Two DFT methods were used to optimize the geometries of the thymine and its five tautomers. The first functional is the hybrid B3LYP method, which incorporates Becke's three-parameter exchange functional (B3) with the Lee, Yang, and Parr (LYP) correlation functional.[20,21] The second approach is the BP86 method, which marries Becke's 1988 exchange functional (B) with Perdew's 1986 correlation functional.[22,23] Double-ζ quality basis sets with polarization and diffuse functions (denoted DZP++) were used throughout structure optimizations and frequency analyses. The DZP++ basis sets were constructed by augmenting the Huzinaga–Dunning[24,25] set of contracted double-ζ Gaussian functions with one set of p-type polarization functions for each H atom and one set of five d-type polarization functions for each C, N, and O atom [α_p (H) = 0.75, α_d (C) = 0.75, α_d (N) = 0.80, α_d (O) = 0.85]. The B3LYP functional with the DZP++ basis sets has been previously reported to yield excellent predictions of the electron affinities of various chemical species.[26] The average absolute error for the computed electron affinities (EAs), compared with 91 species experiment EAs, was 0.14 eV (0.16 eV after ZPE corrections). The geometries of all cations and anions were fully optimized using both the B3LYP/DZP++ and BP86/DZP++ methods. All optimized structures were confirmed to be genuine local minima with no imaginary frequencies through vibration frequency analyses.

All computations were carried out with the Gaussian 03W program[27] in which the fine grid (75 302) is the default for evaluating integrals numerically, and the tight (10^{-8} Hartree) designation is the default for the energy convergence.[28]

To analyze the unpaired electron distributions, molecular orbital and spin density were constructed from the B3LYP/DZP++ method. Natural population atomic (NPA) charges were determined using the natural bond order (NBO) analysis of Reed and Weinhold.[29]

The electron affinities, the ionization potentials of the thymine and its tautomers were determined in the following manner. The adiabatic electron affinity (AEA) is defined as the energy difference between the neutral and corresponding anion species at their respective optimized geometries, AEA = $E_{(\text{optimized neutral})} - E_{(\text{optimized anion})}$. The vertical electron affinity (VEA) of the molecular is defined as VEA = $E_{(\text{optimized neutral})} - E_{(\text{anion at optimized neutral geometry})}$.

The ionization potential is defined as the amount of energy required to remove an electron from a neutral molecular. The adiabatic ionization potential is calculated employing the following formula: AIP = $E_{(\text{optimized cation})} - E_{(\text{optimized neutral})}$. The vertical ionization potential is defined as VIP = $E_{(\text{cation at optimized neutral geometry})} - E_{(\text{optimized neutral})}$.

Results and discussion

Geometry

Thymine

We consider six thymine tautomers (Fig. 1). Geometries and atomic numberings of thymine tautomers are presented in Fig. 1 at the B3LYP/DZP++ level.

The relative energies (with ZPE corrections) of the six neutral structures at the B3LYP/DZP++ and BP86/DZP++ level of theory are presented in Table 1. T1 is the global minimum with the lowest total energy. T2 is obtained when a hydrogen atom is shift from N_1 site to O_7, which is about 10.6 kcal/mol (B3LYP) or 10.7 kcal/mol (BP86) above the global minimum. T3 with C_s symmetry is also derived from T1 when a hydrogen atom is moved from N_3 site to O_8, which lies 12.5 kcal/mol (B3LYP) or 12.1 kcal/mol (BP86) above the global minimum T1. T4 and T5 are predicted to lie 12.7 kcal/mol (B3LYP) and 25.6 kcal/mol (B3LYP) above the global minimum T1, respectively. T4 is obtained by moving a hydrogen atom from N_1 site to O_7 and moving hydrogen atom from N_3 site to O_8. T5 is obtained by moving

Table 2. Relative energies (kcal/mol) of tautomers of thymine anions and cations.

	Anions				Cations			
	Relative energy (kcal/mol)		ZPE corrected relative energy (kcal/mol)		Relative energy (kcal/mol)		ZPE corrected relative energy (kcal/mol)	
Tautomers	B3LYP	BP86	B3LYP	BP86	B3LYP	BP86	B3LYP	BP86
1	0	0	0	0	0	0	0	0

6	27.7	23.3	27.2	23.8	26.6	24.9	25.2	24.1

hydrogen atom from N_1 site to O_8. T6 is the isomer with the highest total energy, namely 29.0 kcal/mol (at B3LYP/DZP++ level of theory without ZPE) higher than T1. For T6, a hydrogen atom is moved from N_3 site to O_7, which causes the C_2–O_7 bond distance to increase significantly by 0.134 Å compared with T1. Thus, the order of the relative energy is T1< T2 < T3 < T4 < T5 < T6, which is different from the results of P.U. Civcir,[6] who predicted that T5 was the unstable by using AM1 and PM3 methods. R.D. Brown et al. predicted the microwave spectrum of thymine tautomers (T1, T2, and T3),[30] indicating that T1 is the most stable. M. Piacenza and S. Grimme studied the relative energies of the energetically low-lying tautomers of pyridine, cytosine, uracil, thymine, guanine, and *iso*-cytosine using a variety of different quantum chemical methods. They also predicted T1 was the most stable tautomer.[31] In Mazurkiewicz's study,[19] they consider four thymine tautomers (T1, T2, T3, and T4) utilizing CCSD(T)/aug-cc-pVDZ level of theory. They found that the energies order of thymine tautomer is T1 < T2 < T4 <T3, consistent with Grime's result.[31] While in most DFT study, the T3 is more stable than T4.[31] The energies of T3 and T4 are rather close (0.2 kcal/mol in our study), which suggests a highly fluxional system due to the localized orbital on the thymine ring.

Optimized geometries of thymine cations and anions, labeled as c1–c6 and a1–a6, are presented in Figs. 2 and 3 at the B3LYP/DZP++ level, in which the natural population analysis (NPA) charges for C, N, and O are indicated. The Mulliken spin density is contained in the Supplementary data. The relative energies of the six cations at B3LYP/DZP++ and BP86/DZP++ levels of theory are listed in Table 2, including the ZPE corrections. The cations keep the C_s symmetry except T6 and T2, for which the geometry shows minor difference from the neutral. Their relative stability agrees with the neutral. The cation of T1 has the lowest energy on the potential surface whose spin density is predicted to primarily on the C_5 (0.53) and N_1 (0.27) atoms. The energetic favourability of the c1 may be due to the conjugation between the centre N_1 and the neighbouring double bond $C_5 = C_6$, as shown in Fig. 2. It can be seen that in the gas phase of cations, C_2 and C_4 positions carry most positive charges (Table S5). Cation c2 lies 2.8 kcal/mol above the c1. The unpaired electron has significant contributions from C_5 (0.54), O_8 (0.26), and N_1 (0.22). Cation c3 lies 7.9 kcal/mol above the c1. The unpaired electron is mainly localized on the C_5, O_7, with spin densities 0.47 and 0.34, respectively. The positive charges are mainly focused on C_2 (0.84 e^-) and C_4 (0.64 e^-) atoms. Cation c4 is predicted to lie 10.3 kcal/mol higher than c1, whose spin density resides on C_5 (0.57). Cations c5 and c6 are predicted to lie 15.0 kcal/mol and 26.6 kcal/mol, respectively, above the c1.

Geometrical structures of six anions are predicted, and their relative energies are reported in Table 2. The energy order of the anions differs significantly from that of the neutrals and cations due to the significant geometrical alterations that accompany anion formation. The six-member ring in anion a3 is seriously distorted from plane compared with T3. These considerable structural changes of the neutrals and their related anions confirm that all anions have distinct covalent character. It is intriguing to compare the geometry alterations between a3 and T3. The bond distances change from T3 to a3 in the following way: C_4–O_8 1.35 to 1.39 Å, C_2–O_7 1.23 to 1.25 Å, C_2–N_3 1.38 to 1.36 Å, and C_4–C_5 1.44 to 1.39 Å. It is seen that longer bond lengths in the neutral become shorter in the anions, while some shorter distances become longer.

The energetic ordering of the anions is a1< a3 < a2 < a5 < a4 < a6. Anion a1 is the most favoured energetically. The unpaired electron is mainly delocalized to the C_6, C_4, with spin densities 0.66 and 0.15, respectively. The nitrogen and oxygen atom have higher negative charges in the NBO analysis (Table S6). A similar condition may occur for other anions. The anion a3 lies 11.8 kcal/mol above a1 without symmetry, whose hydrogen atom at C_6 site depart the plane. The spin density for a3 is predicted to reside on C_6 (0.73). The anion a2 lies above a1 15.9 kcal/mol. The unpaired electron for a2 is mainly localized on the C_6 (0.61). The anions a4, a5, and a6 are very close in the energy, i.e., 21–28 kcal/mol (B3LYP) above a1. However, the energy difference between a3 and a6 is larger than 15.9 kcal/mol (B3LYP). The unpaired electron for a4 and a6 has significant contributions from C_6 atom. For six anions, the C_{11} atom of methyl has a high negative charge (–0.60 e^-) from the NBO analysis.

T1

Bond lengths and bond angles for the most stable tautomers of thymine (T1) are listed in Table 3, compared with the crystalline monomer, which is obtained by X-ray coordinates.[32] Previous HF and MP2 calculations[33,34] predicted T1 to be the most stable. The calculated results are in good agreement with the available experimental data. The differences in the bond lengths hardly exceed 0.1 Å and those in the bond angles 1°. The value of the N_1–C_2–N_3 bond angle

Table 3. Structural parameters of thymine (T1), its cation, and anion at the BP86/DZP++ level of theory (bond lengths in angstroms and angles in degrees).

Bond	Neutral	Cation	Anion	Experimental[32]	Angle	Neutral	Cation	Anion	Experimental[32]

is slightly underestimated by the BP86 computations. In the crystal, the carbonyl moiety can be engaged in hydrogen bonds, and this effect could be even more important in hydrated crystals. This effect can probably explain at least part of the observed discrepancy between experimental and calculated geometries.

For T1 cation, C_1–N_3, C_4–O_8, C_5–C_{11}, C_6–N_1, C_2–N_3, C_2–O_7, C_5–C_6, C_6–N_1, and C_2–N_1 bonds undergo the largest (changed 0.05 Å) modifications. In particular, the C_6–N_1 bond length increases by 0.05 Å (from 1.34 to 1.39 Å at B3LYP/DZP++ level), while the C_5–C_6 bond shortens from 1.42 to 1.37 Å. The C_2–N_1 bond also shortens from 1.45 to 1.40 Å. The changes in the other bond lengths are less significantly. The lengths of both the C_6–H_{10} bond and the N_3–H_{12} bond are unchanged. The bond between C_5 and the methyl group (C_{11}) is increased by about 0.03 Å. Because of the rigid ring structure, the changes in the bond angles are generally negligible.

T1 anion has significant changes in the geometries compared with neutral T1. The bond distances change from T1 to a1 in the following way: the N_3–H_{12} bond is shortened from 1.03 to 1.02 Å, the C_2–N_1 bond also shortened from 1.40 to 1.38 Å, the C_4–C_5 bond from 1.48 to 1.42 Å. The C_4–N_3, C_4–0_8, C_5–C_6, C_6–C_1, and C_2–0_7 bonds are increased. The largest modification is the C_5–C_6 bond (changed 0.06 Å). The lengths of the C_5–C_{11}, C_2–N_3, N_1–H_9, and C_6–H_{10} bonds are unchanged. The differences in the bond angles almost exceed 1°. The biggest change is C_5–C_6–N_1 bond angle (5°). But the C_5–C_4–N_3, C_6–N_1–C_2, and C_4–C_5–C_{11} bond angles change a little.

The ionization potential of thymine tautomers

The formation of cationic centers plays an important role in the mechanism of radiation damage to DNA. These charged species are known to undergo protonation and deprotonation reactions that in turn can lead to a permanent alteration of the original bases and to an uncorrected transfer of genetic information.[38,39] Thus, the determination of ionization potentials (IPs) of DNA bases can assume a great significance, which has been a high frequent subject of theoretical and experimental studies.

The gas-phase adiabatic ionization potentials (AIPs) and vertical ionization potentials (VIPs) for thymine and its tautomers are presented in Table 4. There is good agreement between the calculated IP of thymine and the experimental data. In contrast to the anions, the geometries of the neutral and cationic species have C_s symmetry except T6, c2, and c6, and the formation of cation is achieved by only a bit change in geometry.

Thymine tautomers have been studied using semi-empirical AM1 and PM3 quantum-chemical calculations at the SCF level in the gas and aqueous phase by P.U.Civcir.[6] AM1 and PM3 calculations seem to overestimate the value of thymine (Table 4). Most IP calculations in the literature are given with the ZPE corrections.[40] The ZPE corrections for thymine at the B3LYP/DZP++ and BP86/DZP++ are listed in Table 4. In our work, it can be seen for the canonical bases at least that the corrections are very small for IPs (for T1, 8.69 eV without ZPE corrections and 8.63 eV with ZPE corrections). To T1, B3LYP calculations seem to underestimate the AIP by slightly less than 0.18 eV, com-

Table 4. IP (eV) of thymine (the value in the parentheses with ZPE corrected).

	AIP		VIP		(VIP)[6]		Expt.

T6	0.12(0.22)	0.38(0.44)	0.25	0.37		

pared with the result of W.G. Mallard et al. for BP86 computations is 0.26 eV.[35]

T1 is predicted to be the only species present in measurable abundance under the experimental conditions for IP. Comparing with the experimental data,[35] VIP is excellent agreement, and the maximum deviations are of about 0.14 eV (B3LYP). The BP86 computations overestimate the VIP by 3.49 eV, indicating that the results of the B3LYP are stable and good. The AIP 8.77 eV (B3LYP) is close to the experimental data (8.87 eV),[36] while S.K. Kim et al obtained 9.15 eV using ionization potential measurements.[14]

Other tautomers have no direct experimental measurement of the gas-phase AIPs and VIPs. T4 has the largest AIP in thymine tautomers (8.67 eV with B3LYP method without ZPE corrections), whereas T5 has the lowest values of AIP and VIP with B3LYP and BP86; it keeps the same results with PM3, different from AM1 (T2 has the lowest IP). T6 has 8.66 eV AIP from B3LYP. The AIP ordering of thymine tautomers is T1 > T4 > T6 > T3 > T2 > T5; it is different from the energies order of neutral and cation thymine tautomers. T3 followed T6 with 8.57 eV AIP. T3 is a controversial focus whose stability is not clear. Ab initio study predicted T3 is more unstable than T4, but most DFT study favoured the assumption that T4 is more stable than T3.[31] T2 has 8.43 eV AIP below T3. In our work, T5 has the lowest AIP (8.31 eV). T1 has the largest IP in all thymine tautomers, which shows that T1 is very difficult to form cation, and the other tautomers are more susceptible to radiation damage through the capture of an electron and more readily form cationic sites. T5 forms cation very easily owing to the lowest IP.

Electron affinities of thymine tautomers

There are two kinds of neutral–anion energy difference, namely the adiabatic electron affinity and the vertical electron affinities (VEA), which are shown in Table 5. The EA of T1 was concerned by several studies because it is the most stable of thymine tautomers. There are only a few recent direct experimental determinations on electron affinities.[43–48] S.D. Wetmore et al. computed the AEA (0.14 eV) using B3LYP method with 6–311+G(2df, p) basis set.[49] But N. Russo and co-workers obtained the small value (0.07 eV) using B3LYP method with TZVP basis.[50] In 2001, S. S. Wesolowski et al. calculated the electron affinities of DNA and RNA[24] using different methods. Their results are consistent with our conclusion.

The adiabatic electron affinities of T2 and T4 are negative because their anions are most destabilized with respect to their neutral species. This means that the extra electron interacts weakly with the LUMO of the neutral molecule, which confirmed by the small geometrics distortions from the neutral to the anion structure. On the other hand, T2 and T4 have dipole moments of 2.84 and 1.79 D, respectively, and should not form a dipole-bound anion that stabilizes the negative structure. The adiabatic electron affinities of other tautomers are positive by B3LYP method. The stabilization of their anions is accompanied by a distortion of the geometry, suggesting the entrance of the extra electron in the LUMO of their neutral. The dipole moments of T1, T3, T5, and T6 are 4.59, 5.51, 6.45, and 8.93 D, respectively.

T5 has the largest AEA (0.26 eV with B3LYP, 0.41 eV with BP86), whereas T1 has a nearly zero AEA value (0.07 eV at the B3LYP/DZP++ level of theory), indicating that T1 has a very low propensity to combine an electron. Compared with the experimental value, the results of BP86 are very fine, but the B3LYP method is often considered to be the most reliable.[25,26]

Table 6. Total energies (*E* in Hartree) and HOMO–LUMO gap (eV) for neutral thymine tautomers at the B3LYP/DZP++ level of theory without ZPE corrections.

Structure	T1	T2	T3	T4	T5	T6
-HOMO$^{\alpha}$	0.255	0.244	0.245	0.252	0.238	0.250
-LUMO$^{\alpha}$	0.058	0.052	0.061	0.045	0.064	0.052
Gap	5.36	5.22	5.01	5.63	4.73	5.39
-*E*	454.232894	454.215928	454.212929	454.212635	454.192157	454.186610

Fig. 4. The frontier orbitals for neutral thymine tautomers.

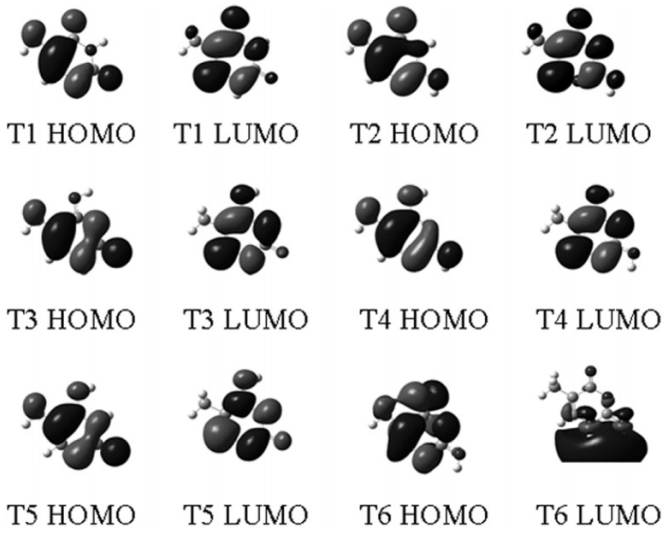

Fig. 5. The frontier orbitals for thymine anions.

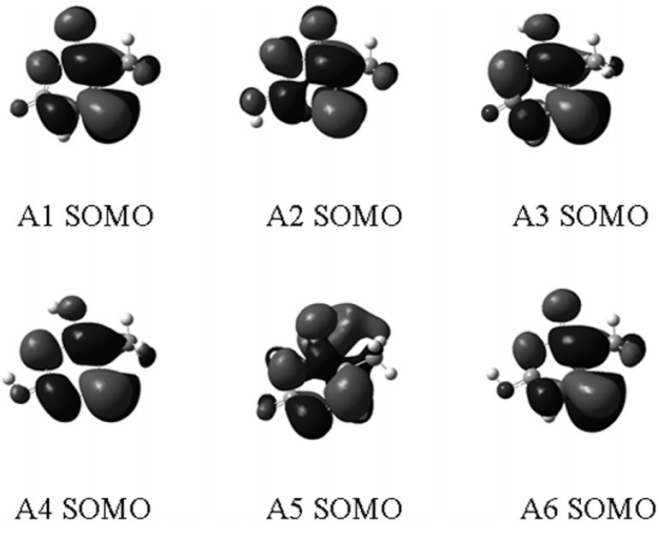

The VEA values of thymine tautomers are negative, except T6, which means that T6 can bind an electron at its equilibrium geometry, whereas others cannot. T1's VEA value (–0.30 eV) is in good agreement with the experimental value (–0.29 eV), which cannot bind an electron at its equilibrium geometry owing to the negative VEA value.

The theoretical VEA values are quite different from the AEA, owing to the considerable geometrical changes between the neutrals and the corresponding anions. Compared with the AEA value, the value of T5 is quite small (–0.68 eV from BP86), because the optimized neutral geometrical structure is significantly different from the optimized anionic structure.

Orbital analysis

Orbital analysis was performed for the thymine tautomers and their anions. The HOMO–LUMO energy gaps are shown in Table 6. The frontier molecular orbitals of thymine tautomers and anions are compared in Figs. 4 and 5. In thymine tautomers, the largest HOMO–LUMO gap, namely 5.63 eV, is found in T4, while the lowest HOMO–LUMO energy gap is in T5. From Fig. 4, for the neutral thymine tautomers, the highest occupied molecular orbital (HOMO) is completely localized on the thymine ring. The lowest unoccupied molecular orbitals (LUMO) of T3, T4, and T5 are mainly localized on the ring, except the methyl group. For T1 and T2, LUMOs are localized on the whole ring. For T6, the LUMO is localized on the methyl group, which leads that T6 is the most unstable. From Fig. 5, we obtain that the SOMOs of anions are completely localized on the ring. But SOMO of a3 and a6 are not localized on O_7 atom, while for a5, SOMOs are localized on the whole atoms except H_{15}. For a2 and a4, SOMO is not localized on the hydrogen atom at O_7 atom.

The proton affinities of thymine tautomers

Protonation reactions are among the most important in chemistry and biology. Protonation/deprotonation is the first step in many fundamental chemical rearrangements and in most enzymatic reactions. The gas-phase basicity and proton affinity are used to characterize the ability of a molecule in the gas phase to accept a proton. Experimental determination of these parameters is not easy; much attention has been given to the possibility of calculating these parameters by quantum methods with the growth in computer power. Ab initio approaches are very successful in providing reliable values of PAs and gas-phase basicities for small molecules; however, due to computational expense, application of Ab initio methods to the estimation of PAs is still impractical for larger molecules. The DFT methods are computationally less and include electron correlation energy via the correlation/exchange potential compared with ab initio approaches. Thus, they are used widely.

In our work, T1 is predicted to be the only species present in measurable abundance under the experimental conditions. There are three double bonds for T1 considered here. Thus, by attaching one hydrogen atom to break a double bond, six isomers can be generated from the thymine structure. The hydrogen could not add to C_4 and C_2 for the structure undergoing a big change. The proton attachment at N_6 implies a significant geometrical distortion of the ring. In a word, we consider five possible sites, which are O_8 (N_3), O_8 (C_5), O_7 (N_3), O_7 (N_1), C_5, and C_6. O_8 (N_3) denotes the proton at-

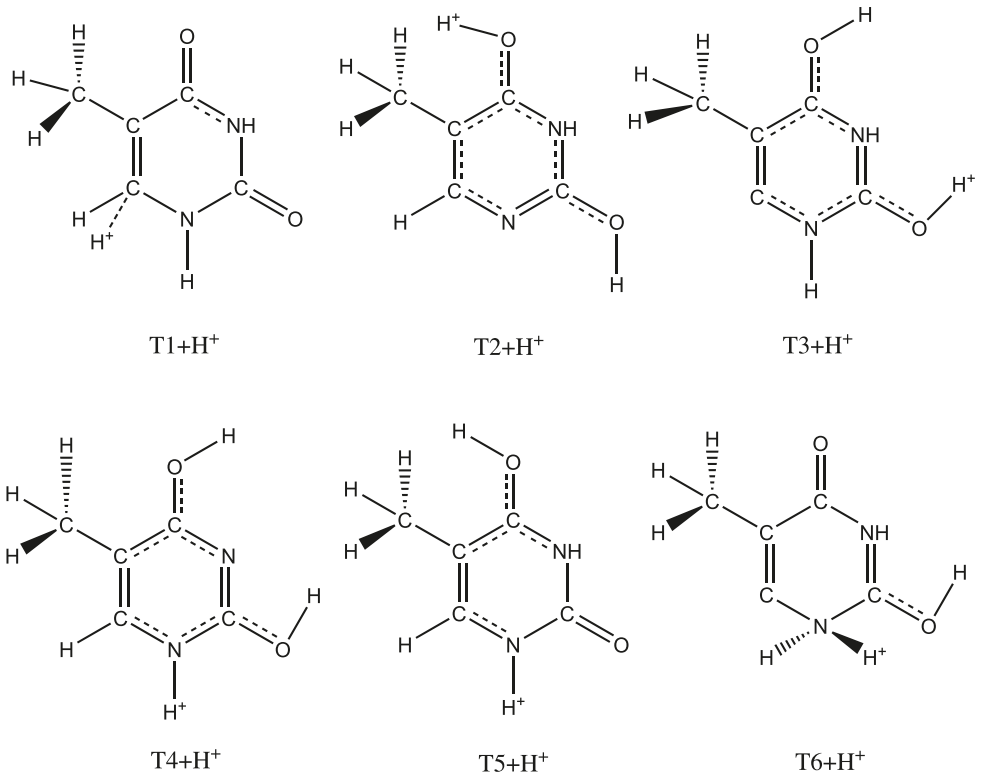
Fig. 6. Optimized geometries of the most stable protonation thymine tautomers.



tached on the N_3 side of the C=O group. The results indicate that O_7 and O_8 are the preferred protonated sites, in good agreement with the N. Russo and A. K. Chandra's conclusions[13,51] and experimental data.[52] The proton affinities of T1 and thymine tautomers are summarized in Table 7 and Table 8, respectively. The six most stable protonated thymine tautomers are shown in Fig. 6.

For T2, the proton attachment sites possess seven possibilities: C_6, C_5, C_4, C_2, O_8, N_3, and N_1, whose order is consistent with the value of PAs. The results display that O_8 is the most preferred protonated site (Fig. 6). The proton added to N_1 site causes the ring rupture. The same value is found when adding the proton to C_4 and O_8 sites. The geometries of the protonated T2 have C_s symmetry except for adding proton to C_6, C_5, and C_2 sites, which have no symmetry.

For T3, there are also seven possibilities corresponding to C_6, C_5, C_4, C_2, N_1, O_7, and N_3. O_7 is the most preferred protonated site (Fig. 6). Adding the proton to C_4 and C_5 produces the same results. The proton added to N_3 site leads to the ring rupture. The geometries of the protonated T3 also have C_s symmetry except for adding proton to C_5, C_4, and C_2 sites, which have no symmetry.

For T4, the proton attachment sites have six possibilities: C_6, C_5, C_4, C_2, N_3, and N_1. The preferred one is N_1 site (Fig. 6). The geometries of the proton added to C_6, N_3, and N_1 sites have C_s symmetry, but adding to C_5, C_4, and C_2 sites have no symmetry.

T5 and T6 all have seven probabilities, namely T5, C_5, C_6, C_4, C_2, N_3, O_7, and N_1 sites and T6, C_6, C_5, C_4, O_8, C_2, N_1, and N_3 sites, respectively. The same value is obtained when adding the proton to C_6, C_2, and N_1 sites for T5.

For T6, the most preferred protonated site is the O_8 (Fig. 6). The geometries of the proton added to O_8, N_1, and N_3 sites have C_s symmetry, but adding to C_6, C_5, C_4, and C_2 sites have no symmetry.

For protonated thymine tautomers, T6 has the largest PA

(233.7 kcal/mol at O_8 site), T1 has the lowest PA (207.9 kcal/mol at O_8 site). The results show that O_8 is the preferred protonated site.

Conclusions

In this work, thymine tautomers and their corresponding cations and anions have been studied theoretically. The structures, energies, theoretical electron affinities, and proton affinities are predicted using the B3LYP and BP86 density functional methods in conjunction with DZP++ basis sets.

(1) The computational results for six neutral tautomers are compared with experiment and previous theoretical studies. T1 is predicted to be the global minimum on the potential energy surface. T6 has the highest energy, namely 29.0 kcal/mol (B3LYP) above the global minimum T1.

(2) The energies order for the anions differs significantly from that of the neutrals. The global minimum among all the anion structures is a1.

(3) The IPs calculated in this work indicate that T1 has the larger IP than other tautomers.

(4) Using the B3LYP and BP86 methods, adiabatic electron affinities are predicted for the thymine tautomers in the ranges of –0.41 to 0.26 eV (B3LYP) and –0.31 to 0.41 eV (BP86), respectively. The ZPE corrections are generally small. T5 has the largest AEA (0.26 eV from B3LYP computation), while T4 and T2 do not bind an electron (–0.41 and –0.16 eV, respectively). The theoretical VEA values are quite different from the adiabatic electron affinities, owing to the considerable geometrical changes between the neutrals and the corresponding anions.

(5) All protonated sites for thymine tautomers are considered, showing that O_8 is the preferred site.

A catalyst-free protocol for the green and efficient condensation of indoles with aldehydes in ionic liquids

Abdolkarim Zare, Abolfath Parhami, Ahmad Reza Moosavi-Zare, Alireza Hasaninejad, Ali Khalafi-Nezhad, and Mohammad Hassan Beyzavi

Abstract: Indoles are efficiently condensed with aromatic and aliphatic aldehydes in the absence of any catalyst in ionic liquid 1-butyl-3-methylimidazolium bromide {bmim]Br} under microwave irradiation to afford bis(indolyl)methanes in good to excellent yields and in short reaction times.

Key words: catalyst-free, indole, aldehyde, ionic liquid, microwave, bis(indolyl)methane.

Résumé : Les indoles se condensent d'une manière efficace avec les aldéhydes aliphatiques et aromatiques, sans nécessité de catalyseur, dans le liquide ionique bromure de 1-butyl-3-méthylimidazolium {[bmim]Br} et sous irradiation par des microondes et ces réactions conduisent, en un court laps de temps, à la formation de bis(indolyl)méthanes avec des rendements allant de bons à excellents.

Mots-clés : sans catalyseur, indole, aldéhyde, liquide ionique, micro-onde, bis(indolyl)méthane.

[Traduit par la Rédaction]

Introduction

In recent years, catalyst-free reactions have attracted increasing interest due to their ease of experimental procedure as well as work-up, low cost, possibility of using acid- or base-sensitive substrates, and their environmentally benign nature.[1–10] This useful technique has been used in several chemical transformations, such as self-assembly of carbon nanotubes, carbon nanowires, and carbon filaments,[1] synthesis of 2-aminothiazoles,[2] N-benzyloxycarbonylation of amines,[3] synthesis of benzoic esters and benzyl esters,[4] gem-bisallylation of carboxylic acid derivatives,[5] synthesis of polyorganosiloxanes,[6] synthesis of dithiocarbamates,[7] regioselective conversion of epoxides to vicinal-halohydrins,[8] transesterification of triglycerides,[9] and Michael-type addition of amines to electron-deficient alkenes.[10] As a part of our continuing interest in developing efficient synthetic methodologies in organic synthesis, we have initiated a program to study useful organic transformations in the absence of catalyst. Herein, we find that the condensation of indoles with aldehydes can be efficiently achieved without any catalyst in neutral ionic liquids under microwave irradiation.

Currently, ionic liquids have been the subject of considerable interest as benign reaction media in organic synthesis because of their unique properties such as non-volatility, non-flammability, recyclability, and ability to dissolve a wide range of materials.[11] During the past decade, a variety of ionic liquids have been demonstrated to be efficient and practical alternatives to volatile organic solvents for many important organic transformations.[11] Together with the substitution of common molecular solvents, non-conventional activation methods, mainly microwave irradiation, have emerged as powerful techniques to decrease reaction times and to enhance reaction rates.[12]

The condensation of indoles with carbonyl compounds is of importance, because this reaction provides a simple route to bis(indolyl)methanes synthesis.[13] For this class of compounds, different pharmacological and biological activities have been reported.[14] Several methods have been developed for the preparation of bis(indolyl)methanes from indoles and carbonyl compounds using catalysts such as silica sulfuric acid,[13a] Ru (III),[13b] $H_3PMo_{12}O_{40}{\cdot}xH_2O$,[13c] P_2O_5/SiO_2,[13d] silica chloride,[13e] $ZrOCl_2{\cdot}8H_2O$,[13f] PPh_3-$HClO_4$(TPP),[13g] $AlPW_{12}O_{40}$,[13h] $In(OTf)_3$,[13i] $Dy(OTf)_3$,[13j] and $La(PFO)_3$.[13k] This transformation has been also carried out in H_2O in the presence of sodium dodecyl sulfate.[13l] Moreover, in this report the same reaction has been performed in the absence of catalyst in MeOH.[13l] In the mentioned paper, the results obtained from a H_2O/sodium dodecyl sulfate system are good; however, the catalyst-free conditions have some drawbacks including low yields, long reaction times, and no generality.[13l] To the best of our knowledge, there is no other report on the condensation of indoles with aldehydes without catalyst.

2	[bmim]Br	8	95
3	[bmim]Cl	8	69
4	[bmim]I	8	47

[a]Isolated yield.

In this study, we report a catalyst-free, efficient, green, and simple method for the condensation of indoles with aromatic and aliphatic aldehydes in [bmim]Br under microwave irradiation (Scheme 1).

Results and discussion

At first, we examined condensation of indole (2 mmol) with benzaldehyde (1 mmol) in the absence of any catalyst under solvent-free and microwave conditions at 400 W of microwave power; but these conditions afforded the corresponding bis(indolyl)methane **1** in trace yield after 30 min (Table 1). Increasing the reaction time or microwave power did not improve the yield. The yield increased to 95% when the reaction was performed in ionic liquid [bmim]Br (0.25 g) at 400 W (max 150 °C) (Table 1 and Scheme 1). Moreover, the reaction of indole with benzaldehyde was examined in ionic liquids [bmim]Cl and [bmim]I (Table 1). As Table 1 indicates, [bmim]Br afforded the best results.

The condensation of indole with benzaldehyde was also tested at different microwave powers (100–600 W, max. 150 °C). The reasonable results were obtained at 400 W.

To assess the generality and the scope of this catalyst-free protocol, indoles were reacted with structurally diverse aldehydes. The results are summarized in Table 2. As can be seen in Table 2, all reactions proceeded efficiently and the desired products were produced in good to excellent yields and in short reaction times. It must be mentioned that aliphatic and aromatic aldehydes possessing electron-releasing substituents gave the corresponding bis(indolyl)methanes in lower yields and in longer reaction times in comparison with the others (Table 2, entries 7–10 and 17).

One of the most interesting properties of ionic liquids is their ease of recycling. For the reaction of indole with benzaldehyde no significant loss of the product yield was observed when [bmim]Br was reused, even after three repeated uses.

It has long been studied that hydrogen bond formation can occur between the solute and cationic or anionic counterpart of ionic liquids.[15] Moreover, Deb et al. have suggested a mechanism for the condensation of indoles with aldehydes based on the activation of a carbonyl group of aldehydes via hydrogen bond formation with solvent.[13l] According to these observations, we suggest a mechanism for our reaction (Scheme 2). In this mechanism, the [bmim]-based ionic liquid has a dual activation role. Activation of the carbonyl group occurs via hydrogen bond between 2-H of the [bmim] moiety of the ionic liquid and oxygen of the carbonyl group. Moreover, indole is activated when the bromide ion of the ionic liquid removes the NH proton of the indole, since it increases the nucleophilicity of the indole. We suggest that firstly (3*H*-indol-3-yl)-phenyl-methanol (**I**) forms as a result of nucleophilic attack of activated indole to electrophilic carbon of activated carbonyl function of benzaldehyde. Then, intermediate **I** eliminates a water molecule to convert into 3-benzylidene-3*H*-indole (**II**). The electrophilicity of the exocyclic double bond of intermediate **II** increases through hydrogen bond formation between sp^2 nitrogen of intermediate **II** and 2-H of [bmim] moiety. Finally, the activated indole attacks the exocyclic double bond providing the bis(indolyl)methane **1**. Ionic liquids also stabilize charged intermediates and enhance reaction rates.[16] Moreover, these polar solvents absorbs microwave irradiation and increase reaction temperature rapidly.[12a,12j]

In summary, we have reported a new application of catalyst-free protocol in organic synthesis. In this study, bis(indolyl)methanes efficiently synthesized from indoles and aldehydes in a ionic liquid under microwave conditions.

Experimental

All chemicals were purchased from Merck or Fluka chemical companies. The ionic liquid was prepared according to the reported methods.[17] All reactions were carried out using a laboratory microwave oven (MicroSYNTH, Milestone Company, Italy). The ^{1}H NMR (250 MHz) and ^{13}C NMR (62.5 MHz) were run on a Bruker Avance DPX-250 FT-NMR spectrometer, δ in ppm. Mass spectra were recorded on a Shimadzu GC MS-QP 1000 EX apparatus. Microanalyses were performed on a PerkinElmer 240-B microanalyzer. Melting points were recorded on a Büchi B-545 apparatus in open capillary tubes.

General procedure for the catalyst-free condensation of indoles with aldehydes

To a mixture of indole (2 mmol, 0.234 g) and aldehyde (1 mmol) in a microwave vessel was added [bmim]Br (0.25 g), and the mixture was stirred carefully with a small rod. The resulting mixture was irradiated in a microwave oven at 400 W for the appropriate time (Table 2). The microwave was programmed to give a maximum internal temperature of 150 °C. Afterward, the reaction mixture was

Table 2. Catalyst-free condensation of indoles with aldehydes in [bmim]Br under microwave irradiation (400 W, max 150 °C).

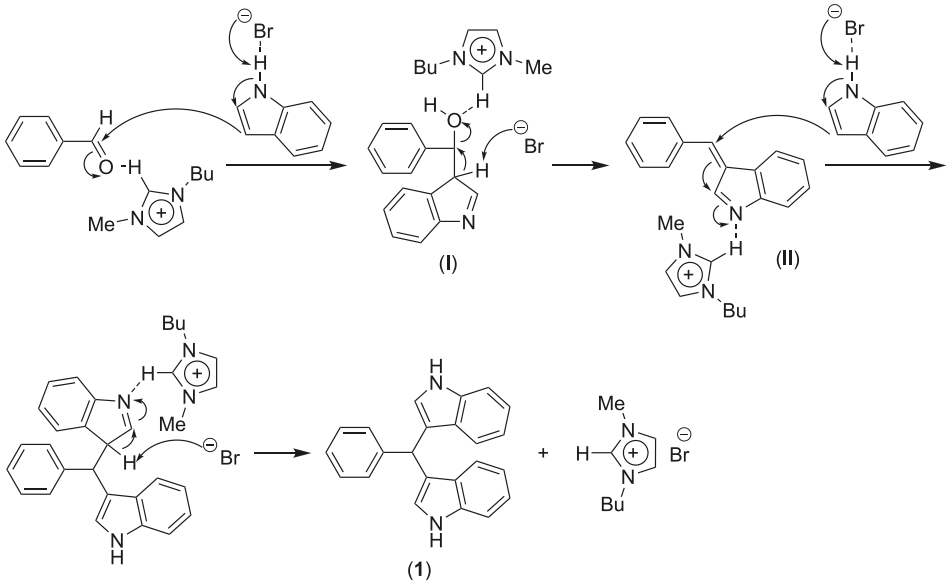
[a]Isolated yield.
[b]This reaction was carried out at 300 W of microwave power (max 150 °C).
[c]This reaction was performed in a sealed vessel.

Scheme 2. Suggested mechanism for the condensation of indoles with aldehydes.



cooled to room temperature and was extracted with Et_2O (2 × 20 mL). The organic extracts were then combined and washed with saturated solution of $NaHSO_3$ (2 × 20 mL) to remove unreacted aldehyde and then with water (2 × 20 mL). The organic layer was separated and dried with $CaCl_2$. The solvent was evaporated and the crude product was purified by recrystallization from EtOAc/petroleum ether (1:2) or plate chromatography on silica gel eluted with EtOAc/petroleum ether (1:2). After isolation of the product, the remaining Et_2O in [bmim]Br was evaporated, and it was used for the next run under identical reaction conditions.

3-((1*H*-Indol-3-yl)(phenyl)methyl)-1*H*-indole (1)

Recrystallization from EtOAc/petroleum ether (1:2) gave pink solid; yield 0.306 g (95%); mp 140–142 °C (lit. 140–142 °C).[13d] ^{1}H NMR ($CDCl_3$, ppm) δ: 5.86 (s, 1H, ArCH), 6.66 (s, 2H), 7.11 (t, 2H, *J* = 6.9 Hz), 7.14–7.22 (m, 3H), 7.28–7.31 (m, 2H), 7.35–7.42 (m, 6H), 7.93 (br, 2H, NH). ^{13}C NMR ($CDCl_3$, ppm) δ: 31.6, 110.9, 111.9, 118.4, 119.5, 121.2, 124.0, 126.3, 127.1, 128.5, 128.6, 137.0, 145.2. MS *m*/*z*: 322 [M$^+$]. Anal. calcd. for $C_{23}H_{18}N_2$: C 85.68, H 5.63, N 8.69; found: C 85.87, H 5.79, N 8.46.

2-Methyl-3-((2-methyl-1*H*-indol-3-yl)(phenyl)methyl)-1*H*-indole (2)

Purification by plate chromatography on silica gel, eluted with EtOAc/petroleum ether (1:2), gave pink solid; yield 0.312 g (89%); mp 246–248 °C (lit. 245–247 °C).[13e] ^{1}H NMR ($CDCl_3$, ppm) δ: 2.05 (s, 6H), 5.88 (s, 1H, ArCH), 6.78–7.01 (m, 6H), 7.14–7.22 (m, 5H), 7.28–7.31 (m, 2H), 8.02 (br, 2H, NH). ^{13}C NMR ($CDCl_3$, ppm) δ: 13.4, 38.7, 109.6, 112.1, 118.9, 120.0, 121.4, 126.5, 128.4, 128.6, 129.1, 132.4, 135.7, 139.8. MS *m*/*z*: 350 [M$^+$]. Anal. calcd. for $C_{25}H_{22}N_2$: C 85.68, H 6.33, N 7.99; found: C 85.47, H 6.48, N 7.86.

3-((1*H*-Indol-3-yl)(4-nitrophenyl)methyl)-1*H*-indole (3)

Recrystallization from EtOAc/petroleum ether (1:2) gave yellow needles; yield 0.355 g (97%); mp 216–218 °C (lit. 217–220 °C).[13l] ^{1}H NMR ($CDCl_3$, ppm) δ: 6.01 (s, 1H, ArCH), 6.72 (s, 2H), 7.02–7.08 (m, 4H), 7.36 (d, 2H, *J* = 8.1 Hz), 7.41 (d, 2H, *J* = 8.1 Hz), 7.49 (d, 2H, *J* = 8.6 Hz), 8.05 (br, 2H, NH), 8.17 (d, 2H, *J* = 8.6 Hz). ^{13}C NMR ($CDCl_3$, ppm) δ: 40.2, 112.0, 113.1, 119.1, 120.4, 121.8, 122.1, 123.7, 127.4, 131.8, 136.1, 145.1, 153.5. MS *m*/*z*: 367 [M$^+$]. Anal. calcd. for $C_{23}H_{17}N_3O_2$: C 75.19, H 4.66, N 11.44; found: C 75.36, H 4.51, N 11.31.

3-((1*H*-Indol-3-yl)(3-nitrophenyl)methyl)-1*H*-indole (4)

Recrystallization from EtOAc/petroleum ether (1:2) gave yellow solid; yield 0.352 g (96%); mp 220–222 °C (lit. 220–222 °C).[13d] ^{1}H NMR ($CDCl_3$, ppm) δ: 6.23 (s, 1H, ArCH), 7.01 (t, 2H, *J* = 7.3 Hz), 7.06 (s, 2H), 7.22 (t, 2H, *J* = 7.0 Hz), 7.45 (d, 2H, *J* = 7.5 Hz), 7.53 (d, 2H, *J* = 8.0 Hz), 7.75 (m, 1H), 8.02 (d, 1H, *J* = 7.6 Hz), 8.26 (d, 1H, *J* = 7.7 Hz), 8.33 (s, 1H), 8.09 (br, 2H, NH). ^{13}C NMR ($CDCl_3$, ppm) δ: 38.7, 111.0, 112.6, 118.4, 119.0, 120.7, 121.9, 123.4, 125.3, 127.8, 129.5, 135.2, 136.8, 138.5, 148.0. Photochemistry of 3-alkoxychromones I — Photocyclisation of 6-chloro-3-alkoxy-2-(furan-3-yl)-4*H*-chromen-4-ones

Ramesh C. Kamboj, Urmila Berar, Surinder Berar, Mandeep Thakur, Rita Arora, and Satish C. Gupta

Abstract: 3-Alkoxy/allyloxy-6-chloro-2-(furan-3-yl)-4*H*-chromen-4-ones yield angular tetracyclic products involving the 2-furyl group on photoirradiation through the intermediacy of 1,4-biradicals. The nature of the 3-alkoxy/allyloxy group influenced the photoproduct distribution. The stereochemical dispositions of the products have been established using the J/Φ relationship and were corroborated by MM2 calculations.

Key words: furylchromone, type-II reaction, 1,5-sigmatropic shift.

Résumé : La photoirradiation des 3-alkoxy/allyloxy-6-chloro-2-(furan-3-yl)-4*H*-chroménones conduit à des produits tétracycliques angulaires impliquant le groupe 2-furyle par l'intermédiaire de biradicaux-1,4. La nature du groupe 3-alkoxy/allyloxy influence la distribution des photoproduits. Les dispositions stéréochimiques des produits ont été déterminées à l'aide de la relation J/Φ et elles ont été corroborées par des calculs théoriques MM2.

Mots-clés : furylchromone, réaction de type II, déplacement sigmatropique 1,5.

[Traduit par la Rédaction]

Introduction

In photochemical transformations of 3-alkoxy-2-aryl-4*H*-chromen-4-one,[1] the products formed depend upon the nature of substituents at C-2 and C-3. The 2-methyl-3-methoxy derivatives produced dimeric oxetanols and underwent demethoxylation.[2] The photolysis of 3-alkoxy-2-(phenyl/furyl/thienyl)-4*H*-chromen-4-one[3] produced angular tetracyclics, whereas 2-styryl[4] derivatives provided linear tricyclics. The photochemical reaction in these substrates are basically γ-H abstractions[1,5] and have provided interesting mechanistic and structural studies as well as synthetic utility.[6] We now report the results of our investigations on the photoreactions of 3-alkoxy/allyloxy-6-chloro-2-(furan-3-yl)-4*H*-chromen-4-ones. The study was aimed at the effect of different 3-alkoxy groups on the product distribution and stereochemistry when the furyl group is tethered to the chromone through its 3-position instead of 2-position.[3]

Results and discussion

The targets, 2-(furan-3-yl)-4*H*-chromen-4-ones (**3a**–**3j**), were synthesized commencing with the condensation of 5-chloro-2-hydroxyacetophenone with furan-3-carbaldehyde as per Scheme 1.

The structures of compounds **3a**–**3j** were found to be consistent with their spectral parameters (IR, ^{1}H-^{13}C NMR, Experimental secion).

The photolysis of the methanolic solution of **3a**–**3j** with pyrex filtered UV light, under nitrogen atmosphere produced the photoproducts **4a**–**4j**, **4b′**, **4h′**, **5g**, and **6g**. The structures of these photoproducts (Fig. 1) were confirmed by their spectral parameters(IR,^{1}H-^{13}C NMR) and elemental analysis.

Here, the interesting feature in the photoproducts isolated is the stereochemistry of ring C, which is in a half chair conformation (Fig. 2). In the photoproducts, **4a**–**4j**, **4b′**, **5g**, and **4h′**, the stereochemistry of the C/D ring junction is cis, as the trans-fusion of a five-membered ring will result in higher conformational strain as calculated by the MM2 energy minimizations program.[7] This is further borne out by the fact that $J_{3a,11b} = \sim 9.0$ Hz, which correlates with calculated values of $\Phi_{3a,11b}$ (karplus rule) with cis-fusion of these protons (Table 1) and also from literature references.[8] Now assuming the C/D ring fusion as cis, the orientation of H-4 can be cis to H-3a or trans to H-3a. Here again, regarding the relative stereochemical disposition of H-3a and H-4, the use of the J/Φ relationship[9] and MM2 program has been invoked. The correlation of $\Phi_{3a,4}$ values obtained from two possible MM2 energy minimized 3D conformations,[7] **A** (H-4 trans to H-3a) and **B** (H-4 cis to H-3a), with $J_{3a,4}$ observed from ^{1}H NMR is shown in Table 1. In compound **4a** and **4c** both conformation are equivalent as substituents at C-4 are the same. A look at Table 1 demonstrates the trans disposition of H-3a and H-4 in compounds **4b**, **4d**–**4f**, and **4h**, whereas it is a cis disposition in compounds **4g**, **4i**, **4j**, **4b′**, **4h′**, and **5g**, which are in accordance with karplus rule.[9] This has given the stereocentre at C-4 - a *R* configuration in compounds **4b**, **4d**–**4f**, and **4h** and a *S* configuration in com-

pounds **4g**, **4i**, **4j**, **4b**′, **4h**′, and **5g**. A correlation of steric energy (E_{kcal}) also shows that in most cases the lower energy conformations are the ones that explain the observed J/Φ relationship (Table 1).

Here it is worth mentioning that in photolysis of chromones **3b** and **3h**, both photoproducts with conformation **A** and **B** were isolated, whereas in all other chromones only one product was isolated (either conformation **A** or **B**). The reason for this behaviour could be from the steric influence of the C-4 substituent, where the second isomer is either not formed or formed in such low concentrations that it escaped isolation. The 3-cinnamyloxychromone, **3g**, along with cyclisation to yield **4g** also underwent isomerization of the cinnamyl double bond to yield two new products, **5g** and **6g**, where the cinnamyl double bond is cis (J = 11.7 Hz).

The phototransformations (Scheme 2) described above can be visualized as having occurred through the formation of the 1,4 biradical intermediate[1] **7**. The products have been expected to be formed through a bond formation between the -CH- and the C-2 atom of the furan ring, which

is followed by ketonisation and H-migration to C-11b (1,5-H migration). The furyl group at C-2 also possesses a 5-carbon for clipping of the 3-alkoxy radical but here, the 1,5-sigmatropic shift is not feasible.

The secondary ring contraction products observed by cleavage of ring D, as isolated in our earlier work on 3-alkoxy-2-(2′-furyl) chromones,[3,10] are altogether absent here and were not even observed by further photolysis of pure photoproducts. The reason attributed to such diversity may be the difference in stabilization of radicals (Fig. 3) formed by the cleavage of ring D, which determines the ease of C–O bond cleavage.

The radical at C-11b in **8** (obtained in photolysis of 2′-furyl chromones) is stabilized by pyrone moiety and thus the C–O bond becomes prone to cleavage. There is no such stabilization available to the radical (at C-3a) in **9** for its formation and for the formation of ring contracted secondary photoproducts.

Fig. 3. Structures of proposed radicals.

8 **9**

Conclusion

3-Alkoxy/allyloxy-6-chloro-2-(furan-3-yl)-4*H*-chromen-4-ones upon photoirradiation yielded angular tetracyclic products through the 1,4-biradical furnished through γ-H abstraction. No ring contracted secondary photoproduct formation was observed.

Experimental

General

Melting points were determined in open capillaries and are thus uncorrected. ^{1}H NMR spectra were recorded on a 300 MHz Bruker spectrometer using TMS as the internal standard. IR spectra were recorded on a Buck Scientific 500 spectrophotometer using KBr pellets. Mass spectra were recorded at 70 eV. Elemental analysis was carried out on a Perkin Elmer 2400 instrument. TLC plates were coated with silica gel G (suspended in $CHCl_3$-MeOH) and iodine vapours were used as the visualizing agent. The columns for purification were packed with Silica gel 100–200 mesh in petroleum ether/benzene (9:1) and left overnight before use. The elution was carried out with increasing proportions of benzene in the petroleum ether–benzene mixture. The yields reported are based on the amount of isolated photoproducts and are calculated by excluding the recovered substrates.

Synthesis of chromones 3a–3j

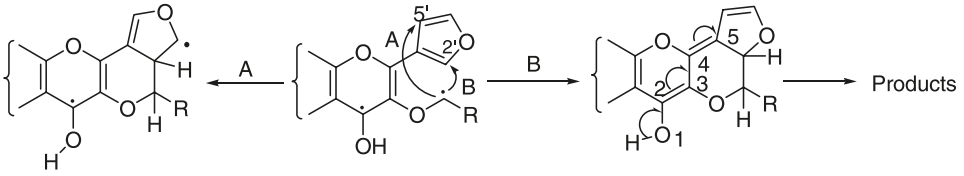
1-(5-Chloro-2-hydroxyphenyl)-3-(furan-3-yl)prop-2-en-1-one (1)

A solution of 5-chloro-2-hydroxyacetophenone (17.0 g, 0.1 mol) and 3-furaldehyde (9.6 g, 0.1 mol) in absolute ethanol and dehydrated S-200 barium hydroxide (dried at 200 °C for 2 h, 20.0 g) were refluxed in a water bath for 20 min. The dark red mixture was cooled and poured on ice-HCl to obtain **1** (17.36 g, 70%) as a yellow solid, crystallized from EtOH, mp 110–113 °C. IR ν_{max} (cm^{-1}): 1648.0 (C=O), 3405(OH). ^{1}H NMR ($CDCl_3$) δ: 12.72 (1H, s, OH), 7.85 (1H, d, $J_{3,2}$ = 15.0 Hz, H-3), 7.80 (1H, d, J_m = 2.7 Hz, H-6′), 7.79 (1H, br s, H-2″), 7.49 (1H, d, $J_{5'',4''}$ = 2.4 Hz, H-5″), 7.42 (1H, dd, J_m = 2.7 Hz, J_o = 9.0 Hz, H-4′), 7.25 (1H, d, $J_{2,3}$ = 15.0 Hz, H-2), 6.96 (1H, d, J_o = 9.0 Hz, H-3′), 6.75 (1H, d, $J_{4'',5''}$ = 2.4 Hz, H-4″). Anal. calcd. for $C_{13}H_9ClO_3$: C 62.79, H 3.65; found: C 62.70, H 3.61.

6-Chloro-3-hydroxy-2-(furan-3-yl)-4H-chromen-4-one (2)

A solution of compound **1** (2.48 g, 0.01 mol) in EtOH at 0 °C was mixed with 12.0 mL 20% aq. NaOH by stirring. To this dark red solution was added H_2O_2 (30%) dropwise until the colour changed to yellow and the stirring was continued for 4 h. The reaction mixture was neutralized with ice-HCl to give creamy white precipitates, crystallized (chloroform-ethanol) to creamy white crystals (2.37 g, 90%), mp 206–208 °C. IR ν_{max} (cm^{-1}): 1615.0 (C=O), 3400(OH). ^{1}H NMR ($CDCl_3$) δ: 8.31 (1H, br s, H-2′), 8.21

Scheme 2. Cyclisation and 1,5-H shift of 1,4-biradical.



(1H, d, J_m = 2.4 Hz, H-5), 7.63 (1H, dd, J_m = 2.4 Hz, J_o = 9.0 Hz, H-7), 7.58 (1H, t, $J_{5',2'}$ = 1.5 Hz, $J_{5',4'}$ = 1.8 Hz, H-5′), 7.51 (1H, d, J_o = 9.0 Hz, H-8), 7.05 (1H, dd, $J_{4',2'}$ = 0.3 Hz, $J_{4',5'}$ = 1.8 Hz, H-4′). Anal. calcd. for $C_{13}H_7ClO_4$: C 59.45, H 2.69; found: C 59.31, H 2.69.

6-Chloro-3-methoxy-2-(furan-3-yl)-4H-chromen-4-one (3a)

The compound **2** (2.50 g, 0.01 mol), CH_3I (1.2 g, 0.01 mol), dry K_2CO_3 (1.0 g), and tetra-*n*-butylammonium iodide (100 mg) were refluxed in dry acetone (50 mL) for 2 h. Filtration, evaporation of the solvent, and crystallization of the residue (MeOH) gave **3a** (80%), a light brown solid, mp 114–117 °C. IR ν_{max} (cm^{-1}): 1655.0 (C=O). ^1H NMR ($CDCl_3$) δ: 8.30 (1H, br s, H-2′), 8.23 (1H, d, J_m = 2.4 Hz, H-5), 7.62 (1H, dd, J_m = 2.4 Hz, J_o = 9.0 Hz, H-7), 7.59 (1H, dd, $J_{5',2'}$ = 1.2 Hz, $J_{5',4'}$ = 1.5 Hz, H-5′), 7.48 (1H, d, J_o = 9.0 Hz, H-8), 7.02 (1H, dd, $J_{4',2'}$ = 0.3 Hz, $J_{4',5'}$ = 1.5 Hz, H-4′), 4.03 (3H, s, OCH_3). ^{13}C NMR ($CDCl_3$) δ: 172.83 (C-4), 153.24 (C-8a), 151.74 (C-2), 145.37 (C-5′), 143.75 (C-2′), 139.31 (C-4a), 133.44 (C-7), 130.67 (C-6), 125.33 (C-3), 125.15 (C-5), 119.50 (C-8), 117.71 (C-3′), 108.61 (C-4′), 59.53 (3-OCH_3). Anal. calcd. for $C_{14}H_9ClO_4$: C 60.78, H 3.28; found: C 63.65, H 3.31.

The other ethers (**3b**–**3j**) were synthesized by reacting 3-hydroxychromone (**2**) with ethyl iodide, isopropyl bromide, allyl bromide, methyl allyl chloride, dimethyl allyl bromide, cinnamyl chloride, propargyl bromide, benzyl chloride, and para methoxy benzyl chloride, respectively, by the procedure as described for compound **3a**.

6-Chloro-3-ethoxy-2-(furan-3-yl)-4H-chromen-4-one (3b)

Yield 82%, colourless solid; mp 104–106 °C (MeOH). IR ν_{max} (cm^{-1}): 1635.0 (C=O). ^1H NMR ($CDCl_3$) δ: 8.33 (1H, br s, H-2′), 8.20 (1H, d, J_m = 2.1 Hz, H-5), 7.60 (1H, dd, J_m = 2.1 Hz, J_o = 9.0 Hz, H-7), 7.57 (1H, t, $J_{5',2'}$ = 1.2 Hz, $J_{5',4'}$ = 1.5 Hz, H-5′), 7.46 (1H, d, J_o = 9.0 Hz, H-8), 7.02 (1H, dd, $J_{4',2'}$ = 0.3 Hz, $J_{4',5'}$ = 1.5 Hz, H-4′), 4.31 (2H, q, J_{vic} = 7.2 Hz, H-1″), 1.44 (3H, t, J_{vic} = 7.2 Hz, H-2″). ^{13}C NMR ($CDCl_3$) δ: 172.98 (C-4), 153.19 (C-8a), 151.70 (C-2), 145.27 (C-5′), 143.62 (C-2′), 139.09 (C-4a), 133.38 (C-7), 130.59 (C-6), 125.29 (C-3), 125.15 (C-5), 119.50 (C-8), 117.91 (C-1′), 108.71 (C-4′), 67.89 (C-1″), 15.71 (C-2″). Anal. calcd. for $C_{15}H_{11}ClO_4$: C 61.98, H 3.81; found: C 61.88, H 3.78.

6-Chloro-3-isopropyloxy-2-(furan-3-yl)-4H-chromen-4-one (3c)

Yield 70%, colourless solid; mp 95–97 °C (MeOH); IR ν_{max} (cm^{-1}): 1639.2 (C=O). ^1H NMR ($CDCl_3$) δ: 8.36 (1H, d, J = 0.9 Hz, H-2′), 8.19 (1H, d, J_m = 2.7 Hz, H-5), 7.59 (1H, dd, J_m = 2.7 Hz, J_o = 9.0 Hz, H-7), 7.55 (1H, t, $J_{5',2'}$ = 1.5 Hz, $J_{5',4'}$ = 1.8 Hz, H-5′), 7.46 (1H, d, J_o = 9.0 Hz, H-8), 7.04 (1H, d, $J_{4',5'}$ = 1.8 Hz, H-4′), 5.15 (1H, septet, J_{vic} = 6.3 Hz, H-1″), 1.32 (6H, d, J_{vic} = 6.3 Hz, $C_{1''}$-CH_3). ^{13}C NMR ($CDCl_3$) δ: 173.07 (C-4), 153.12 (C-8a), 151.79 (C-2), 145.73 (C-5′), 143.32 (C-2′), 137.00 (C-4a), 133.26 (C-7), 130.49 (C-6), 125.13 (C-5), 125.00 (C-3), 119.44 (C-8), 118.13 (C-1′), 108.92 (C-4′), 73.98 (C-1″), 22.49 ($C_{1''}$-CH_3). Anal. calcd. for $C_{16}H_{13}ClO_4$: C 63.06, H 4.30; found: C 62.97, H 4.27.

3-Allyloxy-6-chloro-2-(furan-3-yl)-4H-chromen-4-one (3d)

Yield 85%, light brown solid; mp 93–95 °C(MeOH). IR ν_{max} (cm^{-1}): 1641 (C=O), 1613 (C=C). ^1H NMR ($CDCl_3$) δ: 8.33 (1H, br s, H-2′), 8.20 (1H, d, J_m = 2.4 Hz, H-5), 7.60 (1H, dd, J_m = 2.4 Hz, J_o = 9.0 Hz, H-7), 7.56 (1H, dd, $J_{5',2'}$ = 0.9 Hz, $J_{5',4'}$ = 1.8 Hz, H-5′), 7.47 (1H, d, J_o = 9.0 Hz, H-8), 7.02 (1H, dd, $J_{4',2'}$ = 0.3 Hz, $J_{4',5'}$ = 1.8 Hz, H-4′), 6.08 (1H, tdd, J_{vic} = 6.3 Hz, J_{trans} = 17.4 Hz, J_{cis} = 10.2 Hz, H-2″), 5.39 (1H, td, J_{allyl} = 1.5 Hz, J_{trans} = 17.4 Hz, H-3″b), 5.26 (1H, d, J_{cis} = 10.2 Hz, H-3″a), 4.80 (2H, dd, J_{vic} = 6.3 Hz, J_{allyl} = 1.5 Hz, H-1″). ^{13}C NMR ($CDCl_3$) δ: 171.00 (C-4), 153.10 (C-8a), 153.00 (C-2), 145.50 (C-5′), 143.62 (C-2′), 139.09 (C-4a), 133.45 (C-7), 133.30(C-2″), 130.60 (C-6), 123.14 (C-3), 123.34 (C-5), 119.83(C-3″), 119.10 (C-8), 117.84 (C-3′), 108.70 (C-4′), 72.69 (C-1″). Anal. calcd. for $C_{16}H_{11}ClO_4$: C 63.48, H 3.66; found: C 63.33, H 3.65.

6-Chloro-2-(furan-3-yl)-3-(2-methylallyloxy)-4H-chromen-4-one (3e)

Yield 72%, creamy white solid; mp 90–92 °C (MeOH). IR ν_{max} (cm^{-1}): 1637 (C=O), 1619 (C=C). ^1H NMR ($CDCl_3$) δ: 8.32 (1H, dd, J_m = 0.9 Hz, H-2′), 8.20 (1H, d, J_m = 2.7 Hz, H-5), 7.59 (1H, dd, J_m = 2.7 Hz, J_o = 9.0 Hz, H-7), 7.56 (1H, t, $J_{5',2'}$ = 0.9 Hz, $J_{5',4'}$ = 1.8 Hz, H-5′), 7.46 (1H, d, J_o = 9.0 Hz, H-8), 7.01 (1H, dd, $J_{4',2'}$ = 0.9 Hz, $J_{4',5'}$ = 1.8 Hz, H-4′), 5.15 (1H, s, H-3″b), 5.01 (1H, s, H-3″a), 4.67 (2H, s, H-1″), 1.87 (3H, s, 2″-CH_3). ^{13}C NMR ($CDCl_3$) δ: 172.78 (C-4), 153.18 (C-8a), 151.65 (C-2), 145.44 (C-5′), 143.64 (C-2′),141.18 (C-2″), 138.80 (C-4a), 133.37 (C-7), 130.63 (C-6), 125.29 (C-3), 125.12 (C-5), 119.48 (C-8), 117.76 (C-1′),113.80 (C-3″), 108.68 (C-4′), 75.13 (C-1″), 19.79 (2″-CH_3). Anal. calcd. for $C_{17}H_{13}ClO_4$: C 64.46, H 4.14; found: C 64.30, H 4.11.

6-Chloro-2-(furan-3-yl)-3-(3-methylbut-2-enyloxy)-4H-chromen-4-one (3f)

Yield 70%, off-white solid; mp 81–84 °C (MeOH). IR ν_{max} (cm^{-1}): 1637.2 (C=O), 1608.6 (C=C). ^1H NMR ($CDCl_3$) δ: 8.33 (1H, d, $J_{2',5'}$ = 1.2 Hz, H-2′), 8.21 (1H, d, J_m = 2.4 Hz, H-5), 7.59 (1H, dd, J_m = 2.4 Hz, J_o = 9.0 Hz, H-7), 7.55 (1H, t, $J_{5',2'}$ = 1.2 Hz, $J_{5',4'}$ = 1.8 Hz, H-5′), 7.46 (1H, d, J_o = 9.0 Hz, H-8), 7.01 (1H, d, $J_{4',5'}$ = 1.8 Hz, H-4′), 5.53 (1H, tt, J_{vic} = 7.2 Hz, J_{allyl} = 1.5 Hz, H-2″), 4.78 (1H, d,

J_{vic} = 7.2 Hz, H-1″), 1.75 (3H, d, J_{allyl} = 1.5 Hz, H-4″), 1.73 (3H, s, $C_{3''}$-CH_3). ^{13}C NMR ($CDCl_3$) δ: 172.17 (C-4), 153.18 (C-8a), 152.79 (C-2), 145.63 (C-5′), 143.82 (C-2′), 137.90 (C-4a), 132.96 (C-7), 131.85 (C-3″), 130.42 (C-6), 124.23 (C-5), 123.50 (C-3), 120.80 (C-2″), 119.02 (C-8), 118.13 (C-3′), 108.62 (C-4′), 68.99 (C-1″), 18.05 (C-4″), 25.86 (3″-CH_3). Anal. calcd. for $C_{18}H_{15}ClO_4$: C 65.36, H 4.57; found: C 65.24, H 4.52.

*6-Chloro-2-(furan-3-yl)-3-(3-phenylallyloxy)-4*H*-chromen-4-one (3g)*

Yield 68%, light brown solid; mp 91–94 °C (EtOH). IR ν_{max} (cm^{-1}): 1648.4 (C=O), 1617(C=C). ^{1}H NMR ($CDCl_3$) δ: 8.36 (1H, t/dd, $J_{2',5'}$ = 1.5 Hz, $J_{2',4'}$ = 1.8 Hz, H-2′), 8.22 (1H, d, J_m = 2.4 Hz, H-5), 7.60 (1H, dd, J_m = 2.4 Hz, J_o = 9.0 Hz, H-7), 7.56 (1H, t, $J_{5',2'}$ = 1.5 Hz, $J_{5',4'}$ = 1.8 Hz, H-5′), 7.46 (1H, d, J_o = 9.0 Hz, H-8), 7.29–7.35 (5H, m, H-2‴-6‴), 7.03 (1H, t, $J_{4',2'}$ = 1.8 Hz, $J_{4',5'}$ = 1.8 Hz, H-4′), 6.70 (1H, d, $J_{3',2'}$ = 15.9 Hz, H-3″), 6.44 (1H, td, $J_{2',3'}$ = 15.9 Hz, $J_{2',1'}$ = 6.6 Hz, H-2″), 4.96 (2H, d, $J_{1',2'}$ = 6.6 Hz, H-1″). ^{13}C NMR ($CDCl_3$) δ: 172.94 (C-4), 153.21 (C-8a), 152.03 (C-2), 145.50 (C-5′), 143.67 (C-2′), 136.26 (C-1‴), 134.61 (C-7), 133.44 (C-3″), 130.66(C-4‴), 128.57 (C-2‴, C-6‴), 128.05 (C-3), 126.70 (C-3‴, C-5‴), 125.26 (C-6), 125.14 (C-2″), 125.14 (C-4a), 124.29 (C-5), 119.54 (C-8), 117.91 (C-1′), 108.77 (C-4′), 72.48 (C-1″). Photoirradiation of chromones 3a–3j

*Photolysis of 6-chloro-2-(furan-3-yl)-3-methoxy-4*H*-chromen-4-one (3a)*

A methanolic solution (150 mL) of chromone **3a** (200 mg, 0.72 mmol) was irradiated with light from a 125 W Hg vapor lamp in a pyrex reactor under nitrogen atmosphere for 45 min. The removal of the solvent left a gummy solid, which was chromatographed to yield **4a**.

*Compound **4a***

Yield 45%, white solid; mp 185–188 °C (EtOH). IR ν_{max} (cm^{-1}): 1649.7 (C=O). ^{1}H NMR ($CDCl_3$) δ: 8.23 (1H, d, J_m = 2.4 Hz, H-7), 7.58 (1H, dd, J_m = 2.4 Hz, J_o = 9.0 Hz, H-9), 7.40 (1H, d, J_o = 9.0 Hz, H-10), 6.46 (1H, dd/t, $J_{2,11b}$ = 2.1 Hz, $J_{2,1}$ = 2.4 Hz, H-2), 5.28 (1H, dd/t, $J_{1,2}$ = 2.4 Hz, $J_{1,11b}$ = 2.7 Hz, H-1), 5.10 (1H, d{dd}, $J_{3a,4a}$ = 2.4 Hz, $J_{3a,4b}$ = 9.0 Hz, $J_{3a,11b}$ = 10.2 Hz, H-3a), 4.34 (1H, dd, $J_{11b,1}$ = 2.7 Hz, $J_{11b,3a}$ = 10.2 Hz, H-11b), 4.14–4.07 (2H, m, H-4a, H-4b). ^{13}C NMR ($CDCl_3$) δ: 170.52 (C-6), 153.58 (C-10a), 151.94 (C-11a), 148.39 (C-2), 138.83 (C-6a), 133.47 (C-9), 130.57 (C-8), 125.45 (C-7), 124.73 (C-5a), 119.48 (C-10), 100.60 (C-1), 78.73 (C-4), 65.88 (C-3a), 40.83 (C-11b). Anal. calcd. for $C_{14}H_9ClO_4$: C 60.78, H 3.28; found: C 63.58, H 3.34. Mass (*m*/*z*): 276 (M^+, 100%).

*Photolysis of 6-chloro-3-ethoxy-2-(furan-3-yl)-4*H*-chromen-4-one (3b)*

A methanolic solution of **3b** (0.20 g, 0.7 mmol) on photolysis for 45 min furnished **4b** and **4b**′. These isomeric photoproducts were separated from the starting substrate **3b** by column chromatography. They were further separated from each other by preparative TLC.

*Compound **4b***

Yield 22%, white solid; mp 174–176 °C (EtOH). IR ν_{max} (cm^{-1}): 1651.0 (C=O). ^{1}H NMR ($CDCl_3$) δ: 8.24 (1H, d, J_m = 2.4 Hz, H-7), 7.58 (1H, dd, J_m = 2.4 Hz, J_o = 9.0 Hz, H-9), 7. 41 (1H, d, J_o = 9.0 Hz, H-10), 6.44 (1H, d, $J_{2,1}$ = 2.7 Hz, H-2), 5.36 (1H, dd/t, $J_{1,2}$ = 2.7 Hz, $J_{1,11b}$ = 2.7 Hz, H-1), 4.63 (1H, dd, $J_{3a,11b}$ = 7.8 Hz, $J_{3a,4}$ = 8.4 Hz, H-3a), 4.23 (1H, dd, $J_{11b,1}$ = 2.7 Hz, $J_{11b,3a}$ = 7.8 Hz, H-11b), 3.88 (1H, q{d}, J_{vic} = 6.6 Hz, $J_{4,3a}$ = 8.4 Hz, H-4), 1.65 (3H, d, J_{vic} = 6.6 Hz, C_4-CH_3). ^{13}C NMR ($CDCl_3$) δ: 171.10 (C-6),

153.63 (C-10a), 151.11 (C-11a), 147.27 (C-2), 138.22 (C-6a), 133.43 (C-9), 130.51 (C-8), 125.49 (C-7), 124.79 (C-5a), 119.46 (C-10), 100.69 (C-1), 80.69 (C-4), 71.72 (C-3a), 41.78 (C-11b), 17.69 (C_4-CH_3). Anal. calcd. for $C_{15}H_{11}ClO_4$: C 61.98, H 3.81; found: C 61.90, H 3.80. Mass (*m*/*z*): 290 (M^+, 100%).

*Compound **4b′***

Yield 11%, white solid; mp 160–162 °C (EtOH). IR $\nu_{max.}$ (cm^{-1}): 1652.0 (C=O). ^1H NMR ($CDCl_3$) δ: 8.22 (1H, d, J_m = 2.4 Hz, H-7), 7.56 (1H, dd, J_m = 2.4 Hz, J_o = 9.0 Hz, H-9), 7.38 (1H, d, J_o = 9.0 Hz, H-10), 6.44 (1H, d, $J_{2,1}$ = 2.7 Hz, H-2), 5.25 (1H, d, $J_{1,2}$ = 2.7 Hz, H-1), 4.91 (1H, d, $J_{3a,11b}$ = 9.9 Hz, H-3a), 4.15 (1H, q, J_{vic} = 6.3 Hz, H-4), 4.05 (1H, d, $J_{11b,3a}$ = 9.9 Hz, H-11b), 1.55 (3H, d, J_{vic} = 6.3 Hz, C_4-CH_3). Anal. calcd. for $C_{15}H_{11}ClO_4$: C 61.98, H 3.81; found: C 61.87, H 3.78. Mass (*m*/*z*): 290 (M^+, 100%).

Photolysis of 6-chloro-2-(furan-3-yl)-3-isopropyloxy-4H-chromen-4-one (3c)

A methanolic solution of **3c** (0.20 g, 0.66 mmol) on photolysis for 45 min furnished **4c**.

*Compound **4c***

Yield 48%, white solid; mp 165–167 °C ($CHCl_3$-EtOH). IR ν_{max} (cm^{-1}): 1655.8 (C=O). ^1H NMR ($CDCl_3$) δ: 8.23 (1H, d, J_m = 2.7 Hz, H-7), 7.56 (1H, dd, J_m = 2.7 Hz, J_o = 9.0 Hz, H-9), 7.38 (1H, d, J_o = 9.0 Hz, H-10), 6.43 (1H, dd, $J_{2,11b}$ = 1.8 Hz, $J_{2,1}$ = 3.0 Hz, H-2), 5.30 (1H, dd/t, $J_{1,2}$ = 3.0 Hz, $J_{1,11b}$ = 3.0 Hz, H-1), 4.64 (1H, d, $J_{3a,11b}$ = 9.3 Hz, H-3a), 3.95 (1H, dd{d}/m, $J_{11b,2}$ = 1.8 Hz, $J_{11b,1}$ = 3.0 Hz, $J_{11b,3a}$ = 9.3 Hz, H-11b), 1.62 (3H, s, C_4-CH_3b), 1.39 (3H, s, C_4-CH_3a). ^{13}C NMR ($CDCl_3$) δ: 173.00 (C-6), 159.00 (C-10a), 152.00 (C-11a), 148.20 (C-2), 135.00 (C-6a), 133.18 (C-9), 130.00 (C-8), 125.47 (C-7), 125.00 (C-5a), 119.39 (C-10), 100.49 (C-1), 85.99 (C-3a), 75.37 (C-4), 39.73 (C-11b), 23.94 (C_4-*C*H_3b), 23.38 (C_4-*C*H_3a). Anal. calcd. for $C_{16}H_{13}ClO_4$: C 63.06, H 4.30; found: C 63.01, H 4.25. Mass (*m*/*z*): 304/306 (M^+, 100%).

Photolysis of 3-allyloxy-6-chloro-2-(furan-3-yl)-4H-chromen-4-one (3d)

A methanolic solution of **3d** (0.20 g, 0.66 mmol) on photolysis for 45 min furnished **4d**.

*Compound **4d***

Yield 29%, white solid; mp 145–146 °C (EtOH). IR ν_{max} (cm^{-1}): 1637(C=O). ^1H NMR ($CDCl_3$) δ: 8.17 (1H, d, J_m = 2.4 Hz, H-7), 7.51 (1H, dd, J_m = 2.4 Hz, J_o = 9.0 Hz, H-9), 7.34 (1H, d, J_o = 9.0 Hz, H-10), 6.40 (1H, d, $J_{2,1}$ = 2.7 Hz, H-2), 5.93 (1H, ddd, J_{vic} = 5.1 Hz, J_{trans} = 17.4 Hz, J_{cis} = 10.8 Hz, H-1′), 5.47 (1H, d, J_{trans} = 17.4 Hz, H-2′b), 5.35 (1H, d, J_{cis} = 10.8 Hz, H-2′a), 5.30 (1H, t, $J_{1,2}$ = 2.7 Hz, $J_{1,11b}$ = 2.7 Hz, H-1), 4.77 (1H, dd $J_{3a,4}$ = 6.9 Hz, $J_{3a,11b}$ = 9.6 Hz, H-3a), 4.10 (1H, dd, $J_{11b,1}$ = 2.7 Hz, $J_{11b,3a}$ = 9.6 Hz, H-11b), 4.40 (1H, dd, $J_{4,3a}$= 6.9 Hz, $J_{4,1'}$ = 5.1 Hz, H-4). ^{13}C NMR ($CDCl_3$) δ: 172.00 (C-6), 151.61 (C-10a), 149.35 (C-11a), 145.57 (C-2), 135.47 (C-6a), 131.49 (C-9), 130.76 (C-1′), 128.59 (C-8), 123.51 (C-7), 122.79 (C-5a), 117.67 (C-10), 117.50 (C-2′), 98.77 (C-1), 77.91 (C-4), 73.23 (C-3a), 39.11 (C-11b). Anal. calcd. for $C_{16}H_{11}ClO_4$: C 63.48, H 3.66; Found: C 63.46, H 3.60. Mass (*m*/*z*): 302 (M^+, 100%).

Photolysis of 6-chloro-2-(furan-3-yl)-3-(2-methylallyloxy)-4H-chromen-4-one (3e)

A methanolic solution of **3e** (0.20 g, 0.63 mmol) on photolysis for 45 min furnished **4e**.

*Compound **4e***

Yield 24%, white solid; mp 196–200 °C ($CHCl_3$-EtOH). IR ν_{max} (cm^{-1}): 1641 (C=O). ^1H NMR ($CDCl_3$) δ: 8.22 (1H, d, J_m = 2.4 Hz, H-7), 7.59 (1H, dd, J_m = 2.4 Hz, J_o = 9.0 Hz, H-9), 7. 41 (1H, d, J_o = 9.0 Hz, H-10), 6.47 (1H, d, $J_{2,1}$ = 2.7 Hz, H-2), 5.37 (1H, s, H-2′b), 5.17 (1H, s, H-2′a), 5.13 (1H, dd/t, $J_{1,2}$ = 2.7 Hz, $J_{1,11b}$ = 2.7 Hz, H-1), 4.63 (1H, dd, $J_{3a,11b}$ = 9.3 Hz, $J_{3a,4}$ = 7.5 Hz, H-3a), 4.31 (1H, q{d}, J_{vic} = 6.6 Hz, $J_{4,3a}$ = 7.5 Hz, H-4), 3.88 (1H, dd, $J_{11b,1}$ = 2.7 Hz, $J_{11b,3a}$ = 9.3 Hz, H-11b), 1.85 (3H, s, $C_{1'}$-CH_3). ^{13}C NMR ($CDCl_3$) δ: 171.80 (C-6), 152.68 (C-10a), 149.05 (C-11a), 146.27 (C-2), 135.82 (C-6a), 133.40 (C-9), 140.28 (C-1′), 129.51 (C-8), 126.49 (C-7), 122.70 (C-5a), 118.06 (C-10), 108.45 (C-2′), 99.69 (C-1), 80.10 (C-4), 72.70 (C-3a), 40.15 (C-11b), 18.69 (1′-*C*H_3). Anal. calcd. for $C_{17}H_{13}ClO_4$: C 64.46, H 4.14; found: C 64.34, H 4.12. Mass (*m*/*z*): 316 (M^+, 100%).

Photolysis of 6-chloro-2-(furan-3-yl)-3-(3-methylbut-2-enyloxy)-4H-chromen-4-one (3f)

A methanolic solution of **3f** (0.20 g, 0.6 mmol) on photolysis for 45 min furnished **4f**.

*Compound **4f***

Yield 31%, light brown solid; mp 99–102 °C ($CHCl_3$-EtOH). IR ν_{max} (cm^{-1}): 1637.2 (C=O). ^1H NMR ($CDCl_3$) δ: 8.23 (1H, d, J_m = 2.4 Hz, H-7), 7.58 (1H, dd, J_m = 2.4 Hz, J_o = 9.0 Hz, H-9), 7.44 (1H, d, J_o = 9.0 Hz, H-10), 6.45 (1H, d, $J_{2,1}$ = 2.7 Hz, H-2), 5.49 (1H, dd/t, $J_{1,2}$ = 2.7 Hz, $J_{1,11b}$ = 3.0 Hz, H-1), 5.37 (1H, dd, $J_{1',4}$ = 5.7 Hz, J_{allyl} = 1.5 Hz, H-1′), 4.75 (1H, dd, $J_{3a,11b}$ = 9.0 Hz, $J_{3a,4}$ = 7.8 Hz, H-3a), 4.58 (1H, dd, $J_{4,3a}$ = 7.8 Hz, $J_{4,1'}$ = 5.7 Hz, H-4), 4.21 (1H, dd, $J_{11b,1}$ = 3.0 Hz, $J_{11b,3a}$ = 9.0 Hz, H-11b), 1.80 (3H, d, J_{allyl} = 1.5 Hz, $C_{2'}$-CH_3b), 1.76 (3H, s, $C_{2'}$-CH_3a). ^{13}C NMR ($CDCl_3$) δ: 172.50 (C-6), 153.41 (C-10a), 150.30 (C-11a), 144.28 (C-2), 135.00 (C-6a), 132.78 (C-9), 132.70 (C-2′), 128.00 (C-8), 123.20 (C-1′), 123.50 (C-7), 123.05 (C-5a), 119.19 (C-10), 101.79 (C-1), 79.80 (C-3a), 70.37 (C-4), 39.97 (C-11b), 25.20 (2′-*C*H_3b), 19.20 (2′-*C*H_3a). Anal. calcd. for $C_{18}H_{15}ClO_4$: C 65.36, H 4.57; found: C 65.28, H 4.51. Mass (*m*/*z*): 330 (M^+, 100%).

Photolysis of 6-chloro-2-(furan-3-yl)-3-(3-phenylallyloxy)-4H-chromen-4-one (3g)

A methanolic solution of **3g** (0.20 g, 0.53 mmol) on photolysis for 45 min furnished three photoproducts: **4g**, **5g**, and **6g**.

*Compound **4g***

Yield 16%, light yellow solid; mp 155–157 °C ($CHCl_3$-EtOH). IR ν_{max} (cm^{-1}): 1639.6 (C=O). ^1H NMR ($CDCl_3$) δ: 8.25 (1H, d, J_m = 2.7 Hz, H-7), 7.58 (1H, dd, J_m = 2.7 Hz, J_o = 9.0 Hz, H-9), 7.41 (1H, d, J_o = 9.0 Hz, H-10), 7.28–7.36 (5H, m, H-2″-6″), 6.85 (1H, d, $J_{2',1'}$ = 16.5 Hz, H-2′),

6.50 (1H, dd/t, $J_{2,11b}$ = 2.1 Hz, $J_{2,1}$ = 2.4 Hz, H-2), 6.33 (1H, dd, $J_{1',4}$ = 6.0 Hz, $J_{1',2'}$ = 16.5 Hz, H-1′), 5.40 (1H, dd/t, $J_{1,11b}$ = 2.4 Hz, $J_{1,2}$ = 2.4 Hz, H-1), 4.91 (1H, dd, $J_{3a,4}$ = 7.2 Hz, $J_{3a,11b}$ = 9.6 Hz, H-3a), 4.58 (1H, t, $J_{4,3a}$ = 7.2 Hz, $J_{4,1'}$ = 6.0 Hz, H-4), 4.25 (1H, t{d}, $J_{11b,2}$ = 2.1 Hz, $J_{11b,1}$ = 2.4 Hz, $J_{11b,3a}$ = 9.6 Hz, H-11b). ^{13}C NMR ($CDCl_3$) δ: 172.13 (C-6), 154.05 (C-10a), 151.91 (C-11a), 144.50 (C-2), 138.44 (C-6a), 137.20 (C-1″), 130.78 (C-2′), 129.65 (C-9), 129.06 (C-3″, C-5″), 128.00 (C-4″), 127.77 (C-2″, C-6″), 126.02 (C-1′), 125.81 (C-7), 125.54 (C-8), 124.37 (C-5a), 118.06 (C-10), 98.88 (C-1), 77.56 (C-3a), 75.00 (C-4), 38.75 (C-11b). Anal. calcd. for $C_{22}H_{15}ClO_4$: C 69.75, H 3.99; found: C 69.60, H 3.95. Mass (*m*/*z*): 378 (M^+, 100%).

Compound ***5g***

Yield 10%, light yellow solid; mp 181–182 °C ($CHCl_3$-EtOH). IR ν_{max} (cm^{-1}): 1642 (C=O). ^{1}H NMR ($CDCl_3$): 8.23 (1H, d, J_m = 2.7 Hz, H-7), 7.58 (1H, dd, J_m = 2.7 Hz, J_o = 9.0 Hz, H-9), 7.41 (1H, d, J_o = 9.0 Hz, H-10), 7.28–7.36 (5H, m, H-2″-6″), 6.93 (1H, d, $J_{2',1'}$ = 11.7 Hz, H-2′), 6.39 (1H, dd/t, $J_{2,11b}$ = 2.4 Hz, $J_{2,1}$ = 2.4 Hz, H-2), 5.83 (1H, dd, $J_{1',4}$ = 6.0 Hz, $J_{1',2'}$ = 11.7 Hz, H-1′), 5.35 (1H, dd/t, $J_{1,11b}$ = 2.4 Hz, $J_{1,2}$ = 2.4 Hz, H-1), 4.72 (1H, dd, $J_{3a,4}$ = 7.2 Hz, $J_{3a,11b}$ = 9.0 Hz, H-3a), 4.58 (1H, t, $J_{4,3a}$ = 7.2 Hz, $J_{4,1'}$ = 6.0 Hz, H-4), 4.25 (1H, t{d}, $J_{11b,2}$ = 2.4 Hz, $J_{11b,1}$ = 2.4 Hz, $J_{11b,3a}$ = 9.6 Hz, H-11b). ^{13}C NMR ($CDCl_3$) δ: 172.92 (C-6), 154.56 (C-10a), 151.21 (C-11a), 144.59 (C-2), 137.94 (C-6a), 138.88 (C-1″), 132.05 (C-2′), 129.42 (C-9), 129.86 (C-3″, C-5″), 128.05 (C-4″), 127.95 (C-2″, C-6″), 126.22 (C-1′), 126.01 (C-7), 125.54 (C-8), 124.72 (C-5a), 119.08 (C-10), 98.76 (C-1), 77.25 (C-3a), 75.84 (C-4), 39.08(C-11b). A chromatography-free synthesis of (2*S*,12*Z*)-2-acetoxy-12-heptadecene — The major sex pheromone component of the pistachio twig borer moth (*Kermania pistaciella*)

Robert Britton, Grigori Khaskin, and Gerhard Gries

Abstract: Recently, (2*S*,12*Z*)-2-acetoxy-12-heptadecene was identified as the major sex pheromone component of the pistachio twig borer moth, *Kermania pistaciella*, one of the most serious insect pests of pistachio plantations in Iran and Turkey. In field studies, an attract-and-kill formulation containing (2*S*,12*Z*)-2-acetoxy-12-heptadecene demonstrated efficacy in reducing damage caused by *K. pistaciella* and may become a widely-used, earth-friendly tactic for control of this insect in commercial pistachio production. To further develop this technology, a cost-effective, chromatography-free synthesis of (2*S*,12*Z*)-2-acetoxy-12-heptadecene was required and is described in this communication.

Key words: synthesis, pheromone, (2*S*,12*Z*)-2-acetoxy-12-heptadecene, chromatography-free.

Résumé : On a récemment identifié le (2*S*,12*Z*)-2-acétoxy-12-heptadécène comme le composant principal de la phéromone sexuelle de la pyrale du rameau de pistaches, *Kermania pistaciella*, un lépidoptère reconnu comme l'un des insectes les plus nuisibles pour les plantations de pistaches d'Iran et de Turquie. Dans des études sur le terrain, une formulation destinée à attirer et à tuer contenant du (2*S*,12*Z*)-2-acétoxy-12-heptadécène ont démontré son efficacité à réduire les dommages causés par *K. pistaciella*; il pourrait éventuellement être utilisé comme tactique écologiquement correcte et largement utilisée pour contrôler cet insecte dans la production commerciale de la pistache. Afin d'améliorer cette technologie, il était nécessaire de pouvoir accès à une méthode de synthèse du (2*S*,12*Z*)-2-acétoxy-12-heptadécène n'impliquant pas de chromatographie et efficace d'un point de vue coût et c'est ce qui est décrit dans ce travail.

Mots-clés : synthèse, phéromone, (2*S*,12*Z*)-2-acétoxy-12-heptadécène, sans chromatographie.

[Traduit par la Rédaction]

Introduction

The pistachio twig borer moth (*Kermania pistaciella*) is a major insect pest in pistachio plantations in Turkey and Iran.[1] Each year, female *K. pistaciella* lay up to 60 eggs near the shoot tips and fruit clusters on the pistachio tree and the larvae then bore into and feed upon terminal buds, twigs and shoots, resulting in serious economic damage by fruit wilt and twig weakening.[2] Recently, employing gas chromatographic-electroantennographic detection (GC-EAD) and GC-mass spectrometric analyses of extracts from the pheromone gland of female *K. pistaciella*, (2*S*,12*Z*)-2-acetoxy-12-heptadecene (**1**, Fig. 1) was identified as the major sex pheromone component.[2,3] Exploiting its inherent attractive ability, in a 75 ha field test, plots treated with an attract-and-kill[4] formulation containing **1** (approximately 0.6 mg/tree) had significantly fewer larvae-infested fruit branches than insecticide-treated plots or control plots.[2,5] One study[2] also revealed that the attractiveness of **1** was significantly reduced by the presence of the *R*-enantiomer ((–)-**1**) and consequently enantioselective syntheses of **1** were developed that relied on an enzymatic acetylation of (±)-(*Z*)-12-heptadecen-2-ol[2] or a hydrolytic kinetic resolution of (±)-1,2-epoxy-12-heptadecyne[3] to construct the desired antipode. While these processes provide access to (+)-**1** (15%–45% overall yield), necessary chromatography and loss of >50% of the material following enzymatic/kinetic resolution realistically preclude their application to large-scale production. Thus, further development of this attract-and-kill formulation will rely on an economic and scalable synthesis of optically pure **1**. With this in mind, we report a high-yielding, chromatography-free synthesis of **1** designed to support further field-testing, as well as the potential commercialization of this earth-friendly technology.

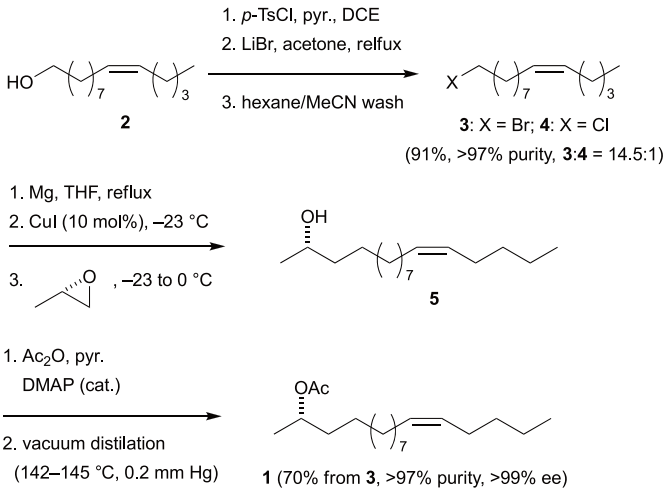
Results and discussions

As detailed in Scheme 1, the synthesis of **1** initiated with the conversion of commercially available (*Z*)-9-tetradecen-1-ol (**2**)[6] into the corresponding alkyl bromide. Thus, treatment of **2** with *p*-TsCl and pyridine in reagent grade DCE provided a crude tosylate (not shown) that was subsequently reacted with LiBr in refluxing acetone to afford (*Z*)-1-bromotetradec-9-ene (**3**). Not surprisingly, the alkyl bromide produced via this route was contaminated with significant amounts of *p*-TsOH and derivatives of this substance. Even following repeated aqueous extractions (neutral, basic, or acidic) we were unable to isolate **3** in >60% purity (as determined by GC analysis). Unfortunately, the presence of these TsCl-derived impurities had a detrimental effect on subsequent Grignard formation from **3** and (or) coupling of the Grignard reagent with (*S*)-propylene oxide. Bearing in mind our ultimate objective, it became essential to develop a non-chromatographic method to remove *p*-TsOH-derived impurities from **3**. As indicated in Scheme 1, a straightforward solution to this problem was eventually discovered that exploits the immiscibility of hexane and MeCN.[7] Thus, extracting a solution of crude **3** in hexane with MeCN effectively removed these impurities and, following concentration of the hexane layer, provided a 14.5:1 mixture of **3** and the corresponding chlorotetradecene **4** with a combined purity of >97%. Formation of the corresponding Grignard reagents from this mixture of alkyl halides proceeded smoothly in refluxing degassed THF.[8] This mixture was subsequently cooled (–30 °C) and treated with a catalytic amount of CuI followed by (*S*)-propylene oxide,[9] while maintaining the reaction temperature between –23 and –15 °C. Following standard workup, the crude product **5**[10,11] was dissolved in pyridine and treated with acetic anhydride and a catalytic amount of DMAP to afford (+)-**1**. Final purification by vacuum distillation provided (2*S*,12*Z*)-2-acetoxy-12-heptadecene (**1**) as a colorless oil (>97% purity, >99% enantiomeric purity).[12]

Scheme 1. Synthesis of the *K. pistaciella* sex pheromone component **1**.



Conclusion

In summary, we have developed a chromatography-free, high yielding (63% overall yield) four-step synthesis of (+)-**1** from readily available chemicals. Of note is the practical method identified to remove organic impurities of divergent polarity on a large scale that exploits the immiscibility of MeCN and hexane, and proved crucial to the success of this process. Based on these efforts, sufficient amounts of **1** have been produced to support further development of earth-friendly pheromone-based tactics to control *K. pistaciella* populations in pistachio plantations in Turkey and Iran.[13]

Experimental

General methods

All reactions were performed in oven-dried glassware. THF was distilled from sodium/benzophenone. Commercial DCE, acetone, and pyridine (reagent grade) were used without further purification. All other reagents were used as supplied. NMR spectra were recorded using deuteriochloroform ($CDCl_3$) as the solvent. Signal positions (δ) are given in parts per million from tetramethylsilane (δ: 0) and were measured relative to the signal of $CDCl_3$ (^{1}H NMR δ: 7.26; ^{13}C NMR δ: 77.0). ^{1}H NMR spectra were recorded on a Varian Inova 500 (500 MHz) and ^{13}C NMR spectra were recorded on a Varian Inova 500 (125 MHz). Optical rotation was measured on a Perkin Elmer Polarimeter 341.

Synthesis of (*Z*)-1-bromotetradec-9-ene (3)

To a stirred solution of (*Z*)-9-tetradecen-1-ol (**2**) (25.0 g, 0.118 mol) in DCE (200 mL) at room temperature (RT) was added *p*-TsCl (29.1 g, 0.153 mol) followed by pyridine (14.3 mL, 0.177 mol), and the reaction mixture was stirred for 20 h. After this time, *p*-TsCl (8.9 g, 0.047 mol) and pyridine (4.7 mL, 0.058 mol) were added, and the reaction was stirred for an additional 20 h. The reaction mixture was filtered through a Büchner funnel to remove the precipitate, and the filtrate was concentrated. The crude residue was dissolved in hexanes (200 mL) and washed successively with 1 N HCl (100 mL), saturated aqueous $NaHCO_3$ (100 mL), and brine (100 mL) and concentrated at RT. The crude concentrate was dissolved in acetone (200 mL), LiBr (30.8 g, 0.354 mol) was added, and the resulting solution was heated at reflux for 3 h. After this time, the reaction mixture was filtered through a Büchner funnel, and the filtrate was concentrated to provide an oily residue that was dissolved in hexane (200 mL), washed with H_2O (100 mL) and MeCN (2 × 100 mL), and concentrated. The combined MeCN washes were extracted with hexane (2 × 50 mL) and these hexane extracts were combined, washed with acetonitrile (2 × 50 mL), and concentrated. Combination of the hexane concentrates afforded a 14.5:1 mixture of **3/4** (28.9 g, 91%) as a colorless oil. The purity of this material was determined to be >97% by GC analysis.[14]

Synthesis of (2*S*,12*Z*)-2-acetoxy-12-heptadecene (1)

A solution of a 14.5:1 mixture of **3/4** (13.7 g, 0.051 mol) in degassed THF (10 mL) was added to a vigorously stirred suspension of magnesium turnings (2.4 g, 0.099 mol, activated with a crystal of iodine) in degassed THF[8] (60 mL), and the resulting mixture was heated at reflux for 2.5 h. After this time, the reaction mixture was cooled to –30 °C, and CuI (93 mg, 4.9 mmol) was added in one portion and

the resulting mixture was warmed to –23 °C. (*S*)-Propylene oxide (4.8 mL, 0.069 mol) was then added dropwise, while maintaining the reaction temperature between –23 °C and –15 °C. After 0.5 h, the black mixture was warmed to 0 °C and treated with saturated aqueous NH_4Cl. After a further 1 h of stirring, the mixture was extracted with Et_2O/pentane (1:1, 60 mL). The organic layer was then washed with H_2O (25 mL) and brine (25 mL), dried ($MgSO_4$), and concentrated to afford 14.1 g of a crude mixture containing (2*S*,12*Z*)-12-heptadecen-2-ol.[10,11] To a solution of this crude mixture in pyridine (6.45 mL) and Ac_2O (6.60 mL) was added a catalytic amount of DMAP (2 mg) and the reaction mixture was stirred for 2 h at RT. After this time, H_2O (50 mL) and Et_2O/pentane (1:1, 60 mL) were added and the organic layer was removed and washed sequentially with 2 N HCl (25 mL), H_2O (25 mL), and saturated aqueous $NaHCO_3$ (25 mL), then dried (Na_2SO_4) and concentrated. Purification of the crude product by vacuum distillation (0.2–0.25 mm Hg) provided a 9.54 g fraction that boiled at 142–145 °C containing (2*S*,12*Z*)-2-acetoxy-12-heptadecene (**1**) (>97% purity, 66.5% yield from bromide).[15] $[\alpha]_D^{20}$ = +0.83° (*c* 4.5; $CHCl_3$). Anal. calcd. for $C_{19}H_{36}O_2$ (%): C 80.24, H 13.47; found: C 79.96, H 13.24.[12]

(10) Analysis of the crude mixture by GC and ^{1}H NMR spectroscopy indicated the presence (and concentration) of the following compounds: (2*S*,12*Z*)-12-heptadecen-2-ol (73%), (*Z*)-9-tetradecen-1-ol (3%), (*Z*)-1,9-tetradecadiene (2%), (*Z*)-1-chloro-9-tetradecene (2%), (5*Z*,23*Z*)-5,23-octacosadiene (10%), (*Z*)-5-tetradecene (10%).

(11) While it proved possible to remove (*Z*)-1-chloro-9-tetradecene and (5*Z*,23*Z*)-5,23-octacosadiene from this mixture by extraction into pentane using a MeCN/CH_3OH/pentane (1:1:1) mixture, the presence of nonvolatiles (e.g., (5*Z*,23*Z*)-5,23-octacosadiene) proved beneficial in the final distillation of **1**.

(12) The enantiomeric purity of **1** was determined by chiral GC analysis following the procedure described in ref. 2.

(13) Following the reaction sequence described in Scheme 1, multi-kg amounts of **1** have been produced to support the commercialization of this technology.

(14) The spectral data derived from **3** were consistent with those reported in Yamagiwa, Y.; Ohashi, K.; Sakamoto, Y.; Hirakawa, S.; Kamikawa, T.; Kubo, I. *Tetrahedron* **1987**, *43*, 3387. doi:10.1016/S0040-4020(01)81629-X.

(15) A further 0.5 g of (2*S*,12*Z*)-2-acetoxy-12-heptadecene could be recovered by flash chromatography from a combination of lower and higher boiling fractions.

^{31}P NMR and ESI-MS studies of metal ion-phosphorus pesticide residue complexes

In Sun Koo, Dildar Ali, Kiyull Yang, Yong Park, Abdelhamid Esbata, Gary W. vanLoon, and Erwin Buncel

Abstract: ^{31}P NMR and ESI-MS structural studies have been carried out for *O*,*O*-dimethylphosphorothioate anion (PA^-) interacting with Ag^+, Hg^{2+}, and Na^+ cations. Evidence is presented for the formation of $PA^-\cdots Ag^+$ and $PA^-\cdots Hg^{2+}$ metal complexes and for ionic PA^-Na^+, with ^{31}P chemical shift values of 43, 40, and 65 ppm, respectively. The ^{31}P chemical shifts for $PA^-\cdots Ag^+$ and $PA^-\cdots Hg^{2+}$ complexes exhibit an initial sharp rise as the $[Ag^+]/[PA]$ and $[Hg^{2+}]/[PA]$ ratio increases from 0 to 1.0 and 0 to 0.5, respectively, and remain almost constant beyond these ratios. These results indicate the formation of 1:1 $PA^-\cdots Ag^+$ and 2:1 $(PA^-)_2\cdots Hg^{2+}$ complexes. Electrospray ionization mass spectroscopy (ESI-MS) revealed peaks corresponding to $[O\text{-}P(=S)(OCH_3)_2 + Ag + H]^+$ and $\{2[O\text{-}P(=S)(OCH_3)_2] + Hg + H\}^+$ for PAH interacting with Ag^+ and Hg^{2+}, supporting the 1:1 $PA^-\cdots Ag^+$ and 2:1 $(PA^-)_2\cdots Hg^{2+}$ stoichiometry. The experimental results support the predominance of species with greater P=O double bond and P–S single bond character, relative to P-O/P=S. Our results on ^{31}P NMR chemical shifts have a bearing on the use of ^{31}P chemical shifts as a tool for organophosphorus pesticide identification.

Key words: ^{31}P NMR, ESI-MS, metal ion-phosphorus pesticide residue complexes, *O*,*O*-dimethylphosphorothioate anion.

Résumé : Faisant appel à la RMN du ^{31}P et à la spectrométrie de masse avec ionisation par électronébulisation (SM-IEN), on a procédé à des études sur de structures de l'anion *O*,*O*-diméthophosphorothionate (PA^-) interagissant avec des cations Ag^+, Hg^{2+} et Na^+. On présente des données relatives à la formation de complexes métalliques $PA^-\cdots Ag^+$ et PA^-Hg^{2+} et du produit ionique PA^-Na^+ pour lesquels les valeurs des déplacements chimiques du ^{31}P sont respectivement de 43, 40 et 65 ppm. Les déplacements chimiques du ^{31}P pour les complexes métalliques $PA^-\cdots Ag^+$ et PA^-Hg^{2+} présentent une augmentation initiale abrupte lorsqu'on augmente les rapports de $[Ag^+]/[PA]$ et $[Hg^{2+}]/(PA)$ respectivement de 0 à 1,0 et de 0 à 0,5 alors que les valeurs deviennent constantes au-delà de ces rapports. Ces résultats indiquent qu'il y a formation de complexes 1:1 $PA^-\cdots Ag^+$ et 2:1 $(PA^-)_2\cdots Hg^{2+}$. Pour le PHA interagissant respectivement avec Ag^+ et Hg^{2+}, la spectrométrie de masse avec ionisation par électronébulisation comporte des pics correspondant aux espèces $[O\text{–}P(=S)(OCH_3)_2\text{+Ag+H}]^+$ et $[2\{O^-P(=S)(OCH_3)_2\}\text{+Hg+H}]$ qui supportent la stoechiométrie 1:1 $PA^-\cdots Ag^+$ et 2:1 $(PA^-)_2\cdots Hg^{2+}$. Les résultats expérimentaux sont en accord avec le fait que, par rapport au rapport P–O/P=S, il existe une prédominance d'espèces avec un caractère de double liaison P=O par rapport aux espèces avec un caractère de simple liaison P–S. Nos résultats sur les déplacements chimiques du ^{31}P en RMN pourraient avoir une incidence pour ceux qui voudraient utiliser les déplacements chimiques du ^{31}P comme outil pour identifier les pesticides du phosphore.

Mots-clés : RMN du ^{31}P, SM-IEN, ion métallique, complexes résiduels de pesticides à base de phosphore, anion *O*,*O*-diméthophosphorothionate.

[Traduit par la Rédaction]

Introduction

Due to their biological and environmental importance, the degradation of organophosphorus (OP) pesticides has been studied extensively over the past several decades.[1] In addition to investigation of the pathways and mechanisms of degradation, metal ion-promoted hydrolysis has also been of interest.[1e,1f] Organophosphorus esters are known to undergo a variety of hydrolysis mechanisms. At the phosphorus centre, three possible mechanisms have been identified: unimolecular nucleophilic substitution, $S_N1(P)$, formation of a pentacoordinate intermediate (addition-elimination), and bimolecular concerted nucleophilic substitution, $S_N2(P)$.[1,2] Equation [1] shows the general reaction for phosphoro-

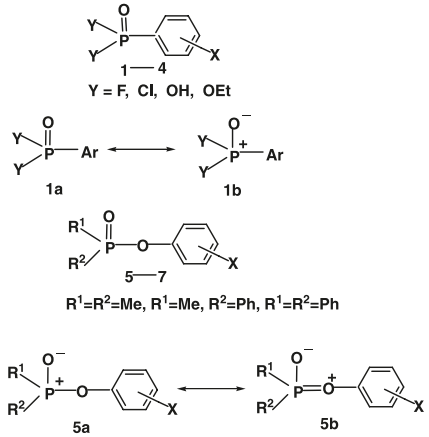
thioate pesticides where L is a leaving group such as para-nitrophenolate, thiolate, etc.

[1] 
An example is the hydrolytic decomposition of the P=S pesticide, fenitrothion (FN), to give 3-methyl-4-nitrophenol (PNP) and *O*,*O*-dimethylphosphorothioate anion (PA$^-$), eq. [2]. Hydrolysis can readily be followed through UV–vis spectroscopy or ^{31}P NMR, hence the spectroscopic characterization of reactants and products.

[2] 
A number of studies of pesticide hydrolysis and alcoholysis have been reported from our laboratory; these have prompted the present ^{31}P NMR study of PA$^-$ and its interaction with metal ions with the view of clarifying some of the factors pertinent to variation of ^{31}P chemical shifts with structural variation among compounds with P=O, P=S, P-O, and P-S moieties.

^{31}P NMR chemical shift values afford insight into factors such as electronegativity (P=O/P-S vs P-O/P=S) and d_π-p_π orbital overlap.[3,4] Interestingly, ^{31}P NMR chemical shifts of

Scheme 1.



the series of compounds **1**–**4** show *upfield* shifts when electronegative atoms or groups X are attached, pointing to a shielding effect on the phosphorus atom.[3–6] Upfield shifts are also observed when transition metal ions are added.[7,8] However, contrastingly, Hoz et al.[3] found in a study of a series of meta- and para-substituted phenyl diphenylphosphinates (**5**–**7**) that $\delta^{31}P$ values exhibit an *increasing downfield* (i.e., normal) trend as the electron-withdrawing property of the substituent X becomes greater.[3,9–12] Buncel and co-workers[4] observed a good correlation between δ ^{31}P NMR chemical shifts in aryl phosphinates with Hammett substituent constants (σ or σ^0); i.e., electron-withdrawing substituents X act to deplete electron density on the aryl

oxygen, via resonance structure **5b**, thereby weakening a p_π-d_π bonding interaction between the aryl oxygen and phosphorus (Scheme 1).[4]

Interestingly, a literature survey showed that the ^{31}P NMR chemical shifts of structurally modified OP pesticides, replacing (RO)P=O by (RS)P=O, (RO)P=S and (RS)P=S functionalities, resulted in ^{31}P chemical shift changes by up to 100 ppm (Table 1).[7,8,13–17] This finding emphasizes the need for a systematic investigation of ^{31}P chemical shifts in which experimental results complement theoretical approaches as one changes structure of the OP residues.

In this work, we report the preparation of a model OP compound, PAH, and experimental measurements of ^{31}P NMR chemical shifts of PA$^-$ in the absence and presence of Ag$^+$, Hg^{2+}, and Na$^+$ cations.

ESI-MS studies have also been carried out with the view of obtaining independent evidence on PA-metal ion complexes.

Results and discussion

Metal ion effects on ^{31}P chemical shifts (PA$^-$)

^{31}P chemical shifts, δ and Δδ, for PA$^-$ in the absence and presence of various Ag$^+$, Hg^{2+}, and Na$^+$ concentrations, in 25% D_2O-75% acetone-d_6 at nominal pH values varying between 1 and 10 are given in Tables 2, 3, and 4. In the absence of metal ions, the ^{31}P chemical shift of PA$^-$ occurs at 65.94 ppm. On addition of Ag$^+$, this undergoes an ~23 ppm upfield shift to 42.54 ppm as the [Ag$^+$]/[PA] ratio increases, Table 2. The plots for [Ag$^+$]/[PA] versus Δδ and [Hg^{2+}]/[PA] versus Δδ are shown in Figs. 1 and 2, respectively. As

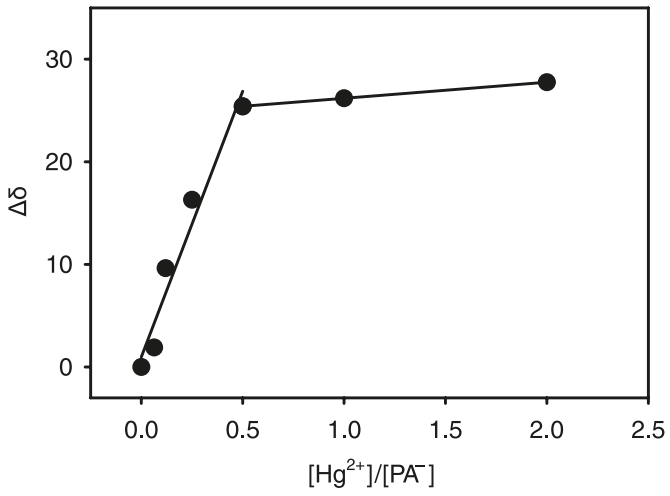
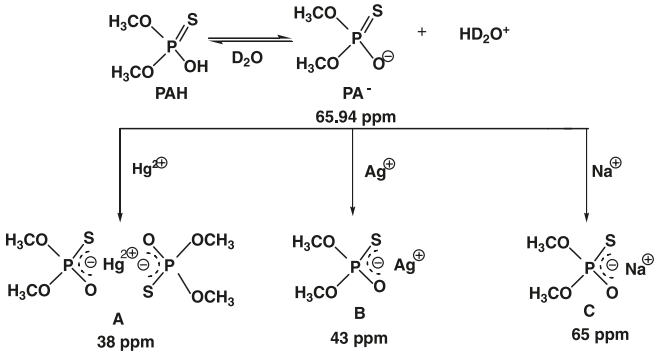


Scheme 2. Complexes of PA^- with Ag^+, Hg^{2+}, and Na^+ and chemical shifts.



the $[Ag^+]/[PA]$ ratio increases from 0 to 1.0 and beyond, the chemical shift for the $PA^-\cdots Ag^+$ complex exhibits an initial sharp increase and then remains nearly constant (Fig. 1), indicating the formation of a 1:1 $PA^-\cdots Ag^+$ complex.

In the presence of Hg^{2+}, the ^{31}P chemical shift of PA^- undergoes an ~28 ppm upfield shift to 38 ppm as the $[Hg^{2+}]/[PA]$ ratio increases, Table 3. Now, the ^{31}P chemical shift for $PA^-\cdots Hg^{2+}$ complex exhibits an initial sharp increase as the $[Hg^{2+}]/[PA]$ ratio increases from 0 to 0.5 and beyond that remains nearly constant (Fig. 2), which indicates the formation of a 2:1 $(PA^-)_2\cdots Hg^{2+}$ complex.

We have considered the possibility of using the data shown diagrammatically in Figs. 1 and 2 to calculate stability constants. It is helpful in this regard to refer to the treatment by Popov.[18] The salient feature is that in the case of AgPA, virtually complete conversion to the 1:1 complex is seen when the ratio of added AgPA is exactly 1:1, i.e., no excess Ag is required to completely form the complex, indicating that the equilibrium

$$Ag^+ + PA^- = AgPA$$

lies far to the right, i.e., very large formation constant. The same applies to the reaction

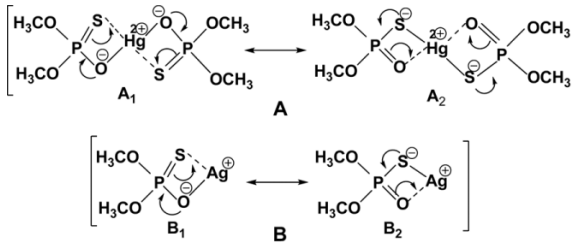
$$Hg^{2+} + 2PA^- = \quad HgPA_2$$

For such strong complexes it is difficult to estimate an accurate K_f value. Our attempts at curve fitting yielded values in the order 10^{14}, however values greater than 10^5 must be considered to be highly inaccurate.[18] Thus, the NMR data are better fitted to the shown linear intersecting plots in Figs. 1 and 2 rather than to curved titration type plots.

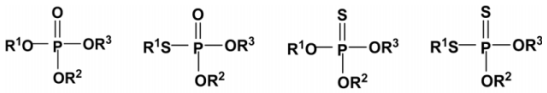
^{31}P chemical shifts (δ and $\Delta\delta$) for PA^- in the absence and presence of various Na^+ concentrations in 25% D_2O–75% acetone-d_6 are given in Table 4. It is seen that the ^{31}P chemical shifts for PA^- with Na^+ remain almost constant (only ~1.5 ppm upfield shift) as Na^+ is added to PA^-. Thus, the chemical shift of PA^- is affected by Ag^+ and Hg^{2+}, but is unchanged on addition of Na^+. The above relationships of ^{31}P chemical shift changes on addition of metal ions can be represented by Scheme 2.

The observed trends in ^{31}P chemical shifts brought about by metal ions can be explained on the basis of the resonance structures for $PA^-\cdots Hg^{2+}$ (A) and $PA^-\cdots Ag^+$ (B) complexes

Scheme 3. Resonance structures of $PA^-\cdots Ag^+$ and $PA^-\cdots Hg^{2+}$ complexes.



Scheme 4.



shown in Scheme 3. Complex A has two contributing resonance structures, A1 and A2, and similarly B has two contributing resonance structures, B1 and B2. Now, the contributing resonance structures A2 and B2 have greater P=O double bond character and P–S single bond character relative to PA^-. Concomitantly, the P=S double bond character decreases while the P–S single bond character increases. It follows that the A2 and B2 resonance structures are more dominant than A1 and B1. As shown in Table 1, the ^{31}P NMR chemical shift for RO-P(=S)$(OR)_2$ (64.58 ± 2.21 ppm) is larger than that for RS-P(=O)$(OR)_2$ (28.11 ± 2.90 ppm).[7,8,13–17] Thus, the ^{31}P chemical shift of structures with P–S single bond (and P=O double bond) is more upfield than that of compounds with P=S double bond (and P–O single bond) in similar structures.

Our results on ^{31}P NMR chemical shifts have a bearing on the use of ^{31}P chemical shifts as a tool for organophosphorus pesticide identification. Literature data show a marked variation of ^{31}P chemical shifts depending on structure. It is possible to classify the OP compounds largely on the basis of P=O versus P=S, and P-O versus P—S bonding shown in Scheme 4 as a subset of the phosphate/thiophosphate functionalities in Table 1.

It is also seen in Table 1 that there is much smaller variation of chemical shift as the nature of the substituents, R^1, R^2, R^3, is changed. This finding is in essential agreement with compilations found in texts and reviews.[5,6] Many factors are considered to contribute to these results; for example, nine important factors are cited in the text by Verkade and Quin.[6b] It is also of importance in the present context that metal ions have an influence on ^{31}P chemical shifts, apparently through influencing O=P-S/S=P-O bonding.

ESI-MS studies — PA^- in the presence of Ag^+ and Hg^{2+}

PAH has been chosen to study possible interaction with transition metals, Ag^+ and Hg^{2+}, utilizing the unshared electron pairs on the S atom. Ag^+ and Hg^{2+} ions have strong affinity for S-containing compounds on the basis of Pearson's hard-and-soft acid-base theory.[19]

The ESI-MS spectra for PAH in the absence and presence of Ag^+ and Hg^{2+} in aqueous methanol are shown in Figs. 3 and 4; data are given in Table 5. The protonated molecular ion peak at 143 (m/z) is attributed to $[PAH + H]^+$; silver has

Fig. 3. ESI-MS spectrum of PAH with Ag^+ in 50% aqueous methanol containing [PAH] = 1.0×10^{-5} mol/L and [Ag^+] = 5.0×10^{-4} mol/L.

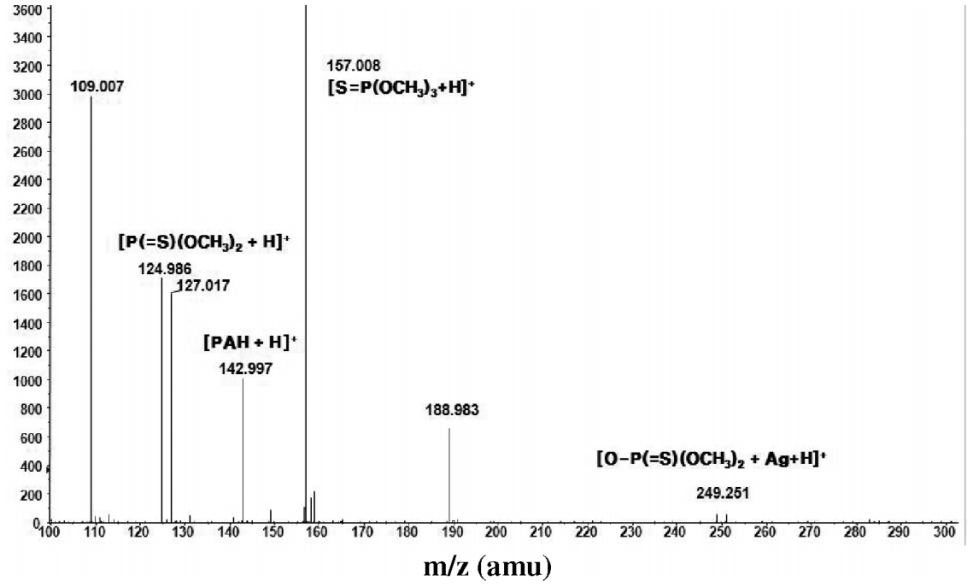


Fig. 4. ESI-MS spectrum of PAH with Hg^{2+} in 50% aqueous methanol containing [PAH] = 1.0×10^{-4} mol/L and [Hg^{2+}] = 5.0×10^{-4} mol/L.

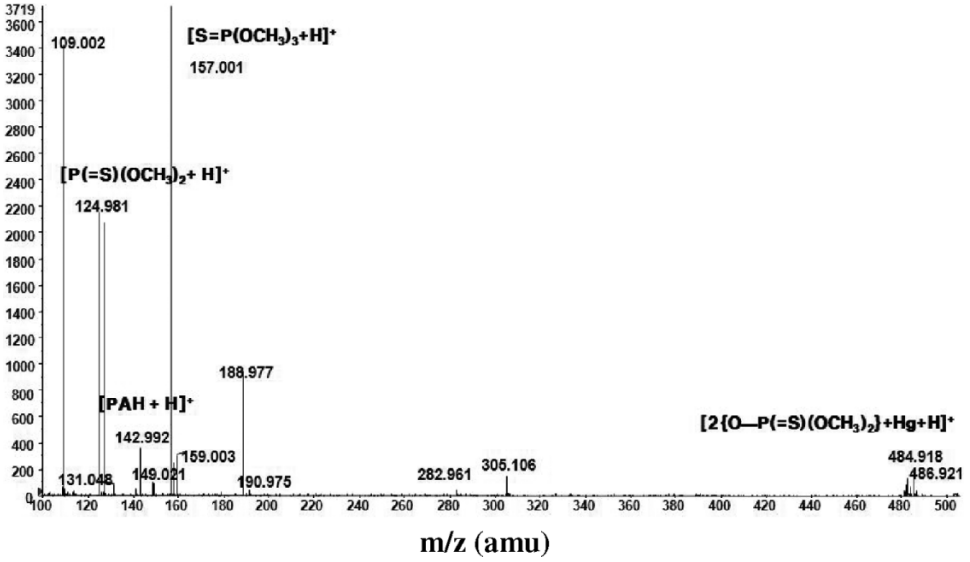

Table 5. ESI-MS data for the PAH in methanol and PAH with Ag^+ and Hg^{2+} in 50% DDW-50% methanol.

Metal salt added	Mode	Ions at *m/z*	Major species
No metal, H^+	MS	143	$[PAH+H]^+$
$AgNO_3$	MS	249, 251	$[O\text{-}P(=S)(OCH_3)_2 + Ag + H]^+$
		157	$[S=P(OCH_3)_3 + H]^+$
		143	$[PAH + H]^+$
		125	$[P(=S)(OCH_3)_2 + H]^+$
$Hg(NO_3)_2$	MS	481, 482, 483, 484, 485, 487	$\{2[S\text{-}P(=O)(OCH_3)_2] + Hg + H\}^+$
		157	$[S=P(OCH_3)_3 + H]^+$
		143	$[PAH + H]^+$
		125	$[P(=S)(OCH_3)_2 + H]^+$

two isotopes (^{107}Ag and ^{109}Ag) with a natural abundance ratio of 52:48.[20a] The major peaks in the PAH/Ag^+ spectrum correspond to $[O\text{-}P(=S)(OCH_3)_2 + Ag + H]^+$: *m/z* = 249, 251; $[S=P(OCH_3)_3 + H]^+$: *m/z* = 157, 143; $[PAH + H]^+$: *m/z* = 143; and $[P(=S)(OCH_3)_2 + H]^+$: *m/z* = 125. Thus, the peaks in the ESI-MS spectrum for $[O\text{-}P(=S)(OCH_3)_2 + Ag + H]^+$ are supportive of a 1:1 $PA^{-}\cdots Ag^+$ complex (discussed under NMR studies).

Peaks containing mercury ion can be recognized readily by the isotopic pattern of Hg: ^{196}Hg, ^{198}Hg,^{199}Hg, ^{200}Hg, ^{201}Hg, ^{202}Hg, and ^{204}Hg, with a natural abundance of 0.14, 10.02, 16.84, 23.13, 13.22, 29.80, and 6.85, respectively[20b]; all other isotopes would be detectable except ^{196}Hg. The major peaks in the PAH/Hg^{2+} spectrum are those of {2[S-P(=S)$(OCH_3)_2$] + Hg + H}$^+$: m/z = 481, 482, 483, 484, 485, 487, [S=P$(OCH_3)_3$ + H]$^+$: m/z = 157, [PAH + H]$^+$: m/z = 143, and [P(=S)$(OCH_3)_2$ + H]$^+$: m/z = 125. The peak in the spectrum for {2[O-P(=S)$(OCH_3)_2$] + Hg + H}$^+$ is supportive of a 2:1 $PA^-\cdots Hg^{2+}$ complex as discussed under NMR studies.

Experimental section

Materials

Methanol was procured from Sigma-Aldrich (HPLC grade) and D_2O, acetone-d_6, and dimethyl chlorothiophosphate from Sigma-Aldrich (GR grade). Fenitrothion was a gift from Sumitomo Chemicals (Japan) and was purified by column chromatography as previously described.[1b]

Preparation of *O*,*O*-dimethylphosphorothioic acid (PAH)

A mixture of 2 mL dimethyl chlorothiophosphate (2.64 g, 16.5 mmol) in 8 mL acetonitrile (MeCN) and 30 mL sodium hydroxide (NaOH, 1.60 g, 42.0 mmol) in 40% MeCN-60% water, was stirred magnetically overnight at 30 °C. After 12 h, the reaction mixture was acidified with HCl (6 mol/L). After thrice extraction with 30 mL CH_2Cl_2, the organic layer was collected and evaporated on rotary evaporator. The residue was dried under vacuum to a pale yellow oil (0.47g, 20%). The product was identified using ^{1}H, ^{13}C, and ^{31}P NMR spectroscopy (400 MHz Bruker). ^{1}H NMR (400 MHz, $CDCl_3$, ppm) δ: 3.80 (d, CH_3O, $^3J_{P\text{-}H}$ = 9.0 Hz, 6H), 6.8 (s, OH). ^{13}C NMR (400 MHz, $CDCl_3$, ppm) δ: 55.63. ^{31}P NMR (400 MHz, $CDCl_3$, relative to external 85% H_3PO_4, ppm) δ: 65.19. Aqueous solution of PAH generated the PA^- product.

[3] 
^{31}P NMR study

A PAH stock solution, 1.41×10^{-2} mol/L, was prepared by dissolving 0.01 g PAH in 5 mL acetone-d_6. Various concentrations of Ag^+, Hg^{2+}, and Na^+ stock solutions (Tables 2, 3, and 4) were prepared by dissolving $AgNO_3$, $HgCl_2$, and $NaNO_3$ in D_2O. For NMR analysis, 0.15 mL of metal ion (Ag^+, Hg^{2+}, and Na^+) 1.41×10^{-2} mol/L stock solution was added to 0.45 mL PAH stock solution in an NMR tube. The ^{31}P NMR experiments were carried out with PA^- in the absence and presence of metal ions. Changes in chemical shifts (Δδ) were calculated by subtracting the ^{31}P chemical shift values in the presence of each metal ion from those of metal free solutions. ^{31}P NMR experiments were carried out with PA^- in the absence and presence of metal ions, Ag^+, Hg^{2+}, and Na^+ using Bruker 400.302 MHz NMR spectrometer. ^{31}P NMR chemical shifts (δ) are reported in parts per million (ppm) with respect to 85% H_3PO_4 external reference. The spectra were acquired using 90° pulses with $1000 \approx 1500$ scans for ^{31}P nucleus.

Electrospray ionization mass spectrometry (ESI-MS)

A 1.0×10^{-4} mol/L PAH stock solution was prepared in HPLC grade methanol. $AgNO_3$ and $HgCl_2$ were dissolved in DDW for preparation of 5.0×10^{-4} mol/L Ag^+ and Hg^{2+} stock solutions. Low micromolar FN solution in methanol and aqueous Ag^+ and Hg^{2+} solutions were acidified to pH 4 using 0.01 mol/L nitric acid. Low micromolar FN solution in methanol (pH 4.0) was added with varying concentrations of aqueous Ag^+ and Hg^{2+} solutions (pH 4.0) and sprayed with a flow rate of 6.0 μL/min into a QSTAR XL QqTOF mass spectrometer (Applied Biosytems/MDS Sciex) employing a regular ESI source setup. Fragmentation of the transition metal-pesticide complex was achieved by two methods: first, in-source fragmentation by elevating the cone voltage, and second, low energy CID in the Q2 collision cell using nitrogen as collision gas. Combination of both methods allowed for pseudo-MS^3 analysis of the complexes. Accurate mass measurements enabled the correct assignment of molecular formulae for fragments in case of isobaric overlap of possible fragmentation products.

Synthesis of arylbromides from arenes and *N*-bromosuccinimide (NBS) in acetonitrile — A convenient method for aromatic bromination

Eli Zysman-Colman, Karla Arias, and Jay S. Siegel

Abstract: Regioselective and chemoselective electrophilic bromination of a wide series of activated arenes using *N*-bromosuccinimide (NBS) in acetonitrile occurs readily. Environmentally friendly conditions, large substrate scope, and ease of synthesis enhance the utility of this method over other electrophilic bromination conditions.

Key words: arylbromides, electrophilic aromatic bromination, *N*-bromosuccinimide.

Résumé : La bromation électrophile chimiosélective et régiosélective d'une grande variétés d'arènes activés, à l'aide de *N*-bromo-succinimide dans l'acétonitrile, se fait facilement. Des conditions expérimentales environnementalement correctes, un large éventail de substrats et la facilité de la synthèse augmentent l'utilité de cette méthode par comparaison avec celles nécessaires pour d'autres bromations électrophiles.

Mots-clés : bromures d'arènes, bromation aromatique, *N*-bromo-succinimide.

[Traduit par la Rédaction]

Introduction

Bromoarenes are important intermediates for synthesis, specifically as useful substrates in metal-mediated aryl-coupling chemistry.[1–3] Since the late 1950s,[4] there has been considerable interest in *N*-bromosuccinimide (NBS) as an electrophilic aromatic brominating reagent. A major advantage in the use of inexpensive NBS is that the succinimide byproduct can be easily recovered and rebrominated.[5] A number of NBS-based aromatic bromination methods have been reported, each with their own scope and conditions (e.g., NBS/Brønsted acids,[6] NBS/Brønsted bases,[7] NBS plus alkyl amines,[8] NBS in chlorinated solvents,[9] NBS in CS_2,[10] hexanes,[11] THF,[12] DMF,[13,14] propylene carbonate,[4] and MeOH,[15] NBS supported on silica gel,[16,17] NBS with Amberlyst® 15,[18] and NBS in ionic liquids[19]). Aromatic heterocycles can also be brominated by NBS in polar solvents.[20] Carreño and co-workers' reports using NBS in acetonitrile (ACN), for the efficient bromination of methoxy-substituted arenes[21] and naphthalenes,[22] drew our attention. Herein we document the substrate scope, regio-,[10] and chemo-selectivity of this relatively safe and user-friendly bromination procedure.

Results and discussion

Bromination of arenes with 1 equiv. of NBS in ACN at 0 °C proceeded readily over a wide range of substrates (Table 1) and was found to be highly para-selective with respect to the most activating substituent; in instances where the para position is blocked, bromination occurred ortho to the most activating group.[23]

Work-ups were trivial, frequently requiring only a water quench to dissolve the succinimide and an extraction using hexanes.[24] Some products even precipitated once water was added and thus were easily filtered off (Table 1, entries 27–28).

The chemoselectivity was also excellent, monobromination occurring at a faster rate than dibromination, even for electron-rich anisidines (Table 1, entries 18–20); additionally, no benzylic bromination was detected. In the vast majority of cases, yields of monobrominated products were excellent, without the use of any additive. In particular, NBS monobromination was possible with phenols (Table 1, entries 10–14)[25] as well as unalkylated anilines (Table 1, entries 16–20). Bromination of arenes bearing deactivating groups occurred in the presence of a strong activating group (Table 1, entries 5, 12, 17); however, bromination of the weakly activated alkyl arenes, toluene (Table 1, entry 21) or *t*-butylbenzene, was not possible even at reflux.

Polyalkylbenzenes spanned the gamut of affinities toward bromination. Ortho- and *p*-xylene (Table 1, entries 23–24) proved to be poor substrates and the conversion to the corresponding monobrominated product was diminutive even using excess NBS and with longer reaction times. Efficient bromination of *m*-xylene (Table 1, entry 22) was possible; however, a reaction time of five days was required to obtain complete conversion. Isomers of trimethylbenzene provide some insight to the reactivity issue. Whereas mesitylene (Table 1, entry 25) readily monobrominates with quantita-

Note: Conditions: 5 mmol NBS in 5 mL dry ACN was added to 5 mmol substrate in 5 mL dry ACN at 0 °C. Solution stirred for 18 h (0 °C – RT). The products were characterized by ^{1}H NMR, ^{13}C NMR, Mp, and MS and quantified by GC. Brominations were repeated at least once per substrate and isolated yields and GC conversions were reproducible.

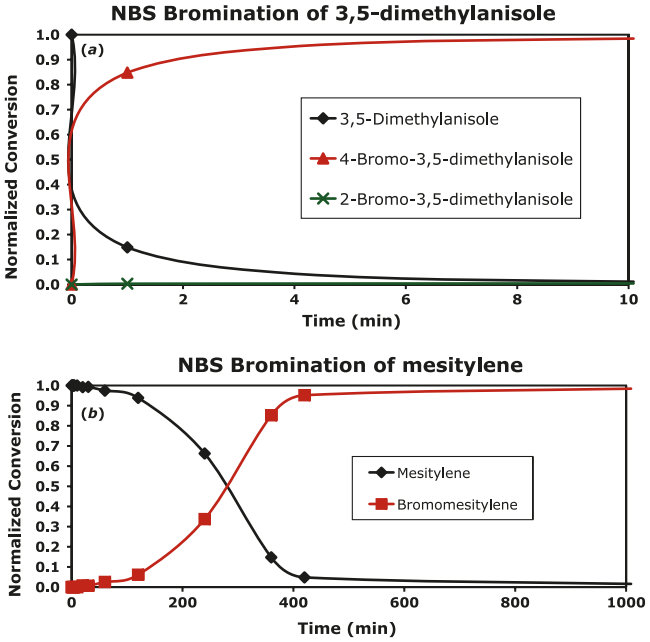
[c]Reaction stirred for five days.

[d]Side product: PhSSPh (see text).

Fig. 1. NBS bromination of (*a*) 0.41 mol/L 3,5-dimethylanisole in ACN and (*b*) 0.36 mol/L mesitylene in ACN. The progress of each of the reactions was monitored by GC-MS with *t*-butylbenzene as an internal standard.



tive conversion, monobromination of 1,2,3-trimethylbenzene (Table 1, entry 26) proceeded much less readily, affording only one regioisomeric product in moderate yield.

Effective bromination by this method appears to require site activation equivalent to at least two (better three) *o*,*p* alkyl groups. Treating this as a linear free energy issue, one sees that phenols and anilines activate roughly equivalent to three methyl groups. After monobromination, the remaining possible sites of bromination are deactivated by being meta to bromine, thus favoring monobromination.

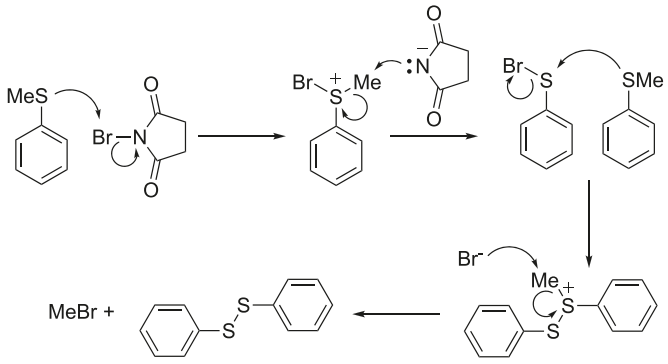
Though our standard protocol reflects a reaction time of 18 h, bromination can actually occur within minutes. For instance, the bromination of 3,5-dimethylanisole (Table 1, entry 1) proceeds smoothly, the reaction attaining completion in 20 min (Fig. 1*a*), as monitored by GC-MS. The bromination of isosteric mesitylene (Fig. 1*b*) is much slower, taking hours to go to completion. The rate of bromination is much faster than that observed in DMF (24 h) for similar substrates.[13]

Reactions are also easily amenable to scale-up; monobromination of 3,5-dimethylanisole, for instance, has been accomplished at a 200 g scale with no loss in yield or purity.

The bromination of thioanisole (Table 1, entry 29) did not proceed cleanly, with the observed formation of ca. 20% diphenyl disulfide as a byproduct, as observed by GC-MS and ^{1}H NMR and compared to an authentic sample. The oxidation of thiols with electrophilic bromine sources such as NBS is not unprecedented[17,25]; however, to our knowledge, the tandem demethylation–oxidation of thioanisoles to form disulfides is not known but can be rationalized (Scheme 1).

Bromination of deactivated aromatics such as halobenzenes and haloaldehydes did not occur under our conditions; bromination of 2-hydroxy-4-methylbenzoic acid also did not

Scheme 1. Formation of diphenyl disulfide.



proceed, perhaps because of the sparing solubility of the substrate in ACN.

Recently, Chhattise et al.[26] reported the photochemically induced aromatic bromination of phenols using NBS in acetonitrile. In that report, alkyl species were avoided due to free radical bromination at the benzyllic positions (Table 2, entry 8 of their paper refers to the benyllic bromination of toluene). We find that light is not needed for the aromatic bromination and therefore our method is amenable to xylene and mesitylene bromination, whereas that of Chhatise et al.[26] is not. Indeed, even cresol derivatives, which undergo bromination rapidly and cleanly under our conditions, brominate less cleanly under their conditions, likely because of complications from light-induced free radical side reactions.

We have demonstrated the useful potential of NBS bromination of activated arenes in ACN. The advantages of our current procedure are simple work-ups, mild reaction conditions tolerant of diverse functionality, and high regio- and chemoselectivity, the products of which could usually be isolated by simple filtration or solvent extraction.

Experimental

All experiments were carried out under nitrogen in reagent grade acetonitrile. Commercial chemicals were used as supplied. Column chromatography was performed using silica gel (Merck 60 0.040–0.063 mm). Analytical thin layer chromatography (TLC) was performed with Mecherey-Nagel SIL N-H/UV$_{254}$ plates with aluminum backings. Compounds were visualized under UV light. GC-MS samples were run through a Zebron Zb5 column. ^{1}H and ^{13}C NMR spectra were recorded on a Brucker Avance (300 MHz) and a Brucker ARX 300 (75 MHz) spectrometer, respectively, with the solvent peak as an internal standard. The following abbreviations have been used for multipilicity assignments: "s" for singlet, "d" for doublet, "t" for triplet, "m" for multiplet, and "br" for broad.

The following is a sample procedure for the bromination of arenes using NBS in ACN.

Bromomanisole

To a 0 °C solution of 3,5-dimethylanisole (685 mg, 5 mmol, 1 equiv.) in 5 mL ACN was added a solution of NBS (890 mg, 5 mmol, 1 equiv.) in 5 mL ACN via addition funnel. The solution was allowed to come to room temperature (RT) and stirred for an additional period, typically between 0.1 and 20 h, depending on the activity of the ring (cf. Fig. 1). The reac-

tion was quenched with H_2O, hexanes were added, and the layers separated. The aqueous phase was extracted with 3 × hexanes. The organic phase was dried over $MgSO_4$, filtered under reduced pressure, and the organic phase concentrated under reduced pressure then under vacuum. A clear liquid (1.09 g) was obtained. Yield: 99%. GC conversion: 100%. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.63 (s, 2H), 3.74 (s, 3H), 2.37 (s, 6H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 158.0, 139.0, 118.1, 113.7, 55.2, 23.9. GC-MS (6.56) $[M]^+$: 213.8. Anal. calcd. for $C_9H_{11}BrO$: C 50.26, H 5.15; found: C 50.37, H 4.95. This procedure could be scaled up to 100 g of 3,5-dimethylanisole with no measurable loss in yield or purity. ^{1}H NMR spectrum is in agreement with that previously reported.[27,28]

2-Bromo-5-methoxybenzaldehyde

White solid. Yield: 81%, mp 76–79 °C (lit.[29] mp 78–80 °C). GC conversion: 98%. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 10.31 (s, 1H), 7.51 (d, J = 8.7 Hz, 1H), 7.40 (d, J = 3.3 Hz, 1H), 7.02 (dd, J = 3.0, 9.0 Hz, 1H), 3.82 (s, 3H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 191.7, 159.3, 134.5, 134.0, 123.1, 117.9, 112.7, 55.7. GC-MS (6.87) $[M]^+$: 216.0. Anal. calcd. for $C_8H_9BrO_3$: C 44.68, H 3.28; found: C 44.85, H 3.51. ^{1}H NMR and ^{13}C NMR spectra are in agreement with those previously reported.[29]

4-Bromo-3,5-dimethylaniline

White solid. The product was purified via flash chromatography (20% EtOAc/hexanes on silica, R_f: 0.15). Yield: 94%, mp 73–75 °C (lit.[29] mp 75–76 °C). GC conversion: 98% with 2% dibrominated side product. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.39 (s, 2H), 3.55 (s, 2H), 2.30 (s, 6H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 144.9, 138.7, 115.8, 115.0, 23.7. GC-MS (7.40) $[M]^+$: 198.8. Anal. Calcd. for $C_8H_{10}BrN$: C 48.02, H 5.04, N 7.00; found: C 48.38, H 5.10, N 7.01. ^{1}H NMR spectrum is in agreement with that previously reported.[30]

1-Bromo-2,3,4,5,6-pentamethylbenzene

White solid. R_f: 0.43 (hexanes on silica). Yield: 94%, mp 160–161 °C (lit.[31,32] mp 159–161 °C; lit.[33] mp 163.5–164.5 °C). GC conversion: 100%. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 2.43 (s, 6H), 2.25 (s, 6H), 2.12 (s, 3H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 133.8, 133.3, 126.7, 21.4, 17.7, 16.8. GC-MS (8.27) $[M]^+$: 225.9. Anal. calcd. for $C_{11}H_{15}Br$: C 58.17, H, 6.66; found: C 58.06, H 6.20.

2-Amino-5-bromobenzonitrile

White solid. R_f: 0.06 (20% EtOAc/hexanes on silica). Yield: 97%, mp 97–99 °C (lit.[34] mp 98 °C). GC conversion: 100%. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.46 (dd, J = 2.1, 13.0 Hz, 1H), 7.37 (dd, J = 2.4, 9.0 Hz, 1H), 6.61 (d, J = 13.0 Hz, 1H), 4.43 (s, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 148.6, 136.9, 134.0, 116.7, 116.2, 108.6, 97.5. GC-MS (7.78) $[M]^+$: 196.0. ^{1}H NMR spectrum is in agreement with that previously reported.[34]

Bromodurene

White solid. The product was purified via flash chromatography (hexanes on silica). R_f: 0.39 (hexanes on silica). Yield: 92%, mp 60–61 °C (lit.[35] mp 59–60 °C). GC conversion: 97%. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.88 (s, 1H), 2.35 (s, 6H), 2.27 (s, 6H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 134.7, 133.8, 130.2, 128.9, 20.8, 20.1. GC-MS (6.76) $[M]^+$: 212.0. Anal. Calcd. for $C_{10}H_{13}Br$: C 56.36, H 6.15; found: C 55.93, H 6.15. ^{1}H NMR spectrum is in agreement with that previously reported.[35]

2-Bromomesitylene

Pale yellowish liquid. Yield: 93%. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.92 (s, 2H), 2.41 (s, 6H), 2.27 (s, 3H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 137.9, 136.2, 129.2, 124.4, 24.1, 20.8. GC-MS (5.24) $[M]^+$: 197.8. ^{1}H NMR and ^{13}C NMR spectra are in agreement with those previously reported.[36]

1-Bromo-2,3,4-trimethylbenzene

Clear oil. The product was purified via flash chromatography (hexanes on silica). R_f: 0.40 (hexanes on silica). Yield: 43%. GC conversion: 66%. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.30 (d, J = 8.1 Hz, 1H), 6.85 (d, J = 8.1 Hz, 1H), 2.41 (s, 3H), 2.47 (s, 6H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 136.9, 135.5, 129.3, 128.5, 122.8, 20.5, 19.9, 16.7. GC-MS (5.80) $[M]^+$: 197.9. ^{1}H NMR spectrum is not in agreement with that previously reported.[37]

Bromohydroquinone

White solid. The product was purified via flash chromatography (1:2:1 CH_2Cl_2/hexanes/Et_2O on silica). R_f: 0.19 (1:2:1 CH_2Cl_2/hexanes/Et_2O on silica). Yield: 42%, mp 110–112 °C (lit.[37] mp 106–109 °C). GC Conversion: 97%. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.97 (d, J = 3.0 Hz, 1H), 6.87 (d, J = 8.7 Hz, 1H), 6.70 (dd, J = 3.0, 9.0 Hz, 1H), 5.10 (s, 1H), 4.74 (s, 1H). ^{13}C NMR (75 MHz, acetone-d_6) δ: 151.8, 147.8, 119.9, 117.6, 116.3, 110.1. GC-MS (6.69) $[M]^+$: 187.9. Anal. calcd. for $C_6H_5BrO_2$: C 38.13, H 2.67; found: C 38.10, H 2.90. ^{1}H NMR and ^{13}C NMR spectra are in agreement with those previously reported.[38]

4-Bromo-3,5-dimethylphenol

White solid. R_f: 0.13 (10% EtOAc/hexanes on silica). The product was purified via flash chromatography (33% CH_2Cl_2/hexanes on silica, R_f: 0.05). Yield: 96%, mp 116–117 °C (lit.[38] mp 114–115 °C). GC conversion: 100%. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.57 (s, 2H), 4.99 (s, 1H), 2.34 (s, 6H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 153.7, 139.4, 118.3, 115.2, 23.7. GC-MS (7.20) $[M]^+$: 199.8. Anal. calcd. for C_8H_9BrO: C 47.79, H 4.51; found: C 47.71, H 4.57. ^{1}H NMR spectrum is in agreement with that previously reported.[39]

4-Bromo-2,6-dimethylphenol

Yellow-orange solid. Yield: 96%, mp 78–79 °C (lit.[40] mp 79–80 °C). GC conversion: 99%. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.10 (s, 2H), 4.55 (s, 1H), 2.22 (s, 6H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 151.2, 130.9, 125.3, 112.0, 15.6. GC-MS (6.64) $[M]^+$: 199.8. ^{1}H NMR and ^{13}C NMR spectra are in agreement with those previously reported.[40]

5-Bromobenzo[d][1,3]dioxole

Brown oil. R_f: 0.10 (hexanes on silica). Yield: 94%. GC conversion: 99%. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.91–6.88 (m, 2H), 6.63 (dd, J = 1.8, 8.1 Hz, 1H), 5.91 (d, J = 0.9 Hz,

2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 148.5, 146.9, 124.2, 113.0, 112.4, 109.4, 101.6. GC-MS (5.42) $[M]^+$: 200.0. ^{1}H NMR and ^{13}C NMR spectra are in agreement with those previously reported.[41] The compound was reported as a colorless oil.

1-(4-Bromophenoxy)benzene

The reaction mixture was stirred for two days. Clear oil. R_f: 0.19 (hexanes on silica). GC conversion: 91% with 7% dibrominated side product. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.41 (d, J = 9.0 Hz, 2H), 7.31 (t, J = 8.1 Hz, 2H), 7.11 (tt, J = 0.9, 6.9 Hz, 1H), 6.99 (dd, J = 1.2, 6.9 Hz, 2H), 6.87 (d, J = 9.0 Hz, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 156.6, 132.6, 129.8, 123.6, 120.5, 120.3, 118.9, 115.5. GC-MS (8.81) $[M]^+$: 247.9. ^{1}H NMR and ^{13}C NMR spectra are in agreement with those previously reported.[42]

4-Bromoanisole

Clear oil. R_f: 0.18 (hexanes on silica). Yield: 97%. GC conversion: 100%. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.36 (d, J = 8.4 Hz, 2H), 6.76 (d, J = 8.4 Hz, 2H), 3.77 (s, 3H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 158.6, 132.1, 115.6, 112.7, 55.3. GC-MS (4.61) $[M]^+$: 185.9. ^{1}H NMR and ^{13}C NMR spectra are in agreement with those previously reported.[20,40]

1-Bromo-2,4-dimethylbenzene

The reaction mixture was stirred for five days. Clear oil. R_f: 0.19 (hexanes on silica). Yield: 98%. GC conversion: 100% with 3% benzyl and other monobrominated side products. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.36 (d, J = 8.1 Hz, 1H), 7.03 (m, 1H), 6.84 (dd, J = 2.4, 8.1 Hz, 1H), 2.34 (s, 3H), 2.25 (s, 3H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 137.0, 135.2, 132.0, 131.7, 127.7, 121.7, 22.8, 20.9. GC-MS (4.23) $[M]^+$: 183.7. ^{1}H NMR and ^{13}C NMR spectra are in agreement with those previously reported.[36]

1-Bromo-4-methoxy-2-methylbenzene

Clear oil, which solidified to a white solid under vacuum. R_f: 0.16 (hexanes on silica). Yield: 97%. ^{1}H NMR conversion: 100%. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.40 (d, J = 8.7 Hz, 1H), 6.79 (d, J = 3.0 Hz, 1H), 6.61 (dd, J = 2.7, 8.7 Hz, 1H), 3.76 (s, 3H), 2.38 (s, 3H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 158.8, 138.7, 132.7, 116.5, 115.3, 112.9, 55.2, 23.0. GC-MS (5.63) $[M]^+$: 200.0. ^{1}H NMR spectrum is in agreement with that previously reported.[43,44]

2-Bromo-1-methoxy-4-methylbenzene

Clear oil. R_f: 0.30 (10% EtOAc/hexanes on silica). The product was purified via flash chromatography (10% EtOAc/hexanes on silica). Yield: 63%. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.34 (d, J = 2.1 Hz, 1H), 7.04 (dd, J = 2.2, 8.1 Hz, 1H), 6.77 (d, J = 8.4 Hz, 1H), 3.84 (s, 3H), 2.26 (s, 3H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 153.7, 133.6, 131.4, 128.8, 111.8, 111.2, 56.2, 20.1. GC-MS (5.72) $[M]^+$: 200.0. ^{1}H NMR spectrum is in agreement with that previously reported.[43,45]

1-Bromo-2,4-dimethoxybenzene

Clear oil. R_f: 0.19 (20% EtOAc/hexanes on silica). Yield: 99%. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.38 (d, J = 8.7 Hz, 1H), 6.46 (d, J = 2.7 Hz, 1H), 6.37 (dd, J = 2.7, 8.4 Hz, 1H), 3.84 (s, 3H), 3.77 (s, 3H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 158.7, 155.0, 131.6, 104.4, 100.9, 98.5, 54.6, 54.0. GC-MS (7.10) $[M]^+$: 217.8. Anal. calcd. for $C_8H_9BrO_2$: C 44.27, H 4.18; found: C 44.18, H 4.25. ^{1}H NMR and ^{13}C NMR spectra are in agreement with that previously reported.[46]

1-Bromo-2,5-dimethoxybenzene

Yellow oil. R_f: 0.06 (10% EtOAc/hexanes on silica). Yield: 99%. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.10 (m, 1H), 6.82 (m, 2H), 3.82 (s, 3H), 3.74 (s, 3H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 154.0, 118.9, 114.6, 113.6, 112.9, 111.9, 56.9, 55.8. GC-MS (6.83) $[M]^+$: 217.8. ^{1}H NMR spectrum is in agreement with that previously reported.[47]

4-Bromo-2-methoxybenzenamine

Red liquid. R_f: 0.07 (20% EtOAc/hexanes on silica). The product was purified via flash chromatography (20% EtOAc/hexanes on silica). Mp 59–60 °C (liquid) (lit.[48] mp 60–61 °C). Yield: 71%. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.86 (m, 2H), 6.55 (dd, J = 2.1, 8.7 Hz, 1H), 3.80 (s, 3H), 3.74 (s, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 147.8, 135.3, 123.6, 115.6, 113.7, 109.4, 55.6. GC-MS (7.17) $[M]^+$: 202.9. ^{1}H NMR and ^{13}C NMR spectra are in agreement with those previously reported.[48] The compound was reported as a brown solid.

3,4-Dibromo-2-methoxybenzenamine

Red liquid, isolated as a side product in the monobromination reaction of *o*-anisidine. R_f: 0.25 (20% EtOAc/hexanes on silica). The product was purified via flash chromatography (20% EtOAc/hexanes on silica). Yield: 12%. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.15 (d, J = 2.1 Hz, 1H), 6.80 (d, J = 2.1 Hz, 1H), 4.12 (s, 2H), 3.81 (s, 3H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 147.6, 134.1, 126.1, 112.5, 108.5, 108.1, 56.0. GC-MS (8.86) $[M]^+$: 278.9. ^{1}H NMR spectrum is in agreement with that previously reported.[48]

4-Bromo-3-methoxybenzenamine

White solid. R_f: 0.05 (30% EtOAc/hexanes on silica). The product was purified via flash chromatography (30% EtOAc/hexanes on silica). Yield: 47%, mp 94–95.5 °C (lit.[23,49] mp 93–94 °C). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.19 (d, J = 8.4 Hz, 1H), 6.20 (d, J = 2.7 Hz, 1H), 6.14 (dd, J = 2.4, 8.4 Hz, 1H), 3.75 (s, 3H), 3.71 (s, 2H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 156.3, 147.3, 133.2, 108.4, 99.6, 99.2, 55.9. GC-MS (7.92) $[M]^+$: 201.0. Anal. calcd. for C_7H_8BrNO: C 41.61, H 3.99, N 6.93; found: C 41.80, H 4.21, N 6.80. ^{1}H NMR and ^{13}C NMR spectra are in agreement with those previously reported.[48]

2-Bromo-4-methoxybenzenamine

Red liquid. R_f: 0.13 (20% EtOAc/hexanes on silica). The product was purified via flash chromatography (20% EtOAc/hexanes on silica). Yield: 20%. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.98 (dd, J = 0.9, 2.1 Hz, 1H), 6.70 (m, 2H), 3.79 (s, 2H), 3.70 (s, 3H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 153.3, 138.6, 118.1, 117.2, 115.6, 110.1, 56.5. GC-MS (6.94) $[M]^+$: 201.0. ^{1}H NMR and ^{13}C NMR spectra are in agreement with those previously reported.[48,49]

5-Bromo-2-hydroxybenzaldehyde

White solid. R_f: 0.37 (20% EtOAc/hexanes on silica). The product was purified via flash chromatography (20% EtOAc/hexanes on silica). Yield: 18%, mp 102–105 °C (lit.[50] mp 104–105 °C). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 10.92 (s, 1H), 9.83 (s, 1H), 7.65 (d, J = 2.4 Hz, 1H), 7.58 (dd, J = 2.7, 9.0 Hz, 1H), 6.89 (d, J = 9.0 Hz, 1H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 196.1, 161.3, 140.5, 136.4, 122.5, 120.6, 112.1. GC-MS (5.53) $[M]^+$: 200.0. ^{1}H NMR and ^{13}C NMR spectra are in agreement with those previously reported.[50,51]

4-Bromo-3,5-dimethyl-*N*,*N*-dimethylaniline

Isolated as a thick colorless oil that solidified to a crystalline white substance after sitting under high vacuum for 16 h. R_f: 0.35 (50% CH_2Cl_2/hexanes on silica). The product was purified via flash chromatography (50% CH_2Cl_2/hexanes on silica). Yield: 95%, mp 25–26 °C. ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.51 (s, 2H), 2.81 (s, 6H), 2.41 (s, 6H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 149.2, 138.2, 114.5, 112.7, 40.6, 24.1. GC-MS (8.12) $[M]^+$: 227.0. ^{1}H NMR spectrum is in agreement with that previously reported.[52] The compound was reported as a colorless liquid.

Bromojulolidine (referred to as 9-bromojulolidine in the reference)

The product was extracted with CH_2Cl_2 to produce a dark red crystalline solid. Yield: 92%, mp 35–37 °C (lit[53] mp 36.5 °C). R_f: 0.30 (CH_2Cl_2 on silica). The product was purified via flash column chromatography (CH_2Cl_2 on silica). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 6.93 (d, J = 0.6 Hz, 2H), 3.17 (t, J = 6.5 Hz, 4H), 2.76 (t, J = 5.7 Hz, 4H), 2.01 (m, 4H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 142.3, 129.6, 124.0, 107.5, 50.3, 28.0, 22.3, 28.0. GC-MS (10.85) $[M]^+$: 251.1.

4-Bromothioanisole

Clear oil. GC conversion: 75%. R_f: 0.21 (hexanes on silica). ^{1}H NMR (300 MHz, $CDCl_3$) δ: 7.37 (d, J = 8.7 Hz, 2H), 7.10 (d, J = 8.7 Hz, 2H), 2.46 (s, 3H). GC-MS (6.16) $[M]^+$: 201.9.

Investigations of the supramolecular host properties of a fluorescent bistren cage compound

Patricia G. Boland, Sara J. Accardi, Carrie A. Snow, and Brian D. Wagner

Abstract: The host properties of a bistren cage compound, previously reported to be an efficient anion sensor, are shown to include encapsulation of small aromatic guest molecules. It is also shown that the intrinsic fluorescence of this cage compound, arising from the anthracenyl moiety in its structure, is sensitive to the encapsulation of aromatic guests in aqueous solution and can be used to measure the binding constants for any such guest. This makes this bistren cage a rare example of a fluorescent host for aromatic guests, and suggests potential applications of this compound as a versatile fluorescent sensor for a variety of guests of interest. The binding of a number of benzene derivatives was studied; these were all found to form 1:2 host–guest inclusion complexes with a wide range in total binding constants (K_1K_2), from 6.4×10^3 to 3.5×10^7 $(mol/L)^{-2}$, indicating a significant degree of selectivity for different benzene derivatives. The binding strength was found to depend on both the guest polarity and aqueous solubility.

Key words: bistren cage, host–guest inclusion, fluorescent host, binding constants.

Résumé : Pour un composé bistrène en forme de cage qui, selon des études antérieures, serait un senseur anionique efficace, on démontre que ses propriétés hôtes incluent l'encapsulation de petites molécules aromatiques invitées. On démontre aussi que la fluorescence intrinsèque de ce composé en cage, qui tire son origine dans la portion anthracényle de sa structure, est sensible à l'encapsulation de molécules aromatiques hôtes dans la solution aqueuse et qu'elle peut être utilisée pour mesurer les constantes de fixation de telles molécules invitées. Cette propriété fait que bistrène en forme de cage est un rare exemple d'un hôte pour invités aromatiques et suggère des applications potentielles de ce composé comme senseur fluorescent versatile pour une variété de molécules invitées présentant des intérêts divers. On a étudié la fixation d'un certain nombre de dérivés aromatiques qui forment tous des complexes d'inclusion hôte:invité 1:2 pour lesquels les constantes de fixation totale (K_1K_2) s'étalent de $6{,}4 \times 10^3$ à $3{,}5 \times 10^7$ $(mol/L)^{-2}$, ce qui suggère un degré significatif de sélectivité pour les différents dérivés du benzène. On a noté que la force de la fixation dépend à la fois de la polarité de la molécule invitée et de la solubilité dans l'eau.

Mots-clés : cage bistrène, inclusion hôte-invité, hôte fluorescent, constantes de fixation.

[Traduit par la Rédaction]

Introduction

Supramolecular host–guest inclusion complexes, in which a small guest molecule becomes encapsulated within the internal cavity of a larger cage-like host molecule, have shown tremendous utility for molecular recognition, with a high degree of guest selectivity.[1] A wide range of applications of inclusion complexes have been reported, including chemical separations,[2] food and chemical industries,[3] drug delivery,[4] and fluorescence-based trace analysis.[5] Fluorescence spectroscopy has been shown to be an extremely sensitive and accurate experimental method for studying such inclusion systems, for example, extracting the binding constant K for the complex formation.[6,7] However, since most commonly used hosts, such as cyclodextrins[8] and cucurbiturils,[9] are non-fluorescent, the use of fluorescence to study their inclusion complexes is limited to the specific cases of polarity-sensitive fluorescent guests.[6,7]

Bistrens are an important class of cryptand ligands and were first prepared by J.-M. Lehn et al. over 30 years ago.[10] The simplest bistrens, *O*-bistren and *C*-bistren, consist of polyamine cages constructed from two tripodal tetramine "tren" (2,2′,2″-triaminetriethylamine) units, which have been joined through their terminal amines by three ether (*O*-bistren) or alkyl (*C*-bistren) spacer groups.[11] The resulting molecule has an ellipsoidal internal cavity, the size and rigidity of which depend on the type and length of the spacer groups.[11] These cages have been shown to be highly selective hosts for metal ions, tightly binding two metal cations.[10,12,13] In addition, the resulting di-metal cation complexes have been shown to be useful hosts for other guests: dicobalt-*O*-bistren as a molecular oxygen carrier[12] and di-copper-*O*- and *C*-bistren for OH^- and F^- anions as bridging "cascade" guests.[13]

Fabbrizzi and co-workers extended the versatility of bistren hosts by adding aromatic groups within the spacer linkages, including 1,4-xylyl[11] and 9,10-anthracenyl.[14] The structure of the latter bistren **1** is shown in Fig. 1; it contains

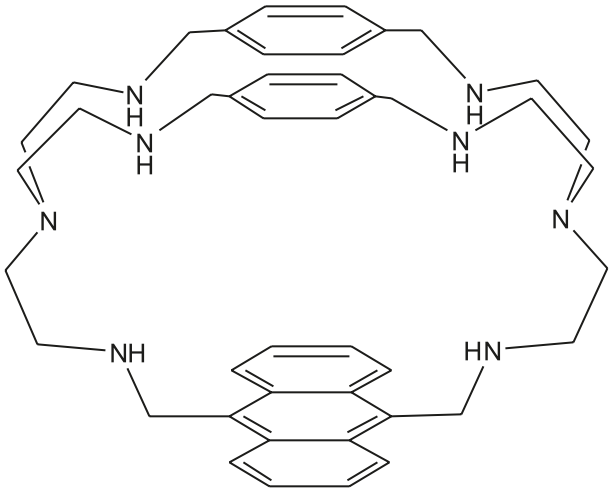
Fig. 1. Structure of the fluorescent bistren host compound **1**.

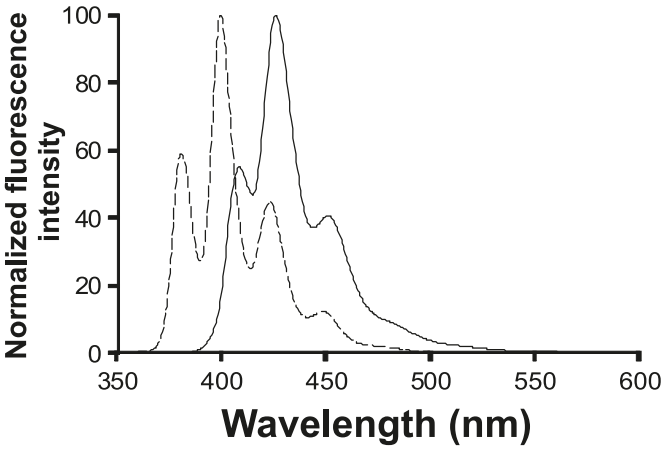


two 1,4-xylyl and one 9,10-anthracenyl group in the spacer arms. This incorporation of the strongly fluorescent 9,10-anthracenyl moiety within the cage architecture makes this bistren **1** a relatively rare example of an intrinsically fluorescent host. Its fluorescence properties were well characterized by Fabbrizzi et al.[14] and shown to be highly pH dependent. The strong fluorescence was found to be greatly reduced above pH 4–6; this was explained to be a result of efficient quenching of the anthracenyl fluorescence by the unprotonated amine groups in the cage structure. At low pH, the amine groups are protonated to the ammonium form, which does not quench anthracene fluorescence and thus the cage is highly fluorescent. At a high enough pH so that at least one adjacent nitrogen is in the amine form, the fluorescence is efficiently quenched. In the presence of two equivalents of Zn(II), however, the Zn cations enter the cage and engage the amines, greatly reducing the amine quenching and restoring the cage fluorescence. This fluorescence was also found to be quenched by the binding of certain anions, such as azide, via a photoinduced electron transfer. The authors proposed this dizinc(II)···**1** complex as an efficient and highly selective sensor for ambidentate anions.[14]

This host compound **1** has huge potential because it has been virtually unexplored as a fluorescent host. Although Fabbrizzi considered anion and metal cation binding, no inclusion complexes of this host with neutral guests have been reported, and in fact there have been no subsequent papers describing its host properties with any guest, since the original publication in 1998.

To explore the host abilities of this interesting cage compound **1**, its binding of a series of substituted benzenes was investigated. These guests were chosen for three reasons: (*i*) they are aromatic, so have the potential to undergo π–π interactions with the aromatic moieties of the cage walls, (*ii*) they absorb well below the host absorption band, so their addition will not interfere with the excitation of the fluorescent cage (this would not be the case for naphthalene derivatives, for example), and (*iii*) they are relatively small and expected to be a good size match for the bistren cavity.

Fig. 2. Normalized fluorescence spectra of the bistren cage compound **1** (—) and anthracene (- - -) in methanol.



Experimental

The following compounds were obtained from the indicated sources and used as received: 9,10-bis(chloromethyl)anthracene (ABCR GmbH and Co. KG); tris(2-aminoethyl)amine, toluene, terephthalaldehyde, sodium borohydride, methanol, dichloromethane, sodium sulfate, phenol (Sigma-Aldrich); benzene (BDH); aniline and anisole (Fisher). The first eight compounds were all used in the synthesis of **1**, the final four were used as aromatic guests.

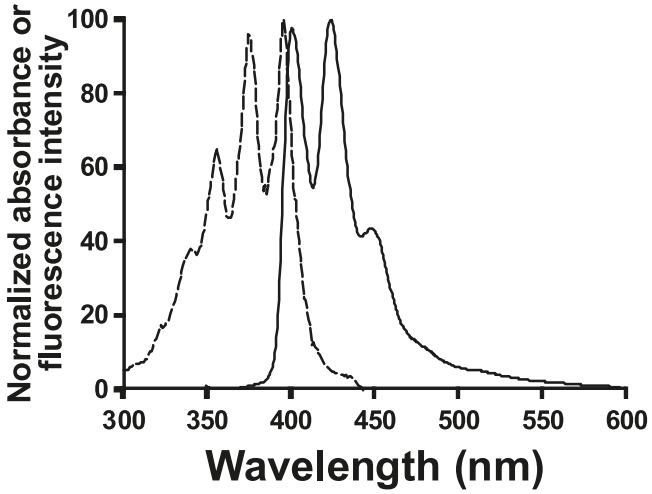
The bistren cage **1** was synthesized according to published methods[14,15] and purified by high-performance liquid chromatography (HPLC). According to the literature, the solid product is recovered as the hydrochloride salt **1**···8HCl.[14] The purified product was characterized by ^{1}H NMR (Bruker 300 MHz Ultra-Shield) and electrospray mass spectrometry, which reproduced the literature-reported mass spectrometry data with a *m*/*z* peak of 699. Furthermore, all of the fluorescence properties previously reported in the literature were able to be reproduced using this synthesized sample (see next section).

Bistren solutions were prepared in nanopure deionized water, with 5 min of sonication, to give an absorbance in the range of 0.20 to 0.25 at the excitation wavelength of 340 nm; these solutions had concentrations of ca. 2×10^{-5} mol/L. Fluorescence spectra were measured on a Photon Technology International LS-100 or a PerkinElmer LS 55 luminescence spectrophotometer.

Results and discussion

The bistren cage was successfully synthesized and purified, and its fluorescence emission was found to be in excellent agreement with that reported in the original literature paper.[14] All of the reported fluorescence properties were able to be reproduced, including the pH dependence, the effect of Zn(II) binding, and the effect of adding azide to the Zn(II)···**1** complex. However, no spectra were shown in Fabbrizzi's paper. Figure 2 shows the normalized fluorescence spectrum of the bistren cage **1**, as well as that of anthracene, the fluorophore of the cage, both in methanol for comparison. It is clear that the rest of the cage architecture

Fig. 3. Normalized absorption (- - -) and fluorescence (—) spectra of the bistren cage compound **1** in water.



has a significant effect on the photophysics of the 9,10-anthracenyl fluorophore, as a significant red-shift is observed.

The fluorescence properties of **1** in nanopure water were then investigated to see if a strong fluorescence signal could be measured in unbuffered aqueous solution. This was done to avoid the effects of competitive binding of the metal cations (e.g., Na^+) present from the buffer salts used by Fabbrizzi et al.[14] The pH of the prepared bistren stock solution was found to be on the order of 4.0 (a result of the fact that the solid bistren is recovered as **1**···8HCl), so the bistren cage will be in its protonated form. Both the absorption and emission spectra of **1** in nanopure water are shown in Fig. 3. These spectra show a strong mirror image relationship, with a very small Stokes shift, indicating minimal displacement of the excited state energy surface relative to that of the ground state. The fluorescence observed at pH 4.0 is very strong, in agreement with the reported pH dependence.[14] It is thus clear that an intense fluorescence emission can be observed for **1** in unbuffered, slightly acidic aqueous solution, which has the potential to allow for the study of its ability to include guests.

The first guest tried was benzene. However, addition of up to 20 mmol/L of benzene (aqueous solubility = 23 mmol/L[16]) showed no effect on the bistren fluorescence. It was decided that a more polar guest would be more likely to bind (considering the fact that the only previous guests reported to bind were all ionic), so aniline was chosen. In this case, a very strong reduction of the bistren host fluorescence was observed upon addition of aniline, as shown in Fig. 4. To quantify this effect, the fluorescence suppression F/F_o was calculated as the ratio of the integrated bistren fluorescence spectrum in the presence (F) and absence (F_o) of added aniline.[6] In the experiment shown in Fig. 4, F/F_o was found to be 0.19, i.e., the bistren emission was reduced by a factor of over 5-fold in the presence of 10 mmol/L of aniline. This very large reduction in intensity was not accompanied by a significant spectral shift; the peak shifted by ≤1 nm.

An analogous set of experiments were performed by adding 10 mmol/L of aniline to solutions of 9,10-dichloromethylanthracene (the source of the 9,10-anthracenyl moiety in the bistren synthesis) and anthracene itself. In both cases, only a very small decrease in fluorescence (<10%) was observed. This indicates that the cage structure of the bistren is essential for this quenching to occur, and provides strong evidence that the aniline is being included within the bistren cage as a guest.

Fig. 4. The effect of added aniline on the fluorescence of the bistren host compound **1**: the relative fluorescence spectrum of bistren in the absence of guest (—) and in the presence of 10 mmol/L of aniline (- - -).

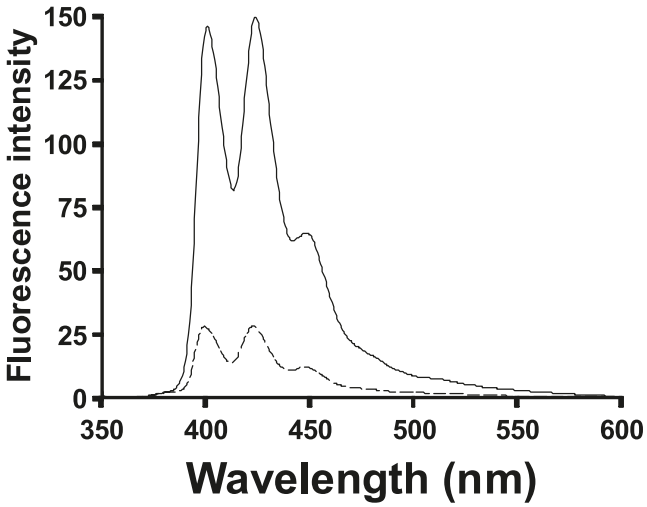


Fig. 5. Fluorescence titration of bistren fluorescence with aniline. The solid line is the best fit to eq. [1] for a 1:2 host–guest complex, with K_1 = 3900 mol/L^{-1}and K_2 = 11 000 mol/L^{-1} for this trial. The inset shows the double reciprocal plot.

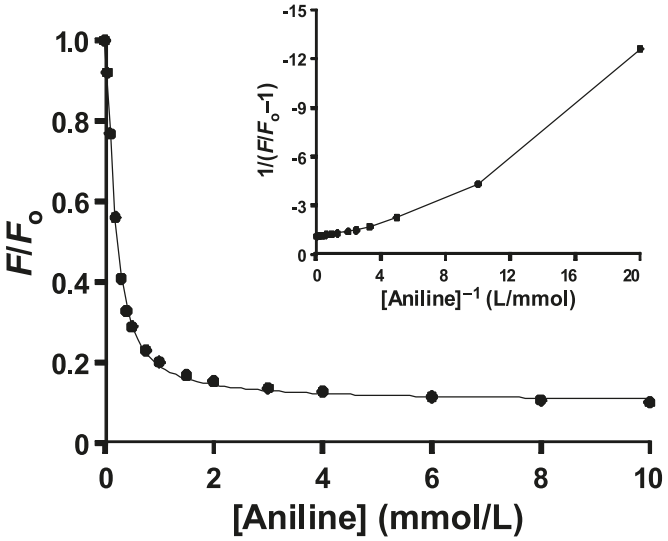

To determine the binding constant, a titration of the bistren fluorescence spectrum was performed in which F/F_o was measured as a function of added aniline concentration. The results are shown in Fig. 5.

To determine whether simple 1:1 host–guest complexation was occurring, a double reciprocal plot of $1/(F/F_o-1)$ versus 1/[aniline] was generated; this plot will be linear for 1:1 complexation but curved if higher-order complexes are

Table 1. Binding of substituted benzene guests by the bistren host (average of three trials).

Guest	Substituent	K_1 ((mol/L)$^{-1}$)	K_2 ((mol/L)$^{-1}$)	K_1K_2 ((mol/L)$^{-2}$)
Benzene	-H	<10	<10	<100
Aniline	-NH_2	$2.6\pm0.8\times10^3$	$1.4\pm0.2\times10^4$	$3.5\pm1.0\times10^7$
Anisole	-OCH_3	$3.2\pm0.6\times10^2$	$1.6\pm0.2\times10^2$	$5.1\pm1.5\times10^4$
Phenol	-OH	$3.5\pm0.5\times10^1$	$1.9\pm0.3\times10^2$	$6.4\pm0.4\times10^3$

being formed.[6] As can be clearly seen in the inset of Fig. 5, this plot was indeed highly curved, indicating that the bistren-aniline complexes are higher order than 1:1. Given the much larger size of the host compared with the guest, the most likely stoichiometry is 1:2 bitren-aniline. The equation for the dependence of the fluorescence of a guest on host concentration in the case of 2:1 host–guest complexes is well-established.[17] This equation is equally valid for the current case of the dependence of the fluorescence of a host as a function of guest concentration ([G]) for a 1:2 host–guest complex, as given below:

$$[1] \qquad \frac{F}{F_o} = \frac{1 + F_a K_1[G] + F_b K_1 K_2[G]^2}{1 + K_1[G] + K_1 K_2[G]^2}$$

In this equation, K_1 and K_2 are the equilibrium constants for the stepwise binding of the first, then the second guest, respectively, and F_a and F_b are the relative fluorescence upon complete 1:1, then 2:1 complexation, respectively. The solid line shows the excellent fit of the data to eq. [1], using a non-linear least-squares fitting program, confirming the 1:2 stoichiometry. In this particular experiment, the following fit values for eq. [1] were obtained: $F_a = 0.94$; $K_1 = 3900$ mol/L^{-1}; $F_b = 0.10$; $K_2 = 11\,000$ mol/L^{-1}. Three trials were performed; the average values of the binding constants obtained are shown in Table 1. These show that aniline is bound very strongly by the bistren cage, with an overall binding constant (K_1K_2) for the two aniline guests per cage of $3.5 \pm 1.0 \times 10^7$ (mol/L)$^{-2}$. The value of K_2 is found to be larger than that of K_1, indicating that once the first aniline is bound, the second binds even more strongly. This might be the result of the first aniline displacing bound solvent molecules, freeing up the cavity, or changing the shape of the cage, making it easier for the second guest to fit in. The strong binding is postulated to be at least partly a result of strong π–π interactions between the polar aromatic guest aniline and the anthracenyl moiety in the host wall; such interactions are found to be stronger for substituted benzenes than for benzene itself.[18]

Two other benzene derivatives were also studied as guests: anisole and phenol. The results averaged over three trials are also shown in Table 1. Both of these guests were also found to bind with the bistren as 1:2 host–guest complexes. It can be seen that in the case of anisole, the binding is much weaker than with aniline, with an overall binding constant K_1K_2 of $5.1 \pm 1.5 \times 10^4$ (mol/L)$^{-2}$. This is almost three orders of magnitude smaller than that in the case of aniline, and is attributed to the lower polarity of anisole relative to aniline, as indicated by either the dielectric constant ε for the liquid (4.30 versus 7.06[19]) or the dipole moment μ (1.26[20] versus 1.53 D[21]). It makes sense that the binding strength of anisole falls between that of benzene and that of aniline, in terms of the relative polarity. However in the case of phenol, which exhibits higher polarity than aniline,[22] the binding is unexpectedly found to be weaker than even anisole, with a K_1K_2 of $6.4 \pm 0.4 \times 10^3$ (mol/L)$^{-2}$. This surprising result is postulated to be a result of the relative aqueous solubility of these guests[16]: phenol is by far the most soluble of the three, with an aqueous solubility of 1 mol/L, compared with aniline (0.4 mol/L) and anisole (0.014 mol/L). Thus, in comparing phenol and anisole, the higher polarity of phenol would be expected to result in a stronger π–π and other interactions with the bistren cage, however its much higher solubility in the bulk water greatly reduces the hydrophobic effect,[23] reducing the driving force for inclusion into the less polar internal cavity. In the case of aniline, while the solubility is significantly higher than that of anisole, the much greater polarity is the dominant factor and results in a much stronger binding. The relative ability of these guests to form hydrogen bonds with the solvent may also play a role (as it does in the relative solubility), as formation of stronger hydrogen bonds with water would also decrease the driving force for inclusion into the host cavity (although hydrogen bonds with the host cage are also possible, which would strengthen the binding). This is a very interesting case of two co-existing driving forces for inclusion that have opposing dependence on the polarity (which is indirectly related to the aqueous solubility) of the guest. This makes it very difficult to predict the strength of binding for benzene derivatives based solely on polarity considerations; the solubility and hydrogen bonding to water also need to be taken into account in this case. This is an excellent illustration of the complexity and variability of the driving forces for host–guest inclusion as a phenomenon and the difficulty in predicting which host–guest partners will bind most strongly.

It is interesting that the bistren fluorescence decreases upon complexation of these aromatic guests. This observation of a decrease in fluorescence of a host with an aromatic fluorophore upon inclusion of an aromatic guest has been observed previously by our group, in the case of a fluorescent analogue of cucurbit[6]uril containing aromatic bisphthalhydrazide walls.[24,25] In that case, the fluorescence was seen to decrease significantly upon binding of both benzene and the aromatic fluorescent dye Nile Red, and there was also no accompanying spectral shift.[24] This effect was explained as a result of conformational changes in the host upon binding of the aromatic guest through strong π–π interactions, resulting in increased non-radiative decay pathways for the host excited state.[24] A similar effect of π–π interaction resulting in significant bistren conformational change, with a concomitant increase in nonradiative decay rate, is also likely for this case of the bistren binding of these benzene derivatives. This proposal will be further investigated by performing a full photophysical study, measuring fluorescence lifetimes and quantum yields to determine the rate

constants for the radiative and non-radiative decay pathways in the absence and presence of bound aromatic guests.

Conclusions

The bistren cage **1** has been shown to be a versatile and extremely useful host for neutral aromatic guests in addition to the ionic guests reported previously. In addition, the intrinsic fluorescence of this host has been shown to be highly sensitive to the presence of included aromatic guests, which makes the study of its inclusion complexes and measurement of binding constants very simple, using fluorescence spectroscopy.

In the case of the simple benzene derivatives studied, 1:2 host–guest complexes were formed, with two substituted benzene rings included in the large, oval-shaped host cavity. Very large total binding constants K_1K_2 were measured, ranging from 6.4×10^3 $(mol/L)^{-2}$ in the case of phenol to 3.5×10^7 $(mol/L)^{-2}$ in the case of aniline. The strength of the binding was found to depend in an interesting manner on two competing guest properties, namely the polarity and aqueous solubility. Strong binding was found to require the presence of strongly electron-donating substituents such as NH_2 in aniline (benzene itself was not found to bind) to strengthen $\pi-\pi$ interactions. Such substituents also allow for hydrogen bonding with the ammonium groups of the cage. However in the case of the relatively polar phenol, binding was much weaker than expected, presumably due to its much higher aqueous solubility, resulting in a decreased hydrophobic driving force for inclusion.

The results obtained in this study using some simple benzene derivatives should be extendable to other aromatic guests. The range of binding constants obtained indicates a good potential for guest selectivity, and this combined with its guest-sensitive intrinsic fluorescence makes this cage compound potentially useful as a versatile fluorescent sensor (for guests that do not absorb at 340 nm). Furthermore, the fact that this bistren cage **1** strongly binds two aniline guests means that there is the potential to form 1-dimensional chains by using 4,4′-diaminobiphenyl as a bridging guest. In this way, it is predicted that nanostructures consisting of long, one-dimensional architectures could be built by self-assembly of the bistren cage compound **1** and 4,4′-diaminobiphenyl in aqueous solution. Such a structure would be an organic supramolecular analogue of one-dimensional coordination polymers based on 4,4′-bipyridine and metal ion nodes.[26]

Comparing the fragmentation chemistry of gas-phase adducts of poly(dimethylsiloxane) oligomers with metal and organic ions

Justin Renaud, Abdulhrahman M. Alhazmi, and Paul M. Mayer

Abstract: Gas-phase ions of poly(dimethylsiloxane) oligomers were formed by electrospray ionization either by protonating them in solution with formic acid or by generating adducts of the oligomers with the metal ions Li^+, Na^+, K^+, and Ag^+ as well as with the organic cations NH_4^+, $CH_3CH_2NH_3^+$, and protonated glycine, aspartic acid, and 1,2-diphenylethylamine. The collision-induced fragmentation of the oligomeric ions was strongly dependent on the nature of the charging species. Ag^+ adducts dissociated in a manner previously observed in secondary ion mass spectrometry experiments generating a series of linear and cyclic fragment ions, while Li^+ adducts fragmented to form two ions: an adduct of the metal ion with the oligomer end-group and one with the remaining oligomer. Na^+ and K^+ adducts simply dissociate to form the bare metal ion. The organic species, to varying extents, transfer the proton to the oligomer to form a protonated poly(siloxane) ion. These protonated oligomers then dissociate at very low laboratory-frame collision energy along the siloxane backbone by loss of a silanol. These backbone fragments can then lose a methyl group to form a second series of fragment ions. Suggestions for probable mechanistic pathways for these processes are presented.

Key words: PDMS oligomers, amino acid, bases, metal ions, CID, mass spectrometry, fragmentation pathways.

Résumé : On a observé la formation en phase gazeuse d'ions d'oligomères poly(diméthylsiloxane) lors de l'ionisation par électronébulisation d'oligomères protonés en solution avec de l'acide formique ou par la génération d'adduits des oligomères avec les ions métalliques Li^+, Na^+, K^+ et Ag^+, les cations organiques NH_4^+, $CH_3CH_2NH_2^+$, ou les formes protonées de la glycine, de l'acide aspartique et de la 1,2-diphényléthylamine. La fragmentation induite par des collisions des ions oligomères dépend fortement de la nature des espèces utilisées pour les charger. Les adduits avec le Ag^+ se dissocient de la façon observée antérieurement lors d'expériences de spectrométrie de masse d'ions secondaires pour une série de fragments ioniques linéaires et cycliques alors que les adduits avec le Li^+ se fragmentent pour donner deux ions, un adduit de l'ion métallique avec la partie terminale de l'oligomère et un avec le reste de l'oligomère. Les adduits du Na^+ et du K^+ se dissocient simplement pour donner un ion métallique nu. Les espèces organiques transfèrent à des degrés variables le proton vers l'oligomère pour former un ion poly(siloxane) protoné. Sous l'influence d'énergie de collisions très faibles dans le cadre d'un laboratoire, les oligomères protonés se dissocient alors le long du squelette siloxane pour conduire à des pertes de silanol. Ces fragments de squelette peuvent alors perdre un groupe méthyle pour conduire à la formation d'une deuxième série de fragments ioniques. On présente des suggestions concernant les voies mécanistiques probables pour ces processus.

Mots-clés : oligomères poly(diméthylsiloxane), acide aminé, bases, ions métalliques, spectrométrie de masse, dissociation induite par des collisions, voies de fragmentations.

Introduction

Mass spectrometry (MS) has found increasing use in studying polymers because unlike other classical methods that provide a bulk characterization of polymers and (or) require a calibration standard, MS is able to examine individual oligomers.[1] Mass spectrometry is also capable of detecting contamination of the polymer sample, identifying endgroups, co-polymer characterization, and examining the fragmentation processes. Secondary ion mass spectrometry using time of flight has also proved to be a valuable tool in studying polymer surfaces and the fragmentation process. The fragmentation of specific polymers can be affected by numerous factors, including conformation in the gas phase.[2]

Polysiloxanes find significant use in a wide range of applications. Poly(dimethylsiloxane) (PDMS) is nontoxic to proteins and cells[3] and has a high thermal and chemical inertness making it ideal for industrial uses such as lubricants, sealants, caulking, water repellents, and resins as well as biomedical and biochemical applications including fabrication of microfluidic devices.[4]

Because of its importance, many studies have examined PDMS, including thermal degradation and mass spectrometry studies into the effects of functional group substitution and endgroup substitution[5] on the fragmentation process. Chen, using ab initio calculations and fourier transform ion cyclotron resonance (FT-ICR) mass spectrometry, has proposed that certain functionalized endgroups can be directly

involved in assisting in the cleavage of the siloxane bond through a backbiting mechanism.[6]

The most industrially relevant endgroup of PDMS is trimethylsilyl because of its increased stability compared with hydroxyl-terminated oligomers.[7] The disadvantage of studying PDMS terminated with this endgroup is that trimethylsilyl cannot be directly protonated such as amine-containing endgroups like (aminopropyl)dimethylsiloxane and (amidopropyl)dimethylsiloxane. Mass spectra of PDMS have been obtained for smaller mass ranges using electron ionization (EI)[8] and pyrolysis[9] methods. Much higher molecular weight samples have been analyzed using secondary ion time of flight mass spectrometry (SIMS-TOF), which has evaluated the molecular weight[10] and fragmentation pathway of PDMS[11] and other polysiloxanes.[12] In the examples above that used SIMS, silver was used as a substrate and so several Ag^+ adducts were observed. The predominant low mass fragment ions observed in the mass spectra were linear and cyclic PDMS oligomers. Dong et al. proposed a mechanism for the formation of the cyclic fragment ions in which the silver ion does not play a role (Scheme 1). However, because of the nature of the SIMS process, it is often difficult to ascertain the origin of the observed fragment ions and the effects the silver ion has on the fragmentation processes. As studies involving other polymers have shown, the complexing agent can directly impact the observed fragmentation patterns.[13]

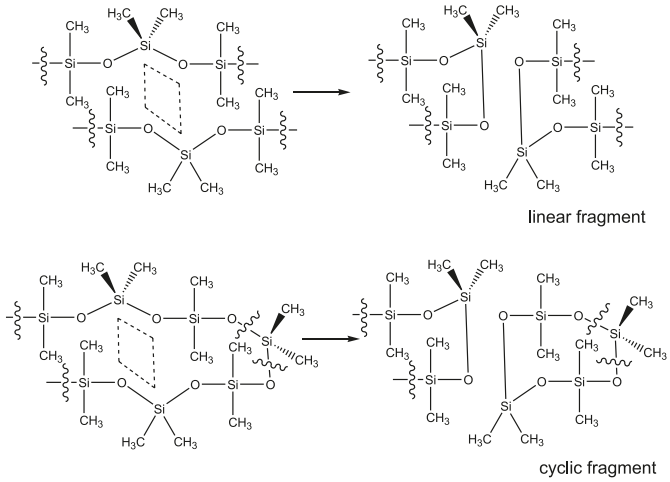
Depending on the polymer, it is possible for it to be directly protonated or cationized by certain metal ions such as Li^+, K^+, or Ag^+. In addition to metals, it has recently been shown that some organic molecules, including amino acids and small peptides, can be used to form proton-bound complexes with oligomers of poly(methylmethacrylate) and poly(butylacrylate) using electrospray ionization mass spectrometry (ESI-MS), and that these complexes fragment in a complimentary way to their metal ion adduct analogues.[14] The aim of this study was to explore a range of conventional and nonconventional ionizing agents capable of forming a complex with PDMS oligomers and to identify and compare their major fragmentation pathways.

Experimental procedures

Poly(dimethylsiloxane), terminated by trimethylsilyl having an average molecular weight of 800 Da, was obtained from Sigma-Aldrich. PDMS concentrations of 0.1 mgL^{-1} were mixed in a 1:1 ratio with a metal salt (LiCl, NaCl, KOH, or $AgNO_3$) or organic molecule (ammonium acetate, ethylamine, 1,2-diphenylethylamine, glycine, and aspartic acid) of concentration of 0.1 mgL^{-1} in a solvent of 1:1 methanol/iso-propanol. One drop of 5% formic acid was added to the organic solutions to protonate the amine. Protonated PDMS was obtained by adding only 1 drop of 5% formic acid directly to the PDMS solution.

A Micromass Quattro LC (Waters Micromass, Manchester, UK) triple quadrupole mass spectrometer was used to carry out the low-resolution electrospray ionization mass spectrometry (ESI-MS) and tandem mass spectrometry (ESI-MS/MS). Sample solutions were introduced by syringe pump at a flow rate of 40 μL/min. The sample cone voltage was set between 20 and 130V. Collision-induced dissociation was carried out with argon at a gas pressure of 1×10^{-3} mbar (1 bar = 100 kPa), and laboratory frame collision energies ranging from 0 to 100 eV (specific settings are included in each figure caption). All collision energies reported are in the laboratory frame. The resolution of the first quadrupole was set to unit mass resolution (15 in the Masslynx software) for all experiments. The resolution of the final quadrupole was held constant at 12 to increase the sensitivity of the ESI-MS/MS experiments. A Micromass Q-TOF 1 was used for the accurate mass CID experiments with a resolution of 6 000 and mass accuracy of 15 ppm. The calibration ion was the doubly charged molecular ion of [glu[1]]-Fibrinopeptide B.

Scheme 1.



Results and discussion

Table 1 summarizes the masses for the PDMS oligomers and assorted ions used to form adducts in ESI-MS.

Electrospray ionization mass spectrometry

While it is straightforward to create protonated PDMS (Fig. 1*a*), any of the metal ion adducts (Fig. 1*b* and Fig. S1 in the Suplementary data) and adducts with any of the organic species listed in Table 1 (Fig. 1*c* and Fig. S2 in the Supplementary data), those with the proton and aspartic acid exhibited a low intensity to the point that the ion series due to $(PDMS)H^+$ and $(PDMS)(Asp)H^+$ were less abundant than those due to $(PDMS)Na^+$ arising from contamination of the glassware use to prepare the samples. A similar oligomer distribution was observed in each case, corresponding to linear trimethylsilyl terminated PDMS. No evidence for the presence of cyclic oligomers could be detected in the mass spectra in the mass range studied (Fig. 1). SIMS-TOF studies of PDMS using a silver substrate observed both cyclic and linear oligomer fragments in the same *m/z* range as this study.[11,12] This illustrates that the cyclic ions proposed in the SIMS work were indeed due to the fragmentation of higher molecular weight oligomers in the ionization–desorption process.

A sample containing equimolar amounts of $AgNO_3$, LiCl, and glycine (0.0018 mmol/L each) was mixed with 0.3 mg/mL of PDMS, and the dependence on cone voltage of the formation of oligomer adducts was examined (Fig. 2).

Table 1. Summary of masses for PDMS oligomers and ionizing agents.

Species	Mass (Da)
$(CH_3)_3Si$-$[OSi(CH_3)_2]_n$-CH_3	
$OSi(CH_3)_2$	74
$(CH_3)_3Si$	73
CH_3	15
Li^+	7
Na^+	23
K^+	39
Ag^+	107, 109
NH_4^+	18
$CH_3CH_2NH_3^+$	46
(Glycine)H^+	76
(Aspartic acid)H^+	134
(1,2-diphenylethylamine)H^+	198

Lower voltages (20 V) favoured adducts with glycine, with the relative abundance of these adducts decreasing with increasing voltage. Moderate cone voltages (> 50 V) completely disrupt the proton-bound complex with glycine, while Li^+ exhibits a tendency to prefer the shorter oligomers and Ag^+ the longer oligomers.

Tandem mass spectrometry

In the following discussion, "R" represents the number of monomers (dimethylsiloxyl) in a fragment ion, while "M" will be used to represent the number of monomers left in a neutral, trimethylsilyl-terminated oligomer.

Lithium

Lithium ion adducts of PDMS exhibit unique fragmentation chemistry upon collision activation. At laboratory-frame collision energies of 50 eV, two dominant fragment ion peaks are observed (Fig. 3*a*), *m*/*z* 81 and a peak resulting from the precursor ion losing 74 Da retaining the lithium. Accurate mass measurements of *m*/*z* 613 and the molecular ion peak in Fig. 3*a* give *m*/*z* 613.287 and 687.262. The accurate mass of the neutral loss between the precursor ion and *m*/*z* 613 in Fig. 3*a* is 73.975 Da, which is closer to that expected for $(CH_3)_2SiO$, 74.018 Da, than for $(CH_3)_3SiH$, 74.0549 Da. The observed fragment ion with *m*/*z* 81 (which lies outside the calibration mass range of the GFP standard and whose accurate mass cannot be used for elemental composition) suggests a mechanism similar to that proposed for the fragmentation of poly(methyl methacrylate) oligomers ionized with sodium.[15] The oligomer ion adopts a cyclic structure, with Li^+ binding near the two terminal ends. Charge-induced methyl group transfer and cleavage near one end would result in the lithium ion departing with one of the $(CH_3)_2SiO$ groups at the end of the oligomer (Scheme 2). If the Li^+ remains with the rest of the oligomer, *m*/*z* 613 results. Fragmentation along the lines of that shown in Scheme 1 should result in a wide distribution of $(R_n)Li^+$ fragment ions and almost never $((CH_3)_2SiO)Li^+$.

Sodium and potassium

CID of the sodiated or potassiated adducts resulted primarily in the dissociation of the complex giving the bare metal ion; increasing collision energy resulted in an increase in the Na^+ or K^+ peak intensity and a decrease in precursor ion intensity. In the case of K^+, weak fragment ions appearing to contain potassium were observed with *m*/*z* 200–400 but could not be reliably identified (Fig. 3*b*). The results of the CID experiments for Li^+, Na^+, and K^+ adducts appear to confirm the binding energy order $Li^+ > Na^+ > K^+$ noted by Gidden et al.[15]

Fig. 1. ESI mass spectra of PDMS oligomers complexed with (*a*) H^+, (*b*) Li^+, and (*c*) NH_4^+.

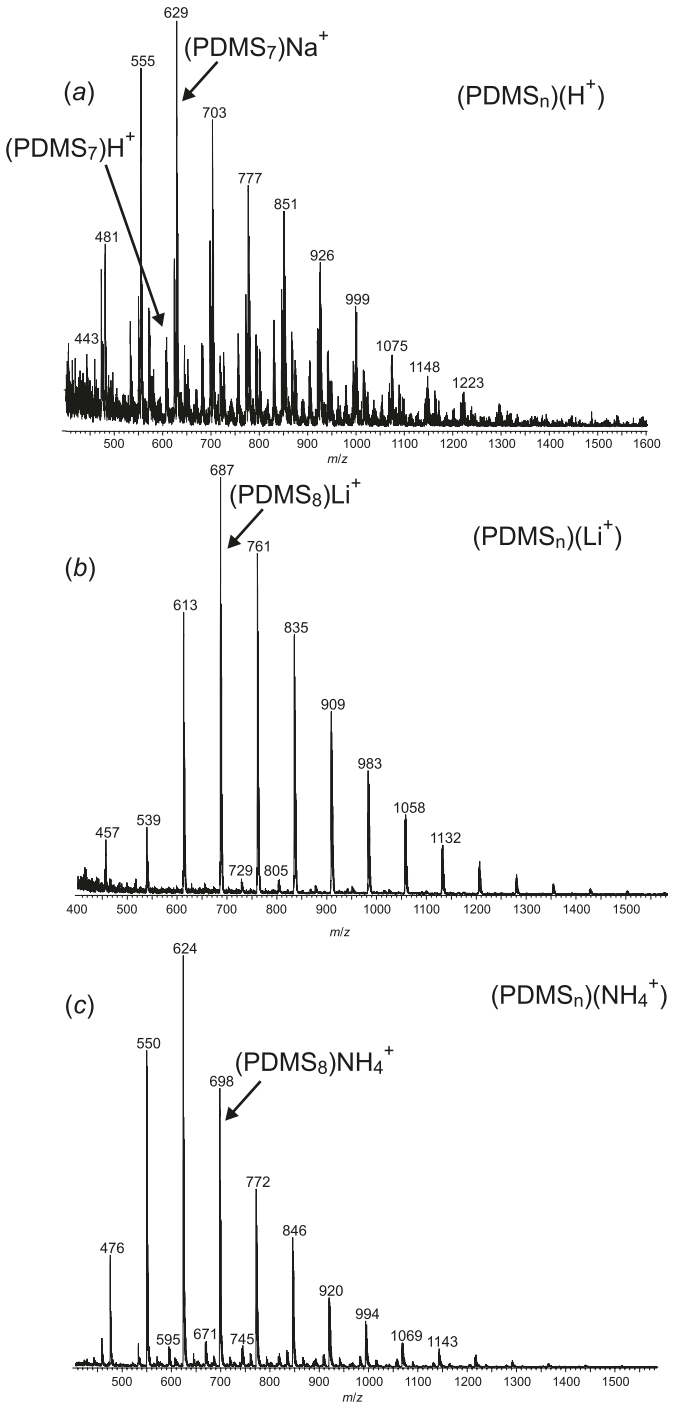


Fig. 2. ESI mass spectra of PDMS oligomers mixed with equimolar amounts of LiCl, $AgNO_3$, and glycine at a cone voltage of (*a*) 20 V and (*b*) 130 V. In each mass spectrum G, L, and A denote the adducts formed with protonated glycine, lithium ions, and silver ions, respectively.

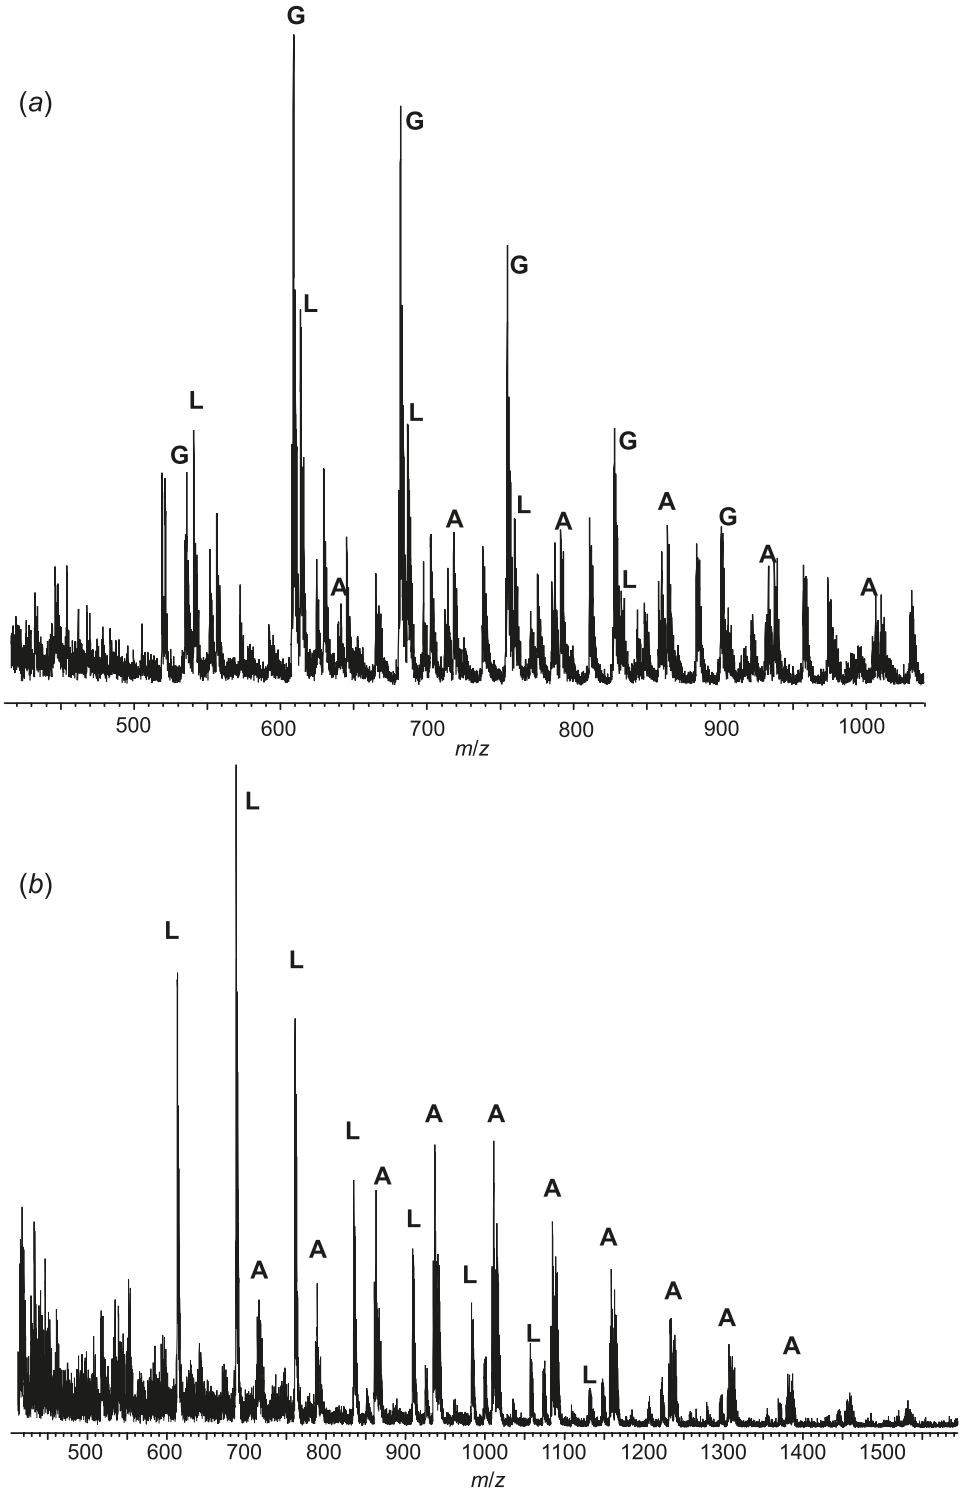

Silver

Two major series of fragment ions are observed above collision energies of 25 eV: $(R_n+73)^+$ and $(R_n+58)^+$ (Fig. 3*c*). Both are due to the initial charge transfer from Ag^+ to the oligomer, followed by fragmentation of the resulting radical cation. The series denoted $(R_n+58)^+$ nominally are due to the loss of a methyl radical and are consistent with the "cyclic" ions observed in the SIMS studies of these complexes. The collision energy dependence of the CID mass spectra shows that $(R_n+73)^+$ and $(R_n+58)^+$ arise simultaneously at a collision energy of 30 eV (Fig. 4*a*), supporting the proposed scheme whereby a four-member siloxane ring is formed, yielding linear and cyclic fragments in the same process (Scheme 1, after charge trans-

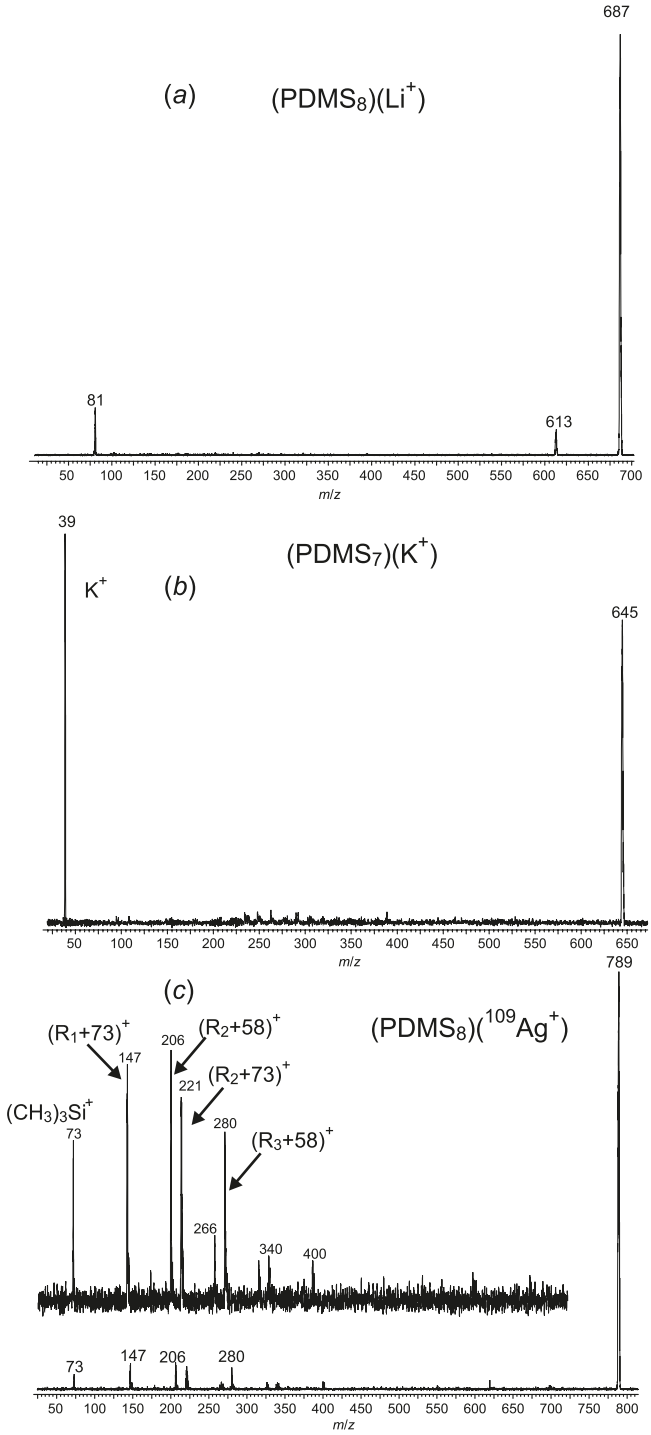

Fig. 4. Collision energy resolved breakdown diagrams for the formation of the $(R_2+73)^+$ and $(R_2+58)^+$ fragment ions from (*a*) $(PDMS_7)(Ag^+)$ and (*b*) $(PDMS_7)(NH_4^+)$ complexes.

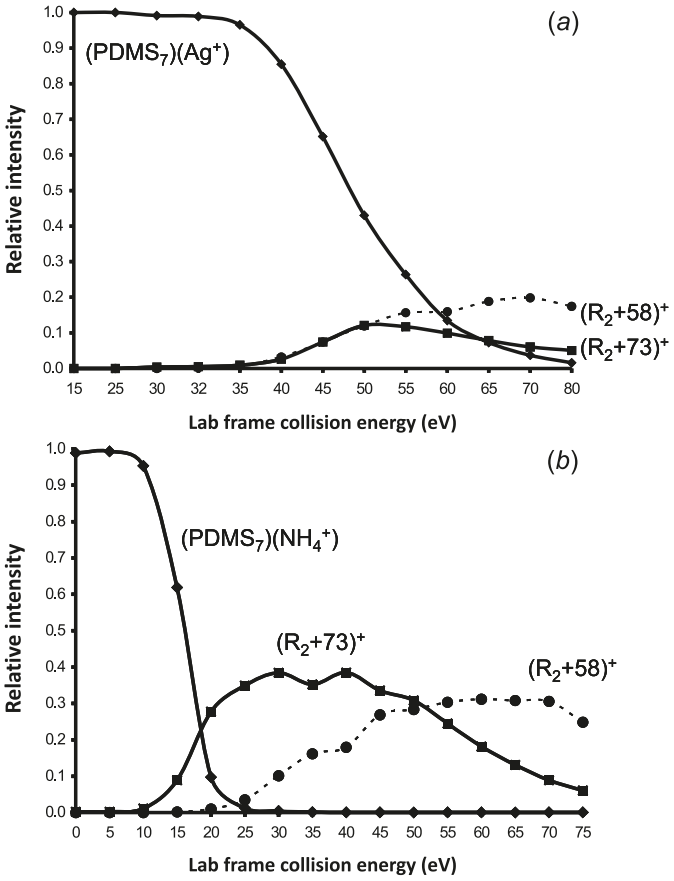

Fig. 5. CID mass spectrum of $(PDMS_7)(NH_4^+)$ (5 eV). Molecular ion at *m/z* 624 not shown.

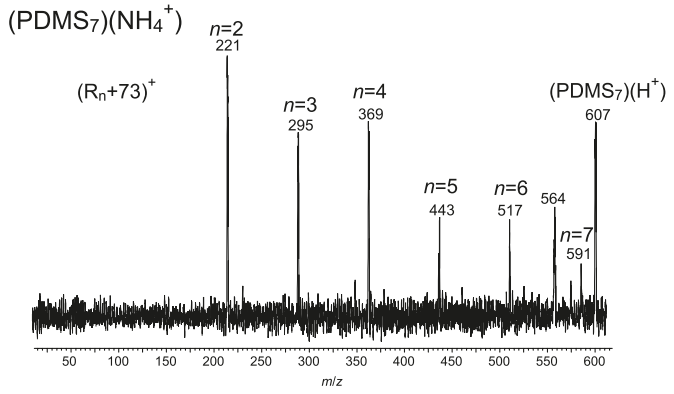
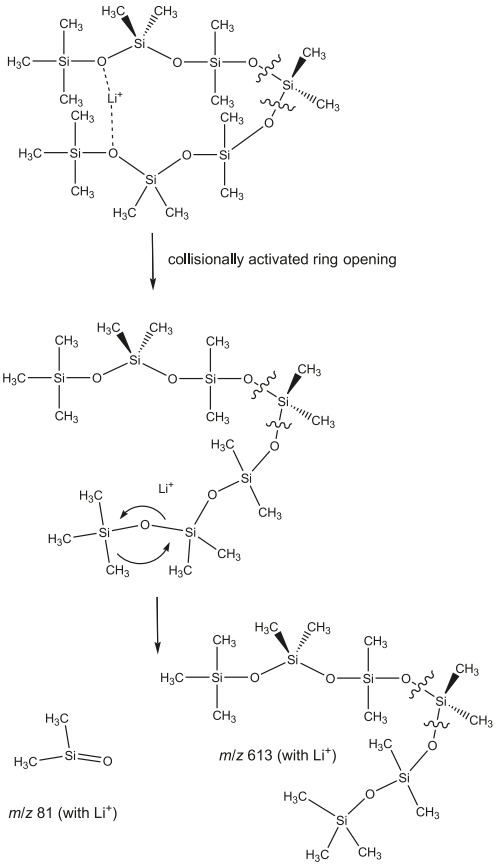


fer to the oligomer). At higher collision energies, the cyclic $(R_2+58)^+$ ions become dominant over the linear $(R_2+73)^+$. The low *m/z* fragment ions are almost the same as those reported in previous SIMS studies, with the exception that the Ag^+ ion peak is not very intense.[11,12]

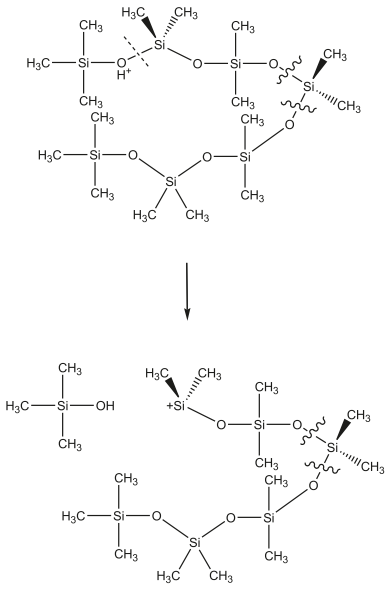
Protonation, ammonia, ethylamine and glycine

CID of the proton-bound oligomer–ethylamine complex results only in the formation of protonated ethylamine, indicating that the gas-phase basicities of the PDMS oligomers are significantly less than that of ethylamine (878 kJ mol^{-1}).[16] In contrast, CID of $(PDMS)H^+$, $(PDMS)NH_4^+$, and $(PDMS)(Gly)H^+$ complexes result in the formation of $(R_n+73)^+$ fragment ions at very low collision energies (Fig. 5). Upon dissociation of the proton-bound complex, the proton may be associated with any of the oxygen atoms along the oligomer backbone, driving cleavage to form the $(R_n+73)^+$ series of ions (Scheme 3). As the length of the oligomers in-

Scheme 2.



Scheme 3.



creases, the same series is observed, but fragment ions above $(R_6+73)^+$ are not as prominent as those with $2 \leq n \leq 6$. The trimethylsilyl fragment (*m/z* 73) and the $(R_1+73)^+$ fragment ions only appear at higher collision energies. $(R_n+58)^+$ fragment ions do appear with low abundance in the CID mass spectra, but the collision energy dependence clearly shows them to be formed sequentially from the $(R_n+73)^+$ ions by methyl radical loss (Fig. 4*b*). It is therefore unlikely that they have the cyclic structure previously proposed, as this would be an entropically unfavourable pathway.

1,2 diphenylethylamine

CID of the (PDMS)(DPEA)H^+ complex results predominantly in the formation of protonated DPEA. Although a small signal due to the protonated oligomer is observed, it does not undergo the same degree of fragmentation observed in the case of H^+, NH_4^+, or $GlyH^+$. One explanation is if the deposited collision energy is statistically distributed among all the degrees of freedom of the complex, relatively less will land up in the protonated oligomer than was the case when the adduct was formed with a smaller molecule.

Conclusion

Changing the complexing agent from a metal ion to a protonated organic base facilitates the formation of a gas-phase protonated PDMS oligomer upon collisional activation. This protonated oligomer undergoes a well-defined cleavage along the Si-O backbone, which is quite distinct from that observed for the metal ion adducts. This approach may be useful for sequencing co-polymers containing dimethylsiloxane or for locating branching sites in more complex samples.

Syntheses, X-ray structures, and redox behaviour of the group 14 bis-boraamidinates M[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ (M = Ge, Sn) and Li$_2$M[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ (M = Sn, Pb)

Jari Konu, Heikki M. Tuononen, and Tristram Chivers

Abstract: The solid-state structures of the complexes M[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ (**1a,** M= Ge; **1b**, M = Sn) were determined to be spirocyclic with two orthogonal boraamidinate (*bam*) ligands N,N′-chelated to the group 14 centre. Oxidation of **1b** with SO_2Cl_2 afforded the thermally unstable, blue radical cation {Sn[PhB(μ-*N*-*t*-Bu)$_2$]$_2$}$^{\bullet+}$, identified by electron paramagnetic resonance (EPR) spectroscopy supported by density functional theory (DFT) calculations, whereas the germanium analogue **1a** was inert towards SO_2Cl_2. The reaction between Li$_2$[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ and $SnCl_2$ or PbI_2 in 2:1 molar ratio in diethyl ether produced the novel heterotrimetallic complexes Li$_2$Sn[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ (**2b**) and (Et$_2$O·Li)LiPb[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ (**2c**·OEt$_2$), respectively. By contrast, treatment of Li$_2$[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ with $C_4H_8O_2$·$GeCl_2$ yielded the germanium(IV) complex **1a** via a redox process. The X-ray structures of **2b** and **2c**·THF revealed polycyclic arrangements in which one *bam* ligand is N,N′-chelated to the Sn(II) or Pb(II) atom and one of the Li$^+$ cations, while the second *bam* ligand exhibits a unique bonding mode, bridging all three metal centres. The fluctional behaviour of **2b** was investigated by variable temperature, multinuclear NMR spectroscopy.

Key words: germanium, tin, lead, boraamidinate, cation radical.

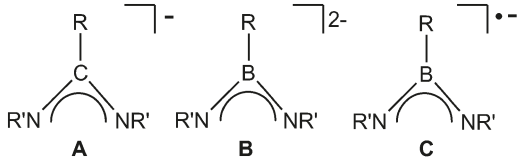
Résumé : On a déterminé que les structures à l'état solide des complexes M[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ (**1a**, M = Ge; **1b**, M = Sn) sont spirocycliques avec deux ligands orthogonaux boraamidinate (bam) avec une chélation N,N′ avec le centre du groupe 14. L'oxydation du produit **1b** à l'aide de SO_2Cl_2 conduit à la formation du cation radical bleu, thermiquement instable {Sn[PhB(μ-*N*-*t*-Bu)$_2$]$_2$}$^{\bullet+}$ identifié par spectroscopie RPE supportée par des calculs à base de la théorie de la fonctionnelle de la densité; l'analogue germanié 1a est inerte vis-à-vis du SO_2Cl_2. La réaction du Li$_2$[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ avec le $SnCl_2$ ou le PbI_2, dans un rapport molaire de 2:1, dans l'éther éthylique, conduit à la formation de nouveaux complexes hétérométalliques Li$_2$Sn[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ (**2b**) et (Et$_2$O·Li)LiPb[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ (**2c**·OEt2). Toutefois, le traitement du Li$_2$[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ par du $C_4H_8O_2$·$GeCl_2$ fournit le complexe de germanium(IV) (**1a**) par le biais d'un processus redox. Les structures des produits **2b** et **2c**·THF, déterminées par diffraction des rayons X, révèlent la présence d'arrangements polycycliques dans lesquels un ligand bam est soumis à une chélation en N,N′ par rapport à l'atome de Sn(II) ou Pb(II) et un des cations Li$^+$ alors que le second ligand bam donne lieu à un mode unique de liaison et qu'il crée un pont pour les trois centres métalliques. On a étudié le comportement fluxionnel du produit en faisant appel à la spectroscopie RMN multinucléaire à température variable.

Mots-clés : germanium, étain, plomb, boraamidinate, cation radical.

[Traduit par la Rédaction]

Introduction

The dianionic boraamidinate (*bam*) ligand, [RB(NR′)$_2$]$^{2-}$ (**B**), is formally isoelectronic with the extensively studied monoanionic amidinate (*am*) ligand, [RC(NR′)$_2$]$^-$ (**A**). A wide range of main-group element and transition-metal complexes have been structurally characterized and a variety of bonding modes have been established for the *bam* ligand.[1–4]



The most intriguing consequence of the 2– charge is the facile tendency for redox transformations to occur in which the dianion **B** is oxidized to the corresponding monoanion radical [*bam*]$^{\bullet-}$ (**C**). This paramagnetic ligand can be stabilized through chelation, e.g., to early main-group metals.[5,6] In the case of group 13 metals it has been possible to isolate *stable* neutral radicals. For example, the intensely coloured paramagnetic species {M[PhB(μ-*N*-*t*-Bu)$_2$]$_2$}$^{\bullet}$ (M = Al, dark red; M = Ga, dark green) are produced by one-electron oxidation of the corresponding anions with iodine, and the X-

ray structures of these spirocyclic complexes have been determined (Scheme 1).[5] The singly occupied molecular orbital (SOMO) of these neutral radicals is located primarily and equally in p-orbitals on the four nitrogen atoms of the two *bam* ligands; there is very little electron density on the group 13 centres. The corresponding boron and indium-containing radicals $\{M[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2\}^\bullet$ (M = B, In) were characterized only in solution by electron paramagnetic resonance (EPR) spectroscopy.[6]

The synthesis and characterization of the group 13 complexes $\{M[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2\}^\bullet$ (M = Al, Ga, In) raises the question of whether the isoelectronic group 14 cation radicals $\{M[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2\}^{\bullet+}$ (M = Si, Ge, Sn) will be accessible by mild oxidation of the corresponding neutral precursors. Several *bam* complexes of group 14 elements (Si, Ge, Sn, Pb) have been reported.[1] Although the metathesis reactions of two equivalents of Li_2*bam* reagents with MCl_4 (M = Ge, Sn) afford the corresponding M(*bam*)$_2$ complexes,[7,8] the synthesis of a silicon analogue (M = Si) by this method has not been reported. The known silicon complexes have only one *bam* ligand chelated to silicon in complexes of the type RR′Si(*bam*); they were prepared by indirect approaches rather than metathesis.[9,10] The solid-state structures of M(*bam*)$_2$ complexes (M = Ge, Sn) have not been determined. Interestingly, the reaction of $Li_2[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]$ with $PbCl_4$ produces the dimeric lead(II) complex $\{Pb[PhB(\mu_3\text{-}N\text{-}t\text{-}Bu)_2]\}_2$, which is preferably prepared by using $PbCl_2$ as a source of lead(II).[11] There are no reports of complexes in which two *bam* ligands are chelated to a group 14 metal in the formal +2 oxidation state, i.e., $[M(bam)_2]^{2-}$ (M = Ge, Sn, Pb). These dianions are isoelectronic with the corresponding group 15 monoanions of the type $[M(bam)_2]^-$ (M = As, Sb, Bi), which exhibit interesting polycyclic structures in the solid state and fluctional behaviour in solution.[12] The synthesis of dilithio derivatives of the group 14 dianions $[M(bam)_2]^{2-}$ (M = Ge, Sn, Pb) is, therefore, of interest for comparison with their group 15 analogues.

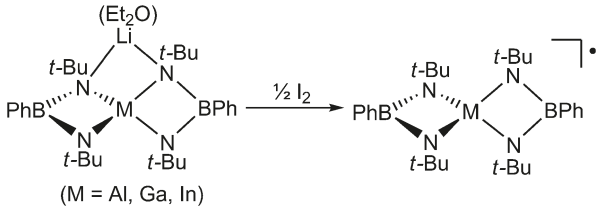
In this contribution we report (*a*) the X-ray structures of the complexes $M[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (**1a**, M = Ge; **1b**, M = Sn), (*b*) oxidation of **1b** with SO_2Cl_2 to give the radical cation $\{Sn[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2\}^{\bullet+}$, which was identified by EPR spectroscopy supported by density functional theory (DFT) calculations, (*c*) the synthesis and X-ray structures of the new heterotrimetallic complexes $Li_2Sn[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (**2b**) and (THF·Li)LiPb$[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (**2c**·THF), and (*d*) variable temperature, multinuclear (^{1}H, ^{13}C, ^{7}Li, ^{11}B, and ^{119}Sn) NMR investigations of the fluctional behaviour of **2b**.

Experimental section

Reagents and general procedures

All reactions and the manipulations of products were performed under an argon atmosphere by using standard Schlenk techniques or an inert atmosphere glove box. The compounds $PhBCl_2$ (Sigma-Aldrich, 97%), $GeCl_4$ (Strem, 99.99%), $C_4H_8O_2{\cdot}GeCl_2$ (Sigma-Aldrich, 99%), $SnCl_4$ (Sigma-Aldrich, 1.0 mol/L soln. in heptane), $SnCl_2$ (Sigma-Aldrich, 98%), PbI_2 (Strem, 99.999%), and *t*-$BuNH_2$ (Sigma-Aldrich, 98%) were used as received. SO_2Cl_2 (Sigma-Aldrich, 97%) was distilled prior to use. LiN(H)-*t*-Bu was prepared by the addition of *n*-BuLi to a solution of anhydrous *t*-$BuNH_2$ in *n*-hexane at –10 °C and its purity was checked by ^{1}H NMR spectroscopy. The compounds $PhB[N(H)\text{-}t\text{-}Bu]_2$ and $Li_2[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]$ were prepared as described earlier.[13] The solvents *n*-hexane, toluene, Et_2O, and THF were dried by distillation over Na/benzophenone under an argon atmosphere prior to use. Elemental analyses were performed by Analytical Services, Department of Chemistry, University of Calgary (Calgary, Alberta).

Scheme 1. Synthesis of spirocyclic $\{M[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2\}^\bullet$ radicals.



Spectroscopic methods

The ^{1}H, ^{7}Li, ^{11}B, ^{13}C, and ^{119}Sn NMR spectra were obtained in d_8-toluene at 23 °C on a Bruker DRX 400 spectrometer operating at 399.59, 155.30, 128.20, 100.49, and 149.00 MHz, respectively. ^{1}H and ^{13}C spectra are referenced to the solvent signal and the chemical shifts are reported relative to $(CH_3)_4Si$. ^{7}Li and ^{11}B NMR spectra are referenced externally and the chemical shifts are reported relative to a 1.0 mol/L solution of LiCl in D_2O and to a solution of $BF_3{\cdot}Et_2O$ in C_6D_6, respectively. Similarly, the ^{119}Sn NMR spectra are referenced externally and the chemical shifts are reported relative to $(CH_3)_4Sn$.

The X-band EPR spectra were recorded on a Bruker EMX 113 spectrometer equipped with a variable-temperature accessory. EPR spectral simulations were carried out by using WINEPR SimFonia (version 1.25, 1996) and PEST WinSim (version 0.98, 2002) softwares.[14]

X-ray crystallography

Crystallographic data for **1a**, **1b**, **2b**, and **2c**·THF are summarized in Table 1 (also see the Supplementary data). Crystals of $Ge[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (**1a**), $Sn[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (**1b**), $Li_2Sn[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (**2b**), and (THF·Li)LiPb$[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (**2c**·THF) were coated with Paratone 8277 oil and mounted on a glass fibre. Diffraction data were collected on a Nonius Kappa CCD diffractometer using monochromated Mo Kα radiation (λ = 0.71073 Å) at –100 °C. The data sets were corrected for Lorentz and polarization effects, and empirical absorption correction was applied to the net intensities. The structures were solved by direct methods using SHELXS-97[15] and refined using SHELXL-97.[16] After full-matrix least-squares refinement of the nonhydrogen atoms with anisotropic thermal parameters, the hydrogen atoms were placed in calculated positions [C-H = 0.98 Å for $C(CH_3)_3$ and 0.95 Å for phenyl hydrogens]. The isotropic thermal parameters of the hydrogen atoms were fixed at 1.2 times to that of the corresponding carbon for phenyl hydrogens and 1.5 times for $C(CH_3)_3$. In the final refinement the hydrogen atoms were riding on their respective carbon atoms.

In the structure of **2b**, the Li2 and Sn1 atoms were disordered with the atoms statistically distributed over the two

atomic sites. The two atoms were constrained to be located in the same position and the anisotropic thermal parameters were restricted to be equal. In the final refinement, the site occupation factors were ca. 93% and 7%, respectively. The scattering factors for the neutral atoms were those incorporated with the programmes.

Computational details

All calculations were done with the Gaussian 03 program using density functional theory.[17] Molecular structures were optimized using the hybrid PBE1PBE exchange-correlation functional[18] together with the Ahlrichs' TZVP basis sets[19]; an effective core potential basis set of similar valence quality was used for the heavy tin nuclei.[20] Hyperfine coupling constants were then calculated by single-point calculations employing the optimized geometries and the basis set combination used for optimizations. The orbital plot was obtained by the program gOpenMol.[21]

Synthesis of Ge[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ (1a)

A solution of Li_2[PhB(μ-*N*-*t*-Bu)$_2$] (0.366 g, 1.50 mmol) in 30 mL of diethyl ether was added to a solution of $GeCl_4$ (0.161 g, 0.75 mmol) in 30 mL of diethyl ether at –80 °C. The reaction mixture was allowed to reach room temperature in 30 min and it was then heated to 35 °C for 15 h. The precipitate of LiCl was removed by filtration and the solvent was evaporated under vacuum giving Ge[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ (**1a**) as a white powder (0.442 g, 83%). The ^{1}H, ^{11}B, and ^{13}C NMR spectra were in good agreement with the literature values.[7] Anal. calcd. for $C_{28}H_{46}B_2N_4Ge$: C 63.10, H 8.70, N 10.51; found: C 62.85, H 8.94, N 10.71. Crystallization from *n*-hexane afforded colourless X-ray quality crystals of Ge[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ (**1a**).

Synthesis of Sn[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ (1b)

A solution of Li_2[PhB(μ-*N*-*t*-Bu)$_2$] (0.244 g, 1.00 mmol) in 25 mL of diethyl ether was added to a solution of $SnCl_4$ (0.5 mL of a 1.0 mol/L solution in heptane, 0.50 mmol) in 25 mL of diethyl ether at –80 °C. The reaction mixture was stirred for 30 min at –80 °C and 6 h at 23 °C. The precipitate of LiCl was removed by filtration and the solvent was evaporated under vacuum giving Sn[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ (**1b**) as a white powder (0.257 g, 87%). The ^{1}H, ^{11}B, and ^{13}C NMR spectra were in excellent agreement with the literature values.[7] ^{119}Sn NMR δ: –83.0 (cf. –117.8 ppm for Sn[(2,4,6-^{i}Pr$_3$C$_6$H$_2$)B(μ-*N*-*t*-Bu)$_2$]$_2$ in $CDCl_3$).[8] Anal. calcd. for $C_{28}H_{46}B_2N_4Sn$: C 58.08, H 8.01, N 9.68; found: C 58.30, H 7.93, N 9.03. Crystallization from *n*-hexane afforded colourless X-ray quality crystals of Sn[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ (**1b**).

Oxidation of Sn[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ (1b) with SO_2Cl_2

A solution of SO_2Cl_2 (0.040 mL, 0.067 g, 0.50 mmol) was dissolved in 10.0 mL of diethyl ether; 1.0 mL (0.05 mmol) of this solution was added to a solution of **1b**

(0.058 g, 0.10 mmol) in 80 mL of diethyl ether at –80 °C. The reaction mixture was allowed to warm up to ca. –40 °C at which point the colourless solution became bright blue and a small amount of white powder (LiCl) appeared. An aliquot of the reaction solution was used for EPR spectroscopic measurements. The remaining reaction solution was allowed to reach room temperature, which resulted in the decomposition of the paramagnetic species at ca. 0 °C as indicated by disappearance of the blue colour.

Synthesis of $Li_2Sn[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (2b)

A solution of $Li_2[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]$ (0.366 g, 1.50 mmol) in 25 mL of diethyl ether was added to a suspension of $SnCl_2$ (0.142 g, 0.75 mmol) in 25 mL of diethyl ether at –80 °C. The reaction mixture was stirred for 30 min at –80 °C and 5 h at 23 °C. The precipitate of LiCl was removed by filtration and the solvent was evaporated under vacuum. The product was then washed with cold *n*-hexane (ca. 10 mL) to give **2b** as a white powder (0.364 g, 75%). ^{1}H NMR (d_8-toluene, 23 °C) δ: 6.98–7.72 (m, 10H, C_6H_5), 1.39 (shoulder, br, 9H, $C(CH_3)_3$), 1.19 (s, br, 27H, $C(CH_3)_3$). ^{1}H NMR (0 °C) δ: 6.96–7.72 (m, 10H, C_6H_5), 1.44 (s, 9H, $C(CH_3)_3$), 1.21 (s, 27H, $C(CH_3)_3$). ^{1}H NMR (–20 °C) δ: 6.92–7.70 (m, 10H, C_6H_5), 1.46 (s, 9H, $C(CH_3)_3$), 1.24 (s, 9H, $C(CH_3)_3$), 1.21 (s, 18H, $C(CH_3)_3$). ^{13}C NMR (–20 °C) δ: 133.9–125.8 (C_6H_5), 54.4 (s, $C(CH_3)_3$), 52.1 (s, $C(CH_3)_3$), 51.1 (s, $C(CH_3)_3$), 37.0 (s, $C(CH_3)_3$), 36.6 (s, $C(CH_3)_3$), 36.1 (s, $C(CH_3)_3$). ^{11}B NMR (–20 °C) δ: 36.6. ^{7}Li NMR (–20 °C) δ: 1.10. ^{119}Sn NMR (d_8-toluene, 23 °C, ppm) δ: –167.9. Anal. calcd. for $C_{32}H_{56}B_2Li_2N_4Sn$: C 56.72, H 7.82, N 9.45; found: C 55.45, H 7.99, N 9.18. X-ray quality crystals of **2b** were obtained by dissolving the white powder in boiling *n*-hexane and then allowing the solution to cool down to room temperature in ca. 3 h.

Synthesis of $(Et_2O{\cdot}Li)LiPb[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (2c·OEt_2)

Method A

A solution of $Li_2[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]$ (0.244 g, 1.00 mmol) in 30 mL of diethyl ether was added to a suspension of PbI_2 (0.231 g, 0.50 mmol) in 30 mL of diethyl ether at –80 °C. The reaction mixture was allowed to reach room temperature in 30 min and it was then heated to 35 °C for 12 h. The precipitate of LiI was removed by filtration and the solvent was evaporated under vacuum giving a pale yellow, amorphous powder (0.294 g). ^{1}H NMR spectroscopy revealed a mixture of products among which the lead(II) complex, $\{Pb[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]\}_2$, was identified (δ: 1.15 ppm, d_8-toluene, 23 °C; lit. value[11] δ: 1.19 in C_6D_6) in addition to the resonances of **2c**·OEt_2 (see discussion of the VT NMR experiments). **2c**·OEt_2: ^{1}H NMR (d_8-toluene, 23 °C) δ: 7.02–7.78 (m, C_6H_5), 3.40 (q, 6H, $(CH_3CH_2)_2O$), 1.27 (s, br, 36H, $C(CH_3)_3$), 1.00 (t, 6H, $(CH_3CH_2)_2O$). ^{1}H NMR (0 °C): δ: 7.08–7.82 (m, C_6H_5), 3.34 (q, 6H, $(CH_3CH_2)_2O$), 1.35 (shoulder, 9H, $C(CH_3)_3$), 1.29 (s, 18H, $C(CH_3)_3$), 1.25 (shoulder, 9H, $C(CH_3)_3$), 0.97 (t, 6H, $(CH_3CH_2)_2O$). ^{1}H NMR (–10 °C) δ: 7.10–7.83 (m, C_6H_5), 3.34 (q, 6H, $(CH_3CH_2)_2O$), 1.36 (s, 9H, $C(CH_3)_3$), 1.30 (s, 18H, $C(CH_3)_3$), 1.25 (s, 9H, $C(CH_3)_3$), 0.96 (t, 6H, $(CH_3CH_2)_2O$). ^{7}Li NMR (–20 °C) δ: 0.87. Crystallization from THF afforded a few colourless crystals of $(THF{\cdot}Li)LiPb[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (**2c**·THF).

Method B

The Pb(II) complex $\{Pb[PhB(\mu_3\text{-}N\text{-}t\text{-}Bu)_2]\}_2$ was prepared by a modification of the procedure reported earlier[11] from the reaction of PbI_2 (0.461 g, 1.00 mmol) and $Li_2[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]$ (0.244 g, 1.00 mmol) in diethyl ether. The purity of the compound was checked by ^{1}H NMR spectroscopy. A solution of $Li_2[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]$ (0.244 g, 1.00 mmol) in 30 mL of diethyl ether was added to a solution of $\{Pb[PhB(\mu_3\text{-}N\text{-}t\text{-}Bu)_2]\}_2$ (0.437 g, 0.50 mmol) in 30 mL of diethyl ether at –80 °C. The reaction mixture was allowed to reach room temperature in 30 min and it was then heated to 35 °C for 18 h. The precipitate of LiI was removed by filtration and the solvent was evaporated under vacuum giving a pale yellow, amorphous powder (0.546 g). The ^{1}H NMR spectrum of this powder in d_8-toluene revealed a complex mixture of products. The reactions described in methods **A** and **B** were also carried out in THF at 55 °C without significant improvement in the yield of **2c.**

Reaction of $Li_2[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]$ with $C_4H_8O_2{\cdot}GeCl_2$

A solution of $Li_2[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]$ (0.183 g, 0.75 mmol) in 25 mL of diethyl ether was added to a solution of $C_4H_8O_2{\cdot}GeCl_2$ (0.174 g, 0.75 mmol) in 25 mL of diethyl ether at –80 °C. The reaction mixture was stirred for 30 min at –80 °C and 16 h at 23 °C. The precipitate of LiCl was removed by filtration and the solvent was evaporated under vacuum giving a pale yellow, amorphous powder (0.185 g, 78% calculated as a 1:2 mixture of **1a** and $\{Ge[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]\}_2$, see discussion). ^{1}H NMR (d_8-toluene, 23 °C) δ: 7.02–7.96 (m, 30H, C_6H_5), 1.41 (s, 36H, $C(CH_3)_3$), 1.39 (s, 36H, $C(CH_3)_3$), 1.30 (s, 36H, $C(CH_3)_3$). ^{11}B NMR (–20 °C) δ: ca. 36.5 (br). Crystallization from *n*-hexane afforded a few colourless crystals of $Ge[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (**1a**).

Results and discussion

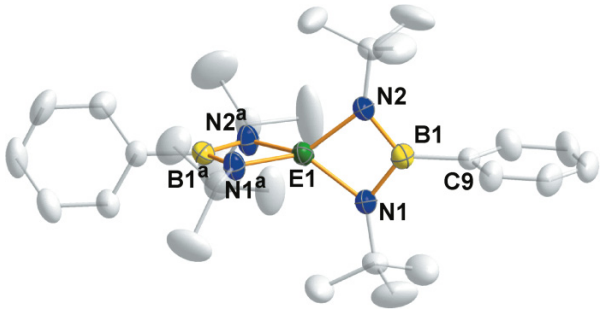
X-ray structures of $M[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (1a, M = Ge; 1b, M = Sn)

The germanium(IV) and tin(IV) complexes **1a** and **1b** were obtained by a modification of the literature synthesis[7] in which the dilithium reagent $Li_2[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]$ was isolated and purified prior to reaction with MCl_4 (M = Ge, Sn) in a 2:1 molar ratio in diethyl ether. This new procedure afforded analytically pure **1a** and **1b** in ca. 85% yields, cf. lit. **1a** (31%) and **1b** (44%).[7] Attempts to make the silicon analogue $Si[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ by a similar procedure were unsuccessful.

The X-ray structural determinations of **1a** and **1b** confirmed the expected spirocyclic structures with two orthogonal *bam* ligands *N*,*N*′-chelated to the distorted tetrahedral metal centres (Fig. 1). In both complexes the molecule lies on a crystallographic twofold axis that imposes equivalence on the two *bam* ligands. The diamagnetic complexes **1a** and **1b** are isostructural with the paramagnetic group 13 analogues $\{M[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2\}^\bullet$ (M = Al, Ga).[5] The centrosymmetric germanium(IV) complex **1a** represents the first structurally characterized germanium *bam* complex.[1]

Selected bond lengths and bond angles for **1a** and **1b** are summarized in Table 2. The distorted tetrahedral germanium centre in **1a** exhibits equal Ge–N bond lengths, which are

Fig. 1. Molecular structure of Ge[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ (**1a**) with the atomic numbering scheme. Hydrogen atoms have been omitted for clarity. The tin complex **1b** is isostructural with **1a**. Symmetry operation: [a] –*x*, *y*, 0.5 – *z* (E = Ge); 1 – *x*, *y*, 1.5 – *z* (E = Sn).



noticeably shorter (by ca. 0.20 Å) than the corresponding M–N bonds in the heavier tin analogue **1b**. Somewhat surprisingly, the Ge–N bonds in **1a** are also significantly shorter than the Ga–N bond lengths of 1.922(2) Å observed in the neutral radical Ga[PhB(μ-*N*-*t*-Bu)$_2$]$_2$•,[5] despite the difference of only one electron between the two centres (Ge and Ga). The Ge–N bond lengths are, however, equal within estimated standard deviation with the Al–N bond lengths of 1.842(2) and 1.852(2) Å reported for {Al[PhB(μ-*N*-*t*-Bu)$_2$]$_2$}•,[5] for which the difference between the two metal centres (Ge and Al) is nine electrons. These trends in bond lengths may be attributed to the weaker Coulomb interaction in the paramagnetic group 13 complexes where the total charge on the ligands is formally 3– compared to the diamagnetic group 14 complexes for which the formal charge is 4–. Interestingly, the Ge–N bonds in **1a** are also ca. 0.04 Å longer than the As–N bond lengths of 1.797(4)–1.811(4) Å observed in the isostructural, and *isoelectronic*, group 15 cation As[PhB(μ-*N*-*t*-Bu)$_2$]$_2^+$ (in the $GaCl_4^-$ salt).[22] Since the single bond covalent radius is the same for Ge and As (1.22 Å),[23] the shorter As–N bonds are probably due to the stronger electrostatic interaction between the positively charged arsenic centre and the two dianionic *bam* ligands. In the tin(IV) complex **1b** the Sn–N bonds within each *bam* ligand are equal in length and are close to the values of 2.043(3)–2.066(3) Å observed in the eight-membered rings {Me$_2$Sn[μ-N(Me)B(R)NMe]$_2$SnMe$_2$} (*R* = 2,4,6-*i*-Pr$_3$C$_6$H$_2$, 2,4,6-*t*-Bu$_3$C$_6$H$_2$), which also involve Sn(IV) centres,[8,24] but they are somewhat shorter than the value of 2.105(1) Å found for the Sn–N bond involving a three-coordinate nitrogen atom in the dimeric Sn(II) complex, {Sn[MeB(μ-NSiMe$_3$)$_2$]}$_2$.[25] The B–N bond lengths in both **1a** and **1b** are equal and represent typical values for the *bam* ligand.[1]

The M-N-B angles in **1a** and **1b** are close to 90° and the geometry about boron atom is trigonal planar as indicated by the sum of bond angles (360°). The N-B-N and all N-Ge-N angles in **1a** are close to the corresponding bond angles observed in {Al[PhB(μ-*N*-*t*-Bu)$_2$]$_2$}•[5] due to the identical Ge-N/Al-N and B–N bond lengths, whereas the longer Sn–N bonds result in a narrower N-Sn-N angle by ca. 7° and 3° within the *bam* ligands in **1b**. The GeBN$_2$ four-membered rings in **1a** are planar with torsion angles of 0.5(2)° and 0.6(2)° for ∠ N2-Ge1-N1-B1 and Ge1-N1-B1-N2, respectively, while the corresponding torsion angles for the slightly puckered SnBN$_2$ four-membered rings in **1b** are 4.6(2)° and 6.5(3)°.

Although all four isostructural compounds (**1a**, **1b**, and M[PhB(μ-*N*-*t*-Bu)$_2$]$_2$• (M = Al, Ga)) exhibit a centre of symmetry at the group 13 or 14 atom, the tin complex **1b** exhibits different crystal packing from the other three complexes as indicated by the crystal system and space group [monoclinic *C*2/*c* for **1b** vs orthorhombic *Pbcn* for **1a** and M[PhB(μ-*N*-*t*-Bu)$_2$]$_2$• (M = Al, Ga)].

EPR spectra and DFT calculations of the radical cation {Sn[PhB(μ-*N*-*t*-Bu)$_2$]$_2$}•+

The intensely coloured spirocyclic group 13 radicals {M[PhB(μ-*N*-*t*-Bu)$_2$]$_2$}• (M = Al, Ga) (Scheme 1) are stable in the solid state,[5] while the indium analogue {In[PhB(μ-*N*-*t*-Bu)$_2$]$_2$}• has only been characterized in solution by EPR spectroscopy.[6] In an attempt to generate the isoelectronic radical cations with a group 14 metal centre, {M[PhB(μ-*N*-*t*-Bu)$_2$]$_2$}•+ (M = Ge, Sn), we have investigated the reactions of **1a** and **1b** with various oxidizing agents (Scheme 2).

The attempted one-electron oxidation of **1a** or **1b** to the corresponding radical cation by one-half equivalent of I_2 in diethyl ether or THF resulted in no reaction even at elevated temperatures. The tin(IV) complex **1b** was also inert towards [NO][SbF_6] and, surprisingly, the germanium(IV) complex **1a** showed no indication of a reaction with SO_2Cl_2. However, the treatment of **1b** with one-half equivalent of SO_2Cl_2 in diethyl ether at low temperatures produced a bright blue solution of {Sn[PhB(μ-*N*-*t*-Bu)$_2$]$_2$}•+ (vide infra), which was persistent below –40 °C, but decomposed above 0 °C, cf. the thermal instability of the isoelectronic indium-containing neutral radical {In[PhB(μ-*N*-*t*-Bu)$_2$]$_2$}•.[6]

The EPR spectrum of the blue solution in diethyl ether displays an eight-line pattern and a highly broadened lineshape (Fig. 2); the g-value of this radical is 2.0055. Several attempts to resolve additional fine structure in the EPR spectrum by variations in the solvent, concentration of the solution, and temperature, as well as changes in the measurement parameters, were unsuccessful. A reasonable simulation of the observed spectrum is obtained by using a line width of 2.85 G (95% Gaussian shape) and by including hyperfine coupling constants to one boron atom (^{11}B, *I* = 3/2, 9.88 G) and two equivalent nitrogen centres (^{14}N, *I* = 1, 9.18 G) (Fig. 2) thus suggesting localization of the unpaired electron in only one of the *bam* units, in contrast to the delocalization over both *bam* ligands observed for the neutral group 13 radicals {M[PhB(μ-*N*-*t*-Bu)$_2$]$_2$}• (M = Al, Ga, In).[5,6] This electron distribution is, however, reminiscent of the behaviour noted for the persistent radicals {(Et$_2$O)Li[PhB(μ-*N*-*t*-Bu)$_2$]$_2$M}• (M = Mg, Zn), which exhibit localization of the unpaired electron on the spin-active nuclei in only one of the *bam* ligands as a consequence of the coordination of the additional lithium counter-cation to the second *bam* unit.[6]

The apparent localization of the unpaired electron in only one of the *bam* ligands, and the strong coordinating nature of the Cl^- counter-anion, raised the possibility of the formation of neutral radicals, {Sn[PhB(μ-*N*-*t*-Bu)$_2$]$_2$Cl}•, comprising a Sn-Cl or B-Cl contact instead of the ion-separated radical cation, {Sn[PhB(μ-*N*-*t*-Bu)$_2$]$_2$}•+ (Scheme 3), cf. the Zwitterionic arsenic(V) complex, {[PhB(μ-*N*-*t*-Bu)$_2$]As[(μ-*N*-*t*-Bu)$_2$B(Cl)Ph]}, with a covalent B–Cl bond.[22] Conse-

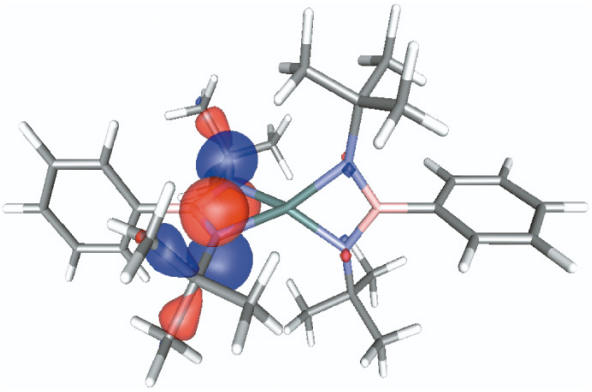
quently, the replacement of the Cl^- anion by the weakly coordinating SbF_6^- was performed by an in situ reaction with $AgSbF_6$. The thermal stability of the radical cation was not improved, but a colour change from blue to purple was observed along with the formation of AgCl. The EPR spectrum of the purple solution, however, was unaffected by the change of the counter-anion, suggesting that the one-electron oxidation product of **1b** is present *in very dilute diethyl ether solutions as the ion-separated radical cation **I*** rather than the "contact ion-pairs" **II** or **III**.

Density functional theory calculations conducted for the cation radical {Sn[PhB(μ-*N*-*t*-Bu)$_2$]$_2$}$^{\bullet+}$ predict a C_{2v}-symmetric minimum structure and localized spin density on only one *bam* ligand (Fig. 3). A D_{2d}-symmetric structure, analogous to that observed for the neutral group 13 radicals {M[PhB(μ-*N*-*t*-Bu)$_2$]$_2$}$^{\bullet}$ (M = Al, Ga) (Scheme 1), is a transition state with respect to Sn-N stretching vibrations and only 5 kJ mol^{-1} higher in energy. Hence, it appears that the spiroconjugative interactions in **1b** are not sufficiently strong to give rise to a fully delocalized electron distribution in the corresponding cation,[26] and the system adopts a structure with the two *bam* ligands bearing different formal charges, i.e., Sn(IV)(*bam*)$^{2-}$(*bam*)$^{-\bullet}$. This is consistent with the finding that optimizations carried out for the lighter group 14 congeners of {M[PhB(μ-*N*-*t*-Bu)$_2$]$_2$}$^{\bullet+}$ (M = Si, Ge) give minima with significantly shorter N···N

Fig. 3. SOMO of the radical cation $\{Sn[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2\}^{\bullet+}$ (±0.05 isodensity surfaces).



separations and, consequently, only D_{2d}-symmetric structures are found.

The hyperfine coupling constants calculated for $Sn[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2\}^{\bullet+}$ ($2 \times {}^{14}N$, 7.35 G; $2 \times {}^{14}N$, 0.05 G; ^{11}B, –10.96 G; ^{11}B, –0.32 G) are in good agreement with the values determined from the experimental spectrum. Similar to the previous observations for the persistent radicals $\{(Et_2O)Li[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2M\}^{\bullet}$ (M = Mg, Zn),[6] the calculated nitrogen couplings are too small, whereas the coupling to the boron nuclei is slightly larger than the value inferred from the simulation; there is an apparent tendency of this functional basis set combination to underestimate couplings that result from the spin density of the unpaired electron while overestimating those that arise from spin-polarization effects.[5,6] The undulating baseline of the EPR spectrum and the low intensity humps visible at both ends of the spectrum most likely arise from the presence of small amounts of isotopomers, which contain the spin-active tin nuclei (^{117}Sn, I = 1/2, 7.6%; ^{119}Sn, I = 1/2, 8.6%). The magnitudes of the two Sn couplings cannot, however, be obtained with the current computational method due to the indirect treatment of relativistic effects via effective core potential basis sets. The observed broad lineshape can, at least in part, be attributed to the numerous smaller couplings to the hydrogen atoms of the *t*-Bu groups.[27]

Synthesis of $Li_2Sn[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (2b) and $(THF{\cdot}Li)LiPb[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (2c·THF)

The reactions of $Li_2[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]$ with group 14 dihalides in a 2:1 molar ratio were investigated with a view to isolating and structurally characterizing complexes of the type $Li_2M[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ in which the dianions $M[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2^{2-}$ (M = Ge, Sn, Pb) are isoelectronic with the previously reported group 15 anions $M[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2^{-}$ (M = As, Sb, Bi), which were obtained as monolithium derivatives.[12] The outcome of these reactions was markedly dependent on the nature of the group 14 metal.

The reaction between $Li_2[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]$ and $SnCl_2$ in a 2:1 molar ratio in diethyl ether proceeded cleanly to produce $Li_2Sn[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (**2b**) in 75% yield (eq. [1]). The unsolvated heterotrinuclear complex **2b** was characterized in solution by multinuclear NMR spectroscopy and in the solid state by single crystal X-ray crystallography.

$$[1]\quad 2Li_2[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2] + SnCl_2 \rightarrow Li_2Sn[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2 + 2LiCl \quad (\mathbf{2b})$$

The reaction of $Li_2[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]$ with PbI_2 in 2:1 molar ratio was conducted under various conditions in an effort to produce the analogous lead(II) complex $Li_2Pb[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (**2c**). The ^1H NMR spectrum of the reaction mixture, however, revealed several products, one of which was identified as the previously reported mononuclear lead(II) complex, $\{Pb[PhB(\mu_3\text{-}N\text{-}t\text{-}Bu)_2]\}_2$.[11] In an alternative synthetic approach, this dimeric Pb(II) complex was prepared and isolated prior to treatment with two equivalents of $Li_2[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]$. However, this two-step method also afforded a mixture of products from which only a few crystals of **2c** were isolated as the tetrahydrofuran solvate, (THF·Li)-$LiPb[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (**2c**·THF).

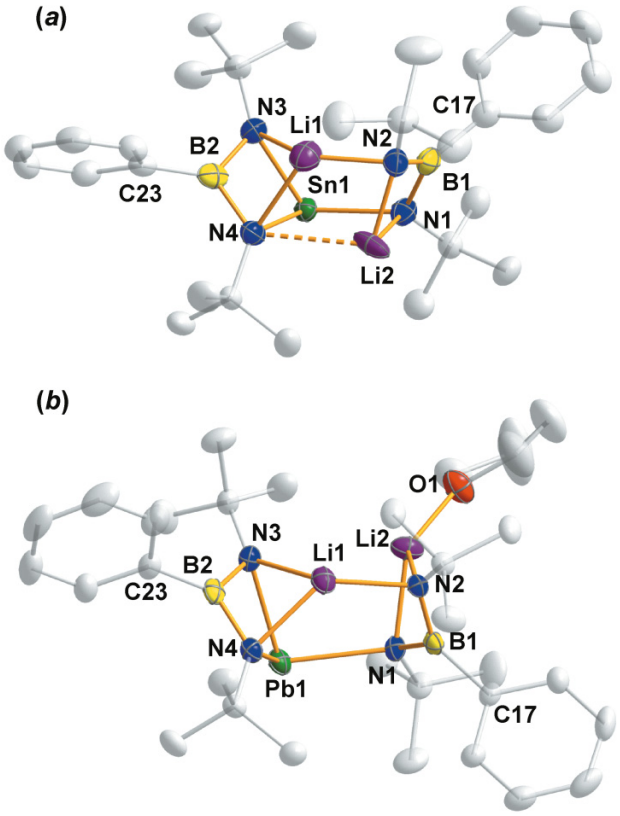
The reaction of $Li_2[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]$ with $C_4H_8O_2{\cdot}GeCl_2$ in 2:1 molar ratio in diethyl ether produced several products (^1H NMR). Consequently, the reaction was repeated in 1:1 molar ratio in an attempt to form the unknown germanium(II) complex, $Ge[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]$, for subsequent reaction with $Li_2[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]$; this two-step approach was previously found to be necessary for the successful synthesis of the aluminum complex $(Et_2O{\cdot}Li)Al[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$.[5] The ^1H NMR spectrum of the product(s) showed three equally intense resonances for *N*-*t*-Bu groups at 1.41, 1.39, and 1.30 ppm (d_8-toluene, 23 °C). The chemical shift of 1.30 ppm is identical with the value observed for the *t*-Bu groups in the germanium(IV) complex $Ge[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (**1a**),[8] suggesting that a redox process has occurred. The resonances at 1.41 and 1.39 are tentatively assigned to the *t*-Bu groups attached to the three- and four-coordinate nitrogen atoms of the dimeric complex germanium(II) complex $\{Ge[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]\}_2$; however, attempts to isolate this second product were unsuccessful.

X-ray structures of $Li_2Sn[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (2b) and $(THF{\cdot}Li)LiPb[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (2c·THF)

Crystals of **2b** and **2c**·THF were obtained by recrystallization from boiling *n*-hexane and THF, respectively.[28] The crystal structures of **2b** and **2c**·THF with the atomic numbering scheme are depicted in Fig. 4 and the pertinent bond parameters are summarized in Table 3. The structures reveal novel polycyclic arrangements, which bear a close similarity with each other despite the introduction of a solvent molecule in **2c**·THF. In both frameworks one of the *bam* ligands is *N*,*N*′-chelated to both the M(II) atom (M = Sn, Pb) and one of the Li^+ ions while the second *bam* ligand exhibits a unique bonding motif by bridging all three metal centres.[1] While one of the Li^+ ions (Li1) in both structures is coordinated to three nitrogens, the second lithium in **2c**·THF is coordinated to two nitrogen atoms and the solvent molecule. The absence of the solvent molecule in **2b** affords a third, albeit relatively weak, Li···N close contact [2.557(6) Å] for the second lithium cation that results in a formal coordination number of five for the N4 atom (Fig. 4*a*).

Lithium salts of the group 15 monoanions $M[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2^{-}$ (**3**, M = Sb; **4**, M = Bi),[12] which are isoelectronic with the group 14 dianions $M[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2^{2-}$ (M = Sn,

Fig. 4. Crystal structures of (*a*) $Li_2Sn[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (**2b**) and (*b*) (THF·Li)LiPb[PhB(μ-*N*-*t*-Bu)$_2$]$_2$ (**2c**·THF) with the atomic numbering scheme. Hydrogen atoms have been omitted for clarity.



Pb), provide an interesting benchmark for comparison with the structures of **2b** and **2c**·THF (Scheme 4). Curiously, the lighter complexes in both group 14 (M = Sn) and group 15 (M = Sb) seem to favour unsolvated structures, whereas solvation of the Li^+ cation is observed for the heavier congeners (M = Pb, Bi). The molecular structure of the antimony complex **3** is comprised of two four-membered rings, BN_2Li and BN_2Sb, connected by Li–N and Sb–N bonds to form a tricyclic compound with both three- and four-coordinate nitrogens.[12] The introduction of a second Li^+ ion in **2b** has a surprisingly small effect on the overall structure; the molecule retains the ladder-like backbone and cisoid arrangement of the PhBN-*t*-Bu units. Most significantly, however, the Li2···N4 contact in **2b** (Fig. 4*a*, dashed line in Scheme 4) is elongated by ca. 0.28 Å compared to the analogous bond in the antimony complex due to the pseudo-five-coordination of the nitrogen atom. The lithium cation in the bismuth complex **4**·OEt_2 (Scheme 4) is four-coordinate, being *N*,*N*′-chelated by one *bam* ligand and bonded to one nitrogen of the second *bam* ligand; the fourth coordination site is occupied by an Et_2O molecule.[12] The introduction of a second Li^+ ion in **2c**·THF ruptures the bond between the solvated Li^+ ion and the second *bam* ligand, and cleaves the fourth M–N bond (M = Bi) that exists in the structure of **4**·OEt_2, although it is elongated compared to the other three Bi–N bonds (by ca. 0.18 Å).[12] As a result, both Li^+ ions are three-coordinate and all four nitrogen atoms are four-coordinate in **2c**·THF.

The average Sn–N bond length of 2.187(4) Å in **2b** (Fig. 4*a*, Table 3) is significantly longer than the values of 2.043(3)–2.066(3) Å observed in **1b** and in the Sn(IV) complexes $\{Me_2Sn[\mu\text{-}N(Me)B(R)NMe]_2SnMe_2\}$ (R = 2,4,6-*i*-$Pr_3C_6H_2$, 2,4,6-*t*-$Bu_3C_6H_2$),[8,24] but slightly shorter than the distance of 2.254(13) Å found for the Sn–N bonds involving four-coordinate nitrogen atoms in the dimeric Sn(II) complex $\{Sn[MeB(\mu_3\text{-}NSiMe_3)_2]\}_2$.[25] Expectedly, the Sn–N bond lengths are also close to the values of 2.145(5) and 2.198(5) Å observed for the Sb–N bonds to the four-coordinate nitrogens in **3** (the single bond covalent radii for Sn and Sb are 1.40 and 1.43 Å, respectively).[23] The Li1–N distance to the bridging *bam* ligand is ca. 0.18 Å shorter than the two Li1–N bonds to the chelating *bam* ligand. To compensate for the long Li2···N4 contact, the two Li2–N bonds of 1.869(5) and 1.884(5) Å are among the shortest lithium–nitrogen bonds observed for this ligand system.[1]

The introduction of a second Li^+ ion in **2b** results in opening the angle between BN_2Sn and LiN_2Sn four-membered rings as illustrated by the N1-Sn1-N3 and Li2-N4-B2 angles, which are ca. 4° and 9° wider, respectively, than the corresponding angles in the related antimony complex, **3**.[12] Widening of these angles and elongation of the Sn1-N1 and Li2-N4 contacts in **2b** compared to the analogous Sb–N and Li–N bonds, however, allows B1 and N2 atoms to incline towards the central $SnLiN_2$ four-membered ring and, consequently, the Sn1-N1-B1 and N4-Li2-N2 angles are ca. 4° and 5° narrower than the comparable angles in **3**. The N-Sn-N angle within the chelating *bam* ligand in **2b** is ca. 5.7° smaller than the corresponding angle in **1b** owing to the slightly longer Sn–N bonds in **2b**.

The average Pb–N bond length in **2c**·THF (Fig. 4*b*, Table 3) of 2.330(3) Å is identical to the value of 2.329(6) Å observed for the Pb–N bond involving a four-coordinate nitrogen atom in the dimeric lead(II) complex $\{Pb[PhB(\mu_3\text{-}N\text{-}t\text{-}Bu)_2]\}_2$.[10] The Pb–N bonds are ca. 0.06 Å longer than the three Bi–N bonds in **4**·OEt_2 (cf. the single bond covalent radii of 1.54 and 1.52 Å for Pb and Bi, respectively),[23] but they are ca. 0.11 Å shorter than the fourth, elongated, Bi–N bond in the bismuth complex.[12] The Li-N distances to the N2 atom in the bridging ligand in **2c**·THF are somewhat shorter than the remaining three Li-N interactions (ca. 0.12 and 0.07 Å for Li1-N2 and Li2-N2, respectively). All these distances are consistent with, for example, those in the group 13 and 15 complexes $(Et_2O\cdot Li)M[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$, which show two (M = Ga, In, As) or three (M = Bi) Li-N interactions.[4,12] The N-Pb-N angle in the chelating ligand is ca. 10° narrower than the N-Li-N angle at the unsolvated Li^+ ion due to the longer Pb–N bonds.

The bridging *bam* ligand in both **2b** and **2c**·THF exhibits a significant disparity in the B–N bond lengths (ca. 0.12 and 0.08 Å, respectively), presumably as a result of the different environments of N1 and N2, whereas the equality of the B–N bonds in the chelating *bam* ligand is not significantly perturbed by the weak Li2···N4 contact. The N-B-N angle in the chelating ligand in both **2b** and **2c**·THF is somewhat smaller (by 7.1° and 6.4°, respectively) than the analogous bond angle in the bridging *bam* ligand. Nevertheless, the boron atom assumes trigonal planar geometry in the *bam* ligands in both complexes. The bond angles at the nitrogen atoms in the chelating ligand are close to 90°, whereas the loss of

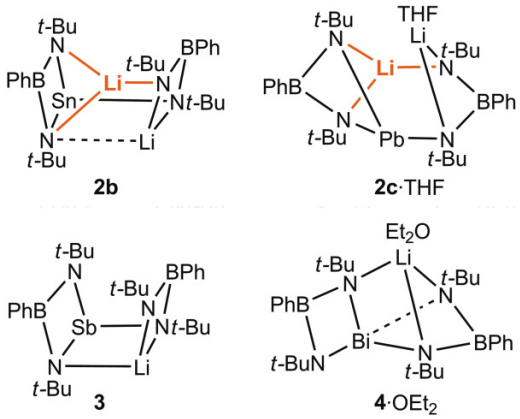
[a]M = Sn.
[b]M = Pb.

Scheme 4. Comparison of the structures of $Li_2M[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (M = Sn, Pb) and $LiM[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (M = Sb, Bi).



the fourth M–N bond results in a wider M1-N1-B1 angle by ca. 32° (M = Sn) and 30° (M = Pb).

NMR spectra and fluctional behaviour of $Li_2Sn[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ (2b)

The ^{1}H NMR spectrum of **2b** in d_8-toluene at 23 °C exhibits a broad, poorly resolved signal for *t*-Bu groups, in addition to typical resonances for the phenyl groups. When the temperature is lowered to 0 °C, this broad resonance resolves into two well-separated signals at 1.44 and 1.21 ppm in a 1:3 intensity ratio. Cooling the solution to –20 °C results in resolution of the latter resonance to give three singlets at 1.46, 1.24, and 1.21 ppm in a 1:1:2 intensity ratio.[29] No further changes are apparent at lower temperatures. Consistently, the ^{13}C NMR spectrum of **2b** at –20 °C exhibits three singlets at 54.4, 52.1, and 51.1 ppm for the α-carbon atoms of the *t*-Bu groups; three singlets are also observed for the methyl carbons at 37.0, 36.6, and 36.1 ppm, in addition to the phenyl resonances. Throughout the temperature range (from –80 to +23 °C) only one broad singlet is observed in both the ^{11}B and ^{7}Li NMR spectrum (at 36.6 and 1.10 ppm, respectively, at –20 °C in d_8-toluene). The ^{119}Sn NMR spectrum of **2b** shows a single resonance at –167.9 ppm, which exhibits a significant shift to higher field from the value of 120 ppm reported for the dimeric tin(II) complex, $\{Sn[MeB(\mu_3\text{-}NSiMe_3)_2]\}_2$.[25] However, chemical shift values of –151.8 to –158.1 ppm have been reported for the related tin(II) complexes $\{Sn[RSi(\mu_3\text{-}N\text{-}t\text{-}Bu)_2]\}_2$ (R = C_3H_6, C_4H_6, C_4H_8 and C_5H_{10}),[30] which exhibit a coordination environment around the tin(II) centres similar to that in **2b**. The three resonances with a 1:1:2 intensity ratio observed at –20 °C in the ^{1}H NMR spectrum of **2b** are assigned to the *tert*-butyl groups attached to N1, N2, and N3/N4, respectively (Fig. 4*a*). The observation of only one broad resonance for the inequivalent boron and lithium atoms in the structure of **2b** even at low temperatures is attributed to overlap of these resonances.

The fluctional behaviour observed for **2b** is reminiscent of the exchange processes exhibited by the related group 15 complexes, **3** and **4**·OEt_2, which both showed only a single *t*-Bu resonance at room temperature.[12] These types of fluctional processes in lithium derivatives of polyimido anions of p-block elements are known to have low activation energies.[31] In the case of **3** and **4**·OEt_2, the fluctionality was determined to originate from a Berry pseudorotation.[12] In a similar manner, the single resonance observed at room temperature in the ^{1}H NMR spectra of **2b** can be attributed to a rapid exchange in which each of the four nitrogens, in turn, occupy the site that is not coordinated to the tin centre.

Conclusions

Comparison of the properties of the cation radicals $\{M[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2\}^{\bullet+}$ (M = Si, Ge, Sn) with those of the isoelectronic neutral radicals $M[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2^{\bullet}$ (M = Al, Ga, In) was limited to the tin derivative as a result of the inertness of $Ge[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ towards oxidizing agents and the inaccessibility of $Si[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$. The blue radical cation $\{Sn[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2\}^{\bullet+}$, which exhibits thermal instability similar to that of the neutral group 13 analogue $In[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2^{\bullet}$, was characterized at low temperatures by EPR spectroscopy. In contrast to the isoelectronic, D_{2d}-symmetric indium bis-*bam* radical, DFT calculations predict a C_{2v} symmetry for the radical cation $\{Sn[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2\}^{\bullet+}$ with spin density localized on only one of the *bam* ligands owing to the weak spiroconjugative N···N interactions that, presumably, prevent the delocalization of the unpaired electron over both ligands.

In the heterotrimetallic complexes $Li_2M[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ [M = Sn, Pb (THF omitted)], one of the *bam* ligands exhibits a novel bonding mode in which it bridges all three metal centres.[1] The solid-state structures of these group 14 complexes are comparable with those of the previously reported group 15 complexes $LiM[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ [M = Sb, Bi (OEt_2 omitted)].[12] Despite the introduction of a second Li^+ ion, the tin complex maintains the ladder-like backbone and cisoid arrangement of the *bam* ligands found in the antimony analogue. The intrusion of a second Li^+ ion in the lead complex results in rupture of the bond between the solvated Li^+ ion and one of the *bam* ligands, as well as cleavage of the fourth M–N bond (M = Bi, Pb) that exists in the structure of $(Et_2O{\cdot}Li)Bi[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$. In view of these structural similarities it is, perhaps, not surprising that the variable temperature NMR spectra of $Li_2Sn[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$ show trends comparable to those previously observed for the group 15 complex $LiSb[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2$,[12] implying that the fluctional processes are also similar.

Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. (25) Fusstetter, H.; Nöth, H. *Chem. Ber.* **1979**, *112*, 3672. doi:10.1002/cber.19791121115.

(26) Spiroconjugation is thought to contribute to the stability of the neutral group 13 radicals $\{M[PhB(\mu\text{-}N\text{-}t\text{-}Bu)_2]_2\}^{\bullet}$ (M = Al, Ga) (see ref. 5 and refs. cited therein).

(27) DFT calculations were also performed for the neutral (C_1 symmetric) systems **II** and **III** (Scheme 3), which comprise a Sn–Cl or a B–Cl bond, respectively. The paramagnetic species **II** is ca. 80 kJ mol^{-1} lower in energy, but the calculated hyperfine coupling constants for **II** and **III** are in poor agreement with those obtained from the experimental spectrum. The Sn–Cl bonded radical **II** exhibits a large (–11.56 G) coupling to the ^{11}B centre but, due to the lack of symmetry, the hfc couplings to the two nitrogen atoms are not equal (9.15 G and 5.56 G). The B–Cl bonded system **III** displays a coupling of –7.37 G to the ^{11}B isotope, and two inequivalent couplings of 11.24 and 2.26 G to the ^{14}N nuclei.

(28) Crystals of **2b** could not be obtained from diethyl ether. The attempted recrystallization of **2b** from THF resulted in a yellow solution, which contained the tin(IV) complex **1b** [^{1}H NMR spectrum (in d_8-THF)] as one component.

(29) The variable temperature ^{1}H NMR spectra of the lead complex **2c** exhibit similar trends; the broad singlet observed for *t*-Bu groups at 1.27 ppm at 23 °C resolves into three resonances at 1.36, 1.30, and 1.25 ppm (with a 1:2:1 intensity ratio) at –10 °C. However, these and other NMR data for **2c** were obtained on a reaction mixture and, consequently, any conclusions are necessarily tentative.

Concise strategy for the synthesis of eleven-membered and ansa-bridged thirteen-membered lactone macrolides by ring-closing metathesis reaction

Krishna C. Majumdar, Buddhadeb Chattopadhyay, and Inul Ansary

Abstract: The eleven-membered macrolides and thirteen-membered ansa-bridged macrolides have been synthesized successfully by ring-closing metathesis reaction in the absence of the additive $Ti(OiPr)_4$, which is essential for the metathesis reaction of the ester precursors.

Key words: ring-closing metathesis, Grubbs catalyst, macrolide, eleven- and thirteen-membered lactone.

Résumé : On a réalisé la synthèse de macrolides à onze chaînons et de macrolides à pont ansa à treize chaînons par le biais d'une réaction de fermeture de cycle impliquant une métathèse, en l'absence du catalyseur $Ti(OiPr)_4$ qui est essentiel aux réactions de métathèse dans lesquelles les précurseurs sont des esters.

Mots-clés : fermeture de cycle impliquant une métathèse, catalyseur de Grubbs, macrolide, lactones à 11 et 13 chaînons.

[Traduit par la Rédaction]

Introduction

Recently, Singh et al. have reported[1] the isolation of two natural products, aspercyclides (Fig. 1, **a** and **b**), from the fungal metabolites and claimed that these natural products (**a** and **b**) possess several important biological activities.[2] The natural products aspercyclides consist of an eleven-membered lactone moiety that is flanked by differently substituted diaryl ether lactone. Subsequently, Furstner and Muller[3] achieved the total synthesis of "aspercyclide C" (Fig. 1, **a**) to explore its biological activity.

Moreover, numerous natural products possess a macrolactone subunit and exhibit important biological and cytotoxic activities.[4] *Pondaplin* D,[5] an ansa-bridged thirteen-membered macrolide isolated from *Annoa glabra* is known to be cytotoxic against six different human tumor cell lines (Fig. 2).[5] This thirteen-membered ansa-bridged macrolide framework confers strong rigidity to the whole structure. Therefore, all these factors made its synthesis a challenging purpose.

With the discovery of useful as well as air-stable catalysts, ring-closing metathesis (RCM) is now a practical and beneficial method of choice for the synthesis of cyclic compounds from highly functionalized molecules.[6] This protocol has been tremendously applied for the synthesis of macrolactones of different ring sizes.[7] The synthesis of ansa-bridged macrolides by ring-closing metathesis has been developed only in few cases.[3,8] This has prompted us to undertake a study of the synthesis of new lactone macrolides[9] for possible evaluation as biologically active compounds or any other useful compounds by the application of the ring-closing metathesis reaction of less studied ester precursors. Additional interest is derived from our interest in the synthesis of heterocycles by transition metal-mediated[10] heterocyclization.

Results and discussion

The preparation of starting materials **6a**–**6f** is depicted on Scheme 1. Commercially available 2-hydroxy ethyl benzoate **1a** was conveniently allylated in dry acetone in the presence of anhyd. K_2CO_3 with allyl bromide for 15 h in refluxing condition to give *O*-allylated compound **2a**. Compound **2a** under saponification condition yielded the corresponding acid **3a**, which was finally converted to acid chloride **4a** by treatment with $SOCl_2$ in the presence of a catalytic amount of DMF. 2-Hydroxyl-1-allyl naphthalene **5a** was prepared according to the earlier reported procedure.[10a] The starting material **6a** was obtained by coupling of two partners **5a** and **4a** in dry DCM–Et_3N solvent in the presence of a catalytic amount of DMAP at 0 °C –RT for 12 h. Similarly, other starting materials **6b, 6c**, and **6d**–**6f** were prepared.

Attempts to carry out the metathesis reaction of the substrate **6a** with Grubbs first-generation catalyst in dichloromethane at RT proved unsuccessful. The entire starting material remained unchanged in the reaction mixture. When the reaction was conducted in refluxing condition for two days, only the decomposition of the catalyst was observed, leaving the starting material unchanged. However, when the substrate **6a** was refluxed with 5 mol% Grubbs second-generation catalyst in dry dichloromethane solution under nitrogen atmosphere for two days, the eleven-membered macrolide **7a** was obtained in 62% yield (Scheme 2). We have obtained only the *E*-olefin as evidenced by the *J* values (17.6 Hz) for the

Fig. 1. Naturally occurring aspercyclides, eleven-membered macrolides.

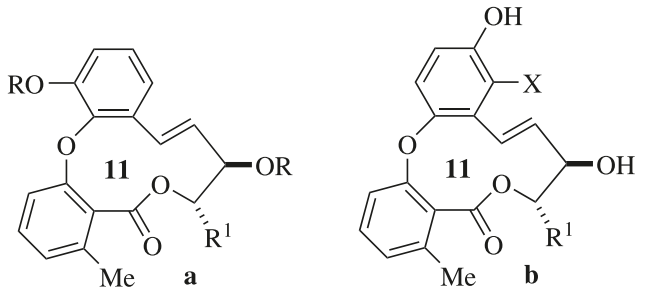

Fig. 2. Pondaplin, ansa-bridged thirteen-membered macrolide.

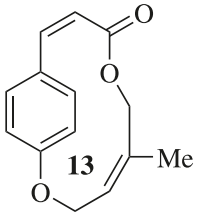


olefinic protons. To test the generality of this macrolization, the substrates **6b** and **6c** were treated under similar reaction conditions as above to afford the macrolides **7b** and **7c** in 59% and 63% yields, respectively.

We then extended the reaction to the synthesis of the thirteen-membered macrolides. Initially, we attempted the reaction of **6d** using Grubbs first-generation catalyst in dry dichloromethane solution under nitrogen atmosphere for 2–3 day without any success. No cyclized product was obtained even at the refluxing conditions. We then tried to carry out the same reaction by changing the solvent DCM with benzene, toluene, or xylene, but no macrolization was observed. Finally, we have succeeded in obtaining the thirteen-membered macrolide **7d** in 63% yield from **6d** by treatment with Grubbs second-generation catalyst in refluxing dichloromethane solution under nitrogen atmosphere for 4 days.

Here, the preparations of both the eleven- and thirteen-membered macrolides were achieved under high dilution.[11] The macrolides **7e** and **7f** were also prepared accordingly.

We have also attempted to extend the reaction by changing the allyl part of the compound **4** by crotyl and propargyl moieties. Unfortunately, we failed to obtain any cyclized product. The reaction conditions are summarized in Table 1.

Recently, Furstner[12] reported that the substrates possessing carboxylate moiety in one of the diene partners of the metathesis precursors cannot undergo the metathesis reaction with the Grubbs catalyst in the absence of additive $Ti(OiPr)_4$ in the reaction mixture. The reaction does not proceed because of the fact that the ruthenium carbene complex coordinates on to the ester by chelation with the ester carbonyl moiety and the olefin (Fig. 3).

When the reaction is conducted in the presence of $Ti(OiPr)_4$ along with the Grubbs catalyst, $Ti(OiPr)_4$ probably acts because of factors such as (*i*) $Ti(OiPr)_4$ is weakly Lewis acidic additive and consequently avoids the formation of unreactive chelate complex by coordination with the ester carbonyl moiety, (*ii*) $Ti(OiPr)_4$ may abstract one of the basic PCy_3 ligands from the Grubbs catalyst and thereby enhancing the catalytic activity of the Grubbs catalyst.

Conclusion

In conclusion, we have successfully synthesized the eleven-membered macrolides that are present in many natural-product core moieties such as aspercyclide C and thirteen-membered ansa-bridged macrolides that are the core structure of the natural product "pondaplin" by the implementation of ring-closing metathesis reaction without $Ti(OiPr)_4$ additive.[12] We believe that the methodology is simple and straightforward and will be useful to the synthetic community.

Experimental

General remarks

Melting points were determined in open capillaries and are uncorrected. IR spectra were run for KBr discs (and neat for liquid samples), and NMR spectra were determined for solutions in $CDCl_3$ with TMS as internal standard. Silica gel (60–120 mesh) was used for chromatographic separation. Silica gel-G was used for TLC. Petroleum ether refers to the fraction between 60 and 80 °C.

General methods for the preparation of compounds 6a–6f

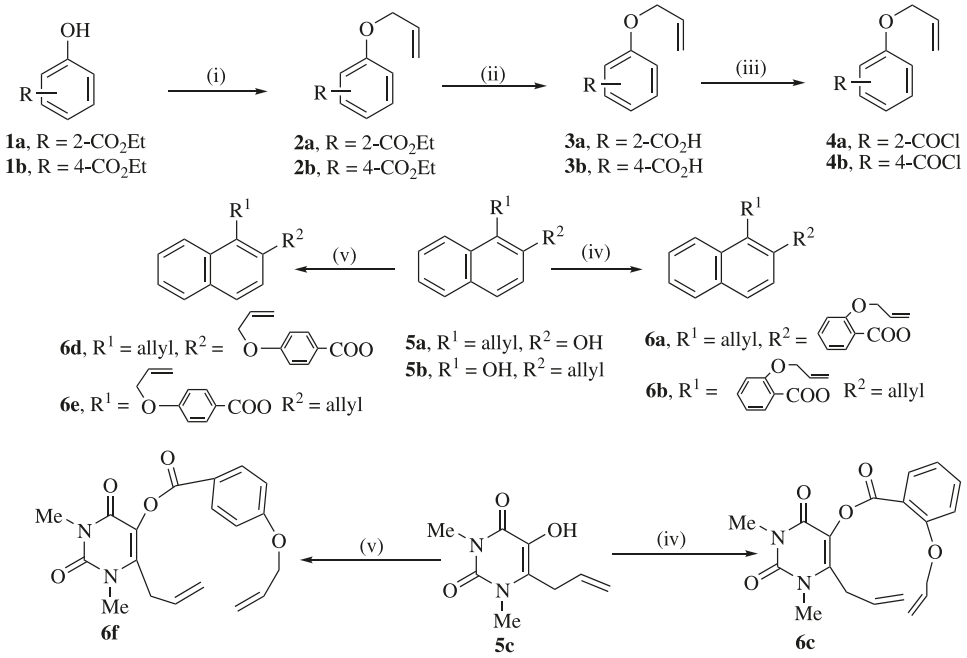
A mixture of 2-hydroxy ethyl benzoate **1a** (4.0 g, 24.07 mmol), allyl bromide (3.49 g, 28.88 mmol), anhyd. potassium carbonate (13.30 g, 96.28 mmol), and catalytic amount of sodium iodide in dry acetone (100 mL) was refluxed for 15 h. The reaction mixture was cooled, filtered, and acetone was evaporated to give the corresponding *O*-allylated compound **2a** (4.9 g). Compound **2a** (4.9 g) was hydrolyzed with potassium hydroxide (3.3 g, 59.41 mmol) in ethanolic solution (50 mL) for 4 h at refluxing condition. Excess ethanol was removed by distillation, and the reaction mixture was cooled and was made acidic by adding 6 N HCl to give the corresponding acid **3a** (4.0 g, 95%).

The acid **3a** (0.425 g, 2.38 mmol) was then refluxed with $SOCl_2$ (1.5 mL) in the presence of DMF (catalytic amount) for 1 h, and excess $SOCl_2$ was removed under reduced pressure to give the acid chloride (0.47 g, 100%) **4a**. Finally, the acid chloride **4a** (0.47 g, 2.39 mmol) in dry dichloromethane (15 mL) was added dropwise to a mixture of 1-allyl-2-naphthol **5a** (440 mg, 2.39 mmol), triethylamine (2 mL), and a catalytic amount of DMAP in dry dichloromethane solution (30 mL) at ice-cold temperature. The reaction mixture was stirred at RT for 12 h to afford the esterified compound **6a** (0.69 g, 82%). Similarly, other starting materials **6b–6f** were prepared. Compounds **6a–6f** were recrystallized from dichloromethane–petroleum ether (60–80 °C).

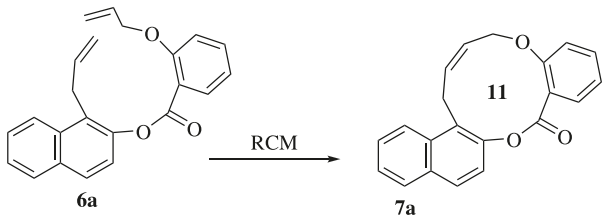
Compound 6a

Yield: 82%; colourless solid; mp 53–54 °C (dichloromethane–petroleum ether). IR (KBr, cm^{-1}): 1744, 2853, 2923. ^1H NMR ($CDCl_3$, 400 MHz) δ_H: 3.85 (d, 2H, J = 5.9 Hz, CH_2), 4.68 (d, 2H, J = 5.0 Hz, OCH_2), 4.99–5.03 (m, 2H, $=CH_2$), 5.25 (dd, 1H, J = 10.6 Hz, J = 1.4 Hz, $=CH_aH_b$), 5.49 (dd, 1H, J = 17.2 Hz, J = 1.4 Hz, $=CH_aH_b$), 5.96–6.08 (m, 2H, =CH), 7.04 (d, 1H, J = 8.2 Hz, ArH), 7.08 (d, 1H, J = 7.7 Hz, ArH), 7.34 (d, 1H, J = 8.8 Hz, ArH), 7.45

Scheme 1. Reagents and conditions: (i) Acetone, K_2CO_3, allyl bromide, reflux, 15 h. (ii) EtOH, KOH, reflux, 4 h. 6 N HCl. (iii) $SOCl_2$, DMF, reflux, 1 h. (iv) dry DCM, **4a**, Et_3N, DMAP, 0 °C –RT, stirring, 12 h. (v) dry DCM, **4b**, Et_3N, DMAP, 0 °C–RT, stirring, 12 h.



Scheme 2.



(d, 1H, *J* = 6.9 Hz, ArH), 7.48–7.55 (m, 2H, ArH), 7.79 (d, 1H, *J* = 8.8 Hz, ArH), 7.86 (d, 1H, *J* = 7.9 Hz, ArH), 8.03 (d, 1H, *J* = 8.0 Hz, ArH), 8.06 (d, 1H, *J* = 1.6 Hz, ArH). ^{13}C NMR ($CDCl_3$, 100 MHz) δ_C: 30.2, 69.4, 113.6, 115.9, 117.7, 119.5, 120.5, 122.0, 124.3, 125.2, 126.2, 126.3, 128.0, 128.6, 132.1, 132.3, 132.5, 132.8, 134.1, 135.8, 146.7, 158.7, 164.9. HRMS: Calcd. for $C_{23}H_{20}O_3$: 367.1318 (M + Na). Found: 367.1310 (M + Na).

Compound 6b

Yield: 88%; colourless solid; mp 56–57 °C (dichloromethane–petroleum ether). IR (KBr, cm^{-1}): 1744, 2868, 2921. ^{1}H NMR ($CDCl_3$, 400 MHz) δ_H: 3.51 (d, 2H, *J* = 6.4 Hz, CH_2), 4.71 (d, 2H, *J* = 5.0 Hz, OCH_2), 5.11–5.16 (m, 2H, $=CH_2$), 5.39 (dd, 1H, *J* = 10.6 Hz, *J* = 1.1 Hz, $=CH_aH_b$), 5.58 (dd, 1H, *J* = 17.2 Hz, *J* = 1.1 Hz, $=CH_aH_b$), 5.99–6.19 (m, 2H, =CH), 7.05 (d, 2H, *J* = 7.9 Hz, ArH), 7.41–7.55 (m, 3H, ArH), 7.78 (d, 1H, *J* = 8.4 Hz, ArH), 7.89 (dd, 1H, *J* = 8.8 Hz, *J* = 1.7 Hz, ArH), 7.93 (dd, 1H, *J* = 7.6 Hz, *J* = 1.7 Hz, ArH), 8.13 (d, 2H, *J* = 8.8 Hz, ArH). MS *m*/*z*: 344 (M$^+$). Anal. calcd. for $C_{23}H_{20}O_3$: C, 80.21; H, 5.85. Found: C, 80.43; H, 6.01.

Compound 6c

Yield: 79%; colourless solid; mp 94–95 °C (dichloromethane–petroleum ether). IR (KBr, cm^{-1}): 1664, 1706, 1753, 2853, 2923. ^{1}H NMR ($CDCl_3$, 400 MHz) δ_H: 3.39 (s, 3H, $-NCH_3$), 3.40 (d, 3H, *J* = 6.3 Hz, $-CH_2$), 3.44 (s, 3H, $-NCH_3$), 4.62 (d, 2H, *J* = 5.0 Hz, OCH_2), 5.18–5.23 (m, 2H, $=CH_2$), 5.25 (dd, 1H, *J* = 10.6 Hz, *J* = 1.3 Hz, $=CH_aH_b$), 5.44 (dd, 1H, *J* = 17.9 Hz, *J* = 1.3 Hz, $=CH_aH_b$), 5.79–5.86 (m, 1H, =CH), 5.98–6.08 (m, 1H, =CH), 6.97–7.04 (m, 2H, ArH), 7.50 (dd, 1H, *J* = 8.6 Hz, *J* = 1.5 Hz, ArH), 8.00 (dd, 1H, *J* = 7.7 Hz, *J* = 1.4 Hz, ArH). MS *m*/*z*: 356 (M$^+$). Anal. calcd. for $C_{19}H_{20}N_2O_5$: C, 64.04; H, 5.66; N, 7.86. Found: C, 63.91; H, 5.88; N, 8.03.

Compound 6d

Yield: 84%; colourless solid; mp 84–85 °C (dichloromethane–petroleum ether). IR (KBr, cm^{-1}): 1730, 2849, 2917. ^{1}H NMR ($CDCl_3$, 400 MHz) δ_H: 3.80 (d, 2H, *J* = 5.9 Hz, CH_2), 4.63 (d, 2H, *J* = 5.2 Hz, OCH_2), 4.96–5.01 (m, 2H, $=CH_2$), 5.34 (dd, 1H, *J* = 10.5 Hz, *J* = 1.1 Hz, $=CH_aH_b$), 5.44 (dd, 1H, *J* = 16.3 Hz, *J* = 1.1 Hz, $=CH_aH_b$), 5.93–6.12 (m, 2H, =CH), 7.01 (d, 2H, *J* = 8.8 Hz, ArH), 7.31 (d, 1H, *J* = 8.8 Hz, ArH), 7.45–7.59 (m, 3H, ArH), 7.79 (d, 1H, *J* = 8.8 Hz, ArH), 7.86 (d, 1H, *J* = 7.9 Hz, ArH), 8.02 (d, 1H, *J* = 8.4 Hz, ArH), 8.19 (d, 1H, *J* = 8.8 Hz, ArH). Compound 6f

Yield: 85%; colourless solid; mp 109–110 °C (dichloromethane–petroleum ether). IR (KBr, cm^{-1}): 1663, 1704, 1741, 2851, 2918. ^1H NMR ($CDCl_3$, 400 MHz) δ_H: 3.39 (s, 3H, $-NCH_3$), 3.40 (d, 2H, J = 6.3 Hz, $-CH_2$), 3.43 (s, 3H, $-NCH_3$), 4.59 (d, 2H, J = 5.0 Hz, $-OCH_2$), 5.08–5.16 (m, 2H, $=CH_2$), 5.19 (dd, 1H, J = 10.6 Hz, J = 1.3 Hz, $=CH_aH_b$), 5.39 (dd, 1H, J = 17.9 Hz, J = 1.3 Hz, $=CH_aH_b$), 5.77–5.81 (m, 1H, =CH), 5.98–6.04 (m, 1H, =CH), 6.99 (d, 2H, J = 8.1 Hz, ArH), 7.41 (dd, 1H, J = 7.7 Hz, J = 1.9 Hz, ArH), 7.99 (dd, 1H, J = 8.2 Hz, J = 1.9 Hz, ArH). MS *m/z*: 356 (M^+). Anal. calcd. for $C_{19}H_{20}N_2O_5$: C, 64.04; H, 5.66; N, 7.86. Found: C, 64.23; H, 5.83; N, 7.68.

General methods for the synthesis of macrolides 7a–7f

To a solution of the substrate **6a** (30 mg, 0.16 mmol) in dry degassed dichloromethane (40 mL) under nitrogen atmosphere was added Grubbs second-generation catalyst (5 mol%, 17 mg) and the reaction was stirred at rt for 1 h. The mixture was then refluxed for 2 days. The solvent was distilled off and the residue was purified by flash column chromatography on silica gel using 10% ethyl acetate-petroleum ether to afford the compound **7a**. Accordingly compounds **7b-7f** were synthesized. Compounds **7a-7f** were recrystallized from dichloromethane-petroleum ether (60–80 °C).

Compound 7a

Yield: 62%; colourless solid; mp 104–105 °C (dichloromethane–petroleum ether). IR (KBr, cm^{-1}): 1740, 2851, 2957. ^1H NMR ($CDCl_3$, 400 MHz) δ_H: 4.04 (d, 2H, J = 5.0 Hz, CH_2), 4.59 (d, 2H, J = 5.0 Hz, OCH_2), 5.96 (dt, 1H, J = 17.6 Hz, J = 5.0 Hz, =CH), 6.09 (dt, 1H, J = 17.6 Hz, J = 5.0 Hz, =CH), 6.94 (d, 1H, J = 6.8 Hz, ArH), 7.02 (dt, 1H, J = 6.0 Hz, J = 3.1 Hz, ArH), 7.30 (d, 1H, J = 7.1 Hz, ArH), 7.45–7.55 (m, 3H, ArH), 7.76 (d, 1H, J = 7.1 Hz, ArH), 7.84 (dd, 1H, J = 7.1 Hz, J = 1.4 Hz, ArH), 7.89 (d, 1H, J = 6.6 Hz, ArH), 8.07 (d, 1H, J = 7.3 Hz, ArH). ^{13}C NMR ($CDCl_3$, 100 MHz) δ_C: 29.1, 70.1, 112.9, 120.4, 120.7, 121.9, 124.2, 125.2, 125.3, 125.9, 126.4, 128.0, 128.7, 131.8, 132.1, 132.8, 133.6, 133.9, 146.5, 157.6, 166.9. HRMS: Calcd. for $C_{21}H_{16}O_3$: 339.0997 (M + Na). Found: 339.0990 (M + Na).

Compound 7b

Yield: 59%; colourless solid; mp 96–97 °C (dichloromethane–petroleum ether). IR (KBr, cm^{-1}): 1742, 2850, 2921. ^1H NMR ($CDCl_3$, 400 MHz) δ_H: 3.49 (d, 2H, J = 5.0 Hz, CH_2), 4.63 (d, 2H, J = 5.0 Hz, OCH_2), 5.85 (dt, 1H, J = 17.6 Hz, J = 5.0 Hz, =CH), 6.06 (dt, 1H, J = 17.6 Hz, J = 5.0 Hz, =CH), 6.98 (dd, 1H, J = 7.9 Hz, J = 1.7 Hz, ArH), 7.40 (d, 1H, J = 6.9 Hz, ArH), 7.44 (m, 2H, ArH), 7.49 (dt, 1H, J = 7.1 Hz, J = 3.0 Hz, ArH), 7.53 (d, 1H, J = 8.1 Hz, ArH), 7.63 (dd, 1H, J = 6.7 Hz, J = 1.0 Hz, ArH), 7.72 (dt, 1H, J = 7.7 Hz, J = 3.0 Hz, ArH), 7.80 (t, 1H, J = 7.0 Hz, ArH), 8.04 (dt, 1H, J = 7.4 Hz, J = 2.3 Hz, ArH). MS *m/z*: 316 (M^+). Anal. calcd. for $C_{21}H_{16}O_3$: C, 79.73; H, 5.10. Found: C, 79.61; H, 5.23.

Compound 7c

Yield: 64%; colourless solid; mp 149–150 °C (dichloromethane–petroleum ether). IR (KBr, cm^{-1}): 1649, 1701, 1739, 2849, 2920. ^1H NMR ($CDCl_3$, 400 MHz) δ_H: 3.37 (s, 6H, -NCH_3), 3.41 (d, 2H, J = 5.4 Hz, CH_2), 5.09 (d, 2H, J = 5.4 Hz, OCH_2), 5.77 (dt, 1H, J = 17.6 Hz, J = 5.0 Hz, =CH), 5.92 (dt, 1H, J = 17.6 Hz, J = 5.0 Hz, =CH), 6.90–7.04 (m, 2H, ArH), 7.47 (dd, 1H, J = 8.5 Hz, J = 1.7 Hz, ArH), 7.99 (dd, 1H, J = 7.5 Hz, J = 1.7 Hz, ArH). MS *m/z*: 328 (M^+). Anal. calcd. for $C_{17}H_{16}N_2O_5$: C, 62.19; H, 4.91; N, 8.53. Found: C, 62.33; H, 5.09; N, 8.66.

Compound 7d

Yield: 63%; colourless solid; mp 120–121 °C (dichloromethane–petroleum ether. IR (KBr, cm^{-1}): 1730, 2850, 2920. ^1H NMR ($CDCl_3$, 400 MHz) δ_H: 3.79 (d, 2H, J = 5.0 Hz, CH_2), 4.61 (d, 2H, J = 5.0 Hz, OCH_2), 5.88 (dt, 1H, J = 17.6, J = 5.0 Hz, =CH), 6.03 (dt, 1H, J = 17.6 Hz, J = 5.0 Hz, =CH), 7.08 (d, 1H, J = 7.5 Hz, ArH), 7.29–7.33 (m, 2H, ArH), 7.49 (dt, 2H, J = 7.9 Hz, J = 3.0 Hz, ArH), 7.69 (dd, 1H, J = 6.9 Hz, J = 1.1 Hz, ArH), 7.79 (t, 1H, J = 8.0 Hz, ArH), 7.81 (dd, 1H, J = 6.8 Hz, J = 1.2 Hz, ArH), 8.01 (d, 1H, J = 8.8 Hz, ArH), 8.11 (d, 1H, J = 7.9 Hz, ArH). MS *m/z*: 316 (M^+). Anal. calcd. for $C_{21}H_{16}O_3$: C, 79.73; H, 5.10. Found: C, 79.86; H, 4.89.

Compound 7e

Yield: 57%; colourless solid; mp 113–114 °C (dichloromethane–petroleum ether). IR (KBr, cm^{-1}): 1731, 2851, 2921. ^1H NMR ($CDCl_3$, 400 MHz) δ_H: 3.47 (dd, 2H, J = 5.7 Hz, J = 1.0 Hz, CH_2), 4.62 (dd, 2H, J = 7.3 Hz, J = 1.0 Hz, OCH_2), 6.00 (dt, 1H, J = 17.6 Hz, J = 5.0 Hz, =CH), 6.09 (dt, 1H, J = 17.6 Hz, J = 5.0 Hz, =CH), 7.00 (d, 1H, J = 6.8 Hz, ArH) 7.08 (d, 1H, J = 7.3 Hz, ArH), 7.38–7.43 (m, 3H, ArH), 7.51 (dd, 2H, J = 8.8 Hz, J = 1.7 Hz, ArH), 7.85 (dt, 1H, J = 7.1 Hz, J = 3.0 Hz, ArH), 8.14 (d, 2H, J = 8.0 Hz, ArH). MS *m/z*: 316 (M^+). Anal. calcd. for $C_{21}H_{16}O_3$: C, 79.73; H, 5.10. Found: C, 79.69; H, 5.33.

Compound 7f

Yield: 59%; colourless solid; mp 157–158 °C (dichloromethane–petroleum ether). IR (KBr, cm^{-1}): 1650, 1705, 1734, 2851, 2921. ^1H NMR ($CDCl_3$, 400 MHz) δ_H: 3.36 (d, 2H, J = 5.6 Hz, CH_2), 3.38 (s, 3H, $-NCH_3$), 3.45 (s, 3H, $-NCH_3$), 5.17 (d, 2H, J = 5.6 Hz, OCH_2), 5.80 (dt, 1H, J = 17.6 Hz, J = 5.0 Hz, =CH), 6.03 (dt, 1H, J = 17.6 Hz, J = 5.0 Hz, =CH), 6.95 (d, 2H, J = 7.7 Hz, J = 1.7 Hz, ArH), 8.09 (dd, 2H, J = 8.9 Hz, J = 3.0 Hz, ArH). MS *m/z*: 328 (M^+). Anal. calcd. for $C_{17}H_{16}N_2O_5$: C, 62.19; H, 4.91; N, 8.53. Found: C, 61.97; H, 5.11; N, 8.69.

Acknowledgements

We thank the DST (New Delhi) and the CSIR (New Delhi) for financial assistance. Two of us (BC and IA) are grateful to the CSIR (New Delhi) and UGC (New Delhi) for a senior and a junior research fellowships, respectively.

Radioisotopic study of ^{11}C-labelling methanol decomposition on iron oxide modified mesoporous MCM-41 silica

Eva Sarkadi-Pribóczki, Tanya Tsoncheva, and Ljubomira Ivanova

Abstract: Novel ^{11}C-radiolabelling method was applied for the investigation of methanol conversion on iron oxide modified mesoporous MCM-41. Changes in the selectivity were observed varying the state of the loaded iron species or the degree of the surface coverage with ^{11}C-radiolabelling methanol. Combining the Moessbauer spectroscopy, X-ray diffraction (XRD), N_2-physisorption, and temperature-programmed reduction- thermogravimetric (TPR-TG) techniques with the high sensitive ^{11}C-radioisotopic catalytic analysis, the contribution of the different reaction pathways of methanol conversion was discussed.

Key words: ^{11}C-radiolabelling technique, methanol conversion, iron oxide modified MCM-41.

Résumé : On a utilisé une nouvelle méthode de radiomarquage du ^{11}C pour étudier la conversion du méthanol sur du MCM-41 mésoporeux modifié avec de l'oxyde de fer. On a observé les changements de sélectivité résultant d'un changement de l'état des espèces de fer ajoutées ou le degré de couverture de la surface avec du méthanol radiomarqué au ^{11}C. En se basant sur une combinaison de la spectroscopie de Mössbauer, de la de physisorption du N_2 et des techniques de TPR-TG avec l'analyse catalytique radioisotopique du ^{11}C à haute sensibilité, on discute de la contribution des diverses voies réactionnelles dans la conversion du méthanol.

Mots-clés : technique de radiomarquage du ^{11}C, conversion du méthanol, MCM-41 modifié avec de l'oxyde de fer.

[Traduit par la Rédaction]

Introduction

Nanosized iron-containing materials are well known for their potential application in the fields of electronic, nonlinear optics medicine, and catalysis because of their unusual magnetic and optical properties and superior catalytic activity.[1–4] It was well established that their behaviour could be successfully tuned, hosting the iron species in various porous materials[5–7] and much of our previous results in this aspect are summarized by Tsoncheva and co-workers.[8–17] Recently, we reported some initial data on a new approach for the characterization of the state of iron and iron oxide species, hosted in MCM-41, via the combination of a conventional catalytic method and high sensitivity ^{11}C-radiolabelling technique.[18] In the current investigation we expand our results with catalytic experiments using different coverage of the solid surface with ^{11}C-labelling methanol. The aim of the study is to elucidate the contribution of various reaction pathways of methanol conversion on iron-modified MCM-41 materials depending on the state of the iron species in them. For this purpose, samples prepared by impregnation of MCM-41 silica with iron nitrate or acetylacetonate precursors are compared.

Experimental

Materials

Iron-modified mesoporous silicas were obtained by impregnation of MCM-41[19] with iron nitrate or acetylacetonate precursors as described by Tsoncheva et al.[9,17] Typically, 1 g of template free silica support was impregnated with 40 mL 0.0286 mol/L aqueous or toluene solution of $Fe(NO_3)_3$ or Fe(III) acetylacetonate, respectively, for 2 h at room temperature. After the impregnation the samples were dried in a rotary evaporator for 1 h at 313 K. The precursor was decomposed in a flow of air at 773 K for 2 h. Materials containing 6% wt. of iron were obtained and denoted as Fe/MCM-41(N) and Fe/MCM-41(A) for the nitrate and acetylacetonate precursor, respectively.

Methods of investigations

Powder X-ray diffraction was carried out on a Bruker AXS D8 Advance diffractometer equipped with a secondary monochromator and automatic divergence slits (filtered Cu Kα radiation, 40 kV, 40 mA). Nitrogen physisorption was conducted at 77 K on a Quantochrome Autosorb 6. The specific surface area was elucidated using the standard BET method. Pore volumes and pore size distribution were calculated by Autosorb 1 for Windows 1.25 software (Quantachrome Instruments) using the Barret–Joyner–Halenda (BJH) method. The temperature-programmed reduction thermogravimetric (TPR-TG) investigations were performed in a Setaram TG92 instrument in a flow of 50 vol% H_2 in Ar (100 cm^3/min) up to 873 K at 5 K/min and a final hold-up of 1 h. Prior to the TPR experiments, the samples were treated in situ in a flow of air (10 K/min) up to 773 K,

followed by a hold-up of 1 h. The Mössbauer spectra were obtained in air at room temperature with a Wissel (Wissenschaftliche Elektronik GmbH, Germany) electromechanical spectrometer working in a constant acceleration mode. A ^{57}Co/Cr (activity $\cong$10 mCi) source and α-Fe standard were used. The experimentally obtained spectra were fitted by the least-squares method.

The catalytic experiments were performed in a fixed-bed reactor (0.055 g catalyst) at a methanol partial pressure of 1.57 kPa and a weight hourly space velocity (WHSV) of 1.5 h^{-1}, argon being used as a carrier gas. On-line gas chromatographic analysis was performed on a Porapak Q column using an absolute calibration method.

The radio-experiments were applied for monitoring of radiolabelled methanol behaviour using a GM (Geiger–Müller) radiodetector as well as FID-radio gas chromatograph.[20–22] About 370 MBq ^{11}C-methanol was formed by a radiochemical process at cyclotron ($T_{1/2}$ = 20.4 min). Catalytic experiments were started, introducing ^{11}C-methanol by He gas flow into a closed static mode reactor. After the ^{11}C-methanol adsorption, the sample was heated up to the required temperature. During desorption, He gas was used to remove and trap the gas phase ^{11}C-methanol into the P_2O_5 trap for radioactivity measuring by a dose calibrator before the further temperature increase. Above 473 K the ^{11}C-labelled gas products were analyzed by GC with FID coupled on-line with a radioactivity detector.

Results and discussion

Physicochemical characterization of the samples

Small angle X-ray diffraction (XRD) patterns (Fig. 1) of parent and differently iron-modified silica materials represent all reflections typical of *p6mm* hexagonal pore symmetry of MCM-41 mesophase.[19] This indicates a high quality of mesoporous silica support and its preservation after the modification procedure. The observed decrease in the intensity of the small angle reflections after the modification could be assigned to an overall decrease in the electron density contrast between the silica walls and the mesopore due to the location of iron oxide species inside the mesopores of the silica support.[23] At the same time, no or very slight reflections are registered in a wide-angle region of the XRD patterns (Fig. 1, inset), which could be assigned to the formation of finely dispersed iron containing species.

N_2-physisorption isotherms and the corresponding calculated parameters are presented in Fig. 2 and Table 1, respectively. The isotherms of parent and iron modified samples are type IV (IUPAC classification) with a well-pronounced capillary condensation step at 0.3–0.4 relative pressure, which is characteristic of mesoporous materials with uniform cylindrical pores and diameters of about 2.9 nm. This confirms the data from the XRD measurements for the preservation of the silica host structure during the iron loading procedure. The observed decrease in the BET surface area and total pore volume after the silica modification (Table 1) could both be from the mass increase or pore filling after the modification. When the correction for the mass of the modified samples was done, a higher degree of iron particles located in the mesoporous volume could be assumed for Fe/MCM-41(A).

Table 1. Nitrogen physisorption parameters of parent and iron modified silicas: BET - specific surface area (BJH), V_p - total pore volume, ΔBET - relative decrease in the samples specific surface area compared to that of the parent silica material, and ΔV_p - relative decrease in the samples pore volume compared to that of the parent silica material.

Sample	BET (m^2/g)	V_p (cc/g)	ΔBET (m^2/g)	ΔV_p (cc/g)
MCM-41	1023	0.88	—	—
Fe/M41(N)	980	0.81	43	0.07
Fe/M41(A)	902	0.74	121	0.14

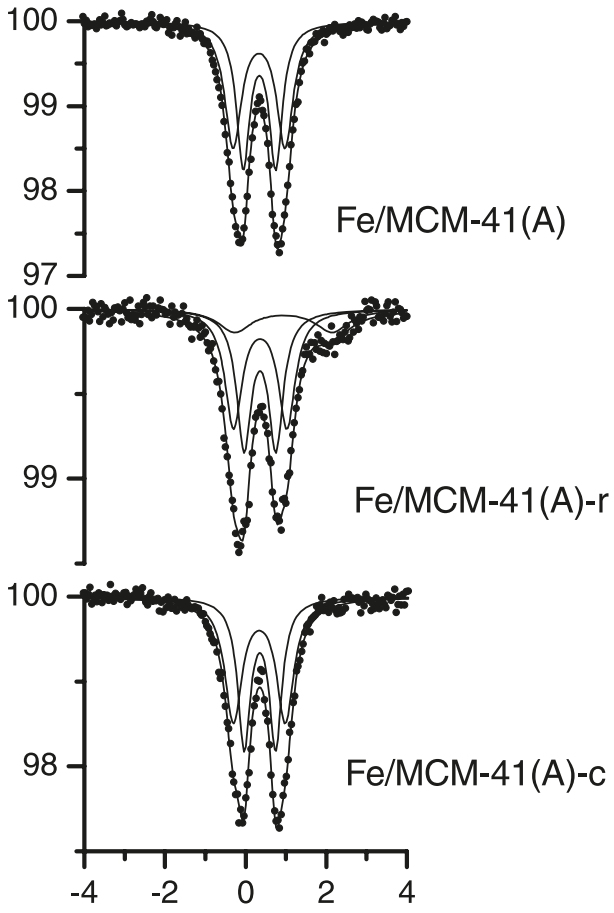
Table 2. Mössbauer parameters of MCM-41 iron modifications: isomer shift (IS), quadrupole splitting (QS), effective internal magnetic field (H_{eff}), line widths (FWHM), and relative weight of the partial components in the spectra (G).

Sample	Compounds	IS (mm/s)	QS (mm/s)	H_{eff} (kOe)	FWHM (mm/s)	G (%)
Fe/M41 (N)	Dbl 1 Fe^{3+}, SPM Fe_2O_3, core	0.34	0.59	—	0.39	52
	Dbl 2 Fe^{3+}, SPM Fe_2O_3, shell	0.32	1.02	—	0.47	48
Fe/M41 (A)	Dbl 1 Fe^{3+}, SPM Fe_2O_3, core	0.33	0.81	—	0.39	48
	Dbl 2 Fe^{3+}, SPM Fe_2O_3, shell	0.34	1.29	—	0.50	52

The main parameters from the Mössbauer spectra of the samples are listed in Table 2 and selected spectra are illustrated in Fig. 3. An idealized core/shell model was applied to distinguish the particles with different sizes more precisely. The spectra of both materials represent only doublets with parameters typical of high spin Fe^{3+} ions in octahedral coordination. The existence of finely dispersed hematite-like species (up to 6 nm) with superparamagnetic behaviour could be assumed,[24,25] and this is in agreement with the data obtained from XRD analysis. The core/shell ratio for Fe/MCM-41(N) is slightly higher, which could be associated with the presence of larger iron oxide species in this sample in comparison with Fe/MCM-41(A). Under the temperature of liquid nitrogen, Mössbauer spectra of both materials preserved their doublet character and no changes in the core/shell ratio were observed, which could be an indication for the presence of ultra finely dispersed iron oxide particles, probably less then 4 nm.

To determine the state of the iron species in both materials more precisely, TPR-TG analyses were also carried out (Table 3, Fig. 4). Total reduction degree for both materials does not exceed 100% up to 870 K, which confirms the formation of finely dispersed iron oxide species. The TPR profiles represent two distinct reductive effects in the 450–660 K and 700–870 K regions. The low temperature (LT) peak could be ascribed to the reduction of bulk hematite (Fe_2O_3) nanoparticles.[26,27] The higher T_{max} in this stage, which is registered for Fe/MCM-41(A), could be evidence for the presence of relatively smaller particles in it, and this assumption is in accordance with the Mössbauer data (see above). The second, high-temperature (HT) TPR peak probably arose from the reduction of the strongly interacting iron supported oxide species with lower degrees of crystallinity.[28] They could be two-dimensional FeO_x patches or even isolated iron ions, grafted to the silica surface. Their relative part seems to be much larger in the case of Fe/MCM-41(N) and this is proved by the lower LT/HT ratio in this case (Table 3).

Fig. 3. Mössbauer spectra of selected samples: initial Fe/MCM-41(A), the same material after reduction Fe/MCM-41(A)-r and after the catalytic test Fe/MCM-41(A)-c.



Catalytic test

In Fig. 5, the kinetic curves of methanol conversion for both iron modified materials at different temperatures are compared. Methanol decomposition to CO and methane as well as its dehydration to dimethyl ether (DME) are observed in all cases. The selectivity to DME is higher for Fe/MCM-41(N), while higher methane selectivity is registered for Fe/MCM-41(A). The catalytic activity of the samples decreases with time on stream, the effect being more pronounced for Fe/MCM-41(N) in comparison with Fe/MCM-41(A). Changes in the products distribution under isothermal conditions are also registered (Fig. 3). At the same time, the Mössbauer spectra of the materials used in the catalytic experiment show the appearance of a new doublet component, with a significantly higher IS value (about 0.97 mm/s), attributable to the presence of Fe^{2+} containing clusters (Fig. 3). These reduction phase transformations, occurring because of the influence of the reaction medium, could be considered as possible reasons for the changes in the catalytic behaviour of the samples under the isothermal conditions (Fig. 5). A higher initial catalytic activity is registered for Fe/MCM-41(N) and this observation is confirmed by the calculated values of the activation energy, which are 7.7 and 14.1 kcal/mol (1 cal = 4.184 J) for Fe/MCM-41(N) and Fe/MCM-41(A), respectively.

Table 3. TPR-TG parameters for the various iron modified materials.

Sample	Tmax (K)*	Weight loss (mg)		Reduction degree (%)†	LT/HT weight loss
		LT stage	HT stage		
Fe/M41(N)	563	0.22	0.43	76	0.51
Fe/M41(A)	572	0.24	0.28	66	0.86

*Temperature of the low-temperature reduction maximum in the DTG curves.

^{11}C-radiolabelling measurements

In Fig. 6, ^{11}C-methanol desorption measurements for both iron modified materials are presented. The experiments were carried out after methanol trapping at ambient temperature and further heating of the samples, up to 463 K. No products of methanol conversion are registered in a whole temperature interval. The sharp decrease in the radioactivity rate above 383 K indicates the start of the desorption process. It could be seen that the desorption curve of Fe/MCM-41(A) is shifted to higher temperatures in comparison with Fe/MCM-41(N). For the former sample, a higher level of radioactivity rate at the final desorption temperature is also found, which could be assigned to the larger amount of non-desorbed methanol in it. These observations point to the differences in the state of the iron species in both materials and it is in accordance with the data discussed above (see the sections titled physicochemical characterization of the samples and catalytic test).

In Fig. 7, some typical ^{11}C labelling radiochromatograms for both iron modifications are presented . The evolution of the process with the temperature confirms the data from the conventional catalytic test for the higher catalytic activity and better dehydration selectivity to DME for Fe/MCM-41(N) in comparison to Fe/MCM-41(A). Formaldehyde (FA) and CO_2 were also registered as products of methanol decomposition. In the case of Fe/MCM-41(N), significant yields of methylal (DMM) are also observed.

Taking into account the data from the physicochemical and catalytic measurements, we could ascribe the higher DME selectivity, which is registered for Fe/MCM-41(N), to the presence of a higher amount of Lewis acidic centres in this sample. According to the literature data,[29] they could be isolated iron ions or FeO_x species in a low degree of coordination, and their reduction probably corresponds to the larger HT reduction effect in the TPR profile of this sample. We could also point out that methanol dehydrogenation to CO, CO_2, and CH_4 seems to be facilitated for the iron oxide species with higher degrees of crystallinity.[30,31] They are in a weaker interaction with the silica support and probably reducible in the LT region. The formation of DMM, which is clearly shown only in the case of Fe/MCM-41(N), indicates the activity of centres with dual redox and Lewis acidic activity.[29,32] In this aspect, the observed differences in the dehydration and dehydrogenation selectivity of the iron modified materials could be a test for variations in the state of iron species in them.

Critical remarks on the mechanism of methanol conversion on iron modified MCM-41 materials

In Fig. 8*a*, radiochromatograms are presented of methanol conversion on Fe/MCM-41(N) when the catalytic experiment was carried out after consecutive adsorption of methanol at room temperature, followed by its partial desorption and removal from the reactor at 473 K. We could expect that under this preliminary treatment, the surface coverage of the solid with methanol is very low and its molecules occupy predominantly the strongest adsorption sites. Under these conditions, only formaldehyde (FA) and small amounts of DME are registered, and in this aspect they could be considered as the primary products of methanol conversion (Fig. 8*a*). The formation of methoxy species as intermediates (Scheme 1, routes 1–2) and their further transformation to FA (Scheme 1, route 3) or DME (Scheme 1, route 4) with the participation of the strongest Fe-O acidic-basic pairs of the hematite species could be proposed.[29–35] Because of the low surface coverage with the predominant engagement of the strongest adsorption sites with methanol, a mechanism of DME formation via dimerization of two non-decomposed methanol molecules seems to be less probable.

In Figs. 8*b*–8*d*, radiochromatograms are presented of methanol conversion with a step by step increase of the surface coverage with methanol. For this purpose, a preliminary adsorption of various amounts of ^{11}C-methanol (a few nanomols, 10 μmol, and 100 μmol, respectively) was carried out at ambient temperature. Obviously, under this adsorption procedure catalytic sites with different adsorption strengths are expected to be occupied. We should stress some variations in the selectivity, which were observed in these cases. At lower methanol loading (Fig. 8*b*), hemimethylal (HM) is

Fig. 5. Total conversion (C) and selectivity to methane (CH_4) and dimethyl ether (DME) vs time on stream on Fe/MCM-41(N) (full circles) and Fe/MCM-41(A) (empty circles) at (*a*) 630 K, (*b*) 650 K, (*c*) 680 K, and (*d*) 700 K.

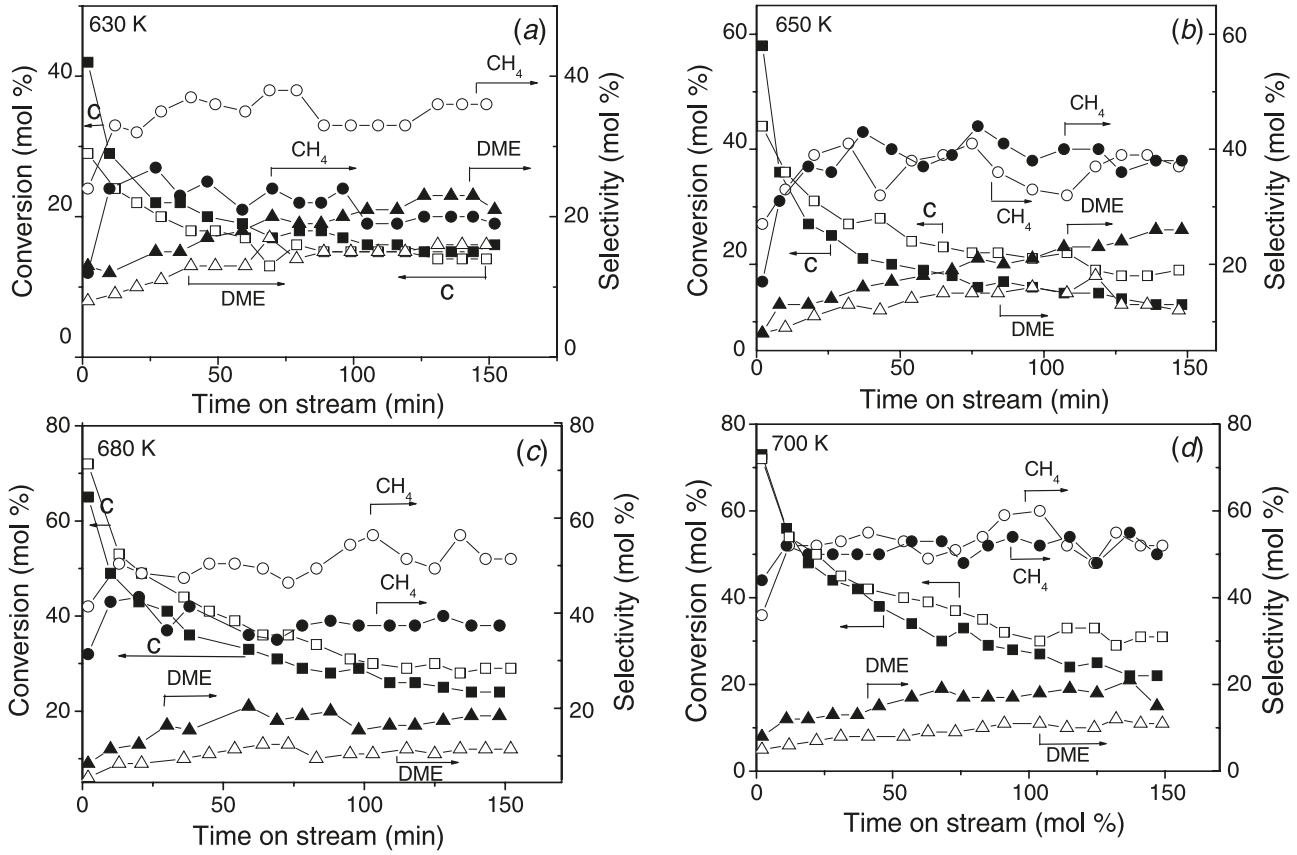

Fig. 6. Radioactivity rates on Fe/MCM-41(A) and Fe/MCM-41(N) (in Geiger-Müller radiation counts) vs temperature of desorption.

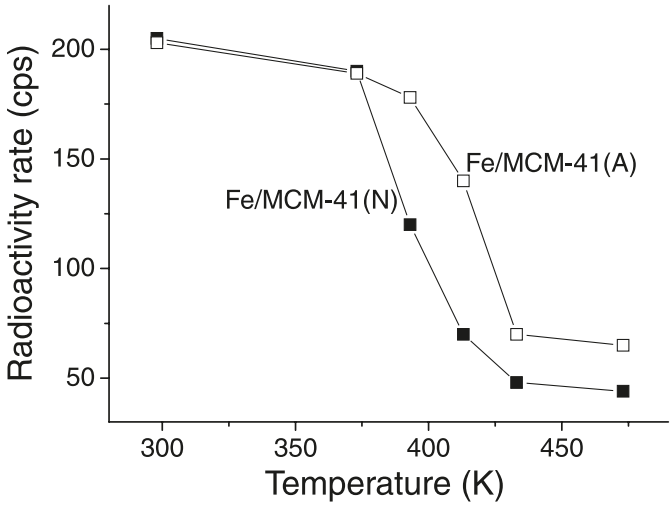

the only registered product at 523 K, which could be produced via interaction of the formed FA with nondecomposed methanol molecules, situated on the close weaker redox or acidic catalytic sites (Scheme 1, route 12). A further temperature increase, up to 573 K ,leads to the formation of CH_4, CO, and CO_2 probably via decomposition of HM and FA (Scheme 1, routes 6–8) or partial oxidation of methoxy intermediates to formic acid with the insertion of oxygen from the solid (Scheme 1, routes 5, 9, 10).[30,36] We suggest that the progressive reduction of the iron oxide species during the experiment, which is confirmed by the Mössbauer spectra of the materials used in the catalytic test (see above), results in the lower contribution of the latter reaction route. With the increase in the amount of the pre-adsorbed methanol, methylformate (MF) is also registered (Fig. 8*c*). Several mechanisms of its formation propose higher surface coverage with methanol or its intermediates could be assumed (Scheme 1, routes 7, 11, 13).[34,37] Further increase in the temperature results in the formation of significant amounts of FA, CH_3OH, CO, and CO_2 (Fig. 8*c*), probably due to the MF conversion via different reaction routes (Scheme 1, route 14). The formation of DMM under these conditions could be assumed as a further interaction of HM with methanol molecules on the Lewis acidic sites, situated in the vicinity of the redox ones (Scheme 1, Route 15). The proposed reaction scheme is also confirmed at higher surface methanol loading (Fig. 8*d*), where MF, HM, and DMM are registered in a much higher extent.

Conclusion

Summarizing the physicochemical data, the results from the conventional catalytic test, and the data from the ^{11}C-labelling measurements, it could be concluded that the impregnation of MCM-41 silica with acetylacetonate and nitrate precursors leads to a simultaneous formation of well-

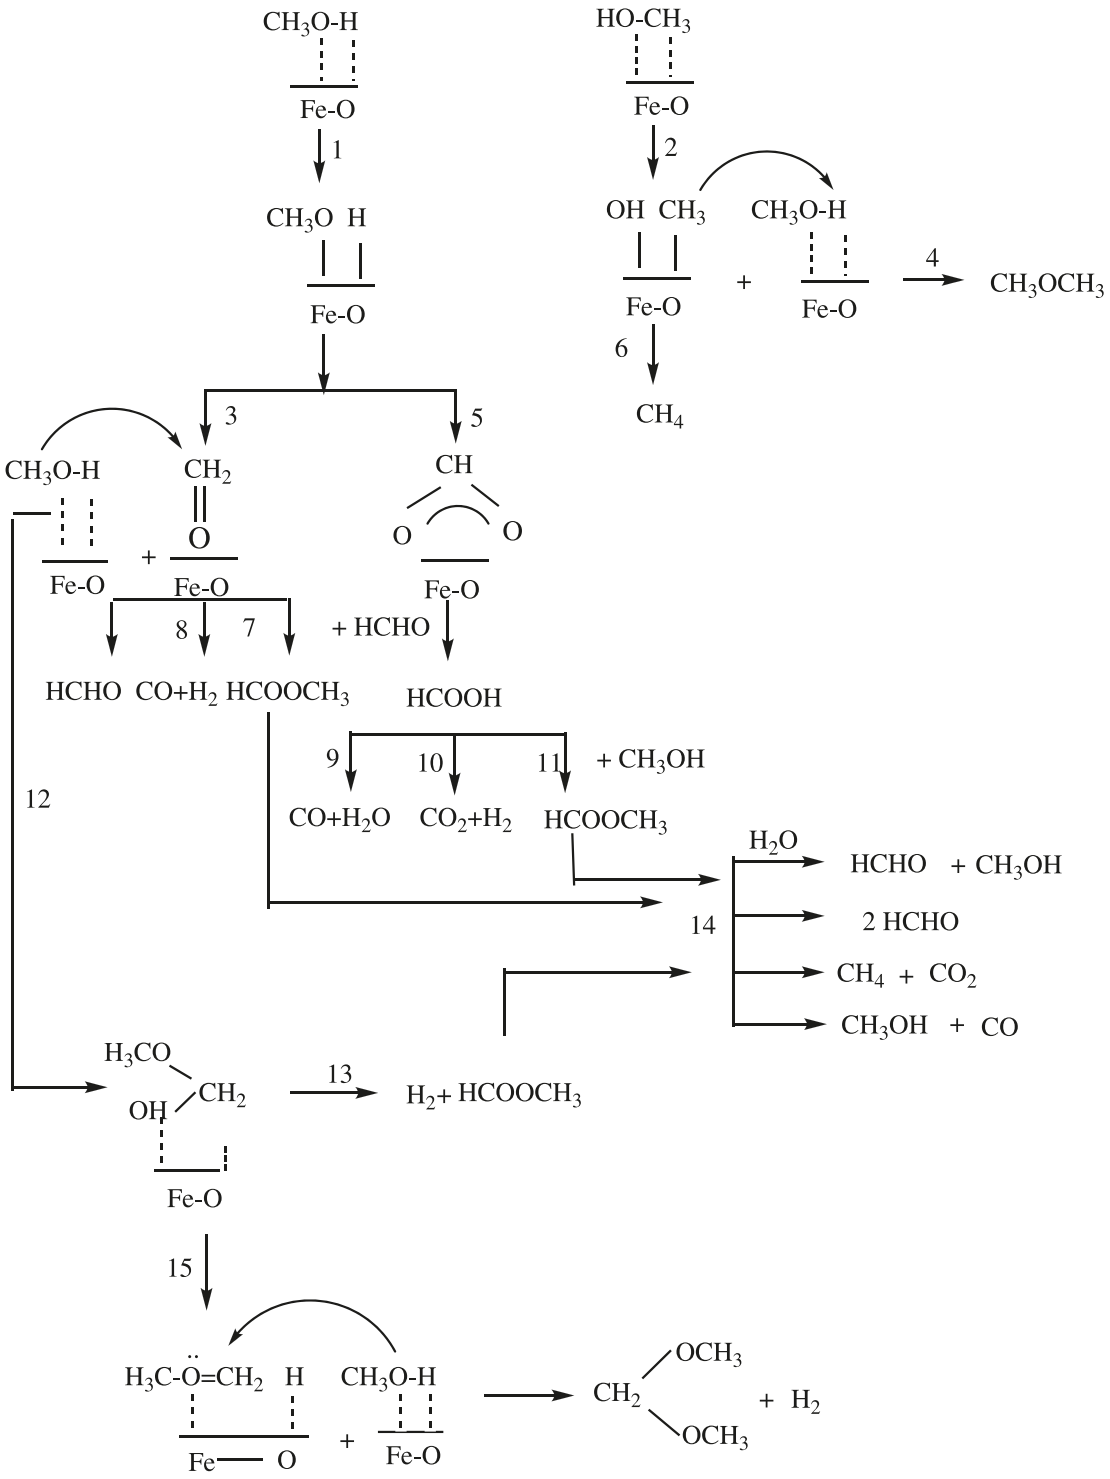
crystallized hematite particles and a relatively large fraction of isolated, strongly interacting support iron ions or FeO_x patches. The different iron species could be easily determined by the nature of the iron precursor. The first type of iron species seems to exhibit high catalytic activity in methanol decomposition to CO and methane. The second one also possesses acidic functionality and facilitates the dehydration of methanol to DME. The formation of HM and

Scheme 1.



DMM could be assigned to the simultaneous activity of sites with dual redox and acidic properties.

Deoxy-cytochalasins from a marine-derived fungus *Spicaria elegans*

Zhen-Jian Lin, Tian-Jiao Zhu, Guo-Jian Zhang, Hong-Juan Wei, and Qian-Qun Gu

Abstract: Treatment of *Spicaria elegans* with cytochrome P-450 inhibitor resulted in two new deoxy-cytochalasins, 7-deoxy-cytochalasin Z_7 (**1**) and 7-deoxy-cytochalasin Z_9 (**2**), which were recognized as plausible precursors of cytochalasins Z_7 and Z_9, respectively. Their structures were elucidated by spectroscopic methods and the absolute configuration of **1** was determined by the conventional Mosher ester method. Their cytotoxicities against two cancer cell lines were evaluated.

Key words: cytochalasin, *Spicaria elegans*, cytochrome P-450 inhibitor, cytotoxicity.

Résumé : Le traitement du *Spicaria elegans* par l'inhibiteur du cytochrome P-450 conduit à la formation de deux nouvelles désoxycytochalasines, le 7-désoxycytochalasine Z_7 (**1**) et 7-désoxycytochalasine Z_9 (**2**) qui ont été reconnues comme des précurseurs plausibles respectivement pour les cytochalasines Z_7 et cytochalsaines Z_9. Les structures des composés **1** et **2** ont été élucidées par des méthodes spectroscopiques et la configuration absolue du produit **1** a été déterminée par la méthode conventionnelle de l'ester de Mosher. On a évalué leurs cytotoxicités contre deux séries de cellules cancéreuses.

Mots-clés : cytochalasine, *Spicaria elegans*, inhibiteur de cytochrome P-450, cytotoxicité.

[Traduit par la Rédaction]

Introduction

In our ongoing search for new bioactive secondary metabolites from marine fungi, a series of cytochalasins has been isolated from the marine-derived fungus *Spicaria elegans*, some of which exhibited interesting cytotoxicities against the A-549 cell line,[1,2] which attracted our continuous attentions. Given that P450 mono-oxygenases are believed to catalyze the oxidative polyketide tailoring reactions of cytochalasins,[3] it is possible to use the inhibitors to obtain various biosynthetic precursor products. The achievement of this was realized by the discovery of 7-deoxy-cytochalasin Z_7 (**1**) and 7-deoxy-cytochalasin Z_9 (**2**) by the addition of metyrapone, an inhibitor of P-450 dependent monooxygenases, in the culture of fungus *S. elegans*. We describe herein the isolation, structure elucidation, and biological activities of **1** and **2**.

Results and discussion

Previous study had shown that the strain *S. elegans* produced 10 phenyl-cytochalasins (Z_7–Z_{15})[1,2] as the major components, which were all oxidized at the 7-position. Metyrapone (1 mmol/L), a cytochrome P-450 inhibitor, was added on the sixth day after inoculation to the culture of *S. elegans*. After an additional 14 days of static fermentation, the metabolites were extracted from the mycelium. Compared with nontreated samples, two new 7-deoxy-cytochalasins (**1** and **2**) were recognized by HPLC-MS analysis and isolated by semiprepared HPLC.

7-Deoxy-cytochalasin Z_7 (**1**) was isolated as a white powder. Its molecular formula was established as $C_{28}H_{35}NO_4$ by HR-ESI-MS (*m/z* 450.2652 $[M + H]^+$, anal. calcd. for $C_{28}H_{36}NO_4$: 450.2644) and indicated twelve degrees of unsaturation. The IR spectrum had bands due to NH and (or) OH (3392 cm^{-1}), an α,β-unsaturated ester/lactone carbonyl (1698 cm^{-1}), and an amide carbonyl (1680 cm^{-1}). The ^1H NMR spectrum (Table 1) showed the presence of an amide NH (δ_H: 5.79), three methyl doublets (δ_H: 0.97, 1.05, and 1.17), a methyl singlet (δ_H: 1.72), and 11 methine and (or) methylene protons. Ten olefinic protons (δ_H: 5.10, 5.34, 5.66, 5.96, and 7.16–7.33), suggesting a monosubstituted benzene ring, were also observed. The ^{13}C NMR spectrum of **1** displayed signals for 28 carbon atoms and confirmed the presence of an α,β-unsaturated ester/lactone carbonyl (δ_C: 167.4) and an amide carbonyl (δ_C: 172.5) (Table 1). Analysis of the DEPT spectrum revealed the presence of four methyl, two methylene, 17 methine, and three quaternary carbons, in addition to the two carbonyls. All of these 1D NMR features of **1** suggested it was closely related to an analog of cytochalasins. Accurate inspection of its 1D NMR spectra revealed, with respect to that of cytochalasin Z_7, the absence of exocyclic olefinic methylene (12-CH_2). Whereas a trisubstituted double bond (δ_H: 5.34, δ_C: 123.9, 140.0) and a methyl goup (12-Me, δ_H: 1.72, δ_C: 19.8) was present. These findings indicated that the 7-OH and the exocyclic olefinic methylene were missing, instead, a trisubstituted double bond was located between C-6 and C-7. The structure of **1** was further supported by its molecular formula ($C_{28}H_{35}NO_4$), with one fewer oxygen than cytochalasin Z_7. Compound **1** possessed a 12-membered macrocyclic ring, the same as that in cytochalasin Z_7. Accurate inspection of the ^1H and ^{13}C NMR data, including ^1H NMR coupling con-

Fig. 1. Structures of compounds **1** and **2**.

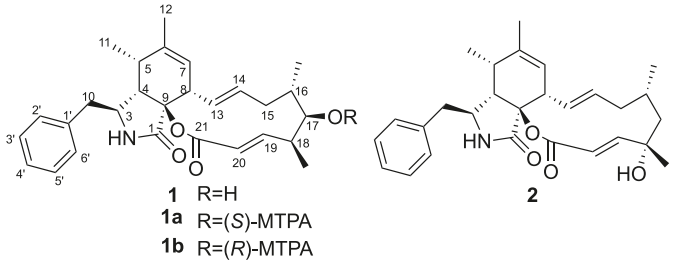

Fig. 2. The key $\Delta\delta$ values [$\Delta\delta$ (in ppm) = $\delta_S - \delta_R$] obtained for (*S*)- and (*R*)-MTPA esters of compound **1**.

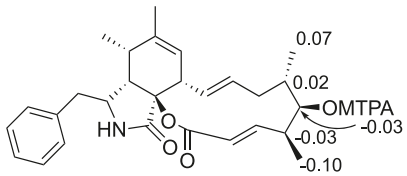

stants, for compound **1** and cytochalasin Z_7 should have the most coincident relative configuration (structure from C-15 to C-19). The absolute configuration of the 17 position in **1** was established by a conventional Mosher ester method using the (*S*)- and (*R*)-α-methoxy-α-trifluoromethyl-α-phenylacetic acid (MTPA) esters (**1a** and **1b**, respectively) (Fig. 1), where the positive values of $\Delta\delta^{S-R}$ for H-16 and 16-CH_3 and negative values of $\Delta\delta^{S-R}$ for H-18 and 18-CH_3 (Fig. 2) suggested a 17-(*R*) configuration in **1**, which was the same as that of cytochalasin Z_7. Therefore, the absolute configurations of **1** could be deduced as shown in Fig. 1.

7-Deoxy-cytochalasis Z_9 (**2**) was isolated as a white powder. Its HR-ESI-MS (*m*/*z* 450.2638 $[M + H]^+$, anal. calcd. for $C_{28}H_{36}NO_4$: 450.2644) suggested that it might be a deoxy-derivative of cytochalasin Z_9, with a molecular formula of $C_{28}H_{35}NO_4$ showing one fewer oxygen atom than cytochalasin Z_9. This assumption could be confirmed by its 1D NMR spectra. Analysis of its 1D NMR spectra, with respect to that of cytochalasin Z_9, revealed that the singlet of 11-CH_3 in cytochalasis Z_9 was upfiled shifted to δ_H: 1.14 and changed to a doublet, which suggested the double bond at C-5,6 was missing in **2**. Most similarly to **1**, the 1D NMR spectra of **2** (Table 1) also showed the absence of the oxygenated methine group at C-7, whereas there was the appearance of a trisubstituted double bond (δ_H: 5.36, δ_C: 123.8, 139.9) assigned between C-6 and C-7. On the basis of these 1D NMR spectra features, the structure of **2** was elucidated as 7-deoxy-cytochalasis Z_9.

Compounds **1**and **2** were evaluated for their cytotoxicities against the A-549 and P-388 cell lines by the MTT [3-

(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide] method. Compound **1** showed moderate cytotoxicity against the A-549 cell line with an IC_{50} value of 15.0 μmol/L, while **2** was inactive. In comparison to that of cytochalasins Z_7 and Z_9, the double bond (C-6,7) in **1** and **2** resulted in a much weaker cytotoxicity.

A new generation of plausible precursors of chaetoglobosin A[4] and epoxycytochalasin H[5] had been obtained by treatment fungi with cytochrome P-450 inhibitors. Those results, as well as the experiments in this paper, indicated that the biosynthetic oxidation at the 7 position of cytochalasins was exactly due to the cytochrome P-450. More frequently, the cytochalasins, likewise cytochalasins Z_7 and Z_9, have an oxidation at the C-9 position, which was believed to be formed from the acetate-derived polyketide chain by an enzymatic 'Baeyer–Villager'-like oxidation.[6] Even though a cytochrome P-450 monooxygenase CYP85A2 had been reported to have a Baeyer–Villiger oxidation activity,[7] it was still unknown whether the Baeyer–Villager-like oxidation in cytochalasins was related to the cytochrome P-450. In our experiments, no more deoxy-cytochalasin was detected except for **1** and **2** when *S. elegans* was treated with metyrapone, therefore, the P-450 enzyme inhibitor can't block the Baeyer–Villager-like oxidation in this strain. Maybe it is not the P-450 enzyme that catalyzed the Baeyer–Villager-like oxidation in the biosynthetic pathway of cytochalasins. This warrants further investigations.

Experimental section

General

Optical rotations were obtained on a JASCO P-1020 digital polarimeter. UV spectra were recorded on Beckman DU® 640 spectrophotometer. IR spectra were taken on a NICOLET NEXUS 470 spectrophotometer in KBr discs. ^1H, ^{13}C NMR and DEPT, and 2D NMR spectra were recorded on a JEOL JNM-ECP 600 spectrometer using TMS as an internal standard and chemical shifts were recorded as δ values. NOESY experiments were carried out using a mixing time of 0.5 s. ESI-MS was measured on a Q-TOF ULTIMA GLOBAL GAA076 LC mass spectrometer. Semiprepartive HPLC was performed using an ODS column (Shin-pak ODS $_H$, 10 mm × 250 mm, 5 μm, 4 mL/min).

Fungal material

The fungus *Spicaria elegans* was isolated from the marine sediments collected in Jiaozhou Bay, China. It was preserved in the China Center for Type Culture Collection (patent depositary number: KLA03 CCTCC M 205049). Working stocks were prepared on potato dextrose agar slants stored at 4 °C.

Fermentation and extraction

The fungus was incubated at 28 °C under static conditions in 30 1000 mL conical flasks containing the liquid medium (300 mL/flask) composed of glucose (20 g/L), peptone (5 g/L), malt extract (3 g/L), yeast extract (3 g/L), and sea-water after adjusting its pH to 7.0. The inhibitor metyrapone (1 mmol/L) was added on the sixth day after inoculation to the culture of *S. elegans*. After an additional 14 days of static fermentation, the fermented whole broth (9 L) was extracted three times with EtOAc to give an EtOAc solution, which was concentrated under reduced pressure to give a crude extract (5.5 g).

Purification

The crude extract (5.5 g) was separated into four fractions (Fr. 1–4) on a Si gel column using a gradient elution of $CHCl_3$:MeOH. Fr. 2 was eluted with $CHCl_3$:MeOH (100:1, 0.4 g) and was purified into 8 subfractions (Fr. 2-1 ~ Fr. 2-8) by Si gel column using stable elution of $CHCl_3$:MeOH (200:1). Subfraction Fr. 2-6 was further purified by reverse-phase column using stable elution of MeOH:H_2O (7: 3) to give 4 subfractions (Fr. 2-6-1 ~ Fr. 2-6-4), respectively. Further purification of subfraction Fr. 2-6-4 by extensive HPLC (75% MeOH, 4.0 mL/min) gave compounds **1** (3 mg) and **2** (2 mg).

7-Deoxy-cytochalasin Z_7 (1)

White powder. $[\alpha]_D^{25}$ +94.8 (*c* 0.1, MeOH). UV (MeOH) λ_{max} (nm) (log ε): 233 (2.43). IR (KBr, cm^{-1}) ν_{max}: 3368, 2937, 1700, 1444, 1214, 1076, 990. ^1H and ^{13}C NMR (see Table 1). HR-ESI-MS *m/z*: 450.2652 $[M + H]^+$. Anal. calcd. for $C_{28}H_{36}NO_4$: 450.2644.

7-Deoxy-cytochalasin Z_9 (2)

White powder. $[\alpha]_D^{25}$ +12.8 (*c* 0.1, MeOH). UV (MeOH) λ_{max} (nm) (log ε): 230 (2.00). IR (KBr, cm^{-1}) ν_{max}: 3298, 2900, 1694, 1321 1201, 999. ^1H and ^{13}C NMR (see Table 1). HR-ESI-MS *m/z*: 450.2638 $[M + H]^+$. Anal. calcd. for $C_{28}H_{36}NO_4$: 450.2644.

Preparation of the (*S*)- and (*R*)-MTPA ester derivatives of 1

Compound **1** (2.0 mg) was divided into two aliquots and transferred into two clean reaction bottles and was dried completely under vacuum. Each solubilized in 0.5 mL of pyridine. The two samples were treated with (*R*)- and (*S*)-α-methoxy-α-trifluoromethylphenylacetyl chloride (1 equiv.) under a N_2 gas stream, and then stirred for 24 h at room temperature. The organic layer was then washed with water, HCl (1 mol/L), water, $NaHCO_3$(satd.), and water, then dried (Na_2SO_4) and concentrated under reduced pressure to obtain the ester. Final purification achieved by HPLC gave **1a** and **1b**, respectively. ^1H NMR data for the (*S*)-MTPA ester derivative (**1a**) of **1** (600 MHz, $CDCl_3$) δ: 5.76 (1H, brs, 2-NH), 3.24 (1H, m, H-3), 3.05 (1H, m, H-4), 3.05 (1H, m, H-5), 5.35 (1H, brs, H-7), 3.48 (1H, m, H-8), 2.90 (1H, dd, *J* = 4.1, 13.8 Hz, H-10a), 2.69 (1H, dd, *J* = 9.6, 13.8 Hz, H-10b), 1.20 (3H, d, *J* = 6.9 Hz, H-11), 1.73 (3H, brs, H-12), 6.04 (1H, ddd, *J* = 13.0, 10.6, 1.8 Hz, H-13), 5.07 (1H, m, H-14), 2.30 (1H, ddd, m, H-15a), 2.09 (1H, brd, *J* = 14.6 Hz, H-15b), 1.80 (1H, m, H-16), 0.88 (3H, d, *J* = 6.4 Hz, 16-CH_3), 5.09 (1H, m, H-17), 2.80 (1H, m, H-18), 0.97 (3H, d, *J* = 7.3 Hz, 18-CH_3), 5.68 (1H, dd, *J* = 15.5, 2.3 Hz, H-19), 7.15 ~ 7.56 (11H, m, H-20 and Ph-H). ^1H NMR data for the (*R*)-MTPA ester derivative (**1b**) of **1** (600 MHz, $CDCl_3$) δ: 5.82 (1H, brs, 2-NH), 3.24 (1H, m, H-3), 3.05 (1H, m, H-4), 3.05 (1H, m, H-5), 5.35 (1H, brs, H-7), 3.48 (1H, m, H-8), 2.90 (1H, dd, *J* = 4.1, 13.8 Hz, H-10a), 2.69 (1H, dd, *J* = 9.6, 13.8 Hz, H-10b), 1.20 (3H, d, *J* = 6.9 Hz, H-11), 1.73 (3H, brs, H-12), 6.04 (1H, ddd, *J* =

13.0, 10.6, 1.8 Hz, H-13), 5.07 (1H, m, H-14), 2.34 (1H, ddd, m, H-15a), 2.05 (1H, brd, J = 14.6 Hz, H-15b), 1.78 (1H, m, H-16), 0.81 (3H, d, J = 6.4 Hz, 16-CH_3), 5.12 (1H, m, H-17), 2.83 (1H, m, H-18), 1.07 (3H, d, J = 7.3 Hz, 18-CH_3), 5.71 (1H, dd, J = 15.5, 2.3 Hz, H-19), 7.15 ~ 7.56 (11H, m, H-20 and Ph-H).

Biological assays

Cytotoxic activity was evaluated by the MTT method using A-549 and H-L60 cell lines. The cell lines were grown in RPMI-1640 supplemented with 10% FBS under a humidified atmosphere of 5% CO_2 and 95% air at 37 °C (tsFT210 cell line at 32 °C). An aliquot (200 μL) of those cell suspensions at a density of 5×10^4 cell mL^{-1} was plated in 96 well microtiter plates and incubated for 24 h at the above condition. Then 2 μL of the test compound solutions (in DMSO) at different concentrations was added to each well and further incubated for 72 h in the same condition. MTT solution (20 μL of 5 mg/mL in IPMI-1640 medium) was added to each well and incubated for 4 h. Old medium containing MTT (150 μL) was then gently replaced by DMSO and pipetted to dissolve any formazan crystals that had formed. Absorbance was then determined on a SPECTRA MAX PLUS plate reader at 570 nm.

Novel pressure control in supercritical fluid chromatography using a resistively heated restrictor

Jian Jun Li and Kevin B. Thurbide

Abstract: An alternative means of independently controlling column pressure in supercritical fluid chromatography (SFC) by resistively heating the post-column restrictor is demonstrated. Compared to conventional block heating methods, resistive restrictor heating provides at least four times greater pressure programming rates and allows for much faster cooling times in between runs, thereby increasing sample throughput. When applying resistive restrictor heating in proximity to a flame ionization detector, the chromatographic baseline noise increases substantially and obscures peaks. However, adding about 100 mL/min of nitrogen into the flame burner essentially removes this noise and returns the detector response to normal. The analyte retention time in consecutive pressure gradient trials reproduces well with a minimal relative standard deviation of 0.36% (n = 3). The resistive restrictor heating technique presented is also found to be equally effective for either capillary or packed SFC operating modes. Results suggest that this method can potentially provide a simple, inexpensive, and convenient alternative to limited passive restrictors or more costly and complex backpressure regulators that are often used to maintain system pressure in supercritical fluid chromatography.

Key words: supercritical fluid chromatography, pressure control, resistive heating, rapid.

Résumé : On a mis au point une méthode alternative qui permet de contrler la pression de la colonne en chromatographie avec des fluides supercritiques et qui fait appel à un chauffage à l'aide d'une résistance après le point de restriction de la colonne. Par comparaison avec les méthodes de chauffage par bloc, la nouvelle méthode permet d'obtenir des taux de programmation quatre fois plus grands et elle permet de bénéficier des temps de refroidissement beaucoup plus courts entre les divers essais, augmentant du coup l'encours. Lorsqu'on applique un chauffage par résistivité à proximité d'un détecteur par ionisation à flamme, le bruit de fond chromatographique augmente considérablement et obscurcit les pics. Toutefois, l'addition d'environ 100 mL/min d'azote dans la flamme du brûleur élimine pratiquement tout ce bruit et permet de retourner à une réponse normale du détecteur. Les temps de rétention de l'analyse dans des essais successifs consécutifs de gradients de pression se reproduisent bien, avec une déviation standard relative minimale de 0,36 % (n = 3). On a aussi observé que la technique de chauffage par résistivité présentée est aussi efficace pour les chromatographies avec des fluides supercritiques en mode capillaire ou remplie. Les résultats suggèrent que cette méthode pourrait éventuellement fournir une alternative simple, peu coûteuse et facile aux processus de restriction passifs ou à ceux plus coûteux et plus complexes faisant appel à des régulateurs de rétropression qui sont souvent utilisés pour maintenir la pression du système en chromatographie avec des fluides supercritiques.

Mots-clés : chromatographie avec des fluides supercritiques, contrôle de la pression, chauffage à l'aide d'une résistance, rapide.

Introduction

Supercritical fluid chromatography (SFC) is an established method that provides separation properties that are complimentary to those of conventional high-performance liquid chromatography and gas chromatography.[1,2] The most widely used mobile phase in SFC is supercritical carbon dioxide. In addition to being relatively inert, nontoxic, inexpensive, and environmentally compatible compared with conventional organic solvents, supercritical carbon dioxide is also a significantly compressible fluid.[3,4] As such, its density and ability to solvate analytes can be directly manipulated through the pressure applied to the chromatographic system. Thus, pressure control is a very important operational parameter in SFC.[1–5]

For SFC employing capillary columns (cSFC) and low flows, system pressure is most commonly maintained by using a length of narrow bore fused silica tubing as a restrictor at the end of the column.[6] Such restrictors have the advantage of being reasonably simple and inexpensive to fabricate and use. However, because they are passive devices, any change in the pressure (or flow rate) setting at the CO_2 pump, will also change the corresponding flow rate (or pressure) in the system. This often complicates cSFC method development since the effects of column pressure and flow rate become convoluted.[5,6]

For SFC employing larger packed columns (pSFC) and flows, system pressure is normally maintained by a backpressure regulator. Through external electronic control, this post-column device variably restricts the quantity of fluid traversing a tiny orifice. In this way it can manage system pressure downstream while an upstream pump maintains column flow. The significant clear advantage of using a backpressure regulator is that column flow and system pressure can each be actively and independently controlled. However, disadvantages include its relatively large cost, limited lifespan, and its incompatibility with narrow bore/capillary columns due to the considerable dead volume it adds to the system.[5,6]

Over the years, a number of interesting alternative methods to control pressure in SFC have also appeared. Many of these involve the addition of a pressure regulating fluid at the column outlet in both cSFC[7–10] and pSFC applications.[11] This approach successfully provides independent control of column flow and pressure. However, several of the designs can be relatively complex, require the use of an extra pump, and (or) may possibly lead to problems in interfacing with flame-based detection systems due to the very large extra gas flows that normally stream from such backpressure devices.[5]

An especially useful alternate means of controlling pressure in SFC involves heating the outlet restrictor as earlier introduced by Greibrokk et al.,[12] Berger and Toney,[13] and Berger.[14] This method essentially houses the restrictor in a heated metal block (e.g., detector heating block), where the applied temperature causes thermal expansion of the tubing material and restriction of the flow. Thus, in conjunction with a constant pressure or flow pump upstream, independent control of column flow and pressure can be attained by this method. Further advantages of this approach are that it is readily achieved with simple apparatus, it does not add dead volume to the system, and it does not require extreme auxiliary gas flows that might interfere with downstream detector operation. However, despite its potential advantages, no separations demonstrating the method are found in these early reports. In fact, to date, extremely few actual chromatographic applications of this approach have been reported.[15,16] One potential reason for this limited activity may concern the relatively large thermal mass of the heating block, which prevents rapid changes in temperature (and hence system pressure).[5] For example, this factor can directly limit the rate of system pressure gradients that can be achieved by this method. As well, it can also seriously impact the sample throughput capacity of the technique due to the considerably long times required for the heating block to cool in between runs. Thus overall, while this approach has great potential for SFC pressure control, it remains much less used relative to conventional methods.

Recently, we developed a method for offsetting efficiency losses due to large pressure drops across the column used in pSFC.[17] This technique involved, in part, the use of a low thermal mass resistively heated wire to gently heat the column outlet area. Overall, the method was found to be rapid, straightforward, rugged, and inexpensive to operate. Given its relative simplicity, it appeared that it could also potentially be effective as a direct restrictor heating device that might act as an alternative approach to the conventional heating block method reported earlier. If so, it could potentially allow for greater sample throughput in this mode and provide a relatively easy means of independently controlling pressure and flow in SFC. This paper explores the use of a resistively heated wire to control the restrictor temperature and hence column pressure in SFC. The characteristics and operating parameters of the method are presented and compared against a conventional heating block apparatus. The approach is also subsequently demonstrated as a pressure control method in cSFC separations and for the first time pSFC separations as well.

Experimental

Instrumentation

A Gilson SF3 (Gilson, Villiers-le-Bel, France) reciprocating pump was usually employed to deliver the CO_2 mobile phase through the system. However, in certain instances, specified in the text, an Isco Model 260D (Isco, Lincoln, Nebraska, USA) syringe pump was also explored for this purpose. All pressure measurements were taken at the pump used. A Rheodyne Model 7520 injection valve with a 0.2 μL sample loop (Alltech, Deerfield, Illinois, USA) was used to introduce samples to the column. A Shimadzu GC 9A (Shimadzu, Kyoto, Japan) gas chromatograph equipped with a flame ionization detector (FID) was used to maintain column temperature and provide detection. The column oven temperature was normally set between 50 and 100 °C. A DB-1 capillary column (30 m × 0.25 mm; 0.25 μm dimethylpolysiloxane coating; J & W Scientific, Folsom, California, USA) was used in cSFC experiments. For pSFC applications, a PRP-1 packed column (50 mm × 4.1 mm; 5 μm particles; Hamilton, Reno, Nevada, USA) with a polystyrene divinylbenzene stationary phase was used. The column outlet was connected to the detector by a restrictor made from a 35 cm length of deactivated fused silica capillary tubing (0.05 mm i.d.). This tubing had a taper on the end, which was achieved by drawing the capillary through a Bunsen burner.[6]

Restrictor heating method

For experiments testing the conventional restrictor heating method, the restrictor typically terminated inside the detector heating block about 1–2 mm below the surface. For experiments testing the resistive heating method proposed here, the restrictor terminated about 3 cm below the surface of a glass burner used for the FID flame. The burner resembles one used earlier in our laboratory[18] and was made of a quartz tube with two bores. The burner end was 55 mm long with an inner diameter of 4 mm, and the connecting end was 25 mm long with an inner diameter of 2 mm. This burner configuration easily allowed stable, sensitive FID flame operation at typical decompressed CO_2 gas flow rates of about 40 mL/min or larger. The resistive heating coil was made of Ni-Cr wire (0.5 mm diameter). A 10 cm length of wire was wrapped around the burner and powered by a standard laboratory variable transformer (120 V supply, 10 A max; model 3PN 1010, Staco Inc., Dayton, OH, USA) to heat the coil and restrictor. The coil was comprised of 20 turns over a distance of 1.5 cm and was centered about the end of the restrictor. Voltages applied to the heating coils were typically up to 10% of the full-scale settings, which provided respective temperatures up to about 600 °C. During these experiments, the detector heating block was turned off.

Chemicals and reagents

Instrument-grade CO_2 (99.99%; Praxair, Calgary, Alberta, Canada) was used as the mobile phase. High purity hydrogen and oxygen (Praxair) were used as the flame gases. High purity nitrogen (Praxair) was used in certain experiments as an auxiliary gas. Linear *n*-alkanes (99%; Sigma-Aldrich, Oakville, Ontario, Canada) were used as standards. Paraffin wax (Sigma-Aldrich) was also used in some demonstrations. All samples were prepared by dissolving the solutes in hexane or carbon disulfide to a final concentration between 2 and 4 μg/μL.

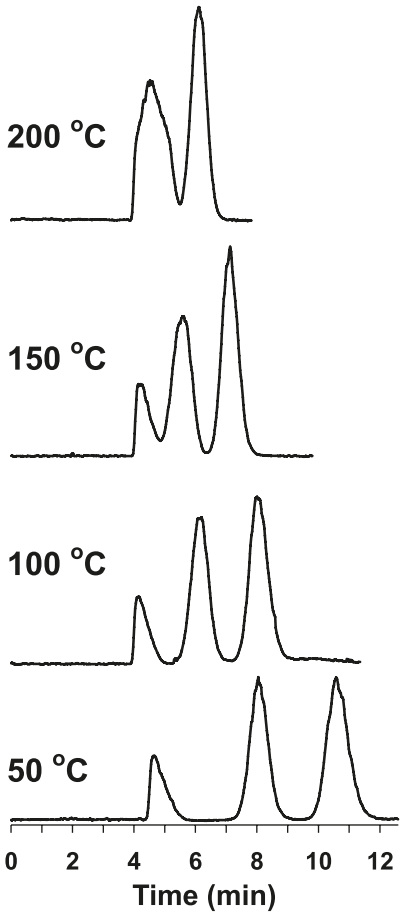
Results and discussion

Detector heating block mode

Initial experiments were performed using the GC detector heating block to control the restrictor temperature similar to the original method described earlier.[12,13,15] Since the restrictor was situated inside the heating block, changes in the detector block temperature were therefore directly used to constrict flow at the outlet and alter the system pressure. Upon applying this approach with a constant flow pump upstream it was found that the system pressure indeed varied as a function of the block (i.e., restrictor) temperature. Of note, at a flow rate of 200 μL/min, as the restrictor temperature increased from 50 to 250 °C the corresponding system pressure increased from 12 to 24 MPa, which is similar to that reported earlier.[12] Figure 1 shows how these restrictor temperature and system pressure changes can impact the separation of some test solutes in pSFC. As seen at a restrictor temperature of 50 °C, the decane and undecane separation is over in 12 min. Subsequently, as the restrictor temperature is increased up to 200 °C and the system pressure rises accordingly, elution time is continually reduced (at the expense of resolution) until the decane and solvent peaks co-elute and undecane emerges around 6 min. This clearly demonstrates that the block restrictor heating method can control column pressure (and hence analyte retention) independent of column flow rate. Somewhat surprisingly, however, only a few cSFC applications of this technique exist,[15,16] and to our knowledge, this is its first demonstration in pSFC.

Perhaps related to this is that pressure programs are often used in SFC to increase analysis speed. To achieve such programs here, the detector heating block temperature was systematically raised. However, in doing so it was observed that the column pressure increased at a relatively small rate. In our experience, a maximum value near only 0.2 MPa/min could be obtained because of the relatively large thermal mass of the heating block and the time required (often 20 min or more) to significantly raise its temperature. Of even greater concern, though, the heating block needed a much longer time to cool down. For example, usually 90 min or more was required for it to fall from about 250 to 50 °C. Therefore, this long cycle time can very negatively impact sample throughput when attempting to use this method. As such, an alternative approach that allows rapid heating and cooling of the restrictor could potentially improve upon this otherwise very useful technique of pressure control and facilitate its broader application in SFC. To investigate this, a resistively heated coil wrapped around the restrictor outlet was explored.

Fig. 1. The effect of detector block restrictor heating on pSFC elution. Conditions are a column temperature of 45 °C and a constant flow rate of 200 μL/min (reciprocating pump) using the PRP-1 column. The peaks in order of elution are solvent (CS_2), *n*-decane, and *n*-undecane. The restrictor temperature is labelled on each run.

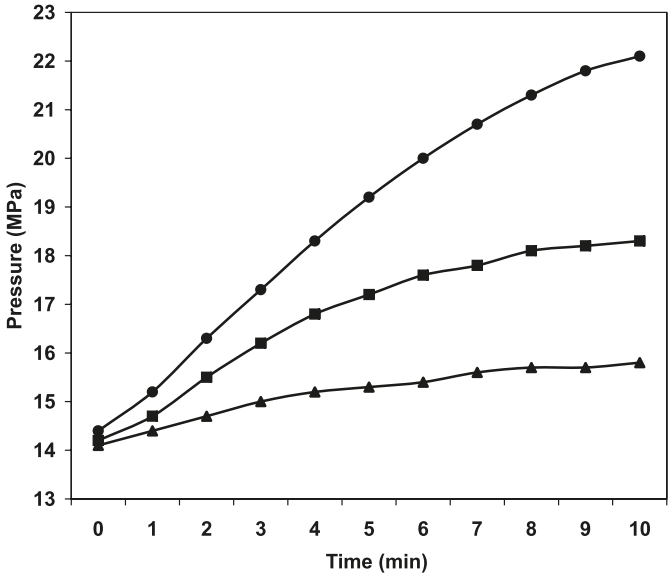


Resistive heating mode

An immediate advantage noted in using the resistive heating method was that the restrictor temperature could be raised relatively much more rapidly. For example, only 1–2 min was required to increase the restrictor temperature from 25 to 450 °C. As well, after the heating was stopped, the restrictor also rapidly cooled from such high temperatures (normally <3 min to achieve 25 °C). This is a direct result of the lower thermal mass of the apparatus, which enormously reduces the cycle time of this method by comparison. Subsequently, the system pressure was also observed to change faster when the restrictor was resistively heated. For instance, pressure programming rates of 0.8 MPa/min could be readily attained by this method. Further, this rate of change could be altered depending on factors such as the mobile phase flow rate, the column used, and how the heating was applied.

Figure 2 displays some pressure-time curves demonstrating the different rates of pressure change obtained when the heating coil was operated at different temperatures. As seen in each trial of Fig. 2, after the selected temperature is applied to the restrictor at 0 min the system pressure steadily rises before it plateaus at the corresponding final value. While closer contact between the heating coil and the re-

Fig. 2. Pressure change over time with the resistively heated restrictor. Conditions are a column temperature of 50 °C and a constant flow rate of 200 μL/min (reciprocating pump) using the DB-1 column. The restrictor temperatures employed are 350 °C (▲), 450 °C (■), and 600 °C (●). In each case the restrictor heating begins at 0 min.

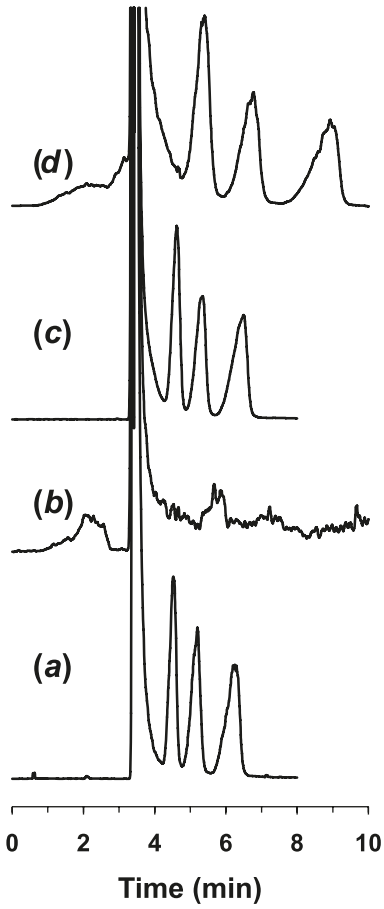


strictor (e.g., a smaller FID flame burner design) or greater voltages applied to appropriate wire coils could potentially translate into even greater rates of pressure increase, these parameters were not further optimized in the current study.

When subsequently exploring the use of the resistive heating method in SFC separations, initial results surprisingly indicated that a relatively excessive amount of noise was generated during the heating period. This, in turn, seriously obscured chromatographic peaks. A possible reason for the increased noise observed was that it might be due to an increase in the burner surface temperature, which caused the adjacent FID polarizer to overheat and induce fluctuations in the detector response. To potentially offset this problem, a flow of nitrogen was added as an auxiliary cooling gas into the bottom of the burner. Consequently, the noise generated by rapid heating was dramatically reduced. Ultimately, a flow of about 100 mL/min of nitrogen essentially removed the noise and peak appearance returned to normal. Figure 3 demonstrates this for the cSFC separation of some test solutes. As shown, the initial separation obtained without heating the restrictor (Fig. 3*a*) is seriously eroded after 450 °C of heat is applied (Fig. 3*b*). However upon adding 100 mL/min of nitrogen, the peak appearance without and with restrictor heating applied (Figs. 3*c* and 3*d*, respectively) is of similar quality to that originally presented in Fig. 3*a*. As such, nitrogen was used in all subsequent trials.

It is worth noting that the separations shown in Fig. 3 were generated using a syringe pump in the constant pressure mode to propel mobile phase through the capillary column. This is a standard arrangement in typical cSFC separations.[6] As such, in contrast to the variable pressure separations shown in Fig. 1, when heating is applied to the restrictor in this case, the flow rate is reduced from about 200 to 100 μL/min and

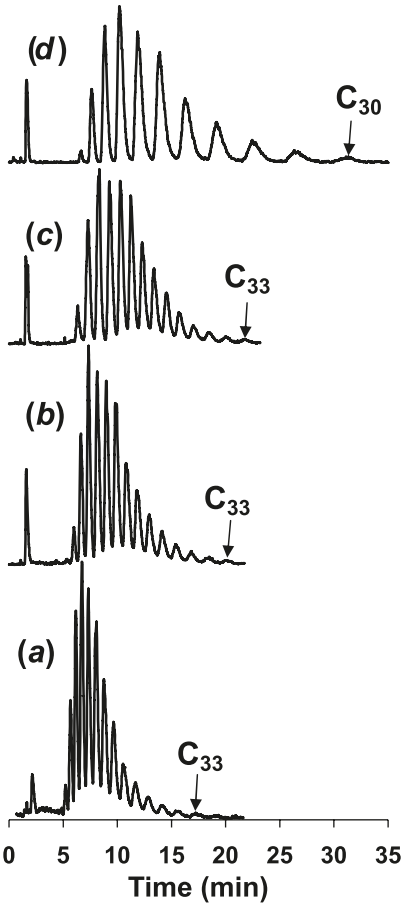
Fig. 3. The effect of resistive restrictor heating on peak appearance with and without nitrogen present. The cSFC conditions are a column temperature of 70 °C and a constant CO_2 pressure of 12.7 MPa (syringe pump) using the DB-1 column. The *n*-alkane solutes in order of elution are C_{20}, C_{22}, and C_{26}. The chromatograms shown have (*a*) no restrictor heating applied and no nitrogen flow, (*b*) 450 °C applied to the restrictor upon injection and no nitrogen flow, (*c*) no restrictor heating applied and 100 mL/min nitrogen, and (*d*) 450 °C applied to the restrictor upon injection and 100 mL/min nitrogen.



analyte retention increases accordingly (Fig. 3*d*). This marks an important difference between typical cSFC and pSFC runs given that the former often uses a syringe pump in constant pressure mode to drive the mobile phase, whereas the latter often uses a reciprocating pump in constant flow mode for this purpose (e.g., as in Fig. 1). Regardless, in our experience this operational difference was inconsequential since the resistive heating method worked equally well in either mode and with either style of pump or column. Still, due to the convenience of continuous mobile phase delivery from the reciprocating pump, it was often preferable in many experiments. As such, it delivered a constant flow of mobile phase while downstream restrictor heating acted to control the system pressure as desired.

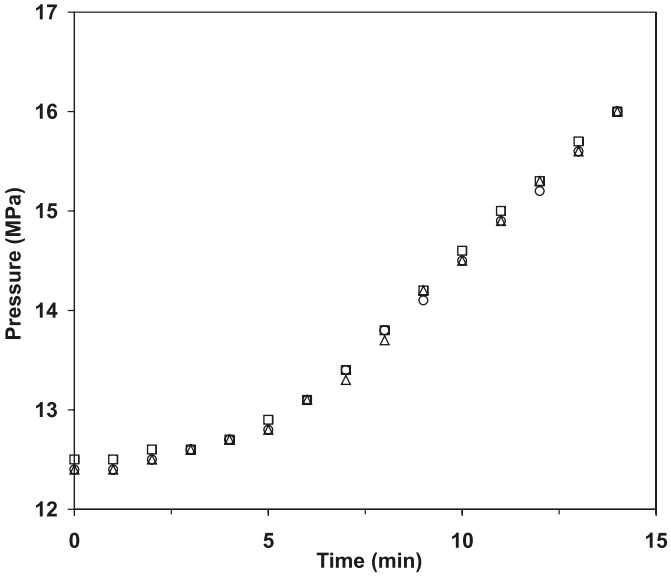
To demonstrate the utility of this resistive restrictor heating approach, the method was applied to the analysis of a wax sample. Figure 4 demonstrates the effect of using various restrictor heating (i.e., pressure) programs on the separation of this sample in the pSFC mode. As seen, the rapid

Fig. 4. The impact of restrictor heating pressure programs on analyte elution in pSFC. Conditions are a column temperature of 80 °C, a constant flow rate of 400 μL/min (reciprocating pump) using the PRP-1 column, and 100 mL/min of nitrogen. Analyte: C_{20}–C_{33} wax sample in CS_2. The pressure programs invoked are (*a*) 25–35 MPa within the first 10 min, (*b*) 25–35 MPa within the first 15 min, (*c*) 25 MPa for the first 5 min then increasing to 35 MPa within the next 10 min, and (*d*) held isobarically at 25 MPa for the entire run.



heating method provides effective control of column pressure and analyte retention in pSFC. Figure 4*a* shows a relatively fast elution of the sample, which was obtained by heating the restrictor such that the pressure changed from 25 to 35 MPa in the first 10 min. Conversely, Fig. 4*b* spans this same pressure change over 15 min and the resulting separation time and resolution both increase. The separation shown in Fig. 4*c* was obtained by maintaining the column pressure at 25 MPa for the first 5 min and then increasing it to 35 MPa over the next 10 min. This also affords increased resolution and analysis time. For comparison, Fig. 4*d* shows how the same separation appears when pressure programming is not applied and conditions are held isobarically at 25 MPa for the whole run. As seen, this results in a weaker elution strength and only C_{30} being one of the last distinguishable peaks. Thus, as shown, analyte elution profiles and analysis times can be directly manipulated through carefully planning the restrictor heating (i.e., pressure program) strategy. As would be expected, it should also be mentioned that these effects are not analyte dependant and similar results were also obtained for fatty acids and alcohols in addition to the alkane trials shown here.

Fig. 5. Reproducibility of column pressure as a function of time in three consecutive trials spanning about an hour. Conditions are a column temperature of 70 °C and a flow rate of 180 μL/min (reciprocating pump) using the PRP-1 column. The pressure program applied is 12.4 MPa at time zero to 16.0 MPa within 14 min.



An important feature in any chromatographic gradient method is its reproducibility. For instance, the ability to precisely recreate pressure programs in SFC can directly impact the precision of analyte retention times. As such, it was essential to probe this aspect of the resistively heated restrictor method. Figure 5 displays the pressure versus time curves obtained from three consecutive runs of the same pressure program performed within about an hour. As can be seen, the plotted values from each pressure program agree very well with each other over the course of time. As a result, a C_{28} alkane test analyte also chromatographed under these conditions eluted quite reproducibly. Of note, the triplicate experiments performed yielded a relative standard deviation of 0.36% for the retention time of this analyte. Thus, no method difficulties appear in this regard.

It should be noted that if the restrictor was not compromised, then the day to day reproducibility of the method gave much the same results as that displayed in Fig. 5. However, restrictor lifetime is limited in SFC. In our experience, this amounted to nearly two months of regular restrictor usage before it required replacement. To minimize dimensional variations in the new tapered restrictor created, we carefully trimmed the taper tip until a similar flow of carbon dioxide streamed through it at set pressure and temperature. Typically this value could be achieved within about 4 mL/min, which resulted in restrictor to restrictor trials of the method agreeing within about 1 MPa of achieved pressure for the same set temperature. Therefore, some fine tuning of the pressure and temperature calibration is expected when changing restrictors, however this is found to be minimal. As such, the method is generally quite robust and reproducible.

Conclusions

The ability to independently control system flow rate and pressure in SFC using a resistively heated restrictor has been demonstrated. The method is inexpensive, convenient, and efficient. Of note, it allows the restrictor to be heated and subsequently cooled much more rapidly than conventional heating block methods, allowing for improved sample cycling times. A significantly increased FID detector noise was noted when using resistive heating. However, this was successfully eliminated by simultaneously introducing an auxiliary nitrogen flow into the flame burner. The method was equally effective when using syringe or reciprocating pumps to deliver the mobile phase and also when using capillary or packed columns as the separation medium. Results indicate that this technique could provide a useful alternative to passive restrictors normally used to maintain pressure in cSFC and also to much more expensive and complex backpressure regulators frequently used to control pressure in pSFC. Further, this method may also be useful in other modes of capillary chromatography (e.g., subcritical fluid methods) where dead volume issues are of concern and independent pressure control is desirable.

On the relationship between free energy difference calculations by thermodynamic integration and harmonic frequency analysis

Jason Jechow and Tom Ziegler

Abstract: Harmonic frequency analysis (HFA), based on statistical mechanics, is a widely used and powerful tool for evaluating free energy changes between molecular states. It has, as such, been employed extensively to evaluate the free energy of reaction and activation for chemical processes. Alternatively, free energy differences can be calculated using thermodynamic integration (TI). In TI, the force on a constrained reaction coordinate is calculated, and this force from *a* to *b* is integrated to obtain the Helmholtz free energy change ΔA_{ab}. Although HFA and TI clearly are related from a fundamental statistical mechanics point-of-view, the relationship is not immediately obvious when one considers the quite different procedures applied in the two methods. This article provides a detailed analysis and proof of the relation between HFA and TI.

Key words: thermodynamic integration, free energy, harmonic approximation.

Résumé : L'analyse de fréquence harmonique (AFH), basée sur la mécanique statistique, est fréquemment utilisée et elle s'avère un outil puissant pour évaluer les changements d'énergie libre entre des états moléculaires. Elle a été couramment utilisée de la sorte pour évaluer l'énergie libre de réaction et l'activation de processus chimiques. D'une façon alternative, on peut calculer des différences d'énergie libre en utilisant l'intégration thermodynamique (IT). Dans cette méthode, on calcule la force sur une coordonnée réactionnelle contrainte et on intègre cette force de a à b pour obtenir le changement d'énergie libre d'Helmholtz, ΔA_{ab}. Même si l'AFH et l'IT sont clairement apparentées d'un point de vue de la mécanique statistique fondamentale, la relation n'est toutefois pas immédiatement évidente lorsqu'on considère les méthodes très différentes appliquées dans les deux méthodes. Dans cet article, on présente une analyse détaillée et une preuve de la relation entre l'AFH et l'IT.

Mots-clés : intégration thermodynamique, énergie libre, approximation harmonique.

[Traduit par la Rédaction]

1. Introduction

Thermodynamic integration (TI) calculates changes in free energy along a predefined reaction path.[1–3] This involves defining the reaction path (the change in a bond length, bond angle, or some other quantity), constraining the molecular system at various points along this reaction path, and performing a molecular dynamics simulation at each of these points. As the molecular system vibrates, a force to hold the constraint is determined, and the derivative of the free energy, with respect to the constraint, can be calculated from this force. Subsequently, the Helmholz free energy change between the molecular states *a* and *b* can be calculated by integrating the force along the reaction coordinate from *a* to *b*.

For a linear constraint, the average force along the constraint in a molecular dynamics simulation is known to be the negative of the derivative of the free energy along the constraint.[4] This derivation is determined by examining the Lagrangian for a constrained molecular system and the Lagrangian for the corresponding unconstrained molecular system, and by observing how the motion would be different in the two systems. Then, by assuming a linear constraint, the formula for the derivative of the free energy simplifies to the negative of the force along the linear constraint.

It is also possible to calculate the Helmholtz free energy change ΔA_{ab} by harmonic frequency analysis (HFA).[5] In HFA we calculate *A* at *a* and *b* based on the well-known formula from statistical mechanics containing atomic masses, geometrical parameters, and harmonic frequencies. We subsequently calculate ΔA_{ab} as the simple difference $A_b - A_a$ without integration.

This article shows how these two seemingly different procedures (TI and HFA) for the determination of ΔA_{ab} are related, and under what condition they will afford the same free energy difference ΔA_{ab}. It is organized as follows: in Sects. 2,3, and 4 we determine the time average force on a constraint that is coupled to a number of harmonic degrees of freedom, and in Sect. 5 we determine the derivative of the free energy from the HFA.

2. Approximating the potential energy near a given conformation

An intrinsic reaction path (IRP) is the minimum energy path that lies along the potential energy surface of a given

chemical reaction.[6] The IRP is a set of conformations for a molecular system that represent the reaction path. The first conformation may be a reactant geometry, a middle conformation may be a transition-state geometry, and the the last conformation may be a product geometry.

The IRP will be represented by ξ. $\xi = a$ could represent a reactant conformation, while $\xi = b$ could represent a product conformation. Any value of ξ will produce a conformation $\vec{x}(\xi)$ of the molecular system. Performing a Taylor expansion of the potential energy surface[7] about a given conformation yields,

$$[1] \qquad V(\vec{x}) = \sum_{i=1}^{n}\left(\frac{\partial V}{\partial x_i}\right)_{\xi^*} x_i + \sum_{i,j=1}^{n}\frac{1}{2}\left(\frac{\partial^2 V}{\partial x_i \partial x_j}\right)_{\xi^*} x_i x_j + \sum_{i,j,k=1}^{n}\frac{1}{6}\left(\frac{\partial^3 V}{\partial x_i \partial x_j \partial x_k}\right)_{\xi^*} x_i x_j x_k$$

This is an approximation of the potential energy surface near a given conformation ξ* on the IRP. The coordinates (x_i) given are with respect to a particular conformation along the IRP, i.e., x_i implies $x_i - x_i(\xi^*)$. The reference energy for eq. [1] is zero. Therefore, $V_{\xi^*} = V(\vec{x}_{\xi^*}) = 0$. Next, the coordinates are converted into mass-weighted coordinates. This ensures that the gradient of the potential energy is parallel to the forces acting on the atoms. Equation [2] shows the conversion between standard coordinates and mass-weighted coordinates,

$$[2] \qquad \left(\frac{\partial V}{\partial x_i}\right)_{\xi^*} x_i = \left(\frac{\partial V}{\sqrt{m_i}\partial x_i}\right)_{\xi^*} \sqrt{m_i} x_i = \left(\frac{\partial V}{\partial x_i'}\right)_{\xi^*} x_i'$$

where x_i prime, x_i', indicates mass-weighted coordinates. Later, a third coordinate system will be introduced and labeled x_i double prime, x_i''. The potential energy function in mass-weighted coordinates is,

$$[3] \qquad V(\vec{x}') = \sum_{i=1}^{n}\left(\frac{\partial V}{\partial x_i'}\right)_{\xi^*} x_i' + \sum_{i,j=1}^{n}\frac{1}{2}\left(\frac{\partial^2 V}{\partial x_i' \partial x_j'}\right)_{\xi^*} x_i' x_j' + \sum_{i,j,k=1}^{n}\frac{1}{6}\left(\frac{\partial^3 V}{\partial x_i' \partial x_j' \partial x_k'}\right)_{\xi^*} x_i' x_j' x_k'$$

To simplify eq. [3], the coordinate system is rotated such that x_1 is parallel to the gradient of the potential energy. This makes coordinate one tangent to the IRP,

$$[4] \qquad V(\vec{x}') = \left(\frac{\partial V}{\partial x_1'}\right)_{\xi^*} x_1' + \sum_{i,j=1}^{n}\frac{1}{2}\left(\frac{\partial^2 V}{\partial x_i' \partial x_j'}\right)_{\xi^*} x_i' x_j' + \sum_{i,j,k=1}^{n}\frac{1}{6}\left(\frac{\partial^3 V}{\partial x_i' \partial x_j' \partial x_k'}\right)_{\xi^*} x_i' x_j' x_k'$$

3. The force along the IRP as a function of time

For mass-weighted coordinates, the force along the IRP is,

$$[5] \qquad F_1' = -\frac{\partial V}{\partial x_1'}$$

Inserting the Taylor-expanded potential (eq. [4]) into eq. [5] yields,

$$[6] \qquad F_1' = -\left(\frac{\partial V}{\partial x_1'}\right)_{\xi^*} - \sum_{i=1}^{n}\left(\frac{\partial^2 V}{\partial x_i' \partial x_1'}\right)_{\xi^*} x_i' - \sum_{i,j=1}^{n}\frac{1}{2}\left(\frac{\partial^3 V}{\partial x_1' \partial x_i' \partial x_j'}\right)_{\xi^*} x_i' x_j'$$

The goal is to determine how the force along coordinate one at $x_1 = 0$ is affected by the other coordinates of the molecular system. Setting $x_1 = 0$ yields,

$$[7] \qquad F_1'(x_1' = 0) = -\left(\frac{\partial V}{\partial x_1'}\right)_{\xi^*} - \sum_{i=2}^{n}\left(\frac{\partial^2 V}{\partial x_1' \partial x_i'}\right)_{\xi^*} x_i' - \sum_{i,j=2}^{n}\frac{1}{2}\left(\frac{\partial^3 V}{\partial x_1' \partial x_i' \partial x_j'}\right)_{\xi^*} x_i' x_j'$$

Coordinate one is parallel to the gradient of the potential energy surface. Therefore,

$$[8] \qquad \left(\frac{\partial V}{\partial x_{i\neq 1}'}\right)_{\xi^*} = 0$$

This means that the force to maintain $x'_1 = 0$ is linearly independent of the other coordinates, i.e., the second term in eq. [7] is zero,

$$[9] \qquad \sum_{i=2}^{n}\left(\frac{\partial^2 V}{\partial x'_1 \partial x'_i}\right)_{\xi^*} x'_i = 0$$

and the force to maintain the constraint $x'_1 = 0$ simplifies to,

$$[10] \qquad F'_1(x'_1 = 0) = -\left(\frac{\partial V}{\partial x'_1}\right)_{\xi^*} - \sum_{i,j=2}^{n}\frac{1}{2}\left(\frac{\partial^3 V}{\partial x'_1 \partial x'_i \partial x'_j}\right)_{\xi^*} x'_i x'_j$$

Equation [10] shows how the force to maintain the constraint $x'_1 = 0$ varies with respect to the other coordinates, namely x'_i and x'_j. Note that the second term on the right-hand side is the change in the energy Hessian $\partial^2 V/\partial x'_i \partial x'_j$ over the harmonic degrees of freedom perpendicular to the reaction coordinate. As the Hessian is related to the vibrational frequencies, the force in eq. [10] is related to the change in the frequencies along the reaction coordinate. In Sect. 5, this force will prove to be identical to the one obtained by differentiating the free energy expression from a Harmonic frequency analysis with respect to the reaction coordinate.

The equations of motion must now be constructed for the other degrees of freedom. To obtain these equations of motion, the force for each degree of freedom needs to be evaluated. The force along coordinate $i \neq 1$ is,

$$[11] \qquad F'_{i\neq 1}(x'_1 = 0) = -\frac{\partial V}{\partial x'_i} = -\sum_{j=2}^{n}\left(\frac{\partial^2 V}{\partial x'_i \partial x'_j}\right)_{\xi^*} x'_j - \sum_{j,k,=2}^{n}\frac{1}{2}\left(\frac{\partial^3 V}{\partial x'_i \partial x'_j \partial x'_k}\right)_{\xi^*} x'_j x'_k$$

The force along $x_{i\neq 1}$ is dominated by linear terms (see eq. [11], whereas the force along x_1 had the quadratic terms as the largest correction (see eq. [10]). The force along $x_{i\neq 1}$ can be simplified by ignoring the quadratic terms. Hence,

$$[12] \qquad F'_{i\neq 1}(x'_1 = 0) = -\sum_{j=2}^{n}\left(\frac{\partial^2 V}{\partial x'_i \partial x'_j}\right)_{\xi^*} x'_j$$

The equation that relates force and change in position is $F = ma$. In mass-weighted coordinates this equation is,

$$[13] \qquad F'_i = \frac{\partial^2 x'_i}{\partial^2 t}$$

Inserting eq. [12] into eq. [13] yields,

$$[14] \qquad \frac{\partial^2 x'_i}{\partial^2 t} = -\sum_{j=2}^{n}\left(\frac{\partial^2 V}{\partial x'_i \partial x'_j}\right)_{\xi^*} x'_j$$

or in matrix form,

$$[15] \qquad \frac{\partial^2}{\partial^2 t}\vec{x}' = -\mathbf{A}'\vec{x}'$$

where,

$$[16] \qquad A'_{ij} = \left(\frac{\partial^2 V}{\partial x'_i \partial x'_j}\right)_{\xi^*}$$

There exists a unitary matrix $\mathbf{U}$ that makes $\mathbf{A}'$ diagonal. Performing this unitary transformation gives,

$$[17] \qquad \frac{\partial^2}{\partial^2 t}\mathbf{U}\vec{x}' = -\mathbf{U}\mathbf{A}'\mathbf{U}^{\mathrm{T}}\mathbf{U}\vec{x}'$$
$$\frac{\partial^2}{\partial^2 t}\vec{x}'' = -\mathbf{A}''\vec{x}''$$

This decouples each vibrational degree of freedom from all other vibrational degrees of freedom. Now, differential equations can be applied to obtain the equations of motion for each individual degree of freedom,

$$[18] \qquad \frac{\partial^2}{\partial^2 t}x''_{i\neq 1}(t) = -A''_{ii}x''_i(t)$$
$$x''_{i\neq 1}(t) = a_i\cos\left(\sqrt{A''_{ii}}t\right) + b_i\sin\left(\sqrt{A''_{ii}}t\right)$$

Equation [18] is the equation of motion for coordinate i, and constants a_i and b_i are determined from the initial conditions. The initial position is chosen to be $x_i(0) = 0$, and the initial velocity is determined from the temperature of the system. Using this choice of initial conditions, the equation of motion becomes,

$$[19] \qquad x''_{i\neq 1}(t) = b_i(T)\sin\left(\sqrt{A''_{ii}}t\right)$$

Equation [19] must be inserted into eq. [10] to obtain the force along coordinate 1 as a function of time, but eq. [10] needs to be transformed into the double prime basis. Simplifying eq. [10] gives,

$$[20] \qquad F'_1 = -\left(\frac{\partial V}{\partial x'_1}\right)_{\xi^*} - \sum_{i,j=2}^{n}\frac{1}{2}\left(\frac{\partial^3 V}{\partial x'_1 \partial x'_i \partial x'_j}\right)_{\xi^*} x'_i x'_j$$
$$= -\left(\frac{\partial V}{\partial x'_1}\right)_{\xi^*} - \sum_{i,j=2}^{n}\frac{1}{2}\left(\frac{\partial}{\partial x'_1}A'_{ij}\right)x'_i x'_j$$
$$= -\left(\frac{\partial V}{\partial x'_1}\right)_{\xi^*} - \sum_{i,j=2}^{n}\frac{1}{2}B'_{ij}x'_i x'_j$$

To convert coordinates from the prime basis ($'$) to the double prime basis ($''$) and vice versa, the unitary transformation is used (eq. [17],

$$[21]\qquad \vec{x}'' = \mathbf{U}\vec{x}' \qquad \vec{x}' = \mathbf{U}^{\mathrm{T}}\vec{x}'' \qquad x_i' = \sum_{k=2}^{n} U_{ki} x_k''$$

Inserting eq. [21] into eq. [20] yields the force along coordinate one as a function of other degrees of freedom in the double prime basis,

$$[22]\qquad F_1' = -\left(\frac{\partial V}{\partial x_1'}\right)_{\xi^*} - \sum_{i,j=2}^{n}\sum_{k,l=2}^{n}\frac{1}{2}B_{ij}' U_{ki} x_k' U_{lj} x_1'$$

Inserting the explicit time dependence of each degree of freedom (eq. [19]) into the force equation of coordinate one (eq. [22]) gives,

$$[23]\qquad F_1'(t) = -\left(\frac{\partial V}{\partial x_1'}\right)_{\xi^*} - \sum_{i,j=2}^{n}\sum_{k,l=2}^{n}\frac{1}{2}B_{ij}' U_{ki} U_{lj} b_k(T)\sin\left(\sqrt{A_{kk}''}t\right) b_l(T)\sin\left(\sqrt{A_{ll}''}t\right)$$

Equation [23] is the force along the IRP (coordinate one) as a function of time.

4. Average force along the Intrinsic Reaction Path (IRP)

The time average for the force along the IRP is,

$$[24]\qquad \begin{aligned} F_{1-\mathrm{ave}}' &= \lim_{\tau\to\infty}\frac{1}{\tau}\int_0^{\tau} F_1'(t)\,dt \\ &= -\left(\frac{\partial V}{\partial x_1'}\right)_{\xi^*} - \sum_{i,j=2}^{n}\sum_{k,l=2}^{n}\frac{1}{4}B_{ij}' U_{ki} U_{lj} b_k(T) b_l(T)\delta_{kl} \\ &= -\left(\frac{\partial V}{\partial x_1'}\right)_{\xi^*} - \sum_{i,j,l=2}^{n}\frac{1}{4}B_{ij}' U_{li} U_{lj} b_l(T)^2 \end{aligned}$$

Next, the functional form of the $b_i(T)$ coefficients needs to be defined. The internal energy of each degree of freedom at a given temperature is,

$$[25]\qquad U_i(T) = k\theta_i\left(\frac{1}{2} + \frac{\exp\left(-\theta_i/T\right)}{1-\exp\left(-\theta_i/T\right)}\right)$$

Taking the high temperature limit, the internal energy is,

$$[26]\qquad U_i(T) = kT$$

At $t = 0$, the kinetic energy of the system is the internal energy because the potential energy of each degree of freedom is chosen to be zero at $t = 0$ ($x_i(t = 0) = 0$, so $V = 0$). The initial kinetic energy of all degrees of freedom in the double prime basis is,

$$[27]\qquad \mathrm{KE}_{\mathrm{tot}} = \frac{1}{2}\left(\left(\frac{\partial x_1''}{\partial t}\right)^2 + \left(\frac{\partial x_2''}{\partial t}\right)^2 + \ldots + \left(\frac{\partial x_n''}{\partial t}\right)^2\right)$$

Equating the initial kinetic energy of each mode (eq. [27]) with the internal energy for each mode (eq. [26]) yields,

$$[28]\qquad \frac{1}{2}\left(\frac{\partial x_i'' x_{i''}}{\partial t}\right)_{t=0}^2 = kT$$

Inserting eq. [19] into eq. [28] yields,

$$[29]\qquad \frac{1}{2}\left(\frac{\partial}{\partial t} b_i(T)\sin\left(\sqrt{A_{ii}''}t\right)\right)_{t=0}^2 = kT$$

Differentiating and solving for the b coefficients:

$$[30]\qquad \frac{1}{2}\left(b_i(T)\ \sqrt{A_{ii}''}\right)^2 = kT$$

$$[31] \qquad b_i(T) = \sqrt{\frac{2kT}{A''_{ii}}}$$

Inserting the amplitude of each vibrational degree of freedom (b coefficients in eq. [31]) into the expression for the average force along the IRP (eq. [24]) yields,

$$[32] \qquad F'_{1-\text{ave}} = -\left(\frac{\partial V}{\partial x'_1}\right)_{\xi^*} - \sum_{i,j,l=2}^{n} \frac{1}{4} B'_{ij} U_{li} U_{lj} b_l(T)^2$$
$$= -\left(\frac{\partial V}{\partial x'_1}\right)_{\xi^*} - \frac{kT}{2} \sum_{i,j,l=2}^{n} \left(\frac{\partial}{\partial x'_1} A'_{ij}\right) U_{li} (\mathbf{A}'')^{-1}_{ll} U_{lj}$$

The unitary matrix remains constant for small changes in x'_1. Simplifying eq. [32],

$$[33] \qquad F'_{1-\text{ave}} = -\left(\frac{\partial V}{\partial x'_1}\right)_{\xi^*} - \frac{kT}{2} \sum_{i,j,l=2}^{n} \left(\frac{\partial}{\partial x_{1'}} U_{li} A'_{ij} U_{lj}\right) (A''_{ll})^{-1}$$
$$= -\left(\frac{\partial V}{\partial x'_1}\right)_{\xi^*} - \frac{kT}{2} \sum_{i=2}^{n} \frac{1}{A''_{ii}} \left(\frac{\partial A''_{ii}}{\partial x'_1}\right)$$

Equation [33] is the average force along the IRP (coordinate 1) for a molecular dynamics simulation where all motion perpendicular to the IRP is harmonic.

5. Derivative of the free energy

It is also possible to calculate the Helmholtz free energy along the IRP. This involves calculating the partition function for all degrees of freedom perpendicular to the IRP, and then applying the following formula,

$$[34] \qquad A_{\xi^*} = -kT \ln\left(Q_{\xi^*}\right) + C$$

where C is a reference energy and Q_{ξ^*} is the partition function. Inserting the partition function for all the vibrational degrees of freedom orthogonal to the IRC gives,

$$[35] \qquad A_{\xi^*} = -kT \sum_{i=2}^{n} \ln\left(q_{i,\xi^*}\right) = -kT \sum_{i=2}^{n} \left(\frac{-\theta_{i,\xi^*}}{2T} - \ln\left(1 - \exp\left(\frac{-\theta_{i,\xi^*}}{T}\right)\right)\right) + C_{\xi^*}$$

where θ_i is the vibrational temperature, which is related to the vibrational frequency, for each vibrational mode. Taking the derivative of the free energy with respect to coordinate 1 (parallel to the IRP) yields,

$$[36] \qquad \left(\frac{\partial A}{\partial x'_1}\right)_{\xi^*} = kT \sum_{i=2}^{n} \left(\frac{1}{2T} \frac{\partial \theta_{i,\xi^*}}{\partial x'_1} + \frac{\exp\left(-\theta_{i,\xi^*}/T\right)}{1 - \exp\left(-\theta_{i,\xi^*}/T\right)} \frac{1}{T} \frac{\partial \theta_{i,\xi^*}}{\partial x'_1}\right) + \left(\frac{\partial C}{\partial x'_1}\right)_{\xi^*}$$
$$= k \sum_{i=2}^{n} \left(\frac{1}{2} + \frac{\exp\left(-\theta_{i,\xi^*}/T\right)}{1 - \exp\left(-\theta_{i,\xi^*}/T\right)}\right) \frac{\partial \theta_{i,\xi^*}}{\partial x'_1} + \left(\frac{\partial C}{\partial x'_1}\right)_{\xi^*}$$

Assuming that T (the temperature) is much greater than θ_i then,

$$[37] \qquad \left(\frac{1}{2} + \frac{\exp\left(-\theta_{i,\xi^*}/T\right)}{1 - \exp\left(-\theta_{i,\xi^*}/T\right)}\right) = \frac{T}{\theta_{i,\xi^*}}$$

where this high temperature simplification is identical to the high temperature simplification done for internal energy (eqs. [25] and [26]). Inserting eq. [37] into eq. [36] yields,

$$[38] \qquad \frac{\partial A}{\partial x'_1} = k \sum_{i=2}^{n} \frac{T}{\theta_{i,\xi^*}} \left(\frac{\partial \theta_i}{\partial x'_1}\right)_{\xi^*} + \left(\frac{\partial C}{\partial x'_1}\right)_{\xi^*}$$

In these derivations, all motion perpendicular to the IRP is harmonic, and the reference energy is at the bottom of the potential well. Therefore, the reference energy is the potential energy along the IRP,

$$[39] \qquad \left(\frac{\partial C}{\partial x'_1}\right)_{\xi^*} = \left(\frac{\partial V}{\partial x'_1}\right)_{\xi^*}$$

Inserting eq. [39] into eq. [38] yields,

$$[40] \qquad \frac{\partial A}{\partial x'_1} = \left(\frac{\partial V}{\partial x'_1}\right)_{\xi^*} + kT \sum_{i=2}^{n} \frac{1}{\theta_{i,\xi^*}} \left(\frac{\partial \theta_i}{\partial x'_1}\right)_{\xi^*}$$

The vibrational temperature of one vibrational degree of freedom is,

$$[41] \qquad \theta_i = \frac{h}{2\pi k} \sqrt{A''_{ii}}$$

The vibrational temperature shown in eq. [41] is identical to the vibrational temperature seen in statistical mechanics texts,[5] namely,

$$[42] \qquad \theta_i = \frac{h}{2\pi k_B}\sqrt{\frac{k}{\mu_i}}$$

One can see that A_{ii}'' is the force constant of a vibrational mode divided by the reduced mass of that vibrational mode. Inserting the vibrational temperature (eq. [41]) into eq. [40] yields,

$$[43] \qquad \frac{\partial A}{\partial x_1'} = \left(\frac{\partial V}{\partial x_1'}\right)_{\xi^*} + kT\sum_{i=2}^{n}\frac{1}{\sqrt{A_{ii}''}}\left(\frac{\partial\sqrt{A_{ii}''}}{\partial x_1'}\right) = \left(\frac{\partial V}{\partial x_1'}\right)_{\xi^*} + \frac{kT}{2}\sum_{i=2}^{n}\frac{1}{A_{ii}''}\left(\frac{\partial A_{ii}''}{\partial x_1'}\right)$$

Equation [43] is the derivative of the free energy along the IRP (coordinate 1), derived by calculating the partition function of harmonic motion perpendicular to the IRP.

6. Summary

The potential energy surface can be Taylor expanded for a particular point along the IRP, to third order along the IRP, and to second order for all other coordinates. The equations of motion, given suitable initial conditions, can be used to determine how the force along the IRP will vary with respect to time at a given temperature. Averaging the force for a long period of time will yield the average force along the IRP as a function of temperature (eq. [33]). This average force is the average force that is expected in a molecular dynamics simulation.

The derivative of the free energy along the IRP can be calculated by using the vibrational partition function (eq. [42]).

Examining eqs. [33] and [43], it is evident that the right-hand side of eq. [33] is the negative of the right-hand side of eq. [43],

$$[44] \qquad F_{1-\mathrm{ave}}' = -\frac{\partial A}{\partial x_1'}$$

Therefore, the average force along the IRP, calculated in a molecular dynamics simulation, is the negative of the derivative of the free energy. Integrating the average force from state *a* to state *b*, as done in TI, yields the free energy change between state *a* and state *b*. This free energy change is identical to the free energy change calculated using HFA.

This derivation reinforces the methodology behind thermodynamic integration. It is common, when verifying the results of thermodynamic integration, to compare the results with the corresponding frequency analysis.[1,8] As shown above, when motion perpendicular to the reaction path is harmonic, the free energy change calculated using thermodynamic integration proves to be identical to the free energy change calculated using frequency analysis.

Magnetic separable PSA@Fe_3O_4/Ag composites — Fabrication and catalytic properties

Cuifeng Jiang, Mingwei Chen, Shouhu Xuan, Wanquan Jiang, Xinglong Gong, and Zhong Zhang

Abstract: A novel PSA@Fe_3O_4/Ag composite, with high efficiency in the degradation of Rhodamine B, was synthesized through a simple wet-chemistry method. The results showed that the rate of the catalytic reaction was significantly concentration-dependent. Furthermore, there was no significant loss in the catalytic activity of the recycled catalysts, even after being recycled nine times (average 83%), from which one can deduce that almost all the nanosilver were regathered due to the super-paramagnetic Fe_3O_4 nanoparticles.

Key words: recyclable catalysts, magnetite, silver, rhodamine B.

Résumé : Faisant appel à une méthode simple de chimie humide, on a synthétisé un nouveau composite PDA@Fe_3O_4/Ag très efficace pour la dégradation de la Rhodamine B. Les résultats montrent que la vitesse de la réaction catalytique dépend fortement de la concentration. De plus, il n'y a pas de perte significative de l'activité des catalyseurs recyclés, même après neuf recyclages (moyenne de 83%); ces résultats permettent de déduire que pratiquement tout le nanoargent est récupéré en raison des nanoparticules de Fe_3O_4 superparamagnétiques.

Mots-clés : catalyseurs recyclables, magnétite, argent, rhodamine B.

[Traduit par la Rédaction]

Introduction

Recently, metal nanoparticles have become a hotspot in various fields,[1–3] not only because of their particular properties,[4,5] which are obviously different from their bulk materials, but also for their widespread applications in the practical world.[6] It has been extensively demonstrated that metal nanoparticles have high catalytic activities for NO reduction, CO oxidation, and degradation of organic dyes[7–9] because of their very large surface-to-volume ratio.

However, metal-nanoparticle catalysts have proved to be of somewhat limited use owing to the difficulties in separating the products and residual catalysts using traditional methods such as filtration or centrifugation.[10] The immobilization of metal-nanoparticle catalysts has therefore attracted a lot of attention. Among various support materials, magnetic-nanoparticle supports are now frequently used just because they allow the catalysts to be recovered conveniently through applying an external magnetic field.[11] Many efforts have been made to develop this kind of recyclable catalyst. For example, T.J. Yoon and co-workers considered magnetic nanoparticles as a catalyst vehicle for simple and easy recycling.[12] Unfortunately, since magnetic nanoparticles themselves have strong magnetic properties and could easily aggregate together, the preparation of magnetic recyclable catalysts with better dispersion is rather challenging.

Generally, to obtain better dispersion, the magnetic components are modified with layers of rigid materials (SiO_2, carbon, and so forth) and (or) functional organic agents (amines, oleate, and so forth) in advance.[4,11,13,14] PSA (poly(styrene-*o*-acrylic acid)), an important and versatile polymer, is the expected template for composites, especially for those needed to be modified. Though various modified metal nanoparticles catalysts have been obtained,[15–17] to the best of our knowledge no PSA-based recyclable metal catalysts have been reported so far. In this report, a novel magnetically recycled PSA@Fe_3O_4/Ag composite catalysts have been successfully synthesized by a simple wet-chemistry method. Consequently, the catalysts cannot only be recovered easily, but also be dispersed homogeneously without an excess amount of surface active agent.

Experimental

Reagents

Ferric chloride hexahydrate ($FeCl_3 \cdot 6H_2O$, AR), sodium sulfite anhydrous (Na_2SO_3, AR), sodium borohydride ($NaBH_4$), hexamethylene tetramine (AR), and rhodamine B (RhB, AR) were obtained from Sinopharm Chemical Reagent Co. Ltd. Silver nitrate ($AgNO_3$) and ammonium hydroxide ($NH_3 \cdot H_2O$, 25%–28%) were obtained from Lingfeng Chemical Reagent Co. Ltd. of Shanghai. All reagents were used as received without further purification.

Preparation of PSA@Fe_3O_4/Ag

Uniform PSA microspheres with an average diameter of 400 nm were synthesized by a method reported previously.[18] In a typical synthesis, PSA was dispersed in a blend solution with volume ratio of 2:1 ($v_{ethanol}/v_{water}$ = 2:1), and 50 mL of $FeCl_3 \cdot 6H_2O$ (0.006 mol/L), which has been purged with nitrogen for 20 min to remove all traces of oxygen, was added. After stirring for 20 min, Na_2SO_3 (0.001 mol/L) aqueous solution was gradually added under stirring, followed by a dropwise addition of $NH_3 \cdot H_2O$ to adjust the pH value to 8. The mixture was stirred for 3 h at 65 °C under nitrogen atmosphere and then placed in a magnetic field (B = 300 mT) for separation. After that, the PSA@Fe_3O_4 precipitate was obtained.

The magnetic catalysts were prepared as follows: First, 0.05 g of $AgNO_3$ was added to an ethanol solution containing 0.1 g of PVP and 0.05 g of PSA@Fe_3O_4 as described above, and the mixture solution was sonicated for dispersion. Then, 20 mL of ethanol solution containing 0.2 g of hexamethylene tetramine was gradually dropped into the above-mentioned mixture suspension under stirring, and the resulting solution was vigorously stirred for 1 h. Then, the reaction system was allowed to stand for 10 h under circumfluence at 85 °C. After being separated by magnetic field, the resulting samples were washed with water and ethanol, then dried at 50 °C under vacuum. Finally, the PSA@Fe_3O_4/Ag composites were obtained.

The catalytic properties of the obtained PSA@Fe_3O_4/Ag composites

A given amount of PSA@Fe_3O_4/Ag composite was well-dispersed in an aqueous solution containing RhB, and the volume of the mixture was adjusted to 30 mL with distilled water. After that, 10 mL of $NaBH_4$ solution were rapidly injected under stirring. The colour of the mixture gradually vanished, indicating the reduction of the dye. Changes in the concentration of RhB were monitored by examining the variations in maximal absorption in UV–vis spectra at 553 nm.

Catalyst-recycling experiments were examined to find the recycle efficiency. 1.5 mL of PSA@Fe_3O_4/Ag solution were used to catalyze RhB ([RhB] = 2×10^{-5} mol/L, [$NaBH_4$] = 1×10^{-2} mol/L). After the reaction was completed, the catalysts were separated by a magnetic field, then followed by another "repeat". The recycle catalytic efficiency was determined by measuring the absorption value of RhB at the end of the catalytic reaction.

Characterization

Transmission electron microscopy (TEM) photographs were taken on a Hitachi model H-800 transmission electron microscope at an accelerating voltage of 200 kV. X-ray powder diffraction (XRD) patterns of the products were obtained on a Japan Rigaku D/Max-γA rotation anode X-ray diffractometer equipped with graphite monochromatized Cu Kα radiation (λ = 0.154 178 nm). The magnetization curves

Results and discussion

The characterization of PSA@Fe_3O_4/Ag composites

As mentioned above, the PSA@Fe_3O_4/Ag composites were prepared by a simple and rapid method. The formation of the composites was confirmed by TEM as presented in Fig. 1, from which monodisperse composites can be seen. TEM analysis on both PSA@Fe_3O_4 and PSA@Fe_3O_4/Ag reveal that silver and magnetite nanoparticles decorated the PSA substrate with a diameter of 400 nm. It is evident that the darker dots represent the silver nanoparticls while the others are Fe_3O_4 nanoparticles. The absorption function is strong enough so that the silver nanoparticles remain attached to the PSA@Fe_3O_4 during the catalytic reaction, which was verified by the TEM images of the silver particles supported on PSA@Fe_3O_4 before and after catalytic reactions (Fig. 1*b* and 1*c*).

To study the stability of the composite catalysts, the sample was subjected to XRD. As shown in Fig. 2, all of the diffraction peaks match well with Ag crystal and Fe_3O_4 crystal.[19,20] As one can see, peaks of both Ag and Fe_3O_4 become a little weaker in Fig. 2*b* compared with Fig. 2*a*, which means that a portion of the crystal has been lost during the catalytic reaction. That is why in the recycle experiments, the composite catalysts deactivated more or less during the degradation reaction.

The magnetic properties of the composites have been elucidated in Fig. 3. The saturation magnetization of the composites is 11 emu/g at an external field of 10 kOe at room temperature. Obviously, it is much lower than the reported saturation magnetization of Fe_3O_4 (68.7 emu/g).[21] The emerging of this phenomenon is because of the existence of silver in very small size. On one hand, this feature allows catalysts separation under relatively low external magnetic field. On the other hand, the negligible coercivity indicates the superparamagnetic property of the sample, which is available for redispersion of the catalysts in solution without the occurrence of severe assembly or aggregation usually appearing in ferromagnetic nanoparticles.[22–25] That is why Fe_3O_4 rather than Fe serves as the magnetic support.

The inset of Fig. 3 illuminates the effective model of catalysts separation and redispersion under an external magnetic field. Before applying an external field, the catalysts were homogeneously dispersed to show their high catalytic activity.[26] After applying an external field, the intact catalysts were separated from the mixture suspension for reusage. Thus, the PSA@Fe_3O_4 composites are very appropriate

as catalyst supports for separation and redispersion[4] because of superparamagnetic Fe_3O_4 nanocrystals.

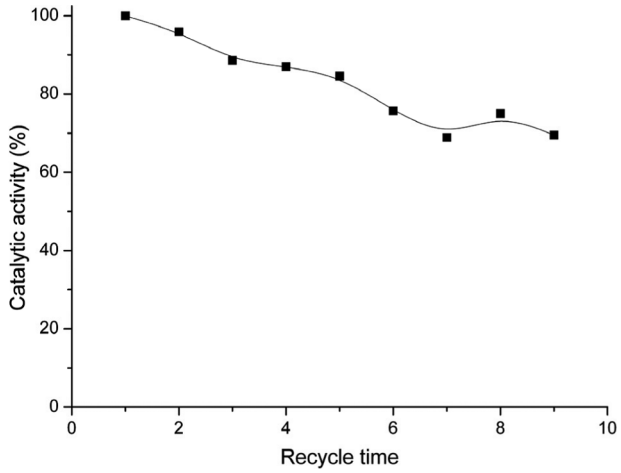
The catalytic properties of as-prepared PSA@Fe_3O_4/Ag catalysts

Previous results[6,27,28] demonstrated that silver nanoparticles exhibit catalysis on organic dyes, such as rhodamine B (RhB), methylene blue (MB), and eosin (EO). In this paper, catalysis experiments were conducted to study the catalytic properties of the nanosilver. Figure 4 shows the evolution of the UV–vis spectra of RhB during catalytic reductions at the PSA@Fe_3O_4/Ag solution. Evidently, the absorbance at λ_{max} = 553 nm of the RhB gradually decreased with reaction time, which is indicative of the reduction of RhB. As expected, the catalytic reduction of RhB proceeded successfully, and no deactivation or poisoning of the catalysts was observed. Changing of RhB's colour in the process of catalysis reaction (Fig. 5) further affirms the degradation. With time, the colour of RhB became lighter and lighter. As one can see, the pure RhB was carmine; after 20 min reaction, the solution became peachblow; and then at the end of the reaction (50 min), the colour almost disappeared. It was observed that the reduction of RhB by PSA or PSA@Fe_3O_4 did not occur to an appreciable extent in the absence of the Ag nanoparticles. This indicates that silver nanoparticles play the key role of the catalysts for the reduction of RhB, while PSA supports the catalyst, and Fe_3O_4 makes it possible to be reused. According to earlier work,[7] the catalytic process can be explained by an electrochemical mechanism, where PSA@Fe_3O_4/Ag serve as an electron relay for an oxidant and a reductant, and electron transfer occurs via the supported silver particles. Dyes are electrophilic, while BH_4^- ions are nucleophilic in nature with respect to silver nanoparicles.

Reactions with various concentrations of catalysts were examined to find the optimal conditions for the reaction. The rate of the catalytic reaction proved to be significantly concentration-dependent.

It is apparent that the rate of the catalyzed reduction of RhB increased with the increase of the concentration of the PSA@Fe_3O_4/Ag as displayed in Table 1. It is obviously observed that after 30 min reaction, the degradation of RhB for three volumes of PSA@Fe_3O_4/Ag solution (1 mL, 1.4 mL, and 2 mL) was 60%, 83%, and almost 100%, respectively. Therefore, to improve catalytic efficiency, increasing the mass of catalysts is effective.

Fig. 6. Recycle experiments of the degradation reaction of RhB catalyzed by PSA@Fe_3O_4/Ag.



Recycleability of the catalysts was examined to evaluate the role of PSA@Fe_3O_4. The hybrid composite catalysts, doped with magnetic particles, can be isolated by a magnetic device and reused for consecutive reactions. When the external magnetic field was applied after the reaction was accomplished, the magnetic composites were regathered (B = 300 mT), and the rest of the solution became clean within 5 min. Under these reaction conditions, the degradation of RhB was carried out nine times with the recycled catalysts. As shown in Fig. 6, there was no significant change in the catalytic activity of the recycled magnetic composite even after being recycled nine times (average 83%). Consequently, the small decrease of the catalytic activity can result from incomplete separation of catalysts or the loss of catalysts during the degradation reduction. All these results showed that the PSA@Fe_3O_4 substrate played an important role in the catalytic process. One is to avoid the aggregation

of the metal nanoparticles during the catalytic process, which ensures the catalyzed reduction of RhB.[6] The other is to facilitate separation of catalysts from the solution system. This fascinating property of magnetic catalysts is expected to be applied in many other important industrial processes.

Conclusion

With the assistance of PSA, a novel magnetically recyclable Ag-based catalyst was synthesized. Results showed the obtained magnetic catalysts exhibited good catalytic activity and could be recycled for several times by magnetic separation without major loss of activity. The significance of PSA@Fe_3O_4 lies in avoiding the aggregation of the silver nanoparticles during the catalytic process and offering an easy separation approach after catalysis. Furthermore, the overall synthetic process for the composites is simple and rapid, and it is anticipated that this synthetic approach may be readily extended to recyclable catalysts that contain catalytically active metals instead of Ag.

Scaled quantum mechanical force fields for trifluoromethyl selenium derivatives. II. The $(CF_3)_2Se$ and $(CF_3Se)_2$ molecules.

L.E. Fernández and E.L. Varetti

Abstract: Force fields and vibrational properties of bis(trifluoromethyl)selenide, $(CF_3)_2Se$, and bis(trifluoromethyl)diselenide, $(CF_3Se)_2$, were calculated using density functional theory (DFT) techniques. The previously available experimental data and assignments for these molecules were confirmed by the theoretical results. These data were subsequently used in the definition of the corresponding scaled quantum mechanical (SQM) force fields. The obtained internal force constants are compared with results previously published for related selenium compounds.

Key words: trifluoromethyl selenium, force constants, structure, DFT calculation.

Résumé : Faisant appel à des calculs à base de la théorie de la fonctionnelle de la densité (TFD), on a calculé les propriétés de champs de force et vibrationnelles du bis(trifluorométhyl)séléniure, $(CF_2)_2Se$, et du bis(trifluorométhyl)diséléniure, $(CF_2)_2Se_2$. Les résultats théoriques ont permis de confirmer les données expérimentales disponibles antérieurement ainsi que les attributions faites pour ces molécules. On a subséquemment utilisé ces données dans la définition des champs de forces correspondants en mécanique quantique . On a comparé les constantes de force internes ainsi obtenues avec les résultats publiés antérieurement pour des composés séléniés apparentés.

Mots-clés : trifluorométhylsélénium, constantes de force, structure, calculs selon la théorie fonctionnelle de la densité (TFD).

Introduction

Theoretical studies on the vibrational properties of the selenium compounds, CF_3SeX (X = H, D, Cl, or Br) and two simple CF_3Se derivatives, i.e., CF_3SeCN and CF_3SeCH_3, were recently performed in our laboratory.[1,2] Now, we turn our attention to the vibrational studies of other two selenium compounds, i.e., $(CF_3)_2Se$ and $(CF_3Se)_2$.

These molecules were prepared by Dale, Emeléus, and Haszeldine[3] and by Emeléus and Dunn.[4] The molecular structures were obtained by Marsden and Sheldrick by means of electron diffraction techniques.[5,6] The vibrational spectra and assignments were reported for these two molecules by Marsden[7] and Clase et al.[8]

In the present work, the vibrational characteristics of the above-mentioned molecules were calculated using the methods of quantum chemistry to check the published normal mode frequencies and their assignments and to obtain the corresponding force constants, which were scaled to reproduce the experimental frequencies. Such adjustment was made using the formalism of the scaled quantum mechanical (SQM) force field, as defined by Pulay et al.[9]

Calculation procedure

Optimized structures, force constants, and vibrational frequencies for the $(CF_3)_2Se$ and $(CF_3Se)_2$ molecules were obtained with density functional theory (DFT) methods using the B3LYP functional[10,11] together with the 6–311G* basis set. These theoretical data allowed a good reproduction of the experimental frequencies and facilitated the comparison of the results with those obtained in previous studies[1,2] in which the same combination of functional and basis set was used. All calculations were made for the isolated molecules using the Gaussian 03 set of programs.[12]

The harmonic force field in Cartesian coordinates given by the theoretical calculation was transformed to natural (local symmetry) coordinates[13] through the corresponding **B** matrix,[14] calculated with a standard program. The resulting force field was subsequently scaled using the scheme of Pulay et al.,[9] in which the diagonal force constants are multiplied by scale factors f_i, f_j, and so forth, and the corresponding interaction constants are multiplied by $(f_i \cdot f_j)^{1/2}$, adjusting the scaled factors by a least-squares procedure to reproduce as well as possible the experimental frequencies. No anharmonicity corrections of these frequencies were made because of the lack of the necessary experimental data. The potential-energy distribution (PED), which gives the participation of each defined coordinate to each

normal mode of vibration, was calculated with the resulting SQM force field.

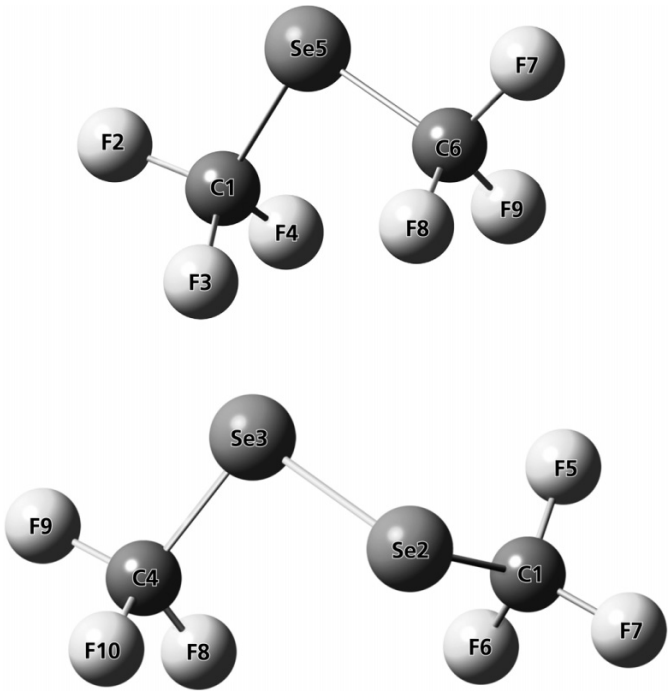
The force field transformation, scaling, and PED calculation were performed with the program FCARTP.[15]

Structural results

The molecular conformations of $(CF_3)_2Se$ were investigated starting with an initial, staggered structure having FCSeC dihedral angles of 180° (C_{2v} symmetry). The CF_3 groups were both rotated around the Se–C bonds in opposite directions, so that the C_2 symmetry was preserved. The twist angles were varied from 0° to 60°, in steps of 5°, and the structure was optimized with that dihedral angle frozen. These calculations showed that only a single conformer exists for this molecule for a twist angle of ~5°. This structure was fully optimized at the B3LYP/6-311G* level to obtain the real position of the minimum, which was located for a twist angle of 6° and FCSeC dihedral angles of 174°. The starting C_{2v} conformation turned out to be a transition state characterized by an imaginary frequency associated with the CF_3 torsion, as expected. However, the difference in energy between both conformations (0.067 kJ mol^{-1} at B3LYP/6–311G* level) is very small. The relative energies of the two forms are listed in Table 1 at various levels of theory; at all investigated approximations, the C_2 conformation was the most stable, always very close in energy to C_{2V}. These theoretical results do not agree completely with the electron diffraction data; in fact, Marsden and Sheldrick[5] found two possible structures in good agreement with the data having CF_3 twist angles of 4° and 33°, respectively.

A similar analysis was performed for the $(CF_3Se)_2$ molecule starting with an initial structure in which the CF_3 groups are in an exactly staggered position in relation to the Se–Se bond. This conformation has CSeSeC and FCSeSe dihedral angles of 91° and 180°, respectively. The CF_3 groups were rotated simultaneously in steps of 5°, preserving always the C_2 symmetry and the mentioned CSeSeC angle. A single minimum in the potential energy curve was found, corresponding to the conformation in which the twist angle was equal to 10° for both CF_3 groups. Subsequently, this structure was fully optimized to a dihedral angle of 9.2°. On the other hand, the potential energy curve was also explored varying the CSeSeC dihedral angle in steps of 5°. These calculations confirmed the existence of only one minimum in the potential energy surface for this molecule. The optimized molecular structure for $(CF_3Se)_2$ agrees with the electron diffraction study.[6]

Fig. 1. The calculated structures for the molecules $(CF_3)_2Se$ and $(CF_3Se)_2$.



The structures of the most stable conformations predicted for $(CF_3)_2Se$ and $(CF_3Se)_2$ molecules are shown in Fig. 1. The corresponding calculated geometric parameters and experimental values appear in Table 2. The (mean) calculated and experimental distances and angles do not differ in more than 0.045 Å (for the Se–Se distance) and 6.5° (for the CSeSeC dihedral angle), respectively. The theoretical tilt angles, existing between the C–Se bonds and the ideal symmetry axis of the CF_3 group, also appear in Table 2; this angle was calculated for the CF_3 groups as $1/3[2\alpha(F_{3,4}CSe)–2\alpha(F_2CSe)]$.[16]

Vibrational results

Marsden[7] and Clase et al.[8] have reported and assigned the vibrational spectra of the two molecules studied. Clase et al checked Marsden's assignments and performed some changes, particularly in the CF_3 stretching region. A revision of the published assignments for both molecules was made by comparison between the existing experimental data and our theoretical results. The computed atomic displacement vectors for each vibrational mode served to understand qualitatively the nature of the molecular vibrations and were used also for such revision. This analysis showed that the assignments proposed by Clase et al. were correct.

The bands observed in the IR spectra of $(CF_3)_2Se$ at 1142 and 1065 cm^{-1} correspond to the CF_3 symmetric stretching modes (ν_3 and ν_{14}, respectively), whereas the bands at 1152, 1193, and 1200 cm^{-1} are assigned to the CF_3 antisymmetric stretching modes (ν_{13}, ν_{12}, and ν_1, respectively). The calculated band at 1162 cm^{-1}, which seems to be too weak to appear in the experimental spectra, is attributed to the

[a]Mean of the calculated values.

CF_3 antisymmetric stretching mode (ν_2), unless it corresponds to the very weak band at 1178 cm^{-1} only reported by Clase et al.

Concerning the $(CF_3Se)_2$ molecule, the IR band at 1188 cm^{-1} corresponds to the CF_3 antisymmetric stretching modes (ν_1 and ν_2, respectively), whereas the band located at 1144 cm^{-1} seems to be spurious, since our theoretical calculations did not predict bands near that frequency.

The assignments adopted in this work for the $(CF_3)_2Se$ molecule are based on the C_2 symmetry, assuming local C_{3v} symmetry for the CF_3Se group. That agrees with Marsden's proposition and the present theoretical results, whereas Clase et al. assumed a C_{2v} symmetry for this molecule.

The normal vibrational modes of the studied molecules are classified as 11A + 10B for $(CF_3)_2Se$ and 13A + 11B for $(CF_3Se)_2$, respectively, in accordance with their C_2 symmetry.

There is a fair agreement between the simulated spectra and the experimental data[8] for both molecules. The calculated frequencies and IR and Raman intensities as well as the corresponding experimental values are shown in Tables 3 and 4. The agreement between measured and calculated frequencies was evaluated by means of the root-mean-square deviation (RMSD), which was equal to 12 cm^{-1} for $(CF_3)_2Se$ and 13 cm^{-1} for $(CF_3Se)_2$. After the force-field scaling procedure, these values fell to 5 and 7 cm^{-1}, respectively.

Force constants

The harmonic force fields in Cartesian coordinates, as generated by the Gaussian programs for the two molecules, were transformed to the set of coordinates defined in Tables 5 and 6. Such coordinates consider the local symmetry of the CF_3 groups and follow the proposals of Fogarasi et al.[13] The resulting force constants were subsequently scaled according to the methodology proposed by Pulay et al.,[9] as mentioned before (in the Calculation procedure Section), to reproduce as well as possible the experimental frequencies.

The final scaling factors, corresponding to each force constant for the studied molecules, appear in Table 7. It can be seen that most of these factors are greater than one; this is the case when heavy atoms (after the second row of the Periodic Table) appear in the molecule. This fact has been reported for many molecules containing nonmetallic heavy atoms[17] as well as for several CF_3SO_2X molecules[18] and CF_3SeX species.[1,2] The scaling factors previously obtained for common coordinates of other selenium compounds[1,2] were similar to those calculated for $(CF_3)_2Se$ and $(CF_3Se)_2$ molecules in this work. The resulting SQM force-constant matrices are available as Supplementary data for this work.

The internal force constants for the two molecules, appearing in Table 8, were also calculated from the corresponding SQM force fields. These force constants are compared with the values previously obtained for other selenium derivates using the same calculation procedure.[2]

The SQM force fields were used to calculate the potential energy distribution (PED) for each molecule. These values appear in Tables 3 and 4, and show that the coordinates corresponding to ν CF_3 symm., δ CF_3 symm., and ν C–Se are strongly mixed, as expected and observed also for other CF_3SeX molecules.[1,2]

Morphology of potassium chloride in aqueous and in formamide solution — An experimental and computational investigation

Ajeet Singh, T. Selvamani, Indrajit Mukhopadhyay, and Bishwajit Ganguly

Abstract: The morphology of potassium chloride grown in pure water as well as in water–formamide solution was investigated. Surface morphology of the crystals was examined by using scanning electron microscopy. It has been observed that the potassium chloride crystals are largely grown with {100} face at different concentrations in pure water, which contradicts earlier reports. Experimental results show that the potassium chloride crystals grown in formamide are also cubic in nature. However, it has been found that the sodium chloride crystals are octahedrons under similar conditions. The difference in the morphological behavior of these two alkali halides with formamide was investigated with computational methods. The calculated results revealed that formamide is largely preferred to adsorb on the {111} surface of NaCl, which can lead to octahedrons. However, the energetics is not substantially different for the adsorption of additives to the important surfaces of potassium chloride and results in the formation of a competing stable {100} surface.

Key words: density functional theory (DFT), crystal morphology, growth from solution, additive.

Résumé : On a étudié la morphologie du chlorure de potassium qui a cristallisé dans de l'eau pure ainsi que d'autre qui a cristallisé à partir d'une solution d'eau et de formamide. On a examiné la morphologie de la surface des cristaux à l'aide de la microscopie électronique à balayage. On a observé que les cristaux de chlorure de potassium croissent principalement avec la face {110} à diverses concentrations dans de l'eau pure et que cette observation est en contradiction avec des rapports antérieurs. Les résultats expérimentaux montrent que les cristaux de chlorure de potassium qui ont cru dans le formamide sont aussi de nature cubique. Toutefois, on a trouvé que, dans les mêmes conditions, les cristaux de chlorure de sodium sont octaédriques. On a étudié la différence de comportement morphologique de ces deux halogénures alcalins avec le formamide en faisant appel à des calculs théoriques. Les résultats calculés révèlent que le formamide s'adsorbe d'une façon préférentielle marquée sur la surface {111} du NaCl qui conduit à la formation d'octaèdres. Toutefois, les niveaux d'énergies impliqués ne sont pas très différents pour l'adsorption d'additifs sur les surfaces importantes du chlorure de potassium, ce qui conduit à la formation d'une surface {100} compétitive stable.

Mots-clés : théorie de la fonctionne de densité, morphologie cristalline, croissance à partir d'une solution, additif.

Introduction

The nucleation, growth, and morphology of crystals can be significantly altered by the presence of low concentrations of impurities. These impurities may be reaction by-products or impurities present in the reactants or they may be additives purposely added to alter the crystallization process. The effect of impurities and additives on crystallization are summarized in some recent reviews.[1,2] Additives can reduce crystal growth rate and alter morphology by binding to crystal faces and interfering with propagation steps.[3,4] The control of crystal morphology by use of additives is a subject of great interest, which has been studied experimentally and theoretically employing molecular modeling techniques.[5–7] The crystallization of common salt has been a subject of many studies of crystal growth in aqueous solution.[8,9] In particular, the influence of additives on its crystal habit has received considerable attention. Rome de 1'Isle[10] showed that octahedrons instead of normal cubes are formed, if rocksalt is grown in the presence of urine. Many authors have since reported the cube-octahedron shape transition under various experimental conditions. In this regard, earlier work reported that octahedron crystals can also be obtained from pure water solution.[11–13] It was observed that crystals with rocksalt structure were octahedrons, if they were grown at high supersaturation conditions. On the other hand, if they were grown at low supersaturation, cubic crystals were formed. Recently, Enckevort and co-workers[14] have shown that the {111} face of sodium chloride, which has the appearance of octahedrons at high

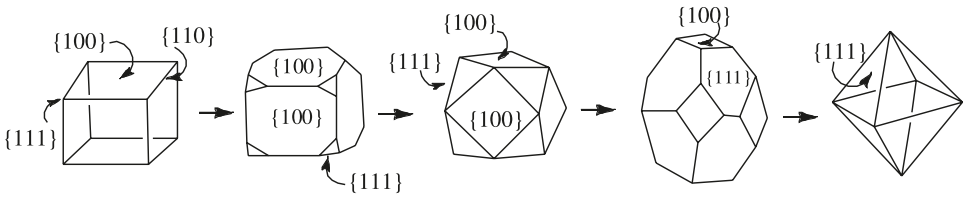
Scheme 1. Progressive change of an alkali halide crystal from cube to octahedron.



supersaturation, is most likely an artifact and in aqueous solutions only the {100} faces are stable. In the experiment of Bienfait et al.,[13] microcrystals of KCl grown from solutions of relatively low supersaturations were mainly cubic. However, when the supersaturation ratio defined by $\beta = c/c_o$ (where c and c_o are the actual and equilibrium solution concentrations, respectively) was greater than the critical supersaturation ratio, $\beta_c = 1.25$ at 293.15 K, microcrystals were cubo-octahedral, and with a further increase in c they were octahedral.[2,13] The conclusion of cubic crystals in supersaturated solutions for sodium chloride being contrary to earlier reports[11–14] prompted us to examine the results reported for the morphology of KCl crystals grown at different concentrations. We have extended the morphological study of KCl with impurity as well. The morphology of KCl crystals has been examined in formamide–water solutions. Earlier reports on the growth of NaCl crystals from water–formamide solutions showed that the crystals were octahedrons in nature.[14,15] Therefore, it is of interest to see whether the similar morphology of KCl crystals can be obtained in formamide–water solutions. Recently, there have been some efforts to crystallize KCl in carbon nanotubes.[16] A schematic diagram for the change in the shape of an alkali halide crystal from cubic to octahedron was shown in Scheme 1.

The observed changes in the morphology of NaCl crystals with additives were rationalized on the basis of charge distributions and strong interactions between the more exposed carbonyl oxygen of amides like formamide and urea with the sodium ions of the {111} surface of sodium chloride.[15] In earlier observations, Speidel[17], Cabrera and Vermilyea,[18] and Bunn[19] have also considered that an additive strongly interacts with certain crystal faces to influence the morphology of the crystal. Bunn[19] explained that the habit modification of NaCl by urea in aqueous solutions is due to adsorption of the impurity on certain crystal faces during crystal growth. Though there are many proposals reported to explain the habit of alkali halides, the studies towards the importance of interactions at the molecular level are limited. There are some efforts to understand the mechanism of growth kinetics and the bulk crystal habit with molecular modeling techniques in the light of additive-step specific interactions in calcite and calcium oxalate crystals.[20–22] The results emphasized the mechanism underlying crystal modification through organic molecules by considering both stereochemical recognition and the effects of binding on the interfacial energies of the growing crystal. These studies shed light on the possible interactions of additives with the surfaces of crystals and the reasons for the growth of specific faces. Therefore, it would be interesting to investigate the influence of formamide on shaping the crystals of sodium chloride and potassium chloride using computational techniques. We report the density functional study on the interaction of formamide with the relevant surfaces of sodium chloride and potassium chloride to understand the difference in the morphology of these two alkali halides in the presence of formamide as an impurity.

Experimental

Materials

The NaCl suprapur (99.99%) and KCl suprapur (99.99%) were obtained from Merck and formamide was obtained from Sigma-Aldrich Chemicals. All chemicals were used without any further purification. For crystallization, mili-Q water was used.

Methods

Batch crystallization

The test samples of KCl and NaCl crystals were obtained by crystallizing them from aqueous solution at different levels of supersaturations under controlled temperature (25 °C ± 2 °C), pressure (atmospheric), and relative humidity (50% ± 10%) conditions. The crystallizations were carried out in glass beakers of 20 mL capacity in the laboratory for facilitating free evaporation. The effect of pH on the crystallization process was studied by controlling the pH of the supersaturated solution during the initial phase of the crystallization process to two limiting values, 3 and 10, by using suitable acid/base. In this study, the supersaturation (β) has been defined as the ratio of the actual concentration to the equilibrium concentration of the halides, where, the equilibrium concentration of NaCl and KCl are 6.14 mol/L and 4.17 mol/L, respectively, at room temperature.[23] For batch crystallization, saturated alkali halide solutions of desired concentration were made using mili-Q water. Potassium chloride crystallizations were carried out with aqueous solution and formamide solution. Different batch crystallization were carried out: (*a*) In the first crystallization experiment, 5 mL of 4.2 mol/L KCl solution were taken in the glass beaker and kept for crystallization. (*b*) In the second batch, the concentration of KCl was increased to 5.5 mol/L (5 mL) and was taken in a glass beaker for crystallization. (*c*) In the third batch, the concentration of KCl was further increased up to 5.8 mol/L (5 mL) and was taken in a glass beaker for crystallization. In this third batch, the dissolution of solute was carried out by heating the mixture temporarily to an elevated temperature (~50 °C). Once the clear solution formed it was decanted to a glass beaker and 5 mL of the solution was taken in another glass beaker for crystallization.

To examine the influence of formamide on the morphology of KCl, separate sets of crystallization experiments were carried out at different concentrations: (*d*) In a beaker,

Table 1. Experimental details showing the effect of halide concentration, additive concentration, and pH on the crystallite size and morphology of alkali halides.

Serial No.	Conc. of the halides	Formamide conc. (wt%)	pH	Crystallite size (μm)	Remarks
a	4.2 mol/L KCl	—	7.0	1.7	Cubic
b	5.5 mol/L KCl	—	7.0	1.8	Cubic
c	5.8 mol/L KCl	—	7.0	1.8	Cubic
d	4.2 mol/L KCl	20	7.0	0.9	Cubic
e	5.5 mol/L KCl	20	7.0	0.7	Cubic
f	5.8 mol/L KCl	20	7.0	0.7	Cubic
g	6.14 mol/L NaCl	20	7.0	0.23	Octahedron

5 mL of 4.2 mol/L KCl solution was taken and 20 wt% (with respect to the net weight of the solute KCl) formamide solution was added. This impurity content KCl solution was kept for crystallization. (*e*) The crystallization of KCl at 5.5 mol/L with 20 wt% of formamide was also kept for crystallization. (*f*) The formamide impurity (20 wt%) was added to increase the concentration of the KCl (5.8 mol/L) and kept for crystallization. (*g*) Finally, for a comparative study, crystals were grown from a saturated 6.14 mol/L NaCl solution contaminated with 20 wt% formamide (with respect to the solute) under similar conditions.[14,15] The study was also performed with other concentrations of formamide, such as 5, 10, 15, 25, and 30 wt% (*w*/*w*) for the above mentioned (i.e., 4.2, 5.5, and 5.8 mol/L) concentrations of KCl (Fig. S3 in the Supplementary data). The representative formamide concentrations are shown for KCl and NaCl in Table 1.

Instrumentation

The surface structure of the grown crystals was observed by scanning electron microscopy (SEM). The samples for the SEM studies were prepared on cleaned and mirror-polished brass stubs by spreading 100 μL of the dispersion and evaporating the solvent in air. A LEO SEM model 1430 VP was used for this purpose. The crystallographic planes were further characterized by recording the X-ray powder diffraction (XRPD) pattern of finely grinded homogeneous alkali halides using Cu Kα radiation (λ = 1.540 56 Å). Optical microscopic images were taken by normal light microscopy (AXIO IMAGER, Carl Zeiss). The statistical distribution of the crystals was observed in the crystallization bath (10 mL volumetric glass beaker). Individual crystals were examined by putting them on glass slides.

Computational

The interaction study of formamide with three-dimensional (3D) slabs of sodium chloride and potassium chloride has been performed employing the density functional program DMol^3 in Material Studio (version 4.1) of Accelrys Inc.; the physical wave functions are expanded in terms of numerical basis sets.[24–26] We used DND double numerical basis set, which is comparable to the 6-31G* basis set. Local spin density approximation with Perdew–Wang correlational (LDA/PWC) and generalized gradient corrected functional (GGA/PW91) has been employed for the adsorption study of formamide on the {100}, {110}, and {111} surface of sodium chloride.[24–28] 3D-slabs of sodium chloride and potassium chloride [{100}, {110}, and {111}] were generated employing periodic boundary conditions. The Perdew–Wang correlational (LDA/PWC) functional with DND basis set was used to optimize the {100} NaCl slab structure. The optimized {100} slab contains seven layers of sodium chloride (112 ions) with a vaccum thickness of 12 Å. The corresponding k-points used were medium and the k-point separations were 0.051/Å. For {110} and {111}, the optimized slabs contain eight layers of sodium and chloride ions (128 ions) with a vaccum thickness of 18 and 14 Å, respectively. For KCl, the {100} slab was optimized with Perdew–Wang correlational (LDA/PWC) functional contains seven layers of KCl (112 ions) and a vaccum thickness of 12 Å, however, {110} and {111} contain eight and seven layers with a vaccum thickness of 12 Å, respectively. To estimate the relaxation effects on additive interaction energies, the top first and second layers of slabs were relaxed, while keeping the bottom layers fixed at a bulk position. The tolerances of energy, gradient, and displacement convergence were 2×10^{-5} Ha, 4×10^{-3} Ha/Å, and 5×10^{-3} Å, respectively. For additive and crystal surface interactions, formamide has been placed at the midpoint of the NaCl and KCl surface in each case and optimized at the LDA/PWC/DND level of theory. The maximum gradient for most of the optimized structures was less than 2×10^{-3} Ha/Å. Adsorption energies were computed by subtracting the energies of the gas and solvent phase additive molecules and surface from the energy of the adsorption system as shown in eq. [1].

$$[1] \qquad E_{ad} = E(\text{additive/surface}) - E(\text{additive}) - E(\text{surface})$$

To examine the effective interaction of formamide with specific surfaces of sodium and potassium chloride, the approach similar to surface docking developed to predict the influence of additives on the crystal morphology was employed.[29–37] The basis of this approach is to analyze the effect of additives on the individual crystal faces, which are cleaved from a crystal. If the additive has a strong interaction on a specific face, the growth of this face will be slower, as a result, the other fast growing surfaces will disappear and eventually, the slow growing surface will control the morphology. In this way, the additive influences the morphology of crystals. The stable {100} surfaces of sodium and potassium chloride were modeled with an alternating arrangement of cations and anions. However, the {111} polar surfaces have a very high divergent electrostatic energy, which makes them theoretically highly unstable.[38–40] In the {111} polar surface, the bulk structure consists of alternating cations and anionic sheets stacked along the <111> directions. It has been shown in earlier studies that the adsorption of additives would be preferred with the positive

ions on the top of the surface of alkali halides.[14,15] Therefore, in the present study, the polar {111} surface has been modeled with Na^+ and K^+ ions on the top of the surface. The {110} surface was modeled with alternating rows of cations and anions in each case. It is important to note that the morphological change in the alkali halide crystals generally takes place in the presence of a higher concentration of organic additives.[14,15] Davey and Mullin[41] have rationalized the theoretical implications of adsorption at sites in relation to experimental observations. A very low impurity level affected the kink site adsorption, whereas, more impurity is required to adsorb to the step sites, while a much higher level may be required if adsorption only occurs on a ledge or face site.[2]

Results and discussion

Experimental observations

In the experiment of Bienfait et al.[13] with crystallization of alkali halides from aqueous solutions it was observed that the geometrical forms of microcrystals depend on solution concentration. KCl crystals grown under supersaturated conditions were cubo-octahedrons or octahedrons. These experimental results were further corroborated by Polak and Sangwal[42] in their theoretical study. Experimental results on crystallization contradicts with their reports as KCl crystals grown from supersaturated solution of KCl at a concentration, c, of 4.2 mol/L in mili-Q water were cubic (Table 1). The scanning electron microscope image of the grown KCl crystals is shown in Fig. 1. This observation is similar to that reported by Bienfait et al.[13] in their study. At a concentration of $c > 5.3$ mol/L, it was reported that the KCl crystals grown in pure water were octahedrons.[13] To examine that, we have performed the experiments at concentration c = 5.5 mol/L in pure water (Table 1). The crystals' appearance under this condition were cubic in contrast to the octahedrons reported (Fig. 2*a*). Further, the KCl crystals grown at an even higher concentration, c = 5.8 mol/L, showed the formation of cubic crystals (Fig. 2*b* and Table 1) and we have not observed the island formation as reported by Bienfait et al.[13] at this concentration. However, the crystals were found to have a lot of defects, such as holes and steps on the surface.

To further confirm the predominant planes in the resulting crystals, we have examined these crystals by XRPD technique. The powder XRD pattern of the KCl crystals, grown from its aqueous solution (concentration of 5.5 mol/L) at room temperature is shown in Fig. 3. The pattern clearly indicates preferential growth of the {100} planes with normal FCC unit cell. The relative ratio of the intensity of {111} to {100} planes is found to be 0.1. We have also performed the growth of KCl crystals at different pH conditions. The concentration of KCl solution was kept at $c \sim 4.2$ mol/L. Under acidic and basic pH 3 and 10, adjusted before initiation of crystallization, KCl crystals were cubic with {100} planes (Fig. S1 in the Supplementary data). Our observation of KCl crystals grown from aqueous solution distinctively shows that, independent of saturation conditions, {100} faces are the only faces that appear. We did not observe the appearance of octahedral faces at the mentioned concentration in the literature. In an earlier report, the experiments carried out with sodium chloride in aqueous solution also showed that the solvent does not work as a habit modifier for NaCl.[15] The earlier claims of octahedral NaCl growth suffered the problem of cubes resting on the {111} face.[15] Such claims were based on the optical microscopic image of the crystals grown in aqueous solutions. These visual disparities were overcome by using SEM in the present study. The three-dimensional image generated with SEM clearly showed the morphology of NaCl and KCl crystals grown in pure water. Figure 4 represents the SEM image of KCl crystals grown in formamide–water solution. In this study, the concentration of KCl solution was varied from c = 4.2 mol/L to 5.8 mol/L. The KCl crystals at 4.2 mol/L grown in the presence of 20 wt% formamide were cubic in nature (Table 1). Some of the grown KCl crystals appeared to be hollowed and broken. The contours of the holes have steps descending from the sides of the cube (Fig. 4*b*).

Continuing the similar study with a KCl saturation composition of c = 5.5 and 5.8 mol/L, we have found the growth of cubic crystals from a bath contaminated with formamide solution (Table 1). The crystals predominantly exhibited the growth of {100} planes (Fig. 5). The variation in concentrations of formamide from 5 to 30 wt% (*w*/*w*) does not show any change in the habit of potassium chloride (Fig. S3 in the Supplementary data, Table 1). These results suggest that the habit remains unaffected, even unchanged, even in the presence of formamide–water solutions. For comparison, we have performed the similar experiment with sodium chloride crystals in formamide–water solutions. The NaCl crystals grown in the presence of 20 wt% (*w*/*w*) formamide solution

Fig. 1. Scanning electron microscopy (SEM) images of KCl crystals obtained from a 4.2 mol/L solution in pure water.

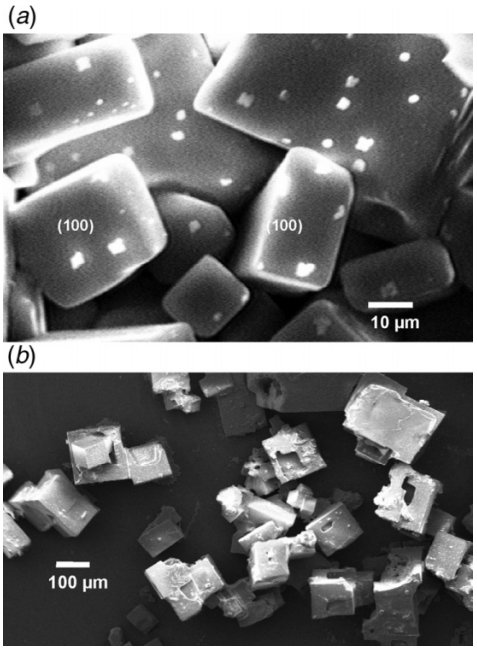

Fig. 3. X-ray powder diffraction (XRPD) pattern of homogeneously grinded KCl crystals obtained by crystallization from aqueous solution.

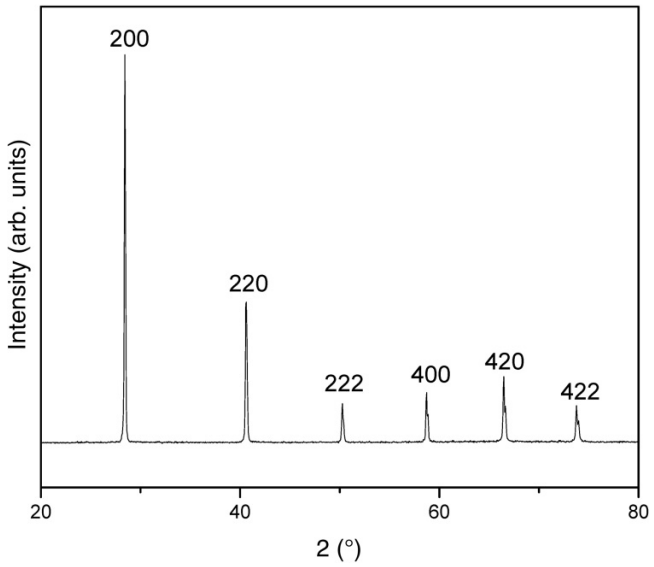

were octahedron in nature. The appearance of the {111} face is visible in the crystals of NaCl (Figs. 6*a* and 6*b*). This observation is in agreement with the earlier reports.[10,14,15]

We have further established the planes of the growing crystals for NaCl and KCl in the presence of formamide by XRPD. Figure 7 shows that both the crystals grown from a formamide contaminated solution at a concentration of 5.5 mol/L have FCC unit cell. However, the ratio of the intensity of the {111} to {100} planes for KCl grown from formamide solution is 0.05 where as the same ratio for NaCl is 0.1, which is enhanced nearly by an order of magnitude from the corresponding XRPD pattern of the NaCl

Fig. 4. Scanning electron microscopy (SEM) images of 4.2 mol/L KCl crystals grown in 20 wt% formamide–water solutions.

crystals obtained from NaCl aqueous solution. This clearly supports the SEM results that the presence of formamide in KCl aqueous solution does not facilitate the growth of unstable surfaces like {110} and {111} planes. These results showed that the influence of formamide was more pronounced in the solutions of sodium chloride towards the change in morphology. Therefore, it appears that the effective interaction of formamide with the {111} surface of

Fig. 6. Scanning electron microscopy (SEM) images of NaCl crystals obtained from 6.14 mol/L NaCl crystals grown in 20 wt% formamide–water solutions.

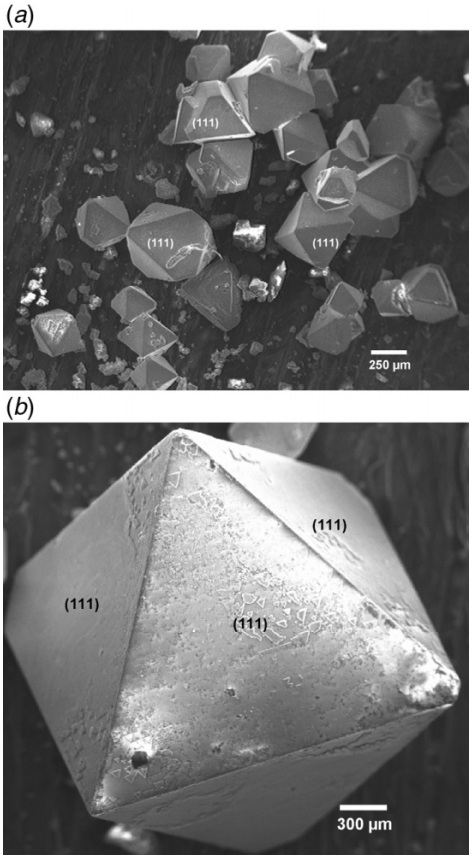

Fig. 7. X-ray powder diffraction (XRPD) patterns of the homogeneous halide crystals obtained by crystallization from (*a*) 20 wt% formamide contaminated 5.5 mol/L KCl solution and (*b*) 20 wt% formamide contaminated 6.14 mol/L NaCl solution. (*c*) 6.14 mol/L NaCl solution.

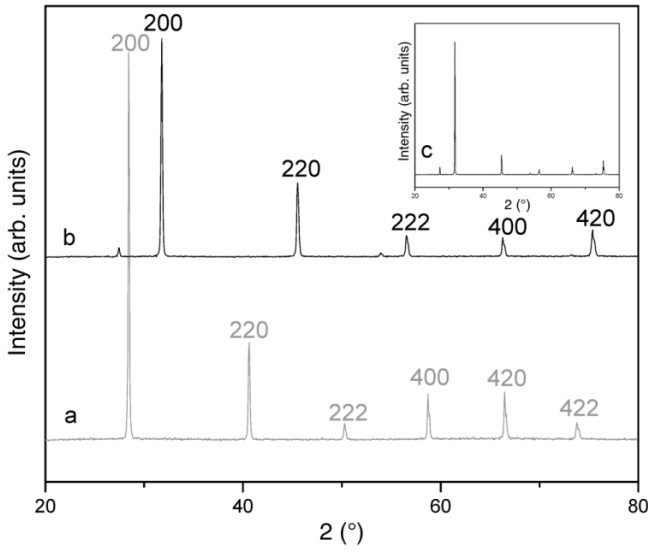

NaCl will be more dominant than that of the more stable {100} surface, as a result, the growth rate of the {111} surface will be slowed down, and this face will become relatively larger than the other faces.[2] Further, one can presume that the effect of an additive is not as pronounced for developing other planes [{110} and {111}] of KCl; as a result, no decisive influence can be seen for this alkali halide. Moreover, it can be noticed from Table 1 that the overall growth rate of the crystals decreases in the presence of formamide impurity.

Density functional theory (DFT) calculations

In the first set of calculations, formamide was fully optimized on the surfaces of sodium and potassium chloride keeping the surface ions fixed. In another set of calculations, the first and second layers of NaCl and KCl surfaces were relaxed, while optimizing formamide on the surfaces to examine the effect of relaxation on the binding energy of an additive at the respective surfaces.[30–36] In this case, the rest of the bottom layers were kept fixed in the bulk position. The interaction energies calculated for formamide with sodium and potassium chloride surfaces are shown in Table 2. The computed results suggest that the interaction of formamide is energetically preferred with the polar {111} surface by $\sim$13.0 kcal/mol than with the {100} surface of sodium chloride. The interaction of formamide with the {110} surface is weaker compared to the {111} surface of sodium chloride.

The amide functionality (-$CONH_2$) of formamide interacts with the {100} and {110} planes of sodium chloride (Figs. 8*a* and 8*b*), whereas, the carbonyl group of the additive interacts with the {111} surface of NaCl (Fig. 8*c*). Formamide fits in a similar fashion to the relaxed sodium chloride surfaces (Fig. S2 in the Supplementary data). The relaxation of layers does not seem to affect the trend of formamide interaction energies with NaCl surfaces (Table 2).

These results corroborate the earlier rationalizations[15,17] that the preferential adsorption of formamide on the {111} plane would reduce the growth of this plane of NaCl compared to the other {100} and {110} planes, consequently, octahedron crystals would form for sodium chloride. In the case of KCl, the interaction energies computed for formamide with a {100}, {110}, and {111} surface suggests that the {110} is slightly energetically preferred, $\sim$3.0 kcal/mol, over {100} and {111} surfaces (Table 2). Relaxation in the surfaces of KCl didn't show much perturbation in the layers and (or) in the geometry of the additive on the surface[30–37,43] (Fig. S2 in the Supplementary data). The amide functionality (-$CONH_2$) of formamide interacts with the {100} and {110} planes of potassium chloride (Figs. 8*d* and 8*e*), whereas, the carbonyl group of the additive interacts with the {111} surface of KCl (Fig. 8*f*). Other orientations of formamide with the {100} plane were also examined, which, however, were found to be higher in energy compared to the one shown in Fig. 8*a* (Table S1 in the Supplementary data). It is important to note that the mode of interaction of formamide with the {111} surface of NaCl and KCl is different (Fig. 8*c* and 8*f*). This presumably arises due to the difference in the distance of ions in the {111} lattice planes of NaCl and KCl. The distance between the neighboring potassium ions in the {111} plane is 4.426 Å, whereas, the corresponding distance for NaCl is 4.06 Å. Formamide maximizes the interaction while tilting on the {111} surface of KCl, whereas, the relatively smaller lattice distance does not allow

Table 2. Interaction energies calculated at the GGA/PW91/DND level using LDA/PWC/DND optimized geometries for formamide with {100}, {110}, and {111} surfaces of NaCl and KCl slab models in kcal/mol.

the additive to tilt on the {111} plane of NaCl. Attempts to achieve the interaction of formamide with the {111} surface of KCl similar to that of NaCl failed and converged to the orientation shown in Fig. 8*f*. The slight preference of formamide towards the {110} face of KCl was not observed in our experiments as the obtained KCl crystals were cubic. It appears that the small interaction energy difference between the planes of KCl with formamide is not sufficient to inhibit growing unstable faces and the competing stable {100} surface appears in the formamide solution.

It has been reported that the habit of alkali halides changes in an aqueous solution with impurities like formamide, hence the competing interaction of formamide with water molecules on these surfaces[44–49] can be important to govern the morphology, besides the effective interaction with additives. It is important to note that the water as a solvent does not influence the habit of alkali halides.[15] Therefore, it can be envisaged that if formamide interaction is stronger compared to water molecules with the unstable growing surfaces, such as {111} of these halides, then such interactions can retard the growth of that particular plane and hence can influence the habit.

We have investigated the competition between the water molecule and formamide by comparing the interaction energies with surfaces of NaCl and KCl. The interaction of a water molecule with different surfaces of NaCl and KCl is shown in Table 3. By comparing the interaction energies for water and formamide with NaCl surfaces, it appears that formamide binds more strongly to the {100}, {110}, and {111} surfaces than the water molecule (Tables 2 and 3). In particular, the interaction of formamide is significantly larger for the {111} NaCl surface compared to that of a water mole-

cule and suggests that the formation of octahedron crystals can take place for NaCl in formamide solution.[15] However, the energetic preferences were found to be comparable for formamide and water with KCl surfaces (Tables 2 and 3). Formamide may not be able to stabilize the {111} surface of KCl sufficiently, and hence, cannot lead to the change in morphology of this alkali halide.

Conclusion

A systematic study of the growth of potassium chloride crystals from pure water and formamide contaminated water at different concentrations and pH conditions was studied. Potassium chloride at c = 4.2 mol/L, only cubic crystals were found to grow from pure water as well as a 20 wt% formamide contaminated solution. At a concentration of $c >$ 5.3 mol/L of KCl (5.5 mol/L) in pure water, we have observed the growth of {100} planes in contrary to earlier reports. At an even higher concentration (5.8 mol/L), the cubic crystals were found with defects, holes and steps on the {100} planes. The effects of the pH of the crystallizing bath on the morphology of KCl crystals are not significant. The calculated results predicted the preferential interaction of formamide with {111} by ~13.0 kcal/mol compared to the stable {100} surface of sodium chloride and is in agreement with the formation of octahedron crystals. However, the interaction energies calculated for formamide with potassium chloride {110} and {111} surfaces are not substantially lower (~1–3 kcal/mol) compared to {100} to stabilize those unstable planes and that was reflected in the crystallization experiments. Further, the competing effect with water on the surfaces of these alkali halides suggest that formamide can displace the water molecules from the surface NaCl, however, this may not be possible with KCl surfaces.

Synthesis and binding characteristics of novel calix[4]arene(amidocrown) diquinones

Har Mohindra Chawla, Satya Narayan Sahu, and Rahul Shrivastava

Abstract: A series of new calix[4]arene(amidocrown) diquinones (**3a**–**3d**) have been synthesized, characterized, and evaluated for cation recognition. It has been observed that **3b** interacts with alkali metal ions (Li^+, Na^+, and K^+) and ammonium ions to induce an unprecedented downfield shift in the NH proton resonance, which can be attributed to polarization of the amidocrown ring of the calix[4]arene diquinone receptor. The observation has been confirmed by a significant anodic shift ($Li^+ > NH_4^+ > Na^+ > K^+$) of the corresponding amidocrown-diquinone redox couple in cyclic and square wave voltammetric experiments. Both NMR and electrochemical studies of the binding characteristics of **3b** with alkali metal cations and ammonium ions revealed a 1:1 binding stoichiometry for all and exhibited the highest association constant for lithium ions. This indicated that the receptor **3b** selectively binds the lithium ion in preference to other alkali metal cations and ammonium ions.

Key words: calix[4]arene diquinones, amidocrowns, cation-induced polarization.

Résumé : Une série de nouvelles calix[4]arène(amidocouronne)diquinones (**3a**–**3d**) a été synthétisée, caractérisée et évaluée pour la reconnaissance des cations. On a observé que le composé **3b** interagit avec les métaux alcalins (Li^+, Na^+ et K^+) et les ions ammonium et induit un déplacement chimique sans précédent vers les bas champs dans la résonance du proton NH qui est attribué à une polarisation du noyau amidocouronne du récepteur calix[4]arènediquinone. L'observation a été confirmée par un déplacement anodique significatif ($Li^+ > NH_4 > Na^+ > K^+$) du couple redox correspondant amidocouronnediquinone dans des expériences de voltampérométrie cycle et à onde carrée. Tant les études de RMN que celles d'électrochimie relatives aux caractéristiques de fixation du composé **3b** avec les cations alcalins et les ions ammonium ont mis en évidence dans tous les cas une stoechiométrie de fixation 1:1 alors que la constante d'association avec le lithium est la plus élevée, ce qui indiquerait que le récepteur **3b** fixe sélectivement le lithium de préférence aux autres cations métalliques alcalins et des ions ammonium.

Mots-clés : calix[4]arènediquinones, amidocouronnes, polarisation induite par les cations.

[Traduit par la Rédaction]

Introduction

Macrocyclic compounds have been widely used as molecular receptors for recognition of ionic and molecular species of biological and environmental importance.[1] In this context, calix[*n*]arene molecular architecture with distinct hydrophobic upper and hydrophilic lower rims has emerged strongly as a building block for obtaining plausible receptors.[2,3] Amongst various functionalized calix[*n*]arenes, the calix[*n*]arene quinones have also been viewed as molecules of considerable inherent potential to develop into electrochemical sensor materials, devices, and models for charge transfer in biological systems.[4] The synthesis and electrochemical behaviour of various calix[4]arene quinones possessing diverse functionalities have been published by many workers.[5–8] Consequently, we envisaged that calix[4]arene(amidocrown) diquinones possessing amidocrown and quinone units in a single molecular framework would possibly offer additional multiple binding options through soft nitrogen and oxygen donors in the pre-organised calixarene cavity (Fig. 1).

Such abiotic receptors would hopefully shed light on the nature of the interaction of cyclic amidocrown calixquinones with different metal ions. The additional amide functionalities in such receptors would be expected to be flexible enough to define a pseudocavity through convergent orientation of >C=O and -NH binding sites for interaction and recognition of guest species through hydrogen bond and electrostatic forces.[9,10] Accordingly, we have synthesized a series of calix[4]arene(amidocrown) diquinones (**3a**–**3d**) with a variable ring size from calix[4]arene derivatives (**2a**–**2d**)[11] through chlorine dioxide oxidation and have examined their interaction with alkali metal and ammonium ions by ^{1}H NMR and electrochemical measurements. It has been observed that calix[4]arene(amidocrown) diquinones on interaction with alkali metal and ammonium ions exhibit a downfield shift in the NH proton resonance, which has not been reported earlier in calixquinone systems.[12] This NH downfield shift is possibly due to cation induced NH polarization within the amidocrown ring, which has been confirmed by cyclic and square wave voltammetric experiments.

Results and discussion

Synthesis and characterization of products

25,27-Di(ethoxycarbonylmethoxy)-26,28-dihydroxy-calix[4]arene (**1**) was obtained from the reaction of calix[4]arene with ethyl bromoacetate in the presence of K_2CO_3/acetonitrile for 15 h.[13] It could be envisaged that **3a–3d** could be synthesized either by conversion of **1** to amidocrown calix[4]arenes followed by oxidation or oxidation of **1** followed by aminolysis to give the target compounds. When **1** was treated with different diamines in a mixture of toluene and methanol for 24–48 h, as reported by Bitter et al.,[11a] it gave **2a–2b** and **2d**. Preparation of **2c** was done by the method recently reported by us.[11b] When **2a–2d** were subjected to oxidation with chlorine dioxide (ClO_2) in the presence of phosphate-buffer in acetone, they gave calix[4]arene(amidocrown) diquinones (**3a–3d**) as yellow powders (Scheme 1). Application of the mentioned alternative strategy involving the oxidation of 25,27-di(ethoxycarbonylmethoxy)-26,28-dihydroxy-calix[4]arene (**1**) followed by aminolysis, resulted in a mixture of products that resisted facile separation to provide useful yields of amidocrown diquinones (**3a–3d**).

The structures of **3a–3d** were established by analysis of their ^{1}H NMR, ^{13}C NMR, and FT-IR spectra. For instance, the molecular structure of **3b** could be confirmed by the analysis of its ^{1}H NMR spectrum (in $CDCl_3$), which revealed a prominent D_2O exchangeable singlet at δ 8.74 for amidic protons while a broad signal for aromatic protons and a singlet for quinonoid protons appeared at δ 6.92 and 6.64, respectively. The ArOCH_2- protons appeared at δ 4.27, while a pair of doublets at δ 3.98 and 3.17 could be assigned to the Ar-CH_2-Q protons. The -NHCH_2 and -NHCH_2CH_2- protons appeared as broad singlets at δ 3.50 and 2.09, respectively.

The presence of a pair of AB-type doublets for Ar-CH_2-Q protons in the ^{1}H NMR spectrum of **3b** suggested that the molecule possessed a symmetrical cone conformation in its solution state, which was further confirmed by the appearance of a distinct signal at δ 30.7 for the methylene carbons in the ^{13}C NMR spectrum.[14] Similarly, other derivatives of the series (**3a**, **3c**, and **3d**) could be characterized by their ^{1}H NMR and ^{13}C NMR spectra. A sharp peak for **3a–3d** was shown at around 1656–1659 cm^{-1} in their FT-IR spectra that indicated the presence of quinonoid groups (Table 1).

Recognition characteristics of calix[4]arene(amidocrown) diquinones (3a–3d) for alkali metal and ammonium cations

NMR studies

The proton NMR spectrum of **3a–3d**, when recorded in three different deuterated solvents (e.g., $CDCl_3$, CD_3CN, and acetone-d_6), exhibited different chemical shifts for the amidic NH proton resonance as depicted in Table 2. This difference in chemical shift of the NH proton is possibly due to a different solvation of NH fragments in aprotic solvents. The VT NMR experiments on **3b** revealed an upfield shift of NH resonance at higher temperatures and the shifts were found to be larger in $CDCl_3$ than in CD_3CN.

These observations indicated that the amido groups of **3b** favour the formation of stronger intramolecular hydrogen bonds in $CDCl_3$[15] than in CD_3CN indicating that CD_3CN should be the preferred solvent for studying the recognition of ions by **3b**. Accordingly, the binding of alkali (Li^+, Na^+, and K^+) perchlorates and ammonium hexafluorophosphate with receptor **3b** were examined in deuterated acetonitrile. It was observed that the addition of alkali metal and ammonium ions to a 10 mmol/L solution of receptor **3b** exhibited a significant downfield shift of NH resonance at δ 8.33 in the proton NMR spectrum. That this downfield shift was due to the cations and not due to counter anions (perchlorate or hexafluorophosphate) was unequivocally confirmed by examining the effect of the addition of tetrabutylammonium perchlorate (TBA.ClO_4) and tetrabutylammonium hexafluorophosphate (TBA.PF_6) to **3b** (in CD_3CN) when no downfield shift in the NH proton resonance was observed. The observed cation-induced downfield shift of NH resonance was found to be more significant in the case of **3b** in comparison to the other receptors (Table 3).

The effect of the addition of Li^+, Na^+, K^+, and NH_4^+cations to **3b** gave different downfield shifts for the NH proton resonance as shown in Fig. 2. For instance, the Li^+ ion exhibited the maximum downfield shift followed by sodium and ammonium ions. The addition of potassium ions exhibited the lowest downfield shift in the NH proton resonance (Table 3).

It was also observed that gradual addition of lithium cation to **3b** (in CD_3CN) exhibited a regular increase in the chemi-

NH_4	—	0.25	—
K	—	0.12	—

cal shift of NH protons till it finally attained a saturation point at 1 equiv. of Li^+ addition revealing a 1:1 binding stoichiometry for the **3b**-Li^+ complex (Fig. 3*a*). A Job's plot experiment of **3b** with Li^+ ions further confirmed the 1:1 binding stoichiometry with maximum complexation at 0.5 mol fraction of cation as shown in Fig. 3*c*. Similarly, gradual addition of Na^+, K^+, and NH_4^+ ions to **3b** also led to a change in the chemical shift of NH proton resonance, indicating a 1:1 binding stoichiometry for all the cations studied. Analysis of the saturation data of **3b**:cation interactions with a nonlinear regression curve-fitting programme WinEQNMR[16] further confirmed the 1:1 binding stoichiometry with an association constant of $2.7(\pm0.6) \times 10^3$ $(mol/L)^{-1}$ and $1.9(\pm0.7) \times 10^3$ $(mol/L)^{-1}$, respectively, for lithium and ammonium ions (Figs. 3*a* and 3*b*). This observation indicated that the receptor **3b** shows high selectivity to the lithium ion in preference to other alkali metal cations. The findings revealed a higher binding constant for lithium cation in comparison to the case of previously reported crown ether and calix[4]arene systems.[8c,17]

The addition of lithium ion to **3b** also led to a change in the chemical shift of aromatic, quinone, and methylene bridged protons of the calix[4]arene unit (Fig. 4).

The downfield shifts observed for quinone (ArH_Q) and ester methylene (-O-CH_2-CO) protons on addition of Li^+ to **3b** suggested that the cation was possibly bound by the calix[4]arene cavity utilizing the lower rim oxygen atoms and amido carbonyl groups. This was further confirmed by the ^{13}C NMR signals of **3b**, which exhibited a downfield

Fig. 2. The partial ^{1}H NMR spectra of **3b** in the presence of various cations in CD_3CN at 298 K and 300 MHz. (*a*) **3b**, (*b*) **3b** + K^+, (*c*) **3b** + Na^+, (*d*) **3b** + NH_4^+, (*e*) **3b** + Li^+.

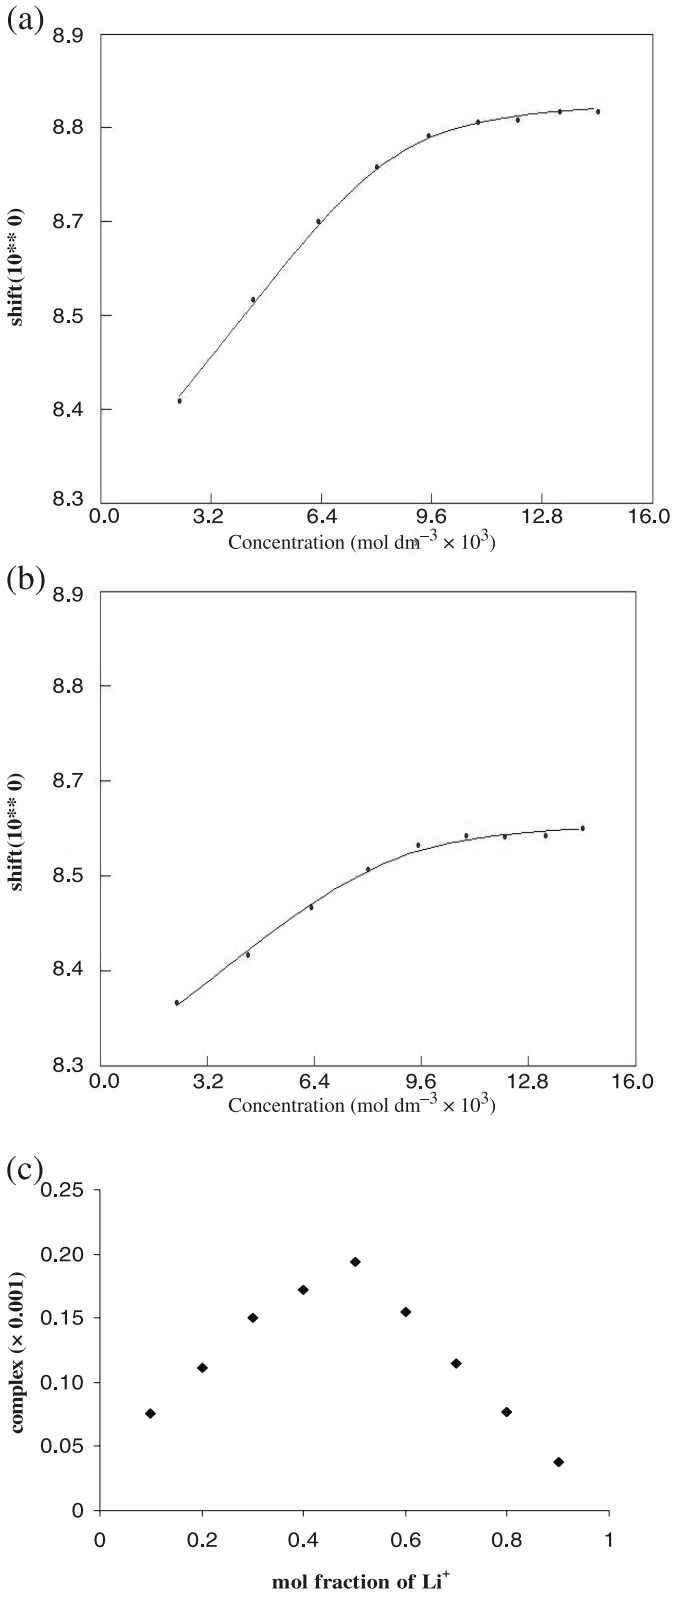
shift (Δδ ≈ 2 ppm) for the amido and quinone carbonyl carbons in the presence of lithium cation.

The observed downfield shift of NH proton resonance in **3b** on interaction with lithium ion is interesting as earlier groups[18] have proposed an upfield shift in NH signals of noncyclic amido-calix[4]arenes when complexed with alkali cations. The observed downfield shift in the NH resonance could possibly be ascribed to the cation induced polarization of the amido carbonyl group, which decreases the electron density over the nitrogen atom to deshield the NH proton (Scheme 2) when it is present in a cyclic amidocrown ring.

A study on the influence of different cations indicated an increase in the chemical shift of the NH signal in the expected order of $K^+ < NH_4^+ \approx Na^+ < Li^+$ (Fig. 2 and Table 3). This could be ascribed to the increased electron-withdrawing character of amido carbonyl groups upon cation complexation, which seemed to follow the order of charge density of cations. However, the greater downfield shift exhibited by am-

Fig. 3. The titration isotherm for the NH proton within **3b** upon addition of (*a*) Li^+ and (*b*) NH_4^+ ions. (*c*) Job's plot for the titration of 0.01 mol/L $LiClO_4$ with 10^{-2} mol/L solution of receptor **3b** in CD_3CN.



monium ions on interaction with **3b** over potassium ion could possibly be ascribed to extra stabilization of ammonium cation through hydrogen bond interactions with the amido carbonyl groups of the receptor molecule in consonance with literature precedents.[19] This was further corroborated from the association constant observed for **3b** with ammonium ions.

Electrochemical studies

The electrochemical behavior of **3a–3d** was investigated by cyclic voltammetry and square wave voltammetry with a glassy carbon electrode using 0.1 mol/L tetrabutylammonium hexafluorophosphate ($TBAPF_6$) in acetonitrile solution. A solution of 1 mmol/L concentration of **3b,** when examined voltammetrically, gave three redox waves in the potential range of 0 to –2.0 V (Fig. 5*a*), which could be attributed to different reduction processes in quinone units as reported in previous electrochemical studies on calix[4]arene diquinones.[6c]

The two cathodic waves observed at –969 mV and –1188 mV (Fig. 5*a*) could be described as 1/1′ and 2/2′, respectively, for two one-electron reduction processes for each quinone unit, while the third more negative wave 3 at –1594 mV could be ascribed to the two-electron irreversible reduction process.[20] Likewise, **3a**, **3c**, and **3d** exhibited three redox waves in their voltammograms for couples 1/1′, 2/2′, and wave 3 in the presence of 0.1 mol/L $TBAPF_6$ in acetonitrile (Table 4).

When examined by cyclic and square wave voltammetry in the presence of 0.1 mol/L $TBAPF_6$ as the supporting electrolyte, **3b** exhibited a decrease in peak intensity of the cathodic waves 1/1′, 2/2′, and 3 on gradual addition of lithium ions to its electrochemical solution (10^{-3} mol/L in acetonitrile). A new set of redox waves at more positive potentials were observed during the cation binding process. The addition of 1 equiv. of lithium ion results in a complete disappearance of the original redox waves at –969, –1188, and –1594 mV with a corresponding increase in the intensities of the new waves observed at –624, –833, and –1266 mV for the couples 4/4′, 5/5′, and wave 6, respectively (Fig. 5*c* and Table 5). This observation again indicated that the lithium ion is possibly bound to **3b** through a 1:1 binding stoichiometry.

Similarly, the cyclic voltammograms recorded after the addition of 1 equiv. of Na^+, K^+, and NH_4^+ ions to the electrochemical solution of **3b** led to a change in the cathodic peak potentials as summarized in Table 5. Square wave voltammetry measurement of **3b** in the presence of 1 equiv.of Li^+ ion also exhibited the new anodically shifted peaks 4, 5, and 6 at –624, –833, and –1266 mV, respectively, in the square wave voltammograms (Fig. 6).

The change in cathodic current of **3b** when examined in the presence of alkali cations indicated that the addition of lithium ions leads to a large decrease in cathodic current while the addition of potassium ions exhibited the least effect. The decrease in cathodic current of the redox waves 1/1′ and 2/2″ was found to follow the order $Li^+ > NH_4^+ > Na^+ > K^+$, which is in consonance with the order of potential shift ($\Delta E_{(1/1')} = E^{complex} - E^{3b}$; Li^+ 345, NH_4^+ 267, Na^+ 32, K^+ 18 mV) observed for wave 1/1′ (Table 5). This indicated that the receptor **3b** binds the lithium ion more strongly than the other cations. Incremental addition of alkali cations to an electrochemical solution of **3b** revealed that the addition of 1 equiv. of lithium ion leads to a complete disappearance of the original redox couples, 1/1′ and 2/2′, while even a fivefold excess of Na^+ and K^+ ions to **3b** could not induce a similar effect (Table 5). On the other hand, addition of 1 equiv. of NH_4^+ ion to **3b** led to the disappearance of the redox couples 1/1′ and 2/2′ (which was not observed in the case of Na^+ and K^+ ions) as depicted in Fig. 5*b*.

The anodic shifts observed in the redox couples of **3b** on addition of Li^+, Na^+, K^+, and NH_4^+ ions could possibly be ascribed to the easier reduction of diquinone units through extra stabilization of the reduced quinone species in the presence of positively charged metal ions. This stabilization was found to be maximum in the case of lithium ion due to its higher charge density. This was evidenced by the observed large decrease in cathodic current of waves 1/1′ and 2/2′ and larger anodic shifts in the new redox waves 4/4′ and 5/5′ of **3b** obtained in the presence of lithium ions (Fig. 5*c* and Table 5). The anodic shift exhibited by NH_4^+ ions was larger than that of Na^+ and K^+ ions ostensibly due to stronger hydrogen bond interactions of ammonium cations with the quinone units in **3b**.[19] This observation was further confirmed by ^{1}H NMR, which revealed a greater downfield shift in δ NH on addition of NH_4^+ ions. The binding enhancement[8c,21] of **3b** on interaction with cationic guests was calculated from the shift in half wave potentials ($E_{1/2}$) of the bound and free **3b**. It was observed that a lithium ion binding with **3b** is roughly ten times stronger than with an ammonium ion (Table 5). These observations are in consonance with the NMR measurements, which show a higher binding affinity of **3b** towards lithium ions amongst the other tested alkali metal cations.

In conclusion, a series of new calix[4]arene(amidocrown) diquinones (**3a–3d**) have been synthesized in good yields. The NMR studies on the interaction of **3b** with alkali metals and ammonium ions exhibited a significant downfield shift

Table 4. Electrochemical data of the synthesized calix[4]arene(amidocrown) diquinone receptors (**3a**–**3d**) in acetonitrile.

Redox couple or wave (mV)	3a	3b	3c	3d
$E_{1/2}$ (1/1′)	–969	–969	–968	–970
$E_{1/2}$ (2/2′)	–1189	–1188	–1187	–1190
E_{pc} (3)	–1596	–1594	–1598	–1601

Note: $E_{1/2}$ values are the cathodic peak potentials of the described couple referenced to an Ag/Ag^+ electrode at 298 K. E_{pc} is the cathodic peak potential of wave 3, which is irreversible.

Table 5. Redox couples and waves of **3b** upon addition of 1 equiv. of Li^+, Na^+, K^+, and NH_4^+ cations.

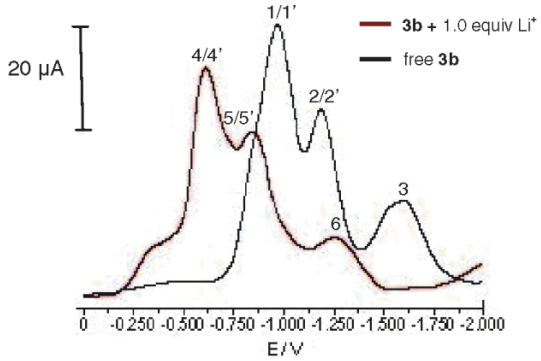
	Redox couple or wave (mV)							
Comp.	(1/1′)	(2/2′)	(3)	(4/4′)	(5/5′)	(6)	Binding enhancement[a]	
Free **3b**	–969	–1188	–1594				K_2/K_1	K_3/K_2
3b + Li^+				–624	–833	–1266	6.7×10^5	9.8×10^5
3b + NH_4^+				–702	–892	–1328	3.2×10^4	9.9×10^4
3b + Na^+[b]	–970	–1192	–1596	–937	–1125	–1502		
3b + K^+[b]	–973	–1191	–1592	–951	–1158	–1532		

Note: Experiments were carried out in acetonitrile using Ag/Ag^+ as the reference electrode and $TBA.PF_6$ as the supporting electrolyte.

[a] K_2/K_1 and K_3/K_2 are the calculated binding enhancements in the presence of metal ions.

[b] The original waves appeared even in the presence of 5 equiv. of metal ions.

Fig. 6. Square wave voltammograms (10 Hz) of free **3b** (black) and in the presence of 1.0 equiv. of Li^+ cations (red) in acetonitrile.



in the NH proton resonance, which could possibly be ascribed to cation-induced polarization of the amidocrown ring. The cyclic voltammetry of **3b** in the presence of lithium ions gives a larger anodic shift in the original redox waves. Both NMR and electrochemical studies revealed a 1:1 binding stoichiometry for the interaction of **3b** with alkali metal and ammonium ions and exhibited the highest binding constant for lithium ions, which indicated that **3b** shows high selectivity for lithium ions in preference to other alkali metal cations and ammonium ions. These studies may be helpful in the development of novel ion-selective electrodes, electrochemical sensors, and molecular devices. Further work in this area is in progress.

Experimental section

Instruments

All the reagents used in the study were purchased from Sigma-Aldrich or Merck and were chemically pure. Solvents used were predried and purified by distillation. Column chromatography was performed on silica gel (60–120 mesh) obtained from Merck. Melting points were recorded on an electric melting point apparatus (Toshniwal, India) and are uncorrected. FT-IR spectra were recorded on a Nicolet Protege 460 spectrometer using KBr discs while CHN analyses were taken on a Perkin-Elmer 240C elemental analyzer. ^1H NMR spectra were recorded on a 300 MHz Bruker DPX 300 instrument at room temperature (RT) using tetramethylsilane (TMS) as an internal standard. The electrochemical measurements were carried out using an AUTOLAB PGSTAT 100 cyclic voltammeter obtained from Metrohm Ltd., Switzerland. The ESI mass spectra were recorded on a MICROMASS QUATTRO II triple quadrupole mass spectrometer setting the ESI capillary at 3.5 kV and the cone voltage at 40 V.

Preparation of starting materials

Debutylated-calix[4]arene and 25,27-di(ethoxycarbonylmethoxy)-26,28-dihydroxy-calix[4]arene (**1**) were synthesized by the methods reported earlier.[13] The amidocrown calix[4]arene derivatives (**2a**–**2d**) were prepared as previously reported.[11]

General procedure for the synthesis of calix[4]arene(amidocrown) diquinones (3a–3d)

A slurry of compound **2a**–**2d** (2.0 g) was dissolved in acetone (170 mL) and phosphate buffer[22] (70 mL) was added to it. A portion of yellowish chlorine dioxide solution[22] (150 mL) was then added and the reaction mixture was stirred at RT for 48–60 h. The reaction was evaporated in vacuo on completion of the reaction to obtain a yellowish precipitate. The precipitate was extracted with chloroform (3 × 50 mL) and washed three times with water. The com-

bined organic layer was dried over anhydrous Na_2SO_4, filtered, and concentrated on a rotary evaporator to obtain a sticky yellow product, which on trituration with methanol gave yellowish solids. The crude products were purified by silica gel chromatography ($CHCl_3$-EtOAc 90:10 *v*/*v*) to give **3a**–**3d** as bright yellow powders.

Analytical procedures for electrochemical and NMR experiments

Cyclic (CV) and square wave voltammetric (SWV) analysis were performed using an AUTOLAB PG-STAT 100 cyclic voltammeter (Metrohm Ltd., Switzerland) fitted with three electrodes consisting of a glassy carbon working electrode (conducting area of 3 mm diameter), a platinum wire counter electrode, and an Ag/Ag^+ reference electrode. Analysis of the cyclic and square wave voltammetric data were performed using the GPES software (version 4.9.005).[23] All the electrochemical measurements were carried out in an electrolyte solution of 0.1 mol/L tetrabutylammonium hexafluorophosphate ($TBA.PF_6$) in acetonitrile, unless otherwise indicated. The electrolytic solutions were sonicated for 20 min and then bubbled with nitrogen for 5–7 min before each measurement to minimize the oxygen interference. A 0.001 mol/L solution (5 mL) of molecular receptor **3b** (5×10^{-6} mol) and tetrabutylammonium hexafluorophosphate (5×10^{-4} mol) was prepared in acetonitrile and the metal salt solution containing a mixture of metal salt (5×10^{-4} mol) and tetrabutylammonium hexafluorophosphate (5×10^{-4} mol) was added directly to the cell through a microsyringe to have the desired cation/ligand ratios. Redox currents were determined from CV scans of the complex solutions at a scan rate of 50 mVs^{-1}.

^1H NMR titration: A 10 mmol/L solution of the receptor **3b** was prepared in CD_3CN. To 0.5 mL of **3b** solution, 0.0–2.5 equiv. of cations (Li^+, Na^+, K^+, and NH_4^+ of 40 mmol/L in CD_3CN) were added to an NMR tube and the spectra were recorded. The chemical shifts of the NH protons were followed after each addition and plotted against the equivalents of cations added.

Job's plot experiments: Stock solutions of the receptor **3b** (10 mmol/L) and $LiClO_4$ (10 mmol/L) were prepared in CD_3CN. A total volume of 500 μL of **3b** and $LiClO_4$ were added to nine NMR tubes in the following volume ratios 50:450, 100:400, 150:350, 200:300, 250:250, 200:300, 150:350, 100:400, and 50:450.

(22) A concentrated aqueous buffer solution was prepared by dissolving 4.36 g of $Na_2HPO_4 \cdot 2H_2O$ and 2.42 g of $NaH_2PO_4 \cdot 2H_2O$ in 100 mL of Milli-Q water. A pH ~ 7.0 buffer solution was obtained when the concentrated solution was diluted five times in volume. Chlorine dioxide (ClO_2) solution was obtained by mixing equal volumes of $NaClO_2 \cdot 2H_2O$ solution (31.60 g in 500 mL Milli-Q water) and $Na_2S_2O_8$ solution (29.70 g in 500 mL Milli-Q water). The mixed solution was then stored in a dark coloured bottle at 0 °C overnight to get the yellowish chlorine dioxide solution.

Preparation and properties of thienyl and 2,2′-bithienyl substituted cobalt-bis(semiquinone) valence tautomers

Thomas J. O'Sullivan, Brandon Djukic, Paul A. Dube, and Martin T. Lemaire

Abstract: The synthesis and characterization of two new 2,2′-bipyridine ligands containing 3-ethynylthiophene and 3,3′-diethynyl-2,2′-bithiophene substituents is presented, along with the preparation, electronic, and magnetic properties of mono- and bimetallic cobalt-semiquinone valence tautomers containing these ligands.

Key words: cobalt complexes, valence tautomerism, semiquinone radical anions, magnetic switches.

Résumé : On a réalisé la synthèse et effectué la caractérisation de deux nouveaux ligands 2,2′-bipyridine portant des substituants 3-éthynylthiophène et 3,3′-diéthynyl-2,2′-bithiophène; on rapporte aussi la préparation ainsi que les propriétés électroniques et magnétiques des tautomères de valence cobalt-semiquinone mono- et bimétalliques contenant ces ligands.

Mots-clés : complexes de cobalt, tautomérie de valence, anions radicaux semiquinones, interrupteurs magnétiques.

[Traduit par la Rédaction]

Introduction

Valence tautomerism (VT) in cobalt(II) coordination complexes containing 2,2′-bipyridine and semiquinone anion-radical ligands was discovered in 1980 by Pierpont and Buchanan.[1] These fascinating molecular materials feature dynamic electronic structures that can switch between different electronic states as a result of a similarity in the frontier orbital energies of cobalt(II) and the coordinated semiquinone. In particular, an intramolecular electron transfer reaction results in the formation of cobalt(III)-catecholate species, and accompanying the cobalt(II)-to-semiquinone electron transfer is a change in spin state of the cobalt ion from high to low. These changes are manifested as observable changes to the structural, electronic, and in particular, the magnetic properties of the complexes over a range of temperatures, even upon application of pressure or light irradiation.[2]

Since the discovery of Pierpont and Buchanan,[1] a number of related VT complexes have been reported, some exhibiting thermal hysteresis in magnetic properties and others exhibiting interesting light induced VT.[3] The vast majority of these complexes are monometallic and the number of these reports dwarfs the number of reported bimetallic VT complexes, and to our knowledge there are no reported VT complexes containing more than two cobalt ions (this does not include two VT *coordination polymers* reported by Pierpont and co-workers[4b] and Shultz and co-workers,[4a] and recently reported VT metal-organic nanoparticles).[4] We are interested in the preparation of new variants of polymetallic VT materials leading to, among other things, new *multistate molecular switches*. We reasoned that a conjugated organic backbone based on the thiophene heterocycle should serve as a nice platform to construct polymetallic VT complexes, and as an added advantage, the synthetic aspects of oligothiophene chemistry are well documented. Herein we report the synthesis and magnetic properties of two new mono- and bimetallic VT complexes (**3** and **4**, respectively) containing new 2,2′-bipyridine derivatives bearing thiophene **1**, or a bridgining 2,2′-bithiophene **2**, substituents. Complexes **3** and **4** serve as models to study the effect of thiophene substitution on the electronic or magnetic properties of cobalt-bis(semiquinone) VT complexes.

Experimental

General procedures

All reagents were commercially available and used as received unless otherwise stated. Deaerated and anhydrous solvents were obtained from a Puresolve PS MD-4 solvent purification system, and all air and (or) moisture sensitive reactions were carried out using standard Schlenk techniques. FT-IR spectra were recorded on a ThermoMattson RS-1 spectrometer as KBr discs. EI and FAB mass spectra were obtained using a Kratos Concept 1S High Resolution E/B mass spectrometer. UV–vis spectra were recorded on a Shimadzu 3600 UV-Vis-NIR spectrophotometer as solutions in ethanol at room temperature. Spectra at 77 K were obtained as frozen ethanol glasses in 5 mm NMR tubes immersed in a liquid N_2 dewar. Elemental analyses were carried out by Guelph Chemical Laboratories Ltd., Guelph, ON, Canada.

Electrochemical measurements

Cyclic voltammetry (CV) experiments were performed with a Bioanalytical Systems Inc. Epsilon electrochemical workstation. Compounds were dissolved in anhydrous solvent (CH_2Cl_2, CH_3CN, or DMF) and deareated by sparging with dinitrogen gas for 20 min. Solution concentrations were approximately 10^{-3} mol/L in analyte containing 0.1 mol/L supporting electrolyte (Et_4NPF_6). A typical three-electrode setup was used, including a platinum working electrode, Ag wire pseudoreference electrode, and a platinum wire auxiliary electrode. Ferrocene was used in all cases as an internal standard in our setup and was oxidized at potentials of +0.50, +0.54, and +0.70 V in CH_2Cl_2, CH_3CN, and DMF, respectively; all potentials quoted are versus the ferrocene oxidation potential. Scan rates for CV experiments were 100 mV/s.

Variable temperature magnetic susceptibility measurements

Variable temperature magnetic susceptibility measurements were recorded on a superconducting quantum interference device (SQUID) magnetometer (Quantum Design MPMS) with a 5.5 T magnet (temperature range from 2 to 300 K) in an external field of 1000 Oe. Samples were carefully weighed into gelatin capsules, with empty gelatin capsules above and below to eliminate background contributions from the gelatin, which were loaded into plastic straws and attached to the sample transport rod. Diamagnetic corrections were made using Pascal's constants.

Synthesis

5-(Trimethylsilylethynyl)-2,2′-bipyridine

The following is a modified version of the procedure reported by Ziessel and co-workers.[5] 5-Bromo-2,2′-bipyridine (1.00 g, 4.385 mmol), $PdCl_2(PPh_3)_2$ (92 mg, 0.131 mmol, 3 mol%), PPh_3 (69 mg, 0.263 mmol, 6 mol%), and CuI (83 mg, 0.438 mmol, 10 mol%) were added successively to a two-necked round-bottomed flask, which was flushed with N_2. Anhydrous *N*,*N*-diisopropylamine (90 mL) was syringed into the flask, and the mixture was stirred and deareated for 30 min. Lastly, ethynyltrimethylsilane (0.579 g, 6.577 mmol, 0.82 mL) was added, and the reaction mixture was refluxed for 20 h. The solvent was evaporated, and the residue was dissolved in chloroform; pentane was used to precipitate impurities that were removed by gravity filtration. The filtrate was passed through a Celite pad and concentrated. The residue was dissolved in acetone, filtered, and concentrated to afford 1.067 g (96%) yield of the product. Spectroscopic properties are consistent with those reported by Ziessel and co-workers.[5] ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 8.75 (d, 1H, J = 2 Hz), 8.70 (d, 1H, J = 5 Hz), 8.40 (m, 2H), 7.84 (m, 2H), 7.33 (m, 1H), 0.29 (s, 9H). MS (EI+) *m*/*z* (%): 252 (M^+, 100).

5-(3-Ethynylthienyl)-2,2′-bipyridine (1)

A solution of 3-bromothiophene (0.100 mL, 1.063 mmol) in anyhydrous *N*,*N*-diisopropylamine (20 mL) was deaerated by sparging with N_2 gas for 30 min. Five mol% of each of the following were successively added to the flask: $PdCl_2(PPh_3)_2$ (0.037 g, 0.053 mmol), PPh_3 (0.014 g, 0.053 mmol), and CuI (0.010 g, 0.053 mmol), followed by 5-ethynyl-2,2′-bipyridine (0.230 g, 1.276 mol). The reaction mixture was refluxed overnight until starting materials had been consumed, as verified by TLC. The crude product was passed through a pad of Celite, and the filtrate was washed with brine (3 × 50 mL), and then dried with sodium sulfate. After concentration, the crude product was recrystallized from acetone(hot)/water (5:1) to yield 0.258 g of a yellow solid (92% yield). Mp 141 °C. FT-IR (KBr, cm^{-1}): 3405 (m, br), 3072 (m), 2920 (w), 2205 (m), 1717 (w), 1586 (m), 1541 (m), 1457 (s), 1433 (m), 1366 (m), 1126 (w), 1090 (w), 1019 (m), 854 (m), 784 (s), 739 (w), 623 (m). ^{1}H NMR (300 MHz, $CDCl_3$, ppm) δ: 8.82 (s, 1H), 8.71 (d, 1H, J = 2 Hz), 8.43 (t, 2H, J = 3.4 Hz), 7.94 (dd, 1H, J = 4, 1 Hz), 7.85 (td, 1H, J = 4, 1 Hz), 7.62 (d, 1H, J = 1 Hz), 7.35 (m, 2H), 7.26 (d, 1H, J = 2 Hz). ^{13}C NMR (600 MHz, $CDCl_3$, ppm) δ: 155.5, 154.7, 151.5, 149.3, 139.2, 137.0, 129.8, 129.4, 125.6, 123.9, 121.7, 121.3, 120.3, 120.3, 88.6, 85.9. MS (FAB+) *m*/*z* (%): 262 (M^+, 100). Anal. calcd. for $C_{16}H_{10}N_2S$ (%): C 73.27, H 3.85, N 10.69; found: C 72.96, H 4.07, N 10.35.

3,3′-Bis(5-ethynyl-2,2′-bipyridine)-2,2′-bithiophene (2)

In a Schlenk flask anhydrous *N*,*N*-diisopropylamine (60 mL) was deaerated by N_2 sparging for 30 min, followed by the successive addition of 5-ethynyl-2,2′-bipyridine (0.500 g, 2.775 mmol), 3,3′-dibromo-2,2′-bithiophene (0.408 g, 1.261 mmol), and 3 mol% each of $PdCl_2(PPh_3)_2$ (0.58 g, 0.083 mmol) and CuI (0.015 g, 0.083 mmol). The reaction mixture was refluxed overnight under N_2. Following consumption of starting materials (TLC), the reaction mixture was concentrated and then passed through a Celite pad. The filtrate was concentrated under reduced pressure, and the residue was pre-absorbed onto neutral alumina, and then loaded onto a plug of neutral alumina. Impurities were separated by elution with hexanes, and the product was eluted with copious amounts of dichloromethane. The residue was recrystallized from 4:1 hot chloroform/hexanes to produce 0.434 g (66%) of a bright yellow solid. Mp >200 °C. Results and discussion

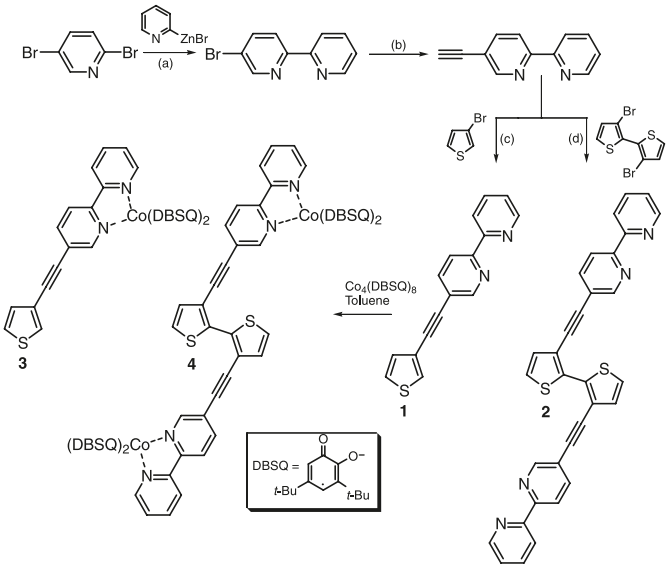
Ligand synthesis and coordination chemistry

Our general synthetic strategy toward multimetallic VT materials is based upon the structural modification of the prototypical VT system, (2,2′-bipyridine)Co(DBSQ)$_2$ (DBSQ = 3,5-di-*tert*-butyl-1,2-semiquinone), to enable covalent attachment to a conjugated backbone. Our first target ligand contains a 3-ethynyl-thienyl substituent joined to the 2,2′-bipyridine structure (**1**) as a model to probe the effect of thiophene substitution on the VT properties of (2,2′-bipyridine)Co(DBSQ)$_2$, and to ensure that this substitution has not altered the electronic properties of the cobalt ion so much that VT is no longer observed. The ethynyl spacer fixed between the thiophene heterocycle and 2,2′-bipyridine is to prevent undesirable steric congestion in future complexes containing oligo- or poly-thiophene backbones. Methodology for preparing monohalogenated derivatives of 2,2′-bipyridine is known, and our first target **1** was prepared as shown (Scheme 1). We followed Fang and Hanan's[6] procedure to obtain 5-bromo-2,2′-bipyridine via a palladium catalyzed Neigishi cross-coupling of 2-pyridylzinc bromide with 2,5-dibromopyridine, and we modified Ziessel and co-worker's[5] procedure, which utilizes Sonogashira methodology, to generate 5-trimethylsilyl-2,2′-bipyridine. Fluoride ion deprotection generated 5-ethynyl-2,2′-bipyridine, which was reacted with 3-bromothiophene in another Sonogashira cross-coupling reaction to afford **1** as a yellow solid. In the FT-IR spectrum of **1**, the acetylene stretch is observed at 2205 cm^{-1}.

Bis(bidentate) bridging ligand **2** was prepared in three steps from commercially available 2,2′-bithiophene (Scheme 1).

Scheme 1. Preparation of **1** and **2**. Reagents and conditions: (a) 5 mol% $Pd(PPh_3)_4$, THF, RT, 24 h; (b) ethynyltrimethylsilane, 10 mol% CuI, 3 mol% $Pd(PPh_3)_2Cl_2$, $^iPr_2NH$, followed by deprotection with KF in MeOH; (c) 3 mol% CuI and $Pd(PPh_3)_2Cl_2$, $^iPr_2NH$, reflux 24 h; (d) 3 mol% CuI and $Pd(PPh_3)_2Cl_2$, $^iPr_2NH$, reflux 24 h.



3,3′,5,5′-Tetrabromo-2,2′-bithiophene is obtained by bromination of 2,2′-bithiophene with aq. HBr and Br_2, and reductive dehalogenation with zinc dust afforded 3,3′-dibromo-2,2′-bithiophene, which was reacted with 2 equiv. of 5-ethynyl-2,2'-bipyridine to provide **2** as a canary yellow powder following chromatography and recrystallization.[7] The spectroscopic properties of **2** are very similar to **1**, with the exception of one missing singlet resonance in the ^1H NMR spectrum of **2**, corresponding to the H atom on C2 of the thiophene ring in **1**.

Complexes **3** or **4** were prepared by combination of stoichiometrically appropriate amounts of **1** or **2** with Pierpont's "tetramer" $Co_4(3,5\text{-}DBSQ)_8$ in toluene solution (Scheme 1).[8] These reactions generated analytically pure powders of complexes; unfortunately, repeated attempts to grow crystals suitable for X-ray diffraction were unsuccessful in all cases. As solids, these complexes are indefinitely stable, even under ambient conditions; however, solutions of these complexes are quite unstable, even under inert conditions. In any event, our analytical data (C, H, N, and S) is in good agreement with theoretical values, and these results in conjunction with FT-IR and other spectrometric data (FAB mass spectrometry) strongly support that the anticipated formulations have been obtained.

Electronic spectroscopy

The electronic absorption properties of **3** and **4** were measured in ethanol solution at 298 K, and as a frozen ethanol glass at 77 K. The vis-NIR spectrum obtained from **3** at each temperature is shown in Fig. 1 (the spectrum of **4** is included in the Supplementary data).

As is typical of cobalt-bis(semiquinone) valence tautomers, changing temperature results in a significant change to the electronic spectrum.[9] At 298 K, the spectrum of **3** fea-

Fig. 1. Vis-NIR spectrum of **3** at 298 and 77 K (bold trace) in ethanol.

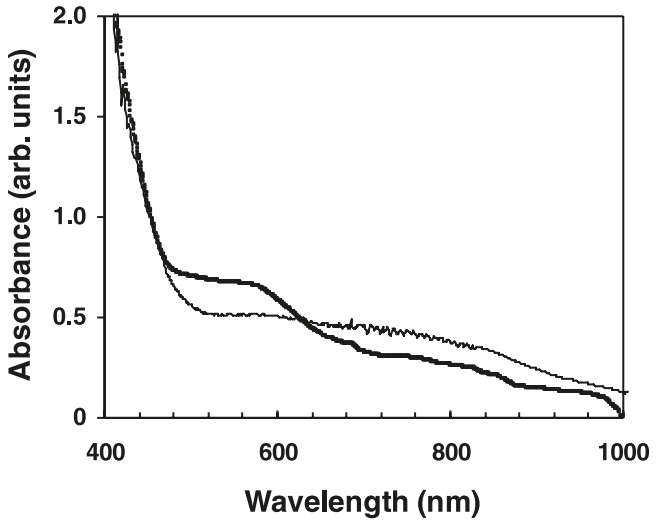


Fig. 2. Cyclic voltammogram of **4** recorded in deareated DMF, containing 0.1 mol/L Et_4NPF_6.

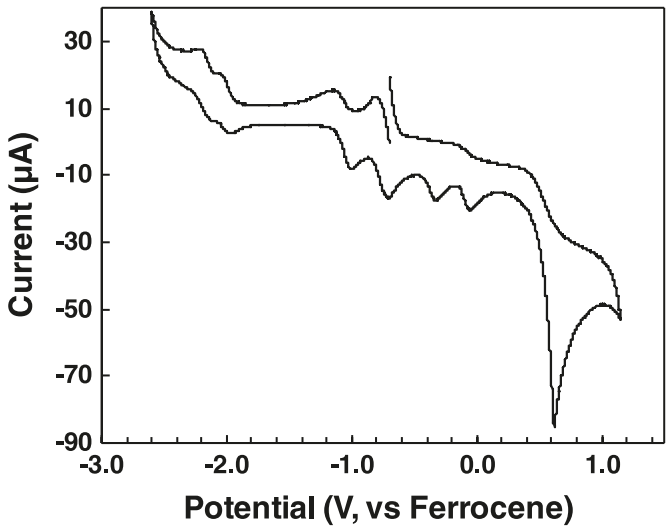


tures broad absorptions across the visible region into the NIR. Typically, the higher temperature tautomer features a cobalt(II)-to-semiquinone charge transfer absorption centered at approximately 800 nm.[10] We observe a decrease in the absorption of this band at 77 K, and an increase in absorption between 500 and 600 nm, consistent with optical changes that have been observed for other reported valence tautomers. The new, more strongly absorbing feature, having a maximum absorbance at 580 nm is consistent with a catecholate-to-cobalt(III) charge transfer band, which is typical for the lower temperature tautomer. Similar features are observed in the electronic spectra of **4** at 298 and 77 K (Supplementary data). All of the observed optical changes are completely consistent with valence tautomerism in **3** and **4**.

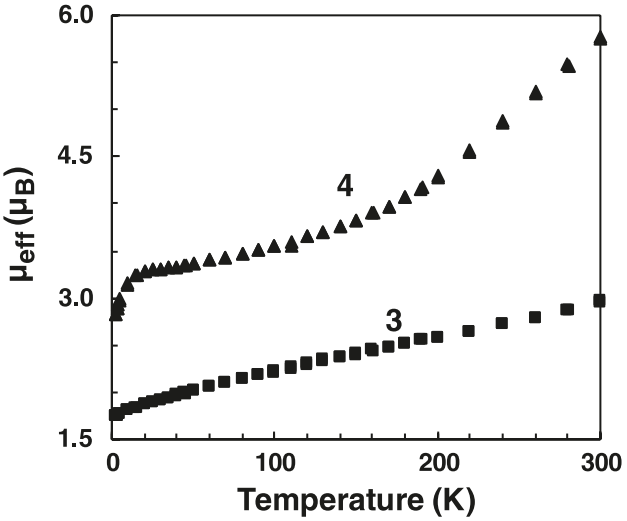
Electrochemical properties

The electrochemical properties of compounds **1**–**4** were studied by cyclic voltammetry. Because of solubility differences between the ligands and coordination complexes, voltammograms of **1** and **2** were run in CH_2Cl_2 and complexes **3** and **4** were run in DMF. In all cases, quoted potentials are referenced to the Fc/Fc^+ couple in the particular solvent noted. As an example, the voltammogram of **4** is presented in Fig. 2; voltammograms of **1**, **2**, and **3** can be found in the Supplementary data. Electrochemical data for all compounds is listed in Table 1.

Table 1. Electrochemical data for compounds **1**–**4** (irr = irreversible).

Compound	E'_{ox} (V) (peak separation, mV)	E'_{red} (V) (peak separation, mV)
1	+0.8 (irr)	–1.3 (180)
2	+0.8 (irr), +0.98 (irr)	–1.3 (200)
3	+0.7 (irr) (CH_3CN)	–2.3 (200), –1.0 (irr), –0.7 (170), –0.3 (irr), –0.05 (irr) (DMF)
4	+0.7 (irr), +0.92 (irr) (CH_3CN)	–2.2 (120), –2.0 (120), –1.1 (200), –0.8 (146), –0.3 (irr), –0.04 (irr) (DMF)

Fig. 3. Temperature dependence of the magnetic moment (μ) for **3** (■) and **4** (▲). External field of 1000 Oe.



Ligands **1** and **2** exhibit very similar voltammograms. In each case, one pseudoreversible cathodic wave is present (–1.3 V), assigned to the reduction of the 2,2′-bipyridine substituent. Over anodic potentials, **1** features an irreversible wave at +0.8 V, likely due to oxidation of the thiophene ring; a similar wave is observed in **2**, with a second irreversible wave noted at a slightly higher potential (+0.98 V). These are assigned to successive oxidations of the 2,2′-bithienyl substituent, producing first a radical-cation and then dication.

In the voltammograms of **3** and **4**, all waves are cathodic versus ferrocene, and a complex series of reduction processes are observed (Fig. 2). Two closely spaced and pseudoreversible waves are present at the most negative potentials (–2.2 and –2.0 V), and represent reduction of 2,2′-bipyridine. These potentials are much more negative than those observed in uncoordinated **1** and **2**, which is typical for electronic changes that occur upon metal ion coordination. Another set of pseudoreversible waves are observed at –1.1 and –0.8 V, followed by two irreversible processes

at –0.3 and –0.04 V. These likely represent DBSQ/DBCAT and cobalt(III)/(II) reduction events.

Presumably, anodic processes that were observed for the thiophene and 2,2′-bithiophene substituents in **1** and **2** fall at higher positive potentials than the solvent (DMF) window will allow measurement of, and so these waves were not observed in the anodic scans of **3** or **4**. We ran anodic scans of **3** and **4** in acetonitrile solution, which is known to exhibit a wider anodic window than DMF. Oxidation of the thiophene ring occurred at +0.7 V in **3**; 2,2′-bithophene oxidation was observed at +0.7 and +0.9 V in **4**. These potentials are only slightly less positive than those observed for the same processes in uncoordinated **1** and **2**, suggesting, as anticipated, that metal coordination has little effect on the electronic structure of the remote heterocyclic substituents.

Repeated cycles (5 to 10 scans) between 0 and 1.5 V in acetonitrile solutions of **3** and **4** did not result in electropolymerization of these complexes. An increase in peak current with increasing scan number was not observed, nor was a deposited electroactive film observed on the working electrode following the experiment. It is likely that the steric bulk of the cobalt(DBSQ)$_2$ substituent prevented electropolymerization.

Variable temperature magnetic properties

Magnetic susceptibility measurements were carried out with a SQUID magnetometer over the temperature range 2–300 K from complexes **3** and **4**. The data are displayed as plots of effective magnetic moment (μ_{eff}) versus temperature in Fig. 3.

The profile of the data clearly suggests that valence tautomerism is operative within each complex. The magnetic moment of **3** at 2 K is 1.74 μ_B, which is equal to the expected value for one unpaired electron residing in the lone coordinated DBSQ ligand of the low temperature tautomer. Increasing the temperature results in a steady increase in magnetic moment, which approaches 3.0 μ_B at 300 K. This value is less than expected for noninteracting S = 3/2 cobalt(II) with two coordinated S = 1/2 DBSQ radicals (4.98 μ_B). The reduced moment results from a combination of antiferromagnetic coupling between cobalt and coordinated DBSQ and the presence of some proportion of the cobalt(III)(DBSQ)(DBCAT) tautomer at this temperature.

At 2 K the magnetic moment of bimetallic **4** is equal to 2.8 μ_B, which is a touch higher than the expected value for two noninteracting unpaired electrons (2.45 μ_B). Between 20 and 200 K, the moment increases very gradually from approximately 3.5 to 4 u_B, but between 200 and 300 K the rate of increase in moment is much faster. At 300 K the moment, which is clearly still ascending, is 5.76 μ_B, which is less than the expected value for two nonintereacting cobalt(II) ions and four semiquinone radical anions (6.95 μ_B), likely a result of cobalt-semiquinone antiferromagnetic coupling and the presence of lower spin tautomers. It is interesting to speculate on the possibility of a high-spin/low-spin intermediate state, in between the expected fully low- and high-spin tautomers in **4**, possibly within the 20 to 200 K regime, where the moment changes gradually. We are currently probing this hypothesis. Whatever the case, our data clearly indicates the presence of valence tautomerism in **3** and **4**.

Conclusions

We have described the synthesis of two new derivatives of 2,2′-bipyridine containing thiophene and a bridging 2,2′-bithiophene substituents. Reaction of these ligands with $Co_4(DBSQ)_8$ resulted in mono- and bimetallic coordination complexes that exhibited valence tautomerism in solution (demonstrated optically) and the solid state (demonstrated by variable temperature magnetic susceptibility experiments). Unfortunately, these complexes did not undergo electropolymerization, and we are actively pursuing the synthesis of other derivatives that should be more amenable to electropolymerization. We are also synthesizing larger 2,2′-bipyridine-substituted oligothiophene backbones for the generation of tri-, tetra-, and penta-metallic VT complexes. These efforts will be reported in due course.

The neutral hydrolysis of methyl acetate — Part 1. Kinetic experiments

Yih-Huang Hsieh, Noham Weinberg, and Saul Wolfe

Abstract: The neutral hydrolysis of methyl acetate and catalysis of the reaction by the acetic acid product have been studied in the temperature range 90–110 °C. Extrapolated to 25 °C, the rate constants are 0.17×10^{-8} s^{-1} for the uncatalyzed reaction and 1.4×10^{-4} $(mol/L)^{-1}s^{-1}$ for the catalyzed reaction. The acid catalysis is specific not general: at 90 °C the rate constants for hydrochloric acid catalysis and catalysis by ionized acetic acid are the same as the rate constant, $k_H = 1.4 \times 10^{-2}$ $(mol/L)^{-1}s^{-1}$, determined in the neutral reaction.

Key words: specific acid catalysis, general acid catalysis, cooperative mechanism.

Résumé : Opérant à des températures allant de 90 à 110 °C, on a étudié l'hydrolyse neutre de l'acétate de méthyle et la catalyse de la réaction par l'acide acétique produit. Extrapolées à 25 °C, les constantes de vitesse sont égales à 0,17 x 10^{-8} s^{-1} pour la réaction non catalysée et à 1,4 x 10^{-4} $(mol/L)^{-1}$ s^{-1} pour la réaction catalysée. La catalyse acide n'est pas générale; à 90 °C, les constantes de vitesse pour la catalyse par l'acide chlorhydrique et pour la catalyse par l'acide acétique ionisé sont les mêmes que la constante de vitesse, k_H = 1,4 x 10^{-2} $(mol/L)^{-1}$ s^{-1}, déterminée pour la réaction en milieu neutre.

Mots-clés : catalyse acide spécifique, catalyse acide générale, mécanisme coopératif.

[Traduit par la Rédaction]

Introduction

In recent publications,[1–4] we have reported that the neutral, acetic acid-catalyzed and 2-hydroxypyridine(2-pyridone) catalyzed aqueous hydrations of carbonyl compounds are paradigms of cooperativity,[5,6] by which we mean that C–O bond formation and proton transfer to oxygen take place in each case through an uncharged bridge of solvent and (or) catalyst molecules. This mechanism provides a preferred neutral alternative to multistep ionic processes in which charged intermediates would be undergoing continuous solvation and desolvation as they appear and disappear.[5]

The series of studies of which the present article is Part 1 was undertaken to determine if a neutral ester hydrolysis, whether via a one-step (Scheme 1) or two-step (Scheme 2) pathway, can also proceed via a cooperative mechanism.

The issue is complicated experimentally because neutral ester hydrolysis produces a carboxylic acid, which can affect kinetics by a combination of general and specific acid catalysis, i.e.,

$$[1] \qquad k_{obs} = k_o + k_{HA}[HA] + k_H[H^+]$$

where k_o is the rate constant of the neutral reaction of interest, k_{HA} is the rate constant resulting from general acid catalysis by the product, and k_H is the rate constant resulting from specific acid catalysis by the product. Our interest is in k_o, but k_{HA}, if important, may also involve cooperativity. The specific objective of the present work is to obtain the experimental values of k_o and k_{HA} or k_H for the hydrolysis of methyl acetate in water solvent, for comparison with the values of k_o and k_{HA} calculated[7] assuming cooperative mechanisms. Prior to this work, it had been reported that ethyl acetate exhibits $k_o = 2.47 \times 10^{-10}$ s^{-1} [8] and ethyl formate exhibits $k_o = 5.0 \times 10^{-6}$ s^{-1} at 298 K.[9]

Experimental

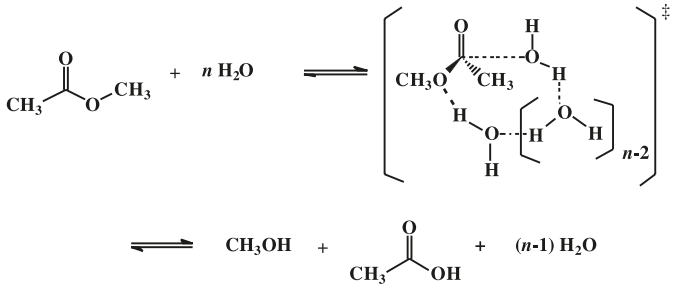
Materials

Methyl acetate was dried over anhyd. copper sulfate, distilled under nitrogen, and stored over 4 Å molecular sieves. $H_2{}^{16}O$ was obtained from an Easypure UV/UF ultrapure water system. Acetic acid (1.000 mol/L, Aldrich) was standardized by titration with 0.1 mol/L sodium hydroxide.

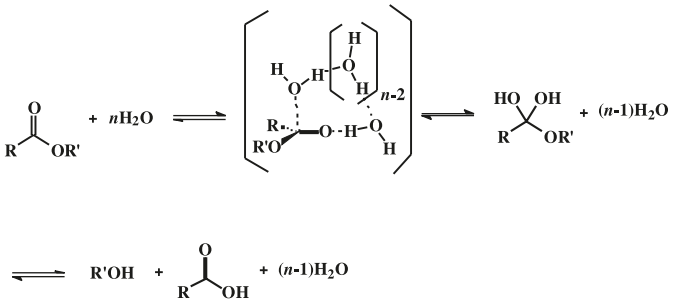
Neutral hydrolyses

Experiments were performed in sealed tubes, which had been washed sequentially with chromic acid and water, and dried at 110 °C. During reactions, all tubes were completely immersed in a stirred, temperature-controlled oil bath for the required time. Temperature control was achieved with a Model 51 Thermotronic temperature controller. To stop reactions, tubes were removed, cooled in ice, and maintained at –20 °C. Kinetics were monitored by measurement of the integrals of the methoxy peaks of methyl acetate and methanol. For reactions at 90 ± 0.5 °C, methyl acetate (4.80 mL, 4.473 g, 60.3 mmol) was added to water (60.0 mL) to give a 1.00 mol/L solution, and this solution was transferred to 60 × 1 cm tubes, which were sealed and frozen until used. For reactions at 100 ± 0.8 °C and 110 ± 0.8 °C, methyl acetate (3.60 mL, 3.355 g, 45.3 mmol) was added to water

Scheme 1.



Scheme 2.



(45.0 mL) to give a 1.00 mol/L solution, and this solution was transferred to two sets of 45 × 1 cm tubes, which were sealed and frozen until used.

Catalysis by hydrochloric acid at 90 °C

0.93 mmol/L HCl

Methyl acetate (2.40 mL, 2.239 g, 30.2 mmol) and hydrochloric acid (0.30 mL, 0.100 mol/L) were added to water (30.0 mL) to give a solution (1.00 mol/L in methyl acetate and 0.93 mmol/L in hydrochloric acid). This solution was transferred to 33 × 1 cm tubes, which were sealed and frozen until needed.

4.8 mmol/L HCl

Methyl acetate (1.60 mL, 1.491 g, 20.1 mmol) and hydrochloric acid (1.0 mL, 0.100 mol/L) were added to water (20.0 mL) to give a solution (1.00 mol/L in methyl acetate and 4.8 mmol/L in hydrochloric acid). This solution was transferred to 22 × 1 cm tubes, which were sealed and frozen until needed.

6.5 mmol/L HCl

Methyl acetate (2.40 mL, 2.239 g, 30.2 mmol) and hydrochloric acid (2.1 mL, 0.100 mol/L) were added to water (30.0 mL) to give a solution (1.00 mol/L in methyl acetate and 6.5 mmol/L in hydrochloric acid), and this solution was transferred to 33 × 1 cm tubes, which were sealed and frozen until needed.

9.1 mmol/L HCl

Methyl acetate (2.40 mL, 2.239 g, 30.2 mmol) and hydrochloric acid (3.0 mL, 0.100 mol/L) were added to water (30.0 mL) to give a solution (1.00 mol/L in methyl acetate and 9.1 mmol/L in hydrochloric acid). This solution was transferred to 33 × 1 cm tubes, which were sealed and frozen until needed.

Catalysis by acetic acid at 90 °C

Methyl acetate (0.168 mL, 0.1562 g, 2.11 mmol) was added to acetic acid (21.0 mL, 1.00 mol/L) to give a solution (0.10 mol/L in methyl acetate and 1.00 mol/L in acetic acid). This solution was transferred to 21 × 1 cm tubes, which were sealed and frozen until needed.

Analysis of kinetic data

Kinetic data for the neutral hydrolyses were treated using Scheme 3 and eq. [2],

$$[2] \qquad v = -\frac{dC_E}{dt} = k_1 C_E - k_{-1} C_A C_B$$

where C_E, C_A, and C_B are the concentrations of ester, acetic acid, and methanol. Since the process is catalyzed by the product,

$$[3] \qquad k_1 = k_1^0 + k_1^H[H^+]$$

and

$$[4] \qquad k_{-1} = k_{-1}^0 + k_{-1}^H[H^+]$$

where k_1^0 and k_{-1}^0 are the neutral rate constants and k_1^H and k_{-1}^H are the specific acid-catalyzed rate constants of the forward and reverse reactions. The contribution of k_{-1}^0 can be neglected because in the initial stages of the reaction there is no reverse reaction, and as hydrolysis proceeds, the acid-catalyzed reverse reaction becomes dominant. Since C_A and C_B are stoichiometrically related to C_E and its initial value C_{E0}, eq. [2] becomes

$$[5] \qquad v = -\frac{dC_E}{dt} = (k_1^0 + k_1^H)C_E - k_{-1}^H(C_{E_0} - C_E)^2$$

The required specific acid concentration $[H^+]$ can be found from eq. [6],

$$[6] \qquad [H^+] = \frac{-(H_o + K_a) + \sqrt{(H_o + K_a)^2 + 4(C_{E_0} - C_E)K_a}}{2}$$

where H_o is 10^{-7} mol/L and K_a is the dissociation constant of acetic acid, $1.7 \pm 0.2 \times 10^{-5}$.[10]

The Verlet algorithm[11] was employed to integrate eq. [5] with a time step δt for a given set of the parameters k_1^0, k_{-1}^0, and k_{-1}^H

$$[7] \qquad C_E(t + \delta t) = C_E(t) + v(t)\delta t + \frac{1}{2}a(t)\delta t^2$$

The required acceleration of the reaction, $a(t)$, was found by differentiation of eq. [5] with respect to time

$$[8] \qquad a(t) = \frac{dv}{dt} = \{2k_{-1}^H[(C_{E_0} - C_E) - (k_1^0 + k_1^H)][H^+]v(t) + k_{-1}^H[(C_{E_0} - C_E)^2 - (k_1^0 + k_1^H)C_E]\} \times \left[\frac{-K_a}{\sqrt{(H_o + K_a)^2 + 4K_a(C_{E_0} - C_E)}}\right] v(t)$$

Results

Tables 1–3 of the Supplementary data and Fig. 1 provide the primary data for the hydrolysis of methyl acetate in water at 90°, 100°, and 110 °C.

The rate constants k_1^0, k_1^H, and k_{-1}^H were obtained by the best root-mean-square fit of the integrated $C(t)$ to these data (Figs. 2–4).

Figures 5 and 6 are the Arrhenius plots for k_1^0 and k_1^H, and Table 4 summarizes the results. At 25 °C, the extrapolated neutral hydrolysis rate constant k_1^0 is $1.7 \pm 1.1 \times 10^{-9}$ s^{-1}.

Catalysis by HCl

Catalysis of the hydrolysis by HCl was examined to obtain an independent determination of k_1^H and k_{-1}^H. Reactions

were performed at 90 °C using 1.0 mol/L methyl acetate and 1, 5, 7, and 9 mmol/L HCl. Tables 5–8 of the Supplementary data and Fig. 7 summarize the results.

The data of Fig. 7 were fitted to theoretical curves obtained by numerical integration of the rate equation, using the Verlet algorithm as before, with the results shown in Fig. 8. The values of $k_1^H = 1.4 \pm 0.2 \times 10^{-2}$ s^{-1}(mol/L)$^{-1}$ and $k_{-1}^H = 1.4 \pm 0.2 \times 10^{-3}$ s^{-1}(mol/L)$^{-2}$ are the same as in Fig. 2.

Catalysis by acetic acid

Table 9 of the Supplementary data summarizes the hydrolysis of 0.10 mol/L methyl acetate in the presence of

Fig. 8. Analysis of hydrochloric acid catalysis of the hydrolysis of 1.0 mol/L methyl acetate at 90 °C.

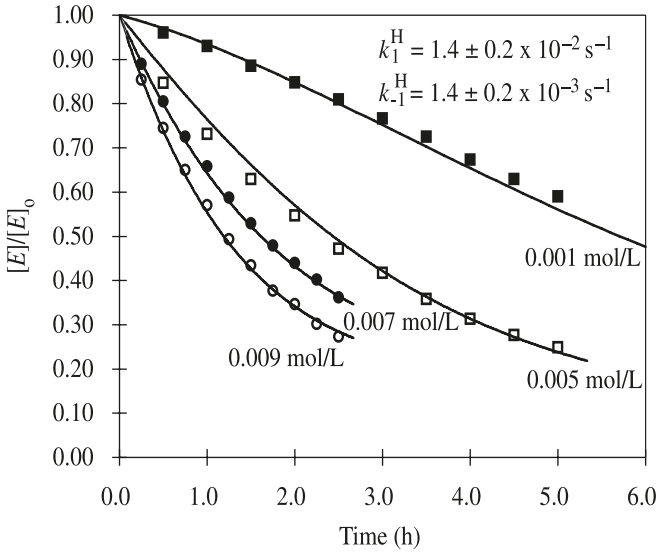

Fig. 9. Pseudo-first-order plot of the hydrolysis of 0.10 mol/L methyl acetate in the presence of 1.0 mol/L acetic acid.

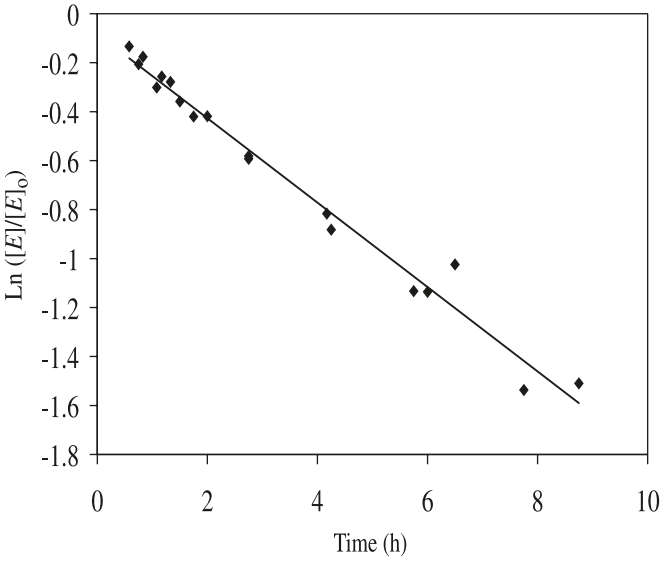

1.00 mol/L acetic acid at 90 °C, and Fig. 9 is a pseudo-first-order plot of the data, giving $k_{obs} = 5.2 \pm 0.5 \times 10^{-5}$ s^{-1}.

From eq. [6] and the dissociation constant of acetic acid, the specific hydrogen-ion concentration of 1.0 mol/L acetic acid is 4.16 × 10^{-3} mol/L. If acetic acid functions by specific acid catalysis, i.e., $k_{obs} = k_H[H^+]$, k_H is calculated to be $1.3 \pm 0.1 \times 10^{-2}$ s^{-1}, identical to the value found in catalysis by HCl and in the analysis of neutral hydrolysis. It can be concluded that the hydrolysis of methyl acetate does not proceed with general acid catalysis by the product.

The neutral hydrolysis of methyl acetate — Part 2. Is there a tetrahedral intermediate?

Zheng Shi, Yih-huang Hsieh, Noham Weinberg, and Saul Wolfe

Abstract: A computational strategy that reproduces the experimental rates of hydration of formaldehyde, acetaldehyde, acetone, and cyclohexanone and the rates of acetic acid and 2-hydroxypyridine-catalyzed hydration of acetone has been extended to the results of the neutral hydrolysis of methyl acetate reported in Part 1. Calculations have been performed for one-step and two-step mechanisms, with cooperative assistance from one to three additional water molecules in the presence and absence of the acetic acid product. The calculations predict that, for the neutral reaction, a one-step mechanism will be favoured if tetrahedral intermediates have a short lifetime and do not interconvert prior to breakdown (case A), and a two-step mechanism will be operative if tetrahedral intermediates are allowed to interconvert prior to breakdown (case B). The experimental results are consistent with the predictions of case A. In the presence of acetic acid, case A predicts that the acid will contribute only 1.6% to the overall rate, a negligible acceleration over the noncatalytic process, and case B predicts general acid catalysis to be an order of magnitude greater than the experimental result. It is concluded that the neutral hydrolysis of methyl acetate is mainly a cooperative one-step process, and that general acid catalysis by the acetic acid product does not occur.

Key words: cooperative mechanism, one-step mechanism, tetrahedral intermediate.

Résumé : Une stratégie théorique permettant de reproduire les vitesses expérimentales d'hydratation du formaldéhyde, de l'acétaldéhyde, de l'acétone et de la cyclohexanone ainsi que les vitesses d'hydratation de l'acétone catalysée par l'acide acétique et la 2-hydroxypyridine a été étendue aux résultats de l'hydrolyse neutre de l'acétate de méthyle rapportée dans la partie 1. Les calculs ont été effectués pour les mécanismes à une et à deux étapes, avec l'assistance coopérative d'une, deux ou trois molécules d'eau, en présence et en absence d'acide acétique produit. Les calculs permettent de prédire que, pour la réaction neutre, le mécanisme en une étape sera favorisé si les intermédiaires tétraédriques sont de courte vie et qu'ils ne donnent pas lieu à une interconversion avec leur rupture (cas A) et un mécanisme en deux étapes qui opérera si les intermédiaires peuvent subir une interconversion avant leur rupture (cas B). Les résultats expérimentaux sont en accord avec les prédictions du cas A. En présence d'acide acétique, le cas A prédit que l'acide ne contribuera qu'à 1,6% de la vitesse globale, une accélération négligeable par rapport au processus non catalytique; le cas B prédit une catalyse acide générale qui serait d'un ordre de grandeur plus important que le résultat expérimental. On peut donc en conclure que l'hydrolyse neutre de l'acétate de méthyle est principalement en processus coopératif en une étape et que la catalyse par l'acide acétique produit n'a pas lieu.

Mots-clés : mécanisme coopératif, mécanisme en une étape, intermédiaire tétraédrique.

Introduction

Background

In recent publications, we have discussed the neutral,[1,2] acetic acid-catalyzed,[3] and 2-hydroxypyridine-catalyzed[4] aqueous hydrations of acetone as exemplars of cooperativity, by which we mean that in each case concurrent C–O bond formation and proton transfer to oxygen take place through a bridge of solvent and (or) catalyst molecules (eq [1]). As originally posited by Eigen[5] and by Long and co-workers,[6] the cooperative mechanism offers a preferred neutral alternative to a multistep ionic mechanism in which charged intermediates are subjected to continuous solvation and desolvation as they appear and disappear.

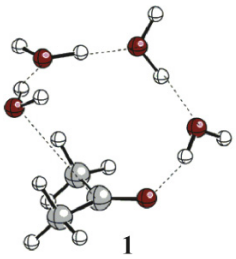
In the work of ref. 1, we found that experimental hydration rates in water solvent can be reproduced by a computational strategy that affords the free energy barriers exhibited by different reaction complexes as well as the concentrations of these complexes. This is achieved by HF/3–21G calculations,[7,8] in conjunction with the self-consistent reaction field (SCRF, Onsager) model[9,10] with a dielectric constant of 78.5. The previously optimized gas-phase structures were used to estimate the radius of the cavity for SCRF calculations. Transition structures were located by the reaction coordinate method.

Free energies of complexes, corrected for loss of translational and rotational degrees of freedom, are calculated using eq. [2].[1,2]

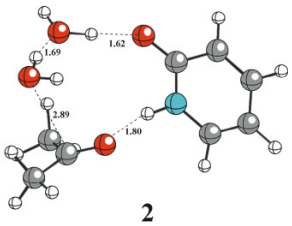
$$[2]\qquad \Delta G = \Delta H - T\Delta S_{\text{vib}} - 6RT\left\{\frac{\hbar\omega/kT}{\exp\left(\hbar\omega/kT\right)-1} - \ln\left[1-\exp\left(-\frac{\hbar\omega}{kT}\right)\right]\right\}$$

The first term on the right-hand side of eq. [2] is the enthalpy change calculated using the 3–21G basis set[8] and augmented by correction for the basis set superposition error (BSSE).[1,11] The second term on the right-hand side accounts for the intramolecular vibration entropy change, and it is also calculated by the Gaussian programme.[8] The third term on the right-hand side refers to the entropy change resulting from the loss of six low-frequency vibration modes representing rotational and translational motions in solution. These vibrations are described by a mass-dependent effective frequency ω, scaled as a root of molecular mass[2] and defined in terms of a single adjustable parameter ω_0, which is estimated numerically for water monomer (m_0 = 18 au) to be 20 cm^{-1}.[1]

At 298 K, the neutral hydration of acetone exhibits k_{obs} = 8.9 × 10^{-6} s^{-1}.[2] The calculated rate is k_{calc} = 19.6 × 10^{-6} s^{-1}, and the principal channel, comprising 97% of the overall reaction, proceeds via the four-water molecule complex **1**, whose free energy barrier and concentration are 11.34 kcal/mol (1 cal = 4.184 J) and 1.63 × 10^{-10} mol/L, respectively.



1



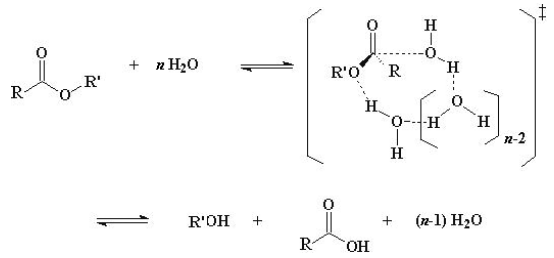
2

Addition of 1 mmol/L 2-hydroxypyridine to a 1 mol/L acetone solution leads to k_{obs} = 1.3 × 10^{-3} s^{-1} at 298 K, a catalytic effect of 150.[4] The calculated rate is k_{calc} = 2.1 × 10^{-3} s^{-1}, and 96% of the reaction, with a free energy barrier of 11.97 kcal/mol, proceeds via the 2-*pyridone* dihydrate **2**, whose concentration of 1.08 × 10^{-7} mol/L is almost 700 times greater than that of **1**. The "bifunctional catalysis"[12] exhibited by 2-hydroxypyridine therefore resides in the exceptional stability of **2**.

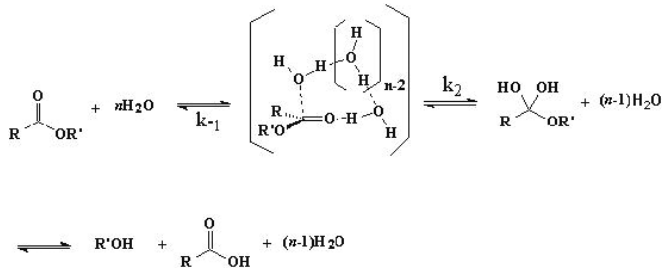
Neutral ester hydrolysis

The present work was undertaken to determine whether an appropriate extension of the cooperative mechanism,

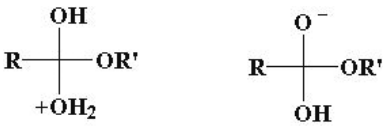
Scheme 1.



Scheme 2.



e.g., Scheme 1 or 2, could be relevant in neutral ester hydrolysis in water solvent. It will be noticed that Scheme 1 suggests the possibility of a one-step process that bypasses the tetrahedral intermediate of Scheme 2,[13] which is well established for acid-catalyzed (**3a**) and base-catalyzed (**3b**) ester hydrolysis.



3a **3b**

In contrast to the extensive literature on acid- and base-catalyzed ester hydrolysis,[13–15] there has been only sporadic interest in neutral hydrolysis (Table 1). At 298 K (Table1, entry 1) the hydrolysis of ethyl acetate proceeds with a first-order rate constant of 2.47 × 10^{-10} s^{-1} ($\Delta G^{\ddagger}$ = 30.6 kcal/mol[21]).

Temperature dependence studies of the hydrolyses of alkyl- and aryl-substituted trifluoroacetates in aqueous acetone lead to rate constants of 1.67–5.67 × 10^{-8} s^{-1} at 25 °C (Table 1, entry 2). For the hydrolysis of chloromethyl chloroacetate (Table 1, entry 3), $\Delta H^{\ddagger}$ = 11.8 kcal/mol and $\Delta S^{\ddagger}$ = –37 cal mol^{-1} K^{-1} at 25 °C. From the rates of hydrolysis of ethyl trifluorothiolacetate in the presence of potassium acetate – acetic acid buffers, and extrapolation to zero buffer concentration, a neutral rate constant of 5.02 × 10^{-3} s^{-1} at 25 °C is obtained (Table 1, entry 4), and proton inventory experiments suggest that there are two to three hydrons in flight. The kinetics and activation parameters for the hydrolysis of ethyl formate in the temperature range 30–50 °C provide a rate constant of 5.0 × 10^{-6} s^{-1} at 298 K (Table 1, entry 5).

The theoretical treatment of neutral ester hydrolysis is even less well-advanced than the limited number of experi-

mental studies just cited. For the hydrolysis of methyl formate via Schemes 1 and 2, with n = 3, gas-phase B3LYP/6–31G* geometry optimizations, followed by single-point calculations with a polarized continuum model of bulk water, give free energy barriers of 45.66 and 48.05 kcal/mol, respectively, for two-step and one-step mechanisms.[22]

For a two-step gas-phase hydrolysis of ethyl acetate with n = 2 (Scheme 2), 6–31+G* calculations afford a free energy barrier of 64.3 kcal/mol.[21] In the B3LYP/6–31G*/SCRF calculations of Yamabe et al. on the aqueous hydrolysis of ethyl acetate in the presence of different numbers of active water molecules,[23] the concerted (one-step) free energy barrier ranges between 42.9 and 47.9 kcal/mol, much higher than the experimental $\Delta G^{\ddagger}$ of Skrabal and Zahorka.[16] A two-step mechanism with $k_{-1} \approx k_2$ gives free energy barriers close to the experimental $\Delta G^{\ddagger}$, the reaction via a four-water molecule complex being favoured.

Each of the theoretical studies just cited has focused on the magnitudes of calculated barriers. However, as in the hydration studies discussed earlier, we presume that the calculation of hydrolysis *rates* will require that the *concentrations* of reaction complexes also be taken into account.

Present work

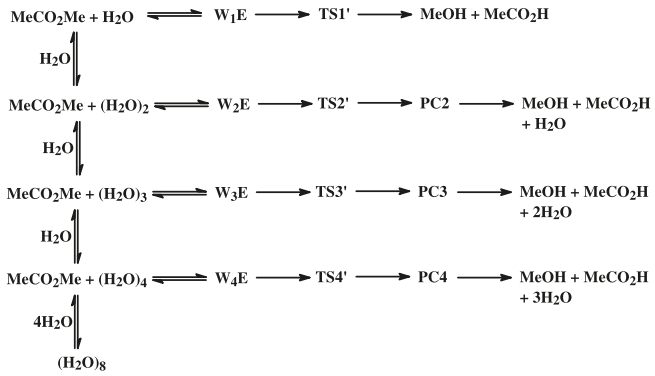
In the present work, of which this is Part 2, we have applied our computational strategy[1,2] to study the neutral hydrolysis of methyl acetate. Since the acetic acid product of hydrolysis catalyzes the reaction,[24] the notion of cooperativity has also been extended to this reaction. The kinetic experiments designed to test the predictions of Part 2 are found in Part 1.[24]

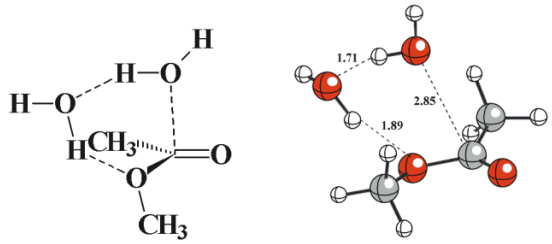
Neutral hydrolysis

One-step mechanism

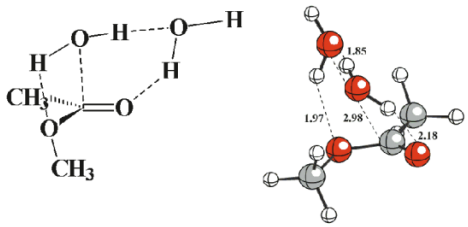
In Scheme 1, the addition of a water molecule to the carbonyl group takes place in concert with proton transfer to the methoxy group. Calculations were performed for n = 1–4 to obtain the free energies of the stationary structures of Scheme 3 in water solvent, where $\mathbf{W}_n\mathbf{E}$ is a cyclic reactant complex of methyl acetate (**E**) with n water molecules (**W**; n = 1–4), **TS***n*′ is a cyclic transition structure derived from $\mathbf{W}_n\mathbf{E}$, and **PC***n* is a product complex of methanol, acetic acid, and (n – 1) water molecules.

Scheme 3.





4b



4c

More than one $\mathbf{W}_n\mathbf{E}$ complex is possible when n > 1, e.g., **4b** and **4c** for n = 2. All conceivable topologies of reactant complexes of Scheme 3 were taken into account.

Table 2 lists the ΔG and $\Delta G^{\ddagger}$ calculated at 298 K. Structures **4a**, **4b–4c**, **4d–4f**, and **4g–4k** are, respectively, one-water, two-water, three-water, and four-water $\mathbf{W}_n\mathbf{E}$, and structures **5a–5k** are the **TS***n*′ derived from these complexes. (Structures not shown in the text and full Tables 2–9 are available in the Supplementary data below.)

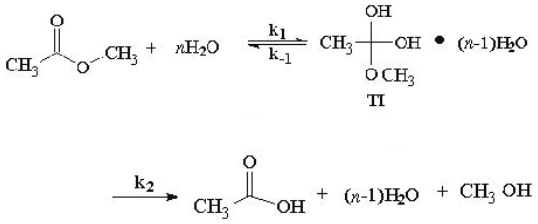
Scheme 4.



Two-step mechanism

Scheme 4 describes a two-step neutral ester hydrolysis via **TI**, a tetrahedral intermediate. In the network of reactions shown in Scheme 5, the hydrolysis proceeds from the reactant complexes $\mathbf{W}_n\mathbf{E}$, via a first transition structure $\mathbf{TS}n''$ to the tetrahedral intermediates $\mathbf{TI}n$, and then via a second transition structure $\mathbf{TS}n'''$ to the product complexes $\mathbf{PC}n$. As before, more than one $\mathbf{W}_n\mathbf{E}$ complex is possible for $n > 1$. All conceivable topologies of reactant complexes of Scheme 5 were taken into account.

Tables 3 and 4 list the ΔG and $\Delta G^{\ddagger}$ calculated at 298 K. Structures **6a**, **6b–6c**, **6d–6g**, and **6h–6o** are, respectively, one-water, two-water, three-water, and four-water $\mathbf{W}_n\mathbf{E}$, structures **7a–7o** refer to $\mathbf{TS}n''$, the transition structures connecting $\mathbf{W}_n\mathbf{E}$ to the tetrahedral intermediates **8a–8o**, and structures **9a–9o** refer to $\mathbf{TS}n'''$, the transition structures connecting the tetrahedral intermediates to the products.

The theoretical rate constant

As in our previous works,[1–4] the hydrolysis rate constant can be calculated by taking into account pre-equilibrium

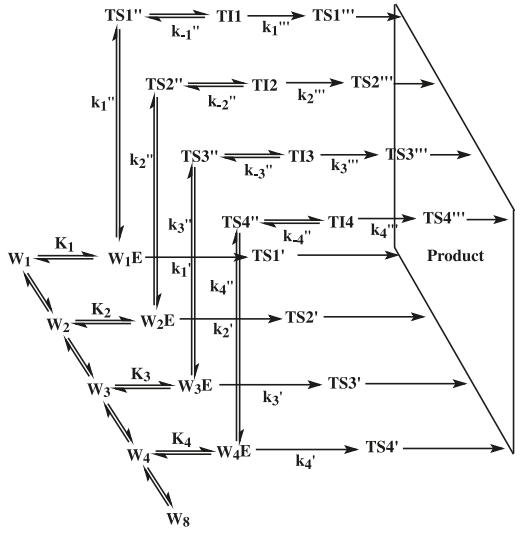
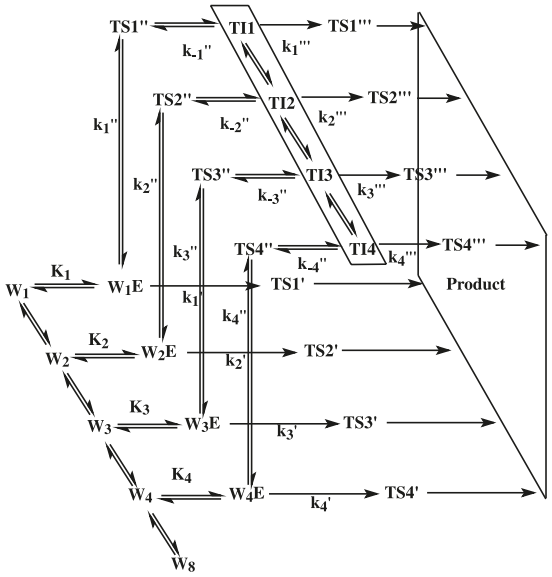
Scheme 6.



Scheme 7.



among water clusters and reactant complexes, as shown in Scheme 6, combining one- and two-step channels of Schemes 3 and 5. There is, however, an additional complication here because **TI**–water complexes may interconvert. To treat this possibility, two limiting cases were considered: in case (A) the **TI** are short-lived and do not undergo exchange with the solvent (Scheme 6); in case (B) the **TI** are sufficiently stable to allow equilibration among complexes containing different numbers of water molecules (Scheme 7). In either case, $\mathbf{W}_n$ refers to n-mers of water, **E** is the ester, $\mathbf{K}_n$ is the equilibrium constant for the formation of $\mathbf{W}_n\mathbf{E}$, k'_n is the rate constant of a reaction channel of the one-step mechanism, and k''_n, k''_{-n}, and k'''_n are the rate constants of the two-step mechanism.

As already noted, more than one $\mathbf{W}_n\mathbf{E}$ complex is possible for $n > 1$. Those that interconvert through a single step mechanism are labelled $\mathbf{W}_n\mathbf{E}'$, and those that interconvert through a two-step mechanism are labelled $\mathbf{W}_n\mathbf{E}''$. The overall concentration $[\mathbf{W}_n\mathbf{E}]$ is,

$$[\mathrm{W}_n\mathrm{E}] = \sum[\mathrm{W}_n\mathrm{E}'] + \sum[\mathrm{W}_n\mathrm{E}'']$$

and the independent relationships among the concentrations of $\mathbf{W}_n$ and $\mathbf{W}_n\mathbf{E}$ are,

$$[\mathrm{W}_n] = K_n^w[\mathrm{W}_1]^n$$
$$[\mathrm{W}_n\mathrm{E}'] = K'_n[\mathrm{W}_n][\mathrm{E}] = K'_nK_n^w[\mathrm{W}_1]^n[\mathrm{E}]$$
$$[\mathrm{W}_n\mathrm{E}''] = K''_n[\mathrm{W}_n][\mathrm{E}] = K''_nK_n^w[\mathrm{W}_1]^n[\mathrm{E}]$$

In addition, the following two equations of material balance apply to these concentrations,

$$[3] \qquad C_{\mathrm{W}} = \sum_n n[\mathrm{W}_n] + \sum_n n[\mathrm{W}_n\mathrm{E}]$$

$$[4] \qquad C_{\mathrm{E}} = [\mathrm{E}] + \sum_n [\mathrm{W}_n\mathrm{E}]$$

where C_{W} and C_{E} are the analytical concentrations of water (55.5 mol/L) and ester, respectively.

[c]Rate constant for **$TIn \rightarrow TSn''$**, the reverse reaction.
[d]The reverse process dominates.

Limiting case A: No interconversion between TI*n* (Scheme 6)

In this case, all two-step channels are considered to be independent of each other. Application of the steady-state approximation leads to a set of effective rate constants,

$$[5] \qquad k_{\text{eff},\,n} = \frac{k''_n k'''_n}{(k''_{-n} + k'''_n)}$$

resulting in eqs. [6] and [7] for the overall rate of hydrolysis and its pseudo first-order rate constant k.

$$[6] \qquad v = kC_E = \sum k'_n[W_nE'] + \sum k_{\text{eff},\,n}[W_nE''']$$

$$[7] \qquad k = \frac{\sum k'_n K'_n[W_n] + \sum k''_n K''_n[W_n]}{1 + \sum K'_n[W_n] + \sum K''_n[W_n]}$$

Table 5 summarizes the results for the hydrolysis of a 1.00 mol/L methyl acetate solution at 298 K. According to this analysis, at 298 K the rate of hydrolysis is 1.34×10^{-8} s^{-1}, 72% of the reaction proceeds by a one-step mechanism from the four-water complex **4g** (Fig. 1) and 26% by a two-step mechanism from the four-water complex **6i** (Fig. 2).

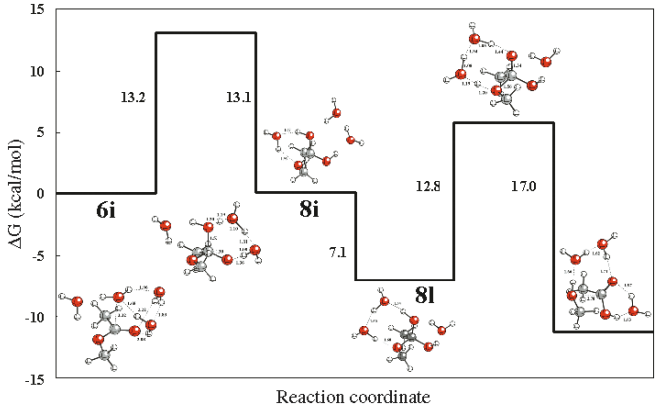
[a]Contribution to the reaction.
[b]Rate constant for **$W_nE \rightarrow TSn''$**, the forward reaction.
[c]Rate constant for **$TIn \rightarrow TSn''$**, the reverse reaction.
[d]The reverse process dominates.

Fig. 3. Reaction coordinate of the major hydrolysis channel of limiting case B.



tion from $\mathbf{W}_n\mathbf{E}''$ to $\mathbf{TI}n$, given by eq. [8], can be negative if the reverse process dominates.

$$[8] \qquad v''_n = k'_n[\mathrm{W}_n\mathrm{E}''] - k''_{-n}[\mathrm{TI}n]$$

The overall rate of the first step of the two-step process is

$$[9] \qquad v'' = \sum v_n = \sum k''_n[\mathrm{W}_n\mathrm{E}'] - \sum k''_{-n}[\mathrm{TI}n]$$

and the rate of the second step is

$$[10] \qquad v''' = \sum v'''_n = \sum k'''_n[\mathrm{TI}n]$$

Applying the steady-state approximation to the overall concentration of TI gives

$$[11] \qquad \frac{\mathrm{d}[\mathrm{TI}]}{\mathrm{d}t} = \sum k''_n[\mathrm{W}_n\mathrm{E}''] - \sum (k''_{-n} + k'''_n)[\mathrm{TI}n] = 0$$

leading to

$$[12] \qquad \sum k''_n[\mathrm{W}_n\mathrm{E}''] = \sum (k''_{-n} + k'''_n)[\mathrm{TI}n]$$

Since $[\mathrm{TI}n] = K_{\mathrm{TI}n}[\mathrm{TI}_1][\mathrm{W}_1]^{n-1}$ where **TI**1 is unsolvated **TI**, and $K_{\mathrm{TI}n}$ are equilibrium constants relating $[\mathrm{TI}n]$ to [TI1], eq. [12] can be converted to,

$$[13] \qquad \sum k''_n[\mathrm{W}_n\mathrm{E}''] = \{\sum (k''_{-n} + k'''_n)K_{\mathrm{TI}n}[\mathrm{W}_1]^{n-1}\}[\mathrm{TI}1]$$

which gives

$$[14] \qquad [\mathrm{TI}1] = \frac{\sum k''_n[\mathrm{W}_n\mathrm{E}'']}{\sum (k''_{-n} + k'''_n)K_{\mathrm{TI}n}[\mathrm{W}_1]^{n-1}}$$

Since the tetrahedral intermediate hydrates **TI***n* are no longer short-lived, their contributions to C_{W} and C_{E} have to be taken into account comparable to the reactant complexes $\mathbf{W}_n\mathbf{E}$, which expands eqs. [3] and [4] to,

$$[15] \qquad C_{\mathrm{W}} = \sum_n n[\mathrm{W}_n] + \sum_n n[\mathrm{W}_n\mathrm{E}] + \sum_n (n-1)[\mathrm{TI}n]$$

$$[16] \qquad C_{\mathrm{E}} = [\mathrm{E}] + \sum_n [\mathrm{W}_n\mathrm{E}] + \sum_n [\mathrm{TI}n]$$

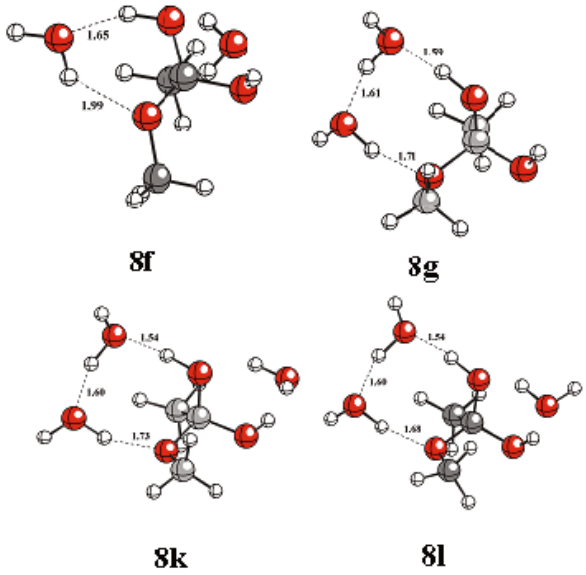
The overall rate of hydrolysis and its pseudo first-order rate constant k can then be found from eqs. [17] and [18].

$$[17] \qquad v = kC_{\mathrm{E}} = \sum k'_n[\mathrm{W}_n\mathrm{E}'] + \sum k'''_n[\mathrm{TI}n]$$

$$[18] \qquad k = \frac{\sum k'_n K'_n[\mathrm{W}_n] + \sum k'''_n[\mathrm{TI}n]}{1 + \sum K'_n[\mathrm{W}_n] + \sum K''_n[\mathrm{W}_n] + \sum [\mathrm{TI}n]}$$

Table 6 summarizes the results for the hydrolysis of a 1.00 mol/L methyl acetate solution at 298 K. In the limiting case B, the rate of hydrolysis is 35.9×10^{-8} s^{-1}, 27 times faster than the rate calculated for the limiting case A, and over 97% of the reaction proceeds by a two–step mechanism via **8f**, **8g**, **8k**, and **8l**, the **TI** having the lowest second-step barrier.

The situation is summarized in the schematic reaction profile of Fig. 3, according to which the four-water complex **6i** is converted to **8i**, which equilibrates with **8l**, which proceeds to the products.

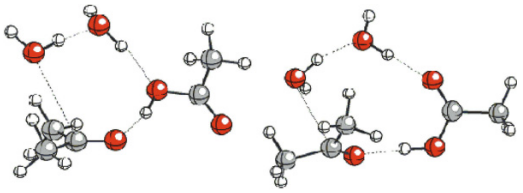


Limiting cases A and B are distinguishable

The calculated reaction rates, 1.34×10^{-8} s^{-1} for case A, in which a one-step four-water mechanism is preferred, and 35.9×10^{-8} s^{-1} for case B, in which a two-step four-water mechanism predominates, would appear to be sufficiently different for the two methods to be distinguishable. The observed rate is 0.17×10^{-8} s^{-1}.[24] It can be concluded that the neutral hydrolysis of methyl acetate mainly proceeds by a one-step cooperative mechanism, as described by limiting case A.

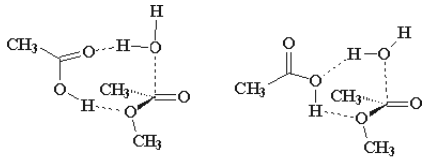
General acid catalysis by acetic acid

Acetic acid provides cooperative *general* acid catalysis of the aqueous hydration of acetone, mainly via complexes **10** and **11**.[3] However, despite the fact that spontaneous hydrolysis of methyl acetate is an autocatalytic process, subject to *specific* acid catalysis by the acetic acid product,[24] no general acid catalysis was experimentally observed in that case. To examine this situation theoretically, we augmented Schemes 6 and 7 by incorporating in them the acetic acid-containing species. The resultant kinetic networks are shown in Schemes 8 and 9 for limiting cases A and B, respectively.



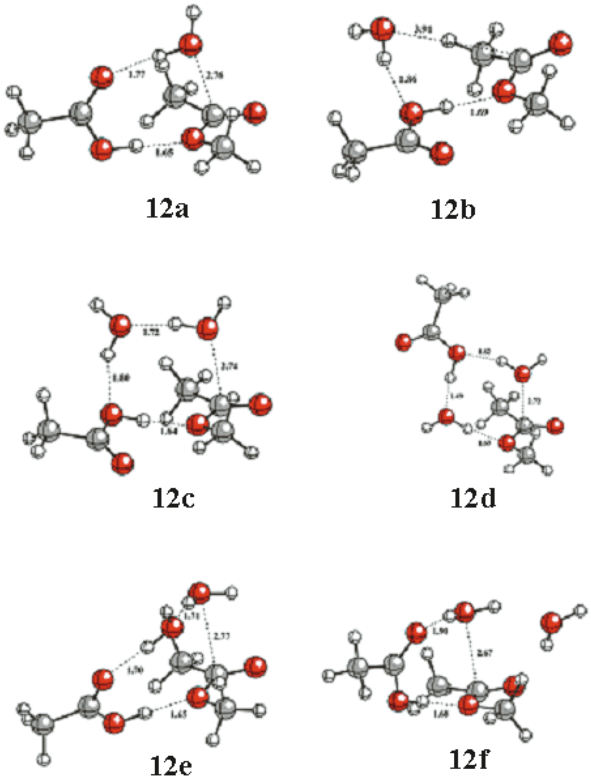
10 11

In these Schemes $\mathbf{W}_n\mathbf{A}$ are complexes of acetic acid with n water molecules and $\mathbf{W}_n\mathbf{EA}$ are cyclic complexes of methyl acetate with one molecule of acetic acid and n water molecules. There is more than one complex for each $\mathbf{W}_n\mathbf{EA}$. For example, **12a** and **12b** are possibilities for n = 1. All conceivable topologies of reactant complexes for n = 1–3 were taken into account.[25]



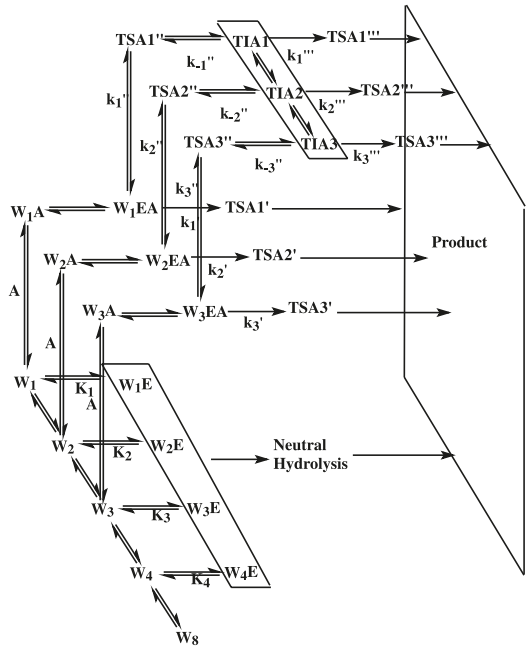
12a 12b

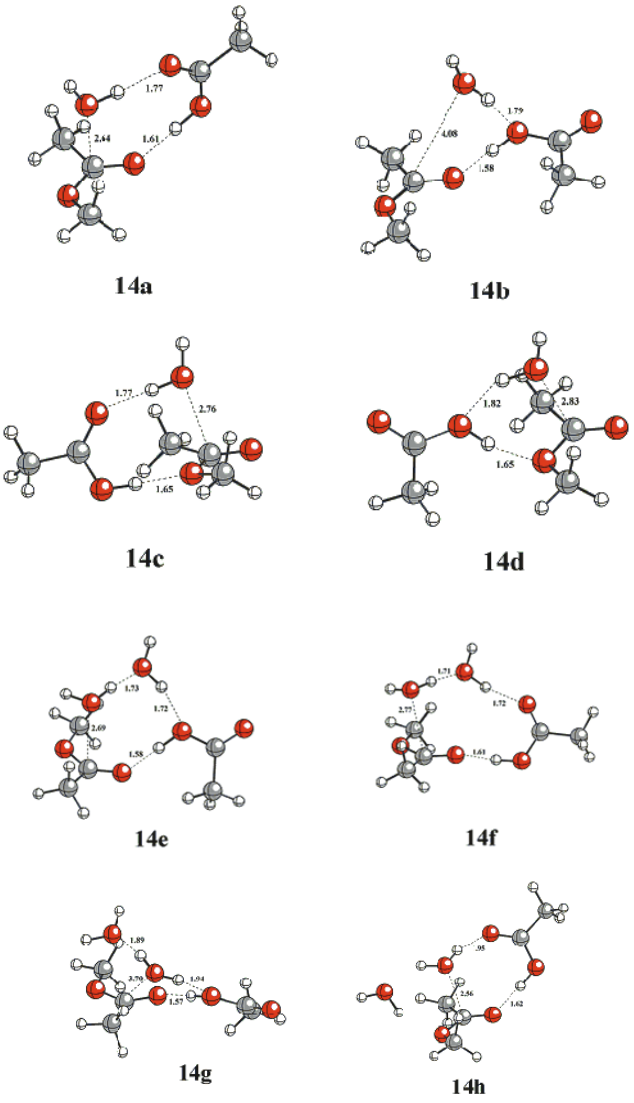
Cyclic transition states **TSA*n***′ (structures **13a–13f**) are derived from $\mathbf{W}_n\mathbf{EA}'$ (structures **12a–12f**). Tetrahedral intermediates **TIA*n*** (structures **16**) are obtained from $\mathbf{W}_n\mathbf{EA}''$ (structures **14**) via transition states **TSA*n***″ (structures **15**) and further transform into product compexes via transition states **TSA*n***‴ (structures **17**).



12a 12b 12c 12d 12e 12f

Scheme 9.





14a 14b 14c 14d 14e 14f 14g 14h

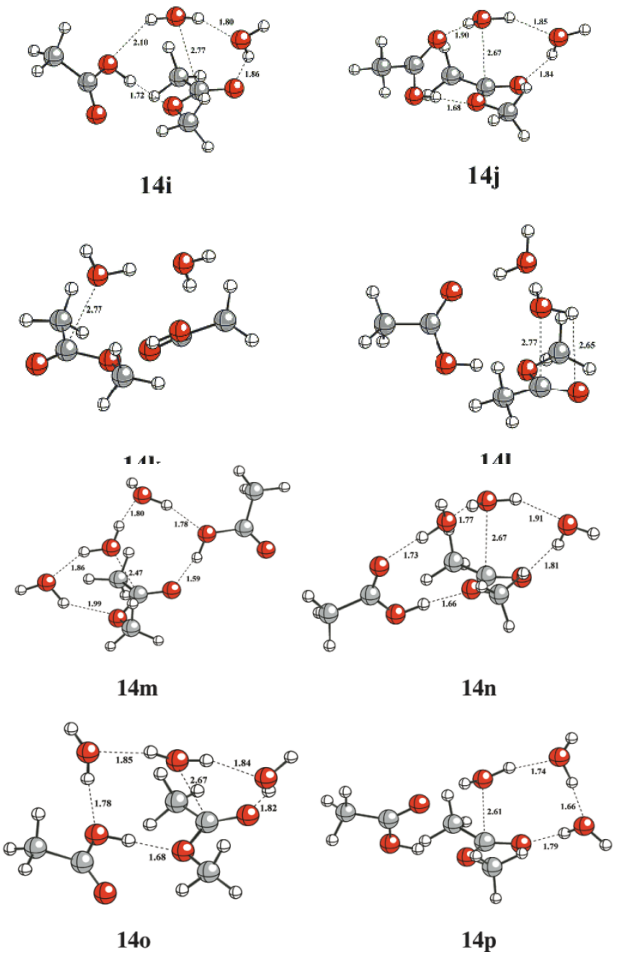


Table 7 lists the ΔG and $\Delta G^{\ddagger}$ at 298 K calculated for species involved in Scheme 8, which were then used to calculate the partial and overall rate constants of hydrolysis of 1 mol/L methyl acetate in the presence of 1 mol/L acetic acid by a trivial extension of the method described in the previous section. The results are summarized in Table 8 (for the limiting case A) and Table 9 (for the limiting case B).

The analysis of these results reveals that on the assumption that tetrahedral intermediates are short-lived and do not interconvert (case A), the acetic-acid-involving channels contribute only 1.6% to the overall rate through non-ionic processes and thus produce a negligible acceleration over the non-catalytic process. This is consistent with the conclusion of Part 1[24] that the catalysis by acetic acid is entirely *specific*.

On the other hand in case B, the computations predict a strong (four orders of magnitude) effect of *general* catalysis by acetic acid, inconsistent with experiment. We therefore conclude that, with and without acetic acid, the non-ionic hydrolysis of methyl acetate predominantly proceeds by a concerted one-step mechanism.

Mapping the sirodesmin PL biosynthetic pathway — A remarkable intrinsic steric deuterium isotope effect on a ^{1}H NMR chemical shift determines β-proton exchange in tyrosine

M. Soledade C. Pedras and Yang Yu

Abstract: Sirodesmin PL is both an antibiotic and a phytotoxin produced by a fungal plant pathogen (*Leptosphaeria maculans,* asexual stage *Phoma lingam*) that causes blackleg disease on crucifers. To determine potential biosynthetic precursors of sirodesmin PL, deuterated compounds were synthesized and incubated with cultures of *L. maculans*. Incorporations of deuterium into sirodesmin PL (**7**) and its precursor phomamide (**4**) were determined using ^{1}H and ^{13}C NMR spectroscopy, LC-HRMS-ESI and HRMS-EI spectrometry. Spectroscopic analyses established that [3,3-$^2H_2$]L-tyrosine (**1a**), [3,3-$^2H_2$]*O*-prenyl-L-tyrosine (**9a**), [3,3,5′,5′,5′-$^2H_5$]*O*-prenyl-L-tyrosine (**9b**), and [5,5-$^2H_2$]phomamide (**4a**) were incorporated efficiently into sirodesmin PL (**7**). Interestingly, an unexpected "twist" revealed that one of the β-deuteria (*pro-R*) of [3,3-$^2H_2$]L-tyrosine (**1a**) was exchanged stereospecifically before incorporation into sirodesmin PL (**7**). As well, our studies revealed that *O*-prenyl-L-tyrosine is likely to be the first committed precursor en route to sirodesmin PL (**7**).

Key words: biosynthesis, isotope effect, deuterium incorporation, *Leptosphaeria maculans*, phytotoxin, sirodesminbiosynthèse, effet isotopique, incorporation de deutérium, , *Leptosphaeria maculans*, phytotoxine, sirodesmine.

Résumé : La sirodesmine PL est à la fois un antibiotique et une phytotoxine produite par un champignon pathogène (*Leptosphaeria maculans*, stade asexuel du Phoma lingam) qui provoque la maladie de la jambe noire chez les crucifères. Dans le but de déterminer la nature des précurseurs biosynthétiques potentiels de la sirodesmine PL, on a effectué la synthèse de produits deutériés qui ont été incubés avec des cultures de *L. maculans*. L'incorporation du deutérium dans la sirodesmine PL (7) et dans son précurseur, la phomamide (**4**), a été déterminé en faisant appel à la RMN du ^{1}H et du ^{13}C ainsi que par chromatographie liquide liée à la spectrométrie de masse à haute résolution avec ionisation par impact électronébulisation (CL-SMHR-IEN) et par spectrométrie de masse à haute résolution avec ionisation par impact électronique (SMHR-IE). Les analyses spectroscopiques ont permis de déterminer que la [3,3-$^2H_2$]L-tyrosine (**1a**), la [3,3-$^2H_2$]*O*-prényl-l-tyrosine (**9a**), la [3,3,5′,5′,5′-$^2H_5$]*O*-prényl-l-tyrosine (**9b**) et la [5,5-$^2H_2$]phomamide (**4a**) s'incorporent d'une façon efficace dans la sirodesmine PL (**7**). Un fait intéressant à été noté, à savoir celui qu'un des atomes de deutérium en β, le *pro-R*, de la [3,3-$^2H_2$]L-tyrosine (**1a**) s'échange d'une façon stéréospécifique avant l'incorporation dans la sirodesmine PL (**7**). Des plus, nos études ont révélé que la *O*-prényl-l-tyrosine est probablement le premier précurseur dédié en route vers la sirodesmine PL (**7**).

[Traduit par la Rédaction]

Introduction

Mapping biosynthetic pathways used by living organisms to assemble complex libraries of natural products is generally accomplished using isotopically labeled precursors. The choice of isotope depends on the chemical structure of the natural product and hypothetical precursors. Currently, the use of stable isotopes is common due to the availability of highly sensitive analytical tools, while a few decades ago only radioactive isotopes were thinkable.[1] Nonetheless, great challenges remain, particularly for unusual and complex pathways assembled by nonribosomal peptide synthases, such as those producing sirodesmins.[2] Sirodesmins are epipolythio-2,5-dioxopiperazines (ETPs) produced by two unrelated fungal species, *Sirodesmium diversum* (sirodesmins A–G)[3] and *Leptosphaeria maculans* (asexual stage *Phoma lingam*, sirodesmin PL, deacetylsirodesmin PL,[4] and sirodesmins H,[5] J, and K[6]). Sirodesmin PL (**7**) is both an antibiotic and a phytotoxin, i.e., toxic to plant cells. Interest in ETPs has increased over the past years because of their biological activity[7] and potential ecological roles. The current focus on sirodesmin PL (**7**) is motivated by its potential involvement in the interaction of the plant pathogen *L. maculans* with its host plants.[8,9]

The primary biosynthetic precursors of sirodesmin PL (**7**) together with its biosynthetic pathway were proposed based on results of experiments using radiolabeled (^{3}H and ^{14}C) and stable (^{13}C) isotopes,[10] and later on confirmed by Bu'Lock and Clough.[11] The proposed pathway involved dioxopiperazine formation between L-tyrosine (**1**) and L-serine (**2**), isoprenylation with dimethylallylpyrophosphate (DMAPP) to form phomamide (**4**), followed by a number of oxidative rearrangements. As well, the isolation of a toxin structurally related to sirodesmin PL (**7**), phomalirazine (**6**), led us to propose a modification of the Curtis–Férézou pathway.[12]

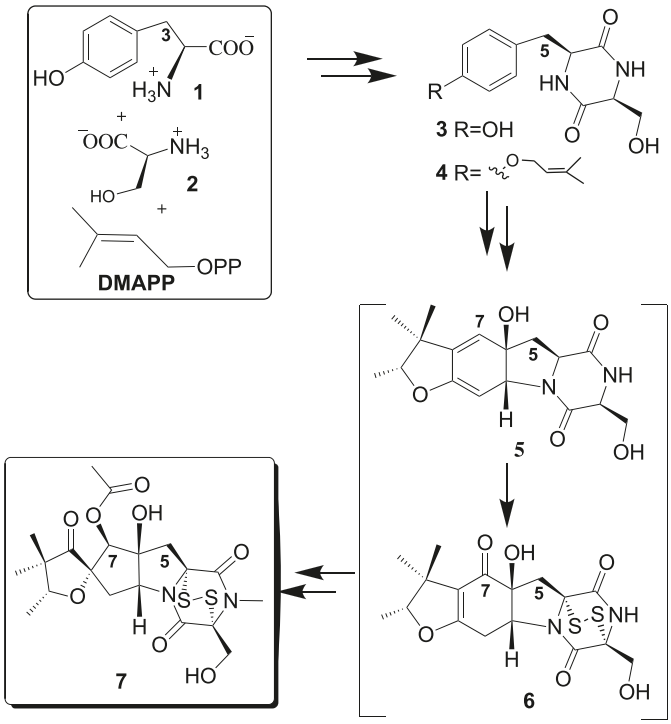
Scheme 1. Biosynthetic pathway of sirodesmin PL (**7**): precursors L-tyrosine (**1**), L-serine (**2**), and DMAPP (dimethylallylpyrophosphate) and potential intermediates **3**–**6**.



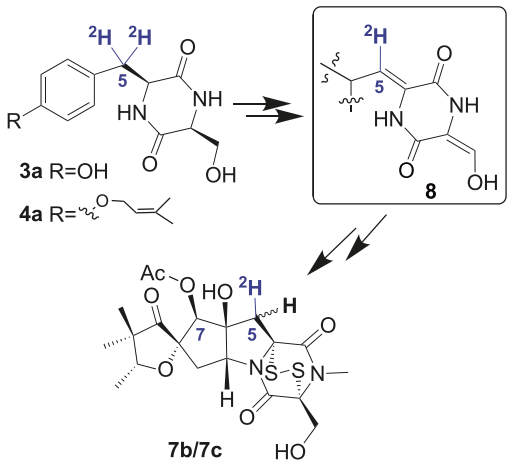
The recent cloning of a gene cluster involved in the biosynthesis of sirodesmin PL (**7**) suggested a more detailed pathway that took into account the ascribed functions of the cloned genes.[8] A simplified pathway showing relevant potential intermediates is depicted in Scheme 1.

These recent developments reawakened our interest in the sirodesmin PL (**7**) biosynthetic pathway. Specific goals to uncover the structure(s) of intermediate(s) immediately preceding insertion of the disulfide bridge and to determine the stage at which prenylation occurred directed our experimental design. Based on the structures of metabolites recently isolated,[13] we hypothesized that a compound containing a bis-ylidine 2,5-dioxopiperazine moiety (**8**) might be a plausible substrate for enzymatic introduction of the disulfide bridge into sirodesmin PL (**7**). If **8** was a precursor, then incorporation of dideuterated [3,3-$^2H_2$]L-tyrosine (**1a**) or [5,5-$^2H_2$]phomamide (**4a**) would lead to the incorporation of only one deuterium into sirodesmin PL (**7**, ^{2}H–C-5, Scheme 2). Alternatively, the presence of two deuteria in sirodesmin PL would eliminate **8** from this biosynthetic map (Scheme 2). Toward this end, we describe work to establish biosynthetic precursors of phomamide (**4**) and sirodesmin PL (**7**).

Results and discussion

The deuterated compounds [3,3-$^2H_2$]*O*-prenyl-L-tyrosine (**9a**),[14] [3,3,5′,5′,5′-$^2H_5$]*O*-prenyl-L-tyrosine (**9b**), [5,5-$^2H_2$]cyclo-L-Tyr-L-Ser (**3a**), and [5,5-$^2H_2$]phomamide (**4a**)[15] were prepared from [3,3-$^2H_2$]L-tyrosine (**1a**) following modifications of previously reported methods, as described in the Supplementary data. HRMS-EI analyses indicated that the percentage of deuterium in the synthetic deuterated compounds was higher than 98%.

Scheme 2. Hypothetical intermediate **8** for introduction of sulfur into sirodesmin PL (**7**).



Incorporation experiments using deuterated compounds [3,3-$^2H_2$]L-tyrosine (**1a**), [3,3-$^2H_2$]*O*-prenyl-L-tyrosine (**9a**), [3,3,5′,5′,5′-$^2H_5$]*O*-prenyl-L-tyrosine (**9b**), [2,3,3-$^2H_3$]L-serine (**2a**), [5,5-$^2H_2$]phomamide (**4a**), and [5,5-$^2H_2$]cyclo-L-Tyr-L-Ser (**3a**) were carried out using a wild type isolate of *L. maculans*. After incubation of the fungal cultures with deuterated compounds, cultures were extracted and phomamide (**4**) and sirodesmin PL (**7**) were purified as described in the experimental. Similar conditions were used for control experiments in which the corresponding natural abundance compounds were administered to fungal cultures. Incorporation of deuterium, or lack of it, was determined using ^{1}H and ^{13}C NMR spectroscopy, LC-HRMS-ESI and HRMS-EI spectrometry.

First analysis of HRMS data established that (*i*) [3,3-$^2H_2$]L-tyrosine (**1a**), [3,3-$^2H_2$]*O*-prenyl-L-tyrosine (**9a**), [3,3,5′,5′,5′-$^2H_5$]*O*-prenyl-L-tyrosine (**9b**), and [5,5-$^2H_2$]phomamide (**4a**) were incorporated efficiently (>10%) into sirodesmin PL (**7**); (*ii*) [3,3-$^2H_2$]L-tyrosine (**1a**), [3,3-$^2H_2$]*O*-prenyl-L-tyrosine (**9a**), and [3,3,5′,5′,5′-$^2H_5$]*O*-prenyl-L-tyrosine (**9b**) were incorporated efficiently (>20%) into phomamide (**4**); (*iii*) [5,5-$^2H_2$]cyclo-L-Tyr-L-Ser (**3a**) and [2,3,3-$^2H_3$]L-serine (**2a**) were incorporated poorly (<5%) into either phomamide (**4**) or sirodesmin PL (**7**) (Table 1). Detailed analyses of spectroscopic data obtained for phomamide (**4**) and sirodesmin PL (**7**) isolated from fungal cultures incubated with deuterated compounds (summarized in Table 1 and Fig. 1) provided important additional information, as described below.

The HRMS-EI data of purified phomamide (**4**) isolated from cultures incubated with [3,3-$^2H_2$]L-tyrosine (**1a**) indicated that its $[M + 1]^+$ and $[M + 2]^+$ were about 20% and 12% higher, respectively, than those of control samples, suggesting that 20% of phomamide (**4**) was monodeuterated (equation for calculation is shown in Table 1) and 12% was dideuterated, i.e., 32% of phomamide (**4**) resulted from incorporation of [3,3-$^2H_2$]L-tyrosine (**1a**) (Table 1, entry 1). The ^{1}H NMR spectrum (provided in the Supplementary data) of phomamide (**4**) showed that the protons H-5a (δ_H 3.30, dd, J = 14.0, 3.5 Hz) and H-5b (δ_H 2.99, J = 14.0, 8.9 Hz) integrated for ca. 0.7 and 0.9, respectively, whereas control samples showed the expected integration of ca. 1 for H-5a and H-5b (H-5a (δ_H 3.30) / H-5b (δ_H 2.99) = 1.0). The

Table 1. Percentages of incorporation of deuterated compounds into phomamide (**4**) and sirodesmin PL (**7**) in cultures of *Leptosphaeria maculans.*

Entry	Deuterated compound	Phomamide (**4**) (% of ^2H, analytical method)	Sirodesmin PL (**7**) (% of ^2H, analytical method)
1	 **1a**	32 (HRMS-EI: monodeuterated = 20; dideuterated = 12)[a]; 30 (^1H NMR, H_2-5a,5b)	32 (HRMS-EI: monodeuterated = 19; dideuterated = 13)[a]; 30 (^1H NMR, H-7)[b]
2	 **9a**	41 (HRMS-EI: monodeuterated = 24; dideuterated = 17)[a]; 39 (^1H NMR, H_2-5a,5b)	35 (HRMS-EI: monodeuterated = 21; dideuterated = 15)[a]; 32 (^1H NMR, H-7)[b]
3	 **2a**	3 (HRMS-EI)[a]	4 (HRMS-EI)[a]
4	 **4a**	—	30 (HRMS-EI: monodeuterated = 4; dideuterated = 26)[a]; 27 (^1H NMR, H-7)[b]
5	 **3a**	3 (HRMS-EI: monodeuterated = 1; dideuterated = 2)[a]	2 (HRMS-EI: monodeuterated = 0; dideuterated = 2)[a]
6	 **9b**	23 (HRMS-ESI: tetradeuterated = 16; pentadeuterated = 7)[c]; 26 (^1H NMR, H_2-5a,5b)	13 (HRMS-ESI: tetradeuterated = 9; pentadeuterated = 4)[c]; 23 (^1H NMR, H-7)[b]

[a]The percentage of incorporation (*I*) was determined by HRMS-EI and was calculated using the formula $I = \{([M + n]^+ - [M + n]^+_{Ctl}) / ([M]^+ + [M + 1]^+ + [M + 2]^+)\} \times 100$; $n = 1, 2$; $[M + n]^+$ = intensity of deuterated molecular ion; $[M + n]^+_{Ctl}$ = intensity of molecular ion of control samples (natural abundance).

[b]Resolution of signals was enhanced through a Lorentz–Gaussian lineshape transformation (gb = 0.3, lb = –1).

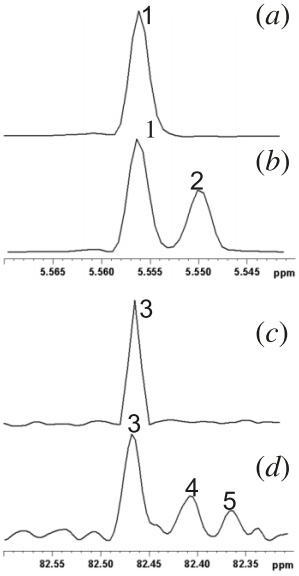
[c]The percentage of incorporation (*I*) was determined by HRMS-ESI (positive mode) and was calculated using the formula $I = \{([M + 1 + n]^+ - [M + 1 + n]^+_{Ctl}) / ([M + 1]^+ + [M + 2]^+ + [M + 5]^+ + [M + 6]^+)\} \times 100$; $n = 4, 5$; $[M + n]^+$ = intensity of deuterated molecular ion; $[M + n]^+_{Ctl}$ = intensity of molecular ion of control samples (natural abundance).

percentage of deuterium at the C-5 of phomamide resulting from feeding [3,3-$^2H_2$]L-tyrosine (**1a**) was calculated to be 30% for H-5a (δ_H 3.30) and 11% for H-5b (δ_H 2.99). These ^1H NMR data indicated that about 11% of phomamide (**4**) was dideuterated, whereas the remaining 19% of phomamide was monodeuterated (Table 1, entry 1), in complete agreement with the HRMS data. Similar results were obtained when cultures were incubated with [3,3-$^2H_2$]*O*-prenyl-L-tyrosine (**9a**, Table 1, entry 2).

Similarly, the HRMS-EI spectroscopic data of purified sirodesmin PL (**7**) isolated from cultures fed with [3,3-$^2H_2$]L-tyrosine (**1a**) provided percentages of deuterium incorporation. Because the $[M]^+$ of sirodesmin PL (**7**) observed in the HRMS-EI spectrum was very weak, the base peak $[M - S_2]^+$ was used to calculate the percentage of deuterium incorporation, as follows. The intensity of the $[M - S_2 + 1]^+$ of sirodesmin PL was ca. 19% higher than that of control samples, whereas that of $[M - S_2 + 2]^+$ was ca. 13% higher than that of control samples. These results indicated that both monodeuterated (19%) and dideuterated (13%) sirodesmin PL (**7**) were biosynthesized from **1a** (Table 1, entry 1). Therefore, the total amount of deuterated **7** (mono plus di) calculated from the HRMS-EI data was ca. 32%.

The ^1H NMR spectrum of sirodesmin PL (**7**) was less informative (provided in the Supplementary data) than that of phomamide (**4**) because the signals due to protons H_2-5 (δ_H 3.27) appeared as a broad AB quartet; this signal integrated for ca. 2 in natural abundance samples of **7** and for <2 (1.4–1.6) in samples resulting from incorporation of [3,3-$^2H_2$]L-tyrosine (**1a**). Unexpectedly, a closer inspection of the signal due to H-7 (δ_H 5.56) in the ^1H NMR spectrum of sirodesmin PL (**7**) isolated from feeding experiments using [3,3-$^2H_2$]L-tyrosine (**1a**) showed two partially overlapping peaks attributable to H-7 (δ_H 5.56) that were not apparent in nondeuterated samples (i.e., natural abundance samples of **7**). Integration of these signals (δ_H 5.56) using resolution enhancement (Lorentz–Gaussian lineshape transformations and baseline corrections) showed resonances at δ_H 5.556 and δ_H 5.550 in a 2:1 ratio (Figs. 1*a* and 1*b*). The presence of both peaks suggested that replacement of H_2-5 of sirodesmin PL (**7**) with deuterium affected the chemical shift of H-7, i.e., the new peak at δ_H 5.550 was caused by the isotope shift effect of $^2H_2$-5 on H-7. The integrated area of this peak (δ_H 5.550) in conjunction with the HRMS-EI data (Table 1, entry 1) indicated that it accounted for the total amount of monodeuterated and dideuterated **7** (ca. 33%). Nonetheless, detection of a deuterium isotope shift effect over four covalent bonds was not expected.[1,16] To further understand this result, the proton decoupled ^{13}C NMR spectrum of this deuterated sample of sirodesmin PL (**7**) was obtained and analyzed. The signal of C-5 (single plus multiplet) had low intensity due to the presence of deuterium; as well, C-4 (δ_C 75.46, 75.40, 75.32) and C-6 (δ_C 82.44, 82.38, 82.34, Figs. 1*c* and 1*d*) displayed the expected two additional peaks

Fig. 1. Sections of NMR spectra of sirodesmin PL: (*a*) ^{1}H NMR, H-7 signal of natural abundance **7**; (*b*) ^{1}H NMR, H-7 signal (peaks 1 at δ 5.556 and 2 at δ 5.550) of **7** due to partial deuteration at C-5; (*c*) ^{13}C NMR, peak 3: C-6 signal of natural abundance **7**; (*d*) ^{13}C NMR, peak 3: C-6 signal of **7**, peak 4: C-6 signal of **7b**, and peak 5: C-6 signal of **7a** due to partial deuteration at C-5 (full ^{1}H NMR spectra of isolated deuterated phomamides and sirodesmins PL are provided in the Supplementary data).



due to the β-isotope shift.[1,16] Importantly, only one ^{13}C NMR peak was observed for C-7 (δ_C 79.2), indicating that the deuterium at C-5 caused no isotope shift effect on C-7, as expected due to the additional bond separation. Similar results were obtained when cultures were incubated with [3,3-$^{2}H_2$]*O*-prenyl-L-tyrosine (**9a**) (Table 1, entry 2). Furthermore, feeding [2,3,3-$^{2}H_3$]L-serine (**2a**) and [5,5-$^{2}H_2$]cyclo-L-Tyr-L-Ser (**3a**) led to very low incorporation of deuterium into sirodesmin PL (**7**) (Table 1, entries 3 and 5, respectively).

The results described above and summarized in entries 1 and 2 of Table 1 demonstrated that 30%–35% of both monodeuterated (**7b**) and dideuterated (**7a**) sirodesmin PL (**7**) was obtained from incorporation experiments with dideuterated precursors **1a** and **9a**, whereas mostly dideuterated **7a** was obtained from incorporation of **4a** (full ^{1}H NMR spectra of isolated deuterated phomamides and sirodesmins PL are provided in the Supplementary data). Consequently, these results indicated that deuterium exchange took place before the final step of phomamide (**4**) biosynthesis and thus the proposed bis-ylidine 2,5-dioxopiperazine (**8**) is not a likely intermediate of the biosynthetic pathway.

Further data analysis and additional calculations clarified the specific nature of this deuterium exchange, as follows. The HRMS-EI data (Table 1, entry 1) showed that the total amount of monodeuterated (19%) and dideuterated (13%) molecules of **7** was 32% (19% + 13%, relative to natural abundance compound), whereas the two ^{1}H NMR peaks due to H-7 at δ_H 5.556 and 5.550 (2:1, Figs. 1*a* and 1*b*) were due to the total amount of **7**, i.e., natural abundance, monodeuterated, and dideuterated. Since integration of both H-7 NMR peaks showed that the signal at δ_H 5.550 represented ca. 33% of H-7 and this amount corresponded to the total amount of deuterated **7** determined by HRMS-EI (19:13 ratio), the 33% accounted by ^{1}H NMR must necessarily represent a mixture of dideuterated (**7a**) and monodeuterated (**7b**) compound in a 19:13 ratio, respectively. This unexpected isotope shift effect (higher field signal of H-7, δ_H 5.550) could be explained by a through space intrinsic deuterium isotope effect on H-7.

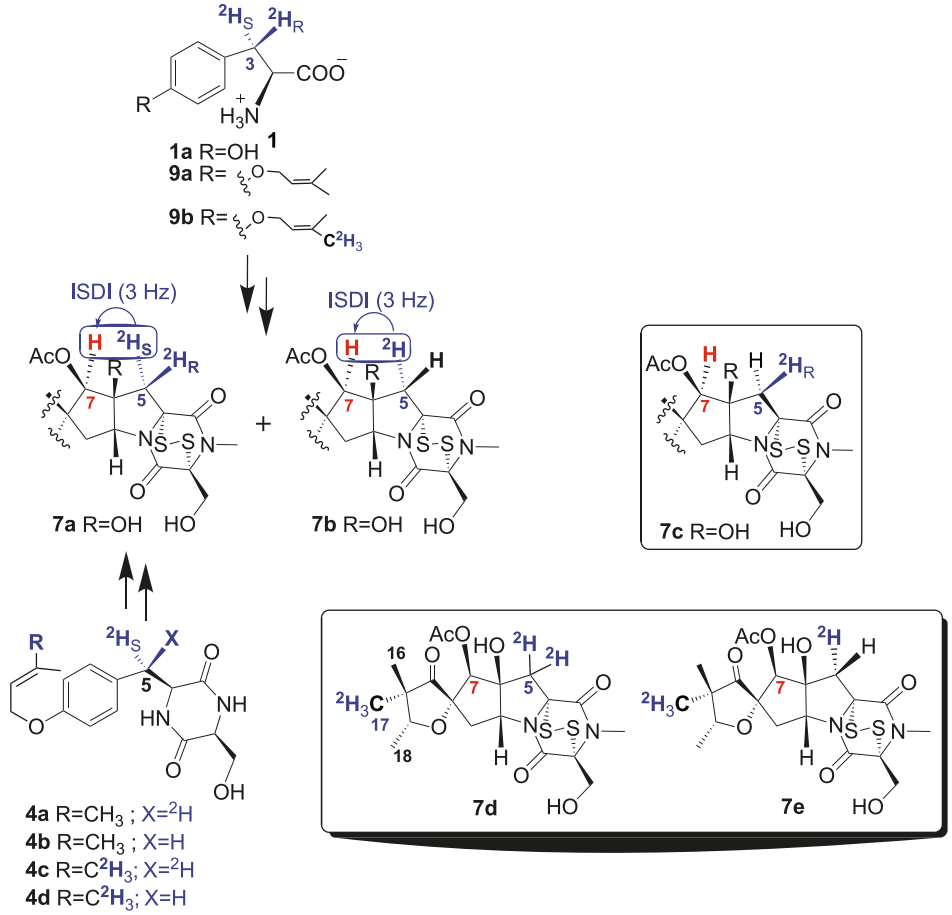
Isotope effects on proton and (or) carbon chemical shifts in compounds where deuterium and the observed proton(s)/carbon(s) were separated by four or more covalent bonds but where the nuclei were close together in space, termed "intrinsic steric isotope effects", have been reported and characterized.[17] The dideuterated sirodesmin molecules had both *pro-R* and *pro-S* deuteria at C-5 (13%), whereas the monodeuterated molecules (19%) in principle could have either the *pro-R* or the *pro-S* deuterium (corresponding to the *pro-R* or the *pro-S* hydrogens) or a mixture of *pro-R* and *pro-S* (e.g., a 1:1 ratio). However, considering the nature of intrinsic steric deuterium isotope effects, it would be expected that only the deuterated molecules having the deuterium close to H-7 (ca. <3 Å) would display this effect. Molecular mechanics calculations[18] showed that structure **7b** has the *pro-S* hydrogen at C-5 in closer proximity of H-7 (2.47 Å) than the *pro-R* hydrogen (3.59 Å). Therefore, these interatomic distances are in close agreement with previous reports[17] on intrinsic steric deuterium isotope effects on proton(s).

From the overall analysis it was concluded that only the monodeuterated structure **7b** was formed (but not **7c**), in addition to the dideuterated **7a**. Finally, extrapolation of this conclusion to the precursor [3,3-$^{2}H_2$]L-tyrosine (**1a**) indicated that its $^{2}H_R$ was partially and stereospecifically exchanged before incorporation into phomamide (**4**), which in turn was incorporated without further deuterium exchange into sirodesmin PL. Furthermore, considering that feeding either [3,3-$^{2}H_2$]L-tyrosine (**1a**) or [3,3-$^{2}H_2$]*O*-prenyl-L-tyrosine (**9a**) yielded monodeuterated products as well, it is surmised that deuterium exchange occurred before formation of phomamide, i.e., either in L-tyrosine or *O*-prenyl-L-tyrosine or both (Scheme 3).

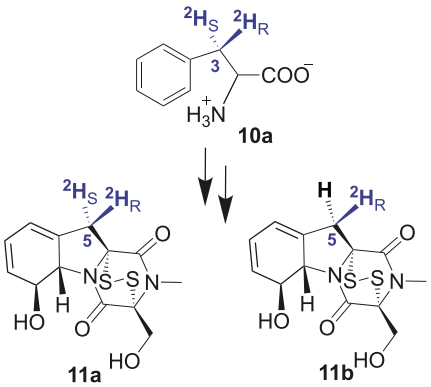
Comparable results in which dideuterated (**11a**) and monodeuterated (**11b**) gliotoxin were obtained from feeding experiments using [3,3-$^{2}H_2$]D,L-phenylalanine (**8a**) were reported previously;[19] however, stereospecific exchange of the *pro-S* deuterium of deuterated phenylalanine (Scheme 4) was established using stereospecifically monodeuterated phenylalanines **10b** and **10c**.

Finally, to clarify the stage at which prenylation occurred (i.e., amino acid or dioxopiperazine), incorporation of [3,3,5′,5′,5′-$^{2}H_5$]*O*-prenyl-L-tyrosine (**9b**) was investigated. The ^{1}H NMR spectra of both phomamide (**4**) and sirodesmin PL (**7**) isolated from cultures incubated with [3,3,5′,5′,5′-$^{2}H_5$]*O*-prenyl-L-tyrosine (**9b**) showed that integration of the peak area of protons H-5a, H-5b, and H_3-5′ of phomamide (**4**) and H_2-5 and H_3-17 of sirodesmin PL (**7**) were lower than those of control samples. That is, both pentadeuterated and tetradeuterated phomamide (**4c**, 7%; **4d**, 16%) and sirodesmin PL (**7d**, 4%; **7e**, 9%) were produced in cultures incubated with pentadeuterated prenyl tyrosine **9b** (Table 1, entry 6). These amounts of deuterium incorporation and the

Scheme 3. Incorporation of [3,3-$^2H_2$]L-tyrosine (**1a**), [3,3-$^2H_2$]*O*-prenyl-L-tyrosine (**9a**), and [5,5-$^2H_2$]phomamide (**4a**) into sirodesmin PL showing partial structures of dideuterated (**7a**) and monodeuterated (**7b**) sirodesmin PL; **7c** is not formed; **7d** and **7e** result from incorporation of [3,3,5′,5′,5′-$^2H_5$]*O*-prenyl-L-tyrosine (**9b**). The curved arrow indicates an intrinsic steric deuterium isotope (ISDI) effect (ca. 3 Hz) of ^2H_S-5 on the ^1H NMR chemical shift of H-7.



Scheme 4. Incorporation of [3,3-$^2H_2$]D,L-phenylalanine (**10a**) into dideuterogliotoxin (**11a**) and monodeuterogliotoxin (**11b**).[19]



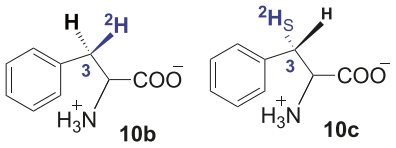
much lower incorporation of **3a** (≤2%) relative to compounds **1a**, **9a**, and **4a** indicated that **3** was not a likely intermediate in the sirodesmin PL (**7**) pathway. In addition, the incorporation of specifically deuterated prenyl derivative demonstrated clearly that CH_3-17 is derived from the deuterated methyl of substituted tyrosine **9b**, which agrees with previous data.[10] Substantially lower incorporations of serine than tyrosine may reflect a faster deployment of serine into other primary pathways (e.g., synthesis of proteins and tryptophan and (or) degradation to pyruvate and glycine). Previous results using radiolabeled serine and tyrosine reported a rather low incorporation of both amino acids into phomamide (**4**) and sirodesmin PL (**7**).[10]

Conclusion

In summary, this work demonstrated that both dideuterated and monodeuterated sirodesmin PL (**7a** and **7b**) and phomamide (**4a** and **4b**) were produced when the precursors [3,3-$^2H_2$]L-tyrosine (**1a**) and [3,3-$^2H_2$]*O*-prenyl-L-tyrosine (**9a**) were incubated with cultures of *L. maculans*. Importantly, a remarkable intrinsic steric deuterium isotope effect detected on the NMR chemical shift of H-7 of monodeuterated sirodesmin PL (**7b**) revealed that the *pro-R* deuterium of sirodesmin PL exchanged stereospecifically. This stereospecific exchange occurred before incorporation of tyrosine (**1a**) into phomamide (**4**), thus the proposed bis-ylidine 2,5-dioxopiperazine (**8**) is not a likely intermediate of the sirodesmin pathway. That is, a percentage of [3,3-$^2H_2$]L-tyrosine (**1a**) is directly channelled into sirodesmin biosynthesis and another fraction rechannelled after diverging into a pathway(s) where a β-deuterium is exchanged stereospecifically. Such a pathway(s) might involve transamination via pyri-

doxal phosphate with concomitant stereospecific exchange of the *pro-R* β-deuterium with a proton.[20] A fraction of the resulting monodeuterated tyrosine ([3-^2H_S]L-tyrosine) could eventually be redirected into the sirodesmin pathway. In addition, our results strongly suggested that prenylation occurred before dioxopiperazine formation and thus *O*-prenyl-L-tyrosine is a likely intermediate of phomamide (**4**) en route to sirodesmin PL (**7**). Therefore, prenylation of tyrosine by the prenylase sirD appears to be the first committed step in the biosynthetic pathway to sirodesmin PL (**7**).

As a final point, it is of interest to highlight that, in general, demonstration of stereospecific isotope exchange observed in biological pathways[20,21] require feeding experiments with stereospecifically labeled substrates, e.g., phenylalanine (**10b** and **10c**) → gliotoxin (**11** and **11b**) (Scheme 4). By contrast, in this work, the detection and substantiation of an intrinsic steric deuterium isotope shift effect revealed clearly a stereospecific deuterium exchange (**7b** and **7e**) in the biosynthetic pathway to sirodesmin PL (**7**).



Materials and methods

General experimental procedures

All solvents were HPLC grade and used as such. Organic extracts were dried with Na_2SO_4 and solvents removed under reduced pressure in a rotary evaporator. Preparative thin layer chromatography was carried out on silica gel plates, Kieselgel 60 F_{254} (20 cm × 20 cm × 0.25 mm), compounds were visualized under UV light. NMR spectra were recorded on Bruker Avance 500 series spectrometers; for ^1H (500 MHz), δ values were referenced as follows for ^1H to $CHCl_3$ (7.27 ppm) and for ^{13}C to $CDCl_3$ (77.23 ppm). Mass spectra (MS) were obtained on a mass spectrometer using a solids probe.

Synthesis of labeled precursors

The deuterated materials [3,3-$^2H_2$]*O*-prenyl-L-tyrosine (**9a**), [3,3,5′,5′,5′-$^2H_5$]*O*-prenyl-L-tyrosine (**9b**), [5,5-$^2H_2$]cyclo-L-Tyr-L-Ser (**3a**), and [5,5-$^2H_2$]phomamide (**4a**) were prepared following modifications of previously reported methods, as described in the Supplementary data. All compounds gave satisfactory spectroscopic data; in each case the percentage of deuterated synthetic compound was ≥98% (HRMS-EI).

Incorporation of labeled precursors

Fungal cultures of *L. maculans* isolate BJ 125 were obtained from the IBCN collection, Agriculture and Agri-Food Canada Research Station, Saskatoon, SK. Cultures were handled as described previously.[22] Isolate BJ 125 was grown in 250 mL Erlenmeyer flasks containing 100 mL minimal media inoculated with fungal spores at 1×10^9 cells per flask. The cultures were incubated on a shaker at 130 rpm, at 24 ± 2 °C for 3 d, then deuterated compounds (dissolved in sterile distilled water, 5.0 mmol/L) were added to cultures. At the 5th day, the broth of each flask was extracted with EtOAc (100 mL × 3) and concentrated to dryness. The residue was separated by preparative TLC (MeOH–CH_2Cl_2, 10:90) to give sirodesmin PL (**7**) (R_f = 0.75, ca. 90 mg/L) and phomamide (**4**) (R_f = 0.25, ca. 10 mg/L).

Measurement and calculation of ^{13}C and ^{15}N NMR chemical-shift tensors of a push–pull ethylene

Saeed K. Amini, Mohsen Tafazzoli, Hilary A. Jenkins, Gillian R. Goward, and Alex D. Bain

Abstract: Methyl 3-dimethylamino-2-cyanocrotonate (MDACC) has a remarkably weak carbon–carbon double bond. It has strong electron-withdrawing groups on one end and electron-donating groups on the other: a so-called push–pull ethylene. To investigate this unusual electronic structure, we have determined the crystal structure and measured both the ^{13}C and ^{15}N NMR chemical-shift tensors. These measurements are supplemented by shielding-tensor calculations done with density functional methods. The large difference (approximately 100 ppm) between isotropic chemical shifts of the two alkenyl carbons reflects a large charge release from the electron-donating side of C=C double bond to the electron-withdrawing groups. Comparison of the calculated orientations of the principal components of the alkenyl carbons obtained from ab initio calculations shows that the primary changes in charge density occur in the molecular plane. On the other hand, smaller charge density changes above and below the plane of the C=C double bond establish the conjugation of donor and acceptor groups with π^* and π molecular orbitals of the central double bond, respectively, which lowers the barrier to rotation about this bond.

Key words: density functional methods, NMR, shielding anisotropy, CSA, push–pull ethylenes, crystal structure.

Résumé : La double liaison carbone-carbone du 3-diméthylamino-2-cyanocrotonate de méthyle (DMACCM) est extrêmement faible. Il porte des groupes électroattracteurs à une extrémité et des groupes électrodonneurs à l'autre, un éthylène de type « push-pull ». Dans le but d'étudier ce type de structure électronique inhabituelle, on a déterminé sa structure électronique et on a aussi mesuré les tenseurs des déplacements chimiques en RMN tant du ^{13}C que du ^{15}N. Pour ajouter à ces mesures, on a aussi fait des calculs de tenseur de blindage à l'aide de méthodes de la fonctionnelle de la densité. Une différence importante (d'environ 100 ppm) entre les déplacements chimiques isotropes des deux atomes de carbone du groupe alcényle est un reflet d'un dont important de charge à partir du çté électrodonneur de la double liaison C=C vers les groupes électroattracteurs. Une comparaison des valeurs calculées pour les orientations des principaux composants des carbones alcényles obtenues par des calculs ab initio montre que les changements primaires dans la densité de charge se produisent dans le plan moléculaire. Par ailleurs, des changements plus faibles dans la densité de la charge, au-dessus et au-dessous du plan de la double liaison C=C, permettent d'établir la conjugaison des groupes donneurs et accepteurs respectivement avec les orbitales moléculaires π^* et π de la double liaison centrale qui abaisse la barrière à la rotation autour de cette liaison.

Mots-clés : méthodes de la fonctionnelle de la densité, RMN, anisotropie de blindage, ASC, éthylènes « push-pull », structure cristalline..

Introduction

Push–pull alkenes are special derivatives of ethylene in which hydrogen nuclei are substituted with electron-donating and electron-withdrawing functional groups at opposite ends of a double bond.[1–9] The π electrons of the central C=C double bond are strongly delocalized so that push–pull alkenes are extremely polarized along this bond. It is clear from extensive investigations that this interaction depends on the individual combination of donor and acceptor substituents in a non-additive manner.[10,11] This effect has been described by some parameters, such as bond length and π-bond order of the central double bond. A further manifestation is a much lower barrier to rotation in comparison to ordinary C=C double bonds.

Evaluation of the barrier to rotation about this bond by NMR methods[12–14] has been a major part of studies of push–pull alkenes. In most cases, either dynamic NMR lineshapes or 2D EXSY NMR experiments were employed to study this barrier.[4,15–17] These studies include the use of both the barrier to rotation about the double bond and the chemical-shift difference between two alkenyl carbons to quantify the push–pull effect. However, corresponding barriers to rotation have been correlated poorly to bond length and π-bond order of the central partial double bond. This may be due to steric hindrance, hydrogen bonding, or stabilization and destabilization effects of donor and acceptor groups in both the ground state and the transition state of

Fig. 1. Structure and numbering scheme for MDACC. Carbon 3 (called C+ in the text) is much less shielded than carbon 2 (C–).

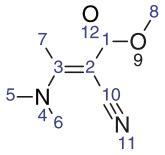

Fig. 2. View of the crystal structure of MDACC, looking down the carbon-–carbon double bond. Carbons are grey, nitrogens are blue, oxygens are red, and hydrogens are white.

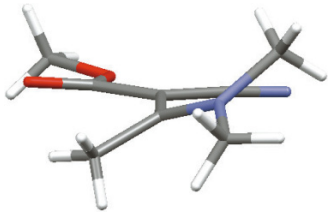

the restricted rotation. So, not only the π-bond order of the central C=C double bond, but also the total π-charge density along the central C=C double bond affect these stabilization and destabilization processes.[15]

This encouraged us to quantify the push–pull effect by measuring the full chemical-shift tensors of a typical push–pull ethylene, methyl 3-dimethylamino-2-cyanocrotonate (MDACC),[17–19] in the solid state. As well, the crystal structure of this molecule is reported here. This compound, which has a small barrier to rotation, has been the subject of both 2D EXSY studies in solution and some ab initio calculations.[17] Such calculations can give insight into the way that NMR parameters are affected by a multiple bond.[20–26] The literature contains many calculations of isotropic chemical shifts, but relatively few take it to the level of comparing individual shielding-tensor elements with experimental values. In the present paper, we determine the principal components of the ^{13}C and ^{15}N shift tensors and compare them to those calculated using high-level density functional theory.[27–37] The combination of accurate structure determination with calculated and observed shift tensors[38–42] gives a very detailed picture of the unusual electronic structure of this molecule.

Experimental

MDACC was prepared by reacting 24 mL (0.18 mol) of *N*,*N*-dimethylacetamide dimethyl acetal with 14.2 mL (0.16 mol) of methyl cyanoacetate and stirring for 30 min.[17,19] Both reagents were purchased from Sigma-Aldrich and used without further purification. The resultant crude product was purified using a cold-finger sublimation apparatus operating at 140 °C under vacuum conditions to yield a pale brown solid.

The molecule exists as an equilibrium mixture of *E* and *Z* conformations in solution, but it crystallizes in the *E* structure. For the crystallography, a colourless rod (0.20 × 0.40 × 0.60 mm) was mounted on the end of a glass fibre. Data were collected on a Bruker Smart 6000 CCD three-circle D8 diffractometer with a Cu RA (Rigaku) X-ray source at 295 K. Cross-coupled parallel focusing mirrors were used to monochromate the X-ray radiation. The data were collected using 60 s frames for the detector at –40° (2θ) and using 120 s frames for the detector at –100° (2θ). Data were integrated using SAINT, corrected for absorption (empirical correction) using SADABS and then solved using the BRUKER SHELXTL Suite 6.14. All non-hydrogen atoms were treated as anisotropic thermal ellipsoids; hydrogen atoms were placed in calculated positions based on the framework of the molecule. Final *R* values were R_1 = 2.96%, wR_2 = 8.64%. Selected bond lengths and angles are given in Table 1, and the full set of crystallographic data and derived bond lengths and angles are given in Tables S1–S6 in the Supplementary data. Figures 1 and 2 show the structure of MDACC (also see Supplementary data).

Slow-spinning magic-angle (MAS) NMR experiments were carried out to measure the intensities of spinning sidebands. The experiments were done on Bruker AVANCE instruments operating at 7.1 and 11.7 T. A 4 mm solid state MAS probe was used, spinning at 3.7, 4.2, 4.5, and 5.8 kHz for the ^{13}C data and 2.0 and 3.5 kHz for the ^{15}N data. All experiments were done at room temperature and spectra were acquired using a ramped cross polarization, with a 7 ms contact time and TPPM decoupling. Spinning sideband patterns were analyzed using the DMFIT program.[43]

^{13}C chemical shifts were referenced to the carbonyl carbon of glycine at 176.14 ppm with respect to TMS at 0 ppm (absolute shielding of 188.1 ppm[30,44]). The ^{15}N values were set relative to the amide nitrogen of glycine, which was calibrated at –347.5 ppm relative to liquid CH_3NO_2 at

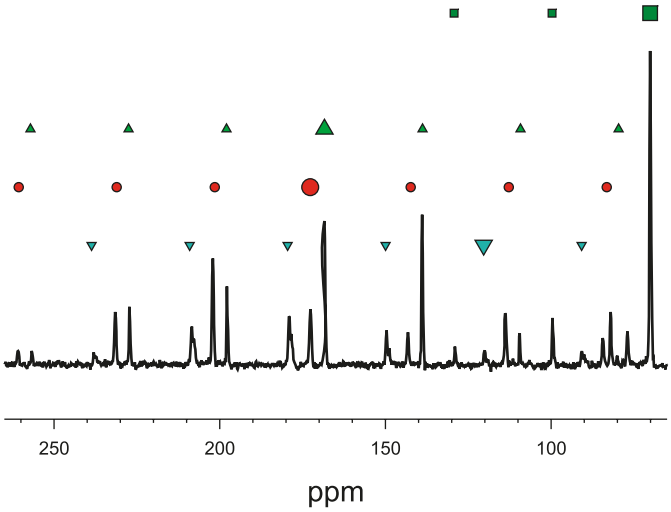
Centrebands are denoted by large symbols, and sidebands by smaller symbols.



0 ppm (absolute shielding of –135.8 ppm[30,45]). Chemical shifts can also be calculated by performing a calculation on the chemical-shift reference at the same level of theory. Such calculations were done on both TMS and CH_3NO_2, as well as on benzene, which is also used as a reference compound for ^{13}C chemical shifts.[46,47]

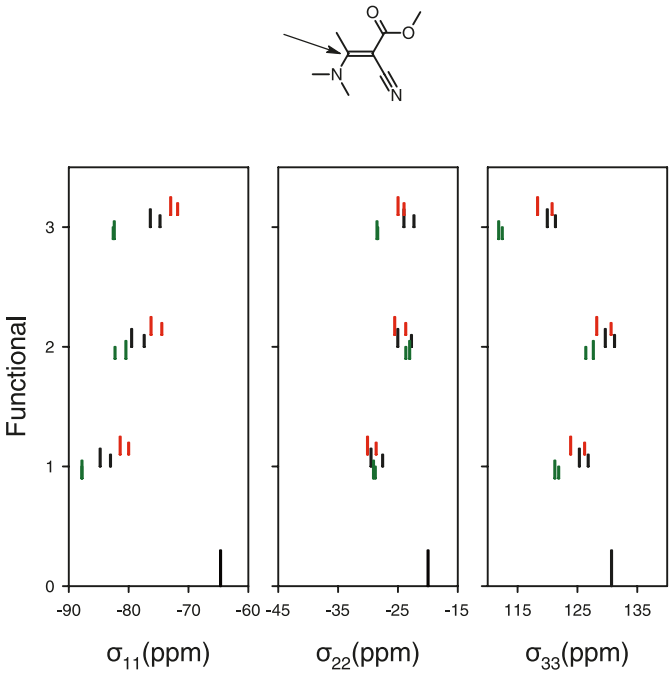
Both ab initio geometry optimization and chemical-shielding calculations were performed using the G03 package from Gaussian, Inc.[48] on an Intel Pentium-4 based computer operating at 1.6 GHz with 512 megabytes of RAM. The chemical shielding calculations used the gauge invariant atomic orbital (GIAO) method. Since both basis set size and method can have large effects on chemical-shielding calculations, different methods were used: B3LYP, MPW1PW91, and MPWLYP, with different basis sets: 6–31++G(d,p), 6–311++G(d,p), and 6–311++G(3df,p). Three different geometries were used for each basis set/functional combination. One was the molecular structure optimized using the same level of theory used in the NMR calculations, and the second was the measured crystal structure. The third was based on the crystal structure, but the hydrogen positions were optimized using the MPW1PW91 functional and the 6–311++G(d,p) basis set.

Results

The measured structure, summarized in Table 1, corresponds closely to the structure calculated at various levels of theory with various functionals. The geometry around the C=C double bond is not planar, but this appears to be a steric effect. Calculations on a similar molecule with the *N*,*N*-dimethyl group replaced by an NH_2 group show a planar structure around the central double bond. The carbon-—carbon bond length at 1.405 Å is intermediate between a standard double bond and a single bond, and is similar to reported values in similar molecules.[49–52]

Measured chemical-shift values of ^{13}C and ^{15}N nuclei and their principal components obtained from spectra at different

Fig. 4. Calculated absolute NMR shielding tensor elements for C+ (carbon 3, shown with arrow in diagram) of MDACC, for different geometries, basis sets and functionals. Data are from Table S7 in the Supplementary data. The two basis sets are denoted by the heights of the bars, and the three geometries by different colours and slightly different vertical positions. The large bar at the bottom represents the experimentally determined value. Functional 1 is B3LYP, functional 2 is MPW1PW91, and functional 3 is MPWLYP. The two different basis sets used were 6–311++G(d,p) (shorter bars) and 6–311++G(3df,p) (taller bars). The black bars represent calculations using the experimental crystal structure, the red bars represent a geometry in which the hydrogen positions of the crystal structure were optimized at the level of MPW1PW91/6–311++G(d,p), and the green bars represent a fully optimized geometry with the same basis set and functional as that used for the shielding calculation.



spin rates using the 11.7 T instrument are collected in Table 2. Figure 3 presents the ^{13}C spectra at 4.5 kHz spin rate acquired at 11.7 T. The results of different spinning rates were similar and their differences are in error regimes of experimental and fitting processes.

In the calculations, it was found that in many cases, the basis set 6–31++G(d,p) gave substantially (up to 20 ppm) different results from the higher basis sets, so only the results based on 6–311++G(d,p) and 6–311++G(3df,p) are reported here. The experimentally measured chemical shifts were converted to absolute shieldings using the absolute shielding of carbon in TMS as 188.1 ppm[44] and absolute shielding of –135.8 ppm[45] for the ^{15}N in CH_3NO_2. The results are presented graphically in Figs. 4 through 8 and Tables S7–S11 in the Supplementary data. They give the calculated absolute shieldings for the carboxyl carbon, the two carbons connected by the double bond, the cyano carbon, and the cyano nitrogen, in the order of the isotropic shifts. Figure 9 plots the calculated isotropic shifts of the shift reference standards (TMS, benzene, and CH_3NO_2) using the same levels of theory.

Fig. 5. Calculated absolute NMR shielding tensor elements for the designated carboxyl carbon in MDACC, for different geometries, basis sets, and functionals. Data from Table S8 (see Supplementary data). Symbols and scales as in Fig. 4.

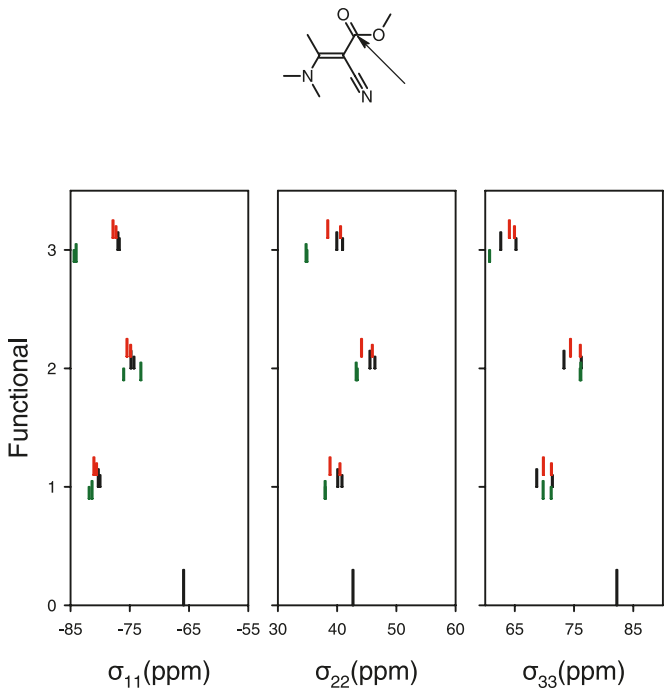


Fig. 6. Calculated absolute NMR shielding tensor elements for the cyano carbon of MDACC, for different geometries, basis sets, and functionals. Data from Table S9 (see Supplementary data). Symbols and scales as in Fig. 4.

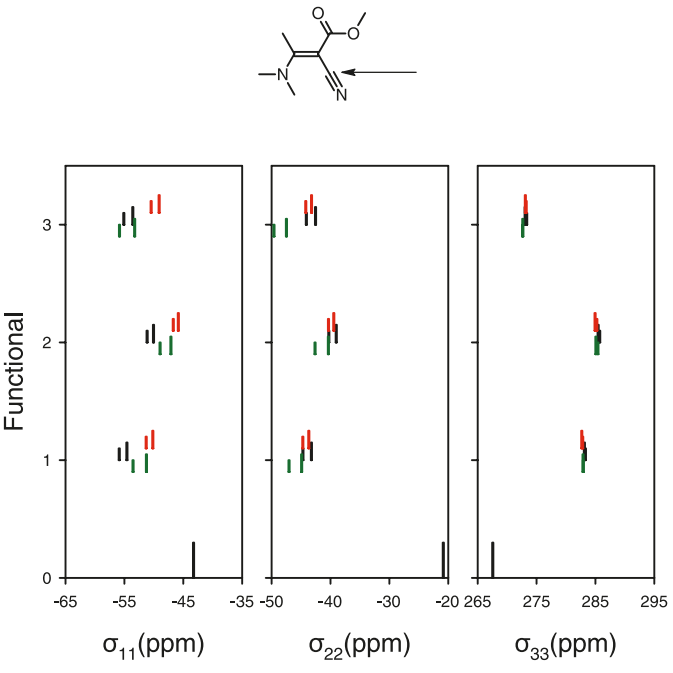

Fig. 7. Calculated absolute NMR shielding tensor elements for the designated C– carbon of MDACC at the other end of the formal double bond from Fig. 4, for different geometries, basis sets, and functionals. Data from Table S10 (see Supplementary data). Symbols and scales as in Fig. 4.

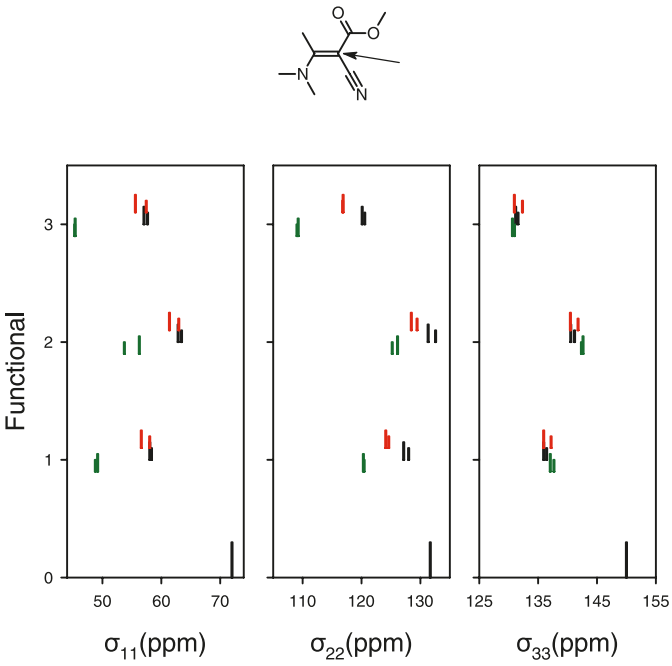

Fig. 8. Calculated absolute NMR shielding tensor elements for the cyano nitrogen of MDACC, for different geometries, basis sets, and functionals. Data from Table S11 (see Supplementary data). Symbols are the same as previous figures, but the horizontal scale (in ppm/cm) is twice the previous value.

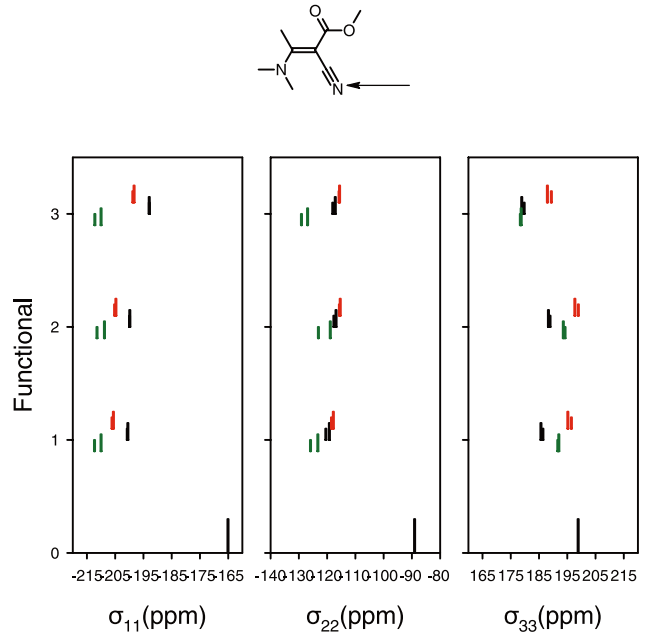
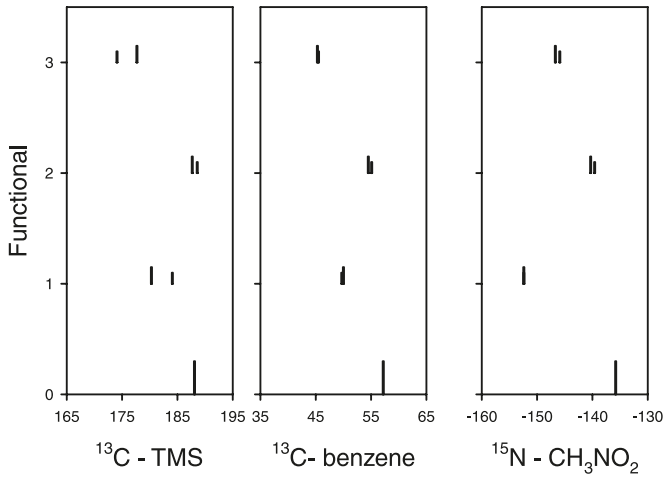


Discussion

Figures 4 through 8 and the numerical values in the Supplementary data show the effects of basis set, functional, and geometry on the calculated shielding-tensor elements. The

Fig. 9. Calculated absolute NMR isotropic shieldings for the chemical-shift reference materials, for different basis sets and functionals. The two basis sets are denoted by the heights of the bars. The large bar at the bottom represents the experimentally determined value.[44,45] Functional 1 is B3LYP, functional 2 is MPW1PW91, and functional 3 is MPWLYP. The two different basis sets used were 6–311++G(d,p) (shorter bars) and 6–311++G(3df,p) (taller bars). In each case, the geometry used is a fully optimized geometry with the same basis set and functional as that used for the shielding calculation.



two basis sets, 6–311++G(d,p) and 6–311++G(3df,p), give substantially the same numbers for all cases, so these basis sets and higher should be sufficient for a molecule with this unusual electronic structure. However, as mentioned previously, the basis set 6–31++G(d,p) gave significantly worse results, and they are not shown. The carbon shieldings (Figs. 4–7) are more accurate than the nitrogen in the cyano group (Fig. 8, note the change of horizontal scale from the previous figures).

Geometry and functional lead to most of the variation, but no clear pattern emerges. There are also significant differences in the reproducibility of numbers between the various tensor elements: some patterns in the figures are very tight, whereas others are spread out. In almost all cases, the calculated shielding is less than the measured value. The functional MPWLYP often leads to less shielding in all the tensor elements, but this is also true in calculations of the standards, so chemical shifts relative to a calculated standard will be better.

The ethylene molecule is the prototype for these discussions. It has the following absolute shieldings[53,54] (Table 3): in-plane, perpendicular to the carbon–carbon bond (+164 ppm); in-plane, parallel to the carbon–carbon bond (+68 ppm); and perpendicular to the molecular plane (–46 ppm). This pattern of the out-of-plane direction being the most de-shielded, the in-plane, perpendicular to the bond, being the most shielded, and the direction along the bond being the intermediate value is confirmed in similar olefins.[55,56] The experiments on powders do not give the orientations of the tensors, but estimates are available from the calculations.

Table 3 gives the experimental eigenvalues of the shielding tensors and the calculated associated direction cosines

Table 3. Direction cosines of the shielding tensor elements for ethylene[45,46] and for the double-bond carbons in MDACC.

(eigenvectors). The planar ethylene molecules lies exactly in the *yz* plane, with the double bond along *z*. MDACC is not planar, but we have oriented the molecule so the carbon–carbon double bond lies along the *z* axis and the cyano carbon lies in the *yz* plane. In other words, the carbons of the double bond and the cyano carbon define the *yz* plane. These results show that the out-of-plane component of the shielding tensor is not strongly affected by the push–pull interactions. The component along the double bond of the two carbons (the *z* axis) is shielded and deshielded relative to ethylene. The in-plane component perpendicular to the bond (along *y*) is shielded (relative to ethylene) for both carbons of the double bond; one dramatically more so than the other.

The cyano group shows some interesting phenomena. In the case of carbon, the largest calculated tensor component, σ_{33}, is larger than the experimental value, whereas for almost all the other components, the calculated values are smaller (less shielded) than the experimental values. In experimental terms, this means the shielding anisotropy of the cyano carbon is significantly overestimated by the calculations.[57] Furthermore, the shielding tensor is close to cylindrical, in contrast to the cyano nitrogen.

The cyano nitrogen isotropic shielding is close to typical values,[58] but the three tensor elements are quite different, as shown in Fig. 8. A good deal of the study of cyano nitrogens has been based on more ionic cyanide-ion species,[30,59,60] where the electronic environment is more cylindrical. As well, there is a good deal of work on nitrogens in sp^2 hybridization[61] and the important amide nitrogen tensors in proteins.[62–66] In the case of MDACC, the asymmetry of the nitrogen-shift tensor reflects the overall planar nature of the molecule much more than the carbon tensor of the cyano group.

The frontier orbitals can help us understand the mechanism behind these large shifts. Detailed lists of coefficients are difficult to read, so Table 4 presents the coefficients of just the 2s and the three 2p orbitals in the HOMO and the orbital below it in energy, and the two lowest unoccupied MO's (LUMO and LUMO+1). We ignore the hydrogen atoms and the methyl groups on the nitrogen. The molecule lies approximately in the *xz* plane with the double bond along *z*. The coefficients suggest that HOMO-1 is mainly the in-plane lone pair of the carbonyl oxygen. The HOMO has significant density in the out-of-plane p orbitals on both the nitrogens, but on only one of the carbons of the formal double bond. This is carbon 2 in Fig. 1, which we have called C–, the more shielded carbon. By contrast, the LUMO has a large coefficient on other carbon, C+, of the double bond.

Only an in-plane magnetic field will strongly mix the HOMO and LUMO, as in the rationalization of the ethylene shifts. In particular, a field perpendicular to the bond, but in the same plane will have the biggest mixing of the HOMO (polarized one way along the double bond) and the LUMO (polarized the other way). This is exactly what we see in the measurements.

Conclusions

This powerful combination of structural methods and theoretical calculations gives a very detailed view of the electronic structure of this class of molecules. In particular, the experimental and theoretical resolutions of the components of the shielding tensors give us further information, since most of the push–pull effect is due to in-plane elements of the shielding tensors. Conjugation with the rest of the π system in the molecule appears to maintain the out-of-plane values. In general, the elements of the shift tensor are always available from a calculation, and the experimental values are readily obtained with a modern solid-state NMR instruments and current software. All these methods are well within the capabilities of many laboratories, so we hope that many future studies will be done at this or higher levels.

Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 3897. For more information on obtaining material, refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml. CCDC 717038 contains the crystallographic data for this manuscript. These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (Or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

Effect of surface heterogeneity steps-terraces in a mean field model for the catalytic CO-NO reaction

Joaquín Cortés and Eliana Valencia

Abstract: Based on a model proposed by Olsson et al. (*Surf. Sci.* **2003**, *529*, 338), a study is made through a mean field scheme of the effect of steps-terraces superficial heterogeneity, whose energy differences have been determined recently by means of density functional theory (DFT), in the catalytic reduction reaction of NO by CO over palladium. Several aspects are seen, such as the relation between the activities produced in both sectors of the surface as a function of temperature and the energy difference between them, the activity and coverage versus the temperature and the gas phase concentration curves, and the effect on these variables of the activation energy values on the steps of some stages of the kinetic mechanism. The system shows a reaction order with respect to CO and NO that changes sign between low and high temperatures, from negative to positive in the case of CO and the opposite for NO.

Key words: mean field model in a superficial reaction, catalytic CO-NO reaction, surface heterogeneity in a superficial reaction, superficial catalytic reaction, CO-NO reaction over palladium, steps-terraces superficial heterogeneity.

Résumé : En se basant sur un modèle proposé par Olsson et al. (*Surf. Sci.* **2003**, *529*, 338), on a effectué une étude à l'aide d'un schéma de champ moyen de l'effet de l'hétérogénéité superficielle en paliers et en terrasses dont les différences d'énergie ont récemment été déterminées à l'aide de la théorie de la fonctionnelle de densité, dans la réaction de réduction catalytique du NO par le CO sur le palladium. On a observé plusieurs aspects, telle la relation entre les activités produites dans les deux secteurs de la surface en fonction de la température et la différence d'énergie entre elles, l'activité et la couverture en fonction de la température et des courbes de concentration en phase gazeuse ainsi que l'effet de ces variables sur les valeurs de l'énergie d'activation sur les paliers de certaines étapes du mécanisme cinétique. Le système présente un ordre de réaction qui varie par rapport au CO et au NO avec des changements de signe entre les basses et les hautes températures et qui vont de négatif à positif dans le cas du CO et l'inverse dans le cas du NO.

Mots-clés : modèle de champ moyen dans une réaction superficielle, réaction catalytique CO-NO, hétérogénéité de la surface dans une réaction superficielle, réaction catalytique superficielle, réaction CO-NO sur du palladium, hétérogénéité superficielle en paliers et terrasses.

[Traduit par la Rédaction]

Introduction

Over the last decades great progress has been made in the knowledge of superficial catalytic reactions, partly due to modern laboratory techniques and partly to the greater understanding of the behavior of irreversible dynamic systems of which superficial reactions are an example. These kinds of systems have attracted the joint attention of chemists, because of their applications in catalysis, and of physicists, because they are good examples of nonequilibrium models that show interesting complex phenomena like oscillations, kinetic phase transitions, hysteresis, chaos, dissipative structures, etc.[1]

Because of the complexity of the kinetics of these superficial reactions, the interpretation of experimental data by theoretical models is generally poor, as has been discussed by our laboratory[2] and analyzed in detail in an interesting article by Zhdanov and Kasemo,[3] and for that reason usually the mechanisms proposed by experimenters are only used to carry out qualitative observations of the data obtained. This is due to the simplifications introduced in the models because of the difficulties in interpreting the adequate stages of the kinetic mechanism, the various kinds of lateral interactions of the reactants that occur at moderately high pressures (0.1–30 torr (1 torr = 133.322 4 Pa)), and the unavoidable heterogeneity of the surface of the catalyst corresponding to actual experimental situations.

In general, the theoretical models used are, in one way or another, mean field schemes. This introduces an inevitable difficulty in the interpretation of all forms of heterogeneity of the real system, which has been partially overcome by using simulations, generally Monte Carlo. Both kinds of techniques have been widely used in the study of superficial reactions that have been reviewed in some excellent monographs by Evans,[4] Albano et al.,[5] and Zhdanov and Kasemo.[6]

For quite some time at our laboratory we have been interested in studying the kinetics of some systems that are also of practical importance in the catalytic control of motor ve-

hicle exhaust emissions, like the CO-O_2 and CO-NO reactions, which we have used as prototypes to relate various mean field models and Monte Carlo simulations with experimental results.[7,8] Our interest in introducing the heterogeneity factor in a mean field model, which goes back to our work in the field of adsorption on heterogeneous surfaces[9] commented in the monograph of Rudzinski and Everett,[9] led us to later propose a mean field theory of a superficial reaction on a disordered substrate.[10] In that paper, we proposed a sites as well as a pairs approximation, characterizing the substrate through the set $\{q_i\}$ of probabilities that the superficial site has i neighbors that belong to the substrate in the model. A different approach has been considered recently by Olsson, Zhdanov, and Kasemo (OZK model),[11] in an interesting paper that, by taking into account the existence of terraces and steps in the catalyst's surface, introduces the heterogeneity of the substrate in a mean field model that analyzes the kinetics of the CO-NO reaction. That paper also takes into account recent advances that use the density functional theory (DFT) approximation[11–13] to determine the role of the steps in the study of heterogeneous catalytic reactions.

In this paper we have used the OZK model, together with some recent studies made by our laboratory on the CO-NO reaction, to analyze various aspects of the heterogeneity of the catalytic substrate from the standpoint of a mean field theory of a superficial reaction. This paper has the purpose of promoting the use of mean field kinetics equations that take into account the existence of simple surface heterogeneities that occur in real systems, as suggested by models like that of OZK, in experimental catalysis research, where use is commonly made of kinetics equations that assume uniform surfaces to interpret the data. This line of research is currently under way in our laboratory.

The kinetic sheme of the CO-NO reaction

The reduction reaction of NO by CO (CO-NO reaction) over rhodium has been studied extensively in the last decades, particularly because of its applications in catalytic converters of automobiles.[14] Recently, however, there has been increasing interest in the study of palladium catalysts, moved by economic reasons for its possible use in converters, since the latest progress in the purification of gasoline avoids the poisoning of these catalysts with lead.[15]

The determination of the kinetic mechanism of the CO-NO reaction over rhodium has a long and controversial history, since the first work of Hecker and Bell,[16] followed by, among others, the studies of Oh et al.,[17] Cho,[18] Chiang and Tan,[19] Peden et al.,[20] and Permana et al.,[21] and those from our laboratory,[22] in the latter case considering recent experiments carried out by Zaera's group.[23] In the case of palladium, however, as admitted by some authors,[15] no adequate mechanism has been established for the CO-NO reaction, largely because of the scant information on adequate experimental data. In a recent paper,[8] we have used the kinetic mechanism proposed by Peden et al.[20] and Permana et al.,[21] which appears most frequently in the literature and is shown in Scheme 1, to interpret some experiments that we have made with the CO-NO reaction over palladium. Table 1 shows the parameters that we used in the paper, some of them belonging to a previous paper by Nakao et al.[25] for

Scheme 1. Mechanism of the CO-NO reaction used in the paper.

$$CO + S \underset{}{\overset{k_1}{\rightleftarrows}} CO_{(a)} \qquad (M1)$$

$$CO_{(a)} \xrightarrow{k_2} CO + S \qquad (M2)$$

$$NO + S \xrightarrow{k_3} NO_{(a)} \qquad (M3)$$

$$NO_{(a)} \xrightarrow{k_4} NO + S \qquad (M4)$$

$$NO_{(a)} + S \xrightarrow{k_5} N_{(a)} + O_{(a)} \qquad (M5)$$

$$2N_{(a)} \xrightarrow{k_6} N_2 + 2S \qquad (M6)$$

$$CO_{(a)} + O_{(a)} \xrightarrow{k_7} CO_2 + 2S \qquad (M7)$$

$$NO_{(a)} + N_{(a)} \xrightarrow{k_8} N_2O + 2S \qquad (M8)$$

the same system in the low pressure zone, adjusting other parameters to our experimental data, and considering for the adsorption constants ka_j of gas j, the kinetic theory of gases expression

$$[1] \qquad k_{aj(\mathrm{ads})} = S_j \sigma (2\pi M_j RT)^{-1/2}$$

where M_j is the molecular mass of j, S_j is the corresponding sticking coefficient, and σ is the area occupied by one mole of metal atoms on the catalyst's surface.

The system described by Scheme 1 and Table 1 will be used as the basis for the discussion presented in this paper. The OZK model proposed originally considered a simplified mechanism for the CO-NO reaction, and the activation energies calculated by Hammer[13] according to the DFT for a palladium surface were used. In these calculations Hammer[13] determined the differences between the activation energies of different stages of the mechanism of the CO-NO reaction over Pd(111) and Pd-step. His results show that there is practically no variation in the desorption stages. On the other hand, it is seen that for various stages the activation energy on the steps is lower than its values on the terraces (Pd(111)): 70% in stage M5 of NO dissociation, 65% in stage M6 of N_2 production, and 71% in stage M7 of CO_2 production. No calculations were made for stage M8 of N_2O production, and adsorption usually takes place without activation energy.

In this paper, a qualitative analysis of the OZK model will be made, however, considering the complete mechanism, which includes stage M8 and the existence of oxygen adsorbed on the surface. The latest DFT calculations,[13] on the other hand, show the existence of a lower activation energy in the steps for certain stages, and that has encouraged us to analyze the influence of different variations of that energy.

Table 1 shows the kinetics parameters used in the paper. For the activation energy, except for stage M8 of N_2O production, use has been made of the values published by Nakao et al.[25] obtained under ultra high vaccum (UHV) conditions. The use of UHV parameters to interpret experiments in higher pressure zones leads to interpretation errors because, in general, the kinetic parameters depend on the coverage. This problem, which has been called the "pressure gap problem", has been studied in the literature by Zdanov

Table 1. Kinetics parameters of Nakao et al.[24] and the fitting parameters used in the paper.

Events	Activation energy, *Ei* (kcal/mol)	Frequency factor, *νi* (sec^{-1})
CO desorption (k_2)	35.5[a]	(1.0×10^{17})[a]
NO desorption (k_4)	36.0[b]	(1.0×10^{17})[c]
NO dissociation (k_5)	34.2[d]	(7.9×10^{21})[c]
N_2 production (k_6)	29.0[e]	(6.5×10^{13})[e]
N_2O production (k_8)	32.7[f]	(5.3×10^{16})[c]
CO_2 production (k_7)	33.6[g]	(1.2×10^{16})[c]
S_{CO}= 0.93[h], S_{NO} = 0.9[h]		

[a](Behm et al. 1980; Guo and Yates 1989).[25]

[b](Ramsier et al. 1994).[26]

[c]Values of *νi* in parentheses correspond to a fit with experimental data from Fig. 1 of Cortés et al. (2007).[8]

[d](Nakao et al. 2005).[24]

[e](Olsson et al. 2003; Sellers and Anderson 2001).[11,27]

[f](Walker et al. 1997).[29]

[g](Olsson et al. 2003).[11]

[h](Hirsimaki and Valden 2001).[28]

and Kasemo,[3] with discouraging results. With the purpose of partially overcoming that situation, in our calculations we have used some frequency factors from a previous paper[8] obtained by fitting experiments made at the same medium pressures used in this paper. Taking that set of parameters for the (Pd(111)) terraces, we have considered that the steps in the M5, M6 and M7 stages have activation energies lower than those by the percentages given in the previous paragraph, corresponding to the variations found by Hammer[13] in his DFT calculations. Since the corresponding frequency factors have not been determined theoretically, we have assumed that they are equal for the steps and the terraces, considering implicitly that the activation energies absorb the total differences between the various zones of the surface.

In the calculations we will define the relation KK(*i*) between the activation energy of stage *Mi* in the steps (*s*) and terraces (*t*) by the expression $E^s(i) = KK(i)E^t(i)$, so that the set of KK(*i*) values describe completely the analyzed case. In all cases KK(*i*) = 1 was considered for desorption stages M2 and M4 and stage M8 of N_2O formation.

The mean field model

Appendix A shows the details of the analytical solution of a mean field model that we had published earlier[8,22] for the mechanism of Scheme 1. It represents the development of the corresponding kinetic equations if it is assumed that the catalyst's surface is uniform and that the adsorbates $CO_{(a)}$ and $NO_{(a)}$ remain in equilibrium with the gas phase during the process. This means that the adsorption–desorption stages are considered to be sufficiently fast, as has been done in the literature.[11] Below we will extend this development to the analysis of the OZK model using the parameters given in Table 1.

The study of the OZK model is very interesting because it allows the application of a mean field scheme to a catalytic surface with simple heterogeneity, made of few sectors with different energy characteristics. The most obvious examples are surfaces formed by different crystal faces or that have step sites of different activity, presumably more active, than the terrace sites of the rest of the surface. The latter was the case studied by OZK, motivated by the quantum studies that use DFT to investigate the role of the steps in the heterogeneous catalysis phenomenon.[12,13] On the other hand, there have been reports of experimental information of systems in which activity differences have been observed between steps and terraces,[30] as well as cases in which these differences have apparently not been found.[31]

The OZK model analyzes two situations. In the first it is assumed that the terraces and the steps operate independently, and the second case considers that they are interconnected due to the fast diffusion of the adsorbates.[32]

The first case can be treated by simply applying independently the kinetic equations of the uniform case developed in Appendix A to each of the sectors of the surface. If n^t and n^s are the numbers of site terraces and steps, respectively, then $f = n^s/(n^s + n^t)$ is the fraction of sites belonging to the steps. The total production R_i of species (*i*) will be equal to the weighted sum of productions R^t and R^s of terraces and steps, respectively, so

$$[2] \qquad R_{N_2} = (1-f)k_6^t(\theta_N^t)^2 + fk_6^s(\theta_N^s)^2$$

$$[3] \qquad R_{CO_2} = (1-f)k_7^t\theta_{CO}^t\theta_O^t + fk_7^s\theta_{CO}^s\theta_O^s$$

$$[4] \qquad R_{N_2O} = (1-f)k_8^t\theta_{NO}^t\theta_N^t + fk_8^s\theta_{NO}^s\theta_N^s$$

where θ_i^t and θ_i^s are the fractions of covered surface of species (*i*) in terraces and steps.

The second case assumes that the steps and terraces are interconnected. Let us consider also the situation in which the kinetic constants of CO and NO desorption are identical in the terraces and in the steps, approximately in agreement with the data published by Hammer[13] for the CO-NO reaction over palladium, which is the system that will be used as a prototype in this analysis, as we comment in greater detail below. Since eq. [1] also assumes adsorption without activation energy, it means that eqs. [A1]–[A4] in Appendix A are valid for this case. The conservation eqs. [A5] and [A6], however, which represent steady states for the superficial species $N_{(a)}$ and $O_{(a)}$ ($d\theta_N/dt = 0$ and $d\theta_O/dt = 0$), now have the following form

$$[5] \qquad n^tk_5^t\theta_{NO}^t\theta_S^t + n^sk_5^s\theta_{NO}^s\theta_S^s = 2n^tk_6^t(\theta_N^t)^2 + 2n^sk_6^s(\theta_N^s)^2 + n^tk_8^t\theta_{NO}^t\theta_N^t + n^sk_8^s\theta_{NO}^s\theta_N^s$$

$$[6] \qquad n^tk_5^t\theta_{NO}^t\theta_S^t + n^sk_5^s\theta_{NO}^s\theta_S^s = n^tk_7^t\theta_{CO}^t\theta_O^t + n^sk_7^s\theta_{CO}^s\theta_O^s$$

In the development of the model we will assume a rapid diffusion of all the superficial species according to the OZK model.[11,32] As those authors point out, the values published[32] for the activation energies for the diffusion of superficial species, even atomic ones like N and O, are in general smaller than for the other stages *Mi* of the mechanism of Scheme 1. This leads to considering, as a fundamental assumption of the model, that the fraction of covered surface of species (*i*) is the same for all the heterogeneous surface S12, i.e., θ_i^t is equal to θ_i^s for each species (*i*) if the sectors

are interconnected. Introducing eq. [A4] into expressions eqs. [5] and [6], using the definition $y = n^s/n^t$, and recalling that $\theta_i^t = \theta_i^s = \theta_i$, we get

$$[7] \quad k_5^t AB\theta_{CO}^2 + yk_5^s AB\theta_{CO}^2 = 2k_6^t\theta_N^2 + 2yk_6^s\theta_N^2 + k_8^t A\theta_N\theta_{CO} + yk_8^s A\theta_N\theta_{CO}$$

$$[8] \quad k_5^t AB\theta_{CO}^2 + yABk_5^s\theta_{CO}^2 = k_7^t\theta_{CO}\theta_O + yk_7^s\theta_{CO}\theta_O$$

from which it is possible to obtain eq. [9] for the covered fraction of $O_{(a)}$

$$[9] \quad \theta_O = E\theta_{CO}$$

where

$$[10] \quad E = AB(k_5^t + yk_5^s)/(k_7^t + yk_7^s)$$

If we also define for θ_N, the coverage $N_{(a)}$, $\theta_N = F\theta_{CO}$, from eq. [7] we get that

$$[11] \quad F = \left[(-A(k_8^t + yk_8^s) + (A^2(k_8^t + yk_8^s)^2 + 8AB(k_6^t + yk_6^s)(k_5^t + yk_5^s))^{1/2}\right]/4(k_6^t + yk_6^S)$$

and using conservation eq. [A7] we obtain for the coverage of $CO_{(a)}$

$$[12] \quad \theta_{CO} = 1/(1 + A + B + E + F)$$

The production expressions are similar to eqs. [2]–[4] of the previous case, in which now $\theta_i^t = \theta_i^s = \theta_i$.

Relative contribution of terraces and steps to the activity of the CO-NO reaction

The first aspect of interest is the relative importance of both sectors of the surface on the activity of the catalytic process. In this analysis we will take into account the case of R_{CO2}, the production of CO_2, defining RTS as the fraction of the contribution of the terraces sector to the total production of CO_2 by

$$[13] \quad RTS = R_{CO_2}^t/(R_{CO_2}^t + R_{CO_2}^s)$$

In general terms, surface heterogeneity is manifested only in intermediate situations of the values of RTS, where 1 >> RTS >> 0. In the extreme cases the system becomes uniform, because when RTS = 0 the phenomenon only occurs in the steps, and if RTS = 1 only in the terraces.

If we assume that the rate constants can be expressed by Arrhenius' equation

$$[14] \quad k_i^j = \nu_i^j \exp(-E_{ai}^j/RT)$$

where ν_i^j and E_{ai}^j are, respectively, the frequency factor and the activation energy of terraces and steps ($j = t,s$), then we have

$$[15] \quad RTS = \frac{(1-f)\nu_{CO_2}^t\theta_{CO}^t\theta_O^t\exp(-E_{CO_2}^t/RT)}{((1-f)\nu_{CO_2}^t\theta_{CO}^t\theta_O^t\exp(-E_{CO_2}^t/RT) + f\nu_{CO_2}^s\theta_{CO}^s\theta_O^s\exp(-E_{CO_2}^s/RT))}$$

In the later calculations we will assume that the frequency factors are equal in terraces and steps, so that they only differ in the value of the corresponding activation energies that characterize them. If $\Delta E = E_{CO_2}^t - E_{CO_2}^s$ expresses that difference, from eq. [15] we can write the following expressions for RTS in the cases of independent sectors, RTS_{ind}, and interconnected sectors RTS_{int}, respectively

$$[16] \quad RTS_{int} = \frac{1}{\left(1 + \left(\frac{f}{1-f}\right)\right)\exp(\Delta E/RT)}$$

$$[17] \quad RTS_{ind} = \frac{1}{\left(1 + \left(\frac{f}{1-f}\right)\right)\left(\frac{\theta_{CO}^s\theta_O^s}{\theta_{CO}^t\theta_O^t}\right)\exp(\Delta E/RT)}$$

Figure 1 shows the changes of RTS at different temperatures in both cases. The first aspect of interest that arises from the above expressions is that the RTS of the interconnected case does not depend on the configuration of the adsorbed phase, but only on ΔE and temperature. In that case it is seen that RTS always increases with temperature according to eq. [16], as shown by the examples of Fig. 1*a*.

On the other hand, Figs. 1*b* and 1*c* show that when the sectors are independent RTS can increase or decrease with temperature due to the influence of the relations between the different coverages in the steps or the terraces as shown in eq. [17]. In these cases RTS depends on the values chosen for KK(*i*), which are kept constant in both figures. Since $\Delta E = (1 - KK_{(CO2)})E^t(_{CO2})$ and the value of $KK_{(CO2)}$ is kept constant, the various values of ΔE can be assumed to be generated by the variation of $E_{CO_2}^t$, leading to a set of ΔE values for constant $E_{CO_2}^s/E_{CO_2}^t$. Alternatively, the energy of steps or terraces can be fixed and the energy difference, ΔE, can be varied. On the other hand, it is seen that in all the cases of Fig. 1 a value of RTS = 1 is obtained for ΔE = 0, and in the last two figures (Fig. 1*b* and 1*c*) it would correspond to the case of $KK_{(CO2)} = 1$.

Figure 2*a* shows some examples of changes of RTS with temperature when ΔE is constant, where two situations have been chosen for each case. When the sectors are interconnected an increase with temperature occurs, while that happens in only one of the examples chosen when the sectors are independent. In Figs. 2*b* and 2*c* we have graphed, for the independent sectors examples, the changes of RTS and of the CO and O coverages with temperature in the steps and in the terraces, because the latter appeared in eq. [17]. This makes it possible to see how the interrelations of the coverages in terraces and steps are the cause of the different behavior of RTS. For example, in the case in which RTS decreases at low temperatures the phenomenon occurs mainly in the terraces, since coverage with oxygen in the steps has significant values only at high temperatures, in contrast with

Fig. 1. RTS (fraction of CO_2 production in terraces). Equation [13] versus ΔE (energy difference between terraces and steps) at different temperatures, P_{CO} = 20.52 torr; P_{NO} = 39.52 torr and y = 0.01: ○ (450 K); ● (500 K); △ (550 K); ▲ (600 K); □ (650 K); ■(700 K). the case in which RTS increases. Finally, it must be kept in mind that in all cases RTS is independent of the pressure or concentration of the gas phase.

Effect of temperature on the activity of the system and Arrhenius behavior

In general, a maximum of activity, R_i, with temperature is seen in all cases, the same as in the situation of a uniform surface that we have reported recently.[8] This is shown in Fig. 3 for systems having interconnected systems in the cases in which RTS has an intermediate value, when the system is heterogeneous with a similar influence of the terraces and the steps, and when it has a small value and the phenomenon occurs only in the steps, except at high temperatures. The maximum of R_i, which in general coincides with the maximum found for coverage with nitrogen, occurs because at low temperatures oxygen coverage is very low, while at high temperatures the fraction covered with CO is small. The maximum then occurs at intermediate temperatures where both coverages show a substantial value. The above can be visualized in the corresponding figures (Fig. 3) of coverage versus temperature for the three cases chosen. In the first of them (Fig. 3*a*) the selectivity (SE) curve for N_2 defined by $R_{N_2}/(R_{N_2} + R_{N_2})$ has been added, which in the second case (Fig. 3*b*) has always been equal to one.

The changes of the superficial configuration commented in the previous paragraph, which lead to the formation of a maximum in the graph of CO_2 production versus temperature has as a consequence a similar behavior in the $\ln R_i$ versus $1/T$ Arrhenius curves, distinguishing two zones around the maximum where only one of them allows the calculation of an apparent positive activation energy that has physical meaning. This maximum between production and tempera-

ture has been observed experimentally for this system over single-crystal Pd catalysts that presumably have steps and terraces zones on the surface[33] and on supported Pd in UHV zones.[15] The energy obtained in this way is only apparent and its value, although of a reasonable size, is sufficiently high compared to that of the steps in Table 1 to indicate that in the corresponding zone in which the energy has been calculated, the phenomenon does not occur through a controlling step like those that were considered in Scheme 1. In general, this kinetic process is complex, and it has been reported in the case of single crystals of Pd, for example, that the dissociation of NO is the rate limiting stage at low temperatures, while CO adsorption is rate-limiting at high temperatures.[34]

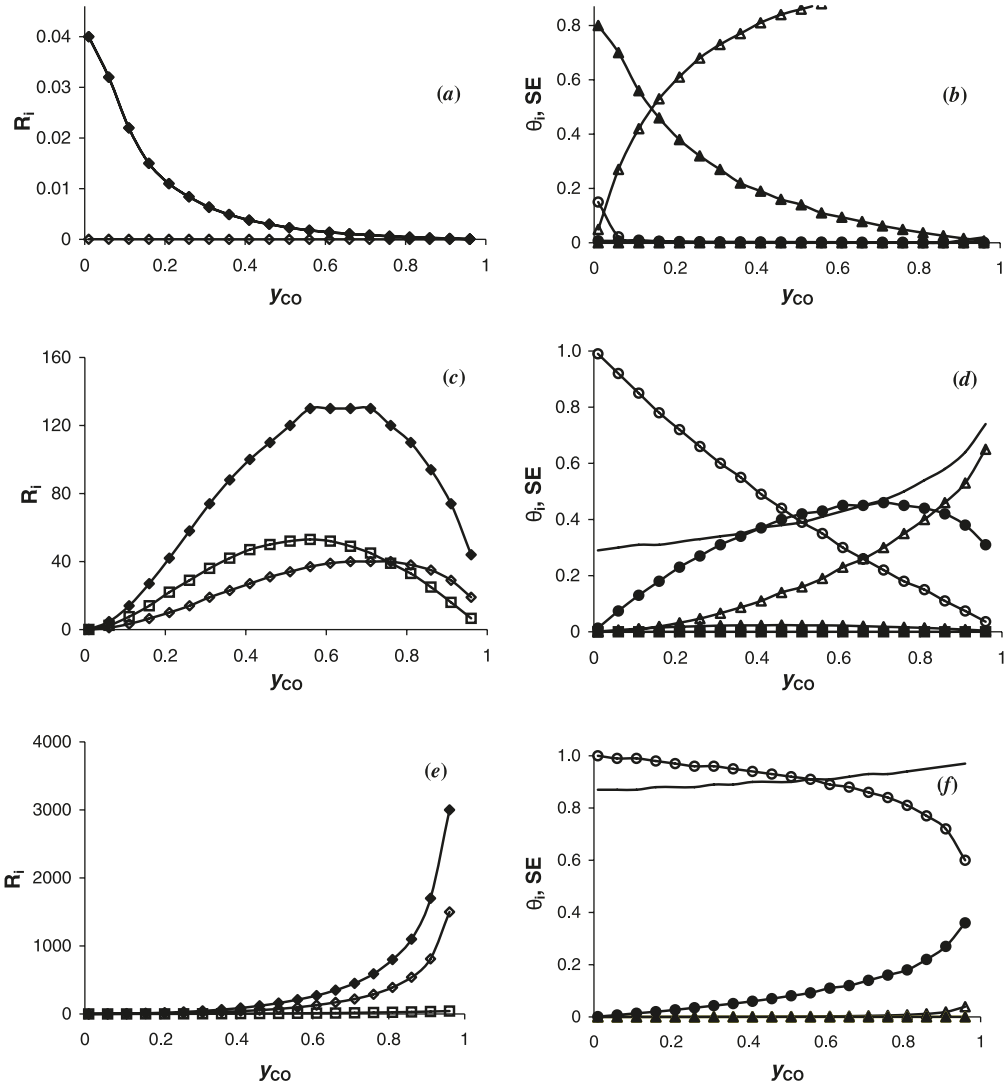
Effect of gas phase concentration, phase and activity diagrams, and reaction order

Figure 4 shows the phase and concentration diagrams at three different temperatures in the case of interconnected step and terrace zones, for systems that show a substantial degree of heterogeneity with RTS values higher than 10%. The types of activity diagrams (R_i, y_{CO}) are a direct consequence of the behavior of the phase diagrams (θ_i, y_{CO}). At a low temperature, for example, it is seen only at low CO concentrations, y_{CO} in the gas phase, that there is sufficient oxygen adsorbed on the surface for production to exist. At a high temperature, on the other hand, production is seen only in the zone of high CO concentration in the gas phase, because only then is there sufficient CO adsorbed on the surface. Finally, for intermediate temperatures the activity curve presents a maximum, because production decreases at low y_{CO} concentrations where there is little superficial CO, and at high y_{CO} concentrations because coverage with oxygen decreases.

Figure 5 shows how, in the case of interconnected sectors, the model has a reaction order m with respect to CO and n with respect to NO, if we assume that the following empirical expression, with which experimenters often describe their data, is valid

$$[18] \qquad R_i = k_i P_{CO}^m P_{NO}^n$$

Fig. 4. Production (R_i, y_{CO}) and phase (θ_i, y_{CO}) diagrams versus CO concentration in the gas (y_{CO}) interconnected sectors $KK_{(CO2)} = 0.71$; $KK_{(NO)} = KK_{(N2)} = 1$; $P_{CO} = 20.52$ torr; $P_{NO} = 39.52$ torr; $y = 0.01$. ♦ (R_{CO2}); ◊ (R_{N2}); □ (R_{N2O}); —— (SE (selectivity)); △ (θ_{CO}); ▲ (θ_{NO}); ○ (θ_O); ● (θ_N); ■ (θ_S). (*a*) and (*b*) $T = 450$ K; RTS = 0.10. (*c*) and (*d*) $T = 550$ K; RTS = 0.28. (*e*) and (*f*) $T = 650$ K; RTS = 0.48.



The figures (Fig. 5) show straight lines with a high correlation if the logarithm of production is graphed versus the logarithm of the corresponding pressure, keeping the other pressure constant, allowing for the determination of the respective *m* and *n* parameters. In all the cases studied a change of sign of the order with temperature was seen. In the case of CO, *m* was negative at low temperatures and positive at high temperatures, while the opposite occurred with *n* for NO. This behavior of the reaction order has been reported in experiments made in the low temperature zone on supported Pd with values similar to those of Fig. 5 by Rainer et al.[35] On the other hand, Holles et al.[36] reported experimental results for a series of supported Pd catalysts having different characteristics at relatively low temperatures, getting various positive values for the order of NO and negative values for CO. Holles et al.,[37] on the other hand, made interesting experiments on a bimetallic Pd/Rh supported catalyst, finding that it behaved in a manner similar to the Rh catalyst, showing orders close to zero for NO, in both cases at temperatures around 550 K. The catalysts in all these experiments must be considered in some way heterogeneous, with zones of the steps and terraces or similar types on the surface.

Effect of the variation of the activation energy of the steps for different stages of the kinetic mechanism

Considering the interest caused by the recent DFT studies, which have shown the catalytic importance of the energy differences between the step and terrace sites, it may be significant to visualize the behavior of the system for different values of the activation energy of various stages corresponding to step sites if the energy of the terrace sites is kept constant. Figure 6 shows the activity and surface coverage curves versus the activation energy of the steps for stage M5 of NO dissociation, stage M6 of N_2 production, and stage M7 of CO_2 production.

Fig. 5. Reaction order (eq. [18]). $y = 0.01$. (*a*) CO_2 production as a function of CO pressure with a fixed NO pressure of 39.52 torr at 450 K in the steady state for $KK_{(CO2)} = 0.82$; $KK_{(NO)} = KK_{(N2)} = 1$. (*b*) The same as (*a*) at 650 K. (*c*) The same as (*a*) as a function of NO pressure with a fixed CO pressure of 20.53 torr. (*d*) The same as (*c*) at 650 K.

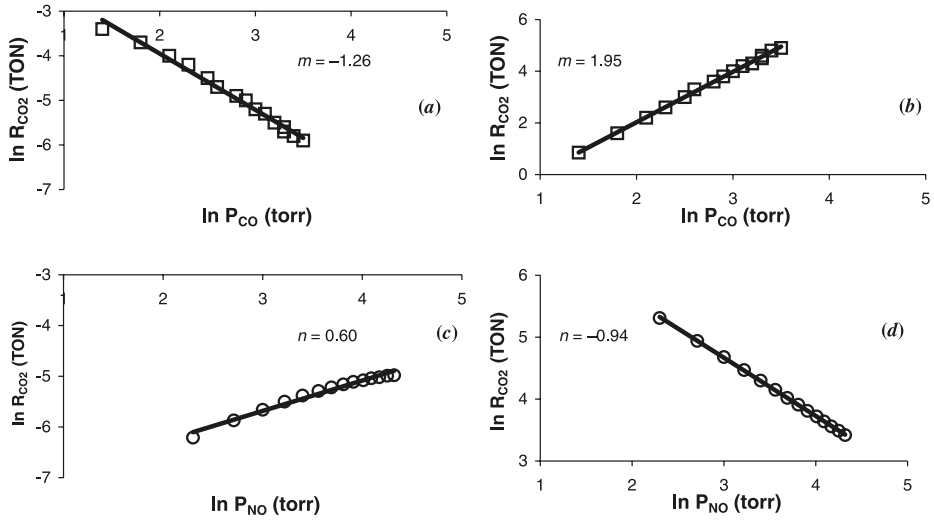


Fig. 6. Production (R_i), superficial coverage (θ_i), and selectivity (SE) versus the variation of the activation energy of stages M5 (E^s_{EDINO}), M6 (E^s_{N2}), M7 (E^s_{RCO}); interconnected sectors; $T = 500$ K; $P_{CO} = 20.52$ torr; $P_{NO} = 39.52$ torr; $y = 0.01$. Symbols R_i and θ_i are the same as in Fig. 4, and ---- RTS; (*a*) and (*b*) $KK_{(CO2)} = 0.71$; $KK_{(N2)} = 0.65$; (*c*) and (*d*) $KK_{(CO2)} = 0.71$; $KK_{(NO)} = 0.7$; (*e*) and (*f*) $KK_{(NO)} = 0.70$; $KK_{(N2)} = 0.65$.

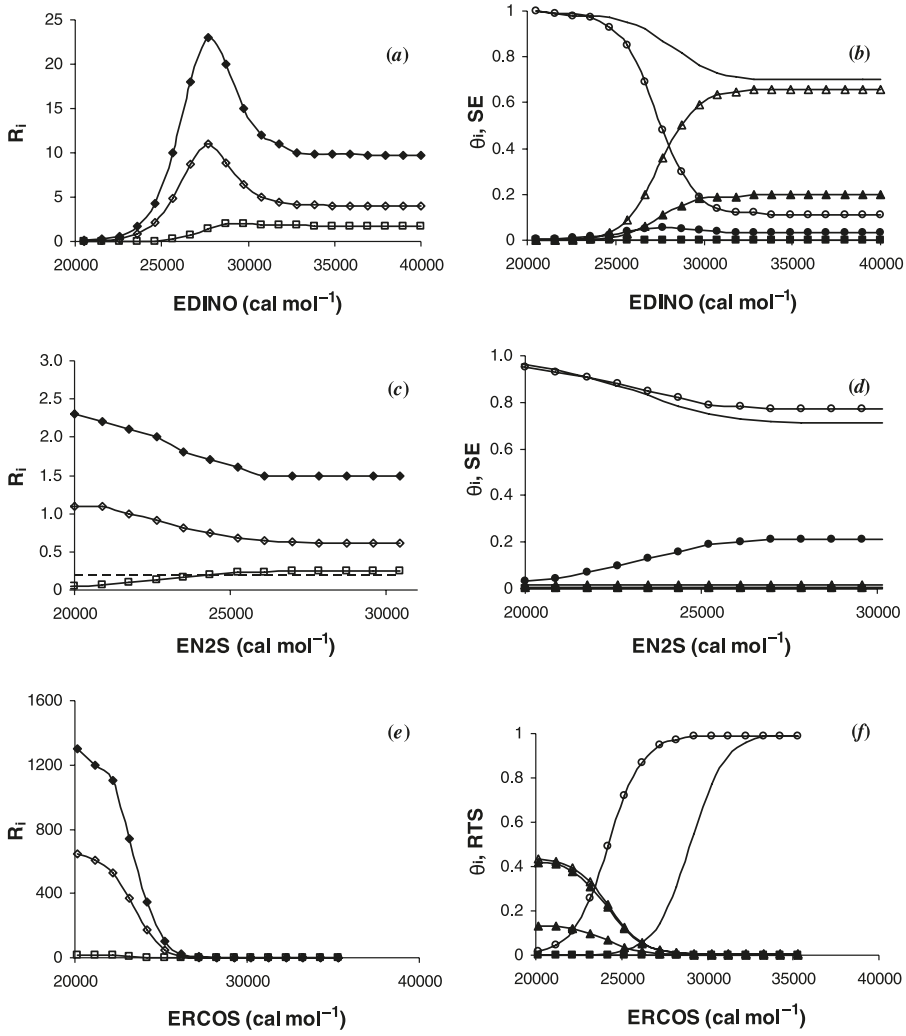

The maximum seen in Fig. 6*a* for the system's productions when the dissociation energy of the steps is varied is explained because all low values of this energy has the high dissociation of NO producing an excess of adsorbed oxygen, because superficial CO remains constant, leaving few vacant sites where the process can take place. The opposite effect occurs in the case of a high activation energy for dissociation, where there will be a deficiency of superficial nitrogen and oxygen that leads to decreased production. In a manner similar to the phase and production diagrams versus gas phase concentration, the production maximum coincides with the maximum nitrogen coverage and the intersection of the O and CO surface coverage curves.

The diagrams corresponding to the N_2 and CO_2 production stages have a similar behavior, because in both cases the decrease in production due to the increase in activation energy causes poisoning of the surface with the corresponding surperficial element produced by the dissociation of NO that does not react, like nitrogen with the increased production energy of N_2, and oxygen in the case of the production energy of CO_2.

Conclusions

The study of a mean field model, based on a previous formulation by Olsson et al.,[11] for the case of the CO-NO reaction on a heterogeneous catalytic surface formed by steps and terraces has been developed in the paper. Also, from the analysis of the behavior of the model in terms of various parameters of the system, its formulation is validated, contrasting some of its results with experiments in the literature carried out with the same reaction on heterogeneous substrates, stressing the interest of using a mean field heterogeneous model of catalysis to interpret the experimental data. Some of the most important results are stated below.

The relative importance of both sectors of the surface (steps and terraces) depends only on the energy difference between the sectors and the temperature if interconnected steps and terraces are assumed. If they are assumed to be independent, this relation also depends on the relation between the coverages of the different zones of the surface. This implies, for example, that the fraction of the process that occurs in the terraces always increases with temperature in the interconnected case, while it can increase or decrease in the case of independent sectors.

In all the cases maximum production with temperature is seen, in agreement with what happens in the superficial configuration, and it accounts for the Arrhenius behavior shown by the phenomenon. This behavior has been reported in the literature in experiments with the CO-NO reaction on heterogeneous substrates.

The activity versus concentration curves of the gas phase in contact with the surface show various behaviors that can be explained by what happens to the configuration of the adsorbed surface.

The system shows a reaction order with respect to CO and NO. In the case of CO, it is negative at low temperatures and positive at higher temperatures. In the case of NO, the opposite is true. These results interpret reasonably well, qualitatively and quantitatively, with some experimental data from the literature obtained at relatively low temperatures for the CO-NO reaction on heterogeneous substrates.

The activity of the process versus the value of the activation energy of the dissociation of NO in the steps has a maximum that can be accounted for by the behavior of the configuration of the adsorbed phase. An increase of the activation energy of N_2 or CO_2 production in the steps causes a decrease of the system's activity, with the consequent increase of surface poisoning with nitrogen or oxygen.

Appendix A. Analytical solution of the reaction model used in the paper

In a manner similar to the development shown in one of our previous papers,[1,2] we will synthetize the equations used in this paper for the mechanism of Scheme A1. Since it is assumed that the $CO_{(a)}$ and $NO_{(a)}$ adsorbates are in equilibrium with the gas phase, it is possible to write the relations

$$[A1] \qquad \frac{k_1}{k_2} = K_{CO} = \frac{\theta_{CO}}{\theta_S P_{CO}}, \quad \frac{k_3}{k_4} = K_{NO} = \frac{\theta_{NO}}{\theta_S P_{NO}}$$

where the equilibrium constants are expressed as functions of the coverages (θ_{CO} and θ_{NO}), and the partial pressures (P_{CO} and P_{NO}) of the gas phase, and θ_s represents the coverage of the vacant surface sites. The procedure used consists in expressing the coverages (θ_i) as functions of θ_{CO}, for which, if we define

$$[A2] \qquad A = \frac{P_{NO}K_{NO}}{P_{CO}K_{CO}}$$

$$[A3] \qquad B = \frac{1}{P_{CO}K_{CO}}$$

it is possible to write the relations

$$[A4] \qquad \theta_{NO} = A\theta_{CO} \quad \theta_S = B\theta_{CO}$$

The following conservation equations can be written, where the first two represent the steady state for the surface species $N_{(a)}$ and $O_{(a)}$ $\left(\frac{d\theta_N}{dt} = 0 \quad \text{and} \quad \frac{d\theta_O}{dt} = 0\right)$

$$[A5] \qquad k_5\theta_{NO}\theta_S - 2k_6\theta_N^2 - k_8\theta_{NO}\theta_N = 0$$

$$[A6] \qquad k_5\theta_{NO}\theta_S - k_7\theta_{CO}\theta_O = 0$$

$$[A7] \qquad \theta_S + \theta_{CO} + \theta_{NO} + \theta_N + \theta_O = 1$$

If we define the relations

$$[A8] \qquad C = (-k_8A + ((k_8A)^2 + 8k_5k_6AB)^{1/2})/4k_6$$

Scheme A1. Mechanism of the CO-NO reaction used in the paper.

$$CO + S \overset{k_1}{\underset{}{\rightleftarrows}} CO_{(a)} \quad \text{(M1)}$$

$$CO_{(a)} \xrightarrow{k_2} CO + S \quad \text{(M2)}$$

$$NO + S \xrightarrow{k_3} NO_{(a)} \quad \text{(M3)}$$

$$NO_{(a)} \xrightarrow{k_4} NO + S \quad \text{(M4)}$$

$$NO_{(a)} + S \xrightarrow{k_5} N_{(a)} + O_{(a)} \quad \text{(M5)}$$

$$2N_{(a)} \xrightarrow{k_6} N_2 + 2S \quad \text{(M6)}$$

$$CO_{(a)} + O_{(a)} \xrightarrow{k_7} CO_2 + 2S \quad \text{(M7)}$$

$$NO_{(a)} + N_{(a)} \xrightarrow{k_8} N_2O + 2S \quad \text{(M8)}$$

$$[A9] \qquad D = k_5AB/k_7$$

it is possible to write

$$[A10] \qquad \theta_N = C\theta_{CO}, \quad \theta_O = D\theta_{CO}$$

so that from eq. [A7] we have

$$[A11] \qquad \theta_{CO} = 1/(1 + A + B + C + D)$$

Therefore, the productions R_i are the following

$$[A12] \qquad R_{CO_2} = k_7\theta_{CO}\theta_O, R_{N_2} = k_6\theta_N^2, R_{N_2O} = k_8\theta_{NO}\theta_N$$

and the selectivity (SE) for the nitrogen is defined by

$$[A13] \qquad SE = R_{N_2}/(R_{N_2} + R_{N_2O})$$

Reversible decomposition of mono(α-hydroxy)-phosphines and their reaction with α,β-unsaturated aldehydes

Dmitry V. Moiseev, Paolo Marcazzan, and Brian R. James

Abstract: The mono(α-hydroxy)phosphines $R_2PCH(OH)R'$ (R = Ph, R′ = H, Et, CH_2Ph, Ph, *p*-X-C_6H_4; R = cyclohexyl, R′ = Ph) are prepared under solvent-free conditions by a 1:1 reaction of Ph_2PH with the appropriate aldehyde, and their stabilities (with respect to reversible dissociation into reactants), studied in DMSO, Et_2O, and MeOH, increase with decreased basicity of the hydroxyphosphine; for example, for the $Ph_2PCH(OH)C_6H_4$-*p*-X phosphines, stability decreases in the order: X = CN > Cl > F > H > Me > OMe. A 1:1 room-temperature reaction of the (α-hydroxy)phosphines (except for R′ = H) with cinnamaldehyde in DMSO slowly yields the known mono- and di-phosphines $Ph_2PCH(Ph)CH_2CHO$ (**4a**) and $Ph_2PCH(Ph)CH_2CH(PPh_2)OH$ (**10a**), and the corresponding R′CHO aldehyde. In MeOH, the sequentially formed intermediates, $PhCH{=}CHCH(OH)PPh_2$, $PhCH(OH)CH{=}CHPPh_2$, and $Ph_2PCH(Ph)CH{=}CHOH$, were detected en route to **4a** and **10a**. Reaction of cinnamaldehyde with Ph_2PCH_2OH gives **4a** and the hemiacetal $Ph_2PCH_2OCH_2OH$ formed from the reactant hydroxyphosphine with the co-product formaldehyde. Reactions carried out in MeOH are faster because of the formation of hemiacetals from the phosphine-containing aldehyde products; thus, **4a** is seen as $Ph_2PCH(Ph)CH_2CH(OMe)(OH)$, which on dissolution in Et_2O, reverts to the aldehyde. The reaction rates and equilibrium concentrations of the various species depend on the R′ group of the reactant phosphine; the rates of consumption of the hydroxyphosphines in the reactions with cinnamaldehyde decrease in the order: $Ph_2PCH(OH)Ph > Ph_2PCH(OH)Et > Ph_2PCH(OH)CH_2Ph >> Ph_2PCH_2OH$. The reactivity pattern of $Ph_2PCH(OH)Ph$ with sinapaldehyde [3,5-$(OMe)_2$-4-OH-cinnamaldehyde] in DMSO follows that seen for cinnamaldehyde. Reaction of Ph_2PH with cinnamaldehyde in DMSO affords **4a** and **10a** via the same intermediates seen with the $Ph_2PCH(OH)R'$ reagents, but these latter reactions are thought to occur via direct attack on cinnamaldehyde by the hydroxyphosphine rather than via Ph_2PH.

Key words: (α-hydroxy)phosphines, α,β-unsaturated aldehydes, diphenylphosphine, hydrophosphination.

Résumé : On a préparé des mono(α-hydroxy)phosphines $R_2CH(OH)R'$ [R = Ph, R′ H, Et, CH_2Ph, Ph, *p*-X-C_6H_4; R = cyclohexyle; R′ = Ph] dans des conditions sans solvant, en faisant réagir des quantités équimoléculaires (1:1) de Ph_2PH et de l'aldéhyde approprié. On a de plus étudié leurs stabilités par rapport à leur dissociation en réactifs dans le DMSO, Et_2O et MeOH qui augmente avec une diminution de la basicité de l'hydroxyphosphine; par exemple, pour les phosphines $Ph_2PCH(OH)C_6H_4$-*p*-X, la stabilité diminue dans l'ordre X = CN > Cl > F > H > Me > OMe. Une réaction de quantités équimoléculaires des (α-hydroxy)phosphines (à l'exception de celle dans laquelle R′ = H) et de cinnamaldéhyde, dans le DMSO, conduit lentement à la formation des mono- et diphosphines connues, $Ph_2PCH(Ph)CH_2CHO$ (**4a**) et $Ph_2PCH(Ph)CH_2CH(PPh_2)OH$ (**10a**), ainsi qu'à l'aldéhyde correspondant, R′CHO. Dans le méthanol, les produits $PhCH{=}CH(OH)PPh_2$, $PhCH(OH){=}CHPPh_2$ et $Ph_2PCH(Ph)CH{=}CHOH$, qui se forment successivement comme intermédiaires entre **4a** et **10a**. La réaction du cinnamaldéhyde avec le Ph_2PCH_2OH conduit à la formation du produit **4a** et de l'hémiacétal, $Ph_2PCH_2OCH_2OH$, qui résulte de la réaction du réactif hydroxyphosphine avec le formaldéhyde obtenu comme coproduit. Les réactions effectuées dans le MeOH sont plus rapides en raison de la formation d'hémiacétals à partir des produits aldéhydiques contenant une phosphine; ainsi, le produit **4a** observé sous la forme de $Ph_2PCH(Ph)CH_2CH(OMe)(OH)$ qui, par dissolution dans Et_2O se retransforme en aldéhyde. Les vitesses de réaction et les concentrations à l'équilibre des diverses espèces dépendent de la nature du groupe R′ présent sur la phosphine; les vitesses de consommation des hydroxyphosphines dans les réactions avec le cinnamaldéhyde diminuent dans l'ordre $Ph_2PCH(OH)Ph > Ph_2PCH(OH)Et > Ph_2PCH(OH)Ph > Ph_2PCH(OH)CH_2Ph > Ph_2PCH_2OH$. Le patron de réactivité du $Ph_2PCH(OH)Ph$ avec le sinapaldéhde [3,5-(Ome)2-4-OH-cinnamaldéhyde], dans le DMSO, est similaire à celui du cinnamaldéhyde. La réaction du Ph_2PH avec le cinnamaldéhyde, dans le DMSO, conduit à la formation des produits **4a** et **10a** par le biais des mêmes intermédiaires que ceux observés avec les réactifs $Ph_2PCH(OH)R'$; on croit toutefois que ces dernières réactions se produisent par le biais d'une attaque directe de l'hydroxyphosphine sur le cinnamaldéhyde pluṭt que par le biais d'une attaque via Ph_2PH.

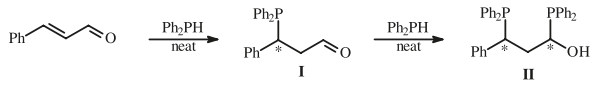
Introduction

Collaborative research involving our group has revealed that (hydroxymethyl)phosphines, particularly $P(CH_2OH)_3$ (abbreviated THP), are excellent bleaching and brightness stabilization agents for pulps, and interaction of such phosphines with conjugated carbonyl components of lignin is important in the bleaching process.[1] A current, widely used pulp-bleaching agent is sodium dithionite ($Na_2S_2O_4$), industrially called "hydrosulfite", and the collaborative studies revealed a remarkable synergistic effect in the use of a combination of THP and $Na_2S_2O_4$ for the bleaching;[2] this led us to study the complicated interaction between these two chemicals in aqueous solution, where some bis(hydroxymethyl)phosphine $PH(CH_2OH)_2$ was observed.[3] This encouraged us to study the reaction of secondary phosphines with lignin-model compounds, exemplified by cinnamaldehyde, where use of neat reagents gave isolable products from hydrophosphination of first the C=C and subsequently the C=O bonds (Scheme 1).[4] The isolated (α-hydroxy)phosphine **II** was found in solution to decompose reversibly to **I** and Ph_2PH with rates that were highly solvent-dependent.[4] The analogous reversible decomposition of $Ph_2PCH(OH)Et$ to propionaldehyde and Ph_2PH was also demonstrated,[4] and this confirmed the generality of such a process, which was first noted for the benzaldehyde/Ph_2PH system;[5] a more recent study with phenolic aldehydes has also demonstrated such equilibria.[6] This chemistry was clearly relevant for our studies involving THP, a tris(α-hydroxy)phosphine, and we decided to investigate reactivity between cinnamaldehyde and mono(α-hydroxy)phosphines, which could well be present in the bleaching systems formed via addition of PH of the observed $PH(CH_2OH)_2$ across carbonyl and (or) olefinic functionalities. This paper presents our findings on these systems, studied in organic solvents. The studies complement those of our recent papers, which describe the interactions in aqueous solution between cinnamaldehyde and $P[(CH_2)_2OH]_3$,[7] and between substituted cinnamaldehydes and non-functionalized tertiary phosphines.[8]

There is literature describing reactivity of (α-hydroxy)phosphines (mostly THP) with α,β-unsaturated carbonyl-containing compounds in organic solvents, where the phosphorus atom attacks the activated C=C bond followed by loss of an aldehyde; e.g., THP with acrylonitrile gives $P(CH_2CH_2CN)_3$ with loss of formaldehyde, the net reaction being addition of P–H across the C=C bond (eq. [1]).[9,10] Similarly, reaction of the bis(α-hydroxy)phosphines $RP(CH_2OH)_2$ (R = Me, Et) with acrylonitrile can lead to formation of $RP(CH_2CH_2CN)_2$.[11] Reaction of THP with methyl acrylate in organic solvents generates the phosphine oxide $O=P(CH_2CH_2CO_2Me)_3$ formed because of the presence of trace water,[12] while THP (formed from the tetrakis(hydroxy)phosphonium salt $[P(CH_2OH)_4]Cl$ and base) reacts with acrylamide to give a mixture of $[(HOCH_2)P(CH_2CH_2NHCH_2OH)_3]OH$ and $O=P(CH_2CH_2NHCH_2OH)_3$, and with acrylic acid to yield a phosphobetaine (eq. [2]).[10] In this relatively early literature work, studied during the early days of ^{31}P NMR, the products, although likely correct, were not always well-characterized.

Scheme 1. 1:1 and 2:1 reactions of Ph_2PH with cinnamaldehyde; * indicates a chiral centre (ref. 4).



$$[1]\quad P(CH_2OH)_3 + 3CH_2{=}CHCN \rightarrow P(CH_2CH_2CN)_3 + 3CH_2O$$

$$[2]\quad [P(CH_2OH)_4]Cl + NaOH + CH_2{=}CHCO_2H \rightarrow (HOCH_2)_3P^+CH_2CH_2CO_2^- + CH_2O + H_2O + NaCl$$

Our studies reported here describe mainly reactions of cinnamaldehyde with the hydroxyphosphines $R_2PCH(OH)R'$ (R = Ph, R′ = H, Et, CH_2Ph, Ph, or *p*-substituted-Ph) in DMSO and in MeOH, as well as reversible decomposition of the hydroxyphosphines.

Experimental section

Cinnamaldehyde, sinapaldehyde [3,5-$(OMe)_2$-4-OH-cinnamaldehyde], PhCHO, and 4-X-C_6H_4CHO (X = CN, Cl, F, Me, and MeO), all Aldrich products, were distilled under reduced pressure or recrystallized, and stored under Ar before use. Ph_2PH and Cy_2PH (Cy = cyclohexyl) from Strem Chemicals were used as received. Ph_2PCH_2OH was prepared as reported from Ph_2PH and paraformaldehyde,[13] but purified by trituration using hexane/$CHCl_3$ (6:1), while $Ph_2PCH(OH)Et$, $Ph_2PCH(OH)CH_2Ph$, $Ph_2PCH(OH)Ph$, and $Cy_2PCH(OH)Ph$ were prepared from the appropriate secondary phosphine and aldehyde by our recently described procedure under Ar using Schlenk glassware or a glovebox.[4] ^1H, $^1H\{^{31}P\}$, and $^{13}C\{^1H\}$ NMR data for a DMSO-d_6 solution, and elemental analyses, of the new (α-hydroxy)phosphines are given in Table S1 (see Supplementary data). The $^{31}P\{^1H\}$ singlets for these phosphines in different solvents are listed in Table S2 (see Supplementary data). Organic solvents were dried over the appropriate reagents, and then distilled under Ar, while CD_3OD and DMSO-d_6 (Cambridge Isotope Laboratory) were used as received. $^{31}P\{^1H\}$ NMR spectra were recorded on a Bruker AV300 spectrometer (121 MHz) at 300 K unless otherwise stated; ^1H and ^{13}C NMR spectra were similarly recorded on an AV400 instrument (400 MHz for ^1H, 100 MHz for $^{13}C\{^1H\}$). A residual deuterated solvent proton (relative to external $SiMe_4$) and external 85% aq. H_3PO_4 were used as references: br = broad, s = singlet, d = doublet, t = triplet, p = pentet, and m = multiplet. *J* values are given in Hertz. When necessary, atom assignments were made by means of ^1H–^1H, ^1H–$^{13}C\{^1H\}$ (HMQC and HMBC) and ^1H–$^{31}P\{^1H\}$ NMR correlation spectroscopies.

Stability (with respect to reversible dissociation) of mono(α-hydroxy)phosphines in organic solvents

In a glovebox, the phosphine (0.05 mmol) was dissolved in 1 mL of a selected solvent, and a sample (~0.7 mL) of the solution was placed under Ar in a J-Young NMR tube; $^{31}P\{^{1}H\}$ NMR spectral changes were then monitored as a function of time at 300 K.

Reactions of Ph_2PH with aromatic aldehydes in MeOH

In a glovebox, Ph_2PH (18.6 mg, 0.1 mmol) was added to a MeOH solution of the aldehyde (0.1 mmol in 1 mL), and $^{31}P\{^{1}H\}$ NMR spectral changes of a sample were then monitored as described above.

Reactions of Ph_2PH or a mono(α-hydroxy)phosphine with an α,β-unsaturated aldehyde

As above, the phosphine (0.1 mmol) was added under Ar to a solution of the aldehyde (0.1 mmol) in air-free DMSO/DMSO-d_6 or MeOH/CD_3OD (1 mL), and a sample was monitored by NMR spectroscopy at 300 K.

Results and discussion

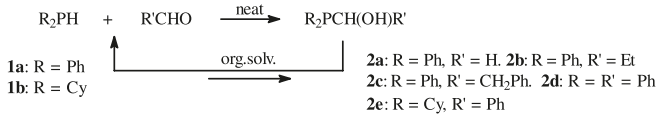
Synthesis and decomposition of (α-hydroxy)phosphines

The (α-hydroxy)phosphines **2a**–**2e** were prepared quantitatively as white solids by reaction of Ph_2PH (**1a**) or Cy_2PH (**1b**) with the corresponding aldehydes under solvent-free conditions at room temperature (Scheme 2), following the procedure reported earlier for **2b**;[4] the ^{1}H, $^{1}H\{^{31}P\}$, and $^{13}C\{^{1}H\}$ NMR data in DMSO-d_6 (Table S1 of the Supplementary data) are assigned as done previously for **2b**.[4] We have shown[4] that **2b** in solution at ambient conditions reversibly decomposes into Ph_2PH and propionaldehyde, greater stability being seen generally in higher donor number (DN) solvents such as DMSO, DMF, and pyridine,[14] and for this reason, the NMR data obtained in DMSO-d_6 are listed. The $^{31}P\{^{1}H\}$ data in four solvents (Table S2 of the Supplementary data) reveal a qualitative decomposition trend, and semiquantitative studies on **2a**–**2e** were undertaken in DMSO, Et_2O, and MeOH by monitoring the $^{31}P\{^{1}H\}$ singlet; decomposition in $CHCl_3$ and CH_2Cl_2 was significantly faster.

In DMSO (DN = 29.8), **2a**–**2d** are stable, with only trace amounts of **1a** being detected even after several hours, while **2e** essentially decomposes completely over 12 h (Fig. S1). In Et_2O (DN = 19.2), **2e** fully decomposes within 5 min, while Fig. S2 shows decomposition curves for **2b**–**2d** in this solvent, where the rates and degree of decomposition of **2d** are the highest, an equilibrium with ~90% conversion being set up with $t_{1/2} \approx 5$ h; for **2c**, an equilibrium is established with ~45% conversion ($t_{1/2} \approx 12$ h), while for **2b**, there is only ~60% conversion after 10 days, and no decomposition is evident for **2a**.

In MeOH, although a good donor (DN = 30.0), all the (hydroxy)phosphines show some instability, because they now decompose to the secondary phosphine and some hemiacetal formed from the aldehyde and MeOH; data in Fig. S3 show that the rates and the degree of decomposition decrease in the order: **2e >> 2b > 2d > 2c > 2a** (with **2e,** the $^{31}P\{^{1}H\}$ spectrum after 5 min showed only the resonance of **1b**). Rapid removal of the aldehyde as hemiacetal impedes regeneration of the (hydroxy)phosphines. Methanol is the only solvent studied where decomposition of **2a** was observed (~15% equilibrium, with $t_{1/2} \approx 3$ h). Establishing overall equilibria requires that measureable equilibria exist also between the aldehyde and its methanol hemiacetal, which is consistent with literature data, for example, in the case of **2d**, for benzaldehyde[15] (see below). The decompositions of **2a**–**2d** occur faster and to a greater extent in MeOH than in Et_2O, and hemiacetal formation must be one factor, although the presence of trace water in the MeOH possibly plays a role by favouring formation of a phosphonium intermediate. We have suggested previously[4] that decomposition of (α-hydroxy)phosphines could occur via an acid–base interaction between the OH proton and phosphine lone pair to give a phosphonium intermediate that re-arranges to the aldehyde and secondary phosphine (Scheme 5 in ref. 4); this implies also that a more electron-rich P atom gives a less stable (α-hydroxy)phosphine, and the above data for $Ph_2PCH(OH)Ph$ (**2d**) versus those for $Cy_2PCH(OH)Ph$ (**2e**) support such a premise. Of note, the tertiary phosphines $P[(CH_2)_nOH]_3$ (n = 1, 3) react quite differently with benzaldehyde in aqueous solution at ~90 °C via a redox reaction to give benzyl alcohol and the corresponding phosphine oxide.[16]

Scheme 2. Preparation and reversible decomposition of (α-hydroxy)phosphines.



We then investigated, by NMR-scale reactions in MeOH (see Experimental section), the effect of a *p*-substituent (X) in a series of benzaldehydes on the stability of the (α-hydroxy)phosphines derived from Ph_2PH (eq. [3]). The data are summarized in Fig. S4, which shows that the rates and degrees of formation of the (α-hydroxy)phosphines decrease in the order: CN > Cl > F > H > Me > OMe; an excellently linear Hammett relationship results from plotting the relative equilibrium concentration vs. σ (Fig. S5). Thus, similar to the effect of the nature of the secondary phosphine, electron-withdrawing groups of the aldehyde favour the formation of the (α-hydroxy)phosphines and, consistent with this, the pentafluorophenyl derivative $Ph_2PCH(OH)C_6F_5$ is known to be stable.[5] It should be pointed out that the linearity of the Hammett plot may be fortuitous in that the presence of the aldehyde ⇌ hemiacetal equilibria is ignored, while the degree of formation of the hemiacetal is reported to be favoured with increasing electron-withdrawing nature of X.[15] Indeed, experimental NMR and enthalpy data[15] imply relatively little hemiacetal formation for the benzaldehydes that we studied, although there are significant discrepancies between some of the measured and calculated values;[15] one set of data is X = OMe (1.5% formation of hemiacetal), Me (2.1%), H (3.7%), and Cl (13%). The data of Figs. S4 and S5 must reflect the effect of X on (α-hydroxy)phosphine stability because the effect of X on the hemiacetal equilibria would itself give an apparent decrease in formation of the hydroxyphosphines by removal of the aldehyde.

[3] 
Fig. 1. The in situ $^{31}P\{^{1}H\}$ spectrum during reaction of cinnamaldehyde (**3a**) with Ph_2PCH_2OH (**2a**) (1:1, Ar, 300 K, DMSO-d_6): (A) after 2 days and (B) 22 days.

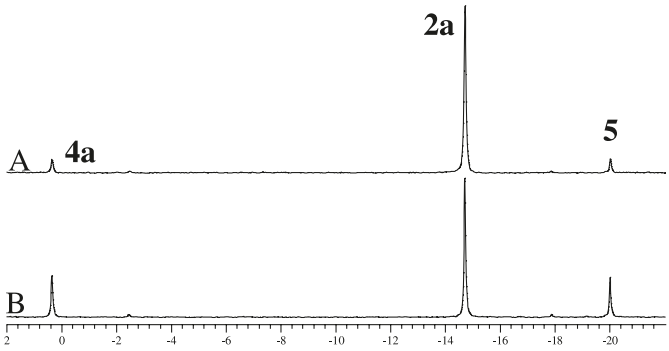


Fig. 2. The in situ $^{31}P\{^{1}H\}$ spectrum of the reaction of cinnamaldehyde (**3a**) with Ph_2PCH_2OH (**2a**) (1:1, Ar, 300 K, MeOH): (A) after 25 min, (B) 50 min, (C) 2 h, (D) 4 h, (E) 8 h, (F) 22 h, and (G) 48 h.

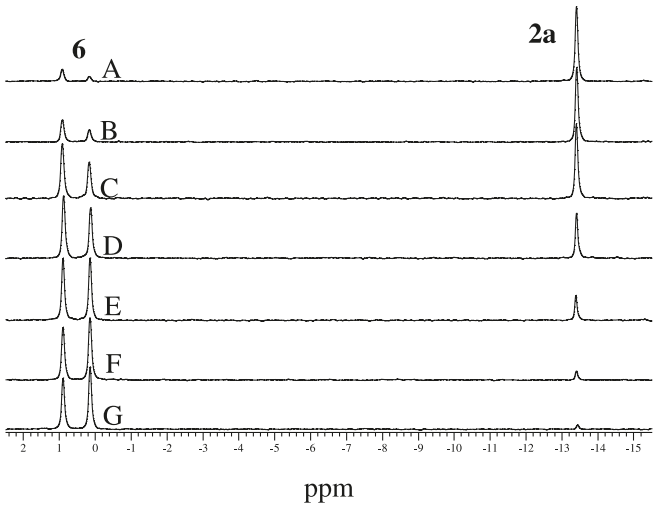


Reactions of (α-hydroxy)phosphines with α,β-unsaturated compounds

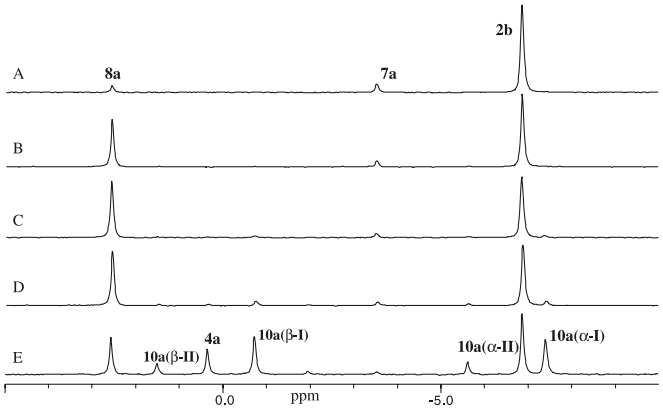
On a 1:1 reaction of Ph_2PCH_2OH (**2a**) with cinnamaldehyde (**3a**) in DMSO-d_6, the $^{31}P\{^{1}H\}$ resonance of **2a** (δ_P –14.7) was very slowly displaced by two almost equal intensity singlets at δ_P 0.4 and –20.0 (Fig. 1A); ^{1}H–^{1}H COSY and ^{1}H–$^{31}P\{^{1}H\}$ HMQC data (Figs. S6 and S7) show that the singlets are associated, respectively, with the known phosphine **4a** (**I** in Scheme 1)[4] and the phosphinated hemiacetal co-product **5** (eq. [4]). The net reaction would seem to be the formation of **4a** by nucleophilic attack of **2a** at the C=C bond of **3a** (but see below), with concomitant liberation of formaldehyde, which is not detected because it interacts via the OH group of **2a** to afford **5**. The P–CH_2 protons of **5** appear in the ^{1}H spectrum as a doublet at δ_H 4.27 ($^{2}J_{PH}$ = 5.0 Hz), which collapses to a singlet in the $^{1}H\{^{31}P\}$ spectrum. The corresponding protons of **2a** appear at δ_H 4.25 as a doublet of doublets due to extra coupling to the OH proton ($^{2}J_{PH}$ = 6.8, $^{3}J_{HH}$ = 5.5 Hz), and this reduces to a doublet in the $^{1}H\{^{31}P\}$ spectrum. The CH_2OH protons of **5** appear as a doublet at δ_H 4.67 both in the ^{1}H and $^{1}H\{^{31}P\}$ spectra ($^{3}J_{HH}$ = 7.9 Hz), and the OH proton is seen as a triplet at δ_H 6.45. After 22 days, integration of the $^{31}P\{^{1}H\}$ signals (Fig. 1B) shows that **4a** and **5** are each formed in ~20% yield (based on **2a**). Attempts to isolate pure **5** from reaction of CH_2O with **2a**, which itself is prepared from the reversible reaction of CH_2O with Ph_2PH,[13] have thus far been unsuccessful. Phosphines of this type have been synthesized previously from CH_2O and the (α-hydroxy)phosphine $P(CH_2OH)_3$.[17] There is no evidence for hemiacetal formation from **4a** and **2a**, consistent with higher reactivity (electrophilicity) of CH_2O versus that of **4a**.

[4] 
The reaction of **2a** with **3a** in MeOH is much faster than that in DMSO, the products now being the hemiacetal **6** (formed from **4a** and MeOH) and formaldehyde–hemiacetal (seen in CD_3OD as CD_3OCH_2OD, δ_H 4.65). Compound **6** is formed as a mixture of diastereomers (eq. [5]), observed in the $^{31}P\{^{1}H\}$ spectrum as two singlets δ_P 0.9 and 0.1 (Fig. 2), the diastereomeric ratio (d.r.) of a presumed mixture of *S*,*S*/*R*,*R*- and *S*,*R*/*R*,*S*-enantiomers changing from 0.37 (after 25 min) to 1.25 (after 2 days). The phosphine **4a** is almost insoluble in MeOH, but slowly dissolves as the hemiacetal **6**, when the δ_P 0.9 diastereomer is again initially preferred, the d.r. changing from 0.65 (90 min) to 1.25 (5 days) (Fig. S8). The same d.r. values result from integration of the ^{1}H signals, where the C*H*(OD)-protons appear as ddd

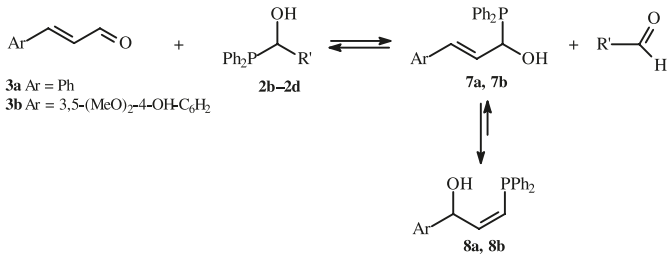
[5] 
patterns at δ_H 4.17 and 4.09 with similar coupling constants ($^{3}J_{HH}$ = 8.9, $^{3}J_{HH}$ = 2.7, and $^{4}J_{PH}$ = 0.8 Hz), and the PhC*H*-protons are seen as overlapping ddd patterns at δ_H 3.76 and 3.73 ($^{3}J_{HH}$ = 12.0, $^{3}J_{HH}$ = 3.4, and $^{2}J_{PH}$ = 6.7 Hz). $^{13}C\{^{1}H\}$ NMR data for **6** are as follows: δ 142–127 (s and d, Ph groups), δ 97.9 (s, *C*HOMe), 42.2 (d, $^{1}J_{PC}$ = 11.0, Ph*C*H), and 41.7 (d, $^{2}J_{PC}$ = 20.6, *C*H_2) for one diastereomer; δ 97.8 (s, C*H*OMe), 42.1 (d, $^{1}J_{PC}$ = 11.3, Ph*C*H), and 41.0 (d, $^{2}J_{PC}$ = 20.6, *C*H_2) for the second diastereomer; the assignments for the Ph*C*H and *C*H_2 carbons, although unusual in that $^{2}J_{PC} > {}^{1}J_{PC}$, are based on definitive correlation NMR data for the corresponding C atoms of **4a**, which have such δ and *J* values.[4]

Of note, we have previously synthesized **4a** by the reaction of **3a** with Ph_2PH using neat reagents[4] (Scheme 1 in the Introduction), and it is plausible that the formation of **4a** illustrated in eq. [4] might involve the same chemistry, Ph_2PH being formed by decomposition of **2a** with formaldehyde as co-product (Scheme 2). This will be discussed later when data from reactions of cinnamaldehydes with the other (hydroxy)phosphines **2b**–**2d** have been considered (here, a different set of products and intermediates were observed). For example, a 1:1 reaction of $Ph_2PCH(OH)Et$ (**2b**) with cinnamaldehyde (**3a**) in DMSO-d_6 generates after 30 min two new singlets at δ_P –3.5 and 2.6 in the $^{31}P\{^{1}H\}$ spectrum

Fig. 3. The in situ $^{31}P\{^{1}H\}$ spectrum of the reaction of cinnamaldehyde (**3a**) with $Ph_2PCH(OH)Et$ (**2b**) (1:1, Ar, 300 K, DMSO): (A) after 30 min, (B) 6 h, (C) 22 h, (D) 46 h, and (E) 12 days; **10a** is a mixture of diastereomers (**α-I** and **β-I**) and (**α-II** and **β-II**) (Ref. 4).



Scheme 3. Formation of intermediates in reactions of (α-hydroxy)-phosphines with α,β-unsaturated compounds.



(Fig. 3A), which are assigned to the racemates of the phosphines species **7a** and **8a**, respectively (Scheme 3). A kinetic intermediate, (α-hydroxy)phosphine **7a**, is formed by nucleophilic attack of the P atom at the aldehyde C atom. In the ^{1}H spectrum (Fig. S9), the γ- and β-vinyl protons (δ_H 6.43 and 6.19, respectively) give dd and ddd patterns, which collapse to a doublet and a doublet of doublets in the $^{1}H\{^{31}P\}$ spectrum, respectively (Fig. S10) [$^{3}J_{HH}$ (trans H atoms) = 16.0, $^{4}J_{PH}$ = 3.3, $^{3}J_{PH}$ = 4.6 Hz]; the α-H appears as a broad doublet centered at δ_H 5.21 both in the ^{1}H and in the $^{1}H\{^{31}P\}$ spectrum, and the broad singlet of the OH proton is seen at δ_H 5.73. Intramolecular re-arrangement within **7a**, involving OH migration from the α- to the γ-C, affords **8a**. The downfield shift of the ^{31}P resonance (compared to that for **7a**) is consistent with the relative positions of the C=C moiety. The β- and α-vinyl ^{1}H proton signals are upfield-shifted (dd and ddd at δ_H 4.78 and 4.48, respectively) versus those for **7a**, the $^{3}J_{HH}$ value of 10.8 Hz implying a cis conformation ($^{2}J_{PH}$ = 6.5, $^{3}J_{PH}$ = 6.6 Hz), while the γ-H signal appears at δ_H 6.23 and overlaps with the β-H resonance of **7a**; the $^{1}H\{^{31}P\}$ spectra support the assignments (Figs. S9 and S10). The cis conformation might entail hydrogen-bonding between the OH proton and the P atom. The $^{1}H–^{31}P\{^{1}H\}$ correlation spectra of **7a** and **8a** are shown in Fig. S11. The eventual higher concentration of **8a** (vs. that of **7a**) implies a higher thermodynamic stability of the former (Figs. 3A–3D).

The hydroxyphosphines (**2c**–**2d**) also react with cinnamaldehyde (**3a**) according to Scheme 3. Figure 4 shows the rate of consumption of **2b**–**2d** in the reaction with **3a** under iden-

Fig. 4. The consumption of the starting phosphine in the reactions: (A) **2c** + **3a**, (B) **2b** + **3a**, (C) **2d** + **3b**, (D) **2d** + **3a**, and (E) **1a** + **3a**. Reactions were carried out under standard conditions (1:1, Ar, 300 K, DMSO).

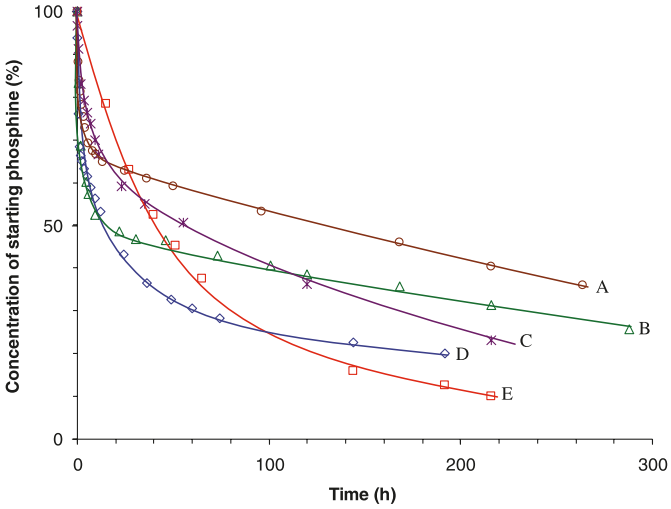


Fig. 5. The relative concentration of the intermediate **7** in the reactions: (A) **2c** + **3a**, (B) **2b** + **3a,** (C) **2d** + **3b,** (D) **2d** + **3a, and** (E) **1a** + **3a**. Reactions were carried out under standard conditions (1:1, Ar, 300 K, DMSO).

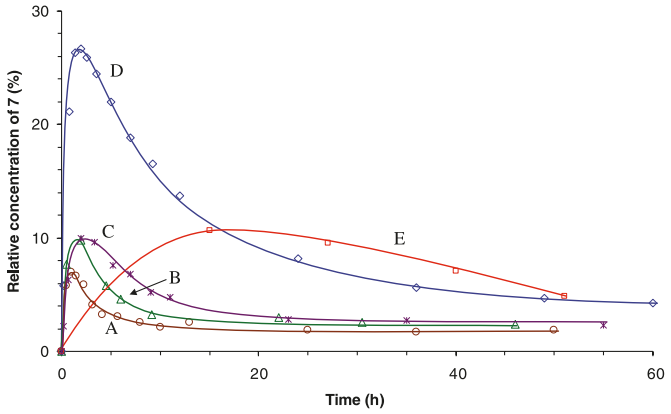

Fig. 6. The relative concentration of the intermediate **8** in the reactions: (A) **2c** + **3a**, (B) **2b** + **3a,** (C) **2d** + **3b,** (D) **2d** + **3a,** and (E) **1a** + **3a**. Reactions were carried out under standard conditions (1:1, Ar, 300 K, DMSO).

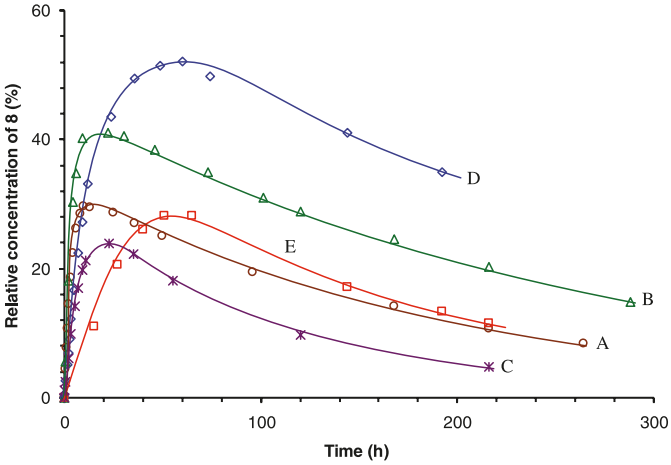

Fig. 7. The relative concentration of the diphosphine **10** in the reactions: (A) **2c** + **3a**, (B) **2b** + **3a,** (C) **2d** + **3b,** (D) **2d** + **3a,** and (E) **1a** + **3a**. All reactions were carried out under standard conditions (1:1, Ar, 300 K, DMSO).

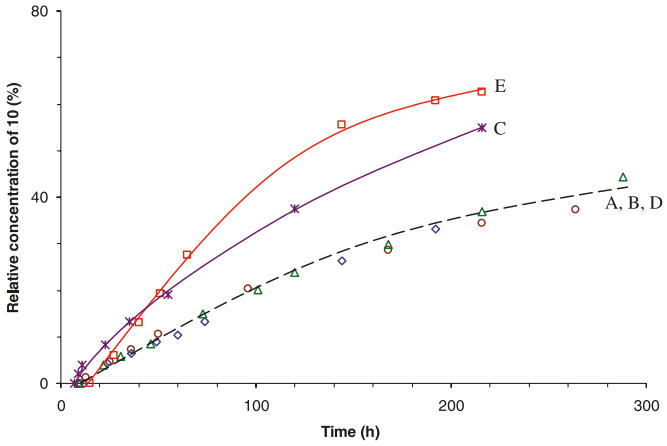

Fig. 8. The relative concentration of the phosphine **4a** or **4b** in the reactions: (A) **2c** + **3a,** (B) **2b** + **3a,** (C) **2d** + **3b,** (D) **2d** + **3a,** and (E) **1a** + **3a**. All reactions were carried out under standard conditions (1:1, Ar, 300 K, DMSO).

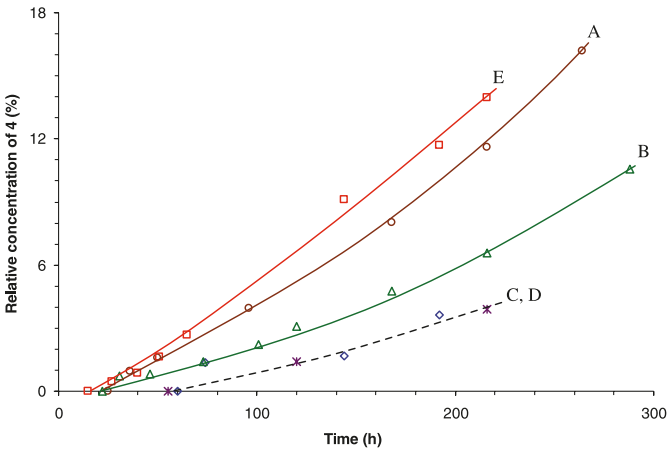

tical conditions (1:1, DMSO, 300 K, Ar), while Figs. 5 and 6 show the relative concentrations of the corresponding intermediates **7** and **8**, respectively. The degree of the consumption of **2b**–**2d** in their reaction with **3a** to form **7a/8a** (Scheme 3) decreases in the order: **2d** > **2b** > **2c** (Fig. 4), and also the extents of generation of **7a** (Fig. 5) and of **8a** (Fig. 6) decrease in the same order. This means that within the upper reaction of Scheme 3, benzaldehyde is a better "leaving group" than propionaldehyde, which is better than phenylacetaldehyde; with a more electrophilic aldehyde component of the reactant hydroxyphosphine, this equilibrium will be shifted to the left, and recall that in the reaction of **2a** (involving CH_2O, the most electrophilic of aldehydes) with **3a**, intermediates of the type **7** or **8** were not detected, and **4a** and **5** were the products (see above).

With the **2b**–**2d** systems, the concentrations of **7a** and **8a** do decrease slowly with formation of **4a** (Figs. 3, 5, and 6). However, **4a** can also then react with the starting phosphine **2b**–**2d** to generate the known diphosphine **10a** as a mixture of diastereomers, which is seen in the $^{31}P\{^1H\}$ spectrum as two sets of two equal intensity singlets (δ_P 1.5, –5.6 and –0.7, –7.4) (Figs. 3C-3E); eqs. [6] and [7] summarize the later stages of the chemistry (**9a** was detected in MeOH, see below). In recent work, we have characterized **10a**, where it was isolated from reaction of cinnamaldehyde with Ph_2PH via intermediate formation of **4a**[4] (see Scheme 1 in the Introduction) where **4a** and **10a** are labelled **I** and **II**, respectively.

Of note, the concentration of **10a** generated is independent of the reactant phosphine (**2b**–**2d**) used (Fig. 7), while the rate of formation of **4a** depends on the starting phosphine and decreases in the order: **2c** > **2b** > **2d** (Fig. 8). These findings can be rationalized qualitatively by considering the reverse reactions of the aldehydes with the diphosphine **10a** (eq. [7], Figs. 4 and 8), where again a more reactive aldehyde will shift the equilibrium to the left. The concentrations of **2b** and **8a** decrease simultaneously after the relatively fast stage (10 h), while the concentration of **7a** remains constant (Figs. 4–6), and this requires the upper reaction of Scheme 3 to be an equilibrium. This was confirmed by addition of EtCHO (the precursor to **2b**) to a solution containing **7a** and **8a** such as the one used to measure spectrum A in Fig. 3: the **7a**:**2b** ratio decreased rapidly from 0.15 to 0.02 on addition of two equiv. of EtCHO to the solution, while the **8a**:**2b** ratio increased from 0.15 to 0.30. The final product in these systems is **4a** (evident after 2 months!), and this requires also the reaction of eq. [7] to be reversible, and this was confirmed by addition of EtCHO to a DMSO solution of **10a**, when production of **2b** and **4a** was seen by using $^{31}P\{^1H\}$ NMR spectroscopy.

Evidence that **4a** likely derives from **7a** via the enol intermediate **9a** (formed from **7a** by migration of the Ph_2P group from the α- to γ- position) (eq. [6] was obtained by carrying out 1:1 reactions of **2b**–**2d** with cinnamaldehyde in MeOH/CD_3OD, which are much faster than the reaction in DMSO. Figure 9 shows a $^{31}P\{^1H\}$ NMR profile of the reaction for **2d** in MeOH, which is complete in 1 h. The final products of the reaction are the diastereomeric mixture of the hemiacetal **6** formed from **4a** (eq. [5], Fig. 9) and traces of the diastereomers of diphosphine **10a**. The 1:1 stoichiometry determines that **6** is essentially the sole product, while the observed intermediacy of **10a** again reveals the reversibility of the eq. [7] reaction. The **10a** diastereomers are detected at δ_P 2.6, –4.5, and 0.3, –6.6 (Fig. 9C). Figure 10 shows the ^1H–$^{31}P\{^1H\}$ HMQC correlation spectrum of this system in CD_3OD recorded after ~10 min, when the intermediates **7a,** **8a**, and **9a** are readily identified. The ^{31}P signals of **7a** (δ_P –2.3) and **8a** (δ_P 3.9) are downfield-shifted from those seen in DMSO, while the associated α-, β-, and γ-proton signals are at chemical shifts similar to those observed in DMSO-d_6 (see above) but are better resolved; e.g., the α-H of **7a** appears at δ_H 5.17 as a pseudo-doublet of triplets ($^2J_{PH}$ = $^4J_{HH}$ = 1.5, $^3J_{HH}$ = 6.5 Hz). Three ^1H resonances correlating with the $^{31}P\{^1H\}$ resonance at δ_P –0.7 in the ^1H–$^{31}P\{^1H\}$ HMQC spectrum (Fig. 10) are assigned to the enol species **9a**: the vinyl α- and β-protons appear at δ_H 4.10 and 5.02, respectively, as dd and ddd patterns ($^4J_{PH}$ = 6.8, $^3J_{PH}$ = 7.1, $^3J_{HH}$ = 9.1 Hz), the $^3J_{HH}$ value again implying a cis conformation at the olefinic bond, while the γ-H appears as a dd pattern centered at δ_H 6.15 and overlaps with the γ-H of **7a**; the $^3J_{HH}$ coupling constant to the β-H is 12.3 Hz ($^2J_{PH}$ is diffi-

Fig. 9. The in situ $^{31}P\{^{1}H\}$ spectrum of the reaction of cinnamaldehyde (**3a**) with $Ph_2PCH(OH)Ph$ (**2d**) (1:1, Ar, 300 K, MeOH): (A) after 8 min, (B) 11 min, (C) 20 min, (D) 30 min, (E), and (F) 50 min; **10a** is a mixture of diastereomers (**α-I** and **β-I**) and (**α-II** and **β-II**) (Ref. 4).

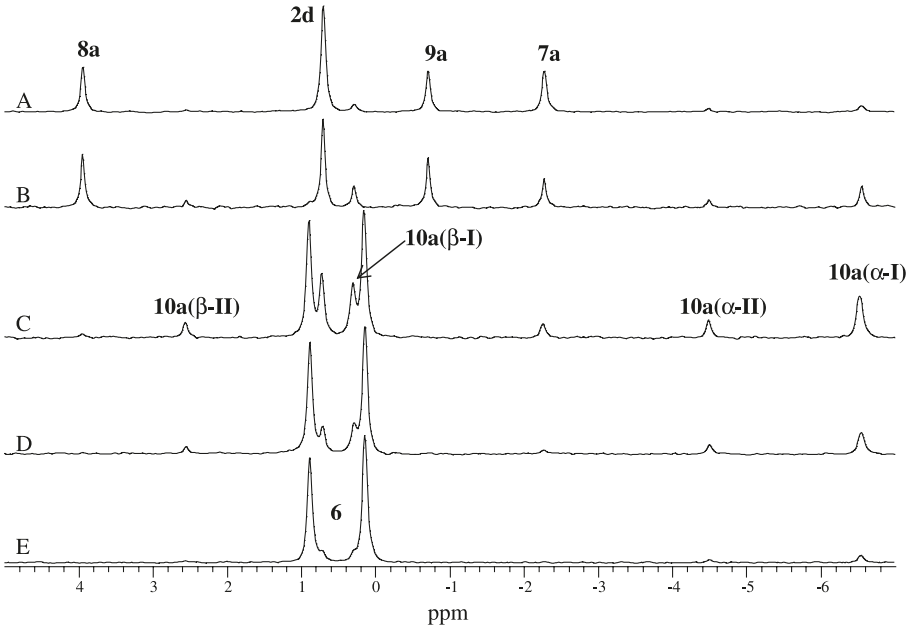

Fig. 10. The in situ ^{1}H–$^{31}P\{^{1}H\}$ HMQC spectrum of the reaction of cinnamaldehyde (**3a**) with **2d** (1:1, Ar, 300 K, CD_3OD) after ~10 min.

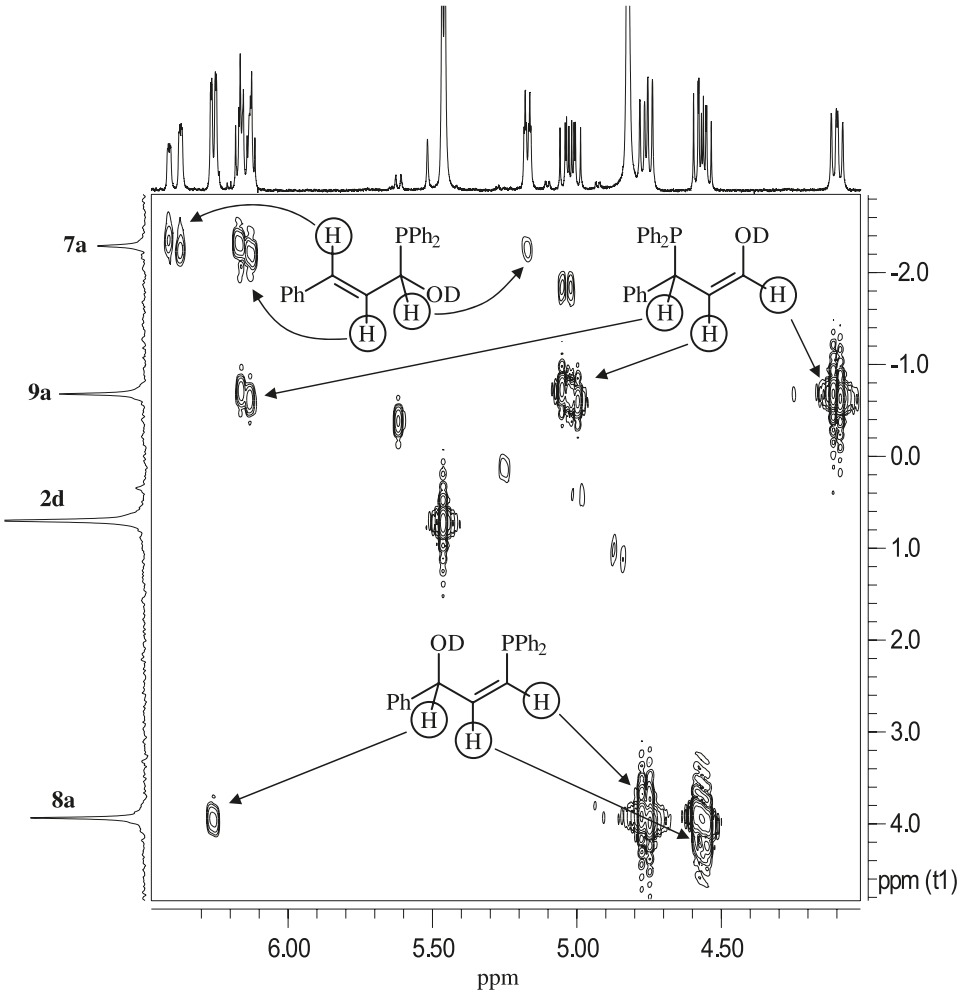

Fig. 11. The in situ $^{31}P\{^{1}H\}$ spectrum of the reaction of sinapaldehyde (**3b**) with $Ph_2PCH(OH)Ph$ (**2d**) (1:1, Ar, 300 K, DMSO): (A) after 40 min, (B) 3 h, (C) 7 h, (D) 24 h, (E) 5 days, and (F) 12 days; **10a** is a mixture of diastereomers (**α-I** and **β-I**) and (**α-II** and **β-II**) (Ref. 4).

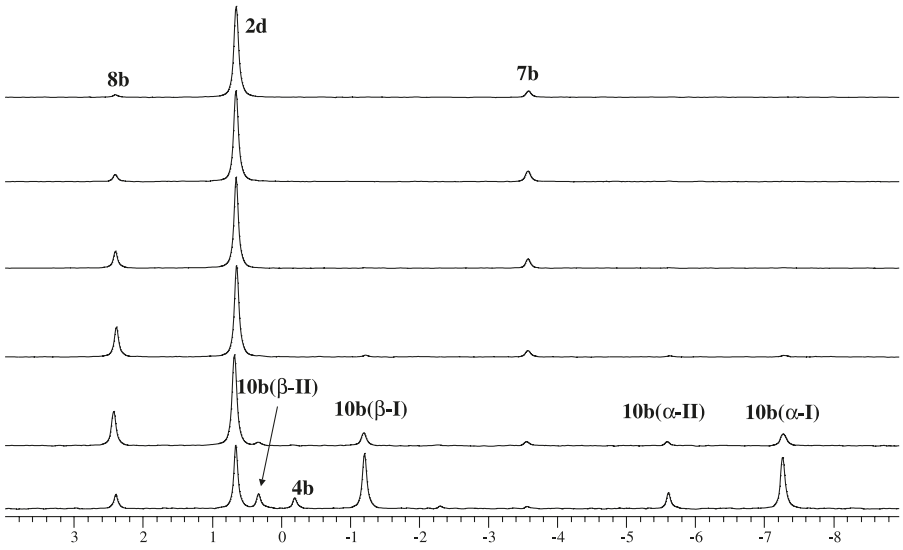

cult to determine). In CD_3OD, the product **6** is monodeuterated in the β-position, consistent with an enol-OD intermediate being involved in the formation of **4a**.

[6]

[7] 
4a, 4b **2b–2d** **10a, 10b**

Sinapaldehyde (**3b**), a lignin-type aldehyde,[18] was also reacted with $Ph_2PCH(OH)Ph$ (**2d**) in DMSO to compare its reactivity with that of cinnamaldehyde (**3a**). The reason for this study was that the presence of an OH group para to the unsaturated aliphatic chain of **3a** has been shown to change significantly in aqueous solution the interaction of such aldehydes with PR_3 phosphines, where R does not contain an α-OH group.[8] However, in DMSO, the reactivity of **2d** with **3b** is found to be similar to that with **3a**, with corresponding intermediates and products (**4b**, **7b, 8b**, and **10b**) being detected by NMR (Fig. 11). Data in Figs. 4–6 (C curves) show that the consumption of **2d** is slower in the reaction with **3b**, leading to lower concentrations of **7b** and **8b** at a selected reaction time; the resulting higher concentration of **2d** leads to a higher concentration of **10b** (Fig. 7, eqs. [6] and [7]), although the rate of the generation of phosphine product **4b** is the same as for **4a** (Fig. 8).

It cannot be completely ruled out that **4a** and **4b** derive via **9a** and **9b**, respectively, formed at least partially by initial direct nucleophilic attack of a hydroxyphosphine at the C=C bond of the α,β-unsaturated aldehyde (eq. [6]). Further, **10a/10b**, which are hydroxyphosphines, could react with the cinnamaldehydes to form **4a/4b** giving intermediates **7a/7b** as co-products (cf. Scheme 3, upper equilibrium). However, the NMR studies support strongly the overall chemistry as presented in Scheme 3 and eqs. [6] and [7], and, although complicated because of the various equilibria involved, the reaction pathways are considered substantiated.

Because Ph_2PH (**1a**) is a decomposition product of the (α-hydroxy)phosphines (**2a**–**2d**) in organic media (Scheme 2), **1a** was always detected by $^{31}P\{^{1}H\}$ and ^{1}H NMR in small amounts (<6%) in all the reactions discussed above (δ_P –39.7 in DMSO, δ_P –39.8 in MeOH; δ_H 5.22, d, $^{1}J_{PH}$ = 222 Hz; see Figs. S9 and S12), and further, since **1a** is known to react with **3a** to give **4a**,[4] we thus studied the reaction of **3a** with **1a** in DMSO to see the plausibility of whether **4a** was being formed by this "decomposition" route. The expected intermediates and product discussed above (**7a**, **8a**, and **4a**) were detected; the consumption rate of Ph_2PH was slower than in the case of the hydroxyphosphines **2c** and **2d** (Fig. 4), presumably due to the lower nucleophilicity of the secondary phosphine compared with that of the tertiary phosphines and, as a result, the generation of **7a** and **8a** is also slower (Figs. 5 and 6). The formations of monophosphine **4a** (Fig. 8) and diphosphine (**10a**) (Fig. 7) are faster because no aldehyde is present in the reaction mixture (see the reversible reactions involving R′CHO shown in Scheme 3 and eq. [7]). The slower reactions seen with Ph_2PH (vs. **2c** and **2d**) are consistent with reaction pathways for the hydroxyphosphines via their direct attack on the unsaturated aldehydes rather than via Ph_2PH, although this latter route might contribute also; direct attack is expected to form (via nucleophilic attack of the phosphine at the C=O moiety) an (α-hydroxy)phosphonium intermediate such as $PhCH{=}CHCH(OH){-}R_2P^{+}CH(O^{-})R'$,[8,17b,19] which subsequently forms **7a** with release of R′CHO (Scheme 3). When Ph_2PH was reacted with **3a** (1:1) in MeOH, intermediates **7a**–**10a** were seen, while the only final product was hemiacetal **6** (see eq. [5]) formed from **4a** (see Scheme 1, where **I** ≡ **4a**); removal of the MeOH yielded **6** as a pink, viscous liquid, which could be dissolved in Et_2O and then removal of the Et_2O regenerated **4a** (see also the discussion on eq. [5]). From an experimental point of view, the solid mono(α-hydroxy)phosphines are useful storage agents for Ph_2PH, a foul smelling, easily oxidizable liquid.

Conclusions

Several synthesized mono(α-hydroxy)phosphines, $R_2PCH(OH)R'$, are confirmed to be generally reversibly unstable in organic solvents to give R_2PH and R′CHO, the degree of decomposition depending on the following: (a) the solvent, where stability typically increases with solvent donor number, except in the case of MeOH for which hemiacetal formation promotes decomposition, and (b) the nature of substituents R and R′, where more basic phosphines promote decomposition. Reactions of the phosphines with cinnamaldehyde in DMSO and in MeOH yield the known phosphine $Ph_2PCH(Ph)CH_2CHO$ (**4a**) and, depending on R′, the known diphosphine $Ph_2PCH(Ph)CH_2CH(PPh_2)OH$ (**10a**), as well as the liberated R′CHO aldehyde and hemiacetal co-products that result from interactions between aldehyde and alcohol functionalities. A series of sequential intermediates, more readily detected in MeOH, includes $PhCH=CHCH(OH)PPh_2$, $PhCH(OH)CH=CHPPh_2$, and $Ph_2PCH(Ph)CH=CHOH$; relative rates of formation of **4a**, **10a**, and the intermediates as a function of R′ in various equilibria are described. The reactions are thought not to proceed via Ph_2PH, which is formed by decomposition of the $Ph_2PCH(OH)R'$ compounds, although the secondary phosphine reacts with cinnamaldehyde to give the same products and intermediates.

Activation of the *N*C–H bond of Morita–Baylis–Hillman adducts of *N*-substituted isatins with cerium ammonium nitrate (CAN) and alcohol (ROH)

Ponnusamy Shanmugam and Vadivel Vaithiyanathan

Abstract: A study on the activation of the *N*C–H bond of Morita–Baylis–Hillman adducts of *N*-substituted isatin with cerium ammonium nitrate (CAN) and saturated and unsaturated alcohols have been carried out. The choice of a Morita–Baylis–Hillman adduct for this study is screened with a number of adducts. A comparative and reactivity pattern study on *N*C-H activation of Morita–Baylis–Hillman adducts of *N*-substituted isatin derivatives viz. *N*-methyl, *N*-ethyl, *N*-methyl acetate, *N*-benzyl, *N*-propargyl, and *N*-isopropyl isatins have been carried out. Effect of aryl ring substitution has also been investigated. A plausible mechanism for the formation of the ether products has been outlined.

Key words: cerium ammonium nitrate (CAN), Morita–Baylis–Hillman adduct, *N*-CH activation, functionalised ethers, nitration.

Résumé : On a effectué une étude sur l'activation, par le nitrate d'ammonium cérique (NAC), de la liaison *N*C-H d'adduits Morita–Baylis–Hillman d'isatine *N*-substituée et d'alcools saturés et non saturés. Le choix de l'adduit Morita–Baylis–Hillman pour cette étude est évalué avec un certain nombre d'adduits. On a aussi réalisé une étude comparative et une étude de patron de réactivité sur l'activation *N*C-H d'adduits Morita–Baylis–Hillman d'isatines *N*-substituées, entre autre par des groupes *N*-méthyle, *N*-éthyle, *N*-méthylacétate, *N*-benzyle, *N*-propargyle et *N*-isopropyle. On a aussi étudié l'effet de la substitution sur les groupes aryles. On propose un mécanisme plausible pour la formation d'éthers comme produits.

Mots-clés : NAC, adduit de Morita–Baylis–Hillman, activation *N*C-H, éthers fonctionnalisés, nitration.

Introduction

The C–H bond activation method is one of the challenging synthetic routes in organic synthesis.[1–12] Activation of C–H bonds particularly by oxidative processes[1–5] and by organometallic reagents[6–12] has been of great interest to organic chemists in recent years. Cerium(IV) ammonium nitrate (CAN) has emerged as a versatile reagent for a number of synthetic transformations.[13,14] The synthetic flexibility of isatin and its derivatives has led to the extensive use of this compound in synthetic organic chemistry.[15] Recently, the Morita–Baylis–Hillman (MBH) reaction has emerged as an important carbon–carbon bond, forming reactions that, in general, afford densely functionalized molecular frame works and the reaction is considered as atom economic.[16–19] As part of our ongoing research in the area of novel synthetic methodologies based on MBH adducts,[20–26] we have reported the preliminary results on activation of the *N*C–H bond of MBH adducts of *N*-methylisatin with CAN/ROH (alcohol).[27] In continuation of the work, a detailed study on *N*C-H activation of various MBH derivatives of *N*-substituted isatins with CAN as a one electron oxidant and with a number of alcohols as reagents was carried out. The details of this study are the subject matter of this paper.

Results and discussion

Optimization of the *N*C-H activation and choice of MBH adducts of isatin

The optimization studies were initiated using the MBH adduct of *N*-methylisatin (**1**) as a model substrate. The preliminary study and results are shown in Table 1. Initially, adduct **1** was treated with 2 equiv. of CAN and excess methanol (10 mL) to afford the *N*C-H activated product **2** in trace amount (5%) (Table 1, entry 1). Repeating the reaction with 3 equiv. of CAN and MeOH (5 mL) for 12 h afforded **2** in a slightly improved yield (10%, Table 1, entry 2). Fine-tuning of the reaction conditions is shown in Table 1. Thus, the optimum condition was found as 4 equiv. of CAN and MeOH (1.6 mL, 40 equiv.) and CH_3CN (0.5 mL) and at room temperature (RT) for 24 h (Table 1, entry 4).

Further, to examine the selectivity and structural requirements of *N*-methyl isatin derivatives for *N*C-H activation, we chose different isatin derivatives (**1, 4–9**), as shown in Fig. 1.

Under the optimized condition, MBH adducts **1, 4**, and **5** of *N*-methyl isatin afforded the ether products **2, 10**, and **12** in 24%–66% yields and the nitrated compound **3, 11**, and **13** in trace-30% yields, respectively (Table 2, entries 1–3). In-

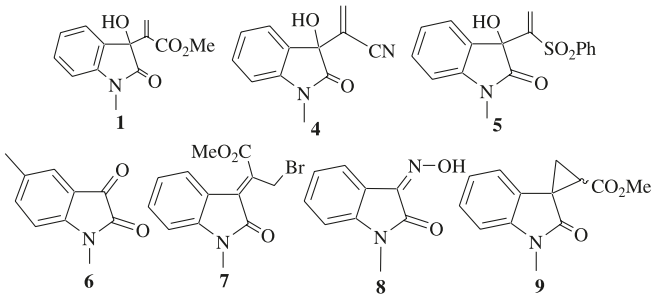
Fig. 1. A Choice of different isatin derivatives (1, 4–9) for C-H activation.



terestingly, the simple *N*-methyl isatin **6** yielded only the nitrated product **14** in 15% yields. Other *N*-methylisatin derivatives such as the bromo-derived adduct (**7**), oxime derivative of *N*-methyl isatin (**8**), and *N*-methyl-3-spirocyclopropyl-2-indolone (**9**) did not yield any *N*C-H activated ether product or nitrated product. The results of the preliminary investigation are summarized in Table 2. Hence, the study showed that the MBH adduct of *N*-methyl isatin was the most suitable substrate for *N*C-H activation reaction.

Excellent preliminary results on *N*C-H activation of MBH adduct of *N*-methyl isatin prompted us to investigate a systematic activation study of various *N*-substituted MBH adducts of isatin derivatives. Thus, we chose various MBH adducts with different *N*-alkyl substitutions such as methyl, methylene, and methine, which in principle generate 1•, 2•, and 3• radical cation intermediates during the *N*C-H activation process (Fig. 2).

*N*C-H activation study of primary methyl radical sources

To investigate the *N*C-H activation via primary radical cation intermediates, MBH adducts **1, 3, 4**, and **15** were chosen (Fig. 3.) and the details are discussed in the following section.

NC-*H activation of MBH adducts of* N-*methyl isatin 1 and 4*

As discussed earlier, during the optimization study the MBH adduct **1** with CAN/MeOH afforded the products **2** (ether) and **3** (nitrate). This observation prompted us to further explore the study using adducts **1** and **4** with various saturated and unsaturated 1• alcohols (R^4OH)/CAN. The reactions afforded the *N*C-H activated ethers **10** and **16–23** along with nitrated products **3** and **11** in moderate yield (Table 3, entries 1–9). Notably, the reaction of MBH adduct **1** with 2•- and 3•-alcohols (isopropanol and *t*-butanol) did not yield any *N*C-H activated product and only the nitrated product **3** was obtained in good yields (Table 3, entries 10 and 11). However, the reactions with allyl alcohol/CAN and cinnamyl alcohol/CAN did not afford the *N*C-H activated product. Only alcohol oxidation was observed during the course of the reaction (Table 3, entries 12 and 13). All the new compounds were characterized by spectroscopic (IR, ^1H, and ^{13}C NMR) and HRMS data. The results are summarized in Table 3.

Effect of aryl ring substitution on NC-*H activation of MBH adducts 15 and 3*

To circumvent nitration and to check the effect of substitution at the aryl ring, we examined the activation study with MBH adduct **15** with CAN and alcohols such as methanol, ethanol, homopropargyl alcohol, and *t*-butanol. The reactions underwent smoothly at an enhanced rate (1.5–2 h) and afforded the *N*C-H activated compounds (**24–27**) in good yields (Table 3, entries 14–17). Investigation on the effect of substitution and to understand the reactivity pattern

of adducts due to electron withdrawing substitution, the reactions with 5-nitro substituted adduct **3** in methanol and ethanol were tested (Table 3, entries 18 and 19). No *N*C-H activation was found even after allowing the reaction to proceed for a longer period of time (48 h) and with an excess of CAN (6 equiv.); only starting material was recovered quantitatively.

*N*C-H activation study of secondary methylene radical sources

To inspect and understand the *N*C-H activation reaction, which proceeded through a secondary radical intermediate, MBH adducts **28**–**35** were chosen (Fig. 4).

A general synthesis of MBH adducts **28–35** is shown in Scheme 1. Accordingly, *N*-alkylation of isatin was carried out with CaH_2 and alkyl halide in DMF at 60 °C to afford *N*-alkyl isatins in excellent yield. The MBH adducts formation of *N*-alkyl isatins with methyl acrylate and DABCO (1,4-diazabicyclo[2.2.2]octane) in methanol afforded the desired MBH adducts (**28–35**) in excellent yield.

Activation study of MBH adducts 28 and 29 of N-*ethyl isatin*

Activation reaction of adduct **28** with CAN/MeOH in CH_3CN for 24 h provided only the nitrated compound **36**

and no *N*C-H activated product was observed (Table 4, entry 1). Experiments with other alcohols such as ethanol, propargyl alcohol, and propane-1,3-diol provided only nitrated compound **36** and no *N*C-H activated product was observed in all the cases (Table 4, entries 2–4). The structure of nitrated compound **36** was analyzed by spectroscopic studies. The number of aromatic protons and chemical shifts were the tool for detection of nitration. Accordingly, in the aromatic region, a doublet at δ 6.97 due to ortho coupling (J = 8.6 Hz, 1H), meta coupled doublet at δ 8.04 (J =

2.3 Hz, 1H), and one doublet of doublet at δ 8.31 (J = 8.6, 2.3 Hz, 1H) due to ortho and meta couplings appeared. The alkyl and olefin region were similar to that of starting material **28**. To demonstrate and to check the effect of electron donating substitution at the aryl ring on *N*C-H activation, another adduct (**29**) was selected. Reactions in methanol and ethanol were carried out (Table 4, entries 5 and 6). To our surprise, we found only a trace of *N*C-H activated product formation (**37**, **38**) as evidenced from its ^{1}H NMR of crude reaction mixture at regular intervals for 48 h.

Activation study of MBH adduct of N-*methyl/ethyl acetate isatin 30 and 31*

Since, the compound **28** with electron releasing substitution at α to the *N*C-H bond did not yield any C-H activation products, we considered checking electron withdrawing substitution at α to the *N*C-H bond for *N*C-H activation of MBH adduct such as **30**. In contrast to the substrates **28** and **29**, activation of adduct **30** with CAN/methanol under optimized reaction condition provided a good yield of *N*C-H activated product **39** (Table 4, entry 7). The presence of -OMe group due to *N*C-H activation in the product **39** was confirmed from its ^{1}H NMR spectrum. Thus, the methoxy protons were observed at δ 3.63 as a singlet and the methine proton was observed as a singlet at δ 5.96. The reactions with ethanol and propargyl alcohol were also tested and the respective *N*C-H activated products (**40** and **41**) were isolated in moderate to good yields (Table 4, entries 8 and 9). Similarly, reactions of adduct **31** with benzyl alcohol and homopropargyl alcohol afforded the corresponding *N*C-H activated products **42** and **43**, respectively (Table 4, entries 10 and 11).

Activation study on MBH adduct of N-*benzyl and propargyl derivatives of isatin 32–35*

Having surprising results obtained from adducts **30** and **31**, we were interested in surveying the *N*C-H activation of highly functionalized MBH adducts **32–33** and **34–35** of *N*-benzyl and *N*-propargyl isatins, respectively. The desired adducts **32–33** and **34–35** were synthesized using standard procedure described earlier (Scheme 1).

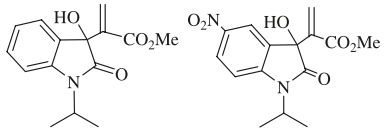
The adduct **32** with CAN/methanol and CAN/ethanol under optimized reaction conditions yielded neither *N*C-H activated product nor nitrated derivative and the starting material was recovered quantitatively (Table 4, entries 12 and 13). However, the 5-bromo MBH adduct **33** afforded the desired *N*C-H activated product (**44**) in good yield (Table 4, entry 14). In the case of adduct (**34**), the reaction mixture became complex (TLC) with CAN/methanol and CAN/ethanol mixture and no *N*C-H activated and nitrated product was obtained (Table 4, entries 15 and 16), while the adduct **35** provided an excellent yield of *N*C-H activated product **45** in 2 h (Table 4, entry 17).

*N*C-H activation study of tertiary methine radical source *N*-isopropyl isatin (46)

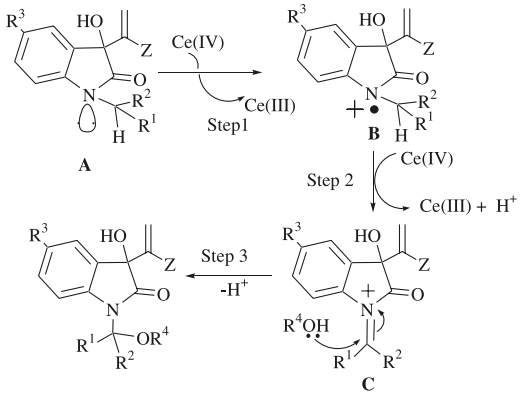
For a comparative study on *N*-alkyl series of isatin derivatives, we chose the MBH adduct of *N*-isopropyl isatin (**46**) as substrate, which is believed to precede the *N*C-H activation via a tertiary radical intermediate (Fig. 5). Adduct **46** was prepared under standard procedure described earlier.

The *N*C-H activation of adduct **46** with CAN/MeOH, under optimized condition did not yield any *N*C-H activated product, instead only a moderate yield of nitrated product **47**

Fig. 5. Choice of MBH adducts having methine *N*C-H source.



Scheme 2. A plausible mechanism for ether formation.



was obtained. Similarly, reactions with ethanol, propargyl alcohol, and propane-1,3-diol furnished only nitrated compound **47**. The results are collected in Tables 2 and 3. The structure of nitrated compound **47** was confirmed from its proton NMR data. Thus, the aromatic protons in **47** showed an ortho coupled doublet at δ 7.10 (J = 8.7 Hz, 1H), a meta coupled doublet at δ 8.03 (J = 2.3 Hz, 1H), and ortho-meta coupled doublet of doublet at δ 8.28 (J = 2.3, 8.7 Hz, 1H). The alkyl and olefin region were similar to that of starting material **46**.

A plausible mechanism of *N*-CH activation/nitration

A plausible mechanism for the formation of the ether products is delineated in Scheme 2. In the first step, the MBH adduct **A** is oxidized by CAN to form a radical cation[28–30] **B**. Further oxidation of radical cation **B** and liberation of H^+ by CAN produce a cation intermediate **C**, which is quenched by alcohol to afford the *N*C-H activated ether product. The proposed mechanism is supported from the results obtained in the studies. It should be noted that for comparison among MBH adducts **1**, **15**, and **3,** only adduct **15** underwent *N*C-H activation in 1.5–2.0 h whilst adduct **1** took 24 h for *N*C-H activation and adduct **3** did not provide any *N*C-H activation product with a clear indication of direct involvement of the nitrogen lone pair in the reaction mechanism.

The reactivity nature of MBH adducts **28**–**35** and **46** towards *N*C-H activation can be explained based on the effect of bulky substitution, which reduces the availability of lone pair on the nitrogen atom, which prevents the first step oxidation and less approach possibility by bulky reagent Ce(IV) towards nitrogen in adducts **28**, **32**, **34**, and **46**. The 5-bromo substitution, which increases the electron density on nitrogen, is clearly found from the reactivity of adducts **29** (trace of *N*C-H activation, 48 h), **33** (47% *N*C-H activation, 24 h), and **35** (85% *N*C-H activation, 2 h). However, quite the opposite occurs; the nitro substituent, having direct resonance

Fig. 6. Effect of substitution and magnitude of lone pair availability on nitrogen.

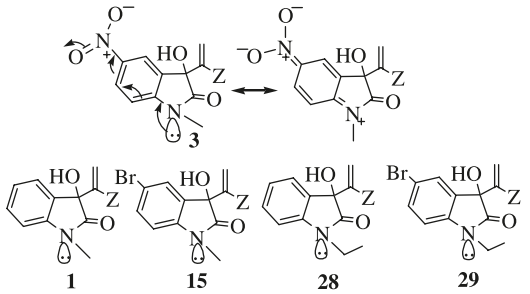


Fig. 7. Selectivity reason for *N*C-H activation towards MBH adducts alone.

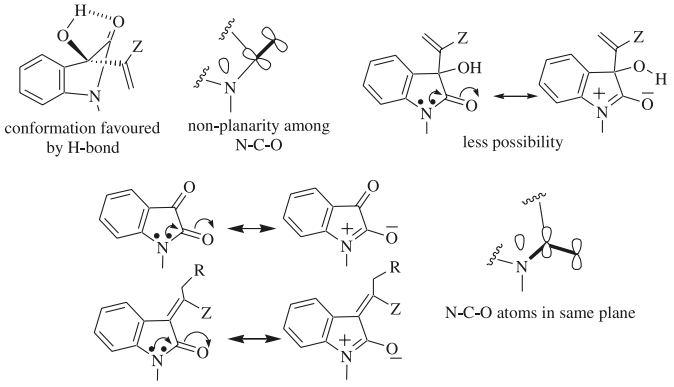

with nitrogen lone pair, averts the reactivity of the adduct **3**. A pictorial representation for substitution effect and magnitude of nitrogen lone pair is shown in Fig. 6. The nitration mechanism of the aromatic ring with CAN is well known in the literature.[31]

The selectivity reason for *N*C-H activation towards MBH adducts alone may be due to the conformation favoured by H-bonding in the adduct structure, which brings more availability of lone pair on nitrogen atom and avoids resonance with the adjacent carbonyl group. However, the highly planar structure in the compounds **6**–**9** allows the nitrogen lone pair to be in resonance with the adjacent carbonyl group. Hence, no *N*C-H activation happened with simple isatin derivatives (Fig. 7).

Conclusion

In conclusion, we have carried out a novel study on *N*C-H activation of various Morita–Baylis–Hillman adducts of *N*-substituted isatin with a number of alcohols using CAN as a single electron oxidizing agent. A plausible mechanism of the reaction is proposed. It is noteworthy that the compounds obtained here are highly functionalized and can be used for further synthetic manipulations. Further studies using the reagent system for novel synthetic methods are in progress in our laboratory.

Experimental

General consideration

Analytical thin layer chromatography was performed on silica gel TLC plates. Purification by gravity column chro-

matography was carried out using silica gel (100–200 mesh). Mixture of ethyl acetate and hexane and pure ethyl acetate were used as eluent as required. IR spectra were run on a Nicolet (impact 400D FT-IR) spectrophotometer. NMR spectra were obtained using chloroform-d as solvent on Bruker DPX 300 MHz NMR spectrometer. Chemical shifts are given in δ scale with TMS as the internal reference. HRMS were measured on the JMS 600 JEOL mass spectrometer. Yields refer to quantities obtained after chromatography. Solvents used are reagent grade and were purified before use according to the literature procedure.[32]

General experimental procedure for alkylation of isatin

A mixture of isatin (1 mmol), alkyl bromide/iodide (1.5 mmol), and calcium hydride (3 mmol) in DMF was stirred at 60 °C for 1 h. After completion of the reaction (monitored by TLC), the crude mixture was diluted with water, neutralized with 2 N HCl and extracted using ethyl acetate. The organic layer was separated, dried (Na_2SO_4), and concentrated in vacuo. The crude product obtained was purified by silica gel chromatography using EtOAc–hexane (20:80) as eluent to afford the desired *N*-alkylisatin derivatives.

General procedure for the preparation of MBH adducts

A mixture of *N*-alkyl isatin (1 mmol), methyl acrylate (1.5 mmol), and DABCO (0.02 mmol) in MeOH (5 mL) was stirred at RT for 3–4 d. After completion of the reaction (monitored by TLC), the reaction mixture was diluted with ethyl acetate. The organic layer was washed successively with 0.2 N HCl, water, and brine. The organic layer was separated, dried (Na_2SO_4), and concentrated in vacuo. The crude product obtained was purified by silica gel column chromatography using EtOAc–hexane (20:80) as eluent to afford the desired MBH adducts of *N*-alkyl isatin.

Spectral data of MBH adducts 28, 30, 34, and 46

Methyl 2-(1-ethyl-3-hydroxy-2-oxoindolin-3-yl)acrylate (28)

Colourless solid. Mp 148–150 °C. R_f = 0.48 (25% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3341, 1723, 1615. ^1H NMR ($CDCl_3$) δ_H: 1.32 (3H, t, J = 7.2 Hz), 2.45 (1H, brs), 3.62 (3H, s), 3.74 (2H, q, J = 7.2 Hz), 6.41 (1H, s), 6.56 (1H, s), 6.88 (1H, d, J = 7.8 Hz), 7.05 (1H, t, J = 6.7 Hz), 7.19 (1H, d, J = 6.4 Hz), 7.32 (1H, t, J = 7.7 Hz). ^{13}C NMR ($CDCl_3$) δ_C: 12.4, 52.3, 64.5, 70.5, 110.4, 123.6, 124.1, 128.0, 129.1, 130.72, 139.2, 143.3, 165.3, 176.5. Anal. calcd. for $C_{14}H_{15}NO_4$: 261.1001; found: 261.1000.

Methyl 2-(1-methylene carbomethoxy-3-hydroxy-2-oxoindolin-3-yl)acrylate (30)

Colourless waxy solid. R_f = 0.29 (25% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3350, 1716, 1615, 1087, 1063. ^1H NMR ($CDCl_3$) δ_H: 3.64 (3H, s), 3.78 (3H, s), 4.41 (1H, brs), 4. 41 (1H, d, J = 17.6 Hz), 4.61 (1H, d, J = 17.6 Hz), 6.44 (1H, s), 6.59 (1H, s), 6.74 (1H, d, J = 7.8 Hz), 7.06 (1H, t, J = 7.4 Hz), 7.06–7.34 (2H, m). ^{13}C NMR ($CDCl_3$) δ_C: 41.4, 52.1, 52.7, 76.0, 108.6, 123.4, 124.1, 128.3, 129.4, 130.3, 138.5, 142.9, 165.2, 168.2, 176.0. Anal calcd. for $C_{15}H_{15}NO_6$: 305.0899; found: 305.0896.

Methyl 2-(3-hydroxy-2-oxo-1-(prop-2-ynyl) indolin-3-yl)acrylate (34)

Colourless waxy solid. R_f = 0.34 (25% EtOAc–Hexanes). ν_{max}(CH_2Cl_2, cm^{-1}): 3425, 2131, 1718, 1611. ^1H NMR ($CDCl_3$) δ_H: 2.28 (1H, t, J = 2.2 Hz), 3.59 (3H, s), 4.07 (1H, s), 4.51–4.58 (2H, m), 6.44 (1H, s), 6.57 (1H, s), 7.04–7.09 (2H, m), 7.18 (1H, d, J = 6.48 Hz), 7.35 (1H, t, J = 7.6 Hz). ^{13}C NMR ($CDCl_3$) δ_C: 29.5, 52.1, 72.6, 76.1, 76.6, 109.6, 123.3, 123.9, 128.1, 129.2, 130.2, 138.9, 142.5, 164.9, 175.4. Anal. calcd. for $C_{15}H_{13}NO_4$: 271.0845; found: 271.0841.

Methyl 2-(3-hydroxy-1-isopropyl-2-oxoindolin-3-yl)acrylate (46)

Colourless waxy solid. R_f = 0.42 (25% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3353, 1699, 1611. ^1H NMR ($CDCl_3$) δ_H: 1.52 (6H, d, J = 8.15 Hz), 3.55 (1H, br s), 3.61 (3H, s), 4.58 (1H, sept, J = 7.0 Hz), 6.42 (1H, s), 6.56 (1H, s), 7.02 (2H, d, J = 7.7 Hz), 7.17 (1H, d, J = 6.6 Hz), 7.30 (1H, t, J = 6.8 Hz). ^{13}C NMR ($CDCl_3$) δ_C: 19.1 (2C), 43.3, 51.8, 75.8, 109.7, 122.3, 124.0, 127.6, 129.8 (2C), 139.3, 143.1, 164.8, 176.1. Anal. calcd. for $C_{15}H_{17}NO_4$: 275.1158; found: 275.1152.

General experimental procedure for *N*C-H activation

A mixture of MBH adduct (1 mmol), 4 equiv. of cerium ammonium nitrate (4 mmol), and 40 equiv. of ROH (1.6 mL) in CH_3CN (0.5 mL) was allowed to stir at RT for 2–48 h. The progress of reaction was monitored by TLC. After completion of the reaction, the solvent was removed under reduced pressure. The crude reaction mixture was extracted with dichloromethane and washed with water and brine. The organic layer was separated, dried (Na_2SO_4), and concentrated in vacuo. The crude mixture was purified by silica gel column chromatography using gradient elution with hexane and hexane and EtOAc to afford pure functionalized ethers and aromatic nitrated products.

Spectral data for *N*C-H activated compounds

Methyl 2-(3-hydroxy-1-(methoxy methyl)-2-oxoindolin-3-yl)acrylate (2)

Waxy solid. R_f = 0.35 (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3386, 1716, 1085, 1063. ^1H NMR ($CDCl_3$) δ_H: 2.57 (1H, bs), 3.41 (3H, s), 3.65 (3H, s), 5.13 (1H, d, J = 11.1 Hz), 5.17 (1H, d, J = 11.1 Hz), 6.42 (1H, s), 6.59 (1H, s), 7.06–7.10 (2H, m), 7.20 (1H, d, J = 7.5 Hz), 7.32 (1H, t, J = 7.5 Hz). ^{13}C NMR ($CDCl_3$) δ_C: 52.5, 53.2, 70.5, 76.6, 110.4, 123.7, 124.1, 127.8, 129.1, 130.6, 139.5, 143.3, 164.8, 176.9. Anal. calcd. for $C_{14}H_{15}NO_5$: 277.0950; found: 277.0947.

2-(3-Hydroxy-1-(methoxymethyl)-2-oxoindolin-3-yl)acrylonitrile (10)

Waxy solid. R_f = 0.44 (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3376, 2209, 1726, 1614, 1087. ^1H NMR ($CDCl_3$) δ_H: 3.36 (3H, s), 4.07 (1H, s), 5.10 (1H, d, J = 10.9 Hz), 5.19 (1H, d, J = 10.9 Hz), 6.21 (1H, s), 6.39 (1H, s), 7.12 (1H, d, J = 7.7 Hz), 7.17 (1H, t, J = 8.1 Hz), 7.41 (2H, d, J = 7.5 Hz). ^{13}C NMR ($CDCl_3$) δ_C: 52.1, 70.7, 76.7, 110.8,

115.5, 123.2, 123.9, 124.8, 126.8, 128.1, 131.5, 142.5, 176.3. Anal. calcd. for $C_{13}H_{12}N_2O_3$: 244.0848; found: 244.0836.

Methyl 2-(1-(ethoxymethyl)-3-hydroxy-2-oxoindolin-3-yl)acrylate (16)

Waxy solid. R_f = 0.43 (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3382, 1716, 1089, 1053. ^1H NMR ($CDCl_3$) δ_H: 1.20 (3H, t, J = 6.9 Hz), 2.67 (1H, bs), 3.65 (5H, m), 5.17 (1H, d, J = 11.1 Hz), 5.22 (1H, d, J = 11.1 Hz), 6.43 (1H, s), 6.58 (1H, s), 7.05–7.13 (2H, m), 7.20 (1H, d, J = 7.2 Hz), 7.35 (1H, t, J = 7.2 Hz). ^{13}C NMR ($CDCl_3$) δ_C: 15.1, 52.3, 64.6, 70.5, 76.6, 110.4, 123.6, 124.1, 128.0, 128.9, 130.6, 139.2, 143.2, 165.2, 176.9. Anal. calcd. for $C_{15}H_{17}NO_5$: 291.1107; found: 291.1088.

Methyl 2-(3-hydroxy-2-oxo-1-((prop-2-ynyloxy)methyl) indolin-3-yl)acrylate (17)

Waxy solid. R_f = 0.37 (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3390, 2210, 1716, 1615, 1087, 1064. ^1H NMR ($CDCl_3$) δ_H: 2.48 (1H, t, J = 2.4 Hz), 2.67 (1H, bs), 3.63 (3H, s), 4.28 (2H, d, J = 2.4 Hz), 5.20 (1H, d, J = 11.2 Hz), 5.37 (1H, d, J = 11.2 Hz), 6.48 (1H, s), 6.59 (1H, s), 7.05–7.20 (3H, m), 7.35 (1H, t, J = 7.6 Hz). ^{13}C NMR ($CDCl_3$) δ_C: 30.5, 52.3, 56.3, 70.3, 75.5, 78.6, 110.7, 123.6, 124.2, 128.1, 129.1, 130.5, 139.3, 143.2, 165.3, 176.9. Anal. calcd. for $C_{16}H_{15}NO_5$: 301.0950; found: 301.0941.

Methyl 2-(1-[(but-3-ynyloxy)methyl]-3-hydroxy-2-oxoindolin-3-yl)acrylate (18)

Waxy solid. R_f = 0.47 (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3406, 1716, 1614, 1089, 1050. ^1H NMR ($CDCl_3$) δ_H: 1.80 (1H, bs), 1.95 (1H, t, J = 2.4 Hz), 2.46 (2H, td, J = 6.6, 2.4 Hz), 3.63 (3H, s), 3.66 (2H, t, J = 6.6 Hz), 5.20 (1H, d, J = 11.1 Hz), 5.28 (1H, d, J = 11.1 Hz), 6.46 (1H, s), 6.59 (1H, s), 7.05–7.20 (3H, m), 7.35 (1H, t, J = 7.8 Hz). ^{13}C NMR ($CDCl_3$) δ_C: 19.8, 30.4, 52.3, 66.9, 69.5, 70.6, 81.3, 110.5, 123.7, 124.1, 126.2, 127.9, 130.7, 139.2, 143.1, 165.2, 176.9. Anal. calcd. for $C_{17}H_{17}NO_5$:315.1107; found: 315.1101.

Methyl 2-(1-((2-hydroxyethoxy)methyl)-3-hydroxy-2-oxoindolin-3-yl)acrylate (19)

Waxy solid. R_f = 0.23 (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3416, 1716, 1614, 1085, 1065. ^1H NMR ($CDCl_3$) δ_H: 2.67 (2H, bs), 3.62 (3H, s), 3.69–3.75 (4H, m), 5.21 (1H, d, J = 11.1 Hz), 5.28 (1H, d, J = 11.1 Hz), 6.50 (1H, s), 6.60 (1H, s), 7.05–7.26 (3H, m), 7.34 (1H, t, J = 6.6 Hz). ^{13}C NMR ($CDCl_3$) δ_C: 52.4, 59.7, 66.1, 70.5, 76.3, 110.1, 123.5, 123.9, 128.3, 129.4, 130.6, 139.0, 143.2, 165.3, 175.6. Anal. calcd. for $C_{15}H_{17}NO_6$: 307.1056; found: 307.1047.

Methyl 2-(1-[(3-hydroxypropoxy)methyl]-3-hydroxy-2-oxoindolin-3-yl)acrylate (20)

Waxy solid. R_f = 0.28 (20% EtOAc-Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3418, 1716, 1613, 1086, 1055. ^1H NMR ($CDCl_3$) δ_H: 1.73 (2H, quintet, J = 7.2 Hz), 3.11 (2H, bs), 3.48–3.80 (7H, m), 5.14 (1H, d, J = 11.4 Hz), 5.21 (1H, d, J = 11.4 Hz), 6.55 (1H, s), 6.60 (1H, s), 7.03–7.16 (3H, m),7.33 (1H, t, J = 7.5 Hz). ^{13}C NMR ($CDCl_3$) δ_C: 32.6, 52.4, 59.8, 66.2, 70.5, 76.3, 110.1, 123.6, 123.9, 128.4, 129.4, 130.5, 139.0, 143.1, 165.4, 177.2. Anal. calcd. for $C_{16}H_{19}NO_6$: 321.1212; found: 321.1205.

Methyl 2-(1-((benzyloxy)methyl)-3-hydroxy-2-oxoindolin-3-yl)acrylate (21)

Waxy solid. R_f = 0.29 (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3314, 1716, 1617, 1083, 1055. ^1H NMR ($CDCl_3$) δ_H: 2.67 (1H, bs), 3.62 (3H, s), 4.36 (1H, d, J = 11.6 Hz), 4.72 (1H, d, J = 11.6 Hz), 5.24 (1H, d, J = 11.1 Hz), 5.32 (1H, d, J = 11.1 Hz), 6.47 (1H, s), 6.59 (1H, s), 7.08–7.35 (9H, m). ^{13}C NMR ($CDCl_3$) δ_C: 52.1, 70.1, 70.7, 76.4, 110.3, 123.5, 123.8, 127.8 (2C), 128.2(2C), 128.3 (2C), 128.7, 130.5, 137.5, 138.9, 143.0, 165.0, 176.6. Anal. calcd. for $C_{20}H_{19}NO_5$: 353.1263; found: 353.1254.

2-(1-(Ethoxymethyl)-3-hydroxy-2-oxoindolin-3-yl) acrylonitrile (22)

Waxy solid. R_f = 0.34 (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3378, 2917, 2185, 1732, 1613, 1487, 1097. ^1H NMR ($CDCl_3$) δ_H: 1.19 (3H, t, J = 7.2 Hz), 1.90 (1H, bs), 3.57 (2H, q, J = 7.2 Hz), 5.15 (1H, d, J = 11.1 Hz), 5.25 (1H, d, J = 11.1 Hz), 6.21 (1H, s), 6.36 (1H, s), 7.14–7.22 (2H, m), 7.40–7.45 (2H, m). ^{13}C NMR ($CDCl_3$) δ_C: 15.0, 64.8, 70.7, 76.8, 111.1, 115. 6, 123.3, 124.6, 124.9, 126.5, 128.6, 131.6, 142.0, 175.5. Anal. calcd. for $C_{14}H_{14}N_2O_3$: 258.1004; found: 258.0992.

2-(3-Hydroxy-2-oxo-1-[(prop-2-yloxy)methyl] indolin-3-yl)acrylonitrile (23)

Waxy solid. R_f 0.42 = (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3390, 2305, 1733, 1614, 1073. ^1H NMR ($CDCl_3$) δ_H: 1.80 (1H, bs), 2.48 (1H, t, J = 2.4 Hz), 4.21 (2H, d, J = 2.4 Hz), 5.24 (1H, d, J = 11.1 Hz), 5.36 (1H, d, J = 11.1 Hz), 6.21 (1H, s), 6.37 (1H, s), 7.10–7.29 (2H, m), 7.42 (2H, d, J = 7.5 Hz). ^{13}C NMR ($CDCl_3$) δ_C: 30.6, 56.4, 69.5, 75.8, 78.7, 110.9, 115.7, 123.1, 125.0, 126.9, 128.8, 131.6, 132.6, 141.9, 174.9. Anal. calcd. for $C_{15}H_{12}N_2O_3$: 268.0848; found: 268.0840.

Methyl 2-(5-bromo-3-hydroxy-1-(methoxymethyl)-2-oxoindolin-3-yl)acrylate (24)

Waxy solid. R_f = 0.47 (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3376, 1710, 1079, 1060. ^1H NMR ($CDCl_3$) δ_H: 3.40 (3H, s), 3.58 (1H, s), 3.65 (3H, s), 5.09 (1H, d, J = 11.0 Hz), 5.16 (1H, d, J = 11.0 Hz), 6.47 (1H, s), 6.62 (1H, s), 6.97 (1H, d, J = 8.3 Hz), 7.30 (1H, d, J = 1.8 Hz), 7.46 (1H, dd, J = 8.3, 1.8 Hz). ^{13}C NMR ($CDCl_3$) δ_C: 52.5, 53.1, 70.6, 76.7, 111.8, 116.1, 126.8, 128.3, 130.8, 133.2, 138.6, 142.1, 164.7, 174.4. Anal. calcd. for $C_{14}H_{14}BrNO_5$: 355.0055; found: 355.0051.

Methyl 2-(5-bromo-1-(ethoxymethyl)-3-hydroxy-2-oxoindolin-3-yl)acrylate (25)

Waxy solid. R_f = 0.45 (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3379, 1715, 1084, 1062. ^1H NMR ($CDCl_3$) δ_H: 1.19 (3H, t, J = 7.8 Hz), 1.89 (1H, bs), 3.45–3.63 (5H, m), 5.13 (1H, d, J = 11.1 Hz), 5.19 (1H, d, J = 11.1 Hz), 6.47 (1H, s), 6.60 (1H, s), 7.00 (1H, d, J = 8.3 Hz), 7.28 (1H, d, J = 1.9 Hz), 7.46 (1H, dd, J = 8.3, 1.9 Hz). ^{13}C NMR ($CDCl_3$) δ_C: 14.8, 52.1, 64.4, 70.4, 76.2, 111.8, 116.0, 127.1, 128.3, 130.8, 133.2, 138.6, 142.1, 164.7, 174.3. Methyl 2-(5-bromo-1-((but-3-ynyloxy)methyl)-3-hydroxy-2-oxoindolin-3-yl)acrylate (26)

Waxy solid. R_f = 0.39 (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3390, 2210, 1716, 1085, 1063. ^1H NMR ($CDCl_3$) δ_H: 1.94 (1H, t, J = 2.4 Hz), 2.46 (2H, td, J = 6.7, 2.4 Hz), 3.61–3.76 (5H, m), 5.18 (1H, d, J = 11.2 Hz), 5.18 (1H, d, J = 11.2 Hz), 5.25 (1H, d, J = 11.2 Hz), 6.48 (1H, s), 6.62 (1H, s), 7.01 (1H, d, J = 8.3 Hz), 7.29 (1H, d, J = 1.7 Hz), 7.46 (1H, dd, J = 8.3, 1.7 Hz). ^{13}C NMR ($CDCl_3$) δ_C: 19.3, 30.4, 52.5, 67.3, 69.5, 70.5, 81.1, 110.9, 116.2, 127.1, 128.3, 130.7, 133.2, 138.5, 143.0, 164.8, 176.3. Anal. calcd. for $C_{17}H_{16}BrNO_5$: 393.0212; found: 393.0203.

Methyl 2-(1-(t-butoxymethyl)-5-bromo-3-hydroxy-2-oxoindolin-3-yl)acrylate (27)

Waxy solid. R_f = 0.47 (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3376, 1710, 1079, 1060. ^1H NMR ($CDCl_3$) δ_H: 1.23 (9H, s), 3.58 (1H s), 3.65 (3H, s), 5.07 (1H, d, J = 10.8 Hz), 5.30 (1H, d, J = 10.8 Hz), 6.38 (1H, s), 6.58 (1H, s), 7.02 (1H, d, J = 8.3 Hz), 7.29 (1H, d, J = 1.9 Hz), 7.46 (1H, dd, J = 8.3, 1.9 Hz). ^{13}C NMR ($CDCl_3$) δ_C: 28.4, 29.7, 65.3, 75.1, 76.3, 109.8, 114.3, 117.1, 121.5, 127.1, 128.3, 133.1, 138.4, 159.0, 164.9. Anal. calcd. for $C_{17}H_{20}BrNO_5$: 397.0525; found: 397.0523.

Methyl 2-(3-hydroxy-1-(methyl 2-methoxyacetate)-2-oxoindolin-3-yl)acrylate (39)

Waxy solid. R_f = 0.44 (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3420, 1718, 1606, 1051. ^1H NMR ($CDCl_3$) δ_H: 1.90 (1H, bs), 3.59 (3H, s), 3.63 (3H, s), 3.79 (3H, s), 5.96 (1H, s), 6.55 (1H, s), 6.63 (1H, s), 7.04–7.10 (2H, m), 7.17–7.32 (2H, m). ^{13}C NMR ($CDCl_3$) δ_C: 46.9, 52.1, 56.9, 76.0, 79.7, 111.4, 123.6, 123.8, 128.1, 128.7, 130.5, 138.6, 140.8, 164.7, 166.9, 176.3. Anal. calcd. for $C_{16}H_{17}NO_7$: 335.1005; found: 335.1001.

Methyl 2-(3-hydroxy-1-(methyl 2-ethoxyacetate)-2-oxoindolin-3-yl)acrylate (40)

Waxy solid. R_f = 0.42 (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3421, 1727, 1615, 1056. ^1H NMR ($CDCl_3$) δ_H: 1.28 (3H, t, J = 7.2 Hz), 3.97 (1H, bs), 3.65 (3H, s), 3.79 (3H, s), 4.25 (2H, q, J = 7.2 Hz), 6.02 (1H, s), 6.44(1H, s), 6.59 (1H, s), 7.06–7.31 (4H, m). ^{13}C NMR ($CDCl_3$) δ_C: 14.8, 52.1, 53.7, 62.4, 76.0, 79.7, 110.6, 123.6, 123.8, 127.8, 128.7, 130.4, 137.9, 141.5, 165.5, 166.9, 176.2. Anal. calcd. for $C_{17}H_{19}NO_7$: 349.1162; found: 349.1155.

Methyl 2-(3-hydroxy-1-(methyl 2-(prop-2-ynyloxy)acetate)-2-oxoindolin-3-yl)acrylate (41)

Waxy solid. R_f = 0.48 (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3294, 2120, 1712, 1610, 1051. ^1H NMR ($CDCl_3$) δ_H: 2.54 (1H, t, J = 2.4 Hz), 3.57 (1H, bs), 3.63 (3H, s), 3.81 (3H, s), 4.46 (2H, d, J = 2.4 Hz), 6.24 (1H, s), 6.57 (1H, s), 6.62 (1H, s), 7.07–7.13 (2H, m), 7.19–7.34 (2H, m). ^{13}C NMR ($CDCl_3$) δ_C: 22.3, 41.5, 52.2, 55.9, 62.7, 75.9, 77.9, 109.3, 111.5, 123.7, 124.1, 128.1, 130.3, 138.7, 140.8, 165.9, 176.1, 176.5. Anal. calcd. for $C_{18}H_{17}NO_7$: 359.1005; found: 359.0996.

Methyl 2-(3-hydroxy-1-(methyl 2-(benzyloxy)acetate)-2-oxoindolin-3-yl)acrylate (42)

Waxy solid. R_f = 0.43 (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3396, 1717, 1084, 1065. ^1H NMR ($CDCl_3$) δ_H: 1.19 (3H, t, J = 7.17 Hz), 3.51 (1H, s), 3.64 (3H, s), 4.24 (2H, q, J = 7.17 Hz), 4.72 (1H, d, J = 11.8 Hz), 4.91 (1H, d, J = 11.8 Hz), 6.03 (1H, s), 6.44 (1H, s), 6.64 (1H, s), 7.01 (1H, t, J = 7.5 Hz), 7.18 (2H, t, J = 7.6 Hz), 7.27–7.39 (6H, m). ^{13}C NMR ($CDCl_3$) δ_C: 14.4, 52.6, 62.9, 70.7, 76.5, 112.3, 114.6, 124.4, 128.7 (2C), 128.8 (2C), 129.3 (2C), 130.7 (2C), 136.7, 141.5, 165.6, 167.2, 177.8. Anal. calcd. for $C_{21}H_{20}NO_5$: 366.1341; found: 366.1326.

Methyl 2-(3-hydroxy-1-(methyl 2-(but-3-ynyloxy)acetate)-2-oxoindolin-3-yl)acrylate (43)

Waxy solid. R_f = 0.46 (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3388, 2210, 1718, 1615, 1087, 1064. ^1H NMR ($CDCl_3$) δ_H: 1.24 (3H, t, J = 7.20 Hz), 1.90 (1H, t, J = 2.5 Hz), 3.56 (1H, s), 3.63 (3H, s), 4.13–4.28 (4H, m), 6.01 (1H, s), 6.54 (1H, s), 6.62 (1H, s), 7.06–7.29 (4H, m). ^{13}C NMR ($CDCl_3$) δ_C: 13.9, 19.3, 31.6, 62.5, 66.9, 69.7, 76.0, 78.2, 80.2, 111.7, 123.6, 124.0, 128.1, 128.8, 130.3, 138.4, 140.9, 164.7, 165.9, 176.2. Anal. calcd. for $C_{18}H_{18}NO_5$: 328.1185; found: 328.1183.

Methyl 2-(5-bromo-3-hydroxy-1-(methoxy(phenyl) methyl)-2-oxoindolin-3-yl)acrylate (44)

Waxy solid. R_f = 0.39 (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3382, 1717, 1085, 1057. ^1H NMR ($CDCl_3$) δ_H: 2.15 (1H, s), 3.45 (3H, s), 3.66 (3H, s), 6.48 (1H, s), 6.53 (1H, s), 6.58 (1H, s), 7.19–7.45 (8H, m). ^{13}C NMR ($CDCl_3$) δ_C: 52.1, 53.4, 65.4, 76.4, 110.3, 123.5, 124.3, 127.8 (2C), 128.1 (2C), 128.2 (2C), 128.7, 131.3, 137.4, 139.0, 143.0, 164.5, 175.5. Anal. calcd. for $C_{20}H_{18}BrNO_5$: 431.0368; found: 431.0357.

Methyl 2-(5-bromo-3-hydroxy-1-(1-methoxyprop-2-ynyl)-2-oxoindolin-3-yl)acrylate (45)

Waxy solid. R_f = 0.48 (20% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3396, 2212, 1714, 1089, 1055. ^1H NMR ($CDCl_3$) δ_H: 2.61 (1H, d, J = 2.1 Hz), 3.48 (3H, s), 3.61 (3H, s), 3.79 (1H, s), 6.12 (1H, d, J = 2.1 Hz), 6.38 (1H, s), 6.43(1H, s), 7.27 (1H, d, J = 8.3 Hz), 7.32 (1H, d, J = 1.9 Hz), 7.46 (1H, dd, J = 8.3, 1.9 Hz). ^{13}C NMR ($CDCl_3$) δ_C: 52.3, 55.9, 56.4, 72.3, 75.1, 75.8, 114.1, 116.4, 126.9, 128.6, 130.9, 132.9, 138.3, 139.5, 164.5, 175.3. Anal. calcd. for $C_{16}H_{14}BrNO_5$: 379.0055; found: 379.0043.

Spectral data for nitrated derivatives

Methyl 2-(1-ethyl-3-hydroxy-5-nitro-2-oxoindolin-3-yl)acrylate (36)

Waxy solid. R_f = 0.48 (25% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3348, 1706, 1611. ^1H NMR ($CDCl_3$) δ_H: 1.32 (3H, t, J = 7.23 Hz), 2.2 (1H, bs), 3.62 (3H, s), 3.77–3.9 (2H, m), 6.58 (1H, s), 6.67 (1H, s), 6.97 (1H, d, J = 8.6 Hz), 8.04 (1H, d, J = 2.3 Hz), 8.31 (1H, dd, J = 2.3 Hz, J = 8.6 Hz). ^{13}C NMR ($CDCl_3$) δ_C: 12.1, 43.6, 52.3, 76.1, 109.6, 120.32, 122.3, 123.1, 128.7, 129.9, 144.4, 144.7, 164.8, 176.1. Anal. calcd. for $C_{14}H_{14}N_2O_6$: 306.0852; found: 306.0841.

Methyl 2-(3-hydroxy-1-isopropyl-5-nitro-2-oxoindolin-3-yl)acrylate (47)

Waxy solid. R_f = 0.49 (25% EtOAc–Hexanes). ν_{max} (CH_2Cl_2, cm^{-1}): 3351, 1709, 1612. ^1H NMR ($CDCl_3$) δ_H:

1.55 (6H, d, J = 8.1 Hz), 3.47 (1H, s), 3.63 (3H, s), 4.58–4.63 (1H, m), 6.56 (1H, s), 6.67 (1H, s), 7.1 (1H, d, J = 8.7 Hz), 8.03 (1H, d, J = 2.3 Hz), 8.28 (1H, dd, J = 2.3, J = 8.7 Hz). ^{13}C NMR ($CDCl_3$) δ_C: 19.1 (2C), 43.3, 51.8, 75.8, 109.7, 122.3, 124.0, 127.6, 129.8 (2C), 140.4, 143.2, 164.8, 176.1. Anal. calcd. for $C_{15}H_{16}N_2O_6$: 320.1008; found: 320.1008.

Acknowledgements

The authors thank Professor T. K. Chandrashekar, Director, for providing infrastructure facilities. Financial support (SR/S1/OC-38/2005) from the Department of Science Technology (DST, New Delhi) is gratefully acknowledged. V.V. thanks the Council of Scientific and Industrial Research (CSIR, New Delhi) for the award of Senior Research Fellowship (SRF). Thanks are due to Mrs. Viji and Mrs. Soumini Mathew for providing HRMS and NMR data, respectively.

X-ray absorption spectroscopy of aqueous solutions in the X-ray energy region from 1800 to 3700 eV

Astrid Jürgensen

Abstract: A methodology for the X-ray XANES and EXAFS analyses of aqueous solutions was developed for the Double Crystal Monochromator (DCM) beamline of the Canadian Synchrotron Radiation Facility (CSRF). The technique is based on the implementation of a liquid cell, which is compatible with the standard solid-state sample holding mechanism used at the beamlines of CSRF and the Canadian Light Source (CLS). Aluminized Mylar film with a thickness of 5 μm has been thoroughly investigated for use as a window material for the cell, and found acceptable for the collection of the S, Cl, and K K-edge spectra of ions in aqueous solution, but not for P K-edge or Rb $L_{2,3}$-edge spectra. Some of the limitations of this methodology, such as diffusion of the solution through the window and the detection limit at low ion concentration, are investigated and discussed.

Key words: XANES, EXAFS, aqueous solutions, X-ray region from 1800 to 3700 eV.

Résumé : Une méthodologie était développée pour analyser les solutions aqueuses avec la spectroscopie XANES et EXAFS en la région des rayons-X à la Double Crystal Monochromator (DCM) beamline de la Canadian Synchrotron Radiation Facility (CSRF). Cette technique est basée sur la mise en oeuvre d'une cellule des liquides, qui est compatible avec la mécanisme du cadre support des spécimens solides à les beamlines de CSRF et aussi à certaines beamlines de la Canadian Light Source (CLS). Une pellicule Mylar aluminisée avec une épaisseur de 5 μm était examinée pour l'utilisation comme matériel de la fenêtre de la cellule. On a trouvé que cette matériel est acceptable pour mesurer les spectres d'absorption pour les discontinuités K de S, Cl et K des ions en solution aqueuse, mais pas pour les spectres de la discontinuité K de P et la discontinuité $L_{2,3}$ de Rb. Quelques limitations de cette méthodologie (la diffusion de la solution par la fenêtre et la limite de détection a concentration base) sont analysée et examinée.

Mots-clés : XANES EXAFS, solutions aqueuses, rayons X de 1800 à 3700 eV.

Introduction

Many chemical and biochemical reactions involving metal ions occur in aqueous solutions. The kinetics of these reactions depend upon the stability of the region around the solute species, the hydration shell. This very narrow region, typically ~5 Å for monatomic ions,[1] represents the transition region between the solute species and the bulk structure of liquid water. Molecular dynamics simulations suggest that the structure of the hydration shell depends on electrostatic interactions between ions and water molecules[1] and the formation of hydrogen bonds.[1–5] The formation of short-lived (a few ps) ionic clusters is predicted to become more common at higher concentrations (≥1.0 mol/L), even for alkali halide solutions.[6–8] Both charge and size of the ion can have significant effects on the structure[1–4] and stability[9] of the hydration shell, which, in turn, can affect the properties of the solute ion, such as the luminescence intensity[10,11] and the permeability through cell membranes.[9–12]

X-ray absorption spectroscopy can be used to study the local structure and chemical bonding of ions in aqueous solution. The X-ray absorption near edge structure (XANES) spectrum provides information about the oxidation state of the absorbing atom and the electronic interactions between it and its neighbours. The identity, interatomic distance, and coordination geometry of the neighbouring atoms can be determined from the extended X-ray absorption fine structure (EXAFS) spectrum. For ions in aqueous solution, this information represents a time-averaged structure of the hydration shell.

These spectroscopic methods have been used to study the structure of transition-metal aquo complexes, $TM(H_2O)_6^{n+}$ (n = 2, 3), and its correlation with the water-exchange rate, the electron exchange reactions of transition-metal complexes, and structural differences of metal complexes in solids compared to aqueous solutions.[13] More recent applications include the characterization of arsenite in water,[12] the study of the $Pb^{2+}_{(aq)}$ adsorption mechanisms at the calcite–water interface,[14] and the hydration structure of Ca^{2+} in aqueous solution.[15] The structural information about the hydration shell obtained from X-ray spectroscopy data

can also be used to test and improve the theoretical molecular dynamics models, and thus provide us with a better understanding of solute–solvent interactions.

These spectroscopies are, furthermore, element-specific and relatively non-destructive. The analysis can be performed on samples without prior chemical treatments. Thus, XANES and EXAFS are now widely used to study the elemental composition and chemical speciation of various environmental samples, including bacteria, manure, meteorites, plants, sediments, and soils.[16–23] These substances often contain water, and thus, ions in aqueous solution. Upon dissolving in water, the local environment of a molecular species changes compared to the solid state. The crystal structure of the solid breaks down, and isolated ions or molecules surrounded by water molecules are formed. These structural changes lead to modifications in the observed fine structure of the XANES and EXAFS spectra. To identify the features observed in the XANES spectra properly, the set of standard compounds used to analyze the spectra of environmental samples should therefore include aqueous solutions. Furthermore, with minor adaption, the methodology for the XANES and EXAFS measurement of aqueous solutions can also be used to analyze environmental samples in their natural wet state, eliminating the need for freeze-drying them and, thus, avoiding possible changes in chemical speciation caused by the freeze-drying process.

In the X-ray energy region from 1800 to 3700 eV, the mean free path of photons in air at atmospheric pressure is ≤11 cm.[24] Thus, the XANES spectra need to be collected in vacuo ($P \leq 2 \times 10^{-6}$ torr) (1 torr = 133.322 Pa). At such pressures and room temperature, water is not stable in the liquid phase (at 20 °C, the vapour pressure of water is 17.51 torr[25]). Solutions need to be contained in a sample holder that isolates them from the vacuum but, at the same time, allows the X-rays to reach the sample. Alternatively, the experimental station could be put under a helium atmosphere.[26–28] Here too, a sample holder is required, which minimizes exposure of the solution to the dry helium surrounding it; and a windowed barrier is required to separate the experimental station (P ~760 torr) from the ultra-high-vacuum ($P < 1 \times 10^{-9}$ torr) in the rest of the beamline.

This paper describes a technique for the XANES and EXAFS study of aqueous solutions in the X-ray region from 1800 to 3700 eV. It is based on the implementation of a liquid cell, which isolates the solution from the vacuum in the absorption chamber while allowing the X-rays to reach the sample. The design aspects of the cell and the resulting experimental limitations for the XANES spectroscopy of solutions are discussed, and the first experimental data at the S, Cl, and K K-edges are shown. This methodology is currently used at the Double Crystal Monochromator (DCM) beamline of the Canadian Synchrotron Radiation Facility (CSRF). By adapting the cell design to the solid-state sample holding mechanism actually used, it could be implemented at other beamlines.

Experimental

Cell design

For convenience, the liquid cell was designed to be compatible with the standard solid-state sample holding mechanism used at the CSRF beamlines. This determined the shape and size of the cell, as shown in Fig. 1. The stainless steel cell body is hollow in the centre, and the volume of this cavity is 0.6 mL. Liquids are trapped inside this cavity using o-ring seals. The plate attached to the back of the cell is an aluminum disk with a diameter of 1.897 cm and a thickness of 0.152 cm. The front plate consists of two doughnut-shaped disks, each with an outer diameter of 2.223 cm and a thickness of 0.076 cm. The centre hole of each disk has a diameter of 0.953 cm. A thin film, sandwiched between the disks, covers the hole. It is glued to the disks with VACSEAL® (Trademark of Space Environment Laboratories) to hold it in place and to provide a proper seal. This creates a window that allows X-rays to pass through while keeping the liquid trapped inside the cell. The material chosen for this window has to meet two stringent requirements. It has to withstand the pressure differential between the liquid on the inside and the vacuum on the outside; and it has to be transparent to both the incident X-rays and the lower-energy fluorescence X-rays. These impose opposing requirements on the film thickness. The former needs the film to be as thick as possible, while a very thin film would be ideal for the latter. Furthermore, the film must not contain an element that has an absorption edge in the energy region of interest, and it must not react with the liquid inside the cell.

Fig. 1. The sample holder for liquids. The protrusions (three in total) on the cell body are bayonets used to attach the cell to the sample holder support in the vacuum chamber. The front plate is composed of two doughnut-shaped disks, each with a thickness of 0.076 cm. The window is sandwiched between them.

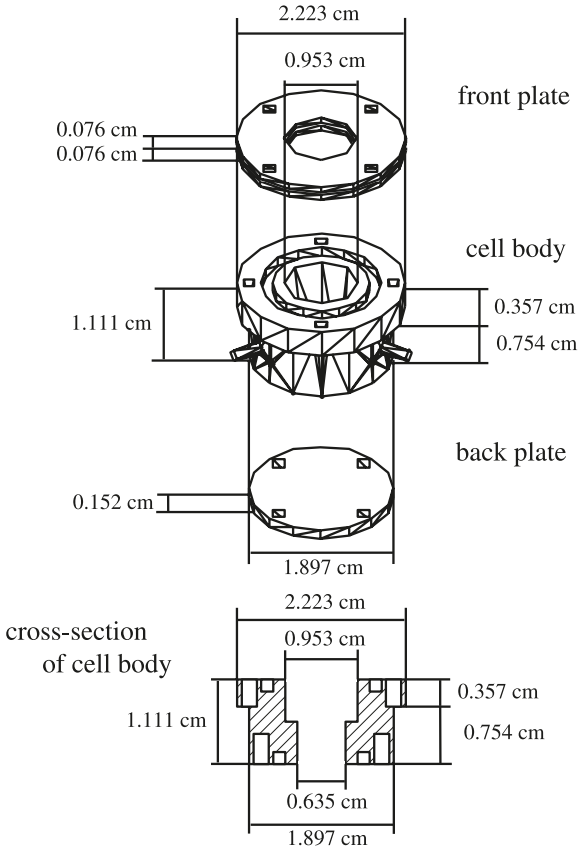

Fig. 2. The theoretical X-ray transmission of a 5 μm aluminized Mylar (Al-Mylar) film, assuming the following thickness: Mylar = 5 μm, Al = 0.15 μm, total = 5.15 μm, and assuming that the total transmission of the film is the product of the transmission of the individual layers. The data for the 5 μm Mylar and 0.15 μm Al layers were obtained from the Web site of the Center for X-Ray Optics (CXRO) at Berkeley Lab, using the routine for calculating the X-ray transmission of a solid.[29]

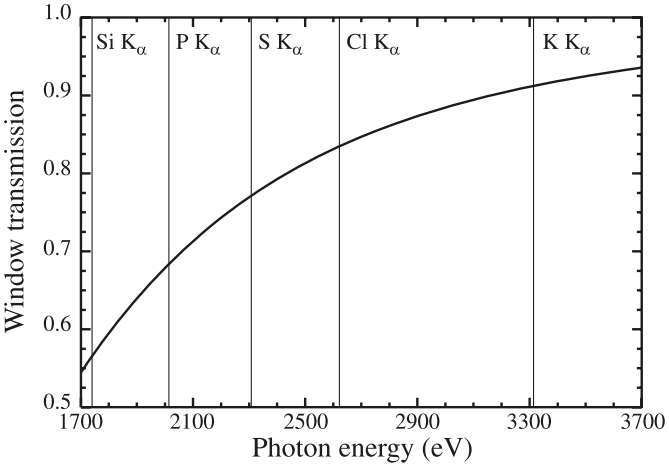

The material chosen, aluminized Mylar® (Trademark of DuPont Teijin Films) (Al-Mylar) with a thickness of 5 μm, is an adequate compromise to meet these conditions. It is relatively inert, it can withstand the pressure differential, and it is fairly transparent to X-rays with energies between 1700 and 3700 eV (Fig. 2). The transmission of the window is, however, not uniform over this energy range. It increases from ~54% at 1700 eV to ~94% at 3700 eV.[29] This variation in the window transmission can distort the relative peak intensities of the measured spectra, especially for long-range EXAFS scans. Corrections for this can be made readily by dividing the measured spectrum by the theoretical transmission of the window material.

This cell design does not permit data collection in the transmission mode, because the back plate (a solid aluminum disk) is not transparent to the X-rays. Also, the present path length through the cell is 1.1 cm (11000 μm), and all of the incident photon flux is absorbed by the solvent (water)[30] over this distance. It might be possible to make the cell suitable for transmission by using a windowed back plate. However, a reduction of the path length through the cell to < 100 μm is also required to make the measurement of transmission spectra feasible, a major design challenge. Thus, it is preferable to use the fluorescence-yield-detection method for the XANES measurement of aqueous solutions.

Method of filling the cell

First, the window is attached to the front of the cell. If necessary, the window is conveniently assembled simultaneously. The cell is then filled from the back. The liquid is added dropwise with the aid of a pipette, and the cell is filled to slightly above capacity, so that the meniscus forms a convex surface. Then, the back plate is screwed tightly onto the cell body, forming an o-ring seal. If the closed cell is filled properly, the window should have a smooth convex surface.

Collection of XANES spectra

The liquid cell is loaded into the sample chamber using the standard procedure employed for solid samples. With the liquid cell in the chamber, the pressure is typically between 5×10^{-7} and 3×10^{-6} torr. XANES spectra of a variety of different aqueous solutions were collected at the Rb $L_{2,3}$-edge and the P, S, Cl, and K K-edges. They were measured by fluorescence yield (FY) using an Ortec nine-element solid-state photon detector. Specific X-ray fluorescence energies, for example the sulfur K_α-line, can be selected for measurement, while all others are excluded. This enhances the detectability of the XANES spectra of elements present in low concentration in the sample, and eliminates the background fluorescence signal from the window material. The FY detector was attached to the absorption chamber at a port that is at 90° to the incident photon beam. To maximize the fluorescence photons reaching the detector, the sample holder was oriented so that the angle between the incident photon beam and the window surface was ~60° (The sample surface was not exactly on the rotation axis, causing the beam spot to move horizontally upon rotation. The 60° angle kept the beam spot approximately centred on the cell window while maximizing the FY signal).

The XANES spectra were normalized with respect to the incident photon flux (I_0) using the total-electron-yield (TEY) spectrum from an in-line ion chamber with ~1.5 torr air that is located upstream from the main absorption chamber. Energy calibration was achieved by measurement of the K-edge XANES spectra of standards (powders of SiO_2, $Na_4P_2O_7$, $ZnSO_4$, KCl, and $CaCO_3$) and then adjusting the energy scale using a fourth-order polynomial calibration function obtained from these standard spectra. Effects of the variable window transmission on the peak intensities were removed by dividing the XANES spectra by the theoretical transmission (Fig. 2) of the window material for the incident X-rays. Solutions of RbCl, Na_3PO_4, $Na_2S_2O_3$, Na_2SO_4, NaCl, $NaClO_4$, and KCl were used in this study. The salts were obtained commercially from Sigma-Aldrich and used without further purification.

Results and discussion

Background signal from the window and the solution

The measured FY signal is a combination of the signal from the solution and the signal from the window. The window material, Al-Mylar, contains the elements hydrogen, carbon, oxygen, and aluminum. None of these chemical elements has an absorption edge in the 1700–3700 eV energy region, and thus, the FY signal from them will only contribute to the overall scattered light background signal. Furthermore, most of this background signal is effectively eliminated from the FY spectrum by using the nine-element Ortec detector. Figure 2 shows the transmission of the Al-Mylar film to X-rays from 1700 to 3700 eV. This transmission increases with increasing photon energy, from ~57% for the Si K_α-line to ~91% for the K K_α-line, increasing the detection efficiency at higher photon energies. This, however, is partially offset by the reduction in overall photon flux from the beamline at higher energies.

Impurities in the window material could contain chemical elements that have absorption edges in the 1700–3700 eV

Fig. 3. Impurities in the Al-Mylar window.

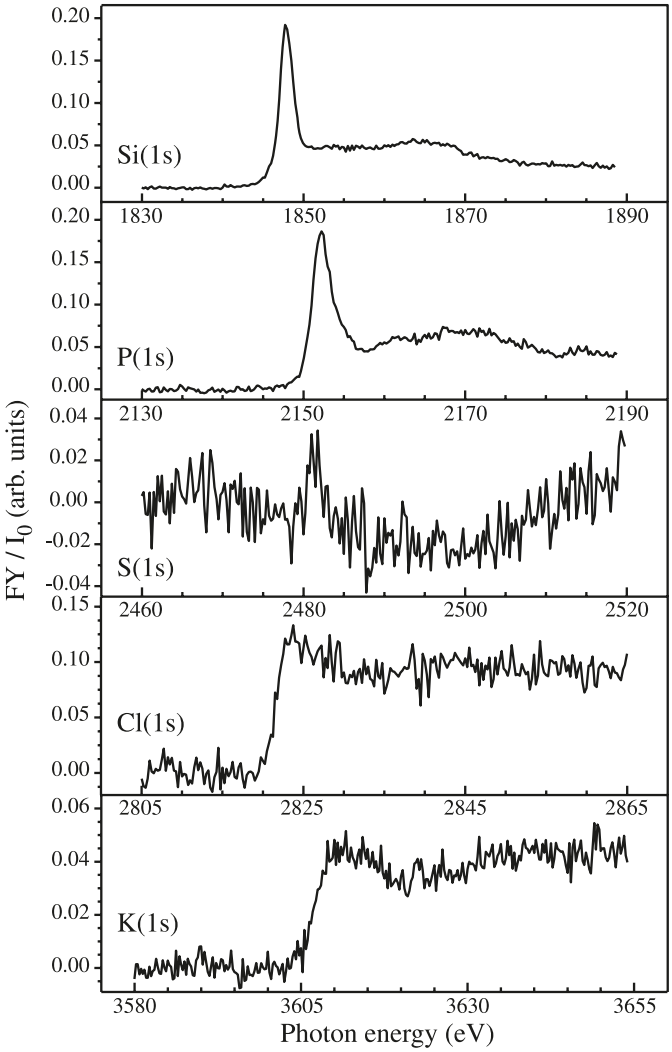

Fig. 4. The effect of window impurities on the XANES spectra of solutions: (*a*) Comparison of the P K-edge spectra from the window and from a 0.268 mol/L Na_3PO_4 solution, (*b*) Comparison of the Cl K-edge spectra from the window and from a 0.0024 mol/L NaCl solution, and (*c*) The Rb $L_{2,3}$-edge XANES spectrum of RbCl, solid powder, and a 1.005 mol/L aqueous solution.

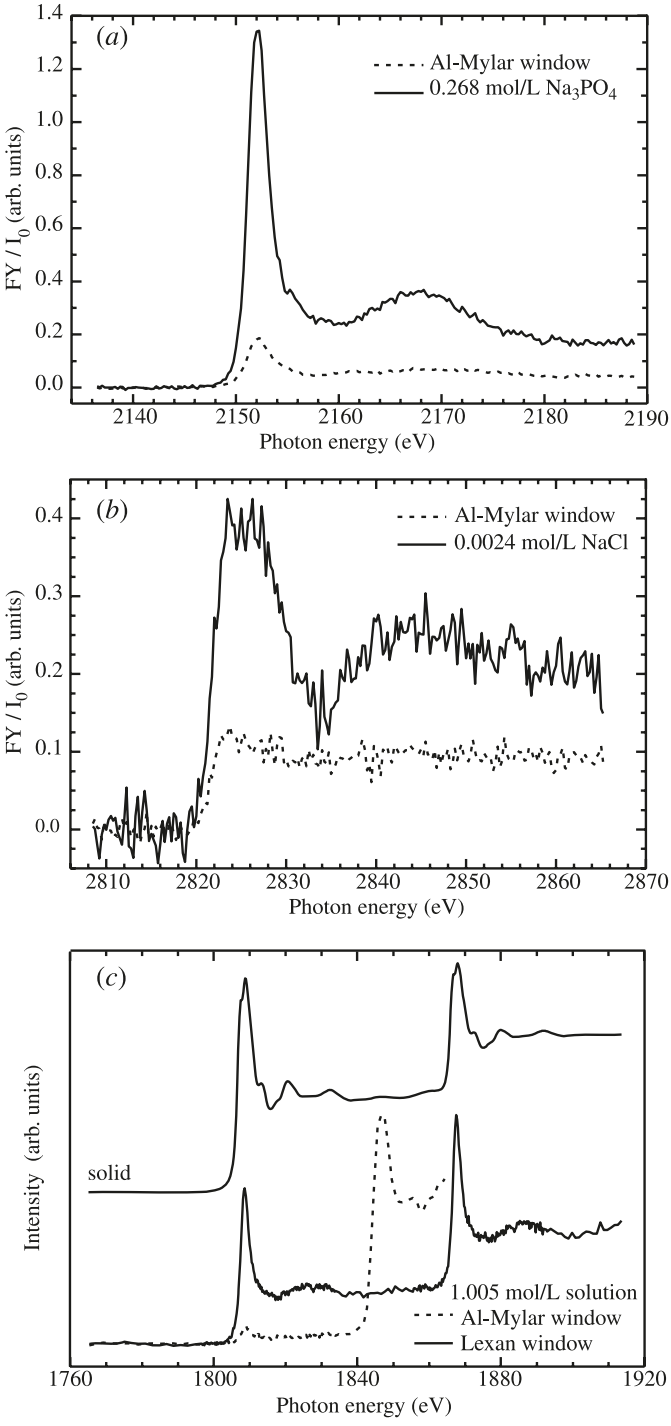

energy region. If these overlap with the absorption edge of the ion of interest, the FY signal from these impurities can contribute to the measured XANES spectrum. To check for possible Si, P, S, Cl, or K impurities, K-edge XANES spectra for these elements were collected from the empty cell, with a clean unused window at the front, and the back being open. The collection time for each data point was 15 s/pt. Four scans were collected at each edge and averaged. The resulting spectra (Fig. 3) show that the window contains silicate and phosphate impurities. Small amounts of chloride and potassium are present as well.

The integrated intensity (area under the curve) of the phosphate XANES spectrum of the window is ~20% of the integrated intensity obtained for a 0.268 mol/L PO_4^{3-} solution (Fig. 4*a*). Hence, there is a significant contribution from the window to the observed XANES spectrum, even for fairly concentrated solutions. The intensity of the Si K-edge of the window is of similar magnitude as that of the P K-edge. While the feasibility of the cell for Si in solution has not been tested, it is expected that the signal from the window would make at least a similar contribution to the overall Si K-edge as it does for the P K-edge. Furthermore, it is not possible to completely resolve the Al-K_α (1487 eV) and Si-K_α (1740 eV) lines with the nine-element Ortec detector, so that the Si K-edge always has some extra background signal from the Al in the window. The window transmission is also lowest at the Si K-edge, ~61% for the incident photons at 1840 eV and ~57% for the Si-K_α fluo-

rescence at 1740 eV (Fig. 2), further increasing the intensity of the signal from the window impurity relative to the signal from the solution.

The Cl K-edge XANES signal from the window has much lower integrated intensity, only ~39% of the signal obtained from a 0.0024 mol/L Cl^- solution (Fig. 4*b*). While it does limit the detectability of Cl^- at low concentration, it does not contribute significantly to the measured XANES spectrum of concentrated Cl^- solutions. The intensity of the K K-edge from the window is of similar magnitude as the Cl K-edge signal (Fig. 3), ~12% of the signal from a 0.0024 mol/L K^+ solution. Furthermore, the K-impurity can be removed from the window by rinsing it with deionized water. Hence, the K K-edge spectrum of the window can be eliminated, and it does not limit the detectability of K^+ at low concentration.

This window material is thus suitable for the study of S, Cl, and K K-edges in aqueous solution, but less desirable for the K-edges of Si and P. XANES spectra of elements with absorption edges and fluorescence lines close to those of Si and P, for example, Rb ($L_{3,2}$-edges: 1804 and 1864 eV, L_α-line: 1694 eV), also cannot be adequately measured using the 5 μm Al-Mylar window. An investigation into the suitability of other window materials is in progress. Initial results have shown that a 6 μm Lexan® (Trademark of General Electric Company) window is a better choice for the measurement of Rb $L_{2,3}$-edge (Fig. 4*c*) and P K-edge XANES spectra in aqueous solution. However, it is not as resistant to radiation damage. The resulting development of pinholes necessitates frequent window replacement, making Lexan an inferior choice for the S, Cl, and K K-edges compared to Al-Mylar. A third window material, 3 μm Mylar, could potentially be a better choice than the 5 μm Al-Mylar for the S, Cl, and K K-edges. It has a higher X-ray transmission (~77% at the Si-K_α line and ~96% at the K-K_α line) than the 5 μm Al-Mylar, it is strong enough to withstand the pressure differential between the liquid and the vacuum, and it is resistant to radiation damage. However, the diffusion rate through the window and the low concentration detection limit of solute species have not yet been tested. Other window materials[31] were also considered for this cell, but found to be unsuitable. Kapton, Mica, Al-foil, and Si_3N_4 all have insufficient transmission, and Be-foil might be too reactive with solvent or solute.

The FY signal from the solution is the combined signal resulting from interactions of the incident X-rays with the solvent and all solute species. In the specific case of aqueous solutions, the solvent (water) does not have an absorption edge in the 1700–3700 eV energy region, and thus absorption by the solvent only generates a background FY signal, which is effectively eliminated from the FY spectrum by using the nine-element Ortec detector. The change in X-ray transmission of the solvent with increasing photon energy leads to a change in the penetration depth of the incident X-rays, but the energy and thus the escape depth of the fluorescence X-rays remain constant. As long as the former exceeds the latter, the actual sampling depth of the FY detection method remains constant, and the change in X-ray transmission has minimal effect on the measured spectrum. However, at absorption edges of the solvent or of solutes in high concentration, the penetration depth of the incident X-rays could decrease to values below the escape depth of the fluorescence X-rays. This leads to a dependence of the sampling depth on the incident X-ray energy, and thus to distortions in the spectrum (the self-absorption effect often detected for solid samples). The correction techniques for solids[32–35] can also be applied to the spectra of aqueous solutions.

Diffusion of the liquid through the window

With the liquid cell in the chamber, the base pressure is relatively high (5×10^{-7} to 3×10^{-6} torr), compared with when the cell is absent ($\leq 5 \times 10^{-8}$ torr). This indicates that the cell is not perfectly sealed, and some liquid slowly leaks out of the cell. This is supported by the observation that after long stays (~14 h or more) in vacuum, the cell window is no longer smooth and convex. Leakage of liquid out of the cell could occur through the o-ring seals or, more likely, through the window. Diffusion of the solution through the window, followed by the deposition of solids on the outside window surface, could possibly affect the measured FY spectrum of the solution.

The possibility of diffusion through the window and its potential effect on the XANES spectrum were investigated for the S K-edge by collecting 18 successive spectra of a 0.001 mol/L $S_2O_3^{2-}{}_{(aq)}$ solution over a time period of about 9.5 h with a collection time of 12 s/pt. There are two observations (Fig. 5*a*): (*i*) the overall intensity of the sulfur signal increased with time, and (*ii*) the spectral features changed with time. The early spectra (Nos.1–4) resemble that of a more concentrated $S_2O_3^{2-}{}_{(aq)}$ solution (Fig. 5*b*). The peaks are, however, not as well-resolved owing to the low ion concentration and the corresponding decrease in *S/N* in the spectrum. A gradual increase in the overall signal intensity is observed starting with scan No. 5. Relative to scan No. 1, the integrated intensity (area) has increased by a factor of 2.28 for scan No. 8, a factor of 2.94 for scan No. 9 and a factor of 4.80 for scan No. 18. This gradual intensity increase over time can be explained by the deposition of solid-state sulfur compounds on the outside surface of the window following diffusion of the solution through the window and evaporation of the solvent. In addition, changes in the spectral features are observed. Starting with scan No. 5, the sulfide peak increases relative to the sulfate peak and, starting with scan No. 9, a shift in the sulfide peak position toward lower energy is observed. This indicates the gradual formation of new sulfur species, probably the products of various redox reactions. Least-squares fitting of scan No. 18 with the XANES spectra of various standards suggests that the most abundant forms of sulfur are Al_2S_3 (50%), S_8 (25%), $S_2O_3^{2-}{}_{(aq)}$ (15%), and $Al_2(SO_4)_3$ (1.2%) (Fig. 6). Possible reactions that could produce these compounds include

[1] $$S{-}SO_3^{2-} + 2H_2O + h\nu \rightarrow S + H_2SO_3 + 2OH^-$$

[2] $$H_2SO_3 + 2\,OH^- + S \rightarrow SO_4^{2-} + H_2S + H_2O$$

[3] $$H_2SO_3 + H_2O + S \rightarrow SO_4^{2-} + 2H^+ + H_2S$$

[4] $$8S \rightarrow S_8$$

Fig. 5. (*a*) The effect of diffusion through the window on the S K-edge XANES of a 0.001 mol/L $Na_2S_2O_3$ solution and (*b*) The S(1s) XANES of a 0.0916 mol/L $Na_2S_2O_3$ solution.

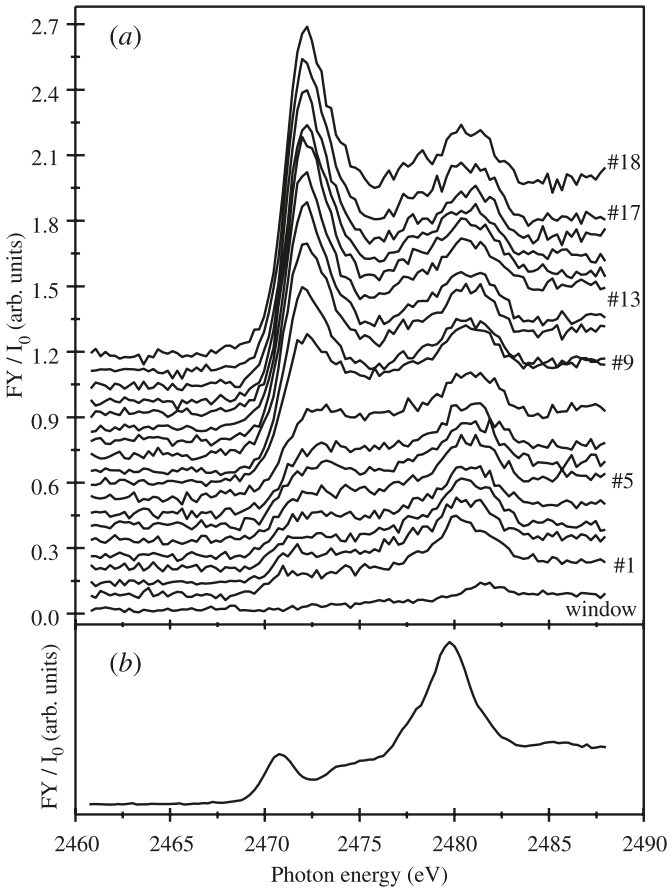

Fig. 6. Least-squares fit of the 18th scan of the 0.001 mol/L $S_2O_3^{2-}{}_{(aq)}$ solution (Fig. 5). The individual-component spectra of standards are also shown with their intensities adjusted according to their contribution to the overall fit.

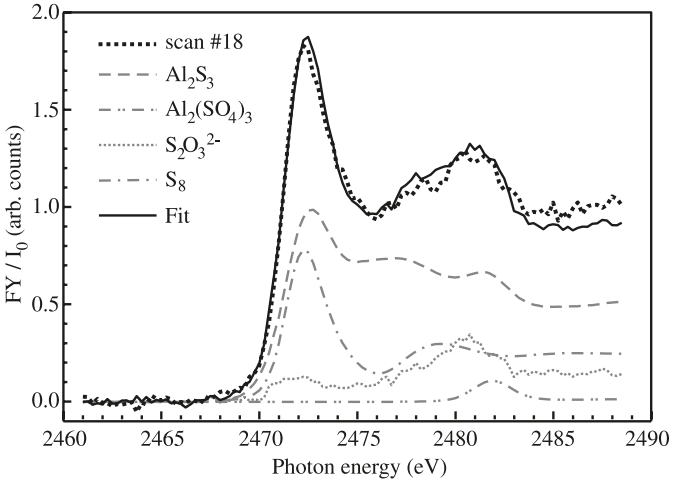


[5] $2\,Al + 3\,S \rightarrow Al_2S_3$

[6] $6H^+ + 2\,Al + 3\,SO_4{}^{2-} \rightarrow 3H_2 + Al_2(SO_4)_3$

The slow formation rate of the new compounds coupled with the overall intensity increase suggest that they are formed in the vicinity of the outside window surface. They could also be products of photochemical reactions that occur in the solution.

The results of this study suggest that window diffusion is a relatively slow process occurring over several hours. It is therefore possible to measure reliable XANES spectra with minimal contribution from the window, if the experiment is conducted in a timely manner (e.g., < 1 h). The measurement of good quality EXAFS spectra typically takes more than 1 h. Thus, the signal resulting from solids deposited on the outside window surface could contribute significantly to the overall spectrum. Corrections for this can be made through the application of the following procedure:

i) The EXAFS spectrum of the solution of interest is collected.

ii) The inside of the cell is rinsed repeatedly with deionized water, and then dried with a Kimwipe® (Trademark of Kimberly-Clark Worldwide Inc.).

iii) The EXAFS spectrum is collected from the empty cell, with the used window at the front, and the back being open. Alternatively, the cell is filled with deionized H_2O and the EXAFS spectrum of the window plus the solvent is measured. The scan parameters are kept the same as for the spectrum of the solution.

iv) After normalization with respect to I_0, the spectrum of the window is subtracted from the spectrum of the solution.

The effectiveness of this procedure is illustrated in Fig. 7 for the Cl K-edge EXAFS spectrum of a 1.003 mol/L $NaClO_4$ solution, where the contribution to the spectrum due to diffusion through the window is minor.

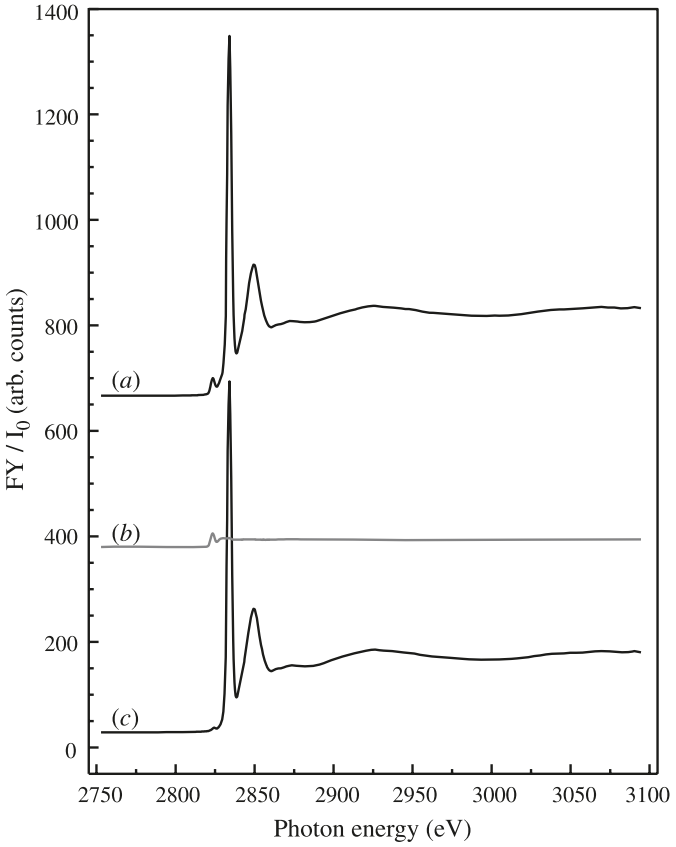
It should be noted that this diffusion-rate study was done for $S_2O_3^{2-}{}_{(aq)}$ at low concentration, and the results are not universally applicable. Further studies are needed to investigate the effects of ion concentration and ion identity on the diffusion rate. The above procedure for the removal of the signal from solids on the outside window surface can be applied to XANES spectra as well.

The loss of liquid caused by the diffusion through the window represents a flaw of the cell that might not be easily eliminated. To allow the X-rays to pass through with sufficient intensity for meaningful measurement, the window needs to be very thin. However, such a very thin window is also more permeable than a thicker window, increasing the diffusion rate. It might be possible to use another less permeable window material, but only if it is also transparent to the X-rays. However, the present study suggests that diffusion through the window is a relatively slow process that does not affect the measurements significantly. Hence, this flaw of the cell can be tolerated.

XANES spectra: solid state vs. solution

Upon dissolution in water, the local environment of a molecular species changes compared with the solid state. The crystal structure of the solid breaks down and isolated ions and molecules are formed that are surrounded by water molecules, forming the hydration shell. The structure of this hydration shell depends on the type and size of the solute ion

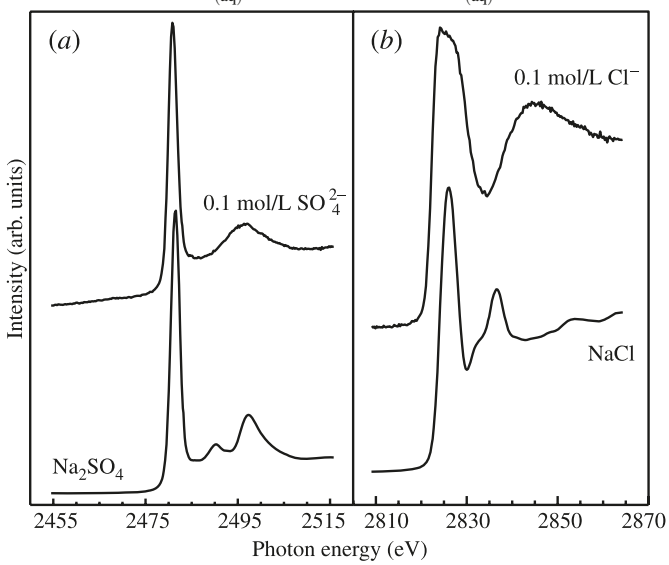
Fig. 7. Elimination of the window spectrum from the Cl K-edge EXAFS spectrum of $ClO_{4(aq)}^-$: (*a*) The spectrum of a 1.003 mol/L $NaClO_4$ solution and the 5 μm Al-Mylar window. (*b*) The spectrum of the 5 μm Al-Mylar window after the measurement of the $NaClO_4$ solution. (*c*) The spectrum of $ClO_{4(aq)}^-$, obtained by subtracting the spectrum of the window (*b*) from the combined spectrum (*a*).



and the concentration of the solute. These structural changes between the solid and the solution lead to modifications in the observed structure of the XANES spectrum. In particular, the long-range crystal structure of the solid is lost upon solvation, leading to alterations in the scattering pattern of photoelectrons and, thus, to changes in the spectrum following the main absorption peak. The overall extent of the spectral changes depends upon the species involved, as illustrated for Na_2SO_4 vs. $SO_{4(aq)}^{2-}$ and NaCl vs. $Cl_{(aq)}^-$ (Fig. 8).

In the case of Na_2SO_4, the anion (SO_4^{2-}) is a tetrahedral polyatomic anion with the sulfur atom at the centre. The first coordination shell of the S atom, four oxygen atoms, remains the same in solution as in the solid, except for minor perturbations. The water molecules of the hydration shell form the 2nd and 3rd coordination shells of the S atom. In consequence, there are only minor changes to the electronic structure and chemical bonding of the sulfur upon solvation of Na_2SO_4. This is reflected in the XANES spectra (Fig. 8*a*). The position and intensity of the main absorption peak are the same in both spectra. The fine structure following the main peak, however, is caused by scattering of the photoelectrons by atoms in the first few coordination shells of sulfur. The structural differences in the 2nd and higher coordination shells between the solid and the solution lead to significant differences in the spectra: two peaks at 2490.3

Fig. 8. K-edge XANES spectra (solid state vs. aqueous solution): (*a*) $Na_2SO_{4(s)}$ vs. $SO_{4(aq)}^{2-}$ and (*b*) $NaCl_{(s)}$ vs. $Cl_{(aq)}^-$.



and 2497.4 eV for the solid vs. one peak at 2496.5 eV for the solution.

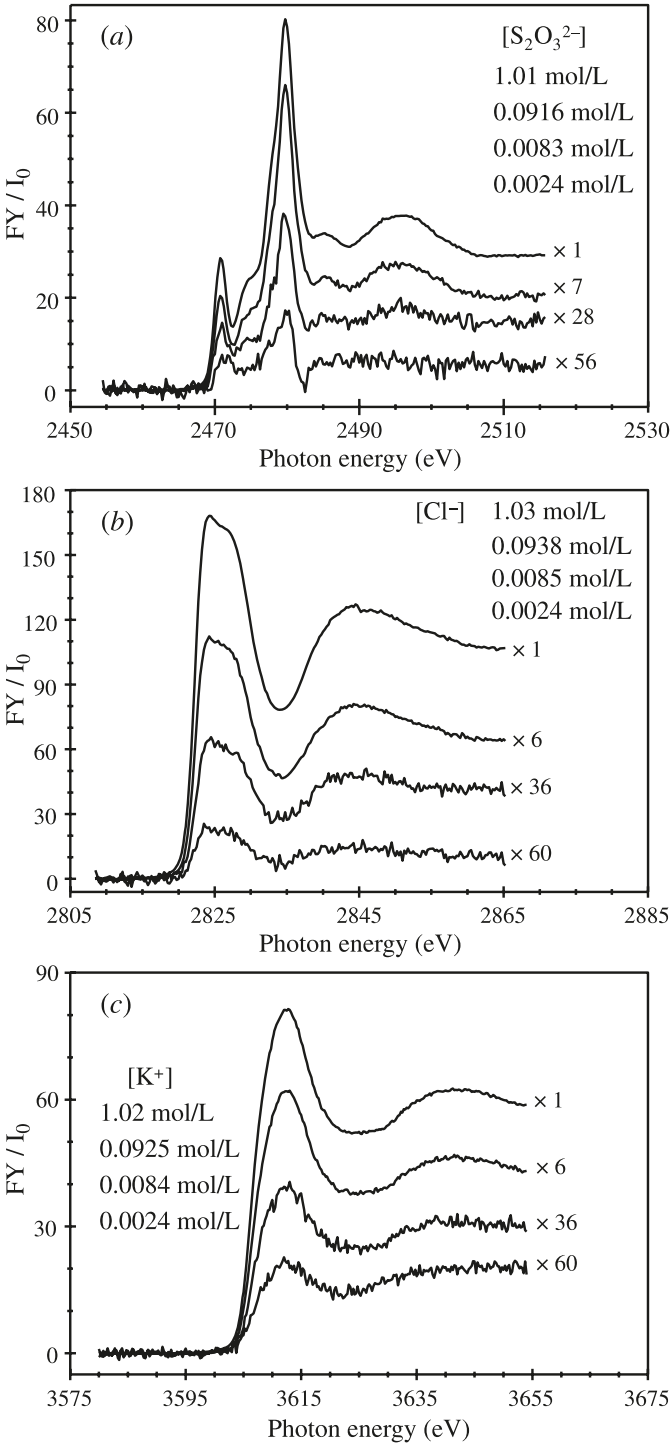
In contrast, the anion of NaCl, Cl^-, is a monatomic ion with eight Na^+ ions as nearest neighbours. Upon solvation, these Na^+ cations are replaced by water molecules, causing significant changes to the electronic structure and chemical bonding of the Cl^- ion. This is reflected in the XANES spectra (Fig. 8*b*). There are changes to the main absorption peak as well as to the fine structure. The absorption edge shifts down by ~1.7 eV, and the main peak (much broader than for solid-state NaCl) is composed of two partially resolved peaks. They could possibly result from the presence of $Cl_{(aq)}^-$ ions in two different chemical environments, i.e., the first coordination shell of the $Cl_{(aq)}^-$ ion has two distinct structures. The position and relative intensity of these peaks are not dependent on the ion concentration (Fig. 9*b*), and a dependence on the pH of the solution still needs to be investigated.

A similar effect on the XANES spectrum of the cation can be seen in Fig. 4*c*, where the fine structure in the Rb $L_{2,3}$-edge XANES of RbCl is not observed in the spectrum of a 1.005 mol/L RbCl solution. In all three cases ($SO_{4(aq)}^{2-}$, $Cl_{(aq)}^-$, and $Rb_{(aq)}^+$), the lack of fine structure following the main peak can be attributed to a lack of long-range order in the solution.

XANES spectra: effect of ion concentration

Liquid environmental samples, for example, lake water, probably contain the ions of interest in fairly low concentrations. Thus, the sensitivity of the experimental apparatus in detecting ions at low concentration was investigated. The dependence of the signal intensity on the ion concentration was tested for the S, Cl, and K K-edges by measurement of the XANES spectra of solutions with different ion concentrations. Solutions of $Na_2S_2O_3$, NaCl, and KCl were used for the S, Cl, and K K-edge spectra, respectively. Their concentrations are listed in Table 1. The XANES spectra obtained for these solutions show that measurement is possible

Fig. 9. K-edge XANES spectra as a function of the concentration of the solution. The intensity (FY/I_0) of the signal decreases with decreasing ion concentration, as listed. For clarity, the spectra of the solutions were multiplied by a constant scaling factor given next to the corresponding XANES spectrum: (*a*) $S_2O_3^{2-}_{(aq)}$, (*b*) $Cl^-_{(aq)}$, and (*c*) $K^+_{(aq)}$.



for concentrations as low as 0.0024 mol/L (Fig. 9). All 12 spectra were collected with the synchrotron ring energy at 800 MeV. With the ring energy at 1 GeV, the incident photon flux increases by a factor of 4 to 12, depending on the photon energy, which would probably enable the XANES measurement of ions at even lower concentration.

As seen in Fig. 9, the intensity of the signal increases with increasing ion concentration. For both the maximum of the main absorption peak and the integrated intensity, this increase with respect to ion concentration is approximately linear for the concentration range investigated (Fig. 10). XANES spectroscopy can thus be used to quantitatively determine the concentration of ions in liquid environmental samples. However, for the concentration range (~three orders of magnitude) studied here, it would be desirable to have a few additional calibration points to establish a suitable conversion formula between the FY signal intensity and the ion concentration.

Vacuum vs. helium atmosphere

In other XANES studies of aqueous solutions using X-rays below 3000 eV,[26–28] the sample was put in a helium atmosphere (P ~760 torr), while in the present study a vacuum (5×10^{-7} torr $\leq P \leq 3 \times 10^{-6}$ torr) was used. The solutions investigated in those studies had ion concentrations of comparable magnitude to the ones studied here, and the XANES spectra obtained were of comparable quality.

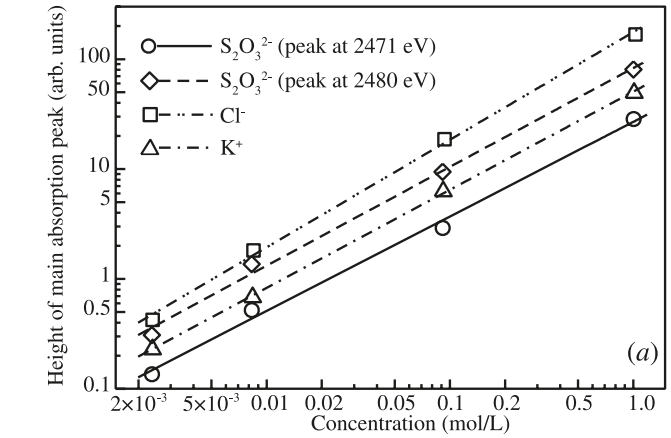
A clear advantage of using a helium atmosphere is that there is a lower risk of the sample cell window breaking because of the pressure differential between the inside and the outside of the cell. It is even possible to dispense with a windowed sample cell and use a straw with a small slit instead.[28] However, the use of a helium atmosphere also comes with a few challenges. The most difficult of these is how to effectively isolate the experimental station (P ~760 torr He) from the beamline ($P < 1 \times 10^{-9}$ torr), unless the beamline itself is also filled with helium.[26] One possibility is to attach a Si_3N_4 membrane at the end of the beamline.[28] This works well for the Al K-edge at 1560 eV (attenuation length = 4.33 μm[30]), but the membrane becomes opaque at the Si K-edge (attenuation length = 1.28 μm[30]). At the S K-edge, the absorption length has increased to 2.69 μm,[30] which might be sufficient for the measurement of S(1s) XANES spectra. A second possibility is to use a 3 μm Mylar film window supported by a capillary array, which has ~50% transmission at the S K-edge.[27] This represents a significant loss of photon flux, and in conjunction with the loss at the sample cell window, it could limit the measurement of XANES spectra to solutions with high ion concentration. Both barriers require fast acting gate valves interlocked with ion gauges to prevent beamline venting in case that the window breaks.

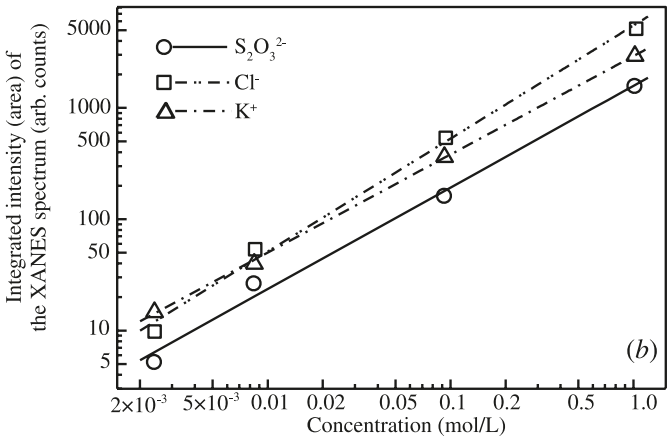
Use of the liquid cell in vacuum has the same requirements as a gas-phase experiment: a barrier window of sufficient strength between the sample and the vacuum and fast-acting gate valves interlocked with ion gauges to protect the beamline from venting. The use of a helium atmosphere does not eliminate these requirements. Instead, it adds the extra complexity of a high-pressure gas-phase experiment (typical pressures for gas-phase experiments are between 1×10^{-5} and 2 torr, depending on the experimental set-up). In addition, the helium atmosphere does not improve the X-ray transmission: at 2472 eV, the attenuation length of 3×10^{-6} torr H_2O (the vacuum) is 9.953×10^8 cm compared with 1959 cm for 760 torr He.[36] For a reasonable path length, e.g., 15 cm, the difference in X-ray transmission is

Table 1. The concentrations of the sensitivity-test solutions.

		Concentration (mol/L)			
Edge	Compound	Solution I	Solution II	Solution III	Solution IV
S K-edge	$Na_2S_2O_3$	1.01	9.16×10^{-2}	8.3×10^{-3}	2.4×10^{-3}
Cl K-edge	NaCl	1.03	9.38×10^{-2}	8.5×10^{-3}	2.4×10^{-3}
K K-edge	KCl	1.02	9.25×10^{-2}	8.4×10^{-3}	2.4×10^{-3}

Fig. 10. The effect of ion concentration on the intensity of the XANES signal: (*a*) the height of the main absorption peak vs. ion concentration (best fits: $S_2O_3^{2-}$ peak at 2471 eV, log(height) = 1.43 + 0.86 log([$S_2O_3^{2-}$]); $S_2O_3^{2-}$ peak at 2480 eV, log(height)=1.92 + 0.90 log([$S_2O_3^{2-}$]); Cl^- peak, log(height) = 2.24 + 0.98 log([Cl^-]); K^+ peak, log(height) = 1.92 + 0.89 log([K^+])) and (*b*) the integrated intensity (area) of the XANES spectrum vs. ion concentration (best fits: $S_2O_3^{2-}$, log(area) = 3.20 + 0.91 log([$S_2O_3^{2-}$]); Cl^-, log(area) = 3.74 + 1.02 log([Cl^-]); K^+, log(area) = 3.46 + 0.88 log([K^+])). Note that in Fig. 10*a* the K^+ peak intensity was shifted down by a factor of $10^{0.2}$ for clarity.





negligible in the 1700 to 3700 eV region (100% for 3×10^{-6} torr H_2O and 97%–100% for 760 torr He[36]), but at lower energies, the loss of flux to the He atmosphere can become significant (e.g., at 600 eV with a 15 cm path length: 100% transmission for 3×10^{-6} torr H_2O and 48% for 760 torr He[36]).

The DCM beamline of CSRF was designed to permit the XANES measurement of corrosive gases, for example, PF_3. Thus, it has a built-in barrier section between the ultra-high-vacuum of the beamline and the experimental station. This barrier consists of the gas cell used for the I_0 measurement (12.5 cm long with a 12.5 μm Be window at each end and filled with ~1.5 torr air) followed by a differential pumping section. A gate valve, set to close automatically at $P > 1 \times 10^{-4}$ torr, separates the latter from the experimental station. It is thus possible to conduct the XANES measurement under a helium atmosphere. Only two steps are needed to set it up: (*i*) adding another 12.5 μm Be window between the differential pumping section and the solid-state chamber and (*ii*) filling the solid-state chamber with ~760 torr He.

The present study, however, has demonstrated that the extra complexity of a helium atmosphere is not required for the XANES measurement of aqueous solutions. The standard vacuum conditions used for solid samples were sufficient, simplifying the experimental procedure. Using a vacuum rather than a helium atmosphere also makes it easier to extend the XANES analysis of solutions to even lower energy X-ray photons. A vacuum in the experimental station will allow the use of very thin (e.g., 1.5 μm Mylar) windows between it and the beamline, thus maximizing the transmission of the incident X-rays. If an effective differential pumping station is present, it might even be possible to run the experiment without the barrier window. Under these conditions and with a 3 μm Mylar window, the liquid cell could probably be used to study the L-edges of first-row transition-metal ions.

Summary

A methodology for the XANES and EXAFS study of aqueous solutions in the 1800–3700 eV energy region has been implemented successfully at the DCM beamline of CSRF. The design of the required sample holder for liquids is compatible with the standard solid-state sample holding mechanism used at the CSRF beamlines, thus allowing for easy loading of solution samples into the vacuum chamber. An aliquot of 0.6 mL can be contained in this liquid cell, and a 5 μm Al-Mylar film proved sufficient as a window material. An investigation into the impurity components of this window material, however, revealed that it cannot be employed for the measurement of P K-edge and Rb $L_{2,3}$-edge spectra of, for example, $PO_{4(aq)}^{3-}$ and $Rb_{(aq)}^{+}$ ions.

The measurement of XANES spectra at the S, Cl, and K K-edges is limited to solutions with ion concentrations of ~0.0025 mol/L or higher, owing to the dependence of signal intensity on ion concentration. It might be possible to decrease the lower concentration limit by increasing the incident photon flux or by using a window material with higher transmission of the X-rays. Diffusion of the solution through the window followed by the deposition of solids on the outside window surface was investigated. The results suggest that this is a relatively slow process, and that for concentrated solutions, the signal from these solids has low inten-

sity compared with the signal from the solution. Thus, window diffusion effects play only a minor role in limiting the measurement of reliable XANES and EXAFS spectra of aqueous solutions.

Investigations to use this methodology to study electron-transfer reactions in aqueous solutions with X-ray excitation optical luminescence (XEOL) spectroscopy are in progress. Future development of this methodology will include ways to adapt the cell design to allow the study of solid–solution interfaces, wet environmental samples (e.g., leaves), and solvents other than water. By adapting the cell design to the solid-state sample holding mechanism actually used, this methodology could be implemented at other beamlines.

8-Isocyanoamphilecta-11(20),15-diene, a new antimalarial isonitrile diterpene from the sponge *Ciocalapata* sp.

Chatchai Wattanapiromsakul, Naphatson Chanthathamrongsiri, Somchai Bussarawit, Supreeya Yuenyongsawad, Anuchit Plubrukarn, and Khanit Suwanborirux

Abstract: A new isonitrile diterpene of the amphilectane family, 8-isocyanoamphilecta-11(20),15-diene (**4**), was isolated from the sponge *Ciocalapata* sp., along with three known isonitriles, 8,15-diisocyano-11(20)-amphilectene (**1**), 7-isocyanoamphilecta-11(20),15-diene (**2**), and 8-isocyanoamphilecta-11(20),14-diene (**3**), and two steroidal peroxides, ergosterol peroxide (**5**) and 5α,9α-epidioxy-8α,14α-epoxy-(22*E*)-ergosta-6,22-dien-3β-ol (**6**). The structure of the new isonitrile was elucidated spectroscopically. In addition, anomalous multiplicities in the NMR spectra of some isolated isonitriles were observed and are reported here. The four isonitriles were strongly active against *Plasmodium falciparum* K1 with IC_{50} in a range of 0.09–1.07 μmol/L. Except for **1**, which was cytotoxic against both MCF-7 and fibroblast cell lines, the other three diterpenes showed no significant cytotoxicity against either targeted cell lines. On the other hand, the steroidal peroxides **5** and **6**, which were less active in the antimalarial bioassay (IC_{50} values of 6.28 and 7.13 μmol/L, respectively), were strongly cytotoxic against MCF-7 (IC_{50} values of 0.025 and 0.003 μmol/L, respectively), with very little toxicity against human fibroblasts.

Key words: isonitrile diterpenes, antimalarial, *Ciocalapata*, steroidal peroxides, *Plasmodium falciparum*.

Résumé : À partir de l'éponge *Ciocalapata* sp., on a isolé un nouvel isonitrile diterpénique de la famille des amphilectanes le 8-isocyanatoamphilecta-11(20)-15-diène (**4**), ainsi que cinq produits déjà connus dont trois isonitriles, le 8,15-diisocyanoamphilect-11(20)-ène (**1**), le 7-isocyanoamphilect-11(20),15-diène (**2**) et le 8-isocyanoamphilect-11(20),14-diène (**3**) ainsi que deux peroxydes stéroïdaux, le peroxyde d'ergostérol (**5**) et le 5α,9α-épidioxo-8α14α-épidioxo-(22E)-ergosta-6,22-diène-3β-ol (**6**). On a élucidé les structures des deux nouveaux isonitriles sur la base de la spectroscopie. De plus, on a observé des multiplicités anormales dans les spectres RMN de certains isonitriles isolés et elles sont rapportées ici. Les quatre isonitriles sont fortement actifs contre *Plasmodium falciparum* K1 avec des concentrations inhibant 50% de l'effet observé, CI_{50}, de l'ordre de 0,09 à 107 μmol/L. à l'exception du composé **1** qui est cytotoxique contre les lignées cellulaires MCF-7 et fibroblaste, les deux autres diterpènes ne présentent pas de cytotoxicité significative contre l'une ou l'autre des lignées cellulaires visées. Par ailleurs, les peroxydes stéroïdaux **5** et **6** qui étaient moins actifs dans les essais biologiques antipaludéens (CI_{50} de 6,28 et 7,13 μmol/L respectivement) sont fortement cytotoxiques contre MCF-7 (CI_{50} de 0,025 et 0,003 μmol/L respectivement), mais très peu toxiques contre les fibroblastes humains.

Mots-clés : diterpène isonitrile, antipaludéen, *Ciocalapata*, peroxydes stéroîdaux, *Plasmodium falciparum*.

Introduction

Malaria is one of the deadliest infectious diseases troubling the global healthcare system. Despite the severity and high mortality of the disease, to date only two classes of antimalarial drugs, antimalarial quinolines and endoperoxides, are available for clinical use. Whereas the precise mechanisms of the two classes of drugs are still debated, it

is widely accepted that both classes antagonize hemozoin biocrystallization in the malarial parasites by means of heme-drug complex formation.[1,2] Such complexes cause a blockade in the sequestration of heme in such a way that the parasites are unable to polymerize heme into hemazoin, resulting in the toxic monomeric heme that causes damage to the parasites via oxidative stresses.[3] Using heme as an antimalarial drug target is therefore a reasonable approach for antimalarial drug design, since heme detoxification is a distinctive metabolic pathway found specifically in *Plasmodium* and a few other blood parasites and not in mammal cells.

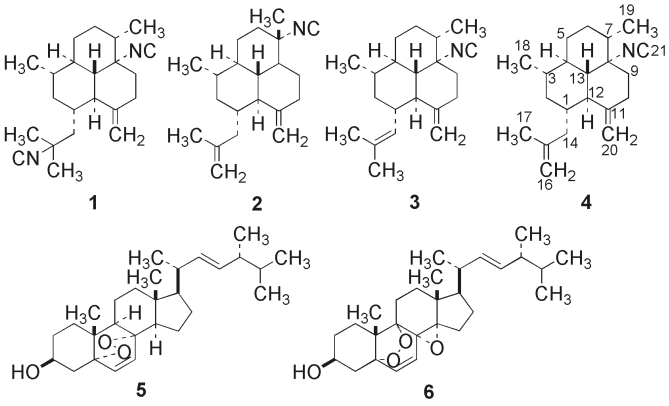
Apart from the quinolines and endoperoxides, several classes of bioactive natural products have been reported to be active against various species and strains of *Plasmodium*. These include sponge-derived terpenoids bearing isonitrile and related functionalities. Despite a wide variety in the core terpenoid skeletons, ranging from sesquiterpenes of the spiroaxanes, cadinanes, eudesmanes, and guaianes,[4] to diterpenes of the bifloranes, amphilectanes, and cycloamphilectanes,[4g–4i,5] it was the nitrogen-bearing functionalities, i.e., isonitrile, isocyanate, and isothiocyanate, that were proposed to be important in imparting antimalarial activity. In fact, a recent report on pseudoreceptor modeling of isonitrile terpenoids suggested that the complex formation between the axial isonitrile functionality and Fe(III) of protoporphyrin could be crucial in the inhibition of heme detoxification in the parasites.[6]

As part of a research project aimed towards the isolation of bioactive metabolites from Thai marine invertebrates against certain tropical disease pathogens, we found that an extract from a sponge of the genus *Ciocalapata* showed strong antimalarial activity against *Plasmodium falciparum* K1. Further investigation led to the isolation of four antimalarial isonitrile diterpenes, **1**–**4**, among which **4** was a new derivative. In addition, two known steroidal peroxides, **5** and **6**, were also isolated. Here, the isolation and structure elucidation of the new compounds are discussed, and the biological activities of all the isolated compounds are reported.

Results and discussion

The sponge *Ciocalapata* sp. was collected from the vicinity of Koh-Tao, Surat-Thani Province, Thailand, in April 2002. The freeze-dried sponge (279 g) was crushed and extracted consecutively and exhaustively with hexane, CH_2Cl_2, and MeOH. The hexane extract, which showed strong antimalarial activity (IC_{50} 0.05 μg/mL), was subjected to a chromatographic separation to yield **1** (101 mg) after repeated crystallization in hexane. Two other major active fractions pooled from the first chromatographic step were also selected for further separation. The less polar fraction of the two (IC_{50} 0.27 μg/mL) was chromatographed to yield **2**, **3**, and **4** (4, 7, and 6 mg, respectively). Successive chromatography of another main active fraction (IC_{50} 0.45 μg/mL) led to the isolation of **5** and **6** (3 and 4 mg, respectively).

The identification of the isolated compounds was carried out by means of spectroscopic analysis and data comparison with published reports. Compounds **1**, **2**, and **3** were identified to be the known isonitrile diterpenes: 8,15-diisocyano-11(20)-amphilectene, 7-isocyanoamphilecta-11(20),15-diene, and 8-isocyanoamphilecta-11(20),14-diene.[4g,5d,5e] The structures of **5** and **6**, elucidated in the same manner as discussed above, were identified as two known steroidal peroxides: ergosterol peroxide and 5α,9α-epidioxy-8α,14α-epoxy-(22*E*)-ergosta-6,22-dien-3β-ol.[7]



Compound **4**, which was obtained from the same chromatographic step as for **2** and **3**, possesses a molecular formula of $C_{21}H_{31}N$, according to the pseudomolecular ion peak $[M + Na]^+$ at *m/z* 320.2338 in the HR-ESI mass spectrum (calcd. for $C_{21}H_{31}NNa$ 320.2348). The proposed molecular formula yields an unsaturation degree of 7, belonging to two olefinic and one isonitrile functional groups, and three ring systems.

The presence of the isonitrile functionality in **4** was easily recognized from the characteristic IR absorption band at 2150 cm^{-1} and from two triplets (from ^{13}C–^{14}N coupling) carbon resonances at δ 159.9 ($^1J_{CN}$ = 4.2 Hz; C-21) and 66.6 ($^1J_{CN}$ = 4.2 Hz; C-8). The ^1H and ^{13}C NMR spectra (Table 1, 500 MHz for ^1H, C_6D_6) of **4** also showed downfield resonances of two methylidene moieties at δ_H 4.66 (d, *J* = 1.1 Hz; H-20pro-*Z*), 4.77 (br s, 2H; overlapping H-16pro-*Z* and H-20pro-*E*), and 4.85 (br s; H-16pro-*E*), and at δ_C 105.8 (C-20), 111.5 (C-16), 144.2 (C-15), and 150.1 (C-11). The remaining signals in the ^1H NMR spectrum of **4** were found clustered in the highfield region, and the elucidation of all the signals relied heavily on the analysis of the ^1H–^1H COSY spectrum, which led to the proposed amphilectane skeleton of **4** (Fig. 1). The connection of the quaternary carbons via the HMBC correlations (Fig. 1), especially from C-8 to H-9 (δ 1.90 and 0.86), H-12 (δ 1.93, br t, *J* = 11.0 Hz), H-13 (δ 0.64, tt, *J* = 11.0, 3.2 Hz), and H-19 (δ 0.82, br s, 3H); from C-11 to H-10 (δ 2.34, td, *J* = 13.1, 4.4 Hz; and 2.00, ddd, *J* = 13.0, 4.3, 2.3 Hz), H-12, and H-20; and from C-15 to H-1 (δ 1.67), H-16, and H-17 (δ 1.66, s, 3H), confirmed the proposed structure of **4** as a new amphilectane-type isonitrile diterpene, 8-isocyanoamphilecta-11(20),15-diene.

The relative configuration of **4** was determined on the basis of nOe-ds experiments and on that of coupling constant analysis. Six methine protons, i.e., H-1, H-3, H-4, H-7, H-12, and H-13, adopt the axial orientation according to their ^1H–^1H coupling constants (Table 1, 500 MHz, $CDCl_3$). Based on the dipolar couplings among H-1, H-3, H-7, and H-13, and between H-4 and H-12, the first four protons reside on the same plane (i.e., β plane) whereas the latter two reside on the other (i.e., α plane). The close similarity of the ^1H chemical shifts and coupling constants among **1, 3** and **4**, both from the published data[4g,5d,5e] and from our observa-

4

tions, indicated that the three compounds held the same relative configurations at all chiral centers. Regarding the absolute stereochemistry, the close observation suggested that for the 8-axial isonitrile amphilectane-type diterpenes with all *trans* ring junctions and with no endocyclic olefinic functionality (i.e., as of **1**, **3**, and **4**), an analog with 8*S* configuration generally corresponds with a levorotatory optical rotation.[4g,5d,5e] The configurations of all seven asymmetric carbons of **4** are therefore arbitrarily proposed here to be identical to those of **3** as the following: 1*S*, 3*S*, 4*R*, 7*S*, 8*S*, 12*S*, and 13*S*.

During the course of the NMR spectral analysis of **1**, **2**, and **4**, we noticed unconventional multiplicities in their ^{1}H NMR spectra. In spite of the fact that all spectral data of each isonitrile strongly indicated the substitutions of the methyl-18 on the secondary carbon C-3 (for **1**, **2**, and **4**) and of methyl-19 on C-7 (for **1** and **4**), the NMR signals of both methyls obtained from C_6D_6 did not resolve into the conventional doublets. Instead, singlet resonances were observed for H-18 for all three isonitriles and for H-19 of **4** (Table 1). The typical doublet methyl resonances resumed when $CDCl_3$ was used as an operating NMR solvent. For instance, H-18 and H-19 of **4** (Table 1, 500 MHz, $CDCl_3$) resonated as doublets at δ 0.86 (J = 6.1 Hz) and 0.96 (J = 6.4 Hz), respectively. It is noteworthy to mention that H-19 of **1**, on the other hand, resonates as a theoretical doublet in C_6D_6 (J = 6.4 Hz).

It can be argued that such unresolved multiplicity had resulted either from the operating concentrations or from intrinsic factors of the spectrometer itself (for example, the homogeneity in the magnetic field). However, similar phenomena were also observable when the re-dissolved samples in C_6D_6 were re-analyzed on other NMR spectrometers (Bruker 300 and 500 MHz spectrometers, data not shown). It could also be argued that such singlets were in fact parts of second-order spectra caused by the strong coupling between each methyl and its vicinal proton (e.g., for **4**, esti-

[a]No inhibition was observed or cell viability was higher than 80% at the highest concentration of 5 μg/mL.

[b]The IC_{50} could not be calculated because of inconsistent statistical results.

mated $\Delta\nu/J$ between H-3 and H-18 ca. 2.5; between H-7 and H-19 ca. 2.0; 500 MHz, C_6D_6); nevertheless, this argument was not applicable to the singlet signals of methyl-18 of **1** and **2** (estimated $\Delta\nu/J$ between H-3 and H-18 of **1** ca. 23; of **2** ca. 25; 500 MHz, C_6D_6). The solvent effects on the NMR chemical shifts are widely acknowledged. Also, the effect of the concentration upon the proton chemical shifts of the methyl groups on steroid nucleus when operated in C_6D_6 were reported.[8] Nonetheless, to our knowledge, such unresolved multiplicity and coupling constants due to the changes in operating solvents have never been documented. At the moment, we are yet unable to account for such abnormalities, although it could be speculated that the stacking interaction between the molecules of each sample and C_6D_6, facilitated by the rigid and planar amphilectane skeleton, might exert its role to a certain extent. To make a generalized statement on this solvent effect, however, a larger compound dataset with a wider variety of operating solvents, structural features, and field strengths, is required. This extensive investigation is currently underway.

All the isolated compounds were subjected to biological activity determination, namely antimalarial activity against *P. falciparum* K1 and cytotoxicity against MCF-7 and fibroblasts, respectively, representing cancer and normal cell lines (Table 2). Except **2**, which was previously reported to be active against *P. falciparum* D2 and W2 (IC_{50} 1.7 and 0.8 μmol/L, respectively)[9], the antimalarial activity of all the isolated compounds is reported here for the first time. With the IC_{50} values in a range of 0.04–1.07 μmol/L (Table 2), albeit 10–100 times less active than the standards artemisinin and dihydroartemisinin, the antimalarial activity of **1–4** is nonetheless considerably strong. The range of the antimalarial activity of the isolated isonitriles was also in a range similar to that of other related isonitriles and isothiocyanates, whose IC_{50} values were reported to be in a range of 0.01–10 μmol/L.[9,10] In addition, the dramatic contrast between the antimalarial and cytotoxic activities (against both cancer and normal cell lines) suggested their potential as promising leads for the development of new class of antimalarial agents.

The steroidal peroxides **5** and **6**, on the other hand, although less active as antimalarial agents, were rather interesting as cytotoxic agents. Their strong cytotoxicity against the MCF-7 cancer cell line and undetectable toxicity against human fibroblasts are also reported here for the first time. Such selectivity suggests their possible applications in anticancer drug development programs in the future.

Conclusion

A new amphilectane-type isonitrile diterpene, 8-isocyanoamphilecta-11(20),15-diene (**4**), along with its three known isonitrile analogs and two known steroidal peroxides, were isolated from the Thai sponge *Ciocalapata* sp. The antimalarial and cytotoxic activities of all the isolated compounds were assessed to show strong activities with promising selectivity for two bioassays. Regarding the possible targets and mechanisms of actions, especially for the diterpenes, it has been long known that the isonitrile functionality can bind specifically to Fe(III) in heme, and that such binding causes conformation distortions in the heme molecule.[11] The influence of complex formation between isonitrile terpenoids and Fe(III) in protoporphyrin on the inhibition of heme detoxification in *Plasmodium* parasites based on the modeled pseudoreceptor of isonitriles has also been reported.[6] Our findings therefore support previous postulations and extend the possibility of the isonitrile terpenoids as a potential source of future antimalarial agents. In addition, the selective cytotoxicity of the steroidal peroxides **5** and **6** suggests that these may be of use in anticancer drug development programs.

Experimental

General

Specific rotations were recorded on a PerkinElmer 341 polarimeter. IR spectra were obtained using a Jasco IR-810 infrared spectrometer. UV spectra were measured on a Hewlett Peckard 8452 diode array spectrophotometer. Mass spectra, both low- and high-resolution ones, were obtained on an MAT 95 XL mass spectrometer. All NMR experiments were performed on an FT-NMR Varian Unity Inova 500 spectrometer (500 MHz for ^1H), referencing solvent signals as stated accordingly. For the chromatographic separation, the chromatographic supporting materials were Scharlau SiO_2 (230–400 mesh) for flash chromatography and GE Health-

care Sephadex LH-20 for size exclusion chromatography. HPLC separations were performed on a Water 600E multisolvent delivery system, equipped with a Water 484 UV tunable detector and a Rheodyne 7125 injector port.

Animal material

The sponge *Ciocalapata* sp. (family Halichondriidae)[12] was collected in April 2002, at a depth of 15–20 m in the vicinity of Koh-Tao, Surat-Thani Province, Thailand (10° 7.569′ N, 99° 48.665′ E). Upon surfacing, the specimen appeared as a lumpy mass with porous texture and rough external surface. The outer color was pale khaki with dark brown to green spots. Taxonomic identification was carried out by one of us (SB),[12] and a voucher specimen (PMBC24607) was deposited at Phuket Marine Biological Center, Phuket, Thailand.

Extraction and isolation

The freeze-dried sponge (279 g) was consecutively and exhaustively macerated in a series of solvents to yield hexane, CH_2Cl_2, and MeOH extracts (7, 6, and 63 g, respectively). In this report, only the hexane extract, which showed the most potent antimalarial activity (IC_{50} 0.05 μg/mL), was studied further. The chemical investigations of the less active CH_2Cl_2 and MeOH extracts, which are now underway, will be reported elsewhere. The hexane extract was subjected to a SiO_2 vacuum chromatography (stepped gradient from hexane to MeOH/CH_2Cl_2 1:1). The fractions containing the major constituent were combined and recrystallized repeatedly in hexane to yield **1** as white needles (101 mg, 1.4% of hexane extract). Two additional major fractions from subsequent fractional pools were also selected for the separation based on their potent antimalarial activity. The first fraction was subjected to the following chromatographies: SiO_2 flash chromatography (EtOAc/hexane 1:49), then C-18 reverse-phase HPLC (Phenomenex 250 × 10 mm, 10 μm particle size; H_2O/MeCN 1:9, 4.5 mL/min), and **2**, **3**, and **4** (4, 7, and 6 mg; 0.06%, 0.1%, and 0.09% of hexane extract, respectively) were obtained (t_Rs 20.8, 22.6, and 24.0 min, respectively). The second fraction was subjected to the following: Sephadex LH-20 chromatography (EtOAc/hexane 1:1), SiO_2 flash chromatographies (EtOAc/hexane 1:1 and THF/EtOAc/hexane 9:18:73), and C-18 reverse-phase HPLC (Phenomenex 250 × 10 mm, 10 μm particle size; H_2O/MeCN 1:19, 3 mL/min), and **5** and **6** (3 and 4 mg; 0.04% and 0.06% of hexane extract, respectively) were obtained (t_Rs 21.1 and 33.8 min, respectively).

Antimalarial activity determination

The antimalarial bioassay was serviced by BIOTEC Central Research Unit, BIOTEC, Thailand, according to the microculture radioisotope technique.[13] The targeted parasite was *P. falciparum* K1 (chloroquine- and pyrimethamine-resistant strain), and the potency was assessed using artemisinin and dihydroartemisinin as standard reference drugs.

Cytoxicity determination

The cytotoxicity bioassay was performed in-house using the sulforhodamine B assay protocol.[14] The targeted cell lines were MCF-7 breast adenocarcinoma and human oral fibroblasts, representing cancer and normal cell lines, respectively. The cytotoxicity was assessed using camptothecin as a standard reference.

Controlling the regioselectivity of the di-π-methane rearrangements of 1,2-naphtho-annelated barrelene derivatives — Solution versus solid-state photochemistry

Jia Luo, Heiko Ihmels, Hans-Jörg Deiseroth, and Marc Schlosser

Abstract: The synthesis of 1,2-naphtho-annelated barrelene derivatives, namely dimethyl-7,12-dihydro-7,12-ethenobenzo[*a*]anthracene-13,14-dicarboxylate (**4a**) and dimethyl-7,14-dihydro-7,14-ethenodibenzo[*a,j*]-anthracene-15,16-dicarboxylate (**4b**), and the investigation of their photoreactivity in solution and in the solid state is reported. The irradiation of **4a** and **4b** resulted in regioselective di-π-methane rearrangements to give semibullvalene products; however, the product distribution is inverted upon changing the reaction medium from solution to the solid state. In solution, an α-naphtho–vinyl bridging predominates as the initial photochemical step because of the selective stabilization of the corresponding transition state, as discussed on the basis of the structures of the related biradical intermediates, whereas the solid-state photoreaction is significantly influenced by the steric constraints within the crystal lattice that only allow a β-naphtho–vinyl bridging.

Key words: di-π-methane rearrangement, barrelene derivatives, solid-state photochemistry.

Résumé : On a réalisé la synthèse de dérivés condensés 1,2-naphtobarrèlènes, à savoir le 7,12-dihydro-7,12-éthénobenzo[*a*]anthracène-13,14-dicarboxylate de diméthyle (**4a**) et le 7,14-dihydro-7,14-éthénobenzo[*a,j*]anthracène-15,16-dicarboxylate de diméthyle (**4b**), et on a étudié leur photoréactivité en solution et à l'état solide. L'irradiation des composés **4a** et **4b** conduit à des réarrangements di-π-méthane régiosélectifs et à la formation de produits semibullvalènes; toutefois, la distribution des produits est inversée lorsque le milieu réactionnel passe de la solution à l'état solide. En solution, un pont α-naphtovinyle prédomine comme étape photochimique initiale en raison de la stabilisation sélective de l'état de transition correspondant, tel que discuté sur la base des structures des intermédiaires biradicalaires apparentés, alors que la photoréaction à l'état solide est fortement influencée par des contraintes stériques dans le réseau cristallin qui ne permettent que la formation d'un pont β-naphtovinyle.

Mots-clés : réarrangement di-π-méthane, dérivés du barrèlène, photochimie à l'état solide.

Introduction

The di-π-methane rearrangement[1] of benzo-annelated derivatives of barrelene (bicyclo[2.2.2]octatriene)[2] and norbornadiene (bicyclo[2.2.1]heptadiene)[3] has been shown to be an appropriate model reaction for the assessment of the substituent effects on the selectivity of organic photoreactions. In particular, the structural features that govern the type-selectivity, the regioselectivity, and the stereoselectivity of dibenzobarrelene photoreactions in solution[1c–1f] and in constrained media have been evaluated in detail.[4] Thus, in a pivotal paper,[2a] Zimmerman et al. have shown that the irradiation of dibenzobarrelene **1a** leads to the selective formation of the dibenzosemibullvalene **2a** (Scheme 1), and this remarkable regioselectivity has been rationalized in terms of the selective stabilization of one of the four possible biradicals by the electron-accepting substituent on the benzene ring. In addition, it has been shown that the nature and the position of the substituents at the benzene rings of dibenzobarrelene derivatives **1b**–**1f** have a strong influence on the regioselectivity of the di-π-methane rearrangement (Scheme 1).[2b,2c] Notably, both donor and acceptor substituents were shown to influence the regioselectivity of the photorearrangement of dibenzobarrelenes. At the same time, there are only a few studies with a focus on the influence of an annelated naphthalene unit on the regioselectivity of the di-π-methane rearrangement of barrelene derivatives.[5] In particular, the competition between vinyl–naphtho and vinyl–vinyl bridging in the initial step of the di-π-methane rearrangement of naphthobarrelenes was examined, and the following order of reactivity was deduced: α-naphtho–vinyl > vinyl–vinyl > β-naphtho–vinyl > benzo-vinyl. Nevertheless, no studies have been reported on the direct competition between photoinduced benzo–vinyl and α-naphtho–vinyl bridging in annelated barrelene derivatives. To fill this gap, we synthesized the naphtho-annelated

barrelene derivatives **4a** and **4b** and investigated their photochemical behavior. Herein, we show that the photoinduced di-π-methane rearrangements of these compounds proceed with high regioselectivity in solution and in the solid state, notably with inverse selectivities.

Results

Synthesis

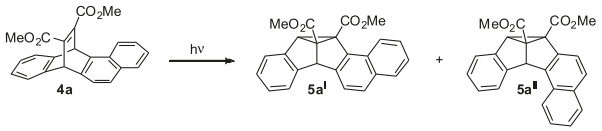
The benzonaphthobarrelene **4a** was obtained in 68% yield by a Diels–Alder reaction of dimethyl acetylenedicarboxylate (DMAD) with benzo[*a*]anthracene (**3a**) (Scheme 2).[6] For the analogous synthesis of dinaphthobarrelene derivatives **4b** and **4c**, a mixture of the two isomeric dibenzoanthracene derivatives **3b** and **3c** was employed. The latter were obtained from the reaction of 1-bromonaphthalene with *N*-lithio-2,2,6,6-tetramethylpiperidine in THF in a ratio of 72:28, as determined by ^{1}H NMR spectroscopic analysis.[7] Since the dibenzoanthracene derivatives are air and light sensitive, the product mixture was immediately made to react with DMAD to give the dinaphthobarrelenes **4b** and **4c** in 30% overall yield in a ratio of 71:29 (Scheme 2). Attempts to separate the two isomers **4b** and **4c** by column chromatography failed; however, the dinaphthobarrelene **4b** was isolated by crystallization in 6% yield. At the same time, we observed a strong tendency of the two isomers **4b** and **4c** to co-crystallize in a 1:1 ratio.

It should be noted that all chiral products are formed without enantioselectivity. Thus, all presented chiral compounds are actually racemic mixtures.

Photoreactions

In acetone solution, the naphthobenzobarrelene **4a** (long-wavelength absorption: $\lambda_{abs,max}$ = 292 nm) underwent an essentially clean di-π-methane rearrangement upon irradiation (λ_{ex} > 254 nm) to give the two semibullvalene derivatives **5a^{I}** and **5a^{II}** in a 87:13 ratio, as determined by ^{1}H NMR spectroscopic analysis (Scheme 3). Although it was impossible to separate the two semibullvalenes **5a^{I}** and **5a^{II}** by

Scheme 3. Photoreaction of benzonaphthobarrelene **4a**.



column chromatography, the major photoproduct **5a^{I}** was isolated in 61% yield by crystallization directly from the reaction mixture. The preferential formation of the photoproduct **5a^{I}** in solution was also observed in MeCN and benzene solution, however, with slightly lower selectivity (Table 1). Thus, as commonly observed for free-radical reactions, there is no pronounced solvent effect on the selectivity.[8] Moreover in all employed solvents, the product distribution did not change with varying irradiation wavelength, i.e., from λ > 254 nm (quartz glass) to λ > 310 nm (Pyrex glass). Nevertheless in MeCN and benzene, the reactions were significantly slower when the light was filtered through Pyrex glass, most likely because the Pyrex glass cuts off a significant area of the chromophore absorption.

The irradiation of crystalline samples of benzonaphthobarrelene **4a** resulted in the formation of the same two semibullvalenes **5a^{I}** and **5a^{II}**, but the selectivity was reversed compared with the photoreaction in solution, i.e., the semibullvalene **5a^{II}** was formed predominantly upon solid-state photolysis (Table 1). The direct irradiation of crystals of barrelene **4a**, obtained by crystallization from methanol, gave the photoproducts **5a^{I}** and **5a^{II}** in 22:78 ratio at 10% conversion. The conversion was improved to 41% with only a slight decrease of selectivity (25:75) by the irradiation of ground crystals, which were placed between quartz slides, i.e., by increasing the surface area exposed to the UV light. Prolonged irradiation times did not increase the conversion further, probably because of an inner-filter effect that protects the inside of the solid sample towards the light. On the other hand, the selectivity was improved to 16:84 by using ground *single crystals* of **4a**.

The low conversion and small scale of the solid-state photoreactions often limits their potential application in synthetic organic chemistry;[7] however, this drawback may be overcome by the performance of the photoreaction with a suspension of the finely ground substrate in a solvent in which it is insoluble.[9] To test this approach, thoroughly stirred suspensions of the benzonaphthobarrelene **4a** in hexane or water were irradiated. Thus, on the scale of 60.0 mg (0.16 mmol) of compound **4a**, the photoreaction in hexane resulted in 90% conversion with a ratio of 33:67 between the semibullvalenes **5a^{I}** and **5a^{II}**. In water suspension, the irradiation proceeded with lower conversion of 67%, but the selectivity was much better (**5a^{I}**:**5a^{II}** = 14:86). From each reaction mixture, the semibullvalene **5a^{II}** was isolated in yields as high as 37% as colorless cubes, by crystallization of the photolysate.

The product structures were identified on the basis of ^{1}H and ^{13}C NMR spectroscopy and elemental analysis. The annelated semibullvalene structure in compounds **5a^{I}** and **5a^{II}** was indicated by the characteristic shifts of the cyclopropane methine protons (**5a^{I}**: δ 5.21 ppm; **5a^{II}**: δ 5.59 ppm) and the proton in the benzylic position (δ 4.64 ppm for both **5a^{I}** and **5a^{II}**). In particular, the unambiguous structure assignment of

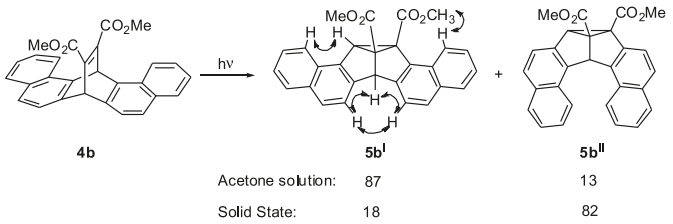
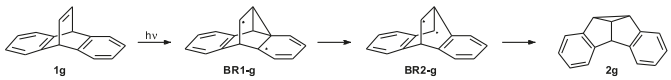
the two isomers **5a^{I}** and **5a^{II}** was made by NOESY NMR experiments (Fig. 1). In both cases, the substitution pattern of the cyclopropane ring, i.e., the position of the ester groups, was indicated by the NOE between the methine proton of the cyclopropane and the *ortho*-proton of the annelated benzene part (arrow a and a′). The assignment of the benzene protons was confirmed by additional NOE data, in particular by the NOE between the benzylic proton and the benzene and naphthalene protons (arrows c,d and b′–d′) . Moreover, the orientation of the naphthalene unit in compounds **5a^{I}** and **5a^{II}** was determined by the NOE between the protons of the methyl substituent and the aromatic proton (8′-H) of the naphthalene part in isomer **5a^{I}** (arrow b).

The photoreactivity of dinaphthobarrelene **4b** resembles the one of barrelene derivative **4a** (Scheme 4). In acetone solution, the irradiation of **4b** led to a mixture of semibullvalenes **5b^{I}** and **5b^{II}** in a ratio of 87:13, whereas the regioselectivity is reversed to 18:82 upon irradiation in the solid state. The product **5b^{I}** was obtained by crystallization in 55% yield and fully characterized by ^{1}H and ^{13}C NMR spectroscopy and elemental analysis. Additional NOESY NMR experiments confirmed the structure of the semibullvalene derivative **5b^{I}** by characteristic NOE signals between an 8′-H proton of naphthalene and the cyclopropane methine proton, as well as between the benzyl proton and the 8′-H proton of naphthalene (Scheme 4). The isomer **5b^{II}** could not be isolated, but its structure was identified by NMR spectroscopic analysis directly from the product mixture.

Scheme 4. Photoinduced di-π-methane rearrangement of dinaphthbarrelene **4b** (arrows indicate NOEs between the corresponding protons).



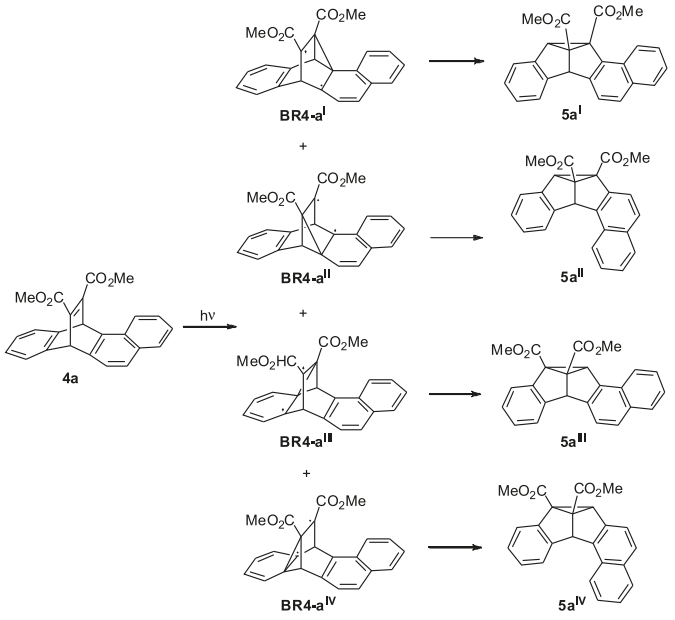
Scheme 5. Reaction mechanism of the di-π-methane rearrangement of dibenzobarrlene (**1g**).



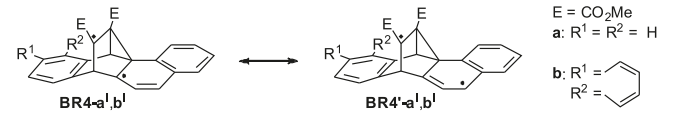
Discussion

The photoinduced di-π-methane rearrangement of annelated barrelenes, e.g., the parent dibenzobarrelene **2g**, is initiated by a carbon–carbon bond formation between the etheno unit and an *ipso* carbon of the annelated aromatic ring to form a 1,4-biradical intermediate **BR1-g** (Scheme 5), followed by rearomatization to afford the biradical **BR2-g**, and subsequent radical recombination to the semibullvalene **2g**.[1a,1d] Depending on the substitution pattern of the substrate, up to four different regioisomeric products may be formed, and it was demonstrated that the selectivity of the initial reaction step determines the selectivity of the overall reaction (Scheme 1).[1c] It should be noted, however, that the selectivity of a chemical reaction, in particular the di-π-methane rearrangement, is mainly governed by the different reaction rates, i.e., by the energies of the different transition states rather than the ones of the corresponding reaction intermediates. Nevertheless, it is assumed that factors that stabilize one particular 1,4-biradical intermediate also stabilize the preceding transition state and thus lead to the preferen-

Scheme 6. Reaction pathways of the di-π-methane rearrangement of barrelene derivative **4a**.



Scheme 7. Resonance stabilization in biradicals **BR4-a^{I}** and **BR4-b^{I}**.



tial formation of the corresponding semibullvalene isomer. According to these considerations, the regioselectivity observed in the photoreactions of the barrelene derivatives **4a** and **4b** may be discussed in terms of the relative stability of the possible biradical intermediates. Thus, during the di-π-methane rearrangemenent of the barrelene derivative **4a**, the four regioisomeric biradicals **BR4-a^{I}**–**BR4-a^{IV}** may be formed initially, which lead to the four isomeric benzonaphthosemibullvalenes **5a^{I}**–**5a^{IV}** (Scheme 6). Nevertheless, the products **5a^{III}** and **5a^{IV}** are not formed in detectable amounts, indicating that the intermediates **BR4-a^{III}** and **BR4-a^{IV}** are only generated to negligible extents. We propose that the high preference for the photoinduced vinyl–naphtho bridging is governed by the significantly higher stabilization of the intermediate radicals in the naphthalene unit, compared with the stabilization in the cyclohexadienyl radical part in **BR4-a^{III}** and **BR4-a^{IV}**. Moreover, the biradicals **BR4-a^{I}** and **BR4-a^{II}** still contain two intact benzene rings, whose resonance energy contributes more to the overall stabilization than the one of the single naphthalene ring in **BR4-a^{III}** and **BR4-a^{IV}**.[10]

It was demonstrated that the di-π-methane rearrangemenent of the unsubstituted 1,2-naphthobarrelene is introduced by a highly selective vinyl–naphtho bridging that takes place *exclusively* between a vinyl carbon atom and the C1 position (α position) of the naphthalene.[3] These observations have been explained by a higher extent of delocalization within the aromatic part of the corresponding 1,4-biradical. The same argument may be employed to rationalize the enhanced formation of the products **5a^{I}** and **5b^{I}** resulting from initial bridging to the C1 carbon upon irradiation of annelated barrelene derivatives **4a** and **4b**. In contrast to the intermediate **BR4-a^{II}**, the biradicals **BR4-a^{I}** and **BR4-b^{I}** exhibit two resonance structures with a complete benzene ring providing additional aromatic stabilization. Moreover, one of the resonance forms, indicated as **BR4′**, reveals a particular stabilization as the radical is located both in allylic and benzylic position (Scheme 7).

Notably, the solid-state photoreaction of the annelated barrelene derivatives **4a** and **4b** yields the semibullvalene derivative **5a^{II}** and **5b^{II}** as the main products. Apparently, the stereoelectronic factors that determine the regioselectivity of the di-π-methane rearrangement of **4a** and **4b** in solution are no longer effective in the solid state. Since it has been demonstrated that solid-state photoreactions often proceed on a reaction pathway that avoids steric interactions with neighboring molecules,[11] it may be assumed that inter- or intra-molecular steric factors determine the solid-state reactivity of **4a** and **4b** rather than electronic effects. To investigate this aspect, an X-ray diffraction analysis was performed with single crystals of compound **4a**. The benzonaphthobarrelene **4a** crystallizes in the monoclinic space group of $P2_1/c$ (a = 11.3159 Å, b = 11.8742 Å, c = 14.586 Å; β = 104.55°), with each unit cell containing two pairs of enantiomers of the barrelene molecules. Most notably, significant close contacts between two molecules were detected. The two different views of the molecular arrangement in the solid state given in Fig. 2 reveal that the benzene unit of one molecule (black in Fig. 2) is partially positioned between the vinyl unit and the naphthalene part of a neighboring molecule (Fig. 2, white, red, blue, respectively). In this arrangement, the closest contacts between the two molecules were identified between one carbonyl carbon atom of an ester group (Fig. 2, red) and an *ortho*-hydrogen atom of the benzene ring (Fig. 2*a*, C···H: 289 pm), and between the carbonyl oxygen atom of the same ester functionality and the bridgehead hydrogen atom (Fig. 2*a*, O···H: 262 pm). These distances correspond essentially to the sum of the van der Waals radii of the respective atoms (C···H: 290 pm, O···H: 272 pm)[12] and may thus result in significant intermolecular steric repulsion during the solid-state rearrangement of compound **4a**. In particular, the movement of one of the ester functionalities, namely the one at the C16 position (Fig. 2, red), in the course of a di-π-methane rearrangement appears to be significantly hindered. To achieve the vinyl–naphtho bridging to give **BR4-a^{I}**, this ester group needs to pass the proximate benzene unit of the neighboring molecule, and the close contacts described above clearly indicate that this pathway is essentially blocked. At the same time, the other ester group (Fig. 2, blue) is free to move as there are no significant contacts with the proximate molecule (>350 pm; not shown), so that an almost unhindered vinyl–naphtho bridging is possible in the solid state to afford biradical **BR4-a^{II}**. Notably, both vinyl–benzo bridging pathways leading to the semibullvalene products **5a^{III}** and **5a^{IV}** are not sterically hindered in the crystal. Thus, in the absence of steric constraints in the crystal, the solid-state photoreaction is determined by the same electronic factors as in isotropic solution.

Fig. 2. Structure of the benzonaphthobarrelene **4a** in the solid state (dashed lines indicate closest contacts between two neighboring molecules).

Summary and conclusion

In summary, we have shown that the di-π-methane rearrangement of 1,2-naphtho annelated barrelene derivatives **4a** and **4b** proceeds with high regioselectivity. Most notably, a drastic change of the selectivity was observed upon changing from isotropic solution to the solid state. Whereas in solution, the course of the reaction is mainly governed by the selective stabilization of the corresponding transition states, which lead to the primary biradical intermediates **BR4**, the solid-state photoreaction is significantly influenced by the steric constraints within the crystal lattice. To be stressed is the fact that in the case of **4a**, the major products from both reactions, i.e., in solution and in the solid state, could be isolated in reasonable yields. Considering the importance of the annelated semibullvalene derivatives as synthons in organic synthesis,[1f] the presented systems may be employed along these lines as a useful source for the selective synthesis of complex 1,2-naphtho-annelated polycyclic aromatic compounds.[1f]

Experimental section

General

NMR spectra: Bruker Avance 400 (^{1}H NMR: 400 MHz; ^{13}C NMR: 100 MHz) and a Varian NMR System 600 (^{1}H NMR: 600 MHz; ^{13}C NMR: 150 MHz). ^{1}H NMR chemical shifts refer to δ_{TMS} 0.0 ppm. ^{13}C NMR chemical shifts refer to solvent signals ($CDCl_3$: δ 77.0 ppm). Melting points: Büchi 510K apparatus (uncorrected). Mass spectra: Hewlett-Packard HP 5968 (EI, 70 eV). Elemental analyses: KEKA-tech EuroEA combustion analyzer by Mr. H. Bodenstedt, Organic Chemistry I, University of Siegen. Benzo[*a*]anthracene[5] and benzotetracenes[6] were prepared according to literature procedures. All the other reagents and solvents were obtained from Acros Organics and Sigma-Aldrich and used as received.

*Dimethyl-7,12-dihydro-7,12-ethenobenzo[**a**]anthracene-13,14-dicarboxylate (4a)*

Under nitrogen-gas atmosphere, a suspension of benzo[*a*]anthracene (5.89 g, 25.8 mmol), DMAD (9.18 mL, 75.0 mmol), and $AlCl_3$ (0.2 g) in xylene (15 mL) was heated at 140 °C for 5 days. The mixture was cooled to room temperature (RT) and diluted with ethyl acetate (100 mL). The organic phase was extracted with 2N aq. HCl (50 mL) and brine (50 mL), and subsequently separated, dried with Na_2SO_4. The solvent was removed in vacuo and the residue was purified by column chromatography (SiO_2; EtOAc/hexane = 1:2, *v*/*v*; R_f = 0.45) to give an orange oil, which was solidified upon treatment with methanol to give dimethyl-7,12-dihydro-7,12-ethenobenzo[*a*]anthracene-13,14-dicarboxylate (**4a**) as ^{1}H NMR spectroscopically pure light yellow granules (6.47 g, 17.5 mmol, 68%). An analytical sample was prepared by recrystallization from methanol as clusters of colorless prisms, mp 142–144 °C. UV ($CHCl_3$): λ_{max} (log ε) = 245 (4.40), 270 (3.85), 281 (3.90), 292 (3.92), 329 (3.27). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 3.79 (s, 3H, OCH_3), 3.80 (s, 3H, OCH_3), 5.64 (s, 1H, CH), 6.32 (s, 1H, CH), 6.98–7.01 (m, 2H, ar-CH), 7.39–7.47 (m, 3H, ar-CH), 7.53–7.61 (m, 3H, ar-CH), 7.81 (d, *J* = 8 Hz, ar-CH), 8.27 (d, *J* = 8 Hz, ar-CH). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 48.2 (CH_3), 52.4 (overlapped CH_3 and CH), 53.6 (CH), 122.0 (ar-CH), 122.5 (6,11-CH), 123.7 (ar-CH), 123.8 (ar-CH), 125.1 (ar-CH), 125.2 (two ar-CH overlapped), 125.6 (ar-CH), 126.4 (ar-CH), 128.7 (ar-CH), 129.0 (C_q), 131.7 (C_q), 141.2 (C_q), 142.6 (C_q), 144.0 (C_q), 144.8 (C_q), 146.8 (C_q), 149.0 (C_q), 165.8 (C=O), 166.2 (C=O). EI-MS (70 eV): 370 [M^+]. Elemental analysis calcd. (%) for $C_{24}H_{18}O_4$ (370.40): C 77.82, H 4.90; found C 77.62, H 4.86.

*Dimethyl-7,14-dihydro-7,14-ethenodibenzo[**a**,**j**]-anthracene-15,16-dicarboxylate (4b)*

Under argon protection, a mixture of dibenzo[*a,h*]- and dibenzo[*a,j*]anthracene (28:72, 690 mg, 2.48 mmol), DMAD (0.50 mL, 4.1 mmol), and $AlCl_3$ (20 mg) in xylene (15 mL) was heated at 140 °C for 5 days. After cooling RT, the mixture was diluted with EtOAc (70 mL). The organic phase was extracted with 2N aq. HCl (20 mL) and brine (50 mL), and subsequently separated, dried with Na_2SO_4. The solvent was removed in vacuo and the residue was purified by column chromatography (SiO_2; EtOAc/hexane = 1:4, *v*/*v*; R_f = 0.31) to give a mixture of the two dinaphthobarrelenes **4b** and **4c** (**4b**/**4c** 71:29, 312 mg, 0.74 mmol, 30%). Two-fold recrystallization from EtOAc/hexane gave pure **4b** as colorless needles (42 mg, 6%), mp 223–225 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 3.79 (s, 3H, CH_3), 3.82 (s, 3H, CH_3), 5.80 (s, 1H, CH), 7.23 (s, 1H, CH), 7.39 (d, *J* = 8 Hz, 2H, ar-CH), 7.55–7.59 (m, 4H, ar-CH), 7.65 (d, *J* = 8 Hz, 2H, ar-CH), 7.80 (d, *J* = 8 Hz, 2H, ar-CH). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 44.0 (CH), 52.5 (CH_3), 52.5 (CH_3), 54.8 (CH), 122.1 (ar-CH), 122.5 (ar-CH), 125.2 (ar-CH), 125.3 (ar-CH), 126.6 (ar-CH), 128.8 (ar-CH), 129.2 (C_q), 131.6 (C_q), 141.7 (C_q), 144.1 (C_q), 146.8 (C_q), 151.0 (C_q), 165.7 (C=O), 166.4 (C=O). MS (*m*/*z*): 420 [M^+]. Elemental analysis calcd. (%) for $C_{28}H_{20}O_4$ (420.46): C 79.98, H 4.79; found C 79.60, H 4.67.

Photoreactions

Irradiations were performed with a TQ150 middle-pressure mercury lamp (Heraeus, UV-Consulting Peschl), which was placed in a quartz cooling tube. The sample container was placed 10–15 cm in front of the lamp. The solution contained one molar equivalent of *m*-dimethyl isophthalate as internal standard for the quantitative ^{1}H NMR spectroscopic analysis of the photolysate.

Photolysis in solution

Solutions (10^{-3} to 10^{-2} mol/L) were placed in a 200 mL Pyrex tube (acetone) or a 50 mL quartz tube (other solvents) and purged with argon for at least 20 min. The stirred solution was irradiated for 6–13 h until the starting material was fully consumed as determined by ^{1}H NMR analysis. After evaporation of the solvent in vacuo, the photolysate was analyzed by ^{1}H NMR spectroscopy, or, in preparative experiments, recrystallized from EtOAc/hexane to obtain the major photoproduct.

Photolysis in crystalline state

15–25 μmol of the crystalline starting material were placed in an argon-purged and sealed quartz test tube and irradiated. Afterwards, the stock solution of *m*-dimethyl iso-

phthalate was added as internal standard, and the mixture was dissolved in dichloromethane. The solvent was removed and the mixture was analyzed by ^{1}H NMR analysis.

Alternatively, the crystalline solids were ground to powders and sandwiched between a pair of quartz slides, which were sealed in an argon-purged polyethylene bag and irradiated. The photolysate was dissolved in dichloromethane and the stock solution of *m*-dimethyl isophthalate was added as internal standard. After the removal of solvent, the mixture was analyzed by ^{1}H NMR analysis.

Photolysis in suspensions

In a 20 mL quartz tube, 0.05–0.16 mmol of starting material and 10 mL of hexane or water were added. The mixture was sonicated for 10 min to destroy the larger crystals and purged with argon for 20 min. After irradiation, dichloromethane was used to dissolve (hexane) or extract (water) the photolysate. After evaporation of the solvent in vacuo the product mixture was subjected to ^{1}H NMR spectroscopic analysis, or redissolved in acetone/methanol to crystallize the major photoproduct.

Dimethyl-4b,10b-dihydro-benzo[5,6]cyclopropa[3,4]pentaleno[1,2-a]naphthalene-4c,10d-dicarboxylate (5a^I)

Prepared by photoreaction in acetone solution. Yield 61%, colorless needles, mp 177–179 °C. UV ($CHCl_3$): λ_{max} (log ε) = 246 (4.44), 281 (3.73), 328 (2.97). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 3.76 (s, 3H, CH_3), 3.83 (s, 3H, CH_3), 4.64 (s, 1H, CH), 5.21 (s, 1H, CH), 7.00–7.08 (m, 2H, ar-CH), 7.17 (d, *J* = 7 Hz, 1H, ar-CH), 7.33–7.44 (m, 4H, ar-CH), 7.64–7.68 (m, 2H, ar-CH), 7.75 (d, *J* = 8 Hz, 1H, ar-CH). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 49.7 (CH_3), 52.4 (CH), 52.9 (CH), 55.5 (CH_3), 58.4 (C_q), 66.8 (C_q), 120.2 (ar-CH), 121.3 (ar-CH), 123.5 (ar-CH), 125.0 (ar-CH), 125.7 (ar-CH), 126.6 (ar-CH), 126.8 (ar-CH), 127.4 (ar-CH), 127.7 (C_q), 128.8 (ar-CH), 129.5 (ar-CH), 130.3 (C_q), 133.1 (C_q), 134.8 (C_q), 147.8 (C_q), 150.0 (C_q), 169.6 (C=O), 169.6 (C=O). MS (*m*/*z*): 370 [M$^+$]. Elemental analysis calcd. (%) for $C_{24}H_{18}O_4$ (370.40): C 77.82, H 4.90; found C 77.74, H 4.81.

Dimethyl-4b,10c-dihydro-benzo[5,6]cyclopropa[1,2-h]naphthalene-4c,10e-dicarboxylate (5a^{II})

Prepared by photoreaction in water suspension. Yield 37%, colorless cuboids, mp 173–175 °C. ^{1}H NMR (600 MHz, CD_3Cl) δ: 3.75 (s, 3H, CH_3), 3.91 (s, 3H, CH_3), 4.64 (s, 1H, CH), 5.59 (s, 1H, CH), 6.98–7.04 (m, 2H, ar-CH), 7.28 (d, *J* = 8 Hz, 1H, ar-CH), 7.34 (d, *J* = 8 Hz, 1H, ar-CH), 7.38 (d, *J* = 9 Hz, 1H, ar-CH), 7.34 (d, *J* = 8 Hz, 1H, ar-CH), 7.44 (dd, *J* = 7 Hz, 1H, ar-CH), 7.59 (dd, *J* = 7 Hz, 1H, ar-CH), 7.62 (d, *J* = 8 Hz, 1H, ar-CH), 7.62 (d, *J* = 8 Hz, 1H, ar-CH), 7.78 (d, *J* = 8 Hz, 1H, ar-CH), 8.14 (d, *J* = 8 Hz, 1H, ar-CH). ^{13}C NMR (150 MHz, CD_3Cl) δ: 50.1 (CH_3), 52.4 (CH), 52.9 (CH), 53.7 (CH_3), 67.8 (C_q), 68.7 (C_q), 121.4 (ar-CH), 123.3 (ar-CH), 123.7 (ar-CH), 125.7 (two overlapped ar-CH), 126.7 (ar-CH), 127.0 (ar-CH), 127.3 (ar-CH), 127.8 (ar-CH), 128.8 (ar-CH), 129.8 (C_q), 133.2 (C_q), 134.9 (C_q), 145.3 (C_q), 148.9 (C_q), 168.6 (C=O), 169.4 (C=O), one C_q signal is overlapped. MS (*m*/*z*): 370 [M$^+$]. Elemental analysis calcd. (%) for $C_{24}H_{18}O_4$ (370.40): C 77.82, H 4.90; found C 77.98, H 4.81.

Dimethyl-6d,12b-dihydro-cyclopropa[3,4]pentaleno-[1,2-a;6,5-c′]dinaphthalene-6c,12d-dicarboxylate (5b^I)

Prepared by photoreaction in acetone solution. Yield 55%, white granules, mp 217–218 °C. ^{1}H NMR (600 MHz, $CDCl_3$) δ: 3.78 (s, 3H, CH_3), 3.89 (s, 3H, CH_3), 5.13 (s, 1H, CH), 5.34 (s, 1H, CH), 7.30–7.38 (m, 4H, ar-CH), 7.41 (d, *J* = 8 Hz, 1H, ar-CH), 7.46 (dd, *J* = 7 Hz, 1H, ar-CH), 7.59 (d, *J* = 8 Hz, 1H, ar-CH), 7.64 (two overlapped doublet, *J* = 8 Hz, 2H, ar-CH), 7.68–7.71 (m, 2H, ar-CH), 8.10 (d, *J* = 8 Hz, 1H, ar-CH). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 48.5 (CH), 52.4 (CH_3), 53.0 (CH_3), 56.3 (CH_3), 58.8 (C_q), 67.4 (C_q), 120.0 (ar-CH), 120.1 (ar-CH), 123.5 (ar-CH), 124.3 (ar-CH), 125.0 (ar-CH), 125.3 (ar-CH), 126.6 (ar-CH), 126.6 (ar-CH), 127.5 (C_q), 128.3 (ar-CH), 128.4 (ar-CH), 128.8 (ar-CH), 129.4 (ar-CH), 129.8 (C_q), 130.5 (C_q), 130.7 (C_q), 132.5 (C_q), 133.1 (C_q), 146.9 (C_q), 148.0 (C_q), 169.6 (C=O), 169.7 (C=O). MS (*m*/*z*): 420 [M$^+$]. Elemental analysis calcd. (%) for $C_{28}H_{20}O_4$ (420.46): C 79.98, H 4.79; found C 79.47, H 4.71.

X-ray diffraction analysis of compound 4a

The conditions and parameters adopted for the determination of crystallographic data of compound **4a** are listed in Table 2.

Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 3912. For more information on obtaining material refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml. CCDC 720890 contains the crystallographic data for this manuscript. These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (Or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

Acknowledgement

This paper is dedicated to Trevor Linden on the occasion of his retirement and in appreciation of his exemplary behavior on and off the ice. We thank Dr. Thomas Paululat for carrying out the NOESY experiments and for helpful discussions on spectra analysis.

Abstract: A novel biomimetic DNA analogue with fluorescence has been synthesized to generate functional supramolecular architectures. Experimental studies show that triaminopyrimidine nucleoside (**2**) undergoes a sterically controlled self-assembly into hydrogen-bonded linear tapes and hexameric rosettes. Self-association of the hydrogen-bonded triaminopyrimidine–cyanuric acid complex into elongated, rodlike nanostructures was shown by dynamic light scattering and transmission electron microscopy, suggesting hierarchical formation of higher-order, π-stacked assemblies. The hydrogen-bond self-assembly of the DNA analogue decreased the fluorescence of the nucleosides. This guest-induced fluorescence quenching can be used to develop DNA-hybridization probes. MM^+ molecular modelling and semi-empirical molecular orbital PM3 calculations (**1**) predicted the incorporation of triaminopyrimidine nucleoside into new types of artificial DNA strands and triplex formation with natural, complementary DNA strands containing thymine (**1**).

Key words: hydrogen bond, self-assembly, DNA analogues.

Résumé : Dans le but de générer des architectures supramoléculaires fonctionnelles, on a synthétiser un nouvel analogue biomimétique de l'ARN fluorescent. Les études expérimentales montrent que le nucléoside de la triaminopyrimidine (**2**) donne lieu à un autoassemblage sous contrôle cinétique qui conduit à des bandes linéaires ou des rosettes hexamères reliées par liaisons hydrogènes. Faisant appel à la diffusion dynamique de la lumière et à la microscopie électronique de transmission, on a pu démontrer que l'autoassociation du complexe triaminopyrimidine–acide cyanurique par des liaisons hydrogènes conduit à des nanostructures allongées, en forme de baguettes, suggérant qu'il y a une formation hiérarchique d'un ordre élevé d'assemblages par empilement π. L'autoassemblage par liaisons hydrogènes de l'analogue de l'ADN diminue la fluorescence des nucléosides. Cette extinction de la fluorescence induite par l'hôte pourrait être utilisée pour développer des sondes d'hybridation de l'ADN. Des calculs de modelage moléculaire, MM+, et des calculs d'orbitales moléculaires semi-empiriques, PM3 (**1**), permettent de prédire qu'il y aura incorporation du nucléoside de la triaminopyrimidine dans les nouveaux types de brins artificiels d'ADN et formation de triplex des brins naturels complémentaires d'ADN contenant de la thymine (**1**).

Mots-clés : liaison hydrogène, autoassemblage, analogues de l'ADN.

[Traduit par la Rédaction]

Introduction

Hierarchical assembly of low molecular weight building blocks has generated functional supramolecular architectures with high predictability.[1] Molecularly self-assembled photoresponsive systems were constructed by combining strong, directional, hydrogen bonds or metal coordination, with weak isotropic, intramolecular π-stacking and van der Waals interactions. These supramolecular structures have been investigated theoretically[1] and now experimentally, stressing the use of light-induced isomerization on self-organization. Theory[1] and the present experiments were intimately connected to characterize the hierarchical assemblies and improve the binding selectivity and strength. Theoretical calculations[1] predicted the noncovalently bound oligomeric geometries and thermodynamic properties for the experimentally designed and synthesized monomeric species.

To identify these monomers and their self-assembly behaviour, which were found to agree with theoretical predictions, it was essential to combine molecular and bulk characterization techniques. These theoretical methods were consequently extended to novel biologically interesting systems based on deoxyribonucleoside DNA analogues.

Engineering materials with controlled physical and chemical properties at the nanoscale have proved attractive to researchers. Supramolecular chemistry is a powerful method to achieve this goal because of its ability to efficiently generate well-defined, functional architectures.[2] In particular, hydrogen-bond self-assembly has successfully exploited the specificity of Watson–Crick pairing between complementary DNA bases to create cages,[2] helical,[3] linear,[4] and macro-cyclic structures[5,6] with controlled functionality from DNA building blocks.

Incorporating novel nucleosides in DNA[7] gave new artificial hydrogen-bonded,[7a–7e] π-stacked,[7] or metal-coordinated[7] DNA base pairs, which were enzymatically replicated to perform biological tasks. DNA[8,9] forms higher-order aggre-

gates in vitro by hydrogen bonding. Among these DNA aggregates, triple helices[10] and G-quadruplexes,[11] are interesting because of their well-defined morphologies, biological properties, and therapeutic applications.[12,13] A DNA *iso*-guanosine pentaplex has been generated using metal-assisted hydrogen bonding.[14]

Procedure

The design and self-assembly of artificial nucleosides to create new DNA motifs, and to expand the repertoire of DNA assemblies, from pentaplexes to hexameric architectures, is reported.

This approach integrates knowledge from chemical biology with organo-supramolecular chemistry. The newly synthesized DNA-base analogues are used to generate new hydrogen-bonded supramolecular structures. The synthesis and characterization of a DNA-base analogue (**2**) (Fig. 1), which undergoes hydrogen-bond self-assembly with natural and artificial DNA bases and with small molecules, is described theoretically and experimentally by its hydrogen-bonding and π-stacking: self-assembly of (**2**) by hydrogen-bonding and π-stacking leads to rodlike nanostructures.

DNA-base analogue (**2**) is a triaminopyrimidine base attached to a 3′,5′-disiloxane protected ribofuranose (Fig. 1), providing two donor–acceptor–donor (DAD) type hydrogen-bonding sites. The spatial orientation of these hydrogen-bonding groups is similar to the relative position of the carboxylic acid groups in isophthalic acid; therefore, a 120° angle is expected between the DAD faces. Nucleoside (**2**) can thus be associated with two complementary thymine residues to form DNA-based triple helices and with barbituric acid derivatives like (**1**) and cyanuric acid derivatives like (**3**) to give linear tapes or hexameric rosettes (Fig. 1 and Scheme 1).

Results and discussion

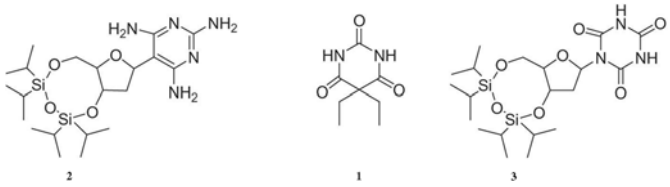
Synthesis of DNA-base analogues (2) and (3)

Synthesis of triaminopyrimidine DNA-base analogue (2)

Several approaches were considered to synthesize triaminopyrimidine DNA-base analogue (**2**). The first synthetic route involved coupling of tosyl-activated 2-deoxy-D-ribose (**6**) with the lithiated *t*-BOC-protected 1,3,5-triaminopyrimidine, generated through transmetallation of the brominated triaminopyrimidine (**7**) using *n*-BuLi (Scheme 2). However, instead of producing the desired protected nucleoside (**8**), this method lead to a mixture of *t*-BOC-protected 1,3,5-triaminopyrimidine and 3′,5′-protected sugar (**5**), suggesting unfavourable steric hindrance between the disiloxane and *t*-butoxycarbonyl protecting group, or amine deprotonation before halogen–metal exchange.

A second synthetic method used two main coupling steps (Scheme 3). First, the tosylated sugar (**6**) was allowed to undergo nucleophilic attack of malononitril, under basic conditions, to give the dicyano derivative, which was then reacted with guanidine to obtain the desired triaminopyrimidine (**2**). Although the first coupling reaction successfully led to malonate (**9**), the isolated yield was disappointingly low (<10%). Mass spectrometry analysis of the reaction products revealed formation of dimeric species and deprotected sugar derivatives, suggesting the instability of tosylated sugar to basic reaction conditions, possibly because of the labile tosyl leaving group or because of a base-sensitivty of the protecting group.

Fig. 1. Diethylbarbituric acid (**1**), triaminopyridine (**2**), and cyanuric acid nucleosides (**3**).



Direct reaction of malononitrile with the 3′,5′-protected sugar under similar conditions (Scheme 4),[15,16] through nucleophilic attack of the *keto* form of the 2-deoxyribofuranose derivative (**10**), improved the coupling yield, allowing synthesis of (**2**) with neutralized guanidinium hydrochloride. Reduction of the basicity of the reaction mixture, by decreasing the NaH/malononitrile ratio, or even by using catalytic amounts of K_2CO_3, resulted in isomer (**11**), as detected by mass spectrometry and ^{1}H NMR (Scheme 4). ^{1}H NMR spectroscopy suggested the presence of both α- and β-anomeric sugars in solutions of the triaminopyrimidine nucleoside (**2**), which was used in the same way as in the self-assembly studies.

A third approach used the palladium-mediated cross-coupling reaction[17] of 3′,5′-diprotected ribofuranoid glycal (**12**) with iodinated benzoyl-protected triaminopyrimidine to improve the overall yield (Scheme 5). Preliminary synthetic attempts at the first elimination step gave the glycal in low yields (ca. 10%).

Synthesis of cyanuric acid DNA-base analogue (3)

Scheme 6 outlines the synthesis of DNA-base analogue (**3**), derived from a previously published procedure where a toluyl-protected 2-deoxyribofuranosylchloride is used as a starting material.[18] The tosyl derivative of the 3′,5′-disiloxane protected sugar was formed and coupled with in situ protected cyanuric acid, under basic conditions, to yield the cyanuric acid DNA-base analogue (**3**). Nucleoside (**3**) was obtained as a mixture of α- and β-sugar anomers, as shown by the ^{1}H NMR data; it was not purified further for the self-assembly studies.

Self-assembly of triaminopyrimidine (15) with diethylbarbituric acid (1)

^{1}H NMR titration of DNA-base analogue (2) by diethylbarbituric acid (1)

The hydrogen-bonded self-assembly of DNA-base analogue (**2**), with diethylbarbituric acid (**1**), was investigated by doing an ^{1}H NMR titration experiment (Fig. 2). The ^{1}H NMR of the triaminopyrimidine (**2**) in CD_2Cl_2 showed broad peaks in the three main regions corresponding to the amino groups (ca. 6.9 ppm), to the sugar protons (3.0–5.0 ppm), and to the disiloxane protecting groups (ca. 1.1 ppm). These broad peaks suggest the presence of oligomeric aggregates that arise from the self-association of individual triaminopyrimidine units in solution. Progressive addition of a diethylbarbituric acid solution in deuterated dichloromethane induced a downfield shift

of the NH_2 protons from 6.96 to 8.71 ppm, characteristic of hydrogen-bond formation. However, the ^{1}H NMR of the triaminopyrimidine/diethylbarbituric acid equimolar mixture did not display improved peak widths even after 2 days of ultrasonication. This suggests the formation of hydrogen-bonded polydisperse, oligomeric structures from DNA-base analogue (**2**) and diethylbarbituric acid (**1**).[5,6]

Electrospray ionization mass spectrometry of DNA-base analogue (2) and diethylbarbituric acid (1) mixture

The ^{1}H NMR titration experiment suggested that the self-assembly of triaminopyrimidine nucleoside (**2**) with diethylbarbituric acid (**1**) had resulted in hydrogen-bonded oligomers. However, these ^{1}H NMR experiments do not provide quantitative information about the size of these hydrogen-bonded aggregates. Electrospray ionization mass spectrometry (ESI-MS) analysis was therefore used to quantify the number of monomers involved in the hydrogen bonding of triaminopyrimidine nucleoside (**2**) with diethylbarbituric acid (**1**).

Scheme 4. Synthesis of triaminopyrimidine (**2**). Fig. 2. ^{1}H NMR titration of DNA-base analogue (**2**) using diethylbarbituric acid (**1**) in CD_2Cl_2. (*a*) Before titration; (*b*) after adding 0.5 equiv. of diethylbarbituric acid (**1**); (*c*) after adding 1.0 equiv. of diethylbarbituric acid (**1**).

pected molecular weight (M = 2004) was detected, consistent with the absence of discrete supramolecular structures from triaminopyrimidine (**2**) and diethylbarbituric acid (**1**).

Self-assembly of triaminopyrimidine (2) with DNA-base analogue (3)

^{1}H NMR titration of DNA-base analogue (2) by cyanuric acid (3)

Similar ^{1}H NMR titration experiments showed the hydrogen-bonded self-assembly of triaminopyrimidine DNA-analogue (**2**) (Fig. 4*a*) with cyanuric acid DNA-analogue (**3**) (Fig. 4*b*) to differ dramatically from its assembly with diethylbarbituric acid (**1**) (Fig. 5). Addition of cyanuric acid (**3**) caused the same 1.75 ppm downfield shift of the NH_2 protons as for diethylbarbituric acid guest molecules, caused by intermolecular hydrogen-bonding between the two DNA-base analogues. However, addition of 1 equiv. of a CD_2Cl_2 solution of cyanuric acid (**3**) resulted in the immediate emergence of a finer structure for complementary molecules (Fig. 5), suggesting the creation of discrete, macrocyclic structures from (**2**) and (**3**) in solution. Despite a significant gain in peak resolution, the NMR peaks were still slightly broad. This is probably caused by the presence of two anomers for each of the triaminopyrimidine (**2**) and cyanuric acid (**3**), which result in a less selective self-assembly for the system.

Electrospray ionization mass spectrometry of DNA-base analogue (2) and cyanuric acid (3) mixtures

For the triaminopyrimidine nucleoside (**2**)–diethylbarbituric acid (**1**) system, ESI-MS analysis was used to evaluate the size of the discrete supramolecular structures formed from DNA-base analogues (**2**) and (**3**).

The hydrogen-bonded aggregates seen for equimolar mixture of nucleosides (**2**) and (**3**) correspond to highly charged hexameric rosettes containing sodium or potassium ions in the 1700–2000 Da mass range (Fig. 6). Using M_1 and M_2 for the monomer molecular weights (M_1 for (**2**) = 483, M_2 for (**3**) = 486), R_6 for the hexameric rosette expected molecular weights (R_6 = 2907), *m*/*z* molecular ions detected can be listed as $[3(R_6–6H^+{+}6Na^+){+}5H^+]/5$, $[3R_6{+}2Na^+{+}Li^+{+}2H^+]/5$, $[R_6{+}2H^+{+}MeOH]/2$, $[3R_6{+}2H^+]/6$, $M_1{+}M_2$, and $M_1{+}Na^+$. Many other possible structures were tried and were inconsistent with the observed peaks. These molecular ions suggest the possible presence of monomeric, dimeric, and hexameric hydrogen-bonded species in the equimolar mixture of (**2**) and (**3**). Consequently, our preliminary ^{1}H NMRspectroscopy and ESI-MS studies, as well as theoretical MM+ and PM3 calculations are all consistent with the probable self-assembly of triaminopyrimidine DNA-analogue (**2**) with cyanuric acid DNA-analogue (**3**) into cyclic hexamers by hydrogen bonding. Whereas, the data suggest that oligomeric linear tapes were obtained from triaminopyrimidine nucleoside (**2**) and diethylbarbituric acid (**1**).

Absorbance and fluorescence properties of DNA-base analogue (2)

DNA-strand hybridization has usually been assayed by absorbance. Fluorescence spectroscopy has been used to evaluate DNA-hybridization using fluorophore labelled-

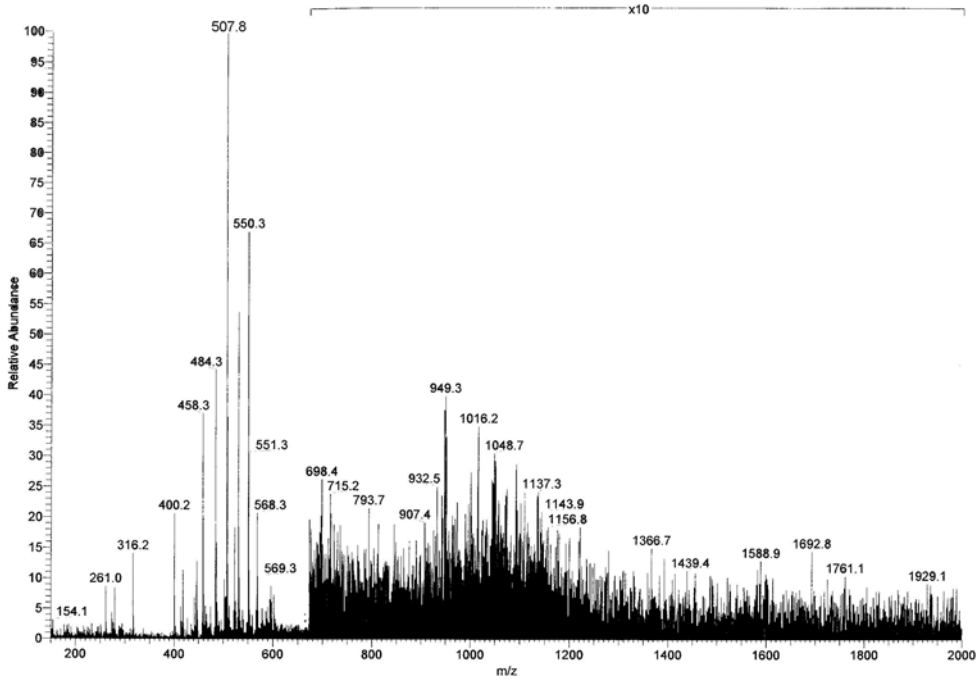
Fig. 3. Electrospray ionization mass spectrum of equimolar triaminopyrimidine nucleoside (**2**) and diethylbarbituric acid (**1**) mixture.



oligonucleotides, which can be attached to microarrays.[18] Substituted pyrimidines, including a few 2,4,6-triaminopyrimidine derivatives,[19] have shown fluorescence properties. Triaminopyrimidine nucleoside (**2**) was strongly fluorescent under UV–vis light.[16] The fluorescence of triaminopyrimidine (**2**) solutions, in chloroform, was measured using its UV–vis absorbance spectra (Figs. 7 and 8).

The UV–vis absorbance spectra gave a principal absorbance at λ_{max} = 254 nm, corresponding to a $\pi \rightarrow \pi^*$ transition of the triaminopyrimidine (**2**), along with a shoulder around 350 nm (Fig. 8). Preliminary fluorescence measurements monitored the self-assembly between triaminopyrimidine (**2**) and its complementary cyanuric acid building block (**3**) and probed the potential abilities of nucleoside analogue (**2**) to detect hybridization, which reflects the combined effects of hydrogen-bonding and π-stacking interactions. Addition of 1 equiv. of cyanuric acid (**2**) solution, in chloroform, induced a 1.4-fold fluorescence quenching along with a 3 nm bathochromic shift. These fluorescence experiments suggest that π-stacking might be involved in the hydrogen-bond assembly of triaminopyrimidine (**2**) and cyanuric acid (**3**) and generate higher-order structures from these complementary units.

Transmission electron microscopy and dynamic light scattering studies of triaminopyrimidine (2)/diethylbarbituric acid (1) and triaminopyrimidine (2)/cyanuric acid (3) mixtures

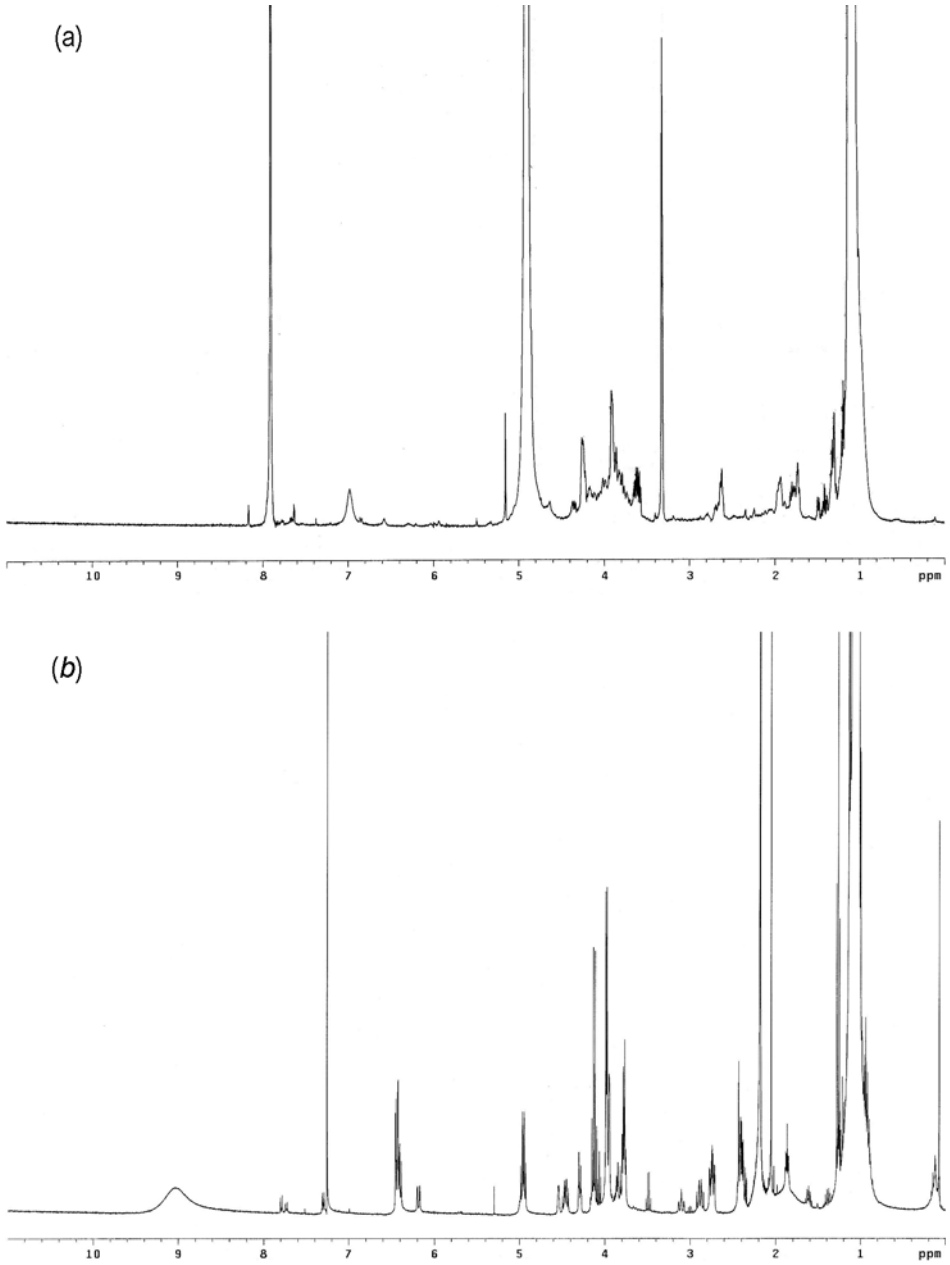
Transmission electron microscopy (TEM) studies of triaminopyrimidine (**2**)/diethylbarbituric acid (**1**), and triaminopyrimidine (**2**)/cyanuric acid (**3**) mixtures, allowed direct visualization of the second level of self-organisation of these molecules, as well as their different self-assembly behaviour. Figures 9 and 10 show transmission electron micrographs of carbon-coated grids, prepared from deposited solutions of triaminopyrimidine (**2**)/diethylbarbituric acid (**1**) and triaminopyrimidine(**2**)/cyanuric acid (**3**) mixtures, in dichloromethane. On the micrographs, the uranyl acetate appears dark gray and the carbon light gray. The error on the measurements is estimated to be ±1 nm.

Large, sheetlike aggregates are observed for triaminopyrimidine (**2**)/diethylbarbituric acid (**1**) (Fig. 10). Similar electron micrographs were generated from hydrogen-bonded linear tapes of *trans*-azobenzoic acid derivatives. No fine structure was detected at higher magnification, consistent with the absence of rodlike nanostructures from the triaminopyrimidine (**15**)/diethylbarbiturate (**14**) mixture.

On the other hand, the TEM of samples of triaminopyrimidine (**2**)/cyanuric acid (**3**) mixtures showed formation of significantly different supramolecular structures. In contrast with triaminopyrimidine (**2**)/diethylbarbituric acid[1] mixture, elongated aggregates, with lengths as great as 170 nm, arise from the triaminopyrimidine (**2**)/cyanuric acid (**3**) pair (Fig. 10). The outer hydrodynamic diameter of these elongated aggregates was determined from the intensity profile of the electron micrograph (Figs. 10*c* and 10*d*), which measures the contrast across the rodlike structures, hence the topography. The outer hydrodynamic diameter of these rodlike structures was measured as ca. 4.2 ± 1.0 nm, in close agreement with the estimated diameter of the self-assembled hexameric macrocycles of triaminopyrimidine (**2**) and cyanuric acid (**3**) (3.2 nm). This diameter was observed on freshly purified samples of triaminopyrimidine (**2**) and cyanuric acid (**3**) mixtures and for various direct deposition conditions, with and without staining; unstained samples of equimolar triaminopyrimidined (**15**)/cyanuric acid (**16**) mixtures showed rodlike structures by electron microscopy, but staining was needed to give a good contrast (Experimental section). The fluorescence measurements confirm further interaction of the hydrogen-bonded structures from triaminopyrimidine (**2**) and cyanuric acid (**3**) equimolar mixtures by π–π stacking and (or) alkyl–alkyl interactions.

Dynamic light scattering (DLS) studies for equimolar

Fig. 4. (*a*) ^{1}H NMR spectrum of DNA-base analogue (**2**) in MeOD; (*b*) ^{1}H NMR spectrum of DNA-base analogue (**3**) in $CDCl_3$.



Can. J. Chem. Downloaded from www.nrcresearchpress.com by Sichuan Normal University on 09/14/12
For personal use only.

mixtures of triaminopyrimidine (**2**) and cyanuric acid (**3**) in dichloromethane, at scattering angles of 45°, 90°, and 135°, confirmed the presence of elongated aggregates in solution. The hydrodynamic diameters obtained for these angles were significantly different from one angle to the other, e.g., 165.1 nm at 45° and 93.8 nm at 135°, consistent with the presence of elongated, rather than spherical aggregates in solution.

Therefore, the molecules (**2**) and (**3**) undergo self-assembly into elongated aggregates both in solution (DLS) and in the solid state (TEM).

Conclusion

A novel biomimetic DNA analogue with interesting fluorescence properties has been successfully synthesized to generate functional supramolecular architectures. These preliminary experimental studies suggest that triaminopyrimidine nucleoside (**2**) might undergo sterically controlled self-assembly into hydrogen-bonded linear tapes and hexameric rosettes. Self-association of the hydrogen-bonded triaminopyrimidine–cyanuric acid complex into elongated, rodlike nanostructures was shown using DLS and TEM and suggested the possible hierarchical formation of higher-order, π–π stacked assemblies. The hydrogen-bond self-assembly of the DNA analogue significantly decreased the fluorescence of the nucleosides, and this guest-induced fluorescence quenching can be used to develop DNA-hybridization probes. Preliminary MM^+ molecular modelling and semi-empirical molecular orbital PM3 calculations[1] predicted the possible incorporation of the triaminopyrimidine nucleoside into new types of artificial DNA strands and triplex forma-

tion with natural, complementary DNA strands containing thymine, extending the application of this monomer of DNA analogues to antisense–antigene technologue.[2]

Experimental section

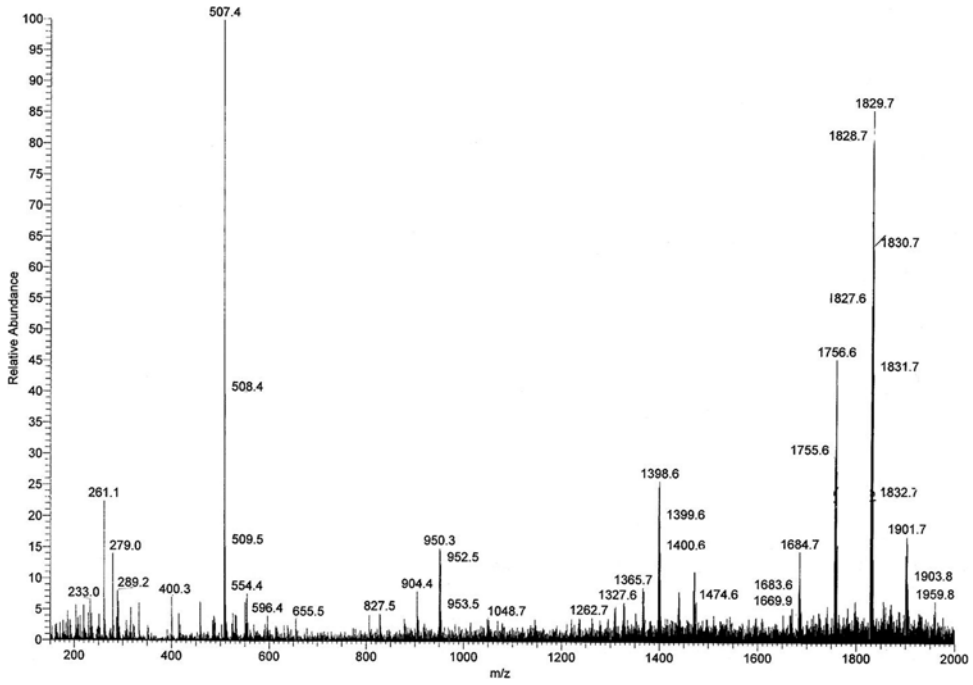
Materials

All reagents were purchased from the Sigma-Aldrich Chemical Co. The structures of the intermediates and the final products were confirmed by NMR spectroscopy and mass spectrometry.

Equipment

^{1}H and ^{13}C NMR spectra were acquired on Varian Mercury 400 and Varian Unity 500 spectrometers and 2D-COSY NMR spectra were acquired on a Varian Unity 500 spectrometer. Electrospray ionization (ESI) and atmospheric pressure chemical ionization (APCI) mass spectra were acquired by direct infusion into a Quattro II triple quadrupole (Micromass, Manchester, UK) with the spray voltage set to 3.5 kV, the source temperature 150–200 °C, sample infusion rate 5° μl/min using a syringe pump (Harvard Apparatus). UV–vis spectra were measured on a Varian CARY 1 UV–

Fig. 6. Electrospray ionization mass spectrum of equimolar triaminopyrimidine (**2**) and cyanuric acid (**3**) mixture.



vis spectrophotometer equipped with a Peltier temperature controller. Fluorescence data was acquired using a PTI (Photon Technology International) TimeMaster model C-720F spectrofluorimeter. TEM was conducted on a JEOL-2000 FX instrument by using the direct method with and without uranyl staining.

Experimental synthesis

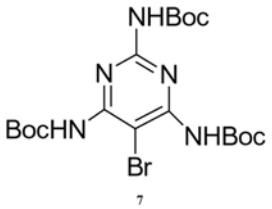
Et_3N (0.1 µL) for 2 h. The reaction was diluted with CH_2Cl_2 (10 mL) and quenched by adding water (10 mL). The organic layer was washed with saturated $NaHCO_3$ (2 × 10 mL) and water (10 mL), then dried over $MgSO_4$. The solvents were evaporated under reduced pressure. The formation of the *p*-toluenesulfonyl derivative (**6**) was verified by ^1H NMR in $CDCl_3$, which showed two sets of doublets in the aromatic region and two singlets corresponding to the methyl protons, consistent with the presence of two anomers α and β. The compound was used without further purification (341.7 mg, crude yield 97%). ^1H NMR (400 MHz, $CDCl_3$) δ: 7.92 (d, Ar-H_1, 8.0 Hz), 7.78 (d, Ar-H_1', 8.0 Hz), 7.40 (d, Ar-H_2, 8.0 Hz), 7.12 (d, Ar-H_2', 8.0 Hz), 5.56 (t, H_1, 7.2 Hz), 4.57 (dd, H_4, 7.2 Hz), 4.12–3.84 (m, H_3, $2H_5$), 3.17 (dd, H_2, 6.8 Hz, 11.6 Hz), 3.00 (m, H_2), 2.50 (s, $1CH_3$), 2.50 (s, $1CH_3$), 2.33 (s, $1CH_3$), 1.04 (s, 28 H).

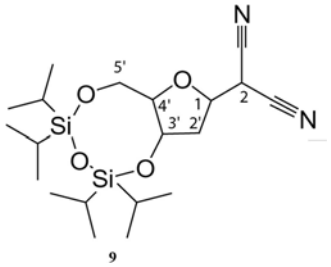
(Tri-*N*-tert-butoxycarbonyl)-2,4,6-triamine-5-bromopyrimidine (7)



7

2,4,6-Triamino-5-bromopyrimidine was synthesized from 2,4,6-triaminopyrimidine using a protocol in the literature (29) The brominated pyrimidine (721.9 mg, 3.52 mmol), di(-*tert*-butoxy)carbonate (5.096 g, 24.79 mmol), and dimethylaminopyridine (310.4 mg, 2.48 mmol) were dissolved, in the presence of Et_3N (4.04 mL, 28.34 mmol), in freshly distilled THF (45 mL). The reaction mixture was stirred under N_2 atmosphere at RT for 15 h resulting in an orange brown suspension. The reaction was quenched using aqueous 5% $NaHCO_3$ (1.5 mL), and the solvents evaporated under reduced pressure. The residue was dissolved in diethyl ether (25 mL), and the organic layer washed with aqueous 5% $NaHCO_3$ (2 × 25 mL), water (25 mL) and brine (25 mL). The organic layer was dried over anhydrous $MgSO_4$, filtered, and the solvents evaporated under reduced pressure. The desired compound **7** (972.7 mg, 54%) was isolated by column chromatography on silica gel. using ethyl acetate/hexanes (40:60) as the eluent. R_f ~0.75. ^1H NMR (400 MHz, $CDCl_3$, ppm) δ: 1.10–1.90 (27 H).

1-(2′-deoxy-5′,3′-bis-*O*-(tetraisopropylsiloxyl)-ribofuranosyl) propanedinitrile (9)



9

Method A

Malononitrile (149.0 mg, 2.26 mmol) in freshly distilled THF (1 mL) was added dropwise to a suspension of 95% NaOH (54 mg, 2.26 mmol) in THF (0.25 mL) at 0 °C. Tosylate (**6**) (400 mg, 0.75 mmol) in THF (0.5 mL) was added dropwise, and the reaction mixture stirred at RT overnight under N_2 atmosphere. The reaction was quenched with 5% aqueous NH_4Cl (6 mL). The reaction mixture was diluted with ethyl acetate, or dichloromethane (25 mL), and washed with water (2 × 25 mL) and brine (25 mL). The organic layer was dried over anhydrous $MgSO_4$, filtered, and the solvents evaporated under reduced pressure. Compound (**9**) (20 mg, 5%) was obtained as an off-white oil, after silica gel chromatography, using ether/hexanes (60:40) as eluent.

Fig. 10. (*a*) and (*b*) Electron micrographs prepared from deposited solutions of triaminopyrimidine (**2**)/cyanuric acid (**3**) using uranyl acetate as a staining agent; (*c*) and (*d*) profile analysis of the TEM images. Insets: magnified profile analysis to single rodlike structures (see text).

Method B

Malononitrile (52.7 mg, 0.80 mmol) in freshly distilled THF (0.5 mL) was added dropwise to a suspension of 95% NaOH (19.2 mg, 0.80 mmol) in THF (0.25 mL) at 0 °C. Protected sugar (**5**) (100 mg, 0.26 mmol) in THF (0.5 mL) was added dropwise, and the reaction mixture stirred at RT under N_2 atmosphere. The reaction was monitored by TLC until the disappearance of the starting material (1 h), then quenched with saturated NH_4Cl (6 mL). The reaction mixture was diluted with dichloromethane (25 mL) and washed with water (2 × 25 mL) and brine (25 mL). The organic layer was dried over anhydrous $MgSO_4$, filtered, and the solvents evaporated under reduced pressure. Compound (**9**) (37.7 mg, 33%) was obtained as an off-white oil after silica gel chromatography using ether/hexanes (60:40) as eluent. R_f ~0.25. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 4.38 (dd, H_4', 8.0 Hz, 2.4 Hz), 4.13–3.98 (m, H_1', H_3', H_5'), 3.77 (dd, H_5', 6.0 Hz, 9.6 Hz), 3.13–3.18 (m, H_2'), 2.55–2.22 (m, H_2'), 1.06 (s, 28 H). APCI-MS *m/z*: calcd. 425.0 (M + 1), 849.0 (2M + 1); found: 425.4 (M + 1), 849.1 (2M + 1).

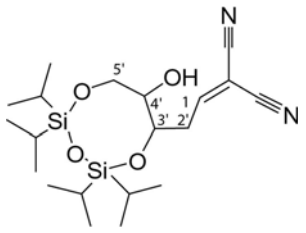
1-(2′-deoxy-5′,3′-bis-O-(tetraisopropylsiloxyl)-ribofuranosyl) propylidene dinitrile (11)



11

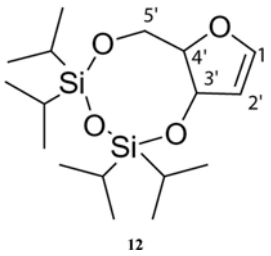
Method A

Malononitrile (17.6 mg, 0.26 mmol) in freshly distilled MeOH (1 mL) was added to a suspension of K_2CO_3 (3.7 mg, 0.026 mmol) in MeOH (0.5 mL) at RT. Protected sugar (**5**) (50 mg, 0.13 mmol) in THF (0.5 mL) was added dropwise, and the reaction mixture stirred at RT overnight under N_2 atmosphere. The reaction was quenched with saturated NH_4Cl (6 mL). The reaction mixture was diluted with dichloromethane (25 mL) and washed with water (2 × 25 mL) and brine (25 mL). The organic layer was dried over anhydrous $MgSO_4$, filtered, and the solvents evaporated under reduced pressure. Compound (**11**) (8.3 mg, 15%) was obtained as an off-white oil after silica gel chromatography, using ether/hexanes (60:40) as eluent. $R_f \sim 0.5$.

Method B

Malononitrile (17.8 mg, 0.27 mmol) in freshly distilled THF (0.5 mL) was added dropwise to a suspension of 95% NaOH (12.2 mg, 0.53 mmol) in THF (0.25 mL) at 0 °C. Protected sugar (**5**) (200 mg, 0.53 mmol) in THF (0.5 mL) was added dropwise, and the reaction mixture stirred at RT under N_2 atmosphere. The reaction was monitored by TLC until the disappearance of the starting material (1 h), then quenched with saturated NH_4Cl (6 mL). The reaction mixture was diluted with dichloromethane (25 mL) and washed with water (2 × 25 mL) and brine (25 mL). The organic layer was dried over anhydrous $MgSO_4$, filtered, and the solvents evaporated under reduced pressure. Compound (**11**) (29.1 mg, 13%) was an off-white oil after silica gel chromatography, using ether/hexanes (60:40) as eluent. $R_f \sim 0.5$. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 4.53 (d, H_1), 4.14 (dd, H_4'), 4.04 (dd, H_5'), 3.97 (dd, H_3'), 3.82 (dd, H_1'), 3.77 (dd, H_5'), 3.04 (m, H_2'), 2.40–2.19 (m, H_2'), 1.06 (s, 28 H).

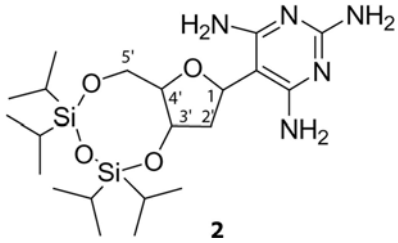
1,4-anhydro-(5′,3′-bis-O-(tetraisopropylsiloxyl))- 2′-deoxy-D-erythro-pent-1-enitol (12)



12

The 3,5-diprotected sugar (**5**) (100 mg, 0.265 mmol) was placed under vacuum in a flame-dried three-necked flask, equipped with a condenser. Dichloromethane (2 mL) was added under N_2 atmosphere with Et_3N (139 μL, 1.006 mmol). The resulting solution was cooled to –40 to –50 °C, and then mesyl chloride (25.5 μL, 0.331 mmol) was added dropwise. The reaction mixture was maintained at –40 to –50 °C for 3 h, then warmed to RT, and heated to reflux (50–60 °C) for 15 h. The solution was cooled to RT and filtered through a short silica gel column. The filtrate evaporated under reduced pressure to give a clear oil, which was purified by silica gel chromatography using diethyl ether/petroleum ether (2:98) as eluent, to give (**12**) (9.5 mg, 10%). ^{1}H NMR (400 MHz, $CDCl_3$) δ: 6.40 (dd, H_1'), 4.84 (t, H_2'), 4.44 (t, H_3'), 4.12 (dt, H_4'), 3.89 (dd, H_5'), 3.78 (m, H_5'), 1.07 (s, 28 H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 146.16, 100.90, 70.56, 64.75, 64.63, 18.14, 17.99, 17.95, 17.90, 17.83, 17.65, 17.56, 17.54, 14.60, 13.70, 13.63, 13.05.

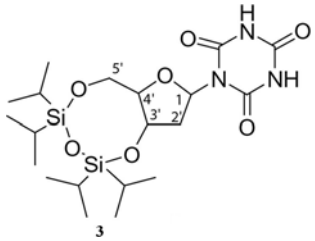
1-(2′-deoxy-3′,5′-bis-O-(tetraisopropylsiloxyl)-ribofuranosyl)pyrimidine-2,4,6-triamine (2)



2

Sodium (15.05 mg, 0.65 mmol) and guanidine hydrochloride (62.5 mg 0.65 mmol) were stirred in freshly distilled EtOH (1.5 mL), under N_2 atmosphere until a solution was obtained. A solution of (**22**) (185.0 mg, 0.44 mmol) in freshly distilled EtOH was added dropwise to the mixture, which was heated to reflux for 5 h. The reaction mixture was cooled to RT and the solvents evaporated under reduced pressure. The compound (60.9 mg, 29%) was isolated as a mixture of α and β anomers by column chromatography on silica gel, using dichloromethane/ethanol (0:100 to 40:60 gradient). $R_f \sim 0.1$ (10:90 dichloromethane/ethanol). ^{1}H NMR (400 MHz, CD_3OD) δ: 6.98 (s, NH_2), 4.25 (m, H_1'), 3.82–4.01 (dd, H_3', H_4'), 3.61 (m, H_5'), 2.63 (m, H_5'), 2.01–1.71 (m, $2H_2'$), 1.06 (s, 28 H). ^{13}C NMR (100 MHz, CD_3OD) δ: 159.34, 158.65, 118.69, 77.52, 77.16, 76.41, 69.27, 68.85, 44.85, 38.29, 36.06, 24.43, 23.82, 16.98, 13.00. ESI-MS *m/z*: calcd. 484 (M + 1), 507 (M + Na + 1); found 484.3 (M + 1), 507.3 (M + Na + 1).

1-(2-deoxy-3,5-bis-O-(tetraisopropylsiloxyl)-ribofuranosyl)cyanuric acid (3)



3

A mixture of the tosyl derivative (**6**) (353 mg, 0.67 mmol), cyanuric acid (85.2 mg, 0.67 mmol), potassium nonafluorobutanesulfonate (539.6 mg, 1.75 mmol), hexamethyldisilazane (98 μL, 0.54 mmol), and trimethylsilyl chlor-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Sichuan Normal University on 09/14/12
For personal use only.

ide (261 μL, 2.08 mmol) was heated to reflux, in freshly distilled acetonitrile (6.66 mL) under N_2 atmosphere. The reaction proceeded for 16 h and then cooled to RT. The solvents evaporated under reduced pressure and the residue was dissolved in $CHCl_3$ (25 mL), washed with saturated $NaHCO_3$ (25 mL) and water (25 mL), dried over $MgSO_4$. After solvent evaporation, the compound (119.2 mg, 37%) was isolated by two consecutive column chromatographies on silica gel, using dichloromethane, and then ethyl acetate/hexanes 1:1 as the eluents. ^{1}H NMR (400 MHz, $CDCl_3$) δ: 6.44 (m, H_1'), 4.96 (dd, H_4'), 4.55–4.28 (m, H_3'), 3.98 (dd, H_5'), 3.78 (dd, H_5'), 2.75 (m, H_2'), 2.40 (m, H_2'), 1.07 (s, 28 H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 148.53, 148.16, 147.91, 85.79, 83.60, 81.75, 72.74, 70.42, 63.58, 38.87, 17.86, 13.69.

Characterization of the self-assembly of nucleoside (2) with barbituric acid (1) and cyanuric acid (3)

Electrospray ionization mass spectrometry (ESI) measurements

An equimolar solution of triaminopyrimidine (**2**) with diethylbarbituric acid (**1**) or cyanuric acid (**3**) in a 10% $MeOH/CH_2Cl_2$ mixture was directly infused into a Quattro II triple quadrupole (Micromass, Manchester, UK), configured for positive product ion analysis and used with a spray voltage of 3.5 kV, a source temperature of 100–200 °C, a sample infusion rate of 5° μl/min, using a syringe pump (Harvard Apparatus). For molecular weight determination, the spectrometer was programmed to scan for product ions from *m/z* 150 to 2000, in the multichannel acquisition mode (MCA) showing *m/z* for the monomers and the hexamer.

Sample preparation for TEM measurements by the direct method

A solution of cyanuric acid and 2,4,6-triaminopyrimidine (1:1) was prepared by dissolving the sample in dichloromethane. A carbon-coated 400 mesh copper grid, prewashed with chloroform for 12 h, was dipped into the solution for approximately 1 min and dried on a filter paper.

Sample preparation for TEM measurements by staining

A solution of cyanuric acid and 2,4,6-triaminopyrimidine (1:1) was prepared by dissolving the sample in dichloromethane. The solution (10 μL) was deposited on a carbon-coated 400 mesh copper grid, prewashed with chloroform for 12 h, and blotted. A drop of aqueous 2% uranyl acetate was deposited on the air-dried copper grid, blotted, rinsed with a drop of water after 30 s, and then dried on paper filter.

Dynamic light scattering (DLS) measurements

Dynamic light scattering measurements were performed using a 532 nm laser equipped photo-multiplier detector. The autocorrelation functions were acquired for θ values of 45°, 90°, and 135° for prefiltered equimolar solutions of triaminopyrimidine (**2**) and cyanuric acid (**3**) in dichloromethane. Data acquisition was carried out at 20 °C within a few hours to get a better particle size distribution. Inverse Laplace transforms of the data were performed using Provencher's FORTRAN programme CONTIN,[20] and diffusion coefficients were determined from the slope of the relaxation frequencies (Γ) versus q^2. Assuming a spherical behaviour for the particles and using the translational coefficient DTr and the Stokes–Einstein equation, the hydrodynamic diameters were calculated for each scattering angle.

Cleavage of models for RNA mediated by a diZn(II) complex of bis[1,4-N_1,N_1'(1,5,9-triazacyclododecanyl)]butane in methanol and ethanol

C. Tony Liu, Stephanie A. Melnychuk, Chaomin Liu, Alexei A. Neverov, and R. Stan Brown

Abstract: The cleavage of seven RNA model 2-hydroxypropyl aryl phosphates (**1**) catalyzed by a dinuclear Zn(II) complex of bis[1,4-N_1,N_1'(1,5,9-triazacyclododecanyl)]butane (**4**) was studied in methanol and ethanol at 25 °C under pH controlled conditions. The results are compared with what was reported earlier for the dinuclear Zn(II) complex of the lower homologue bis[1,3-N_1,N_1'(1,5,9-triazacyclododecanyl)]propane (**3**). In methanol, the higher homologue exhibits saturation binding with substrates having poor aryloxy leaving groups. With good leaving groups there is an observed linear dependence of k_{obs} versus complex concentration without saturation binding over the catalyst concentration range investigated. In ethanol, strong saturation binding between the active form of the catalyst ((RO^-):$Zn(II)_2$:**4**) and all substrates is observed, the results observed in both solvents being similar to what was reported for the lower (RO^-):$Zn(II)_2$:**3** homologue. Energetics calculations are presented for the (RO^-):$Zn(II)_2$:**4**-catalyzed cleavage of each substrate in both solvents to assess the catalytic efficiency via the $\Delta\Delta G^{\ddagger}$ for catalyst binding a transition state comprising $[RO^-$:**1**$]^{\ddagger}$ or its kinetic equivalent.

Key words: dinuclear Zn(II) catalyst, RNA model cleavage, methanolysis, ethanolysis, kinetics, mechanism.

Résumé : Opérant dans des conditions de pH contrôlé, à 25 °C, en solution dans le méthanol et l'éthanol, on a étudié la réaction de clivage de sept phosphates d'aryle et de 2-hydroxypropyle (**1**), des modèles de l'ARN, catalysé par un complexe dinucléaire du Zn(II) et le bis[1,4-N_1,N_1'(1,5,9-triazacyclododécanyl)]butane (**4**). On compare les résultats avec ceux rapportés antérieurement pour le complexe dinucléaire du Zn(II) l'homologue inférieur bis[1,3-N_1,N_1'(1,5,9-triazacyclododécanyl)]propane (**3**). Dans le méthanol, l'homologue supérieur on observe qu'il y a saturation du site de fixation avec les substrats pour lesquels l'habilité à partir des groupes aryloxy est faible. Avec de bons groupes partant, pour toute la plage de concentration de catalyseur utilisée dans ce travail, on observe une dépendance linéaire de k_{obs} en fonction de la concentration du complexe. Dans l'éthanol, on observe une forte saturation des sites de fixation entre tous les substrats et la forme active du catalyseur [(RO^-):$Zn(II)_2$:**4**]; dans les deux solvants, les résultats sont similaires à ceux rapportés pour l'homologue inférieur [(RO^-):$Zn(II)_2$:**3**]. Afin d'évaluer l'efficacité catalytique par le biais du $\Delta\Delta G^{\ddagger}$ de la fixation par le catalyseur d'un état d'activation comportant $[RO^-$:**1**$]^{\ddagger}$ ou son équivalent cinétique, on a effectué des calculs d'énergie pour le clivage de chacun des substrats, catalysés par [(RO^-):$Zn(II)_2$:**4**].

Mots-clés : catalyseur de Zn(II) dinucléaire, clivage d'un modèle d'ARN, méthanolyse, éthanolyse, cinétique, mécanisme.

Introduction

Phosphate diesters that form the backbone of RNA and DNA are highly stable toward hydrolytic cleavage under physiological conditions in the absence of enzymes or specific catalysts.[1,2] However, with the assistance of enzymes, the cleavage of these sorts of phosphate diesters can be accelerated by up to 10^{15}–10^{17}.[1] Many naturally occurring phosphodiesterases have active sites containing two or more metal ions such as Zn(II), Ca(II), Mg(II), Fe(III), and Mn(II) in close proximity (3–4 Å apart).[3] In an effort to understand the origins of this exalted catalysis numerous researchers have studied mono- and di-nuclear metal ion catalysts for cleaving selected phosphate diesters.[4–7] We have reported the rapid cleavage of a series of activated RNA (**1**)[8,9] and DNA (**2**)[8,10] models catalyzed by the dinuclear **3**:$Zn(II)_2$:($^-$OR) complex in methanol and ethanol under ^S_SpH controlled conditions.[11] As shown in Scheme 1, the catalyzed cleavage of **1** involves intramolecular participation of the 2-hydroxylpropyl group to form a cyclic phosphate intermediate (**5**), which rapidly opens up to the two isomeric products, **6** and **7**.[12]

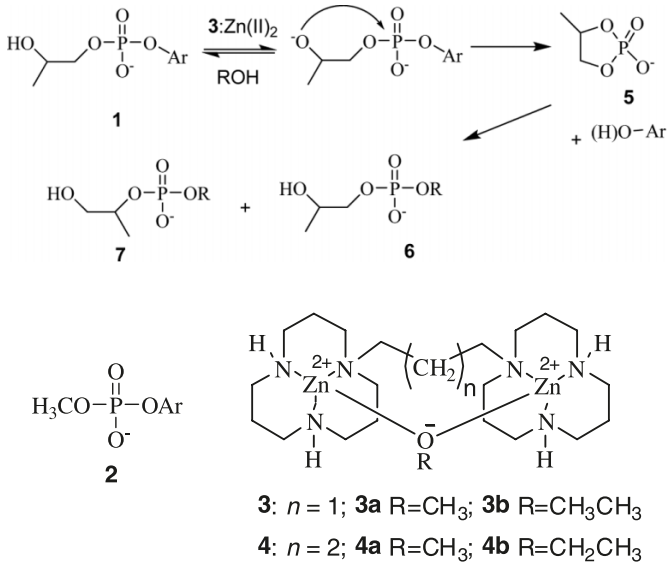
Scheme 1.



Although **3**:$Zn(II)_2$ is reported to exhibit poor catalysis of the cleavage of bis-*p*-nitrophenyl phosphate in water,[13] it is dramatically different in methanol[9] and ethanol[14] where, as an alkoxy form (**3a**, **3b**), it accelerates the cleavages of **1a**–**1g** by 10^{11} to 10^{14} relative to the background alkoxide-facilitated reactions at near neutral $^{S}_{S}$pH values and 25 °C. The origin of the very large enhancement of activity obtained by an apparently simple change in solvent is uncertain at this time, but is probably related to a variety of factors including a reduced polarity and dielectric constant (dielectric constant, ϵ = 78, 31.5, and 24.3 for water, methanol, and ethanol, respectively[15]) and overall solvation changes that enhance the interaction between the oppositely charged catalyst and substrate in the ground state and increasingly so in the transition state for the catalyzed reaction.

Herein, we report on a slightly more flexible $Zn(II)_2$ complex of ligand **4**, which is the C_4 higher homologue of **3**. To shed light on how the additional flexibility of the higher homologue might affect the catalysis under $^{S}_{S}$pH controlled conditions, studies of the **4**:$Zn(II)_2$-catalyzed transesterification of **1a**–**1g** in methanol and ethanol were undertaken to compare with what was seen earlier with **3**:$Zn(II)_2$. As will be shown, **4**:$Zn(II)_2$ accelerates the cleavage reactions of **1a**–**1g** by around 10^{11} to 10^{12} (at $^{S}_{S}$pH [11] 9.5 and 25 °C) in methanol and a factor of 10^{15} to 10^{16} (at $^{S}_{S}$pH 9.0 and 25 °C) in ethanol relative to the background alkoxide-promoted reactions in the respective solvents.[16]

Experimental

Materials

Anhydrous methanol (99.8%), sodium methoxide (0.50 mol/L solution in methanol, titrated against N/50 certified standard aqueous HCl solution and found to be 0.49 mol/L), sodium ethoxide (21 wt. % solution in denatured ethanol, titrated against N/50 standard aqueous HCl solution and found to be 2.68 mol/L), $Zn(CF_3SO_3)_2$, and tetrabutylammonium trifluoromethanesulfonate (99%) were used without further purification. $HClO_4$ (70% aqueous solution, titrated to be 11.40 mol/L) was used as supplied as was Paraoxon® (diethyl *p*-nitrophenyl phosphate, 99.5%), methanol-d_4 (D, 99.8%) and absolute ethanol which was then de-gassed by bubbling Ar through it for 1h prior to storing it under Ar. Freshly dispensed degassed ethanol ([H_2O], determined to be 0.028 ± 0.007 mol/L[14,17] by Karl Fischer titration) was used for conducting kinetic experiments. The sodium salts of the 2-hydroxylpropyl aryl phosphates (**1a**–**1g**) were prepared as described in earlier reports[9,18,19] where the characterizations of the compounds can be found. The dinuclear catalyst was prepared as 2.5 mmol/L stock solutions by sequential addition of aliquots of stock solutions of sodium alkoxide, **4**, and $Zn(CF_3SO_3)_2$ such that the relative ratios were 1:1:2 in either solvent at 25 °C. The complete formation of the complexes required 25 and 80 min in methanol and ethanol (as monitored by the changed in catalytic activity over time).

Bis[1,4-N_1,N_1'(1,5,9-triazacyclododecanyl)]butane (4)

To a solution of 1,5,7-triazabicyclo[4,4,0]dec-5-ene[20] (2.50 g, 13.8 mmol) in 50 mL of dry acetonitrile, 1.48 g (6.9 mmol) of 1,4-dibromobutane was added. The reaction mixture was heated at reflux for 3 d and the resulting off-white solid was filtered and washed with dry acetonitrile. The crude product was then mixed with 6 N aqueous HCl (20 mL) and heated to reflux for 48 h before the majority of the solvent was removed in vacuo. Absolute ethanol was added to the residue to induce precipitation. The white precipitates were washed four times with 8 mL portions of absolute ethanol and then dried in vacuo after which they were recrystallized from 1:9 aqueous ethanol to afford the HCl salt of **4** as a white solid in 67% overall yield. Conversion of the HCl salt into the free amine (**4**) was accomplished by stirring 897 mg (1.48 mmol) in 30 mL of water along with excess 5 N NaOH for 2 h at ambient temperature, followed by extracting the solution with four 25 mL portions of $CHCl_3$. The combined $CHCl_3$ extracts were dried over $MgSO_4$ and filtered before the solvent was removed in vacuo affording pure **4** as a nearly colorless oil in 78% yield (456 mg). ^{1}H NMR (400 MHz, CD_3OD, 25 °C) δ: 2.80 (t, 8H, J = 6.0 Hz, $HNCH_2CH_2CH_2NH$), 2.75 (t, 8H, J = 6.0 Hz, $HNCH_2(CH_2)_2N(CH_2)_2$), 2.59 (t, 8H, J = 6.0 Hz, $N(CH_2)_2CH_2$), 2.46 (m, 4H, $N(CH_2)_2CH_2$), 1.70 (m, 12H, $HNCH_2CH_2CH_2N$), 1.49 (m, 4H, $CH_2CH_2CH_2CH_2$). ^{13}C NMR (100 MHz, D_2O, 25 °C) δ: 53.2, 51.8, 48.8, 47.3, 25.4, 25.2, 23.2. HRMS (EI-TOF) *m/z*: calcd. for ($C_{22}H_{48}N_6$): 396.3940; found: 396.3943 (M^+).

Methods

^{1}H NMR and ^{31}P NMR spectra were determined at 400 and 162.04 MHz. The $CH_3OH_2^+$ and $CH_3CH_2OH_2^+$ concentrations were determined potentiometrically with a combination glass electrode (Radiometer model # XC100-111-120-161) calibrated with standard aqueous buffers (pH = 4.00 and 10.00) as described previously.[11] The $^{S}_{S}$pH values in methanol and ethanol were determined by subtracting the correction constants of –2.24[11a,11b] and –2.54,[11c] respectively, from the electrode readings. The autoprotolysis constants are $10^{-16.77}$ $(mol/L)^2$ for methanol and $10^{-19.1}$ $(mol/L)^2$ for ethanol. The kinetic experiments were conducted under buffer-free conditions of low but variable ionic strength determined by the catalyst concentration since the presence of buffer and excess salts that might be used to keep ionic strength

constant is observed to inhibit the catalysis, probably due to binding of the anions.

Stopped-flow kinetics

The rates for the catalyzed transesterification of **1a**–**1g** were determined by following the appearance of the phenolic products using a stopped-flow reaction analyzer thermostatted at 25.0 ± 0.1 °C. The production of the phenol was monitored at the following wavelengths: **1a**, 320 nm; **1b**, 323 nm; **1c**, 340 nm; **1d**, 284 nm; **1e**, 282 nm; **1f**, 280 nm; and **1g**, 292 nm. Stock solutions (2.5 mmol/L) of **4**:$Zn(II)_2$:($^-OCH_3$) in methanol and **4**:$Zn(II)_2$:($^-OCH_2CH_3$) in ethanol were prepared in oven-dried vials that were capped and sealed with Parafilm®. These were used to prepare catalyst solutions of concentrations ranging from 0.34 mmol/L ≤ **4**:$Zn(II)_2$:($^-OCH_3$) ≤ 2.06 mmol/L in methanol and 0.06 mmol/L ≤ **4**:$Zn(II)_2$:($^-OCH_2CH_3$) ≤ 0.28 mmol/L in ethanol. The catalyst solutions were loaded into one of the two syringes in the stopped-flow analyzer while a solution containing 0.1 mmol/L of substrate **1a**–**1g** in either methanol or ethanol was loaded into the other. The final concentrations of catalyst after mixing in the cell of the stopped-flow analyzer were 0.17 mmol/L ≤ **4**:$Zn(II)_2$:($^-OCH_3$) ≤ 1.03 mmol/L in methanol and 0.03 mmol/L ≤ **4**:$Zn(II)_2$:($^-OCH_2CH_3$) ≤ 0.14 mmol/L in ethanol while the final concentration of **1a**–**1g** was 0.05 mmol/L in either alcohol. At each catalyst concentration at least five kinetic runs were recorded and the average values were used for the k_{obs} for the appearance of the product. The $^S_Sp K_a$ values of the corresponding phenol leaving groups of **1a**–**1g** in methanol[9] and ethanol[14] have been reported.

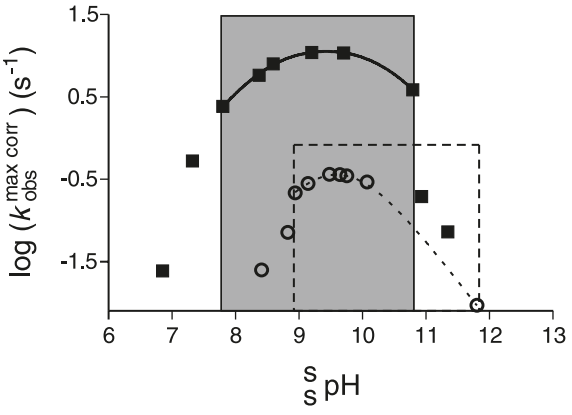
The degree of triflate inhibition on the catalysis in methanol was determined from a kinetic experiment that involved monitoring the cleavage of paraoxon (0.05 mmol/L) mediated by 0.43 mmol/L of **4**:$Zn(II)_2$:($^-OCH_3$) in the presence of added tetrabutylammonium triflate so that the final $[\text{triflate anion}]_{total}$ ranged between 2.0 and 8.0 mmol/L. The effect of [triflate anion] on the catalyzed reactions in ethanol was determined by following the change in reactivity of 0.08 mmol/L **4**:$Zn(II)_2$:($^-OCH_2CH_3$) mediating the cleavage of **1a** (0.05 mmol/L) in ethanol with varying tetrabutylammonium triflate concentration so that the final $[CF_3SO_3^-]_{total}$ ranged between 0.3 and 3.4 mmol/L.

Kinetic titration of 4:$Zn(II)_2$ for reactions of 1g in methanol and 1b in ethanol

Ethanol

Varying amounts of $NaOCH_2CH_3$ or $HClO_4$ stock solutions (5 mmol/L) in ethanol were added to solutions containing 1.6×10^{-4} mol/L of a preformed **4**:$Zn(II)_2$:($^-OCH_2CH_3$) complex in ethanol, which had been prepared 80 min in advance to allow for complete formation of the complex. After the introduction of the additional acid or base, the mixture was allowed to stand for 15 min to equilibrate (independent experiments showed that this time was optimum to stabilize the kinetic activity) and then loaded into one syringe of the stopped-flow analyzer while a 1.0×10^{-4} mol/L solution of **1b** in ethanol was loaded into the other. The final concentrations after mixing were 8×10^{-5} mol/L of **4**:$Zn(II)_2$ and 5×10^{-5} mol/L of **1b** in ethanol. The ^S_SpH values were measured at the end of the reactions and assumed to have been set immediately on mixing. The ^S_SpH/log rate constant profile plot is presented in Fig. 1 with the line through the data being derived from a fit of the solid squares data to a process that depended on two ionizable groups having $^S_Sp K_a$ values of 8.48 and 10.38 (see the Supplementary data).

Fig. 1. Two ^S_SpH/log $k_{obs}^{max\ corr}$ profiles for the reaction of **4**:$Zn(II)_2$:($^-OCH_2CH_3$) and **1b**, as well as **4**:$Zn(II)_2$:($^-OCH_3$) with **1g** conducted at 25 °C in ethanol and methanol. The lines through the data points in the indicated boxes are computed on the basis of a bell-shaped ^S_SpH/rate profile. (See text and ref. 14).



Methanol

The ^S_SpH/log rate constant profile for the cleavage of **1g** catalyzed by **4**:$Zn(II)_2$ in methanol was conducted as described above. The final concentrations of triflate-free **4**:$Zn(II)_2$ and **1g** after mixing in the reaction chamber of the stopped-flow analyzer were 6.4×10^{-4} mol/L (after triflate correction) and 5×10^{-5} mol/L, respectively. The kinetic data, shown in Fig. 1, were fitted to a process depending on two ionizable groups having $^S_Sp K_a$ values of 9.38 and 9.80.

Results

4:$Zn(II)_2$:($^-OCH_3$)-catalyzed cyclization of 1a–1g in methanol

As is the case with **3**:$Zn(II)_2$-catalyzed methanolysis reactions, triflate anion inhibits the catalysis afforded by **4**:$Zn(II)_2$ (inhibition constant, K_i = 7.2 ± 0.9 mmol/L; see the Supplementary data). The raw kinetic data are accordingly corrected for triflate inhibition to determine the concentration of free catalyst, $[\mathbf{4}:Zn(II)_2:(^-OCH_3)]_{free}$. The detailed methodology for these treatments can be found in earlier publications[8,9] and is applied specifically to this system in the Supplementary data.

Unfortunately, the kinetic data we have for the catalyzed reactions with substrates **1** are available only over a 0.2 mmol/L < $[\mathbf{4}:Zn(II)_2:(^-OCH_3)]_{free}$ < 0.75 mmol/L range due to the limited solubility of the catalyst (2.3 mmol/L in one drive syringe of the stopped-flow reaction analyzer is diluted by a factor of 2 on mixing) and to its relatively high triflate inhibition constant. Due to these limitations, fitting of the data to any given model has a larger error than was the case with $[\mathbf{3}:Zn(II)_2:(^-OCH_3)]_{free}$.[8–10] Nevertheless, the following limited observations and analysis can be made.

Fig.2. A plot of k_{obs} vs [**4**:Zn(II)$_2$:($^-$OCH$_3$)]$_{free}$ for the catalyzed methanolysis of **1a** (5×10^{-5} mol/L) determined from the rate of appearance of product phenol at 320 nm, ^S_SpH 9.5 ± 0.2, and 25.0 ± 0.1 °C. Linear regression of the data gives a second order rate constant (k_2) of (2.08 ± 0.04) $\times 10^4$ (mol/L)$^{-1}$s^{-1} with an intercept of A = 0.12 ± 0.02 mmol/L, r^2 = 0.998.

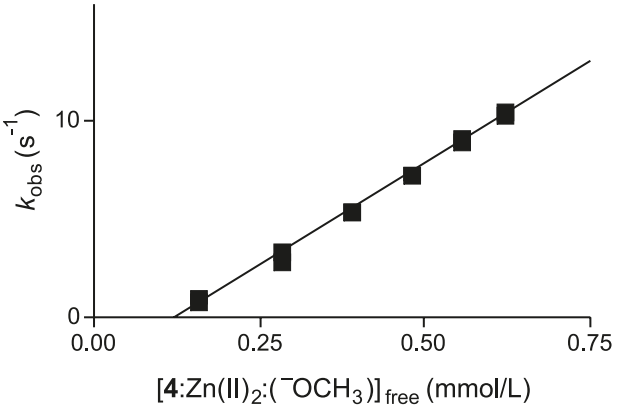


Fig.3. A plot of k_{obs} vs [**4**:Zn(II)$_2$:($^-$OCH$_3$)]$_{free}$ for the catalyzed methanolysis of **1g** (5×10^{-5} mol/L) determined from the rate of appearance of product phenol at 295 nm, ^S_SpH 9.5 ± 0.2, and 25.0 ± 0.1 °C. Fitting the data to the expression given in eq. [S1] of the Supplementary data gives k_{cat}^{max} = (5.2 ± 0.4) $\times 10^{-1}$ s^{-1}, K_M = (1.9 ± 0.3) $\times 10^{-4}$ mol/L, and an x-intercept of A = 0.20 ± 0.01 mmol/L, r^2 = 0.986.

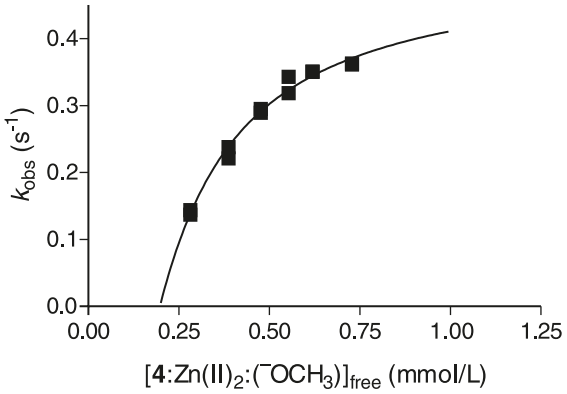

The more reactive substrates (**1a**–**1d**) exhibited a linear relationship between k_{obs} versus [**4**:Zn(II)$_2$:($^-$OCH$_3$)]$_{free}$ for the catalyzed reactions, whereas the less reactive ones (**1e**–**1g**) showed apparent saturation over that same concentration range. Shown in Figs. 2 and 3 are k_{obs} versus [**4**:Zn(II)$_2$:($^-$OCH$_3$)]$_{free}$ plots for the catalyzed transesterifications of **1a** and **1g**. It was earlier observed that the k_{obs} versus [**3**:Zn(II)$_2$:($^-$OCH$_3$)]$_{free}$ plots displayed a prominent x-intercept that was attributed to a dissociation of Zn(II) away from the catalytic complex at very low concentrations,[8–10] and the data in Figs. 2 and 3 show the same trend with [**4**:Zn(II)$_2$:($^-$OCH$_3$)]$_{free}$. The kinetic k_{obs} versus catalyst concentration data for substrates **1a**–**1c** are linear (as are those for **1d**, which may have a perceptible downward curvature but are analyzed as being linear) over the concentration range investigated. However, these data for **1e**–**1g** show a definite downward curvature suggestive of saturation binding.

The saturation kinetics observed for each of **1e**–**1g** were fit by nonlinear least-squares (NLLSQ) treatment to a universal binding equation presented in earlier reports,[8–10,14] which is applicable to both weak and strong binding cases (this is given as eq. [S1] of the Supplementary data, which also describes the mathematical treatment to account for the x-intercept). In Table 1, the best fit K_M and k_{cat}^{max} constants for the [**4**:Zn(II)$_2$:($^-$OCH$_3$)]$_{free}$ catalyzed transesterification of **1e**–**1g** are presented, along with the experimentally observed second order rate constants (k_2^{cat}) for substrates **1a**–**1d** derived from the linear regression of the rate constant versus [**4**:Zn(II)$_2$:($^-$OCH$_3$)]$_{free}$ data.

4:Zn(II)$_2$:($^-$OCH$_2$CH$_3$)-catalyzed cyclization of 1a–1g in ethanol

The rates of the reactions of **1a**–**1g** as a function of increasing [**4**:Zn(II)$_2$:($^-$OCH$_2$CH$_3$)] exhibit saturation kinetics with very strong binding (see the Supplementary data), similar to what was observed previously with **3**:Zn(II)$_2$ in ethanol.[14] A few key points are notable. First, a kinetic study where the [$^-$OCH$_2$CH$_3$] is varied shows that the rate for the cyclization of **1a** is highest when the ratio of [**4**:Zn(II)$_2$]/[$^-$OCH$_2$CH$_3$] is in unity (see the Supplementary data). Second, the inhibition constant of triflate anion on the catalysis afforded by **4**:Zn(II)$_2$:($^-$OCH$_2$CH$_3$) in ethanol is found to be K_i = 1.21 mmol/L (see the Supplementary data) suggesting that triflate inhibition is even stronger in ethanol than in methanol. However, the triflate inhibition observed with **4**:Zn(II)$_2$:($^-$OCH$_2$CH$_3$) is not as significant as that for the **3**:Zn(II)$_2$:($^-$OCH$_2$CH$_3$) system in ethanol (K_i = 0.36 ± 0.02 mmol/L).[14] Third, as is the case with the **3**:Zn(II)$_2$ system in ethanol,[14] triflate is an uncompetitive[21] inhibitor of the **4**:Zn(II)$_2$:($^-$OCH$_2$CH$_3$)-catalyzed reactions. Thus, the raw kinetic data (k_{obs}^{uncorr}) were corrected for triflate inhibition using eqs. [1] and [2] as described[14] to yield k_{obs}^{corr} values.

$$[1] \qquad [\mathbf{4}\text{:Zn(II)}_2\text{:}(^-\text{OCH}_2\text{CH}_3)]_{free} = \frac{(K_i)[\mathbf{4}\text{:Zn(II)}_2\text{:}(^-\text{OCH}_2\text{CH}_3)]_{total}}{K_i + [^-\text{OTf}]}$$

$$[2] \qquad k_{obs}^{corr} = \frac{k_{obs}^{uncorr}(K_i + [^-\text{OTf}])}{K_i}$$

The k_{obs}^{corr} values obtained as a function of [**4**:Zn(II)$_2$:($^-$OCH$_2$CH$_3$)] in ethanol follow saturation behaviour with a strong binding for the entire series of **1a**–**1g** as is exemplified by the plot shown in Fig. 4 for **1a**. We have not used buffers due to the inhibitory effect of their associated anions, so it is important to note that the solution ^S_SpH decreases slightly as the ratio of catalyst concentration/[**1**] increases up to the point where it finally stabilizes at a reasonably constant value of 9.0 ± 0.3 (measured after the stopped-flow reaction) at the plateau region, where the first order rate constant of the catalyzed reaction, corrected for triflate inhibition is defined as $k_{cat}^{max\ corr}$.

Fitting of the kinetic data to the universal binding equation and iteratively varying the **4**:Zn(II)$_2$:($^-$OCH$_2$CH$_3$):**1** dissociation constant (K_M) until the goodness-of-fit is maximized[14] allows estimation of upper limits for the K_M ($10^{-7.5}$ mol/L (3.2×10^{-8} mol/L)) and $k_{cat}^{max\ corr}$ values for catalytic cleavage of the bound substrates given in Table 2.

Table 1. Kinetic constants (maximum rate constants (k_{cat}^{max}), Michaelis–Menten constants (K_M), and second-order rate constants (k_2 or k_{cat}^{max}/K_M)) for the cleavage of **1a**–**1g** mediated by [**4**:Zn(II)$_2$:($^-$OCH$_3$)]$_{free}$ in anhydrous methanol at ^S_SpH 9.5 ± 0.2 and 25.0 ± 0.1 °C.

[a]K_M and k_{cat}^{max} values were not determined for the faster reacting substrates (**1a**–**1d**).

[b]Acceleration in terms of 1 mmol/L catalyst reacting with the observed second order rate constant relative to the methoxide reaction at ^S_SpH 9.5.

[c]Acceleration in terms of k_{cat}^{max} relative to the methoxide reaction at ^S_SpH 9.5 where [$^-$OCH$_3$] = 5.37 × 10^{-8} mol/L.

[d]The k_2 values for **1a**–**1d** are the experimentally observed values from the slopes of the k_{obs} versus [**4**:Zn(II)$_2$:($^-$OCH$_3$)]$_{free}$ plots. The k_2 values in italics are computed from k_{cat}^{max}/K_M.

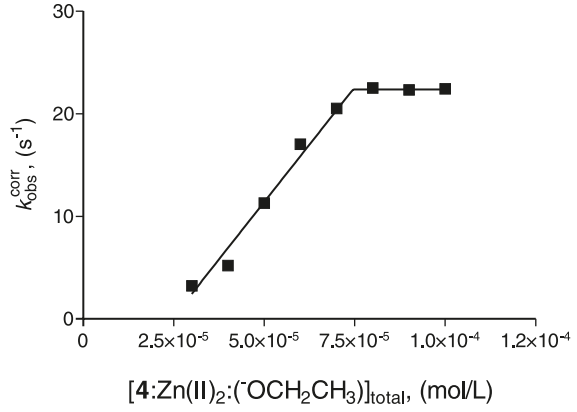

Fig. 4. A plot of k_{obs} versus [**4**:Zn(II)$_2$:($^-$OCH$_2$CH$_3$)]$_{total}$ for the catalyzed cleavage of **1a** (5 × 10^{-5} mol/L) at 323 nm, ^S_SpH 9.0 ± 0.3, and 25.0 ± 0.1 °C. Fitting of the data to the universal binding expression given in the Supplementary data gives k_{cat}^{max} = 22.4 ± 0.5 s^{-1} and an intercept, A = (2.5 ± 0.1) × 10^{-5} mol/L. The raw kinetic data have been corrected for $^-$OTf inhibition as described in the text.

Shown in Fig. 5 is a Brønsted plot of log ($k_{cat}^{max\ corr}$) for the catalyzed reactions versus the ^S_SpK_a values[14] of the corresponding phenols in ethanol. The two lines through the data are from a linear regression and a nonlinear regression as described in the legend of Fig. 5.

Determination of kinetic ^S_SpK_a values for formation of 4:Zn(II)$_2$:($^-$OR) in methanol and ethanol

In the absence of any buffer, the ^S_SpH values depend on the catalytic system itself and were generally found to be 9.0 ± 0.3 in the plateau region of the k_{obs}^{corr} versus [**4**:Zn(II)$_2$:($^-$OCH$_2$CH$_3$)]$_{total}$ plots. Unfortunately, as was the case with **3**:Zn(II)$_2$, the complexes with **4**:Zn(II)$_2$ require re-equilibration when the ^S_SpH is altered so it is not possible to undertake potentiometric titrations of the complexes in either methanol or ethanol due to the time required for the catalyst to reach equilibrium following addition of each aliquot of acid or base. However, the kinetic ^S_SpH/$k_{obs}^{max\ corr}$ profile shown in Fig. 1 for the cleavage of **1b** catalyzed by **4**:Zn(II)$_2$ in ethanol can be constructed as described in the Experimental above. The plot exhibits a broad plateau from ^S_SpH 7.9–10 and a precipitous drop in rate constant at higher and lower values. The line through the data was derived from a fit of the solid squares data to a kinetic process that depended on two ionizable groups[14] having first and second ^S_SpK_a values of 8.48 ± 0.02 and 10.38 ± 0.03. Only the data in the shaded box were used for the fitting because of the rapid fall-off in the rate constant at lower and higher ^S_SpH values, where the **4**:Zn(II)$_2$ complex that is substantially devoid of alkoxide or has more than one alkoxide apparently decomposes during the timescale of the experiment.

In an analogous way, the kinetic ^S_SpK_a values were determined for **4**:Zn(II)$_2$ in methanol from the reaction of **4**:Zn(II)$_2$:($^-$OCH$_3$) with **1g** conducted at 25 °C in methanol as described in the Experimental above. The fit of the bell-shaped data set enclosed in the dotted box of Fig. 1 gave two ^S_SpK_a values of 9.38 ± 0.07 and 9.80 ± 0.06.

Discussion

General considerations

Earlier studies of the cyclization of **1a**–**1g** promoted by **3**:Zn(II)$_2$($^-$OR) in methanol[9] and ethanol[14] were interpreted in terms of the general process illustrated in Scheme 1 involving at least two binding events, followed by one or more chemical steps that released the observed phenol product of the reaction. The binding steps were proposed to involve phosphate diester association with one metal followed by a rearrangement where it becomes doubly activated via binding to the second metal ion. The chemical step was considered to involve internal deprotonation of the 2-hydroxyl group followed by cyclization with expulsion of the aryloxy leaving group. The major difference between methanol and ethanol was the very much stronger binding of the anionic alkoxide and substrate to the complex in ethanol. Thus, for the process in Scheme 2, the first substrate binding step (k_1/k_{-1}) is very much larger in ethanol. The findings with **4**:Zn(II)$_2$ in the present study are consistent with this general scheme.

Table 2. Maximum catalytic rate constant ($k_{cat}^{max\ corr}$), for the **4**:Zn(II)$_2$:($^-$OCH$_2$CH$_3$)-catalyzed reactions, second order rate constants for the ethoxide-promoted reactions (k_2^{OEt}),[14] and accelerations of cleavage provided for bound **1a–1g** at ^S_SpH 9.0 in ethanol at 25 ± 0.1 °C.

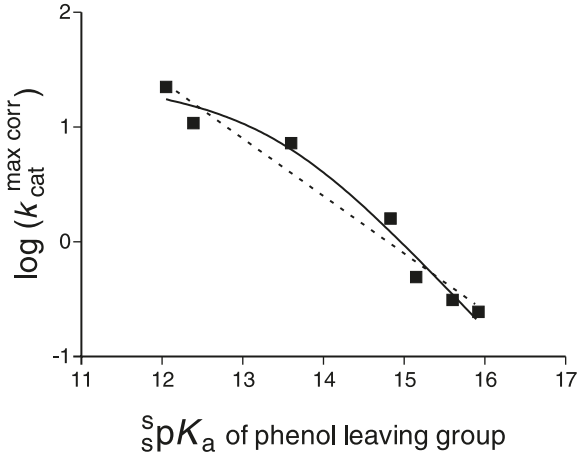
1e	15.15	0.50±0.02	3.7×10^{-7} [c]	1.7×10^{16}
1f	15.60	0.31±0.01	1.4×10^{-7} [c]	2.8×10^{16}
1g	15.92	0.25±0.01	7.4×10^{-8} [c]	4.2×10^{16}

[a] k_{cat}^{max} values are determined as described in text by fitting the k_{cat}^{corr} vs [**4**:Zn(II)$_2$:($^-$OCH$_2$CH$_3$)] data to eq. [S1], Supplementary data.

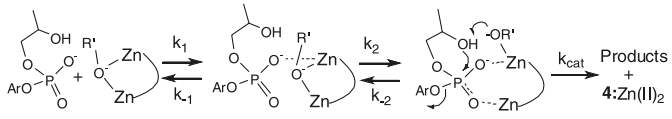
[b] Acceleration was calculated at ^S_SpH 9.0 in ethanol, which corresponds to $10^{(-19.1+9.0)}$ mol/L of ethoxide. For example, for substrate **1c** the acceleration = 7.3 s^{-1}/[($10^{-10.1}$ mol/L) × (9.7 × 10^{-6} (mol/L)$^{-1}$ s^{-1})] = 9.5 × 10^{15}.

[c] k_2^{OEt} values for the base promoted reactions of the less reactive substrates (**1e–1g**) were estimated from the linear regression equation for the Brønsted plot in Fig. 1 of ref. 14.

Fig. 5. Brønsted plot of log ($k_{cat}^{max\ corr}$) vs the $^S_S pK_a$ values of the corresponding phenol leaving groups for the **4**:Zn(II)$_2$:($^-$OCH$_2$CH$_3$)-catalyzed cleavage of **1a–1g** in absolute ethanol at 25 °C. The line was constructed by NLLSQ fitting all the data to an expression $k_{cat}^{max\ corr} = k_1k_2 / (k_{-1} + k_2) = C_1C_2 10^{(\beta 1+\beta 2)pK_a}/(C_{-1}10^{\beta -1 pK_a} + C_2 10^{\beta 2 pK_a})$.[22] The two fitted β values are –0.76 and –0.10, r^2 = 0.9768, with a point of transition at $^S_S pK_a$ = 14.3. The linear regression of the data (dotted line) has a gradient of –0.50 ± 0.05, r^2 = 0.9537 (7 data).



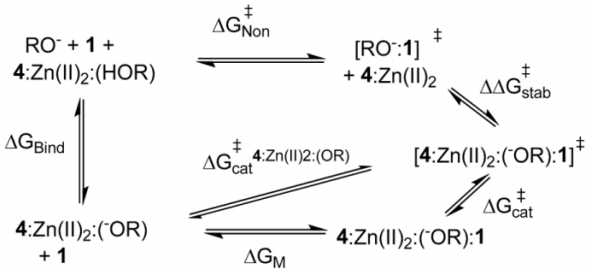
Scheme 2. R′ = CH$_3$ or CH$_2$CH$_3$



4:Zn(II)$_2$:($^-$OCH$_3$)-promoted cleavage of 1a–1g in methanol

The k_{obs} versus catalyst concentration profiles for catalyzed cleavage of phosphates **1a–1g** of both **3**:Zn(II)$_2$ and **4**:Zn(II)$_2$ complexes show the same trend of being linear for substrates containing good leaving groups (**1a–1c**, e.g., Fig. 2) and downward curved for substrates with poorer leaving groups (**1e–1g**, e.g., Fig. 3). Unfortunately, due to the combination of poorer solubility and a greater triflate inhibition

Scheme 3. Thermodynamic cycle for assessing the binding energy of catalyst **4**:Zn(II)$_2$ to a hypothetical transition state comprising alkoxide and substrate.



for **4**:Zn(II)$_2$ than **3**:Zn(II)$_2$, the concentration range over which the former's catalytic activity could be investigated was limited, which introduces considerable error into the calculated k_{cat}^{max} and K_M values given in Table 1. Nevertheless, it appears that **4**:Zn(II)$_2$:($^-$OCH$_3$) is slightly less catalytically active than its lower homologue and binds slightly weaker with phosphates **1e–1g** than does **3**:Zn(II)$_2$:($^-$OCH$_3$) in methanol, although the differences for substrates where saturation behaviour is observed are not large. When comparing the maximum rate constants (k_{cat}^{max}) for the bound substrates **1e–1g**, a given reaction promoted by **3**:Zn(II)$_2$ is about 3–5 times faster than that with **4**:Zn(II)$_2$. In this case, the shift from a rate-limiting binding process (for **1a–1c**) to a rate-limiting chemical process (for **1e–1g**) seems to occur around substrate **1d** (see the Supplementary data).

The Brønsted plot (not shown) of the observed k_2 or computed k_{cat}^{max}/K_M values for the entire series of substrates gives a poorly defined linear regression, log(k_2) = –(0.28 ± 0.05) $^S_S pK_a$ + (7.41 ± 0.70) (r^2 = 0.84, 7 data). This can be compared with what was found for the **3**:Zn(II)$_2$:($^-$OCH$_3$) reaction, log k_{cat}^{max} = (–0.97 ± 0.05) $^S_S pK_a$ + (14.36 ± 0.57), and with the regression of the CH$_3$O$^-$-promoted reaction, log(k_2^-OMe) = (–0.72 ± 0.08) $^S_S pK_a$ + (5.36 ± 1.08).[9] In the case of the C$_3$ catalyst, the larger negative β_{lg} is consistent with a rate limiting step where there substantial cleavage of the P–OAr bond. The apparent reduced value of the β_{lg} observed for the catalyzed reaction promoted by **4**:Zn(II)$_2$:($^-$OCH$_3$) indicates a more modest dependence on

Table 3. Summary of the ($k_{cat}^{max}/K_M/k_2^{-OR}$ constants and the computed free energies for the formation of catalytic complexes ($\Delta G_{Bind} - \Delta G_M$), the free energies of activation for k_{cat}^{max} ($\Delta G_{cat}^{\ddagger}$), and the free energies of stabilization of the RO^-:**1** transition state through its binding to **4**:Zn(II)$_2$ ($\Delta\Delta G_{stab}^{\ddagger}$) as in the reaction of **4**:Zn(II)$_2$:($^-$OR) with substrates **1a**–**1g** at 25 °C in methanol (M) and ethanol (E).

[a]Kinetic first $^{S}_{S}pK_a$ in methanol determined as in the Experimental section to be $10^{-9.38}$; $K_W^{methanol} = 10^{-16.77}$; $(K_a/K_w)^M = 2.5 \times 10^7$; $\Delta G_{Bind}^{MeOH} = -10.1$ kcal/mol. Kinetic first $^{S}_{S}pK_a$ in ethanol is $10^{-8.48}$; $K_W^{ethanol} = 10^{-19.1}$; $(K_a/K_w)^E = 4.16 \times 10^{10}$; $\Delta G_{Bind}^{EtOH} = -14.5$ kcal/mol.

[b]Computed as $(\Delta G_{Bind} - \Delta G_M) = -RT\ln((K_a/K_w)/K_M)$.

[c]Computed from $\Delta G_{cat}^{\ddagger} = -RT\ln(k_{cat}^{max}/(kT/h))$ or $\Delta G_{Non}^{\ddagger} = -RT\ln(k_2^{-OR}/(kT/h))$ from the Eyring equation where $(kT/h) = 6 \times 10^{12}$ s^{-1} at 298 K.

[d]k_{cat}^{max} and K_M values for substrates **1e**–**1g** from Table 1 and 2; k_2 values for substrates **1a**–**1d** from Table 1 determined as gradients of the k_{obs} vs [**4**:Zn(II)$_2$:($^-$OCH$_3$)]$_{free}$ plots. k_2^{-OMe} and k_2^{-OEt} values from refs. 9 and 14.

[e]$\Delta\Delta G_{stab}^{\ddagger}$ computed from application of kinetic and equilibrium constants to eqs. [3] and [4].

the nature of the leaving group, and is consistent with the mechanism shown in Scheme 1 where there is relatively little cleavage of the P–OAr bond in the cases where the chemical steps are rate limiting. This could be indicative of a stepwise cleavage reaction where there is little change in the P–OAr bonding in a rate limiting cyclization step forming a phosphorane intermediate or alternatively to a concerted process with an early transition state having a component of the intramolecular rearrangement. Possibly due to the increased flexibility of the longer linker chain, this rearrangement process is slower for **4**:Zn(II)$_2$:($^-$OCH$_3$) than **3**:Zn(II)$_2$:($^-$OCH$_3$) as evidenced by the k_2 values (Table 1) for **1a** and **1b** of 21 000 and 15 000 (mol/L)$^{-1}$s^{-1}, respectively, which are 13 times lower than observed for those same substrates when reacted with **3**:Zn(II)$_2$:($^-$OCH$_3$) (275 000 and 194 000 (mol/L)$^{-1}$s^{-1}, respectively[9]).

4:Zn(II)$_2$:($^-$OCH$_2$CH$_3$)-promoted cleavage of 1a–1g in ethanol

The findings for **4**:Zn(II)$_2$-promoted cleavage of **1a**–**1g** in ethanol are very similar to those found for **3**:Zn(II)$_2$ in ethanol.[14] Following correction of the kinetic data for triflate inhibition (as described in ref. 14) the plots of k_{obs}^{corr} versus [**4**:Zn(II)$_2$:($^-$OCH$_2$CH$_3$)]$_{total}$ for all substrates showed very strong binding behavior illustrated in Fig. 4. Due to the strong binding, exact determination of the K_M values is not possible, so an iterative procedure was used[14] where the K_M was held constant, but varied until the goodness-of-fit was optimized. This upper limit for the K_M value for all substrates, defined as the dissociation constant for the **4**:Zn(II)$_2$:($^-$OCH$_2$CH$_3$):**1** Michaelis complex, is $\sim 10^{-7.5}$ mol/L (3.2×10^{-8} mol/L).

The Brønsted plot of log($k_{cat}^{max\ corr}$) versus the $^{S}_{S}pK_a$ of the corresponding phenols of **1a**–**1g** is shown in Fig. 5. Due to the rather scattered nature of the $k_{cat}^{max\ corr}$ data, we cannot distinguish with certainty whether the plot is linear (dotted line suggestive of a single step being rate limiting with $\beta_{lg} = 0.5$) or a downward curving line suggestive of a change in rate limiting step for the $k_{cat}^{max\ corr}$ term. The latter would be consistent with what was proposed for the **3**:Zn(II)$_2$:($^-$OCH$_2$CH$_3$) system in ethanol where there was a transition from substrate binding being rate limiting for substrates with good leaving groups, and chemical cleavage being rate limiting for substrates with poorer leaving groups.[14] The line through the data in Fig. 5 is obtained by NLLSQ fitting to the equation given in the caption[22] depending on the two β values of –0.76 ± 0.33 for poor leaving groups, and –0.1 ± 0.69 for good leaving groups. Although the parameters, particularly the latter one, are poorly defined in the fit, the β_{lg} value of –0.1 suggests that the rate limiting step for this process does not involve much change in the POAr bonding as would expected for a process such as depicted in Scheme 1 involving a rate limiting rearrangement step.[14] The data also support the contention that the rearrangement process for **4**:Zn(II)$_2$:($^-$OCH$_2$CH$_3$) is about 10 times slower than that for **3**:Zn(II)$_2$:($^-$OCH$_2$CH$_3$) since the respective $k_{cat}^{max\ corr}$ values of substrates **1a** and **1b** are 22 and 11 s^{-1} for the C$_4$ catalyst and 168 and 133 s^{-1} with the C$_3$ catalyst, respectively.

Energetics of 4:Zn(II)$_2$:($^-$OR) catalyzed cleavages of 1a–1g in methanol and ethanol

One can quantify the catalytic efficiency by calculating the difference in energy of a transition state containing only [RO$^-$:**1**], and one where the latter is bound to the catalyst[23] to form a hypothetical transition state [**4**:Zn(II)$_2$:($^-$OR):**1**]‡ or its kinetic equivalent [**4**:Zn(II)$_2$:($^-$**1**)]‡. Presented in Scheme 3 is a thermodynamic cycle involving both the alkoxide reaction and the **4**:Zn(II)$_2$:($^-$OR) promoted reactions of **1a–1g**. Equation [3] provides the free energy difference ($\Delta\Delta G^{‡}_{stab}$) between [**4**:Zn(II)$_2$:($^-$OR):**1**]‡ relative to [RO$^-$:**1**]‡. In Scheme 2, ΔG_{Bind}, $\Delta G^{‡}_{cat}$ and $\Delta G^{‡}_{Non}$ are the respective free energies for (1)

$$[3]\qquad \Delta\Delta G^{\neq}_{stab} = (\Delta G_{Bind} - \Delta G_M + \Delta G^{\neq}_{cat}) - \Delta G^{\neq}_{Non} = -RT\ln\left[\frac{(k_{cat}/K_M)(K_a/K_w)}{k_2^{-OR}}\right]$$

$$[4]\qquad \Delta\Delta G^{\neq}_{stab} = \left(\Delta G_{Bind} + \Delta G^{\neq \mathbf{4}:Zn(II)_2:(-OR)}_{cat}\right) - \Delta G^{\neq}_{Non} = -RT\ln\left[\frac{(k_2^{obs})(K_a/K_w)}{k_2^{-OR}}\right]$$

methoxide binding to **4**:Zn(II)$_2$, (2) the free energy of activation for unimolecular reaction of the **4**:Zn(II)$_2$:($^-$OR):**1** complex or its kinetic equivalent, and (3) the free energy of activation for the reaction of alkoxide with **1**. ΔG_M is the free energy for association of **1** and **4**:Zn(II)$_2$:($^-$OR) computed from the Michealis constant for each substrate in either solvent. In eq. [4] is the free energy calculation specific for the reactions with **1a–1d** in methanol that show only a first order dependence on [**4**:Zn(II)$_2$:($^-$OCH$_3$)]$_{free}$ throughout the concentration range investigated. The various terms in eqs. [3] and [4] are described in earlier publications.[9,14] K_a/K_w can be readily shown to be formally equivalent to the binding constant of alkoxide to the dinuclear complex **4**:Zn(II)$_2$ to form **4**:Zn(II)$_2$:($^-$OR). K_a refers to the first acid dissociation constant of **4**:Zn(II)$_2$:(HOR), determined from the kinetic $^{S}_{SP}K_a$ studies above as $10^{-8.48}$ in ethanol and $10^{-9.38}$ in methanol, and K_w is the autoprotolysis constant for ethanol ($10^{-19.1}$) and methanol ($10^{-16.77}$). Finally, k_2^{-OR} is the second order rate constant for the methoxide[9] and ethoxide[14] reactions of each substrate.

Listed in Table 3 are the $k_{cat}/K_M/k_2^{-OR}$ (or $k_2^{\mathbf{4}:Zn(II)_2:OMe}/k_2^{-OR}$) constants and computed ΔG_{Bind}, ΔG_M, ΔG_{cat}, ΔG_{Non}, and $\Delta\Delta G^{‡}_{stab}$ values for the various processes described in Scheme 2 for the complex and alkoxide catalyzed and reactions of **1**; all values were computed at the standard state of 1 mol/L and 25 °C. The first ratio provides the acceleration in second order rate constant for the complex catalyzed reactions relative to the alkoxide reactions, while the various ΔG values, when inserted into eqs. [3] and [4], provide the free energy of stabilization ($\Delta\Delta G^{‡}_{stab}$) of the complex catalyzed reaction relative to the methoxide reaction. Of these constants, the K_a/K_w terms contributes –10.1 and –14.5 kcal/mol while the ($\Delta G_{Bind} - \Delta G_M$) term contributes approximately –15 and –24.5 kcal/mol in methanol and ethanol, respectively, to the $\Delta\Delta G^{‡}_{stab}$ for the series. This means that in the less polar solvent, the binding of both alkoxide and substrate to the **4**:Zn(II)$_2$ complex is more exergonic. In the two solvents, the $k_{cat}/K_M/k_2^{-OMe}$ term contributes –11.0 to –13.2 kcal/mol in methanol and approximately –17 to –19 kcal/mol in ethanol, with the slowest reacting substrates having the more negative values. These numbers give the energetic reduction of the catalyzed apparent second order rate constant for the **4**:Zn(II)$_2$ promoted reactions relative to the alkoxide reactions.

Conclusions

The rate constants and energetics for the cyclizations of **1a–1g** promoted by **4**:Zn(II)$_2$ found in this study invite comparison with what was found recently for the same cyclization reactions catalyzed by **3**:Zn(II)$_2$ in both methanol[9] and ethanol.[14] In methanol, **4**:Zn(II)$_2$ is somewhat more fragile than **3**:Zn(II)$_2$ as is judged from the kinetic stability as a function of time. Whereas **3**:Zn(II)$_2$ retains good activity for nearly one day, the activity of **4**:Zn(II)$_2$ diminishes after about 10 h. Additionally, **4**:Zn(II)$_2$ suffers from a somewhat reduced solubility in methanol and a larger triflate ion inhibition, which reduces the overall concentration range over which the study can be conducted. Although we have determined that **4**:Zn(II)$_2$ can promote cleavage of the DNA models **2** with appreciable rate accelerations, the above technical factors prevent determination of meaningful binding and k_{cat} constants for the entire series that was investigated with **3**:Zn(II)$_2$ in methanol.[8,10]

In spite of these difficulties, it appears that the overall mechanism by which **4**:Zn(II)$_2$ cleaves **1** is similar to what we proposed to be operative for **3**:Zn(II)$_2$. From the available data in Table 1 above and the comparable data in Table 4 of ref. 9, the k^{max}_{cat} and K_M terms for both catalysts are similar for substrates where the chemical steps are rate limiting (**1e–1g**), although the binding of the C_4 catalyst for these slower reacting substrates is slightly weaker. On the other hand, the apparent second order rate constants for those substrates that do not show saturation kinetics, and where the rate limiting step is proposed to be a nonchemical one, such as substrate binding and translocation (**1a–1d**), is about one order of magnitude less than was seen for **3**:Zn(II)$_2$. Perhaps this is a consequence of the flexibility of the system, which resists the putative intramolecular rearrangement to reposition the first bound substrate complex into a doubly-activated complex as shown in Scheme 1.

In ethanol, both catalysts display very strong binding for which only upper limits can be set for the dissociation of the Michaelis complex ($10^{-7.5}$ and $10^{-6.5}$ mol/L, respectively, for **4**:Zn(II)$_2$ and **3**:Zn(II)$_2$). The apparent greater binding constant for the C_4 complex relative to the C_3 complex probably cannot be considered significant given that the determination of the K_M values in each case gave only an upper limit for the dissociation constant. When comparing the data obtained with the C_4 catalyst in this study with that disclosed in Table 3 of ref.14 for the C_3 catalyst, the ($\Delta G_{Bind} - \Delta G_M$) term, which refers to the composite energy of binding of the ethoxide and substrate to the catalyst, is nearly the same for each catalyst (only about ~0.4 kcal/mol less for the C_3 complex than the C_4 complex). This results from an apparent stronger binding of the phosphate substrate to the C_4 catalyst compensated by weaker binding of ethoxide. What is interesting is the k^{max}_{cat} values for the various substrates are about 5–20 times less for the C_4 complex relative to the C_3 com-

plex, which translates into about 1 to 1.6 kcal/mol increase in the ΔG_{cat} activation energy for the C_4 catalyst. It is likely that this stems from a less tightly bound substrate/catalyst complex at the transition state for the C_4 catalyzed process, perhaps suggesting that flexibility, while required for the initial strong catalyst:substrate binding, has a deleterious effect on the transition state for the catalyzed reaction.

(16) For the designation of pH in nonaqueous solvents we use the forms recommended by: IUPAC (International Union of Pure and Applied Chemistry). *Compendium of Analytical Nomenclature. Definitive Rules 1997,* 3rd ed.; Blackwell: Oxford, UK, 1998. If one calibrates the measuring electrode with aqueous buffers and then measures the pH of an aqueous buffer solution, the term ${}^{W}_{W}pH$ is used; if the electrode is calibrated in water and the pH of the neat buffered alcohol solution measured, the meter reading gives ${}^{S}_{W}pH$; if the electrode is calibrated in the same solvent and the pH reading is made, then the term ${}^{S}_{S}pH$ is used. Since the autoprotolysis constant of methanol and ethanol are $10^{-16.77}$ and $10^{-19.1}$, neutral ${}^{S}_{S}pH$ is 8.38 and 9.55, respectively.

Chiral α-substituted allylboronates in a one-pot three-component asymmetric allylic alkylation/carbonyl allylation reaction sequence — Applications to the syntheses of (+)-(3*R*,5*R*)-3-hydroxy-5-decanolide and (–)-massoialactone

Abstract: The use of different organomagnesium reagents in the copper-catalyzed allylic alkylation of 3-chloropropenyl boronates with chiral phosphoramidite ligands produces the desired α-substituted allylic boronate reagents in high regioselectivity and with modest to high enantioselectivities (up to 96% ee). The size of the incoming alkyl substituent from the organomagnesium reagent was found to impact the yield and selectivity of the allylic alkylation. A one-pot procedure for the preparation of these chiral allylic boronates followed by a Lewis acid (BF_3) catalyzed addition to aldehydes delivers the desired allylboration products, homoallylic secondary alcohols, in good yields and very high diastereoselectivity. This three-component reaction methodology was applied to the syntheses of two lactone-containing natural products, (–)-massoialactone and (+)-(3*R*,5*R*)-3-hydroxy-5-decanolide. The key step of these syntheses involved the one-pot enantioselective copper-catalyzed allylic alkylation/allylboration reaction with a benzylic aldehyde, and afforded the desired product in 87% yield, 92% ee, and high *E*/*Z* selectivity in a ratio of 22:1. Remarkably, the allylic alkylation step of this sequential reaction was performed with a low catalyst loading of 2 mol% on a scale of >15 mmol that can provide multiple grams of the three-component product.

Key words: allylboration, allylic alkylation, boronic esters, carbonyl allylation, copper catalysis.

Résumé : L'utilisation de divers réactifs organomagnésiens dans une réaction d'alkylation allylique des boronates 3-chloropropénylés catalysée par le cuivre et un ligand chiral de type phosphoramidite produit les réactifs boronates allyliques α-substitués avec une haute régiosélectivité et une enantiosélectivité variant de modeste à élevée (jusqu'à 96 % ee). Il fut observé que la grosseur du substituant alkyle sur le réactif organomagnésien joue un rôle déterminant sur le rendement chimique et la sélectivité de l'alkylation allylique. Une procédure réactionnelle de type « one-pot » pour la préparation des boronates allyliques chiraux est suivie d'une addition sur les aldéhydes catalysée par un acide de Lewis (BF_3) qui mena aux produits désirés d'allylboration, les alcools secondaires homoallyliques, avec un bon rendement chimique et une diastereoselectivité très élevée. Cette réaction à trois-composants fut par la suite appliquée à une synthèse de deux produits naturels, la (–)-massoialactone and la (+)-(3*R*,5*R*)-3-hydroxy-5-decanolide. L'étape-clé de ces synthèses impliqua la réaction « one-pot » catalytique énantioselective d'alkylation allylique/allylboration avec un aldehyde benzylique, produisant le produit désiré dans un rendement chimique de 87 %, avec un ee de 92 % et une sélectivité *E*/*Z* élevée dans un ratio de 22 :1. Il est remarquable de constater que l'étape d'alkylation allylique de cette réaction séquentielle fut réalisée avec une faible charge catalytique de 2 mol% sur une échelle supérieure a 15 mmol qui permet d'isoler plusieurs grammes du produit de réaction à trois-composants.

Mots-clés : alkylation allylique, allylation de composés carbonylés, allylboration, catalyse du cuivre, esters boroniques.

Introduction

Over the past three decades, additions of allylic boron reagents have undergone tremendous developments and have emerged as one of the most powerful methods for stereoselective C–C bond formation.[1] In additions of allylic boron reagents to achiral aldehydes, three strategies were set forth to provide control of the enantiofacial selectivity of the reaction: (1) the use of "B-chiral" allylic boranes and boronates where the two nonallylic substituents on the boron are chiral directors such as terpene units,[2] a chiral diol,[3] or a chiral diamine;[4] (2) the use of a chiral Lewis or Brønsted acid catalyst with achiral reagents;[5] and (3) the use of optically pure α-substituted allylboronates of type **1**,[6] also called "C-chiral" or "α-chiral" allylboronates. Amongst these methods, the use of B-chiral allylic boron reagents has been in use for a long time and is still the method of choice even though it is far from ideal, as it uses a stoichiometric amount of chiral directors. Nevertheless, this class of reagents has been widely

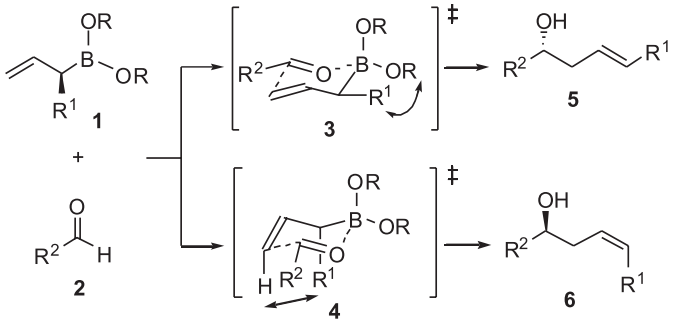
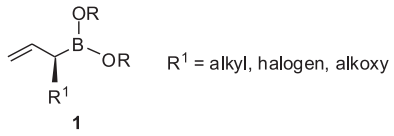
Fig. 1. Possible transition structures in additions of α-substituted allylboronates **1** to aldehydes.



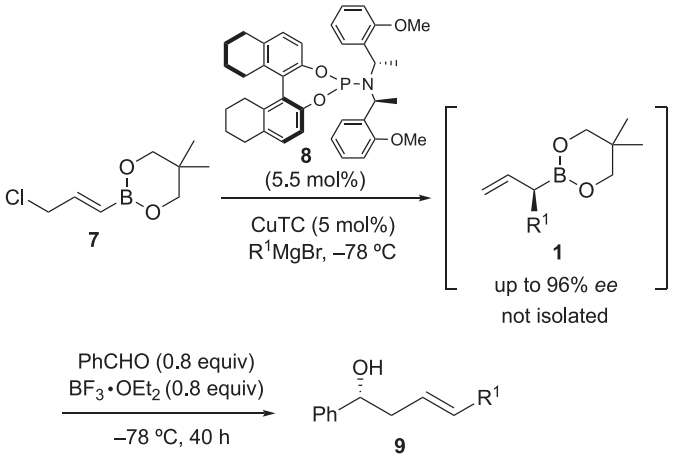
used in the synthesis of acetate and propionate units found in numerous polyketide natural products.[1b] In contrast, chiral α-substituted allylboronate reagents of type **1** have undergone modest development and applications, which is likely due to their stepwise preparation and the difficulty to control the enantiofacial selectivity of their additions to carbonyl compounds.



Selectivity with α-substituted allylboronates

Hoffmann and co-workers[6] have demonstrated that the reagent-controlled additions of optically enriched α-substituted allylboronates (**1**) to achiral aldehydes (**2**) proceed with near perfect transfer of chirality from the chiral reagent to the allylic alcohol product. As seen in Fig. 1, the two possible transition states lead to diastereomeric homoallylic alcohol products, **5** and **6**, which have opposite stereochemistry at the alcohol center and opposite alkene geometry. Hence, the *E*/*Z* proportion in the reaction products mirrors the enantioselectivity of the reaction process.[6] The proportion of *E* and *Z* diastereomers is dependent on the nature of the α-substituent and on the structure of the boronic ester. The selectivity between transition states **3** and **4** can be explained in terms of dipolar effects and steric effects. With a nonpolar α-substituent (R^1) such as an alkyl group, steric effects are dominant. It is known that the use of a nonpolar α-substituent leads to mixtures of products **5** and **6** with a modest selectivity for product **5**. In fact, there are unfavorable interactions in both transition states. In the chairlike transition structure, **3**, the unfavorable nonbonding interactions between the boronic ester and the pseudo-equatorial α-substituent (R^1) can be aggravated by the use of a large boronic ester or a bulky α-substituent.[7] In contrast, transition structure **4**, with the α-substituent at the pseudo-axial position, suffers from 1,3-allylic strain between the α-substituent and the pseudo-axial olefinic hydrogen. One transition state can be favored over the other by changing the size of the boronic ester.[7] Hence, the use of the bulky pinacol boronic ester will provide a modest selectivity for transition state **4** leading to the *Z* isomer **6**. On the other hand, the use of the smaller 2,2-dimethyl-1,3-propanediol boronic ester provides selectivity for transition state **3** leading to the *E* isomer **5**.[7] Furthermore, the use of Lewis or Brønsted acid catalysis can provide improved selectivity for the *E* isomer.[8] Recent density functional theory (DFT) calculations by Sakata and Fujimoto[9] have shown that under Lewis acid activation, the transition state displays a shorter B–O bond and a longer B–C bond with the aldehyde. Compared to the uncatalyzed reaction, this longer B–C bond alleviates the unfavorable steric interactions between the boronic ester and the α-substituent in transition state **3**. As a result, the use of Lewis acid catalysis can afford high selectivity for the *E* isomer even with the bulky pinacol boronic ester.[8]

Scheme 1. Optimal conditions for the one-pot three-component allylic alkylation/aldehyde allylation with substrate **7** and exemplified with benzaldehyde.



Enantioselective approaches to α-substituted allylboronates

The preparation of α-substituted allylboron reagents is limited to the more stable allylic boronic esters because allylic dialkyl boranes undergo a rapid 1,3-borotropic shift at and below ambient temperatures.[1e,10] Hoffmann and co-workers[6] pioneered the preparation and applications of acyclic optically enriched α-substituted allylboronates. Equations [1]–[4] show examples of preparative methods for chiral α-substituted allylic boronates (pin = $OCMe_2CMe_2O$). Until the mid-1990s, methods to access these reagents were limited to the asymmetric Matteson homologation reaction using a stoichiometric chiral directing group,[11] which may subsequently be exchanged through a transesterification reaction (eq. [1]). Recently, additional methods to access chiral α-substituted allylboronates were reported. For example, a [3,3] sigmatropic rearrangement reaction of chiral 3-hydroxy propenyl boronates was developed (eq. [2]).[12] The ideal approach would be catalytic and would avoid the use of stoichiometric chiral directors. Such methods were also reported and include the use of a palladium-catalyzed enantioselective diboration of allenes (eq. [3]),[13] and the use of a copper-catalyzed enantioselective allylic substitution of allylic carbonates with diboron reagents (eq. [4]),[14a,14b] or an iridium-catalyzed variant.[14c]

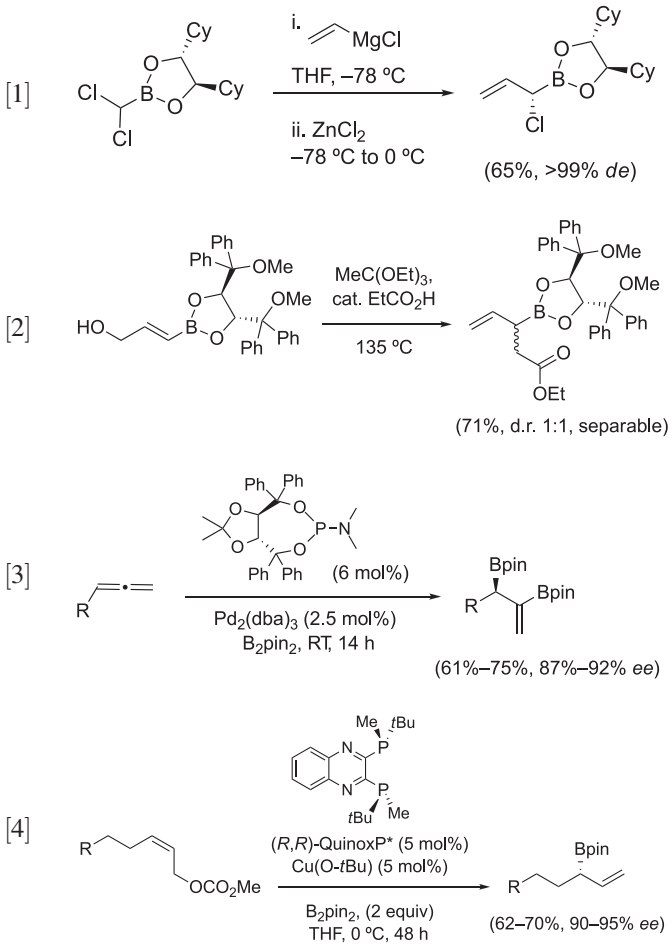


Table 1. Exploration of the scope of the Grignard reagent with **7** under the optimal conditions of Scheme 1.

[b]Measured by ^1H NMR spectroscopy of an aliquot of the crude reaction mixtures.

[c]Measured by chiral HPLC of isocyanate derivatives (**11**) of oxidation products (**10**) of boronates (**1**) as shown in the above scheme.

In 2007, we reported a new preparative method based on a copper-catalyzed enantioselective allylic substitution reaction (Scheme 1).[15] We were able to employ the resulting chiral α-substituted allylboronates (**1**) in a one-pot sequential protocol initiated by the enantioselective copper-catalyzed allylic alkylation and followed by an aldehyde allylation. The optimal combination of alkenylboronate (**7**) and chiral phosphoramidite (**8**)[16] led to reagent **1** with up to 96% ee.

This protocol resulted in a new enantioselective multicomponent route to homoallylic alcohols. Even though the preliminary communication included the scope and limitations of the three-component reaction sequence with regards to the aldehyde, it provided little information on the scope of the alkyl α-substituent (i.e., the organomagnesium reagent). Herein we report on the scope of the reaction with regards to the alkyl α-substituent, and on the application of this methodology to the synthesis of two small α-lactone natural products.

Results and discussion

Reaction scope

Our preliminary results on the nature of the Grignard reagent had indicated that the size of the organomagnesium alkyl group had an important effect on the enantioselectivity of the allylic substitution reaction.[15] To further investigate this trend, we prepared aliphatic Grignard reagents with various size and length. We then used these reagents in the allylic substitution reaction with the 3-chloropropenyl boronate (**7**) using our previously optimized reaction conditions. The outcome of this study is summarized in Table 1. In this initial study, the enantioselectivity was measured on carbamate derivatives (**11**), which were obtained from the boronate oxidation products (**10**). It is well-established that this oxidation process occurs with near perfect retention of stereochemistry.[17] Because of the volatility of alcohols **10**, no yields were compiled for this derivatization process.

We found that the use of linear organomagnesium reagents allow for a higher level of enantioselectivity. The length of the alkyl chain also affects the S_N2'/S_N2 regioselectivity and the level of enantioselectivity. The short ethylmagnesium bromide reagent afforded the best enantioselectivity, giving **1a** with 96% ee (Table 1, entry 1), whereas the longer butylmagnesium or pentenylmagnesium bromide provided very good, albeit lower enantioselectivity (Table 1, entries 2–3). On the other hand, the bulkier cyclohexylmagnesium bromide gave a much lower level of enantioselectivity (Table 1, entry 4). With this data in hand, we set out to gain information on the behavior of the chiral α-substituted allylboronates in their additions to aldehydes. Performing the one-pot allylic alkylation/aldehyde allylation protocol with our previously optimized reaction conditions allowed us to verify the efficiency of the chirality transfer

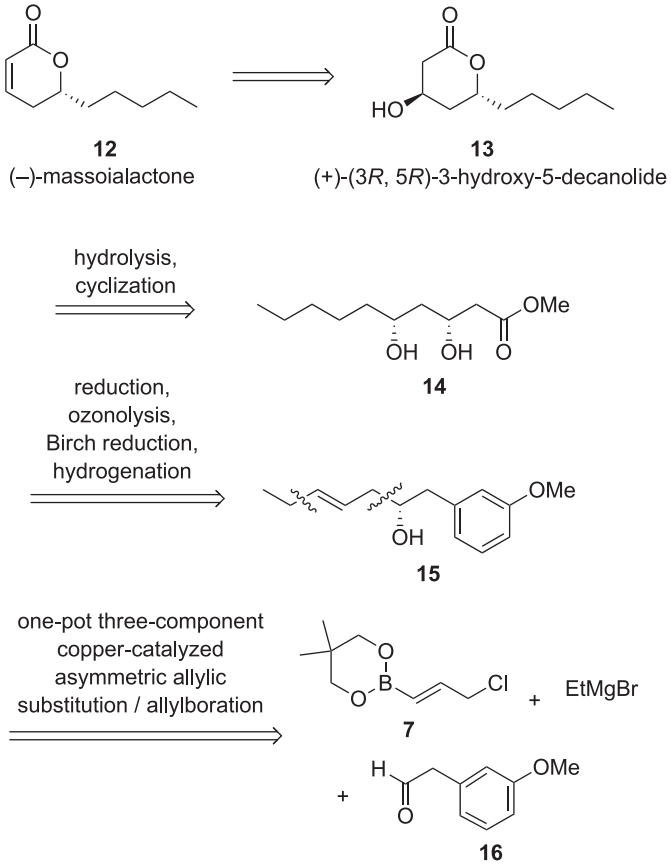
from reagents **1a**–**1d** to the homoallylic alcohol products **9a**–**9d**. Indeed, the enantioselectivity level found in the chiral α-substituted allylboronates (Table 1) was representative of that found in the benzaldehyde allylation products (Table 2). Larger α-substituents proved to be favorable in providing high selectivity for the *E* isomer. Unfortunately, the overall efficiency of the transformation was negatively affected by the use of larger α-substituents as lower yields were obtained with the butylmagnesium, pentenylmagnesium, and cyclohexylmagnesium bromides (respective products are **9b**–**9d** in Table 2, entries 2–4). Small amounts of the undesired allylic alcohol products resulting from the 1,3-borotropic shift of the allylboronates, followed by aldehyde allylboration, were found in these cases. Trombini and co-workers[18] had found that with α-substituted allylboronates, the nature of the boronic ester has a big influence on the propensity of the 1,3-borotropic shift to take place. For instance, the 2,2-dimethyl-1,3-propanediol boronic ester is known to undergo this shift more easily than the corresponding pinacol ester. Nevertheless, as demonstrated with the preparation of **9a** from reagent **1a** (Table 2, entry 1), our approach to homoallylic alcohols via a one-pot enantioselective copper-catalyzed allylic alkylation/aldehyde allylation reaction sequence allows for high selectivity of the desired products (**9**) in good yield from two steps.

Application to the synthesis of lactone natural products

Our next objective was to demonstrate the versatility of this methodology with an application in target-oriented synthesis. As targets, we selected two naturally occurring δ-lactones: (+)-(3*R*,5*R*)-3-hydroxy-5-decanolide

Scheme 2. Retrosynthesis of (–)-massoialactone from (+)-(3*R*,5*R*)-3-hydroxy-5-decanolide using the one-pot three component allylic alkylation/aldehyde allylation.



and (–)-massoialactone (**13** and **12** in Scheme 2). (+)-(3*R*,5*R*)-3-Hydroxy-5-decanolide was isolated in 1971 from the culture liquor of the fungus *Cephalosporium recifei* NRRL 5161.[19] This metabolite is part of the *trans*-β-hydroxy-δ-lactone family, which is known to inhibit the enzyme HMG-CoA reductase, thus it is potentially a cholesterol-lowering agent.[20] (–)-Massoialactone's structure is related to (+)-(3*R*,5*R*)-3-hydroxy-5-decanolide's structure as it lacks the 3-hydroxy group, which is replaced by the α,β-unsaturation. (–)-Massoialactone has antibacterial and antifungal activity,[21] it is a skin irritant, and can be isolated from many different natural sources. Abe[22] first isolated (–)-massoialactone in 1937 from the bark oil of *Cryptocarya massoia*, an oil used for centuries in native medicine. It was found to be the defense secretion of two species of formicin ants of the genus *Camponotus* found in western Australia.[23] Numerous syntheses of both (+)-(3*R*,5*R*)-3-hydroxy-5-decanolide and (–)-massoialactone have been reported.[24] As well, separate syntheses for (+)-(3*R*,5*R*)-3-hydroxy-5-decanolide[25] or for (–)-massoialactone[26] have been published. Various strategies were used to introduce chirality, including stereoselective reduction with Baker's yeast,[24a,24b,25a] enzymatic lactonization,[24d] dynamic kinetic resolution of starting material,[26c] metal-catalyzed enantioselective reduction,[26e] allylboration with a chiral auxiliary,[26a] and simply using the chiral pool.[24c, 24e, 24f, 26b, 26d, 26f] Amongst all those strategies, the most efficient synthesis

For personal use only.

of (–)-massoialactone to date features the chiral auxiliary directed allylboration reaction as the key initial step followed by esterification and ring closing metathesis providing (–)-massoialactone with an overall yield of 49%.[26a]

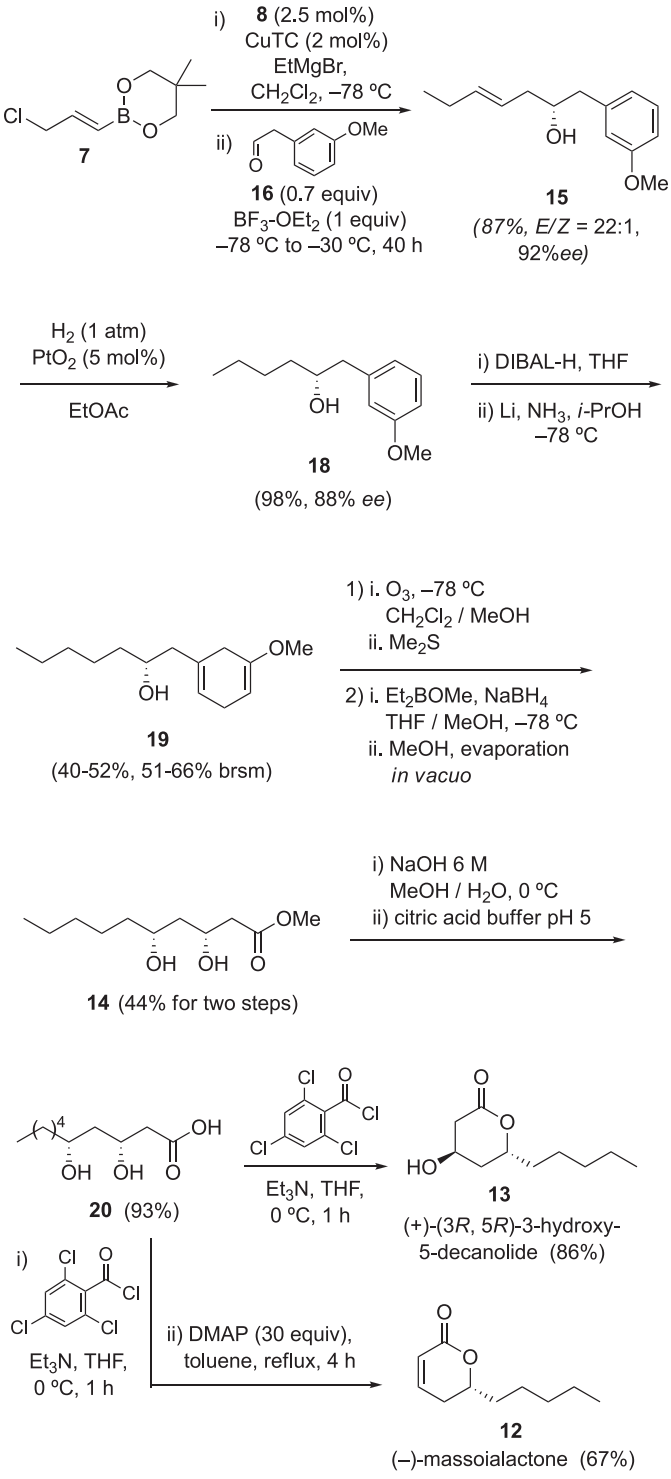
Retrosynthetically, we first planned to access (–)-massoialactone, **12**, from (+)-(3*R*,5*R*)-3-hydroxy-5-decanolide (**13**) through a dehydration reaction (Scheme 2). Our strategy to access (+)-(3*R*,5*R*)-3-hydroxy-5-decanolide was to perform the lactonization reaction from the open chain intermediate **14**. This intermediate could be accessed through a Birch reduction followed by ozonolysis of the aromatic precursor **15**, which in turn could be synthesized from our key enantioselective copper-catalyzed allylic alkylation/aldehyde allylation one-pot reaction sequence with benzylic aldehyde **16**. The use of reagent **1a**, assembled from **7** and EtMgBr, will provide the requisite pentyl side chain of **12** and **13** following hydrogenation of the disubstituted alkene of **15**.

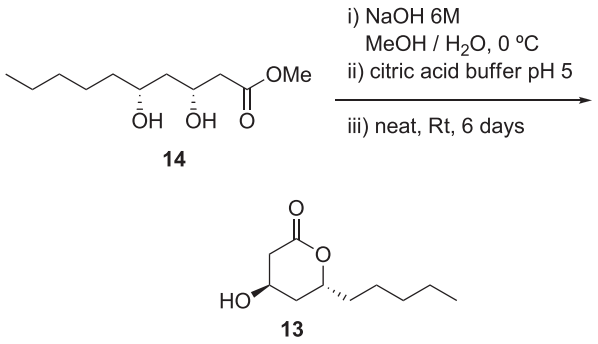
Even though aldehyde **16** is commercially available, its prohibitive price prompted us to find a more affordable source. Therefore, it was synthesized in two steps: reduction of the inexpensive (3-methoxyphenyl)acetic acid, **17**, followed by Dess–Martin periodinane oxidation. This sequence provided aldehyde **16** in high yield (eq. [5]).[27]

[5] 
From **16**, the key step of one-pot enantioselective copper-catalyzed allylic substitution/allylboration reaction afforded the desired product **15** in 87% yield, 92% ee, and high *E*/*Z* selectivity with a ratio of 22:1 (Scheme 3). Furthermore, scale-up of this key step was straightforward: the catalyst loading had to be lowered to 2 mol% to provide a constantly high *E* selectivity and the allylboration reaction had to be performed at –30 °C to ensure reaction completion. Additionally, the reaction was performed on up to 16 mmol of starting material **7** resulting in over 2 g of pure product **15**.

Hydrogenation of **15** was first attempted with palladium on charcoal but when this reaction was performed on a larger scale, isomerization of the alcohol's stereogenic center was observed, providing product **18** with only 76% ee. In this event, hydrogenation of the double bond was performed with Adams catalyst to afford the desired product **18** in 98% yield with 88% ee. The decrease in enantiomeric excess observed under these conditions, from 92% ee for the starting material **15** to 88% ee for the product **18**, is expected. This decrease is due to the diastereomeric nature of the inseparable *E* and *Z* mixture of **15** obtained after the allylboration step. From **18**, the carbonyl and the 1,3-diol moieties of **14** were introduced in a three-step sequence. First, a Birch reduction with in situ protection of the alcohol with DIBAL-H provided diene **19** in moderate yield with recoverable unreacted starting material. A longer reaction time, a higher reaction temperature, or the addition of more lithium did not provide a better conversion. On the other hand, Birch reduction without in situ protection of the alcohol afforded a full, but messy conversion of the starting material with a lower yield. Therefore, we chose to use the Birch reduction with in situ protection of the alcohol. Following this sequence, ozonolysis of diene **19** and immediate stereoselective 1,3-syn reduction of the ketone afforded compound **14** in 44% yield for the two steps. Hydrolysis of the methyl ester was performed with sodium hydroxide in methanol and water. Letting acid **20** stand at room temperature for 6 d formed the desired natural product in 71% yield (eq. [6]).

Scheme 3. Synthesis of (–)-massoialactone and (+)-(3*R*,5*R*)-3-hydroxy-5-decanolide.





[6]

(+)-(3*R*, 5*R*)-3-hydroxy-5-decanolide (71%)

Alternatively, (+)-(3*R*,5*R*)-3-hydroxy-5-decanolide (**13**) could be accessed from **20** by forming the mixed anhydride, which self-cyclized immediately in 86% yield.[28] Thus, the synthesis of (+)-(3*R*,5*R*)-3-hydroxy-5-decanolide was completed in five or six steps with an overall yield of 15%. Optical rotation for pure (+)-(3*R*,5*R*)-3-hydroxy-5-decanolide (**13**) ($[\alpha]_D^{20}$: +25.5° (*c* 1.2, $CHCl_3$)) matched that from its natural source (lit.[20] $[\alpha]_D^{25}$: +27.4° (*c* 11.7, $CHCl_3$)).

On the other hand, (–)-massoialactone (**12**) was also formed from intermediate **20** by performing the cyclization, which was immediately followed by dehydration with DMAP in refluxing toluene. This sequence provided (–)-massoialactone in six steps with an overall yield of 13%. The optical rotation of synthetic (–)-massoialactone ($[\alpha]_D^{20}$: –74.2° (*c* 1.0, $CHCl_3$)) was lower than that of its natural source (lit.[23] $[\alpha]_D^{25}$: –91° (*c* 1.0, $CHCl_3$)), but all other analytical data for the sample of synthetic (–)-massoialactone agreed to that reported in the literature. It is interesting to note that the high-dilution Yamaguchi lactonization of **20** has been alleged to provide the macrocyclic dimeric lactone verbalactone,[29] which is also a natural substance.[30] However, under several conditions and after numerous attempts, in our hands verbalactone was never isolated, and the only products observed were **12** and **13**.

Conclusion

In summary, the one-pot three-component enantioselective copper-catalyzed allylic substitution/allylation reaction sequence proved to be efficient with regards to various chiral α-alkyl allylboronate reagents. The α-substituent was used in a productive way for the short syntheses of two natural products: (+)-(3*R*,5*R*)-3-hydroxy-5-decanolide and (–)-massoialactone.

Experimental

Unless otherwise noted, all reactions were performed under an argon atmosphere using flame-dried glassware. Toluene, hexanes, and dichloromethane were distilled over CaH_2. THF and Et_2O were distilled over sodium/benzophenone ketyl. Ethylmagnesium bromide was purchased from Sigma-Aldrich as a 3.0 mol/L solution in Et_2O and titrated using a literature procedure.[31] Other Grignard reagents were prepared[32] and titrated using literature procedures. Alkenylboronate **7** was prepared according to refs. 15 and 17. Ligand **8** was prepared according to refs. 15 and 16a. Thin layer chromatography (TLC) was performed on Merck Silica Gel 60 F_{254} plates and was visualized with UV light and 5% phosphomolybdic acid in EtOH (PMA); or 1% potassium permanganate in water ($KMnO_4$); or 5% vanillin, 4% concentrated sulfuric acid in ethanol (vanillin); or 4% ammonium molybdate, 0.08% cerium (IV) sulfate in 10% aqueous sulfuric acid. Flash chromatography was performed on Silicycle SiliaFlash® F60 ultra pure silica gel 230–400 mesh or on a Teledyne Isco Combiflash® Companion® automated flash instrument. NMR spectra were recorded on Varian INOVA-300, INOVA-400, or INOVA-500 MHz instruments. The residual solvent protons (^1H) or the solvent carbons (^{13}C) were used as internal standards. ^1H NMR data are presented as follows: chemical shift in ppm downfield from tetramethylsilane (multiplicity, integration, coupling constant). The accuracy of coupling constants is deemed to be ±0.4 Hz. High-resolution mass spectra were recorded by the University of Alberta Mass Spectrometry Services Laboratory using either electron impact (EI) or electrospray (ES). Infrared spectra were obtained on a Nicolet Magna-IR 760 instrument equipped with a Nic-Plan microscope. Elemental analyses were performed on a Carlo Erba EA1108 system. Optical rotations were obtained with a PerkinElmer 241 polarimeter. Infrared spectra, elemental analyses, and optical rotations were recorded by the University of Alberta Analytical and Instrumentation Laboratory.

General procedure for the synthesis and characterization of chiral α-substituted allylboronates (1a–1d)

Copper thiophene carboxylate (CuTC) (9.5 mg, 0.050 mmol) and ligand **8** (0.054 mmol) were charged in a 25 mL round-bottom flask equipped with a magnetic stirrer. The flask was purged three times with a light vacuum and argon sequence. Dichloromethane (1.5 mL) was added and the mixture was stirred for 30 min at room temperature. In the meantime, a solution of boronic ester **7** (0.19 g, 1.0 mmol) in dichloromethane (0.5 mL) was prepared. The solution of **7** was added dropwise and the reaction mixture was stirred another 5 min at room temperature before cooling to –78 °C (the reaction turned to a blue-green color). The Grignard reagent (3.0 mol/L in Et_2O, 1.2 mmol) diluted with dichloromethane (0.6 mL) was added at –78 °C over 4 h using a syringe pump, keeping the needle immersed in the reaction mixture. The reaction mixture turned to a bright yellow color after about 3.5 h of addition. Once the addition was complete, the mixture was stirred for another 1.5–2 h at –78 °C. At that point a small aliquot was taken to verify for completion of reaction and for S_N2/S_N2' ratio measurement by ^1H NMR of chiral α-substituted allylboronates (**1a**–**1d**). In situ oxidation to alcohols **10a**–**10d** was performed using the following sequence: water (0.5 mL) and tetrahydrofuran (2 mL) were added and the reaction mixture was brought to 0 °C. An aqueous 3 mol/L solution of sodium acetate (1 mL, 3 mmol) was added followed by 30% aqueous hydrogen peroxide (0.6 mL, 5 mmol). The mixture was stirred overnight while being allowed to reach room temperature. After this time, an aqueous saturated solution of sodium sulfite (1.5 mL) was added and the mixture was stirred for 15 min at room temperature. The mixture was then extracted three times with Et_2O. The combined organic phases were washed once with a saturated aqueous solution of ammonium chloride and once with brine. It was dried over anhydrous sodium sulfate, filtered, and partially con-

centrated in vacuo due to high volatility of the allylic alcohol product. The isocyanate derivative was synthesized as follows: the allylic alcohol solution was cooled to 0 °C, dichloromethane (1 mL) was added followed by pyridine (0.17 mL, 2.0 mmol) and phenylisocyanate (0.17 mL, 1.5 mmol). The mixture was stirred overnight while being allowed to reach room temperature. It was quenched with water and the water layer was extracted three times with dichloromethane. The combined organic phases were dried over anhydrous magnesium sulfate, filtered, and concentrated in vacuo to afford the crude isocyanate derivatives **11a**–**11d**. Although yields for these products were not compiled due to the high volatility of alcohols (**10a**–**10d**), analytical samples were characterized as follows.

(3S)-3-[Phenylcarbamic ester] 1-pentene (11a) for chiral α-substituted allylboronate (1a)

Flash chromatography (5% Et_2O–pentane) yielded a colorless oil (52 mg, 25% yield), which had satisfactory analytical data (NMR, MS) as reported in the literature.[15] TLC (30% Et_2O–pentane, UV, PMA): 0.53. HPLC followed a literature procedure: Chiralcel OD, 25 °C, 20% *i*-PrOH hexanes, 0.60 mL/min, UV detection at 280 nm, major peak at 9.8 min, minor peak at 11.6 min, 96% ee.

(3S)-3-[Phenylcarbamic ester] hept-1-ene (11b) for chiral α-substituted allylboronate (1b)

Flash chromatography (100% hexane to 2% EtOAc–hexane) yielded a colorless oil (82 mg, 34% yield). TLC (25% EtOAc–hexane, UV, PMA): 0.53. $[\alpha]_D^{20}$: +5.7° (*c* 1.2, $CHCl_3$). IR (neat, cm^{-1}): 3322, 3061, 2957, 2872, 1700, 1601, 1539, 1444, 1313, 1228, 1120, 752, 692. ^1H NMR (500 MHz, $CDCl_3$) δ: 7.39–7.29 (m, 4H), 7.06 (dd, 1H, *J* = 7.4, 7.4 Hz), 6.58 (br s, 1H), 5.83 (ddd, 1H, *J* = 17.3, 10.7, 6.6 Hz), 5.31 (ddd, 1H, *J* = 17.3, 1.3, 1.3 Hz), 5.23 (ddd, 1H, *J* = 6.6, 6.6, 6.6 Hz), 5.20 (ddd, 1H, *J* = 10.6, 1.3, 1.3 Hz), 1.75–1.68 (m, 1H), 1.67–1.60 (m, 1H), 1.40–1.32 (m, 4H), 0.91 (t, 3H, *J* = 7.1 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 153.06, 138.00, 136.81, 129.01, 123.30, 118.56, 116.64, 75.82, 34.11, 27.23, 22.50, 14.0. HRMS (EI, *m*/*z*) calcd. for $C_{14}H_{19}O_2N$: 233.1416; found: 233.1414. HPLC: Chiralcel OD, 25 °C, 5% *i*-PrOH hexanes, 0.60 mL/min, UV detection at 280 nm, major peak at 16.3 min, minor peak at 19.8 min, 86% ee.

(3S)-3-[Phenylcarbamic ester] 1,7-octadiene (11c) for chiral α-substituted allylboronate (1c)

Flash chromatography (100% hexane to 2% EtOAc–hexane) yielded a colorless oil (62 mg, 25% yield). TLC (25% EtOAc–hexane, UV, PMA): 0.52. $[\alpha]_D^{20}$: +9.6° (*c* 1.0, $CHCl_3$). IR ($CHCl_3$ cast film, cm^{-1}): 3322, 3078, 2940, 1705, 1602, 1537, 1445, 1313, 1226, 1052, 915, 753. ^1H NMR (500 MHz, $CDCl_3$) δ: 7.37–7.35 (m, 2H), 7.30–7.26 (m, 2H), 7.03 (dd, 1H, *J* = 7.3, 7.3, Hz), 6.58 (br s, 1H), 5.84–5.74 (m, 2H), 5.29 (ddd, 1H, *J* = 17.2, 1.3, 1.3 Hz), 5.24 (ddd, 1H, *J* = 6.2, 6.2, 6.2 Hz), 5.18 (ddd, 1H, *J* = 10.5, 1.3, 1.3 Hz), 5.03–4.98 (m, 1H), 4.97–4.94 (m, 1H), 2.12–2.07 (m, 2H), 1.75–1.61 (m, 2H), 1.52–1.44 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 152.9, 138.3, 137.9, 136.6, 129.0, 123.3, 118.6, 116.8, 114.9, 75.6, 33.8, 33.4, 24.3. HRMS (EI, *m*/*z*) calcd. for $C_{15}H_{19}O_2N$: 245.1416; found: 245.1414. HPLC: Chiralcel OD, 25 °C, 5% *i*-PrOH hexanes, 0.60 mL/min, UV detection at 280 nm, major peak at 18.4 min, minor peak at 26.7 min, 88% ee.

(3S)-3-[Phenylcarbamic ester]-3-cyclohexyl-1-propene (11d) for chiral α-substituted allylboronate (1d)

Flash chromatography (100% hexane to 2% EtOAc–hexane) yielded a white solid (136 mg, 53% yield). TLC (25% EtOAc–hexane, UV, PMA): 0.56. $[\alpha]_D^{20}$: +18.7° (*c* 1.0, $CHCl_3$). IR ($CHCl_3$ cast film, cm^{-1}): 3319, 3061, 2928, 2854, 1704, 1602, 1542, 1444, 1230, 1050, 751. ^1H NMR (500 MHz, $CDCl_3$) δ: 7.39–7.36 (m, 2H), 7.30–7.26 (m, 2H), 7.03 (dd, 1H, *J* = 7.4, 7.4 Hz), 6.58 (br s, 1H), 5.79 (ddd, 1H, *J* = 17.4, 10.5, 7.0 Hz), 5.27 (ddd, 1H, *J* = 17.2, 1.5, 1.5 Hz), 5.21 (ddd, 1H, *J* = 10.5, 1.5, 1.5 Hz), 5.03 (dd, 1H, *J* = 6.8, 6.8 Hz), 1.83–1.57 (m, 6H), 1.28–1.01 (m, 5H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 153.03, 137.96, 135.17, 128.93, 123.20, 118.53, 117.45, 79.82, 41.66, 28.53, 28.34, 26.30, 25.90, 25.88. HRMS (EI, *m*/*z*) calcd. for $C_{16}H_{21}O_2N$: 259.1572; found: 259.1575. HPLC: Chiralcel OD, 25 °C, 5% *i*-PrOH hexanes, 0.60 mL/min, UV detection at 280 nm, major peak at 14.9 min, minor peak at 16.4 min, 69% ee.

General procedure for the one-pot protocol of enantioselective copper-catalyzed allylic substitution/aldehyde allylation — Preparation of homoallylic alcohols (9a–9d)

Copper thiophene carboxylate (CuTC) (9.5 mg, 0.050 mmol) and ligand **8** (33 mg, 0.054 mmol) were charged in a flame-dried 25 mL round-bottom flask equipped with a magnetic stirrer. The flask was purged three times with a light vacuum and argon sequence. Dichloromethane (1.5 mL) was added and the mixture was stirred for 30 min at room temperature. In the meantime, a solution of boronic ester **7** (188 mg, 1.0 mmol) in dichloromethane (0.5 mL) was prepared. The solution of **7** was added dropwise to the reaction mixture and stirred for 5 min at room temperature (the reaction mixture turned to a blue-green color) before cooling to –78 °C. The Grignard reagent (3.0 mol/L in Et_2O, 1.2 mmol) diluted with dichloromethane (0.6 mL) was added at –78 °C over 4 h using a syringe pump, keeping the needle immersed in the reaction mixture. The reaction mixture turned to a bright yellow color after about 3.5 h of addition. Once the addition was complete, the mixture was stirred another 1.5–2 h at –78 °C. The aldehyde (0.7–0.8 mmol) was added at –78 °C immediately followed by boron trifluoride diethyl etherate (BF_3-OEt_2) (0.10 mL, 0.80 mmol). The reaction mixture was stirred approximately 24 h at –78 °C and 16 h at –30 °C. The reaction was cooled back to –78 °C and was quenched with the addition of a saturated aqueous solution of sodium bicarbonate (1.5 mL). The mixture was then warmed up to room temperature over 3 h and stirred for an additional 30 min at room temperature. The phases were separated and the aqueous phase was extracted three times using dichloromethane. The combined organic extracts were dried over anhydrous sodium sulfate, filtered, and concentrated in vacuo.

(3E,1R)-1-Phenyl-3-hexen-1-ol (9a)

Flash chromatography (100% hexanes to 5% EtOAc–

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Sichuan Normal University on 09/14/12
For personal use only.

hexanes) yielded a colorless oil (108 mg, 75%), which gave satisfactory analytical data (NMR, MS) as reported in the literature.[15,33] TLC: (20% EtOAc–hexanes, UV, PMA) 0.34. $[\alpha]_D^{20}$: +57.4° (*c* 1.0, $CHCl_3$). HPLC for *E*/*Z* ratio measurement on the crude product: Zorbax SB-C18 4.6 mm × 150 mm, 5 μm, 40 °C, mobile phase A: 0.05% formic acid – H_2O, mobile phase B: 0.05% formic acid – MeOH, program: 70:30 at 0 min, 64.5% of B at 55 min, 80% of B at 58 min, 30% of B at 58.01 min, 1 mL/min, UV detection at 220 nm, retention times: (3*Z*)-1-phenyl-3-hexen-1-ol, 44.5 min; (3*E*)-1-phenyl-3-hexen-1-ol, 45.8 min. HPLC for enantiomeric excess measurement on purified product is based on a literature procedure:[15] Chiralcel OD, 10 °C, 5% *i*-PrOH hexane, 0.3 mL/min, UV detection at 220 nm, retention times: (3*E*,1*R*)-1-phenyl-3-hexen-1-ol, 25.8 min; (3*Z*,1*R* or 1*S*)-1-phenyl-3-hexen-1-ol, 29.4 min; (3*E*,1*S*)-1-phenyl-3-hexen-1-ol, 32.0 min; (3*Z*,1*R* or 1*S*)-1-phenyl-3-hexen-1-ol, 35.2 min; 92% ee.

*(3*E*,1*R*)-1-Phenyl-3-octen-1-ol (9b)*

Flash chromatography using an automated flash system (4 g SiO_2 column, 10 column volumes (CV) 100% petroleum ether, 20 CV 100% petroleum ether to 5% EtOAc, 30 CV 5% EtOAc, 10 CV 5% EtOAc to 50% EtOAc) yielded a colorless oil (84 mg, 52%), which gave satisfactory analytical data (NMR, MS) as reported in the literature.[34] Note: 34 mg (21%) of the borotropic shift/allylation product was also isolated. TLC (10% EtOAc–petroleum ether, PMA): 0.28. $[\alpha]_D^{20}$: +32.2° (*c* 1.0, $CHCl_3$). HPLC for *E*/*Z* ratio measurement on crude product: Zorbax SB-C18 4.6 mm × 150 mm, 5 μm, 40 °C, mobile phase A: 0.05% formic acid – H_2O, mobile phase B: 0.05% formic acid – MeOH, program: 70:30 at 0 min, 64.5% of B at 110 min, 30% of B at 110.01 min, 1 mL/min, UV detection at 210 nm, retention times: (3*Z*)-1-phenyl-3-octen-1-ol, 104.4 min; (3*E*)-1-phenyl-3-octen-3-ol, 106.9 min. HPLC for enantiomeric excess measurement on purified product: Chiralcel OD, 10 °C, 2% *i*-PrOH hexane, 0.5 mL/min, UV detection at 254 nm, retention times: (3*E*,1*R*)-1-phenyl-3-octen-1-ol, 22.7 min; (3*E*,1*S*)-1-phenyl-3-octen-1-ol, 26.5 min; 85% ee.

*(3*E*,1*R*)-1-Phenyl-3,8-nonadien-1-ol (9c)*

Flash chromatography using an automated flash system (4 g SiO_2 column, 10 column volumes (CV) 100% petroleum ether, 20 CV 100% petroleum ether to 5% EtOAc, 30 CV 5% EtOAc, 10 CV 5% EtOAc to 50% EtOAc) yielded a colorless oil (68 mg, 40%). Note: 41 mg (24%) of the borotropic shift/allylation product was also isolated. TLC (10% EtOAc–petroleum ether, PMA): 0.24. $[\alpha]_D^{20}$: +30.9° (*c* 1.0, $CHCl_3$). IR ($CHCl_3$ cast film, cm^{-1}): 3378, 3030, 2927, 2855, 1640, 1454, 970, 911. ^1H NMR (500 MHz, $CDCl_3$) δ: 7.36–7.35 (m, 4H), 7.29–7.27 (m, 1H), 5.78 (dddd, 1H, *J* = 17.0, 10.3, 6.7, 6.7 Hz), 5.55 (dm, 1H, *J* = 15.1 Hz), 5.39 (dm, 1H, *J* = 15.5 Hz), 4.98 (dm, 1H, *J* = 17.1 Hz), 4.93 (dm, 1H, *J* = 10.2 Hz), 4.67 (ddd, 1H, *J* = 8.0, 4.9, 3.2 Hz), 2.50–2.38 (m, 2H), 2.06–2.00 (m, 5H), 1.48–1.42 (m, 2H). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 144.0, 138.7, 134.6, 128.3, 127.4, 125.8 (2C), 114.5, 73.5, 42.8, 33.2, 32.0, 28.5. HRMS (EI, *m*/*z*) calcd. for $C_{15}H_{20}O$: 216.1514; found: 216.1520. HPLC for *E*/*Z* ratio measurement on crude product: Zorbax SB-C18 4.6 mm × 150 mm, 5 μm, 40 °C, mobile phase A: 0.05% formic acid – H_2O, mobile phase B: 0.05% formic acid – MeOH, program: 70:30 at 0 min, 64.5% of B at 110 min, 30% of B at 110.01 min, 1 mL/min, UV detection at 210 nm, retention times: (3*Z*)-1-phenyl-3,8-nonadien-1-ol, 104.4 min; (3*E*)-1-phenyl-3,8-nonadien-1-ol, 106.7 min. HPLC for enantiomeric excess measurement on purified product: Chiralcel OD, 10 °C, 2% *i*-PrOH hexane, 0.5 mL/min, UV detection at 270 nm, retention times: (3*E*,1*R*)-1-phenyl-3,8-nonadien-1-ol, 25.6 min; (3*E*,1*S*)-1-phenyl-3,8-nonadien-1-ol, 33.2 min; 83% ee.

*(3*E*,1*R*)-4-Cyclohexyl-1-phenyl-3-buten-1-ol (9d)*

Flash chromatography using an automated flash system (4 g SiO_2 column, 10 column volumes (CV) 100% petroleum ether, 20 CV 100% petroleum ether to 5% EtOAc, 30 CV 5% EtOAc, 10 CV 5% EtOAc to 50% EtOAc) yielded a colorless oil (74 mg, 41%), which gave satisfactory analytical data (NMR, MS) as reported in the literature.[35] Note: 46 mg (23%) of the borotropic shift/allylation product was also isolated. TLC (10% EtOAc–petroleum ether, PMA): 0.28. $[\alpha]_D^{20}$: +23.2° (*c* 1.0 $CHCl_3$). HPLC for *E*/*Z* ratio measurement on crude product: Zorbax SB-C18 4.6 mm × 150 mm, 5 μm, 40 °C, mobile phase A: 0.05% formic acid – H_2O, mobile phase B: 0.05% formic acid – acetonitrile, program: 50:50 at 0 min, 95% of B at 25 min, 50% of B at 25.01 min, 1 mL/min, UV detection at 210 nm, retention times: (3*Z*)-4-cyclohexyl-1-phenyl-3-buten-1-ol, 12.6 min; (3*E*)-4-cyclohexyl-1-phenyl-3-buten-1-ol, 13.2 min. HPLC for enantiomeric excess measurement on purified product: Chiralcel OD, 10 °C, 2% *i*-PrOH hexane, 0.5 mL/min, UV detection at 220 nm, retention times: (3*E*,1*R*)-4-cyclohexyl-1-phenyl-3-buten-1-ol, 23.4 min; (3*E*,1*S*)-4-cyclohexyl-1-phenyl-3-buten-1-ol, 33.4 min; 68% ee.

Experimental procedures in the syntheses of (+)-(3*R*,5*R*)-3-hydroxy-5-decanolide (13) and (–)-massoialactone (12)

2-(3-Methoxyphenyl) ethanol

This compound was synthesized following a literature procedure[27a] and yielded a colorless oil (4.33 g, 95%), which gave satisfactory analytical data (NMR, MS), as reported in the literature,[27b] and was used without further purification.

(3-Methoxyphenyl) acetaldehyde (16)

This compound was synthesized following a published procedure.[27c] Flash chromatography (5% Et_2O–dichloromethane) yielded a light yellow oil (1.74 g, 93%). TLC (50% Et_2O–dichloromethane, UV, $KMnO_4$): 0.38. IR (CH_2Cl_2 cast film, cm^{-1}): 3004, 2941, 2837, 2728, 1723, 1602, 1492, 1258, 1152, 1042, 782, 697. ^1H NMR (400 MHz, $CDCl_3$) δ: 9.74 (t, 1H, *J* = 2.4 Hz), 7.30 (dd, 1H, *J* = 7.9, 7.9 Hz), 6.88–6.76 (m, 3H), 3.82 (s, 3H), 3.66 (d, 2H, *J* = 2.4 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 199.3, 160.1, 133.2, 130.0, 121.9, 115.3, 112.8, 55.2, 50.6. HRMS (EI, *m*/*z*) calcd. for $C_9H_{10}O_2$: 150.0681; found: 150.0683. Anal. calcd. for $C_9H_{10}O_2$: C 71.98, H 6.71; found: C 71.78, H 6.71.

*(4*E*,2*R*)-1-(3-Methoxyphenyl)-4-heptene-2-ol (15)*

Copper thiophene carboxylate (CuTC) (61 mg, 0.32 mmol) and ligand **8** (240 mg, 0.39 mmol) were charged in a flame-dried 100 mL round-bottom flask equipped with a

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Sichuan Normal University on 09/14/12
For personal use only.

magnetic stirrer. The flask was purged three times with a light vacuum and argon sequence. Dichloromethane (24 mL) was added and the mixture was stirred for 30 min at room temperature. In the meantime, a solution of boronic ester **7** (3.01 g, 16.0 mmol) in dichloromethane (8 mL) was prepared. The solution of **7** was added dropwise to the reaction mixture and stirred for 5 min at room temperature (the reaction mixture turned to a blue-green color) before cooling to –78 °C. Ethylmagnesium bromide (3.0 mol/L in Et_2O, 19 mmol) diluted with dichloromethane (10 mL) was added at –78 °C over 4 h using a syringe pump, keeping the needle immersed in the reaction mixture. The reaction mixture turned to a bright yellow color after about 3.5 h of addition. Once the addition was complete, the mixture was stirred for another 2 h at –78 °C. Boron trifluoride diethyl etherate (BF_3-OEt_2) (2.0 mL, 16 mmol) was added immediately followed by (3-methoxyphenyl) acetaldehyde (**16**) (1.65 g, 11.0 mmol) at –78 °C. The reaction mixture was stirred for approximately 24 h at –78 °C and 16 h at –30 °C. The reaction was quenched at –78 °C via the addition of a saturated aqueous solution of sodium bicarbonate (20 mL). The mixture was then warmed up to room temperature over 3 h and stirred for an additional 30 min at room temperature. The phases were separated and the aqueous phase was extracted three times using dichloromethane. The combined organic extracts were dried over anhydrous sodium sulfate, filtered, and concentrated in vacuo.

Flash chromatography (100% hexanes to 20% Et_2O–hexanes) yielded a colorless oil as an inseparable mixture of *E*/*Z* isomers **15** in a 22:1 ratio (2.12 g, 87%). TLC (50% Et_2O–hexanes, UV, PMA): 0.27. $[\alpha]_D^{20}$: –2.9° (*c* 1.0, $CHCl_3$). IR ($CHCl_3$ cast film, cm^{-1}): 3421, 2961, 2934, 1602, 1585, 1489, 1261, 1046. ^1H NMR (400 MHz, $CDCl_3$) δ: 7.23, (dd, 1H, *J* = 8.9, 7.5 Hz), 6.79–6.76 (m, 3H), 5.62 (dm, 1H, *J* = 15.1 Hz), 5.45 (dm, 1H, *J* = 15.5 Hz), 3.88–3.81 (m, 1H), 3.81 (s, 3H), 2.79 (dd, 1H, *J* = 13.6, 5.1 Hz), 2.70 (dd, 1H, *J* = 13.6, 7.9 Hz), 2.29–2.27 (m, 1H), 2.17–2.15 (m, 1H), 2.10–2.02 (m, 2H), 1.71 (d, 1H, *J* = 3.2 Hz), 1.00 (t, 3H, *J* = 7.4 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 159.6, 140.1, 136.1, 129.3, 124.5, 121.7, 115.0, 111.7, 71.8, 55.0, 43.2, 39.9, 25.6, 13.7. HRMS (EI, *m*/*z*) calcd. for $C_{14}H_{20}O_2$: 220.1463; found: 220.1461. HPLC for enantiomeric excess: Chiralcel OD, 10 °C, 2% *i*-PrOH hexane, 0.7 mL/min, UV detection at 280 nm, retention times: (4*E*,2*S*)-1-(3-methoxyphenyl)-4-heptene-2-ol, 20.8 min; (4*Z*,2*R* or 2*S*)-1-(3-methoxyphenyl)-4-heptene-2-ol, 22.7 min; (4*E*,2*R*)-1-(3-methoxyphenyl)-4-heptene-2-ol, 28.2 min; (4*Z*,2*R* or 2*S*)-1-(3-methoxyphenyl)-4-heptene-2-ol, 30.2 min; 92% ee.

*(2**R**)-1-(3-Methoxyphenyl)-2-heptanol (18)*

(4*E*,2*R*)-1-(3-Methoxyphenyl)-4-heptene-2-ol (**15**) (2.12 g, 9.6 mmol) was charged in a flame-dried flask under argon. Ethyl acetate (100 mL) and Adams's catalyst (PtO_2) (108 mg, 0.48 mmol) were added and the flask was purged three times with a light vacuum and argon sequence and three times with a light vacuum and H_2 sequence. The reaction mixture was stirred for 1.5 h at room temperature under an atmospheric pressure of H_2 (using a H_2 balloon). The reaction mixture was then purged with a light vacuum and argon sequence before being filtered on celite and rinsed with EtOAc. The filtrate was concentrated in vacuo. Flash chromatography on a short column (30% Et_2O–hexanes) yielded a yellow oil (2.10 g, 98%). TLC: (50% Et_2O–hexanes, UV, $KMnO_4$, vanillin (blue stain)) 0.33. Note: even though the product and the starting material have the same R_f, the product took longer to stain with $KMnO_4$. $[\alpha]_D^{20}$: –10.4° (*c* 1.0, $CHCl_3$). IR ($CHCl_3$ cast film, cm^{-1}): 3407, 2931, 2858, 1602, 1489, 1465, 1259, 1154, 1046. ^1H NMR (400 MHz, $CDCl_3$) δ: 7.24 (ddd, 1H, *J* = 7.4, 7.4, 1.2 Hz), 6.83–6.78 (m, 3H), 3.82–3.81 (m, 1H), 3.81 (s, 3H), 2.82 (dd, 1H, *J* = 13.5, 4.2 Hz), 2.63 (dd, 1H, *J* = 13.6, 8.5 Hz), 1.57–1.51 (m, 4H), 1.34–1.31 (m, 5H), 0.91 (t, 3H, *J* = 6.9 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 159.7, 140.2, 129.4, 121.6, 115.0, 111.7, 72.5, 55.0, 44.0, 36.7, 31.8, 25.3, 22.6, 13.9. HRMS (EI, *m*/*z*) calcd. for $C_{14}H_{22}O_2$: 222.1620; found: 222.1621. Anal. calcd. for $C_9H_{10}O_2$: C 71.98, H 6.71; found: C 71.78, H 6.71. HPLC for enantiomeric excess: Chiralcel OD, 10 °C, 2% *i*-PrOH hexane, 0.7 mL/min, UV detection at 280 nm, retention times: (2*S*)-1-(3-methoxyphenyl)-2-heptanol, 21.0 min; (2*R*)-1-(3-methoxyphenyl)-2-heptanol, 28.8 min; 88% ee.

*(2**R**)-1-(5-Methoxy cyclohexadienyl)-2-heptanol (19)*

This compound was synthesized following a literature procedure performed on a different substrate.[36] Flash chromatography (100% petroleum ether to 6% EtOAc–petroleum ether) yielded a colorless oil (239 mg, 46%) along with starting material (152 mg, 65% yield brsm). TLC: (20% EtOAc–petroleum ether, vanillin (red stain)): 0.38. $[\alpha]_D^{20}$: –8.1° (*c* 1.0, $CHCl_3$). IR (microscope, cm^{-1}): 3418, 2930, 1695, 1665, 1467, 1390, 1222, 1136, 1024, 776. ^1H NMR (400 MHz, $CDCl_3$) δ: 5.56 (brs, 1H), 4.64 (dd, 1H, *J* = 3.6, 3.6 Hz), 3.80–3.69 (m, 1H), 3.56 (s, 3H), 2.87–2.81 (m, 2H), 2.78–2.68 (m, 1H), 2.66–2.56 (m, 1H), 2.19 (br d, 1H, *J* =13.8 Hz), 2.09 (dd, 1H, *J* = 13.8, 9.1 Hz), 1.63 (br s, 1H), 1.49–1.43 (m, 3H), 1.37–1.27 (m, 5H), 0.90 (t, 3H, *J* = 6.9 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 152.7, 131.3, 122.1, 90.2, 68.5, 53.9, 45.3, 37.0, 31.9, 31.6, 26.8, 25.4, 22.6, 14.0. HRMS (EI, *m*/*z*) calcd. for $C_{14}H_{24}O_2$: 224.1776; found: 224.1781. Anal. calcd. for $C_{14}H_{24}O_2$: C 74.95, H 10.78; found: C 74.94, H 10.81.

*(3**R**,5**R**)-Methyl 3,5-dihydroxydecanoate (14)*

Ozonolysis was performed following modified literature procedures performed on different substrates.[36,37] In a three-neck flask equipped with a $CaCl_2$ drying tube, a solution of (2*R*)-1-(5-methoxy cyclohexadienyl)-2-heptanol (**19**) (0.22 g, 1.0 mmol) in dichloromethane (4.2 mL) and methanol (1.8 mL) was prepared and pyridine (90 mL, 1.1 mmol) was added. The solution was cooled to –78 °C and a light stream of ozone was bubbled through until the reaction was saturated at which point the reaction mixture turned blue and the color persisted. Ozone was removed with oxygen until the blue color disappeared. Dimethyl sulfide (3 mL) was added at –78 °C and the reaction mixture was stirred for 1 h at room temperature. A saturated sodium chloride solution was added, the layers were separated, and the aqueous layer was extracted four times with dichloromethane. The combined organic extracts were dried over anhydrous sodium sulfate, filtered, and concentrated in vacuo. The unstable crude material was immediately used in the following step.

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Sichuan Normal University on 09/14/12
For personal use only.

The ketone reduction was performed following a modification of a literature procedure.[37,38] Crude (5*R*)-methyl-5-hydroxy-3-oxodecanoate was charged in a flame-dried flask under argon. It was diluted with THF (12 mL) and methanol (3 mL) and cooled to –78 °C for dropwise addition of diethylmethoxyborane (1.1 mL, 1.1 mmol) as a 1.0 mol/L solution in THF. The reaction mixture was stirred for 15 min at –78 °C and sodium borohydride (0.19 g, 5.1 mmol) was added in one portion. The reaction mixture was stirred for 3 h at –78 °C and was quenched with the addition of a saturated aqueous solution of ammonium chloride. The reaction flask was brought carefully to room temperature as gas evolution occurred. The reaction was stirred at room temperature until no more gas evolution was observed. The phases were separated and the aqueous phase was extracted three times with Et_2O. The combined organic extracts were dried over anhydrous sodium sulfate, filtered, and concentrated in vacuo. The resulting boronate was purified on a short pad of silica (1% MeOH, 50% Et_2O–hexanes) and the diol was freed by performing the following cycle four times: addition of MeOH and evaporation in vacuo. The resulting oil (96 mg, 44% for two steps) was used without further purification as flash chromatography on the free diol resulted in decomposition. TLC (80% EtOAc–hexanes, 0.08% cerium (IV) sulfate in 10% aqueous sulfuric acid): 0.40. $[\alpha]_D^{20}$: –17.7° (*c* 1.1, $CHCl_3$). IR (neat, cm^{-1}): 3406, 2932, 1738, 1439, 1164. ^1H NMR (400 MHz, $CDCl_3$) δ: 4.30–4.23 (m, 1H), 3.86 (br s, 1H), 3.70 (s, 3H), 3.30 (br s, 1H), 2.49–2.48 (m, 2H), 1.61–1.53 (m, 2H), 1.50–1.37 (m, 3H), 1.34–1.24 (m, 6H), 0.87 (t, 3H, *J* = 6.8 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 172.8, 72.2, 69.0, 51.8, 42.2, 41.6, 37.8, 31.8, 25.0, 22.6, 14.0. HRMS (ES, *m/z*) calcd. for $C_{11}H_{22}O_4$ (M + Na): 241.1410; found: 241.1410.

(3R,5R)- 3,5-Dihydroxydecanoic acid (20)

(3*R*,5*R*)-Methyl 3,5-dihydroxydecanoate (**14**) (0.20 g, 0.92 mmol) was diluted with MeOH (20 mL) and water (3 mL). The reaction flask was cooled to 0 °C and sodium hydroxide (3 mL, 18 mmol) as a 6 mol/L aqueous solution was added. The reaction was stirred at 0 °C for 1 h, and a sodium hydroxide/citric acid pH 5 buffer was added followed by a 1 mol/L aqueous citric acid solution until pH 5 was reached (measured with a pH meter). The aqueous phase was extracted three times with EtOAc. The combined organic extracts were washed once with brine, dried over anhydrous sodium sulfate, filtered, and concentrated in vacuo to afford a colorless oil (175 mg, 93%) containing 13% of cyclized product. This compound was used immediately, without purification, in subsequent reactions since it rapidly cyclized upon standing.

(–)-Massoialactone (12)

This compound was prepared following a modification of a literature procedure.[28b,29] In a flame-dried flask under argon, (3*R*,5*R*)-3,5-dihydroxydecanoic acid (**20**) (56 mg, 0.27 mmol) was added, then diluted with THF (27 mL) and cooled to 0 °C. Freshly distilled triethylamine (0.23 mL, 1.6 mmol) was added followed by freshly distilled 2,4,6-trichlorobenzoyl chloride (65 μL, 0.41 mmol). The reaction was stirred at 0 °C for 1 h. In the meantime, a three-neck flask equipped with a condenser in one neck, a 25 cm Vigreux column in the other, and a rubber septum in the third neck, was charged with DMAP (0.99 g, 8.1 mmol) and toluene (27 mL) and was heated at reflux so that 15 cm of the Vigreux column (isolated with cotton) would be heated with the refluxing toluene. The first reaction mixture, containing the mixed anhydride, was transferred to a syringe and added over 2 h using a syringe pump, at the top of the Vigreux column to the DMAP solution in refluxing toluene. Once the addition was complete the reaction mixture was refluxed for another 2 h. The reaction mixture was cooled to room temperature and the solvents were evaporated in vacuo. Flash chromatography (30% EtOAc–hexanes to 80% EtOAc–hexanes) afforded (–)-massoialactone (**12**) (30 mg, 67%) as a light yellow oil with a strong coconut fragrance. TLC (40% EtOAc–hexanes, 0.08% cerium (IV) sulfate in 10% aqueous sulfuric acid): 0.44. $[\alpha]_D^{20}$: –74.2° (*c* 1.0, $CHCl_3$) (lit.[23] $[\alpha]_D^{25}$: –91° (*c* 1.0, $CHCl_3$)). IR (neat, cm^{-1}): 3056, 2955, 2862, 1725, 1389, 1251, 1040, 816. ^1H NMR (300 MHz, $CDCl_3$) δ: 6.88 (ddd, 1H, *J* = 9.7, 3.6, 3.6 Hz), 6.03 (ddd, 1H, *J* = 9.7, 1.5, 1.5 Hz), 4.47–4.38 (m, 1H), 2.36–2.31 (m, 2H), 1.87–1.27 (m, 8H), 0.90 (t, 3H, *J* = 6.9 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 164.6, 145.0, 121.5, 78.1, 34.9, 31.6, 29.4, 24.5, 22.5, 14.0. HRMS (EI, *m/z*) calcd. for $C_{10}H_{16}O_2$: 168.1150; found: 168.1150.

(+)-(3R,5R)-3-Hydroxy-5-decanolide (13)

In a flame-dried flask under argon, (3*R*,5*R*)-3,5-dihydroxydecanoic acid (**20**) (25 mg, 0.12 mmol) was charged, diluted with THF (1 mL), and cooled to 0 °C. Freshly distilled triethylamine (0.10 mL, 0.72 mmol) was added followed by freshly distilled 2,4,6-trichlorobenzoyl chloride (30 μL, 0.18 mmol). The reaction was stirred at 0 °C for 1 h and solvents were removed in vacuo. Flash chromatography (30% EtOAc-hexanes to 50% EtOAc-hexanes) afforded (+)-(3*R*,5*R*)-3-Hydroxy-5-decanolide **13** (19 mg, 86%) as a colorless oil. TLC (80% EtOAc–hexanes, 0.08% cerium (IV) sulfate in 10% aqueous sulfuric acid): 0.31. $[\alpha]_D^{20}$: +25.48° (*c* 1.2, $CHCl_3$) (lit.[19] $[\alpha]_D^{20}$: +27.4° (*c* 11.7, $CHCl_3$)). IR ($CHCl_3$ cast film, cm^{-1}): 3415, 2932, 2861, 1713, 1256, 1069. ^1H NMR (500 MHz, $CDCl_3$) δ: 4.69 (dm, 1H, *J* = 11.0 Hz), 4.41–4.40 (m, 1H), 2.75 (1H, dd, *J* = 17.6, 5.1 Hz), 2.62 (ddd, 1H, *J* = 17.6, 3.7, 1.7 Hz), 1.96 (dm, 1H, *J* = 14.5 Hz), 1.75 (ddd, 1H, *J* = 14.6, 11.4, 3.4 Hz), 1.73–1.69 (m, 1H), 1.63–1.49 (m, 2H), 1.45–1.38 (m, 2H), 1.34–1.29 (m, 4H), 0.90 (t, 3H, *J* = 6.4 Hz). ^{13}C NMR (100 MHz, $CDCl_3$) δ: 170.8, 76.0, 62.7, 38.6, 35.9, 31.5, 24.5, 22.5, 13.9. HRMS (ES, *m/z*) calcd. for $C_{10}H_{18}O_3$ (M + Na): 209.1148, found: 209.1150.

Matrix effects on mass spectrometric determinations of four pharmaceuticals and personal care products in water, sediments, and biota

Ève B. Dussault, Vimal K. Balakrishnan, Keith R. Solomon, and Paul K. Sibley

Abstract: Simple analytical methods were developed for the extraction and determination of four pharmaceuticals and personal care products (PPCPs) from water, sediments, and biota. PPCPs were determined using tandem LC–MS in electrospray ionization mode, and interactions with matrix co-eluents were investigated. Extractions of water samples were performed using solid-phase extraction (SPE), sediments were extracted by pressurized liquid extraction (PLE), and biota was extracted by liquid extraction. The selected analytical methods yielded recoveries ≥ 61% in all matrixes. Matrix interactions were investigated throughout the linear range of quantification of each compound, revealing that dissolved salts had relatively minor effects on ionization (between 14% suppression to 12% enhancement), but that sediment and biota extracts caused significant matrix effects (ranging from 56% suppression to 25% enhancement). The direction and magnitude of matrix interactions reflected the physico-chemical properties of each analyte, particularly their pK_a. Among the compounds analyzed in electrospray positive mode, carbamazepine was insensitive to matrix interactions, because it is a strong proton acceptor (pK_a = 14.0). In contrast, atorvastatin (pK_a = 4.5), a weaker proton acceptor, was particularly sensitive to matrix effects. For those compounds analyzed in negative-ion mode, sample alkalinity was found to be important. With a pK_a of 10.4, 17α-ethinylestradiol generally exhibited matrix enhancement with increased sample alkalinity. However, the presence of acidic co-eluents contributed to matrix suppression. Lastly, TCS was particularly sensitive to matrix suppression, as its circumneutral pK_a (7.9) caused even slight changes in sample pH to considerably impact ionization. We conclude that while different matrixes have clear impacts on ionization of these PPCPs, matrix effects can be quantified and overcome.

Key words: pharmaceuticals and personal care products, matrix effects, LC–MS/MS, sediments, biota.

Résumé : On a développé des méthodes analytiques simples pour l'extraction et la détermination de quatre produits pharmaceutiques et de soins personnels (PPSP) à partir de solutions aqueuses, de sédiments et du biote. On a déterminé les PPSP en faisant appel à la chromatographie liquide opérant en tandem avec spectrométrie de masse en mode d'ionisation par électronébulisation (CL–SM) et on a étudié les interactions avec les coéluants de la matrice. Les extractions à partir de solutions aqueuses ont été effectuées en utilisant l'extraction en phase solide (EPS) alors que les sédiments ont été soumis à une extraction avec un liquide pressurisé (ELP) et que le biote a été soumis à une extraction liquide. Dans l'ensemble des matrices, les méthodes analytiques choisies ont permis d'obtenir des taux de récupération d'au moins 61 %. On a étudié les interactions avec la matrice pour la plage entière de quantification de chaque composé et ces études ont révélé que les sels dissous n'ont que des effets mineurs sur l'ionisation (allant de 14 % de suppression à 12 % de renforcement); toutefois, dans les cas des extractions des sédiments et du biote, on observe des effets de matrice importants allant de 56 % de suppression à 25 % de renforcement. La direction et l'amplitude des interactions de matrice sont des reflets des propriétés physico-chimiques de chaque analyte, en particulier de leur pK_a. Parmi les composés analysés en mode d'électronébulisation positive, la carbamazépine est insensible aux interactions de matrice dû au fait qu'il s'agit d'un produit fortement accepteur de proton (pK_a = 14,0). À l'opposé, l'atorvastatine (pK_a = 4,5), un accepteur de proton beaucoup plus faible, est particulièrement sensible aux effets de matrice. Pour les composés analysés en mode d'ion négatif, on a trouvé que l'alcalinité de l'échantillon est importante. Avec un pK_a de 10,4, le 17α-éthinylestradiol présente généralement un renforcement de matrice avec une augmentation de l'alcalinité de l'échantillon. Toutefois, la présence de coéluants acides contribue à la suppression de l'effet de matrice. Enfin, le « TCS » est particulièrement sensible à la suppression de la matrice dû au fait que son pK_a pratiquement neutre (7,9) provoque des changements considérables dans l'ionisation même pour de faibles changements dans le pH des échantillons. On en conclut que même si les diverses matrices ont une influence certaine sur

[Traduit par la Rédaction]

Introduction

Environmental contamination of aquatic systems by pharmaceuticals and personal care products (PPCPs) has been of increasing concern in the last decade. However, limited availability of adequate analytical tools, mass spectral libraries, and analytical standards had, until the 1990s, significantly hindered investigations.[1,2] Since then, hundreds of products have been detected in wastewater effluents and surface water, including lipid regulators, analgesics, antimicrobials, and endocrine disruptors.[2–4] In addition, as the fate, effects, and environmental risks posed by the presence of PPCPs in aquatic systems are evaluated, there is an increasing demand for reliable analytical methods permitting their quantification in various matrixes.

Monitoring studies have generally detected PPCPs at low concentrations. However, some compounds are relatively persistent, due to their continuous usage and release into aquatic environments.[1–3] Consequently, aquatic organisms may be exposed to a multitude of these bioactive compounds at sublethal concentrations over the duration of their life cycle.

Despite the important role they play in aquatic food webs, potential effects of PPCPs on aquatic invertebrates, such as the midge *Chironomus tentans* and the freshwater amphipod *Hyalella azteca*, have been less frequently investigated than vertebrate species (e.g., fish). To execute studies into the effects of PPCPs on these aquatic organisms, it is critical to first establish and validate analytical methods for their extraction and determination in environmental matrixes.

PPCPs differ from many other pollutants in that they are specifically designed to elicit responses from target species with the potential for unintended consequences on non-target species. Accordingly, these compounds are generally moderately water-soluble, non-volatile, and thermally labile, hindering analysis by GC–MS without prior derivatization.[1] In contrast, analysis by LC–MS provides a more facile alternative to GC–MS analysis. However, a complication associated with LC–MS analysis is the potential for interactions with other matrix co-eluents, believed to arise from competition between the analyte ions and co-eluents for gas-phase emission in the electrospray ionization source.[5,6] As the number of co-eluents increases, their interactions with the target analytes interferes with adequate quantification, thereby hindering investigations.[5,7,8]

Several approaches have been suggested for the resolution of matrix effects. Quantification via matrix-matched calibration has been suggested, but the availability of non-contaminated material is problematic when studying contaminated sites. Another method consists of the addition of an internal standard (typically isotopically labelled) to each sample prior to analysis to correct for variations in ionization efficiency brought about by interactions with matrix co-eluents. Although widely accepted, this technique is most effective when the co-eluents have an identical effect on both the internal standard and the target analyte(s).[7] However, in their study of matrix effects on sulfonamide antibiotics, Balakrishnan et al.[9] recently showed that such an assumption is not necessarily valid, even in comparing $^{13}C_6$-sulfamethazine with unlabelled sulfamethazine. In cases where the internal standard interacts with matrix components in a different manner than do the target analytes, the use of this approach would incorporate a non-systematic bias into calculations, resulting in quantification errors.

The objectives of this study were two-fold: to develop separate extraction and analytical methods for the determination of four PPCPs in water, sediment, and biota, and to investigate the impact of these matrixes (water, sediment, and biota) on compound ionization. First, various extraction techniques were explored for each PPCP of interest, via extraction of samples spiked with known concentrations of analytical standards, and for which the recovery of each compound was calculated. Once satisfactory extraction methods were established, the matrix interactions of these extracts were individually assessed and quantified for each target analyte.

Experimental

Materials

Compound selection

The four compounds of interest were selected based on various criteria, including usage in Canada, persistence, and previous work in our laboratory, as described in Dussault et al.,[10] and included the lipid-regulator atorvastatin, the antiepileptic drug carbamazepine, the synthetic hormone 17α-ethinylestradiol, and the antimicrobial triclosan. The structures are shown in Table 1.

Chemicals

Atorvastatin (ATO, ≥99%) was obtained from Rugao Foreign Trade Corp. (Shanghai, China), carbamazepine (CBZ, ≥99%) was purchased from China Jiangsu Textiles (Nanjiing, China), and 17α-ethinylestradiol (EE2, ≥98%) and triclosan (TCS, ≥97%) were acquired from Sigma-Aldrich (Oakville, ON, Canada).

Calcium chloride ($CaCl_2$), calcium sulfate dihydrate ($CaSO_4{\cdot}2H_2O$), magnesium sulfate ($MgSO_4$), potassium chloride (KCl), sodium bicarbonate ($NaHCO_3$), and sodium bromide (NaBr), were purchased from Fisher Scientific (Whitby, ON, Canada). Ammonium carbonate was obtained from Caledon Laboratories (Georgetown, ON, Canada).

Acetonitrile (MeCN, HPLC grade), methanol (MeOH, HPLC grade), and acetone ($(CH_3)_2CO$, distilled in glass) were acquired from Caledon Laboratories (Georgetown, ON, Canada). Deionized water was obtained by Milli-Q (Millipore) filtration.

Isotopically labelled $^{13}C_5$-atorvastatin ($^{13}C_5$-ATO, ≥98%) was purchased from Toronto Research Chemicals (North

*denotes C-17.

York, ON, Canada), $^2H_{10}$-carbamazepine ($^2H_{10}$-CBZ, ≥98%) was purchased from Cambridge Isotope Laboratories (Andover, MA, USA), and $^2H_2$-17β-estradiol ($^2H_2$-E2, atomic purity 98%) was obtained from Sigma-Aldrich (Oakville, ON, Canada). $^{13}C_6$-Triclosan ($^{13}C_6$-TCS, ≥99%) was purchased from Wellington Laboratories (Guelph, ON, Canada).

Standard solutions

A 10 mg/L stock solution of each analyte was prepared in 1:1 MeOH/H_2O. Calibration standards corresponding to the linear range of detection (10–5000 μg/L) were prepared by dilution in MeOH/H_2O. To correct for instrumental variability, an internal standard was added to each vial prior to analysis, by addition of 50 μL of either 10 mg/L $^{13}C_5$-ATO or $^2D_2$-E2, 5 mg/L $^2D_{10}$-CBZ or 1 mg/L $^{13}C_6$-TCS, as appropriate, to 250 μL of sample. Standards and QC samples were stored at –20 °C until analysis. QC samples were analyzed with the study samples; the results of which formed the basis of accepting or rejecting a run.

Reconstituted water

Two types of reconstituted water for standard toxicity testing were selected and prepared, representing the range of variability commonly found in southern Ontario waters. Recon A represented Lake Ontario water (Ontario, Canada; pH 7.7, conductivity 395 mS/cm, alkalinity 0.11 mequiv., hardness 0.13 mmol), and contained 147 mg $CaCl_2$, 84 mg $NaHCO_3$, 1 mg NaBr, 3.7 mg KCl, and 30.1 mg $MgSO_4$ per litre of distilled water.[14] Recon B was selected to represent the water hardness of the Grand River watershed (Ontario, Canada; pH 8.4, conductivity 606 mS/cm, alkalinity 0.35 mequiv., hardness 0.25 mmol), and contained 192 mg of $NaHCO_3$, 120 mg of $CaSO_4{\cdot}2H_2O$, 120 mg of $MgSO_4$, and 8 mg of KCl in 1 L of distilled water.[15]

Analytical methods

Separation

Individual isocratic liquid chromatographic methods were developed for each PPCP, using an Acquity UPLC (Waters, Milford, MA, USA). Ten microlitre aliquots were injected into an Xterra MS-C8 column (particle size 3.5 μm, 2.1 id × 100 mm) fitted with a column guard, kept at 35 °C. For all compounds, HPLC separation involved the use of two solvents: H_2O (A) and MeCN (B), at a flow rate of 300 μL/min, with the exception of TCS, for which a flow rate of 200 μL/min was used. For ATO, an isocratic mixture of 20% A: 80% B was used, where A and B both contained 0.1 formic acid (*v*/*v*). The CBZ and EE2 solvent mixture was 40% A: 60% B, and the TCS solvent mixture was 10% A: 90% B. EE2 required the post-column infusion of 0.5% ammonium carbonate, at a rate of 10 μL/min.

Detection

Analyses were performed using a Quatro Ultima tandem LC triple quadrupole mass spectrometer (Micromass, Manchester, UK) equipped with a Z-Spray electrospray ionization (ESI) source. A positive-ionization mode was used for the determination of ATO and CBZ, while a negative-ionization mode was used for analysis of EE2 and TCS. Nitrogen was used as both drying and nebulizing gas, at flow

rates of 500 and 70 L/h, respectively. Argon was used as the collision gas, at a pressure of 2.5×10^{-3} mbar (1 bar = 100 kPa), with the exception of TCS, where the pressure was lowered to 2.5×10^{-4} mbar. Source and desolvation temperatures were 120 and 350 °C, respectively.

For the detection of TCS, ion fragmentation did not provide satisfactory quantifiable transitions, even at low ion energy, a phenomenon that has been observed in other studies.[6,16] Quantification was therefore performed using precursor-to-precursor transitions (i.e., both quadrupoles were set to select the $[M - H]^-$ mass) for the TCS ions (*m/z* 288.8 and 286.8, found in proportion to the isotopic ratio of chlorine) and internal standard (*m/z* 299.1 and 301.1). Tandem LC–MS conditions are summarized in Table 2.

Extraction procedures: development and validation

Water extractions

For each solid-phase extraction (SPE) cartridge tested, triplicate 500 mL aliquots of ultrapure water were spiked with a known quantity of each individual PPCP, using 100 μL of either a 5 or 10 mg/L solution of ATO, CBZ, EE2, or TCS in MeOH. Samples were acidified to pH 2 using 50% sulfuric acid, after which they were extracted through a SPE cartridge. For comparison purposes, SPE cartridges used were Supelco ENVI-18 (Sigma-Aldrich, Oakville, ON, Canada), OASIS MAX and OASIS HLB (Waters, Mississauga, ON, Canada). Cartridges were first conditioned with 6 mL of $(CH_3)_2CO$, followed by 6 mL of MeOH, and 12 mL of deionized water, adjusted to pH 2 with 50% H_2SO_4. Cartridges were loaded at a rate of approximately 10 mL/min, and eluted with 3 × 2 mL MeOH. Samples were then evaporated to 1 mL, and reconstituted to 2 mL with ultrapure water. Samples were frozen at –20 °C until analysis, usually performed within 2 weeks (with the exception of EE2 samples, which were analyzed after 9 weeks).

Sediment extractions

For each compound investigated, triplicate samples of 10–15 g of wet sediment from Environment Canada Reference site No. 112, pH 8.17, alkalinity 89 mg/L, 36% clay, 55% silt, 9% sand, 1.9% total organic carbon,[17] was added to pressurized liquid extraction (PLE) cells previously filled with 10–15 g of Ottawa sand reference material (Fisher Scientific, Whitby, ON, Canada). The sediments were then spiked with 1 μg of ATO, CBZ, EE2, or TCS, by adding 100 μL of 10 mg/L in MeOH of the analyte to the sediments. The remaining volume of the cells was filled with Ottawa sand, and samples were extracted in MeOH by PLE (ASE 300 Accelerated Solvent Extraction System; Dionex, Oakville, ON, Canada) at a temperature of 100 °C and pressure of 1500 psig. The extraction procedures included four cycles of 15 min (static), using a solvent delivery of 60% of cell volume. The extracts were evaporated to 1–5 mL, after which an equal volume (1–5 mL) of $CaCl_2$ (0.5 mol/L) was added to facilitate the precipitation of suspended solids.[18] Samples were vortexed and centrifuged at 1000*g* for 30 min at 4 °C. The supernatant was collected, filtered through 0.45 μm syringe filters (Chromatographic Specialties, Brockville, ON, Canada), and stored at –20 °C pending analysis, which typically took place within 2 months of extraction (however, due to unforeseen complications, the EE2 samples were stored for 12 months prior to analysis).

To compare the results of the PLE of ATO and in the absence of data from the literature, a triplicate Soxhlet extraction was performed using MeOH. Approximately 2 g of sediments were spiked with 0.1 μg of ATO by addition of 1 mL of a 0.1 mg/L ATO solution in MeOH, after which the sediments were extracted for 24 h using a Soxhlet extraction apparatus. The extracts were then evaporated following the same procedures as with the PLE extractions.

Biota extractions

Extractions were performed on two benthic invertebrates, the midge *Chironomus tentans* and the freshwater amphipod *Hyalella azteca*. For each organism and compound investigated, the extraction consisted of the addition of 9–12 animals to 2 mL of $(CH_3)_2CO$ ($n = 6$), into which 10 μL of a 10 mg/L solution of ATO, CBZ, EE2, or TCS in MeOH was added. Samples were thoroughly mixed and sonicated for 30 min (Branson Ultrasonic, Danbury, CT, USA). After additional mixing, samples were centrifuged at 1000*g* for 30 min at 4 °C, and the supernatant was collected and evaporated to dryness. Samples were reconstituted in 1 mL of 50:50 MeOH/H_2O, filtered through 0.45 μm syringe filters, and stored at –20 °C pending analysis that was performed within 5 days.

Precision and accuracy

Method precision was determined using replicate extractions ($n = 3$) of spiked samples in all matrixes investigated in the present study. For biota (*C. tentans* and *H. azteca*), six replicate sample extractions were performed ($n = 6$) because of the expected greater matrix complexity. The linearity of all standard curves was verified in each matrix by plotting the peak area of the analyte versus its concentration, and the Response (R) of the analyte against concentration was calculated using the equation

$$[1] \qquad R = \frac{\text{Peak area}_{\text{Std}} \times \text{Concn}_{\text{IS}}}{\text{Peak area}_{\text{IS}}}$$

The accuracy of the method was estimated using the standard error of the mean and the relative standard deviation. The standard error of the mean was calculated using the equation

$$[2] \qquad \text{SEM} = \frac{\text{SD}}{\sqrt{n}}$$

where SD is the standard deviation, and n is the number of replicates. The relative standard deviation (RSD) was calculated using the equation

$$[3] \qquad \text{RSD}(\%) = \frac{\text{SD}_\text{A}}{\text{Concn}_\text{A}} \times 100\%$$

where SD_A is the standard deviation of the analyte, and $Concn_A$ is the average concentration of the analyte.

Method selectivity

For each PPCP, the selectivity (susceptibility to cross-contamination) of the LC–MS/MS methods employed in the

Table 2. Optimized LC–MS/MS conditions for the analysis of four pharmaceuticals and personal care products and their internal standards in water and sediments. Argon served as the collision gas, at a pressure of 2.5×10^{-3} mbar.

Analyte	ES mode (+/–)	Retention time (min)	Parent ion (*m/z*)	Daughter ions		Cone voltage (kV)	Collision energy (eV)

			301.1	301.1	—	20	0

Note: Collision-gas pressure for triclosan was 2.5×10^{-4} mbar to avoid excessive fragmentation.

[a]Internal standard.

[b]Quantification of triclosan was performed using only the precursor-to-precursor transition.

present study was investigated by analyzing solutions that contained the individual PPCP, or its internal standard, across all MRM channels. For all PPCPs, a solution concentration of 5000 μg/L was used, while the internal standards were used at concentrations of 1667 (ATO, EE2), 833 (CBZ), or 167 (TCS) μg/L, corresponding to the final concentrations of each internal standard to be employed during sample analysis. The extent of cross-contamination was calculated using the equation

$$[4] \qquad \text{CC}\ (\%) = \left[\frac{\text{Area}_\text{A}}{\text{Area}_\text{C}}\right] \times 100\%$$

where Area_A is the peak area for the analyte quantitation ion, and Area_C is the peak area for the quantitation ion of the suspected cross-contaminant.

Matrix effects

Given the well-established susceptibility of LC–MS/MS techniques to matrix effects,[5,7,8] the impact of reconstituted water, sediments, and biota on the MS/MS ionization responses of the four PPCPs was carefully assessed in each extracted matrix as follows. Spiked samples were frozen at –20 °C and analyzed within 1 week.

Water

For each analyte, matrix interactions were investigated by spiking the target analyte in 50:50 MeOH/Recon (A or B) at concentrations corresponding to those of the standard curve prepared in MeOH/Milli-Q water (10–5000 μg/L). Each series of spikes was prepared in duplicate. The appropriate internal standard (see standard solutions Section) was added to each vial prior to analysis.

Sediments

A 13 g sample of wet sediment was extracted by PLE, as outlined above. The sediment extracts were used to spike various concentrations of the target analyte (10–5000 μg/L) for comparison with the standard curve prepared in Milli-Q water. For each PPCP, each series of spikes was prepared in duplicate. The suitable internal standard was added to each sample prior to analysis.

Biota

A pooled sample of 10–15 animals each of *Chironomus tentans* or *Hyalella azteca* was extracted following the procedures outlined above. Twelve biota extracts were pooled in two groups of six, to provide duplicates of 6 mL, for biota tissue concentrations of 10.5 mg/mL (*C. tentans*) and 1.9 mg/mL (*H. azteca*). A series of spiked samples (10–5000 μg/L) were prepared from both duplicates, for each PPCP investigated, and the appropriate internal standard was added to each vial prior to analysis.

Calculations

For each solution sample (in 50:50 MeOH/Milli-Q) and corresponding spiked matrix sample, the matrix effect was calculated at each concentration as

$$[5] \qquad M_x(\%) = \left[\frac{\left(\frac{\text{Area}_\text{A}}{\text{Area}_\text{IS}}\right)_\text{matrix}}{\left(\frac{\text{Area}_\text{A}}{\text{Area}_\text{IS}}\right)_\text{standard}} - 1\right] \times 100\%$$

where M_x is the matrix effect at concentration x (%); $M_x > 0$ corresponds to matrix enhancement and $M_x < 0$ corresponds to matrix suppression. According to this calculation, the standard solvent, by definition, produces no matrix effects. In addition, if the internal standard fully corrects for the variation in ionization efficiency, the ratio $\frac{\text{Area}_\text{A}}{\text{Area}_\text{IS}}$ will be the same, regardless of the matrix, and the matrix effect will be zero ($M_x = 0$). This approach resembles the method proposed by Matuszewski et al.,[19] which is calculated using the equation

$$[6] \qquad M_x(\%) = \left[\frac{\text{Area}_\text{matrix}}{\text{Area}_\text{MilliQ}} - 1\right] \times 100\%$$

with the exception that we have chosen to include an internal standard (IS) in our calculations, thus permitting differentiation between those effects caused by actual matrix

components from effects arising from simple variations in the ionization efficiency of the mass spectrometer.

Statistical analyses

For each analyte, differences between concentrations and matrixes were determined using a multiple factor Analysis of Variance and Tukey's adjustment for multiple comparisons.[20] The interactions of the following factors were analyzed: concentration, matrix, and concentration × matrix, the results of which are presented in the Matrix effects Section (below). All statistical computations were performed using SAS® (Version 9.1, Cary, NC, USA).

Results and discussion

Extraction procedures: development and validation

The calibration curves for each matrix extract are presented in the Supplementary data, Fig. S1 (peak area vs. concentration) and Fig. S2 (response vs. concentration). All calibration curves exhibited satisfactory linearity throughout the range of concentrations examined (limit of quantification: 5000 μg/L), with R^2 values of 0.9881–0.9999 (Table 3). 3). The limit of detection (LOD) and limit of quantification (LOQ), calculated for each matrix investigated, are also presented in Table 3.

Water extractions

The use of solid-phase extraction for the determination of PPCPs in aqueous environmental samples has been investigated in several studies.[21–23] In the present study, the recovery of PPCPs after SPE varied with cartridge selection (Table 4). The Supelco ENVI-18 yielded the most satisfactory accuracy for the extraction of CBZ, EE2, and TCS with average recoveries of 91%, 87%, and 84%, respectively. Given the better accuracy and precision provided by the Oasis HLB cartridge, the latter was selected for the recovery of ATO (71%; Table 4), a finding in agreement with those of Miao and Metcalfe.[24] Our recoveries are consistent with those obtained in similar studies, where recoveries for ATO ranged from 77% to 86%,[24,25] CBZ varied between 57% and 100%,[4,21,26–29] EE2 ranged from 76% to 96%,[30] and TCS varied between 36% and 95%.[16,22,31,32] Satisfactory linearity was obtained, with R^2 values of 0.9964 to 0.9999 (Table 3).The limit of detection for each analyte in Milli-Q water was 1.12, 1.12, 3.45, and 4.33 μg/L for ATO, CBZ, EE2, and TCS, respectively, while the limit of quantification was 3.76, 3.76, 11.50, and 14.42 μg/L, respectively (Table 3). For Recon A, the limit of detection was 0.65, 0.82, 6.29, and 5.37 μg/L, and the limit of quantitation was 2.18, 2.74, 20.97, and 17.91 μg/L for ATO, CBZ, EE2, and TCS, respectively (Table 3). For Recon B, the limit of detection was 0.61, 1.00, 5.41, and 3.03 for ATO, CBZ, EE2, and TCS, while the limit of quantitation was 2.03, 3.35, 18.06, and 10.10 μg/L, respectively (Table 3).

Sediment extractions

PLE proved to be a straightforward and reliable technique for the extraction and determination of PPCPs in sediments, with recovery rates varying between 70% (ATO) and 116% (EE2) (Table 5). The recovery of ATO following Soxhlet extraction was 42 ± 9.3% (mean ± SEM, n = 3), considerably lower than that obtained via PLE. Although PLE is a widely used technique for the analysis of several organic contaminants (e.g., PAHs, PCBs, surfactants, and pesticides),[33,34] there are notably fewer studies using this method for the extraction of PPCPs. Miao et. al.[35] successfully used PLE for the extraction of CBZ from biosolids, and had similar recoveries, while another study reported EE2 recovery of 87% from sediments.[36] Lastly, three studies successfully extracted TCS by PLE, and obtained 100%–120% recovery in sediments,[16,32,37] which is consistent with our values. To our knowledge, this study is the first to report extraction of ATO by PLE. Linearity varied between 0.9918 and 0.9997 (Table 3). The limit of detection of each analyte in sediment extracts was 4.72, 7.99, 7.62, and 17.76 μg/L for ATO, CBZ, EE2, and TCS, respectively. The limit of quantification was 15.72, 26.63, 25.39, and 59.19 μg/L, respectively (Table 3).

Biota extractions

Although the use of PLE presents clear advantages for the analysis of sediments and biota, the large sample sizes required (e.g., several grams) preclude its use with very small animals, such as benthic invertebrates, due to limitations in the availability of animal tissue. The liquid extraction we present here is a simple and flexible technique, which could be adapted to various sample sizes. All compounds exhibited satisfactory recoveries, ranging from 61% to 129% (Table 6). 6). Few studies to date have investigated the extraction of PPCPs from non-target organisms. Liquid–liquid extraction methods have been proposed for the analysis of estrogens in algae,[38] and for a wide variety of PPCPs and triclosan in fish,[39,40] with recoveries varying between 40% and 119%. Recently, a study proposed the extraction of selective serotonin re-uptake inhibitors from fish by PLE.[39] It is noteworthy that the studies reporting methods for estrogens and triclosan proposed GC–MS analyses, which involved preliminary derivatization of the target analytes. To the best of our knowledge, this study is also the first to propose extraction procedures for both ATO and CBZ in biota. In addition, the quantification we propose by tandem LC–MS represents an alternative to the derivatization processes involved in the analysis of PPCPs by GC–MS. Linearity (R^2 values) varied between 0.9881 and 0.9993 (*C. tentans*) and 0.9888 and 0.9998 (*H. azteca*; Table 3). For the *C. tentans* extracts, the limit of detection for ATO, CBZ, EE2, and TCS was 0.34, 1.12, 3.74, and 7.67 μg/L, respectively; the limit of quantification of each analyte was 1.12, 2.87, 12.47, and 25.58 μg/L (Table 3). For the *H. azteca* extracts, the limit of detection was 1.29, 1.10, 6.50, and 7.99 μg/L for ATO, CBZ, EE2, and TCS, respectively, while the limit of quantification was 4.31, 3.66, 21.68, and 26.65 μg/L, respectively (Table 3).

Method selectivity

Cross-talk between the MRM channels of each analyte and internal standard was investigated using individual solutions of each PPCP and its internal standard, the results of which are presented in Supplementary data Figs. S3–S10. We observed negligible cross-talk between each analyte and their respective internal standard. For ATO, a cross-talk of 0.05% was calculated (S3), representing the percentage of

Table 3. Limit of detection (LOD; μg/L), limit of quantification (LOQ; μg/L), and linearity (R^2; 5–5000 μg/L) for four pharmaceuticals and personal care products in various matrixes.

[a]The LOD was calculated as 3σ, where σ is the relative standard deviation of 6–7 analyses of a low-concentration standard in the matrix of interest.
[b]The LOQ was calculated as 10σ, where σ is the relative standard deviation of 6–7 analyses of a low-concentration standard in the matrix of interest.

the peak area detected in the quantitation MRM channel of its internal standard. For $^{13}C_5$-ATO, a cross-talk of 0.03% was calculated; in other words, the peak area detected in the quantitation MRM channel of ATO was 0.03% of that detected for the quantitation ion of $^{13}C_5$-ATO (Fig. S4). This level of cross-talk is neglible in comparison with the purity of the internal standard, which was ≥98%. CBZ exhibited a cross-talk of 0.01% (Fig. S5), while that of $^2H_{10}$-CBZ was 0.05% (Fig. S6), both are also negligible compared with the purity of the chemical (≥98%). For EE2 and $^2D_2$-E2, no cross-talk was detected (Figs. S7–S8), because the analyte and its internal standard were different compounds. For TCS, the cross-talk was calculated for both precursor transitions; the cross-talk of TCS was 0.4% for both transitions (Fig. S9), but that of $^{13}C_6$-TCS was 6.1% and 3.1% for the heavier and lighter precursors, respectively (Fig. S10). While these values are greater than those expected based on the purity of the internal standard (≥99%), they remain well under the RSD (precision) associated with the various extractions (9.2%–21.8%), and thus further correction against the impact of cross-talk was deemed unnecessary.

Matrix effects

To further minimize the potential impact of matrix interactions, we selected an internal standard that closely resembled the properties of each target analyte. For ATO, CBZ, and TCS, an isotopically labelled version of the compound of interest was used, while for EE2, a deuterated estradiol standard was selected, from which the target analyte differs only by the presence of an ethinyl group on C-17 (Table 1). The physico-chemical properties of both compounds are relatively similar, and they exhibited nearly identical elution times (Table 2). The impact of various matrixes on each analyte was investigated at concentrations ranging from 10 to 5000 μg/L. The greatest matrix effects were generally detected at lower concentrations of analyte, since the co-eluents (i.e., matrix) are present in a greater proportion relative to the analyte. The calibration curves for each analyte and matrix prior to correction for variations in ionization efficiency are presented in Fig. S1, while the calibration curves corrected for each analyte using their respective internal standard are presented in Fig. S2.

To illustrate the benefits of integrating an internal standard into the calculation of matrix interactions, the absolute matrix effects, calculated using the approach of Matuszewski et al.,[19] are represented in Fig. S11 for comparison with the approach used in the present study (Fig. 1). Although the differences are minimal for the two aqueous matrixes, the absolute matrix effects calculated using the approach of Matuszewski et al.[19] were greater than those calculated using our method, especially with complex matrixes such as sediment and biota, (note the change in *y* axis, increased to 250%–400% in Figs. S11C–S11E). In the absence of internal standards, the variation in ionization efficiency brought about by the presence of matrix co-eluents is incorporated into the absolute matrix effect, thus increasing its intensity. These data are in agreement with the calibration curves presented in Fig. S1, where, for example, a significant matrix enhancement was associated with the presence of sediment or biota with TCS (see Fig. S1D).

Table 4. Recovery (accuracy ± SEM (precision)) of four pharmaceuticals and personal care products in aqueous samples, and cartridge selected for each PPCP investigated. In each case, $n = 3$ and optimum recoveries are denoted in bold font.

	Recovery[a] (%)			
	ENVI-18	MAX	HLB	Cartridge selected
Atorvastatin	62±1.3 (3.6)	71±4.9 (11.9)	**71±1.9 (4.7)**	HLB
Carbamazepine	**95±3.4 (6.1)**	82±1.2 (1.5)	75±4.5 (6.0)	ENVI-18
17α-Ethinylestradiol	**92±7.9 (14.7)**	79±5.2 (11.4)	86±8.1 (16.3)	ENVI-18
Triclosan	**103±5.5 (9.2)**	96±13.2 (33.5)	43±3.8 (8.9)	ENVI-18

Note: Precision was expressed as RSD × 100.

[a]Cartridges selected for recovery experiment were Supelco ENVI-18, Waters Oasis MAX, and Waters Oasis HLB.

Table 5. Recovery (% ± SEM (precision)) of four pharmaceuticals and personal care products in sediments by pressurized liquid extraction (PLE). In each case, $n = 3$.

Compound	Recovery (%)
Atorvastatin	70±2.5 (6.2)
Carbamazepine	89±2.7 (5.2)
17α-Ethinylestradiol	116±4.0 (6.0)
Triclosan	109±6.2 (9.9)

Note: Precision was expressed as RSD × 100.

Table 6. Recovery (% ± SEM (precision)) of four pharmaceuticals and personal care products in biota, after sonication. In each case, $n = 6$.

	Compound	Recovery (%)
Chironomus tentans	Atorvastatin	61±2.8 (11.0)
	Carbamazepine	118±2.2 (4.5)
	17α-Ethinylestradiol	98±5.7 (14.3)
	Triclosan	69±7.0 (21.8)
Hyalella azteca	Atorvastatin	108±2.8 (6.3)
	Carbamazepine	129±1.4 (2.6)
	17α-Ethinylestradiol	95±2.9 (7.4)
	Triclosan	81±3.3 (17.0)

Note: Precision was expressed as RSD × 100.

Water

When the compounds of interest were dissolved in reconstituted water, the presence of salts generally had minor effects on compound ionization, which were usually adequately corrected by the selected internal standards (Fig. 1). CBZ was generally insensitive to either Recon A or B, as reflected by the low amplitude of matrix effects (5% enhancement) and the absence of differences in matrix interactions between the two water types. With a pK_a of 14, CBZ is a very strong proton acceptor compared with other bases in solution, such as HCO_3^- (pK_a 6.1). Consequently, CBZ will be preferentially protonated, regardless of the differences in the composition of Recon A or B. In contrast, the presence of salts in the softer water (Recon A) caused, on average, 4% and 8% suppression with TCS and ATO, respectively (Fig. 1). This interaction is not surprising, given the known ability of sulfates and phosphates to cause matrix suppression.[8] However, effects were more noticeable with EE2, where the addition of salts caused, on average, 12% matrix enhancement, which was most pronounced at lower concentrations (Fig. 1). The addition of further salts, as found in Recon B, did not appear to significantly affect CBZ and EE2, leaving matrix effects relatively unchanged. Meanwhile, Recon B yielded greater matrix suppression (14% on average) of ATO than did Recon A (Fig. 1). Matrix suppression was not dependent on ATO concentration ($p = 0.99$), suggesting that the increased suppression is attributable to differences between the two matrixes (Recon A and B). The main difference in these two systems lies in their relative alkalinity and buffering capacity, with Recon A having an alkalinity of 0.11 mequiv. (compared with 0.35 mequiv. for Recon B), and a buffering capacity of 84 mg $NaHCO_3$ (vs. 192 mg $NaHCO_3$ for Recon B). In effect, the higher alkalinity and buffering capacity of Recon B would serve as a "proton sponge", steadily reducing the protonation of ATO, regardless of concentration. The reduced protonation of ATO in solution would thus lead to a greater suppression in Recon B than in Recon A, due to the presence of a larger quantity of a stronger base (HCO_3^-).

Addition of 0.5 mol/L ammonium carbonate base post-injection facilitated the ionization of EE2 in ES^- mode, resulting from the increased alkalinity of the mobile phase. The presence of carbonate (via HCO_3^-) in Recon A and B likely further increased the alkalinity of the mobile phase, thus facilitating the ionization of the target analyte even further, and resulting in matrix enhancement. In the case of TCS (pK_a 7.9), it is suspected that the alkalinity in Recon B (pH 8.4) may have facilitated ionization, thus causing a slight matrix enhancement (3%), whereas Recon A (pH 7.7) may not have been sufficiently alkaline to fully ionize a compound of comparable pK_a (as expected under the Henderson–Hasselback equation), as seen by the overall 6% matrix suppression.

Sediments

In contrast with the generally minor matrix effects in water, the presence of sediment extracts had a noticeable impact on compound ionization, especially with ATO, where the signal amplitude was reduced 10 fold in comparison with Milli-Q water (see Fig. S1). This is also reflected in the higher limits of detection and quantitation associated with analyses in sediment extracts, which increased by a factor of 2–8 compared with the standards prepared in Milli-Q water (Table 3). When the appropriate internal standards were used to correct for these variations in ionization efficiency, the matrix effects varied, on average, be-

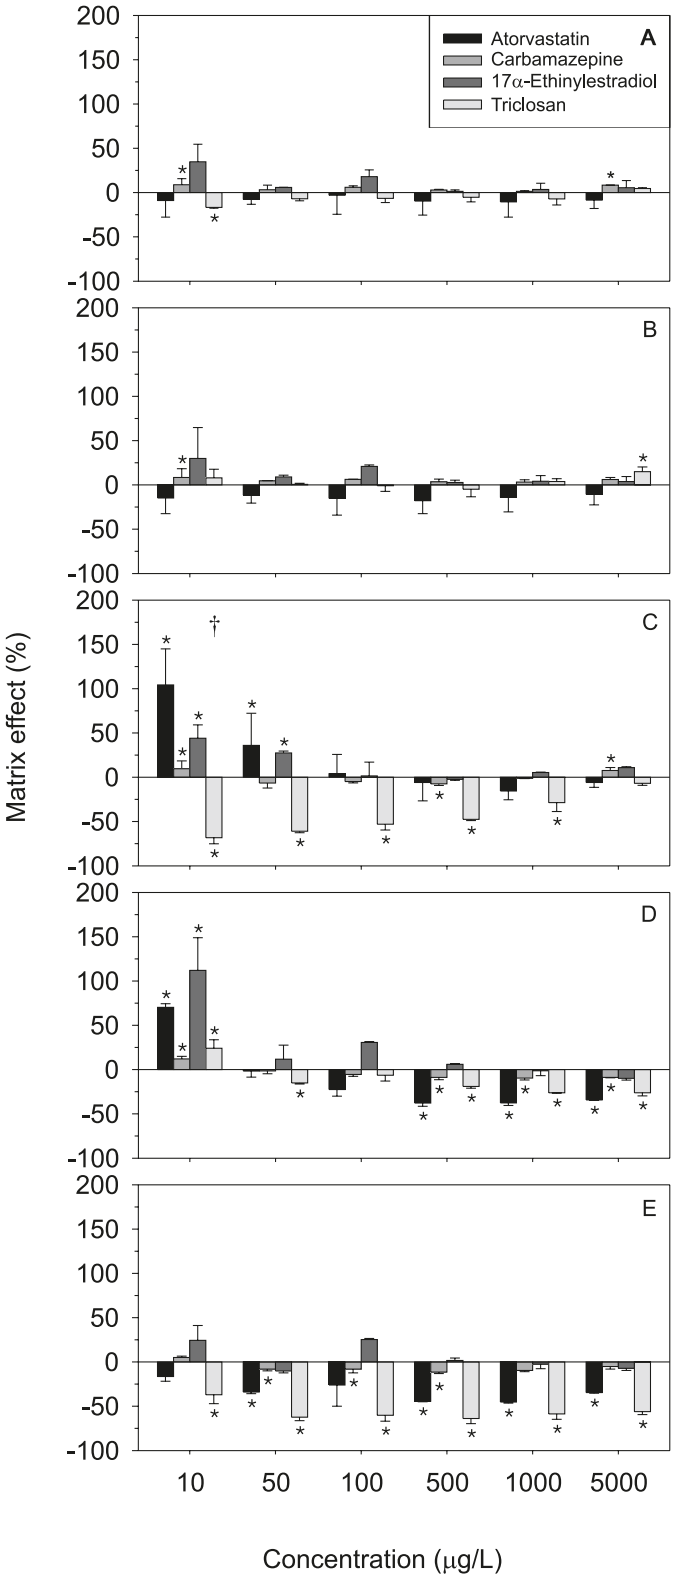

Fig. 1. Matrix effects (mean ± SEM; $n = 2$) in two types of reconstituted water (A, B), sediment extracts (C), and biota extracts (D, *Chironomus tentans*; E, *Hyalella azteca*) with increasing standard concentration on four pharmaceuticals and personal care products. The matrix effect signifies the compound is *X*% more or less recoverable than in the absence of the matrix of interest. * denotes values significantly different from zero ($p < 0.05$). †denotes concentrations below the limit of detection (LOD) and should be interpreted with caution.

tween 39% suppression (TCS) and 19% enhancement (ATO). There were negligible matrix effects associated with CBZ (no overall matrix effect), while EE2 showed, on average, a 15% enhancement (Fig. 1). All effects were concentration-dependent, with most significant interactions at the lowest concentration investigated (10 μg/L, $p \leq 0.012$), where the relative amount of matrix constituents to target analytes were highest. The presence of humic and fulvic acids have been reported to cause matrix suppression in the LC–MS analysis of the pesticide dichlorvos, as well as naphthenic acids,[41,42] and may have been responsible for the matrix interactions observed in the present study. Given the comparatively low pK_a of ATO, the addition of such acidic components to the ionization matrix would increase the protonation of ATO, leading to the observed matrix enhancement. At low concentrations of ATO, the higher [acid]:[ATO] ratio would lead to proportionately greater ATO protonation than would be seen at higher ATO concentrations. In contrast, because of its high pK_a, the presence of additional acids had no impact on CBZ ion formation. Lastly, suppression was observed at all but the highest TCS concentration (Fig. 1). The pK_a (7.9) of TCS was closest to the pH of the sediments (8.17), and was the compound most affected by the presence of dissolved acids.

Biota

Matrix interactions in the presence of biota extracts were remarkably similar to observations made with other matrixes. The presence of *C. tentans* extracts had neglible effects on the analysis of CBZ, with an overall matrix suppression of 4% (Fig. 1). A 25% matrix enhancement was observed with EE2, while an average matrix suppression of 11% and 14% was observed with ATO and TCS, respectively (Fig. 1). However, these values were mainly due to a significant matrix enhancement observed at the lowest concentration with all analytes in *C. tentans* extracts: CBZ (15%), TCS (24%), ATO (70%), and EE2 (112%; $p \leq 0.0024$). The effects then became of lower magnitude with increasing concentrations (Fig. 1), as the relative ratio of matrix:analyte decreased. Note that while the lowest concentrations used for EE2 and TCS with *C. tentans* were below the LOQ, the concentrations exceeded the LOD. Since the compounds could be detected, the impact of the matrix on the ionization response could thus be determined.

Given the smaller animal size, and hence, lower biomass extracted, we expected the magnitude of effects in *H. azteca* extracts to be lower than in *C. tentans*. Indeed, matrix effects of low magnitude were observed with CBZ (6% suppression) and EE2 (5% enhancement; Fig. 1). However, greater matrix suppression was observed with ATO and TCS, throughout the range of concentrations investigated, with average suppressions of 33% and 56%, respectively, indicating that the composition of the matrix plays a greater role than its quantity. Given the wide variety of possible co-eluents associated with each species (particularly ionizable groups, such as amines from amino acids or phenolic moieties found in lipids, which are present in greater relative abundance in *H. azteca*, 6%,[43] than in *C. tentans*, 1%[44]), we

recommend that further investigations be conducted to identify the origin of this matrix suppression.

Recent studies dedicated to the extraction of PPCPs from fish tissues have reported the presence of significant matrix effects.[39,45] While investigating the extraction of the selective serotonine re-uptake inhibitors from fish tissue, Chu and Metcalfe[45] reported matrix suppression of 19%, 35%, and 39% for paroxetine, fluoxetine, and norfluoxetine, respectively. Another study also describing analytical methods for the extraction of PPCPs from fish tissue reported matrix effects varying between –95% for miconazole and +867% for erythromycin.[39]

In some respects, the observation of matrix effects in the presence of isotopically labelled analogues of the target analytes themselves may appear somewhat surprising. After all, it has been posited that the structural similarity of isotopically labelled substrates to their unlabelled analogues should lead to both compounds exhibiting similar behaviour, and hence, similar matrix effects. However, it has been well-established that acid dissociation constants (much like kinetic rate constants) are subject to often significant isotope effects. For example, laccase has been shown to have a pK_a of 8.98 in water, whereas in deuterated water, the pK_a becomes 9.24.[46] Meanwhile, the pK_a of chloracetic acid differs from that of ^{2}H-chloracetic acid labelled in the alpha position.[47] If the labelled and unlabelled compounds have different susceptibilities to ionization (as suggested by their differing pK_a values), then matrixes that can affect ionization in the mass spectrometer will have different impacts on the labelled and unlabelled compounds; hence, differing matrix effects will be observed.[9]

Conclusions

This study aimed to develop simple and straightforward methods for the extraction of four PPCPs from water, sediments, and biota, with the objective of subsequently applying these techniques to toxicological studies. The four compounds of interest were successfully extracted from water by solid-phase extraction with recoveries of at least 71%. Meanwhile, the pressurized liquid extraction method, developed to extract PPCPs from sediments, yielded recoveries > 70%. Lastly, the liquid extraction method, developed specifically to accommodate small tissue samples, yielded recoveries for the four compounds ranging from 61% to 129%.

Despite the use of carefully chosen internal standards to appropriately correct for variation in the ionization efficiency of each analyte, matrix effects of variable direction and amplitude were detected in the four PPCPs investigated. Although matrix suppression of greater amplitude has been observed in more polar compounds,[7] we found that physicochemical properties of each analyte, especially pH–pK_a interactions, could explain the direction and even magnitude of the matrix effect. For example, because of its high pK_a of 14.0, CBZ was not particularly sensitive to matrix effects at circumneutral pH. Meanwhile, matrix suppression was generally observed in ATO, which had the lowest pK_a (4.46), and for which the addition of alkaline salts likely caused significant matrix suppression. On the other hand, sediments having low concentrations of ATO were subject to matrix enhancement, presumably due to the additive effect of acidic co-eluents, such as humic and fulvic acids. Conversely, EE2 was generally susceptible to matrix enhancement in the presence of alkaline salts, which improved the ionization efficiency in negative electrospray mode. However, the presence of sediment co-eluents (presumably of acidic nature) had suppressive effects at low analyte concentrations. Lastly, TCS was the analyte most susceptible to matrix effects, exhibiting considerable matrix suppression in sediment and biota matrixes. We believe that its circumneutral pK_a (7.9) makes this compound more sensitive to pH-related changes. Overall, we have shown that matrix effects exist and may not be fully corrected using isotopically labelled analogues of target analytes. Our results demonstrate that potential matrix interactions should be taken in consideration during the development and application of analytical methods for pharmaceuticals and personal care products in environmental and biological matrixes, since failure to do so could drastically bias quantification and undermine study validity.

NanoMORALs — Metal nanoparticles doped with organic molecules

Giovanni Palmisano, Vincenzo Augugliaro, Rosaria Ciriminna, and Mario Pagliaro

Abstract: A new class of nanosized metal–organic alloys (MORALs) has been synthesized for the first time. Silver nanoparticles doped with Cu(II) and Fe(III) phthalocyanines were thus synthesized in the presence of sodium dodecyl sulfate (SDS). The resulting materials were characterized by means of XRD, SEM, TEM coupled to energy dispersive X-ray analysis, and thermogravimetric analysis. No leaching of the photoactive dopant species was observed in water or in common organic solvents.

Key words: hybrid, alloy, nanoparticle, metal–organic.

Résumé : On a synthétisé pour la première fois une nouvelle classe d'alliages métallo-organiques « MORALs » à l'échelle nano. On a ainsi synthétisé des nanoparticules d'argent dopées avec des phtalocyanines de Cu(II) et de Fe(III) en présence de sulfate de dodécyle et de sodium. Les produits obtenus ont été caractérisés par les techniques de diffraction des rayons X (DRX), de microscopie électronique à balayage (MEB) et de microscopie électronique à transmission (MET) couplées à des analyses de rayons X à dispersion d'énergie et d'analyse thermogravimétrique. On n'a observé aucune lixiviation des espèces dopantes photoréactives, que ce soit dans l'eau ou dans les solvants organiques communs.

Mots-clés : hybride, alliage, nanoparticule, métallo-organique.

[Traduit par la Rédaction]

Introduction

Metal–organic alloys (MORALs) are new materials with a variety of potential applications in different fields. Organic molecules as diverse as dyes[1] and polymers,[2] both water-soluble and not, have been efficiently incorporated within Ag, Au, and Cu either by simple homogeneous reduction of the corresponding metal cations in the presence of the desired organic species, or by heterogeneous reduction by a sacrificial reducing metal in solution.[3] In general, the encapsulated organic dopant is not affected by the mild encapsulation process, and once entrapped, it remains accessible to reactants in solution. As expected, however, the physicochemical properties of the doped metal species are largely altered. For example, various functional applications were readily proved, such as the use of Nafion@Ag as acid catalyst,[4] and the improvement of Ag catalytic performance upon encapsulation of Congo Red for oxidation of methanol to formaldehyde.[5] Clearly, considering the immense variety of organic molecules and the abundance of metals in the periodic table, these findings have opened the route to a new, and large, chemistry of doped metals.[1–5]

Entrapment is markedly distinct from adsorption and confers interesting new properties to the resulting hybrid composites. For example, although a water-soluble species such as Congo Red readily leaches out in water when adsorbed at the surface of Ag,[1] no leaching is observed from the corresponding MORAL (with DMSO being the only solvent capable to extract the organic dopant molecules).[3] Moreover, a one-to-two orders of magnitude larger amount of organics can be entrapped in metal compared with simple surface adsorption. Such first-generation MORALs consist of macro-mesoporous materials.

Herein, we report the first preparation of Ag-based MORAL nanoparticles made of silver doped with Cu(II) and Fe(III) phthalocyanines (CuPc and FePc, respectively). We demonstrate that carrying out the reductive encapsulation in the presence of micellar sodium dodecyl sulfate (SDS) makes it possible to obtain particles with diameters as small as the nanometer fraction. The method is general and opens the way to the practically viable synthesis of a new class of nanostructured hybrid metals of large applicative potential.

Experimental

Silver nanoparticles doped with metal phthalocyanines (MPc) were prepared by reducing Ag(I) ions with NaH_2PO_2 in the presence of SDS micelles (Scheme 1).

A solution of SDS (6.92 mmol) and NaH_2PO_2 (34.1 mmol) in H_2O (0.5 L) was left under agitation at

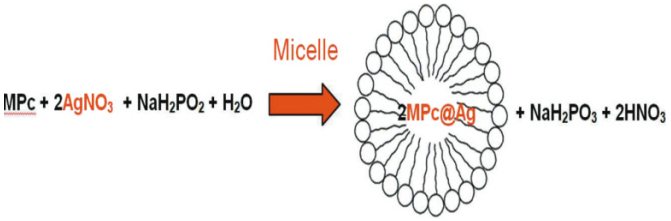
Scheme 1. Reaction scheme describing the synthesis of MORALs nanoparticles.



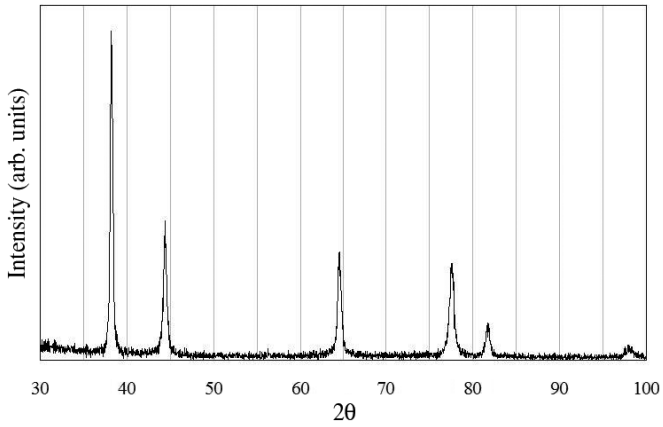
room temperature for 5 min, after which $AgNO_3$ (712 μmol) was added. Both doped and pure Ag samples were prepared. In the case of doped silver, 6.46 μmol CuPc or FePc were added to the starting solution, sonicating the reaction mixture (Bandelin Sonorex Digitec instrument) for 1 h to ensure complete solubility of the phthalocyanines. The solution thereby obtained was kept under slow agitation (300 rpm) for 4 days, after which it was centrifuged at 5 °C to separate the doped nanoparticles, which segregate from the micelles. The resulting silver MORAL particles were characterized by X-ray diffraction on Bruker D8 Advance instrument (40 kV, 35 mA, Cu Kα 1.542 Å). A Zeiss DSM-950 instrument operating at 80 kV was used for scanning electron microscopy images. Tablets of MORALs and pure silver powders were prepared applying uniaxial pressure (2.26 t/cm^2) and metallizing with gold before the analysis. Transmission electron microscopes JEOL mod. JEM-2000 FX and LEO 910 were employed for TEM analyses at 200 kV. Samples for TEM were prepared by sonicating a diluted suspension of MORAL in water (~10 mg MORAL in 1 L H_2O) for 10 min . A drop of this suspension was deposited on the Cu grid support used for analysis. Eventually, water was evaporated at 50 °C for 2 days. EDAX analyses were carried out with an energy dispersive X-ray analysis system connected to TEM. Thermogravimetric analysis (TGA) was performed on a SEIKO TG/ATD 320U, SSC 5200 (Seiko Instruments) from 25 to 900 °C at a heating rate of 10 °C/min in flowing dry air (100 mL/min). UV spectra were recorded on a UV–vis Shimadzu UV2401 spectrometer.

Results and discussion

Phosphite is a mild reducing agent, which does not react with the MPc (as shown in blank experiments). The SDS surfactant, in its turn, does not interfere with the efficiency of the molecular entrapment in the metal particles. The resulting nanoparticles of doped silver in the aqueous phase, in which the inorganic salts are dissolved, are thus readily sequestered in the hydrophobic core of the micelle as their formation takes place. Silver nanoparticles, indeed, are highly hydrophobic, and this property has been exploited, for example, in the synthesis of elegant nanostructures.[6]

The by-products together with SDS were easily washed off with EtOH and after a mild thermal treatment powders with the classical shine of silver (in the case of the undoped metal) or coloured in green (FePc@Ag) and blue (for the CuPc@Ag) were eventually isolated. No leaching was observed by keeping the metal–organic composite particles in contact with water or with common organic solvents, such as ethanol, acetone, and toluene, for prolonged time (as shown by the UV spectra of the filtered suspension, which showed no presence of organics even after 4 weeks). Ag nanocrystals slowly form and agglomerate within the structure of the SDS micelles. The crystallinity of silver is revealed by XRD diffractogram (Fig. 1) that showed the absence of silver oxides or salts.

Fig. 1. XRD spectrum of undoped silver.



It may be noted that all the peaks are attributable to the metal. The presence of entrapped phthalocyanines does not influence the position and shape of typical lines in the diffractogram (2θ = 38.2°, 44.4°, 64.6°, 77.6°, 81.8°, 97.9°). Thus, similar patterns were obtained for both the doped and undoped metal. The primary particle size by the Scherrer's equation[7] applied to all the six peaks gave results ranging from 9 to 13 nm, with an average value of 11 nm, both for doped and undoped silver. The presence of smaller particle sizes, however, is evident from TEM images (Fig. 2), coupled with EDAX (Fig. 3), that show how MORALs nanoparticles ranging from ~30 nm down to fraction of nanometers are actually obtained by carrying out the synthesis in the presence of the micelle (the particles are not mono-disperse, as the synthesis protocol was not optimized for that purpose).

It is also worth noting that the principal Ag peak in the EDAX spectrum was present (at ~3 keV) even in the case of particles with dimensions less than 1 nm (Fig. 3*b*). Peaks of Cu, Si, and O atoms in the same spectra were all due to the support used for the analysis, whereas the signal of C can be ascribed to the organic moiety of Pc and partly to the support.

Moving observation at a larger scale, the morphology of the powders appeared to be the same for both doped MORALs and undoped silver (Fig. 4) with aggregates of hundreds of nanometers up to few micrometers being clearly visible in SEM images.

Successful encapsulation of phthalocyanines was verified by means of thermogravimetric analysis. Figure 5 indeed shows that, although the very close peaks for the free and encapsulated phthalocyanine point to the presence of the organic dopant inside the metal bulk, quite different thermal degradations occurred for CuPc@Ag and FePc@Ag.

Fig. 2. TEM images of CuPc@Ag (*a*) and FePc@Ag (*b*, *c*). Magnifications: (*a*) × 400 000, (*b*) and (*c*) × 300 000.

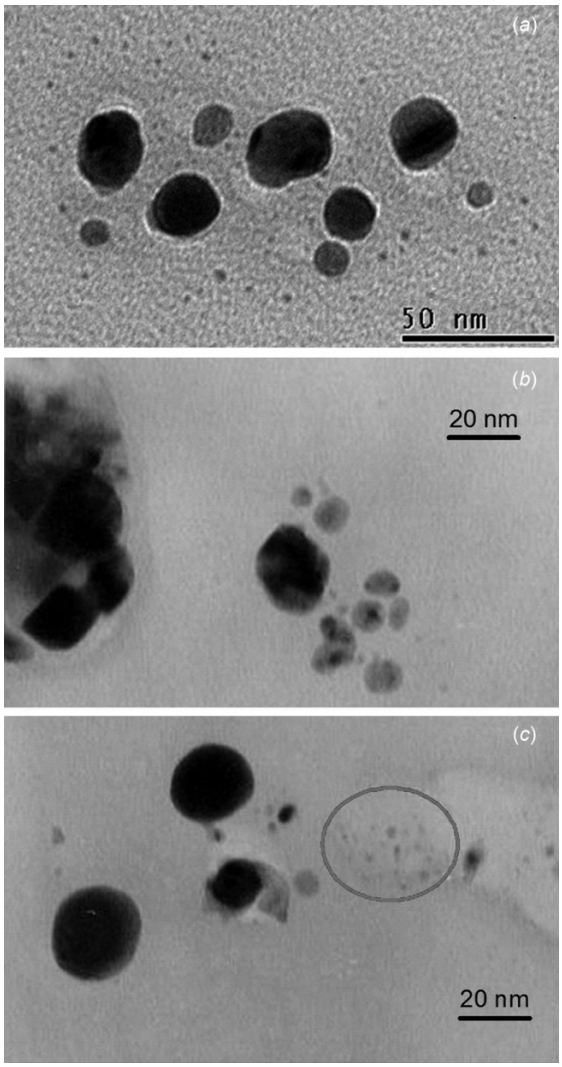


Fig. 3. EDAX spectra corresponding to images of (*a*) Fig. 2*a* and (*b*) circle in Fig. 2*c*.

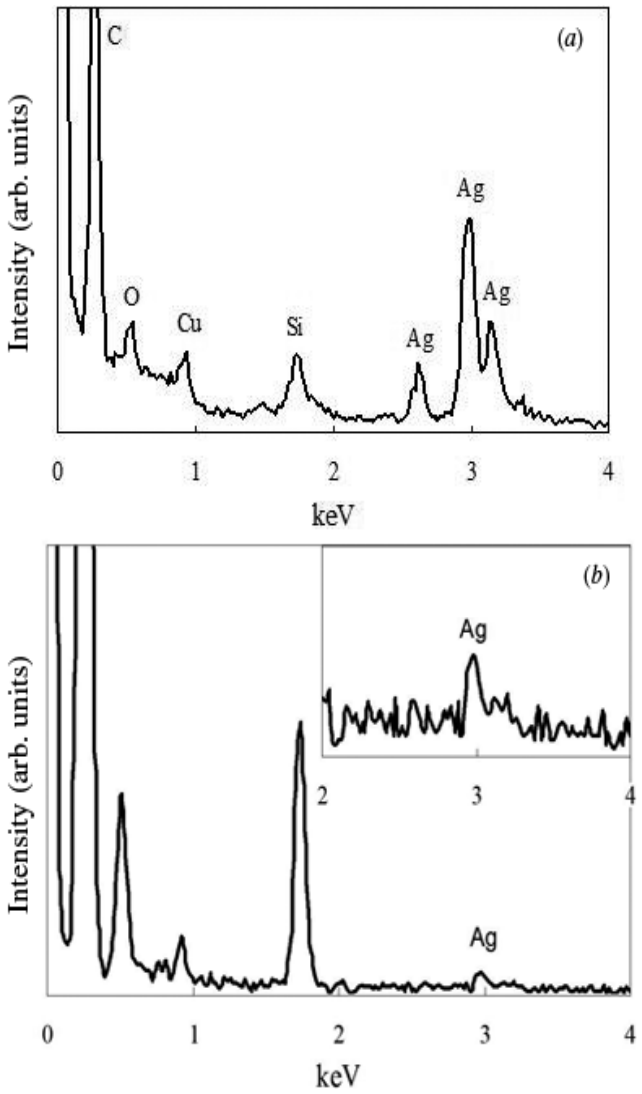

In fact, a clear degradation peak was obtained at 438 °C for the free phthalocyanine (Fig. 5*a*), whereas in the CuPc@Ag MORAL, concomitant narrowing of the decomposition temperature range and enhancement in thermal stability are noticed upon entrapment (ΔT = 24 °C between the degradation temperature of the free and encapsulated CuPc, Fig. 5*b*). The first effect may be due to the known catalytic action of Ag in thermal oxidative degradation processes,[5] as well as to being a clue to material's homogeneity; whereas the second effect is in accord with the behaviour previously observed for the polyacid Nafion entrapped in silver.[4]

Free FePc degrades between 320 °C and 410 °C (Fig. 5*c*) in a two-step process resulting in a main peak at 376 °C and a lower signal at 349 °C. On the other hand, in the case of FePc entrapped in silver, a broad peak is observed at 359 °C with degradation of the organic species occurring over a rather large temperature range in which the material apparently reacts with oxygen. Indeed, the increase in mass shown by the TGA profile of FePc@Ag after the decomposition points to oxygen fixation and shows how markedly the reactivity of the metal is changed upon its doping with the iron phthalocyanine.

The shown TGA analyses are in some ways similar to those previously reported of similar materials, and the lack of organics' stability with temperature can be ascribed to the catalytic effect of silver.[4]

Finally, the TGA data, along with observation of (*i*) complete segregation of the metallocomplexes from the starting solution and (*ii*) lack of leaching in most common solvents, indirectly prove that MPc are located into the metallic particle, namely incorporated into the regular periodic structure of Ag nanoparticle as MPc and not as metal ions (Cu and Fe) left after washing or loose adsorbed complexes at the surface. In the latter case, in fact, water easily washes away the adsorbed molecules, while the TGA spectra should point to inhomogeneous materials when, to the opposite, data in Fig. 5 clearly point to materials' homogeneity.

It is still an open question whether, in the case of Nano-MORALs, entrapment takes place inside or outside the

metal particle, making shells. Further structural studies on related materials are in course. In conclusion, we have developed the synthesis of nanosized metal–organic composites by employing a straightforward micelle-assisted synthesis. Silver nanoparticles[8] and metal phthalocyanines[9] have many functional applications, and soon these new nanomaterials might find practical use. From a fundamental viewpoint, however, the method described in this report is general and opens the route to the synthesis of a new class of metal–organic nanocomposites, termed NanoMORALs, whose forthcoming applications may indeed go beyond those, remarkable, being discovered in the case of the corresponding MORAL materials.

On the reactivity of indium(III) benzenechalcogenolates (chalcogen = sulfur and selenium) towards organyl halides for the synthesis of organyl phenyl chalcogenides

Clovis Peppe and Liérson Borges de Castro

Abstract: The reactivity of indium(III) benzenechalcogenolates (chalcogen = sulfur, selenium) towards organyl halides (organyl = alkyl, allyl, benzyl, acyl) was examined. A practical one-pot method to prepare organyl phenyl chalcogenides from indium metal and diphenyl dichalcogenide was found. The coupling is fairly broad in scope and generally works better for organyl halides capable to produce stable carbocations.

Key words: diphenyl diselenide, diphenyl disulfide, indium(III) benzenechalcogenolates, organyl phenyl chalcogenides.

Résumé : On a étudié la réactivité des benzènechalcogénolates d'indium(III) (chalcogène = soufre, sélénium) vis-à-vis des halogénures d'organyles (organyle = alkyle, allyle, benzyle, acyle). On a mis au point une méthode monotope pratique de préparer des chalcogénures d'organyle et de phényle à partir de l'indium métallique et du dichalcogénure de diphényle. La portée de la réaction de couplage est assez large et elle fonctionne généralement mieux avec les halogénures d'organyle susceptibles de donner naissance à des carbocations stables.

Mots-clés : diséléniure de diphényle, disulfure de diphényle, benzènechalcogénolates d'indium(III), chalcogénures d'organyle et de phényle.

Introduction

Indium(III) arylchalcogenolates, $In(EAr)_3$ (E = S, Se), were prepared by methathetical reactions,[1,2] redox processes,[3,4] and electrochemically by sacrificing indium electrodes.[5] Heteroleptic compounds bearing a halide ligand, $XIn(EPh)_2$ (X = Cl, Br, I; E = S, Se), were prepared by the oxidative insertion of the corresponding indium monohalide into the dichalcogenides.[6] $In(SePh)_3$ was found polymeric by X-ray means, crystallizing in two polymorfic forms: a triclinic containing five-coordinated indium centers with asymmetrical bridging benzeneselenolate ligands[7] and a monoclinic containing six-coordinated indium atoms with symmetrical bridging benzeneselenolate ligands.[8] The sulfur analogue, $In(SPh)_3$, is also believed to be polymeric,[2] but its X-ray structure was not established until now. However, the sterically hindered arylthiolate complex $(2,4,6\text{-}t\text{-}Bu_3C_6H_2S)_3In$, soluble in organic solvents, was crystallized and had its distorted trigonal planar structure determined by X-ray methods.[9] A common property relating both the homoleptic $In(EPh)_3$ and the heteroleptic $XIn(EPh)_2$ compounds is that they act as Lewis acids, forming stable molecular adducts with several nitrogen,[1–3,6,8] phosphorus,[1,3,4] sulfoxide,[1] and halide[1,3] ligands.

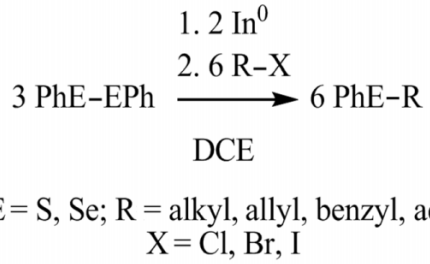
Indium(III) chalcogenolates contain indium–chalcogen bonds made of a hard In(III) cation[10] and a soft thiolate and (or) selenolate anions.[11,12] Hard acids – soft bases complexes possess intrinsic thermodynamic unstability, suggesting that the chalcogenolate anion could effectively be used as a nucleophile in organic reactions to produce new carbon–chalcogen bonds. Our group and other groups have introduced the heteroleptic $XIn(EPh)_2$ compounds as sources of the benzenechalcogenolate nucleophiles to produce organic chemicals of interest in reactions, such as ring opening of epoxides to β–hydroxyselenides[13] and sulfides,[14] ring opening of aziridines to selenocysteine and selenotreonine,[15] hydrochalcogenation of alkynes[16–18] to vinyl chalcogenides, also obtained through Pd(0)-catalyzed coupling of $IIn(SePh)_2$ with vinyl bromides[19], and finally for coupling with organyl halides to organyl phenyl chalcogenides.[20,21]

Recently, while trying to hydrochalcogenate aminoalkines with the heteroleptic compounds, $XIn(EPh)_2$, we observed ineffectiveness.[22] The task was accomplished with the indium(III) benzenechalcogenolate complexes, $In(EPh)_3$ (E = S, Se) generated by refluxing a 2:3 molar ratio of the metallic element and the corresponding diphenyl dichalcogenide in dichloroethane (DCE). The cleavage of the chalcogen–chalcogen bond by indium metal in mild conditions to the $In(EPh)_3$ compounds capable to deliver the benzenechalcogenolate nucleophiles is very attractive to the synthetic chemist because of the nontoxic nature and the stability of indium towards air and moisture. Furthermore, to replace the air-sensitive indium(I) halides to promote the cleavage of the chalcogen–chalcogen bonds is also desirable because it will allow to conduct one-pot

preparations directly from the stable metal. To gain a better understanding on the reactivity pattern of the $In(EPh)_3$ compounds generated by this method, we have examined their reactions with organyl halides (Scheme 1). We also compared the new results with the ones obtained using earlier similar procedures leading to PhER compounds involving the cleavage of the dichalcogenides by InI[20,21] and In metal.[23] A striking difference in reactivity, depending on the organyl halides, was observed; this was interpreted in terms of the polymeric nature of the $In(EPh)_3$ compounds and allowed to design experiments to the chemoselective production of a desired PhER compound.

Scheme 1. One-pot preparation of organyl phenyl chalcogenides.



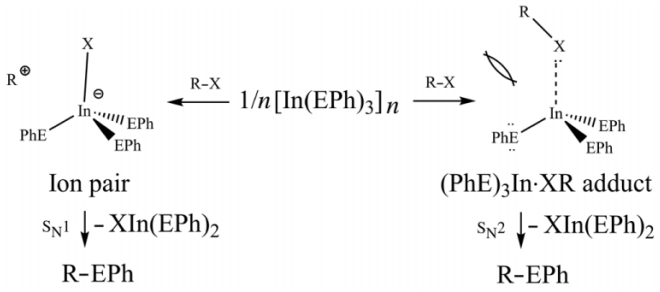
Results and discussion

The $In(EPh)_3$ (E = S, Se) compounds were easily prepared by refluxing 2:3 molar quantities of elemental indium and the dichalcogenide in DCE. Typically, the metal was consumed after 1–2 h, but sonication of a suspension of the metal in DCE for 10 min prior to heating accelerated the process. The selenium product remained in solution, while the sulfur analogue precipitated as a white powder. Addition of 3 equiv. of the organyl halides depicted in Table 1 afforded the corresponding organyl phenyl chalcogenides products with condensation of up to three benzenechalcogenolate ligands from the $In(EPh)_3$ reagents. The nucleophilic substitution is easily followed by TLC chromatography, and in the case of the sulfur complex, reaction completeness is verified just by observing the dissolution of the reagent in the reaction media; in most cases, optimum yields were obtained as soon as the white precipitate dissolved.

The reactivity trends of the organyl halides in condensations with the benzenechalcogenolate nucleophiles from the $IIn(EPh)_2$ (E = S, Se) compounds in dichloromethane was investigated by Ranu and co-workers, who demonstrated that primary, secondary, benzylic, and allylic chlorides, bromides, and iodides as well as acid chlorides readily participated in the reaction to form the desired organyl phenyl chalcogenides.[20,21] Jang and co-workers examined the problem through a one-pot reaction involving metallic indium, diphenyl diselenide, and organyl halides; in that work, they found that the reaction is initiated by organyl radicals generated by a one-electron reduction of the R–X substrate by metallic indium. Accordingly, a relative I > Br > Cl reactivity order was established for the organyl halides.[23]

There are remarkable differences in the reactivity of the $In(EPh)_3$ compounds towards organyl halides compared with the reagents discussed above. In the present work, we have verified that the nature of the organyl moiety of the halide controls the efficiency of the process. Tertiary, benzylic, allylic (leading exclusively to the α-coupling product), and acyl halides (Table 1, entries 22–39) instantaneously reacted with the $In(EPh)_3$ compounds at room temperature to produce good yields of the desired product. Reactions involving primary halides (Table 1, entries 1–17 and 40–42), on the other hand, took several hours for completion even with heating at 83 °C or completely resisted the transformation as observed for the chlorides (Table 1, entries 1 and 2). We further note that only the higher members of the series of bis(phenyl chalcogen)alkanes $PhE(CH_2)_nEPh$ (n = 1, 2, 3, 5, or 10) were efficiently obtained from the corresponding

Scheme 2. Proposed pathway for reaction of $In(EPh)_3$ and RX.



dibromo substrates (Table 1, entries 9–17). Secondary alkyl halides (Table 1, entries 18–21) failed to undergo efficient condensations, and surprisingly, from these reactions with $In(SePh)_3$ (Table 1, entries 19 and 21), we have isolated 1,4-bis(phenyl selanyl)butane, $PhSe(CH_2)_4SePh$ (0.83 mmol per 1 mmol of $In(SePh)_3$), fully characterized by elemental analysis, mass spectrometry, and ^1H and ^{13}C NMR spectroscopy; the actual course of the reaction leading to the butane derivative is still undetermined, but it is important to notice that we did not observe any direct reaction between $In(SePh)_3$ and the DCE solvent under these experimental conditions, except perhaps in these two cases for which it is reasonable to assume solvent participation in the process.

The experimental observations made above seem to indicate that the polymeric nature of the $In(EPh)_3$ compounds is an important aspect ruling their reactivity pattern towards organyl halides, and that allows one to understand the differences when compared with reactions involving the $IIn(EPh)_2$ compounds[20,21] and the proposed free-radical process initiated by metallic indium.[23] The polymeric nature involving bridging benzenechalcogenolate ligands together with the ability of the $In(EPh)_3$ complexes to act as Lewis acids strongly suggest that depolymerization to reactive monomeric intermediates is achieved by halide coordination to the indium centers replacing the bridging chalcogenolate ligands responsible for holding the polymeric structures. Thus, it is expected that organyl halides capable to produce stable tertiary, benzylic, allylic, and acyl carbocations would be the most reactive substrates and that these will react according to an S_N1 path, possibly through an ion-pair intermediate. The instantaneous reactions at room temperature involving these substrates together with the deep colouration, typical of carbocations, developed in the DCE solutions particularly in reactions with benzylic and allylic halides, are in agreement with this picture (Scheme 2). The enormous difference in reactivity presented by primary alkyl

halides, which only reacted after prolonged refluxing in DCE (83 °C), and the lack of reactivity of secondary alkyl halides suggest an alternative pathway. We propose for these cases that depolymerization to reactive monomeric intermediates is achieved by formation of $(PhE)_3In{\cdot}X{-}R$ adducts by coordination of the halogen atom of the organyl halide to the indium centers. This description accommodates well the failure of secondary alkyl halides to react efficiently due to stereo-hindrance during adduct formation (Scheme 2). Together with the product of the coupling between the first equivalent of the phenyl chalcogenolate nucleophile with the organyl halide leading to the first equivalent of the non-symmetric PhE–R chalcogenide, occurs the simultaneous production of the indium(III) heteroleptic product $XIn(EPh)_2$ used by Ranu and co-workers in their earlier work,[20,21] a compound responsible for formation of the two extra equivalents of the PhE–R final product. Considering these ideas, one can understand the higher reactivity of the $IIn(EPh)_2$ compared with the indium(III) benzenechalcogenolate reagents with primary and secondary alkyl halides in terms of the degree of polymerization of the $XIn(EPh)_2$ and the $In(EPh)_3$ reagents. Although $In(EPh)_3$ are polymeric, there

must not be significant association of the $XIn(EPh)_2$ compounds in solutions.

The milder reactivity of the $In(EPh)_3$, compared with the $XIn(EPh)_2$ reagents[20,21] and with the radical species generated from the in situ reaction involving indium metal and diphenyl diselenide,[23] suggests that the indium(III) benzenechalcogenolates can chemoselectively produce R–EPh (R = ^{t}alkyl, allyl, or benzyl) in the presence of primary or secondary alkyl halides. Accordingly, a competitive experiment involving $In(SePh)_3$ with 3 mol of allyl bromide and *n*-bromobutane produced C_3H_5–SePh exclusively with no signs of ^{n}Bu–SePh being detected.

Conclusion

The development of a one-pot efficient synthesis of organyl phenyl chalcogenides from alkyl halides and diphenyl dichalcogenides with the cleavage of the chalcogen–chalcogen bond performed by metallic indium is very attractive to the synthetic chemists because of the easy handling and accentuated stability of the metallic element towards moisture and air. We have interpreted this process as being intermediated by $[In(EPh)_3]_n$ polymers whose association must be broken to monomeric complexes by coordination and (or) interaction with the halide atom of the organyl halide. The degree of this coordination or interaction determines the reactivity of these reagents towards the organyl halide. Organyl halides, giving stable carbocations, react promptly following an S_N1-type reaction pathway leading to high yields of the nonsymmetrical chalcogenides, while primary alkyl halides require long periods of continuous heating, possibly following an S_N2-type process. The striking difference in reactivity, depending on the nature of the organyl halide, allows selective condensations as we have demonstrated with the experiment involving allyl bromide and bromobutane, which produced exclusively the allyl selenide.

Experimental

General

Indium powder and diphenyl disulfide were commercial products from Aldrich. Diphenyl diselenide was prepared from phenylmagnesium bromide and elemental selenium.[35] DCE was dried over CaH_2 and distilled before use. All the organyl halides were obtained from commercial suppliers and distilled, when necessary, before use. ^{1}H and ^{13}C NMR spectra were acquired on a Bruker DPX 200 and (or) Bruker DPX 400 spectrometers.

Preparation of organyl phenyl chalcogenides

To a Schlenk tube truly dried (flame) was sequentially added DCE (2 mL), diphenyl dichalcogenide (0.52 mmol), and indium powder (0.35 mmol). The mixture was sonicated for 10 min and then heated under reflux for 1–2 h. After all the metal being consumed, a yellow solution is obtained for the selenium derivative and a white precipitate for the sulfur case. At this point, the reaction was brought to room temperature, and the organyl halide (1 mmol) was added. The substrates corresponding to entries 22–39 (Table 1) were immediately (1–3 min) consumed as verified by TLC, while the remaining were consumed after heating for the periods specified in Table 1. The reactions were quenched with distilled water (10 mL), the organics extracted with dichloromethane (3 × 10 mL), the extracts were sequentially dried over sodium sulfate, evaporated to dryness (vaccum), and the organyl phenyl chalcogenides purified by column chromatography over silica gel using hexanes/ ethyl acetate mixtures. The sulfur derivatives are colourless oils or solids, while the selenium products are yellow compounds. All products are known compounds, and they were identified by comparison of their spectral data (^{1}H and ^{13}C NMR) with those reported in the literature (see Table 1 for references).

n-*Butyl phenyl sulfide (Table 1, entries 3 and 5)*

^{1}H NMR ($CDCl_3$) δ: 7.25–7.04 (m, 5H), 2.81 (t, *J* = 7.5 Hz, 2H), 1.53 (qui, *J* = 7.5 Hz, 2H), 1.34 (sex, *J* = 7.5 Hz, 2H), 0.81 (t, *J* = 7.5 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 136.96, 128.70, 128.67, 125.48, 33.10, 31.11, 21.87, 13.57.

n-*Butyl phenyl selenide (Table 1, entries 4 and 6)*

^{1}H NMR ($CDCl_3$) δ: 7.42–7.38 (m, 2H), 7.18–7.10 (m, 3H), 2.83 (t, *J* = 7.6 Hz, 2H), 1.61 (qui, *J* = 7.6 Hz, 2H), 1.34 (sex, *J* = 7.6 Hz, 2 H), 0.82 (t, *J* = 7.3 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 132.29, 130.66, 128.90, 126.50, 32.19, 27.55, 22.89, 13.50.

n-*Octyl phenyl sulfide (Table 1, entry 7)*

^{1}H NMR ($CDCl_3$) δ: 7.28–7.04 (m, 5H), 2.84 (t, *J* = 7.5 Hz, 2H), 1.58 (qui, *J* = 7.5 Hz, 2H), 1.32–1.16 (broad, 10H), 0.82 (t, *J* = 6.6 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 137.04, 128.94, 128.68, 125.46, 33.44, 31.73, 29.10, 29.06, 28.78, 22.58, 14.03.

n-*Octyl phenyl selenide (Table 1, entry 8)*

^{1}H NMR ($CDCl_3$) δ: 7.44–7.39 (m, 2H), 7.20–7.12 (m, 3H), 2.84 (t, *J* = 7.3 Hz, 2H), 1.64 (qui, *J* = 7.3 Hz, 2H), 1.33–1.16 (broad, 10H), 0.82 (t, *J* = 6.6 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 132.28, 130.70, 128.86, 126.46, 31.74, 30.09, 29.78, 29.11, 28.99, 27.87, 22.58, 14.03.

1,10-Bis(phenylthio)decane (Table 1, entry 9)

Mp 64–65 °C. ^{1}H NMR ($CDCl_3$) δ: 7.25–7.10 (m, 10H), 2.82 (t, *J* = 7.4 Hz, 4H), 1.56 (qui, *J* = 7.3 Hz, 4H), 1.36–1.15 (broad, 12H). ^{13}C NMR ($CDCl_3$) δ: 136.98, 128.97, 128.73, 125.53, 33.46, 33.28, 29.31, 29.04, 28.72.

1,10-Bis(phenyl selanyl)decane (Table 1, entry 10)

Mp 67–68 °C. ^{1}H NMR ($CDCl_3$) δ: 7.41–7.35 (m, 4H), 7.18–7.10 (m, 6H), 2.81 (t, *J* = 7.4 Hz, 4H), 1.60 (qui, *J* = 7.2 Hz, 4H), 1.32–1.14 (broad, 12H). ^{13}C NMR ($CDCl_3$) δ: 132.23, 130.63, 128.86, 126.46, 30.03, 29.70, 29.30, 28.94, 27.81.

1,5-Bis(phenylthio)pentane 7 (Table 1, entry 11)

^{1}H NMR ($CDCl_3$) δ: 7.24–7.06 (m, 10H), 2.80 (t, *J* = 6.9 Hz, 4H), 1.61–1.41(m, 6H). ^{13}C NMR ($CDCl_3$) δ: 136.62, 128.93, 128.77, 125.69, 33.33, 28.56, 27.78.

1,5-Bis(phenyl selanyl)pentane (Table 1, entry 12)

^{1}H NMR ($CDCl_3$) δ: 7.38–7.34 (m, 4H), 7.15–7.08 (m, 6H), 2.76 (t, *J* = 7.3 Hz, 4H), 1.58 (qui, *J* = 7.6 Hz, 4H), 1.40 (m, 2H). ^{13}C NMR ($CDCl_3$) δ: 132.34, 130.32, 128.86, 126.54, 29.72, 29.41, 27.49.

1,3-Bis(phenyl selanyl)propane (Table 1, entry 14)

^{1}H NMR ($CDCl_3$) δ: 7.38–7.34 (m, 4H), 7.16–7.11 (m, 6H), 2.89 (t, J = 7.3 Hz, 4H), 1.95 (qui, J = 7.3 Hz, 2H). ^{13}C NMR ($CDCl_3$) δ: 132.59, 129.81, 128.95, 126.77, 30.10, 27.34.

sec-*Butyl phenyl selenide (Table 1, entry 19)*

^{1}H NMR ($CDCl_3$) δ: 7.51–7.44 (m, 2H), 7.19–7.15 (m, 3H), 3.16 (sex, J = 6.8 Hz, 1H), 1.57 (m, 2H), 1.31 (d, J = 6.9 Hz, 3H), 0.92 (t, J = 7.3 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 134.78, 129.12, 128.77, 127.18, 41.44, 30.37, 21.53, 12.25.

tert-*Butyl phenyl sulfide (Table 1, entry 22)*

^{1}H NMR ($CDCl_3$) δ: 7.48–7.41 (m, 2H), 7.28–7.19 (m, 3H), 1.22 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 137.47, 128.62, 128.41, 127.13, 45.82, 30.92.

tert-*Butyl phenyl selenide (Table 1, entry 23)*

^{1}H NMR ($CDCl_3$) δ: 7.59–7.53 (m, 2H), 7.29–7.17 (m, 3H), 1.33 (s, 9H). ^{13}C NMR ($CDCl_3$) δ: 138.11, 128.52, 128.36, 128.28, 43.00, 32.12.

Benzyl phenyl sulfide (Table 1, entry 24)

Mp 39–40 °C. ^{1}H NMR ($CDCl_3$) δ: 7.25–7.08 (m, 10H), 4.02 (s, 2H). ^{13}C NMR ($CDCl_3$) δ: 137.37, 136.32, 129.71, 128.76, 128.74, 128.41, 127.09, 126.24, 38.93.

Benzyl phenyl selenide (Table 1, entry 25)

Mp 32–33 °C. ^{1}H NMR ($CDCl_3$) δ: 7.35–7.31 (m, 2H), 7.14–7.05 (m, 8H), 3.98 (s, 2H). ^{13}C NMR ($CDCl_3$) δ: 138.48, 133.37, 130.33, 128.85, 128.72, 128.29, 127.14, 126.73, 32.07.

1-Phenylethyl phenyl sulfide (Table 1, entry 26)

^{1}H NMR ($CDCl_3$) δ: 7.29–7.15 (m, 10H), 4.32 (q, J = 7.0 Hz, 1H), 1.61 (d, J = 7.0 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 143.14, 135.07, 132.40, 128.60, 128.31, 127.20, 127.05, 127.02, 47.91, 22.27.

1-Phenylethyl phenyl selenide (Table 1, entry 27)

^{1}H NMR ($CDCl_3$) δ: 7.44–7.38 (m, 2H), 7.23–7.12 (m, 8H), 4.42 (q, J = 7.0 Hz, 1H), 1.72 (d, J = 7.0 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 143.48, 135.32, 129.76, 128.68, 128.19, 127.65, 127.12, 126.80, 42.33, 22.09.

Allyl phenyl sulfide (Table 1, entry 28)

^{1}H NMR ($CDCl_3$) δ: 7.27–7.07 (m, 5H), 5.79 (d of sex, J = 6.8 Hz, 3.0 Hz, 1H), 5.01 (m, 2H), 3.45 (d of t, J = 6.7 Hz, 0.9 Hz, 2H).

Allyl phenyl selenide (Table 1, entry 29)

^{1}H NMR ($CDCl_3$) δ: 7.51–7.46 (m, 2H), 7.28–7.20 (m, 3H), 5.94 (d of sex, J = 7.0 Hz, 2.3 Hz, 1H), 4.95 (m, 2H), 3.51 (d, J = 7.4 Hz, 2H). ^{13}C NMR ($CDCl_3$) δ: 134.35, 133.31, 129.15, 128.91, 127.10, 116.81, 30.65.

Crotyl phenyl sulfide, mixture of isomers, cis:trans = 1:4 (Table 1, entry 30)

^{1}H NMR ($CDCl_3$) δ: 7.26–7.04 (m, 5H), 5.53–5.39 (m, 2H), 3.48–3.44 (m, 1.6H), 3.22–3.18 (m, 0.4H), 1.59 (t, J = 4.8 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 130.22, 129.55, 129.25, 129.05, 128.90, 128.70, 127.46, 127.13, 126.03, 126.03, 125.96, 125.92, 36.79, 36.34, 17.95, 17.73.

Crotyl phenyl selenide, mixture of isomers, cis:trans = 1:4 + traces of 3-benzenoselanyl-butene-1 (Table 1, entry 31)

^{1}H NMR ($CDCl_3$) δ: 7.52–7.41 (m, 2H), 7.24–7.20 (m, 3H), 5.67–5.31 (m, 2H), 3.55(d, J = 7.8 Hz, 0.4H), 3.48 (dd, J = 7.0 Hz, 1.1 Hz, 1.6H), 1.61 (dd, J = 6.0 Hz, 1.1 Hz, 2.4H), 1.47 (dd, J = 5.2 Hz, 1.3 Hz, 0.6H). ^{13}C NMR ($CDCl_3$) δ: 133.53, 133.15, 131.39, 130.31, 129.07, 128.76, 128.74, 128.22, 127.59, 127.00, 126.92, 126.88, 126.82, 126.01, 29.99, 24.29, 17.60, 12.27.

trans-*Cinnamyl phenyl sulfide (Table 1, entry 32)*

Mp 74–75 °C. ^{1}H NMR ($CDCl_3$) δ: 7.39–7.11 (m, 10H), 6.40 (d, J = 15.8 Hz, 1H), 6.21 (d of t, J = 15.8 Hz, 6.9 Hz, 1H), 3.67 (d, J = 6.9 Hz, 2H). ^{13}C NMR ($CDCl_3$) δ: 136.59, 135.36, 132.65, 130.05, 128.75, 128.42, 127.47, 126.27, 126.23, 124.91, 36.93.

trans-*Cinnamyl phenyl selenide (Table 1, entry 33)*

Mp 61–62 °C. ^{1}H NMR ($CDCl_3$) δ: 7.45–7.37 (m, 2H), 7.18–7.09 (m, 8H), 6.30–6.07 (m, 2H), 3.57 (d, J = 6.6 Hz, 2H). ^{13}C NMR ($CDCl_3$) δ: 136.72, 133.81, 131.97, 129.77, 128.87, 128.41, 127.34, 127.23, 126.17, 125.79, 30.63.

2-Methylallyl phenyl sulfide (Table 1, entry 34)

^{1}H NMR ($CDCl_3$) δ: 7.34–7.15 (m, 5H), 4.81 (dd, J = 0.7 Hz, 2H), 3.51 (s, 2H), 1.84 (d, J = 0.7 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 140.75, 136.40, 129.92, 128.66, 126.13, 113.90, 41.85, 21.09.

2-Methylallyl phenyl selenide (Table 1, entry 35)

^{1}H NMR ($CDCl_3$) δ: 7.42–7.38 (m, 2H), 7.18–7.13 (m, 3H), 4.63 (m, 1H), 4.61 (m, 1H), 3.42 (d, J = 0.8 Hz, 2H), 1.77 (dd, J = 0.8 Hz, 0.5 Hz, 3H). ^{13}C NMR ($CDCl_3$) δ: 141.70, 133.42, 130.47, 128.80, 127.04, 113.38, 35.95, 21.26.

S-*Phenyl ethanethioate (Table 1, entry 36)*

^{1}H NMR ($CDCl_3$) δ: 7.31 (s, 5H), 2.30 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 193.76, 134.29, 129.26, 129.04, 127.83, 30.01.

Se-*Phenyl ethaneselenoate (Table 1, entry 37)*

^{1}H NMR ($CDCl_3$) δ: 7.44–7.40 (m, 2H), 7.29–7.25 (m, 3H), 2.34 (s, 3H). ^{13}C NMR ($CDCl_3$) δ: 196.55, 135.58, 129.24, 128.81, 126.54, 33.90.

S-*Phenyl benzothioate (Table 1, entry 38)*

^{1}H NMR ($CDCl_3$) δ: 8.06 (m, 2H), 7.64–7.46 (m, 8H). ^{13}C NMR ($CDCl_3$) δ: 190.07, 136.54, 135.04, 133.60, 129.47, 129.19, 128.69, 127.42, 127.26.

S-*Phenyl benzoselenoate (Table 1, entry 39)*

^{1}H NMR ($CDCl_3$) δ: 7.96 (m, 2H), 7.65–7.60 (m, 3H), 7.52–7.42 (m, 5H). ^{13}C NMR ($CDCl_3$) δ: 193.33, 138.44, 136.28, 133.84, 129.32, 129.02, 128.89, 127.28, 125.71.

Ethyl 2-(phenylthio)acetate (Table 1, entry 40)

^{1}H NMR ($CDCl_3$) δ: 7.43–7.18 (m, 5H), 4.16 (q, J = 7.2 Hz, 2H), 3.63 (s, 2H), 1.22 (t, J = 7.2 Hz, 3H). ^{13}C

Theoretical study on the scattering resonance state and isotope effect of the F + HD(H_2) → HF + D(H) reactive system

Hong Yue, Xi Lu, Zhengting Cai, and Xiaomin Sun

Abstract: The scattering resonance state of the F + H_2 reactive system has been the focus of the reactive resonance or Feshbach resonance, since the reaction can generate infrared laser. The partial potential-energy surface is constructed with the ab initio method, and the formation mechanism of the scattering resonance is studied. The resonance energy is given, and the first resonance life is estimated. The F + H_2 and F + HD reactive systems are investigated simultaneously to study the isotope effect, and some valuable results are achieved.

Key words: F + H_2 system, the partial potential-energy surface, isotope effect, scattering resonance state.

Résumé : Compte tenu du fait que la réaction associée à l'état de résonance de diffusion du système réactif F + H_2 peut générer un laser infrarouge, elle a fait l'objet d'attentions particulières de la résonance réactive et de la résonance de Feshbach. La surface d'énergie potentielle partielle a été construite à l'aide de méthodes théoriques ab initio et on a étudié le mécanisme de formation de la résonance de diffusion. On rapporte l'énergie de résonance et on a évalué la vie de la première résonance. On a étudié d'une façon simultanée les systèmes réactifs F + H_2 et F + HD afin d'évaluer l'effet isotopique et on a obtenu quelques résultats utiles.

Mots-clés : système F + H_2, surface d'énergie potentielle partielle, effet isotopique, état de résonance de diffusion.

[Traduit par la Rédaction]

Introduction

In 1970, Kuppermann[1] predicted the existence of the scattering resonance phenomenon in elementary chemical reactions based on the calculation of quantum-scattering theory. The reactive resonance, or Feshbach resonance, is one of the most fascinating phenomena in chemical reaction dynamics.[2] The term "resonance state" in this context refers to a metastable or quasi-bound state, also called scattering resonance state. The scattering resonance state of the F + H_2 reactive system has been the focus of study. As an important infrared pump source, more attention has been paid to it.

Schatz and Kuppermann[3] calculated the reaction probability of the F + H_2 → HF + H system on the semi-experience potential-energy surface, discovered the oscillation behaviour of reaction probability with the collision energy, and predicted the scattering resonance state in the chemical reaction, which promoted the cross-beam molecular detection of the reactive resonance of the F + H_2 system. Using the crossed-beam scattering experiment, Lee[4] measured the curve of the differential cross section with the collision energy, $\sigma(E, \theta) \sim E$, and verified the prediction of Schatz and Kuppermann. However, after the average of scattering angle θ, the peak on the curve of integral cross section with collision energy (also known as excitation function) $\sigma(E) \sim E$ is no longer apparent. Therefore, it has been a controversial issue whether the resonance phenomenon exists in chemical reaction or not. Liu[5] measured the curve of $\sigma(E) \sim E$ using the crossed molecular-beam experiment in his study of the F + HD → HF + D (H + DF) reaction in 2000. Yang and Zhang[6,7] observed the Feshbach resonance in the F + H_2 → HF + H reaction. Both studies confirmed the existence of the resonance. This discovery is of great importance in both the academic field and the application area. Schatz[8] and Zare[9] ever highly praised it as an important advance in the field of chemical reaction dynamics and called for more theoretical and experimental chemists to study the scattering resonance state. However, the formation mechanism of the resonance state and the lifetime of the resonance state have been rarely investigated.

The partial potential-energy surface (PPES) is constructed with the ab initio method. Then, the formation mechanism of scattering resonance state is discussed using the PPES, which can also provide many important dynamic quantities, such as the resonance energy, the lifetime of resonance, and so on. The vibrational dynamic behaviour in the strong interaction region can be shown clearly on the PPES. The results obtained using the PPES are in good agreement with previous theoretical and experimental work.

Fig. 1. The PPES of the F + HD → HF + D reaction system.

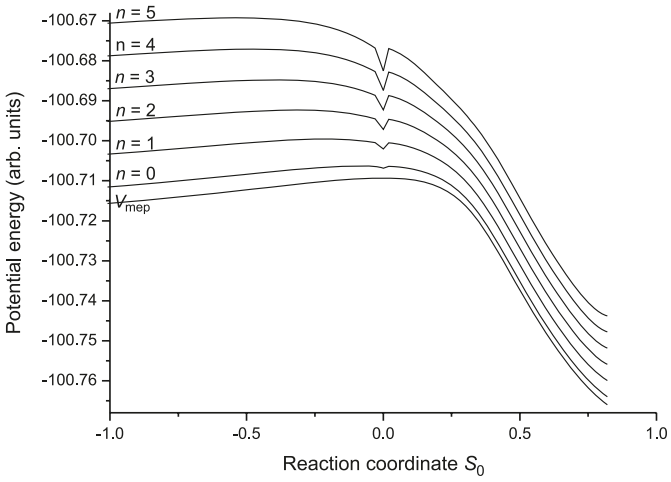

Fig. 2. The PPES of the F + H_2 → HF + H reaction system.

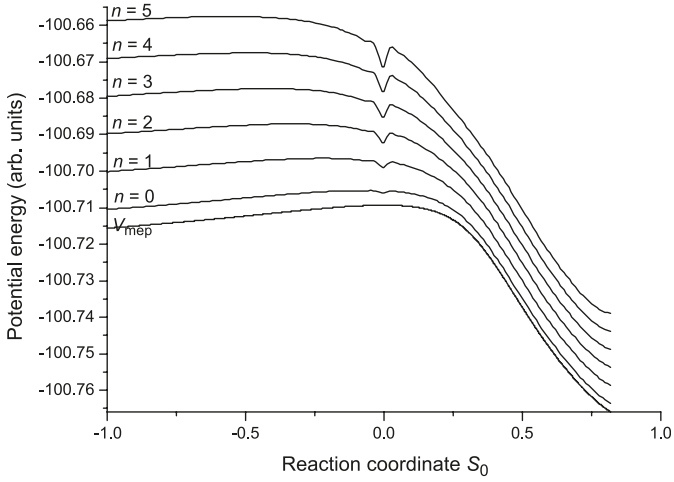


In this paper, the F + H_2[10] and F + HD reactive systems are investigated simultaneously, and the isotope effect is discussed. Some valuable results are achieved.

The theoretical method

For the sake of convenience, the construction of the partial potential-energy surface is briefly introduced as follows. According to the literature,[11] the scattering equation in the natural collision coordinate of the A + BC → AB + C exchange reaction can be written as

$$[1] \qquad \widehat{H}\psi(s,\rho) = E\psi(s,\rho)$$

and Hamiltonian operator is as follows:

$$[2] \qquad \widehat{H} = -\left(\frac{\hbar^2}{2\mu}\eta^{-1}\frac{\partial}{\partial s}\eta^{-1}\frac{\partial}{\partial s}\right) - \left(\sum_{i=1}^{f}\frac{\hbar^2}{2\mu}\eta\frac{\partial}{\partial \rho_{\mathrm{i}}}\eta^{-1}\frac{\partial}{\partial \rho_{\mathrm{i}}}\right) + V(s,\rho)$$

Full-dimensional potential-energy surface $V(s, \rho)$ is expanded by Taylor series expansion

$$[3] \qquad V(s,\rho) = V_{\mathrm{o}}(s) + \sum_{n=2}\sum_{i=1}\left(\frac{1}{n!}\frac{\partial^n V(s,\rho)}{\partial \rho_i^n}|\rho = 0\right)\rho_i^n$$

where s is the reaction coordinate, $\rho = \rho_1, \rho_2, \ldots, \rho_f$ is the normal vibration coordinates, and f is the freedom degree of the normal vibration. The whole wave function of the reaction system can be spread as follows:

$$[4] \qquad \psi(s,\rho) = \sum_{n_1,\, n_2,\, \ldots,\, n_f} \xi_{n_1,\, n_2,\, \ldots,\, n_f}(s)\ \varphi_{n_1,\, n_2,\, \ldots,\, n_f}(s,\rho)$$

where $\xi_{n_1,\, n_2,\, \ldots,\, n_f}(s)$ is the translation wave function. $\varphi_{n_1,\, n_2,\, \ldots,\, n_f}(s,\rho)$ is the orthogonal normalized complete set, and given by the solutions of the following equation:

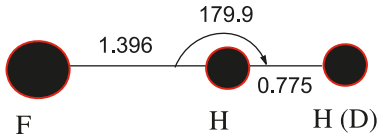
$$[5] \qquad \left[-\sum\frac{\hbar^2}{2\mu}\eta\frac{\partial}{\partial \rho_i}\eta^{-1}\frac{\partial}{\partial \rho_i} + V(s,\rho)\right]\varphi_{n_1,\, n_2,\, \ldots,\, n_f}(s,\rho) = \varepsilon_{n_1,\, n_2,\, \ldots,\, n_f}(s)\varphi_{n_1,\, n_2,\, \ldots,\, n_f}(s,\rho)$$

The $\varepsilon_{n_1,\, n_2,\, \ldots,\, n_f}(s)$ can be called as the PPES. First, $V(s, \rho)$ is full-dimensional potential function, while $\varepsilon_{n_1,\, n_2,\, \ldots,\, n_f}(s)$ is only a function of reaction coordinate s. Second, $\varepsilon_{n_1,\, n_2,\, \ldots,\, n_f}(s)$ provides a potential field for the translation of the scattering system. The latter can be seen clearly from the following derivation.

Equation [4] is substituted into the eq. [1], left-multiplied by $\varphi^*_{n_1',\, n_2',\, \ldots,\, n_f'}(s,\rho)$, integrated to ρ, and then associated with eq. [5], the Schrödinger eq. [6] can be obtained which is satisfied by $\varepsilon_{n_1,\, n_2,\, \ldots,\, n_f}(s)$.

$$[6] \qquad \left[\left(-\frac{\hbar^2}{2\mu}\eta^{-1}\frac{\partial}{\partial s}\eta^{-1}\frac{\partial}{\partial s}\right) + \varepsilon_{n_1,\, n_2,\, \ldots,\, n_f}(s) - E\right]\xi_{n_1,\, n_2,\, \ldots,\, n_f}(s) = \sum_{n_1',\, n_2',\, \ldots,\, n_f'} G_{n_1',\, n_2',\, \ldots,\, n_f';\, n_1,\, n_2,\, \ldots,\, n_f}(s)\xi_{n_1',\, n_2',\, \ldots,\, n_f'}(s)$$

Fig. 3. The structure of the transition state of the F + HD(H_2) → HF + H(D) reaction system.



In the equation, $G_{n'_1, n'_2, ..., n'_f; n_1, n_2, ..., n_f}(s)$ is the non-adiabatic coupling mode of vibration, and can be presented by the following equation:

$$[7] \quad G_{n'_1, n'_2, ..., n'_f; n_1, n_2, ..., n_f}(s) = \left\langle \varphi_{n'_1, n'_2, ..., n'_f}(s,\rho) \left| -\frac{\hbar^2}{2\mu}\eta^{-1}\frac{\partial}{\partial s}\eta^{-1}\frac{\partial}{\partial s} \right| \varphi_{n_1, n_2, ..., n_f}(s,\rho) \right\rangle_\rho$$

When there is only one degree of freedom of vibration (for example, the exchange reaction of three atoms in line) and Taylor equation spreads for two grade (i.e., harmonic oscillator model), eq. [8] can be obtained.

$$[8] \quad \varepsilon_n(s) = V_o(s) + (n + \frac{1}{2})\hbar\omega(s)$$

and

$$[9] \quad \omega^2(s) = \frac{1}{\mu}\left[\frac{\partial^2 V(s,\rho)}{\partial\rho^2}\right]_{\rho=0}$$

Obviously, $\omega(s)$ can be calculated according to the Hessian matrix, and can be used to calculate the potential-energy surface. In the PPES, $V_{mep}(s)$ is the so-called minimum-energy reaction pathway (MEP). It is worth emphasizing that the construction of the PPES need not build full-dimensional potential-energy surface $V(s, \vec{\rho})$, but could solve the vibration equation of scattering system to get the potential-energy surface and obtain the basis set of the spreading of $\psi(s, \vec{\rho})$.

In this paper, we optimize the structure of the transition state of the F + H_2 → HF + H using MP2 method with the 6–311++G** basis set. The PPESs of the F + HD and F + H_2 systems (Figs. 1 and 2) are constructed using the above methods, which have been applied to some typical heavy-light-heavy systems.[12–19] The transient collision complex state structures of the two systems are shown in Fig. 3.

Results and discussions

According to the curves on the PPES (Figs. 1 and 2), it can be seen that the curves of V_{mep} have no shallow well, which is difficult to satisfy the existence of the scattering resonance state. However, if $n \geq 1$, the well will appear obviously in the neighbourhood of $s = 0$ (the strong interaction region on the PPES or transition region), which is called dynamic shallow well[20] in the literature. The existence of reactive resonance can be conceptually traced back to dynamic trapping in wells on the vibrationally adiabatic PES, even when there is no potential well on the Born–Oppenheimer PES. It is the dynamic shallow well that traps the reactive system to form the so-called quasi-bound or scattering resonance state, which means the formation of resonance state.

From Figs. 1 and 2, the first resonance energy of the two reactions is 43.82 kJ/mol and 50.13 kJ/mol, respectively. Evidently, the resonance energy is reduced comparing the F + HD → HF + D reaction with the F + H_2 → HF + H reaction.

Comparing Fig. 1 with Fig. 2, the potential well in F + HD → HF + D reaction is a little deeper than that of the F + H_2 → HF + H reaction. Therefore, the former scattering resonance state has longer lifetime than that of the latter.

The geometry structure of transition collision complex is drawn in Fig. 3. According to the Born–Oppenheimer approximation, adopting different isotopes has no impact on the optimization of the geometric and the calculation of the electronic structure of the transient collision complex. Therefore, the transition collision complex structures of two reactions are identical. The calculation of the frequency of the constant matrix (Hessian matrix) is unchanged, but reduced mass changes, so the frequencies in the two reactions are different form each other. The frequencies of the two reactions, F + HD → HF + D and F + H_2 → HF + H, are 1120.37(i), 135.50, 2640.61; 1231.96(i), 146.42, and 3316.32.

According to the uncertainty principle $\Delta E\ \Delta\tau \sim \hbar$, the lifetime of the first reactive resonance state of the F + HD → HF + D reaction is about 21 *fs*, which is very close to Neumark's result[10] obtained from the high-resolution threshold photo detachment spectroscopy, 19 *fs*. ΔE is the first resonance energy. Compared with the experimental result, the relative error is only 10%. As for the F + H_2 system, the first scattering resonance state lifetime is 14 *fs*. It is obvious that the lifetime of the first scattering resonance state of the F + HD system is longer than that of the F + H_2 system. After D atom replaces H atom, it is reasonable that the reduced mass of the system increases, and the force constant of the symmetrical stretching vibration decreases. The force constant of the symmetrical stretching vibration in F + HD system and F + H_2 system is 0.9857 and 1.0279, respectively. Then, the vibration frequency decreases, which results in the decrease of the resonance energy and the increase of the resonance lifetime.

Conclusions

There is no potential wells on the minimum-energy reaction pathway (V_{mep}) of the F + H_2 and F + HD reactions, but the dynamical wells exist near the transition-state region of PPES. It is the dynamical wells that trap the system to form the scattering resonance state. After D replaces H, the reduced mass of the system becomes a little larger, the resonance energy decreases, and the resonance lifetime increases. There is also slight difference in the location of dynamical well. It can be seen that the isotope effect is obvious.

It is convenient to study the resonance energy, the resonance lifetime, and the isotope effect using the partial potential-energy surface.

Oxyhalogen–sulfur chemistry — Kinetics and mechanism of oxidation of methionine by aqueous iodine and acidified iodate

Edward Chikwana, Bradley Davis, Moshood K. Morakinyo, and Reuben H. Simoyi

Abstract: The oxidation of methionine (Met) by acidic iodate and aqueous iodine was studied. Though the reaction is a simple two-electron oxidation to give methionine sulfoxide (Met–S=O), the dynamics of the reaction are, however, very complex, characterized by clock reaction characteristics and transient formation of iodine. In excess methionine conditions, the stoichiometry of the reaction was deduced to be $IO_3^- + 3Met \rightarrow I^- + 3Met–S=O$. In excess iodate, the iodide product reacts with iodate to give a final product of molecular iodine and a 2:5 stoichiometry: $2IO_3^- + 5Met + 2H^+ \rightarrow I_2 + 5Met–S=O + H_2O$. The direct reaction of iodine and methionine is slow and mildly autoinhibitory, which explains the transient formation of iodine, even in conditions of excess methionine in which iodine is not a final product. The whole reaction scheme could be simulated by a simple network of 11 reactions.

Key words: methionine, organosulfur, iodine, antioxidant, nonlinear dynamics, methionine sulfoxide.

Résumé : On a étudié la réaction d'oxydation de la méthionine (Met) par l'ion iodate, en milieu acide et en présence d'iode aqueux. Même si la réaction d'une simple oxydation à deux électrons pour conduire au sulfoxyde de méthionine (Met–S=O), la dynamique de la réaction est toutefois fort complexe ayant les caractéristiques d'une réaction horloge et comportant la formation transitoire d'iode. Dans des conditions où la méthionine est en excès, on a déduit que la stoechiométrie de la réaction est $IO_3^- + 3Met \rightarrow I^- + 3Met–S=O$. Dans des conditions où l'iodate est en excès, l'iodure produit réagit avec l'iodate pour donner de l'iode moléculaire comme produit final avec une stoechiométrie 2:5: $2IO_3^- + 5Met + 2H^+ \rightarrow I_2 + 5Met–S=O + H_2O$. La réaction directe de l'iode avec la méthionine est très lente et donne lieu à une légère autoinhibition qui explique la formation transitoire d'iode, même dans des conditions d'excès de méthionine dans lesquelles l'iode n'est pas un produit final. L'ensemble des réactions peut être simulé par un réseau simple de onze réactions.

Mots-clés : méthionine, organosulfuré, iode, antioxydant, dynamique non linéaire, sulfoxyde de méthionine.

[Traduit par la Rédaction]

Introduction

Methionine is an essential amino acid, obtained only from dietary sources and found mainly in animal protein. In addition to its role as a precursor in protein synthesis, L-methionine participates in a wide range of biochemical reactions, including the production of *S*-adenosyl methionine, homocysteine, L-cysteine, taurine, and sulfate. It is believed to be the major methyl donor for methylation of DNA, RNA, proteins, and other molecules.[1,2] Methionine is also thought to keep fat from building up in the liver, and it is often included in liver-detoxifying products called lipotropic combinations.[3] These formulations are believed to accelerate the flow of bile and cell-damaging toxins away from the liver.

Depletion of methionine is strongly linked to inhibited growth, apoptotic death, and necrosis of cancerous cells, especially in combination with chemotherapy.[4] On the other hand, high levels of methionine in the physiological system are associated with several metabolic disorders such as homocystinuria, which is characterized by increased levels of homocysteine in the serum.[5] Homocystine is one of the products of methionine metabolism and its accumulation has been linked to atherosclerosis and arteriosclerosis.[1,5] Atherosclerosis is characterized by the development of lesions within and around blood vessels.[5,6] While atherosclerosis provides the plaque that narrows the artery, arteriosclerosis stiffens the arteries so that they cannot expand with each heart beat to compensate for the blockage caused by plaque formation.[6,7] In most cases of myocardial infarction, both atherosclerosis and arteriosclerosis have been shown to be present.

It has been proposed that methionine residues in proteins serve as an antioxidant defense system for the protection of proteins from oxidation under conditions of oxidative stress.[8,9] Various biological oxidants, such as hydrogen peroxide, hydroxyl radicals, ozone, peroxynitrite, and hypochlorite, have been shown to mediate the oxidation of methionine.[9,10] Methionine has been shown to be effective in radical scavenging processes, such as those involving reactive nitrogen species, to form methionine sulfoxide and ethylene.[9] In the physiological environment, oxidation of methionine residues to methionine sulfoxide is easily re-

Fig. 1. Titration results for the oxidation of methionine in excess iodate conditions. The *x*-intercept strongly suggest a 1:3 (iodate:methionine) stoichiometric ratio. $[Met]_0 = 3.0 \times 10^{-3}$ mol/L, $[H^+]_0 = 6 \times 10^{-3}$ mol/L.

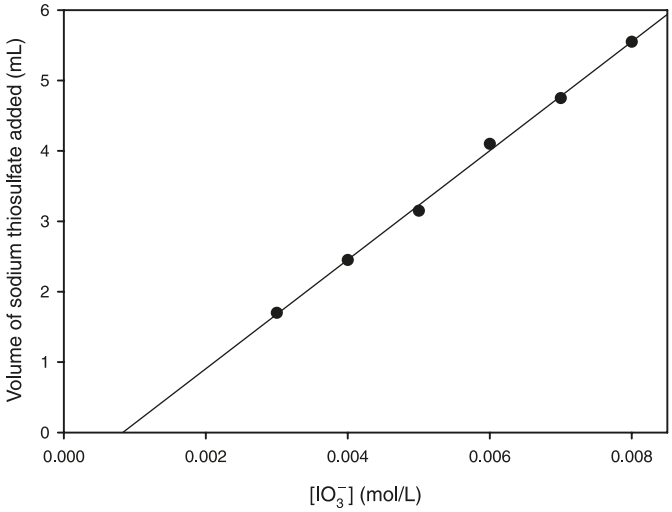

Fig. 2. (A) NMR spectrum for the product of the DL-methionine oxidation by acidic iodate/iodine solution showing the *S*-methyl peak at 2.79 ppm. (B) Spectrum of DL-methionine shows the peak initially at 2.12 ppm. Spectra for reagent grade methionine sulfoxide (C) and methionine sulfone (D) shows the shifting in the *S*-methyl group as expected from the oxidation of the sulfur center. The product solution in this case shows strong similarity to the spectrum of the sulfoxide as predicted from the stoichiometric determination.

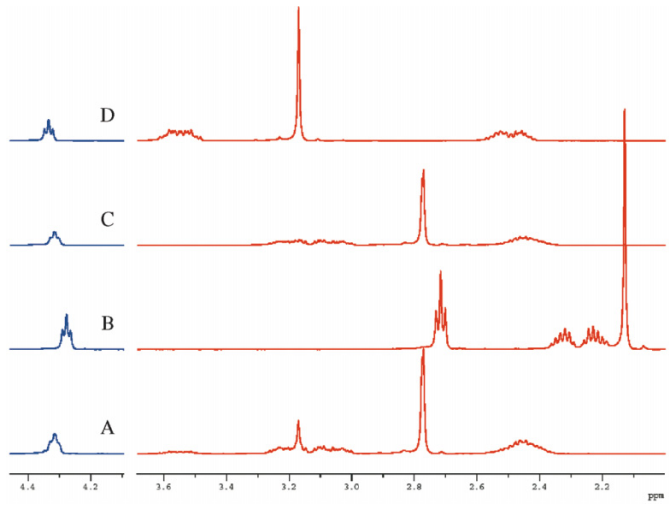
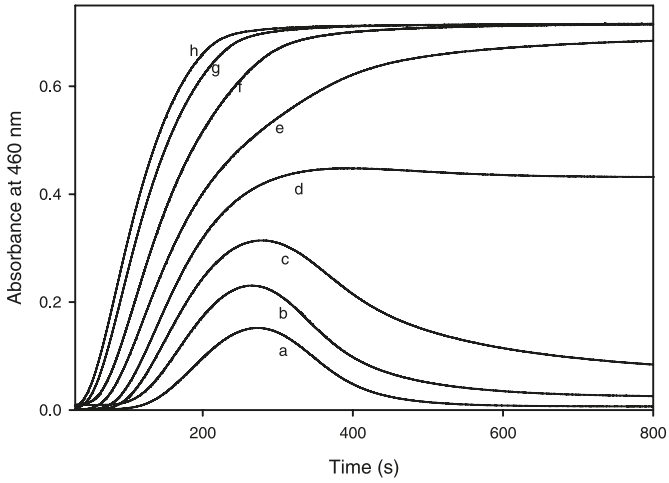


versed by the action of the enzyme methionine sulfoxide reductase.[9] Even though methionine has three coordinating centers (O, N, and S), studies have shown that the sulfur center is the most susceptible to oxidative attack.[9,11–13]

The key to understanding the physiological role of methionine requires an understanding of its specialized function, its reactive intermediates, and oxidation products. Even though most of the methionine is believed to be metabolized in the liver via the transmethylation and transsulfuration pathways,[1] alternative pathways cannot be excluded. Its interaction with different oxidants in the physiological

Fig. 3. Iodate variation shows transient iodine formation below the stoichiometry (traces a–c). In excess iodate conditions, the final iodine amount reaches a maximum determined by the methionine concentration as shown by traces e–h. The relation between iodate concentration and induction time is also apparent. $[Met]_0$ = 0.005 mol/L, $[H^+]_0$ = 0.02 mol/L, $[IO_3^-]_0$ = (a) 0.001, (b) 0.00125, (c) 0.0015, (d) 0.00175, (e) 0.002, (f) 0.0025, (g) 0.003, (h) 0.004 mol/L.



system, such as the oxygen radical species, hydrogen peroxide, hypobromous acid, hypochlorous acid, and iodine, can go a long way in providing data on the depletion of excessive dietary methionine in tissues that, unlike the liver, do not contain the complete methionine cycle.

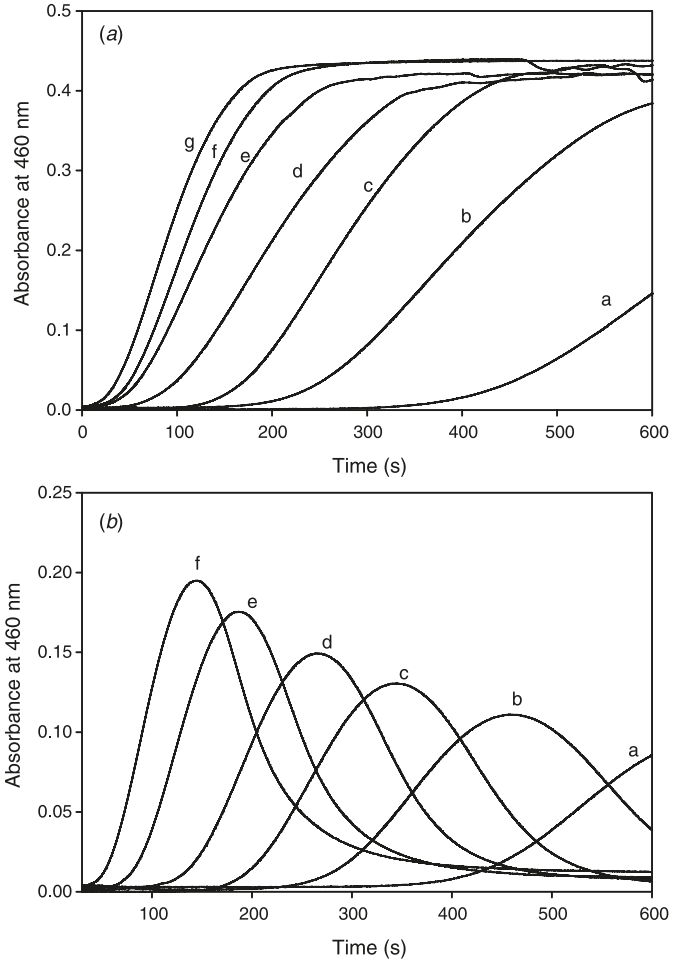
Methionine has also been shown to inhibit in vivo thyroid peroxidase (TPO) iodide oxidation and iodination activities.[11,14] Its reaction with iodine is expected to play a major role in its interaction with the thyroid enzymes. Several organosulfur compounds are well-known goitrogenics whose actions are based on their ability to abstract the active iodine cation from the thyroid, thereby reducing its hyperactivity.[15–19] We report, in this manuscript, on a detailed kinetics and mechanistic study of the oxidation by iodate/iodine of DL-methionine. This simple oxidation reaction was surprisingly complex, characterized by nonlinear exotic kinetics behavior.

Experimental

Materials

Iodine, potassium iodide (Sigma-Aldrich), sodium perchlorate (98%) (Acros Organics), potassium iodate, DL-methionine (99%), DL-methionine sulfone (99%), DL-methionine sulfoxide, perchloric acid (72%), soluble starch, sodium thiosulfate, and hydrochloric acid (Fisher Scientific) were used without further purification. The concentration of iodine was determined by standardization against thiosulfate with starch as the indicator. Spectrophotometry was also utilized by measuring iodine absorbance at its isosbestic point with triiodide at 460 nm where the extinction coefficient had been deduced to be 770 $(mol/L)^{-1}$ cm^{-1}. This standardization was carried out before each series of kinetics experiments due to the volatile nature of iodine. Methionine solutions were prepared just before use and not kept for more than

Fig. 4. (*a*) The effect of varying acid concentrations for reactions run in excess iodate. Acid is not a reactant in the reaction but strongly catalyzes the reaction by reducing the induction period. $[Met]_0$ = 0.003 mol/L, $[IO_3^-]_0$ = 0.03 mol/L, $[H^+]_0$ = (a) 0.003, (b) 0.004, (c) 0.0045, (d) 0.005, (e) 0.006, (f) 0.007, (g) 0.008 mol/L. (b) The effect of acid variation in excess methionine. The effect of increasing acid can be seen in the form of a shorter induction period and a higher maximum transient iodine concentration. $[Met]_0$ = 0.005 mol/L, $[IO_3^-]_0$ = 0.001 mol/L, $[H^+]_0$ = (a) 0.0125, (b) 0.015, (c) 0.0175, (d) 0.02, (e) 0.025, (f) 0.03 mol/L.



24 h. All solutions were prepared using distilled water from a Barnstead Sybron Corporation water purification unit. Inductively coupled plasma mass spectrometry (ICPMS) was used to show that our reaction medium did not contain enough copper ions to affect the overall reaction kinetics and mechanism.[20]

Methods

All experiments were carried out at 25.0 ± 0.1 °C and with a constant ionic strength of 1.0 mol/L ($NaClO_4$). Methionine, sodium perchlorate, and perchloric acid solutions were mixed in one vessel and iodate (or iodine) solutions in another. Kinetics measurements for the slower reactions and spectrophotometric determinations were performed on a PerkinElmer Lambda 25 UV–vis Spectrophotometer. The faster reactions, especially those involving iodine oxidations were monitored on a Hi-Tech Scientific SF-61 stopped-flow spectrophotometer as well as on a Hi-Tech Scientific SF-DX2 double-mixing stopped-flow spectrophotometer.

Fig. 5. Absorbance traces for methionine variation in its oxidation by iodate. Initially, the final iodine absorbances increase (a–d) but as the stoichiometric point is approached they start to decrease and show transient iodine formation (e). $[IO_3^-]_0$ = 0.003 mol/L, $[H^+]_0$ = 0.0045 mol/L, $[Met]_0$ = (a) 0.003, (b) 0.004, (c) 0.005, (d) 0.006, (e) 0.007 mol/L.

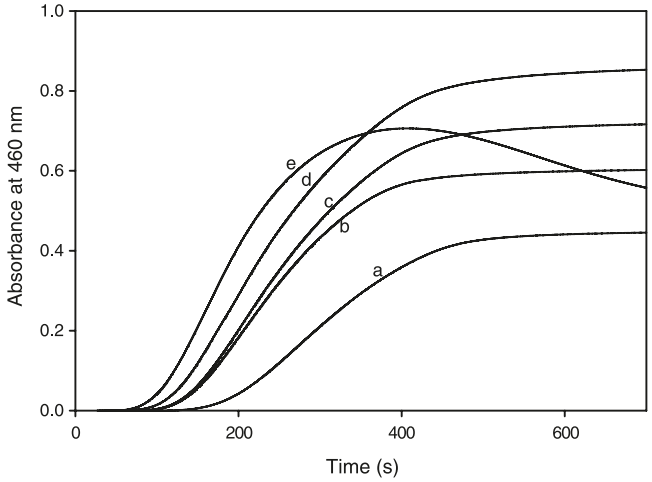


Fig. 6. Iodide effect on the iodate oxidation of methionine. The effect of iodide can be seen on the reduced induction period and increased final absorbance of iodine as iodide concentration is increased. $[Met]_0$ = 0.003 mol/L, $[H^+]$ = 0.0045 mol/L, $[IO_3^-]$ = 0.0275 mol/L, $[I^-]$ = (a) no iodide, (b) 6×10^{-6}, (c) 9×10^{-6}, (d) 5×10^{-5}, (e) 1×10^{-4} mol/L.

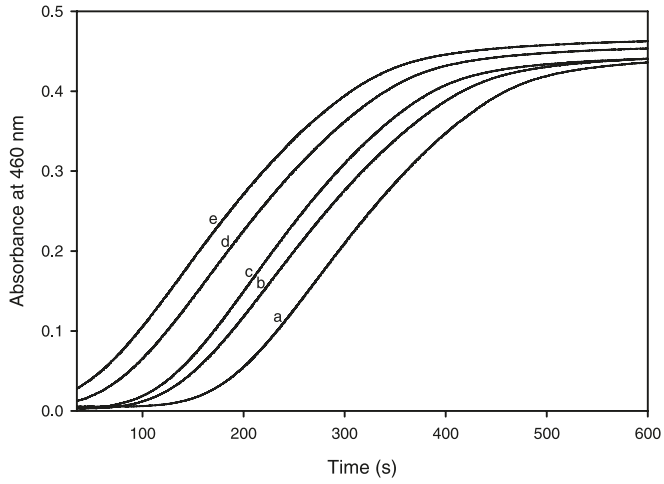
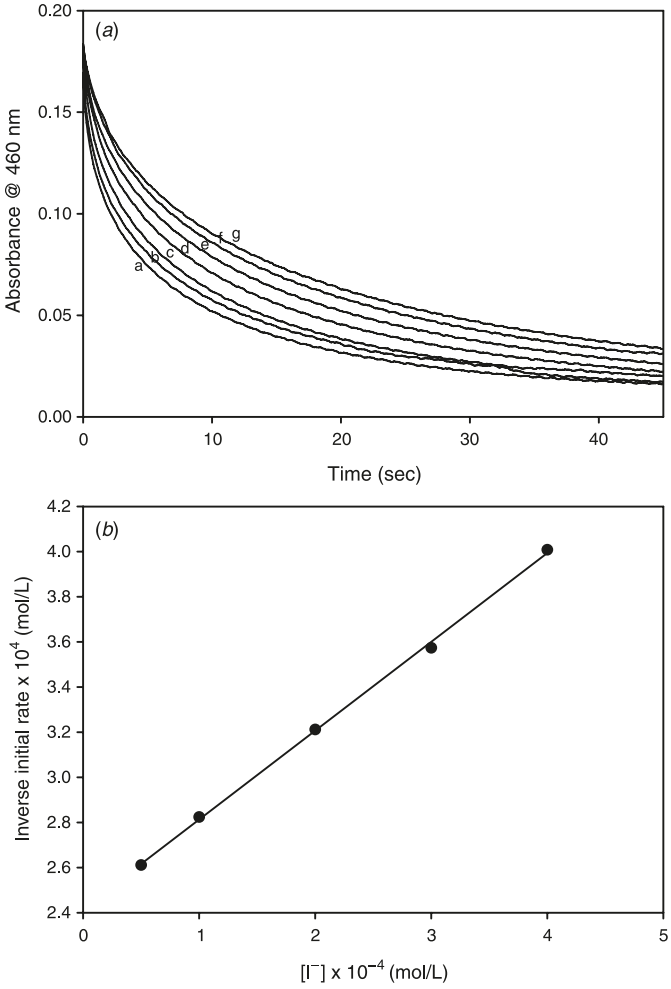


Stoichiometric determinations

The stoichiometry for the methionine–IO_3^- reaction was determined both in excess iodate and excess methionine conditions. In excess iodate the total excess oxidizing power was determined by titration. Excess acidified iodide was added to the reaction solution and the released iodine was titrated against standard thiosulfate. Spectrophotometric measurements were also used to determine the amount of iodine formed in excess iodate by its absorbance at 460 nm. In the I_2–methionine reaction, the stoichiometry was determined by titrating standardized iodine solution from a bu-

Fig. 7. (*a*) Traces showing variation of Methionine concentration with constant iodine concentration. As the methionine is increased, the reaction takes a much shorter time to reach completion. $[I_2]_0$ = 0.0003 mol/L; $[Met]_0$ = (a) 0.01, (b) 0.015, (c) 0.02, (d) 0.025, (e) 0.03, (f) 0.04, (g) 0.045, (h) 0.05 mol/L. (*b*) The data shown in Fig. 7*a* shows a linear dependence between initial rate of reaction and methionine concentration.

The inability of these data to reproduce the rate constant and K_{eq} indicates that the I_3^- is not inert.



rette into a solution of methionine of known strength. The end point, which was enhanced by the starch indicator, was detected as the point where the blue-black color lingers. In excess iodine conditions, spectrophotometric determinations were used to complement the titrimetric techniques.

Results

Stoichiometry

Solutions with varying ratios of iodate to methionine were prepared and their excess oxidizing power determined by iodometric titrations. Excess oxidant was acidified and mixed with excess iodide to generate iodine according to the Dushman reaction, eq. [R1].

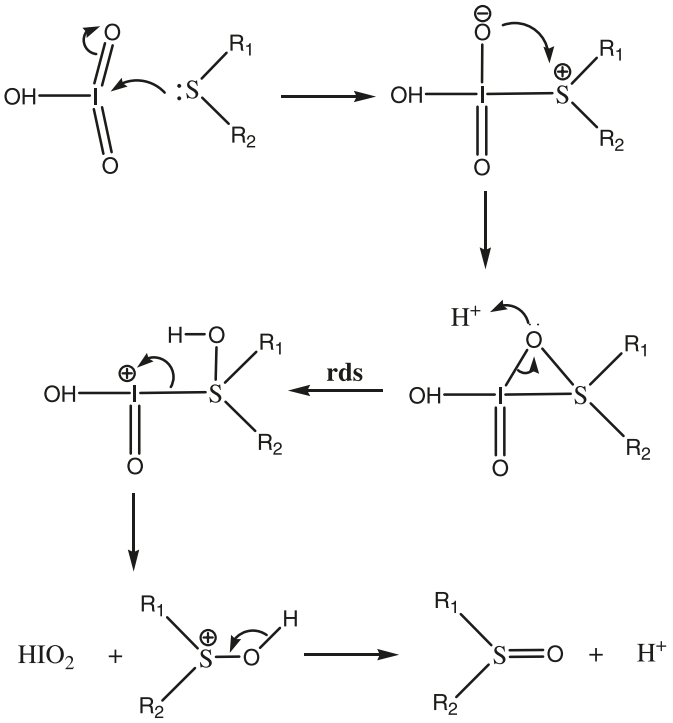
$$[R1] \qquad IO_3^- + 5I^- + 6H^+ \rightarrow 3I_2 + 3H_2O$$

The iodine was titrated against standard sodium thiosulfate and a plot of thiosulfate titer required versus initial iodate concentration was made and is shown in Fig. 1. The number of moles of iodate that were required to react with methionine without formation of iodine (from excess iodate) can be determined from extrapolation to the methionine concentration axis.[21] The data in Fig. 1, which were derived using a constant concentration of 0.003 mol/L methionine, show that there is no excess oxidizing power when $[IO_3^-]_0 = 0.001$ mol/L, which simplifies to a ratio of 1:3. In excess methionine, the stoichiometry for the reaction involved 1 mol of iodate reacting with 3 moles of methionine. This suggests a two-electron oxidation of the sulfur center, with methionine sulfoxide as the most likely product. Titrimetric and spectrometric techniques were both used to verify the following stoichiometry

$$[R2] \qquad IO_3^- + 3\ \text{Methionine (Met)} \rightarrow I^- + 3\ \text{Methionine sulfoxide(Met-S=O)}$$

In stoichiometric excess of iodate, in addition to MetS=O, iodine is also produced with an overall reaction stoichiometry of

Scheme 1. Mechanism of reaction of methionine with iodic acid.



$$[R3] \quad 2IO_3^- + 5Met + 2H^+ \rightarrow I_2 + 5Met{-}S{=}O + H_2O$$

Essentially, stoichiometry eq. [R3] is a linear combination of stoichiometry eqs. [R1] and [R2]: [R1] + 5[R2]. Iodide produced in stoichiometry eq. [R1] is consumed by the excess iodate to produce iodine, and the end of reaction is determined by a complete consumption of iodide for as long as there is still excess iodate to fuel the Dushman reaction, eq. [R1]. Initially there is an increase in the amount of iodine produced as the iodate to substrate ratio, $R = [IO_3^-]_0/[Met]_0$, is increased from 0.333 (stoichiometry eq. [R2]), until a saturation point is reached where the methionine becomes limiting at a ratio of 0.400. In this short range of ratios, the final iodine amount was reproducibly determined spectrophotometrically to be 0.2 times the amount of methionine used as predicted by stoichiometry eq. [R3].

The direct reaction of methionine with iodine was rapid enough for the stoichiometry to be determined by direct titration of an iodine solution with methionine and vice-versa. The detection of the end point was aided by the starch indicator and the stoichiometry was determined to be

$$[R4] \quad Met + I_2 + H_2O \rightarrow Met{-}S{=}O + 2I^- + 2H^+$$

Stoichiometry eq. [R4] could also be obtained spectrophotometrically in excess iodine conditions by observing the absorbance of the excess iodine at 460 nm (at the end of the reaction).

Confirmation of products

The two major products that could possibly be obtained from the oxyhalogen oxidation of the sulfur center in methionine are the sulfoxide and the sulfone. Due to the lack of $BaSO_4$ precipitation, there was no evidence to suggest further oxidation resulting in cleavage to the C–S bond. Proton NMR spectroscopy was used to confirm the products as predicted from the stoichiometry. In Fig. 2, spectrum A is of the product of reaction between acidic iodate and methionine. Spectrum B is pure DL-methionine, which shows the expected strong singlet for the *S*-methyl group at 2.12 ppm. These protons appear as a singlet due to the presence of the sulfur, which acts as a shield from the splitting effects of the other protons on adjacent carbon atoms. Spectrum C shown is of reagent grade DL-methionine sulfoxide, showing a downfield shift of the methyl protons (2.79 ppm) due to the presence of the oxygen on the sulfur center. Addition of another oxygen to form the sulfone results in a further downfield shift of these protons to 3.20 ppm. Spectrum D is reagent grade methionine sulfone. Spectrum A, the reaction product, is similar to the spectrum for the reagent grade sulfoxide (C). Solutions to obtain spectra B–D were prepared in neutral conditions while DCl was used to acidify the solution used to obtain spectrum A. The difference in pH between these solutions accounts for the small difference between spectra A and C. The spectrum of oxidation of methionine by acidified iodate shows that there is a small amount of sulfone formed as a minor product, but this could not be detected iodometrically due to the oxidation of iodide by the sulfone to iodine and the sulfoxide. To further confirm the sulfoxide as the major product, reagent grade sulfoxide was mixed with acidified iodate solution and no further reaction was observed.

Reaction dynamics

The reaction exhibited clock behavior[22] with transient iodine formation. Figure 3 shows both aspects of this dynamical behavior. When the oxidant-to-reductant ratio, $R = [IO_3^-]_0/[Met]_0$, is less than 0.333, no iodine is expected to be formed at the end of the reaction as predicted by stoichiometry eq. [R2]. Traces a–c in Fig. 3 are derived from reaction solutions in which $R < 0.333$, but, however, show transient iodine formation, which is an indication of the dominance of the reactions that form iodine over those that consume it during the initial stages of the reaction. As the reaction proceeds, iodine consumption reactions later become dominant. Clock reaction characteristics, in which there is an initial quiescent period followed by formation of iodine, are also exhibited for all values of *R*, as shown by traces a–h (Fig. 3). In stoichiometric excess of oxidant, which gives stoichiometry eq. [R3], i.e., $R \geq 0.333$, the final iodine formation is determined by the concentration of methionine. When $R > 0.4$, however, the amount of iodine formed becomes invariant to further increases in iodate concentrations. The increase in final iodine concentration between traces d and e (Fig. 3) is justified based on the fact that stoichiometry eq. [R3] is a step wise linear combination of eqs. [R1] and [R2].

Figure 3 also shows that as the iodate concentration is increased, the rate of iodine formation increases while the quiescent time before iodine formation commences (induction period), decreases.[23] Formation of iodine, in all traces (Fig. 3), is not sharp, but gradual. Thus the induction period was estimated to be the point where rapid formation of iodine commenced.

Figure 4*a* shows that not only does an increase in acid decrease the induction period, but it also increases the rate of

Table 1. Iodate–Iodine–Methionine reaction network.

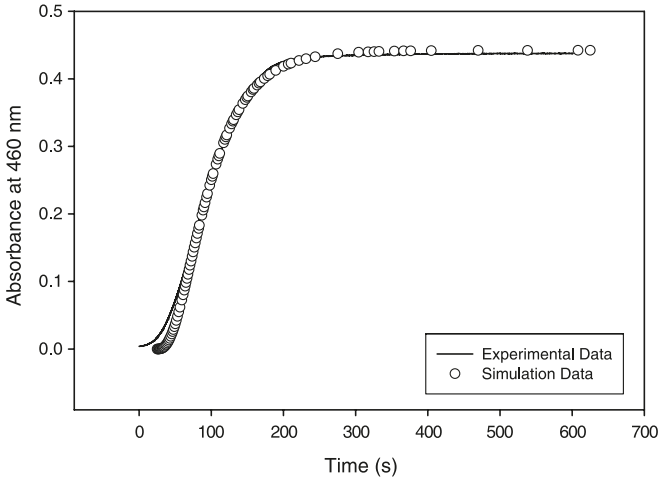
Fig. 9. Computer modeling: traces showing the simulated results (circles) and the experimental data (solid line) for trace g shown in Fig. 4*a*. $[Met]_0 = 0.003$ mol/L, $[IO_3^-]_0 = 0.03$ mol/L, $[H^+] = 0.008$ mol/L.



formation of iodine. The catalytic effect of acid on the Dushman[24–27] reaction (eq. [R1]) is responsible for the increase in rate of formation of iodine in conditions where $R > 0.4$. Since the final amount of iodine does not change with an increase in acid, acid influences only the overall rate of formation of iodine, which in turn affects the induction period. The effect of acid for low R values ($R < 0.33$), however, is more complex as shown in Fig. 4*b*. Figure 4*b* shows traces in excess methionine conditions where no final iodine accumulation is expected. As the acid is increased from a to f (Fig. 4*b*), the induction period is shortened while the maximum amount of transient iodine is increased. This indicates acid catalysis in formation of iodine, resulting in rapid accumulation of iodine and shorter induction periods as acid concentrations are increased. Higher acid traces in Fig. 4*b* also show a narrower "excursion" indicating that an increase in acid also increases the rate of consumption of iodine. Given that the general shape of the traces is not symmetrical, it would also appear that acid catalyzes the formation of iodine to a greater extent than it catalyzes its consumption.

The oxidant-to-reductant ratio, R, plays an important role in determining the dynamics of the reaction as can be seen in Fig. 5, which shows the effect of progressively increasing the methionine concentration at constant iodate and acid concentration. As R is reduced from a–d (Fig. 5), the final iodine amount increases to a final concentration that is determined by stoichiometry eq. [R3]. As reaction stoichiometry eq. [R2] is approached, the monotonic formation of iodine gives way to transient formation of iodine as shown in trace e (Fig. 5).

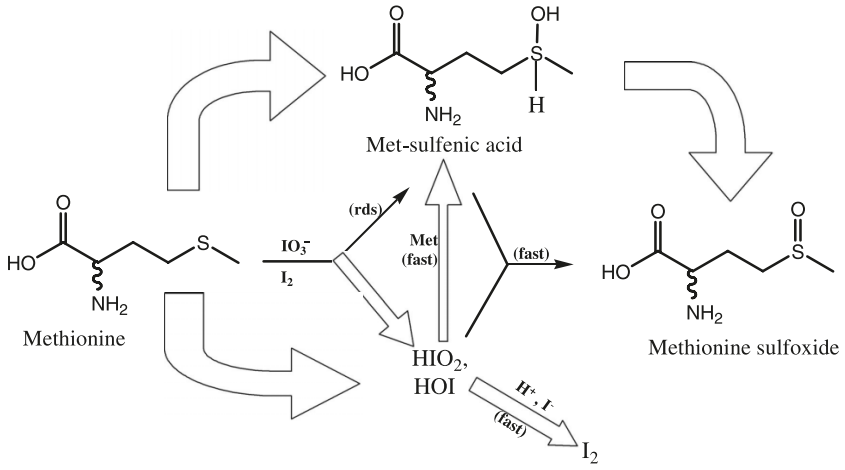
In excess oxidant conditions, the effect of iodide can easily be seen by the increase in final iodine concentration. This is expected in conditions where $R > 0.4$, in which the iodide ions initially added to the reaction mixture combine with those produced by the reaction in eq. [R2] to fuel the Dushman reaction,[24,26] eq. [R1]. This is clearly evident in Fig. 6 where an increase in iodide concentrations increases the final iodine concentration as well as reducing the induction time.

The direct reaction of iodine and methionine plays a crucial role in this mechanism. The rate at which iodine oxidizes methionine determines whether methionine can coexist with iodine. If this reaction is fast, then final iodine formation would mean that all the methionine has been consumed. Figure 7*a* shows the iodine consumption of methionine in high excess of methionine. Despite this high excess, no pseudo-first-order kinetics are observed, indicating that this is not a simple electrophilic attack of iodine on the thioether group. There is a linear dependence between the initial rate of reaction with both methionine and iodine concentrations. Figure 7*b* shows the methionine dependence. Figure 8*a* shows that iodide is inhibitory to the oxidation of methionine by iodine. Figure 8*b* shows that there is an inverse dependence relationship between the initial rate of reaction and iodide concentrations. Iodide is a product of the iodine–methionine reaction, and thus its effect is autoinhibitory. This explains why no pseudo-first-order kinetics were observed in the data shown in Fig. 7*a*.

Mechanism

The bulk of iodate-based oxidations are borne by the reactive oxyiodine species HIO_2, IO_2, and HOI as well as molecular iodine, I_2. These species can be generated in acidic iodate conditions, and the rate of iodate oxidations are usually controlled by the rate at which these reactive species are generated.[28,29] There is some debate as to the exact initiation sequence of iodate oxidations, but a nucleophilic attack on a protonated iodate species (see reaction eq. [R7]) appears to be the most widely accepted initiation to produce iodous and hypoiodous acids.

Scheme 2. Schematic representation of all possible reactions, intermediates, and products in the oxidation of methionine by acidic iodate and aqueous iodine.



$$[R5] \quad IO_3^- + H^+ \rightleftharpoons IO_3H$$

Investigators of the Briggs–Rauscher[30,31] and Bray–Liebhafsky[25,32] reactions have suggested that this nucleophilic species is the trace amount of iodide ions that are contained in normal iodate solutions.

$$[R6] \quad IO_3H + H^+ \rightleftharpoons {}^+IO(OH)_2$$

$$[R7] \quad {}^+IO(OH)_2 + I^- \rightleftharpoons I{-}IO(OH)_2$$

The $H_2I_2O_3$ species formed in eq. [R7] can then break down in a rate-determining step to produce the reactive species, HIO_2 and HOI.[29]

$$[R8] \quad I{-}IO(OH)_2 \rightarrow HIO_2 + HOI$$

HOI is extremely reactive as an oxidizing species, and will rapidly react with the substrate, methionine, to produce iodide and the oxidation product, methionine sulfoxide.

$$[R9] \quad HOI + :SR_1R_2 \rightarrow R_1R_2S{=}O + H^+ + I^-$$

The iodide produced in eq. [R9] feeds back into reaction eq. [R7] to facilitate further oxidation of the reactive species. While we may accept iodous acid as a viable oxidant, it, however, rapidly reacts with iodide to produce more hypoiodous acid:

$$[R10] \quad HIO_2 + H^+ + I^- \rightleftharpoons 2HOI$$

Addition of the reactions leading to the oxidation of methionine in the initial stages shows that the reaction's initial activity is the build-up of iodide, which is autocatalytically produced in these early stages of the reaction of eqs. [R5] + [R6] + [R7] + [R8] + 3[R9] + [R10];

$$[R11] \quad IO_3^- + 2I^- + 3MetS \rightarrow 3I^- + 3MetSO$$

The iodide material balance for the initial stages suggests a mechanism that is based on cubic autocatalysis in iodide.

There are, however, two major flaws with the eqs. [R5]–[R10] sequence. The first flaw is from pure mass action kinetics. The expected iodide concentrations, which exist in these iodate solutions, should be approximately 5.0×10^{-7} mol/L. Assuming eqs. [R9] and [R10] are relatively rapid, one can utilize reaction eq. [R8] to determine the rate of formation of iodide and subsequently the rate of oxidation of methionine. A simple integration gives a sigmoidal curve for iodide generation. Literature values give the composite forward rate constant of reaction eq. [R8] as 2.2 $(mol/L)^{-3}$ s^{-1}. Using these values, one generates a very slow rate of iodide formation and subsequent rate of reaction, giving reaction times in the order of hours instead of the observed 2–10 min. This suggests that iodide formation is not solely through the composite reaction eq. [R11]. The next flaw arises from the effect of iodide observed in Fig. 6. With cubic autocatalysis, as profiled in reaction eq. [R11], addition of minute amounts of iodide should result in a greatly enhanced rate of reaction. Figure 6 shows that, while iodide is catalytic, it is not as strong as would have been expected from an autocatalyst.

It appears then, that initial formation of iodide should be derived from the substrate itself acting as a nucleophile on either the iodic acid or the protonated iodic acid. Both scenarios would produce kinetically indistinguishable reaction profiles and mechanisms. In Scheme 1, methionine is represented as R_1SR_2.

The iodous acid produced in Scheme 1 can be further reduced successively by methionine to hypoiodous acid and iodide. Reaction eq. [R9] is a rapid oxygen transfer reaction, and thus, the overall rate of reaction should be the rate of formation of HOI.

Accumulation of iodide will then transfer the rate of reaction to standard Dushman reaction kinetics with the composite rate-determining step eq. [R12]:

$$[R12] \quad IO_3^- + I^- + 2H^+ \rightleftharpoons HIO_2 + HOI$$

Iodine is formed from the reverse of its hydrolysis reaction:

$$[R13] \quad HOI + I^- + H^+ \rightleftharpoons I_2(aq) + H_2O$$

Through relaxation spectroscopy, reaction eq. [R13] is known to be very rapid and acid-catalyzed.[33] Basic condi-

tions catalyze and support the hydrolysis reaction. Our experiments, however, were carried out in acidic conditions since iodate is essentially inert in basic environments. A summary of all possible reactions, intermediates, and products in the oxidation of methionine by acidic iodate and its oxidative derivatives is shown in Scheme 2.

The methionine–iodine reaction

The direct reaction of methionine with aqueous iodine is very important in determining the overall global dynamics observed with respect to iodine formation. Transient iodine formation, as observed in Fig. 4*b*, is derived from the coupling of the reaction that forms iodine, eq. [R13],[33] with those that consume iodine. If the methionine-iodine reaction is extremely rapid (e.g., diffusion controlled), no transient iodine formation would be observed and the end of the induction period would be very sharp, and would signify complete consumption of methionine. The nonlinear kinetics observed indicate that the reactions involved in the formation and consumption of iodine are comparable in magnitude and each set asserts itself based on the availability of the relevant reagents and mass action kinetics.

The reaction commences with an electrophilic attack by aqueous iodine on the electron-rich sulfur center of methionine:

$$[R14] \qquad R_1R_2S: + I{-}I \rightleftharpoons [R_1R_2S{-}I]^+ + I^-$$

followed by the standard hydrolysis:

$$[R15] \qquad [R_1R_2S{-}I]^+ + H_2O \rightarrow R_1R_2S{=}O + 2H^+ + I^-$$

Addition of eqs. [R14] and [R15] gives the 1:1 experimentally observed stoichiometry for this reaction. Initial rate data, before accumulation of iodide, was used to evaluate $k_{14} = 72 \pm 1.4$ (mol/L)$^{-1}$ s^{-1}.

Although the reaction is autoinhibitory, the autoinhibition is not as strong as the one observed with the iodine–thiocyanate[34,35] and iodine–thiourea reactions.[36] In these systems, it was assumed that iodine reacts with the product, iodide, to produce an inert product, triiodide:

$$[R16] \qquad I_2 + I^- \rightleftharpoons I_3^-; K_{eq}$$

If one assumes that the triiodide anion is inert, then the following rate law emerges:

$$[1] \qquad \left|\frac{1}{\text{Rate}}\right| = \frac{1}{k_{14}[\text{Met}]_0[I_2]_0}(1 + K_{eq}[I^-])$$

A plot of the inverse of the rate versus iodide concentrations on the basis of eq. [1] should give a straight line, which should allow for the calculation of k_{14} and a confirmation of the well known value of $K_{eq} = 770$ (mol/L)$^{-1}$. This plot is shown in Fig. 8*b* where the data gave a value of k_{14} that was much lower than that derived from initial rate data, and also gave a much lower K_{eq} value that was an order of magnitude lower than the literature value.[37] This suggests that I_3^- is not inert, and that the autoinhibition observed is derived from the sluggish kinetics obtained with I_3^- when it predominates in concentrations as iodide accumulates.

$$[R17] \qquad R_1R_2S: + I_3^- + H_2O \rightarrow R_1R_2S{=}O + 3I^- + 2H^+$$

Combining reaction eqs. [R14] and [R17] gives a rate law of the form

$$[2] \qquad \text{Rate} = \frac{[\text{Met}]_0[I_2]_0}{1 + K_{eq}[I^-]}[k_{14} + k_{17}K_{eq}[I^-]]$$

In the initial stages, before iodide accumulates, rate law eq. [2] simplifies to a simple bimolecular rate law. In the limit of high initial iodide concentrations, in which one can assume constant iodide concentrations, an upper limit rate constant for k_{17} was derived as 16.0 (mol/L)$^{-1}$ s^{-1}.

Computer simulation

The reaction scheme was modeled using the Kintecus software generated by James Ianni.[41] The full mechanism, which takes into account the formation and consumption of iodine, is shown in Table 1. It is a very simple mechanism made up of 11 reactions with the most important reactions being M1 and M7 (Table 1), which are responsible for initiating the reaction. Since iodate oxidations only proceed at reasonable rates in highly acidic media, the simulations could be simplified by assuming that acid concentrations were buffered throughout the duration of the reaction. By using a constant acid concentration, reactions M2–M4 and M7 (Table 1) could be reduced to the simpler bimolecular kinetics. Reactions M1–M4 (Table 1) are the standard oxyiodine reactions whose rate constants are well-known and were derived from literature.[24–27] These were not altered during the modeling exercises. Reaction M5 (Table 1) was studied by laser-Raman techniques and the forward and reverse rate constants and subsequent equilibrium constant were also derived from literature and also not varied.[37,38] Reaction M6 (Table 1) is a rapid protolytic process in which the only relevant parameter was the assumed K_a of iodic acid. Literature reports a wide range of values for this K_a.[39] The K_a value is apparently heavily dependent on the reaction medium, especially acid concentrations.[29] Elegant experimental work done by Naidich and Ricci[40] in 1939 established that concentrations of iodic acid become significant in acidic iodate solutions at a pH of less than 2.00. All our reactions were run at pH conditions lower than this value. The final adopted value of 0.400 was extrapolated from the barium iodate solubility data of Naidichi and Ricci.[40] The simulations were insensitive to the adopted values of the forward and reverse rate constants for M6 (Table 1) for as long as they were both rapid and linked by K_a. More realistic diffusion-controlled rate constants for M6 (Table 1) stiffened the simulations considerably and slowed the calculations but without affecting the resulting simulations. Reactions M7–M9 (Table 1) represent the initiation reactions in the absence of initially added iodide. Reactions M8 and M9 (Table 1) are not important in determining the observed reaction dynamics for as long as they are faster than M7 (Table 1). Rate constants for reactions M10 and M11 (Table 1) were determined from this study. Effectively, since half of the reactions' parameters were obtained from literature values, the only parameters that could be altered for best fit to the data were K_a for iodic acid and k_{M7}. Figure 9 shows that this simple mechanism gave a reasonably good fit of the experimental data for the case involving excess io-

date concentrations, resulting in a monotonic formation of iodine. The transient iodine formation traces (Figs. 3 and 4*b*) were more difficult to reproduce with this abbreviated mechanism. It was easier to fit the initial formation of iodine but much more difficult to fit its consumption, even though the model could easily reproduce the trivial iodine consumption traces shown in Fig. 7*a*. The inability to correctly simulate Figs. 3 and 4*b* lay in our inability to correctly ascribe the correct activity of aqueous iodine in these highly acidic solutions. Literature does not contain reliable data on these solutions, especially when spiked with iodide.

Conclusion

Our short study has shown that iodine oxidizes the simple biologically important thioether, methionine, to just the sulfoxide. Organosulfur compounds are the most effective goitrogenics available, and their reaction rate and mechanism with iodine would be a significant physiological interaction.

Cerium(IV) sulfate catalyzed one-pot three-component diastereo selective synthesis of 4-amidotetrahydropyrans

Nagarajan Panneer Selvam and Paramasivan T. Perumal

Abstract: A convenient and diastereoselective one-pot synthesis of *cis*-4-amidotetrahydropyrans is described. This simple protocol involves Prins cyclization of homoallylic alcohol and aldehydes, followed by Ritter reaction of acetonitrile leading to the formation of *cis*-4-acetamidopyrans in good yields.

Key words: cerium(IV) sulfate, diastereoselective, tetrahydroamidopyrans, Prins–Ritter reaction.

Résumé : On décrit une méthode de synthèse monotope commode et diastéréosélective des *cis*-4-amidotétrahydropyranes. Ce protocole simple implique des réactions de cyclisation de Prins entre l'alcool homoallylique et divers aldéhydes, suivies d'une réaction de Ritter avec de l'acétonitrile qui conduit à la formation des *cis*-4-acétamidopyranes avec de bons rendements.

Mots-clés : sulfate de cérium(IV), diastéréosélective, tétrahydroamidopyranes, réaction de Prins–Ritter.

[Traduit par la Rédaction]

Introduction

Multicomponent one-pot syntheses are highly important because of their wide range of applications in pharmaceutical chemistry for the production of structural scaffolds and combinatorial libraries for drug discovery.[1] The tetrahydropyran ring has attracted significant attention in recent years, as it is part of the backbone of many natural products.[2] It is featured widely in many natural products, such as phorboxazole A, psymberin, and (–)-centrolobine. The 4-amino tetrahydropyran ring system is a core unit in a number of natural products, such as ambruticin VS, glycamino acid, and others[3] (Fig. 1). Because of their prevalence, there are multiple strategies for the construction of these six-membered ring systems, including Prins cyclization,[4] hetero Diels–Alder reactions,[5] and intramolecular nucleophilic reactions.[6] Among the several methods available, Prins cyclization[7] offers one of the most versatile methods for the construction of the tetrahydropyran ring. A few reports on the use of the Ritter reaction to terminate Prins cyclizations;[8] the scope of this process has not been explored extensively. Recently, Yadav et al. described the synthesis of substituted tetrahydroamidopyran derivatives using $CeCl_3 \cdot 7H_2O$/acetyl chloride,[9] phosphomolybdic acid[10] catalyst. Because of the unique pharmacological, biological, and industrial importance, simple and efficient protocols for the synthesis of these compounds are highly desirable.

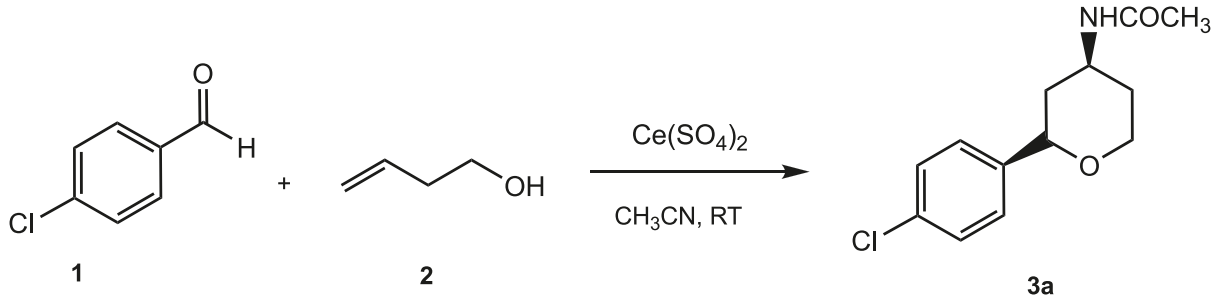
Results and discussion

In continuation of our work on the development of useful synthetic methodologies using cerium(IV) sulfate,[11] we herein describe an efficient Prins–Ritter reaction sequence for the direct synthesis of 4-acetamidotetrahydropyrans from homoallylic alcohols, carbonyl compounds, and acetonitrile. First, we carried out a three-component coupling reaction of 4-chlorobenzaldehyde with but-3-en-1-ol in acetonitrile in the presence of 20 mol% $Ce(SO_4)_2$ at room temperature. The reaction proceeded to completion in 6.5 h, and the product, 4-acetamidotetrahydropyran (**3a**), was obtained in 93% yield with cis-selectivity (Scheme 1).

Other Lewis acid catalysts, such as zinc(II) chloride, ferric chloride hexahydrate, stannous chloride dihydrate, potassium hydrogen sulfate, cerium(IV) sulfate, and phosphotungstic acid, were tested, but $Ce(SO_4)_2$ was found to be the most efficient in terms of conversion.

Thus encouraged, we examined various substituted aryl aldehydes and homoallylic alcohols for the synthesis of 4-acetamidotetrahydropyrans under optimized reaction conditions. 4-Chlorobenzaldehyde, 2,4-dichlorobenzaldehyde, 4-nitrobenzaldehyde, 3-nitrobenzaldehyde, 4-methylbenzaldehyde, 4-bromobenzaldehyde, and 4-methoxybenzaldehyde reacted well with 3-buten-1-ol and acetonitrile to produce the corresponding 4-acetamidotetrahydropyrans in high yields (Table 1, entries 1–8). An aliphatic aldehyde (propionaldehyde) also reacted with 3-buten-1-ol and acetonitrile to afford the product in 82% yield (Table 1, entry 9). Furthermore, substituted homoallylic alcohols, such as 1-phenyl-but-3-en-1-ol, 1-(3-nitrophenyl)-but-3-en-1-ol, 1-(4-chlorophenyl)but-3-en-1-ol, and 1-(2,4-dichlorophenyl)-but-3-en-1-ol also participated in this transformation (Table 1, entries 10–15). Ketones, such as cyclohexanone and cyclopentanone, reacted comparably

Scheme 1. Synthesis of 4-acetamidotetrahydropyran derivatives.



Scheme 2. Synthesis of spirocyclic 4-acetamidotetrahydropyrans.

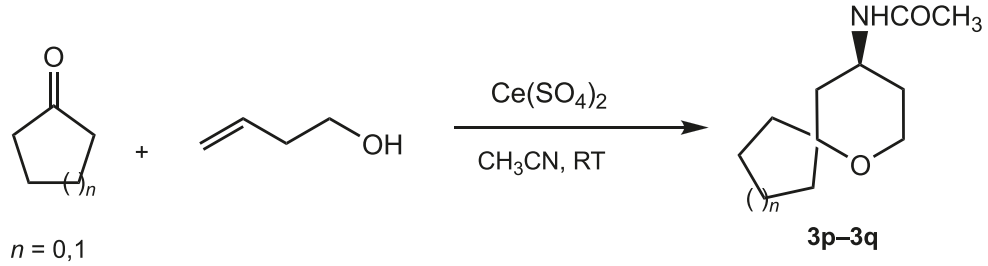


Fig. 1. Examples of tetrahydropyran derivatives.

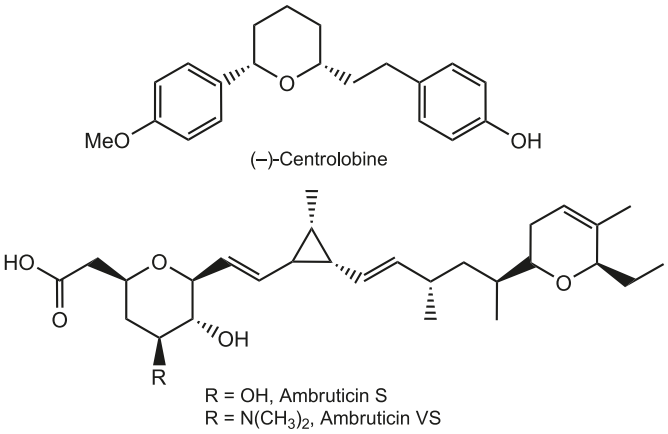

giving spirocyclic 4-acetamidotetrahydropyrans in good yields (Table 1, entries 16 and 17; Scheme 2).

The reactions were clean, and the products were obtained in excellent yields with high diastereoselectivity as determined from the NMR spectra of the products. In all cases, cis-isomer were obtained exclusively, and the structure of which was confirmed by NOE experiments. The formation of the products can be explained by hemi-acetal formation followed by Prins cyclization and subsequent Ritter amidation (Scheme 3).

The structures of compounds **3a**–**3q** were characterized by spectral and elemental analyses. Compound **3j** showed peaks at 3282, 3071, 1638, and 1114 cm^{-1}, indicating the presence of –NH–, –CH, –CO, and –C–O–C– groups in the IR spectrum. A singlet at δ 1.96 and a doublet at 5.49 (D_2O exchangeable) in the ^1H NMR and signals at δ 22.7 and 168.5 in the ^{13}C NMR spectrum confirmed the presence of acetamido group in the molecule. The mass spectral data and elemental analysis also supported the structural assignments. The structure of **3j** was also established by NOE experiments (Fig. 2).

A rationale for the cis selectivity could be explained by assuming the formation of an (*E*)-oxocarbenium ion via a chair-like transition state, which has an increased stability relative to the open oxocarbenium ion due to delocalization. The optimal geometry for this delocalization places the hydrogen atom at C4 in a pseudo-axial position, which favours equatorial attack of the nucleophiles.[12]

The structure **3j** shown in Fig. 2 was deduced from the NMR data, where the two substituents were shown to be cis to each other. The H2 and H6 protons have a large coupling of J = 10.0 Hz. Presence of the large coupling indicates that it is in axial position, with large diaxial coupling with H3a and H5a, which implies an equatorial position for the aromatic group at C2. Similarly, the equatorial orientation of the substituent at C4 is suggested by the multiplicities of H3a and H5a protons. The equatorial orientation of the substituents at C2 and C4 was also confirmed by NOESY cross peaks for H2 with H4 and H6. This structure was further confirmed by NOESY cross peaks for NH/H3a, NH/H3e, NH/H5a, NH/H5e, Ar/H3a, and Ar/H3e.

In summary, we have described an efficient Prins–Ritter reaction to produce highly substituted 4-acetamidotetrahydropyrans in high yields with all cis selectivity. The use of inexpensive and readily available cerium(IV) sulfate makes this procedure simple, convenient, and practical. In addition to its simplicity, efficiency, and milder reaction conditions, this method provides an easy access for 4-acetamidotetrahydropyran derivatives with diverse chemical structures.

tained from S.D. Fine Chemicals. Cerium(IV) sulfate and phosphotungstic acid were purchased from Aldrich. Reagent-grade acetonitrile was used. All melting points are uncorrected. IR spectra were recorded on a PerkinElmer FTIR spectrophotometer. ^{1}H and ^{13}C NMR spectra were recorded in DMSO-d_6 and $CDCl_3$ using TMS as an internal standard on a JEOL and Bruker spectrometers at 500 MHz and 125 MHz, respectively. Mass spectra were recorded on a Thermo Fennign mass spectrometer using electrospray ionization method. Elemental analyses were recorded using a Thermo Finnigan FLASH EA 1112 CHN analyzer. Column chromatography was performed on silica gel (100–200 mesh, SRL, India). Analytical TLC was performed on precoated plastic sheets of silica gel G/UV-254 of 0.2 mm thickness (Macherey-Nagel, Germany).

General procedure for the synthesis of 4-acetamidotetrahydropyrans (3a–3q)

A mixture of homoallylic alcohol (1.0 mmol), carbonyl compound (1.0 mmol), and cerium(IV) sulfate (20 mol%) in acetonitrile (5 mL, used as a solvent) was stirred at room temperature for a specified time (Table 1). After completion of the reaction as indicated by TLC, the reaction mixture was quenched with ice water (10 mL) and extracted with ethyl acetate (2 × 15 mL). The combined organic layers were dried over anhydrous Na_2SO_4. Removal of solvent followed by purification on silica gel (Merck, 100–200 mesh, ethyl acetate – hexane, 4:6) gave pure 4-acetamidotetrahydropyran.

Found: C, 76.09; H, 7.16; N, 5.17%.

N-[2-(2,4-Dichlorophenyl)tetrahydropyran-4-yl]acetamide 3c (Table 1, entry 3)

White solid. Isolated yield: 94%, mp 153–155 °C. ^{1}H NMR (500 MHz, DMSO-d_6) δ: 1.07 (q, 1H, J = 12.2 Hz), 1.41 (m, 1H), 1.72 (m, 4H), 1.99 (m, 1H), 3.54 (t, 1H, J = 11.5 Hz), 3.91 (m, 1H), 4.01 (m, 1H), 4.56 (d, 1H, J = 10.7 Hz), 7.38 (d, 1H, J = 8.4 Hz), 7.44 (d, 1H, J = 8.4 Hz), 7.51 (s, 1H), 7.86 (d, 1H, J = 6.9 Hz, D_2O exchangeable). ^{13}C NMR (125 MHz, DMSO-d_6) δ: 23.7, 32.5, 39.0, 45.77, 67.1, 74.8, 127.5, 128.4, 129.7, 131.8, 133.1, 139.3, 169.1. IR ν_{max} (KBr): 3299, 2934, 2864, 1642, 1540,

1366, 1145, 1086, 817, 714 cm^{-1}. Mass (ESI): 288 (M + 1). Anal. calcd. for $C_{13}H_{15}NO_2Cl_2$: C, 54.18; H, 5.25%; N, 4.86. Found: C, 54.39; H, 5.29; N, 4.81%.

_N_-[2-(4-Nitrophenyl)tetrahydropyran-4-yl]acetamide 3d (Table 1, entry 4)

White solid. Isolated yield: 92%, mp 164–166 °C. ^{1}H NMR (500 MHz, DMSO-d_6) δ: 1.14 (q, 1H, J = 11.5 Hz), 1.40 (m, 1H), 1.71 (m, 4H), 1.99 (d, 1H, J = 12.2 Hz), 3.52 (t, 1H, J = 12.2 Hz), 3.93 (m, 1H), 4.02 (dd, 1H, J_1 = 3.85 Hz, J_2 = 11.5 Hz), 4.52 (d, 1H, J = 10.0 Hz), 7.55 (d, 2H, J = 8.4 Hz) 7.97 (d, 1H, J = 7.7 Hz), 8.14 (d, 2H, J = 8.4 Hz, D_2O exchangeable). ^{13}C NMR (125 MHz, DMSO-d_6) δ: 23.8, 32.6, 39.3, 44.8, 68.4, 74.3, 126.8, 129.7, 132.9, 139.6, 168.4. IR ν_{max} (KBr): 3288, 2922, 2858, 1672, 1519, 1425, 1345, 1148, 1084, 854 cm^{-1}. Mass (ESI): 265 (M + 1). Anal. calcd. for $C_{13}H_{16}N_2O_4$: C, 59.08; H, 6.10; N, 10.60%. Found: C, 58.87; H, 6.16; N, 10.56%.

_N_-[2-(3-Nitrophenyl)-tetrahydropyran-4-yl]acetamide 3e (Table 1, entry 5)

White solid. Isolated yield: 92%, mp 186–188 °C. ^{1}H NMR (500 MHz, DMSO-d_6) δ: 1.17 (q, 1H, J = 12.3 Hz), 1.41 (m, 1H), 1.73 (m, 4H), 2.03 (m, 1H), 3.54 (t, 1H, J = 11.5 Hz), 3.92 (m, 1H), 4.03 (m, 1H), 4.52 (d, 1H, J = 11.5 Hz), 7.57 (t, 1H, J = 8.4 Hz) 7.73 (d, 1H, J = 7.7 Hz), 7.86 (d, 1H, J = 7.7 Hz), 8.07 (d, 1H, J = 8.4 Hz, D_2O exchangeable), 8.11 (s, 1H). ^{13}C NMR (125 MHz, DMSO-d_6) δ: 23.2, 32.5, 41.6, 45.9, 66.9, 76.8, 120.5, 122.6, 130.3, 133.5, 145.3, 148.2, 169.2. IR ν_{max} (KBr): 3288, 2930, 2855, 1635, 1536, 1345, 1148, 1090, 735 cm^{-1}. Mass (ESI): 265 (M + 1). Anal. calcd. for $C_{13}H_{16}N_2O_4$: C, 59.08; H, 6.10; N, 10.60%. Found: C, 59.31; H, 6.16; N, 10.58%.

_N_-(2-_p_-Tolyltetrahydropyran-4-yl)acetamide 3f (Table 1, entry 6)

White solid. Yield: 88%, mp 163–165 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.43 (m, 2H), 1.90 (s, 3H), 1.98 (m, 1H), 2.21 (m, 1H), 2.36 (s, 3H), 3.65 (m, 1H), 4.17 (m, 2H), 4.37 (dd, 1H, J_1 = 3.1 Hz, J_2 = 12.6 Hz), 5.46 (d, 1H, J = 8.4 Hz, D_2O exchangeable), 7.73 (m, 4H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 21.6, 21.9, 23.4, 26.1, 34.0, 40.6, 42.8, 126.3, 128.3, 134.8, 136.3, 169.3. IR ν_{max} (KBr): 3286, 2957, 2938, 1651, 1556, 1371, 1096, 1042, 871, 730 cm^{-1}. Mass (ESI): 256 (M + Na). Anal. calcd. for $C_{14}H_{19}NO_2$: C, 72.07; H, 8.21; N, 6.00%. Found: C, 72.37; H, 8.26; N, 6.02%.

_N_-[2-(4-Bromophenyl)tetrahydropyran-4-yl]acetamide 3g (Table 1, entry 7)

White solid. Yield: 90%, mp 176–178 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 0.96 (t, 3H, J = 7.5 Hz), 1.61 (m, 4H), 2.19 (m, 4H), 3.69 (m, 1H), 4.10 (m, 2H), 4.36 (dd, 1H, J_1 = 2.2 Hz, J_2 = 11.6 Hz), 5.21 (d, 1H, J = 7.7 Hz, D_2O exchangeable), 7.19 (d, 2H, J = 8.4 Hz), 7.49 (d, 2H, J = 8.4 Hz).^{13}C NMR (125 MHz, $CDCl_3$) δ: 22.7, 32.8, 39.6, 47.1, 69.1, 77.9, 122.3, 128.4, 132.6, 142.1, 173.2. IR ν_{max} (KBr): 3296, 2956, 2849, 1648, 1560, 1268, 1096, 741 cm^{-1}. Mass (ESI): 327 (M + 1). Anal. calcd. for $C_{15}H_{20}BrNO_2$: C, 55.23; H, 6.18; N, 4.29%. Found: C, 55.46; H, 6.23; N, 4.32%.

_N_-[2-(4-Methoxyphenyl)tetrahydropyran-4-yl]acetamide 3h (Table 1, entry 8)

Pale green solid. Yield: 88%, mp 182–184 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.36 (q, 1H, J = 12.5 Hz), 1.39 (m, 1H), 1.98 (s, 3H), 2.10 (m, 1H), 2.16 (m, 1H), 3.69 (m, 1H), 3.78 (s, 3H), 4.17 (m, 2H), 4.33 (dd, 1H, J_1 = 2.2 Hz, J_2 = 11.8 Hz), 5.36 (d, 1H, J = 7.7 Hz, D_2O exchangeable), 6.96 (d, 2H, J = 8.4 Hz), 7.18 (m, 2H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 23.1, 41.4, 43.1, 46.7, 54.7, 59.6, 74.1, 114.8, 129.1, 134.3, 156.8, 169.4. IR ν_{max} (KBr): 3341, 2956, 2937, 1649, 1561, 1371, 1079, 1043, 814, 733 cm^{-1}. Mass (ESI): 250 (M + 1). Anal. calcd. for $C_{14}H_{19}NO_3$: C, 67.45; H, 7.68; N, 5.62%. Found: C,67.63; H,7.71; N, 5.66%.

_N_-(2-Ethyltetrahydropyran-4-yl)acetamide 3i (Table 1, entry 9)

White solid, Isolated yield: 82%, mp 80–83 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 0.96 (t, 3H, J = 7.5 Hz), 1.26 (m, 4H), 1.86 (m, 2H), 1.97 (s, 3H), 3.28 (m, 1H), 3.47 (m, 1H), 3.96 (m, 2H), 5.46 (d, 1H, J = 8.4 Hz, D_2O exchangeable) . ^{13}C NMR (125 MHz, $CDCl_3$) δ: 9.9, 23.6, 29.3, 33.1, 39.3, 47.3, 68.9, 77.7, 169.3. IR ν_{max} (KBr): 3288, 3097, 2956, 2936, 2847, 1648, 1560, 1439, 1374, 1156, 1096, 978, 738 cm^{-1}. Mass (ESI): 194 (M + Na). Anal. calcd. for $C_9H_{17}NO_2$: C, 63.13; H, 10.01; N, 8.18%. Found: C, 63.37; H, 10.08; N, 8.21%.

_N_-(2,6-Diphenyltetrahydropyran-4-yl)acetamide 3j (Table 1, entry 10)

Pale yellow solid. Isolated yield: 85%, mp: 220–222 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.38 (q, 2H, J = 12.2 Hz), 1.96 (s, 3H), 2.26 (m, 2H), 4.35 (m, 1H), 4.64 (d, 2H, J = 10.0 Hz), 5.49 (d, 1H, J = 8.4 Hz, D_2O exchangeable), 7.27 (m, 2H), 7.32 (t, 4H, J = 6.9 Hz), 7.40 (d, 4H, J = 6.9 Hz). ^{13}C NMR (125 MHz, DMSO-d_6) δ: 22.7, 45.8, 77.3, 125.6, 127.2, 128.2, 142.5, 168.5. IR ν_{max} (KBr): 3282, 3071, 2832, 1638, 1547, 1438, 1290, 1114, 738 cm^{-1}. Mass (ESI): 296 (M + 1). Anal. calcd. for $C_{19}H_{21}NO_2$: C, 77.26; H, 7.17; N, 4.74%. Found: C, 77.47; H, 7.21; N, 4.69%.

_N_-[2-(4-Bromophenyl)-6-phenyltetrahydropyran-4-yl]acetamide 3k (Table 1, entry 11)

Pale yellow solid. Yield: 87%, mp 169–172 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.30 (m, 2H), 1.79 (s, 3H), 2.36 (m, 2H), 4.39 (m, 1H), 4.62 (m, 2H), 5.39 (d, 1H, J = 7.7 Hz, D_2O exchangeable), 7.30 (m, 5H), 7.46 (m, 2H), 7.52 (m, 2H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 23.2, 40.8, 42.6, 47.8, 77.9, 79.3, 125.8, 128.3, 129.6, 130.6, 132.1, 141.6, 142.9, 143.2, 169.3. IR ν_{max} (KBr): 3321, 2956, 2846, 1656, 1548, 1363, 1078, 946, 813, 736 cm^{-1}. Mass (ESI): 375 (M + 1). Anal. calcd. for $C_{19}H_{20}BrNO_2$: C, 60.97; H, 5.39; N, 3.74%. Found: C, 61.10; H, 5.40; N, 3.76%.

_N_-[2-(3-Nitrophenyl)-6-phenyltetrahydropyran-4-yl]acetamide 3l (Table 1, entry 12)

Off-white solid. Isolated yield: 87%, mp 178–180 °C. ^{1}H NMR (500 MHz, DMSO-d_6) δ: 1.35 (m, 2H), 1.89 (s, 3H), 2.09 (m, 2H), 4.15 (m, 1H), 4.65 (m, 2H), 7.23 (m, 9H), 8.74 (d, 1H, J = 7.5 Hz, D_2O exchangeable). ^{13}C NMR

(125 MHz, DMSO-d_6) δ: 22.7, 24.0, 33.4, 45.6, 56.9, 77.5, 120.1, 120.8, 122.3, 125.6, 127.2, 129.9, 132.3, 142.1, 144.6, 147.8, 168.9. IR ν_{max} (KBr): 3301, 1663, 1533, 1347, 1096, 698 cm^{-1}. Mass (ESI): 341 (M + 1). Anal. calcd. for $C_{19}H_{20}N_2O_4$: C, 67.05; H, 5.92; N, 8.23%. Found: C, 67.29; H, 5.98; N, 8.27%.

***N*-[2-(4-Chlorophenyl)-6-(4-fluorophenyl)-tetrahydropyran-4-yl]acetamide 3m (Table 1, entry 13)**

Pale brown solid. Yield: 86%, mp 108–111 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.35 (m, 2H), 1.96 (s, 3H), 2.23 (m, 2H), 4.35 (m, 1H), 4.59 (d, 2H, J = 10.7 Hz), 5.61 (d, 1H, J = 7.7 Hz, D_2O exchangeable), 6.99 (t, 2H, J = 8.4 Hz), 7.30 (m, 6H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 24.0, 36.3, 40.3, 46.2, 62.4, 78.3, 115.6, 126.5, 127.9, 129.3, 133.3, 137.7, 140.4, 162.7 (J_{C-F} = 210.2 Hz), 169.6. IR ν_{max} (KBr): 3314, 2924, 1639, 1545, 1372, 1219, 1075, 828, 579 cm^{-1}. Mass (ESI): 348 (M + 1). Anal. calcd. for $C_{19}H_{19}NO_4FCl$: C, 65.61; H, 5.51; N, 4.03%. Found: C, 65.73; H, 5.52; N, 4.06%.

***N*-[2-(2,4-Dichlorophenyl)-6-(3-nitrophenyl)tetrahydropyran-4-yl]acetamide 3n (Table 1, entry 14)**

White solid. Yield: 88%, mp 128–131 °C. ^{1}H NMR (500 MHz, DMSO-d_6) δ: 1.24 (q, 1H, J = 11.5 Hz), 1.37 (q, 1H, J = 11.5 Hz), 1.76 (s, 3H), 2.09 (t, 2H, J = 13.8 Hz), 4.17 (m, 1H), 4.88 (t, 2H, J = 10.0 Hz), 7.46 (d, 1H, J = 8.4 Hz), 7.57 (s, 1H), 7.62 (m, 2H), 7.85 (d, 1H, J = 7.7 Hz), 7.91 (d, 1H, J = 7.7 Hz), 8.11 (d, 1H, J = 8.4 Hz, D_2O exchangeable), 8.20 (s, 1H). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 23.2, 38.6,, 40.3, 45.8, 74.7, 77.1, 121.1, 122.1, 123.6, 128.1, 129.1, 129.9, 131.2, 132.2, 133.6, 138.9, 144.7, 148.3, 169.1. IR ν_{max}: 3277, 2926, 2849, 1634, 1535, 1473, 1346, 1128, 1098, 815 cm^{-1}. Mass (ESI): 409 (M + 1). Anal. calcd. for $C_{19}H_{18}N_2O_4Cl_2$: C, 55.76; H, 4.43; N, 6.84. Found: C, 55.96; H, 4.46; N, 6.80%.

***N*-[2-(2,4-Dichlorophenyl)-6-(4-nitrophenyl)tetrahydropyran-4-yl]acetamide 3o (Table 1, entry 15)**

White solid. Yield: 86%, mp 118–120 °C. ^{1}H NMR (500 MHz, DMSO-d_6) δ: 1.30 (q, 2H, J = 12.3 Hz), 1.79 (s, 3H), 2.02 (m, 2H), 4.12 (m, 1H), 4.94 (m, 2H), 7.23 (m, 3H), 7.40 (m, 4H), 8.23 (d, 1H, J = 8.4 Hz, D_2O exchangeable). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 23.2, 36.8, 42.7, 48.7, 63.1, 74.6, 122.3, 126.9, 129.6, 132.1, 133.9, 134.3, 137.1, 138.2, 139.3, 147.6, 169.4. IR ν_{max} (KBr): 3291, 3066, 2929, 2854, 1648, 1520, 1348, 1079, 848, 746, 699 cm^{-1}. Mass (ESI): 431 (M + Na). Anal. calcd. for $C_{19}H_{18}N_2O_4Cl_2$: C, 55.76; H, 4.43; N, 6.84%. Found: C, 55.99; H, 4.47; N, 6.81%.

***N*-(6-Oxaspiro[4.5]dec-9-yl)acetamide 3p (Table 1, entry 16)**

Pale yellow solid. Yield: 85%, mp 148–150 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.26 (m, 12H), 1.89 (s, 3H), 3.47 (m, 2H), 3.97 (m, 1H), 5.80 (d, 1H, J = 8.4 Hz, D_2O exchangeable). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 23.2, 24.6, 33.6, 42.9, 43.4, 45.7, 63.1, 85.2, 169.8. IR ν_{max} (KBr): 3353, 3041, 2976, 1638, 1600, 1563, 1367, 1145, 994, 746 cm^{-1}. Mass (ESI): 198 (M + 1). Anal. calcd. for $C_{11}H_{19}NO_2$: C, 66.97; H, 9.71; N, 7.10%. Found: C, 67.21; H, 9.77; N, 7.06%.

***N*-(1-Oxaspiro[5.5]undec-4-yl)acetamide 3q (Table 1, entry 17)**

White solid. Yield: 83%, mp 146–148 °C. ^{1}H NMR (500 MHz, $CDCl_3$) δ: 1.27 (m, 12H), 1.87 (m, 1H), 1.98 (s, 3H), 2.00 (m, 1H), 3.71 (m, 1H), 3.69 (m, 1H), 4.16 (m, 1H), 5.21 (d, 1H, J = 7.2 Hz, D_2O exchangeable). ^{13}C NMR (125 MHz, $CDCl_3$) δ: 21.3, 23.8, 27.6, 33.4, 36.4, 41.8, 47.9, 68.4, 79.8, 169.4. IR ν_{max} (KBr): 3346, 2958, 2931, 2847, 1648, 1536, 1349, 1208, 1098, 746 cm^{-1}. Mass (ESI): 234 (M + Na). Anal. calcd. for $C_{12}H_{21}NO_2$: C, 68.21; H, 10.02; N, 6.63%. Found: C, 68.43; H, 10.07; N, 6.59%.

Résumé : Les cations compensateurs alcalins et alcalino-terreux sont introduits dans les supports à base de zéolithe pour étudier l'influence de leurs basicités sur l'activité du palladium supporté dans la réaction de combustion totale du méthane. Cette étude a aussi pour objectif de montrer que les propriétés acido-base du support peuvent affecter la structure et l'état d'oxydation du palladium. Les résultats montrent que tous les échantillons s'activent légèrement avec le temps. De plus, à une température inférieure à 430 °C, PdLiNaY semble être le catalyseur le plus actif, tandis qu'à des températures plus élevées, PdHY est l'échantillon le plus actif. À l'exception de PdHY, tous les catalyseurs au palladium ont une énergie d'activation (E_a) dans la gamme entre 79 et 97 kJ mol^{-1}.

Mots-clés : zeolithe NaY, basicité, palladium, combustion de méthane.

Abstract: Alkali and alkaline earth metal cations were introduced into zeolite to explore their influence on the activity of supported palladium in the total combustion of methane and to study how the acido-basic properties of the support affected the structure and the oxidation state of Pd. The results show that all samples exhibit a slight activation with time. Moreover, at temperatures below 430 °C, PdLiNaY seems to be the most active catalyst, while PdHY is the most active sample at higher temperatures. Except for PdHY, all Pd catalysts lead to an activation energy (E_a) value in the range of 79–97 kJ mol^{-1}.

Key words: NaY zeolite, basicity, palladium, methane combustion.

Introduction

La réaction de combustion du méthane étudiée sur les catalyseurs à base de palladium ou de platine a été considérée sensible à la structure.[1–4] La nature de la phase active dans l'oxydation complète du méthane sur du palladium supporté demeure l'objet de discussions. En effet, la nature des sites catalytiques évoqués dans la littérature sont : le palladium métallique Pd^0, l'oxyde de palladium PdO et une phase mixte de Pd^0/PdO,[4] cependant plusieurs travaux de recherches ont affirmé que la palladium métallique est inactif dans l'oxydation du méthane.

Parmi les supports utilisés dans la réaction d'oxydation du méthane, les zéolithes ont fait l'objet également de plusieurs études. En vue d'obtenir un catalyseur performant à basse température et thermiquement stable, Li et Armor[5] ont étudié l'échange cationique du palladium dans les zéolithes ZSM-5, mordenite et ferrite pour l'oxydation du méthane. Ils ont conclu que l'activité élevée enregistrée pour ces catalyseurs par rapport à celle de Pd/Al_2O_3 est due à la haute dispersion du palladium sur les supports zéolithiques.

Certes les catalyseurs basiques ont eu de l'intérêt mais pas autant que les catalyseurs acides. Cependant, il s'est avéré que ce type de catalyseur possède une activité considérable dans plusieurs réactions telles que la déshydrogénation du 2-propanol, l'alkylation du toluène,[6] l'isomérisation, la condensation, l'addition et la polymérisation.[7] Des chercheurs ont mené des travaux sur des zéolithes échangées aux cations alcalins dans la réaction de condensation du benzaldéhyde et l'éthyle cyanoacétate, et ils ont remarqué que l'activité du catalyseur étudié augmente quand le rapport Si/Al diminue et le rayon cationique de l'ion compensateur augmente.[8] U.D. Joshi et al.[9] ont étudié la corrélation entre l'activité et la basicité des zéolithes. Ils ont montré, également, que l'activité catalytique de la zéolithe NaX échangée aux cations alcalins dans une réaction de condensation croît lorsque la taille du cation échangé augmente selon la séquence CsX > RbX > KX > NaX. D'autres travaux[8] ont suggéré que la cristallinité du support peut influer son activité catalytique.

Notre étude consiste en la modification des supports zéolithiques NaY par échange ionique des cations Na^+ par des cations alcalins Li^+, K^+, Cs^+, des cations alcalino-terreux Ca^{2+} et Mg^{2+} et par les ions ammonium NH_4^+ et la préparation de catalyseurs monométalliques à base de palladium supporté sur la zéolithe modifiée. Nous avons étudié, en premier lieu, l'effet de la nature du cation compensateur sur les propriétés structurales et texturales. En second lieu, nous avons testé l'activité catalytique du palladium supporté dans la réaction d'oxydation totale du méthane.

Partie expérimentale

Préparation et traitement des échantillons

La zéolithe, objet de notre étude, est la faujasite NaY (SK40) de formule $Na_{56}(AlO_2)_{56}(SiO_2)_{136}\cdot x H_2O$ et de rap-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Sichuan Normal University on 09/14/12
For personal use only.

port Si/Al = 2,4. Elle est fournie par la firme Union Cabride Linde Division (New York, USA). Dans le but de varier la basicité du support zéolithique, nous avons procédé à une opération d'échange en solutions aqueuses de sels de cations alcalins Li, K, Ca (LiCl : VWR Prolabo (Fontenay sous Bois, France), KCl : VWR Prolabo; $CaCl_2$: Acros Organics (Paris, France)) et alcalino-terreux Mg et Cs ($MgCl_2$: Acros Organics; $CsNO_3$: Acros Organics). La forme NH_4Y utilisée dans ce travail est obtenue par des échanges ioniques répétés de la forme NaY dans une solution de NH_4Cl.[10]

Expérimentalement, 2 g de zéolithe NaY sont mis en contact avec 100 mL de la solution à 0,1 mol L^{-1} de l'un des sels de cations alcalins et alcalino-terreux à 80 °C pendant 6 h,[11] la suspension est maintenue ensuite sous agitation à la température ambiante pendant une nuit. Une fois l'opération d'échange achevée, l'échantillon obtenu est filtré et lavé abondamment à l'eau distillée afin d'éliminer les ions NO_3^-, Cl^- et Na^+ libres dans les différentes solutions. Le produit final est enfin séché à l'étuve à 80 °C pendant 24 h. Les matériaux obtenus sont notés MY avec M = Li, K, Ca, Mg ou Cs.

Le protocole d'échange du palladium dans les zéolithes modifiés est inspiré de la méthode décrite dans la littérature,[10] qui consiste à diluer la solution commerciale de chlorure de palladium tétrammine $Pd(NH_3)_4Cl_2$ (Pallic Soc., Engelhart) (à pH 10,0) puis l'ajouter à la zéolithe NaY. Le mélange est gardé sous agitation pendant 24 h à la température ambiante. Après filtration, le produit est lavé abondamment à l'eau distillée puis séché à 90 °C à l'étuve.

Les différents catalyseurs préparés précédemment PdMY (M = Na, H, Li, K, Ca, Mg ou Cs) sont soumis à un prétraitement thermique sous atmosphère oxydante. Les échantillons sont calcinés sous débit d'oxygène de 1,5 L h^{-1} en montée lente de température (1 °C min^{-1}) jusqu'à la température de 500 °C. La calcination à 500 °C est maintenue pendant 12 h.

Caractérisation des échantillons

Les analyses chimiques sont effectuées à l'aide d'un spectromètre d'absorption atomique de type PerkinElmer modèle 3300. Le taux de palladium dans tous les échantillons est d'environ 1 % en masse. L'analyse du sodium dans les différents échantillons montre que les taux d'échange sont inférieurs à 100 % pour tous les cations étudiés (tableau 1). Par ailleurs, on remarque que les différents cations n'ont pas la même facilité de s'échanger. En effet, d'après les résultats, et pour le même mode opératoire d'échange, l'ion Li^+ est le cation le plus difficile à échanger.

Les échantillons calcinés ont été caractérisés par diffraction des rayons X (DRX) au moyen d'un diffractomètre automatisé modèle Philips Panaletical équipé d'un détecteur de type Celator. La radiation utilisée est celle du cuivre Kα, sous une tension accélératrice de 40 kV et d'un courant de 30 mA. L'angle de balayage 2θ pour les diffractogrammes se situe entre 2° et 50°. Les paramètres de maille ont été déterminés à l'aide du programme d'affinement « CELREF/ERACEL ».

Les surfaces spécifiques « BET » des échantillons sont évaluées à partir des isothermes d'adsorption–désorption de l'azote à 77 K, utilisant un appareil volumétrique. Les mesures du volume d'azote adsorbé en fonction de la pression relative P/P° sont déterminées à l'aide d'un appareil Micromeritics de type ASAP 2000.

Tableau 1. Taux d'échange en cations.

Supports	mmol g^{-1} de Na	% de Na échangé
NaY	3,39	0
HY	1,65	51,3
LiY	2,52	25,7
KY	1,09	67,8
CsY	1,13	66,7
MgY	1,30	61,7
CaY	0,96	71,7

Test catalytique

Les catalyseurs ont été réactivés sous atmosphère oxydante et en montée de température de 5 °C min^{-1} jusqu'à 500 °C, puis maintenus sous O_2 pendant 1 h à 500 °C. La réaction de combustion du méthane est réalisée sous pression atmosphérique dans un réacteur à lit fixe traversé par le mélange réactionnel constitué de méthane et d'oxygène dilués dans l'hélium. Les débits volumiques pour le méthane, l'oxygène et l'hélium sont, respectivement, de 1, 4 et 95 mL min^{-1}, et le débit volumique global du mélange est de 6 L h^{-1} (mélange riche en oxygène $O_2/CH_4 = 4$ et masse du catalyseur de 50 mg).

L'analyse des effluents est effectuée à l'aide d'un chromatographe de type Intersmat IGC équipé d'un détecteur à conductivité thermique (catharomètre).

Résultats expérimentaux

Caractérisation des catalyseurs

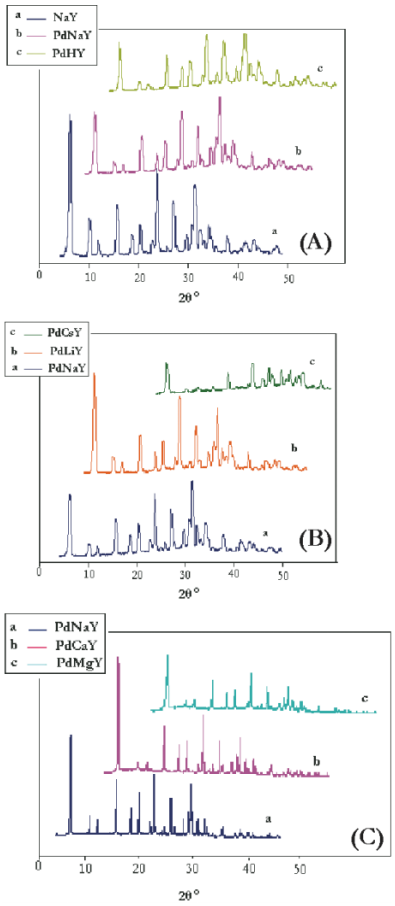
Étude par DRX

La pureté et la cristallinité des phases cristallines des échantillons traités ont été étudiées par diffraction des rayons X. La zéolithe NaY brute ainsi que les zéolithes échangées ont été analysées dans les mêmes conditions. Le diffractogramme représenté par la figure 1A est celui de la zéolithe NaY, produit de départ des catalyseurs préparés dans ce travail; ce diffractogramme montre essentiellement les pics de diffraction caractéristiques de la zéolithe de type faujasite qui appartient au groupe d'espace Fd3m et est de structure cubique.

À partir des diffractogrammes obtenus des différents échantillons (fig. 1), aucun pic, autre que ceux caractéristiques de la zéolithe Y, lié à des impuretés dues à la préparation ou au traitement des échantillons n'a été détecté. Néanmoins, les diffractogrammes de certains échantillons montrent un léger fond lié à une phase amorphe aux alentours de $2\theta \approx 30°$. En effet, la figure 1 montre que le diffractogramme relatif au catalyseur PdHY présente une phase amorphe détectée vers $2\theta = 29°$ due à une destruction partielle du réseau zéolithique. Ceci est confirmé par la valeur obtenue de la cristallinité de cet échantillon évaluée à 85 %. On observe aussi qu'après échange de la zéolithe, les intensités des pics caractéristiques (111), (220), (311) et (331) diminuent considérablement par rapport à la zéolithe NaY

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Sichuan Normal University on 09/14/12
For personal use only.

Fig. 1. Diffractogrammes des échantillons traités : (A) NaY, PdNaY et PdHY; (B) PdNaY, PdLiY et PdCsY; (C) PdNaY, PdCaY et PdMgY.



brute. Le diffractogramme relatif au catalyseur PdNaY montre une diminution des intensités des raies de diffraction caractéristiques par rapport à la zéolithe NaY. Toutefois, la cristallinité n'a pas été affectée puisqu'elle vaut 96 %.

Plusieurs études[9,12,13] ont montré que la procédure d'échange ionique n'affecte ni la structure zéolithique ni la nature des phases cristallines. En revanche, dans notre cas, les deux échantillons PdHY et PdCsY ont révélé une légère baisse de la cristallinité générée par une désalumination partielle du support. Le tableau 2 regroupe les valeurs des paramètres de la maille et des rapports Si/Al obtenus à partir de la relation de Breck.[14]

Caractérisation texturale des catalyseurs par la méthode volumétrique

Les isothermes d'adsorption et de désorption de l'azote à 77 K des échantillons permettent d'accéder à la surface spécifique de l'échantillon déterminée selon la méthode « BET ». Les isothermes d'adsorption obtenues sont du type I selon la classification BDDT.[15] Les solides examinés contiennent donc essentiellement des micropores de diamètre inférieur à 20 Å. Le tableau 3 regroupe les résultats obtenus de la caractérisation texturale des échantillons après calcination.

Les zéolithes de type faujasite NaY montrent une surface spécifique élevée dérivant de leur structure microporeuse. Les modifications et les traitements réalisés sur ces supports

Tableau 2. Rapport Si/Al et paramètres de la maille.

Échantillons	*a* (Å)	Si/Al
NaY	24,612	2,96
PdNaY	24,648	2,65
PdHY	24,538	3,80
PdLiY	24,628	2,81
PdKY	24,667	2,50
PdCsY	24,602	3,05
PdCaY	24,668	2,49
PdMgY	24,668	2,49

entraînent des variations dans les paramètres caractéristiques de leur texture qui dépendent de la nature de l'ion échangé.

L'introduction du palladium dans la structure zéolithique a entraîné une légère diminution de la surface spécifique par rapport à la zéolithe de départ, probablement due à l'occupation des ions Pd^{2+} dans les cavités internes de la zéolithe. Par ailleurs, le volume microporeux est presque constant après l'échange.

Le tableau 3 montre également que la surface spécifique S_{BET} ainsi que le volume microporeux accusent une baisse appréciable lorsque les ions Na^+ sont remplacés par les cations monovalents K^+ ou Cs^+ (fig. 2). Dans le cas de la zéolithe échangée au césium (PdCsY), on a noté une réduction d'environ 23 % de la surface spécifique et de 22 % du volume microporeux par rapport à la zéolithe sodique en raison de la taille importante du cation Cs^+.

Cette diminution résulte probablement de l'augmentation de la taille des cations échangés. En effet, plus le cation est volumineux moins la S_{BET} et le volume microporeux sont développés. Ce résultat est confirmé par l'étude obtenue par DRX qui a montré que la cristallinité de ces deux échantillons a été affectée. En revanche, la surface spécifique S_{BET} des échantillons échangés au cations moins volumineux est légèrement affectée, contrairement à celle correspondante aux échantillons échangés par des cations de plus grande taille.

Comme il a été suggéré par Langmi et al.,[16] l'accessibilité des molécules d'azote aux pores dans le cas où le support a subi un échange cationique est limitée, et la présence de cations de large taille affecte le volume poreux disponible. Par ailleurs, pour les échantillons échangés aux cations bivalents Mg^{2+} et Ca^{2+}, une légère diminution de la surface S_{BET} et du volume poreux par rapport à la zéolithe NaY est enregistrée.

Des études antérieures[17] ont montré que la surface spécifique du catalyseur PdHY est légèrement plus élevée que celle du catalyseur PdNaY en raison du remplacement des ions sodium par les protons moins volumineux. Toutefois, les résultats obtenus, dans le cadre de nos travaux, montrent une diminution du volume des micropores ainsi que de la surface spécifique de l'échantillon PdHY, ceci est dû à la destruction partielle de la structure causée par une désalumination du support. Cette suggestion est appuyée par les résultats de l'analyse par diffraction des rayons X.

Test catalytique

Dans ce travail, nous avons suivi la combustion catalytique du méthane en CO_2 et H_2O en fonction du temps et contrôlé la variation de l'activité des catalyseurs en fonction

Tableau 3. Résultats de l'étude texturale des catalyseurs.

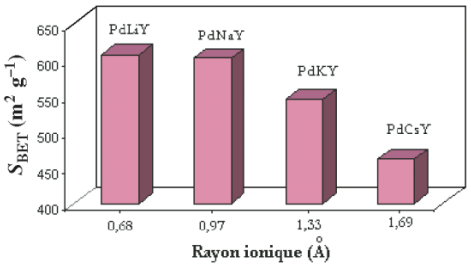
Fig. 2. Évolution de la surface spécifique en fonction du rayon ionique des ions alcalins échangés.



de la température. Les chromatogrammes obtenus nous ont permis de déterminer les taux de transformations globales de la réaction considérée.

Variation du taux de conversion en fonction du temps

La réaction de combustion du méthane en présence des différents catalyseurs a été étudiée pendant 180 min. L'activité propre du support zéolithique a été testée dans les mêmes conditions des catalyseurs préparés, et il s'est avéré que le support a une activité négligeable par rapport à celle du palladium supporté. Par ailleurs, seuls le dioxyde de carbone et l'eau sont obtenus, et aucune trace de monoxyde de carbone n'a été détectée lors de ce travail. De plus, nous signalons que les bilans en carbone sont respectés.

Les figures 3A et 3B représentent les variations du taux de transformation globale en fonction du temps à 500 °C pour les catalyseurs dont le support à été modifié par échange cationique avec H^+ ou des cations alcalins (fig. 3A). Ces courbes montrent que tous les échantillons s'activent légèrement au cours du temps et évoluent d'une manière pratiquement similaire. Cependant, les catalyseurs PdNaY et PdKY se stabilisent après 30 min, alors que PdHY, PdLiY et PdCsY atteignent leur régime quasi-stationnaire après une période relativement plus longue. Signalons aussi que l'activité initiale de PdNaY est la plus élevée et se stabilise rapidement, alors que celle de PdHY est plus faible mais augmente et devient supérieure à celle de PdNaY après 30 min de réaction.

Par ailleurs, pour le catalyseur PdKY, la conversion du méthane est faible par rapport à l'échantillon de référence PdNaY et évolue légèrement en fonction du temps. Lorsqu'on observe le comportement du catalyseur PdCsY, on remarque que son activité est la plus faible par rapport aux autres catalyseurs et que le taux de conversion augmente légèrement au cours du temps et atteint un état quasi-stationnaire après plus de 2,5 h de réaction.

La figure 3B regroupe les résultats des tests catalytiques correspondant aux catalyseurs au palladium supportés sur zéolithes échangées aux cations Ca^{2+} et Mg^{2+} ainsi que le catalyseur de référence PdNaY. La courbe relative à l'échantillon PdCaY révèle une activité initiale légèrement plus faible que celle de PdNaY, mais les taux de conversions de ces deux catalyseurs sont quasi égaux après 90 min de réaction. De plus, l'activité de PdCaY atteint l'état stationnaire au bout d'1 h. En revanche le catalyseur déposé sur MgY révèle une faible activité initiale qui augmente et atteint son régime stationnaire après 2 h de réaction. Quant au taux de conversion, il est nettement inférieur à celui de PdCaY mais comparable à celui de PdKY.

Variation du taux de conversion en fonction de la température

Nous avons étudié l'évolution de la conversion du méthane en fonction de la température de la réaction entre 300 et 500 °C pour les catalyseurs dont les supports ont été échangés par les cations monovalents et bivalents. Les courbes obtenues révèlent que tous les catalyseurs étudiés sont quasiment inactifs à une température inférieure à 300 °C (fig. 4) et montrent qu'à des températures inférieures à 400 °C, le catalyseur PdLiY est le plus actif, alors qu'à des températures plus élevées c'est le catalyseur PdHY qui devient le plus actif. Cependant, dans ce domaine de température, le catalyseur PdCsY présente l'activité catalytique la plus faible.

L'analyse de l'évolution de l'activité en fonction de la température montre que le catalyseur supporté sur la zéolithe sodique est le plus sensible à la température du fait qu'aux alentours de 500 °C, la variation du taux de conversion du méthane est la plus élevée. En effet, en évaluant la pente de la tangente de chaque courbe à 500 °C et les températures relevées pour des taux de conversion du méthane de 10 %, 30 % et 60 %, on trouve les valeurs rassemblées dans le tableau 4. Les valeurs déterminées T_{10} et T_{30} montrent que l'échantillon PdNaY est légèrement plus actif que PdCaY dans les régions de basses températures.

On remarque que la valeur de T_{30} pour le catalyseur PdHY est comparable à celle rapportée par Ishihara et al.[18] En ce qui concerne le catalyseur PdNaY, les valeurs déterminées (tableau 4) sont proches que celles trouvées dans la littérature.[19,20]

Les résultats du tableau 4 montrent que pour les échantillons PdKY et PdCsY, une conversion du méthane de 60 % est obtenue à des températures supérieures à 600 °C, alors que pour le catalyseur PdLiY, ce taux de conversion est obtenu à une température de l'ordre de 495 °C. Ce catalyseur s'active donc à des températures plus basses que celles des échantillons PdKY et PdCsY.

En effet, l'évolution de l'activité catalytique en fonction de la température montre que les catalyseurs supportés sur les zéolithes échangées aux cations moins volumineux s'activent à des températures plus basses que celles relatives aux échantillons échangées par des cations de taille plus élevée

*Valeur déterminée par extrapolation des courbes représentatives de la conversion en fonction de la température.

(K^+ et Cs^+). Les courbes représentées par la figure 4B révèlent que le catalyseur supporté sur zéolithe échangée au calcium (PdCaY) est plus actif à des températures inférieures à 500 °C, alors que l'échantillon PdMgY est nettement moins actif dans ce domaine de température. Il est à préciser également, que ces catalyseurs sont pratiquement inactifs à des températures inférieures à 300 °C.

L'allure des courbes présentant le taux de conversion en fonction de la température montre qu'au voisinage de 500 °C, l'activité de PdCaY semble s'égaliser à celle de PdNaY, seulement la pente de la courbe à cette température pour l'échantillon PdNaY est supérieure à celle de PdCaY (tableau 4). Quant à l'échantillon PdMgY, il est beaucoup moins actif que PdNaY ou PdCaY et ne semble pas voir son activité catalytique augmenter à des températures supérieures à 500 °C, puisque la pente de la courbe correspondante en ce point est plus faible.

Les énergies apparentes d'activation E_a sont déterminées dans le domaine de température variant de 350 C à 425 °C correspondant à des taux de conversion de méthane inférieures à 50 % pour lesquels les limitations diffusionnelles sont minimisées. Le tableau 5 présente les valeurs de E_a obtenues en présence des différents catalyseurs.

Discussions

L'activité des catalyseurs au palladium supporté sur zéolithe modifiée par échange cationique de cations alcalins et alcalino-terreux dans la réaction d'oxydation totale du méthane dépend de la nature du cation compensateur et varie selon les séquences suivantes :

$$\text{PdHY} \approx \text{PdNaY} > \text{PdLiY} > \text{PdKY} > \text{PdCsY et PdCaY} \approx \text{PdNaY} > \text{PdMgY}$$

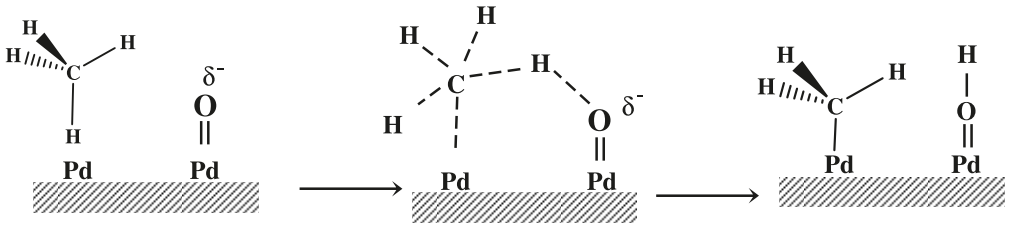
Schéma 1. Activation du méthane sur une surface de particule composée de deux sites adjacents formés d'une paire Pd–PdO.

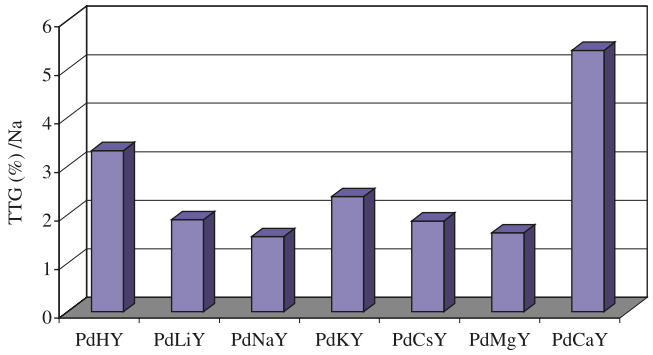


En se basant sur les résultats obtenus de la caractérisation physicochimique des catalyseurs supportés sur zéolithe échangée aux cations alcalins, on peut déduire que l'activité du palladium supporté est sensible à la structure et la texture du support. En effet, la caractérisation texturale par la méthode volumétrique a montré que la porosité et la surface spécifique sont affectées par la nature et la taille du cation compensateur. En effet, plus le cation est volumineux, moins la S_{BET} et le volume microporeux sont développés, et l'activité des catalyseurs PdNaY, PdKY et PdCsY augmente quand la taille du cation diminue, excepté pour PdLiY qui révèle une activité légèrement moins élevée que celle de PdNaY. Le catalyseur PdHY a montré l'activité la plus importante dans cette réaction, toutefois il présente une surface spécifique réduite, probablement en raison de la destruction partielle due à une désalumination du support qui conduit à un rapport Si/Al plus élevé, donc une activité plus importante. Ce résultat rejoint celui de Okumara et al.[21] qui ont trouvé que l'activité du palladium dans la réaction de combustion du méthane augmente lorsque le rapport Si/Al croît.

Les travaux de la littérature ont relié l'activité relativement élevée de certains catalyseurs, sur le support sodique, à la présence des ions Na^+ qui conduisent à un enrichissement électronique de la surface des particules de palladium et par conséquent de celle des espèces PdO, supposées être les sites actifs qui assurent la rupture de la liaison C—H dans la réaction de combustion du méthane[22] (schéma 1). Par conséquent, en rapportant le taux de conversion du méthane par mole d'atome de sodium dans une maille (fig. 5), on constate alors qu'à 500 °C le catalyseur PdCaY est le plus actif. Par ailleurs, il est probable que l'augmentation du taux d'échange du support en Ca pourrait améliorer le taux de conversion du méthane.

Par ailleurs, des études[23,24] ont montré que suite à une calcination sous atmosphère oxydante à 500 °C, les complexes $Pd(NH_3)_4^{2+}$ se désaminent, et les ions Pd^{2+} migrent dans les sites de positions S_I et $S_{I'}$ situés près des prismes hexagonaux et les cages sodalites qui sont des sites inaccessibles aux molécules réactives. Néanmoins, dans le cas du catalyseur supporté sur zéolithe échangée au calcium qui montre une activité importante dans la combustion du méthane, les cations Ca^{2+} ont une grande affinité pour le site de position S_I, où ils s'y situent préférentiellement. De ce fait, les ions Pd^{2+} migrent pour occuper des sites plus accessibles qui sont les sites S_{II} et $S_{II'}$ situés dans la supercage et

Fig. 5. Taux de conversion du méthane par atome de sodium dans une maille élémentaire de la zéolithe.



la cavité sodalite. Ceci est prouvé par les études de Michalik et al.[25] portant sur la réactivité des catalyseurs à base de palladium supporté sur des zéolithes X échangées aux ions Ca^{2+}, Mg^{2+} et K^+ dans la réaction de dimérisation de l'éthylène, mais aussi, par les travaux de Ghosh et al.[26] et ceux de Z. Zhang et al.[27]

La faible activité enregistrée pour le catalyseur PdCsY peut être attribuée à la localisation des cations Cs^+ qui occupent principalement les sites $S_{II'}$ situés dans les cages sodalites, et les sites S_{II} et S_{III}, situés dans la supercage,[28] ces cations ne peuvent pas en effet accéder aux sites de position localisés à proximité des prismes hexagonaux (S_I), et bloquent ainsi la migration des ions Pd^{2+} vers des sites plus accessibles.

Des travaux antérieurs[29] ont montré que la basicité de la structure zéolithique est liée à la charge partielle négative des atomes d'oxygène. Cette charge peut être augmentée par un échange ionique du cation compensateur moins électronégatif que Na^+ (schéma 2). En effet, les travaux de Breysse[29] sur la zéolithe NaX échangée par les cations des métaux alcalins K, Rb et Cs ont montré que la charge négative (δ^-) de l'oxygène du réseau croît selon la séquence suivante : $Na_{100}X < K_{98,5}Na_{1,5}X < Rb_{64}Na_{36}X < Cs_{68}Na_{32}X$.

Il a été aussi établi[30] pendant longtemps que l'échange cationique des zéolithes X induit une force de basicité du support qui dépend de la nature du cation échangé et qui croît dans l'ordre suivant : Li < Na < K < Rb < Cs. De plus d'après Chatterjee,[31] l'énergie de stabilisation des cations dans les sites S_I suit l'ordre suivant : $Mg^{2+} > Ca^{2+} > Li^+ >$

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Sichuan Normal University on 09/14/12

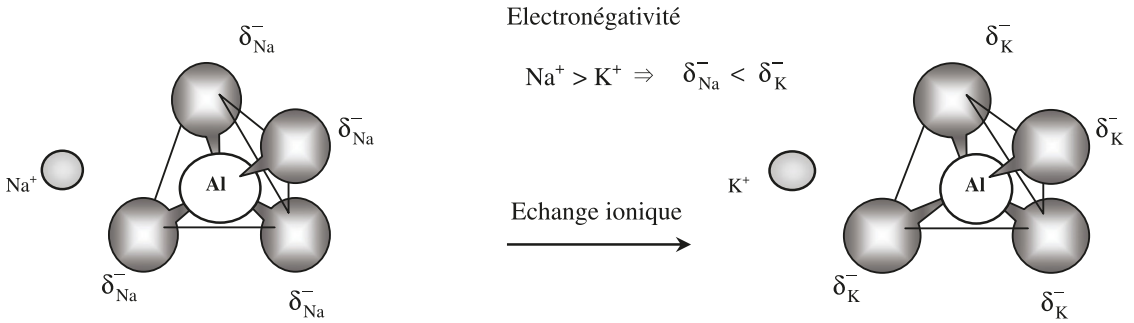
Schéma 2. Influence de l'échange cationique dans la zéolithe sur la charge négative des oxygènes du réseau.



$$\delta^-_{Li} < \delta^-_{Na} < \delta^-_K < \delta^-_{Cs} \quad \text{et} \quad \delta^-_{Na} < \delta^-_{Ca} < \delta^-_{Mg}$$

$K^+ > Na^+$, alors que dans les sites S_{II}, l'énergie de stabilisation des cations varie selon la séquence $Mg^{2+} < Ca^{2+} < Na^+ < K^+ < Li^+$. Par conséquent, Na^+ est le moins stable en site S_I, alors que Li^+ se trouve le plus stable en site S_{II}.

Toutefois, des résultats expérimentaux[32] ont mis en évidence la migration de ces cations en présence d'un réactif et ont montré par RMN et DRX une interaction entre Na^+ et le réactif. Ces travaux ont été poursuivis plus tard[33] pour montrer que les liaisons de la molécule de réactif avec le support sont contrôlées par des interactions électrostatiques locales incluant la combinaison de H–R (réactif) avec la charpente zéolithique et le cation compensateur.

De ce qui précède, on peut alors avancer que les ions alcalins et alcalino-terreux modifient l'activité intrinsèque du palladium suite au changement de la densité de charge du site actif. Par ailleurs, la basicité ou l'aptitude de l'électrodonnation des additifs joue un rôle important dans les performances des catalyseurs au palladium. Si on adopte le schéma proposé par Fujimoto[34] montrant l'adsorption du méthane sur une paire de sites adjacents composés de Pd et PdO, où le méthane est adsorbé dans une lacune d'oxygène et est en interaction avec PdO (schéma 1), la densité électronique de la lacune d'oxygène responsable de l'activité catalytique dépend de son environnement, donc du caractère acido-basique du support, de la nature du cation compensateur et de sa localisation.

Conclusion

Le présent travail a montré que les propriétés basiques des zéolithes ont une influence sur l'interaction métal–support et donc sur l'activité catalytique du palladium. En effet la basicité de la zéolithe varie, entre autre, avec la nature des cations alcalins extra-réseau compensateurs de charge qui jouent un rôle très important dans la localisation des espèces catalytiques actives et leur migration dans les sites accessibles aux molécules réactives.

De ce fait, la modification du support par échange des cations compensateurs a un effet sur le taux de conversion du méthane. En effet, la nature et la taille du cation agissent sur le comportement du catalyseur dans la réaction d'oxydation du méthane, de plus l'acidité du support est un paramètre influant sur l'activité du palladium dans cette réaction.

Abstract: An improved, simple, and facile synthesis of amidoalkyl naphthols by employing three-component one-pot condensation reaction of β-naphthol, aromatic aldehydes, and amides in ionic liquids using ytterbium triflate as a mild Lewis acid catalyst is described. Advantageously, amidoalkyl naphthols were obtained in high yield under eco-friendly, economical, and non-corrosive conditions, and the catalyst was recycled.

Key words: amidoalkyl naphthols, ytterbium triflate, ionic liquid, β-naphthol, three-component condensation.

Résumé : On a mis au point une méthode simple, facile et améliorée de synthèse d'amidoalkylnaphtols impliquant une réaction de condensation monotope à trois composants, dont le β-naphtol, des aldéhydes et des amides aromatiques dans des liquides ioniques et faisant appel au triflate d'ytterbium comme catalyseur acide de Lewis doux. L'avantage de la méthode est que les amidoalkylnaphtols sont obtenus avec des rendements élevés, dans de bonnes conditions écologiques, économiques et non corrosives et que le catalyseur peut être recyclé.

Mots-clés : amidoalkylnaphtols, triflate d'ytterbium, liquide ionique, condensation à trois composants.

[Traduit par la Rédaction]

Introduction

Multicomponent reactions (MCRs) are of increasing importance in organic and medicinal chemistry and have emerged as a powerful strategy in the preparation of structurally diverse libraries of drug-like molecules.[1] MCRs constitute an especially attractive synthetic strategy, since they provide easy and rapid access to large libraries of drug-like organic compounds with diverse substitution patterns.[2] As MCRs are one-pot reactions, they are easier to carry out and offer significant advantages over conventional linear-type syntheses.

The amidoalkyl naphthols are important precursors for the synthesis of 1,3-amino oxygenated compounds. The 1,3-amino oxygenated functionality is present in various biologically important natural products and drug molecules.[3] The amidoalkyl naphthols have been prepared by multi-component condensation of aldehydes, 2-naphthol, and acetonitrile or amide in the presence of Lewis[4–6] or Brønsted acid[7] catalysts. However, some of these catalysts require prolonged reaction times and suffer from low yields, toxicity, and recovery and reusability of the catalyst. Therefore, there is great need of an eco-friendly and green catalysts, which can be recycled at the end of reactions and give high yields of amidoalkyl naphthols under mild reaction conditions.

Recently, rare-earth metal triflates have enjoyed extensive applications in a variety of Lewis acid catalyzed organic reactions.[8] The growing interest in use of these salts is due to their ease of handling, non-corrosiveness, reusability, and unique reactivity and selectivity. Among all rare-earth metal triflates, ytterbium triflate has high acidity due to its small ionic radii.[8b] It was first used by Forsberg et al.,[9] and since then, it has found a wide utility in deprotection,[10] cycloaddition reactions,[11] aldol-Grob reaction,[12] imino-ene reaction,[13] electrophilic substitutionn, cyclization,[14] and synthesis of heterocyclic[15] and natural products.[16]

The ionic liquids, especially those based on 1,3-dialkylimidazolium cations, have gained considerable interest as green alternative to volatile organic solvents.[17] Various reactions have been reported with the immobilization of metal triflates in ionic liquids with increased catalytic activity along with their easy reuse.[18] During the course of our recent studies directed towards the development of eco-friendly procedures for various organic transformations,[19] we wish to report three-component, one-pot condensation of β-naphthol, aromatic aldehydes, and amides to amidoalkyl naphthols using $Yb(OTf)_3$ as a catalyst in ionic liquids (Scheme 1). To the best of our knowledge, there is no report on the use of lanthanide triflates and ionic liquids for the synthesis of amidoalkyl naphthols.

Results and discussion

First, we studied the three-component condensation reaction of 4-chlorobenzaldehyde, 2-naphthol, and acetamide in the presence of catalytic amount of several Lewis acids in [bmim][BF_4] ionic liquid (Table 1). In the absence of the catalyst, no product formation was observed even after 48 h at 80 °C (Table 1, entry 1). Ytterbium triflate was found to be the most useful catalyst among all the used catalysts under these conditions, giving highest yield of product (92%) (Table 1, entry 7). The high activity of $Yb(OTf)_3$ compared with the metal triflates used may be attributed to its high acidity.

[a]Isolated yield.

[b]No product formation observed.

The condensation of 4-chlorobenzaldehyde (**1**), 2-naphthol (**2**), and acetamide (**3**) at 80 °C in ionic liquid, [bmim][BF_4], containing 20 mol% $Yb(OTf)_3$, gave 92% of **4a** (Table 2, entry 1). After extraction from ionic liquid, the product was purified by recrystallization with ethanol and characterized by IR, MS, ^{1}H NMR, and ^{13}C NMR spectroscopy. Presence of a doublet at δ 8.53 ppm in ^{1}H NMR spectrum for –CH–NH group along with other aromatic protons, peak at δ 169.45 ppm for C=O group in ^{13}C NMR, and a strong peak at 1663 cm^{-1} for –$NHCOCH_3$ group in IR confirms the structure of **4a**.

Next, we examined the effect of different solvents, such as [bmim][BF_4], toluene, DMSO, DMF, Ethanol, H_2O, PEG-400, 1,2-dichloroethane, $CHCl_3$, and DCM, as model reaction using $Yb(OTf)_3$ as catalyst. All the reactions were run using 20 mol% of the catalyst. As shown in Table 3, **4a** was obtained in excellent yield (92%) in the ionic liquid [bmim][BF_4]. Therefore, we chose [bmim][BF_4] as the solvent of choice for further reactions. These results point towards the need of the proper catalyst and solvent system, which play the key role for the success of the reaction. As shown in Table 3, no product formation was observed in polar organic solvents, such as DMSO, DMF, and ethanol, as well as aqueous solvent. It may be due to the interaction of these solvents with the catalyst.

Encouraged by our results for the one-pot condensation of 2-naphthol and acetamide with 4-chlorobenzaldehyde in ionic liquid, we next examined the generality of this methodology for the synthesis of various amidoalkyl naphthols by condensation of substituted β-naphthols, aldehydes, and amides. The results are shown in Table 2. Several functionalities present in the aldehydes and 2-naphthols, such as halogen, methoxy, and nitro groups, were tolerated. In all cases, the corresponding amidoalkyl naphthols were obtained in good to excellent yields (Table 2). When benzamide was used instead of acetamide in the one-pot condensation of 2-naphthol with benzaldehyde in ionic liquid, it resulted only in 35% yield of **4p** (Table 2, entry p). Similarly, when we used *N*-methylacetamide, we found that the reaction is slower compared with acetamide, and the yield of the corresponding product was only 61% after 12 h.

A plausible mechanism for the formation of amidoalkyl naphthols by the reaction of 2-naphthol with aldehydes in presence of ytterbium triflate is shown in Scheme 2. As reported in the literature, in situ generation of *ortho*-quinone methides (*o*-QMs) is expected to take place.[7a,7b] These *o*-QMs, generated in situ, react with amides via conjugate addition to form the amidoalkyl naphthols. The aromatic aldehydes with electron-withdrawing groups reacted faster than the aromatic aldehydes with electron-donating groups, which is in agreement with the reaction mechanism. The rate of conjugate addition is higher to *o*-QMs as the lowest unoccupied molecular orbital (LUMO) of alkene in *o*-QMs is at lower energy in the presence of electron-withdrawing groups compared with electron-donating groups.[20] The role of the ionic liquid is not yet clear, but it is expected that the noncoordinating nature and high dielectric constant of the ionic liquid may help in the generation of *o*-QMs and enhance the rate of nucleophilic conjugate addition. Such effect of ionic liquid on the rate of nucleophilic substitution reaction is reported in literature.[21] The lower reactivity of

[b] All products were characterized by IR, MS, ^{1}H NMR, and ^{13}C NMR.

[c] Yields for recycling of catalyst were 92, 91, 87, 85, and 86, respectively for five cycles.

benzamide compared with acetamide may be attributed to the difference in acidity constants of these weakly basic substrates in acidic media. The reported pK_a values of acetamide and benzamide are –0.73 and –1.54, respectively.[22]

From an environmental point of view, it is desirable to minimize the amount of waste for each organic transformation. In this context, we recycled the catalyst solution for subsequent runs. To study the reusability, $Yb(OTf)_3$ immobi-

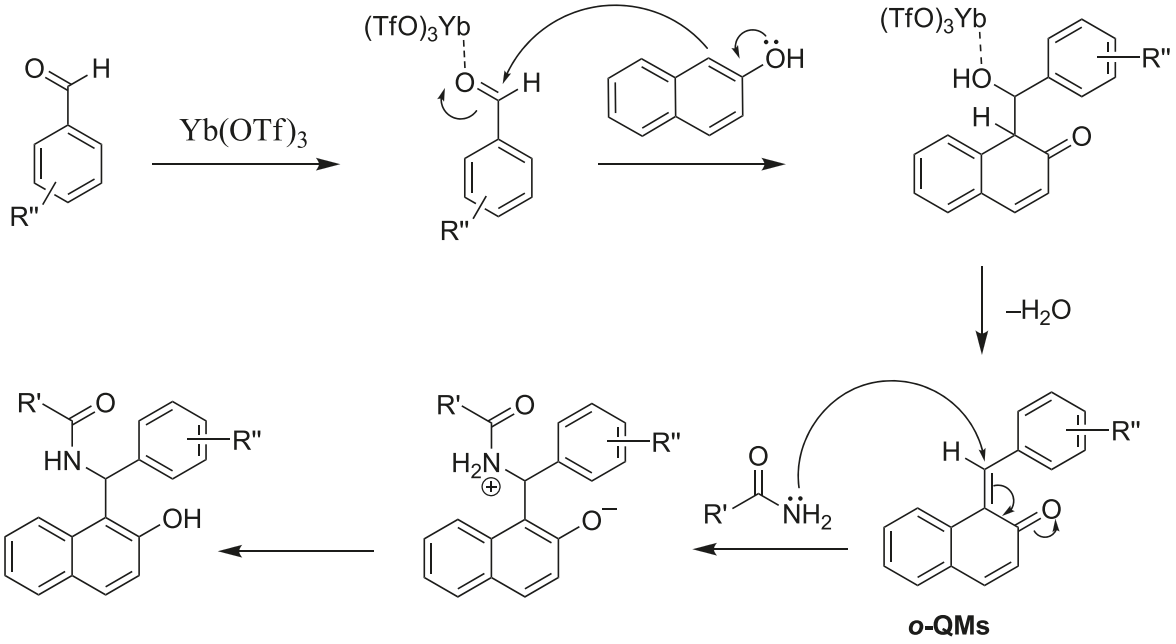
Scheme 2. Probable mechanism for the synthesis of amidoalkyl naphthols catalyzed by $Yb(OTf)_3$.



lized in ionic liquid, [bmim][BF_4], was reused for the synthesis of amidoalkyl naphthol **4a**. After extraction of amidoalkyl naphthols from ionic liquid with ethyl acetate – hexane mixture, the ionic liquid containing $Yb(OTf)_3$ was concentrated on rotatory evaporator under reduced pressure to remove the organic solvent for 30 min. To this dried ionic liquid containing $Yb(OTf)_3$, β-naphthol, 4-chlorobenzaldehyde, and acetamide were added and stirred at room temperature for 4 h. The reaction mixture was extracted by ethyl acetate – hexane mixture, and the combined organic layer was evaporated to give amidoalkyl naphthols **4a**. This cycle was repeated for five times. The catalysts showed good reactivity and yield even after five cycles with little deterioration in catalytic activity (Table 2, entry a).

Conclusion

In conclusion, an efficient, simple, and eco-friendly method has been described for the synthesis of amidoalkyl naphthols by employing three-component one-pot condensation reaction of β-naphthol, aromatic aldehydes, and amides in ionic liquids using ytterbium triflate as a mild Lewis acid catalyst. The catalyst was recovered and recycled in successive reaction cycles.

Experimental section

All chemicals and reagents were of analytical grade. β-Naphthol, acetamide, aldehydes, and acetyl chloride were purchased form S. D. Fine and Spectrochem, India. Sodium tetrafluoroborate and 1-methylimidazole were purchased from Aldrich. Ionic liquid, [bmim][BF_4], was prepared according to earlier reported procedure.[19a,19b] The ^1H NMR spectra were recorded on a Brucker Heaven Avance 11 400 (400 MHz) spectrophotometer using TMS as internal standard and $CDCl_3$ as solvent, and the chemical shifts were expressed in ppm. The IR spectra were recorded using KBr pellets on Shimadzu Prestige-21 FTIR spectrophotometer and ν_{max} was expressed in cm^{-1}. Mass spectra were recorded on a KC455 Waters TOF MS spectrometer. TLC was run on the silica-gel-coated aluminium sheets (Silica gel 60 F_{254}, E. Merck, Germany) and visualized in UV light (254 nm).

General procedure for the synthesis of amidoalkyl naphthols catalyzed by $Yb(OTf)_3$ in ionic liquid

4-Chlorobenzaldehyde (103 μL, 1.49 mmol), β-naphthol (110 μL, 1.49 mmol), acetamide (1.79 mmol), and $Yb(OTf)_3$ (20 mol%, 46.2 mg) were added to a 10 mL round-bottom flask containing the ionic liquid, $[bmim][BF_4]$ (3.0 mL). The reaction mixture was stirred at 80 °C for 4 h in oil bath. After completion of the reaction as indicated by TLC, the reaction mixture was cooled to room temperature and extracted with ethyl acetate – hexane (2 × 5 mL, 4:1, *v*/*v*). The ionic liquid, containing ytterbium triflate, was recovered and dried under vacuum. The combined organic layer was evaporated under reduced pressure. The product was recrystallized from ethanol to give pure **4a** (450 mg, 92%). The product was characterized by ^1H and ^{13}C NMR, IR, and mass spectroscopic data.

Spectral data of selected amidoalkyl naphthols

N-*((4-Chlorophenyl)(2-hydroxynaphthalen-1-yl)-methyl)acetamide (4a)*

^1H NMR (Me_4Si; 400 MHz, DMSO-d_6) δ: 2.02 (s, 3H), 7.14–7.32 (m, 7H), 7.39 (brs, 1H), 7.77–7.82 (m, 3H), 8.53 (s, 1H), 10.02 (s, 1H). ^{13}C NMR (100 MHz, DMSO-d_6) δ: 22.61, 47.42, 117.67, 118.42, 122.42, 123.16, 124.62, 126.47, 127.03, 127.89, 128.45, 129.47, 130.64, 133.23, 141.78, 153.22, 169.45. HR-MS-EI: *m*/*z* calcd. for $C_{19}H_{16}ClNO_2$ 325.0870; found: 326.1458 $[M + H]^+$.

Chemical-bond properties and hardness of nonlinear optical crystals LiB_3O_5 and β-BaB_2O_4

Guangping Zhao and Bingjie Yu

Abstract: The chemical-bond parameters of LiB_3O_5 (LBO) and β-BaB_2O_4 (BBO) nonlinear optical crystals have been calculated using the chemical-bond theory of complex crystals. Their hardnesses have been predicted by the chemical-bond definition of hardness. The calculated results indicate that their hardnesses are determined only by Li–O and Ba–O bonds. The BO_3 anionic clusters do not contribute to their hardness. The calculation of hardness indicates that all of the compounds possess good mechanical properties.

Key words: nonlinear optical crystal, chemical bond, hardness, borate.

Résumé : Faisant appel à la théorie de la liaison chimique des cristaux complexes, on a calculé les paramètres des liaisons chimiques des cristaux optiques non linéaires de borate de lithium (LBO) et de borate de baryum (BBO). Leur dureté a été prédite par la définition de la dureté en fonction de la liaison chimique. Les résultats calculés indiquent que leurs duretés ne sont déterminées que par la liaison Li–O, Ba–O. Les agrégats anioniques de BO_3 ne contribuent pas à ces duretés. Le calcul de la dureté indique que tous les composés possèdent de bonnes propriétés mécaniques.

Mots-clés : cristal optique non linéaire, liaison chimique, dureté, borate.

[Traduit par la Rédaction]

The materials exhibiting nonlinear optical (NLO) properties have become objects of an extensive recent interest. Lithium triborate (LBO) and β-BaB_2O_4 (BBO) are the relatively new nonlinear optical borate material. They possess distinguished NLO properties and high optical-damage resistance. These unique properties, combined with high mechanical stability and nonhygroscopic behaviour, make LBO and BBO the suitable candidates for high-power lasers and optical parametric processes.[1,2] Therefore, the studies of properties governing the applicability of LBO and BBO single crystals are important. A number of papers focused on their optical properties, electrical conductivity, thermal properties, and dielectric constants.[3–7] However, the mechanical properties of LBO and BBO are little investigated, although they are obviously important for all kinds of device applications. The theoretical study on the mechanical properties of novel materials is of interest.[8–13] Therefore, this paper gives a theoretical prediction of hardness values of these crystals by using the chemical-bond theory of complex crystals[14–17] and hardness theory.[18–21] It helps to understand further the other mechanical properties. The calculations of the chemical-bond parameters may obtain some useful information concerning the modification of NLO responses of borate crystals. It is also interesting to study the effect of the BO_3^{-3} clusters on the hardness of borate crystals.

A theory describing the chemical bond of complex crystals has been developed by Zhang et al.[14–17,22,23] It has been successfully applied to the optical properties.[24–26] Zhang[14] has pointed out that the properties of a crystal can be described by chemical-bond parameters, and any complex crystal can be decomposed into different kinds of pseudo-binary crystals. In theory, the "crystal formula" is a combination of sub-formulae for a chemical bond. The sub-formula for any kind of chemical bond A–B in the multibond crystal A_aB_b can be expressed by the following formula:

$$[1] \qquad \left[\frac{N(\mathrm{B}-\mathrm{A})a}{N_{\mathrm{CA}}}\right]\mathrm{A}\left[\frac{N(\mathrm{A}-\mathrm{B})b}{N_{\mathrm{CB}}}\right]\mathrm{B}$$

where A, B represent different elements or different sites of the same element in the crystal formula; a, b represent numbers of the corresponding element; N(B–A) represents the number of B ions in the A ion coordination group, and N_{CA} represents the nearest coordination number of an A ion. After decomposing the complex crystal into different kinds of pseudo-binary crystals, which form an isotropic system, and then introducing an effective charge to the valence electron by the Pauling bond-valence method, P–V–L theory[22,23] can be used directly to calculate the chemical-bond parameters in the complex crystal compound.

The average energy gap E_g^μ for every μ bond can be separated into homopolar E_h^μ and heteropolar C^μ parts

$$[2] \qquad (E_g^\mu)^2 = (E_h^\mu)^2 + (C^\mu)^2$$

The ionicity f_i^μ and covalency f_c^μ of any type of chemical bond is defined as follows

$$[3] \qquad f_i^\mu = (C^\mu)^2/(E_g^\mu)^2$$

Table 1. Chemical-bond parameters and calculated hardnesses of LBO crystals, where H_ν^μ is the hardness of a psuedo-binary compound composed of μ-type bonds, $H_{avg.}$ and $H_{v\ exptl.}$ are calculated average value and experimental microhardness, respectively.

$$[4]\qquad f_c^\mu = (E_h^\mu)^2/(E_g^\mu)^2$$

where

$$[5]\qquad E_h^\mu\ (\mathrm{eV}) = 39.74/(d^\mu)^{2.48}$$

where d^μ is the bond length. For any binary crystal AB_n-type compounds, the heteropolar C^μ part is defined as

$$[6]\qquad C^\mu\ \ (\mathrm{eV}) = \{14.4b^\mu[(Z_A^\mu)^* + \Delta Z_A^\mu - n(Z_B^\mu)^*]e^{-k_s^\mu r_0^\mu}\}/r_0^\mu$$

$$[7]\qquad r_0^\mu = d^\mu/2$$

$$[8]\qquad k_s^\mu = (4k_F^\mu/\pi a_B)^{1/2}$$

$$[9]\qquad (k_F^\mu)^3 = 3\pi^2 N_e^\mu$$

where $(Z_A^\mu)^*$ is the number of effective valence electrons of A ion, ΔZ_A^μ is correction factors from d electron effects, such as the crystal field stable energy and Jahn–Teller effect,[15] n is the ratio of element B to element A in the subformula, k_s^μ is Thomas–Fermi screening wave number of valence electron in binary crystal composed of only one type of bond μ, a_B is the Bohr radius, k_F^μ is Fermi wave number of valence electron in binary crystal composed of only one type of bond μ, N_e^μ is the number of valence electrons of type μ bond per cubic angstroms, b^μ is proportional to the square of the average coordination number N_c^μ

$$[10]\qquad \begin{aligned} b^\mu &= \beta(N_c^\mu)^2 \\ N_c^\mu &= [N_{CA}^\mu/(1+n)] + [nN_{CB}^\mu/(1+n)] \end{aligned}$$

where b^μ depends on a given crystal structure.

The hardness of a pseudo-binary compound composed of μ-type bonds can be calculated as follows[18–21]

$$[11]\qquad H_v\ (\mathrm{GPa}) = 556\left[\frac{N_a e^{-1.191 f_i}}{d^{2.5}}\right] = 350\left[\frac{(N_e)^{2/3} e^{-1.191 f_i}}{d^{2.5}}\right]$$

where N_a is the number of bonds per unit area, N_e^μ is expressed as follows

$$[12]\qquad N_e^\mu = (n_e^\mu)^*/v_b^\mu$$

$$[13]\qquad (n_e^\mu)^* = [(Z_A^\mu)^*/N_{CA}^\mu] + [(Z_B^\mu)^*/N_{CB}^\mu]$$

$$[14]\qquad v_b^\mu = (d^\mu)^3/\sum_\nu [(d^\nu)^3 N_b^\nu]$$

where $(n_e^\mu)^*$ is the number of effective valence electrons per μ bond, v_b^μ is the bond volume.

The hardness of a multicomponent compound system can be expressed as an average of the hardnesses of all binary systems in the solid. Hardness surely involves the cooperative softening of many bonds. When there are differences in the strength among different types of bonds, the trend of breaking the bonds will start from a softer one. Therefore, the hardness H_v of complex crystals should be calculated by a geometric average of all bonds as follow

$$[15]\qquad H_v = \left[\prod_\mu^\mu (H_\nu^\mu)^{n^\mu}\right]^{1/\Sigma n^\mu}$$

where n^μ is the number of bonds of type μ composing the actual complex crystal.

Lithium triborate, LiB_3O_5 (LBO), is characterized by orthorhombic structure (space group: (33) $Pna2_1$; unit-cell parameters: a = 8.444 Å, b = 7.378 Å, c = 5.146 Å[1] at ambient conditions). The space group of BBO is $R3$, and its unit-cell parameters are a = 12.532 Å, c = 12.717 Å.[2] Theoretically,[14] LBO and BBO can be decomposed into the sum of pseudo-binary crystals as follows

$$\begin{aligned}[16]\qquad LiB_3O_5 = {} & 1/4LiO(1)_{4/3} + 1/4LiO(3)_{4/3} + + 1/4LiO(3)_{4/3} + 1/4LiO(4)_{4/3} + 1/3B(1)O(3) + + 1/3B(1)O(4) \\ & + 1/3B(1)O(5) + 1/4B(2)O(3)_{4/3} + 1/4B(2)O(3)_2 + 1/4B(2)O(4)_{4/3} + 1/4B(2)O(5)_{4/3} + 1/3B(3)O(1) \\ & + 1/3B(3)O(2)_{3/2} + 1/3B(3)O(3)\end{aligned}$$

Table 2. Chemical-bond parameters and calculated hardnesses of BBO crystals, where H_v^μ is the hardness of a psuedo-binary compound composed of μ-type bonds, $H_{avg.}$ and $H_{v\ exptl.}$ are calculated average value and experimental microhardness, respectively.

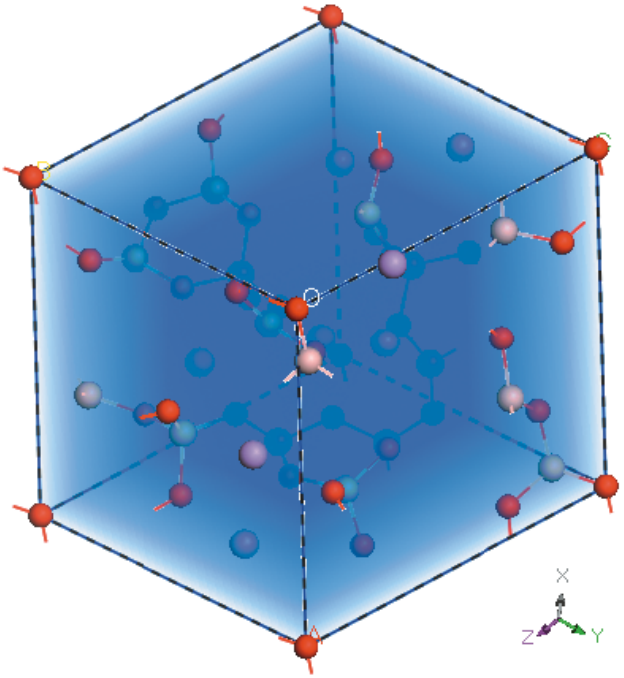
By using the above theories, the chemical-bond covalency of each type of the constituent chemical bonds and the hardness of pseudo-binary crystals composed of the corresponding constituent bonds can be calculated. Results are listed in Tables 1 and 2. Since BO_3 is an anionic cluster, its B–O bond may not break in hardness test. In other words, the hardness of LBO results only from the breaking of the other bonds, including Li–O bond. The hardness of BBO results only from the breaking of the other bonds, including Ba–O bond. Our calculated values of the average hardness for LBO, taking only Li–O bond, 11 GPa, is in good agreement with the available experimental one. Therefore, we can conclude that the anionic cluster, BO_3, does not contribute to the hardness of LBO and BBO; it would slip in one unit under indenter. The calculated hardness of BBO in Table 2 is lower than that of LBO.

According to eq. [11], the ionicity plays an important role in the hardness calculation. The hardness of ionic crystals is far lower than that of covalent crystals. Hence, the hardness resulting from a covalent component plays a determining role in partially covalent ionic crystals. Although the electronegativity of Li, 1.0, is less than that of B, 2.0, our chemical-bond calculations show that the covalencies of Li–O bonds are greater than those of B–O bonds. Pauling's empirical electronegativity scale is derived from thermochemical bond-energy data. Although decreasing Pauling's electronegativity differences within each binary compound of a series can usually be taken as an indication for increasing covalency, this is not necessarily the case for a series of binary oxides, i.e., for P_2O_5, SiO_2, $A1_2O_3$, MgO, and Na_2O, the electronegativity difference, $X_o - X_M$, decreases gradually from MgO to P_2O_5 in accordance with the expected increasing covalency, but for Na_2O, the difference is approximately equal to that for SiO_2. From the point of view of chemical bond, it is expected that the bonding in SiO_2 is significantly

Fig. 1. Structure of LiB_4O_7.



more covalent than that in Na_2O. Therefore, it is acceptable that the calculated covalency of Li–O bond is slightly larger than that of B–O bond. It is because of the larger covalency of Li–O bonds that the hardness of LBO crystal is up to about 11 GPa, comparable to that of SiO_2 quartz.

Using the above-mentioned method, the hardness of another nonlinear optical crystal LiB_4O_7, its crystal structure is shown in Fig. 1, is also estimated at 9.1 GPa, which is in agreement with the measured value.[28] Results indicate that the Li–O bonds play the key role in determining the hardness of the nonlinear optical crystal LiB_4O_7.

For BBO crystal, the covalency of the Ba–O bonds is remarkably smaller than that of the BO bonds, leading to the lower-hardness BBO crystal.

In summary, the chemical-bond parameters of LBO and BBO compounds have been calculated using the chemical-bond theory of complex crystals. Their hardnesses have been predicted by the chemical-bond definition of hardness. The calculated results indicate that their hardnesses are determined only by Li–O and Ba–O bonds. The BO_3 anionic cluster does not contribute to their hardness.

Abstract: Synthesis of various substituted fluoreno[1,2-*d*]imidazol-10-ones (**5a**–**5g**) has been accomplished by the cyclization of diazotized 1-substituted 4-benzoyl-5- aminobenzimidazoles (**4a**–**4g**). Compounds **4a**–**4g** were prepared by reductive ring opening of 3*H*-imidazo[4′,5′:3,4]benzo[*c*]isoxazoles (**3a**–**3g**) with zinc dust in EtOH/NaOH solution.

Key words: fluoreno[1,2-*d*]imidazol-10-ones, diazotation, imidazo[4′,5′:3,4]benzo[*c*]isoxazoles, reductive ring opening.

Résumé : On a réalisé la synthèse de diverses fluoréno[1,2-*d*]imidazol-10-ones substituées, **5a**–**5g**, en procédant à la cyclisation de 4-benzoyl-5-aminobenzimidazoles diazotés, substitués en position 1, **4a**–**4g**. Les produits **4a**–**4g** ont été obtenus par l'ouverture réductrice de cycle de 3*H*-imidazo[4′,5′:3,4]benzo[*c*]isoxazoles, **3a**–**3g**, avec de la poudre de zinc dans une solution EtOH/NaOH.

Mots-clés : fluoréno[1,2-*d*]imidazol-10-ones, diazotation, imidazo[4′,5′:3,4]benzo[*c*]isoxazoles, ouverture réductrice de cycle.

[Traduit par la Rédaction]

Introduction

Fluorenones (fluorine-9-ones) are among the oldest classes of bioactive compounds, which are widely used as antiviral[1–3] and anticancer[4,5] agents and act as the key synthetic intermediates in many reactions.[6,7] Also, fluorenones with a suitable functionality can be used as a fluorescent electrophilic reagent.[8] Recently, they have mainly been considered as an important unit in polymer chemistry.[9–12] The fluorenone structural unit provides both rigidly planarized biphenyl units within the polymer backbone and the possibility of remote functionalization at C-9, the latter offer the prospect of improving both polymer processibility and mediating potential interchain interactions in films.[13]

There are several methods for the synthesis of these useful compounds, including the Friedel–Crafts ring closures of biarylcarboxylic acid derivatives,[14,15] intramolecular [4+2] cycloaddition reactions of conjugated enynes,[16] oxidation of fluorenes,[17] remote metalation of *m*-teraryl and biaryl amides[18] or combined directed ortho metalation-directed remote metalation,[19] palladium-catalyzed cyclocarbonylation of ortho halobiaryls,[20] and several other new methods.[21–23] Intramolecular reaction of diazotized 2-aminobenzophenones is one of the oldest methods for the preparation of fluorenones with relatively well-clarified mechanistic features.[24] A literature survey disclosed that the diazotized 4-benzoyl-5-aminobenzimidazoles have not been converted to fluoreno[1,2-*d*]imidazol-10-ones. Owing to our growing interest in the synthesis of bioactive heterocycles,[25] we became interested in examining the cyclization of diazotized compounds **4a**–**4g** to new fluoreno[1,2-*d*]imidazol-10-ones (**5a**–**5g**).

Results and discussion

The new 3*H*-imidazo[4′,5′:3,4]benzo[*c*]isoxazoles (**3a**–**3g**) were obtained via the nucleophilic substitution of hydrogen of 1-alkyl-5-nitrobenzimidazoles (**1a**–**1c**) with arylacetonitriles (**2a**–**2d**) in basic MeOH solution[26] (Scheme 1). The reaction does not occur when R_2 is an electron-withdrawing group, since the conjugated base of **2d** is a weak nucleophile.

The reductive ring opening of benzo[*c*]isoxazoles has been reported with Fe/HOAC[27] and Raney Ni/$N_2H_4{\cdot}H_2O$[28] methods. Herein, we introduce the reduction of benzo[*c*]isoxazoles with zinc dust in EtOH and 20% NaOH solution as a highly efficient route to the synthesis of new key intermediates **4a**–**4g** in excellent yields and short reaction times (Scheme 2).

Diazotized compounds **4a**–**4g** underwent cyclization in moderate-to-high yields to new fluoreno[1,2-*d*]imidazol-10-ones (**5a**–**5g**) at 70 °C (Scheme 3). The yield of reaction varies with the nature of the substituent on the benzoyl ring and is better with electron-donating groups (EDGs), since with EDGs, the electron density of the aromatic ring is higher, and it can act as a better nucleophile.

The structural assignments of compounds **5a**–**5g** were based on the analytical and spectral data. For example, in the ^{1}H NMR spectrum of **5c**, the signal at δ 4.16 ppm, assignable to exchangeable protons (NH_2 group), and two doublet signals at δ 6.78 ppm and δ 7.36 ppm, attributed to four aromatic protons of *p*-methoxyphenyl ring of compound **4c**, are not present. Instead, there are the doublet of doublet signal at δ 6.64 ppm (J = 8.1 Hz and J' = 2.1 Hz), the doublet signal at δ 7.03 ppm with meta J (2.1 Hz), and the doublet signal at δ 7.66 ppm with ortho J (8.1 Hz), assignable to three aromatic protons of methoxyphenyl ring. Moreover,

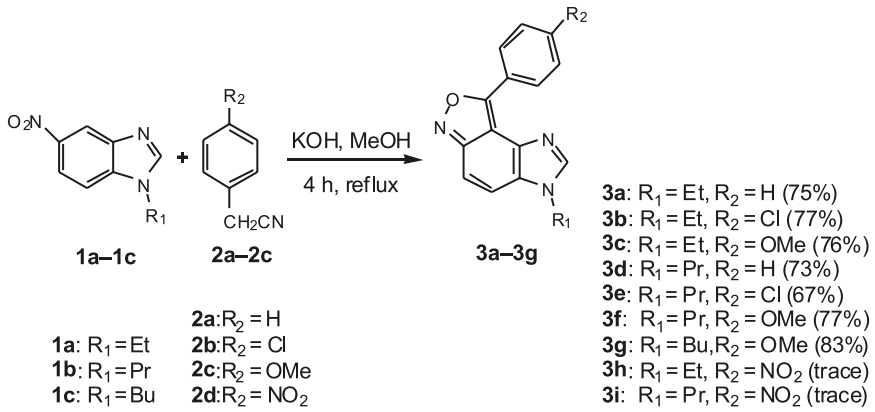
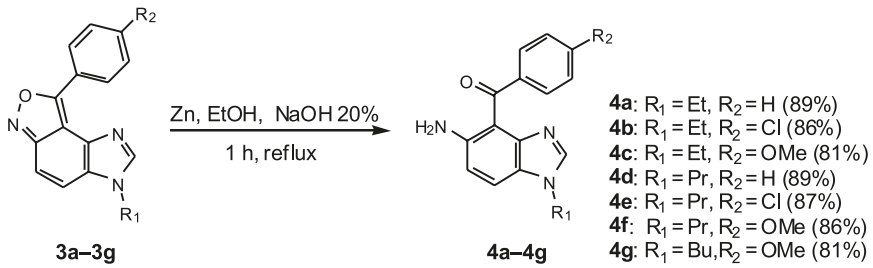
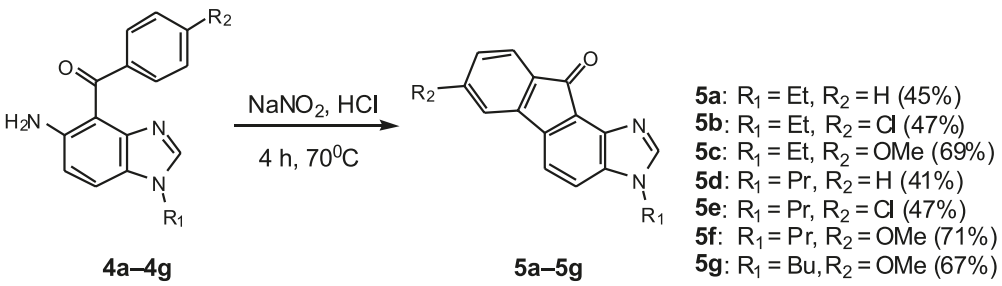
Scheme 1.



Scheme 2.



Scheme 3.



the FTIR spectrum of **5c** in KBr did not show the absorption band at 3320 cm^{-1}, corresponding to NH_2 group. All these evidences plus the molecular-ion peak at *m/z* 278 and micro-analytical data strongly support the tetracyclic structure of compound **5c**.

Conclusion

In summary, this research has demonstrated that the cyclization of diazotized *o*-amino-ketones is a reliable work, which can be extended to the synthesis of other new heterocyclic compounds.

Experimental

CH_2Cl_2 and MeOH were distilled from CaH_2. Silica gel 60 (0.040–0.063 mm, Merck) was used for column chromatography. Compounds **1a**–**1c** were obtained according to the published methods.[29] Other reagents were commercially available. Melting points were recorded on an Electrothermal type-9100 melting-point apparatus and are uncorrected. The IR spectra were obtained on a 4300 Shimadzu spectrometer, and only noteworthy absorptions are listed. The ^1H NMR (100 MHz) spectra were recorded on a Bruker AC 100 spectrometer. Chemical shifts are reported in ppm downfield from TMS as internal standard; coupling constance *J* are given in Hz. The mass spectra were recorded on a Varian Mat. CH-7 at 70 eV. Elemental analysis was performed on a Thermo Finnigan Flash EA microanalyzer.

Synthesis of imidazo[4′,5′:3,4]benzo[*c*]isoxazoles (3a–3g)

General procedure

Compounds **1a**–**1c** (10 mmol) and **2a**–**2c** (12 mmol) were added with stirring to a solution of KOH (20 g, 357 mmol) in methanol (80 mL). The mixture was refluxed with stirring for 4 h, and then poured into water. The precipitate was collected by filtration, washed with water, and air-dried to give **3a**–**3g**.

*3-Ethyl-8-phenyl-3*H*-imidazo[4′,5′:3,4]benzo[*c*]isoxazole (3a)*

Compound **3a** was obtained as colourless needles (EtOH). Yield (75%); mp 99–101 °C. ^1H NMR ($CDCl_3$) δ: 1.56 (t, *J* = 7.0 Hz, 3H), 4.25 (q, *J* = 7.0 Hz, 2H), 7.44–7.66 (m, 5H), 7.88

(s, 1H), 8.88 (dd, J = 8.0 Hz, J' = 2.0 Hz, 2H). MS (*m*/*z*): 263 (M^+). Anal. calcd. for $C_{16}H_{13}N_3O$ (263.3): C, 72.99; H, 4.98; N, 15.96. Found: C, 72.75; H, 4.83; N, 15.88.

8-(4-Chlorophenyl)-3-ethyl-3*H-*imidazo[4′,5′:3,4]benzo[c]isoxazole (3b)

Compound **3b** was obtained as colourless needles (EtOH). Yield (77%); mp 186–188 °C. ^{1}H NMR ($CDCl_3$) δ: 1.59 (t, J = 7.0 Hz, 3H), 4.27 (q, J = 7.0 Hz, 2H), 7.43 (d, J = 9.5 Hz, 1H), 7.59 (d, J = 9.5 Hz, 1H), 7.65 (d, J = 8.6 Hz, 2H), 7.89 (s, 1H), 8.91 (d, J = 8.6 Hz, 2H). MS (*m*/*z*): 299 (M^+ + 2). Anal. calcd. for $C_{16}H_{12}ClN_3O$ (297.7): C, 64.54; H, 4.06; N, 14.11. Found: C, 64.34; H, 3.97; N, 13.86.

3-Ethyl-8-(4-methoxyphenyl)-3*H-*imidazo[4′,5′:3,4]benzo[c]isoxazole (3c)

Compound **3c** was obtained as colourless needles (EtOH). Yield (76%); mp 173–174 °C. ^{1}H NMR ($CDCl_3$) δ: 1.62 (t, J = 7.3 Hz, 3H), 3.89 (s, 3H), 4.28 (q, J = 7.3 Hz, 2H), 7.17 (d, J = 9.0 Hz, 2H), 7.38 (d, J = 9.5 Hz, 1H), 7.55 (d, J = 9.5 Hz, 1H), 7.88 (s, 1H), 8.84 (d, J = 9.0 Hz, 2H). MS (*m*/*z*): 293 (M^+). Anal. calcd. for $C_{17}H_{15}N_3O_2$ (293.3): C, 69.61; H, 5.15; N, 14.33. Found: C, 69.55; H, 5.12; N, 14.44.

8-Phenyl-3-propyl-3*H-*imidazo[4′,5′:3,4]benzo[c]isoxazole (3d)

Compound **3d** was obtained as colourless needles (EtOH). Yield (73%); mp 119–122 °C. ^{1}H NMR ($CDCl_3$) δ: 0.99 (t, J = 7.0 Hz, 3H), 1.77–2.12 (m, 2H), 4.21 (t, J = 7.0 Hz, 2H), 7.47–7.69 (m, 5H), 7.89 (s, 1H), 8.89 (dd, J = 8.0 Hz, J' = 2.0 Hz, 2H). MS (*m*/*z*): 277 (M^+). Anal. calcd. for $C_{17}H_{15}N_3O$ (277.3): C, 73.63; H, 5.45; N, 15.15. Found: C, 73.87; H, 5.51; N, 15.47.

8-(4-Chlorophenyl)-3-propyl-3*H-*imidazo[4′,5′:3,4]benzo[c]isoxazole (3e)

Compound **3e** was obtained as colourless needles (EtOH). Yield (67%); mp 158–160 °C. ^{1}H NMR ($CDCl_3$) δ: 1.05 (t, J = 7.3 Hz, 3H), 1.85–2.21 (m, 2H), 4.18 (t, J = 7.3 Hz, 2H), 7.40 (d, J = 9.5 Hz, 1H), 7.56 (d, J = 9.5 Hz, 1H), 7.62 (d, J = 8.6 Hz, 2H), 7.86 (s, 1H), 8.89 (d, J = 8.6 Hz, 2H). MS (*m*/*z*): 313 (M^+ + 2). Anal. calcd. for $C_{17}H_{14}ClN_3O$ (311.8): C, 65.49; H, 4.53; N, 13.48. Found: C, 65.25; H, 4.41; N, 13.55.

8-(4-Methoxyphenyl)-3-propyl-3*H-*imidazo[4′,5′:3,4]benzo[c]isoxazole (3f)

Compound **3f** was obtained as colourless needles (EtOH). Yield (77%); mp 155–157 °C. ^{1}H NMR ($CDCl_3$) δ: 0.97 (t, J = 7.3 Hz, 3H), 1.83–2.19 (m, 2H), 3.90 (s, 3H), 4.17 (t, J = 7.3 Hz, 2H), 7.12 (d, J = 9.0 Hz, 2H), 7.40 (d, J = 9.5 Hz, 1H), 7.57 (d, J = 9.5 Hz, 1H), 7.85 (s, 1H), 8.85 (d, J = 9.0 Hz, 2H). MS (*m*/*z*): 307 (M^+). Anal. calcd. for $C_{18}H_{17}N_3O_2$ (307.3): C, 70.34; H, 5.58; N, 13.67. Found: C, 70.25; H, 5.62; N, 13.55.

3-Butyl-8-(4-methoxyphenyl)-3*H-*imidazo[4′,5′:3,4]benzo[c]isoxazole (3g)

Compound **3g** was obtained as colourless needles (EtOH). Yield (83%); mp 139–141 °C. ^{1}H NMR ($CDCl_3$) δ: 0.98 (t, J = 7.0 Hz, 3H), 1.23–1.58 (m, 2H), 1.82–2.10 (m, 2H), 3.90 (s, 3H), 4.18 (t, J = 7.0 Hz, 2H), 7.11 (d, J = 9.0 Hz, 2H), 7.39 (d, J = 9.5 Hz, 1H), 7.57 (d, J = 9.5 Hz, 1H), 7.87 (s, 1H), 8.84 (d, J = 9.0 Hz, 2H). MS (*m*/*z*): 321 (M^+). Anal. calcd. for $C_{19}H_{19}N_3O_2$ (321.4): C, 71.01; H, 5.96; N, 13.08. Found: C, 70.75; H, 5.82; N, 13.45.

Synthesis of *o*-amino-ketones (4a–4g)

General procedure

Zinc dust (1 g, 15.3 mmol) was added with stirring over 5 h period to a solution of **3a**–**3g** (4 mmol) in EtOH (30 mL) and 20% NaOH (20 mL). After the addition was completed, the mixture was refluxed for 1 h and then poured into water. The product was extracted with $CHCl_3$ (2 × 30 mL). The extract was washed with water (2 × 30 mL), and then it was dried and evaporated to give pure **4a**–**4g**.

(5-Amino-1-ethyl-1*H-*benzo[d]imidazol-4-yl)(phenyl)methanone (4a)

Compound **4a** was obtained as colourless needles. Yield (89%); mp 185–187 °C. IR (KBr): 3315 cm^{-1} (NH_2), 1635 cm^{-1} (C=O).^{1}H NMR ($CDCl_3$) δ: 1.51 (t, J = 7.3 Hz, 3H), 3.75 (br s, 2H), 4.13 (q, J = 7.3 Hz, 2H), 6.67 (d, J = 8.5 Hz, 1H), 7.09 (d, J = 8.5 Hz, 1H), 7.19–7.60 (m, 5H), 7.78 (s, 1H). MS (*m*/*z*) 265 (M^+). Anal. calcd. for $C_{16}H_{15}N_3O$ (265.3): C, 72.43; H, 5.70; N, 15.84. Found: C, 72.21; H, 5.65; N, 15.76.

(5-Amino-1-ethyl-1*H-*benzo[d]imidazol-4-yl)(4-chlorophenyl)methanone (4b)

Compound **4b** was obtained as colourless needles. Yield (86%); mp 174–176 °C. IR (KBr): 3320 cm^{-1} (NH_2), 1635 cm^{-1} (C=O).^{1}H NMR ($CDCl_3$) δ: 1.51 (t, J = 7.3 Hz, 3H), 3.86 (br s, 2H), 4.12 (q, J = 7.3 Hz, 2H), 6.63 (d, J = 8.5 Hz, 1H), 7.11 (d, J = 8.5 Hz, 1H), 7.22 (d, J = 10.5 Hz, 2H), 7.42 (d, J = 10.5 Hz, 2H), 7.77 (s, 1H). MS (*m*/*z*): 301 (M^+ + 2). Anal. calcd. for $C_{16}H_{14}ClN_3O$ (299.8): C, 64.11; H, 4.71; N, 14.02. Found: C, 63.96; H, 4.61; N, 13.83.

(5-Amino-1-ethyl-1*H-*benzo[d]imidazol-4-yl)(4-methoxyphenyl)methanone (4c)

Compound **4c** was obtained as colourless needles. Yield (81%); mp 142–144 °C. IR (KBr): 3320 cm^{-1} (NH_2), 1635 cm^{-1} (C=O). ^{1}H NMR ($CDCl_3$) δ: 1.50 (t, J = 7.3 Hz, 3H), 3.74 (s, 3H), 4.13 (q, J = 7.3 Hz, 2H), 4.16 (br s, 2H), 6.65 (d, J = 8.5 Hz, 1H), 6.78 (d, J = 10.0 Hz, 2H), 7.09 (d, J = 8.5 Hz, 1H), 7.36 (d, J = 10.0 Hz, 2H), 7.77 (s, 1H). MS (*m*/*z*): 295 (M^+). Anal. calcd. for $C_{17}H_{17}N_3O_2$ (295.3): C, 69.14; H, 5.80; N, 14.23. Found: C, 68.83; H, 5.71; N, 13.99.

(5-Amino-1-propyl-1*H-*benzo[d]imidazol-4-yl)(phenyl)methanone (4d)

Compound **4d** was obtained as colourless needles. Yield (89%); mp 168–169 °C. IR (KBr): 3315 cm^{-1} (NH_2), 1635 cm^{-1} (C=O). ^{1}H NMR ($CDCl_3$) δ: 0.94 (t, J = 7.5 Hz, 3H), 1.75–2.10 (m, 2H), 4.04 (t, J = 7.5 Hz, 2H), 4.12 (br s, 2H), 6.62 (d, J = 8.5 Hz, 1H), 7.03 (d, J = 8.5 Hz, 1H), 7.11–7.52 (m, 5H), 7.75 (s, 1H). MS (*m*/*z*): 279 (M^+). Anal. calcd. for $C_{17}H_{17}N_3O$ (279.3): C, 73.10; H, 6.13; N, 15.04. Found: C, 72.86; H, 6.01; N, 14.83.

(5-Amino-1-propyl-1*H-*benzo[d]imidazol-4-yl)(4-chlorophenyl)methanone (4e)

Compound **4e** was obtained as colourless needles. Yield

Synthesis of fluoreno[1,2-*d*]imidazol-10-one (5a–5g)

General procedure

To a solution of **4a**–**4f** (2 mmol) in 3 N HCl (4 mL) maintained at 0–5 °C, a solution of sodium nitrite (0.2 g, 6 mmol) in water (2 mL) was added with stirring over a 5 min period. After the addition was completed, the mixture was stirred at 0–5 °C for 15 min, and then it was maintained at 70 °C in a water bath for 4 h. After pouring this mixture into crushed ice and water (50 mL), the precipitated solid was removed by filtration, washed with water, and dried to give crude **5a**–**5f**.

3-Ethyl-3,10-dihydrofluoreno[1,2-*d*]imidazol-10-one (5a)

Compound **5a** was passed through silica-gel column ($CHCl_3$/MeOH 30:1) to give **5a** as yellow crystals. Yield (45%); mp 160–162 °C. IR (KBr): 1660 cm^{-1} (C=O).^1H NMR ($CDCl_3$) δ: 1.56 (t, *J* = 7.2 Hz, 3H), 4.24 (q, *J* = 7.2 Hz, 2H), 7.09–7.55 (m, 5H), 7.63 (d, *J* = 9.0 Hz, 1H), 8.01 (s, 1H). MS (*m*/*z*): 248 (M^+). Anal. calcd. for $C_{16}H_{12}N_2O$ (248.3): C, 77.40; H, 4.87; N, 11.28. Found: C, 77.23; H, 4.73; N, 11.12.

7-Chloro-3-ethyl-3,10-dihydrofluoreno[1,2-*d*]imidazol-10-one (5b)

Compound **5b** was passed through silica-gel column ($CHCl_3$/MeOH 20: 1) to give **5b** as yellow crystals. Yield (47%); mp 170–172 °C. IR (KBr): 1660 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ: 1.50 (t, *J* = 7.1 Hz, 3H), 4.12 (q, *J* = 7.1 Hz, 2H), 7.38 (dd, *J* = 9.0 Hz, *J*′ = 2.1 Hz, 1H), 7.58 (d, *J* = 9.0 Hz, 1H), 8.02 (d, *J* = 8.4 Hz, 1H), 8.12 (d, *J* = 2.1 Hz, 1H), 8.25 (d, *J* = 8.4 Hz, 1H), 8.02 (s, 1H). MS (*m*/*z*): 284 (M^+ + 2). Anal. calcd. for $C_{16}H_{11}ClN_2O$ (282.7): C, 67.97; H, 3.92; N, 9.91. Found: C, 67.65; H, 3.81; N, 9.70.

3-Ethyl-7-methoxy-3,10-dihydrofluoreno[1,2-*d*]imidazol-10-one (5c)

Compound **5c** was passed through silica-gel column ($CHCl_3$/MeOH 20:1) to give **5c** as yellow crystals. Yield (69%); mp 165–167 °C. IR (KBr): 1660 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ: 1.56 (t, *J* = 7.3 Hz, 3H), 3.90 (s, 3H), 4.23 (q, *J* = 7.3 Hz, 2H), 6.64 (dd, *J* = 8.1 Hz, *J*′ = 2.1 Hz, 1H), 7.03 (d, *J* = 2.1 Hz, 1H), 7.40 (d, *J* = 8.6 Hz, 1H), 7.49 (d, *J* = 8.6 Hz, 1H), 7.66 (d, *J* = 8.1 Hz, 1H), 8.01 (s, 1H). MS (*m*/*z*): 278 (M^+). Anal. calcd. for $C_{17}H_{14}N_2O_2$ (278.3): C, 73.37; H, 5.07; N, 10.07. Found: C, 73.56; H, 5.21; N, 9.83.

3-Propyl-3,10-dihydrofluoreno[1,2-*d*]imidazol-10-one (5d)

Compound **5d** was passed through silica-gel column ($CHCl_3$/MeOH 30:1) to give **5d** as yellow crystals. Yield (41%); mp 135–137 °C. IR (KBr): 1660 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ: 0.97 (t, *J* = 7.3 Hz, 3H), 1.77–2.12 (m, 2H), 4.13 (t, *J* = 7.3 Hz, 2H), 7.08–7.54 (m, 5H), 7.65 (d, *J* = 9.0 Hz, 1H), 8.00 (s, 1H). MS (*m*/*z*): 262 (M^+). Anal. calcd. for $C_{17}H_{14}N_2O$ (262.3): C, 77.84; H, 5.38; N, 10.68. Found: C, 78.05; H, 5.41; N, 10.50.

7-Chloro-3-propyl-3,10-dihydrofluoreno[1,2-*d*]imidazol-10-one (5e)

Compound **5e** was passed through silica-gel column ($CHCl_3$/MeOH 30:1) to give **5e** as yellow crystals. Yield (47%); mp 159–161 °C. IR (KBr): 1660 cm^{-1} (C=O).^1H NMR ($CDCl_3$) δ: 1.01 (t, *J* = 7.3 Hz, 3H), 1.77–2.15 (m, 2H), 4.22 (t, *J* = 7.3 Hz, 2H), 7.43 (dd, *J* = 9.0 Hz, *J*′ = 2.1 Hz, 1H), 7.56 (d, *J* = 9.0 Hz, 1H), 8.03 (d, *J* = 8.4 Hz, 1H), 8.12 (d, *J* = 2.1 Hz, 1H), 8.23 (d, *J* = 8.4 Hz, 1H), 8.02 (s, 1H). MS (*m*/*z*): 298 (M^+ + 2). Anal. calcd. for $C_{17}H_{13}ClN_2O$ (296.8): C, 68.81; H, 4.42; N, 9.44. Found: C, 68.60; H, 4.31; N, 9.31.

7-Methoxy-3-propyl-3,10-dihydrofluoreno[1,2-*d*]imidazol-10-one (5f)

Compound **5f** was passed through silica-gel column ($CHCl_3$/MeOH 30:1) to give **5f** as yellow crystals. Yield (71%); mp 140–142 °C. IR (KBr): 1660 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ: 0.98 (t, *J* = 7.2 Hz, 3H), 1.77–2.13 (m, 2H), 3.91 (s, 3H), 4.14 (t, *J* = 7.2 Hz, 2H), 6.66 (dd, *J* = 8.1 Hz, *J*′ = 2.1 Hz, 1H), 6.98 (d, *J* = 2.1 Hz, 1H), 7.38 (d, *J* = 8.6 Hz, 1H), 7.47 (d, *J* = 8.6 Hz, 1H), 7.62 (d, *J* = 8.1 Hz, 1H), 8.03 (s, 1H). MS (*m*/*z*): 292 (M^+). Anal. calcd. for $C_{18}H_{16}N_2O_2$ (292.3): C, 73.95; H, 5.52; N, 9.58. Found: C, 74.12; H, 5.69; N, 9.31.

3-Butyl-7-methoxy-3,10-dihydrofluoreno[1,2-*d*]imidazol-10-one (5g)

Compound **5g** was passed through silica-gel column ($CHCl_3$/MeOH 30:1) to give **5g** as yellow crystals. Yield (67%); mp 120–122 °C. IR (KBr): 1660 cm^{-1} (C=O). ^1H NMR ($CDCl_3$) δ: 0.91 (t, *J* = 7.0 Hz, 3H), 1.15–1.55 (m, 2H), 1.71–2.01 (m, 2H), 3.88 (s, 3H), 4.14 (t, *J* = 7.0 Hz, 2H), 6.65 (dd, *J* = 8.1 Hz, *J*′ = 2.1 Hz, 1H), 6.96 (d, *J* =

2.1 Hz, 1H), 7.39 (d, J = 8.6 Hz, 1H), 7.46 (d, J = 8.6 Hz, 1H), 7.66 (d, J = 8.1 Hz, 1H), 7.98 (s, 1H). MS (m/z): 306 (M^+). Anal. calcd. for $C_{19}H_{18}N_2O_2$ (306.4): C, 74.49; H, 5.92; N, 9.14. Found: C, 74.21; H, 5.79; N, 8.86.

Synthesis, characterization, and surface studies of conjugated polymers possessing 2,2′-biimidazole moieties

D.T. Walker, C.D. Douglas, and B.J. MacLean

Abstract: Two novel 2,2′-biimidazole-thiophene structures, 5,5′-bis(2,2′-bithiophene-5-yl)-1,1′-dimethyl-2,2′-biimidazole and 5,5′-bis(3,4-ethylenedioxythiophene-2-yl)-1,1′-dimethyl-2,2′-biimidazole, have been synthesized and electrochemically polymerized. These materials underwent facile oxidation on Pt and ITO surfaces in CH_2Cl_2/Bu_4NPF_6 to yield conjugated, electroactive polymer films. The films were characterized with cyclic voltammetry, electronic absorption spectroscopy, and atomic force microscopy.

Key words: imidazole, conjugated polymer, electropolymerization.

Résumé : On a effectué la synthèse de deux nouvelles structures de 2,2′-biimidazole-thiophène, le 5,5-bis(2,2′-bithiophén-5-yl)-1,1′-diméthyl-2,2′-biimidazole et le 5,5′-bis(3,4-éthylènedioxythiophén-2-yl)-1,1′-diméthyl-2,2′-biimidazole, et on a réalisé leur polymérisation par voie électrochimique. En solution dans un mélange de CH_2Cl_2/Bu_4NPF_6, sur des surfaces de Pt et d′ITO, ces produits donnent facilement lieu à des réactions d'oxydation qui conduisent à la formation de films de polymères conjugués électroactifs. On a caractérisé ces films par voltampérométrie cyclique, spectroscopie d'absorption électronique et par microscopie des forces atomiques.

Mots-clés : imidazole, polymère conjugué, électropolymérisation.

[Traduit par la Rédaction]

Introduction

Although published reports of electroactive heterocyclic polymers appeared as early as 1876,[1] these structures became more interesting to materials scientists around the time the first reports of highly conductive conjugated polymers emerged.[2–4] Since this event, homopolymers consisting of pyridine (**1**), pyrrole (**2**), thiophene (**3**), and other heterocyclic structures (Chart 1) have abounded and have found applications in electronics, corrosion inhibition, sensing, actuators, and energy technology, to name just a few of the more popular areas.[5] Several of these heterocycles may be polymerized electrochemically (e.g., aniline, pyrrole, and thiophene).[6–9] Electrochemical polymerization offers several advantages over chemical polymerization routes.[10] This collection of techniques comprises methods which allow controlled oxidation and (or) reduction of redox-active species at an electrode–solution interface, and thus the methods enable a degree of control over polymerization rate and provide a means of producing polymer films of a desired thickness (and perhaps, quality). Often, the most important advantage provided by electrochemical polymerization, however, is that problems which accompany low polymer solubilities (i.e., difficulties in polymer processing) can be circumvented. For structures which are unable to be polymerized via electrochemical methods (e.g., pyridine), it is usually possible to achieve this goal through the incorporation of polymerizable substituents. The most popular substituent in this application appears to be thiophene and its derivatives. Thienyl substituents have been used in the polymerization of a wide variety of heterocyclic compounds and in many cases, metal complexes.[11–15]

Imidazole (**4**) (Chart 1) has been the topic of relatively few investigations concerning conjugated polymers. This may seem surprising at first, since imidazole possesses pyrrole-like and pyridine-like nitrogens, which should make it an attractive candidate for chemical studies of this sort. The imine centers on imidazole enable derivatives like 2,2′-biimidazole (**5a**) (Chart 1) and others to be utilized as ligands in metal complexes.[16,17] Such assemblies have been shown to display pH-dependent properties and are thus intriguing in sensory applications.[18,19] Benzimidazole polymers and metallopolymers have also been reported to exhibit pH-responsive electrochemistry, which influences electronic communication between metal centers in these materials.[20]

There appear to be two reasons why imidazoles are not as widely studied as other heterocycles. Importantly, protecting groups are required when chemistry is to be carried out at any of the carbon centers on the ring, which adds to preparation time and cost.[21] Furthermore, when bicyclic **5a** is considered, low solubilities in most common organic solvents, due to strong self-association (hydrogen bonding and π-stacking), is a real problem.[22] Here, the use of protecting groups (e.g., benzyl, trimethylsilylethoxymethyl substituents) has been shown to greatly enhance solubility.[23,24]

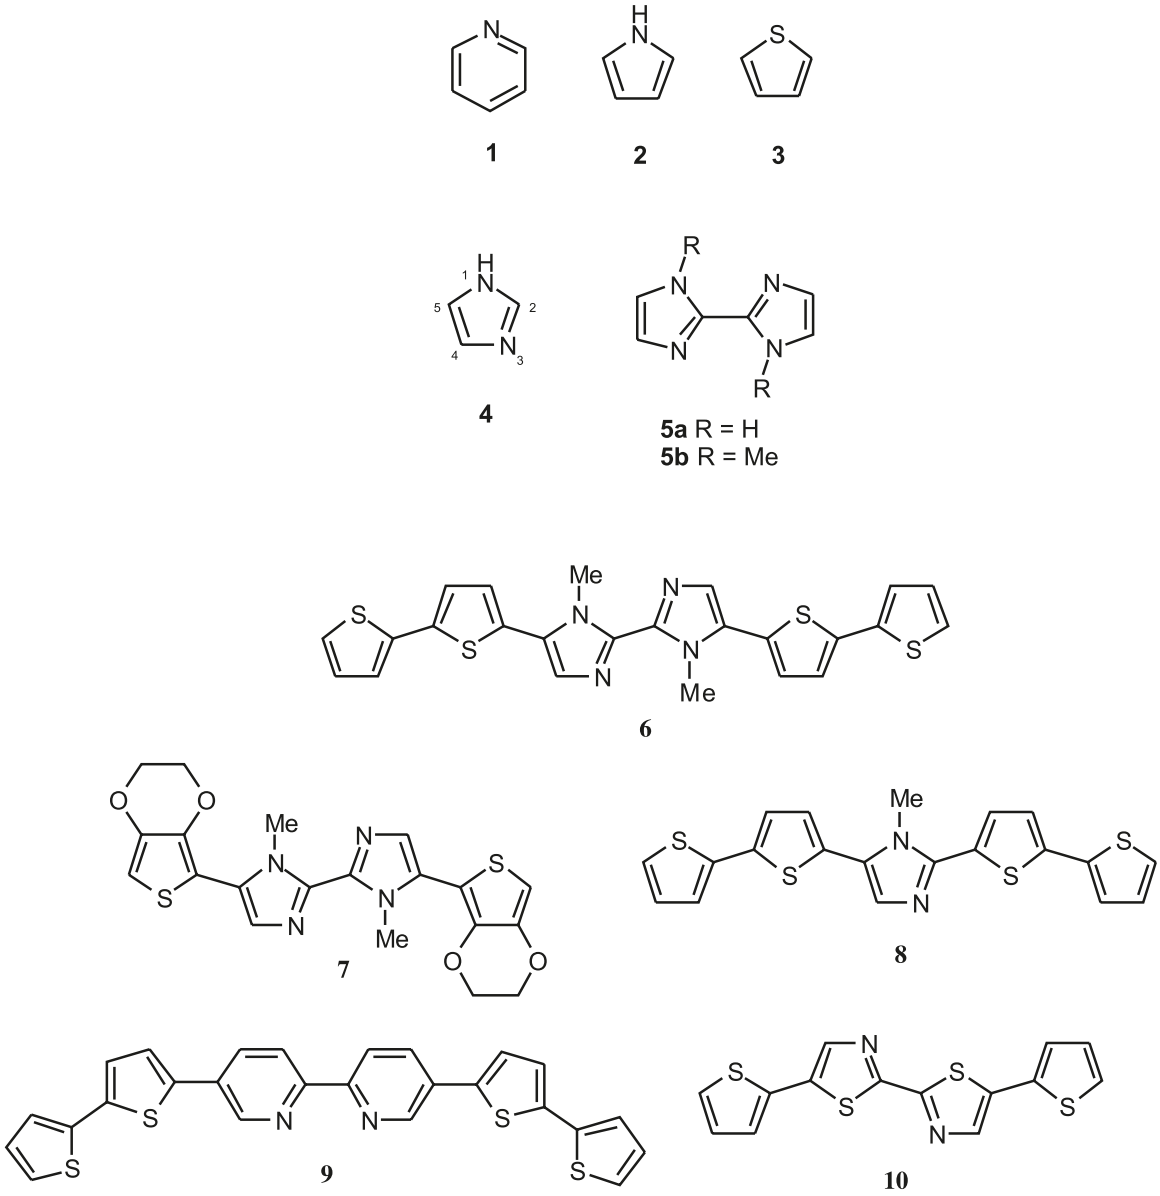
Chart 1.



Chemically polymerized 1,1′-diprotected-2,2′-biimidazoles have been detailed by Yamamoto et al.[25,26] In these studies, a range of biimidazoles that were 1,1′-difunctionalized with either alkyl (e.g., **5b**) (Chart 1) or methoxymethyl (MOM) substituents were polymerized via chemical polycondensation reactions. In the case of poly(1,1′-dimethoxymethyl-2,2′-biimidazole), 90% deprotection of the MOM-protected biimidazole sites was possible, yielding a polymer with H-functionalized 2,2′-biimidazole units. Electropolymerizable models, such as 5,5′-bis(2,2′-bithiophene-5-yl)-1,1′-dimethyl-2,2′-biimidazole (**6**) (Chart 1) and 5,5′-bis(3,4-ethylenedioxythiophene-2-yl)-1,1′-dimethyl-2,2′-biimidazole (**7**) (Chart 1), would enable the synthesis of thiophene–imidazole copolymers through convenient electrochemical polymerization experiments. Structures possessing 1,1′-disubstituted biimidazole moieties would be interesting because they would be soluble in organic solvents and because the facile chemistry that yields 1,1′-disubstitution could be varied to provide a means of tuning the electronic properties of such compounds and their polymers. Additionally, as noted earlier, it should be possible to tune their chemical behavior through judicious choice of solution pH. In fact, such a study has recently been reported for a related structure, 2,5-bis(2,2′-bithiophene-5-yl)-1-methylimidazole (**8**) (Chart 1), for which significant blue-shifts in the p-doping potentials of its polymerized form, poly-**8,** were observed upon the addition of trifuoroacetic acid to test solutions.[27]

A promising avenue of research for conjugated polymers containing 2,2′-biimidazole units would be heterogeneous catalysis, since these compounds would be capable of coordinating metal ions, and may thus be interesting for their potential as catalyst supports.[28] The ability to tune the electronic and chemical properties of such complexes would be of paramount importance in this application. Towards this end, we have synthesized the electropolymerizable 2,2′-biimidazole structures **6** and **7**.

Experimental section

Equipment

Cyclic voltammetry experiments were carried out with a PC-interfaced CH Instruments 750C bipotentiostat. Data acquisition was accomplished using CH Instruments software (version 6.24). Voltammetry experiments were conducted on platinum-button electrodes (CH Instruments, 1 mm diameter) in a three-compartment glass cell. Pt electrodes were cleaned prior to each experiment by polishing with an Al_2O_3 dispersion (0.05 μm). Potentials are referenced to an Analytical Sensors, Inc. calomel electrode having a 4 mol L^{-1} KCl internal solution. A platinum wire served as a counter electrode. A scan rate of 0.100 V s^{-1} was used in each experiment, unless otherwise noted. Polymers obtained from electropolymerization experiments were washed with acetone and air-dried before subsequent experiments were carried out on them. Electrochemical solutions were purged for 10 min with nitrogen gas before experiments were carried out. A flow of nitrogen was maintained over the surface of each solution for the duration of these studies. All cyclic voltammetry experiments were carried out at 25 °C.

Electronic absorption spectrophotometry experiments were conducted with a JASCO J-815 instrument running in absorbance mode, employing baseline correction. Data acquisition was accomplished with Spectra Manager software (JASCO, version 1.54.03). The energies of π–π* transitions for the monomers in solution were determined from the onset of absorption by extrapolation of the low-energy side of these peaks and the baseline. Scans were conducted at a rate of 1 nm s^{-1} with data collection at 2 nm intervals. Indium – tin oxide coated glass electrodes for experiments on polymer films were purchased from Delta Technologies (R_s = 8–12 Ω).

Nuclear magnetic resonance (NMR) experiments were carried out on a Bruker Avance II 400 MHz instrument at room temperature. Chemical shifts are referenced to a TMS peak, which was assigned a value of 0 ppm. Elemental analyses were performed by Canadian Microanalytical Services Ltd., Delta, BC. Atomic force microscopy (AFM) was used to investigate polymer-film topology using a XE-120 Park Systems Inc. instrument in contact mode under ambient conditions. Melting points were carried out in air using an Electrothermal Mel-Temp capillary tube apparatus and are not corrected.

AM1 calculations were performed with Gaussian 03 and Gaussview 3.09 software.[29,30]

Materials

All chemicals employed in this study were of reagent-grade or better and were used as received unless otherwise noted. Syntheses of biimidazole monomers were carried out under an atmosphere of UHP-grade argon using standard Schlenk-line techniques. Acetonitrile (CH_3CN) and *N*,*N*-dimethylformamide (DMF) were both anhydrous and purchased from Caledon Laboratories Ltd. These solvents were delivered from an MBraun solvent purification system onto type 4 Å molecular sieves and stored under argon before use. Dichloromethane (CH_2Cl_2, VWR) for cyclic voltammetry experiments was purified by distillation from P_2O_5 and stored on type 4 Å molecular sieves prior to use. CH_3CN for electrochemical experiments was stored on activated alumina under a blanket of argon until use. Tetraethylammonium perchlorate (Et_4NClO_4) was synthesized from perchloric acid and tetraethylammonium bromide, recrystallized three times from water, and dried in a vacuum oven at 110 °C. Tetrabutylammonium hexafluorophosphate (Bu_4NPF_6) was synthesized from hexafluorophosphoric acid and tetrabutylammonium bromide, recrystallized three times from ethanol, and dried in a vacuum oven at 110 °C.

Synthesis of 2,2′-biimidazole, 5a

Ammonium hydroxide (300 mL, 18 mol L^{-1}) was added dropwise over a 30 min period to an ice-cooled conical flask that contained a solution of 40% *w*/*w* glyoxal (170 mL). The opening between the funnel and flask was covered with a wax film to prevent leakage of NH_3(g). The resulting, dark brown mixture was stirred overnight and then filtered. The residue was dissolved with 0.1 mol L^{-1} HCl and heated to boiling. It was then treated with activated charcoal, filtered, and neutralized with a saturated K_2CO_3(aq) solution, precipitating a tan coloured solid. The product was collected by filtration and air-dried. ^{1}H NMR data were in agreement with those reported.[23] Yield: 21.22g (32%). Mp > 300 °C (Lit.[31] 307 °C). ^{1}H NMR (400 MHz, DMSO-d_6) δ (ppm): 12.65 (s (br), 2H), 7.06 (s, 4H).

Synthesis of 1,1′-dimethyl- 2,2′-biimidazole, 5b

A method reported by Logemann and co-workers.[32] was followed: 2,2′-biimidazole (2.00 g, 1.49 mmol) was refluxed in a solution of 11.5 mL of 20% NaOH in 40 mL of ethanol. Dimethyl sulfate (8.66 g, 69 mmol) was added dropwise over a 30 min period. Refluxing was continued overnight. By the next day, the mixture had changed from a deep brown solution to an opaque, golden mixture. The reaction flask was cooled to room temperature and neutralized with aqueous $NaHCO_3$. It was then filtered and extracted with $CHCl_3$ (3 × 50 mL). The organic layer was washed with aqueous NaOH (2.4 g in 30 mL of H_2O) and dried over $MgSO_4$. It was then filtered and evaporated to dryness to yield an orange solid. This was recrystallized from heptane to yield pale-yellow needles. ^{1}H NMR signals were in agreement with those published for this structure.[33] Yield: 1.84g (76%). ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.11 (s, 2H, *J* = 1.0 Hz), 6.95 (s, 2H, 1.0 Hz), 4.04 (s, 6H). ^{13}C NMR (400 MHz, $CDCl_3$) δ (ppm): 138.74, 127.88, 122.64, 35.37.

Synthesis of 5,5′-dibromo-1,1′-dimethyl-2,2′-biimidazole

N-Bromosuccinimide (0.764 g, 4.3 mmol) was added portionwise via a powder-addition funnel to a solution of 1,1′-dimethyl-2,2′-biimidazole (0.349 g, 2.15 mmol) in $CHCl_3$ (25 mL). The solution immediately turned green before gradually becoming a brown–orange colour. The mixture was stirred overnight. The following day, the solution was washed with $NaHCO_3$(aq) and then water. The organic solution was then dried over $MgSO_4$, filtered, and evaporated to yield a beige solid, which was dried in vacuo. The product was recrystallized from heptane to yield pale yellow needles. ^{1}H NMR results were in agreement with the results reported by Yamamoto et al.[26] Yield: 0.524g (76%). Mp 155–156 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.12 (s, 2H), 3.96 (s, 6H).

Synthesis of 5,5′-bis(2,2′-bithiophene-5-yl)-1,1′-dimethyl-2,2′-biimidazole, 6

5,5′-Dibromo-1,1′-dimethyl-2,2′-biimidazole (0.678 g, 2.12 mmol) was stirred in a solution of $Pd(PPh_3)_2Cl_2$ (0.149 g, 0.212 mmol) in anhydrous DMF (50 mL). 5-Tributyltin-2,2′-bithiophene (2.41 g, 5.29 mmol)[34] was added through a syringe, and the mixture was refluxed, causing a gradual colour change from pale yellow to dark brown. After removal of the solvent, the residue was washed with CH_2Cl_2 using a Soxhlet extractor. The organic effluent was then washed with brine solution (25 mL), water (3 × 25 mL), and dried over $MgSO_4$. The solution was then filtered and treated with petroleum ether. Dropwise addition of the ether caused precipitation of a bright yellow solid, which was filtered and dried in vacuo. Yield: 0.675 g (65%). Mp 205–208 °C. ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.31 (s, 2H), 7.26 (d, 2H), 7.22 (d, J = 2.7 Hz, 2H), 7.20 (d, J = 3.7 Hz, 2H), 7.08 (d, J = 3.5 Hz, 2H), 7.05 (m, 2H), 4.10 (s, 6H). ^{13}C NMR (400 MHz, $CDCl_3$) δ (ppm): 140.0, 138.3, 136.7, 129.3, 128.6, 128.4, 128.0, 127.5, 124.9, 124.2, 124.1, 33.9. Elemental analysis: Calculated for $C_{24}H_{18}N_4S_4$: C 58.75%, H 3.70%, N 11.42%. Found: C 58.98%, H 3.93%, N 12.18%.

Synthesis of 5,5′-bis(3,4-ethylenedioxythiophene-2-yl)-1,1′-dimethyl-2,2′-biimidazole, 7

5,5′-Dibromo-1,1′-dimethyl-2,2′-biimidazole (0.185g; 0.58 mmol) was dissolved in a solution of $Pd(PPh_3)_2Cl_2$ (0.041 g, 0.058 mmol) in dry DMF (50 mL). 5-Tributyltin-3,4-ethylenedioxythiophene (0.623 g, 1.44 mmol)[35] was added through a syringe, and the resulting mixture was refluxed. The appearance of the mixture changed from a pale yellow to a deep brown overnight. Following removal of the solvent, the product was extracted from the residue with CH_2Cl_2, using a Soxhlet extractor. The resulting solution was dried over $MgSO_4$, filtered, and concentrated on a rotary evaporator. The residue was redissolved in CH_2Cl_2 and precipitated by dropwise addition of petroleum ether. A pale, yellow product obtained, and was dried in vacuo. Yield: 0.241 g (94%). Mp 238–240 °C ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm): 7.25 (s, 2H), 6.44 (s, 2H), 4.26 (s, 8H), 2.98 (s, 6H). ^{13}C NMR (400 MHz, $CDCl_3$) δ (ppm): 141.6, 139.6, 139.4, 129.1, 126.1, 104.5, 100.1, 68.8, 68.5, 33.6. Elemental analysis: Calculated for $C_{20}H_{18}N_4O_4S_2$: C 54.29%, H 4.10%, N 12.66%. Found: C 54.89%, H 4.25%, N 12.29%.

Results and discussion

Synthesis

An early report concerning the synthesis of 2,2′-biimidazole involved bubbling ammonia gas into a solution of glyoxal to obtain the product as a light brown powder after purification.[36] Other preparations have emerged since this time[37]; however, we chose to use a modified version of the above route, since the reactants for this approach were readily available and because of the route's simplicity. We obtained better yields through a slow addition of NH_4OH(aq) to a cooled, covered glyoxal solution. The product could be recrystallized from DMF to yield small, pale-yellow crystals; however, even without recrystallization, the product was pure enough to proceed with the next step. 1,1′-Dimethyl-2,2′-biimidazole was produced following a literature method.[32] On each occasion, the preparation was carried out in our hands, the reaction of dimethyl sulfate with deprotonated 2,2′-biimidazole yielded an acidic solution, unlike the mixture described by Logemann and co-workers.[32] Neutralization was thus accomplished with a bicarbonate salt rather than HCl, as described. A Stille coupling reaction involving 5,5′-dibromo-1,1′-dimethyl-2,2′-biimidazole was used to attach 2,2′-bithiophene and 3,4-ethylenedioxythiophene (EDOT) groups to the 2,2′-biimidazole moiety. Because of overlap with the solvent peak for **6** in $CDCl_3$, a coupling constant for the signal at 7.26 ppm could not be determined. Both **6** and **7** were soluble in chloroform and dichloromethane, and insoluble in hexanes and petroleum ether, which permitted their precipitation from a mixed solvent system. The carbon content in the elemental analysis data for **7** is slightly high, a result of residual grease used in the preparation of this compound, which could not be removed after repeated washing with petroleum ether (Weak signals at 0.93 and 1.26 ppm could be seen in the ^{1}H NMR spectrum for this compound).

Electrochemistry

Both **6** and **7** were able to be electrochemically polymerized using cyclic voltammetry from 1 mmol L^{-1} monomer solutions in CH_2Cl_2/0.1 mol $L^{-1}Bu_4NPF_6$. Cyclic voltammtery is often utilized in electrochemical polymerization experiments because it provides real-time "evidence" of electrochemical coupling. During potential cycling, electroactive polymer films deposited onto the electrode sufaces. With each potential cycle, as more electroactive polymer material is formed, a greater amount of charge is stored in the immobilized film. As a consequence of this, greater currents will be observed with each scan (Fig. 1). Films prepared by anodic electropolymerization are typically grown by recurrent cycling of the working electrode potential between a low limit (0 V vs. calomel electrode in this study), at which the monomer is not involved in an electron-transfer reaction, and a potential just above the monomer's peak oxidation potential. Poly-**6** and poly-**7** films were also able to be grown at constant applied potentials; however, no significant differences were observed in the cyclic voltammograms grown by potentiostatic polymerization versus potentiodynamic polymerization. Oxidation of **6** yielded a peak at ~0.90 V and a following wave centered at ~1.05 V. It was necessary to cycle the working electrode potential as high as 1.30 V to produce poly-**6**-coated modified electrodes having good coverage. Poly-**6** films were grown by cycling the working electrode potential 10 times, and were obtained as dark yellow films on platinum and ITO-coated glass substrates. These films were dark green in the oxidized state. For **7**, an oxidation peak is observed at ~0.84 V on the first scan; this peak decayed on subsequent scans. Repetitive potential cycling between 0 V and 0.90 V suggested sustained polymerization of the monomer; however, visual inspection of the electrode surface following these experiments indicated that the surface coverage of the film was quite poor, even after 20 potential cycles. Scanning through a second oxidation peak at ~1.15 V permitted polymer-film deposition. Thus, poly-**7** films were deposited by potential cycling within a 0 V to 1.20 V window. The films produced in this manner were dark green.

Fig. 1. Anodic polymerization of (*a*) **6** and (*b*) **7** from 1 mmol L^{-1} solutions of each monomer in CH_2Cl_2/0.1 mol L^{-1} Bu_4NPF_6.

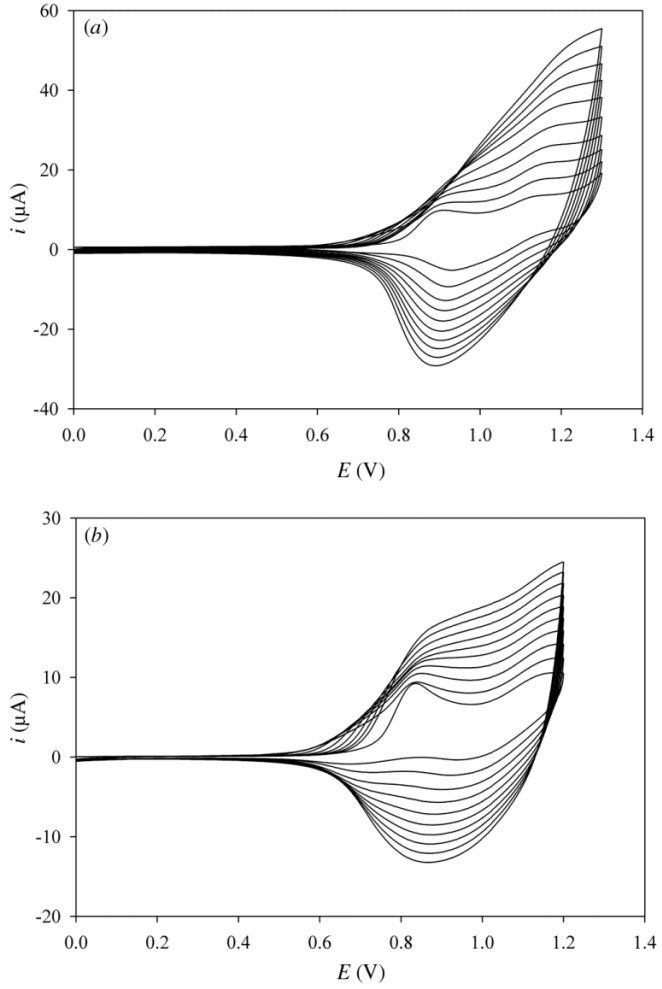


Fig. 2. P-doping and n-doping experiments for (*a*) poly-**6** and (*b*) poly-**7** in CH_3CN/0.1 mol L^{-1} Et_4NClO_4.

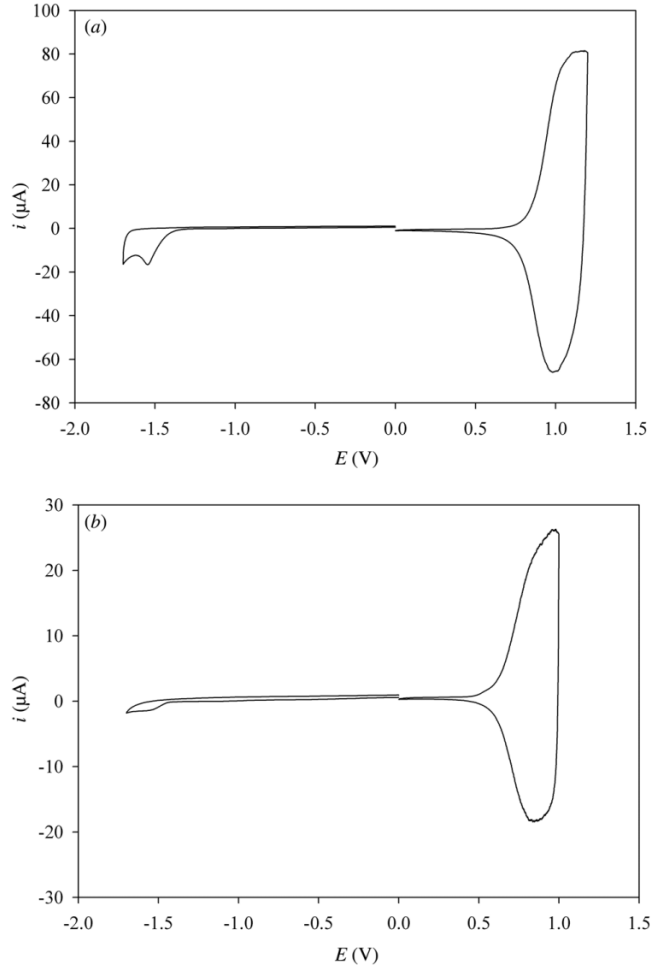

While distinct oxidation processes were observable for both monomers **6** and **7**, it was found that reduction peaks for neither monomer were observed within the electrochemical window provided by the CH_2Cl_2/Bu_4NPF_6 medium.

Immediately following their preparations, the polymer films were studied in monomer-free CH_3CN/0.01 mol L^{-1} Et_4NClO_4 solutions (Fig. 2). The voltammograms shown in this figure illustrate the films' redox behavior after two complete cycles of the working electrode potential (0 V → λ → 0 V; λ = 1.20 V for poly-**6** and 1.00 V for poly-**7**). It was found that the appearance of the voltammograms did not change significantly in subsequent cycles. Oxidation of the polymers yields their p-doping, while reduction yields n-doped polymers. Poly-**6** films were stable when p-doped; however, at potentials above 1.20 V, significant decreases in doping/undoping currents were observed, suggesting deactivation of the poly-**6** conjugated backbone under these conditions. This outcome is likely due to attack of oxidized sites in the p-doped polymer by trace nucleophiles present in the solvent–electrolyte system. It is expected that such reactions would occur at electron-rich tetrathiophene segments of poly-**6**, rather than at dimethybiimidazole segments. Oxidation of thiophene at potentials that yield its polymerization is known to result in decreased conjugation lengths in the resulting polymers.[38] For poly-**6**, the p-doping and undoping peaks are centered around 1.05 V. Interestingly, a small reduction peak for poly-**6** was found at ~ –1.65 V, which was not present in subsequent scans. This observation, as well as the magnitude of the peak (compared with the peak observed for p-doping) suggests that n-doped poly-**6** is less stable than its p-doped form. Poly-**7** films were stable at applied potentials of up to 1.00 V. The p-doping/undoping peak for poly-**7** is centered at ~0.88 V, a significantly lower potential than what was found for poly-**6** films. Polymerized 3,4-ethylenedioxythiophene (PEDOT) films have been shown to undergo oxidation at low potentials to produce very stable p-doped materials.[39] The fused, electron-donating dioxyethylene component in EDOT facilitates oxidation in this structure and also enhances stereoregularity in polymers by preventing α–β′ coupling. A slight reduction wave for this polymer was evident at ~ –1.60 V, which was absent on following scans. Cyclic voltammograms collected at varying scan rates for these polymers indicate that the electrochemical reactions observed during p-doping/undoping cycles are surface-confined, and not due to reactions involving a solution species (i_p is proportional to the square root of the scan rate). Figure 3 illustrates the scan-rate-dependence behavior of a poly-**6** film.

Fig. 3. Cyclic voltammograms for poly-**6** film at scan rates = 0.025, 0.050, 0.075, 0.100, 0.125, and 0.150 V s^{-1}. Scan rate increases in the direction indicated by the arrow.

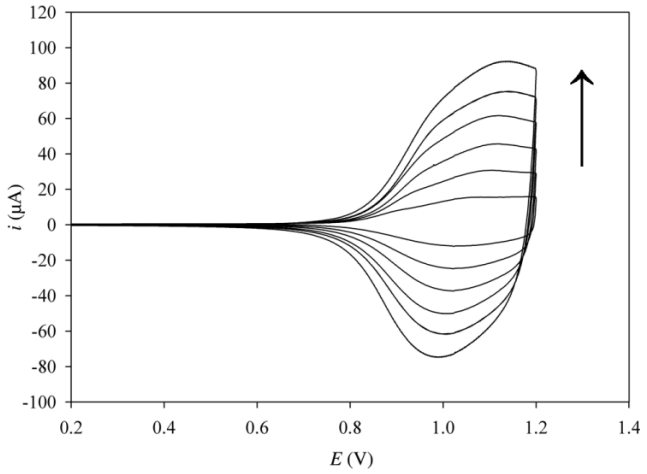

Table 1 presents a comparison of data for **6**, **7**, poly-**6,** and poly-**7** films with the related systems, 5,5′-bis(2,2′-bithiophene-5-yl)-1,1′-dimethyl-2,2′-bipyridine (**9**) and 5,5′-bis(2-thienyl)-2,2′-bithiazole (**10**) (Chart 1), from cyclic voltammetry and electronic absorption spectroscopy experiments.[34,35,40] Data in Table 2 present AM1 energies for the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) in each of these same systems. The 2,2′-bipyridine-containing system, **9**, displays the lowest HOMO energy in the series, while **7** possesses the highest LUMO energy. Since oxidation involves the HOMO, it should be expected that oxidation will be observed at a higher potential for poly-**9** than for poly-**6** and poly-**7**. Likewise, reduction of poly-**9** should occur at higher (less negative) potentials as compared with poly-**6** and poly-**7**. Experimentally, oxidation is found to occur at higher potentials for poly-**9**, and a distinct reduction process is observable for this polymer.[34] On the basis of the calculated energies, it should be easier to reduce poly-**6** than poly-**7**; however, the above experiments demonstrate that both poly-**6** and poly-**7** are unstable when n-doped. The higher HOMO energy in **7** supports the notion of the greater electron-donating capacity of the EDOT groups in this compound, as compared with the bithiophene substituents of **6**. Poly-**10** incorporates bithiophene segments in its conductive backbone, unlike the tetrathiophene links present in poly-**6**, poly-**7**, and poly-**9**. Poly-**10** would thus be expected to undergo p-doping at the highest potential, and this is confirmed by the data presented in Table 1.

Electronic absorption spectrophotometry

Polymer-coated ITO electrodes for electronic absorption studies could be grown as described above, through cyclic voltammetry experiments. However, more uniform films could be grown on ITO-coated glass electrodes by application of a constant potential, and so this approach was used to coat electrodes for electronic absorption studies. The best results were found for poly-**6** films grown at 1.25 V and poly-**7** films grown at 1.00 V.

Table 1. Comparison of electrochemical data (formal potential for oxidation, $E^{\circ\prime}$) and spectroscopic data (λ_{max}, λ_{onset}) for poly-**6** and poly-**7** with related 2,2′-bipyridine and 2,2′-bithiazole systems. The data for poly-**9** were reported in MeCN/0.1 mol L^{-1} Bu_4NPF_6 vs. Ag wire (ferrocene internal reference) and poly-**10** data in MeCN/0.1 mol L^{-1} Et_4NClO_4 vs. SSCE. Polymer absorption data are presented for solid films deposited onto ITO-glass slides, while the monomer data are presented for CH_2Cl_2 solutions.

Compound	$E^{\circ\prime}$	λ_{max} (nm)	λ_{onset} (nm)
6	—	364	430
7	—	316	370
9	—	400	442
10	—	404	—
Poly-**6**	1.05	402	532
Poly-**7**	0.88	326	418
Poly-**9**	1.12	—	—
Poly-**10**	1.24	—	—

Table 2. Semi-empirical AM1 HOMO and LUMO energies for **6**, **7**, **9**, and **10**.

Compound	HOMO (eV)	LUMO (eV)
6	–7.957	–0.936
7	–7.807	–0.657
9	–8.363	–1.169
10	–8.464	–1.375

Data obtained in electronic absorption studies are summarized in Table 1. Absorption peaks (λ_{max}) for **6** and **7** were found at 364 nm and 316 nm, respectively. For the polymer films, absorption peaks were broader, and red-shifted (Fig. 4). The peak absorption for poly-**6** was shifted by about 38 nm, and was considerably broader. Conversely, λ_{max} for poly-**7** was found to be red-shifted by only 10 nm. These red shifts can be explained by an enhanced degree of conjugation in the longer polymer structures relative to what exists in the monomers. It is also acknowledged here that absorption data obtained for monomers will be influenced by solvents, and that absorption data for solid polymers will be influenced by counter-ions to a small degree. The broader polymer absorption profiles can be attributed to the polydispersity of poly-**6** and poly-**7,** as well as non-uniform (α–α′, α–β′) links between thiophenes in poly-**6** chains. The absorption peak observed for poly-**7** was less broad than for poly-**6**, likely a consequence of the greater stereoregularity provided by the EDOT substituents of **7**. HOMO–LUMO energy differences for **6** and **7** can be estimated using the low energy wavelength edge (λ_{onset} in Table 1) for π–π* absorptions. These energies are 2.88 eV for **6** and 3.35 eV for **7**. Optical bandgaps for the polymer films, estimated from λ_{onset} values, are found to be 2.33 eV for poly-**6** and 2.97 eV for poly-**7**.

A comparison of the absorption data shows that **9** displays a smaller optical bandgap than the other systems considered here. Since both **6** and **7** undergo oxidation at comparatively

Fig. 4. Normalized electronic absorption spectra for monomers and polymers. Monomer spectra collected on CH_2Cl_2 solutions. Polymer spectra collected for poly-**6**- and poly-**7**-coated ITO-glass electrodes with a bare ITO electrode used for baseline correction.

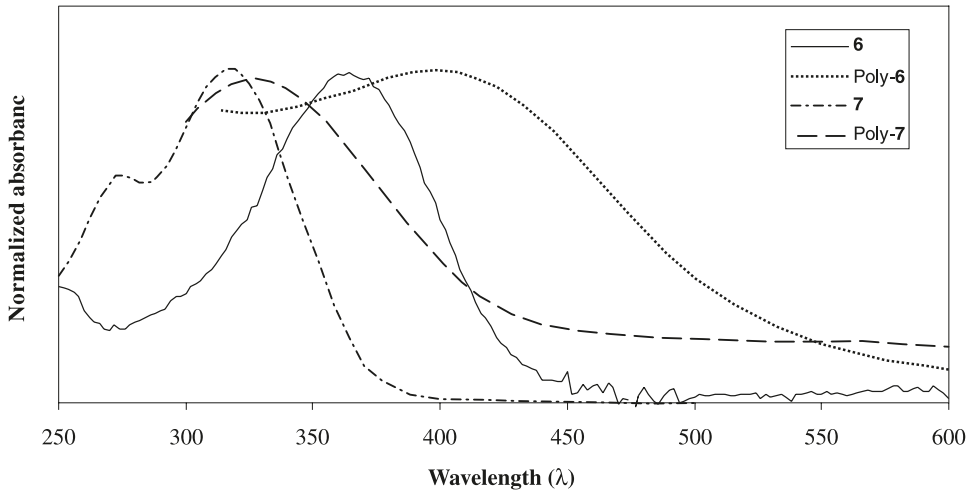

Fig. 5. Atomic force microscopy images of top: poly-**6**; middle: poly-**7**; and bottom: a bare ITO-coated glass slide. Images are presented as 3-D surfaces (left) and 1st derivatives (right).

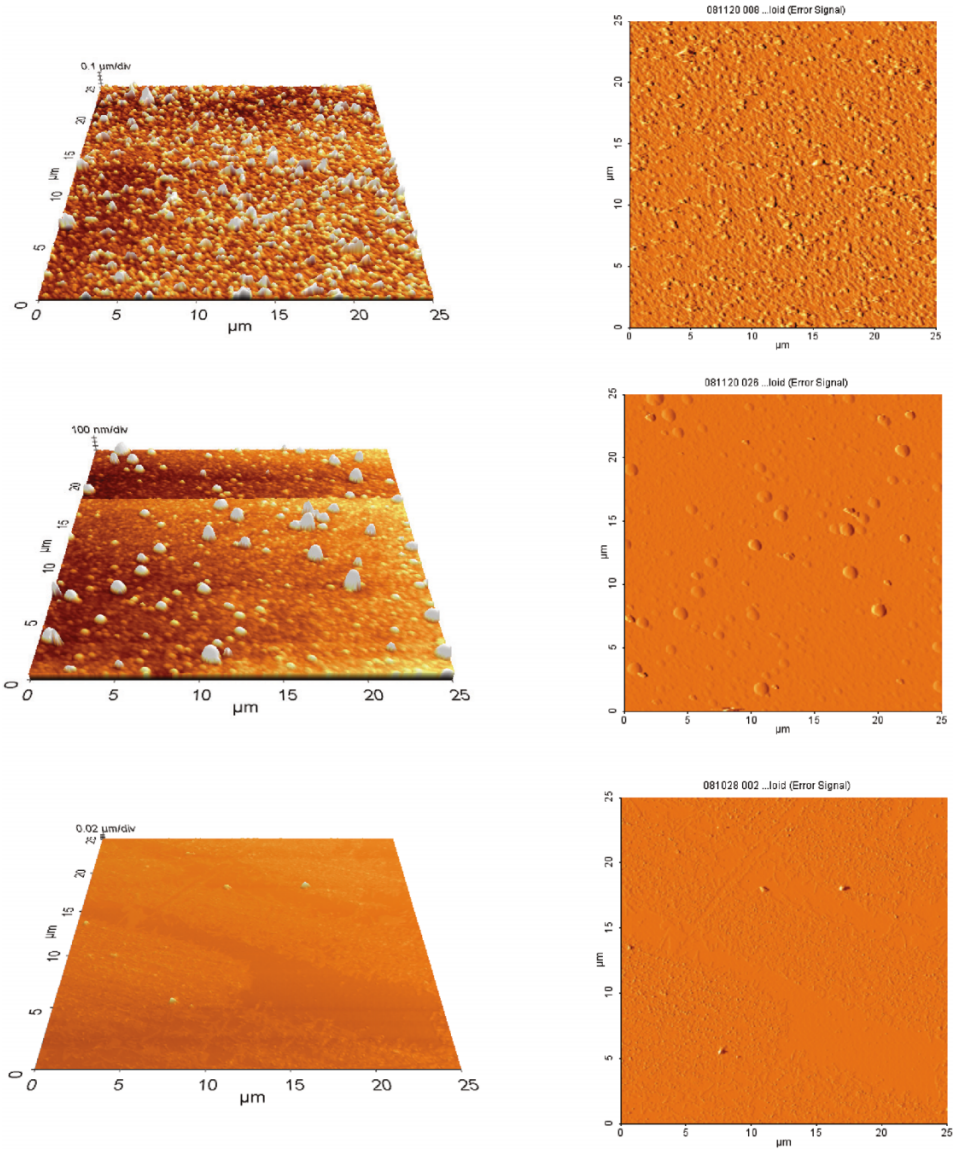

low, positive potentials, it would be expected that reduction of both of these monomers must require quite negative potentials, presumably a consequence of the greater electron-donating nature of the dimethylbiimidazole center. Indeed, we were unable to observe these processes in our experiments.

Atomic force microscopy

Atomic force microscopy (AFM) was used to investigate the topography of poly-**6** and poly-**7** films deposited onto ITO-coated glass electrodes (Fig. 5). These films appeared smooth to the naked eye. The 25 μm × 25 μm images of poly-**6** show a fairly homogeneous polymer surface, with polymer particles of roughly 1 μm diameter distributed on the electrode surfaces. Note that the vertical scale in this image is roughly one-tenth the *x*- and *y*-axis scales. The poly-**7** surface looks smooth in most areas, but also shows regions where larger grains have deposited, of approximately 1 μm diameter, on average.

Conclusions

Two novel thiophene–imidazole structures have been synthesized, and their electrochemical and electronic properties were investigated. Polymer films of 5,5′-bis(2,2′-bithiophene-5-yl)-1,1′-dimethyl-2,2′-biimidazole and 5,5′-bis(3,4-ethylenedioxythiophene-2-yl)-1,1′-dimethyl-2,2′-biimidazole were grown on platinum and indium-tin oxide-coated glass through electrochemical polymerization. The films deposited were fairly homogeneous, as indicated by AFM studies. The facile polymerization of these materials and the potential to vary the identity of the substituent on N_1 makes these materials promising candidates for further studies aimed at creating supports for tunable heteogeneous electrocatalysts.

Acknowledgements

We gratefully acknowledge the Natural Sciences and Engineering Research Council of Canada (NSERC) and St. Francis Xavier University for funding this work. We would also like to express our gratitude to the Canada Foundation for Innovation (CFI) for a Leaders Opportunity Fund award, which permitted the purchase of instruments used in this study.

Stable phenylene- and biphenylene-bis(isobenzofuran)s related to diphenylisobenzofuran

Sheri A. Klassen, Richard Boehme, Sean D. Derrick, Klaus Moock, A. Elizabeth Baker, Deryn E. Fogg, René T. Boeré, and Peter W. Dibble

Abstract: A series of phenyl-substituted bis(isobenzofuran)s in which the furan moieties are linked by 1,3-phenylene, 1,4-phenylene, or 4,4′-biphenylene linkers have been prepared in only two steps. They are comparable to diphenylisobenzofuran in their absorption and luminescent properties, their electrochemistry, and their reactivity. Their degree of similarity to diphenylisobenzofuran was found to depend significantly on the nature of the linking group. Diels–Alder reaction of the title compounds and subsequent aromatization gave very rapid access to penta- or hexa-aryl products.

Key words: isobenzofuran, diphenylisobenzofuran, fluorescence, UV spectroscopy, electrochemistry, pentaphenyl, hexaphenyl.

Résumé : On a préparé, par des réactions n'impliquant que deux étapes, une série de bis(isobenzofuranes) substitués par un groupe phényle dans lesquels les portions furanes sont liées par des tronçons 1,3-phénylène, 1,4-phénylène ou 4,4′-biphénylène. Par leurs propriétés d'absorption et de luminescence, d'électrochimie et de réactivité, ces produits se comparent au diphénylisobenzofurane. On a observé que leur degré de similarité avec le diphénylisobenzofurane dépend beaucoup de la nature du groupe qui les relie. La réaction de Diels–Alder des composés mentionnés dans le titre et l'aromatisation subséquente des produits obtenus donne un accès très rapide aux produits penta- ou hexarylés.

Mots-clés : isobenzofurane, diphénylisobenzofurane, fluorescence, spectroscopie UV, électrochimie, pentaphényle, hexaphényle.

[Traduit par la Rédaction]

Commercially available 1,3-diphenylisobenzofuran (**1**, Fig. 1) has found wide application in the identification of reactive olefins, as an analytical tool for measuring the rate of singlet-oxygen generation and is of interest for its fluorescence, electrochemical, chemi-, and electro-luminescent properties.[1,2] Examples have also been used as electron-transport materials.[3] The chemistry of the parent hydrocarbon isobenzofuran (IBF, **2**) and its derivatives continues to be of significant interest and has been reviewed regularly.[1,2,4–8]

In view of the many useful properties of **1**, we now wish to report the efficient synthesis of several compounds (**3a**–**3c**, Fig. 1) closely related to **1** but bearing two isobenzofuran moieties linked via one or two aromatic rings. Subsequent elaboration of these compounds into penta- and hexa-aryls is also described. Most preparations of diarylisobenzofurans are based on the addition of Grignard reagents to anhydrides or phthalides.[1,9] This work extends that of a report describing the preparation of teraryls via adducts of phenylenebis(isobenzofuran)s in which the furan species is generated transiently[10] from hemiaminal precursors.[11]

The title compounds were prepared in only two steps (Scheme 1) using an extension of methodology previously developed.[11] Phenyllithium was added to 2-bromobenzaldehyde, and the resulting addition product was metalated with *n*-BuLi. Addition of the appropriate dicyanoaryl gave, after hydrolysis, hemiaminal **4** as a mixture of diastereomers. The ^{1}H NMR spectrum of **4** contained singlets between 6.2 and 6.5 ppm corresponding to the methine protons on the furan ring of diastereomeric products. The oily hemiaminal product was refluxed with *p*-toluenesulfonic acid (TsOH) to form the stable IBFs (**3**) in approximately 50% yield (based on dinitrile).

A second method could also be used to prepare 4,4′-biphenylenebis(3-phenylisobenzofuran) (**3c**) (Scheme 2). Metalation of 4,4′-dibromobiphenyl and reaction of the dianion with 2 equiv. of bromobenzaldehyde was followed by metalation with *n*-butyllithium. Subsequent reaction with benzonitrile followed by hydrolysis gave hemiaminal **5**, confirmed by the appearance of two peaks at 6.24 ppm and 6.42 ppm in the ^{1}H NMR spectrum as for compound **4**. The hemiaminal and a catalytic amount of TsOH were refluxed in methanol to form the stable IBF (**3c**) in 39% yield (from 4,4′-dibromobiphenyl).

The three title compounds are all highly coloured: **3a** is a beautiful blood red, **3b** is orange, and **3c** is yellow. Solutions

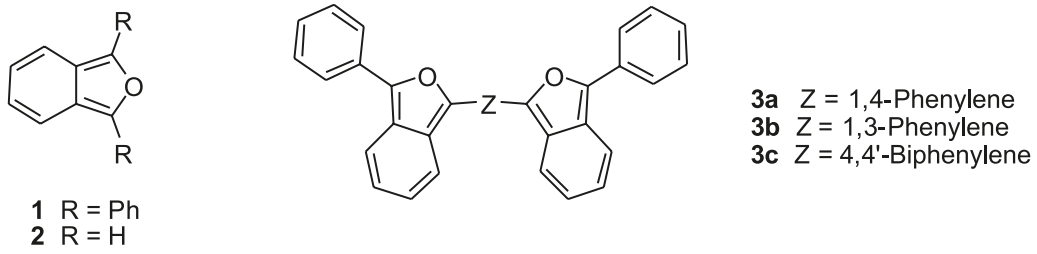
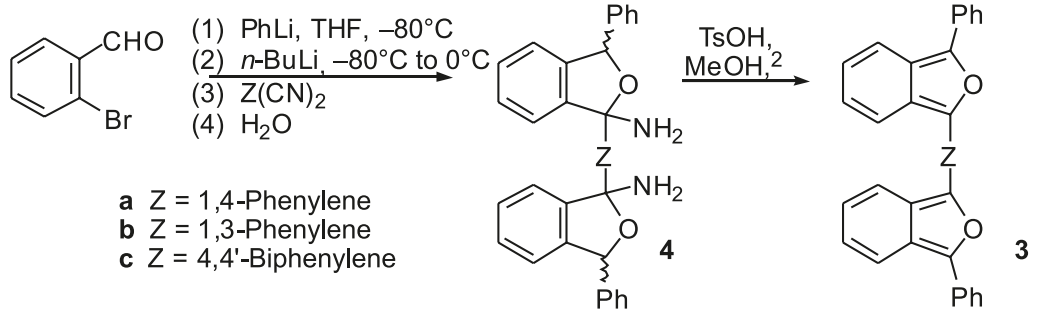
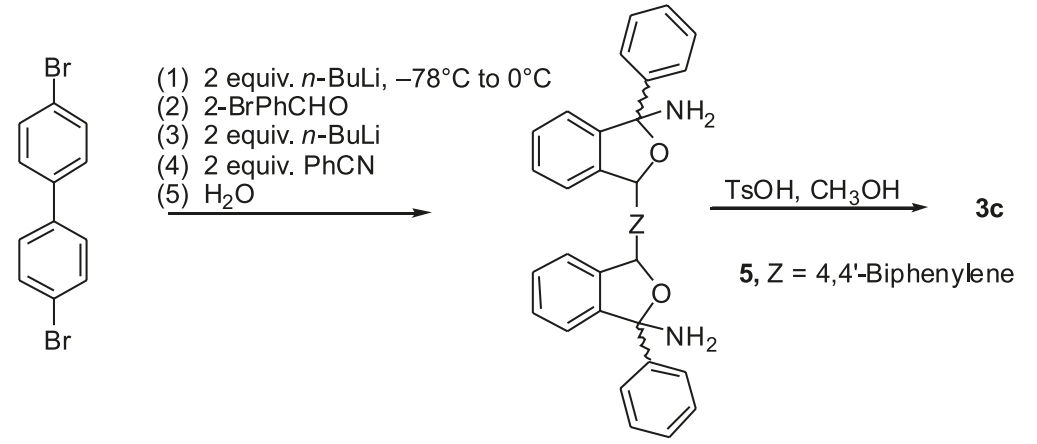


Scheme 1. Synthesis of **3a**–**3c.**



Scheme 2. Alternative synthesis of **3c**.



of all three compounds are also highly coloured and show the same fluorescent character as **1**, especially when irradiated with long-wavelength UV radiation. Example **3b** resembles **1** most closely in its visible fluorescence in solution.

The NMR spectra of **3** were largely unremarkable. The presence of a ring current in isobenzofurans is well-established, and all of the protons and carbon resonances were found in the aromatic region. In the carbon spectra, the quaternary carbons next to oxygen were found downfield in the 140 ppm region, typical for carbons of this type. In the proton NMR spectra, the typical AA′BB′ patterns of the isobenzofuran rings were obscured by the resonances of the phenyl substituents. Some protons of the central aromatic linker all experience significant downfield shifts: in **3b**, there is a singlet at 8.49 ppm (the proton between the two isobenzofurans); in **3a**, a four-proton singlet appears at 8.10 ppm; in **3c**, the biphenyl protons appear as an AB quartet centered at 7.80 ppm and 8.04 ppm. In **1**, the protons on the phenyl substituents ortho to the isobenzofuran appear at 7.9 ppm. These shifts are likely the result of steric-contact deshielding,[12,13] additive in the downfield signal of **3b**.

The UV absorbances for **1** and **3a**–**3c** are given in Table 1. For **1**, there are two principal bands at 415 and 261 nm. The latter band is common to all of **3a**–**3c** and is likely due to the phenyl substituents. The longer wavelength band of **1**, attributed to a π–π^* transition[1] is matched by one in **3b**, while in **3c** and **3a**, this band is found at progressively longer wavelength. These, and other data, make it clear that of **3a**–**3c**, it is the meta-substituted **3b** that most closely resembles **1**. Its high-wavelength band is found in the same position as **1**, while the other two examples exhibit significant red shifts expected of extended conjugation. Interestingly, of **3a** and **3c**, it is the smaller π-system of **3a** that exhibits the greatest red shift. We attribute this to steric hindrance about the biphenyl linkage that inhibits coplanarity of the π-systems, a structural feature that is absent in **3a**.

Emission data for this series of compounds are presented in Table 2. The luminescence properties of diarylisobenzo-

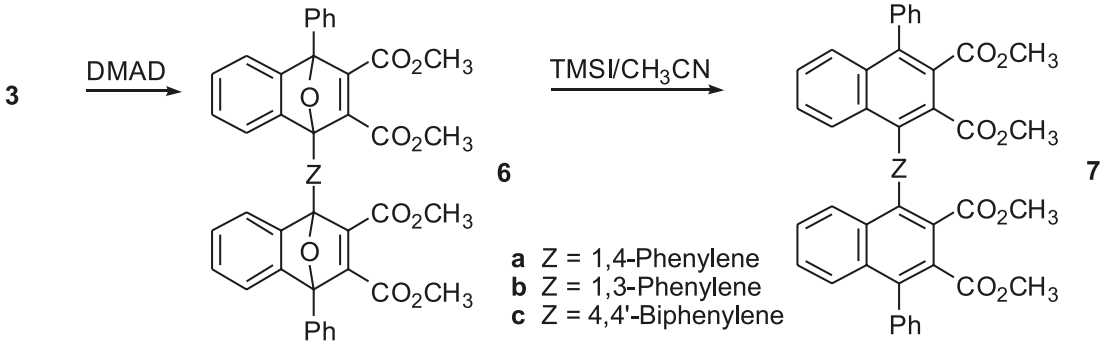
furans have been summarized.[1] The emission spectrum of **3b** is almost identical to that observed for **1**, exhibiting two bands at equal intensity at 461 and 480 nm. The trends for this series of compounds observed in the UV spectra are repeated here. Example **3a** has its fluorescence band shifted to higher wavelength to the greatest extent and appears as a single broad band. Compound **3c** is intermediate between the other two in terms of the position of its principal bands. Its spectrum differs in that it has an additional band at 333 nm (a band corresponding to the fluorescence band of biphenyl) and a shoulder at 470 nm.

The electrochemistry of **1** has been investigated, and we compared its behavior with **3a–3c** (Table 3). Compound **3a** shows four reduction processes and one oxidation process. Compounds **3b** and **3c** show four and three reductions, respectively, while **1** has two reductions and one oxidation. The data indicate **3a** is more easily reduced than **1**, but **3b** and **3c** are more difficult to reduce. The mechanism of reduction of **3a** and **3b** can be speculated by comparison with **1**. It can be estimated that the difference between the first reduction potential and the second reduction potential of **1** is in general the potential required to form a doubly reduced IBF dianion from the anion radical. For **1**, the second reduction requires an additional 0.54 V from the anion radical. The difference in potential for $[\mathbf{3a}]^{0/-}$ and $[\mathbf{3a}]^{-/2-}$ is 0.16 V, which is less than that required to form a doubly reduced IBF. This suggests that each IBF in **3a** has been reduced once. The next reduction requires an additional 0.58 V, which corresponds to the potential required to form a doubly reduced IBF. The magnitude of the potential of $[\mathbf{3a}]^{3-/4-}$ is comparable to the second reduction for **1**. A similar comparison can be made for **3b**. The data obtained for **3c** are not consistent with that of the other examples but may be compromised due to poor solubility in THF. The anions produced, excluding the anion formed from the last reduction, are stable under the conditions of the electrochemical experiment and may or may not be stable outside the conditions of the experiment.

The physical appearance, UV–visible spectra, and electrochemical data all show that it is meta-substituted **3b** that most closely resembles **1**. The other examples indicate that the through-conjugated connecting rings offer a better electronic interaction between the IBF moieties. This is seen in the shift of the 415 nm UV band of **1** to lower wavelengths in **3a** and **3c**. It is also consistent with the relative ease of reduction of **3a** in comparison to **3b**. We are interested in preparing polymeric versions of these molecules with alternating phenylene or biphenylene and isobenzofuran rings. These examples suggest that if one desires a polymeric form of **1**, then meta-phenylene linkages will serve to electronically insulate the IBF rings such that they retain the character of **1**. If it is desirable to tune the electronic properties of the IBF rings conjugatively, then through-conjugative linkages will work best.

Not surprisingly, **3a–3c** react in a fashion identical to **1**. When refluxed with an excess of dimethyl acetylene dicarboxylate (DMAD), Diels–Alder adducts **6** (Scheme 3) were isolated in yields of 67% to 75%, as mixtures of diastereomers. The presence of a mixture was clear in the case of **4c** where there were many methyl peaks evident in the proton NMR. In the case of **3a** and **3c**, the spectra showed only the number of peaks expected of a single diastereomer.

Scheme 3. Diels–Alder reactions.



There is no reason to expect any diastereoselectivity in this reaction, however, so we conclude that the diastereomers formed in this reaction have identical NMR spectra. The adducts were deoxygenated by treatment with trimethylsilyl iodide[15,16] to form polyaryls **7**. This represents a very efficient synthesis of such molecules in only four steps from commercially available materials.

We did not anticipate, nor did we observe, any difference in reactivity between **3a**–**3c** and their DMAD monoadducts. Significant rate differences in fused difuran systems have been observed.[17] Reaction of **3a** with 1 equiv. of DMAD gave a mixture of monoadduct, bisadduct, and starting material. The presence of the monoadduct during reaction could be observed visually during the Diels–Alder reactions by the presence of the characteristic yellow-green colour of the diphenylisobenzofuran chromophore.

In summary, we have prepared and characterized a series of novel bis(isobenzofuran)s with properties similar to 1,3-diphenylisobenzofuran. The syntheses are efficient and should be easily generalized to other substituted examples. Reaction with DMAD and subsequent aromatization gives rapid access to penta- or hexa-aryl systems.

We have begun to explore the possibilities of preparing polymeric versions of **3** as well as preparing Diels–Alder polymers by reaction of **3** with quinone, DMAD and bis(maleimide) dienophiles. Furan/maleimide polymers have been reported to be self-mending.[18] Other examples of monomers based on diarylisobenzofurans have been reported.[19,20]

Experimental section

Cyclic voltammetric (CV) studies (scan rates N = 20–5000 mV/s) were made with a PAR 173 potentiostat, 175 Universal Programmer and recorded on a Houston Graphics 2000 XY plotter. Electrochemical experiments were performed on a platinum three-electrode system with the platinum working electrode either a 0.5 mm Pt wire or a 0.5 mm diameter Pt micro-tip. A positive feedback circuitry was employed to minimize iR drop losses. The vacuum-tight all glass electrochemical cell has been described in detail elsewhere.[21] The cell was charged with the supporting electrolyte NBu_4PF_6 with solvent THF. Compounds under investigation and ferrocene acting as an internal reference compound were added to the cell using break-seal techniques. Ferrocene was sublimed prior to use.

NMR spectra were recorded on a Bruker AC250 MHz spectrometer unless otherwise indicated. Melting points were performed in open capillaries and are uncorrected. Mass spectra were obtained from the Mass Spectroscopy Lab at the University of Alberta or the Centre for Molecular Architecture, Central Queensland University. Combustion analyses were performed by MHW Labs in Phoenix, Arizona.

1,4-Phenylenebis(1,3-dihydro-3-phenyl-1-isobenzofuranamine), 4a

In 300 mL of dry THF was dissolved 2-bromobenzaldehyde (3.5 g, 19 mmol), purged with N_2, and cooled to –80 °C. Phenyllithium (11 mL of a 1.8 mol/L solution in cyclohexane/ether, 20 mmol) was added by syringe. After 10 min, the reaction was warmed to room temperature. A small aliquot analyzed by proton NMR showed the presence of aldehyde, so an additional 1 mL of phenyllithium was added. After 5 min, the reaction was cooled to –80 °C, and 8.0 mL of 2.5 mol/L *n*-BuLi (in hexanes, 20 mmol) was added. After 15 min, the reaction was warmed to 0 °C, and stirring was continued for 20 min. An aliquot, quenched with water, was analyzed by proton NMR and indicated the loss of bromine. 1,4-Dicyanobenzene (1.09 g, 9.1 mmol) was added to the solution in a single portion, and the solution went dark. The reaction was allowed to warm to room temperature and stirred for 10 h. Water (300 mL) was added, and the reaction mixture was then extracted with diethyl ether (250 mL). The organic phase was separated and dried over $MgSO_4$. After filtration, the solvent was removed under reduced pressure and the residue recrystallized in methanol to give 2.0 g **4a** (63%) as a mixture of diastereomers: mp 90 °C (dec.). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 2.50 (s, 4H, exchanges with D_2O), 6.14 and 6.33 (s, 2H), 6.91–7.51 (m, 18H), 7.72 (s, 4H). ^{13}C NMR (62.5 MHz, $CDCl_3$) δ: 82.9, 83.6, 98.59, 98.62, 98.71, 98.77, 122.28, 122.32, 122.37, 123.08, 123.12, 123.15, 123.3, 125.45, 125.6, 126.3, 126.4, 126.5, 127.2, 128.1, 128.25, 128.31, 128.37, 128.57, 128.64, 128.7, 140.7, 141.1, 141.75, 141.84, 141.86, 143.3, 143.9, 144.11, 144.17, 144.20. IR (KBr): 3391 and 3320, 1264, 1032, 1015, 953, 743 cm^{-1}. MS (EI) *m/e*: 478 (4), 462 (100), 295 (23), 231 (23), 165 (22), 154 (39), 85 (51), 83 (78). Analysis calcd. for $C_{34}H_{28}N_2O_2$: C, 82.23; H, 5.68; N, 5.64. Found: C, 82.00; H, 5.40; N, 5.66.

1,4-Phenylenebis(3-phenyl-1-isobenzofuran), 3a

To 120 mL of methanol were added 315 mg (0.64 mmol) of bishemiaminal (**4a**). The solution was brought to reflux,

and a total of 240 mg (1.26 mmol) TsOH was added over 5 h. After a further two hours at reflux, the solution was cooled and filtered of a bright red solid. Recrystallization from $CHCl_3/CH_3OH$ gave 222 mg of **3a** (76%). Use of crude hemiaminal **4a** gave a 63% yield from 1,4-dicyanobenzene: mp 216–218 °C. ^{1}H NMR (250 MHz, CD_2Cl_2) δ: 7.06–7.14 (m, 4H), 7.33 (t, J = 7.4 Hz, 2H), 7.53 (t, J = 7.8 Hz, 4H), 7.88–8.03 (m, 8H), 8.10 (s, 4H). ^{13}C NMR (62.5 MHz, $CDCl_3$) δ: 120.3, 122.4, 122.5, 124.9, 125.0 125.29, 125.35, 127.0, 129.0, 129.7, 131.6, 143.6, 144.0. IR (KBr): 1618, 1493, 829, 760, 683, 657 cm^{-1}. UV–vis (c = 1.0 × 10^{-5}, MeOH) ν_{max}: 261 (4.7), 313 (4.3), 473 (4.4) nm. MS (EI) *m/e*: 463 (M^+ + 1, 36), 462 (M^+, 100), 385 (2), 231 (20), 209 (51), 165 (6), 105 (10), 77 (11). Analysis calcd. for $C_{34}H_{22}O_2$: C, 88.29; H, 4.79. Found: C, 88.16; H, 4.96.

1,3-Phenylenebis(3-phenyl-1-isobenzofuran), 3b

A solution of 150 mL of dry THF and 1.943 g of 2-bromobenzaldehyde (10.50 mmol) was purged with N_2 and cooled to –80 °C with stirring. After 11.2 mL (15.75 mmol) of 1.4 mol/L Ph-Li was added via syringe, the mixture was warmed to 0 °C and allowed to react for 40 min. At –75 °C, 4.4 mL of *n*-butyllithium was added, and after 15 min, the reaction was warmed to 0 °C and allowed to react for 1 h. 1,3-Dicyanobenzene (0.6727 g, 5.25 mmol) was dissolved in dry THF and added very slowly by syringe, and the mixture was warmed to room temperature, reacting for 16 h. After treatment with H_2O, the mixture was extracted three times with ether, separating and collecting the organic phase. The ether was dried over $MgSO_4$, and then removed by vacuum to leave a brown oil. The oil was dissolved in methanol with TsOH (an equivalent amount) and brought to reflux for 4 h. The orange solid that precipitated out of the reaction mixture was recrystallized in methanol/acetone. The mother liquor was washed with 10% NaOH and extracted three times with chloroform. The organic phase was collected, and the solvent was dried over $MgSO_4$ and removed by vacuum leaving a brown oil. The oil was dissolved in acetone/methanol to give crystalline product **3b** (50%): mp 179–182 °C. ^{1}H NMR (250 MHz, $CDCl_3$) δ: 7.03–7.12 (m, 4H), 7.26–7.35 (m, 2H), 7.48–7.62 (m, 5H), 7.84–8.00 (m, 10H), 8.49 (s, 1H). ^{13}C NMR (250 MHz, $CDCl_3$) δ: 120.0, 120.7, 120.9, 122.2, 122.4, 123.1, 124.8, 125.2, 125.1, 127.0, 129.0, 129.4, 131.6, 132.2, 143.4, 144.0. IR (Nujol): 652.07, 676.35, 732.9, 763.81, 775.46, 1207.81, 1498.57, 1593.2 cm^{-1}. UV–vis (c = 1.0 × 10^{-5}, dioxane) ν_{max}: 256 (4.6), 321 (3.8), 413 (4.1) nm. MS (EI) *m/e*: 462 (M^+, 100), 446 (**3c**), 385 (5), 357 (2), 326 (2), 269 (2), 231 (2). Analysis calcd. for $C_{34}H_{22}O_2$: C, 88.29; H, 4.79. Found: C, 88.10; H, 5.00.

4,4′-Biphenylbis(3-phenyl-1-isobenzofuran), 3c from 4,4′-dibromobiphenyl

In a two-necked round-bottom flask, equipped with a stir bar and stoppers, a mixture of 4,4′-dibromobiphenyl (0.50 g, 1.60 mmol) and dry THF was purged with N_2 and cooled to –80 °C. After *n*-butyllithium (2.5 mol/L, 1.41 mL, 3.53 mmol) was added via syringe, the mixture was warmed to 0 °C and allowed to react for 40 min. At –75 °C, 2-bromobenzaldehyde (0.35 mL, 3.2 mmol) was added dropwise. The mixture was warmed to 0 °C, then to room temperature, and stirred for 16 h. After *n*-butyllithium (2.5 mol/L, 1.4 mL, 3.5 mmol) was added at –75 °C, the mixture was warmed to 0 °C and allowed to react for 40 min. At 0 °C, 0.36 mL (3.53 mmol) of benzonitrile was added. The mixture was warmed to room temperature and allowed to react for 1.5 h leaving a bright red-orange, fluorescent solution. The reaction was quenched with H_2O (120 mL) and extracted three times with ether. The organic phases were collected, dried over $MgSO_4$, and removed under vacuum to leave an orange oil. The yellow oil was dissolved in methanol, with a catalytic amount of PPTS and was brought to reflux with stirring. After 16 h, the reaction showed no change, and TsOH monohydrate was added and the mixture immediately turned from pale green to orange with solid precipitating out of solution. Recrystallization from DMF gave **3c** (39%): mp 296 °C (darkens, dec.). ^{1}H NMR (250 MHz, CD_2Cl_2) δ: 7.00–7.04 (m, 4H), 7.26 (t, J = 7 Hz, 2H), 7.45 (t, J = 7 Hz, 4H), 7.77–8.04 (m, 16H). IR (KBr): 657.8, 692.5, 742.6, 761.9, 821.7, 1491.1, 1595.2, 1676.2 cm^{-1}. UV–vis (c = 9.5 × 10^{-6}, dioxane) ν_{max}: 270 (4.3), 447 (3.9) nm. MS (EI) *m/e*: 538 (M^+, 100), 346 (35), 269 (14), 239 (16), 209 (17), 105 (25), 77 (20), 73 (57). Analysis calcd. for $C_{40}H_{26}O_2$: C, 89.19; H, 4.87. Found: C, 88.92; H, 4.98.

4,4′-Biphenylenebis(3-phenyl-1-isobenzofuran), 3c from 4,4′-dicyanobiphenyl

In 125 mL of dry THF was dissolved 2-bromobenzaldehyde (2.0 g, 10.8 mmol), and the solution cooled to –80 °C under nitrogen. Phenyllithium (6.0 mL of 1.8 mol/L in cyclohexane, 10.8 mmol) was added by syringe and the mixture warmed to 0 °C for 10 min. *n*-Butyllithium (4.7 mL of 2.5 mol/L in hexanes, 11.8 mmol) was then added. After 10 min, 0.99 g of 4,4′-dicyanobiphenyl was added as a solid in one portion. The solution was allowed to warm to room temperature overnight. Water (100 mL) and diethyl ether (150 mL) were added. The ether phase was separated, dried over anhydrous $MgSO_4$, filtered, and the solvent removed under reduced pressure. The resulting yellow oil (**4c**) had ^{1}H NMR (250 MHz, $CDCl_3$) δ: 2.4 (br s, 4H), s (5.88, 6.23, and 6.38 in a 1:2.4:1.3 ratio, total 2H), 7.0–7.9 m (26 H). It was not characterized further but was treated with TsOH to form **3c** as described in the preceding paragraph.

Dimethyl 1,4-phenylenebis(1,4-epoxy-1,4-dihydro-4-phenyl-1-naphthalene-2,3-dicarboxylate), 6a

In a 50 mL RBF were placed 67 mg of **3a**, 15 drops of DMAD, and a stirring bar. Dioxane (30 mL) was added, the flask wrapped in foil, and purged with nitrogen. The mixture was stirred for 10 h at which point it was colourless. The solvent was removed by rotary evaporation and the residue crystallized from $CHCl_3/CH_3OH$ to give 72 mg of adduct **6a** (67%): mp 284–287 °C (dec.). ^{1}H NMR (250 MHz, $CDCl_3$) δ: 3.68 (s, 6H), 3.69 (s, 6H), 7.15–7.17 (m, 4H), 7.47–7.53 (m, 10H), 7.73–7.76 (m, 4H), 7.85 (s, 4H). ^{13}C NMR (62.5 MHz, $CDCl_3$) δ: 52.6, 93.9, 93.9, 94.4, 122.3, 122.5, 126.26, 126.29, 128.23, 128.39, 128.44, 128.8, 129.4, 133.2, 134.2, 149.08, 149.18, 153.95, 154.06, 164.2. IR (Nujol): 1721, 1314, 1262, 1128, 752 cm^{-1}. MS (EI) *m/e*

calcd. for $C_{46}H_{34}O_{10}$: 746.21521, found: 746.21162; 746 (M^+, 2), 670 (51), 604 3b, 462 (38), 439 (50), 297 (38), 231 (18), 105 (100). Analysis calcd. for $C_{46}H_{34}O_{10}$: C, 73.99; H, 4.59. Found: C, 74.06; H, 4.66.

Dimethyl 1,3-phenylenebis(1,4-epoxy-1,4-dihydro-4-phenyl-1-naphthalene-2,3-dicarboxylate), 6b

In a round-bottom flask, **3c** (0.053 g, 0.115 mmol) and DMAD (0.082 g, 0.573 mmol) were dissolved in toluene. As the mixture was allowed to reflux (with stirring) for 2 h, the solution turned from bright yellow to clear. The solvent was removed by rotary evaporation to leave a pale yellow oil. The oil was crystallized in ethyl acetate / petroleum ether to give a 67% yield of **6b**, a white solid: mp 162–170 °C. ^{1}H NMR (250 MHz, $CDCl_3$) δ: 3.65–3.68 (m, 12H), 7.14–7.18 (m, 4H), 7.44–7.61 (m, 11H), 7.72–7.84 (m, 6H), 8.11 (s, 1H). ^{13}C NMR (62.5 MHz, $CDCl_3$) δ: 52.53, 52.56, 94.05, 94.08, 94.21, 94.24, 122.28, 122.36, 126.3, 127.7, 128.2, 128.8, 129.0, 129.1, 129.3, 133.3, 133.9. IR (KBr pellet): 702.08, 755.37, 793.51, 976.44, 1003.12, 1122.84, 1255.91, 1309.09, 1434.14, 1452.68, 1630.93, 1727.95, 2951.15 cm^{-1}. MS (EI) *m/e* calcd. for $C_{46}H_{34}O_{10}$: 746.2152, found: 746.2173; 746 (M^+, 0.3), 604 (27), 463 (14), 462 (38), 439 (41), 269 (18), 111 (12), 105 (100). Analysis calcd. for $C_{46}H_{34}O_{10}$: C, 73.99; H, 4.59. Found: C, 74.16; H, 4.70.

Dimethyl 4,4′-biphenylenebis(1,4-epoxy-1,4-dihydro-4-phenyl-1-naphthalene-2,3-dicarboxylate), 6c

In a round-bottom flask, 47.5 mg (0.088 mmol) of **3c** and 0.108 mL (0.882 mmol) of DMAD were dissolved in toluene. The mixture was allowed to reflux with stirring for 0.5 h as the solution turned from orange to lime green to clear. The solvent was removed, and the resulting yellow oil was dissolved in methanol to crystallize. Adduct **6c**, a white solid was obtained in 75% yield: mp 224–228 °C (melt/dec.). ^{1}H NMR (250 MHz, CDCl3) δ: 3.71 (s, 6H), 3.72 (s, 6H), 7.17–7.20 (m, 4H), 7.47–7.56 (m, 10H), 7.72–7.75 (m, 8H), 7.82–7.85 (m, 4H). ^{13}C NMR (250 MHz, $CDCl_3$) δ: 52.58, 52.62, 94.1, 94.3, 122.43, 122.46, 126.3, 127.6, 128.2, 128.8, 129.3, 132.7, 133.3, 141.5, 149.27, 149.33, 153.6, 154.5, 164.3, 164.4. IR (Nujol): 752.3, 1255.7, 1311.7, 1454.4, 1722.5 cm^{-1}. MS (FAB) *m/e*: 823 (MH^+, 0.9), 791 (2.4), 680 (2.1), 538 (2.5), 515 (2.9), 309 (5.1), 155 (39.7), 135 (48.7), 119 (100), 105 (73.1). Analysis calcd. for $C_{52}H_{38}O_{10}$: C, 75.90; H, 4.65. Found: C, 75.89; H, 4.86.

Dimethyl 1,4-phenylenebis(4-phenyl-1-naphthalene-2,3-dicarboxylate), 7a

Adduct **6a** (0.23 g, 0.32 mmol) and NaI (0.29 g, 1.9 mmol) were dissolved in 30 mL of dry acetonitrile. Trimethylsilyl chloride (0.25 mL, 1.9 mmol) was added by syringe and the mixture refluxed for 2 days. An equal volume of water was added and the mixture extracted twice with 50 mL of chloroform. The combined chloroform extracts were washed with 10% $NaHSO_3$ solution and dried over $MgSO_4$. The solvent was removed and the residue columned on 4 inches of silica eluting with chloroform graded to 1% ethyl acetate in chloroform. The fractions containing the product were stripped of solvent, and the product was precipitated by the addition of methanol. Filtration gave 0.17 g of **7a** (78%): ^{1}H NMR (250 MHz, $CDCl_3$) δ: 3.45 (6), 3.58 (6), 7.4–7.8 (m, 22H). ^{13}C NMR (75 MHz, $CDCl_3$) δ: 52.5, 53.5, 127.4, 127.7, 128.0, 128.1, 128.3, 129.0, 129.3, 129.97, 130.01, 132.8, 133.0, 137.45, 137.53, 137.7, 138.7, 139.5, 168.8, 168.9. IR (KBr): 1741 and 1726, 1436, 1241, 1221, 1130, 773, 702 cm^{-1}. MS (EI) *m/e* calcd. for $C_{46}H_{34}O_8$: 714.2253, found: 714.2267; 714 (M^+, 100), 651 (18), 326 (10), 87 (5).

Dimethyl 1,3-phenylenebis(4-phenyl-1-naphthalene-2,3-dicarboxylate), 7b

Adduct **6b** (0.43 g, 0.58 mmol) and NaI (0.43 g, 2.9 mmol) were dissolved in 50 mL of dry acetonitrile under nitrogen. The solution was cooled to 0 °C and TMSCl (0.37 mL, 2.9 mmol) added by syringe. The solution was then stirred at room temperature for 24 h. Saturated $NaHSO_3$ was added, and the solution was extracted twice with 50 mL portions of chloroform. The organic phase was separated, dried over $MgSO_4$, and stripped of solvent. The residue solidified and was recrystallized from methanol to give, in several crops, a total of 0.32 g (78%): mp 214–215 °C. ^{1}H NMR (250 MHz, $CDCl_3$) δ: 3.52 (3.67 and 3.68, J = 3s Hz, 12H), 7.33–7.78 (m, 22H). ^{13}C NMR (62.5 MHz, $CDCl_3$) δ: 52.32, 52.35, 52.5, 52.6, 127.3, 127.5, 127.6, 127.7, 127.8, 127.95, 127.98, 128.90, 128.08, 128.13, 128.18, 128.24, 128.27, 128.33, 128.4, 128.8, 129.01, 129.07, 129.21, 129.5, 129.98, 130.13, 130.2, 130.3, 131.7, 132.2, 132.89, 132.95, 133.00, 137.72, 137.74, 137.80, 138.88, 139.4, 139.5, 168.86, 168.89, 168.97. IR (KBr): 1741 and 1726 (C=O), 1436, 1241, 1221, 1130, 773, 702 cm^{-1}. Analysis calcd. for $C_{46}H_{34}O_8$: C, 77.30; H, 4.79. Found: C, 77.33; H, 5.00.

Dimethyl 4,4′-biphenylenebis(4-phenyl-1-naphthalene-2,3-dicarboxylate), 7c

Difuran **3c** (0.30 g, 0.56 mmol) and 240 mg DMAD (1.7 mmol) were refluxed in 150 mL dioxane for 8 h. The solvent was removed by rotary evaporation and evacuation under high vacuum. Acetonitrile (30 mL) and sodium iodide (0.54 g, 3.4 mmol) were added, the flask purged with nitrogen, and cooled to 0 °C. Chlorotrimethylsilane (0.50 mL, 3.9 mmol) was added by syringe and the reaction stirred for 6 h. The mixture was filtered and the solid material recrystallized from $CHCl_3$/MeOH to give 246 mg of **7c**, (57%): mp 368–370 °C. ^{1}H NMR (250 MHz, $CDCl_3$) δ: 3.54 (s, 6H), 3.60 (s, 6H), 7.40–7.55 (m, 18H), 7.68–7.79 (m, 4H), 7.87 (d, J = 7 Hz, 4H). ^{13}C NMR (62.5 MHz, $CDCl_3$) δ: 52.4, 52.6, 126.9, 127.6, 127.7, 127.96, 127.98, 128.1, 128.3, 129.0, 130.2, 130.8, 133.0, 137.1, 137.8, 138.9, 139.4, 140.1, 169.0. IR (Nujol): 1742, 1227, 1163, 1130, 774, 721, 700 cm^{-1}. MS (EI) *m/e*: 790 (M^+, 22), 744 (5), 552 (21), 457 (44), 456 (100), 207 (20), 126 (9), 78 (11).

Abstract: The reaction of lithium dienolates derived from *N*,*N*-dialkylsenecioamides (**1a**–**1c**) with triorganosilyl electrophiles occurs initially at the oxygen atom predominantly, and is followed by an O → C silicon migration to afford the γ-silylated senecioamides (**4a**–**4h**). The γ-silylated senecioamide ***Z*-4a** undergoes fluoride-ion-mediated condensations with aromatic aldehydes to give kinetic α-(**6**) and thermodynamic γ-(**5**) condensation product patterns comparable to lithium dienolates. The $TiCl_4$-mediated reactions with aldehydes gives α-products (**6**) in a highly syn-selective manner. Possible transition-state models for the syn-selective condensations are discussed and a chair-like transition state featuring bidentate coordination to titanium (**11**) is proposed.

Key words: silicon migration, amide dienolate, allylsilane, Hosomi–Sakurai reaction, stereoselective.

Résumé : La réaction des diénolates de lithium dérivés des *N*,*N*-dialkylsénécioamides (**1a**–**1c**) avec des électrophiles triorganosilyles se produit dans un premier temps par le biais de l'atome d'oxygène et l'intermédiaire subit une migration O → C de l'atome de silicium qui conduit éventuellement aux sénécioamides γ-silylés (**4a**–**4h**). Le sénécioamide γ-silylé ***Z*-4a** donne des réactions de condensation avec les aldéhydes aromatiques, catalysées par l'ion fluorure, qui conduisent à la formation des produits de condensation cinétique, α-(**6**), et thermodynamique, γ-(**5**) avec des patrons similaires à ceux observés pour les diénolates de lithium. Les réactions des aldéhydes, catalysées par le $TiCl_4$, conduisent aux produits α-(**6**) avec une haute sélectivité syn. On discute de divers modèles d'états de transition qui pourraient expliquer la sélectivité syn des condensations et on suggère que la meilleure explication est un état de transition en forme de chaise comportant une coordination bidentate vers le titane (**11**).

Mots-clés : migration du silicium, diénolate amide, allylsilane, réaction de Hosomi–Sakurai, stéréosélective.

[Traduit par la Rédaction]

Introduction

From the considerable body of literature on dienolates derived from α,β-unsaturated acid derivatives,[2] including our work on α,β-unsaturated amides,[3] a clear pattern of reactivity has emerged, especially for carbon-based electrophiles. In the absence of additional heteroatom substitution, predominant to exclusive α-carbonyl substitution is observed, with preferential γ-substitution products arising under thermodynamic conditions. Conversely, the seminal work of Casey[4] demonstrated that dienolates derived from esters undergo kinetic O-silylation to give vinyl ketene *O*,*O*-acetals,[5] which then experience a [1,5]-sigmatropic O → C silicon migration to γ-silylated products. An analogous migration has been observed in β-pyrrolidino vinyl ketene *O*,*N*-acetals,[6] and O → C or C → O silicon migrations have been observed on related systems,[7–9] for many cases after our initial report in this area.[10] These combined results prompted the present systematic study on tertiary amide dienolate silylation and the potential rearrangement of the resulting vinyl ketene *N*,*O*-acetals to γ-silylated α,β-unsaturated amides (Scheme 1).

An additional incentive for the present study was the consideration that, with few exceptions, the reactivity of γ-silylated alkenoic acid derivatives has been restricted to electrophilic cyclizations on alkenes and epoxides.[11,12] Given the rich chemistry of allylsilanes,[13] such γ-silylated carbonyl compounds may be considered as storable dienolate equivalents. This is particularly relevant in the 3-methyl-2-butenamide (senecioamide) case, as the lithio dienolates give modest to poor α- kinetic aldol selectivity. Consequently, we set as a goal to test the functionalized allylsilane dienolate equivalent in fluoride- and Lewis acid mediated aldol chemistry to provide a contribution to the area of diastereoselective C–C bond formation.[10,14] The results of

our studies concerning lithium dienolates derived from *N*,*N*-dialkylsenecioamides and their γ-silylated reaction products are presented herein.

Enolate silylation and silicon migration reactions of senecioamides

N,*N*,3-Trimethyl-2-butenamide (*N*,*N*-dimethylsenecioamide) (**1a**) was deprotonated with LDA under the established conditions,[3a] and the resultant dienolate underwent silylation with Me_3SiCl to afford the vinylketene *O*,*N*-acetal (**2a**) (Scheme 2). Compound **2a** was found not to be stable to an aqueous workup or chromatographic purification, but was identified by ^{1}H NMR spectroscopy; its characterization as the *Z*-isomer was supported by NOE difference experiments showing an enhancement of the vinyl CH resonance (δ 4.48) upon irradiation of the N-substituted methyl resonances (δ 2.26).[15] Furthermore, **2a** was trapped by Diels–Alder reaction with dimethyl acetylene dicarboxylate to give the phthalate ester **3** in low yield (Scheme 3) (see Supplementary data).[8] In normal practice, however, **2a** was heated at reflux in THF for 18 h to afford two isomeric 4-trimethylsilylated-2-butenamides, ***Z*-4a** and ***E*-4a**, in 74% and 2% yields, respectively. The stereochemistry of the two compounds was determined on the basis of the downfield ^{1}H NMR chemical shifts of the protons γ and cis to the amide function relative to those γ and trans to the carbonyl, and the expected aromatic solvent induced shift (ASIS)[16] of the γ,cis- and γ,trans-protons observed in their ^{1}H NMR spectra in C_6D_6 (Scheme 2).

[a]The THF at reflux step was not carried out.

The basic protocol outlined above was extended to other chlorosilanes (chlorotriethylsilane, chlorotriisopropylsilane, and chloromethyldiphenylsilane) and other senecioamides (**1b**, **1c**), and the combined results are presented in Table 1. For reaction of the dienolates with $MePh_2SiCl$, C-silylation did not require the heating-to-reflux step, and it was therefore omitted in these cases (Table 1, entries 4 and 8). In the isolated γ-silylated products (**4**) other than **4a**, the most noteworthy feature was the increased relative amounts of

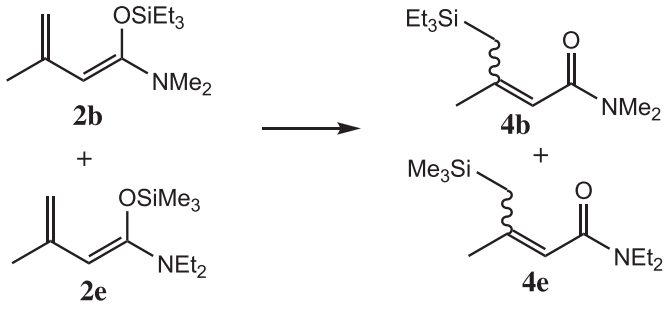
the *E*-isomer to the point where the *E*-isomer predominated in several instances (Table 1, entries 4, 6, and 7).

To further clarify the source of the γ,*E*-isomer silylation products, the reaction of the dienolate of **1a** with Et_3SiCl was examined more closely prior to the reflux step by subjecting an aliquot of the product to an anhydrous workup and the remainder to a conventional aqueous workup. For the former aliquot, integration of the respective vinyl proton resonances in the ^1H NMR spectrum showed a 23:77 ratio for γ-silylated products (***Z*- + *E*-4b**) and the ketene *O*,*N*-acetal (**2b**). Conversely, the material subjected to aqueous workup gave ***Z*-4b** and ***E*-4b** in 4% and 16% yields, respectively. Comparing this to entry 2 in Table 1 (***Z*-4b**, 58%; ***E*-4b**, 18%), it is apparent that most of the γ,*Z*-silylated product arose from the O- to C-[1,5]-silicon migration of the vinylketene *O*,*N*-acetal (**2b**), whereas the corresponding γ,*E*-silylated product most likely resulted from direct attack on the dienolate (Scheme 4). In the cases with $MePh_2SiCl$ as the electrophile, it is likely that both isomers of γ-silylation products result from direct silylation, in keeping with the relatively greater HSAB "softness" of $MePh_2SiCl$,[17] and in the fact that **2d** and **2h** are not actually formed in significant amounts.

The variation of *E/Z* ratios in these γ-silylated amides is worthy of further comment. In the *N*,*N*-dimethyl amide series, increasing amounts of *E*-isomers may reflect increasing direct γ-silylation due to a greater reactivity with bulkier chlorotrialkylsilanes when the dienolate is in the s-trans form. This proposal breaks down for the *N*,*N*-diisopropyl amide series, as $MePh_2SiCl$ undergoes reaction by direct γ-attack and yet gives predominantly ***Z*-4h.** The regiochemistry for direct γ-attack is clearly a more complex process in these cases.

To establish the inter- or intra-molecularity of the [1,5]-silicon migration, a crossover experiment was performed. The lithium dienolates of **1a** and **1b** were allowed to react

Scheme 5. Reagents and conditions: (a) THF, Δ, 19h.



at –78 °C with Et_3SiCl and Me_3SiCl, respectively, and, after warming to room temperature, the respective solutions of the two reactions were mixed in a 1:1 ratio and heated to reflux (19 h). Analytical HPLC of the resultant mixture revealed the presence of γ-silylation products ***Z*-4b**, ***E*-4b**, ***Z*-4e**, and ***E*-4e,** but not crossover products ***Z*-4a**, ***E*-4a**, ***Z*-4f**, or ***E*-4f** (Scheme 5) (see Supplementary data).[8] This constitutes strong evidence for the intramolecular nature of the [1,5]-silicon migrations of these silylated vinylketene *O*,*N*-acetals.

With a facile method for generating γ-silylated-α,β-unsaturated amides in hand, attention was turned to the condensation chemistry of these compounds. Since ***Z*-4a** was obtained with the highest stereoselectivity and possesses the most widely employed silyl group, the reactivity of this compound with carbonyl derivatives was pursued. As described below, fluoride- and Lewis acid mediated condensation reactions were investigated.

Fluoride-mediated condensations of *Z*-4a

The reaction of ***Z*-4a** with benzaldehyde was induced by subjecting its THF solution to a catalytic amount of *n*-Bu_4NF (5 mol%) at RT to afford a mixture of γ-hydroxyalkylated compounds ***Z*-5a** and ***E*-5a** in 58% and 14% yields, respectively (Scheme 6). This process was extended to other aromatic aldehydes, and gave some interesting differences in the reaction products (Table 2). Aromatic aldehydes bearing strong electron-withdrawing groups (EWGs) gave mixtures of γ-(**5**) and α-hydroxyalkylation products (**6**) (Table 2, entries 4 and 5); conversely, substrates not possessing these EWGs gave only γ-hydroxyalkylated products (Table 2, entries 1–3). Reaction with benzophenone resulted in the formation of the γ-condensation products, but unless the reaction was performed at low temperature (–45 °C), these underwent elimination to give **7** (Table 2, entries 6 and 7). By contrast, attempted reaction with aliphatic aldehydes resulted in desilylation of ***Z*-4a** and isolation of only trace amounts of condensation products.

These condensations, if effected at lower temperatures (–45 °C) for short periods of time, required the use of stoichiometric amounts of fluoride ion. Under such conditions, however, α-condensation products predominated as separable syn/anti diastereomeric mixtures, together with small amounts of the γ,*Z*-condensation products (Scheme 6, Table 3).

The identities of the condensation products were readily established from their ^1H NMR spectra. The α-products (**6**)

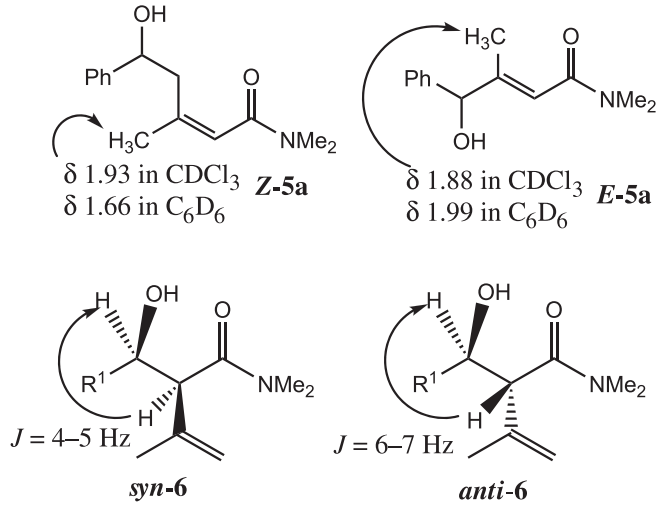
were distinguished by virtue of the larger vicinal coupling constant of the α-methine proton in the anti-diastereomer (J = 6–7 Hz) relative to the syn-diastereomer (J = 4–5 Hz).[18] The *Z*- and *E*-isomers of the γ-condensation products (**5**) were most readily discriminated by the downfield ASIS of the allylic methyl groups of the *Z*-isomers, versus the upfield ASIS of the corresponding group in the *E*-isomers (Fig. 1).

The observation of predominant α-condensation products at low temperatures and short reaction times but γ-condensation products at higher temperatures and longer reaction times is a clear kinetic (α-) versus thermodynamic (γ-) product control situation similar to that observed for analogous lithium dienolate condensation chemistry.[3a] In the cases of 4-nitrobenzaldehyde and pyridine-4-carboxaldehyde, the EWGs render the initial kinetic condensation favourable to

Fig. 1. Stereochemical assignments of aldol adducts.



such a degree that reversibility is suppressed completely (4-nitrobenzaldehyde) or partially (pyridine-4-carboxaldehyde). We note that the amount of γ-product with 4-nitrobenzaldehyde under kinetic conditions is relatively high, although it is still the minor product. We attribute the nearly non-existent diastereoselectivity of the α-condensation in all cases to the re-

action proceeding via the nearly equal in energy acyclic transition states **8** and **9** (Scheme 7). While the pattern of reactivity is consistent with a reaction proceeding via a free enolate, we do not consider this as an unambiguous proof. Attempts to induce fluoride-ion-catalyzed reactions of silyl ketene acetal (**2a**) with benzaldehyde afforded only hydrolysis products.[19]

$TiCl_4$-mediated condensations of *Z*-4a with aromatic and aliphatic aldehydes and benzophenone

The condensation reaction of the γ-silylated amide ***Z*-4a** with benzaldehyde could also be initiated by a Mukaiyama-type process, often referred to as the Hosomi–Sakurai reaction,[14d] in the presence of stoichiometric amounts of $TiCl_4$ under mild conditions. The condensation was found to occur with exclusive α selectivity and nearly complete syn-diastereoselectivity to give product **6a** in reasonable yield (Scheme 8, Table 4). This process was extended to other aromatic and aliphatic aldehydes (**6e**–**6j**), with some caveats: aldehydes with Lewis basic sites (4-methoxybenzaldehyde and 3,4-dimethoxybenzaldehyde) gave only desilylation, without condensation, while branched aliphatic aldehyde (2-methylpropanal) gave much lower levels of diastereoselection (syn/anti **6h** = 59:41).

Alteration of this basic protocol was much less successful in obtaining condensation products stereoselectively. The use of a monodentate Lewis acid ($BF_3{\cdot}OEt_2$) and benzaldehyde under otherwise identical conditions resulted only in minimal conversion (<10%) of ***Z*-4a** to ***syn*-6a**; even excesses of $BF_3{\cdot}OEt_2$ (4.4 equiv.) and PhCHO (4.8 equiv.) afforded ***syn*-6a** in only 7% yield (see Supplementary data). Similarly, allylsilane ***E*-4a** was much less reactive than ***Z*-4a** under identical conditions. Even at higher temperature, attempted reaction of ***E*-4a** with benzaldehyde in the presence of $TiCl_4$ resulted mainly in the isolation of recovered starting material, along with only trace amounts of condensation product ***syn*-6a** and desilylation product **10a** (see Supplementary data). In the alternative obvious approach,[20] reaction of the lithium dienolate of **1a** with $TiCl_4$, followed by treatment with benzaldehyde, resulted only in the formation of oligomeric materials (see Supplementary data).

The observed high syn diastereoselectivity in the $TiCl_4$-mediated reactions of ***Z*-4a** with aromatic and linear aliphatic aldehydes is striking, particularly in light of the related condensation reactions of γ-stannyl- and γ-germylsenecioic "esters" reported by Yamamoto[21] and Hudlicky,[22] and indium-mediated Reformatsky reactions of γ-bromocrotonates,[23] which generally show high anti diastereoselectivity.[24] While experimentally the results are nicely complementary, clearly our results cannot be rationalized in terms of an acyclic transition state with an anti-periplanar relationship between the allylsilane and aldehyde functions, as advanced by Yamamoto.[25] A more plausible explanation is based on the ability for bidentate coordination to $TiCl_4$, and the greater basicity of the amide relative to the ester function.[26] Working on the assumption that the predominant s-cis-conformation of the unsaturated tertiary amide[27] is maintained, we envisage a cyclic transition state featuring coordination of both the amide and aldehyde carbonyls to Ti, with the allylsilane function positioned in an exocylic mode. Formulating this transition state as a chair, with the aldehyde R group pseudoequatorial and a synclinal orientation of the allylsilane and aldehyde (**11**), allows rationalization of the observed syn-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Sichuan Normal University on 09/14/12

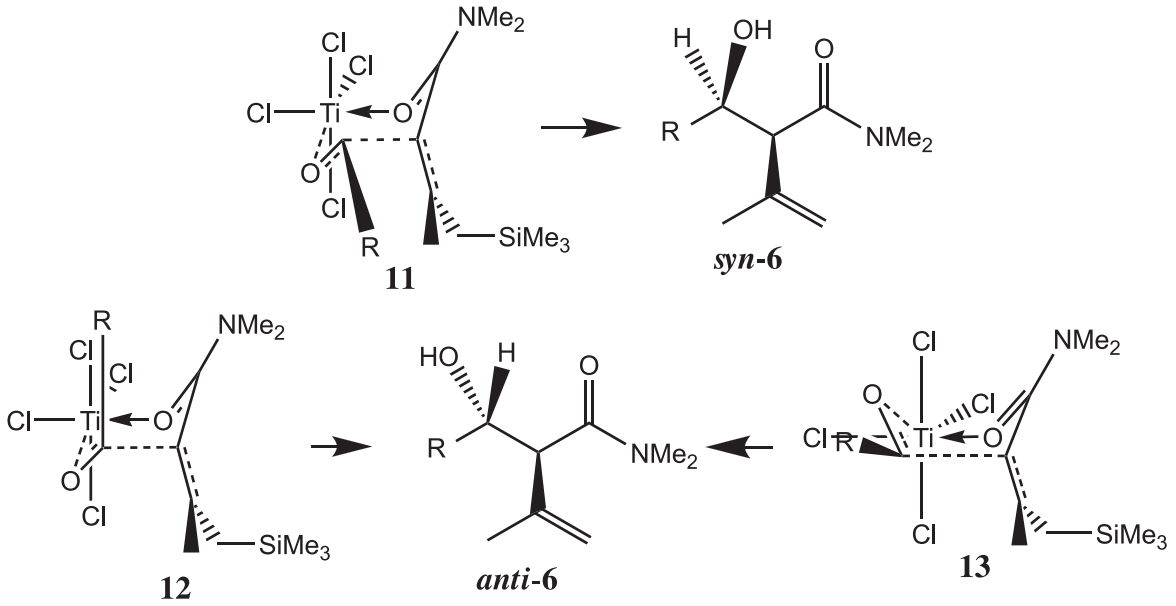
Scheme 9.



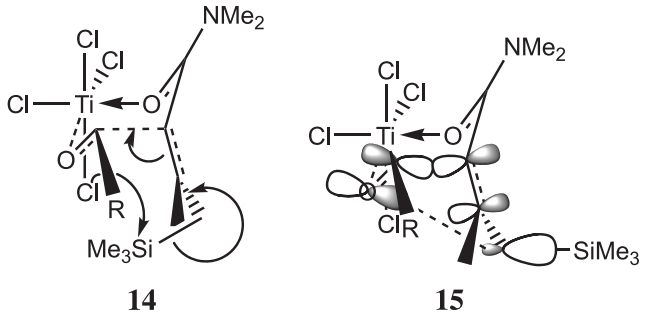
diastereomeric product (Scheme 9).[28] Formation of the anti-diastereomer would require either a pseudoaxial aldehyde R group (**12**), or boat transition state (**13**). In context of this proposal, the analogous $TiCl_4$-mediated condensations of γ-stannyl-/germyl-senecioic esters[21,22] lead to reduced anti-diastereoselection, which may indicate destructive competition of analogous bidentate coordination in these cases. In addition, it has been demonstrated that chiral senecioyl oxazolidinones undergo *n*-Bu_2BOTf-mediated reactions with aldehydes with high syn-selectivity and high diastereofacial selectivity.[29] For esters, however, the selectivity profile appears complementary to our work in that there is an apparent requirement for branching in aliphatic aldehydes to achieve high diastereoselectivity.[30]

The greater reactivity of ***Z*-4a** relative to ***E*-4a** may be rationalized in two possible ways. In a chair transition state for ***Z*-4a**, the depicted orientation (**14**) of the C–Si bond suggests potential intramolecular transfer of an apically ligated chloride to a syn-oriented silicon (Scheme 10), an analogous possibility does not exist for ***E*-4a**. This possibility has been advanced on occasion in Hosomi–Sakurai reactions,[10,31] and in silyl ketene acetal-aldehyde and allylsilane-enone condensation chemistry,[32] and has received computational support at the DFT level.[33] In contrast, careful experiments on intramolecular condensations of aldehydes with chiral allylsilanes and allylstannanes are not consistent with the stereochemical outcome for such a syn-S'_E orientation.[34]

The alternate plausible source of the greater reactivity of ***Z*-4a** stems from the possibility of a stabilizing secondary orbital overlap of the allylsilane (HOMO) with the aldehyde (LUMO) (**15**), which would not be available in the reaction path of ***E*-4a**. Originally proposed for aldol condensation chemistry,[35] this rationalization has been invoked in support of synclinal orientations in allylstannane-aldehyde condensations,[28d,36] and should, in principle, be capable of extension to Lewis acid mediated allylsilane-aldehyde condensations.

Pursuant to this question, transition states approximating **14** and **15** were calculated at the DFT level. An "outside" trimethylsilyl transition state corresponding to **11/15** was located (**16**, Scheme 11); it features a relatively short forming bond (1.81 Å), a significantly lengthened senecioamide C4–Si bond (2.00 Å), and nearly equal amide C2–C3 and C3–C4 bonds (1.44 and 1.44 Å). Furthermore, a senecioamide C4 – aldehyde oxygen distance (3.17 Å) shorter than the sum of the van der Waals radii is found, consistent with a weak bonding interaction between the two atoms. In contrast, an "inside" trimethylsilyl transition state corresponding to **14** was found to be 2.9 kcal mol^{-1} higher in energy (**17**). The nearest Cl–Si contact (3.85 Å) is larger than the sum of the van der Waals radii. Consequently, the intramolecular transfer of chloride transition state **14** is not supported in our system at this level of calculation.

Scheme 10.



In summary, we have shown that γ-silylated senecioamides **4a**–**4h** are easily obtained by [1,5] O→C silicon migration or direct silylation of the corresponding enolates, depending upon the softness of silyl groups. The isomeric γ-(*Z*)-silylsenecioamides ***Z*-4a** – ***Z*-4c**, ***Z*-4e** – ***Z*-4g** are obtained by the O→C silicon migration but also are formed from the direct silylation reactions, whereas the corresponding *E*-isomers are exclusively or near-exclusively formed from the direct silylation process. The simplest γ-silylseneciomamide serves as a stable and easily stored (>1 year at –20 °C) senecioamide dienolate equivalent. Fluoride-catalyzed reactivity of ***Z*-4a** with aromatic aldehydes or

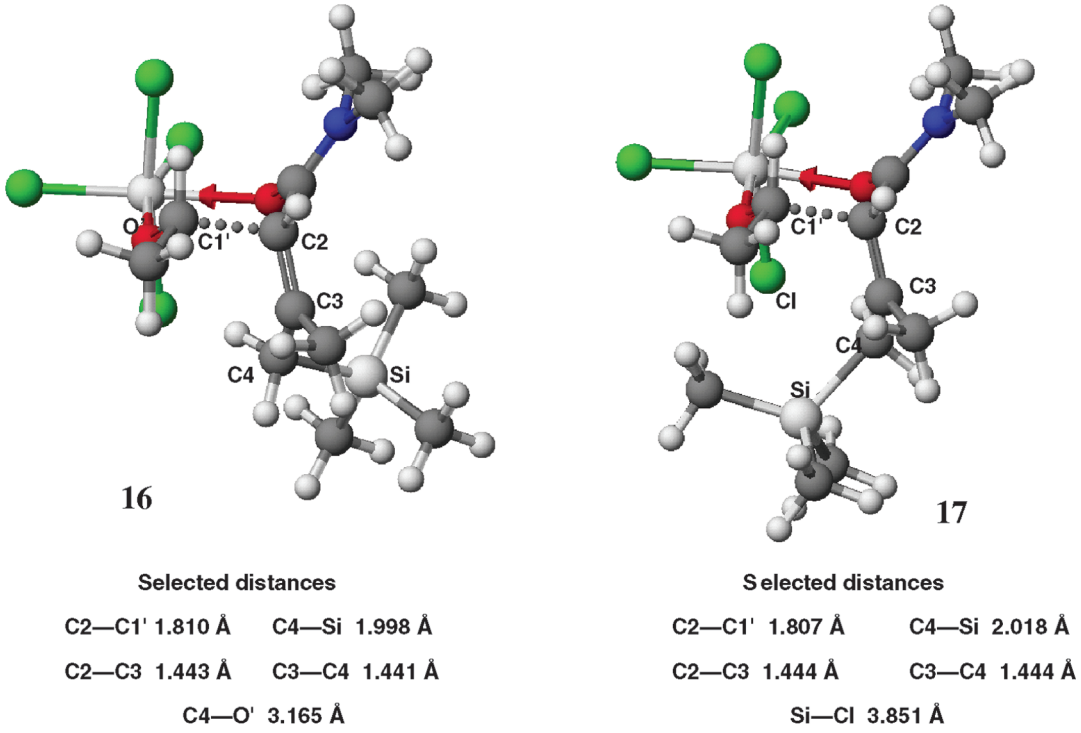
Scheme 11. DFT-minimized transition states of **15**, **14**, R = CH_3.



benzophenone shows product patterns analogous to those observed in dienolate chemistry, [2,3a] which is therefore consistent with, but not proof of, reaction via free enolates. The reaction of ***Z*-4a** with aromatic and aliphatic aldehydes mediated by $TiCl_4$ gives syn-α-condensation products **6a**–**6h**, and is proposed to proceed by a chair-like transition state featuring bidentate coordination to titanium (**11**). Further refinement by DFT calculations suggest involvement of the "outside TMS" **15** over the "inside TMS" **14** transition state. Although limited in scope, the diastereoselectivity observed for the $TiCl_4$-mediated reactions of α,β-unsaturated amides is complementary to that observed on analogous stannyl- and germyl-senecioates.[21,22]

The utility of the reported chemistry for the construction of diasteriomerically pure functionalized amides, especially in view of the recent availability of a mild method for amide to aldehyde conversion using the Schwartz reagent,[37] and adaption to enantioinduction modes of reaction may create further opportunities in synthetic chemistry.

Experimental section

General methods

Elemental analyses were performed by M-H-W Laboratories, Phoenix, Arizona. Melting points were determined on a Buchi SMP-20 instrument and are uncorrected. Infrared spectra were determined on a PerkinElmer 983 spectrophotometer. ^{1}H NMR spectra were determined with Bruker WP-80, Bruker AM-250, and Bruker Avance-500 spectrometers. The spectra were recorded at 80 MHz in $CDCl_3$ with tetramethylsilane as an internal standard unless otherwise stated. Spectral features are tabulated in the following order: chemical shift (δ, ppm), number of protons; multiplicity (s: singlet, d: doublet, t: triplet, q: quartet, sept: septet, m: multiplet, br: broad), coupling constant (*J*, Hz), number of protons; assignment. Low-resolution mass spectra were determined on a VG 7070F instrument at 20 eV unless otherwise stated. High-resolution mass spectra were determined on a VG ZAB-E spectrometer. Analytical gas chromatography (GC) was performed on either a Hewlett Packard 5840 A instrument or a Varian 6500 instrument using commercially available 10% SE-30 packed or capillary columns, respectively. Analytical thin layer chromatography (TLC) was performed using Merck precoated silica gel 60F-254 or aluminum oxide 150F-254 neutral (type T) sheets. Preparative TLC was performed using Merck silica gel 60GF-254 with a plate thickness of 1 mm. Column chromatography was carried out using silica gel 60 (0.063–0.20 mm and 0.04–0.063 mm). "Flash chromatography" refers to the method reported by Still.[38] Liquid chromatography was performed on a Varian 5000 Liquid Chromatography employing a reverse phase (C-18) column, and preparative HPLC was done on a Waters PREP-500 with a SiO_2 column.

All dry solvents were employed after distilling from the appropriate drying agent.[39] Diethyl ether (Et_2O), benzene, and tetrahydrofuran (THF) were distilled from benzophenone-ketyl immediately prior to use. Solutions of *n*-BuLi were titrated with 2,5-dimethoxybenzyl alcohol as a standard.[40] Diisopropylamine was dried and distillated over CaH_2 and stored in brown bottles over 4 Å molecular sieves in a dessicator containing $CaCl_2$. All other reagents were purified according to literature procedures. All lithiation reactions, and fluoride- or Lewis acid mediated reactions of ***Z*-4a** were carried out under high purity nitrogen or argon (Linde). Tetra(*n*-butylammonium) fluoride (TBAF, 1 mol/L in THF) was allowed to sit over 4 Å molecular sieves for approxi-

mately 15 min prior to use. Amides **1a** and **1c** were prepared by literature procedures.[3a]

The term "–78 °C" refers to the temperature of a CO_2 – acetone bath (normally –75 to –78 °C). The term "at –45 °C" refers to a reaction done in an acetonitrile–CO_2 slush bath (normally –45 to –50 °C). The term "at 0 °C" refers to a reaction done in an ice bath.

The phrase "workup in the usual manner" or "standard workup" refers to addition of saturated aqueous NH_4Cl to the reaction mixture, followed by evaporation of the organic solvent under reduced pressure, extraction of the residue with CH_2Cl_2 or diethyl ether (Et_2O), drying of the organic extract over $MgSO_4$, followed by filtration, and subsequent evaporation to dryness under reduced pressure to afford the crude product. Subsequent chromatography and (or) recrystallization and (or) distillation of the crude material afforded pure products.

DFT calculations were carried out using the B88-PW91 method, and a DZVP basis set, using CAChe® version 6.1.12.33 (see Supplementary data). All stationary points were confirmed via frequency calculations.

General procedure for the formation of lithium dienolates

Preparation of LDA

Diisopropylamine (5 mmol, 0.70 mL) was dissolved in THF (25 mL) and cooled to 0 °C. To this solution, *n*-BuLi (5 mmol) was added by syringe injection over a period of ~30 s. The solution was then stirred for a further 0.5 h at 0 °C.

Lithiation with LDA

Procedure A — The amide in question was added by syringe to 1.05 equiv. of LDA in THF at –78 °C such that the concentration in solution was roughly 0.2 mol/L. This solution was stirred at –78 °C for 1 h prior to electrophile addition.

Procedure B — The amide in question was added by syringe to 1.05 equiv. of LDA in THF at 0 °C such that the concentration in solution was roughly 0.2 mol/L. This solution was stirred at 0 °C for 0.5 h prior to electrophile addition.

Procedure C — The amide in question was added by syringe to 1.05 equiv. of LDA in THF at RT such that the concentration of the amide or amide dienolate in solution was roughly 0.2 mol/L. This solution was stirred at RT for 1 h prior to electrophile addition.

Silylations of lithium dienolates

To the solution of the lithium dienolate in THF at –78 °C was added, by syringe, 1.1 equiv. of the chlorosilane. The resulting solution was stirred at –78 °C for 0.5 h before the low temperature bath was removed and the reaction mixture allowed to warm to RT. Unless the silylating reagent was diphenylmethylsilyl chloride, the reaction mixture was then heated to reflux for the indicated amount of time, after which a standard workup was performed. In the case of chloromethyldiphenylsilane, the reaction mixture was subjected to a standard workup without prior heating.

N,N-*diethylsenecioamide*(N,N-*diethyl-3-methyl-Z-butenamide) 1b*

To a solution of senecioic acid (5.72 g, 57.1 mmol) in benzene (60 mL) under a drying tube was added thionyl chloride (9 mL, 123 mmol). The solution was allowed to stir overnight. The benzene and excess thionyl chloride were removed by evaporation under reduced pressure, and the resulting senecioyl chloride was slowly added to diethylamine (20 mL, 193 mmol) in diethyl ether (75 mL). The resulting mixture was subjected to filtration, and the filtrate was successively washed with H_2O (50 mL), 10% aqueous NaOH (2 × 50 mL), and H_2O (50 mL). The ethereal layer was dried over $MgSO_4$, subjected to filtration, and the filtrate was concentrated in vacuo. Distillation of the crude product gave 6.19 g (70%) of **1b**, bp 37.5–38.5 °C at 0.02 torr (1 torr = 133.322 Pa). IR (neat) ν_{max}: 1653, 1624 cm^{-1}. ^1H NMR, δ: 1.14 (t, *J* = 7, 6H), 1.84 (s, 3H), 1.93 (s, 3H), 3.37 (2 q, overlapping, *J* = 7, 4H), 5.81 (br s, 1H). MS *m/e* (rel. intensity): 155 (M^+, 25), 140(27), 83(100). Anal. calcd. for for $C_9H_{17}NO$: C, 69.63; H, 11.04; N. 9.02. Found: C, 69.70; H, 11.21; N, 9.18.

Z*-N,N,*3-trimethyl-1-trimethylsiloxyl-3-butadienamine 2a

N,*N*-Dimethylsenecioamide **1a** (1.916 g, 15.1 mmol) was lithiated according to procedure C. Chlorotrimethylsilane (1.91 mL, 15.1 mmol) was then added to the solution at 0 °C. After stirring for 20 min, the solvent was evaporated under reduced pressure, and hexane (20 mL) was added. This mixture was subjected to filtration through glass wool, and the hexane filtrate was evaporated under reduced pressure. An NMR spectrum of the crude product revealed the presence of **2a**. ^1H NMR (C_6D_6) δ: 0.18 (s, 9H), 2.06 (s, 3H), 2.26 (s, 6H), 4.48 (s, 1H), 4.67, 5.16 (2 m, 2H). Irradiation of the resonance at 2.26 ppm gave rise to a 7% integrated enhancement of the 4.48 ppm peak. ^{13}C NMR (C_6D_6): 0.4, 24.6, 40.6, 92.0, 109.3, 140.7, 155.1.

Z- and* E-N,N,*3-Methyl-4-trimethylsilyl-2-butenamide Z-4a and* E-*4a

N,*N*-Dimethylsenecioamide **1a** (8.2 mL, 60 mmol) was lithiated according to procedure A and silylated with chlorotrimethylsilane (8.4 mL, 66 mmol) in the normal manner for silylation (reflux 18 h) followed by a standard workup. Preparative HPLC (5:2 hexane – ethyl acetate) gave, in order of elution: ***Z*-4a** (8.9 g, 74%), bp 50–53 °C at 0.01 torr. IR (neat) ν_{max}: 1646 cm^{-1}. ^1H NMR (C_6D_6) δ: 0.11 (s, 9H), 1.66 (d, *J* = 1.4, 3H), 2.41 (d, *J* = 0,6, 2H), 2.54 (br s, 6H), 5.62 (br s, 1H). ^{13}C (125 MHz) δ: –1.0, 25.9, 27.4, 34.9, 37.5, 113.3, 152.1, 168.4. tion (0.9631 g, 13%) proved to be a mixture of the starting material **1a** and its deconjugated isomer **10a**.[3a]

Z- and E-N,N,*3-Trimethyl-4-triethylsilyl-2-butenamide Z-4b and* E-*4b*

N,*N*-Dimethylsenecioamide, **1a** (0.70 mL, 5.0 mmol), was lithiated according to procedure A, and the resulting dienolate was silylated with 0.92 mL (5.5 mmol) of chlorotriethylsilane in the normal manner. After a standard workup, column chromatography gave, in order of elution: ***Z*-4b** (0.71 g, 58%), bp 83–84 °C at 0.17 torr. IR (neat) ν_{max}: 1642 cm^{-1}. ^{1}H NMR (C_6D_6) δ: 0.5–1.2 (A_2B_3 spin system, 15H), 1.69 (d, *J* = 1.2, 3H), 2.46 (s, 2H), 2.56 (br s, 6H), 5.63 (br s, 1H). MS *m/e* (rel. intensity): 241 (M^+, 4), 226(93), 212(100), 198(45), 115(10), 87(27). HR-MS calcd. for $C_{13}H_{27}NOSi$: 241.1863. Found: 241.1847. ***E*-4b** (0.21 g, 18%), bp 94–96 °C at 0.15 torr. IR (neat) ν_{max}: 1642, 1618 cm^{-1}. ^{1}H NMR (C_6D_6) δ: 0.4–1.0 (A_2B_3 spin system, 15H), 1.54 (d, *J* = 1.0, 2H), 2.19 (d, *J* = 1.5, 3H), 2.51, 2.73 (2 br s, 6H), 5.68 (br s, 1H). MS *m/e* (rel. intensity): 241 (M^+, 8), 226(100), 212(76), 198(93). Anal. calcd. for $C_{13}H_{27}NOSi$: C, 64.67; H, 11.27; N 5.80. Found: C, 64.49; H, 11.11; N, 6.01.

N,*N*-Dimethylsenecioamide, **1a** (0.67 mL, 4.9 mmol) was lithiated according to procedure A. To the resulting dienolate, at –78 °C, was added chlorotriethylsilane (0.92 mL, 5.5 mmol). After stirring the solution for 0.5 h at –78 °C, the solution was allowed to warm to RT, and the solvents were removed under reduced pressure. A small amount of the residual material was removed; the ^{1}H NMR spectrum (C_6D_6) of this sample showed δ 4.35 (s, vinyl CH of **2b**) and δ 5.62 (br s, vinyl CH of ***Z*-** and ***E*-4b**) with rel.ative integrals of 77:23. The rest of the material was worked up in the usual manner, and the resultant crude product subjected to preparative HPLC. Three fractions were isolated. The first fraction (0.048 g, 4%) contained ***Z*-4b** (see above for spectral data). The second fraction (0.20 g, 16%) was shown to be ***E*-4b** (see above for spectral data). The third fraction (0.34 g, 53%) was found to contain a mixture of the starting **1a** and its β,γ-unsaturated isomer **10a**.

Z- and E-N,N,*3-Trimethyl-4-triisopropylsilyl-2-butenamide Z- and* E-*4c*

N,*N*-Dimethylsenecioamide, **1a** (0.66 mL, 4.8 mmol), was lithiated according to procedure A, and the resulting dienolate was silylated with 1.2 mL of chlorotriisopropylsilane (5.5 mmol) in the normal manner (reflux 40 h). Following standard workup, the crude mixture was subjected to preparative HPLC (ethyl acetate – hexane) to give, in order of elution: ***Z*-4c** (0.31 g, 23% bp 80–85 °C at 0.005 torr. TBAF-mediated aldol condensations of Z-4a

Thermodynamic conditions

To a 0.3–0.4 mol/L solution of ***Z*-4a** in THF under an inert atmosphere was added 1.2 equiv. of the aldehyde or ketone in question. Five mol% of a 1 mol/L solution of tetra(*n*-butylammonium) fluoride (in THF) was then added by syringe. The resulting brown solution was stirred at ambient temperature for 16 h and worked up in the usual manner.

Kinetic conditions

To a 0.3–0.4 mol/L solution of ***Z*-4a** in THF under an inert atmosphere was added 1.2 equiv. of the aldehyde or ketone in question. The solution was cooled to –45 °C before a 1 mol/L solution of TBAF (in THF) was added by syringe. The resulting solution was stirred at –45 °C for 2 min before saturated aqueous NH_4Cl was added (at –45 °C), and a standard workup was performed.

$TiCl_4$-mediated aldol condensations of Z-4a

To 1.2 equiv. of the aldehyde in question under an inert atmosphere was added CH_2Cl_2 such that the eventual concentration of ***Z*-4a** was 0.3 mol/L. This solution was cooled to 0 °C, 1.1 equiv. of $TiCl_4$ was added by syringe, and the mixture was allowed to stir for 5 min. At this point, a solution of ***Z*-4a**, in a minimum amount of CH_2Cl_2, was added by syringe. The ice-bath was immediately removed, and the reaction mixture was allowed to stir for 3 h during which time it reached ambient temperature. A standard workup was then performed.

syn- *and* anti-Z-*Hydroxyphenylmethyl-N,N,3-trimethyl-3-butenamide* syn- *and* anti-*6a*

$TiCl_4$-mediated reaction

A mixture of compound ***Z*-4a** (0.3247 g, 1.63 mmol) and benzaldehyde (0.20 mL) in the presence of $TiC1_4$ (0.20 mL) was allowed to react in the manner described earlier. After a standard workup, column chromatography (1:l hexane – ethyl acetate) gave one fraction, 0.2763 g, which proved to be a 90:10 mixture (by ^{1}H NMR integration) of ***syn*-6a** (67%) and starting material ***Z*-4a** (7%). Recrystallization gave pure ***syn*-6a**, mp 59.5–61 °C (Et_2O – petroleum ether) (Lit.[3a] 59–61 °C (Et_2O – hexane)) whose ^{1}H NMR spectral data were identical to those reported.[3a]

TBAF-mediated reaction

A mixture of compound ***Z*-4a** (0.3217 g, 1.61 mmol) and benzaldehyde (0.20 mL) in the presence of TBAF (1.61 mL of a 1 mol/L solution) was allowed to react under the previously described kinetic control conditions. After a standard workup, the crude reaction mixture was subjected to preparative TLC (5:2 ethyl acetate – hexane) to give, in order of elution: ***syn*-6a** (0.1145 g, 30%), and 72:16:12 mixture (by ^{1}H NMR integration) (0.1610 g) of ***anti*-6a** (33%), ***Z*-4a** (6%), and desilylated material (7%). ***anti*-6a** was purified by recrystallization, mp 113–114 °C (CH_2Cl_2 – hexane) (Lit.[3a] 114–114.5 °C (Et_2O)) and showed ^{1}H NMR spectral data consistent with those reported.[3a]

Z- *and* E-*5-Hydroxy*-N,N,*3-trimethyl-5-phenyl-2-pentenamide* Z- *and* E-*5a*

A mixture of compound ***Z*-4a** (0.3770 g, 1.89 mmol) and benzaldehyde (0.23 mL) in the presence of TBAF (0.1 mL of a 1 mol/L solution) was allowed to react under the previously described thermodynamic control conditions. Following a workup in the usual manner, separation by flash chromatography (fine silica, 4:l ethyl acetate – hexane) gave, in order of elution: ***Z*-5a** (0.2564 g, 58%), mp 75–

77 °C (CH_2Cl_2 – hexane) (Lit.[3a] 76–76.5 °C (CH_2Cl_2 – hexane)), and ***E*-5a** (0.0625 g, 14%) as an undistillable viscous oil. IR (neat) ν_{max}: 1647, 1606 cm^{-1}. ^1H NMR δ: 1.89 (d, *J* = 1.2, 3H), 2.49 (d, *J* = 7, 2H), 2.81, 2.90 (2s, 6H), 3.51 (br, 1H, exchangeable), 4.85 (t, *J* = 7, 1H), 5.76 (br s, 1H), 7.32 (s, 5H). MS *m/e* (rel. intensity): 234 (M^+ + l, 3), 215(11), 127(100), 112(25). HR-MS calcd. for $C_{14}H_{19}NO_2$ + H: 234.1495. Found: 234.1492.

syn- *and* anti-*2-(3,4-Dimethoxy)phenylhydroxyethyl*-N,N,*3-trimethyl-3-butenamide* syn- *and* anti-*6b*

A mixture of compound ***Z*-4a** (0.2752 g, 1.38 mmol) and veratraldehyde (0.3238 g) in the presence of TBAF (1.38 mL of a 1 mol/L solution) was allowed to react under the previously described kinetic control conditions. After a standard workup, the crude reaction mixture was subjected to preparative TLC (5:2 ethyl acetate – hexane) yielding two fractions. The first fraction (0.123 g) was identified by ^1H NMR spectroscopy as a 79:21 mixture of ***syn*-6b** (25%) and desilylated starting material (7%) from which ***syn*-6b** was obtained by recrystallization, mp 102–103 °C (Et_2O – hexane) (Lit.[3a] 100–1.5 °C (Et_2O – hexane)). The second fraction (0.1197 g) was shown to be 81:19 mixture (by ^1H NMR spectroscopy) of ***anti*-6b** (27%) and ***Z*-5b** (6%) from which ***anti*-6b** was obtained by recrystallization, mp 120–12l °C (Et_2O) (Lit.[3a] 118 °C (CH_2C1_2 – hexane)). Products ***syn*-6b** and ***anti*-6b** showed ^1H NMR spectral data consistent with those reported.[3a]

Z- and E-*5-(3,4-Dimethoxy)phenyl-5-hydroxy*-N,N,*3-trimethyl-2-pentenamide Z- and E-5b*

A mixture of compound ***Z*-4a** (0.4695 g, 2.36 mmol) and veratraldehyde (0.4695 g) in the presence of a catalytic amount of TBAF (0.12 mL of a 1 mol/L solution) was allowed to react under the previously described thermodynamic control conditions, followed by workup under the usual conditions. The crude mixture was subjected to column chromatography, yielding three fractions. Fraction 1 (0.067 g, 12%) was shown to be desilylated starting material **1a/10a**. Fraction 2 (0.3520 g, 49%) was shown to be ***Z*-5b**, mp 78–80 °C (CH_2C1_2 – hexane) (Lit.[3a] 78–80 °C (CH_2Cl_2 – hexane)) by comparison with its ^1H NMR spectra with that reported.[3a] Fraction 3 (0.1880 g, 26%) proved to be ***E*-5b** as an undistillable viscous oil. IR (neat) ν_{max}: 3378, 1646, 1608 cm^{-1}. ^1H NMR δ: 1.93 (d, *J* = 1.2, 3H), 2.50 (d, *J* = 7, 2H), 2.90, 2.94 (2s, 6H), 3.87, 3.89 (2s, 6H), 4.83 (t, *J* = 7, 1H), 5.82 (br s, 1H), 6.8–7.0 (m, 3H), OH not observed. MS *m/e* (rel. intensity): 293 (M^+, 3), 127(100), 112(27). HR-MS calcd. for $C_{16}H_{23}NO_4$: 293.1628. Found: 293.1629.

Z- and E-*5-Hydroxy-5-(3-pyridyl)*-N,N,*3-trimethyl-2-pentenamide Z- and E-5c*

A mixture of compound ***Z*-4a** (0.3428 g, 1.72 mmol) and 3-pyridinecarboxaldehyde (0.18 mL) in the presence of a catalytic amount of TBAF (0.17 mL of a 1 mol/L solution) was allowed to react under the previously described thermodynamic control conditions. Following a standard workup, the crude product was subjected to column chromatography (100% acetone) yielding two fractions. Fraction 1 was shown to contain ***Z*-5c** (0.2289 g, 57%) as an undistillable, viscous oil. IR (neat) ν_{max}: 3223, 1648, 1598 cm^{-1}. ^1H NMR δ: 1.96 (d, *J* = 1.4, 3H, CH_3), 2.32 (dd, *J* = 13 and 3.5, 1H), 3.01, 3.05 (2s, 6H), 3.0 (obscured, 1H), 4.89 (dd, *J* = 10 and 3, 1H), 6.16 (br s, 1H), 6.2 (br, 1H, exchangeable), 7.27 (m, 1H), 7.87 (m, 1H), 8.4–8.7 (m, 2H). MS *m/e* (rel. intensity): 235 (M^+ + l, 4), 189(44), 162(29), 144(86), 112(100). HR-MS calcd. for $C_{13}H_{18}N_2O_2$ + H: 235.1448. Found: 235.1452. Fraction 2 was shown to be ***E*-5c** (0.0536 g, 13%) as an undistillable, viscous oil. IR (neat) ν_{max}: 3344, 1646, 1607 cm^{-1}. ^1H NMR δ: 1.92 (s, 3H), 2.49 (d, *J* = 7, 2H), 2.87, 2.91 (2s, 6H), 4.6 (br, 1H, exchangeable), 4.92 (t, *J* = 7, 1H), 5.81 (br s, lH), 7.28 (m, 1H), 7.73 (m, 1H), 8.52 (m, 2H). MS *m/e* (rel. intensity): 234 (M^+, 2), 216(40), 171(44), 144(63), 127(100), 109(63). HR-MS calcd. for $C_{13}H_{18}N_2O_2$: 234.1369. Found: 234.1362.

syn- *and* anti-*2-Hydroxy(4-pyridyl)methyl*-N,N,*3-trimethyl-3-butenamide* syn- *and* anti-*6d and Z-5-Hydroxy-5-(4-pyridyl)*-N,N,*3-trimethyl-2-pentenamide Z-5d*

TBAF-mediated reaction

A mixture of compound ***Z*-4a** (0.2720 g, 1.36 mmol) and 4-pyridinecarboxaldehyde (1.9 mL) in the presence of TBAF (1.37 mL of a 1 mol/L solution) was allowed to react under kinetic control conditions. After a standard workup, the resulting crude product was subjected to preparative TLC (in 1: 1 ethyl acetate – acetone) to give, in order of elution, three fractions identified by ^1H NMR spectroscopy: Fraction 1 (0.0364 g, 13%) was shown to be starting ***Z*-4a**. Fraction 2 was identified as a 1:l mixture of ***syn*-** and ***anti*-6d** (0.1718 g), while fraction 3 was shown to be a 35:65 mixture of ***anti*-6d** and ***Z*- 5d** (0.0646 g). The individual isomers of **6d** were purified by recrystallization: ***syn*-6d** (27%), mp 111–113 °C (CH_2Cl_2 – Et_2O – hexane) (Lit.[3a] 98–99 °C (CH_2Cl_2 – hexane)), mixture mp 109–116 °C. ***anti*-6d** (34%), mp 125 °C (CH_2Cl_2 – hexane) (Lit.[3a] 128–129 °C (CH_2Cl_2 – hexane)). Compounds ***syn*-6d** and ***anti*-6d** showed ^1H NMR spectral data consistent with those reported.[3a] Compound ***Z*-5d** (13%) was identified by its ^1H NMR spectrum (see below).

A mixture of compound ***Z*-4a** (0.3804 g, 1.908 mmol) and 4-pyridinecarboxaldehyde in the presence of TBAF (0.10 mL of a 1 mol/L solution) was allowed to react under thermodynamic control conditions. After a standard workup, chromatography on aluminum oxide (activity III, 5:2 ethyl acetate – hexane) gave two fractions. Fraction 1 (0.2813 g) was identified as a 2:l mixture of ***Z*-5d** (42%) and ***syn*-6d** (21%). Fraction 2 proved to be ***anti*-6d** (0.0743 g, 17%). Compound ***Z*- 5d** was further purified by repeated preparative TLC, but remained a viscous, undistillable oil. IR (neat) ν_{max}: 3229, 1637, 1598 cm^{-1}. ^1H NMR δ: 1.95 (s, 3H), 2.33 (d, *J* = 13 and 3, 1H), 3.00, 3.05 (2s, 6H), 3.0 (obscured, 1H), 4.85 (br d, *J* = 10, 1H), 6.17 (br s, 1H), 7.35, 8.55 (AA′BB′ spin system, *J* = 6, 4H), OH not observed. MS *m/e* (rel. intensity): 235 (M^+ + l, 2), 216(33), 127(100), 112(68), 83(30). HR-MS calcd. for $C_{13}H_{18}N_2O_2$ + H: 235.1448. Found: 235.1454.

syn- *and* anti-*2-Hydroxy(4-nitro)phenylmethyl*-N,N,*3-trimethyl-3-butenamide* syn- *and* anti-*6e and Z-5-Hydroxy-5-(4-nitro)phenyl*-N,N,*3-trimethyl-2-pentenamide Z-5e*

$TiCl_4$-mediated reaction

A mixture of compound ***Z*-4a** (0.3766 g, 1.89 mmol) and

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Sichuan Normal University on 09/14/12
For personal use only.

4-nitrobenzaldehyde (0.3429 g) in the presence of $TiC1_4$ (0.23 mL) was allowed to react under the previously described conditions. After a standard workup, the crude reaction product was subjected to column chromatography (3:2 ethyl acetate – hexane) to give in order of elution: ***syn*-6e** (0.3578 9, 73%), mp 119.5–121 °C (Et_2O – hexane). IR ($CHCl_3$) ν_{max}: 3404, 1624 cm^{-1}. ^1H NMR δ: 1.64 (s, 3H), 2.96 (s, 6H), 3.42 (d, J = 3.7, 1H), 4.51, 4.96 (2s, 2H), 5.26 (s, 1H, exchangeable), 5.36 (d, J = 3.7, 1H), 7.54 and 8.18 (AA′BB′ spin system, J = 9, 4H). MS *m/e* (rel. intensity): 278 (M^+, 1), 127(100), 112(90), 83(100). Anal. calcd. for $C_{14}H_{18}N_2O_4$: C, 60.42; H, 6.52; N, 10.07. Found: C, 60.66; H, 6.51; N, 10.21. ***anti*-6e** (0.0047 g, 1%), mp 177–178 °C (CH_2Cl_2 – hexane). IR ($CHCl_3$) ν_{max}: 3443, 1626 cm^{-1}. ^1H NMR δ, 1.69 (s, 3H),. 2.91, 2.94 (2s, 6H), 3.41 (d, J = 6, 1H), 4.65–5.25 (m, 4H; on addition of D_2O gives 4.73 (s, 1H), 4.96 (s, 1H), 5.11 (d, J = 6, 1H)), 7.53, 8.19 (AA′BB′ spin system, J = 8, 4H). MS *m/e* (rel. intensity): 278 (M^+, 1), 127(100), 112(38), 83(89). Anal. calcd.. for $C_{14}H_{18}N_2O_4$: C, 60.42; H, 6.52; N, 10.07. Found: C, 60.54; H, 6.45; N, 10.06.

TBAF-mediated reaction

A mixture of compound ***Z*-4a** (0.3061 g, 1.54 mmol) and 4-nitrobenzaldehyde (0.3139 g) in the presence of TBAF (1.55 mL of a 1 mol/L solution) was allowed to reaction under the previously described kinetic control conditions. Following a standard workup, preparative (5:2 ethyl acetate – hexane) TLC of the crude product gave, in order of elution: recovered ***Z*-4a** (0.0096 g, 3%), ***syn*-6e** (0.1082 g, 25%), and a 51:49 mixture (by ^1H NMR spectroscopy) of ***anti*-6e** (31%) and ***Z*-5e** (30%) (0.2631 g). Compound ***Z*-5e** was obtained by crystallization, mp 113–115 °C (CH_2Cl_2 – Et_2O – hexane). IR ($CHCl_3$) ν_{max}: 3194, 1650, 1598 cm^{-1}. ^1H NMR δ: 1.95 (s, 3H), 2.33 (dd, J = 13 and 3), 3.0 (obscured, 1H), 3.01, 3.06 (2 s, 6H), 4.94 (m, 1H; on addition of D_2O becomes dd, J = 10 and 3), 6.18 (br s, 1H), 7.19 (d, J = 6, 1H, exchangeable), 7.63, 8.20 (AA′BB′ spin system, J = 9, 4H). MS *m/e* (rel. intensity): 278 (M^+, 2), 260(37), 216(39), 127(100), 112(97), 83(100). Anal. calcd. for $C_{14}H_{18}N_2O_4$: C, 60.42; H, 6.52; N, 10.07. Found: C, 60.35; H, 6.44; N, 9.93.

A mixture of compound ***Z*-4a** (0.3053 g, 1.53 mmol) and 4-nitrobenzaldehyde (0.2905 g) in the presence of TBAF (0.08 mL of a 1 mol/L solution) was allowed to reaction under the previously described thermodynamic control conditions. After a standard workup, the crude product was subjected to column chromatography (2:1 – 4:1 ethyl acetate – hexane) to give, in order of elution, two fractions: ***syn*-6e** (0.0926 g, 22%) and a 46:54 mixture of ***anti*-6e** (27%) and ***Z*-5e** (31%) (0.2468 g).

Z-5-Hydroxy-N,N,*3-trimethyl-5,5-diphenyl-2-pentenamide Z-5g and Z- and* E-N,N,*3-trimethyl-5,5-diphenyl-5-trimethylsiloxy-2-pentenamide Z- and* E-*5f*

TBAF-mediated reaction

To a solution of ***Z*-4a** (0.4794 g, 2.40 mmol) and benzophenone (0.5461 g, 1.24 equiv.) in 5 mL of THF cooled to –45 °C was added TBAF (0.12 mL of a 1 mol/L solution in THF, 5 mol%). After stirring for 1 h at –45 °C, the reaction mixture was quenched with saturated aqueous NH_4Cl (at –45 °C) and was worked up in the usual manner. The resultant crude product was subjected to flash chromatography (fine silica, 3:1 – 9:1 ethyl acetate – hexane), to give, in order of elution: ***Z*-5f** (0.1872 g, 20%). IR (neat) ν_{max}: 1623 cm^{-1}. ^1H NMR (C_6D_6) δ: –0.13 (s, 9H), 1.92 (s, 3H), 2.34, 2.78 (2s, 6H), 3.76 (s, 2H), 5.57 (br s, 1H), 7.36 (apparent s, 10H). This compound slowly underwent desilylation on standing to give ***Z*-5g**, mp 143–145 °C (Et_2O – petroleum ether). IR ($CHCl_3$) ν_{max}: 3191, 1643, 1598. cm^{-1}. ^1H NMR δ: 1.25 (s, 3H), 2.96, 3.03 (2 s, 6H), 3.42 (s, 2H), 6.08 (br s, 1H), 7.1–7.7 (m, 10H), 7.41 (s, 1H, exchangeable). MS *m/e* (rel. intensity): 291 (M^+ –18, 8), 182(49), 128(41), 105(100), 84(24), 77(48), 72(32). Anal. calcd. for C_{20} $H_{23}NO_2$: C, 77.64; H, 7.49; N, 4.53. Found: C, 77.16; H, 7.46; N, 4.62. ***E*-5f** (0.4418 g, 48%), mp 65–67 °C (Et_2O – petroleum ether). IR ($CHCl_3$) ν_{max}: 1646, 1610 cm^{-1}. ^1H NMR (C_6D_6) δ: –0.12 (s, 9H), 1.71 (s, 3H), 2.36, 2.81 (2s, 6H), 3.18 (s, 2H), 5.45 (br s, 1H), 7.25 (s, 10H). MS *m/e* (rel. intensity): 366 (M^+ – 15, 2), 291(6), 255(100), 199(28), 73(100). Anal. calcd. for $C_{22}H_{31}NO_2Si$: C, 72.39; H, 8.19; N, 3.67. Found: C, 72.62; H, 8.25; N, 3.80.

$TiCl_4$-mediated reaction

A mixture of compound ***Z*-4a** (0.211 g, 1.06 mmol) and benzophenone (0.273 g) in the presence of $TiC1_4$ (0.23 mL) was allowed to react under the previously described conditions. After a standard workup, the crude reaction product was subjected to column chromatography (3:1 ethyl acetate – hexane) to afford **6g** (0.236 g, 72%), whose spectroscopic data was shown to be identical with those reported.[3a]

Z- and* E-N,N,*3-Trimethyl-5,5-diphenyl-2,4-butadienamide Z- and* E-*7

A mixture of compound ***Z*-4a** (0.5210 g, 2.61 mmol) and benzophenone (1.6385 g, 3 equiv.) in the presence of TBAF (0.13 mL of a 1 mol/L solution) was allowed to react under thermodynamic conditions. After a standard workup, the crude product was subjected to flash chromatography (4:1 – 9:1 ethyl acetate – hexane) to give a mixture of ***Z*-** and ***E*-7** (0.2815 g, 29%), bp 145–150 °C at 0.01 torr. IR (neat) ν_{max}: 1630 cm^{-1}. ^1H NMR δ: 1.56 and 1.81 (s, 3H), 2.65 and 2.89 (s, 6H), 5.89 (br s, 1H), 6.55 and 7.24 (obscured) (br s, 1H), 7.24 (s, 10H). The relative integrals of the 1.8 and 1.56 peaks established the ratio of ***E*-7:*Z*-7** as 65:35. MS *m/e* (rel. intensity): 291 (M^+, 38), 219(100), 214(25), 204(49). HR-MS calcd. for $C_{20}H_{21}NO$: 291.1624. Found: 291.1631.

syn- *and* anti-*2-(1-Hydroxy-l-propyl)*-N,N,*3-trimethyl-3-butenamide* syn- *and* anti-*6h***

A mixture of compound ***Z*-4a** (0.4114 g, 2.06 mmol) and butanal (0.22 mL) in the presence of $TiCl_4$ (0.25 mL) was allowed to react under the previously described conditions. Following standard workup, the crude reaction product was subjected to column chromatography (2:l hexane – ethyl acetate) to give, in order of elution: ***syn*-6h** (0.2552 g, 62%), mp 44–45 °C (Et_2O – hexane) (Lit.[3a] 44–46 °C (Et_2O – hexane)). ***anti*-6h** (0.0097 g, 2%), mp 68–70 °C (CH_2Cl_2 – hexane) (Lit.[3a] 70 °C (CH_2Cl_2 – hexane)) both of which were shown to exhibit ^1H NMR spectral data consistent with their structures,[3a] and a mixture of desilylated 2- and 3-butenamides (0.0391 g, 14%).

A 53:47 mixture of ***anti*-6j** (7%) and desilylated butenamides (6%) (0.0111g)**;** pure ***anti*-6j** was obtained by recrystallization, mp 80–82 °C (hexane). IR (neat) ν_{max}: 3415, 1623 cm^{-1}. ^1H NMR (500 Mz) δ: 0.96 (t, J = 7.3), 1.43 (m, 1H), 1.54 (m, 1H), 1.73 (s, 3H), 2.94, 2.97 (2s, 6H), 3.16 (d, J = 6.8, 1H), 3.85 (m, 1H), 4.84 (s, 1H), 4.97 (m, 1H). ^{13}C NMR: 10.2, 20.8, 21.2, 35.6, 37.2, 56.1, 72.8, 115.4, 140.5, 172.8. MS *m/e*: 185 (M^+, 13), 127 (75), 125 (100), 111(24). HR-MS calcd.. for $C_{10}H_{19}NO_2$: 185.1405 (M^+). Found: 185.1416.

Supplementary data

The experimental procedures and spectral data for the preparation of **3,** the crossover experiment of **1a** and **1b**, the attempted $TiCl_4$ mediated reaction of ***E*-4a** with benzaldehyde, the $BF_3{\cdot}OEt_2$ mediated reaction of ***Z*-4a** with benzaldehyde, the attempted generation of the titanium dienolate of **1a**, the attempted fluoride mediated reaction of **2a** with benzaldehyde, and the minimized structures and final Cartesian coordinates and energies for the calculated transition states **16** and **17,** have been deposited as Supplementary data for this article available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 3932. For more information on obtaining material, refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml.

Acknowledgements

We are grateful to the Natural Sciences and Engineering Research Council of Canada (NSERC) for support of our synthetic programs. We also wish to thank Prof. James Gauld, Dr. Haining Liu, and Prof. Charles MacDonald (University of Windsor) for assistance with the DFT calculations on the allylsilane – aldehyde transition states.

Novel formation of isoxazoline *N*-oxide in addition to Michael adduct from the reaction of β-nitrostyrenes with 2-methoxyfuran — Experimental and theoretical studies

Kuniaki Itoh, Shigehisa Kishimoto, and Kazuo Sagi

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Sichuan Normal University on 09/14/12
For personal use only.

Abstract: 2-Methoxyfuran reacts with β-nitrostyrenes to give Michael adducts. Interestingly, isoxazoline *N*-oxides were obtained in the reactions with β-nitrostyrenes possessing additional electron-withdrawing groups [COPh (**2f**) and CO_2Et (**2g**)]. (*Z*)-Nitrostyrene (**2g**) gives *trans*-isoxazoline (**4g**) and (*E*)-nitrostyrene (**2f**) leads to the *cis*-form product **4f**. We have used theoretical methods to investigate the mechanism and to probe the regio- and stereo-selectivity observed in the rearrangement and the Michael reactions. To account for the selectivity observed in these reactions, we examined the Fukui functions and located the transition states (TS) using density functional theory (DFT) calculations at the B3LYP/6–31G* level. The first step involves a nucleophilic attack by the α-carbon atom (C4) of the furan ring on the vinyl C-atom (C5) of the nitrostyrene part to give a zwitterionic intermediate (IN1). Fission of the C–O bond of the furan ring in the intermediate and ring closure via the oxygen atom (endo-O atom) of the nitro group gives the isoxazoline *N*-oxide. Alternatively, the intermediate (IN1) may be transformed into the Michael adduct by an intramolecular proton transfer mediated by the formation of a four-membered transition-state structure. The potential-energy barriers for these reactions had the following values: 5.1 kcal/mol for **2f** and 17.0 kcal/mol for **2g′** (CO_2Me) at the rearrangement step, and 41–49 kcal/mol for the proton-transfer step. The solvent effect in $CHCl_3$ stabilized the electrophilic attack by 1–14 kcal/mol. DFT analysis of these reactions is in good agreement with the experimental results.

Key words: reaction mechanisms, nitrogen heterocycles, zwitterions, rearrangement, density functional calculations.

Résumé : Le 2-méthoxyfurane réagit avec les β-nitrostyrènes pour conduire à la formation d'adduits de Michael. À notre grande surprise, les réactions avec des β-nitrostyrènes possédant des groupes électro-attracteurs supplémentaires [COP (**2f**) et CO_2Et (**2g**)] conduisent à la formation de *N*-oxydes d'isoxazoline. Le (*Z*)-nitrostyrène (**2g**) conduit à la *trans*-isoxazoline (**4g**) alors que le (*E*)-nitrostyrène (**2f**) conduit à la *cis*-isoxazoline (**4g**). On a fait appel à des méthodes théoriques pour étudier le mécanisme et pour chercher à expliquer la régio- et la stéréo-sélectivité observée dans les réactions de réarrangement et de Michael. Pour expliquer la sélectivté observée dans ces réactions, on a examiné les fonctions de Fukui et localisé les états de transition (ET) en faisant des calculs au niveau B3LYP/6-31G* de la théorie de la fonctionnelle de la densité (TFD). La première étape implique une attaque nucléophile par l'atome de carbone C4 du noyau furane sur l'atome de carbone C5 vinylique de la partie nitrostyrène qui conduit à la formation d'un intermédiaire zwitterionique (IN1). La fission de la liaison C–O du cycle du furane intermédiaire et la cyclisation par le biais de l'atome d'oxygène (atome d'oxygène endo) du groupe nitro conduit à la formation du *N*-oxyde d'isoxazoline. D'une façon alternative, il est possible que l'intermédiaire IN1 se transforme en adduit de Michael par le biais d'un transfert de proton intramoléculaire catalysé par la formation d'un état de transition de structure à quatre chaînons. On a calculé que les barrières d'énergie potentielle de ces réactions sont les suivantes: 5,1 kcal/mol pour **2f** et 17,0 kcal/mol pour **2g′** (CO_2Me) au niveau de l'étape de réarrangement et de 41 à 49 kcal/mol pour l'étape de transfert de proton. L'effet de solvant dans le $CHCl_3$ stabilise l'attaque électrophile par 1 à 14 kcal/mole. Les résultats de l'analyse par la théorie de la fonctionnelle de la densité de ces réactions sont en bon accord avec les résultats expériementaux.

Mots-clés : mécanismes réactionnels, hétérocycles azotés, zwitterions, réarrangement, calculs suivant la théorie de la fonctionnelle de la densité.

[Traduit par la Rédaction]

Introduction

We have been studying the Diels–Alder reactions of furan derivatives with various types of electron-deficient dienophiles[1] for some time, with a view to synthesizing *C*-nucleosides via the Diels–Alder reaction of furan with methyl 3-nitroacrylate.[1b] Furans have been condensed with a wide variety of dienophiles, but they are known to be rather unreactive dienes because of their stabilized aromatic electronic configuration.[2] In some instances, Lewis acids or high-pressure conditions[3]

were employed in the reactions with less-reactive dienophiles. Sometimes, the incorporation of an electron-donating group into the 2-position of furan has been used as a means to enhance the reactivity of the heteroaromatic ring function.[4]

It appears therefore that Diels–Alder reactions of furans require the use of more reactive dienophiles. Nitro-olefins are powerful and versatile reagents,[5] which have found ample application in organic synthesis. Because of the strong electron-withdrawing property of the nitro group, conjugated nitroalkenes are excellent Michael acceptors and dienophiles in Diels–Alder reactions. Furthermore, the nitro group can be further transformed into a wide variety of functionalities.[6] In Diels–Alder reactions, nitroalkenes react not only with dienes to give nitrocycloalkenes,[7] but also with electron-deficient alkenes to afford cyclic alkyl nitronates.[8] The use of nitrostyrene derivatives in combination with cyclohexadiene or cyclopentadiene in the presence of $SnCl_4$ affords exclusively a nitronate. These compounds are biologically important intermediates in the synthesis of isoxazolines and many five-membered heterocyclic systems via 1,3-dipolar cycloaddition reactions.[9] Recently, we described some reactions of β-nitrostyrenes with 2-methoxyfurans.[10] In the present paper, our purpose is to use a computational approach to contribute to a better understanding of the mechanistic features of these processes, especially by locating and characterizing all the stationary points along the reaction coordinate involved in these types of addition and rearrangement reactions.

The Diels–Alder reaction may occur via either a synchronous concerted mechanism or a stepwise mechanism with zwitterionic intermediates.[11,12] In the case considered here, the presence of an electron-releasing group on the furan, the electron-withdrawing NO_2 group on the dienophile, and also the presence of the Ph group allows for an effective stabilization of developing electronic charge, which favors a stepwise mechanism via a zwitterionic intermediate.

Although the mechanism of the Diels–Alder reaction with furans has long been settled through a quantum chemistry approach,[1e,13] there is little agreement as to that of the Michael reaction.[14] We find that the Michael addition of furans with activated dienophiles proceeds via a two-step process by formation of a zwitterionic intermediate and an intermolecular proton transfer mediated by the formation of a four-membered structure, similar to the reaction of 1-methylpyrrole with dimethyl acetylenedicarboxylate reported by Domingo and co-workers[13] and by us.[1e]

Computational details

The density functional method computations for the gas-phase calculations were performed with the Spartan 04 for Windows package.[15] The reactant, product, and transition-state (TS) geometries for the above reactions were optimized by DFT calculations at the B3LYP/6–31G* level.[16] After the optimization of all transitional structures, we carried out vibrational analyses to check the nature of the stationary points. The transition states are defined by exactly one imaginary frequency. Unless otherwise indicated, all energies in the B3LYP/6–31G* optimizations reported in this paper include zero-point energies without scaling. To calculate the free energies of solvation needed to understand the effect of the solvent on the stereoselectivity,[17] we used the Gaussian 03 program.[18] To evaluate the solvent effect, we carried out a B3LYP/6–31G* single-point calculation, using the method based on the polarized continuum model (PCM).[19] The solvent used in the experimental work was chloroform; therefore, we employed the dielectric constant, $\varepsilon = 4.81$ and the solute radius, $\alpha = 3.92$. To reduce the time of the calculation, we used the β-methoxycarbonyl nitrostyrene (**2g′**) in the calculation instead of the β-ethoxycarbonyl nitrostyrene (**2g**) used in the experiments. Electrophilic and nucleophilic Fukui functions condensed to atoms were evaluated from single-point calculations performed in the ground state of molecules at the same level of theory.[20] This method evaluated Fukui functions using the gross charges of the Mulliken's population analysis.

Results and discussion

Experimental results

No reaction of nitrostyrenes with furan or 2-methylfuran took place under the reaction conditions defined below; therefore, in the present study, we used 2-methoxyfuran as a more reactive diene.[21]

A typical experimental procedure was as follows: to a stirred solution of 2-methoxyfuran (**1**) (1.5 mmol) in $CHCl_3$ (3 mL) was added β-bromo-β-nitrostyrene (**2d**) (1.1 mmol) at room temperature under N_2 atmosphere. After stirring for 3 days, the resultant solution was evaporated under reduced pressure leaving an oil, which was separated by column chromatography on silica gel (eluate mixture: AcOEt/hexane = 1/9) to give a mixture of Michael adducts **3d** (34%) (Scheme 1). An NMR analysis showed that the mixture was composed of a 1:1 mixture of two diastereoisomers (**I**, **II**), which showed different signals for furyl and alkyl H-atoms (**I**: 6.40 ppm (d, J = 10.7), 6.20 ppm (d, J = 3.3), 5.07 ppm (d, J = 3.3), 4.66 ppm (d, J = 10.7); **II**: 6.36 ppm (d, J = 10.7), 6.06 ppm (d, J = 3.3), 5.00 ppm (d, J = 3.3), 4.71 ppm (d, J = 10.7)). Results of reactions with other β-nitrostyrenes are given in Table 1. In general, β-nitrostyrenes **2a**–**2d** reacted with **1** to yield the corresponding Michael adducts (Table 1, entries 1–4). However, β-methyl-β-nitrostyrene (**2e**) gave no adduct and was recovered almost totally even after 4 days, presumably due to the presence of the electron-donating methyl group at the β-position.

Hence, the reaction of a more electron-deficient β-nitrostyrene, (*E*)-β-benzoyl-β-nitrostyrene (**2f**), with **1** was examined in the hope that the Diels–Alder reaction would occur,[22] but gave neither Michael adducts nor Diels–Alder adducts. Instead, an unexpected compound (**4f**, 27%) was obtained that showed no evidence of furan-ring signals in its ^1H and ^{13}C NMR spectra. The ^1H and ^{13}C NMR spectra of the main adduct indicated the presence of a methyl ester group (CO_2Me: 3.61 ppm, s, 3H (Me), and 53.4 (Me), 165.7 (CO_2) ppm) and an ethen-1,2-diyl group (CH=CH, (*Z*)-configuration: 6.05 ppm, dd, J = 1.5, 11.6 and 6.57 ppm, ddd, J = 1.5, 7.5, 11.6). Furthermore, the (*Z*)-configuration was confirmed by NOE experiments. The observed signals showed that scission of the furan ring had occurred. In addition, the two H-signals at higher field (4.70 ppm, d, J = 4.1, 1H, and 6.18 ppm, ddd, J = 1.5, 4.1, 7.5, 1H) are correlated

with an H-atom of the ethen-1,2-diyl group (δ = 6.57 ppm). Finally, the structure of the main adduct was determined to be an isoxazoline *N*-oxide derivative by a single-crystal X-ray diffraction analysis (Fig. 1, X-ray crystallographic analysis, and Supplementary data).

The product **4f** showed a cis relation between the Ph and (*Z*)-MeOCOCH=CH groups. We also obtained a minor product (**4f′**, 2%). Since the product was isolated in a small amount, we could not fully clarify its structure. However, the ^{1}H NMR spectrum of **4f′** was similar to that of **4f**. The coupling constant between H–C(3) and H–C(4) amounts to 3.2, in agreement with the structure of the trans isomer of the main product. To confirm this stereoselectivity, (*Z*)-β-ethoxycarbonyl-β-nitrostyrene (**2g**) was reacted with **1**. The isoxazoline *N*-oxide derivative (**4g,** 68%) was the major product, and a Michael adduct occurred in lower yield (**3g**, 8%) in this reaction. The H-signals of the isoxazoline ring showed up at 4.41 (d, *J* = 2.4) and 6.03 ppm (ddd, *J* = 1.7, 2.4, 7.5). The signal pattern indicated a trans arrangement between the Ph and the (*Z*)-MeOCOCH=CH group. The structure of the adduct **4g** was confirmed by a single-crystal X-ray diffraction analysis (Fig. 2, X-ray crystallographic analysis, and Supplementary data). These results are informative and imply that the product formation involves a sterically controlled inter- or intra-molecular reaction. In addition, the sterically controlled nature of the reaction was confirmed by the

Fig. 1. Structure (ORTEP) of isoxazoline *N*-oxide (**4f**).

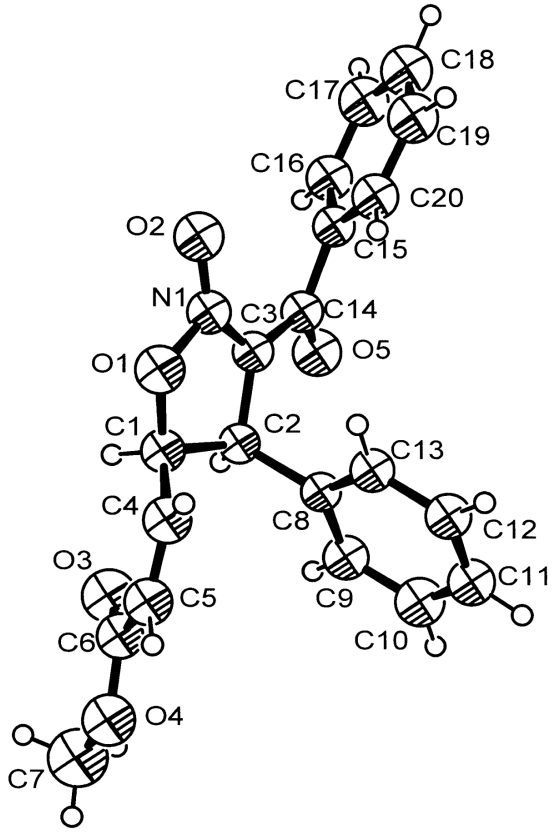

Fig. 2. Structure (ORTEP) of isoxazoline *N*-oxide (**4g**).

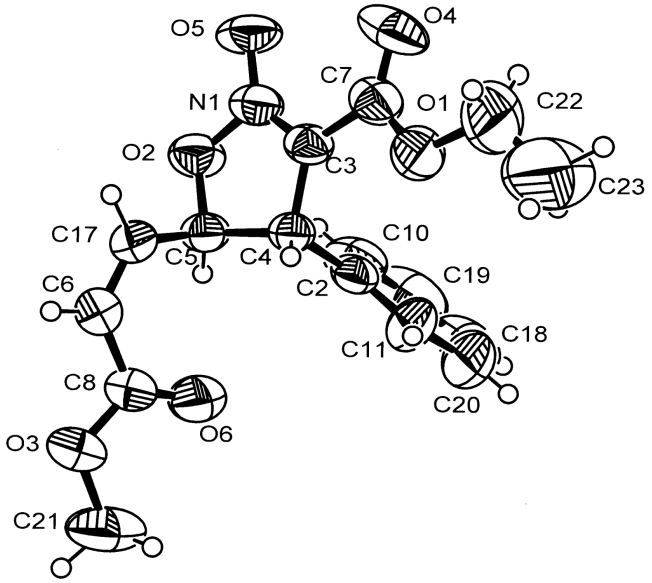

reaction of (*E*)- and (*Z*)-β-*p*-methoxybenzoyl-β-nitrostyrene (**2h** and **2i**, respectively).

Interestingly, the isoxazoline *N*-oxide was not formed via a Michael intermediate, as no trace of the isoxazoline *N*-oxide was detected after allowing the authentic Michael adduct to stand in $CHCl_3$ solution at room temperature for 2 weeks.

Concerning the formation of isoxazoline *N*-oxides, it is of interest to note that these products are mainly obtained from nitroacetate with aldehydes[24] or nitromethane with sulfonium salts[25] in the presence of an inorganic salt. They are also obtained from the decomposition of the Ag^+ salt of an aryldinitromethane in the presence of diarylethylene.[26] However, the reaction of β-nitrostyrene with alkenes in the presence of "Lewis" acids gave the corresponding nitronates (4*H*-[1,2]oxazine 2-oxides),[27] which is a quite different process in comparison with the present isoxazoline *N*-oxide-forming reaction. Therefore, it appears that the formation of isoxazoline *N*-oxides described here represents a new approach in comparison with the reactions conventionally employed.

Two processes may account for the formation of the isoxazoline *N*-oxide ring together with Michael adduct. In the first (Scheme 2), **1** and **2** react in one of their polarized mesomeric forms, **1**′ and **2**′, to give the intermediate IN1. It may then be transformed into the Michael adduct **3** by ordinary H^+-transfer. On the other hand, it could undergo ring formation to give an isoxazoline *N*-oxide **4** accompanied by C–O bond fission of the furan ring induced by an intramolecular nucleophilic attack by the nitronate part.

In an alternative route, the cycloaddition of the furan **1** and the β-nitrostyrene (**2**) yields a Diels–Alder adduct (DA).[28] This adduct may be transformed into the Michael adduct **3** by cleavage of the cyclohexenyl ring, promoted by the steric interaction between the phenyl group and the nitro group. On the other hand, cleavage of the cyclohexenyl ring, attributable to the stability of the mesomeric form of the methoxy group and steric effect, followed by intramolecular attack of the nitronate anion and cleavage of the oxygen bridge resulted in the formation of the isoxazoline *N*-oxide (**4**).

The regioselectivity for the addition reaction is predicted easily from the values of the orbital coefficients of the olefinic C-atoms found from a frontier molecular orbital model.[13] Consequently, we found that the C-atom bearing the Ph group of the olefin adds to the furyl C(4)-atom. However, by this means, we could not determine clearly which mechanism best satisfies the stereoselectivity. Therefore, we sought to predict the selectivity from the values of the potential energy at the transition states and the intermediates determined from DFT calculations at the B3LYP/6–31G* level.

Geometries and energies

Figure 3 and 4 display schematic representations of the energy profiles and the locations of the stationary points for the reactions. Figures 5, 6, and 7 present the geometry of these transition-state structures, including selected distances, while Tables 2 and 3 show the relative energies and thermodynamic parameters of the stationary points. In Table 4, the corresponding geometric parameters are reported for the INs and the TSs. For comparison, Tables 5 and 6 show some parameters for the Michael addition reactions.

The present reactions take place by a stepwise mechanism, which is initiated by the nucleophilic attack of the unsubstituted C(4)-atom of **1** on the C(5)-atom (the C-atom that bears the Ph group) of **2** to give a zwitterionic intermediate (IN1) (see Scheme 2). Bond formation between **1** and **2** can take place via an *re, re* and *re, si* approach of the involved C-atoms of the reactants. The resulting zwitterions, IN1-ax and IN1-eq are diastereoisomers with erythro- and threo-configuration at C(4) and C(5), respectively. The reactive nitronate ion part O(2) then attacks the electrophilic C(4) position of the

Scheme 2.

methoxyfuran accompanied by the C(4)–O(1) bond fission of the furan ring to give the isoxazoline *N*-oxide (**4**). Furthermore, in the case of the β-methoxycarbonyl-β-nitrostyrene (**2g**′), the intermediate (IN1) may be transformed into the Michael adducts **3g**′ by deprotonation reaction.

The reaction of 2-methoxyfuran (1) and β-benzoyl-β-nitrostyrene (2f)

At the first transition state of the attack of **1** on **2**, the potential-energy barriers associated with TS1-ax and TS1-eq are 31.9 and 18.8 kcal/mol, respectively, which indicates that the latter is 13.1 kcal/mol more favorable than TS1-ax (see Table 2 and Fig. 3). In the structure of TS1-ax, the NO_2 group is located on the face of the furan ring. Thus, the favorable Coulomb interaction that appears between the donor 2-methoxyfuran, positively charged from the O-atom, and the acceptor styrene, negatively charged from the N-atom of the NO_2 group, are responsible for the "axial"

stereoselectivity found in those additions. On the other hand, at TS1-eq, the NO_2 group is located on the face of the furan ring, but the group is situated far away (C1–N1: 3.48 Å) because of the steric repulsion between the benzoyl group and the methoxy group of the furan ring (see Table 4). The lengths of the C4–C5 bond being formed in TS1-ax and TS1-eq are 1.55 Å and 1.63 Å, respectively, whereas the distances between C(1) and C(6) are 2.70 Å and 3.48 Å. In these transition structures of TS1, the NO_2 group at C(6) is in the plane of the C5–C6 bond, and the carbonyl group at C(6) is also in the plane of the C5–C6 bond. The values of the C5–C6–N1, C5–C6–C7 bond angles in TS1-ax are 117.04°, 120.93°, respectively, and those of TS1-eq are 114.71°, 119.91°, respectively. These bond angles show that there is sp^2 hybridization at C(6) in the transition structure (TS1). This arrangement allows for the effective delocalization of the negative charge being formed at C(6).

The zwitterionic intermediates (IN1-ax and IN1-eq) are diastereomers as shown before (threo conformer). The potential energy for the intermediate (IN1-eq) has a value of 0.8 kcal/mol and is lower than that of IN1-ax (3.6 kcal/mol) due to a favorable arrangement. In the intermediate (IN1-ax), the C1–C4–C6–N1 dihedral angle (3.06°) indicated that the furan ring and the C6=N1 double bond of the NO_2 group are parallel to each other. Further, the distance between the C(4) and O(2) atoms of the NO_2 group (2.82 Å) indicates

that separation of these atoms is near to the van der Waals distance. On the other hand, for the IN1-eq intermediate, the dihedral angle of C1–C4–C6–C7 (–132.70°) indicates that the C1–C4 axis and the C6–C7 bond are approximately perpendicular, and the angle of C1–C4–C6–N1 (0.09°) suggests that the C1–C4 axis is located parallel to the C6–N1 bond. This arrangement, which is present in intermediates (IN1), allows to a smooth promotion of the next rearrangement reaction.

It is also possible that the intermediates (IN1) may occur via the scission of a (4+2) cycloadduct (Diels–Alder adduct) (TS4 and TS5 in Scheme 2) as observed in our paper concerning the reaction of the furan.[1,11,12,28] The potential-energy barrier of the transition state for the concerted (4+2) addition reaction are 22.9 kcal/mol (for the "axial" form) and 23.6 kcal/mol (for the "equatorial" form), values that are over 4 kcal/mol higher than the energy of TS1-ax (18.8 kcal/mol). They are due to the steric repulsion between the methoxy group of the furan ring and the benzoyl group or the NO_2 group of the styrene. Furthermore, not only the higher energy barrier but also the large electrophilic gaps on the reaction sites (see the next section) should inhibit this pathway.

The final step of these reactions corresponds to a rearrangement of the zwitterionic intermediate (IN1-eq) to give the final isoxazoline *N*-oxide (**4f**). This rearrangement process can take place by the nucleophilic attack of the O(2)-atom of the NO_2 group on the C(4)-atom of the furan ring with formation of the C–N bond, together with the fission process in the plane of the C4–O1 bond of the furan ring to produce of the CO_2 group. In the TS2-ax transition structure for this process, the bond angle O1–C4–O2 is only 64.71°, which makes this transformation very unlikely. The length of the C4–O2 bond being formed is 2.93 Å and the length of the C4–O1 bond being cleaved is 2.08 Å. The value of the H4–C4–C5–H5 dihedral angle (20.35°) is consistent with the formation of the cis-form product (**4f**).

On the other hand, the process involving TS2-eq has a low potential-energy barrier (5.1 kcal/mol). In the transition structure (see Fig. 5), the center tetrahedral carbon C4 (C3–C4–C5: 109.09°, C3–C4–H4: 112.49°, C5–C4–H4: 111.17°, C5–C4–O1: 111.41°) is located between the O(2)-atom of the NO_2 group and O(1)-atom of the furan. The O1–C4–O2 bond angle is 117.72°, that is, the O(1)-atom, the C(4)-atom, and the O(2)-atom are arranged almost on a single straight line. The value of this bond angle indicates that the C(4) center presents an sp hybridization, in which the charge lo-

cated at C(4) occupies a p atomic orbital. The length of the C4–O2 bond being formed is 2.49 Å and the length of the C4–O1 bond being cleaved is 1.46 Å. The value of the H4–C4–C5–H5 dihedral angle is –68.18°. These angles are consistent with the formation of the cis-form product (**4f**) in accords with the experimental results. The potential-energy gaps of the transformation process (TS2) are 32.2 kcal/mol for the ax conformer and 5.1 kcal/mol for the eq former. The latter is 27.1 kcal/mol more favorable than TS2-ax due to a favorable arrangement.

We have also computed relative entropies at 25 °C for the different stationary points (Table 2). At TS1, the large negative entropy change (61–65 cal/mol K) due to the restricted geometry associated with the intermolecular nature of the process is similar to that seen in Diels–Alder reaction.[29] However, for the second step (TS2), the activation entropy change is very small (–2.1 cal/mol K for ax form and –10.4 cal/mol K for eq form) due to the smooth intramolecular nature of the rearrangement process. Moreover, the formation of the *cis*-isoxazoline *N*-oxide (**4f**) is exothermic by –17.5 kcal/mol.

Thus, the formation of the isoxazoline via the eq form is kinetically and sterically more favorable than formation via the ax form. As a consequence, there is a large "equatorial" stereoselectivity along the path of nucleophilic attack of **1** on **2** in this stepwise mechanism in agreement with the experimental outcome.

The value of the H4–C4–C5–H5 dihedral angle in **4f** from the B3LYP/6–31G* calculation is 20.35°, which is in reasonable agreement with the value of 18.6(2)° found from the X-ray analysis (see Table 7). The other geometrical parameters obtained for the isoxazoline *N*-oxide (**4f**) from the calculation are in agreement with the experimental analysis of the structure of **4f**. The bond distances in the hetero-

cyclic ring for the calculated structure are slightly longer than those found by experiment (0.02 Å is the highest difference for the C4–C5 bond) with the sole exception of the C4–O2 bond distance, which is 0.015 Å shorter.

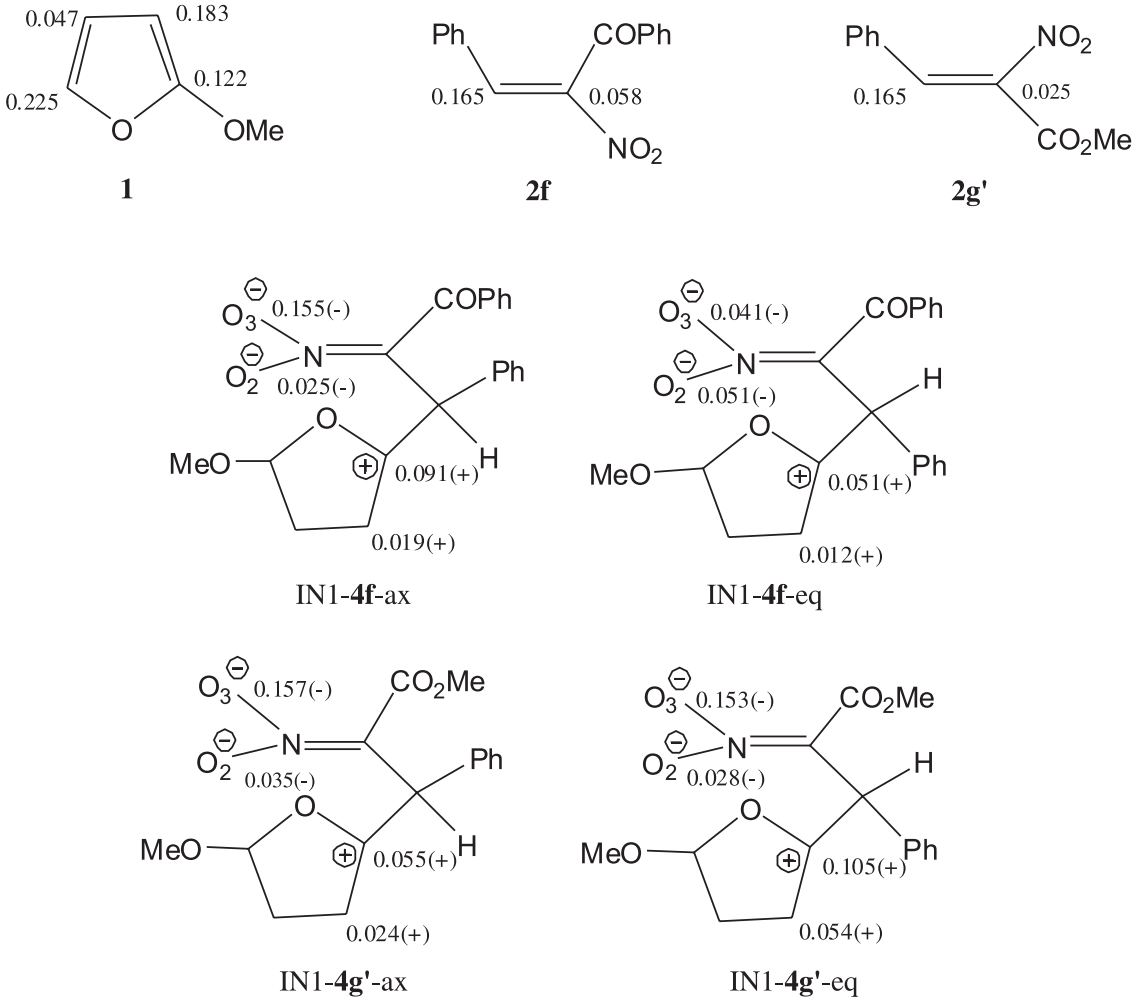
The reaction of 2-methoxyfuran (1) and β-methoxycarbonyl-β-nitrostyrene (2g′)

For these reactants, the potential-energy barriers associated with TS1-ax and TS1-eq are 13.4 and 15.2 kcal/mol, respectively, and the latter is disfavored by 2 kcal/mol relative to TS1-ax (see Table 2 and Fig. 3). In the structure of TS1-ax, the NO_2 group is located on the face of the furan ring. On the other hand, the NO_2 group is located out of the furan ring in TS1-eq. In these TS1 transition structures, the nitro group at C(6) is in the plane of the C5–C6 bond from C5–C6–N1–O2 dihedral angles (–7.76°, 5.03°), whereas the carbonyl group at C6 is also in the plane of C5–C6 bond from C5–C6–C7–O3 dihedral angles (57.36°, 5.69°) (see Table 4). This arrangement allows for the effective delocalization of the negative charge being formed at C(6) as in the case of **2f**.

In the zwitterionic intermediates (IN1-ax), the distance between C1 and N1 (2.6 Å), C4 and C6 (2.6 Å), and the dihedral angle of C1–C4–C6–N1 (–1.95°) all indicate that the nitro group is parallel to the plane of the furan ring and that of the C5=N1 double bond being attacked. On the other hand, the distance (2.8 Å) between the C(4) and O(2) atoms indicates that these atoms are positioned close to the sum of their van der Waals radii. The values of the C5–C4–O1 bond angles are ~110° and those of C3–C4–H4 are 113°, which show that C(4) is sp^3-hybridized. The intermediate (IN1-ax) has a potential energy that is 4.2 kcal/mol lower than IN1-eq due to a favorable electronic interaction between the furan ring and the NO_2 group.

With **2g′** as a reactant, the intermediates (IN1) can also undergo two transformations. One of them corresponds to the rearrangement process of the zwitterionic intermediate to give the final isoxazoline *N*-oxide (**4g′**). The other process (TS3) gives the Michael adducts. In the transition structure for this process (TS2) (see Figs. 5 and 6), the center tetrahedral carbon C4 (C3–C4–C5: 121°, C3–C4–H4: 118°, C5–C4–H4: 119°) is located between the O(2)-atom of the NO_2

Fig. 8. Fukui functions for the furan (**1**), the styrenes (**2f** and **2g′**), and the intermediates (IN1-**4f**, IN1-**4g′**).



group and O(1)-atom of the furan. In TS2-ax, the O1–C4–O2 bond angle is 170.89°, that is, the O(1), C(4), and O(2) atoms are aligned in a single straight line. The length of the C4–O2 bond being formed is 2.18 Å and the length of the C4–O1 bond being cleaved is 1.84 Å. The value of the H4–C4–C5–H5 dihedral angle is 139.12°. These angles indicate that the reaction proceeds smoothly to the trans-form product (**4g′**). On the other hand, in TS2-eq, the O(1), C(4), and O(2) atoms are not arranged on a single straight line because the O1–C4–O2 bond angle is only 67.54°, which make this transformation unlikely. Furthermore, the value of the H4–C4–C5–H5 dihedral angle (78.18°) is consistent with the formation of the cis-form product, which is not consistent with the experimental results. The potential-energy gaps for the TS2 transformation process are 17.0 kcal/mol for the ax former and 34.9 kcal/mol for the eq former. The latter is 17.9 kcal/mol more disfavorable than TS2-ax.

As before, we have computed the relative entropies (see Table 2). At TS1, the large negative entropy change (58–63 cal/mol K) is due to the intermolecular nature of the process. However, for the second process (TS2), the difference of the negative activation entropy change is only 2–8 cal/mol K, the small value being due to the smooth intramolecular nature of the rearrangement process. Again, we find that the formation of the *trans*-isoxazoline *N*-oxide (**4g′**) is exothermic by –19.6 kcal/mol.

Thus, the formation of the isoxazoline from the ax form is kinetically more favorable than the formation from the eq form. As a consequence, there is a large axial stereoselectivity along the nucleophilic attack path of **1** on **2** in this stepwise mechanism in agreement with the experimental outcome.

The calculated geometrical parameters for the **4g** product are in good agreement with experiment. The value of the H4–C4–C5–H5 dihedral angle from the B3LYP/6–31G* calculation is –102.07°, which is in good agreement with the X-ray analysis for **4g** (–105.4(4)°) (see Table 7). The other geometrical parameters obtained for the isoxazoline *N*-oxide (**4g′**) from the calculation are in agreement with the experimental analysis of the structure of **4g**. The bond distances in the heterocyclic ring for the calculated structure are slightly longer than those from experiment, and the calculated bond angles only differ slightly from the experimental values (less than 1.5%).

Solvent effect on the rearrangement reactions

Solvent effects on cycloaddition are well-known[30] and have received considerable attention. Table 3 shows the relative energies of the stationary points corresponding to the

reaction in the $CHCl_3$ used as the experimental solvent. The energy differences of the transition state TS1 in this solvent are stabilized by 8–10 kcal/mol over that in the gas phase. The transition structure involving nucleophilic attack is preferentially stabilized relative to the reactants due to the large charge transfer that is developed along this polar transfer path. The solvent-effect increases for TS1 are more dramatic than those of TS2. Thus, inclusion of the solvent effect may accelerate this polar reaction, thanks to a larger stabilization of the transition state corresponding to nucleophilic attack, and decrease the energies. However, the data on IN1 do not show a definite difference between the gas phase and in-solvent. These results are due to the low variation of the dipole moments along the reactive channels and are related to the effective delocalization of the charge. Also, in the reaction of **2g′** at TS2, the transition structures in solvent are stabilized over the gas phase by 7 kcal/mol. This difference of TS energies in the solvent and in the gas phase is related to localization of the charge around the ester group. The low energy barrier found for the reaction is in good agreement with the fact that, experimentally, this reaction can be carried out at room temperature.

The formation process of the Michael adduct

The intermediate IN1 in the reaction of β-methoxycarbonyl-β-nitrostyrene (**2g′**) may also undergo an alternative process pathway that leads to the formation of a Michael adduct. Also, the reaction of **2a**–**2e** with **1** gave the Michael adducts.[31]

The canonical structure showed as IN1 at the zwitterionic intermediate formed in the previous process (TS1) takes to the other canonical structure (IN2) by the cation transfer from the O-atom of the furan to the atom of C(3) (see Scheme 2).[32] The intermediate IN2 may lead to the formation of the Michael adducts (**3**) via a four-membered transition structure in which the intramolecular proton (H4) transfers from the C(4) to the anionic C(6) center with furan ring (TS 3) (see Fig. 7). The energy barriers associated with TS3 together with TS1 and IN2, and the geometric parameters are shown in Tables 5 and 6 and Fig. 4.

This process (TS3) presents a high potential-energy barrier (46.7, 49.5 kcal/mol for **2a**; 42.4, 42.5 kcal/mol for **2d**) relative to the former addition steps (TS1), and the energies of the two stereoisomers do not show a definite difference. However, the potential energy (31.8 kcal/mol at the B3LYP/6–31G* level) for **2g′**-ax is significantly lower than those of **2a** and **2d**, but is unfavorable compared with that of the competitive pathway (TS2-ax: 17.0 kcal/mol). The larger potential-energy barrier in TS3 for **2g′** relative to TS2 is responsible for the lower reactivity seen in the former experiment.[33]

In the transition state TS3, the length of the C4–H4 bond being broken is 1.25–1.35 Å and the C6–H4 bond being formed is 1.55–1.71 Å. These lengths suggest a concerted bond-breaking and -formation process for the intramolecular proton transformation. One of the causes of the high potential energy of TS3 relative to TS1 is the angular strain associated with the formation of this transition structure. The C3–C4–C5 bond angle is 128°–133° (~110° at TS1) and the H4–C4–C5 bond angle is 79°–86° for **3a** and **3d** and 110° for **3g′**. These values show that the C(4) center is far from being sp^3-hybridized. In addition, the C4–C5–C6 bond angle (~98°) is associated with the strain that appears during the formation of this four-membered transition structure. In contrast, the TS1 route has a lower energy due to a favorable π–π electric interaction between the furan (**1**) and the nitrostyrene (**2**) taking a syn-periplanar conformation. However, for the intramolecular process, the negative activation entropy is lower by 15–20 cal/mol K for **2a**, 5–7 cal/mol K for **2d,** and 5 cal/mol K for **2g′**, compared with the more entropically favorable value for the asymmetrical addition reaction (TS1). In addition, the computed free energy of activation is found to be 5–8 kcal/mol. These cooperative factors permit the intramolecular process to occur with the smooth motion of the H(4) atom from the C(4) to the C(6) center. In addition, the energy differences of the transition state TS3 in solvent are stabilized by 11–15 kcal/mol over that in the gas phase. The transition structure involving proton transfer is preferentially stabilized relative to the reactants due to the large charge transfer that is developed along this polar transfer path.

Two Michael adducts (**3d** and **3d′**) are obtained from the reaction of **2d**. The new intermediates (IN2′), which corresponded to the anti conformation between the Ph and Br groups, have been found. The rotational barrier around the C5–C6 single bond may allow the easy equilibration between the two conformers (IN2 and IN2′); therefore, two isomers of the products (**3d** and **3d′**) are obtained in equivalent yields. In IN2′, the bond distances C4–C5 (1.55, 1.55 Å) and C1–C6 (3.52, 3.19 Å) and the C1–C4–C6–C5 angle (–38.5° and 54.3°) are similar to those of IN2. Also, the potential-energy barriers (40.7, 43.6 kcal/mol) at TS3′ are similar to those of TS3, and the geometrical parameters for TS3′ show similar values to those of TS3. They indicate that the Michael adduct from the IN2 and IN2′ may produce equivalent yields; the former gives the threo product and the latter gives the erythro product.

This transition structure presents a very high imaginary frequency (1500–2000i cm^{-1}), indicating that this process is associated mainly with the motion of the H4 atom from C4 to C6 centers.

Local electrophilicity/nucleophilicity analysis

Recent studies of cycloaddition reactions with a polar character have used an analysis of the electrophilic and nucleophilic Fukui functions to explain the observed experimental region-selectivities.[34] The local functions for our case are summarized in Fig. 8. The 2-methoxyfuran (**1**) has the largest nucleophilic activation at the nonsubstituted C4 position (f^- = 0.225); hence, this is the more reactive site for the electrophilic attack. On the other hand, for the styrene systems **2f** and **2g′**, there are two electrophilic sites (at the C5 and C6 carbon atoms). Analysis of the electrophilic Fukui functions for **2f** and **2g′** indicate that the C5 position has the lower electrophilic activity (f^+ = 0.165 > 0.058 for **2f**, 0.165 > 0.025 for **2g′**). Thus, the most favorable interaction will take place between the C4 carbon atom of **1** and the C5 carbon atom of **2**, in agreement with the regioselectivity observed.

The second step in the reaction is the rearrangement reaction of the zwitterionic intermediates IN1-ax and IN1-eq to give the isoxazoline **4**. This process involves the nucleophilic attack of the O(2)-atom of the NO_2 group at the styrene **2** side to the electron-poor furan residue (C4). As a conse-

Can. J. Chem. Downloaded from www.nrcresearchpress.com by Sichuan Normal University on 09/14/12
For personal use only.

quence, for IN1-ax and IN1-eq, the site analysis must be carried out at the electrophilic positions (C4) of the furan residues, the C4 (f^+ = 0.091(+), 0.051(+) for IN1-**4f**, and f^+ = 0.055(+), 0.105(+) for IN1-**4g′**, respectively) center, and the nucleophilic position of the styrene, O2 center (f^- = 0.025(–), 0.051(–) for IN1-**4f** and f^- = 0.035(–), 0.028(–) for IN1-**4g′**, respectively)[35] (see Fig. 8). These local Fukui functions show that the more favorable interaction along the addition reaction process corresponds to the attack of the nucleophilic C4 center on the electrophilic O2 and lead to formation of isoxazoline. Moreover, comparison of the nucleophilic function for the both isomers at **4f** and **4g′** indicate an activity at O2, but a quite large difference is found between the isomers, the value exhibiting an opposite tendency. The function has a larger value for the eq form at **4f** (0.025 < 0.051), but on the other hand, shows a larger value (0.035 > 0.028) for the ax form at **4g′**. These contrasting results allow us to explain the predominant isomer products, the more reactive nucleophilic attack for the eq form at **4f**, and the more reactive attack for the ax form at **4g′**. Thus, this local analysis is in agreement with the experimental results.

Experimental

IR spectra were recoreded in KBr bellets using *Hitachi I-2000*r instrument in cm^{-1}. ^1H and ^{13}C NMR Spectra were recorded on a Bruker *AC-250* and *GX-400* spectrometers in $CDCl_3$ solutions; δ in ppm; relative to $SiMe_4$ as the internal reference; *J* in Hz. Mass spectra (MS) were recorded on a *GCMS-QP2000A* instrument in *m/z*. Melting points were recorded using a *Yanaco* micro hot-plate apparatus and are uncorrected.

Materials

β-Nitrostyrene derivatives (**2a**–**2i**) were prepared according to the Knoevenagel condensation of benzaldehyde with nitroalkenes reported by either Dornow et al.[36] or Yamamura and co-workers.[37]

1-(2-Methoxyfuran-5-yl)-1-phenyl-2-nitroethane, (3a)

1-(*p*-Chlorophenyl)-1-(2-methoxyfuran-5-yl)-2-nitroethane, (3c)

Oil. IR: 3024, 2940, 1620, 1556, 1092. ^1H NMR (250 MHz) δ: 3.80 (3H, s), 4.74 (1H, d, *J* = 8.0, 16.1), 4.76 (1H, d, *J* = 8.0, 11.1), 4.94 (1H, d, *J* = 11.1, 16.1), 5.04 (1H, d, *J* = 3.4), 5.96 (1H, d, *J* = 3.4), 7.27 (4H, m). ^{13}C NMR (67.8 MHz) δ: 43.0, 57.9, 80.1, 109.1, 114.7, 128.9, 129.3, 134.1, 135.4, 141.0, 161.7. MS: 138, 115, 77, 75, 55. Anal.calcd. for $C_{13}H_{12}NO_4Cl$: C 55.43, H 4.29, N 4.97; found: C 55.19, H 4.42, N 4.82.

2-Bromo-1-(2-methoxyfuran-5-yl)-1-phenyl)-2-nitroethane, (3d-I)

Oil. IR: 3028, 2988, 1570, 1356, 752, 700. ^1H NMR (250 MHz,) δ: 3.82 (3H, s), 4.66 (1H, d, *J* = 10.7), 5.07 (1H, d, *J* = 3.3), 6.20 (1H, d, *J* = 3.3), 6.40 (1H, d, *J* = 10.7), 7.36 (5H, m). ^{13}C NMR (67.8 MHz) δ: 51.8, 57.8, 80.4, 81.0, 110.8, 128.1, 129.0, 129.7, 135.2, 139.4, 161.9. MS: 297, 295, 217, 185, 183, 155, 115, 102, 77. Anal. calcd. for $C_{13}H_{12}NO_3Br$: C 56.14, H 4.35, N 5.04; found: C 56.10, H 4.66, N 4.82.

2-Bromo-1-(2-methoxyfuran-5-yl)-1-phenyl-2-nitroethane, (3d-II)

Oil. IR: 3108, 2960, 1570, 1346, 772, 702. ^1H NMR (250 MHz) δ: 3.77 (3H, s), 4.71 (1H, d, *J* = 10.7), 5.00 (1H, d, *J* = 3.3), 6.06 (1H, d, *J* = 3.3), 6.36 (1H, d, *J* = 10.7), 7.36 (5H, m). ^{13}C NMR (67.8 MHz) δ: 51.4, 57.8, 80.1, 80.8, 110.7, 128.0, 128.5, 129.2, 135.1, 138.7, 161.8. Anal. calcd. for $C_{13}H_{12}NO_3Br$: C 56.14, H 4.35, N 5.04; found: C 56.44, H 4.25, N 5.08.

Methyl-(2*z*)-3-(*N*-oxy-3-benzoyl-*cis*-(4-phenyl-4,5-dihydroisoxazol-5-yl))-propyl-2-enolate, (4f)

Mp 169.0–170.3 °C. IR: 3064, 2956, 1722, 1652, 1602, 1450, 1374, 1256, 1228, 1204, 798, 702. ^1H NMR (400 MHz) δ: 3.61 (3H, s), 4.70 (1H, d, *J* = 4.10), 6.05 (1H, dd, *J* = 1.47, 11.64), 6.18 (1H, ddd, *J* = 1.47, 4.10, 7.54), 6.57 (1H, ddd, *J* = 1.47, 7.54, 11.64), 7.18 (2H, m), 7.27 (3H, m), 7.42 (2H, m), 7.52 (1H, m), 7.72 (2H, m). ^{13}C NMR (67.8 MHz) δ: 52.0, 53.4, 85.6, 118.8, 123.1, 127.4, 128.1, 128.4, 128.5, 128.9, 129.1, 131.7, 133.4, 141.6, 159.2, 165.7, 184.9. MS: 351, 292, 171, 114, 105, 77. Anal. calcd. for $C_{20}H_{17}NO_5$: C 68.37, H 4.88, N 3.99; found: C 68.25, H 5.06, N 3.91.

Methyl-(2*z*)-3-(*N*-oxy-3-benzoyl-*trans*-(4-phenyl-4,5-dihydroisoxazol-5-yl))propyl-2-enolate, (4f′)

Mp 71.3–72.5 °C. IR: 1730, 1652, 1602, 1452, 1374, 1200, 798, 700. ^1H NMR (250 MHz) δ: 3.58 (3H, s), 4.75 (1H, d, *J* = 3.2), 6.04 (1H, dd, *J* = 1.4, 11.5), 6.21 (1H, ddd, *J* = 1.4, 3.2, 7.5), 6.56 (1H, dd, *J* = 7.5, 11.5), 7.50 (10H, m).

Ethyl 3-(5-methoxy(2-furyl))-2-nitro-3-phenylpropanoate, (3g)

Oil. ^1H NMR (250 MHz) δ: 1.22 (3H, t, *J* = 7.1), 3.79 (3H, s), 4.00 (2H, q, *J* = 7.1), 4.92 (1H, d, *J* = 11.5), 5.02 (1H, d, *J* = 3.2), 5.73 (1H, d, *J* = 11.1), 6.09 (1H, d, *J* = 3.2), 7.33 (5H, s). ^{13}C NMR (67.8 MHz) δ: 13.3, 48.2, 57.6, 62.9, 80.0, 90.0, 109.6, 128.0, 128.4, 135.7, 140.0, 161.0.

Anal. calcd. for $C_{16}H_{17}NO_4$: C 60.18, H 5.37, N 4.39; found: C 59.06, H 5.33, N 4.16.

2-Ethoxycarbonyl-1-(2-methoxyfuran-5-yl)-1-phenyl-2-nitroethane, (3g′)

Oil. ^{1}H NMR (250 MHz) δ: 0.96 (3H, t, J = 7.2), 3.79 (3H, s), 4.21 (2H, q, J = 7.2), 4.90 (1H, d, J = 11.4), 5.02 (1H, d, J = 3.2), 5.76 (1H, d, J = 11.4), 6.03 (1H, d, J = 3.2), 7.33 (5H, s).

Methyl-(2*z*)-3-(*N*-oxy-3-ethoxycarbonyl-*trans*-(4-phenyl-4,5-dihydro-isoxazol-5-yl))propyl-2-enolate, (4g)

Mp 63–64 °C. IR: 1732, 1728, 1626, 1442, 1382, 1354, 1286, 1230, 1200, 1198, 1026, 754. ^{1}H NMR (400 MHz) δ: 1.17 (3H, t, J = 3.7), 3.61 (3H, s), 4.18 (2H, q, J = 3.7), 4.41 (1H, d, J = 2.4), 6.01 (1H, dd, J = 1.7, 11.5), 6.03 (1H, ddd, J = 1.7, 2.4, 7.5), 6.51 (1H, dd, J = 7.5, 11.5), 7.36 (5H, m) . ^{13}C NMR (67.8 MHz) δ: 13.8, 51.7, 55.9, 61.6, 79.6, 111.2, 122.5, 127.4, 128.8, 129.1, 138.2, 145.2, 158.3, 165.8. MS: 319 (M^+), 197, 171, 147, 131, 117, 106. Anal. calcd. for $C_{16}H_{17}NO_4$: C 60.18, H 5.37, N 4.39; found: C 60.03, H 5.22, N 4.30.

Methyl-(2*z*)-3-(*N*-oxy-3-benzoyl-*cis*-(4-*p*-methoxyphenyl-4,5-dihydro-isoxazol-5-yl))-propyl-2-enolate, (4h)

Mp 164–165 °C. ^{1}H NMR (400 MHz) δ: 3.60 (3H, s), 3.80 (3H, s), 4.47 (1H, d, J = 3.7), 6.02 (1H, dd, J = 1.5, 11.6), 6.17 (1H, ddd, J = 1.5, 3.7, 7.8), 6.49 (1H, ddd, J = 1.5, 7.8, 11.6), 6.92 (2H, d, J = 7.7), 7.31 (2H, d, J = 7.7), 7.58 (5H, m). ^{13}C NMR (67.8 MHz) δ: 51.80, 54.58, 55.24, 85.83, 114.25, 122.27, 127.44, 128.16, 128.91, 129.92, 131.73, 132.36, 144.94, 159.16, 165.22, 184.80. MS: 381, 364, 350, 335, 322, 303, 275, 265, 239, 202, 146, 105. Anal. calcd. for $C_{20}H_{19}NO_6$: C 65.04, H 5.19, N 3.79; found: C 65.16, H 5.07, N 3.67.

Methyl-(2*z*)-3-(*N*-oxy-3-benzoyl-*trans*-(4-*p*-methoxyphenyl-4,5-dihydro-isoxazol-5-yl))-propyl-2-enolate, (4i)

Mp 67.5–69.0 °C. ^{1}H NMR (400 MHz) δ: 3.60 (3H, s), 3.78 (3H, s), 4.70 (1H, d, J = 4.1), 6.05 (1H, d, J = 11.6), 6.18 (1H, dd, J = 4.1, 7.5), 6.57 (1H, d, J = 7.5, 11.6), 6.90 (2H, d, J = 8.7), 7.34 (2H, d, J = 8.7), 7.57 (5H, m). ^{13}C NMR (67.8 MHz) δ: 51.84, 55.23, 56.21, 80.23, 114.54, 123.06, 128.39, 128.41, 128.91, 128.91, 129.59, 133.54, 135.15, 144.48, 159.52, 165.19, 184.93. MS: 381, 364, 350, 335, 322, 306, 265, 239, 238, 217, 202, 146, 105. Anal. calcd. for $C_{20}H_{19}NO_6$: C 65.04, H 5.19, N 3.79; found: C 65.13, H 5.12, N 3.70.

X-ray crystallographic analysis

X-ray crystallographic analysis was carried out on Rigaku AFC5R diffractometer. The diffraction data were collected by using Mo Kα radiation, and 4350 independent reflections were used for solving the structure by the teXsan program.[38] All non-H atoms were located by directed methods using SIR92[39] and were refined anisotropically.

Crystal data for the $C_{20}H_{17}NO_5$: formular weight = 339.35; monoclinic, space group $P2_1/C$; a = 15.197(1), b = 5.808(2), c = 19.563(1) Å; β = 95.321(5)°; V = 1719.2(6) Å^3; Z = 4; $d_{calcd.}$ = 1.31g cm^{-1}; R = 0.055 (R_w = 0.045) for 4509 reflection data with $I > \sigma$ and 2823 valuables.

Crystal data for the $C_{16}H_{17}NO_6$: formular weight = 319.31; triclinic, space group P-1; a = 9.753(7), b = 10.28(1), c = 9.25(1) Å; α = 106.0(2)°, β = 109.3(1)°, γ = 94.13(8)°; V = 828(1) Å^3; Z = 2; $d_{calcd.}$= 1.28 gcm^{-1}; R = 0.068 (R_w = 0.045) for 1389 reflection data with $I > 3\sigma$ and 208 valuables.

Summary

This study examined the reaction of 2-methoxyfuran with β-nitrostyrenes and the nature of the mechanism of the isoxazoline *N*-oxide and the Michael adduct produced using quantum mechanical calculations. Experimental data showed that by the reaction with the β–nitrostyrenes (**2f** and **2g′**), with electron-withdrawing groups, the isoxazoline is obtained and the *Z*-form of the nitrostyrene (**2g′**) gives the trans-product and the *E*-form (**2f**) gives the cis-product. We have shown the following:

(*i*) An analysis of the results of the calculation shows that the reaction takes place via a polar stepwise mechanism. The first step (TS1) corresponds to the nucleophilic attack of the furan ring on the nitrostyrene to give two zwitterionic intermediates (IN-ax and IN-eq). For the second step (TS2), an intramolecular substitution in the intermediate (IN) gives the formation of the isoxazoline (**4g′** and **4f**) together with fission of the furan ring. Alternatively, the intermediate (IN) is transformed into the Michael adduct (**3g′**) by an intramolecular proton transfer.

(*ii*) The isoxaszolines (**4g′** and **4f**) come from the ring closure via the oxygen atom (endo-O atom) of the nitro group of the intermediate (IN).

(*iii*) The Michael adduct, also, comes from the similar intermediate (IN-ax′).

(*iv*) From the theoretical results, the selectivity of the reaction is determined by the difference between the ax-form and the eq-form energies at TS1 and TS2.

(*v*) The solvent-effect increase for TS1 is more dramatic than that of TS2 owing to the localization of the charge.

(*vi*) The formation process of the Michael adducts (TS3) show a high potential energy, but that of **2g′**-ax is significantly higher than that of the competitive pathway (TS2).

(*vii*) The high potential energy of TS3 is due to the angular strain associated with the formation of the four-membered transition structure.

(*viii*) The local Fukui function analysis gave the good suggestion for the reaction site.

(*iv*) The calculation analysis obtained in this paper offered the reasonable explanation for the experimental results.

Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca) or may be purchased from the Depository of Unpublished Data, Document Delivery, CISTI, National Research Council Canada, Ottawa, ON K1A 0R6, Canada. DUD 3948. For more information on obtaining material, refer to cisti-icist.nrc-cnrc.gc.ca/cms/unpub_e.shtml. CCDC 440/175 and 291612 contain the X-

(32) Ranganathan et al. (ref. 27) reported that furan and nitroethylene gave 2-(β-nitromethyl)-furan and proposed that the Michael product yielded from a Diels–Alder adduct.

(33) The yields were calculated from the products isolated after column chromatography. For the isoxazoline, the separation was difficult; therefore, a small percentage loss may result.

(34) Mulliken and natural population analysis atomic charge indicate that the C1 center has the largest degree of electrophilic activation. Thus, the most favorable interaction takes place between the C1 and C6 atoms with the formation of the (4+2) cycloadduct, which is at odds with the experimental results. Thus, these rearrangement reactions cannot be successfully analyzed using these population analysis methods.

(35) The other O3-atom of the NO_2 group has the higher electrophilic activity, but the length from the nucleophilic center C4 is over 4.5 Å, so the O3-atom should not take part in bond formation.

Combined tight-binding/DFT investigation of the electronic structure of triimine-platinum(II)/TCNQ extended stacks[1,2]

Hassan Rabaâ, Thomas R. Cundari, and Mohammad A. Omary

Abstract: . The [Pt(tbtrpy)(X)][TCNQ] (X = OH or SH) complexes form sandwich stacks with nitrile acceptors leading to extended-chain supramolecular assemblies, tbtrpy = 4,4′,4″-*tert*-Bu_3-2,2′:6′,2″-terpyridine. Calculations with the extended Hückel tight-binding (EHTB) method are performed upon crystalline {[Pt (tbtrpy)(X)][TCNQ]}$_\infty$ species to analyze their electronic structure and consequent properties, TCNQ = 7,7,8,8-tetracyanoquinodimethane. The donor/acceptor extended chains in the solid state are predicted to exhibit metallic behavior with a large contribution from π and π* bands of TCNQ to the valence and conduction bands, respectively. Moreover, the valence band moves upward (i.e., to a less negative energy) for X = SH as compared to X = OH. Density functional theory (DFT) calculations suggest that this is due to large thiolate character in the HOMO of the square-planar donor complex, which also supports the experimental assignment of the electronic absorption bands and redox potentials. Calculations of infrared (ν_{CN} bands of TCNQ) and structural (CC bond lengths within TCNQ) data explain the metallic behavior of the stacks in terms of charge delocalization, leading to fractionally-charged species of the form $[Pt(tbtrpy)X]^{(1+\delta)+}[TCNQ]^{(1+\delta)-}$ with $\delta > 0$ and a greater δ value for X = SH vs OH.

Key words: DFT, TCNQ, platinum complexes, solid-state calculations.

Résumé : Les complexes [Pt(tbtrpy)(X)][TCNQ], {tbtrpy = 4,4′,4″-*tert*-Bu_3-2,2′:6′,2″-terpyridine; X = OH, SH; TCNQ = 7,7,8,8-tétracyanoquinodiméthane} forment des empilements sandwiches avec des accepteurs nitriles qui conduisent à la formation d'assemblages supramoléculaires à chaînes étendues. Des calculs en utilisant la méthode de Hückel étendue à liaisons fortes ("EHTB") ont été faits sur les espèces cristallines{[Pt(tbtrpy)(X)][TCNQ]}$_\infty$ afin d'analyser leur structure électronique et les propriétés qui en découlent. Les calculs permettent de prédire que les chaînes étendues de donneur-accepteur devraient présenter un comportement métallique avec une contribution importante des bandes π et π* du TCNQ aux bandes de valence et de conduction respectivement. De plus, la bande de valence se déplace vers le haut (c'est-à-dire vers une énergie moins négative) avec X = SH par rapport à X = OH. Des calculs selon la théorie de la fonctionnelle de la densité (TFD) suggèrent que cette situation est due au caractère thiolate important dans l'orbitale moléculaire haute occupée du complexe donneur plan carré et ils supportent l'attribution expérimentale des bandes d'absorption électronique et des potentiels redox. Des calculs infrarouges (bandes ν_{CN} du TCNQ) et des données structurales (longueurs des liaisons CC dans le TNCQ) expliquent le comportement des empilements en fonction de la délocalisation de la charge, conduisant à des espèces à charge fractionnaire de la forme $[Pt(tbtrpy)(X)]^{(1+\delta)+}[TCNQ]^{(1+\delta)-}$ dans lesquelles $\delta > 0$ alors que la valeur de δ pour X = SH est plus grande que celle pour X = OH.

Mots-clés : TFD, TCNQ, complexe du platine, calculs à l'état solide.

[Traduit par la Rédaction]

Introduction

The Pt(II)-polyimine class of square-planar complexes has become an interesting series of targets in inorganic spectroscopy.[3,4] Much work has been done to demonstrate the ability to modify the spectroscopic and electrochemical properties of such complexes upon variation of ligands and their substituents, as well as on their relevance for applications that include solar energy conversion, nonlinear optics, optical sensing, DNA intercalation, protein probing, and photoinduced electron transfer for hydrogen production.[5,6]

Dunbar, Omary, and co-workers have reported that neutral (diimine)(dithiolato) Pt^{II} and Pd^{II} complexes form supramolecular stacks with nitrile acceptors (see Fig. 1).[7a] The crystal structure of [Pt(tbtrpy)(OH)]TCNQ with (tbtrpy = 4,4′,4″-*tert*-Bu_3-2,2′;6′,2″-terpyridine, TCNQ = 7,7,8,8-tetracyanoquinodimethane) exhibits a distorted square planar coordination (tbtrpy bite angles of 80.8° and N_{tbtrpy}-Pt-O angles of 97.7° and 100.4°). The mean metal-ligand distances are Pt–N = 1.98 ± 0.02 Å and Pt–O = 2.24 Å. The material crystallizes in the *Pbcn* space group with a = 13.84(3) Å, b = 23.17(4) Å, and c = 23.38(4) Å, within Z = 8. The 1:1 stacking motif between [Pt(tbtrpy)(OH)] and TCNQ shows an in-

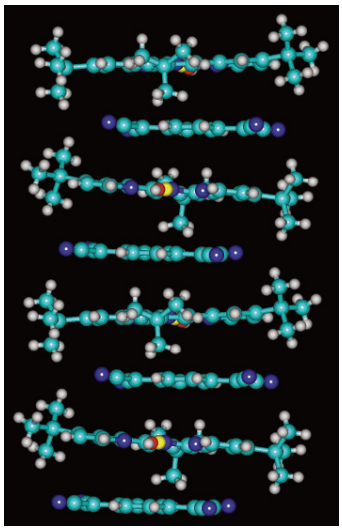
Fig. 1. Plot showing a single [Pt(tbtrpy)(OH)]TCNQ stack. The atoms are colored as follows: Pt (violet), O (red), N (blue), and C (grey).



ter-planar separation between the respective centroids of ~3.5 Å. Within a stack the Pt···Pt distances are 7.7 Å, while intra-stack distances are 12 Å or longer.[7a]

These stacks exhibit favorable properties for solar cell applications, including strong absorptions across a wide spectral range. In subsequent work by the same researchers, the electronic absorption spectra were obtained for selected [Pt(tbtrpy)X]Y complexes (X = Cl, NCS, OH, or arylthiolates (SAr); Y^- = Cl^-, BF_4^-, or $TCNQ^-$ = 7,7,8,8,-tetracyanoquinodimethane radical anion).[7b] It was shown that varying the anionic ligand X to arythiolate leads to red shifts of charge transfer bands to the visible region, which can be red- or blue-shifted CT absorptions by using electron-donating or -withdrawing substituents, respectively.[7b] Additionally, varying the counterion to $TCNQ^-$ radical anion gives rise to additional absorptions in the near-infrared (NIR) region, thus rendering a recipe to attain "black absorbers", which might be suitable for solar energy conversion due to their continuous and strong absorptions across a wide spectral range in the UV–vis and NIR regions.

In this paper we examine the electronic structure of the [Pt(trpy)X]Y class of materials via quantum mechanical computations based on density functional theory (DFT) and semi-empirical (extended Hückel) methods. One important aspect in this research pertains to investigating the conducting behavior of metal compounds with $TCNQ^-$ as counterion. This present research is inspired by the experimental observations reported in ref. 5b that suggested possible charge delocalization in [Pt(tbtrpy)(X)]TCNQ, as inferred by electronic absorption features near 490 nm, characteristic of the $TCNQ^{2-}$ dianion as well as ν_{CN} infrared frequencies (~2175–2180 cm^{-1}) that were lower than those reported for both neutral TCNQ (2227 cm^{-1}) and $TCNQ^-$ (2195 cm^{-1}, Na^+ salt).[8] Similar charge delocalization has been reported for tetrathiafulvalene (TTF)–/TCNQ binary donor–/acceptor complexes. Related organic[9] and inorganic[10] complexes have also been reported to exhibit anisotropic, one-dimensional crystal structures with conducting properties.[11] Thus, we undertook a computational investigation of the bonding and structure of [Pt(trpy)X]TCNQ materials using two levels of theory. Extended Hückel tight binding (EHTB)[12] calculations of crystalline [Pt(tbtrpy)(X)]TCNQ (X = OH or SH) are used to provide insights regarding the possible solid-state electronic structure of this class of materials. We also scrutinize whether charge delocalization occurs by which the donor complex is partially oxidized to $[Pt(tbtrpy)X]^{(1+\delta)+}$, while the acceptor is accordingly reduced to $TCNQ^{(1+\delta)-}$; this is done via DFT computations that evaluate the ν_{CN} IR frequencies in model complexes compared with isolated TCNQ species. Both computational methods are also used to examine the electronic structure of $[Pt(trpy)X]^+$ complexes as a function of X.

Computational methods

The solid-state calculations described in this work are performed within the framework of the extended Hückel tight binding (EHTB) method[12], for which standard parameters are used within the YAeHMOP[13] software package. The off-diagonal elements of the Hamiltonian are evaluated with the Wolfsberg–Helmholtz formula.[14] Numerical integrations over the symmetry unique section of the Brillouin zone of the three-dimensional structure of [Pt(tbtrpy)(X)]TCNQ (X = OH or SH) were performed using a set of 40 k-points.[12,13] The EHTB approach has been used to describe or predict conductivity from band structure. For example, this method was used to describe the superconductivity of Chevrel phases.[14c] In another application, Lopes et al. used the EHTB method to study the 1-D conductor $(TTDM\text{-}TTF)_2[Au(mnt)_2]$[14d] (mnt = bis-maleonitriledithiolate, TTDM = thiophenothio-dimethylene).

The Gaussian 03 program is used for all density functional calculations described herein.[15] The valence basis sets (augmented with a d polarization function for main group atoms) and compact effective potentials of Stevens et al. are employed in conjunction with the B3LYP hybrid functional.[16,17] All geometries are optimized with restricted Kohn–Sham methods for singlets and unrestricted Kohn–Sham methods for higher multiplicities. Vibrational frequencies are calculated at all stationary points to characterize them as minima (no imaginary frequencies).

Results and discussion

Solid-state electronic structure of [Pt(tbtrpy)(X)]TCNQ

Figure 2 shows a plot of the total EHTB density of states (DOS) for [Pt(tbtrpy)(OH)]TCNQ plus DOS projections for Pt, tbtrpy, and TCNQ. The Fermi level is found to lie in the region of high DOS at –11.9 eV. *Therefore, [Pt(tbtrpy)(OH)]TCNQ is predicted to be metallic by the EHTB calculations.* Figure 2 indicates the role of the Pt(II) complex as a donor and TCNQ as an acceptor, as shown by the Pt projection in the valence band containing the Fermi level (top right) and the TCNQ projection in the band immediately above the Fermi level (bottom right). The substantial electron affinity of TCNQ[9k,11c] is consistent with the predicted metallic behavior of this solid, as TCNQ can readily accept electrons from the Pt complex via the low energy unoccupied π* orbitals of the former, which dominate the bands immediately above the Fermi level. Figure 2 also shows that the filled π orbitals of the terpyridyl ligand lie

Fig. 2. Plot of the density of states (DOS) for the crystal structure of [Pt(tbtrpy)(OH)]TCNQ showing the total DOS (top left), platinum projection (top right), tbtrpy projection (bottom left), and TCNQ projection (bottom right). The horizontal dashed line corresponds to the Fermi level.

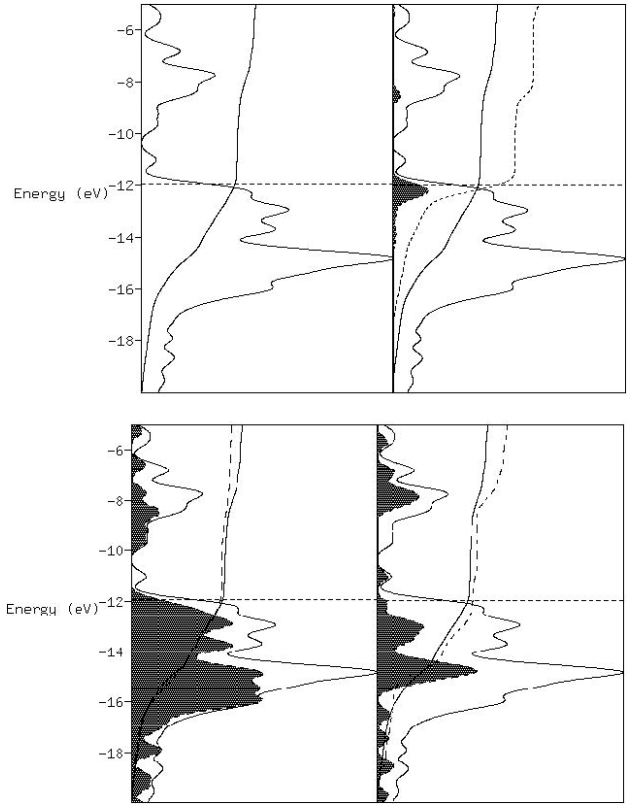


Fig. 3. View of the DOS of $[Pt(tbtrpy)(OH)]^+$ (left) and TCNQ (right) units in the crystal structure of [Pt(tbtrpy)(OH)]TCNQ. Note the nonmetallic behavior shown by the band gap in absence of interaction of these units with one another. The top of each band located around –11 eV corresponds to the Fermi level (horizontal dashed line).

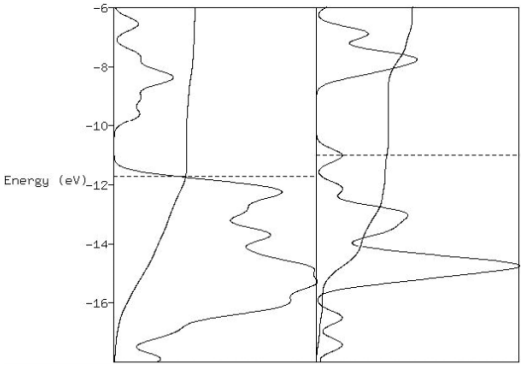
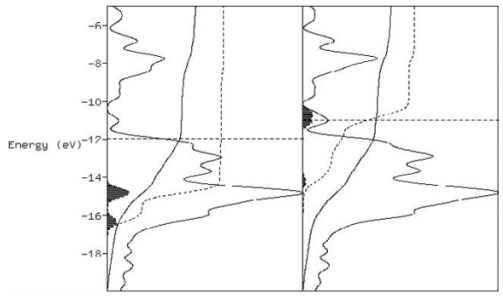


below both the Pt d_π orbitals and the TCNQ π orbitals, while the vacant π* orbitals of the terpyridyl ligand lie above the TCNQ π* orbitals. The results from the solid-state EHTB calculations are thus consistent with the electronic structure proposed in ref. 7b and are further assessed below for molecular models using DFT computations.

In solid [Pt(tbtrpy)(OH)]TCNQ, the interaction of the square planar Pt(II) complex with TCNQ results in an almost

Fig. 4. Density of states for [Pt(tbtrpy)(X)]TCNQ with projection for X = OH (left) and X = SH (right). The horizontal dashed line corresponds to the Fermi level.



completely occupied valence band centered at –11.9 eV (Fig. 2). The critical role of donor–acceptor interaction in the conducting behavior can be seen by contrasting the results in Fig. 2 with those in Fig. 3, which illustrate nonmetallic behavior for both the solid-state arrangement of the metal donor species (Fig. 3, left) and the TCNQ acceptor (Fig. 3, right) in isolation. A pronounced band gap is seen for both situations (Fig. 3). In other words, the band structure changes drastically from an insulator (isolated TCNQ and [Pt(tbtrpy)(X)]) to that of a conductor ([Pt(tbtrpy)(X)]TCNQ). We further note that the band structure is flat (no sign of interaction) in the inter-stack direction because the overlap is very small.

Figure 4 presents DOS plots for the thiolate complex, [Pt(tbtrpy)(SH)]TCNQ. This model complex, which has yet to be synthesized experimentally, was constructed by assuming the same crystallographic structure of [Pt(tbtrpy)(OH)]TCNQ after adjusting the Pt–S and S–H distances with reasonable values based on reported structures of Pt(II)-thiolate complexes. While thiolate is expected to be a good electronic model for an arylthiolate, it must be kept in mind that the larger steric bulk of the latter may affect the separation between donor and acceptor moieties within the stack. *Significantly, the data in Fig. 4 suggest that [Pt(tbtrpy)(SH)]TCNQ is predicted to also be metallic with an improved conducting behavior versus [Pt(tbtrpy)(OH)]TCNQ.* Thus, the Fermi level shifts from –11.9 (X = OH) to –10.7 eV (X = SH), and the valence band becomes more dispersed in the case of X = SH. Figure 4 (right) also shows that the valence band has strong SH character for [Pt(tbtrpy)(SH)]TCNQ, as the SH projection occupies nearly half of this band. This is in sharp contrast to the analogous situation for [Pt(tbtrpy)(OH)]TCNQ, in which the OH ligand contributes only to bands that are well below the valence band (Fig. 4, left). One reason for the different Fermi level behavior is the relative energy of S_{3p} and O_{2p} orbitals ($\sim$1.2 eV difference in H_{ii} with sulfur higher in energy). The EHTB results are also consistent with the electronic structure proposed in ref. 7b, which predicted a significant thiolate character in the HOMO of $[Pt(tbtrpy)(thiolate)]^+$ complexes, based on an analysis of spectral and electrochemical data; further discussion of the electronic structure of the molecular units is provided in the DFT sections below.

We conclude from the EHTB calculations that sulfur incorporation in the donor–acceptor stacks that have X = SH can generate a more dispersed band compared with the DOS of the stacks that have X = OH. Consequently, this

Fig. 5. Contour plots of the Kohn–Sham HOMO (bottom) and LUMO (top) orbitals of $[Pt(tbtrpy)(X)]^+$ with different X ligands, based on DFT computations. The HOMO orbital energy is computed to be –0.343, –0.346, –0.330, –0.305, and –0.271 eV (left to right, respectively).

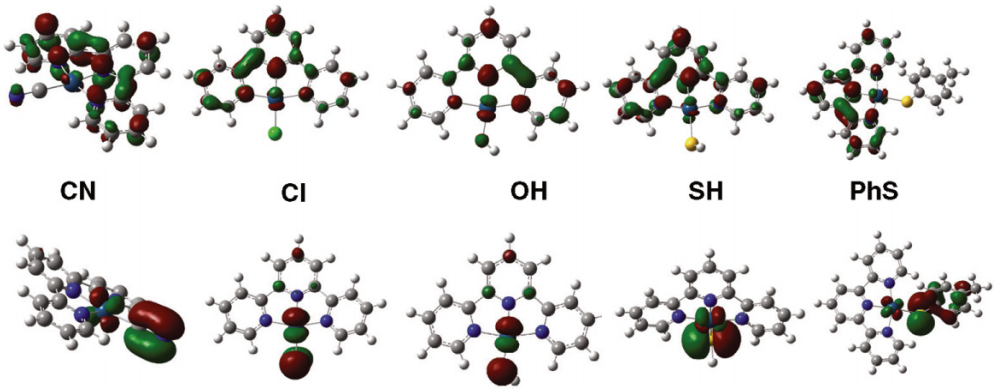


Fig. 6. Top: Singly-occupied molecular orbital (SOMO) for $TCNQ^-$ monoanion, which corresponds to the LUMO of neutral TCNQ. Bottom: Average crystallographic CC bond lengths (Å) reported in the CSD for different oxidation states of TCNQ. Given in parentheses are the sample standard deviations.

	R_1	R_2	R_3	R_4
neutral	1.346(14)	1.436(14)	1.384(22)	1.430(13)
anion	1.361(8)	1.419(12)	1.414(11)	1.419(10)

energy shift enhances the overlap between the bands of the $[Pt(tbtrpy)(SH)]^+$ and $TCNQ^-$ fragments. Any electronic excitation or CT effects are expected to involve this zone, which implies a great sensitivity of the spectroscopic and electrical properties of [Pt(tbtrpy)X]TCNQ to a judicious choice of X. Thus, using S-donor ligands as X is predicted to lead to better conductivity than that for [Pt(tbtrpy)(OH)]TCNQ because the lower ionization potential (inferred from a less negative Fermi level), the significant thiolate character, and the greater dispersion of the valence bands of [Pt(tbtrpy)(thiolate)]TCNQ solids suggest an easier partial oxidation and thus greater charge mobility in such binary stacks.

Density functional calculations for donor and acceptor units

Density functional calculations were carried out on molecular $[Pt(tbtrpy)(X)]^+$ and [Pt(tbtrpy)(X)][TCNQ] complexes, as well as free TCNQ models in neutral, anionic, and dianionic states. The modeling of a single link in the solid-state chains (and a better understanding of the donor–acceptor properties of TCNQ in their ground and excited states) can be useful when studying the optoelectronic properties of the crystalline materials.

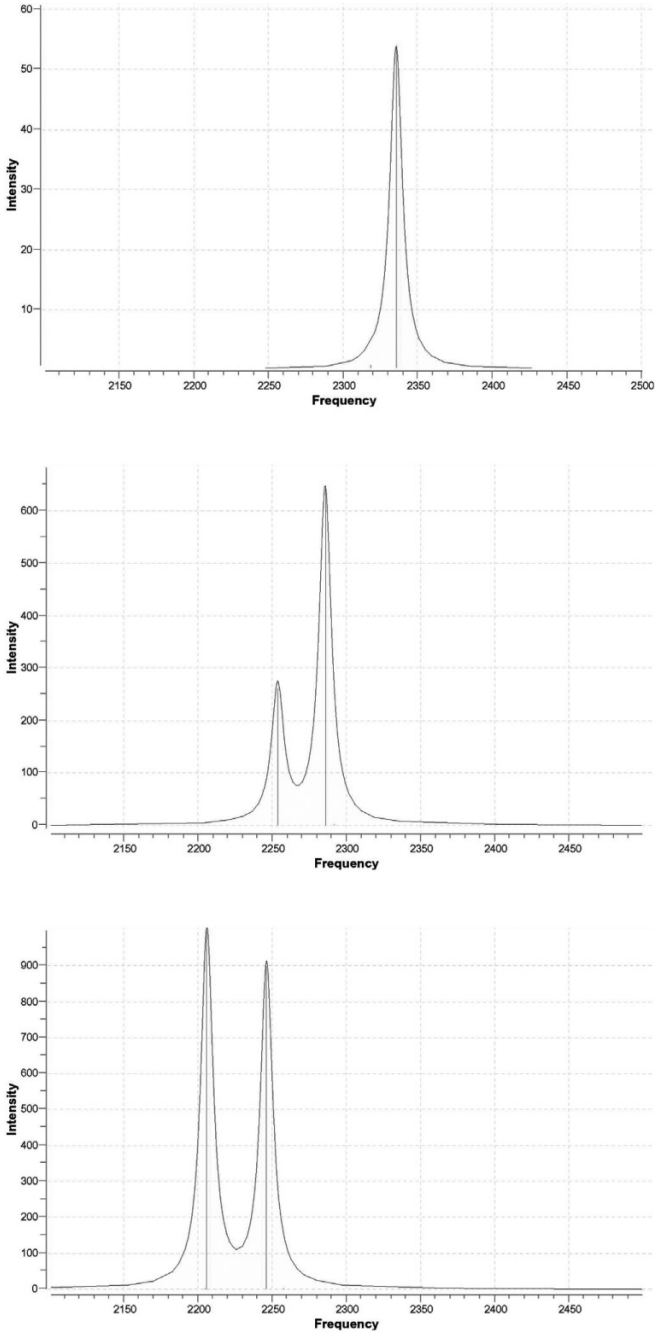
Electronic structure assignment of Pt donor complexes

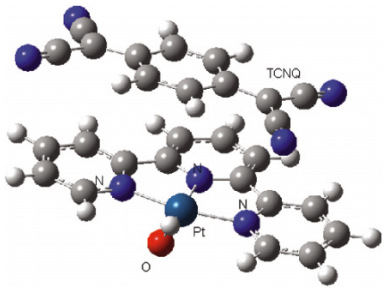
It is worthwhile to start this section with a summary of the electronic absorption bands and their assignment for [Pt(tbtrpy)(X)]Y complexes based on the experimental study in ref. [7b]. The high-energy region of the electronic spectrum at $\lambda < 350$ nm is dominated by $\pi \rightarrow \pi^*$ transitions localized on the terpyridyl ligand, which are generally insensitive to X

Fig. 7. Computed (B3LYP/6-311+G(d,p)) IR spectra of (top) TCNQ neutral, (middle) anion, and (bottom) dianion. Unscaled frequencies (see Table 2) were used to generate these figures.



and Y modification.[7b] Longer-wavelength regions represent charge transfer (CT) transitions. The CT bands are presumed to be MLCT (metal-to-ligand CT) transitions in the near UV region for X = Cl^-, NCS^-, or OH^-, whereas changing the anionic ligand to SAr^- leads to a drastic red shift to the visible region because of a mixed thiolate-Pt HOMO.[7b] Figure 5 shows contour plots of the Kohn–Sham frontier orbitals of $[Pt(tbtrpy)(X)]^+$ with different X ligands, based on DFT computations. These computational results bear out both the aforementioned experimental assignment and the EHTB solid-state computations above because a greater thiolate

Fig. 8. B3LYP/SBKJC(*d*) optimized structure of [Pt(trpy)OH]TCNQ.



contribution as well as higher orbital energy have been obtained for the HOMO of the models that contain X = SH or PhS instead of other anionic ligands. The LUMO and other low-lying virtual orbitals, on the other hand, have a terpyridyl π* character regardless of X.

Molecular structure of TCNQ species

Considerable efforts have been devoted to the synthesis and study of TCNQ derivatives with enhanced materials characteristics.[7–9,11] The electron-accepting ability of TCNQ plays a fundamental role in the charge transfer process. Thus, several investigations into the structure and spectra of TCNQ, $TCNQ^-$, and $TCNQ^{2-}$ have been reported.[7–9,11] Different carbon–carbon bond lengths are observed for TCNQ in the solid state because its structure depends on the nature of the counterion (if TCNQ is not neutral) and the total charge of TCNQ (typically between 0 and 2–).

Figure 6 summarizes the results of an analysis of the Cambridge Structural Database (CSD).[18] In Fig. 6 are presented the averages and sample standard deviations (given in parentheses; the sample size is 154 for neutral TCNQ and 31 for $TCNQ^-$) for CC bonds as a function of the reported charge of the TCNQ. Systems whose TCNQ charge is obfuscated due to the presence in the unit cell of multiple TCNQ moieties with different assigned charges are ignored to isolate only the most reliable oxidation state assignments. For clarity in the text, the CC bonds are labeled R_1, R_2, R_3, and R_4 (Fig. 6). The endocyclic CC (R_1 and R_2) bonds and the CC bond to the cyano group (R_4) show changes upon reduction of TCNQ that are commensurate with the sample standard deviations. However, the CC exocyclic bonds (R_3) change more substantially, going from 1.384(22) Å in neutral TCNQ to 1.414(11) Å for $TCNQ^-$. Hence, reduction of TCNQ weakens R_3, which is consistent with the orbital character of the LUMO of TCNQ that is populated upon reduction (Fig. 6). *Thus, simple orbital arguments and analysis of extant crystallographic data suggest that the exocyclic CC bond length (R_3) is the most reliable structural indicator of TCNQ charge.*

The only TCNQ complex that we have been able to identify within the CSD that is designated as a dianion is the $[Cp^*_2Co]_2(TCNQ)\cdot 1/2^*(CH_3CN)$ complex reported by Miller et al.[9i] The exocyclic CC bonds lengths are 1.45(1) and 1.43(1) Å. The exocyclic CC bond, R_3, thus does continue the lengthening trend seen upon going from neutral to anionic TCNQ, as expected on the basis of calculations reported by Miller et al.[9i] Such a structural result is reasonable as the second reducing equivalent would go into the SOMO

Table 3. Critical distances (Å) in [Pt(triimine)(X)][TCNQ].

	X = OH (Calcd.)	X = SH (Calcd.)	X = OH (Exptl.)
R_1	1.38	1.40	1.35
R_2	1.43	1.45	1.43

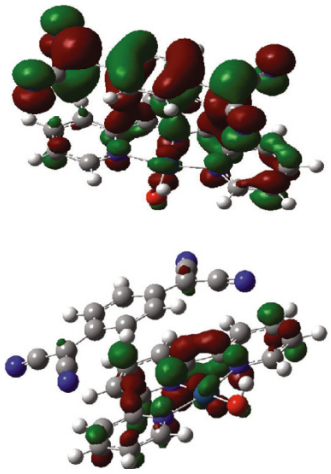
Pt-X	2.01	2.41	2.24
Interplanar (Pt-C)[a]	3.99	3.87	3.71

Note: For the computational models, triimine = trpy; for the experimental system, triimine = tbtrpy.

[a]Interplanar distances correspond to the closest platinum–carbon (on TCNQ counterion) distance.

Fig. 9. (Bottom) Kohn–Sham HOMO and (top) LUMO orbitals of [Pt(trpy)(OH)]TCNQ.



of the TCNQ radical anion, which a priori is expected to be very similar to the LUMO of neutral TCNQ.

DFT computations have been carried out for isolated TCNQ neutral, radical anion, and dianion to calibrate the experimental results for neutral and anionic TCNQ and to extend them to $TCNQ^{2-}$. All geometry optimizations have been performed under D_{2h} symmetry, and calculation of the energy Hessian has indicated each species to be at a potential energy minimum. Several basis sets have been utilized: modest (6-31G(d)), large (6-31G(3d,p)), and extended (6-311++G(d,p)) (Table 1). Little difference has been found in the computed CC bonds with different basis sets, and both the large and extended basis sets have shown good agreement with experimental averages.

IR spectra of TCNQ species

Theoretical computation of the IR spectra of TCNQ species is undertaken herein, as motivated by the experimental use of the cyano groups as "reporter" groups (through their CN stretching frequencies), for assessing the state of reduction of the TCNQ counterion.[8] The vibrational spectra for various TCNQ species have been studied experimentally.[7–9,11] The measurement of the IR spectra of Na_xTCNQ, prepared by a solvent-free vapor codeposition method, show a decrease in ν_{CN} from 2227 cm^{-1} in the neutral, to 2185 cm^{-1} in the anion, and to 2164 cm^{-1} for the dianion.[8] A theoretical investigation of the IR frequencies of TCNQ was undertaken using the B3LYP functional, and the same basis sets were used for geometry optimization tests. Similar calculations on Li_xTCNQ and K_xTCNQ (x = 1, 2) were also performed and show nearly identical trends. In this section we will focus on isolated TCNQ species in different oxidation states to minimize ancillary effects due to counterion and will likewise focus on the results with the extended 6-311++G(d,p) basis set. The b_{1u} and b_{2u} modes in the point group D_{2h} are the most intense in the IR and thus are the most reliable in terms of experimental assignments. The b_{1u} and b_{2u} modes correspond to symmetric and asymmetric stretching of all four CN bonds, respectively. Inspection of the data in Table 2 confirms the shift to lower ν_{CN} upon going from TCNQ to $TCNQ^{-}$ to $TCNQ^{2-}$. The anion to dianion differences in ν_{CN} are 48 cm^{-1} for b_{1u} and 56 cm^{-1} for b_{2u} using the scaled frequencies.

In Fig. 6, the calculated IR spectra are plotted in the range 2000–2500 cm^{-1}, the region that encompasses the ν_{CN} of TCNQ. Inspection of Fig. 7 shows the expected shift to lower frequencies upon reduction of TCNQ. What is more interesting is the change in IR peak shapes (Fig. 7, top). The neutral TCNQ displays a single ν_{CN} peak, due to the very low intensity of the b_{1u} stretch at 2310 cm^{-1}. Two peaks in this region are observed for the anion and dianion with intensity ratios (b_{1u}/b_{2u}) of $\sim$3:1 for the anion and $\sim$1:1 for the anion. While the comparison of calculated and experimental IR spectra is complicated by medium effects and the nature of the counterions (for charged species), the present results imply that IR peak shape analysis may be a useful tool for quickly gauging the reduction state of TCNQ in conducting materials.

Disproportionation of TCNQ species

The utility of TCNQ in solid-state applications is, in large part, due to its electronic "flexibility." As seen above for the hydroxo and thiolate complexes in the solid state, electron transfer to and from TCNQ can be easily (although perhaps not yet systematically) varied through modification of its chemical environment. To address this issue, we investigated the disproportionation of TCNQ anion (eq. [1]).

Table 4. CN Stretching Frequencies in [Pt(triimine)(XR)][TCNQ].

	XR = OH[a] (Calcd.)	XR = SH[a](Calcd.)	XR = SAr[b](Exptl.)
ν_1	2187	2187	2180 SPh
l_1	112	118	
ν_2	2190	2190	2178 DMBT[b] (KBr)
l_2	90	102	2179 DMBT (Nujol)
ν_3	2221	2222	2185 DMeOBT[b] (KBr)
l_3	553	519	2183 DMeOBT (Nujol)
ν_4	2228	2228	
l_4	10	8	

Note: For the computational models, triimine = trpy; for the experimental system, triimine = tbtrpy.

[a]These are the unscaled CN stretching frequencies (ν_n, cm^{-1}) and intensities (I_n, KM/Mole) calculated at the B3LYP/CEP-31G(d) level of theory.

$$[1] \qquad 2\,TCNQ^{-} \leftrightarrow TCNQ + TCNQ^{2-}$$

The disproportionation reaction provides insight into the ease with which TCNQ can accept and (or) donate electrons in response to chemical variations. The free energy of eq. [1] is calculated to be +97 kcal/mol (1 cal = 4.184 J) in the gas phase at the B3LYP/6-311++G(d,p) level of theory. However, this disproportionation is expected to become substantially more thermodynamically feasible when environmental factors such as solvation or the stabilization of counterions in the crystalline state are incorporated. To incorporate environmental effects, polarizable continuum model[19] calculations were carried using a solvent of moderate dielectric constant (acetonitrile, $\varepsilon = 37.5$). While reaction 1 remained endergonic, preferential stabilization of the dianion product yielded a ΔG_{rxn} of +19 kcal/mol in a polar acetonitrile environment. This change is due to the more substantial solvation of $TCNQ^{2-}$ (ΔG_{solv}(PCM,acetonitrile) = –145 kcal/mol) vs that for the anion (ΔG_{solv}(PCM,acetonitrile) = –44 kcal/mol) and neutral (ΔG_{solv}(PCM,acetonitrile) = –20 kcal/mol) TCNQ. The sensitivity of charge transfer to and from TCNQ in the solid state, with respect to changes in the polarity of the environment, lends further credence to the observed changes in the solid-state EHTB structure of [Pt(tbtrpy)(X)]TCNQ and further highlights the ability to fine-tune the properties of this family of complexes via modification of the chemical environment.

Density functional calculations on [Pt(tbtrpy)(X)][TCNQ]

In this part of the research, a molecular model is constructed representing a single [Pt(trpy)(X)]TCNQ link from the solid-state chain. In our model, the tbtrpy ligand is substituted by the parent trpy (trpy - 2,2′:6′,2″-terpyridine) ligand to reduce computational costs for the DFT simulations.

Molecular structure of [Pt(trpy)(X)][TCNQ]

We note that while direct calculation of atomic charges (and indeed other properties such as spin densities) is obviously possible via population analyses such as those of Mulliken, Löwdin, or the natural population method, such atomic charges are not only sensitive to the method utilized as well as the basis set and level of theory, they also do not yield an observable property that can be correlated with an experimental value. Hence, we focus on bond length metrics that may serve as an indicator of the extent of charge transfer, and which, once established, could be interrogated via techniques such as X-ray crystallography. In Fig. 8, the optimized structure of [Pt(trpy)OH]TCNQ obtained via DFT calculation (B3LYP/SBKJC(d)) is shown. A pseudopotential method was employed because of the presence of the heavy element platinum; test calculations indicated that the utilization of pseudopotentials had only a negligible effect on the calculated structural (Table 1) and vibrational (Table 2) data for TCNQ and its anionic forms, with changes of $\sim$1% and less than 10 cm^{-1}, respectively, for comparable all-electron and pseudopotential calculations. Table 3 lists the computed bond lengths of [Pt(trpy)(X)][TCNQ]. For clarity, the same CC bond labels in Fig. 6 (R_1, R_2, R_3, and R_4) were used. Recall from the previous discussion of the crystallographic data and DFT calculations on TCNQ ions that the R_3 bond is deemed to be the most reliable structural indicator of TCNQ oxidation state. Thus, it is very interesting that the calculated exocyclic CC bond length (R_3) is 1.438 Å (X = OH) and further lengthens to 1.451 Å for the thiolate (X = SH) congener. These calculated values compare quite favorably with the experimental value of R_3 for [Pt(tbtrpy)(OH)]TCNQ, which is 1.433 Å. Moreover, the R_3 bond lengths in Miller's $TCNQ^{2-}$ complex $[Cp^*_2Co]_2(TCNQ)\cdot 1/2^*(CH_3CN)$ complex are 1.45(1) and 1.43(1) Å.[9i] *Taken together, the present calculated and reported experimental values of R_3, when compared to the exemplars in Table 1, imply that the oxidation state of TCNQ in [Pt(triimine)(X)][TCNQ] complexes is between 1– and 2–, consistent with the hypothesized charge in ref. 7b.* Moreover, for the analysis and design of related materials, the data suggest that the degree of charge transfer between the platinum donor and TCNQ acceptor is quite sensitive to X.

In Fig. 9, the Kohn–Sham HOMO and LUMO are plotted for the optimized geometry of the [Pt(trpy)(OH)]TCNQ complex. *The figure clearly illustrates the localization of the electron density on the platinum donor complex in the HOMO and on the $TCNQ^{-}$ acceptor in the LUMO, thus providing further theoretical support for the contention that the Pt(II) complex acts as donor despite being a cation and the $TCNQ^{-}$ acts as an acceptor despite being an anion.*

IR spectra of [Pt(trpy)(X)][TCNQ]

The CN stretching frequencies of [Pt(trpy)(X)]TCNQ are calculated and organized in Table 4. The calculated CN stretching frequency for the most intense IR peak (~b_{1u} of

Table 2) are 2221 cm^{-1} for the hydroxo complex and 2222 cm^{-1} for the thiolate complex. Scaling these ν_{CN} by 0.95 yields estimated ν_{CN} of 2111 and 2110 cm^{-1}, respectively. Comparing the computed CN stretching frequencies for [Pt(trpy)(X)][TCNQ] with those calculated for isolated TCNQ ions (Table 2), the scaled ν_{CN} are much closer to the b_{1u} stretch of $TCNQ^{2-}$ (2110 cm^{-1}) than $TCNQ^{-}$ (2158 cm^{-1}). Of course, the effects of medium, counterions, and anharmonicity will certainly play a role in any comparison of theoretical and experimental IR frequencies. Reported experimental values are thus also organized in Table 4, along with the medium in which the IR experiment (KBr pellet or Nujol mull) was performed; the experimental values for the most intense peak range from 2178 to 2185 cm^{-1} for a variety of aryl-thiolates with differing substituents, [Pt(tbtrpy)(SAr)][TCNQ][7b] (Table 4). For NaTCNQ, ν_{CN} = 2185 cm^{-1} and 2164 cm^{-1} for Na_2TCNQ. The experimental values of ν_{CN} for the platinum complexes[7b] are intermediate ν_{CN} for NaTCNQ and Na_2TCNQ.[8] *Thus, the calculated and experimental CN stretching frequencies support a proposed charge distribution of* $[Pt(tbtrpy)X]^{(1+\delta)+}$ *complexed with* $TCNQ^{(1+\delta)-}$ where $0 < \delta < 1$.

Summary and conclusions

Several important conclusions have emerged from this computational analysis of solid-state and molecular Pt-TCNQ complexes. The most important among these are summarized here.

Tight-binding analyses of crystalline [Pt(tbtrpy)(X)][TCNQ] (X = OH or HS) and density functional calculations on molecular models of these materials indicate that they display conductor behavior. The valence-conduction band in solid-state [Pt(tbtrpy)(X)][TCNQ] has a Pt(II) donor character and TCNQ π^* acceptor character. The calculations suggest substantial changes in the transfer energy and the conduction properties of crystalline [Pt(tbtrpy)(X)][TCNQ] upon modification of X from OH to SH. For example, from the widening of the band gap in the thiolate complex, it is anticipated that electron excitation from the valence to the conduction band is more facile for this material. Additionally, the thiolate is predicted to be a better conductor and its UV–vis absorption peak should be red-shifted compared with the hydroxyl complex, which is consistent with experimental observations.[7b]

Density functional theory calculations are performed to probe the electronic, molecular, vibrational, and spectral properties of TCNQ (neutral, anion, and dianion) and the molecular complex [Pt(tbtrpy)(X)][TCNQ] (X = OH and SH). Of particular interest is the response of these properties in the TCNQ fragment to its oxidation level, i.e., δ in $[Pt(tbtrpy)X]^{(1+\delta)+}TCNQ^{(1+\delta)-}$. Orbital arguments and analysis of extant structural data suggest that the exocyclic CC bond length (R_3) is the most reliable structural indicator of TCNQ oxidation level and thus δ. Two major peaks in the ν_{CN} region are calculated for the anion and dianion states of TCNQ with intensity ratios of $\sim$3:1 and $\sim$1:1, respectively. Hence, in addition to analysis of shifts in ν_{CN}, IR peak shape analysis may be a useful experimental tool for quickly gauging the exact oxidation state of TCNQ in conducting and luminescent materials and thus the response of this important parameter to chemical modification.

The calculated and experimental bond lengths and IR spectra for [Pt(tbtrpy)(X)][TCNQ], support a proposed charge distribution of $[Pt(tbtrpy)X]^{(1+\delta)+}$ complexed with $TCNQ^{(1+\delta)-}$ where $0 < \delta < 1$, i.e., the TCNQ counterion possesses an oxidation state between 1– and 2– in these Pt(triimine) materials. In terms of the design of new and improved materials, the data suggest that the degree of charge transfer between the platinum donor and TCNQ acceptor is quite sensitive to X, which is perhaps the most easily modifiable chemical group.

Moshinsky atom and density functional theory — A phase space view[1]

Jens Peder Dahl

Abstract: The problem of two particles in a common harmonic oscillator potential interacting through harmonic oscillator forces is discussed in the Weyl–Wigner phase-space representation. The Wigner function of the system is an ordinary function of the phase-space constants of the motion. The density functional description of the system is touched upon. The functional that determines the confining harmonic potential from the particle density is also an ordinary function.

Key words: harmonium, Hooke's atom, phase space, Wigner function, DFT.

Résumé : Le problème de deux particules dans un potentiel d'oscillateur harmonique commun interagissant par le biais de forces d'oscillateur harmonique est discuté dans la représentation phase-espace de Weyl–Wigner. La fonction de Wigner du système est une fonction ordinaire des constantes phase-espace du mouvement. On aborde la question de la description de la fonctionnelle de densité du système. La fonctionnelle qui détermine le potentiel harmonique confinant de la densité de particule est aussi une fonction ordinaire.

Mots-clés : harmonium, atome de Hooke, fonction de Wigner, phase-espace, théorie de la fonctionnelle de densité (TFD).

[Traduit par la Rédaction]

1. Introduction

Tom Ziegler's first article, from 1970, was written while he was a student under Professor Carl J. Ballhausen in the Department of Physical Chemistry at the University of Copenhagen. The department was an international center in theoretical chemistry, with many foreign postdocs and other visitors. Several bright Danish students also contributed to the scientific achievements of the department. I held a position as lecturer in valence theory and co-supervised many of Ballhausen's students, among them Tom Ziegler.

A major effort at the Department was the study of the electronic structure of molecules, in particular transition-metal complexes. We applied crystal-field theory, ligand-field theory, semiempirical and semiquantitative molecular-orbital theory, and ab initio theory. We discussed the various theoretical methods and their basis in seminars and group discussions. I found the standard derivation of the Hartree–Fock (HF) equations, with its emphasis on Lagrangian multipliers, rather cumbersome. I had therefore constructed an alternative derivation (reproduced in Dahl's *Introduction to the Quantum World of Atoms and Molecules*, 2001[2]), which was easier to handle and gave a more direct understanding of the role played by the off-diagonal multipliers. Tom took interest in this derivation, as did the Canadian postdoc D. Rodney Truax.

An article in the current literature caught the interest of Tom and Rodney. In the article, the assertion was made that the method of Lagrangian multipliers leads to incomplete conditions on the HF orbitals. We all set down over the weekend and were able to show that this was a false assertion, caused by certain logical imprecisions in the standard discussion of open-shell HF theory. We immediately wrote an article with our conclusions and published it in the fairly new Chemical Physics Letters.[3]

Studying the basics of HF theory was one thing. Applying the theory was something else. Transition-metal complexes contain many electrons, and to describe the chemical bond in these compounds it is necessary to include not only s- and p-orbitals, but also d-orbitals. In fact, we could only get through the calculations on these compounds by introducing serious approximations, such as neglecting small overlap integrals, etc. These approximations were tied to acronyms like ZDO, CNDO, INDO, etc. Tom was also interested in such methods and later included them in several calculations.

All of these approximations are, however, of little practical interest today. Another approximation has had a different history. This is the local density approximation (LDA) that evolved into density functional theory (DFT). We also discussed this kind of theory in our group, and in 1982 John Avery and I arranged the first major international symposium on *Local Density Approximations in Quantum Chemistry and Solid State Physics*, in Copenhagen. In the meantime, Tom had acquired his Master's degree at the University of Copenhagen in 1972, left Denmark, and earned a Ph.D. at the University of Calgary in 1978. He contributed to the multi-author book[4] that we edited on the occasion of the symposium with the article *On the Extension of the Statistical Energy Expression to Multi-Determinantal Wave Functions*.

Tom is a prominent international figure in the area of theoretical inorganic chemistry. He is a member of the Royal Danish Academy of Sciences and Letters. It is a pleasure to have worked with him when we were both quite young, and

[1]Present address: Institut für Quantenphysik, Universität Ulm, D-89069 Ulm, Germany.

I am happy to be given the opportunity to contribute to this special issue of the Canadian Journal of Chemistry.

My contribution has the form of an essay in which I discuss one of the simplest model analogues to a two-electron atom, i.e., Moshinsky's harmonium atom, using the Weyl–Wigner formulation of quantum mechanics. The model is sufficiently simple that some implicitly given functionals become ordinary functions. Thus the Wigner function is a function of the constants of the motion as expressed in phase space. Also, the Hohenberg–Kohn relation[5] between the confining potential and the particle density is expressed by an explicit function.

The following section contains a few introductory and partly personal remarks on density functional theory. The discussion of the Moshinsky atom is given is Section 3 and its subsections. Section 4 is the summary.

2. Approximate density functional theory

One of Tom's key publications is his 1991 review article in Chemical Reviews, entitled *Approximate Density Functional Theory as a Practical Tool in Molecular Energetics and Dynamics*.[6] It is written with a clear understanding of the science on which it builds. And the author chooses his words with care. He uses the familiar acronym DFT for density functional theory in general, but always refers to the computational work as approximate density functional theory. I think this calls for a specific acronym for the latter. Hence, I shall refer to approximate density functional theory through the acronym ADFT.

My own relation to ADFT goes back to the mid-1960s when I worked as a postdoc in Professor John C. Slater's Solid-State and Molecular Theory Group (SSMTG) at MIT. Among other things, I studied electronic band structures by means of augmented plane wave (APW) calculations.[7] To make such calculations at all possible, it was necessary to approximate the non-local exchange potential with a local one, and the way this was done at the time was by invoking Slater's $\rho^{1/3}$ approximation,[8] in which the exchange potential, measured in Hartree units, is written

$$[1] \qquad V_{\mathrm{XS}}(\boldsymbol{r}) = -3\left[\frac{3}{4\pi}\rho\prime(\boldsymbol{r})\right]^{1/3}$$

where $\rho'(\boldsymbol{r})$ is the same-spin particle density at the point $\boldsymbol{r}$. This expression may be obtained by replacing the HF exchange potential by the average exchange potential in a free-electron gas, as described elsewhere.[9] This replacement takes place after the HF equations have been derived by applying the variational principle to the HF energy expression. If, instead, one approximates the energy expression before the variation, then one obtains an expression only two-thirds as great, as shown by Gaspar in 1954[10] and Kohn and Sham in 1965.[11] Both exchange potentials are contained in the expression

$$[2] \qquad V_{\mathrm{X}\alpha}(\boldsymbol{r}) = -3\alpha\left[\frac{3}{4\pi}\rho\prime(\boldsymbol{r})\right]^{1/3}$$

with $\alpha = 1$ for Slater's expression and $\alpha = 2/3$ for the Gaspar–Kohn–Sham expression. In the Xα method, one allows α to vary to also include some correlation beyond HF. In ADFT, the Xα expression is much refined and merged into the exchange-correlation potential. At the same time, the HF equations get replaced by the Kohn–Sham equations.

The exchange-correlation potential is in general a complicated functional of the spin-up and spin-down particle densities. When it happens that the functional takes on a simple form like that of eq. [2], it is in fact an ordinary function.

As is well known, the HF description approximates the many-electron wave function for a closed-shell system by a single Slater determinant, whereas ADFT puts focus on the particle density. Both HF theory and ADFT have led to an enormous progress in our understanding of the structure of atoms, molecules, and solids. Tom has given us a solid impression of some of these advances in the review article mentioned above.

ADFT is based on the (first) Hohenberg–Kohn theorem[5], which applies to a non-degenerate ground state of a system of N identical and interacting particles, moving in an external potential $v(\boldsymbol{r})$. It states that $v(\mathbf{r})$, and hence the total energy, is a unique functional of the particle density $\rho(\boldsymbol{r})$. The form of the functional is not known. To determine it may well be compared with the task of determining the wave function of the universe. Yet, the study of particular cases and simple models do give us some insight. Many such studies now exist. In the following I shall add a simple study, in which I invoke the phase-space representation of quantum mechanics.

3. The Moshinsky atom

The original proof of the theorem that $v(\boldsymbol{r})$ is a functional of $\rho(\boldsymbol{r})$ is formally quite simple.[2,5] Yet, some delicate objections have been raised (See for instance, Kryachko 2006[12] and Szczepanik et al. 2007[13] for a quite recent discussion). We shall not focus on the proof here. It proceeds by reductio ad absurdum and is accordingly implicit by nature. My goal is to present an explicit example of how to go from $\rho(\hat{\boldsymbol{r}})$ to $v(\hat{\boldsymbol{r}})$. This example is represented by a model atom consisting of two identical interacting particles moving in a confining harmonic potential. This is the so-called harmonium atom or Hooke's atom. It has been much studied in the literature. The interaction between the two particles has usually been taken to be Coulombic,[14] but some studies also exist in which it has been assumed to be harmonic. The first such study was performed by Moshinsky.[15] Lately, his study has been extended by March and co-workers[16,17] Independent investigations have been performed by Neal[18] and Schindlmayr.[19] I shall limit myself to the harmonic version of the harmonium atom, and following March et al., refer to it as the Moshinsky model atom or just the Moshinsky atom.

3.1. Hamiltonian and ground-state wave function

The Moshinsky atom is defined by the Hamiltonian,

$$[3] \qquad \hat{H}_{\mathrm{D}} = \frac{\hat{\boldsymbol{p}}_1^2}{2m} + \frac{\hat{\boldsymbol{p}}_2^2}{2m} + \frac{1}{2}m\omega^2\hat{\boldsymbol{x}}_1^2 + \frac{1}{2}m\omega^2\hat{\boldsymbol{x}}_2^2 + \frac{1}{2}m\omega^2\kappa|\hat{\boldsymbol{x}}_1 - \hat{\boldsymbol{x}}_2|^2$$

where $(\hat{\boldsymbol{x}}_1, \hat{\boldsymbol{p}}_1)$ are the position and momentum vectors of particle 1, and $(\hat{\boldsymbol{x}}_2, \hat{\boldsymbol{p}}_2)$ are the position and momentum vectors of particle 2. With the position and momentum vectors ex-

pressed in the usual Cartesian coordinates, the Hamiltonian becomes a sum of independent but equivalent sub-Hamiltonians, one for each of the D coordinate directions. It is therefore sufficient to consider the one-dimensional problem defined by the Hamiltonian,

$$[4] \qquad \hat{H} = \frac{\hat{p}_1^2}{2m} + \frac{\hat{p}_2^2}{2m} + \frac{1}{2}m\omega^2\hat{x}_1^2 + \frac{1}{2}m\omega^2\hat{x}_2^2 + \frac{1}{2}m\omega^2\kappa(\hat{x}_1 - \hat{x}_2)^2$$

Unlike Moshinsky who took $D = 3$, we shall therefore work in a single dimension.

In eqs. [3] and [4], m is the mass of a particle, ω^2 determines the strength of the potential in which the particles move, while $\omega^2\kappa$ determines the strength of the particle–particle interaction. This interaction is an attraction when κ is positive and a repulsion when κ is negative.

The Hamiltonian of eq. [4] may be separated into a center-of-mass or extracule part and a relative-distance or intracule part by introducing the new position variables,

$$[5] \qquad \hat{X} = \frac{1}{2}(\hat{x}_1 + \hat{x}_2), \quad \hat{x} = \hat{x}_1 - \hat{x}_2$$

and the corresponding momentum variables

$$[6] \qquad \hat{P} = \hat{p}_1 + \hat{p}_2, \quad \hat{p} = \frac{1}{2}(\hat{p}_1 - \hat{p}_2)$$

Thus, we get

$$[7] \qquad \hat{H} = \hat{H}_{\mathrm{cm}} + \hat{H}_{\mathrm{rel}}$$

where

$$[8] \qquad \hat{H}_{\mathrm{cm}} = \frac{\hat{P}^2}{4m} + m\omega^2\hat{X}^2$$

and

$$[9] \qquad \hat{H}_{\mathrm{rel}} = \frac{\hat{p}^2}{m} + \frac{1}{4}m\omega^2(1 + 2\kappa)\hat{x}^2$$

Equation [7] shows that $\hat{H}$ is the Hamiltonian for two uncoupled harmonic oscillators, provided $-1/2 < \kappa < \infty$. We restrict the values of κ to this interval.

Drawing on the textbook treatment of the harmonic oscillator,[2] we find that the ground state $|\Psi_0>$ of the Moshinsky atom has the energy,

$$[10] \qquad E_0 = \frac{1}{2}\hbar(1 + \sqrt{1 + 2\kappa})\omega$$

and the position-space wave function

$$[11] \qquad \Psi_0(x_1, x_2) = (1 + 2\kappa)^{1/8}\frac{\alpha}{\sqrt{\pi}}e^{-\alpha^2X^2}e^{-\frac{1}{4}\sqrt{1+2\kappa}\,\alpha^2x^2}$$

where $\alpha = \sqrt{m\omega/\hbar}$.

Accepting a slightly different notation, these results agree with those of Moshinsky[15] and March and co-worlers.[16,17] Those authors went on to study the Hartree–Fock description and the correlation problem. The results are also in accordance with those of Neal[18] and Schindlmayr[19] who went on to discuss the Kohn–Sham description.

Here, we shall continue by transforming the description into phase space. In so doing, we follow the general outline given in Dahl and Schleich[20].

3.2. Liouville space

To begin with, we go from Hilbert space where the ket $|\Psi_0>$ belongs, to operator space or Liouville space where the Hamiltonian lives together with other operators, in particular the state operator, or density matrix.

$$[12] \qquad \hat{\rho}_0 = |\Psi_0\rangle\langle\Psi_0|$$

For a non-degenerate ground state, the state operator is a function of the Hamiltonian. To see this, we introduce the orthonormal set of eigenkets of $\hat{H}$, that is, $|\Psi_0>$, $|\Psi_1>$, $|\Psi_2>$, ... and verify the well-known fact that $\hat{\rho}_0$ is a projection operator,

$$[13] \qquad \hat{\rho}_0\sum_{j=0}^{\infty}c_j|\Psi_j\rangle = c_0|\Psi_0\rangle, \quad \hat{\rho}_0^2 = \hat{\rho}_0$$

According to the general theory of projection operators,[21,22] we may therefore write,

$$[14] \qquad \hat{\rho}_0 = \prod_{j\neq 0}\frac{\hat{H} - E_j}{E_0 - E_j}$$

This expression shows indeed that $\hat{\rho}_0$ is a function of the Hamiltonian, that is,

$$[15] \qquad \hat{\rho}_0 = F(\hat{H})$$

To proceed, we move from Liouville space to phase space.

3.3. Phase space. The Weyl–Wigner representation

Among the different phase-space representations of quantum mechanics, the Weyl–Wigner representation[23–26] may be considered the canonical representation because of its simplicity.[28,29] It is a representation of quantum mechanics in its own right,[30–33] but may also be considered a mapping from Liouville space to phase space. Adopting the latter point of view, it maps Liouville-space operators $\hat{A}$ into phase-space functions $a(\mathbf{x}, \mathbf{p})$. The mapping may be expressed by the transformation,

$$[16] \qquad a(\boldsymbol{x}, \boldsymbol{p}) = \int_{-\infty}^{\infty}\mathrm{d}\boldsymbol{y}\langle\boldsymbol{x} + \boldsymbol{y}/2|\hat{A}\,|\boldsymbol{x} - \boldsymbol{y}/2\rangle e^{-\mathrm{i}\boldsymbol{p}\cdot\boldsymbol{y}/\hbar}$$

where the integration is over D-dimensional y-space. Equation [16] transforms operators of the form $G_1(\hat{\boldsymbol{x}}) + G_2(\hat{\boldsymbol{p}})$ into phase-space functions of the similar form $G_1(\boldsymbol{x}) + G_2(\boldsymbol{p})$. For operators containing products of position and momentum variables, there will be extra $\hbar$-dependent contributions.[28] Choosing $\hat{A}$ to be $\hat{\rho}/h^{\mathrm{D}}$, where $\hat{\rho}$ is a state operator, gives a Wigner function,

$$[17] \qquad W(\boldsymbol{x}, \boldsymbol{p}) = \frac{1}{(2\pi\hbar)^D} \times \int_{-\infty}^{\infty}\mathrm{d}\boldsymbol{y}\ \Psi^*(\boldsymbol{x} - \boldsymbol{y}/2)\Psi(\boldsymbol{x} + \boldsymbol{y}/2)e^{-\mathrm{i}\boldsymbol{p}\cdot\boldsymbol{y}/\hbar}$$

Now, let $a(\boldsymbol{x}, \boldsymbol{p})$ and $b(\boldsymbol{x}, \boldsymbol{p})$ be the phase-space images of the operators $\hat{A}$ and $\hat{B}$, respectively. The phase-space function $c(\boldsymbol{x}, \boldsymbol{p})$ corresponding to the operator $\hat{C} = \hat{A}\hat{B}$ is then

$$[18] \qquad c(\boldsymbol{x}, \boldsymbol{p}) = a(\boldsymbol{x}, \boldsymbol{p}) * b(\boldsymbol{x}, \boldsymbol{p})$$

This is a non-commutative binary operation known as a star multiplication. Explicitly, the star product may be written in the following form,[25]

$$[19] \qquad c(\boldsymbol{x}, \boldsymbol{p}) = \exp\left[\frac{i\hbar}{2}\left(\frac{\partial}{\partial \boldsymbol{x}_1}\cdot\frac{\partial}{\partial \boldsymbol{p}_2} - \frac{\partial}{\partial \boldsymbol{p}_1}\cdot\frac{\partial}{\partial \boldsymbol{x}_2}\right)\right] a(\boldsymbol{x}, \boldsymbol{p})b(\boldsymbol{x}, \boldsymbol{p})$$

The subscript 1 on a differential operator indicates that this operator acts only on the first function in the product $a(\boldsymbol{x}, \boldsymbol{p})b(\boldsymbol{x}, \boldsymbol{p})$. Similarly, the subscript 2 is used with operators that only act on the second function in the product. Alternative expressions for $c(\boldsymbol{x}, \boldsymbol{p})$ are,

$$[20] \qquad c(\boldsymbol{x}, \boldsymbol{p}) = a(\hat{\mathbf{X}}, \hat{\mathbf{P}})b(\boldsymbol{x}, \boldsymbol{p})$$

and

$$[21] \qquad c(\boldsymbol{x}, \boldsymbol{p}) = b(\hat{\mathbf{X}}^*, \hat{\mathbf{P}}^*)a(\boldsymbol{x}, \boldsymbol{p})$$

where we have introduced the Bopp operators,[32,34]

$$[22] \qquad \hat{\mathbf{X}} = \boldsymbol{x} + \frac{i\hbar}{2}\frac{\partial}{\partial \boldsymbol{p}}, \quad \hat{\mathbf{P}} = \boldsymbol{p} - \frac{i\hbar}{2}\frac{\partial}{\partial \boldsymbol{x}}$$

and

$$[23] \qquad \hat{\mathbf{X}}^* = \boldsymbol{x} - \frac{i\hbar}{2}\frac{\partial}{\partial \boldsymbol{p}}, \quad \hat{\mathbf{P}}^* = \boldsymbol{p} + \frac{i\hbar}{2}\frac{\partial}{\partial \boldsymbol{x}}$$

For yet other expressions, see the literature.[28]

By means of the above expressions it is easily seen that for combinations like $a(\boldsymbol{x}) * b(\boldsymbol{x})$ and $a(\boldsymbol{p}) * b(\boldsymbol{p})$, star multiplication is the same as ordinary multiplication. On the other hand, the star product $a(\boldsymbol{x}, \boldsymbol{p}) * a(\boldsymbol{x}, \boldsymbol{p})$ will in general be different from $a(\boldsymbol{x}, \boldsymbol{p})^2$. As far as the operators listed in Sect. 3.1 are concerned, each may be transformed into the corresponding phase-space function by simply removing the operator symbol for every variable. Thus for example, $H(x, p)$ becomes the phase-space function corresponding to the operator $\hat{H}(\hat{x}, \hat{p})$.

To determine the Wigner function $W_0(x_1, x_2, p_1, p_2)$ corresponding to the state operator $\hat{\rho}_0$, we first consider the one-dimensional oscillator with the Hamiltonian,

$$[24] \qquad \hat{H} = \frac{\hat{p}^2}{2m} + \frac{1}{2}m\omega^2\hat{x}^2$$

The ground-state wave function is

$$[25] \qquad \psi_0(x) = \left(\frac{\alpha^2}{\pi}\right)^{\frac{1}{4}} e^{-\frac{1}{2}\alpha^2 x^2}$$

Inserting this expression into the right-hand side of eq. [17] gives the ground-state Wigner function,

$$[26] \qquad W_0(x, p) = \frac{1}{\pi\hbar}\exp(-2H(x, p)/\hbar\omega)$$

This is a special case of the general expression,[20,25]

$$[27] \qquad W_n(x, p) = \frac{(-1)^n}{\pi\hbar}L_n(4H(x, p)/\hbar\omega) \times \exp(-2H(x, p)/\hbar\omega), \quad n = 0, 1, 2, \ldots$$

where L_n is a Laguerre polynomial.[27]

When applied to the one-dimensional oscillator, eq. [15] says that the state operator $\hat{\rho}_0$ is a function of $\hat{H}(\hat{x}, \hat{p})$. On the other hand, the Wigner function and $H(x, p)$ are the phase-space images of $\hat{\rho}_0$ and $\hat{H}(\hat{x}, \hat{p})$, respectively. Hence, we may in principle determine the form of the Wigner function by replacing the $\hat{H}$ on the right-hand side of eq. [14] by $H(x, p)$ and treating all multiplications as star products. We see that the result is an explicit function of $H(x, p)$ in the present case. This is a quite remarkable result. As we have discussed in Dahl and Schleich,[20] such a situation can only hold if $(H(x, p)^*)^n$ is a function of $H(x, p)$ for arbitrary n. We found that this condition is fulfilled whenever the Hamiltonian contains the position and momentum variables in a polynomial not higher than quadratic. In particular, it holds for the harmonic oscillator, and this is the reason why the Wigner function of eq. [27] merely depends upon x and p through $H(x, p)$.

Similar results hold in several dimensions, but here more than one constant of the motion may be present, and they may all enter into the expression for the Wigner function, This is in fact the case for the Moshinsky atom.

3.4. Densities and energies

The sub-Hamiltonians (eqs. [8] and [9]) both commute with the total Hamiltonian (eq. [7]), that is, they are constants of the motion. Both operators are of the type (eq. [24]) and define Wigner functions of the form (eq. [26]). The total ground-state Wigner function therefore becomes,

$$[28] \qquad W(x_1, x_2, p_1, p_2) = \frac{1}{(\pi\hbar)^2} \times \exp\left(-\frac{2H_{\mathrm{cm}}(X, P)}{\hbar\omega} - \frac{2H_{\mathrm{rel}}(x, p)}{\hbar\omega\sqrt{1+2\kappa}}\right)$$

It is the product of an extracule and an intracule phase-space density.

By integrating $W(x_1,x_2,p_1,p_2)$ over some of its variables we obtain reduced phase-space densities. Thus, integration over x_2 and p_2 followed by multiplication with 2 leads to the single-particle phase-space density,

$$[29] \qquad w(x_1, p_1) = \frac{2}{\pi\hbar}\sqrt{a(\kappa)b(\kappa)} \times \exp\left[-\alpha^2 a(\kappa)x_1^2 - \frac{b(\kappa)}{(\alpha\hbar)^2}p_1^2\right]$$

with α as defined earlier and

$$[30] \qquad a(\kappa) = \frac{2\kappa + 1 - \sqrt{2\kappa + 1}}{\kappa}$$
$$b(\kappa) = \frac{\sqrt{2\kappa + 1} - 1}{\kappa}$$

By further integration over p_1 we get the particle density in position space,

$$[31] \qquad \rho(x_1) = 2\alpha\sqrt{\frac{a(\kappa)}{\pi}}\exp[-\alpha^2 a(\kappa)x_1^2].$$

If instead, we integrate over x_1, we get the particle density in momentum space,

$$[32] \qquad \Pi(p_1) = \frac{2}{\alpha\hbar}\sqrt{\frac{b(\kappa)}{\pi}}\exp\left[-\frac{b(\kappa)}{(\alpha\hbar)^2}\, p_1^2\right]$$

By means of these densities we may evaluate the expectation values of symmetric operators. In this way, we find for instance the different contributions to the energy E_0 of our two-particle system,

$$[33] \qquad E_0 = \frac{\sqrt{2\kappa + 1} + 1}{4}\,\hbar\omega + \frac{\kappa}{2(2\kappa + 1 - \sqrt{2\kappa + 1})}\,\hbar\omega \quad + \frac{\kappa}{2\sqrt{2\kappa + 1}}\,\hbar\omega$$

Here, the first term is the kinetic energy, the second term is the confinement energy, and the last term is the interaction energy. The sum of the three terms is $E_0 = \frac{1}{2}(\sqrt{2\kappa + 1} + 1)\hbar\omega$, in accordance with the value given in eq. [10]. We note that the kinetic energy is just half the total energy, as expected from the virial theorem as applied to a harmonic system.[2,22]

The expectation values above could, of course, also have been evaluated by means of reduced density matrices in position space together with differential expressions for the momentum operators. The reduced density matrices would then have to be derived from the position-space wave function of eq. [11] in the usual way. However, the present procedure treats position and momentum symmetrically. We shall now consider the relation between the external potential and the particle density in position space.

3.5. The confining potential as a function of the particle density

According to the (first) Hohenberg–Kohn theorem,[5] the ground-state particle density in position space determines the external potential (the confining potential), that is, $v(x)$ is a functional of $\rho(x)$. Each type of interaction (Coulomb, harmonic, etc.) has its own branch of this functional. Here we consider the branch corrresponding to the harmonic interaction. When we also take the confining potential to be harmonic, we realize that we have to do with a lobe of that branch in which the functional simplifies to an ordinary function.

The $\rho(x)$ of eq. [31] has been determined by the direct method, namely, by solving the Schrödinger equation with the external potential $v(x) = \frac{1}{2}m\omega^2x^2$. We would, of course, have obtained the same $\rho(x)$ if we had taken $v(x)$ to be $v(x) = v_0 + \frac{1}{2}m\omega^2x^2$, where v_0 is an arbitrary constant. Let us therefore adopt this general form. We must then determine $v(x)$ by the inverse method, namely, from $\rho(x)$. To this end, we simply note that eq. [31] may be written,

$$[34] \qquad \rho(x) = 2\alpha\sqrt{\frac{a(\kappa)}{\pi}}\exp\left[\frac{2a(\kappa)}{\hbar\omega}v_0\right]\exp\left[-\frac{2a(\kappa)}{\hbar\omega}v(x)\right]$$

Inverting this relation gives,

$$[35] \qquad v(x) = -\frac{\hbar\omega}{2a(\kappa)}\ln\rho(x) + \tilde{v}_0$$

where $\tilde{v}_0$ is an arbitrary additive constant. This relation certainly gives us $v(x)$ if we know $a(\kappa)$ and ω.

To relate this result to density functional theory, we lock the strength of the particle–particle interaction, but include all strengths of the confining potential. We therefore rewrite eq. [4] in the form,

$$[36] \qquad \hat{H} = \frac{\hat{p}_1^2}{2m} + \frac{\hat{p}_2^2}{2m} + \frac{1}{2}m\omega^2\hat{x}_1^2 + \frac{1}{2}m\omega^2\hat{x}_2^2 + \frac{1}{2}m\eta(\hat{x}_1 - \hat{x}_2)^2$$

The fixed strength η now defines the particle type, and the free ω defines the class of confining potentials.

We have put $\kappa = \eta/\omega^2$. The $a(\kappa)$ of eq. [30] becomes therefore,

$$[37] \qquad a(\omega, \eta) = \frac{\omega^2 + 2\eta - \omega\sqrt{\omega^2 + 2\eta}}{\eta}$$

and eq. [35] reads

$$[38] \qquad v(x) = -\frac{\hbar\omega}{2a(\omega, \eta)}\ln\rho(x) + \tilde{v}_0$$

The determination of $v(x)$ from $\rho(x)$ now proceeds via the following arguments. We study a specific kind of interacting particle. Hence, η is fixed and known to us. We also know that a harmonic confining potential must produce a maximum in $\rho(x)$, at $x = x_0$ say, and according to eq. [31] we must at this point have,

$$[39] \qquad \rho''(x_0)/\rho(x_0) = -2a(\omega, \eta)m\omega/\hbar$$

The mass m we know, and measuring $\rho''(x_0)/\rho(x_0)$ therefore gives us ω. Thus, we have determined the external potential from the density.

This topological procedure is similar to the topological procedure used for interacting electrons in a nuclear framework. To fix η is similar to specifying the electronic charge. The determination of ω corresponds to exploiting the cusp condition at the nuclei.The difference is that in our case we have an explicit function instead of an implicit functional.

This is as far as we shall take the discussion of the Moshinsky atom. I refer the reader to the earlier cited literature[15–19] for discussions of, inter alia, the Hartree–Fock description, the correlation problem, and the Kohn–Sham description.

4. Summary

In this contribution I have discussed the ground state of Moshinsky's harmonium atom, which consists of two harmonically confined particles interacting through a harmonic force. The discussion has been tied to the phase-space representation of quantum mechanics in the Weyl–Wigner formulation. Explicit expressions and relations have been derived both for two-particle densities and one-particle densities. Special attention has been paid to the (first) Hohenberg–Kohn theorem and its relation between particle density and the external potential. In a general system, this relation is expressed by an implicit functional. In the simple case of the Moshinsky atom, the functional becomes an ordinary function. We have found the explicit form of this function and thus fulfilled an old desiderate[35]: *Could it be possible, for example, to obtain this functional for the oscillator model of the hydrogen atom, where all the Coulomb type potentials are replaced by their oscillator analogues?*

The Moshinsky atom is obviously an unrealistic substitute for a real atom. Its value as a model lies in the relative ease with which explicit expressions can be derived for most of its properties and in the way that some, generally intricate, relations simplify to ordinary functions.

5. Acknowledgments

I acknowledge fruitful conversations with W.P. Schleich, M. Springborg, and J.M. Gracia-Bondia. I am grateful to the Alexander von Humboldt Foundation for its support and to the Institut für Quantenphysik for its great hospitality. Finally, I thank the referee for the reference to the desiderate mentioned in the summary.

An implementation of the conductor-like screening model of solvation within the Amsterdam density functional package — Part II. COSMO for real solvents[1]

Cory C. Pye, Tom Ziegler, Erik van Lenthe, and Jaap N. Louwen

Abstract: The conductor-like screening model for real solvents (COSMO-RS) has been implemented in the Amsterdam density functional program. The surface building routines now allow for finer discretization of the GEPOL-based surfaces, and an additional surface due to Delley has been incorporated. One problem identified is the need for accurate density fitting in the region of the surface points. Another difficulty is the need to explicitly state for which atoms the hydrogen-bonding term applies. We present some vapour–liquid equilibrium curves of binary solvent systems to demonstrate the utility of the method.

Key words: Amsterdam density functional package, conductor-like screening model for real solvents, solvation, thermodynamics, chemical potential, chemical engineering.

Résumé : On a appliqué le modèle de triage apparenté aux conducteurs pour des solvants réels [« COSMO-RS »] dans le programme de la fonctionnelle de la densité d'Amsterdam. Les méthodes de construction des surfaces permettent maintenant d'obtenir des surfaces à base GEPOL beaucoup plus distinctes et on y a incorporé une surface additionnelle de Delley. La nécessité d'avoir des ajustements précis de densité dans la région des points de surface a été identifiée comme un problème. Une autre difficulté est la nécessité de spécifier explicitement à quels atomes le terme de liaison hydrogène s'applique. On présente quelques courbes d'équilibre vapeur–liquide de systèmes de solvants binaires pour démontrer l'utilité de la méthode.

Mots-clés : méthode de la fonctionnelle de la densité d'Amsterdam, modèle de triage apparenté aux conducteurs pour des solvants réels, solvatation, thermodynamique, potentiel chimique, génie chimique.

[Traduit par la Rédaction]

Introduction

The modelling of solvent effects in complex systems of technological, geochemical, and biological significance is an important field of study. In the past several years, the conductor-like screening model by Klamt[2] has emerged as a promising tool for efficiently treating these effects. We have implemented this method[3] into the Amsterdam density functional package (ADF).[4,5] Since the original implementation of the conductor-like screening model (COSMO), Klamt has subsequently developed the COSMO method for real solvents, COSMO-RS, which goes beyond the dielectric approximation and is very successful at predicting free energies of hydration, vapor pressure, and partition coefficients[6,7] as well as activity coefficients for use in chemical engineering.[8] In this paper, our implementation of the COSMO-RS method in the ADF package is described.

Since the publication of the original 1998 version of COSMO-RS, several variants have been published,[9–13] while in the commercial implementation COSMOtherm the method has been further developed, although precise details have not been published.[14] In this study we have restricted ourselves to the original 1998 version (with some necessary exceptions to be discussed later). This is because one of our purposes is to show that the implementation of COSMO-RS in a Slater orbital based quantum mechanical program like ADF leads to results similar to those obtained with non-Slater based programs. The 1998 COSMO-RS training data was published as supplementary material[7] including the deviations between observed and modeled data. This enables a detailed comparison between the original DMol and the ADF implementation.

Theory and implementation

Changes between ADF 2.3 and ADF99 COSMO

Several minor changes were made as part of the overall improvement of the software before general release in ADF99.[15]

(1) The GEPOL93 algorithm for constructing surfaces[16] was converted from Fortran 77 to Fortran 90 to take advantage of dynamic memory allocation. In addition, the original tessellation of 60 triangles per sphere was recently generalized to $60*4^{FDIV-1}$, where FDIV is a user-specified parameter.
(2) The fitted potential (default) method for calculating the C-matrix was incompatible with the disk potential smearing technique used for avoiding singularities in evaluating C-matrix and Fock matrix elements. One can now use the disk potential for the Fock matrix and the fitted potential for the C-matrix. Although the result is not fully variational, the effect is usually small (10^{-5} au).
(3) COSMO now works with both the Pauli and ZORA relativistic Hamiltonians in both scalar and spin-orbit forms for all C-matrix options.
(4) A more flexible input format for solute atomic radii was added for ease of use.

Theory of COSMO-RS

We briefly outline the COSMO-RS method of Klamt. For full details, including the derivation of the statistical mechanical expressions, the reader is referred to the description of the original DMol implementation of Klamt.[7] We keep the same notation to avoid confusion.

COSMO-RS is quite different from the underlying COSMO method in treating interactions between molecules in full detail. It achieves this in a fraction of the time required for traditional molecular simulations by making use of two essential features:

(1) By taking the molecule in the conductor as the reference state, instead of working out the long-range electrostatic forces between molecules, COSMO-RS deals only with charge mismatches at the cavity surface, thereby replacing the computationally very expensive evaluation of long-range intermolecular forces by the much more tractable computation of only local interactions.
(2) Segments of the molecular cavity are considered to be independent of each other. Although this leads to loss of information (i.e., on steric hindering and the multipolar nature of the electric field of a molecule), in practice this does not appear to create grave artefacts.

In the underlying COSMO method, the ideal net screening energy of molecule X can be written,

$$[1] \qquad \Delta^X = E^X_{\mathrm{COSMO}} - E^X_{\mathrm{gas}}$$

where the two terms on the right are the expectation values of the COSMO and gas-phase Hamiltonian, respectively. The dielectric component of this energy is,

$$[2] \qquad E^X_{\mathrm{diel}} = \frac{1}{2}\sum_{\nu} \Phi^X_{\nu} q^*_{\nu} = \frac{1}{2}\sum_{\nu} \Phi^X_{\nu} s_{\nu} \sigma^*_{\nu}$$

where each tessera ν is associated with a molecular electrostatic potential Φ^X_{ν}, and screening charge q^*_{ν}, which is equal to the product of the surface area s_{ν} and charge density σ^*_{ν}. The remainder accounts for the response of the wave function to the charges. In the original implementation of COSMO-RS, the two energies are linearly correlated and

$$[3] \qquad \Delta^X \approx \lambda_{\mathrm{reg}} E^X_{\mathrm{diel}}$$

with the regression coefficient $\lambda_{\mathrm{reg}} \approx 0.8$. We consider λ_{reg} as being variable and possibly a function of the theoretical level employed and the total molecular charge.

We consider the ideal reference state as that of the ideally screened molecule within a conductor. In condensed media with several molecules, this conductor must be removed to obtain the real system, and the molecular cavities touch each other over a surface patch of effective area a_{eff}. To regain the reference state for each molecule, imaginary charge densities need to be placed between the surface patches of the individual molecules that in general lead to a residual screening charge density over this area.

The residual screening charge density equals the negative of the sum of the screening charge densities of the two patches $\sigma + \sigma'$ as computed in the conductor, and the cost of introducing this imaginary charge density (due to the self-interaction of the residual charge density) is called the misfit energy and is a quadratic function of this residual.

To relate the average patch screening charge density to the charge density on the (generally much smaller) tessera used in the COSMO calculation, averaging formulae are employed

$$[4] \qquad \sigma_{\nu} = \frac{\sum_{\mu} \sigma^*_{\mu} \mathrm{I}_{\mu\nu}}{\sum_{\mu} \mathrm{I}_{\mu\nu}}$$

where

$$[5] \qquad I_{\mu\nu} = \frac{r^2_{\mu} r^2_{\mathrm{av}}}{r^2_{\mu} + r^2_{\mathrm{av}}} \exp\left\{ -\frac{d^2_{\mu\nu}}{r^2_{\mu} + r^2_{\mathrm{av}}} \right\}$$

and where r_{μ} is the mean radius of tessera μ, r_{av} is the mean radius of a patch, and $d_{\mu\nu}$ is the distance between the centers of tesserae μ and ν. Note that the charges obtained from multiplying the averaged charge density by the area of every segment do not in general add up to zero. This, however, does not appear to be a problem in practice.

The charge densities obtained after averaging determine the actual reference state. To be consistent in the comparison between gas-phase and condensed states, an expression for the gas-phase potential to the true reference state needs to be derived.

To that end, we define an average ideal screening energy,

$$[6] \qquad \Delta'^X = \Delta^X - \lambda_{\mathrm{reg}}(E'^X_{\mathrm{diel}} - E^X_{\mathrm{diel}})$$

in which E'^X_{diel} stands for the dielectric energy recomputed according to eq. [2], with the charge densities averaged as in eqs. [4] and [5].

The chemical potential of the gas-phase molecule with respect to the ideally screened state (albeit with averaged charges) can now be written as,

$$[7] \qquad \mu = -\Delta'^X - \sum_k \gamma_k A^X_k - \omega n^X_{\mathrm{ring}} + \eta RT$$

The second term is the dispersion energy of exposed surface area A^X_k of atom k with surface tension γ_k; the third term is a ring correction possibly related to entropy differences, as solvation should result in a larger entropy loss for

molecules without rings (n_{ring} is the number of atoms of X that are part of a ring, ω is a model parameter); the fourth term corrects for the gas-phase entropy as well as the different reference states (η is another model parameter).

We now turn to the chemical potential in the condensed phase. In the statistical mechanical treatment to follow, it is assumed that the surface patches are independent (i.e., there is no correlation between them). However, we will account for short-range correlation between surface patches so we can form a new screening charge density σ_ν° by averaging over a distance $2r_{av}$, instead of r_{av} in eqs. [4] and [5] and then orthogonalizing them over the entire data set to form a second descriptor of the surface patches,

$$[8] \qquad \sigma_\nu^\perp = \sigma_\nu^\circ - \lambda_{orth}\sigma_\nu$$

where $\lambda_{orth} = 0.816$ was estimated in the original implementation. In this work we will treat it as a free parameter.

The interaction energy between two surface patches is comprised of two terms, the misfit energy

$$[9] \qquad E_{misfit}(d,d') = \frac{\alpha'}{2}(\sigma+\sigma')[(\sigma+\sigma') + \lambda_{reg}(\sigma^\perp + \sigma^{\perp\prime})]$$

(introducing d as a general descriptor for the surface patch) and the hydrogen-bond energy

$$[10] \qquad \begin{cases} E_{hb}(d,\ d') = c_{hb}\max(0,\ \sigma_{acc} - \sigma_{hb})\min(0,\ \sigma_{don} + \sigma_{hb}) \\ \sigma_{acc} = \max[\sigma, \sigma'] \\ \sigma_{don} = \min[\sigma, \sigma'] \end{cases}$$

With these expressions in place, we now proceed to the computation of the pseudochemical potential of a component X of a mixture S. The pseudochemical potential was defined by Ben-Naim[17] as the chemical potential of a molecule at a fixed position in the mixture.

The pseudochemical potential of a surface patch with descriptor d is defined as,

$$[11] \qquad \tilde{\mu}_S(d) = -\ln\left[W^{-1}\sum_{X\in S} x_X \sum_{\nu\in X} s_\nu \exp\{-\beta^{-1}E(d,\ d_\nu^i) + \tilde{\mu}_S(d_\nu^i)\}\right]$$

where

$$[12] \qquad W = \sum_{X\in S} x_X \sum_{\nu\in X} s_\nu$$

and $\beta = RT/a_{eff}$. This equation is iterated to self-consistency. The residual part of the pseudochemical potential of solute X in solvent S is then written as

$$[13] \qquad \mu_{S,res}^{*X} = \beta\sum_{\nu\in X} s_\nu \tilde{\mu}_S(d_\nu)$$

To obtain the full pseudochemical potential, a cavitation–combinatorial term has to be added. In the original COSMO-RS scheme this term was chosen to be,

$$[14] \qquad \mu_{S,comb}^{*X} = -\lambda RT \ln A^{av}$$

where A^{av} is the mole fraction weighted average of the cavity surface of the individual components of the mixture.

It was later recognized that use of expression eq. [14] for the combinatorial part of the chemical potential leads to thermodynamic inconsistency (violation of the Gibbs–Duhem relation). Therefore, Klamt[14] introduced the following alternative expression,

$$[15] \qquad \mu_{S,comb}^{*X} = RT\left[\lambda_0 \ln\ V^X + \lambda_1\left(1 - \frac{V^X}{V^{av}} - \ln\ V^{av}\right) + \lambda_2\left(1 - \frac{A^X}{A^{av}} - \ln\ A^{av}\right)\right]$$

where A^X is the cavity surface area of component X in the mixture, and A^{av} the average as defined above. V^X and V^{av} are correspondingly defined for the cavity volume. We note that the areas and volumes are divided by 1 Å^2 and 1 Å^3, respectively, to render them dimensionless.

Despite our intention to remain true to the 1998 COSMO-RS implementation, we chose not to work with a combinatorial term that has been recognized as thermodynamically inconsistent (eq. [14]) and instead chose eq. [15]. Since, according to Klamt,[14] the estimated values for λ_0, λ_1, and λ_2 are usually of similar magnitude, we simply set: $\lambda = \lambda_0 = \lambda_1 = \lambda_2$ and thus replace one single parameter expression with another. We obtained a slightly better fit with eq. [15], which demonstrates its superiority. Note that for a pure liquid, the two expressions are identical if $\lambda = \lambda_0 = \lambda_1 = \lambda_2$.

Once the pseudochemical potential is defined, the other thermodynamic functions can be obtained through standard formulae.

Validation and fitting

To test the code as well as the viability of doing COSMO-RS modeling with ADF generated COSMO charge densities, the set of 217 molecules from the supplementary material of Klamt et al. [7] was recreated and optimized at the TZP level with the Becke–Perdew GGA density functional. COSMO calculations were then done on these molecules at the same level of theory to generate the σ-profiles. In contrast to the procedure advocated in the original COSMO-RS paper,[7] we did not optimize the molecular geometry in the conductor. Our COSMO calculations are all based on gas-phase optimized molecular geometries. We chose to do so for three reasons. Firstly, we obtained a slightly better fit this way. Secondly, the value of optimizing the molecular geometry in the conductor is, in general, of doubtful value. It biases the molecular geometry to environments of high dielectric constant. This bias may not have seemed unreasonable in the 1998 COSMO-RS implementation, which was aimed primarily at water-based properties, but since then COSMO-RS has increasingly been applied to engineering problems, e.g., to the solubility of solutes in apolar solvents. A final, more mundane reason for not doing geometry optimization in the conductor is that these are time consuming, in particular since convergence is often poor because changes in the cavity are not accounted for smoothly in the energy gradients.

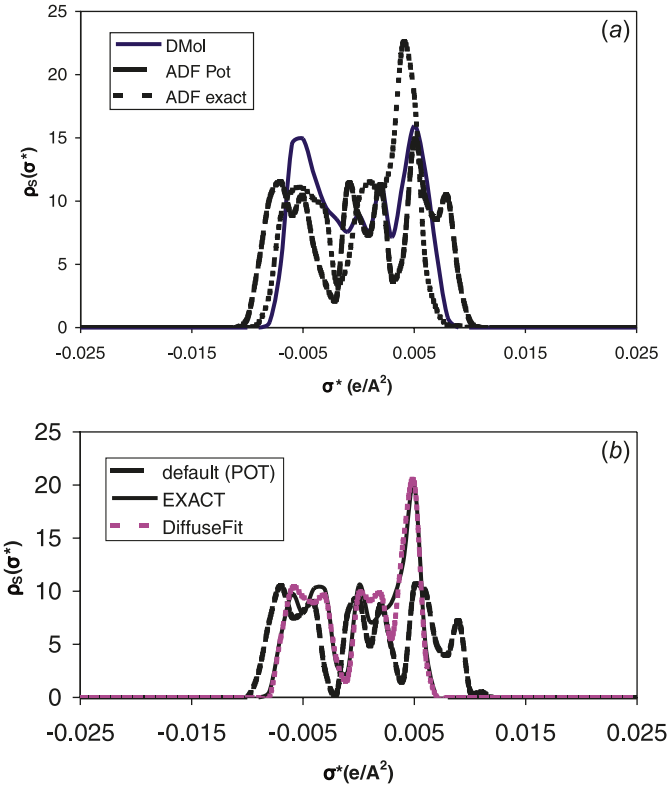
The COSMO-RS parameters were then optimized to reduce the sum-of-squares error over the fit set. The radii used were initially fixed at the values published by Klamt. When we later tried to optimize the value for the radii, we found the values were already optimal to within 0.01 Å for the Becke–Perdew functional but not necessarily for other functionals. We did not fully optimize the radii for other functionals. Apparently, the optimal shape of the COSMO cavity depends on the density functional used, much more than on the type of basis set (Slater orbitals in our case, numerical atomic orbitals in the original DMol implementation).

In the initial stages of parameter estimation, a great deal of computer time was saved by replacing the exponential function with an approximation devised by Schraudolph and Cawley for use in neural networks.[18,19]

Exact versus fitted density — A caveat

In the early stages of estimating the COSMO-RS parameters using the default COSMO settings, it was noted that compounds containing aromatic rings seemed to dominate the set of outliers, and the σ-profile was broader than expected (Fig. 1). Because of the delocalized π-systems of these molecules, the electron density is more diffuse than that of comparable σ-only systems. Use of the **C-Matrix Exact** option (instead of the default **C-Matrix Potential** option), which details how the surface charge – electron density interaction is calculated[3], remedies this, which implies that the fitted density is less accurate than the exact density in the region of the surface points. Another option is to use the defaults, but to add the line **AddDiffuseFit** to improve the fitted density (or potential) in the region of the surface

Fig. 1. The σ-profile $\rho_S(\sigma^*)$ as a function of program and C-matrix evaluation scheme for (*a*) styrene: reference DMol.[20] ADF potential (default), and ADF exact (*b*) benzene: ADF potential (default), ADF exact, ADF potential with diffuse fit functions added.

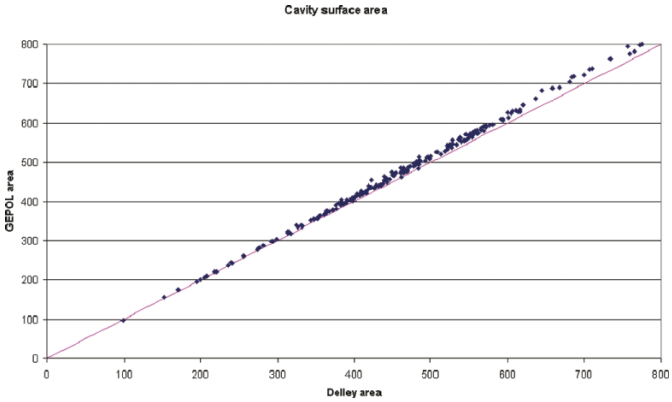


points. In Table 6 of the original ADF COSMO paper,[3] we noted that the energies calculated for ions using the **Potential** and **Fitted** methods are closer to each other for the most part than to the **Exact** method, which is probably a manifestation of this problem.

Surface construction

While pondering ways to improve the agreement between experimentally and theoretically derived quantities as part of our fitting procedure, we were curious whether our use of GEPOL, which tessellates each atom with 60 triangles, is introducing more error compared with the standard Klamt construction of 92 points per atom. One would expect that increasing the number of surface points per atom would increase the stability of the calculated σ-profiles with respect to small changes in the structure or orientation of the molecule. We decided to introduce the surface of Delley[21] to see if the tessellation scheme improves the results. This is specified by using **Surf Delley** in the Solvation block, and additional parameters **Leb1**, **Leb2**, and **Rleb** control the discretization per atom (i.e., if the radius of the atom is less than Rleb, use the Lebedev l-value Leb1, if it is greater, use the Lebedev l-value Leb2, maximum value 29). No significant overall improvement was noted in the comparison with experiment for Leb1 = 11 (60 points per atom) and Leb2 = 17 (110 points per atom), with some values getting better and some getting worse. The Delley surface area was only slightly smaller than the solvent-excluding surface area (Fig. 2).

Fig. 2. A plot of the solvent excluding surface area versus the Delley surface area for the test set of 217 molecules.



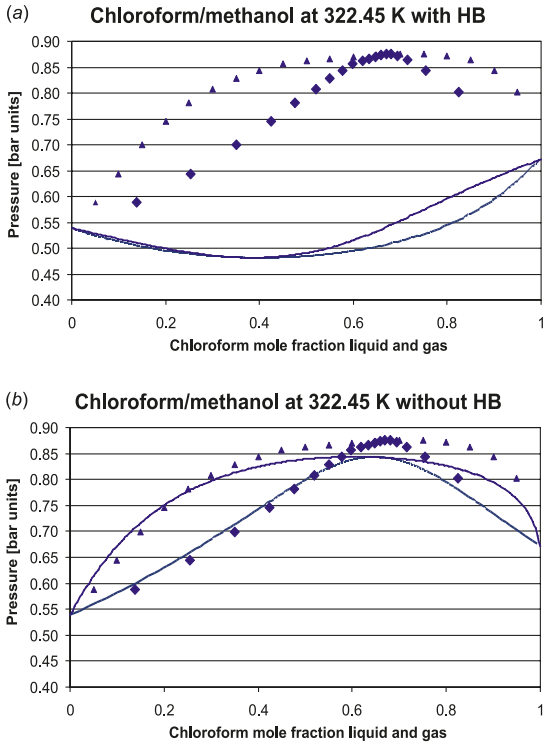
Hydrogen bonding term

In the initial phases of parameter estimation, we found most of the chlorinated molecules among the outliers. The issue with chlorinated molecules is demonstrated by considering the binary vapour–liquid equilibrium (VLE) diagram of chloroform and methanol predicted by an early version of our COSMO-RS implementation (see Fig. 3*a*). A strong negative deviation from Raoult's Law is predicted, whereas the observed deviation is positive. This indicates that experimentally the cohesive forces between like molecules are larger than between unlike, but we predict the reverse. It seemed plausible that the source of the poor agreement with experiment was due to the inappropriate use of the "hydrogen-bonding" term (eq. [10]). The hydrogen atom on chloroform is very electron-deficient, and therefore the magnitude of charge density on the associated surface patches is greater than the tolerance used to turn on the hydrogen-bonding term. In the case of the phase diagram with methanol, this hydrogen atom will form a hydrogen bond with the oxygen atom of methanol. By explicitly turning this interaction off for chloroform, considerably improved results were obtained. The residual error in the parameter estimation decreased markedly. As can be seen from the VLE diagram of chloroform and methanol, switching off the hydrogen bonding term for C-H hydrogen atoms on chlorinated molecules leads to a much more realistic account of the intermolecular interactions (Fig. 3*b*). It is not made clear in Klamt's paper describing the DMol implementation[7] whether or not such modifications are done. We chose to follow Lin et al.[10] and stipulate that only "classical" hydrogen bonds should be treated by the hydrogen bond term (i.e., the hydrogen must be bonded to an O, N, or F and be interacting with another O, N, or F).

Fitting

As object function in our fitting we have simply used the sum of squares between the numerical values of fitted and observed quantities, as given in the original fit set. The final result is expressed as kcal/mol (1 cal = 4.184 J). Klamt was able to achieve a rms value of 0.40 kcal/mol in his fitting, using the DMol implementation. Our various fitting attempts are chronicled in Tables 1 and 2. It is clear that the optimized parameters within each of the options that we explored was very self-consistent, which suggests that we are not overfitting our data.

Fig. 3. The vapor liquid equilibrium diagram (322.45 K) of methanol and chloroform (*a*) with, and (*b*) without explicit hydrogen bonding terms turned on. The triangles represent the experimental vapor pressure of the liquid with the specified composition, and the diamond at the same pressure indicates the composition of the resulting vapor. The lines represent the theoretical prediction.



Examples

Though not originally developed for that purpose, COSMO-RS is increasingly being used in chemical engineering where the prediction of activity coefficients is the dominant application.[8] The activity coefficient of a component X in a mixture S is given by,

$$[16] \qquad \gamma_S^X = \exp\left(\frac{\mu_S^{*X} - \mu_{\text{pure}}^{*X}}{RT}\right)$$

where μ_S^{*X} and μ_{pure}^{*X} are the pseudochemical potential of component X in the mixture and its pure state, respectively.

Neiman et al. investigated the potential of COSMO-RS for predicting activity coefficients.[22] They used simulations of vapor–liquid equilibria of binary mixtures as a test case, since experimental VLE data of high quality is available. They concluded that COSMO-RS is capable of semiquantitatively correct predictions. Here, we have taken some examples from their paper to evaluate our ADF COSMO-RS implementation.

In generating the isothermal VLE diagrams, we assumed ideal gas behavior for the vapor phase, as did Neiman et al. That is, the total pressure in equilibrium with a binary liquid mixture is computed as,

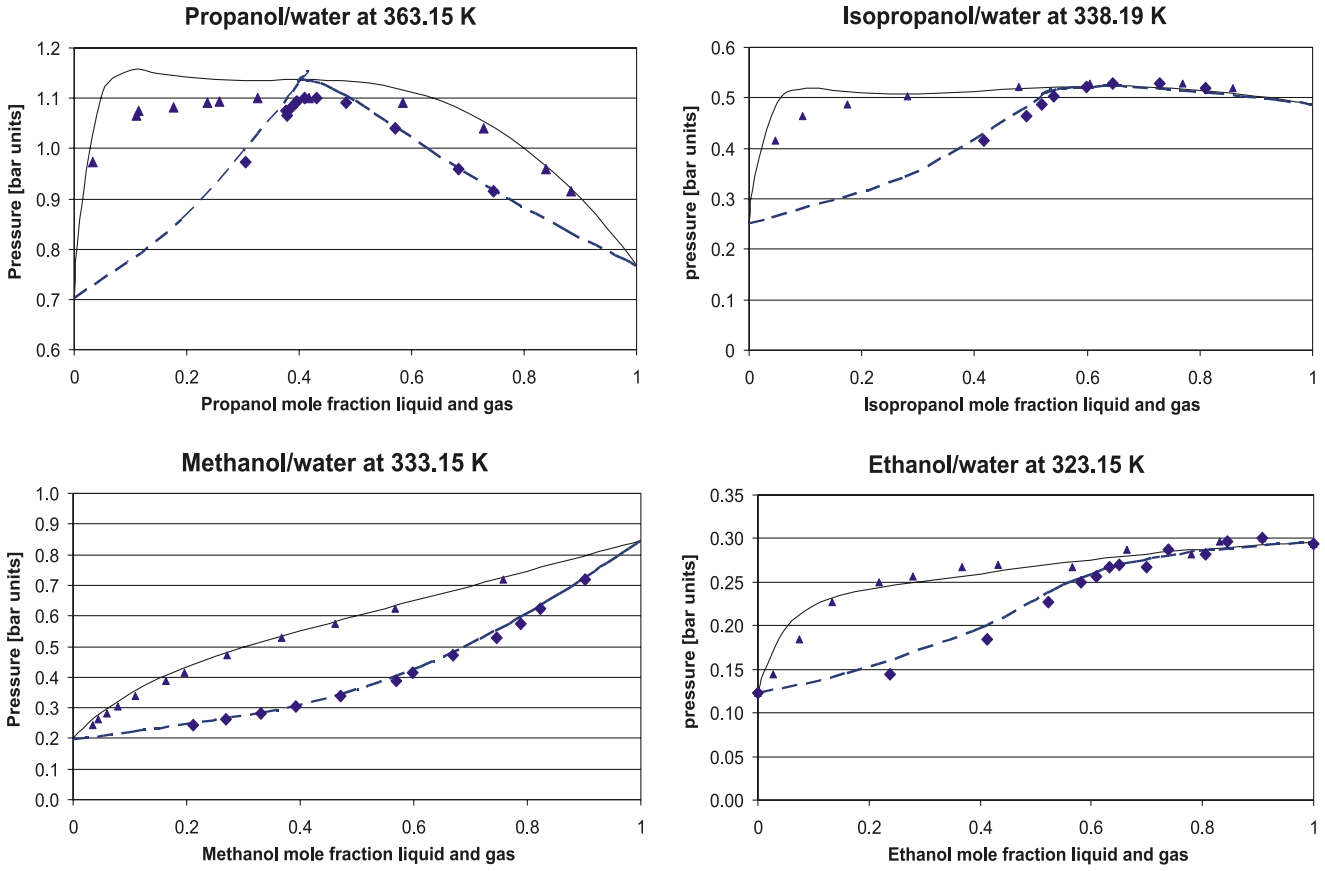

Fig. 5. Some vapor liquid equilibrium diagrams for acetone/methanol systems.

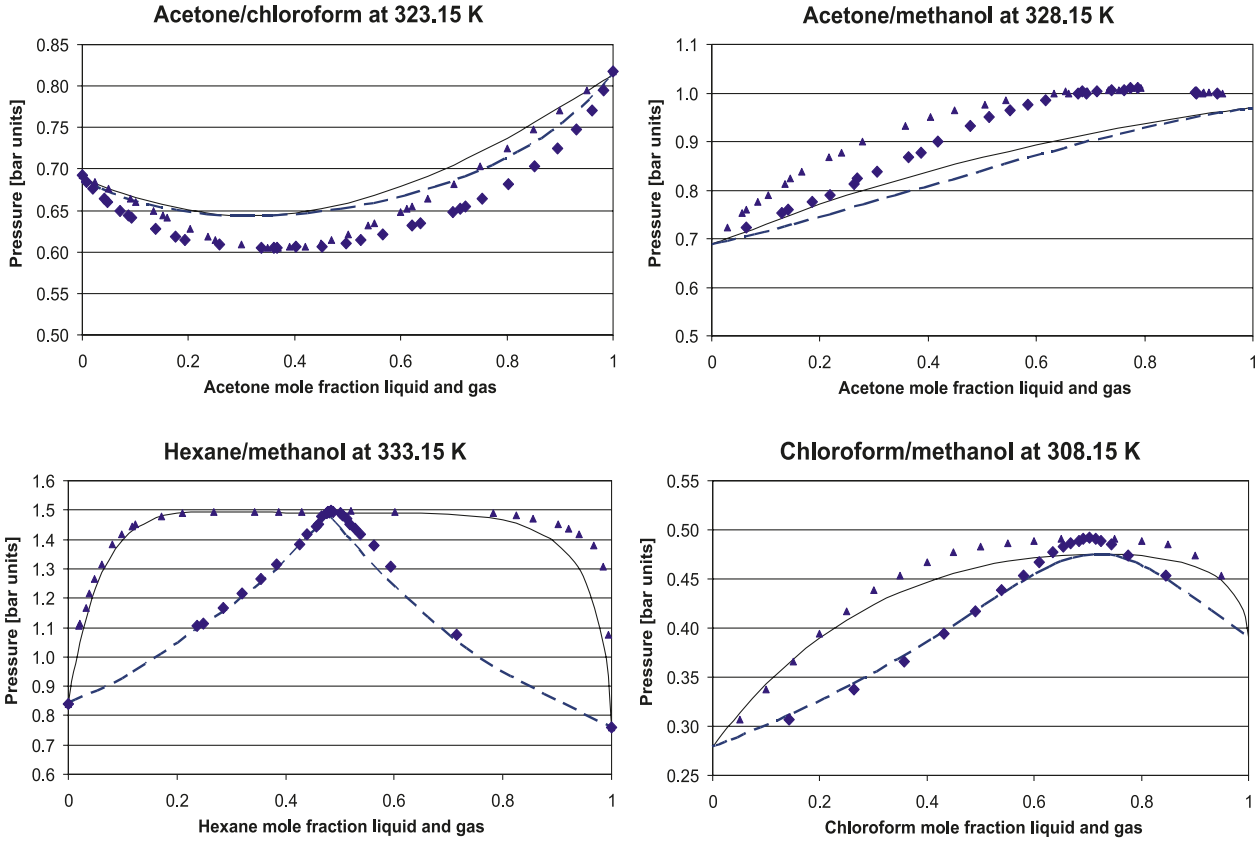

$$[17] \qquad p_{tot} = x_1\gamma_1 p_1 + x_2\gamma_2 p_2$$

where p_1 and p_2 are the vapor pressures of the pure liquids 1 and 2 at the operative pressure, x_1 and x_2 (= 1 – x_1) are the mole fractions for components 1 and 2, and γ_1 and γ_2 are the respective activity coefficients that we compute.

Subsequently, we compute the mole fraction of component 1 in the vapor phase as,

$$[18] \qquad y_1 = \frac{x_1\gamma_1 p_1}{p_{tot}}$$

Although the COSMO-RS method is capable of predicting the vapor pressure of the pure components, the accuracy of such predictions is limited and we used either experimental values or values derived from the Antoine equation for the pure component vapor pressures,[23] since our primary concern here is the prediction of the activity coefficients. Experimental data were taken from the literature.[24–29]

We reach the same conclusion as Neiman et al. for the VLE predictions of the ADF COSMO-RS implementation. In most cases, the results are quite good (see Fig. 4). The azeotrope point of isopropanol and water is correctly predicted, but COSMO-RS has difficulty predicting the azeotrope for ethanol and water. Note, however, that for both the propanol/water and isopropanol/water systems, a heterogeneous azeotrope is predicted contrary to experimental observations. There appear to be problems with acetone (see Fig. 5). The results for the acetone/chloroform mixture are rather poor, whereas the acetone/methanol prediction is quite bad. Other VLE diagrams involving methanol and chloroform are reasonably described. COSMO-RS significantly underestimates the activity coefficients and predicts pressures that are closer to linear interpolation than to the truth. Note, however, that the experimentally determined activity coefficients for this mixture are rather small (between 1 and 2), and small deviations have a relatively large effect. Probably, for this associating system a more detailed account of the interactions than offered by the empirical hydrogen bonding term is required.

Comparing our results to those reported by Neiman et al.[22] for the DMol implementation of COSMO-RS, we can see that the results are on par, with neither consistently superior to the other.

Conclusions

A COSMO-RS (1998 version) in ADF has been achieved that performs on par with the earlier DFT implementations. Although we are aware of several published and unpublished revisions to the original COSMO-RS, here we have chosen to retain the original procedure to be able to separate the effect of a different DFT scheme from proposed embellishments. Based on the current implementation, we foresee future developments, in particular for associating systems, where the current hydrogen-bond term in the segment interaction energy can provide only a crude account of the true physical interactions.

Bonding analysis for sterically uncongested simple aurocarbons C_nAu_m[1]

Patryk Zaleski-Ejgierd and Pekka Pyykkö

Abstract: The title series of simple model aurocarbons, CAu_4, C_2Au_2, C_2Au_4, C_2Au_6, and C_6Au_6, is investigated using density functional theory with TPSS and B3LYP functionals and the second-order Møller–Plesset perturbation theory, with the latest Karlsruhe basis sets. The vibrational frequencies and the 0 K thermodynamical properties are calculated. The bonding mechanism is also investigated. For C_2Au_n the calculated MP2 formation energy suggests increased stabilization with increasing n, due to the Au–Au aurophilic pair interactions.

Key words: aurocarbons, aurides, aurophilicity, metallophilicity, clusters, DFT, MP2.

Résumé : La série d'aurocarbones modèles simples mentionnés dans le titre, CAu_4, $C2Au_2$, C_2Au_4, C_2Au_6 et C_6Au_6, a été étudiée à l'aide de la théorie de la fonctionnelle de la densité, en faisant appel à des fonctions TPSS et B3LYP, ainsi qu'à l'aide de la théorie perturbationnelle de Møller–Plesset en faisant appel aux derniers ensembles de base de Karlsruhe. On a calculé les fréquences vibrationnelles et les propriétés thermodynamiques à 0 K. On a aussi étudié le mécanisme de liaison. Pour le C_2Au_n, l'énergie de formation MP2 calculée suggère que la stabilisation augmente avec une augmentation de n en raison d'interactions dans la paire aurophile Au–Au.

Mots-clés : aurocarbones, aurures, caractère aurophile, caractère métallophile, agrégats, théorie de la fonctionnelle de densité (TFD), MP2.

[Traduit par la Rédaction]

Introduction

Gold chemistry is fascinatingly rich. One of the conceptual tools in predicting new possible components is the chemical analogy between H and Au (or -$AuPR_3$). This was used to discuss CAu_4[2] or $SiAu_4$.[3] Interestingly, the attempts to completely aurate methane resulted in the C_{4v} system $[HC(AuPR_3)_4]^+$,[4] theoretically found to have a large proton binding energy.[5]

We furthermore note the existence of gold acetylides. A solid C_2Au_2 has been reported to be highly explosive.[6] For other examples on gold–acetylide bonds, see Puddephatt.[7] Recently, Naumkin[8] considered the possibility of completely aurating neopentane, $C(CH_3)_4$. The triple-bonded CAu^+ was predicted by Barysz and Pyykkö[9] and produced in the gas phase by Aquirre et al.[10] The dication CAu_2^{2+} was observed by Gibson by mass spectroscopy.[11] Its electronic structure was interpreted by Pyykkö et al.[12] as $[Au{=}C{=}Au]^{2+}$, with bonding, similar to that of O=C=O. They also considered the D_{3h} CAu_3^+, observed by Gibson,[11] and the C_2Au_2 that could be compared to either HCCH or $OCCO^{2-}$.

Against this background, we felt that a study of the aurated analogs of the simplest sp-, sp^2-, and sp^3-hybridized hydrocarbons would be interesting. The same uncongested conformations, as for their hydrocarbon analogs, are given preferential treatment.

Computational procedure

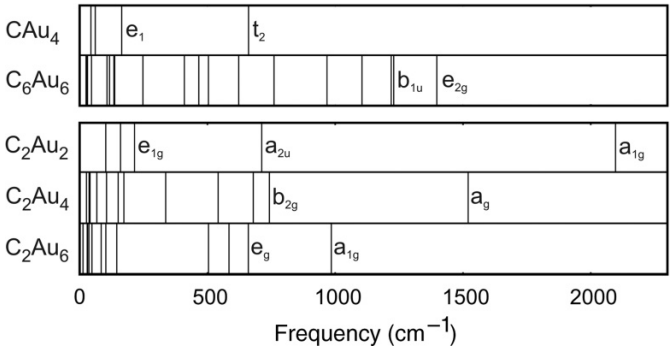
All the reported calculations were performed using the TURBOMOLE (version 5.10) program package.[13] Because of the expected presence of the aurophilic interactions, the results were calculated with both density functional theory (DFT),[14,15] and the second-order Møller-Plesset perturbation theory (MP2)[16] using the resolution of identity (RI) approximation, as implemented in TURBOMOLE.[17] The recent, Karlsruhe quadruple-zeta (def2-QZVPP) basis sets were employed for all elements. In the case of gold, the 19-VE "small-core" effective core potential (ECP) of Andrae et al.[18] was introduced to account for scalar relativistic effects. For carbon and nitrogen, we used the corresponding all-electron basis sets. The currently applied combination of bases and ECPs was found to be suitable for calculations involving weak Au–Au interactions.[19]

The vibrational analysis was performed within the harmonic approximation at both DFT and RIMP2 levels of theory. The DFT/TPSS results are depicted in Fig. 1.

In case of the DFT approach, two exchange-correlation functionals were used, namely, the B3LYP hybrid functional[20,21] and the meta-generalized gradient approximation TPSS functional.[22] We used the small sized grid (434 grid-points) for numerical integration.

For the RI-assisted MP2, the corresponding auxiliary basis sets were applied,[23] and all the explicitly treated electrons were correlated.

Fig. 1. The DFT/TPSS harmonic frequency spectra (cm^{-1}) calculated for the family of aurocarbons.



The spin–orbit interactions were neglected. For an s-element such as gold, and closed-shell species, this is expected to be reasonable.

The partial atomic charges were estimated using the Mulliken population analysis scheme, as implemented in the TURBOMOLE package. The molecular orbital (MO) contours were generated using Molden (version 4.6) package.[24]

Each of the six model compounds was optimized with the specific symmetry constrains: CAu_4 (C_1, effectively T_d), C_2Au_2 (C_{2v}, effectively $D_{\infty h}$), C_2Au_4 (D_{2h}), C_2Au_6 (D_{3d}), C_6Au_6 (D_{6h}), and $[CNAu_2]^+$ (C_{2v}, effectively $C_{\infty v}$). The resulting equilibrium structures were subjected to numerical vibration analysis. We did not find any imaginary frequencies.

Results and discussion

The geometry trends

We first note that although the investigated structures exhibit only real vibrational frequencies, the presented structures do not necessarily correspond to the global energy minima. It is possible that planar structures may be favored; for instance, 2D "flakes" are known to be exceptionally stable up to a certain number of gold atoms, depending on the electrical charge.[25,26]

In this work, we did not try to identify such energetically lowest isomers. Instead, we rather investigated the general trends of a new family of aurocarbons. The digold monocyanide cation, $[AuCNAu]^+$, was added as a potential isoelectronic species to C_2Au_2 for cation experiments.

The calculated equilibrium structures are depicted in Fig.2, while the corresponding geometrical parameters are presented in Table 1.

The DFT results obtained with the two different functionals (B3LYP and TPSS) agree. The average C–C bond length difference is $\sim$0.93 pm, and the Au–C difference is $\sim$2.15 pm. The discrepancy rises with the saturation of C–C bond.

The RIMP2 and DFT structures differ slightly. Two clear trends can be observed. In case of the Au–C and Au–Au/Au′–Au′ bonds, the RIMP2 distances are always the shortest, followed by TPSS and B3LYP. The opposite trend is observed in case of the C–C bond, with the notable exception of C_6Au_6.

The calculated Au–C and C–C bond lengths in C_2Au_2 are in good agreement with the experimental data obtained by Puddephatt et al. for species containing similar bonding patterns.[27]

Fig. 2. The aurocarbons, including the isoelectronic $[AuCNAu]^+$. The Au–Au and Au′–Au′ notations denote the shorter and longer aurophilic distances, respectively.

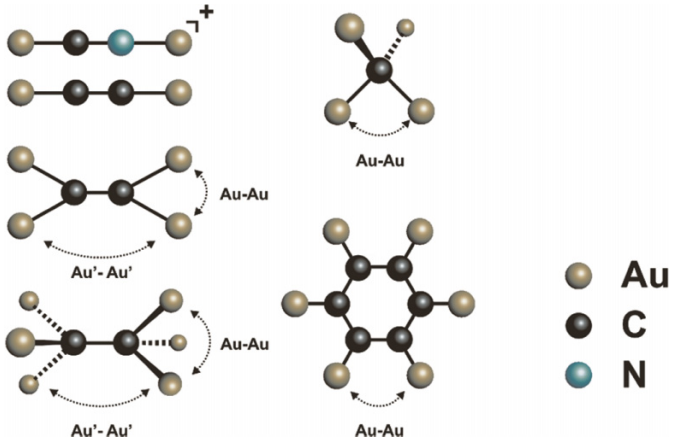


Table 1. The calculated bond distances for aurocarbons in Fig. 2. All values in pm.

Case	Method	C–C	Au–C	Au–Au	Au′–Au′
CAu_4	B3LYP	—	198.74	324.55	—
	TPSS	—	196.54	320.94	—
	RI-MP2	—	190.21	310.62	—

	TPSS	122.49	190.13	—	—
	RI-MP2	122.51	184.99	—	—
C_2Au_4	B3LYP	131.60	199.13	326.50	359.88
	TPSS	132.99	196.78	325.59	354.06
	RI-MP2	133.14	189.92	314.26	346.48
C_2Au_6	B3LYP	147.94	203.32	317.38	372.35
	TPSS	148.83	200.31	314.12	365.67
	RI-MP2	146.66	193.15	304.66	353.19
	HF	148.57	207.99	322.15	382.96
C_6Au_6	B3LYP	139.68	200.07	339.75	—
	TPSS	140.13	197.85	337.98	—
	RI-MP2	138.84	190.99	329.80	—

The C–C distances in the C_2Au_2, C_2Au_4, and C_2Au_6 are closely comparable with the corresponding hydrocarbons, suggesting analogous bonding. Interestingly, the C–C bond in C_2Au_6 is shorter than in C_2H_6 by $\leq$10 pm.

The Au–C distance varies from one molecule to the other by up to $\sim$12 pm and depends strongly on the type of the C–C bond. It lengthens with the level of substitution (or shortens with the hybridization as $sp < sp^2 < sp^3$, like the C–H bonds do).

While the Au′–Au′ distances only yield weak aurophilic interactions, the Au–Au distances are expected to have stronger ones. The Au-C-C angles remain practically constant for different methods: 124.18°, 124.96°, and 124.17° for C_2Au_4 and 115.12°, 115.68°, and 114.40° for C_2Au_6 at the B3LYP, TPSS, and RIMP2 levels of theory, respectively.

Vibrations

The harmonic frequencies were calculated at three levels of theory: DFT with the B3LYP, the TPSS exchange-correlation functionals, and the RIMP2.

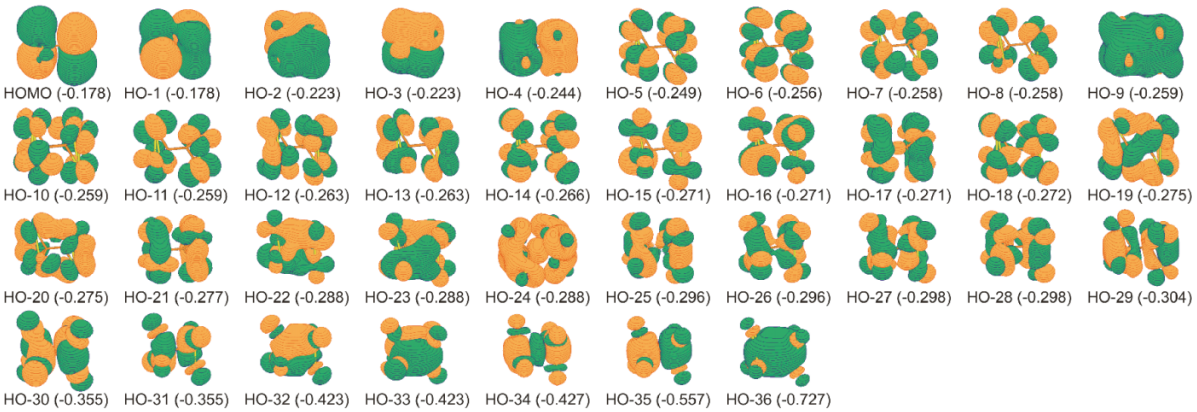
Fig. 3. (Color online) The 37 highest occupied Kohn–Sham (TPSS) molecular orbitals of C_2Au_6 (D_{3d}). The LUMO orbital energy is –0.130 a.u., resulting in a gap of 0.048 a.u. or +1.31 eV. (HO-n stands for HOMO-n).



The TPSS frequencies are depicted in Fig. 1. The B3LYP results are similar, while the RIMP2 tend to give slightly higher values. The fact can be related to the M-C overbinding typical for MP2 method. The highest frequencies correspond to C–C stretch, while the lowest, to the out-of-plane deformations and the rotations with respect to the C–C axis. In the unlikely case of quantum dynamics for the gold nuclear motions, six gold atoms could still occupy the same special quantum state, with nuclear spin M_I from –5/2 to +5/2.[28]

Thermochemistry

The thermochemical analysis for a series of reactions listed in Table 2 was performed with respect to the isolated Au_2 and the $C(^3P_j)$ atoms. The CAu_4 and C_2Au_2 formation energy from pure elements (Table 2, cases 1–2) was found to be strongly negative for all methods. The energy of Au_2 addition in a C_2Au_2, C_2Au_4 series (Table 2, cases 3–4) varies with method. It remains negative for TPSS and RIMP2 but changes sign in case of B3LYP results. The trimerization energy of C_2Au_2 units (Table 2, case 5) is strongly exothermic. Since the accuracy of such estimates might be questionable, we applied an isodesmic approach (Table 2, cases 6–10) to make sure that the broken chemical bonds are of the same type as the type of bonds formed in the reaction. The DFT formation energy calculated per one Au–C bond is approximately constant for a given functional. Interestingly, the same energy calculated at RIMP2 level decreases systematically in the C_2Au_n (n = 2, 4, 6) series and became thermoneutral for C_2Au_6, most likely because of aurophilic stabilization. It is known that this attraction is exaggerated at the MP2 level.[29]

Bonding

The TPSS Kohn–Sham orbitals are given in the Supplementary data. They all correspond to the combinations expected from the existing C–C and Au–C local bonding orbitals. A fair amount of hybridization is also seen in the Au 5d band. An example on C_2Au_6 is depicted in Fig. 3. The simplest way to understand the bonding orbitals of C_2Au_6 (D_{3d}) in Fig. 3 is to classify the bonding orbitals HOMO to HOMO-4, and HOMO-9, as the e_g (2x), t_{1u} (3x), and a_{1g} combinations of the six Au–C local bonding orbitals under octahedral, quasi-O_h symmetry. The corresponding nodal structures are conspicuous in Fig. 3. The Mulliken charges are shown in Table 3. The C atoms are negative and the Au atoms positive.

Possible extensions

The present ideas can be extended by considering ionic isoelectronic analogs (BAu_4^-, CAu_4, NAu_4^{+1}) or by introducing other rows of the periodic table (CAu_4, $SiAu_4$, etc.). Another possibility is to replace the plain -Au by -$AuPR_3$.[5] The latter proposition is more realistic for bulk compounds. Many such monocentric compounds already exist, while the bicentric (C_2Au_6, etc.) gold compounds are more rare.

Table 3. The partial Mulliken charges, δ, for structures considered in Fig. 2.

Case	Method	δC	δAu(C)/δAu(N)	δN
$[AuCNAu]^+$	B3LYP	–0.25	+0.79/+0.79	–0.30
	TPSS	–0.27	+0.76/+0.83	–0.33

C_2Au_2	B3LYP	–0.31	+0.31/—	—
	TPSS	–0.34	+0.34/—	—
	HF	–0.47	+0.47/—	—
C_2Au_6	B3LYP	–1.31	+0.44/—	—
	TPSS	–1.43	+0.48/—	—
	HF	–1.43	+0.48/—	—
C_6Au_6	B3LYP	–0.61	+0.61/—	—
	TPSS	–0.64	+0.64/—	—
	HF	–0.42	+0.42/—	—

Conclusions

We have considered the H→Au analogs of the simplest hydrocarbons CH_4, C_2H_2, C_2H_4, C_2H_6, and C_6H_6. All are found to be local minima, but their Au–C bonding energies are smaller than the corresponding C–H ones.

The C_2Au_6 system possesses increased stability at the MP2 level and has in its D_{3d} structure altogether twelve aurophilic Au^I–Au^I attractions.

The nuclear quadrupole moment of ^{69}Ga and ^{115}In[1]

Hana Yakobi, Ephraim Eliav, and Uzi Kaldor

Abstract: Electric field gradients at the nuclei of gallim and indium are determined by finite field calculations of the atomic energies as functions of the nuclear quadrupole moments. The four-component Dirac–Coulomb–Gaunt Hamiltonian serves as framework, and all electrons are correlated by Fock-space coupled cluster with single and double excitations or by single reference coupled cluster with approximate triples. Large, converged basis sets (e.g., 28s24p20d13f5g4h for In) and virtual spaces are used. Together with experimental nuclear quadrupole coupling constants, known with high precision, the calculated electric field gradients yield the nuclear quadrupole moments. For ^{69}Ga, we get Q = 174(3) mb, in agreement with the earlier 171(2) mb obtained from molecular calculations. The ^{115}In moment is Q = 772(5) mb, considerably lower than the previously accepted 810 mb, and in good agreement with the recent molecular value of 770(8) mb.

Key words: nuclear quadrupole moments, gallium, indium, relativity, coupled cluster method.

Résumé : En faisant appel à des calculs de champ fini des énergies atomiques en fonction des moments nucléaires quadripolaires, on a calculé les gradients de champs électriques des noyaux de gallium et d'indium. L'hamiltonien à quatre composants de Dirac–Coulom–Gaunt sert de référence et on a établi une corrélation entre tous les électrons à l'aide de l'agrégat couplé dans un espace de Fock avec des excitations simples ou doubles ou par l'agrégat couplé par référence simple avec des approximations de triplets. On a utilisé de grands ensembles de bases convergents (tels 28s24p20d13f5h4h pour l'indium) et des espaces virtuels. En se basant sur les constantes de couplage quadripolaire nucléaire expérimentales qui sont connues avec une grande précision, les gradients de champs électriques calculés ont permis de calculer les moments nucléaires quadripolaires. Pour le ^{69}GA, on a obtenu une valeur de Q = 174(3) mb, en accord avec la valeur de 171(2) mb obtenue antérieurement par calculs moléculaires. Pour le ^{115}In, le moment est de Q = 772(5) mb, une valeur beaucoup plus basse que celle acceptée antérieurement, 810 mb, mais en bon accord avec la valeur moléculaire de 770(8) mb obtenue récemment.

Mots-clés : moments quadripolaires nucléaires, gallium, indium, relativité, méthode de l'agrégat couplé.

[Traduit par la Rédaction]

Introduction

The nuclear quadrupole moment (NQM) of ^{115}In listed in Pyykkö's 2001 compilation[2] is 810 mb (with 7% uncertainty), obtained by Belfrage et al.[3] from the observed hyperfine structure of the 5s, 7p, and 8p ^{2}P states of the atom and the empirically derived $\langle r^{-3} \rangle$ value. A lower value of 760 mb (with 6% uncertainty) was later proposed,[4] based on X-ray data and calculations on the muonic atom.[5] DFT calculations on metallic indium[6] gave values of 760(20) and 780(20) mb, depending on the density functional used. The best effort to date involved relativistic coupled cluster calculations on several In-including molecules,[7] yielding a moment of 770(8) mb. The accepted value of the Ga NQM has been more stable. The reference value of 171(2) mb[2,8] is in agreement with the earlier 173(3) mb.[9]

An approach of potentially high accuracy combines experimentally observed nuclear quadrupole coupling constants of the atom, B, with calculated electric field gradients (EFG) at the nucleus, q. The NQM value Q (in barns) may be obtained from the equation

$$[1] \qquad Q[\mathrm{b}] = \frac{B[\mathrm{MHz}]}{234.9647q[\mathrm{au}]}$$

Since B is usually known with high accuracy, the quality of the calculated NQM depends solely on that of the EFG. This "atomic" approach has recently been applied to the halogen atoms[10] and to gold.[11] Here we apply it to Ga and In, for which accurate measurements of the coupling constants are available,[12,13] and compare the results to recent "molecular" values.[7,8]

Methodology

The relativistic Fock-space coupled cluster method with single and double excitations (FSCCSD) used here has been described earlier,[10,11,14] and only a few pertinent points will be discussed below. The inclusion of triple excitations in FSCC has been reported recently.[15]

Atomic and molecular properties are usually observed via the energy shifts generated by coupling to an external field. The desired property is the derivative of the energy with respect to the external field. The derivative may be calculated analytically by the Z-vector or Λ-operator method[16]; alternatively, the finite field approach[17] may be used, whereby an external field is added to the Hamiltonian and the derivative is obtained numerically. Early FSCC calculations were carried out for the EFG of several light elements, up to Mg.[18] Note that the analytic evaluation of general properties by FSCC is

still an open problem, although some progress has been made.[19] The finite field scheme circumvents this difficulty.

The finite field approach is used here to calculate the electric field gradient at the In and Ga nuclei. The Hamiltonian is modified to include the interaction with an (arbitrary) nuclear electric quadrupole Q,

$$[2] \qquad \hat{H}(Q) = \hat{H}_0 - eqQ/h$$

where e is the electron charge. The energy, which is the expectation value of $\hat{H}(Q)$, may be expanded as

$$[3] \qquad E(Q) = \langle \Psi(Q)|\hat{H}(Q)|\Psi(Q)\rangle = E_0 + Q\left(\frac{dE(Q)}{dQ}\right)_0 + \frac{Q^2}{2}\left(\frac{d^2E(Q)}{dQ^2}\right)_0 + \cdots$$

Differentiating and invoking the Hellmann–Feynman theorem, one obtains

$$[4] \qquad \frac{dE(Q)}{dQ}|_{Q=0} = -\frac{e}{h}\langle \Psi_0|\hat{q}_{ZZ}|\Psi_0\rangle$$

neglecting higher-order derivatives. The first derivative of the energy with respect to the nuclear quadrupole moment gives the required expectation value of the electric field gradient (multiplied by some constants).

Conflicting considerations determine the value of Q used in the calculations, which is *not* the physical NQM. The perturbation must be large enough for the energy change not to disappear in the precision of the calculations, yet small enough to stay in the linear regime. The linearity must be monitored by using several values of Q.

The four-component Dirac–Coulomb–Gaunt (DCG) Hamiltonian is used. In the presence of the electric field Q,

$$[5] \qquad H = \sum_i h_D(i) + \sum_{i<j}(1/r_{ij} + G_{ij}) - eqQ$$

where h_D is the one-electron Dirac operator with a Gaussian finite nucleus, and G_{ij} is the Gaunt operator.[20] Interaction with the external field is thus included from the start. The DIRAC relativistic ab initio electronic structure program[21] is used in all calculations, and the symmetry of the system is taken as $D_{\infty h}$. The Gaunt interaction is included fully at the HF stage; at the correlation stage it is taken using the atomic mean-field integral (AMFI) approximation.[22]

Electron correlation must be included at a high level to obtain accurate results. The FSCCSD method was applied here to the ns^2np states of In and Ga. Starting with the ionic state ns^2 as reference, an electron was added in the np orbitals, and the correlated energies in the presence of the field were obtained. In addition, the single reference coupled cluster method (SRCC) was applied to the $ns^2np_{3/2}$ $^2P_{3/2}$ state, which (for M_J=3/2) may be described by a single determinant. There is a major difference between the two approaches: The SRCC scheme gives the energy shift of the probed state with Q, while the FSCCSD method also yields the splitting between the $P_{3/2,3/2}$ and $P_{3/2,1/2}$ levels, which is the source of the experimental coupling constant B. In previous calculations,[10,11] we observed that the splittings remain linear for Q values as high as 10^{-5} au, whereas shifts start to show nonlinearity even at Q=10^{-8} au On the other hand, available programs make possible the approximate inclusion of triple excitations for the SRCC approach only.

Calculations and results

The uncontracted, well-tempered basis sets of Huzinaga and Klobukowski[23] were employed. The basis sets were increased to obtain convergence of the EFG, and all electrons were correlated at the final stage. Virtual orbitals with energies above 130 au were discarded at the CC stage. Raising the cutoff from 100 to 130 au changed the value of Q by less than 0.1 mb for Ga and 0.3 mb for In. The convergence of the calculated EFG with respect to the basis is demonstrated in Tables 1 and 2 for Ga and In, respectively. Basis functions with both higher and lower exponents were added for each l until the EFG converged. The values in these tables were obtained by the FSCCSD method, with virtual orbital cutoffs of 100 au and Q values of 0 and 5.0×10^{-6} au The basis functions giving convergence in the different l sectors were combined to give the basis sets shown in the

last row of Tables 1 and 2, which served in subsequent calculations.

As linearity of the energy change vs. Q is crucial to the precision of the calculations, it was carefully monitored. For the single reference methods, where the shift of one level is calculated, we used the differences between energies obtained for Q and $-Q$, thus eliminating the quadratic term in eq. [3]. This was not necessary in the multi-reference FSCCSD calculations, where the splitting of the two sublevels (see above) makes this elimination automatic. In both cases, a calculation with $2Q$ was carried out to test the linearity. For single reference methods it was necessary to take $Q = 2.5 \times 10^{-9}$ au to reduce nonlinearity below 0.2%, whereas FSCCSD gave this result for $Q = 2.5 \times 10^{-6}$ au

The EFG values at the Ga and In nuclei, calculated in the framework of the DCG Hamiltonian by the Hartree–Fock (HF), MP2, and single-reference and Fock-space CCSD methods, are collected in Table 3. Perturbative triple excitations were added to the SRCCSD values by the +T, (T), and –T schemes. Q values giving linearity of 0.2% or better were used, 2.5×10^{-6} au for FSCCSD and $\pm 2.5 \times 10^{-9}$ au for all other methods. The virtual orbital energy cutoff was 130 au The calculated EFG values and experimental nuclear quadrupole coupling constants[12,13] were inserted in eq. [1] to give the nuclear quadrupole moments, which are shown in Table 4. The Gaunt contribution to the final NQM is 0.5 mb for Ga and 1 mb for In.

Discussion

Considerable effort has been made to minimize the errors in the calculated EFGs, both systematic and numerical. The basis sets used are nearly complete, and deviations from linearity and other problems involving the extraction of the EFG from the energy data are small. The largest error comes from truncating the coupled cluster expansions at the SD or SD(T) level. Note that the definition of triple excitations may differ for the Fock space and single reference approaches, since they use different atomic orbitals and model spaces. In the present application, the SR approach is more accurate, as it uses AOs of the neutral atom (vs. the cation for FSCC) and includes approximate triples. The difference between these two schemes at the SD level may provide an indication of the triples contribution. Taking all these factors into account, our final NQMs are 174(3) mb for ^{69}Ga and 772(5) mb for ^{115}In. The gallium NQM agrees with the molecular value 171(2) mb.[2,8] The ^{115}In result is significantly lower than the previously accepted[2] 810 mb, and agrees with the value of 770(8) mb obtained in recent molecular calculations.[7]

Bond activation by group-11 transition-metal cations[1]

G. Theodoor de Jong and F. Matthias Bickelhaupt

Abstract: We have computationally explored C–X bond activation by the group-11 transition-metal cations Cu^+, Ag^+, and Au^+, and, for comparison, Pd, using relativistic density functional theory (DFT) at ZORA-BLYP/TZ2P. Oxidative insertion of the second-row transition-metal species Ag^+ and Pd leads, for a given bond, to the highest overall reaction barriers. On the other hand, if we compare the different bonds oxidative insertion into the C–F bond is associated with (one of the) highest overall barriers whereas insertion into the C–Cl bond leads to the lowest overall barrier for any transition metal. The main trends in reactivity are rationalized using the activation strain model of chemical reactivity, which is an extension of the fragment approach to reaction profiles. In this model, the shape of the reaction profile $\Delta E(\zeta)$ and the height of the overall reaction barrier $\Delta E^{\neq} = \Delta E(\zeta=\zeta^{TS})$ are interpreted in terms of the strain energy $\Delta E_{strain}(\zeta)$ associated with deforming the reactants along the reaction coordinate ζ plus the interaction energy $\Delta E_{int}(\zeta)$ between these deformed reactants: $\Delta E(\zeta) = \Delta E_{strain}(\zeta) + \Delta E_{int}(\zeta)$.

Key words: activation strain model, catalysis, density functional calculations, oxidative addition, palladium, ligand effects, reaction mechanisms.

Résumé : Faisant appel à la théorie de la fonctionnelle de densité (TFD) relativiste au niveau ZORA-BLYP/TZ2P, on a évalué l'activation de la liaison C–X par les cations des métaux de transition du groupe 11, Cu^+, Ag^+ et Au^+ et, pour fins de comparaison, par le Pd. L'insertion oxydante d'espèces métalliques de transition de la deuxième rangée, Ag^+ et Pd, conduit pour une liaison donnée barrières réactionnelles globales les plus élevées. Par ailleurs, si on compare les diverses liaisons, l'insertion oxydante dans la liaison C–F est associée avec une des barrières globales les plus élevées alors que l'insertion dans une liaison C–Cl, pour n'importe lequel des métaux de transition, conduit à la barrière globale la plus faible. Les tendances principales dans la réactivité sont rationalisées à l'aide du modèle de la contrainte d'activation de la réactivité chimique qui est une extension de l'approche fragmentaire aux profils de réaction. Dans ce modèle, la forme du profil réactionnel $\Delta E(\zeta)$ et la hauteur de la barrière réactionnelle globale $\Delta E^{\neq} = \Delta E(\zeta=\zeta^{TS})$ sont interprétées en fonction de l'énergie de contrainte, $\Delta E_{contrainte}(\zeta)$, associée avec la déformation des réactifs le long de la coordonnée de réaction ζ plus l'énergie d'interaction, $\Delta E_{int}(\zeta)$, entre ces réactifs déformés: $\Delta E(\zeta)= \Delta E_{contrainte}(\zeta) + \Delta E_{int}(\zeta)$.

Mots-clés : modèle de contrainte d'activation, catalyse, calculs de la fonctionnelle de densité, addition oxydante, palladium, effets de ligand, mécanismes réactionnels.

[Traduit par la Rédaction]

Introduction

Oxidative addition and reductive elimination are ubiquitous as elementary reaction steps in homogeneous catalysis[2–4] (Scheme 1) and have been intensively investigated both experimentally[4–6] and theoretically.[6–12] A well-known class of processes involving oxidative addition is catalytic C–X bond activation.[2,13] The catalytically active species in these processes are in general coordination complexes of palladium or another transition metal. Oxidative addition is an efficient tool for selectively converting simple educts, via C–C bond formation, into more complex compounds, and it is therefore of major importance for synthetic chemistry. The most intensively used substrates for such C–C coupling reactions are aryl halides, whereas it is more difficult in this context to exploit alkyl halides.[14]

In a previous study, we investigated the activation of the C–H and C–C bonds by Pd compared with main group metals (Be, Mg, and Ca) and group-12 transition metals (Zn and Cd).[11] It was shown that Pd is able to activate these bonds better than the other metals, i.e., with lower reaction barriers, because it has both good electron-donating and good electron-accepting capacities due to the small gap between its occupied 4d and unfilled 5s atomic orbitals (AOs). In other studies, the profound effect of anion assistance in the case of the $PdCl^-$ complex (compared with uncoordinated Pd) on the activation barriers and the selectivity of reaction pathway was demonstrated and explained.[12]

In the present study, we extend these investigations to the cations of the group-11 transition-metal triad (Cu^+, Ag^+, and Au^+), which are also of interest for C–X bond activation processes.[15] To this end, we have investigated the oxidative insertion of the three d^{10} transition-metal cations and, for

comparison, palladium into the C–H, C–C, C–F, and C–Cl bonds of methane, ethane, fluoromethane, and chloromethane, respectively (see eq. [1]: M = Pd, Cu^+, Ag^+, Au^+; X = H, CH_3, F, Cl), using density functional theory (DFT) at ZORA-BLYP/TZ2P, as implemented in the ADF program (see Methods section below).

$$[1] \qquad M + CH_3X \rightarrow CH_3 - M - X$$

To obtain a better understanding of the major trends in reaction barriers, we have analyzed our model reactions in terms of the activation strain model of chemical reactivity.[8,12,16] In this model, the energy of the reaction system $\Delta E(\zeta)$ is decomposed along the reaction coordinate ζ into the strain $\Delta E_{strain}(\zeta)$ within the increasingly deformed reactants plus the stabilizing interaction between these reactants $\Delta E_{int}(\zeta)$: $\Delta E(\zeta) = \Delta E_{strain}(\zeta) + \Delta E_{int}(\zeta)$.

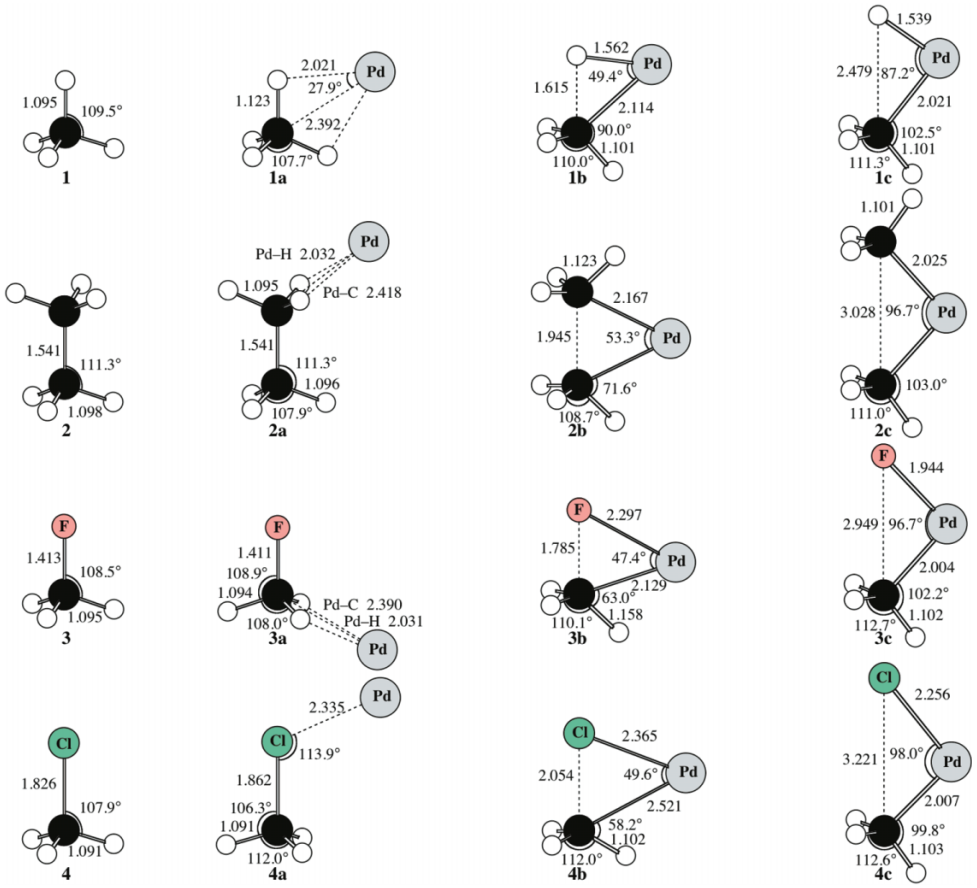
Methods

Computational details

All calculations are based on density functional theory (DFT),[17] using the Amsterdam Density Functional (ADF) program.[18,19] The BLYP density functional was used,[20] in combination with a large uncontracted set of Slater-type orbitals (STOs) containing diffuse functions. This basis set is designated TZ2P: it is of triple-ζ quality and has been augmented with two sets of polarization functions, 2p and 3d on H, 3d and 4f on C, F, and Cl, 4p and 4f on Cu, 5p and 4f on Pd and Ag, 6p and 5f on Pd. The core shells of carbon (1s), fluorine (1s), chlorine (1s2s2p), copper (1s2s2p), palladium (1s2s2p3s3p3d), silver (1s2s2p3s3p3d), and gold (1s2s2p3s3p3d4s4p4d) were treated by the frozen-core approximation.[18] An auxiliary set of s, p, d, f, and g STOs was used to fit the molecular density and to represent the Coulomb and exchange potentials accurately in each SCF cycle.[18] Relativistic effects were accounted for using the zeroth-order regular approximation (ZORA).[21] Recently, it has been shown that our approach is in good agreement with high-level ab initio calculations for oxidative addition reactions to Pd.[9,10]

Equilibrium and transition-state geometries were fully optimized using analytical gradient techniques. All structures were verified by frequency calculations: for minima all normal modes have real frequencies, whereas transition states have one normal mode with an imaginary frequency. The

Fig. 2. Geometries (Å, °) of stationary points along the potential energy surface for oxidative insertion of Pd into the C–X bond of CH_3X, computed at ZORA-BLYP/TZ2P.



character of the normal mode associated with the imaginary frequency was analyzed to ensure that the correct transition state was found.

Activation strain analyses

Insight into how the reaction barriers arise is obtained through activation strain analyses of the various C–X bond activation processes.[8,12,16] The activation strain model is a systematic extension of the fragment approach (first introduced in the ADF program and in the context of DFT by Ziegler and Rauk[19]) from equilibrium structures to transition states as well as *nonstationary* points, e.g., points along a reaction coordinate. It is a fragment approach to understanding chemical reactions in which the height of reaction barriers is described and understood in terms of the original reactants. Thus, the potential energy surface $\Delta E(\zeta)$ is decomposed along the reaction coordinate ζ into the strain $\Delta E_{\text{strain}}(\zeta)$ associated with deforming the individual reactants plus the actual interaction $\Delta E_{\text{int}}(\zeta)$ between the deformed reactants,

$$[2] \qquad \Delta E(\zeta) = \Delta E_{\text{strain}}(\zeta) + \Delta E_{\text{int}}(\zeta)$$

The strain $\Delta E_{\text{strain}}(\zeta)$ is determined by the rigidity of the reactants and by the extent to which groups must reorganize in a particular reaction mechanism, whereas the interaction $\Delta E_{\text{int}}(\zeta)$ between the reactants depends on their electronic structure and on how they are mutually oriented as they approach each other. It is the interplay between $\Delta E_{\text{strain}}(\zeta)$ and $\Delta E_{\text{int}}(\zeta)$ that determines if and at which point along ζ a barrier arises. The activation energy of a reaction $\Delta E^{\neq} = \Delta E(\zeta^{\text{TS}})$ consists of the activation strain $\Delta E^{\neq}_{\text{strain}} = \Delta E_{\text{strain}}(\zeta^{\text{TS}})$ plus the TS interaction $\Delta E^{\neq}_{\text{int}} = \Delta E_{\text{int}}(\zeta^{\text{TS}})$,

$$[3] \qquad \Delta E^{\neq} = \Delta E^{\neq}_{\text{strain}} + \Delta E^{\neq}_{\text{int}}$$

This is illustrated in Fig. 1.

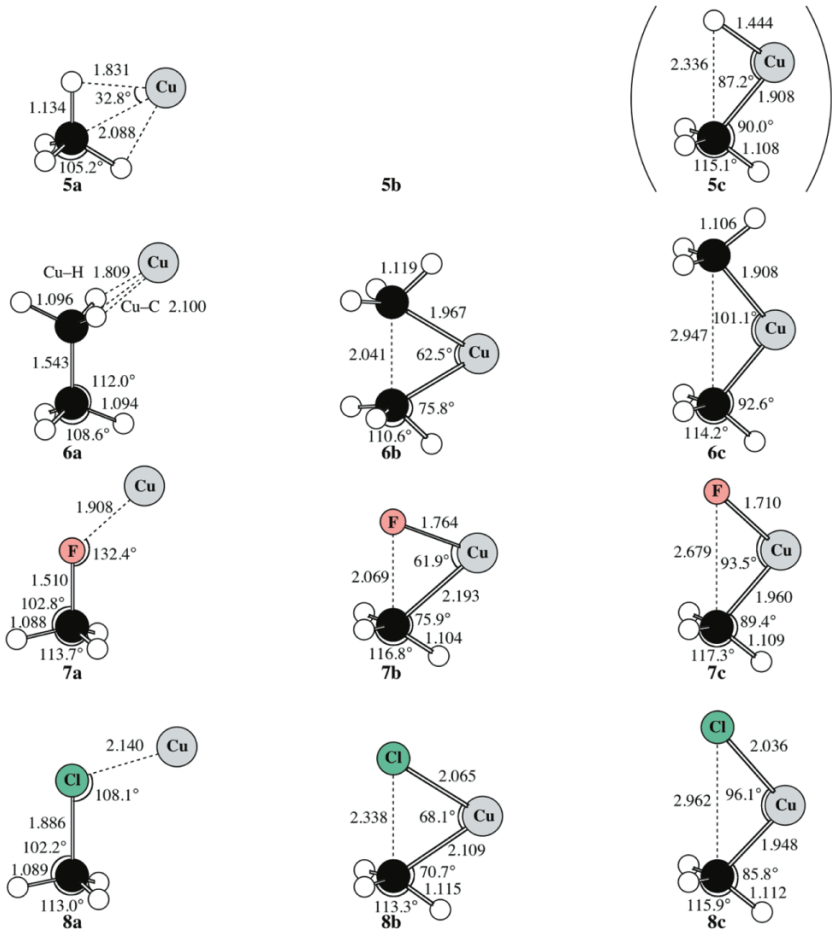
The reaction coordinate ζ is defined here as the path of steepest descent from the transition state down to the local energy minima on the educt and product side, connected by this transition state. This path is determined through the intrinsic reaction coordinate (IRC) method.[22] In the graphical representations shown hereafter, ζ is then projected onto the stretch of the C–X bond that is being activated. This C–X stretch is generally the dominant component of the reaction coordinate in our model systems and undergoes a well-defined change from an intact to a dissociated bond.

Results and discussion

Reaction profiles and geometries

Our ZORA-BLYP/TZ2P results for the 16 oxidative insertion (OxIn) reactions are collected in Table 1 (energies) and Figs. 2–5 (geometries). All model reactions (eq. [1]) involve the formation of a stable reactant complex (RC) between the

Fig. 3. Geometries (Å, °) of stationary points along the potential energy surface for oxidative insertion of Cu^+ into the C–X bond of CH_3X, computed at ZORA-BLYP/TZ2P. Structures **5b** and **5c** do not exist as stationary points; **5c** is modeled by the labile structure with the C-M-X angle frozen to the value in the corresponding Pd product **1c** and all other internal coordinates fully optimized.



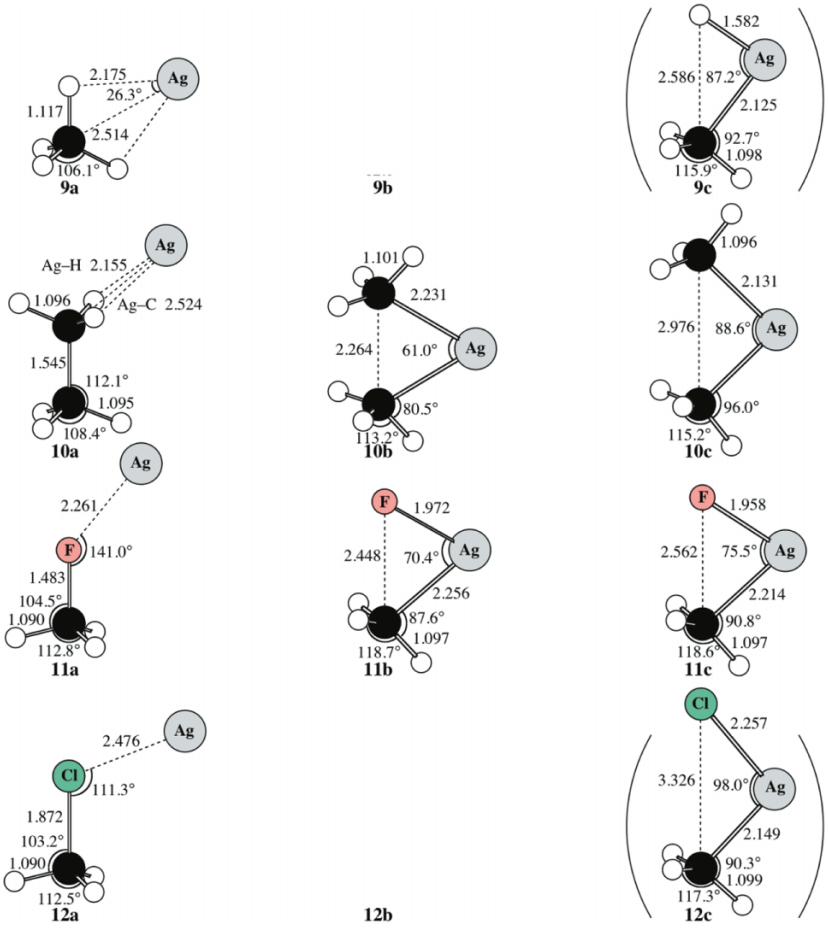
reactants (R) in which the substrate coordinates to the metal or metal cation, either via the hydrogen atoms or via the halogen atom. Coordination via hydrogen, M···H-C, occurs for all reactions of methane and ethane, and if M = Pd, also in the case of fluoromethane (see **1a**, **2a**, **3a**, **5a**, **6a**, **9a**, **10a**, **13a**, and **14a** in Figs. 2–5). Coordination via halogen, M···X-C, occurs in all other reactions with the substrates fluoromethane and chloromethane (see **4a**, **7a**, **8a**, **11a**, **12a**, **15a**, and **16a**). Most of the model reactions then proceed from the RC via the transition state (TS, see **1b**–**16b**) to the insertion product (P, see **1c**–**16c**).

Note, however, that OxIn of Cu^+ and Ag^+ into the methane C–H bond and OxIn of Ag^+ into the chloromethane C–Cl bond have no reverse barrier, that is, there are no stationary points corresponding to a TS or a stable product P. In other words, the conceivable OxIn product CH_3MX undergoes spontaneous reductive elimination. For these three model reactions, we have computed labile (i.e., nonstationary) model-product structures (see **5c**, **9c**, and **12c** in Figs. 3 and 4) by optimizing the geometries under the constraint that the C-M-X angle is frozen to its value in the corresponding OxIn product of Pd (see **1c** in Fig. 2). These structures are used as an estimate of the effective OxIn reaction barrier and also as starting points for exploring the reaction coordinate and profile through IRC calculations.

The formation of the RC is substantially more exothermic for the transition-metal cations (–16 to –50 kcal/mol) than for the neutral Pd (–6 to –13 kcal/mol), as can be seen in Table 1. The larger complexation energy of the cations has been traced to their increased ability to accept electronic charge from the substrate. This is reflected by the lowest unoccupied "molecular" orbitals (LUMOs) of Cu^+, Ag^+, and Au^+, i.e., the 4s, 5s and 6s atomic orbitals (AOs), respectively, which are consistently at much lower energy than the corresponding 5s acceptor orbital on Pd. This is illustrated in Fig. 6, which compares the energy levels of the four metal species and the four substrates on scale. We wish to point out, however, that in terms of HOMO–LUMO interactions with the substrate orbitals, the picture in Fig. 6 suggests an exaggerated stabilization of the AOs in the transition-metal cations compared with Pd. This is because in the vicinity of the metal cation the substrate orbitals also experience stabilization due to the net positive charge, although less so than the metal AOs, and are therefore effectively at lower energies than in the vicinity of the neutral Pd or in the isolated substrates shown in the figure.

All reactions are exothermic by –3 to –45 kcal/mol, except those involving Ag^+, which are all endothermic by 8 to 28 kcal/mol (see Table 1). The overall reaction barriers (TS relative to reactants) are graphically represented in the two-

Fig. 4. Geometries (Å, °) at ZORA-BLYP/TZ2P of stationary points along the potential energy surface for oxidative insertion of Ag^+ into the C–X bond of CH_3X. Structures **9b**, **9c**, **12b**, and **12c** do not exist as stationary points; **9c** and **12c** are modeled by the labile structures with the C-M-X angle frozen to the value in the corresponding Pd product **1c** and all other internal coordinates fully optimized.



dimensional bar diagram of Fig. 7. As already pointed out above, oxidative insertion of Cu^+ and Ag^+ into the methane C–H bond and OxIn of Ag^+ into the chloromethane C–Cl bond have no reverse barriers, and the effective reaction barrier corresponds to the endothermicity associated with forming the OxIn product (which is labile with respect to reductive elimination, the reverse reaction).

Figure 7 shows that oxidative insertion of the second-row transition-metal species Ag^+ and Pd leads, for a given bond, to the highest overall reaction barriers. For example, the overall barrier for M + CH_3F is –3 (Cu^+), +8 (Au^+), +18 (Pd), and +32 kcal/mol (Ag^+). On the other hand, if we compare the different bonds, oxidative insertion into the C–F bond is associated with (one of the) highest overall barriers, whereas insertion into the C–Cl bond leads for any transition metal to the lowest overall barrier. For example, the overall barrier for Ag^+ + CH_3X is +9 (C–Cl), +13 (C–C), +28 (C–H), and +32 kcal/mol (C–F).

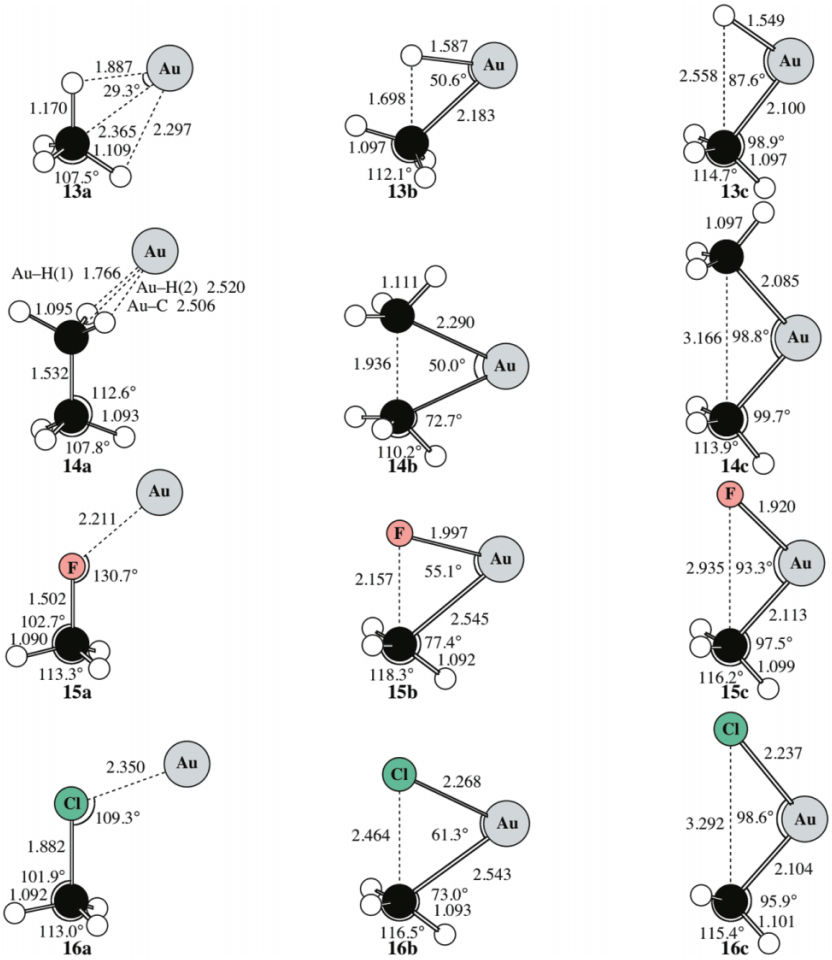
Apart from these global trends, there are also interesting changes in selectivity along the metal species for C–H versus C–C activation. Thus, Cu^+ favors the activation of C–C over C–H with overall barriers of –19 versus –3 kcal/mol whereas, on the other hand, Au^+ favors C–H over C–C activation with overall barriers of –34 versus –28 kcal/mol (see Table 1).

Activation strain analyses of reactions with Pd

The results of our activation strain analyses are shown in Fig. 8 in which they are collected, both per C–X bond reacting with each of the four metal species (Fig. 8*a*) and also per metal species M inserting into each of the four bonds (Fig. 8*b*). As a starting point for our discussion, we take the OxIn reactions of palladium that have been analyzed and discussed previously.[12] Here, we focus on the main trends of the Pd + CH_3X model systems.

The low reaction barrier for palladium-induced C–Cl bond activation compared with the other bonds is straightforwardly explained by the lower C–Cl bond strength, which manifests itself in a less destabilizing ΔE_{strain} curve (green in Fig. 8*b*, Pd). The bond dissociation energy (BDE) increases in the order C–Cl < C–C << C–H ≤ C–F from 82 to 90 to 110 to 115 kcal/mol, respectively, as computed at ZORA-BLYP/TZ2P.[12] The other bonds, i.e., C–H, C–F, and C–C, have more destabilizing ΔE_{strain} curves, which mutually differ comparatively little (see Fig. 8*b*, Pd). As far as the C–H and C–F bonds are concerned, this reflects again the relative bond strengths of these bonds that increase only slightly in the order C–H ≤ C–F. The fact that the ΔE_{strain} curve for the C–C bond also practically coincides here with those of the much stronger C–H and C–F bonds is not what

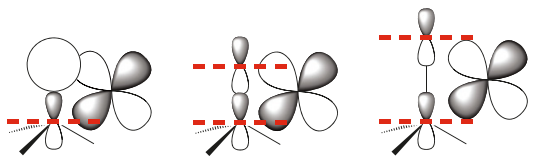
Fig. 5. Geometries (Å, °) of stationary points along the potential energy surface for oxidative insertion of Au^+ into the C–X bond of CH_3X, computed at ZORA-BLYP/TZ2P.



one would expect on the basis of the relative bond strengths. We will return to this issue later on.

Thus, the reaction barrier for C–H activation is higher than that for C–Cl activation because the C–H bond is stronger. However, the further increase of the barrier along C–H, C–C, and C–F appears to have its origin in the metal–substrate interaction ΔE_{int}. In Fig. 8*b* (Pd), it can be seen that initially the ΔE_{int} curves of the C–C and C–F bonds, and to a lesser extent also that of the C–Cl bond, lag behind that of the C–H bond, while later on they catch up. This initial lagging behind of the ΔE_{int} curves has the effect of pushing up the net energy profile ΔE, which causes the C–F and C–C barrier to be higher than that of C–H activation. The catching up in a somewhat later stage along the reaction coordinate ζ causes an increased (negative) slope in the ΔE_{int} curves. Compared with the situation for C–H, this shifts the stationary point (i.e., the TS) on the net potential energy surface $\Delta E(\zeta) = \Delta E_{strain}(\zeta) + \Delta E_{int}(\zeta)$ towards the left.

The origin of the lagging behind of the ΔE_{int} curves of C–C, C–F, and C–Cl compared with C–H is diverse.[12] One factor that the former three bonds have in common derives from the dependence of the metal 5s-substrate σ^*_{C-X} overlap on the progress along the reaction coordinate. The interaction of palladium with the C–H bond has, from the beginning, a relatively favorable overlap between a metal 4d AO and the σ^*_{C-H} acceptor orbital of the substrate with its large nodeless 1s lobe at hydrogen. This overlap situation is shown schematically below in **A** (the red dashed line indicates the nodal surface of the carbon 2p component of the σ^*_{C-H} MO, which contributes especially when the C–H bond begins to be stretched).



A **B** **C**

The corresponding overlap with the σ^*_{C-X} acceptor orbital of C–X bonds in which X is a main group atom (i.e., C–C, C–F, C–Cl) is less favorable, in the beginning, because now there is also a nodal surface at X that cuts through the metal 4d lobe, resulting in cancellation of overlap (see **B** above). However, the overlap soon catches up as the reaction proceeds and the C–X bond expands, because this causes the nodal surfaces of the substrates σ^*_{C-X} MO to move out of the way of the metal 4d AO (see **C** above). The ΔE_{int} curve for C–Cl activation benefits, in addition, from being already

Fig. 6. Orbital energies (eV) of the frontier orbitals of Pd, Cu^+, Ag^+, Au^+, CH_4, C_2H_6, CH_3F, and CH_3Cl, computed at ZORA-BLYP/TZ2P. All metals have closed $(nd)^{10}$ shells.

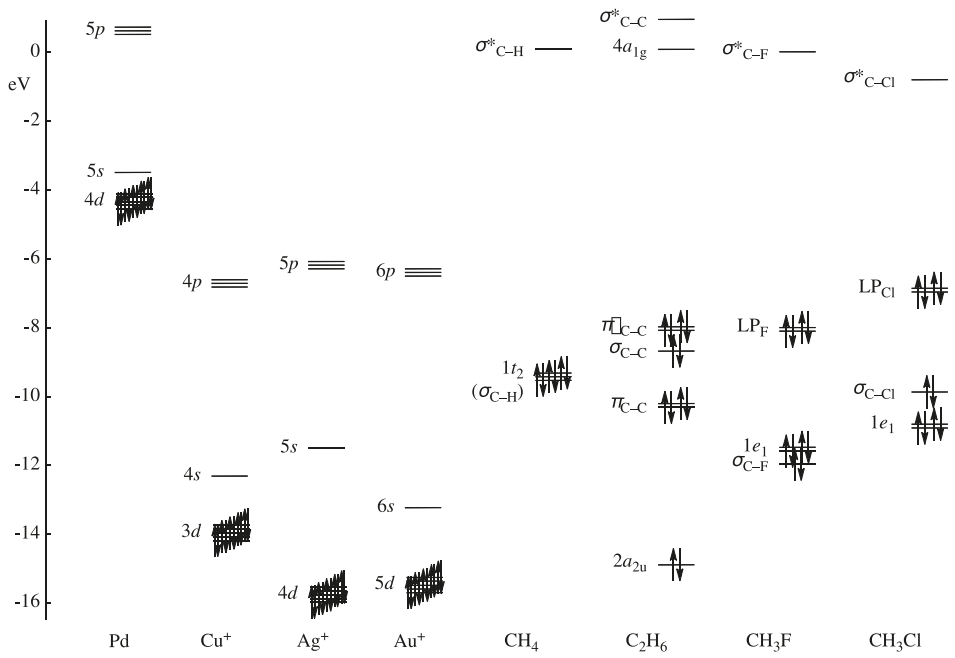


Fig. 7. Trends in overall activation energies relative to that of $Cu^+ + CH_3Cl$ ($\Delta E^{\neq}[M + CH_3X] - \Delta E^{\neq}[Cu^+ + CH_3Cl]$ in kcal/mol) for the oxidative insertion of Cu^+, Au^+, Pd, and Ag^+ into the C–Cl, C–C, C–H, and C–F bonds of CH_3X, computed at ZORA-BLYP/TZ2P.

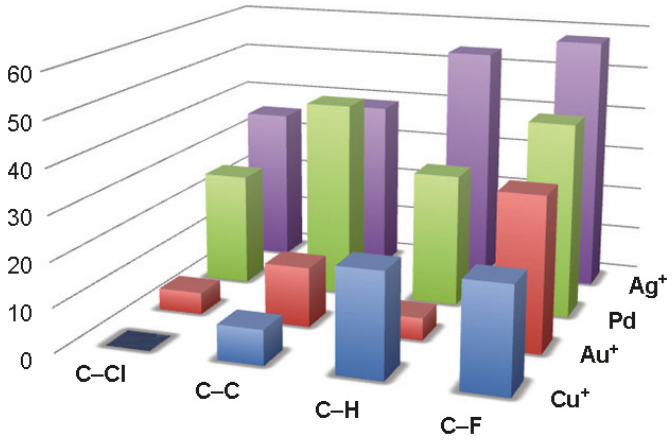


longer and thus closer to situation **C** in the RC, if compared with the C–F and C–C bonds (see Fig. 2).

The ethane C–C bond activation is special in the sense that yet another important mechanism is at work, namely, sterical shielding by the surrounding C–H bonds. Before palladium can achieve direct contact with the C–C bond, the C–H bonds have to be pushed away. This is achieved by C–C bond stretching and, importantly, the well-known tilting of the methyl groups along the reaction path, in particular, in the transition state **2b** (Fig. 2). The most eye-catching effect of this "first making room for the metal" is again a delay in the ΔE_{int} curve (compare blue C–C with black C–H curves in Fig. 8*b*, Pd).

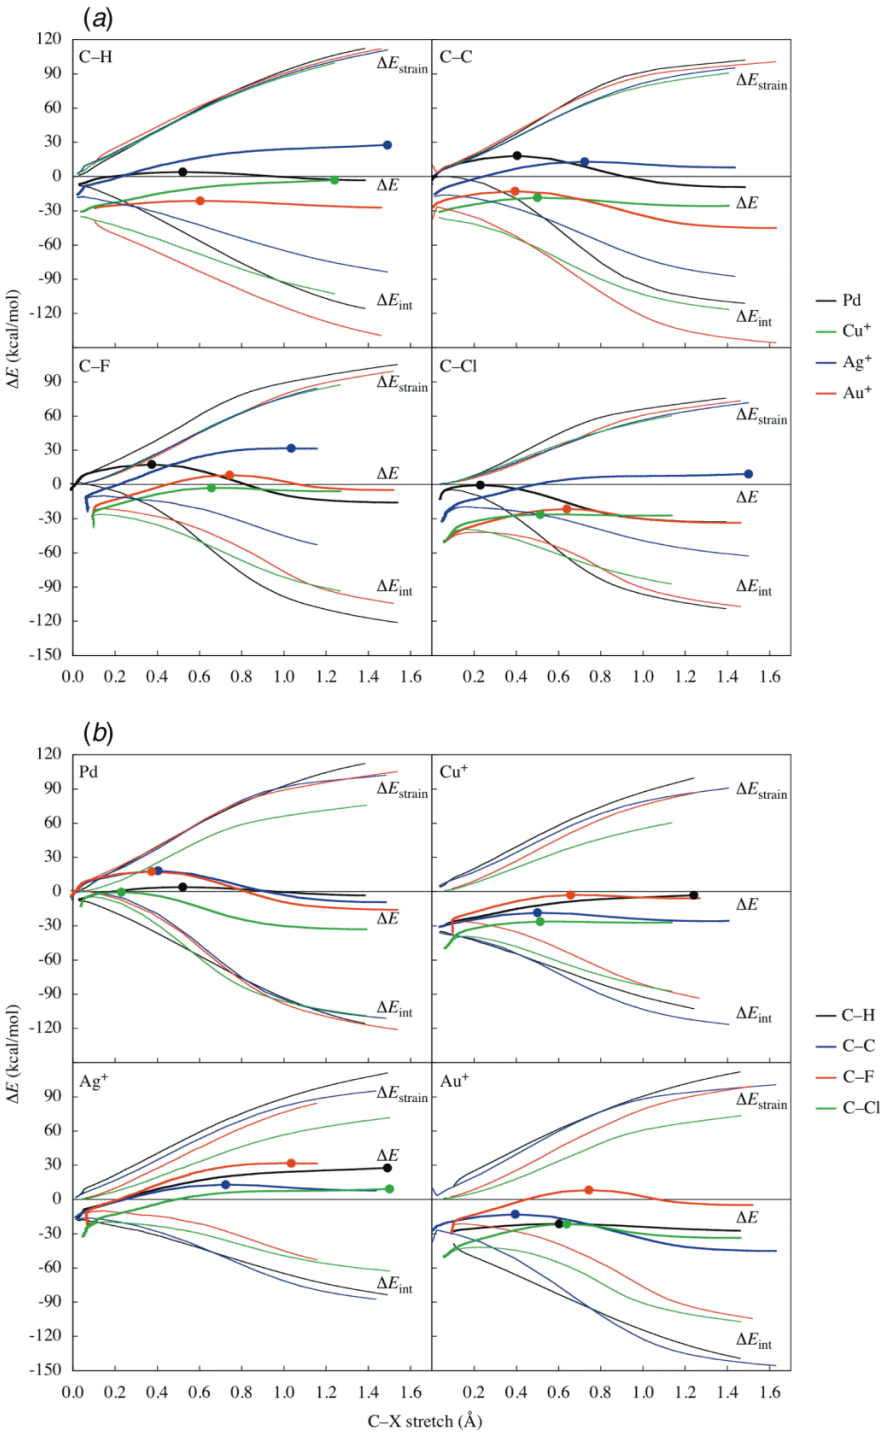
The tilting of the methyl groups in ethane also represents an additional geometrical deformation that is the reason behind the unexpectedly high substrate strain that was mentioned above. Thus, the methyl tilting causes the ΔE_{strain} curve of C–C activation to be raised to the same level as that of C–H, even though the former (BDE = 90 kcal/mol) is 20 kcal mol^{-1} *weaker* than the latter bond (BDE = 110 kcal/mol). Note however that despite the tilting, the strain curve of C–C is not more destabilizing than that of C–H. Therefore, without the delay in interaction between metal and the initially sterically shielded C–C bond, the activation of the latter would not have a higher reaction barrier than C–H bond activation.

Activation strain analyses of reactions with Cu^+, Ag^+, and Au^+

Next, we consider how and why OxIn reactivity changes if the metal species is varied from Pd to the metal cations Cu^+, Ag^+, and Au^+. We begin with the oxidative insertion into the methane C–H bond (see Fig. 8*a*, C–H). Three striking observations can be made if one goes from Pd to the three metal cations: (*i*) the strain curves hardly change; (*ii*) the interaction curves all become more shallow; and (*iii*) as a result, the transition states all shift to a later, more product-like position along the reaction coordinate.

The reason for the more shallow interaction curves is easy to understand. At the beginning of the reaction, to the left in the activation strain plots in Fig. 8*a* (C–H), the transition-metal cations bind more strongly to the substrate than Pd because their low-energy ns AOs are better charge acceptors (see Fig. 6). On the other hand, towards the end of the reaction, at the right in the plots of Fig. 8*a*, (C–H), back-donation from the metal to the substrate σ^*_{C-X} becomes relatively more important. And this is something at which the metal cations are less good, because the low energy of

Fig. 8. Activation strain analysis for oxidative insertion of transition metals M into $H_3C–X$ bonds, along the IRC reaction coordinate ζ projected onto the C–X bond stretch, (*a*) grouped per C–X bond; (*b*) grouped per metal M (dots indicate TS).

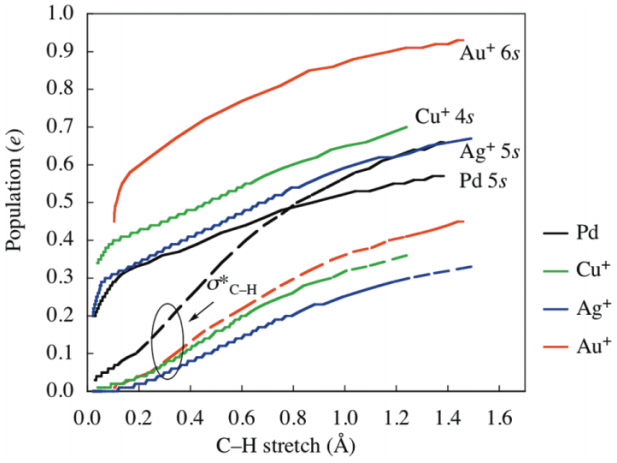


their nd AOs makes them less favorable donor orbitals in donor–acceptor interactions with the substrate $\sigma^*_{C–X}$.

This is nicely illustrated by Fig. 9, which shows the gross populations of the Pd 5s, the Cu^+ 4s, the Ag^+ 5s, and the Au^+ 6s acceptor AOs as well as the methane $\sigma^*_{C–X}$ acceptor orbital. At small C–H stretch, the population in the $\sigma^*_{C–H}$ orbital is small, which corresponds to little back-donation of electronic charge from metal to substrate. The population in the metal ns orbital is larger, which corresponds to a more important contribution of donation of electronic charge from substrate to metal in the interaction energy in the RC. The population in the Pd 5s AO is smaller than in the metal-cation ns AOs. The magnitude of the ns orbital populations decreases in the order Au^+ 6s > Cu^+ 4s > Ag^+ 5s, in line with the corresponding orbital energies that increase in the same order, i.e., –13.2, –12.3, and –11.5 eV (compare Figs. 6 and 9).

As the reaction proceeds, i.e., with increasing C–H stretch, the populations of all fragment LUMOs increase,

Fig. 9. Populations of the transition-metal ns orbital (solid lines: Pd 5s, Cu^+ 4s, Ag^+ 5s, or Au^+ 6s) and the methane substrate σ^*_{C-H} orbital (dashed lines), along the IRC reaction coordinate ζ for oxidative insertion projected onto the C–H bond stretch.



but most importantly the population in the σ^*_{C-H} orbital in the case of Pd insertion increases the most. Thus, back-donation from Pd to methane becomes larger than donation from methane to Pd. This large increase of back-donation is directly connected to the large increase in interaction energy in the case of Pd insertion. And it is the poor capability of the metal cations to back-donate electronic charge into the methane substrate that results in the less-pronounced stabilization of the interaction-energy curve in the corresponding OxIn reactions.

The effect of shifting the TS to the right is illustrated by a generic activation strain diagram in Fig. 10*a*. The additional stabilization at the beginning of the reaction makes the ΔE_{int} curve shallower. Consequently, the transition state, which is the point where $d[\Delta E_{int}(\zeta)]/d\zeta = -d[\Delta E_{strain}(\zeta)]/d\zeta$, is reached at a later stage, i.e., at larger ζ.

Note that the above effect leads to a different result than reinforcing an interaction mechanism that begins to play a role later on along the reaction coordinate, such as strengthening back-donation or diminishing Pauli repulsion (both play a role in situations of advanced C–H stretch and short metal-substrate distances).[12] Such a situation leads consistently to a stabilization and a shift of the TS "to the left", as is illustrated by the generic activation strain diagram in Fig. 10*b*.

Activation strain analyses of M + H_3C – X

There is a striking contrast between the systematic effect that the step from palladium to the metal cations has on the *position* of the TS along the reaction coordinate (nearly always a shift towards the product side) and the seemingly chaotic behavior of the *energy* of the TS, i.e., the overall reaction barrier, which in some cases is reduced whereas in other cases it goes up (see Table 1 and Fig. 8*a*). This is so, not only for OxIn reactions with the C–H bond but also for the other C–X bonds. Only the insertion of Au^+ into the C–C bond has a TS at a similar (in fact, a slightly smaller) elongation of the activated bond compared with the insertion of Pd (see Fig. 8*a*, C–C).

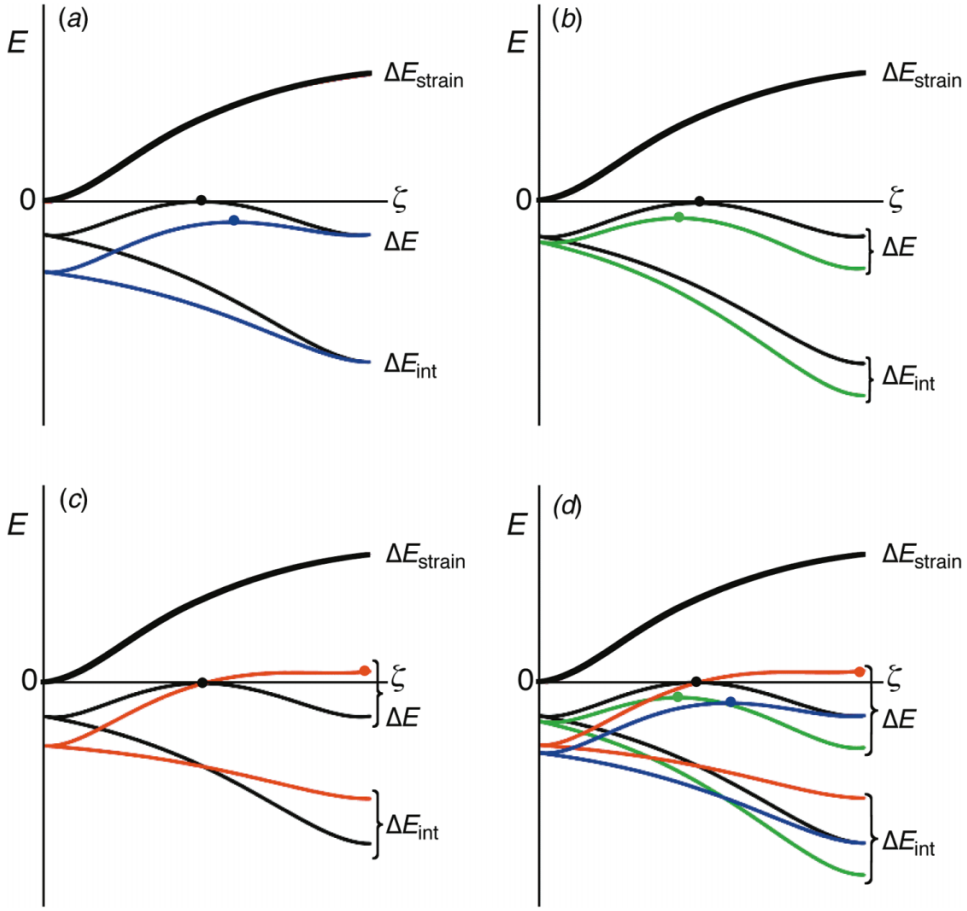
Seemingly chaotic, this behavior has a simple cause that can be easily recognized in terms of the activation strain model. Thus, the stabilization of the interaction curve $\Delta E_{int}(\zeta)$ at the reactant side also causes the net energy curve $\Delta E(\zeta)$ (the reaction profile) to be stabilized at that early stage of the reaction. But, because of the concomitant shift of the TS to the right, the latter occurs at a point at which the strain $\Delta E_{strain}(\zeta)$ is higher. If the shift of the TS to the right is not too pronounced (i.e., if the interaction curve does not become too shallow), the TS occurs at a point at which the additional stabilization of the interaction curve at the reactant side still outweighs the "shift-induced" increase in strain. Such a situation leads to a reduction of the barrier height as observed, for example, for the reactions of $Cu^+ + CH_4$ and C_2H_6. This is the situation that is schematically illustrated by the idealized activation strain diagram in Fig. 10*a*.

However, the shift of the TS to the right can also become so pronounced (i.e., if the interaction curve does become very shallow) that the TS, in a sense, merges into the product, which makes both of them disappear as stable stationary points. Such a situation leads to a high effective barrier, as observed for example, for the reactions of $Ag^+ + CH_4$ and CH_3Cl (see Fig. 8*b*, Ag^+). This situation is schematically illustrated by the idealized activation strain diagram in Fig. 10*c*.

Finally, we return to the strain curves which, as we already noticed, vary much less than the interaction curves if one changes the metal species (see Fig. 8*a*). This is because the dominant factor that determines the strain curves is the strength of the activated C–X bond. Nevertheless, the metal species also has a certain indirect, more subtle effect on the precise shape of the strain curve, as the exact geometrical deformation of the substrate depends also on the metal–substrate interaction. We wish to point out the two most prominent effects: (*i*) methyl-group tilting and (*ii*) methyl-group pyramidalization. The methyl groups, in particular in ethane, have to tilt away to make room for the approaching Pd atom, as discussed earlier (sub-section on activation strain analyses of reactions with Pd). This causes the C–C strain curve to be higher than one would expect on the basis of the C–C bond strength, namely, always close to the strain curve of the stronger C–H bond. This phenomenon is encountered also for the metal cations Cu^+, Ag^+, and Au^+, as can be seen in Fig. 8*b*.

Furthermore, as the metal cations are poor back-donation agents (vide supra), their OxIn reactions proceed with reduced charge transfer to the substrate compared with the reactions of palladium. In particular in the reactions with CH_3F and CH_3Cl, in which most of the back-donated charge goes into the halogen, this leads to methyl moieties with lower effective electron populations and thus less pyramidalization.[23] For example, the H-C-H angle in the OxIn product of M + CH_3F increases from 112.7° for Pd (see **3c** in Fig. 2) to 117.3°, 118.6°, and 116.2° for Cu^+, Ag^+, and Au^+ (see **7c**, **11c**, and **15c** in Figs. 3, 4, and 5, respectively). The relatively planar configuration of the methyl moieties in the reactions of the metal cations resembles more closely the intrinsic behavior of dissociating CH_3X. Furthermore, the partially positively charged methyl moiety tends to orient somewhat more towards the partially negatively charged

Fig. 10. Generic activation strain diagrams for qualitatively illustrating the effect on the black OxIn reaction profile ΔE of (*a*) stabilizing the ΔE_{int} curve at the reactant side, blue curves; (*b*) stabilizing the ΔE_{int} curve at the product side, green curves; (*c*) stabilizing the ΔE_{int} curve at the reactant side and destabilizing it at the product side, red curves. In (*d*) the four situations are combined, with black curves for the reference situation. Note that the ΔE_{strain} curves are identical in *a*–*d*, corresponding to a variation of the metal species inserting into one and the same model substrate.



halogen, which corresponds to less tilting (compare Figs. 2–5). Together, these effects translate into a lowering of the corresponding strain curves for the reactions of the metal cations with fluoromethane and chloromethane compared with those with palladium (see Fig. 8*a*, C–F and C–Cl).

Conclusions

We have computationally explored C–X bond activation by the group-11 transition-metal cations Cu^+, Ag^+, and Au^+, and, for comparison, Pd, using relativistic density functional theory (DFT) at ZORA-BLYP/TZ2P. The main trends in reactivity are rationalized using the activation strain model in which the shape of the reaction profile $\Delta E(\zeta)$ and the height of the overall reaction barrier $\Delta E^{\neq} = \Delta E(\zeta{=}\zeta^{TS})$ is interpreted in terms of the strain energy $\Delta E_{strain}(\zeta)$ associated with deforming the reactants along the reaction coordinate ζ plus the interaction energy $\Delta E_{int}(\zeta)$ between these deformed reactants: $\Delta E(\zeta) = \Delta E_{strain}(\zeta) + \Delta E_{int}(\zeta)$.[12,16]

Oxidative insertion of the second-row transition-metal species Ag^+ and Pd leads, for a given bond, to the highest overall reaction barriers. On the other hand, if we compare the different bonds, oxidative insertion into the C–F bond is associated with (one of the) highest overall barriers, whereas insertion into the C–Cl bond leads for any transition metal to the lowest overall barrier.

It is tempting, but incorrect, to attribute the similar barrier heights for Ag^+ and Pd to a presumed similarity in the metal–substrate interaction of these isolelectronic second-row transition metal species. In fact, the difference in net charge translates into completely different bonding capabilities of the three metal cations on one hand and the neutral palladium on the other hand. The former have more shallow interaction curves (because of favorable substrate → metal ns donation in early stages of the reaction and reduced metal → substrate back-donation from the (n – 1)d AOs at later stages of the reaction), which causes the transition state (TS) to shift towards the product side where the strain curves are more destabilizing. The final position along the reaction coordinate depends in a subtle manner on the shape and balance between $\Delta E_{strain}(\zeta)$ and $\Delta E_{int}(\zeta)$ and may yield a stabilized (Cu^+, Au^+) but also a destabilized TS, as in the case of Ag^+. On the other hand, the low barrier for C–Cl activation originates straightforwardly from the low bond strength of this bond and thus the low strain curves along the reaction coordinate.

The above insights can, in principle, be used to more rationally design catalytically active and selective metal complexes, for example, by amplifying or attenuating the metal–substrate interaction in an early or late stage along the reaction coordinate. However, we stress once more that the precise point of balance between strain and interaction curves depends delicately on their exact shape. A quantitative verification of the activity of such a qualitatively designed catalyst is therefore still required.

Structure and stability of aquotetrafluorouranyl(VI) in the solid state — Density functional study of $[UO_2F_4(H_2O)][NMe_4]_2 \cdot 2H_2O$[1,2]

Michael Bühl

Abstract: Periodic density functional computations have been performed for solid $[UO_2F_4(H_2O)][NMe_4]_2 \cdot 2H_2O$ at the BLYP level. A model with disordered fluoro and aquo ligands in the uranyl anion is significantly lower in energy than one with a symmetrical assignment of these sites, which was favored in the original X-ray crystallography study. According to optimized energies and Car–Parrinello molecular dynamics (CPMD) simulations, the $[UO_2F_4(H_2O)]^{2-}$ ion in the solid is stable with respect to loss of the coordinated water molecule. In contrast, CPMD simulations had found this ligand to be unbound in aqueous solution. The role of the counterions in stabilizing the higher coordination number in the crystal is discussed.

Key words: uranyl complexes, density functional computations, molecular dynamics, simulations, counterion effects.

Résumé : Opérant au niveau BLYP, on a effectué des calculs de fonctionnelle de la densité périodique sur le solide $[UO_2F_4(H_2O)][NMe_4] \cdot 2H_2O$. L'énergie d'un modèle comportant des ligands fluoro et aquo dans l'anion uranyle est beaucoup plus faible que celle d'un modèle comportant une attribution symétrique de ces sites qui était favorisé dans l'étude originale par diffraction des rayons X. Sur la base d'énergies optimisées et de simulations de dynamique moléculaire Car-Parrinello (DMPC), l'ion $[UO_2F_4(H_2O)]^{2-}$ à l'état solide est stable par rapport à la perte de la molécule d'eau coordonnée. Par opposition, des simulations DMPC avaient suggéré que ce ligand se détache en solution aqueuse. On discute le rôle des contre-ions dans la stabilisation du nombre de coordination plus élevé dans le cristal.

Mots-clés : complexes d'uranyle, calculs de la fonctionnelle de densité, dynamique moléculaire, simulations, effets des contre-ions.

[Traduit par la Rédaction]

Introduction

Approximate density functional theory (DFT) has fertilized computational transition-metal chemistry tremendously,[3] especially since relativistic methods have been implemented that allow the proper treatment of heavy metals.[4] Complexes of the heaviest metals, actinides, have been early challenging targets for DFT[5,6] and are important benchmarks for calculations of spectroscopic properties such as NMR parameters.[7] DFT-based molecular dynamics simulations, long established as powerful tools to study elementary reaction steps at transition-metal centers,[8,9] are now also being applied to actinide chemistry.[10–13]

We have been applying Car–Parrinello molecular dynamics (CPMD) simulations to study structure,[11,12] speciation,[14] reactivities,[15] and NMR chemical shifts of uranyl(VI) complexes in aqueous solution. A protocol based on constrained CPMD and pointwise thermodynamic integration (PTI) has been shown to capture salient structural and energetic features reasonably well. With the possibility of evaluating changes in free energies under realistic conditions (i.e., taking temperature and solvation effects explicitly into account), this approach often surpasses static quantum-chemical computations with simpler solvation models. For instance, the acidity constant[16] and ligand-exchange barrier[15] in uranyl hydrate, $[UO_2(H_2O)_5]^{2+}$, as well as the free binding energies between the latter and ligands such as nitrate,[14] chloride,[17] and fluoride[18] have all been reproduced within ca. ±2.5 kcal/mol (1 cal = 4.184 J) of experiment, a rather respectable accuracy for present-day DFT.

In our recent study on mixed aquo fluoro uranyl species,[18] an apparent inconsistency between DFT and experiment was noted for the tetrafluoro complex. In two salts with organic counterions, this anion had been characterized as $[UO_2F_4(H_2O)]^{2-}$ (**1a**) by X-ray crystallography,[19,20] and evidence for its presence in aqueous solution had been given by EXAFS.[21] In CPMD simulations of pristine **1a**, in contrast, the water ligand turned out to be unbound both in gaseous and aqueous phases, where it spontaneously detaches, affording four-coordinate $[UO_2F_4]^{2-}$ (**1b**).[18] Employing the PTI technique and the U–O(water) distance as reaction coordinate, a shallow minimum corresponding to **1a** was found in water, but the driving force for dissociation of the aqua ligand from **1a** into the bulk was indicated to be substantial, $\Delta A = -7.2 \pm 1.5$ kcal/mol (1 cal = 4.184 J). Even when allowing for the general tendency of DFT to underestimate metal–ligand bond strengths,[22,23] this result appeared to be at odds with the observation of **1a** in the EXAFS experiment. No experimental value for this dissociation energy is

known, but the EXAFS data furnished strong evidence for the presence of two shells in the equatorial plane of the tetrafluoride, corresponding to F and O atoms. Because it was difficult to refine the precise number of coordinated water ligands, in the adopted model this number was fixed to one (as observed in the solid),[21] implying rather strong binding of water (with a positive free energy for dissociation, and, possibly, zero as its lower limit[24]).

The BLYP density functional was used in the simulations. Rather well suited to describing the properties of liquid water and aqueous solutions,[25,26] it is not the first choice for geometries of transition-metal complexes in general.[27] BLYP is a typical member of the GGA family, i.e., pure, gradient-corrected functionals, which are sometimes outperformed by hybrid variants when it comes to reaction energies involving actinides.[28] As mentioned above, in the CPMD–PTI studies of aqueous uranyl complexes BLYP has performed quite well so far, but if it turns out to fail for the aquo tetrafluoro complex, the predictive power of this approach may be at stake. An utter failure would for instance be the incorrect prediction that **1a** should also be unstable in the environment of a known, stable crystal. In the present paper, initial investigations to that effect are reported, including, to the best of my knowledge, the first CPMD simulations of a uranyl complex in the solid state.

Of the two solids containing **1a**, $[UO_2F_4(H_2O)][NMe_4]_2{\cdot}2H_2O$ (**2**)[20] was chosen as the target, because it has the smaller unit cell. In addition, an ambiguity in the assignment of the atomic positions had been noted during analysis of the crystal structure, which will be addressed as well.

Computational details

All computations used the CPMD program[29] and the same settings as in the previous gas-phase and solution studies (BLYP functional,[30,31] Troullier–Martins pseudopotentials,[32,33] 80Ry plane-wave cutoff). The heavy-atom coordinates as deposited in the Cambridge Structure Database (refcode DAPWUM)[20] were used as the starting point. A simple orthorhombic cell with lattice constants fixed to the experimental values (a = 7.006 Å, b = 8.938 Å, c = 13.619 Å) and two formula units in the unit cell were used (affording a total of 100 atoms). Unfortunately, the current version of the CPMD program does not allow optimization of lattice constants for systems containing f-electrons. Hydrogen atoms were placed on the water oxygen atoms (pointing toward potential H-bond acceptors, but otherwise arbitrarily) and their positions relaxed both at the Γ-point and using 2, 2, and 1 k-points along the reciprocal a, b, and c axes, respectively.[34] Attempts to use more k-points resulted in severe convergence problems or, where wave functions could be converged, in relatively minor changes in total energies. Unless otherwise noted, results from the 2 × 2 × 1 k-point calculations are discussed in the following section. CPMD simulations were performed at the Γ-point, however (see discussion below), using a fictitious electronic mass of 600 au, a time step of 0.121 fs, and the deuterium mass for H atoms. Starting from the Γ-point optimized coordinates, the system was equilibrated for 0.5 ps, during which a temperature of 320 ± 50 K was maintained via velocity rescaling, and then propagated for 3 ps without constraints in the NVE ensemble. For population analysis, the orbitals represented in plane waves were projected onto suitable atomic orbitals, which were taken from the pseudo wave functions involved in construction of the pseudopotentials, except for hydrogen where a standard Slater function was used.[35]

Results and discussion

In the refinements of the X-ray data of **2**, an ambiguity concerning the location of F and O atoms was noted, and the simplest model had been adopted (denoted Model 1 here), in which an O atom of the coordinated water ligand (O2 in Fig. 1) resides on a symmetry plane.[20] Because the resulting U–O2 distance would be exceptionally short, however, this assignment was later questioned[21] and it was suggested that this O2 position would rather be occupied by an F atom, and that the O atom would be disordered over the F1 and F1^a sites, a possibility that was already mentioned in the X-ray study. This alternative assignment would be more consistent with the rather long bond distances between uranium and the F1 and F1^a sites. A corresponding model (denoted Model 2) was constructed by exchanging F and O in the F1^a and O2 sites in both uranyl moieties of the unit cell.

After relaxation of the H positions, Model 2 is lower in energy than Model 1 by ca. 125 kcal/mol; after full optimization (with fixed lattice constants), it is still favored by 13.4 kcal/mol. This result is thus in complete accord with the suggested revision of the atomic positions in the crystal and the concomitant disorder.[36]

In the following, only results for Model 2 will be discussed. Figure 2 shows perspective drawings of solid **2** after H-relaxation (top) and full optimization (bottom). To illustrate the packing more clearly, 8-fold unit cells with doubled lattice constants are displayed. The most notable change upon full optimization is that the O atoms of the two crystal water molecules move somewhat above and below the equatorial uranyl plane (which is a plane of symmetry in the point group of the crystal), and that the uranyl fluoride moieties rotate somewhat about the O=U=O axis. This can be seen in Fig. 3, an overlay of X-ray and optimized coordinates (both sets of coordinates are supplied in the Supplementary data for 3D visualization).

These changes could to some extent be due to the initial choice of the location of the H atoms, which would induce a bias for a particular H-bond pattern. An exhaustive search of all possible such patterns would be very involved and was not conducted at this point. It is rather noted that the overall features of the observed solid-state structure are reasonably well preserved in the DFT-optimized crystal, in particular if one allows for disorder in the former. Observed and correspondingly averaged computed bond distances are found to be in good accord, except for the U–F(O2) distance, the experimental value of which appears to be rather short also for an U–F bond (compare Expt. and CP-opt values in italics in Table 1).

In CPMD simulations of a single $[UO_2F_4(H_2O)]^{2-}$ anion, both in gaseous and aqueous phases, the water ligand has detached spontaneously from the complex.[18] To test if the same would happen in the crystal, CPMD simulations were performed for solid **2**. Unfortunately, CPMD simulations are not possible using k-point integration. The usual procedure

Fig. 1. Labeling of atoms in the original X-ray crystallography study (reference [20]; W denotes O atoms of crystal water).

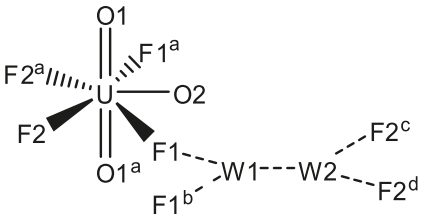

Fig. 2. Stereoviews of the solid after H-relaxation (top) and full optimization (bottom), showing 8 unit cells (over doubled lattice parameters).

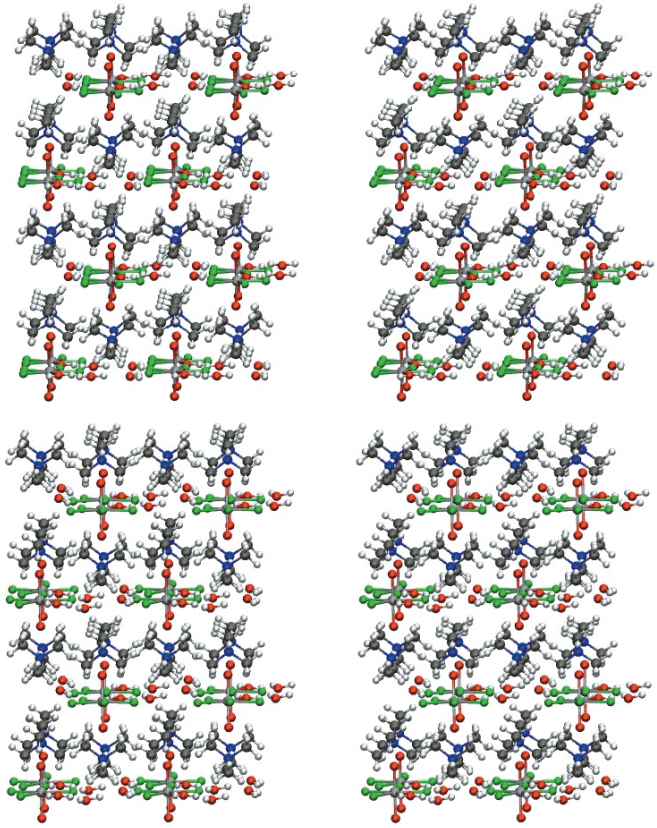

is to use supercells large enough that calculations at the Γ-point are sufficient. In the present case, this would mean that the lattice constants *a* and *b* would have to be doubled, which would render the simulations rather expensive. On the other hand, the structural parameters of the uranyl complex are very similar whether the solid is optimized using k-points or at the Γ-point only (compare CP-opt and Γ-opt entries in Table 1). It is thus to be expected that the artifacts of just using the Γ-point would not be too severe. In fact, if anything, neglect of the k-points appears to weaken the U–O(water) interaction, as evidenced by the increase of the U–O(F1[a]) distance on going from the CP-opt to the Γ-opt value (by 0.02 Å, Table 1). CPMD simulations were therefore performed at the Γ-point for the regular unit cell, bearing in mind that this procedure might artificially weaken the binding of the water ligands. Nonetheless, the five-coordinated uranyl complexes remain stable during a total simulation time of 3.5 ps (including equilibration) at a mean temperature of 314 K. Except for the U–O(water) distance, which increases noticeably by 0.04 Å, only minor changes are found on going from equilibrium to thermal-averaged bond distances (compare Γ-opt and CPMD values in Table 1).

Table 1. Observed and simulated uranium-ligand distances in the uranyl aquo fluoro anion **1a** [in Å]. For labeling see Fig. S1, with F(O2) and O(F1[a]) indicating the atoms that have been switched in model 2.

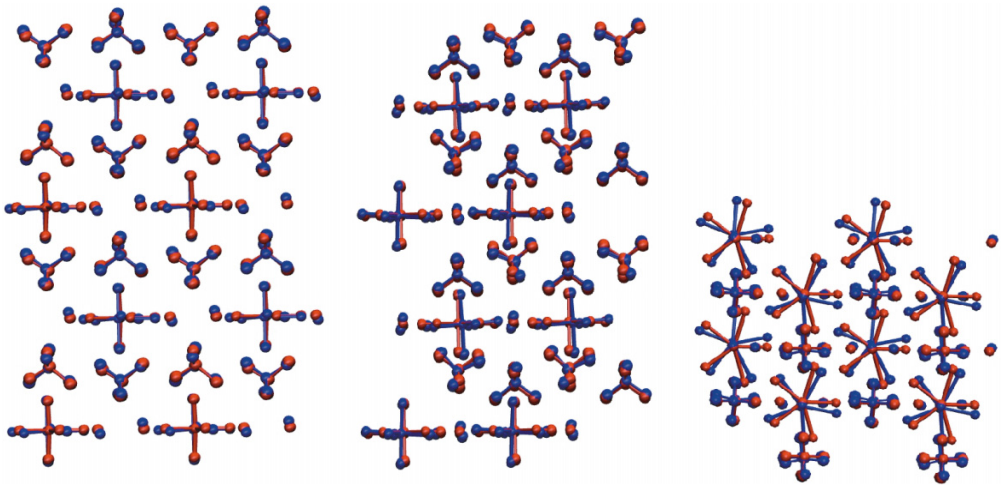
[b]Using Γ-point integration only (see Computational details).

[c]Mean values (in parentheses: standard deviations) over 3 ps of unconstrained MD.

Of course, the apparent stability of five-coordination in the solid during the CPMD simulations might just be caused by the confines of the fixed unit cell. To estimate how strongly the aquo ligand would be bound in the solid, a coordinated water molecule was removed from one of the optimized uranyl complexes in the unit cell (the other complex retaining five-coordination). The combined total energies of the fragments, i.e., that of the unit cell without one water and that of the water molecule in the same empty box, is 23.2 kcal/mol above that of the full, optimized solid (k-point results). Upon relaxation of these fragments, in the course of which the four-coordinated $[UO_2F_4]^{2-}$ moiety with its vacant coordination site optimizes to the usual approximately square-bipyramidal conformation of **1b**, this energy difference reduces to 7.9 kcal/mol. Thus, a substantial binding energy is indicated for the water ligand in the solid. Because the lattice constants were fixed throughout, this value is only to be used as a rough guide. It is quite possible that the "dehydrated" crystal would have a slightly smaller unit cell than the intact one or, more likely, that it would adopt a different, more stable morphology altogether. In particular, the latter question is impossible to address at present because the sheer size of the system precludes a true ab initio prediction of its crystal structure.

In any event, the estimated water dissociation energy of ca. +8 kcal/mol within the constraints of the solid is noteworthy, as it contrasts with the results obtained for free **1a** in the gas phase or in solution, where the water ligand is indicated to be unbound, with a computed dissociation energy of ca. –7 kcal/mol (ΔE at the BLYP/SDD(+)/PCM level or ΔA from constrained CPMD and PTI).[37] To shed more light on the possible reasons for the apparent stabilization of $[UO_2F_4(H_2O)]^{2-}$ in the solid,[38] a single such anion was retained in the fully optimized crystal and all other atoms deleted. The resulting slabs of $[UO_2F_4(H_2O)]^{2-}$ moieties approaching each other with their equatorial ligands are

Fig. 3. Overlay of X-ray derived (red) and optimized (blue) positions of the non-hydrogen atoms, viewed along the *a*-, *b*-, and *c*-axes (from left to right).



highly unphysical because of the strong Coulomb repulsion between them, but are an instructive model for comparison with the estimated water binding energy discussed above for the full crystal. When this "pristine" $[UO_2F_4(H_2O)]^{2-}$ moiety is further separated into $[UO_2F_4]^{2-}$ and H_2O fragments (again with the same unrelaxed structures in the otherwise empty cell), the combined energies of these fragments are 9.7 kcal/mol above that of the $[UO_2F_4(H_2O)]^{2-}$ slabs. When the fragments are relaxed, their combined energies drop below that of the complex (in its structure adopted in the full crystal), namely to –12.8 kcal/mol. In other words, it costs more energy (ca. 13 kcal/mol) to distort the separated fragments, **1b** and water, into the structures they adopt in the complex than is released upon binding between these distorted fragments (ca. –10 kcal/mol). Without the counterions (and the crystal water), the water ligand in **1a** is thus indicated to be unbound. Apparently, the interactions with the counterions are instrumental to the stability of **1a** in the solid, where each of these complexes is surrounded by eight NMe_4^+ ions (forming two "crowns" above and below the equatorial plane, see Fig. 2).

To assess the effect of this polar environment on the overall charge distribution, Mulliken population analysis was performed for the whole crystal and for the periodic $[UO_2F_4(H_2O)]^{2-}$ slabs cut out therefrom. The results are summarized in Table 2. While the absolute numbers should not be over-interpreted,[39] the general trend is interesting: When the neighbors around **1a** are removed, the overall charge density on the UO_2F_4 unit increases significantly, i.e., this fragment becomes more negative (by more than a fourth electronic charge unit, see last entry in Table 2). This additional negative charge is shared roughly equally between terminal oxo and equatorial fluoride ligands, but the U atom also becomes slightly less positive. Apparently, this increased negative charge makes the uranyl moiety less electrophilic toward the fifth water ligand, consistent with the computed drop in dissociation energy of the latter (from ca. 23 kcal/mol to 10 kcal/mol using the unrelaxed fragments, see above). Similarly, the Mayer bond orders between U and the water O atom decrease from 0.19 in the full crystal **2** to 0.15 in the slabs of **1a**.

Table 2. Mulliken charges in the uranyl aquo fluoro anion **1a**.

Atoms	Full crystal (**2**)	only **1a**[a]
U	2.32	2.29
$O(H_2O)$	–0.90	–0.90
F (mean)	–0.64	–0.67
O(uranyl)	–0.63	–0.69
$\Sigma\ UO_2F_4$[b]	–1.48	–1.75

[b] Total charge of this fragment.

Apparently, when pristine **1a** is immersed in water, the environment is not polar enough to increase the electrophilic character of the uranyl center to the same extent as the counterions do in the crystal. At this point it is tempting to speculate if counterions in solution, which were not included in the CPMD simulations so far, could be more efficient in that respect. In the EXAFS experiments, a considerable excess of NaF (ca. 9-fold) had been used to produce solutions that contain **1a** as major uranyl component.[21] It is possible that the notable concentration of Na^+ ions about **1a** in water (or the increased ionic strength) could result in an increased affinity between the tetrafluoro uranyl complex and the water ligand, which could eventually help to reconcile the apparent discrepancy between the DFT and EXAFS results. More work should be directed toward this question.

Conclusion

According to periodic DFT/BLYP computations for solid $[UO_2F_4(H_2O)][NMe_4]_2{\cdot}2H_2O$, a model with disordered fluoro and aquo ligands in the uranyl anion is significantly lower in energy than the originally adopted symmetrical assignment of these sites. This result supports the proposed revision of this structural detail that was based on a critical analysis of the refined bond distances. Thus, DFT computa-

tions akin to those presented here can be helpful in X-ray crystallography of uranyl complexes, when, as in the present case, competing structural models cannot be proved or disproved based on the diffraction data alone.

In these static model computations and in dynamic (CPMD) simulations, the water ligand in the $[UO_2F_4(H_2O)]^{2-}$ anion (**1a**) is indicated to be bound. There is no evidence that the DFT-based approach employed, including the BLYP functional, would fail utterly for **1a** in the sense that it would incorrectly predict an unbound water ligand in the solid state. This finding therefore does not invalidate our previous results for gaseous and aqueous phases, according to which the free tetrafluoride does not bind this fifth water ligand and should be formulated as four-coordinated $[UO_2F_4]^{2-}$ (**1b**), in apparent contrast to EXAFS experiments, which favor the formulation as five-coordinated **1a** in solution. Computational evidence has been presented suggesting that it is the crystal environment that stabilizes the higher coordination number in the solid. Studies are underway to explore if counterions in the aqueous solution, so far neglected in the simulations, could also increase the propensity of free **1b** to bind an additional water ligand, which would help to resolve the apparent discrepancy between theory and experiment on the structure of uranyl tetrafluoride in water.

(34) k-Points are special integration points used to sample the first Brillouin zone in reciprocal space. When the unit cell is large enough, that zone is small and integration using just its center (the Γ-point) is sufficient.
(35) We note in passing that this type of Mulliken population analysis in a plane-wave basis is plagued by an incomplete partitioning of the total electron density onto the atomic pseudo-orbitals. The total amount of this "unassigned charge" is on the order of ca. 1% of the total number of

electrons (similar to findings in other ionic solids, see for example, Haiber, M.; Parrinello, M. *Am. Mineral.* **1997**, *82*, 913), which is most probably contained in regions of a more diffuse density shared by all atoms.

(36) To model the actual disorder, larger supercells with a 50:50 distribution of water molecules over the F1 and F1a sites would have to be employed. This was not pursued, because the concomitant effect on structural parameters and energies are expected to be too small to affect the qualitative conclusions.

(37) According to the relative energies at the SDD(+)–PCM level, water dissociation from **1a** is less endothermic with B3LYP than with the BLYP functional, but only by 2 kcal/mol (Table 3 in ref. 16).

(38) Quantitatively, a "water sublimation energy" from the crystal of ca. 8 kcal/mol (which should be close to the corresponding enthalpy of sublimation) does not indicate a particularly high stability, as it is slightly smaller than the enthalpy of desolvation of a single water molecule from the bulk liquid, 10.0 kcal/mol at 25 °C (cf. Ben-Naim, A.; Marcus, Y. J. *Chem. Phys.* **1984**, *81*, 2016).

Theoretical investigation of CO adsorption on Rh_n (n = 3–13) clusters[1]

Sharan Shetty, Sebastian Strych, A.P.J. Jansen, and Rutger A. van Santen

Abstract: The adsorption of CO onto Rh_n (n = 3–13) clusters has been investigated using the density functional approach. Stable active sites for CO adsorption such as top, bridge, and hollow have been identified on these clusters. Our results show that CO mostly prefers the bridge or top site, except on the Rh_4 and Rh_{11} clusters where it prefers hollow sites. Rh_6 demonstrates two different active sites of almost equal energies for CO adsorption. Highly stable clusters show weak CO adsorption behavior. We also observe that the magnetic moment of the clusters is usually reduced after the CO adsorption. The preference of the active sites for CO adsorption has been analyzed using the charge density difference plots.

Key words: rhodium, clusters, carbon monoxide, adsorption, catalysis.

Résumé : Faisant appel à l'approche de la fonctionnelle de la densité, on a étudié l'adsorption du CO sur le Rh_n (n =3 à 13). On a identifié les sites actifs stables pour l'adsorption du CO sur ces agrégats, tels les sommets, les ponts et les trous. Nos résultats montrent que le CO s'adsorbe préférentiellement sur les ponts ou les sommets, à l'exception des agrégats Rh_4 et du Rh_{11} dans lesquels les trous sont privilégiés. Dans le Rh_6, il existe deux sites actifs différents d'énergies pratiquement égales pour l'adsorption du CO. Les agrégats très stables présentent des comportements d'adsorption faibles. On a aussi observé que le moment magnétique des agrégats est considérablement réduit après l'adsorption du CO. On a analysé la préférence des sites actifs pour l'adsorption du CO en faisant appel à des courbes de différence de densité de charge.

Mots-clés : rhodium, agrégats, monoxyde de carbone, adsorption, catalyse.

[Traduit par la Rédaction]

Introduction

CO dissociation on transition metal surfaces is considered to be the initial step for several important catalytic reactions.[2–4] This has led to a fundamental understanding of the catalytic reactivity of several transition metal surfaces. One of the important reactions is the Fischer–Tropsch (F–T) synthesis where the initial step is the dissociation of the adsorbed CO molecule on the surface.[5,6] Later reactions involve the synthesis of alcohols, ketones, etc.[3] The formation of these hydrocarbons depends on the activation of the CO molecule on the surface. The factors that decide chemisorption interactions are the unsaturation of the surface atoms, the coordination of the C–O bond, the electronic effect, and the change in the C–O bond energy.[7] The weakening of the C–O bond due to the adsorption at the low coordinated metal atoms was originally explained through the bonding and back-bonding concept proposed by Blyholder.[8] In contrast to this, Bagus et al. proposed that the CO adsorption on metals such as Na, Mg, and Al is through backdonation and σ repulsion between the filled 5σ orbital (HOMO) of CO and filled states at the metal center.[9] This was also confirmed on the transition metal clusters such as Ni, Cu, Ru, Rh, Pd, Ag, Ir, Pt, and Au using the density functional approach.[10] They showed that an increase of the d-shell occupancy and the principal quantum number cause an increase in the vibrational frequency of CO. Föhlisch et al. showed that the weakening of the CO bond on the metal surface is due to the rehybridization of the 1π and 2π* orbitals.[11] The weakening of the C–O bond is also correlated to the decrease in the C–O stretching frequency.[12] Several experimental and theoretical studies have been carried out to examine the reactivity of the metal surfaces towards CO adsorption.[7,12,13] These studies reveal that some transition metals such as Pt, Pd, and Rh have low reactivity for CO adsorption, wherease other transition metals such as Fe, Co, and Ru have the ability to adsorb CO strongly. Recent studies mainly focus on the reactivity of the metal surfaces having low coordinated atoms, such as the steps, kinks, or open surfaces. Recently Mongeot et al. showed that CO dissociation takes place on the faceted Rh(110) surface, which was not possible otherwise.[14] Ciobica and van Santen showed that the CO dissociation on the stepped Ru(1015) surface requires 130 kJ/mol less energy than on the flat Ru(0001) surface.[15] This was also confirmed by the experimental study by Zubkov et al.[16] Recently, Ge and Neurock have shown that the barrier required for CO dissociation on Co steps is less than on the flat Co(0001) surface.[17]

Correlation between the adsorption of CO and the coordination of the metal atoms on the surface has recently raised the possibility of using small metal particles for catalytic

purposes.[18] Xiao et al. observed aqueous phase F–T synthesis on small Ru clusters with dimensions of 2.0 to 2.5 nm.[19] The same synthesis was also carried out on Co clusters supported on carbon nanotubes.[20] Finely dispersed Au nanoparticles have been shown to be highly active in CO oxidation, H oxidation, and alkene epoxidation.[21] Izumi amd Iwasawa experimentally showed that the flexibility of small Ru and Rh clusters is crucial for the adsorption of CO molecules.[22] These studies reveal that there is a strong relationship between the size of the particle and its activity for a certain reaction. As a consequence, the activity of the reaction on small particles goes through a maximum as a function of particle size.[7]

Recent developments in experimental techniques have made it possible to study the adsorption of CO and NO molecules on small transition metal clusters consisting of less than 13 atoms. Knickelbein has used molecular beam deflection for analyzing the influence of the adsorbate on the magnetic moments of the Ni clusters.[23] This study showed that the adsorption of CO and H quench the magnetization on the Ni clusters. Anderson et al. studied the decomposition of NO on Rh_n ($n \leq 13$) charged clusters using cyclotron resonance mass spectrometry.[24] Their results revealed the size-dependent effect of the Rh clusters on N_2 formation. Hanmura et al. showed that NO reacts strongly with Co cations in the presence of H.[25] Andersson et al. have demonstrated the dissociation of CO on Rh clusters deposited on alumina substrates.[26] They showed that the CO dissociation highly depends on the structure of the adsorption site. Weber et al.. experimentally showed that Ir_4 and Rh_6 clusters supported in NaY zeolite have high catalytic activity.[27] Vayssilov et al. have studied the role of the Rh_6 cluster in the hydrogen spillover in zeolite.[28,29] There are several theoretical studies on CO adsorption on small Rh clusters. However, these studies were restricted to small clusters of two to five Rh atoms.[30,31] Guillermina and Zerner have investigated the bonding of CO on linear and two dimensional Rh clusters.[32] They showed that the CO binds to sites such as top and bridge through donation and back-donation. Nayak et al. studied the influence of the H-bonding on the magnetic and structural effects of Rh clusters.[33] A similar study was also made by Kumar and Kawazoe on Pd, Rh, and Ru clusters.[34] The other theoretical studies have mostly focused on the structural and magnetic properties of the bare Rh clusters.[35] These studies indicate that the structural, magnetic, and electronic properties of small transition metal clusters such as Pd, Rh, Ni, and Ru can influence the catalytic activity.

The present theoretical study follows a recent experimental work on the adsorption of CO on Rh_n clusters. The experimental work was carried out using IR multiple photon dissociation spectroscopy by Fielicke et al.[36] They analyzed the active sites for the adsorption of CO on the Rh clusters on the basis of the stretching frequency of C–O. Their study demonstrated that the CO binds to more than one Rh atom on clusters with $n \leq 4$ atoms such as the bridge and hollow sites. This was also supported by density functional calculations. The theoretical study was only confined to CO adsorption on Rh_3 and Rh_4. The clusters with more than five atoms exhibit either top or bridge sites. Moreover, other experimental studies have also explained the catalytic activity of the Rh clusters for CO adsorption on supported alumina.[37] Several issues still remain unanswered as mentioned in the experimental work: (1) Does a single cluster exhibit two or more adsorbing sites for CO? (2) Why do some of the sites show strong adsorbing behavior compared to others? (3) Is the magnetic moment suppressed after the CO adsorption? (4) How does the bonding of CO take place on these clusters? (5) Does strong adsorption of CO imply a dissociation? These issues will be investigated in the present theoretical work.

Computational details

The calculations were performed using a density functional approach with a plane wave basis set in conjunction with ultra-soft pseudopotential as implemented in the VASP code.[38] We made spin polarized calculations using generalized gradient approximation (GGA) with the PW-91 functional for the exchange correlation.[39] The bare and the CO-adsorbed Rh clusters were placed in a cubic supercell maintaining a vacuum gap of 10 Å between the neighboring images. The calculations were restricted to the gamma point in the Brillouin zone sampling. The energy cutoff used for the plane wave was 400 eV. The energy was converged till the forces on the atoms were less than 0.03 eV/Å. The structures were optimized using the conjugate gradient technique.

Results

Structure and energetics

In this section, we discuss the structure and stability of the bare Rh clusters and the CO adsorbed on different sites of these clusters. Several isomers were generated by changing the symmetry of the clusters and optimized to confirm the most stable structures of the bare Rh clusters. The CO adsorption was studied only on the most stable state Rh clusters. All the possible adsorption sites were explored on these clusters, and the most stable top, bridge, and hollow sites were analyzed.

Bare Rh clusters

The most stable structures and the first low-lying isomers of Rh_3 to Rh_6 are shown in Fig. 1. The stability and the magnetization of the Rh clusters are represented by the binding energy (B.E.) per atom (B.E./atom) and magnetic moment per atom (μ/atom), respectively, and are given in Table 1. These are defined as follows

$$[1] \qquad \text{B.E./atom} = \frac{(E(\text{cluster}) - nE(\text{atom}))}{n}$$

$$[2] \qquad \mu/\text{atom} = \frac{S_\alpha - S_\beta}{n}$$

The parameters defined in eqs. [1] and [2] are as follows: E(cluster), E(atom), and n are the energy of the Rh cluster, the energy of single Rh atom, and the number of Rh atoms in the cluster, respectively. S_α and S_β are the number of electrons with alpha and beta spins, respectively. The calculated B.E./atom of the bulk Rh is –5.59 eV/atom, in good agreement with the experimental value of –5.75 eV/atom.[40]

The most stable structure for Rh_3 is triangular. This is about 0.21 eV/atom more stable than the linear Rh_3 struc-

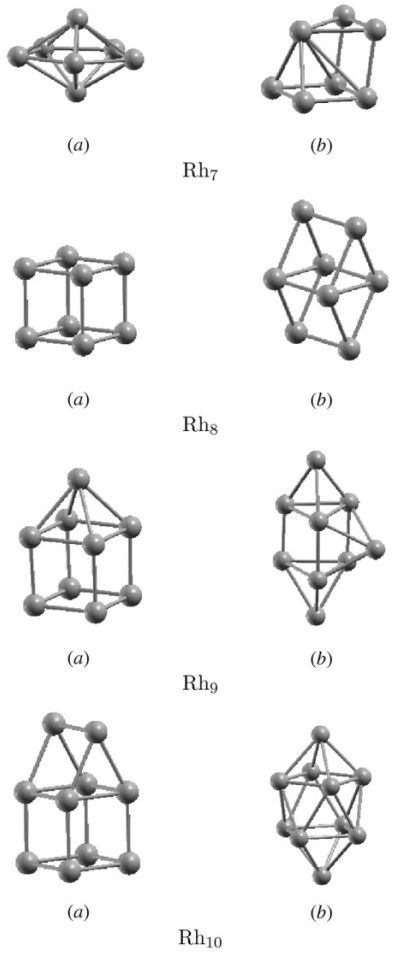
Fig. 2. (*a*) Most stable and the (*b*) first low-lying isomers of Rh_n (n = 7,8,9,10).



ture. The triangular structure has a magnetic moment of 1.0 μ/atom in contrast to 0.3 μ/atom for the linear isomer. The Rh–Rh distance is 2.40 Å. Rh_4 is a distorted tetrahedral structure with bond lengths between 2.4 and 2.8 Å and a magnetic moment of 1.5 μ/atom. The three-dimensional Rh_4 structure is only 0.02 eV/atom more stable than the square isomer. The geometry of the most stable Rh_5 is a square pyramid (Fig. 1) and is 0.06 eV/atom more stable than the triangular bipyramid. The stability and the geometries of the above clusters are in agreement with the earlier theoretical studies.[41,42] However, Rh_6 and Rh_7 clusters show a different trend. Rh_6 is a square bipyramid that is 0.02 eV/atom more stable than the triangular bi-prism isomer (Fig. 1) in contrast to the recent study by Bae et al.[41] Interestingly, the stable geometry of the Rh_6 cluster is in agreement with the study of Vayssilov et al.[29] They used a linear combination of Gaussian-type orbitals fitting functions density functional method (LCGTO-FF-DF) with a Becke–Perdew (BP) exchange correlation function. The average Rh–Rh distance of the stable square bipyramid and the triangular bi-prism isomer (Fig. 1) of the Rh_6 cluster corresponds to 2.54 and 2.48 Å, respectively, which are in agreement with the study of Vayssilov et al.

Moreover, Rh_7 (Fig. 2) shows the pentagonal bi-pyramid to be more stable than the bi-capped distorted pyramidal

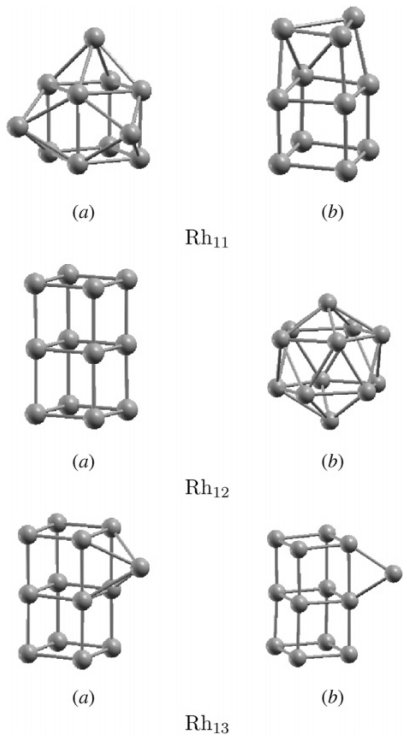
structure. The difference between our calculations and the earlier results by Bae et al. is probably due to the high energy cutoff (400 eV) used in our calculations compared to the earlier studies (205.5 eV).[41] The magnetic moment of Rh_6 and Rh_7 are 1.0 and 1.8 μ/atom, respectively (Table 1). The most stable structure of Rh_8 is a cubic structure. This structure is 0.11 eV/atom more stable than its rhomboidal isomer (Fig. 2). The cubic Rh_8 cluster has a high magnetic moment of 1.5 μ/atom (Table 2) compared to the other clusters. This shows that it contains unpaired d-electrons which remain non-bonded and give rise to high magnetic moment.

The most stable and the isomeric structures of the Rh_9 cluster (Fig. 2) are degenerate with a difference of only 0.003 eV/atom. Consequently, they correspond to the same magnetic moment of 1.4 μ/atom (Table 2). Rh_{10} is a bi-capped cubic structure which is 0.005 eV/atom more stable than the bi-capped square anti-prism (Fig. 2). However, the magnetic moments are different. Interestingly, Rh_{11} is also

Fig. 3. (*a*) Most stable and (*b*) first low-lying isomers of Rh_n (n = 11,12,13)).



0.005 eV/atom more stable than the triangular capped cubic structure. This clearly shows that there exist low lying isomers as predicted by the experimental study.[36] Interestingly, we can see that the growth from Rh_9 to Rh_{11} is over the Rh_8 cubic core (Figs. 2 and 3). The most stable Rh_{12} cluster has a cuboid geometry, similar to the Rh_8 structure (Fig. 3). This structure is about 0.17 eV/atom more stable than the icosahedral structure. The magnetic moment of the stable Rh_{12} cluster is 0.67 μ/atom. Although, the structure has a similar symmetry to Rh_8 the magnetic moment is less than for Rh_8 (Table 1). This would be due to the number of bonding and non-bonding electrons involved in these systems. Rh_{13} consists of a single atom attached to the fourfold hollow site of the Rh_{12} cubic structure. This results in a slightly higher magnetic moment than for the Rh_{12} cluster. The isomeric Rh_{13} cluster is an Rh atom attached to the twofold bridge site (Fig. 3). The stability of the Rh_{12} is almost equal to the Rh_{13} cluster.

CO adsorption on Rh_n clusters

We now discuss the structure and stability of CO adsorption on the different stable sites such as the top, bridged, and hollow sites of the most stable Rh_n clusters discussed earlier. Figure 4 shows the CO adsorption on Rh_3 to Rh_6 clusters at different sites. The adsorption energies and corresponding magnetic moments of the CO adsorbed Rh clusters are given in Table 2. The adsorption energies (A.E.) are calculated as follows

$$[3] \qquad \text{A.E.} = E(\text{Rh}_n\text{CO}) - (E(\text{Rh}_n) + E(\text{CO}))$$

The most stable site for the adsorption on Rh_3 is the bridge site with an adsorption energy of –2.67 eV. This adsorption is 0.19 and 0.89 eV more stable than the threefold hollow and

Fig. 4. (*a*) Most stable, (*b*) second most stable, and (*c*) third most stable sites for the CO adsorption on the most stable Rh_n (n = 3,4,5,6) cluster. The grey, yellow, and red spheres indicate the Rh, C and O atoms, respectively.

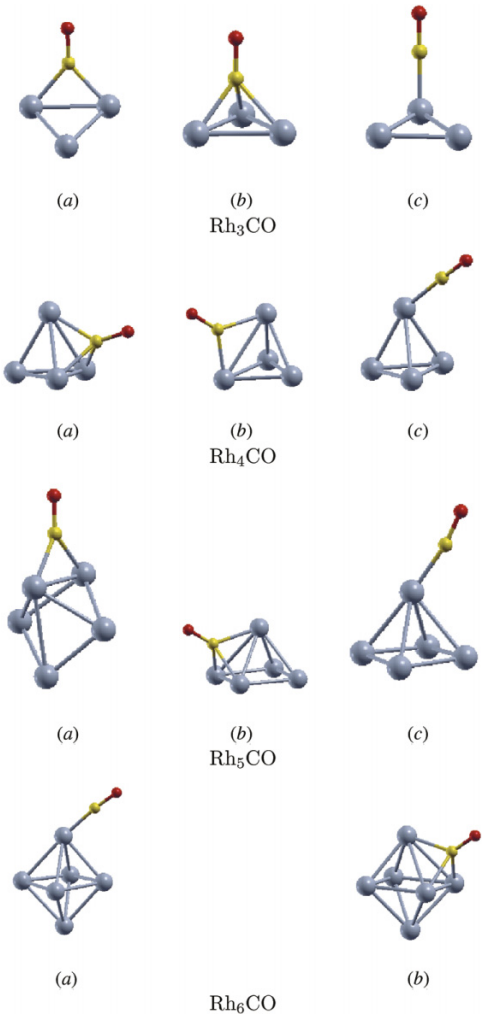


Fig. 5. (*a*) Most stable, (*b*) second most stable, and (*c*) third most stable sites for the CO adsorption on the most stable Rh_n (n = 7,8,9,10) cluster. The grey, yellow (light grey), and red spheres (dark) indicate the Rh, C, and O atoms, respectively (shades in parentheses refer to the printed version).

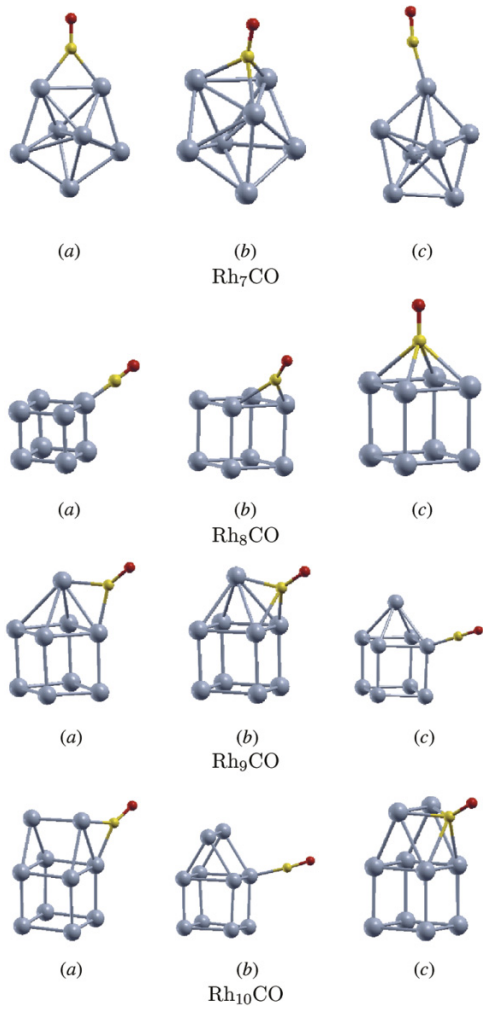
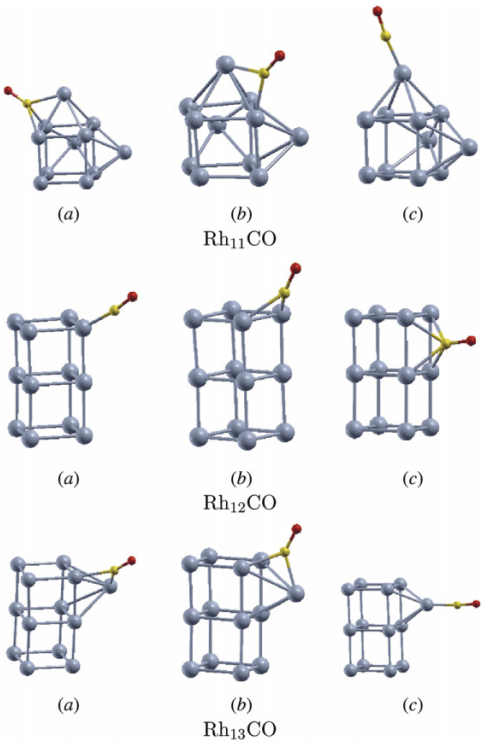


the top site, respectively. The bond length of the Rh–C in the bridge site is 1.93 Å. The C–O bond is stretched to 1.21 Å. CO adsorption on the bridge site does not affect the magnetic moment in Rh_3 . However, there is a considerable decrease in the magnetic moment with CO adsorbed in the other two stable sites (Table 2). The CO on the Rh_4 prefers a hollow site with an adsorption energy of –2.53 eV, as shown in the Fig. 4. Here the C–O is stretched to 1.22 Å. We can see that the CO adsorption energy on Rh_4 is decreased compared to that of Rh_3. This can be understood from the high stability of Rh_4 cluster compared to that of Rh_3 cluster. The CO adsorption on the Rh_4 cluster reduces the magnetic moment in all the three stable sites. This kind of reduced magnetic effect due to the CO adsorption on the Ni clusters has been experimentally observed.[23] The above trend on active sites for CO adsorption on Rh_3 and Rh_4 are in agreement with the earlier theoretical results obtained from all-electron calculations with localized basis set.[36]

The most stable adsorption site on Rh_5 is the bridge site with an energy of –2.17 eV. The other two sites, viz. the hollow and top sites, are almost equal in energy with a difference of 0.02 eV. Surprisingly, the magnetic moment has been increased from 1.0 to 1.4 μ/atom. This may be due to more non-bonding electrons available on the cluster due to back-donation from the Rh atoms to the $2\pi^*$ of the CO molecule. Only two adsorption states were found for the Rh_6 cluster. The top site is more stable than the hollow site by only 0.04 eV. The CO adsorbed in the bridge site moves into either a hollow or top site during the optimization. This indicates that there exist more than one binding site for the CO molecule on Rh_5 and Rh_6 clusters. This kind of behavior has been suggested by the experimental study.[36] Hence, the presence of more than one frequency band observed in the experiments can be attributed to the possibility of CO adsorbing in two different stable sites with degenerate adsorption energies. CO adsorbs strongly at the bridge site of the Rh_7 cluster with an adsorption energy of –2.22 eV. The hollow and the top sites have similar adsorption energies. CO adsorption on the cubic Rh_8 cluster is mostly stable on the top site. The magnetic moment is also reduced due to the adsorption. One can see that the adsorption energy of CO on the Rh_8 cluster is small compared to the other clusters.

Fig. 6. (*a*) Most stable, (*b*) second most stable and (*c*) third most stable sites for the CO adsorption on the most stable Rh_n (n = 11,12,13) cluster. The grey, yellow (light grey), and red (dark) spheres indicate the Rh, C, and O atoms, respectively (shades in parentheses refer to the printed version)



This is due to the high stability of the Rh_8 cluster. In the next section we will give a bonding analysis to explain how CO adsorbs in different sites.

On the Rh_9 cluster, bridge is the most stable site with an energy of –2.55 eV (Fig. 5). This pattern is also observed on the Rh_{10} cluster. As with CO adsorption on the Rh_5 cluster, CO adsorption on the Rh_{10} cluster increases the magnetic moment compared to the bare cluster. CO strongly adsorbs in a threefold hollow site on the Rh_{11} cluster. The stable adsorption site on Rh_{12} is the top site with an adsorption energy of –2.01 eV (Fig. 6). This site is similar to that of the cubic Rh_8 cluster. The adsorption at the bridge and fourfold hollow sites are –1.65 and –0.91 eV, respectively. Rh_{13} shows the bridge site as the most stable for the CO adsorption. The average stretching of the C–O bond on the above clusters is observed between 1.17 to 1.22 Å. Although, some of the Rh clusters adsorb CO strongly, one cannot deduce from this that the CO would easily decompose on these clusters as suggested by the experimental study.[36]

Bonding

In this section, we explain how the CO molecule adsorbs in different sites on the clusters through donation and back-donation. We use the charge density difference analysis to explain this behavior on some selected clusters with different adsorbing sites. Figure 7 shows the charge density difference of the CO adsorbed on the Rh_3 and Rh_4 cluster at the bridge, top, and hollow sites. The red and blue regions represent the charge depleted and gained, respectively. Let us

Fig. 7. Difference charge densities of the (*a*) most stable, (*b*) second most stable, and (*c*) third most stable sites for CO adsorption on the most stable Rh_n (n = 3 and 4) cluster. The blue (light) and red (dark) regions show the charge gained and lost, respectively (shades in parentheses refer to the printed version).

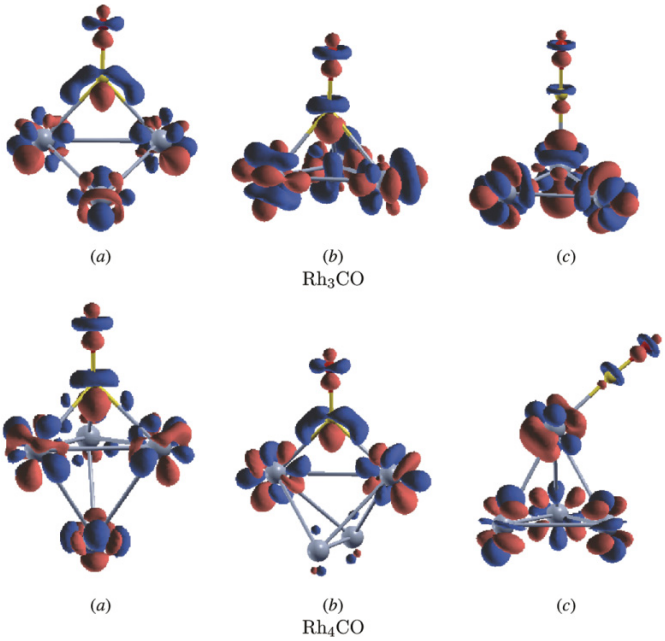


Fig. 8. Difference charge densities of the (*a*) most stable, (*b*) second most stable, and (*c*) third most stable sites for CO adsorption on the most stable Rh_n (n = 6 and 8) clusters. The blue (light) and red (dark) regions show the charge gained and lost, respectively (shades in parentheses refer to the printed version).

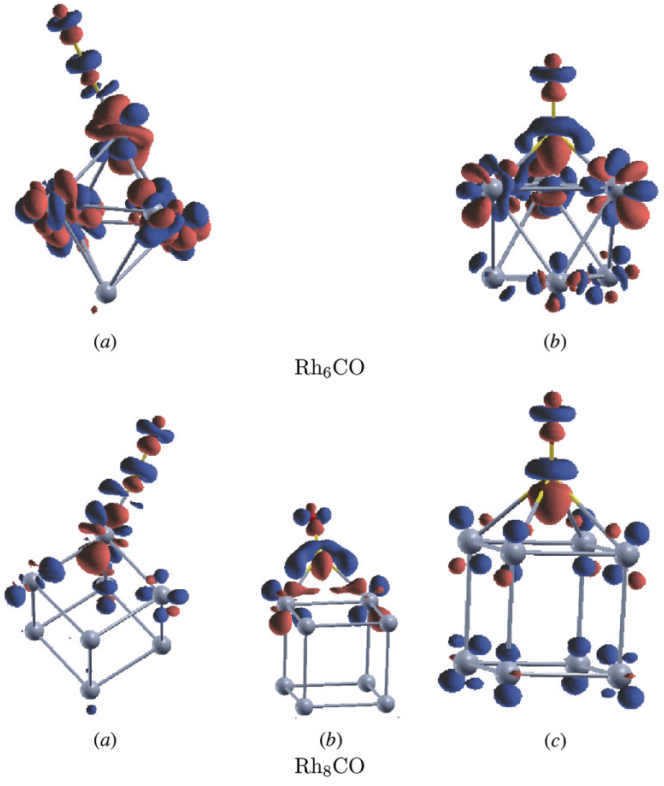

first consider the CO adsorption on Rh_3 at the most stable bridge site. We can clearly see that density from the bonding 5σ orbital of CO is lost and the anti-bonding 2π* has gained charge. It can be seen that there is a considerable change in the orbitals on the metal clusters. The Rh atoms involved in bonding with the CO have lost charge from one orbital and gained in another. This reflects back-donation in the 2π* orbitals of CO and donation from the 5σ orbital of CO to d orbitals corresponding to different symmetry. This agrees very well with the Blyholder model.[8] However, the decrease in the density of the bonding 5σ orbital of CO does not agree with the Bagus model.[9] This is also the reason that the C–O bond is stretched after the adsorption. This kind of picture is also observed on the other sites, viz. top and hollow sites. The important point to note is that in the bridge site there is strong build-up of the density between the C–Rh bond which is not the case in the top and the hollow sites. This is the reason for the strong adsorption of CO in the bridge site of Rh_3 cluster. In the case of Rh_4 we see a similar build-up of the density when the CO molecule adsorbs in the hollow site which is also the most stable site compared to the bridge and top sites. The rearrangement of the d-orbitals on the Rh atoms which are not involved in bonding are due to the relaxation of the cluster as a result of strong CO adsorption. This relaxation rearranges the d-orbitals on these atoms resulting in the flow of electron density from the occupied d-orbitals to the unoccupied d-orbitals of different symmetry.

In Rh_6 the top site and the hollow sites have very similar CO adsorption energies as discussed earlier. The charge density difference isosurface of the CO at the top site and hollow site of Rh_6 is shown in Fig. 8. We can clearly see that in both cases density is similarly built up between the Rh–C bond. This is the reason for a comparable bond strengths of Rh–C bond on the top and hollow sites resulting in near degenerate adsorption energies. It also explains the experimental predictions for the single cluster exhibiting two binding sites. The CO adsorbs more strongly on the top site of Rh_8 which is justified by the density lying between the Rh–C bond as seen the Fig. 8. CO adsorbed in the hollow site does not show much of the density build-up between the Rh–C bonds and this decreases the adsorption energy of CO in the hollow site of Rh_8. The other clusters also show a similar bonding nature for the top, bridge, and hollow sites as discussed above.

Conclusion

The present theoretical work follows a recent experimental study on the CO adsorption on small Rh_n clusters. Our study gives an insight into the different kinds of stable adsorption sites, viz. top, bridge, and hollow, on the Rh clusters. The important findings of the present investigation are as follows.

(1) The analysis of the bare Rh clusters reveal that some of the clusters are energetically degenerate and could result in cluster isomerism.

(2) The CO molecule predominantly prefers the bridge or the top site for adsorption on the cluster. The Rh_4 and Rh_{11} clusters show hollow as the stable adsorbing site. The bridge and the top site on the Rh_6 cluster have very close adsorption energies. This is consistent with the fact that two binding sites are predicted by the experimental study.

(3) We notice that the adsorption of CO reduces the magnetic moment of the cluster. This we predict due to the smaller number of unpaired electrons because of the donation and back-donation.

(4) The bonding analysis reveals that the CO prefers an active site where a strong build-up of the density is seen between the Rh–C bond. This is also the reason why the CO molecule prefers a particular adsorption site. It should be noted that in the case of degenerate isomers the density build-up will not be too different resulting in close adsorption energies as in the case of Rh_6.

(5) Although the CO molecule is strongly adsorpted on these clusters and the stretching of the C–O bond is observed between 1.17 and 1.22 Å, we don't see the dissociation of the adsorbed CO molecule. Our investigation indicates that the adsorption of CO on small Rh clusters is a combined effect of different binding sites of identical energies and metal cluster isomerism.

Ethene trimerization at Cr^{I}/Cr^{III} — A density functional theory (DFT) study[1]

Peter H.M. Budzelaar

Abstract: Catalytic ethene trimerization at a chromium(I) indolate-AlR_2Cl centre has been studied by density functional theory (DFT) methods. The reaction is found to follow the standard metallacycle mechanism. At most stages of the reaction, coordination of Cr to the pyrrole ring of the indolate is preferred. In all 13-*e* intermediates, coordination of the Al-bound chloride to Cr provides additional stabilization: the chloride behaves as a hemilabile ligand. Benzene is found to compete with ethene for coordination to Cr^{I}. The final hexene-forming step involves direct Cβ → Cα′ hydrogen transfer; reductive elimination from a possible (hydride)(hexenyl) intermediate is more difficult. The kinetic isotope effect calculated for the direct hydrogen transfer (4.1) agrees well with the experimental value for a bis(phosphino)amide chromium catalyst. Side products obtained in such systems (methylenecyclopentane, methylcyclopentane) can plausibly be explained through routes not involving any (hydride)(alkyl) reductive elimination. Our results indicate that a Cr^{I}/Cr^{III} trimerization cycle is possible for some chromium trimerization catalysts, and also suggest that direct hydrogen transfer is most likely a general feature of trimerization at Cr centres.

Key words: trimerization, density functional theory (DFT), hydrogen transfer, mechanism.

Résumé : Faisant appel aux méthodes de la théorie de la fonctionnelle de densité (TFD), on a étudié la trimérisation catalytique de l'éthène au niveau du de l'indolate-AlR_2Cl de chrome(I). On a trouvé que la réaction se produit par un mécanisme impliquant un métallacycle standard. À la plupart des stades de la réaction, il y a une préférence pour la coordination du Cr avec le noyau pyrrole de l'indolate. Dans tous les intermédiaires 13-*e*, la coordination du chlorure lié à l'aluminium avec le Cr fournit une stabilisation additionnelle: le chlorure se comporte comme un ligand semilabile. On a observé que le benzène est en compétition avec l'éthène pour établir une coordination avec le Cr(I). L'étape finale de formation de l'hexène implique un transfert direct d'hydrogène Cβ → Cα′; l'élimination réductrice à partir d'un intermédiaire potentiel (hydrure)(hexényle) est plus difficile. L'effet isotopique cinétique calculé pour le transfert direct d'hydrogène (4,1) est en accord avec la valeur expérimentale obtenue avec un catalyseur de bis(phosphino)amide chrome. Les produits secondaires obtenus dans de tels systèmes (méthylènecyclopentane et méthylcyclopentane) peuvent facilement être expliqués par des voies n'impliquant aucune élimination réductrice à partir d'un intermédiaire potentiel (hydrure)(hexényle). Les résultats présentés ici indiquent qu'un cycle de trimérisation Cr(I)/Cr(III) est possible pour certains catalyseurs de trimérisation au chrome et ils suggèrent aussi que le transfert d'hydrogène direct est probablement la caractéristique générale des trimérisations à des centres de Cr.

Mots-clés : trimérisation, théorie de la fonctionnelle de densité (TFD), transfert d'hydrogène, mécanisme.

[Traduit par la Rédaction]

Introduction

Ethene dimerization, oligomerization, and polymerization are catalyzed by a wide range of transition metal complexes. These reactions generally follow a common propagation mechanism (migratory olefin insertion) and only differ in the relative rates of propagation and chain transfer, resulting in a Schulz–Flory distribution of molecular weights. There is, however, a small group of catalysts (mostly based on chromium,[2] although titanium[3] and tantalum[4] variations are known) that show a surprisingly high selectivity to the *trimer* 1-hexene. Since selective 1-hexene formation is commercially much more attractive than isolating the trimer from a Schulz–Flory distribution of products, this select group of catalysts has received considerable attention.

Trimerization generally follows a metallacycle mechanism[5] quite distinct from that of polymerization (Scheme 1). The most important fundamental difference is that two different oxidation states of the metal are involved. A common feature of most catalysts reported to date is the presence of hemilabile ligands, which presumably help to balance the energies of the two oxidation states.

While the general features of the metallacycle mechanism have been accepted for some time, the computational study by Yu and Houk[6] (for the Ta system[4]) was the first to point out that conversion of metallacycloheptane intermediate **D** to 1-hexene complex **E** occurs by direct Cβ → Cα′ hydrogen transfer rather than through discrete (hydride)(hexenyl) intermediate **F**.

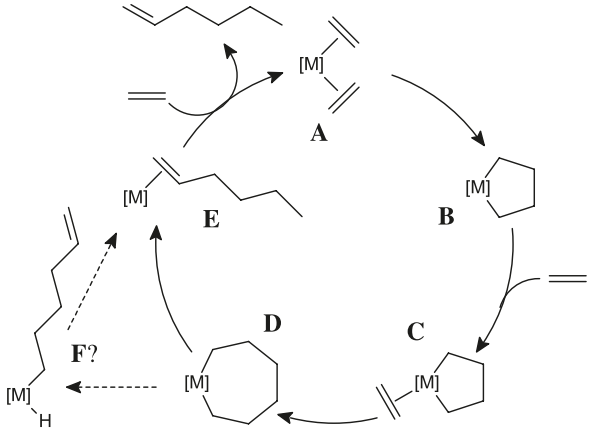
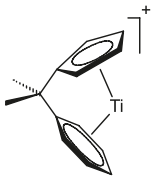
Scheme 1. Basic metallacycle mechanism for 1-hexene formation.



The Cp/arene Ti system described by Hessen and co-workers[3] is probably the "cleanest" trimerization system known to date, in the sense that little uncertainty remains about the nature of the active species. As a consequence, it has been the subject of a number of computational studies,[7–9] which all confirm the mechanism shown in Scheme 1. In addition, these studies revealed the importance of the hemilabile arene ligand in balancing the energies of the Ti^{II} and Ti^{IV} oxidation states.



In contrast, knowledge of the commercially more important[10] chromium systems is limited. The system patented by Phillips Petroleum Company[11] uses chromium(III) alkanoates as precursors, pyrroles as co-catalysts, and aluminium alkyls as activators. Neither the structure of the active species nor even its oxidation state have been firmly established. A computational study of this system by van Rensburg and Steynberg[12] assumed a Cr^{II}/Cr^{IV} mechanism and obtained a viable catalytic cycle. "Hemilability" in that case showed up as η^5/σ flipping of a pyrrolate ligand and modulation of the interaction with the Et_3AlCl^- counterion. BP Chemical Ltd. has patented[13] Cr systems based on bis(phosphino)amide (PNP) ligands. These systems have been studied extensively by Bercaw and co-workers.[14] They concluded that the active species is most likely cationic and switches between Cr^{I} and Cr^{III}. However, even their well-defined precursors show an induction period for the catalysis, indicating that formation of the active species may not be straightforward. Some of the side products characterized by Bercaw and co-workers, most notable methylenecyclopentane and methylcyclopentane,[14b] appear to be derived from a (hydride)(hexenyl) intermediate, suggesting that perhaps this Cr system differs from others in not following a direct $C\beta \rightarrow C\alpha'$ hydrogen transfer path. However, it remains possible that these side products are not related to the main catalytic cycle. Van Rensburg and Steynberg[15] have reported calculations on the possible role of MAO in the PNP chromium system but not on the catalytic cycle itself.

Gambarotta and co-workers[16] recently described the preparation of two well-defined Cr/Al trinuclear compounds that, *without further activation*, are active in trimerization (complex **1**, Cr^{I}) or polymerization (complex **2**, Cr^{II}). Since complex **1** contains Cr^{I}, and no obvious oxidant is added, a $Cr^{II/IV}$ cycle seems unlikely for this system. In the present work, we analyze a possible $Cr^{I/III}$ cycle for the trimerizing species and discuss the implications for other chromium systems.

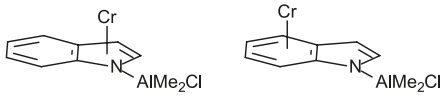
Methods

All geometry optimizations were done using the Turbomole program[17] coupled to PQS OPTIMIZE[18] as an external optimizer. All geometries were optimized at the unrestricted b3-lyp[19] level using the SV(P)[20] basis set. Vibrational analyses were carried out to check the nature of all stationary points, and also to calculate thermal corrections (enthalpy and entropy) for 273 K, 1 bar (1 bar = 100 kPa), gas phase. Improved single-point energies were calculated at the b3-lyp/TZVPP[21] level, and combined with the SV(P) thermal corrections to produce the final free energy values mentioned in the text. For lists of total energies and optimized geometries, see the Supplementary data.

Results and discussion

The $Cr^{I/III}$ trimerization cycle

The assumed mechanism corresponds to that in Scheme 1. To simplify calculations, we used an indolyl ligand as a model for the tetrahydrocarbazolyl ligand used by Gambarotta and co-workers,[16] and replaced the Al-bound ethyl groups by methyl groups. At all stages, the $AlMe_2Cl$ group stays coordinated to the indolate nitrogen, which means that the Cr atom must be π-coordinated to either the pyrrolate or the arene ring of the indolate ligand,[22] leading to models **3** and **4** for the Cr fragment in the active species.



3 **4**

Both possibilities were explored; pyrrolate coordination was preferred by a modest margin (0–10 kcal/mol, 1 cal = 4.184 J) at most stages of the reaction, but slippage of the chromium fragment over the aromatic system was found to be very easy. The dangling $AlMe_2Cl$ group has the possibility of orienting its chloride towards Cr, thus constituting a hemilabile group. Indeed, we found Cl coordination to Cr in all 13-*e* Cr^{III} intermediates (in both **3** and **4**), but not in the
