years ago by Wilkinson and co-workers.[20,21] Since then, this framework of a neutral Ru(II)–hydride with three two-electron donors has served as the basis for vast amounts of research in homogeneous hydrogenation. Variation of the two-electron donor trans to the chloride found that a strongly bonding but compact CO ligand yields exceptionally good catalytic activity.[11,12] Another branch of optimization led to the substitution of the aryl phosphines for alkyl phosphines.[22–24]



1: L = CO, R = ^{i}Pr

Computational modeling has made increasingly significant contributions in organometallic chemistry.[25,26] In particular, density functional theory (DFT) modeling of catalytic cycles has contributed greatly to catalyst design, and in some recent examples, novel catalysts have been designed computationally in advance of their synthesis.[27–30] In our own research, we have attempted to move beyond the traditional procedures for modeling organometallic reactions, which has led us to study the dynamic features of catalytic

reaction mechanisms,[31,32] to evaluate novel catalysts prior to experiment,[33,34] and to pursue in-depth collaborations with experimentalists.[35]

One exceptionally productive collaboration sparked our interest in this class of olefin-hydrogenation catalysts. In that study, we modeled the catalytic cycle of hydridoruthenium complex **1** using DFT calculations. Kinetic studies had established that the catalytic cycle begins with the dissociation of a phosphine from the metal, although the subsequent steps were more opaque. Some published catalytic cycles proposed that the olefin undergoes insertion into the Ru–H bond to form a four-coordinate alkyl-containing intermediate.[36] Instead, we found that the putative four-coordinate ethyl intermediate formed by this insertion is not a potential-energy minimum and H_2 must be coordinated trans to the hydride prior to the insertion to stabilize this intermediate. As the coordination of H_2 is initially weak due to the trans influence of the hydride, this association is endergonic and increases the activation free energy of the rate-limiting insertion step.

This need for an external stabilizing donor led us to consider how the catalyst could be modified so that it would not be necessary for H_2 to coordinate before the insertion. In principle, another two-electron donor could be introduced to stabilize the metal in the insertion step, although a strong donor could inhibit the activity of the catalyst or induce the complex to isomerize to an inactive form. Conversely, a weak donor may not be able to coordinate trans to the hydride ligand, which has a strong trans influence.

Hemilabile ligands[37–40] could provide an elegant solution to this problem. Hemilabile ligands are polydentate ligands with at least two different coordinating groups. Notably, these coordinating groups can be chosen to have dramatically different interactions with the metal centre. Many highly active catalysts from groups 8–10 contain bidentate DZ-type hemilabile ligands with a strongly coordinating soft donor (D), such as a phosphine or carbene, and a weakly coordinating hard N or O donor (Z). The weakly coordinating donor can stabilize the metal in some steps of the catalytic cycle, but can adjust to interact weakly in other steps. A hemilabile P,N,P ligand was recently used in a related Ru(II) hydride catalyst for the dehydrogenation of alcohols[41] and the hydrogenation of esters,[42] providing precedence for this strategy. In this study, we have used DFT calculations to explore whether incorporating a DZ-type hemilabile ligand to ruthenium–hydrido catalysts similar to **1** could eliminate the need for H_2 to serve as the trans-hydride two-electron donor in the insertion step.

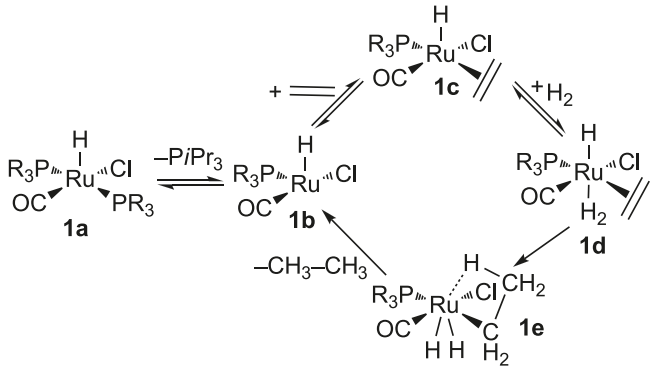
This paper is divided into three sections. In the first section, we present the calculated reaction profile of H_2 hydrogenation of ethylene catalyzed by the benchmark monodentate phosphine complex **1**. In the second section, we screen three potential catalysts containing DZ-type hemilabile ligands. In the last section, we model the catalytic cycle of a novel complex featuring one of these ligands.

Results and discussion

Monodentate phosphine catalyst

To provide a consistent point of comparison, we have included the reaction profile for the catalytic cycle of **1**, based on the mechanism we previously reported. The specific numerical values differ from our earlier report as we have used a different computational procedure in this report; BP86/def2-TZVP is used throughout this paper (see Computational methods for full details), while B3LYP/LACV3P+** was used in our first report. The relative energies and structures are generally consistent for both methods, although in our first report we found that a metastable nonclassical ethyl-dihydrogen intermediate formed after the insertion step. This structure is not a potential-energy minimum with the methodology used in this paper and only the $Ru(H)_2$ intermediate is present in this revised reaction profile.

Fig. 1. Catalytic cycle of ethylene hydrogenation by **1**.

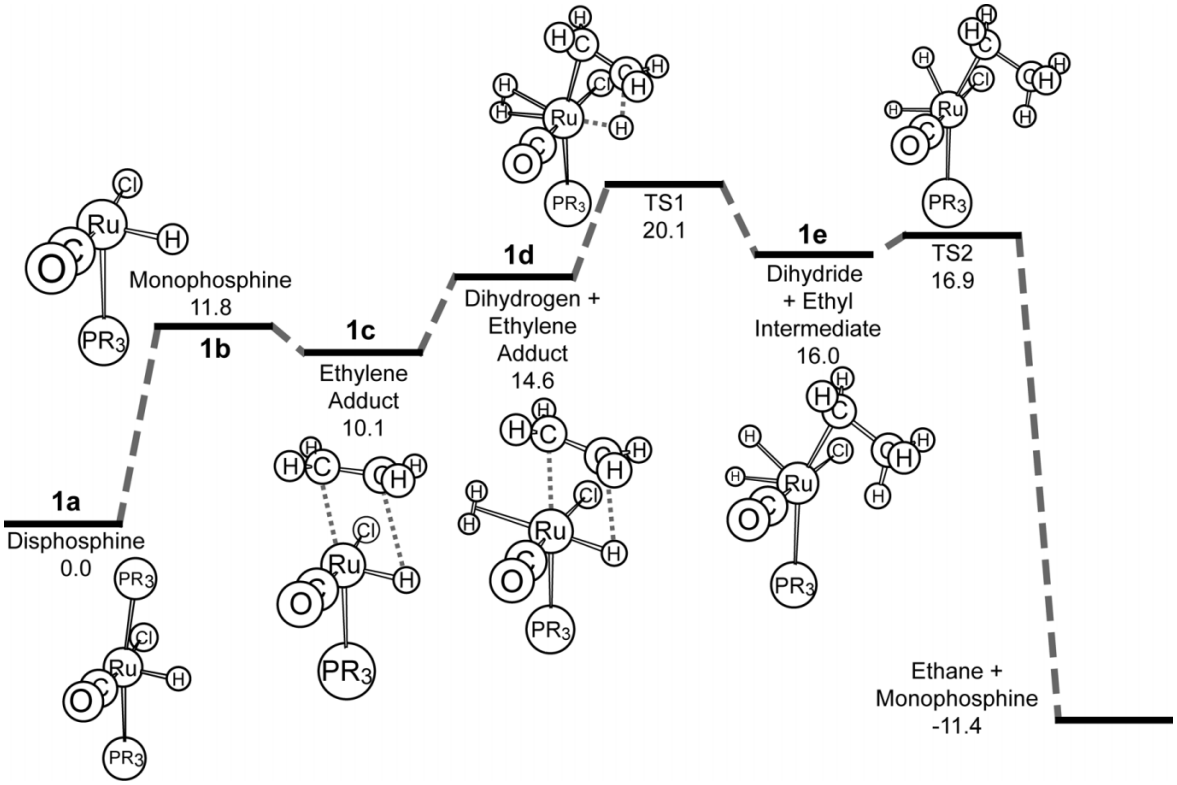


The catalytic cycle of **1** (Fig. 1) begins with the dissociation of P^iPr_3 to form a four-coordinate monophosphine complex **1b**. The olefin can then coordinate to the site vacated by the phosphine to form an η^2 metal-olefin complex (**1c**). Coordination of H_2 trans to the hydride forms **1d**, the immediate precursor to the olefin insertion. This insertion forms a metastable Ru(IV) dihydride intermediate (**1e**), which can facilely undergo reductive elimination to release the product alkane and regenerate **1b**. A path sampling study of this step demonstrated that this elimination generally occurs within 1 ps of the insertion due to localization of vibrational energy into the H–Ru–H bending mode.[33]

We have included the reaction profile of this catalytic cycle in Fig. 2. The dissociation of P^iPr_3 to form **1b** is significantly endergonic (11.8 kcal mol^{-1}). The coordination of ethylene is considerably weaker than that of the phosphine, so **1c** is only marginally more stable (10.1 kcal mol^{-1}). The reaction profile shows that **1d** is an unstable complex, at 14.6 kcal mol^{-1} with respect to the reactants. This is due to the strong trans influence of the hydride ligand and the entropic cost the complexation. As a result, subsequent olefin insertion into the ruthenium–hydride bond is the rate-limiting step on the reaction profile. Although the coordination of H_2 is weak in **1d**, our previous study[35] showed that the H_2 must be present to stabilize the metal during the insertion. The transition state of the insertion step (TS1) has a relative energy of 20.1 kcal mol^{-1}, the rate-limiting step of this profile.

The coordinated H_2 cleaves concurrently to the insertion, resulting in a Ru(IV) dihydride intermediate (**1e**), which is 1.4 kcal mol^{-1} less stable than **1d**. While Ru(IV) dihydrides had been thought to be generally less stable than the alternative non-classical $Ru(H_2)$ form,[43] a growing number of Ru(IV) dihydrides have been identified.[44–49] Given appropriate electron-donating auxiliary ligands and favourable trans

Fig. 2. Gibbs free-energy reaction profile of **1**. Free energies are given below the labels in kcal mol^{-1}.



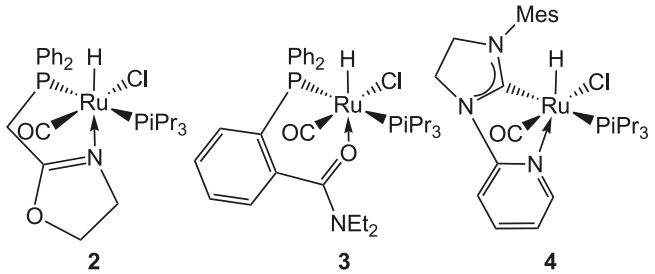
interactions, these dihydrides are viable reaction intermediates in some cases.

Potential hemilabile ligands

With the aim of identifying a ligand system that would allow the insertion to occur before the coordination of H_2, we have considered a series of complexes containing D–Z hemilabile ligands, where D is a strong donor and Z is a weak donor. In these complexes, the D donor occupies the coordinate site trans to the phosphine, while the Z donor occupies the site trans to the hydride (Fig. 3, **DZ-a**).

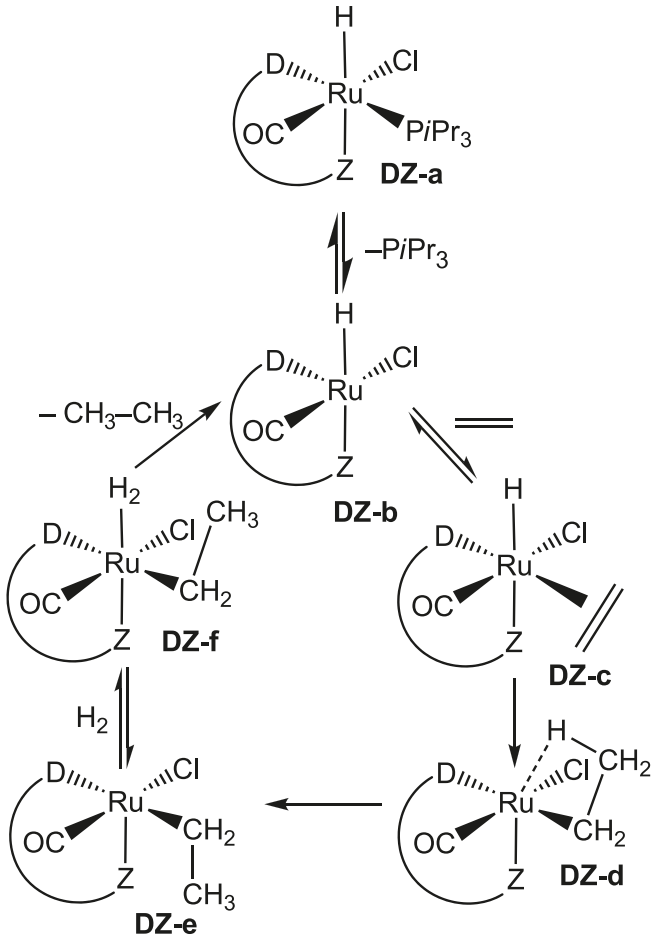
With the hemilabile ligand present, the catalytic cycle will be somewhat different than for **1** (Fig. 3). While the catalytic cycle still begins with the dissociation of phosphine (**DZ-b**) and the coordination of ethylene to form an olefin adduct (**DZ-c**), the donation from Z should allow the olefin insertion to occur directly from **DZ-c**. The insertion generates an alkyl-containing intermediate (**DZ-d**), which is stabilized by Z. As **DZ-d** is coordinately saturated, a ligand must dissociate to allow the coordination of H_2. Dissociation of Z would cause the complex to immediately revert to **DZ-c**, so the β-agostic interaction in **DZ-d** must be broken instead. This forms a square-pyramidal intermediate, **DZ-e**. Coordination of H_2 to this empty coordination site affords **DZ-f**, which can undergo reductive elimination to release the product and regenerate **DZ-b**.

We initially screened three catalysts containing established hemilabile ligands, **2**, **3**, and **4** with P–N, P–O, and C–N atoms acting as the DZ donors, respectively. The hemilabile ligand in **2** is diphenylphosphanodihydrooxazole, which coordinates to the metal through both the phosphine and the sp^2-hybridized N moiety. This type of ligand has been used extensively by Braunstein and co-workers in Pd-,[50] Ru-,[51,52] Cu-,[53] and Co-based[54] catalysts. **3** contains a benzamide-derived aryl phosphine, which was developed by Kwong et al. for Suzuki–Miyaura cross-coupling reactions.[55] We also evaluated **4**, where the hemilabile ligand is an N-heterocyclic carbene with a pendant pyridine group. This carbene was considered because Dharmasena et al. demonstrated that adding an N-heterocyclic carbene in the place of the alkyl phosphine in **1**, in conjunction with a more labile trans-phosphine, significantly improves hydrogenation activity.[56]



For these ligands to function effectively, they must stabilize **DZ-d** in the absence of H_2 coordinating trans to the hydride. To test this, we constructed **2d**, **3d**, and **4d**, then constrained the C–H(ag) distance to 1.1 Å to generate optimized structures corresponding to these intermediates. We then reoptimized these structures without the C–H(ag) constraint to test whether these complexes are stable. **3d** and **4d** are not potential-energy minima, as they reverted to their

Fig. 3. Catalytic cycle for H_2 hydrogenation of ethylene catalyzed by a hydridoruthenium complex with a hemilabile ligand (DZ).



ethylene adduct structures (**3c** and **4c**, respectively), indicating that these hemilabile ligands are not sufficiently strong donors to stabilize this intermediate. The ethyl intermediate of **2** is a potential-energy minimum, indicating that the oxazoline is a strong enough donor to stabilize this intermediate. The relatively high basicity of the oxazoline, as well as the comparatively large bite angle of this ligand, appears to be critical for stabilizing the ethyl intermediate. We have focused our efforts on catalyst **2** as a result.

Evaluating the phosphaoxazoline-containing catalyst

We have calculated the full catalytic cycle for **2**, following the mechanism in Fig. 3. The reaction profile is presented in Fig. 4. The hydride is trans to the oxazoline donor in the minimum-energy isomer of the precatalyst (**2a**), although the alternative isomer where the hydride is trans to the chloride is close in energy. As in the catalytic cycle of **1**, the first step is the dissociation P^iPr_3 ligand. This forms a square-pyramidal monophosphine complex (**2b**) with a vacant coordination site trans to the remaining phosphine. This occurs more readily for this catalyst, as this step is endergonic by 6.6 kcal mol^{-1} vs. 11.8 kcal mol^{-1} for **1**. We attribute this to steric repulsion between P^iPr_3 and the oxazoline and more limited donation of the phosphine to the more electron-rich metal centre in **2**. The oxazoline–metal interaction is relatively weak in this step (the Ru–N bond order is 0.40), as the hydride has a strong trans influence (Table 1).

This step is followed by the η^2 coordination of ethylene to the vacant coordination site to form **2c**. This coordination is relatively strong, and the calculations predict a small preference to the coordination of ethylene (–0.9 kcal mol^{-1}) over the phosphine. This coordination is considerably stronger than in **1c** due to stronger back-donation interactions (vide infra).

As the oxazoline is able to stabilize the metal in this step, the insertion can proceed immediately after the coordination of ethylene (TS1). The catalytic cycle of **2** differs from **1** beginning at this step, as this insertion occurs prior to the coordination of H_2. The barrier to insertion is modest, at 6.2 kcal mol^{-1} with respect to the initial reactants, as opposed to 20.1 kcal mol^{-1} in the reaction profile of **1**. This indicates that this hemilabile ligand successfully lowers the activation free energy of the insertion step. The oxazoline begins to stabilize the metal significantly in this transition state, as the Ru–N distance decreases to 2.14 Å, and the bond order increases to 0.5.

This transition state leads to **2d**, an intermediate containing the newly formed ethyl ligand. The ethyl group interacts with the metal through an extremely strong β-agostic interaction (Ru–H(ag) = 1.75 Å; C–H(ag) = 1.27 Å). Further, this intermediate is very shallow, with a barrier of only 0.3 kcal mol^{-1} for the β-hydride elimination of the ethyl ligand. The Ru–N bond order increases even further in this step, to 0.54, indicating that the oxazoline is donating to the metal to a greater degree to stabilize this intermediate.

To coordinate H_2 to the metal, the β-agostic interaction in **2d** must be broken. As this agostic interaction is exceptionally strong and the metal is electron poor, the square-pyramidal intermediate formed in this process is 18.1 kcal mol^{-1} on the reaction profile, making this step the rate-limiting process in the catalytic cycle. With the agostic interaction broken, the oxazoline must donate strongly to the metal to stabilize this complex (**2e**); the Ru–N bond length is the shortest of any of the steps of the catalytic cycle (2.00 Å), and the Ru–N bond order is 0.73, considerably larger than in any other step. As this is the rate-limiting step, we would expect that this reaction would be zero order in $[H_2]$, unlike related Ru–monohydride catalysts, which are first order in $[H_2]$.[6,8,10,57]

This intermediate is the highest point on the reaction coordinate. The transition state preceding it would correspond to rotation of the Ru–ethyl segment to break the agostic interaction. This transition state could not be located on the potential-energy surface as this barrier is extremely flat, so we have assumed that the height of this barrier can be approximated by the energy of this intermediate.

With the β-agostic interaction broken, H_2 can coordinate to metal trans to the oxazoline, forming **2f**. This coordination is very strong, resulting in an elongation of the H–H bond to 0.92 Å. This coordination significantly stabilizes the metal and is considerably lower on the reaction profile than **2e** (7.0 kcal mol^{-1} vs. 18.1 kcal mol^{-1}).

The cleavage of dihydrogen and the elimination of the alkane occurs in a concerted fashion (TS2). This step is facile, with an energy barrier of only 11.2 kcal mol^{-1}. The metal

stabilizes the transition state via a partial hydridic bond with the transferred hydrogen. In contrast to **1**, no transient dihydride intermediate is formed in this elimination. Avoiding this unstable Ru(IV) dihydride intermediate is another advantage of the use of this hemilabile ligand.

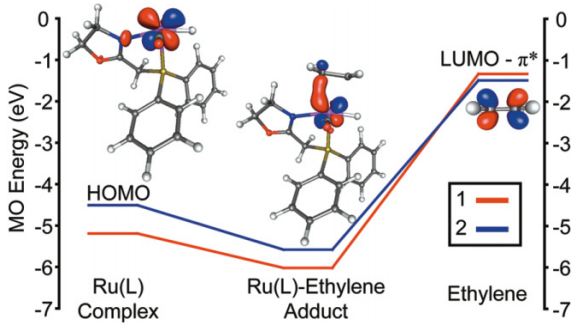
Ethylene coordination

The free energy of coordination of ethylene to **1b** is exergonic by 1.7 kcal mol^{-1}, but the coordination to **2b** is exergonic by 7.7 kcal mol^{-1}. This difference is predominately due to the bond energy of the Ru–ethylene bond, which is

Table 3. Donation, back-donation, and repulsion components of CDA for Ru(L)↔ethylene interactions for the ethylene adducts of **1** and **2**.

Complex	Donation	Back-donation	Repulsion
1c	0.74	0.25	–0.41
2c	0.75	0.33	–0.45

Fig. 5. MO scheme of back-donation interaction in the complex between the monophosphine complex and ethylene for **1c** and **2c**.



approximately 5 kcal mol^{-1} higher in **2c** than **1c** (Table 2).[58] The alternative conformation of **2c** where the oxazoline is not coordinated to the metal is 6.7 kcal mol^{-1} less stable with respect to the analogous reactants than structures where the oxazoline is coordinated, indicating that the coordination of the oxazoline causes this difference. This is surprising given that the oxazoline donor should make the metal centre more electron-rich and therefore have a lower Lewis acidity. Intrigued by this effect, we used fragment bonding analysis to investigate this further.

In the first stage of our analysis, we applied Ziegler–Morokuma energy decomposition analysis (EDA)[59–61] to complexes **1c** and **2c** (Table 2). EDA divides the bonding energy of two molecular fragments (in these cases, the ethylene ligand is one fragment, and the metal plus all the other ligands is the second fragment) into four components: the Pauli energy, the electrostatic interaction, the orbital interactions, and the preparation energies. The Pauli energy originates from the repulsion of the electron density of the two fragments, the electrostatic term includes the Coulomb interactions between the two fragments, and the orbital interactions term originates from covalent overlap between the fragment orbitals. The preparation energy results from the distortion of each fragment from their minimum-energy geometry to the geometry they adopt in the complex.

2c has a 4.8 kcal mol^{-1} stronger total bond energy than **1c** (Table 2). The Pauli repulsion term is larger for **2c**, although this repulsion is approximately cancelled by greater electrostatic interactions. Metal-fragment preparation energies are roughly equivalent, although the ethylene in **2c** has a higher preparation energy due to greater C=C bond elongation, typical of more strongly coordinated olefins. The crucial difference is that **2c** experiences 7.9 kcal mol^{-1} stronger orbital interactions. As this difference in coordination energies stems from the orbital interaction component, we next investigated the donation and back-donation interactions in complexes **1c** and **2c**.

Charge decomposition analysis (CDA) is a fragment analysis technique for investigating metal–ligand interactions[62] that is complimentary to EDA. This method calculates the relative weights of ligand-to-metal donation, metal-to-ligand back-donation, and an electron repulsion term resulting from the change in interelectron repulsion when the complex is formed. Within Dewar–Chatt–Duncanson theory,[63,64] bonding between transition-metal complexes and olefins results from two types of MO interactions: donation from the π bonding orbital of the olefin to the metal and back-donation from the metal to the π* antibonding orbital of the olefin. CDA data for the interaction between the coordinated ethylene and the metal fragment are presented in Table 3. **2c** has a distinctly higher proportion of back-donation than **1c** relative to the donation and repulsion terms. This indicates that the coordination of the oxazoline increases the interaction between the metal and the π* orbital of the ethylene.

We have identified the origin of this greater orbital interaction by examining the molecular orbitals corresponding to the metal–ethylene bonding. In each complex, the MO corresponding to back-donation is a predominantly combination of the d-character HOMO of the monophospine complex and the unoccupied ethylene π* orbital. Fragment orbital analysis shows that the Ru d-orbitals involved in this back-donation are destabilized by a repulsive interaction with the lone pair of the oxazoline (Fig. 5). This raises the energy of the back-donating Ru d-orbital, thereby reducing the energy difference between the interacting orbitals and making the interaction stronger.

As strong coordination of the olefin substrate is essential in this catalytic cycle, the increase in olefin coordination energy when the oxazoline is coordinated provides an additional benefit for the hemilabile ligand catalyst. Generally, it may be possible to increase the partitioning between ethylene and alkyl phosphines in Ru(II) complexes by introducing a hard, electron-donating ligand to destabilize filled d-orbitals. This favours bonding to olefins, which have higher back-bonding abilities than phosphines.

Conclusions

We have designed and computationally tested RuHCl(CO)(PR_3)(DZ) hydrogenation catalysts with hemilabile DZ-type ligands and compared them with an established catalyst RuHCl(CO)(P^iPr_3)$_2$ (**1**). In a previous mechanistic study of **1**, it was determined that H_2 must coordinate to the catalyst before ethylene can insert into the Ru–H bond of the catalyst. In this work, we have proposed that a hemilabile ligand could act as a two-electron donor to stabilize the metal during the insertion step such that it would not be necessary for H_2 to coordinate before ethylene coordination.

Three catalysts, **2**, **3**, and **4**, with P,N, P,O, and C,N hemilabile ligands, respectively, were computationally screened. Of the three hemilabile ligands that we considered, we determined that only a P,N coordinating phospha-oxazoline (**2**) could stabilize the metal sufficiently for the olefin inser-

tion to occur prior to coordinating H_2 to the metal. In principle, such a catalyst would be more active, as the entropic cost of weakly coordinating H_2 to the metal during the rate-limiting process is avoided.

Somewhat surprisingly, the introduction of the hemilabile ligand was found to significantly increase the olefin complexation energy relative to **1**. The reason for this was found to be a stronger Ru–ethylene back-donating interaction that was enhanced by a destabilization of the d-orbitals on the metal by the lone pair on the oxazoline ligand. This was found to lower the energy barriers associated with the ethylene coordination steps of the catalytic cycle.

On the other hand, the introduction of the hemilabile ligand has the detrimental consequence of producing a metal center that is coordinatively saturated after the insertion step. This results in an additional step where the β-agostic interaction between the newly formed alkyl ligand and the metal must be broken in to coordinate H_2. This process is rate-limiting, and we predict that the reaction should be zero-order in $[H_2]$, whereas this reaction with the traditional catalysts is known to be first-order in $[H_2]$. The formation of the intermediate with the strong β-agostic interaction therefore mitigates the rate enhancement induced by the hemilabile ligand.

The calculations presented here suggest that the overall ethylene hydrogenation barrier for the proposed hemilabile phospha-oxazoline containing catalyst, **2**, should be comparable to the more established $RuHCl(CO)PR_3)_2$, **1**, catalyst. Although simulating the reaction on the computer can never replace actually testing the catalyst in the lab, we have rationally designed a new catalyst motif based on our theoretical analysis of the parent catalyst system (**1**). This proposed catalyst motif may provide experimentalists with additional avenues to tune and optimize an important class of catalysts. For example, we believe there are opportunities to further optimize the donor properties of the hemilabile ligands as to stabilize the formation of the rate-determining ethyl intermediate (**2e**).

In addition to any rate enhancement resulting from the hemilabile ligand, the presence of the N donor may improve the catalyst lifetime. Fogg and co-workers have recently concluded that catalyst stability is critical for high activity in these systems,[11] which suggests that blocking decomposition pathways could be a fruitful approach to developing a more robust catalyst. Coordinately saturating the metal and inhibiting the dissociation of the hemilabile phosphine through the chelate effect could deter the degradation of the catalyst.

Computational methods

The calculations presented here were made with DFT,[26] as implemented in Turbomole 5.9[65] using the BP86[66,67] functional and the def2-TZVP basis set.[68] Thermal corrections were determined by reoptimizing these structures with the def2-SV(P) basis set, then running frequency analysis. We confirmed that the imaginary mode of the reported transition-state structures connects the adjacent steps in the reaction profile. Our first report used the B3LYP functional; however, the larger systems we have studied here required that we adopt a "pure" DFT functional so that the resolution-of-identity (RI)[69] approximation could be used. The BP86 calculations were benchmarked against the alternative PBE functional[70] and found to be consistent. Ziegler–Morokuma EDA analysis was performed by reoptimizing the complexes in ADF 2007.1 with the BP86 functional and the TZP basis set. Fragment orbital analysis was performed using the AOmix package.[71,72]

Binding of polar monomers in the complexes with organometallic ethylene polymerization catalysts — Natural orbitals for chemical valence and energy decomposition analysis[1]

Monika Srebro, Mariusz Mitoraj, and Artur Michalak

Abstract: The binding mode of polar monomers in complexes with late-transition-metal catalysts for ethylene polymerization was studied by density functional theory (DFT) calculations. The Ziegler–Rauk energy decomposition scheme was used to characterize the geometry distortion and steric and orbital-interaction terms in the bonding energy, while Natural Orbitals for Chemical Valence (NOCV) were applied to describe the donation and back-bonding components of the bond between the monomer and the catalyst. The NOCV analysis allowed for comparison of the donor–acceptor properties of different monomers in the σ- and π-complexes. The complexes with the model, cationic Ni– or Pd–diimine catalysts, N^N–Ni(H)+ and N^N–Pd(H)+, and the neutral Ni–anilinotropone system, N^O–Ni(H), were investigated. The monomers studied included: simple olefins (Et and Pr); examples of oxygen- and nitrogen-containing polar monomers (methyl acrylate (MA), vinyl acetate (VAc), their fluorinated derivatives (FMA, FVAc), vinyl ether (VE), acrylonitrile (AN), and β-butenoic nitrile (BN); vinyl and allyl amines (VAm, PrAm); and a tertiary dimethyl vinyl amine (MVAm). The results demonstrate that the metal-based fragment has a significant influence on the relative stability of the σ- and π-complexes; the π-binding mode increases in the following order: N^N–Ni(H)+ < N^N–Pd(H)+ < N^O–Ni(H). The results of the Ziegler–Rauk bond-energy decomposition indicate that for some monomers (MA, FMA, VAc, AN, VAm, MVAm) the preference of the coordination mode has a steric (electrostatic and Pauli) origin. For other monomers (VE, FVAc, BN, PrAm) the changes in the orbital-interaction terms are important as well. The results of the NOCV analysis indicate that for both, σ- and π-coordination modes there exist components describing σ-donation and π-back-bonding. The sequences of σ-donor and π-acceptor properties of monomers in the π-complexes as well as σ-complexes are similar for the considered catalysts.

Key words: NOCV, bonding analysis, donor–acceptor properties, copolymerization of olefins with polar monomers, single-site catalysts.

Résumé : Faisant appel à des calculs basés sur la théorie de la fonctionnelle de densité (TFD), on a étudié le mode de fixation de monomères polaires dans des complexes avec des catalyseurs de métaux de transition utilisés pour la polymérisation de l'éthylène. On a fait appel au schéma de décomposition de l'énergie de Ziegler–Rauk pour caractériser la distorsion de la géométrie et des termes d'interactions orbitalaires et stériques dans l'énergie de fixation; on a aussi appliqué la théorie de la valence chimique des orbitales naturelles (VCON) pour décrire les composantes de donation et de rétrodonation de la liaison entre les divers monomères et le catalyseur. Une analyse selon la VCON a permis de faire une comparaison entre les propriétés donneur–accepteur des divers monomères dans des complexes σ- et π-. Avec ce modèle, on a étudié les catalyseurs cationiques Ni– Pd–diimine, N^N–Ni(H)+ et N^N–Pd(H)+, et le système neutre Ni–anilinotropone system, N^O–Ni(H). Les monomères examinés comprennent les oléfines simples (éthylène, Et, et propylène, Pr) ainsi que des exemples de monomères polaires contenant de l'oxygène et de l'azote, tel l'acrylate de méthyle (AM), l'acétate de vinyle (AcV) et leurs dérivés fluorés (FAM; FacV), l'éther vinylique (EV), l'acrylonitrile (AN) et le β-butènenitrile (BN), les vinylamine (Vam) et allylamiine (PrAm) et une amine tertiaire, lal diméthylvinylamine (MVAm). Les résultats démontrent que le fragment porté par le métal exerce une influence significative sur la stabilité relative des complexes σ- et π- et que le mode de fixation π augmente dans l'ordre suivant: N^N–Ni(H)+ < N^N–Pd(H)+ < N^O–Ni(H). Les résultats de la décomposition de l'énergie de liaison de Ziegler–Rauk indiquent que, pour quelques-uns des monomères (AM, FAM, AcV, AN, VAm, MVAm), la préférence du mode de coordination est d'origine stérique (électrostatique et Pauli). Pour quelques monomères (EV, FAcV, BN, PrAm), les changements dans les termes de l'interaction d'orbitale sont aussi importants. Les résultats de l'analyse selon la théorie VCON indiquent que pour les deux modes de coordination σ- et π-, il existe des composants décrivant la donation σ et la rétrocession π. Les séquences des propriétés σ-donneur et π-accepteur des monomères dans les complexes π ainsi que dans les complexes σ sont semblables pour les catalyseurs considérés.

Introduction

Copolymers of ethylene and higher α-olefins with monomers bearing a polar functional group have attracted the growing interest of material researchers, especially because the incorporation of even small amounts of the polar monomer into the polyolefin chain dramatically modifies polymer properties.[2] Since commercially available polar copolymers are still overwhelmingly produced in radical polymerization processes under high temperature and high pressure conditions,[3] great attention has been paid to the development of new, less expensive routes of their production.[2]

In this context, use of the organometallic single-site catalysts based on the late transition metals is especially promising,[2b,4] as they are more tolerant toward Lewis bases than early-transition-metal complexes. The development of such catalysts for random copolymerization processes would not only decrease the production costs of the copolymers, but it could additionally enable the synthesis of new materials, potentially possessing new, interesting properties.

However, only a limited number of polar vinyl monomers has so far been efficiently copolymerized with α-olefins via the coordination–insertion mechanism[5] using catalysts based on late-transition-metal complexes. A list of proposed catalysts for controlled, direct copolymerization processes includes: Brookhart Ni– and Pd–diimine catalysts,[6] which have been shown to copolymerize ethylene and higher α-olefins with acrylates and vinyl ketones;[7] salicylaldiminato Ni-complexes, developed by Grubbs et al.,[8] able to polymerize and copolymerize some polar monomers;[9] Brookhart and Gibson (imino)pyridine Fe or Co systems[10] active in the copolymerization of ethylene with vinyl chloride and vinyl acetate;[11] and the Pd(II) complexes containing anionic bidentate sulfonate ligands recently developed by Drent et al., giving rise to copolymers of ethylene with acrylates, acrylonitrile, vinyl ethers, and vinyl fluoride.[12] Consequently, in view of the great variety of available polar monomers, the design of an effective catalyst for the random copolymerization of α-olefins with monomers bearing a polar functional group still remains one of the fundamental goals of organometallic catalysis.

Simultaneously with experimental research, theoretical mechanistic studies on various aspects of homopolymerization[13,14] and copolymerization mechanisms[15,16] have been carried out to understand the factors that are important for stabilizing catalytic–active metal centers and controlling their activity and selectivity; here the contribution from the group of Prof. Tom Ziegler has been particularly significant. Basically, the copolymerization of α-olefins with polar monomers proceeds via the same reaction mechanism as that of traditional α-olefin Ziegler–Natta homopolymerization,[5] including such steps as complexation, insertion, isomerization, and termination. Nevertheless, these elementary reactions reveal some specificity compared to homopolymerization because of the presence of donor atoms provided by polar monomers.[15d] One of the most important is the formation of σ-complexes, in which the monomer is bound to the metal center by its functional group. According to the standard Cossee–Arlman mechanism for α-olefin polymerization[5] the monomer insertion into the metal–polymer chain bond may start only from the σ-complex. Thus, formation of too stable σ-complexes results in the poisoning of the catalyst. Consequently, the preferred binding mode of the nitrogen- or oxygen-containing monomers seems to be crucial for the activity of the catalyst.

The main goal of the present study is to explore the important factors that influence the binding mode of various monomers in complexes with organometallic ethylene polymerization catalysts. The list of monomers investigated in the present work includes examples of the important oxygen- and nitrogen-containing molecules containing a vinyl group, as well as simple non-polar olefins. Complexes with model, cationic Ni– or Pd–diimine catalysts,[6,7] and neutral Ni–anilinotropone systems[17] were investigated in this work. On the basis of the DFT calculations, the role of the electronic and steric factors together with the donor–acceptor properties of a series of monomers for all considered catalysts in both types of coordination modes (π- and σ-complexes) will be discussed.

To date, many theoretical methods[18–23] have been proposed to describe the bond formed between the metal center and the ligand according to the "classical" Dewar–Chatt–Duncanson model[24] of donation–back-donation in transition-metal systems. Among the most widespread there are charge decomposition analysis[19] (CDA), constrained space orbital variation[20] (CSOV), interaction-energy partitioning schemes,[21] and natural bond orbitals[22] (NBO). One of the most recently proposed approaches is based on analysis of the natural orbitals for chemical valence[23] (NOCV). A main advantage of NOCV is that it allows for the direct separation of the contributions to the deformation (differential) density, $\Delta\rho$, of the ligand → metal and metal → ligand electron charge transfer processes. The NOCV, together with the Ziegler–Rauk[21b–21c] bond-energy decomposition analysis, will be used in the present work. It was shown in our previous papers[23] that NOCV approach gives a picture in agreement with other measures of donation–back-bonding.

Computational details and the model systems

The polar monomers and the catalysts studied in the present work are shown in Fig. 1. We considered complexes of polar monomers with the model cationic diimine catalysts based on Ni and Pd[6,7] and the neutral Ni–anilinotropone catalyst.[17] As the simplest models for the active form of the respective catalysts, the hydride complexes were considered: N^N–Ni(H)+, N^N–Pd(H)+, and N^O–Ni(H), depicted in

Fig. 1. Complexes studied in the present work: models for catalysts (panel *a*), monomers (panel *b*), and optimized geometries of the acrylonitrile π- (left) and σ-complexes (right) with Ni-based diimine (top) and anilinotropone (bottom) catalysts (panel *c*).

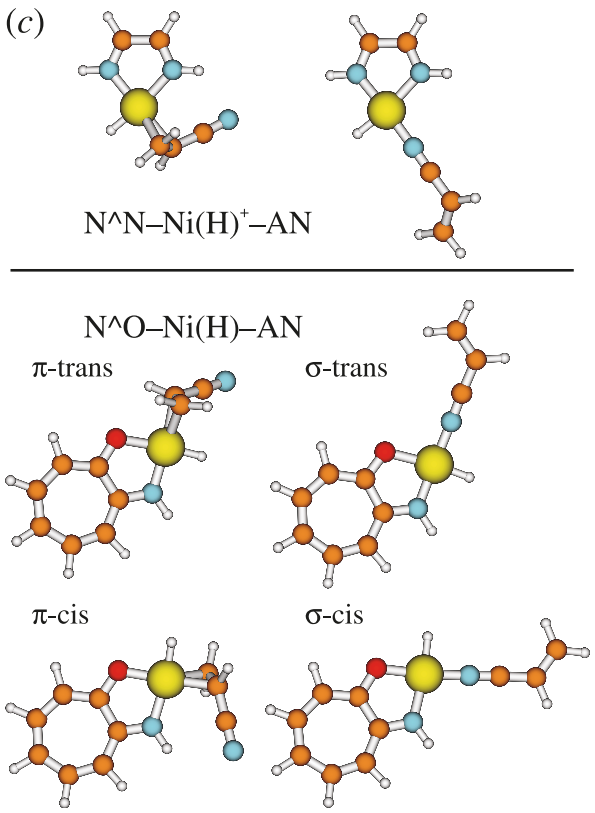

Fig. 1*a*. Since our goal was to compare two different binding modes in the complexes of various monomers, use of the hydride complexes instead of longer alkyl chains was justified here.

A list of the monomers studied is presented in Fig. 1*b*. It includes simple olefins (Et and Pr) as well as examples of oxygen- and nitrogen-containing polar monomers ("O-monomers" and "N-monomers"): methyl acrylate (MA), vinyl acetate (VAc), their fluorinated derivatives (FMA, FVAc), vinyl ether (VE), acrylonitrile (AN), and β-butenoic nitrile (BN); vinyl and allyl amines (VAm, PrAm), and an example of tertiary dimethyl vinyl amine (MVAm).

Following the mechanism of the copolymerization of α-olefins with polar monomers,[5,15d] we have considered complexes in which the polar monomer is bound to the metal center by either its double C=C bond (π-complexes), or by a donor atom (nitrogen or oxygen) of the polar group (σ-complexes). Examples of optimized structures of such

systems for acrylonitrile and the model Ni–diimine and Ni–anilinotropone catalysts are presented in Fig. 1*c*. It should be emphasized that, in the case of anilinotropone system, N^O–Ni(H), two pairs of the π- and σ-complexes are possible for each polar monomer, since it can be coordinated in the position trans or cis with respect to the nitrogen atom. However, for all monomers the trans complexes were found to be more stable (by 3.1–8.9 kcal/mol) than the corresponding cis complexes. Therefore, all the results for Ni–anilinotropone catalyst presented in this work will refer to the trans π- and σ-complexes, i.e., the most stable species.

All the results were obtained from the DFT calculations based on the Becke–Perdew exchange–correlation functional,[25] using the Amsterdam density functional[26] (ADF) program, version 2004.01. A standard triple-ζ STO basis with one set of polarization functions (TZP) was used for transition metals Ni and Pd, while a standard DZP basis set was employed for main-group elements H, C, N, and O. For fluorine, a triple-ζ STO basis with two sets of polarization functions (TZ2P) was employed. The 1s electrons of C, N, O, and F, as well as the 1s–2p electrons of Ni and 1s–3d electrons of Pd were treated as frozen core. Auxiliary s, p, d, f, and g STO functions, centered on all nuclei, were used to fit the electron density and obtain accurate Coulomb potential in each SCF cycle. Relativistic effects were considered using the first-order scalar relativistic correction.[27]

Bonding between monomers and catalysts in all systems was described using the Ziegler–Rauk bond-energy decomposition scheme[21b–21c] and the analysis of NOCV.[23]

In the Ziegler–Rauk bond-energy decomposition analysis,[21b–21c] the overall bonding energy is decomposed as

$$[1]\qquad \begin{aligned}\Delta E_{\mathrm{b}} &= \Delta E_{\mathrm{geom.}} + \Delta E_{\mathrm{tot.}} \\ &= \Delta E_{\mathrm{geom.}} + [\Delta E_{\mathrm{ster.}} + \Delta E_{\mathrm{orb.int.}}] \\ &= \Delta E_{\mathrm{geom.}} + [(\Delta E_{\mathrm{el.}} + \Delta E_{\mathrm{Pauli}}) + \Delta E_{\mathrm{orb.int.}}]\end{aligned}$$

where $\Delta E_{\mathrm{geom.}}$ is a geometry distortion term, comprising the contributions from both considered fragments (monomer and catalyst), and $\Delta E_{\mathrm{tot.}}$ is the total interaction energy of distorted reactants. The latter can be further decomposed into the orbital-interaction term, $\Delta E_{\mathrm{orb.int.}}$, and the steric contribution consisting of the electrostatic interaction and the Pauli repulsion, $\Delta E_{\mathrm{ster.}} = \Delta E_{\mathrm{el.}} + \Delta E_{\mathrm{Pauli}}$.

NOCV have been defined[23a] as the eigenvectors of the chemical valence operator of the Nalewajski–Mrozek theory of valence and bond-order indices[28]

$$[2]\qquad \hat{V}\varphi_i = v_i\varphi_i \; i = 1, \ldots, n$$

with the valence operator given in a matrix form as

$$[3]\qquad \mathbf{V} = 1/2\mathbf{\Delta P}$$

where $\mathbf{\Delta P} = \mathbf{P} - \mathbf{P^0}$ corresponds to a difference between the density matrices (*charge-and-bond-order* matrices) of a molecule **P** and promolecule $\mathbf{P^0}$. In the present work a promolecule built of two fragments (the monomer and the transition-metal-containing fragment) was considered.

One of the features of NOCV is that they can be grouped in pairs of complementary orbitals characterized by eigenvalues of opposite sign and the same absolute value[23a,23f]

$$[4]\qquad \hat{V}\varphi_{-k} = -v_k\varphi_{-k},\ \hat{V}\varphi_k = v_k\varphi_k,\ k = 1, \ldots, n/2$$

Using eq. [4], the deformation density, $\Delta\rho = \rho(\text{complex}) - \rho(\text{fragments})$, can be written in terms of the NOCV-pairs as

$$[5]\qquad \Delta\rho(r) = \sum_{k=1}^{n/2} v_k[-\varphi^2_{-k}(r) + \varphi^2_k(r)] \equiv \sum_{k=1}^{n/2} \Delta\rho_k(r)$$

In eq. [5] an eigenvalue v_k corresponds to the fraction of electron density that is transferred from the φ_{-k} orbital to the φ_k orbital, when the molecule is formed from the fragments. Thus, a complementary pair of NOCV defines a channel for electron charge transfer between the molecular fragments.[23a] The total charge transferred in this channel is:

$$[6]\qquad \Delta q_k = v_k$$

It should be also pointed out that only a few pairs of orbitals contribute to bonding, and a large majority of eigenvalues v_k are practically equal to zero. Thus, there exist only a few non-vanishing $\Delta\rho_{\mathrm{k}}$ components.

It has been found for many transition-metal complexes,[23a–23e] that among the $\Delta\rho_{\mathrm{k}}$ contributions, it is often possible to recognize components with negative sign on one fragment (i.e., an outflow of charge density from it) and the positive on the other fragment (i.e., an accumulation of charge density). Thus, in such a case, NOCV led to a separation of the charge transfer channels corresponding to donation–back-donation and the respective eigenvalue, v_k provides a quantitative measure of a donor–acceptor ability of the two fragments in the complex.

However, a separation of the donation and back-donation channels is not always naturally achieved. In some systems the two channels are inherently mixed. It will be demonstrated later that this is the case of the π-complexes of polar monomers. Thus, to characterize donor–acceptor properties of the monomers in the π-complexes one has to apply additional constraints or different approaches. In the present study, we have applied the CSOV-like[20] technique combined with the NOCV analysis. This will be discussed in a more detailed way in further parts of this work.

Results and discussion

In the following we will first discuss the energetic preference of the σ- and π-binding mode for different monomers in the complexes with the model catalysts. Further, the results of the Ziegler–Rauk bond-energy decomposition analysis will be presented to rationalize the observed changes in the preference of the binding mode in terms of the orbital-interaction, steric, and geometry distortion components to the bond-energy. Finally, the NOCV picture of bonding will be presented and used to compare the donor–acceptor properties of a series of monomers in the σ- and π-complexes.

The energetic preference of the binding mode: σ-complexes vs. π-complexes

The differences in the energies of the π-complex and σ-complex ($\Delta E(\pi\text{–}\sigma) = E(\pi) - E(\sigma)$) for all studied polar monomers bound to the transition-metal-based fragments are collected in Fig. 2 and Table 1. Since the positive or negative value of $\Delta E(\pi\text{–}\sigma)$ corresponds to the preference for σ-

Fig. 2. The preference of the co-monomer binding mode for all the studied systems, measured by the energy difference between the π- and σ-complexes, $\Delta E(\pi-\sigma)$.

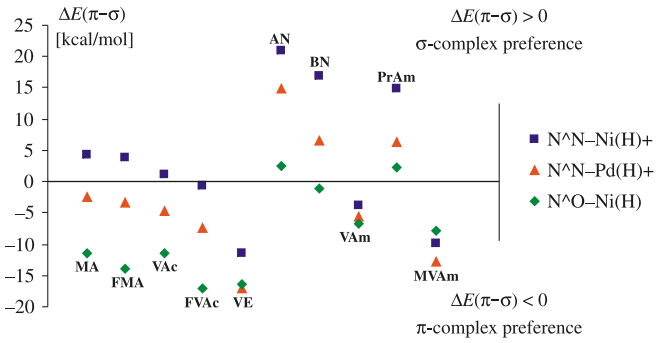

Table 1. The differences in the energies of the π- and σ-complexes, ($\Delta E(\pi-\sigma) = E(\pi) - E(\sigma)$).

	$\Delta E(\pi$-$\sigma)$ [kcal/mol]		
	N^N–Ni(H)+	N^N–Pd(H)+	N^O–Ni(H)
MA	4.20	–2.55	–11.43
FMA	3.81	–3.31	–14.01
VAc	1.14	–4.67	–11.37
FVAc	–0.73	–7.29	–17.07
VE	–11.50	–17.04	–16.46
AN	21.03	14.79	2.40
BN	17.00	6.66	–1.19
VAm	–3.87	–5.62	–6.82
PrAm	14.82	6.22	2.19
MVAm	–9.84	–12.74	–7.81

complex or π-complex preference, respectively, a lower (more negative) $\Delta E(\pi-\sigma)$ value describes a higher preference of the π-binding mode. Thus, Fig. 2 illustrates which binding mode is preferred for each monomer in the complexes with different model catalysts, and allows us to discuss how this preference varies with the change of the transition-metal-based fragment.

It is clearly seen from Fig. 2 that the polar monomers can be divided into three groups: (1) the monomers with a noticeable preference for σ-complex for all model catalysts (AN and PrAm), (2) the monomers for which the π-complex is preferred (FVAc, VE, VAm, and MVAm), and (3) the monomers with variable preference of the binding mode, depending on transition-metal fragment (MA, FMA, VAc, BN).

Furthermore, comparing the metal-containing fragments, the highest $\Delta E(\pi-\sigma)$ values were generally obtained for the cationic Ni–diimine systems, followed by the cationic Pd–diimine complexes and the neutral Ni–anilinotropone systems. There are, however, two exceptions, VE and MVAm, for which the $\Delta E(\pi-\sigma)$ values change in the order N^N–Ni(H)+ > N^O–Ni(H) > N^N–Pd(H)+ and N^O–Ni(H) > N^N–Ni(H)+ > N^N–Pd(H)+, respectively.

The increase in the π-binding mode preference when Pd replaces Ni in the cationic diimine model catalyst is in agreement with the previous DFT calculations for related systems; the qualitatively similar trend was observed by Ziegler and Michalak for O-monomers and by Ziegler and Deubel for N-monomers.[15e,16a] The differences between $\Delta E(\pi-\sigma)$ values obtained here and in refs. 15e and 16a result from differences in the structure of model complexes. Specifically, in the present work hydride complexes were studied, whereas in refs. 15e and 16a the results for propyl and ethyl complexes were presented.

A decrease in the $\Delta E(\pi-\sigma)$ values in the order N^N–Ni(H)+ > N^N–Pd(H)+ > N^O–Ni(H) reflects a decrease in the positive charge on the metal in these complexes. It has been shown previously[15e] that for MA complexes with Ni– and Pd–diimine systems the electrostatic component is the major factor determining the preference of the binding mode. However, the results of Fig. 2 and Table 1 indicate that for different monomers the shift in the $\Delta E(\pi-\sigma)$ values is not constant when going from Ni–diimine to Pd–diimine, and in particular to Ni–anilinotropone complexes. This suggests that for some polar monomers a difference in the orbital-interaction components for σ- and π-complexes may also change with a change of the catalyst.

Monomers ranked according to their $\Delta E(\pi-\sigma)$ value are in the order: AN > BN > PrAm > MA > FMA > VAc > FVAc > VAm > MVAm > VE in the cationic Ni–diimine complex; this order is preserved for the Pd–diimine complex, with one minor exception (VAm > FVAc). In the neutral complexes the sequence is slightly different: AN > PrAm > BN > VAm > MVAm > VAc > MA > FMA > VE > FVAc, with all the N-monomers exhibiting higher $\Delta E(\pi-\sigma)$ values than the O-monomers.

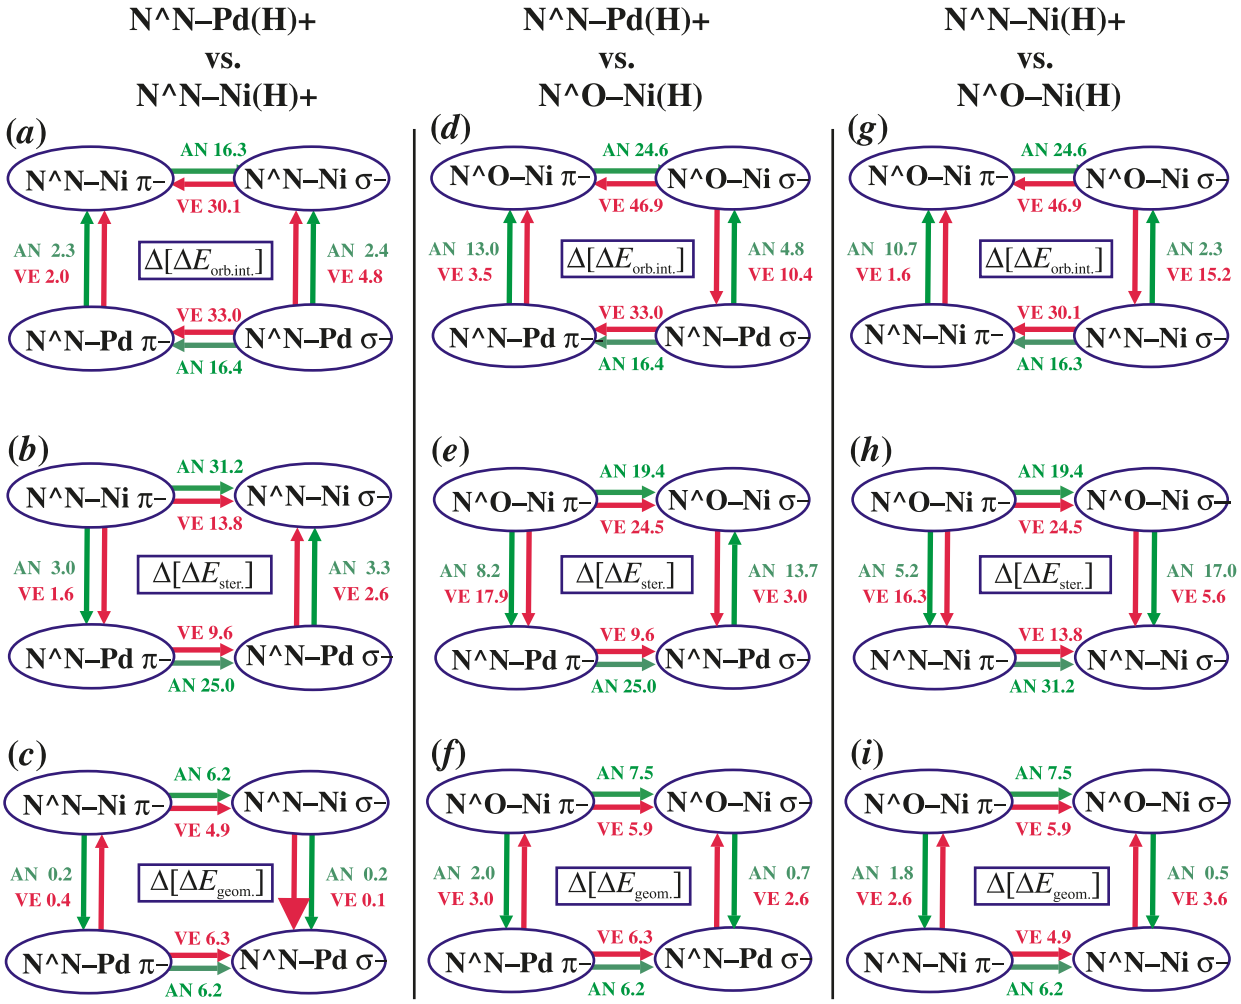
Ziegler–Rauk bond-energy decomposition analysis for the σ- and π-complexes

Let us now examine the origin of the difference between these transition-metal-based fragments in terms of the Ziegler–Rauk bond-energy decomposition analysis.

To facilitate the discussion, in Fig. 3 we schematically present the differences in the contributions to the bond-energies between Pd– and Ni-based complexes and the two binding modes (π- and σ-) for AN and VE monomers used as examples. The left-hand side of the figure (panels *a*–*c*) shows the results for both diimine systems (N^N–Pd(H)+ and N^N–Ni(H)+), while the middle part (panels *d*–*f*) refers to the comparison between the Pd–diimine and Ni–anilinotropone catalysts (N^N–Pd(H)+ and N^O–Ni(H)). For completeness, the results for N^N–Ni(H)+ and N^O–Ni(H) are compared in the right-hand side of the figure. The same kind of diagram was used in ref. 15e to analyze the differences between the σ- and π-complexes of MA and VAc with the Ni– and Pd-diimine catalyst. In these diagrams, the differences between the two binding modes (for the same catalyst) are shown horizontally, whereas the differences between the two catalysts (for the same binding mode) are shown vertically.The arrows point to the preferred complex of the respective pair and the numbers correspond to the differences in the orbital-interaction (panels *a*, *d*, and *g*), steric (panels *b*, *e*, and *h*), and geometry distortion contributions (panels *c*, *f*, and *i*), $\Delta[\Delta E_{\text{orb.int.}}]$, $\Delta[\Delta E_{\text{ster.}}]$ and $\Delta[\Delta E_{\text{geom.}}]$, respectively.

We will start the discussion from the comparison between the two binding modes for AN and VE in the Ni- and Pd-based diimine model catalysts. It was demonstrated previously by Ziegler and Michalak for MA and VAc[15e] that the difference between these two catalysts has a mainly steric (electrostatic and Pauli repulsion) origin.

Fig. 3. Schematic representation of the differences ($\Delta[\Delta E]$ in kcal/mol) in the contributions to the bonding energies between the σ- and π-complexes of AN and VE monomers with the Ni- and Pd-based Brookhart catalysts (left), the Ni-based anilinotropone and Pd-based Brookhart catalysts (middle), and the Ni-based anilinotropone and Ni-based Brookhart catalysts (right). Respective panels display the differences in the orbital-interaction, $\Delta[\Delta E_{orb.int.}]$, (*a*, *d*, and *g*), steric, $\Delta[\Delta E_{ster.}]$, (*b*, *e*, and *h*), and geometry distortion contributions, $\Delta[\Delta E_{geom.}]$, (*c*, *f*, and *i*). The arrows point to the preferred complex of the considered pair.



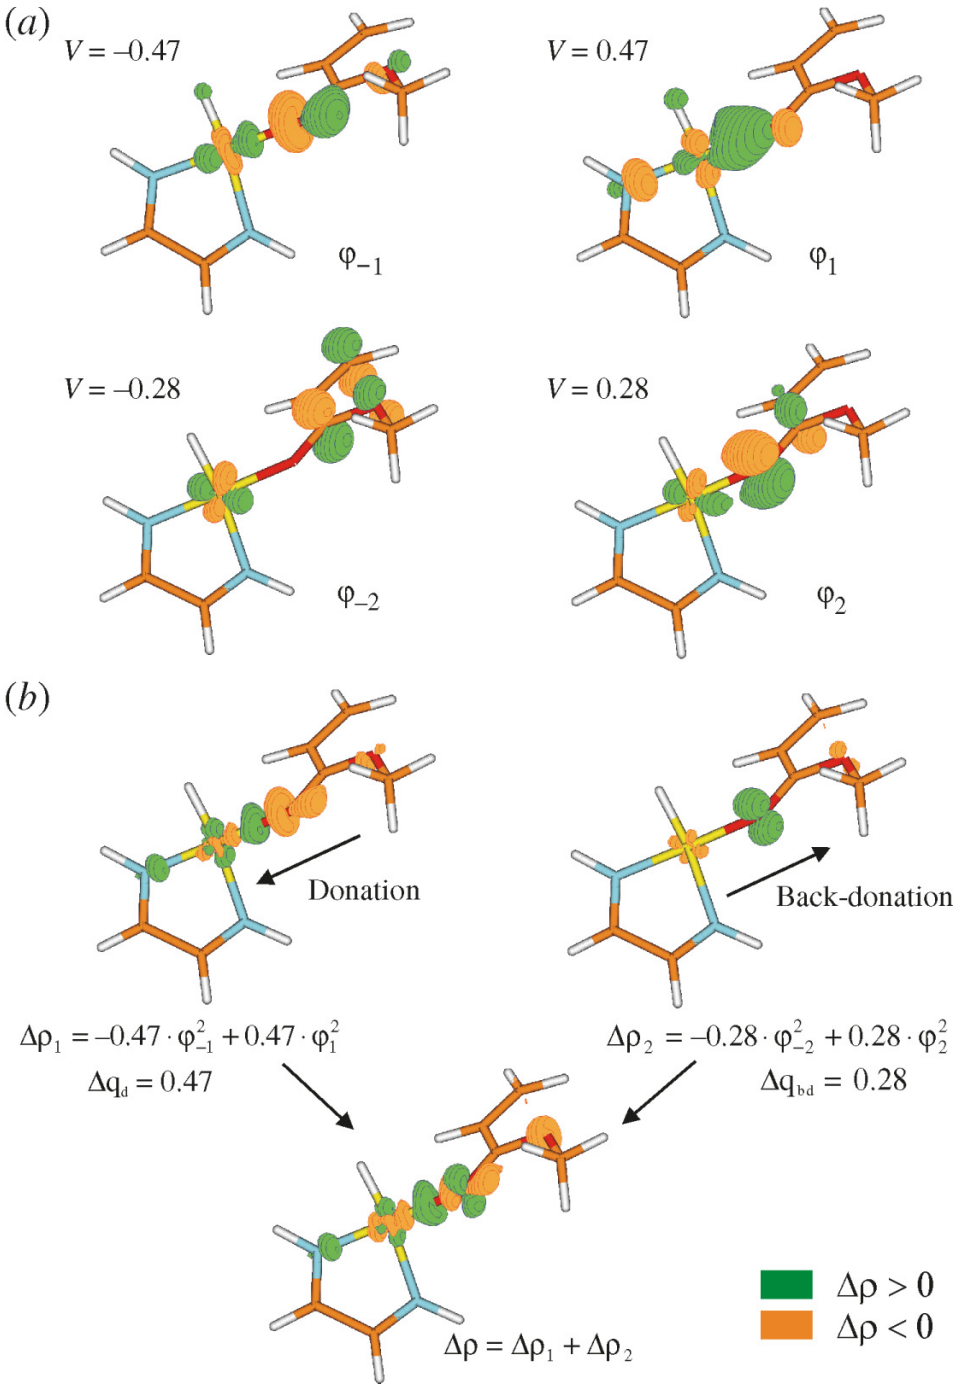
Our results for AN lead to a similar conclusion. As far as the comparison between the two coordination modes is concerned (a "horizontal" comparison), there is practically no difference in the orbital-interaction contribution to the bonding energy (16.3 vs. 16.4 kcal/mol), nor in the geometry distortion term (6.2 kcal/mol for both catalysts). The steric term, on the other hand, shows a substantial difference (31.2 vs. 25.0 kcal/mol). A "vertical" comparison (Ni– and Pd– π-complexes vs. σ-complexes) leads to a similar conclusion: there is practically no difference in the orbital-interaction (2.3 vs. 2.4 kcal/mol) and the geometry distortion components (0.2 kcal/mol for both systems), whereas the steric terms are qualitatively different: the steric destabilization of the π-complex is lower for Pd by 3.0 kcal/mol, wherease for the σ-complex it is higher by 3.3 kcal/mol.

However, for VE the difference in the orbital-interaction term becomes noticeable in both the "horizontal" (30.1 vs. 33.0 kcal/mol) and "vertical" (2.0 vs. 4.8 kcal/mol) cases. The corresponding differences for the steric component are of comparable magnitude. Thus, it may be concluded that in the case of VE, the difference between the Ni– and Pd–diimine catalysts is not completely determined by the steric term; the orbital-interaction component is as well important.

Similar analysis performed for all the monomers shows that for MA, FMA, VAc, AN, VAm, and MVAm the differences in the orbital-interaction terms are insignificant compared to those in steric terms, as far as the comparison between Ni– and Pd-catalysts is concerned. For VE, FVAc, BN, and PrAm, however, the difference in the Ni- and Pd-complexes has both a steric and electronic (orbital-interaction) origin.

Comparing the cationic Pd–diimine catalyst with the neutral Ni–anilinotropone catalyst (Figs. 3*d*–3*f*), the "horizontal" differences in the orbital-interaction term are non-negligible for both monomers (24.6 vs. 16.4 kcal/mol for AN, and 46.9 vs. 33.0 kcal/mol for VE), and qualitatively comparable with the differences in the corresponding steric components (19.4 vs. 25.0 kcal/mol for AN, and 24.5 vs. 9.6 kcal/mol for VE). A "vertical" comparison of the bond-energy components leads to the same conclusions. A similar picture can be drawn for the other monomers.

Fig. 4. Contours of the NOCV (panel *a*) and corresponding contributions to the deformation density, $\Delta\rho$, (panel *b*) characterizing the bond formed between the Ni–diimine complex, N^N–Ni(H)+, and MA in the σ-complex. The contour values are 0.1 au for orbitals and 0.01 au for the $\Delta\rho$ contributions.



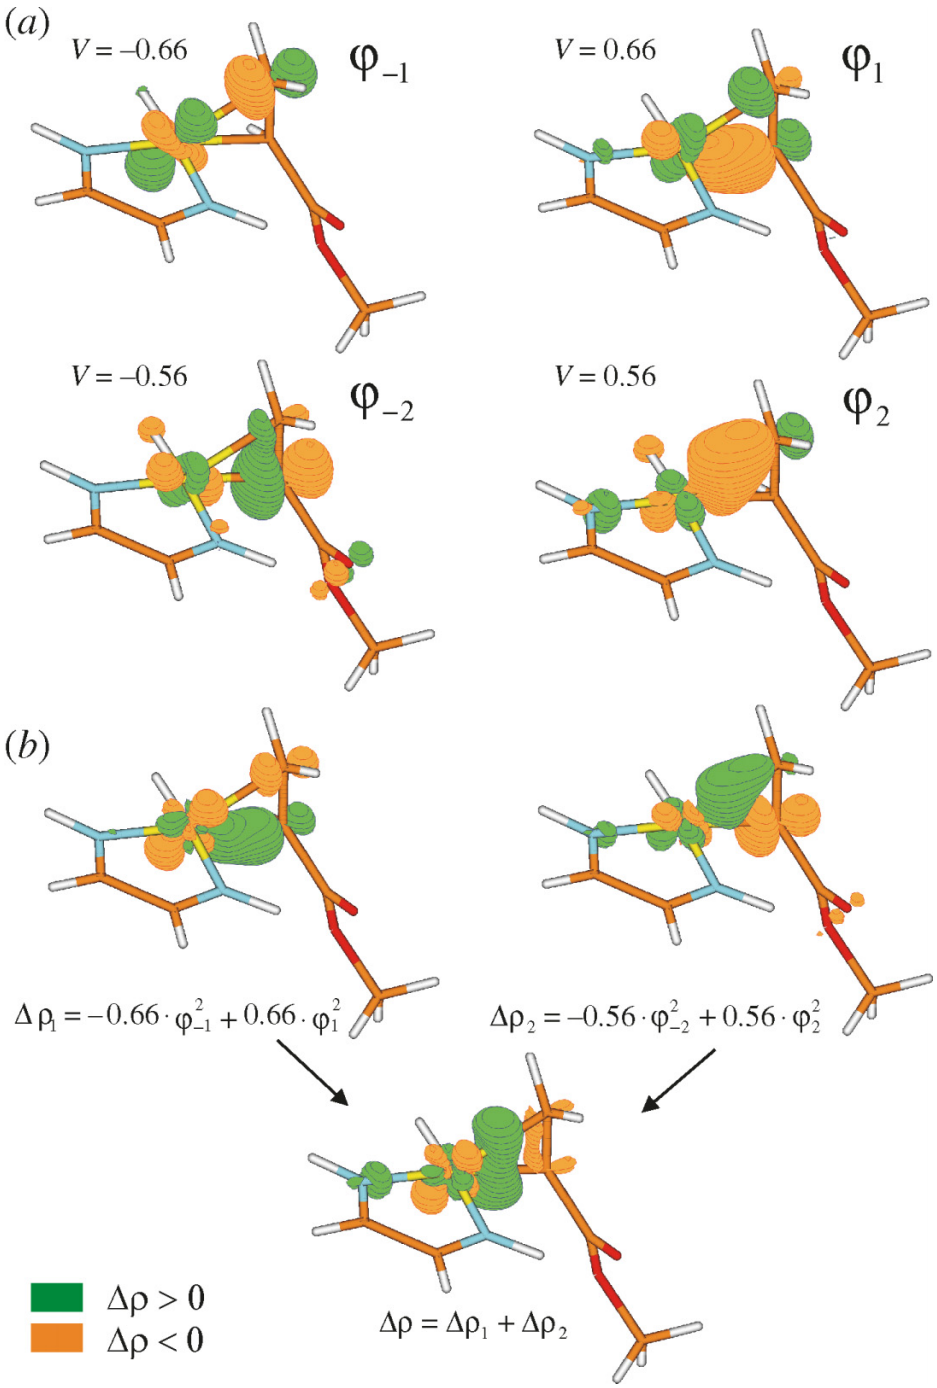
NOCV description of bonding in the σ-complexes and π-complexes

As an example of the NOCV-representation of bonding in the σ-complexes, in Fig. 4 the NOCV are presented that describe the bond between methyl acrylate and the Ni–diimine catalyst, N^N–Ni(H)+.

There are two pairs of NOCV localized in the bond region. The first pair, corresponding to $|v_1|$=0.47, represent a bonding and anti-bonding orbital of σ-character. The second pair, corresponding to $|v_2|$=0.28, represent a bonding and anti-bonding orbital of π-character.

In Fig. 4*b*, the corresponding contributions to the deformation density $\Delta\rho$ are shown. The first pair of NOCV describes a channel for the ligand → metal electron transfer (donation). The second pair represents the metal → ligand π-back-bonding. Thus, NOCV allow one to separate the donation and back-donation channels and the corresponding NOCV-eigenvalues that provide measures of the donation–

Fig. 5. Contours of the NOCV (panel *a*) and corresponding contributions to the deformation density, $\Delta\rho$, (panel *b*) characterizing the bond formed between the Ni–diimine complex, N^N–Ni(H)+, and MA in the π-complex. The contour values are 0.1 au for orbitals and 0.01 au for the $\Delta\rho$ contributions.



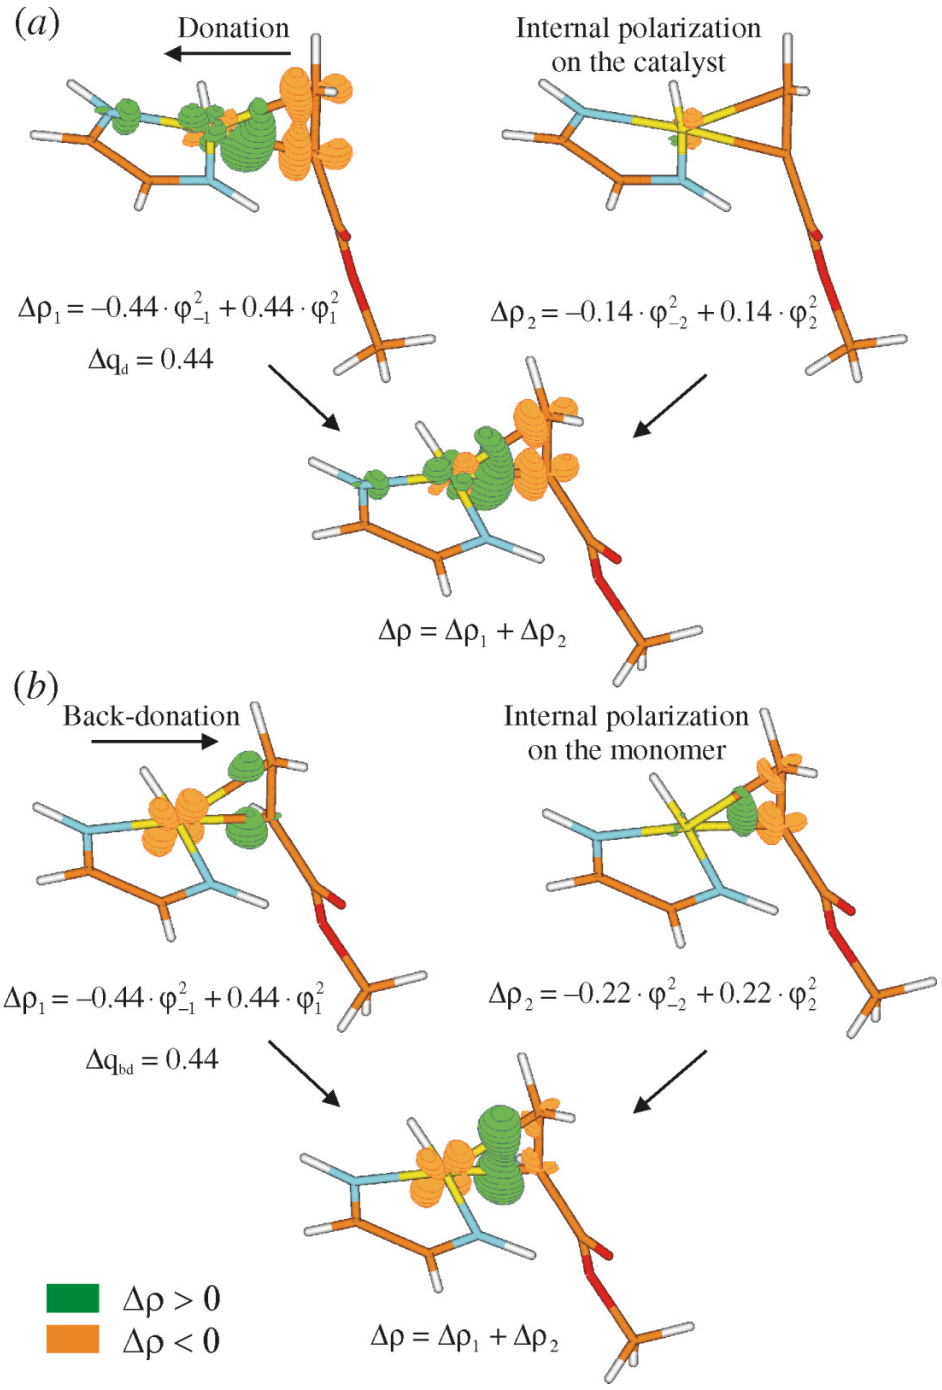
back-bonding charge flows ($\Delta q_d = \nu_1 = 0.47$ and $\Delta q_d = \nu_2 = 0.28$) can be used to characterize the donor–acceptor properties of different monomers.

It is worth mentioning that for the σ-complex, the charge transfer due to π-back-bonding is undoubtedly non-negligible. The NOCV analysis performed for the complexes with different monomers shows similar features. A detailed comparison of the donor–acceptor properties of considered polar monomers will be presented in the next section.

Let us now characterize the bond between the monomer and the metal fragment in the π-complexes in terms of NOCV. As an example, the Ni–diimine complex with methyl acrylate is shown in Fig. 5. The NOCV for this system together with the corresponding contribution to the deformation density are presented in Figs. 5*a* and 5*b*, respectively.

As we mentioned earlier, in this case there is no clear separation between the donation–back-bonding channels. Each of the two pairs describes a localized covalent bond

Fig. 6. Contributions to the deformation density, $\Delta\rho$, for the bond formed between the Ni–diimine complex, N^N–Ni(H)+, and MA in the π-complex obtained using CSOV-like technique combined with the NOCV analysis by the elimination of the virtual orbitals on the monomer (panel *a*) and the virtual orbitals on the metal fragment (panel *b*) from the basis. The contour value is 0.01 au.

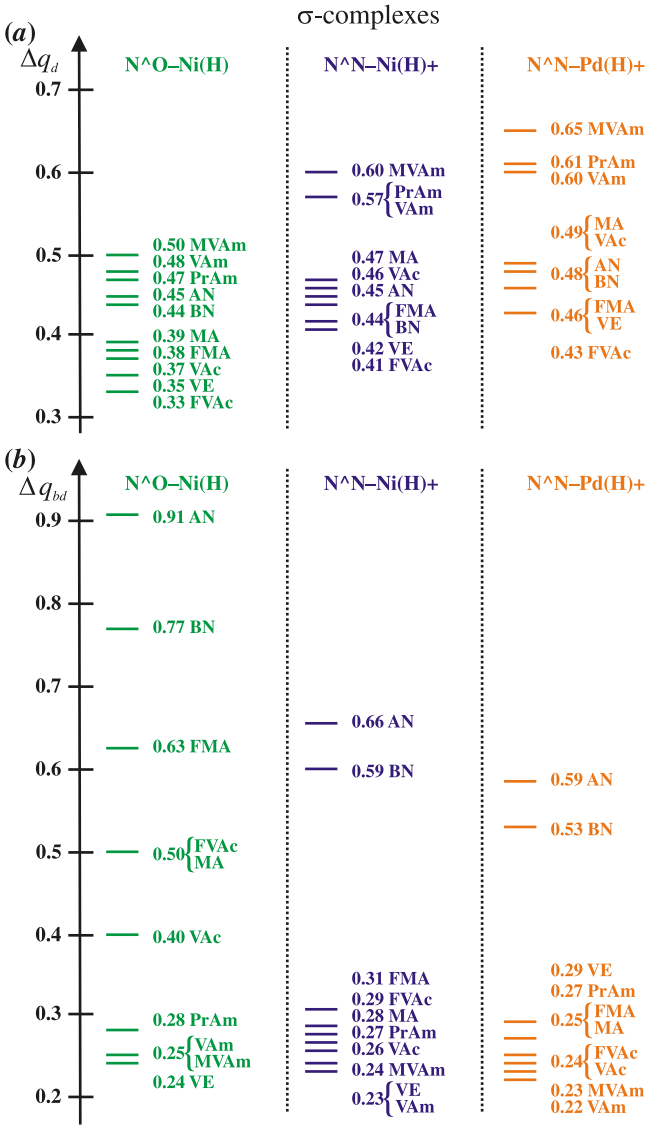


between one carbon atom of MA and the metal (positive $\Delta\rho$), with a negative $\Delta\rho$ contribution in the vicinity of the other carbon atom. Thus, NOCV-eigenvalues cannot be directly used as measures of the donation–back-bonding charge flows.

Thus, to characterize the donor–acceptor properties of different monomers in the π-complexes, one has to use an additional constraint or approximation. In the present study, we have applied the CSOV-like[20] technique combined with the NOCV approach. Specifically, the NOCV analysis was repeated, based on the results of the DFT calculations in which (1) the virtual orbitals on the monomer were removed from the basis, to characterize the ligand → metal donation, and (2) the virtual orbitals on the metal fragment were removed from the basis, to describe independently the metal → ligand back-bonding.

The NOCV-contributions to the bond between the monomer and the metal fragment obtained for N^N–Ni(H)$^+$–MA

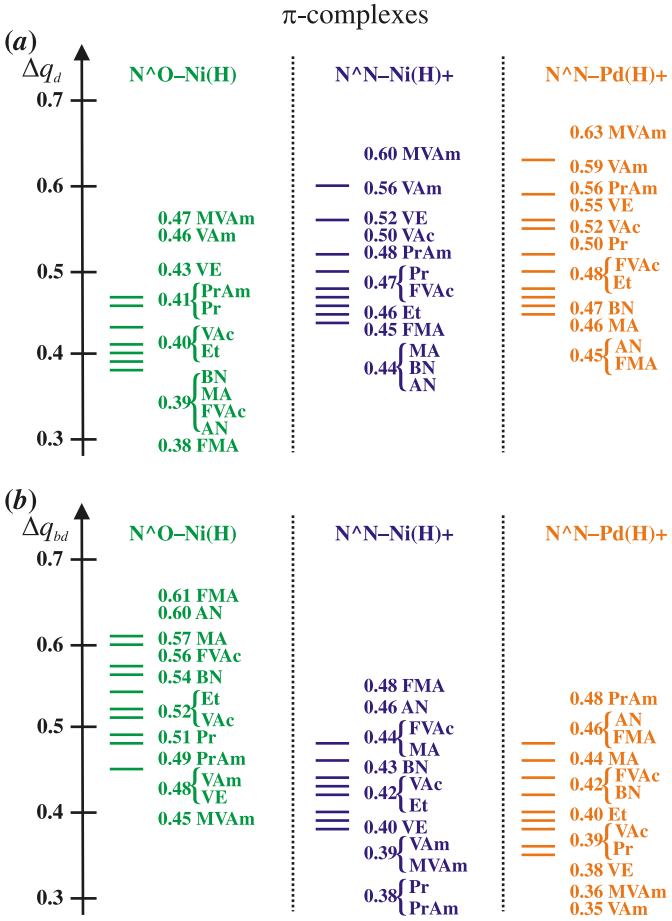
Fig. 7. σ-Donor (panel *a*) and π-acceptor (panel *b*) properties of polar monomers in the σ-complexes with N^O–Ni(H), N^N–Ni(H)+, and N^N–Pd(H)+ measured by the NOCV eigenvalues, Δq_d and Δq_{bd}, respectively.



π-complex are presented in Fig. 6*a* and 6*b*, respectively. It is clearly seen that the donation (Fig. 6*a*) and the back-bonding (Fig. 6*b*) are characterized by similar Δq_d and Δq_{bd} values (0.44).

In addition to pure donation–back-bonding channels, the NOCV pairs describing internal polarization of the catalyst and the monomer are present, when the CSOV-like technique is applied. The eigenvalues corresponding to these polarization channels are relatively large. However, they are comparable for all the monomers. Thus, a comparison of the donor–acceptor properties of different monomers based on the NOCV donation and back-donation channels obtained within a CSOV-like approach is justified. In the next section a comparison of the donor–acceptor properties of monomers in the π-complexes based on the similar NOCV analysis will be presented.

Fig. 8. σ-Donor (panel *a*) and π-acceptor (panel *b*) properties of polar monomers in N^O–Ni(H), N^N–Ni(H)+, and N^N–Pd(H)+ based π-complexes, measured by the NOCV eigenvalues, Δq_d and Δq_{bd}, respectively.



Comparison of the donor–acceptor properties of monomers in the σ-complexes

Figure 7 collects Δq_d and Δq_{bd} values calculated for all the σ-complexes studied in the present work, i.e., for all polar monomers and all transition-metal-based fragments. We will start the discussion with the σ-donor properties of the monomers, measured by the Δq_d value, i.e., the eigenvalue for NOCV describing the donation process (Fig. 7*a*). Let us first look at the Δq_d values calculated for N^N–Ni(H)+ based complexes (the middle part of the figure). The highest values of Δq_d were obtained for amine monomers: MVAm (0.60), and PrAm and VAm (0.57). Other N-monomers, as well as all O-monomers are characterized by relatively close values of Δq_d, lower in comparison with amines, ranging from 0.47 to 0.41, with the highest values obtained for MA, VAc, and AN (0.47, 0.46, and 0.45), intermediate for FMA and BN (0.44), and the lowest for VE and FVAc (0.42 and 0.41). Thus, MA and VAc monomers reveal slightly better σ-donor properties (higher Δq_d values by 0.03 and 0.05, respectively) compared to their fluorinated analogues, FMA and FVAc.

The right-hand side of Fig. 7*a* shows the Δq_d values calculated for σ-complexes with the Pd–diimine system,

Table 2. Comparison of the results calculated for the model and real catalysts (see Fig. 9).

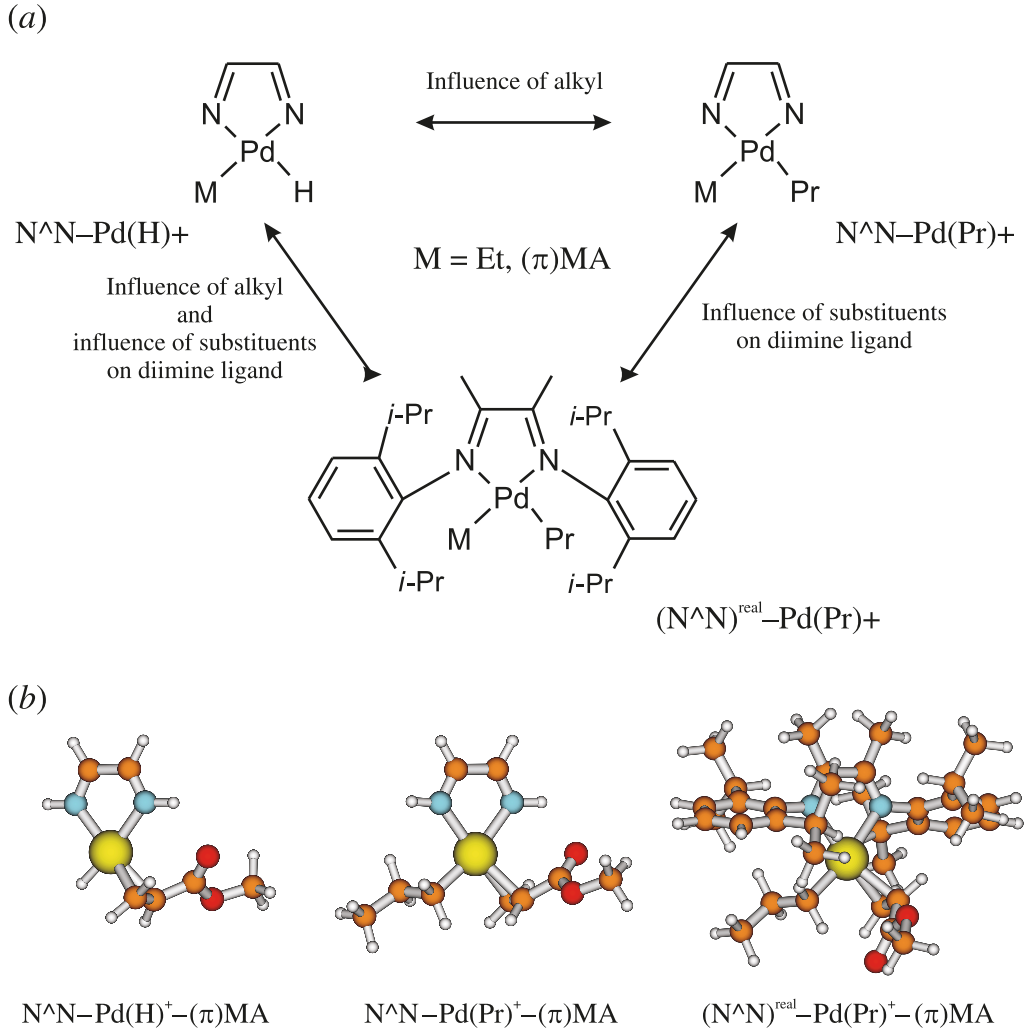
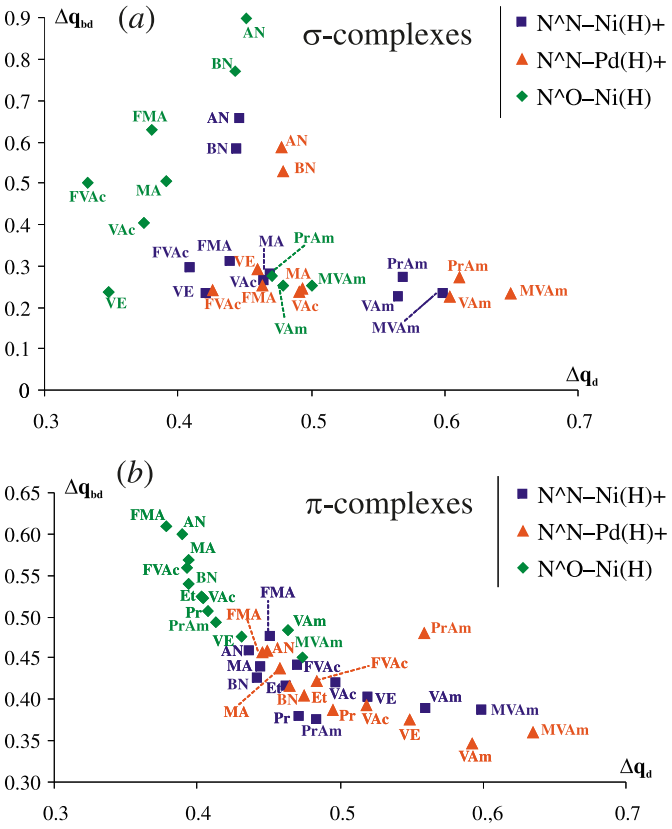
Fig. 9. The model and real systems compared in Table 2.



N^N–Pd(H)+. As can be seen from the figure, changing the metal in the Brookhart catalysts introduces only small changes in the Δq_d values: they are all slightly increased (by 0.02–0.05) in the N^N–Pd(H)+ based system compared to the Ni–diimine catalyst. Furthermore, the monomer sequence does not change compared to the Ni-catalyst; only the positions of monomers characterized by close σ-donation eigenvalues are exchanged.

Let us now discuss the σ-donor properties of the monomers bound in N^O–Ni(H) based σ-complexes (the left-hand side of Fig. 7*a*). In this case the eigenvalues are visibly decreased compared to N^N–Ni(H)+ complexes (by 0.06–

Fig. 10. Two-dimensional maps of donor–acceptor properties for monomers binding in transition-metal-based σ-complexes (panel *a*) and π-complexes (panel *b*).



0.10); the only exceptions are AN and BN, for which the Δq_d values remain unchanged. Furthermore, in this case there is a clear distinction between the N-monomers and O-monomers, with the former revealing higher values of Δq_d (0.50–0.44) than the latter (0.39–0.33).

In conclusion, the sequence of monomers ordered according to their σ-donor properties is hardly dependent on the transition-metal-based fragment, starting with the amine monomers as the strongest σ-donors, and ending with VE and FVAc as the weakest σ-donors. Only monomers characterized by close the Δq_d values can exchange their position. Furthermore, MA and VAc reveal slightly higher values of Δq_d in comparison with the corresponding fluorinated systems, FMA and FVAc. It is also clearly seen that the Δq_d values are shifted upwards in the sequence: N^O–Ni(H) < N^N–Ni(H)+ < N^N–Pd(H)+ with more significant increase in the first step, i.e., from the neutral Ni–anilinotropone to the cationic Ni–diimine system.

We will now focus on the π-acceptor properties of the polar monomers bound in the same group of σ-complexes. Figure 7*b* presents the Δq_{bd} values corresponding to the NOCV eigenvalues describing the back-donation electron transfer.

Again, we will start the discussion with the N^N–Ni(H)+ case, for which the results are shown in the middle part of Fig. 7*b*. Clearly, the best π-acceptor properties (the highest values of Δq_{bd}) are demonstrated by both nitrile monomers, i.e., AN and BN (0.66 and 0.59). All other polar monomers studied in the present work are characterized by relatively close Δq_{bd} eigenvalues, ranging from 0.31 to 0.23, significantly lower than AN and BN: FMA (0.31) > FVAc (0.29) > MA (0.28) > PrAm (0.27) > VAc (0.26) > MVAm (0.24) > VE ≈ VAm (0.23). Further, it is seen that the MA and VAc monomers show slightly lower π-acceptor eigenvalues than their fluorinated analogues, FMA and FVAc. It is also worth emphasizing that amine monomers, which are characterized by the highest Δq_d values, reveal the lowest Δq_{bd} values.

For the Pd–diimine system the results are very similar to its Ni-analogue, with a small decrease in all the values for the Pd complexes. In the case of the neutral Ni–anilinotropone catalyst, the Δq_{bd} values are higher than for the cationic systems. Nevertheless, the order of monomers remains unchanged; as noted previously, only the monomers characterized by very close values exchange their positions.

To conclude, the results of the NOCV analysis indicate that the nitrile monomers in the σ-binding mode can be classified as the strongest, whereas the amine systems together with VE are the weakest π-acceptors. Further, the absolute values of Δq_{bd} are shifted down in the sequence: N^O–Ni(H) > N^N–Ni(H)+ > N^N–Pd(H)+.

Comparing the monomer donor–acceptor ranking, one can notice that amine monomers are characterized by the highest Δq_d values, and simultaneously the lowest Δq_{bd} values (the strongest σ-donors and the weakest π-acceptors). However, stronger σ-donor ability is not always accompanied by weaker π-acceptor properties. VE can be used here as an example, since it is weakest in both the σ-donor and π-acceptor ability.

Comparison of the donor–acceptor properties of monomers in the π-complexes

The Δq_d and Δq_{bd} values, determined for all the π-complexes, are collected in Fig. 8. Let us first discuss the σ-donor properties of monomers in the π-coordination mode (Fig. 8*a*), starting with Ni–diimine system. The Δq_d values calculated for N^N–Ni(H)+ based π-complexes are shown in the middle part of Fig. 8*a*. Similarly to the corresponding σ-complexes, the best σ-donor abilities are demonstrated by the vinyl amine monomers, MVAm and VAm (Δq_d = 0.60 and 0.56, respectively). Other monomers reveal relatively close values of Δq_d, varying from 0.52 to 0.44. Among them, the highest Δq_d values were obtained for VE, VAc, and PrAm (0.52, 0.50, and 0.48), intermediate for Pr, FVAc (0.47), and Et (0.46), and the lowest for FMA and MA (0.45 and 0.44) and both nitrile monomers, BN and AN (0.44). Furthermore, comparing the σ-donor abilities of simple olefins and the polar monomers, it can be noticed that Et and Pr are located in the middle of the range, revealing the intermediate values of Δq_d.

Let us now consider the σ-donor properties of monomers bound to the metal center in the Pd–diimine system. The results presented in the right-hand side of Fig. 8*a* show close similarity to those characterizing the Ni-based system. Finally, for monomers binding in N^O–Ni(H) based π-complexes presented in the left-hand side of Fig. 8*a*, the Δq_d values are noticeably decreased in comparison with N^N–Ni(H)+ (by 0.05–0.13). However, as noted previously, the monomer sequence remains almost unchanged. Again, only

the positions of monomers characterized by close σ-donation eigenvalues are exchanged.

We will now analyze the π-acceptor properties of monomers binding in the π-complexes. The quantitative measures of metal → monomer π-back-donation processes, Δq_{bd} values are collected in Fig. 8*b*. We will start the discussion with the results obtained for N^N–Ni(H)+ systems (the middle part of the figure). In this case, all monomers are characterized by close values of Δq_{bd}, ranging from 0.48 to 0.38. The highest Δq_{bd} values were obtained for FMA and AN (0.48 and 0.46), intermediate for FVAc and MA (0.44) and BN (0.43) together with VAc and Et (0.42), and the lowest for VE (0.40), both vinyl amine monomers, VAm and MVAm (0.39), and Pr and PrAm (0.38). It should be also pointed out that the results obtained for these systems correspond very well with a common intuitive way of thinking of the ligand properties (the stronger σ-donor, the weaker π-acceptor).

Comparing the π-acceptor properties of monomers binding in the Ni- and Pd-based Brookhart catalysts (the middle and the right-hand side of Fig. 8*b*), it is clearly seen that the replacement of Ni with Pd does not introduce any significant differences in the values of Δq_{bd}, nor in the sequence of monomers. Specifically, all monomers in the π-complexes with the Pd–diimine catalyst are characterized by relatively close values of Δq_{bd}, varying from 0.48 to 0.38. As far as the π-acceptor eigenvalues determined for the complexes with the neutral anilinotropone catalyst are concerned (the left-hand side of Fig. 8*b*), a visible shift upwards in the absolute values of Δq_{bd} is observed. Again, the sequence of monomers remains almost the same.

Thus, AN, MA, and both fluorinated monomers, FMA and FVAc, can be classified as the strongest, and the amine monomers as the weakest π-acceptors. The analysis of both Δq_d and Δq_{bd} values indicates that in the case of the π-complexes, the σ-donor and π-acceptor abilities of the monomers are strongly coupled, i.e., the monomers which are characterized by the highest Δq_d values, reveal the lowest Δq_{bd} values, and vice versa.

In the present study, we analyzed the complexes of different monomers with *model* catalysts in which the bulky substituents were replaced by hydrogen atoms. Further, the olefin–hydride complexes were used, while in the catalytic cycle, the alkyl complexes are present. Use of the model systems is justified by the fact that we focus on the donor–acceptor properties, determined mainly by the orbital–interaction terms. Thus, it can be expected that they are independent from the steric terms, mostly affected by the bulky substituents. However, some *indirect* steric influence on the orbital-interaction exists, since the steric bulk alters the coordination geometry, especially the monomer–metal distance.

Therefore, it is important to compare the results obtained for the model systems and for the real catalysts. Such a comparison is presented in Table 2 for the ethylene and methyl acrylate complexes with Pd-based catalysts shown in Fig. 9. Here, we compared the model olefin–hydride and olefin–propyl complexes, N^N–Pd(H)+ and N^N–Pd(Pr)+, as well as the olefin–propyl complexes with the real catalyst, $(N^N)^{real}$–Pd(Pr)+.

The results presented in Table 2 confirm that use of the model systems is indeed justified as far as the donor–acceptor properties are concerned. Even for the monomers such as Et and MA, which are characterized by relatively close donation and back-bonding NOCV descriptors, their order is preserved. The absolute NOCV eigenvalues change by 0.01–0.04 in the model and real systems. However, the difference in the σ- and π-bonding energies is visibly affected (by ~ ±0.5 kcal/mol relative to the real catalyst), as shown in the previous studies.[15,16]

To conclude the results of the NOCV analysis performed for all monomers in both σ- and π-coordination mode, the values of Δq_d and Δq_{bd} are presented in the form of a two-dimensional map, separately for σ-complexes (Fig. 10*a*) and π-complexes (Fig. 10*b*). In both cases the absolute Δq_d value (the σ-donor property) increases and the Δq_{bd} value (π-acceptor property) decreases, in the sequence of the transition-metal-based fragments: N^O–Ni(H) → N^N–Ni(H)+ → N^N–Pd(H)+. These differences are more pronounced in the neutral and the cationic systems than the Ni– and Pd–diimine complexes.

Concluding remarks

In this article, we analyzed the binding mode of a series of polar monomers in complexes with late-transition-metal catalysts for ethylene polymerization. The σ- and π-complexes with the model, cationic Ni– and Pd–diimine catalysts, N^N–Ni(H)+ and N^N–Pd(H)+, and the neutral Ni–anilinotropone system, N^O–Ni(H), were investigated. The Ziegler–Rauk energy decomposition scheme was used to characterize the geometry distortion, and steric and orbital-interaction terms in the bonding energy, while NOCV were applied to quantitatively describe donation and back-bonding components of the bond between the monomer and the catalyst. Further, NOCV analysis allowed for comparison of the donor–acceptor properties of different monomers in the σ- and π-complexes.

In agreement with earlier theoretical studies,[15,16] the results demonstrate that the metal-based fragment has a significant influence on the relative stability of the σ- and π-complexes. Generally, the preference of the π-binding mode increases in the following order: N^N–Ni(H)+ < N^N–Pd(H)+ < N^O–Ni(H). Thus, for the neutral catalyst, the preference of the π-coordination is enhanced. The results of the Ziegler–Rauk bond-energy decomposition indicate that for some monomers (MA, FMA, VAc, AN, VAm, and MVAm) the preference of the coordination mode has a steric (electrostatic and Pauli) origin, as found previously for methyl acrylate.[15e] However, for other monomers (VE, FVAc, BN, and PrAm) the changes in the orbital-interaction terms are important as well.

The results of the NOCV analysis indicate that for both σ- and π-coordination modes there exist components describing σ-donation and π-back-bonding. Furthermore, the sequences of σ-donor and π-acceptor properties of monomers in the π-complexes as well as σ-complexes are nearly the same for all model catalysts studied. The absolute values of Δq_d are shifted upwards and the absolute values of Δq_{bd} are shifted downwards in the sequence of metal-based fragments: N^O–Ni(H) < N^N–Ni(H)+ < N^N–Pd(H)+ with a more pronounced effect observed for N^O–Ni(H). However, the

change of the metal center in the diimine systems has a relatively small effect on the donor–acceptor ability of the coordinated monomer.

In the case of the π-complexes, the strong "coupling" between σ-donor and π-acceptor properties of monomers can be observed. In a series of the monomers studied, the better the monomer's σ-donor ability is (the higher Δq_d), the worse its σ-acceptor character becomes (the lower Δq_{bd}). However, for the σ-coordination mode, such a relationship between donor and acceptor properties is not a rule. This is in agreement with our previous NOCV analysis for other transition metal complexes.[23b]

An investigation of $(C_5H_5)Fe(C_5H_4–C(OBF_3)–CH_3)$[1,2]

Francis O. Ogini, Philip J. W. Elder, James F. Britten, and Ignacio Vargas-Baca

Abstract: Acetylferrocene readily forms an adduct with BF_3. The product is a neutral model for protonated acetylferrocene, a species that is a crucial intermediate in the formation of 1,3,5-trisferrocenyl-benzene and other conjugated heterometallic derivatives by cyclocondensation. The title compound's structure was determined in the solid state by X-ray diffraction and its spectroscopic properties were examined in detail, particularly the electronic excitation spectrum, which confirms the previous identification of the in situ generated protonated ketone.

Key words: organometallic ketones, BF_3 adducts, ferrocenyl cations, density functional theory (DFT) calculations.

Résumé : L'acétylferrocène forme facilement un adduit avec le BF_3. Le produit est un modèle neutre pour un acétylferrocène, une espèce qui est un intermédiaire crucial dans la formation du 1,3,5-trisferrocényl-benzène et d'autres dérivés hétérométalliques par cyclocondensation. La structure du composé mentionné dans le titre a été déterminée à l'état solide par diffraction des rayons X et on a examiné ses propriétés spectroscopiques en détail, en particulier son spectre d'excitation électronique qui confirme l'identification antérieure de la cétone protonée générée in situ.

Mots-clés : cétones organométalliques, adduits avec le BF_3, cations ferrocényles, calculs d'après la théorie de la fonctionnelle de la densité (TFD).

[Traduit par la Rédaction]

Introduction

Aldehydes and ketones are weak bases, with the typical pK_a values of their conjugated acids being below –6, e.g., –6.99 in the case of benzaldehyde and –6.04 for acetophenone.[3] A wide variety of organometallic functional groups can increase the basicity of a carbonyl group. This is attributed to a stabilizing effect on the positive charge of the protonated form. Examples of such groups include ferrocenyl (Fc = $(C_5H_5)Fe(C_5H_4)$), cymantrenyl (Cym = $(CO)_3Mn(C_5H_4)$),[4] (cyclobutadienyl)$Fe(CO)_3$,[5] (cyclobutadienyl)$Co(C_5H_5)$,[6] and (cyclobutadienyl)$Cr(CO)_2NO$.[7] Indeeed, the pK_a values of $[(CO)_3Mn(C_5H_4–C(OH)–CH_3)]^+$ and $[(C_5H_5)Fe(C_5H_4–C(OH)–CH_3)]^+$ (**1**) are –4.0 and –2.6, respectively.[8] Such protonated species are considered key intermediates in the acid-catalyzed oligomerization of the ketones,[9] which yields 3,1 disubstituted (*E*)-2-buten-1-ones (**2**) and 1,3,5-trisubstituted benzenes (**3**). The relative yields of the heterometallic condensation products from mixtures of acetylferrocene (**4**) and acetylcymantrene has been rationalized by considering the relative stabilities of those cations. Such a condensation process begins with a striking colour change, which was attributed to the formation of the cationic intermediates. That interpretation was supported by calculations of the electronic spectra of simplified models of the cations and the reactants. The shape of the calculated spectra and the relative position of the first excitation bands were in reasonable agreement with the experimental data. However, conclusive identification of the chromophores was precluded by the inherent reactivity of the transient intermediates.

In lieu of protons, Lewis acids can be used to induce the condensation reaction of ketones and aldehydes. Such activation is usually explained with two different effects: (*i*) enhancement of the acidity of the α-hydrogens of a ketone or an aldehyde, which promotes enolization[10] and (*ii*) enhancement of the electrophilicity of the carbonylic carbon.[11–13] The practical uses of this type of Lewis acid activation in organic chemistry have been reviewed.[13]

Lewis acid catalysts that are useful in this context include the trihalides of group-13 elements.[3,14–16] Thermochemical and theoretical studies of BF_3–Carbonyl adducts have shown that coordination of BF_3 transforms simple carbonyl compounds into gas-phase superacids and superelectrophiles with enhancements in acidity of up to 50 kcal/mol and hydride affinity of up to 66 kcal/mol.[10] On the other hand, α-deprotonation results in strengthening of the B–O bond, increasing the bond energy from 11 kcal/mol in the carbonyl adduct to 60 kcal/mol in the BF_3-enolate[10] Correspondingly, addition of H^- to the carbonyl carbon also increases the B–O bond energy to 78 kcal/mol.[10] Both the enolate and the alkoxide forms enable stabilization of negative charge by the fluorine atoms.

Here, we report the isolation of a stable adduct of **4** with BF_3, compound **5**, which is in effect a neutral analogue to the cation $[(C_5H_5)Fe(C_5H_4–C(OH)–CH_3)]^+$. The product was isolated in pure form, structurally characterized by single crystal X-ray crystallography and studied by electronic, vibrational, and NMR spectroscopy. These experimental observations were analyzed and interpreted in comparison to the results of computational modeling.

Experimental

Materials and methods

All manipulations of air- and moisture-sensitive materials were performed under an atmosphere of dry nitrogen in a glovebox or using standard Schlenk techniques. Pentane and methylene chloride were carefully dried over CaH_2. Acetylferrocene and $BF_3{\cdot}OEt_2$ were purchased from Sigma-Aldrich and used as received. $^1H/^{13}C$ and $^{11}B/^{19}F$ NMR spectra were acquired on Bruker AC 500 and AC 600 spectrometers, respectively. Chemical shifts for ^1H and ^{13}C are reported in ppm with respect to $Si(CH_3)_4$ and were determined using the resonances of the residual proton and the natural-abundance ^{13}C in $CDCl_3$ as internal standards. Chemical shifts for ^{11}B and ^{19}F spectra are reported with respect to $BF_3{\cdot}OEt_2$ and $CFCl_3$ (respectively) and were measured using an internal standard of $BF_3{\cdot}OEt_2$. Infrared spectra were recorded in pellets of anhydrous AgCl using a Bio-Rad FTS-40 spectrometer with a 4 cm^{-1} resolution. Ultraviolet–visible spectra were recorded on a Cary 300 ultraviolet/visible spectrophotometer. Raman spectra were recorded on a Bruker RFS 100/s at –78 °C. Melting points (uncorrected) of samples in sealed capillaries were measured on a Thomas Hoover melting-point apparatus.

Preparation of $[(C_5H_5)Fe(C_5H_4–C(O–BF_3)–CH_3)]$ (5)

Mixing of a diethyl ether solution of acetylferrocene (2 mmol in 2 mL) and $BF_3{\cdot}OEt_2$ (2 mmol) resulted in the immediate appearance of a purple coloration. The adduct was quantitatively recovered in pure form (by ^1H NMR) after evaporation of the solvent. Moisture-sensitive dark purple crystals of the adduct were grown by vapor diffusion of pentane into a chloroform solution at –30 °C over 2 d, mp 124–126 °C. UV–vis (10.8 mmol L^{-1} in CH_2Cl_2) λ_{max} (nm), [Abs]: 290 [1.76], 350 [0.38], 505 [0.25]. ^1H NMR (500 MHz, $CDCl_3$, T = –50 °C, ppm) δ: 5.33 (H8, ddd, $^3J_{H9–H8}$ = 2.8 Hz, $^3J_{H8-H7}$ = 2.7 Hz, $^4J_{H8–H6}$ = 1.2 Hz), 5.24 (H7, ddd, $^3J_{H7-H6}$ = 2.8 Hz, $^4J_{H7-H9}$ = 1.4 Hz), 5.18 (H9, ddd, $^4J_{H9–H6}$ = 1.3 Hz), 4.90 (H6, ddd). ^{13}C NMR (125 MHz, $CDCl_3$, T = 50 °C) δ: 209.89 (C11), 80.91 (C7, C8), 75.15 (C10), 74.20 (C9), 73.31 (C_5H_5), 70.78 (C6), 23.57 (CH_3). ^{19}F NMR (470 MHz, $CDCl_3$, T = –50 °C) δ: –148.8 (s). ^{11}B NMR (160 MHz, $CDCl_3$, T = 50 °C) δ: –0.11 (s). IR (AgCl, cm^{-1}): 1534 (νCO), 1312 and 1339 ($C_{ring}–C_\alpha$). Raman (cm^{-1}): 1534 (νCO), 1312 and 1339 ($C_{ring}–C_\alpha$).

X-ray crystallography (see the Supplementary data section for the supplementary crystallographic data for this paper)

A single crystal of $[(C_5H_5)Fe(C_5H_4–C(O–BF_3)–CH_3)]$ was mounted on a nylon loop at –78 °C using a high-density perfluoropolyether oil. Data were collected on a P4 Bruker diffractometer upgraded with a Bruker SMART 1000 CCD detector and a rotating anode utilizing Mo Kα radiation (λ = 0.7103 Å, graphite monochromator) equipped with an Oxford cryosystems cryostat. A full sphere of reciprocal lattice was scanned by 0.36° steps in ω with a crystal-to-detector distance of 4.9 cm. Preliminary orientation matrices were obtained from the first frames using SMART.[17] The collected frames were integrated using the preliminary orientation matrices, which were updated every 100 frames. Final cell parameters were obtained by refinement on the positions of reflections with $I > 10\sigma(I)$ after integration of all the frames using SAINT.[17] The structure was solved by Patterson methods and refined by full-matrix least squares on all F2 data using SHELXTL.[18] The non-H atoms were refined anisotropically, while H atoms were constrained to idealized positions using appropriate riding models. Molecular graphics were produced using ORTEP-3.[19]

Computational methods

All calculations were performed using the ADF density functional theory (DFT) package (versions 2006.01 to 2008.01).[20–22] The adiabatic local density approximation (ALDA) was used for the exchange-correlation kernel[23,24] and the differentiated static LDA expression was used with the Vosko–Wilk–Nusair parametrization.[25] The optimization

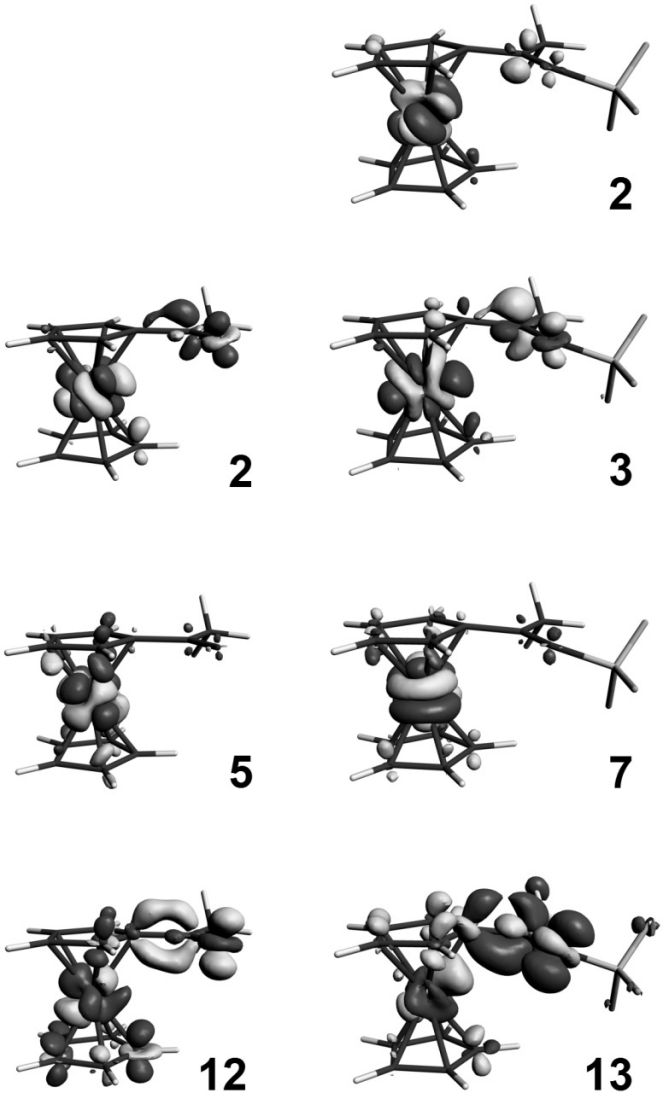
of model geometries was gradient-corrected with the exchange and correlated functionals of the gradient correction proposed in 1988 by Becke,[26] Perdew,[27] and Lee, Yang and Parr.[28] Preliminary geometry optimizations were conducted using a double-ζ basis set with frozen cores corresponding to the configuration of the preceding noble gas and one set of polarization functions; the resulting structures were refined using a triple-ζ all electron basis set with two polarization functions. The geometry optimizations were followed by a vibrational calculation[29,30] to verify that all the computed frequencies were real. Electronic excitations were calculated using time-dependent density functional theory (TDDFT) as implemented within the ADF package; the statistical average of different model potentials for occupied Kohn–Sham (KS) orbitals (SAOP)[31,32] was used for the exchange-correlation potentials in the zeroth-order KS equations.

Results and discussion

Preliminary experiments and synthesis

The early stages of the acid-catalyzed cyclocondensation of acetylferrocene are characterized by a strong colour change from orange to purple, due to the appearance of a strong absorption band with λ_{max} at 490 nm in the UV–visible absorption spectrum (Fig. 1). Very similar colour and spectral changes are observed when a small amount of H_2SO_4 is added to a solution of **4** in ethanol. Although it is reasonable to attribute the new absorption band to the cation **1**, other intermediates, such as the enol $(C_5H_5)Fe(C_5H_4–C(OH)=CH_2)$, could not be ruled out a priori. It was therefore necessary to isolate and characterize the coloured species. Initial attempts in this respect were based on multiple combinations of protic acids (trichloroacetic, trifluoroacetic, acetic, sulfuric, and hydrochloric acid) and organic solvents (acetonitrile, methylene chloride, hexanes, pentane, ethanol, chloroform, tetrahydrofuran, and ether; pure and mixtures) at different temperatures

Fig. 3. Transition densities for the most intense transitions in the electronic spectra of **4** and **5**. Clear and dark lobes represent positive and negative lobes, respectively.



(25 °C, 0 °C, –30 °C). Each attempt invariably led to the separation of an oily phase, which could not be purified and characterized further.

Because all attempts to crystallize the coloured intermediate were unsuccessful, the preparation of Lewis acid–base adducts of **4** with group-13 trihalides ($InCl_3$, $AlCl_3$, and BF_3) was attempted. In each case, the expected colour and spectral changes were observed in solution, with the spectrum of the **4**-BF_3·OEt_2 mixtures resembling very closely that of **4** in acidic medium (Fig. 1). The mixtures with $InCl_3$ and $AlCl_3$ separated as oils and were impossible to purify. In contrast, the equimolar combination of **4** and BF_3·OEt_2 yielded almost quantitatively a dark purple microcrystalline solid, which was easily recrystallized.

Molecular structure

The crystal structure of **5** was determined by X-ray diffraction, and final results are summarized in Table 1. The molecule of the Lewis acid–base adduct is chiral and the unit cell contains the two enantiomers within the asymmetric unit (Fig. 2). The Cp rings are nearly 50% disordered. Selected internal dimensions of both molecules are summarized in Table 2, where the magnitudes of individual pairs are equal within statistical error. The adduct displays a boron centre with tetrahedral geometry, with B–F bond distances in the range of 1.363(8)–1.380(8) Å. The B–O bond lengths of 1.536(8) and 1.539(8) Å are comparable to the average 1.561(22) Å observed in other adducts of BF_3 with ketones.[33,34,35] The F–B–F bond angles, which vary between 111.2°(5) and 112.5°(6), are comparable to those observed in the X-ray structure of $C_6H_6CHO{\cdot}BF_3$ (110.2°(6)–111.3°(5)).[36] The C=O bond shows significant lengthening in both enantiomers, with respect to the distance observed in acetylferrocene,[37] r(C=O) = 1.211(7) Å.

The increase of the C=O bond is complemented by a substantial contraction of the C_{Cp}–Cα bond. The values for this bond distance, 1.423(7) and 1.420(8) Å for each enantiomer, are well below the 1.470(8) Å measured in the parent ketone; it is very close to the 1.416(9) Å observed in the X-ray structure of $[(C_5H_5)Fe(C_5H_4{=}C(C_6H_5)_2)]^+$ $(BF_4)^-$,[38] but slightly longer than the 1.357(5) Å of the neutral iron fulvene complex, $(CO)_3Fe(C_5H_4{=}C(C_6H_5)_2)$.[39] The pattern of change in bond lengths is typical of donor–acceptor interactions[40] and, in this case, can be interpreted as the result of the adoption of a fulvene Lewis structure.

Table 4. Calculated atomic charges (au) of selected atoms or fragments in the molecules of **4** and **5**.

Fig. 4. Vibrational spectra (top: infrared, bottom: Raman) of acetylferrocene (·····) and its BF_3 adduct (—). Selected assignments: (a) ν(C=O), (b) $\nu(C_{ring}{-}C_\alpha)$.

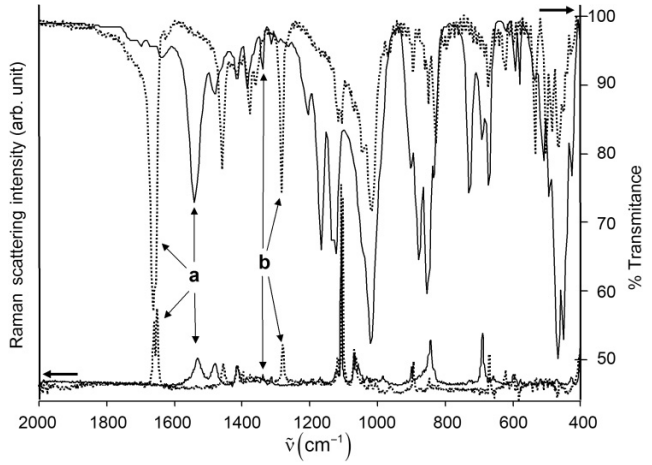

Fig. 5. Selected normal vibrational modes. **4**: (**a**) ν(C=O), (**b**) ν(C_{ring}–C_α); **5**: (**c**) ν(C–O), (**d**) and (**e**) ν(C_{ring}=C_α).

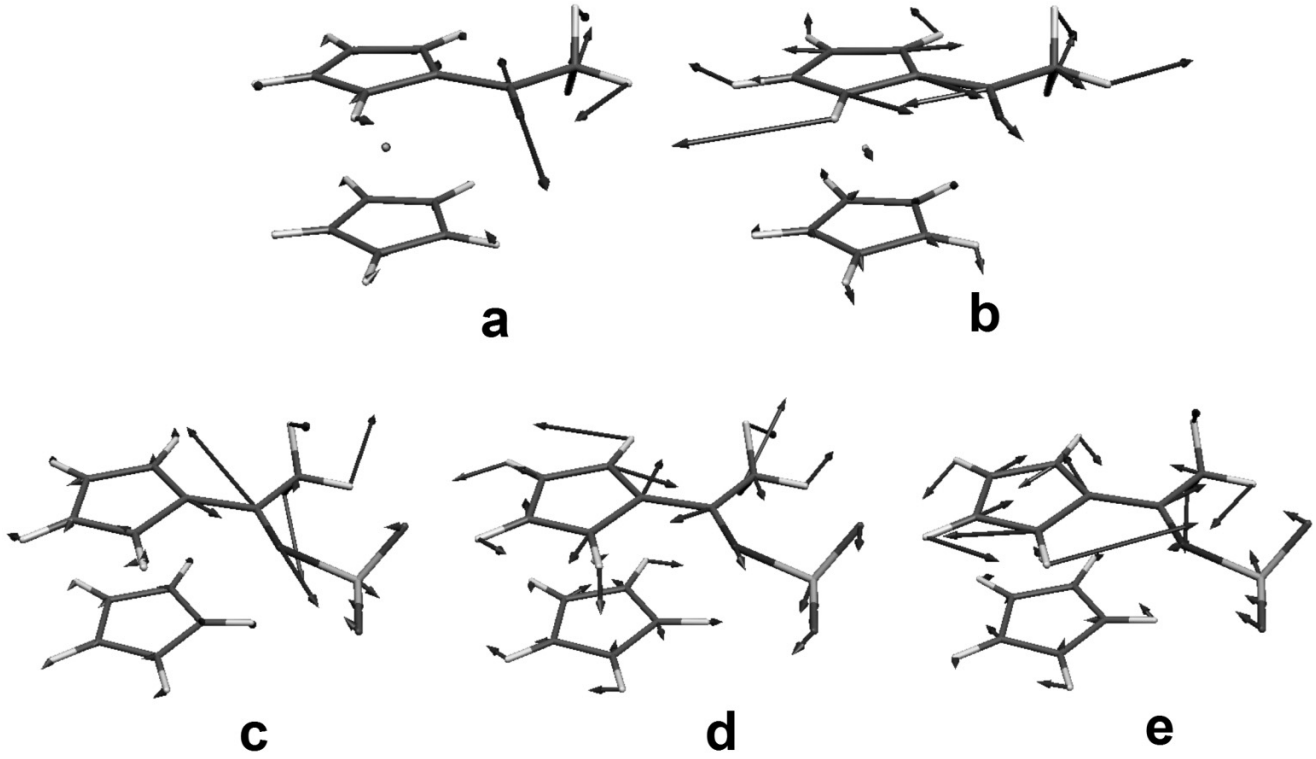

Both enantiomers also exhibit a displacement of the O–C_α–C_{Me} exocyclic moiety below the plane of the Cp ring, to enable coordination of the metal by C_g. The corresponding Fe(1)–C(11) bond distances are 2.908(6) Å and 2.883(6) Å, the angles described by the C(10)–C(11) bond and the plane of the five-membered ring are 10.4° and 12.7°. Such geometrical features are characteristic of cyclopentadienyl organometallic cations[38,41–43] in which the bent geometry is interpreted as a consequence of the electron deficiency at the α–Carbon; overlap of the vacant p with a filled d orbital of the metal is thought to stabilize the molecule.[41,42] The dip angle of **5** is less pronounced than that observed in α-ferrocenylcarbocations such as $[(C_5H_5)Fe(C_5H_4C(C_6H_5)_2)]^+BF_4^-$ (20.7°; r(Fe···C_α): 2.715(6) Å).[38] Fulvene complexes of electron richer iron atoms usually display a different structure, for example, in the X-ray structure of $(CO)_3Fe(C_5H_4C(C_6H_5)_2)$ the C_α atom bends away from the metal to a distance of 3.679 Å and has an exo fold angle of 18.5°.[39]

The above geometric features are well reproduced by DFT calculations. The optimized molecular dimensions are compared to the experimental values in Table 2. Most calculated bond distances fall within 3σ of the measured values, larger deviations are observed for bond angles. The most significant differences are in those dimensions that involve the metal atom and the B–O bond.

Electronic absorption spectra

The UV–vis absorption spectra of **4** and **5** are similar to each other: both display three absorption bands above 240 nm. The most important differences between them are the red shift and increased intensity of the first band of the BF_3 adduct. When TDDFT calculations were used to interpret the spectrum of **1** using the models $[(C_5H_5)Fe(C_5H_4C(O)H)]$ and $[(C_5H_5)Fe(C_5H_4C(OH)H)]^+$, the first band was attributed to a M–L charge transfer involving the $\pi^*_{C=O}$ empty orbital.[8] In this work, we calculated the first 40 transitions of **4** and **5**, used these to model the total absorption spectra, and identified the main contributions to the lowest three bands of each compound. There was good agreement in the shape and relative intensity of the bands, although their λ_{max} was underestimated by up to 45 nm. This analysis revealed that, remarkably, each band in the spectrum of **4** has essentially the same nature as the corresponding band of **5**. The first absorption originates in charge transfer transitions (**4**: 2a; **5**: 2a, 3a) from the metal–Centred HOMO-1 (and HOMO-2 in the case of **5**) to the $\pi^*_{C=O}$ LUMO. The second band arises from the excitation of d electrons to M–C_{cp} antibonding orbitals. The third band is the result of a transition from M–C bonding orbitals to the LUMO. The lowest 14 transitions of these compounds are listed in Table 3 and Fig. 3 presents the transition densities for the most prominent excitations of both molecules, calculated as

$$[1] \qquad \rho_{ge}(r) = \psi^*_g(r)\psi_e(r)$$

The red shift corresponds to the decrease of the HOMO–LUMO gap as the ligand acquires a fulvene character, the C=C bond shortens and the C–O bond elongates. The relative magnitudes of calculated oscillator strengths were consistent with the observed increase of intensity of the bands upon adduct formation. An explanation for the observed change of absorption intensity can be proposed from simple arguments based on the Lewis structures; the BF_3 adduct molecule is more polar, hence, the transition moments are larger. The calculated dipole moments (3.5 and 9.8 D for **4** and **5**, respectively) support this interpretation.

Fig. 6. Variable temperature NMR spectra of **5**; (*a*) ^{13}C, (*b*) ^{1}H.

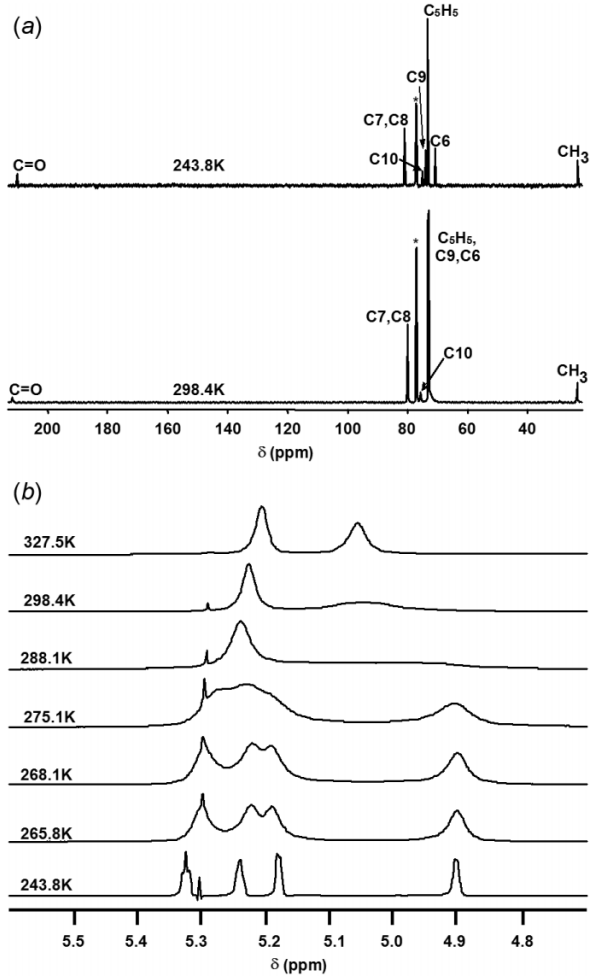

Fig. 7. Calculated potential-energy profile for the rotation of the C_{ring}–C_{α} bond of **5**.

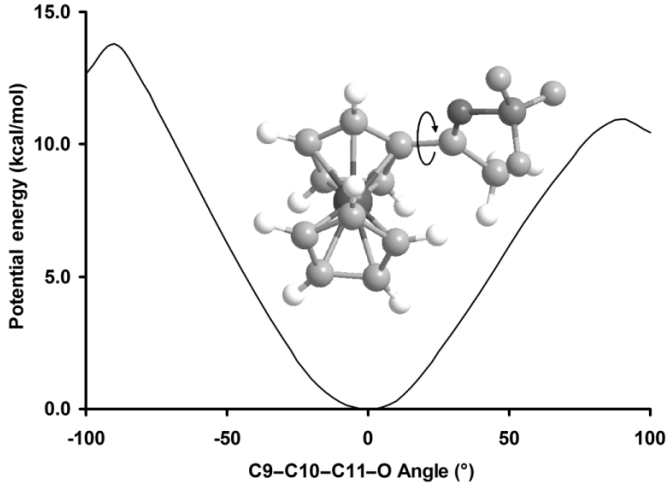

To examine the origin of the change in dipole moment upon binding to the Lewis acid, the atomic charges of **4** and **5** were calculated using methods based on electron density (Voronoi deformation density[44] and Hirshfeld[45]), as well as the natural population analysis (NPA).[46,47] The results are summarized in Table 4. The three schemes do attribute a significantly negative character to the BF_3 group. However, the the organometallic fragment bears only a small amount of charge, which doesn't significantly change upon coordination of BF_3, instead it is the carbon atom of the carbonyl group which bears the largest increase of charge.

Vibrational spectroscopy

The normal modes of **4** and its donor–acceptor complexes are already discussed in detail elsewhere.[48,49] For the purposes of this study, the most relevant sections of the vibrational spectrum correspond to the stretch vibrations of the C–O and C_{ring}–C_{α} bonds. Both the infrared and Raman spectra of solid **5** are compared to those of **4** in Fig. 4.

The ν(C–O) band is readily perturbed by bonding to BF_3. In the case of **4,** it is observed at 1683 cm^{-1} in the infrared spectrum; in Raman, the centrosymmetric character of the crystal splits the band and two maxima appear at 1681 cm^{-1} and 1671 cm^{-1}. These peaks are absent in the spectra of **5**; instead, broad and intense bands appear at 1534 cm^{-1} in both techniques. The shift of this vibration to lower wavenumbers is consistent with the decrease of bond order upon formation of the donor–acceptor adduct and parallels the observations made for other adducts of Lewis acids with carbonyl compounds.[50–52] DFT calculations showed that in both molecules the ν(C–O) vibrations have little mixing with other interatomic motions (Fig. 5) and, without scaling, the calculated shift is from 1670 to 1542 cm^{-1}.

Similarly, the increase of bond order makes the ν(C_{ring}–C_{α}) sensitive to Lewis acids, in principle.[53] However, DFT calculations show that this stretch is coupled to changes in other bonds (Fig. 5). The mode that best corresponds to this vibration in **4** is calculated at 1261 cm^{-1} and is assigned to the absorption band at 1280 cm^{-1}, in agreement with Pavlík et al.[49] According to the calculations, the stretch of the C_{ring}–C_{α} is strongly coupled in **5** and contributes to two modes at 1324 and 1302 cm^{-1}. Experimentally, in the spectra of **5** there is no significant band at 1280 cm^{-1} and new vibrations appear at 1312 cm^{-1} and 1339 cm^{-1}.

NMR spectroscopy

The dynamic structure of **5** in $CHCl_3$ solution was examined using variable temperature (VT) NMR spectroscopy from 203.0–328.0 K under N_2 in a sealed glass tube. ^{1}H and ^{13}C NMR spectral assignments for **5** were accomplished using two-dimensional methods (including HSQC and HMBC), the magnitudes of the coupling constants, and the relative chemical shifts of the observed peaks. The final assignments were consistent with published studies of a variety of ferrocenyl carbenium ions.[54] In comparison to **4**, the room temperature ^{1}H and ^{13}C NMR spectra of **5** display high frequency shifts for most resonances, except those of C(10) and C(11), which is consistent with the fulvenoid structure acquired by the acetylcyclopentadienyl ligand upon protonation. The double bond character restricts the rotation of the C_{ring}–C_{α} bond, as it has been observed in ferrocenyl carbenium ions.[55–63] Consistently, the five ^{13}C peaks observed at room temperature, split at 243.8 K (Fig. 6*a*). However, only seven bands are discernible because the resonances of C(7) and C(8) remain coincident at 80.91 ppm. In the room temperature ^{1}H spectrum, the peaks of H(6), H(7), H(8), and H(9) appear as two broad singlets at 5.05 and

5.23 ppm, which split upon cooling into four signals at 243.8 K (Fig. 6*b*), while all other peaks remained unchanged. At 238.0 K, all the coupling constants in the ^{1}H NMR spectrum become discernible; they all fall within the range of values observed for monosubstituted cyclopentadienyl rings.[64] Lineshape simulations and an Eyring analysis[65] provided a rotational barrier of 13.7 kcal/mol. The magnitude is comparable to the 10.9 kcal/mol that correspond to the smaller barrier evaluated with DFT calculations of the potential energy as a function of the rotation of the C(10)–C(11) bond (Fig. 7). This barrier is smaller than the 16.6–21.2 kcal/mol measured for cations prepared from 1-hydroxyalkylferrocenes in acidic medium.[62] Similarly, the DFT calculated barrier for restricted rotation after protonation of 3-ferrocenyl-2,4,5-triphenylcyclopentadienone[66] was over 19 kcal/mol but it could not be experimentally determined.

Conclusions

The Lewis acid–base adduct, $[(C_5H_5)Fe(C_5H_4–C(OBF_3)–CH_3)]$, features an alkoxyfulvene moiety, which results from electron reorganization of the acetylcyclopentadienyl ligand upon attachment of the borane to the oxygen atom. This is the same type of structural change that has been attributed to the protonation of the ligand. The electronic excitation spectrum of the compound does reproduce the observations made by UV–vis spectroscopy at the beginning of the cyclocondensation reaction of acetylferrocene, providing confirmation of the identity of the coloured intermediate. On the other hand, DFT calculations do model accurately the structure and some spectroscopic properties of this compound.

Supplementary data

Chemical bonding and aromaticity in metalloporphyrins[1,2]

Ferran Feixas, Miquel Solà, and Marcel Swart

Abstract: We report here the chemical bonding and aromaticity patterns in metalloporphyrins, which were obtained with density functional theory (DFT) calculations at the OPBE/TZP level. This level of theory was previously shown to be very accurate for determining spin-state splittings [*J. Chem. Theory Comput.* **2008**, *4*, 2057] of transition-metal complexes. We considered metalloporphyrins along the first-row transition metals (Sc–Zn) extended with alkaline-earth metals (Mg, Ca) and several second-row transition metals (Ru, Pd, Ag, Cd). An energy decomposition analysis was performed to study the metal–ligand interactions, which showed that almost all complexes are significantly stabilized through (covalent) orbital interactions. The only exception is with calcium as the central metal, which interacts with the porphyrin mainly through electrostatic interactions. Furthermore, we studied aromaticity patterns for these complexes by looking at a number of (structural and electronic) aromaticity descriptors, for both the inner-ring and outer-ring of the porphyrin and of the pyrroles. The inner-ring (N16) aromaticity is shown to be unaffected by metal complexation, while the outer-ring (N20) and the pyrrole (N5) aromaticities are found to increase significantly in the metal coordinated porphyrins.

Key words: porphyrins, transition-metal complexes, aromaticity, density functional theory.

Résumé : On a déterminé les patrons de liaison chimique et d'aromaticité de métalloporphyrines à l'aide de calculs selon la théorie de la fonctionnelle de densité, au niveau OPBE/TZP. Il a été démontré antérieurement que ce niveau de la théorie est très précis dans la détermination des couplages de métaux de spin [*J. Chem. Theory Comput.* **2008**, *4*, 2057] dans des complexes d'états de transition. On a considéré les métalloporphyrines des métaux de transition de la première période (Sc–Zn) avec leurs métaux alcalino-terreux (Mg, Ca) et plusieurs métaux de transition de la deuxième période (Ru, Pd, Ag, Cd). On a effectué une analyse de l'énergie de décomposition dans le but d'étudier les interactions métal–ligand; elle a démontré que pratiquement tous les complexes sont fortement stabilisés par des interactions orbitalaires covalentes. La seule exception est le calcium qui comme métal central, interagit avec la porphyrine principalement par le biais d'interactions électrostatiques. De plus, on a étudié les patrons d'aromaticité de ces complexes en examinant un certain nombre descripteurs d'aromaticité (structural et électronique) tant des cycles internes que des cycles externes de la porphyrine et des pyrroles. On a démontré que l'aromaticité du cycle interne (N16) n'est pas affectée par une complexation métallique alors que les aromaticités du cycle externe (N20) et du pyrrole (N5) augmentent d'une façon significative dans les porphyrines en coordination avec un métal.

Mots-clés : porphyrines, complexes de métaux de transition, aromaticité, théorie de la fonctionnelle de la densité.

[Traduit par la Rédaction]

Introduction

Metalloporphyrins play an important role in biology and catalysis, in which they are observed with a multitude of central metals and peripheral substituents (see Fig. 1).[3–6] The most common of them is formed by the heme group where the central particle is usually an iron(II) or iron(III) ion.[7] This heme group serves a wide range of functions, ranging from electron transfer or oxygen carrier to hydroxylation oxidant.[8,9] To be able to perform this wide range of functions, both the axial ligands to iron and the nature of the immediate protein environment around the heme seem to play an important role. In many cases, however, the active species of a heme-containing enzyme is too reactive to be isolated and characterized, which is for instance the case for the catalytic cycle of P450 enzymes.[10] For that reason, there is an overwhelming amount of experimental studies that use more simple and smaller metal complexes.[11] Many of these are based on, e.g., tetraphenylporphyrin (TPP), octaethylporphyrin (OEP), or phtalocyanines (PC). The relationship between the porphyrin orbitals and the UV–vis spectra of several porphyrin systems was reported some years ago by Baerends and co-workers,[12] which was recently shown to hold also for magnetic circular dichroism (MCD) spectra by Ziegler and co-workers.[13] Furthermore, the synergy between substituents, core-saddling, and meso-phenyl twisting was reported by Rosa and co-workers.[14]

Here, we are interested in the "naked" (metallo)porphyrins, i.e., the porphyrin without peripheral substituents

and axial ligands. In particular, we are interested in the metal–ligand bonding interactions and aromaticity, and how these are influenced by the nature of the central metal and (or) spin-state. Recently, validation studies of density functional theory (DFT)[15] functionals by some of us[16,17] have shown the excellent performance of the OPBE[18–20] functional for spin-state splittings of transition-metal complexes, which is corroborated by good results in other studies.[21–34] Moreover, also for NMR chemical shifts and reaction barriers, OPBE seems to perform significantly better than other DFT functionals.[22,24,26,35] In a very recent systematic investigation of the influence of the basis set on the spin-state energies and geometries of iron compounds with the OPBE functional,[36] we have obtained reliable and consistent results when using Slater-type orbital (STO) and large Gaussian-type orbital (GTO) basis sets. Therefore, we have used the OPBE functional together with an STO basis set of triple-ζ quality to study metalloporphyrins along the first-row transition metals (Sc–Zn), extended with alkaline-earth metals (Mg, Ca) and several second-row transition metals (Ru, Pd, Ag, Cd). For those metal ions with multiple spin-states in close proximity, we have studied all spin-states separately.

Computational details

The calculations using the unrestricted formalism have been performed with the Amsterdam density functional (ADF) suite of program.[37] MOs were expanded in an uncontracted set of STOs of triple-ζ quality containing diffuse functions and one set of polarization functions (TZP). Energies and gradients were calculated using the local density approximation (LDA; Slater exchange and VWN correlation) with gradient-corrections (GGA) for exchange (OPTX)[19] and correlation (PBE)[20] included self-consistently, i.e., the OPBE functional.[18] Geometries were optimized with a locally modified version of the QUILD program[38] using adapted delocalized coordinates[39] until the maximum gradient component was less than 1.0×10^{-5} au. The frequen-

cies of all complexes were calculated to ensure that they correspond to minima.

For some spin-states of the transition-metal complexes, an energy decomposition analysis (EDA)[40] has been performed to study the chemical bonding in these compounds. In this EDA analysis, the total energy ΔE_{total} for the heterolytic association[26] reaction between the metal, M(II), cation and the porphyrin ligand, Por, with charge –2 ($M^{2+} + Por^{2-} \rightarrow MPor$) results directly from the Kohn–Sham molecular orbital (KS-MO) model[40] and is made up of two major components: preparation and interaction. The preparation energy contains the energy needed to bring the cation and ligands together from their isolated equilibrium geometry to the positions they attain in the complex, and consists of the deformation energy ΔE_{deform} and the energy needed to excite, e.g., the iron(II) cation from its quintuplet ground state to the spin state (with corresponding orbital occupations) it attains in the complex (ΔE_{valexc}). Note that the latter do not concur to the ones of the isolated cation, and can thus not be compared to experimental ionization energies for the metal(II) cation. Moreover, for the ground state of the isolated metal(II) cation, we use the "average of configuration" (AOC) approach,[41] which is a one-determinant approximation to the true atomic state, and serves here mainly as reference energy. The interaction energy gives the subsequent interaction between the cation on one side, and the porphyrin ligand on the other, and consists of Pauli repulsion ΔE_{Pauli}, electrostatic interactions ΔE_{elstat}, and the (covalent) orbital interactions ΔE_{orbint} (see Supplementary data for full details).

Descriptors of aromaticity

As a structure-based measure, we have employed the harmonic oscillator model of aromaticity (HOMA) index, defined by Kruszewski and Krygowski[42] as

$$[1] \qquad \mathrm{HOMA} = 1 - \alpha/n\sum_{i=1}^{n}(R_{opt} - R_i)^2$$

where n is the number of bonds considered, and α is an empirical constant (for C–C and C–N bonds, α = 257.7 and 93.5, respectively) fixed to give HOMA = 0 for a model nonaromatic system, and HOMA = 1 for a system with all bonds equal to an optimal value R_{opt} (1.388 and 1.334 Å for C–C and C–N bonds, respectively), assumed to be achieved for fully aromatic systems. R_i stands for a running bond length. This index has been found to be one of the most effective structural indicators of aromaticity.[43]

In addition, two aromaticity criteria (FLU and MCI) based on electron delocalization measures have been employed. These indices measure the cyclic electron delocalization of mobile electrons in aromatic rings. The electron delocalization is measured by means of the so-called delocalization indices (DIs), or, in a more general nomenclature, the electron sharing indices (ESI). The ESI value between atoms A and B, δ(A,B), is obtained by double integration of the exchange-correlation density ($\gamma_{XC}(\vec{\mathbf{r}}_1, \vec{\mathbf{r}}_2)$) over the molecular space regions corresponding to atoms A and B

$$[2] \qquad \delta(\mathrm{A,B}) = -2\int_{\mathrm{A}}\int_{\mathrm{B}}\gamma_{XC}(\vec{\mathbf{r}}_1, \vec{\mathbf{r}}_2)\mathrm{d}\vec{\mathbf{r}}_1\mathrm{d}\vec{\mathbf{r}}_2$$

For single-determinant closed or open-shell wave functions, one obtains

$$[3] \qquad \delta(\mathrm{A,B}) = 2\sum_{i,j} S_{ij}(\mathrm{A})S_{ij}(\mathrm{B})$$

The summations in eq. [3] run over all occupied molecular spin orbitals (MSOs). S_{ij}(A) is the overlap between MSOs i and j within the molecular space assigned to atom A, the elements of the so-called atomic overlap matrices (AOM). δ(A,B) provides a quantitative idea of the number of electrons delocalized or shared between atoms A and B. Although several atomic partitions may be used in the ESI definition, the most popular one is that where the partition is carried out in the framework of the quantum theory of atoms-in-molecules (QTAIM) of Bader,[44] by which atoms are defined from the condition of zero-flux gradient in the one-electron density, $\rho(\mathbf{r})$. The aromatic fluctuation index (FLU)[45] is based on the fact that aromaticity is related to the *cyclic* delocalized circulation of π-electrons, and is constructed not only considering the amount of electron sharing between contiguous atoms, which should be substantial in aromatic molecules, but also taking into account the similarity in terms of electron sharing between adjacent atoms. Let us consider a ring structure of N atoms represented by the following string $\mathcal{A} = (A_1, A_2, \ldots, A_N)$, whose elements are ordered according to the connectivity of the atoms in the ring. For such ring, the FLU index is defined as

$$[4] \qquad \mathrm{FLU}(\mathcal{A}) = \frac{1}{N}\sum_{i=1}^{N}\left[\left(\frac{V(A_i)}{V(A_{i-1})}\right)^{\alpha} \times \left(\frac{\delta(A_i, A_{i-1}) - \delta_{ref}(A_i, A_{i-1})}{\delta_{ref}(A_i, A_{i-1})}\right)\right]^2$$

where $A_0 \equiv A_N$ and half the values of V(A) is recognized by some authors as the atomic valence defined as

$$[5] \qquad V(A_i) = \sum_{A_j \neq A_i}\delta(A_i,A_j)$$

and α is a simple function to make sure that the first term in eq. [4] is always greater than or equal to 1, thus taking the values

$$[6] \qquad \alpha = \begin{cases} 1 & V(A_i) > V(A_{i-1}) \\ -1 & V(A_i) \leq V(A_{i-1}) \end{cases}$$

The $\delta_{ref}(A_i, A_{i-1})$ reference values are δ_{ref}(C,C) = 1.389 e and δ_{ref}(C,N) = 1.204 e (the δ_{ref}(C,C) and δ_{ref}(C,N) values in benzene and pyridine, respectively, at the OPBE/TZVP level). FLU is close to 0 in aromatic species, and differs from it in non-aromatic ones. Second, we have employed the multicenter index (MCI),[46] whose formula reads

$$[7] \qquad \mathrm{MCI}(\mathcal{A}) = \frac{1}{2N}\sum_{P(\mathcal{A})} I_{ring}(\mathcal{A})$$

where $P(\mathcal{A})$ stands for a permutation operator which interchanges the atomic labels $A_1, A_2, \ldots, A_N$ to generate up to the $N!$ permutations of the elements in the string A. In turn, I_{ring} is defined as[47,48]

$$[8] \qquad I_{\text{ring}}(\mathcal{A}) = \sum_{i_1,i_2,\ldots,i_N} n_{i_1} \ldots n_{i_N} S_{i_1 i_2}(A_1) S_{i_2 i_3}(A_2) \ldots S_{i_N i_1}(A_N)$$

where n_i is the occupancy of orbital i. For the series of indices used, the lower the FLU index, and the higher the HOMA and MCI values, the more aromatic the rings.

Calculation of AOM and computation of FLU and MCI have been performed with the AIMPAC[49] and ESI-3D[50] collection of programs. These two programs work with GTO basis sets. In consequence, single-point calculations at the OPBE/TZP(STO)-optimized geometries have been performed with the Gaussian 03[51] program at the OPBE level of theory with a TZVP basis set[52] to generate the wave function and obtain the necessary AOM.

Calculation of these ESIs with DFT cannot be performed exactly because the electron-pair density is not available at this level of theory.[53] As an approximation, we have used the Kohn–Sham orbitals obtained from a DFT calculation to compute Hartree–Fock-like DIs through eq. [3] that does not account for electron correlation effects. In practice, the values of the ESIs obtained using this approximation are generally closer to the Hartree–Fock (HF) values than correlated ESIs obtained with a configuration interaction method.[53,54]

The numerical accuracy of the QTAIM calculations has been assessed using two criteria: (*i*) the integration of the Laplacian of the electron density ($\nabla^2\rho(r)$) within an atomic basin must be close to zero, and (*ii*) the number of electrons in a molecule must be equal to the sum of all the electron populations of the molecule, and also equal to the sum of all the localization indices and half of the DIs in the molecule. For all atomic calculations, integrated absolute values of $\nabla^2\rho(r)$ were always less than 0.001 au. For all molecules, errors in the calculated number of electrons were always below 0.01 au.

Finally, we have not used NICS[55] values in our discussion because, for complexed porphyrins, the results obtained are largely influenced by the nature of the metal center.[56]

Results and discussion

We have studied the chemical bonding and aromaticity of metalloporphyrins, where we considered both first-row (Sc–Zn) and second-row (Ru, Pd, Ag, Cd) transition metals and alkaline-earth metals (Mg, Ca). This series of metals comprises the metalloporphyrins that are observed experimentally[4–6,57] (although the latter are in many cases with substituents present on the porphyrin ring). For those metal ions with several spin states in close proximity (Fe, Ru, Mn, and so forth), we studied each spin state separately but will limit our discussion here to the ground state; data for the other spin states can be found in the Supplementary data. Previous theoretical studies focused either on only a small subset of these metalloporphyrins (e.g., Fe, Co, Ni, Cu, Zn in refs. 58 and 59), on the time-dependent (TD) DFT properties of a number of (metallo)porphyrins,[12,60] on the effect of the axial ligand,[3] or on comparing porphyrins with porphyrin analogues.[12,61,62] However, a complete study on the full set of metalloporphyrins, consistently studied with the same DFT functional and basis set, has to the best of our knowledge never been done before.

For most systems, there was no problem with spin contamination, as indicated by the expectation values of the S^2 operator, which gave values very close to the pure spin-state values (0.0 for singlet, 0.75 for doublet, 2.0 for triplet, 3.75 for quartet, 6.0 for quintet, and 8.75 for sextet). For four singlet systems (^{1}Cr, ^{1}Fe, ^{1}Ru, and ^{1}Ti) and one doublet system (^{2}V), the spin contamination was however substantial and had to be corrected. For the singlet systems, the S^2 value was 1.0, indicating that the contaminated system contained 50% of a triplet state, while for the doublet system, the S^2 value was 1.75, indicating an admixture of 33% of a quartet state. This spin-contamination correction[63] is easily handled by the QUILD program for both the geometry optimization and energy calculation.

The spin density was in almost all cases located mainly on the metal, with two exceptions. The quintet state of ruthenium–porphyrin is in fact obtained from the coupling of a Ru(III) quartet with a porphyrin^{3-} doublet. Furthermore, the triplet state of palladium–porphyrin is in fact obtained through the coupling of a Pd(II) singlet with a porphyrin^{2-} triplet.

Geometry and ground state of the metalloporphyrins

The geometry of all metalloporphyrins was optimized for each spin state separately within a number of symmetry representations (C_{2v}, C_{4v}, D_{4h}, and S_4) for the geometry. In all these cases, the orbitals and densities were described by C_{2v} symmetry, in which the metal d orbitals are more conveniently treated. This separation of the geometric vs. orbital point-group symmetry is one of the advantages of using the QUILD program in our studies. For most of the systems we studied, the actual symmetry imposed was irrelevant because the optimizations ended up in D_{4h} symmetry. For a small number of systems however (see Table 1), the most stable configuration was found with the metal ion displaced from the porphyrin plane (i.e., within C_{4v} symmetry). For two of them (chromium–porphyrin and nickel–porphyrin), this out-of-plane distortion has no effect, since it occurs in the triplet state, which is significantly less stable than the corresponding ground states, by 40 and 21 kcal mol^{-1}, respectively. It is another matter for the scandium– and calcium–porphyrins, for which it is observed in the ground state. For the calcium—porphyrin, this out-of-plane distortion is significant (0.86 Å) in similar fashion to that observed for a larger porphyrin system (where it is 1.21 Å out of the N_4 plane).[57]

The calculated spin ground states (see Table 1) of the metalloporphyrins correspond to those observed experimentally,[7] i.e., we find a quintet for chromium, a sextet for manganese, a triplet for iron, and a doublet for cobalt. For many of these systems, the experimental situation is such that no clear determination of the ground state of the "naked" metalloporphyrin can be made. For instance, for the early transition metals (Ti, V), the porphyrin system is most frequently obtained with an oxygen bound to the metal (the oxo-compound). Also, other axial ligands are usually present, which are known to have a determining influence on the spin ground state. For instance, in the catalytic cycle of cytochrome P450s, a spin flip occurs from a doublet to a sextet state after substrate binding in the active site of the enzyme. For cytochrome P450cam, the substrate is found to be anchored to a tyrosine residue present in the active site in close proximity of the heme, and not directly ligated to iron. However, in the process of substrate binding, six water mol-

[b]Corrected for spin contamination.

ecules are expelled from the active site, one of which was previously present as axial ligand to iron. Therefore, the spin flip merely reflects the change from six-coordinate iron to five-coordinate iron. Nevertheless, based on trends in experimental data, it was (correctly) predicted that the "naked" unligated iron(II)–porphyrin should be a pure intermediate-spin complex. This is corroborated by our OPBE data,[64] for which there now exists the consensus that it gives the correct spin ground state of transition-metal complexes in general, and for iron complexes in particular.[16,17]

Chemical bonding in the metalloporphyrins

The optical spectrum of porphyrins and analogues is well-understood in terms of the Gouterman model,[12] but a similarly simple model for understanding the metal–ligand interactions themselves is not yet available. Recently however, a generalization of these interactions in terms of their spin-state preferences has been put forward.[17,26] It successfully explains the spin ground state of transition-metal complexes in terms of a compromise between Hund's rule of maximum multiplicity and metal–ligand covalent interactions. Initially, it was proposed for metal–ligand interactions in metallocenes, but later was shown to hold also for challenging iron complexes that contain the mono- and di-pyridylmethylamine ligands. Key ingredient in these studies was the application of an energy decomposition analysis (EDA),[40] which describes the metal–ligand interactions in terms of the preparation and interaction components (see Computational details). Here, we have likewise applied the EDA analysis to study the metal–ligand interactions in terms of the heterolytic association reaction between the cationic metal M^{2+} and the anionic porphyrin ligand (Por^{2-}), see Table 2 (and Table S1 for the data of the different spin states). As anticipated, the interaction between the metal and porphyrin is, for a large part, electrostatic in nature. This shows up clearly in the EDA analysis where the electrostatic interactions contribute between –528 and –658 kcal mol^{-1} to the total metal–ligand interactions. This range of ~130 kcal mol^{-1} between the different metalloporphyrins is accompanied by Pauli repulsion interactions that are (with the exception of Mg–Por, see below) found within a range of ~180 kcal mol^{-1}, e.g., between +134 and +311 kcal mol^{-1}. More discriminating however are the (covalent) orbital interactions, which are found in the range from –223 to –467 kcal mol^{-1}. In most cases, the orbital interactions are sufficiently large to overcome the Pauli repulsion, and therefore positively contribute to the metal–ligand interactions. Moreover, for the stable metalloporphyrins, such as nickel–porphyrin or iron–porphyrin, the orbital interactions are significantly large compared with Pauli repulsion such that a substantially enhanced total energy (> –700 kcal mol^{-1}) is obtained. The only exceptions to this rule are the alkaline earth metals Mg and Ca, for which the (covalent) orbital interactions are much reduced (–223 to –229 kcal mol^{-1}). For calcium–porphyrin, the metal–ligand interaction is therefore purely electrostatic, as the Pauli repulsion of 250 kcal mol^{-1} more or less cancels the (covalent) orbital interactions. Surprisingly enough, this is not the case for magnesium–porphyrin, where the small (covalent) orbital interactions (of –223 kcal mol^{-1}) are still substantially larger than the Pauli repulsion (of +81 kcal mol^{-1}). Therefore, for all metalloporphyrins (except the calcium–porphyrin), the covalent interactions are one of the most important factors that determine their stabilities. Moreover, the fact that the metal–ligand interac-

Fig. 2. Correlation between vibrational frequency and metal – porphyrin-core distance.

tions in calcium–porphyrin are only electrostatic in nature, and not covalent, might explain why this is the only metalloporphyrin where the metal is found far away from the porphyrin plane and at the longest M–N bond distances. Both the out-of-plane distorsion and the large Ca–N bond distance lead to smaller orbital overlaps and, consequently, low orbital-interaction energies.

Correlation between frequency and metal-core distance

In the 1970s, there were a number of papers that describe the relationship between resonance Raman frequencies and structural properties of metalloporphyrins. Initially, it was suggested that one particular frequency (at ~1590 cm^{-1}) could be used as probe for the metal being out-of-plane or in-plane. This was later on[5] corrected to show a correlation between this frequency and the metal – porphyrin-core distance. Since we have computed here both the metal–core distances and the vibrational frequencies, we thought it might be interesting to establish if there exists a relationship between the vibrational frequencies at ~1590 cm^{-1} region, and either the out-of-plane distance of the metal or the metal – porphyrin-core distance. Shown in Fig. 2 is, for each of the systems, the largest vibrational frequency in the 1500–1700 cm^{-1} region as function of the metal – porphyrin-core distance. This figure shows a clear correlation between the two, i.e., the larger the metal – porphyrin-core distance, the smaller the frequency, which corroborates the notions by Spaulding and co-workers.[5]

Aromaticity of the metalloporphyrins

We have investigated the aromaticity of the metalloporphyrins using several descriptors (see Computational details). We noticed several interesting trends. For the HOMA and FLU analysis, we looked at a number of different patterns, i.e., either the inner ring (N16) or the outer ring (N20), or the pyrrole rings (N5) (see Fig. 3 for the description of these different patterns). For the MCI measures, we only analyzed the N5 rings because of the computational cost of generating up to 16! and 20! permutations of the members of the N16 and N20 rings. The inner-ring and pyrrole-ring patterns had previously been used by Krygowski, Schleyer, and co-workers in combination with the HOMA and NICS analyses to investigate aromaticity in (metallo)-

Fig. 3. Inner ring, outer ring, and pyrrole patterns.

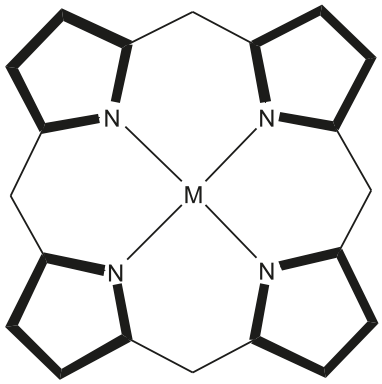
Outer ring



Pyrroles

porphyrins.[65] However, they looked mainly at experimentally obtained structures (of non-"naked" porphyrins) and only investigated one metalloporphyrin (Mg(II)–porphyrin) together with isolated porphyrin and porphyrin dianion by quantum chemistry.

To understand the behavior of aromaticity in metalloporphyrins, the analysis of free base porphyrin ($PorH_2$) has been performed, and the HOMA, FLU, and MCI values are given in Table 3. In the free base porphyrin, two out of the four pyrrole rings are protonated. In previous work, it has been demonstrated by means of HOMA and NICS calculations that the aromaticity of two pyrrole rings with an NH group is higher than the other two deprotonated rings.[65,66] This is attributed to the fact that five-membered rings (5-MRs) with an NH group have six π-electrons and behave like true pyrrole rings in contrast to deprotonated rings that formally possess only five π-electrons. Both the aromatic ring current shielding (ARCS) analysis[67] and the calculation of the induced ring current[68,69] show a strong diamagnetic current in the 5-MRs in porphyrin with an inner H atom of the similar magnitude as the pyrrole molecule, whereas the pyrrole rings without the H atom present much lower local ring currents. In the latter 5-MRs, the C_2H_2 group was considered by Krygowski, Schleyer, and co-workers as simple exocyclic bridges.[65] The same trends were found in an imidazole-containing analogue of porphycene,[70] in porphyrazine and tautomers of triazoleporphyrazine,[71] and in N-confused porphyrins.[72] Our calculated HOMA, FLU, and MCI values follow the expected trends, and the rings with an NH group are closer to the free-pyrrole values than the 5-MRs with the N group (see Table 3). Deprotonation of $PorH_2$ leads to its dianion (Por^{2-}). The charge is distributed over the whole molecule, and the symmetry of the molecule becomes D_{4h}. The aromaticity of inner N16 is more or less the same as in $PorH_2$ but the four N5 pyrrole rings are less aromatic according to HOMA and FLU values. This trend also showed up in the study by Krygowski and Schleyer[65] for a large number of experimental crystal structures. Finally, MCI results indicate that the aromaticity of the 5-MRs with an NH group remains unaltered, while that of the 5-MRs with the N group is slightly increased.

In $PorH_2$ and Por^{2-}, the number of contributing π electrons is 18 in N16 and 22 in N20, consistent with the $(4n + 2)$ rule for aromatic monocycles. In agreement with previous studies,[65,68,69] the aromaticity of the inner N16 ring is higher than that of the N20 ring that contains the C_2H_2 group of the 5-MRs acting as simple exocyclic bridge. To obtain the neutral deprotonated porphyrin (Por), the removal of two electrons causes the localization of π electrons, and the symmetry of the system becomes D_{2h}. It is worth mentioning here that the localization/delocalization patterns are not simply the result of the π-bonding, as it was shown that π-bonding in itself is distortive while it is actually the σ-bonding that tends to favor delocalized structures.[73–81] Therefore, Por has 16 and 20 π electrons in N16 and N20 consistent with the $(4n)$ rule of antiaromaticity. So, the aromaticity of N16, N20, and N5 clearly decreases in Por. The diatropic (aromatic) ring current in Por^{2-} and paratropic (antiaromatic) in Por were reported by Steiner and co-workers.[69] Therefore, HOMA, FLU, and MCI reproduce the expected trends for free-base porphyrins ($PorH_2$, Por^{2-}, and Por).

The metalloporphyrins studied in this work contain the metal M(II) cation and the dianion porphyrin ligand ($M^{2+} + Por^{2-} \rightarrow MPor$). We have studied the behavior of aromaticity in the N16, N20, and N5 rings upon complexation of the metal dication (see Table 4). First, we have analyzed the aromaticity of inner N16 and outer N20 in Por^{2-} and MPor. As far as N16 is concerned, one can see that the aromaticity keeps almost unchanged after metal complexation, which

was also observed by Krygoswki and Schleyer in their study of a large number of experimental crystal structures.[65] So, the inner ring keeps the aromatic character of Por^{2-} with HOMA values close to 1 and the FLU index close to 0. Usually the spin state with high N16 aromaticity corresponds to the ground state but there are some exceptions, like in Ni and Fe. As we have commented before, the outer N20 ring of Por^{2-} is significantly less aromatic because the electrons of the pyrrole ring are highly localized in C–C bonds. However, after complexation, the aromaticity of N20 MPor increases significantly, the alternation between C–C decreases, and the electrons are delocalized both in the N16 and N20 rings. The aromaticity of N5 in metalloporphyrins increases and becomes quite close to that of NH rings in $PorH_2$. This increase in the aromatic character of the outer N20 and N5 rings is attributed to two main factors: polarization of the π-cloud and charge transfer. The polarization of the π-cloud is caused by the divalent positive charge of the metal that moves the more polarizable π-electrons near to the N atoms. As a result, the N5 rings become more aro-

matic (and the N20 pathway too) as they approach the formally six π-electron count from the initial five π-electrons. This is what is observed for ^{1}Mg, ^{1}Ca, ^{6}Mn, and ^{1}Zn that have, in general, small orbital interactions (see Table 2). In these cases, these orbital interactions are mainly due to polarization and not to two-electron – two-orbital interactions. This effect was already reported by Steiner and co-workers[69] who calculated the total π current density maps of model systems obtained by replacement of the Mg^{2+} cation in MgPor by charges Z_e, $ZPor^{2-}$(Z = 0, Z = 2, and Z = 4). For Z = 2, the current density is almost the same as in MgPor. So, the ring current is bifurcated, and N16 and N20 are both aromatic. The replacement of Mg^{2+} by Z = 0 ring current presents a reduction of bifurcation in favor of the inner N16, and Z = 4 favors outer N20. So, the increase of central charge leads to a decrease of aromaticity in N16 and an increase in N20. For the rest of the MPor, apart from polarization, there are significant two-electron – two-orbital interactions as can be seen from the orbital interaction terms in the EDA. These orbital interactions are basically σ-donation from the N lone pair to empty d orbitals of the metal and π-retrodonation from filled d orbitals to the π-system of Por^{2-}. As a consequence of retrodonation, there is an increase in the π-population of the 5-MRs that makes them more aromatic. This is especially clear in the case of ^{5}Ru. As we showed before, the quintet state of ruthenium porphyrin is obtained from the coupling of Ru(III) quartet with a porphyrin(3–) doublet. In this case, the aromaticity of N20 is the highest and the aromaticity of N16 is the lowest among the metalloporphyrins analyzed. As we mentioned, the increase of the central charge leads to a strong delocalization of the outer N20 and decrease of the inner N16.

Finally, it is worth noting that the MCI descriptor shows only a small reduction upon metal complexation, and hardly makes any difference between the different metal ions or spin states present. This index did already not differentiate between aromaticities of the 5-MRs in $PorH_2$ and Por^{2-} (Table 3).

Conclusions

We have studied chemical bonding and aromaticity patterns in metalloporphyrins using DFT at the OPBE/TZP level. A number of the complexes showed spin contamination, which was corrected for using standard techniques within the QUILD program that can be used for both the energy and the geometry optimization. The geometry optimization was performed with QUILD using a number of geometric symmetries (C_{2v}, C_{4v}, D_{4h}, and S_4), together with C_{2v} symmetry for the orbitals within the ADF program. Nevertheless, for most complexes, the final geometry turned out to be D_{4h}. Four complexes were found to be more stable within C_{4v} symmetry, in which the metal was found slightly displaced from the porphyrin plane. Only for calcium was this out-of-plane distortion significantly large (0.86 Å), which concurs with a recent crystal structure of a related calcium–porphyrin complex.

The chemical bonding in these complexes was studied with an energy decomposition analysis, which showed, as anticipated, strong electrostatic interactions between the metal(II) cation and the porphyrin dianion. For most complexes, this was accompanied by significant (covalent) orbital interactions, apart from calcium–porphyrin that showed mainly electrostatic interactions.

Finally, we have studied aromaticity patterns in these transition-metal complexes using a number of (structural and electronic) aromaticity descriptors. The inner-ring (N16) aromaticity is hardly affected by the complexation of the metal cation, i.e., it keeps the aromatic character of the porphyrin dianion. On the other hand, the aromaticity of the 5-MR (N5) and the outer-ring (N20) aromaticity are significantly enhanced by the presence of the metal. This increase in the aromatic character of the outer N20 and N5 rings is attributed to two main factors: polarization of the π-cloud and charge transfer.

Supplementary data

Supplementary data (detailed description of the components of the energy decomposition analysis, EDA analysis for all spin-states, and Cartesian coordinates of the transition-metal complexes) for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 3965. For more information on obtaining material, refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml.

Hetero-Diels–Alder reactions involving $Fe(CO)_3$-coordinated dienal and formyltrimethylenemethane catalyzed by Lewis acids — A theoretical study[1]

Carles Acosta-Silva, Òscar González-Blanco, and Vicenç Branchadell

Abstract: The hetero-Diels–Alder reactions of butadiene with $Fe(CO)_3$-coordinated formylbutadiene and formyltrimethylenemethane catalyzed by Lewis acids have been theoretically studied through density functional calculations. The results obtained show that, for the reaction with (formylbutadiene)$Fe(CO)_3$, the kinetically most favourable product is the one corresponding to the attack of butadiene on the *s-cis* conformer of the formylbutadiene fragment when the reaction is catalyzed by BF_3, and the one corresponding to the attack on the *s-trans* conformer when the catalyst is $TiCl_4$. On the other hand, for the reaction with (formyltrimethylenemethane)$Fe(CO)_3$ catalyzed by BF_3, the product corresponding to the attack on the *s-trans* conformer is predicted to be favoured. These results have been interpreted through an energy decomposition analysis of the potential-energy barriers.

Key words: $Fe(CO)_3$ complexes, hetero-Diels–Alder reactions, density functional theory, Lewis acid catalysis.

Résumé : Faisant appel à la méthode de calcul de la fonctionnelle de la densité, on a étudié d'une façon théorique les réactions d'hétéro-Diels–Alder catalysées par des acides de Lewis du butadiène avec du formylbutadiène et du formyltriméthylèneméthane coordinés au $Fe(CO)_3$. Les résultats obtenus montrent que, pour la réaction avec le (formylbutadiène)$Fe(CO)_3$ catalysée par le BF_3, le produit le plus favorable d'un point de vue cinétique correspond à celui obtenu par une attaque du butadiène sur le conformère *s-cis* du fragment formylbutadiène alors que pour la réaction catalysée par le $TiCl_4$ le produit le plus favorable correspond à une attaque sur le conformère *s-trans*. Par ailleurs, pour la réaction avec le (formyltriméthylèneméthane)$Fe(CO)_3$, catalysée par le BF_3, les calculs prédisent que le produit favorisé serait celui correspondant à une attaque sur le conformère *s-trans*. On interprète ces résultats par le biais d'une analyse par décomposition de l'énergie des barrières à l'énergie potentielle.

Mots-clés : complexes $Fe(CO)_3$, réactions hétéro-Diels-Alder, théorie de la fonctionnelle de la densité, catalyse par un acide de Lewis.

[Traduit par la Rédaction]

Introduction

Diene tricarbonyl iron complexes are very valuable tools in organic synthesis.[2–12] The iron tricarbonyl unit is a very efficient protecting group for 1,3-diene and facilitates an excellent chirality transfer to the stereogenic centers created close to it. Moreover, the iron tricarbonyl unit directs the *anti* attack to the vicinal groups.

Experimental results suggest that the stereochemistry of the reactions taking place in unsaturated systems in positions vicinal to the organometallic unit is determined by the conformational bias of the reactant.[7–9] In this way, the addition of a nucleophile to a carbonyl group vicinal to a diene iron tricarbonyl moiety may lead to two different products, depending on the *s-cis* or *s-trans* conformation of the carbonyl group (see Scheme 1).

The *s-cis–s-trans* conformational equilibrium in this kind of compound has been theoretically studied,[13] and the results obtained were in good agreement with the diastereoselectivities experimentally observed in addition reactions.

A carbonyl group vicinal to diene iron tricarbonyl may also participate in cycloaddition reactions such as the hetero-Diels–Alder reaction reported by Donaldson et al.[14] In this case, a different ratio between diastereomers was obtained depending on the Lewis acid used as catalyst. In the presence of BF_3, the major product was the one corresponding to the attack of the *s-cis* conformer, whereas in the presence of $TiCl_4$, the product coming from the *s-trans* conformer was predominant . The same kind of dependence on the Lewis acid has been observed by Harvey and Selchau for the addition of several nucleophiles to the carbonyl group of (dienal)$Fe(CO)_3$ complexes.[11]

A similar hetero-Diels–Alder reaction has also been reported for a (formyltrimethylenemethane)$Fe(CO)_3$ complex.[15] In this case, the reaction catalyzed by BF_3 leads to the diastereomer corresponding to the attack of the *s-trans* conformer as the only product.

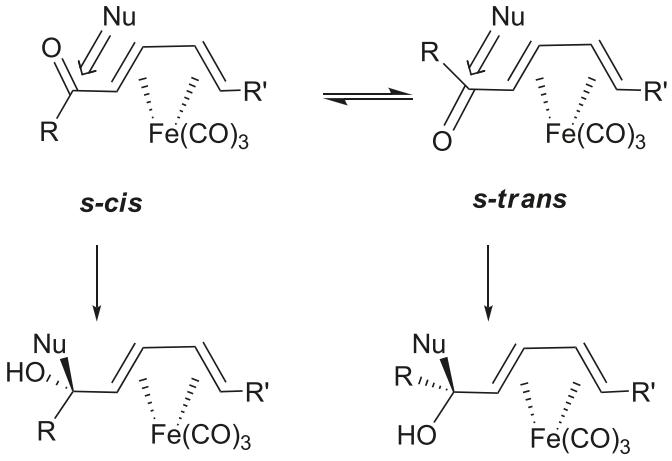
Scheme 1.



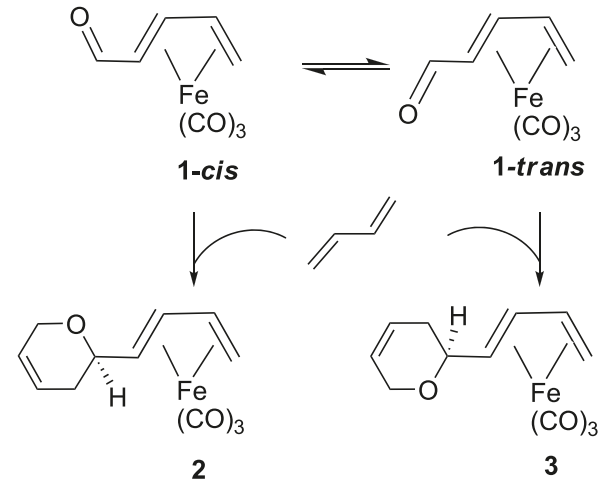
In this paper, we report a theoretical study of the hetero-Diels–Alder reactions of butadiene with formylbutadiene and formyltrimethylenemethane $Fe(CO)_3$ complexes catalyzed by Lewis acids. Our goals are to establish the role played by the conformational preferences of these complexes in the outcome of the reactions and to understand the different effect of the Lewis acids in the stereochemistry of the reactions.

Computational details

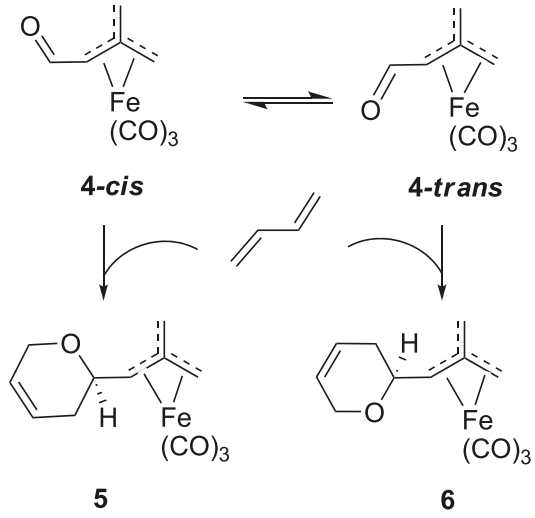
The geometries of all stationary points were optimized using the BPW91[16,17] density functional method with a LANL2DZ basis set[18] supplemented with d polarization functions for B, C, O, F, and Cl (LANL2DZ(d)). This basis set includes effective core potentials for the inner shells of Fe, Ti (up to 2p), and Cl, with a double-ζ expansion for the valence shells. For H, B, C, O, and F, the D95 basis set[19] was used. Harmonic vibrational frequencies were calculated for all structures to characterize them as energy minima (all frequencies are real) or transition states (one and only one imaginary frequency). All these calculations were carried out using the Gaussian-03 program.[20] To correct for possible deficiencies of the basis set, the energies of all structures were recalculated with the same functional and a larger basis set. These calculations were done with the ADF program[21] using a TZP basis set. This basis set is a triple-ζ basis set of uncontracted Slater orbitals supplemented by polarization functions (f for Fe and Ti; d for B, C, O, F, and Cl; and p for H). The inner shells of all atoms were treated with the frozen core approximation.[22]

Solvent effects were included using the CPCM method[23] implemented in the Gaussian-03 program. We used diethyl ether as solvent (ε = 4.335). Calculations in solution were done for geometries optimized in the gas phase. The hetero-Diels–Alder reaction between butadiene and acrolein was used as a model to check how the results change when geometries are optimized including the solvent effect. The obtained structures are shown as Supplementary data. The length of the forming C–O and C–C bonds vary by 0.085 and 0.067 Å, respectively, while the potential-energy barrier changes by only 0.1 kcal mol^{-1}.

Scheme 2.



Scheme 3.



The reported reaction energies and potential-energy barriers correspond to those calculated with the TZP basis set for the gas phase results and they have been corrected with the solvation energies computed with the LANL2DZ(d) basis set. Regarding the Gibbs energies, the reported values were computed from energies calculated with the TZP basis set and zero-point correction, and thermal energies and entropy were computed with the LANL2DZ(d) basis set. For bimolecular processes in solution, the correction associated to the change of reference state between gas phase (1 atm) and solution (1 mol L^{-1}) was included.

Results and discussion

We studied the reactions of butadiene with (formylbutadiene)$Fe(CO)_3$ **1** (see Scheme 2) and with (formyltrimethylenemethane) $Fe(CO)_3$ **4** (Scheme 3).

In both cases, the presence of the bulky $Fe(CO)_3$ group directs the attack *anti* with respect to this group. There are two different conformations arising from the rotation around the C–C(carbonyl) bond: *s-cis* and *s-trans*. The attack of butadiene to each one of these two conformers would lead to

Fig. 1. Structures of conformers of **1** and of their complexes with Lewis acids. Selected interatomic distances in Å.

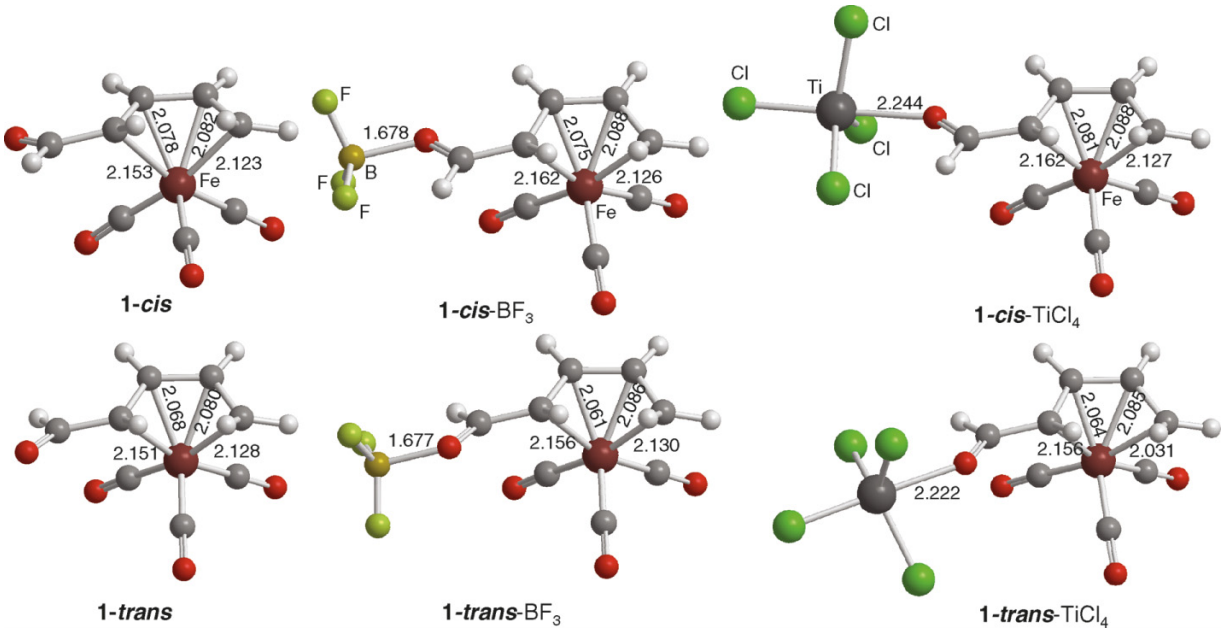


Fig. 2. Structures of conformers of **4** and of their complexes with BF_3. Selected interatomic distances in Å.

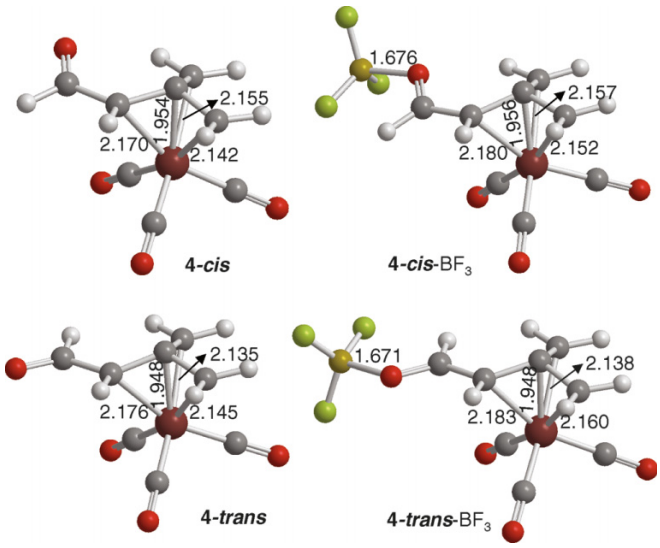

the formation of two diasteromers, **2** and **3**, for the reaction of **1,** and **5** and **6** for the reaction of **4**.

Figures 1 and 2 show the structures of *s-cis* and *s-trans* conformers of **1** and **4** and of their respective complexes with Lewis acids. Table 1 presents the relative energies of both conformers as well as their interconversion energy barriers.

The coordination of the Lewis acid always takes place in the plane of the carbonyl group with the Lewis acid *syn* with respect to the aldehydic hydrogen atom.[24]

Complexes with *trans* coordination were also studied, but they are higher in energy than those shown in Fig. 1. For **1**-*cis*, the coordination of BF_3 to one of the CO ligands was also considered, but the calculation led to a B–O distance of 2.98 Å.

For $TiCl_4$, the coordination of the carbonyl group led to a trigonal bipyramidal environment, with the oxygen occupying one of the axial positions.[25]

Other coordination modes were also explored for **1**-*cis*-$TiCl_4$, such as the out-of-plane coordination to the carbonyl group and the formation of a chelate complex involving the carbonyl group of the aldehyde and one of the CO ligands, but the system evolved to the structure shown in Fig. 1.

Table 1 shows that in all cases the *s-trans* conformer is the most stable one, the largest Gibbs energy difference between both conformers being 1.8 kcal mol^{-1} for **4**-BF_3 in solution. The Gibbs activation energies associated to the *s-trans–s-cis* conformational rearrangements are lower than 9 kcal mol^{-1} for the uncomplexed systems, and increase to values larger than 11 kcal mol^{-1} when the carbonyl group is complexed by a Lewis acid. For **1**-BF_3, there is a significant increase due to solvation.

We studied the reactions of **1**, **4**, and their complexes with Lewis acids with butadiene. For the uncatalyzed reactions, we considered both *endo* and *exo* transition states, the *endo* ones being the most favourable ones in all cases.

The structures of the transition states corresponding to all reactions are shown in Figs. 3 and 4, whereas those of the reaction products can be found in the Supplementary data.

Table 2 presents the values of the potential-energy barriers and Gibbs activation energies of all reactions. As we can observe, in all cases the potential-energy barriers for the cycloaddition reactions are notably larger than the *s-cis–s-trans* rearrangement barriers (see Table 1), so that an equilibrium between both conformers may be assumed.

For the catalyzed reactions, the inclusion of the solvent effect leads to a larger decrease in the Gibbs activation energies than for the uncatalyzed processes.

Regarding the geometries of the transition states, we can observe that, for the uncatalyzed reactions, the C–C and C–O bonds being formed are of similar lengths. By contrast, coordination of a Lewis acid produces a notable asymmetry in the transition states. A similar effect has already been

Table 1. Reaction and activation energies[a] and Gibbs energies[a,b] for the *s-trans–s-cis* conformational rearrangements of **1**, **4**, and their complexes with Lewis acids.

observed for hetero-Diels–Alder reactions of formaldehyde with butadiene catalyzed by BH_3[26] and of methyl vinyl ketone with furan catalyzed by BF_3.[27]

As we can observe in Table 2, for the reaction between **1** and butadiene catalyzed by BF_3, the attack to the *s-cis* conformer is the kinetically most favourable. The difference in energy barriers in solution leads to a predicted **3**:**2** ratio of 76.5:23.5 at 298.15 K, in excellent agreement with the experimental 75:25 ratio.[14] On the other hand, for the reaction catalyzed by $TiCl_4$ the attack to the *s-trans* conformer becomes the most favourable one with a predicted **3**:**2** ratio at 298.15 K of 34:66. In this case, the experimentally observed ratio is 21:79, so that the agreement is only qualitative.[14] For the reaction in the absence of a Lewis acid, the results predict that the attack to the *s-trans* conformer would also be the most favourable one.

Regarding the reactions between **4** and butadiene, the results presented in Table 2 show that in the absence of a Lewis acid the attack to the *s-trans* conformer is the most favourable one, while catalysis by BF_3 increases this preference. In this case, the difference between Gibbs activation energy barriers is not large enough to be consistent with the experimental results, since only a product like **6** was exper-

[a]In kcal mol^{-1}. See text for definitions.

imentally observed,[15] whereas the predicted **5**:**6** ratio at 298.15 K is actually only 18:82. In general, there is a good qualitative agreement between our results, obtained for reactions with butadiene, and the experimental observations made for reactions with substituted derivatives of butadiene. In most cases, the kinetically preferred products arise from the attack of the diene to the most stable conformer of the iron tricarbonyl complex. The only exception is the reaction of **1** catalyzed by BF_3.

For the catalyzed reactions, the selectivity of the reactions may also be predicted from gas phase potential-energy barriers instead of Gibbs activation energies in solution. For this reason, we carried out an energy partition analysis[28] to determine the origin of the selectivity.

The potential-energy barrier ($\Delta E^{\ddagger}$) for a cycloaddition reaction between a carbonyl group and butadiene can be partitioned into several terms[29]:

$$\Delta E^{\ddagger} = E_{prep} + E_{Pauli} + E_{elstat} + E_{orb}$$

The preparation energy, E_{prep}, is the energy necessary to distort the reactant molecules from their equilibrium geometries to the geometries they have at the transition state. E_{Pauli} is the Pauli repulsion term associated with closed-shell repulsions between both fragments at the transition state. E_{elstat} is the electrostatic interaction energy arising from the interaction between both fragments, each one having the electron density that it would have in the absence of the other fragment. The orbital interaction term, E_{orb}, arises when the electron densities of both fragments are allowed to relax and accounts for charge transfer and polarization. The results obtained from this analysis are shown in Table 3.

Table 4. LUMO energies of **1**, **4**, and their complexes with Lewis acids and charge transfer at the transition states of their reactions with butadiene.

In all cases, the Pauli repulsion term favours the attack to the *s-trans* conformers, whereas the electrostatic and orbital interaction terms favour the attack to the *s-cis* conformers. Since the *s-trans* conformers are more stable than the *s-cis* ones, the preparation energy is lower for the attack to the *s-trans* conformers, with the exception of the reaction of **1** in the absence of a Lewis acid. For this reaction, formation of the product arising from the attack to the *s-cis* conformer is the most favourable one kinetically. As we can observe in the *cis* transition state, the sum of the electrostatic and orbital interaction terms overcompensates for the larger Pauli repulsion.

In the reaction catalyzed by BF_3, the same trends are observed. However, when the reaction is catalyzed by $TiCl_4$, the contribution of the preparation energy and Pauli repulsion to the differences between energy barriers becomes dominant and the formation of the product arising from the attack to the *s-trans* conformer is predicted to be the most favourable one.

Regarding the uncatalyzed reaction between **4** and butadiene, the computed energy barrier has the same value for the attacks to both conformers of **4**. In the presence of BF_3, the sum of the contribution of preparation and Pauli repulsion terms dominates over the contribution of the electrostatic and orbital interaction terms, so that the formation of the product arising from the attack to the *s-trans* conformer becomes kinetically favoured.

In all reactions, butadiene acts as an electron donor, so that the most important interaction between fragment molecular orbitals involves the HOMO of butadiene and the LUMO of the organometallic fragment. Table 4 shows the energies of the LUMO of **1**, **4**, and their complexes with Lewis acids at their equilibrium geometries and at the geometries corresponding to the transition states of the reactions with butadiene and the charge transfer between butadiene and the organometallic fragments at these transition states.

Complexation of **1** or **4** by a Lewis acid stabilizes the LUMO and so increases the electrophilicity of the carbonyl group. As a consequence, the absolute value of the orbital interaction term (see Table 3) and the charge transfer from butadiene to the organometallic fragment at the transition state (see Table 4) increase. This fact is associated with a notable decrease of the distance between butadiene and the carbonylic carbon atom at the transition state, which also leads to an increase in the Pauli repulsion energy and in the absolute value of the electrostatic term.

The coordination by a Lewis acid always tends to favour the transition states corresponding to the *s-trans* conformers. In the uncatalyzed reaction between **1** and butadiene, the attack on the *s-cis* conformer of **1** is kinetically favoured. The difference between energy barriers decreases when the reaction is catalyzed by BF_3, but the formation of **2** is still kinetically favourable. Complexation by $TiCl_4$ makes the transition state corresponding to the attack to the *s-trans* conformer the lowest in energy, so that the formation of **3** becomes kinetically favoured over the formation of **2**.

Regarding the reaction between **4** and butadiene, for the uncatalyzed process there is no preference for either of the two possible transition states. In this case, the effect of BF_3 complexation makes the formation of **6** the kinetic most favourable process.

Concluding remarks

We have studied the hetero-Diels–Alder reactions of butadiene with (formylbutadiene)$Fe(CO)_3$ (**1**) and (formyltrimethylenemethane)$Fe(CO)_3$ (**4**) catalyzed by Lewis acids. The potential-energy barriers of these reactions are always larger than the barriers associated with the *s-cis*–*s-trans* conformational rearrangement of the formyl group, so that an equilibrium between both conformers may be assumed. In all cases the *s-trans* conformer is the most favourable one. However, the reactions with butadiene leading to the formation of the most favourable diastereomers do not always involve the most stable conformer of the corresponding reactant. In the reaction between **1** and butadiene catalyzed by BF_3, the most favourable product corresponds to the attack of butadieneon the *s-cis* conformer of **1**. On the other hand when the reaction is catalyzed by $TiCl_4$, the most favourable attack takes place on the *s-trans* conformer. In the reaction between **4** and butadiene catalyzed by BF_3, the kinetically most favourable diasteromer corresponds to the attack of butadiene on the *s-trans* conformer of **4**. All these results may be interpreted through an energy partition analysis of the potential-energy barriers. According to this analysis, complexation by a Lewis acid tends to favour the reaction with *s-trans* conformers, since steric repulsion dominates over electrostatic and orbital interaction terms which favour the attack to *s-cis* conformers. In the reaction between **1** and butadiene, catalysis by BF_3 decreases the selectivity with respect to the uncatalyzed reaction, while with $TiCl_4$ the selectivity is reversed. Finally, for the reaction between **4** and butadiene, the catalyst increases the preference for the attack to the *s-trans* conformer of **4**.

Supplementary data

Supplementary data for this article (structures of the transition state of the reaction between butadiene and acrolein in the gas phase and in diethyl ether solution, structures of the reaction products and reaction energies of the reactions of **1** and **4** with butadiene) are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 3967. For more information on obtaining material, refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml.

Nonlinear time-dependent density functional theory studies of the ionization of CO_2 by ultrashort intense laser pulses[1]

Emmanuel Penka Fowe and André Dieter Bandrauk

Abstract: Time-dependent density functional theory (TDDFT) studies of the ionization of CO_2 by intense laser pulses (3.50×10^{14}, 1.40×10^{15}, 2.99×10^{15}, and 1.25×10^{16} W/cm^2) at 800 nm ($\omega = 0.0584$ au) are presented in the nonlinear nonpertubative regime. Special emphasis is placed on elucidating molecular orbital orientation and various peak-intensities effects on the ionization processes. The results reveal that molecular orbital ionizations are strongly sensitive to their symmetry and the laser intensities. Most notably, we found that with a proper choice of the laser intensity (3.5×10^{14} W/cm^2), the sensitivity is strong enough such that the nature and symmetry of the highest occupied molecular orbital (HOMO) can be directly probed and visualized from the angular dependence of laser-induced ionization. At higher intensities, ionization is found to occur also from inner orbitals, thus complicating the imaging of simple orbitals. A time-dependent electron-localization function (TDELF) is used to get a visual insight on the time evolution process of the electron density.

Key words: TDDFT, orbital ionization, molecular ionization, molecular symmetry, TDELF.

Résumé : Opérant dans un régime non perturbant et non linéaire, on a effectué des études selon la théorie de la fonctionnelle de la densité en fonction du temps (TFDFT) de l'ionisation du CO_2 par des pulsations laser intenses ($3{,}50 \times 10^{14}$; $1{,}40 \times 10^{15}$; $2{,}99 \times 10^{15}$ et $1{,}25 \times 10^{16}$ W/cm^2) à 800 nm ($\omega = 0{,}0584$ au). On a placé une emphase spéciale sur l'élucidation de l'orientation de l'orbitale moléculaire et sur les effets des intensités des divers pics sur les processus d'ionisation. Les résultats révèlent que l'ionisation des orbitales moléculaires est très sensible à leur symétrie et aux intensités laser. La caractéristique la plus notable observée a trait au fait qu'avec un choix approprié d'intensité laser ($3{,}50 \times 10^{14}$ W/cm^2), la sensibilité est suffisamment forte que la nature et la symétrie de l'orbitale moléculaire haute occupée peuvent être directement examinées et visualisées à partir de la dépendance angulaire de l'ionisation induite par le laser. À des intensités plus élevées, on a trouvé que l'ionisation se produit aussi à partir des orbitales internes et que cette situation complique la visualisation des orbitales simples. On a fait appel à une fonction de localisation électronique en fonction du temps (FLEFT) pour obtenir une meilleure compréhension du processus d'évolution de la densité électronique en fonction du temps.

Mots-clés : théorie de la fonctionnelle de la densité en fonction du temps (TFDFT), ionisation d'orbitale, ionisation moléculaire, symétrie moléculaire, fonction de localisation électronique en fonction du temps (FLEFT).

[Traduit par la Rédaction]

Introduction

In the last two decades, the interaction of atoms and molecules with intense laser pulses has attracted widespread research. One of the reasons is that laser fields induce interesting nonlinear electron dynamics, such as multiphoton ionization[2] (MPI), above-threshold ionization[3] (ATI), and tunnelling ionization[4] (IT). Numerous experiments on the molecular ionization have been performed[5–7] thanks to the refinement technique[8] of the molecular orientation and alignment. More recently, tomography[9] imaging has emerged as a powerful tool to obtain the shape of the active molecular orbital. While experimental efforts for better understanding of the ionization processes are growing, theoretical investigations are still limited, even though computational power is increasing rapidly. Our group (Kamta and Bandrauk[10]) has developed recently, for one-electron systems[11] (H_2^+, HeH^{++}, and H_3^{++}), an approach of solving exactly the time-dependent Schrödinger equation (TDSE) to investigate the sensitivity of the orientation dependence of molecular ionization to the symmetry and the electron distribution in active molecular orbitals, based on Born–Oppenheimer (fixed nuclei) and dipole approximations ($r << \lambda$, where r is the dimension of charges and λ is the wavelength of the electric field). For the theoretical study of multielectrons system, the so-called ADK[12] (Ammosov–Delone–Krainov) model.

In the ADK, one commonly assumes that each electron moves independently in the ionization single-electron approximation where only the weakest bound valence electron interacts with the laser. The ionization process is also treated

by tunnelling in the laser field of one-center expansions of a field-free multicenter function. The MO-ADK theory does not account for the many-electron effect, including the change of screening such as those discussed in the density functional approach. The theory also does not extend to regions where tunneling ionization is not the dominant ionization mechanism.

The major difficulties in the theoretical study of molecular systems in a laser field reside on the multicenter nature of the molecule, including the treatment of the electron–electron interactions.[10,11]

In this paper, we study the ionization process of CO_2 in an intense few laser field. CO_2 is an important molecule present in the earth's atmosphere, volcanic gases, oceans, ice cores in Antarctica, and so forth. It plays a primordial role in the photosynthesis process of plants, in human physiology, and in atmospheric processes. Its electronic structure determination via ionization has been the subject of several studies.[6,7,13] Villeneuve et al.[7] have obtained the angular dependence of ionization of linear molecules N_2, O_2, and CO_2 by recording the ion yield as a function of the angle between the polarization axis of the ionizing field and the main axis of the alignment distribution. Their fitted-results from the deconvolution of the ionization yield with the alignment distribution yield a butterfly-like distribution from the π symmetry of the HOMO of O_2 and CO_2; additionally, the angular dependence of the ionization of carbon dioxide is narrowness and peaks at 46° to the laser field, whereas the MO-ADK model predicts 25°. We remarked that in Fig. 6 in a previous work,[14] where single-electron π-orbital probabilities bend to smaller angles with increasing atoms separation, since there is no electron repulsion. So, the difference may be regarded as the manifestation of multielectron interactions effects, which are not properly take into account in the MO-ADK models.

To analyze the electron dynamics of the ionization process in CO_2, we have considered various laser pulse intensities and durations to probe the behaviour (symmetry and orientation) of the different molecular orbitals in the presence of a few cycles intense laser pulse. We have used the time-dependent density functional theory[15] approach, TDDFT, in the nonlinear nonperturbative regime (beyond conventional linear response theory,[16] which is extensively used nowadays for different spectroscopy properties[17]). This method is found to give a good compromise between accuracy and computer time, and is currently used.[18] Because details of our theoretical approach are given elsewhere,[19] we briefly review the formulation necessary for the present study in strong laser fields.

For a visual understanding of the electron motion on CO_2 during the time propagation under strong laser pulses, we used the time-dependent approach of the electron-localization function (ELF).[20–22] Conceptually, the physical idea is based on the fact that a highly localized electron repels other electrons stronger. Then, the ELF makes use of the probability to find a second like-spin electron in the vicinity of the first one as a measure for electronic localization. When applied to molecules, ELF's usefulness stem from the manner it allows to show a clear separation between the core and valence electron, and also shows covalent bonds and lone pairs, in the spirit of valence-shell electron-pair repulsion theory (VSEPR).

Nonpertubative TDDFT

Kohn–Sham formalism

The TDDFT method provides the most detailed and feasible ab initio approach for tackling many-body problems. Density functional theory (DFT) as first introduced by Hohenberg and Kohn,[23] and extended by Kohn and Sham (KS[24]) is based on the existence of an exact mapping between one-particle density and external potentials. This leads to the density of the interacting system being obtained from the density of an auxiliary system of non-interacting particles moving in an effective local single-particle potential. A time-dependent generalization of DFT was provided by Runge and Gross,[15] showing that there is a one-to-one correspondence between the external (time-dependent) potential, $\upsilon_{ext}(r,t)$, and the time-dependent one-electron density, $n(r,t)$, for many-body systems evolving from a fixed initial state. The time-dependent electronic density is written as[25]

$$[1] \qquad n(r,t) = \sum_{\sigma=\uparrow,\downarrow} n_\sigma(r,t) = \sum_{\sigma=\uparrow,\downarrow} \sum_{i}^{N_\sigma} |\psi_{i\sigma}(r,t)|^2$$

where, N_σ is the number of the electrons in the spin state σ and $\psi_{i\sigma}$ (r,t) is the orbital obtained through the time-dependent KS equations (in au):

$$[2] \qquad i\frac{\partial}{\partial t}\psi_{i\sigma}(r,t) = \left[-\frac{1}{2}\nabla^2 + \upsilon_{\text{eff}}(r,t)\right]\psi_{i\sigma}(r,t)$$

where

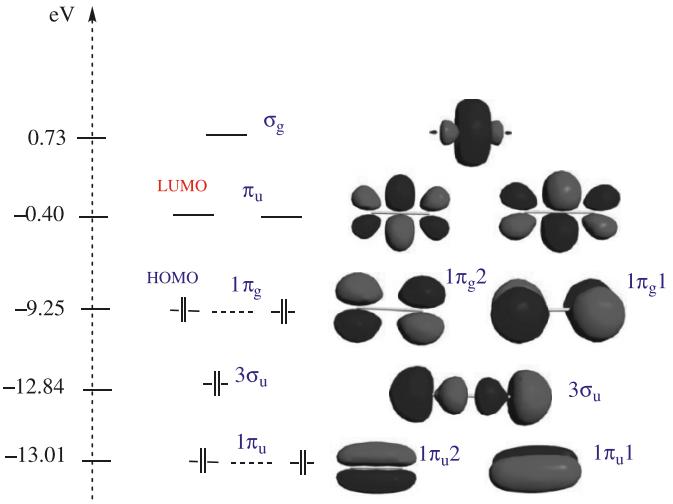
$$[3] \qquad \upsilon_{\text{eff}}(r,t) = \upsilon_{\text{ext}}(r,t) + \upsilon_{\text{h}}(r,t) + \upsilon_{\text{xc},\sigma}(r,t)$$

The first term is the external potential, due to the interaction of the electron with an external laser field and the nuclei, while the second term accounts for the classical hartree electrostatic interaction between electrons, and the third, the exchange correlation (xc) potential includes all non-trivial many body effects, and has an extremely complex (and essentially unknown) functional[19,24] dependence on the density. This dependence is non-local both in space and in time; thus, the quality of numerical solutions of eq. [2] will depend on the quality of the approximation to the xc potential used. KS proposed a simple approximation to xc, the local density approximation (LDA[26]). This functional uses the knowledge of the xc energy of the homogeneous electron gas[27] and has turned out to be quite adequate for a number of applications in time-independent problems.

Time-dependent electron-localization function (TDELF)

The ELF is a method for the mapping of electron-pair probability in multielectron systems. It was first introduced by Becke and Edgecombe[22] as a descriptor of electronic localization, using arguments based on the conditional same-spin pair probability function, generally for the Hartree–Fock approach. Thereafter, the function was readapted for DFT by Savin et al.[28] They interpreted the ELF in terms of the excess of local kinetic energy density due to the Pauli repulsion, and the Thomas–Fermi kinetic energy density for a homogeneous electron gas used as reference. Here, we briefly recall the definitions of the extension of the ELF for the time-dependent processes,[20,21] the time-dependent ELF, or TDELF, $\eta(r,t)$, is given as

Fig. 1. DFT/LDA images of the molecular orbitals of CO_2. Only the five highest occupied molecular orbitals are plotted.



$$[4a] \qquad \eta(r,t) = \frac{1}{1 + [C(r,t)/C_h(r,t)]^2}$$

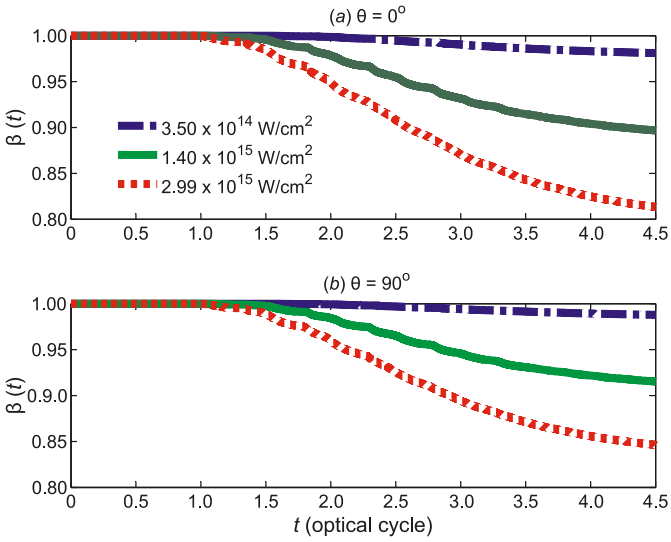
where

$$[4b] \qquad C(r,t) = \sum_{\sigma} \left\{ \sum_{i=1}^{N_\sigma} |\nabla \psi_{i\sigma}(r,t)|^2 - \frac{1}{4}\frac{[\nabla n_\sigma(r,t)]^2}{n_\sigma(r,t)} - \frac{j_\sigma^2(r,t)}{n_\sigma(r,t)} \right\}$$

$$[4c] \qquad C_h(r,t) = \frac{3}{5}(6\pi^2)^{2/3} n_\sigma(r,t)^{5/3}$$

j_σ^2 is the squared modulus of the current density. $C(r,t)$ measures the probability of finding one electron in the near vicinity of a reference like-spin electron at position r and time t. Thus, the Pauli repulsion between two like-spin electrons, described by the smallness of $C(r,t)$, is taken as a measure of the electron localization. $C_h(r,t)$ is the corresponding factor found for uniform electron gas, i.e., a homogeneous electron gas whose density is the same as that of the real system. Equation [4*b*] is valid only for one-determinantal wave functions, and therefore lends itself to be used within the context of HF or DFT. This expression has a convenient scaling factor to obtain values between 0 and 1. High values, $\eta(r,t) \rightarrow 1$, are associated to a high probability to find an electron pair, whereas the value $\eta(r,t) = 0.5$ indicates that the effect of the Pauli repulsion is the same as in the uniform electron gas of the same density. When applied to molecules, an analysis of the ELF shows a clear separation between the core and valence electron pairs (bonds and lone pairs) in the spirit of the Lewis theory. So, the ELF performs a partition of real molecular space into chemically meaningful regions and has been proven useful for describing the nature of the chemical bond in a wide variety of situations in comparison with electron densities.[21,29] In the present work, the TDELF will be used for the time-resolved observation of the molecular ionization, and can thus provide a visual understanding of the particle dynamic (most notably lone-pair and bond electrons) under strong laser pulses.

Fig. 2. Normalized total population, $\beta(t)$, as a function of laser intensities I (W/cm^2).



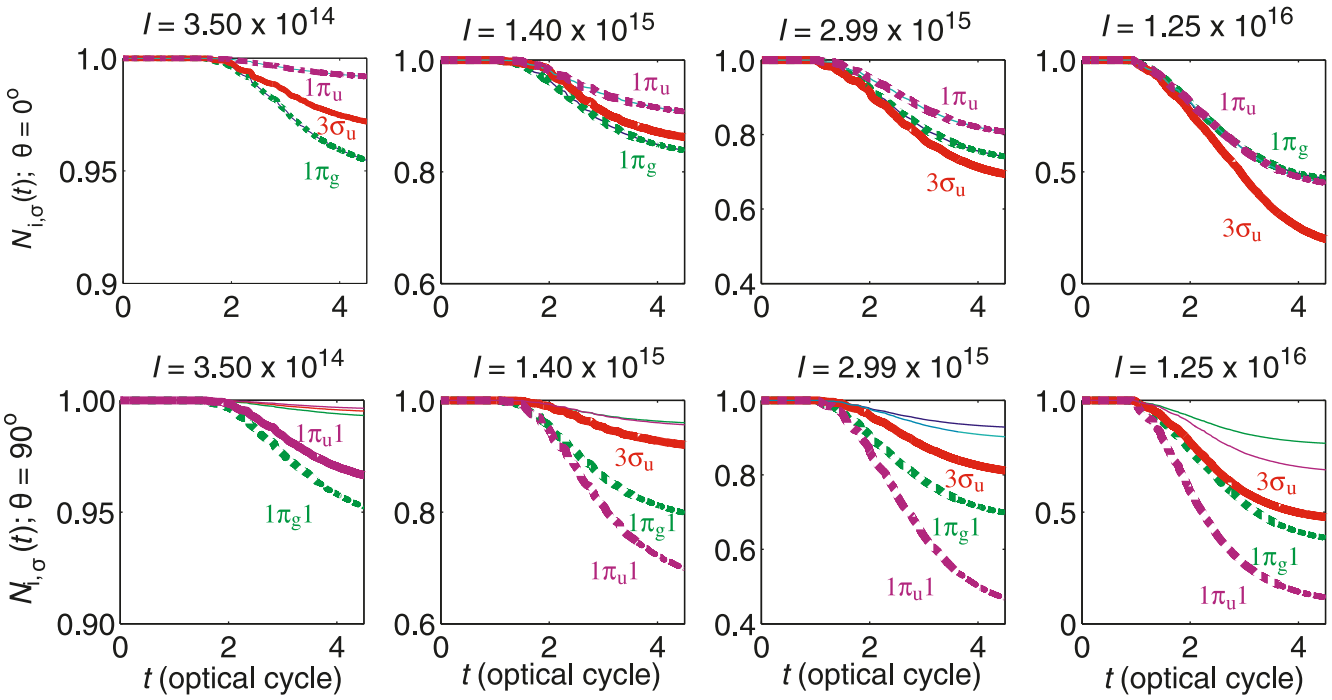
Computational details

The TDDFT KS equation, eq. [2], was discretized in space using grid technique combined with the Troullier–Martin pseudopotential,[30] and the resulting computer code was parallelized to run on a massively parallel processor. We have placed a CO_2 molecule in a large three-dimensional (3D) cubic grid cell (atomic units au, are used) of dimension a = 64 au The uniform finite-difference grid spacing, Δa = 0.26 au, was used for numerical integration, and the convergence of the calculations was checked against results with slightly smaller grid spacing. The external potential caused by an intense laser field is assumed to arise from an oscillating electric field with a cosinoidal envelope of the form:

$$[5] \qquad \upsilon_{ext}(r,t) = r \cdot E(t);\ E(t) = A_o \cos^2\left(\frac{\pi(t - 2\tau - t_o)}{2\tau}\right)\sin(\omega t)$$

A_o is the maximum field strength, τ is half of the total pulse duration, ω = 0.0584 au, and t_o is chosen such that $|t\text{-}t_o| < \tau$. The laser field linear polarization is set parallel to the molecular axis (z), and we have defined θ as the molecular orientation angle. The total area, $\int_{-\infty}^{+\infty} E(t)dt = 0$ ensures no spurious static effects.[4] The time-dependent equations are solved using the approximated enforced time-reversal symmetry method[31] to propagate the electronic wave functions with the time step Δt = 0.003 au. This method was found stable and provided a correct energy,[32] norm conservation, and was less computer-time-consuming than a Crank–Nicolson scheme.[33] We have used the local density approximation (LDA) of Perdew and Zunger[34] to represent the exchange-correlation potential υ_{xc}. To absorb the electrons reflecting spuriously at the boundary of the box, we included an imaginary poten-

Fig. 3. KS orbital population, $N(t)$, as a function of the laser intensities I (W/cm^2); only the relevant KS orbitals, which possess an important response to the laser fields, are shown with their label. Upper (*a*): the laser is parallel to the CO_2 axis, and bottom (*b*): the laser is perpendicular to the CO_2 axis.



tial[35] in the Hamiltonian of the system. Thus, once the time-dependent wave functions and the time-dependent electron density were obtained, we have easily calculated the time-dependent ionization probability, $P_{i,\sigma}$, of an individual spin-orbital according to

$$[6] \qquad P_{i,\sigma} = 1 - N_{i,\sigma}(t)$$

where

$$[7] \qquad N_{i,\sigma}(t) = \langle \psi_{i,\sigma}(t) | \psi_{i,\sigma}(t) \rangle$$

is the time-dependent population (suvival probability) of the i,σ-th spin-population. In the grid, the number of the electrons inside the box is given as

$$[8] \qquad N_{\text{bound}}(t) = \int_{\text{inside the box}} d^3r \; n(r,t)$$

and the normalized remaining electron population is

$$[9] \qquad \beta(t) = \frac{\int_{\text{inside the box}} d^3r \; n(r,t)}{\int_{\text{inside the box}} d^3r \; n(r,0)} = e^{-\Gamma t}$$

Γ is the ionization rate, and

$$n\,(r,0) = \sum_{\sigma=\uparrow,\downarrow} n_\sigma(r,0) = \sum_{\sigma=\uparrow,\downarrow} \sum_{i}^{N_\sigma} |\psi_{i\sigma}(r,0)|^2$$

is the total number of electrons in the initial state (without external field). The ionization yield probability, $\gamma(t_f)$, computed at the final time, t_f, of the propagation is then deduced as the following difference:

$$[10] \qquad \gamma(t_f) = 1 - \beta(t_f)$$

and the KS orbital ionization, $\delta(t_f)$, is deduced as

$$[11] \qquad \delta(t_f) = 1 - N_{i,\sigma}(t_f)$$

Results and discussion

Electronic analysis and ionization potential in DFT/LDA

The relevant information of the ground-state geometry of CO_2 is that the molecule is linear and the computed CO bond length is 1.161 Å, which is in good agreement with the experimental[36] value (CO = 1.162 Å).

The analysis of the electronic structure from the DFT-KS equation is depicted in Fig. 1. The five highest occupied KS molecular orbitals with their phases are presented. The nodal properties, which correctly reflect the g and u character of the orbitals, are visible. One finds that the highest occupied molecular orbital (HOMO), $1\pi_g$, is antibonding. It is formed of π lobes lying perpendicular to the internuclear axis and located on the oxygen atoms. We note from our DFT/LDA calculation that the energies of the $1\pi_u$ and $3\sigma_u$ are close (we have found a difference of the magnitude of 0.2 eV). Recently, it has been established that Kohn–Sham orbitals are physically[37] sound and are expected to be more suitable for use in qualitative molecular-orbital theory than either Hartree–Fock or semiempirical orbitals. In fact, the exact exchange–correlation potential, υ_{xc}, should give the exact ionization potential (IP) corresponding to the negative of the KS HOMO energy ($-\varepsilon_{HOMO}$). In the present work, due to the LDA approximation, we have carried out the calculation of IP by the computation of the vertical ionization potential. This is done by a proper subtraction of the total

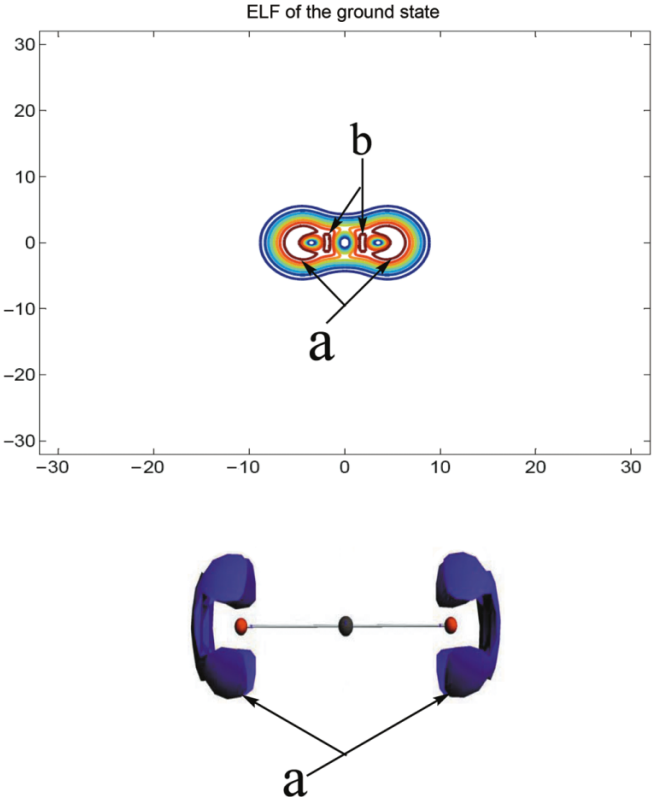
energies for the neutral and the cation obtained at the equilibrium geometry of the neutral. One has to emphasize that "vertical" here means the underlying assumption that no geometrical structural changes occur during the ionization process. The computed value of the vertical IP is 14.26 eV, which is near to the available experimental[38] data 13.77 eV.

CO_2 ionization

Our time-dependent calculation allows a detailed analysis of the ionization process as it evolves with time. From the initial ground state, we have propagated in time the KS orbitals, and computed the ionization factor according to eq. [9]. We display in Fig. 2 the dependence of the total normalized remaining population, $\beta(t)$, with different laser peaks intensities (3.50×10^{14}, 1.40×10^{15}, and 2.99×10^{15} W/cm^2) at

Fig. 6. DFT/LDA representation of the ELF for the ground state of CO_2: isosurfaces (bottom) of the ELF with a value of 0.85 reveal the lone pairs (a) as lobes on the oxygen atoms and contour maps (top) of the ELF for throughout the plane containing all atoms. The most localized electron regions, which correspond to the lone pair (a) and the CO bond (b), are clearly visible.



800 nm wavelength. Calculations have been done for four optical cycle pulse duration.

Two molecular orientations have been considered, $\theta = 0^\circ$ and $\theta = 90^\circ$. One observes a strong dependence of the remaining electron population, $\beta(t)$, on the laser intensities. So, the higher the laser intensity, the lower the remaining electron population. A close look reveals that the ionization is sensitive to the orientation, θ, of the molecule with respect to the laser field; ionization at $\theta = 0^\circ$ is higher than that at $\theta = 90^\circ$. Similar results have been observed in H_2^+ from exact TDSE calculations.[10]

Orbital influence on the ionization

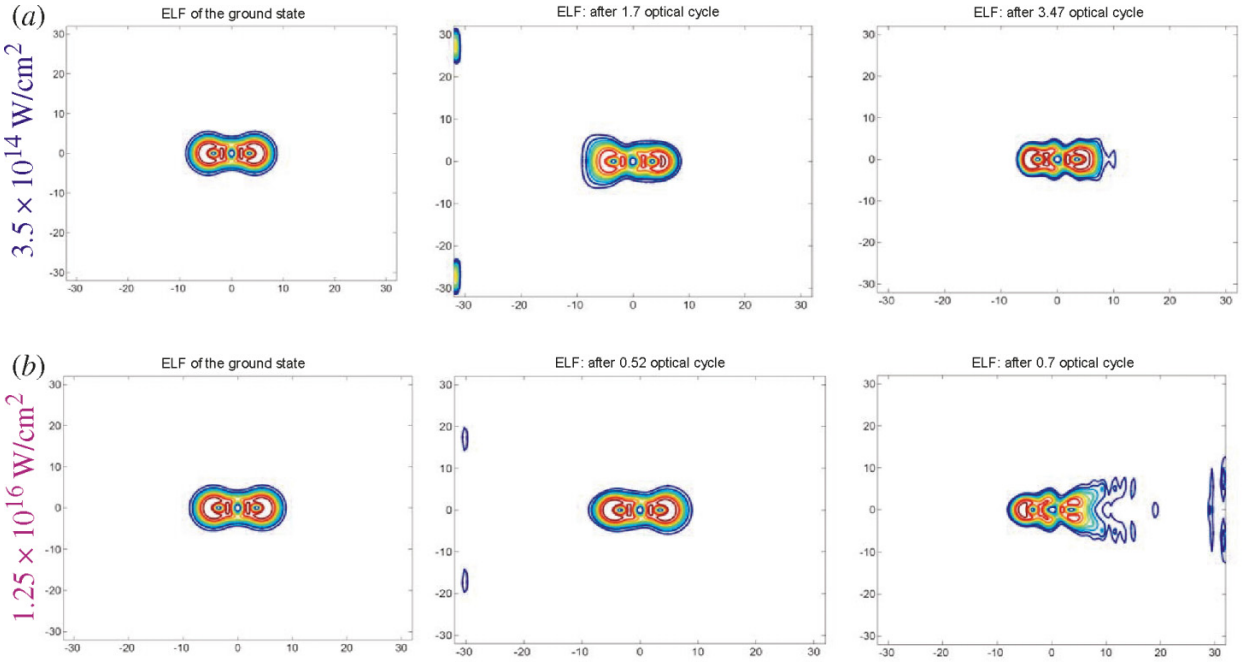
To gain a better understanding of the ionization dynamics as a function of the orbital symmetries, we investigate, in Fig. 3, the time-dependent evolution of some relevant KS molecular orbitals by the aid of eq. [7].

The ionization rate of each KS, $\Gamma_i = -(\ln(N_{i,\sigma}(t))/t$ for the molecular orbital, $\psi_i(r,t)$ can be obtained as the slope of the decay of the population in time (see Supplementary data, Table S) of its orbital norm (see eqs. [9]–[10]). The laser (electric) field is assumed to be either parallel ($\theta = 0^\circ$) or perpendicular ($\theta = 90^\circ$) to the CO_2 molecular axis, and the internuclear distance for the molecule is fixed at its equilibrium distance. Results for four laser intensities, 3.50×10^{14}, 1.40×10^{15}, 2.99×10^{15}, and 1.25×10^{16} W/cm^2, are shown. According to the molecular orientation, we have subdivided Fig. 3 in two parts, named respectively, Fig. 3*a* where $\theta = 0^\circ$ and Fig. 3*b* with $\theta = 90^\circ$. In Fig. 3*a*, one sees that for symmetry reason, the two components of each π orbital have the same behaviour. One finds also that the KS molecular orbitals are sensitive to the applied laser field intensities, so at lower intensities, 3.50×10^{14} and 1.40×10^{15} W/cm^2, it emerges that the $1\pi_g$ molecular orbital shows the dominant response to the field and is followed by the inner $3\sigma_u$ orbital whose ionization is growing with the laser intensities. For the last two intensities, 2.99×10^{15} and 1.25×10^{16} W/cm^2, the inner $3\sigma_u$ molecular orbital presents the dominant response to the field, whereas the effect of the valence $1\pi_g$ orbital on the ionization process is decreasing and is getting closer to that of the $1\pi_u$ orbital, probably resulting from the enhancement of the coupling between these orbitals, which results in charge–resonance enhanced ionization (CREI), enhanced ionization in H_2^+ at large internuclear distance.[11] Our results show that the orientation effect of the orbital plays a key role in the ionization process. In regard to our data, we can say that the anisotropy of the ionization of CO_2 is more significant at smaller laser intensities where the expected higher valence orbital is more active, whereas at higher intensity, the inner, $3\sigma_u$ electrons whose orbital orientation is parallel to the polarization direction of the laser field ionizes faster.

Figure 3*b* treats the cases of the laser oriented perpendicularly to the CO_2 molecular axis, the symmetry contribution of the different components of the π orbital (e.g, π_g components are renamed π_g1 and π_g2) is broken, as a consequence of their orientation, i.e., each component of the KS π orbital is feeling the presence of the laser field in a different way. At lower intensity, 3.50×10^{14} W/cm^2, as in the previous analysis, the $1\pi_g$ molecular orbital shows the dominant response to the field and is followed by the inner $1\pi_u$ orbital. As the intensity is increasing, the response effect of the $1\pi_u$ orbital becomes more and more pronounced than that of $1\pi_g$. This behaviour illustrates a rather complicated correlated response of the orientation of the different orbitals to the intense laser field. Meanwhile, one of the main results is that at 3.50×10^{14} W/cm^2, the $1\pi_g$ orbital remains the most influenced by the laser. Thus, it appears that at 3.50×10^{14} W/cm^2, single ionization of CO_2 occurs predominantly by ionization of the valence electron of the HOMO. To see the effect of the laser pulse duration, τ, on the ionization process, we have calculated, for 3.50×10^{14} W/cm^2, the orbital ionization during 10 laser pulse cycles, and we have found that it is increasing with the pulse duration, and more importantly, the electron is always ionized from HOMO, the highest occupied molecular orbital $1\pi_g$.

To analyze the details of the angular-dependent ionization rate of CO_2, the corresponding ionization probability, $\gamma(t_f)$, eq. [10] vs. the orientation angle, θ, is plotted in polar coordinates in Fig. 4. Some experimental data are also showed for comparison. The calculations were performed with, θ, varying from 0° to 90° (5° angle step) and were reflected to the rest of the trigonometric circle to give a complete picture. It appears from our result that the ionization rate peaks somewhere between 30° and 40°, and shows minima at 0° and 90°. This, because the HOMO has a nodal plane containing (or perpendicular to) the molecular axis, is giving

Fig. 7. Snapshot of the TDELF for 3.5×10^{14} W/cm^2 (left and noted (*a*) in the text) and for 1.25×10^{16} W/cm^2 (right and noted (*b*) in the text).



rise to a low probability for ionization when aligned parallel (or perpendicular) to the laser electric field, and this is corroborated by exact TDSE calculations in H_2^+.[10]

Furthermore, the ionization at $\theta = 0^\circ$ is higher compared with that at $\theta = 90^\circ$, in good correlation with our orbital ionization results in Fig. 3. More generally, our plot (Fig. 4*d*) exhibits a butterfly pattern, which is characteristic of the $1\pi_g$ orbital and clearly shows a good agreement with the experimental result (Fig. 4*b*).[7] The nonzero and negligible ionization at $\theta = 0^\circ$ and $\theta = 90^\circ$ reflects contributions from the $3\sigma_u$ orbital at $\theta = 0^\circ$ and the $1\pi_u$ at $\theta = 90^\circ$. We repeated the previous operation to image the $3\sigma_u$ and $1\pi_u$ molecular orbitals by the calculation of the molecular-orbital ionization from the eq. [11]. The results are shown in Fig. 5. We find once again that for the selected molecular orbitals, our model reproduces the shape of the corresponding ground-state molecular orbital. However, one observes an absence of nodal planes on the $1\pi_u$ molecular orbital, and a lengthening of the form of the $3\sigma_u$ molecular orbital. This may be regarded as the result of a coupling of the selected MO with some virtual orbitals.[10]

TDELF analysis

The two-dimensional representation of the ELF isosurfaces for the ground state of CO_2 is presented in Fig. 6. The figure depicts a slab of the ELF passing through the plane containing the molecule. The most localized domains are clearly visible, and they correspond to the lone pairs on the oxygen atoms and the C–O bond electrons.

The comparison of ELFs in the ground state and during the time propagation (TDELF) is showed in Fig. 7*a* for 3.5×10^{14} W/cm^2 and in Fig. 7*b* for 1.25×10^{16} W/cm^2. We point out that the induced dipoles from $1\pi_u$ (HOMO) and $3\sigma_u$ (HOMO-1) are polarized in opposite direction. In Fig. 7*a*, one sees that after 1.7 optical cycles, the first electronic perturbation occurs as expected on the lone pairs of the oxygen atom and while the two domains (lone pair and C–O bond) are subsequently affected by the laser field during the propagation, we note that the perturbation is much higher on lone pairs. In Fig. 7*b*, our results show that at the very beginning of the interaction of CO_2 with the laser field (after 0.52 optical cycle), as previously, one observes that the electronic perturbation appears on the lone pairs of the oxygen, but thereafter and suddenly, it is greatly exceeded by that emerging from the C–O bond domain. It will remain so throughout the simulation. These observations are consistent with our findings in Fig. 3. We add a table of the ionization rate, which shows the increasing importance of inner orbitals with the laser intensities.

Conclusion

In this work, orbital populations, $N_{i,\sigma}(r, t)$, and ionization yields, $\gamma(t_f)$, have been computed for CO_2 molecule with different laser intensities from a nonlinear nonpertubative TDDFT approach.[19,25] In view of all results, we conclude that both the symmetry of the KS orbitals and the laser intensities play an important role in the ionization process. We showed that for 3.5×10^{14} W/cm^2, the orientation dependence of the ionization probability maps the electron distribution in the active orbital, thereby allowing to image the contour of electron density distributions in molecules. We have introduced time-dependent electronic localization function, TDELF, to visualize the ionization dynamics. Further refinements are required, since it is a well-known property of the static DFT/LDA that the single-particle ionization threshold is underestimated,[19] due to the wrong asymptotic behaviour of the KS potential or the self interaction error (SI).[25,37] The SI effect arises from the interaction of an electron with itself, and it is related to Coulomb energy of the KS Hamiltonian, which is not, in contrast to the Hartree–

Fock (HF) and post-HF approach, totally cancelled by the exchange contribution. Work to improve the cancellation of the SI by either the mixing in of half-and-half exchange, combining a (local) GGA exchange functional with the (nonlocal) HF (so-called hybrid functionals[39]) or by using the exact exchange based on the optimized effective potential[40] (OEP) as developed by Krieger, Li, and Iafrate (KLI[41]), is in progress for orbital functionals to include memory effects and derivative discontinuities.[7,42]

A solid-state ^{31}P NMR study of 1:1 silver–triphenylphosphine complexes — Interpretation of $^{1}J(^{107,109}Ag,^{31}P)$ values[1,2]

Fu Chen, Se-Woung Oh, and Roderick E. Wasylishen

Abstract: High-resolution solid-state ^{31}P NMR spectroscopy was used to investigate a series of 1:1 silver–triphenylphosphine complexes, $[Ph_3PAgX]_n$, where X is a monovalent anion and n = 1, 2, 3, 4, or ∞. The ^{31}P CP MAS NMR spectra reveal the number of distinct phosphorus sites in these complexes as well as the $|^{1}J(^{109}Ag,^{31}P)|$ values, which range from 401 ± 10 Hz ($X = N_3^-$) to 869 ± 10 Hz ($X = SO_3CF_3^-$). The data obtained here and in earlier investigations indicate that $|^{1}J(^{109}Ag,^{31}P)|$ values for silver–tertiary phosphine complexes decrease as Ag–P bond lengths increase. This experimental conclusion is supported by DFT calculations, which also indicate that the Fermi-contact mechanism is the only important spin–spin coupling mechanism for $^{1}J(^{109}Ag,^{31}P)$ in these complexes. In addition, the crystal structure of a silver–triphenylphosphine trifluoroacetate tetramer was determined using X-ray crystallography, and the structure of a silver–triphenylphosphine chloride tetramer was reinvestigated.

Key words: silver(I)–triphenylphosphine complexes, solid-state ^{31}P NMR, $^{1}J(^{107,109}Ag,^{31}P)$ values, DFT calculations.

Résumé : On a fait appel à la RMN du ^{31}P en phase solide et à haute résolution pour étudier une série de complexes 1:1 argent:triphénylphosphine, $[Ph_3PAgX]_n$ dans lesquels X est un anion monovalent et n = 1, 2, 3, 4, ou ∞. Les spectres RMN du ^{31}P par la technique de polarisation croisée avec rotation à l'angle magique (PC RAM) révèlent le nombre de sites distincts de phosphore dans ces complexes ainsi que les valeurs de $|^{1}J(^{109}Ag,^{31}P)|$ qui s'échelonnent de 401 ± 10 Hz ($X = N_3^-$) jusqu'à 869 ± 10 Hz ($X = SO_3CF_3^-$). Les données obtenues dans ce travail et dans d'autres effectués antérieurement indiquent que les valeurs de $|^{1}J(^{109}Ag,^{31}P)|$ pour les complexes d'argent avec des phosphines tertiaires diminuent avec une augmentation de la longueur des liaisons Ag–P. Cette conclusion expérimentale est en accord avec les résultats de calculs effectués d'après la théorie de la fonctionnelle de la densité (TFD), ce qui indique aussi que le mécanisme de contact de Fermi est le seul mécanisme important de couplage spin–spin affectant la valeur de $^{1}J(^{109}Ag,^{31}P)$ dans ces complexes. De plus, faisant appel à la diffraction des rayons X, on a déterminé la structure cristalline d'un tétramère d'argent et de trifluoroacétate de triphénylphosphine et on a réétudié la structure du tétramère d'argent et du chlorure de triphénylphosphine.

Mots-clés : complexes d'argent(I) et de triphénylphosphine, RMN du ^{31}P en phase solide, valeur de $^{1}J(^{109}Ag,^{31}P)$, calculs selon la théorie de la fonctionnelle de la densité (TFD).

[Traduit par la Rédaction]

Introduction

Coinage-metal tertiary phosphine complexes $[L_mMX]_n$, where L is a tertiary phosphine ligand, m = 1–4, M is Cu(I), Ag(I), or Au(I), X is a monovalent anion, and n = 1, 2, 3, 4, or ∞, have attracted much interest because they display a wide variety of structure types involving a range of metal coordination numbers.[3–14] Most of these studies have involved ligands such as triphenylphosphine (Ph_3P), tricyclohexylphosphine (Cy_3P), 1-phenyldibenzylphosphole (DBP), 1-phenyl-3,4-dimethylphosphole (DMPP), butyldiphenylphosphine (Ph_2BuP), or other closely related phosphines. For most group-11 metal phosphine complexes, the metal oxidation state is +1 and the valence electron configuration is nd^{10}. This electron configuration generally leads to complexes with low coordination numbers, typically two, three, or four. Vibrational and NMR spectroscopy as well as X-ray diffraction are critical tools for characterizing group-11 transition-metal phosphine complexes. In particular, solid-state ^{31}P NMR spectroscopy has been demonstrated to be significantly important in providing insights about molecular structure and bonding in the complexes; for example, see refs. 9–27.

The most common structure for the 1:1 coinage-metal tertiary phosphine complexes of the type $[LMX]_n$ are the cubane and chair structures (Scheme 1).[10,28–31] However, several other structures are also known, depending on the steric requirements of both the ligand L and the anion X.[32–38] The number of distinct phosphorus sites or metal–phosphorus bonds in these complexes can be identified by the number of distinct ^{31}P chemical shifts from NMR spectroscopy. Here, we illustrate the value of solid-state ^{31}P NMR spectroscopy in characterizing a series of 1:1 silver–

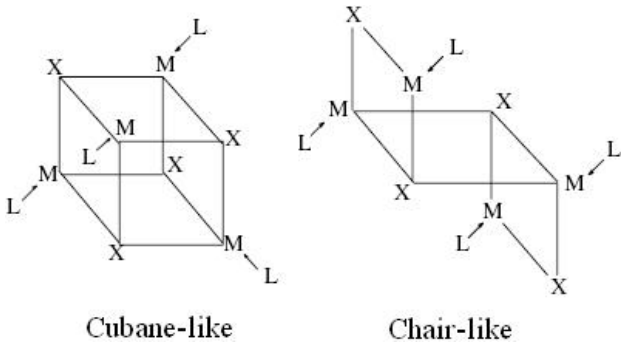
Scheme 1.



triphenylphosphine complexes of the type $[Ph_3PAgX]_n$. In general, for these complexes, each distinct phosphorus site consists of four peaks in the ^{31}P NMR spectrum, two due to ^{109}Ag–^{31}P indirect spin–spin coupling (^{109}Ag, I = 1/2, N.A. = 48.2%, $\gamma = -1.2518 \times 10^7$ rad s^{-1} T^{-1}) and two due to ^{107}Ag–^{31}P indirect spin–spin coupling (^{107}Ag, I = 1/2, N.A. = 51.8%, $\gamma = -1.0889 \times 10^7$ rad s^{-1} T^{-1})[39]; the $^1J(^{109}Ag,^{31}P)$ values are approximately 1.15 times those for $^1J(^{107}Ag,^{31}P)$ because ^{109}Ag has a slightly larger (in magnitude) magnetogyric ratio than ^{107}Ag. It should be mentioned that, on the basis of first-principles calculations (vide infra), the $^1J(^{109}Ag,^{31}P)$ and $^1J(^{107}Ag,^{31}P)$ values reported here are negative.

Earlier, Nelson and co-workers found a linear relationship between $^1J(^{63,65}Cu,^{31}P)$ and the inverse cube of the Cu–P bond length, $1/r^3_{CuP}$ for a series of copper(I)–tertiary phosphine complexes.[9–11] They also found a linear relationship between ^1J(Ag,P) and $1/r^3_{AgP}$ for $[(Ph_3P)_nAgNO_3]$ (n = 1–4),[10,11] although at that time the number of silver–tertiary phosphine complexes for which both solid-state ^{31}P NMR and X-ray crystal structure data had been reported was limited. The authors suggested that these results indicate that the Fermi-contact mechanism is the dominant mechanism for $^1J(^{63,65}Cu,^{31}P)$ and $^1J(^{107,109}Ag,^{31}P)$. However, based on these observations alone, such a conclusion is difficult to prove. For example, in the "simple" hydrogen molecule where the Fermi-contact mechanism completely dominates, ^1J(H,H) increases as the bond length increases.[40–42] In this study, we have examined several silver–tertiary phosphine complexes to determine if indeed there is a correlation between experimental ^1J(Ag,P) values and the Ag–P bond length as reported by Nelson.[10,11] We have also carried out density functional theory (DFT) calculations of ^1J(Ag,P) to determine whether the experimental trends are reproduced and to determine the dominant mechanism contributing to ^1J(Ag,P) values.

Background and theory

Ramsey[43] first described the theory of indirect nuclear spin–spin coupling in 1953, using second-order perturbation theory, in terms of three mechanisms, which together account for the interaction of the coupled nuclei with the electronic network of the molecule. These mechanisms, generally denoted as the spin-orbital (SO), spin-dipolar (SD), and Fermi-contact (FC) mechanisms, have been described in numerous review articles and textbooks (see ref. 44 for an example). In 1964, Pople and Santry[45] presented an approximate molecular orbital description of spin–spin coupling, which was later extended by Buckingham and Love.[46] Following Ramsey,[43] the isotropic indirect spin–spin coupling, ^nJ(A,B), can be written as a sum of three contributions,

$$[1] \qquad {}^nJ(A,B) = {}^nJ(A,B)_{SO} + {}^nJ(A,B)_{SD} + {}^nJ(A,B)_{FC}$$

The SO mechanism describes the interaction between the nuclear magnetic moment and the orbital magnetic moment arising from the motion of the electrons and can be further divided into diamagnetic SO (DSO) and paramagnetic SO (PSO) contributions; the former depends on the ground electronic state while the latter involves allowed excitations between the ground and singlet excited states. The PSO mechanism contributes significantly to both the isotropic J and the anisotropy of the **J** tensor in the presence of formal multiple bonds.[47] The second mechanism, SD, is the interaction between the nuclear magnetic moment and the magnetic field arising from the spin of the electrons not located at the nucleus. The FC mechanism accounts for the interaction between a nuclear spin and an electron spin which has a finite probability of being at the nucleus (i.e., s electrons); this term is purely isotropic and hence does not contribute to anisotropy of the **J** tensor. In addition to the three mechanisms discussed above, there is also a purely anisotropic SD × FC cross term, which only contributes to the anisotropic **J** tensor and does not contribute to J.[46] In 1977, Pyykkö[48] extended Ramsey's nonrelativistic theory to include relativistic effects; other relativistic theories have since been presented.[49,50] For any given spin–spin coupling tensor, all these mechanisms may be important;[51] however, in the early literature, it was common to assume that the FC mechanism was the most important contribution to the isotropic J.

In this study, ^1J(Ag,P) values were calculated for model complexes, $[(CH_3)_3PAgX]$, with different monovalent anions using DFT. This method was selected because of its applicability to relatively large systems as opposed to ab initio methods, which are currently limited to small molecules containing relatively light atoms.

Experimental

Sample preparation

Because silver compounds are generally light sensitive, all synthetic work was undertaken in a dark room and where appropriate, the reactions were carried out in dry solvents under an N_2 atmosphere. All silver salts and triphenylphosphine, Ph_3P, were purchased from Sigma-Aldrich Chemicals, Inc. Most 1:1 silver–triphenylphosphine complexes, silver triphenylphosphine halides, $[Ph_3PAgX]_4$ (X = Cl, Br, I),[28–31] silver triphenylphosphine trifluoromethane sulfonate, $[Ph_3PAgSO_3CF_3]_3$,[32,33] silver triphenylphosphine acetate, $[Ph_3PAgOC(O)CH_3]_4$,[34] silver triphenylphosphine bromate, $[Ph_3PAgBrO_3]_4$,[35] silver triphenylphosphine nitrate, $[Ph_3PAgNO_3]_\infty$,[20,36] silver triphenylphosphine azide, $[Ph_3PAgN_3]_n$,[36] silver triphenylphosphine nitrite, $[Ph_3PAgNO_2]_\infty$,[37] and silver triphenylphosphine quinine,[38] were prepared as reported in the literature. Silver triphenylphosphine trifluoroacetate, $[Ph_3PAgOC(O)CF_3]_4$, and silver triphenylphosphine hexafluorophosphate, $[Ph_3PAgPF_6]_n$,

were synthesized using the same method as for $[Ph_3PAgOC(O)CH_3]_4$.[34] Silver triphenylphosphine thiocyanate, $[Ph_3PAgSCN]_n$, and silver triphenylphosphine cyanate, $[Ph_3PAgCNO]_n$, were synthesized following the method used for the preparation of $[Ph_3PAgN_3]_n$.[36]

Single-crystal X-ray diffraction

Single-crystal X-ray diffraction data were acquired for two complexes, $[Ph_3PAgCl]_4$ and $[Ph_3PAgOC(O)CF_3]_4$, using a Bruker PLATFORM/SMART 1000 CCD diffractometer (Mo Kα, λ = 0.71073 Å graphite monochromator). Structures for $[Ph_3PAgCl]_4$ and $[Ph_3PAgOC(O)CF_3]_4$ were solved by direct methods using DIRDIF-99[52] and refined with SHELXL-93.[53] A single crystal of $[Ph_3PAgCl]_4$ was slowly recrystallized from a mixture of $CHCl_3$ and ether; 35517 reflections were collected in the range $4.54^\circ < 2\theta < 52.62^\circ$, of which 6863 were independent. A single crystal of $[Ph_3PAgOC(O)CF_3]_4$ was slowly recrystallized from toluene; 25974 reflections were collected in the range $5.24^\circ < 2\theta < 53.24^\circ$, of which 8459 were independent.

Solid-state ^{31}P NMR spectroscopy

Phosphorus-31 NMR spectra were acquired using a Chemagnetics CMX Infinity 200 (B_0 = 4.70 T) spectrometer as well as Bruker Avance 300 (B_0 = 7.05 T) and 500 (B_0 = 11.75 T) NMR spectrometers with the combination of standard cross-polarization (CP), magic angle spinning (MAS), and proton decoupling. Samples were packed in 4 mm o.d. rotors. Proton 90° pulse widths of 2.5 or 4.0 μs, contact times of 3 or 5 ms, and pulse delays of 10 to 120 s were used to acquire most ^{31}P NMR spectra. Phosphorus-31 chemical shifts were referenced with respect to 85% aqueous phosphoric acid by setting the isotropic peak of an external solid ammonium dihydrogen phosphate sample to 0.81 ppm.[54] All spectra were acquired at ambient temperature with a sample spinning frequency of 3.0 or 5.0 kHz.

Theoretical calculations of ^1J(Ag,P)

To reduce computational times, the phenyl groups for the 1:1 silver–triphenylphosphine complexes were replaced with methyl groups. The effect of different monovalent anions, $[(CH_3)_3PAgX]$ (X = Cl, Br, I, CN, NC, OCH_3, OC(O)H and $OC(O)CH_3$) on ^1J(Ag,P), was investigated. The molecular structures used to generate the nuclear coordinates for the ^1J(Ag,P) calculations were obtained from geometries optimized using Gaussian 03.[55] The optimizations were performed using the B3LYP functional with the DZVP basis set for Ag, the LANL2DZ basis set for I, and the 6–31G* basis set for the remaining atoms. The same functional and basis sets were also employed to calculate ^1J(Ag,P) with the same program.

DFT calculations of ^1J(Ag,P) were also performed using the CPL module[56–59] of the ADF program (ADF 2005.01).[60–64] The Vosko–Wilk–Nusair (VWN) local density approximation,[65] with the Becke–Perdew generalized gradient approximation (GGA),[66–68] was used for the exchange-correlation functional. Relativistic calculations including spin-orbital and scalar corrections were carried out using the zeroth-order regular approximation (ZORA) formalism.[69–72] The FC, SD, PSO, and DSO mechanisms were included in all *J* calculations; a description of these mechanisms, as implemented in the ZORA formalism, has been presented.[73] The basis sets available with the ADF program consist of Slater-type functions. The TZ2P basis set is of triple-ζ quality with two sets of polarization functions while the DZP basis set is of double-ζ quality with one set of polarization func-

tions. For relativistic calculations, the TZ2P basis set, optimized for ZORA calculations, was used for the silver, phosphorus, oxygen, carbon, nitrogen, chlorine, bromine, and iodine nuclei, while the DZP basis set was used for the hydrogen atoms.

Results and discussion

Solid-state ^{31}P NMR spectroscopy

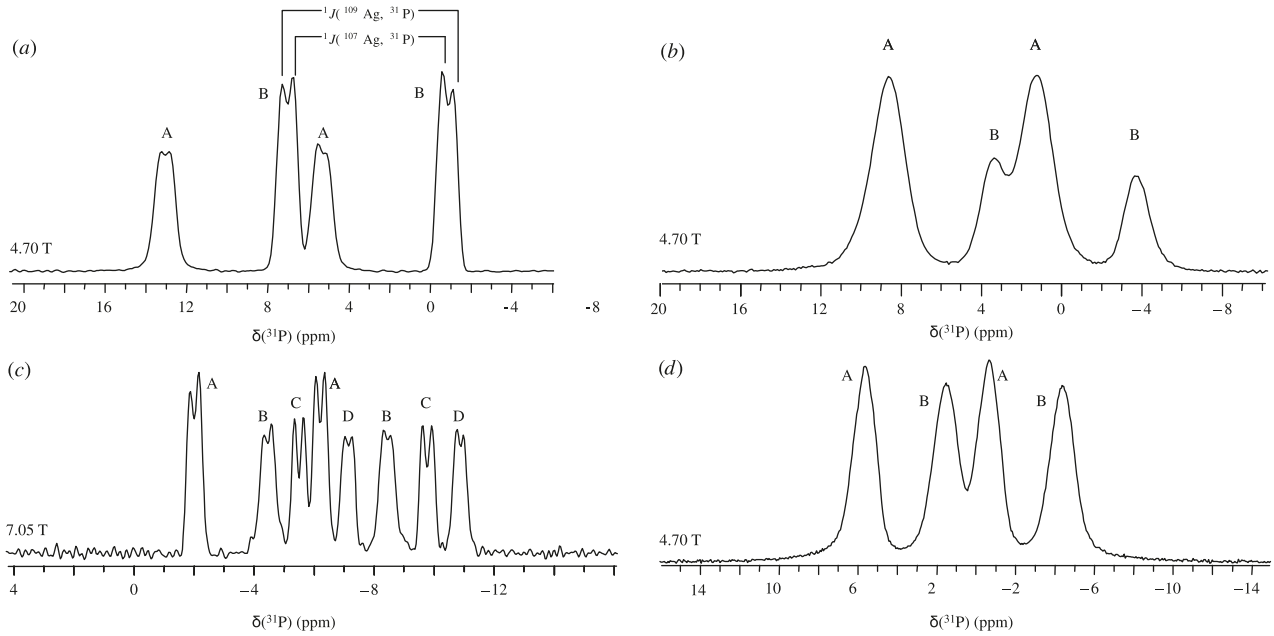
Selected single-crystal X-ray diffraction data for several of the 1:1 silver–triphenylphosphine complexes considered here are summarized in Table 1. Phosphorus-31 chemical shifts and ^1J(Ag,P) values measured for these complexes in the solid state are summarized in Table 2.

X = Cl⁻, Br⁻, and I⁻

The single-crystal X-ray diffraction data (see Supplementary data) for $[Ph_3PAgCl]_4$ indicate that this compound possesses a distorted cubane-like structure with C_2 symmetry along the *b*-axis. There are two distinct phosphorus sites with two crystallographically equivalent phosphorus atoms in each. These results are in agreement with previous X-ray results.[29] A ^{31}P NMR spectrum of an MAS sample of $[Ph_3PAgCl]_4$ is shown in Fig. 1*a*. As mentioned earlier, each distinct phosphorus site generally consists of four peaks in the ^{31}P NMR spectrum due to the indirect spin–spin coupling of ^{109}Ag–^{31}P and of ^{107}Ag–^{31}P. Thus, the eight peaks in the isotropic region indicate that there are two distinct phosphorus sites, in agreement with the single-crystal X-ray diffraction data. The isotropic chemical shifts are 9.2 ± 0.2 and 3.1 ± 0.2 ppm. The $|^1J(^{109}Ag,^{31}P)|$ values corresponding to the two phosphorus sites are 663 ± 10 and 681 ± 10 Hz, whereas the $|^1J(^{107}Ag,^{31}P)|$ values are 586 ± 10 and 593 ± 10 Hz, respectively.

A ^{31}P NMR spectrum of an MAS sample of $[Ph_3PAgBr]_4$ recrystallized from a mixture of $CHCl_3$ and ether is shown in Fig. 1*b*. The four peaks in the isotropic region indicate that there are also two distinct phosphorus sites with isotropic chemical shifts of 5.1 ± 0.2 and 0.1 ± 0.2 ppm; in this case, $^1J(^{107}Ag,^{31}P)$ cannot be resolved from $^1J(^{109}Ag,^{31}P)$. The line

Fig. 1. Solid-state ^{31}P NMR spectra of MAS samples (ν_{rot} = 5 kHz) of (*a*) $[Ph_3PAgCl]_4$, (*b*) $[Ph_3PAgBr]_4$, (*c*) $[Ph_3PAgI]_4$, (cubane-like), and (*d*) $[Ph_3PAgI]_4$ (chair-like) acquired at room temperature. The labels, A, B, C, and D correspond to distinct phosphorus sites for each complex.



broadening in the experimental spectra are attributed to ^{79,81}Br–^{31}P residual dipolar interactions. The average $|^1J(^{107,\ 109}Ag,^{31}P)|$ values corresponding to the two phosphorus sites are 593 ± 15 and 564 ± 15 Hz, respectively. From the reported single-crystal X-ray data, the distorted cubane-like structure of $[Ph_3PAgBr]_4$ has C_3 symmetry, with three phosphorus atoms that are crystallographically equivalent and one distinct site,[30] consistent with the ~3:1 ratio of integrated intensities for the two ^{31}P sites.

$[Ph_3PAgI]_4$ is known to crystallize in a cubane-like or chair-like structure, depending on how it is recrystallized.[31] According to the literature,[31] $[Ph_3PAgI]_4$ recrystallized from a mixture of $CHCl_3$ and ether has the cubane-like structure; the ^{31}P NMR spectrum of an MAS sample of this polymorph is shown in Fig. 1*c*. The sixteen peaks in the isotropic region indicate that there are four distinct phosphorus sites in the unit cell; the ^{31}P chemical shifts and $^1J(^{107,109}Ag,^{31}P)$ values are listed in Table 2. The ^{31}P NMR results are in agreement with the reported distorted cubane-like structure with C_1 symmetry,[31] in which all four phosphorus atoms are crystallographically distinct. Chair-like $[Ph_3PAgI]_4$ was obtained by recrystallizing the complex in a mixture of CH_2Cl_2 and ether; the ^{31}P NMR spectrum of an MAS sample of this polymorph, shown in Fig. 1*d*, indicates that there are two distinct phosphorus sites in this complex, in agreement with the centrosymmetric C_i chair-like geometry.[31] However, unlike for the cubane-like structure, the pair of doublets for each phosphorus site, arising from indirect spin–spin coupling to both ^{107}Ag and ^{109}Ag, is not resolved; the reason for this is unclear. Possibly, ^{127}I–^{31}P residual dipolar coupling contributes to the ^{31}P NMR linewidth in the chair-like complex. Cubane-like and chair-like $[Ph_3PAgI]_4$ have different $|^1J(Ag,P)|$ values and ^{31}P chemical shifts for each phosphorus site, although the average $|^1J(Ag,P)|$ values for the two polymorphs are similar, approximately 490 Hz. The spectra shown in Figs. 1*c* and 1*d* provide an excellent example of the sensitivity of ^{31}P NMR spectra to polymorphism.

X = $CO_2CF_3^-$, $CO_2CH_3^-$, BrO_3^-, $SO_3CF_3^-$, and PF_6^-

The structure of $[Ph_3PAgOC(O)CF_3]_4$ determined by single-crystal X-ray diffraction (see Supplementary data), shown in Fig. 2*a*, as well as those for $[Ph_3PAgOC(O)CH_3]_4$,[34] and $[Ph_3PAgBrO_3]_4$,[35] indicate that these complexes have an Ag_2O_2 core and possess a centrosymmetric C_i pseudo-chair-like geometry with two distinct phosphorus sites. Phosphorus-31 NMR spectra of MAS samples of $[Ph_3PAgOC(O)CF_3]_4$ are shown in Fig. 3*a*; those for $[Ph_3PAgOC(O)CH_3]_4$ are similar. The eight well-resolved peaks in the isotropic regions of the spectra for these compounds indicate that there are indeed two distinct phosphorus sites.[34]

Unfortunately, we were unable to prepare $[Ph_3PAgBrO_3]_4$ following the literature method.[35] However, the ^{31}P NMR spectrum (not shown) of an MAS sample of the compound is similar to that for $[(Ph_3P)_2AgBrO_3]$ published previously.[35] The ^{31}P NMR spectrum indicates that there are two similar phosphorus sites with similar $|^1J(Ag,P)|$ values, 490 ± 15 Hz (Table 2), in agreement with the literature values for $[(Ph_3P)_2AgBrO_3]$.[35] Thus, the compound prepared here is $[(Ph_3P)_2AgBrO_3]$, not $[Ph_3PAgBrO_3]_4$.

The molecular structure of $[Ph_3PAgSO_3CF_3]_3$ (Fig. 2*b*) consists of one unique silver atom (Ag1) in a trigonal-planar arrangement bonded to a phosphorus atom (P1) of one phosphine and to two oxygen atoms from different triflate units. There are two other silver atoms in the structures (Ag2 and Ag3), each in distorted tetrahedral configurations bonded to the phosphorus atom (P2 or P3) of one phosphine and three oxygen atoms from different triflate units.[32,33] This indicates that the bonding environments about P2 and P3 are similar

Fig. 2. Molecular structures of (*a*) $[Ph_3PAgOC(O)CF_3]_4$ (see Supplementary data for further details) and (*b*) $[Ph_3PAgSO_3CF_3]_3$.[32,33] For clarity, the fluorine atoms of the CF_3 groups are not shown.

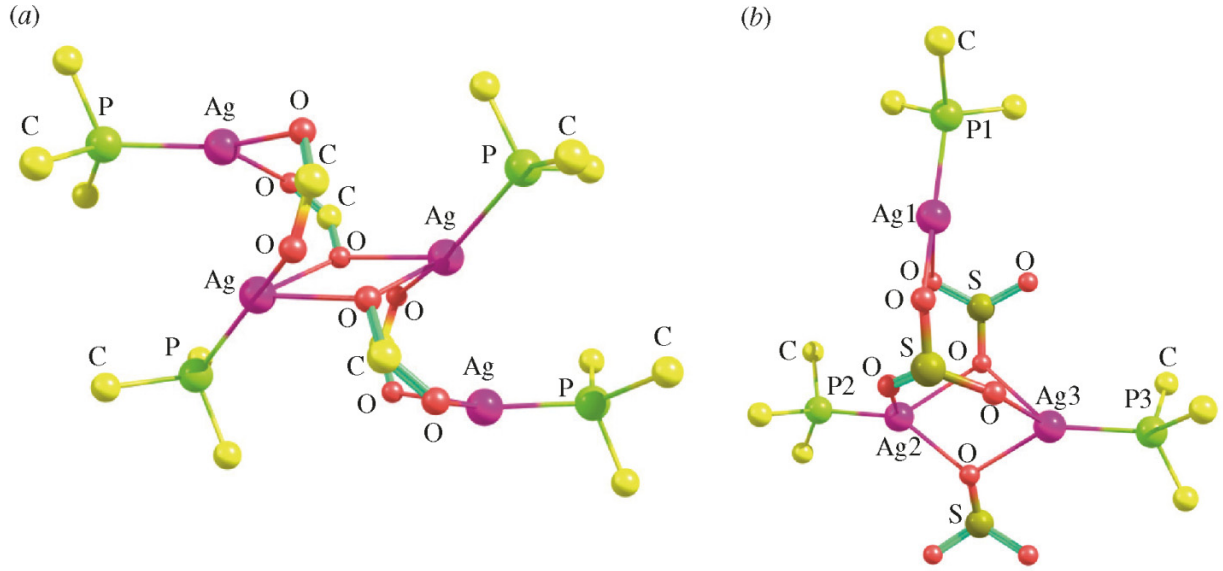


Fig. 3. Solid-state ^{31}P NMR spectra of MAS samples (ν_{rot} = 5 kHz) of (*a*) $[Ph_3PAgOC(O)CF_3]_4$, (*b*) $[Ph_3PAgSO_3CF_3]_3$, (*c*) $[Ph_3PAgNO_2]_\infty$, and (*d*) $[Ph_3PAgN_3]_4$ acquired at room temperature and at the indicated magnetic field strengths. The labels, A, B, C, and D correspond to distinct phosphorus sites for each complex.

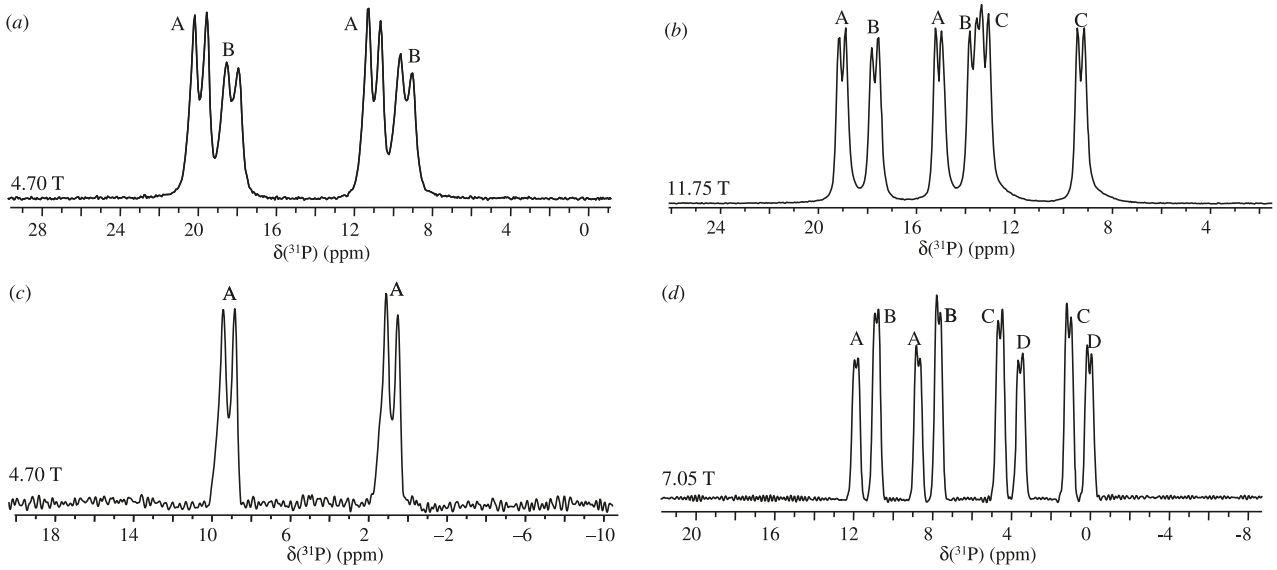


and that of P1 is different, consistent with the ^{31}P NMR spectrum of an MAS sample shown in Fig. 3*b*: there are three distinct phosphorus sites, two of which have similar chemical shifts and $^1J(^{107\,109}Ag,^{31}P)$ values (Table 2).

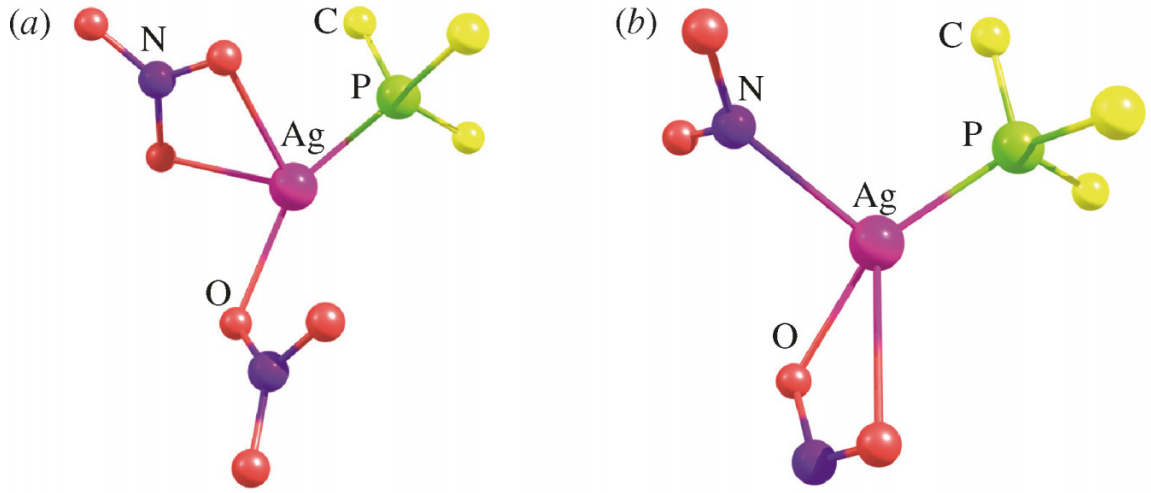
Single-crystal structural data for silver–triphenylphosphine hexafluorophosphate, $[Ph_3PAgPF_6]_n$, are unavailable. Phosphorus-31 NMR spectra of MAS samples of $[Ph_3PAgPF_6]_n$, which are similar to that shown in Fig. 3*a*, indicate that there are two distinct phosphorus sites of equal population for the PPh_3 group in this complex, suggesting the molecular formula is either $[Ph_3PAgPF_6]_2$ or $[Ph_3PAgPF_6]_4$.

X = NO_3^- and NO_2^-

The structure of $[Ph_3PAgNO_3]_\infty$ determined by X-ray diffraction measurements at 193 and 295 K, and the ^{31}P chemical shifts as well as $^1J(^{107,109}Ag,^{31}P)$ values (Table 2) have been reported previously.[20] Because $[Ph_3PAgNO_3]_\infty$ undergoes a phase transition at 299 K, different NMR parameters are obtained above and below this temperature.[20]

Single-crystal X-ray diffraction data indicate that the structure of $[Ph_3PAgNO_2]_\infty$[37] at 295 K is similar to that of $[Ph_3PAgNO_3]_\infty$.[20] Both are monoclinic with the same space group, $P2_1/c$ (No. 14), and similar unit cell parameters: a = 10.2430(14) Å, b = 18.521(3) Å, c = 9.1373(12) Å, β = 90.596(3)° for $[Ph_3PAgNO_3]_\infty$[20]; a = 10.191(1) Å, b = 8.906(2) Å, c = 18.086(2) Å, β = 88.281(3)° for $[Ph_3PAgNO_2]_\infty$.[37] For $[Ph_3PAgNO_3]_\infty$, shown in Fig. 4*a*, the silver atom is coordinated with two oxygen atoms from one $-NO_3^-$ group, one oxygen atom from another $-NO_3^-$ group and the phosphorus atom of the $-PPh_3$ group.[20] For

Fig. 4. Molecular structures of (*a*) $[Ph_3PAgNO_3]_\infty$[20] and (*b*) $[Ph_3PAgNO_2]_\infty$.[37]



$[Ph_3PAgNO_2]_\infty$, shown in Fig. 4*b*, the silver atom is coordinated with the two oxygen atoms of one $-NO_2^-$ group, the nitrogen atom of another $-NO_2^-$ group and the phosphorus atom of the $-PPh_3$ group.[37]

The ^{31}P NMR spectrum of an MAS sample of $[Ph_3PAgNO_2]_\infty$ shows that there is one phosphorus site (Fig. 3*c*). The ^{31}P chemical shift is different from the value $\delta(^{31}P)$ = 16.1 ppm obtained in solution, probably arising from a different silver coordination environment for $[Ph_3PAgNO_2]_\infty$ dissolved in solvent; however, the $|^1J(^{109}Ag,^{31}P)|$ value obtained for the solid sample is in agreement with that obtained for a sample in solution, 769 Hz.[37]

X = N_3^-, SCN$^-$, and CNO$^-$

For the three silver–triphenylphosphine pseudo-halide complexes, $[Ph_3PAgN_3]_n$, $[Ph_3PAgSCN]_n$, and $[Ph_3PAgCNO]_n$, single-crystal data are unavailable, and all attempts to grow suitable single-crystals for X-ray diffraction failed. The ^{31}P NMR spectrum (Fig. 3*d*) for the X = N_3^- complex indicates four distinct phosphorus sites, suggesting that the molecular formula is $[Ph_3PAgN_3]_4$. The ^{31}P NMR spectra for the X = SCN^- complex, which are similar to those shown for the X = Cl^- complex in Fig. 1*a*, indicate two distinct phosphorus sites, so the formula is likely either $[Ph_3PAgSCN]_2$ or $[Ph_3PAgSCN]_4$. The ^{31}P NMR spectra for the X = CNO^- complex, which are similar to that shown in Fig. 3*b*, indicate three distinct phosphorus sites; thus, the molecular formula is probably $[Ph_3PAgCNO]_3$.

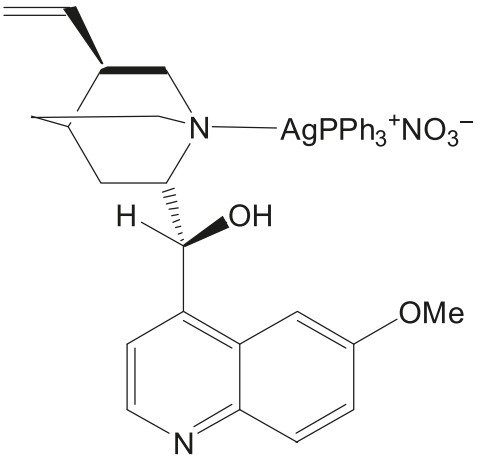
X = quinine

The silver atom of silver-triphenylphosphine quinine nitrate is coordinated to the phosphine and the tertiary nitrogen atom (Scheme 2).[38] A ^{31}P NMR spectrum of an MAS sample of this compound is similar to that shown for the X = NO_2^- complex in Fig. 3*c*. The spectrum indicates that there is a single phosphorus site, in agreement with the structure of this complex.[38] The ^{31}P chemical shift is in agreement with that obtained for a sample in solution, 12.4 ppm.[38]

Summary of solid-state ^{31}P NMR results

For those $[Ph_3PAgX]_n$ complexes with X-ray diffraction data, solid-state ^{31}P NMR spectra contain the number of distinct phosphorus sites predicted from this data. We have shown that solid-state ^{31}P NMR spectroscopy can provide information concerning the number of distinct phosphorus sites from the distinct ^{31}P NMR chemical shifts. In addition, the ^1J(Ag,P) values were also determined for these complexes from solid-state ^{31}P NMR spectroscopy. The ^{31}P NMR parameters including chemical shifts and ^1J(Ag,P) values for many silver–phosphine complexes are unavailable from solution NMR measurements because these complexes are often insoluble in non-coordinating solvents.

Scheme 2.



Relationship between $|^1J(^{107,\,109}Ag,^{31}P)|$ and Ag–P bond-length

Experimental results

Table 3 summarizes the average $|^1J$(Ag,P)| values and the average Ag–P bond lengths for the silver–tertiary phosphine complexes which have been investigated by both solid-state ^{31}P NMR spectroscopy and single-crystal X-ray diffraction. Average $|^1J$(Ag,P)| values and bond lengths are taken for complexes with multiple $|^1J$(Ag,P)| values and P sites since we are unable to assign these to a specific Ag–P bond. As discussed earlier, Nelson and co-workers[9–11] found a linear relationship between $^1J(^{63,65}Cu,^{31}P)$ and $1/r^3_{CuP}$ for a series of

Table 3. Reported $|^1J(^{107,109}Ag,^{31}P)|$ values obtained from solid-state ^{31}P NMR and Ag–P bond-lengths obtained from single-crystal X-ray diffraction for a variety of silver–tertiary phosphine complexes.

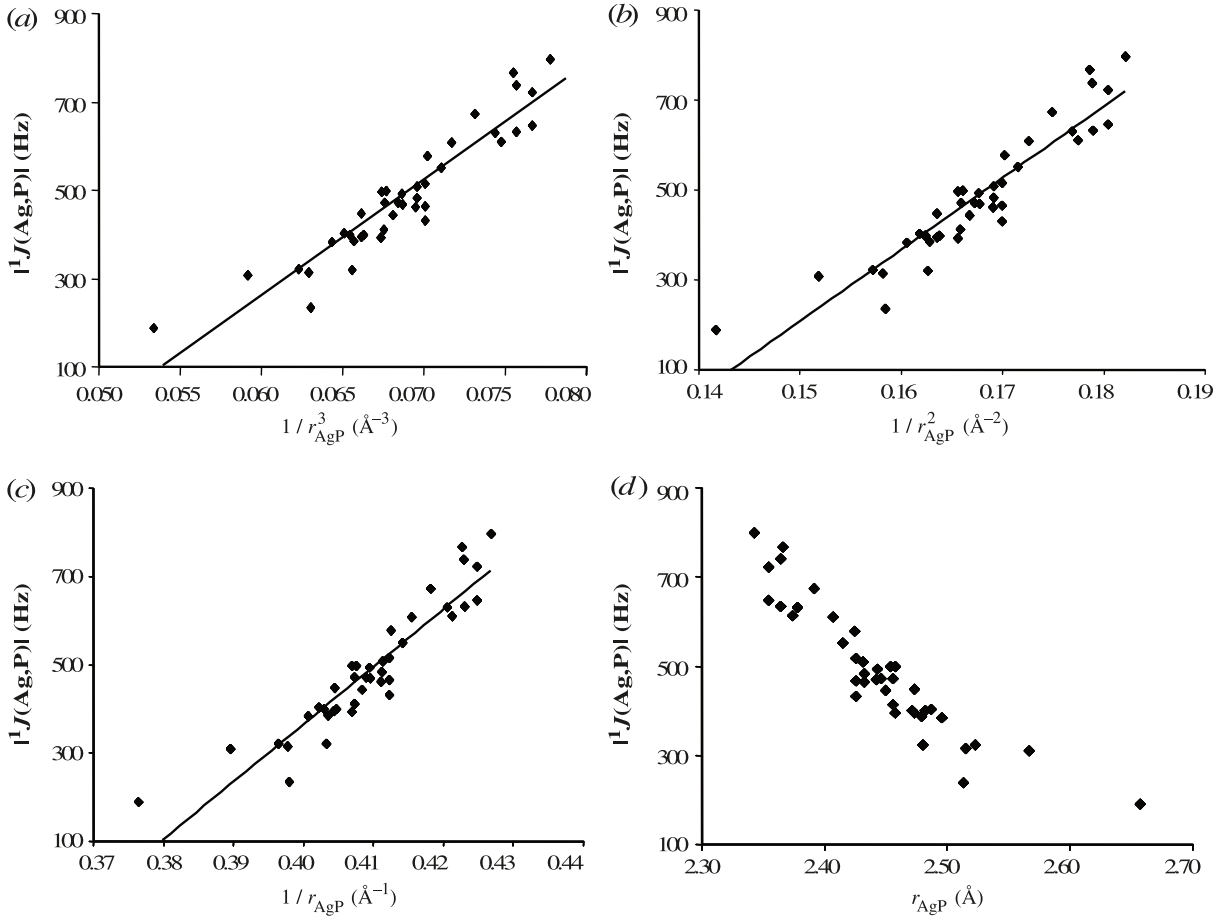
Fig. 5. Plot of experimental $|^1J(Ag,P)|$ versus (*a*) $1/r^3_{AgP}$ ($R = 0.935$), (*b*) $1/r^2_{AgP}$ ($R = 0.932$), (*c*) $1/r_{Ag,P}$ ($R = 0.927$), and (*d*) $r_{Ag,P}$ (see Table 3) for a variety of silver–tertiary phosphine complexes. The lines in (*a*), (*b*), and (*c*) were obtained by using the linear regression method.



copper(I)–tertiary phosphine complexes as well between $|^1J(Ag,P)|$ and $1/r^3_{AgP}$ for $[(Ph_3P)_nAgNO_3]$ ($n = 1 - 4$). Similarly, a plot of $|^1J(Ag,P)|$ vs. $1/r^3_{AgP}$ for the series of silver–tertiary phosphine complexes, shown in Fig. 5*a*, suggests a linear relationship between these parameters. However, there is no obvious theoretical reason for expecting a linear relationship between $|^1J(Ag,P)|$ and $1/r^3_{AgP}$.[43–47] Furthermore, plots between $|^1J(Ag,P)|$ and $1/r^2_{AgP}$ or $1/r_{AgP}$, shown in Figs. 5*b* and 5*c*, respectively, are reasonably linear; thus, there is no reason for plotting $|^1J(Ag,P)|$ as a linear function of $1/r^3_{AgP}$. Clearly, plots of $J(Ag,P)$ vs. $1/(r_{AgP})^n$ are not very sensitive to n. To demonstrate that $|^1J(Ag,P)|$ values are related to bond length, we have simply plotted $|^1J(Ag,P)|$ versus r_{AgP}, see Fig. 5*d*. It is obvious that the magnitudes of $^1J(Ag,P)$ are very sensitive to the variation of r_{AgP}; $|^1J(Ag,P)|$ values decrease with increasing r_{AgP} for silver–tertiary phosphine complexes. The $|^1J(Ag,P)|$ values have a wide range, *i.e.*, 798–190 Hz, and r_{AgP} values range from 2.343 to 2.657 Å. Similar empirical trends also exist for other metal complexes, such as $^1J(^{63,65}Cu,^{31}P)$ vs. r_{CuP},[9–11] $^1J(^{195}Pt,^{31}P)$ vs. r_{PtP}[74–76] and $^1J(^{113}Cd,^{14}N)$ vs. r_{CdN}.[77]

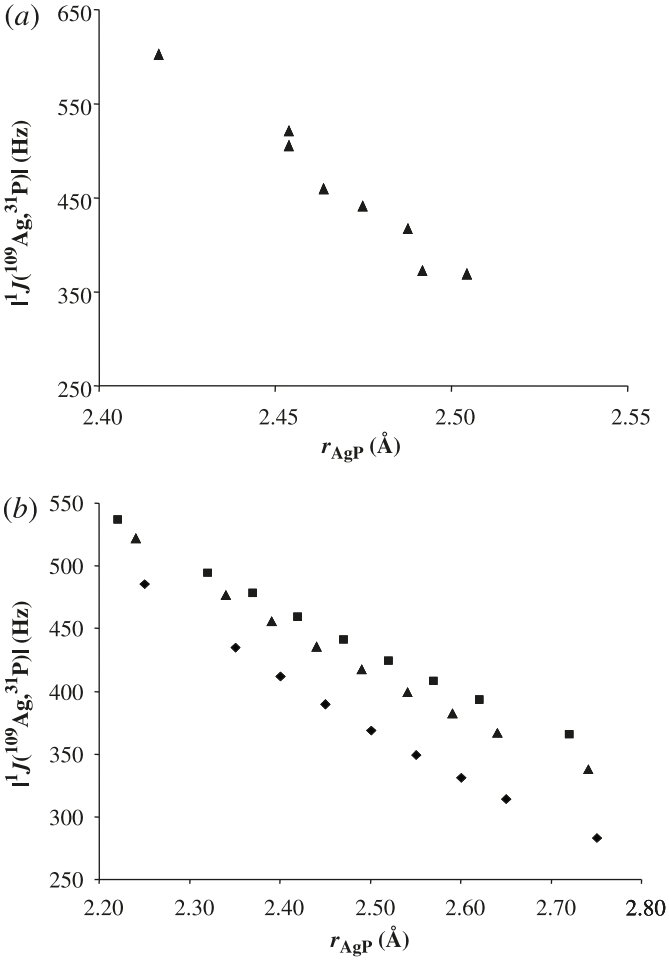
Theoretical calculations

To shed light on the origins of the correlation between $|^1J(Ag,P)|$ values and r_{AgP}, we have carried out quantum chemistry calculations as outlined below. The geometries of model complexes $[(CH_3)_3PAgX]$ for $[Ph_3PAgX]$, $X^- = Cl^-$, Br^-, I^-, CN^-, NC^-, OCH_3^-, $OC(O)H^-$, and $OC(O)CH_3^-$, were optimized using the B3LYP functional. Calculated $^1J(^{109}Ag,^{31}P)$ values for these model complexes were obtained at the DFT level using both the Gaussian 03 and ADF packages. The optimized r_{AgP} and calculated $^1J(^{109}Ag,^{31}P)$ values are summarized in Table 4. The $^1J(^{109}Ag,^{31}P)$ values obtained for the same model complex from both calculations differ, depending on the basis sets (see Experimental section) employed. However, both calculation methods suggest that the magnitudes of the calculated $^1J(Ag,P)$ values for these model complexes are also very sensitive to the variation of r_{AgP}; the trends between the calculated $|^1J(^{109}Ag,^{31}P)|$ values and r_{AgP} are in agreement with experimental results. A plot of calculated $|^1J(^{109}Ag,^{31}P)|$ values, obtained with the ADF package, vs. r_{AgP} for these model complexes is shown in Fig. 6*a*. The $^1J(Ag,P)$ values were also calculated for model complexes $[(CH_3)_3PAgX]$, where $X = Cl^-$, Br^-, and I^-, by varying r_{AgP} and keeping all other structural parameters constant. The plot of calculated $|^1J(^{109}Ag,^{31}P)|$ values vs. r_{AgP} for these complexes (Fig. 6*b*) shows that the $|^1J(^{109}Ag,^{31}P)|$ values are very sensitive to r_{AgP} and have a negative slope, in agreement with the experimental results. The calculations performed with both ADF and Gaussian 03 packages indicate that the FC term com-

Table 4. Calculated $^1J(^{109}Ag,^{31}P)$ values for $[Me_3PAgX]$ (see text for details).

$[Me_3PAgX]$:	ADF (2005.01)		Gaussian 03		
X	^1J(Ag,P) (Hz)	FC (total %)	^1J(Ag,P) (Hz)	FC (total %)	r_{AgP} (Å)
Cl	–441	99.7	–386	98.9	2.475
Br	–418	99.5	–359	98.8	2.488
I	–370	99.2	—	—	2.504
CN	–460	99.8	–391	99.0	2.464
NC	–373	99.6	–309	98.7	2.491
OCH_3	–603	99.7	–477	99.4	2.417
OC(O)H	–507	99.7	–434	99.1	2.454
$OC(O)CH_3$	–522	99.8	–440	99.1	2.454

Fig. 6. Plot of $|^1J(Ag,P)|$ values calculated with ADF versus $r_{Ag,P}$ for (*a*) $[Me_3PAgX]$, where X is a monovalent anion (see Table 4) and (*b*) $[Me_3PAgX]$, where X = Cl^- (squares), Br^- (triangles), and I^- (prisms).



pletely dominates the $^1J(^{109}Ag,^{31}P)$ (Table 4), in agreement with the suggestions by Nelson and co-workers.[9–11]

Conclusions

Solid-state ^{31}P NMR spectroscopy has been used to investigate a series of silver–triphenylphosphine complexes of the type $[Ph_3PAgX]_n$. The number of distinct P sites revealed in the high-resolution solid-state ^{31}P NMR spectra of $[Ph_3PAgX]_n$ are consistent with the available crystal structures. The ability to identify the number of distinct phosphorus sites by solid-state ^{31}P CP/MAS NMR spectroscopy is particularly useful when X-ray diffraction data are unavailable. The $|^1J(^{109}Ag,^{31}P)|$ values for those complexes investigated here range from 401 ± 10 Hz (X = N_3^-) to 869 ± 10 Hz (X = $SO_3CF_3^-$). The data obtained here and in earlier literature indicate that $|^1J(Ag,P)|$ values decrease with increasing r_{AgP} for silver–tertiary phosphine complexes. This conclusion is supported by DFT calculations which also indicate that the Fermi-contact mechanism is the only important spin–spin coupling mechanism contributing to $^1J(Ag,P)$.

Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 3963. For more information on obtaining material, refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml. CCDC 724007 and 724008 contain the X-ray data in CIF format for for $[Ph_3PAgCl]_4$ and $[Ph_3PAgOC(O)CF_3]_4$ for this manuscript. These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

Acknowledgements

We thank Guy Bernard for many helpful comments and discussions, and Scott Kroeker for obtaining preliminary experimental ^{31}P NMR data for some of the silver halide triphenylphosphine complexes many years ago. We are also grateful to Robert McDonald and Michael Ferguson in the X-ray Crystallography laboratory for acquiring the X-ray data. We acknowledge WestGrid for allowing the use of their clusters for Gaussian 03 calculations. REW is a Canada Research Chair in Physical Chemistry and would like to acknowledge the Natural Sciences and Engineering Research Council of Canada (NSERC) for funding. SWO is grateful to Mokpo National University, Republic of Korea for an award under the Professors' training program. Finally, we thank a referee for pointing out that a plot of $\log_{10}|^1J(Ag,P)|$ versus r_{AgP} has a slope of –2.0 (R = 0.944); however, the theoretical significance of this relationship is unknown and we prefer to state that it is simply an empirical observation.

TRIBUTE

A tribute to Tom Ziegler

Biographical sketch — From Copenhagen to Calgary

Tom Ziegler was born in Copenhagen in 1945. He received his M.Sc. degree from the University of Copenhagen in 1972 in the field of Theoretical Chemistry, and his Ph.D. from the University of Calgary, in 1978 in the area of Inorganic/Theoretical Chemistry. After postdoctoral studies at the Free University in Amsterdam and McMaster University, he returned to Calgary in 1981, first as an NSERC University Research Fellow, and then Assistant Professor in 1986. He moved quickly through the ranks to Full Professor in 1993. Between 1996 and 1999, he held a Canada Council Killam Professorship, and two years later, in 2001, became a Tier 1 Canada Research Chair in Theoretical Inorganic Chemistry in recognition of his world-class achievements.

Tom is one of the earliest proponents of density functional theory (DFT), an electronic structure scheme that today is widely accepted as the method of choice in the description of large molecules. He began his life-long development work on a DFT-based computer code during his graduate years (1972–1978) as a Ph.D. student in Calgary under my supervision. This project has since been carried out in collaboration with the group of E. J. Baerends at the Free University in Amsterdam. It has resulted in the powerful Amsterdam density functional (ADF) program package that is widely used and still under development. The applications of this program have in particular been in the area of transition-metal chemistry, a field Tom became acquainted with as an M.Sc. student in Copenhagen under the supervision of J. P. Dahl and C. J. Ballhausen.

During the period 1978–1992, Tom's group (together with a few other sites, including that of D. Salahub in Montréal) demonstrated that DFT in the formulation by their Canadian compatriot A. Becke from Queens University was able to predict molecular energetics and structures with higher accuracy than the traditional electronic structure methods, and at a much lower computational cost. The work on structure and energetics culminated in an influential review paper (*Chem. Rev.* 1991), as well as the general acceptance of DFT in the Becke formulation, as the electronic structure theory of choice for large molecules.

Since 1992, Tom has demonstrated the power of DFT in applications to homogeneous catalysis in a number of highly cited papers mainly concentrating on olefin polymerization. Several petrochemical companies in Europe, Japan, and North America have supported this work. His polymerization research has considerably enhanced our understanding of the different role played by early and late transition metals as polymerization catalysts. More recently, Tom has turned towards heterogeneous catalysis in connection with research on solid oxide fuel cells (SOFC) and Fischer–Tropsch synthesis, again with substantial support from industry and government.

The Ziegler group has at the same time extended the number of molecular properties that can be modelled by DFT. In the period 1992–2000, the group introduced one of the first DFT codes for calculations of NMR chemical shifts and spin–spin coupling parameters as well as the ESR g- and A-tensors. These codes were based on methods that included relativistic effects and could as a result treat catalytic transition-metal systems with heavy metals. The NMR and ESR work is currently being extended to metal surfaces. Another ongoing development of use in homogenous and bioinorganic catalysis has been methods that can calculate electronic (ECD) and magnetic (MCD) circular dichroism. The group is currently applying their ECD and MCD codes to a number of metallo-enzymes. Other developments worth mentioning are their bonding analysis scheme with more than 1000 citations as well as their molecular dynamics method that makes it possible to optimize transition-state structures on the free energy surface.

Most recently, Tom has embarked on a critical assessment of the way in which we describe excited states. He has shown that the currently used method based on time-dependent DFT can be reformulated into a more simple static and time-independent method based on variation theory. The new formulation promises to extend the capability of DFT in studies of excited states.

Tom has been a Visiting Professor at a number of famous universities, the Institute of Molecular Sciences in Okazaki, Japan, the Free University in Amsterdam, and the University of Fribourg in Switzerland. Most recently, in 2008, he was the Lise–Meitner Lecturer at the Lise–Meitner–Minerva Center for Computational Quantum Chemistry in Israel.

Over the course of his career, he has won numerous awards, including a CNC-IUPAC Award (1988), the CSC's Alcan Award (1994), the Award in Pure and Applied Inorganic Chemistry (2000), and Steacie Award (2005). He was elected Fellow of the Royal Society of Canada in 1997, Fellow of the Royal Danish Academy of Sciences and Letters in 2000, and Fellow of the International Academy of Quantum Molecular Science in 2007. In 2004, Tom was awarded the prestigious Schrödinger Medal, the highest award of the World Association for Theoretically Oriented Chemists (WATOC).

Tom has also made significant contributions to the chemical community, serving on the Advisory Boards of *Organometallics* (1998–2001), and *Journal of Computational Chemistry* (2005–2009), and as a member of the NSERC Grant Selection Committee for Analytical and Physical Chemistry (1998–2001), the Fellowship Selection Committee for the Royal Society of Canada (2001–2004), and as Secretary, Academy of Science, Royal Society of Canada (2000–2004). Many of his students and co-workers have gone on to hold academic positions at various Canadian and International Universities, or have accepted industrial positions.

Tom is one of the two most cited chemists in Canada with over 7000 citations, and ranks in the top 100 most cited in the World with an H-index of 70. The number and quality of the papers submitted to this dedicated issue of the *Canadian Journal of Chemistry* attests to the breadth and reach of his influence in the chemical, theoretical, and computational community.

HOMMAGE

Hommage à Tom Ziegler

Tom Ziegler est né à Copenhague en 1945. Il a obtenu une maîtrise ès sciences en chimie théorique de l'Université de Copenhague (1972), puis un doctorat dans le domaine de la chimie inorganique théorique de l'Université de Calgary (1978). Après ses études postdoctorales à l'Université libre d'Amsterdam et à l'Université McMaster, il est de retour à Calgary en 1981, tout d'abord à titre de chercheur universitaire du CRSNG, et ensuite à titre de professeur adjoint en 1986. Il a rapidement gravi les échelons pour atteindre le poste de professeur titulaire en 1993. Entre 1996 et 1999, il a obtenu une bourse de recherche Killam du Conseil des arts du Canada. Deux ans plus tard, en 2001, il est devenu titulaire de la chaire de recherche du Canada (niveau 1) en chimie inorganique théorique pour ses réalisations incomparables.

Tom est l'un des partisans de la première heure de la théorie de la fonctionnelle de la densité (TFD), un schéma de structure électronique généralement accepté de nos jours comme la méthode préconisée pour décrire les grosses molécules. Il a commencé ses travaux de recherche, qui le suivront tout au long de sa carrière, sur un code informatique basé sur la TFD au cours de son doctorat (1972–1978) à Calgary, sous ma direction. Depuis, ce projet est réalisé en collaboration avec l'équipe d'E. J. Baerends de l'Université libre d'Amsterdam. Ces travaux ont donné lieu au puissant logiciel ADF (Amsterdam Density Functional), couramment utilisé et encore en développement. Les applications de ce logiciel se situent particulièrement dans le domaine de la chimie des métaux de transition, discipline dont Tom a pris connaissance au cours de ses études à la maîtrise sous la direction de J. P. Dahl et de C. J. Ballhausen, à Copenhague.

Entre 1978 et 1992, l'équipe de Tom (ainsi que quelques autres laboratoires, dont celui de D. Salahub, à Montréal) a démontré que la TFD, dans la formulation issue de leur compatriote canadien A. Becke de l'Université Queen's, pouvait prédire la structure et l'énergie des molécules avec une plus grande précision qu'en utilisant les méthodes de structure électronique traditionnelles, et ce, à un coût bien moindre en temps de calcul. Les travaux sur la structure et l'énergétique ont été couronnés aussi bien par la parution d'un article de synthèse influent (*Chemical Reviews,* 1991) que par l'acceptation générale de la TFD selon la formulation de Becke comme étant la théorie de la structure électronique à préconiser pour les grosses molécules.

Depuis 1992, Tom démontre la puissance de la TFD dans des applications à la catalyse homogène dans de nombreux articles fréquemment cités qui portent principalement sur la polymérisation de l'oléfine. Plusieurs sociétés pétrochimiques en Europe, au Japon et en Amérique du Nord ont financé ces travaux. Ses recherches sur la polymérisation ont grandement contribué à l'amélioration de notre connaissance du rôle différent que jouent les métaux de transition précoce et tardive comme catalyseurs de la polymérisation. Plus récemment, Tom s'est tourné vers la catalyse hétérogène relative aux travaux effectués sur les piles à combustible à oxyde solide (piles SOFC) et sur la synthèse de Fischer–Tropsch grâce, encore une fois, à l'aide importante de l'industrie et du gouvernement.

Au même moment, l'équipe de Ziegler a accru le nombre de propriétés moléculaires qui pouvaient être modélisées par la TFD. Entre 1992 et 2000, cette équipe a mis en place l'un des premiers codes de la TFD pour calculer aussi bien les déplacements chimiques en RMN et les paramètres de couplage spin–spin que les tenseurs g et A en RPE. Ces codes reposaient sur des méthodes qui comprenaient les effets relativistes; l'équipe a donc pu traiter des systèmes catalytiques de métaux de transition à base de métaux lourds. On étend actuellement les travaux en RMN et en RPE aux surfaces métalliques. Le développement actuel d'une autre utilisation en catalyse homogène et bioorganique consiste à mettre au point des méthodes qui permettent de calculer le dichroïsme circulaire électronique (DCE) et magnétique (DCM). L'équipe applique actuellement ses codes de DCE et de DCM à de nombreux métalloenzymes. On ne peut passer sous silence d'autres innovations apportées par cette équipe comme le schéma d'analyse des liaisons, cité à plus de 1000 occasions, et la méthode de dynamique moléculaire qui permet d'optimiser les structures des états de transition sur la surface d'énergie libre.

Tout récemment, Tom a entrepris une évaluation critique de la façon dont on décrit les états d'excitation. Il a montré que la méthode utilisée actuellement, fondée sur la TFD en fonction du temps, peut être reformulée en une méthode plus simple, statique et indépendante du temps, et fondée sur la théorie de la variation. Cette nouvelle formulation annonce un potentiel accru de la TFD dans des études portant sur les états d'excitation.

Tom a été professeur invité dans plusieurs universités prestigieuses, soit l'Institut des sciences moléculaires d'Okazaki (Japon), l'Université libre d'Amsterdam et l'Université de Fribourg (Suisse). Tout récemment, en 2008, il a été nommé maître de conférence Lise–Meitner au Lise–Meitner–Minerva Center for Computational Quantum Chemistry (Israël).

Tout au long de sa carrière, Tom a gagné de nombreux prix, dont celui du CNC-UICPA (1988), le prix Alcan de la SCC (1994), le prix de chimie inorganique pure ou appliquée (2000) et le prix Steacie (2005). Il a été élu membre de la Société royale du Canada (1997), membre de l'Académie royale danoise des sciences et des lettres (2000), et membre de l'Académie internationale des sciences moléculaires quantiques (2007). En 2004, Tom a reçu la prestigieuse médaille Schrödinger, la plus haute distinction remise par la World Association for Theoretically Oriented Chemists (WATOC).

Tom a contribué de façon importante au milieu de la chimie en siégeant au comité consultatif des revues *Organometallics* (1998–2001) et *Journal of Computational Chemistry* (2005–2009), et à titre de membre du Comité de sélection des subventions du CRSNG pour la chimie analytique et physique (1998–2001), de membre du Comité de sélection des bourses pour la Société royale du Canada (2001–2004), et de secrétaire pour l'Académie des sciences de la Société royale du Canada (2000–2004). Beaucoup de ses étudiants et collègues occupent maintenant des postes dans diverses universités canadiennes ou étrangères, ou dans l'industrie.

Fort de plus de 7000 citations à son actif, Tom est l'un des deux chimistes les plus cités au Canada, et il se situe parmi les cent premiers chimistes les plus cités dans le monde avec un indice h de 70. Le nombre et la qualité des articles soumis à ce numéro spécial de la *Revue canadienne de chimie* attestent l'ampleur et la portée de son influence dans le milieu de la chimie, de la théorie et de l'informatique.

TRIBUTE

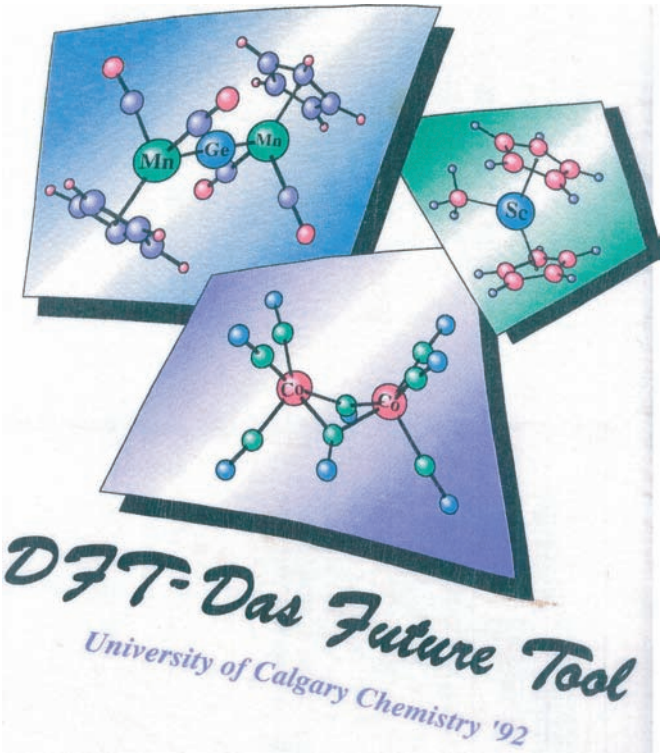
DFT — Das Future Tool

"Das Future Tool" was the title of the group T-shirt[1] that we had made for Tom Ziegler as graduate students in the early nineties. In those days, DFT was only beginning to gain popularity in theoretical chemistry community. Tom had just published his influential review article "Approximate Density Functional Theory as a Practical Tool in Molecular Energetics and Dynamics" in *Chem. Rev.* and had organized one of the first, if not the first, ACS symposium dedicated solely to DFT titled "Chemical Applications of Density Functional Theory" at the spring national meeting in Anaheim. Even the Gaussian suite of programs had finally incorporated DFT into their G92 package (However, not with the original G92 release but as a later interim release they dubbed G92/DFT).

Nonetheless, even at that time, there were a large number of detractors in the theoretical chemistry community who were skeptical of DFT and considered it just another semi-empirical method.[2] Tom, however, realized that DFT was "Das Future Tool" long before then and in fact had started to develop DFT as a practical tool in chemistry some ten years before beginning in the late 1970s. In those "early days", there was an even more skeptical attitude towards DFT in the theoretical chemistry community. For example, Tom's first NSERC operating grant, intended to run his whole research program, was a mere $5000 per year. Even adjusting 1982 dollars for inflation which brings this grant amount to $10 585 in today's dollars, that is a very skeptical level of funding. Things have dramatically changed since the 1980s. Not only is Tom's research funding level much higher, but DFT is now the quantum chemical method of choice for most researchers.

One impressive aspect of Tom's body of work is that he is able to communicate both to "hard core" theoretical chemists interested in fundamental theory, as well as non-theoretical chemists who were interested in gaining a deeper understanding of their chemistry from a theoretical point of view. Tom's work has always focused on two equally important aspects of computational chemistry, namely the development of new methodology and its application to problems of chemical relevance. Owing to this duality, Tom's work has inspired theoretically as well as experimentally inclined researchers alike. This is evidenced by that fact that Tom is one of Canada's most highly cited chemists with a towering H-index of 70.

Tom's kaleidoscopic research interests present many different facets. If five out of Tom's former graduate students were asked to name their favorites out of all his contributions to science, five different answers would probably be generated – be it his work on molecular structure and properties, or on the nature of the chemical bond, or on relativistic effects which led to the Dutch Revolution in the theory of relativity, be it his work on NMR calculations or his contributions to catalysis or DFT based molecular dynamics. With all the different hats that Tom wears, DFT is the common denominator that amalgamates his many interests, from the early days up to the present time. Based on his work done in fulfillment of a Ph.D. degree, Tom published a seminal work in which he became aware of and circumvented the problem of calculating reliable bond energies by DFT. The transition state method was at the heart of many research topics that Tom worked on in the beginning of his career. Now, some thirty years later, Tom tackles excited states as well as solid states in search for answers to many relevant chemical problems.



Tom and his Calgary group were certainly pivotal in the meteoric rise of DFT as a powerful tool in chemical research. Tom was not only an early pioneer some 25 years ago, but he has continued to make significant contributions to fundamental DFT theory and its applications to chemical systems since then. In these two special issues of *Can. J. Chem.*, we wish to celebrate Tom Ziegler's vision and many contributions to chemistry. It was a privilege to be a group member in the early nineties and to witness our then whimsical interpretation of DFT (Das Future Tool) become a reality alongside one of its most influential contributors.[2]

[1]The T-shirt featured images of "large" organometallic complexes, that were chosen not only for their aesthetic beauty and symmetry, but also to symbolize the fact that DFT could treat these systems accurately and with a practical amount of computing effort, when, at the time, no other quantum chemical methods could do so. There was also an ongoing discussion as to whether we should use "Der" or "Das". From a German language point of view "Der" may be better but we opted for "Das".

[2]We recall a number of heated debates at the ACS meeting in Anaheim involving some of the "unconverted".

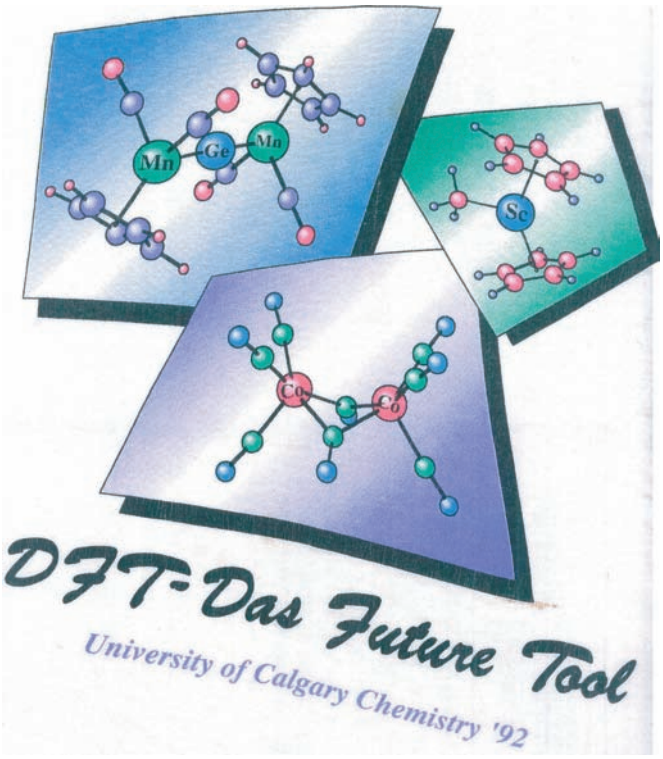
HOMMAGE

DFT — Das Future Tool (TFD: l'outil de l'avenir)

« Das Future Tool » (l'outil de l'avenir) était le titre inscrit sur le t-shirt[1] que nous, l'équipe d'étudiants diplômés, avions fait confectionner pour Tom Ziegler au début des années 1990. À cette époque, la TFD commençait à gagner en popularité dans le milieu de la chimie théorique. Tom venait tout juste de publier son article de synthèse influent intitulé « Approximate Density Functional Theory as a Practical Tool in Molecular Energetics and Dynamics » (la théorie approximative de la fonctionnelle de la densité comme outil pratique en énergétique et en dynamique moléculaires) dans la revue *Chemical Reviews*. Par ailleurs, il avait organisé l'un des premiers, sinon le premier symposium de l'ACS consacré uniquement à la TFD et intitulé « Chemical Applications of Density Functional Theory » (applications chimiques de la théorie de la fonctionnelle de la densité) lors de la réunion printanière nationale qui avait eu lieu à Anaheim. Même la suite logicielle de la société Gaussian avait fini par incorporer la TFD dans son progiciel G92 (pas lors de la sortie de la première version de ce progiciel, mais plutôt dans une version provisoire ultérieure appelée G92/DFT).

Néanmoins, même à cette époque, il y avait un grand nombre de détracteurs dans le milieu de la chimie théorique qui demeuraient sceptiques par rapport à la TFD et qui la considéraient uniquement comme une autre méthode semi-empirique[2]. Cependant, Tom s'est rendu compte que la TFD était « l'outil de l'avenir » bien avant et qu'en fait, il avait commencé à concevoir la TFD comme outil pratique en chimie quelque dix ans auparavant, soit à la fin des années 1970. À cette époque, le scepticisme à l'égard de la TFD était encore plus grand dans le milieu de la chimie théorique. À titre d'exemple, la première subvention pour dépenses courantes de recherche qu'a reçue Tom du CRSNG, et qui visait à assurer le fonctionnement de son programme de recherche en entier, n'atteignait que 5000 $ par année. Même en tenant compte de l'inflation depuis 1982, ce qui porte le montant de cette subvention à 10 585 $ en dollars actuels, il s'agit d'un niveau de financement qui témoigne de ce scepticisme. Toutefois, les choses ont considérablement changé depuis les années 1980. Non seulement le niveau de financement en recherche de Tom est beaucoup plus important, mais la TFD est maintenant la méthode préconisée par la plupart des chercheurs en chimie quantique.

Un aspect impressionnant des travaux de Tom réside dans le fait qu'il réussit à joindre aussi bien le « noyau dur » de chimistes théoriciens qui s'intéressent à la théorie fondamentale que les chimistes non théoriciens qui désirent obtenir une meilleure compréhension de leur discipline d'un point de vue théorique. Les travaux de Tom ont toujours porté essentiellement sur deux aspects de la chimie informatique tout aussi importants l'un que l'autre, à savoir la conception d'une nouvelle méthodologie et son application aux problèmes ayant une pertinence chimique. Grâce à cette dualité, les travaux de Tom inspirent autant les chercheurs théoriciens qu'expérimentaux,



comme le prouve le fait que Tom est l'un des chimistes les plus cités au Canada avec un indice h de 70.

En constante évolution, les travaux de recherche de Tom présentent de multiples facettes. Si on demandait à cinq des anciens étudiants diplômés de Tom de nommer la contribution à la science qu'ils préfèrent parmi toutes celles qu'il a apportées, on obtiendrait probablement cinq réponses différentes. Mentionnons, à titre d'exemples, ses travaux sur la structure et les propriétés moléculaires, sur la nature de la liaison chimique ou sur les effets relativistes qui ont mené à la révolution néerlandaise de la théorie de la relativité, ou encore ses travaux sur des calculs en RMN ou ses contributions à la catalyse ou à la dynamique moléculaire fondée sur la TFD. Peu importe les fonctions occupées par Tom, la TFD constitue le dominateur commun qui amalgame ses nombreux sujets de prédilection, depuis ses débuts jusqu'à aujourd'hui. À partir de ses travaux effectués au cours de son doctorat, Tom a publié un ouvrage novateur dans lequel il s'est rendu compte du problème de fiabilité des calculs des énergies de liaison par la TFD et l'a contourné. La méthode de l'état de transition était au cœur de nombreux sujets de recherche sur lesquels Tom a travaillé au début de sa carrière. Maintenant, quelque trente ans plus tard, Tom s'attaque aussi bien aux états excités qu'aux états solides, à la recherche de réponses à de nombreux problèmes chimiques importants.

1. Ce t-shirt comportait des images de « gros » complexes organométalliques choisis non seulement pour leur esthétisme et leur symétrie, mais également pour symboliser le fait que la TFD pouvait traiter ces systèmes de façon précise et avec un volume acceptable de calculs informatisés quand, à cette époque, aucune autre méthode de chimie quantique ne permettait de le faire. Il y avait également des discussions constantes autour de l'utilisation de « Der » ou de « Das ». Du point de vue de la linguistique allemande, « Der » serait plus juste, mais nous avons opté pour « Das ».

For personal use only.

Tom et son équipe de Calgary ont certainement joué un rôle crucial dans l'ascension fulgurante de la TFD comme outil puissant de recherche en chimie. Tom n'a pas seulement été un précurseur il y a quelque 25 ans, il continue, depuis ce temps, à contribuer grandement à la théorie fondamentale de la TFD et à ses applications dans les systèmes chimiques. Dans ces deux numéros spéciaux de la *Revue canadienne de chimie*, nous voulons célébrer la vision de Tom Ziegler et ses nombreuses contributions apportées à la chimie. Ce fut un privilège de faire partie de cette équipe, au début des années 1990, et d'être témoins du fait que notre interprétation fantaisiste à l'époque de la TFD (l'outil de l'avenir) soit devenue réalité, et ce, en œuvrant aux côtés d'un de ses contributeurs les plus influents.[2]

2. On se souviendra de plusieurs débats houleux avec certains des « non-convertis » lors de la réunion de l'ACS, à Anaheim.

Quasi-classical trajectory calculation of the Ba + HBr chemical reaction

Wen Wen Xia, Ning Lu, Haiyang Zhong, and Li Yao

Abstract: The results of the reaction between Ba atom and HBr are studied by using the quasi-classical trajectory (QCT) calculation on extended London–Eyring–Polanyi–Sato (LEPS) potential-energy surface (PES). The vibrational distribution, reaction cross section, and rotational alignment of the product BaBr have been calculated. The calculations predict that the reaction cross section decreases, while the translation energy and rotational energy increase with the increasing of collision energy. It has been found that low collision energy favors the abstraction reaction, whereas high collision energy leads to an insertion reaction. The calculated results agree with the experimental data and some relative theoretical results as well.

Key words: QCT, LEPS PES, vibrational distribution, reaction cross section, rotational alignment.

Résumé : On a réalisé une étude théorie de la réaction entre un atome de baryum et du HBr en faisant appel à des calculs de trajectoire quasi-classique (TQC) sur une surface d'énergie potentielle (SEP) étendue de London–Eyring–Polanyi–Santo (LEPS). On a calculé la distribution vibrationnelle, la section droite de la réaction et l'alignement rotation du produit BaBr. Les calculs ont permis de prédire que, une augmentation de l'énergie de collision s'accompagne d'une diminution de la section droite de la réaction alors que l'énergie de translation et l'énergie de rotation augmentent. On a trouvé qu'une faible énergie de collision favorise une réaction d'abstraction alors qu'une énergie de collision élevée conduit à une insertion. Les résultats calculés sont en bon accord avec les données expérimentales ainsi qu'avec certains résultats théoriques.

Mots-clés : trajectoire quasi-classique (TQC), LEPS SEP, distribution vibrationnelle, section droite de réaction, alignement réactionnel.

[Traduit par la Rédaction]

Introduction

Along with the interaction of experiments and theories in the field, the study of molecular reaction dynamics has obtained great development and extraordinary achievements in recent decades. The first quasi-classical trajectory (QCT) method that investigated the reaction collisions were carried out during the 1930s.[1] Since the 1960s, QCT method has developed rapidly.[2] From the experimental part, by means of electric field, supersonic molecular beam, and laser,[3–5] the translational energy, electric state, and vibration state of the reagent molecules can be well-prepared. The alignment of the rotation state under the same experimental conditions could also be obtained. By using the technologies of chemiluminescence (CL), laser-induced fluorescence (LIF), and cross molecular beam,[6,7] the nascent internal energy states of the molecular product can be detected. Similarly, the velocity and space-angle distributions of the product can also be measured.

In practice, LIF, which uses tunable dye lasers, has been employed to measure the reaction product's internal-state distribution, and actually most of these LIF studies were conducted under thermal collision-energy environment. In 1980, Siegel and Schultz[8] performed a lot of experimental work on the Ba + HBr reaction using the LIF method. They measured the vibrational distribution, mean product energies, and the total reaction cross section of the product BaBr. From the experiment, they concluded that only the change of the collision energy can slightly influence the vibrational distribution. They also determined that the mean rotational energy increases with the increasing collision energy and the total reaction cross section decreases as the collision energy is raised. Kasuya and co-workers[9] studied the crossed beam reaction (Ba + CH_3Br) by means of the LIF method when the collision energy was controlled in the range from 2.9 to 4.9 kcal/mol. Through the systematic simulation of the observed LIF spectra, they found that an increase of the collision energy brought about a drastic decrease of the vibrational excitation. Recently, in 2002, Zhang et al.[10] calculated the exothermic reaction Ba + HF based on the extended LEPS PES using the QCT method. They carried out the vibrational distribution, the internal-energy distribution, and product rotational alignment of the Ba + HF reaction. In their article, they described the reaction mechanism as two pathways, abstraction and insertion. There also exist some other studies on the reaction between an alkaline earth metal atom and a hydrogen halide molecule, such as Ba + HF,[11–17] Ba + HCl,[8,12,18] and Ba + HI.[12,19–23]

On all accounts, by means of the QCT method and some dynamics calculation, the experiment is able to be simulated, and the reaction principle can be further proved and discussed. So, in this paper, we calculate the vibrational distribution, product rotational alignment, reaction cross section, and some other results of the reaction Ba + HBr → BaBr + H and analyze the differences between the experimental re-

sults and the theoretical ones. In the conclusions, we provide a reasonable explanation of the experimental results.

Theory

Potential-energy surface (PES)

The PES is the basis of the analysis and calculation of the reaction rate and reaction mechanism in the study of the molecular reaction dynamics. The London–Eyring–Polanyi–Sato (LEPS) PES is the one that has been widely used. In fact, we must use accurate PES to study the kinetic property of the Ba + HBr reaction; however, obtaining an intact PES is not an easy work. This is the reason why a lot of people use this primary PES in their calculations. In our calculation, we used the LEPS PES, which is just suitable for systems such as three or pseudo-three-body systems. Compared with other methods, such as QM and ab initio, QCT was a good fit for our request.

As for the system of ABC, semi-empirical generalized LEPS PES can be interpreted as follows[24]:

$$[1]\qquad U(R_1,R_2,R_3) = Q_1 + Q_2 + Q_3 - \{1/2[(J_1 - J_2)^2 + (J_2 - J_3)^2 + (J_3 - J_1)^2]\}^{1/2}$$

R_i, Q_i, and J_i represent the nuclear separation of diatomic molecule, the Coulomb integral, and exchange integral of electron, respectively.

$$[2]\qquad Q_i = \frac{D_e}{4 \times (1 + S_i)}[X_i^2(3 + S_i) - 2X_i(1 + 3S_i)]$$

$$[3]\qquad J_i = \frac{D_e}{4 \times (1 + S_i)}[X_i^2(1 + 3S_i) - 2X_i(3 + S_i)]$$

where

$$[4]\qquad X_i = \exp[-\beta_i(R_i - R_i^0)]$$

S_i is an adjustable parameter (so-called Sato parameter), and D_e, β_i, and R_i^0 are the Morse parameters of the diatom. D_e is defined as the classical dissociation energy, β_i stands for the spectrum constant, and R_i^0 is the equilibrium nuclear separation. Subscript i = 1, 2, 3 indicates Ba–Br, H–Br, and Ba–H, respectively. All the parameters are presented in Table 1. In our calculation, we used the adjustable parameters, which are called Sato parameter, given in Table 1 to obtain more reasonable PES. Although the Sato parameters do not have any physical meaning, we can use them to achieve the main feature about the PES and dynamical properties of the Ba + HBr reaction in our work. When we adjusted the Sato parameters, we had to compare our calculation results with the experimental results. If they correspond with each other, the Sato parameters are appropriate. If they do not, then we have to re-adjust the Sato parameters. When we found the right Sato parameters for one experimental result, we used the same Sato parameters to calculate the other experimental results.

Quasi-classical trajectory calculation

In the present study, the conventional quasi-classical algorithm, which is sixth order symplectic routine with energy conservation checked[17] is employed for the numerical solution of the classical Hamilton's equations in three dimensions. The calculations of the product vibrational distribution, reaction cross section, and rotational alignment for the Ba + HBr reaction had been performed on LEPS PES by means of QCT method. To compare with the experimental measurements of the product state distribution for the Ba + HBr reaction,[8] the collision energy was chosen to be 0.51 eV in this work. In our calculations, a batch of 100 000 trajectories was run for the case and also the integration step size was chosen to be 0.1 fs. Trajectories were initiated at a Ba–HBr inter-nuclear separation of 15 Å and HBr molecule at the v = 0 and j = 0 levels. The parameters should be suitable to guarantee the conservation of total energy and angular momentum. The calculated results deviate slightly from the experimental ones because of the number limitation of trajectories.

Table 1. Parameters are calculated at the mp2/lanl2dz level using Gaussion03 program of the LEPS PES for the Ba + HBr reaction.

Species	D_e (eV)	β_i (Å^{-1})	R_0 (Å)	S_i
BaBr	2.6667	1.202	3.2323	0.370
HBr	3.7838	1.998	1.4608	0.220
BaH	0.7771	1.553	2.54	0.578

Product rotational alignment

It is a simple method to describe the degree of polarization of $\vec{J}'$, which is through the center of mass-frame orientation and alignment parameters. During reactive encounter, the total angular momentum is conserved $\vec{J} + \vec{L} = \vec{J}' + \vec{L}'$, where $\vec{L}$ and $\vec{L}'$ are the reagent and product orbital momenta, respectively. When the reagent angular momentum $\vec{J}$ is small (as is common), the product rotation can only result from $\vec{L}$. The distribution of the rotational angular momentum $\vec{J}'$ of the product molecule, which is mainly determined by $\vec{L}$, can be described by a function $f(\theta)$, where θ is the angle between $\vec{J}'$ and the relative velocity vector $\vec{K}$. $f(\theta)$ can be expanded in a set of Legendre polynomials[25]

$$[5]\qquad f(\theta) = \sum a_l P_l(\cos\theta)$$

l = 2 indicates the product rotational alignment

$$[6]\qquad a_2 = 5\langle P_2(\cos\theta)\rangle = 5\langle P_2(\vec{J}' \cdot \vec{K})\rangle$$

$$[7]\qquad \langle P_2(\vec{J}' \cdot \vec{K})\rangle = 1/2\langle 3\cos^2\theta - 1\rangle$$

where P_2 is the second Legendre momentum, and the brackets indicate an average over the distribution of $\vec{J}'$ about $\vec{K}$.[26]

Apparently, the heavy–heavy–light (HHL) mass combination leads to the product rotation being strongly aligned about the reagents' relative velocity, and $\langle P_2(\vec{J}' \cdot \vec{K})\rangle$ should be equal to –0.5. However, the HHL mass combination is not strictly proper for the Ba + HBr reaction any more. The calculated $\langle P_2(\vec{J}' \cdot \vec{K})\rangle$ values, which are less than –0.5, first decrease then increase slightly and then decrease with increasing the collision energy.

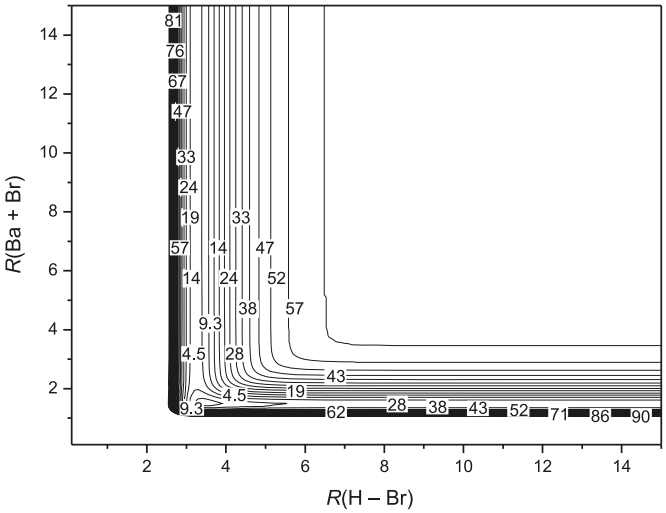
Results and discussion

The internal-energy state was described by two quantum numbers (v, j), and the internal-energy state of reagent is

Table 2. Selected values of b_{max} at different collision energies in the Ba + HBr reaction.

E_{col} (eV)	b_{max} (Å^2)
0.1	4.0
0.12	3.87
0.2	3.55
0.3	3.40
0.4	3.33
0.51	3.25

Fig. 1. The contour plot of LEPS PES for the Ba + HBr reaction. The unit of the R is Å and of the energy is erg × 10^{16}.



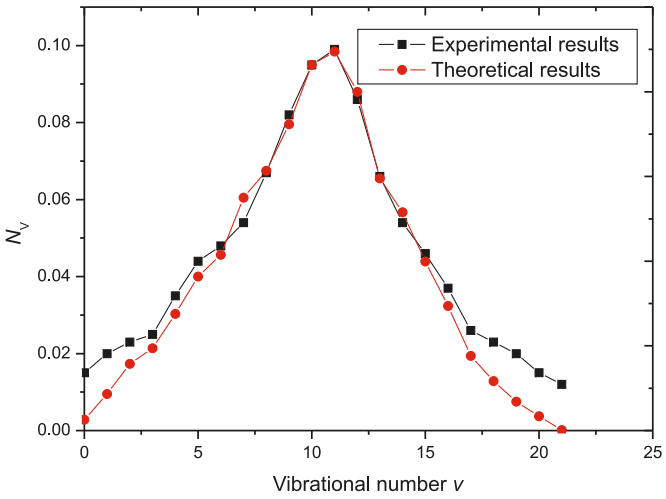
the lowest ($v = 0, j = 0$) because the reagent was "frozen" in the crossed molecular beam experiment.[24] So, the point of Ba + HBr (0, 0) can be the start point in every trajectory. Prior to the calculation, the biggest impact parameter b_{max} must be confirmed, and for different collision energies, the values of b_{max} are shown in Table 2.

In terms of the results of the LIF and the molecular beam,[8] there are several special laws in the Ba + HBr reaction: (*i*) the vibrational excitation of the product BaBr is very high, and the reaction cross section is big too; (*ii*) the collision energy of the reagent plays an important role in the internal-energy distribution and vibrational distribution.

LEPS potential-energy surface (PES)

The features of the PES are the most basic conditions to obtain the information of a chemical reaction. When we know as much information as possible about the PES, then we can study problems like the energy distribution and the product rotational alignment. The extended LEPS PES for the Ba + HBr → BaBr + H reaction is constructed using parameters listed in Table 1. Figure 1 shows the contour plot of this LEPS PES of the collinear configuration of Ba–Br–H. The values of the potential barrier and the potential well are the important data of the reaction potential-energy surface in the QCT calculation. From Fig. 1, one can see that in this reaction, there is a shallow barrier located in the entrance path whose value is 4.5 kcal/mol, and the potential energy decreases gradually from the entrance

Fig. 2. Vibrational distribution of the BaBr product in collision energy 11.761 kcal/mol. The experimental results are from ref. 16.



($R_{Sr,CH_3Br} = \infty$, corresponding to reactants) to the exit ($R_{CH_3,SrBr} = \infty$, corresponding to products). Because the shallow barrier, the reaction cross section decreases first from 0.1 eV to 0.16 eV, then it increases slightly and reaches the maximum value at 0.165 eV, after that it decreases with the increase of the collision energy.

Vibrational distribution

The vibrational distribution of the product BaBr versus collision energy using QCT is shown in Fig. 2. Obviously, Fig. 2 shows that the experimental and calculated results tend to be similar when the vibrational energy is changed.

It can be seen from Fig. 2 that as v is increased, when the value of E_{col} is 11.761 kcal/mol, N_v first increases then decreases. When the value of v is 11, the value of N_v reaches its maximum, which is 0.098. The computational results are different from the experimental ones at the high vibrational quantum numbers. Clearly, the QCT result in the present work is in good agreement with the experimental data.

Reaction cross section

The absolute cross section of the state reaction in the trajectory calculation can be obtained, and its formula and estimate of error are

$$[8] \qquad \sigma_r(E_{col}, v, j) \approx \pi b_{max}^2 \frac{N_r(E_{col}, v, j)}{N(E_{col}, v, j)}$$

$$[9] \qquad \Delta\sigma_r \approx \pi b_{max}^2 \frac{N_r}{N}\left(\frac{N - N_r}{N_r N}\right)^{1/2} = \sigma_r\left(\frac{N - N_r}{N_r N}\right)^{1/2}$$

where N_r is the number of reaction trajectories, and N is the total number of trajectories, while b_{max} is the maximum-impact parameter and $\Delta\sigma_r$ is the estimate of error of σ_r. The relative cross section can be obtained through the experiment, while the absolute cross section can be obtained through the calculation.

The product channel BaBr results of the present and elder's are integrated to get the reaction cross section for the Ba + HBr reaction to compare our result with the experimental results.[8]

Fig. 3. The reaction cross section versus the collision energy for the Ba + HBr reaction. The experimental results are from ref. 16.

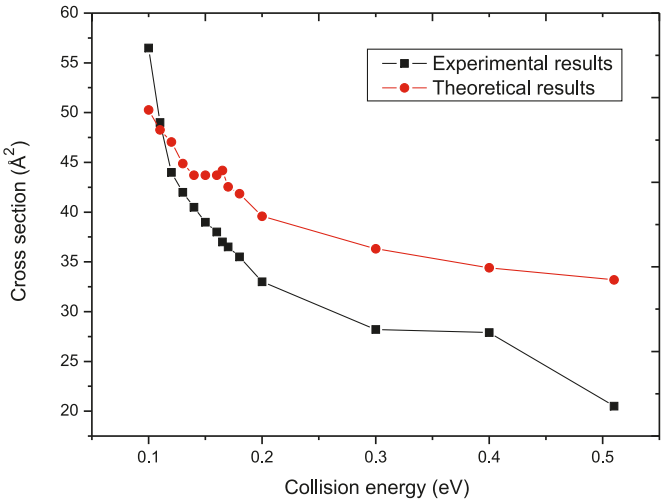


Fig. 4. Maximum-impact parameter b^2_{max} as a function of collision energy. The experimental results are from ref. 16.

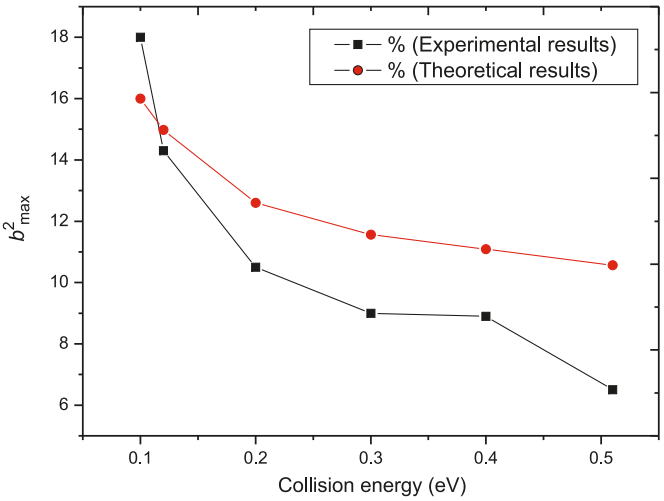

Fig. 5. The product rotational alignment of the Ba + HBr reaction versus the collision energy on LEPS PES.

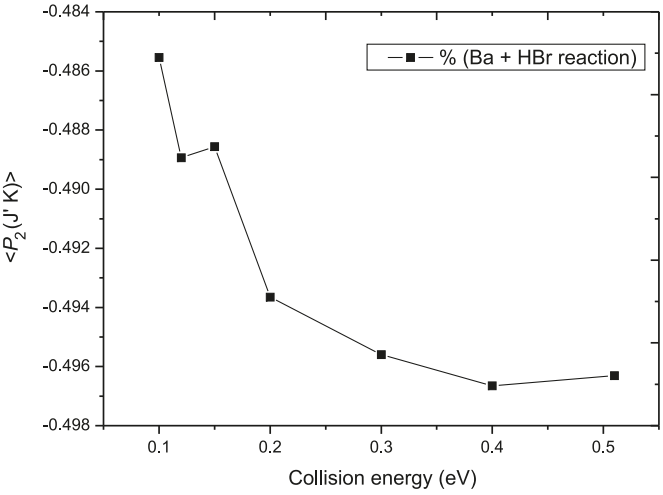

Fig. 6. Mean product energies for BaBr. The experimental results are from ref. 16.

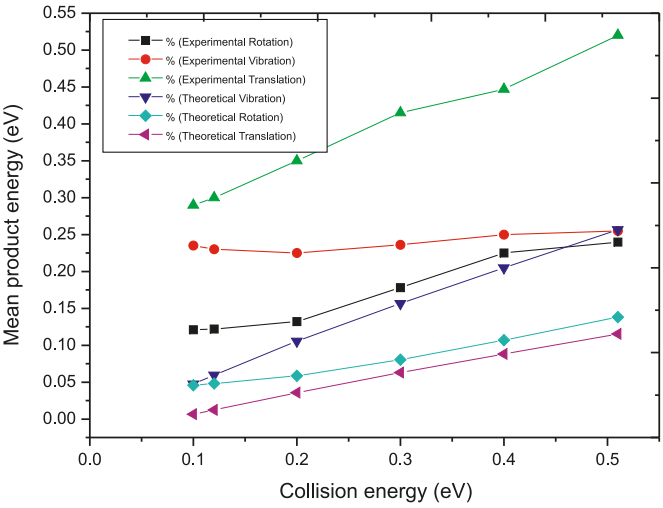

Equation [8] has been used to determine the reaction cross sections, which are given in Fig. 3 for the Ba + HBr → BaBr + H reaction.

The reaction cross section decreases from 50 Å^2 to 33 Å^2 as the calculated increase in the collision energy from 0.1 eV to 0.51 eV takes place. It is very interesting to find the high reaction cross sections at low energies, while low reaction cross sections are found at high energies.

From Fig. 3, it can be seen that the QCT calculation on the PES posts a strong impact on producing BaBr for the Ba + HBr reaction. The decrease of σ_r with E_{col} agrees with the general behavior of exothermic chemical reactions with little or no activation energy, and it can be rationalized as a decrease of b_{max}. We can see from Fig. 3 that as the collision energy increases, the reaction cross sections decrease first and then increase lightly to the maximum value when the collision energy is 0.165 eV then decrease again. These results are consistent with the results of LEPS PES whose potential barrier value is 4.5 kcal/mol. Figure 4 shows the distribution of b^2_{max} when the collision energy increases. Therefore, the values of our reaction cross sections are in the same range (from 50 Å^2 to 33 Å^2) as the experimental results. Clearly, the QCT-computed results of reaction cross section are in good agreement with the experimental data.

Product rotational alignment

The product rotational alignment of the HHL mass-combination reaction, a function of the collision energy, was independent of the characters of the PES. It just increases as the collision energy increases. Whether it is the attractive or the repulsive PES, it can be seen that the product rotational alignment depends on the collision energy slightly.

The Ba + HBr reaction, which is the reaction of interest in this paper, belongs to the HHL-type of reactions. The product rotational alignment tendency of BaBr versus collision energy is shown in Fig. 5.

The variation of $\langle P_2(\vec{J}' \cdot \vec{K}) \rangle$ with the change in the R group in R–Br molecules is probably due to the difference

of the mass factor.[27] The expected values for $\langle P_2(\vec{J}' \cdot \vec{K})\rangle$ are between 0.0 (randomly aligned) and –0.5 (completely aligned).[27] Usually, when $|L| \gg |J|$ and $|L'| \ll |J'|$ are satisfied, the maximum product rotational alignment occurs.[27] The first condition is satisfied for reactions with large cross section, while the typical HHL mass-configuration reaction system leads to the second condition.[27] The product rotational alignment decreases as the collision energy increases, which is achieved by the significant disposal of angular momentum into product orbital motion, and this happens in the condition of high energy.

The excessive translation energy will turn into rotational and translational excitation, as we have already known, and the collision energy is allocated in the rotation momentum in a great measure, which also can be detected from the distinct increment of the alignment. The reaction between an alkaline earth atom (M) and a hydrogen halide (HX) to produce MX + H constitutes a series of related results. In the reaction, two pathways are under discussion, which are abstraction and insertion.

When Ba is attacking HBr on the area that is closer to the Br, there is an attractive area, while Ba on the area closer to the H, is on a repulsive area. The initial velocity was modulated by the action field, which shows that the reaction was affected by the collision energy of the reagent in the following manner: when Ba is close to HBr on the repulsive area and the collision energy is so little that it cannot conquer the repel, Ba prefers the attractive area, and the insertion reaction will occur. At this moment, the vibrational excitation of the product BaBr is strong. When the collision energy of the Ba and HBr is big enough to conquer the repel action, Ba and HBr become close to each other to some degree, and now the bond of H–Br fracture suddenly, and this is the abstraction reaction, which shows that the vibrational excitation is weak, while the translation energy of the product is high. The abstraction reaction is favored by low collision energy, while the insertion reaction is more likely to occur at high collision energy based on the dynamical calculation of this reaction. The progress of reaction is prolonged because of the transfer, which will make the life of the complex long.

For the Ba + HBr reaction, QCT calculations on PES show a great preference for producing BaBr. The reason is probably that the center of mass of the HBr molecule is closer to the Br atom; for the attack of Ba to this end of the molecule, it implies a greater cone of acceptance and thus reproducing the preference for the BaBr product well. The reaction cross section and the product rotational alignment as the function of the collision energy are given in this paper. It is interesting that the reaction cross section and product rotational alignment were all affected by the collision energy.

Other result

Figure 6 shows the mean product energies for BaBr. It can be seen from Fig. 6 that the nearly constant mean vibrational energy reflects the insensitivity of N_v against variations of the E_{col}. It presents the energy dependence of the mean rotational energy. Figure 6 also contains the mean translational energy E_{trans} of the product. It was obtained by subtracting the mean energies E_{vib} and E_{rot} from the totally available energy E_{col}. A constant equivalent to the error in the dissociation energy of BaBr may offset the curves for E_{trans}.

Conclusions

Research on the dependence of the product vibrational distribution, reaction cross section, the product rotational alignment, and other distributions on the collision energy for the Ba + HBr reaction has been carried out. Through the QCT method, the studies of those rules have been performed on LEPS PES at different collision energies. In summary, it is shown that the QCT calculations are in good agreement with the experimental data for the exothermic reaction of Ba + HBr. Comparing the dynamic calculated results on constructed semi-empirical extended LEPS PES with the experimental results, we can know that the extended LEPS PES under the "quasi-three-body" approximation condition can describe the main dynamic rules of multiatomic reaction system well. The calculation shows that when the reagent is in the vibrational ground state, the vibrational distribution of the product BaBr increases and then decreases. The relationship between the product rotational alignment and the collision energy depends greatly on mass combination. The calculated results show that the product rotational alignment decreases when the collision energy of reagent increases. With the increasing of collision energy, the reaction cross section also decreases, while mean product energies increase. The reaction mechanism was discussed using the obtained conclusion that the rule of reaction dynamics, which depends on the reactant collision energy can be explained by the bi-model (abstraction reaction and insertion reaction). Moreover, abstraction is much more probable at low collision energy, and insertion becomes more probable to occur at high collision energy. As mentioned above, the calculated results for the Ba + HBr rection are consistent with the experimental ones.

Photoelectrochemical studies on poly[1-(2-aminophenyl)pyrrole] — Creation of a photoactive inorganic–organic semiconductor interface (IOI)

Kasem K. Kasem, Sara Menges, and Stephenie Jones

Abstract: The compound 2-APPy [1-(2-aminophenyl)pyrrole] as an organic phase in an inorganic–organic semiconductor interface (IOI) assembly was the subject of photoelectrochemical studies in aqueous solutions. Results show that thin films of poly(2-APPy) can be prepared using oxidative electropolymerization. Furthermore, absorption spectroscopic studies indicate that the protonated 2-APPy polymer's ionization potential (IP) is 4.7 eV, the electron affinity (EA) is 1.90 eV, and a gap of 2.80 eV separates the higher occupied molecular orbital's (HOMO) and lower unoccupied molecular orbital's (LUMO) energy levels of this polymer. Impedance measurements under illumination show an increase in the film charge capacitance compared with those measured under darkened conditions. The behavior of the poly(2-APPy) film as a host for redox-active dopants was also explored. The results show that the film did not alter the redox potentials of a large dopant such as $PMo_{12}O_{40}^{3-}$. The photoactivities of the IOI assemblies consisting of 2-APPy and nanoparticles of ZnO, and of Fe_2O_3 were investigated using fluorescence emissions. Results show that the fluorescence emissions generated by 2-APPy were quenched by 5% and 55% on ZnO and on Fe_2O_3, respectively. The charge injection rate constants, k_{ct}, at the inorganic metal oxide–2-APPy interface, were calculated.

Key words: poly[1-(2-aminophenyl)pyrrole], photoelectrochemistry, semiconductors, material, charge transfer.

Résumé : Opérant en solutions aqueuses, on a effectué des études photoélectrochimiques sur un assemblage du 1-(2-aminophényl)pyrrole (2-APPy)dans une interface inorganique/organique semiconductrice (IIO). Les résultats obtenus montrent qu'il est possible de préparer le poly(2-APPy) par électropolymérisation oxydante. De plus les études spectroscopiques d'absorption indiquent que le potentiel d'ionisation (PI) du polymère 2-APPy protoné est égal à 4,7 eV; l'affinité électronique (AE) est de 1,90 eV et que 2,80 eV séparent les niveaux d'énergie de l'orbitale moléculaire haute occupée (HO) et de l'orbitale moléculaire basse vacante (BV) de ce polymère. Des mesures d'impédance sous illumination mettent en évidence une augmentation dans la capacitance de la charge du film par comparaison avec celles mesurées en l'absence d'illumination. On a aussi examiné le comportement du film de poly-2-APPy comme hôte pour des dopants redox actifs. Les résultats montrent que le film n'altère pas les potentiels redox d'un dopant volumineux, tel le $PMo_{12}O_{40}^{3-}$. Les photoactivités des assemblages d'interfaces inorganique/organique semi-conductrices formées de 2APPy et de nanoparticules de ZnO et de Fe_2O_3 ont aussi été examinées à l'aide d'émission de fluorescence. Les résultats montrent que les émissions de fluorescence générées par le 2-APPy sont piégées respectivement par 5% et 55% de ZnO et de Fe_2O_3. On a calculé les constantes d'injection de charge, k_{ct}, à l'interface oxyde métallique inorganique/2-APPy.

Introduction

The interest in developing sensitizers that improve interfacial charge transfer and suppress charge recombination substantiates the need for a wider investigation of organic semiconductors. Organic compounds with semiconducting character have been developed during the last two decades. These types of semiconductors have the potential to minimize the hole–electron recombination rates by polaron production. They also have a proven resistance to photocorrosion and mitigate some of the other disadvantages of inorganic semiconductors as well. Integrating these organic semiconductors at the interface between inorganic semiconductors and electrolytes[1–5] could enhance the process of charge separation and further charge transfer.

Understanding the photoinduced electron-transfer process in organic semiconductors requires correlating their molecular structure and band structure to their observed photoelectrochemical responses.[6–8] Some extrinsic semiconducting properties such as the capacity to transport charge generated by light, which is injected by electrodes or provided by chemical dopants, has been exhibited by many conjugated organic compounds.[1–8] 2-APPy, a conjugated organic molecule, containing both aniline and pyrrole units has the

potential to exhibit these extrinsic properties. Many studies have been carried out on pyrrole-[9–18] and on aniline-related polymers.[19–22] These studies showed noticeable differences in the polymerization mechanisms and in the chemical, electrochemical, and photoelectrochemical behavior of the polymeric films. These studies also showed that both aniline- and pyrrole-related polymers possess the capability for charge injection and (or) transfer. Due to the limitations imposed by the stability requirements and the scope of applications of these polymers, the structure of 2-APPy substantiates interest to explore its potential as an organic semiconductor using photoelectrochemical studies.

The present work focuses on the investigation of the electropolymerization of 2-APPy and a study of the behavior of this polymer towards charge injection from the electrode and from the dopant in aqueous electrolytes. This study was also extended to investigate UV–vis absorption and fluorescence emission spectra to explore the light induced charge transfer process in this compound. Photoelectrochemical and spectroscopic data obtained for 2-APPy were integrated to investigate its semiconductor properties and information related to its band structure including its ionization potential (IP), electron affinity (EA), and band gap (BG or E_g). Adsorption of this compound in monomer or polymer form on metal oxides (inorganic semiconductors) creates assemblies that consist of inorganic–organic interfaces (IOI). Gaining intrinsic information about charge transfer behavior across this IOI was another goal of this study.

Experimental

Reagents

1-(2-Aminophenyl)pyrrole (Sigma-Aldrich) and all other reagents were of an analytical grade. All solutions, unless otherwise stated, were prepared using deionized water.

Instrumentation

All electrochemical experiments were carried out using a conventional three electrode cell consisting of a Pt wire as a counter electrode, Ag/AgCl as the reference electrode, and GCE (glassy-carbon electrode) as the working electrode. A BAS 100W electrochemical analyzer (Bioanalytical Co.) was used to perform the electrochemical and impedance studies. X-ray photoelectron spectroscopy (XPS) was performed using PerkinElmer 5500 ESCA. An Amery 1000A was used to produce scanning electron micrographs of the polymer films. A UV–vis spectrophotometer was used to generate absorption spectra of the thin solid films on ITO electrodes. FTIR (Thermo Nicolet 4100s) was used to confirm the existence of the amino group (NH_2) within the polymer phase.

Fluorescence lifetime measurements

Fluorescence lifetime measurements were performed using a Chronos (ISS, Champaign, IL) with a laser diode as the excitation source.

Impedance measurement

Impedance measurements were carried out within a frequency range between 0.1 mHz and 1 KHz.

Results and discussion

Electropolymerization of 2-APPy

Because of the stability limitations of the dopant used ($PMo_{12}O_{40}^{3-}$) in this study, a mixture of 50% acetonitrile/water was used as a solvent throughout the study. Within the potential window of –1.0 to 2.0 V, 2-APPy polymerized and lost its monomer identity. No reduction or oxidation peaks were evident for 2-APPy when the potential was scanned between –1.0 and 0.9 V during cyclic voltammetric (CV) experiments. Therefore, the only electrochemical behavior observed was that of poly(2-APPy). Oxidative electropolymerization of 2-APPy was used to generate thin films of poly(2-APPy). Figure 1A is a display of the repeti-

tive cycling of the potential of the GCE between –1.0 V and 2.0 V versus the Ag/AgCl in 50% acetonitrile/water mixture containing 0.5 mol/L H_2SO_4 and 5 mmol/L monomer. As the positive potential scanning started at 0.0 V, a shoulder anodic peak appeared at 0.75 V, followed by the large broad irreversible oxidation wave, which were recorded in the first cycle. The anodic peak current of this irreversible anodic wave started to decay as the cycling continued. The 2-APPy monomer has three active sites that can initiate the polymerization process. The drop of the anodic peak current in the second and subsequent cycles can be attributed to the semiconducting nature of the polymer film and to the high degree of cross-linking that hinders the contact of monomer species with the electrode surface.

To get an understanding of the polymerization process of 2-APPy consider the fact that 2-APPy is a combination of pyrrole and aniline units. The CV of the electropolymerization of aniline (Fig. 2A) gives a CV wave where the anodic and cathodic peak currents grow with the successive scan (note the scan number). The CV of the electropolymerization of pyrrole under similar conditions gives an irreversible anodic wave during the first scan followed by a significant drop of anodic current, which reflects a passive film nature. On the other hand, the CV of electropolymerization of an equiconcentration aniline/pyrrole mixture shows a decay of both anodic and cathodic current (note the scan number) with succession potential scans (Fig. 2B). This indicates that pyrrole is the dominating component in the mixture under the experimental conditions. Although Fig. 2B does not resemble Fig. 1, the commonality between these two figures is the decay of the current after the first scan, which reflects the passive nature of the generated films.

Polymeric film characterizations

Figure 3A illustrates the CV for the electrode modified with a thin film of poly(2-APPy) (dashed line) overlaid with the CV for an electrode modified with a thin film of the polymer generated from an aniline/pyrrole monomer mixture (solid line) in 0.5 mol/L $HClO_4$. Under the experimental conditions, the noticeable difference between these two polymer films is that polypyrrole did not show any redox peaks within the experimental potential window (CV are not shown); therefore, polypyrrole is redox inactive. This leads us to conclude that the polymerization of 2-APPy is controlled by the pyrrole portion of 1-(2-aminophenyl)pyrrole, while the redox behavior of poly(2-APPy) is quite different from what might be expected from the aniline part in the polymer. Recalling that in an acidic solution, the pyrrole ring in the monomer is more stable than that of the aniline, and it is easier to quaternize (protonate) the N-terminal NH_2 group on the phenyl ring versus the N within the pyrrole ring. Under the experimental conditions, the quaternized amino group will hinder participation of the aniline side of the monomer in the polymerization process. Furthermore, IR

studies indicate the presence of amino groups within the neutral polymer film (peaks at 1633 and 3385 cm^{-1} represent scissoring and aromatic stretching of NH_2 vibrations, respectively). These facts support our assumption that electropolymerization through the pyrrole ring within 2-APPy is kinetically favored. The fact that 2-APPy polymerization is achieved using oxidative electropolymerization suggests that a cation radical has played an important role in initiation of the propagation steps of the polymerization process. The mechanism and the kinetics of the electropolymerization will be the subject of future investigation.

Electrochemical behavior of poly(2-APPy)

The redox behavior of poly(2-APPy) in 0.5 mol/L $HClO_4$ is displayed in Fig. 3B (solid line). The CV shows a reversible wave at $E^{0'} = 0.45$ V and an ill-overlapping anodic wave at $\approx$0.7 V. Also present is a broad cathodic wave between –0.4 and –0.06 V. In 0.5 mol/L $KClO_4$ (a neutral electrolyte), although the reversible wave shows up at $E^{0'} = 0.175$ V, an irreversible anodic peak appears at $\approx$0.7 V and a broad cathodic peak appears between –0.4 and –0.06 V (Fig. 3B dashed line). Considering the fact that polypyrrole is electrochemically inactive within the experimental potential window, the cyclic voltammetric behavior described above as displayed in Fig. 3B, can be explained as follows: The reversible CV wave can be attributed to aniline activity within the polymer film. Aniline (in one of the polymer segments) acts as a functional group for the charge injection that takes place through the amino group in L (Leucoemeraldine). Furthermore, these side reactions can lead to the formation of cation radicals ($L^{\bullet+}$), and their protonated forms (LH_2^{2+})[23] during the potential cycling. The CV wave at 0.175 V in the neutral electrolyte is due to the unprotonated form of the polymer. The protonated forms require a more positive potential to be oxidized. This explains the positive shift of the formal potential ($E^{0'}$) from 0.175 V in a neutral electrolyte to 0.450 V in an acidic electrolyte. The ill-developed anodic peak shown at $\approx$ 0.7 V is pH independent, and is attributed to further oxidations of the L form to $L^{\bullet+}$ to form PH_2^{2+} (protonated pernigraline). The lack of a cathodic peak makes perfect reversible behavior impossible. However, it is noticeable that the reduction peaks in the CV wave in acidic and in neutral media are greater than the anodic peaks. This may be due to the reduction of the PH_2^{2+} (formed at 0.7 V) that causes these waves to overlap. This also may indicate that the reduction of PH_2^{2+} is quasi-reversible.

Performing a CV in both the absence and the presence of oxygen indicates that peaks appear in the potential range between –0.4 and –0.06 V due to the reduction of trapped O_2. Figure 3B also indicates that the protonated film of poly(2-APPy) possesses less capacitive current than the unprotonated film.

Poly(2-APPy) film was subjected to XPS and IR studies. IR results show peaks at 1633 and 3385 cm^{-1}, which indicates aromatic NH_2 group scissoring and stretching vibrations, respectively. The XPS results are displayed in Fig. 1B. It can be noticed that the N peak is $\approx$20% of that of the C peak. This reflects the N to C ratio in the monomer. The inset in Fig. 1B is the scanning electron micrograph of the polymer films, which describes some discontinuity in the film matrices as indicated by small and large particles.

Ion-exchange properties of poly(2-APPy)

Poly(2-APPy) acts as an anion dopant exchange polymer. The quaternized N centers within an acidic solution produces ion pairing with electrolyte anions such as SO_4^{2-} or ClO_4^-. Doping this film with large redox anions becomes possible because of these centers. Phosphomolybdate anions ($PMo_{12}O_{40}^{3-}$) were incorporated in the poly(2-APPy). The CV for poly(2-APPy) doped with $PMo_{12}O_{40}^{3-}$ is displayed in Fig. 4. The well-developed consecutive redox waves of $PMo_{12}O_{40}^{3-}$ indicate that the doped redox oxoanion underwent multiple electron transfers (2 e^- each) without interference from the host film. This behavior is similar to that previously reported for the $PMo_{12}O_{40}^{3-}$'s CV in a liquid electrolyte only.[24] It is worth noticing the lack of the host film's CV wave appearing in the displayed CV. This indicates that the rates of charge transfer among Mo(VI) centers in $PMo_{12}O_{40}^{3-}$ are greater than that in the film network structure, and that the charge transfer process is not hindered by the conjugate Π electrons of the polymer. Furthermore, poly(2-APPy) doped with $PMo_{12}O_{40}^{3-}$ exhibits less capacitive current than that undoped one. The incorporated oxoanions have electrochromic properties that can be used to manipulate the photonic properties of poly(2-APPy) that are doped with $PMo_{12}O_{40}^{3-}$ assemblies.

Optical activities of poly(2-APPy)

Absorption spectra of poly(2-APPy) thin films deposited over ITO (indium–tin oxide glass) are displayed in Fig. 5. In this figure, we can identify a broad absorption peak in the wavelength range of 430–490 nm. This broad absorption peak corresponds to an E_g range from 2.8 to 2.5 eV. This is also an indication of energy intervals with high density states that represent HOMO (higher occupied molecular orbitals) and LUMO (lower unoccupied molecular orbitals). The absorbed photons are consumed in generating charge carriers, probably by an extrinsic mechanism.

Energy map of poly(2-APPy)

To draw the energy map of the studied organic semiconductor film of poly(2-APPy), along with the band gap (E_g), parameters such as IP and EA are required. Furthermore, these parameters are needed to explain the electrical and optical properties of the film. Relating electrochemical data, such as the onset oxidation potential (E'_{ox}), the onset reduction potential (E'_{Red}), and the band gap, leads to an understanding of the integrated energy diagram of the film. Onset potentials can be estimated from the intersection of the two tangents drawn at the rising oxidation current and the background current in the CV using the following formula:[25]

$$[1] \qquad E_{ox} = E'_{ox} + E_{\text{reference electrode}} \approx E_{vac} + 4.6\,\text{eV}$$

As Ag/AgCl was used as a reference electrode (E^0 = 0.197 V vs normal hydrogen electrode (NHE)), and $E_{vac} \approx 0$, the above equation can be written as follows:

$$[2] \qquad \text{IP} \approx E'_{ox} + 4.4\,\text{eV}$$

Considering the energy gap between HOMO (valence band) and LUMO (conduction band) to be the band gap (E_g), and the energy gap between the LUMO and vacuum

level to be the electron affinity (EA), we can write the following equation:

$$[3] \quad IP = EA + E_g$$

The determined E'_{ox} obtained for the protonated polymer ($\approx$0.3 V) generates a 4.70 eV for IP, and a 2.12 eV for EA. In neutral media (unprotonated film), quantities for IP and EA are 4.56 eV and 1.98 eV, respectively. The reported low solid state EAs of poly(2-APPy) reflect an electron donor nature (p-type) and can be compared to those reported for PBZT {poly[*p*-(2-hydroxy)phenylenebenzbisthiazole]}.[26,27] To draw the energy diagram of poly(2-APPy) we recognize that IP and EA values can be influenced by polarization effects and structural relaxation. This would explain why conjugated polymers do not present an energy band similar to that of inorganic crystalline semiconductors, but rather they show energy intervals with a high density of states representing HOMO or LUMO of the polymer chain segments. Diagram 1 displays an energy-level diagram for poly(2-APPy) film that is based on the determined values for E_g, IP, and EA assuming molecular symmetry conditions.

Electrochemical impedance studies

Impedance studies were carried out at two potentials, with and without illumination. These conditions were used to demonstrate the effect of charge transfer and injection induced by electrochemical or photonic methods. The admittance plots at 0.0 V and $\approx$–0.8 V, taken both in the dark and under illumination, are displayed in Fig. 6. The simplified equivalent circuit that describes the data is displayed in Fig. 6, where R_{ct}, C_{dl}, and R_{Ω} are the charge transfer resistance, double layer capacitance, and ohmic solution resistance, respectively. Impedance studies at 0.0 V (below the onset oxidation potential) would give some information about the film in the absence of charge removal. Studies under illumination (Fig. 6, trace 2) at this potential will indicate the photonic effects only (if any photonic effects are present). Previous studies[15] reported that E_{fb} (the flat band potential) of polypyrrole derivatives is $\approx$–0.8 V versus the Ag/AgCl electrode. Impedance studies were performed at $\approx$–0.8 V to determine the effect of illumination (Fig. 6, trace 4) on electrical properties such as charge injection and capacitance of the film. The lack of band bending at E_{fb}, and the lack of band features for organic semiconductors suggests that a higher density of states, and consequently greater capacitance, was created at –0.8 V rather than at 0.0 V. Impedance measurements and calculations of the film capacities were performed as described in ref. 28 and summarized in Table 1. The data displayed in Table 1 show that:

At 0.00 V illumination there was no tangible change in the charge capacitance in the film. This is consistent with the fact that the applied potential is less than the onset oxidation of the film assembly. Therefore, no charges can be removed and no anions from the electrolyte will be incorporated.

Capacitance measured under an applied potential closer to the E_{fb}, while in the dark, almost doubles at 0.00 V. This can be attributed to the reduction of molecular oxygen that is entrapped within the film forming superoxides (O^{2-}), and these cause further changes at the film–electrolyte interface at the flat band potential.

Upon illumination at –0.800 V, the capacitance is 3.3 times that measured in the dark. This is an evidence of charge injection and the formation of a new dielectric system. Further, it suggests that this capacitance increase indicates restructuring of the double layer at the film–electrolyte interface. This is because double layer illumination causes an increase in the temperature at the electrode–electrolyte interface, which causes a drop in double layer capacitance ($C\alpha\ T^{-1}$) . The charge injection as a direct interaction of the polymer network structure with the electrolyte anions takes place concurrently with the double layer restructuring process. This may include photoinduced film polarity as a major factor in the film capacitance. Furthermore, illumination does not change the equivalent circuit of the film but rather changes the capacitor charge.

Potential integration with inorganic semiconductor assembly

Charge injection from one system to the other depends on, first, the potential maps (conduction and valence band) in the inorganic semiconductor and the higher unoccupied and lower occupied molecular orbitals (HUMO–LOMO) of the organic semiconductor; second, it depends on the lifetime of the excited state of each semiconductor; and third, it depends on the amount of overlapping between the band gaps of these two systems. Fluorometric emission studies indicate that the 2-APPy monomer and its polymer generated an emission when excited with a 320 nm source. The lifetime of the excited state of the monomer was measured to be 299 ps (rate constant of charge injection (k_{ct}) = $3.3 \times 10^9\ s^{-1}$), while that of the polymer was 437 ps (with k_{ct} = $2.3 \times 10^{9}\ s^{-1}$). Such elongation of the lifetime in the polymer is attributed to the increasing of the LUMO in the polymer compared with that in the monomer. The polymer maintained the conjugated structure, which allows coordination of LUMOs of the polymer units. These LUMOs can accommodate the excited electrons for some time before these electrons return to the ground state. The studies show that 2-APPy in colloidal SiO_2 gives a strong emission at λ = 360 nm (Fig. 7a). While the greater band gap of SiO_2 explains the lack of absorption of emitted photons from 2-APPy, it also indicates that the LUMO of 2-APPy is far below the conduction band in SiO_2.

IOI involving Fe_2O_3

A colloidal system of SiO_2 containing 5% iron oxide and the 2-APPy shows a great quenching of emission (drop of 55%) as displayed in Fig. 7b. This observation indicates that the junction at iron oxide colloidal particles–2-APPy interface has a band-energy structure that favors this emission absorption. The fact that the flat band potential of poly(2-APPy) is more negative than that of the conduction band (CB) of Fe_2O_3 (CB = –0.58 vs Ag/AgCl) would explain the observed quenching of emission in the presence of Fe_2O_3. Schematic Diagram 2 illustrates the relative band structure of poly(2-APPy) and Fe_2O_3. The fluorescence lifetime of 2-APPy is 0.437 ns. The shorter lifetime of the organic semiconductor excited state compared to that reported for Fe_2O_3 suggests that organic semiconductors will inject

charges into the iron colloidal particles because the hole in the valence band (VB) has a longer life than the hole generated from 2-APPy. These electrons can be injected to neutralize the holes in the VB of Fe_2O_3. This will certainly reduce the electron–hole recombination process. The lifetime of the polaron created in the organic semiconductor will determine whether these polarons will be partially or totally used in an oxidation of the chemical agent in conjunction with this illuminated IOI. It is worth noting that the Fe_2O_3 – 2-APPy assembly acts as a potential capturer of UV solar radiation and makes it available for absorption at a longer wavelength for a dopant with a correspondent band gap.

IOI involving ZnO

Aqueous colloidal solution of nanoparticles of ZnO containing 2-APPy was subject to fluorescence emission studies. The results are displayed in Fig. 7c. Unlike d^5 Fe_2O_3, a d^{10} ZnO–2-APPy assembly shows a sharp emission peak at 370 nm with emission tails at longer wavelengths ($\approx$430 nm). Although such behavior was reported for ZnO quantum dots (QDs)[29] and for other oxides,[30,31] we expect that the emission at 430 nm is due to 2-APPy only. This is due to the lack of excess OH^- that causes the emission at this wavelength. Figure 7c indicates that very small emissions were absorbed by the ZnO–2-APPy assembly. This can be attributed to the high barrier potential[32] at this interface (calculated to be 3.4 eV), and the low EA of ZnO (2.09 eV), which categorizes it as a p-type semiconductor. A p–p junction interface does not promote charge injection. Establishing a database about this organic semiconductor–metal oxide interface would find greater application relevant to organic light emitting diodes.[33] Further studies will be performed on inorganic–organic interface (IOI) systems to investigate the effect in lowering the electron–hole recombination rate and suppressing the photo-corrosion of an inorganic semiconductor.

Conclusions

The results obtained in this study represent an attempt to establish a database regarding the photoelectrochemical behavior of 2-APPy. The photoelectrochemical studies on 2-APPy indicate that this compound possesses the characteristics of a p-type organic semiconductor. Studies also show that the course of the polymerization process of this compound was different from those of the parent compounds. Although this work answers some questions, it, however, raises more questions that need to be answered in future detailed studies.

Synthesis of both isomers of aziridine derived from the mixture of *cis*- and *trans*-limonene oxide

Hossein Mehrabi

Abstract: A short and efficient route is described for both isomers of aziridine derived from the commercially available 1:1 mixture of limonene oxides. The process is amenable to scale-up and allows easy access to multigram quantities of these useful chiral building blocks.

Key words: cis- and *trans*-limonene oxide, β-amino alcohol, *o*-tosylation, limonene aziridine.

Résumé : On a décrit une méthode courte et efficace d'obtention des deux isomères de l'aziridine qui peut être obtenue à partir d'un mélange 1 :1 commercialement disponible d'oxydes de limonène. Le processus pourrait être amener à produire de grandes quantités et il permet d'accéder facilement à des quantités multigrammes de ces importants intermédiaires chiraux.

Mots-clés : oxydes des *cis*- et *trans*-limonène, β-amino alcool, *o*-tosylation, aziridine du limonène.

[Traduit par la Rédaction]

Terpenes, particularly limonenes, are an important class of naturally occurring chiral compounds widely used in organic synthesis either as starting materials in the synthesis of optically pure molecules[1] or as the chiral core of the numerous chiral auxiliaries or asymmetric ligands employed in enantioselecive transformations.[2] In the majority of cases, the ligands derived from terpenes are amino alcohols as opposed to diamines, and the use of diamines as ligands in asymmetric synthesis is well-established.[3] The simplest way to access diamines in an enantiomerically pure form is from stereoselective ring opening of chiral aziridines.[4]

While methods for the synthesis of chiral epoxides, and thus chiral amino alcohols, have been an area of active research interest for some time, the area of asymmetric aziridination has only recently become implemented.[4] An alternative to this approach would be to utilize molecules from the chiral pool and develop chemistry to transform them into optically active aziridines. The most obvious starting materials to carry out such transformations would be amino acids, and indeed numerous methods have been developed for the transformation of amino acids into the corresponding optically pure aziridines[4,5] via the corresponding amino alcohols. Although, this would offer simple, rapid access to a number of diamines, the flexible nature of the amino acids side chain would not be suitable for developing chiral ligands.[6] Thus, the attention of our group was turned to the naturally occurring terpenes, the substituents of which are in geometrically defined environments as a result of the rigidity of the ring systems. In conjunction with our program to develop ligands for such asymmetric transformations, as well as our general interest in the chemistry of these naturally occurring chiral building blocks,[7] our group aimed to obtain the aziridines derived from limonene in diastereomericaly pure form. While several methods for the preparation of terpene aziridines have been reported, they vary in their degree of regio- and diastereo-selectivity.[8]

Herein, a method is reported for the selective synthesis of either diastereomer of aziridine from the commercially available 1:1 mixture of limonene oxides.

The separation of limonene oxide diastereomers by distillation is difficult,[9] though partial separation has been achieved by this method.[10] However, to separate the epoxides, there are chemical methods of isomer resolution based on the difference in rates of the *cis*-limonene oxide and *trans*-limonene oxide opening either by amines[10,11] or via hydrolysis.[12,13] Trans-diaxial ring opening of the *trans*-limonene oxide is more facile; hence, this isomer reacts faster than the other one, and this difference can be exploited in the separation of the corresponding products.

The reaction of a 1:1 mixture of *trans*-limonene oxide (**1a**) and *cis*-limonene oxide (**1b**) with ethanolamine gave a mixture of the β-amino alcohol (**2a**) and the unreacted *cis*-limonene oxide (**1b**).[12a] The *cis*-limonene oxide was recovered from the reaction mixture in 85% yield after a simple distillation in greater than 98% purity. The crude β-amino alcohol was purified by isolation of the oxalate salt, followed by treatment with potassium hydroxide to give the free base,[10b] which was subsequently recrystallizad (Scheme 1).

The selectivity observed in these reactions can be explained by the inherent conformational difference between *cis*- and *trans*-limonene oxides (Scheme 2). Because of its large *A* value, the isopropenyl group prefers the equatorial orientation in both the *cis*- and *trans*-isomers. For the *trans*-isomer, **1a**, an S_N2-type reaction with ethanolamine can be envisioned to occur at the less hindered C-2 carbon through a thermodynamically stable chair-like transition state (Scheme 2A). In contrast, for S_N2-type attack at the C-2 carbon atom to occur, the *cis*-isomer would have to attain the unfavorable, energetically demanding "boat-like" transition state. Consequently, the *cis*-isomer is left largely unreacted (Scheme 2B).

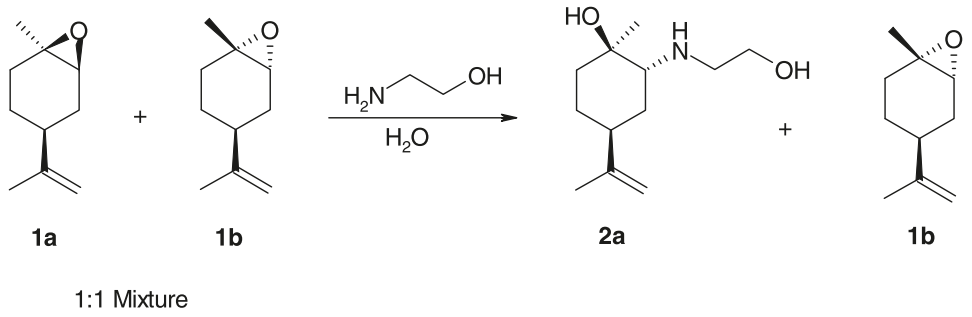
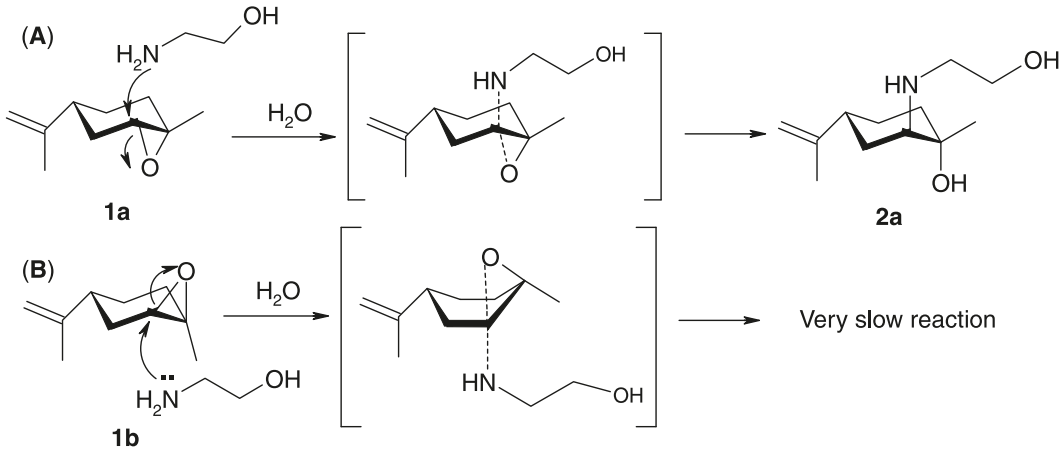
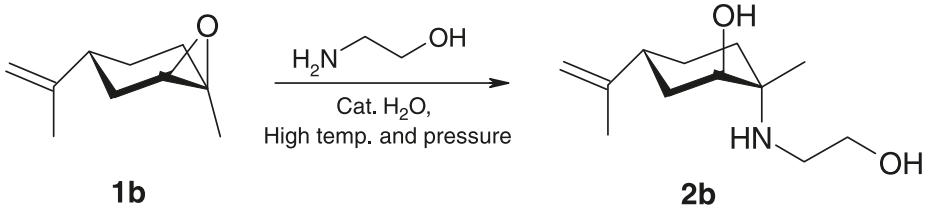
Scheme 1.



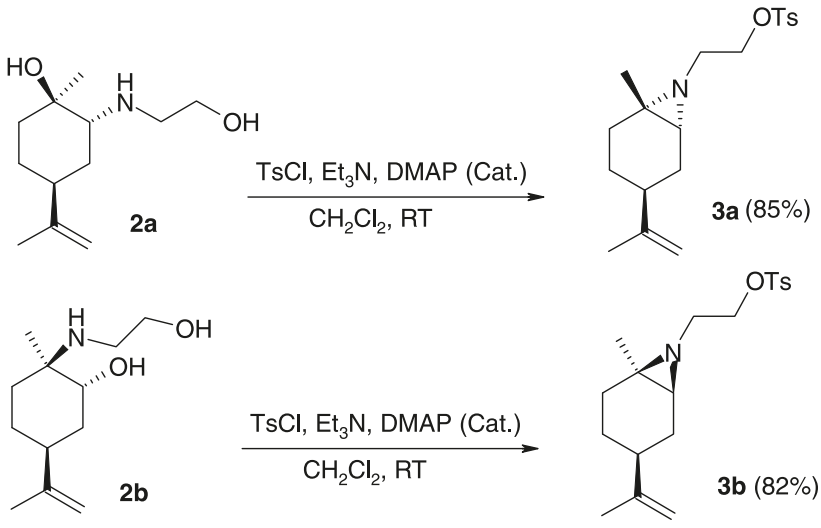
Scheme 2.



Scheme 3.



Scheme 4.



The amino alcohol **2b** can be prepared from the recovered pure *cis*-limonene oxide and ethanolamine under high temperature and pressure (sealed tube) in the presence of a catalytic amount of water.[14] Epoxide ring opening of the cis-diastereomer provides amino alcohol where the amine is attached to the more C-1 carbon atom (Scheme 3).

The products **2a** and **2b** were fully characterized by elemental analyses, IR, ^{1}H NMR, ^{13}C NMR, and mass spectrometry (see Appendix I).

It was thought that the *o*-tosylation and cyclization could be performed in a single operation starting from the β-amino alcohols **2a** and **2b** (Scheme 4). Therefore, the reaction involved 1.0 equiv. of β-amino alcohol with 2.5 equiv. of tosyl chloride and excess (3.0 equiv.) triethylamine in CH_2Cl_2 and in the presence of a catalytic amount of DMAP (see Appendix II), observing that the expected chiral aziridines **3a** and **3b** were formed cleanly after 24 h with high yields. When these conditions were applied at a larger scale (10 g), the reaction showed to be equally effective, giving comparable yields of the final compound (**3a,** 8.5 g and **3b,** 8.2 g).

The structure of compounds **3a** and **3b** were confirmed by their analytical and spectroscopic data (^{1}H NMR, ^{13}C NMR, IR, and MS) (see Appendix II). The coupling constants of the aziridinyl proton of **3b** (2.62, dd, $^3J_{HH}$= 16.8 Hz, $^3J_{HH}$= 2.4 Hz, N–C**H**) showed a clear difference from the aziridinyl proton of **3a** (2.62, dd, $^3J_{HH}$= 10.4 Hz, $^3J_{HH}$= 5.6 Hz, N–C**H**).

In conclusion, this paper reports an efficient and convenient procedure for the highly selective synthesis of either diastereomer of aziridine derived from limonene starting from the commercially available 1:1 mixture of limonene oxides. It is important to point out that the reaction was performed on a 10 g scale, which allowed the preparation of high quantities of the target aziridines in a single step and using a simple protocol.

Appendix II

General procedure for the preparation of compounds 3a and 3b

Et_3N (0.10 mol) was added to a cooled (0 °C) solution of the starting β-amino alcohols **2a** and **2b** (0.03 mol), TsCl (0.07 mol), and DMAP (30 mg) in dry CH_2Cl_2 (200 mL). The mixture was allowed to reach RT and stirred at this temperature for 24 h after which a saturated NH_4Cl solution (100 mL) was added. The mixture was extracted with CH_2Cl_2 (3 × 50 mL), and the organic fractions were collected, dried over Na_2SO_4, filtered, and the solvent removed in vacuo, affording the desired aziridines (**3a** and **3b**) after flash column chromatography purification (hexane/AcOEt 8:2).

Commercial ZrO_2 as a new, efficient, and reusable catalyst for the one-step synthesis of quinolines in solvent-free conditions

Mona Hosseini-Sarvari

Abstract: Commercially available zirconia (ZrO_2) is reported as an extremely efficient catalyst for the synthesis of quinolines. A one-step reaction of 2-aminoarylketones and a carbonyl compound (Friedlander reaction) took place under solvent-free conditions to afford the corresponding quinolines in good-to-high yields in the presence of ZrO_2. Furthermore, the catalyst is reused several times without any significant loss of its catalytic activity.

Key words: ZrO_2, Quinoline, Friedlander reaction, solvent-free, 2-aminoarylketones.

Résumé : On a observé que la zircone commercialement disponible est un catalyseur extrêmement efficace pour la synthèse des quinoléines. En présence de ZrO_2, la réaction de Friedlander, une réaction en une étape entre une 2-aminoarylcétones et un composé carbonylé, se produit dans des conditions sans solvant pour conduire aux quinoléines correspondantes avec des rendements allant de bons à excellents. De plus, on peut réutiliser le catalyseur à plusieurs reprises sans perte significative de son activité catalytique.

Mots-clés : ZrO_2, réaction de Friedlander, sans solvant, 2-aminoarylcétones.

[Traduit par la Rédaction]

Introduction

Quinolines are well-known for a wide range of medicinal properties and for being used as antimalarial, antiasthmatic, antihypertensive, antibacterial, and tyrosine-kinase-inhibiting agents.[1] They also undergo hierarchical self-assembly into a variety of nano- and meso-structures with enhanced electronic and photonic functions.[2] Thus, a great deal of effort has been drawn to develop new and efficient synthetic routes to quinoline derivatives. Among several routes to quinoline synthesis, an acid- or base-catalyzed condensation followed by a cyclodehydration between a 2-aminoarylketone and a carbonyl compound containing a reactive α-methylene group, namely the Friedlander reaction, is one of the simplest and straightforward methods.[3] This classical method is still not fully satisfactory with regard to the relatively low yield, harsh reaction conditions, side reactions, and also under base-catalyzed conditions. In addition, *o*-aminobenzophenone fails to react with simple ketones such as cyclohexanone and β-ketoesters.[4] Recently, modified methods employing $ZnCl_2$, $SnCl_2$, $Bi(OTf)_3$, $AuCl_3$, $CeCl_3$, and so forth[5,6] have been reported for the synthesis of quinolines. In these methods, the catalyst is destroyed during the work-up and cannot be recovered. However, development of a new catalyst, which can be reused, commercially available, new, and simplest for the synthesis of this important class of heterocyclic compounds is of demand.

Today, active surfaces, such as metal oxides, play an ever growing role in organic synthesis and are widely employed not only for preparative organic reactions but also in the industry. Such reactions normally proceed under mild conditions, with high chemo-, regio-, and stereo-selectivities, securing simpler isolation procedures compared with similar reactions in solution.[7,8]

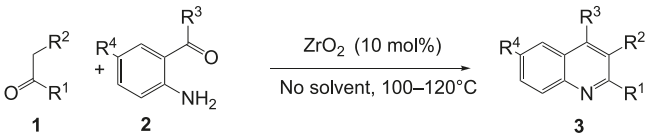
Results and discussion

Herein, I have studied the reaction of ethylacetoacetate with 2-aminoacetophenone in the presence of metal oxides as a model reaction in solvent-free conditions (Table 1). The progress of the reaction was monitored by TLC and ^1H NMR spectra from the reaction mixture.

For the first time, it is shown (Table 1) that certain metal oxides are active catalysts for the interaction studied, particularly ZrO_2, TiO_2, and both acidic and basic types of Al_2O_3. So, by considering the reaction time and yield, ZrO_2 was found to be the most effective in comparison with other metal oxides that were chosen. Subsequently, a series of substituted quinolines were synthesized following the same method using this catalyst (Scheme 1, Table 2). Interestingly, cyclic ketones, such as cyclohexanone and cyclopentanone, reacted with 2-arylketones to afford the respective tricyclic quinolines. The reaction is fairly general, clean, and efficient. The experimental procedure is very simple. The good-to-high yield transformation did not form any significant amounts of undesirable side products.

The condensation of 2-aminoarylketones (**2**) (R^3 = Me, Ph; R^4 = H, Cl) with unsymmetrical 1,3-diones (**1**) gave exclusively the regioisomer **3** if the two carbonyl groups present in **1** had dissimilar reactivity with regard to enamine

Scheme 1.



formation. However, the condensation of 2-aminoarylketones (**2**) with ethyl-4,4,4-trifluoro-3-oxobutanoate led to regioisomeric mixtures of quinolines **3** and **4**, respectively (Table 2, entries 3 and 12). This can be discussed by the similar activity of the two carbonyl groups present in ethyl-4,4,4-trifluoro-3-oxobutanoate, where the actual mechanism seems to be that the enamine formation may proceed in the condensation step; however, in this case, it is rather an iminoether (**4c**, **4l**).

From an environmental point of view, it is desirable to minimize the amount of waste for organic transformation. In this context, the catalyst was recycled for subsequent runs. The recyclability of the catalyst was investigated using a model reaction of the synthesis of quinoline **3a** in the presence of 10 mol% of the catalyst in solvent-free conditions. After the completion of the reaction (monitored by TLC), EtOAc was added to the reaction mixture and then filtered to separate the catalyst. The recycled catalyst was used for further runs, and it was found that its activity does not show any significant decrease even after six runs. It should be noted that although no solvents are used in the reaction itself, but to separate the catalyst and for the isolation and purification of the products, quantitative amounts of solvent are used.

In summary, the present protocol is the first example of ZrO_2-catalyzed synthesis of quinolines in benign conditions. The advantages of this method are the use of a cheap and commercially available catalyst. No toxic reagents, solvents, or byproducts were involved, and no laborious purifications were necessary. These conditions are also environment-friendly, cost-effective, and possess high generality to make our methodology industrialized as a valid contribution to the existing methodologies in the field of quinoline synthesis.

Experimental

Chemicals were purchased from Fluka, Merck, BDH, and Aldrich Chemical Companies. Progress of the reactions was followed by TLC using silica gel polygrams SIL G/UV 254 plates. NMR spectra were recorded on a Bruker DPX 250 MHz instrument. Microanalyses were performed on a PerkinElmer 240-B microanalyzer.

General procedure

To a mixture of 2-aminoaryl ketone (1 mmol) and a methylene carbonyl compound (1.5 mmol) ZrO_2 (0.12 g, 10 mol%) was added. The mixture was heated in an oil bath at 100–120 °C, and the reaction was monitored by TLC. After the reaction was complete, EtOAc was added to the reaction mixture, which was filtered to separate the catalyst. The organic solvent was removed under reduced pressure. After purification by chromatography on silica gel (*n*-hexane/ethyl acetate, 70:30), the product was obtained. The structures of the products were confirmed by ^{1}H NMR, IR, and comparison with authentic samples obtained commercially or prepared by reported methods. All products are known and were characterized by ^{1}H NMR, IR, and mass spectral data, which were found to be identical to those described in the literature, and for the new compounds, complete spectroscopic data are described below.

Table 1. ^{1}H NMR spectroscopic monitoring of the reaction of ethylacetoacetate (**1a**, 1.5 mmol) with 2-aminoacetophenone (**2a**, 1 mmol) at 100 °C under solvent-free condition.

Rearrangement mechanisms for azoxypyridines and azoxypyridine *N*-oxides in the 100% H_2SO_4 region — The Wallach rearrangement story comes full circle[1]

Erwin Buncel, Sam-Rok Keum, Srinivasan Rajagopal, and Robin A. Cox

Abstract: Kinetic studies of the Wallach rearrangements of four azoxypyridines, four azoxypyridine *N*-oxides, and one azoxypyridine *N*-methiodide have been carried out in the 100% H_2SO_4 acidity region. For all of the β-isomers in the study the reactions proceeded at a spectrally measurable rate, and the log observed rate constants were found to be linear functions of the log $H_3SO_4^+$ concentration, as previously found for azoxybenzene itself, suggesting that the reaction mechanism for these substrates is the same as that previously deduced for axozybenzene, i.e., a general-acid-catalysis A-S_E2 process. For the α-azoxypyridines no reaction could be observed at all. The two α-azoxypyridine *N*-oxides in the study did react, albeit very slowly, but for these two compounds the log observed rate constants were not linear functions of the log $H_3SO_4^+$ concentration, but were instead found to be linear in the H_0 acidity function, which is known for the 100% H_2SO_4 acidity region. It follows that the reaction mechanism for these α-isomers is a different one, presumably an A1 process. This mechanism was proposed back in 1963 for azoxybenzene, but has never actually been observed for any substrate before the work reported in this study. Thus, the Wallach rearrangement story can be said to have come full circle.

Key words: azoxypyridines, azoxypyridine *N*-oxides, Wallach rearrangement, reactivities, mechanisms.

Résumé : Opérant dans la région d'acidité du H_2SO_4 à 100 %, on a effectué des études cinétiques sur les réarrangements de Wallach de quatre azoxypyridines, de quatre *N*-oxydes d'azoxypyridines et d'un *N*-méthiodure d'azoxypyridine. Pour tous les isomères β de l'étude, les réactions procèdent à des vitesses spectroscopiquement mesurables et on a trouvé que le log des constantes de vitesse observées sont linéaires avec le log de la concentration en $H_3SO_4^+$, tel qu'on l'avait observé antérieurement avec l'azoxybenzène lui-même, ce qui suggère que le mécanisme de la réaction pour ces substrats est le même que celui déduit antérieurement pour l'azoxybenzène, c'est-à-dire un processus de catalyse acide générale, A-S_E2. Pour les α-azoxypyridines, on n'a observé aucune réaction. Les deux *N*-oxydes de la α-azoxypyridne réagissent, mais la réaction est toutefois très lente et les log des constantes de vitesses de ces deux produits ne donnent pas de relation linéaire avec le log de la concentration en $H_3SO_4^+$; elles sont toutefois linéaires avec une fonction d'acidité H_0 qui est connue pour la réaction d'acidité du H_2SO_4 à 100 %. On peut donc en conclure que le mécanisme de la réaction pour les isomères α est différent, probablement un processus A1. Ce mécanisme avait déjà été proposé en 1963 pour l'azoxybenzène, mais il n'avait jamais été observé avec un substrat avant celui rapporté dans ce travail. On peut donc dire que l'histoire du réarrangement de Wallach a retrouvé son point de départ.

Mots-clés : azoxypyridines, *N*-oxydes d'azoxypyridines, réarrangement de Wallach, réactivités, mécanismes.

[Traduit par la Rédaction]

Introduction

Many of the kinetic and other studies of the Wallach rearrangement, discovered in 1880[2] and shown below for azoxybenzene **1**, have been extensively reviewed, along with other aromatic rearrangements.[3] Over the years, this reaction has proven to occupy a pivotal position in physical organic chemistry, providing unique insights into reaction mechanisms. For instance, it was the first reaction for which a general-acid-catalysis mechanism in strong aqueous acid media was proved to take place,[4,5] the possibility having been suggested previously.[6] Catalysis by the species H_2SO_4 and $H_3SO_4^+$ occurred in concentrated H_2SO_4, but not by $(H^+)_{aq}$ (or H_3O^+), which was found to be not a strong enough

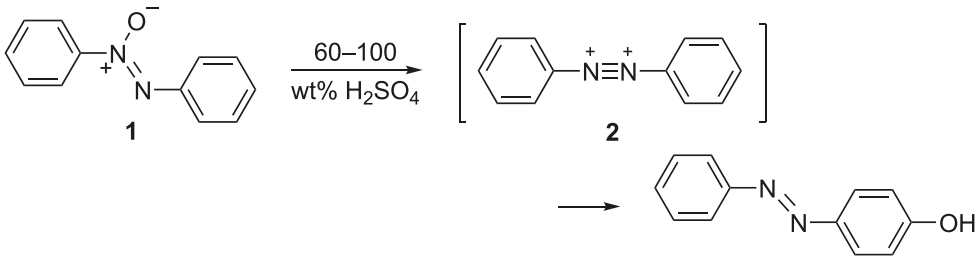
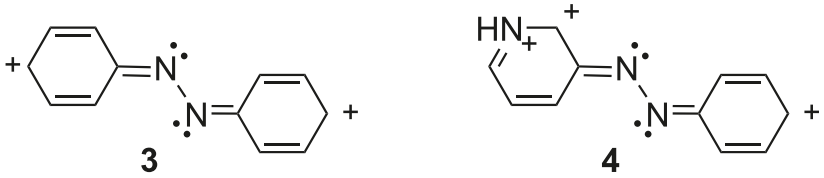
acid species to catalyze the reaction.[4] This was again shown to be the case, quite strikingly, when the reaction was found not to take place at all in $HClO_4$, a stronger acid than H_2SO_4 in H_0 terms, but containing no acidic species other than H_3O^+ and other $(H^+)_{aq}$.[7] Since that time, other general-acid-catalysis mechanisms have been found, for instance, in benzamide hydrolysis,[8] and others proposed[8] in concentrated aqueous acids.



The first kinetic study of the reaction of azoxybenzene,[9,10] which we reported as early as 1963,[9] quantified the relationship between substrate protonation ($pK_{BH}^+ = -5.18$[11]) and rearrangement, and demonstrated the requirement for a second proton transfer;[10] the proposed mechanism involved the formation of a dicationic intermediate, which at the time we wrote as having the structure **2**.[9,10] However, recent accurate theoretical calculations on several dicationic intermediates shown to be present in various Wallach rearrangements[12] indicate that the structure is more accurately rendered as **3**, with the positive charges being almost entirely situated on the two rings, not on the nitrogens, which retain their lone pairs.[12] Dicationic intermediates can actually be observed as stable species in suitable superacid media.[13]



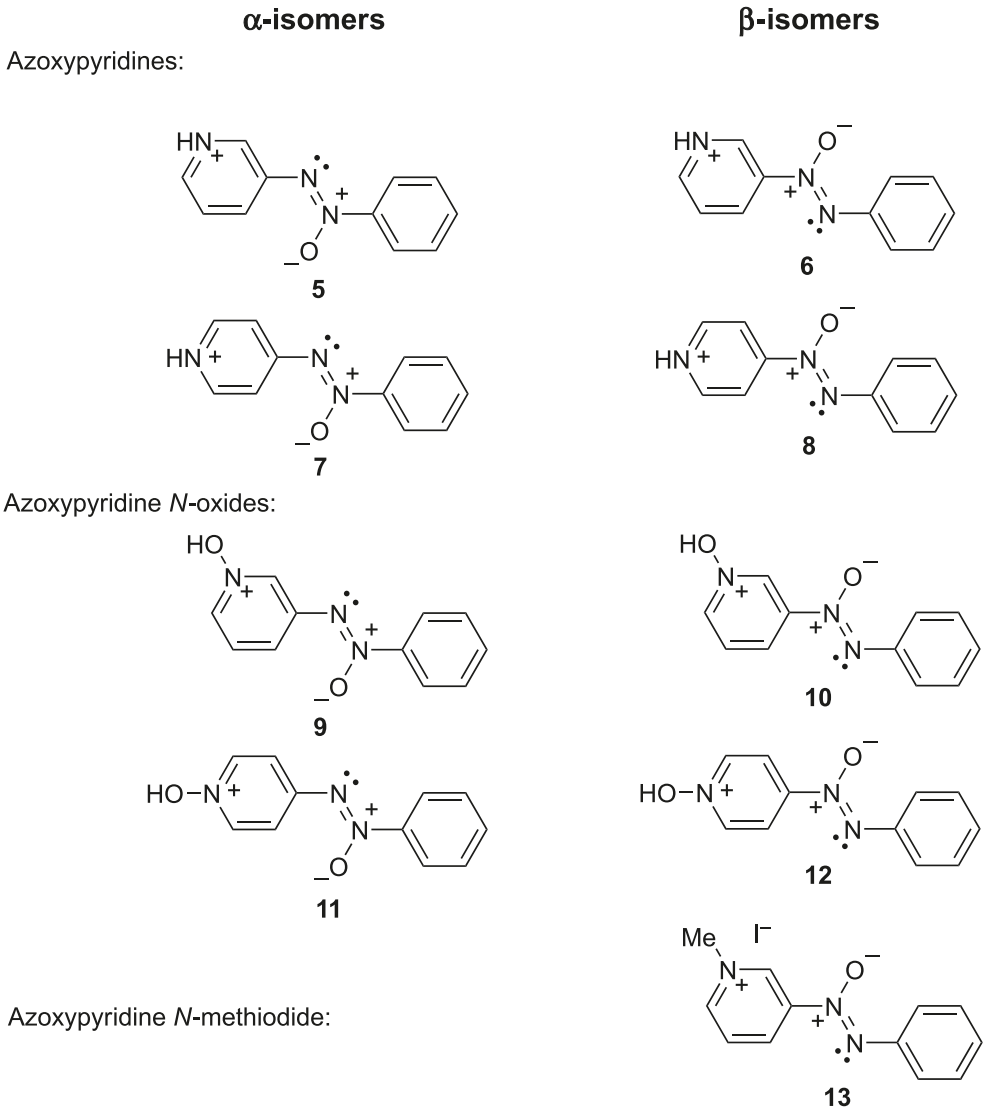
This prompted the question as to whether a tricationic species, for instance **4**, could be generated on going to heteroaromatic structures. (For clarity only one resonance form is given for **3** and for **4**.) We have found, using modern theoretical calculations, that the charge distributions in di- (or tri-) cationic intermediates like this can have dramatic effects on their reactivities,[11] and we developed a novel method of showing this by using the differences in charge distribution over the two halves of the species concerned.[11] The latter study used a series of azoxypyridines and azoxypyridine *N*-oxides. One of the observations that the calculation results helped to explain was the large reactivity difference found between α- and β-isomers of these molecules,[11,14] and this paper deals in detail with their kinetic behaviour; it happens that as well as the reaction rates being quite different, the reaction mechanisms are different as well. The compounds used in this study, **5**–**13**, are shown below, in the protonated forms, which are the true reactants,[11] the parent species being entirely monoprotonated under the reaction conditions used. (Except for **13**, the counteranions would be sulfate or bisulfate.) The α and β nomenclature is used here in preference to the formal NNO and ONN nomenclature, simply because of the convenience. The pK_{BH}^+ values for diprotonation of those molecules for which these could be measured have been given before.[11]

Experimental

We have reported the syntheses of **5**–**12** previously.[11,15] The methiodide **13** has also been reported;[15] in brief, it was obtained from **6** by methylation, refluxing **6** with a slight excess of methyl iodide for 5 h and recrystallizing the resulting red-brown crystals from ethanol. The acid solutions, in the 100% H_2SO_4 range, were prepared from 96% H_2SO_4 and fuming 30% oleum, and their concentrations determined accurately by conductivity measurements according to Gillespie and Wasif.[16] Reaction rates were determined spectrophotometrically by the "direct method".[10,11]

The 90%–100% H_2SO_4 acidity region is interesting and not particularly complex, the only species present being H_3O^+ (there is no free water), HSO_4^-, $H_3SO_4^+$, and undissociated H_2SO_4 molecules.[4] Accurate H_2SO_4 activities are available,[17] and with these and the value of $(7.8 \pm 1.7) \times 10^{-4}$ mol^2 l^{-2} given by Liler[18] for the best value for the autoprotolysis constant of H_2SO_4 at 25 °C (combined from several sources) it is possible to calculate the concentrations (although not the activities) of the species $H_3SO_4^+$ and HSO_4^- between 90% and 100% H_2SO_4 (at 25 °C). This was done. Above 100% H_2SO_4 the medium becomes much more complex, as $H_2S_2O_7$ and higher sulfur acids are formed, together with the ions resulting from their dissociation, and species concentrations cannot be calculated. However, acidity functions for these media are available;[19] the one used in this work is the one generally called H_0, measured at "room temperature" by Gillespie, Peel, and Robinson.[20] This scale was determined using the protonation equilibria of aromatic nitro compounds, which protonate on an oxygen of the nitro group, and was adjudged suitable to use in this work because of the similarity of the nitro compounds to the azoxy compounds used here. (The other acidity scale in these media, measured by Frederick and Poulter[21] and called H_A, uses protonated uracils and related compounds as indicators and was adjudged to be less suitable.)

All of the observed pseudo-first-order rate constants, k_ψ, at different sulfuric acid concentrations, some at 50 °C and some at 65 °C, obtained for **6** and for **8**–**13** are given as Supplementary data in Tables S1–S7, together with the H_0 values used and the values calculated for the $H_3SO_4^+$ concentrations. Rate constants at 25 °C were already available for **1**,[10,22] and no reaction could be observed for **5** or for **7**.



Results

Previously, we found that the log observed rate constants for **1** were a linear function of the log $H_3SO_4^+$ concentration at sulfuric acid concentrations between 90% and 100%,[4] and the same was also found to be true, at least under some circumstances, for hexamethylazoxybenzene[5] and some azoxynaphthalenes.[23] Shown in Fig. 1 are the log rate constants for azoxybenzene **1**[10,21] plotted against the log $H_3SO_4^+$ concentrations as recalculated for this work; as it can be seen, the linearity is excellent. For these data log rate constant plots against $-H_0$ are known to exhibit multiple curvature.[4]

It therefore seemed reasonable to plot the log rate constant results obtained in this work against the log $H_3SO_4^+$ concentrations in the same way. Dealing with the β-isomers first: Fig. 2 demonstrates the excellent linearity obtained for the azoxypyridines **6** and **8**, and Fig. 3 that obtained for the azoxypyridine *N*-oxide **12** at two temperatures; the results for **10** were very similar. For **10** and **12**, results at two temperatures were available; although both temperatures gave linear plots, the slopes were not the same, but we attach little significance to this as the rate data were obtained by two different workers at different times. There could be other reasons. The results for the *N*-methiodide **13** are shown in Fig. 4, which, as might be expected, exhibits very similar behaviour to that of **10**. It is shown in Fig. 5 that the observed log rate constants for **10** and **12** are in fact not linear in $-H_0$. The observed slopes, intercepts, etc. for the various correlations in this paper, many of which are shown in Figs. 1–4, are collected together in Table 1.

The α-isomers behaved differently, however; in fact, no reaction at all was observed for the azoxypyridines **5** and **7**. The azoxypyridine *N*-oxides **9** and **11** did react, but much more slowly than did the β-isomers under the same conditions. The log rate constants were not linear in the log

Fig. 1. Plot of log observed rate constants for **1** at 25 °C against the log $H_3SO_4^+$ concentration.

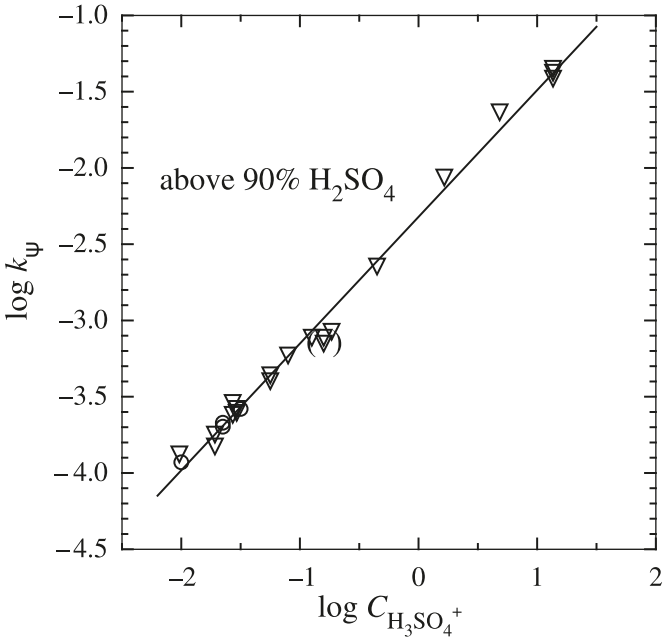


Fig. 2. Plot of the log observed rate constants for **6** and **8** at 50 °C against the log $H_3SO_4^+$ concentration.

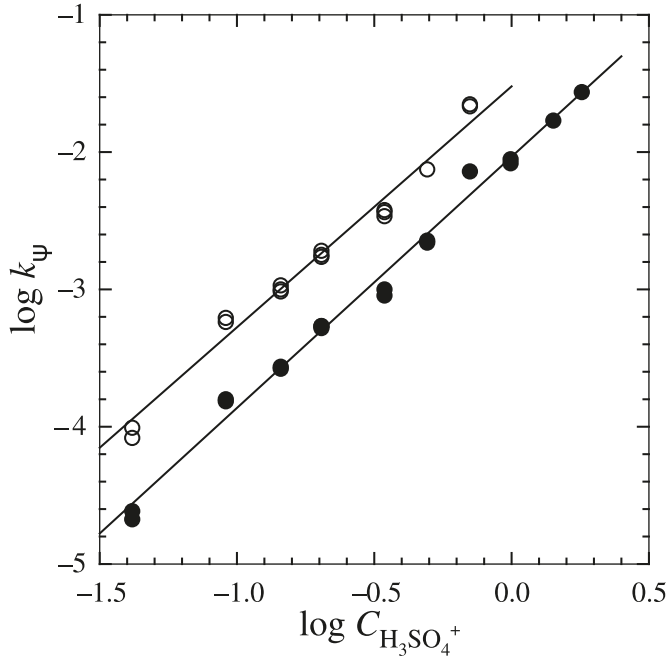

Fig. 3. Plot of the log observed rate constants for **12** at 50 °C (lower) and 65 °C (upper) against the log $H_3SO_4^+$ concentration.

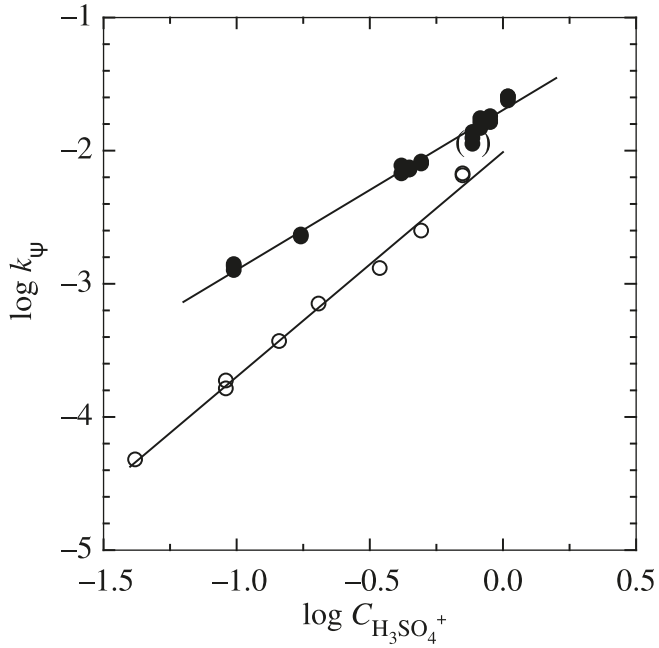

Fig. 4. Plot of the log observed rate constants for **13** at 50 °C against the log $H_3SO_4^+$ concentration.

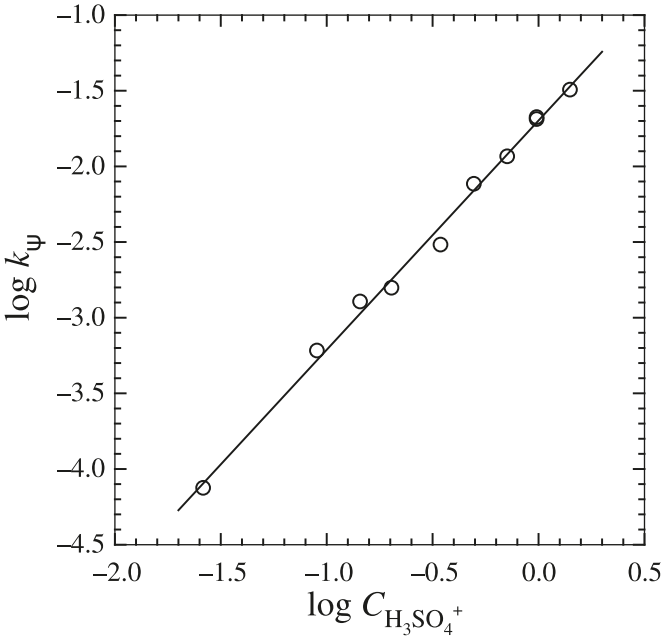


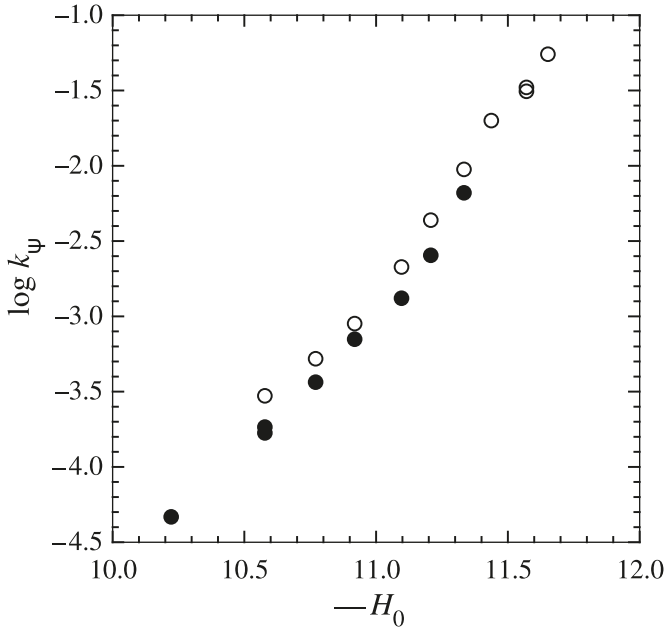
$H_3SO_4^+$ concentration, as is illustrated in Fig. 6, however, when the log rate constants for **9** and **11** were instead plotted against the $-H_0$ acidity function for this medium,[20] excellent linearity resulted, as can be seen from Fig. 7. The slopes, etc. of these plots are also given in Table 1.

Discussion

The excess acidity (*X*-function) method, developed for the study of the mechanisms of reactions in acid media,[17] has proved itself to be an excellent tool for this task.[17] However, it does not work well in the 90%–100% H_2SO_4 acidity range, primarily because an extrapolation to pure water is required, which is unrealistic here. It does not work at all above 99.5% H_2SO_4, as the *X*-function cannot be defined in this region,[17] and clearly extrapolating to pure water from oleum solutions, which contain no water at all, is not reasonable. Similarly, the Bunnett–Olsen[24] and Bunnett[25] methods, both of which require the water activity, cannot be used in media, which contain no free water either.

Therefore, in this acidity region it is more reasonable to ascertain whether the log rate constants can achieve linearity

Fig. 5. Plot of the log observed rate constants for **10** and **12** at 50 °C against $-H_0$, illustrating the lack of linearity in these plots for the β-isomers.



when plotted against known species activities or concentrations, or against a reliable acidity function.[26] The fact of linearity is what is actually important. The slopes and intercepts of these lines may not mean much, as there is little data with which to compare them, but at least some meaning can be attached to the relative values. As mentioned above, 90%–100% aqueous sulfuric acid is not a particularly complex medium, only four species being present, H_3O^+, HSO_4^-, $H_3SO_4^+$, and H_2SO_4, and the concentrations of all of them can be calculated.

Much previous work[3–5] has led to the conclusion that azoxybenzene itself reacts with undissociated H_2SO_4 molecules in sulfuric acid, which is more dilute than 90%, and with $H_3SO_4^+$ at higher concentrations. The reaction scheme has been given recently[11] and need not be repeated here. The linearity against log $C_{H_2SO_4^+}$ also found for all of the β-isomers in this study strongly suggests the same mechanism applies to them. The azoxybenzene mechanism, modified so as to apply to **6**, is given here as Scheme 1; the same Scheme 1 (with suitable atom arrangements) also applies to **8**, **10**, **12**, and **13**.

The α-isomers, however, behave differently; no reaction could be observed at all for **5** and **7**, while for **9** and **11** the log rate constants are not linear functions of log $C_{H_2SO_4^+}$, but are instead linear in $-H_0$ (see Figs. 6 and 7). Linearity in different acidity functions has long been attributed to the A1 and A-S_E2 reaction mechanisms;[17,18,26] this is part of the original Zucker–Hammett hypothesis.[27] We have just ruled out an A-S_E2 process for this reaction, leaving an A1 reaction as the only possibility. A likely reaction scheme for this process is given for **9** in Scheme 2. (In Schemes 1 and 2 the proton in dilute acid media is written as having the form $H^+(H_2O)_n$, as this is the most likely situation applying there.[8])

The reaction mechanism shown in Scheme 2 is in fact analogous to one proposed for azoxybenzene **1** itself as far back as 1963,[9,10] but never actually observed in practice for any substrate until now. A second protonation of the monoprotonated substrate **9**, $pK_{SH^+} = -10.49$,[11] occurs first. Following this, the (third) proton transfer to the azoxy OH group, giving **14**, is a pre-equilibrium process, rather than being concerted with water loss and di- (actually tri-) cationic intermediate formation as in Scheme 1, and the actual rate-determining step is loss of water to give the intermediate as shown in Scheme 2. (In Scheme 2, no attempt is made to show the full electron flow from **14** to the intermediate, as this would look confusing.) The actual concentration of the triprotonated precursor must be vanishingly small, even at these acidities, and the formation of the intermediate from it is an uphill process, as we found when we calculated the charge distributions in these species,[11] and so the reaction is very slow. Once the intermediate is formed it will react with almost anything nucleophilic very quickly, probably a bisulfate ion at these acidities, as shown. The difference from the β-isomers is that, for these, intermediate formation is downhill in energy,[11] and so it can be concerted with the third proton transfer.

The information in Table 1 is useful for internal comparisons of the reactions of **1** and **5**–**13**, but very few other correlations of this type are available for other reactions, and so other comparisons are difficult; for instance, the similar reaction found in the hydrolysis of benzamides at high acidity involves $(H^+)_{aq}$ as the catalyzing acid, not $H_3SO_4^+$.[8] We can make no reliable use of the information obtained at different temperatures for two reasons: (*i*) because the log rate constant data, obtained at 50 °C or at 65 °C, is plotted as functions of $H_3SO_4^+$ concentrations calculated at 25 °C (or an acidity function measured at room temperature); and (*ii*) there is no reliable "acidity" at which to calculate them, since any value will also have variations due to different species concentrations built into it (for instance, we cannot extrapolate to "pure water", as we can when using the excess acidity method[17]).

Having said that, there are some conclusions to draw from the information in Table 1. The intercept values for **10** and the corresponding methiodide **13** are about the same, as would be expected. The β-3-isomers react consistently faster than do the β-4-isomers, by about 0.3 of a log unit. The β-4-isomers **8** and **12** react at the same rate, whereas the azoxypyridine **6** reacts slightly faster than does the azoxypyridine *N*-oxide **10**. Little difference seems apparent between the axoxypyridines and the azoxypyridine *N*-oxides. Most of the differences can be explained by considering the charge separation in the various reaction intermediates, and we have already done this.[11] Little difference is apparent between the intercepts for the α-isomers **9** and **11**. Some comments can be made about the slopes listed in Table 1: it seems that the reaction temperature may have a large effect on them, looking at the differences between the 50 °C and 65 °C results for **10** and **12**, but unfortunately, they are in opposite directions for these two; however, the slope for **1** at 25 °C is much smaller than all of the other slopes. The behaviour of the α-isomers **9** and **11** seem much the same as one another.

Table 1. Slopes, intercepts, etc. for the observed log rate correlations for **1**, **6**, and **8**–**13**.

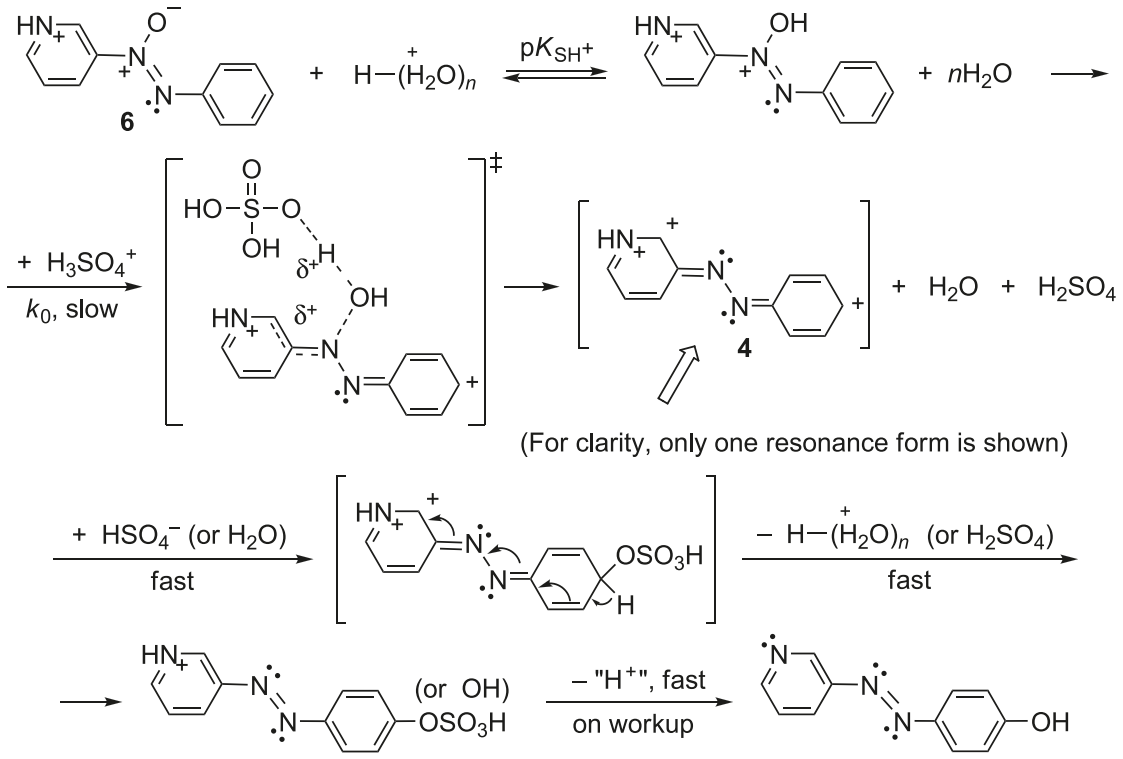
General conclusions

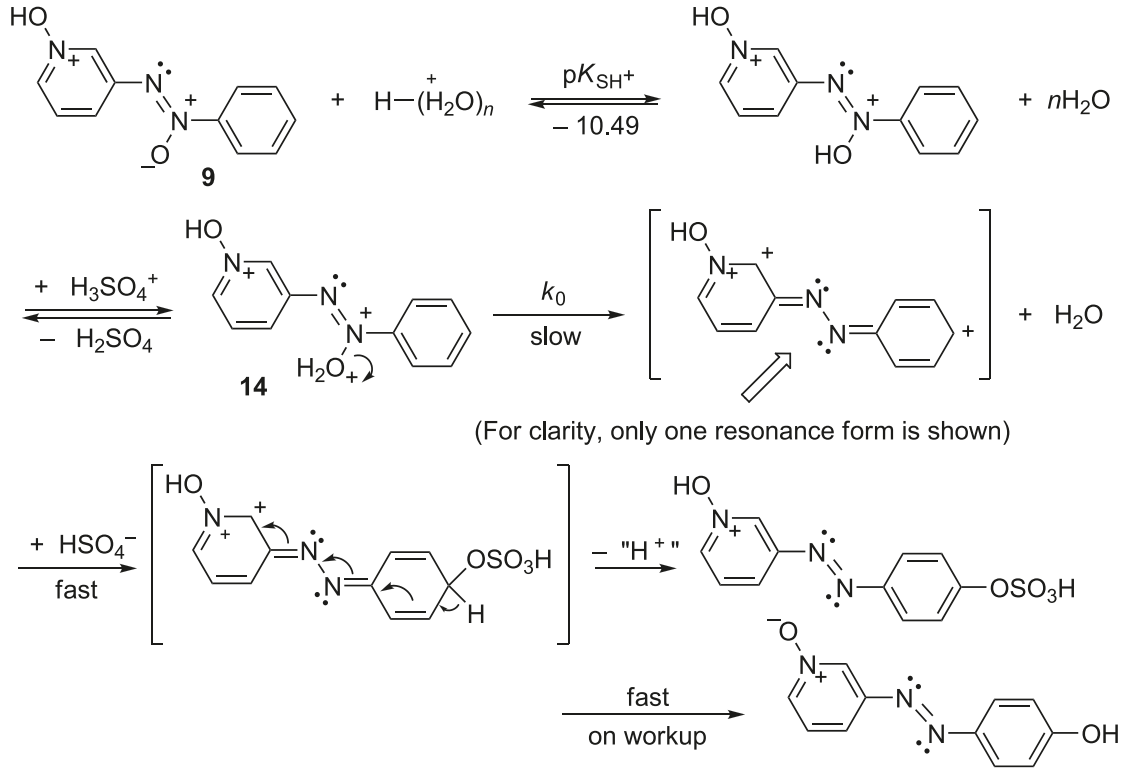
Having delineated the various possible Wallach rearrangement mechanisms in the 100% H_2SO_4 region, it is of interest that in more dilute acid media another reaction mechanism is possible, proceeding via the monoprotonated species,[5,23] but only for those azoxy compounds in which the intermediate species can be stabilized in some way. For instance, by the retention of full aromaticity in one of the aromatic rings of several azoxynaphthalenes.[23] If formation of one of these is not possible, the general-acid-catalysis mechanism of **1** is followed,[23] thus completing the spectrum of Wallach rearrangement mechanisms resulting from structural changes, as one traverses the H_2SO_4 acidity region from dilute to moderately concentrated to highly concentrated and oleum media. Moreover, analogies between the Wallach and benzidine rearrangements are apparent,[28] such as two possible mechanisms also being possible in this case, involving mono- and di-cationic reaction pathways.[29]

This whole class of azo and azoxy compounds and the reactions they undergo have contributed much to our understanding of physical organic chemistry. For instance, we have found that there are two different pathways for the

Scheme 1.



Scheme 2.



acid hydrolysis of the two methoxy groups in 4-[(3,4-dimethoxyphenyl)azo]pyridine,[30] and an excess acidity analysis of the acid-catalyzed aryl hydroxylation of phenylazopyridines showed that the reaction was an A2 process with nucleophilic attack of HSO_4^- or H_2O on the diprotonated substrate in the slow step.[31]

More generally, studies of the heteroaromatic azoxyarene series led to the examination of the solvatochromic behaviour of hydroxyazo products and their analogs, and the establishment of the π^*_{azo} solvent polarity scale.[32] More recently, we have been studying azo moieties as optical transducers, through light absorption, energy transfer, and

cis/trans isomerism, for molecular photo switching.[33] This continues to be a very fruitful area of research.

Studies on chemo- and diastereo-selectivity of the Diels–Alder reactions of sulfinyltoluquinones with cyclopentadiene

Andrea L. F. de Sousa, José E. P. Cardoso Filho, Blanka Wladislaw, Liliana Marzorati, and Claudio Di Vitta

Abstract: Sulfinyltoluquinones (**2a**–**2c**) were submitted to thermal or catalyzed [4+2] cycloaddition reactions with cyclopentadiene. For *p*-tolylsulfinyltoluquinones (**2b**) and (**2c**), almost complete C2–C3-chemo- and *unlike*-diastereoselectivity was achieved by catalysis with $ZnBr_2$, yielding adducts **6**. Under thermal conditions, Diels–Alder reaction took place at the C5–C6 double bonds of quinones **2a**–**2c**, generating mixtures of diastereoisomeric *like*- and *unlike*-adducts **4**.

Key words: Diels–Alder reaction, sulfinyltoluquinones, sulfinyl group, stereochemical control, π-facial selectivity.

Résumé : On a soumis les sulfinyltoluquinones (**2a**–**2c**) à des réactions de cycloaddition thermiques ou catalysées avec le cyclopentadiène. Avec le $ZnBr_2$ comme catalyseur, les *p*-tolylsulfinyltoluquinones (**2b**) et (**2c**) conduisent à la formation des adduits **6** et la diastéréosélectivité chimique et dissemblable au niveau de la liaison C2–C3 est pratiquement complète. Dans des conditions thermiques, la réaction de Diels–Alder se produit au niveau des doubles liaisons C5–C6 des quinones **2a**–**2c** qui conduit à la formation d'adduits **4** sous la forme de mélanges diastéréomères semblables et dissemblables.

Mots-clés : réaction de Diels–Alder, sulfinyltoluquinones, groupe sulfinyle, contrôle stéréochimique, sélectivité de la face π.

[Traduit par la Rédaction]

Introduction

The Diels–Alder (DA) reaction remains as one of the most powerful methods for the construction of cyclic systems with potential for stereochemical control of up to four stereogenic centers in only one step.[1,2] Many natural products like steroids,[3] alkaloids,[4] and terpenoids,[5] among others,[6] were synthesized by using quinones as dienophiles. However, due to the lack of π-facial selectivity, during the cycloaddition step, many of the above-mentioned syntheses proceeded in a racemic way. Only by the intervention of chiral enantiopure dienes[7] or quinones,[8] or by employing chiral Lewis acids or catalysts,[9,10] it was possible to conduct asymmetric DA reactions leading to enantiopure or enantioenriched adducts. Although resolution steps after the DA reaction may also be applied, the loss of material, intrinsically associated to the resolution process, limits its synthetic usefulness.

Recently, we became interested in an alternative synthesis of the enantiomerically pure adducts **1** (Fig. 1). It should be mentioned that (+)-**1a** was prepared by Corey et al.[10] to be used as precursors of natural products like (+)-hirsutene, (–)-corioline, pleurotellol, and pleurotellic acid via the photothermal olefinic metathesis methodology (PTOM).[5b,5d,5h]

Considering the ability of the sulfinyl group to control the chemo- and π-facial diastereoselectivity in DA reactions,[11] especially in the case of benzoquinones acting as dienophiles, the synthesis of adducts (+)- or (–)-**1** by π-facial discrimination of enantiopure sulfinyltoluquinones (**2a**–**2c**) (Fig. 2) seemed quite feasible to us.

Only two reports were found in the literature for the DA reactions of sulfinylbenzoquinones (**3**), bearing a group different from hydrogen at C3.[12,13] Carreño and Ruano[12] reported a complete chemoselectivity but a moderate π-facial diastereoselectivity (40%–60% de under catalytic conditions vs. 0% de under thermal conditions) for the DA reaction of cyclopentadiene with benzoquinones (+)-(*SS*)-**3** (X = Cl) and (+)-(*SS*)-**3** (X = Et) with exclusive formation of cycloadducts by reaction at the C5–C6 double bond. Better results were obtained when 2,3-dimethyl-1,3-butadiene was employed (40%–72% de under catalytic conditions vs. 20%–34% de under thermal conditions). Similar π-facial diastereoselectivity but complete reversal of chemoselectivity was observed for the thermal DA reaction of (+)-(*SS*)-**3** (X = CN)[13] (at C2–C3; 0% de for cyclopentadiene and 58%–84% de for 1-methoxy-1,3-butadiene).

Results and discussion

To evaluate the chemo- and diastereo-selectivity of toluquinones, (±)-**2b** and (±)-**2c** (R = *p*Tol, *i*Pr, and *i*Bu) were prepared by addition of the corresponding thiols to the 2,6- and 2,5-dimethylbenzoquinones,[14] respectively, followed by subsequent oxidation at sulfur with H_2O_2/SeO_2,[15] and of the aromatic ring with CAN.[12] As for the synthesis of quinone **2a**, although the analogous compound (+)-**3** (X = Et) could be obtained by the reaction[12] of (+)-**3** (X = H) with $Zn(Et)_2$,

(±)-**2c** (R = pTol; R' = H; R'' = Me) (±)-*like*-**4c** (4) : (±)-*unlike*-**4c** (1)

the same precursor proved to be unreactive toward $Zn(Me)_2$. In a search for an alternative methodology, we tried the reaction of 2-bromo-1,4-dimethoxy-3-methylbenzene[16] with *n*BuLi, followed by the quenching of the lithiated aromatic compound with methyl *p*-toluenesulfinate. However, better yields (37%) of sulfinylated product were obtained by using (*SS*)-menthyl *p*-toluenesulfinate as sulfinylating agent. After subsequent oxidation of the obtained aromatic compound with CAN, quinone (+)-**2a** was isolated in 79% yield (Scheme 1).

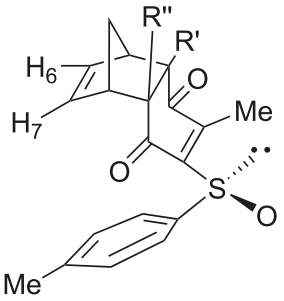
Due to the deactivating effect of the methyl group on the C2–C3 double bond of (+)-**2a**, its chemoselective DA reaction with cyclopentadiene yielded an inseparable mixture of adducts *like*-**4a**[17] and *unlike*-**4a**, resulting from the approach of the diene to each side of the C5–C6 double bond (Scheme 2).

Evidence for the formation of such isomeric adducts was provided by the inspection of the ^{1}H NMR spectrum of the reaction crude mixture, which revealed, for the absorptions of the norbornenyl hydrogens, only two clusters: one, at 6.07, and the other, centered at 5.71 ppm (composed by two separated multiplets at 5.89 and 5.53 ppm), suggesting the absence of adducts arising from the cycloaddition at the C2–C3 double bond of the quinone. A 1.3:1 integral ratio was obtained for the olefinic clusters in favor of signals at 6.07 ppm.

It should be mentioned that a different result was reported by Carreño et al.[18] for the analogous DA reaction performed using (+)-(*SS*)-**3** (X = H). In that case, the H6/H7 lower field signals (6.13 vs 5.85/4.82 ppm) corresponded to the less abundant isomer. According to the authors, for the major isomer ((+)-*like*-**5**; Fig. 3) the S–O and the C2–C3 bonds would lie in an *s-cis*-favored conformation, in which the *p*-tolyl ring would shield the H6/H7 protons. Such effect would be absent in the other isomer ((+)-*unlike*-**5**[18]), which would be formed by cycloaddition to the C5–C6 top (*re*) face of the (+)-(*SS*)-**3** (X = H).

When (±)-**2b** was treated with cyclopentadiene, under the same conditions (Scheme 3), a mixture of two adducts was obtained, as evidenced by the ^{1}H NMR spectra of the crude mixture, which presented only two pairs of signals in the olefinic region. Additionally, two doublets, at 2.77 and 2.92 ppm (J = 3.9 Hz), attributed to H8a of the (±)-*like*-**4b** and (±)-*unlike*-**4b** adducts (Scheme 3), respectively, were also observed, indicating that *endo*-cycloadditions took place chemoselectively at both sides of the C5–C6 double bond. For this mixture, a 1:1 ratio for the isomeric (±)-**4b** adducts could be determined by integration of the absorptions, at 6.06/6.02 and at 5.96/5.56 ppm. However, for toluquinone (±)-**2c** (R = *p*Tol) (Scheme 3), a 4:1 mixture of adducts was obtained. Accordingly, in this case, signals at lower field (6.14/6.01 ppm) were attributed to H6/H7 of the most abundant (±)-*like*-**4c** (R = *p*Tol), and those at 5.82/5.67 ppm were attributed to the (±)-*unlike*-**4c** (R = *p*Tol) isomer.

Fig. 4. Representation of the *s-trans* conformation between the S–O and C2–C3 bonds for adducts *unlike*-**4**.



unlike-**4**

Thermal DA reactions of cyclopentadiene with sulfinyltoluquinones **2c** (R = *i*Pr) and **2c** (R = *i*Bu) yielded mixtures of adducts for which the most abundant isomers (ratios: 2.3 to 1, for R = *i*Pr; 4 to 1, for R = *i*Bu) presented H6/H7 absorptions at 6.04/6.21 ppm for R = *i*Pr and at 6.04/6.23 ppm for R = *i*Bu. For the minor isomers, the corresponding H6/H7 signals were observed at 6.04/6.13 ppm (R = *i*Pr) and at 6.04/6.15 ppm (R = *i*Bu).

Considering that, in the case of adducts arising from benzoquinone (+)-(*SS*)-**3**, the major isomer presents H6/H7 ^{1}H NMR absorptions at higher field in comparison with the minor isomer, and that the opposite was observed starting from toluquinones (+)-**2a** and (±)-**2c** (for R = *p*Tol), and assuming the same π-facial diastereoselectivity for the DA reaction of all three quinones, the observed lower-field absorptions for H6/H7 of the *unlike*-**4** adducts can only be explained if, in these compounds, an *s-trans* conformation (instead of an *s–cis* conformation) between the S–O and C2–C3 bonds is assumed (Fig. 4). Accordingly, for the *like*-**4c** and *unlike*-**4c** (R = *i*Pr and *i*Bu) adducts, for which no *p*-tolyl shielding effects are expected, similar chemical shifts values were observed for H6/H7.

However, a reversed π-facial diastereoselectivity for the DA reactions of quinones (+)-**2a** and (±)-**2c**, as compared with that for (+)-(*SS*)-**3** (X = H), with preferential *unlike* approach of the diene to the top (*re*) face of (+)-**2a** and (±)-**2c**, considering the *SS* configuration, giving rise to the *unlike*-**4a** and (±)-*unlike*-**4c** (R = *p*Tol) adducts, could not be discarded. Thus, aiming to elucidate the stereochemistry of adducts **4**, and to obtain diastereoisomerically pure compounds, required for the synthesis of enantiomerically pure **1**, we decided to essay some catalytic conditions for the DA reactions with toluquinones **2**.

When quinone (+)-**2a** was submitted to the $ZnBr_2$-catalyzed DA reaction with cyclopentadiene, the same chemo- and diastereo-selectivities were observed as compared with the thermal process. However, a completely reversed π-facial diastereoselection was observed for (±)-**2c** (R = *p*Tol) under $BF_3{\cdot}Et_2O$ catalysis (see Table 1), as the most abundant adduct is the one with the H6/H7 signals at higher field. Furthermore, when (±)-**2b** and (±)-**2c** (R = *p*Tol) were treated with $ZnBr_2$, only one product was formed in each case. The ^{1}H NMR spectra of these last adducts showed no doublets for the ring-junction hydrogens, but the presence of a broad singlet at 5.88 ppm (in the case of (±)-**2b**) and of a quartet at 6.13 ppm (J is ~1.5 Hz) in the case of (±)-**2c** (R = *p*Tol) indicated that the DA reactions took place at the C2–C3 double bond for both quinones. Thus, assuming the sterically favoured *unlike-endo* approach of the diene to the bottom face of the chelates formed between $ZnBr_2$ and toluquinones (±)-**2b** or (±)-**2c** (R = *p*Tol), products (±)-*unlike*-**6b** and (±)-*unlike*-**6c** could be advanced (Scheme 4).

The catalytic DA reactions of cyclopentadiene with toluquinones **2c** (R = *i*Pr or *i*Bu; see Table 1) showed similar results and, in some cases, it became possible to separate and isolate pure adducts by flash chromatography.

Having in hands the diastereomerically pure adducts **4c**, and due to the unambiguous structure assignment for compounds *unlike*-**6c** (R = *p*Tol or *i*Bu), we envisaged that the stereochemical outcome of the DA reactions of (+)-**2b** and (±)-**2c** could be determined by comparison of the $[\alpha]_D$ values of the enantiomerically pure desulfurized compounds arising from *like*- or *unlike*-**4c** and *unlike*-**6**. Therefore, if the initially proposed structures for compounds (±)-*like*-**4c** and (±)-*unlike*-**4c** were correct, the same enantiomer would result from desulfurization of the (*SS*)-*like*-**4c** and the (*SS*)-*unlike*-**6c** compounds. On the other hand, enantiomeric products would result from desulfurization of adducts (*SS*)-*unlike*-**4c** and the (*SS*)-*unlike*-**6c**. Furthermore, these desulfurized compounds would correspond to the desired enantiomerically pure forms of adduct **1a**.

To establish the best experimental conditions for the removal of the sulfinyl group, racemic *unlike*-**6c** and *like*-**4c** and *unlike*-**4c** were submitted to the reactions with three different desulfurizing agents. Thus, reaction of (±)-*unlike*-**6c** (R = *p*Tol) with aluminum amalgam[19] yielded, after 3 h at 0 °C, an equimolar mixture of adduct (±)-**1a** and its corresponding (±)-C2–C3-dihydro derivative **7**[20] (Scheme 5). This last compound was also obtained when aluminum amalgam was used for reduction of (±)-*like*- or *unlike*-**4c** (R = *i*Bu). The use of Ni_2B[21] resulted in the formation of the (±)-C6–C7-dihydro derivative (±)-**8**, starting from (±)-*unlike*-**6c** (R = *p*Tol) but converted (±)-*unlike*-**4c** (R = *i*Pr) into (±)-**1a** in low yield (12%) (Scheme 5). On the other hand, employing Raney–Ni[22] for desulfurizing (±)-*unlike*-**6c** (R = *p*Tol), an equimolar mixture of (±)-**7** and (±)-**8** was obtained. However, by using deactivated Raney–Ni,[23] we were able to obtain pure (±)-**1a**, although in a moderate yield (50%) (Scheme 5).

Having established the conditions for the successful synthesis of adduct (±)-**1a** by desulfurization of (±)-*unlike*-**6c** (R = *p*Tol) and *unlike*-**4c** (R = *i*Pr), we prepared the optically active quinones (*SS*)-**2c** (R = *p*Tol) and (*SR*)-**2c** (R = *i*Pr) to compare the $[\alpha]_D$ values of their desulfurized cyclopentadiene DA adducts. Thus, by treating 3-bromo-1,4-dimethoxy-2,5-dimethylbenzene[24] with *n*BuLi, followed by quenching with the adequate sulfinylating agent, toluquinones (+)-(*SS*)-**2c** (R = *p*Tol) and the (–)-(*SR*)-**2c** (R = *i*Pr) were isolated[25] after oxidation with CAN. Next, cyclopentadiene was used for the reactions with (+)-**2c** (R = *p*Tol) chelated with $ZnBr_2$, and with (–)-**2c** (R = *i*Pr) complexed with $BF_3{\cdot}Et_2O$. After desulfurization of the corresponding obtained adducts (Scheme 6), the observed $[\alpha]_D$ value for the resulting adducts **1a**,[10a] was +7.6 in both cases, thus confirming the initially proposed relative configurations for adducts **4**.

Table 1. Diels–Alder catalytic reactions of cyclopentadiene with (±)-**2c**.

Entry	R	Condition	Time (days)[a]	*like*-**4c**[b]	*unlike*-**4c**[b]	*unlike*-6**c**[b]
1	*p*Tol[c]	$BF_3{\cdot}Et_2O$	14	1	2.3	—
2	*p*Tol[c]	$ZnBr_2$	3	—	—	1
3	*i*Bu	$BF_3{\cdot}Et_2O$	8	1	2	—
4	*i*Bu	$ZnBr_2$	5	—	1	2.5
5	*i*Pr[d]	$BF_3{\cdot}Et_2O$	4	—	1	—

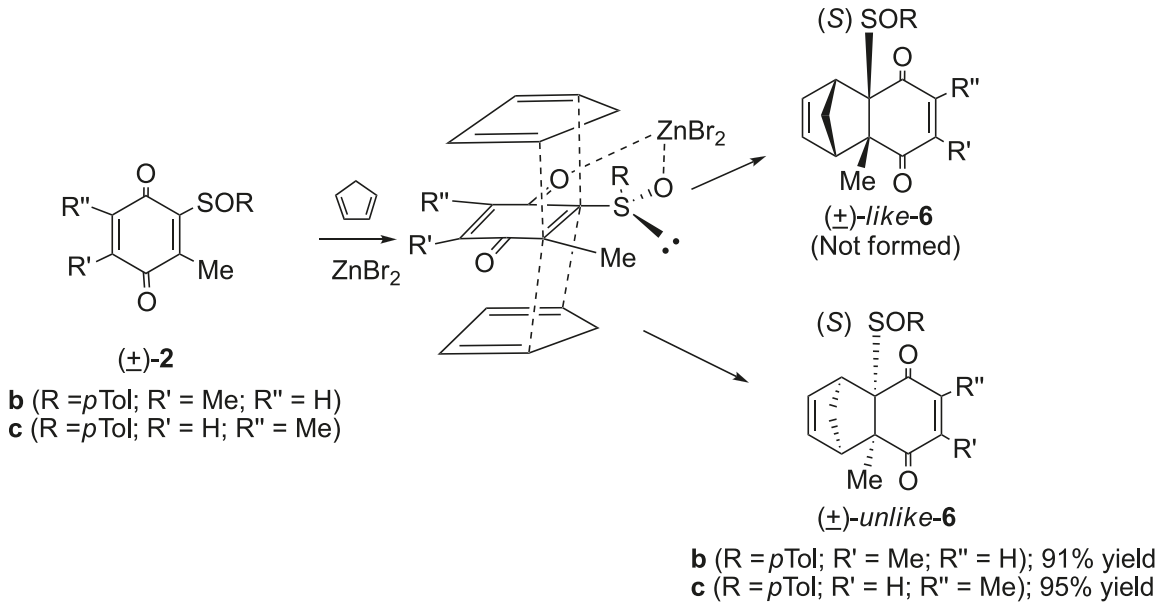
[a]At –20 °C.

[b]In this Table, *like*-**4c** and *unlike*-**4c** adducts were named according to the chemical shifts of H6 and H7: *like* for highest and *unlike* for lowest chemical shifts, respectively.

[c]Also prepared in an enantiomericaly pure *SS* form.

[d]Prepared in racemic and in enantiomerically pure *SR* form.

Scheme 4. Modes of approaching of cyclopentadiene to both faces of C2–C3 double bonds of racemic chelates formed between $ZnBr_2$ and toluquinones **2b** and **2c**, considering only the (*SS*) isomers.



Conclusion

The above results indicate that the same stereochemical outcome is observed for the DA reactions of cyclopentadiene with sulfinylbenzo- and sulfinyl-toluquinones, despite the presence of an extra methyl group attached to the C5–C6 double bond of such toluquinones. However, in the case of adducts **4**, the C2 methyl group sterically interacts with the sulfinyl group, thus imposing an *s-trans* conformation between the S–O and the C2–C3 bonds, causing, in the case of *p*Tol derivatives, a shielding effect on the olefinic hydrogens (H6/H7) only for the *unlike* adducts.

It should be also mentioned that we could establish the adequate conditions for the synthesis of (+)-**1a**, a valuable precursor for synthesis of (+)-hirsutene, (–)-corioline, pleurotellol, and pleurotellic acid.

Experimental

General

Melting points were determined on a Koffler micro hot stage and are uncorrected. ^{1}H NMR spectra were recorded with a Bruker AC 200 or a Varian INOVA 300 spectrometer using TMS as an internal standard. ^{13}C NMR spectra were recorded on the same instruments at 50 or 75 MHz, and are referenced against the central line of the solvent signal ($CDCl_3$ triplet at 77.0 ppm). The coupling constants (*J*) are given in Hz. IR spectra were obtained with a BOMEN instrument (KBr pellets for all compounds). TLC was carried out on Merck silica-gel TLC-cards. All reagents and solvents were used as received from commercial suppliers.

Sulfinyl 1,4-benzoquinones (±)-2b and (±)-2c (R = *p*Tol, *i*Bu, and *i*Pr)

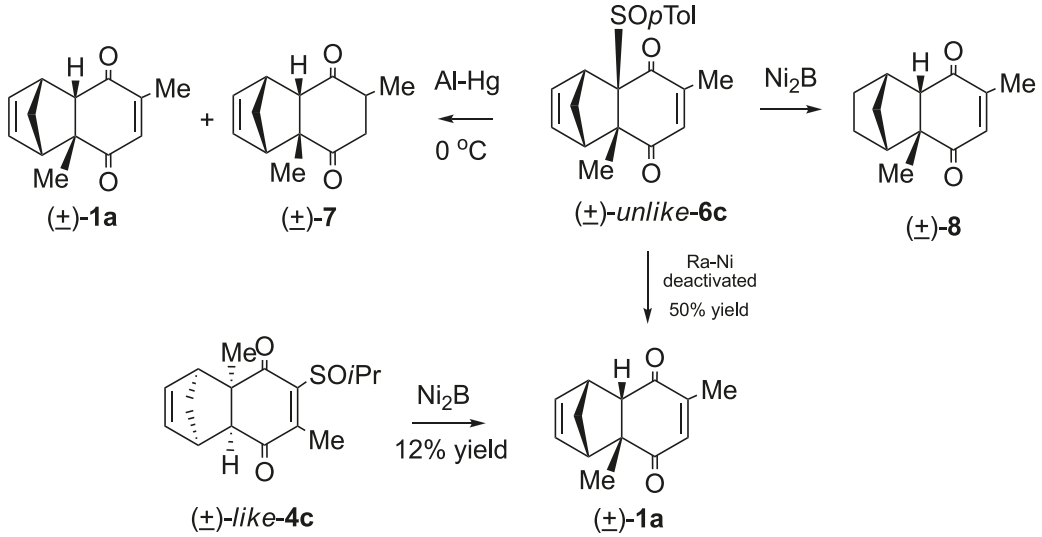
(±)-**2b** and (±)-**2c** (R = *p*Tol, *i*Bu, and *i*Pr) were prepared by the following three-step procedure.

Step 1: addition of thiol to quinone[14]

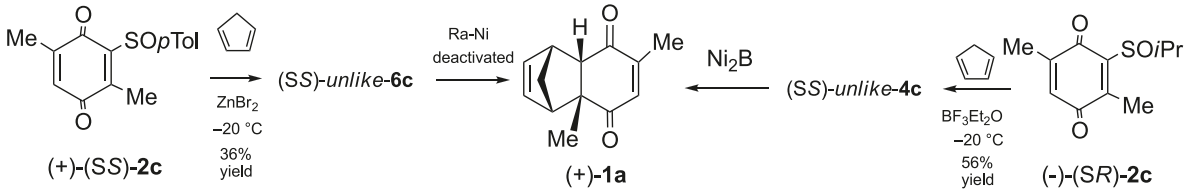
To a solution of quinone (2.2 mmol) in ethanol (10 mL) was added dropwise a solution of the thiol (2.2 mmol) in ethanol (10 mL), under stirring and at room temperature. After 2 h, the solvent was removed under vacuum, and the residue was submitted to flash chromatography.

3-(Isobutylthio)-2,5-dimethylbenzene-1,4-diol was obtained as a colorless oil, in 96% yield, using hexane/ethyl acetate (6:1) as eluting solvent. δ_H (300 MHz, $CDCl_3$): 1.02 (d, 6H, *J* = 6.6), 1.76 (m, 1H), 2.21 (s, 3H), 2.41 (s, 3H),

Scheme 5. Products arising from reactions of adducts (±)-*unlike*-**6c** and (±)-*unlike* **4c** with desulfurizing agents.



Scheme 6. Product resulting from desulfurization of the Diels–Alder adducts between cyclopentadiene and toluquinones (+)-(*SS*)-**2c** and (–)-(*SR*)-**2c**.



2.48 (d, 2H, J = 6.9), 4.30 (s, 1H), 6.62 (s, 1H), 6.83 (s, 1H). δ_C (75 MHz, $CDCl_3$): 14.5, 16.7, 22.4, 29.2, 45.5, 119.2, 120.2, 121.9, 125.6, 146.9, 149.9. Elemental analysis (%) ($C_{12}H_{18}O_2S$): C 63.7, H 8.0 (calcd.); C 63.2, H 7.8 (found).

3-(Isopropylthio)-2,5-dimethylbenzene-1,4-diol was obtained as a white solid, in 82% yield, using hexane/ethyl acetate (6:1) as eluting solvent. Mp 71–74 °C. δ_H (300 MHz, $CDCl_3$): 1.23 (d, 6H, J = 6.6), 2.22 (s, 3H), 2.40 (s, 3H), 3.05 (m, 1H, J = 6.4), 4.32 (s, 1H), 6.64 (s, 1H), 6.84 (s, 1H). Elemental analysis (%) ($C_{11}H_{16}O_2S$): C 62.2, H 7.6 (calcd.); C 61.8, H 7.8 (found).

Step 2: oxidation at the sulfur atom[15]

To a water cooled solution of the sulfanylbenzene-1,4-diol (1.1 mmol) in methanol (3 mL) was slowly added a solution of H_2O_2 30% (0.11 mL; 1.1 mmol) and SeO_2 (0.12 g; 1.1 mmol) in water (1 mL). After 1 h, water (5 mL) was added, and the mixture was extracted with $CHCl_3$. After drying (Na_2SO_4) and concentration, the solid sulfinyl derivative was isolated.

(±)-2,5-Dimethyl-3-(*p*-tolylsulfinyl)benzene-1,4-diol was obtained, in 74% yield, starting from 2,5-dimethyl-3-(*p*-tolylthio)benzene-1,4-diol,[14] and was used without purification. Mp 171–174 °C. δ_H (300 MHz, $CDCl_3$): 2.13 (s, 3H), 2.22 (s, 3H), 2.38 (s, 3H), 4.80 (bs, 1H), 6.70 (s, 1H), 7.28 (d, 2H, J = 7.5), 7.56 (d, 2H, J = 7.5), 10.61 (bs, 1H). δ_C (75 MHz, $CDCl_3$): 11.6, 15.2, 21.4, 119.2, 121.3, 125.8, 126.7, 130.3, 139.8, 142.3, 145.7, 152.4.

(±)-3,5-Dimethyl-2-(*p*-tolylsulfinyl)benzene-1,4-diol was obtained, in 90% yield, starting from 3,5-dimethyl-2-(*p*-tolylthio)benzene-1,4-diol.[14] Mp 163–165 °C. IR (KBr, cm^{-1}): 1428, 1471, 2915, 3133, 3314. δ_H (300 MHz, $CDCl_3$): 2.20 (s, 3H), 2.22 (s, 3H), 2.38 (s, 3H), 4.63 (bs, 1H), 6.57 (s, 1H), 7.27 (d, 2H, J = 7.8), 7.56 (d, 2H, J = 8.1), 10.49 (s, 1H). δ_C (75 MHz, $CDCl_3$): 12.6, 16.9, 21.8, 119.2, 119.6, 122.1, 126.2, 130.1, 130.7, 140.5, 142.7, 145.4, 154.3. Elemental analysis (%) ($C_{15}H_{16}SO_3$): C 65.2, H 5.8 (calcd.); C 64.9, H 5.8 (found).

(±)-3-(Isobutylsulfinyl)-2,5-dimethylbenzene-1,4-diol was obtained, as a colorless oil, in 87% yield, starting from 3-(isobutylthio)-2,5-dimethylbenzene-1,4-diol. δ_H (300 MHz, $CDCl_3$): 1.12 (d, 3H, J = 6.6), 1.16 (d, 3H, J = 6.6), 2.14 (s, 3H), 2.16 (s, 3H), 2.25 (m, 1H), 2.63 (dd, 1H, *vic* J = 9.3 and *gem* J = 13.2), 3.36 (dd, 1H, *vic* J = 4.8 and *gem* J = 12.9), 4.62 (bs, 1H), 6.70 (s, 1H), 10.51 (s, 1H). δ_C (75 MHz, $CDCl_3$): 11.4, 15.3, 21.6, 22.9, 24.4, 62.6, 118.6, 121.0, 121.3, 126.8, 146.0, 152.9.

(±)-3-(Isopropylsulfinyl)-2,5-dimethylbenzene-1,4-diol was obtained, in 79% yield, starting from 3-(isopropylthio)-2,5-dimethylbenzene-1,4-diol. Mp 129–132 °C. δ_H (300 MHz, $CDCl_3$): 1.24 (d, 3H, J = 6.8), 1.45 (d, 3H, J = 6.8), 2.14 (s, 3H), 2.16 (s, 3H), 3.39 (h, 1H, J = 6.5), 6.73 (s, 1H). δ_C (75 MHz, $CDCl_3$): 12.4, 15.6, 16.0, 17.1, 54.0, 119.3, 120.4, 121.8, 126.7, 146.3, 153.2.

Step 3: oxidation with CAN

To a solution of the sulfinyl derivative (1.0 mmol) in MeCN (10 mL) was added 5 mL of an aqueous solution of CAN (3.0 mmol), and the resulting mixture was stirred for 1 h at room temperature. After removal of half volume of the solvent, the quinone was extracted with CH_2Cl_2. The ex-

tract was dried (Na_2SO_4) and concentrated under vacuum, resulting in a red solid.

(±)-2,5-Dimethyl-3-(*p*-tolylsulfinyl)cyclohexa-2,5-diene-1,4-dione, (±)-2c (R = *p*Tol), was obtained from (±)-2,5-dimethyl-3-(*p*-tolylsulfinyl)benzene-1,4-diol in 82% yield. Mp 138–139 °C. δ_H (300 MHz, $CDCl_3$): 2.02 (s, 3H), 2.40 (s, 3H), 2.49 (s, 3H), 6.64 (s, 1H), 7.31 (m, 2H), 7.64 (m, 2H). δ_C (75 MHz, $CDCl_3$): 9.9, 16.0, 22.0, 125.3, 130.5, 134.1, 140.0, 142.0, 146.1, 146.5, 147.5, 185.2, 186.2. Elemental analysis (%) ($C_{15}H_{14}SO_3$): C 65.7, H 5.1 (calcd.); C 65.3, H 5.5 (found).

(±)-3,5-Dimethyl-2-(*p*-tolylsulfinyl)cyclohexa-2,5-diene-1,4-dione, (±)-2b, was obtained from (±)-3,5-dimethyl-2-(*p*-tolylsulfinyl)benzene-1,4-diol in 90% yield. Mp 100–102 °C. IR (KBr, cm^{-1}): 1630, 1647, 1665, 3044. δ_H (300 MHz, $CDCl_3$): 2.04 (d, 3H, J = 1.8), 2.39 (s, 3H), 2.49 (s, 3H), 6.54 (q, 1H, J = 1.5), 7.30 (d, 2H, J = 7.8), 7.63 (d, 2H, J = 8.1). δ_C (75 MHz, $CDCl_3$): 9.6, 16.5, 21.7, 125.2, 130.4, 133.2, 140.0, 141.9, 146.1, 147.0, 147.2, 184.8, 187.1. Elemental analysis (%) ($C_{15}H_{14}SO_3$): C 65.7, H 5.1 (calcd.); C 65.2, H 5.0 (found).

(±)-2,5-Dimethyl-3-(isobutylsulfinyl)cyclohexa-2,5-diene-1,4-dione, (±)-2c (R = *i*Bu), was obtained from (±)-3-(isobutylsulfinyl)-2,5-dimethylbenzene-1,4-diol in 87% yield. Mp 75–78 °C. IR (KBr, cm^{-1}): 1650, 1603, 1466, 1438, 1042. δ_H (300 MHz, $CDCl_3$): 1.12 (d, 3H, J = 6.6), 1.19 (d, 3H, J = 6.9), 2.05 (d, 3H, J = 1.5), 2.25 (m, 1H), 2.45 (s, 3H), 3.22 (dd, 1H, J = 4.8 and 12.9), 3.26 (dd, 1H, *vic* J = 4.5 and 12.3), 6.69 (q, 1H, J = 1.8). δ_C (75 MHz, $CDCl_3$): 9.4, 15.7, 21.6, 23.2, 24.9, 63.4, 134.3, 145.9, 146.3, 148.4, 185.5, 185.8. Elemental analysis (%) ($C_{12}H_{16}SO_3$): C 60.0, H 6.7 (calcd.); C 59.2, H 6.5 (found).

(±)-2,5-Dimethyl-3-(isopropylsulfinyl)cyclohexa-2,5-diene-1,4-dione, (±)-2c (R = *i*Pr), was obtained from (±)-3-(isopropylsulfinyl)-2,5-dimethylbenzene-1,4-diol in 78% yield. Mp 83–84 °C. IR (KBr, cm^{-1}): 1665, 1650, 1595, 1465, 1432, 1059. δ_H (300 MHz, $CDCl_3$): 1.35 (d, 3H, J = 6.9), 1.40 (d, 3H, J = 7.2), 2.05 (d, 3H, J = 1.8), 2.44 (s, 3H), 3.43 (h, 1H, J = 7.9), 6.70 (q, 1H, J = 1.8). δ_C (75 MHz, $CDCl_3$): 9.7, 15.2, 15.8, 17.7, 53.4, 134.4, 144.2, 146.3, 149.9, 185.7, 185.8. Elemental analysis (%) ($C_{11}H_{14}SO_3$): C 58.4, H 6.2 (calcd.); C 58.7, H 6.0 (found).

Sulfinyltoluquinones (+)-2a, (+)-2c (R = *p*Tol), and (–)-2c (R = *i*Pr)

(+)-**2a**, (+)-**2c** (R = *p*Tol) and (–)-**2c** (R = *i*Pr) were prepared by a two-step procedure, as described below, by employing the adequate combination of bromo-1,4-dimethoxyarene and the sulfinylating agent.

Step 1

To a cooled solution (–20 °C) of *n*BuLi (3.0 mmol) in ethyl ether (5 mL) was added a solution of the bromo-1,4-dimethoxy-arene (2.7 mmol) in ethyl ether (5 mL). After 1 h at –20 °C, a solution of the sulfinylating agent (3.3 mmol) in ethyl ether (5.0 mL) was slowly added. The mixture was stirred for 2 h at –20 °C and for 1 h at RT. Cold aqueous saturated ammonium chloride (50 mL) was added to the mixture, and the organic layer was separated. The aqueous phase was extracted with ethyl ether (25 mL), and the extracts were dried ($MgSO_4$) and concentrated. The resulting sulfoxide was isolated by column chromatography.

(–)-(*S*,*S*)-1,4-Dimethoxy-2-methyl-3-(*p*-tolylsulfinyl)benzene was obtained, in 37% yield, from 2-bromo-1,4-dimethoxy-3-methylbenzene[16] and (*S*,*S*)-menthyl *p*-toluenesulfinate. $[\alpha]_D$ –115 (*c* 1.8, CH_2Cl_2). δ_H (300 MHz, $CDCl_3$): 2.36 (s, 3H), 2.41 (s, 3H), 3.71 (s, 3H), 3.77 (s, 3H), 6.74 (d, 2H, J = 9.0), 6.90 (d, 1H, J = 9.0), 7.21 (d, 2H, J = 8.4), 7.43 (d, 2H, J = 8.4). δ_C (75 MHz, $CDCl_3$): 11.3, 21.2, 56.3, 56.6, 110.1, 114.5, 124.3, 129.2, 130.2, 132.1, 139.5, 141.5, 152.4, 152.7. Elemental analysis (%) ($C_{16}H_{18}SO_3 \cdot 1/2H_2O$): C 64.2, H 6.4 (calcd.); C 64.2, H 6.0 (found).

(–)-(*S*,*S*)-1,4-Dimethoxy-2,5-dimethyl-3-(*p*-tolylsulfinyl)-benzene was obtained, in 37% yield, from 3-bromo-1,4-dimethoxy-2,5-dimethylbenzene[24] and (*S*,*S*)-menthyl *p*-toluenesulfinate. Mp 132–135 °C. $[\alpha]_D$ –123.7 (*c* 1, $CHCl_3$). δ_H (300 MHz, $CDCl_3$): 2.28 (s, 3H), 2.29 (s, 3H), 2.36 (s, 3H), 3.70 (s, 3H), 3.81 (s, 3H), 6.77 (s, 1H), 7.23 (m, 2H), 7.44 (m, 2H). δ_C (75 MHz, $CDCl_3$): 10.4, 16.0, 21.2, 56.0, 62.1, 116.6, 124.3, 124.8, 127.0, 129.4, 129.9, 136.8, 139.7, 141.6, 151.0, 154.4. Elemental analysis (%) ($C_{17}H_{20}SO_3$): C 67.1, H 6.6 (calcd.); C 66.8, H 6.7 (found).

(+)-(*S*,*R*)-3-(Isopropylsulfinyl)-1,4-dimethoxy-2,5-dimethylbenzene was obtained, in 45% yield as a colorless oil, from 3-bromo-1,4-dimethoxy-2,5-dimethylbenzene[24] and 1,2:5,6-di-*O*-isopropylidene-α-D-glucofuranosyl (+)-(*R*)-2-propanesulfinate.[25] $[\alpha]_D$ + 91 (*c* 0.45, $CHCl_3$). δ_H (300 MHz, $CDCl_3$): 1.05 (d, 3H, J = 6.9), 1.44 (d, 3H, J = 6.9), 2.28 (s, 3H), 2.45 (s, 3H), 3.64 (m, 1H), 3.80 (s, 3H), 3.81 (s, 3H), 6.75 (s, 1H). δ_C (75 MHz, $CDCl_3$): 10.9, 15.8, 16.6, 16.7, 52.0, 55.9, 61.7, 115.8, 127.1, 129.4, 133.9, 150.7, 154.1

Step 2

To a solution of the sulfoxide (1.0 mmol) in MeCN (5 mL) was added 5 mL of an aqueous solution of CAN (2.5 mmol), and the resulting mixture was stirred 1 h at room temperature. After removal of half volume of the solvent, the quinone was extracted with CH_2Cl_2 (two portions of 20 mL). The extract was dried (Na_2SO_4) and concentrated under vacuum, yielding a solid.

(+)-(*S*,*S*)-2-Methyl-3-(*p*-tolylsulfinyl)cyclohexa-2,5-diene-1,4-dione, (+)-2a, was obtained, in 79% yield, from 1,4-dimethoxy-2-methyl-3-(*p*-tolylsulfinyl)benzene. Mp 107–109 °C. $[\alpha]_D$ +898 (*c* 0.50, CH_2Cl_2). δ_H (300 MHz, $CDCl_3$): 2.40 (s, 3H), 2.50 (s, 3H), 6.70 (d, 1H, J = 9.9), 6.80 (d, 1H, J = 9.9), 7.31 (d, 2H, J = 8.7), 7.63 (d, 2H, J = 8.7). δ_C (75 MHz, $CDCl_3$): 9.2, 21.3, 124.8, 130.1, 136.0, 136.8, 139.2, 141.7, 146.0, 146.8, 184.3, 185.9. Elemental analysis (%) ($C_{14}H_{12}SO_3 \cdot 1/2H_2O$): C 62.4, H 4.9 (calcd.); C 62.9, H 4.7 (found).

(+)-(*S*,*S*)-2,5-Dimethyl-3-(*p*-tolylsulfinyl)cyclohexa-2,5-diene-1,4-dione, (+)-2c (R = *p*Tol), was obtained as a red solid, in 71% yield, from (–)-(*S*,*S*)-1,4-dimethoxy-2,5-dimethyl-3-(*p*-tolylsulfinyl)benzene. Mp 136–139 °C. $[\alpha]_D$ +440 (*c* 0.40, $CHCl_3$). Spectroscopic data are identical to those described for (±)-**2c** (R = *p*Tol).

(–)-(*S*,*R*)-3-(Isopropylsulfinyl)-2,5-dimethylcyclohexa-2,5-diene-1,4-dione, (–)-2c (R = *i*Pr), was obtained as a red solid, in 79% yield, from (+)-(*S*,*R*)-3-(isopropylsulfinyl)-1,4-

dimethoxy-2,5-dimethylbenzene. Mp 82–84 °C. $[\alpha]_D$ –806 (*c* 0.2, $CHCl_3$). Spectroscopic data are identical to those reported for (±)-**2c** (R = *i*Pr).

Diels–Alder reactions

Thermal conditions

A solution of sulfinyl-1,4-benzoquinone (1.0 mmol) and cyclopentadiene (3.0 mmol) in CH_2Cl_2 (2 mL) was stirred at –20 °C. After complete consumption of the quinone, the solvent was removed under vacuum, and the DA adduct was isolated by column chromatography.

Catalytic conditions

A solution of sulfinylquinone (1.0 mmol) and the Lewis acid (see Table 1) in CH_2Cl_2 (2 mL) was stirred at –20 °C for 1 h, and at room temperature for 1 h. The mixture was cooled to –20 °C, and cyclopentadiene (3.0 mmol) was added. The mixture was stirred at –20 °C, and after complete consumption of the quinone, the solvent was removed under vacuum, and the adduct was isolated by column chromatography.

(±)-*Like*-4b was isolated as a yellow solid, in 40% yield, using hexane/ethyl acetate (4.5:1) as eluting solvent. Mp 97–99 °C. IR (KBr, cm^{-1}): 1329, 1659, 1673, 2977. δ_H (300 MHz, $CDCl_3$): 1.47 (s, 3H), 1.48 (m, 1H), 1.65 (m, 1H), 2.32 (s, 3H), 2.39 (s, 3H), 2,92 (d, 1H, *J* = 3.9), 3.04 (s, 1H), 3.35 (s, 1H), 5.56 (m, 1H), 5.96 (m, 1H), 7.29 (m, 2H), 7.55 (m, 2H). δ_C (75 MHz, $CDCl_3$): 9.9, 21.8, 26.8, 46.8, 49.3, 53.5, 54.2, 58.1, 125.2, 130.4, 135.0, 141.8, 138.6, 139.5, 151.9, 152.8, 196.9, 201.7. Elemental analysis (%) ($C_{20}H_{20}SO_3$): C 70.6, H 5.9 (calcd.); C 69.9, H 6.2 (found).

(±)-*Unlike*-4b was isolated as a yellow oil, in 30% yield, using hexane/ethyl acetate (4.5:1) as eluting solvent. δ_H (300 MHz, $CDCl_3$): 1.41 (s, 3H), 1.54 (m, 1H), 1.64 (m, 1H), 2.37 (s, 3H), 2.39 (s, 3H), 2.77 (d, 1H, *J* = 3.9), 3.06 (s, 1H), 3.39 (s, 1H), 6.02 (m, 1H), 6.06 (m, 1H), 7.29 (m, 2H), 7.60 (m, 2H). δ_C (75 MHz, $CDCl_3$): 10.8, 21.8, 27.0, 47.0, 49.5, 53.6, 54.4, 58.2, 125.4, 130.4, 135.6, 138.4, 140.0, 141.9, 151.7, 153.0, 196.2, 201.5.

(±)-*Like*-4c (R = *p*Tol) was isolated as a yellow oil in admixture with (±)-*unlike*-**4c** (R = *p*Tol), using hexane/ethyl acetate (3.5:1) as eluting solvent. δ_H (300 MHz, $CDCl_3$): 1.25 (s, 3H), 1.55 (m, 2H), 2.39 (s, 3H), 2.40 (s, 3H), 2.80 (d, 1H, *J* = 3.9), 3.04 (m, 1H), 3.42 (m, 1H), 6.01 (m, 1H), 6.14 (m, 1H), 7.29 (m, 2H), 7.58 (m, 2H).

(±)-*Unlike*-4c (R = *p*Tol) was isolated as a yellow oil in admixture with (±)-*like*-**4c** (R = *p*Tol) using hexane/ethyl acetate (3.5:1) as eluting solvent. δ_H (300 MHz, $CDCl_3$): 1.49 (s, 3H), 1.55 (m, 2H), 2.35 (s, 3H), 2.40 (s, 3H), 2.86 (d, 1H, *J* = 3.9), 3.04 (m, 1H), 3.40 (m, 1H), 5.67 (dd, 1H, *J* = 3.0 and 2.4), 5.82 (dd, 1H, *J* = 3.0 and 2.4), 7.58 (m, 2H), 7.49 (m, 2H).

(±)-*Like*-4c (R = *i*Bu) was isolated as a yellow oil, in 22% yield, using hexane/ethyl acetate (2:1) as eluting solvent. δ_H (300 MHz, $CDCl_3$): 1.10 (d, 3H, *J* = 6.6), 1.16 (d, 3H, *J* = 6.6), 1.49 (s, 3H), 1.65 (m, 2H), 2.30 (m, 1H), 2.31 (s, 3H), 2.70 (dd, 1H, *J* = 4.2 and 12.6), 2.92 (d, 1H, *J* = 4.2), 3.08 (bs, 1H), 3.20 (dd, 1H, *J* = 4.5 and 12.6), 3.44 (bs, 1H), 6.04 (m, 1H), 6.23 (m, 1H).

(±)-*Unlike*-4c (R = *i*Bu) was isolated as a yellow oil, in 20% yield, using hexane/ethyl acetate (2:1) as eluting solvent. δ_H (300 MHz, $CDCl_3$): 1.10 (d, 3H, *J* = 6.6), 1.16 (d, 3H, *J* = 6.6), 1.49 (s, 3H), 1.65 (m, 2H), 2.30 (m, 1H), 2.40 (s, 3H), 2.70 (dd, 1H, *J* = 4.2 and 12.6), 2.92 (d, 1H, *J* = 4.2), 3.15 (m, 2H), 3.44 (m, 1H), 6.04 (m, 1H), 6.15 (m, 1H).

(±)-*Like*-4c (R = *i*Pr) was isolated as a yellow oil, in 25% yield, using hexane/ethyl acetate (3:1). δ_H (300 MHz, $CDCl_3$): 1.29 (d, 3H, *J* = 6.6), 1.35 (d, 3H, *J* = 6.6), 1.49 (s, 3H), 1.59 (m, 2H), 2.31 (s, 3H), 2.91 (d, 1H, *J* = 3.9), 3.09 (bs, 1H), 3.45 (m, 1H), 3.48 (m, 1H), 6.04 (m, 1H), 6.21 (m, 1H).

(±)-*Unlike*-4c (R = *i*Pr) was isolated as a yellow oil, in 60% yield, using hexane/ethyl acetate (3:1) as eluting solvent. δ_H (300 MHz, $CDCl_3$): 1.29 (d, 3H, *J* = 6.0), 1.37 (d, 3H, *J* = 6.0), 1.52 (s, 3H), 1.60 (m, 2H), 2.38 (s, 3H), 2.90 (d, 1H, *J* = 3.3), 3.09 (bs, 1H), 3.37 (m, 1H), 3.50 (bs, 1H), 6.04 (m, 1H), 6.13 (m, 1H). δ_C (75 MHz, $CDCl_3$): 9.6, 15.3, 18.0, 26.9, 46.8, 49.6, 53.8, 53.9, 57.3, 135.5, 138.7, 149.8, 155.7, 197.8, 200.8.

(±)-*Unlike*-6b (R = *p*Tol) was isolated, in 91% yield, as a yellow solid by employing hexane/ethyl acetate (3.5:1) as eluting solvent. δ_H (200 MHz, $CDCl_3$): 1.66 (m, 1H), 1.75 (d, 3H, *J* = 1.5), 1.81 (s, 3H), 2.29 (m, 1H), 2.41 (s, 3H), 3.24 (bs, 1H), 4.02 (bs, 1H), 5.88 (q, 1H, *J* = 1.2), 6.05 (m, 1H), 6.22 (m, 1H), 7.27 (m, 2H), 7.49 (m, 2H). δ_C (50 MHz, $CDCl_3$): 16.3, 21.5, 25.0, 43.3, 49.6, 54.3, 57.5, 81.4, 126.2, 129.2, 136.8, 137.4, 139.4, 140.3, 142.6, 149.6, 191.2, 201.4.

(±)-*Unlike*-6c (R = *p*Tol) was isolated, in 95% yield, as a yellow solid, using hexane/ethyl acetate (3.5:1) as eluting solvent. Mp 111–114 °C. δ_H (300 MHz, $CDCl_3$): 1.24 (d, 3H, *J* = 1.5), 1.68 (m, 1H), 1.85 (s, 3H), 2.23 (m, 1H), 2.40 (s, 3H), 3.25 (bs, 1H), 4.09 (bs, 1H), 6.05 (m, 1H), 6.13 (q, 1H, *J* = 1.5), 6.23 (m, 1H), 7.28 (m, 2H), 7.48 (m, 2H). δ_C (75 MHz, $CDCl_3$): 15.3, 21.3, 25.6, 43.3, 50.2, 54.4, 58.0, 81.3, 126.1, 129.7, 136.4, 136.6, 137.7, 140.4, 142.3, 153.2, 192.0, 200.4. Elemental analysis (%) ($C_{20}H_{20}SO_3$): C 70.6, H 5.9 (calcd.); C 70.7, H 6.0 (found).

(–)-*Unlike*-6c (R = *p*Tol) was isolated as a yellow oil, in 36% yield, employing hexane/ethyl acetate (3.5:1) as eluting solvent. $[\alpha]_D$ –134 (*c* 0.5, $CHCl_3$). Spectroscopic data are identical to those described for (±)-*unlike*-**6c** (R = *p*Tol).

(±)-*Unlike*-6c (R = *i*Bu) was isolated as a yellow oil, in 34% yield, using hexane/ethyl acetate (2:1) as eluting solvent. δ_H (300 MHz, $CDCl_3$): 1.08 (d, 3H, *J* = 6.9), 1.10 (d, 3H, *J* = 6.9), 1.50 (s, 3H), 1.61 (m, 1H), 2.02 (d, 3H, *J* = 1.5), 2.20 (m, 1H), 2.30 (m, 1H), 2.35 (m, 1H), 2.45 (m, 1H), 2.50 (dd, 1H, *J* = 3.9 and 4.2), 3.20 (bs, 1H), 3.95 (bs, 1H), 6.10 (dd, 1H, *J* = 2.7 and 3.0), 6.24 (dd, 1H, *J* = 2.7 and 3.0), 6.50 (q, 1H, *J* = 1.5). δ_C (75 MHz, $CDCl_3$): 15.9, 21.7, 22.8, 23.4, 25.4, 43.2, 50.3, 55.2, 57.6, 60.5, 136.5, 138.4, 140.5, 153.1, 193.1, 200.6.

(–)-*Unlike*-4c (R = *i*Pr) was isolated as a yellow oil, in 56% yield, using hexane/ethyl acetate (6:1). $[\alpha]_D$ –132 (*c* 0.5, $CHCl_3$). Spectroscopic data are identical to those described for (±)-*unlike*-**4c** (R = *i*Pr).

Desulfurization reactions

Using Al–Hg

To a solution of the DA adduct (0.42 mmol) in THF/water (9:1; 12 mL), pieces of aluminum foil[19] (1.0 g; recently immersed into a $HgCl_2$ aqueous solution and washed

with ethanol and ethyl ether) were added, and the mixture was stirred at room temperature for 3.5 h. The solids were filtered off, and the solvent was removed under vacuum. The residue was submitted to flash chromatography separation.

Using Raney–Ni

A suspension of Raney–Ni (W2[22] or deactivated;[23] ~1 mL of the decanted solid metal) in ethanol (5 mL) was added to a solution of the DA adduct (0.45 mmol) in ethanol (10 mL) under stirring at room temperature. The desulfurization process was monitored by the consumption of the DA adduct (by TLC). The residual metal was removed by filtration, and the solvent was evaporated under vacuum. The residue was purified by flash chromatography.

Using Ni_2B[21]

To a well-stirred mixture of the DA adduct (0.21 mmol) and $NiCl_2{\cdot}6H_2O$ (0.10 g; 0.42 mmol) in methanol/THF (3:1; 12 mL) at 0 °C, $NaBH_4$ (0.050 g; 1.3 mmol) was added, resulting in a black solid. After 15 min, the mixture was filtered over Celite, and the solvent was removed under vacuum. The residue was dissolved in CH_2Cl_2 (20 mL) and washed with water (20 mL). After drying (Na_2SO_4) and concentration under vacuum, the residue was purified by flash chromatography.

(±)-4a,7-Dimethyl-1,2,3,4,4a,8a-hexahydro-1,4-methano-naphthalene-5,8-dione, 8, was isolated as a colorless oil, in 40% yield, using hexane/ethyl acetate (3:1) as eluting solvent. δ_H (300 MHz, $CDCl_3$): 1.25 (s, 3H), 1.35 (m, 1H), 1.45 (m, 2H), 1.69 (m, 1H), 1.97 (bs, 2H), 2.02 (d, 3H, J = 1.5), 2.48 (bs, 1H), 2.56 (dd, 1H, J = 1.5 and 1.8), 2.86 (bs, 1H), 6.56 (q, 1H, J = 1.5).

Aluminum nitrate and silica sulfuric acid as efficient nitrating media for the mononitration of phenols under mild and heterogeneous conditions

Arash Ghorbani-Choghamarani, Hamid Goudarziafshar, Mohsen Nikoorazm, and Somaieh Yousefi

Abstract: A variety of phenol derivatives were successfully nitrated via combination of $Al(NO_3)_3{\cdot}9H_2O$ and silica sulfuric acid in the presence of wet SiO_2 (50% *w*/*w*) in dichloromethane at room temperature with moderate-to-good yields.

Key words: nitration, phenol, heterogeneous conditions, aluminum nitrate [$Al(NO_3)_3{\cdot}9H_2O$], silica sulfuric acid (SiO_2–OSO_3H).

Résumé : Opérant à la température ambiante, dans le dichlorométhane et faisant appel à une combinaison de $Al(NO_3)_2{\cdot}9H_2O$ et d'acide sulfurique lié à de la silice, en présence de SiO_2 humide (50 % *w*/*w*), on a réalisé avec succès la nitration des dérivés du phénol, avec des rendements allant de modérés à bons.

Mots-clés : nitration, phénol, conditions hétérogènes, nitrate d'aluminium [$Al(NO_3)_2{\cdot}9H_2O$], acide sulfurique lié à de la silice (SiO_2–OSO_3H).

[Traduit par la Rédaction]

Introduction

Nitrophenols have been identified in the atmospheric gas phase and in cloud and rainwater.[1] Nitration of organic substrates is a widely studied reaction of great industrial significance, as many nitro-compounds are extensively utilized and act as intermediates for the manufacture of plastics, dyes, perfumes, drugs, and pharmaceuticals.[2] However, nitration in a manufacturing process requires the use of potent mixtures of concentrated or fuming nitric acid with sulfuric acid, leading to excessive acid-waste streams and added expense.[3] Nitrophenols are very important organic intermediates, and hence, it is still interesting to develop regiospecific pollution-free nitrating procedures for phenolic compounds under mild conditions.[4] Even though various nitrating reagents for the nitration of phenols have been emerged in the recent years,[5–10] many of these methods still suffer from some drawbacks, including low selectivity, low yields of products, tedious work-up, toxicity, and expensive reagents.

Recent research has demonstrated that the heterogeneous reagent systems have many advantages, such as simple experimental procedures, mild reaction conditions, and minimization of chemical waste as compared with the liquid-phase counterparts.[11–16]

Therefore, we decided to design new heterogeneous media for the selective mononitration of phenolic compounds.

Result and discussion

In this article, we report a new, simple, cheap, and convenient protocol for the mononitration of phenols using SiO_2–OSO_3H and $Al(NO_3)_3{\cdot}9H_2O$ in the presence of wet SiO_2 (50% *w*/*w*) under mild and heterogeneous conditions. Silica sulfuric acid can be readily prepared via the reported procedure by Zolfigol (Scheme 1).[17]

A wide variety of substituted phenols were nitrated by silica sulfuric acid (SiO_2–OSO_3H) (**I**) and aluminum nitrate [$Al(NO_3)_3{\cdot}9H_2O$] (**II**) in the presence of wet SiO_2 (50%, *w*/*w*) in dichloromethane (Scheme 2).

The nitration reactions were performed at room temperature with moderate-to-good yields, and the results are summarized in Table 1.

The mixing of the nitrating agents and phenols in dichloromethane and stirring the resulting heterogeneous mixture at room temperature can selectively produce mononitrated phenols. Highly pure mononitrophenols can be obtained by flash column chromatography. A combination of aluminum nitrate nine hydrate and silica sulfuric acid can act as a solid nitrating agent, which can be readily weighed, handled, and used in the presence of moist SiO_2. Water molecules or wet SiO_2 are necessary for the nitration of phenols. Therefore, we think that wet SiO_2 acts as a heterogeneous effective surface area for in situ generation of HNO_3.

In summary, herein, we report an efficient method for the selective nitration of phenols under mild and heterogeneous conditions with acceptable yields. Furthermore, this method exhibits substrate versatility, mild reaction conditions, easy and clean work-up of products.

Experimental section

The chemicals and solvents were purchased from Fluka, Merck, and Aldrich chemical companies and were used without further purifications.

Mononitration of 4-chloro-3-methylphenol with silica sulfuric acid, $Al(NO_3)_3{\cdot}9H_2O$, and wet SiO_2 (a typical procedure)

A suspension of 4-chloro-3-methylphenol (0.142 g, 1 mmol), silica sulfuric acid (0.225 g), wet SiO_2 (50% *w*/*w*, 0.2 g), and $Al(NO_3)_3{\cdot}9H_2O$ (0.143 g, 0.5 mmol) in CH_2Cl_2 (5 mL) was stirred at room temperature for 110 min (the progress of the reaction was monitored by TLC) and then filtered. Anhydrous Na_2SO_4 (1.5 g) was added to the filtrate. After 15 min, the resulting mixture was also filtered; CH_2Cl_2 was removed by distillation in a water bath. Crude product was purified by flash silica-gel column chromatography using CH_2Cl_2 as eluent and pure product obtained in 60% yield (0.112 g). Crystalline pale yellow solid, mp 130–132 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 10.46 (s, 1H), 8.10 (s, 1H), 7.27 (s, 1H), 7.07 (s, 1H), 2.43 (s, 3H) ppm. ^{13}C NMR (100 MHz, $CDCl_3$) δ: 153.4, 147.6, 131.8, 125.8, 124.5, 121.4, 20.8 ppm.

4-tert-*Buthyl-2-nitrophenol*

Yellow oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 10.49 (s, 1H), 8.07 (s, 1H), 7.63–7.66 (d, 1H, *J* = 8.8 Hz), 7.09–7.12 (d, 1H, *J* = 8.8 Hz), 1.33 (s, 9H) ppm. ^{13}C NMR (100 MHz, $CDCl_3$) δ: 153.0, 143.6, 135.4, 132.9, 120.8, 119.5, 34.3, 31.0 ppm.

*2-Nitro-4-*iso*-propylphenol*

Yellow oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 10.48 (s, 1H), 7.94 (s, 1H), 7.47–7.49 (d, 1H, *J* = 7.6 Hz), 7.09–7.11 (d, 1H, *J* = 8.8 Hz), 2.89–2.96 (septet, 1H, *J* = 8 Hz), 1.25–1.27 (d, 6H, *J* = 8 Hz) ppm. ^{13}C NMR (100 MHz, $CDCl_3$) δ: 153.3, 141.2, 136.4, 133.3, 121.9, 119.7, 33.1, 23.7 ppm.

2-Nitro-4-phenoxyphenol

Yellow oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 10.41 (s, 1H), 7.7–7.71 (m, 1H), 7.34–7.4 (m, 3H), 7.16–7.18 (m, 2H), 6.99–7.0 (m, 2H) ppm. ^{13}C NMR (100 MHz, $CDCl_3$) δ: 156.6, 151.2, 149.8, 133.3, 130.1, 129.6, 124.1, 121.1, 118.6, 113.6 ppm.

2-tert-*Buthyl-4-methyl-2-nitrophenol*

Crystalline pale yellow solid, mp 89–90 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 11.43 (s, 1H), 7.79 (s, 1H), 7.38 (s, 1H), 2.32 (s, 3H), 1.43 (s, 9H) ppm. ^{13}C NMR (100 MHz, $CDCl_3$) δ: 153.1, 140.2, 136.1, 133.8, 128.6, 122.2, 35.4, 29.3, 20.7 ppm.

Theoretical study of the electronic spectra of *s*-triazine vapour

Delano P. Chong

Abstract: The ionization and excitation spectra of valence and core electrons of *s*-triazine in the gas phase are studied with ab initio, density functional, and semi-empirical methods. The results are compared with available experimental data and previous calculations. New estimates are proposed for the ionization energies of both valence and core electrons. The calculated excitation energies are consistent with experiment.

Key words: ionizations, photoelectron spectra, excitations, UV absorption, electron spectra, *s*-triazine, core-electron binding energies, ESCA, DFT.

Résumé : Faisant appel à des méthodes de calculs semi-empiriques, ab initio et selon la théorie de la fonctionnelle de la densité, on a étudié les spectres d'excitation et d'ionisation des électrons de coeur et de valence de la *s*-triazine en phase gazeuse. On compare les résultats de ces calculs avec les données expérimentales disponibles et les résultats de calculs antérieurs. On propose de nouvelles évaluations pour les énergies d'ionisation des électrons de valence et de coeur. Les énergies d'excitation calculées sont cohérentes avec les résultats expérimentaux.

Mots-clés : ionisations, spectres photoélectroniques, excitations, absorption UV, spectres électroniques, *s*-triazine, énergies de liaison des électrons de coeur, spectroscopie électronique pour l'analyse chimique (SEAC), théorie de la fonctionnelle de densité (TFD).

[Traduit par la Rédaction]

Introduction

The photoelectron spectra of 1,3,5-(*sym*)-triazine ($C_3N_3H_3$) vapour were reported by several workers in 1972.[1–4] The assignments of some of the bands were somewhat tentative, since the interpretation of the photoelectron spectra was based on the use of Rydberg transitions,[1] extended Hückel treatments,[2] or the perfluoro effect,[3,4] and vertical ionization energies (VIEs) within 0.3 eV of each other can easily be misinterpreted. In my opinion, none of the assignments is completely correct, and the best estimates of the VIEs of gas-phase *s*-triazine are presented in Table 1.

On the other hand, although the excitation spectrum[1,5,6] was better understood, the Rydberg-like assignments, such as *n*s and *n*p (leaving the centre of the Rydberg orbitals unspecified), are not entirely satisfactory. Experimental studies of the excitation of the core electrons of *s*-triazine were more recent,[7–9] but the core-electron binding energies (CEBEs) have only been estimated from similar molecules,[7] and those values are quite different from ab initio[8] and density functional theory (DFT) calculations.[9]

As is well-known, *s*-triazine is planar with D_{3h} symmetry. The purpose of this work is to calculate the ionization and excitation spectra of both valence and core electrons of *s*-triazine in the gas phase with various theoretical methods and to compare the results with the available experimental data. The calculations are performed with standard program packages. The motivation for this work is partly to stimulate experimentalists to try similar computations for the interpretation of their observed electron spectra after they see the encouraging results of this work.

Computational details

Electron spectra are generally not very sensitive to small variations in geometry. Since the experimental geometry of gas-phase *s*-triazine (D_{3h} symmetry) has been determined by electron diffraction,[10] it is used instead of optimizing the geometry theoretically. However, the angles around each carbon do not add up to 360° exactly, with the H–C–N angle having the largest uncertainty. I therefore decided to use a value of 116.95° for the H–C–N angle instead of the reported value of 116.9° ± 0.1°.[10] For runs with Gaussian03 program package,[11] Dunning's cc-pVTZ basis set[12] is used, while the aug-TZP basis set of Slater-type orbitals[13,14] is chosen for runs with the Amsterdam density functional (ADF) program.[15]

Results and discussions

Valence ionizations

In the absence of significant shake-up satellite bands, the most reliable method for the computation of VIEs is outer-valence Green's function (OVGF). This is true for our molecule *s*-triazine as well, as shown in Table 2, with an average absolute deviation (AAD) of 0.34 eV from experiment. The $1a_2''$ and the doubly degenerate $1e''$ orbitals are similar to the familiar π-MOs of benzene. In the OVGF output, there is no calculated VIE between $1e''$ cation at 11.69 eV and the $1e''$ cation at 13.23 eV, confirming the suggestion

of Robin et al.[4] that the observed peak at 12.2 eV is due to Jahn–Teller effects. Because of the D_{3h} symmetry, most of the occupied σ-MOs exist in combinations of a_1' and e′. For example, the N1s cores become $1a_1'$ and 1e′ MOs; and those of C1s, $2a_1'$, and 2e′.

The shortcut approximations, parametrized second-order Green's function (pGF2),[16] and meta-Koopmans' theorem (mKT),[17] fare less well, with AAD = 0.56 and 0.58 eV, respectively. The latest DFT methods[18] are ΔE(PBE0) and ΔE(mPW1PW) for the density obtained with the exchange–correlation potential V_{xc} known as statistical averaging of orbital potential (SAOP),[19,20] perform reasonably well, with AAD = 0.42 and 0.45 eV, respectively. Of the semi-empirical MO methods, the heavily parametrized HAM/3,[21] outperforms the others,[22,23] not only in giving a lower AAD, but also in providing VIE estimates for more MOs, as shown in Table 2.

The calculation of adiabatic ionization energies (except the lowest one) is more difficult because one needs to optimize the geometry of each cationic state of interest. In this work, the geometry of the ground-state cation of *s*-triazine was first optimized with the exchange–correlation functional E_{xc} known as PW91 using the polarized triple-zeta TZP basis set in the ADF program package. Then, the energy difference between parent and cation was computed with the method of coupled-cluster with single and double excitations and perturbative correction due to triple excitations CCSD(T) using the polarized valence triple-zeta basis set 6–311G(d,p) in the Gaussian03 program. The adiabatic ionization energy thus obtained is 10.05 eV, in excellent agreement with the observed value of 10.01 eV.[1]

In short, the combination of past experimental and present theoretical studies provides a better interpretation of the photoelectron spectra of *s*-triazine vapour.

Valence excitations

One of the nice features of the exchange–correlation potential V_{xc} = SAOP is its correct asymptotic behavior, leading to reliable excitation energies from time-dependent DFT (TDDFT) calculations, as indicated by previous studies,[13,19,20,24,25] provided one uses adequate basis sets such as aug-TZP. As an example, the excitation energies of the N_2 molecule as calculated by various methods are compared in Table 3. It can be seen that, in favorable situa-

tions, our procedure of TDDFT(SAOP)/aug-TZP can be as reliable as the other methods. In this work, TDDFT is used with V_{xc} = SAOP to compute the excitation of valence electrons of *s*-triazine vapour. The results are compared with experiment and other studies in Table 4.

Excitations of valence electrons for *s*-triazine in different solutions and in solid state, studied by various workers, are beyond the scope of the present work. For gas-phase *s*-triazine, there have been very few studies.[1,5,6,34] The most reliable data seem to be from the electron-impact energy-loss spectrum reported by Fridh et al.[1] The intensity in electron energy-loss spectra (EELS), of course, does not correspond to *f*-values.

The lowest triplet states from our calculation are $^3A_2''$ at 3.85 eV and $^3E''$ at 3.92 eV, which probably correspond to the triplet at 3.59 eV for *s*-triazine crystal.[34] The first singlet peak with nonzero *f*-value from our calculation is $^1A_2''$ at 4.30 eV, compared with $^1A_2''$ at 4.5 eV observed in EELS,[1]

and the maximum absorption at 4.59 eV in low-resolution UV spectra.[5] The very intense excitation to the ^{1}E′ state at 7.77 eV from EELS and the estimated maximum UV at 7.12 eV in the high-resolution UV spectrum are confirmed by our 7.20 eV with *f*-value > 1.5 for ^{1}E′ state from the 1e″ to 2e″ excitation. However, the $^1A_1'$ state for the same 1e″ to 2e″ excitation is calculated with no intensity, even though the calculated energy of 6.88 eV agrees well with the observed ~6.7 eV. The reason for the disagreement in intensity is probably the neglect of vibronic interactions in this work. The interpretation of the higher energy peaks is tentative.

Core-electron ionizations

There does not appear to be any reported measurement(s) of the CEBEs of *s*-triazine vapour. Apen et al[7] estimated the C1s and N1s values from similar molecules while Duflot et al.[8] made ab initio calculations and Vall-Ilosera et al.[9] did DFT computations for them. In this work, DFT calculations are also performed but with an exchange–correlation functional E_{xc} known as PW86x-PW91c, which has been shown to lead to reliable CEBEs for C, N, O, and F.[35] Moreover, it is well-known that the calculated values for symmetric core holes for equivalent nuclei are much less reliable than those for localized core holes.[36] Table 5 presents best estimates, obtained by this work, of the CEBEs of C1s and N1s in *s*-triazine based on the results of MP2,[8] B88P86,[9] and the present PW86PW91 calculations. I believe that 293.3 and 405.8 eV are better estimates of the CEBEs of C1s and N1s than the previous estimates of Apen et al.[7]

Core-electron excitations

Excitations from core electrons in degenerate symmetry MOs are difficult to treat in this work's approach because core holes are better approximated by localized holes, but localizing a core hole would reduce the full symmetry of the symmetric molecule. Moreover, this work's simplification of limiting the TDDFT treatment to excitations from the core levels gives only estimates of the oscillator strengths. To overcome the localized versus delocalized difficulty, term values (TVs) are compared in Table 6.

Although this work's calculated value of 6.51 eV for the TV of N1s going to 2e″ MO deviates from the observed value around 7 eV, the assignment of the two main bands in the N1s excitations to 2e″ and $2a_2'$ are definitely confirmed. However, the assignment of the observed N1s excitation at 399.9 eV by Vall-Ilosera et al.[9] and that at 404.12 eV by Duflot et al.[8] remain uncertain.

Except for the first excitation from C1s to the 2e″ LUMO, the excitations from C1s are not well-understood. The second main band at 290.1 eV was assigned to $2a_2'$ by Apen et al.[7] The value corresponds well to 290.09 eV observed but Duflot et al.,[8] who however assigned it to π* MO. The TV

value of this work and estimated intensity seem to favour the assignment to $6a_1'$, supporting Duflot et al.

Conclusions

In this work, previous photoelectron spectra of *s*-triazine vapour are reviewed and the best estimates of the vertical ionization energies are presented in Table 1, and the results of ab initio, DFT, and semi-empirical MO methods are compared in Table 2. As expected, the best method is OVGF, and the best semi-empirical method is HAM/3. On the other hand, the approach of TDDFT(SAOP)/aug-TZP provides a good interpretation of the experimental excitation spectra of valence electrons.

Spectra of core-electron are usually more difficult. Based on previous and present calculations, more reliable values for the core-electron binding energies than the previous estimates from similar molecules are proposed. Although the core excitations from C1s and N1s to the π^* MOs of e'' and a_2' are definitely confirmed, the identity of other levels are less certain.

A test of various computational solvation models on a set of "difficult" organic compounds

J. Peter Guthrie and Igor Povar

Abstract: Various dielectric continuum models in Gaussian 03, based on the SCRF approach, PCM, CPCM, DPCM, IEFPCM, IPCM, and SCIPCM, have been tested on a set of 54 highly polar, generally polyfunctional compounds for which experimental solvation energies are available. These compounds span a range of 13 kcal/mol in ΔG_t. The root-mean-square (RMS) errors for the full set of compounds range from 2.48 for DPCM to 1.77 for IPCM. For each method, classes of compounds which were not handled well could be identified. If these classes of compounds were omitted, the performance improved, and ranged from 1.58 (PCM, 39 compounds) to 1.02 (IPCM, 42 compounds). Models in the PCM family (PCM, CPCM, DPCM, and IEFPCM) with the recommended UAHF or UAKS sets of radii rely on a highly parameterized definition of the solvent cavity. Where this parameterization was inadequate, the calculated solvation energies were less reliable. This has been demonstrated by devising a new parameterization for PCM and halogen compounds, which markedly improves performance for polyhalogen compounds. The effective radius for the portion of the cavity centered on a halogen atom was assumed to be linear in the electron-withdrawing or -donating properties of the rest of the molecule as measured by Hammett σ (for halogens on aromatic rings) or Taft σ* (for halogens on aliphatic carbons). This new parameterization for PCM was tested on a set of 45 aliphatic and 22 aromatic polyhalogen compounds and shown to do well. IPCM, which was already the best of the methods in Gaussian, can be considerably improved by a parameterization to allow for cavitation, dispersion, and hydrogen bonding. A large set of compounds was used for the parameterization to have multiple examples for each parameter and as far as possible to have molecules with multiple instances of each structural feature. In the end, 15 parameters were found to be defined by the data for 241 compounds. With this parameter set, the RMS error for the set used for fitting was 0.81 kcal/mol, and the RMS error for the original set of 54 compounds was 0.85. With this new parameterization, IPCM is clearly the best of the methods available in Gaussian 03.

Key words: solvation energy, polyfunctional molecules, computational chemistry, parameterization, IPCM.

Résumé : Utilisant un ensemble de 54 composés hautement polaires et généralement polyfonctionnels pour lesquels des données expérimentales sur les énergies de solvatation sont disponibles, on a évalué divers modèles diélectriques continus dans la gaussienne 03, basée sur l'approche du champ réactionnel autocohérent (CRAC), dans des modèles du continuum polarisable divers, tel le modèle apparenté à un conducteur « CPCM », le modèle diélectrique « DPCM », le modèle dans un formalisme d'équation intégrale « IEFPCM », le modèle avec surface d'isodensité « IPCM » ou son équivalente en champ autocohérent « SPICM ». Les valeurs du ΔG_t pour ces composés s'étalent sur une plage de 13 kcal/mol. La valeur quadratique moyenne (VQM) des erreurs pour l'ensemble des composés varie de 2,48 pour la méthode « DPCM » à 1,77 pour l' « IPCM ». Pour chacune des méthodes, il a été possible de bien identifier des classes de produits qui ne pouvaient pas être examinés. Si on omet ces classes de produits, la performance s'améliore et elle varie de 1,58 (« PCM », 39 composés) à 1,02 (« IPCM », 42 composés). Les modèles de la famille « PCM » « PCM, CPCM, DPCM, IEFPCM » utilisés avec les ensembles recommandés de rayons atomiques d'atome unis de Hartree–Fock « UAHF » ou de "UAKS" reposent sur une définition hautement paramétrisée de la cavité du solvant. Lorsque cette paramétrisation n'était pas adéquate, les énergies de solvatation étaient moins fiables. On a démontré ce point en mettant au point une nouvelle paramétrisation pour la méthode "PCM" et les composés halogénés qui a permis d'améliorer grandement la performance pour les dérivés polyhalogénés. On fait l'hypothèse que le rayon effectif de la portion de la cavité centrée sur un atome d'halogène est linéaire dans le caractère électroaffinitaire ou électrodonneur du reste de la molécule, tel que mesuré par les valeurs σ de Hammett (pour les atomes d'hydrogène sur les noyaux aromatiques) et σ* de Taf (pour les atomes d'halogène sur les carbones aliphatiques). On a testé cette nouvelle paramétrisation dans le modèle « PCM » sur un ensemble de 45 composés polyhalogénés aliphatiques et 22 aromatiques et on a montré qu'elle donne de bons résultats. La méthode « IPCM » qui était déjà la meilleure des méthodes gaussiennes peut être considérablement améliorée par une paramétrisation qui tient compte de la cavitation de la dispersion et des liaisons hydrogènes. Afin de couvrir plusieurs exemples de chacun des paramètres et pour avoir des molécules comportant de multiples instances de chacune des caractéristiques structurales, on a utilisé un large ensemble de composés pour effectuer la paramétrisation. On a trouvé que les paramètres sont définis par les données relatives à 241 composés. Avec cet ensemble de paramètres, l'erreur quadratique moyenne pour l'ensemble utilisé est de 0,81 kcal/mol alors qu'elle était de 0,85 pour l'ensemble original de 54 composés. Avec cette nouvelle paramétrisation, la méthode "IPCM" est nettement la meilleure disponible dans la gaussienne 03.

Introduction

Reading the literature might leave one with the impression that the problem of calculating solvation energies with precision similar to experiment, i.e., errors less than 1 kcal/mol, had been solved. Barone et al. have stated that "mean error ... below 0.20 kcal/mol for ... 43 neutral solutes";[1] Takano and Houk tested several methods and reported that with CPCM, the mean absolute deviation was 1.10 kcal/mol for 30 neutrals.[2] Based on our previous work on solvation energies,[3] we were skeptical of these implicit claims that general solutions to the problem of calculating solvation energies for any organic molecules had been achieved because these approaches were based on calculations for simple molecules. Hine and Mookerjee[4] found that additivity schemes allowed the calculation of solvation energies for monofunctional compounds but that polyfunctional compounds were much harder because of distant polar interactions. We have reported a parameterization for distant polar interactions, which allowed the calculation of the solvation energies for polyfunctional molecules,[3] and have had occasion to determine solvation energies for a number of polar polyfunctional molecules in the course of work concerned with reactive species in solution.[5–11]

In the present work, we have carried out a critical examination of various solvation models in current use, focused on compounds expected to be difficult. These compounds are highly polar and mostly polyfunctional, belonging to a variety of chemical classes. It was our expectation that many of the currently available solvation models, which are often parameterized to fit a range of relatively simple compounds, were likely to have difficulty with polyfunctional compounds.

As will be seen in this report, this is what we have found: all of the methods tested had problems with some of the test compounds and showed systematic errors. We will demonstrate that for halogens, the popular UAHF model is seriously under-parameterized and will show how it can be improved. We will also report that a small number of parameters permit the IPCM method to be significantly improved so that it becomes the best of the currently available continuum models.

Our long term goal is to establish a reliable general approach for the calculation of equilibrium constants for reactions in solution and especially for the formation of reactive intermediates (for which models of known solvation energy are frequently unavailable). Such equilibrium constants are often unknown and difficult to measure; computation would be an attractive alternative. The equilibrium constant in solution for the rate-determining step is a key input datum for calculation of the rate of a reaction by no-barrier theory.[12–16] Calculation of equilibrium constants in the gas phase is close to being a solved problem, at least for small molecules.[17–21] The difficulty is to have a general method for calculating solvation energies with chemical accuracy.

During the past few years, there has been increasing interest in calculating solvation free energies via self-consistent reaction field (SCRF) methodologies, involving the inclusion of a dielectric continuum model of the solvent in an electronic structure calculation. For a dielectric continuum model, the solute, treated as having a low dielectric constant, is in a cavity outside of which the solvent has its continuum dielectric constant. Definition of the cavity surface is crucial and commonly based on either scaled atomic radii or parameterized atomic radii adjusted to give good results.

The IPCM, isodensity polarizable continuum model,[22] simplifies the cavity definition by a modification of the original formalism. In this model, the solute cavity is determined by a specific value of the electronic isodensity contour (typically in the range 0.0004 – 0.001). This quantity defines the cavity boundary in terms of a surface of constant electron density for the solute. In this method, for a given solvent at a given theoretical level, there is only one parameter. The IPCM process, however, is not fully self-consistent. SCIPCM overcomes this problem as it contains a suitable term, which couples the isodensity and solute Hamiltonian. Consequently, the isodensity surface can either be based on a gas-phase calculation (IPCM) or can be determined self-consistently in the SCF procedure, i.e., taking account of the effect of solvation on the isodensity contours (SCIPCM).[22–27] Unfortunately, SCIPCM is prone to convergence failures. Neither IPCM nor SCIPCM as implemented in Gaussian03 makes any attempt to calculate a non-electrostatic contribution to ΔG_s. Published results[22,26,28] have shown that a value of 0.0004 for the isodensity parameter is a good choice and closely reproduces molar volumes of the liquid phase.

In general, the interactions of the solute with the solvent depend on the geometry of the solute, and in principle, the computation of solvation energies should use an average over solute geometries. In practice, this procedure is usually replaced by a single calculation using either the optimized gas-phase geometry or the optimized solution-phase geometry. On the other hand, geometry reoptimization in the presence of the solvent has a limited effect on the computed solvation energy.[1]

Solvation energies can be calculated with different standard states for gas and solution; two of the commonest are ΔG_s (1 mol/L to 1 mol/L) and ΔG_t (1 atm to 1 mol/L). Both are legitimate: ΔG_t is the most convenient for calculating free energies in solution (normal standard state 1 mol/L) from free energies in the gas phase (normal standard state 1 atm); ΔG_s is more convenient when thinking about the solvation process because it has no arbitrary entropic contribution from a change in concentration scales. In this paper, we will mainly use ΔG_t but will sometimes find it convenient to use ΔG_s.

Computational methodology

Initial three-dimensional geometries of the chemical structures were generated and optimized using the PCModel molecular modeling program.[29] Equilibrium geometries were

obtained for most compounds by the optimization at Hartree–Fock (RHF) or density functional (B3LYP)[30,31] levels of electronic structure theory using the 6–31+G(d,p) basis set in the gas phase. For molecules which have more than one possible conformation, the conformation with the lowest electronic energy was chosen. Each final optimized geometry was confirmed by RHF/6–31+G** or B3LYP/6–31+G** frequency calculations to be a real minimum on the potential-energy surface with no imaginary frequencies. The optimized geometries were used in subsequent single-point calculations of solvation energies with the same basis set. The solvent was always water at 25 °C.

For most compounds, calculations (geometry optimizations and solvation calculations) were carried out at two levels: (*a*) RHF/6–31+G** and (*b*) B3LYP/6–31+G**. For a few compounds, we carried out the geometry optimization and single-point calculations using correlated ab initio levels of theory, MP2 and MP4, with the 6–31+G(d,p) and 6–311+G(2df,2p) basis sets for MP2 and 6–31+G(d,p) for MP4. In the case of the isodensity methods IPCM and SCIPCM, the size of the solvent cavity was calculated with an isodensity value of 0.0004 and a dielectric constant of 78.39 for aqueous solution. For the PCM calculations carried out with the Gaussian03 suite of programs, we typically used the default settings, with radii from the United Atom Topological Model optimized at the HF/6–31G(d) level of theory (specified with RADII=UAHF), and the default scaling factor. All calculations were carried out with Gaussian03 or Gaussian98[32] series of programs.

We used the ideal gas at 1 atm as the reference state for the gas phase and 1 mol/L ideal solution with an infinitely dilute reference state for aqueous solution in all solvation energy calculations. Thus, we were calculating the free energy of transfer of a compound from the gas at 1 atm to 1 mol/L aqueous solution, ΔG_t. Solvation energies calculated by Gaussian are for transfer from the gas at 1 mol/L to aqueous solution at 1 mol/L, ΔG_s. The relationship for the solvation energy between the 1 atm standard state (e.g., energy of transfer, ΔG_t) and 1 mol/L standard state (ΔG_s) is

$$[1] \qquad \Delta G_t = \Delta G_s + RT\ln(\tilde{R}T)$$

where $\tilde{R} = 0.082053\ \mathrm{K}^{-1}$. At 298 K, $RT\ln(\tilde{R}T)$ equals 1.896 kcal/mol. All experimental data were converted to these reference states

Results

We began with a somewhat arbitrary set of polar molecules to use as a test set, strongly biased by the availability of experimental solvation free energies. This test set is given in Table 1; we recommend that this set of data or one similarly biased towards polar polyfunctional molecules be used for any test of solvation models. Figure 1 shows the performance of all methods which we examined on the test set of compounds. These results for various methods at two levels of theory for this test set of 54 compounds can be found in the Supplementary data (Tables S1 to S5). The SCIPCM method failed to converge for all compounds, so the number of points for this model is only 42; see Supplementary data (Table S6) for details. Table 2 gives a summary of the performance of the various models. The immediate conclusion is that none of the currently available methods is very good when challenged with difficult compounds. This is very unfortunate because it is for such difficult polar polyfunctional compounds that general computational methods are most needed. For simple monofunctional compounds, additivity methods are quite successful, and computationally very cheap. On reviewing the data and looking for classes of compounds which posed problems for each method, we could recognize the following problem classes: for IPCM and SCIPCM, amides, hydrogen bonding bases, and polyfluorinated compounds; for PCM and its relatives (CPCM, DPCM, IEFPCM), orthoesters, amides, SO compounds, and PO compounds. In some cases, there were members of the problem classes that were handled correctly, but each class of compounds was either all included or all excluded. These reduced sets of compounds are, not surprisingly, handled much better as also shown in Fig. 1. The numbers of compounds left in the data sets are IPCM, 42; PCM and its variants, 39; and SCIPCM, 31. In both cases, IPCM is the best method with a root-mean-square error (RMSE) of 1.79 for 54 compounds (full set), and 1.02 for 42 compounds (restricted set).

IPCM and SCIPCM do badly on any compounds where the experimental ΔG_s is positive (or where ΔG_t is more positive than +1.90 kcal/mol), such as hydrocarbons and polyfluoro compounds. Although adding the non-electrostatic contribution for such compounds, from a PCM calculation, improved these values, adding this contribution to all 54 compounds in the full set led to a poorer RMSE: this is documented for IPCM in the Supplementary data (Table S7). We prefer to work with ΔG_t, but Gaussian03 reports values leading naturally to ΔG_s, and the problem is that ΔG_s calculated by IPCM is never positive.

Since IPCM failed for fluorocarbons and hydrocarbons, we had to consider the possibility that part of the problem was the omission of any term for the cost of cavity formation. To see how general the problem was, we examined a number of hydrocarbons and found that IPCM does not lead to correct ΔG_s values for hydrocarbons. We carried out calculations on simple hydrocarbons of various sizes and also on cyclohexanone, chosen as a molecule with considerable hydrocarbon character, five CH_2s, and one polar group. The results, Supplementary data (Table S8), showed that calculated solvation free energies for hydrocarbons were in error by about 2 kcal/mol, but that ΔG_s for cyclohexanone was correctly calculated.

Since there seemed to be a problem for both IPCM and PCM with fluorocarbon compounds, we did a more extensive examination of halocarbons both by IPCM and PCM. The results, in Table S9, show that for brominated compounds, IPCM is somewhat better, RMSE = 1.19 vs. 2.62 for PCM; for chlorinated compounds, IPCM is good, RMSE = 0.54 and PCM is poor, RMSE = 3.65; and for fluorinated compounds, PCM is slightly better, RMSE = 2.89, than IPCM, RMSE = 3.36, though neither is very good. We examined plots of ΔG_{calc} vs. ΔG_{obs}, Fig. 2, and found that for both methods, solvation energies for fluorinated compounds are invariably more negative than they should be. For chlorinated compounds, the correlation was very bad for PCM, while IPCM gives a fairly good correlation. For brominated compounds and IPCM, the points were scattered about the line of perfect correlation, while with PCM, there is a strong tendency for ΔG_{calc} to be

too negative. It is noteworthy that PCM and IPCM show similar errors for fluorinated hydrocarbons; whatever the problem is for IPCM and these molecules, it is not just the absence of non-electrostatic contributions in IPCM, since PCM does poorly despite having such contributions.

Since it became clear that there were serious problems when PCM was used for polyhalogenated molecules, we investigated whether the problem might be inadequate parameterization in the standard UAHF model for the radii used to define the cavity. The UAHF parameterization for F, Cl, and

Fig. 1. Plots of ΔG_t^{calc} vs. ΔG_t^{exptl} for the various solvent models. First, with the full data set (except for SCIPCM for which some calculations failed to converge) and then with selected data sets, omitting compound classes which caused problems for particular methods. Full data set of 54 compounds: (a) IPCM; (b) SCIPCM (only 42 compounds); (c) PCM; (d) CPCM; (e) DPCM. Selected data sets: (f) IPCM, 42 compounds; (g) SCIPCM, 31 compounds; (h) PCM, 39 compounds; (i) CPCM, 39 compounds; (j) DPCM, 39 compounds. The lines are the lines of perfect correlation and lines displaced by one or two times the RMSE.

[d]Leaving out those classes of compounds for which the method fails.

Br was based on CH_3F, C_6H_5Cl, CH_3Cl, and CH_3Br.[1] Specifically, we treated the radius for a halogen atom as a linear function of the electron-withdrawing properties of groups in the rest of the molecule. The idea behind this was that electron-withdrawing substituents would cause the halogen atom to bear less partial negative charge and thus to contract. To make determining the parameters relatively simple, we used only compounds with only one halogen environment per molecule. For aromatic compounds, the Hammett σ values[33] for the substituents affecting a halogen were used. For aliphatic compounds, the Taft σ* values[33] for substituents on the carbon bearing the halogen were used. First, we adjusted the radius for the compounds with all halogens in the same environment to give a good fit to experimental values. Then, we did a linear fit of these radii to the sum of appropriate sigma values:

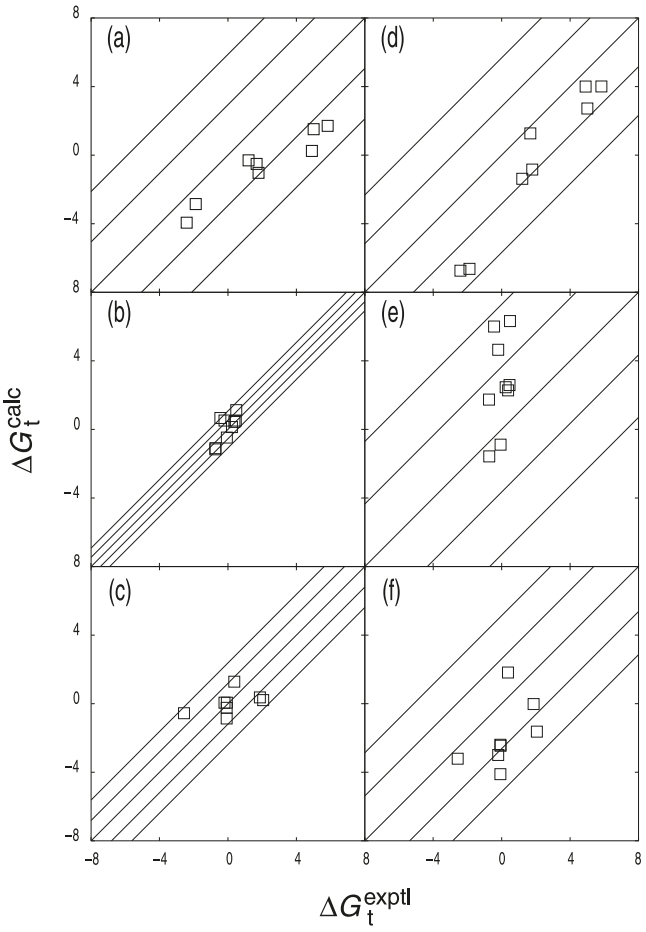
$$[2] \qquad \begin{cases} \mathbf{r} = \mathbf{r_0} + \mathbf{a}\sum\sigma \\ \mathbf{r} = \mathbf{r_0} + \mathbf{a}^*\sum\sigma^* \end{cases}$$

In this way, we determined the parameters in Table 3. Tables S10 and S11 and Fig. 3 show that with our refinement in the cavity definition, solvation energies for polyhalogenated compounds are calculated with much better accuracy than with the default radii. The procedure for a calculation with new radii is illustrated in the Supplementary data, Appendix 6.

It seems very likely that similar improvements could be achieved for other functional groups if one wished to take the time. The more important lesson is that methods such as PCM are totally dependent on the quality and appropriateness of the parameterization and will fail very badly for any compounds which do not match the parameterization in place.

Early in this work, we examined whether the use of a higher level of theory (larger basis set or MP2 in place of RHF or B3LYP) would lead to better results for some of the more difficult compounds: the results (Table S12) showed that this led at best to slight improvement and often to poorer results. A similar test on a few small molecules using MP4 in place of RHF or B3LYP led to similar conclusions; see Supplementary data in Table S13.

Fig. 2. Plots of ΔG_t^{calc} vs. ΔG_t^{exptl} for halogenated compounds, using IPCM and PCM. The lines are the lines of perfect correlation and lines displaced by one or two times the RMSE.



Having found that improved parameterization to incorporate a physically reasonable model dramatically improved the performance of PCM for halocarbons, we were led to ask if a modest parameterization would improve the performance of IPCM, which was already the best of the methods in Gaussian03, for the test set of compounds. The deficiencies, which we hoped to address, were the lack of any accounting for the cost of forming a cavity, the lack of any accounting for dispersion interactions, and the lack of any explicit accounting for hydrogen bonds (and particularly the covalent component of hydrogen bonds). To address these issues, we put in a constant term, a term in the molecular volume of the solute (taken as the final value reported during an IPCM calculation), and a term for the presence of a ring (these first three terms should allow for the cost of cavitation), terms for each kind of atom with a lone pair and each π-bonded feature (hoping that these terms would account for dispersion and hydrogen bonding with solvent as hydrogen donor), and a term for the presence of an acidic hydrogen (thus far limited to species containing OH). We had expected to need terms in the basicity or acidity of each hydrogen bonding group, but found that the pK_a of the relevant feature was only significant

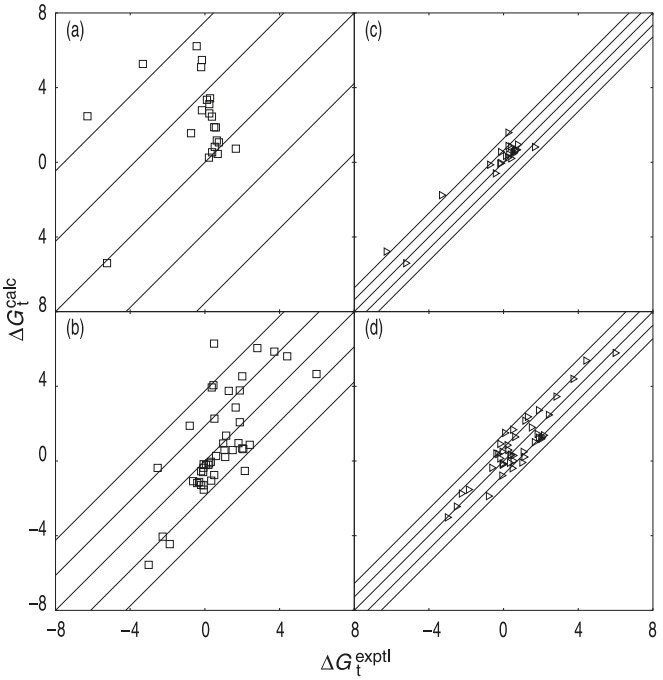
for amines; for hydroxyl compounds, the corresponding parameter was not defined by the data. This can be rationalized as a consequence of the dual nature of the hydroxyl group, functioning as both a hydrogen bond donor and acceptor. A change which increases acidity strengthens hydrogen-donor properties but weakens hydrogen-acceptor properties; these effects would be expected to cancel. For amines, only the hydrogen-bond-acceptor property matters, since NH is too weakly acidic to hydrogen bond significantly to water. In this simpler situation, electronic effects of substituents do matter. Some functional groups did not require terms (i.e., if such a term were included, the coefficient was not meaningfully determined by least squares); these were NO_2, CN, SO_2, and alkene. All are so weakly basic that they are unlikely to engage in hydrogen bonding to water. There was a meaningful contribution for the presence of a ring. Carboxylic acids could be treated as CO plus OH, and the OH parameter served for alcohols, phenols, and carboxylic acids. Carboxylate ester is not CO plus O; it could be treated as CO alone. This can be rationalized as a consequence of resonance delocalization making the ether oxygen of an ester much less polarizable or hydrogen-bondable, while similar resonance for a carboxylic acid increases the hydrogen-bonding ability of the OH in a way that compensates for the loss of basic properties of the hydroxyl oxygen. Amides with strong resonance delocalization show no sign of nitrogen basicity but have enhanced carbonyl oxygen basicity. Trimethyl phosphate was left in the set because it was found to be well-behaved if one treated the P(+)–O(–) as a carbonyl, and the phosphate ester oxygens as ethers (no p–π resonance). Dimethyl sulfoxide was the only sulfoxide for which we had data and would require special treatment (treat S(+)–O(–) as a carbonyl and the S as a thioether sulfur), so it was not included.

The parameters were evaluated by least-squares fitting to an augmented set of 241 compounds with numerous simple compounds added so that each parameter was based on at least 7 instances. After most of this work was completed,

Fig. 3. Plots of ΔG_t^{calc} vs. ΔG_t^{exptl} (kcal/mol) for halogenated compounds, using both the original and revised radii for halogen atoms and the PCM method. (□) original radii; (△) revised radii. (a) and (c) Aromatic compounds; (b) and (d) aliphatic compounds. The lines are the lines of perfect correlation and lines displaced by one or two times the RMSE.



we derived another set of solvation energies for polar compounds for use in a Blind Challenge. [34] The best defined values from this set were added to the data set as part of the 241 compounds. The data were fit to

$$[3] \qquad \Delta G_t^{obs} = \Delta G_t^{calc} + A_0 + \sum n_i A_i$$

where A_0 is a constant term, n_i is the number of times the ith structural feature appears, and A_i is the corresponding parameter. Least-squares fitting provided the parameters in Table 4. The n_i values for all 241 compounds are given in Table S14.

A few compounds posed problems and were deleted from an initial, larger, set. Although phenols and anilines required no special treatment in most cases, *p*-nitroaniline deviated severely. This was attributed to the increased polarizability of this highly delocalized molecule; this compound was deleted from the data set. A number of molecules did not converge with the isodensity parameter set at 0.0004; such compounds, often highly polarizable as for example 4-amino-4′-nitroazobenzene, were not used in fitting. At the moment, we do not know how to extend the IPCM solvation method to this class of highly polarizable compounds. 2,4-Dinitrophenol was the only example with an intramolecular hydrogen bond; it was described by [O] and not [OH] and was fitted satisfactorily with this description. With this parameterization, ultimately using 15 parameters (after trial parameters, which were not defined by the data had been deleted), the overall RMSE for 241 compounds was 0.81. The parameters are surprisingly close to being orthogonal; the only terms in the covariance matrix greater than 0.7 were

Table 4. Parameters for additive corrections to IPCM solvation energies.

Number	Parameter	Value for 241 compounds	Uncertainty

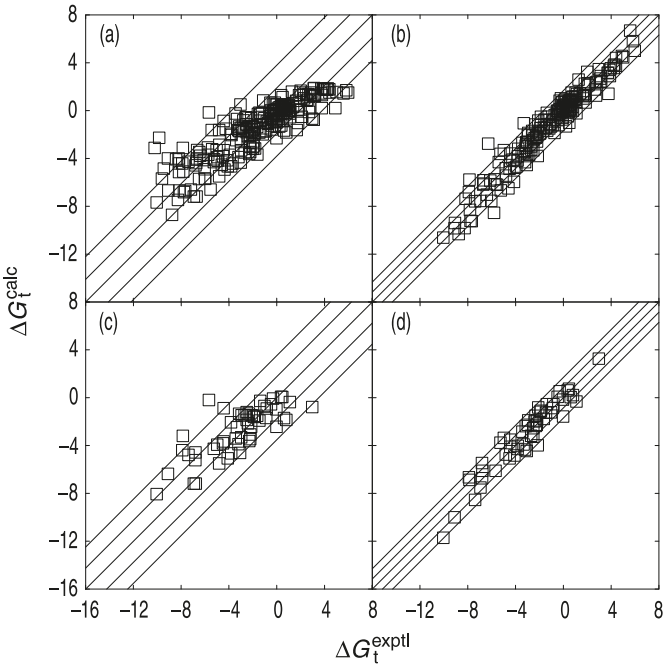
Fig. 4. Free energies of transfer calculated using IPCM solvation energies and energies corrected using the new parameters; results are shown for the large data set (241 compounds; (a) raw IPCM values, (b) parameters from the large data set); and the original test set (54 compounds; (c) raw IPCM values, (d) parameters from the large data set). The lines are the lines of perfect correlation and lines displaced by one or two times the RMSE.



for parameters 1 and 2 (constant and volume) and parameters 12 and 13 (N and pK_a of N). See Supplementary data, Table S14, for this set of compounds. The parameters are close to the ideal of being at the atomic rather than the group level, which leads to an inherently small number of possible parameters. The major exception is the amide parameter, which is specific to one functional group. Given a larger data set including more functional groups, it might be possible to derive a better and less specific description. That

one parameter does for all hydroxyl containing compounds (alcohols, phenols, and carboxylic acids) and two for all basic nitrogen compounds shows the general simplicity of the parameterization.

We also tested the various methods on the original test set of 54 compounds (using the parameter for [C=O ↔ C^+–O^-] for [P^+–O^-] and [S^+–O^-] in sulfinyl but not sulfonyl compounds (sulfonyl compounds are distinctly less basic and would not hydrogen bond)), and treating sulfinyl sulfur as a thioether. When this was done, we obtained the results shown in Fig. 4, and documented in Table S15; the RMSE value was 0.85. Figure 4 demonstrates that, with this parameterization, the results are distinctly better than the raw IPCM solvation energies. The role of the parameterization seems to be to correct small deficiencies in the IPCM model while the computational method does most of the work of calculating solvation free energy. With this new parameterization, IPCM is clearly the best of the methods currently available.

Summary and conclusions

Tests of solvation models must use a wide range of compounds to indicate how well they perform. IPCM is the best of the solvation methods in Gaussian03 as it stands, and with parameterization to compensate for its deficiencies, it becomes even better.

PCM and CPCM give rather similar results for the test set (RMSE = 2.13 and 2.09) and both are very good for classes of compounds falling within their parameterization. They are much poorer for compounds which do not. We illustrate this by showing that results for polyhalogenated compounds are dramatically improved by further parameterization of atomic radii for the halogens. The RMSE improved from 2.64 to 0.67 for 67 halogenated compounds with our new parameterization. Presumably, similar improvements could be obtained by additional parameterization for other groups.

A serious problem for users of continuum solvation methods is that PCM or CPCM give no warning when a compound contains structural features not covered by the parameterization, and then give unreliable results for such compounds. Users of these versions of the polarized continuum models in Gaussian must realize that they are all semiempirical and consequently their performance for a particular compound depends on whether all the structure features of that compound are well-described by the parameters of the method.

There is a great need for more experimental data to test computational methods for solvation energies and where necessary to allow parameterization. The problem is that where the need for data is greatest (polar functional groups, polyfunctional molecules containing such groups), the experiments are difficult.

While this paper was in press, we learned of an excellent computational solvation method based on IEF-PCM developed by Chuanjie Wu and Jay Ponder (personal communication from Prof. Ponder).

Hafnium–phosphinimide complexes

Osamah Alhomaidan, Gregory C. Welch, Guangcai Bai, and Douglas W. Stephan

Abstract: A series of phosphinimide complexes of Hf are prepared and characterized. Reaction of the phosphinimine *t*-Bu_3PNH with $Hf(NEt_2)_4$ gave (*t*-$Bu_3PN)Hf(NEt_2)_3$ (**1**) but this species was not readily converted to the corresponding $HfCl_3$-derivative. The reaction of 2 equiv. of *t*-Bu_3PNH with $Hf(NEt_2)_4$, however, gave (*t*-$Bu_3PN)_2Hf(NEt_2)_2$ (**2**), which was readily converted to (*t*-$Bu_3PN)_2HfCl_2$ (**3**) and (*t*-$Bu_3PN)_2HfMe_2$ (**4**). Employing *t*-Bu_3PNLi and $HfCl_4$ afforded (*t*-$Bu_3PN)_3HfCl$ (**5**) while reaction with $CpHfCl_3$ gave rise to ligand redistribution reactions affording (*t*-$Bu_3PN)_2HfCl_2$ and Cp_2HfCl_2. However, Cp(*t*-$Bu_3PN)_2HfCl$ (**7**) was prepared by treating (*t*-$Bu_3PN)_2HfCl_2$ with CpNa. The related species of Cp_2(*t*-$Bu_3PN)HfCl$ (**8**) was synthesized by the reaction of Cp_2HfCl_2 and *t*-Bu_3PNLi. Ligand redistribution was avoided in the reaction of Cp^*HfCl_3 as Cp^*(*t*-$Bu_3PN)HfCl_2$ (**9**) and Cp^*(*i*-$Pr_3PN)HfCl_2$ (**10**) were readily obtained and derivatized as Cp^*(*t*-$Bu_3PN)Hf(NMe_2)_2$ (**11**) and Cp^*(*t*-$Bu_3PN)HfMe_2$ (**12**), respectively. Similarly, $((Me_3Si)_2C_5H_3)$(*t*-$Bu_3PN)HfCl_2$ (**13**) was converted to $((Me_3Si)_2C_5H_3)$(*t*-$Bu_3PN)HfMe_2$ (**14**). Reactions with Lewis acid activators were used to prepare Cp^*(*t*-$Bu_3PN)HfMe(THF)MeB(C_6F_5)_3$ (**15**), (Cp^*(*t*-$Bu_3PN)HfMe)(B$(C_6F_5)_4$) (**16**), and (*t*-$Bu_3PN)_2Hf(H_2B(C_6F_5)_2)_2$ (**17**). Preliminary testing of **3**, **9**, and **13** in ethylene polymerization is reported. Compounds **3**, **4**, **7**, **9**, and **17** are characterized crystallographically.

Key words: hafnium, phosphinimide, ligand redistribution, cyclopentadienyl ligands, ethylene polymerization.

Résumé : On a préparé et caractérisé une série de complexes de Hf avec le phosphinimide. La réaction de la phosphinimine *t*-Bu_3PNH avec le $Hf(NEt_2)_4$ conduit à la formation du composé (*t*-$Bu_3PN)Hf(NEt_2)_3$ (**1**); toutefois, cette espèce ne se transforme pas facilement en dérivé $HfCl_3$ corrrespondant. Toutefois, la réaction de 2 equiv. de *t*-Bu_3PNH avec du $Hf(NEt_2)_4$ conduit à la formation de (*t*-$BuPN)_2Hf(NEt_2)_2$ (**2**) qu'on peut facilement transformer en (*t*-$Bu_3PN)_2HfCl_2$ (**3**) et en (*t*-$Bu_3PN)_2HfNe_2$ (**4**). L'utilisation de (*t*-BuPNLi) et de $HfCl_4$ conduit à la formation de (*t*-$Bu_3PN)_2HfCl$ (**5**) alors que la réaction avec du $CpHfCl_3$ conduit à une réaction de redistribution de ligand conduisant au (*t*-$Bu_3PN)_2HfCl_2$ et au Cp_2HfCl_2. Toutefois, on a pu préparer le Cp(*t*-$Bu_3PN)_2HfCl$ (**7**) par traitement du (*t*-$Bu_3PN)_2HfCl_2$ avec du CpNa. On a effectué la synthèse de l'espèce apparentée Cp_2(*t*-$Bu_3PN)HfCl$ (**8**) par réaction du Cp_2HfCl_2 avec le *t*-Bu_3PNLi. La réaction de redistribution des ligands a été évitée dans la réaction du Cp^*HfCl_3 et il a été possible d'obtenir facilement de Cp^*(*t*-$Bu_3PN)HfCl_2$ (**9**) et Cp^*(*t*-$BuPN)HfCl_2$ (**10**) et de les transformer en dérivés Cp^*(*t*-$Bu_3PN)Hf(NMe_2)_2$ (**11**) et Cp^*(*t*-$BuPN)Hf(NMe_2)_2$ (**12**) respectivement. De la même manière, on a pu transformer le produit $[(Me_3Si)_2C_5H_3]$(*t*-$Bu_3PN)HfCl_2$ (**13**) en $[(Me_3Si)_2C_5H_3]$(*t*-$Bu_3PN)HfCl_2Me_2$ (**14**). On a fait appel à des réactions avec des activateurs d'acide de Lewis pour préparer les produits Cp^*(*t*-BuPH)HgMe(THF)MeB$(C_6F_5)_3$ (**15**), (Cp^*(*t*-$Bu_3PN)HfMe)(B(C_6F_5)_4$) (**16**) et (*t*-$Bu_3PN)Hf(H_2B(C_6F_5)_2)_2$ (**17**). On rapporte les résultats préliminaires de l'évaluation des composés **3**, **9** et **13** dans des polymérisations de l'éthylène. Les structures des composés **3**, **4**, **7**, **9** et **17** ont été caractérisées par cristallographie.

Mots-clés : hafnium, phosphonimide, redistribution de ligand, ligands cyclopentadiényles, polymérisation de l'éthylène.

[Traduit par la Rédaction]

Introduction

The drive to discover new homogeneous catalysts for olefin polymerization has stimulated much research over the last 25 years. Several reviews have described such studies.[1–9] While synthetic routes to a large number of potential catalysts have been developed, only very few have been shown to operate effectively under commercial conditions.[10] One system that has indeed been commercialized is based on the early metal derivatives of a cyclopentadienyl-amide ligand,[11] affording the so-called "constrained geometry catalysts".[12–15] Another system that has drawn considerable recent attention is that based on the "FI" catalysts developed by researchers at the Mitsui Chemical Co.[7,16–20] During the last decade, we have studied olefin polymerization catalysts based on Ti-phosphinimide complexes and examined in detail the structure–activity relationship,[21–33] as well as the mechanisms of deactivation.[34–39] These systems yield highly active olefin polymerization catalysts[10,40] and indeed, some of these systems are also operative under commercially relevant conditions.[10,31,40]

While the majority of early metal catalysts have been derived from Ti or Zr complexes,[1–9] we have also probed the reactivity of V[41] and Cr[42] phosphinimide complexes. Derivatives of the third-row element Hf have drawn much less attention, presumably due to the high stability of Hf–C bonds.[43] Nonetheless, recent publications have described nonmetallocene Hf complexes, which are highly active for olefin polymerization. These systems incorporated bis(phenoxy-imine) ligands (Fig. 1*a*),[44–47] first introduced by Mitsui

researchers for the FI catalysts. In addition, researchers at Dow have described Hf systems based on the pyridyl-amido ligand depicted in Fig. 1*b*.[48–50] In this paper, we describe synthetic routes to a series of Hf–phosphinimide derivatives. The reactivity of these species with Lewis acid activators is considered and a preliminary evaluation of the polymerization activity is presented.

Experimental section

General considerations

All preparations were performed under an atmosphere of dry O_2-free N_2 employing either Schlenk-line techniques or a Vacuum Atmospheres inert atmosphere glovebox. Solvents were purified employing Grubbs-type column systems manufactured by Innovative Technologies or were distilled from the appropriate drying agents under N_2. ^1H and ^{13}C NMR spectra were recorded on Bruker Avance 300 and 500 spectrometers. Deuterated benzene, toluene, and methylene chloride were purchased from Cambridge Isotopes Laboratories, vacuum distilled from the appropriate drying agents, and freeze-pump-thaw degassed (three times). Trace amounts of protonated solvents were used as references, and ^1H and $^{13}C\{^1H\}$ NMR chemical shifts are reported relative to $SiMe_4$. $^{31}P\{^1H\}$, $^{11}B\{^1H\}$, and ^{19}F NMR spectra were referenced to external 85% H_3PO_4, $BF_3{\cdot}Et_2O$, and $CFCl_3$, respectively. Combustion analyses were performed at the University of Windsor Chemical Laboratories employing a PerkinElmer CHN Analyzer. High temperature gel permeation chromatography (GPC) data were provided by the technical staff at NOVA Chemicals Corporation. *t*-Bu_3PNLi[51] and $(Me_3SiC_5H_4)HfCl_3$[52] were prepared as previously reported.

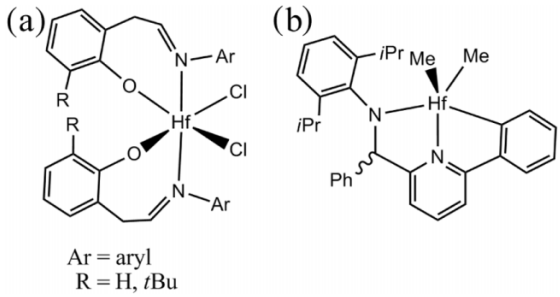
Synthesis of (*t*-Bu_3PN)$Hf(NEt_2)_3$ (1)

t-Bu_3PNH (0.46 g, 2.119 mmol) was dissolved in 5 mL of toluene and then added dropwise to a toluene solution (10 mL) containing $Hf(NEt_2)_4$ (1.0 g, 2.119 mmol) at room temperature. The light yellow solution was heated overnight at 70 °C. Toluene was removed under vacuum to give a crystalline white solid (1.27 g, 2.077 mmol, 96%). ^1H NMR (C_6D_6): 3.60 (q, ^3J = 7.3 Hz, 12H, NCH_2CH_3), 1.29 (t, ^3J = 7.3 Hz, 18H, NCH_2CH_3), 1.28 (d, $^3J_{PH}$ = 13.0 Hz, 27H, P-*t*-Bu). $^{13}C\{^1H\}$ NMR (C_6D_6): 44.3 (NCH_2CH_3), 40.4 (d, $^1J_{PC}$ = 48 Hz, P-*t*-*Bu*), 30.0 (P-*t*-Bu), 16.9 (NCH_2CH_3). ^{31}P NMR (C_6D_6): 38.5. Anal. calcd. for $C_{24}H_{57}N_4PHf$: C 47.16, H 9.40, N 9.17; found: C 46.88, H 9.24, N 9.59.

Synthesis of (*t*-$Bu_3PN)_2Hf(NEt_2)_2$ (2)

t-Bu_3PNH (0.93 g, 4.279 mmol) was dissolved in 5 mL of toluene and then added dropwise to toluene solution (10 mL) containing $Hf(NEt_2)_4$ (1.0 g, 2.119 mmol) at room temperature. The solution was refluxed for 12 h. Toluene was removed under vacuum to give an orange oil. It was dissolved in pentane (5 mL) and stirred for 10 min. Removing pentane under vacuum gave a colorless crystalline solid (1.55 g, 2.052 mmol, 96%). ^1H NMR (C_6D_6): 3.79 (q, ^3J = 7.3 Hz, 8H, NCH_2CH_3), 1.38 (d, $^3J_{PH}$ = 12.5 Hz, 54H, *t*-Bu), 1.36 (t, ^3J = 7.3 Hz, 12 H, NCH_2CH_3). $^{13}C\{^1H\}$ NMR (C_6D_6): 44.8 (NCH_2CH_3), 40.7 (d, $^1J_{PC}$ = 45 Hz, P-*t*-*Bu*), 30.4 (P-*t*-Bu), 16.9 (NCH_2CH_3). ^{31}P NMR (C_6D_6): 35.8.

Fig. 1. Recent examples of Hf olefin-polymerization catalysts.



Anal. calcd. for $C_{32}H_{74}N_4P_2Hf$: C 50.88, H 9.87, N 7.42; found: C 50.73, H 10.13, N 6.99.

Synthesis of (*t*-$Bu_3PN)_2HfCl_2$ (3)

Compound **2** (1.00 g, 1.323 mmol) was dissolved in 10 mL of toluene. Me_3SiCl (1.40 mL, 10.590 mmol) was added dropwise to the clear solution at room temperature. A white solid started forming in a few minutes. It was stirred for 8 h and the volatiles removed under vacuum. The white solid was washed with hexanes (5 mL) and then dried under vacuum (0.85 g, 1.257 mmol, 95%). ^1H NMR (C_6D_6): 1.28 (d, $^3J_{PH}$ = 10.0 Hz, 54H, P-*t*-Bu). $^{13}C\{^1H\}$ NMR (C_6D_6): 41.0 (d, $^1J_{PC}$ = 48 Hz, P-*t*-*Bu*), 30.0 (P-*t*-Bu). ^{31}P NMR (C_6D_6): 41.3. Anal. calcd. for $C_{24}H_{54}N_2P_2HfCl_2$: C 42.26, H 7.98, N 4.11; found: C 42.68, H 8.11, N 4.28.

Synthesis of (*t*-$Bu_3PN)_2HfMe_2$ (4)

Compound **3** (0.10 g, 0.147 mmol) was dissolved in 10 mL of diethyl ether. MeMgBr (3 mol/L, 0.19 mL; 0.588 mmol) was added dropwise at room temperature. The solution was stirred overnight and then pumped to dryness. The product was extracted with hot hexanes (10 mL) and then filtered through celite. Removing hexanes under vacuum gave a white solid (0.09 g, 0.145 mmol, 93%). ^1H NMR (C_6D_6): 1.33 (d, $^3J_{PH}$ = 10.5 Hz, 54H, P-*t*-Bu), 0.42 (s, 6H, $HfMe_2$). $^{13}C\{^1H\}$ NMR (C_6D_6): 41.6 ($HfMe_2$), 40.7 (d, $^1J_{PC}$ = 45 Hz, P-*t*-Bu), 30.1 (P-*t*-Bu). ^{31}P NMR (C_6D_6): 37.2. Anal. calcd. for $C_{26}H_{60}N_2P_2Hf$: C 48.70, H 9.43, N 4.37; found: C 48.54, H 9.79, N 4.28.

Synthesis of (*t*-$Bu_3PN)_3HfCl$ (5)

$HfCl_4$ (0.50 g, 1.561 mmol) was suspended in 5 mL of THF. *t*-Bu_3PNLi (1.05 g, 4.685 mmol) in 5 mL of THF was added quickly at room temperature. The suspension became clear within 30 min. It was stirred for another 8 h and the volatiles removed under vacuum. The product was dissolved in 15 mL of toluene and then filtered through celite. The solution was concentrated to ca. 3 mL and then stored in a freezer at −35 °C for 48 h. A white solid precipitated, which was isolated and dried under vacuum (0.83 g, 0.961 mmol, 62%). ^1H NMR (C_6D_6): 1.44 (d, $^3J_{PH}$ = 12.0 Hz, 81H, P-*t*-Bu). $^{13}C\{^1H\}$ NMR (C_6D_6): 41.1 (d, $^1J_{PC}$ = 45 Hz, P-*t*-Bu), 30.7 (P-*t*-Bu). ^{31}P NMR (C_6D_6): 36.0. Anal. calcd. for $C_{36}H_{81}N_3P_3HfCl$: C 50.11, H 9.46, N 4.87; found: C 50.13, H 9.71, N 4.95.

Synthesis of (*t*-$Bu_3PN)_3HfMe$ (6)

Compound **5** (0.20 g, 0.231 mmol) was dissolved in 5 mL of diethyl ether. MeMgBr (3 mol/L, 0.23 mL, 0.693 mmol)

was added dropwise at room temperature. The solution was stirred for 4 h and the volatiles removed under vacuum. The product was extracted with hexanes (2 × 5 mL) and then filtered through celite. Removing hexanes under vacuum gave a white solid (0.17 g, 0.201 mmol, 87%). ^{1}H NMR (C_6D_6): 1.44 (d, $^3J_{PH}$ = 12.0 Hz, 81H, P-*t*-Bu), 0.36 (s, 3H, HfMe). ^{13}C{^{1}H} NMR (C_6D_6): 41.0 (d, $^1J_{PC}$ = 45 Hz, P-*t-Bu*), 30.7 (P-*t*-Bu), 29.1 (HfMe). ^{31}P NMR (C_6D_6): 34.1. Anal. calcd. for $C_{37}H_{84}N_3P_3HfCl$: C 52.75, H 10.05, N 4.99; found: C 52.63, H 9.99, N 4.95.

Synthesis of Cp(*t*-Bu$_3$PN)$_2$HfCl (7)

Compound **3** (0.13 g, 0.191 mmol) was dissolved in 5 mL of THF. Solid CpNa (16.78 mg, 0.191 mmol) was added to the above at −35 °C. The solution was stirred at room temperature for 8 h and the volatiles removed under vacuum. The product was dissolved in 7 mL of toluene and then filtered through celite. Toluene was removed under vacuum to give a white solid (0.13 g, 0.183 mmol, 95%). ^{1}H NMR (C_6D_6): 6.57 (s, 5H, Cp), 1.31 (d, $^3J_{PH}$ = 12.5 Hz, 54H, P-*t*-Bu). ^{13}C{^{1}H} NMR (C_6D_6): 110.7 (Cp), 41.1 (d, $^1J_{PC}$ = 48 Hz, P-*t*-Bu), 30.4 (P-*t*-Bu). ^{31}P NMR (C_6D_6): 37.4. Anal. calcd. for $C_{29}H_{59}N_2P_2HfCl$: C 48.94, H 8.36, N 3.94; found: C 48.86, H 8.61, N 3.71.

Synthesis of Cp$_2$(*t*-Bu$_3$PN)HfCl (8)

Cp_2HfCl_2 (0.85 g, 2.24 mmol) was dissolved in 10 mL of THF. Solid *t*-Bu$_3$PNLi (0.50 g, 2.24 mmol) was added in portions at room temperature. The cloudy solution was stirred for 24 h and then pumped to dryness. The product was dissolved in 10 mL of toluene and then filtered through celite. The solution was concentrated to ~5 mL and then stored in a freezer at −35 °C for 48 h. A pale yellow solid precipitated, which was isolated and dried under vacuum (0.97 g, 1.73 mmol, 77%). ^{1}H NMR (C_6D_6): 6.15 (s, 10H, Cp), 1.18 (d, $^3J_{PH}$ = 12.5 Hz, 27H, P-*t*-Bu). ^{13}C{^{1}H} NMR (C_6D_6): 111.9 (s, Cp), 41.3 (d, $^1J_{PC}$ = 45 Hz, P-*t*-Bu), 30.3 (s, P-*t*-Bu). ^{31}P{^{1}H} NMR (C_6D_6): 40.8. Anal. calcd. for $C_{22}H_{37}NPHfCl$: C 47.15, H 6.65, N 2.50; found: C 46.90, H 6.30, N 2.23.

Synthesis of Cp*(*t*-Bu$_3$PN)HfCl$_2$ (9)

Cp*$HfCl_3$ (1.09 g, 2.595 mmol) was suspended in 10 mL of toluene. Solid *t*-Bu$_3$PNLi (0.58 g, 2.597 mmol) was added in portions at room temperature. The cloudy solution was stirred for 24 h and then filtered through celite. The solution was concentrated to ~5 mL and then stored in a freezer at −35 °C for 48 h. A white solid precipitated, which was isolated, washed with pentane, and then dried under vacuum (1.30 g, 2.163 mmol, 83%). ^{1}H NMR (C_6D_6): 2.19 (s, 15H, Cp*), 1.21 (d, $^3J_{PH}$ = 12.5 Hz, 27H, P-*t*-Bu). ^{13}C{^{1}H} NMR (C_6D_6): 121.0 (*Cp**), 41.3 (d, $^1J_{PC}$ = 45 Hz, P-*t-Bu*), 30.0 (P-*t*-Bu), 12.3 (Cp*). ^{31}P NMR (C_6D_6): 46.3. Anal. calcd. for $C_{22}H_{42}NPHfCl_2$: C 43.97, H 7.04, N 2.33; found: C 44.08, H 7.07, N 2.34.

Synthesis of Cp*(*i*-Pr$_3$PN)HfCl$_2$ (10)

Cp*$HfCl_3$ (0.11, 0.262 mmol) was suspended in 3 mL of toluene. Solid *i*-Pr$_3$PNLi (0.05 g, 0.276 mmol) was added in portions at room temperature. The cloudy solution was stirred overnight and then filtered through celite. Toluene was removed under vacuum to give a white solid (94 mg, 0.168 mmol, 64%). ^{1}H NMR (C_6D_6): 2.19 (s, 15H, Cp*), 1.64 (m, 3H, PC*H*), 0.95 (dd, $^3J_{PH}$ = 14.0 Hz, ^3J = 7.0 Hz, 18H, *i*-Pr). ^{13}C{^{1}H} NMR (C_6D_6): 120.9 (Cp*), 26.9 (d, $^1J_{PC}$ = 58 Hz, P*C*H), 17.3 (P-*i*-Pr), 12.3 (Cp*). ^{31}P NMR (C_6D_6): 35.3. Anal. calcd. for $C_{19}H_{36}NPHfCl_2$: C 40.83, H 6.49, N 2.51; found: C 41.22, H 6.64, N 2.48.

Synthesis of Cp*(*t*-Bu$_3$PN)Hf(NMe$_2$)$_2$ (11)

Compound **9** (100 mg, 0.166 mmol) was dissolved in 3 mL of THF. Me_2NLi (50 mg, 0.980 mmol) was dissolved in 3 mL of THF and then added dropwise to the above solution at room temperature. The solution was stirred for 36 h and the volatiles removed under vacuum. The product was extracted with hexanes (10 mL) and then filtered through celite. Hexanes were removed under vacuum to give a crystalline solid (91 mg, 0.147 mmol, 88%). ^{1}H NMR (C_6D_6): 3.10 (s, 12H, NMe_2), 2.19 (s, 15H, Cp*), 1.28 (d, $^3J_{PH}$ = 12.0 Hz, 27H, P-*t*-Bu). ^{13}C{^{1}H} NMR (C_6D_6): 116.9 (*Cp**), 46.4 (NMe_2), 40.3 (d, $^1J_{PC}$ = 45 Hz, P-*t-Bu*), 30.1 (P-*t*-Bu), 12.1 (Cp*). ^{31}P NMR (C_6D_6): 38.1. Anal. calcd. for $C_{26}H_{54}N_3PHf$: C 50.51, H 8.80, N 6.80; found: C 50.28, H 8.54, N 6.64.

Synthesis of Cp*(*t*-Bu$_3$PN)HfMe$_2$ (12)

Compound **9** (0.71 g, 1.181 mmol) was suspended in 8 mL of diethylether. MeMgBr (3 mol/L, 1.97 mL, 5.905 mmol) was added dropwise at room temperature. The cloudy solution was stirred for 12 h and the volatiles removed under vacuum. The product was extracted with hot hexanes (2 × 8 mL) and then filtered through celite. Removing hexanes under vacuum gave a white solid (0.62 g, 1.107 mmol, 95%). ^{1}H NMR (C_6D_6): 2.11 (s, 15H, Cp*), 1.24 (d, $^3J_{PH}$ = 11.0 Hz, 27H, P-*t*-Bu), −0.03 (s, 6H, $HfMe_2$). ^{13}C{^{1}H} NMR (C_6D_6): 116.5 (*Cp**), 41.7 ($HfMe_2$), 41.0 (d, $^1J_{PC}$ = 45 Hz, P-*t-Bu*), 30.1 (P-*t*-Bu), 11.9 (Cp*). ^{31}P NMR (C_6D_6): 40.3. Anal. calcd. for $C_{24}H_{48}HfNP$: C 51.46, H 8.64, N 2.50; found: C 51.07, H 8.59, N 2.43.

Synthesis of (Me$_3$Si)$_2$Cp(*t*-Bu$_3$PN)HfCl$_2$ (13)

$(Me_3Si)_2CpHfCl_3$ (0.10 g, 0.202 mmol) was dissolved in 5 mL of toluene. Solid *t*-Bu$_3$PNLi (0.45 g, 0.202 mmol) was added to the above at room temperature. The clear solution was stirred at room temperature for a week upon which it became cloudy and the volatiles removed under vacuum. The product was extracted with hot hexanes (5 mL) and then filtered through celite. Hexanes were removed to give a colorless oil, which solidified on standing for a few hours as a white material (0.08 g, 0.118 mmol, 59%). ^{1}H NMR (C_6D_6): 7.01 (t, ^4J = 2.1 Hz, 1H, H2 of Cp″), 6.81 (d, ^4J = 2.1 Hz, 2H, H3 and H4 of Cp″), 1.17 (d, $^3J_{PH}$ = 13.0 Hz, 27H, P-*t*-Bu), 0.46 (s, 18H, $SiMe_3$). ^{13}C{^{1}H} NMR (C_6D_6): C1, C2, and C3 of Cp″ not seen, 120.9 (C4 and C5 of Cp″), 41.4 (d, $^1J_{PC}$ = 45 Hz, P-*t-Bu*), 30.0 (P-*t*-Bu), 0.73 ($SiMe_3$). ^{31}P NMR (C_6D_6): 45.0. Anal. calcd. for $C_{23}H_{48}NPSi_2HfCl_2$: C 40.91, H 7.17, N 2.07; found: C 40.59, H 7.06, N 1.94.

Synthesis of (Me$_3$Si)$_2$Cp(*t*-Bu$_3$PN)HfMe$_2$ (14)

Compound **13** (0.15 g, 0.222 mmol) was dissolved in 3 mL of diethylether. MeMgBr (3 mol/L, 0.37 mL,

1.110 mmol) was added dropwise at room temperature. The solution was stirred for 8 h and the volatiles removed under vacuum. The product was extracted with hexanes (5 mL) and then filtered through celite. Hexanes were removed to give a crystalline white solid (0.12 g, 0.189 mmol, 86%). ^{1}H NMR (C_6D_6): 6.75 (t, ^4J = 1.6 Hz, 1H, H2 of Cp″), 6.54 (d, ^4J = 1.6 Hz, 2H, H3 and H4 of Cp″), 1.22 (d, $^3J_{PH}$ = 12.5 Hz, 27H, P-*t*-Bu), 0.38 (s, 18H, $SiMe_3$), 16 (s, 6H, $HfMe_2$). $^{13}C\{^1H\}$ NMR (C_6D_6): 125.2 (C1 and C3 of Cp″), 123.4 (C2 of Cp″), 41.1 (d, $^1J_{PC}$ = 47 Hz, P-*t-Bu*), 39.9 ($HfMe_2$), 30.1 (P-*t*-Bu), 1.0 ($SiMe_3$). ^{31}P NMR (C_6D_6): 39.8 Anal. calcd. for $C_{25}H_{54}NPSi_2Hf$: C 42.58, H 7.72, N 1.99; found: C 42.50, H 7.60, N 1.93.

Synthesis of Cp*(*t*-Bu$_3$PN)HfMe(THF)MeB(C$_6$F$_5$)$_3$ (15)

Compound **12** (50 mg, 0.089 mmol) was dissolved in 2 mL of CH_2Cl_2 containing 72 µL of THF (10 equiv.). $B(C_6F_5)_3$ (45 mg, 0.088 mmol) was dissolved in 2 mL of CH_2Cl_2 and then added dropwise to the above solution at room temperature. The colorless solution was stirred for 30 min and then pumped to dryness to give a white solid, washed with pentane (3 mL), and then dried under vacuum (91 mg, 0.079 mmol, 89%). ^{1}H NMR (CD_2Cl_2): 4.13 (br, 4H, OCH_2CH_2), 2.11 (s, 15H, Cp*), 2.03 (br, 4H, OCH_2CH_2), 1.39 (d, $^3J_{PH}$ = 13.5 Hz, 27H, P-*t*-Bu), 0.47 (br s, 3H, $MeB(C_6F_5)_3$), 0.27 (s, 3H, HfMe). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): 149.0 (dm, $^1J_{CF}$ = 225 Hz, *o*-C_6F_5), 138.1 (dm, $^1J_{CF}$ = 240 Hz, *p*-C_6F_5), 137.1 (dm, $^1J_{CF}$ = 240 Hz, *m*-C_6F_5), 121.9 (*Cp**), 121.9 (*Cp**), 75.9 (OCH_2CH_2), 41.1 (d, $^1J_{PC}$ = 46 Hz, P-*t-Bu*), 29.8 (P-*t*-Bu), 29.1 (HfMe), 26.0 (OCH_2CH_2), 11.7 (Cp*), 11.0 (br, $CH_3B(C_6F_5)_3$). ^{19}F NMR (CD_2Cl_2, 282 MHz): −133.59 (d, $^3J_{FF}$ = 22 Hz, 6F, *o*-F), −165.71 (t, $^3J_{FF}$ = 20 Hz, 3F, *p*-F), −168.25 (m, 6F, *m*-F). ^{31}P NMR (CD_2Cl_2): 51.3. ^{11}B NMR (CD_2Cl_2, 96 MHz): −14.9. The extreme air sensitivity of this species precluded satisfactory elemental analysis.

Synthesis of (Cp*(*t*-Bu$_3$PN)HfMe)(B(C$_6$F$_5$)$_4$) (16)

Compound **12** (50 mg, 0.09 mmol) and $(Ph_3C)(B(C_6F_5)_4)$ (82 mg, 0.09 mmol) were dissolved in 2 mL of CH_2Cl_2 in two separate vials. The borate solution was added dropwise to the other at −35 °C. The clear yellow solution was stirred for 15 min and the volatiles removed under vacuum to give an orange foam. It was washed with benzene (3 × 3 mL) and then dried under vacuum for 12 h. ^{1}H NMR (CD_2Cl_2): 2.07 (s, 15H, Cp*), 1.40 (d, $^3J_{PH}$ = 13.0 Hz, 27H, *t*-Bu), 0.03 (s, HfMe). $^{13}C\{^1H\}$ NMR (CD_2Cl_2): 148.7 (d, $^1J_{CF}$ = 240 Hz, *o*-C_6F_5), 138.8 (dm, $^1J_{CF}$ = 240 Hz, *p*-C_6F_5), 136.9 (d, $^1J_{CF}$ = 247 Hz, *m*-C_6F_5), 120.1 (s, *Cp**), 41.8 (s, HfMe), 41.5 (d, $^1J_{PC}$ = 45 Hz, *t*-Bu), 30.0 (s, *t*-Bu), 11.7 (s, $C_5(CH_3)_5$). ^{19}F NMR (CD_2Cl_2): −133.5 (s, 8F, *o*-F), −164.1 (t, $^3J_{FF}$ = 20 Hz, 4F, *p*-F), −168.0 (m, 8F, *m*-F). ^{31}P NMR (CD_2Cl_2): 48.2. ^{11}B NMR (CD_2Cl_2, 96 MHz): −16.9. The extreme air sensitivity of this species precluded satisfactory elemental analysis.

Synthesis of (*t*-Bu$_3$PN)$_2$Hf(H$_2$B(C$_6$F$_5$)$_2$)$_2$ (17)

Compound **4** (15 mg, 0.023 mmol) and $HB(C_6F_5)_2$ (33 mg, 0.093 mmol) were combined in a small vial containing 1 mL of benzene. The vial was capped and sonicated for 10 min at room temperature. The cloudy solution was heated at 50 °C for 30 min until it became clear. The product precipitated as colorless crystals on cooling to room temperature. The solvent was removed under vacuum to give a white solid. The solid was washed thoroughly with hexanes (5 × 2 mL) to remove $MeB(C_6F_5)_2$ and side products and then dried under vacuum (25 mg, 0.019 mmol, 83%). ^{1}H NMR (C_6D_6): 4.67 (br q, µ-H, J_{HB} = 65 Hz, 4H), 0.92 (d, $^3J_{PH}$ = 10 Hz, 54H, *t*-Bu). $^{13}C\{^1H\}$ NMR (C_6D_6): 148.3 (d, $^1J_{CF}$ = 241 Hz, *o*-C_6F_5), 139.5 (dm, $^1J_{CF}$ = 250 Hz, *p*-C_6F_5), 138.1 (d, $^1J_{CF}$ = 245 Hz, *m*-C_6F_5), 40.2 (d, $^1J_{PC}$ = 45 Hz, *t*-Bu), 29.2 (s, *t*-Bu). ^{19}F NMR (C_6D_6): −130.7 (s, 8F, *o*-F), −157.8 (t, $^3J_{FF}$ = 28 Hz, 4F, *p*-

F), −163.9 (m, 8F, *m*-F). ^{31}P NMR (C_6D_6): 47.2. ^{11}B NMR (C_6D_6): −15.0 (t, J_{BH} = 65 Hz). Anal. calcd. for $C_{48}H_{58}B_2F_{20}N_2P_2Hf$: C 44.18, H 4.48, N 2.15; found: C 44.09, H 4.33, N 2.03.

X-ray data collection and reduction

Crystals were manipulated and mounted in capillaries in a glovebox, thus maintaining a dry, O_2-free environment for each crystal. Diffraction experiments were performed on a Siemens SMART System CCD diffractometer. The data ($4.5^\circ < 2\theta < 45^\circ - 50.0^\circ$) were collected in a hemisphere of data in 1329 frames with 10 s exposure times. The observed extinctions were consistent with the space groups in each case. A measure of decay was obtained by recollecting the first 50 frames of each data set. The intensities of reflections within these frames showed no statistically significant change over the duration of the data collections. The data were processed using the SAINT and SHELXTL processing packages. An empirical absorption correction based on redundant data was applied to each data set. Subsequent solution and refinement was performed using the SHELXTL solution package.

Structure solution and refinement

Non-hydrogen atomic scattering factors were taken from the literature tabulations.[53] The heavy atom positions were determined using direct methods employing the SHELXTL direct methods routine. The remaining non-hydrogen atoms were located from successive difference Fourier map calculations. The refinements were carried out by using full-matrix least-squares techniques on F, minimizing the function $\omega(F_o - F_c)^2$ where the weight, ω, is defined as $4F_o^2/2\sigma(F_o^2)$ and F_o and F_c are the observed and calculated structure factor amplitudes, respectively. In the final cycles of each refinement, all non-hydrogen atoms were assigned anisotropic temperature factors in the absence of disorder or insufficient data. In the latter cases, atoms were treated isotropically. C−H atom positions were calculated and allowed to ride on the carbon to which they are bonded assuming a C−H bond length of 0.95 Å. H-atom temperature factors were fixed at 1.10 times the isotropic temperature factor of the C-atom to which they are bonded. The H-atom contributions were calculated, but not refined. The locations of the largest peaks in the final difference Fourier map calculation as well as the magnitude of the residual electron densities in each case were of no chemical significance. Additional details are provided in the Supplementary data.

Polymerization protocol

For comparable results, routine standards were run regularly to ensure reproducibility. The polymerizations were performed in a 1 L Buchi reactor system. Following assembly, the reactor vessel and solvent storage unit were refilled with nitrogen via four refill and evacuation cycles over at least 90 min. Approximately 600 mL of toluene was transferred to the solvent storage container from the purification column. The solvent was purged with dry nitrogen for 20 min and then transferred to the reactor vessel by differential pressure. The solvent was stirred at 1500 ± 5 rpm and the temperature was kept constant at 30 ± 2 °C. The system was then exposed to ethylene via five vent and refill cycles. The precatalyst, cocatalyst, and scrubber stock solutions were freshly prepared and loaded into syringes in a glovebox, then transferred to the reactor immediately before injection to limit the possibility of catalyst decomposition. A prepared solution of TiBAl (3.0 mL) was injected into the reaction vessel through the catalyst injection inlet and allowed to stir for 5 min. The prepared precatalyst solution (1.0 mL) was injected, followed immediately with the injection of the $B(C_6F_5)_3$ solution (1.5 mL) into the reactor vessel. The mixture was stirred at 1500 ± 5 rpm at 30 °C under 2 atm (1 atm = 101.325 kPa) of dynamic ethylene flow for 10 min. The temperature and ethylene flow rate were recorded manually at regular intervals. After 5−10 min, the polymerization was stopped by closing the ethylene inlet valve and venting the reactor, the stirring was stopped, and the reactor was disassembled. The contents of the reactor were emptied into a 4 L beaker containing approximately 100 mL of 10% HCl (*v*/*v*) in MeOH. The precipitated polymer was collected by filtration, washed with toluene and acetone, and dried overnight. The resulting polymer was weighed and polymerization activity calculated.

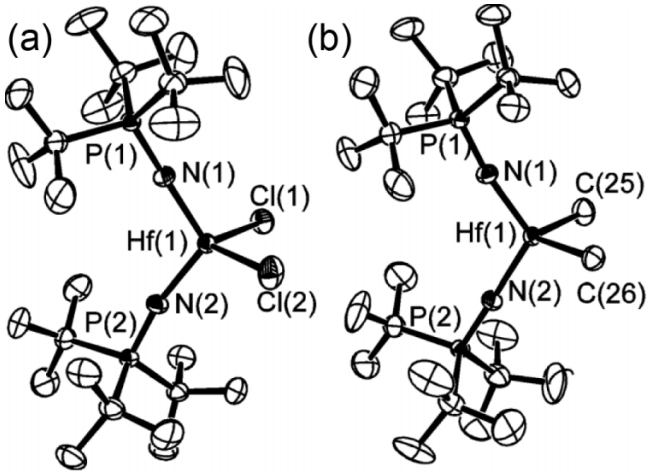
Results and discussion

The dehalosilylation reaction of silyl-phosphinimides and a titanium halide proved to be a simple and successful method for the preparation of titanium-phosphinimide complexes. However, this method does not work well for zirconium.[54] Previously, several phosphinimide complexes of Zr and Hf have been prepared at high temperature using an equimolar amount of KF to remove a N-silyl substituent as the by-product Me_3SiF.[54,55] However, the most convenient route to Zr compounds involves either salt metathesis (LiCl) or alkane or amine elimination. Thus, using these latter methods we targeted Hf−phosphinimide complexes.

The parent phosphinimine, *t*-Bu_3PNH, was reacted stoichiometrically with $Hf(NEt_2)_4$ to afford (*t*-Bu_3PN)$Hf(NEt_2)_3$ (**1**) in 96% yield (Scheme 1). Subsequent treatment of **1** with excess Me_3SiCl in an effort to affect amide cleavage and prepare (*t*-Bu_3PN)$HfCl_3$ proved to be problematic. Based on spectroscopic data it appeared Me_3SiCl effects nonselective Hf−N bond cleavage.

Similarly, reaction of *t*-Bu_3PNH with $Hf(NEt_2)_4$ in a 2:1 ratio afforded the species (*t*-$Bu_3PN)_2Hf(NEt_2)_2$ (**2**) in 96% yield. In contrast to the above species, **2** reacts cleanly at room temperature with excess Me_3SiCl to give (*t*-$Bu_3PN)_2HfCl_2$ (**3**). This compound showed a singlet at 41.3 ppm and a doublet at 1.28 ppm in the ^{31}P NMR and ^{1}H

Fig. 2. ORTEP drawings of (a) **3** and (b) **4**; 20% thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity. Selected bond distances (Å) and angles (°): **3**: Hf(1)—N(2) 1.922(3), Hf(1)—N(1) 1.927(3), Hf(1)—Cl(1) 2.3855(13), Hf(1)—Cl(2) 2.3856(14), P(1)—N(1) 1.569(3), P(2)—N(2) 1.570(4); N(2)−Hf(1)−N(1) 111.22(15), N(2)−Hf(1)−Cl(1) 109.81(12), N(1)−Hf(1)−Cl(1) 108.87(12), N(2)−Hf(1)−Cl(2) 109.70(12), N(1)−Hf(1)−Cl(2) 109.89(12). Cl(1)−Hf(1)−Cl(2) 107.27(6), P(1)−N(1)−Hf(1) 175.0(3), P(2)−N(2)−Hf(1) 168.3(2); **4**: Hf(1)—N(2) 1.946(3), Hf(1)—N(1) 1.948(3), Hf(1)—C(26) 2.237(4), Hf(1)—C(25) 2.251(5), N(1)—P(1) 1.554(3), N(2)—P(2) 1.555(3); N(2)−Hf(1)−N(1) 114.92(13), N(2)−Hf(1)−C(26) 108.74(15), N(1)−Hf(1)−C(26) 110.11(15), N(2)−Hf(1)−C(25) 109.69(17), N(1)−Hf(1)−C(25) 109.06(18), C(26)−Hf(1)−C(25) 103.73(17), P(1)−N(1)−Hf(1) 170.8(2), P(2)−N(2)−Hf(1) 175.7(2).



NMR spectra, respectively. The pseudotetrahedral arrangement around Hf was confirmed by X-ray crystallography (Fig. 2*a*). The Hf−N distances were found to be 1.922(3) Å and 1.927(3) Å and the Hf−Cl distances were 2.3855(13) Å and 2.3856(14) Å. The P−N−Hf angles (175.0(3)° and 168.3(2) °) are approximately linear and typical of early metal phosphinimide complexes.[54,56] This geometry suggests the presence of some degree of multiple bonding character in the Hf−N bond.

Compound **3** was subsequently alkylated with MeMgBr to give (t-$Bu_3PN)_2HfMe_2$ (**4**) as a white solid in 93% yield. An upfield shift in ^{31}P NMR at 37.2 ppm is consistent with the presence of electron donating methyl substituents. The structure of **4**, determined by X-ray crystallography (Fig. 2*b*), was similar to **3**, although the Hf−N bonds were longer at 1.946(3) and 1.948(3) Å. In addition, the P−N bonds (1.554(3) and 1.555(3) Å) were shorter, a consequence of the more electron-rich Hf.

It has been previously shown that efforts to prepare Zr analogs of **3** and **4** employing (t-Bu_3PNLi) and $ZrCl_4$ were unsuccessful as the tris ligand complexes, (t-$Bu_3PN)_3ZrCl$, were preferentially formed.[36] In a similar fashion, reactions of the lithium phosphinimide with $HfCl_4$ in a 1:1 ratio did not give (t-$Bu_3PN)HfCl_3$. Instead, a product mixture was evidenced by ^{31}P NMR spectroscopy. However, by employing a 3:1 ratio of reagents the phosphinimide compound (t-$Bu_3PN)_3HfCl$ (**5**) was prepared and isolated in 62% yield. The structure of this white product (**5**) was also confirmed crystallographically (Fig. 3). The Hf−N bonds in

Scheme 2. Synthetic routes to **5** and **6**.

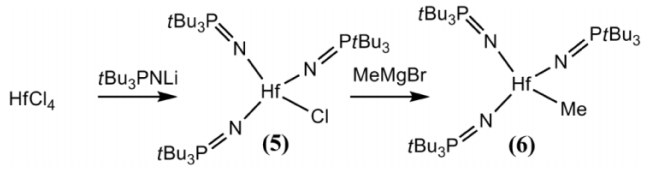


Fig. 3. ORTEP drawing of **5**; 20% thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity. Selected bond distances (Å) and angles (°): Hf(1)—N(3) 1.969(3), Hf(1)—N(2) 1.971(3), Hf(1)—N(1) 1.983(3), Hf(1)—Cl(1) 2.4272(13), P(1)—N(1) 1.551(4), P(2)—N(2) 1.557(3), P(3)—N(3) 1.561(3); N(3)−Hf(1)−N(2) 111.16(16), N(3)−Hf(1)−N(1) 112.93(16), N(2)−Hf(1)−N(1) 110.95(15), Hf(1)−Cl(1) 107.64(11), N(2)−Hf(1)−Cl(1) 106.50(11), N(1)−Hf(1)−Cl(1) 107.31(11), P(1)−N(1)−Hf(1) 164.8(2), P(2)−N(2)−Hf(1) 165.0(2), P(3)−N(3)−Hf(1) 168.1(2).

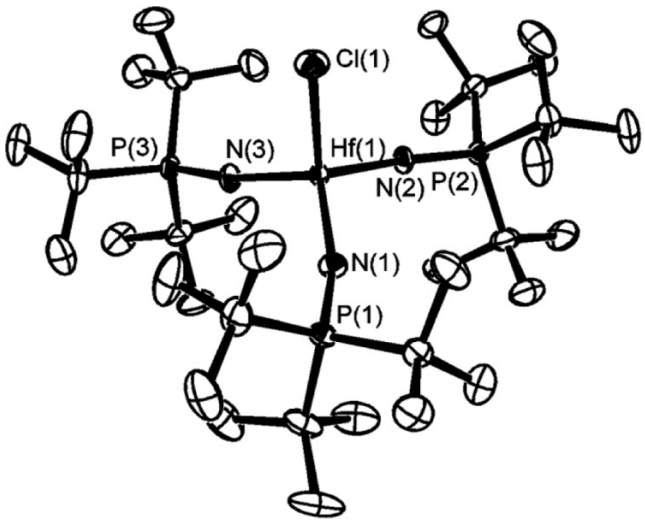
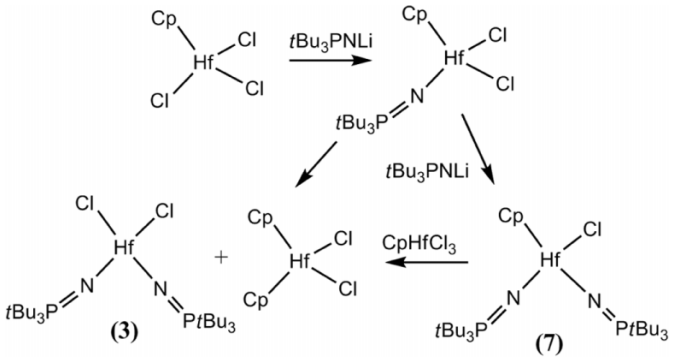


5 (1.969(3), 1.971(3), and 1.983(3) Å) were longer than those seen in **3**, presumably a result of reduced Lewis acidity and greater steric congestion at Hf. The methylated analog (t-$Bu_3PN)_3HfMe$ (**6**) was obtained from the treatment of **5** with MeMgBr. This species exhibited a sharp ^{31}P NMR signal at 34.1 ppm and two ^1H NMR signals, a doublet at 1.44 ppm for *tert*-butyl groups and a singlet at 0.36 ppm for methyl protons, consistent with the formulation.

Complexes of the form Cp(t-$Bu_3PN)MCl_2$ (M = Ti, Zr) have been shown to be active olefin polymerization catalysts.[30,56,57] Thus, the Hf analog was targeted. Reaction of 1equiv. of t-Bu_3PNLi with $CpHfCl_3$ was performed. The product showed a single ^{31}P NMR resonance at 41.3 ppm and two ^1H NMR signals, a singlet at 5.82 ppm for the cyclopentadienyl group and a doublet at 1.28 ppm for *tert*-butyl protons. The ^{31}P and ^1H NMR spectra for the phosphinimide ligand correspond to those observed for **3** while the ^1H NMR resonance attributed to the cyclopentadienyl group corresponds to that seen for Cp_2HfCl_2. Indeed, **3** was isolated as a crystalline product from this reaction mixture and its identity confirmed crystallographically. It is noteworthy that the reaction of $IndHfCl_3$ with t-Bu_3PNLi proceeding in a similar fashion yielded **3** and Ind_2HfCl_2. Attempts to probe the mechanism of this ligand redistribution reaction were

Scheme 3. Proposed ligand redistribution process to **3**.



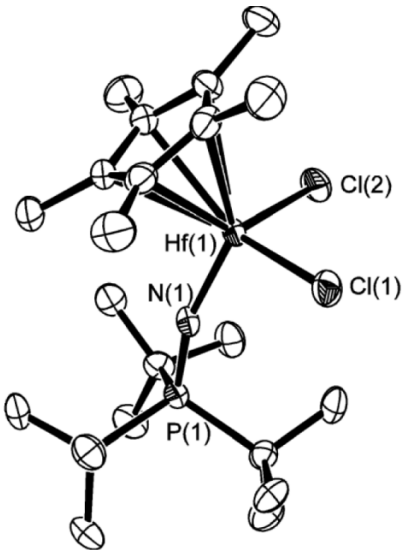
performed by a variable temperature ^{31}P NMR spectroscopy. Although solubility was problematic, on mixing at 15 °C, a broad resonance at 56.6 ppm was observed, which slowly transformed to a sharp signal at 41.3 ppm corresponding to **3**. One possible mechanism could involve metathesis generating Cp(*t*-Bu_3PN)$HfCl_2$,which then undergoes ligand redistribution to give (*t*-$Bu_3PN)_2HfCl_2$ and Cp_2HfCl_2. Alternatively, the improved solubility of Cp(*t*-Bu_3PN)$HfCl_2$ could result in a second metathesis to give Cp(*t*-$Bu_3PN)_2HfCl$, which could then react with $CpHfCl_3$ to give the two redistribution products (Scheme 3). This would suggest that the initial species giving rise to the resonance at 56.6 ppm could be Cp(*t*-Bu_3PN)$HfCl_2$, although the mechanistic details of this disproportionation were not confirmed.

The proposed intermediate in the latter mechanism, Cp(*t*-$Bu_3PN)_2HfCl$ (**7**), was prepared independently in 95% yield by treating (*t*-$Bu_3PN)_2HfCl_2$ with an equimolar amount of CpNa. Compound **7** gave rise to ^{31}P resonance at 37.4 ppm and a ^1H NMR signal at 6.57 ppm arising from the cyclopentadienyl protons. This species is stable on its own at elevated temperature. However, upon addition of a stoichiometric amount of $CpHfCl_3$, **7** reacts to give **3** and Cp_2HfCl_2, thus supporting the role of **7** in the ligand redistribution process described above. In a related and analogous synthesis, the species Cp_2(*t*-Bu_3PN)HfCl (**8**) was readily synthesized in 77% isolated yield by reacting Cp_2HfCl_2 with *t*-Bu_3PNLi.

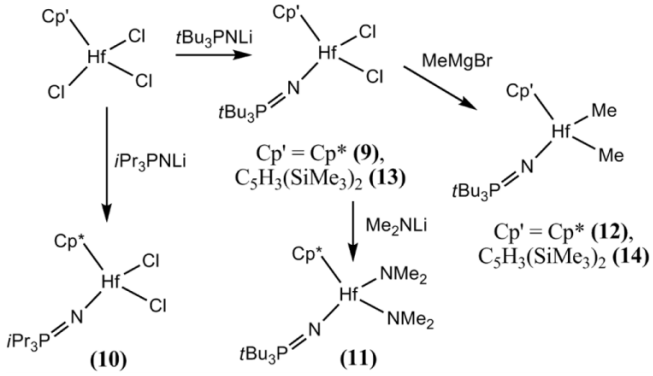
While the species Cp(*t*-Bu_3PN)$HfCl_2$ was not accessible, use of substituted cyclopentadienyl groups afforded the target species that were stable with respect to ligand redistribution. For example, Cp*$HfCl_3$ reacts with *t*-Bu_3PNLi smoothly to give Cp*(*t*-Bu_3PN)$HfCl_2$ (**9**) as evidenced by NMR data. The pseudotetrahedral arrangement about Hf was unambiguously confirmed by X-ray crystallography (Fig. 4). The Hf−N distance was found to be 1.925(7) Å while the Hf−Cl distances were 2.398(3) Å and 2.402(3) Å, which are quite similar to those in **3**. Additionally, the approximately linear P−N−Hf vector (163.2(4)°) in **9** is significantly larger than that observed in $(Hf_3Cl_6(NPMe_3)_5)^+(Hf_2Cl_7(NPMe_3)_2)^-$ (133.1(8)°, 125.9(6)°, and 132.6(8)°),[55] where the phosphinimide ligand bridges two Hf atoms.

In addition, reaction of Cp*$HfCl_3$ with *i*-Pr_3PNLi afforded Cp*(*i*-Pr_3PN)$HfCl_2$ (**10**). The ^1H NMR signal attributable to the Cp* group was observed at 2.19 ppm, downfield from that seen for $Cp^*_2HfCl_2$ (1.88 ppm). The halide atoms in **9** could be readily replaced with amides or methyl groups via reaction with $LiNMe_2$ or MeMgBr, affording Cp*(*t*-$Bu_3PN)Hf(NMe_2)_2$ (**11**) and Cp*(*t*-Bu_3PN)$HfMe_2$ (**12**) in yields of 88% and 95%, respectively (Scheme 4).

Fig. 4. ORTEP drawing of **9**; 20% thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity. Selected bond distances (Å) and angles (°): Hf(1)—N(1) 1.925(7), Hf(1)—Cl(2) 2.398(3), Hf(1)—Cl(1) 2.402(3), N(1)—P(1) 1.574(8); N(1)−Hf(1)−Cl(2) 104.3(2), N(1)−Hf(1)−Cl(1) 103.3(2), Cl(2)−Hf(1)−Cl(1) 103.46(12), P(1)−N(1)−Hf(1) 163.2(4).



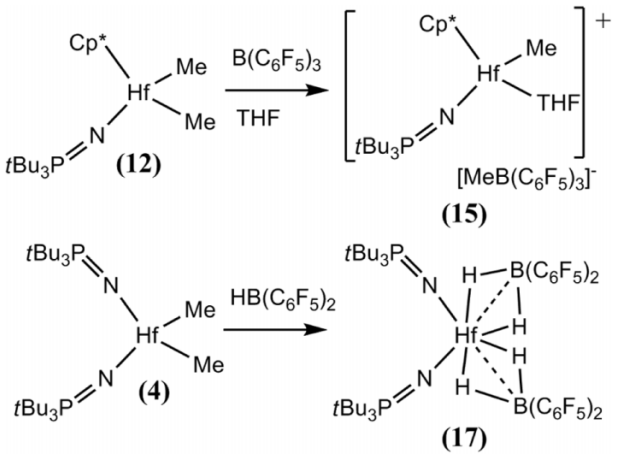
Scheme 4. Synthetic routes to **9**−**14**.



In a procedure similar to that employed for the synthesis of **8**, other cyclopentadienyl derivatives could be employed. For example, $((Me_3Si)_2C_5H_3)HfCl_3$ reacted stoichiometrically with *t*-Bu_3PNLi to form $((Me_3Si)_2C_5H_3)$(*t*-Bu_3PN)$HfCl_2$ (**13**). This reaction proceeded slowly, presumably as a result of the sterically demanding substituents on the Cp-ring. Nonetheless, this afforded **13** in 59% isolated yield. Compound **13** exhibits a sharp ^{31}P NMR signal at 45.0 ppm and four ^1H NMR resonances at 7.01, 6.81, 1.17, and 0.46 ppm attributable to the Cp, *tert*-butyl, and trimethylsilyl groups, respectively. This species was readily alkylated with MeMgBr to give $((Me_3Si)_2C_5H_3)$(*t*-Bu_3PN)$HfMe_2$ (**14**) as a crystalline white solid in a high yield of 86% (Scheme 4).

The reactions of Lewis acid activators are commonly used to generate cationic species, which serve as single-site catalysts in olefin polymerization.[58] Reaction of **12** with $B(C_6F_5)_3$ in CH_2Cl_2 under various conditions, showed no clear indica-

Scheme 5. Reactions of Hf−dialkyls with boranes.

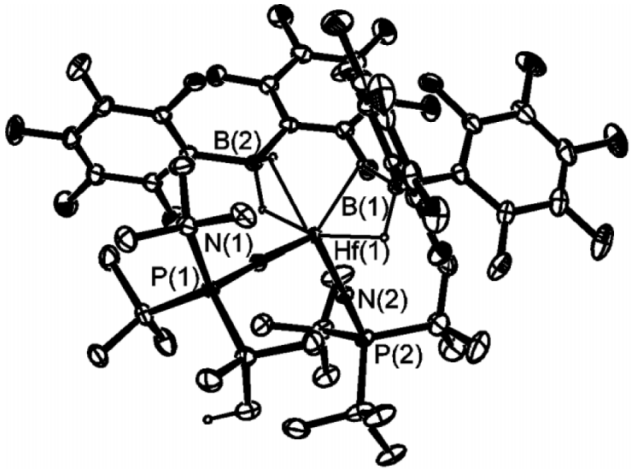


tion of the formation of a cationic species by NMR spectroscopy. However, reaction in the presence of THF afforded [Cp*(*t*-Bu_3PN)HfMe(THF)][$MeB(C_6F_5)_3$] (**15**) in 89% yield (Scheme 5). The ^{1}H NMR spectrum showed a broad singlet at 0.47 ppm attributable to the Me-B and a sharp singlet at 0.27 ppm attributable to the Hf−Me. The sharp ^{11}B NMR signal at −14.9 ppm confirmed a tetracoordinate boron environment.[59] In a similar fashion, methyl-abstraction by [Ph_3C][$B(C_6F_5)_4$] from **12** affords the cationic species [Cp*(*t*-Bu_3PN)HfMe][$B(C_6F_5)_4$] (**16**). In this species, the Hf−Me gave rise to a broad singlet at 0.03 ppm in the ^{1}H NMR spectrum, while a sharp ^{11}B NMR signal was observed at −16.9 ppm. This reactivity towards Lewis acids resembles that of the analogous Zr species, Cp(*t*-Bu_3PN)$ZrMe_2$.[60]

The corresponding reactions of **4** with $B(C_6F_5)_3$ or [Ph_3C][$B(C_6F_5)_4$] gave complex mixtures of unidentified products. However, **4** was found to react cleanly with $(C_6F_5)_2BH$ at room temperature. The resulting product was isolated as a white solid (**17**) in 89% yield. The ^{1}H NMR spectrum exhibited a resonance centered at 4.67 ppm consisting of four broad peaks separated by 65 Hz. The ^{11}B NMR showed a triplet at −15.00 ppm. This complex (**17**) was further confirmed by X-ray crystallography and confirmed to be (*t*-Bu_3PN)$_2$Hf($H_2B(C_6F_5)_2$)$_2$ (Scheme 5, Fig. 5). The Hf−N distances in **17** were found to be 1.909(3) Å and 1.921(3) Å, while the P−N−Hf angles were nearly linear at 177.4(2)° and 173.3(2)°. The Hf−B distances of 2.588(5) Å and 2.655(4) Å were consistent with the close proximity of one *ortho*-F of a C_6F_5 group (Hf···F 2.678(3) Å). This interaction was not seen in the related zirconocene complex, $Cp_2Zr(H_2B(C_6F_5)_2)_2$.[61]

Preliminary testing of the ability of compounds **3**, **9**, and **13** to effect ethylene polymerization was probed. The polymerizations were performed for 5 min at 30 °C, under 2 atm of ethylene, and using Al(*i*-Bu)$_3$ as a scavenger. Employing 500 equiv. of methylaluminoxane (MAO) as the alkylatingand activating reagent, negligible amounts of polyethylene were obtained. Similarly, using **12** and **14** while employing 2 equiv. of $B(C_6F_5)_3$ as the activator, no polymer formation occurred. However, activation of **12** and **14** with [Ph_3C][$B(C_6F_5)_4$] gave rise to activities of 5900 and 5800 g/mol/h/atm, respectively. This compares to 6400 and 8000 g/mol/h/atm, obtained for Cp_2HfMe_2 and Cp(*t*-Bu_3PN)$TiMe_2$, respectively, under the same condition. The insolubility of the resulting polyethylene, which precluded GPC data infers high molecular weight. Similar observations have been made for other phosphinimide-based olefin polymerization catalysts.[54]

Fig. 5. ORTEP drawing of **17**; 20% thermal ellipsoids are shown. Hydrogen atoms are omitted for clarity. Selected bond distances (Å) and angles (°): Hf(1)—N(1) 1.909(3), Hf(1)—N(2) 1.921(3), Hf(1)—B(1) 2.588(5), Hf(1)—B(2) 2.655(4), Hf(1)—F(16) 2.678(3), P(1)—N(1) 1.594(3), P(2)—N(2) 1.587(3); N(1)−Hf(1)−N(2) 112.85(14), N(1)−Hf(1)−B(1) 104.05(14), N(2)−Hf(1)−B(1) 111.07(15), N(1)−Hf(1)−B(2) 101.36(14), N(2)−Hf(1)−B(2) 113.45(14), B(1)−Hf(1)−B(2) 113.32(15), P(1)−N(1)−Hf(1) 177.4(2), P(2)−N(2)−Hf(1) 173.3(2).



Conclusions

Phosphinimide complexes of hafnium can be synthesized either by salt metathesis or amine elimination. Cyclopentadienyl redistribution precludes the synthesis of Cp(*t*-Bu_3PN)$HfCl_2$, although use of bulkier substituted cyclopentadienyl ligands readily affords the analogous derivatives. Activation of several Hf−phosphinimide-dihalide species proved to be inactive in olefin polymerization upon activation by MAO. In contrast, activation of dimethyl analogs by [Ph_3C][$B(C_6F_5)_4$] generate catalysts of moderate activity.

Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 3979. For more information on obtaining material, refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml. CCDC 732437−732441 contain the X-ray data in CIF format for this manuscript. These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (Or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

Triterpenes of *Commiphora holtziana* oleo-gum resin

Lawrence Onyango Arot Manguro, Sylvia Awino Opiyo, Eberhardt Herdtweck, and Peter Lemmen

Abstract: Chemical analysis of the acetone extract of *Commiphora holtziana* gum resin has led to the isolation of triterpenes characterized as methyl 3-oxo-1α,19α,28-trihydroxyurs-12-en-24-oate (**1**), methyl 3β-acetyl-2α,11α,19α,28-tetrahydroxyurs-12-en-24-oate (**2**), methyl 3β,11α-diacetyl-1α,2α,28-trihydroxyurs-12-ene-24-oate (**3**), and 3β,28-diacetyl-1α,2α,25-trihydroxydammar-23-ene (**4**). The known compounds isolated from the same extract included cabraleadiol monoacetate (**5**), mansumbinol (**6**), 3β-acetylamyrin (**7**), 3α-acetylboswellic acid (**8**), 2-methoxy-8,12-epoxygermacra-1(10),7,11-trien-6-one (**9**), 2-methoxy-5-acetylfuranogermacra-1(10),7,11-trien-6-one (**10**), furadienone (**11**), 2-methoxy-5-acetyl-4-furanogermacra-1(10)*Z*-en-6-one (**12**), α-amyrin (**13**), sistosterol (**14**) and stigmasterol 3-*O*-acetate (**15**). Structural elucidation was carried out using spectroscopic and physical methods as well as by comparison with the literature data.

Key words: Commiphora holtziana, Burseraceae, triterpenes, gum-oleo-resin exudate.

Résumé : L'analyse chimique des produits extraits à l'acétone à partir de la gomme résine *Commiphora hostziana* a permis d'extraire des triterpènes caractérisés comme le 3-oxo-1α,19α,28-trihydroxyurs-12-én-24-oate de méthyle (**1**), le 3β-acétyl-2α,11α,19α,28-tétrahydroxyurs-12-én-24-oate de méthyle (**2**), le 3β,11α-diacétyl-1α,2α,28-trihydroxyurs-12-én-24-oate de méthyle (**3**) et le 3β,28-diacétyl-1α,2α,25-trihydroxydamma-23-ène (**4**). On a aussi isolé les produits connus suivants: monoacétate de cabraléadiol (**5**), mansumbinol (**6**), 3β-amyrine (**7**), acide 3-α-acétylboswellique (**8**), 2-méthoxy-8,12-époxy-germacra-1(10),7,11-trién-6-one (**9**), 2-méthoxy-5-acétylfuranogermacra-1(10),7,11-trién-6-one (**10**), furadiénone (**11**), 2-méthoxy-5-acétyl-4-furanogermacra-1(10)*Z*-én-6-one (**12**), α-amyrine (**13**), sistostérol (**14**) et 3-*O*-acétate du stigmastérol (**15**). L'élucidation des structures a été réalisée à l'aide de méthodes physiques et spectroscopiques ainsi que par comparaison avec des données tirées de la littérature.

Mots-clés : Commiphora holtziana, Burseraceae, triterpènes, exsudate de gomme-oléo-résine.

[Traduit par la Rédaction]

Introduction

The genus *Commiphora* (*Burseraceae*) is widely distributed in the tropics and subtropics, particularly in Africa, Asia, and Australia.[1] Over 46 *Commiphora* species are acclimatized in the northeastern province of Kenya, and a good number of them are characterized by oleo-resin exudates used in medicine, food, and perfumery industries.[2] *Commiphora holtziana* (syn. *Commiphora erythraea*) is one such species growing in the wild and produces resin, an article of commerce.[3] The plant is used in the indigenous system of medicine as a remedy for microbial infections, anti-inflammatory, and as an acaricide.[4,5] Previous chemical analyses of the plant resin exudate yielded 2-methoxy-8,12-epoxygermacra-1(10),7,11-trien-6-one, 2-methoxy-5-acetylfuranogermacra-1(10),7,11-trien-6-one, and furadienone.[5,6] In the present study, steam-distilled residue of *C. holtziana* resin exudate was examined chemically leading to the isolation and identification of triterpenes of ursane and dammarane types.

Experimental part

General experimental procedure

IR data were recorded on a PerkinsElmer FTIR 600 series. NMR data were measured in $CDCl_3$ and $CDCl_3$ + DMSO-d_6 on a Bruker DRX-400 NMR spectrometer operating at 400 and 100 MHz, respectively. MS data were obtained on a MAT 8200A instrument of Varian (Bremen). Preparative HPLC was performed on an instrument of JASCO labor und daten technik GmBH (RP-18, 250 × 20 mm, 7.4 μm JASCO Kromasil 100).

Oleo-gum resin material

Oleo-gum resins were collected from *C. holtziana* trees in Samburu district of Kenya by Mr. Norman Gachathi in March 2002 and were kept in a deep freezer in sealed polyethylene bags. Voucher specimens were confirmed after comparison with authentic herbarium samples at the Kenya Forestry Research Institute, Muguga, Kenya.

Extraction and isolation

Steam-distilled residues of the resin (~1 kg) were extracted at room temperature with acetone (2.5 L) for 5 days. The extract was filtered and concentrated to give a brownish gummy material (350 g). Approximately 245 g was dissolved in a small amount of acetone and then adsorbed onto silica gel. Removal of acetone under reduced pressure yielded a free-flowing mass that was chromatographed over silica gel (medium pressure, pressure ~ 1 bar); eluted with *n*-hexane/EtOAc mixtures with increasing concentration of the more polar solvent, EtOAc, followed by EtOAc/MeOH mixtures (9:1, 4:1, 7:3, and 2:1), and elution concluded with MeOH, affording 250 fractions (100 mL each) whose compositions were monitored by TLC (eluent: *n*-hexane/EtOAc (9:1, 4:1, 2:1) and EtOAc/MeOH (9:1, 4:1). Those showing similar TLC profiles were combined, resulting into four pools (I–IV). Pool I (fractions 1–105, 35 g), an oily resinous material was further purified by medium-pressure chromatography to afford 2-methoxy-8,12-epoxygermacra-1(10), 7,11-trien-6-one (**9,** 78 mg), furadienone (**11,** 105 mg), 2-methoxy-5-acetylfuranogermacra-1(10),7,11-trien-6-one (**10,** 62 mg), and 2-methoxy-5-acetyl-4-furanogermacra-1(10)*Z*-en-6-one (**12,** 85 mg).[6–8] Fractions 111–170 constituted pool II (25 g) and was found to contain four major spots, which were resolved into α-amyrin (**13**, 200 mg), sistosterol (**14**, 104 mg), stigmasterol 3-*O*-acetate (**15**, 84 mg), and mansumbinol (**6,** 65 mg), using *n*-hexane/ethyl acetate (4:1, 3:2).[9–11] Pool III (fractions 171–205, 10 g) upon repeated fractionation using *n*-hexane/ethyl acetate (3:2, 1:2), collecting 20 mL each, allowed the isolation of 3β-acetylamyrin (**7,** 150 mg), 3α-acetylboswellic acid (**8,** 97 mg),[12,13] methyl-3β,11α-diacetyl-1α,2α,28trihydroxyurs-12-ene-24-oate (**3**, 35 mg), and cabraleadiol monoacetate (**5**, 95 mg).[14] Pool IV (21 g) was a gummy material, and its constituents were resolved into individual compounds using preparative HPLC (eluent: acetonitrile/H_2O, 35:65), mobile flow rate 10 mL min^{-1}, injecting 10 μL each time. The process afforded methyl 3-oxo-1α,19α, 28-trihydroxyurs-12-en-24-oate (**1**, 65 mg), methyl-3β-acetyl-2α,11α,19α,28-tetrahydroxyurs-12-en-24-oate (**2**, 87 mg), and 3β, 24-diacetyl-1α,2α,25-trihydroxydammar-23-ene (**4**, 75 mg).

Compound 1

Colorless amorphous powder, mp > 250 °C. $[\alpha]_D^{25}$ +13 (MeOH, *c* 0.05). UV (CH_3CN) λ_{max} (nm): 202 (log ε 3.4). IR ν_{max} (KBr) (cm^{-1}): 3430–3300 (OH), 2950, 2863, 1719 (CO_2Me), 1706 (C=O), 1646 (C=C), 1450, 1380, 1260, 1190, 1020, 960. ^1H NMR ($CDCl_3$ + DMSO-d_6, 400 MHz): see Table 1. ^{13}C NMR ($CDCl_3$ + DMSO-d_6, 100 MHz): data are in Table 2. EIMS *m/z* (%): 516 $[M]^+$ (1), 498 $[M - H_2O]^+$ (3), 480 $[M - 2H_2O]^+$ (7), 448 (2), 440 (3), 266 $[C_{15}H_{22}O_4]^+$ (10), 250 $[C_{16}H_{26}O_2]^+$ (3), 248 (15), 238 (100), 232 (1), 231 (45), 219 (17), 207 (2), 203 (11), 201 (21), 189 (75), 173 (27), 119 (55), 95 (34), 56 (48). Fig. 1. Key NOESY correlations for compounds **3** and **4**.

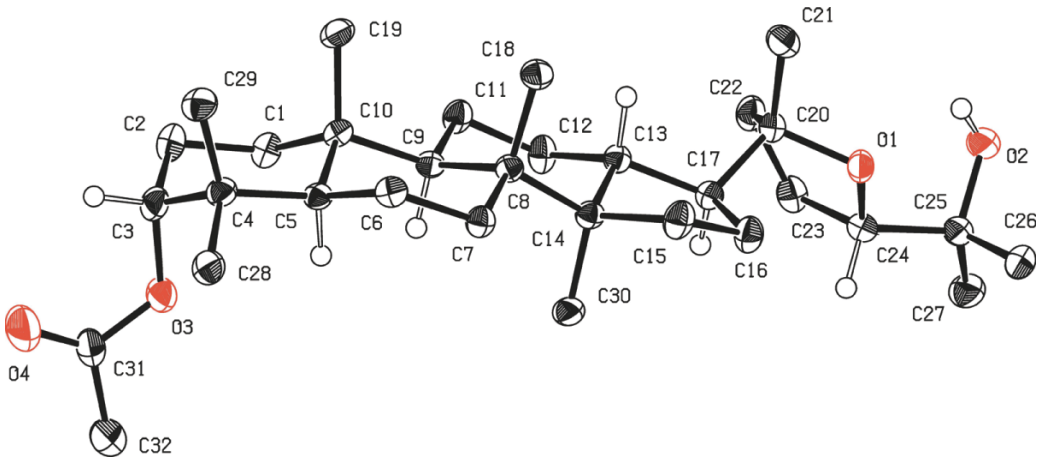
Results and discussion

Fractionation of the acetone extract of *C. holtziana* yielded compounds (**1**–**4**) together with eleven known ones (**5–15**) identified on the basis of spectroscopic and physical methods.

Compound **1**, isolated as colorless amorphous powder afforded positive Liebermann–Burchard test, suggesting the presence of a triterpene or sterol skeleton. Its molecular-ion peak at *m/z* 516.3589 (calcd. *m/z* 516.3473) by accurate mass measurement corresponds to the formula $C_{31}H_{48}O_6$, confirmed by ^{13}C NMR and DEPT spectra, which exhibited 31 carbon atoms resolved into 9 methylenes, 7 methyls, 6 methines, and 9 quaternary. The ^1H NMR spectrum (Table 1) indicated five tertiary methyls (δ 1.30, 1.22, 1.10, 1.06, 0.98), a methoxy carbonyl (δ 3.54), a secondary methyl group (δ 1.16, d, *J* = 6.6 Hz, CH_3-30), an oxymethine (δ 3.60, t, *J* = 10.0, 4.5 Hz, H-1), a terminal hydroxymethylene (δ 4.00, d, *J* = 10.6 Hz, H-28b; δ 3.80, d, *J* = 10.6 Hz, H-28a), and a trisubstituted double bond (δ 5.26, d, *J* = 4.0 Hz, H-12). In combination with the characteristic EIMS fragmentation ions at *m/z* 266 $[C_{15}H_{22}O_4]^+$ and 250 $[C_{16}H_{26}O_2]^+$ attributed to retro-Diels–Alder cleavage between C-9 and C-11, and between C-8 and C-14 bonds, it suggested that compound **1** is either an ursane- or oleanane-type triterpene containing a keto, two hydroxyls, a methyl carbonyl, and a terminal hydroxymethylene functional group. On the basis of the cleavage, it was suggested that the oxo, one hydroxyl, and the methoxy carbonyl were present in the rings A/B, whereas the terminal hydroxymethylene and another hydroxyl group were positioned in the rings C/D part of the molecule.[15–19] The ^1H NMR singlet peak at δ 2.36 is a characteristic signal for the H-18 of an ursane-type with 19-O-substitution.

Fig. 2. ORTEP-style plot of compound **5** showing the atom-numbering scheme and the solid-state conformation. Thermal ellipsoids are drawn at the 50% probability level.



Together with the ^{13}C NMR olefinic carbon signals at δ 127.3 (C-12) and δ 140.0 (C-13) and an oxygen bearing quaternary carbon at δ 72.8 (C-19), it confirmed the 19α-hydroxyurs-12-ene skeleton for the compound.[17,20] The positions of the substituents and their stereochemistry were established by 2D experiments, whereby the key proton resonances were assigned by gHSQC correlations. The long-range correlation (gHMBC) showed significant cross peaks between H-1 (δ 3.60) and C-3 (δ 216.0), between H-18 (δ 2.36) and C-19 (δ 72.8) and C-28 (δ 66.6), between H-5 (δ 1.02) and C-24 (δ 181.4), and between H-18 and C-20 (δ 43.0). The position of a hydroxyl-bearing methine proton at δ 3.60 (H-1) was confirmed to be at C-1, as its carbon resonance (δ 73.4) showed a gHMBC correlation with Me-25, a fact further corroborated by the ^{13}C NMR shielded resonances for C-5 (δ 48.4) and C-9 (δ 38.4), respectively.[21] The stereochemistry of the hydroxyl group at C-1 was determined as α and axial on the basis of NOESY cross peaks between H-1 and Me-23 and also between H-1 and Me-25. This was further supported by the coupling $J_{H\text{-}1/H\text{-}2}$ (cis) = 4.5 Hz consistent with the 1α-hydroxy-substituted ring A, which is in agreement with literature report for rings A/B part of 1α-hydroxy-3-oxoolean-12-en-oic acid.[21] Thus, based on the results, compound **1** was concluded to be methyl-3-oxo-1α,19α,28-trihydroxyurs-12-en-24-oate.

Compound **2** was isolated as colorless powder from CH_2Cl_2/MeOH (9:1). According to EIMS, ^{13}C NMR, and DEPT, its composition is $C_{33}H_{52}O_8$, consistent with nine degrees of unsaturation. Data from ^1H and ^{13}C NMR (Tables 1 and 2) indicated a secondary metabolite with a structure similar to that of compound **1**. The major structural difference is the additional acetyl group (δ 1.98) and two oxygenated methines (δ 4.50, d, J = 11.6 Hz, H-3; δ 3.70, dd, J = 10.2, 3.6 Hz, H-11). Both the ^1H and ^{13}C NMR depicted data typical of a triterpene of ursane skeleton containing a double bond between C-12 and C-13.[17,22,23] Support for this conclusion was further provided by the mass spectrum. Retro-Diels–Alder cleavage, characteristic of Δ^{12}-pentacyclic triterpenes, leads to m/z 310 $[C_{17}H_{26}O_5]^+$ and 250 $[C_{16}H_{26}O_2]^+$. The fragments at m/z 249 $[C_{15}H_{21}O_4]^+$, resulting from m/z 310, and those at m/z 232 $[C_{16}H_{24}O]^+$ and 201 $[C_{16}H_{21}]^+$, resulting from m/z 250, indicated the presence of hydroxyl, acetyl, and a methoxy carbonyl group in rings A/B, whereas another hydroxyl, an oxymethylene and an oxygenated tertiary methyl group were in rings D/E part of the molecule.[24] This was further corroborated by the singlet proton signal at δ 2.38 (H-18), typical of 19α-hydroxyurs-12-ene skeleton, which correlated with C-28 (δ 65.7), C-12 (δ 126.0), and C-20 (δ 42.6) in the HMBC spectrum. On the other hand, in the ^1H–^1H homonuclear chemical correlation spectrum, the comparatively low field oxymethine proton at δ 4.50 correlated with one proton and hence was assigned to C-3, further evidenced by gHSQC correlation between H-3 (δ 4.50) and C-3 (δ 78.2). The large coupling constant (J = 11.6 Hz) allowed the assignment of β and equatorial orientation of the acetyl group. Similarly, the positions of two hydroxyl-bearing methine protons at δ 3.65 (ddd, J = 12.4, 10.0, 3.2 Hz, H-2) and δ 3.70 (d, J = 10.2, 3.6 Hz, H-11) and their disposition as both α was suggested by the coupling constants, which agreed well with 2α, 11α-dihydroxy substitution on rings A/C,[25,26] respectively, and were confirmed by gHMBC cross peaks between H-2 (δ 3.65) and C-4 (δ 55.0), and between H-11 (δ 3.70) and C-13 (δ 141.6). Spin-decoupled and NOESY experiments allowed the complete assignment of the stereochemistry of compound **2**. Thus, on the basis of accrued data, **2** was concluded to be methyl 3β-acetyl-2α,11α,19α,28- tetrahydroxyurs-12-en-24-oate.

Compound **3** was isolated as colorless powder from CH_2Cl_2–MeOH (9:1). It afforded an IR spectrum indicating the presence of hydroxyl, ester, methoxylated carbonyl group, and a double bond (3540, 1734, 1725, 1635 cm^{-1}). Its ^1H NMR spectrum showed a vinyl proton (δ 5.25, br s, H-12), an oxymethine proton (δ 4.40, d, J = 12.0 Hz, H-3), an allylic methine proton attached to an oxygen functionality (δ 4.23, d, J = 8.8, 3.4 Hz, H-11), a terminal hydroxymethylene (δ 4.10, d, J = 11.1 Hz) and δ 3.86 (d, J = 11.1 Hz, CH_2-28), two hydroxy methine protons (δ 3.50, dd, J = 10.2, 3.4 Hz, H-2; δ 3.75, d, J = 3.6 Hz, H-1), two acetyl groups (δ 2.03, 2.00, both singlets), four tertiary methyls (δ 1.17, δ 1.15, δ 1.13, δ 0.94), and two secondary methyl groups (δ 0.88, d, J = 6.8 Hz, Me-29; δ 0.87, d, J = 6.6 Hz, Me-30). The compound exhibited an HR-EIMS molecular ion peak at m/z 618.2354, compatible with the formula $C_{35}H_{54}O_9$. Other significant peaks at m/z 326 $[C_{17}H_{26}O_6]^+$

and 234 $[C_{16}H_{26}O]^+$ were in accord with the retro-Diels–Alder cleavage, typical of C-12 unsaturated pentacyclic triterpenes.[27] From the fragmentation pattern, it was evident that rings A/B contained two hydroxyls, an acetyl, and a methoxy carbonyl group, a fact that was evidenced by the daughter ions at *m/z* 266 $[C_{15}H_{22}O_4]^+$ and 249 $[C_{15}H_{21}O_3]^+$ from the ions *m/z* 326 $[C_{17}H_{26}O_6]^+$. Similarly, fragments at *m/z* 261 $[C_{17}H_{25}O_2]^+$, 232 $[C_{16}H_{24}O]^+$, and 201 $[C_{15}H_{21}]^+$ signified the presence of another acetoxy and an hydroxymethylene group in the rings D/E. The foregoing conclusions were confirmed by gHSQC and gHMBC experiments; in particular, the gHMBC correlations observed between H-18 (δ 1.75) and C-28 (δ 67.5), between H-11 (δ 4.23) and C-13 (δ 139.0), and between H-5 (δ 0.98) and C-24 (δ 180.8) and C-3 (δ 80.1). The relative stereochemistry of substituents was assigned by NOESY experiments (Fig. 1). Therefore, on the basis of spectroscopic data, as well as comparison with known compounds, **3** was structurally concluded to be methyl 3β,11α-diacetyl-1α,2α,28-trihydroxyurs-12-en-24-oate.

Compound **4** was obtained as colorless powder, mp 248–250 °C after crystallization from a CH_2Cl_2/MeOH. Its molecular formula, $C_{34}H_{56}O_7$, was deduced from the HR-ESIMS molecular ions at *m/z* 599.2495 $[M + Na]^+$ (calcd. 599.2431) and by quantification of methyls, methylenes, methines, and quaternary carbon atoms revealed in the ^{13}C NMR and DEPT spectra. The IR spectrum displayed significant bands at 3500, 1736, and 1644 cm^{-1}, signifying the presence of OH, ester, and a carbon–carbon double bond, respectively. The EIMS fragment peaks at *m/z* 558 $[M - H_2O]^+$, 540 $[M - 2H_2O]^+$, and 516 $[M - HOAc]^+$ are characteristic features of the dammarane skeleton with two acetoxy and two hydroxyl groups in the rings A/B.[20,28] The ^1H NMR spectrum corroborated the findings by showing nine signals for methyl groups, two of them acetoxy, a fact further supported by two ester carbonyl peaks at δ 170.3 and δ 169.8 with corresponding methyls at δ 24.1 and δ 23.5, respectively. A singlet at δ 1.36, typical of a hydroxyl isopropyl moiety, and signals of an isolated double bond at δ 5.64 and δ 5.58 evidenced the presence of a $–CH(CH_3)–CH_2–CH=C(CH_3)_2–OH$ system in the C-17 side chain.[12] This was confirmed by ^1H-detected gradient heteronuclear single quantum coherence (gHSQC) experiments where the two peaks at δ 126.3 (C-23) and δ 141.4 (C-24) represented the isolated double bond while the other peak at δ 79.9 corresponded to hydroxy isopropyl moiety. Further insight into the structure of **4** was provided by close examination of both the mass spectrum and the ^1H NMR data, whereby the EIMS fragments in combination with ^1H NMR peaks at δ 4.65 (d, J = 12.4 Hz, H-3), δ 3.77 (dd, J = 11.0, 3.3 Hz, H-2), and δ 3.60 (d, J= 4.5 Hz, H-1) confirmed the presence of an acetoxy and three oxymethines linked in a $CH_{eq}(O-H_{ax})–CH_{eq}(OH_{ax})–CH_{ax}(OAc_{eq})–CCH_3(CH_2OAc)$ system requiring the two oxymethine protons to be at C-1 and C-2 both as α, while the acetoxy to be at C-3 as β[20,28] and was consistent with gHSQC, gHMBC, and NOESY correlations (Fig. 1). On this basis, the structure of compound **4** was concluded as 3β,28-diacetyl-1α,2α,25-trihydroxydammar-23-ene.

Compound **5** was isolated as colorless crystals from *n*-hexane/EtOAc (2:1). Its HR-EIMS showed a peak at *m/z* 502.4074 $[M]^+$, corresponding to the formula $C_{32}H_{54}O_4$. The ^1H and ^{13}C NMR spectral data revealed a close relationship, if not identity, with cabraleadiol monoacetate.[14] However, HMQC and HMBC experiments lead to minor but possibly significant differences from the reported ^1H NMR spectrum data, as concluded from HETCOR experiments. Thus, the structure of **5** was validated by an X-ray crystallographic study (Fig. 2) to be cabraleadiol monoacetate.[29]

Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 3974. For more information on obtaining material, refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml. CCDC 727028 contains the X-ray data in CIF format for this manuscript. These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

Acknowlegements

The authors are grateful to the African Academy of Science (AAS) for providing funds that initiated the research. Alexander von Humboldt foundation is sincerely thanked for the fellowship awarded to L. Manguro that made part of analysis done at Technische Universitaet Munich, Germany. Prof. Thomas Bach, Director of the Institute of Organic Chemistry and Biochemistry, Technical University of Munich, is highly appreciated for accepting to host L. Manguro. Mr. Norman Gachathi of Kenya Forestry Research Institute is acknowledged for identification and collection of the plant products. Mr. Liu of Quangzhou Institute of Chemistry, Chinese Academy of Sciences, is acknowledged for NMR data analysis of some compounds.

Design, chemical synthesis, and in vitro biological evaluation of simplified estradiol–adenosine hybrids as inhibitors of 17β-hydroxysteroid dehydrogenase type 1

Marie Bérubé and Donald Poirier

Abstract: A series of estradiol (E_2) derivatives were designed to interact with both the substrate- and the cofactor-binding sites of 17β-hydroxysteroid dehydrogenase type 1 (17β-HSD1). These analogues of potent E_2–adenosine hybrid inhibitor EM-1745, where the adenosine moiety was replaced by a more stable benzene derivative, were synthesized from estrone using alkene cross-metathesis and Sonogashira coupling reactions as key steps. In vitro biological evaluation of these steroid derivatives revealed that a spacer of 13 methylenes, between the 16β-position of E_2 and the adenosine mimic bearing a carboxylic acid group, gave the best inhibition of 17β-HSD1.

Key words: 17β-hydroxysteroid dehydrogenase, enzyme, inhibitor, steroid, metathesis, Sonogashira coupling.

Résumé : Plusieurs dérivés de l'estradiol (E_2) ont été préparés pour interagir avec le site de liaison du substrat et le site de liaison du cofacteur de la 17β-hydroxystéroïde déshydrogénase type 1 (17β-HSD1). Ces analogues du puissant inhibiteur EM-1745, un hybride E_2–adénosine dont la partie adénosine a été remplacée par un dérivé benzylique plus stable, ont été obtenus à partir de l'estrone en utilisant la métathèse de Grubbs et le couplage de Sonogashira comme étapes clé. L'évaluation biologique in vitro de ces dérivés stéroïdiens a montré qu'une chaîne ayant 13 groupes méthylènes, entre la position 16β du stéroïde E_2 et le noyau benzylique porteur d'un acide carboxylique, provoquait la meilleure inhibition de l'enzyme 17β-HSD1.

Mots-clés : 17β-hydroxystéroïde déshydrogénase, enzyme, inhibiteur, stéroïde, métathèse, couplage de Sonogashira.

Introduction

17β-Hydroxysteroid dehydrogenase type 1 (17β-HSD1) or human estradiol dehydrogenase [E.C.1.1.1.62] was partially purified from human placenta by Langer and Engel in 1958.[1] It is a 327-amino-acids protein that exists as a homodimer. This enzyme preferentially catalyzes the transformation of estrone (E_1) into estradiol (E_2), the most potent estrogen, using NAD(P)H as cofactor (Fig. 1),[2–7] but also catalyzes the reduction of dehydroepiandrosterone (DHEA) into 5-androstene-3β,17βdiol (Δ^5-diol).[4] 17β-HSD1 activities have been found in many human tissues such as placenta, ovary, endometrium, liver, and breast.[8] In peripheral tissues such as the breast, enzyme substrates come from circulating DHEA-sulfate (DHEAS) or E_1-sulfate (E_1S), which are converted into DHEA and E_1 by steroid sulfatase.[9–11]

E_2 and Δ^5-diol have, respectively, high and weak affinity for the estrogen receptor (ER). The resulting receptor–estrogen complex produces estrogenic effects. Thus, in estrogen-dependent breast cancer, activation of ER by E_2 is crucial for the stimulation of growth of tumour cells. In fact, E_2 concentration has been found to be significantly higher in breast tumours than in normal breast tissue.[12,13] Furthermore, the intratumoral E_2 levels are high in postmenopausal patients with very low serum E_2 levels; a study aimed at explaining this revealed that the expression of 17β-HSD1 and the E_2/E_1 ratio are higher in breast cancer tissues of postmenopausal patients than in those of premenopausal ones.[14] Such results suggest that the accumulation of E_2 in breast cancer tissue is mainly caused by the intracrine activity of 17β-HSD1. In fact, because E_2 increases breast-cancer-cell proliferation, inhibition of 17β-HSD1 activity constitutes a good way to reduce tumour estrogen levels, thus promoting tumour regression. Consequently, the steroidogenic enzyme 17β-HSD1 is an interesting therapeutic target for the treatment of estrogen-sensitive diseases such as breast cancer.

The design of potent 17β-HSD1 inhibitors has been attempted during the past decades, but progress was not significant enough to justify their use in the treatment of estrogen-sensitive diseases.[15–17] However, interesting clini-

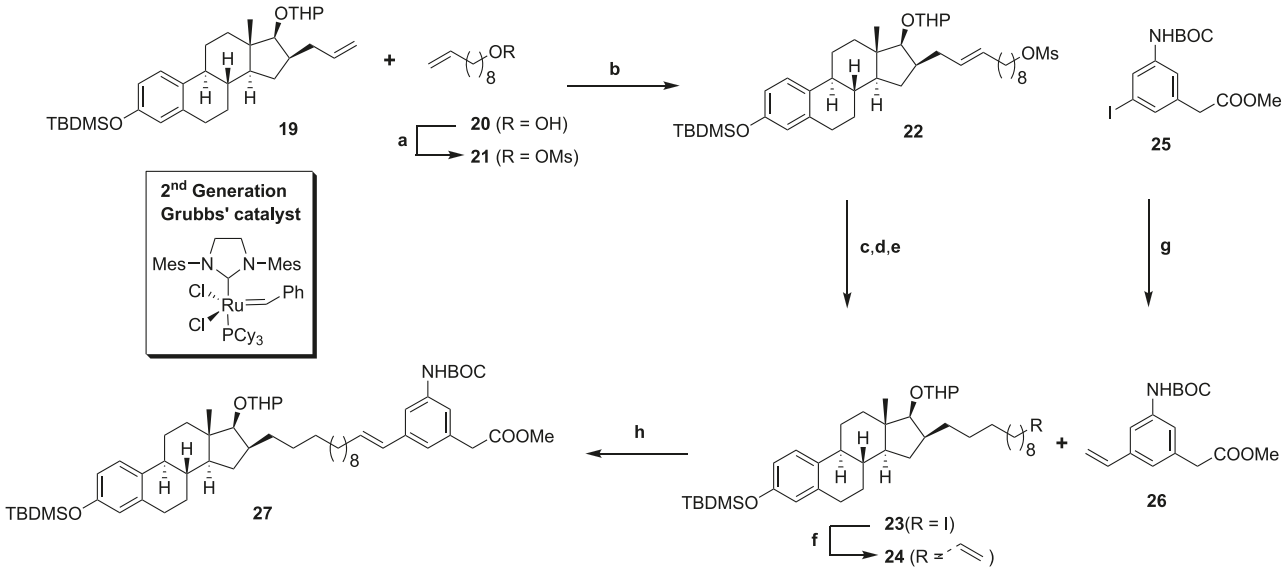
cal success has been achieved in reducing mammary tumours with inhibitors of aromatase, another enzyme involved in the biosynthesis of E_2.[18–20] Based on three-dimensional structures of 17β-HSD1 and on structure–activity relationship (SAR) studies, inhibitors that could interact with both the substrate- and the cofactor-binding sites were designed.[21–23] EM-1745 (**1**) (Fig. 2), one of these E_2–adenosine hybrid compounds, inhibited the transformation of E_1 into E_2 by 17β-HSD1 with an IC_{50} value of 52 nmol/L.[22] Furthermore, EM-1745 (**1**) was crystallized inside the enzyme, and X-ray analysis confirmed that it interacts with both the substrate- and the cofactor-binding sites.[23]

EM-1745 (**1**) is however a complex molecule. To become a potential drug, it needs to be simplified to improve its in vivo stability and enzyme inhibitory activity. Special care needs to be taken for the ester link and the adenosine moiety.[24] With that in mind, simplified hybrid inhibitors were then designed using the main interaction between EM-1745 (**1**) and the enzyme (compounds **2**–**18**, Fig. 3). The E_2 core was kept for interacting with His221, Ser142, and Tyr155, as well as with the hydrophobic residues that recognize the steroid substrate. Adenosine mimics were designed keeping in mind that the primary amino group of the adenosine template forms a strong interaction with Asp65. Other functionalities, such as an ester, a carboxylic acid, an alcohol, a bromide, and a phosphotriester, were added on the aniline core to potentially interact with Ser11 or other amino acids in this area of the enzyme. The carboxylic acid and the phosphotriester were chosen because they should interact in a way similar to that of a phosphate group. In fact, the cofactor NADPH has a better affinity than NADH for this en-

Mes: mesityl or 2,4,6-trimethylphenyl; Cy: cyclohexyl.



zyme, and the main structural difference between these two cofactors is a phosphate group on the C2′ of the adenosine moiety.[25] Furthermore, the ester function in EM-1745 (**1**) was removed and the E_2 nucleus was joined to the adenosine mimic by an alkyl chain, the length of which needs to be optimized (n = 13−17). We report herein two chemical approaches developed to synthesize compounds **2**−**18**. The in vitro biological evaluation of compounds **2**−**18** as inhibitors of 17β-HSD1 is also reported and discussed.

Results and discussion

Chemistry

The first approach to synthesize simplified hybrid inhibitors of 17β-HSD1 is presented in Scheme 1. The bisubstrate compound **27** was obtained by two cross-metathesis reactions[26] used as key steps to join E_2 and the adenosine mimic represented by an aniline derivative. Briefly, 9-decenol (**20**) was activated as the mesylate **21** using standard conditions and then linked to diprotected 16β-allyl-E_2 (**19**)[27] using the 2nd generation Grubbs' catalyst in refluxing dichloromethane (DCM) to afford **22** in 67% yield. Formation of a side product resulting from the metathesis of two molecules of steroid **19** was also observed. Hydrogenation of olefin **22** followed by substitution of the mesylate by an iodide afforded **23**. Partial deprotection of the C17β-OTHP group however necessitated a subsequent protective step.

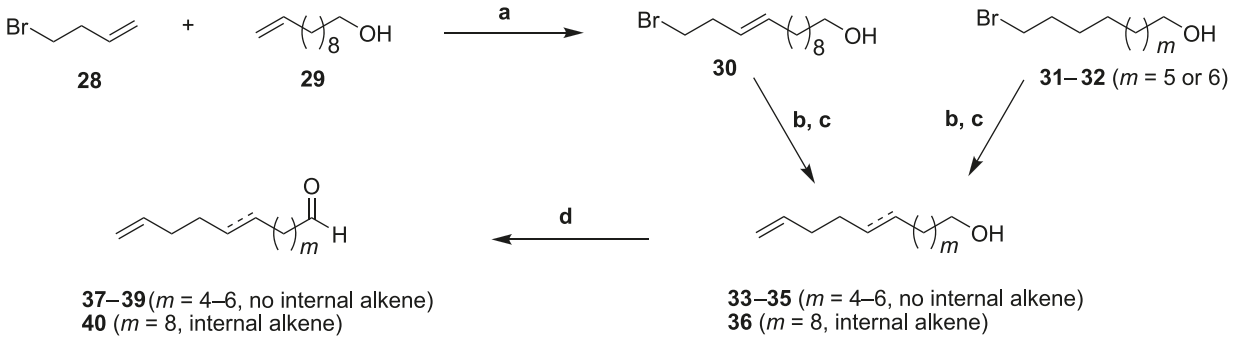
For the next step, our first idea was to obtain a terminal olefin similar to **24** by dehydrohalogenation. However, no terminal olefin was observed when **23** was treated with various bases (DBU, KOH, and *t*-BuOK) under different conditions. In fact, there are few dehydrohalogenation methodologies to prepare unconjugated terminal olefins in good yields and mild conditions. Although we later resolved this synthetic problem by developing a new methodology for obtaining terminal olefins,[28] we applied another strategy for the synthesis of **24**. This terminal olefin was easily obtained by addition of a vinyl cuprate on iodide **23** using hexamethylphosphoramide (HMPA) and triethyl phosphite as additives.[29]

Synthesis of aniline derivative **25** was described in our earlier report.[30] Addition of a vinyl group on **25** using Stille coupling procedure (tributyl(vinyl)tin, $Pd(PPh_3)_2Cl_2$, toluene, 75 °C)[31] afforded **26** in an excellent 88% yield. The next step was to join by cross-metathesis the side chain of **24** to the adenosine mimic **26** using the 2nd generation Grubbs' catalyst. However, the bisubstrate compound **27** was obtained in only 34% yield. Furthermore, the main product recovered after the reaction came from the metathesis of two steroids **24** that was obtained in 47% yield. Because product **27** was only obtained in low yield and synthesis of starting materials for this reaction necessitated numerous steps (nine steps for the synthesis of **24** from commercially available estrone and six steps for the synthesis of **26** from 2,6-diiodo-4-nitroaniline), a new synthetic strategy was developed.

This second synthetic approach for the preparation of simplified hybrid inhibitors was reported by us earlier as a short communication.[30] Briefly, an olefinic aldehyde (Scheme 2), used to elaborate the alkyl side-chain spacer, was joined to steroid **19** through cross-metathesis (Scheme 3). The aldehyde was transformed into an alkyne, and a Sonogashira coupling was used to link the steroid/spacer to the adenosine mimic **25** in excellent yields.

The first step in this approach was to synthesize spacers of various lengths as outlined in Scheme 2. Depending on the spacer length, the synthesis of aldehydes **37**−**39** started from the commercially available olefin **33** or the commercially available bromides **31** and **32**. However, for the synthesis of the aldehyde **40**, no olefin or bromide with the appropriate length were available from commercial sources. Bromide **30** was then synthesized in a good 80% yield from

Scheme 2. Second chemical approach: synthesis of spacers **37**−**40**. Reagents, conditions, and yields: (a) 2nd generation Grubbs' catalyst, DCM, reflux, 72 h (80%); (b) NaI, acetone, reflux, 16 h; (c) (i) CuI, vinylMgBr, THF, −40 °C, 15 min; (ii) HMPA, $P(OEt)_3$, −40 °C to RT, 3 h (60%−71% for two steps); (d) TPAP, NMO, molecular sieves, DCM, RT, 1 h (65%−94%).

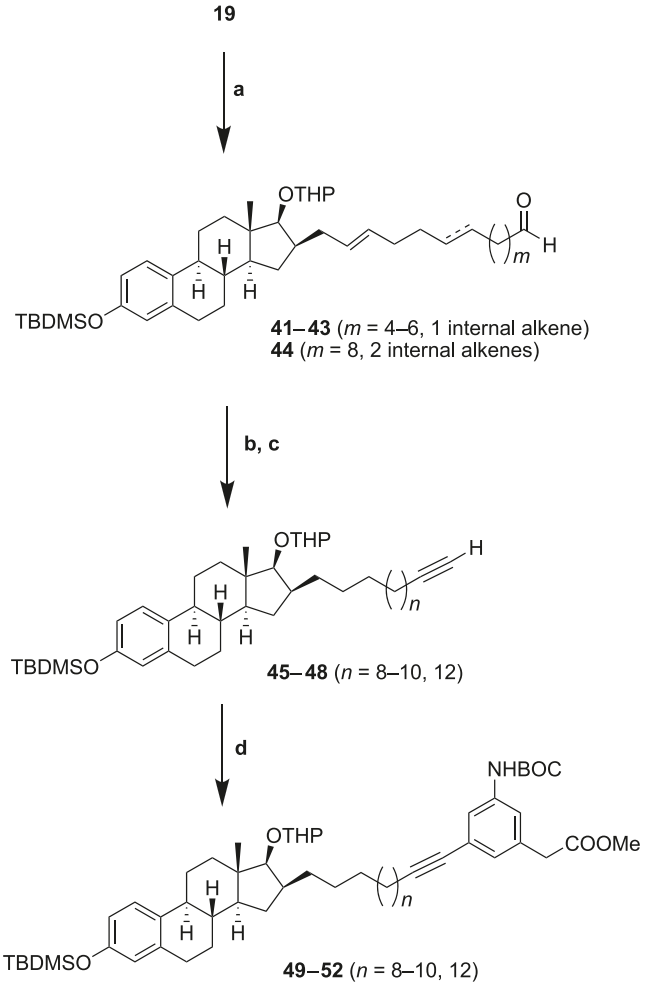


the cross-metathesis of 4-bromobutene (**28**) and 10-undecenol (**29**) with the 2nd generation Grubbs' catalyst. Iodination of bromides **30**−**32** using Finkelstein conditions followed by addition of a vinyl cuprate as described above afforded olefins **34**−**36** in 60%−71% yields for two steps. Alcohols **33**−**36** were next subjected to a tetrapropylammonium perruthenate (TPAP) oxidation to gain aldehydes **37**−**40**.

The next steps, as illustrated in Scheme 3, were to join the three components: the steroid **19**, a spacer originating from aldehydes **37**−**40**, and the adenosine mimic **25**. A cross-metathesis of steroid **19**[27] and freshly prepared aldehydes **37**−**40** using the 2nd generation Grubbs' catalyst provided compounds **41**−**44**. Hydrogenation of internal olefin(s) catalyzed by palladium followed by treatment with lithium diisopropylamide (LDA), (trimethylsilyl)diazomethane, and heat afforded alkynes **45**−**48** in 15%−33% yields for three steps.[32] Finally, applying optimized Sonogashira coupling procedure ($Pd(PPh_3)_4$, CuI, Et_3N),[33] alkynes **45**−**48** were added to aryl iodide **25**,[30] giving **49**−**52** in excellent yields (91%−95%).

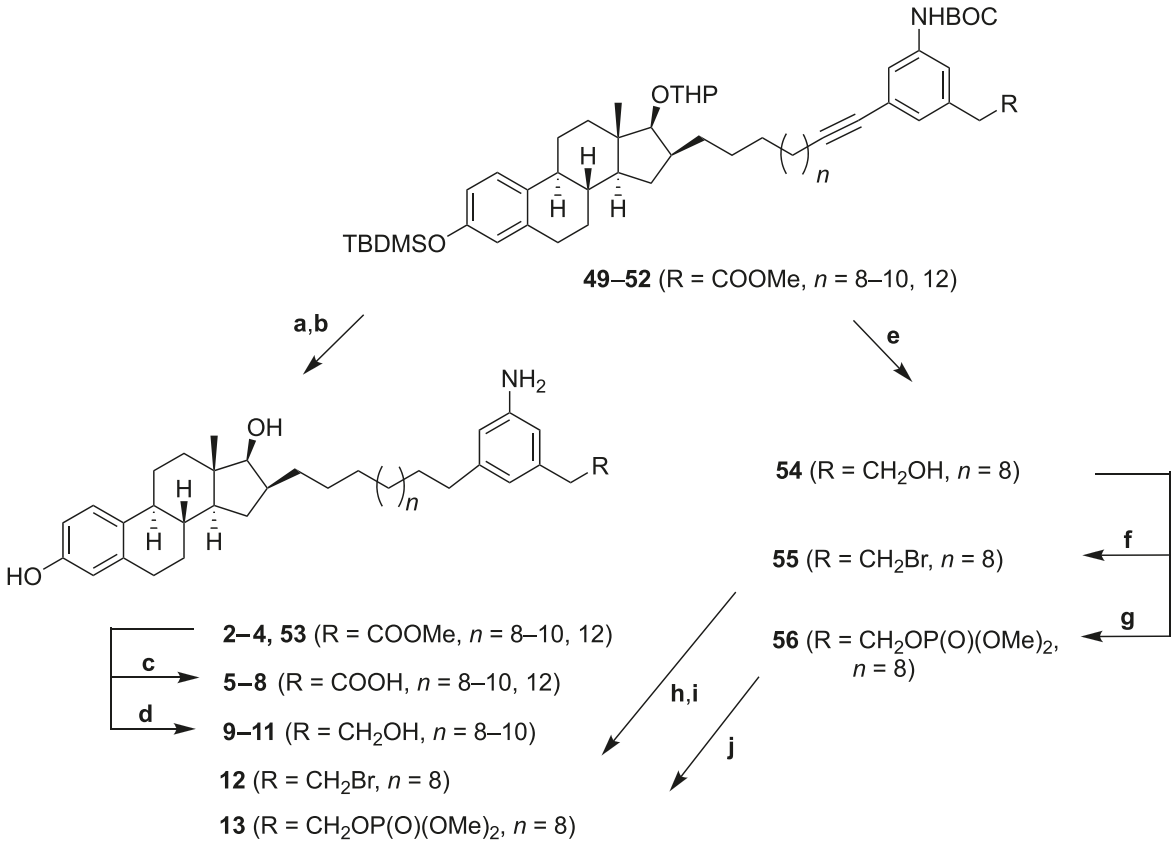
Molecular diversity was next added on the adenosine mimic moiety as described in Scheme 4. Depending on the type of functional group introduced, two synthetic procedures were applied. The first procedure was used to synthesize ester, carboxylic acid, and alcohol derivatives. Hydrolysis of the three protective groups (TBDMS, THP, and BOC) under acid conditions, followed by hydrogenation of the alkyne, provided ester derivatives **2**−**4** and **53** in 41%−66% yield for two steps. To obtain the salt-free product, the crude product−NH_2·HCl, resulting from the hydrolysis step, was treated with a solution of Cs_2CO_3 in MeOH. Carboxylic acid derivatives **5**−**8** and alcohol derivatives **9**−**11** were, respectively, obtained from esters **2**−**4** and **53** by acid hydrolysis or by hydride reduction. The second procedure was used to prepare bromide and phosphotriester derivatives **12** and **13**, respectively. To avoid formation of side products, the bromide and the phosphotriester needed to be introduced before removal of protective groups. Thus, reduction of ester **49** with $LiAlH_4$ afforded alcohol **54** in good yield of 80%. From **54**, the bromide **55** was obtained by reaction with CBr_4 and PPh_3 in DCM. Phosphotriester **56** was obtained by treatment of alcohol **54** with CBr_4 and $P(OMe)_3$ in pyridine.[34] Bromide **12** and phosphotriester **13** were finally obtained by hydrolysis of the three protective groups and hydrogenation of alkyne as described above.

Scheme 3. Second chemical approach: synthesis of **49**−**52**. Reagents, conditions, and yields: (a) **37**−**40**, 2nd generation Grubbs' catalyst, DCM, reflux, 16 h; (b) 10% Pd/C, H_2, EtOAc, RT, 16 h; (c) (i) LDA, $TMSCHN_2$ (2.0 mol/L in hexanes), THF, −78 °C, 1 h; (ii) reflux, 3 h (15%−33% for three steps); (d) **25**, CuI, Et_3N, $Pd(PPh_3)_4$, benzene, 40 °C, 3 h (91%−95%).



As described in the Biological activity section, the best inhibitor of 17β-HSD1 obtained amongst compounds **2**−**13** is the carboxylic acid derivative **5** with an alkyl-side-chain spacer of 13 methylenes. To improve its inhibitory potency, new inhibitors **14**−**16** were designed by changing the dis-

Scheme 4. Introduction of molecular diversity: synthesis of **2**−**13**. Reagents, conditions, and yields: (a) (i) HCl (4 mol/L in dioxane), DCM, MeOH, RT, 16 h; (ii) Cs_2CO_3, MeOH, 15 min; (b) 10% Pd/C, H_2, EtOAc, RT, 16 h (41%−66% for two steps); (c) HCl (1 N in H_2O), THF, reflux, 2 to 5 h (58%−91%); (d) $LiAlH_4$, THF, 0 °C, 4 to 16 h (45%−87%); (e) $LiAlH_4$, THF, 0 °C to RT, 2 to 16 h (80%); (f) CBr_4, PPh_3, DCM, 0 °C, 15 min to 4 h (70%); (g) CBr_4, $P(OMe)_3$, pyridine, RT, 3 h (82%); (h) HCl (4 mol/L in dioxane), DCM, MeOH, RT, 16 h; (i) 10% Pd/C, H_2, EtOAc, RT, 16 h (Bromide derivative: 25% for two steps); (j) 10% Pd/C, H_2, MeOH, RT, 16 h (Phosphotriester derivative: 35% for two steps).



tance between the carboxylic acid and the aryl group (m = 0−3). Two compounds, **17** and **18**, bearing only a carboxylic acid or an amino group were also prepared to complement our SAR study.

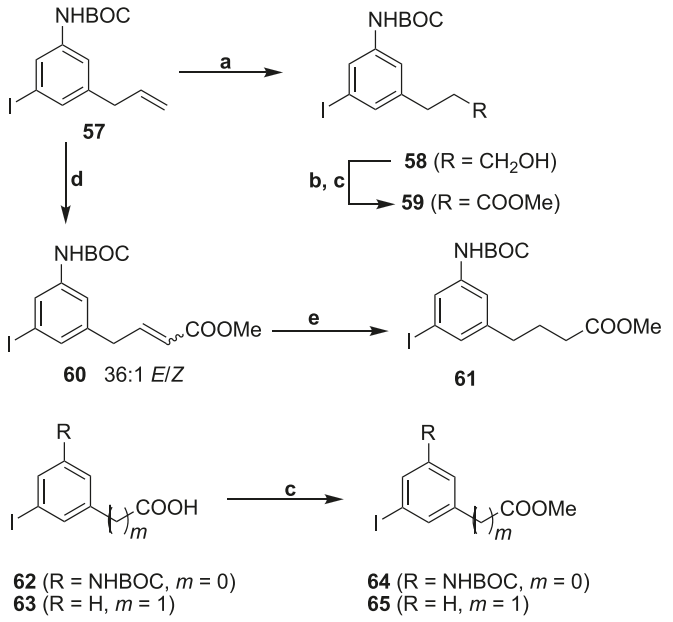
First of all, the new adenosine mimic template had to be synthesized (Scheme 5). Starting from **57**,[30] an intermediate in the synthesis of adenosine mimic **25**, ester **59** was synthesized in three steps. Oxidative hydroboration of olefin **57** afforded alcohol **58** in 74% yield. Oxidation with Jones' reagent, followed by esterification with (trimethylsilyl)diazomethane in MeOH, provided ester **59** in 76% yield for the two steps. Synthesis of ester **61** began with a cross-metathesis between olefin **57** and methyl acrylate used in large excess to obtain **60** in an excellent 87% yield. However, when hydrogenation catalyzed by Pd/C was used in EtOAc or MeOH, reduction of the olefin was not observed. Thus, hydrogenation catalyzed by PtO_2 in anhydrous THF was necessary to reduce the olefin and provide **61** in 93% yield. Esters **64** (m = 0) and **65** (m = 1, no amino group) were obtained by esterification of their corresponding carboxylic acids **62**[35,36] and **63**.

The synthesis of carboxylic acid derivatives **14**−**17** and aniline derivative **18** was achieved using a methodology similar to that used for the synthesis of **5**−**8** as summarized in Scheme 6. Briefly, a Sonogashira coupling of alkyne **45** with adenosine mimics **59**, **61**, and **64**−**66** afforded **67**−**71** in 66%−74% yields. Hydrolysis of protective groups (TBDMS, THP, and BOC) in acid conditions, followed by hydrogenation of the alkyne, afforded final compound **18** and esters **72**−**75**, which after hydrolysis with LiOH in refluxed acetone provided derivatives **14**−**17**. Control compound **79** that should only interact with the cofactor-binding site was also prepared as outlined in Scheme 7. This compound was synthesized easily using the same Sonogashira coupling strategy described above for the preparation of **5**−**8** and **14**−**18**. Final compounds **2**−**18** and **79**, which were needed for our SAR study, were carefully purified by flash column chromatography and fully characterized by IR, ^{1}H NMR, ^{13}C NMR, and HR-MS to validate their structure.

Biological activity

The inhibition of the transformation of [^{14}C]-E_1 (0.1 μmol/L) into [^{14}C]-E_2 by compounds **2**−**18** and **79** was evaluated with homogenated HEK-293 cells transfected with a vector encoding for 17β-HSD1.[37] NADH (0.1 mmol/L) was added as cofactor, and the enzymatic assay was performed at pH and temperature close to physiological conditions (pH = 7.4 and T = 37 °C). The first series of simplified hybrid inhibitors, compounds **2**−**13**, were tested at two concentrations: 0.1 and 1 μmol/L, and the results are presented

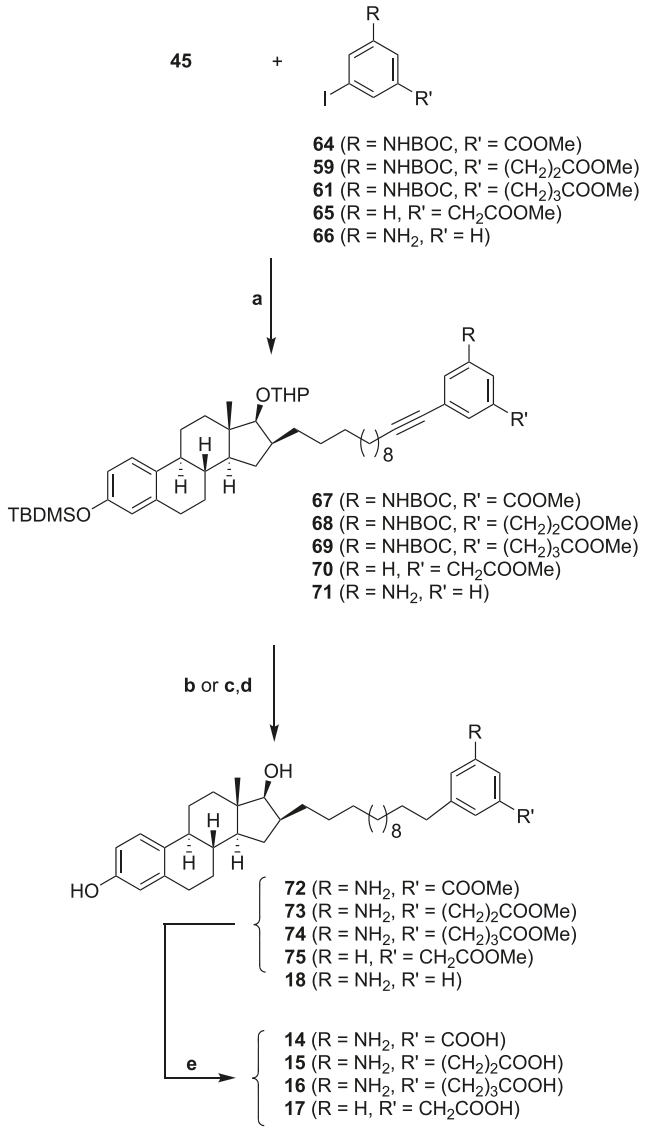
Scheme 5. Synthesis of new adenosine mimics **59**, **61**, **64**, and **65**. Reagents, conditions, and yields: (a) (i) BH_3·THF, THF, 0 °C, 3 h; (ii) NaOH (3 N in H_2O), H_2O_2 (30% *w*/*v*), 2 h, RT (74%); (b) Jones' reagent, acetone, 0 °C, 90 min; (c) $TMSCHN_2$ (2.0 mol/L in hexanes), MeOH, 0 °C, 10 min (**59**: 76% for two steps, **64**: 93%, **65**: 99%); (d) methyl acrylate, 2nd generation Grubbs' catalyst, DCM, reflux, 16 h (87%); (e) H_2, PtO_2, THF, RT, 16 h (93%).



in Table 1 as percentage of 17β-HSD1 inhibition or IC_{50} values (the concentration that inhibited 50% of enzyme activity).

Two points must be highlighted in these results. First, carboxylic acid derivatives **5**–**7** are by far the best inhibitors of that series with percentages of inhibition varying from 88% to 90% at 1 μmol/L. On the opposite, esters **2**–**4**, alcohols **9**–**11**, bromide **12**, and phosphotriester **13** presented almost no inhibition of 17β-HSD1. Second, varying the length of the alkyl-side-chain spacer had almost no effect on the inhibition of 17βHSD1. In fact, the inhibition of the enzyme by carboxylic derivatives **5**–**7** (from 13 to 15 methylenes) varied only from 88% to 90% at 1 μmol/L. To determine the optimal spacer length, a compound with a longer side-chain spacer (**8**, n = 17 methylenes) was prepared. As presented in Table 1, compound **5**, with an alkyl spacer of 13 methylenes, is the best inhibitor with an IC_{50} of 56 nmol/L. Compounds **6**–**8**, with spacers of 14, 15, or 17 methylenes, inhibit the enzyme slightly less effectively compared with compound **5** with IC_{50} of 83, 99, and 108 nmol/L, respectively. In fact, compound **5** is a better inhibitor than compounds **6**–**8** by less than twofold. These biological results confirm that the alkyl-side-chain spacer is very flexible and that its length may vary to a certain extent. However, shortening it too much would result in a huge drop of inhibition as was observed in the SAR study carried out to develop hybrid inhibitor EM-1745 (**1**).[22] In addition to its better inhibitory potency, a spacer of 13 methylenes was chosen to continue the SAR study because the synthesis of the aldehyde spacer **37** required only one synthetic step, as compared with three steps for the 14- and 15-methylene spacers (**38** and **39**, respectively) and four steps for the 17-methylene one (**40**).

Scheme 6. Synthesis of **14**–**18**. Reagents, conditions, and yields: (a) CuI, Et_3N, $Pd(PPh_3)_4$, benzene, 40 °C, 3 h (66%–74%); (b) HCl (4 mol/L in dioxane), DCM, MeOH, RT, 2 h (for **70**) or 16 h (for **67**–**69**); (c) HCl (5% *v*/*v* in MeOH), DCM, RT, 1 h (for **71**, 81%); (d) 10% Pd/C, H_2, EtOAc, RT, 16 h (**72**–**75**: 54%–75% for two steps, **18**: 67%); (e) LiOH (1 mol/L in H_2O), acetone, reflux, 1 h (66%–78%).



As presented above, carboxylic acid derivatives **5**–**8** give better inhibition than the other derivatives synthesized. To explain this result, speculation on the main interactions between inhibitor **5** and 17β-HSD1 was attempted. Starting from X-ray analysis of the crystallized EM-1745 (**1**)/17β-HSD1 complex,[23] we assumed that the E_2 moiety of **5** would form the same interactions with His221, Ser142, and Tyr155 as the E_2 moiety of EM-1745 (**1**) (see Figs. 2 and 3). Moreover, the amino and the carboxylic acid groups of compound **5** should, respectively, interact with Asp65 and Ser11 found in the cofactor-binding site, as observed for the adenosine moiety of EM-1745 (**1**). Furthermore, 17β-HSD1 prefers cofactor NADPH over NADH,[25] and the structural difference between these two entities is the presence of a phosphate

Scheme 7. Synthesis of monosubstrate compound **79**. Reagents, conditions, and yields (a) CuI, Et_3N, $Pd(PPh_3)_4$, benzene, 40 °C, 1 h (88%); (b) HCl (1 N in H_2O), THF, reflux, 4 h (94%); (c) 10% Pd/C, H_2, MeOH, RT, 16 h (75%).

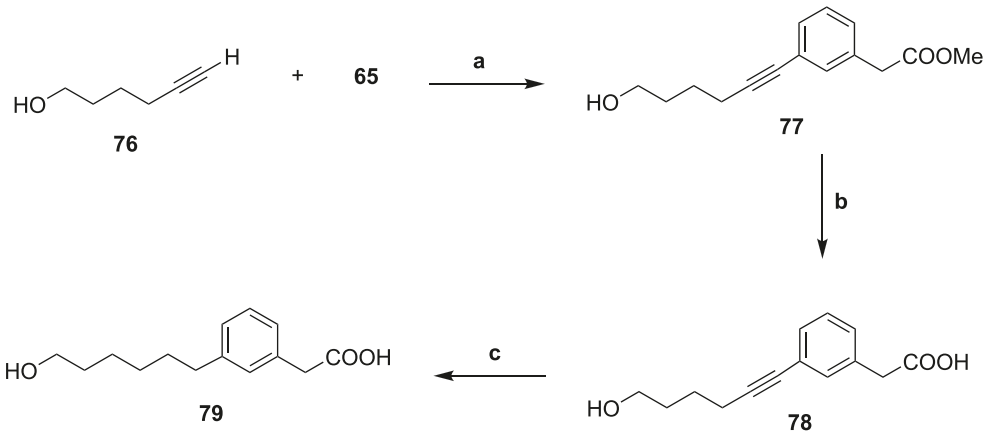


Table 1. Inhibition of 17β-HSD1 by simplified hybrid inhibitors **2**–**13** and known inhibitors.

			Inhibition (%)		
Compound	R	*n*	At 0.1 μmol/L	At 1 μmol/L	IC_{50} (nmol/L)

Note: Nd: not determined. For the transformation of [^{14}C]-E_1 (0.1 μmol/L) into [^{14}C]-E_2. The error for screening assay was ± 10%. See Experimental section for more details.

group on the adenosine C2′. Accordingly, NADPH was also crystallized with the enzyme, and X-ray analysis revealed that the phosphate group forms its main interactions with three amino acids: Ser11, Arg37, and Lys195.[38] The disappointing inhibitory activity obtained with the phosphate derivative **13** suggests no interaction between this dimethylated phosphate group and one of the three amino acids identified by X-ray analysis (Ser11, Arg37, and Lys195). Considering the best inhibition results provided by compounds **5**–**8**, the carboxylic acid probably interacts with at least one of these amino acids. This hypothesis remains however to be confirmed by docking studies, or better, by crystallization of compound **5** with 17β-HSD1.

To improve the interactions between the adenosine mimic part of **5** and the enzyme, we next undertook the optimization of the distance between the carboxylic acid (COOH) and the aniline moiety. Compounds **14**–**16** were then synthesized as described above (Schemes 5 and 6) with a spacer of 0 to 3 methylenes between the COOH group and the aryl moiety. Compounds **17** and **18**, bearing only one of the components, respectively, the carboxylic acid and the amino group, were also prepared. Compounds **5** and **14**–**18** were next tested to determine their potential to inhibit the 17β-HSD1 activity at 0.1 and 1 μmol/L, and the results are presented in Table 2. Compounds **5** and **14**–**16** gave almost the same percentages of inhibition with 22% to 29% and 89% to

Table 2. Inhibition of 17β-HSD1 by simplified hybrid inhibitors **5** and **14**–**18** and known inhibitors.

			Inhibition (%)

[a]Inhibition of compound **17** is statistically different ($P < 0.01$) from inhibition of compounds **5** and **14**–**16**.

92% at 0.1 and 1 μmol/L, respectively. Thus, the distance between the aryl group and the carboxylic acid did not affect the inhibition of 17β-HSD1. Compound **18**, which bears no carboxylic acid, gave, as expected, lower inhibition with, respectively, 5% and 66% at 0.1 and 1 μmol/L. However, with only a carboxylic acid on the aryl (no amino group), compound **17** gave a surprisingly higher inhibition with 49% and 92% at 0.1 and 1 μmol/L, respectively. This last result reveals that the positions of the carboxylic acid and the amino group are not optimal and, consequently, opens the door to additional optimization studies.

However, when simplified hybrid inhibitors are compared to the activity of EM-1745 (**1**), the inhibitory potency of carboxylic acid derivatives **5** and **14**–**17** was weaker at 0.1 μmol/L (22%–49% compared with 90% for **1**). To verify that our best simplified hybrid inhibitors, compounds **5** and **14**–**17**, kept their bisubstrate characteristics, compound **79**, which should interact only with the cofactor-binding site of the enzyme, was synthesized (Scheme 7) and tested as inhibitor of 17β-HSD1. The monosubstrate compound showed, as expected, almost no inhibition (30% at 1 μmol/L). When tested in the same conditions, the monosubstrate 16β-nonyl-E_2 gave the same results (no enzyme inhibition).[22] Furthermore, unlabeled E_1, which interacts only with the substrate-binding site, gave lower inhibition (60% at 1 μmol/L) than compounds **5** and **14**–**17** (89%–92% at 1 μmol/L). According to IC_{50} values (Table 1), inhibitor **5** (56 nmol/L) is only seven times less potent than EM-1745 (7.8 nmol/L), but four times more potent than EM-251 (239 nmol/L),[39] a known inhibitor of 17β-HSD1, and 15 times more potent than unlabeled E_1. Thus, **5** and **14**–**17** cause more interactions with the enzyme than E_1, and they should interact with both the substrate- and the cofactor-binding site of 17β-HSD1 as EM-1745 (**1**).

Conclusion

Two chemical approaches were investigated in the preparation of simplified hybrid inhibitors of 17β-HSD1 represented by compounds **2**–**18**. The first approach uses two olefin cross-metathesis reactions as key steps to join the steroid, the spacer, and the adenosine mimic, but failed to give satisfactory results because of the very low cross-metathesis yield for the coupling of the spacer and the adenosine mimic. However, the second approach, using an olefin cross-metathesis and a Sonogashira coupling as key steps, was more effective, giving a better coupling yield of the spacer to the adenosine mimic. Using this new approach, a series of steroid derivatives (compounds **2**–**18**) were synthesized as simplified hybrid inhibitors of 17β-HSD1. These compounds featured ester, carboxylic acid, alcohol, bromide, phosphotriester, and (or) amine as functional groups to interact with the cofactor-binding site, and an E_2 nucleus to bind in the substrate-binding site. Inhibitory potency of these compounds was tested on homogenated HEK-293 cells overexpressing 17β-HSD1 activity. Carboxylic acid derivatives **5**–**8** and **14**–**17** were found to be the best bisubstrate inhibitors of that group. A small effect on the inhibition was observed when varying the length of the alkyl-side-chain spacer between the steroid and the adenosine mimic (n = 13, 14, 15, and 17), but no effect was observed according to the length of the alkyl chain between the aryl and the carboxylic acid group (m = 0–3). The inhibition potency of carboxylic acid derivatives **5**–**8** and **14**–**17** was weaker than the potency of bisubstrate inhibitor EM-1745 (**1**), but higher than that of known inhibitors that interact only with one binding site like unlabeled E_1, EM-251, and **79**. In addition, even if compounds **5**–**8** and **14**–**17** are less potent than EM-1745, they should be more stable, since they have no ester group and no

ribose moiety. Furthermore, a better inhibition of 17β-HSD1 was surprisingly observed with compound **17** that contains only a carboxylic acid group (no amine) on the adenosine mimic. This result suggests that better hybrid inhibitors than **17** could be obtained with the optimization of the position of the carboxylic acid and the amino groups on the adenosine mimic. Docking studies using 3D structure of crystallized EM-1745/17β-HSD1 complex will be undertaken to achieve this task.

Experimental

General methods

Reagents were obtained from Sigma-Aldrich Canada Co. (Oakville, ON, Canada) except for 3-iodophenylacetic acid purchased from Matrix Scientific (Colombia, SC, USA). The tricyclohexylphosphine [1,3-bis(2,4,6-trimethylphenyl)-4,5-dihydroimidazol-2-ylidene] [benzylidine] ruthenium(IV)dichloride (2nd generation Grubbs' catalyst) was purchased from Strem Chemicals (Newburyport, MA, USA) and Sigma-Aldrich Canada Co. (Oakville, ON, Canada). Usual solvents were obtained from Fisher Scientific and VWR (Ville Mont-Royal, QC, Canada) and were used as received. Anhydrous solvents were purchased from Aldrich and VWR in SureSeal bottles, which were kept under positive argon pressure. Tetrahydrofuran (THF) was distilled from sodium/benzophenone under argon. All anhydrous reactions were performed under positive argon pressure in oven-dried glassware. Thin-layer chromatography (TLC) was performed on 0.25 mm silica gel 60 F_{254} plates (Whatman, Maidstone, UK), and compounds were visualized by exposure to UV light (254 nm) and (or) with a solution of ammonium molybdate/sulphuric acid/water (with heating). Flash chromatography was performed on Silicycle 60 (Quebec, QC, Canada) 230−400 mesh silica gel. IR spectra were obtained neat, from KBr pellets or from a thin film of the solubilized compound on NaCl pellets (usually in CH_2Cl_2). They were recorded on a PerkinElmer series 1600 FTIR spectrophotometer (Norwalk, CT, USA); only significant bands are reported (in cm^{-1}). ^1H and ^{13}C NMR spectra were recorded with a Bruker AC/F 300 spectrometer (Billerica, MA, USA) at 300 and 75 MHz, respectively, and a Bruker AVANCE 400 spectrometer at 400 (^1H) and 100 (^{13}C) MHz. The chemical shifts (δ) are expressed in ppm and referenced to chloroform (7.26 and 77.0 ppm), acetone (2.07 and 206.0 ppm), or methyl sulfoxide (2.51 and 39.5 ppm) for ^1H and ^{13}C, respectively. Duplication of ^1H NMR signals was observed for all THP derivatives (presence of two stereoisomers). Low-resolution mass spectra (LR-MS) were recorded with an LCQ Finnigan apparatus (San Jose, CA, USA) equipped with an atmospheric pressure chemical ionization (APCI) source on positive or negative mode. High-resolution mass spectra (HR-MS) were provided by the Regional Laboratory for Instrumental Analysis (Université de Montréal, Montréal, QC, Canada).

Synthesis of compound 27 using the first chemical approach

Synthesis of 9-decenyl methanesulfonate (21)

To a solution of 9-decen-1-ol (1.0 mL, 5.6 mmol) in anhydrous DCM (30 mL) under an argon atmosphere at 0 °C were added Et_3N (1.2 mL, 8.4 mmol) and methanesulfonyl chloride (0.48 mL, 6.2 mmol). The mixture was stirred for 15 min at 0 °C and extracted with DCM. The organic phase was washed with an aqueous solution of HCl (1 N) and brine, dried over $MgSO_4$, filtered, and evaporated to dryness. Purification by flash chromatography (hexanes/EtOAc, 8:2) afforded **21** (1.27 g, 97% yield) as a colourless oil. IR (neat) ν: 3075 (C−H, alkene), 1640 (C=C, alkene), 1355 and 1176 (O=S=O). ^1H NMR (400 MHz, $CDCl_3$) δ: 1.34 (m, 5 × CH_2), 1.73 (m, CH_2CH$_2$OS), 2.02 (m, CH_2CH=CH$_2$), 2.99 (s, CH_3), 4.20 (t, J = 6.6 Hz, CH_2OS), 4.95 (m, CH=CH_2), 5.79 (m, CH=CH$_2$). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 25.3, 28.7, 28.8 (2×), 29.0, 29.1, 33.6, 37.2, 70.1, 114.1, 139.0.

*Synthesis of 9-undecen-11-[3′-(***tert***-butyldimethylsilyloxy)-17′β-(tetrahydro-2***H***-pyran-2-yl-oxy)-estra-1′,3′,5′(10′)-trien-16′β-yl)-methanesulfonate (22)*

A mixture of 16β-allyl-estradiol (**19**)[27] (3.00 g, 5.87 mmol), 9-decenyl methanesulfonate (**21**) (2.75 g, 11.7 mmol), and 2nd generation Grubbs' catalyst (500 mg, 0.587 mmol) in dry DCM (100 mL) was refluxed for 16 h under an argon atmosphere. The crude mixture was preadsorbed on silica gel, and a flash chromatography was performed (hexanes/EtOAc, 9:1 to 8:2) to afford **22** (2.83 g, 67%) as a viscous yellowish oil. IR (film) ν: 1352 and 1174 (O=S=O). ^1H NMR (400 MHz, $CDCl_3$) δ: 0.18 (s, Si$(CH_3)_2$), 0.79 and 0.84 (2s, 18′-CH_3), 0.80 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 0.97 (s, SiC$(CH_3)_3$), 2.79 (m, 6′-CH_2), 3.01 (s, CH_3SO), 3.51 and 3.95 (2m, OCH_2 of THP), 3.72 and 3.79 (2d, J = 10.0 Hz, 17′α-CH), 4.23 (t, J = 6.6 Hz, CH_2SO), 4.64 and 4.74 (2m, CH of THP), 5.38 (m, CH=CH), 6.55 (s, 4′-CH), 6.61 (d, J = 8.2 Hz, 2′-CH), 7.11 (m, 1′-CH). LR-MS calculated for $C_{41}H_{69}O_6SSi$ $[M + H]^+$ 717.5, found 717.2 *m*/*z*.

*Synthesis of 13-[3′-(***tert***-butyldimethylsilyloxy)-17′β-(tetrahydro-2***H***-pyran-2-yl-oxy)-estra-1′,3′,5′(10′)-trien-16′β-yl)-tridecene (24)*

Hydrogenation

A suspension of steroid **22** (2.76 g, 3.85 mmol) and 10% Pd/C (414 mg) in EtOAc (150 mL) was stirred at room temperature under hydrogen atmosphere. After 16 h, the resulting suspension was filtered through a pad of Celite, and EtOAc was evaporated to dryness. ^1H NMR analysis of the crude mixture revealed the disappearance of alkene protons that were at 5.38 ppm.

Iodination

The crude product (2.72 g, 3.78 mmol) was dissolved in acetone (50 mL), and NaI (1.98 g, 13.2 mmol) was added. The reaction mixture was refluxed for 16 h. The product was then extracted with EtOAc, and the organic phase was washed with a saturated aqueous solution of $Na_2S_2O_3$ and washed with brine, dried over $MgSO_4$, filtered, and evaporated to dryness. Flash chromatography (hexanes/EtOAc, 95:5) afforded a mixture of **23** and 17β-OH form of **23** that was protected again as a THP derivative (dihydropyran, *p*-TSA, DCM, RT, 3 h) using a previously described procedure.[27] Then, **23** (2.12 g, 57% yield for three steps) was obtained as a white solid.

Vinylation

CuI (484 mg, 2.54 mmol) was suspended in anhydrous THF (5 mL) under an argon atmosphere. The mixture was cooled to −40 °C and vinylmagnesium bromide (1 mol/L in THF) (7.63 mL, 7.63 mmol) was added. The reaction was stirred for 15 min at −40 °C. Then, HMPA (0.880 mL, 5.08 mmol) and triethyl phosphite (0.880 mL, 5.08 mmol) were added, and the mixture was stirred for 5 min at −40 °C. **23** (1.91 g, 2.54 mmol) was added, and the reaction mixture was stirred for 1 h at −40 °C and for 2 h at room temperature. The reaction was quenched by the addition of a saturated solution of NH_4Cl. The crude product was extracted with EtOAc, washed with brine, dried over $MgSO_4$, filtered, and evaporated under reduced pressure.

Purification by flash chromatography (hexanes/EtOAc, 95:5) yielded **24** (1.48 g, 89% yield) as a colourless viscous oil. IR (film) ν: 1640 (C=C, alkene). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.18 (s, $Si(CH_3)_2$), 0.79 and 0.83 (2s, 18′-CH_3), 0.80 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 0.97 (s, $SiC(CH_3)_3$), 2.79 (m, 6′-CH_2), 3.52 and 3.95 (2m, OCH_2 of THP), 3.72 and 3.79 (2d, J = 9.6 Hz, 17′α-CH), 4.62 and 4.75 (2m, CH of THP), 4.97 (m, CH_2=CH), 5.81 (m, CH=CH_2), 6.55 (d, J = 2.2 Hz, 4′-CH), 6.60 (d, J = 8.3 Hz, 2′-CH), 7.11 (m, 1′-CH). LR-MS calculated for $C_{42}H_{71}O_3Si$ $[M + H]^+$ 651.5, found 651.3 *m*/*z*.

Synthesis of methyl 2-(3′-*tert*-butoxycarbonylamino-5′-vinylphenyl)-acetate (26)

To a solution of **25**[30] (800 mg, 2.04 mmol) in anhydrous toluene (68 mL) under an argon atmosphere were added tributyl(vinyl)tin (1.8 mL, 6.1 mmol) and $Pd(PPh_3)_2Cl_2$ (143 mg, 0.204 mmol). The reaction was stirred for 4 h at 75 °C and quenched by addition of H_2O. The product was extracted with EtOAc, and the organic phase was washed with brine, dried over $MgSO_4$, filtered, and evaporated to dryness. The crude product was purified by flash chromatography (hexanes/EtOAc, 9:1) to gain **26** (520 mg, 88% yield) as a yellowish oil. IR (film) ν: 3344 (NH, carbamate), 1728 (C=O, ester and carbamate). ^{1}H NMR (300 MHz, acetone-d_6) δ: 1.50 (s, $(CH_3)_3$C of *N*-BOC), 3.62 (s, CH_2COOCH_3), 3.65 (s, $COOCH_3$), 5.24 (d, J = 11.1 Hz, 1H of CH=CH_2), 5.78 (dd, J_1 = 17.6 Hz, J_2 = 1.1 Hz, 1H of CH=CH_2), 6.72 (dd, J_1 = 17.6 Hz, J_2 = 10.9 Hz, CH=CH_2), 7.05 (s, 6′-CH), 7.45 (s, 2′-CH), 7.59 (s, 4′-CH), 8.44 (s, NH). ^{13}C NMR (75 MHz, acetone-d_6) δ: 28.3 (3×), 41.2, 51.8, 79.8, 114.2, 115.1, 119.3, 122.0, 136.1, 137.5, 138.8, 140.8, 153.5, 171.9. LR-MS calculated for $C_{16}H_{20}NO_4^-$ $[M - H]^-$ 290.1, found 290.2 *m*/*z*.

Synthesis of methyl 2-{3′-(tert-butoxycarbonylamino)-5′-[13″-(3‴-(tert-butyldimethylsilyloxy)-17‴β-(tetrahydro-2H-pyran-2-yl-oxy)-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-tridecenyl]-phenyl}-acetate (27)

A mixture of steroid **24** (860 mg, 1.32 mmol), adenosine mimic **26** (500 mg, 1.71 mmol), and 2nd generation Grubbs' catalyst (112 mg, 0.132 mmol) in dry DCM (20 mL) was refluxed for 16 h under an argon atmosphere. The solvent was evaporated, and the crude product was purified by flash chromatography (hexanes/EtOAc, 97:3 to 93:7) to afford **27** (413 mg, 34% yield) as a white foam. IR (film) ν: 3364 (NH, carbamate), 1732 (C=O, ester and carbamate). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 0.18 (s, $Si(CH_3)_2$), 0.79 and 0.83 (2s, 18‴-CH_3), 0.80 to 2.30 (CH and CH_2 of steroid skeleton and alkyl chain), 0.97 (s, $SiC(CH_3)_3$), 1.51 (s, $(CH_3)_3$C of *N*-BOC), 2.78 (m, 6‴-CH_2), 3.52 and 3.96 (2m, OCH_2 of THP), 3.57 (s, CH_2COOCH_3), 3.68 (s, $COOCH_3$), 3.71 and 3.79 (2d, J = 10.2 Hz, 17‴α-CH), 4.62 and 4.75 (2m, CH of THP), 6.26 (m, CH=CH), 6.48 (s, NH), 6.55 (s, 4‴-CH), 6.60 (d, J = 8.3 Hz, 2‴-CH), 6.93 (s, 6′-CH), 7.12 (m, 1‴-CH, 2′-CH), 7.29 (s, 4′-CH). LR-MS calculated for $C_{56}H_{86}NO_4Si^-$ $[M - H]^-$ 912.6, found 912.5 *m*/*z*.

Synthesis of spacers 37–40

Synthesis of 13-bromo-10-tridecenol (30)

A mixture of 4-bromobutene (**28**) (3.0 mL, 29.6 mmol), 10-undecenol (**29**) (23.7 mL, 118 mmol), and the 2nd generation Grubbs' catalyst (1.25 g, 1.48 mmol) in dry DCM (200 mL) was refluxed for 3 days under an argon atmosphere. The crude mixture was purified by flash chromatography (hexanes/EtOAc, 8:2) to afford **30** (6.46 g, 80% yield) as a colourless oil. IR (neat) ν: 3365 (OH). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.25 (m, 6 × CH_2), 1.53 (m, CH_2CH_2OH), 1.97 (m, CH_2CH_2CH=CH), 2.02 (s, OH), 2.51 (q, J = 7.0 Hz, CH_2CH_2Br), 3.34 (m, CH_2Br), 3.59 (m, CH_2OH), 5.35 and 5.50 (2m, CH=CH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 25.6, 28.8, 29.0, 29.2, 29.3, 29.5, 32.4, 32.6, 32.9, 35.9, 62.8, 126.3, 133.9. LR-MS calculated for $C_{13}H_{26}BrO$ $[M + H]^+$ 277.1 and 279.1, found 276.9 and 278.9 *m*/*z*.

General procedure to synthesize 34–36

The iodination and vinylation procedures described above for the synthesis of **24** were used without modification except that 5 and 4 equiv. of vinylmagnesium bromide were used for the synthesis of **35** and **36**, respectively, instead of 3 equiv. It is noteworthy that alcohol **33** is commercially available.

11-Dodecenol (34)

We reported earlier the synthesis and characterization of **34**.[40]

12-Tridecenol (35)

Colourless oil (4.24 g, 71% yield for two steps). IR (neat) ν: 3355 (OH), 1641 (C=C, alkene). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.26 (m, 8 × CH_2), 1.55 (m, CH_2CH_2OH), 2.02 (m, CH_2CH=CH_2), 3.62 (t, J = 6.6 Hz, CH_2OH), 4.95 (m, CH=CH_2), 5.80 (m, CH=CH_2). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 25.7, 28.9, 29.1, 29.4, 29.5 (4×), 32.7, 33.8, 63.0, 114.0, 139.2.

Pentadeca-10,14-dien-1-ol (36)

Colourless oil (3.65 g, 70% yield for two steps). IR (neat) ν: 3332 (OH), 1641 (C=C, alkene). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.26 (m, 6 × CH_2), 1.54 (m, CH_2CH_2OH), 1.90 to 2.10 (m, 3 × CH_2CH=CH_2 and OH), 3.60 (t, J = 7.4 Hz, CH_2OH), 4.97 (m, CH=CH_2), 5.39 (m, CH=CH), 5.80 (m, CH=CH_2). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 25.7, 29.1, 29.4 (2×), 29.5 (2×), 31.9, 32.5, 32.7, 33.8, 62.8, 114.4, 129.3, 130.8, 138.4. LR-MS calculated for $C_{15}H_{29}O$ $[M + H]^+$ 225.2, found 225.1 *m*/*z*.

General procedure to synthesize 37–40

The TPAP oxidation procedure that we described previously for the synthesis of 10-undecenal (**37**)[30] was used without modification.

11-Dodecenal (38)

We reported earlier the synthesis and characterization of **38**.[40]

12-Tridecenal (39)

Colourless oil (2.66 g, 67% yield). IR (neat) ν: 2713 (C–H, aldehyde), 1728 (C=O, aldehyde), 1641 (C=C, alkene). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 1.25 (m, 7 × CH_2), 1.60 (m, CH_2CH$_2$CHO), 2.02 (m, CH_2CH=CH$_2$), 2.41 (dt, J_1 = 7.4 Hz, J_2 = 1.6 Hz, CH_2CHO), 4.95 (m, CH=CH_2), 5.78 (m, CH=CH$_2$), 9.74 (t, J = 1.6 Hz, CHO). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 22.0, 28.9, 29.1 (2×), 29.3, 29.4 (2×), 29.5, 33.8, 43.9, 114.1, 139.2, 203.0.

Pentadeca-10,14-dien-1-al (40)

Colourless oil (2.61 g, 74% yield). IR (neat) ν: 2715 (C–H, aldehyde), 1728 (C=O, aldehyde), 1640 (C=C, alkene). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.28 (m, 6 × CH_2), 1.61 (m, CH_2CH$_2$CHO), 1.90 to 2.10 (m, 3 × CH_2CH=), 2.41 (dt, J_1 = 7.4 Hz, J_2 = 1.6 Hz, CH_2CHO), 4.97 (m, CH=CH_2), 5.40 (m, CH=CH), 5.80 (m, CH=CH$_2$), 9.75 (t, J = 1.6 Hz, CHO). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 22.0, 29.0, 29.1, 29.2, 29.3, 29.5, 32.0, 32.5, 33.8, 43.9, 114.4, 129.4, 130.8, 138.5, 202.9.

Synthesis of 49–52 using the second chemical approach

General procedure to synthesize 45–48

The procedure that we described previously for the synthesis of **45** from **37**[30] was used without modification to prepare alkynes **46**, **47**, and **48**, from aldehydes **38**, **39**, and **40**, respectively.

14-[3′-(*tert*-butyldimethylsilyloxy)-17′β-(tetrahydro-2*H*-pyran-2-yl-oxy)-estra-1′,3′,5′(10′)-trien-16′β-yl]-tetradecyne (46)

Colourless viscous oil (801 mg, 15% yield for three steps). IR (film) ν: 3313 (C–H, alkyne). ^{1}H NMR (300 MHz, acetone-d_6) δ: 0.20 (s, Si(CH$_3$)$_2$), 0.82 and 0.86 (2s, 18′-CH$_3$), 0.99 (s, SiC(CH$_3$)$_3$), 0.80 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 2.18 (dt, J_1 = 6.8 Hz, J_2 = 2.5 Hz, CH$_2$C≡C), 2.33 (t, J = 2.7 Hz, C≡C–H), 2.83 (m, 6′-CH$_2$), 3.47 and 3.95 (2m, OCH$_2$ of THP), 3.74 and 3.79 (2d, J = 10.0 Hz, 17′α-CH), 4.63 and 4.73 (2m, CH of THP), 6.58 (s, 4′-CH), 6.63 (d, J = 8.8 Hz, 2′-CH), 7.15 and 7.17 (2d, J = 8.4 Hz, 1′-CH). LR-MS calculated for $C_{43}H_{71}O_3Si$ [M + H]$^+$ 663.5, found 663.3 *m*/*z*.

15-[3′-(*tert*-butyldimethylsilyloxy)-17′β-(tetrahydro-2*H*-pyran-2-yl-oxy)-estra-1′,3′,5′(10′)-trien-16′β-yl]-pentadecyne (47)

Colourless viscous oil (1.36 g, 33% yield for three steps). IR (film) ν: 3312 (C–H, alkyne). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.20 (s, Si(CH$_3$)$_2$), 0.82 and 0.87 (2s, 18′-CH$_3$), 1.00 (s, SiC(CH$_3$)$_3$), 0.90 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 2.18 (dt, J_1 = 6.8 Hz, J_2 = 2.6 Hz, CH$_2$C≡C), 2.33 (t, J = 2.6 Hz, C≡C-H), 2.81 (m, 6′-CH$_2$), 3.48 and 3.92 (2m, OCH$_2$ of THP), 3.74 and 3.80 (2d, J = 10.0 Hz, 17′α-CH), 4.63 and 4.73 (2m, CH of THP), 6.58 (d, J = 2.4 Hz, 4′-CH), 6.64 (d, J = 8.5 Hz, 2′-CH), 7.15 and 7.17 (2d, J = 5.7 Hz, 1′-CH). LR-MS calculated for $C_{44}H_{73}O_3Si$ [M + H]$^+$ 677.5, found 677.4 *m*/*z*.

17-[3′-(*tert*-butyldimethylsilyloxy)-17′β-(tetrahydro-2*H*-pyran-2-yl-oxy)-estra-1′,3′,5′(10′)-trien-16′β-yl]-heptadecyne (48)

Colourless viscous oil (636 mg, 24% yield for three steps). IR (film) ν: 3313 (C–H, alkyne). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.20 (s, Si(CH$_3$)$_2$), 0.82 and 0.87 (2s, 18′-CH$_3$), 1.00 (s, SiC(CH$_3$)$_3$), 0.90 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 2.18 (m, CH$_2$C≡C), 2.33 (t, J = 2.6 Hz, C≡C–H), 2.81 (m, 6′-CH$_2$), 3.48 and 3.92 (2m, OCH$_2$ of THP), 3.75 and 3.80 (2d, J = 10.0 Hz, 17′α-CH), 4.64 and 4.73 (2m, CH of THP), 6.58 (d, J = 2.3 Hz, 4′-CH), 6.64 (d, J = 8.4 Hz, 2′-CH), 7.15 and 7.17 (2d, J = 5.6 Hz, 1′-CH). LR-MS calculated for $C_{46}H_{77}O_3Si$ [M + H]$^+$ 705.6, found 705.5 *m*/*z*.

General procedure to synthesize 49–52

The procedure that we described previously for the synthesis of **49**[30] was used without modification for the synthesis of **50**–**52**. The chemical synthesis of **25** was also described in this earlier report.

Methyl 2-{3′-(*tert*-butoxycarbonylamino)-5′-[14″-(3‴-(*tert*-butyldimethylsilyloxy)-17‴β-(tetrahydro-2*H*-pyran-2-yl-oxy)-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-tetradecynyl]-phenyl}-acetate (50)

Viscous yellowish oil (540 mg, 61% yield (non-optimized)). IR (film) ν: 3354 (NH, carbamate), 1732 (C=O, ester and carbamate). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.20 (s, Si(CH$_3$)$_2$), 0.82 and 0.86 (2s, 18‴-CH$_3$), 1.00 (s, SiC(CH$_3$)$_3$), 1.50 (s, (CH$_3$)$_3$C of *N*-BOC), 1.00 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 2.42 (t, J = 6.9 Hz, CH$_2$–C≡C), 2.81 (m, 6‴-CH$_2$), 3.47 and 3.92 (2m, OCH$_2$ of THP), 3.60 (s, CH_2COOMe), 3.66 (s, COOCH$_3$), 3.74 and 3.79 (2d, J = 10.0 Hz, 17‴α-CH), 4.63 and 4.73 (2m, CH of THP), 6.58 (d, J = 2.0 Hz, 4‴-CH), 6.64 (d, J = 8.4 Hz, 2‴-CH), 6.97 (s, 6′-CH), 7.16 (m, 1‴-CH), 7.45 (s, 2′-CH), 7.58 (s, 4′-CH), 8.46 (s, NH). LR-MS calculated for $C_{57}H_{86}NO_7Si$ [M – H]$^-$ 924.6, found 924.5 *m*/*z*.

Methyl 2-{3′-(*tert*-butoxycarbonylamino)-5′-[15″-(3‴-(*tert*-butyldimethylsilyloxy)-17‴β-(tetrahydro-2*H*-pyran-2-yl-oxy)-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-pentadecynyl]-phenyl}-acetate (51)

White foam (1.41 g, 95% yield). IR (film) ν: 3353 (NH, carbamate), 1732 (C=O, ester and carbamate). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.20 (s, Si(CH$_3$)$_2$), 0.82 and 0.86 (2s, 18‴-CH$_3$), 1.00 (s, SiC(CH$_3$)$_3$), 1.50 (s, (CH$_3$)$_3$C of *N*-BOC), 1.00 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 2.42 (t, J = 7.0 Hz, CH$_2$–C≡C), 2.81 (m, 6‴-CH$_2$), 3.48 and 3.92 (2m, OCH$_2$ of THP), 3.60 (s, CH_2COOMe), 3.66 (s, COOCH$_3$), 3.73 and 3.79 (2d, J = 10.0 Hz, 17‴α-CH), 4.63 and 4.73 (2m, CH of THP), 6.58 (d, J = 2.2 Hz, 4‴-CH), 6.64 (d, J = 8.4 Hz, 2‴-CH), 6.97 (s, 6′-CH), 7.16 (m, 1‴-CH), 7.45 (s, 2′-CH), 7.58 (s, 4′-CH), 8.48 (s, NH). LR-MS calculated for $C_{58}H_{88}NO_7Si$ [M – H]$^-$ 938.6, found 938.5 *m*/*z*.

Methyl 2-{3′-(tert-butoxycarbonylamino)-5′-[17″-(3‴-(tert-butyldimethylsilyloxy)-17‴β-(tetrahydro-2H-pyran-2-yloxy)-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-heptadecynyl]-phenyl}-acetate (52)

Yellowish foam (219 mg, 91% yield). IR (film) ν: 3356 (NH, carbamate), 1736 (C=O, ester and carbamate). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.20 (s, Si(CH$_3$)$_2$), 0.82 and 0.86 (2s, 18‴-CH$_3$), 1.00 (s, SiC(CH$_3$)$_3$), 1.49 (s, (CH$_3$)$_3$C of *N*-BOC), 1.00 to 2.35 (CH and CH$_2$ of steroid skeleton and alkyl chain), 2.43 (t, J = 6.9 Hz, CH$_2$−C≡C), 2.81 (m, 6‴-CH$_2$), 3.48 and 3.91 (2m, OCH$_2$ of THP), 3.61 (s, C*H*$_2$COOMe), 3.66 (s, COOCH$_3$), 3.74 and 3.79 (2d, J = 10.0 Hz, 17‴α-CH), 4.63 and 4.73 (2m, CH of THP), 6.58 (d, J = 2.3 Hz, 4‴-CH), 6.64 (d, J = 8.5 Hz, 2‴-CH), 6.97 (s, 6′-CH), 7.16 (m, 1‴-CH), 7.45 (s, 2′-CH), 7.58 (s, 4′-CH), 8.49 (s, NH). LR-MS calculated for $C_{60}H_{92}NO_7Si$ [M − H]$^-$ 966.7, found 966.5 *m*/*z*.

Introduction of molecular diversities: synthesis of 2−13

General procedure to synthesize ester derivatives 2−4 and 53

Esters **2**−**4** and **53** were synthesized in two steps from **49**−**52**. The first step is an acid treatment to remove the three protective groups, and the second is the hydrogenation of alkyne catalyzed by palladium. The procedure that we described previously for the synthesis of **2**[30] was used without modification except that 8 equiv. of HCl (4 mol/L) in dioxanes were used for the synthesis of **3**, **4**, and **53** instead of 4 equiv.

Methyl 2-{3′-amino-5′-[14″-(3‴,17‴β-dihydroxy-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-tetradecyl]-phenyl}-acetate (3)

Colourless viscous oil (83 mg, 62% yield for two steps). IR (film) ν: 3372 (OH and NH$_2$), 1732 (C=O, ester). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.80 (s, 18‴-CH$_3$), 0.95 to 2.35 (CH and CH$_2$ of steroid skeleton and alkyl chain), 2.45 (t, J = 7.4 Hz, 1″-CH$_2$), 2.78 (m, 6‴-CH$_2$), 3.44 (s, C*H*$_2$COOMe), 3.62 (m, COOCH$_3$, 17‴β-OH), 3.74 (dd, J_1 = 9.7 Hz, J_2 = 5.7 Hz, 17‴α-CH), 4.53 (s, NH$_2$), 6.37 (s, 6′-CH), 6.42 (s, 2′-CH and 4′-CH), 6.54 (d, J = 2.5 Hz, 4‴-CH), 6.60 (dd, J_1 = 8.4 Hz, J_2 = 2.6 Hz, 2‴-CH), 7.10 (d, J = 8.4 Hz, 1‴-CH), 8.06 (s, 3‴-OH). ^{13}C NMR (75 MHz, acetone-d_6) δ: 12.7, 26.8, 28.0, 28.7 to 30.2 (11C under solvent peaks), 30.4, 31.8, 32.3, 33.0, 36.2, 38.3, 39.1, 40.9, 41.2, 44.5 (2×), 49.2, 51.5, 81.9, 113.1 (2×), 113.6, 115.5, 118.4, 126.6, 131.7, 135.3, 138.0, 144.0, 148.8, 155.5, 172.1. HR-MS calculated for $C_{41}H_{62}NO_4$ [M + H]$^+$ 632.46734, found 632.46636 *m*/*z*.

Methyl 2-{3′-amino-5′-[15″-(3‴,17‴β-dihydroxy-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-pentadecyl]-phenyl}-acetate (4)

Colourless viscous oil (115 mg, 53% yield for two steps). IR (film) ν: 3376 (OH and NH$_2$), 1734 (C=O, ester). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.80 (s, 18‴-CH$_3$), 0.95 to 2.35 (CH and CH$_2$ of steroid skeleton and alkyl chain), 2.46 (t, J = 7.5 Hz, 1″-CH$_2$), 2.78 (m, 6‴-CH$_2$), 3.44 (s, C*H*$_2$COOMe), 3.56 (d, J = 5.4 Hz, 17‴β-OH), 3.62 (s, COOCH$_3$), 3.74 (dd, J_1 = 9.8 Hz, J_2 = 5.4 Hz, 17‴α-CH), 4.53 (s, NH$_2$), 6.37 (s, 6′-CH), 6.42 (s, 2′-CH and 4′-CH), 6.54 (d, J = 2.6 Hz, 4‴-CH), 6.60 (dd, J_1 = 8.4 Hz, J_2 = 2.6 Hz, 2‴-CH), 7.11 (d, J = 8.4 Hz, 1‴-CH), 7.97 (s, 3‴-OH). ^{13}C NMR (100 MHz, acetone-d_6) δ: 13.0, 27.1, 28.2, 29.1 to 30.3 (12C under solvent peaks), 30.6, 32.0, 32.5, 33.2, 36.4, 38.6, 39.4, 41.2, 41.5, 44.79, 44.82, 49.5, 51.7, 82.2, 113.4, 113.8, 115.8, 118.7, 124.5, 126.8, 132.0, 135.6, 138.2, 144.3, 149.1, 155.7, 172.2. HR-MS calculated for $C_{42}H_{64}NO_4$ [M + H]$^+$ 646.48299, found 646.48402 *m*/*z*.

Methyl 2-{3′-amino-5′-[17″-(3‴,17‴β-dihydroxy-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-heptadecyl]-phenyl}-acetate (53)

Yellowish viscous oil (61 mg, 41% yield for two steps). IR (film) ν: 3376 (OH and NH$_2$), 1732 (C=O, ester). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.80 (s, 18‴-CH$_3$), 0.95 to 2.35 (CH and CH$_2$ of steroid skeleton and alkyl chain), 2.46 (t, J = 7.5 Hz, 1″-CH$_2$), 2.78 (m, 6‴-CH$_2$), 3.45 (s, C*H*$_2$COOMe), 3.54 (d, J = 5.4 Hz, 17‴β-OH), 3.62 (s, COOCH$_3$), 3.72 (dd, J_1 = 9.8 Hz, J_2 = 5.5 Hz, 17‴α-CH), 4.54 (s, NH$_2$), 6.37 (s, 6′-CH), 6.41 and 6.42 (2s, 2′-CH and 4′-CH), 6.54 (d, J = 2.5 Hz, 4‴-CH), 6.60 (dd, J_1 = 8.4 Hz, J_2 = 2.6 Hz, 2‴-CH), 7.11 (d, J = 8.4 Hz, 1‴-CH), 7.96 (s, 3‴-OH). ^{13}C NMR (100 MHz, acetone-d_6) δ: 12.9, 27.1, 28.2, 29.1 to 30.3 (14C under solvent peaks), 30.6, 32.1, 32.5, 33.2, 36.4, 38.6, 39.4, 41.2, 41.4, 44.77, 44.81, 49.4, 51.7, 82.1, 113.3, 113.4, 113.8, 115.8, 118.6, 126.9, 132.0, 135.6, 138.3, 144.3, 149.2, 155.7, 172.2. General procedure to synthesize alcohol derivatives 9−11

The procedure that we described previously for the synthesis of **9**[30] was used without modification for the synthesis of **9**−**11** except that 1.1 to 3 equiv. of $LiAlH_4$ were used. Completion of the reaction was monitored by TLC (4 to 16 h).

2-{3′-Amino-5′-[14″-(3‴,17‴β-dihydroxy-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-tetradecyl]-phenyl}-ethyl alcohol (10)

Yellowish foam (15 mg, 45% yield). IR (film) ν: 3400 (OH and NH_2). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.79 (s, 18‴-CH_3), 0.75 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 2.44 (t, J = 7.7 Hz, 1″-CH_2), 2.65 (t, J = 7.3 Hz, CH_2CH$_2$OH), 2.79 (m, 6‴-CH_2), 3.58 (m, 17‴β-OH and CH$_2$OH), 3.70 (m, CH_2OH and 17‴α-CH), 4.44 (s_{br}, NH_2), 6.32 (s, 6′-CH), 6.36 (s, 2′-CH and 4′-CH), 6.54 (d, J = 2.5 Hz, 4‴-CH), 6.60 (dd, J_1 = 8.4 Hz, J_2 = 2.6 Hz, 2‴-CH), 7.11 (d, J = 8.4 Hz, 1‴-CH), 8.01 (s, 3‴-OH). ^{13}C NMR (75 MHz, acetone-d_6) δ: 12.9, 27.1, 28.2, 28.9 to 30.4 (11C under solvent peaks), 32.1, 32.5, 33.2, 36.3, 36.5, 38.5, 39.3, 40.2, 41.2, 44.8 (2×), 49.4, 63.8, 82.1, 113.4, 115.7, 117.7, 118.0, 124.2, 126.8, 132.0, 138.2, 140.7, 143.9, 152.6, 155.7. HR-MS calculated for $C_{40}H_{62}NO_3$ $[M + H]^+$ 604.47242, found 604.47243 *m*/*z*.

2-{3′-Amino-5′-[15″-(3‴,17‴β-dihydroxy-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-pentadecyl]-phenyl}-ethyl alcohol (11)

Colourless viscous oil (25 mg, 61% yield). IR (film) ν: 3354 (OH and NH_2). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.80 (s, 18‴-CH_3), 0.85 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 2.44 (t, J = 7.7 Hz, 1″-CH_2), 2.65 (t, J = 7.3 Hz, CH_2CH$_2$OH), 2.78 (m, 6‴-CH_2), 3.57 (m, 17‴β-OH and CH$_2$OH), 3.71 (m, CH_2OH and 17‴α-CH), 4.43 (s_{br}, NH_2), 6.33 (s, 6′-CH), 6.36 (s, 2′-CH and 4′-CH), 6.54 (d, J = 2.5 Hz, 4‴-CH), 6.60 (dd, J_1 = 8.4 Hz, J_2 = 2.6 Hz, 2‴-CH), 7.11 (d, J = 8.5 Hz, 1‴-CH), 7.97 (s, 3‴-OH). ^{13}C NMR (100 MHz, acetone-d_6) δ: 13.0, 27.2, 28.3, 29.1 to 30.3 (11C under solvent peaks), 30.4, 30.7, 32.4, 32.6, 33.3, 36.6, 38.7, 39.5, 40.5, 41.3, 44.88, 44.92, 49.6, 64.1, 82.3, 113.2, 113.4, 113.5, 115.9, 118.7, 126.9, 132.1, 138.3, 140.6, 144.1, 149.0, 155.8. HR-MS calculated for $C_{41}H_{64}NO_3$ $[M + H]^+$ 618.48807, found 618.48783 *m*/*z*.

*Synthesis of 2-{3′-(***tert***-butoxycarbonylamino)-5′-[13″-(3‴-(***tert***-butyldimethylsilyloxy)-17‴β-(tetrahydro-2***H***-pyran-2-yl-oxy)-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-tridecynyl]-phenyl}-ethyl alcohol (54)*

The procedure that we described previously for the synthesis of **9**[30] was used without modification except that 1.2 equiv. of $LiAlH_4$ were used instead of 1 equiv. Purification by flash chromatography using hexanes/EtOAc (8:2) as eluent afforded **54** as white foam (491 mg, 80% yield). IR (film) ν: 3340 (OH and NH carbamate), 1718 (C=O, carbamate). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.21 (s, Si(CH$_3$)$_2$), 0.82 and 0.86 (2s, 18‴-CH_3), 1.00 (s, SiC(CH$_3$)$_3$), 0.95 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 1.49 (s, (CH$_3$)$_3$C of *N*-BOC), 2.42 (t, J = 7.0 Hz, CH$_2$−C≡C), 2.75 (t, J = 6.7 Hz, CH_2CH$_2$OH), 2.81 (m, 6‴-CH_2), 3.48 and 3.91 (2m, OCH$_2$ of THP), 3.74 (m, 17‴α-CH and CH_2OH), 4.63 and 4.73 (2m, CH of THP), 6.58 (d, J = 2.3 Hz, 4‴-CH), 6.64 (d, J = 8.4 Hz, 2‴-CH), 6.92 (s, 6′-CH), 7.16 (2d, J = 5.8 Hz, 1‴-CH), 7.37 (s, 2′-CH), 7.53 (s, 4′-CH), 8.39 (s_{br}, NH). LR-MS calculated for $C_{55}H_{84}NO_6Si$ $[M - H]^-$ 882.6, found 882.6 *m*/*z*.

*Synthesize of 2-{3′-(***tert***-butoxycarbonylamino)-5′-[13″-(3‴-(***tert***-butyldimethylsilyloxy)-17‴β-(tetrahydro-2***H***-pyran-2-yl-oxy)-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-tridecynyl]-phenyl}-ethyl bromide (55)*

To a solution of alcohol **54** (150 mg, 0.172 mmol) in anhydrous DCM under an argon atmosphere at 0 °C were added PPh_3 (90 mg, 0.344 mmol) and CBr_4 (114 mg, 0.344 mmol). The reaction mixture was stirred for 3.5 h at 0 °C. Then, a saturated aqueous solution of $NaHCO_3$ was added to quench the reaction, and the product was extracted with DCM. The organic phases were washed with brine, dried over $MgSO_4$, filtered, and evaporated to dryness. The crude product was purified by flash chromatography (hexanes/EtOAc, 8:2) to afford a mixture of the desired, deprotected form of **55** (113 mg, 70% yield). Desired product **55** was collected with its deprotected form (without THP) as a minor compound produced during this bromination reaction, since the next step was to hydrolyze protective groups under acid conditions. Only the characterization of the major compound **55** is described. Colourless viscous oil (113 mg, 70%

yield). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.21 (s, $Si(CH_3)_2$), 0.82 and 0.86 (2s, 18‴-CH_3), 0.85 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 1.00 (s, $SiC(CH_3)_3$), 1.50 (s, $(CH_3)_3C$ of *N*-BOC), 2.43 (t, *J* = 7.0 Hz, $CH_2-C\equiv C$), 2.81 (m, 6‴-CH_2), 3.12 (t, *J* = 7.3 Hz, CH_2CH_2Br), 3.47 and 3.92 (2m, OCH_2 of THP), 3.68 (t, *J* = 7.4 Hz, CH_2Br), 3.73 and 3.79 (2d, *J* = 9.9 Hz, 17‴α-CH), 4.63 and 4.73 (2m, CH of THP), 6.58 (d, *J* = 2.4 Hz, 4‴-CH), 6.64 (d, *J* = 8.5 Hz, 2‴-CH), 6.97 (s, 6′-CH), 7.15 (m, 1‴-CH), 7.42 (s, 2′-CH), 7.57 (s, 4′-CH), 8.46 (s_{br}, NH).

*Synthesize of dimethyl 2-{3′-(***tert***-butoxycarbonylamino)-5′-[13″-(3‴-(***tert***-butyldimethylsilyloxy)-17‴β-(tetrahydro-2***H***-pyran-2-yl-oxy)-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-tridecynyl]-phenyl}-ethyl phosphate (56)*

In a round-bottom flask, alcohol **54** (300 mg, 0.345 mmol) and CBr_4 (171 mg, 0.517 mmol) were purged under an argon atmosphere for 10 min. Then, pyridine (2.3 mL) and $P(OMe)_3$ (163 μL, 1.38 mmol) were added. The reaction mixture was stirred for 3 h at room temperature. Then, the product was extracted with EtOAc. The organic phase was washed with an aqueous solution of $CuSO_4$ 1 mol/L and re-extracted with EtOAc. The combined organic phases were washed with H_2O and brine, dried over $MgSO_4$, filtered, and evaporated to dryness. Purification by flash chromatography (hexanes/EtOAc, 6:4) provided **56** (275 mg, 82% yield) as a yellowish solid. IR (film) ν: 3284 (NH carbamate), 1727 (C=O, carbamate). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.20 (s, $Si(CH_3)_2$), 0.82 and 0.86 (2s, 18‴-CH_3), 1.00 (s, $SiC(CH_3)_3$), 0.95 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 1.49 (s, $(CH_3)_3C$ of *N*-BOC), 2.42 (t, *J* = 6.9 Hz, $CH_2-C\equiv C$), 2.81 (m, 6‴-CH_2), 2.95 (t, *J* = 6.7 Hz, $CH_2CH_2OP(O)(OMe)_2$), 3.48 and 3.91 (2m, OCH_2 of THP), 3.67 (d, $^3J_{PH}$ = 11.1 Hz, 2 × OMe), 3.74 and 3.79 (2d, *J* = 9.8 Hz, 17‴α-CH), 4.23 (q, *J* = 7.0 Hz, $CH_2CH_2O-P(O)(OMe)_2$), 4.63 and 4.73 (2m, CH of THP), 6.58 (d, *J* = 2.1 Hz, 4‴-CH), 6.64 (d, *J* = 8.4 Hz, 2‴-CH), 6.98 (s, 6′-CH), 7.16 (m, 1‴-CH), 7.44 (s, 2′-CH), 7.56 (s, 4′-CH), 8.48 (s, NH). LR-MS calculated for $C_{57}H_{90}NO_9PSiNa$ $[M + Na]^+$ 1014.6, found 1014.5 *m*/*z*.

Synthesize of 2-{3′-amino-5′-[13″-(3‴,17‴β-dihydroxy-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-tridecyl]-phenyl}-ethyl bromide (12)

Deprotection

A solution of **55** (80 mg, 0.086 mmol) in dry DCM (0.5 mL) and dry MeOH (0.5 mL) under an argon atmosphere was treated with HCl (4 mol/L in dioxane) (160−255 μL, 0.858 mmol). The resulting mixture was stirred at room temperature for 16 h. The reaction was quenched by addition of a saturated aqueous $NaHCO_3$ solution, and extraction was performed with DCM. The organic phase was washed with brine, dried over $MgSO_4$, filtered, and evaporated to dryness under reduced pressure. Purification of the crude product by flash chromatography (hexanes/EtOAc, 8:2) afforded a mixture of the desired products (NH_2) and its salt (NH_2·HCl).

Hydrogenation

To a solution of the deprotected form of alkyne **55** (35 mg, 0.054 mmol) in EtOAc (2 mL) was added 10% Pd/C (7 mg). This mixture was stirred for 16 h under a hydrogen atmosphere at room temperature. The resulting suspension was filtered through Celite, washed with EtOAc, and the filtrate was evaporated to dryness. The crude compound was purified by flash chromatography (hexanes/EtOAc, 8:2 to 7:3) to provide a mixture of bromide derivative **12** and its salt (NH_2·HCl). White foam (12 mg, 25% yield for two steps). IR (film) ν: 3356 (OH and NH_2). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.80 (s, 18‴-CH_3), 1.00 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 2.46 and 2.58 (2t, *J* = 7.7 Hz, 1″-CH_2), 2.77 (m, 6‴-CH_2), 2.99 and 3.11 (2t, *J* = 7.6 Hz, CH_2CH_2Br), 3.56 (s_{br}, 17‴β-OH), 3.60 and 3.68 (2t, *J* = 7.6 Hz, CH_2Br), 3.73 (d, *J* = 9.2 Hz, 17‴α-CH), 6.40 (m, 2′-CH, 4′-CH and 6′-CH), 6.54 (s, 4‴-CH), 6.60 (d, *J* = 8.4 Hz, 2‴-CH), 6.83 (s, NH_2), 7.11 (d, *J* = 8.5 Hz, 1‴-CH), 7.98 (s, 3‴-OH). ^{13}C NMR (75 MHz, acetone-d_6) δ: 12.9, 27.1, 28.2, 28.9 to 30.4 (10C under solvent peaks), 30.5, 32.0, 32.5, 33.2, 34.1, 36.2, 38.5, 39.3, 39.7, 41.2, 44.76, 44.81, 49.4, 82.1, 113.3, 115.7, 117.9, 118.7, 124.2, 126.9, 132.0, 138.3, 140.4, 144.4, 146.4, 155.7. HR-MS calculated for $C_{39}H_{59}BrNO_2$ $[M + H]^+$ 652.37237, found 652.37128 *m*/*z*.

Synthesize of dimethyl 2-{3′-amino-5′-[13″-(3‴, 17‴β-dihydroxy-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-tridecyl]-phenyl}-ethyl phosphate (13)

The procedure described above for the synthesis of **12** was used without modification except that MeOH was used as solvent in the hydrogenation step instead of EtOAc. Deprotected form of **56** and phosphotriester derivatives were purified by flash chromatography using hexanes/EtOAc (2:8) followed by DCM/MeOH (97:3) as eluent. Compound **13** was obtained as a mixture with its salt (NH_2·HCl). Yellowish foam (22 mg, 35% yield for two steps). IR (film) ν: 3364 (OH and NH_2). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.80 (s, 18‴-CH_3), 0.85 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 2.46 and 2.57 (2t, *J* = 7.7 Hz, 1″-CH_2), 2.78 (m, 6‴-CH_2), 2.83 and 2.94 (2t, *J* = 6.8 Hz, $CH_2CH_2OP(O)(OMe)_2$), 3.65 (d, $^3J_{PH}$ = 11.1 Hz, 2 × OMe), 3.72 (d, *J* = 9.8 Hz, 17‴α-CH), 4.18 and 4.21 (2q, *J* = 7.1 Hz, $CH_2OP(O)(OMe)_2$), 6.40 (m, 2′-CH, 4′-CH and 6′-CH), 6.54 (s, 4‴-CH), 6.60 (d, *J* = 8.4 Hz, 2‴-CH), 6.81 (s, NH_2), 7.11 (d, *J* = 8.4 Hz, 1‴-CH). ^{13}C NMR (100 MHz, acetone-d_6) δ: 13.0, 27.2, 28.3, 29.1 to 30.3 (10C under solvent peaks), 30.6, 32.1, 32.6, 33.3, 36.3, 37.2, 38.7, 39.5, 41.3, 44.86, 44.92, 49.6, 54.15, 54.22, 68.5 (68.6), 82.1, 113.4, 115.8, 118.2, 118.4, 124.4, 126.9, 132.1, 138.3, 138.9, 144.4, 151.8, 155.8. HR-MS calculated for $C_{41}H_{65}NO_6P$ $[M + H]^+$ 698.45440, found 698.45359 *m*/*z*.

Synthesis of new adenosine mimics 59, 61, 64, and 65

*Synthesis of 3-(3′-***tert***-butoxycarbonylamino-5′-iodophenyl)-propanol (58)*

To a solution of alkene **57**[30] (100 mg, 0.278 mmol) in anhydrous THF (3 mL) under an argon atmosphere at 0 °C was added BH_3·THF (1.0 mol/L in THF, 0.64 mL, 0.64 mmol). The mixture was stirred 3 h at 0 °C. Then, 3 N aqueous NaOH (0.23 mL, 0.695 mmol) and 30% (*w*/*v*) hydrogen peroxide (0.17 mL, 1.53 mmol) were added. After 2 h at room temperature, the reaction was quenched with water, and extraction was performed with EtOAc. The organic phase was

washed with brine, dried over $MgSO_4$, filtered, and evaporated to dryness. The crude product was purified by flash chromatography (hexanes/EtOAc, 6:4) to give 77 mg (74% yield) of the desired alcohol **58** as a white foam. IR (film) ν: 3316 (OH and NH carbamate), 1700 (C=O carbamate). ^{1}H NMR (400 MHz, acetone-d_6) δ: 1.49 (s, $(CH_3)_3C$ of *N*-BOC), 1.80 (m, CH_2CH_2OH), 2.64 (t, J = 7.5 Hz, $CH_2CH_2CH_2OH$), 3.58 (m, CH_2OH), 3.67 (t, J = 5.4 Hz, OH), 7.25 (s, 6′-CH), 7.40 (s, 2′-CH), 7.90 (s, 4′-CH), 8.49 (s, NH). ^{13}C NMR (75 MHz, acetone-d_6) δ: 28.2 (3×), 32.2, 34.9, 61.3, 80.1, 94.4, 118.2, 124.7, 131.8, 141.6, 146.1, 153.2. LR-MS calculated for $C_{14}H_{19}INO_3$ $[M - H]^-$ 376.0, found 375.9 *m/z*.

*Synthesis of methyl 3-(3′-***tert***-butoxycarbonylamino-5′-iodophenyl)-propanoate (59)*

Oxidation

To a solution of alcohol **58** (329 mg, 0.872 mmol) in acetone (44 mL) was added dropwise Jones' reagent (0.48 mL of a $CrO_3 \cdot H_2SO_4$, 2.7 mol/L solution) at 0 °C, and the reaction mixture was stirred for 90 min. Then, 2-propanol (few drops) and brine were added. Acetone was partially evaporated under reduced pressure, the mixture was extracted with EtOAc. The organic phase was dried over $MgSO_4$, filtered, and evaporated to dryness.

Esterification

The crude acid was dissolved in anhydrous MeOH (9 mL) under an argon atmosphere at 0 °C. $TMSCHN_2$ (2.0 mol/L in hexanes, 2.6 mL, 5.2 mmol) was added slowly, and the mixture was stirred for 10 min at 0 °C. Then, MeOH was removed under reduced pressure. The crude product was purified by flash chromatography (hexanes/EtOAc, 9:1) to afford ester **59** (269 mg, 76% yield for two steps) as a white foam. IR (film) ν: 3339 (NH, carbamate), 1725 (C=O, ester and carbamate). ^{1}H NMR (400 MHz, acetone-d_6) δ: 1.49 (s, $(CH_3)_3C$ of *N*-BOC), 2.63 (t, J = 7.6 Hz, CH_2COOMe), 2.86 (t, J = 7.6 Hz, CH_2CH_2COOMe), 3.63 (s, $COOCH_3$), 7.29 (s, 6′-CH), 7.40 (s, 2′-CH), 7.93 (s, 4′-CH), 8.49 (s, NH). ^{13}C NMR (75 MHz, acetone-d_6) δ: 28.3 (3×), 30.9, 35.5, 51.5, 80.3, 94.5, 118.2, 125.3, 131.8, 141.8, 144.5, 153.3, 173.0. LR-MS calculated for $C_{15}H_{19}INO_4$ $[M - H]^-$ 404.0, found 403.9 *m/z*.

*Synthesis of methyl 4-(3′-***tert***-butoxycarbonylamino-5′-iodophenyl)-2-butenoate (60)*

Alkene **57**[30] (500 mg, 1.39 mmol) was dissolved in anhydrous DCM (23 mL) under an argon atmosphere. Methyl acrylate (2.5 mL, 27.8 mmol) and the 2nd generation Grubbs' catalyst (118 mg, 0.139 mmol) were added. The reaction mixture was refluxed for 16 h. Then, DCM was removed under reduced pressure, and the crude product was purified by flash chromatography (hexanes/EtOAc, 9:1) to yield **60** (505 mg, 87% yield, 36:1 *E*/*Z* as determined by integration of peaks at 5.91 and 6.02 ppm in the ^{1}H NMR spectrum) as a white amorphous solid. IR (film) ν: 3335 (NH, carbamate), 1700 (C=O, conjugated ester and carbamate), 1654 (C=C, conjugated alkene). ^{1}H NMR (400 MHz, acetone-d_6) δ: 1.49 (s, $(CH_3)_3C$ of *N*-BOC), 3.53 (dd, J_1 = 7.0 Hz, J_2 = 1.1 Hz, CH_2CH=), 3.68 (s, $COOCH_3$), 5.91 (dt, J_1 = 15.6 Hz, J_2 = 1.6 Hz, CH=C*H*−COOMe), 7.03 (dt, J_1 = 15.5 Hz, J_2 = 7.0 Hz, CH_2CH=CH), 7.28 (s, 6′-CH), 7.42 (s, 2′-CH), 7.97 (s, 4′-CH), 8.56 (s, NH). ^{13}C NMR (75 MHz, acetone-d_6) δ: 28.2 (3×), 38.0, 51.4, 80.3, 94.6, 118.5, 122.7, 125.5, 132.0, 141.8, 142.0, 147.4, 153.2, 166.6. LR-MS calculated for $C_{16}H_{19}INO_4$ $[M - H]^-$ 416.0, found 415.9 *m/z*.

*Synthesis of methyl 4-(3′-***tert***-butoxycarbonylamino-5′-iodophenyl)-butanoate (61)*

To a solution of alkene **60** (240 mg, 0.57 mmol) in anhydrous THF (6 mL) was added PtO_2 (60 mg). This mixture was stirred for 16 h under a hydrogen atmosphere at room temperature. The resulting suspension was filtered through Celite, and THF was evaporated under reduced pressure. Purification by flash chromatography (hexanes/EtOAc, 85:15) afforded **61** (222 mg, 93% yield) as a white solid. IR (film) ν: 3342 (NH, carbamate), 1720 (C=O, ester and carbamate). ^{1}H NMR (400 MHz, acetone-d_6) δ: 1.49 (s, $(CH_3)_3C$ of *N*-BOC), 1.89 (dt, J_1 = 15.2 Hz, J_2 = 7.5 Hz, CH_2CH_2COOMe), 2.35 (t, J = 7.4 Hz, CH_2COOMe), 2.60 (t, J = 7.5 Hz, $CH_2CH_2CH_2COOMe$), 3.63 (s, $COOCH_3$), 7.26 (s, 6′-CH), 7.39 (s, 2′-CH), 7.93 (s, 4′-CH), 8.49 (s, NH). ^{13}C NMR (75 MHz, acetone-d_6) δ: 27.0, 28.3 (3×), 33.4, 35.0, 51.4, 80.2, 94.5, 118.3, 125.1, 131.8, 141.8, 145.4, 153.3, 173.6. LR-MS calculated for $C_{16}H_{21}INO_4$ $[M - H]^-$ 418.0, found 417.9 *m/z*.

*Synthesis of methyl 3-***tert***-butoxycarbonylamino-5-iodophenyl)-benzoate (64)*

The starting material **62** was obtained according to an already described procedure.[35,36] The esterification procedure described above for the synthesis of **59** was used without modification. Purification by flash chromatography (hexanes/EtOAc, 9:1) yielded ester **64** (962 mg, 93% yield) as a white solid. IR (film) ν: 3343 (NH, carbamate), 1710 (C=O, ester and carbamate). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 1.52 (s, $(CH_3)_3C$ of N-BOC), 3.90 (s, $COOCH_3$), 6.70 (s, NH), 7.86 (dd, J_1 = 2.0 Hz, J_2 = 1.5 Hz, 6-CH), 8.02 (t, J = 1.5 Hz, 4-CH), 8.16 (s, 2-CH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 28.2 (3×), 52.5, 81.3, 94.0, 118.6, 131.0, 132.1, 132.7, 139.6, 152.2, 165.4. LR-MS calculated for $C_{13}H_{15}INO_4$ $[M - H]^-$ 376.0, found 376.0 *m/z*.

Synthesis of methyl 2-(3′-iodophenyl)-acetate (65)

The procedure described above for the synthesis of **59** was used without modification. Purification by flash chromatography (hexanes/EtOAc, 95:5) afforded ester **65** (263 mg, 99% yield) as a colourless oil. IR (film) ν: 1738 (C=O, ester). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 3.57 (s, CH_2), 3.70 (s, $COOCH_3$), 7.06 (t, J = 7.8 Hz, 5′-CH), 7.25 (d, J = 7.4 Hz, 6′-CH), 7.61 (d, J = 7.9 Hz, 4′-CH), 7.64 (s, 2′-CH). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 40.5, 52.2, 94.4, 128.6, 130.2, 136.1, 136.2, 138.2, 171.4. LR-MS calculated for $C_9H_{10}IO_2$ $[M + H]^+$ 277.0, found 276.8 *m/z*.

Synthesis of 14−18 using the second chemical approach

General procedure to synthesize 67−71

The Sonogashira coupling procedure described previously[30] for the synthesis of **49** was used without modification except for the synthesis of **71** where 2 equiv. of 3-iodoaniline were used instead of 1 equiv.

Methyl 3-*tert*-butoxycarbonylamino-5-[13′-(3″-(*tert*-butyldimethylsilyloxy)-17″β-(tetrahydro-2*H*-pyran-2-yl-oxy)-estra-1″,3″,5″(10″)-trien-16″β-yl)-tridecynyl]-benzoate (67)

Yellowish foam (249 mg, 72% yield). IR (film) ν: 3355 (NH, carbamate), 1732 (C=O, ester), 1712 (C=O, carbamate). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.20 (s, $Si(CH_3)_2$), 0.81 and 0.85 (2s, 18″-CH_3), 1.00 (s, $SiC(CH_3)_3$), 1.00 to 2.40 (CH and CH_2 of steroid skeleton and alkyl chain), 1.51 (s, $(CH_3)_3C$ of *N*-BOC), 2.45 (t, J = 6.9 Hz, CH_2–C≡C), 2.80 (m, 6″-CH_2), 3.48 and 3.94 (2m, OCH_2 of THP), 3.72 and 3.78 (2d, J = 10.0 Hz, 17″α-CH), 3.89 (s, $COOCH_3$), 4.62 and 4.72 (2m, CH of THP), 6.57 (d, J = 1.8 Hz, 4″-CH), 6.63 (d, J = 8.4 Hz, 2″-CH), 7.15 (m, 1″-CH), 7.63 (d, J = 1.4 Hz, 6-CH), 7.89 (s, 4-CH), 8.20 (d, J = 1.5 Hz, 2-CH), 8.71 (s, NH). LR-MS calculated for $C_{55}H_{87}N_2O_7Si$ [M + NH_4]$^+$ 915.6, found 915.8 *m*/*z*.

Methyl 3-{3′-*tert*-butoxycarbonylamino-5′-[13″-(3‴-(*tert*-butyldimethylsilyloxy)-17‴β-(tetrahydro-2H-pyran-2-yl-oxy)-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-tridecynyl]-phenyl}-propanoate (68)

Yellowish foam (263 mg, 74% yield). IR (film) ν: 3354 (NH, carbamate), 1732 (C=O, ester and carbamate). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.20 (s, $Si(CH_3)_2$), 0.82 and 0.86 (2s, 18‴-CH_3), 1.00 (s, $SiC(CH_3)_3$), 1.00 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 1.49 (s, $(CH_3)_3C$ of *N*-BOC), 2.42 (t, J = 6.9 Hz, CH_2–C≡C), 2.62 (t, J = 7.6 Hz, CH_2COOMe), 2.81 (m, 6‴-CH_2), 2.86 (t, J = 7.7 Hz, CH_2CH$_2$COOMe), 3.47 and 3.92 (2m, OCH_2 of THP), 3.63 (s, $COOCH_3$), 3.73 and 3.78 (2d, J = 10.0 Hz, 17‴α-CH), 4.63 and 4.72 (2m, CH of THP), 6.58 (s, 4‴-CH), 6.63 (d, J = 8.4 Hz, 2‴-CH), 6.92 (s, 6′-CH), 7.16 (m, 1‴-CH), 7.37 (s, 2′-CH), 7.54 (s, 4′-CH), 8.43 (s, NH). LR-MS calculated for $C_{57}H_{91}N_2O_7Si$ [M + NH_4]$^+$ 943.7, found 943.8 *m*/*z*.

Methyl 4-{3′-*tert*-butoxycarbonylamino-5′-[13″-(3‴-(*tert*-butyldimethylsilyloxy)-17‴β-(tetrahydro-2*H*-pyran-2-yl-oxy)-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-tridecynyl]-phenyl}-butanoate (69)

Yellowish viscous oil (238 mg, 66% yield). IR (film) ν: 3342 (NH, carbamate), 1734 (C=O, ester and carbamate). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.20 (s, $Si(CH_3)_2$), 0.82 and 0.86 (2s, 18‴-CH_3), 1.00 (s, $SiC(CH_3)_3$), 1.00 to 2.30 (CH and CH_2 of steroid skeleton, alkyl chain and CH_2CH$_2$COOMe), 1.49 (s, $(CH_3)_3C$ of *N*-BOC), 2.34 (t, J = 7.4 Hz, CH_2COOMe), 2.42 (t, J = 7.0 Hz, CH_2–C≡C), 2.60 (t, J = 7.6 Hz, CH_2CH$_2$CH$_2$COOMe), 2.81 (m, 6‴-CH_2), 3.46 and 3.91 (2m, OCH_2 of THP), 3.63 (s, $COOCH_3$), 3.73 and 3.79 (2d, J = 10.0 Hz, 17‴α-CH), 4.63 and 4.72 (2m, CH of THP), 6.58 (d, J = 2.2 Hz, 4‴-CH), 6.64 (dd, J_1 = 6.7 Hz, J_2 = 2.2 Hz, 2‴-CH), 6.89 (s, 6′-CH), 7.16 (m, 1‴-CH), 7.37 (s, 2′-CH), 7.53 (s, 4′-CH), 8.42 (s, NH). LR-MS calculated for $C_{58}H_{90}NO_7Si$ [M + H]$^+$ 940.6, found 940.4 *m*/*z*.

Methyl 2-{3′-[13″-(3‴-(*tert*-butyldimethylsilyloxy)-17‴β-(tetrahydro-2*H*-pyran-2-yl-oxy)-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-tridecynyl]-phenyl}-acetate (70)

Yellowish viscous oil (220 mg, 72% yield). IR (film) ν: 1742 (C=O, ester). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.21 (s, $Si(CH_3)_2$), 0.82 and 0.86 (2s, 18‴-CH_3), 1.00 (s, $SiC(CH_3)_3$), 1.00 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 2.43 (t, J = 6.9 Hz, CH_2–C≡C), 2.81 (m, 6‴-CH_2), 3.47 and 3.92 (2m, OCH_2 of THP), 3.66 (s, CH_2COOCH_3), 3.74 and 3.79 (2d, J = 10.0 Hz, 17‴α-CH), 4.63 and 4.73 (2m, CH of THP), 6.58 (s, 4‴-CH), 6.64 (d, J = 8.4 Hz, 2‴-CH), 7.15 (m, 1‴-CH), 7.30 (m, 2′-CH, 4′-CH, 5′-CH and 6′-CH). LR-MS calculated for $C_{51}H_{80}N_2O_5Si$ [M + NH_4]$^+$ 814.6, found 814.8 *m*/*z*.

3-[13′-(3″-(*tert*-butyldimethylsilyloxy)-17″β-(tetrahydro-2H-pyran-2-yl-oxy)-estra-1″,3″,5″(10″)-trien-16″β-yl)-tridecynyl]-aniline (71)

Yellowish viscous oil (151 mg, 71% yield). IR (film) ν: 3460 and 3354 (NH_2). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.21 (s, $Si(CH_3)_2$), 0.82 and 0.86 (2s, 18″-CH_3), 1.00 (s, $SiC(CH_3)_3$), 1.00 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 2.39 (t, J = 6.9 Hz, CH_2–C≡C), 2.81 (m, 6″-CH_2), 3.49 and 3.92 (2m, OCH_2 of THP), 3.74 and 3.79 (2d, J = 9.7 Hz, 17″α-CH), 4.69 (m, CH of THP and NH_2), 6.58 (d, J = 2.1 Hz, 4″-CH), 6.62 (m, 2″-CH, 4-CH and 6-CH), 6.71 (d, J = 1.7 Hz, 2-CH), 7.00 (t, J = 7.8 Hz, 5-CH) 7.16 (m, 1″-CH). LR-MS calculated for $C_{48}H_{74}NO_3Si$ [M + H]$^+$ 740.5, found 740.6 *m*/*z*.

General procedure to synthesize 72–75

The same procedure described above for the preparation of **12** was used without modification except that 15% *w*/*w* of 10% Pd/C was used instead of 20% *w*/*w* in the hydrogenation step. The salt product (NH_2·HCl) was not observed for compounds **72**–**75**.

Methyl 3-amino-5-[13′-(3″, 17″β- dihydroxy-estra-1″,3″,5″(10″)-trien-16″β-yl)-tridecyl]-benzoate (72)

White solid (98 mg, 63% yield for two steps). IR (film) ν: 3368 (OH and NH_2), 1704 (C=O, ester). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.79 (s, 18″-CH_3), 0.95 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 2.54 (t, J = 7.5 Hz, 1′-CH_2), 2.78 (m, 6″-CH_2), 3.56 (d, J = 5.4 Hz, 17″βOH), 3.74 (dd, J_1 = 9.8 Hz, J_2 = 5.5 Hz, 17″α-CH), 3.82 (s, $COOCH_3$), 4.84 (s, NH_2), 6.54 (d, J = 2.5 Hz, 4″-CH), 6.60 (dd, J_1 = 8.4 Hz, J_2 = 2.6 Hz, 2″-CH), 6.77 (s, 4-CH), 7.13 (m, 1″-CH, 2-CH and 6-CH), 7.97 (s, 3″-OH). ^{13}C NMR (100 MHz, acetone-d_6) δ: 12.9, 27.1, 28.2, 29.1 to 30.2 (9C under solvent peaks), 30.3, 30.6, 32.0, 32.6, 33.2, 36.3, 38.5, 39.3, 41.2, 44.7, 44.8, 49.4, 51.8, 82.1, 113.2, 113.4, 115.8, 118.5, 119.4, 126.9, 131.6, 132.0, 138.3, 144.5, 149.3, 155.7, 167.6. LR-MS calculated for $C_{39}H_{58}NO_4$ [M + H]$^+$ 604.4, found 604.6 *m*/*z*.

Methyl 3-{3′-amino-5′-[13″-(3‴, 17‴β- dihydroxy-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-tridecyl]-phenyl}-propanoate (73)

Yellowish viscous oil (97 mg, 63% yield for two steps). IR (film) ν: 3366 (OH and NH_2), 1734 (C=O, ester). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.80 (s, 18‴-CH_3), 0.95 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 2.44 (t, J = 7.5 Hz, 1″-CH_2), 2.55 (t, J = 7.8 Hz, CH_2COOMe), 2.76 (m, 6‴-CH_2, CH_2CH$_2$COOMe), 3.54 (d, J = 5.4 Hz, 17‴β-OH), 3.62 (s, $COOCH_3$), 3.73 (dd, J_1 = 9.8 Hz, J_2 = 5.6 Hz, 17‴α-CH), 4.46 (s, NH_2), 6.32 (s, 6′-CH), 6.35 (s, 2′-CH and 4′-CH), 6.54 (d, J = 2.4 Hz, 4‴-CH), 6.60 (dd, J_1 = 8.4 Hz, J_2 = 2.6 Hz, 2‴-CH), 7.11 (d, J = 8.4 Hz, 1‴-

CH), 7.96 (s, 3‴-OH). ^{13}C NMR (100 MHz, acetone-d_6) δ: 12.9, 27.1, 28.2, 29.1 to 30.2 (8C under solvent peaks), 30.3, 30.5, 30.6, 31.5, 32.1, 32.5, 33.2, 36.1, 36.5, 38.6, 39.4, 41.2, 44.7, 44.8, 49.4, 51.4, 82.1, 112.5, 113.2, 113.4, 115.8, 117.7, 126.8, 132.0, 138.3, 142.0, 144.2, 149.1, 155.7, 173.8. LR-MS calculated for $C_{41}H_{62}NO_4$ [M + H]$^+$ 632.5, found 632.6 *m*/*z*.

Methyl 4-{3′-amino-5′-[13″-(3‴, 17‴β- dihydroxy-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-tridecyl]-phenyl}-butanoate (74)

Yellowish viscous oil (81 mg, 64% yield for two steps). IR (film) ν: 3377 (OH and NH_2), 1732 (C=O, ester). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.80 (s, 18‴-CH_3), 0.95 to 2.35 (CH and CH_2 of steroid skeleton, alkyl chain and CH_2CH$_2$COOMe), 2.32 (m, CH_2COOMe), 2.46 (m, 1″-CH_2), 2.58 (m, *J* = 7.8 Hz, CH_2CH$_2$CH$_2$COOMe), 2.78 (m, 6‴-CH_2), 3.56 (m, 17‴β-OH), 3.62 (s, $COOCH_3$), 3.73 (dd, J_1 = 9.8 Hz, J_2 = 5.9 Hz, 17‴α-CH), 4.45 (s, NH_2), 6.33 (m, 2′-CH, 4′-CH and 6′-CH), 6.54 (d, *J* = 2.2 Hz, 4‴-CH), 6.59 (d, *J* = 8.4 Hz, 2‴-CH), 7.11 (d, *J* = 8.5 Hz, 1‴-CH), 7.97 (s, 3‴-OH). ^{13}C NMR (75 MHz, acetone-d_6) δ: 12.9, 27.0, 27.2, 28.2, 28.9, 29.1 to 30.2 (7C under solvent peaks), 30.3, 30.4, 30.6, 32.1, 32.5, 33.2, 33.5, 35.6, 36.5, 38.5, 39.3, 41.1, 44.8 (2×), 49.4, 51.3, 82.1, 112.7, 113.0, 113.3, 115.7, 118.0, 126.8, 131.9, 138.2, 142.8, 144.0, 149.0, 155.7, 173.8. LR-MS calculated for $C_{42}H_{64}NO_4$ [M + H]$^+$ 646.5, found 646.3 *m*/*z*.

Methyl 2-{3′-[13″-(3‴, 17‴β- dihydroxy-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-tridecyl]-phenyl}-acetate (75)

The deprotection step was carried out in 2 h instead of 16 h. Purification by flash chromatography (hexanes/EtOAc, 8:2) afforded **75** (105 mg, 75% yield for two steps) as a white foam. IR (film) ν: 3400 (OH), 1732 (C=O, ester). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.80 (s, 18‴-CH_3), 0.95 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 2.61 (t, *J* = 7.6 Hz, 1″-CH_2), 2.78 (m, 6‴-CH_2), 3.55 (d, *J* = 5.4 Hz, 17‴β-OH), 3.62 (s, CH_2COOCH$_3$), 3.65 (s, $COOCH_3$) 3.73 (dd, J_1 = 9.7 Hz, J_2 = 5.6 Hz 17‴α-CH), 6.54 (d, *J* = 2.4 Hz, 4‴-CH), 6.60 (dd, J_1 = 8.4 Hz, J_2 = 2.6 Hz, 2‴-CH), 7.12 (m, 1‴-CH, 2′-CH, 4′-CH and 6′-CH), 7.23 (t, *J* = 7.4 Hz, 5′-CH), 7.97 (s, 3‴-OH). ^{13}C NMR (75 MHz, acetone-d_6) δ: 12.9, 27.0, 28.2, 28.9, 29.1 to 30.1 (8C under solvent peaks), 30.4, 30.6, 32.1, 32.5, 33.2, 36.2, 38.5, 39.3, 41.1, 41.2, 44.8 (2×), 49.4, 51.7, 82.1, 113.3, 115.7, 126.8, 127.2, 127.5, 128.9, 130.0, 131.9, 135.1, 138.2, 143.6, 155.7, 172.1. LR-MS calculated for $C_{40}H_{62}NO_4$ [M+NH$_4$]$^+$ 620.5, found 620.6 *m*/*z*.

General procedure to synthesize 14–17

To a solution of esters **72**–**75** (40–68 mg, 0.066–0.113 mmol) in acetone (2.0–3.5 mL) was added LiOH (1 mol/L in H_2O, 2.0–3.5 mL). The mixture was refluxed for 1 h and quenched by addition of an aqueous solution of HCl (1 N) until it reached pH 7. Then, a saturated $NaHCO_3$ aqueous solution was added, and extraction was performed with EtOAc. The organic phase was washed with brine, dried over $MgSO_4$, filtered, and evaporated to dryness. The crude product was purified by flash chromatography (DCM/MeOH, 97:3 to 90:10) to provide carboxylic acids **14**–**17** (26–44 mg, 66%–78% yield).

3-amino-5-[13′-(3″,17″β-dihydroxy-estra-1″,3″,5″(10″)-trien-16″β-yl)-tridecyl]-benzoic acid (14)

Yellowish foam (26 mg, 66% yield). IR (KBr) ν: 3600–2300 (OH, carboxylic acid), 3415 (OH and NH_2), 1694 (C=O, carboxylic acid). ^{1}H NMR (400 MHz, DMSO-d_6) δ: 0.65 (s, 18″-CH_3), 0.80 to 2.25 (CH and CH_2 of steroid skeleton and alkyl chain), 2.45 (t, *J* = 7.4 Hz, 1′-CH_2), 2.69 (m, 6″-CH_2), 3.55 (d, J_1 = 9.4 Hz, 17″α-CH), 4.39 (s_{br}, 17″β-OH), 5.21 (s_{br}, NH_2), 6.43 (d, *J* = 2.2 Hz, 4″-CH), 6.50 (dd, J_1 = 8.3 Hz, J_2 = 2.4 Hz, 2″-CH), 6.58 (s, 4-CH), 6.92 (s, 2-CH), 6.98 (d, *J* = 1.7 Hz, 6-CH), 7.03 (d, *J* = 8.5 Hz, 1″-CH), 9.03 (s_{br}, COOH). ^{13}C NMR (75 MHz, DMSO-d_6) δ: 12.7, 26.1, 27.2, 28.4, 28.7, 28.9, 29.1 (7×), 29.5, 30.9, 31.7, 32.3, 35.2, 37.5, 38.2, 38.7 to 40.3 (1C under solvent peaks), 43.6, 43.7, 48.2, 80.5, 112.3, 112.7, 114.9, 116.9, 117.9, 126.0, 130.5, 131.6, 137.2, 142.9, 148.7, 154.9, 168.1. HR-MS calculated for $C_{38}H_{56}NO_4$ [M + H]$^+$ 590.42039, found 590.42017 *m*/*z*.

3-{3′-amino-5′-[13″-(3‴,17‴β-dihydroxy-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-tridecyl]-phenyl}-propanoic acid (15)

Yellowish foam (42 mg, 78% yield). IR (KBr) ν: 3600–2400 (OH, carboxylic acid), 3378 (OH and NH_2), 1708 (C=O, carboxylic acid). ^{1}H NMR (400 MHz, DMSO-d_6) δ: 0.65 (s, 18‴-CH_3), 0.80 to 2.30 (CH and CH_2 of steroid skeleton and alkyl chain), 2.35 (t, *J* = 7.5 Hz, 1″-CH_2), 2.42 (t, *J* = 7.9 Hz, CH_2COOH), 2.61 (t, *J* = 7.5 Hz, CH_2CH$_2$COOH), 2.70 (m, 6‴-CH_2), 3.55 (d, J_1 = 9.5 Hz, 17‴α-CH), 4.85 (s_{br}, NH_2), 6.18 (s, 6-CH), 6.20 (s, 2′-CH and 4′-CH), 6.43 (d, *J* = 2.2 Hz, 4‴-CH), 6.49 (dd, J_1 = 8.4 Hz, J_2 = 2.4 Hz, 2‴-CH), 7.03 (d, *J* = 8.5 Hz, 1‴-CH). ^{13}C NMR (75 MHz, DMSO-d_6) δ: 12.7, 26.1, 27.2, 28.3, 28.8, 29.0, 29.1 (7×), 29.5, 30.6, 31.0, 31.7, 32.3, 35.4, 35.6, 37.5, 38.2, 38.7 to 40.3 (1C under solvent peaks), 43.6 (2×), 48.2, 80.5, 111.3, 111.8, 112.7, 114.9, 116.0, 126.0, 130.5, 137.1, 141.2, 142.8, 148.4, 154.9, 174.0. HR-MS calculated for $C_{40}H_{60}NO_4$ [M + H]$^+$ 618.45169, found 618.45148 *m*/*z*.

4-{3′-amino-5′-[13″-(3‴,17‴β-dihydroxy-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-tridecyl]-phenyl}-butanoic acid (16)

Yellowish foam (43 mg, 66% yield). IR (KBr) ν: 3600–2300 (OH, carboxylic acid), 3384 (OH and NH_2), 1707 (C=O, carboxylic acid). ^{1}H NMR (400 MHz, DMSO-d_6) δ: 0.65 (s, 18‴-CH_3), 0.80 to 2.10 (CH and CH_2 of steroid skeleton, alkyl chain and CH_2CH$_2$COOH), 2.18 (t, *J* = 7.3 Hz, CH_2COOH), 2.36 (m, 1″-CH_2, CH_2CH$_2$CH$_2$COOH), 2.69 (m, 6‴-CH_2), 3.55 (d, J_1 = 9.5 Hz, 17‴α-CH), 4.41 (s_{br}, 17″β-OH), 4.87 (s_{br}, NH_2), 6.14 (s, 6′-CH), 6.19 (s, 2′-CH and 4′-CH), 6.43 (d, *J* = 2.2 Hz, 4‴-CH), 6.50 (dd, J_1 = 8.3 Hz, J_2 = 2.3 Hz, 2‴-CH), 7.03 (d, *J* = 8.5 Hz, 1‴-CH). ^{13}C NMR (100 MHz, DMSO-d_6) δ: 12.7, 26.1, 26.3, 27.2, 28.4, 28.8, 29.0, 29.1 (5×), 29.2, 29.3, 29.5, 31.0, 31.8, 32.3, 33.2, 34.7, 35.4, 37.6, 38.2, 38.9 to 40.2 (1C under solvent peaks), 43.6, 43.7, 48.2, 80.5, 111.5, 111.7, 112.7, 115.0, 116.4, 126.1, 130.6, 137.2, 141.9, 142.7, 148.5,

154.9, 174.5. HR-MS calculated for $C_{41}H_{62}NO_4$ [M + H]$^+$ 632.46734, found 632.46672 *m/z*.

2-{3′-[13″-(3‴,17‴β-dihydroxy-estra-1‴,3‴,5‴(10‴)-trien-16‴β-yl)-tridecyl]-phenyl}-acetic acid (17)

White gummy solid (44 mg, 66% yield). IR (KBr) ν: 3600−2400 (OH, carboxylic acid), 3400 (OH), 1708 (C=O, carboxylic acid). ^{1}H NMR (400 MHz, DMSO-d_6) δ: 0.65 (s, 18‴-CH_3), 0.80 to 2.30 (CH and CH_2 of steroid skeleton and alkyl chain), 2.51 (m, 1″-CH_2 under solvent peaks), 2.70 (m, 6‴-CH_2), 3.50 (s, CH_2COOH), 3.55 (d, J_1 = 9.5 Hz, 17‴α-CH), 6.43 (d, J = 2.3 Hz, 4‴-CH), 6.50 (dd, J_1 = 8.4 Hz, J_2 = 2.4 Hz, 2‴-CH), 7.06 (m, 1‴-CH, 2′-CH, 4′-CH and 6′-CH), 7.19 (t, J = 8.0 Hz, 5′-CH). ^{13}C NMR (75 MHz, DMSO-d_6) δ: 12.7, 26.1, 27.2, 28.3, 28.7, 28.9, 29.0 (4×), 29.1, 29.2, 29.5, 29.6, 31.1, 31.7, 32.3, 35.1, 37.5, 38.2, 38.7 to 40.3 (1C under solvent peaks), 41.0, 43.59, 43.63, 48.2, 80.5, 112.7, 114.9, 126.0, 126.4, 126.7, 128.1, 129.3, 130.5, 135.1, 137.1, 142.2, 154.9, 172.8. HR-MS calculated for $C_{39}H_{57}O_4$ [M + H]$^+$ 589.4179, found 589.4202 *m/z*.

Synthesis of 3-[13′-(3″, 17″β- dihydroxy-estra-1″,3″,5″(10″)-trien-16″β-yl)-tridecyl]-aniline (18)

Compound **71** (133 mg, 0.180 mmol) was dissolved in a minimum amount of DCM (~0.5 mL). Then, a solution of concentrated HCl in MeOH (5% *v*/*v*, 3.6 mL) was added. The mixture was stirred for 1 h at room temperature. The reaction was quenched by addition of H_2O, followed by evaporation of MeOH. Then, a saturated solution of $NaHCO_3$ was added, and extraction was performed with EtOAc. The organic phase was washed with brine, dried over $MgSO_4$, filtered, and evaporated to dryness. Purification by flash chromatography (hexanes/EtOAc, 8:2 to 7:3) afforded the deprotected product (79 mg, 81%) as a white foam. This compound was then hydrogenated, using the hydrogenation procedure described previously for the synthesis of **12**, except that 15% *w*/*w* of 10% Pd/C were used instead of 20% *w*/*w*, to afford **18** (49 mg, 67% yield) as a white foam. IR (film) ν: 3366 (OH and NH_2). ^{1}H NMR (400 MHz, acetone-d_6) δ: 0.80 (s, 18″-CH_3), 0.95 to 2.35 (CH and CH_2 of steroid skeleton and alkyl chain), 2.47 (t, J = 7.5 Hz, 1′-CH_2), 2.78 (m, 6″-CH_2), 3.58 (d, J = 5.4 Hz, 17″β-OH), 3.73 (dd, J_1 = 9.7 Hz, J_2 = 5.4 Hz, 17″α-CH), 4.50 (s, NH_2), 6.43 (d, J = 7.4 Hz, 6-CH), 6.47 (dd, J_1 = 7.9 Hz, J_2 = 1.4 Hz, 4-CH), 6.52 (s, 2-CH), 6.54 (d, J = 2.5 Hz, 4″-CH), 6.60 (dd, J_1 = 8.4 Hz, J_2 = 2.6 Hz, 2″-CH), 6.95 (t, J = 7.7 Hz, 5-CH), 7.11 (d, J = 8.4 Hz, 1″-CH), 8.00 (s, 3″-OH). ^{13}C NMR (75 MHz, acetone-d_6) δ: 12.9, 27.0, 28.1, 28.9, 29.1 to 30.2 (8C under solvent peaks), 30.4, 30.6, 32.1, 32.5, 33.1, 36.4, 38.5, 39.3, 41.1, 44.7 (2×), 49.3, 82.1, 112.4, 113.3, 115.1, 115.7, 117.5, 126.8, 129.4, 131.9, 138.2, 144.0, 148.9, 155.7. HR-MS calculated for $C_{37}H_{56}NO_2$ [M + H]$^+$ 546.43056, found 546.43092 *m/z*.

Synthesis of monosubstrate 79

Synthesis of methyl 2-[3′-(6″-hydroxyhex-1″-ynyl)-phenyl]-acetate (77)

The Sonogashira coupling procedure described previously[30] for the synthesis of **49** was used without modification except that 2 equiv. of **76** were used instead of 1.2 equiv., and the reaction mixture was stirred for 1 h at 40 °C instead of 3 h. Purification by flash chromatography (hexanes/EtOAc, 7:3) gained **77** (156 mg, 88% yield) as colourless oil. IR (film) ν: 3390 (OH), 1732 (C=O, ester). ^{1}H NMR (400 MHz, acetone-d_6) δ: 1.69 (m, 2 × CH_2), 2.46 (m, CH_2−C≡C), 3.54 (m, OH), 3.61 (m, CH_2OH), 3.66 (s, CH_2COOCH_3), 7.29 (m, 2′-CH, 4′-CH, 5′-CH, and 6′-CH). ^{13}C NMR (100 MHz, acetone-d_6) δ: 19.5, 26.0, 32.8, 40.8, 52.0, 61.9, 81.1, 91.0, 125.0, 129.2, 129.5, 130.6, 133.1, 135.7, 171.5. LR-MS calculated for $C_{15}H_{19}O_3$ [M + H]$^+$ 247.1, found 247.1 *m/z*.

Synthesis of 2-[3′-(6″-hydroxyhex-1″-ynyl)-phenyl]-acetic acid (78)

The procedure that we described previously[30] for the synthesis of **5** was used without modification except that the reaction mixture was stirred at reflux for 4 h instead of 5 h. Purification by flash chromatography (DCM/MeOH, 97:3 to 70:30) afforded **78** (128 mg, 94% yield) as a white viscous oil. IR (film) ν: 3700−2200 (OH, carboxylic acid), 3322 (OH), 3420 (OH), 1711 (C=O, carboxylic acid). ^{1}H NMR (400 MHz, $CDCl_3$ and few drops of MeOH-d_4) δ: 1.67 (m, 2 × CH_2), 2.41 (t, J = 6.7 Hz, CH_2−C≡C), 3.54 (s, CH_2COOH), 3.64 (t, J = 6.1 Hz, CH_2OH), 7.22 (m, 2′-CH, 4′-CH, 5′-CH, and 6′-CH). ^{13}C NMR (100 MHz, acetone-d_6) δ: 19.1, 24.9, 31.7, 40.9, 62.1, 80.7, 90.1, 124.1, 128.4, 128.6, 130.1, 132.4, 134.2, 174.2. LR-MS calculated for $C_{14}H_{15}O_3$ [M − H]$^-$ 231.1, found 231.0 *m/z*.

Synthesis of 2-[3′-(6″-hydroxyhexyl)-phenyl]-acetic acid (79)

The general hydrogenation procedure described for the synthesis of **13** was used without modification. Purification by flash chromatography (DCM/MeOH, 95:5 to 70:30) provided **79** (72 mg, 75% yield) as a white solid. IR (film) ν: 3700−2400 (OH, carboxylic acid), 3398 (OH), 1711 (C=O, carboxylic acid). ^{1}H NMR (400 MHz, $CDCl_3$ and few drops of MeOH-d_4) δ: 1.32 (m, 2 × CH_2), 1.52 (t, J = 6.9 Hz. CH_2CH$_2$OH), 1.60 (t, J = 7.1 Hz, 5″-CH_2), 2.58 (t, J = 7.6 Hz, 6″-CH_2), 3.57 (t, J = 6.6 Hz, CH_2OH), 3.58 (s, CH_2COOH), 7.11 (m, 2′-CH, 4′-CH, and 6′-CH), 7.22 (t, J = 7.4 Hz, 5′-CH). ^{13}C NMR (100 MHz, acetone-d_6) δ: 25.4, 28.8, 31.1, 32.4, 35.6, 41.1, 62.7, 126.4, 127.2, 128.4, 129.4, 133.8, 143.0, 175.2. HR-MS calculated for $C_{14}H_{21}O_3$ [M + H]$^+$ 237.14852, found 237.14839 *m/z*.

Enzymatic assay: inhibition of 17β-HSD1 in homogenated cells

This enzymatic assay was performed as previously described.[37] Briefly, HEK-293 cells transfected with a 17β-HSD1 cDNA fragment were sonicated in 50 mmol/L sodium phosphate buffer (pH 7.4), containing 20% glycerol and 1 mmol/L EDTA to obtain cellular fragmentation. The cytosol fraction containing the enzyme was isolated as the supernatant after centrifugation (100 000*g*, 5 min, 4 °C). The enzymatic reaction was performed at 37 °C for 2 h in 1 mL of a solution, which included 870 μL of 50 mmol/L sodium phosphate buffer (pH 7.4, 20% glycerol and 1 mmol/L EDTA), 100 μL of 1 mmol/L NADH in phosphate buffer, 10 μL of 10 μmol/L [^{14}C]-estrone in ethanol (54 mCi/mmol, American Radiolabeled Chemicals Inc., St-Louis, MO, USA),

10 μL of the indicated inhibitor dissolved in ethanol, and 10 μL of diluted enzymatic source in phosphate buffer. Each inhibitor was assessed in duplicate (Table 1) or in triplicate (Table 2). To obtain the IC_{50} values, each inhibitor was assessed in duplicate at 0.001, 0.01, 0.03, 0.06, 0.1, 0.3, 0.6, 1, 10, and 30 μmol/L. Afterward, radiolabeled steroids were extracted twice from the reaction mixture by 1 mL of diethyl ether. The organic phases were pooled and evaporated to dryness with nitrogen. Residues were dissolved in 50 μL of DCM, applied on silica gel 60 F_{254} thin-layer chromatography plates (EMD Chemicals Inc., Gibbstown, NJ, USA), and eluted with a mixture of toluene/acetone (4:1). Substrate ([^{14}C]-E_1) and metabolite ([^{14}C]-E_2) were identified by comparison with reference steroids and quantified using the Storm 860 system (Molecular Dynamics, Sunnyvale, CA, USA). The percentage of transformation of [^{14}C]-E_1 into [^{14}C]-E_2 was calculated as follows: % transformation = $100 \times [[^{14}C]\text{-}E_2 / ([^{14}C]\text{-}E_2 + [^{14}C]\text{-}E_1)]$, and subsequently, % inhibition = $100 \times$ [(% transformation without inhibitor − % transformation with inhibitor) / % transformation without inhibitor]. The IC_{50} values were calculated using an unweighted iterative least-squares method for four-parameters logistic curve fitting (DE_{50} program, CHUL Research Center, Québec, QC, Canada).

Supplementary data

Supplementary data (^{1}H NMR spectra and ^{13}C NMR spectra of compounds tested as inhibitors of 17β-HSD1) for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 3985. For more information on obtaining material, refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml.

Acknowledgements

This work was supported by the Canadian Institutes of Health Research (CIHR) (D.P. for an operating grant, and M.B. for a scholarship). We thank Dr. Van Luu-The for providing HEK-293 cells overexpressing 17β-HSD1. We are grateful to Fatima Kamal for chemical synthesis of intermediate compound **19** and to Julie Lefebvre for performing some of the enzymatic assays. We also thank Ms. Sylvie Méthot for careful reading of the manuscript.

AWARD LECTURE / CONFÉRENCE D'HONNEUR

2008 Macromolecular Science and Engineering Division Award Lecture — Conjugated polymers: From micro-electronics to genomics

Mario Leclerc, Ahmed Najari, and Serge Beaupré

Abstract: Conjugated polymers have received a lot of attention, since they combine the best features of metals or semiconductors with those of synthetic polymers. For instance, solar cells based on poly(2,7-carbazole) derivatives have revealed power-conversion efficiencies up to 6%. This class of materials could lead to printable and flexible photovoltaic devices. Moreover, water-soluble luminescent polythiophenes have allowed the specific, rapid, and ultra-sensitive detection of unlabelled DNA, RNA, or proteins. This new optical detection mechanism is based on electrostatic interactions between a cationic polythiophene derivative and negatively charged oligonucleotides. This method makes now possible the rapid assessment of the identity of single nucleotide polymorphisms (SNPs), genes, and pathogens without the need for nucleic acid amplification.

Key words: conjugated polymers, plastic electronics, biosensors, polyfluorenes, polythiophenes, polycarbazoles.

Résumé : Les polymères conjugués suscitent beaucoup d'intérêt puisqu'ils combinent les propriétés des métaux ou des semiconducteurs à celles des polymères synthétiques. Par exemple, des piles solaires fabriquées à l'aide de dérivés du poly(2,7-carbazole) ont montré des efficacités de conversion énergétique de l'ordre de 6 %. Cette classe de matériaux pourrait donc conduire à la mise en place de dispositifs photovoltaïques flexibles et imprimables. Par ailleurs, des polythiophènes luminescents et solubles dans l'eau ont permis une détection rapide, spécifique, ultra-sensible et directe d'ADN, d'ARN ou de protéines. Ce nouveau mécanisme de détection optique utilise les interactions électrostatiques entre un dérivé cationique du polythiophène et les charges négatives de sondes à base d'oligonucléotides. Cette méthode rend maintenant possible l'identification rapide de mutations génétiques, de gènes spécifiques ou de pathogènes sans le recours d'amplification du matériel génomique.

Mots-clés : polymères conjugués, électronique plastique, biocapteurs, polyfluorènes, polythiophènes, polycarbazoles.

Introduction

In the field of micro-electronics and medicine, polymeric materials were traditionally used in applications such as packaging and electrical insulators. However, new opportunities emerged with the discovery of conducting polymers in 1977.[1] After more than 30 years of progress, these unusual polymeric materials can now be utilized as transparent antistatic coatings, modified electrodes, electrochromic windows, biosensors, transistors, light-emitting diodes, conducting photoresists, photovoltaic cells, and so forth.[2,3] The significance of this class of polymers has been outlined by the awarding of the 2000 Nobel Prize in Chemistry to the three scientists (H. Shirakawa, A.G. MacDiarmid, and A.J. Heeger) who pioneered this novel research field. This attribution of the Nobel Prize recognizes also indirectly a fruitful collaboration between two chemists and one physicist.

As often happens in science, the discovery of conducting polymers was accidental. A student of the Shirakawa's laboratory was working on Ziegler–Natta (1963 Nobel Prize in Chemistry) polymerization of acetylene. By accident, this student prepared a thousand times more concentrated catalyst than required and obtained a polyacetylene thin film, which looked like an aluminum foil instead of the usual dark, powdery material.[4] During a visit to the University of Tokyo, Prof. MacDiarmid (University of Pennsylvania) met Prof. Shirakawa and invited him to come to Philadelphia to investigate in more detail this new form of polyacetylene.[5] In collaboration with Prof. A.J. Heeger, this trio discovered that upon partial oxidation or reduction (so-called doping reaction), the conductivity of polyacetylene increases more than a billionfold (up to 100 S/cm).[6] Electrical conductivities up to 10^5 S/cm are obtained with some forms of polyacetylene. The delocalized electronic structure (alternation of single and double bonds) of polyacetylene (see Scheme 1A) is responsible for such good intrachain and interchain mobility

of the charge carriers (radical cations and dications) created upon doping. This delocalized (conjugated) structure is also responsible for strong absorption in the UV–visible range. Unfortunately, this first conducting polymer is difficult to process and unstable in presence of oxygen or water. Rapidly, chemists investigated the more stable, aromatic conjugated polymers. This paper will review advances in this research field together with some significant contributions from our laboratory.

Aromatic conducting polymers

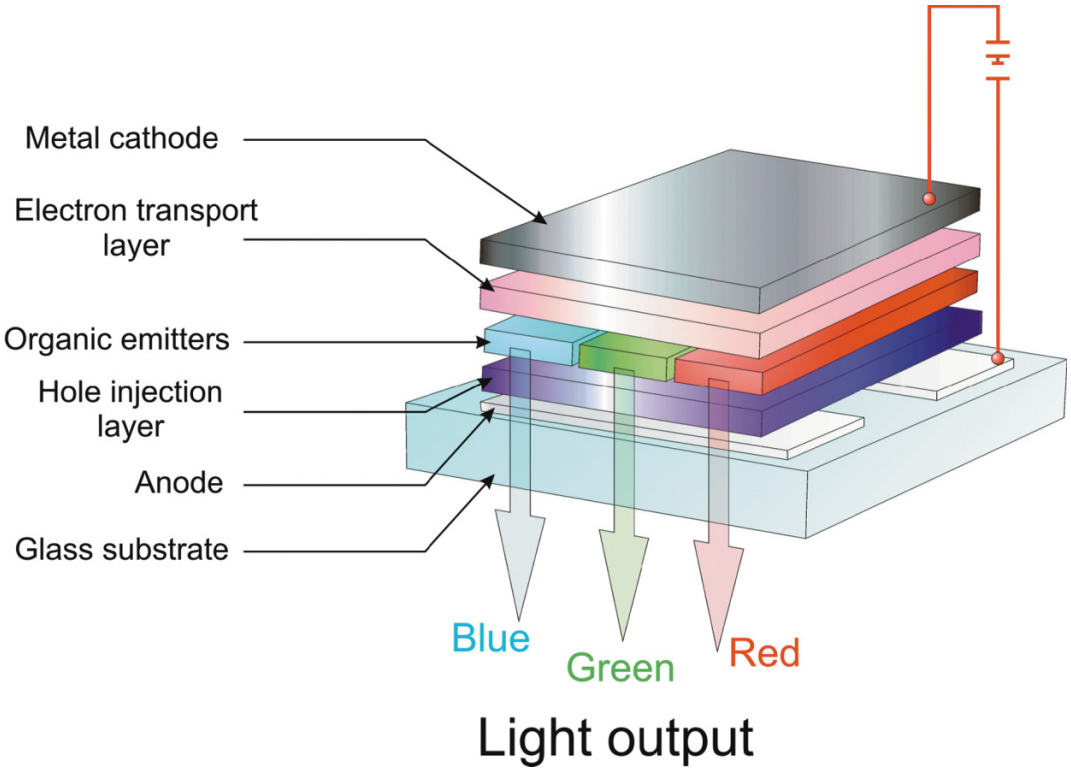
In the beginning of the 1980s, a lot of studies were devoted to electropolymerized polypyrrole[7] (Scheme 1B), polythiophene[8] (Scheme 1C), and polyaniline[9] (Scheme 1D). This method has the advantage of being able to prepare thin films of these infusible and insoluble conjugated polymers in one step. However, the ultimate goal was and still is the development of polymeric materials that "combine" the electrical and optical properties of metals and semiconductors with the processing advantages and mechanical properties of commodity polymers. For this purpose, substituted conjugated polymers were prepared, since the unsubstituted parent polymers are not melt- or solution-processable owing to strong interchain interactions and chain stiffness. Experiments carried out on substituted polyacetylenes[10] and polyanilines[11] revealed that the presence of bulky substituents forces a twisting of the backbone that led to processable but poorly conjugated materials with reduced electrical properties. A breakthrough occurred with the synthesis of highly conjugated, conducting, and processable poly(3-alkylthiophene)s [12] (Scheme 1E).

Following these first studies on the synthesis and characterization of processable poly(3-alkylthiophene)s, it became quite clear that the synthesis of well-defined head-to-tail coupled (which should give the lowest steric hindrance from the side chains and, possibly, a more efficient three-dimensional packing) conjugated polymers should lead to a significant improvement in the performance of these polymeric materials.[13] Therefore, in attempts to bring more reliable synthetic procedures to the field of electronic materials, a variety of synthetic tools were utilized and allowed significant advances in this research field. These investigations have led to the discovery of new and interesting conjugated structures, such as well-defined regioregular poly(3-alkylthiophene)s [14] (Scheme 1F), poly(3-alkoxy-4-methylthiophenes)s [15] (Scheme 1G), and poly(3,4-ethylenedioxythiophene) (also called PEDOT)[16] (Scheme 1H). Up to now, regioregular poly(3-alkylthiophene)s exhibit the highest conductivities (up to 1000 S/cm) for processable conjugated polymers but alkoxy-substituted polythiophenes show the best compromise between processability, conductivity, and air-stability.[14,16,17]

Polymeric light-emitting diodes

In the 1990s, the focus shifted from the synthesis of metallic-like conductors to the design of stable semi-conducting poly-

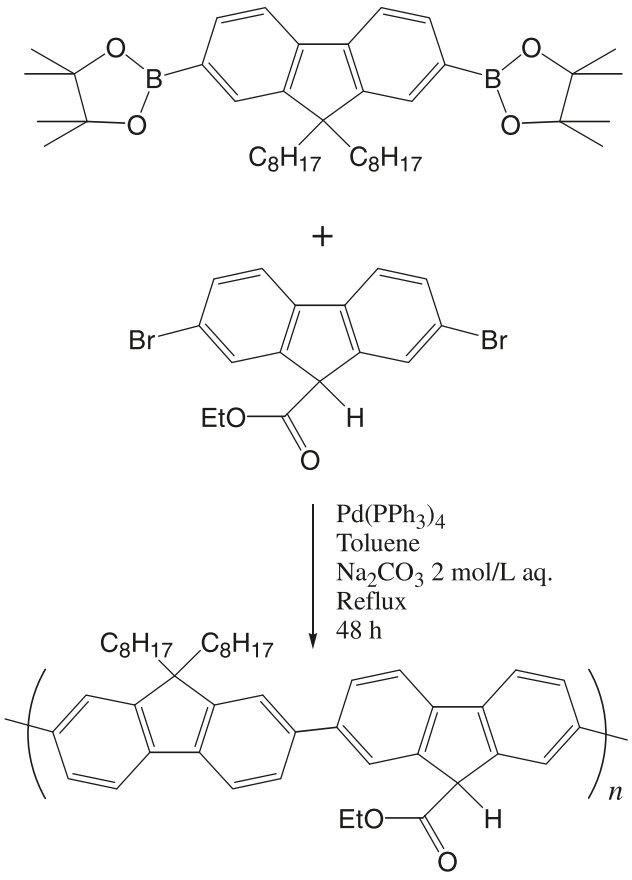
Scheme 2. Schematic description of a polymer light-emitting diode (PLED).



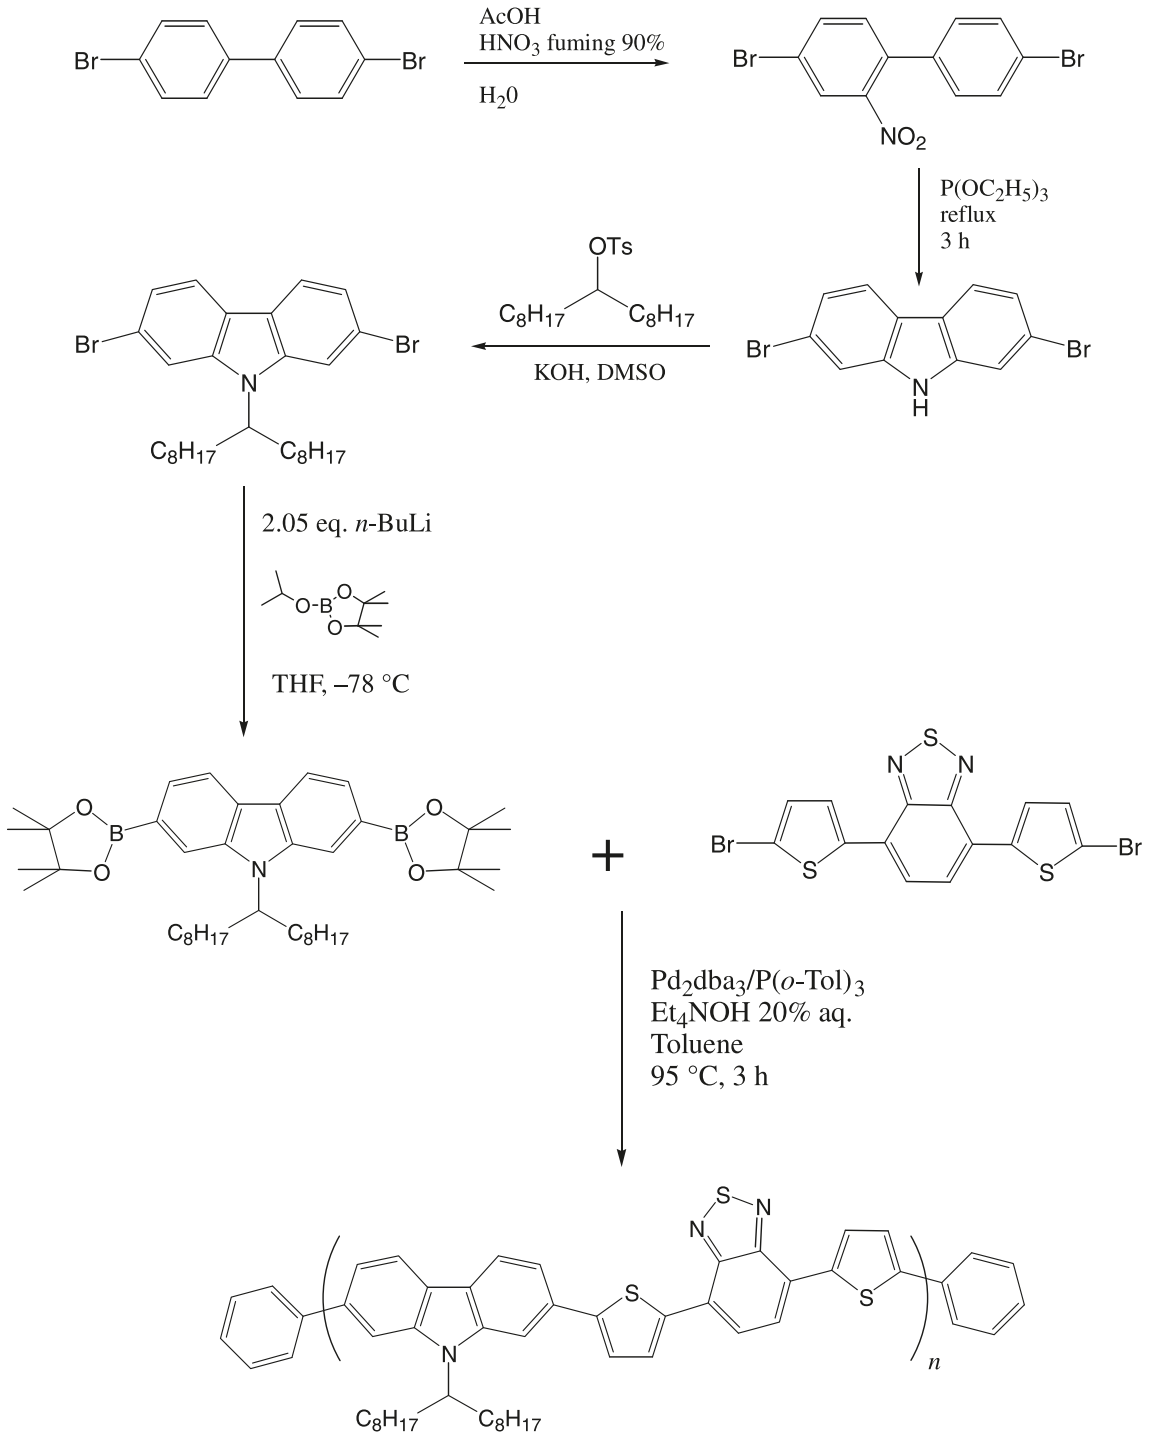
mers. This new driving force is based on the aim to set up the so-called plastic electronics where micro-electronic devices could be printed on flexible substrates. For instance, the last 15–20 years have witnessed the emergence of conjugated (undoped, semi-conducting) polymers in light-emitting diodes (PLEDs).[18] The basic structure of a polymeric light-emitting diode consists of a positive hole-injecting electrode (usually transparent) with a high work function such as ITO or a conducting polymer, a negative electron-injecting electrode with a low work function such as Al, In, Mg, or Ca, and the light-emitting polymer film sandwiched between these two electrodes. In this layered structure, the injected holes and electrons migrate across the polymer layer, combine to form excitons, which then decay with photon emission (see Scheme 2). Depending upon the chemical structure of the emissive polymer, different colors can be obtained.

Among all reported conjugated polymers, our synthetic procedures (based on Suzuki cross-coupling reactions, see Scheme 3) for the preparation of well-defined poly(2,7-fluorene) derivatives[19] rapidly received a lot of attention, since this class of polymeric materials can emit light ranging from blue to red.[20] However, blue-light-emitting poly(2,7-fluorene)s show some problems of stability, probably owing to an oxidative electro- and photo-degradation.[21] To try to solve this problem, we reported the first syntheses of poly(2,7-carbazole) derivatives.[22] Indeed, carbazole-based conjugated polymers exhibit many advantages: the nitrogen atom can be easily functionalized with a large variety of substituents to modulate the physical properties without increasing the steric hindrance near the backbone, and its fully aromatic configuration provides good chemical and environmental stabilities. Following our first reports, optimized

Scheme 3. Suzuki cross-coupling reaction for the synthesis of poly(2,7-fluorene) derivatives.



Scheme 4. Synthesis of a processable poly(2,7-carbazole) derivative.

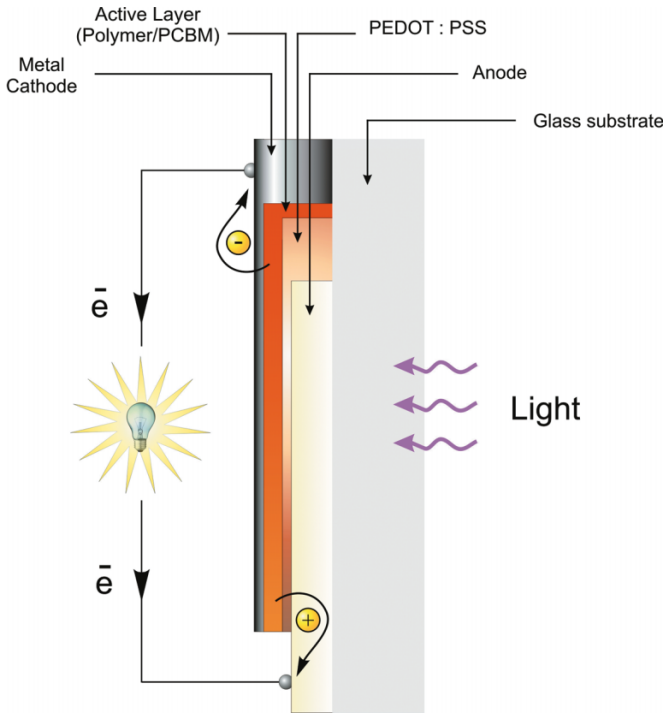


synthetic strategies have been reported to improve the simplicity and the efficiency of the preparation of such poly(2,7-carbazole) derivatives[23] (see Scheme 4). Unfortunately, PLEDs made of poly(2,7-carbazole)s generally suffered from improper balance of charge injection and charge transport. In other words, the hole mobility is favoured, and that limits the efficiencies of the resulting light-emitting diodes.[24] Therefore, despite some stability issues, poly(2,7-fluorene) derivatives remain the most widely-studied polymers for light-emitting applications.[25]

Polymeric photovoltaic cells

If one reverses the energy input, instead of a light-emitting diode, one obtains a photovoltaic device (Scheme 5). Interestingly, solar cells are becoming more and more attractive because they represent a green and renewable energy alternative to fossil energy and nuclear power. Along these lines, polymer bulk heterojunction (BHJ) solar cells based on composites of electron-donating and hole-transporting conjugated polymers and electron-accepting and electron-

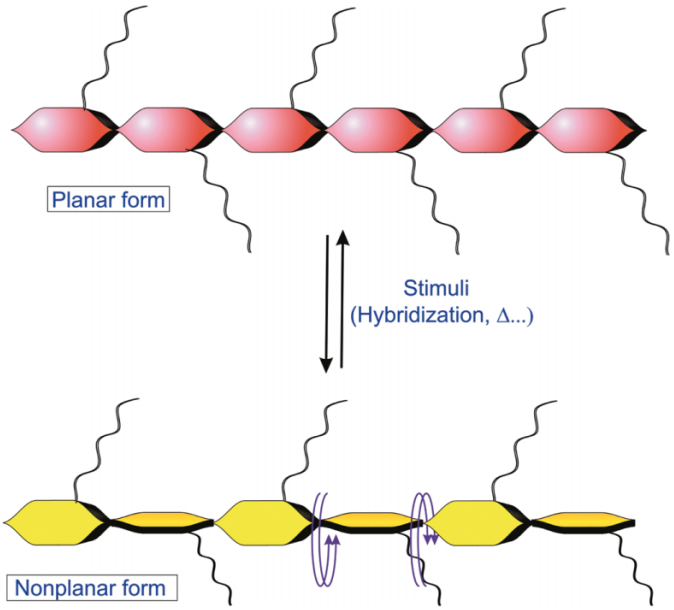
Scheme 5. Schematic description of a bulk-heterojunction photovoltaic device.



transporting fullerenes offer promise for the realization of a low-cost, printable, portable, and flexible renewable source of energy.[26] The fundamental BHJ concept involves self-assembly of nano-scale heterojunction by spontaneous phase separation of the polymeric donor and the fullerene acceptor (usually PCBM). During the past decade, research has mainly focused on regioregular poly(3-alkylthiophene)s, as the donor and power-conversion efficiencies about 5% were recently reported.[27] However, the performances of these polymers are somehow limited by their relatively large band gap and the limited possibilities to modulate their physical properties. Therefore, besides those recent advances, there is still a need for new polymeric materials to go beyond the 5% efficiency.

As mentioned above, poly(2,7-carbazole) derivatives exhibit good hole mobilities and should therefore be considered as promising candidates for photovoltaic applications. Among them, poly[*N*-9″-heptadecanyl-2,7-carbazole-*alt*-5,5-(4′,7′-di-2-thienyl-2′,1′,3′-benzothiadiazole)] (PCDTBT, see Scheme 4) has allowed to obtain a power-conversion efficiency up to 6%.[28] These remarkable results are partly explained by the optimized morphology of the active layer by which electron transfer and charge transport can be facilitated. Moreover, the synthetic flexibility of carbazole-containing conjugated copolymers should lead to an easy modulation of their electronic structures to better harvest the solar radiation. For instance, new low-band-gap poly(2,7-carbazole) derivatives have just been reported, and high power-conversion efficiencies are anticipated from these new polymeric materials.[29] Clearly, more efficient polymeric solar cells are foreseen in a near future. In addition, efficient polymeric solar cells mean high mobilities, and this research program should therefore also lead to highly efficient transistors.[30]

Scheme 6. Schematic description of conformational transition in polythiophenes.

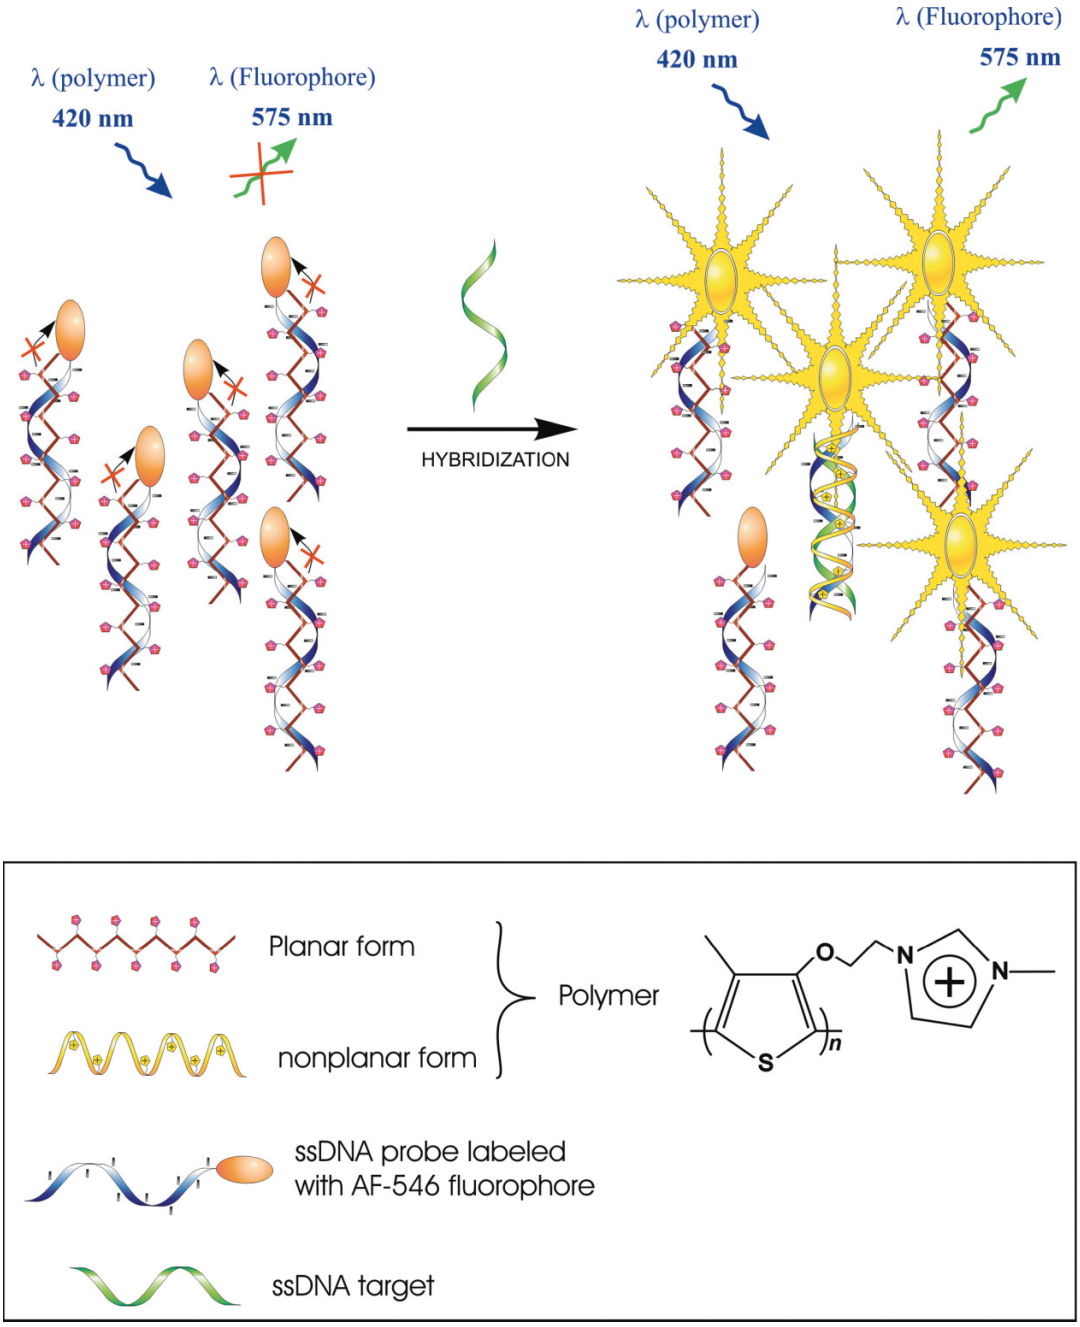


Optical biosensors

Optical and electrical sensors have become another important research topic for conjugated and electroactive polymers.[31] For instance, some neutral conjugated polymers (mainly polythiophenes) can undergo striking color changes upon exposure to various external stimuli. In most cases, these optical changes seem to be related to a conformational transition of the polymer backbone, from a planar to nonplanar form (Scheme 6), triggered by adequately functionalized and field-responsive side chains.[32] In addition to optical transitions induced by heating (thermochromism) or solvent quality changes (solvatochromism),[31,33] we have generated new phenomena with different regioregular poly(3-alkoxy-4-methylthiophene) derivatives, including the detection of ions (ionochromism),[34] UV radiation (dual photochromism),[35] and molecular recognition of chemical or biological moieties (affinitychromism).[36] In addition to the use of colorimetric detection, a modification of the conformation of a conjugated polymer can also modify its luminescence. Conjugated polymers are very sensitive to minor perturbations due to amplification by a collective system response and offer then a key advantage over small-molecule-based sensors.[37]

Along these lines, our recent studies have been mainly devoted to the detection of DNA and proteins.[38] More precisely, we have developed a new concept that utilizes a water-soluble, cationic polythiophene derivative as a polymeric stain that can specifically transduce the binding of an appropriate single-stranded DNA probe to its target into a clear optical signal. This simple, rapid, and selective methodology is based on conformationally flexible polyelectrolytes and complementary electrostatic interactions. For example, the starting neutral polythiophene–oligonucleotide complex is red in solution (aggregated and planar form) and presents a weak fluorescence. After hybridization with a perfect-match target, the solution becomes yellow and more fluorescent because of the formation of a so-called triplex structure. The fluorescence signal, measured at 570 nm,

Scheme 7. Schematic description of the proposed signal amplification detection mechanism based on the conformation change of a cationic polythiophene and energy transfers for ultrasensitive, selective, and rapid DNA detection.



shows a clear contrast between perfect complementary targets and those having two or even one mismatch. A slightly different approach has even allowed the detection of a few copies of a human-gene target (Scheme 7). In this last case, oligonucleotide capture probes are labelled with a fluorophore whose excitation spectrum gets a good overlap with the emission spectrum of the polymer. It seems that through Förster resonance energy transfer (FRET), one polythiophene donor can rapidly transfer its energy to a large number of neighbouring acceptors. This new and exciting but still unclear amplification phenomenon is called fluorescence chain reaction (FCR). Interestingly, recent studies have shown the possibility to transfer these methodologies to micro-arrays.[39] On the basis of these recent advances, we are currently targeting the development of PCR-free methods for genotyping, diagnostics, and so forth.

Conclusion and perspectives

From all these examples, it is quite evident that conjugated polymers promise a bright future. Research is not only conducted into academic institutions but many small and large companies are now involved in R & D projects devoted to conducting and semi-conducting polymers. On the basis of this tremendous momentum, it is firmly believed that the next few years should show how the design and the

better understanding of the structure–property relationships in conjugated polymers have contributed to address important society problems such as the production of renewable energy with minimum detrimental effects on the environment or the development of simple and inexpensive tests for the rapid detection and identification of genes, infections, and so forth. As Benjamin Braddock is told in The Graduate, the future is in plastics…

Acknowledgements

We would like to thank all students and collaborators who have participated to our research activities described here and whose names are cited in the references. Behind these scientific results, there were and still are students and scientists totally devoted to the development of conjugated polymers and to their future utilization in our day-to-day life. We would like also to acknowledge the Natural Sciences and Engineering Research Council (NSERC) of Canada and the Fonds Québécois de Recherche sur la Nature et les Technologies (FQRNT) for their continuous financial support over the years. We sincerely hope that our governments will continue to see their support to basic sciences as a very important investment in our next generation of scientists and as a source of socio-economical development. Finally, we would like to thank colleagues at Université Laval for their support and collaboration to our research program.

Iodine-catalyzed efficient synthesis of chalcones by grinding under solvent-free conditions

Hongshe Wang and June Zeng

Abstract: Chalcones are useful intermediates in organic synthesis and exhibit a large number of different biological activities. Chalcones have been synthesized in high yields by Claisen–Schmidt condensation of substituted acetophenones with various aromatic aldehydes in the presence of 10 mol% of iodine at room temperature by grinding under solvent-free conditions.

Key words: iodine, chalcones, Claisen–Schmidt condensation, grinding, solvent-free.

Résumé : Les chalcones sont des intermédiaires importants en synthèse organique et elles présentent un grand nombre d'activités biologiques diverses. On a réalisé la synthèse de chalcones avec des rendements élevés, par le biais d'une condensation de Claisen–Schmidt d'acétophénones substituées avec divers aldéhydes aromatiques, en présence de 10 moles % d'iode, à la température ambiante, par simple broyage dans des conditions sans solvant.

Mots-clés : iode, chalcones, condensation de Claisen–Schmidt, broyage, sans solvant.

[Traduit par la Rédaction]

Introduction

Chalcones and their derivatives are useful intermediates in organic synthesis.[1] Many chalcone derivatives display interesting pharmacological and biological activities.[2] Therefore, much attention has been paid to the synthesis of chalcones. Traditionally, chalcones are obtained via Claisen–Schmidt condensation carried out using alkaline hydroxides as catalysts.[3] However, the poor selectivity, generation of wastes, and laborious separation techniques make these catalysts practically inconvenient. Thus, more efficient methods have been developed for the synthesis of chalcones, which include the use of NaOH,[4] $FeCl_3 \cdot 6H_2O$,[5] $SOCl_2$/EtOH,[6] $BF_3 \cdot Et_2O$,[7] sulfonic-acid-functionalized organosilica materials,[8] $ZrCl_4$,[9] bamboo char sulfonic acid,[10] and ionic liquid[11] microwave[12] and ultrasonic irradiation.[13] However, some of the previously reported procedures have various disadvantages, such as long reaction times, special efforts needed to prepare the catalysts, high temperatures, and the use of expensive reagents and hazardous solvents. Thus, there is scope for further improvement involving more environment-friendly and milder reaction conditions.

With the increasing public concern over environmental pollution, it is of great importance for chemists to come up with new approaches that are less hazardous to human health and environment. The use of environmentally benign solvents, like water, and solvent-free reactions represent very powerful green chemical technology procedures from both the economical and synthetic points of view.[14] Grinding under solvent-free conditions is an environment-friendly method for the organic synthesis reactions.

In recent years, molecular iodine has been considered as an inexpensive and readily available catalyst for a variety of organic transformations.[15] In continuation to our work on studying iodine-catalyzed reactions,[16] we report herein an efficient and convenient procedure for the synthesis of chalcones from substituted acetophenones and various aromatic aldehydes via Claisen–Schmidt condensation in the presence of a catalytic amount of iodine at room temperature by grinding under solvent-free conditions (Scheme 1).

Results and discussion

To determine the efficiency of this procedure, we carried out the reaction of acetophenone with benzaldehyde using various other Lewis acids, such as $InCl_3$, $FeCl_3$, $ZnCl_2$, $(NH_4)_2Fe(SO_4)_2$, $Bi(NO_3)_3$, $Al_2(SO_4)_3$, and $Mg(ClO_4)_2$ at room temperature by grinding under solvent-free conditions (Table 1). Among these catalysts, I_2 was found to be the most effective catalyst for this conversion. As for the amount of the catalyst used, we found that 10 mol% of I_2 is sufficient to promote reaction efficiently (Table 2). No reaction was observed when acetophenone was reacted with benzaldehyde under similar conditions in the absence of I_2 even after grinding for 180 min. Any excess of I_2 beyond this loading did not show any further increase in conversion and yield. Use of less than the required catalyst loading resulted in low yields.

Note: The reaction was performed with 1 mmol of benzaldehyde and 1 mmol of acetophenone by grinding at room temperature.

[a]Isolated yield.

To explore the generality of this method, a series of chalcones were prepared under the optimized reaction conditions. By this method, the reactions were carried out simply by mixing a variety of substituted acetophenones and substituted benzaldehydes in the presence of a catalytic amount (10 mol%) of iodine at room temperature by grinding under solvent-free conditions, and the results are summarized in Table 3. The components of the mixture were ground together in a mortar with a pestle for several minutes. In all the cases, the reactions proceeded smoothly to afford the corresponding products in good-to-excellent yields using ethanol recrystallization. Their physical properties were determined, and the structures were confirmed by ^{1}H and ^{13}C NMR, IR, and MS. All acetophenones and benaldehydes with either electron-withdrawing or electron-donating substitutes, such as nitro, and methoxy groups on aromatic rings produced a satisfactory yield ranging from 83% to 95%. It was found from ^{1}H NMR spectral data that all chalcones were with trans configuration.

In conclusion, we have developed a new methodology to prepare a variety of chalcones in the presence of a catalytic amount of iodine at room temperature by grinding under solvent-free conditions. The advantages, such as the easy procedure, shorter reaction times, green and clean to the environment, mild reaction conditions, and high yields, make our method an attractive alternative to the preparation of chalcones.

Experimental

Melting points were determined on an XT4A electrothermal apparatus equipped with a microscope. ^{1}H NMR and ^{13}C NMR spectra were recorded on a Bruker Avance 400 spectrometer (^{1}H: 400 MHz, ^{13}C: 100 MHz) in $CDCl_3$ with TMS as an internal standard. Mass spectra were measured by HP5973 spectrometer. IR spectra were measured on a Nicolet FTIR-750 spectrometer. The benzaldehyde was distilled prior to use. All other reagents were commercially available products and were used without further purification.

Table 2. Effect of different amounts of iodine on the reaction of benzaldehyde with acetophenone.

Entry	I_2 (mol%)	Time (min)	Yield[a](%)

5	15	5	92
6	20	5	91

Note: The reaction was carried out at room temperature by grinding under solvent-free conditions.

[a]Isolated yield.

General procedure for the synthesis of chalcones

A mixture of acetophenone (1 mmol), benzaldehyde (1 mmol), and iodine (0.1 mmol) was ground in a mortar with a pestle (the mortar and pestle are thoroughly cleaned between runs) at room temperature until the reaction was completed (monitored by TLC). The reaction mixture was treated with 5% aqueous sodium thiosulfate. The precipitated products were then separated, washed with water, and recrystallized from ethanol to afford the pure products.

Except for compounds **3d**, **3e**, **3h**, and **3l**, all the products are known compounds. The spectroscopic and physical data for all known compounds corresponded to those given in the literatures.

Ruthenium-catalyzed efficient routes to oxindole derivatives

Khalil Tabatabaeian, Manouchehr Mamaghani, Nosratollah Mahmoodi, and Alireza Khorshidi

Abstract: Ruthenium-catalyzed preparation of oxindoles from one-pot trimerization of indoles under oxidative conditions and from electrophilic substitution reaction of indoles with isatins or isatin-derived imines under very mild reaction conditions is reported.

Key words: ruthenium, oxindoles, isatins, indoles, oxidative conditions.

Résumé : On a réalisé la préparation d'oxindoles par la réaction de trimérisation monotope d'indoles dans des conditions oxydantes et catalysée par le ruthénium ainsi que par la réaction de substitution électrophile d'indoles avec des isatines ou des imines dérivées de l'isatine, dans des conditions réactionnelles très douces.

Mots-clés : ruthénium, oxindoles, isatines, indoles, conditions oxydantes.

[Traduit par la Rédaction]

Introduction

Various indole derivatives occur in many pharmacologically and biologically active compounds,[1] and the chemistry of indoles has been and continues to be one of the most active areas of heterocyclic chemistry.[2,3] Isatins are also familiar for their biological activity. Oxindoles are well-known amongst different isatin derivatives and are useful as antibacterials, antiinflammatories, and laxatives.[4,5] Although these heterocyclic compounds were recently isolated from plants, for example, the marine alkaloid Convolutamydine A from the marine bryozoan *Amathia convoluta*,[6] oxindole derivatives have been prepared by different methods, such as the reaction of indoles and isatin in acid conditions,[7] silica sulfuric acid catalysis,[8] $KAl(SO_4)_2$ catalysis under microwave conditions,[9] bismuth triflate catalysis,[10] and few others. All of these methods have their own drawbacks, such as long reaction times, non-environment-friendly solvents, low yields of products, and so forth. Recently, we have been involved in the study of the catalytic activity of ruthenium towards organic reactions.[11–14] As a matter of fact, many organic transformations, which involve ruthenium species as catalyst, are known and well-documented.[15–17] We found that ruthenium chloride hydrate smoothly acts as homogeneous catalyst in one-pot trimerization of indoles under oxidative conditions and also in condensation of indoles with isatins or isatin-derived imines, providing the desired oxindoles in high yields under mild reaction conditions and using a relatively easy work-up.

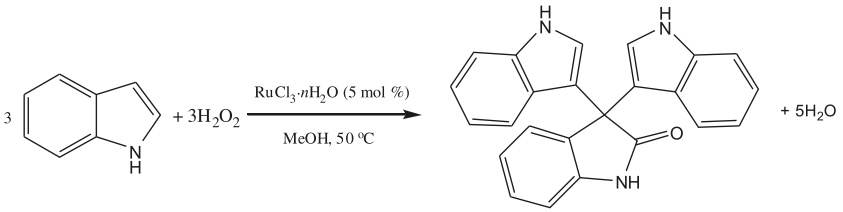
Results and discussion

A recent report on the trimerization of indole through laccase catalysis,[18] along with previous reports, such as iodine-catalyzed trimerization,[19] prompted us to evaluate the trimerization of indoles under ruthenium catalysis. We have recently reported the efficient condensation of indoles with aldehydes or ketones using $RuCl_3{\cdot}nH_2O$ as homogeneous catalyst.[11] To obtain oxindoles directly from indoles, as it is shown in Scheme 1, the scheme of reaction involves in situ oxidation to isatins and then condensation of the latter with excess indoles.

In an optimized procedure, treatment of indole (3 mmol) with hydrogen peroxide (3 mmol) in the presence of $RuCl_3{\cdot}nH_2O$ (5 mol%) in methanol (5 mL) at 50 °C for 120 min gave the corresponding 3,3-di(1*H*-indole-3-yl)indolin-2-one as a white solid precipitate, which was easily purified (see Experimental section). NMR data were consistent with those previously reported for 3,3-di(1*H*-indole-3-yl)indolin-2-one (**1a**),[20] while laccase catalysis was shown to produce 2,2-di(1*H*-indol-3-yl)indolin-3-one.[18] From a mechanistic point of view, initial oxidation of indole to isatin followed by the coordination of C3-located carbonyl group of isatin with ruthenium and then aldol condensation may be responsible for the formation of products, while laccase catalysis proceeds via a different pathway.[18] A mechanistic pathway for oxidation under ruthenium catalysis could be found in our previous report.[14] As shown in Table 1, indoles bearing substitution on 2- or 3-position failed to produce the desired products (Table 1, entries 5 and 6) probably because of oxidation to products other than isatin.

To further explore the formation of oxindoles, the condensation reaction of indoles and isatins was examined. In the condensation of indole (2 mmol) with isatin (1 mmol) in the presence of $RuCl_3{\cdot}nH_2O$ catalyst (5 mol%) in methanol (3 mL) at 50 °C, the reaction furnished an excellent yield of the product **1a** in a rather short time (95%, 5 min). This may be due to the fact that the product is insoluble in the

Scheme 1. Trimerization of indole under oxidative conditions.



reaction solvent. As shown in Table 2, this method worked with a variety of substrates. In most cases, the products are insoluble in the reaction solvent, and a simple filtration and rinsing (with methanol) work-up provides spectroscopically pure products. One interesting example is the reaction of 3-methylindole with isatin (Table 2, entry 4), which provided the alcohol product **4b**, while other reported methods failed for this reaction. $RuCl_3 \cdot nH_2O$ was found to be an efficient catalyst in the view of handling, temperature, yields, and reaction times as indicated in comparison with the reported methods.[7–10]

Although bis-indolylalkanes were usually prepared by nucleophilic addition of indoles to aldehydes, the addition of indoles to Schiff bases is also studied. However, the reactivity of Schiff bases is lower in comparison with aldehydes. Some reports in this context involve the reaction of indoles with aromatic aldimines in low-to-moderate yields in the presence of BF_3 etherate or Me_3SiCl,[21] $InCl_3$-catalyzed addition to aromatic aldimines in an extremely difficult procedure,[22] and the addition of indoles to *N-tert*-butanesulfinylaldimines, which requires long reaction times.[23] We found that isatin-derived imines bearing an electron-withdrawing group on the amine moiety, also, react with indoles in a smooth fashion to provide the desired oxindoles as an alternative route (Scheme 2). Typical results in this context are listed in Table 3. To ensure that the products were not formed from isatin due to hydrolysis of aldimine in the presence of Ru^{III}, a control reaction was set up without indole, and no isatin was detected (checked by TLC). To the best of our knowledge, this is the first report on efficient addition of indoles to aldimines. Here again, the unique feature of the protocol is the insolubility of the products in the reaction solvent, offering an easy work-up.

Conclusion

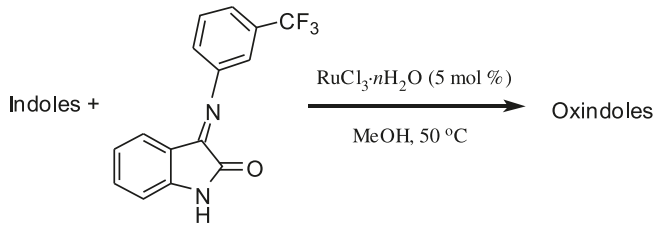
In conclusion, we have developed convenient routes to oxindole derivatives.

Experimental

General

IR spectra were recorded on a Shimadzu FTIR-8400S spectrometer. ^1H NMR spectra were obtained on a Bruker DRX-500 Avance spectrometer and ^{13}C NMR spectra were obtained on a Bruker DRX-125 Avance spectrometer. Chemical shifts of ^1H and ^{13}C NMR spectra were expressed in ppm downfield from tetramethylsilane. Melting points were measured on a Büchi Melting Point B-540 instrument and are uncorrected. Elemental analyses were performed by a Carlo-Erba EA1110 CNNO-S analyzer and agreed with the calculated values. Microwave irradiation was performed in a LBP125 microwave oven.

Scheme 2. Ru^{III}-catalyzed condensation of indoles with an isatin-derived aldimine.



Materials

All materials were purchased from Merck and used without further purification.

General procedure for trimerization of indoles under oxidative condensations

To a solution of indole (3 mmol) and $RuCl_3 \cdot nH_2O$ (10.7 mg, 0.05 mmol) in methanol, H_2O_2 (340 mg of a 30% solution) was added, and the reaction mixture was heated in an oil bath at 50 °C under reflux conditions for the time specified in Table 1. After completion of the reaction, the white solid precipitate was filtered and washed with cold methanol until removal of all traces of impurities (checked by TLC), providing the product **1a** (273 mg, 75%). The same procedure was used for the other products, except for products **3a** (Table 1, entry 3), **4b**, and **5b** (Table 2, entries 4 and 5, respectively), which were purified by preparative TLC (*n*-hexane/ethyl acetate 10:5).

Characterization data for the products

3,3-Di(1H-indol-3-yl)indolin-2-one, 1a

White solid, mp 310–312 °C. IR (KBr) ν (cm^{-1}): 758, 1012, 1103, 1336, 1473, 1614, 1706, 3056, 3280, 3323, 3427. ^1H NMR (500 MHz, $CDCl_3$, 25 °C) δ: 6.51 (2H, t, J = 7.5 Hz), 6.59 (1H, t, J = 7.5 Hz), 6.62 (2H, s), 6.69 (1H, d, J = 7.7 Hz), 6.72 (2H, t, J = 7.5 Hz), 6.88 (1H, t, J = 7.6 Hz), 6.97 (1H, d, J = 7.4 Hz), 7.02 (4H, t, J = 7.65 Hz), 9.78 (1H, s), 9.89 (2H, s) ppm. ^{13}C NMR (125 MHz, $CDCl_3$, 25 °C) δ: 53.41, 110.48, 112.47, 115.14, 119.01, 119.13, 121.62, 122.26, 125.05, 125.21, 126.55, 128.70, 135.45, 137.77, 142.17, 179.60 ppm. Phenolic constituents of *Phellodendron chinense* bark

Xue-Hu Li, Wen-Juan Zhang, Huan-Yang Qi, and Yan-Ping Shi

Abstract: The bark of *Phellodendron chinense* is a very important herbal medicine in traditional Chinese medicine. In a detailed phytochemical investigation, a new phenolic lactone, 2β,3β-dihydroxy-3α-vanilloylmethyl-γ-lactone (named as phellolactone) (**1**), and nine known phenolic compounds (**2–10**) were isolated from the bark of *P. chinense* Schneid. Their structures were characterized by spectroscopic methods, including IR, UV, HR-ESI-MS, NMR, and chemical transformation analysis.

Key words: Phellodendron chinense, Rutaceae, Phenolic constituents, Phellolactone.

Résumé : L'écorce du *Phellodendron chinense* est un produit très important dans la médication chinoise traditionnelle. Dans une étude phytochimique détaillée de l'écorce du *P. chinense* Schneid, on a isolé une nouvelle lactone phénolique, la 2β,3β-dihydroxy-3α-vanilloylméthyl-γ-lactone (dénommée phellolactone) (**1**) et neuf nouveaux composés phénoliques (**2–10**). Les structures ont été caractérisées par des méthodes spectroscopies, dont l'IR, l'UV, la spectrométrie de masse à haute résolution avec ionisation par électronébulisation, la RMN et l'analyse des transformations chimiques.

Mots-clés : Phellodendron chinense, rutaceae, constituants phénoliques, phellolactone.

[Traduit par la Rédaction]

Introduction

Phellodendron chinense Schneid (Rutaceae) is a deciduous tree found widely in Southwest China. The bark extracts of the tree have been used for the treatment of meningitis, bacillary dysentery, pneumonia, tuberculosis, and liver cirrhosis in traditional Chinese medicine.[1] However *Phellodendron amurense* is listed as invasive species in both the United States and Canada.[2] Previous phytochemical investigations of this plant revealed the presence of some alkaloids, flavonoids, and coumarins.[3–5] In the continuous search for new and bioactive components from traditional Chinese medicine, we selected the bark of *P. chinense*. This paper details the isolation and identification of eleven phenolic components obtained from *P. chinense*, two of the eleven components are new compounds.

Results and discussion

The 95% ethanol extract of the *P. chinense* was subjected to column chromatography to give a new phenolic lactone (**1**) (Fig. 1), together with nine other known phenolic compounds (**2–10**) (Fig. 1). The structures of the known compounds were elucidated using 1D and 2D NMR spectroscopic data and compared with those reported in the literature.

Phellolactone (**1**) was obtained as colorless oil. Its molecular formula, $C_{13}H_{14}O_8$, was deduced from HR-ESI-MS data at *m/z* 321.0582 $[M + Na]^+$ (calcd.: 321.0581 for $C_{13}H_{14}O_8Na$). The IR spectrum showed absorption bands for hydroxyl (3410 cm^{-1}), ester carbonyl (1706 and 1786 cm^{-1}), and phenyl (1599, 1516, and 1462 cm^{-1}) groups. The UV spectrum displayed maximal absorptions at 210, 258, and 292 nm. The CD spectrum showed negative Cotton effect at 212 and 225 nm.

In the ^1H and ^{13}C NMR spectra (Table 1), the aromatic signals at δ_H 7.61 (d, J = 8.0 Hz, H-6′), 7.57 (s, H-2′), and 6.88 (d, J = 8.0 Hz, H-5′) were assigned to a 1,3,4-trisubstituted benzene ring. An oxymethine signal at δ_H 4.64 (m, H-2) and two oxymethylene signals at δ_H 4.42 (m, H-5), δ_H 4.26 (d, J = 10.0 Hz, H-4a), and δ_H 4.44 (m, H-4b), as well as the five carbon resonances at δ_C 64.3 (C-5), 69.6 (C-2), 71.4 (C-4), 75.1 (C-3), and 174.5 (C-1) implied the presence of a five-carbon substructure. The HMBC correlations of H-2 and H-4 with C-1 (Fig. 2), combined with the IR absorption band at 1786 cm^{-1}, indicated that the five-carbon substructure should include a γ-lactone moiety with two hydroxyl groups. The functional groups could be attached by key correlations in the HMBC experiment (Fig. 2). The correlations of H-2′ and H-6′ with C-7′ indicated that the carbonyl carbon (C-7′) at δ_C 165.1 was connected to the C-1′ of the benzene ring. The correlation of the methoxyl protons at δ_H 3.87 (s, 3H) with C-3′ indicated that it was connected to C-3′. Therefore, compound **1** should include a vanilloyl moiety, and both substructures could also be put together by observable correlation between H-5 and C-7′ in the HMBC.

The NOE correlation of H-2 with H-5b was an important evidence for the cis-orientation of H-2 and H-5b, but two

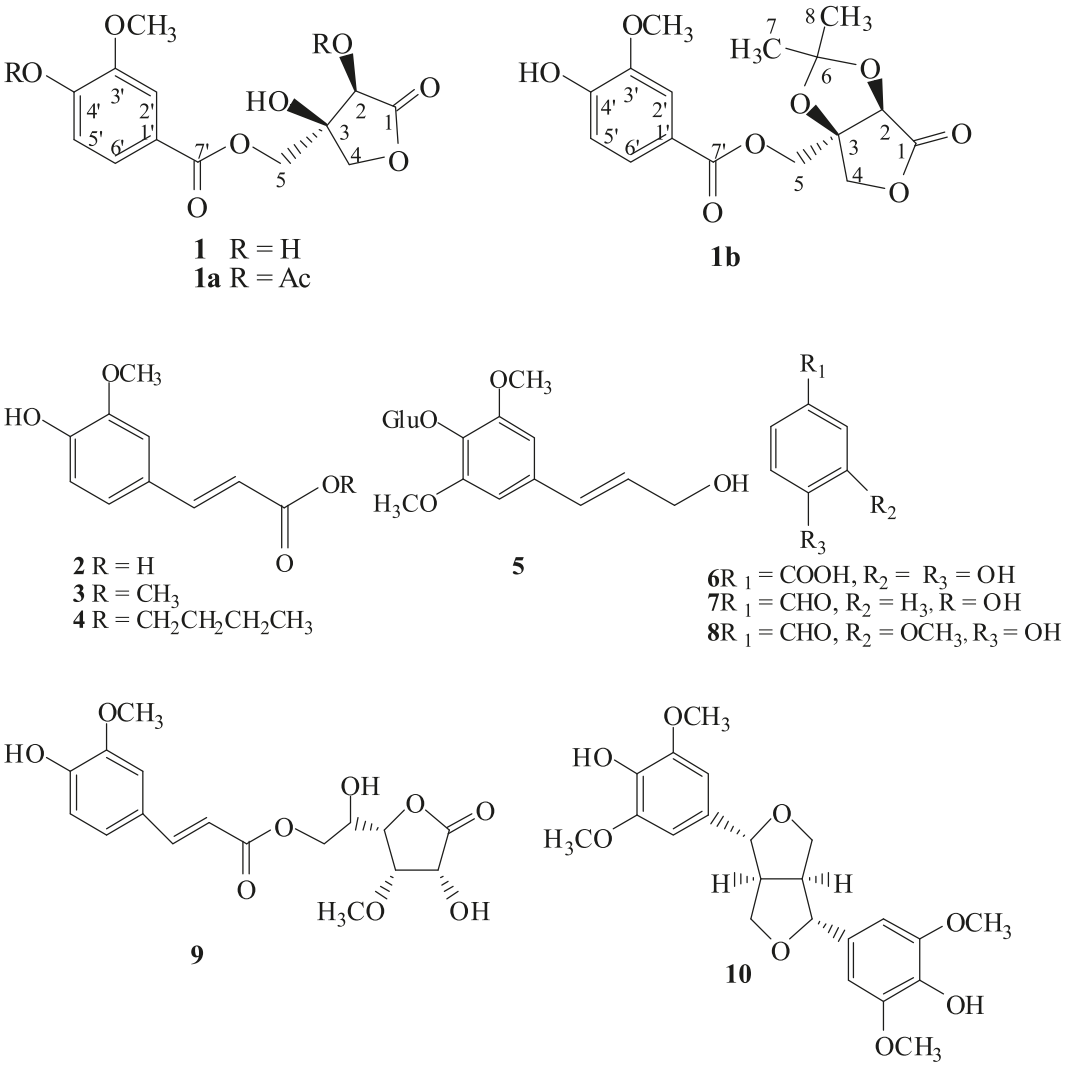
Fig. 1. Structures of compounds **1**–**10**.



key proton signals of the H-4b and H-5 could not be exactly distinguished (Table 1). To further confirm the relative configuration of compound **1** by NMR techniques, this material was transformed into the acetate **1a**. HR-ESI-MS of the acetylated product **1a** (Fig. 1) gave a molecular ion peak at *m*/*z* 400.1233 $[M + NH_4]^+$ ($C_{17}H_{18}O_{10}N$). The assignments of all proton signals and carbon signals were established from the results of the 1D and 2D NMR as shown in Table 1. Additionally, a clear correlation was observed in NOESY experiment of **1a** between H-5 and H-2; it is another important evidence for the cis-orientation of H-2 and C-5, and the correlation of the methoxyl protons at δ_H 3.87 (s, 3H) with C-2′ confirmed that the methoxy was connected to C-3′. So, the structure of phellolactone **1** was elucidated as 2β,3β-dihydroxy-3α-vanilloylmethyl-γ-lactone and named as phellolactone after the plant (Fig. 1).

Phellolactone-2,3-acetonide (**1b**) was obtained as colorless oil. The molecular formula of **1b** was established as $C_{16}H_{18}O_8$ on the basis of HR-ESI-MS analysis (*m*/*z* 356.1330 $[M + NH_4]^+$, calcd.: 356.1340) with eight degrees of unsaturation. The IR spectrum showed absorption bands for the ester carbonyl (1712 cm^{-1}) and phenyl (1598, 1516, and 1425 cm^{-1}) groups. The presence of acetonide was indicated by a strong absorption of a geminal dimethyl (1362 cm^{-1}) and a dioxolane ring (1095 and 1223 cm^{-1}). The structure of **1b** was determined also from the ^1H and ^{13}C NMR spectra (Table 1) and compared with the corresponding data of phellolactone (**1**). The additional resonance corresponding to two methyl singlets at δ_H 1.44 and 1.49, a downfield shift of H-2 (0.13 ppm) in the ^1H NMR spectrum (Table 1), and the carbon signals at δ_C 115.1, 27.9, and 27.4, together with downfield shifts of C-2 (7.3 ppm) and C-3 (9.1 ppm), against **1b** in the ^{13}C NMR spectrum (Table 1), implyed that **1b** could be an acetonide of **1** originating from the addition of an acetone unit with the OH groups attached to C-2 and C-3. HMBC correlations of H-2 and of H-7/8 with C-6 were observed, and therefore, the gross structure of **1b** was depicted.

Additionally, a clear correlation between H-5 and H-2 could be observed in NOESY experiment of **1b**, and it confirmed the cis-orientation of H-2 and C-5. So, compound **1b** could be confirmed as phellolactone-2,3-acetonide (Fig. 1). Since acetone has been used as a solvent in the isolation and purification of these compounds, compound **1b** should be an artifact resulting from the isolation process. When we repeated the isolation procedure without acetone, compound

1b was not observed by TLC, which confirmed the conclusion above.

The remaining compounds were characterized as ferulic acid (**2**),[6] methyl ferulate (**3**),[7] *n*-butyl ferulate (**4**),[8] syringin (**5**),[9] protocatechuic acid (**6**),[10] *p*-hydroxybenzaldehyde (**7**),[11] vanillin (**8**),[12] amurenlactone A (**9**),[13] and (–)(–) syringaresinol (**10**)[14] (Fig. 1) by comparison with their reported physical and spectroscopic data. Compounds **3**, **4**, **6**, **9**, and **10** were isolated and identified from this plant species for the first time.

Experimental

General experimental procedures

Optical rotations were recorded in $CHCl_3$ using a PerkinElmer 241 polarimeter. UV spectra were measured on a Spect 50-UV–vis instrument (Analytic Jena AG). IR spectra were measured on an FTS 165-IR spectrometer (Bio-Rad, USA). CD spectra were recorded on an Olis DSM 10000 spectrophotometer. ^{1}H NMR (400 MHz), ^{13}C NMR (100 MHz), and 2D NMR were recorded on a Varian INOVA-400 FTNMR spectrometer (USA) in $CDCl_3$ with TMS as internal standard. HR-ESI-MS (high resolution electrospray ionization mass spectrometry) was determined on a Bruker APEX II. EI-MS was determined on a HP 5988A MS (70 eV). Separation and purification were performed by column chromatography (CC) over silica gel. Silica gel (200–300 mesh), used for CC, and silica gel (GF_{254}) for TLC were supplied by the Qingdao Marine Chemical Factory, Qindao, P. R. China. Spots were detected on the TLC under UV light or by heating over 110 °C after spraying with 98% H_2SO_4/EtOH (*v*/*v*, 5:95).

Plant material

The commercial bark of *P. chinense*, which was collected from Sichuan province and was authenticated by Dr. Huan-Yang Qi in Lanzhou Institute of Chemical Physics, Chinese Academy of Sciences, Lanzhou, was obtained from Lanzhou Ltd. Co. of Fuxinhou herbal medicines. A voucher specimen (No. ZY2007P001) is deposited at the Key Laboratory for Natural Medicine of Gansu Province.

Extraction and isolation

The air-dried and powdered bark of *P. chinense* (9.8 kg) was extracted three times with 95% ethanol under reflux. The extract was obtained by vacuum concentration, suspended in water, and successively extracted with petroleum ether, ethyl acetate, and *n*-butanol. The ethyl acetate fraction was subjected to silica-gel CC, eluted with $CHCl_3$/MeOH (*v*/*v*, 20:1–1:1) to afford eight fractions (fractions 1–8). Fraction 2 was separated on CC over silica gel (200–300 mesh) with $CHCl_3$/acetone (15:1) to give crude **2**, which was further isolated and purified on a silica-gel column (200–300 mesh) with petroleum ether/acetone (2:1) to give the pure compound **2** (15.0 mg). Fraction 3 was subjected to a silica-gel

eluting with petroleum ether/acetone (4:1) to yield **7** (12.0 mg) and **8** (10.0 mg). Fraction 4 was purified by repeated CC over silica gel, eluted by petroleum ether and acetone (2:1) to provide **1b** (8.0 mg) and **1** (30 mg). Fraction 5 was chromatographed on silica gel and eluted with $CHCl_3$/acetone (4:1) to produce **6** (11.0 mg). Fraction 6 was separated by silica-gel chromatography using $CHCl_3$/acetone (3:1) to yield **9** (20.0 mg) and **10** (9.0 mg). From the *n*-butanol fraction, compounds **3** (13.0 mg), **4** (15.0 mg), and **5** (20.0 mg) were isolated after repeated column chromatography and recrystallization. In addition, fraction 4 was checked by TLC (run by $CHCl_3$/MeOH, 15:1) to find compound **1**, not **1b**.

Synthesis and properties of ladder-type 1,4-dihydro-1,4-phosphasilins

Yi Ren, Thomas Linder, and Thomas Baumgartner

Abstract: The synthesis and advanced characterization of a series of extended dithieno[2,3-*b*:3′,2′-*e*][1,4-dihydro-1,4]phosphasilins is reported, and their suitability as new building blocks for organic electronics is evaluated. Synthesis of basic, as well as benzo-extended dithienophosphasilins, can be achieved using appropriate 2,3-dibromothiophene precursors in a two-step protocol introducing the silicon and phosphorus centers subsequently. Both ladder-type materials show the typical reactivity of trivalent phosphorus species and can quantitatively be converted into the corresponding oxides or gold complexes, the latter exemplified with the basic dithienophosphasilin. Their optoelectronic properties were found to be inferior to those of related dithieno[3,2-*b*:2′,3′-*d*]phospholes, indicating a disruption of the π-conjugation in the molecular scaffold. X-ray crystallographic studies revealed that the molecular scaffold is planar in the oxidized benzo-extended material, whereas the basic dithieno materials show some small deviation from planarity. Density functional theory calculations suggest all materials to be planar, with the exception of the benzo-extended trivalent phosphasilin. This structure–property study illustrates that the disruption of the π-conjugation in the molecular scaffold of the extended phosphasilins is exclusively due to the presence of the silicon center and its electronic effects, rather than structural features.

Key words: phosphorus heterocycles, silicon heterocycles, organic electronics, thiophene, π-conjugation.

Résumé : On a effectué la synthèse et la caractérisation avancée d'une série étendue de dithiéno[2,3-*b*:3′,2′-*e*][1,4-dihydro-1,4-]phosphasilines et on a évalué la possibilité de les utiliser dans la synthèse de composés organiques électroniques. On peut réaliser la synthèse du produit de base ainsi que de diverses benzodithiénophosphasilines en utilisant comme précurseurs des 2,3-dibromothiophènes appropriés dans un protocole en deux étapes au cours desquelles on introduit les centres siliciés et phosphorés ultérieurement. Les deux types de matériaux en échelle présentent la réactivité type des espèces contenant du phosphore trivalent et ils peuvent être transformés quantitativement en oxydes correspondants ou en complexes d'or, un exemple de ce dernier ayant été préparé avec la dithiénophosphasiline basique. On a trouvé que leurs propriétés optoélectroniques sont inférieures à celles des dithiéno[2,3-*b*:3′,2′-*d*]phospholes, ce qui indique qu'il se produit une interruption dans la conjugaison π dans l'échafaudage moléculaire. Les études cristallographiques par diffusion des rayons X révèlent que l'échafaudage moléculaire est plan dans les dérivés benzo-condensés oxydés alors que les matériaux dithiéno de base présentent de faibles déviations par rapport à la planéité. Des calculs à base de la théorie de la fonctionnelle de la densité suggèrent que tous les matériaux doivent être plans, à l'exception de la benzophosphasiline trivalente. L'étude structure propriété illustre le fait que la disruption de la conjugaison π dans l'échafaudage moléculaire de phosphasilines étendues est exclusivement due à la présence du centre silicium et de ses effets électroniques et n'a rien à voir avec ses caractéristiques structurales.

Mots-clés : hétérocycles du phosphore, hétérocycles du silicium, électroniques organiques, thiophène, conjugaison π.

[Traduit par la Rédaction]

Introduction

Organic π-conjugated materials have received significant attention in recent years owing to their beneficial photophysical and electronic properties that provide intriguing opportunities for the field of organic electronics. Their semiconducting properties, in particular, show great potential for application in electronic devices such as molecular or polymer-based light-emitting diodes, photovoltaic cells, field-effect transistors, and sensory materials.[1–5]

Surprisingly, organophosphorus π-conjugated materials have received relatively little attention up until recently, despite the fact that the incorporation of σ^3,λ^3-phosphorus centers allows for a number of facile, nearly quantitative chemical modifications to be performed that significantly impact the materials' electronic structure.[6] The versatile reactivity of trivalent phosphorus centers allows for the preparation of entire families of materials from a single precursor, through oxidation or complexation of the phosphorus center.[7] Well-defined molecular systems thus allow for the investigation of important structure–property relationships through the systematic variation of the model's chemical structure that may then be used subsequently to tailor the materials' properties towards certain applications.[6a]

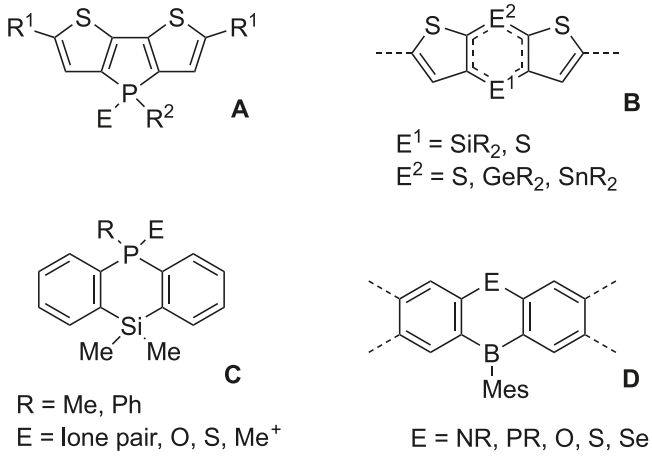
Chart 1. Relevant, ring-annelated dithieno- and dibenzo-heterocycles reported in the literature.

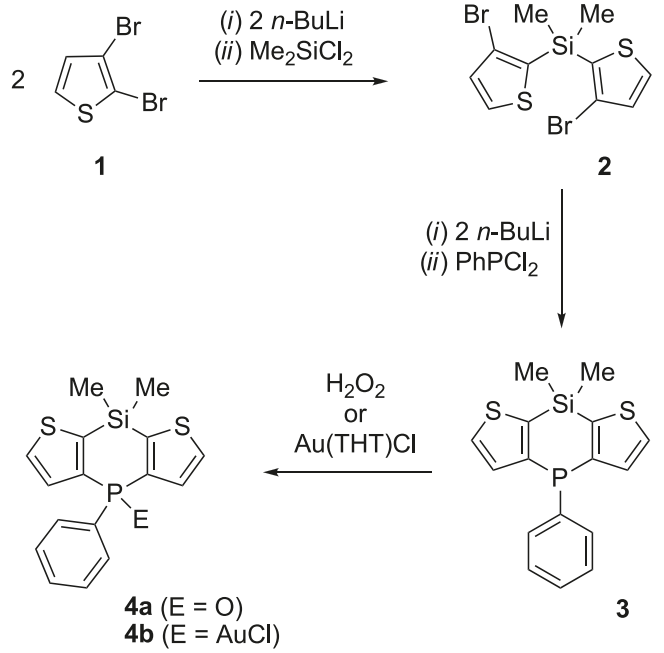


A few years ago, we introduced the dithieno[3,2-*b*:2′,3′-*d*]phosphole system (Chart 1A) as a new building block for π-conjugated materials.[8] This system conjoins two thiophene subunits with a central phosphole moiety via annelation. Fused bithiophene materials are generally promising candidates for an application in organic electronics, as they provide a high degree of π-conjugation due to their rigidified, planar structure that intrinsically affords smaller HOMO–LUMO (highest occupied molecular obrital – lowest unoccupied molecular orbital) gaps.[9] Our extensive, systematic investigations to date have revealed that this is also true for the dithienophosphole system and we were able to confirm a doping function for the phosphorus center, rather than it being an integral part of the π-conjugated system.[8]

The materials obtained in the context of our studies display intriguing photophysical properties with respect to emission wavelengths, intensity, and tunability that are far superior over those of related dibenzophospholes;[10,11] the parent dithienophosphole scaffold is strongly blue-light emitting with photoluminescence efficiencies of up to 90%. Notably, its photophysical properties can efficiently be tuned by simple modifications at either the phosphorus center (E = lone pair) via oxidation (E = O, S), complexation with main group centers (E = BH_3, CH_3^+) or transition metals (E = [M]), or by variation of the substitution pattern (R^1 on the thieno units or R^2 on the central phosphorus atom; see Chart 1).[6f,8,11]

Expanding our work on dithienophospholes, in this paper we now report our initial structure–property investigations on a new class of ladder-type, π-conjugated materials with a central 6-membered, 1,4-dihydro-1,4-phosphasilin ring (Chart 1B; E^1 = PPh, E^2 = $SiMe_2$). We were interested in how the addition of an additional silylene group within the molecular scaffold of dithienophospholes would impact the structure and properties of the resulting class of materials. It should be mentioned in this context that the number of reported six-membered, heterocyclic fused bithiophene materials to date is limited to a few thia-silins,[12,13] -germins, and -stannins (Chart 1B),[12] as well as dithieno-1,2-disilins[14]; most of the dithieno materials reported to date showcase five-membered central heterocycles.[9a] Although dibenzophosphasilins (Chart 1C) have been reported by Skvortsov, Toldov, and co-workers[15] in the early 1990s, and

Scheme 1. Synthesis and reactivity of the dithienophosphasilin (**3**).



Nakayama and co-workers[16] have reported somewhat related phospha-sila-thienotrypticenes in 1993, neither manuscript focuses on organic electronics. It is noteworthy, however, that Kawashima and co-workers[17] have recently reported a series of dibenzoborin-based materials (Chart 1D) that show very promising optoelectronic features for a potential application in organic electronics.

This present investigation now explores the synthetic accessibility and properties of dithieno[2,3-*b*:3′,2′-*e*][1,4-dihydro-1,4]phosphasilins, and the chemical versatility of the phosphorus center for additional fine-tuning. The study is further supported by theoretical investigations to gain a deeper understanding of the properties of this new ladder-type system.

Results and discussion

Synthesis and characterization

The synthesis of the targeted dithienophosphasilin (**3**) (Scheme 1) is straightforward using 2,3-dibromothiophene as starting material. Due to the ortho-directing effect of the sulfur atom, the 2-position of the thiophene is favored towards selective lithiation with *n*-butyllithium at –78 °C. Subsequent treatment with 0.5 equiv. of Me_2SiCl_2 affords the formation of the dithienyldimethylsilane (**2**) in good yield (80%). The further addition of 2 equiv. of *n*-butyllithium at –78 °C allows for the remaining bromo-substituents of **2** to be lithiated, and the central six-membered ring is closed by addition of $PhPCl_2$, providing **3** in a similarly high yield (80%). The dithienophosphasilin (**3**) shows a ^{31}P NMR resonance at δ = –20.7 ppm that is related to those of dithienophospholes (cf.: δ = –20 ± 3 ppm).[8,10] A ^{29}Si NMR shift of δ = –17.7 ppm further supports the successful formation of **3**;[18] the same is true for the ^1H and ^{13}C NMR data. As mentioned in the introduction, the trivalent phosphorus center in **3** is an excellent site for further modification, allowing for the generation of a whole family of new materi-

als. To verify this important tool of organophosphorus π-conjugated materials[6a] for this new ladder-type system, we have performed two representative chemical modifications converting **3** into the corresponding oxide **4a** by treatment with hydrogen peroxide, and the gold complex **4b** by treatment with Au(THT)Cl at room temperature, respectively (Scheme 1). The distinct lowfield shifted ^{31}P NMR resonances observed for the modified compounds **4a** (δ = 11.5 ppm) and **4b** (δ = 5.4 ppm) clearly support the successful transformation, as they again relate fairly well to the values of the corresponding dithienophosphole oxides and gold complexes;[8,11] the same is true for the ^{1}H and ^{13}C NMR data. The ^{29}Si NMR resonances, on the other hand, are less of a clear indicator, as they remain essentially unchanged at δ = –17.8 ppm (**4a**) and δ = –17.6 ppm (**4b**).

To our surprise, however, none of the three phosphasilin materials, **3**, **4a**, or **4b**, showed any notable fluorescence, which is in stark contrast to strongly emitting dithienophospholes.[8,11] This indicates that the incorporation of the silicon center appears to disrupt the π-conjugation across the system by essentially separating the chromophore into two independent thiophene units. The observation is also supported by the UV–vis spectroscopic data of the three compounds that only show narrow absorptions in the deep UV region of the optical spectrum at λ_{max} = 236 nm for **3**, 237 nm for **4a**, and 250 nm for **4b** (cf. thiophene: λ_{max} = 230 nm).[19]

The investigations on the related dibenzophosphasilins have illustrated that their scaffold is nonplanar at the P–Si sites, and the central ring generally shows a pronounced boat conformation. Furthermore, the resulting dihedral angle between the two halves of the molecule was found to depend on the chemical nature of the P center.[15] To verify whether the scaffold in the dithienophosphasilin system is also bent (or planar), we have investigated the solid-state structures of the two modified species, **4a** and **4b**. We were able to obtain single crystals suitable for X-ray diffraction studies of both compounds at room temperature from acetone solutions. The structure of **4a** shows two independent molecules in the unit cell, both of which show a somewhat bent molecular scaffold with dihedral angles amounting to approximately 20° and 17.5° (Fig. 1). In contrast to the dibenzo system, the central phosphasilin ring in both molecules is fairly planar, with the silicon center showing a slightly more pronounced deviation from planarity (Si: 0.31/0.32 Å; P: 0.20/0.13 Å). The bond lengths of the molecular scaffold suggest two isolated thiophene units without significant conjugation across the central phosphasiline ring, which is in line with the features observed for the dibenzophosphasilins.[15]

The gold complex **4b**, on the other hand, exhibits an essentially planar central phosphasiline ring (deviation: 0.17 Å for Si and 0.15 Å for P), and the rest of the molecular scaffold shows a significantly smaller deviation from planarity (~11°; Fig. 2). Remarkably, the dithienophosphasilin scaffold of **4b** is bent towards the exocyclic phenyl ring, whereas in **4a** the opposite direction is observed (away from phenyl group). The bond lengths and angles of the molecular scaffold of **4b** support a comparably more delocalized electronic structure within the central 1,4-phosphasilin ring. Whereas endocyclic C–C bonds are significantly elongated (C3–C4: 1.382(7) Å, C5–C6: 1.371(8) Å), when compared

Fig. 1. Two views of the molecular structure of **4a** in the solid state (50% probability level; H atoms are omitted for clarity). Selected bond lengths (Å) and angles (°): P1—O1 1.496(4), C1—C2 1.368(9), C2—C3 1.437(8), C3—C4 1.383(8), C5—C6 1.377(8), C6—C7 1.433(8), C7—C8 1.358(9), P1—C3 1.789(6), P1—C6 1.800(6), P1—C11 1.807(5), Si1—C4 1.863(6), Si1—C5 1.870(6), Si1—C21 1.855(7), Si1—C22 1.860(6); dihedral angle at P–Si axis: 20.09/17.46.

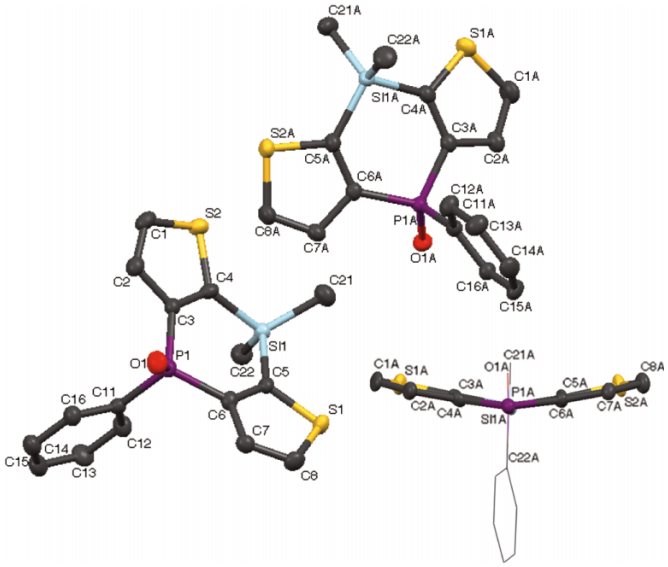


Fig. 2. Two views of the molecular structure of **4b** in the solid state (50% probability level; H atoms are omitted for clarity). Selected bond lengths (Å) and angles (°): Au1—Cl1 2.2861(13), Au1—P1 2.2297(13), C1—C2 1.358(8), C2—C3 1.423(7), C3—C4 1.382(7), C5—C6 1.371(8), C6—C7 1.433(7), C7—C8 1.355(9), P1—C3 1.802(5), P1—C6 1.810(6), P1—C11 1.813(6), Si1—C4 1.853(6), Si1—C5 1.865(6), Si1—C21 1.856(6), Si1—C22 1.858(6); P1–Au1–Cl1 178.24(5); dihedral angle at P–Si axis: 10.94.

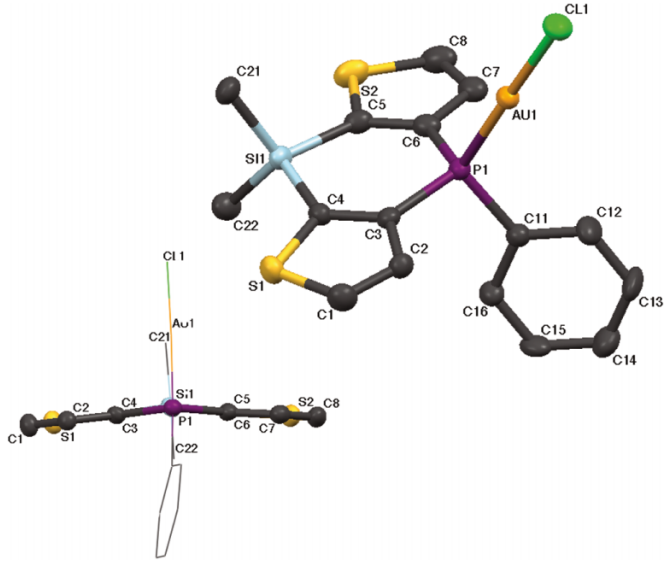
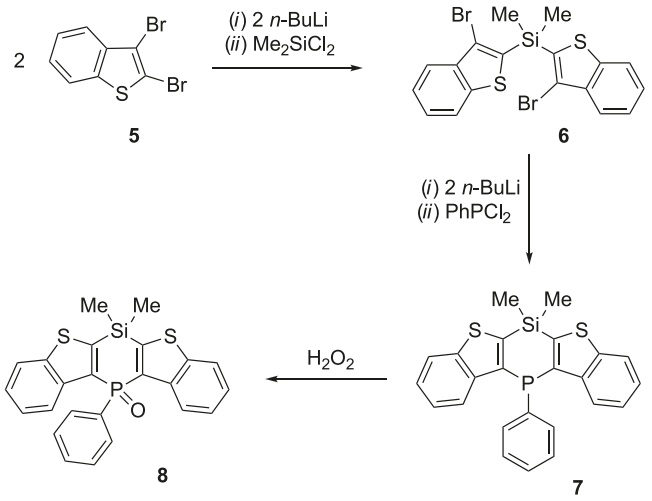


with the peripheral C1–C2 and C7–C8 bonds at 1.358(8) and 1.355(9) Å, respectively, the endocyclic Si–C (1.865(6) and 1.856(6) Å) and P–C bonds (1.802(5) and 1.810(6) Å)

Scheme 2. Synthesis and chemical modification of the benzoannelated dithienophosphasilin (**7**).



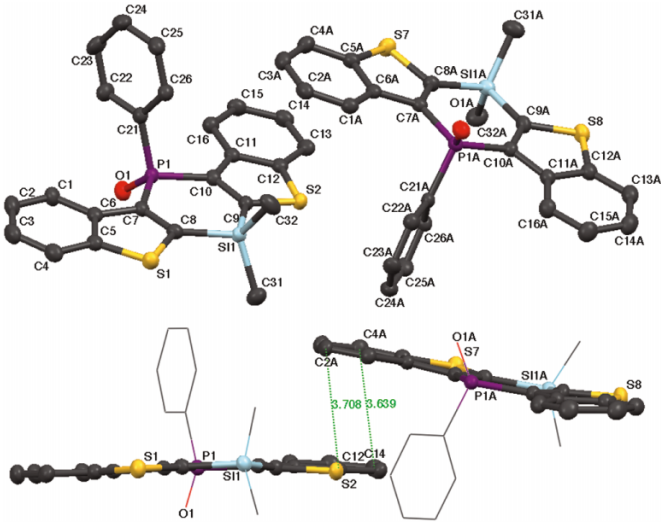
are similar in length to the respective exocyclic Si–C/P–C bonds within the margin of error (Fig. 2).

The bond lengths between the gold center and P1 (2.2297(13) Å) or Cl1 (2.2861(13) Å) relate well to those observed for the dithienophosphole system.[11b,11e] Remarkably, **4b** exists as a monomer in the solid state and shows no intermolecular contacts through aurophilic interactions. Although we have observed this feature with the dithienophosphole system once before,[11b] related complexes usually show dimerization through aurophilic interactions in the solid state.[11e,20] The monomeric structure of **4b** can, however, be explained through sterics, as the somewhat bulky dimethylsilylene group does not easily allow for π-stacking interactions between two neighboring dithienophosphasilines brought together in a potential dimer, as observed in the dimeric dithienophosphole gold complexes.

To potentially reduce the band gap of the dithienophosphasiline scaffold and to increase the degree of delocalization for improved optoelectronic properties of the materials, we have targeted corresponding benzo-extended dithienophosphasilins next. We could recently confirm this feature with the benzo-extended dithienophosphole system that does indeed show a smaller band gap than the parent system.[21] Synthesis of the corresponding benzoannelated dithienophosphasilin is possible in a protocol similar to that for the parent dithienophosphasilins (vide supra), using 2,3-dibromobenzo[*b*]thiophene as starting material. Selective lithiation with *n*-butyllithium and treatment with Me_2SiCl_2 affords the silane (**6**), which can then be converted into the extended phosphasilin (**7**) with another 2 equiv. of *n*-BuLi and 1 equiv. of $PhPCl_2$ (Scheme 2).

Compared to the non-benzoannelated phosphasilin (**3**), compound **7** shows a highfield shifted ^{31}P NMR resonance at δ = –36.5 ppm and a somewhat lowfield shifted ^{29}Si NMR resonance at δ = –16.9 ppm that suggest a significantly different structure for **7**, likely involving a more strongly bent central phosphasilin ring (vide infra). Oxidation with hydrogen peroxide affords the oxidized species **8** with a ^{31}P NMR shift at δ = 11.3 ppm that, on the other hand, is very similar to that of the non-extended oxide **4a**. The ^{29}Si NMR resonance at δ = –17.1 ppm is again only slightly shifted

Fig. 3. Two views of the molecular structure of **8** in the solid state (50% probability level; H atoms are omitted for clarity). Selected bond lengths (Å) and angles (°): P1—O1 1.4878(18), C5—C6 1.410(4), C6—C7 1.452(3), C7—C8 1.378(4), C9—C10 1.379(4), C10—C11 1.450(4), C11—C12 1.415(4), P1—C7 1.801(3), P1—C10 1.803(3), P1—C21 1.810(3), Si1—C8 1.862(3), Si1—C9 1.860(3), Si1—C31 1.860(3), Si1—C32 1.854(3); dihedral angle at P–Si axis: 4.81/5.83; helical torsion angle: 10.5/12.



from that of **6**. However, neither of the extended compounds shows any noteworthy fluorescence emission indicating that the extension of the π-conjugated system in **7** and **8** is not sufficient enough to significantly enhance the photophysical properties of the materials. Again, UV–vis spectroscopic data suggest that the central phosphasiline ring breaks the system down into two independent benzothiophene chromophores without delocalization across the entire scaffold (λ_{max} = 232 nm for **7**, 237 nm for **8**). To confirm the planarity of the system and to support the electronic 'decoupling effect' of the central phosphasilin ring, we have also studied the structure of **8** in the solid state. Suitable single crystals for an X-ray diffraction study were obtained from a concentrated acetone solution at room temperature.

The structure of **8** in the solid state shows two independent molecules in the unit cell that each overlap with parts of one of their terminal benzene rings (Fig. 3). This overlap gives rise to some π-stacking type interactions in the typical range of 3.6–3.7 Å. The bond lengths of **8** are similar to those of a related benzoannelated dithienophosphole oxide[21] and reflect a somewhat delocalized electronic system similar to **4b**. The exocyclic Si–C (1.860(7) Å by average) and P–C bonds (1.805(10) Å by average) of the central rings relate well to the other two phosphasiline systems reported herein. In terms of the molecular geometries, the scaffold of **8** is indeed significantly more planar than those of compounds **4a** and **4b**; the central phosphasilin ring is perfectly planar. Surprisingly, however, both independent molecules of **8** show the onset of a helical structure, although the terminal benzene subunits are too far away from each other for claiming steric issues to be responsible. There are also no distinct intermolecular interactions that could cause the twisting from planarity; electronic factors appear to be intrinsically responsible for the unusual helicity that generates a dihedral torsion

angle of 11°–12° between the C1(C1A) and C16(C16A) atoms in each of the two molecules.

Computational investigations

To better understand the observed properties of the new dithienophosphasilin materials, we have optimized the structures of **3**, **4a**, **7**, and **8** on the B3LYP-6/31G* level of theory.[22] The density functional theory (DFT) calculations suggest that three of the materials, **3**, **4a**, and **8**, are planar, whereas **7** is significantly bent at the P–Si axis with a dihedral angle of ca. 30° between the two benzothiophene halves. These observations relate well to the observed ^{31}P NMR resonances for the four compounds and the observed molecular structures of **4a** (and **4b**) and **8** in the solid state. The planar structures clearly suggest that geometry is not a factor in the inferior photophysical properties. In fact, the frontier orbitals for all four compounds extend well over the whole π-conjugated framework, irrespective of the molecular geometry. However, the energy of the frontier orbitals can be used to explain the observed properties. The generally lower energy levels of the HOMOs as well as the higher energy levels of the LUMOs lead to significantly increased band gaps for the phosphasiline-based materials ranging from E_{bg} = 5.06 eV for **3** to E_{bg} = 4.57 eV for **7** that are basically more than 1 eV larger than those for related dithienophospholes.[8b,21] Notably, the band gap of the phosphasilin even increases when the phosphorus center is oxidized (**4a**: E_{bg} = 5.36 eV, **8**: E_{bg} = 4.60 eV), which is contrary to the phosphole system, where the LUMO can generally be stabilized significantly leading to smaller band gaps in the dithienophosphole oxides.[8b,11f,21] These observations support an inherently different electronic structure for the phosphasilin-based materials, although they should theoretically be able to allow for delocalization of the π-system via hyperconjugative σ*–π* interactions through the Si centers.[23]

Conclusions

In conclusion, we have synthesized a series of dithieno[2,3-*b*:3′,2′-*e*][1,4-dihydro-1,4]phosphasilins that extend our studies on the dithieno[3,2-*b*:2′,3′-*d*]phosphole system. Our studies have shown that the phosphasilin framework can efficiently be constructed in two steps and subsequent modification of the central phosphorus atom allows for the formation of a family of derivatives. Investigations of their properties, however, have revealed that the incorporation of an additional silylene center within the scaffold of dithienophospholes significantly impacts the photophysical properties of the materials, not necessarily due to nonplanar geometries, but significantly increased band gaps (>4.5 eV). As a result, no strong fluorescence emission is observed for the phosphasiline system, which is in stark contrast to the dithienophosphole system.

Experimental section

General procedures

Reactions were carried out in dry glassware and under inert atmosphere of purified nitrogen using Schlenk techniques. Solvents were dried using an MBRAUN solvent purification system. *n*-BuLi (2.5 mol/L in hexane), 2,3-dibromothiophene, and hydrogen peroxide (30% in water) were used as received. Dichlorodimethylsilane and phenyldichlorophosphane were distilled prior to use. 2,3-Dibromo-benzo[*b*]thiophene[24] and Au(THT)Cl[25] were prepared by literature methods. ^{1}H NMR, ^{13}C{^{1}H} NMR, ^{31}P{^{1}H} NMR, and ^{29}Si{^{1}H} NMR spectra were recorded on a Bruker AC200, Bruker DMX-300, or Bruker DRX-400 spectrometer. Chemical shifts were referenced to external 85% H_3PO_4 (^{31}P) or tetramethylsilane (TMS) (^{13}C, ^{1}H, ^{29}Si). Elemental analyses were performed at the Department of Chemistry at the University of Calgary. Mass spectrometry (chemical ionization) was performed using a Finigan SSQ700 and Waters GCTOF Premier instrument. Optical spectroscopy was performed with dichloromethane solutions using a Jasco FP-6600 spectrofluorometer and UV-Vis-NIR Cary 5000 spectrophotometer.

X-ray crystallography

Crystallographic data for **4a**, **4b**, and **8** are summarized in Table 1 (also see the Supplementary data). Diffraction data were collected on a Nonius Kappa CCD diffractometer using monochromated Mo Kα radiation (λ = 0.71073 Å) at –80 °C (**4b**) and –100 °C (**4a**, **8**). The data sets were corrected for Lorentz and polarization effects, and empirical absorption correction was applied to the net intensities. The structures were solved by direct methods and refined using SHELX.[26] After full-matrix least-squares refinement of the nonhydrogen atoms with anisotropic thermal parameters, the hydrogen atoms were placed in calculated positions using a riding model. Refinement of the structure model for **4a** resulted in unsatisfactory agreement factors (wR_2 = 0.44, R_1 = 0.13) and high residual electron density (2 e Å^{-3}). Comparison of observed and calculated intensities showed that the most disagreeable reflections were consistently associated with much higher observed intensities than expected. This feature was interpreted as the effect of intensity addition due to nonmerohedral twinning with the help of PLATON;[27] the same twin law was confirmed for a second crystal. Refinement of an intensity data set taking into account the overlap of ca. 80% of the reflections resulted in a batch scale factor of 0.15 for the smaller individual. Due to incomplete overlap of reflections, the final agreement factors are still higher than in the case of the untwinned structures; the residual electron density dropped to 0.9 e Å^{-3}.

Bis(3-bromothiophen-2-yl)dimethylsilane (2)

To the solution of 2,3-dibromothiophene (**1**) (0.918 g, 3.79 mmol) in Et_2O (20 mL), *n*-BuLi (1.52 mL, 3.79 mmol) was added dropwise at –78 °C. After stirring for 40 min, Me_2SiCl_2 (0.245 g, 1.897 mmol) was added dropwise at this temperature. After another 15 min at –78 °C, the reaction was allowed to warm up, and stirred overnight at room temperature. Subsequently, the mixture was filtered through neutral alumina and the solvent was removed under vacuum, affording a light yellow oil (yield: 0.580 g, 80%). ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 7.52 (d, $^{2}J_{HH}$ = 4.8 Hz, 2H, thiophene), 7.13 (d, $^{2}J_{HH}$ = 4.8 Hz, 2H, thiophene), 0.81 (s, 6H, Si(CH_3)$_2$). MS (CI) *m*/*z*: 383.4 [*M* + H]$^{+}$.

Compound 3

To the solution of bis(3-bromothiophen-2-yl)dimethylsilane (0.986 g, 2.58 mmol) in Et_2O (200 mL), *n*-BuLi (2.06 mL, 5.16 mmol) was added dropwise at –78 °C. After

Compound 4a

To the solution of dithienophosphasilin (**3**) (0.800 g, 2.42 mmol) in $CHCl_3$ (20 mL), H_2O_2 (3 mL, 30% aqueous solution) was added at room temperature. After stirring overnight, all volatiles were removed under vacuum. Pure product **4a** was obtained as a white solid after recrystallization from Et_2O at room temperature (yield: 0.713 g, 85%). ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 7.76 (dd, $^3J_{HP}$ = 4.8 Hz, $^4J_{HH}$ = 1.6 Hz, 2H, thiophene), 7.61–7.56 (m, 4H, thiophene and Ph), 7.46–7.35 (m, 3H, Ph). ^{13}C{^{1}H} NMR (100 MHz, $CDCl_3$, ppm) δ: 143.3 (d, $^3J_{CP}$ = 19.2 Hz, thiophene), 142.0 (d, $^2J_{CP}$ = 109.4 Hz, ipso-thiophene), 135.4 (d, $^2J_{CP}$ = 108.1 Hz, ipso-Ph), 133.0 (d, $^2J_{CP}$ = 15.5 Hz, thiophene), 131.4 (d, $^4J_{CP}$ = 2.8 Hz, *p*-Ph), 131.1 (d, $^3J_{CP}$ = 15.8 Hz, thiophene), 130.3 (d, $^2J_{CP}$ = 10.6 Hz, *o*-Ph), 128.5 (d, $^3J_{CP}$ = 7.6 Hz, *m*-Ph), 1.7 (s, Si(CH_3)$_2$), 1.1 (s, Si(CH_3)$_2$). ^{31}P{^{1}H} NMR (162 MHz, $CDCl_3$, ppm) δ: 11.5 (s). ^{29}Si{^{1}H} NMR (80 MHz, $CDCl_3$, ppm) δ: –17.8 (d, $^3J_{SiP}$ = 9.04 Hz). Elemental anal. calcd. (%) for $C_{16}H_{15}OPS_2Si$ (346.48): C 55.46, H 4.36; found: C 55.19, H 4.44.

Compound 4b

To the solution of dithienophosphasilin (**3**) (0.984 g, 2.98 mmol) in CH_2Cl_2 (20 mL), Au(THT)Cl (0.827 g, 2.98 mmol) was added at room temperature. After stirring overnight, all volatiles were removed under vacuum. The crude product was washed with acetone and pentane affording the pure product **4b** as a white solid (yield: 1.005 g, 60%). ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 7.81 (dd, $^3J_{HH}$ = 4.8 Hz, $^4J_{HH}$ = 2.0 Hz, 2H, thiophene), 7.53–7.47 (m, 2H, *o*-Ph), 7.44 (dd, *J* = 5.6 Hz, *J* = 4.8 Hz, 2H, thiophene), 7.43–7.35 (m, 3H, Ph), 0.62 (d, J_{HP} = 35.6 Hz, 6H, Si(CH_3)$_2$). ^{13}C{^{1}H} NMR (100 MHz, $CDCl_3$, ppm) δ: 141.6 (d, $^2J_{CP}$ = 10.9 Hz, thiophene), 135.4 (d, $^1J_{CP}$ = 66.8 Hz, ipso-thiophene), 131.9 (d, $^1J_{CP}$ = 62.1 Hz, ipso-Ph), 133.2 (d, $^2J_{CP}$ = 14.7 Hz, thiophene), 133.0 (d, $^3J_{CP}$ = 8.4 Hz, thiophene), 132.7 (s, *p*-Ph), 131.7 (d, $^2J_{CP}$ = 2.6, Hz, *o*-Ph),

129.2 (d, $^3J_{CP}$ = 12.2 Hz, *m*-Ph), 1.6 (s, Si(CH_3)$_2$), 1.0 (s, Si(CH_3)$_2$). $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, ppm) δ: 5.4 (s). $^{29}Si\{^1H\}$ NMR (80 MHz, $CDCl_3$, ppm) δ: –17.6 (d, $^3J_{SiP}$ = 7.74 Hz). Elemental anal. calcd. (%) for $C_{16}H_{15}AuClOPS_2Si$ (562.90): C 34.14, H 2.69; found: C 34.19, H 2.99.

Bis(3-bromobenzo[*b*]thiophen-2-yl)dimethylsilane (6)

To the solution of 2,3-dibromobenzo[*b*]thiophene (**5**) (1.038 g, 3.56 mmol) in Et_2O (30 mL), *n*-BuLi (1.420 mL, 3.56 mmol) was added dropwise at –78 °C. After stirring at this temperature for 40 min, Me_2SiCl_2 (0.2294 g, 3.555 mmol) was added dropwise. After stirring for another 15 min at –78 °C, the reaction was allowed to warm up and was left stirring overnight at room temperature. The mixture was subsequently filtered through neutral alumina. Pure product **6** was obtained as a white solid by recrystallization from Et_2O (yield: 0.520 g, 60%). ^1H NMR (400 MHz, $CDCl_3$, ppm) δ: 7.85 (m, 4H, benzo), 7.43 (m, 4H, benzo), 0.88 (s, 6H, Si(CH_3)$_2$).

Compound 7

To the solution of bis(3-bromobenzo[*b*]thiophen-2-yl)-dimethylsilane (**6**) (0.558 g, 1.16 mmol) in Et_2O (200 mL), *n*-BuLi (0.930 mL, 2.31 mmol) was added dropwise at –78 °C. After stirring for 50 min, $PhPCl_2$ (0.207 g, 1.157 mmol) was added dropwise at –78 °C. The reaction was allowed to warm up quickly to room temperature and then left stirring overnight. The mixture was subsequently filtered through neutral alumina and evaporated to dryness. The pure product **7** was obtained as a white solid by recrystallization from acetone at 0 °C (0.300 g, 60%). ^1H NMR (400 MHz, $CDCl_3$, ppm) δ: 8.17–8.14 (m, 2H), 7.97–7.94 (m, 2H), 7.53–7.49 (m, 2H), 7.39–7.35 (m, 4H), 7.19–7.15 (m, 3H), 0.70 (J_{HP} = 18.4 Hz, 6H, Si(CH_3)$_2$). $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$, ppm) δ: 143.7 (d, $^2J_{CP}$ = 6.5 Hz, thiophene), 142.8 (d, $^1J_{CP}$ = 30.1 Hz, ipso-thiophene), 139.3 (d, $^3J_{CP}$ = 3.8 Hz, thiophene), 138.4 (d, $^2J_{CP}$ = 11.5 Hz, thiophene), 137.0 (d, $^1J_{CP}$ = 8.4 Hz, ipso-Ph), 133.3 (d, $^2J_{CP}$ = 20.6 Hz, *o*-Ph), 129.0 (s, *p*-Ph), 128.6 (d, $^3J_{CP}$ = 7.7 Hz, *m*-Ph), 125.0 (s, benzo), 124.3 (s, benzo), 123.6 (d, $^3J_{CP}$ = 12.8 Hz, benzo), 1.5 (s, Si(CH_3)$_2$), 1.0 (d, $^4J_{CP}$ = 4.2 Hz, Si(CH_3)$_2$). $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, ppm) δ: –36.5 (s). $^{29}Si\{^1H\}$ NMR (80 MHz, $CDCl_3$, ppm) δ: –16.9 (s). HR-MS *m/z* calcd for $[M + H]^+$: 430.0435; found: 430.0435.

Compound 8

To the solution of the benzanellated dithienophosphasilin (**7**) (0.500 g, 1.16 mmol) in $CHCl_3$ (20 mL), H_2O_2 (3 mL, 30% aqueous solution) was added at room temperature. After stirring overnight, all volatiles were removed under vacuum. The pure product **8** was obtained as a white solid after recrystallization from Et_2O at room temperature (yield: 0.415 g, 80%). ^1H NMR (400 MHz, $CDCl_3$, ppm) δ: 8.52–8.48 (m, 2H), 7.94–7.92 (m, 2H), 7.84–7.78 (m, 2H), 7.39–7.33 (m, 7H), 0.75 (J_{HP} = 14.8 Hz, 6H, Si(CH_3)$_2$). $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$, ppm) δ: 145.5 (d, $^2J_{CP}$ = 18.1 Hz, thiophene), 143.5 (d, $^3J_{CP}$ = 12.8 Hz, thiophene), 140.9 (d, $^2J_{CP}$ = 15.1 Hz, thiophene), 136.2 (d, $^1J_{CP}$ = 109.4 Hz, ipso-thiophene), 134.2 (d, $^1J_{CP}$ = 106.4 Hz, ipso-Ph), 131.4 (d, $^4J_{CP}$ = 2.7 Hz, *p*-Ph), 130.8 (d, $^3J_{CP}$ = 10.7 Hz, *m*-Ar), 128.6 (d, $^2J_{CP}$ = 12.6 Hz, *o*-Ph), 125.5 (s, benzo), 125.2 (s, benzo), 125.1 (s, benzo), 122.1 (s, benzo), 1.3 (s, Si(CH_3)$_2$), 0.5 (s, Si(CH_3)$_2$). $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$, ppm) δ: 11.3 (s). $^{29}Si\{^1H\}$ NMR (80 MHz, $CDCl_3$, ppm): –17.1 (d, $^3J_{SiP}$ = 11.0 Hz). Elemental anal. calcd. (%) for $C_{24}H_{19}OPS_2Si$ (446.60): C 64.55, H 4.29; found: C 63.78, H 4.29.

Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 3992. For more information on obtaining material, refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml. CCDC 732433–732435 contain the X-ray data in CIF format for seven complexes for this manuscript. These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (Or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

Acknowledgements

Financial support by the Natural Sciences and Engineering Research Council of Canada (NSERC) and the Canada Foundation for Innovation (CFI) is gratefully acknowledged. We thank Alberta Ingenuity for a graduate scholarship (Y.R.) and a New Faculty Award (T.B.). We would also like to thank Ulli Englert (RWTH Aachen University) for his help with the X-ray diffraction data of **4a**.

Dammarane triterpenoid saponins from *Bacopa monnieri*

Pamita Bhandari, Neeraj Kumar, Bikram Singh, and Inderjeet Kaur

Abstract: *Bacopa monnieri* is a well-known Ayurvedic Indian medicinal plant traditionally used as a memory enhancer. Its memory-enhancing effect is mainly attributed to dammarane triterpenoid saponins. In the present study, two new dammarane-type triterpenoid saponins, bacopaside-XI (**1**) and bacopaside-XII (**2**), together with known compounds, bacopaside IV, bacopaside V, and apigenin, were isolated from the aerial parts of the *B. monnieri*. The structures of the new saponins were elucidated as 3-*O*-[α-L-arabinofuranosyl(1→3)]-6-*O*-sulfonyl-β-D-glucopyranosyl pseudojujubogenin (**1**) and 3-*O*-{β-D-glucopyranosyl(1→3)[α-L-arabinofuranosyl(1→2)]-β-D-glucopyranosyl}-20-*O*-α-L-arabinopyranosyl pseudojujubogenin (**2**) on the basis of extensive investigations of 1D and 2D NMR (HMQC and HMBC), ESI-QTOF-MS/MS spectroscopic methods, and chemical evidences.

Key words: scrophulariaceae, *Bacopa monnieri*, triterpenoid saponins, bacopaside-XI, bacopaside-XII.

Résumé : Le *Bacopa monnieri* est un plante médicinale bien connue chez les indiens ayurvediques où elle est utilisée pour améliorée la mémoire. Cet effet est généralement attribué aux saponines triterpénoïdes dammarane. Dans la présente étude sur les parties aériennes du *B. monnieri*, on a isolé deux nouvelles saponines triterpénoïdes du type dammarane, le bacopaside-XI (**1**) et le bacopaside-XII (**2**) aux côtés de composés connus, dont le bacopaside-IV, le bacopaside-V et l'apigénie. Faisant appel à des études extensives de données chimiques, de RMN mono- et bidimensionnelles (« HMQC » et « HMBC ») et de spectrométrie de masse (« ESI-QTOF-MS/MS »), on a élucidé les structures des nouvelles saponines, la 3-*O*-[α-L-arabinopyranosyl-(1→3)-6-*O*-sulfonyl-β-D-glucopyranosylpseudojujubogénine (**1**) et la 3-*O*-{β-D-glucopyranosyl(1→3)[α-L-arabinofuranosyl(1→2)]-β-D-glucopyranosyl}-20-*O*-L-arabinopyranosylpseudojujubogénine (**2**).

Mots-clés : scrofulariacée, *Bacopa monnieri*, sapogénines triterpénoïdes, bacopaside-XI, bacopaside-XII.

[Traduit par la Rédaction]

Introduction

Bacopa monnieri (L) WETTST. (Scrophulariaceae) (commonly known as "Brahmi") is a reputed medicinal herb, found throughout the Indian subcontinent in wet and marshy places.[1] It is used in the Ayurvedic system of medicine as a brain tonic and memory enhancer, for the improvement of intellect, and as a revitalizer of sensory organs.[2] It is claimed to be useful in the treatment of cardiac, respiratory,[3] and neuropharmacological[4] disorders like insomnia, insanity, depression, psychosis, epilepsy, and stress. In addition, *B. monnieri* is reported to show anti-inflamatory, antiulcerogenic, anti-*Helicobactor pylori*, anthemintic, adaptogenic, anticancer, cardiotonic, bronchodilatatory, and mast-cell-stabilizing activities.[3,5,6]

The major chemical constituents isolated and characterized from *B. monnieri* are dammarane-type triterpenoid saponins with jujubogenin or psuedojujubogenin as aglycone. These saponins include bacosides A_1–A_3, bacopasaponins A–G, bacopasides I–VIII.[7,8] The pharmacological effects of *B. monnieri* are mainly attributed to these saponins, especially bacoside A and bacoside B, which are therefore, considered as bioactive marker compounds for this species.[9] The composition of bacoside A, and bacoside B, has been established very recently as a mixture of four triglycosidic and four diglycosidic saponins, respectively (bacoside A as a mixture of bacoside A_3, bacopaside II, 3-*O*-{α-L-arabinofuranosyl-(1→2)-[β-D-glucopyranosyl-(1→3)]-α-L-arabinopyranosyl} jujubogenin, and bacopasaponin C; and bacoside B as a mixture of bacopaside N1, bacopaside N2, bacopaside-IV, and bacopaside-V).[10,11] Besides saponins, cucurbitacins,[12] phenylethanoid glycosides, flavonoids, and alkaloids, such as brahmine and herpestine,[13] were also reported. In continuation to our work on the isolation of novel bioactive molecules from the western Himalayan bioresources, here, we report two new dammarane-type triterpenoid saponins from *B. monnieri*.[12,14–18]

Results and discussion

Defatted powdered aerial parts of *B. monnieri* were extracted with methanol/water (50:50), concentrated, and kept overnight. The extract was filtered and fractionated with EtOAc and *n*-BuOH, successively. The EtOAc extract was chromatographed over Diaion HP-20 resin, which resulted in the isolation of two new triterpenoid saponins (Fig. 1).

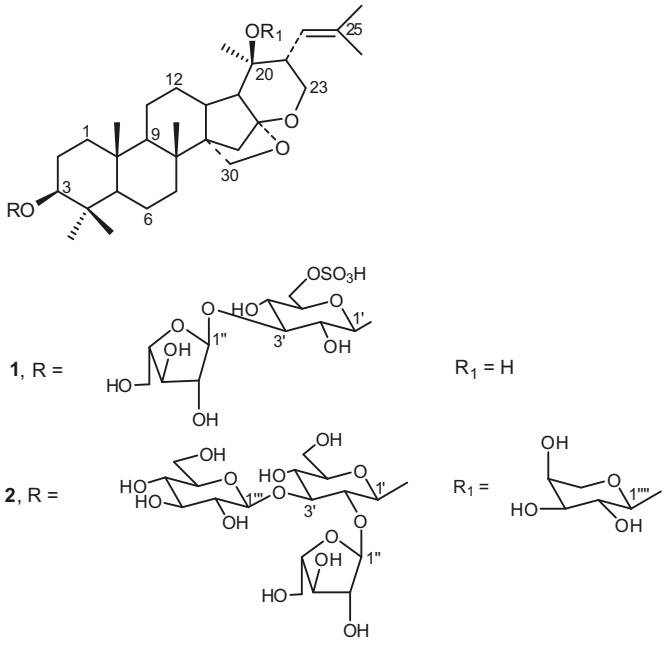
Fig. 1. Structures of bacopaside-XI (**1**) and bacopaside-XII (**2**).



Compound **1** was obtained as a white amorphous powder, which showed a positive Liebermann–Burchard test for triterpenoids. The HR-ESI-QTOF-MS displayed a pseudomolecular ion peak at *m/z* 847.0171 $[M + H]^+$ (calcd. 847.0191) corresponded to the formula $C_{41}H_{66}O_{16}S$. Its IR spectrum showed a strong and broad band at 3430 cm^{-1} due to multiple hydroxyl groups in the compound. The IR absorptions at 1220 and 809 cm^{-1} were observed due to the presence of sulfate group. The ^1H NMR spectrum (Table 1) of **1** exhibited seven methyl singlets at δ 0.59 (3H-19), 0.93 (3H-18), 0.95 (3H-29), 1.16 (3H-28), 1.27 (3H-26), 1.49 (3H-27), and 1.57 (3H-21). In ^{13}C NMR spectrum (Table 2), these methyls were observed at δ 16.1 (C-19), 18.6 (C-18), 16.2 (C-29), 27.5 (C-28), 26.9 (C-26), 18.2 (C-27), and 25.8 (C-21). Two olefinic signals were observed at δ 123.0 and 132.7 for C-24 and C-25 positions of the isobutenyl group. The presence of a ketal group (C-16) and an oxygen-bearing methylene (C-30) in aglycone moiety was evidenced from its ^{13}C NMR signals at δ 110.1 and δ 65.9, respectively. On the basis of NMR spectral data and the saponins previously isolated from this species, the aglycone was identified as pseudojujubogenin.[2,19–21] In ^1H NMR, the upfield signals of H-23 at δ 3.78 (1H, d, J = 10.2) and 3.70 (overlapped) and further upfield of C-23, C-24, and C-25 (δ 65.6, 123.0, and 132.7, respectively) in ^{13}C NMR confirmed the aglycone as pseudojujubogenin. Two anomeric proton and carbon signals were observed for the presence of two sugar moieties at δ 5.06 (1H, d, J = 7.8 Hz), 6.18 (1H, brs), and δ 104.9 and 109.8, respectively. The anomeric signals, their coupling constants, together with ^{13}C NMR values clearly indicated the identity of the sugars as α-L-arabinofuranosyl and β-D-glucopyranosyl. These sugars were further confirmed by TLC analysis of the acid-hydrolyzed product with authentic sugars. The attachment of a sugar moiety to the C-3 of aglycone and interglycosidic linkage (C-3′–C-1″) was confirmed by downfield shifting of C-3 (δ 88.4) and C-3′ (δ 84.7) NMR signals (α-effect) and upfield shifting of neighbouring carbon signals (β-effect). The linkages were further confirmed by HMQC and HMBC spectral studies (Fig. 2).

ESI-QTOF-MS/MS of **1** (*m/z* 847) displayed the fragment ion peak at *m/z* 767 $[M + H - 80]^+$, indicating the loss of a sulfate group. In ^{13}C NMR, a downfield shift of ~3.00 ppm in C-6′ signal and an upfield shift (γ effect) of ~2.00 ppm in C-5′ signal suggested the attachment of a sulfate group at C-6′. Further, two fragments at *m/z* 635 $[M + H - 80 - 132]^+$ and 473 $[M + H - 80 - 132 - 162]^+$ were observed due to the sequential release of a pentose and a desulfated hexose sugars, respectively. Thus, on the basis of the above-mentioned spectroscopic evidences, the structure of compound **1** was unambiguously assigned as 3-*O*-[α-L-arabinofuranosyl (1→3)]-6-*O*-sulfonyl-β-D-glucopyranosyl pseudojujubogenin and named as bacopaside-XI (Fig. 1).

Compound **2** was obtained as a white amorphous powder. Its positive ESI-QTOF-MS showed a pseudomolecular ion peak at *m/z* 1061.5453 $[M + H]^+$ (calcd. 1061.5454), which corresponded to the molecular formula $C_{52}H_{84}O_{22}$. Detailed ^1H and ^{13}C NMR spectrum study indicated that compound **2** shared the same aglycone as compound **1**. ^1H and ^{13}C NMR spectrum exhibited four anomeric proton and carbon signals for the presence of four sugar moieties at δ 4.63 (1H, d, J = 8.0 Hz), 6.01(1H, brs), 4.95 (overlapped with water signal), and 4.63 (1H, d, J = 7.1 Hz), and at δ 105.5, 110.1, 104.6, and 98.7, respectively. The anomeric signals, their coupling constants, together with ^{13}C NMR values clearly indicated the identity of sugars as β-D-glucopyranosyl, α-L-arabinofuranosyl and α-L-arabinopyranosyl. The sugars were further confirmed by TLC analysis of the acid-hydrolyzed product of compound **2** by comparison with authentic sugar samples.The attachment of sugar units to C-3 and C-20 of aglycone as well as intersugar linkages (C-2′–C-1″ and C-3′–C-1‴) were determined by downfield shifting of C-3 (δ 88.4), C-20 (δ 75.1), C-2′ (δ 78.2), and C-3′ (δ 88.4) NMR signals and upfield shifting of the neighbouring carbon signals. The linkages were further confirmed by HMQC and HMBC spectral studies (Fig. 3).

ESI-QTOF-MS/MS of **2** (*m/z* 1061) displayed the fragment ion peak at *m/z* 929 $[M + H - 132]^+$, representing the loss of a pentose sugar unit. Further, the fragment ion was observed at *m/z* 473 $[M + H - 132 - 162 - 132 - 162]^+$, indicating the loss of four sugar moieties. Thus, on the basis of the above-mentioned spectroscopic evidences, the structure of compound **2** was unambiguously assigned as 3-*O*-{β-D-glucopyranosyl(1→3)[α-L-arabinofuranosyl(1→2)]-β-D-glucopyranosyl}-20-*O*-α-L-arabinopyranosyl pseudojujubogenin and named as bacopaside-XII (Fig. 1).

Experimental

General methods

Melting points were determined on a Barnstead Electrothermal 9100. Optical rotation was determined on Horiba Sepa-300 Polarimeter, and IR spectra were recorded on a PerkinElmer 1760 FTIR spectrometer with KBr discs. Mass spectra were recorded on QTOF-Micro of Waters Micromass. NMR experiments were performed on a Bruker Avance-300 spectrometer. Diaion HP-20 for column chromatography, TLC silica gel 60 F_{254} plates, and all other chemicals used were purchased from Merck India Ltd.

Plant material

The plant material was collected in May 2006 from the Institute of Himalayan Bioresource Technology (IHBT) farm, Palampur, Himachal Pradesh, India.

Extraction and isolation

Air-dried powdered aerial parts of *B. monnieri* (2.2 kg) were defatted with petroleum ether (bp 60–80 °C) in a soxhlet. The defatted material was extracted with MeOH/H_2O (1:1, 3 × 2 L) in a percolator at room temperature. The combined MeOH percolations were concentrated followed by dilution with MeOH (250 mL) and kept overnight at room temperature. A deep green residue was precipitated, which was filtered. The filtrate was concentrated, dissolved in water, and partitioned with EtOAc and *n*-BuOH, successively. The EtOAc and *n*-BuOH fractions were dried under vacuum to yield 43.3 g and 57.9 g extracts, respectively. The EtOAc fraction (10.0 g) was subjected to column chromatography on Diaion HP-20 (500 g) and eluted with pure water followed by increasing polarity of methanol as 10%, 20%, 30%, 50%, 70%, 90%, and 100%. A total of 196 fractions (100 mL each) were collected sequentially and combined on the basis of the TLC pattern. Fractions 177–182, eluted with methanol/water (90:10), afforded compound **1** (25 mg) as a white amorphous powder after crystallization in methanol. Fractions 191–196, eluted with pure methanol, yielded compound **2** (20 mg) as a white amorphous powder.

Bacopaside-XI (2)

White amorphous powder; mp 262–265 °C. $[\alpha]_D^{29}$ – 35.2 (*c* 0.5, MeOH). IR (KBr) ν_{max} cm^{-1}: 3425, 2932, 2860, 1641, 1465, 1380, 1280, and 1078. ^{1}H NMR (300.13 MHz, Py-d_5): see Table 1. ^{13}C NMR (75.46 MHz, Py-d_5): see Table 2. HR-ESI-QTOF-MS (positive) *m/z*: 1061.5453 $[M + H]^+$ (calcd. for $C_{52}H_{84}O_{22}$: 1061.5454). MS^2 *m/z*: 929 $[M + H - 132]^+$, 767 $[M + H - 132 - 162]^+$, 635 $[M + H - 132 - 162 - 132]^+$, 473 $[M + H - 132 - 162 - 132 - 162]^+$, 455

$[M + H - 132 - 162 - 132 - 162 - H_2O]^+$, 437 $[M + H - 132 - 162 - 132 - 162 - 2 \times H_2O]^+$, 419 $[M + H - 132 - 162 - 132 - 162 - 3 \times H_2O]^+$.

Acid hydrolysis of saponins

Saponins **1** and **2** (15 mg each) were refluxed with 2 mol/L HCl in aq. MeOH (10 mL) at 90 °C for 4 h. The reaction mixture was cooled, diluted with water (10 mL), and extracted with $CHCl_3$. The aquous part was neutralized with Ag_2CO_3 and filtered. The filtrate was concentrated under reduced pressure and examined for sugars by TLC using authentic sugars. Arabinose and glucose sugars were identified in both the saponins. Two spots were observed corresponding to arabinose (R_f = 0.45) and glucose (R_f = 0.25) in both the compounds.

In situ high-pressure study of ammonia borane by Raman and IR spectroscopy

Shuntai Xie, Yang Song, and Zhenxian Liu

Abstract: Pressure-induced structural transformations of the ammonia borane complex ($NH_3{\cdot}BH_3$) were investigated in diamond anvil cells by Raman spectroscopy and synchrotron IR spectroscopy up to 14 GPa at room temperature. Starting with a disordered tetragonal structure, $NH_3{\cdot}BH_3$ is found to undergo several transformations upon compression as monitored by in situ Raman measurements. These transformations are indicated by the sequential changes of characteristic Raman modes as well as by the pressure dependence of these modes. Synchrotron IR absorption spectroscopy provided supplementary and consistent information about the structural evolution of $NH_3{\cdot}BH_3$ under compression. Decompression measurements on $NH_3{\cdot}BH_3$ suggest the pressure-induced transformations are reversible in the entire pressure region. The combined Raman and IR data allowed analysis of possible high-pressure structures of $NH_3{\cdot}BH_3$. Our study significantly complements previous high-pressure Raman studies by providing new information on the structures and stabilities of $NH_3{\cdot}BH_3$.

Key words: ammonia borane, hydrogen storage, high pressure, Raman spectroscopy, IR spectroscopy, diamond anvil cell.

Résumé : Opérant à la température et à des pressions allant jusqu'à 14 GPa et faisant appel à la spectroscopie Raman et à la spectroscopie infrarouge (IR) synchrotron avec une cellule avec contre-partie de diamant, on a étudié les transformations induites par la pression du complexe ammoniac-borane ($NH_3{\cdot}BH_3$). Tel qu'on a pu l'observer par des mesures Raman in situ, on a trouvé que, par compression, le $NH_3{\cdot}BH_3$ subit plusieurs transformations à partir de sa structure tétragonale désordonnée initiale. Ces transformations sont caractérisées par des changements séquentiels des modes Raman caractéristiques ainsi que par l'influence de la pression sur ces modes. La spectroscopie d'absorption IR synchrotron fournit des informations supplémentaires et consistantes au sujet de l'évolution structurale du $NH_3{\cdot}BH_3$ soumis à une compression. Des mesures de décompression sur le $NH_3{\cdot}BH_3$ suggèrent que les transformations induites par la pression sont réversibles sur l'ensemble de la région de pression. Les données combinées des spectroscopies Raman et IR permettent de faire une analyse des structures du $NH_3{\cdot}BH_3$ à haute pression. Ce travail apporte des compléments aux études antérieures par spectroscopie Raman en fournissant de nouvelles informations sur les structures et les stabilités du $NH_3{\cdot}BH_3$.

Mots-clés : ammoniac-borane, emmagasinage de l'hydrogène, haute pression, spectroscopie Raman, spectroscopie infrarouge, cellule avec contre-partie de diamant.

Introduction

The ammonia borane complex ($NH_3{\cdot}BH_3$) has received intensive investigation in recent years because of its promising potential as a hydrogen storage material.[1,2] Ammonia borane is a chemical hydride with high gravimetric (19.6 wt% H) and volumetric (145 gH L^{-1}) hydrogen density and low molecular mass (30.7 g mol^{-1}). At room temperature and ambient pressure, $NH_3{\cdot}BH_3$ is a stable solid, neither flammable nor explosive. Heating $NH_3{\cdot}BH_3$ releases hydrogen at temperatures from 350 to 410 K to yield polyaminoborane $(BH_2NH_2)_x$.[3–5] The reaction is moderately exothermic (ΔH = –21 kJ mol^{-1}).[6] Continued heating releases a second equivalent hydrogen at temperatures from 380 to 470 K, yielding polyiminoborene $(BHNH)_x$ and trace quantities of borazine $(B_3N_3H_6)$.[6–9]

In addition to the hydrogen storage development, the molecular and electronic structures of ammonia borane are of fundamental interest. Although the ammonia borane complex is isoelectronic with gaseous ethane at ambient conditions, it contains a highly polarized dative N→B bond (μ = 5.1 D) formed by the electron donor–acceptor pair. The N→B bond has a dissociation energy of ~130 kJ mol^{-1},[10] which is much stronger than a typical van der Waals interaction. In addition, this dative bond is much shorter (1.58 Å)[11] in the molecular solid than in the gas phase (1.67 Å).[12] As a result, ammonia borane forms a stable molecular solid under ambient conditions that is characterized by strong dipole–dipole interactions in the crystalline network. More significantly, this complex is known to contain "dihydrogen" bonding. A dihydrogen bond is an unconventional hydrogen bond with, for example, N–H···H–B intermolecular interactions in $NH_3{\cdot}BH_3$ crystals, with 2.02 Å being the shortest H–H distance.[11] Typically, dihydrogen bonding is characterized by a short H–H contact distance (<2.2 Å) and a strongly bent angle (i.e., the angle between N–H and H–B). The effects of dihydrogen bonding on the

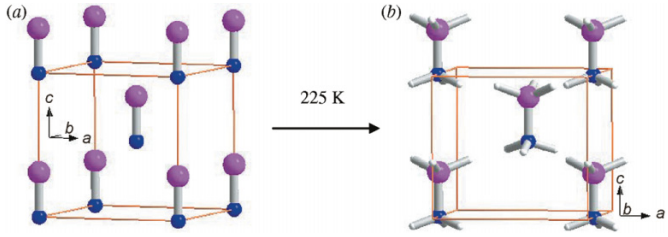
vibrational dynamics of the molecular crystal were recently demonstrated using incoherent inelastic neutron scattering.[13] These structural characteristics, including bond strength, bond length, and the directionality of dihydrogen bonding, critically determine the molecular and crystal symmetries and, therefore, the stabilities of $NH_3{\cdot}BH_3$.

$NH_3{\cdot}BH_3$ crystal structures have been examined using X-ray diffraction techniques.[14–16] At room temperature, $NH_3{\cdot}BH_3$ adopts a tetragonal structure with the space group $I4mm$ (C_{4v}^9) and cell parameters $a = b = 5.240$ Å and $c = 5.028$ Å.[15–18] Each unit cell contains two molecules occupying 2a Wyckoff sites with a C_{3v} molecular axis that coincides with the C_{4v} site symmetry (Fig. 1*a*).[16–18] This molecular crystal undergoes a phase transition from an orientationally disordered tetragonal phase to an orthorhombic structure (Fig. 1*b*) when cooled to 225 K, resulting in a significant change in the lattice dynamics. However, the molecular structure of the $NH_3{\cdot}BH_3$ molecule is preserved.[19] This orthorhombic structure was shown to have the space group $Pmn2_1$ with two molecules per unit cell and the parameters $a = 5.517$ Å, $b = 4.742$ Å, and $c = 5.020$ Å. At this temperature the NH_3 and BH_3 groups are "frozen" such that an ordered structure with a staggered conformation is formed with coinciding N–B and c axes. The crystal structure reveals that the complex has C_s symmetry only, although a recent low-temperature ^{2}H NMR study suggests that the symmetry of the molecule is very close to C_{3v}, and, therefore, it largely retains its symmetric gas-phase structure.[20]

Furthermore, $NH_3{\cdot}BH_3$ has been studied extensively using vibrational spectroscopy under varying conditions. Early IR and Raman studies on ammonia borane and its isotopologues focused on the nature and behaviour of the B–N bond.[21–23] Subsequent studies investigated the vibrational frequencies of ammonia borane (and its isotopologues) using an argon matrix[21] and by performing computational work on free molecules.[24,25] More recently, Hess et al.[19] have used Raman spectroscopy to study single-crystal ammonia borane complexes at temperatures as low as 88 K. In addition, ammonia borane has been studied under pressures as high as 4 GPa using Raman spectroscopy[22,26] to investigate the pressure effects of dihydrogen bonds on the crystalline network. It is well known that the vibrational frequencies of molecular solids under pressure exhibit a blue shift because the corresponding chemical bonds stiffen as a result of the compression. In contrast, it has been well documented that, during compression, the stretching mode of A–H shifts to lower frequencies when A–H acts as the proton donor and forms an A–H···A hydrogen bond, which subsequently weakens the A–H bond. By analogy, an N–H···H–B dihydrogen bond is expected to form in the ammonia borane complex because of the short distance between the two hydrogens, where N–H acts as the proton donor and H–B acts as the proton acceptor. This dihydrogen bond model is confirmed by the observation of a red shift in the N–H stretch frequency and a blue shift in the B–H stretch frequency with increasing pressures.[22,26] In addition, pressure-induced phase transitions were reported in both studies, but with different transition pressures and detailed spectroscopic features.[22,26]

Although ammonia borane has been studied extensively, more questions remain about the structures and properties of ammonia borane at higher pressure regions. For example, will ammonia borane form any other structures in addition to the observed tetragonal and orthorhombic phases? Will the continuous weakening of the N–H bond when compressed result in dissociation or other chemical transformations in which hydrogen is discharged? Addressing these questions, especially the possibility of hydrogen discharge and reverse processes with pressure variations, is of fundamental interest for developing this potential hydrogen storage material. Therefore, it is critical to investigate the stability, inter- and intra-molecular interactions, transformations, and reversibility of ammonia borane subjected to greater compression. Here we report the in situ high-pressure study of $NH_3{\cdot}BH_3$ by Raman and IR spectroscopy using synchrotron light sources up to 14 GPa using the diamond anvil cell (DAC) technique.[27] We note that this complex was recently studied under pressures as high as 20 GPa using Raman spectroscopy by Lin et al.[28] In this study, two new possible phase transitions were identified at 5 and 12 GPa. Although we observed some similar ammonia borane transitions, we also observed new pressure-induced structural transformations. To our knowledge, this is the first time that IR measurements, which provide sensitive and quantitative structural information, have been performed on this complex at high pressures in situ. In addition, we obtained the first high-quality spectroscopic data in the lattice region, especially in the far-IR spectral measurements. The combined spectroscopic techniques used allowed us to perform an in-depth analysis on the high-pressure structures and stabilities of the complex. Compared with previous Raman studies, this study provides the most comprehensive understanding of the pressure behaviours and structures of $NH_3{\cdot}BH_3$.

Fig. 1. Ambient-pressure crystal structures and temperature-induced transitions of $NH_3{\cdot}BH_3$. The coordinate systems showing the orientations of the unit cell are indicated. The color codes for atoms are: boron (pink), nitrogen (blue), and hydrogen (white). (*a*) The tetragonal structure of $NH_3{\cdot}BH_3$ with space group $I4mm$ ($Z = 1$) at room temperature is shown. Because of the orientational disorder associated with the free rotation of the NH_3 and BH_3 groups, the hydrogen atoms are not shown. (*b*) The ordered orthorhombic structure of $NH_3{\cdot}BH_3$ formed at 225 K with space group $Pmn2_1$ ($Z = 2$) is shown.



Experimental

Ammonia borane as a fine crystalline white powder with ~97% purity was purchased from Sigma-Aldrich and used without further purification. The purity was checked by ambient-pressure Raman spectroscopy and all observed Raman modes were found to be associated with the complex without any unassignable modes that originated from impurities. A symmetrical DAC with two type-I diamonds each with a 400 μm culet was used for the high-pressure Raman meas-

urements, while a pair of type II diamonds with a culet size of 300 μm was used for the IR measurements. A stainless steel gasket sample chamber was preindented to 70 μm thickness, and a 150 μm wide hole was drilled in the center. $NH_3{\cdot}BH_3$ was loaded in a MBraun LABmaster 130 glovebox equipped with a 20× microscope on the front panel. A dry inert atmosphere of <20 ppm O_2 and H_2O was maintained to accommodate the hygroscopicity of the material. The samples were loaded at room temperature with slightly elevated ambient pressures and then carefully pressurized incrementally. After each pressure change, the samples were allowed to equilibrate for a few minutes before subsequent spectroscopic measurements were taken. A few ruby (Cr^{3+} doped α-Al_2O_3) chips were used as a pressure calibrant and carefully placed inside the gasket chamber before the sample was loaded. The pressure was determined by using the R_1 ruby fluorescence line pressure shift with an accuracy of ±0.05 GPa under quasi-hydrostatic conditions.[29] For the entire pressure region, ruby fluorescence spectra obtained on different ruby chips across the sample chamber indicated no significant pressure gradient. The ruby spectral profiles suggested no obvious non-hydrostatic effects, particularly at the lower pressure regions (e.g., <10 GPa). Therefore, no pressure transmission media were used.

Raman experiments were carried out with a customized Raman microspectroscopy system constructed in our lab. A 488 nm line from an Innova Ar^+ laser (Coherent Inc.) was used as the excitation source. The laser was focused to <5 μm on the sample by an Olympus 20× objective and a 15× eyepiece and a digital camera allowed precise alignment of the focused laser beam. The Raman scattering signal was collected by the same objective lens with backscattering geometry. The Rayleigh scattering was removed by a pair of notch filters that enabled a spectral range >100 cm^{-1} to be measured before the total scattered photons were focused on the entrance slit of a spectrometer. The scattered light was then dispersed using an imaging spectrograph that housed a 0.5 m focal distance monochromator equipped with multiple gratings. A 1800 lines/mm grating with 0.1 cm^{-1} resolution was used. The Raman signal was recorded using an ultrasensitive, liquid nitrogen cooled, back-illuminated, charge-coupled device (CCD) detector from Acton. The system was calibrated using neon lines with an uncertainty of ±1 cm^{-1}. As a result of the strong diamond T_{2g} Raman mode at 1334 cm^{-1}, the spectra were collected in ranges of 50 to 1300 cm^{-1} and 1400 to 3500 cm^{-1} in several dispersive collection windows. These frequency ranges allowed all active ammonia borane Raman modes to be observed. The Raman signal was collected for 20 s for each window, and the average laser power on the sample was maintained at ~30 mW. Pressure effects on ammonia borane were examined both in the compression and decompression directions. All experiments were conducted at room temperature at pressures of up to 13.5 GPa and reproduced several times.

Infrared experiments were performed at the U2A beamline at the National Synchrotron Light Source (NSLS) at Brookhaven National Laboratory (BNL). The IR beam from the storage ring was extracted through a wedged diamond window from a source in a 40 × 40 mrad solid angle and was collimated to a 3.8 cm diameter beam before entering a Bruker IFS 66V vacuum FTIR spectrometer in conjunction with three microscope systems. The spectrometer was equipped with a number of beam splitters and detectors including a silicon bolometer and MCT. For mid-IR measurements, the IR beam was focused onto the sample by a Bruker IR microscope and then the spectrum was collected in transmission mode by the MCT detector in the 600–4000 cm^{-1} spectral range. The far-IR spectra of $NH_3{\cdot}BH_3$ were collected using a customized IR microscope with high collection efficiency and recorded by the bolometer in the 100–600 cm^{-1} spectral region. A resolution of 4 cm^{-1} was used in all IR measurements. For IR measurements, a sample thickness of 35 μm was used to allow sufficient IR transmission measurements. For all measurements, mid-IR spectra were collected through a 30 × 30 μm^2 aperture, whereas the effective IR transmission area covered the entire sample (i.e., a circle of ~90 μm in diameter) for the far-IR measurements. The reference spectrum, i.e., the diamond anvil absorption at ambient pressure, was later divided as background from each sample spectrum to obtain the absorbance. IR spectra in the decompression sequence (in ~2 GPa decrements) were also collected to investigate the reversibility of the pressure effect.

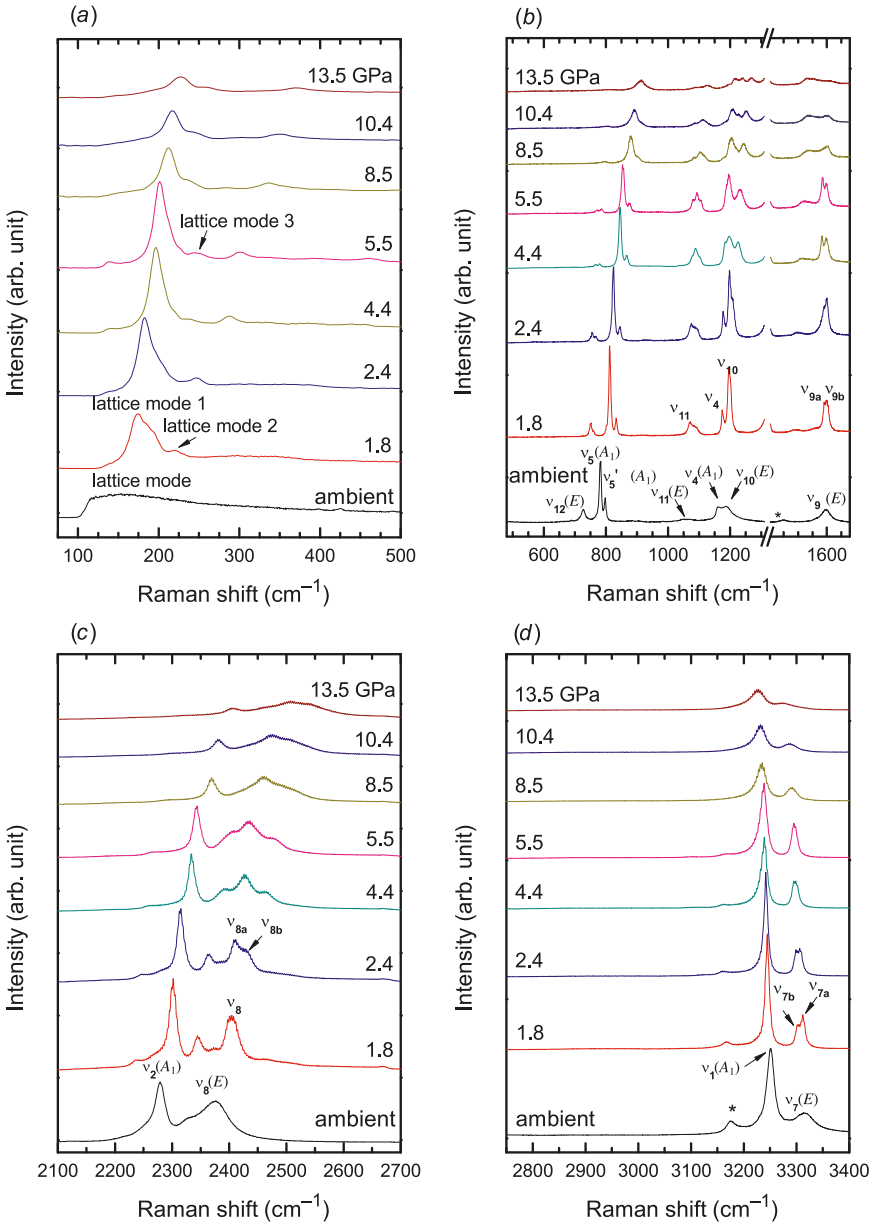
Results and discussion

Raman spectra of $NH_3{\cdot}BH_3$ during compression

Raman spectra of ammonia borane were collected from ambient pressures up to 13.5 GPa. Selected spectra are shown in Fig. 2 in four regions based on the molecular nature of the complex: the lattice region (50–600 cm^{-1}), the B–N stretching, the BH_3/NH_3 deformations and NBH rocking region (600–1650 cm^{-1}), the B–H stretching region (2100–2700 cm^{-1}), and the N–H stretching region (2750–3400 cm^{-1}).

At ambient pressure and room temperature, $NH_3{\cdot}BH_3$ crystallizes into a tetragonal phase with space group *I*4*mm* with two $NH_3{\cdot}BH_3$ molecules per unit cell.[16–18] Using factor group analysis[19], 12 distinct modes, including 11 internal modes plus one lattice librational mode, are predicted to be both Raman and IR active for the tetragonal phase of $NH_3{\cdot}BH_3$. Initially, a Raman spectrum measured at room temperature and ambient pressure is depicted at the bottom of Figs. 2*a*–2*d*. As shown, all Raman active modes except one (i.e., B–N torsion mode ν_6) are observed as predicted, in good agreement with previously reported Raman data.[19] Mode assignments are labeled in Fig. 2 and listed in Table 1. Compared with those observed in Ar-matrix isolated molecules, the N–H stretching modes (ν_7 and ν_1) in our powder sample are significantly red-shifted by 67 and 84 cm^{-1}, respectively, as a result of the dihydrogen bond in the solid phase. The analogous B–H modes (ν_8 and ν_2) are blue-shifted by 39 and 60 cm^{-1}, respectively. The assignment of the B–N stretching mode, which was originally assigned to be 787 cm^{-1} in ether solution by Taylor and Cluff[21], has long been disputed. Taylor and Cluff's assignment was confirmed by Sawodny and Goubeau[23] with a similar value of 776/790 cm^{-1} ($^{11}B/^{10}B$); however, it was reassigned by Smith et al.[30] to be 968/987 cm^{-1} ($^{11}B/^{10}B$) in argon matrices and by Jagielska et al.[31] to be 1005 cm^{-1} using an ab initio calculation.[31] In our research, we observed the B–N stretching mode (ν_5/ν_5') at 783/798 cm^{-1} ($^{11}B/^{10}B$), consistent with the original assignment and some recent observations,[22,26,28] indicating that the

Fig. 2. Selected Raman spectra of $NH_3{\cdot}BH_3$ collected at room temperature on compression in the spectral region of (*a*) 50–600 cm^{-1}, (*b*) 600–1650 cm^{-1}, (*c*) 2100–2700 cm^{-1}, and (*d*) 27503400 cm^{-1}. The relative intensities are normalized and thus are directly comparable. Because of the intense T_{2g} Raman mode of the diamond anvil at 1332 cm^{-1}, the region of 1270–1440 cm^{-1} is truncated in (*b*).The pressures in GPa are labeled for each spectrum. The assignments of Raman modes are labeled for several spectra. Unassigned peaks are labeled with asterisks (see text). The spectra are offset vertically for clarity.



structure and behaviour of $NH_3{\cdot}BH_3$ in argon matrices is closer to the gas phase than the solid phase. For peaks at 1067 and 728 cm^{-1}, the NBH rocking modes (ν_{11} and ν_{12}) assignment of Hess et al.[19] was adopted, which are described as rocking motions involving planes of hydrogen atoms from both the NH_3 and BH_3 groups. Several previously observed but unassigned peaks, such as those at 3175 and 1447 cm^{-1}, for example, are also seen.[19,22,26] On the basis of limited polarized measurements,[19] the peak at 3175 cm^{-1} is assigned as polarized, whereas the peak at 1447 cm^{-1} is a depolarized mode.

Upon compression from ambient pressure to 1.8 GPa, a phase transition can be identified by the splitting of the modes with *E* symmetry, as well as the by the significant narrowing of the lattice mode (Fig. 2). For instance, the doubly degenerate modes ν_7 (asymmetrical N–H stretching) at 3319 cm^{-1} and ν_9 (NH_3 deformation) at 1595 cm^{-1} each split into two modes, i.e., ν_{7a}/ν_{7b} (3303 cm^{-1}/3312 cm^{-1}) and ν_{9a}/ν_{9b} (1593 cm^{-1}/1602 cm^{-1}). The phase transition is also apparent by the development of the lattice mode near 141 cm^{-1} at ambient pressure, which becomes more pronounced and finally evolves into two lattice modes at 174 and 220 cm^{-1} at 1.8 GPa. The sharp lattice modes strongly suggest a phase transition from the disordered tetragonal structure at ambient pressure to an ordered structure at 1.8 GPa. It is also noted that modes ν_4 and ν_{10}, which are

very close to each other at ambient pressure, become sharply resolved at 1.8 GPa, whereas the very weak NBH rocking mode ν_{11} (1067 cm^{-1}) is greatly enhanced. In addition, a new peak appears at 2344 cm^{-1}, which was also observed but unassigned in some earlier studies.[19,22,26,28] This unassigned mode is likely a depolarized band.[19]

Upon further compression to 13.5 GPa, rich Raman features were observed to reveal the pressure-induced structural revolutions. As seen in Fig. 2*a*, the most prominent peak in the lattice in the whole pressure region is lattice mode 1, which appears at 174 cm^{-1} at 1.8 GPa. This mode becomes sharper and more intense as pressures increase to 5.5 GPa, at which point it noticeably broadens with decreasing intensity when compressed to 13.5 GPa. Lattice mode 2, although very weak at 1.8 GPa, is a characteristic mode of the new phase that is different than the disordered tetragonal structure and remains distinct as pressures increase to 13.5 GPa. The most prominent change in the lattice region is the observation of a third lattice mode at 245 cm^{-1} at 5.5 GPa, indicating a possible transformation of the crystal structure of $NH_3{\cdot}BH_3$. In addition, a clearly developed mode at 140 cm^{-1} was also observed at this pressure. These new modes, together with lattice mode 2, become weaker with increasing pressure such that only lattice mode 1 remains the dominant mode at 13.5 GPa. We note that in previous Raman studies only two lattice modes were observed in all pressure regions,[28] which is in strong contrast to our results. It is likely that the missing mode at 140 cm^{-1} is associated with the detection limit achieved.

The internal modes in the spectral region 600–1650 cm^{-1} (Fig. 2*b*), including the ν_{12}, ν_{11}, ν_{10}, and ν_9 modes when compressed to 2.4 GPa, are characterized by further splitting of the doubly degenerate modes with E symmetry during compression. Upon further compression to 5.5 GPa, these modes exhibit the maximum splitting with the exception of ν_7, which merged into a singlet. Continuous compression from 5.5 to 8.5 GPa results in merging with a markedly reduced intensity for most of the modes. All modes are significantly broadened when compressed above 13.5 GPa. These observations are in general agreement with those of Lin et al.,[28] except for the detailed profile of a few bands. For instance, the NH_3 deformation mode (ν_9) at ~1600 cm^{-1} that exhibits clear splitting up to 5.5 GPa shows a drastically different profile: no splitting was observed in the entire pressure region.[28]

The splitting at ν_5 mode is due to an isotopic effect rather than the removal of degeneracy. The ^{11}B and ^{10}B contributions to the B–N symmetric stretch (ν_5 and ν_5') are readily apparent up to 8.5 GPa. Both ^{11}B–N (ν_5) and ^{10}B–N (ν_5') stretching modes are sharp in the pressure region under 5.5 GPa, whereas ν_5' is much weaker than ν_5 because of the lower abundance of ^{10}B (19.9%). The frequency difference at 8.5 GPa is ~19–21 cm^{-1}, which is larger than that observed under ambient conditions (i.e., 15 cm^{-1}). However, this value is still in agreement with the frequency difference of 18 cm^{-1} reported by Custelcean and Dreger[22] and of 20 cm^{-1} observed by Lin et al.[28]

The symmetric B–H stretching mode ν_2 (A_1), one of the most intense Raman bands at ambient pressure, exhibits a pressure-induced blue shift and weakening (Fig. 2*c*); it becomes significantly broadened above 8.5 GPa. The doubly degenerate asymmetric B–H stretching mode ν_8 readily splits when compressed to 2.4 GPa, exhibiting a strongly asymmetric doublet labeled as ν_{8a} and ν_{8b}. As pressures continue to increase, mode ν_{8a} becomes most pronounced at 4.4 GPa and subsequently becomes much broader at higher pressures (e.g, 8.5 GPa) because of coalescence with ν_{8b} and a nearby depolarized peak.[19] In contrast to the BH stretching modes, both the symmetric and asymmetric N–H stretching modes shift to red with increasing pressures (Fig. 2*d*). The symmetric N–H stretching mode ν_1 with A_1 symmetry, the most intense $NH_3{\cdot}BH_3$ Raman band in the en-

Fig. 3. tire pressure region, becomes much broader and weaker when compressed to 8.5 GPa. The asymmetric N–H stretching mode ν_7 (*E*) that displays a doublet (ν_{7a} and ν_{7b}) at 1.8 GPa becomes a convoluted mode on compression. Similar to the ν_1 mode, this mode also broadens markedly beyond 8.5 GPa. Above 13.5 GPa, this mode is barely visible. These observations are consistent with those of Lin et al.[28]

Pressure effects on Raman modes of $NH_3{\cdot}BH_3$

To confirm the possible phase transformations on compression, the pressure dependence (i.e., Raman shift versus pressure) of selected Raman modes are depicted in Fig. 3. Calculated pressure coefficients ($d\nu/dP$ (cm^{-1} GPa^{-1})) for the monitored peaks obtained by linear regression of the experimental data are listed in Table 2. Phase transitions are further indicated when sharp differences in pressure coefficients are observed. Compared with previous analysis,[28] more phase boundaries were identified in this study.

In general, most Raman modes exhibit pressure-induced blue shifts, consistent with the finding that the bonds stiffen upon compression. However, both the symmetric and asymmetric N–H stretching modes (ν_7 and ν_1) undergo red shifts with increasing pressures in all pressure regions (i.e., $d\nu/dP < 0$), indicating the weakening of the N–H bond. This is believed to be a result of the lengthening of the N–H bond owing to the formation and strengthening of the dihydrogen bonding (N–H···H–B) as pressures increase. In strong contrast, the stretching modes (ν_8 and ν_2) involving the B–H proton acceptor group in the dihydrogen bond exhibit large blue shifts with pressure. For example, $d\nu_8/dP$ has the largest pressure coefficients (16.1 and 10.3 cm^{-1} GPa^{-1} in the 2.4–5.5 and >10.4 GPa pressure regions, respectively) indicating the significant strengthening of B–H bonding with decreasing bond length. Because the N–H and B–H bond strengths become strongly disproportionate when compressed, and the B–N bond is strengthened ($d\nu_5/dP > 0$), it is reasonable to speculate that at certain high pressures, the N–H bond may break and new materials may form.

As shown in Fig. 3 and Table 2, the pressure dependences of the major Raman modes collectively indicate several distinct pressure regions at which $NH_3{\cdot}BH_3$ could exist as different phases. These pressure regions are 2.4–5.5, 5.5–8.5, 8.5–10.4, and >10.4 GPa, which we label as phases III, IV, V, and VI, respectively (phases I and II are the known room-temperature tetragonal phase and low-temperature orthorhombic phase, respectively). In general, the pressure coefficients of the stretching modes are noticeably larger for phase III than for phase IV, which are larger than those for

phase V. The pressure coefficients of the rocking and deformation modes, however, do not exhibit consistent trends along phase transformations. Interestingly, the pressure coefficients of these modes seem to become larger again when compressed beyond 10.4 GPa. In summary, although the phase boundaries of 2.4 and 5.5 GPa observed in this study can be roughly aligned with those at 2 and 5 GPa noted previously,[28] new phase boundaries along with more high-pressure phases are observed in the present study.

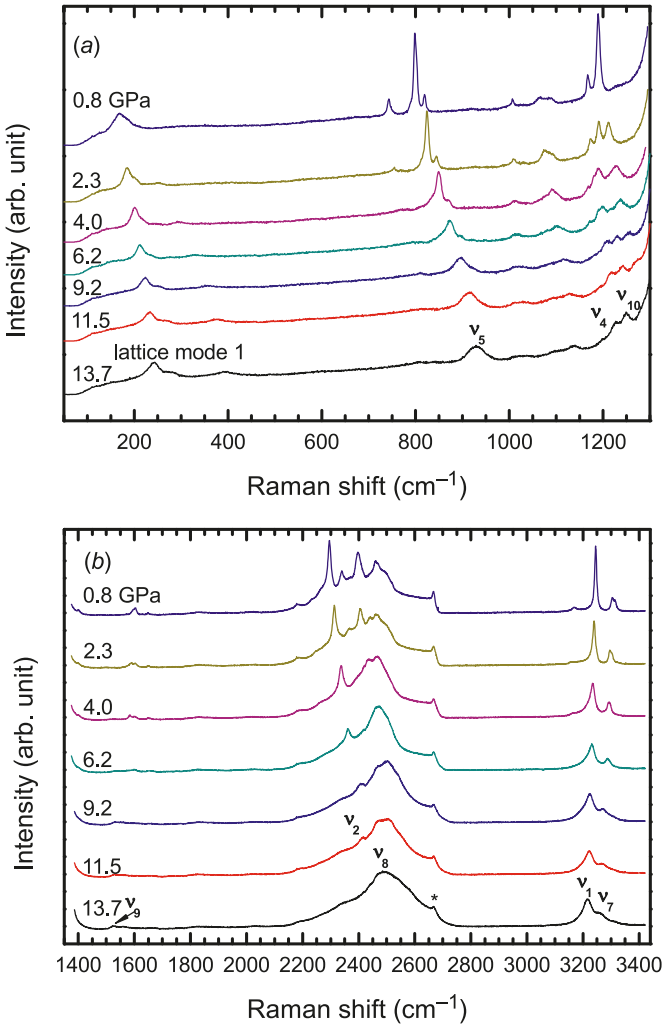
Raman spectra of $NH_3{\cdot}BH_3$ during decompression

The reversibility of pressure effects on molecular structures provides important information on transformation mechanisms. Therefore, upon compression of $NH_3{\cdot}BH_3$ to the highest pressure of 13.7 GPa, we conducted Raman measurements on decompression all the way down to a near ambient pressure. Selected spectra are depicted in Fig. 4. In general, the change in the Raman profile is very gradual on decompression. At 13.7 GPa, one lattice mode and ν_5, ν_4, ν_{10}, ν_9, ν_8, ν_1, and ν_7 modes resolve. Starting at 6.2 GPa, the ν_2 mode at 2362 cm^{-1} recovers from decompression. Simultaneously, the ν_1 and ν_7 modes are completely deconvoluted. Further decompression to 4.0 GPa results in the development of ν_5', ν_{511}, and $\nu_{9a,b}$ modes. The onset pressure for the observation of ν_{12} and ν_4 along decompression is 2.3 GPa. When the pressure is reduced to 0.8 GPa, the Raman profile is almost identical to that at 1.8 GPa on compression. These observations suggest that, although there is some hysteresis upon decompression characterized by "delayed" back-transformations, the pressure-induced phase transitions are reversible in the entire pressure range in this study.

Mid-IR spectra of $NH_3{\cdot}BH_3$

Figure 5*a* shows the mid-IR absorption spectrum of $NH_3{\cdot}BH_3$ measured at room temperature and at 1.5 GPa (the first pressure point on compression). According to a factor group analysis,[19] all spectral active modes of $NH_3{\cdot}BH_3$ are both IR and Raman active. Therefore, the fundamental IR modes can be assigned by comparing our IR spectrum with previous IR and Raman measurements as reported in Table 3. In addition, vibrational frequencies observed from low-temperature inelastic neutron scattering (INS) measurements, which have no selection rules, are also listed to confirm the assignments in the spectra region below 1400 cm^{-1}.[25] In contrast to the Raman spectra, many more IR bands are observed as a result of overtones and (or) combinations of fundamental modes, which are labeled with asterisks in Fig. 5*a*. For instance, a new band is observed at 3479 cm^{-1}, which is very close to the combination of ν_{11} and ν_3 as $2\nu_{11} + \nu_3$, where ν_{11} = 1055 cm^{-1} and ν_3 = 1362 cm^{-1}. Similarly, the bands at 2674, 2123, and 1483 cm^{-1} are likely to be overtones of ν_3 (1362 cm^{-1}), ν_{11} (1055 cm^{-1}), and ν_{12} (751 cm^{-1}) as $2\nu_3$, $2\nu_{11}$, and $2\nu_{12}$, respectively. The band at 1767 cm^{-1} is not coincident with any combination of internal modes, but it is likely a combination of lattice modes and internal modes. Although some modes could not be distinguished because of the saturated absorptions in regions 1050–1250 cm^{-1} and 3150–3400 cm^{-1}, all

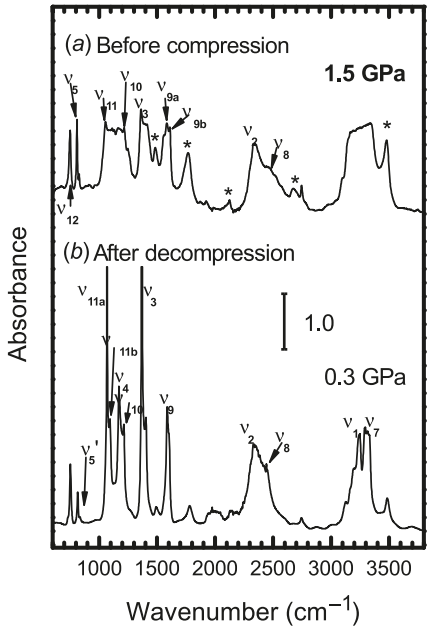
Fig. 4. Selected Raman spectra of $NH_3{\cdot}BH_3$ on decompression from 13.7 GPa all the way down to ambient pressure. The relative intensities are normalized and thus are directly comparable. The pressures in GPa are labeled for each spectrum. The spectra are offset vertically for clarity.



fundamental internal modes except a BH_3 deformation mode and an N–H stretching mode were observed, which is in agreement with previous Raman and IR data.[21–23]

Figure 6*a* shows the IR absorption spectra of $NH_3{\cdot}BH_3$ when compressed to 13.7 GPa at room temperature. Compared with Raman measurements on compression, the pressure evolution of the $NH_3{\cdot}BH_3$ bands is very gradual and lacks distinctive profile changes, which is mainly associated with the extremely strong or even saturated absorptions in most of the spectral regions. In addition, the absorption is markedly enhanced as pressures increase such that the multiple bands in the spectral region of 1000–1600 cm^{-1} convolute to two broad bands at 13.7 GPa. As a result, it is difficult to visualize phase transitions from the IR spectra. The only discernable profile change occurs at 7.8 GPa as indicated by the broadening of the ν_{12} mode and by the enhanced intensity of the ν_8 mode. However, the pressure dependences of the IR bands shown in Fig. 7 and Table 4 show roughly consistent pressure-induced phase transitions

Fig. 5. Synchrotron mid-IR absorption spectrum of $NH_3{\cdot}BH_3$ collected at room temperature and (*a*) 1.5 GPa upon compression in comparison with (*b*) 0.3 GPa upon decompression in the spectral region 600–3800 cm^{-1}. The assignments of the fundamental modes are shown above the corresponding IR bands. The IR bands labeled with asterisks are overtones or combinations of lattice modes and (or) internal modes (see text).



as established by our Raman measurements. Generally, most of the IR modes exhibit blue shifts with increasing pressure, consistent with the pressure-induced bond stiffening. For example, a pressure coefficient as large as 26.8 cm^{-1} GPa^{-1} is observed for the B–H stretching mode ν_8 in the pressure region of 7.8–10.8 GPa. Although the N–H stretching modes cannot be monitored owing to strong absorption, the NH_3 deformation modes (ν_{9a}, ν_{9b}, and ν_3) exhibit unambiguous red shifts, yielding consistent information obtained by Raman measurements interpreted as the weakening of N–H bonds with the formation of dihydrogen bonds.

After compressing $NH_3{\cdot}BH_3$ to pressures as high as 13.7 GPa, we conducted IR measurements on decompression to near ambient pressures (e.g., 0.3 GPa). Selected spectra are depicted in Fig. 6*b* and compared with the compression data in Fig. 6*a*. Apparently, the decompression data provide more information because the absorption is markedly reduced as the sample thins out after the compression–decompression cycle. For instance, when the pressure is reduced to 8.9 GPa, the previously saturated ν_4 and ν_{11} bands are resolved. Furthermore, IR bands ν_1 and ν_7 are clearly visible when decompressed to 2.9 GPa. Finally, as seen in Fig. 5*b*, all modes observed before compression at 1.5 GPa are recovered after decompression at 0.3 GPa. These observations indicate that the structural transformations upon compression are completely reversible in the entire pressure region, consistent with our Raman measurements.

Far-IR spectra of $NH_3{\cdot}BH_3$

Using the unique synchrotron far-IR setup dedicated to in situ high-pressure measurements, we obtained the first far-IR

$NH_3{\cdot}BH_3$ absorption spectra at 13.5 GPa. Similar to the mid-IR region, the lattice modes in the far-IR region at 100–600 cm^{-1} are overwhelmed by extremely strong absorptions that do not allow individual modes to be identified. Therefore, we performed a compression to 13.5 GPa stepwise (the IR spectra are not shown on compression) and then measured the IR absorption on decompression with selected spectra, shown in Fig. 8*a*. At the highest pressure, two lattice modes at 294 cm^{-1} (band 1) and 415 cm^{-1} (band 2) are clearly observed. Compared with the Raman lattice region (Figs. 2*a* and 3*a*), band 1 is close to the Raman lattice mode 3 by extrapolation, whereas band 2 is a new lattice mode (IR active only). On decompression, both modes shift to lower frequencies. When decompressed to 3.5 GPa, band 1 displays enhanced absorption but subsequently diminishes into a shoulder peak when decompressed to 1.2 GPa. At this pressure, only one major band with a frequency of 210 cm^{-1} is observed, which is comparable with the Raman lattice mode 2 (219 cm^{-1}) at 1.8 GPa, but with strongly contrasting intensities.

We plotted the frequencies of the IR active modes observed in the lattice region as a function of pressure on both compression and decompression (Fig. 8*b*). Again, owing to strong absorption, $NH_3{\cdot}BH_3$ produces a broad, saturated band below 3.3 GPa upon compression. At this pressure, a clearly defined band evolved at 420 cm^{-1} (as band 3 in Fig. 8*b*) and rapidly shifted to higher frequencies ($d\nu/dP$ = 18.8 cm^{-1} GPa^{-1}) as pressures increased to 9.5 GPa when the intensity diminished almost completely. Interestingly, this band is not observed in this pressure region upon decompression, but only displays barely visible intensities below 3.5 GPa. As seen in Fig. 8, bands 1 and 2 could not be distinguished from the saturated bands until the sample was compressed to 8.5 GPa, at which point they remain resolved up to the highest pressure. Upon decompression, however, these two modes exhibit different pressure dependences (i.e., smaller pressure coefficients) than when compressed, indicating that back transformation is more sluggish owing to hysteresis. The pressure dependences of both these modes show a distinct change around 5.5 GPa, coinciding with one of the transition pressures established by our Raman measurements.

Discussion

In previous Raman studies of $NH_3{\cdot}BH_3$ in the low pressure range (i.e., <4 GPa),[22,26] two solid-to-solid transitions at 0.5 and 1.4 GPa were found by Trudel and Gilson,[26] which is different from Custelcean and Dreger's study[22] in which only one phase transition was found (at 0.8 GPa). This discrepancy may result from the differences in the hydrostatic conditions used in the two studies. Both of our Raman and IR measurements are in general agreement with these two studies in terms of phase regions, i.e., the spectroscopic features observed below and above 2 GPa roughly align with those before and after the phase transitions observed below 1.5 GPa in both studies, except that we extend the previously observed second high-pressure phase from 4 to ~5.8 GPa (we label this as phase III), which is in qualitative agreement with Lin et al.'s study.[28] Above this pressure, our Raman and IR measurements show two more phase transitions at 8.5 and 10.4 GPa, whereas the only transition observed in Lin et al.'s study was near 12 GPa.[28] In addition to the different boundaries, differences in Raman profiles, such as those in the lattice region, were also observed. One possible explanation is that our materials had a different purity and crystallinity: we used a reagent grade with a purity of 97% (purchased directly from Sigma-Aldrich), whereas Lin et al.[28] used synthetic laboratory and heat-treated samples with an unknown purity. In addition, as discussed in the following, the phase transitions are characterized by

Fig. 6. Synchrotron mid-IR spectra of $NH_3{\cdot}BH_3$ in the spectral range of 600–3800 cm^{-1} measured at room temperature for selected pressures (indicated in GPa above each spectrum) on (*a*) compression and (*b*) decompression. The absorbance has been normalized with respect to the beam current of the synchrotron light source. The spectra are offset vertically for clarity.

subtle changes in the unit cell without major, irreversible modifications. Such transitions are generally sensitive to compression conditions and therefore may be affected by additional factors such as kinetics. Nevertheless, our parallel measurements yielded reproducible and consistent results.

Then the remaining question is what are the possible structures of high-pressure phases of ammonia borane induced by compression and decompression. To our knowledge, no in situ high-pressure X-ray diffraction study of this complex has been reported. Therefore, these combined Raman and IR spectroscopic measurements, especially in the lattice region, provide important insight for understanding the high-pressure structures of the ammonia borane complex. Unfortunately, Hess et al.'s[19] recent low-temperature Raman study does not include lattice data, and lattice features were not analyzed in depth in any of the previous high-pressure Raman studies because of measurement limitations.[22,26]

For the phase below 2.4 GPa, the Raman measurement at 1.8 GPa (Fig. 2*a*) and IR measurement at 1.2 GPa (Fig. 8*a*) in the present study clearly indicate that there are at least two lattice modes associated with this phase. It is known that high pressures and low temperatures often induce similar phase transitions for many materials that have normal *P–T* phase diagrams. Therefore, to assume that the low-pressure phase has the same or similar crystal structure as the low-temperature orthorhombic phase is reasonable and can be examined for consistency by the observed spectroscopic features. Using factor group analysis, the orthorhombic structure ($Pmn2_1$) with two molecular units per unit cell has the following lattice modes[19]:

$$[1]\quad \Gamma^{NH_3{\cdot}BH_3}_{\text{lattice vib.}} = A_1 + A_2 + B_2$$
$$\Gamma^{NH_3{\cdot}BH_3}_{\text{lattice lib.}} = A_1 + 2A_2 + 2B_1 + B_2$$

where Γ_{vib} and Γ_{lib} are the irreducible representations for lattice vibration (translation) and lattice liberation (rotation), respectively. Species A_2 is Raman active and A_1, B_1, and B_2 are both IR and Raman active. Thus, nine lattice modes are predicted with all Raman active modes and six are IR active. Apparently, the two lattice modes observed are only a subset of the predicted modes if the assumed crystal structure is correct. Because the notch filters used in our Raman system and far-IR setup at the synchrotron beamline do not

allow unambiguous measurements below 100 cm^{-1}, it is possible that some additional lower frequency lattice modes were not detected. Nevertheless, the additional splitting features observed in the internal mode region, such as those for the ν_{11}, ν_9, and ν_7 modes, strongly suggest the structure is orthorhombic rather than tetragonal.

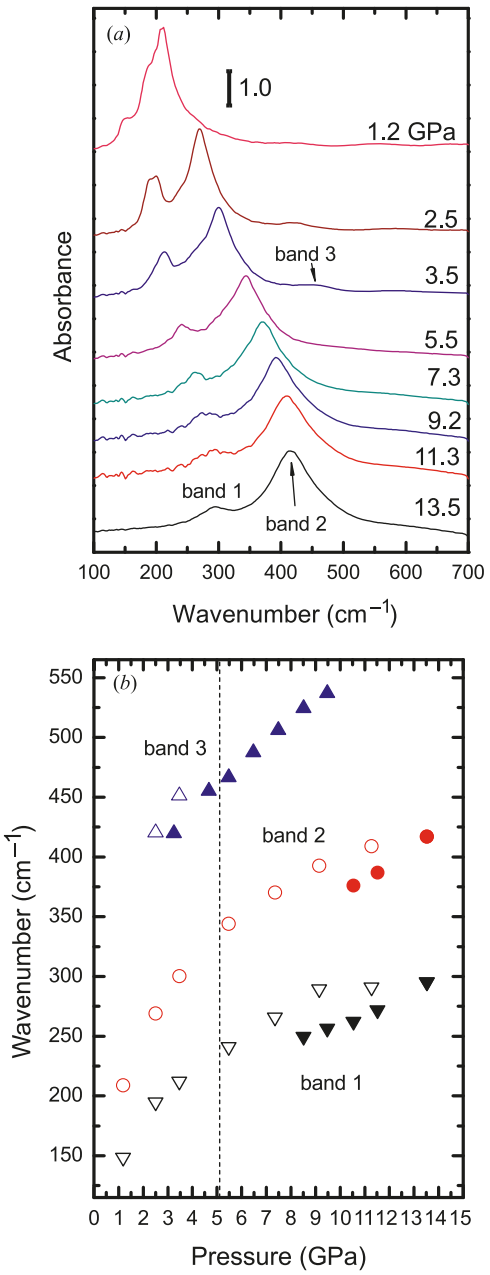
The next high-pressure phase (phase III, 2.4–5.5 GPa) may have a structure very similar to the low-pressure orthorhombic phase. This is indicated by the similarity of the lattice profile both in the Raman and IR measurements as well as in the more prominent splittings observed for the ν_{12}, ν_{11}, ν_8, and ν_9 modes. These observations strongly suggest enhanced intermolecular interactions as a result of compression as manifested by the largest pressure coefficient (Table 2) observed among all pressure regions. In addition, the bending deformation modes for BH_3 and NH_3 (i.e., ν_{10} and ν_9, respectively) at 2.4 GPa have a broad profile, indicating some degree of rotational disorder for NH_3–BH_3 along its molecular axis at this pressure. Upon compression, both modes split into narrower doublet peaks that suggests that the free rotation of the BH_3 and NH_3 groups is likely hindered by pressure and thus the complex may undergo a rotational disorder–order process in this pressure region. We note that our observation is in contrast to that of Lin et al.[28] where the splitting of these modes is lacking in this pressure region.

From 5.5 to 8.5 GPa, the complex undergoes a more prominent structural modification. In this region, up to four Raman lattice modes and three IR lattice modes were observed. The Raman frequencies are 139, 201, 246, and 301 cm^{-1} at 5.5 GPa, whereas the IR frequencies observed at the same pressure are 241, 344, and 467 cm^{-1}. However, the IR bands at 241 and 344 cm^{-1} measured during decompression are known to exhibit higher frequencies than those measured on compression owing to hysteresis. Therefore, we linearly extrapolated the high-pressure frequencies of IR bands 1 and 2 (Fig. 8*b*) to 5.5 GPa to obtain the corrected "compression" data (215 and 311cm^{-1}). As a result, these two major IR bands are roughly aligned with the two major Raman bands at 201 and 301 cm^{-1} as observed in other pressure regions, suggesting the new modes are 139 and 246 cm^{-1} for Raman measurements and 467 cm^{-1} for IR measurements. Again, because the observed Raman and IR modes are generally a subset of the predicted ones, it is difficult to perform a full factor group analysis without crystal structures. However, these observations can temporarily rule out a significant change to the factor group of the $NH_3{\cdot}BH_3$ crystal lattice, especially changes to centrosymmetric groups such as D_{2h} for orthorhombic or C_{2h} for monoclinic systems. The observation of new lattice modes can be interpreted as enhanced correlation field interactions within the C_{2v} factor group or even lower symmetry groups, such as those for monoclinic systems. X-ray diffraction measurements are required to understand the detailed structures of this $NH_3{\cdot}BH_3$ phase.

Above 8.5 GPa, both the Raman and IR spectra are characterized by significant profile broadening in almost all spectral regions. Split Raman modes are merged into broad bands with significantly reduced intensity (e.g., ν_{11}, ν_9, and ν_8), whereas the lattice modes measured both by Raman and IR spectroscopy become much weaker and broad. Above 10.4 GPa, the number of lattice modes in both Raman and IR measurements is reduced, whereas the remaining modes undergo continuing weakening and broadening. These observations suggest that the $NH_3{\cdot}BH_3$ complex is transforming from an ordered crystalline structure to a possibly disordered or ultimately amorphous structure when compressed to high enough pressures. The phase between 8.5 and 10.4 GPa can be considered as an intermediate phase for the disordering process, whereas the phase above 10.4 GPa is characterized by significant disordering. Although pressure gradients at high pressure may contribute to the profile broadening, our ruby fluorescence measurements across the sample suggest that the non-hydrostatic effect contributes only very insignificantly to this broadening.

In Lin et al.'s[28] analysis of the possible high-pressure structures based on the features of a few characteristic internal modes and the observation of two lattice modes, it is proposed that the crystal structure is unaltered in the entire pressure region. However, the additional lattice modes observed by our Raman and IR measurements clearly indicate that there is a possible pressure-induced formation of new crystal structures. They further speculate that the dimerization of ammonia borane complex may be associated with one of the high pressure phases. Again, if dimerization occurs, more internal modes with different vibrational frequencies are expected. In addition, dimerization implies that the number of the molecular unit Z halves per unit cell, which is contradictory to the observation that there was an increase in the number of lattice mode. In situ X-ray diffraction measurements are required to resolve the discrepancy between the structural interpretation of the two spectroscopic studies.

Fig. 8. (*a*) Synchrotron far-IR spectra of $NH_3{\cdot}BH_3$ in the spectral range of 100 to 700 cm^{-1} measured at room temperature for selective pressures (indicated in GPa above each spectrum) on decompression. The absorbance has been normalized with respect to the beam current of the synchrotron light source. The spectra are offset vertically for clarity. (*b*) Pressure dependences of IR frequencies of $NH_3{\cdot}BH_3$ for lattice modes. The solid symbols denote frequencies observed on compression and open symbols denote frequencies for decompression. The vertical dashed lines indicate one of the proposed phase boundaries.



Finally, it is clear that both the Raman and IR measurements show that the pressure-induced transformations of the $NH_3{\cdot}BH_3$ complex are reversible upon decompression. The almost identical spectroscopic details in both Raman and IR internal mode regions before and after compression indicate that the chemical structure of the complex is completely unaltered by pressure and thus $NH_3{\cdot}BH_3$ is stable (i.e., no hydrogen release) up to the highest pressure yielded in this study. However, the different profiles of the lattice modes from both Raman and IR measurements suggest that crystalline structures may have been modified by pressure, even if very slightly. In addition, hysteresis has been observed in most of the pressure regions upon decompression. Our observations agree with those of Custelcean and Dreger,[22] who also found all pressure-induced transformations were reversible at <4 GPa, but that there was some hysteresis. Hysteresis is typically considered to be a result of kinetics-mediated transformations characterized by some barriers. To overcome the kinetic barrier, it would be interesting to investigate the pressure-induced transformations at elevated temperatures.

Conclusions

Using Raman and synchrotron IR spectroscopy, we investigated the pressure behaviour of the ammonia borane complex as a promising hydrogen storage material. In the low pressure region (<2 GPa), we discovered that the complex undergoes a structural transformation from a disordered tetragonal to an ordered, possibly orthorhombic, structure, consistent with previous Raman studies. Upon further compression, our Raman and IR measurements identified several solid-to-solid transformations with phase boundaries that roughly occurred at 2.4, 5.5, 8.5, and 10.4 GPa. These transformations are characterized by distinctive profiles and the pressure dependences of characteristic modes. Spectroscopic measurements on decompression suggest that these pressure-induced transformations are reversible within the intact chemical structure of the $NH_3{\cdot}BH_3$ complex, with possible modifications to the crystal structures. Analysis of combined Raman and IR measurements, especially the lattice features, suggests that $NH_3{\cdot}BH_3$ structures below 5.5 GPa resemble a low-pressure orthorhombic structure, whereas in the higher pressure regions, $NH_3{\cdot}BH_3$ complexes may undergo transformations to disordered or amorphous structures. Detailed high-pressure structural information needs to be confirmed by in situ X-ray diffraction measurements.

Rhodium(I)–(*N*-heterocyclic carbene)–diphosphine complexes

Hongsui Sun, Xiao-Yan Yu, Paolo Marcazzan, Brian O. Patrick, and Brian R. James

Abstract: Reactions of $[RhCl(COE)(IPr)]_2$ (**1**) and $[RhCl(COE)(IMes)]_2$ (**2**) (COE = cyclooctene; IPr = *N*,*N*′-bis(2,6-diisopropylphenyl)imidazolin-2-ylidene; IMes = *N*,*N*′-bis(2,4,6-trimethylphenyl)imidazolin-2-ylidene) with the diphosphines $Ph_2P(CH_2)_nPPh_2$ and 1,2-bis(diphenylphosphino)benzene (dppbz) give the *N*-heterocyclic carbene (NHC)–diphosphine–rhodium(I) complexes: $RhCl(NHC)[Ph_2P(CH_2)_nPPh_2]$ [NHC = IPr, *n* = 1 (**3**); NHC = IMes, *n* = 1 (**4**); NHC = IPr, *n* = 2 (**5**); NHC = IMes, *n* = 2 (**6**); NHC = IPr, *n* = 4 (**7**); NHC = IMes, *n* = 4 (**8**)] and RhCl(NHC)(dppbz) [NHC = IPr (**9**); NHC = IMes (**10**)]. All the complexes are characterized by ^1H, $^{31}P\{^1H\}$, and $^{13}C\{^1H\}$ NMR spectroscopy, elemental analysis, and mass spectrometry. Complexes **3**, **7**, and **9** are also characterized crystallographically. In benzene solution, the complexes decompose in the presence of O_2 with formation of the diphosphine dioxide, whereas reaction with CO leads to replacement of the NHC ligand to give known carbonyl–diphosphine complexes.

Key words: rhodium, *N*-heterocyclic carbenes, bis(diphenylphosphino) ligands, crystallography.

Résumé : Les réactions du $[RhCl(COE)(IPr)]_2$ (**1**) et du $[RhCl(COE)(IMes)]_2$ (2) [COE = cyclooctène; IPr = *N*,*N*′-bis(2,6-diisopropylphényl)imidazoline-2-ylidène; IMes = *N*,*N*′-bis(2,4,6-triméthylphényl)imidazoline-2-ylidène] avec les diphosphines $Ph_2P(CH_2)_nPPh_2$ et 1,2-bis(diphénylphosphino)benzène (dppbz) conduisent à la formation de complexes carbène *N*-hétérocyclique (NHC)–diphosphine–rhodium(I): $RhCl(NHC)[Ph_2P(CH_2)_nPPh_2]$ [NHC = IPr, *n* = 1 (**3**); NHC = IMes, *n* = 1 (**4**); NHC = IPr, *n* = 2 (**5**); NHC = IMes, *n* = 2 (**6**); NHC = IPr, *n* = 4 (**7**); NHC = IMes, *n* = 4 (**8**)] et RhCl(NHC)(dppbz) [NHC = IPr (**9**); NHC = IMes (**10**)]. Tous les complexes ont été caractérisés par des analyses élémentaires, par spectroscopie RMN du ^1H, du $^{31}P\{^1H\}$ et du $^{13}C\{^1H\}$ et par spectrométrie de masse. Les complexes **3**, **7** et **9** ont aussi été caractérisés par diffraction des rayons X. En solution dans le benzène, les complexes se décomposent en présence de O_2 avec formation d'oxyde de diphosphine, alors qu'une réaction avec le CO conduit au remplacement du ligand NHC pour conduire aux complexes carbonyl–diphosphines connus.

Mots-clés : rhodium, carbènes *N*-hétérocycliques, ligands bis(diphénylphosphino), cristallographie.

[Traduit par la Rédaction]

Introduction

A just-published special issue of *European Journal of Inorganic Chemistry* demonstrates the growing interest in transition-metal *N*-heterocyclic carbene (NHC) complexes.[1] Seven of the papers in the issue are concerned with Rh–NHC chemistry, including one from our group, which describes reactions of $[RhCl(COE)(NHC)]_2$ complexes with H_2 and with CO, where COE is cyclooctene and NHC is either *N*,*N*′-bis(2,6-diisopropylphenyl)imidazolin-2-ylidene (IPr) or *N*,*N*′-bis(2,4,6-trimethylphenyl)imidazolin-2-ylidene (IMes).[2] More generally, studies on Rh–NHC systems often pertain to comparisons with the chemistry and catalytic activity of Rh–tertiary phosphine systems, i.e., with replacement of PR_3 ligand(s) by NHC ligand(s) or use of mixed NHC–tertiary phosphine species.[2–5] Of prime interest to our group is the interaction of O_2 with Rh(I) complexes containing coordinated NHC ligands with or without ancillary phosphine ligands. We have shown that RhCl(NHC)(P–N) and *cis*-$RhCl(NHC)(PPh_3)_2$ complexes oxidatively add O_2 to generate "standard" six-coordinate Rh(III)–peroxide species (see Scheme 1), where P–N = *P*,*N*-chelated *o*-(diphenylphosphino)-*N*,*N*-dimethylaniline and NHC = IPr or IMes;[5] in an as yet unpublished work, our X-ray data for a five-coordinate $RhCl(IPr)_2(O_2)$ are also consistent with a peroxide.[6] However, recent communications by Crudden and coworkers[3,4a] report that $RhCl(NHC)_2(O_2)$ (NHC = IPr or IMes) and $RhCl(IMes)(PPh_3)(O_2)$ are best described as being Rh(I) singlet oxygen species. In efforts to understand the nature of this important discrepancy, we decided to synthesize Rh(I)–diphosphine–NHC complexes in the hope that their reactivity toward O_2 might prove helpful — a hope that was not fulfilled!

Experimental section

General procedures

All manipulations were performed under an atmosphere of dry Ar using standard Schlenk techniques or in a glove box. Solvents (Fisher Scientific) were dried using standard procedures and, before use, were purged with a stream of Ar. C_6D_6 (Cambridge Isotope Laboratory) was distilled from Na and stored under Ar. The diphosphines were used as received from Strem Chemicals. Complexes $[RhCl(COE)(IPr)]_2$ (**1**) and $[RhCl(COE)(IMes)]_2$ (**2**) were prepared by our literature procedure.[5] NMR spectra were recorded in C_6D_6 at room temperature (~20 °C) either on a Bruker AV 400 or AV 300 spectrometer, data being reported in ppm relative to TMS with the solvent signals as internal references (^{1}H, δ 7.16; ^{13}C, δ 128.38); ^{31}P{H} NMR shifts are relative to external 85% H_3PO_4. *J* values are given in Hz (s = singlet, d = doublet, *t* = triplet, spt = septet, m = multiplet, br = broad, ps = pseudo); assignments were sometimes aided by the use of ^{13}C{^{1}H}-APT and ^{1}H–^{13}C{^{1}H}–HSQC experiments. Mass spectra were obtained on a Kratos MS-50 spectrometer operating in the EI mode or on a Bruker Biflex IV spectrometer operating with a MALDI ion source. Elemental analyses were done on a Carlo Erba EA 1108 elemental analyzer.

RhCl(IPr)($Ph_2PCH_2PPh_2$) (3)

63.8 mg (0.05 mmol) of **1** and 38.5 mg (0.10 mmol) of dppm were dissolved in C_6H_6 (6 mL). The resulting yellow solution became orange on being stirred at room temperature for 5 h and was then concentrated to ~2 mL; hexane (~2 mL) was then added to precipitate the product, which was filtered off and dried in vacuo. Yield: 85 mg (93%). ^{1}H NMR δ: 0.53 (6H, d, J = 6.7, Me), 1.00 (6H, d, J = 6.7, Me), 1.16 (6H, d, J = 6.7, Me), 1.89 (d, 6H, J = 6.7, Me), 3.35 (br t, 2H, J_{HP_A} = 9.0, J_{HP_B} = 8.7, PCH_2P), 3.62 (spt, 2H, J = 6.7, CHMe$_2$), 3.74 (spt, 2H, J = 6.7, CHMe$_2$), 6.79 (s, 2H, NCH), 6.88 (ps t, 6H, *m*-Ph (4H) + *m*-IPr (2H)?), 6.96–6.99 (m, 8H, *o*-Ph (4H) + *p*-Ph (4H)?), 7.23 (t, 2H, $^3J_{HH}$ = 7.6, *p*-IPr), 7.30–7.37 (ps t, 6H, *m*-Ph (4H) + *m*-IPr (2H)?), 7.88–7.95 (m, 4H, *o*-Ph). ^{13}C{H} NMR δ: 22.87, 24.36, 26.87, 27.03, 29.09, 29.69, 48.29 (dd, J_{CP} = 19, J_{CP} = 30, PCH$_2$P), 123.78, 124.52, 124.91, 128.05, 128.21, 128.31, 128.88, 129.48, 129.77, 133.01 (d, J_{CP} = 22, C_{Ph}P), 133.96 (d, J_{CP} = 12, C_{Ph}P), 136.35, 136.65, 136.73, 137.02, 138.13, 144.89, 149.16, 195.45 (ddd, J_{CP_A} = 10, J_{CP_B} = 48, J_{CRh} = 128, Rh–*C*). ^{31}P{H} NMR: AB portion of the P_A, P_B, Rh (ABX) spin system simulated by the parameters: δ_A = –35.68, δ_B = –20.92, J_{AB} = 101.0, J_{AX} = 104.0, J_{BX} = 178.0 (see text). MS (EI) (*m*/*z*): 910 [M]$^+$, 387 [IPr – 1]$^+$. Anal calcd. for $C_{52}H_{58}N_2ClP_2Rh$: C 68.55, H 6.42, N 3.08; found: C 68.8, H 6.4, N 2.9. X-ray quality crystals of **3** containing 0.5 mol C_6H_6 solvate were grown by layering a C_6H_6 solution of the compound with hexane.

RhCl(IMes)($Ph_2PCH_2PPh_2$) (4)

The synthetic procedure for complexes **4**–**10** follows that given for **3**; here, 55.0 mg (0.05 mmol) of **2**, 38.6 mg (0.10 mmol) of dppm, and C_6H_6 (5 mL) were used. Yield: 74 mg (89%). ^{1}H NMR δ: 1.73 (s, 6H, *o*-Me), 2.22 (s, 6H, *o*-Me), 2.77 (s, 6H, *p*-Me), 3.40 (br t, 2H, J_{HP_A} = 9.1, J_{HP_B} = 8.8, PCH_2P), 6.25 (s, 2H, NCH), 6.60 (s, 2H, *m*-IMes), 6.88 (s, 2H, *m*-IMes), 6.95–7.09 (m, 12H, *o*-Ph (4H) + *m*-Ph (4H) + *p*-Ph (4H)?), 7.43–7.49 (m, 4H, *m*-Ph), 7.80–7.87 (m, 4H, *o*-Ph). ^{13}C{H} NMR δ: 19.45 (Me), 21.02 (Me), 21.61 (Me), 51.11 (dd, J_{CP} = 18, J_{CP} = 23, PCH$_2$P), 122.93 (NCH), 122.97 (NCH), 128.99, 129.40, 130.31, 131.70, 131.92, 133.84 (d, J_{CP} = 20, C_{Ph}P), 133.96 (d, J_{CP} = 16, C_{Ph}P), 135.35, 136.69, 136.98, 137.79, 138.07, 138.33, 138.54, 193.15 (ddd, J_{CP_A} = 10, J_{CP_B} = 47, J_{CRh} = 129, Rh–*C*). ^{31}P{H} NMR: AB portion of the P_A, P_B, Rh (ABX) spin system simulated by the parameters δ_A = –33.57, δ_B = –19.93, J_{AB} = 107.0, J_{AX} = 102.0, J_{BX} = 179.0 (see text). MS (EI) (*m*/*z*): 826 [M]$^+$, 790 [M – HCl]$^+$, 303 [IMes – 1]$^+$. Anal. calcd. for $C_{46}H_{46}N_2ClP_2Rh$: C 66.81, H 5.61, N 3.39; found: C 66.8, H 5.6, N 3.3.

RhCl(IPr)($Ph_2PCH_2CH_2PPh_2$) (5)

Complex **5** was prepared using 50.0 mg (0.04 mmol) of **1**, 31.0 mg (0.08 mmol) of dppe, and 10 mL C_6H_6. Yield: 66 mg (91%). ^{1}H NMR δ: 0.40 (d, 6H, J = 6.8, Me), 0.90 (d, 6H, J = 6.8, Me), 1.11 (d, 6H, J = 6.8, Me), 1.42–1.64 (m, 4H, CH_2-dppe), 1.68 (d, 6H, J = 6.8, Me), 3.38 (m, 2H, CHMe$_2$), 3.81 (m, 2H, CHMe$_2$), 6.81 (s, 2H, NCH), 6.87 (d, 2H, J = 7.4, *m*-IPr), 6.93 (t, 4H, J = 7.0, *m*-Ph), 7.02 (t, 2H, J = 7.0, *p*-Ph), 7.07–7.14 (m, 6H, *o*-Ph (4H) + *p*-Ph (2H)?), 7.26 (t, 2H, J = 7.7, *p*-IPr), 7.35 (d, 2H, J = 7.6, *m*-IPr), 7.45 (t, 4H, J = 8.5, *m-Ph*), 7.73–7.78 (m, 4H, *o*-Ph). ^{13}C{H} NMR δ: 22.90, 24.34, 27.04, 27.17, 28.90, 29.71, 32.84 (d, J_{CP} = 25, CH$_2$), 33.17 (d, J_{CP} = 23, CH$_2$), 123.90, 124.86, 124.94, 127.83, 127.92, 127.98, 128.93, 129.16, 129.75, 133.64 (d, J_{CP} = 12, C_{Ph}P), 135.16 (d, J_{CP} = 12, C_{Ph}P), 136.20, 136.60, 137.94, 138.25, 144.91, 149.61, 196.72 (dd, J_{CP} ~ 48, J_{CRh} = 121). ^{31}P{H} NMR δ: 62.10 (dd, $^2J_{PP}$ = 38, $^1J_{RhP}$ = 123), 65.84 ($^2J_{PP}$ = 38, $^1J_{RhP}$ = 208). MS (EI) (*m*/*z*): 924 [M]$^+$, 536 [M – IPr]$^+$, 387 [IPr – 1]$^+$. Anal. calcd. for $C_{53}H_{60}N_2ClP_2Rh$: C 68.81, H 6.54, N 3.03; found: C 68.5, H 6.4, N 3.0.

RhCl(IMes)($Ph_2PCH_2CH_2PPh_2$) (6)

Complex **6** was prepared using 75.0 mg (0.07 mmol) of **2**, 54.0 mg (0.14 mmol) of dppe, and 10 mL C_6H_6. Yield: 98 mg (86%). ^{1}H NMR δ: 1.23–1.24 (m, 4H, CH_2-dppe), 1.61 (s, 6H, *o*-Me), 2.23 (s, 6H, *o*-Me), 2.79 (s, 6H, *p*-Me), 6.23 (s, 2H, NCH), 6.60 (s, 2H, *m*-IMes), 6.85 (s, 2H, *m*-IMes), 6.97–7.11 and 7.04–7.08 (m, 12H, *o*-Ph (4H) + *m*-Ph(4H) + *p*-Ph (4H)?), 7.51 (t, 4H, J = 8, *m*-Ph), 7.80 (m, 4H, *o*-Ph). ^{13}C{H} NMR δ: 19.72 (Me), 21.56 (Me), 21.59 (Me), 32.05 (d, J_{CP} = 25, CH$_2$), 32.40 (d, J_{CP} = 25, CH$_2$), 123.16 (NCH), 127.77, 127.86, 127.93, 128.87, 128.93, 129.01, 129.14, 130.39, 134.52 (d, J_{CP} = 11, C_{Ph}P), 135.04 (d, J_{CP} = 10, C_{Ph}P), 135.58, 137.57, 138.49, 138.53, 139.04, 139.36. AB portion of the P_A, P_B, Rh (ABX) spin system simulated by the parameters δ_A = –64.26, δ_B = –64.96, J_{AB} = 36.6, J_{AX} = 125.7, J_{BX} = 205.7 (see text). MS (EI) (*m*/*z*): 840 [M]$^+$, 804 [M – HCl]$^+$, 536 [M – IMes]$^+$, 303 [IMes – 1]$^+$. Anal. calcd. for $C_{47}H_{48}N_2ClP_2Rh$: C 67.13, H 5.76, N 3.33; found: C 67.0, H 5.8, N 3.23.

RhCl(IPr)[$Ph_2P(CH_2)_4PPh_2$] (7)

Complex **7** was prepared by using 63.8 mg (0.05 mmol) of **1**, 42.7 mg (0.10 mmol) of dppb, and 10 mL C_6H_6. Yield: 76 mg (80%). ^{1}H NMR δ: 0.59 (br s, 6H, Me), 1.05 (m,

12H, Me), 1.29 (br s, 6H, Me), 1.72 (br s, 4H, CH_2), 1.85 (br s, 4H, CH_2), 3.56 (br s, 4H, CHMe$_2$), 6.89 (s, 2H, NCH), 6.98–7.08 (m, 16H, *Ar*), 7.30–7.41 (m, 10H, *Ar*). ^{13}C{H} NMR δ: 21.86 (Me), 23.89 (*C*H$_2$), 23.97, 25.14, 25.58 (d, J_{CP} = 20, P*C*H$_2$), 27.34 (Me), 29.64 (Me), 29.73 (Me), 30.24 (*C*H$_2$), 36.17 (d, J_{CP} = 25, P*C*H$_2$), 123.61, 124.05, 125.20, 127.15 (d, J_{CP} = 9, C_{Ph}P), 128.30, 128.69, 128.93, 129.03, 129.61, 131.42, 131.51, 131.58, 133.36 (d, J_{CP} = 11, C_{Ph}P), 145.10, 150.55. ^{31}P{H} NMR δ: 13.85 ($^2J_{PP}$ = 48, $^1J_{RhP}$ = 114), 48.94 (dd, $^2J_{PP}$ = 48, $^1J_{RhP}$ = 208). MS (MALDI) (*m*/*z*): 952 [M]$^+$. Anal. calcd. for $C_{55}H_{64}ClN_2P_2Rh$: C 69.30, H 6.77, N 2.94; found: C 69.5, H 6.7, N 3.1. X-ray quality crystals of **7** were grown by layering a C_6H_6 solution of the compound with hexane.

RhCl(IMes)[Ph$_2$P(CH$_2$)$_4$PPh$_2$] (8)

The yellow complex **8** was obtained using 75.0 mg (0.07 mmol) of **2**, 58.0 mg (0.14 mmol) of dppb, and 10 mL of benzene. Yield: 91 mg (77%). ^{1}H NMR δ: 1.91 (s, 6H, *o*-Me), 2.09 (m, 4H, CH_2), 2.26 (s, 6H, *o*-Me), 2.46 (br s, 4H, CH_2), 2.83 (s, 6H, *p*-Me), 6.29 (s, 2H, NCH), 6.75 (s, 2H, *m*-IMes), 6.90–7.11 (m, 14H, *o*-Ph (4H) + *m*-Ph (4H) + *p*-Ph (4H) + *m*-IMes (2H)?), 7.32 (t, 4H, *J* = 8, *m*-Ph), 7.62 (m, 4H, *o*-Ph). ^{13}C{H} NMR δ: 19.90 (Me), 21.89 (Me), 22.48 (Me) 24.08 (*C*H$_2$), 32.74 (d, *J* = 18, P–*C*H$_2$), 32.99 (*C*H$_2$), 122.03, 122.05, 123.11, 126.84 (d, J_{CP} = 10, C_{Ph}P), 127.64, 127.82, 129.13, 129.54 (d, J_{CP} = 8, C_{Ph}P), 133.44, 134.39, 134.65, 134.92, 135.43, 135.68, 137.38, 137.41, 138.20, 138.60, 138.90, 144.34. ^{31}P{H} NMR δ: 12.38 (dd, $^2J_{PP}$ = 48, $^1J_{RhP}$ = 118), 54.04 ($^2J_{PP}$ = 48, $^1J_{RhP}$ = 207). MS (MALDI) (*m*/*z*): 868 [M]$^+$. Anal. calcd. for $C_{49}H_{52}ClN_2P_2Rh$: C 67.70, H 6.04, N 3.23; found: C 67.9, H 6.0, N 3.3.

RhCl(IPr)(Ph$_2$PC$_6$H$_4$PPh$_2$) (9)

The orange complex **9** was obtained using 55.0 mg (0.04 mmol) of **1** and 44.0 mg (0.10 mmol) of dppbz in 5 mL of C_6H_6. Crystalline material contained 0.5 mol solvate C_6H_6. Yield: 82 mg, 96%. Dried material was of the formulation $C_{57}H_{60}ClN_2P_2Rh$. ^{1}H NMR δ: 0.70 (d, 6H, *J* = 6.7, Me), 0.90 (d, 6H, *J* = 6.7, Me), 1.10 (d, 6H, *J* = 6.7, Me), 1.65 (d, 6H, *J* = 6.5, Me), 3.37 (m, 2H, CHMe$_2$), 3.91 (m, 2H, CHMe$_2$), 6.72 (br s, 2H, NCH), 6.80–6.82 (m, 4H, *m*-Ph), 6.89–6.95 (br t, 6H, *J* ~ 6.5), 7.09–7.15 (m, 8H), 7.25 (d, 2H, *J* = 7.6), 7.43 (ps t, 6H), 7.81 (m, 4H). ^{13}C{H} NMR δ: 22.73, 24.27, 26.99, 27.14, 29.21, 29.62, 123.63, 124.99, 127.87, 127.97, 128.32, 128.51, 128.69, 128.92, 129.10, 129.81, 133.10, 133.22, 135.13 (d, J_{CP} = 11, $C_{C_6H_4}$P?), 137.10 (d, J_{CP} = 45, C_{Ph}P?), 138.55, 139.57 (d, J_{CP} = 36, C_{Ph}P?), 144.47, 149.05, 194.96 (ddd, J_{CP_A} = 11, J_{CP_B} = 48, J_{CRh} = 122, Rh–*C*). ^{31}P{H} NMR δ: 65.96 (dd, $^2J_{PP}$ = 39, $^1J_{RhP}$ = 205), 71.36 ($^2J_{PP}$ = 39, $^1J_{RhP}$ = 124). MS (EI) (*m*/*z*): 972 [M]$^+$, 387 [IPr – 1]$^+$. Anal. calcd: C 70.35, H 6.22, N 2.88; found: C 70.6, H 6.3, N 2.7. The layering method given for complex **3** yielded X-ray quality crystals of **9** again containing 0.5 mol C_6H_6 solvate.

RhCl(IMes)(Ph$_2$PC$_6$H$_4$PPh$_2$) (10)

The orange complex **10** was obtained using 55.0 mg (0.05 mmol) of **2** and 44.0 mg (0.10 mmol) of dppbz in 5 mL of C_6H_6. Yield: 71 mg (80%). ^{1}H NMR δ: 1.62 (s, 6H, *o*-Me), 2.16 (s, 6H, *o*-Me), 2.74 (s, 6H, *p*-Me), 6.21 (s, 2H, NCH), 6.53 (s, 2H, *m*-IMes), 6.66–6.71 (m, 2H, *o*-C_6H_4), 6.74 (s, 2H, *m*-IMes), 6.95–7.04 (m, 12H, *o*-Ph (4H) + *m*-Ph (4H) + *p*-Ph (4H)), 7.25 (ps t, 2H, *m*-C_6H_4), 7.67 (t, 4H, *J* = 8.6, *m*-Ph), 7.79 (m, 4H, *o*-Ph). ^{13}C{H} NMR δ: 18.58, 20.79, 122.48, 127.09, 127.18, 127.25, 127.34, 127.81, 127.96, 128.16, 128.37, 128.88 (d, J_{CP} = 3, C_{Ph}P?), 129.21 (d, J_{CP} = 4, C_{Ph}P?), 129.65, 130.57, 130.70, 131.68, 131.83, 133.99, 134.11, 134.22, 134.32, 134.68, 136.38, 136.80, 137.53, 137.64, 138.02, 138.36, 192.32 (dd, J_{CP} ~ 9, J_{CRh} = 118, Rh–*C*). ^{31}P{H} NMR: AB portion of the P_A, P_B, Rh (ABX) spin system simulated by the parameters δ_A = –66.77, δ_B = –67.33, J_{AB} = 39.60, J_{AX} = 206.8, J_{BX} = 125.6 (see text). MS (EI) (*m*/*z*): 888 [M]$^+$, 303 [IMes – 1]$^+$. Anal. calcd. for $C_{51}H_{48}ClN_2P_2Rh$: C 68.90, H 5.45, N 3.15; found: C 69.0, H 5.3, N 3.3.

X-ray crystallographic analysis of complexes 3, 7, and 9

Measurements were made at 173.0(1) K on a Bruker X8 APEX diffractometer with graphite-monochromated Mo-Kα radiation (0.71 069 Å). Data were collected and integrated using the Bruker SAINT software package[7] and were corrected for absorption effects using the multi-scan SADABS technique.[8] All structures were solved by direct methods,[9] and refinements were performed using the SHELXTL program.[10] All non-hydrogen atoms were refined anisotropically and all H atoms were included in calculated positions but not refined.

Crystal data for 3

$C_{52}H_{58}N_2ClP_2Rh{\cdot}0.5C_6H_6$, fw = 949.31, orange tablet, size 0.15 mm × 0.20 mm × 0.50 mm, monoclinic, space group *P* 2$_1$/*n* (No. 14), *a* = 11.0616(2) Å, *b* = 21.9905(4) Å, *c* = 20.1095(4) Å, β = 90.774(1)°, *V* = 4891.2(2) Å^3, *Z* = 4, D_{calcd} = 1.291 g cm^{-3}, μ = 0.507 mm^{-1}. *F*(000) = 1988.00, 62 508 total reflections (11 674 independent of symmetry, 8726 for $I > 2\sigma(I)$), 558 variables, residuals (refined on F^2, all data): *R*1 = 0.038, *wR*2 = 0.088.

Crystal data for 7

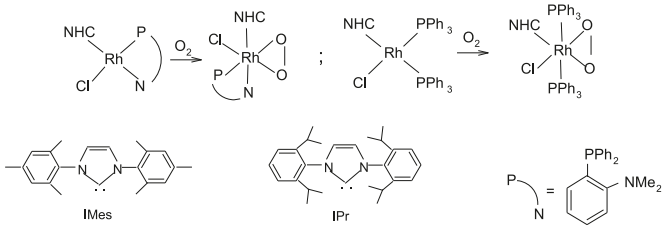
$C_{55}H_{64}N_2ClP_2Rh$, fw = 952.33, orange plate, size 0.20 mm × 0.25 mm × 0.50 mm, monoclinic, space group *P* 2$_1$/*n* (No. 14), *a* = 11.1595(6) Å, *b* = 20.971(1) Å, *c* = 20.938(1) Å, β = 95.693(2)°, *V* = 4875.8(5) Å^3, *Z* = 4, D_{calcd} = 1.299 g cm^{-3}, μ = 0.509 mm^{-1}. *F*(000) = 2000.00, 69 860 total reflections (11 679 independent of symmetry, 9737 for $I > 2\sigma(I)$), 558 variables; residuals (refined on F^2, all data): *R*1 = 0.037, *wR*2 = 0.067.

Crystal data for 9

$C_{57}H_{60}N_2ClP_2Rh{\cdot}0.5C_6H_6$, fw = 1011.32, orange plate, size 0.04 mm × 0.15 mm × 0.25 mm, triclinic, space group *P*-1 (No. 2), *a* = 12.6856(8) Å, *b* = 17.438(1) Å, *c* = 24.693(2) Å, α = 80.911(3)°, β = 81.812(2)°, γ = 86.156(3)°, *V* = 5333.1(6) Å^3, *Z* = 4, D_{calcd} = 1.256 g cm^{-3}, μ = 0.476 cm^{-1}. *F*(000) = 2116.00, 69 026 total reflections (18 891 independent of symmetry, 14 480 for $I > 2\sigma(I)$), 1200 variables, residuals (refined on F^2, all data): *R*1 = 0.061, *wR*2 = 0.103. The material crystallized with two molecules of the Rh-complex, one C_6H_6 molecule and one additional solvent molecule, in the asymmetric unit; the solvent

resembled hexane, but could not be modeled satisfactorily and was thus removed from the model, with the SQUEEZE program[11] used to correct data for any residual electron density found in the space formerly occupied by the solvent.

Scheme 1. Reactions of O_2 with some Rh–*N*-heterocyclic carbene (NHC)–phosphine complexes.



Reactivity of the complexes

The complexes (~0.05 mmol) were dissolved in C_6D_6 (1 mL), and a sample (~0.7 mL) of the solution was placed in a J-Young NMR tube and subjected to an atmosphere of O_2, CO, or H_2 at room temperature; $^{31}P\{^1H\}$ NMR spectral changes were then monitored.

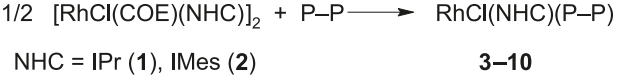
Results and discussion

Synthesis and spectroscopic characterization of complexes

The diphosphines $Ph_2P(CH_2)_nPPh_2$ (n = 1, dppm; n =2, dppe; n = 4, dppb) and 1,2-bis(diphenylphosphino)benzene (dppbz) react at room temperature with $[RhCl(COE)(NHC)]_2$ complexes in benzene to give yellow RhCl(NHC)(P–P) species in 77%–96% isolated yields (NHC = IPr or IMes, and P–P is the chelating diphosphine). All eight complexes (**3**–**10**) have been synthesized (see Scheme 2) and well characterized by elemental analysis, ^1H, $^{31}P\{^1H\}$, and $^{13}C\{^1H\}$ NMR spectroscopy, mass spectrometry and, for **3**, **7**, and **9**, by X-ray crystallography.

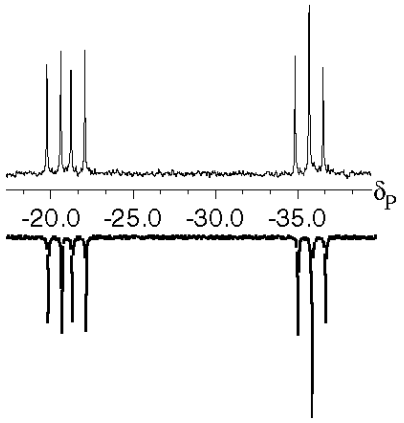
The solution NMR data for the complexes are generally straightforward, and most of the shifts are readily assigned based on previously reported data, for example, for *cis*-$RhCl(NHC)(PPh_3)_2$ and RhCl(NHC)(P–N) species (see Scheme 1).[5] All the complexes show a ^1H singlet for NC*H* between δ_H 6.79–6.89 and 6.21–6.29 for the IPr- and IMes-containing species, respectively. The IPr species **3**, **5**, and **9** show four sets of doublets for inequivalent IPr–Me groups, with coupling of ~6.7 Hz to a IPr–methine proton; the doublets indicate restricted rotation about the Rh–C bond or, less likely, the N_{imid}–C_{arene} bond.[12] Complex **7** shows broad signals for these methyls, presumably because of the relative greater flexibility of the dppb chelate ring, which might allow for more rotational motion.[13] The Me signals are sometimes shifted downfield (e.g., to δ_H 1.89 for **3**), which could result from a deshielding effect from a phenyl ring of the diphosphine (see the following section for the structure of **3**). The IPr–methine protons appear as two septets (for **3**), two multiplets (for **5**), or one broad singlet (for **7**). For each of the IMes species **4**, **6**, **8**, and **10**, the Me protons are seen as three singlets at δ_H ~2.8, ~2.2, and between 1.9 and 1.6, implying that the two *o*-Me groups on one aromatic ring are inequivalent, consistent again with some restricted rotation.

Scheme 2. Synthesis of complexes and their numbering.



NHC	dppm	dppe	dppb	dppbz
IPr	**3**	**5**	**7**	**9**
IMes	**4**	**6**	**8**	**10**

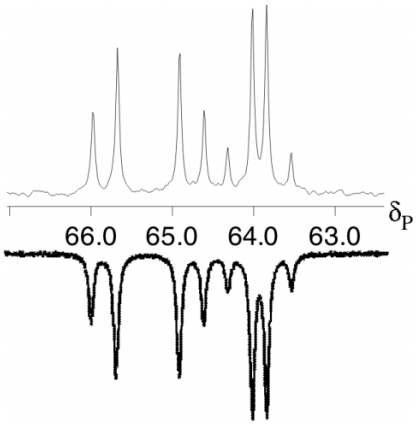
Fig. 1. The experimental (upper) and simulated (lower) $^{31}P\{^1H\}$ NMR spectra of RhCl(IPr)(dppm) (**3**). δ_{P_A} = –35.68, δ_{P_B} = –20.92, J_{AB} = 101.0 Hz, J_{RhP_A} = 104.0 Hz, J_{RhP_B} = 178.0 Hz.



The two singlets seen for the *m*-protons of the IMes ligand similarly imply inequivalence of these protons within one ring; the same description has been noted for the analogous *cis*-$RhCl(IMes)(PPh_3)_2$ complex.[4j] Where possible, we have assigned the *m*- and *p*-protons of the IPr ligand, the *m*-protons of the IMes ligand, and the phenyl protons of the PPh_2 groups, based on (*i*) expected splitting patterns (e.g., the *m*-H of IPr and of IMes are doublets and singlets, respectively, and the *p*-H of IPr is a triplet),[2,5,14] (*ii*) data for free IPr and IMes,[15], and (*iii*) data for the free diphosphines.[16] The more tentative assignments of these aromatic protons are indicated by a query (?) in the Experimental section. The CH_2 protons of the carbon backbone of the diphosphine ligand in **5**–**8** appear as a multiplet or broad singlets. Those of dppm in **3** and **4** are seen as a broadened triplet, which is in fact a set of overlapping doublets that result from two equivalent protons coupling to the two inequivalent P atoms; the ^{31}P-decoupled spectra showed a slightly broadened singlet.

The $^{31}P\{^1H\}$ NMR spectra reveal the expected inequivalent P atoms. For **5** and **7**–**9**, first-order spectra show doublets of doublets with J_{PP} values of 48–38 Hz and J_{RhP} values of 123–114 and 208–205 Hz (for the P atom cis and trans to Cl, respectively[4d,4e,5]). For the other complexes, the spectra are more complex ABX systems but are readily simulated. Figure 1 shows the data for **3** and those of **4** (the other dppm derivative) are very similar: the J_{PP} values are now ~100 Hz, with J_{RhP} values of ~100 and 180 Hz, respectively, for the P atoms cis and trans to Cl. The ABX spectra of **6** (Fig. 2) and **10** are similar to each other, with J_{PP} and

Fig. 2. The experimental (upper) and simulated (lower) $^{31}P\{^1H\}$ NMR spectra of RhCl(IMes)(dppe) (**6**) δ_{P_A} = –64.26, δ_{P_B} = –64.96, J_{AB} = 36.6 Hz, J_{RhP_A} = 125.7 Hz, J_{RhP_B} = 205.7 Hz.



J_{RhP} values close to those seen in the first-order spectra of **5** and **7**–**9**. Spectra akin to those of Fig. 2 have been noted previously for analogous *cis*-RhCl(IMes)$[P(OPh)_3]_2$ species.[4e]

The expected ddd pattern (coupling to Rh and inequivalent P atoms) in the $^{13}C\{^1H\}$ spectra for the Rh–*C* signals is seen at δ ~195 for **3**, **4**, and **9**, with J_{RhC} being ~125 Hz and the J_{PC} values being ~10 and ~50 Hz. For **5** and **10**, only somewhat broader dd patterns are seen, whereas for **6**–**8** these signals are not seen and are presumably broadened into the baseline by some exchange processes, reflecting a relatively labile Rh–carbene bond (see the last section on the reactivity toward CO); the flexibility of the dppb ring might account in part for the lack of the Rh–*C* signal in **7** and **8**. The non-appearance of carbene-carbon resonances in Rh–NHC species is not unusual.[2,4e,5] There is no question about the identity of the complexes, which are all essentially square-planar Rh(I) species, with some distortion induced by the chelating phosphines, as seen particularly in the structure of **3**, the dppm derivative (see the following section). For **3** and **4**, the $^{13}C\{^1H\}$ signal for the P*C*H_2P carbon is seen as a doublet of doublets at δ ~50 with J_{CP} values for the inequivalent P atoms in the 18–30 Hz range. For complexes **5**–**10**, $^{13}C\{^1H\}$ signals for the C atoms attached to P atoms are seen as doublets in the expected regions δ_C 25–36 and 125–139, respectively, for alkyl and aryl carbons; uncertain assignments are again indicated by ?.

Mass spectral data reveal the parent peak for all the complexes using either the EI mode (for **3**–**6**, **9**, and **10**) or the MALDI-TOF ion source (for **7** and **8**).

Structural characterization of 3, 7, and 9

The crystal structures of **3**, **7**, and **9** (all containing IPr) were established by X-ray analysis; the molecular structures and selected bond lengths and angles are shown in Figs. 3, 4, and 5, respectively. Complex **3** crystallized with one-half of a benzene molecule, whereas **9** crystallized as two independent molecules with one benzene molecule and one additional solvent molecule (likely hexane) in the asymmetric unit; **7** was nonsolvated. The essentially square-planar structures show some distortion, particularly in the dppm of **3** where the P1–Rh–P2 bond angle is 72.81° and the adjacent

Fig. 3. ORTEP diagram of RhCl(IPr)(dppm) (**3**) with 50% probability thermal ellipsoids; H atoms are omitted for clarity. Selected bond lengths (Å) and angles (°): Rh1—C1, 2.067(2); Rh1—Cl1, 2.3793(6); Rh1—P1, 2.2005(6); Rh1—P2, 2.2516(6); P1—C28, 1.854(2); P2—C28, 1.845(2); C1–Rh1–Cl1, 90.30(6); Cl1–Rh1–P2, 93.94(2); P2–Rh1–P1, 72.81(2); P1–Rh1–C1, 103.07(6); C1–Rh1–P2, 175.28(6); Cl1–Rh1–P1, 166.32(2).

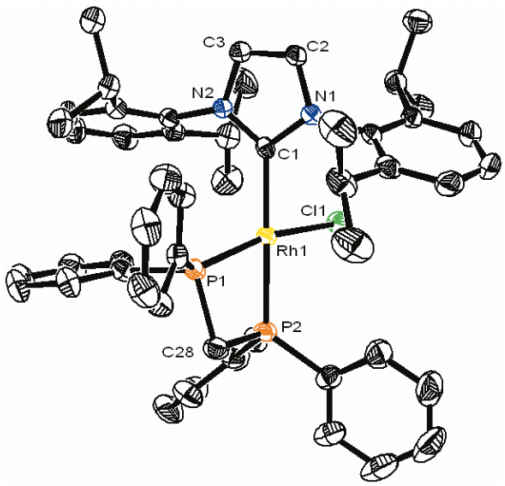


Fig. 4. ORTEP diagram of RhCl(IPr)(dppb) (**7**) with 50% probability thermal ellipsoids; H atoms are omitted for clarity. Selected bond lengths (Å) and angles (°): Rh1—C1, 2.0484(15); Rh1—Cl1, 2.3846(4); Rh1—P1, 2.2888(4); Rh1—P2, 2.2043(4); P1—C28, 1.8427(18); P2—C31, 1.8681(16); C1–Rh1–Cl1, 86.01(4); Cl1–Rh1–P1, 82.569(15); P1–Rh1–P2, 91.046(15); P2–Rh1–C1, 100.39(4); C1–Rh1–P1, 168.34(4); Cl1–Rh1–P2, 173.587(15).

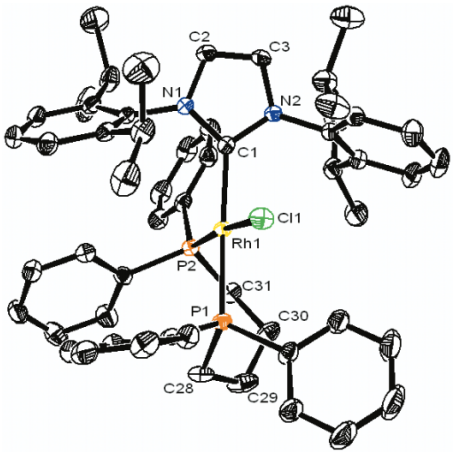
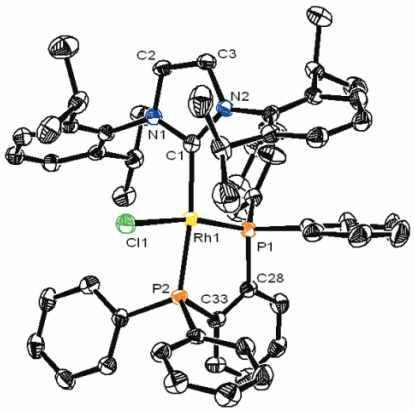


Cl1–Rh1–P2 and P1–Rh1–C1 bond angles are 93.94 and 103.07(6)°, respectively. In **7**, the more flexible dppb allows for a P1–Rh–P2 bond angle of 91.05°. Steric interactions between the IPr and a PPh_2–phenyl ring are evident in all three structures, this accounting for cis C–Rh–P angles of ~100°. The Rh–C and Rh–Cl bond lengths are in the established range for such chloro(carbene)–Rh(I or III) complexes.[2,5,4d,17–21] In all three complexes, the Rh–P bond trans to the carbene is 0.04–0.08 Å longer than the one cis to the carbene, a finding compatible with data for *cis*-RhCl(IMes)$(PPh_3)_2$, where the difference is about 0.09 Å.[4d] Our data also agree with a finding from Crudden's group that

Fig. 5. ORTEP diagram of RhCl(IPr)(dppbz) (**9**) with 50% probability thermal ellipsoids; the other independent molecule in the asymmetric unit, and H atoms, are omitted for clarity. Selected bond lengths (Å) and angles (°): Rh1—C1, 2.101(3); Rh1—Cl1, 2.3929(8); Rh1—P2, 2.2239(8); Rh1—P1, 2.1796(9); P1—C28, 1.852(3); P2—C33, 1.832(3); C1–Rh1–Cl1, 91.58(8); Cl1–Rh1–P2, 83.92(3); P2–Rh1–P1, 85.30(3); P1–Rh1–C1, 99.66(8); C1–Rh1–P2, 173.14(9); Cl1–Rh1–P1, 173.73(3).



Rh–P bonds in *cis*-RhCl(NHC)$(PPh_3)_2$ complexes are marginally shorter (by up to 0.03 Å) than corresponding bonds in $RhCl(PPh_3)_3$ and *trans*-RhCl(CO)$(PPh_3)_2$;[4d] in the case of RhCl(IPr)(dppbz) (**9**), the difference is up to 0.08 Å. Data from Herrmann's group on other chloro(carbene)phosphine–phosphite–Rh(I) complexes[18] also support this finding, which is likely general within analogous Rh–carbene and Rh–phosphine species.

Reactivity of the complexes

Complexes **3**–**10** are all highly soluble in benzene, toluene, CH_2Cl_2, $CHCl_3$, and polar aprotic solvents, but are insoluble in solvents such as hexane. In the solid state, these complexes are air-stable, but in solution (e.g., in C_6H_6/C_6D_6), they are sensitive to air or oxygen and rapidly decompose at room temperature with formation of free diphosphine dioxide, as demonstrated by in situ $^{31}P\{^1H\}$ NMR data; singlets were seen at δ_P = 24.4, 12.2, 31.7, and 32.0, respectively, for the dioxides of dppm, dppe, dppb, and dppbz, in agreement with literature data,[22,23] and were identical to values measured by in situ oxidation of the free diphosphine in C_6D_6 with H_2O_2. The reactivity toward O_2 of these diphosphine complexes is markedly different to that of the analogous *cis*-RhCl(NHC)$(PPh_3)_2$ complex, which under the same conditions undergoes irreversible oxidative addition to form a Rh(III)–peroxide that contains, however, *trans*-PPh_3 ligands (see Scheme 1)[5]; this peroxide is stable in both the solid state, and even in solution shows no sign of decomposition to $OPPh_3$ over 24 h in air.[5] The necessarily cis-chelating diphosphines clearly do not allow for formation at ambient conditions of a stable peroxide, although the chelated P–N ligand mentioned in the Introduction (Scheme 1) does so.[5] Whether oxidation of the diphosphines occurs via an intermediate with coordinated O_2 requires detailed low-temperature studies. Loss of a chelating diphosphine as the dioxide during oxygenation of a Rh(I)–tris(pyrazolyl)borate–dppe complex in solution in attempts to study formation of peroxide species has been demonstrated previously,[22] although the chelating diphosphine ligands are retained when $Rh(dppm)_2^+$ and $Rh(dppe)_2^+$ react in solution with O_2 at ambient conditions to form the respective *cis*-Rh(P–P)$_2(O_2)^+$ peroxide species, where (P–P) is the chelating diphosphine.[13b] Our findings at this stage on the reactivity of O_2 toward the RhCl(NHC)(P–P) complexes unfortunately cannot contribute to the question of the nature of the coordinated O_2 in Rh–NHC complexes with and without an ancillary phosphine ligand, in which singlet oxygen has been suggested (see Introduction).[3,4a] Studies on such systems are ongoing.

Reaction of a benzene solution of RhCl(NHC)(dppe) [NHC = IPr (**5**), IMes (**6**)] with CO at ambient conditions rapidly precipitated a yellow solid, which was recrystallized by layering of a CH_2Cl_2 solution of the compound with hexane. The material, however, was shown by elemental analysis and $^{31}P\{^1H\}$ NMR and IR spectroscopies to be the known compound RhCl(CO)(dppe).[24,25] Reactions of CO with the dppm and dppb analogues (complexes **3**, **4**, **7**, and **8**) also resulted in displacement of the NHC ligand by CO as shown by in situ ^1H NMR, when resonances of the free carbenes were generated.[26]

The Rh products were not investigated, but are presumed to be the well-known dimeric, bridged-diphosphine complexes *trans*-$[RhCl(CO)]_2(\mu$-P–P$)_2$ that are formed with dppm and dppb.[25] The substitution of an NHC ligand by CO, to the best of our knowledge, has not been reported, and implies a relatively labile NHC ligand; indeed, substitution of IMes by PPh_3 has been reported (see the following).[3,4f] Within Rh–NHC–carbonyl systems, $RhCl(CO)(NHC)_2$[2,14,27] and $RhCl(CO)_2(NHC)$[2,19,28] complexes have been synthesized by reacting CO with Rh–NHC precursors, whereas RhCl(CO)(PPh_3)(NHC) has been made from $RhCl(PPh_3)_2$(NHC) and CO.[3,4d,4f,4j]

The RhCl(NHC)(P–P) complexes in benzene solution do not react with H_2 at ambient conditions. Known hydrido complexes of the type $Rh(H)_2Cl(NHC)_2$ and $[Rh(H)_2Cl(NHC)]_2$ have been made by reaction of H_2 with Rh(I)–NHC precursors,[2,3,14,27] whereas Rh–hydrido–NHC species have also been generated via intramolecular C–H activation of the Me group of IMes.[14,29] Hydrido derivatives of Rh–NHC–phosphine species have not yet been reported.

Supplementary data

Morphology-dependent luminescence from ZnO nanostructures — An X-ray excited optical luminescence study at the Zn K-edge

Olga Lobacheva, Michael W. Murphy, Jun Young Peter Ko, and Tsun-Kong Sham

Abstract: ZnO nanostructures have been synthesized by thermal evaporation on Si substrates. It is found that the morphologies of the nanostructures are governed by growth conditions such as temperature, carrier-gas flow rate, and the nature of the substrate (with and without a catalyst). We report X-ray excited optical luminescence from ZnO nanostructures of distinctly different morphologies in the energy and time domain using excitation photon energies across the Zn K-edge. X-ray excited optical luminescence (XEOL) and X-ray absorption near edge structure (XANES) study has clearly shown the morphology dependence of the ZnO optical properties. A correlation of luminescence with morphology, size, and crystallinity emerges.

Key words: ZnO nanostructures, XEOL, TRXEOL, XANES, vapour deposition.

Résumé : On a synthétisé des nanostructures de ZnO par évaporation thermique de substrats contenant de l'étain. On a trouvé que les morphologies des nanostructures sont gouvernées par les conditions de croissance, la vitesse d'écoulement du gaz porteur et la nature du substrat, avec ou sans catalyseur. Utilisant des énergies photoniques d'excitation sur l'arête K du zinc, on a pu observer de la luminescence optique excitée par les rayons X à partir de nanostructures de ZnO de morphologies comportant des différences importantes dans le domaine du temps et de l'énergie. Des études de luminescence optique excitée par les rayons X « XEOL » et par la spectroscopie de la structure fine d'absorption des rayons X près du seuil « XANES » ont clairement démontré l'importance de la morphologie sur les propriétés optiques du ZnO. Il en émerge une corrélation entre la luminescence et la morphologie, la taille et la cristallinité.

Mots-clés : nanostructures de ZnO, luminescence optique excitée par les rayons X « XEOL », spectroscopie de la structure fine d?absorption des rayons X près du seuil « XANES », dépôt de vapeur.

[Traduit par la Rédaction]

Introduction

Zinc oxide, a wide-band-gap semiconductor (E_g = 3.37 eV at room temperature), ranks high among oxide semiconductors for its unique properties. With suitable doping, the band gap of ZnO can be tuned from 3.0 eV to 4.28 eV.[1,2] Relatively large exciton binding energy (60 meV) makes zinc oxide a desirable technological material for electronic and photonic applications, such as UV lasers and light emitters.[3] It can also be used in the fabrication of gas sensors, varistors, and piezoelectronic devices.[4–6]

The properties of zinc oxide have been under investigation for decades.[7] The shift from bulk to nanosized materials has introduced new electronic and optical properties due to surface effects, defect formations, and quantum confinement. Using different synthesis methods, the growth of ZnO nanostructures on a number of substrates with and without catalyst has been successfully controlled. A variety of ZnO nanostructures have been produced, including nanowires, nanorods, nanoneedles, nanobelts, nanotubes, nanoparticles, nanosprings, and nanorings.[8–17]

Here, we report (*i*) the synthesis of ZnO nanowires and nanorods on a long slab of a silicon (100) wafer substrate with and without Au catalyst using a thermal evaporation technique, and (*ii*) the optical properties of ZnO nanostructures using X-ray excited optical luminescence (XEOL) and X-ray absorption near edge structure (XANES) across the Zn K-edge.[18,19]

In XEOL, X-ray photon excites the core electron into previously unoccupied levels or into the continuum. The core hole produced by the X-ray photon gets immediately filled with electrons from shallower levels. The process is accompanied by the emission of photo and Auger electrons as well as fluorescence photons, which can produce even more secondary electrons and holes on their track during the thermalization process. Thus, the absorption of a single X-ray photon can lead to more than one electron-hole pair. The thermalization process of electrons and holes is very fast and ends up with holes in the top of the valence band and electrons in the bottom of the conduction band. Radiative recombination of the holes and the electrons via excitonic deexcitation produces optical luminescence with energy close to that of the band gap, and energy transfer to defect levels lying within the band gap produces much broader emission bands in longer wavelengths.

By tuning the X-ray energy across an absorption edge in an excitation process, it is often possible to investigate the site-specific optical response of light-emitting material upon X-ray absorption. In addition, the time structure of the synchrotron enables time-resolved X-ray excited optical luminescence (TRXEOL) measurements, providing information about lifetime and dynamics of the radiative de-excitation.[18,19] Combining XEOL and XANES has been proven to be a very powerful method for the studies of the origin of luminescence of materials, especially nanostructures.[20,21] XANES refers to the study of the absorption coefficient in the vicinity of an absorption edge up to ~50 eV above the threshold, and it probes the unoccupied densities of states (LUMO and so forth in molecules) above the Fermi level via bound-to-bound and bound-to-quasi-bound dipole transitions. XEOL excited across absorption edges and the corresponding XANES can be element-, site-, and excitation-channel-specific, since X-ray edges are unique to the element and chemically sensitive when the probing photon is sufficiently monochromatic (as is often the case at synchrotron light sources).[18,19]

Experimental procedures

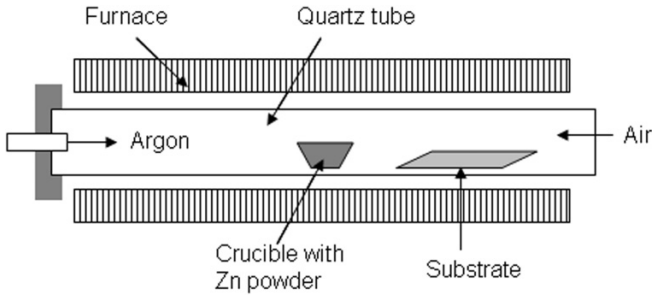
ZnO nanostructures of interest were deposited on a slab of Si (100) wafer, which was pre-washed in ethanol and distilled water as described previously.[10] Briefly, an alumina boat containing Zn powder (99.99%, Alfa Aesar) was placed in the centre of a quartz tube, which was then mounted inside a horizontal tube furnace (Fig. 1). A carrier gas (argon) was introduced into the system at one end of the tube with a flow rate (typically of 75–80 sccm). The other end of the quartz tube was open to air. The substrate, a slab of Si wafer ~0.5 inch wide, was placed downstream of the alumina boat. We fabricated nanostructures on both clean and colloidal Au (colloid solution of thiol-capped gold nanoparticles) covered substrates. To track the influence of the catalyst on the morphology of the grown nanostructures, colloid Au was deposited on half of the Si slab along its length.

Inside the furnace, the gold particles on the substrate act as a catalyst during the growth by the vapour–liquid–solid (VLS) mechanism. ZnO (or Zn) vapour dissolves in the catalyst droplet forming Au/Zn alloy. When the concentration reaches supersaturation at a given temperature, ZnO nanorods begin to grow on the droplet–substrate interface. As shown in previous work,[9–11,22] the nanostructures thus prepared consist of zinc oxide without detectable Au impurities along the length. A catalyst particle locates on the tip of the nanorod as expected for a VLS mechanism. ZnO nanostructures can also be fabricated without any catalyst. In this case, the ZnO growth occurs by vapour–solid (VS) process, which initiates with the formation of Zn nucleus on the substrate surface. However, in a number of cases, the presence of catalyst provides an aligned nanostructure growth with a smaller size and a more uniform distribution.[23]

The temperature in the growth region was determined by the position of the substrate relative to the center of the furnace. It was calibrated by a thermocouple. Typically, the temperature in the growth region of interest was 15–20 °C less than that in the center of the furnace.

ZnO samples thus obtained appear as a grey-white coating on the surface of the Si wafer with a slowly varying morphology along the thermal gradient of the slab. When excited by an ultraviolet lamp, these samples produced green emission. Differences in synthesis conditions (the thermal gradient of the substrate, deposition time, carrier-gas flow rate, and the nature of the substrate) result in a variety of morphologies.[24,25] This combinatorial approach provides some very desirable specimens for the studies of the morphology dependence of the optical properties of ZnO nanostructure. Selected areas of uniform morphology (nanowires and nanorods) will be reported here.

Fig. 1. Schematic diagram of the ZnO nanostructure fabrication process.



Images of the fabricated nanostructures were obtained at the Nanofabrication Facility of the University of Western Ontario using a LEO 1530 field-emission scanning electron microscope (FE SEM) fitted with a laser interferometer-controlled stage. SEM images were taken at EHT = 2 kV and a working distance of 5 mm.

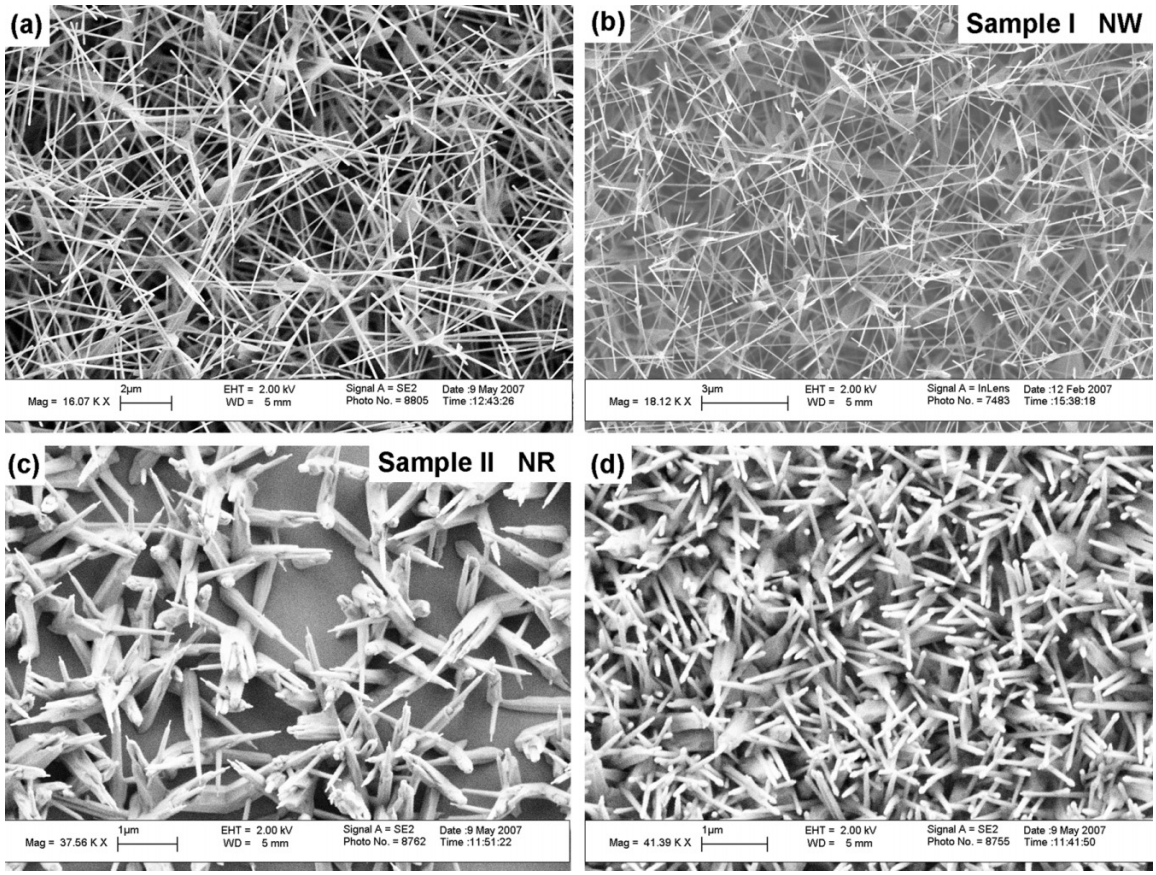
XEOL and TRXEOL experiments were carried out on the PNC/XOR beamline (20-BM) at the Advanced Photon Source (APS) at Argonne National Laboratory with APS running at the top-up mode (100 mA, 24 bunches, ~100 ps pulse, and 153 ns repetition rate). We used the optical signal as the start and the synchrotron pulse as the stop in a pump-probe arrangement. Light was collected using a JY H-10 optical monochromator equipped with a Hamamatsu 943–02 PMT and suitable delays. Briefly, fast and slow time windows are selected from the decay curve of the zero-order light emitted by the specimen for time-gated measurements. Thus, TRXEOL only collects light emitted within this time window subsequent to excitation ($t = 0$). We also recorded the Zn K-edge XANES using the yield of ungated and time-gated optical emission. More details have been described previously.[18,20]

Results and discussions

SEM images

We show some representative morphologies in Fig. 2, which presents SEM images of several ZnO nanostructures. ZnO nanowires (Figs. 2a and 2b) were grown on the same region of the Si wafer without and with Au catalyst, respectively, according to the following conditions: the temperature in the center of the furnace was 570 °C, and the argon flow rate was 75 sccm. The samples were collected at a distance of 12 cm from the furnace center. Temperature in the growth region was ~550 °C. Figure 2a shows the nanowires grown on the clean Si substrate with an average diameter of ~70 nm, and Fig. 2b depicts nanowires grown on the Si substrate with Au catalyst with an average diameter of ~50 nm.

Fig. 2. SEM images of ZnO samples: (a) ZnO nanowires (NW) grown on clean Si and (b) on Si substrate with Au catalyst; and (c) ZnO nanorods (NR) grown on clean Si and (d) on Si substrate with Au catalyst .



In both cases, some ribbon structures can be seen beneath the nanowires. At other locations along the slab, we also found nanoparticles and nanowires grown on clean Si and Si with Au catalyst, respectively.

ZnO nanorods shown in Figs. 2c and 2d were produced without and with Au catalyst under conditions different from to those shown in Figs. 2a and 2b: the furnace temperature was 550 °C, and Ar gas flow rate was 80 sccm. They were grown at a distance of 9 cm from the furnace center (the temperature was ~530 °C). Nanorods fabricated on clean Si substrate are ~300 nm in diameter with taper tips of ~90 nm (Fig. 2c). Nanorods grown with catalyst are ~350 nm in diameter with taper tips of ~70 nm (Fig. 2d). Nanostructures produced at other locations have similar morphology (nanorods with pointed tips) though different diameters. In general, the use of catalyst has led to a dense nanostructure growth (e.g., Fig. 2d), whereas nanorods produced without catalyst tend to expose part of the substrate (e.g., Fig. 2c).

The nanowires and nanorods obtained in this experiment are randomly oriented on the substrate without any preferential direction even when grown with catalyst. Apparently, using colloidal gold on a flat substrate could not align the growth because it is difficult to obtain the uniform coverage of the substrate with gold.

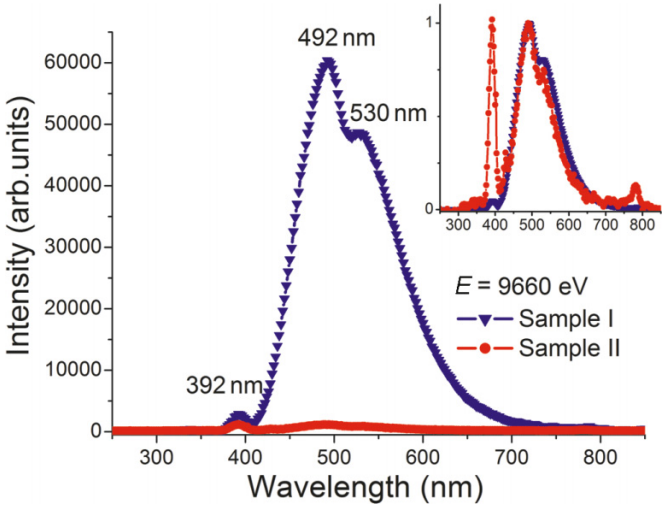
XEOL and time-resolved XEOL (TRXEOL)

For further characterization on the morphology-dependent optical properties, we chose one sample from each pair with distinctly different morphology: the 50 nm nanowires (NW) (marked as sample I) grown with Au catalyst (Fig. 2b), and 300 nm nanorods (NR) (marked as sample II) grown on clean Si (Fig. 2c).

In ZnO, light emission typically consists of a sharp peak with energy close to the band-gap energy (excitonic peak) and a broad-band emission due to defect levels formed within the band gap. More often than not, except in the case of a near-perfect nanocrystal,[12,26] green emission due to oxygen vacancies is observed on undoped ZnO nanostructures.[7,25] XEOL spectra from NW (sample I) and NR (sample II) are shown in Fig. 3. These XEOL spectra were excited at Zn K-edge (at 9660 eV).

From Fig. 3, we see that both samples show a weak near-band-gap emission at 392 nm (3.16 eV), and broad green bands at 492 nm (2.52 eV) and 530 nm (2.34 eV) (defect emission). NW exhibits a much stronger green emission than the NR (partly due to a denser packing of the materials). The inset in Fig. 3 presents a more revealing comparison (the same spectra normalized to the green emission). It can be seen that, for NW, the defect emission prevails, while for NR, the near-band-gap emission peak is relatively intense and comparable to the defect emission. The dominant broad-band green emission relative to near-band-gap emission for the NW can be explained by the presence of more oxygen-based surface defects in comparison with the relatively large NR. During vapour deposition in the quartz tube with argon as a carrier gas, the synthesis occurs in an oxygen-deficient

Fig. 3. XEOL from ZnO nanowire (sample I) and nanorod (sample II) excited with photon energy at the Zn K-edge of ZnO; the inset plot is normalized to the maximum intensity of the green emission.



atmosphere, which leads to the formation of oxygen vacancies in the grown ZnO nanostructures. On the nanoscale, defects tend to collect in the surface area so to decrease the strain energy. It is reasonable to assume that NRs have a lower concentration of oxygen-vacancy defects than NWs, which have higher surface-to-volume ratio in comparison with NRs. The larger branching ratio (intensity of the individual peak over the overall intensity) of the near-band-gap emission for the NR compared with that of the NW suggests that the NR sample is superior in crystallinity. It was shown previously that near-perfect nanocrystals exhibit luminescence predominantly in the near-band-gap region.[12,26]

Figure 4 shows the ungated XEOL and the fast-window (0–10 ns), intermediate-window (0–50 ns), and slow-window (50–150 ns) time-gated TRXEOL from ZnO NW (sample I). These time windows are set such that only optical photons coming through the preset time interval are counted.[27] The fast-window gated XEOL shows that the branching ratio of the near-band-gap emission is the largest compared with that of the ungated XEOL and the slower time windows. With the time window opened up to 50 ns, both peaks are still present but the branching ratio of the defect emission increases markedly. With the slow window (50–150 ns), the near-band-gap peak at 392 nm completely disappears. This observation confirms that the near-band-gap emission is fast and the defect emission, which results from energy transfer through secondary processes, is relatively slow.[27]

The ungated XEOL and TRXEOL from ZnO NR are displayed in Fig. 5. The fast-time-gated (0–10 ns) XEOL contains only the 392 nm peak, which suggests a significant drop in defects compared with the ZnO NW. The defect emission becomes apparent with the 0–50 ns window. A small peak at about 427 nm is observed, and it conceivably originates from the exposed surface oxide of the Si substrate.[28] In the slow-window-gated XEOL (50–150 ns), defect emission predominates. Although no specific measurements of the decay lifetime have been made for the two samples, these TRXEOL results are consistent with other ZnO nanostructure studies, i.e., the near-band-gap emission is fast and its intensity is strongly correlated to the crystallinity of the nanostructure.[26] It is also interesting to note that bulk single crystal yields a defect-rich luminescence.[27] It is most likely that near-perfect crystal can only be obtained in the nano regime, and these materials will exhibit an XEOL with dominant near-band-gap luminescence.

Fig. 4. Time-resolved XEOL from ZnO NW (sample I) excited at the Zn K-edge: ungated and with selected time window at 0–10 ns, 0–50 ns, and 50–150 ns (time window available for timing is 153 ns).

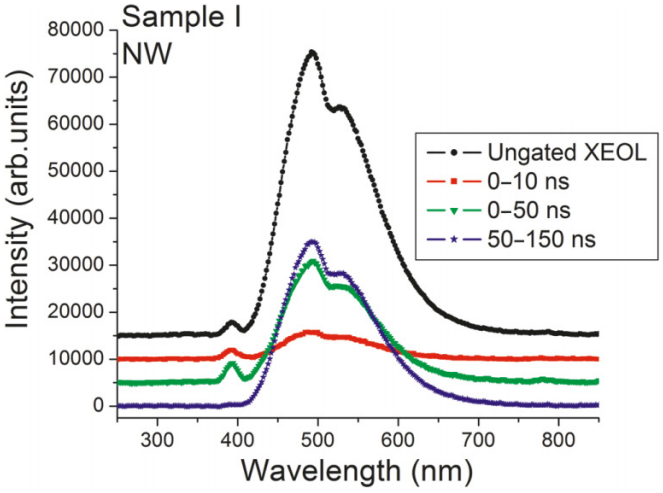


Fig. 5. Time-resolved XEOL from ZnO NR (sample II) excited at the Zn K-edge: ungated and with selected time window at 0–10 ns, 0–50 ns, and 50–150 ns. The spike with some periodicity is the electronic noise pick up from the hutch. They are not apparent in Fig. 3 where the signal is 20 times stronger.

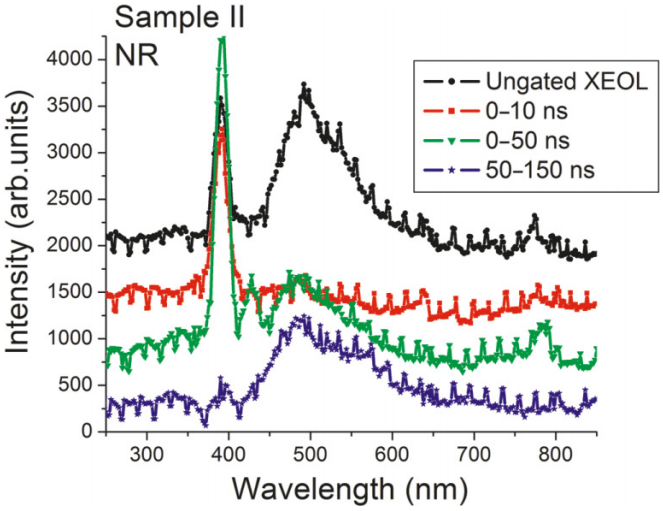
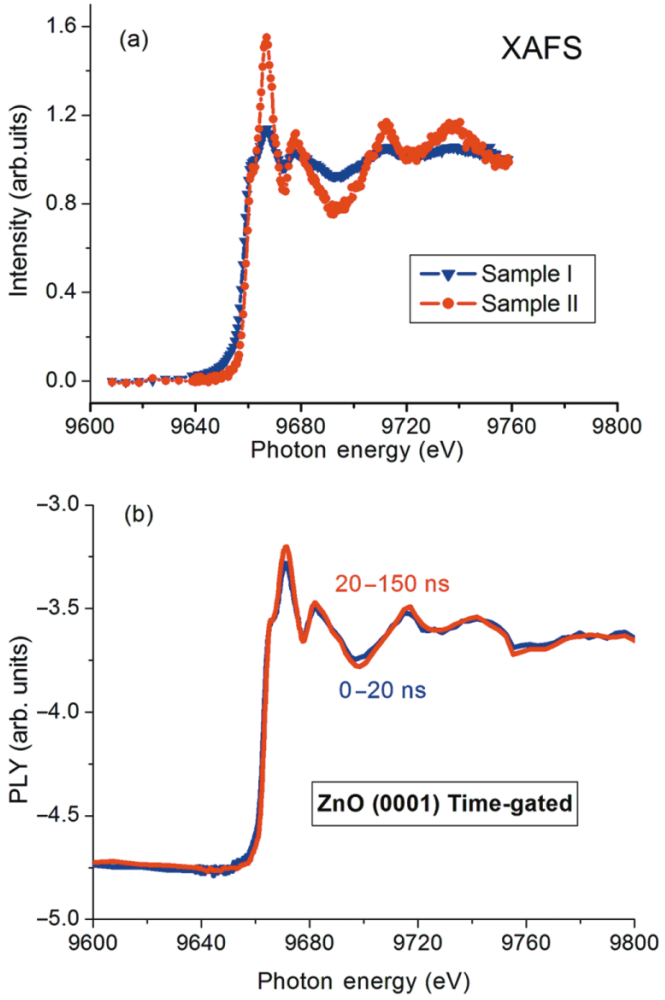


Zn K-edge XANES

Normalized Zn K-edge XANES, shown in Fig. 6a, were recorded with photoluminescence yield (PLY) using zero-order light (the entire optical emission was collected by tuning the optical monochromator to zero-order). PLY is proportional to the absorption coefficient if the X-ray energy absorbed by the system is converted to visible light with the same efficiency across the absorption edge and the sample is sufficiently thin. On the whole, absorption spectra from the two samples have the same features as that of ZnO single crystal. Interestingly, while the PLY XANES for the NR

Fig. 6. (a) Zn K-edge XANES for ZnO NW (sample I) and ZnO NR (sample II) recorded with PLY (zero order); (b) the PLY (time-gated) XANES for a 1 mm thick ZnO (0001) single crystal. Note that PLY for the single crystal has been inverted (thickness effect, see ref. 27).



(highly crystalline) is exactly the same as XANES recorded in total electron yield or transmission, the PLY XANES for the thin nanowires exhibits considerable broadening and reduced modulation amplitude. At first glance, the latter observation is analogous to XANES recorded in X-ray fluorescence yield observed in a concentrated sample and is attributed to saturation effect. However, if we examine this problem closely, it becomes clear that both samples are too thin to exhibit the thickness effect in the PLY XANES, since the one-absorption length for ZnO below and above the Zn K-edge is about 60 and 10 micron (1 micron = 1 μm), respectively, whereas our sample thickness is in the order of microns at best. Thus, the dramatic difference in the PLY XANES between NW (~50 nm) and NR (~300 nm) indicates that conversion from X-ray energy to optical photons is less efficient per photon absorbed for the NW than for NR.

Since PLY collects the zero-order light dominated by defect emission resulting largely from secondary processes (e.g., energy loss from fluorescence X-rays and Auger electrons), there will be little contribution to the optical channel if fluorescence X-rays and Auger electrons leave the system without losing its energy. This is more likely to happen for a 50 nm than a 300 nm 1D system, since the former has a larger fraction of its atoms on the surface and a more confined region for the secondary process to take place. Thus, the broadening observed in the PLY for the NW specimen is attributed to the confinement or truncation for the secondary process. In a nanostructure, the thermalization track that creates secondary electrons and holes is truncated by the limited dimension, reducing the quantum efficiency of the secondary process, which plays an important part in the optical de-excitation process via energy transfer to the defect sites. For comparison, time-gated XANES from a ZnO (0001) single crystal with two different time windows are also shown in Fig. 6b.[27] Note that the negative scale means that the PLY for the single crystal (1 mm thick) actually recorded was inverted due to thickness effect.[19]

Summary and conclusion

In summary, we have shown that ZnO nanostructures with varying morphologies can be prepared with a combinatorial approach using the thermal gradient of the substrate and other relevant preparation conditions and that optical emission from ZnO nanostructures is morphology- and crystallinity-dependent. Thin ZnO nanowires, prepared with catalyst, produce strong green-defect emission. ZnO nanorods, prepared without catalyst, exhibit a relatively intense near-band-gap emission. TRXEOL spectra from these samples show that the green-emission lifetime is much longer than the near-band-gap-emission lifetime. This observation confirms previously observed morphology-crystallinity correlation with luminescence in that the larger the branching ratio for the near-band-gap emission, the closer to the perfection of the nanocrystal.[12,20] We also observed that the zero-order PLY XANES at the Zn K-edge is a good representative of the normal XANES for ZnO nanomaterial with good crystallinity and a desired thickness (less than one absorption length). Thus, a combined XEOL and XANES study provides additional insight for the luminescent properties of nanomaterials in terms of crystallinity, defect, morphology, and size.

Structural analysis of phosphatidyl choline lipids and glycerol precursors

Annick Goursot, Tzonka Mineva, Sailaja Krishnamurty, and Dennis R. Salahub

Abstract: The structures and stabilities of the glycerol (G) and glycerol 3-phosphate (G3P) isomers have been calculated in the gas phase, using an ab initio density functional theory (DFT) method. The different conformational structures are shown to be at the origin of the various phospholipid conformers, except, obviously, for the alkyl chain torsions. The G3P conformations have been examined taking into account the experimental structures of the complexation sites in the glycerol kinase (GK) and glycerol 3-phosphate acyl transferase (G3PAT) enzymes, which correspond to the first and second steps of the "de novo" phospholipid biogenesis, respectively. The conformational analysis of the glycerophosphate skeleton is shown to determine most of the structural characteristics of the phosphatidyl choline lipids, which differ by the length of their diacyl chains, i.e., dilauroyl (DL), dimyristoyl (DM), and dipalmitoyl (DP) phosphatidylcholines (PC). Higher energy conformers with kinks in the acyl chains have been found, in preparation for molecular dynamics studies of the chain melting phase transformation.

Key words: glycerol, glycerol 3-phosphate, phosphatidylcholines, DLPC, DMPC, DPPC, conformational analysis, density functional theory, DFT-D.

Résumé : Les structures et stabilités relatives du glycérol (G) et du glycérol 3-phosphate (G3P) ont été calculées en phase gaseuze avec une méthode ab initio, basée sur la théorie de la fonctionnelle de la densité (TFD). A l'exception des formes gauches des chaînes alkyles, les différentes conformations de ces molécules sont effectivement à l'origine des conformères possibles des phospholipides. Les conformations de G3P ont été analysées en considérant les structures expérimentales des sites de complexation des enzymes glycérol kinase (GK) et glycérol 3-phosphate acyl transférase (G3PAT) qui correspondent, respectivement, aux deux premières étapes de la biosynthèse « de novo » des phospholipides. L'analyse conformationnelle du squelette glycérophosphate montre qu'il détermine la plupart des caractéristiques structurales des lipides phosphatidylcholines qui diffèrent par la longueur de leurs chaînes alkyles, c.-à-d. dilauroyl (DL), dimyristoyl (DM) et dipalmitoyl (DP) phosphatidylcholines (PC). Des conformères d'énergie plus élevée, présentant des formes gauches dans les chaînes alkyles, ont été étudiés en relation avec les simulations par dynamique moléculaire des transformations structurales des chaînes, au cours de la transition principale de phase.

Mots-clés : glycérol, glycérol 3-phosphate, phosphatidylcholine, DLPC, DMPC, DPPC, analyse conformationnelle, théorie de la fonctionnelle de la densité, TFD-D.

Introduction

Phospholipids and proteins are the main components of biological membranes, separating the cell and its various constituents from their environment. Cell membranes also have different functional roles, including protein synthesis, ion pumps and channels, receptor molecules, energy production and storage, and so forth. This versatility is due to the large range of phospholipid and protein structures, which can be involved in the membrane bilayers. The necessary fluid plasticity of these bilayers is obtained by the regulation of the lipid composition in the membrane. This regulation is accomplished by the "de novo" synthesis of the lipids in the various compartments of the cells of all living organisms.[1]

The synthesis protocol, in particular for the glycerophospholipids studied in this work, is a long and complex pathway, which starts with the enzymatic phosphorylation of the glycerol molecule and proceeds by three further successive enzymatic reactions.[2,3] The phospholipid molecule is thus built step by step through different enzyme-catalyzed reactions. The location in the enzymes of the different substrate-binding sites and their selectivity have not been identified unambiguously.[4–8] The structures of the phospholipid molecules synthesized and transferred to the membranes have thus not been determined, and there is no information concerning the existence of possible different conformers.

The presence of such conformers within phospholipid bilayers in their liquid-crystalline state has, however, been

suggested from NMR experiments, that have also provided some structural information on the overall structure of the lipids.[9,10] X-ray diffraction data demonstrate the possible presence of two structurally different molecules in the solid-crystalline state of a few phospholipids.[11,12] In a previous theoretical work on the dimyristoyl phosphatidylcholine (DMPC) molecule, we have shown that several conformational structures can exist (minima on the potential-energy surface), a number of them having comparable energies.[13] The dynamics of the individual DMPC has been studied for a series of temperatures, and the nature of lipid melting has been elucidated.[14] The existence in the membranes of different lipid conformers, even iso-energetic ones, depends, of course, on the barriers for their in situ interconversion. One may also infer that the synthesis pathway itself selects the lipid conformations within the specific enzymatic catalytic sites at one or at several steps of the synthesis.

In this work, we present the structures and stabilities of the glycerol (G) and glycerol 3-phosphate (G3P) isomers, calculated in the gas phase, using an ab initio density functional theory (DFT) method. We show that their different conformational structures are at the origin of the various phospholipid conformers, except, obviously, for the alkyl chain torsions. The G3P conformations are then examined taking into account the experimental structures found for the complexation sites in the glycerol kinase (GK) and glycerol 3-phosphate acyl transferase (G3PAT) enzymes, which correspond to the first and second steps of the "de novo" phospholipid biogenesis, respectively. Finally, the conformational analysis of the glycerophosphate skeleton is shown to determine most of the structural characteristics of the phosphatidyl choline lipids, which differ by the length of their diacyl chains, i.e., DMPC, dilauroyl (DL), and dipalmitoyl (DP) phosphatidylcholines (PC).

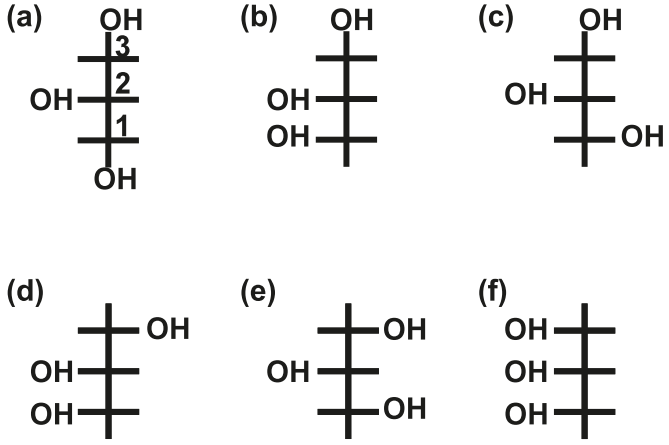
Computational methods

Models

The carbon numbering (C1, C2, and C3), illustrated in Figs. 1 and 2, refers to the standard biochemical nomenclature defined for the glycerol molecule: if the hydroxyl group on C2 is oriented to the left, C1 is the carbon below and C3 the carbon above. When the hydroxyl on C3 is phosphorylated, the glycerol 3-phosphate molecule formed is chiral. Its in vivo synthesis produces, following the stereospecific numbering (sn) system, the sn-glycerol 3-phosphate. The diacyl phosphatydilcholine lipids have been generally characterized as a head group or α chain that is connected through one CH_2 group (C3 carbon) to two glycerolipid β and γ chains, as shown in Fig. 1b. The nomenclature defining the characteristic lipid torsion angles is illustrated in Fig. 1.

In addition, for a better understanding of the torsion angles, we have chosen to partition the molecule into four building blocks, labelled as head (H), neck (N), body (B), and tails. The head is built from the $N(CH_3)_3$–CH_2–CH_2–PO_4 atoms and is described by the α1 to α6 torsion angles. The neck includes the glycerol C3–C2–C1 fragment, characterized by the θ1 and θ2 angles, and defines the orientation of the head with respect to the carbonyl groups and the tails. The body is formed by the next two O–CO–CH_2–CH_2

Fig. 2. The glycerol conformers with the standard nomenclature: C2, secondary carbon; C3, carbon where phosphorylation will occur.



groups of the β and γ chains and is characterized by the θ3, θ4, β1 to β4, and γ1 to γ4 torsion angles. The tails consist of the two β and γ alkane chains and are defined by the β_n and γ_n torsions with $n \geq 5$. Following the calculations for the DMPC molecule,[13] for the search of the ground-state conformers, only trans β and γ angles ($n \geq 5$) have been considered for the starting geometries.

The DLPC and DPPC lipid molecules differ from DMPC only in their hydrocarbon chain lengths, namely, 12, 14, and 16 carbons for DLPC, DMPC, and DPPC, respectively.

Methods

The calculations were performed in the framework of density functional theory (DFT), using a linear combination of Gaussian orbitals, as implemented in the deMon2k program.[15] All calculations were performed using the revised PBE exchange functional (revPBE)[16] and the LYP[17] correlation functional, augmented by a damped empirical correction for dispersion-like interactions,[18] referred to as DFT-D. This DFT-D approach is necessary to account for the stabilizing interaction between the alkyl chains.[19]

DFT-optimized double-zeta plus valence polarization (DZVP) basis sets[20] were employed for all atoms, associated with automatically generated functions up to l = 2 for fitting the density.[15] The exchange-correlation potential was numerically integrated on an adaptive grid.[21] The grid accuracy was set to 10^{-5} in all calculations. The Coulomb energy was calculated by the variational fitting procedure proposed by Dunlap, Connolly, and Sabin.[22,23] A quasi-Newton method in internal redundant coordinates with analytical energy gradients was used for the structure optimization.[24] The convergence was based on the Cartesian gradient and displacement vectors with a threshold of 10^{-4} and 10^{-3} au, respectively.

Results and discussion

Conformational analysis of the glycerol and glycerol 3-phosphate molecules

The in vivo phosphatidyl choline lipid synthesis involves first the phosphorylation of glycerol in the GK enzyme, at the expense of ATP (adenosine triphosphate). The product formed is exclusively the G3P molecule (phosphate group at C3), which is further esterified at the free primary alcohol with one fatty acid molecule by an acyl transferase enzyme using an acyl carrier protein (ACP) or an acyl coenzyme A (CoA) as substrate. A second esterification at the secondary carbon leads further to a phosphatidate or phosphatidic acid including two fatty acid chains. The phosphatidate phosphatase enzyme, which regulates the glycerolipid synthesis, catalyzes its hydrolysis into diacylglycerol (or diglyceride). The reaction of this molecule with the cytidine diphosphate (CDP)-choline (via a transferase enzyme) leads finally to a phosphatidyl choline lipid.[25]

Table 1. Relative energies (ΔE in kcal/mol), dipole moment (D), and characteristic torsion angles (θ in degrees) of the different glycerol isomers (without internal hydrogen bonds).

Name	ΔE	Dipole moment (D)	θ1/θ2[a]	θ3/θ4[a]
a	0.6	3.4	178/59	180/–60
b	0.0	3.9	68/–55	182/–54
c	2.5	2.0	184/59	60/180
d	1.7	1.5	74/–50	61/185
e	2.7	1.9	–68/170	58/182
f	0.0	3.3	76/–50	–50/76

[a]The θ angles are defined in Fig. 1.

The G3P molecule provides, in some sense, the precursor of the neck–body skeleton (Fig. 1) that is common to all glycerophospholipids. The catalytic reaction forming G3P occurs at a site of the GK enzyme, which forms a complex with Mg-ATP and the G molecule. Structural information on this site has been provided by several X-ray studies[4,26,27] and molecular dynamics simulations.[28,29]

Chemically, the G molecule is achiral, since the two –CH_2OH groups are equivalent. The total number of combinations of the three OH relative positions reduces to six, taking into account mirror-image structures. Figure 2 illustrates these isomers.

The GK active site for glycerol phosphorylation is a deep cleft where ATP and glycerol are stabilized. The X-ray structures of GK show that the glycerol molecule forms hydrogen bonds with several residues.[4,27] Therefore, it is reasonable to assume that, during the glycerophosphate synthesis, external hydrogen bonds rather than internal ones are favoured. The calculated relative stabilities of the G isomers without internal hydrogen bonds are displayed in Table 1, along with the dipole-moment values and characteristic torsion angles, as defined in Fig. 1. These torsion angles are also characteristic of the final phospholipid, once the phosphocholine head and acyl chains have been bound. It is interesting to note that three glycerol structures are competitive at the lowest energy, i.e., the a, b, and f isomers (Fig. 2), which correspond very clearly to the largest dipole moments. The calculated ΔE values are only indicative of the possible conformers in the GK channel, since they do not take into account the interaction of glycerol with the surrounding residues. It is interesting to note that two types of "necks" (180/60 and 60/–60) and "bodies" (180/–60 and –60/60) are represented among the a, b, and f isomers.

The crystallization of GK leads to tetrameric structures, which are inactive forms of the enzyme.[26] Among the mono-

mers, a "closed" and an "open" form were distinguished.[27] The glycerol conduction to the GK enzyme-binding site could be facilitated by its hydrogen bonding with the surrounding GK residues more than with water molecules, due to the deepness of the GK cleft that argues for poor accessibility to the solvent.[27] The processing of glycerol from the cleft opening to the catalytic site could be helped by fluctuations of its large dipole moment interacting with the electric field along the cleft. MD simulations have shown that the protein attracts a substrate with a strong dipole moment, requiring its change of orientation at some positions in the cleft.[28] Binding the glycerol at the catalytic site is performed through tight hydrogen bonds to the closest residues (Asp245, Arg83, and Tyr135). All of these features would be in favour of promoting the a, b, and f isomers in the GK site.

X-ray structures of GK (pdb access 1glf[26] and 1glj[27]) also contain glycerol molecules. The structures of the glycerol molecule inside the tetramers are different in the "closed" and the "open" forms, with neck and body torsion angles very comparable to the conformer a for pdb.1glf ("closed" GK structure) and to a deformed f conformer (torsions of about 100°–120° instead of 60°–70°) for pdb.1glj ("open" GK structure).

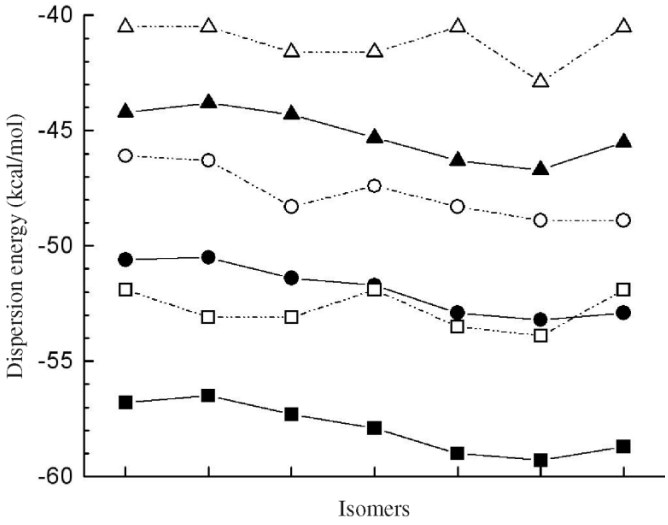
The phosphorylation of one $-CH_2OH$ group of glycerol leads to a chiral C2 carbon in the sn-glycerol-3 phosphate. Starting from each of the six glycerol isomers allows one to generate the possible glycerol phosphate isomers. There are, in fact, nine topologically different structures, due to the lowering of the molecular symmetry. The presence of the phosphate group generates also additional rotational isomers, taking into account the rotation of the $-PO_3H_2$ group around the C3–O bond. Variations of the C2–C3–O–P torsion angle, α1, when sterically possible, leads to more rotational isomers. It must be noted that most of these rotations generate a steric strain due to the P=O or P–OH groups being confined too close to the atoms of the free primary CH_2OH group. In the same spirit as for the glycerol molecule, intramolecular hydrogen bonds have been avoided. After geometry optimization, 12 isomers were obtained with relative total energies within a range of 0 to about 4.0 kcal/mol. The five most stable structures (between 0 and 1.5 kcal/mol) are reported in Table 2. They are labelled by priming the letter of the original glycerol conformers. The isomers a′ and f′ are the counterparts of the a and f glycerol isomers mentioned above. They could thus both exist as products of the GK phosphorylation. These two isomers have different θ1/θ2 and θ3/θ4 values. It is thus not clear why the other isomers of equivalent energies, differing by either θ1/θ2 or θ3/θ4, could be much less stabilized through their interaction with the GK residues. It seems possible that the glycerol 3-phosphate, already before binding the acyl chains and the phosphatidyl choline head, has some structures with comparable energies.

The site and the mechanism of acylation of the G3P primary alcohol have not yet been completely elucidated. However, the X-ray structure of the squash G3PAT enzyme has been reported, and a presumptive G3P binding site is identified.[6,7] A fatty acid binding site is also proposed, in which the reactive thio ester group of the acyl-coA is located in the vicinity of the C1 alcohol of G3P. Thus, at present, there are no experimental data, which specifically contradict the possibility of finding several different conformers for the precursors of phospholipids.

Table 2. Relative energies and characteristic torsion angles of the glycero-3-phosphate most stable isomers. The primed labels correspond to the non-primed labels used for glycerol (Fig. 1).

Isomers	ΔE (kcal/mol)	θ1/θ2	θ3/θ4	α1
a′	0.7	180/60	180/–60	180
b′	0.8	70/-60	180/–60	180
e_1'	0.8	60/185	70/–60	90
e_2'	0.8	50/180	–70/180	70
f′	0.0	60/–70	–70/60	–100

Fig. 3. Damped empirical dispersion energies for the DLPC (triangles), DMPC (circles), and DPPC (squares) ground-state conformers. The conformers are ordered from left to the right as follows: $H1N1B_{A1}$, $H1N3B_{A1}$, $H2N3B_{A1}$, $H1N1B_{A2}$, $H1N2B_{A2}$, $H2N2B_{A2}$, and $H2N2B_{B1}$. The filled symbols are for T1 isomers and the open symbols are for T2 isomers.



Structural analysis of the DLPC, DMPC, and DPPC molecules

Ground-state conformers with all trans chains

As in the case of the DMPC molecule, the DFT-D energy optimization for the DLPC and DPPC isomers led to 14 conformers in the range between 0 and 2 kcal/mol. The 14 lowest isoenergetic conformers are subsequently grouped into two sets of structures, differing by the mutual orientations of the carbon skeletons of the β and γ alkyl chains: in the first group of seven lowest energy structures, these two carbon skeletons are in two parallel planes (T1), and in the second half of the minimum-energy conformers, the two carbon skeletons are in two perpendicular planes (T2) (Fig. 1*c*). For a given T1 or T2 orientation of the hydrocarbon chains, the ground-state conformers arise from the following combinations between two heads (H1, H2), three necks (N1, N2, and N3) and three bodies (B_{A1}, B_{A2}, and B_{B1}): $H1N1B_{A1}$, $H1N3B_{A1}$, $H2N3B_{A1}$, $H1N1B_{A2}$, $H1N2B_{A2}$, $H2N2B_{A2}$, and $H1N1B_{B1}$.

These conformational structures are described in detail for the DMPC molecules in ref. 13. Their averaged α, β, and γ

Table 3. Relative energies in kcal/mol with respect to all-trans conformers of the DPPC, DMPC, and DLPC gauche isomers ($H1N1B_{A2}T2$) at various positions of the chain.

angles and their mutual combinations leading to those ground-state isomers are not affected by the chain length, e.g., the same arrangement of α, β, and γ chains is obtained for the DLPC, DMPC, and DPPC molecules. As a consequence, the characteristic geometries of the head, body, and neck conformations display very similar structural parameters. The displacement of the polar head with respect to the β or γ alkyl chains in the various isomers is characterized by the distances of the closest C=O oxygen to the choline N atom (N···C=O) and to the non-ester phosphate O atom (P=O···O=C). These distances do not vary with the chain length.

The 14 isomers have the same relative energy stability for the DLPC, DMPC, and DPPC molecules. The computed damped empirical dispersion energies, E_{disp}, plotted in Fig. 3, indicates an increase of approximately 3.1 kcal/mol per CH_2 unit for the lipids with 12, 14, and 16 carbons in the alkyl chains in their T1 and T2 arrangements. This value is somewhat smaller than the E_{disp} increase of 3.8 kcal/mol per CH_2 in the case of *n*-alkane dimers (from butane to dodecane) in their most stable arrangement.[19] The averaged DFT-D empirical dispersion in the T1 isomers is higher than the average value for the T2 isomers. This difference increases slightly with the chain length, e.g., E_{disp} of T1 isomers is higher by 3.8, 4.0, and 5.2 kcal/mol for the DLPC, DMPC, and DPPC molecules, respectively. The E_{disp} difference for both tail arrangements correlates with the difference between the β and γ hydrocarbon chain separation in T1 and T2. The relative dispersion energy in the case of isomers with parallel tails (T1) follows a very similar trend for the three lipid molecules as seen from Fig. 3. This regular behaviour is not so well-respected for the T2 isomers for a particular diacyl PC lipid. It indicates, thus, some influence of the chain length when T2 chains are coupled with a specific head and body conformation. However, this "discrepancy" is less than 3%–4% of the dispersion energy values.

Higher energy structures with gauche conformers in the alkyl chains

Gauche chain conformers are predominantly formed in phospholipid aggregates in their liquid phase. The relative energies of the possible gauche conformers with one kink per alkyl chain, optimized at $T = 0$ K, with respect to the all trans structures are presented in Table 3 for the DLPC, DMPC, and DPPC $H1N1B_{A2}T2$ isomers. For comparison, relative energies between gauche and trans isomers of tetradecane are reported in the same table. The torsions in Table 3 follow the nomenclature indicated in Fig. 1 for the β and γ chains. In contrast to tetradecane, the gauche conformers in DLPC, DMPC, and DPPC are not degenerate with, however, insignificant relative energy variations for three of the four possible gauche conformers in the DLPC molecule. Interestingly, comparable stability is obtained for the structures with a kink at the free end of the C12, C14, and C16 chains. The DPPC gauche conformers follow the behaviour of DMPC: the least stable structures are those with kinks in the middle of the hydrocarbon chains (at β_n, γ_n = 8, 10, 12 for DPPC and β_n, γ_n = 8, 10 for DMPC); the most stable conformation is the one with a torsion of 300° at β_n, γ_n = 6. The latter is obtained also for the DLPC molecules.

Comparison of the G3P and phospholipid conformers

The precursor G3P values of θ1/θ2 and θ3/θ4, characterizing the "neck" and "body", respectively, correspond to those found for the complete phospholipid structures. Indeed, if one considers all the isomers of Table 2, the three phospholipid necks are found with the combinations 180/60 (N1), 60/–60 (N2), and 60/180 (N3). Since G3P has no acyl chains, only three types of body exist: two of them correspond to those found for the phospholipids: B_A and B_B, with the θ3/θ4 values of 180/60 and 60/–60, respectively. The value of –70/180, (e'_2 in Table 2), related to two opposite OH groups at the C1 and C2 carbons, i.e., acyl chains in opposite directions, would not lead to the formation of phospholipid bilayers. Actually, this configuration (opposite acyl chains) was reported in NMR studies for PC lipids at low concentration in water, i.e., isolated molecules or very small aggregates.[9] In the same work, the B_A and B_B conformers were proposed as the only two present in the PC lipid bilayers, related with specific ^{1}H NMR signals (rotamers A and B, respectively, in ref. 9).

We thus see that G3P already provides the basis of the conformations found for the final phospholipids, moreover corresponding to similar energies. The bonding of the β and then γ acyl chains and finally that of the head α chain will allow the possibility of two relative orientations for the carbonyl groups (splitting B_A into B_{A1} and B_{A2}) and for the alkyl chains (T1 and T2).

If the G3P isoenergetic structures are not specifically selected in the G3PAT enzyme at the binding site with the fatty acyl chain, more than one or a few different neck and body conformers could exist in the final phospholipids. Indeed, at the two next steps, i.e., dephosphorylation and addition of the phosphocholine, one could assume that the glycerol backbone and the acyl chains will keep their conformations. The existence of more than one phospholipid conformer in the "de novo" synthesis is thus not unreasonable.

Conclusion

The different conformational structures of the glycerol (G) and glycerol 3-phosphate (G3P) molecules have been shown to be at the origin of the various phospholipid conformers, except, obviously, for the alkyl chain torsions. Conformations lacking internal hydrogen bonds are imposed by the enzymes involved in the synthesis, and these persist through the various subsequent steps of the synthesis, adding the tails and the head. The conformational analysis of the glycerophosphate skeleton determines most of the structural characteristics of the phosphatidyl choline lipids, which differ by the length of their diacyl chains, i.e., DLPC, DMPC, and DPPC.

Higher energy conformers with kinks in the acyl chains have been found, in preparation for molecular dynamics studies of the chain melting phase transformation, which will be published elsewhere.[30] The comparison of their relative energies with respect to the acyl chain length shows that DLPC, the shortest lipid to form bilayers, may have a different thermodynamical behaviour at the melting transition from the other two lipids, displaying more similar gauche energies along the alkyl chains.

Exact exchange-correlation potentials in spin-density functional theory and their discontinuities at unit electron number

John P. Perdew and Espen Sagvolden

Abstract: The exact exchange-correlation potential of Kohn–Sham density functional theory is known to jump discontinuously by a spatial constant as the average electron number, N, crosses an integer in an open system of fluctuating electron number, with important physical consequences for charge transfers and band gaps. We have recently constructed an essentially exact exchange-correlation potential v_{xc} for N electrons ($0 \le N \le 2$) in the presence of a $-1/r$ external potential, i.e., for a ground ensemble of H^+ ion, H atom, and H^- ion densities. That construction illustrates the discontinuity at $N = 1$, where it equals $I_H - A_H$, the positive difference between the ionization energy and the electron affinity of the hydrogen atom. Here we construct the corresponding essentially exact spin-up and spin-down exchange-correlation potentials $v_{xc,\uparrow}$ and $v_{xc,\downarrow}$ of the Kohn–Sham spin-density functional theory, more commonly used for electronic structure calculations, for the ground ensemble with most-negative z-component of spin (or equivalently in the presence of a uniform magnetic field of infinitesimal strength). The potentials v_{xc}, $v_{xc,\uparrow}$, and $v_{xc,\downarrow}$, which vanish as $r \to \infty$ (except when N approaches an integer from above), are identical for $0 \le N \le 1$ and for $N = 2$ but not for $1 < N < 2$. We find that the majority or spin-down potential has a spatially constant discontinuity at $N = 1$ equal to $I_H - A_H$. The minority or spin-up potential has a discontinuity which is this constant in one order of limits, but is a spatially varying function in a different order of limits. This order-of-limits problem is a consequence of a special circumstance: the vanishing of the spin-up density at $N = 1$.

Key words: density functional theory, spin-density functional theory, exchange-correlation potential, derivative discontinuity, integer discontinuity.

Résumé : Il est bien connu que le potentiel exact d'échange-corrélation de la théorie de la fonctionnelle de densité de Kohn–Sham augmente considérablement par le biais d'une constante spatiale quand le nombre moyen d'électron, N, change de nombre entier dans un système ouvert comportant un nombre variable d'électron et que cette variation comporte des conséquences physiques importantes pour les transferts de charge et les énergies entre les bandes interdites. On a récemment développé un potentiel essentiellement exact d'échange-corrélation, v_{xc}, pour N électrons ($0 \le N \le 2$), en présence d'un potentiel externe a $-1/r$, à savoir pour un ensemble fondamental des densités ioniques de l'ion H^+, de l'atome H et de l'anion H^-. Cette construction illustre la discontinuité au niveau $N = 1$, où elle est égale à $I_H - A_H$, la différence positive entre l'énergie d'ionisation et l'affinité électronique de l'atome d'hydrogène. Dans ce travail, on construit les potentiels essentiellement exacts correspondants d'échange-corrélation des spins positifs et négatifs, $v_{xc,\uparrow}$ et $v_{xc,\downarrow}$, de la théorie de la fonctionnelle de densité de spin de Kohn–Sham qui est généralement utilisée pour les calculs de structure électronique, pour l'ensemble fondamental avec des composantes de spin z plus négatives (ou, d'une façon équivalente, en présence d'un champ magnétique uniforme de force infinitésimale). Les potentiels v_{xc}, $v_{xc,\uparrow}$, et $v_{xc,\downarrow}$, qui disparaissent quand $r \to \infty$ (excepté quand la valeur de N s'approche d'un nombre entier en venant du haut), sont identiques pour $0 \le N \le 1$ et pour $N = 2$, mais pas pour $1 < N < 2$. On a trouvé que la majorité ou le potentiel à spin descendant comporte une discontinuité de constante spatiale pour $N = 1$ qui est égale à $I_H - A_H$. La minorité ou le potentiel à spin croissant comporte une discontinuité qui est constante dans un ordre de limite, mais qui est une fonction variant dans l'espace dans un ordre différent de limites. Le problème de l'ordre des limites est une conséquence d'une circonstance spéciale, à savoir la disparition de la densité du spin croissant à $N = 1$.

Mots-clés : théorie de la fonctionnelle de densité, théorie de la fonctionnelle de densité de spin, potentiel d'échange-corrélation, discontinuité de nombre entier.

Kohn–Sham theory[1–4] is used throughout quantum chemistry and condensed-matter physics to find the nonrelativistic ground-state energy E and electron spin densities $n_\uparrow(\mathbf{r})$ and $n_\downarrow(\mathbf{r})$ of a collection of mutually interacting electrons in a scalar external potential $v(\mathbf{r})$. The theory is exact in principle, although in practice the exchange-correlation energy $E_{xc}[n_\uparrow,n_\downarrow]$ as a functional of the spin densities must be approximated. Computational efficiency is achieved because the equations to be solved are those for an auxiliary system of noninteracting electrons moving in an effective potential, which is the sum of the external potential, a Hartree electrostatic potential

$$[1] \qquad u([n];\mathbf{r}) = \int d^3r' \quad n(\mathbf{r}')/|\mathbf{r}' - \mathbf{r}|$$

(where $n = n_\uparrow + n_\downarrow$ is the total density), and a spin-dependent exchange-correlation potential which is the functional derivative

$$[2] \qquad v_{xc,\sigma}([n_\uparrow, n_\downarrow];\mathbf{r}) = \delta E_{xc}/\delta n_\sigma(\mathbf{r})$$

The functional derivative is defined so that

$$[3] \qquad \delta E_{xc} = \sum\nolimits_\sigma \int d^3r [\delta E_{xc}/\delta n_\sigma(\mathbf{r})]\delta n_\sigma(\mathbf{r})$$

If the number N_σ of electrons of spin σ is not allowed to vary ($\delta N_\sigma = \int d^3r\, \delta n_\sigma(\mathbf{r}) = 0$), then the potential $v_{xc,\sigma}$ contains an arbitrary additive constant.

A conceptually simpler version[1] of exact Kohn–Sham theory predicts the ground-state energy E and total electron density $n(\mathbf{r})$ from a functional $E_{xc}[n]$ of the total density and its functional derivative $v_{xc}([n];\mathbf{r})$. This theory was extended to open systems of fluctuating electron number by Perdew, Parr, Levy, and Balduz.[5] Such an open system can be described by an ensemble of wave functions with different electron numbers. Alternatively, the closed system comprising the open system and its electron reservoir can be described by a single wave function.[6] Since the average electron number N in the open system can then vary continuously, there is no arbitrary constant in the corresponding v_{xc}. The energy E was found to vary linearly between adjacent integers, with derivative discontinuities at the integers. The potential v_{xc} was found to jump discontinuously by a constant at integer N, and otherwise to tend to zero as $r \to \infty$ [6–8].

The discontinuity of the potential explains (*i*) why the band structure of the exact Kohn–Sham potential underestimates the fundamental band gap of a solid,[9–12] and (*ii*) why neutral molecules really dissociate to neutral atoms of integer electron number,[5,6] although semilocal approximations to E_{xc} often predict dissociation to atoms of fractional charge,[13] and more generally why semilocal approximations overly favor charge transfer.[14–16] In a closed system composed of isolated open subsystems, the exact Kohn–Sham potential can develop a different constant region[6] around each open system to prevent spurious charge transfer. Only fully nonlocal approximations, such as those of refs. 16–18, can properly describe such effects. Semilocal approximations, which display no discontinuity of v_{xc}, can work well only when all occupation numbers in a compact isolated open subsystem are integers.[3,19]

Recently, the discontinuity of v_{xc} at integer N has been questioned by Zahariev and Wang.[20] In response,[21] we have rigorously established the existence of a nonzero, spatially constant discontinuity at $N = 1$, and illustrated it by construction of an essentially exact v_{xc} for N electrons ($0 \le N \le 2$) in the presence of a $-1/r$ external potential. A similar construction, using accurate numerical densities instead of analytic ones, was given earlier by Savin, Colonna, and Pollet.[22] We have also made the spatially constant discontinuity more plausible at integer N greater than 1, and have pointed out[23] the error in the argument of ref. 20. However, our work has been done within total-density functional theory,[1] and not within the spin-density functional theory[2] that is almost always employed in practical applications (because its approximations are more accurate for open-shell spin-polarized systems, even in the absence of an external magnetic field). Thus, here we will extend our results to spin-density functional theory. While a general discussion of the discontinuity in this theory has been presented by Chan,[24] we will present a particularly clear and simple argument for the special case $0 \le N \le 2$, which establishes the nonzero discontinuity beyond all doubt. Ayers and Yang[25] have recently discussed some other formal issues of spin-density functional theory.

An ensemble is a collection of wave functions and their probabilities, with density and energy given by probability-weighted averages. As shown in Ref. 5 (and in more detail in ref. 26), the ground ensembles for N between adjacent integers $J - 1$ and J are composed of the ground states for the $J - 1$ and J electron systems, provided that (as expected) the ionization energy is greater than the electron affinity for all bound states of integer electron number. The ground states for integer electron number can be degenerate or nondegenerate.

Although the ground state of H^- is a spin singlet, the ground state of H is a spin doublet. We employ a ground ensemble in which the spin densities are probability-weighted averages of the spin densities of the contributing ground-state wave functions. By the arguments of ref. 5, the ground ensemble for $0 \le N \le 1$ must be composed of the H^+ ion (no electrons), the spin-up H atom, and the spin-down H atom, i.e.,

$$[4] \qquad \begin{array}{ll} n_\uparrow = \varepsilon n_H & (N_\uparrow = \varepsilon) \\ n_\downarrow = (N-\varepsilon) n_H & (N_\downarrow = N - \varepsilon) \\ n = N n_H & (N = N) \end{array}$$

for $0 \le \varepsilon \le N$). Similarly, the ground ensemble for $1 < N \le 2$ must be composed of the spin-up H atom, the spin-down H atom, and the H^- ion, i.e.,

$$[5] \qquad \begin{array}{ll} n_\uparrow = (N-1) n_{H^-}/2 + \varepsilon n_H & (N_\uparrow = N - 1 + \varepsilon) \\ n_\downarrow = (N-1) n_{H^-}/2 + (2 - N - \varepsilon) n_H & (N_\downarrow = 1 - \varepsilon) \\ n = (N-1) n_{H^-} + (2-N) n_H & (N = N) \end{array}$$

for $0 \le \varepsilon \le 2 - N$. The spin-disorder parameter ε measures the deviation of each N-electron ground ensemble from the one of most negative z-component of spin. Note that, for a given $N = N_\uparrow + N_\downarrow$ and in the absence of an external magnetic field, there is a continuous ground-level degeneracy labeled by ε or by $N_\downarrow - N_\uparrow$. The parameters we can control are N and ε, or equivalently $N_\uparrow$ and $N_\downarrow$ (the latter both in the

range from 0 to 1, inclusive). Within total-density functional theory, we choose ε so that $n_\uparrow = n_\downarrow = n/2$, i.e., $\varepsilon = N/2$ for $0 \le N \le 1$ and $\varepsilon = 1 - N/2$ for $1 < N \le 2$. Within spin-density functional theory, the ensemble with as much down spin as possible is attained in the limit $\varepsilon \to 0^+$ (and all potentials are evaluated before this limit is taken). This limit yields the nondegenerate ground ensemble in the presence of a uniform magnetic field of infinitesimal strength along the *z*-axis. For the exact energy in the $(N_\uparrow,N_\downarrow)$ plane, see Fig. 1 of ref. 27.

Note that the spin densities (but not their derivatives) are continuous functions of *N* in the interval $0 \le N \le 2$. At $N = 0$, $n_\uparrow = n_\downarrow = 0$. At $N = 2$, $n_\uparrow = n_\downarrow = (n_{H^-})/2$. At $N = 1$ in density functional theory $n_\uparrow = n_\downarrow = n_H/2$, but in spin density functional theory $n_\uparrow = 0$ and $n_\downarrow = n_H$.

For $0 \le N \le 2$, there are at most two occupied or partly occupied orbitals, with occupation numbers $N_\uparrow$ and $N_\downarrow$ and shapes proportional to $n_\uparrow^{1/2}$ and $n_\downarrow^{1/2}$. The Kohn–Sham eq.[1,2] is

$$[6] \qquad [(-1/2)\nabla^2 - 1/r + u([n];r) + v_{xc,\sigma}]n_\sigma^{1/2} = e_\sigma n_\sigma^{1/2}$$

Let $E(N_\uparrow,N_\downarrow)$ be the ground-ensemble energy for average spin electron numbers $N_\uparrow$ and $N_\downarrow$. By Janak's theorem,[28] $e_\sigma = \partial E/\partial N_\sigma$, where the derivative is taken at constant $N_{-\sigma}$. Since the external magnetic field vanishes, the energy *E* depends only upon $N = N_\uparrow + N_\downarrow$, and not at all upon $N_\downarrow - N_\uparrow$, making $\partial E/\partial N_\sigma = dE/dN = \mu$, where μ is also the chemical potential of the reservoir:

$$[7] \qquad \mu = \begin{matrix} -I_H & (0 \le N \le 1) \\ -A_H & (1 < N \le 2) \end{matrix}$$

where $I_H = 0 - E_H = 0.50000$ hartree is the ionization energy of the H atom and $A_H = E_H - E_{H^-} = 0.02775$ hartree is the electron affinity of the H atom. Janak's theorem applies here for all occupation numbers in the closed interval from 0 to 1, including the end points. At the end points, the derivative is one-sided. Thus

$$[8] \qquad v_{xc,\sigma} = \mu + 1/r - u([n];r) + (1/2)\nabla^2 n_\sigma^{1/2}/n_\sigma^{1/2}$$

Equation [8] (along with eqs. [1], [4], [5], and [7]) determines the exact exchange-correlation potentials we seek. Note that the choice $\varepsilon = 0$ in eq. [4] would leave $v_{xc,\uparrow}$ of eq. [8] undefined for $N \le 1$. The hydrogen atom density $n_H(r)$ is a simple and familiar analytic function. In ref. 21, we have constructed an accurate analytic model for the H^- ion density $n_{H^-}(r)$.

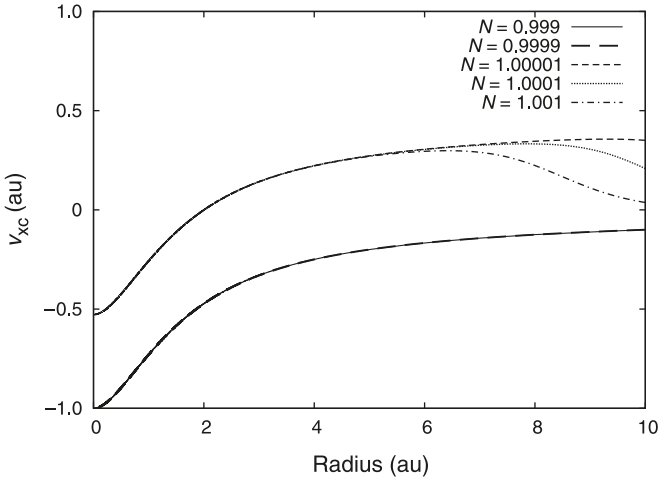
Although we have invoked Kohn–Sham orbitals and Janak's theorem to derive eq. [8], this equation can also be found from the Euler equations for the spin densities, since the non-interacting kinetic energy functional for $N_\uparrow \le 1$ and $N_\downarrow \le 1$ is the sum of von Weizsaecker functionals for $n_\uparrow$ and $n_\downarrow$[21].

The result for $0 \le N \le 1$ is especially simple, because it involves only the density of the H atom. We easily find

$$[9] \qquad v_{xc,\sigma} = -Nu([n_H];r)$$

independent of σ and ε. In this range, exchange and correlation simply provide a self-interaction correction to the Hartree potential.

Fig. 1. The exact exchange-correlation potential v_{xc} of total-density functional theory, for average electron number *N* around 1 in the $-1/r$ external potential. To the eye, the lower curves $N = 0.999$ and $N = 0.9999$ coincide. Note the jump by a positive constant as *N* increases through 1, and the asymptotic ($r \to \infty$) vanishing of all plotted curves.



Figures 1, 2, and 3 illustrate our results for v_{xc}, $v_{xc,\downarrow}$, and $v_{xc,\uparrow}$, respectively, for values of *N* just below and just above 1. Figure 1 repeats Fig. 1 of ref. 21, for ease of comparison with total-density functional theory, while Figs. 2 and 3 for spin-density functional theory are new to this work.

The first thing to notice is that all the plotted potentials tend to 0 as $r \to \infty$. This is a simple consequence of eq. [8]: $1/r$ and $u([n];r)$ vanish in this limit, while the known asymptotic exponential decays of n_H and n_{H^-} [7] make the last term of eq. [8] tend to $-\mu$.

The second thing to notice is that the plotted potentials display a discontinuity as *N* crosses the integer 1. The discontinuity is the spatial constant $I_H - A_H$, except in Fig. 3, where the discontinuity of $v_{xc,\uparrow}$ at $N = 1$ is a function of *r*. This is also a simple consequence of eq. [8]: $1/r$, $u([n];r)$ and n_σ are all continuous in *N*, while μ jumps up by $I_H - A_H$ when *N* crosses 1. The last term of eq. [8] is also continuous, so long as n_σ is nonzero at $N = 1$. This is the case for all $\varepsilon > 0$ in eqs. [4] and [5], so the $\varepsilon \to 0^+$ limit of the discontinuity is $I_H - A_H$. But for $v_{xc,\uparrow}$ this result is only for the order of limits in which $N \to 1^+$ before $\varepsilon \to 0^+$. In the opposite order of limits, as illustrated in Fig. 3, the discontinuity of $v_{xc,\uparrow}$ is spatially varying. The latter ($\varepsilon \to 0^+$ first) is the one relevant to the nondegenerate ground ensemble in the presence of an infinitesimal magnetic field. The order-of-limits problem is manifest in the expression $\{\nabla^2[(N-1)n_{H^-} + \varepsilon n_H]^{1/2}\}/[(N-1)n_{H^-} + \varepsilon n_H]^{1/2}$.

For $0 \le N \le 1$, there is no difference between v_{xc}, $v_{xc,\uparrow}$, and $v_{xc,\downarrow}$. For *N* just above 1, there is a strong similarity between the majority-spin $v_{xc,\downarrow}$ (for most-negative z-component of spin) and v_{xc}. There is, however, a discernable difference in the approach to zero as $r \to \infty$, which is slower in $v_{xc,\downarrow}$ because $n_\downarrow$ has more of n_H when the *z* component of spin is most negative.

In summary, we have constructed exact exchange-correlation potentials for *N* electrons ($0 \le N \le 2$) in the presence of a $-1/r$ external potential, within both density

Fig. 2. The exact down- or majority-spin exchange-correlation potential $v_{xc,\downarrow}$ of spin-density functional theory, for average electron number N around 1 in the $-1/r$ external potential, and for the ground ensemble with the most-negative possible z component of spin. To the eye, the lower curves $N = 0.999$ and $N = 0.9999$ coincide. Note the jump by a positive constant as N increases through 1, and the asymptotic vanishing of all plotted curves.

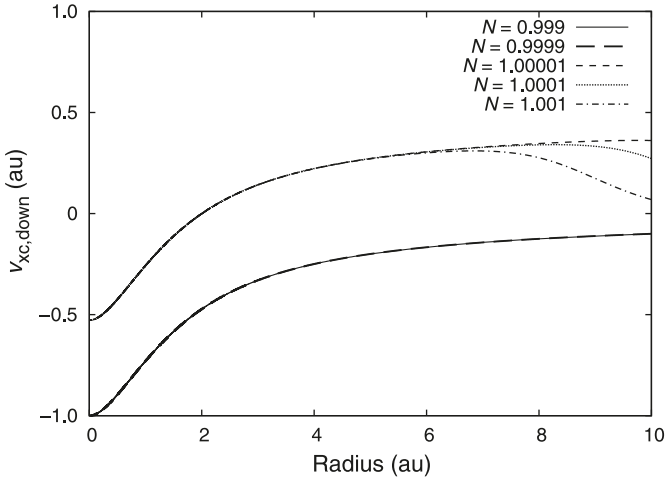


Fig. 3. The exact up- or minority-spin exchange-correlation potential $v_{xc,\uparrow}$ of spin-density functional theory, for average electron number N around 1 in the $-1/r$ external potential, and for the ground ensemble with the most-negative possible z component of spin. To the eye, the lower curves $N = 0.999$ and $N = 0.9999$ coincide, and the upper curves $N = 1.00001$, $N = 1.0001$, and $N = 1.001$ also coincide. Note the jump by a positive spatially-varying function as N increases through 1, and the asymptotic vanishing of all plotted curves.

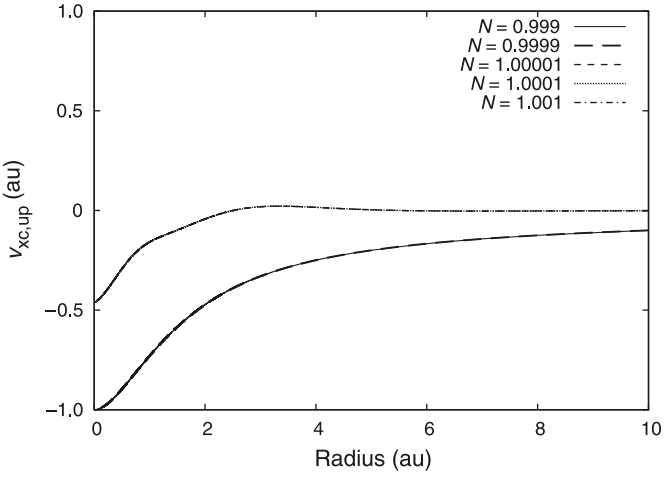

functional and spin-density functional theories. All these potentials vanish as $r \to \infty$ for all noninteger N, and all display a discontinuity at $N = 1$. The discontinuity is the spatial constant $I_H - A_H$ for the density functional potentials, and for the majority-spin but not in an important order of limits for the minority-spin potential in the spin-density functional for the case of most-negative z-component of spin. The spatial dependence of the discontinuity in the minority-spin or $\uparrow$ potential, displayed in Fig. 3, is a consequence of the special situation $n_\uparrow = 0$ at $N = 1$.

The results we have found here have a simple and direct generalization to N electrons ($0 \le N \le 2$) in the presence of *any* spin-independent external potential that vanishes as $r \to \infty$, since the degeneracy of spin $\uparrow$ and spin $\downarrow$ one-electron ground states persists, permitting the use of $N_\uparrow - N_\downarrow$ as an independent variable describing a continuum of degenerate ground-level ensembles for fixed $N_\uparrow - N_\downarrow$. For any one-electron system in the absence of a magnetic field, we earlier proved[23] that $I - A$ is positive. A weaker generalization to many-electron systems (up to the maximum number that can be bound) has also been established.[29] Moreover, the high-density limit of $I - A$ under uniform density scaling for any one-electron system has been shown to be twice the Hartree electrostatic energy[30,31] of the scaled density.

Physically, we can introduce a uniform magnetic field B along the z axis, and a temperature T. Our approach, which sets $B = T = 0$ at the start, provides unambiguous answers for the spin-dependent exchange-correlation potentials. If instead we had set $T = 0$ from the start, but had then taken the limit $B \to 0$, then $v_{xc,\uparrow}$ would have been undefined for $0 \le N \le 1$, where $n_\uparrow = 0$. Our Fig. 1 is found in the order of limits $B \to 0$ first, then $T \to 0$, while our Figs. 2 and 3 are found in the opposite order of limits.

A DFT/MM analysis of the effect of ligand substituents on asymmetric hydrogenation catalyzed by rhodium complexes with phosphine–phosphinite ligands

Steven M. A. Donald, Anton Vidal-Ferran, and Feliu Maseras

Abstract: DFT and DFT/MM calculations are carried out on the rate-determining step of the addition of dihydrogen to methyl-(*N*)-acetylaminoacrylate catalyzed by a rhodium catalyst containing a bidentate phosphine–phosphinite ligand. DFT calculations reproduce the experimental results, while DFT/MM calculations do not. The failure of DFT/MM methods for this particular problem is analyzed through a series of calculations with different partitions between the DFT and MM regions, which show that electronic effects of all ligand substituents considered are critical. The analysis of these electronic effects provides key information on the role of each of the substituents in the outcome of the overall catalytic process.

Key words: asymmetric hydrogenation, density functional theory, quantum mechanics/molecular mechanics methods, enantioselectivity.

Résumé : Opérant sur la base de la TDF et de la TDF/MM, on a effectué des calculs sur l'étape cinétiquement limitante de l'addition du dihydrogène sur le *N*-acétylaminoacrylate de méthyle, catalysée par un catalyseur de rhodium contenant un ligand phosphine–phosphinite bidentate. Les calculs sur la base de la TDF permettent de reproduire les résultats expérimentaux alors que ceux effectués sur la base de la TDF/MM ne le permettent pas. On a analysé les causes de l'échec des méthodes TDF/MM dans ce problème particulier en effectuant une série de calculs avec différentes partitions entre les régions TDF et MM qui montrent que les effets électroniques de tous les ligands substituants considérés jouent un rôle critique. L'analyse de ces effets électroniques fournit de l'information pertinente sur le rôle de chacun de substituants dans le résultat du processus catalytique global.

Mots-clés : hydrogénation asymétrique, théorie de la fonctionnelle de la densité, méthodes de la mécanique quantique/mécanique moléculaire, énantiosélectivité.

Introduction

Over the past three decades, the field of asymmetric catalysis, in general, and asymmetric hydrogenation, in particular, has received considerable interest in academia with the notable contributions of Knowles, Noyori, and Sharpless "for their work on chirally catalyzed hydrogenation and oxidation reactions" leading to their Nobel Prize awards in 2001.[1] Furthermore, the broad applicability of chiral compounds as drugs,[2] polymers,[3] biological probes,[4] and new materials[5] means that an entire industry focused on chirality has taken form. The never-ending search for new chiral compounds is now one of the most prominent areas of modern chemistry.

The abundance of experimental data for catalytic asymmetric hydrogenation lends itself very well to kinetic and computational investigations into the mechanism of this important reaction.[6] However, the only clear conclusion from this research is that the precise mechanism is highly dependent on the exact combination of ligand, substrate, and solvent.[7] Significant progress has been made for specific systems, although we have not yet reached the stage where we can make confident predictions on the behaviour of any ligand that experimental chemists can come to design.

Whilst computer power has risen steadily over the years, it is still the case that high accuracy calculations on large, electronically complex systems such as biological or large organometallic compounds are not practicable. Even though density functional theory offers a good compromise between accuracy and efficiency,[8] there are systems for which a full

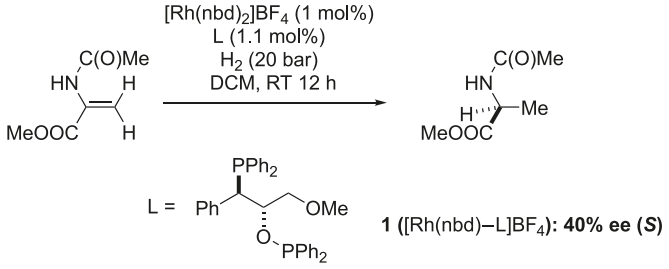
Scheme 1. Asymmetric hydrogenation by catalyst **1**.



description at this level of theory is seen as too costly. Whilst the common approach of reducing the size of the system by using a "model" where bulky substituents on the ligands are replaced by a hydrogen atom (e.g., removal of phenyl substituents from PPh_3 to give a simple PH_3 ligand) describe the metal–ligand interactions relatively well, they will neglect ligand–ligand interactions. In systems where the steric interactions in the full ligand system play a vitally important role in determining enantioselectivity, the full ligand must be computed. Hybrid quantum mechanics/molecular mechanics (QM/MM) approaches, which offer a description of the full system in a reasonable time, have proven to be an extremely useful tool to the computational chemist. In particular, the IMOMM[9] (integrated molecular orbital and molecular mechanics) and ONIOM[10] (our own N-layered integrated molecular orbital and molecular mechanics) approaches have been quite successful for organometallic systems and homogeneous catalysis.[11] By partitioning the molecule, only the most important section, the metal and its close surroundings, is modelled at the more costly QM level whilst the rest of the molecule is modelled within the MM section. Many examples are available on the successful application of QM/MM methods in catalytic systems including hydrogenation,[12] hydroformylation,[13] sulfoxidation,[14] and olefin polymerization.[15]

We describe here results of the application of the ONIOM method to the study of the asymmetric hydrogenation of methyl-(*N*)-acetylaminoacrylate by the bidentate phosphine–phosphinite (Rh^I) catalyst **1**, recently published by some of us and shown in Scheme 1.[16]

Results and discussion

Computational details

We computed the complete mechanistic scheme according to Landis et al.,[8b] comprising the following stages:

(A) Addition of dihydrogen to the catalyst–substrate adduct to form a five-coordinate dihydrogen intermediate (**MolH_2**).

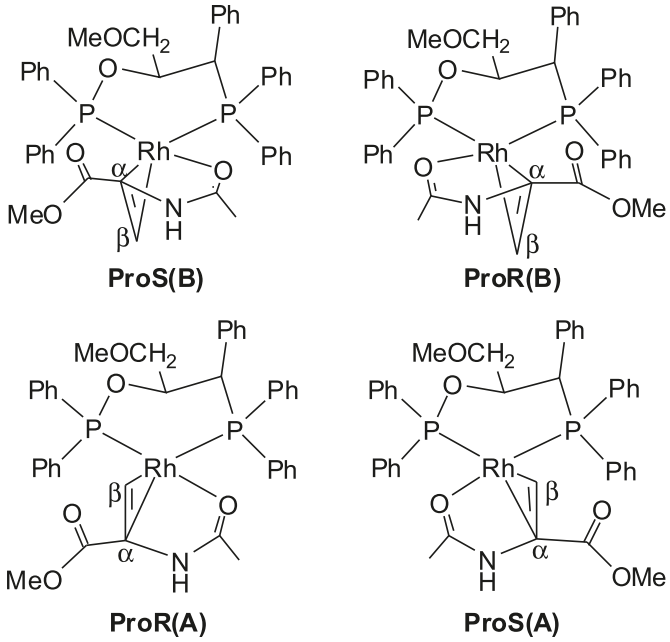
(B) Oxidative addition of dihydrogen to give the dihydride intermediate (**DIHY**).

(C) Migratory insertion of the β-carbon of the olefin into a Rh–H bond to form an alkyl hydride complex with a C–H···Rh agostic bond (**ALHYag**).

(D) Breaking of the agostic bond to give a five-coordinate alkyl hydride (**ALHY**).

(E) C–H reductive elimination to form the product, bound to the metal by the two carbonyl oxygens (**Prod**).

Fig. 1. Four possible catalyst–substrate adducts.



The choice of partition in such systems is of crucial importance and can lead to significant error if the partition is cut too close to the metal centre, as highlighted in a previous study on cobalamins by this group.[17] The study on the DuPHOS system by Landis et al. utilized a three-layer ONIOM approach, describing the core atoms at the DFT level, the phospholane rings at the Hartree–Fock ab inito level, and the phospholane-ring methyl groups with the universal force field (UFF).[18]

In the catalytic system under study, the ligand is non-C_2-symmetric, giving two sets of catalyst–substrate diastereomers (sets A and B, shown in Fig. 1), each diastereomer representing a possible hydrogenation manifold. Also, the catalyst contains considerably more degrees of freedom than the DuPHOS system due to a flexible six-membered backbone and freely rotating phenyl substituents on the phosphorous atoms (P-phenyls). Given the conformational flexibility, a conformation search for the catalyst–substrate adducts and the key transition states was deemed essential. This was carried out using the Monte Carlo rigid conformational scan within the Macromodel program.[19] The lowest energy conformations from each search were then optimized using the two-layer ONIOM method implemented in Gaussian 03,[20] partitioned by placing all four P-phenyls and both backbone substituents in UFF as illustrated in Fig. 2. The model system was described with the B3LYP[21] hybrid density functional, using the Stuttgart RECP and associated basis sets[22] on rhodium and phosphorous with added f (ζ^{Rh} = 1.35) and d (ζ^{P} = 0.387) polarization functions, respectively.[23] The backbone ring, substrate, and dihydrogen molecule were described with the 6–31G(d) basis.[24] The rest of the system (including the P-phenyl groups and the methoxymethyl and phenyl backbone substituents) was described using UFF.

DFT/MM vs. full DFT

Both sets of diastereomers and their possible hydrogenation manifolds were computed, and it was found that hydro-

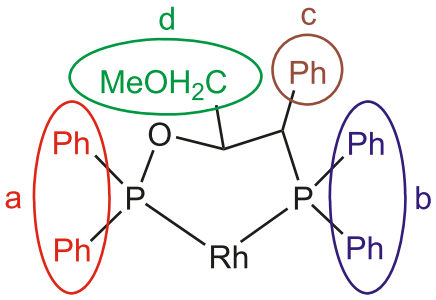
genation from the two B diastereomers, where the bulky α-substituents of the substrate are present in the same face as the backbone phenyl group, was much higher in energy than hydrogenation of the A diastereomers due to increased steric crowding. The B diastereomers are thus highly unlikely to contribute to product formation. In both A-manifolds, the oxidative addition of dihydrogen (**MolH$_2$-TS**) is clearly the rate-determining step; however, the potential energy of the R transition state is 1.88 kcal/mol lower than that of the S transition state, in sharp contrast with the experimentally reported enantiomeric excess of 40% (S), which represents a difference of 0.7 kcal/mol in favour of forming the S product. Inclusion of free-energy correction to the potential energy improves this situation slightly, but still with a 0.83 kcal/mol favourability for R. However, a full-DFT singlepoint calculation on the **MolH$_2$-TS** structures (describing the previously UFF atoms at the 6–31G basis level) reveals an even greater preference for the R pathway (4.15 kcal/mol). This suggests an underlying problem with the ONIOM model itself. Optimization of the two transition-state structures at the full-DFT level results in significant relaxation of the S-isomer, which becomes more stable than the R-isomer by 1.20 kcal/mol and just 0.80 kcal/mol after zero-point and PCM solvation corrections. This translates to an enantiomeric excess of 60% ee (vs. 40% ee experimentally).

Figure 2 shows the structures of the R and S oxidative-addition transition states at the ONIOM and full-DFT levels. At the DFT level, the catalyst backbone increases the space available to the substrate via rotation throughout the six-membered backbone ring. Also in **SMolH$_2$-TS**, the M–C$_\alpha$ and M–C$_\beta$ distances are much longer in the ONIOM model than in the DFT model (M–C$_\alpha$ = 2.37 Å vs. 2.26 Å and M–C$_\beta$ = 2.26 Å vs. 2.17 Å, respectively).

To investigate the effect of the force field, we performed IMOMM[9] test calculations on the oxidative-addition transition states, using the MM3 force field to describe the MM region. IMOMM is a very similar scheme to ONIOM, the application here owing only to the availability of the MM3 force field. IMOMM single-point calculations on the ONIOM-optimized geometries reveal a greater preference

Fig. 3. The four principal UFF regions.



for the R-product (by 2.54 kcal/mol) and optimization at the IMOMM method still favours the R-product, but by 1.29 kcal/mol, representing a slight (0.59 kcal/mol) improvement over the ONIOM results. Whilst MM3 performs a better job than UFF in this system, the electronic effects of the ligands are still not sufficiently well-described. It is thus clear that, for this particular system, the reproduction of the critical experimental parameter, the enantiomeric excess, can only be accomplished by full DFT calculations, including geometry optimization,. It is nevertheless still possible to apply the DFT/MM approach to analyze the electronic effect of each of the regions of the system.[25]

Partitioning effects on the enantioselectivity

Given the problems, described above, with the DFT/MM partition originally applied, it was decided to carry out a detailed and systematic probe of the effect of changing the partitioning of the molecule on the relative energies of the R and S oxidative-addition transition states. The ONIOM method (and the UFF force field) was used for this study due to the easier program use than that of IMOMM, even though the MM3 force field is more accurate. The four principal UFF regions (phosphinite-phenyls (a), phosphine phenyls (b), backbone phenyl (c), and backbone methoxymethyl (d), see Fig. 3) in the initial partition system were systematically placed within the model system of the ONIOM calculation at the DFT level of theory. Single-point calculations were used to keep a consistent geometry, enabling an accurate assessment of the difference in both DFT and UFF brought about by changing the partitioning system.

Table 1 shows the changes in relative ONIOM extrapolated energies, DFT model energies, and UFF model energies for every possible partitioning of the molecule. It reveals that there is significant variation in the final ONIOM energy depending on the partitioning system used. Looking at the two components of the ONIOM energies, the DFT on the model section varies slightly, and the difference is mostly on the UFF component. The chemical relevance of this result is however dubious because of the different partitions used.

The most striking result from Table 1 is the large variation of the energetics. The simplest behaviour would have been a smooth variation between the –1.88 kcal/mol corresponding to the ONIOM calculation with the smallest QM region and the –4.15 kcal/mol corresponding to the full QM calculation. Instead, the energy differences between transition states leading to the R and S products oscillate widely within a range between –9.48 and +4.10 kcal/mol. To shed some light within this unexpected disarray, we decided to analyze the individual effect of each of the substituent blocks by assuming their contributions are additive.

We first computed the effect of the MM to QM replacement of each substituent from the original ONIOM calculation. To do this, we calculated the change in the R–S difference when introducing a given block in the QM region. For instance, the effect of the a substituents was estimated by the subtraction ΔEp(R–S)(a) – ΔEp(R–S)(original). The difference between –8.93 and –1.88 yielded a very large effect of –7.05 kcal/mol for the a block, the two phenyl substituents in the phosphinite centre. The corresponding values for the b, c, and d blocks, computed in a similar way, were +5.98, +1.17, and –1.89 kcal/mol, respectively.

We repeated then the same procedure starting from the full DFT calculation, labelled as abcd in Table 1. This means that we evaluated the effect of the a substituents by the subtraction ΔE_p(R–S)(abcd) – ΔE_p(R–S)(bcd). The resulting values for the a, b, c, and d blocks were in this case –5.56, +3.23, +0.18, and –0.51 kcal/mol, respectively.

The two procedures do not produce exactly the same values, because the effects of the blocks are not exactly additive, but the trends seem to be well-reproduced. It is clear that blocks a and b, the substituents on the phosphorous, have a large effect, above 3 kcal/mol each, and in opposite directions. The substituents on the backbone have a smaller effect, below 2 kcal/mol, but still significant for enantioselectivity calculations.

The analysis could be further refined by introduction of cross-terms, where the effect of having together two blocks in the QM region could be considered. These cross-terms could be easily computed from the results in Table 1, but a simple check shows that the cross-terms are always a minor correction, and their introduction would complicate the analysis of the chemical implications of the results.

Effect of phenyl substituents on phosphorous

The use of an MM or a QM representation of the phenyl substituents on the phosphorous atoms has a large effect on the computed enantiomeric excess. This effect is masked to a certain extent when the four phenyl substituents are considered as a block (ab calculation differs *only* by 1.83 kcal/mol from the original partition) because the a and b blocks have opposite effects, but it is very clear when one block is in the QM region and the other one in the MM region (a, b, ac, ad, bc, bd, acd, and bcd calculations).
