BZ<sup>8</sup> were first to point out that  $\gamma(y)$  is negligible at small  $0 < y < \bar{y}$  but dominates eq. [3] at  $y$  exceeding the threshold  $\bar{y}$  determined as the largest of the three roots of the equation

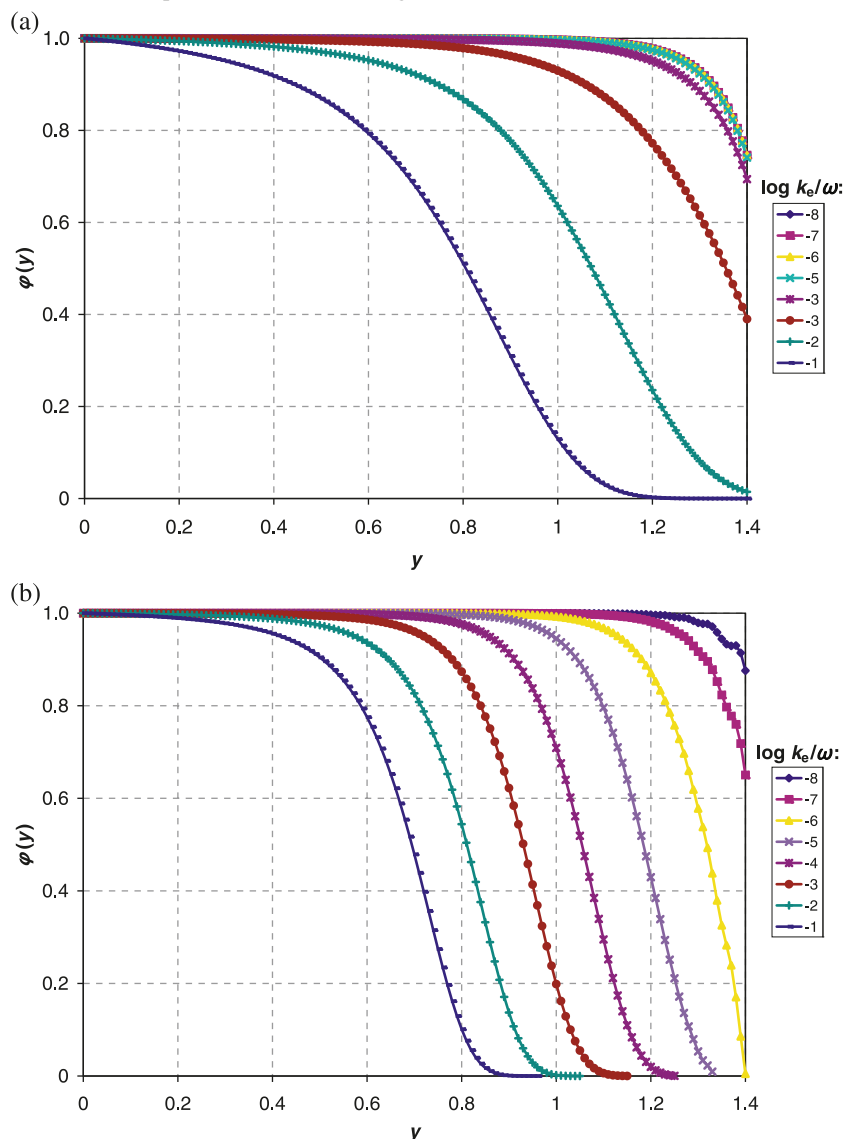

$$\frac{\beta D}{2} \left[ \left( \frac{dV}{dy} \right)^2 - \frac{d^2 V}{dy^2} \right] = \gamma(y)$$

Nonequilibrium solvent effects arise when  $\bar{y} < 1$ , and in the high viscosity limit, the overall rate constant is practically determined by the mean first passage time (MFPT) to point **RS\*** with  $y = \bar{y}$ <sup>8</sup>

$$[6] \quad k \approx k_{\text{MFPT}} = \beta D \left( \frac{d^2 V}{dy^2} \right)_{y=0} \sqrt{\frac{\beta V(\bar{y})}{\pi}} \exp(-\beta V(\bar{y}))$$

thus effectively localizing exponential sink  $\gamma(y)$  to a  $\delta$ -function centered at  $y = \bar{y}$ . BZ and co-workers also used perturbation theory to obtain interpolating solutions for the case

**Fig. 2.** Exact numerical solutions  $\varphi(y)$  of eq. [7] for  $\rho = 1.5$  and  $\log k_e/\omega$  from  $-8$  to  $-1$ : (a)  $\varepsilon = 5$ ; (b)  $\varepsilon = 10$ .

of intermediate viscosities.<sup>12</sup> A solution of eq. [3] similar to eq. [6] has also been reported by Sebastian<sup>13</sup> for a parabolic potential  $V(y)$  and a  $\delta$ -function sink, although no recipe was given for the determination of the sink location  $\bar{y}$ .

The purpose of this work is to obtain a simple approximate solution of eq. [3] suitable for the quantitative interpretation of high pressure kinetics of thermal isomerization reactions in viscous media<sup>14</sup>. For this, we use the idea of a sliding localized sink, although in a somewhat different context than BZ, and give it a simple intuitive interpretation in terms of a two-step kinetic scheme. We then compare the values of the rate constants and sink locations obtained from the approximate and exact numerical solutions.

### Exact numerical solutions

The degree of deviation of a nonequilibrium distribution function  $f(y)$  from the equilibrium distribution function  $f_e(y)$  can be conveniently described by their ratio  $\varphi(y) = f(y)/f_e(y)$ . In accordance with eq. [3],  $\varphi(y)$  must obey equation

$$[7] \quad D \frac{\partial^2 \varphi}{\partial y^2} - \beta D \frac{dV}{dy} \frac{\partial \varphi}{\partial y} + (k - \gamma) \varphi = 0$$

or, in harmonic approximation (eq. [4]), equation

$$[8] \quad \frac{\partial^2 \varphi}{\partial y^2} - 2\varepsilon y \frac{\partial \varphi}{\partial y} + 2\varepsilon \frac{k_e}{\omega} \left( \frac{k}{k_e} - \frac{\gamma}{k_e} \right) \varphi = 0$$

According to eqs. [2] and [5],

$$[9] \quad \frac{\gamma(y)}{k_e} = \sqrt{\rho} \exp[-\rho \varepsilon (y - 1)^2 + \varepsilon y^2]$$

i.e., for  $\rho > 1$ ,  $\gamma(y)/k_e$  is a Gaussian function that reaches its maximum value of  $\sqrt{\rho} \exp[\varepsilon \rho / (\rho - 1)]$  at  $y = \rho / (\rho - 1)$ . For  $\rho = 1$ , it degenerates into a simple exponent  $\gamma(y)/k_e = \exp[\varepsilon(2y - 1)]$ .

Typical examples of exact numerical solutions of eq. [8] obtained by its direct integration<sup>15</sup> for a range of parameters  $\rho$ ,  $\varepsilon$ , and  $\log k_e/\omega$  are shown in Fig. 2. As expected, for relatively slow reactions ( $\log k_e/\omega < -5$ ), the values of  $\varphi(y)$  are

**Fig. 3.** Integrand of eq. [10] and its Gaussian approximation for  $\rho = 1.5$  and  $\varepsilon = 10$ : (a)  $\log k_e/\omega = -2$ ; (b)  $\log k_e/\omega = -1$  (note the difference in the scales for the vertical axes in the two cases).

close to unity up to  $y = 1$  (TS), and thus  $k \approx k_e$ . As reaction becomes faster or solvent slower,  $\varphi(y)$  departs from its equilibrium value of 1 quite significantly. However, even in the most nonequilibrium cases,  $\varphi(y)$  is reasonably close to 1 for  $y < 0.6$ , i.e., the equilibrium is not perturbed at the bottom of the reactant well, where the bulk reactant resides, since both  $f(y)$  and  $f_e(y)$  exponentially decay with  $y$ . It can therefore be expected that the norms  $\|f\|$  and  $\|f_e\|$  are approximately equal and  $\varphi(y) \approx P(y)/P_e(y)$ . Accordingly,

$$[10] \quad \frac{k}{k_e} = \int F(y) dy$$

$$F(y) = \frac{\gamma(y)}{k_e} P_e(y) \varphi(y)$$

### Approximate solution: localized sink model

As a product of an exponentially increasing function  $\gamma(y)/k_e$

and an exponentially decreasing function  $P(y)$ , the integrand  $F(y)$  of eq. [10] is bell-shaped, although somewhat skewed from a perfect Gaussian curve (Fig. 3).

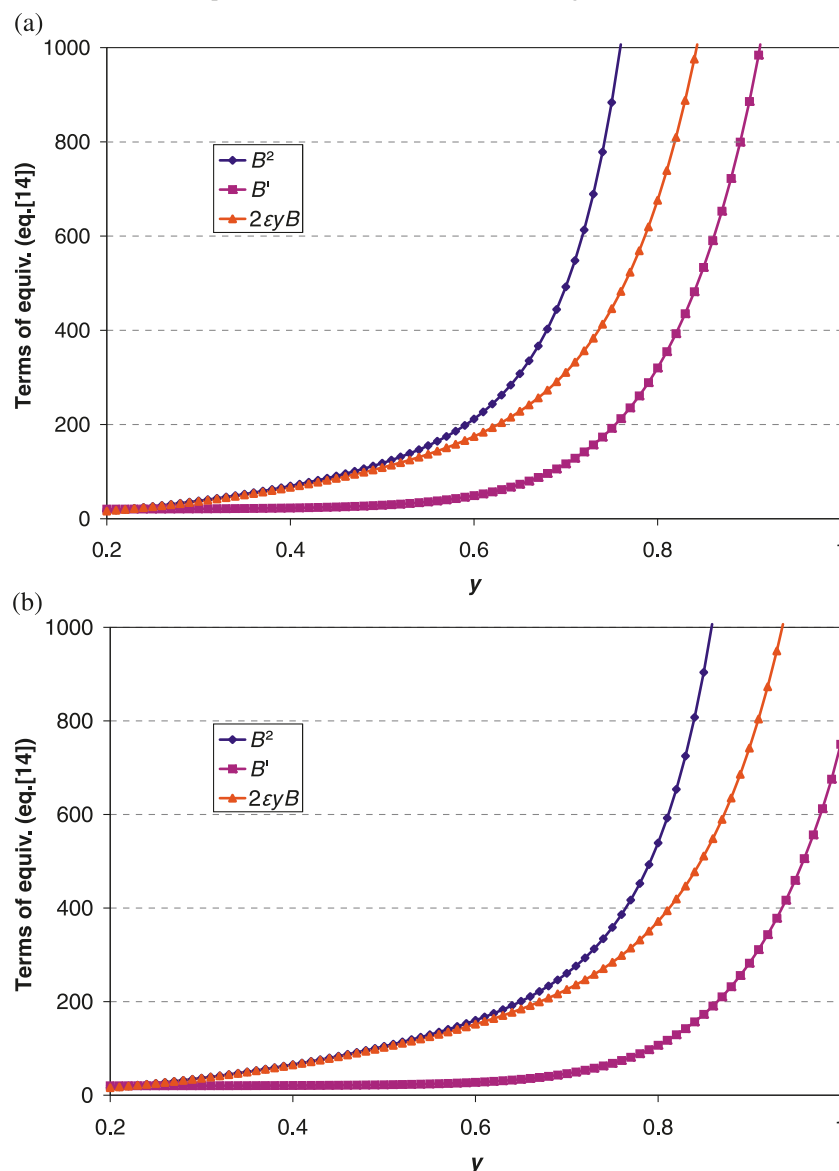

The dominant contribution to the integral of eq. [10] comes therefore from the close vicinity of the maximum of its integrand  $F(y)$ , point  $y^*$ , and thus the sink of eq. [8] is effectively localized at  $y^*$ . As solvent viscosity increases,  $y^*$  slides towards the bottom of the reactant well. Since only a close vicinity of point  $y^*$  gives notable contribution to the integral of eq. [10], the value of  $k/k_e$  can be approximated by Gaussian integral:<sup>16</sup>

$$\frac{k}{k_e} \approx \int F(y) dy \approx \int F(y^*) \exp\left(-\frac{A(y - y^*)^2}{2}\right) dy$$

$$= \sqrt{\frac{2\pi}{A}} F(y^*)$$

**Fig. 4.** Comparison of the first three terms of eq. [14] for  $\rho = 1.5$  and  $\varepsilon = 10$ : (a)  $\log k_e/\omega = -2$  ( $y^* = 0.79$ ); (b)  $\log k_e/\omega = -1$  ( $y^* = 0.71$ ).

In harmonic approximation

$$F(y) = \sqrt{\frac{\rho\varepsilon}{\pi}} \exp[-\rho\varepsilon(y-1)^2] \varphi(y)$$

and

$$A = -\left(\frac{d^2 \ln F}{dy^2}\right)_{y=y^*} = 2\rho\varepsilon + B'(y^*)$$

where

$$[11] \quad B(y) = -\left(\frac{d \ln \varphi}{dy}\right); \quad B'(y) = -\left(\frac{dB}{dy}\right)$$

thus giving

$$[12] \quad \frac{k}{k_e} \approx \sqrt{\frac{1}{1 + (B'(y^*)/2\rho\varepsilon)}} \varphi(y^*) \exp[-\rho\varepsilon(y^*-1)^2]$$

### Solution in quadratures

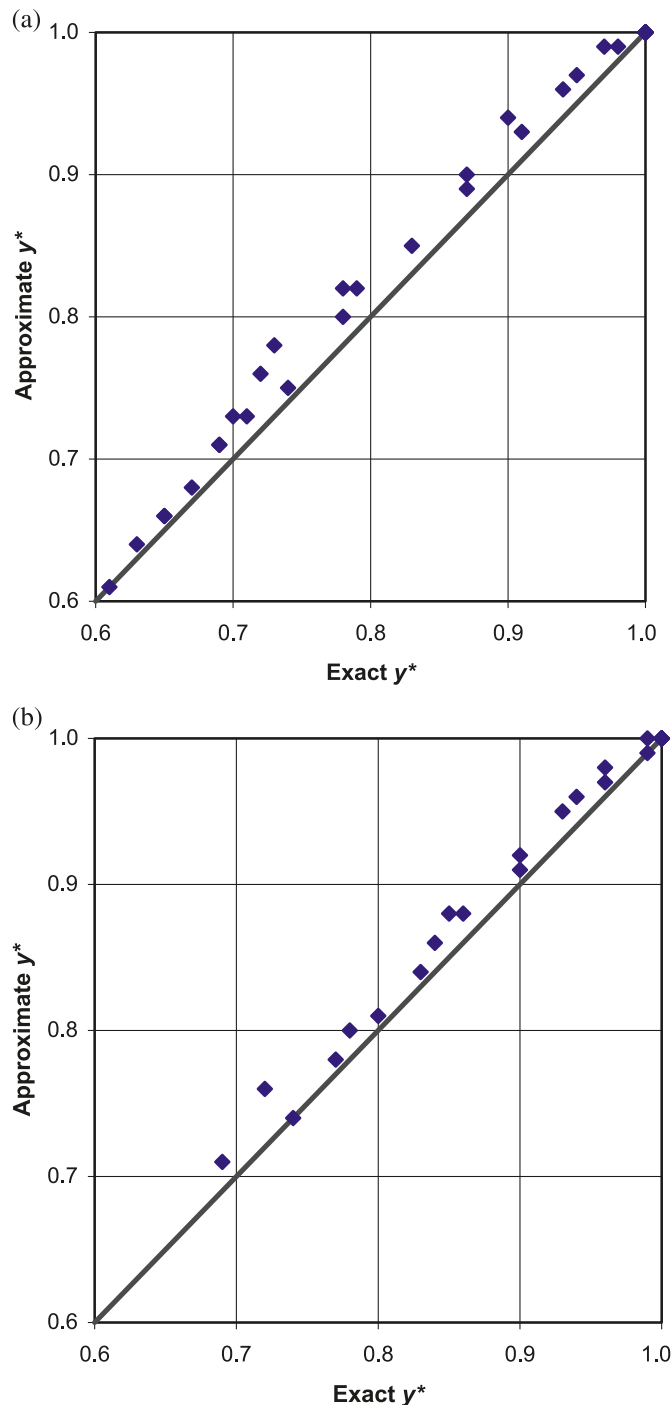

To apply eq. [12] one needs to know the sink location  $y^*$  as well as the value of function  $\varphi$  and its second logarithmic derivative  $B'$  at this point. The value of  $y^*$  can be determined from the stationary-point condition

$$[13] \quad 0 = -\left(\frac{d \ln F}{dy}\right)_{y=y^*} = 2\rho\varepsilon(y^*-1) + B(y^*)$$

if  $B(y)$  is known.

According to eq. [11],  $\varphi' = -B\varphi$  and  $\varphi'' = (B^2 - B')\varphi$ , which, substituted into eq. [8], gives

**Fig. 5.** Comparison between the exact and approximate values of  $y^*$  (eq. [16]) for  $\varepsilon$  from 5 to 40 and  $\log k_e/\omega$  from  $-8$  to  $-1$ : (a)  $\rho = 1.5$ ; (b)  $\rho = 4.0$ . The diagonal solid lines represent the ideal case of a perfect fit.

$$[14] \quad B^2 - B' + 2\varepsilon yB + 2\varepsilon \frac{k_e}{\omega} \left( \frac{k}{k_e} - \frac{\gamma}{k_e} \right) = 0$$

In the vicinity of  $y^*$ ,  $k \ll \gamma$  and thus can be neglected. In addition, as can be seen from Fig. 4 where the first three terms of eq. [14] are compared,  $B'$  can also be neglected compared to  $B^2$  and  $2\varepsilon yB$ , thus transforming differential eq. [14] into quadratic equation

$$[15] \quad B^2 + 2\varepsilon yB - 2\varepsilon \frac{k_e}{\omega} \frac{\gamma}{k_e} = 0$$

Combined with condition of eq. [13], it converts into the following transcendental equation for  $y^*$ :

$$[16] \quad 2\rho^2 \varepsilon (y^* - 1)^2 - 2\rho \varepsilon y^* (y^* - 1) - \frac{k_e}{\omega} \frac{\gamma(y^*)}{k_e} = 0$$

The values of  $y^*$  obtained from eq. [16] for various combinations of parameters  $\rho$ ,  $\varepsilon$ , and  $k_e/\omega$  are compared to the exact numerical solutions in Fig. 5. For  $\rho = 1.5$ , the deviations of the approximate  $y^*$  from the exact values do not exceed 7% and average to 2%. The results are somewhat better for  $\rho = 4.0$ , giving the maximum and average deviations of 6% and 1%, respectively.

Equation [15] can be resolved for  $B(y)$  to give

$$[17] \quad B(y) = -\varepsilon y + \sqrt{\varepsilon^2 y^2 + 2\varepsilon \sqrt{\rho} \frac{k_e}{\omega} \exp(-\rho \varepsilon (y - 1)^2 + \varepsilon y^2)}$$

from which  $\varphi(y^*)$  can be found by integration

$$[18] \quad \ln \varphi(y^*) = \int_0^{y^*} B(y) dy$$

It can then be substituted in eq. [12] to obtain  $k/k_e$ . This, however, leaves the answer in quadratures. To avoid that, we will try to find a simpler expression for  $\varphi(y)$  based on the analysis of its properties.

### Stepwise approximation for $\varphi(y)$

Function  $\varphi(y)$  quickly changes from 1 to 0 near point  $y^*$  because of the exponential rise of the sink  $\gamma(y)$ . It can therefore be presented as

$$[19] \quad \varphi(y) = \frac{\xi(y)}{\xi(y) + \gamma(y)}$$

where  $\xi(y) \gg \gamma(y)$  for  $y < y^*$  and  $\xi(y) \ll \gamma(y)$  for  $y > y^*$ . Accordingly, its logarithmic derivative (eq. [11]) takes the form of

$$B(y) = \frac{\xi'(y) + \gamma'(y)}{\xi(y) + \gamma(y)} - \frac{\xi'(y)}{\xi(y)}$$

The values of  $\xi(y^*)$  obtained from the exact numerical  $\varphi(y)$  by reversal of eq. [19] are close to  $\rho^{1/2}\omega$  (Fig. 6a). It also appears that functions  $\xi(y)$  are stationary in the vicinity of  $y^*$ :  $\xi'(y^*) \approx 0$  (Fig. 6b). The values of  $\varphi(y^*)$  and  $B(y^*)$  can therefore be approximated as

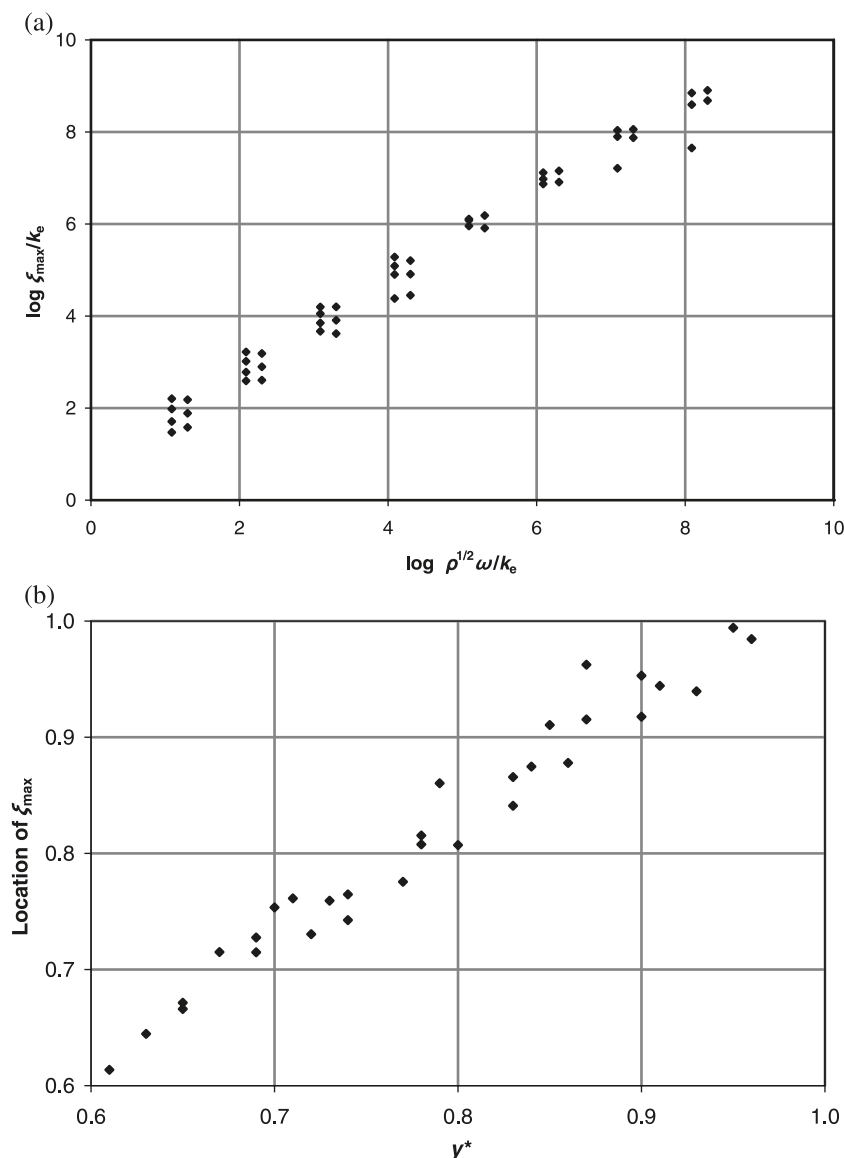

$$[20] \quad \varphi(y^*) \approx \frac{\rho^{1/2}\omega}{\rho^{1/2}\omega + \gamma(y^*)}$$

and

$$[21] \quad B(y^*) \approx \frac{\gamma'(y^*)}{\rho^{1/2}\omega + \gamma(y^*)}$$

Substituted in eqs. [12] and [13] on the assumption that

**Fig. 6.** Properties of functions  $\xi(y)$ : (a) correlation between their maximum values and the values of  $\rho^{1/2}\omega$ ; (b) correlation between locations of their stationary points and the values of  $y^*$ . The data points are for  $\varepsilon$  from 5 to 40,  $\log k_e/\omega$  from  $-8$  to  $-1$ , and  $\rho = 1.5$  and  $4.0$ .

$B'(y^*) \ll 2\rho\varepsilon$ , they give eq. [22] for the relative value of the rate constant

$$[22] \quad \frac{k}{k_e} \approx \frac{\rho^{1/2}\omega}{\rho^{1/2}\omega + \gamma(y^*)} \exp[-\rho\varepsilon(y^* - 1)^2]$$

and eq. [23] for the location of the sink  $y^*$  as the point of maximum of function  $\ln F(y)$

$$[23] \quad 2\rho\varepsilon(y^* - 1) + \frac{\gamma'(y^*)}{\rho^{1/2}\omega + \gamma(y^*)} = 0$$

Alternatively,  $y^*$  can be found as the point of minimum of the reciprocal function  $1/F(y)$ :

$$[24] \quad \frac{1}{F(y)} = \frac{k_e}{\gamma(y)P_e(y)} + \frac{k_e}{\rho^{1/2}\omega P_e(y)}$$

defined by the stationary condition  $(1/F(y))' = 0$ .

### The high viscosity limit

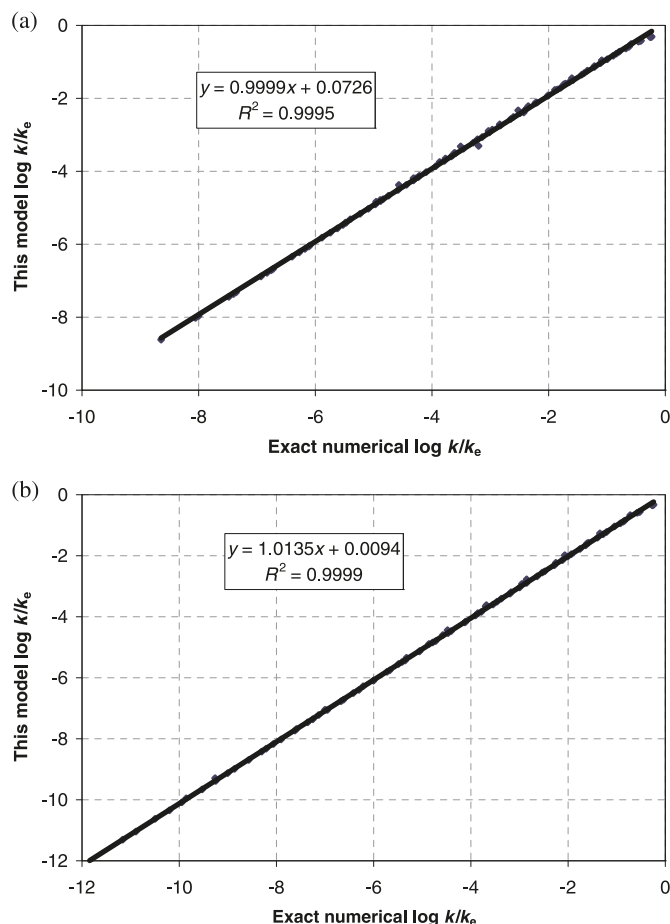

Equation [24] function represents the sum of two exponential terms, the first of which is a decreasing function of  $y$  and the second is an increasing function of  $y$  for  $0 \leq y \leq 1$ . In the high viscosity limit, these terms are comparable in the vicinity of  $y^*$ , and the exact condition  $(1/F(y))' = 0$  can be replaced by an approximate condition of the equality of the two exponential terms:

$$[25] \quad \frac{\rho^{1/2}k_e}{\gamma(y^*)} = \frac{k_e}{\omega}$$

which, by virtue of eq. [9], simplifies to the quadratic equation

$$[26] \quad \rho\varepsilon(y^* - 1)^2 - \varepsilon(y^*)^2 - \ln \frac{k_e}{\omega} = 0$$

**Fig. 7.** Comparison between the exact and approximate values of  $k/k_e$  (eq. [27]/eq. [26]) for  $\varepsilon$  from 5 to 40 and  $\log k_e/\omega$  from  $-8$  to  $-1$ : (a)  $\rho = 1.5$ ; (b)  $\rho = 4.0$ .

and, in accordance with eq. [18], it gives

$$[27] \quad \frac{k_e}{k} \cong 2 \frac{k_e}{\omega} \exp[\varepsilon(y^*)^2] = 2 \exp[\rho \varepsilon (y^* - 1)^2]$$

Approximate analytical solutions given by eq. [27]/eq. [26] are compared to the exact numerical solutions in Fig. 7 and demonstrate a good fit.

### The low viscosity limit

The validity of eqs. [25–27] is limited to nonequilibrium high viscosity cases, for which the right-hand side of eq. [24] contains comparable exponential terms. For sufficiently slow reactions in reasonably nonviscous solvents, parameter  $k_e/\omega$  is very small, and eq. [25] no longer accurately estimates the location  $y^*$  of the true minimum of function  $1/F(y)$ . The full equation  $(1/F(y))' = 0$  needs to be used instead.

When the second term of  $1/F(y)$  in eq. [24] is negligible compared with the first term owing to the smallness of  $k_e/\omega$ , eqs. [22] and [24] transform into eqs. [28] and [29], respectively:

$$[28] \quad \frac{k}{k_e} \cong \exp[-\rho \varepsilon (y^* - 1)^2]$$

$$[29] \quad \frac{1}{F(y)} \approx \frac{k_e}{\gamma(y)P_e(y)} = \rho^{-1/2} \exp[\rho \varepsilon (y - 1)^2]$$

Equation [29] function has a minimum at  $y^* = 1$ , under which condition eq. [28] gives  $k = k_e$ . Thus, eqs. [22] and [24] demonstrate proper asymptotic behavior at low viscosities.

As solvent viscosity increases, so does the value of parameter  $k_e/\omega$ . As a borderline case between equilibrium (TST) and nonequilibrium kinetics, we can consider a situation where  $y^*$  is still close to 1 (as in the TST case), but the second term in eq. [24] becomes comparable to the first term, thus validating nonequilibrium eq. [27]. Combination of these conditions leads to eq. [30]

$$[30] \quad \ln \frac{k_e}{\omega} + \varepsilon \cong 0$$

that defines the boundary of the equilibrium kinetics. In accordance with eq. [27], this corresponds to the condition  $k/k_e = 0.5$ . The line of  $k/k_e = 0.5$ , obtained from the numerical solutions of eq. [3] for  $\rho$  ranging from 1.0 to 4.0, is shown in Fig. 8. It demonstrates a linear relationship between  $\varepsilon$  and  $\ln(k_e/\omega)$  with a slope close to  $-1$  independent of  $\rho$ , as predicted by eq. [30].

### Phenomenological interpretation

Despite its extreme simplicity, the solution of eqs. [26] and [27] approximates the exact numerical solutions of eq. [3] remarkably well. This makes it a useful alternative to the latter, especially in the context of the analysis of numerical results or experimental data. The following two-step-kinetics scheme<sup>14</sup> offers a simple phenomenological interpretation of eqs. [22] and [25] underlying this solution

According to this scheme, the reactant  $R$  converts reversibly into a transient intermediate  $Z^*$ , which then transforms irreversibly into product  $P$ . The scheme is similar to the one used in early formulations of the TST<sup>17</sup> with the exception that the transient species  $Z^*$  in it represents the sink (i.e., the reactant solvated by the solvent in configuration  $y = y^*$ ; Fig. 1b, point  $RS^*$ ) rather than the TS. The position of  $Z^*$  on the PES and hence the values of the step rate constants  $k_1$ ,  $k_{-1}$ , and  $k_2$  depend on  $y^*$ . In the steady-state approximation, the rate constant of the overall process described by eq. [31] is

$$[32] \quad k = \frac{k_1(y^*)k_2(y^*)}{k_{-1}(y^*) + k_2(y^*)}$$

which, by virtue of eq. [9], matches eq. [22] if  $k_2 = \gamma(y^*)$ ,  $k_{-1} = \rho^{1/2}\omega$ , and  $k_1 = \omega \exp[-\varepsilon(y^*)^2]$ .

The average rate constant  $k$  given by eq. [1] can be seen as a composition of partial rate constants  $k(y)$  associated with a quasi-continuum of parallel two-step processes, similar to eq. [31], but with variable sink states  $Z(y)$  spread along the solvent coordinate  $y$ . Equation [25] condition identifies  $Z^* = Z(y^*)$  as a point for which  $k_{-1} = k_2$ . For  $y$  exceed-

**Fig. 8.** Linear relationship between  $\varepsilon$  and  $\ln(k_e/\omega)$  for the boundary of equilibrium (TST) kinetics defined by the condition  $k/k_e = 0.5$  as obtained from the numerical solutions of eq. [3] for  $\rho$  ranging from 1.0 to 4.0.

ing  $y^*$ ,  $k_{-1} \ll k_2$  and the partial rate constant  $k(y) = k_1(y) = \omega \exp[-\varepsilon y^2]$ , which is exponentially less than  $k(y^*) = (\omega/2) \exp[-\varepsilon(y^*)^2]$ . For  $y$  preceding  $y^*$ ,  $k_{-1} \gg k_2$  and  $k(y) = \rho^{-1/2} k_2(y) \exp[-\varepsilon y^2] = k_e \exp[-\rho \varepsilon (y - 1)^2]$  is again exponentially smaller than  $k(y^*) = (k_e/2) \exp[-\rho \varepsilon (y^* - 1)^2]$ . Equation [25] condition thus defines the optimum sink  $Z^*$  that gives the dominant contribution  $k(y^*)$  to the overall rate constant  $k$ , i.e., it identifies the localized sink. As the viscosity of the solvent increases, the rates  $k_1$  and  $k_{-1}$  of the diffusion step decrease, and the localized sink  $Z^*$  slides towards the bottom of the reactant valley (i.e.,  $y^*$  gets smaller) to maintain the optimum condition  $k_{-1} = k_2$ .

# Theoretical analysis of the (HNO)<sub>2</sub>, (HNO...HNS), and (HNS)<sub>2</sub> dimers — A case of red and blue shifts of N–H stretching frequency

Nguyen Tien Trung, Tran Thanh Hue, and Minh Tho Nguyen

**Abstract:** The hydrogen-bonded interactions in the simple (HNZ)<sub>2</sub> dimers, with Z = O and S, were investigated using quantum chemical calculations with the second-order Møller–Plesset perturbation (MP2), coupled-cluster with single, double (CCSD), and triple excitations (CCSD(T)) methods in conjunction with the 6-311++G(2d,2p), aug-cc-pVDZ, and aug-cc-pVTZ basis sets. Six-membered cyclic structures were found to be stable complexes for the dimers (HNO)<sub>2</sub>, (HNS)<sub>2</sub>, and (HNO–HNS). The pair (HNS)<sub>2</sub> has the largest complexation energy (–11 kJ/mol), and (HNO)<sub>2</sub> the smallest one (–9 kJ/mol). A bond length contraction and a frequency blue shift of the N–H bond simultaneously occur upon hydrogen bond formation of the N–H...S type, which has rarely been observed before. The stronger the intramolecular hyperconjugation and the lower the polarization of the X–H bond involved as proton donor in the hydrogen bond, the more predominant is the formation of a blue-shifting hydrogen bond.

**Key words:** blue-shifting hydrogen bond, hyperconjugative interaction, rehybridization.

**Résumé :** On a effectué des calculs de chimie quantique à l'aide des méthodes MP2, CCSD, CCSD(T) en association avec des ensembles de bases 6-311++G(2d,2p), aug-cc-pVDZ et aug-cc-pVTZ, pour étudier les interactions par liaisons hydrogènes dans des dimères simples (HNZ)<sub>2</sub> dans lesquels Z = O et S. On a trouvé que des structures cycliques à six chaînons sont des complexes stables pour les dimères (HNO)<sub>2</sub>, (HNS)<sub>2</sub> et (HNO–HNS). La paire (HNS)<sub>2</sub> donne lieu à l'énergie de complexation la plus élevée (–11 kJ/mol) alors que celle de la (HNO)<sub>2</sub> donne lieu à l'énergie de complexation la plus faible (–9 kJ/mol). On observe une contraction de la longueur de liaison et un déplacement vers le bleu pour la liaison N–H qui accompagne la formation de la liaison hydrogène de type N–H...S, ce qui n'a été observé que rarement antérieurement. Une hyperconjugaison intramoléculaire est forte et une polarisation de la liaison X–H impliquée comme donneur de proton dans la liaison hydrogène faible favorisent la formation prédominante d'une liaison hydrogène avec déplacement vers le bleu.

**Mots-clés :** liaison hydrogène avec déplacement vers le bleu, interaction par hyperconjugaison, réhybridisation.

[Traduit par la Rédaction]

## Introduction

A hydrogen bond of type X–H...Y plays an important role in many fields of chemistry and biochemistry as they determine the structures and properties of liquids, molecular crystals, and biological molecules.<sup>1–3</sup> A characteristic feature of hydrogen bond formation is a X–H bond lengthening with a concomitant red shift of the X–H stretching frequency. The origin of X–H bond lengthening and associated effects in a conventional hydrogen bond is well-understood. This is a combined effect of the electrostatic and hyperconjugative interactions, which stabilize the forming complex.<sup>4</sup> However, a large number of experimental and theoretical studies have reported in recent years the existence of a new phenomenon,

in which formation of a hydrogen bond results in a shortened X–H bond length, and a blue-shifted stretching frequency.<sup>5–16</sup> Accompanying such a frequency shift, a decrease in infrared intensity is usually predicted, even though this is not always observed. Initially, the latter complex was named “anti-hydrogen bond”,<sup>17</sup> but after vigorous discussion for a long time, the name “blue-shifting hydrogen bond” has been put forward.<sup>17</sup> There are, however, different opinions about the origin of blue shifting and red shifting in hydrogen bonds, and the origin of the blue-shifting hydrogen bond especially remains a matter of debate. A number of hypotheses and models have indeed been proposed to explain the different origin of the two kinds of hydrogen bonds.<sup>6–14,18–22</sup> However, no general explanation has been successfully applied

to all hydrogen-bonded complexes that possess the blue-shifting phenomenon.

Among the available rationalizations for the blue-shifting hydrogen bonds, five schemes have attracted more attention. Let us briefly summarize their arguments: (i) The first explanation suggests a two-step mechanism in which electron density from Y is mainly transferred to remote atoms linked to X rather than to the  $\sigma^*(X-H)$  orbital, and the contraction of the X-H bond is a result of structural reorganization of the proton donor framework.<sup>6,7,14</sup> (ii) The second model attributes the X-H bond length shortening to the short-range repulsive forces faced by H in the complex while attempting stabilization.<sup>13,19,20</sup> (iii) The main argument in the third scheme is that since an electric field is found following contraction of the X-H bond, the observed shortening is partly assigned to the effect of the electric field of Y.<sup>13,21,22</sup> (iv) The fourth explanation is based on two main factors acting in opposite directions, which are the s-character percentage of the X atom and the polarization of the X-H bond on one side and the intermolecular hyperconjugative interaction from  $n(Y)$  lone pair to the  $\sigma^*(X-H)$  orbital on another side. When the hyperconjugative interaction dominates, the X-H bond is elongated. Reversely, the X-H bond is contracted when an increase in the s-character of the X atom and the polarization of the X-H bond overcoming the weakly hyperconjugative interaction is obtained.<sup>8-11</sup> (v) Finally, the fifth scheme proposes that a transfer of electron density available at the right-hand side of the H atom involved in the X-H...Y hydrogen bond to the X-H bond, due to presence of Y, actually leads to a contraction of the X-H bond and an increase in its stretching frequency.<sup>12</sup> In general, each of the schemes mentioned above has its specific advantages and restrictions. These hypotheses rationalize the phenomenon considered on the basis of dimer properties, that is when the hydrogen-bonded complex is already formed. Another approach is to start with the inherent properties of the isolated monomer, in particular, the proton donor, to understand the dimer property. The monomer properties include the deprotonation enthalpy of the X-H bond, s-character of the X atom, electron density in the  $\sigma^*(X-H)$  orbital, and intramolecular interaction. We have recently reported some remarkable results along this direction.<sup>23,24</sup>

While numerous studies have been devoted to the C-H bond as proton donor, the blue-shifting phenomenon with N-H proton donor is less known, due to its large polarization. A few cases have recently been observed showing contraction and blue shift of a N-H bond in the N-H...O complexes.<sup>23-30</sup> Besides, N-H bond length shortening and frequency blue shift were also observed in some dihydrogen bond complexes.<sup>31-33</sup> Earlier, Hobza<sup>34</sup> and Li et al.<sup>19</sup> predicted a shift to blue of the N-H stretching frequency of type N-H...F-H at the MP2 level of calculations. However, Lu et al.<sup>35</sup> found years later an opposite trend of a red shift of the N-H stretching frequency for N-H...F-H complexes using density functional theory (DFT) computations. In an earlier study, Peters<sup>36</sup> reported on the formation of a hydrogen bond in the (HNO)<sub>2</sub> dimer, but did not pay much attention to the characteristic blue-shifting hydrogen bond. Liu et al.<sup>26</sup> recently examined the latter dimer in more detail.

We reported for the first time on the N-H blue shift in N-H...S complexes.<sup>24</sup> In the present theoretical study, we fo-

cus on the intrinsic characteristics of isolated monomers in an attempt to probe the origin of structural changes, rather than on those of the dimers. In addition, it is also established that both HNO and HNS molecules containing a N-H bond can act as either a proton donor or a proton acceptor, which is important in many processes such as pollution formation, energy release, etc.<sup>37</sup> Let us also mention that thionitrosyl hydrogen (HNS) has been generated in the gas phase,<sup>38</sup> and its molecular properties have been determined by subsequent theoretical studies.<sup>39</sup>

## Computational methods

Hydrogen-bond interactions of the (HNZ)<sub>2</sub> dimers were investigated using second-order Møller-Plesset perturbation (MP2) method in conjunction with both 6-311++G(2d,2p) and aug-cc-pVTZ basis sets. The latter basis includes higher polarization f functions on heavy atoms. Geometrical parameters of the two monomers and the three most stable complexes were also reoptimized using coupled-cluster with single and double excitations (CCSD) theory with the aug-cc-pVDZ basis set. Interaction energies were obtained using both MP2 and CCSD with triple excitations (CCSD(T)) methods, as the difference between the energies of the complexes and the respective monomers, and corrected for both zero-point energy (ZPE) and basis set superposition errors (BSSE) using the counterpoise procedure.<sup>40</sup> The ZPE corrections also included all the intermolecular frequencies. While MP2 total energies were obtained from the corresponding geometry optimizations, CCSD(T) electronic energies involved single point calculations with the aug-cc-pVTZ basis set at the CCSD/aug-cc-pVDZ geometries.

Hyperconjugation energy can be evaluated from the second-order perturbation energy of interaction.<sup>41</sup> Energy index,  $R_E$ , of the Z-X-H...Y H-bond is determined as follows:<sup>25,31</sup>

$$[1] \quad R_E = \frac{E_H^{(2)}}{E_{IM-C}^{(2)}}; \text{ in which } E_H^{(2)} = E^{(2)}[n(Y) \rightarrow \sigma^*(X-H)]$$

$$[2] \quad E_{IM-C}^{(2)} = E_{IM}^{(2)}[n(Z) \rightarrow \sigma^*(X-H)] - E_{IC}^{(2)}[n(Z) \rightarrow \sigma^*(X-H)]$$

$E_H^{(2)}$  stands for intermolecular hyperconjugation interaction energy.  $E_{IM}^{(2)}$  and  $E_{IC}^{(2)}$  denote intramolecular hyperconjugation interaction energies in the isolated proton donor and in the proton donor after complex formation, respectively.  $E_{IM-C}^{(2)}$  is symbolled for the change of intramolecular hyperconjugation interaction energy of transferring electron density from the  $n(Z)$  lone pair to the  $\sigma^*(X-H)$  antibonding orbital in the proton donor before and after complexation. The calculated vibrational frequencies were retained unscaled. To avoid vibrational coupling between the N-H stretching modes in dimers HNO...HNO and HNS...HNS, harmonic frequencies were calculated using some isotopomers. Calculations were carried out using the Gaussian 03 package.<sup>42</sup> Electron density,  $\rho(r)$ , and the Laplacian of the electron density,  $\nabla^2(\rho(r))$ , at the bond critical points (BCPs) were performed at the MP2/6-311++G(2d,2p) level using the AIM2000 program.<sup>43</sup> The natural bond orbital (NBO) analysis was also performed making use of the GenNBO 5.G<sup>44</sup>

program for all monomers and complexes at the same MP2/6-311++G(2d,2p) level.

## Results and discussion

### Geometries, frequencies, and infrared intensities

The shape of the three dimers, A, B, and C, identified on the potential energy surface (PES) at the MP2/6-311++G(2d,2p), MP2/aug-cc-pVTZ, and CCSD/aug-cc-pVDZ levels, is displayed in Fig. 1. Both dimers A and C have high point group symmetry ( $C_{2h}$ ) whereas the dimer B possesses a lower point group ( $C_s$ ). Changes of geometrical parameters following dimer formation are gathered in Table 1. Along with the changes in selected bond length, the changes in their stretching frequency and infrared intensity are tabulated in Table 2. Intermolecular distances, angles, and interaction energies upon complexation are also given in Table 3. The trends of the changes determined using the methods mentioned above are similar both qualitatively and quantitatively. In general, the changes of bond lengths of the complex relative to the respective monomer resulting from MP2 using the aug-cc-pVTZ basis set are slightly larger than those obtained by the 6-311++G(2d,2p) set. As a consequence, the changes in the relevant stretching frequencies are smaller with the 6-311++G(2d,2p) basis set than with the aug-cc-pVTZ one.

Interaction energies are similar using the MP2 method, in spite of the much larger aug-cc-pVTZ basis set (cf. Table 3). Interaction energies evaluated with both ZPE and BSSE corrections at CCSD(T)/aug-cc-pVTZ are slightly larger than those obtained at MP2/aug-cc-pVTZ for complexes A and B, but marginally smaller for C. For the purpose of comparison with previous studies using MP2 calculations, only the MP2/aug-cc-pVTZ values are given hereafter. We refer to Tables 1 and 2 for detailed comparison. We use mÅ, which denotes  $10^{-3}$  Å, as a shorthand unit for distance changes. With such a unit, the changes occurring in bond lengths are very small, but in view of the equally small effects induced by the H-bond formation, a variation of a few mÅ can already be considered to be significant.

There is a contraction of 4.1 mÅ of the N3–H5 bond in A, as compared with the monomer HNO. On the other hand, elongation of N3–H5 bonds is predicted for both B and C, as compared with HNS. It is ~2.4 mÅ for the elongation of the N3–H5 bond length in C, which is larger than that in B (~0.2 mÅ). Simultaneously, the N6–H1 bond lengths are shortened upon complexation, by 4.1 and 2.4 mÅ for A and B, respectively, while a smaller elongation of 2.4 mÅ for this bond is obtained in C. Such shifts can be considered as relatively large but consistent with the expected properties of H-bonded systems. All N6=O2 and N3=O4 bonds are elongated, and a slight contraction is noted for N6=S2 and N3=S4 bonds in the dimers considered (Table 1). Therefore, it is clear that the change of the N–H bond length is inversely proportional to the change of the N=Z double bond length in HN=Z whether the Z atom is O or S. The largest contraction of the N3–H5 and N6–H1 bonds in A is associated with a significant increase of their stretching frequencies, amounting to  $80\text{ cm}^{-1}$ . On the contrary, the elongation and the decrease in stretching frequencies of the N3–H5 and N6–H1 bonds are observed in C. The

N3–H5 and N6–H1 bond lengths are both elongated by ~2.4 mÅ, leading to a decrease of  $31\text{ cm}^{-1}$  in their stretching frequencies. For the mixed dimer B, it is worth mentioning that there is an increase by  $\sim 16\text{ cm}^{-1}$  in the N3–H5 stretching frequency, although a very small elongation is predicted, by ~0.2 mÅ. As pointed out in previous papers,<sup>32,45</sup> one should be careful in classifying a hydrogen bond as being blue or red shifting on this basis, because such a small variation upon complexation strongly depends on the level of theory applied. Therefore, it is not yet conclusive to classify the N3–H5 bond in B.

As mentioned in the introduction, contraction of a covalent N–H bond has seldom been detected due to its polarity. In a few remarkable cases, N–H blue shifts with different magnitudes have recently been predicted for both dihydrogen- and hydrogen-bond complexes.<sup>23–33</sup> For a dihydrogen bond, such as in the complex pairing  $\text{BH}_3\text{NH}_3$  with  $\text{HNO}$ ,<sup>31</sup> the N–H frequency undergoes a large blue shift of  $128\text{ cm}^{-1}$ . A moderate N–H blue shift has also been obtained in complexes between  $\text{YH}_2\text{NH}_2$  (Y = B, Al) and  $\text{HNZ}$  (Z = O, S).<sup>32</sup> Significantly strong N–H blue shifts have been found in some hydrogen-bonded complexes of  $\text{HNO-HNO}$ ,<sup>26</sup>  $\text{CH}_3\text{CHO-HNO}$ ,<sup>28</sup>  $\text{HOX-HNO}$  with X = F, Cl, Br,<sup>29</sup>  $\text{CH}_3\text{X-HNO}$  with X = F, Cl, Br,<sup>30</sup>  $\text{RCHZ-HNO}$  with R = H, F, Cl, Br and Z = O, S,<sup>24</sup>  $\text{CHX}_3\text{-HNO}$  with X = F, Cl, Br,<sup>23</sup> and  $\text{HNO-HCONH}_2$ ,<sup>46</sup> which amount up to  $\sim 100\text{ cm}^{-1}$ . A comparable frequency blue shift of  $80\text{ cm}^{-1}$  along with a contraction of 4.1 mÅ of N3–H5 and N6–H1 bonds in the N–H...O type is also obtained in this work, which is significant but consistent with the values reported in ref. 23. In addition, there are a contraction and an increase in the stretching frequency of the N6–H1 bond in the N–H...S type in B. Such a blue shift of the N–H stretching frequency has only been recently revealed.<sup>24</sup> Comparing the N–H...O and N–H...S types of bonds, we found that contraction of the N–H bond length and increase of their stretching frequency are larger for the former than for the latter. This is likely due to the larger basicity at the S site in HNS with respect to that at the O site in HNO. Indeed, calculated proton affinities at O of HNO and at S of HNS amount to 528 and 688  $\text{kJ mol}^{-1}$ , respectively, at the MP2/aug-cc-pVTZ + ZPE level.

As seen from both Tables 1 and 2, the N–H bond length shortening and its blue shift are larger in HNO than in HNS. This difference is due to the larger polarity of N–H bond in HNS, which makes it more difficult to be contracted and shifted to blue. The calculated N–H deprotonation enthalpy of  $1535\text{ kJ mol}^{-1}$  in HNS is lower than that of  $1586\text{ kJ mol}^{-1}$  in HNO. This obtained result implies that the N–H bond is more polarized in HNS than in HNO.

A blue-shifting X–H...Y bond usually shortens the X–H distance and decreases the X–H stretching IR intensity. On the other hand, elongating the X–H bond and increasing its stretching IR intensity are usually observed for a red-shifting hydrogen bond. Indeed, a similar trend is obtained for all N–H bonds in the three dimers considered. Particularly, a consequent decrease in IR intensity by  $\sim 69\text{--}73\text{ km.mol}^{-1}$  is accompanied by a significant contraction of the N6–H1 and N3–H5 bonds in A, and of the N6–H1 bond in B upon, complexation (Tables 1 and 2). Likewise, an increase of  $82\text{ km mol}^{-1}$  in IR intensity is accompanied by an elongation of both the N3–H5 and N6–H1 bonds in C. However, it is

remarkable that an increase in IR intensity of the N3–H5 vibration is also predicted in the mixed dimer B in spite of an increase of the N3–H5 stretching frequency. This amounts to 40 km mol<sup>−1</sup> with a slight increase of 16 cm<sup>−1</sup> and a negligible elongation of 0.2 mÅ. Our results, either obtained in this work or reported in previous papers,<sup>23,24,32</sup> and the data reported by other authors,<sup>47</sup> demonstrated that IR intensity can actually be increased even when an increase in stretching frequency upon complexation occurs. Hence, the change of IR intensity appears to depend on the inherent property of the monomer rather than on that of the resulting dimer.

### Complexation energies and topological analyses

Table 3 shows that the N6–H1...Z4 and N3–H5...Z2 (Z = O, S) intermolecular contacts result in quite stable six-membered cyclic structures in the examined dimers. Indeed, interaction energies with only ZPE correction are −9.5, −9.8, and −12.2 kJ mol<sup>−1</sup> at the MP2/6-311++G(2d,2p) level, and −10.3, −11.5, and −15.2 kJ mol<sup>−1</sup> at the MP2/aug-cc-pVTZ level for A via B to C, respectively. With both ZPE and BSSE corrections, they amount to −6.0, −6.2, and −7.8 kJ mol<sup>−1</sup> by MP2/6-311++G(2d,2p), −7.9, −8.8, and −11.9 kJ mol<sup>−1</sup> by MP2/aug-cc-pVTZ, and −9.1, −9.4, and −11.4 kJ mol<sup>−1</sup> at CCSD(T)/aug-cc-pVTZ in going from A, and B to C, respectively. The dimer A contains two N–H...O hydrogen bonds (cf. Fig. 1 and Table 3). After including all corrections considered, an average value of binding energy per N–H...O hydrogen bond can roughly be estimated to be from ~3.0 kJ mol<sup>−1</sup> (MP2/6-311++G(2d,2p)) to 3.9 kJ mol<sup>−1</sup> (MP2/aug-cc-pVTZ) to 4.6 kJ mol<sup>−1</sup> (CCSD(T)/aug-cc-pVTZ) in A. Similarly, an average value of binding energy per N–H...S hydrogen bond is from ~3.9 kJ mol<sup>−1</sup> (MP2/6-311++G(2d,2p)) to 6.0 kJ mol<sup>−1</sup> (MP2 and CCSD(T) with aug-cc-pVTZ) in C. Accordingly, the N–H...S hydrogen bond is somewhat stronger than the N–H...O counterpart. However, the presence of a N–H...S bond in the mixed dimer (B) causes a decrease in binding energy of the N–H...O bond as compared to that of A, by ~0.7 (MP2/6-311++G(2d,2p)) to 1.0–1.2 kJ mol<sup>−1</sup> (MP2 and CCSD(T) with aug-cc-pVTZ). Data obtained at both levels of theory, with and without BSSE corrections, all concur with each other showing that C is the strongest dimer in terms of binding energy, followed by B and then by A.

The distances of R(H...Z) are slightly longer by the MP2/6-311++G(2d,2p) calculation than those from MP2/aug-cc-pVTZ (Table 3). It is interesting that C is considerably more stable with respect to A, despite the fact that the R(H...Z) intermolecular distances in A are shorter than in C. The  $\alpha_1$  and  $\alpha_3$  bond angles in C are less bent from linearity than those in A, in particular, the  $\alpha_1$  and  $\alpha_3$  angles in C are more linear than that in A by 19°–21°. The smaller deviation from linearity results in a stronger orbital overlap, and as a consequence, the dimer C becomes more stable than A. In the same vein, A is less stable than B in terms of binding energy, which results from the smaller magnitude of  $\alpha_3$  angle, by ~15° as shown in Table 3. The stability ordering of the dimers in going from A to B to C has an intimate relationship with the increase in  $\alpha_1$  and  $\alpha_3$  angularities. Hence, it can be suggested that the strength of the complexes considered here is in part determined by the  $\alpha_1$  and  $\alpha_3$  bond

angles over the R(H...Z) intermolecular distances. Simultaneously, there is a tiny deviation of  $\alpha_2$  and  $\alpha_4$  angles in all three dimers. The R(H1...Z4) and R(H5...Z2) intermolecular distances in three optimized dimers fall within the range of 2.27–2.80 Å, from both methods. These are all shorter than the sum of the van der Waals radii of the H and S atoms (being 3.05 Å) and of the H and O atoms (being 2.60 Å).

The stability ordering of the three dimers and the properties of the H bonds in these dimers can further be understood using the maps of total electron density, which is emphasized by underlying intermolecular interactions. The 0.011 au isosurfaces of total electron density calculated at the MP2/6-311++G(2d,2p) level are plotted in Fig. 2. The relatively large intersection regions of the total electron density between intermolecular contacts such as N6–H1...Z4 and N3–H5...Z2 (Z = O, S) give an obvious indication of the electron-donating character of the lone pairs on the Z2 and Z4 atoms to the electron deficient  $\sigma^*(\text{N6–H1})$  and  $\sigma^*(\text{N3–H5})$  antibonding orbitals. As shown in Fig. 2, the largest intersection region of the total electron density is observed for the N6–H1...S4 and N3–H5...S2 intermolecular contacts in C, followed by the N6–H1...S4 and N3–H5...O2 ones in B, and then for N6–H1...O4 and N3–H5...O2 ones in A. This leads to the fact that C is the most stable dimer, and A the least stable one.

To probe further into the formation of hydrogen bonds in the studied dimers, a topological analysis was carried out by making use of atom in molecules (AIM) theory<sup>48</sup> at the MP2/6-311++G(2d,2p) level. Three of eight AIM criteria are also applied to characterize the hydrogen bond in the examined systems.<sup>49</sup> A bond path with a bond critical point between the proton and proton acceptor exists for the N6–H1...Z4 and N3–H5...Z2 intermolecular contacts (Fig. 3). The topological parameters of bond critical points (BCPs) and ring critical points (RCPs) are gathered in Table 4. There exists a RCP in one complex, which evidently indicates a ring structure in one examined dimer. The values of electron density  $\rho(r)$  (~0.011 au) and Laplacians  $\nabla^2(\rho(r))$  (~0.04 au) of BCPs also fall within the suggested ranges for a hydrogen bond,<sup>49</sup> in such a way that the N6–H1...Z4 and N3–H5...Z2 intermolecular contacts are obviously classified as hydrogen bonds. They are further confirmed on the basis of  $\nabla^2(\rho(r)) > 0$  and  $H_C > 0$  as suggested by Cremer and Kraka<sup>50</sup> and Rozas et al.,<sup>51</sup> and  $-V_C/G_C < 1$  as suggested by Grabowski et al.<sup>52</sup> for medium and weak interactions. Evaluating the contributions of the highest occupied molecular orbital (HOMO) and the innermost valence MO's to hydrogen bond interaction in three dimers are also given in Figure S4 of the Supplementary data.

### NBO analysis

An NBO analysis was carried out at the MP2/6-311++G(2d,2p) level and the selected results are summarized in Table 5. An electron density transfer (EDT) occurs from the HNS → HNO in B (for both A and C, the EDT values are equal to zero, due to symmetry). Recently, some authors<sup>18,19,53</sup> suggested that upon complexation, a change of electron density in the  $\sigma^*(\text{X–H})$  orbital is the result of a combination of two effective factors, namely, an intermolecular hyperconjugation increases the electron density in the  $\sigma^*(\text{X–H})$  orbital, while a decrease in intramolecular hyper-

conjugation tends to decrease the electron density in the  $\sigma^*(X-H)$  orbital. Table 5 points out that the electron densities in both  $\sigma^*(N3-H5)$  and  $\sigma^*(N6-H1)$  orbitals of A decrease with a uniform value of 0.0019 e, implying that a strong decrease of intramolecular hyperconjugation overrides intermolecular hyperconjugation. Indeed, while the intramolecular hyperconjugation energies,  $E(n(O4) \rightarrow \sigma^*(N3-H5))$  and  $E(n(O2) \rightarrow \sigma^*(N6-H1))$ , decrease by up to 10 kJ mol<sup>-1</sup>, the intermolecular hyperconjugation energies,  $E(n(O2) \rightarrow \sigma^*(N3-H5))$  and  $E(n(O4) \rightarrow \sigma^*(N6-H1))$ , are approximately 6 kJ mol<sup>-1</sup>. Decreases of electron density in both  $\sigma^*(N3-H5)$  and  $\sigma^*(N6-H1)$  orbitals strengthen the respective N3–H5 and N6–H1 bonds, and thereby contribute to a blue shift of the corresponding stretching frequencies. On the contrary, increases of electron densities are observed in both  $\sigma^*(N3-H5)$  and  $\sigma^*(N6-H1)$  orbitals ( $\sim 0.0071$  e) in C. The strong intermolecular hyperconjugation (evaluated at  $\sim 18$  kJ mol<sup>-1</sup>) from the  $n(S2)$  lone pair to the  $\sigma^*(N3-H5)$  orbital, and from the  $n(S4)$  lone pair to the  $\sigma^*(N6-H1)$  orbital appears to exceed the smaller decrement of the intramolecular hyperconjugation energy (being  $\sim 5$  kJ mol<sup>-1</sup>). This leads to

an increase in occupation of the  $\sigma^*(N3-H5)$  and  $\sigma^*(N6-H1)$  orbitals, and results in an elongation of the N3–H5 and N6–H1 bonds along with a decrease in their stretching frequencies in C. Furthermore, very slight to moderate increases in electron densities are also observed in the  $\sigma^*(N3-H5)$  and  $\sigma^*(N6-H1)$  orbitals for B (Table 5). The larger value of intermolecular hyperconjugation interaction energy (11 kJ mol<sup>-1</sup>), which is due to a transfer from  $n(S4)$  to  $\sigma^*(N6-H1)$  with respect to a significant decrease of intramolecular  $n(O2) \rightarrow \sigma^*(N6-H1)$  hyperconjugation (10 kJ mol<sup>-1</sup>), causes a moderate increase in occupation of the  $\sigma^*(N6-H1)$  orbital. Likewise, a transfer (evaluated at 8 kJ mol<sup>-1</sup>) of electron density from  $n(O2)$  to  $\sigma^*(N3-H5)$ , despite a decrease (6 kJ mol<sup>-1</sup>) of intramolecular hyperconjugation energy, appears to play an important role in the small increase in occupation of the  $\sigma^*(N3-H5)$  orbital.

For A, electrons are basically transferred from  $n(O4)$  to  $\sigma^*(N6-H1)$ , then most electrons in  $\sigma^*(N6-H1)$  are transferred to  $n(O2)$  and then a part in  $n(O2)$  is transferred to  $\sigma^*(N3-H5)$ , and, finally, most electrons in  $\sigma^*(N3-H5)$  are transferred back to  $n(O4)$ . As a result, these transfers give

**Note:** The  $n$  index denotes for lone pairs on the Z atom; the positive value of EDT means that there is a transfer of electron density from HNS to HNO; the delta ( $\Delta$ ) symbolizes a change of the complex relative to the monomer.

rise to a decrease of electrons available for  $\sigma^*(\text{N6-H1})$  and  $\sigma^*(\text{N3-H5})$  orbitals, and the  $n(\text{O2})$  and  $n(\text{O4})$  lone pairs (cf. Table 5).

For C, most electrons are transferred to the  $\sigma^*(\text{N3-H5})$  and  $\sigma^*(\text{N6-H1})$  orbitals because of the weak electron density redistribution effect of HNS. This results in a large increase of occupation in both  $\sigma^*(\text{N3-H5})$  and  $\sigma^*(\text{N6-H1})$ , and a significant decrease of electron density in  $n(\text{S2})$  and  $n(\text{S4})$  (cf. Table 5).

For B, the changes of electron density in  $\sigma^*(\text{N6-H1})$  and  $\sigma^*(\text{N3-H5})$  and  $n(\text{O2})$  and  $n(\text{S4})$  can be explained as follows: Firstly, electrons are initially transferred from the  $n(\text{S4})$  to  $\sigma^*(\text{N6-H1})$  as suggested by the larger value (11 kJ mol $^{-1}$ ) of  $E(n(\text{S4}) \rightarrow \sigma^*(\text{N6-H1}))$  energy as compared to  $E(n(\text{O2}) \rightarrow \sigma^*(\text{N3-H5}))$  (8 kJ mol $^{-1}$ ), and then a small part is transferred to  $n(\text{O2})$ . As a consequence, an electron increase in the  $\sigma^*(\text{N6-H1})$ ,  $n(\text{O2})$ , and  $\sigma^*(\text{N3-H5})$  orbitals are induced, along with a strong decrease in occupancy of  $n(\text{S4})$  (cf. Table 5).

The obvious difference in electron redistribution can only be understood if one considers properties of the isolated HNO and HNS monomers. Calculated properties of the HNO and HNS monomers show that for HNO, the hyperconjugative  $E(n(\text{O}) \rightarrow \sigma^*(\text{N-H}))$  interaction amounts to up to 74 kJ mol $^{-1}$  and the electron number in the  $\sigma^*(\text{N-H})$  orbital is substantial, being 0.029 e. For HNS, the hyperconjugative  $E(n(\text{S}) \rightarrow \sigma^*(\text{N-H}))$  interaction energy is relatively small (34 kJ mol $^{-1}$ ), and the occupation in the  $\sigma^*(\text{N-H})$  orbital is only 0.015 e. Furthermore, the  $a$  index in the  $sp^a$  hybridization of the N atom in HNO (3.98) is larger than that in HNS (3.18). In addition, the polarization of the N-H bond in HNO is lower than that in HNS as NBO charges on N

(0.04 e) and H (0.26 e) atoms in HNO are sensibly different from those -0.69 e (N) and 0.33 e (H) in HNS. The remarkable difference of both HNO and HNS isolated monomers has recently been reported.<sup>28</sup> Hence, a more intensive electron redistribution is observed in the isolated monomer that possesses a lower bond polarization, higher electron occupancy in the  $\sigma^*(\text{N-H})$  orbital, larger  $a$  index, and larger intramolecular hyperconjugation.

Within a more chemical perspective, the hyperconjugation  $n(\text{Y}) \rightarrow \sigma^*(\text{X-H})$  can be balanced by an increase of the s-character and polarization of the X-H bond<sup>8</sup> to induce a difference between the blue shift and red shift of a hydrogen bond. Normally, a feature is that the X atom becomes more electronegative, and the H atom more electropositive, leading to an increase of the X-H bond polarity, when a blue-shifting hydrogen bond is formed. However, the present results show that in all dimers, A, B, and C, the H1 and H5 atoms become more positive ( $\sim 0.02$ – $0.03$  e), whereas the net charges on the N3 and N6 atoms decrease by  $\sim 0.01$ – $0.03$  e, irrespective of a blue- or red-shifting hydrogen bond. These results are similar to some previous reports on a decrease of the negative charge on the X atom.<sup>24,32,54</sup>

An increase in positive charges on H1 and H5 results in simultaneous increases in the s-character of the N3 and N5 hybrid orbitals in the N3-H5 and N6-H1 bonds, which is consistent with Bent's rule,<sup>55</sup> and contributes to the contraction of their distances. This means that the stretching frequencies of both N3-H5 and N6-H1 bonds could be expected to be shifted to blue in all three dimers examined. However, such a blue shift is only observed in A, and a red shift is found in C.

In summary, both the decrease in electron densities due to

an intensive electron redistribution and increase in s-characters (decreasing of the  $a$  index) of the N3 and N6 atoms in A tend to contribute to contractions of the N3–H5 and N6–H1 bonds, that are accompanied by blue shifts of their stretching frequencies. On the other hand, the strong intermolecular hyperconjugation, overriding the weak intramolecular hyperconjugation, leads to increases of electron densities in the  $\sigma^*(\text{N3–H5})$  and  $\sigma^*(\text{N6–H1})$  orbitals. This results in distance elongation, a stretching frequency decrease of the N3–H5 and N6–H1 bonds in C, even though there are large increases in s-characters (decreasing of the  $a$  index in  $\text{sp}^a$  hybridization) and a moderate increase of positive net charges at the H1 and H5 atoms. For the mixed dimer B, the small elongation of the N3–H5 bond length, relative to monomer, is due to a slight increase of occupation in the  $\sigma^*(\text{N3–H5})$  orbital, plus overwhelming increases of rehybridization of the N3 hybrid orbital and a positive net charge at H3. In contrast, a blue shift is observed for the N6–H1 bond even though there is a tiny increase in population of the  $\sigma^*(\text{N6–H1})$  orbital (0.003 e). Therefore, contraction of the N6–H1 length and increase of its stretching frequency are seemingly correlated with the increase of s-character at the N6 hybrid orbital of the N6–H1 bond.

According to the definition of the energy index,  $R_E$ , given in eq. [1], it can be used to describe the strength of the electron redistribution. In general, the smaller the  $R_E$  value, the stronger the density redistribution. It means that a blue shift occurs with a small  $R_E$ , and vice versa. Indeed, our calculated results coincide well with this prediction. For both N3–H5 and N6–H1 bonds, the smallest  $R_E$  value (0.55) is obtained for A and the largest  $R_E$  (3.67) is predicted in C. More moderate values of  $R_E$  are observed for these bonds in B, in particular, the larger value for N3–H5 (1.42) and the smaller one for the N6–H1 bond (1.09). Overall, the  $R_E$  parameter can be used as a convenient index to classify the hydrogen bond in these systems.

## Concluding remarks

Dimerization of HNZ leads to stable six-membered cyclic dimers whose interaction energies calculated including both ZPE and BSSE corrections are in the range of –8, –9, and –11 kJ mol<sup>–1</sup> for the dimers (HNO)<sub>2</sub> (A), (HNO–HNS) (B), and (HNS)<sub>2</sub> (C), respectively. The dimer A uniformly exhibits two blue shifts of N3–H5 and N6–H1 stretching frequencies. The red shifts are consistently observed for both the N3–H5 and N6–H1 bonds in the dimer C. Upon complexation, contraction of the N6–H1 bond length as well as increase of its stretching frequency are found in the mixed dimer B. However, the N3–H5 bond length is predicted to be elongated, and its stretching frequency and infrared intensity increase accordingly. Both the rehybridization and decrease of electron density in the  $\sigma^*(\text{N3–H5})$  and  $\sigma^*(\text{N6–H1})$  orbitals contribute to the large N–H blue shifts in A. The red shifts are observed for both N–H bonds in C, due to a large increase of electron density in the  $\sigma^*$  orbitals, exceeding rehybridization at the N3 and N6 atoms. The rehybridization at the N6 atom, which overcomes an increase of occupation in the  $\sigma^*(\text{N6–H1})$  orbital, plays an important role in the blue shift of the N6–H1 bonds in B. An electron increase in the  $\sigma^*(\text{N3–H5})$  orbital mainly determines an elongation of this

bond. It appears that whether a blue shift or red shift actually occurs in hydrogen-bonded complexes is more dependent on the proton donor partner.

# Regaining the Woodward–Hoffmann rules for chelotropic reactions via conceptual DFT

Pablo Jaque, José V. Correa, Frank De Proft, Alejandro Toro-Labbé, and Paul Geerlings

**Abstract:** In our continuous effort to retrieve the Woodward–Hoffmann rules from conceptual density functional theory (DFT), we have examined the last type of pericyclic reactions, i.e., chelotropic reactions. Both the initial hardness response and the dual descriptor have been investigated to predict the allowed and forbidden character for the addition of SO<sub>2</sub> to butadiene ( $4n$  system) and 1,3,5-hexatriene ( $4n + 2$  system). It is shown that with both electronic descriptors, the conrotatory/disrotatory mode for the linear and nonlinear mechanisms are retrieved based on a density-only approach, free from consideration of orbital and (or) wave function symmetry. The dual descriptor moreover reveals that stabilizing interactions are presented only for the linear path, which can be considered as an overall favourable mechanism for a chelotropic reaction.

**Key words:** chelotropic reactions, Woodward–Hoffmann rules, conceptual DFT.

**Résumé :** Dans le cadre de nos travaux pour récupérer les règles de Woodward–Hoffmann à partir de la théorie de la fonctionnelle de la densité conceptuelle, on a étudié le dernier type de réactions péri-cycliques, à savoir les réactions chélotropes. On a étudié tant la réponse initiale de la dureté que le descripteur dual pour prédire le caractère permis et interdit pour l'addition du SO<sub>2</sub> sur le butadiène (système  $4n$ ) et hexa-1,3,5-triène (système  $4n + 2$ ). Il est démontré que pour les deux descripteurs électroniques, on peut retrouver le mode conrotatoire/disrotatoire pour les mécanismes linéaires et non linéaires en se basant uniquement sur une approche de densité, sans prendre en considération l'orbitale et (ou) la symétrie de la fonction d'onde. De plus, le descripteur double ne révèle l'existence d'interactions stabilisantes que pour la voie linéaire qui peut être considérée comme le mécanisme global le plus favorable pour une réaction chélotrope.

**Mots-clés :** réactions chélotrope, règles de Woodward–Hoffmann, théorie de la fonctionnelle de la densité conceptuelle (« DFT » conceptuelle).

## Introduction

The Woodward–Hoffmann (WH) rules<sup>1</sup> have played an unprecedented role in predicting/rationalizing the outcome of chemical reactions on the basis of a quantum chemical approach.<sup>2,3</sup> Formulated in the late sixties and based on a highly approximate, semi-empirical MO method, the extended Hückel theory,<sup>4</sup> developed by one of the two fathers of the rules, the WH rules enabled the practicing organic chemist to predict the allowedness/forbiddenness and the associated

stereochemical implications of four types of pericyclic reactions: cycloadditions, electrocyclizations, sigmatropic, and chelotropic reactions.<sup>1</sup>

Fundamental in the approaches developed by Woodward and Hoffmann is the principle of orbital conservation: an orbital, occupied or unoccupied in the reactants, retains its symmetry towards the symmetry operations associated to the geometry of the transition state (TS), when passing from the reactants, through the TS to the products. So, this approach is pervaded by the symmetry or nodal structure of

the orbital and (or) the symmetry of the total wave function to which they combine. These aspects and the concurrent use of correlation diagrams have also been pointed out independently in the pioneering work by Longuet-Higgins.<sup>5</sup>

In recent years, density functional theory<sup>6</sup> (DFT) gained widespread appreciation for its computational efficiency to study the properties and reaction paths for systems of varying complexity, thus entering the fields of organic, inorganic, and biochemistry, including transition-metal chemistry and catalysis. Based on the famous Hohenberg and Kohn theorems,<sup>7</sup> and when casted into the elegant Kohn–Sham formalism,<sup>8</sup> DFT nowadays plays the role of a computational workhorse used by, e.g., most practicing organic chemists when investigating reaction paths and calculating reaction and activation energies.<sup>9</sup> This highlights the role of the electron density function  $\rho(\vec{r})$  as the fundamental carrier of information of a much simpler nature than the extremely complex wave function depending on the three spatial- and single-spin coordinate of all the electrons of the system.

On the other hand, under the impetus of Parr and co-workers, DFT also paved the way for rigorous and sharp definitions of a variety of well-known but often vaguely defined concepts, such as electronegativity ( $\chi$ ), hardness ( $\eta$ ), and softness ( $S$ ), enabling their numerical evaluation. This branch of DFT, called conceptual DFT by its founding father,<sup>10</sup> has been a flourishing subfield for about 25 years, leading to the introduction of new concepts (e.g., Fukui function,<sup>11</sup> electrophilicity,<sup>12</sup> and the dual descriptor<sup>13</sup>) used as such or within the context of principles such as the electronegativity equalization principle,<sup>14</sup> the hard and soft acids and bases principle, and the maximum hardness principle.<sup>15</sup>

A true avalanche of papers have appeared since the mid 1990s presenting further extensions and applications mostly on (generalized) acid/base reactions,<sup>16</sup> including the majority of organic addition/substitution/elimination reactions. Remarkably up to a few years ago, two types of reactions remained unstudied in a conceptual DFT context: redox reactions and pericyclic reactions. Both types of reactions constituted a major line of research in our group in recent years,<sup>17</sup> leading among others to a successful interpretation of the WH rules for cycloadditions, electrocyclizations, and sigmatropic reactions.<sup>18</sup>

The aim of the present paper is to present the results on the fourth type of pericyclic reactions: the chelotropic reactions, and so this study can be seen as the final cornerstone of our endeavour to link pericyclic reactions to conceptual DFT.

Chelotropic reactions were defined by Woodward and Hoffmann as pericyclic reactions in which two  $\sigma$  bonds are formed or broken on a single atom in a concerted manner. Classical examples are the addition of sulfur dioxide ( $\text{SO}_2$ ) and carbenes ( $\text{CR}_2$ ) to a polyene forming a cyclic system due to the formation of two  $\sigma$  bonds. There are two possible mechanisms for the addition leading to different selection rules and stereochemical outcomes (see Table 1): in a linear chelotropic reaction, the attacking small molecule lies in a plane perpendicular to that of the polyene and bisects its central C–C bond, whereas in the nonlinear case, the plane of the attacking molecule no longer bisects the central C–C bond of the polyene but is rotated so that, for example in  $\text{SO}_2$ , the O–O axis parallels the C–C bond.

**Table 1.** Generalized Woodward–Hoffmann rules for chelotropic reactions.

$\pi$ -Electron number	Linear pathway	Nonlinear pathway
$4n$	Disrotatory	Conrotatory
$4n + 2$	Conrotatory	Disrotatory

## Methodology

The methodology is similar to the one adopted in our previous studies on cycloadditions, electrocyclizations and sigmatropic reactions. Two conceptual-DFT-based reactivity descriptors are used: the initial hardness response, which has been advocated by us on the basis of Zimmerman's<sup>19</sup> alternative approach to the WH rules, stressing the importance of the aromaticity of the TS as a criterion for allowedness or forbiddenness of a reaction. On this basis, the slope of the hardness vs. the reaction coordinate curve (initial hardness response) was proposed as a reactivity indicator; the higher the slope (more positive or less negative) the higher the tendency of the system to select this reaction path.<sup>18</sup> A model reaction coordinate  $R$  is thereby chosen to reduce the computational complexity of the few calculations needed for the numerical evaluation of the slope at the onset of the reaction ( $\partial\eta/\partial R$ ) (note that also and precisely at the onset or the beginning of the reaction, the replacement of the full reaction coordinate by a model coordinate is justified).

The quantity is evaluated numerically at the onset of the reaction in a finite difference approach. The hardness itself, the second derivative of the energy  $E$  with respect to the number of electrons  $N$ , at constant external (i.e., due to the nuclei) potential<sup>20</sup>

$$[1] \quad \eta = \frac{1}{2} \left( \frac{\partial^2 E}{\partial N^2} \right)_{v(\vec{r})}$$

is evaluated also in a finite difference approach as

$$[2] \quad \eta = \frac{I - A}{2}$$

where  $I$  and  $A$  are the vertical ionization energy and electron affinity, respectively.<sup>16</sup> Invoking Koopman's theorem yields

$$[3] \quad \eta \approx \frac{\varepsilon_{\text{LUMO}} - \varepsilon_{\text{HOMO}}}{2}$$

where  $\varepsilon_{\text{HOMO}}$  and  $\varepsilon_{\text{LUMO}}$  are the frontier molecular orbital energies. This approach was followed in the present version.

The hardness response is in fact a third-order derivative in the hierarchy of response functions characterizing the sensibility of a system's energy when it is perturbed in its external potential  $v(\vec{r})$  and (or) its number of electrons  $N$ , the basic variables in the so-called perturbational approach to chemical reactivity.<sup>6,16</sup>

In this approach, the change in energy upon perturbation in  $N$  and (or)  $v(\vec{r})$  can be written as

$$[4] \quad dE = \left( \frac{\partial E}{\partial N} \right)_{v(\vec{r})} dN + \int \left( \frac{\delta E}{\delta v(\vec{r})} \right)_N \delta v(\vec{r}) d\vec{r} + \left( \frac{\partial^2 E}{\partial N^2} \right)_{v(\vec{r})} dN^2 + \dots$$

where the first derivative (the electronic chemical potential,

$\mu$ )<sup>21</sup> has been identified as the negative of the electronegativity,  $\chi$ , the functional derivative  $(\delta E/\delta v(\vec{r}))_N$  has been identified as the electron density, and the second derivative  $(\partial^2 E/\partial N^2)_{v(\vec{r})}$  has been identified as the hardness (vide supra). The initial hardness response can now obviously be written as  $(\partial^3 E/\partial N^2 \partial R)$ , where  $R$  stands for the model reaction coordinate, highlighting its third-order derivative character.

An alternative approach was followed in our previous studies on pericyclic reactions<sup>18</sup> by concentrating on the following local (i.e.,  $\vec{r}$ -dependent) descriptor

$$[5] \quad f^{(2)}(\vec{r}) = \left( \frac{\partial f(\vec{r})}{\partial N} \right)_{v(\vec{r})}$$

indicating how the Fukui function changes at each position when the total number of electrons  $N$  is changing. As the Fukui function itself is defined as the first derivative of  $\rho(\vec{r})$  with respect to  $N$

$$[6] \quad f(\vec{r}) = \left( \frac{\partial \rho(\vec{r})}{\partial N} \right)_{v(\vec{r})}$$

$f^{(2)}(\vec{r})$  can be written as the following third-order derivative

$$[7] \quad f^{(2)}(\vec{r}) = \left( \frac{\partial^3 E}{\delta v(\vec{r}) \partial N^2} \right)$$

In a frozen-core approximation, it is easily seen that

$$[8] \quad f^{(2)}(\vec{r}) \approx |\phi_{\text{LUMO}}(\vec{r})|^2 - |\phi_{\text{HOMO}}(\vec{r})|^2$$

indicating that  $f^{(2)}(\vec{r})$  highlights the difference in densities between the LUMO and HOMO, giving a “one-shot” picture of nucleophilic and electrophilic regions, hence its name, the dual descriptor. It was shown that both for intra- and inter-molecular pericyclic reactions, the process proceeds along a path favouring the overlap of positive and negative regions of  $f^{(2)}(\vec{r})$ : favourable chemical reactions occur when regions that are good electron acceptors ( $f^{(2)}(\vec{r}) > 0$ ) are aligned with regions that are good electron donors ( $f^{(2)}(\vec{r}) < 0$ ).<sup>13,18b</sup> Note that it has been shown by some of the present authors that the two descriptors presented above, the initial hardness response (global in nature, i.e.,  $\vec{r}$ -independent) and the local dual descriptor are intimately related, in the sense that  $f^{(2)}(\vec{r})$  can be written as

$$[9] \quad f^{(2)}(\vec{r}) = \left( \frac{\delta \eta}{\delta v(\vec{r})} \right)_N$$

and that in the case where changes in  $v(\vec{r})$  are provoked by changes in nuclear configurations only, it can easily be seen that

$$[10] \quad \left( \frac{\partial \eta}{\partial R} \right)_N = \int f^{(2)}(\vec{r}) \frac{\partial v(\vec{r})}{\partial R} d\vec{r}$$

This indicates that the general information in  $f^{(2)}(\vec{r})$  is refined via  $(\frac{\partial v(\vec{r})}{\partial R})_N$  to result in the initial hardness response.

As both the dual descriptor and the initial hardness response turned out to be successful in interpreting electrocyclizations, cycloadditions, and sigmatropic reactions, we

decided to apply this same “dual” approach to the remaining type of pericyclic reaction: the chelotropic reaction.

We turned to one of the prototypes of chelotropic reactions:<sup>1–3</sup> the extrusion of  $\text{SO}_2$  from sulfonene or higher sulfones yielding butadiene (a  $4n$  system) and 1,3,5-hexatriene (a  $4n + 2$  system), respectively.

For computational reasons, both reactions were considered in the reverse direction. The principle of microscopic reversibility indeed re-assures identical outcomes concerning allowedness or forbiddenness irrespective of the direction considered.

All calculations were performed at the DFT level, using the B3LYP<sup>22,23</sup> functional for geometry optimization and the PBE<sup>24</sup> functional for single-point calculations for the initial hardness response combined with a split-valence double-zeta plus polarization basis set, 6–31G(d,p).<sup>25</sup> The PBE functional is used as we prefer to work in the spirit of the Tozer–De Proft approach. As we also did in previous work in this series<sup>18c</sup> for the evaluation of hardness, pure density functionals are preferred, as in this case discontinuity problems are approximately cancelled.<sup>26,27</sup> All of these calculations were done using the Gaussian 03 program.<sup>28</sup>

## Results and discussion

### Initial hardness response

When considering the particular situation of  $\text{SO}_2$  attacking on, e.g., butadiene, it should be noticed that in a molecular orbital (MO) picture, filled and vacant frontier MOs involved in bonding to a diene (or triene) are situated on the same atom. This situation yields a picture for the dual descriptor (Fig. 1) reminiscent of that of the singlet carbenes<sup>29</sup> or silylenes<sup>30</sup> studied in depth in our group.

The geometry of the linear chelotropic reaction is shown in Fig. 2, where  $\text{SO}_2$  attacks the polyene (in case of butadiene, a  $4n$  system) lying in a plane perpendicular to the polyene plane and bisecting its central C–C bond.

The initial hardness profile (where  $\eta$  was computed as indicated in eq. [3]) together with the energy profile (based on a model reaction coordinate involving the dihedral angle between the  $\text{CH}_2$  groups and the rest of the diene) are given in Fig. 3. It is clear that the energetically less-favoured conrotatory mode is the one that has the less negative  $(\partial \eta/\partial R)$  slope, i.e., leads to the “faster” loss of hardness upon reaction. All these observations are in line with the WH rules stating that a  $4n$  system prefers a disrotatory mode for a linear approach.

Passing now to the nonlinear case, Fig. 4 shows that the  $\text{SO}_2$  molecule approaches the diene molecule in a plane no longer bisecting the central C–C bond of the polyene. The

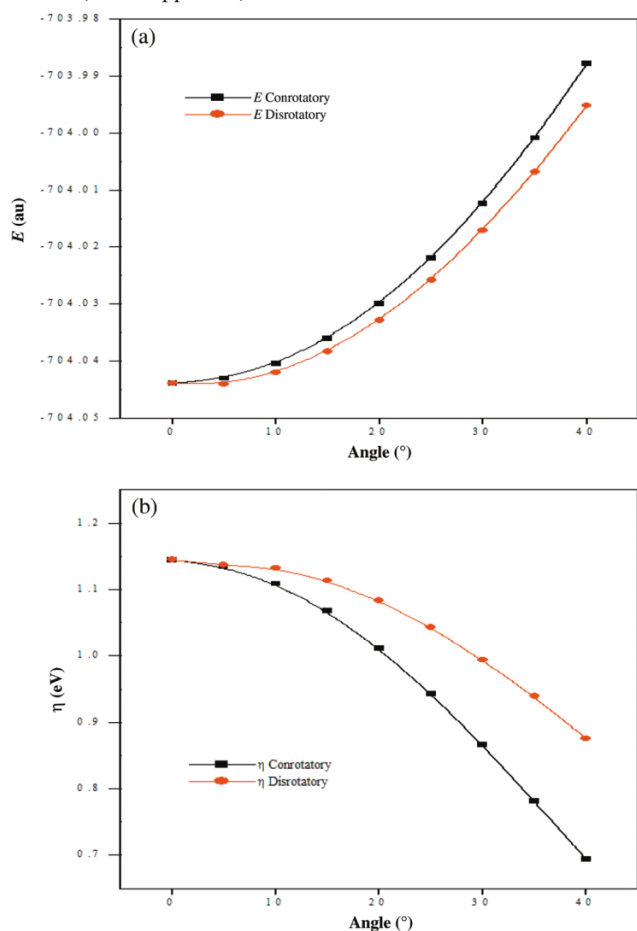

**Fig. 1.** Frontier molecular orbital maps: (a) HOMO ; (b) LUMO (where negative phases are indicated in blue and positive phases are displayed in red); and (c) the dual descriptor map for SO<sub>2</sub>; electrophilic or acidic sites ( $f^2(\vec{r}) > 0$ ) and nucleophilic or basic sites ( $f^2(\vec{r}) < 0$ ) are indicated in red and blue, respectively.

**Fig. 2.** Linear chelotropic reaction: the case of a  $4n$  system (butadiene–SO<sub>2</sub>).

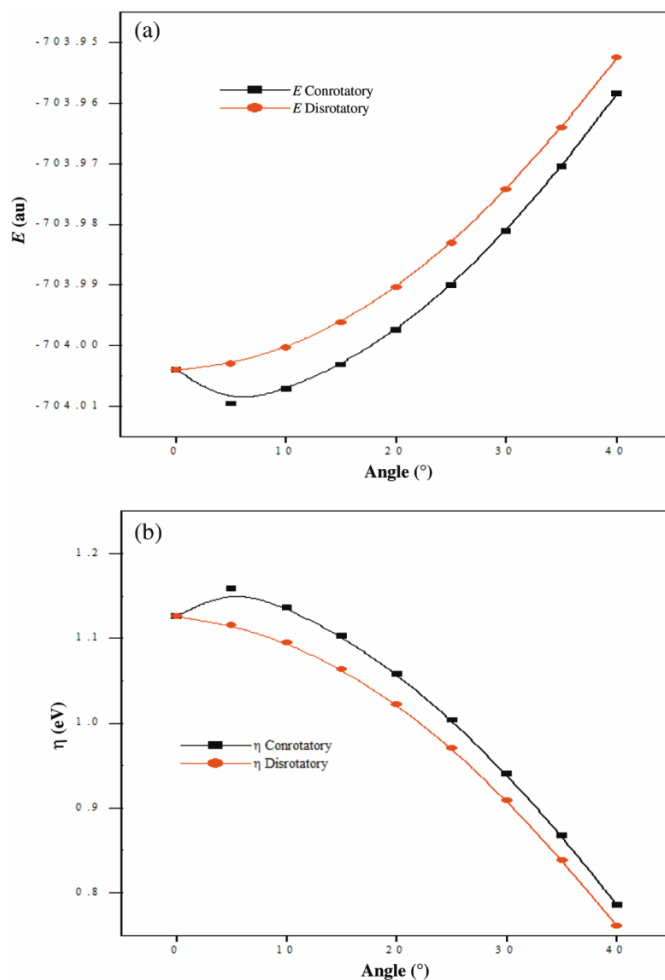

**Fig. 3.** (a) Energy and (b) hardness profiles for the butadiene–SO<sub>2</sub> reaction (linear approach).

**Fig. 4.** Nonlinear chelotropic reaction: the case of a  $4n$  system (butadiene–SO<sub>2</sub>).

**Fig. 5.** (a) Energy and (b) hardness profiles for the butadiene–SO<sub>2</sub> reaction (nonlinear approach).

energy and hardness curves now show the inverse behaviour to the linear case (Fig. 5) with the disrotatory mode preferred on the basis of both energy and initial hardness response, in line with the inversion of the WH rules when passing from a  $4n$  to a  $4n + 2$  polyene.

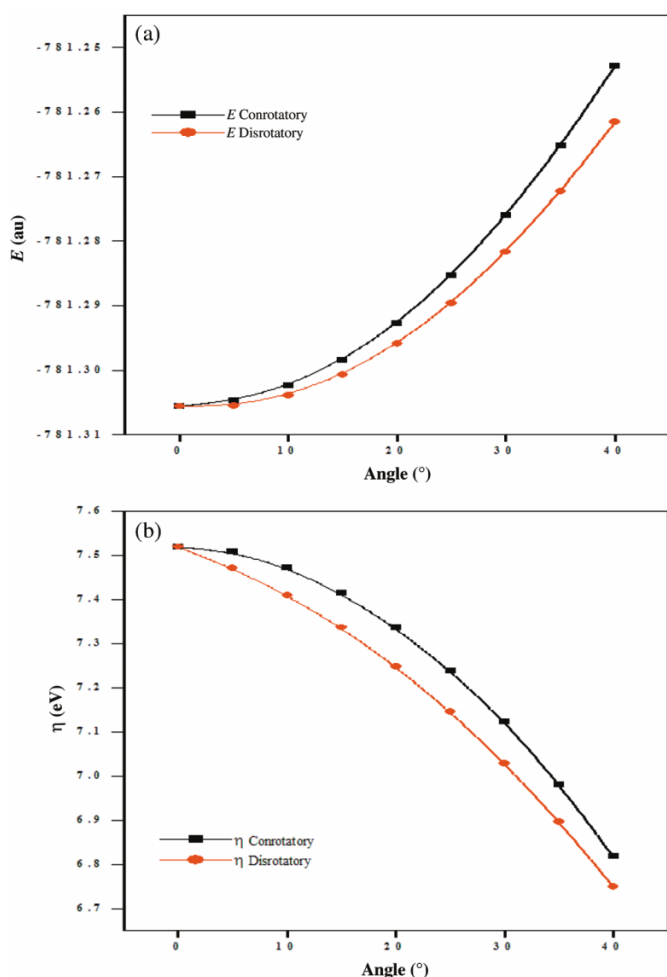

This analysis has also been carried out on the chelotropic reaction between SO<sub>2</sub> and a  $(4n + 2)$  system in both reactive attacks, linear, and nonlinear, as displayed in Figs. 6–9.

Notice that in both cases, the disrotatory mode is more favourable from the energetic point of view, whereas the

**Fig. 6.** Linear chelotropic reaction: the case of a  $(4n + 2)$  system (1,3,5-hexatriene-SO<sub>2</sub>).

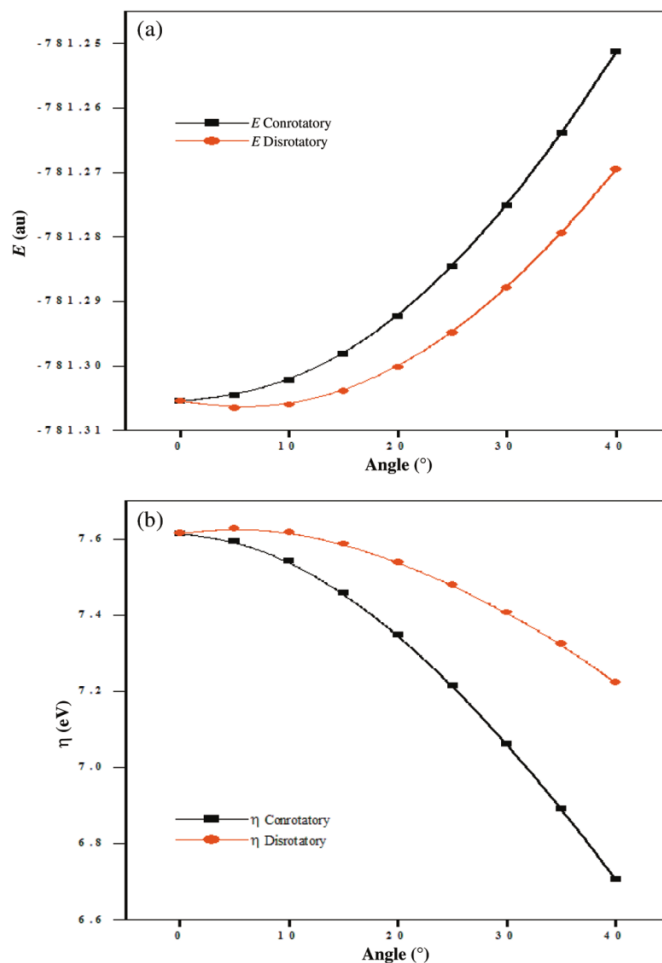

**Fig. 7.** (a) Energy and (b) hardness profiles for the 1,3,5-hexatriene-SO<sub>2</sub> reaction (linear approach).

**Fig. 8.** Nonlinear chelotropic reaction: case of a  $(4n + 2)$  system (1,3,5-hexatriene-SO<sub>2</sub>).

**Fig. 9.** (a) Energy and (b) hardness profiles for the 1,3,5-hexatriene-SO<sub>2</sub> reaction (nonlinear approach).

chemical hardness helps to discriminate between the conrotatory vs. disrotatory modes. An inverse sequence for both the linear and nonlinear mechanisms as compared with the chelotropic reaction between SO<sub>2</sub> and the  $4n$  system is found, in agreement with the WH rules.

### The dual descriptor

In Fig. 10, we depict the dual descriptors of both butadiene and SO<sub>2</sub> represented as counterplots, using colour codes. Red corresponds a positive  $f^{(2)}(r)$  value and blue to a

negative value, i.e., electrophilic and nucleophilic regions, respectively. In the case of the linear approach to butadiene, it is immediately seen that stabilizing interactions are at work between the central C<sub>2</sub>-C<sub>3</sub> region and the terminal C atoms with the lone pair region of SO<sub>2</sub>, and, more importantly, between the C<sub>1</sub>-C<sub>2</sub> and C<sub>3</sub>-C<sub>4</sub> regions of the diene and the empty p orbital region of SO<sub>2</sub>, further optimized by a disrotatory movement of the diene. In other words, the analysis based on the dual descriptors reveals that the linear approach is favoured by a synergism (resembling the so-called  $\sigma$ -donation/ $\pi$  back-donation phenomenon in metal-

**Fig. 10.** The dual descriptor maps for the reactants (butadiene + SO<sub>2</sub>) for the linear approach; electrophilic ( $f^{(2)}(r) > 0$ ) and nucleophilic ( $f^{(2)}(r) < 0$ ) regions are indicated in red and blue, respectively.

**Fig. 11.** The dual descriptor maps for the reactants (butadiene + SO<sub>2</sub>) for the nonlinear chelotropic approach; electrophilic ( $f^{(2)}(r) > 0$ ) and nucleophilic ( $f^{(2)}(r) < 0$ ) regions are indicated in red and blue, respectively.

ligand bonding) driving the disrotatory movement of the CH<sub>2</sub> groups.

Turning finally to the nonlinear case, the  $4n$  system shows in fact only destabilizing interactions (see Fig. 11) between the lone pair of SO<sub>2</sub> and the C<sub>1</sub>–C<sub>2</sub> and C<sub>3</sub>–C<sub>4</sub> regions and the empty p orbital of the S atom and the C<sub>2</sub>–C<sub>3</sub> region and terminal C atoms. The system will only gain stabilization when these destabilizing interactions are reduced, for instance, through a conrotatory movement of the terminal

CH<sub>2</sub>, leading to the conjecture that these reactions are less favoured than their analogues in the linear case.

This is in agreement with the computational data, indicating that upon trying to locate a TS for the nonlinear approach, the system spontaneously evolves to a linear approach geometry. To our knowledge and from the experimental point of view,<sup>31</sup> no clear cut evidence has been presented for cases in which such a nonlinear approach is the preponderant mechanism.

**Fig. 12.** The dual descriptor maps for the reactants (1,3,5-hexatriene + SO<sub>2</sub>) for the linear approach; same colour codes as in Fig. 10.

**Fig. 13.** The dual descriptor maps for the reactants (1,3,5-hexatriene + SO<sub>2</sub>) for the nonlinear approach; same colour codes as in Fig. 10.

The dual descriptor maps for the reaction between SO<sub>2</sub> and 1,3,5-hexatriene are given in Figs. 12 and 13 for the linear and nonlinear path, respectively. A behaviour opposite to that of the  $4n$  system is observed.

## Conclusions

Two DFT-based reactivity descriptors, the initial hardness response and the dual descriptor turn out to be successful in predicting/interpreting the allowedness/forbiddenness of cheletropic reactions in the linear and nonlinear approaches. Combined with our earlier positive results for the three other types of pericyclic reactions (electrocyclizations, cycloadditions, and sigmatropic reactions), this study leads to the con-

clusion that the WH rules, essentially based on orbital and wave function symmetry, can be retrieved in a “density-only” context using conceptual-DFT-based descriptors. This finding highlights the basic role of the electron density, which, despite of its much simpler mathematical form (function of three variables) as compared with the wave function (function of  $4N$  variables), is shown to carry the necessary information to regain the celebrated WH rules based on the symmetry of the wave function.

# A computational study of methanol-to-hydrocarbon conversion — Towards the design of a low-barrier process

Bun Chan and Leo Radom

**Abstract:** Computational quantum chemistry has been employed to examine the production of ethylene with methanol-to-hydrocarbon (MTH) processes via a carbon pool mechanism. We find that the M05-2X functional performs well for the types of reactions that are involved. The methylation reactions of the aromatic cocatalyst are the most energy-demanding steps in the process. For the subsequent production of C<sub>2</sub>H<sub>4</sub>, we have identified a low-energy pathway that involves multiple methyl shifts, followed by concerted deprotonation and C<sub>2</sub>H<sub>4</sub> elimination. The substitutions of the Al and Si atoms in the participating Si–OH–Al moiety of zeolite catalysts with Ga and Ge do not lead to lower barriers for the methylation reactions, nor does the use of a more electron-rich aromatic cocatalyst. However, we find that the use of two cocatalysts, a nucleophile and an aromatic carbon pool, can provide an overall low-energy pathway for the MTH process.

**Key words:** methanol-to-hydrocarbon (MTH) process, zeolite catalysis, computational chemistry.

**Résumé :** On a fait appel à des calculs de chimie quantique impliquant un mécanisme de mise en commun du carbone pour examiner la production d'éthylène par le procédé du méthanol à hydrocarbure (MAH). On a trouvé que la fonctionnelle M05-2X donne de bons résultats pour les types de réactions impliquées. Les réactions de méthylation de la portion aromatique du cocatalyseur sont les étapes qui requièrent le plus d'énergie. Pour la production subséquente du C<sub>2</sub>H<sub>4</sub>, on a identifié une voie de basse énergie qui implique de multiples déplacements de groupes méthyles, suivis d'une déprotonation concertée avec une élimination de C<sub>2</sub>H<sub>4</sub>. Les substitutions des atomes d'aluminium et de silicium de la portion Si–OH–Al participante des catalyseurs comportant du Ga et du Ge ne conduit pas à des barrières énergétiques inférieures pour les réactions de méthylation et c'est aussi le cas lorsqu'on utilise un cocatalyseur aromatique plus riche en électron. Toutefois, on a trouvé que l'utilisation de deux cocatalyseurs, un nucléophile et une mise en commun de carbones aromatiques, peut conduire à une voie de faible énergie globale pour le procédé du MAH.

**Mots-clés :** procédé du méthanol à hydrocarbure (MAH), catalyseur de zéolite, calculs de chimie quantique.

## Introduction

The limited supply of crude oil and the adverse environmental impact of its combustion have led to an increasing interest in alternative sources of energy. One of the most discussed alternatives is the use of hydrogen as the energy carrier.<sup>1</sup> However, there are still many obstacles to the realization of a hydrogen economy, one of which is the problem of dealing with a gas-phase fuel.<sup>2</sup> A methanol economy has been proposed as another alternative.<sup>3</sup> In this scenario, CO<sub>2</sub> is recycled and reduced to give methanol as a convenient and efficient energy carrier. We have previously used computational quantum chemistry to explore the catalytic hydrogenation of CO<sub>2</sub> to methanol by zeolites, and have found low-energy paths for such an approach to carbon fixation.<sup>4</sup>

Petroleum is not only a widely used fuel but it also pro-

vides a number of aliphatic and aromatic hydrocarbons as chemical feedstocks for a wide variety of industrial processes.<sup>5</sup> Thus, an efficient method for methanol-to-hydrocarbon (MTH) transformation would also be advantageous. Such a chemical transformation can be achieved with the use of zeolite catalysts.<sup>6</sup> The carbon pool mechanism is currently considered to be the dominant pathway for MTH processes.<sup>7</sup> According to this mechanism, an aromatic species (Ar) acts as a catalyst and is polymethylated and undergoes multiple internal rearrangements in the course of generating alkene products:

The complete catalytic process is complex but theory can

<sup>2</sup>Corresponding author (e-mail: radom@chem.usyd.edu.au).

potentially provide useful insights into the mechanism. For instance, the production of isobutene from methanol via a ring contraction/expansion “paring” pathway<sup>8</sup> has been modeled.<sup>9</sup> The results show that the methylation reactions of the aromatic species are the most energy-demanding steps in the calculated catalytic cycle. There have also been computational studies<sup>10</sup> indicating that in MTH processes with an “exocyclic” mechanism,<sup>11</sup> the formation of the alkene product involves high-energy intermediates and transition structures and is rate limiting.

While these theoretical studies have identified barriers of as much as 160 kJ mol<sup>-1</sup> for some of the steps involved in MTH processes,<sup>9,10b</sup> the overall reactions are generally exothermic, driven by the formation of water. For instance, the reactions leading to the formation of ethene, propene, and isobutene from methanol ( $n = 2, 3$ , and  $4$  in eq. [1]) have reaction enthalpies of  $-21.2$ ,  $-90.1$  and  $-165.2$  kJ mol<sup>-1</sup>, respectively.<sup>12,13</sup> As a result, improvements in catalysis can potentially lead to greatly reduced energy requirements for MTH processes, and possibly include the associated benefits of achieving higher selectivities and longer lives for the catalysts under milder reaction conditions.

We have been interested for some time in studying transition-metal-free catalysis of hydrogenation processes.<sup>4,14</sup> In particular, we have investigated the zeolite-catalyzed hydrogenation of CO<sub>2</sub> to give methanol.<sup>4</sup> We find that appropriately designed zeolites can provide excellent catalysis for this conversion.

In the present study, we examine the zeolite-catalyzed MTH process that produces ethene via an exocyclic pathway. We aim to reevaluate the reaction mechanism and identify the high-barrier steps in the overall process, and then target these steps to explore the possibility of lower-energy alternatives. We hope that our work will contribute to achieving effective conversion of CO<sub>2</sub> to hydrocarbons using environmentally benign catalysts, and in turn, advance the prospects of a methanol economy.

## Computational details

Standard ab initio molecular orbital theory and density functional theory calculations<sup>15</sup> were carried out with the GAUSSIAN 03,<sup>16</sup> GAUSSIAN 09,<sup>17</sup> and MOLPRO 2006<sup>18</sup> programs. Models representing cavities of the MFI (ZSM-five: zeolite Socony Mobil-five) structure<sup>19</sup> were constructed by extracting an 8T-cluster from the literature crystal structure.<sup>20</sup> Dangling bonds were saturated with hydrogen atoms, whose locations were obtained through optimizations with the PM3 semi-empirical procedure with the heavy atoms being frozen.

For the zeolites and related complexes and transition structures, geometries were obtained at the B3-LYP/6-31+G(d,p) level of theory, with the terminal hydrogen atoms of the 8T-clusters being frozen. Improved relative energies were obtained at the B3-LYP and M05-2X<sup>21</sup> levels with the G3MP2Large<sup>22</sup> basis set. We have inspected the vibrational frequencies of the transition structures for an indication that they link the appropriate adjacent minima.

We have also briefly examined the reaction profile of smaller 2T-clusters to probe the electronic effect of cluster size on the reaction profile. The terminal OSiH<sub>3</sub> groups in

the 8T-clusters of the optimized structures for the zeolites, and related complexes and transition structures, were replaced with hydrogen atoms in these calculations. Lengths of 1.490 and 1.618 Å were used for the Si–H and Al–H bonds, respectively.<sup>23</sup> Single-point energies at the M05-2X/G3MP2Large and G3(MP2)-RAD<sup>24</sup> levels were then obtained for the resulting structures with the 2T-clusters.

Geometrical parameters within the text are B3-LYP/6-31+G(d,p) values, while relative energies correspond to vibrationless M05-2X/G3MP2Large values, unless otherwise noted. In specific cases, zero-point vibrational energies (ZPVEs), and thermal corrections to enthalpy ( $\Delta H$ ) and entropy ( $S$ ) at 298 K, derived from B3-LYP/6-31+G(d,p) frequencies, were incorporated into the relative energies. Literature scaling factors<sup>25</sup> were used in the evaluation of ZPVEs (0.9857),  $\Delta H$  (1.0062), and  $S$  (1.0099) from the calculated B3-LYP harmonic vibrational frequencies.

## Results and discussion

### General

The zeolite models and the aromatic cocatalysts examined in this study are listed in Fig. 1. HZ0-2T and HZ0 are 2T- and 8T-cluster models for H-ZSM-5, respectively. We have previously found that the substitution of Si atoms by Ge can somewhat lower the barrier for the zeolite-catalyzed hydrogenation of CO<sub>2</sub>.<sup>4</sup> Likewise, in the present study we explore the possibility of an improved MTH catalysis by examining the model zeolites HZ1 and HZ2. In HZ1 the Al atom that is adjacent to the acidic OH in HZ0 is substituted by Ga, while in HZ2 the Si atom that is adjacent to the acidic OH is replaced by Ge.

We use *p*-xylene (Ar0) as a prototypical model for the aromatic cocatalyst in the carbon pool mechanism for the MTH process. Since the MTH process involves carbocation intermediates, stabilization with  $\pi$ -electron-donating groups can potentially lead to a more facile set of reactions. Thus, we examine 5,6-dimethyl-1,3-benzodioxole (Ar1), which includes two  $\pi$ -electron-donating alkoxy groups, as an alternative aromatic cocatalyst. Although Ar1 serves as a convenient model for an electron-rich aromatic in our theoretical investigation, we recognize that complications might arise in its experimental usage.

The choice of cluster size for a model zeolite can have a substantial effect on the calculated properties.<sup>26</sup> While it has been demonstrated that relatively small clusters are able to capture the essential chemistry of zeolite reactions, the use of larger clusters has been found to lead to smaller calculated barriers for several types of reactions.<sup>26a,26b</sup> We, therefore, begin by investigating the effect of cluster size on the barrier for the methylation of the aromatic cocatalyst Ar0, which we find to be one of the most energy-demanding steps in the MTH process (see below).

In a recent study,<sup>9</sup> ONIOM(B3-LYP/6-31G(d):HF/6-31G(d)) calculations were employed to probe the complete catalytic cycle of an MTH process. Using a 46T-cluster model for H-ZSM-5, a barrier of 154.9 kJ mol<sup>-1</sup> was obtained for the ortho-methylation of *p*-xylene (Table 1). With the 8T-cluster HZ0, we find a barrier of 178.9 kJ mol<sup>-1</sup> for the ipso-methylation reaction at the B3-LYP/6-31G(d) level. Thus, at a comparable theoretical level and for a similar re-

**Fig. 1.** Model zeolites (HZ0-2T, HZ0, HZ1, and HZ2) and aromatic cocatalysts (Ar0 and Ar1) examined in this study.**Table 1.** Effect of cluster size and level of theory on the calculated barrier (via transition structure 1 (TS1)) for the zeolite-catalyzed ipso-methylation of *p*-xylene (Ar0) by methanol (kJ mol<sup>-1</sup>).

	HZ0-2T	HZ0 (8T)	46T
B3-LYP/6-31G(d)	212.6	178.9	154.9 <sup>a</sup>
B3-LYP/6-31+G(d,p)	210.0	175.7	
B3-LYP/G3MP2Large	201.2	175.4	
M05-2X/G3MP2Large	193.0	167.4	
G3(MP2)-RAD	195.4		

<sup>a</sup>ONIOM(B3-LYP/6-31G(d):HF/6-31G(d))/ONIOM(B3-LYP/6-31G(d):MND0) value for ortho-methylation from ref. 9.

action, our barrier obtained using the 8T-cluster model is 24.0 kJ mol<sup>-1</sup> higher than the value obtained with a 46T-cluster. The use of an even smaller 2T-cluster, HZ0-2T, leads to a further increase in the calculated barrier (to 212.6 kJ mol<sup>-1</sup>). Thus, our results are consistent with the previous findings that increasing cluster size leads to lower calculated barriers.<sup>26a,26b</sup>

Turning our attention to the effect of level of theory on the calculated barrier, we find that the use of the larger 6-31+G(d,p) and G3MP2Large basis sets with B3-LYP lead to somewhat lower barriers than that obtained with the 6-31G(d) basis set (Table 1), with the basis set effect being reduced for the larger 8T cluster. Of the four DFT levels examined, M05-2X/G3MP2Large gives the best agreement with our benchmark G3(MP2)-RAD value for the HZ0-2T-catalyzed process.

We have also compared the energy profile for the complete MTH process with the HZ0-2T cluster, as obtained at the three DFT levels, with that of the G3(MP2)-RAD benchmark (Table 2). We find that M05-2X/G3MP2Large gives the closest agreement for the barriers and reaction energies with the G3(MP2)-RAD values, with a mean absolute deviation (MAD) of 11.2 kJ mol<sup>-1</sup>, compared with 38.0 and 43.4 kJ mol<sup>-1</sup> for B3-LYP/G3MP2Large and B3-LYP/6-31+G(d,p), respectively. The large MADs for B3-LYP can be partly attributed to the poorer description of complexation. For instance, if one uses C1 + MeOH for the reference energy, the MADs for B3-LYP/6-31+G(d,p), B3-LYP/G3MP2Large, and M05-2X/G3MP2Large become 26.8, 18.3, and 12.4 kJ mol<sup>-1</sup>, respectively. Nonetheless, M05-2X/G3MP2Large provides a better compromise between accuracy and computational cost for this study.

### Mechanism of the MTH process catalyzed by HZ0 and *p*-xylene

The reaction profile for the HZ0-Ar0-catalyzed HTH process is shown in Fig. 2, and the transition structures (TS1–TS7) in the reaction scheme are displayed in Fig. 3.

The process begins with the HZ0-catalyzed methylation

of Ar0 by methanol (via TS1), giving the trimethyl-cyclohexadienyl cation intermediate (in the complex C2), followed by elimination of water. Abstraction of a proton from this cation by Z0<sup>-</sup> gives dimethyl-methylene-cyclohexadiene (C3 → C4 via TS2). A second catalytic methylation leads to the formation of the ethyl-dimethyl-cyclohexadienyl cation intermediate (C5 → C6 via TS3), followed again by elimination of water to give C7.

There are many feasible pathways for the elimination of the alkene product, i.e., C<sub>2</sub>H<sub>4</sub>, starting from C7.<sup>10,27</sup> These pathways often involve higher-energy cationic intermediates, associated with high barriers for their formation.<sup>10</sup> On the other hand, a concerted mechanism has been proposed (Fig. 4),<sup>27a</sup> in which the elimination of C<sub>2</sub>H<sub>4</sub> and the regeneration of Ar0 and HZ0 occur concurrently, without the participation of higher-energy cations. However, this pathway has not previously been examined in detail. Because it can potentially provide a lower-energy route to product formation, we have explored this possibility in the present investigation.

For the process shown in Fig. 2, the ethyl-dimethyl-cyclohexadienyl cation in C10 is required in the proposed concerted mechanism. The formation of this cation can be accomplished by multiple methyl migrations, starting from the cation in C7 (C7 → C8 → C9 → C10 via TS4, TS5, and TS6, respectively). The concerted deprotonation and elimination of C<sub>2</sub>H<sub>4</sub> to regenerate Ar0 and HZ0 via TS7 completes the catalytic cycle.

The calculated energy profile for the HZ0-Ar0-catalyzed MTH process and the barriers for the various steps, evaluated from the preceding minima, are shown in Table 3, which also includes free energies at 298 K. We realize that species that involve the zeolite models (HZ0 and Z0<sup>-</sup>) are optimized with structural constraints and, therefore, are not true minima on the potential energy surface. As a result, the inclusion of ZPVEs and thermal corrections for enthalpy and entropy, obtained from calculated harmonic frequencies, is not strictly correct from a theoretical point of view. However, as the same structural constraints are employed for the entire reaction profile, we anticipate substantial cancellation of errors, and that the free energies listed in the table can thus serve as reasonable estimates for the effect of thermal energies and entropies in the zeolite system.

The energies of the various points along the reaction profile span a range of 209.8 kJ mol<sup>-1</sup>, from the lowest point of -105.3 kJ mol<sup>-1</sup> for C1 + MeOH (Fig. 2) to the highest point of 104.5 kJ mol<sup>-1</sup> for TS3 + H<sub>2</sub>O (Fig. 3). We find that the two methylation reactions are the most energy demanding, with barriers of 167.4 and 134.3 kJ mol<sup>-1</sup> for the first (via TS1) and second (via TS3) methylation reactions, respectively. These are substantially higher than the next largest barrier of 64.6 kJ mol<sup>-1</sup> for the elimination of C<sub>2</sub>H<sub>4</sub> from C10 (via TS7), while the methyl shifts that precede

and somewhat higher barriers for most of the reactions (e.g.,  $180.8 \text{ kJ mol}^{-1}$  for  $\Delta G_1^\ddagger$ ). However, the general features for the process remain the same, with the methylation reactions being substantially more energy-demanding than the other reactions.

Thus, our results suggest that, upon methylation of the aromatic cocatalyst, internal methyl shifts, followed by concerted deprotonation and  $C_2H_4$  elimination, can provide a low-energy pathway for completing the catalytic cycle. The methylation reactions that generate the cationic intermediates and the deprotonated zeolite are rate limiting. We will explore various means to reduce the energy requirements for this reaction type in the next two sections.

### Effect of alternative zeolites and cocatalysts on the methylation barriers

In this section, we explore three alternatives to the prototypical HZ0-Ar0-catalyzed MTH process. Our focus is on the methylation reactions of the aromatic cocatalyst (i.e., for the steps up to C6 +  $H_2O$  in Fig. 2), since these represent the most energy-demanding steps.

The first two alternatives involve modified zeolite catalysts HZ1 and HZ2 (Fig. 1), whereby the Al and Si atoms in the Si–O–Al moiety in HZ0 are replaced, respectively, by Ga and Ge, in HZ1 and HZ2. The reaction profiles in these two cases are very similar to that for the HZ0-catalyzed process (Fig. 2). For the third alternative process considered in this section, a modified aromatic cocatalyst (Ar1) is employed. This leads to intermediates that are considerably different from those for the Ar0 process. The intermediates involved in the Ar1 process are shown in Fig. 5.

**Fig. 5.** Reaction profile for the HZ0-catalyzed methylation reactions of Ar1 by methanol.**Table 4.** Calculated energy profiles (kJ mol<sup>-1</sup>) for the methylation reactions of aromatic substrates Ar0 and Ar1, catalyzed by zeolites HZ0–HZ2.

		HZ0-Ar0	HZ1-Ar0	HZ2-Ar0	HZ0-Ar1

	$\Delta E_1^\ddagger$ (2 → 4)	167.4	170.9	177.3	160.7
	$\Delta E_2^\ddagger$ (5 → 7)	30.2	27.2	33.9	41.6
	$\Delta E_3^\ddagger$ (8 → 10)	134.3	136.3	127.2	131.9

The calculated energy profiles and the barriers for the HZ0-catalyzed methylation of Ar0, and for the three alternatives, are shown in Table 4. We find that neither HZ1 nor HZ2 improve the energies for the methylation reactions. In fact, either the substitution of Al by Ga (HZ1) or Si by Ge (HZ2) generally lead to higher methylation barriers for Ar0. This is in contrast to the results from our previous investigation on zeolite-catalyzed hydrogenation of CO<sub>2</sub>,<sup>4</sup> in which we found that substitution of an Si atom by Ge can lead to a lower barrier. On the other hand, the methylation reactions with Ar1 have somewhat lower barriers than those with Ar0.

Interestingly, the use of Ar1 leads to much greater stabilization for the cationic intermediates than for the transition structures. By comparing the energies for C2 + MeOH (Table 4, entry 4) for the two substrates, as well as those for C6 + H<sub>2</sub>O (Table 4, entry 10), we can see that the cationic intermediates derived from Ar1 are relatively more stable compared with those from Ar0 by more than 70 kJ

mol<sup>-1</sup>. In contrast, the greatest decrease in the methylation barriers is just 6.7 kJ mol<sup>-1</sup> for  $\Delta E_1^\ddagger$ .

In general, electron-donating groups can stabilize a cation by delocalizing the positive charge. Similarly, for reactions that lead to the formation of a cation, electron-donating groups generally stabilize the transition structure, as cationic character develops. Why do the additional electron-donating substituents in this case give rise to substantial stabilization for the cation but do not significantly lower the methylation barriers? To answer this question, we have examined the geometries of the transition structures for the methylation reactions. Figure 6 shows selected reactive sections of the transition structures (TS1) for the first methylation of Ar0 and Ar1, as prototypical examples for the HZ0-catalyzed methylation reactions. An intriguing feature for both transition structures is the long O...C distances for the breaking C–O bond of MeOH (2.273 and 2.181 Å for Ar0 and Ar1, respectively), as well as the long C...C distances for the C–

C bond that is being formed (2.066 and 2.114 Å for Ar0 and Ar1, respectively). In addition, the CH<sub>3</sub> moiety is almost planar in both transition structures.

Essentially, the transition structure in both cases is very loose, including a nearly fully-formed CH<sub>3</sub><sup>+</sup> cation. As a result, while the cationic intermediate produced from Ar1 is much more stable than the intermediate produced from Ar0, the transition structure for its formation benefits little from this additional stability. This provides a simple rationalization for the high energy requirements for the methylation reactions.

### Designing an improved MTH process with a second cocatalyst

With the knowledge that the high energy requirements for the methylation reactions are the consequence of kinetic rather than thermodynamic effects, can we design an improved process? We consider the use of a stronger nucleophile, THF in this case, in which the oxygen atom has a more concentrated electron density than the  $\pi$ -electrons in Ar0 and Ar1. The aim is that the higher nucleophilicity of THF might better stabilize the almost naked CH<sub>3</sub><sup>+</sup> cation in the transition structure, and give rise to a lower methylation barrier. While the practical use of THF in zeolite catalysis might involve complications such as the potential for its dehydration, THF serves as a convenient oxygen base for the theoretical testing of the above hypothesis.

Ideally, the base cocatalyst should be able to undergo multiple methylation, and it should be possible to eliminate the product alkene from the methylated intermediate. However, such processes are not possible with THF beyond the initial methylation. Thus, we have also examined the subsequent transfer of a CH<sub>3</sub><sup>+</sup> group from THFMe<sup>+</sup> to Ar0 and Ar1 and their monomethylated intermediates, so that the MTH process may follow through to completion. Thus, THF acts as a second cocatalyst in this mechanism.

The reaction profiles for the process leading up to the formation of the dimethylated intermediates are shown in Fig. 7. The initial methylation of THF (via TS8) gives the methylated THF cation (in the complex C13). The CH<sub>3</sub><sup>+</sup> group is then transferred to the aromatic cocatalyst (via TS9), and this is followed by deprotonation of the resulting cationic intermediate (via TS2) to give C4. The sequence of reactions, THF methylation and CH<sub>3</sub><sup>+</sup> transfer (this time via TS10), is then repeated to give the dimethylated aromatic intermediate (C17).

Table 5 shows the calculated energy profiles for the HZO-THF-catalyzed methylation processes of Ar0 and Ar1. It also shows the energy profile for the HZO-catalyzed methylation of Ar0 for comparison. The species in the HZO-THF-catalyzed processes span energy ranges of 220.6 and 215.7 kJ mol<sup>-1</sup>, for Ar0 and Ar1, respectively. The lowest-energy point on the energy profiles is Ar + C12 + MeOH (Table 5, entry 22) for both cases, where C12 is the HZO-MeOH-THF complex, while the highest energy point is TS10 + 2H<sub>2</sub>O (Table 5, entry 35), where TS10 is the transition structure for the second CH<sub>3</sub><sup>+</sup> transfer from THFMe<sup>+</sup> to Ar'. The energy ranges for these two processes, and the energies of the lowest and highest points along the pathways, are similar to those for the HZO-catalyzed process in the absence of THF. However, we find that the high barriers are eliminated when

**Fig. 6.** Selected bond distances (Å) in the transition structures (TS1) for the HZO-catalyzed methylation of (a) Ar0 and (b) Ar1. The zeolite moieties in the optimized structures are not shown.

THF is involved. Thus, the highest barriers for the HZO-THF-Ar0 and HZO-THF-Ar1 processes are 123.4 and 118.6 kJ mol<sup>-1</sup>, respectively, which are considerably lower than the highest barrier of 167.4 kJ mol<sup>-1</sup> for the HZO-Ar0 process.

While the highest barrier in the HZO-Ar0 process is found for the HZO-catalyzed methylation of Ar0, we find that the corresponding HZO-catalyzed methylation of THF has a much lower barrier of 99.3 kJ mol<sup>-1</sup>. This is consistent with our hypothesis that a more nucleophilic oxygen base favors the methylation reaction compared with  $\pi$ -electron nucleophiles. Instead, the highest barriers in the THF-catalyzed processes correspond to the transfer of CH<sub>3</sub><sup>+</sup> from the methylated THF cation to the aromatic substrates Ar0 and Ar1. Nonetheless, the barriers for the transfer reactions of CH<sub>3</sub><sup>+</sup> are still considerably lower than those for the HZO-catalyzed methylation of the aromatic substrates.

The reactive segments in the transition structures for the HZO-catalyzed methylation reactions of Ar0 and THF, and for the CH<sub>3</sub><sup>+</sup> transfer from THFMe<sup>+</sup> to Ar0 (in the presence of ZO<sup>-</sup>), are shown in Fig. 8. An intriguing observation in comparing the three transition structures is the short C...O distance between the CH<sub>3</sub><sup>+</sup> moiety and THF for the methylation of THF (Fig. 8b). This short distance, along with the nucleophilicity of the O atom, facilitates the stabilization of the CH<sub>3</sub><sup>+</sup> and the lowering of the barrier. We can see that the O...C distance in the ZO<sup>-</sup>-THFMe<sup>+</sup>-Ar0 reaction (Fig. 8c) is comparable to the corresponding distance in the HZO-MeOH-Ar0 reaction (Fig. 8a), and the C...C distance in the former is noticeably longer than that in the latter. The barrier for the CH<sub>3</sub><sup>+</sup> transfer (Fig. 8c) is nevertheless markedly lower. Presumably, this is due to ZO<sup>-</sup>-THFMe<sup>+</sup> being a better donor of CH<sub>3</sub><sup>+</sup> than HZO-MeOH.

Our results show that the use of THF as a "CH<sub>3</sub><sup>+</sup> sink" might lead to facilitation of the methylation of the aromatic cocatalyst, which is likely to be the most energy-intensive reaction in the MTH process. From a practical point of view, it would be more desirable to design a single aromatic cocatalyst that can be easily methylated. In this connection, we have briefly examined the thermodynamics for the various intermediates involved for methylation at oxygen in Ar1 (Fig. 9). Our results show that methylation at the oxygen atom of Ar1 is much less favorable than methylating the aromatic ring. This may be attributed to the delocalization of

**Fig. 7.** Reaction profile for the HZ0-THF-catalyzed methylation of Ar0 and Ar1.

the oxygen lone pair over the  $\pi$ -system, making it substantially less nucleophilic. Thus, among the processes examined in this study, the use of THF as an additional and more nucleophilic cocatalyst appears to provide the least energy intensive path for the MTH conversion.

### Concluding remarks

We have employed computational quantum chemistry to examine the production of  $\text{C}_2\text{H}_4$  in methanol-to-hydrocarbon (MTH) processes via an exocyclic carbon pool mechanism. The following principal findings have emerged from the present study.

The M05-2X functional performs well for the investigation of these reactions, with an MAD of  $11.2 \text{ kJ mol}^{-1}$ , compared with G3(MP2)-RAD, for the species involved in the MTH process. The use of 8T-clusters as models for zeolites appears to provide a good qualitative picture of the catalysis, but tends to overestimate the barriers in the MTH process.

In contrast to previous studies, we find that the methyla-

tion reactions of the aromatic cocatalyst are the most energy-demanding steps in the MTH process. We have identified a low-energy pathway to the production of  $\text{C}_2\text{H}_4$  from the methylated intermediates, which involves multiple methyl shifts, followed by concerted zeolite-catalyzed deprotonation and  $\text{C}_2\text{H}_4$  formation.

We find that the substitution of the SiOH group in our zeolite model with GeOH, or of AlOH with GaOH, does not lead to lower barriers for the methylation reactions. While the use of a more electron-rich aromatic cocatalyst greatly stabilizes the cationic intermediates, it does not provide significant benefit to the transition structures that lead to the formation of these intermediates. This can be attributed to the formation of an almost naked  $\text{CH}_3^+$  in the transition structure, regardless of the aromatic cocatalyst.

The use of a more nucleophilic substrate, such as THF, in the methylation reaction reduces the barrier significantly. We find that the resulting  $\text{THFMe}^+$  cation can also methylate an aromatic molecule with a significantly reduced barrier. Thus,

the combination of two cocatalysts, namely a nucleophile and an aromatic carbon pool, can potentially provide a low-energy pathway for the MTH process.

It would be advantageous to combine the nucleophile and

**Fig. 9.** Relative energies (kJ mol<sup>-1</sup>) for the methylation of Ar1 at various positions.

the aromatic carbon pool in a single molecule. However, our preliminary studies indicate that this is not entirely straightforward. We are currently undertaking further investigations, aiming to design an effective cocatalyst for the MTH process.

## TRIBUTE

Russell Jaye Boyd was born in 1945 in Kelowna, the centre of British Columbia's wine-producing and fruit-growing Okanagan Valley. His early years were devoted to hockey, basketball, baseball, golf, and water-related activities. Just before his fifteenth birthday, his family moved to New Westminster, where he attended Lester Pearson High School and began to show some interest in science and mathematics.

Russ enrolled in the Science program at the University of British Columbia in 1963 and graduated in 1967 with First-Class Honours in Chemistry and the Lefevre Gold Medal for highest standing in the Honours Chemistry program. His Honours thesis focused on the new technique of photoelectron spectroscopy. At the time, there were no commercial instruments and UBC had the only photoelectron spectrometers in Canada. With enthusiastic encouragement from his thesis supervisor, David C. Frost, Russ attempted to carry out the first study of the angular dependence of photoelectron emission. Despite the best efforts of the strong technical support team in the machine shop, two different designs failed to produce meaningful results. To obtain some positive results, Russ rounded up supplies of some boron trihalides and recorded their spectra.

As one of the first recipients of a 1967 Science Scholarship (introduced in 1967 by the National Research Council (NRC) of Canada to celebrate Canada's centennial), he went east to pursue his Ph.D. in Theoretical Chemistry at McGill University under the supervision of M.A. (Tony) Whitehead. As a consequence of the fact that he had recorded the photoelectron spectra of some boron trihalides (and some siloxanes) as an undergraduate, Russ realized that there was no theoretical framework for interpreting such spectra in the absence of electronic structure calculations. In 1967, reliable *ab initio* calculations were restricted to small molecules. In fact, the largest molecule in the 1967 compendium of *ab initio* calculations compiled by Morris Kraus is HCCN for which A.D. McLean and M. Yoshimine reported a single-point SCF calculation with a small basis set. In his first few months as a graduate student, Russ completed some semi-empirical molecular orbital calculations on the boron trihalides and sent the results to David Frost, which led to his first paper entitled "The Ionization Potentials of  $\text{BF}_3$ ,  $\text{BCl}_3$  and  $\text{BBr}_3$ ", in April 1968 in the first volume of *Chemical Physics Letters*.

The existing semi-empirical molecular orbital methods in 1967 were not capable of predicting the equilibrium geometries of molecules. All calculations were carried out at the experimental geometries or using assumed bond lengths and angles. Russ realized that this situation was unsatisfactory for studying reaction mechanisms and set out to develop a method that would yield molecular potential-energy surfaces and properties that agree with the experimental data. He developed a method based on the complete neglect of differential overlap approximation that had been introduced in 1965 by John Pople and his co-workers. He focused on equilibrium geometries, bond energies, and force constants (vibrational frequencies), the three chemically interesting properties associated with the minima of molecular potential-energy surfaces. This was an improvement over any other method that existed and was ultimately superseded by the work of Michael Dewar and his colleagues who used a slightly higher and chemically more reliable level of semi-empirical molecular orbital theory.

After defending his Ph.D. in 1971, Russ joined the group of

Charles A. Coulson in the Mathematical Institute at Oxford University as an NRC Postdoctoral Fellow. He had become disillusioned with semi-empirical approaches by the time he completed his thesis and saw more future in the *ab initio* approaches that John A. Pople and his group were developing within their Gaussian code. Russ turned his attention to electron correlation and published two papers with Coulson, including a description of the Coulomb hole in the first two excited states of the helium atom, his best-known paper from Oxford.

With encouragement from Charles A. McDowell, Russ returned to the University of British Columbia where he held a Killam Postdoctoral Fellowship in the Department of Chemistry from 1973 to 1975, where he renewed his interest in photoelectron spectroscopy. He published a single author letter in *Nature* in 1974 in which he pointed out that contrary to the usual interpretation of structural studies of porphyrin complexes, the lowest lying high-spin state of an atom (ion) in a given configuration is smaller than any state of lower spin. His prediction was verified two years later by scattering experiments on the first two excited states of the helium atom.

Russ joined Dalhousie University as an Assistant Professor of Chemistry in 1975 and rose through the ranks to become a Professor in 1985. He was named a Faculty of Science Killam Professor in 1997, and in 2001 he became the seventh Alexander McLeod Chair of Chemistry. The McLeod Chair, one of the oldest named professorships in chemistry in Canada, was created in 1884 in accordance with a bequest from Alexander McLeod. Russ served as Chair of Chemistry from 1992 to 2005. During this time, 11 new faculty members, including four outstanding senior chemists, were recruited, the graduate program expanded significantly, and an addition to the Chemistry Building was approved. The Department gained four Tier I Canada Research Chairs (Neil Burford, Jeff Dahn, Don Weaver, and Joe Zwanziger) between 2001 and 2003.

His research interests span a range of topics in computational and theoretical chemistry with an emphasis on problems relevant to biological systems. He has published about 240 research papers and 10 review chapters and he co-edited *The Quantum Theory of Atoms in Molecules* with Chérif Matta in 2007. With over 5000 citations of his papers and an H-index of 42, Russ is one of Canada's best-known computational chemists. He has supervised the research of 20 Ph.D. students, more than 25 postdoctoral fellows and senior visitors, and a comparable number of undergraduate students. His former students have successful careers in academic institutions, government laboratories, and the industry. Fourteen former members of his group hold academic appointments in Canadian universities and another eight hold similar appointments abroad. He is especially proud of the number of excellent young scientists who received a significant part of their training in his group.

Russ received the 1983 APICS/Fraser Medal. He was the first and only chemist to receive this prize, which was awarded in the 1970s and 1980s to recognize outstanding research work carried out in the Atlantic Provinces by a young scientist or engineer. His other awards include the Fellowship of The Chemical Institute of Canada (1983), the CNC-IUPAC Award (1986), Dalhousie University Senior Killam Fellowship (1989), and the 2009 Montreal Medal of The Chemical Institute of Canada.

Russ took on leading roles in organizing the Canadian Society for Chemistry Conferences in Halifax in 1981, 1990, and 2006. He was the principal organizer of the 8th Canadian Symposium on Theoretical Chemistry in 1983 and the 7th Canadian Computational Chemistry Conference in 2009. He is a member of the College of Reviewers of the Canada Research Chairs Program, and he has served on many committees of the Natural Sciences and Engineering Research Council of Canada (NSERC). He has served on selection panels for the National Science Foundation (NSF) of the USA and the Canada–US Fulbright Program. He has served on many boards, including the Canadian Society for Chemistry, the *Canadian Journal of Chemistry*, the Dalhousie University Foundation, the Atlantic Provinces Council on the Sciences, and the World Association of Theoretical and Computational Chemists. He was an editor of the *Canadian Journal of Chemistry* from 1988 to 1998 and served as President of the Canadian Society for Chemistry in 2007–2008. His many other

activities include Judge-in-Chief for the 1984 Canada-Wide Science Fair. He is currently the Principal Investigator (Research Director) for the Atlantic Computational Excellence Network (ACEnet), a consortium of nine universities in Atlantic Canada that provides high-performance computing facilities by means of funding from the Canada Foundation for Innovation (CFI).

The number, quality, and countries of origin of the papers submitted to this dedicated issue of the *Canadian Journal of Chemistry* attest to breadth and reach of Russ Boyd's influence in the computational and theoretical chemistry community in Canada and abroad, as well as his contributions to the broader chemical community.

**Neil Burford**  
*Halifax, Nova Scotia*

## HOMMAGE

Russell Jaye Boyd naît en 1945 à Kelowna, située au centre de la région viticole et fruitière de la vallée de l'Okanagan (Colombie-Britannique). Il consacre les premières années de sa vie au hockey, au basketball, au baseball, au golf et aux activités aquatiques. Peu de temps avant son quinzième anniversaire, sa famille déménage à New Westminster où il fréquente l'école secondaire Lester Pearson et commence à manifester un intérêt pour les sciences et les mathématiques.

En 1963, Russ s'inscrit au programme de sciences de l'Université de la Colombie-Britannique (UBC) et en 1967, il obtient son diplôme en chimie avec très grande distinction et la Lefevre Gold Medal pour avoir obtenu les meilleurs résultats dans le programme spécialisé en chimie. Sa thèse de spécialisation porte principalement sur la nouvelle technique de spectroscopie photoélectronique. À ce moment-là, il n'existe aucun spectromètre photoélectronique vendu sur le marché et l'UBC est seule à en posséder au Canada. Fort de l'encouragement enthousiaste de son directeur de thèse, David C. Frost, Russ tente de mener la première étude sur la dépendance angulaire de l'émission de photoélectrons. Malgré tous les efforts déployés par la solide équipe de soutien technique de l'atelier de mécanique, deux concepts différents ne parviennent pas à produire des résultats significatifs. Afin d'obtenir des résultats positifs, Russ rassemble des réserves de trihalogénures de bore et enregistre leur spectre.

Lauréat de l'une des premières bourses 1967 en sciences (instaurée en 1967 par le Conseil national de recherches du Canada pour souligner le centenaire de la Confédération), il se dirige vers l'est pour poursuivre un doctorat en chimie théorique à l'Université McGill sous la direction de M. A. (Tony) Whitehead. En raison du fait qu'au cours de ses études de premier cycle, il a eu à enregistrer les spectres photoélectroniques de trihalogénures de bore (et de siloxanes), Russ se rend compte qu'il n'existe aucun cadre théorique pour interpréter de tels spectres en l'absence de calculs de structures électroniques. En 1967, les seuls calculs ab initio fiables se limitent aux petites molécules. En fait, la plus grosse molécule répertoriée dans le recueil des calculs ab initio de 1967 (Morris Kraus) est le cyanoacétylène (HCCCN) pour laquelle A.D. McLean et M. Yoshimine ont fait état d'un calcul SCF en un seul point avec un petit ensemble de base. Au cours de ses premiers mois comme étudiant diplômé, Russ effectue des calculs semi-empiriques d'orbitales moléculaires sur des trihalogénures de bore et il fait parvenir ses résultats à David Frost, ce qui mène la publication, en avril 1968, de son premier article intitulé « The Ionization Potentials of  $\text{BF}_3$ ,  $\text{BCl}_3$  and  $\text{BBr}_3$  » dans le premier volume de la revue *Chemical Physics Letters*.

En 1967, les méthodes semi-empiriques d'orbitales moléculaires utilisées ne permettent pas de prévoir les géométries d'équilibre des molécules. Tous les calculs sont effectués sur des géométries expérimentales ou au moyen de longueurs et d'angles de liaison présumés. Russ se rend compte que cette situation est peu satisfaisante pour étudier les mécanismes de réaction et entreprend de mettre au point une méthode qui permettrait de produire des surfaces et des propriétés d'énergie potentielle moléculaire qui cadrent avec des données expérimentales. Il met au point une méthode fondée sur l'approximation du recouvrement différentiel nul, introduite en 1965 par John Pople et ses collègues. Il concentre ses efforts

sur les géométries d'équilibre, les énergies de liaison et les constantes de force (fréquences vibrationnelles), trois propriétés revêtant un intérêt certain sur le plan de la chimie et associées aux minima des surfaces d'énergie potentielle. Il s'agit d'une amélioration par rapport à toutes les autres méthodes existantes. Mais finalement, elle sera détrônée par les travaux de Michael Dewar et de ses collègues, qui utilisent un niveau légèrement plus élevé et plus fiable chimiquement de la théorie semi-empirique des orbitales moléculaires.

Après avoir défendu sa thèse de doctorat en 1971, Russ se joint à l'équipe de Charles A. Coulson à l'Institut de mathématiques de l'Université d'Oxford à titre de boursier postdoctoral du CNRC. Désenchanté des méthodes semi-empiriques et avant même qu'il ne termine sa thèse, il se tourne vers les méthodes ab initio plus prometteuses que John A. Pople et son équipe sont à mettre au point dans un cadre gaussien. Russ se penche donc sur la corrélation électronique et publie deux articles avec Coulson, dont une description du trou de Coulomb dans les deux premiers états d'excitation de l'atome d'hélium, son article le mieux connu issu d'Oxford.

Encouragé par Charles A. McDowell, Russ retourne à l'Université de la Colombie-Britannique où il est titulaire d'une bourse postdoctorale Killam au Département de chimie de 1973 à 1975. C'est là qu'il s'intéresse de nouveau à la spectroscopie photoélectronique. En 1974, dans un texte publié dans la revue *Nature*, il fait valoir que contrairement à l'interprétation courante des études structurales des complexes de porphyrine, le plus faible état de spin élevé d'un atome (ion) dans une configuration donnée est plus petit que tout état de spin plus faible. Sa prédiction sera vérifiée deux ans plus tard par des expériences de diffusion menées sur les deux premiers états excités de l'atome d'hélium.

Russ est embauché par l'Université Dalhousie à titre de professeur adjoint de chimie en 1975 et grimpe les échelons pour devenir professeur en 1985. En 1997, on le nomme professeur Killam de la Faculté des sciences, et en 2001, il devient le septième titulaire de la chaire de chimie Alexander McLeod. La chaire McLeod, l'une des plus anciennes chaires dénommées en chimie au Canada, a été créée en 1884 conformément à un legs d'Alexander McLeod. Russ occupe les fonctions de directeur du Département de chimie de 1992 à 2005. Au cours de cette période, onze nouveaux membres du corps professoral sont recrutés (dont quatre éminents chimistes chevronnés), le programme d'études supérieures prend de l'expansion de façon importante et on approuve la construction d'une adjonction à l'édifice de la Faculté de chimie. Entre 2001 et 2003, le Département recrute quatre chercheurs inscrits au Programme des chaires de recherche du Canada de niveau I (Neil Burford, Jeff Dahn, Don Weaver et Joe Zwanziger).

Les travaux de recherche de Russ englobent divers sujets dans les domaines de la chimie théorique et numérique tout en portant une attention particulière aux problèmes liés aux systèmes biologiques. Il a publié jusqu'à maintenant environ 240 articles de recherche et dix chapitres de synthèse et a corédigé, en 2007, l'ouvrage « *The Quantum Theory of Atoms in Molecules* » avec Chérif Matta. Plus de 5000 citations de ses articles et un indice h de 42 font de Russ l'un des chimistes-informaticiens canadiens les plus connus. Au cours de sa carrière, il dirige les travaux de 20 étudiants au doctorat, de plus de 25 boursiers postdoctoraux et de visiteurs

de haut niveau et d'un nombre comparable d'étudiants de premier cycle. Ses anciens étudiants poursuivent des carrières florissantes dans des établissements universitaires, des laboratoires gouvernementaux ou l'industrie. Quatorze anciens membres de son équipe occupent des postes de professeur dans des universités canadiennes et huit autres font de même à l'étranger. Il est particulièrement fier du nombre d'excellents jeunes scientifiques qui ont reçu une partie importante de leur formation au sein de son équipe.

Russ reçoit l'APICS/Fraser Medal en 1983. Il est le premier et le seul chimiste à recevoir ce prix, remis dans les années 1970 et 1980 pour souligner les travaux de recherche remarquables menés par de jeunes scientifiques ou ingénieurs dans les provinces de l'Atlantique. Il compte également parmi ses récompenses la bourse de recherche de l'Institut de chimie du Canada (1983), le prix CNC-UICPA (1986), la bourse de chercheur chevronné Killam de l'Université Dalhousie (1989) et la Médaille de Montréal de l'Institut de chimie du Canada (2009).

Russ assume des rôles de premier plan dans l'organisation des congrès de la Société canadienne de chimie de 1981, de 1990 et de 2006. Il est le principal organisateur du 8<sup>e</sup> symposium canadien de chimie théorique (1983) et du 7<sup>e</sup> congrès canadien de chimie numérique (2009). Il fait partie du Collège d'examineurs du Programme de chaires de recherche du Canada et siège à de nombreux comités au Conseil de recherches en sciences naturelles et en génie du Canada. Il

siège à des jurys de sélection pour la National Science Foundation des États-Unis et le Programme Fulbright Canada-États-Unis. # Equilibrium studies of triphenyltin(IV) complexes with glycine, glycyl-glycine, and glycyl-glycyl-glycine in different aqueous solutions of ethanol

Morteza Jabbari and Farrokh Gharib

**Abstract:** The protonation equilibria of glycine (gly), glycyl-glycine (gly-gly), and glycyl-glycyl-glycine (gly-gly-gly) and their formation constants with triphenyltin(IV) chloride were studied over a wide pH range (pH 1–11), using a combination of spectrophotometric and potentiometric methods at constant temperature (25 °C), different ethanol–water mixtures (50%–80%, v/v), and constant ionic strength (0.1 mol dm<sup>-3</sup> NaClO<sub>4</sub>). Least-squares regression calculations are consistent with the formation of  $\text{ph}_3\text{SnHL}^+$ ,  $\text{ph}_3\text{SnL}$ , and  $\text{ph}_3\text{SnHL}_2\text{L}^-$  complex species, where  $\text{L}^-$  represents the fully dissociated form of each ligand. The stability constant of the formed complexes in different media were analyzed in terms of Kamlet, Abboud, and Taft (KAT) parameters. Single-parameter correlations of the stability constants versus  $\alpha$  (hydrogen-bond donor acidity),  $\beta$  (hydrogen-bond acceptor basicity), and for  $\pi^*$  (dipolarity/polarizability) are relatively poor in all solutions, but multi-parameter correlations represent significant improvements with regard to the single- and dual-parameter models. Linear correlation is observed when the experimental  $\log\beta_{\text{xyz}}$  values are plotted versus the calculated ones, while all the KAT parameters are considered. Also, the stability constant values of the formed complexes are determined in zero percent of organic solvent using the Yasuda–Shedlovsky extrapolation approach. Finally, the results are discussed in terms of the effect of solvent on complexation.

**Key words:** triphenyltin(IV), glycine, glycyl-glycine, glycyl-glycyl-glycine, formation constant, solvent effect.

**Résumé :** Faisant appel à une combinaison de méthodes spectrophotométrique et potentiométrique et opérant à température constante (25 °C), dans divers mélanges d'éthanol–eau (50 % à 80 %, v/v) et à force ionique constante (0,1 mol dm<sup>-3</sup> NaClO<sub>4</sub>), on a étudié l'équilibre de protonation de la glycine (gly), de la glycyl-glycine (gly-gly) et de la glycyl-glycyl-glycine (gly-gly-gly) ainsi que des leurs constantes de formation avec le chlorure de triphénylétain(IV) sur la plage de pH allant de 1 à 11. Les calculs de régression par la méthode des moindres carrés sont en accord avec la formation d'espèces complexes  $\text{ph}_3\text{SnHL}^+$ ,  $\text{ph}_3\text{SnL}$  et  $\text{ph}_3\text{SnHL}_2\text{L}^-$  dans lesquelles  $\text{L}^-$  représente chaque ligand complètement dissocié. On a analysé les constantes de stabilité des complexes formés dans les divers média en fonction des paramètres de Kamlet, Abboud et Taft (KAT). Dans chacune des solutions, les corrélations de paramètres uniques des constantes de stabilité en fonction de  $\alpha$  (acidité comme donneur de liaison hydrogène),  $\beta$  (basicité comme accepteur de basicité) et  $\pi^*$  (dipolarité/polarisabilité) ne sont pas bonnes, mais les corrélations de paramètres multiples représentent des améliorations significatives par rapport aux modèles à un ou deux paramètres. On observe une corrélation linéaire avec les valeurs expérimentales  $\log\beta_{\text{xyz}}$  en fonction des valeurs calculées en considérant tous les paramètres KAT. De plus, les valeurs des constantes de stabilité des complexes formés ont aussi été déterminées pour un solvant contenant zéro pourcent de solvant organique en utilisant l'approche de l'extrapolation de Yasuda–Shedlovsky. Enfin, on discute des résultats en fonction de l'effet de solvant sur la complexation.

**Mots-clés :** triphénylétain(IV), glycine, glycyl-glycine, glycyl-glycyl-glycine, constante de formation, effet de solvant.

## Introduction

Organotin compounds have a wide variety of industrial applications, including pesticides, fire-retardants, anti-fouling paints, anti-mold agents, production of poly(vinyl chloride) stabilizers, industrial catalyst, timber preservatives, and so forth,<sup>1,2</sup> and so they are widespread in the environment. The consumption of organotin(IV) compounds during the last 50 years has led to their accumulation in the environment and finally in biological systems. These compounds

interact with living organisms by affecting various biochemical processes.<sup>3–5</sup> Organotin(IV) compounds are generally toxic (specially triorganotins), even at low concentration, and believed to possess anticancer effects on different tumour cells.<sup>6–15</sup> The moiety  $\text{R}_n\text{Sn(IV)}$  can bond to proteins and glycoproteins of the cell membranes, and also to cellular proteins and DNA.<sup>16</sup> This fact has led to considerable efforts to characterize organotin(IV) complexes with variety of biological ligands containing oxygen, nitrogen, or

sulfur donor atoms.<sup>6–15</sup> Today, a number of organotin(IV) derivatives are known to have an efficient anticancer activity, and their structures are well-characterized in the solid state.<sup>17–20</sup>

Accepting the hypothesis that  $R_2Sn^{2+}$  and  $R_3Sn^+$  are the usual active species for antitumour action of organotin(IV) derivatives, a good antitumour agent should be easily dissociable following administration to animals. This requires weak bonds between tin and the donor atom of the coordinated ligands, which are readily hydrolyzable. If the compound is hydrolytically unstable, the  $R_2Sn^{2+}$  and  $R_3Sn^+$  moieties will be released too soon, and if it is too stable, it may be released too slowly, and consequently lower activity will be observed. Therefore, there is a relationship between the stability of the organotin compounds and their antitumour activity.

This work deals with the study of complexation of triphenyltin(IV) chloride with glycine, glycyl-glycine, and glycyl-glycyl-glycine. Triphenyltin(IV) chloride is not soluble in water, but it is soluble in aqueous-organic mixed solvent with higher percent of the organic solvent. So, the study is performed in different solutions of water-ethanol systems to show how the solvents and their mixtures with various dielectric constants affect the formation reactions of the triorganotin(IV).

In addition, there has been increasing interest during the past decade in the determination of many chemical and biochemical equilibria in aqueous mixed-solvent systems. However, in the literature, it has been shown that water is not an ideal model for *in vivo* reactions. In enzymes, membranes, and other biologically important media, the formation-constant values are different from those in water, as these media tend to be lipophilic rather than hydrophilic.<sup>21,22</sup> Usually, it has been suggested that non-aqueous media, such as ethanol, could provide a better model for *in vivo* reactions.<sup>23,24</sup> Hence, studies in media other than water should provide some understanding of the reactions in living systems. Besides, the knowledge obtained from the mixed-solvent systems could complement the majority of the knowledge collected from the studies in aqueous media of the chemistry and biochemistry of the reactions. However, water and some organic solvents, such as methanol, ethanol, and so forth, are believed to be completely miscible together. These mixtures are macroscopically homogeneous, but it has been reported that water and organic-solvent molecules are not homogeneously dispersed microscopically,<sup>25</sup> owing to the hydrogen-bonding network formation and hydrophobic interactions. Consequently, the molecular composition of the solvation layer around a solute molecule is not the same as that of the bulk mixing ratio of water and organic solvent. The hydrophobic and hydrophilic properties of a solute may be reflected by preferential solvation in such mixed solvents. Therefore, the influence of which solvent exerts on the formation equilibria constant values depends upon the extent and nature of the solute-solvent interactions.

## Experimental section

### Chemicals

Sodium perchlorate was obtained from Merck as analytical reagent-grade material and was dried under vacuum at room temperature at least 72 h before use. The NaOH solu-

tion was prepared from a titrisol solution (Merck). Perchloric acid and ethanol (absolute) were obtained from Merck as analytical reagent-grade materials and were used as supplied. Glycine, gly-gly, gly-gly-gly, and triphenyltin(IV) chloride were obtained from Fluka as reagent-grade materials and were used as received. All dilute solutions were prepared from double-distilled water with specific conductance equal to  $1.2 \pm 0.1 \mu\Omega^{-1} \text{ cm}^{-1}$ . Aqueous stock solutions of the ligands were freshly prepared daily, and their concentrations were determined each time by titration with a NaOH solution.

### Measurements

pH measurements were performed with a Jenway research pH meter, model 3520. All measurements were carried out at 25 °C and constant ionic strength of 0.1 mol dm<sup>-3</sup> sodium perchlorate. The pH meter was calibrated for the relevant  $H^+$  concentration with a solution of 0.01 mol dm<sup>-3</sup> of HClO<sub>4</sub> solution containing 0.09 mol dm<sup>-3</sup> sodium perchlorate (for adjusting the ionic strength to 0.1 mol dm<sup>-3</sup>). For this standard solution, we set  $-\log[H^+]$  to 2.0,<sup>26</sup> assuming the acid is dissociated 100%. The junction potential corrections were calculated from eq. [1]

$$[1] \quad -\log[H^+]_{\text{real}} = -\log[H^+]_{\text{measured}} + a + b[H^+]_{\text{measured}}$$

where  $a$  and  $b$  were determined by measuring the hydrogen ion concentration for two different solutions of perchloric acid or sodium hydroxide with sufficient sodium perchlorate to adjust the ionic strength.

The determination of the hydrogen-ion concentration was performed with a combination electrode (Jenway). The term pH has significance only in aqueous media. The glass electrode potential in an aqueous solution differs from that in a solution of mixed solvents, and a liquid-junction potential of uncertain magnitude may affect the results. To overcome this difficulty, it was necessary to calibrate the glass electrode in different solvent mixtures. The experimental method outlined by van Uitert and Hass<sup>27</sup> was employed for this purpose. The pH meter reading  $B$  in ethanol-water media was converted into  $[H^+]$  using the equation

$$[2] \quad p_c H = B + \log_{10} \mu_H$$

where the concentration factor  $\log_{10} \mu_H$  was obtained for the ionic strength 0.1 mol dm<sup>-3</sup> NaClO<sub>4</sub> from the expression  $\log_{10} \mu_H = \log_{10} \mu_H^\circ + \log_{10} \gamma_{\pm}$ . The value of  $\mu_H^\circ$  is independent of ionic concentration but is dependent on solvent composition, and  $\gamma_{\pm}$  is the mean activity coefficient of perchloric acid in the solvent mixtures. In this work, the values of  $B$  were recorded in various solvent mixtures containing known concentrations of perchloric acid and sufficient sodium perchlorate to give a constant ionic strength of 0.1 mol dm<sup>-3</sup>. The differences between the logarithm of known hydrogen ion concentrations and the corresponding values of  $B$  were used to calculate values of the correction term  $\log_{10} \mu_H = \log_{10}(\mu_H^\circ \gamma_{\pm})$ .

The following species of the ligands may exist in solution at different pH values:  $L^-$ ,  $HL$ , and  $H_2L^+$ , where  $L^-$  represents the fully dissociated ligand anion. The protonation constants of the ligands have been studied previously in different kinds of background electrolytes, and the results are

reported in the literature.<sup>28–30</sup> The protonation constant values of the ligands have been determined using the potentiometric technique under the same conditions of temperature, ionic strength, and mole fraction of ethanol and calculated using a suitable computer program (Microsoft Excel Solver<sup>®</sup>), which employs a nonlinear least-squares method.<sup>31</sup> The protonation constant values, expressed in log units, are collected in Table 1 together with the values reported in the literature for comparison.<sup>28–30</sup>

UV-vis spectra were recorded using a Shimadzu 2100 spectrophotometer with a Pentium-4 computer and using thermostated matched 10 mm quartz cells. The measurement cell was of flow type. A Masterflex pump allowed circulation of the solution under study from the potentiometric cell to the spectrophotometric cell. So, the absorbance and pH of the solution could be measured simultaneously.

A 50 mL acidic solution (0.1 mol dm<sup>-3</sup>) of triphenyltin(IV) chloride (0.6 × 10<sup>-3</sup> to 1.0 × 10<sup>-3</sup> mol dm<sup>-3</sup>), for UV-vis studies, was titrated with an alkali solution (0.1 mol dm<sup>-3</sup> NaOH) of the ligands (1.0 × 10<sup>-3</sup> to 2.2 × 10<sup>-3</sup> mol dm<sup>-3</sup>) both in the same ionic strength and mole fraction of ethanol. The p<sub>c</sub>H (–log[H<sup>+</sup>]) and absorbance were measured after addition of 0.05 mL of titrant, and this procedure extended up to the required p<sub>c</sub>H. To exclude carbon dioxide from the system, a stream of purified nitrogen was passed through a sodium hydroxide solution and then bubbled slowly through the reaction solution. In all cases, the procedure was repeated at least three times, and the resulting average values and corresponding standard deviation are shown in the text and Tables.

### Results and discussion

Organotin(IV) generally hydrolyze to form a series of mono- and poly-nuclear hydroxo complexes. Previously, we performed spectrophotometric titrations to obtain these data in various aqueous solutions of ethanol (50%–80% ethanol, v/v).<sup>32,33</sup> Two hydrolytic species [ph<sub>3</sub>Sn(OH) and ph<sub>3</sub>Sn(OH)<sub>2</sub><sup>–</sup>] were found, and their formation-constant values in different aqueous ethanol solutions are listed in Table 2.

The protonation-constant values of the ligands, expressed in log units (Table 1), are in good agreement with those reported earlier in pure water.<sup>28–30</sup> A comparison between the protonation constants of glycine and gly-gly show the presence of a nucleophilic amide group close to the α-carbon in the peptide decreases the basicity of the amino and increases the acidity of the carboxyl groups. The same rule is governed to gly-gly-gly, and hence causes a smaller protonation

constant for the amino and a greater one for the carboxyl groups in gly-gly and gly-gly-gly with respect to glycine.

The formed complex species  $M_xH_yL_z^{(x+y-z)}$  is characterized by its stoichiometry ( $x:y:z$ ), where  $M$  represents the metal ion. To determine the stability constant of complexation, eq. [4] is defined by  $\beta_{xyz}$ :

$$[4] \quad \beta_{xyz} = [M_xH_yL_z^{x+y-z}] / ([M^+]^x [H^+]^y [L^-]^z)$$

The method of determination of the formation constant was employed using the method mentioned before.<sup>34,35</sup> Absorbance,  $A$ , and  $pH$  were measured by successive addition of an alkali solution of the ligand to the acidic metal ion solution in the UV range of 250 to 280 nm (with an interval of 1 nm). The UV spectral data correlated with  $[H^+]$  were processed using the same computer program, which allows calculation of formation constants for different stoichiometric models.

Considering the protonation constants of the ligands, in acidic  $pH$ , the predominant species for complexation is  $H_2L^+$ . In this case, the spectrophotometric titration data were analyzed by using the absorbance of  $Sn(IV)$  + each ligand at wavelengths in the UV range that is given by

$$[5] \quad A = \varepsilon_M[Sn(IV)] + \varepsilon_C[complex] + A_{ligand}$$

where  $\varepsilon_M$  and  $\varepsilon_C$  are the molar absorptivities of  $Sn(IV)$  and the formed complex species, respectively. The mass balance can be expressed as

$$[6] \quad [Sn(IV)] = C_M - [complex]$$

$$[7] \quad [H_2L^+] = C_L - [complex] - [free\ ligand]$$

where  $C_M$  and  $C_L$  are the total concentrations of  $Sn(IV)$  and each ligand, respectively. Substituting eqs. [5], [6], and [7] into eq. [4] gives the final equation for fitting. Using the same computer program, the data were fitted to the final equation for estimating the formation constant of eq. [3]. The Gauss-Newton nonlinear least-squares method was used in the computer program to refine the absorbance by minimizing the error squares sum from eq. [8]

$$[8] \quad S = \Sigma(A_{exptl.} - A_{calcd.})^2$$

where  $A_{exptl.}$  is the experimental absorbance and  $A_{calcd.}$  is the calculated one. The computer program consisted of two different kinds of fitting: (i) graphical and (ii) numerical. The final selection of the species was based on both graphical and numerical methods, considering in addition, the various statistical criteria, i.e., sums of squared residuals and differences of  $C_M(exptl.)$  and  $C_L(exptl.)$  values from the calculated ones.

As expected, polynuclear complexes and  $MH_2L$ ,  $MH_2L_2$ , and  $MHL_2$  species were rejected by the computer program (the charges are omitted for simplicity). The models finally chosen were  $MHL$ ,  $ML$ , and  $MH_{-1}L$  resulting in a satisfactory numerical and graphical fitting. The correlation between the average values of these parameters for the wavelengths range used in this study and the  $\log_{10}\beta$  is listed in Table 3.

In Fig. 1, the equilibrium distribution of various species of  $Sn(IV)$  + gly system, as a typical example, is shown as a function of  $pH$  at 60% ethanol (by v/v). The calculations are based on the stability-constant values given in Table 3. The curves clearly demonstrate that increasing the  $pH$  is accompanied by an increase in the formation of deprotonated complex species, and so the stability of the species quite depends upon the  $pH$ . The most stable complex species at  $pH$  2–2.5, 4.5–5.5, and  $>9$  are  $Sn(IV)HL$ ,  $Sn(IV)L$ , and  $Sn(IV)H_{-1}L$ , respectively.

### Solvent effect

The stability constants of the formed complexes in water-ethanol mixed solvents have different behavior, Table 3.  $\beta_{MHL}$  and  $\beta_{MH_{-1}L}$  values increased as the solvent became enriched in the organic component, but  $\beta_{ML}$  decreased as ethanol increased in the mixtures. It is very difficult to interpret the variation of the stability-constant values of the complexes with respect to the percentage of ethanol in the mixtures using the dielectric constant of the solutions as a single parameter. In general, the standard free energy of complexation equilibria consists of two terms: an electrostatic term, which can be estimated by the Born equation,<sup>37,38</sup> and a non-electrostatic term, which includes specific solute-solvent interaction. When the electrostatic effects predominate, then in accordance with the Born equation, eq. [9], the plot of  $\log_{10}\beta$  versus the reciprocal of dielectric constant,  $\varepsilon$ , of the media should be linear.

$$[9] \quad \Delta \log_{10}\beta = (121.6n/r)(1/\varepsilon - 0.0128)$$

where  $r$  is the common radius of the ions, and  $n$  is the square summation of the charges involved in the complexation equilibria. For example,  $n = 0$  for the charge type  $M^+ \rightleftharpoons MHL^+$  or  $MHL^+ \rightleftharpoons ML$ , and  $n = 2$  for the charge type  $ML \rightleftharpoons MH_{-1}L^-$ . So, the correlation between  $\log_{10}\beta_{MH_{-1}L}$  and the reciprocal of the dielectric constant of ethanol-water mixtures is linear, with correlation coefficient  $> 0.99$  (Fig. 2). However, there is no change in the number of charges involved in the complexation equilibria when  $n = 0$ , and so, their stability constants deviate from the Born equation. In this case, the correlation between  $\log_{10}\beta_{MHL}$  and  $\log_{10}\beta_{ML}$  values and  $1/\varepsilon$  are poor, Fig. 2, and the complexation possibly depends on the solute-solvent interaction of the different species in the mixed solvents. Therefore, it seems essential to elucidate the nature of solute-solvent interactions for a better understanding of solvent effects.

To obtain a quantitative method for evaluation of the solute-solvent interaction on protonation or the formation constants, we have used the method introduced by Kamlet, Abboud, and Taft.<sup>39,40</sup> The KAT equation contains non-specific as well as specific solute-solvent interactions separately, and that the latter could be subdivided into solvent Lewis acidity interactions (hydrogen-bond acceptor, HBA solute, and hydrogen-bond donor, HBD solvent) and solvent Lewis basicity interactions (HBD solute – HBA solvent). In general, all of these parameters constitute more comprehensive measures of solvent polarity than the dielectric constant or any other single physical characteristic alone, because they reflect more reliably the complete picture of all intermolecular forces acting between solute and solvent molecules. This approach has been widely and successfully applied in the

**Fig. 2.** Plots of the experimental values of  $\log_{10}\beta_{\text{ML}}$ ,  $\log_{10}\beta_{\text{ML}}$ , and  $\log_{10}\beta_{\text{MH}_{1,\text{L}}}$  versus the reciprocal of the dielectric constants of different mixed solvents at 25 °C and ionic strength of 0.1 mol dm<sup>-3</sup> (NaClO<sub>4</sub>).

correlation analysis of all kinds of solvent-dependent processes.<sup>41</sup> The multiparametric equation, eq. [10], has been proposed, using the solvatochromic solvent parameters,  $\alpha$ ,  $\beta$ , and  $\pi^*$ , which have been introduced in previous reports.<sup>42,43</sup>

[10]  $\log_{10}K = A_0 + \alpha\alpha + b\beta + p\pi^*$

where  $A_0$  represents the regression value, and  $\pi^*$  is the index of the solvent dipolarity/polarizability, which is a measure of the ability of a solvent to stabilize a charge or a dipole by its own dielectric effects. The  $\pi^*$  scale was selected to run from 0.0 for cyclohexanone to 1.0 for di-

methylsulfoxide. The  $\alpha$  coefficient represents the solvent HBD acidity; in other words, it describes the ability of a solvent to donate a proton in a solvent to the hydrogen bond of a solute. The  $\alpha$  scale extends from 0.0 for non-HBD solvents to about 1.0 for methanol. The  $\beta$  coefficient is a measure of solvent HBA basicity, and describes the ability of a solvent to accept a proton from a solute to form a hydrogen bond. The  $\beta$  scale was selected to extend from 0.0 for non-HBA solvents to about 1.0 for hexamethylphosphoric triamide.

The regression coefficients  $a$ ,  $b$  and  $p$  measure the relative susceptibilities of the solvent dependence of  $\log_{10}\beta$  to the indicated solvent parameters. To explain the obtained  $\log_{10}\beta$  values through the KAT solvent parameters, the stability constants were correlated with solvent properties by means of single-, dual-, and multi-parameters regression analysis with the same computer program. We used the Gauss–Newton nonlinear least-squares method in the computer program to refine the  $\log_{10}\beta$  values by minimizing the error squares sum from eq. [11].

$$[11] \quad S = \sum (\log_{10}\beta_{\text{exptl.}} - \log_{10}\beta_{\text{calcd.}})^2$$

The procedure used in the regression analysis involves a rigorous statistical treatment to find out which parameter in eq. [10] is best-suited to the water–organic mixed solvents. The KAT parameters for all the water – organic solvent mixtures used in this work were obtained from the plots of each property versus the mole fraction of the organic solvent of the values that have been reported in the literature for some other percentages of aqueous solutions of ethanol used in this study,<sup>44</sup> and the dielectric constant values have been taken from the literature.<sup>45</sup> The calculated KAT-parameter values are listed in Table 4. A stepwise procedure and least-squares analysis were applied to select the significant solvent properties to be influenced in the model and to obtain the final expression for the formation constants. Therefore, the KAT equation, eq. [10], was reduced to single-, dual-, and finally multi-parameters for the correlation analysis of  $\log_{10}\beta$  in various solvent mixtures. The computer program used can produce the values of  $A_0$ ,  $a$ ,  $b$ ,  $p$ , and some statistical parameters including  $r^2$  coefficients.

Although the solvent polarity is identified as the main reason of the variation of  $\log_{10}\beta$  values in water – organic solvent mixtures, but the results show that any single-parameter correlations of  $\log_{10}\beta$  values individually with  $\pi^*$ , as well with  $\alpha$ , and  $\beta$  did not give good results in all cases with  $r^2$  values in the range of 0.88 to 0.97. However, the correlation analysis of  $\log_{10}\beta$  values with dual-parameter equations, indicate significant improvement with regard to

the single-parameter, but finally the multi-parameter equations show the best results and yield the lowest standard deviation and possessing an acceptable correlation coefficients.

The expressions of the KAT equation obtained for multi-parameters are shown by eqs. [12a–12i].

$$[12a] \quad \log_{10}\beta_{\text{MHL}}(\text{glycerine}) = 6.95 - 2.76\alpha + 3.02\beta - 3.22\pi^*$$

$$[12b] \quad \log_{10}\beta_{\text{ML}}(\text{glycine}) = 2.15 - 7.27\alpha + 8.21\beta - 5.86\pi^*$$

$$[12c] \quad \log_{10}\beta_{\text{MH-L}}(\text{glycine}) = 14.54 - 2.37\alpha + 4.59\beta - 5.43\pi^*$$

$$[12d] \quad \log_{10}\beta_{\text{MHL}}(\text{gly-gly}) = 7.76 - 1.83\alpha + 1.24\beta - 3.65\pi^*$$

$$[12e] \quad \log_{10}\beta_{\text{ML}}(\text{gly-gly}) = 1.30 - 5.64\alpha + 6.70\beta - 5.29\pi^*$$

$$[12f] \quad \log_{10}\beta_{\text{MH-L}}(\text{gly-gly}) = 10.99 - 5.97\alpha - 4.86\beta - 5.11\pi^*$$

$$[12g] \quad \log_{10}\beta_{\text{MHL}}(\text{gly-gly-gly}) = 7.65 - 2.18\alpha + 0.21\beta - 2.66\pi^*$$

$$[12h] \quad \log_{10}\beta_{\text{ML}}(\text{gly-gly-gly}) = 4.03 - 5.01\alpha + 6.54\beta - 4.11\pi^*$$

$$[12i] \quad \log_{10}\beta_{\text{MH-L}}(\text{gly-gly-gly}) = 14.83 - 0.22\alpha + 4.44\beta - 4.36\pi^*$$

( $N = 7$ ,  $r^2 > 0.99$  in different cases).

In all cases, the solvent polarity parameter of the media,  $\pi^*$ , has a major role and increases with increasing the mole fraction of water in aqueous solutions of ethanol, Table 4. If the  $\pi^*$  of the media was the only factor for describing the solvent effect on complexation, it may be expected that the  $\log_{10}\beta$  in water should be greater than those of all the other aqueous solutions of ethanol. However,  $\log_{10}\beta_{\text{MHL}}$  values of the complex species increase with an increase in the solvent HBA-basicity parameter,  $\beta$ , and decrease with increasing the solvent polarity  $\pi^*$ . They also increase with increasing the HBD-acidity parameter,  $\alpha$ , of the solvents. In this case, a de-

crease in the polarity of the mixed solvents increases the solvation of the complex species, which has a positive charge and therefore makes formation equilibrium more likely. The  $\log_{10}\beta_{\text{ML}}$  values decrease with decreasing  $\pi^*$  and increasing  $\alpha$  and  $\beta$  parameters. In this case, the formed complex species has no charge, so HBA-basicity parameter of the mixed solvents,  $\beta$ , possibly has a major role in the correlation analysis of  $\log_{10}\beta_{\text{ML}}$ . However,  $\log_{10}\beta_{\text{MH}_{-1}\text{L}}$  of the complexes increases with increasing  $\alpha$  and  $\beta$  and decreasing  $\pi^*$  values. This could be explained as solvation by decreasing the polarity of the mixed solvents affects the formed complex species with a negative charge. Consequently,  $\log_{10}\beta_{\text{MH}_{-1}\text{L}}$  values increase with decreasing  $\pi^*$  parameters.

To show the efficiency of the suggested multi-parameter correlations, the stability constants were calculated by eq. [12] and are listed in Table 5 for comparison. It can be seen that the experimental values of  $\log_{10}\beta$  and the calculated ones are in good agreement.

To obtain  $\log_{10}\beta$  values of the complexation in pure water, a correlation method has been used between the experimental formation-constant values that are introduced by extrapolation of Yasuda–Shedlovsky approach in different aqueous solutions of ethanol.<sup>46,47</sup> This approach was successfully applied to determine the protonation constant of many weak acids or weak bases in pure water as solvent from the protonation-constant values in different water–methanol mixtures.<sup>48</sup> It is claimed that Yasuda–Shedlovsky extrapolation procedure is generally more accurate than the conventional method ( $\log_{10}\beta$  versus weight percent of an or-

**Table 6.**  $\log_{10} \beta_{\text{MHL}}$ ,  $\log_{10} \beta_{\text{ML}}$ , and  $\log_{10} \beta_{\text{MH-L}}$  values of the studied systems by extrapolation of Yasuda–Shedlovsky equation to pure water in different ranges of ethanol% (v/v) used,  $R$ , the regression values,  $r^2$ , are also given in each case.

Species	$\log \beta_{\text{MHL}}$	$R$	$r^2$	$\log \beta_{\text{ML}}$	$R$	$r^2$	$\log \beta_{\text{MH-L}}$	$R$	$r^2$

ganic solvent) for the determination of  $\log_{10} \beta$  of a broad range of insoluble or sparingly water-soluble drug compounds.<sup>48,49</sup> We have applied the Yasuda–Shedlovsky approach to determine  $\log_{10} \beta$  of the formed complexes studied in this work in pure water. On the basis of Born electrostatic model and Bjerrum's theory of ion association, Yasuda<sup>46</sup> and Shedlovsky<sup>47</sup> derived eq. [13]. The plot of  $\log_{10} \beta + \log_{10} [\text{H}_2\text{O}]$  versus  $1/\epsilon$  should produce a straight line in different aqueous – organic solvents mixtures, where  $\beta$  represents the stability constant of the complex species formed,  $[\text{H}_2\text{O}]$  is the molar concentration of water and  $\epsilon$  shows the dielectric constant of the medium.

$$[13] \quad \log_{10} \beta + \log_{10} [\text{H}_2\text{O}] = a\epsilon^{-1} + b$$

where  $a$  and  $b$  are two constants that should be determined for the various ethanol–water mixtures used in this work. Figure 3 shows the Yasuda–Shedlovsky plots for the Sn(IV)–glycine system, and the  $\log_{10} \beta$  values were determined by extrapolation to 0% ethanol and are summarized in Table 6.

# Syntheses of ruthenium(II)-4,4'-biimidazole complexes and their potential anti-tumour activity

David C. Kennedy and Brian R. James

**Abstract:** Synthesis and characterization of the Ru<sup>II</sup> complexes, [Ru(N-N)<sub>3</sub>][CF<sub>3</sub>SO<sub>3</sub>]<sub>2</sub>, where N-N is 4,4'-biimidazole (complex **1a**) or 2,2'-dimethyl-4,4'-biimidazole (**1b**), and the dimethylsulfoxide complexes RuCl<sub>2</sub>(DMSO)<sub>2</sub>(N-N) are reported. The air-stable, water-soluble complexes were characterized by elemental analysis, <sup>1</sup>H NMR and IR spectroscopies, mass spectrometry, and solution conductivity. Evidence is presented also for the existence of the diruthenium complexes Ru<sub>2</sub>Cl<sub>4</sub>(DMSO)<sub>4</sub>(N-N), but there are insufficient data for elucidation of their structure. The complexes (and cisplatin) were tested against human breast-cancer cells (MDA-MB-435S) using an in vitro MTT assay, a colorimetric determination of cell viability: **1a** and **1b** exhibit the lowest IC<sub>50</sub> values of 18 ± 5 and 36 ± 5 µmol/L, respectively, with cisplatin exhibiting an IC<sub>50</sub> value of 35 ± 5 µmol/L. Isolation of DNA from cells treated with a solution of the Ru species showed no evidence of DNA-binding to the metal, although examination of the cells indicated that Ru was being taken up into the cells.

**Key words:** ruthenium complexes, 4,4'-biimidazoles, anti-proliferatory.

**Résumé :** On rapporte la synthèse et la caractérisation de complexes de ruthénium(II), [Ru(N-N)][CF<sub>3</sub>SO<sub>3</sub>]<sub>2</sub>, dans lesquels N-N est un 4,4'-biimidazole (complexe **1a**) ou 2,2'-diméthyl-4,4'-biimidazole (**1b**) ainsi que les complexes du diméthylsulfoxyde RuCl<sub>2</sub>(DMSO)<sub>2</sub>(N-N). On a caractérisé ces complexes stables à l'air et solubles dans l'eau par analyse chimique, spectroscopies IR et RMN du <sup>1</sup>H, spectrométrie de masse et par conductivité de leurs solutions. On présente aussi des données suggérant l'existence des complexes de diruthénium Ru<sub>2</sub>Cl<sub>4</sub>(DMSO)<sub>4</sub>(N-N), mais les données ne sont pas suffisantes pour élucider leurs structures. On a évalué ces complexes, ainsi que le cisplatine, contre des cellules cancéreuses de seins humains (MDA-MB-435S) en faisant appel à un essai MTT in vitro, une détermination colorimétrique de la viabilité de la cellule; les composés **1a** et **1b** présentent les valeurs IC<sub>50</sub> les plus faibles de 18 ± 5 et 36 ± 5 µmol/L respectivement alors que le cisplatine présente une valeur IC<sub>50</sub> de 35 ± 5 µmol/L. L'ADN isolé des cellules traitées avec une solution d'espèces contenant du ruthénium ne présente aucune évidence de liaison de l'ADN au métal, même si l'examen des cellules indique que le ruthénium est absorbé par les cellules.

**Mots-clés :** complexes du ruthénium, 4,4'-biimidazoles, antiprolifération.

## Introduction

The use of cisplatin for the treatment of more than 70% of all cancer patients, coupled with the understanding of its mechanism of action, represents the most widely known, metal-based anti-cancer agent, and the topic has been exhaustively reviewed.<sup>1</sup> Amongst other metal-based anti-cancer agents, the most promising appear to be based on ruthenium. Often quoted complexes showing activity include both Ru<sup>II</sup> and Ru<sup>III</sup> species, exemplified by *cis*-Ru<sup>II</sup>Cl<sub>2</sub>(DMSO)<sub>4</sub>,<sup>1c,2</sup> [HIm][*trans*-Ru<sup>III</sup>Cl<sub>4</sub>(Im)(*S*-DMSO)] (Im = imidazole, a complex called NAMI-A),<sup>1b,1d,1e</sup> [HL][*trans*-Ru<sup>III</sup>Cl<sub>4</sub>L<sub>2</sub>] (L = indazole or Im, called KP1019 and KP418, respectively),<sup>3</sup> and a wide range of arene complexes.<sup>4</sup> The arene derivatives include Ru<sup>III</sup>L<sub>2</sub>(arene)(PTA), where PTA = 1,3,5-triaza-7-phosphaadamantane, so-called RAPTA type complexes, and in place of PTA a related P-N chelating ligand (PTN) has been used; when L is Cl, the formula represents a cationic monochloro complex, while for example, if L<sub>2</sub> is a

chelating O-O dianion, a neutral complex is formed. Many other monocationic and neutral Ru<sup>II</sup>-(arene) and Ru<sup>II</sup>-(half-sandwich) complexes, containing mono- and bi-dentate ancillary ligands and incorporating PTA, PTN, or other P-, N-, O-, and S-donor ligands, have been studied.<sup>4</sup> KP1019 and NAMI-A have both recently completed successful clinical trials, and their mechanisms of action are being hotly pursued, particularly for the NAMI-A system, which exhibits significant anti-metastatic activity.<sup>3,5</sup> More generally, the medicinal chemistry of Ru is an area of intense current interest, and the rapidly expanding literature can be traced through recent reviews<sup>1b,1d,1e</sup> and publications,<sup>3,4</sup> while earlier reviews by Clarke et al. provide excellent background material.<sup>6</sup>

Our group has previously published on the synthesis and anti-proliferatory activity of Ru<sup>III</sup>(O-O)<sub>3</sub> where O-O<sup>-</sup> is maltolato (the monoanion of 3-OH-2-Me-4-pyrone),<sup>7</sup> mixed-ligand Ru<sup>III</sup>(maltolato)(nitroimidazole) systems,<sup>8</sup> Ru<sup>II</sup>(sulfoxide) species with or without ancillary maltolato, acetylaceto-

nato, or nitroimidazole ligands,<sup>9</sup> and  $\text{Ru}^{\text{II}}(\text{arene})(\text{sulfoxide})$  species.<sup>10</sup>

In terms of metal-biimidazole complexes (the relevant topic here), 2,2'-biimidazole (2,2'-biim) has been widely used, including reports on  $\text{Ru}^{\text{II}}$  species,<sup>11,12</sup> some of which have the dianionic form of this ligand bridging in  $\text{Ru}_2^{\text{II}}$  complexes.<sup>12</sup> Metal complexes of 4,4'-biim (see Fig. 1 for numbering) are rare, and we have found references to only Cu and Pd species,<sup>13</sup> even though the syntheses of this biimidazole and the 2,2'-Me<sub>2</sub> derivative (as the diprotonated trifluoroacetate salts) were first published in 1994.<sup>14</sup> This present paper describes the first studies of  $\text{Ru}^{\text{II}}$  complexes containing 4,4'-biim and its 2,2'-dimethyl derivative (Me<sub>2</sub>biim). The anti-proliferative properties of the complexes are examined using a standard MTT assay to test for cell viability,<sup>9a</sup> and Ru-uptake and DNA-binding assays are used to further probe their biological activity. The measured IC<sub>50</sub> values against human breast-cancer cells (MDA-MB-435S) reveal high activity for the  $[\text{Ru}(\text{N}-\text{N})_3][\text{CF}_3\text{SO}_3]_2$  complexes, where N-N is 4,4'-biim or Me<sub>2</sub>biim. To the best of our knowledge, there are no previous reports of studies on the anti-proliferative properties of metal-4,4'-biimidazole complexes.

## Experimental section

### Materials for synthesis

Reagent-grade solvents (Fisher Scientific) were dried using standard procedures under N<sub>2</sub> before use,<sup>15</sup> and deuterated solvents (Cambridge Isotope Laboratories) were used as received.  $\text{RuCl}_3 \cdot 3\text{H}_2\text{O}$  (Colonial Metals) and cisplatin (Aldrich) were used as received; *cis*- $\text{RuCl}_2(\text{DMSO})_4$  and  $[\text{Ru}(\text{DMF})_6][\text{CF}_3\text{SO}_3]_3$  were prepared by literature methods.<sup>16</sup> The 4,4'-biim and Me<sub>2</sub>biim compounds were prepared as the respective biimidazolium trifluoroacetate salts  $[\text{H}_2(\text{biim})][\text{CF}_3\text{CO}_2]_2$  and  $[\text{H}_2(\text{Me}_2\text{biim})][\text{CF}_3\text{CO}_2]_2$  by a literature method.<sup>14</sup> Standard Schlenk techniques using N<sub>2</sub> atmosphere were used for synthesis of the complexes, although these were found to be air-stable.

### Physical techniques and instrumentation

<sup>1</sup>H NMR spectra were recorded at room temperature (RT, ~20 °C) on a Bruker AV300 instrument (s = singlet, br = broad) with chemical shifts being calibrated using residual proton resonances from deuterated solvents. Elemental analyses were performed on a Carlo Erba EA 1108 CHN-O instrument. Mass spectral data (reported as *m/z* values) were acquired on a Bruker Esquire ES spectrometer; M<sup>+</sup> refers to the solid-state formulation plus a proton acquired in the ion-

ization process. IR spectra (KBr pellets, s = strong, m = medium) were recorded on ATI Mattson Genesis or Bomem-Michelson MB-100 FTIR spectrometers; selected  $\nu$  values (cm<sup>-1</sup>) are given with assigned functional groups.<sup>17</sup> Conductivity measurements were carried out on a RCM151B Serfass conductance bridge (A. H. Thomas Co. Ltd.) with a 3403 cell (Yellow Springs Instrument Company) calibrated using 0.01000 mol/L aq. KCl solution ( $\Lambda_{\text{M}} = 141.3 \Omega^{-1} \text{cm}^2 \text{mol}^{-1}$  at 25 °C, cell constant = 1.016 cm<sup>-1</sup>), and data are given in units of  $\Omega^{-1} \text{cm}^2 \text{mol}^{-1}$ .<sup>18</sup>

### Biological assays

All reagents and cell-handling techniques, as well as experimental procedures for the the MTT assay, the Ru-uptake assay into cells, and DNA-binding to Ru have been described in detail in our previous publications.<sup>7-9</sup> For the MTT assay, complexes were dissolved in PBS (phosphate-buffered saline solution), and were tested against MDA-MB-435S cells in Leibovitz's L-15 medium with L-glutamine after incubation at 37 °C for 70 h; Ru-uptake was studied with a Chinese hamster ovary (CHO) cell line.

### $[\text{Ru}(\text{biim})_3][\text{CF}_3\text{SO}_3]_2$ (**1a**)

To a yellow solution of  $[\text{Ru}(\text{DMF})_6][\text{CF}_3\text{SO}_3]_3$  (83 mg, 0.085 mmol) in MeOH (5 mL) was added  $[\text{H}_2\text{biim}][\text{CF}_3\text{CO}_2]_2$  (120 mg, 0.34 mmol). On being refluxed over 24 h, the solution became dark green. The solvent was then removed under vacuum, and acetone (10 mL) was added to the green residue; the resulting mixture was filtered through Celite, and the filtrate was then reduced in volume to ~1 mL. Addition of hexanes (8 mL) yielded a green precipitate that was collected, washed with hexanes (2 × 5 mL), and dried under vacuum at 78 °C for 24 h. Yield: 34 mg (60%). <sup>1</sup>H NMR (CD<sub>3</sub>OD):  $\delta$  8.37 (s, 6H, *H*<sub>2,2'</sub>), 7.62 (s, 6H, *H*<sub>5,5'</sub>). ESI-MS (MeOH): 652 (M<sup>+</sup> – CF<sub>3</sub>SO<sub>3</sub>), 502 (M<sup>+</sup> – 2 CF<sub>3</sub>SO<sub>3</sub>), 369 (M<sup>+</sup> – 2 CF<sub>3</sub>SO<sub>3</sub> – biim).  $\Lambda_{\text{M}}$  (MeOH) = 243. Anal. calcd. for C<sub>20</sub>H<sub>18</sub>F<sub>6</sub>N<sub>12</sub>O<sub>6</sub>S<sub>2</sub>Ru: C, 29.97; H, 2.26; N, 20.97. Found: C, 29.75; H, 2.31; N, 20.64.

### $[\text{Ru}(\text{Me}_2\text{biim})_3][\text{CF}_3\text{SO}_3]_2$ (**1b**)

To a solution of  $[\text{Ru}(\text{DMF})_6][\text{CF}_3\text{SO}_3]_3$  (74 mg, 0.075 mmol) in MeOH (5 mL) was added  $[\text{H}_2(\text{Me}_2\text{biim})][\text{CF}_3\text{CO}_2]_2$  (120 mg, 0.30 mmol). On being refluxed for 16 h, the solution became brown and then dark blue, when the solvent was removed under vacuum, and acetone (10 mL) was added to the black residue; the resulting mixture was filtered through Celite, and the filtrate was reduced in volume to ~1 mL. Addition of hexanes (8 mL) yielded a blue precipitate that was collected and dried under vacuum at 78 °C for 24 h. Yield: 42 mg (63%). <sup>1</sup>H NMR (CD<sub>3</sub>OD):  $\delta$  7.43 (s, 6H, *H*<sub>5,5'</sub>), 2.54 (s, 18H, *CH*<sub>3</sub>). ESI-MS (MeOH): 736 (M<sup>+</sup> – CF<sub>3</sub>SO<sub>3</sub>), 587 (M<sup>+</sup> – 2 CF<sub>3</sub>SO<sub>3</sub>), 575 (M<sup>+</sup> – CF<sub>3</sub>SO<sub>3</sub> – Me<sub>2</sub>biim), 425 (M<sup>+</sup> – 2 CF<sub>3</sub>SO<sub>3</sub> – Me<sub>2</sub>biim).  $\Lambda_{\text{M}}$  (MeOH) = 228. Anal. calcd. for C<sub>26</sub>H<sub>30</sub>F<sub>6</sub>N<sub>12</sub>O<sub>6</sub>S<sub>2</sub>Ru: C, 35.26; H, 3.41; N, 18.98. Found: C, 35.16; H, 3.32; N, 18.44.

### *cis*- $\text{RuCl}_2(\text{DMSO})_2(\text{biim})$ (**2a**)

To a yellow solution of *cis*- $\text{RuCl}_2(\text{DMSO})_4$  (70 mg, 0.15 mmol) in MeOH (10 mL) was added  $[\text{H}_2\text{biim}][\text{CF}_3\text{CO}_2]_2$  (54 mg, 0.15 mmol), and the mixture was refluxed for 4 h. The solvent was then reduced in volume to ~1 mL, when

addition of acetone (10 mL) yielded a yellow precipitate that was collected, washed with acetone ( $2 \times 5$  mL), and dried in vacuo at 78 °C for 24 h. Yield: 59 mg (88%).  $^1\text{H}$  NMR ( $\text{CD}_3\text{OD}$ ):  $\delta$  8.39, 8.37 (s, 2H,  $\text{H}_{2,2'}$ ), 7.72, 7.67 (s, 2H,  $\text{H}_{5,5'}$ ), 3.49 (s, 3H,  $\text{CH}_3$ ), 3.23 (s, 3H,  $\text{CH}_3$ ), 3.01 (s, 3H,  $\text{CH}_3$ ), 2.29 (s, 3H,  $\text{CH}_3$ ). IR: 3451 (s,  $\nu_{\text{N-H}}$ ), 1071 (s,  $\nu_{\text{S=O}}$ ), 1067 (s,  $\nu_{\text{S=O}}$ ), 1020 (m). ESI-MS (MeOH): 463 ( $\text{M}^+$ ), 427 ( $\text{M}^+ - \text{Cl}$ ), 349 ( $\text{M}^+ - \text{Cl} - \text{DMSO}$ ).  $\Lambda_{\text{M}}$  (MeOH) = 127. Anal. calcd. for  $\text{C}_{10}\text{H}_{18}\text{Cl}_2\text{N}_4\text{O}_2\text{S}_2\text{Ru}$ : C, 25.77; H, 3.93; N, 12.12. Found: C, 25.67; H, 3.98; N, 11.99.

#### $\text{RuCl}_2(\text{DMSO})_2(\text{Me}_2\text{biim})$ (**2b**)

This complex was synthesized using the procedure given for **2a**, but using  $[\text{H}_2(\text{Me}_2\text{biim})][\text{CF}_3\text{CO}_2]_2$  (58 mg, 0.15 mmol). Yield: 64 mg (90%).  $^1\text{H}$  NMR ( $\text{CD}_3\text{OD}$ ):  $\delta$  7.65, 7.47, 7.25 (s, 2H,  $\text{H}_{5,5'}$ ), 3.54–3.32, 3.25–2.73, 2.32 (br s, 12H,  $\text{CH}_3$ -S), 1.66, 1.59, 1.58 (s, 6H,  $\text{CH}_3$ - $\text{Me}_2\text{biim}$ ). IR: 3455 (s,  $\nu_{\text{N-H}}$ ), 1420 (s), 1099 (s,  $\nu_{\text{S=O}}$ ), 1091 (s,  $\nu_{\text{S=O}}$ ), 1014 (m). ESI-MS (MeOH): 491 ( $\text{M}^+$ ), 455 ( $\text{M}^+ - \text{Cl}$ ), 377 ( $\text{M}^+ - \text{Cl} - \text{DMSO}$ ).  $\Lambda_{\text{M}}$  (MeOH) = 132. Anal. calcd. for  $\text{C}_{12}\text{H}_{22}\text{Cl}_2\text{N}_4\text{O}_2\text{S}_2\text{Ru}$ : C, 29.39; H, 4.52; N, 11.42. Found: C, 29.58; H, 4.64; N, 11.82.

#### $\text{Ru}_2\text{Cl}_4(\text{DMSO})_4(\text{biim})$ (**3a**)

This complex was synthesized using the procedure given for **2a**, but using  $[\text{H}_2\text{biim}][\text{CF}_3\text{CO}_2]_2$  (26 mg, 0.074 mmol). Yield: 42 mg (73%).  $^1\text{H}$  NMR ( $\text{CD}_3\text{OD}$ ): see Results and discussion. IR: 3449 (br s,  $\nu_{\text{N-H}}$ ), 1086 (s,  $\nu_{\text{S=O}}$ ), 1081 (s,  $\nu_{\text{S=O}}$ ), 1013 (m). ESI-MS (MeOH): 757 ( $\text{M}^+ - \text{Cl}$ ), 679 ( $\text{M}^+ - \text{Cl} - \text{DMSO}$ ).  $\Lambda_{\text{M}}$  (MeOH)  $\approx$  110. Anal. calcd. for  $\text{C}_{14}\text{H}_{30}\text{Cl}_4\text{N}_4\text{O}_4\text{S}_4\text{Ru}_2$ : C, 21.27; H, 3.82; N, 7.09. Found: C, 21.36; H, 4.00; N, 7.51.

#### $\text{Ru}_2\text{Cl}_4(\text{DMSO})_4(\text{Me}_2\text{biim})$ (**3b**)

This complex was synthesized using the procedure given for **2a**, but using  $[\text{H}_2(\text{Me}_2\text{biim})][\text{CF}_3\text{CO}_2]_2$  (29 mg, 0.074 mmol). Yield: 49 mg (81%).  $^1\text{H}$  NMR ( $\text{CD}_3\text{OD}$ ): see Results and discussion. IR: 3457 (s,  $\nu_{\text{N-H}}$ ), 1090 (s,  $\nu_{\text{S=O}}$ ), 1085 (s,  $\nu_{\text{S=O}}$ ). ESI-MS (MeOH): 785 ( $\text{M}^+ - \text{Cl}$ ), 707 ( $\text{M}^+ - \text{Cl} - \text{DMSO}$ ), 629 ( $\text{M}^+ - \text{Cl} - 2 \text{ DMSO}$ ), 551 ( $\text{M}^+ - \text{Cl} - 3 \text{ DMSO}$ ).  $\Lambda_{\text{M}}$  (MeOH)  $\approx$  100. Anal. calcd. for  $\text{C}_{16}\text{H}_{34}\text{Cl}_4\text{N}_4\text{O}_4\text{S}_4\text{Ru}_2$ : C, 23.47; H, 4.19; N, 6.84. Found: C, 23.58; H, 4.19; N, 6.65.

#### In situ experiments on the syntheses

The biimidazole (0.005–0.05 mmol) was added to the Ru precursor ( $\sim 5$  mg, 0.01 mmol) dissolved in 1 mL  $\text{CD}_3\text{OD}$  in an NMR tube, fitted with a septum with a pin-hole for pressure release. The bottom of the tube was immersed in a water bath at 65 °C, so that the tube worked like an effective condenser. After selected times, the tube was cooled to RT, and the  $^1\text{H}$  NMR spectra were recorded.

## Results and discussion

### Ru complexes

Our group has previously used  $[\text{Ru}(\text{DMF})_6][\text{CF}_3\text{SO}_3]_3$ , an air-stable  $\text{Ru}^{\text{III}}$  complex, as a precursor for the synthesis of  $\text{Ru}^{\text{II}}$ -homoleptic complexes of the type  $[\text{RuL}_6][\text{CF}_3\text{SO}_3]_2$ , where L is a range of imidazoles. The syntheses were carried out in MeOH, but it was unclear whether the solvent or the imidazole was reducing the metal.<sup>19</sup> In this current work,

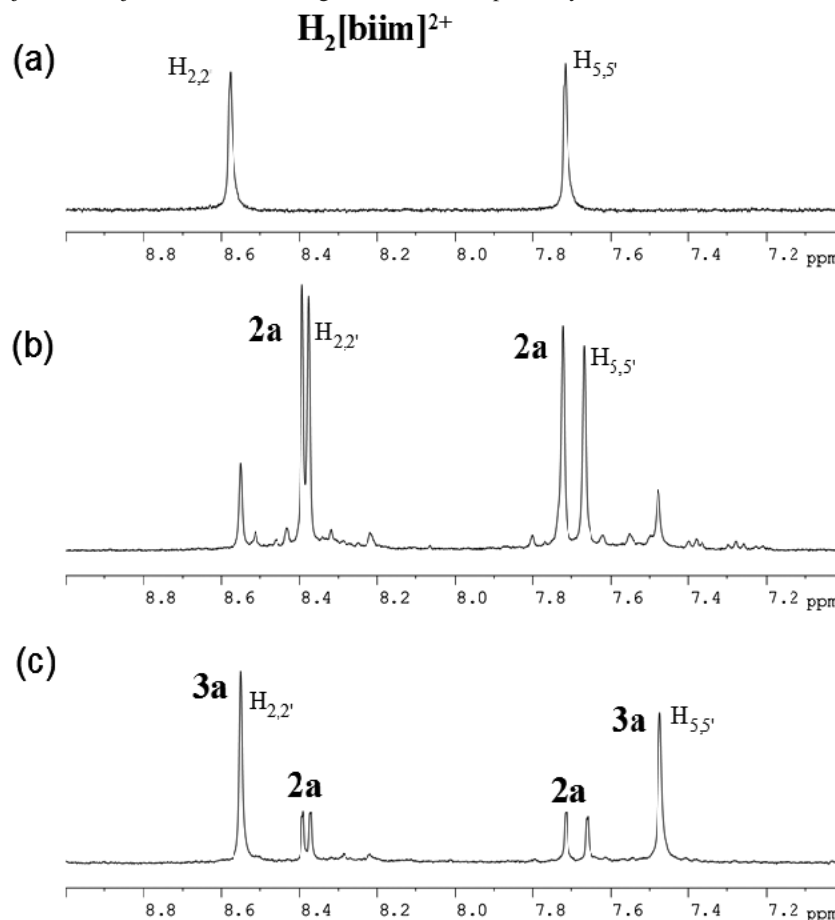

the same general procedure has been used for syntheses of  $[\text{Ru}(\text{N-N})_3][\text{CF}_3\text{SO}_3]_2$  complexes, where N–N is biim (complex **1a**) or  $\text{Me}_2\text{biim}$  (complex **1b**). Qualitative data from in situ experiments using biim:Ru ratios of 3:1 and 4:1 in  $\text{CD}_3\text{OD}$  suggest that biim acts as the reductant. At the 3:1 ratio, the in situ  $^1\text{H}$  spectrum after 12 h showed no trace of free  $[\text{H}_2\text{biim}]^{2+}$  (Fig. 2a),  $\sim 20\%$  formation of **1a** ( $\delta$  8.37 and 7.62; see below), and several other singlets in this same region including two at  $\delta$  8.92 and 7.84. At the 4:1 ratio after the same reaction time, formation of **1a** was close to completion and the other singlets except for those at  $\delta$  8.92 and 7.84 had decreased significantly in intensity. The retained  $\delta$  8.92 and 7.84 singlets are tentatively attributed to a biim oxidation product, while the “several other singlets” are attributed to  $\text{Ru}^{\text{II}}$ -mixed DMF/biim species. Such redox chemistry has been observed previously within  $\text{Ru}^{\text{III}}$ -imidazole systems<sup>20</sup>; the imidazole oxidation product was not identified, but chemistry involving loss of an H-atom to generate a radical that subsequently dimerizes seems feasible.<sup>21</sup>

With use of a biim:Ru reactant ratio of 4:1, **1a** and **1b** are isolated in reasonable yields ( $\sim 60\%$ ), and are well-characterized in the solid state and in solution by elemental analysis,  $^1\text{H}$  NMR spectroscopy, mass spectrometry, and conductivity data, while unfortunately X-ray quality crystals could not be isolated for any of the complexes reported in this paper. The  $^1\text{H}$  NMR spectrum of **1a** displays equal-intensity singlets at  $\delta$  8.37 and 7.62 for the  $\text{H}_{2,2'}$  and  $\text{H}_{5,5'}$  protons, respectively (cf. Fig. 2); the corresponding spectrum of **1b** consists of resonances at  $\delta$  7.43 and 2.54 (in a 1:3 integration ratio) for the  $\text{H}_{5,5'}$  and Me protons, respectively. The mass spectra of **1a** and **1b** do not show the peaks for the parent ionic compound, but peaks for species with the loss of one and two triflate anions, as well as a further loss of one N–N ligand, are evident. The molar conductivity values are consistent with the ionic formulations.<sup>18</sup>

The 1:1 reactions of the biimidazolium salts with *cis*- $\text{RuCl}_2(\text{DMSO})_4$  resulted in replacement of two DMSO ligands by the biimidazole with the isolation of **2a** and **2b** in  $\sim 90\%$  yield, the complexes being characterized by the methods given for **1a** and **1b**. The mass spectra of **2a** and **2b** show the  $\text{M}^+$  species, as well as fragments corresponding to the loss of one  $\text{Cl}^-$  and the subsequent loss of one DMSO ligand, and are consistent with the proposed solid-state formulations. The immediately measured and constant conductivities of **2a** and **2b** in MeOH ( $\sim 130 \Omega^{-1} \text{ cm}^2 \text{ mol}^{-1}$ ) are consistent with dissociation of a chlorido ligand,<sup>18</sup> and thus the ionic species  $[\text{RuCl}(\text{DMSO})_2(\text{MeOH})(\text{N-N})]\text{Cl}$  are considered to be present in solution.

The time-independent solution  $^1\text{H}$  NMR spectra in  $\text{CD}_3\text{OD}$  of **2a** (Fig. 2b) are consistent with this formulation: the four resonances seen for the biim protons show that the two rings are magnetically inequivalent, while four different, equal-intensity resonances seen for the Me groups of the DMSO indicate their inequivalence. Both DMSO ligands are considered to be S-bonded, mainly because of the strong  $\nu_{\text{SO}}$  IR bands seen in the solid state at 1071 and 1067  $\text{cm}^{-1}$ ; IR bands for O-DMSO are typically  $<1000 \text{ cm}^{-1}$  for  $\text{Ru}^{\text{II}}$  complexes.<sup>22</sup> Of the  $^1\text{H}$  NMR shifts for the Me protons of DMSO, the three at  $\delta$  3.49, 3.23, and 3.01 are consistent with S-bound DMSO, while the  $\delta$  2.29 resonance is unique in being upfield-shifted from that of free DMSO ( $\delta$  2.65)

**Fig. 2.**  $^1\text{H}$  NMR spectra (300 MHz,  $\sim 20^\circ\text{C}$ ) in  $\text{CD}_3\text{OD}$  showing the imidazole protons of: (a) free  $[\text{H}_2\text{biim}]^{2+}$ , (b) an in situ, 1:1  $\text{H}_2\text{biim}:\text{RuCl}_2(\text{DMSO})_4$  system after 4 h at  $65^\circ\text{C}$ , and (c) an in situ, 1:2  $\text{H}_2\text{biim}:\text{RuCl}_2(\text{DMSO})_4$  system after 4 h at  $65^\circ\text{C}$ . The spectra for isolated **2a** and **3a** in  $\text{CD}_3\text{OD}$  show just the major resonances of Figs. 2b and 2c, respectively.

but must also be due to an *S*-DMSO ligand. The upfield shift must arise from an interaction of this *S*-DMSO (*cis* to biim) with the  $\pi$ -system of an imidazole ring; similar upfield shifts have been noted by others.<sup>4f</sup> No signal at  $\delta$  2.65 was seen for free DMSO. The  $^1\text{H}$ - $^1\text{H}$  COSY NMR spectrum of **2a** (Fig. S1 of the Supplementary data) shows correlation between the two DMSO singlets at  $\delta$  2.29 and 3.01 and between those at  $\delta$  3.23 and 3.49, each pair corresponding to the two Me groups within one DMSO ligand. Similarly, the imidazole proton resonances correlate to reveal that the signals at  $\delta$  8.39 and 7.67 belong to the  $\text{H}_2$  and  $\text{H}_5$  of one ring, and those at  $\delta$  8.37 and 7.72 are associated with the  $\text{H}_{2'}$  and  $\text{H}_{5'}$  protons of the other ring.

Assuming that no immediate isomerization of **2a** occurs on its dissolution in MeOH, an all-*cis* isomer for the solid-state structure seems reasonable (Fig. 1); replacement of one of the chlorides by MeOH (likely the one *trans* to the DMSO) would give a solution species consistent with the NMR data. Of note, the all-*cis* structure has been demonstrated crystallographically for the similar complex  $\text{RuCl}_2(\text{DMSO})_2(1,2\text{-dimethylimidazole})_2$ <sup>23</sup>; however, a complex of the type  $\text{RuCl}_2(\text{S-S})\text{L}_2$ , where S-S is a bidentate *S*-bonded sulfoxide and L is a nitro-substituted imidazole, has *trans* chlorides in the solid state, although in aqueous solution *cis*- and *trans*-isomers are present.<sup>9a</sup>

Use of an increased 5:1 reactant ratio ( $[\text{H}_2\text{biim}]^{2+}:\text{cis-RuCl}_2(\text{DMSO})_4$ ) was anticipated to form  $\text{RuCl}_2(\text{biim})_2$ , analogous to the production of  $\text{RuCl}_2(\text{pyridine})_4$  when the sulfoxide complex was reacted with pyridine,<sup>24</sup> but only **2a** was isolated.

Complex **2b** is considered to be analogous to **2a**, the IR data (1099, 1091, and 1014  $\text{cm}^{-1}$ ) and the  $^1\text{H}$  NMR data (overlapping signals between  $\delta$  3.51–2.23) are again considered consistent with solely *S*-bonded DMSO; again no free DMSO was detected. However, the  $^1\text{H}$  NMR spectrum of **2b** in  $\text{CD}_3\text{OD}$  (Fig. 3a) is more complicated than that of **2a**, in that three resonances are observed for the  $\text{H}_5$  protons: two equal intensity signals at  $\delta$  7.65 and 7.25, and a more intense signal at  $\delta$  7.47. Further, there are three resonances for the Me protons of the  $\text{Me}_2\text{biim}$ :  $\delta$  1.66, 1.59, and 1.58 (Fig. 3b), the equal intensities of two higher-field ones being three times the intensity of the  $\delta$  7.65 and 7.25 signals. These four resonances correspond to a single isomer (labelled **2b**) in which the two halves of  $\text{Me}_2\text{biim}$  ligand are inequivalent, while the remaining two 1:3 intensity  $\delta$  7.47 and 1.66 signals correspond to a second isomer (**2b'**) containing equivalent Me groups in the  $\text{Me}_2\text{biim}$  ligand. The 1:1 electrolyte conductivity of **2b** in MeOH implies that an average of one  $\text{Cl}^-$  is dissociated, probably from each isomer. In the absence of any rapid isomerization processes,

**Fig. 3.**  $^1\text{H}$  NMR data (300 MHz, 298 K) for  $\text{Me}_2\text{biim}$  complexes in  $\text{CD}_3\text{OD}$ . (a) In situ spectrum shows  $\text{H}_{5,5'}$  protons of **2b** and **2b'**, and the side-product **3b**. (b) Me signals for the  $\text{Me}_2\text{biim}$  of **2b** and **2b'**. (c)  $\text{H}_{5,5'}$  protons for isomers of **3b** (see text). The intensity scales in (a), (b), and (c) are different.

the solution **2b'** species could be generated from a solid-state *trans*-,*cis*- $\text{RuCl}_2(\text{DMSO})_2(\text{N}-\text{N})$  isomer via replacement of a  $\text{Cl}^-$  by  $\text{MeOH}$ . Similarly, the two solid-state “precursor structures” *cis*-,*trans*- $\text{RuCl}_2(\text{DMSO})_2(\text{N}-\text{N})$  and *cis*-,*cis*- $\text{RuCl}_2(\text{DMSO})_2(\text{N}-\text{N})$  could generate the **2b** isomer in solution. The latter is preferred because  $^1\text{H}$  NMR data (in  $\text{CDCl}_3$ ) of  $\text{RuCl}_2(\text{DMSO})_2(2\text{Me-imidazole})_2$ ,<sup>25</sup> and analogous complexes with other substituted imidazoles,<sup>22,23</sup> are consistent with an all-*cis* structure; and further, the same geometry seems likely for **2a**.

The reactions of the biimidazolium salts with *cis*- $\text{RuCl}_2(\text{DMSO})_4$ , but using a  $\text{Ru}:[\text{H}_2(\text{N}-\text{N})]^{2+}$  ratio of 2:1, generate the diruthenium complexes  $\text{Ru}_2\text{Cl}_4(\text{DMSO})_4(\text{N}-\text{N})$ , where (N-N) is biim (complex **3a**) or  $\text{Me}_2\text{biim}$  (complex **3b**). Elemental analyses support this formulation, as well as  $[\text{M}^+ - \text{Cl} - n \times \text{DMSO}]$  fragments in the mass spectra ( $n = 0$  and 1 for **3a**, and 0–3 for **3b**), with isotopic distribution patterns different from those of **2a** and **2b**, and consistent with the presence of two Ru atoms (Figs. S2 and S3). The IR  $\nu_{\text{SO}}$  data for **3a** and **3b** show strong bands in the  $1080\text{ cm}^{-1}$  region that are again consistent with *S*-bonded DMSO.

The immediately measured molar conductivities of a  $\text{MeOH}$  solution of the isolated **3a** and **3b** ( $\sim 100\text{ }\Omega^{-1}\text{ cm}^2\text{ mol}^{-1}$ ) are in the range for a 1:1 electrolyte,<sup>18</sup> again consistent with loss of a chlorido ligand. The immediately measured  $^1\text{H}$  NMR spectrum of **3a** dissolved in  $\text{CD}_3\text{OD}$  reveals two singlets for the  $\text{H}_{2,2'}$  and  $\text{H}_{5,5'}$  protons (Fig. 2), indicating a species with equivalent imidazole rings; this could be formed from a solid-state structure with a  $\text{Ru}^{\text{II}}(\mu\text{-Cl})_n\text{Ru}^{\text{II}}$  core ( $n = 2, 3$ ), but even species with  $\mu\text{-SO}$  cannot be ruled out.<sup>26</sup> In the DMSO region of the  $^1\text{H}$  NMR spectrum, there are signals in the  $\delta\text{ } 3.45\text{--}3.25$  and  $2.65$  regions (Fig. S4), which correspond to *S*-DMSO and free DMSO, but the spectra change with time, and this could be due to solvation and (or) monomer formation. Further studies are needed to determine the true nature of this “dimer”. Loss of  $\text{Cl}^-$  and DMSO ligands from  $\text{Ru}^{\text{II}}$ -chloro(DMSO) complexes in solu-

tion is well-documented, with *S*-DMSO exchanging slower than *O*-DMSO.<sup>27</sup> The **3b** system is more complex because the immediate  $^1\text{H}$  NMR spectrum of **3b** dissolved in  $\text{CD}_3\text{OD}$  shows major resonances for the  $\text{H}_{5,5'}$  protons at  $\delta\text{ } 7.38$  and  $7.33$  with a respective intensity ratio of  $\sim 2:1$  (Fig. 3c), these being attributed to two isomers, each with equivalent imidazole rings; there is also a pair of less intense, 1:1 singlets at  $\delta\text{ } 7.47$  and  $7.46$ , implying the presence of a third isomer with inequivalent imidazoles. The methyl region is complex because of numerous overlapping and unresolved resonances attributed to the Me resonances of DMSO (coordinated and free) and  $\text{Me}_2\text{biim}$  ligands.

### Biological data

The new complexes were tested against MDA-MB-435S human breast-cancer cells for anti-proliferatory activity using the MTT assay (Table 1). Complexes **1a** and **1b** exhibit  $\text{IC}_{50}$  values of 18 and  $36\text{ }\mu\text{mol/L}$ , respectively (Fig. S5), which indicates significant activity better than, or equal to, that of cisplatin ( $35\text{ }\mu\text{mol/L}$ ). No MTT studies have been reported on the analogous  $[\text{Ru}(\text{imidazole})_6][\text{CF}_3\text{SO}_3]_2$  or other similar homoleptic imidazole complexes,<sup>19</sup> and so the toxicity effect of the bidentate versus the corresponding monodentate imidazole ligands cannot be compared. Our group has shown that incubation of mouse squamous-cell carcinoma cells (SCCVII) with  $[\text{Ru}(\text{imidazole})_6][\text{CF}_3\text{SO}_3]_2$  for 3 h did lead to Ru-uptake of about  $15\text{ ng per } 10^6\text{ cells}$ .<sup>28</sup> In the current work, Ru-uptakes of **1a** and **1b** in Chinese hamster ovary (CHO) cells were 26 and  $20\text{ ng per } 10^6\text{ cells}$ , respectively, but the DNA isolated from these cells contained no detectable Ru, implying that the uptake is not associated with DNA-binding at the metal, in contrast to the behaviour of cisplatin.<sup>1</sup> There is considerable evidence elsewhere that biologically active Ru species might react with protein targets other than DNA.<sup>1–3</sup> Although our data are for different cell lines, the respective  $\text{IC}_{50}$  values for **1a** and **1b** possibly correlate with the degree of Ru accumulation, rather than resulting, for example, from a difference in activity of the

**Table 1.** IC<sub>50</sub> values for complexes.

Complex	IC <sub>50</sub> (μmol/L)
[Ru(biim) <sub>3</sub> ][CF <sub>3</sub> SO <sub>3</sub> ] <sub>2</sub> ( <b>1a</b> )	18
[Ru(Me <sub>2</sub> biim) <sub>3</sub> ][CF <sub>3</sub> SO <sub>3</sub> ] <sub>2</sub> ( <b>1b</b> )	36
RuCl <sub>2</sub> (DMSO) <sub>2</sub> (biim) ( <b>2a</b> )	800
RuCl <sub>2</sub> (DMSO) <sub>2</sub> (Me <sub>2</sub> biim) ( <b>2b</b> )	400
Ru <sub>2</sub> Cl <sub>4</sub> (DMSO) <sub>4</sub> (biim) ( <b>3a</b> )	>1000
Ru <sub>2</sub> Cl <sub>4</sub> (DMSO) <sub>4</sub> (Me <sub>2</sub> biim) ( <b>3b</b> )	>1000
Cisplatin	35

**Note:** Error limits are ± 10%; tested against MDA-MB-435S cells in Leibovitz's L-15 medium with L-glutamine after incubation at 37 °C for 70 h (ref. 9a).

complexes inside the cell. Further MTT, Ru-uptake, and DNA-binding studies on the Ru<sup>II</sup>-imidazole and (or) the Ru-biimidazole systems with the use of the same cell line are needed for a more direct comparison between the two systems. The promising activities of **1a** and **1b** are the highest of the Ru<sup>II</sup> complexes that our group has studied with the same cell line (see the Introduction)<sup>7–10</sup> and, of note, the Ru<sup>III</sup> complexes [Ru(O–O)<sub>2</sub>(N–N)]CF<sub>3</sub>SO<sub>3</sub>, where O–O<sup>–</sup> is maltolato (see the Introduction) and N–N is biim or Me<sub>2</sub>-Biim, have respective IC<sub>50</sub> values of 50 and 15 μmol/L against the same cell line,<sup>29</sup> close to the values for **1a** and **1b**; this finding indirectly supports the early premise that Ru<sup>III</sup> complexes are likely activated via in vivo reduction to Ru<sup>II</sup>.<sup>6</sup> To contribute constructively to this aspect, more systematic studies are required on the Ru<sup>III</sup>/Ru<sup>II</sup> reduction potentials of the complexes studied in our group.<sup>7–10,29</sup>

The mixed biimidazole/DMSO complexes **2a** and **2b** exhibit IC<sub>50</sub> values of 800 and 400 μmol/L, respectively, which are close to values measured for the respective free biimidazoles (800 and 650 μmol/L for H<sub>2</sub>biim and Me<sub>2</sub>-biim). IC<sub>50</sub> values for **3a** and **3b** were >1000 μmol/L.

The conclusions on the nature of the new complexes presented here would certainly be strengthened by X-ray data, particularly for type-2 and -3 complexes, but many attempts at growing suitable crystals were unsuccessful. Nevertheless, the findings perhaps suggest that the presence of labile chlorido or DMSO ligands is detrimental for anti-proliferative activity.

## Supplementary data

Supplementary data for this article are available on the journal Web site (<http://canjchem.nrc.ca>).

## Acknowledgments

We thank Dr. Elena Polishchuk of the Biological Services in this department for assistance with the MTT assay, the Natural Sciences and Engineering Research Council of Canada (NSERC) for financial support, and Colonial Metals Inc. for the RuCl<sub>3</sub>·3H<sub>2</sub>O.

# A quasi-classical trajectory (QCT) study of the H + OF reaction stereodynamics

Dan Zhao, Tian Yu Zhang, and Tian Shu Chu

**Abstract:** Based on the global three-dimensional adiabatic potential surface of the  $1^3A'$  excited electronic state (*J. Chem. Phys.* 2005, **123**, 114310) of the OHF system, we investigated the  $H + OF \rightarrow OH + F/HF + O$  reaction stereodynamics by using the quasi-classical trajectory (QCT) method. The four polarization-dependent differential cross sections (PDDCSs) and the three angular distributions  $P(\theta_r)$ ,  $P(\varphi_r)$ ,  $P(\theta_r, \varphi_r)$  were calculated at a low collision energy of 0.48 eV for both product channels. The results indicated that the products are backward-scattering on the triplet state, and the product rotational angular momenta are aligned or oriented. Moreover, there is a remarkable difference between the polarization behaviors of the two product channels. Product orientation exhibited by the  $OH + F$  channel is found to be absent in the  $HF + O$  channel at this collision energy albeit the latter shows stronger alignment along the direction perpendicular to the reagent relative velocity  $k$  than  $OH + F$ .

**Key words:** chemical stereodynamics, product alignment, product orientation, quasi-classical trajectory (QCT).

**Résumé :** En se basant sur la surface de potentiel adiabatique tridimensionnel global de l'état excité électronique excité  $1^3A'$  (*J. Chem. Phys.* 2005, **123**, 114310) du système OHF, on a étudié la stéréodynamique de la réaction  $H + OF \rightarrow OH + F/HF + O$  à l'aide de la méthode de la trajectoire quasi-classique (TQC). On a calculé les quatre sections droites différentielles dépendantes de la polarisation (SDDDP) et les trois distributions angulaires  $P(\theta_r)$ ,  $P(\varphi_r)$  et  $P(\theta_r, \varphi_r)$  à une faible énergie de collision, 0,48 eV, pour chacune des deux voies conduisant au produit. Les résultats indiquent que les produits correspondent à une rétrodiffusion sur l'état triplet et que les moments angulaires rotationnels du produit sont alignés ou orientés. De plus, il existe une différence remarquable entre les comportements de polarisation des deux voies conduisant aux produits. On a trouvé que, à ce niveau d'énergie de collision, l'orientation du produit présentée par la voie  $OH + F$  est absente de la voie  $HF + O$  même si cette dernière présente un alignement plus important le long de la direction perpendiculaire à la vitesse relative du réactif,  $k$ , que celui observé pour la voie  $OH + F$ .

**Mots-clés :** stéréodynamique chimique, alignement du produit, orientation du produit, méthode de la trajectoire quasi-classique (TQC).

[Traduit par la Rédaction]

## Introduction

The HOF system is one of the most elementary trimolecular systems and can be considered as a model system for HOX (X = F, Cl, Br, and so forth). Recently, Gómez-Carrasco et al. have studied the global three-dimensional potential energy surfaces (PESs) for the OHF system at a high ab initio level<sup>1</sup> and obtained the adiabatic PESs of OHF for the ground  $1^1A'$  singlet state and the excited  $2^3A''$  and  $1^3A'$  triplet states.<sup>2</sup> The reaction dynamics of  $F + OH \rightarrow HF + O$  has been studied by a quantum wave packet method within a centrifugal sudden (CS) approximation on the two excited triplet electronic states.<sup>2</sup> A comparative study of the full channels of the  $H + OF$  reaction by quantum mechanical (QM) and quasi-classical trajectory (QCT) methods,<sup>3</sup> as well as the QCT calculations for the reaction  $H + OF \rightarrow OH + F$ <sup>4,5</sup> have also been reported recently using the  $2^3A''$  PES.

In this article, by performing the QCT calculation on the  $1^3A'$  triplet state,<sup>6</sup> we explored the stereodynamics of the ti-

tle reaction at a fixed collision energy of 0.48 eV by means of depicting the polarization-dependent differential cross sections (PDDCSs) and the three angular distributions of  $P(\theta_r)$ ,  $P(\varphi_r)$ , and  $P(\theta_r, \varphi_r)$  for the two product channels. The validity of applying QCT method to the title reaction has been tested and proved in a previous study<sup>3</sup> showing a fairly good agreement between the QM and QCT calculations with the  $2^3A''$  electronic state being involved.

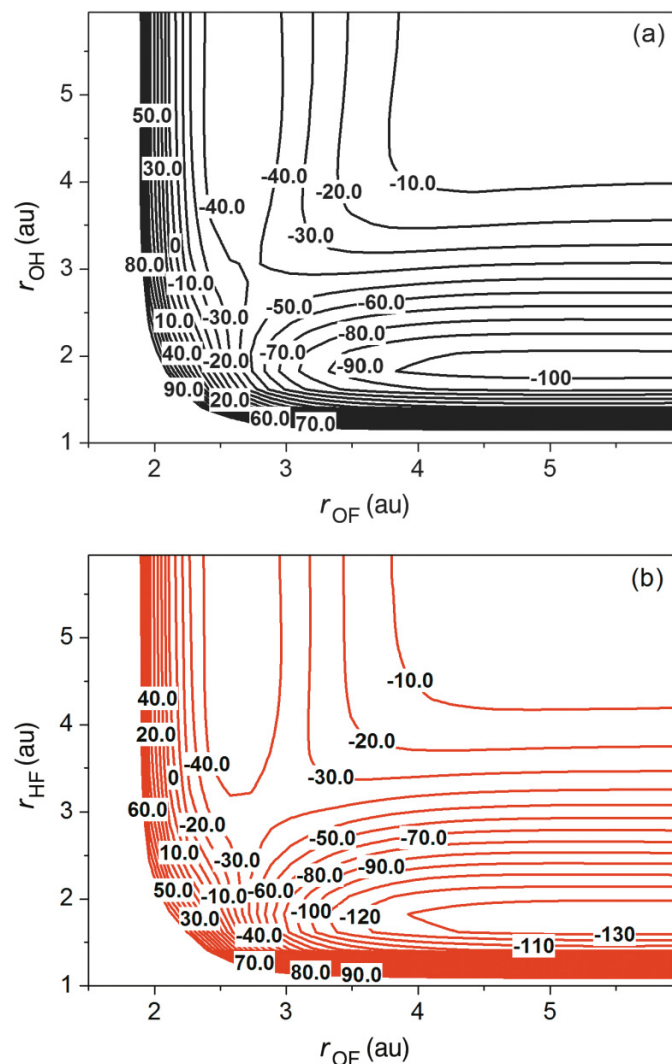

The present study employed the benchmark QCT code<sup>7–18</sup> developed initially to simulate and explain the polarization behaviors of the products in laser-induced molecular beam experiments. Furthermore, an innovative theoretical work came up in 1997 describing the optical preparation of oriented and aligned reagents in weak laser field.<sup>19</sup> Despite the QCT code we employed here, there are many other developed theoretical methods and computational codes,<sup>20–25</sup> which can be used in the stereodynamics exploration of a chemical reaction. In the following section, we briefly de-

scribe the present QCT calculation method together with relevant details of the calculation. Results and discussion are presented in a later section. Finally, the last section is the conclusions.

### Calculation aspects

The calculation method we used here is the same as the one described in refs. 8–18. The QCT calculation is performed within a center of mass frame in which the reagent relative velocity vector  $k$  is parallel to the  $z$  axis, and  $x$ – $z$  plane is the scattering plane containing the initial and final relative velocity vectors,  $k$  and  $k'$ . The scattering angle between the reagent relative velocity and product relative velocity is  $\theta_r$ . The polar and azimuthal angles of the product rotational angular momentum  $j'$  are  $\theta_r$  and  $\varphi_r$ , respectively.

The fully correlated center-of-mass angular distribution is written as the sum,

$$[1] \quad P(\omega_t, \omega_r) = \sum_{kq} \frac{[k]}{4\pi} \frac{1}{\sigma} \frac{d\sigma_{kq}}{d\omega_t} C_{kq}(\theta_r, \varphi_r)^*$$

where  $[k] = 2k + 1$ ,  $\frac{1}{\sigma} \frac{d\sigma_{kq}}{d\omega_t}$  is a generalized polarization-dependent differential cross section, and  $C_{kq}(\theta_r, \varphi_r)$  are modified spherical harmonics.

The PDDCS can be further written as follows:

$$[2] \quad \frac{1}{\sigma} \frac{d\sigma_{kq}}{d\omega_t} = \sum_{k_1} \frac{[k_1]}{4\pi} S_{kq\pm}^{k_1} C_{k_1-q}(\theta_r, 0)$$

where  $S_{kq\pm}^{k_1} = \langle c_{k_1q}(\theta_r, 0) c_{kq}(\theta_r, 0) [(-1)^q e^{iq\varphi_r} \pm e^{-iq\varphi_r}] \rangle$ , which is evaluated using the expected value expression.

The angular distribution function  $P(\theta_r)$  describing the  $k - j'$  correlation can be expanded in a series of Legendre polynomials

$$[3] \quad P(\theta_r) = 1/2 \sum_k (2k + 1) a_0^k P_k(\cos \theta_r)$$

The coefficients  $a_0^k = \langle P_k(\cos \theta_r) \rangle$  are called orientation ( $k$  is odd) or alignment ( $k$  is even) parameters.

The dihedral angle distribution function  $P(\varphi_r)$  describing  $k - k' - j$  correlation can be expanded in Fourier series

$$[4] \quad P(\varphi_r) = \frac{1}{2\pi} \left[ 1 + \sum_{n(\text{even} \geq 2)} a_n \cos(n\varphi_r) + \sum_{n(\text{odd} \geq 1)} b_n \sin(n\varphi_r) \right]$$

where  $a_n = 2\langle \cos n\varphi_r \rangle$  and  $b_n = 2\langle \sin n\varphi_r \rangle$ .

The following expansion is used to obtain the  $P(\theta_r, \varphi_r)$  distribution,

$$[5] \quad P(\theta_r, \varphi_r) = \frac{1}{4\pi} \sum_k \sum_{q \geq 0} (a_{q\pm}^k \cos q\varphi_r - a_{q\mp}^k \sin q\varphi_r) C_{kq}(\theta_r, 0)$$

with  $a_{q\pm}^k = 2\langle C_{kq}(\theta_r, 0) \cos q\varphi_r \rangle$  ( $k$  is even) and  $a_{q\pm}^k = 2i\langle C_{kq}(\theta_r, 0) \sin q\varphi_r \rangle$  ( $k$  is odd).

In this study, the initial distance from the H atom to the center of mass of OF is 10 Å. The batches of 250 000 trajectories were sampled at the collision energy of 0.48 eV (the lowest collision energy to ensure the reaction takes place via both channels), while setting the initial rovibrational conditions of the OF reagent to be  $v = 0$ ,  $j = 0$ . An integration step of 1 fs is found sufficient to ensure the convergence of the calculated stereodynamics quantities we presented here. The optimized maximum impact parameter  $b_{\text{max}}$  at 0.48 eV is 1.2 Å and 0.35 Å for the OH + F and HF + O product channels, respectively.

### Results and discussion

It is known that PES plays a critical role in chemical stereodynamics. Shown in Fig. 1 are the contour plots of the  $1^3A'$  PES for the reactions of  $H + OF \rightarrow OH + F$  and  $H + OF \rightarrow HF + O$  with collinear geometry. The topographic features of the PES reflect that both reactive channels are dominated by abstraction mechanism due to the barrier in reactant region.

Figure 2 shows the calculated four PDDCSs for  $H + OF \rightarrow OH + F$  and  $H + OF \rightarrow HF + O$ . The  $(2\pi/\sigma)(d\sigma_{00}/d\omega_t)$  is proportional to the usual differential cross section and displays the scattering direction of the products. From

**Fig. 2.** The polarization-dependent differential cross sections  $(2\pi/\sigma)(d\sigma_{kl}/d\omega_l)$  for  $\text{H} + \text{OF} \rightarrow \text{OH} + \text{F}$  (solid line) and  $\text{H} + \text{OF} \rightarrow \text{HF} + \text{O}$  (dash-dotted line) at the collision energy of 0.48 eV. (a)  $(2\pi/\sigma)(d\sigma_{00}/d\omega_l)$ , (b)  $(2\pi/\sigma)(d\sigma_{20}/d\omega_l)$ , (c)  $(2\pi/\sigma)(d\sigma_{22+}/d\omega_l)$ , and (d)  $(2\pi/\sigma)(d\sigma_{21-}/d\omega_l)$ .

**Fig. 3.** The distribution of  $P(\theta_r)$  reflecting  $k - j'$  correlation for  $\text{H} + \text{OF} \rightarrow \text{OH} + \text{F}$  (solid line) and  $\text{H} + \text{OF} \rightarrow \text{HF} + \text{O}$  (dashed-dotted line) at the collision energy of 0.48 eV.

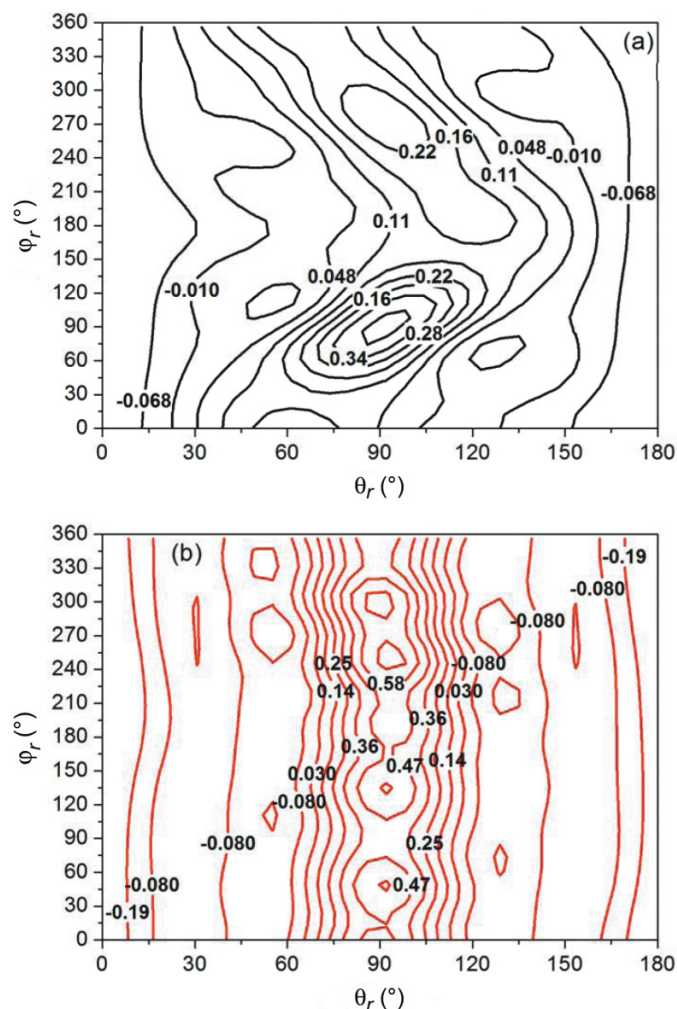

Fig. 2a, it can be seen that the two product channels are obviously backward-scattering and the degree of the backward scattering is much larger in the  $\text{HF} + \text{O}$  product channel. Such backward scattering shown here is in consistence with the abstraction mechanism of the title reaction that occurred on the  $1^3\text{A}'$  electronic state. Figure 2b plotted the  $(2\pi/\sigma)(d\sigma_{20}/d\omega_l)$ , which is found to be opposite to the  $(2\pi/\sigma)(d\sigma_{00}/d\omega_l)$  over the whole range of the scattering angle and for both product channels. This opposite trend suggests that product angular momentum is strongly aligned perpendicular to the reagent relative velocity  $k$ . Figure 2c shows the  $(2\pi/\sigma)(d\sigma_{22+}/d\omega_l)$  of the two product channels. Comparing the two channels, it

**Fig. 4.** The dihedral angle distribution of  $P(\varphi_r)$  with respect to the  $k - k'$  and  $k - j'$  planes for  $\text{H} + \text{OF} \rightarrow \text{OH} + \text{F}$  (solid line) and  $\text{H} + \text{OF} \rightarrow \text{HF} + \text{O}$  (dashed-dotted line) at the collision energy of 0.48 eV.

can be seen that the  $(2\pi/\sigma)(d\sigma_{22+}/d\omega_l)$  of the  $\text{HF} + \text{O}$  product channel is completely different from that of  $\text{OH} + \text{F}$ . That is, the  $(2\pi/\sigma)(d\sigma_{22+}/d\omega_l)$  of the  $\text{HF} + \text{O}$  product channel is almost zero while that of the  $\text{OH} + \text{F}$  product channel is fluctuant with the scattering angle. As indicated by the present calculation, around the two scattering angles of  $145^\circ$  and  $158^\circ$ , the value of  $(2\pi/\sigma)(d\sigma_{22+}/d\omega_l)$  in Fig. 2c is approximately  $-0.6124$  for the  $\text{OH} + \text{F}$  product channel. According to the classical limiting value of the alignment parameters, this value of  $-0.6124$  gives the information that the azimuthal angles ( $\theta_r$  and  $\varphi_r$ ) of  $j'$  are  $(45^\circ, \text{ and } 90^\circ, \text{ respectively})$ . Therefore, around these two scattering angles,

**Fig. 5.** Polar plots of  $P(\theta_r, \varphi_r)$  distribution averaged over all scattering angles for (a)  $\text{H} + \text{OF} \rightarrow \text{OH} + \text{F}$  and (b)  $\text{H} + \text{OF} \rightarrow \text{HF} + \text{O}$ .

the  $\text{OH} + \text{F}$  products tend to align along the direction of the vector addition of  $y$  and  $z$ . In turn, the value of  $(2\pi/\sigma)(d\sigma_{21}/d\omega_r)$  of the  $\text{OH} + \text{F}$  product channel in Fig. 2d is found to be  $-1.2247$  with the scattering angles around  $147^\circ$  and  $173^\circ$ . In these cases, the azimuthal angles ( $\theta_r$  and  $\varphi_r$ ) of  $j'$  are ( $45^\circ$  and  $0^\circ$ , respectively), which means that the product alignment in the  $\text{OH} + \text{F}$  channel is along the direction of the vector addition of  $z$  and  $x$ .

The distribution of  $P(\theta_r)$  reflected the  $k - j'$  correlation of the products. Seen from Fig. 3, the  $P(\theta_r)$  distributions of the two product channels all peaked at  $90^\circ$  and are symmetric with respect to  $90^\circ$ . This symmetric phenomenon observed in the two  $P(\theta_r)$  distributions implies that the product rotational angular momentum is strongly aligned along the perpendicular direction to the reagent relative velocity. Moreover, the  $P(\theta_r)$  peak position in  $\text{H} + \text{OF} \rightarrow \text{HF} + \text{O}$  is much higher than in  $\text{H} + \text{OF} \rightarrow \text{OH} + \text{F}$ , and the  $P(\theta_r)$  distribution in the latter is much broader than the former. As a result, we can say that of the two product channels, there is much stronger product alignment perpendicular to  $k$  in  $\text{H} + \text{OF} \rightarrow \text{HF} + \text{O}$ .

The distribution of  $P(\varphi_r)$  reflected the  $k - k' - j'$  correla-

tion of the products. Figure 4 plotted the  $P(\varphi_r)$  distributions for  $\text{H} + \text{OF} \rightarrow \text{OH} + \text{F}$  and  $\text{H} + \text{OF} \rightarrow \text{HF} + \text{O}$ , respectively. The  $P(\varphi_r)$  distribution can reflect the alignment and orientation of the product rotational angular momentum  $j'$ . In contrast to the distribution of  $P(\theta_r)$ , this kind of distribution is asymmetric with respect to  $\varphi_r = 180^\circ$ . Clearly, in  $\text{H} + \text{OF} \rightarrow \text{OH} + \text{F}$ ,  $P(\varphi_r)$  peaked around  $90^\circ$  and at  $270^\circ$ , reflecting that the  $\text{OH}$  product tends to align along the  $y$  axis or along the direction perpendicular to the scattering  $k - k'$  plane. In addition, the fact that the value of  $P(\varphi_r)$  around  $90^\circ$  is larger than that at  $270^\circ$  has also demonstrated that the orientation of  $j'$  of the product  $\text{OH}$  tends to point to the positive direction of the  $y$  axis. While in  $\text{H} + \text{OF} \rightarrow \text{HF} + \text{O}$ , we see that the corresponding  $P(\varphi_r)$  distribution exhibits rather isotropic behavior with lots of oscillations. This means that as compared with  $\text{OH} + \text{F}$ , the  $k - k' - j'$  correlation is not very remarkable for the  $\text{HF} + \text{O}$  products. The rather isotropic feature of the  $P(\varphi_r)$  distribution observed in the reaction  $\text{H} + \text{FO} \rightarrow \text{HF} + \text{O}$  has nonetheless suggested that, at such a low collision energy, the  $\text{HF} + \text{O}$  products have very weak or almost no polarization (alignment and orientation) behaviors that are indicated by the  $P(\varphi_r)$  distribution. It is notable here that although the  $\text{HF} + \text{O}$  product channel lacked the obvious product alignment along the direction perpendicular to the scattering  $k - k'$  plane as informed by the  $P(\varphi_r)$  distribution, it does illustrate stronger product alignment that is perpendicular to the reagent relative velocity  $k$  as indicated by the  $P(\theta_r)$  distribution in Fig. 3.

The  $P(\theta_r, \varphi_r)$  distribution further supported the above-observed polarization behaviors of both products. Figure 5 plotted the  $P(\theta_r, \varphi_r)$  distribution averaged over all scattering angles for  $\text{H} + \text{OF} \rightarrow \text{HF} + \text{O}$  and  $\text{H} + \text{OF} \rightarrow \text{HO} + \text{F}$ . We can see that the distributions of  $P(\theta_r, \varphi_r)$  are consistent with the distributions of  $P(\theta_r)$  and  $P(\varphi_r)$  in Figs. 3 and 4. Again, these distributions indicated a rather stronger product polarization in  $\text{OH} + \text{F}$  than  $\text{HF} + \text{O}$ , as described by the  $P(\varphi_r)$  distribution. This polar plot also supported a stronger product alignment in  $\text{HF} + \text{O}$  than  $\text{OH} + \text{F}$ , as indicated by the  $P(\theta_r)$  distribution.

## Conclusions

By running a batch of 250 000 trajectories on the excited  $1^3\text{A}'$  electronic state, this paper presented a stereodynamical picture for the title reaction at a low collision energy of 0.48 eV. The calculated PDDCS results revealed that the products in  $\text{H} + \text{OF} \rightarrow \text{OH} + \text{F}$  and  $\text{H} + \text{OF} \rightarrow \text{HF} + \text{O}$  are both backward scattering, with much stronger backward scattering being found in the  $\text{HF} + \text{O}$  product channel. Both channels show the product alignment along the direction perpendicular to the reagent relative velocity  $k$ , and such product alignment is found to be more pronounced in the  $\text{HF} + \text{O}$  product channel. With respect to the  $P(\varphi_r)$  distribution, however, the  $\text{OH} + \text{F}$  product channel is found to have much stronger polarizations, and the product tends to align along the direction perpendicular to the scattering  $k - k'$  plane and orient to the positive direction of the  $y$  axis. Such polarization behaviors are absent in the  $\text{HF} + \text{O}$  product channel. The stereodynamics information is further validated with the calculated results of the  $P(\theta_r, \varphi_r)$  distribution.

# Direct ultrasound-assisted methylation of fatty acids in serum for free fatty acid determinations

Liyan Liu, Ying Li, Rennan Feng, and Changhao Sun

**Abstract:** A method for simultaneous determination of 16 free fatty acids (FFAs) in serum is described. The method involves conversion of FFAs to fatty acid methyl esters (FAMES) using the heat of ultrasonic waves followed by gas chromatography and mass spectrometry (GC–MS) analysis. Optimum levels of the variables affecting the yield of FAMES were investigated. The results indicate that the optimal levels are 55 °C, 60 W, 10% H<sub>2</sub>SO<sub>4</sub>/CH<sub>3</sub>OH, and 50 min. Recoveries ranged from 85.32% to 112.11%, with a detection limit ranging from 0.03 to 0.08 µg mL<sup>-1</sup>. The linearity, using the linear correlation coefficient, was higher than 0.9914.

**Key words:** ultrasound-assisted methylation, fatty acid, gas chromatography and mass spectrometry (GC–MS), serum.

**Résumé :** On décrit une méthode de détermination simultanée de seize acides gras libres (AGL) dans le sérum. La méthode implique la conversion de ces acides gras en esters méthyliques d'acides gras (EMAG) par un chauffage à l'aide d'ondes ultrasoniques, suivi d'une analyse par spectrométrie de masse couplée à une chromatographie gazeuse (SM–CG). On a étudié les niveaux optimum des variables affectant le rendement en esters méthyliques (EMAG). Les résultats indiquent que le niveau optimal est de 55 °C, 60 W, 10 % de H<sub>2</sub>SO<sub>4</sub> dans le méthanol et 50 min. Les taux de récupération varient de 85,32 % à 112,11 %, avec des limites de détection allant de 0,03 à 0,08 µg mL<sup>-1</sup>. La linéarité en fonction du coefficient de corrélation est supérieure à 0,9914.

**Mots-clés :** méthylation assistée par des ultrasons, acide gras, spectrométrie de masse couplée à une chromatographie gazeuse, sérum.

## Introduction

Free fatty acids (FFAs) are one kind of active molecule in the body. They not only play an important role in energy generation and storage, but also act as a critical role in cell, tissue, and organ physiology.<sup>1–3</sup> For example, long-chain fatty acids contribute to the synthesis of phospholipids, molecules necessary for the structure, integrity, and function of plasma membranes, and are precursors for prostaglandins. The n-3 polyunsaturated fatty acids (PUFA), specifically docosahexaenoic acid (22:6n-3, DHA) and eicosapentaenoic acid (20:5n-3, EPA), have beneficial impact on mitochondrial biogenesis, intrinsic antioxidant enzyme expression, and efficiency in oxygen consumption.<sup>4</sup> Some studies have shown that free fatty acids in serum were closely related to many diseases, such as diabetes and cardiovascular disease; they are biomarkers of identifying these diseases and health controls.<sup>5,6</sup> It has been proposed that FFAs measures in serum could be developed into a risk factor for diabetes and cardiovascular disease. Large-scale clinical intervention and population-based studies are needed to support the use of serum measures of FFAs as a risk factor for diabetes and cardiovascular disease.

At present, the common analyses for fatty acids include the enzyme method, spectrophotometry, high performance liquid chromatography (HPLC),<sup>7–9</sup> and gas chromatography (GC).<sup>10–12</sup> Enzyme methods, which are simple and fast, are

widely used in the clinic for the analysis of FFAs, but this method can only obtain the total free fatty acids level, leading to the unknown concentration of each fatty acid.

These disadvantages are avoided by gas chromatography (GC). Present-day GC methods using high quality capillary columns allow sensitive and reproducible fatty acid analysis. When coupled with mass spectrometry (MS), this technique has shown more powerful abilities in fatty acids profiling analysis.<sup>13</sup>

Although GC is the technique most widely used in the determination of fatty acids, they must be converted to convenient volatile derivatives previous to their analysis. There are many derivatization agents for GC, such as trimethylsilyl derivatives, diazomethane, and sulfuric acid–methanol. Trimethylsilyl derivatives are less used for determining the long fatty acids (from 12 to 24 carbon atoms).<sup>14</sup> Reactions of diazomethane in a plasma–methanol medium should not only lead to a higher pH due to the consumption of acids<sup>15</sup> but also by reaction with negative ions like chloride.<sup>16</sup> However, the sulfuric acid – methanol reagent preparing fatty acids methyl esters (FAMES) performed well in terms of cost, speed, safety, and GC response, which is the most suitable for determination of fatty acids in serum.<sup>17,18</sup> Therefore, the conventional methylation of free fatty acids in serum was performed with the batch heat method using sulfuric acid – methanol reagent.

**Fig. 1.** Total-ion chromatogram of a mixture of 17 fatty acid methyl esters with the (a) standard and (b) serum sample. (1) C14:0, (2) C16:0, (3) C16:1, (4) C17:0, (5) C18:0, (6) C18:1, (7) C18:2, (8)  $\gamma$ -C18:3, (9) C18:3, (10) C20:2, (11) C20:4, (12) C20:5, (13) C22:4, (14) C22:5, (15) C22:6, (16) C24:0, (17) C24:1.

The conventional method is a multistep process that requires highly trained manual labor. Although it has also been demonstrated that FAMES can be prepared by direct methylation without prior extraction,<sup>19</sup> the preparation of FAMES remains time consuming with conventional methylation, often requiring 2 h with convectional heat to catalyze the reaction.<sup>20</sup> However, ultrasonic mixing had a significant effect on fatty acids transesterification. Ultrasound-assisted transesterification reactions of fatty acids showed higher (faster) transesterification rates without changing the charac-

teristics of the reaction. The method has been studied for many vegetable oils and biodiesel,<sup>21,22</sup> but this technique has not been widely applied for the determination of fatty acids in serum or tested exhaustively. The yield of FAMES in the process of methylation is affected by several process parameters and variables. The most important variables affecting the yield of FAMES from methylation are the reaction time, ultrasound power level, concentration of the catalyst, and reaction temperature. Therefore, it is necessary to systematically investigate which factors influence methylation and establish an efficient analytical method of free fatty acids in serum.

In the present study, we describe a simple and stable method to methylate free fatty acids with the help of ultrasonic waves. To achieve the optimum reaction conditions, parameters affecting the yield of FAMES, such as the reaction time, power of ultrasonic waves, concentration of the catalyst (sulfuric acid), and reaction temperature, were investigated by using the ultrasound-assisted methylation method. Moreover, the use of ultrasound-assisted methylation was compared to the traditional use of convectional heat for the preparation of FAMES. Gas chromatography and mass spectrometry (GC-MS) were used to isolate and identify the detected fatty acids and the method was applied to establish stable fatty acid metabolic profiles of type 2 diabetic patients (T2DM) and health controls.

## Experimental section

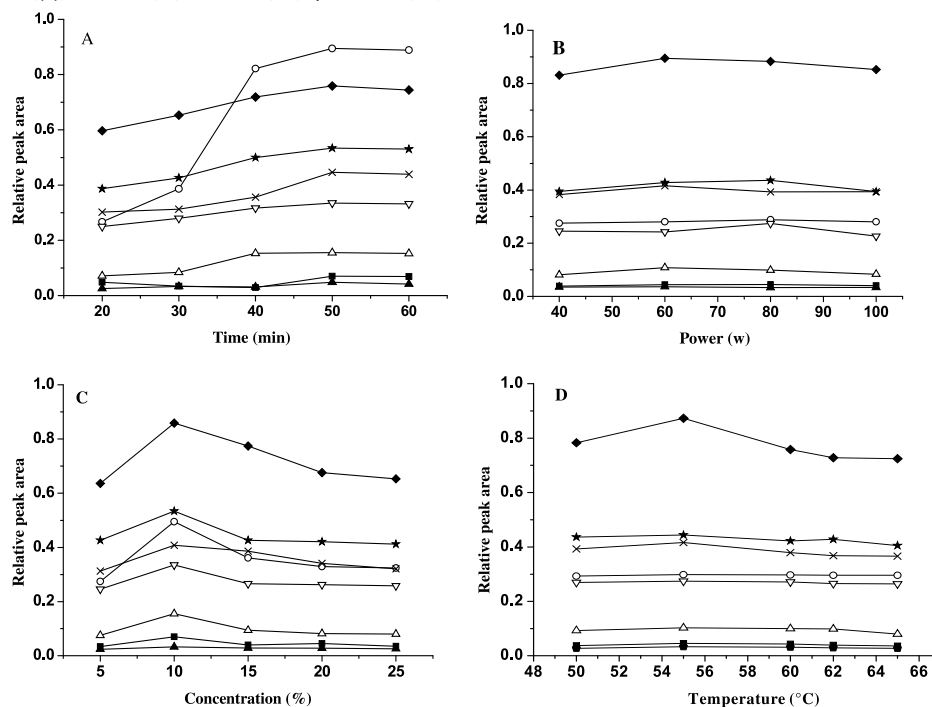

### Chemicals and reagents

Fatty acid standards were purchased from Sigma-Aldrich (St Louis, MO, USA,  $\geq 99\%$  purity): myristic acid (C14:0), palmitic acid (C16:0), palmitoleic acid (C16:1n-7), heptadecanoic acid (C17:0), stearic acid (C18:0), oleic acid (C18:1n-9), linoleic acid (C18:2n-6), linolenic acid (C18:3n-3),  $\gamma$ -linolenic acid (C18:3n-6), *cis*-11,14-eicosadienoic acid (C20:2n-6), arachidonic acid (C20:4n-6), *cis*-5,8,11,14,17-eicosapentaenoic acid (C20:5n-3), *cis*-7,10,13,16,19-docosapentaenoic acid (C22:5n-6), *cis*-4,7,10,13,16,19-docosahexaenoic acid (C22:6n-3), tetracosanoic acid (C24:0), and selacholeic acid (C24:1n-9). The solution of 10%  $\text{H}_2\text{SO}_4/\text{CH}_3\text{OH}$  was freshly prepared with diluting  $\text{H}_2\text{SO}_4$  (purity  $\geq 98.0\%$ ) in chromatographic grade methanol. *n*-Hexane (chromatographic grade), ethyl acetate (analytical reagent), and sodium chloride (analytical reagent) were purchased from Tianjin Guangfu Chemical Reagent Co. (Tianjin, China).

### Preparation of standard solutions and quality-control samples

Stock solutions of the 16 FAs and an internal standard

<sup>a</sup> $x$  is the quality of fatty acids and  $y$  is the relative peak area, which is the peak area of the fatty acid/peak area of the internal standard C17:0.

<sup>b</sup>Linearity is described using the linear correlation coefficients of calibration curves.

(heptadecanoic acid) were prepared at  $1000 \mu\text{g mL}^{-1}$  in methanol. Working solutions were prepared with methanol at concentrations of  $1.25\text{--}800.00 \mu\text{g mL}^{-1}$ . All standard solutions were stored at  $-20^\circ\text{C}$  until required.

To evaluate the recovery of the method, quality-control (QC) samples of FFAs studied came from two fasting male subjects, 28 years of age, for initial quantitative analysis.

#### The choice of the optimal methylated condition

An ultrasonic processor (KQ-250B, Kunshan Ultrasonic In-

strument Co., Kunshan, China) was used to perform the methylation reaction. The processor operated at 25 kHz frequency. The power and the temperature for the reaction were adjustable from 40 to 100 W and from 25 to  $100^\circ\text{C}$ . A series of 200  $\mu\text{L}$  aliquots of serum, which came from one healthy person, were spiked with internal standard (I.S.) working solution (200  $\mu\text{L}$  heptadecanoic acid,  $\text{C17:0}$ ,  $200 \mu\text{g mL}^{-1}$ ) and transferred to the reaction chamber to be subjected to ultrasound waves. Then the solution of  $\text{H}_2\text{SO}_4/\text{CH}_3\text{OH}$  (2 mL) was added to the chamber. The reaction

**Note:** FFA values of type 2 diabetic patients and health controls were compared using  $t$ -tests. A  $p$  value of  $<0.05$  was considered statistically significant and assigned 1, therefore, 0 indicates statistical insignificance.

ution was treated with saturated sodium chloride and then was extracted with 2 mL of hexane. The product, a mixture of FAMES, was analyzed by GC-MS.

## Sample preparation

### Conventional heat methylation

Each collected fasting blood sample was immediately centrifuged at 3000g for 10 min and the serum was transferred into a clean Eppendorf tube. The serum samples were stored at  $-80^\circ\text{C}$  until analysis. Samples were randomly selected for free fatty acids extract and GC-MS acquisition. Briefly, aliquots (200  $\mu\text{L}$ ) of serum were spiked

with internal standard (IS) working solution (200  $\mu\text{L}$  heptadecanoic acid C17:0, 200  $\mu\text{g mL}^{-1}$ ) and 2 mL 10%  $\text{H}_2\text{SO}_4/\text{CH}_3\text{OH}$  was added, vortex-mixed for 30 s, reacted at  $62^\circ\text{C}$ , and had a water bath for 2 h. This was followed by adding 2 mL of saturated sodium chloride solution, then it was extracted with 2 mL of hexane using a vortex mixer for 60 s, and FAMES were obtained. The samples were evaporated to dryness under  $\text{N}_2$  gas and hexane (100  $\mu\text{L}$ ) was then added prior to analysis.

### Ultrasonic wave methylation

Aliquots (200  $\mu\text{L}$ ) of serum were spiked with IS working solution (200  $\mu\text{L}$  heptadecanoic acid, C17:0, 200  $\mu\text{g mL}^{-1}$ ).  $\text{H}_2\text{SO}_4/\text{CH}_3\text{OH}$  (2 mL) was added to the serum and reacted at the optimal reaction condition. After that, 2 mL of saturated sodium chloride solution were added, then it was extracted with 2 mL of hexane using a vortex mixer for 60 s, and FAMES were obtained. The samples were evaporated to dryness under  $\text{N}_2$  gas and hexane (100  $\mu\text{L}$ ) was then added prior to analysis.

### Gas chromatography and mass spectrometry

GC-MS analysis was performed on a gas chromatograph coupled to an ion trap mass spectrometer (TRACE GC/PolarisQ MS, Thermo Finnigan, USA). Separation was accomplished on a J&W DB-WAX capillary column (30 m  $\times$  0.25 mm I.D, 0.25  $\mu\text{m}$  film thickness). Helium was used as the carrier gas with a flow rate of 1.0  $\text{mL min}^{-1}$ . The temperature of the injector was  $230^\circ\text{C}$ , and the sample (1.0  $\mu\text{L}$ ) was injected, with the split ratio of the injector being 1:10. FAMES were separated at a constant flow with the following oven program: (i)  $50^\circ\text{C}$  for 2 min, (ii) increased at a rate of  $10^\circ\text{C/min}$  up to  $200^\circ\text{C}$ , (iii) held at  $200^\circ\text{C}$  for 10 min, (iv) increased at a rate of  $10^\circ\text{C/min}$  up to  $220^\circ\text{C}$ , and (v) held at  $220^\circ\text{C}$  for 15 min. The transfer line was maintained  $230^\circ\text{C}$ . The ion trap mass spectrometer was operated in electron ionization (EI) mode and full scan monitoring mode ( $m/z$  30–450). The source temperature was at  $230^\circ\text{C}$  and electron energy at 70 eV.

## Method validation

Calibration samples were prepared using serum from healthy human subjects, which were spiked at increasing amounts (2.0–700.0  $\mu\text{g mL}^{-1}$ ) with 16 fatty acid standards. The limit of detection (LOD) was defined as the lowest concentrations with signal-to-noise (S/N) ratios of 10. Precisions and accuracies of QC samples were determined using intraday and interday assays that had three different concentrations including a low, medium, and high point of the calibration range (see Table 1), which were expressed as coefficients of variation (CV%) and percentage biases (bias%), respectively.

## Application to the human serum samples

Human serum samples were collected from 31 healthy adults (the age range was 35–69) and 30 patients with type 2 diabetes mellitus (the age range was 35–71). All type 2 diabetic patients were from the Second Affiliated Hospital of Harbin Medical University of China with a fasting plasma glucose concentration above 7.0  $\text{mmol L}^{-1}$ . The study was approved by the Ethical Committee of the Harbin Medical University and an informed consent was obtained from all subjects.

## Statistical analysis

For quantitative analysis in this study, all of the peaks exceeding a signal-to-noise (S/N) of 10 were selected and the internal standard method was used. Statistical analysis was performed using the statistical package of social sciences (SPSS) 13.0 (SPSS Inc., Chicago, USA). Results are presented as mean  $\pm$  standard deviation (SD). Data that were not normally distributed were logarithmically transformed to obtain near normality before analysis. Statistical evaluations of continuous variables were performed by using *t*-tests. All *p* values are two-tailed and a *p* value of  $<0.05$  was considered statistically significant.

## Results and discussion

### GC–MS analysis

First of all, it is important to find a suitable GC–MS condition to establish a stable quantitative metabolite profile with good separation, since there are tens of fatty acids in human serum. Column selection is one of the focuses in the process of optimizing chromatographic conditions. Because many long chain FAMES with high boiling points will be assayed, the highest analytical temperature was set at 220 °C. DB-WAX, which is a polar capillary column, was chosen because of its longer life than other columns at the high temperature.<sup>19</sup> Furthermore, other chromatographic conditions were modified, such as temperature process, split ratio, and injection temperature. Seventeen fatty acid methyl esters in human serum were baseline isolated within 40 min under those final chromatographic conditions, as depicted in the total-ion chromatogram (Fig. 1).

Analytical accuracy and precision data are shown in Table 1. Intraday and interday accuracy and precision (each  $n = 6$ ) were evaluated by analysis of QC samples (15, 150, and 1500  $\mu\text{g mL}^{-1}$  of C18:0 methyl ester). The range of coefficients of variation was 5.82%~9.42%. The results show

that the developed GC–MS method has good precision and accuracy.

### Effect of the parameters on the results of methylation

In this study, optimum levels of the variables affecting the yield of FAMES are obtained. For comparison, the reaction time was established at 20, 30, 40, 50, and 60 min; the powers of ultrasonic waves were taken at 40, 60, 80, and 100 W; and the reaction temperatures were chosen at 50, 55, 60, 62, and 65 °C. Effects of the concentration of catalyst on the yield of FAMES were investigated for 5, 10, 15, 20, and 25% sulfuric acid levels. The analysis results are given in Fig. 2. The reaction time is important for maximizing the yield of FAMES during the methylation process. Figure 2A shows the effects of the reaction time on the yield of FAMES. It was observed that the yield of methylation gradually increased before 50 min and the yield of most fatty acid methyl esters maximized at 50 min. After 50 min, the yield of methylation was approximately invariable. This indicated that the balance of the reaction was obtained at 50 min. The reaction time was, therefore, chosen to be 50 min.

Figure 2B shows that the ultrasound power influenced the yield of methylation. According to Fig. 2B, it is evident that as the power increased, the FAMES yield increased, reached a maximum, and then kept to similar levels. Higher power tends to decrease yields. This was attributed to cracking, which was followed by oxidation of FAMES to aldehydes, ketones, and lower-chained organic fractions under high-power conditions.<sup>23</sup> Accordingly, for the power less than 60 W, most of the FAMES yields were relatively maximized. The power for the methylation should be maintained at 60 W to obtain maximal yields and save energy.

Sulfuric acid is often used as the catalyst in the methylation and transesterification process for fatty acids.<sup>24,25</sup> The concentration of sulfuric acid is another important factor influencing the FAMES yields. Figure 2C summarized the experimental results of the effect of variations in the catalyst concentrations from 5%–25% on the reaction conversion. Figure 2C shows that as the catalyst concentration increased, the FAMES yields also increased. However, at higher catalyst concentrations (15%–25%), this effect became minimal. The upper limit to the catalyst effectiveness was reached at a much lower catalyst concentration for larger methanol excess levels. A higher catalyst concentration increased the solubility of methyl esters in the methanol phase. As a result, the optimal concentration of catalyst was 10%.

Temperature is one of important factors in a methylation reaction. From Fig. 2D, as the temperature increased, the yield of FAMES increased. However, the maximum value of yield was obtained at 55 °C. When the temperature was higher than 55 °C, the yield of FAMES decreased. As is well-known, the reaction rate is raised with the temperature, but high temperature (60–65 °C) makes methanol volatilize. The results indicate that FAMES decomposed to remedy the decrease of methanol. Therefore, high temperature (60–65 °C) was not in favor of the increase of methylation yield and the optimal reaction temperature was 55 °C.

### Method validation

Method validation was conducted by evaluating the linearity, limit of detection (LOD), precision, and accuracy of

the present method using spiked samples prepared from free fatty acids and human serum. The sample was methylated under the optimum condition. The devised method had excellent linearity (correlation coefficient,  $r$ : 0.9914–0.9998). LODs ranged from 0.03 to 0.08  $\mu\text{g mL}^{-1}$  (Table 2). Accuracies and precisions were determined by analyzing three QC samples at three different concentration levels for the 16 FFAs. Intraday ( $n = 3$ ) precisions ranged from 1.75% to 10.23%, whereas accuracies ranged from 85.32% to 108.94%. Interday ( $n = 3$ ) precisions and accuracies were 3.15%–10.50% and 86.40%–112.11%, respectively (Table 3).

### Comparison between conventional and ultrasonic wave heat

Two methylation methods using convectional heat and ultrasonic wave heat were compared. Under the same concentration of catalyst, a single serum sample was analyzed by both methods. The results demonstrated there were no significant differences in fatty acid compositions (Table 4). The concentration of seven FFAs with direct ultrasonic wave methylation was a little higher than the convectional heat's, but there was no significant difference. Moreover, compared with the conventional method, there was higher precision with the ultrasonic method. This suggested that direct methylation of serum by ultrasonic wave heat was much better than the conventional method to a degree. The reason may be that prior FFA extraction from serum followed by conventional heat methylation resulted in values a little lower than those obtained by methylation mediated by ultrasonic wave heat. Moreover, ultrasonication is able to reveal subtle interactions and particular effects of entropic and enthalpic origin. The cavitation and collapse of the cavitation bubble, where transient hot spots with local extremely harsh conditions occur, are generally accepted as the origin of the chemical effects.<sup>26,27</sup> Another beneficial effect of ultrasonication compared to the corresponding convectional heat reaction is the efficient removal of bubbles from the bulk solution. The presence of bubbles is detrimental to the methylation process as they can attach to the drop, thus minimizing the surface available to extraction and facilitating its dislodgement. Furthermore, it was more troublesome with the convectional heat method than direct ultrasonic wave methylation.

### Analysis of human serum samples

According to the optimum ultrasonic wave method, serum FFAs of type 2 diabetic patients (T2DM) and health controls were detected (shown in Table 5). The kinds of FFA in T2DM patients and health controls were almost the same, while the concentrations were different. Sixteen fatty acids were detected including four saturated fatty acids, three monounsaturated fatty acids, and nine polyunsaturated fatty acids. Serum levels of these FFAs were all increased from health controls to T2DM patients. After adjusting for some confounding factors, including age, sex, alcohol consumption, smoking habits, physical activity, blood pressure, and blood lipids, the differences in free fatty acids concentration between groups were evaluated by analyses of  $t$ -test. The  $t$ -test results showed that there were 13 components having distinct differences between T2DM patients and health con-

trols. Moreover, in the clinic, total free fatty acid levels are a very important index for diagnosis of T2DM. Here, total FFA levels (the sum of the sixteen detected FFAs) were also evaluated. Total FFA levels had distinct differences between T2DM patients and health controls. From the above, there are different free fatty acids profiles among human beings. There could be formation of more biologically potent molecules from the fatty acids. Therefore, it seems that metabolic network research of fatty acids is very important for pathogenesis research of diabetes and it will help with our further study of diabetes.

### Conclusion

Initially, the aim of the study was to search for a method for the determination of free fatty acids (FFAs) in serum using ultrasonic waves. In this study, the optimal reaction conditions were observed. The heat from ultrasonic waves produced high FAME yields at significantly short times in comparison to those using the convectional batch heat method. This method was successfully applied to construct quantitative free fatty acid metabolic profiles in human serum. We suggest that the present method is suitable for the analysis of FFAs in metabolic studies of fatty acids.

# Aqueous sodium hypochlorite mediated chemoselective oxidation of chalcogenides to monoxides and dioxides by microwave exposure

Jitender M. Khurana and Bhaskara Nand

**Abstract:** A solvent-free, rapid, and highly selective oxidation of sulfides, selenides, and tellurides (chalcogenides) to the corresponding monoxides (sulfoxides, selenoxides, and telluroxides) or the corresponding dioxides (sulfones, selenones, and tellurones) has been developed using aqueous sodium hypochlorite on solid supports by exposure to microwave. Chemoselectivity and quantitative yields have been attained in most cases.

**Key words:** chalcogenides, selective oxidation, sodium hypochlorite, microwave, solid support, solvent-free.

**Résumé :** On a mis au point une méthode rapide et n'impliquant aucun solvant pour l'oxydation hautement sélective des sulfures, de séléniures et des tellurures (chalcogénures) en monoxydes correspondants (sulfoxydes, sélénoxydes et telluroxydes) ou en dioxydes correspondants (sulfones, sélénones et tellurénones) à l'aide d'hypochlorite de sodium aqueux sur des supports solides exposés à des microondes. Dans la plupart des cas, on a atteint la chimiosélectivité accompagnée de rendements pratiquement quantitatifs.

**Mots-clés :** chalcogénures, oxydation sélective, hypochlorite de sodium, microonde, support solide, sans solvant.

## Introduction

Oxidation of sulfur, selenium, and tellurium compounds has significant importance in organic chemistry, medicinal chemistry, and drug metabolism.<sup>1</sup> Sulfoxides, sulfones, organoselenium, and tellurium compounds are valuable synthons for carbon-carbon bond formation<sup>2</sup> as chiral auxiliaries<sup>3</sup> and for metal-centered catalysis.<sup>4</sup> The chemistry of selenium and tellurium oxides is of particular interest owing to their thermal instability<sup>5</sup> and their ability to stabilize adjacent anionic centers.<sup>6</sup> These transformations have been accomplished in a variety of ways.<sup>7</sup> Many of the reported methods suffer from poor yields, lack of generality, use of expensive reagents/catalysts, complex catalysts, toxic metallic compounds, or rare oxidizing reagents. On the other hand, selective oxidation of chalcogenides to their corresponding monoxides and dioxides with the same reagent system under adjusted reaction conditions is an important process, and only a few reports are available.<sup>8</sup> Diaryl and dialkyl telluroxides and tellurones are not well-explored compounds and have not received significant attention. Recently, microwave-enhanced chemical reactions on inorganic solid supports under solvent-free conditions<sup>9</sup> have attracted attention for various reasons. In view of the importance of these compounds, we decided to investigate the use of inexpensive aq. sodium hypochlorite for the selective oxidation of chalcogenides under microwave irradiation.

## Experimental

All the products were known and were identified by comparison of the spectral and physical data with the literature.<sup>7,8,10</sup> Melting points were recorded on Tropical Labequip apparatus and are uncorrected. IR spectra were recorded on PerkinElmer FTIR spectrum-2000. <sup>1</sup>H NMR spectra were recorded on FTNMR model R-600 Hitachi (60 MHz) with TMS as internal standard. The products were identified by co-TLC, melting point determination (mp), superimposable IR, and NMR spectra with authentic samples. Silica gel (100–200 mesh, for column chromatography) and neutral alumina (S.D. Fine) were used as inorganic solid supports. Sodium hypochlorite was used after estimation by the reported procedure.<sup>11</sup> Sulfides, selenides, and tellurides were prepared by the literature-reported methods.<sup>12–17</sup>

## General procedure

### General procedure for the oxidation of chalcogenides to dioxides

In a typical experiment, diphenyl sulfide (0.2 g, 1.074 mmol) was dissolved in dichloromethane (3 mL) and adsorbed over silica gel (100–200 mesh, 1.2 g). Aqueous sodium hypochlorite (0.65 mol/L, 3 mL) was added and mixed uniformly in a beaker. The reaction mixture was inserted in a silica bath (20 g of silica gel) and placed in a microwave oven (Model No.OM-9925-E, 800 W, 2450 MHz) and irradiated at 100 W

**Note:** Reactions were carried out using 3 mL of aq. NaOCl (0.65 mol/L) per mmol of substrate.

for 10 min. The progress of the reaction was monitored by TLC using petroleum ether as eluent, which showed complete disappearance of starting material after 10 min and formation of a new product having lower  $R_f$  (eluent: ethyl acetate), which was believed to be diphenyl sulfone by co-TLC. The reaction mixture was cooled to room temperature and the product was extracted with dichloromethane (2 × 5 mL). The combined dichloromethane extract was dried over anhyd.  $\text{Na}_2\text{SO}_4$ , filtered, and concentrated to afford 0.22 g (93%) of pure diphenyl sulfone as white solid identified by its mp 126 °C (lit.<sup>10b</sup> mp 128 °C), superimposable IR, and  $^1\text{H}$  NMR spectra.

#### General procedure for the oxidation of chalcogenides to monoxides

In a typical experiment, diphenyl sulfide (0.2 g, 1.074 mmol) is dissolved in dichloromethane (3 mL) and adsorbed over neutral alumina (1.2 g). Aqueous sodium hypochlorite (1 mL, 0.65 mol/L) was added and mixed thoroughly in a beaker. The reaction mixture was inserted in an alumina bath (20 g of neutral alumina) and placed in a microwave oven (Model No.OM-9925-E, 800 W, 2450 MHz) and irradiated at 100 W for 3 min. After cooling for 1 min, another 1 mL of aq. sodium hypochlorite solution (0.65 mol/L) was added, and the mixture was stirred with a glass rod and irradiated again for 3 min. The progress of the reaction was monitored by TLC using petroleum ether as eluent. TLC showed complete disappearance of the starting material after 6 min and formation of a product having lower  $R_f$  (eluent: ethyl acetate), which was believed to be diphenyl sulfoxide by co-TLC. The reaction mixture was cooled to room temperature and the product was extracted with dichloromethane (2 × 5 mL). The combined dichloromethane extract was dried over anhyd.  $\text{Na}_2\text{SO}_4$ , filtered, and concentrated. The product was purified by column chromatography on silica gel using petroleum ether/ethyl acetate as eluent. The

white solid obtained was identified to be diphenyl sulfoxide (0.18 g, 82%) by mp 70 °C (lit.<sup>10e</sup> mp 71 °C), superimposable IR, and  $^1\text{H}$  NMR spectra. Oxidation of selenides and tellurides was carried out in a similar fashion using 0.36 mol/L aq. NaOCl solution.

## Results and discussion

We report herein an efficient, mild, and rapid method for the selective oxidation of chalcogenides (sulfides, selenides, and tellurides) to the corresponding monoxides (sulfoxides, selenoxides, and telluroxides) or the corresponding dioxides (sulfone, selenone, and tellurone) with inexpensive aq. sodium hypochlorite under microwave irradiation. Diphenyl sulfide was chosen as a model substrate for optimization. Oxidation of diphenyl sulfide was attempted with aq. NaOCl (0.65 mol/L) on different inorganic solid supports, e.g., neutral, acidic, and basic alumina; silica gel and montmorillonite K10 by adsorbing the substrate; and aq. sodium hypochlorite on solid support followed by exposing the reaction mixture to microwave irradiation (100 W). Oxidations on silica gel gave diphenyl sulfone in high yields (93%) in shorter time unlike other supports, which required longer reaction times and (or) gave reaction mixtures. Diphenyl selenide and di(*p*-methylphenyl) telluride also underwent oxidation to diphenyl selenone and di(*p*-methylphenyl) tellurone, respectively, under the same reaction conditions but required even shorter exposure to microwaves. Oxidation in the absence of solid support was incomplete, and a mixture of monoxide and dioxide was obtained. Subsequently, oxidation of various substituted aromatic and aliphatic sulfides, selenides, and tellurides was carried out with aq. sodium hypochlorite on silica gel solid support after exposure to microwaves to give the corresponding sulfones, selenones, and tellurones in high yields (eq. [1], Table 1).

**Table 2.** Oxidation of sulfides, selenides, and tellurides with aq. sodium hypochlorite to monoxides under microwave exposure, supported on neutral alumina.

Entry	Substrate	Product	Time (min) <sup>a</sup>	Yield (%)

**Note:** Reactions were carried out using 2 mL of aq. NaOCl per mmol of substrate. Aqueous NaOCl solution (0.65 mol/L) was used for the oxidation of sulfides, and aq. NaOCl (0.36 mol/L) was used for the oxidation of selenides and tellurides.

<sup>a</sup>Sodium hypochlorite used in two lots and the reaction mixture was irradiated in two intervals after a time gap of 1 min.

The applicability of the reagent under microwave irradiation was then investigated for the selective oxidation of different chalcogenides to their monoxides. During our exploratory experiments on diphenyl sulfide, we had observed that higher amount of diphenyl sulfoxide was formed when neutral alumina was used as the solid support. Subsequently, we have found that neutral alumina is the best solid support for selective oxidation to diphenyl sulfoxide using aq. sodium hypochlorite (0.65 mol/L) under microwave irradiation (100 W) only when sodium hypochlorite was added in two portions and the reaction mixture was irradiated twice with a 1 min time interval. No over oxidation to the sulfone was observed.

We conclude that chalcogenides can be selectively oxidized to their monoxides or dioxides in high yields by an environmentally benign and safe protocol using aq. sodium hypochlorite under microwave irradiation. Synergism of microwave methodology, use of aqueous reagent, and solvent-

However, diphenyl selenide and di(*p*-methylphenyl) telluride gave mixtures of corresponding monoxides and dioxides under similar experimental conditions. Reaction conditions for the selective oxidation of selenides and tellurides were achieved with 0.36 mol/L aq. NaOCl solution. Diphenyl selenide and di(*p*-methylphenyl) telluride underwent selective oxidation with 0.36 mol/L aq. NaOCl solution under otherwise identical conditions. Thereafter, selective oxidation of a variety of sulfides was carried out with 0.65 mol/L aq. NaOCl solution, and oxidation of different selenides and tellurides was achieved with 0.36 mol/L aq. NaOCl solution supported on neutral alumina to give the corresponding monoxides in high yields in 5–10 min under microwave exposure (eq. [2], Table 2). The addition of sodium hypochlorite was done in two portions, and microwave exposure was done in two intervals with a gap of 1 min for the addition of reagent and cooling.

free conditions make this oxidation an attractive and facile synthetic protocol.

# Synthesis and characterization of low-molecular-weight azo-acetoxystyrene and azo-naphthalene oligomers via stable free radical polymerization (SFRP)

Dildar Ali, Zaheer Ahmed, Peter M. Kazmaier, and Erwin Buncel

**Abstract:** As an approach toward controlled molecular architecture through stable free radical polymerization (SFRP), we have prepared a series of oligomers of controlled molecular weights ( $M_n$ ) and low polydispersities (structures **2** and **3**, with  $n$  values ranging from 2 to 52). Definitive evidence of structure was obtained through MALDI/MS (inter-peak interval of 162  $m/z$  in azo-acetoxystyrene oligomers **2** and 260  $m/z$  in azo-naphthalene oligomers **3**, which correspond to the acetoxystyrene (AS) and naphthalenic (Np) repeating units, with corroborative evidence from NMR and GPC. Two synthetic pathways were explored. Pathway 1 yields azo-acetoxystyrene oligomer **2** via SFR addition of a TEMPO-capped unimer **1** to acetoxystyrene. Subsequent reactions would convert **2** into **3**. In an alternative pathway 2, SFR addition of **1** to 4-(1-methoxynaphthyl)styrene gives azo-naphthalene oligomer **3** directly. Thus, the present reported methodology for controlled architecture has achieved synthesis of oligomers from low  $M_n$  (chlorobenzene, PhCl, solvent) to relatively high  $M_n$  (bulk), with incorporation of naphthyl (donor) and azobenzene (acceptor) moieties, as well as spacer moieties, in a controlled manner.

**Key words:** azo-acetoxystyrene oligomers, azo-naphthalene oligomers, stable (controlled) free radical polymerization.

**Résumé :** Comme approche à une architecture moléculaire contrôlée par le biais d'une polymérisation à l'aide de radicaux libres stables (PRLS), on a préparé une série d'oligomères de masses moléculaires ( $M_n$ ) contrôlées et de faibles polydispersités (structures **2** et **3**, avec des valeurs de  $n$  allant de 2 à 52). Les données définitives permettant de déterminer les structures ont été obtenues par spectrométrie de masse avec ionisation laser assistée par une matrice de désorption (SM-ILAMD) [intervalle entre pics de 162  $m/z$  dans les oligomères azo-acétoxystyrène **2** et de 260  $m/z$  dans les oligomères azo-naphtalène **3** qui correspondent aux motifs constitutifs de l'acétoxystyrène (AS) et naphtalénique (Np)] et corroborées par RMN et par chromatographie par perméation de gel (CPG). On a exploré deux voies de synthèse. La voie 1 conduit à l'oligomère azo-acétoxystyrène **2** par le biais d'une addition à l'aide de radicaux libres stables (RLS) de l'unimère **1** couvert d'un groupe tétraméthylpipéridine oxyde (TEMPO) à l'acétoxystyrène. Des réactions subséquentes devraient permettre de transformer le produit **2** en **3**. Dans une voie alternative 2, une addition à l'aide de radicaux libres stables aux 4-(1-méthoxynaphtyl)styrène conduit directement à l'oligomère azo-naphtalène **3**. La méthodologie rapportée ici pour obtenir une architecture contrôlée a permis de réaliser la synthèse d'oligomères à partir de produits de masses moléculaires basses (chlorobenzène, PhCl, solvant) à des masses moléculaires relativement élevées (en bloc), avec l'incorporation de portions naphtyles (donneur) et azobenzène (accepteur) ainsi que de portions agissant comme d'espacement d'une façon contrôlée.

**Mots-clés :** oligomères de l'azo-acétoxystyrène, oligomères de l'azo-naphtalène, stable (contrôlée), polymérisation par radicaux libres.

## Introduction

As part of a research program in materials science, we have been engaged in studies of light harvesting (LH) systems and underlying energy transfer (ET) processes.<sup>1-4</sup> Energy transfer and (or) electron transfer are basic to the process of light harvesting and processes such as photosynthesis.<sup>5-10</sup> In turn, the efficiency of ET has been shown to

require specific architecture that, typically, incorporates energy donor (**D**) and energy acceptor (**A**) moieties, as shown in Scheme 1. The donor group(s) absorb light energy, which is then transferred from the excited **D** group (**D\***), with varying degrees of efficiency, to the acceptors. In principle, electron transfer could also occur, depending upon **D** and **A** groups incorporated in the LH system.

Considerable effort has gone into understanding the pho-

Scheme 1.

tochemical and photophysical processes involved in light harvesting and this effort is, partly, reflected in the range of authoritative reviews that have appeared lately.<sup>11–16</sup>

We have taken a two-pronged approach to probing LH systems. First and in common with a number of research groups,<sup>5,6,17,18</sup> we have prepared a range of dendrimer and starburst polymeric LH model systems, including azobenzene moieties as **A** groups and naphthalenes as **D** moieties.<sup>1–4</sup> Second, we have prepared two LH model systems (Scheme 1) using naphthalene **D** and azobenzene **A** groups tethered by methoxy linkages: **A**–(OCH<sub>2</sub>)–**D** and **D**–(CH<sub>2</sub>O)–**A**–(OCH<sub>2</sub>)–**D**. Our study of the photophysical/chemical properties of two models (Scheme 1) revealed a new criterion for efficiency of energy transfer, involving ratios of rate constants for cis–trans isomerization and ratios of light energy absorption; the LH models were each compared to relevant benchmark molecules. According to this new criterion, energy transfer was virtually complete for both model systems. Electron transfer, under the conditions studied, was not found to be feasible. However, a need for a greater loading of light harvesting donor groups was also identified, as a pre-requisite to the preparation of more practical LH systems.<sup>4</sup> To this end, we have now prepared a series of oligomers **3** containing an azobenzene acceptor group at one end of the chain and a progressively larger number of donor naphthalenic repeating units, as shown in Scheme 2. The long-term goal is to study the LH **3** to **4** interconversion and the photophysics involved (Scheme 2).

Herein, we describe our synthetic strategy, which is based on stable free radical polymerization (SFRP, also termed nitroxide-mediated polymerization, NMP)<sup>19–27</sup> to yield LH oligomers in a controlled manner. SFRP has proven to be particularly valuable in the preparation of polymers with controlled architecture. The Georges,<sup>21,23</sup> Hawker,<sup>20,22,25</sup> Fischer,<sup>19</sup> and Matyjaszewski<sup>26</sup> groups, among others, have pioneered and elaborated on this approach to the preparation of high-molecular-weight polymers. Our aim here, however, is the preparation of low-molecular-weight oligomers for the purpose of preparation of controlled oligomeric structures. The starting point in two different synthetic approaches is the same: the azobenzene-containing unimer, **1**, which is capped reversibly with the persistent nitroxyl radical TEMPO. Reaction of the **1** with 4-acetoxystyrene, **5**, was expected to give low-molecular-weight oligomers **2** (Scheme 2, pathway 1) incorporating the acetoxystyrene repeating unit, *n*,

for subsequent conversion of acetoxy functions to naphthyl methoxy donor groups, i.e., formation of **3**. In an alternative preparation (Scheme 2, pathway 2), the SFRP process involved addition oligomerization of 4(1-methoxynaphthyl)styrene, **6**, with the unimer **1** to give **3**. The results of preparation of the LH models containing 4(1-methoxynaphthyl)styrene donor repeating units and their characterization (MALDI-TOF/MS and GPC analyses), as well as corroborative NMR analyses, will be discussed in terms of optimization of reaction time and the use of a suitable solvent to control the molecular weight.

## Results and discussion

### Synthetic strategy

Two synthetic approaches (Scheme 2, pathways 1 and 2), which differed in the structure of the arylvinyl monomer oligomerized with unimer **1**, were examined as routes to the target oligomers, **3**. Addition under SFRP conditions of the benzylic radical derived from **1** (arising from facile scission of the C–O bond of the TEMPO cap) to 4-acetoxystyrene, **5**, should yield oligomers, **2**, with a range of acetoxystyrene repeating units, *n*. Hydrolysis of **2** followed by functionalization with a naphthyl moiety yields the azonaphthyl oligomer **3**.

The alternative route (Scheme 2, pathway 2) consists of SFRP-style addition of the benzylic radical of **1** (formed as before) to the 4-(1-methoxynaphthyl)styrene, **6**, should again give models, **3**.

The difference in the two routes lies, then, in whether the naphthyl donor group is incorporated into the product **3** after oligomerization (pathway 1) or, alternatively, preparation of a suitable arylvinyl monomer, **6**, leads to direct oligomerization to give **3** (pathway 2).

In the preparation of model **3**, controlled low-molecular-weight oligomers were desired. To this end, both the reaction medium and the reaction times were empirically optimized. For the azo-acetoxystyrene oligomerization to yield **2**, bulk (at 130 °C) and solution media (at 120 °C) were studied, where varying amounts, i.e., 1:1 to 1:5 w/w ratios of the arylvinyl monomer to chlorobenzene (PhCl) solvent,<sup>20,22,25,28</sup> were used. Reaction times were varied from 1 min to 5 h in a given set of solvent conditions by quenching a reaction run by pouring the reaction mixture into excess cold methanol (~10 mL). For the azo-naphthalene oligomerizations to yield **3** directly, only the solution conditions (i.e., dilution with PhCl at 120 °C) were studied, as a consequence of the information gleaned from the results in the azo-acetoxystyrene systems, **2**. Reaction times were varied from 10 min to 1 h, again as prompted by the results in the related oligomerization system.

The results of these two preparatory routes are listed in Tables 1 and 2 and will be discussed below.

### Azo-acetoxystyrene oligomers, **2**

The results of the SFRP between the unimer **1** and 4-acetoxystyrene, **5**, as the arylvinyl monomer, are summarized in Table 1. Specifically, the reaction conditions including reaction times, the analysis of the maximum number of acetoxystyrene repeating units (*n*) as determined by MALDI-TOF/MS,<sup>29–31</sup> the number average molecular weight of the

<sup>f</sup>NA: not applicable.

oligomers ( $M_n$ ) as determined by GPC, as well as the polydispersity ( $PD = M_w/M_n$ ) are listed in the Table.

#### Mechanistic effects on oligomerization

As can readily be seen in Table 1, even at short reaction times, bulk conditions (experiment series A) yield relatively

long chain oligomers, **2**. For example, a 3 min reaction time produces **2** with  $M_n$  of 6.7 kDa, corresponding to about a maximum of 37 acetoxystyrene repeating units ( $n = 37$ ), and a relatively broad molecular weight distribution ( $PD = M_w/M_n = 1.4$ ). In fact, repetition of the oligomerization at a somewhat lower temperature (120 °C here versus 130 °C in

<sup>d</sup>Polydispersity,  $M_w/M_n$ .

the bulk system) and with an equal weight of chlorobenzene (experiment series B) requires 240 min (B-3) to yield **2** with approximately the same number of repeating units (according to MALDI/MS), i.e.,  $n = 39$ . Representative MALDI/MS spectra for experimental series C-1 to C-3 are shown in Fig. 1 and illustrate the number of repeating units,  $n$ , analyzed via this method.

These results are consistent with the mechanism of SFRP, where at the temperature of the reaction the TEMPO-capped unimer **1** dissociates to give persistent TEMPO nitroxyl radical and a resonance-stabilized benzylic radical.<sup>32</sup> The benzylic radical concentration is partitioned between recombination with the TEMPO radical and addition to 4-acetoxystyrene, **5**. Under bulk conditions, the TEMPO-benzylic radical pair is effectively caged by **5**, the arylvinyl monomer. Addition of the benzylic radical to the vinyl functional group of the surrounding acetoxystyrenes should be facile, and relatively high  $M_n$  oligomer, **2**, arises in accord with the results listed in Table 1. Recombination of TEMPO with the growing benzylic radical end of the chain provides a termination step in the chain mechanism, and through potential further dissociation, provides an avenue for conversion to a “living” chain mechanism.

#### Chlorobenzene solvent effects on oligomerization

In principle, addition of chlorobenzene solvent could have two effects.<sup>20,22,25,28</sup> The first and presumably smaller effect is a solvent effect on the dissociation of the unimer. Preferential solvation of the dissociated radicals (e.g., via  $\pi$ – $\pi$  stacking) relative to the bulky TEMPO-capped unimer could favour dissociation of the unimer. On the other hand, the concentration of acetoxystyrene in the cage surrounding the radical pair would be reduced as a function of increasing added PhCl and the probability of addition to the vinyl group reduced. At short reaction times, the number of repeating groups incorporated in the oligomer would be reduced, as is observed (Table 1).

Generally, then, increasing dilution (Table 1, experiment series C through F) leads to lower-molecular-weight oligomer at comparable reaction times. At 5 min, a 1:1 dilution (AS:PhCl, B-1) gives an oligomer, **2**, incorporating 25 repeating units according to MALDI/MS analysis, while

with all other series, a 5 min reaction time yields no oligomer detectable by MALDI/MS or GPC. The results at 20 min appear anomalous; a 1:2 dilution (AS:PhCl; Table 1, C-2) yields an oligomer with five repeating units, while 1:3 dilution (D-2) gives 20 repeating unit oligomer and 1:4 dilution gives seven repeating-unit oligomer, but 1:9 dilution (F-2) yields no detectable oligomer, **2**.

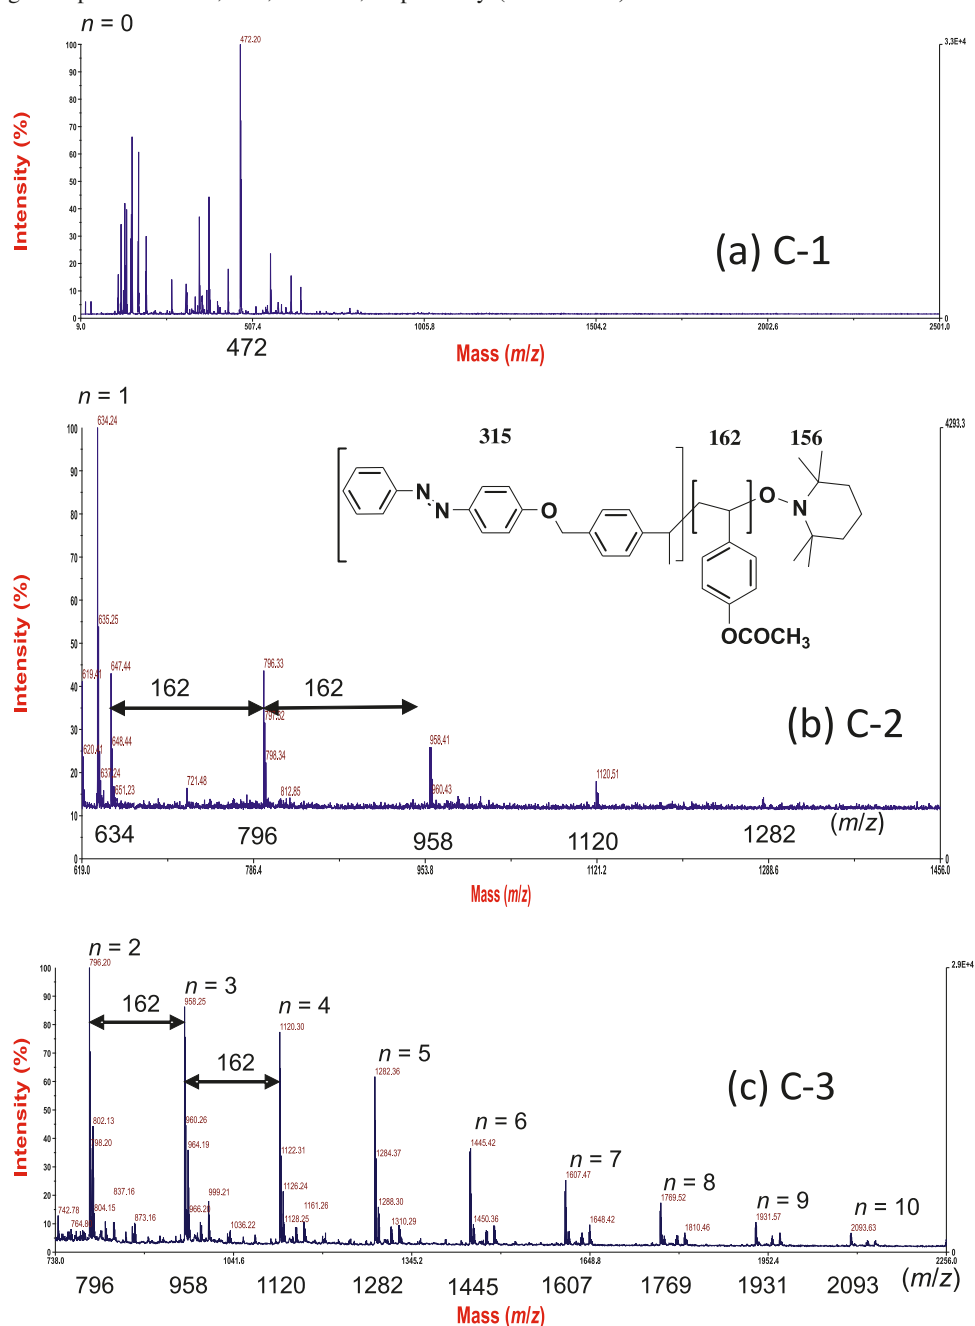

One possibility that accounts for the observed behaviour, namely, an increase in number of repeating units for D-2, as compared to the C-2 and E-2 experiments (Table 1), is that the solvent effect of dilution (i.e., preferential stabilization of the dissociated radicals that would favour dissociation) opposes the concentration effect, that would reduce the probability of radical addition to the arylvinyl monomer. In short, dilution favours dissociation freeing the benzylic radical derived from **1** to add to the vinyl function of **5**, but the decreased concentration of the styrene counteracts this effect partly. The interplay of these factors could lead to the behaviour observed.

At extreme dilution (series F), none of the reaction times studied (5 to 300 min) were sufficient to lead to any oligomer formation. The radicals derived from **1** are effectively free in solution but the concentration of AS is too low to lead to oligomerization.

Also in accord with the foregoing interpretation are the polydispersities determined by GPC (Table 1). In Fig. 2, the GPC traces for experimental series B, D, and F (Table 1) are shown. The bulk run even at 3 min reaction time (Table 1, A-1) gives a PD of 1.6, and modest dilution (B-1, 5 min) yields only a somewhat narrower molecular-weight distribution (PD = 1.4). In living polymerizations, an effective equilibrium is established between dormant or dead polymer (oligomer). This arises from recombination of the benzylic radical end of the growing chain and the TEMPO radical, on the one hand, and propagation of the chain by addition of the benzylic radical to the arylvinyl monomer, on the other. The closer the PD value is to 1 (i.e., monodispersity), the more nearly the polymerization is considered a living process. With a 1:3 dilution with PhCl (D-2, 20 min), the PD drops to 1.3.

The relatively low overall mass recovery found for the acetoxystyrene oligomer **2** indicated that additional steps

**Fig. 1.** MALDI/MS spectra of azo-acetoxystyrene oligomers with varying acetoxystyrene repeating unit ( $n$ ) values: (a),  $n = 0$ ; (b),  $n = 5$ ; (c),  $n = 10$ , corresponding to experiments C-1, C-2, and C-3, respectively (see Table 1).

leading to the desired LH-model oligomer, **3**, could result in little final product. The time-consuming nature of the necessary oligomer characterization at each subsequent step was another consideration that prompted us to consider direct incorporation of the naphthalenic donors (Np) in the SFRP step (Scheme 2). However, the results of the preparation of oligomer **2** indicated that dilutions of 1:3 to 1:5 could yield the appropriate LH oligomer **3** comprising a controlled range of repeating donor units.

### Azo-naphthalene oligomers, **3**

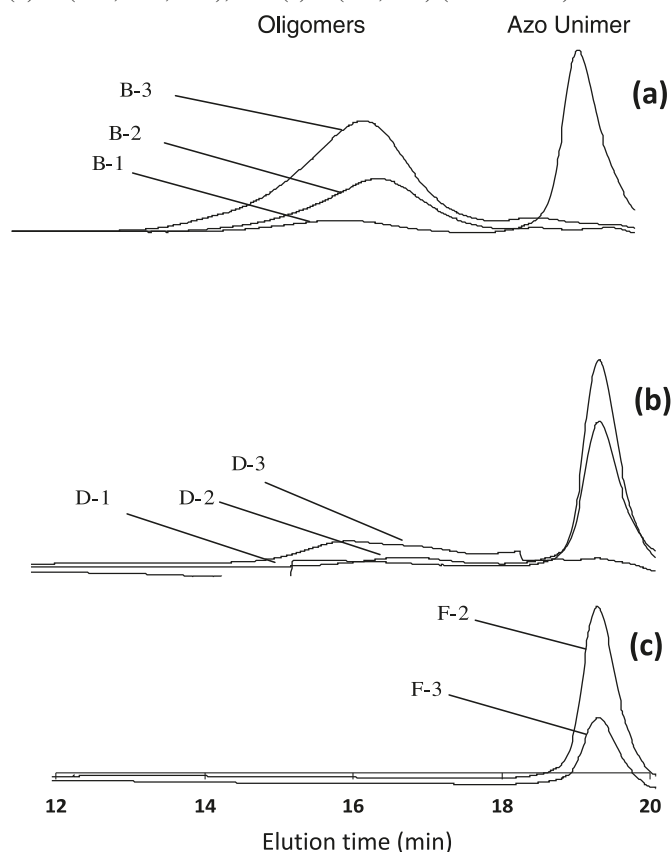

SFRP using unimer **1** and 4-(1-methoxynaphthyl)styrene,

**6**, under the range of conditions identified as favouring formation of low-molecular-weight oligomer **2**, was undertaken to prepare **3** directly (Scheme 2). Table 2 summarizes the MALDI-TOF/MS and GPC characterization of **3**.

With a ratio of 1:3 of the arylvinyl monomer, **6**, to PhCl solvent ( $120\text{ }^{\circ}\text{C}$ ; experiment Q, comparable to the D series of experiments in Table 1), SFRP yields low average molecular weight oligomer ( $M_n = 0.75$  kDa) with low polydispersity ( $PD = 1.2$ ). MALDI/MS analysis shows the expected inter-peak  $m/z$  interval of 260 that corresponds to the naphthalenic repeating unit (Np) as shown in Fig. 3 for experiment R. At 15 min reaction time (experiment Q-1), the

**Fig. 2.** GPC chromatograms for experiments (a) B (B-1, B-2, B-3); (b) D (D-1, D-2, D-3); and (c) F (F-2, F-3) (see Table 1).

maximum number of repeating units found was two; the “oligomer” here consists solely of unimer and dimer. An increase in reaction time to 40 min (Q-2) gives higher-molecular-weight oligomer ( $M_n = 3.9$  kDa; 12 repeating units by MALDI/MS analysis) with only a slight broadening of the molecular weight distribution (PD = 1.3 by GPC). Note, for comparison, that at 20 min reaction time in the acetoxystyrene series (Table 1, D-2), MALDI/MS analysis gave oligomer **2** containing a maximum of 20 repeating units and GPC traces indicated a number average molecular weight of 5.1 kDa for the oligomer with a PD of 1.2, all similar to the results obtained here for experiment Q-2 with a reaction time of 40 min. Clearly, the experimental conditions optimized for the acetoxystyrene SFR oligomerizations (Scheme 2, pathway 1) extend reasonably to the 4-(1-methoxynaphthyl)styrene additions, i.e., formation of **3** directly via pathway 2 in Scheme 2.

Reasonably, the considerations of solvent enhancement of the dissociation of the unimer **1** and the opposing influence of dilution on the addition step apply consistently to pathway 2 to give **3**. It follows that experiments R (1:4, 6:PhCl solvent) through T (1:49, 6:PhCl; Table 2) mimic the trend in degree of oligomerization and polydispersity found for the comparable experimental series D through F (Table 1) found for pathway 1. The number average molecular weight of the oligomer increases, according to GPC, in going from R (1:3) to T (1:4), i.e., from 0.69 kDa to 2.5 kDa with similar PD values and in a maximum number of repeating units of two rising to 10 in the latter run. Experiment T gives an

oligomer with a lower maximum number of repeating units ( $n = 5$ ) and a lower number average molecular weight (1.8 kDa). This parallelism, namely, first increase and then decrease in molecular weight and maximum number of repeating units, which was found in the acetoxystyrene oligomerization runs to give **2**, is consistent with the behaviour found in the oligomerization to give **3**. The same reasons appear to apply: compensatory interplay of solvent and dilution effects on the SFRP chain mechanism.

## Highlights of characterization and fractionation

### MALDI-TOF/MS

Figure 1 shows the MALDI-TOF/MS analysis<sup>29–31</sup> for three experimental runs (Figs. 1a to 1c, C-1 to C-3, Scheme 2, pathway 1). As can be seen in run C-1, no acetoxystyrene oligomer **2** formed (i.e.,  $n = 0$ ); the major MS peak corresponds to unmodified unimer **1** ( $M - H^+ = 472$   $m/z$ ) while in the subsequent runs, C-2 and C-3, the major peaks correspond to the oligomers with  $n = 5$  and  $n = 10$ , repeating units, respectively. Significantly, for C-2 and C-3, the main fragmentation route involves sequential scission of the acetoxystyrene repeating units. Accordingly, in Fig. 1b, main peaks are seen at  $n = 5$  ( $m/z = 1282$ ) and at consecutively smaller  $m/z$  values with intervals of 162  $m/z$  for  $n = 4, 3, 2$ , and 1. This pattern applies equally to C-3 and all experimental runs summarized in Table 1.

An additional feature of these MALDI/MS spectra is the presence of minor peaks at  $m/z$  values significantly greater than that of the main peak. Representative is C-2 (Fig. 1b). Arising from the presence of TEMPO radical in the system and multiple benzylic sites for H-abstraction and coupling, the possibility exists for incorporation of *multiple* TEMPO moieties at the oligomeric end groups. This accounts for these higher  $m/z$  peaks.

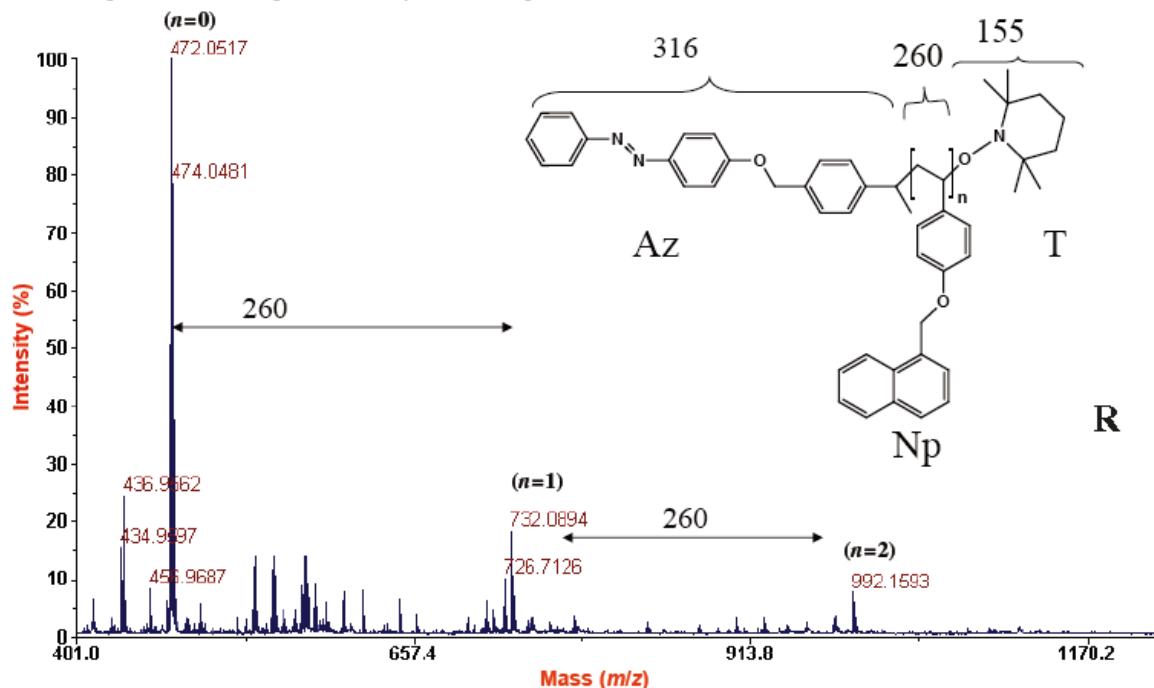

Beyond the major sequential splitting off of repeating units, small fragmentation peaks are evident between the 162  $m/z$  intervals, e.g., between  $n = 5$  and  $n = 4$  in C-3 (Fig. 1c). These small peaks may result from minor defects in the oligomer structure.

Turning to pathway 2 (Scheme 2), the direct preparation of oligomer **3**, representative MALDI/MS spectra are shown in Fig. 3 for experiment R; reaction conditions are given in Table 2. Once again major peaks result from the oligomer molecular ions with the main fragmentation route involving sequential repeating-unit scission with intervals now of 260  $m/z$ . Minor fragmentation routes for **3** are accounted for as previously outlined for **2** (Scheme 2).

Importantly, the dominant features of the MALDI/MS analysis of **2**, which apply equally to **3**, are the observation of the  $M - H^+$  molecular ions corresponding to the maximum number of repeating units in the respective oligomers. Further, the sequential loss of the repeating moiety emphasizes the source of these oligomers: a living SFRP process. Thus, the nature of any minor peaks, arising from impurities or defects, was not investigated in detail, but their presence cannot affect the conclusions or impact the main theme of this study.

### GPC

Oligomers **2** and **3** were analyzed by GPC<sup>30</sup> (UV-vis de-

**Fig. 3.** MALDI/MS spectra for azo-naphthalene oligomer, **3**, experiment R ( $n = 2$ ).

tector; see Experimental). The results of molecular weight determination (polystyrene calibration) and polydispersity (PD) are summarized in Tables 1 and 2 and discussed earlier in the text (see Fig. 2). Typical GPC traces for 4-(1-methoxynaphthyl)styrene monomer **6** (Fig. 4, experiments R, T, and S) show the separation of oligomeric fractions **3** with elution time, as well as the presence/absence of residual monomer.

### $^1\text{H}$ NMR

$^1\text{H}$  NMR spectra (Supplementary data, Figs. S2 and S3) for the acetoxystyrene oligomerizations (Scheme 2, pathway 1) are in accord with the MALDI/MS and GPC analyses summarized in Table 1. Specifically, the spectra for oligomer **2** contain a diagnostic signal at 2.27 ppm for the acetoxy methyl of the repeating unit. This signal increases in relative intensity with increasing  $n$  values for **2**. Similarly, for samples A-2 to A-4, B-1 to B-3, C-2, and C-3 (Fig. S3), increasingly broad signals are centred at 6.2 and 6.9 ppm and are ascribed to the aromatic protons of the acetoxystyrene residues. These NMR peaks for the acetoxystyrene repeating unit of **2** are absent in those runs (e.g., A-1) where oligomerization was deemed to be absent, on the basis of MALDI/MS and GPC determinations.

Considering formation of **3** (Scheme 2, pathway 2),  $^1\text{H}$  NMR spectroscopic analysis agrees with the results given in Table 2 in that higher degrees of oligomerization are accompanied with more intense signals attributable to the Np repeating units and overall broadening of all signals in the relevant spectrum. This is shown in Fig. 5 for experiments T and S.

### Fractionation of azo-naphthalene oligomers **3** via flash chromatography

Reaction of a scaled up quantity of **1** and 1-[(4-vinylphenoxy)methyl]naphthalene (20 min; 1:4, monomer:PhCl)

yielded a mixture of oligomers containing an oligomer **3** with a maximum of 14 Np repeating units. Flash column chromatography (dichloromethane eluant) gave, after recombination based on TLC, five fractions. The first (H-1) consisted only of unmodified arylvinyl monomer, **6**.

The remaining fractions contained mixtures of oligomers **3**; the longest chain oligomers eluted first. Hence, fraction H-2 contained oligomers with a maximum of 14 Np repeating units according to MALDI/MS. The next in order had  $n = 8$  (H-3),  $n = 2$  (H-4), and  $n = 1$  (H-5).

GPC analysis of the crude reaction product (H) prior to fractionation gave a number average molecular weight of 0.73 kDa with a relatively broad molecular weight distribution (PD = 1.5). Fractions H-2 and H-3 gave GPC peaks corresponding to lower-molecular-weight oligomer ( $M_n = 0.57$  kDa) and narrower distribution (PD = 1.4), while fraction H-4 was found to have  $M_n = 1.1$  kDa with a PD of 1.2. Figure 6 shows an ESI-MS spectrum for oligomer **3** where  $n = 1$  (fraction H-5).

The results show that the number of Np repeating units,  $n$ , in the oligomer **3** (via pathway 2 in Scheme 2) and the corresponding molecular weight with low polydispersity (Table 2) may be achieved through careful control of the SFRP reaction conditions (temperature and dilution with PhCl). The oligomeric mixture may be further fractionated by standard flash chromatography.

In conclusion, it can be envisaged that the described methodology will lead to a controlled range of oligomers, varying in the numbers of naphthalenic donor units.

## Experimental

### Instruments and materials

$^1\text{H}$  NMR spectra were recorded using a Bruker Avance-

**Fig. 4.** GPC chromatograms showing the increasing molecular weights of **3** and peaks for **1**, **3**, and **6** (Scheme 2), experiments R, T, and S.

400 spectrometer operating at 400.1 MHz, broad band probe, auto-tuned. All chemical shifts are reported as  $\delta$  in parts per million (ppm) relative to residual  $\text{CHCl}_3$  ( $\delta = 7.28$  ppm) and  $\text{CH}_2\text{Cl}_2$  ( $\delta = 5.30$  ppm) in  $\text{CDCl}_3$  (source: CDN) and  $\text{CD}_2\text{Cl}_2$  (CDN) solvents, respectively. Coupling constants ( $J$ ) are reported in Hz. IR samples were recorded using a Bomem MB-120 FTIR spectrophotometer. Dilute samples dissolved in a suitable volatile solvent were allowed to evaporate to provide a film on a KBr plate. Melting points were measured using a Fisher-Johns melting point apparatus and are reported as uncorrected. Gel permeation chromatography (GPC) was performed using Waters 2695 HPLC (Waters 410 differential refractometer detector,

40 °C) with a separation module consisting of four Waters Ultrastaygel® (HR5.0, HR3.0, HR1.0, and HR0.5) in series. Distilled THF was used as eluant with a flow rate of  $1.0 \text{ mL min}^{-1}$ . The GPC system was calibrated with standard polystyrenes up to an elution time of 35 min. MALDI-TOF/MS traces were recorded using an Applied Biosystems Voyager DE-STR MALDI-time of flight/mass spectrometer with a nitrogen laser (337 nm), delayed extraction and reflectors. An accelerating potential of 20 kV was used in the MS detector in both linear and reflector modes. The optimum matrix used for oligomer characterization was 2,5-dihydroxybenzoic acid (DHB) containing no added salt. Typically, oligomeric samples were prepared by mixing a THF solution of the oligomer(s) ( $1 \text{ mg mL}^{-1}$ ) with a solution of DHB ( $20 \text{ mg mL}^{-1}$  in 1:1 MeCN:MeOH) in 1:1 (v/v) proportions to give the analytical matrix. A  $1 \mu\text{L}$  aliquot of the analytical matrix was placed onto a sample plate and the solvent was evaporated at room temperature to give the MALDI-TOF/MS sample for characterization.

All common solvents (acetone, THF, and so forth) used in the preparations outlined below were purchased commercially in HPLC-grade or better and, where necessary, were further purified by standard methods.<sup>33</sup> 4-Hydroxyazobenzene (Aldrich) was recrystallized from ethanol and THF (VWR) was dried over and distilled from sodium metal/benzophenone. All inorganics (e.g.,  $\text{NaBH}_4$ ) and the remaining requisite chemicals and organic reagents were purchased commercially and used without further purification. 4-Acetoxy styrene (96%, Aldrich), di-*t*-butyl peroxide (3.5 mol/L in decane, Aldrich), 18-crown-6 (98%, Aldrich), 4-ethylbenzaldehyde (98%, Aldrich), oxalyl chloride (95%, Aldrich), and 2,2,6,6-tetramethyl-1-piperidinoxyl (TEMPO, gift of Xerox Research Canada) were used as received.

The azo unimer **1** was prepared in a five-step procedure as previously described<sup>1,27</sup> starting from 4-ethylbenzaldehyde that was reduced with  $\text{NaBH}_4$  to 4-ethylbenzyl alcohol, converted to the bromide, and capped with 2,2,6,6-tetramethyl-1-piperidinoxyl using TEMPO and di-*t*-butylperoxyoxalate. Further reaction with NaI in acetone converted the bromide to the iodide, which, in a final step, was reacted with 4-hydroxyazobenzene in the presence of  $\text{K}_2\text{CO}_3$  and 18-crown-6 in acetone to give **1**. The overall yield of this five-step procedure was 24%. All physical and spectroscopic properties were in good agreement with those previously published.<sup>1</sup> The MALDI/MS of **1** contained small extraneous peaks at greater  $m/z$  values than the protonated molecular ion for **1** (i.e.,  $M - \text{H}^+$  at  $472.28 \text{ m/z}$ ). The minor impurity was not removed by column chromatography (60 mesh silica gel; dichloromethane eluent), and **1** was used as is in the following syntheses.

### Preparation of azo-acetoxystyrene oligomers, **2**

Azo-acetoxystyrene oligomers, **2**, capped with TEMPO were prepared under SFRP reaction conditions via addition of **1** to acetoxystyrene, AS, under bulk and chlorobenzene (PhCl) solvent conditions.

### General bulk procedure

Mixtures of **1** and AS were introduced into silicone-septum-capped ampoules (10 mL), swept with  $\text{N}_2$ , and these were immersed in an oil bath thermostatted to 130 °C. After the

**Fig. 5.**  $^1\text{H}$  NMR spectra for azo-naphthalene oligomers, **3**, experiment T ( $n = 5$ ) and experiment S ( $n = 10$ ).

set reaction times, each mixture was poured into excess cold MeOH (10 mL) to quench the reaction and the precipitate, in each case, was collected by filtration. The precipitates were dried in vacuo (<1 torr, 50 °C) (1 torr = 133.322 Pa) overnight to give yellow coloured powders.

#### General solvent procedure

Experimental series B–F (cf. Table 1) were carried out at 120 °C. Mixtures of the reagents and PhCl solvent were prepared in ampoules, as given above, and the temperature maintained by immersion of the vials in the thermostatted oil bath. The mass ratios of AS to PhCl are listed in Table 1. Three aliquots were withdrawn via gas-tight syringe from each experimental series at different time intervals to yield a range of oligomeric mixtures, **2**, that were analyzed by MALDI-TOF/MS,  $^1\text{H}$  NMR spectrometry, IR spectrophotometry, and GPC (UV–vis detector), as outlined in the previous text and in the Results and discussion section.

Table 3 shows molar ratios and amount of PhCl solvent used in each experimental run.

#### Preparation of azo-naphthalene oligomers, **3**

Saponification of 4-acetoxystyrene (10 g, 0.061 mol in 2.5 g MeOH) with KOH (0.25 g, 0.0045 mol), under  $\text{N}_2$  atmosphere, followed by acidification (glacial AcOH) and addition of toluene to precipitate any poly(4-hydroxystyrene)

gave a colourless solution, after filtration. This filtrate was cooled ( $\sim -70$  °C) from which 4-vinylphenol (4-hydroxystyrene) crystallized as colourless crystals (4.5 g, 45%); mp 59–60 °C (lit. 68–69 °C,<sup>34</sup> 73.5 °C<sup>35</sup>). IR (KBr,  $\text{cm}^{-1}$ )  $\nu$ : 3249, 2977, 1656, 1541, 1410, 1110, 992, 834, 647.  $^1\text{H}$  NMR ( $[\text{CD}_3]_2\text{CO}$ , 400 MHz)  $\delta$ : 8.45 (1H, s, OH), 7.34 (2H, d,  $J = 6.8$ , H-4,8), 6.98 (2H, d,  $J = 6.8$ , H-5,7), 6.67 (1H, d, d, 17.6, 10.4, H-2), 5.60 (1H, d,  $J_{\text{trans}} = 17.6$ , H-1), 5.01 (1H, d,  $J_{\text{cis}} = 10.4$ , H-1).  $^{13}\text{C}$  NMR ( $\text{CD}_3\text{OD}$ , 100 MHz)  $\delta$ : 157.0, C-6; 136.4, C-5,7; 129.4, C-3; 127.0, C-4,8; 114.9, C-1; 109.4, C-2. EI-MS ( $\text{M} + \text{H}^+$ )  $m/z$ : 120.0532 (calcd. for  $\text{C}_8\text{H}_8\text{O}$ : 120.0531 g/mol).

#### 4-(1-methoxynaphthyl)styrene

Weighed quantities of 4-vinylphenol (1.04 g, 8.6 mmol), 1-chloromethylnaphthalene (1.2 g, 6.8 mmol),  $\text{K}_2\text{CO}_3$  (2.05 g, 14.7 mmol), and 18-crown-6 polyether (0.29 g,

1.1 mmol) were mixed with acetone (25 mL) in a round-bottom flask and the reaction mixture was brought to reflux for 36 h. The acetone was removed under reduced pressure (rotary evaporator) and the residue added to water and dichloromethane. Separation, drying, and evaporation of the organic layer yielded crude product as an oil. This product was purified by column chromatography (CH<sub>2</sub>Cl<sub>2</sub>/hexane,

1:1 v/v) to yield after evaporation of solvent colourless crystals of 4-(1-methoxynaphthyl)styrene (1.7 g, 75%); mp 48–50 °C. <sup>1</sup>H NMR (CD<sub>2</sub>Cl<sub>2</sub>, 400 Mz) δ: 8.23 (1H, d, *J* = 7.6, H-16), 7.99 (1H, d, *J* = 8.8, H-13), 7.95 (1H, d, *J* = 8.0, H-11), 7.66 (1H, m, H-15), 7.61 (2H, m overlapping signals, H-10,14), 7.56 (1H, d, *J* = 8.4, H-9), 7.45 (2H, d, *J* = 8.0, H-4,4').

### Oligomerization to give 3

Mixtures of **1**, **6**, and PhCl were placed in a 25 mL round-bottomed flask sealed with Teflon rubber septum and purged with N<sub>2</sub> for 5 min prior to immersion in an oil bath stabilized at 120 °C. After selected reaction times (Table 4), the reaction was quenched by addition of copious cold MeOH to give a gummy material that was dissolved upon addition of THF (2 mL). Precipitation of **3** with MeOH and evaporation of solvent in vacuo yielded **3** after filtration; the product was dried under high vacuum (<1 torr) overnight.

Table 4 lists reaction conditions including mole ratios of reagents and reaction times for the preparation of **3**.

### Supplementary data

Supplementary data (MALDI-MS traces, <sup>1</sup>H NMR spectra, GPC profiles for oligomers) for this article are available on the journal Web site (canjchem.nrc.ca).

# Naphthalene derivatives from *Diospyros wallichii*

Abdul-Wahab Salae, Chatchanok Karalai, Chanita Ponglimanont, Akkharawit Kanjana-Opas, and Supreeya Yuenyongsawad

**Abstract:** Three new naphthalene derivatives, 2-hydroxymethyl-1,5-dimethoxynaphthalen-4-ol (**1**), 2,2'-bis-hydroxymethyl-1,1',5,5'-tetramethoxy-3,3'-binaphthalen-4,4'-diol (**2**), and 5,5'-dihydroxy-2,2'-dimethyl-7,7'-binaphthalen-1,1',4,4'-tetraone (**3**), were isolated from the hexane and CH<sub>2</sub>Cl<sub>2</sub> extracts of the roots and fruits of *Diospyros wallichii*, along with sixteen known compounds comprising nine naphthoquinones (**4–12**), a coumarin (**13**), and six triterpenes (**14–19**). The structures of these compounds were established on the basis of spectroscopic data and comparison with reported values. The antibacterial, antifungal, and cytotoxic activities of naphthalene derivatives were also reported.

**Key words:** *Diospyros wallichii*, Ebenaceae, naphthoquinones, triterpenoids, antibacterial activity, cytotoxicity.

**Résumé :** L'extraction à l'aide d'hexane et de CH<sub>2</sub>Cl<sub>2</sub> des racines et des fruits de *Diospyros wallichii* a permis d'isoler trois nouveaux dérivés du naphthalène, le 2-hydroxyméthyl-1,5-diméthoxynaphthalène-4-ol (**1**), le 2,2'-bis-hydroxyméthyl-1,1',5,5'-tétraméthoxy-3,3'-binaphthalène-4,4'-diol (**2**) et le 5,5'-dihydroxy-2,2'-diméthyl-7,7'-binaphthalène-1,1',4,4'-tétraone (**3**), ainsi que seize composés connus, dont neuf naphthoquinones (**4–12**), une coumarine (**13**) et six triterpènes (**14–19**). Les structures de ces produits ont été établies sur la base de données spectroscopiques et par comparaison avec des données rapportées antérieurement. On rapporte aussi les résultats d'études sur les activités antibactériennes, antifongiques et cytotoxiques des dérivés naphthaléniques.

**Mots-clés :** *Diospyros wallichii*, Ebenaceae, naphthoquinones, triterpénoïdes, activité antibactérienne, cytotoxicité.

## Introduction

The genus *Diospyros* (family Ebenaceae) is found in most part of the tropics and subtropics and many of the species have been used in traditional medicines, e.g., the fruit of *D. montana* is used to treat hiccups, ulcers, urinary diseases, and dysentery. The fruit of *D. decandra* and *D. malabarica* is used as an emmenagogue in Vietnam and leukorrhea in India, respectively.<sup>1</sup> Several workers have isolated triterpenoids and naphthoquinones from some species of *Diospyros*, including the stem bark of *D. decandra*<sup>2</sup> and fruits of *D. ehereitoides*.<sup>3</sup> In our ongoing search for bioactive compounds, we have studied *D. wallichii*, which is known in Thailand as “damtako”.<sup>4</sup> This plant grows to about 10–20 m in height, whose round fruits are poisonous and used for fishing. We report herein the isolation of three new naphthoquinone derivatives (**1–3**), together with sixteen known compounds comprising nine naphthoquinones (**4–12**), a coumarin (**13**), and six triterpenes (**14–19**) from the roots and fruits of *D. wallichii* (Fig. 1). The new compounds were determined to be 2-hydroxymethyl-1,5-dimethoxynaphthalen-4-ol (**1**), 2,2'-bis-hydroxymethyl-1,1',5,5'-tetramethoxy-3,3'-

binaphthalen-4,4'-diol (**2**), and 5,5'-dihydroxy-2,2'-dimethyl-7,7'-binaphthalen-1,1',4,4'-tetraone (**3**).

## Results and discussion

The crude hexane and methylene chloride extracts from the roots and fruits of *D. wallichii* were subjected to a succession of chromatographic procedures to afford three new compounds (**1–3**), together with sixteen known compounds (**4–19**). Characterization of the known compounds was carried out by direct comparison of their physicochemical data with those reported in the literature. The structures of the new compounds were established as follows.

Compound **1** was obtained as a white amorphous powder with a molecular formula of C<sub>13</sub>H<sub>14</sub>O<sub>4</sub>, on the basis of [M]<sup>+</sup> at *m/z* 234.0920 in the HR-EI-MS, which suggested seven unsaturations. The UV spectrum exhibited absorption bands at 231 and 291 nm, while IR spectrum showed absorption bands for a hydroxyl (3400 cm<sup>-1</sup>) and aromatic ring (1613 cm<sup>-1</sup>). The <sup>1</sup>H and <sup>13</sup>C NMR spectral data, together with COSY, DEPT, HMQC, HMBC, and NOESY experiments allowed full assignment of the NMR data.

Received 13 March 2010. Accepted 7 June 2010. Published on the NRC Research Press Web site at canjchem.nrc.ca on 12 August 2010.

**Fig. 1.** Structures of compounds **1–13**.

The analysis of the  $^{13}\text{C}$  NMR spectral data of **1** (Table 1) through DEPT revealed 13 carbons among which are two methoxys ( $\delta_{\text{C}}$  56.1 and 62.3), an oxymethylene ( $\delta_{\text{C}}$  60.3), four  $\text{sp}^2$  methine, and six  $\text{sp}^2$  quaternary carbons. Of the six  $\text{sp}^2$  quaternary carbons, three were linked to oxygen atoms in view of their deshielded chemical shifts at  $\delta_{\text{C}}$  145.5, 150.7, and 156.3. Since two methoxyl groups are present, the third oxygenated quaternary carbon should link to a hydroxyl group. These data, together with seven unsaturations, suggested a naphthalene skeleton.

The  $^1\text{H}$  NMR data (Table 1) showed four aromatic proton signals. The first three signals appeared at  $\delta_{\text{H}}$  6.72 (1H, d,  $J$  = 8.4 Hz, H-6), 7.30 (1H, t,  $J$  = 8.4 Hz, H-7), and 7.60 (1H, d,  $J$  = 8.4 Hz, H-8). The fourth aromatic proton signal appeared as a broad singlet at  $\delta_{\text{H}}$  6.86 (1H, H-3), suggesting a substituent group in ring B and three substituent groups in ring A of a naphthalene skeleton. The two methoxyl protons, a hydroxyl proton and oxymethylene protons, appeared at  $\delta_{\text{H}}$

3.81, 3.98, 9.13, and 4.78 ppm, respectively. The HMBC experiment allowed the assignment of the structure as follows: the methyl singlet of O-CH<sub>3</sub> at  $\delta$  3.81 showed a correlation with C-1 ( $\delta$  145.5), whereas that at  $\delta$  3.98 showed a correlation with C-5 ( $\delta$  156.3), indicating the locations of the two O-CH<sub>3</sub> groups at C-1 and C-5, respectively. A methine proton H-3 ( $\delta$  6.86) showed clear  $^3J$  correlations with oxymethylene carbon C-11 ( $\delta$  60.3), the oxyquaternary carbon C-1 ( $\delta$  145.5), and C-10 ( $\delta$  115.1), and a  $^2J$  correlation with an oxyquaternary carbon C-4 ( $\delta$  150.7), in turn, oxymethylene protons H<sub>2</sub>-11 ( $\delta$  4.78) showed correlations with C-1 ( $\delta$  145.5), C-2 ( $\delta$  131.1), and C-3 ( $\delta$  109.8), hence, the hydroxymethyl group was located at C-2 and a hydroxyl group at C-4 of ring A. The NOESY experiment revealed interactions between 1-OCH<sub>3</sub>-H<sub>2</sub>-11, H<sub>2</sub>-11-H-3, 1-OCH<sub>3</sub>-H-8, and 5-OCH<sub>3</sub>-H-6, thus supporting the assigned structure (Fig. 2). Compound **1** was therefore characterized as 2-hydroxy-

methyl-1,5-dimethoxynaphthalen-4-ol, a reduced and 1-*O*-methylated derivative of compound **9**.

Compound **2** was obtained as a white amorphous powder. The HR-EI-MS spectrum showed a molecular ion peak  $[\text{M}]^+$  at  $m/z$  466.1622, suggesting a molecular formula of  $\text{C}_{26}\text{H}_{26}\text{O}_8$ . A comparison of the NMR and mass spectral data between compounds **1** and **2** suggested that **2** was a dimer of **1** with  $\text{C}_2$  symmetry (see Table 1). A broad singlet signal of H-3 at  $\delta$  6.86 as shown in **1** was absent in **2**, suggesting the dimeric linkage between C-3 and C-3'. In addition, the methylene protons  $\text{H}_2$ -11 and  $\text{H}_2$ -11' were shown as two sets of doublets ( $\delta$  4.50 and 4.56, each  $J = 11.1$  Hz) implying a biaryl axis with four ortho substituents, which led to a restricted rotation. On the basis of this evidence, compound **2** was identified as 2,2'-bis-hydroxymethyl-1,1',5,5'-tetramethoxy-3,3'-binaphthalen-4,4'-diol.

Compound **3** was obtained as a red solid. The HR-EI-MS spectrum showed a molecular ion peak  $[\text{M}]^+$  at  $m/z$  374.0812, corresponding to the molecular formula of  $\text{C}_{22}\text{H}_{14}\text{O}_6$ . The UV spectrum exhibited bands at 210, 270, and 415 nm, typical of the general pattern observed for plumbagin.<sup>5</sup> The IR spectrum showed absorption bands for a hydroxyl ( $3473\text{ cm}^{-1}$ ), carbonyl ( $1664\text{ cm}^{-1}$ ), and aromatic ring ( $1600\text{ cm}^{-1}$ ). The  $^{13}\text{C}$  and  $^1\text{H}$  NMR spectral data revealed only 11 carbon signals and proton signals similar to a plumbagin, but the mass spectrum and the molecular formula revealed 22 carbons, thus suggesting that **3** is a symmetrical dimer of plumbagin. The  $^1\text{H}$  NMR spectrum (see Table 1) of **3** was comparable to that of plumbagin (**4**) except that there were no clear signals for the ortho- and meta-coupled protons, but there was the presence of a broad singlet aromatic proton at  $\delta_{\text{H}}$  7.73 (2H, H-6 and H-8). The triplet proton signal of H-7 at  $\delta$  7.46, as was present in **4**, was absent in **3**, thus suggesting the linkage to be at the 7 to 7' positions. The structure of **3** was thus established to be 5,5'-dihydroxy-2,2'-dimethyl-7,7'-binaphthalen-1,1',4,4'-tetraone, a 7-7'-plumbagin dimer.

In addition, sixteen other compounds of known structures were isolated from *D. wallichii*, viz., plumbagin (**4**),<sup>6</sup> isoshinanolone (**5**), epi-isoshinanolone (**6**),<sup>7</sup> droserone (**7**),<sup>5</sup> 2,3-epoxyplumbagin (**8**),<sup>8</sup> 2-hydroxymethyl-5-methoxy-1,4-naphthoquinone (**9**),<sup>9</sup> diomuscione (**10**),<sup>10</sup> maritnone (**11**),<sup>6</sup> methylene-3,3'-biplumbagin (**12**),<sup>8</sup> scopoletin (**13**),<sup>11</sup> lupeone (**14**), lupeol (**15**), betulin (**16**), betulinaldehyde (**17**), betulinic acid (**18**),<sup>12</sup> and queretaroic acid (**19**).<sup>13</sup> All of the isolates were first reported from this species.

The antibacterial activity of naphthalene derivatives **1–5** and **7–11** are reported in Table 2. Compound **4** showed significant antibacterial activities against *Bacillus subtilis* and *En-*

**Table 2.** Antibacterial and cytotoxic activities of compounds **1–5** and **7–12**

<sup>c</sup>Human breast adenocarcinoma cell line.

*terococcus faecalis*, but moderate activity against methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant *E. faecalis* (VRE), and *Shigella sonei*. Compounds **9** and **10** exhibited moderate antibacterial activities against *B. subtilis* and *S. sonei*, while compound **9** also exhibited moderate antibacterial activities against *E. faecalis* and MRSA. Anti-fungal activity against *Candida albicans* was inactive for all compounds. In addition, the cytotoxicity against MCF-7 (human breast adenocarcinoma) cell line of compounds **1–5** and **7–12** was also evaluated. All compounds except compound **5** were active. Compounds **3** and **11** exhibited better activity than the rest of the tested compounds with IC<sub>50</sub> values of 0.09 and 0.06 µg/mL, respectively.

Experimental

General experimental procedures

Melting points were determined on the Fisher–Johns melting-point apparatus. The optical rotation [α]<sub>D</sub> was measured in chloroform solution with sodium D line (590 nm) on a JASCO P-1020 digital polarimeter. UV and IR spectra were recorded on a SPECORD S100 (Analytikjena) and PerkinElmer FTS FTIR spectrophotometer, respectively. NMR spectra were recorded using 300 and 400 MHz Bruker FTNMR Ultra Shield spectrometers in CDCl<sub>3</sub> with TMS as the internal standard. Chemical shifts are reported in δ (ppm) and coupling constants (*J*) are expressed in hertz. EI and HR-EI mass spectra were measured on a Kratos MS 25 RFA spectrometer. Solvents for extraction and chromatography were distilled at their boiling point ranges prior to use except chloroform was an analytical grade reagent. Quick column chromatography (QCC) and column chromatography (CC) were carried out on silica gel 60H (Merck) and silica gel 100 (Merck), respectively.

Plant material

The roots and fruits of *D. wallichii* were collected in De-

cember 2008 from Satun Province in the southern part of Thailand. This plant was identified by Professor Puangpen Siriruga and a voucher specimen (No. PSU 0013410) has been deposited at the Herbarium of the Department of Biology, Faculty of Science, Prince of Songkla University (PSU), Thailand.

Extraction and isolation

The dried roots of *D. wallichii* (2.5 kg) were extracted with hexane and CH<sub>2</sub>Cl<sub>2</sub> successively (2 × 10 L for each solvent for one week) at room temperature and evaporated under reduced pressure to provide crude hexane (30.7 g) and CH<sub>2</sub>Cl<sub>2</sub> (20.2 g) extracts.  
The crude hexane extract (30.7 g) was subjected to quick column chromatography (QCC) using hexane as eluent and increasing the polarity with EtOAc to give nine fractions (F1–F9). Fraction F2 (8.8 g) was recrystallized from methylene chloride to give **4** (4.3 g). Fraction F4 (3.5 g) was separated by QCC using EtOAc–hexane (1:9, v/v) as the eluting solvent to afford five subfractions (F4a–F4e). Subfraction F4d (762.3 mg) was purified by QCC with EtOAc–hexane (0.5:9.5, v/v) to afford **6** (117.2 mg). Fraction F6 (1.5 g) was separated by QCC using CH<sub>2</sub>Cl<sub>2</sub>–hexane (4:6, v/v) as the eluting solvent to afford three subfractions (F6a–F6c). Subfraction F6c (428.6 mg) was purified by QCC with EtOAc–hexane (2:8, v/v) to give **5** (47.7 mg). Fraction F7 (6.4 g) was separated by QCC with EtOAc–hexane (3:7, v/v) to afford **15** (3.9 g) and **17** (509.2 mg). Fraction F9 (1.3 g) was separated by QCC with EtOAc–CH<sub>2</sub>Cl<sub>2</sub> (1:9, v/v) to give **3** (156.4 mg).  
The CH<sub>2</sub>Cl<sub>2</sub> extract (20.2 g) was separated by QCC using hexane as eluent and increasing the polarity with EtOAc to give six fractions (F1–F6). Fraction F2 (3.6 g) was separated by QCC with EtOAc–hexane (2:8, v/v) to afford **13** (35.4 mg), **14** (3.7 g), and **16** (25.6 mg). Fraction F3 (1.2 g) was separated by QCC using acetone–hexane (2:9, v/v) as

the eluting solvent to afford six subfractions (F3a–F3f). Subfraction F3d (352.8 mg) was purified by QCC with EtOAc–hexane (1:9, v/v) to give **7** (33.6 mg). Fraction F4 (612.8 mg) was separated by QCC with acetone–hexane (1:9, v/v) to afford **10** (18.4 mg). Fraction F5 (2.3 g) was separated by QCC using EtOAc–hexane (3:7, v/v) as the eluting solvent to afford four subfractions (F5a–F5d). Subfraction F5c (1.5 g) was separated by QCC using acetone–hexane (2:8, v/v) as the eluting solvent to afford five subfractions (F5c1–F5c5). Subfraction F5c3 (527.2 mg) was purified by QCC with CH<sub>2</sub>Cl<sub>2</sub>–hexane (4:6, v/v) to give **1** (40.4 mg). Subfraction F5c5 (752.3 mg) was purified by QCC with EtOAc–hexane (3:7, v/v) to give **2** (32.4 mg).

The fresh fruits of *D. wallichii* (0.5 kg) were extracted with MeOH successively (2 × 2 L for each solvent for one week) at room temperature. The extract was evaporated to dryness and the residue was partitioned between CH<sub>2</sub>Cl<sub>2</sub> and H<sub>2</sub>O. The CH<sub>2</sub>Cl<sub>2</sub> layer was evaporated and the residue (9.2 g) was subjected to QCC using hexane as eluent and increasing the polarity with EtOAc to give five fractions (F1–F5). Fraction F2 (1.3 g) was separated by QCC using EtOAc–hexane (1:9, v/v) as the eluting solvent to afford five subfractions (F2a–F2e). Subfraction F2d (452.2 mg) was purified by QCC with EtOAc–hexane (0.5:9.5, v/v) to give **8** (19.5 mg) and **19** (11.7 mg). Subfraction F2e (552.3 mg) was separated by QCC using EtOAc–hexane (0.5:9.5, v/v) as the eluting solvent to afford two subfractions (F2e1 and F2e2). Subfraction F2e2 (359.3 mg) was purified by QCC with CH<sub>2</sub>Cl<sub>2</sub>–hexane (3:7, v/v) to afford **11** (14.7 mg). Fraction F3 (3.3 g) was separated by QCC using acetone–hexane (2:8, v/v) as the eluting solvent to afford five subfractions (F3a–F4e). Subfraction F3a (528.1 mg) was purified by QCC with EtOAc–hexane (3:7, v/v) to give **9** (10.5 mg) and **12** (13.4 mg). Fraction F4 (1.5 g) was separated by QCC with EtOAc–hexane (5:5, v/v) to afford **18** (18.9 mg).

### 2-Hydroxymethyl-1,5-dimethoxynaphthalen-4-ol (**1**)

White amorphous powder; mp 63–65 °C. UV (MeOH, nm)  $\lambda_{\text{max}}$ : 231 and 291. IR (neat, cm<sup>-1</sup>)  $\nu_{\text{max}}$ : 3400, 1633, 1613, 1445, 1387, 1262, 1239, 1072, 996, 755. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 300 MHz) and <sup>13</sup>C NMR (CDCl<sub>3</sub>, 75 MHz), see Table 1. HR-EI-MS *m/z* [M]<sup>+</sup>: 234.0920 (calcd. for C<sub>13</sub>H<sub>14</sub>O<sub>4</sub>: 233.9992).

### 2,2'-Bis-hydroxymethyl-1,1',5,5'-tetramethoxy-3,3'-binaphthalen-4,4'-diol (**2**)

White amorphous powder; mp 115–117 °C. [ $\alpha$ ]<sub>D</sub><sup>27</sup> +5.64 (c 0.36, CHCl<sub>3</sub>). UV (MeOH, nm)  $\lambda_{\text{max}}$ : 228 and 295. IR (neat, cm<sup>-1</sup>)  $\nu_{\text{max}}$ : 3389, 1632, 1605, 1455, 1382, 1357, 1244, 1069, 998, 762. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz) and <sup>13</sup>C NMR (CDCl<sub>3</sub>, 100 MHz), see Table 1. HR-EI-MS *m/z* [M]<sup>+</sup>: 466.1622 (calcd. for C<sub>26</sub>H<sub>26</sub>O<sub>8</sub>: 466.1627).

### 5,5'-dihydroxy-2,2'-dimethyl-7,7'-binaphthalen-1,1',4,4'-tetraone (**3**)

Red solid; mp 250 °C (decomposed). UV (MeOH, nm)  $\lambda_{\text{max}}$ : 210, 270, and 415. IR (neat, cm<sup>-1</sup>)  $\nu_{\text{max}}$ : 3473, 1664, 1641, 1600, 1418, 1367, 1353, 1261, 774. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 300 MHz) and <sup>13</sup>C NMR (CDCl<sub>3</sub>, 75 MHz), see Table 1.

HR-EI-MS *m/z* [M]<sup>+</sup>: 374.0812 (calcd. for C<sub>22</sub>H<sub>14</sub>O<sub>6</sub>: 347.0790).

## Bioassays

### Antibacterial assay

The isolated compounds from the roots and fresh fruits of *D. wallichii* were tested against both Gram-positive and Gram-negative bacteria: *B. subtilis*, *S. aureus* TISTR 517, *E. faecalis* TISTR 459, methicillin-resistant *S. aureus* (MRSA) ATCC43300, vancomycin-resistant *E. faecalis* (VRE) ATCC 51299, *Streptococcus faecalis*, *Salmonella typhi*, *S. sonnei*, and *Pseudomonas aeruginosa*. The microorganisms were obtained from the culture collections from the Department of Industrial Biotechnology and Department of Pharmacognosy and Botany, PSU, Thailand, except for the TISTR and ATCC strains, which were obtained from the Microbial Research Center (MIRCEN), Bangkok, Thailand. The antibacterial assay employed was the same as described in Boonsri et al.<sup>14</sup> Vancomycin, which was used as a standard, showed antibacterial activity against vancomycin-resistant *E. faecalis* (VRE) ATCC 51299 at <2.34 µg/mL.

### Cytotoxic assay

The cancer cell lines MCF-7 (human breast adenocarcinoma) were grown in Dulbecco's modified eagle medium: nutrient mixture F12 (D-MEM/F12) supplemented with 10% fetal bovine serum (FBS). Cells were seeded in 96 wells (3000 cell/well) and allowed to adhere for 24 h at 37 °C with 5% CO<sub>2</sub> in a fully humidified incubator. Then 100 µL of 25 µg/mL crude extract or fivefold diluted pure compound in medium (final concentration 0.008, 0.04, 0.2, 1, and 5 µg/mL) were dispensed into wells of the cell plates and incubated further for 72 h. After removal of the sample medium, the cells were topped up with 200 µL D-MEM/F12 medium and incubated. After 72 h, cells were fixed with cold 40% trichloroacetic acid and kept at 4 °C for 1 h and washed with tap water. The cells were determined by a sulphorhodamine assay. The absorbance was measured at 492 nm using a microplate reader. The results were based on the ability of the extracts to inhibit cell growth compared to control (cells in media without extract) and calculated for IC<sub>50</sub> using probit analysis. Camptothecin, which was used as a standard, showed cytotoxic activity at <0.024 µg/mL.

## Acknowledgements

We are grateful to the Center for Innovation in Chemistry (PERCH-CIC), Commission on Higher Education, Ministry of Education, and the Prince of Songkla University through the Crystal Materials Research Unit and the Graduate School for financial support. AWS thanks Associate Professor Dr. Uma Prawat for her helpful suggestion, Mr. T. Anantapong for the bioactivity tests, and Dr. Yaowapa Sukpondma and Miss Nareerat Thongtip for the NMR measurements.

# Electrochemical oxidation of sulfide ion in synthetic sour brines using periodic polarity reversal at Ebonex<sup>®</sup> electrodes

Shaimaa El-Sherif, Dorin Bejan, and Nigel J. Bunce

**Abstract:** The Magneli phase Ti<sub>4</sub>O<sub>7</sub> (Ebonex<sup>®</sup>) was used as both anode and cathode in the electrochemical oxidation of sulfide ion in alkaline solution in the absence and presence of chloride and naphthenate ions. Ebonex anodes gradually lost their activity through the formation of an over-oxidized surface layer, but their activity could be maintained by periodic polarity reversal. In the context of the current paradigm for the mechanistic behaviour of oxide-based anodes, Ti<sub>4</sub>O<sub>7</sub> has properties that combine those of “inactive” anodes (formation of hydroxyl radicals) and “active” anodes (formation of a higher oxide at the surface), with the exception that the higher oxide in the case of Ti<sub>4</sub>O<sub>7</sub> is TiO<sub>2</sub>, which is incapable of substrate oxidation. Sulfate is the major oxidation product, especially in the presence of chloride, an ubiquitous component of sour brines, via mediated electro-oxidation to hypochlorite. Unlike at boron-doped diamond anodes, at which sulfide is oxidized with near-quantitative current efficiency, significant parasitic oxidation of water to O<sub>2</sub> occurs at Ebonex, and oxidation of sulfide requires ~16 F mol<sup>-1</sup>, corresponding to a 50% current efficiency.

**Key words:** geothermal sour brines, electrochemical oxidation of sulfide, Magneli phase Ti<sub>4</sub>O<sub>7</sub>, hydroxyl radicals.

**Résumé :** La phase Magneli du Ti<sub>4</sub>O<sub>7</sub> (Ebonex<sup>®</sup>) a été utilisée tant comme anode que comme cathode dans l'oxydation électrochimique de l'ion sulfure en solution alcaline, en l'absence et en présence d'ions chlorure et naphténate. Les anodes d'Ebonex perdent graduellement leur activité en raison de la formation d'une couche superficielle suroxydée; toutefois, leur activité peut être maintenue par un renversement périodique de polarité. Dans le contexte du paradigme actuel pour le comportement mécanistique des anodes à base d'oxydes, le Ti<sub>4</sub>O<sub>7</sub> possède des propriétés qui combinent celles des anodes « inactives » (formation de radicaux hydroxyles) et celles des anodes « actives » (formation à la surface d'un oxyde plus élevé); toutefois, dans le cas du Ti<sub>4</sub>O<sub>7</sub>, l'oxyde plus élevé est le TiO<sub>2</sub> qui est incapable de donner lieu à une oxydation du substrat. Le sulfate est le produit d'oxydation majeur, particulièrement en présence de l'ion chlorure, un composant normal de toutes les saumures acides obtenu par l'électrooxydation en hypochlorite. Contrairement aux anodes de diamant dopées au bore avec lesquelles le sulfure est oxydé avec une efficacité de courant pratiquement quantitative, l'Ebonex donne lieu à une oxydation parasite importante de l'eau en O<sub>2</sub> et l'oxydation du sulfure requiert environ 16 F mol<sup>-1</sup>, ce qui correspond à une efficacité de courant d'environ 50 %.

**Mots-clés :** saumures acides géothermiques, oxydation électrochimique du sulfure, phase Magneli du Ti<sub>4</sub>O<sub>7</sub>, radicaux hydroxyles.

## Introduction

Geothermal “sour brines” that accompany natural-gas extraction contain inorganic sulfide at concentrations up to ~60 mmol L<sup>-1</sup> and have pH ~8.<sup>1</sup> Volatilization of hydrogen sulfide (pK<sub>a1</sub> = 6.88, pK<sub>a2</sub> = 14.15)<sup>2</sup> from sour brines is problematic in terms of odour and toxicity, and the brine itself causes corrosion of metal pipes.<sup>3–6</sup> Electrolysis is of interest for their remediation because sulfide ion is readily oxidizable, and because geothermal brines contain sufficient electrolytes that no additional supporting electrolyte is required. Advantages of electrochemical oxidation include the low cost of electrons per mol compared with chemical reagents, and avoiding the cost of disposal of toxic sludge when metal-based oxidants or precipitants are used.<sup>7,8</sup> Major anionic species present in sour brines include chloride (up to

5% NaCl) and naphthenates (up to 6%); the latter are polycyclic aliphatic carboxylates ubiquitously associated with hydrocarbon resources.

Our research into the electrochemical oxidation of sulfide in geothermal brines has the goal of finding cheap, rugged, and long-lasting anode materials that oxidize sulfide efficiently. The experimental approach involves studying the kinetics and products of sulfide oxidation in synthetic solutions in the absence and presence of chloride and naphthenate ions. To date, no anode material satisfies all the above conditions. Boron-doped diamond (BDD) anodes gave exceptional (near quantitative) chemical and current efficiencies for the oxidation of sulfide to sulfate in both the absence and presence of chloride ion,<sup>9</sup> but are not available inexpensively in large format. Carbon anodes (graphite,

granulated activated carbon, and industrial coke) behaved sacrificially, giving preponderantly organosulfonate species as products.<sup>10,11</sup> Dimensionally stable anodes based on Ti/IrO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> were gradually poisoned by sulfide,<sup>12</sup> as previously observed with other noble metal anodes.<sup>13-16</sup>

Ebonex<sup>®</sup> is the registered trademark for an electrically conductive and corrosion-resistant ceramic “sub-oxide” of TiO<sub>2</sub> having the approximate composition Ti<sub>4</sub>O<sub>7</sub>.<sup>17</sup> Ebonex is structurally a Magneli phase, with interleaved layers averaging one TiO unit for every three TiO<sub>2</sub> units. Ebonex is like BDD with respect to its wide stability range vs. water decomposition under both anodic (>2 V vs. SCE) and cathodic (-1.4 V vs. SCE) polarization.<sup>18-21</sup> To date, the chief commercial application of Ebonex is cathodic protection of the reinforcing bars in structural concrete, to inhibit corrosion through exposure to road salt<sup>17</sup> and as coated electrodes in bipolar lead-acid batteries.<sup>22,23</sup>

Our interest in the use of Ebonex as an anode for environmental remediation<sup>24</sup> was stimulated by a report of the mineralization of trichloroethylene at an Ebonex anode.<sup>25</sup> The present investigation was undertaken to evaluate the performance of Ebonex for the remediation of sour brines.

## Materials and methods

### Materials

Sodium sulfide nonahydrate (ACS reagent, 98%) and barium chloride dihydrate were provided by Sigma-Aldrich (St. Louis, MO). Sodium chloride and sodium hydroxide were supplied by Fisher Scientific (Fair Lawn, NJ) and naphthenic acids were supplied by Fluka (Sigma-Aldrich, Oakville, ON). Bleach “No Name” was bought from Zehrs, Guelph. Sodium thiosulfate and starch indicator used in iodometric titrations, magnesium chloride, potassium nitrate, anhydrous sodium acetate, hydrochloric acid, and glacial acetic acid were provided by Fisher Scientific (Fair Lawn, NJ). Iodine, potassium iodide, and sodium sulfate (anhydrous, 99%) were provided by Caledon Laboratories, Georgetown, ON. Solutions were prepared using distilled water and reagent-grade chemicals.

Cylindrical Ebonex electrodes (length 7.5 cm and diameter 1.8 cm) were supplied by Vector Corrosion, Stoney Creek, ON, and were cut lengthwise for use as semicylindrical electrodes. The immersed area was 10 cm<sup>2</sup>. In initial experiments, stainless steel plates (machine shop, University of Guelph) were used as cathodes.

### Apparatus

Batch electrolyses were performed at constant current in a 100 mL Pyrex beaker with 80 mL of solution under stirring using a magnetic stir bar. Power was supplied by an EG&G Model 363 potentiostat/galvanostat. The electrode material was cut into pieces of 7.5  $\times$  1.8 cm and the immersed area was 10 cm<sup>2</sup>. Electrical connections were made to the electrodes with alligator clips. The electrodes were positioned vertically to allow the escape of gases evolved during electrolysis. Most experiments were done by switching polarity between two Ebonex electrodes using a Siemens Logo! 12/24 RC device. A multimeter (Wavetek DM5XL) was used to monitor the voltage as well as the anode potential, against a Hg/HgSO<sub>4</sub> reference electrode, in some experiments.

Electrolysis in flow mode of operation utilized a rectangular Plexiglas cell (internal dimensions: 2.9  $\times$  2.9  $\times$  7.5 cm) whose lid (also Plexiglas) held four cylindrical Ebonex electrodes (7.5 cm length and 1 cm diameter, external dimensions) and immersed 6 cm length in 40 mL of solution. A single-pass upward flow was provided by a Masterflex C/L peristaltic pump with adjustable flow. The electrodes were connected in diagonal pairs and operated with periodically reversed polarity.

### Experimental procedures

The solutions contained sodium sulfide (5–60 mmol L<sup>-1</sup>) with 0.25 mmol L<sup>-1</sup> sodium hydroxide supporting electrolyte. Experiments were also conducted in the presence of sodium chloride (1%–5% w/v) and (or) naphthenic acids (1% w/v). Concentrations of sulfide and tetrathionate were determined iodometrically.<sup>26,27</sup> The concentration of sulfate was determined by turbidimetry at 420 nm using a Pharmacia LKB Novaspec II UV-vis spectrophotometer. Throughout the paper, including in Tables 1–4, the “rate of sulfate formation” is based on the fit to a linear model (where appropriate), but “sulfate yield” is calculated as mol sulfate formed per mol sulfide consumed, based on the final data point in the experiment. For samples containing naphthenic acids, a 1 mL sample was acidified with two drops of concentrated HCl, and the naphthenic acids were extracted with 1 mL of chloroform prior to analyzing for sulfate turbidimetrically. Hypochlorite was determined iodometrically.<sup>26</sup>

X-ray photoelectron spectroscopy was carried out using a Kratos Axis Ultra X-ray photoelectron spectrometer at the Surface Science Western laboratories of the University of Western Ontario, London, ON. Survey scan analyses were carried out with an analysis area of 300  $\times$  700 microns (1

**Table 2.** Repeated use of the same Ebonex pair of electrodes in the electrolysis of sulfide with reverse polarity every 60 min; supporting electrolyte: 0.25 mol L<sup>-1</sup> NaOH; current: 100 mA; experiments 4, 5, and 6 with 1%, 3%, and 5% sodium chloride, respectively. ## Results and discussion

### Batch cell experiments in the absence of naphthenic acids

Initial experiments were carried out in the undivided cell with an Ebonex anode and stainless steel cathode, using Na<sub>2</sub>S in the presence of 0.25 mol L<sup>-1</sup> NaOH as supporting electrolyte at constant current of 100 mA (10 mA cm<sup>-2</sup>). The loss of sulfide was current-controlled (linear with time/charge). The formation of sulfate ion was also linear with time, and corresponded to a yield of 79% based on moles of sulfide reacted (Fig. 1). The anode lost its activity upon repeated use, as shown in Table 1, which shows the trends for loss of sulfide and formation of sulfate (in mmol L<sup>-1</sup> min<sup>-1</sup>).

The Ebonex anode was regenerated after 10 experiments by sandblasting its surface to remove the presumed surface oxide layer. When it was then used for the oxidation of 30 mmol L<sup>-1</sup> sulfide, the activity was greater than that of an unused and untreated anode in the first hour of use (rate of

oxidation of sulfide: 0.087 mmol L<sup>-1</sup> min<sup>-1</sup>) but then decreased to 0.034 mmol L<sup>-1</sup> min<sup>-1</sup> (see Fig. 1 in the Supplementary data).

In previous work, a galvanic cell was produced when Ebonex anode and Ebonex cathode were used in an electrolytic cell. This indicated that the surface of the former anode had been oxidized to a composition Ti<sub>4</sub>O<sub>7</sub> and that of the former cathode had been reduced to Ti<sub>4</sub>O<sub><7</sub>.<sup>28</sup> In that work, Ebonex gradually lost its anodic activity towards the oxidation of the organic substrates *p*-nitrosodimethylaniline and acetaminophen upon repeated use, but could be partly reactivated by a single reversal of the polarity. This technique was also used in the present work, but a more successful method was to use Ebonex as both anode and cathode, and to reactivate the anode by reversing the polarity periodically. When a pair of Ebonex electrodes was used for the oxidation of sulfide under the same conditions as before, but with polarity reversal every 60 min, the efficiency of sulfide oxidation was maintained (Table 2) (the apparent anomaly that the activity was highest on the first use of the electrodes will be discussed below). Polarity reversal was used in all subsequent experiments except as noted. Unlike at BDD,<sup>9</sup>

**Fig. 1.** Loss of sulfide (■) and formation of sulfate (▲) in the electrolysis of a 28 mmol L<sup>-1</sup> sulfide solution at an unused Ebonex anode; cathode: stainless steel; supporting electrolyte: 0.25 mol L<sup>-1</sup> NaOH; current: 100 mA.

**Fig. 2.** Electrolysis of sulfide using an Ebonex pair of electrodes with polarity reversal every 60 min; supporting electrolyte: 0.25 mol L<sup>-1</sup> NaOH; current: 100 mA; sulfide (■); sulfate (▲).

the oxidation of sulfide at Ebonex was accompanied by significant evolution of O<sub>2</sub> at the anode, showing that the current efficiency for oxidation of sulfide was not quantitative.

Tables 1 and 2 show that sulfate was not formed quantitatively when sulfide ion was oxidized at an Ebonex anode. Missing material was identified as tetrathionate ion;<sup>27</sup> one such experiment (still in the absence of chloride), starting with 32 mmol L<sup>-1</sup> sulfide, produced 88% sulfate and 8% tetrathionate, leaving only 4% unaccounted for. Tetrathionate is formed by a sequence involving formation and disproportionation of polysulfide (written here as HS<sub>2</sub><sup>-</sup>), yielding thiosulfate ion, which is further oxidized (Scheme 1).<sup>14</sup>

**Scheme 1.**

**Fig. 3.** Electrolysis of sulfide using a sandblasted Ebonex pair of electrodes with polarity reversal every 60 min; supporting electrolyte: 0.25 mol L<sup>-1</sup> NaOH; current: 100 mA.

Kinetically, the rate of oxidation of 30–60 mmol L<sup>-1</sup> sulfide was independent of the initial substrate concentration, and proportional to the applied current (50 and 100 mA). In a current-controlled process such as this, there is always an abundance of substrate at the anode. In a series of experiments beginning with a low concentration of sulfide (5 mmol L<sup>-1</sup>), the kinetics tended towards mass-transport control.<sup>29</sup> We noted that the relationship between [sulfate] and absorbance was nonlinear in this low concentration range (for the calibration curve, see Fig. 2 in the Supplementary data). A typical experiment is shown in Fig. 2.

Possible mechanisms for sulfide oxidation include direct oxidation of HS<sup>-</sup> at the anode and chemical oxidation of sulfide by electrolytically produced hydroxyl radicals. We attempted to resolve this question by voltammetry. Previously, Lawrence et al.,<sup>30</sup> had reported that the overpotential for the two-electron oxidation of sulfide at pH 10 was anode-dependent: *E* values (vs. SCE) were +1.30, +0.76, +0.45, and +0.36 V at BDD, gold, glassy carbon, and platinum, respectively. The thermodynamic value for oxidation of sulfide to elemental sulfur is +0.44 V vs. SHE.<sup>31</sup>

To avoid the reproducibility problems encountered in previous voltammetry experiments with Ebonex anodes<sup>28</sup>, the microelectrodes in this work were prepared by cutting a slice (~1 mm) of Ebonex, making an electrical contact, and then encasing the assembly in epoxy resin in a small polypropylene test tube. Once cured, the bottom of the test tube was sawn off, and the rigidity of the assembly allowed fresh anode surfaces (~3 mm<sup>2</sup>) to be obtained by abrasion. No ox-

**Table 5.** Survey XPS spectra of Ebonex samples (area percent); sample 1: unused Ebonex; sample 2: Ebonex used as an anode for electrolysis of 0.25 mol L<sup>-1</sup> NaOH; sample 3: Ebonex used as a cathode for electrolysis of 0.25 mol L<sup>-1</sup> NaOH; sample 4: Ebonex used as an anode for electrolysis of 0.25 mol L<sup>-1</sup> NaOH with 30 mmol L<sup>-1</sup> Na<sub>2</sub>S; sample 5: Ebonex used as a cathode for electrolysis of 0.25 mol L<sup>-1</sup> NaOH with 30 mmol L<sup>-1</sup> Na<sub>2</sub>S.

5	cathode	NaOH/ Na <sub>2</sub> S	24.3	32.6	0.4	3.3	27.1

idation current for sulfide was seen independent of the oxidation of water, consistent with a high overpotential for oxidation of sulfide at this material.<sup>32</sup>

We interpreted the behaviour of Ebonex anodes in the context of the paradigm developed by Kapalka et al.<sup>33</sup> to explain the oxidation chemistry of substrates at oxide-based anodes. At “inactive” anodes such as Ti/SnO<sub>2</sub>, β-PbO<sub>2</sub>, and BDD, the substrate undergoes a series of one-electron oxidations with hydroxyl radicals sorbed to the anode surface A, i.e., A~OH•. By contrast, at “active” anodes based on noble metals (e.g., Ti/IrO<sub>2</sub>, Ti/RuO<sub>2</sub>), the initially formed A~OH• is further oxidized to A=O, and substrate oxidation is a two-electron reaction. Panizza and Cerisola<sup>34</sup> have recently suggested that not all anodes necessarily fall neatly into active and inactive classifications; there may be some overlap in properties.

In this work, significant evolution of O<sub>2</sub> at the anode, combined with the high overpotential for sulfide oxidation, indicated the intermediacy of hydroxyl radicals by partial oxidation of water. The wide anodic range of water stability<sup>18–21</sup> indicates that Ebonex probably behaves as an inactive (BDD-like) anode, acting as a source of sorbed hydroxyl radicals A~OH•.<sup>35</sup> This conclusion is consistent with our previous observation that ethanol quenched the oxidation of *p*-nitrosodimethylaniline at an Ebonex anode.<sup>28</sup>

HS<sup>-</sup>(aq) and HO•(aq) react together at nearly the rate of diffusion ( $k = 5.4 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ ),<sup>36</sup> so it is likely that the reaction between HS<sup>-</sup>(aq) and anode-sorbed HO• is also fast. However, the products of this reaction are unknown. Equations [1–3] show three possibilities, although we cannot unequivocally rule out direct electron transfer between sulfide ion and the anode, because the kinetics of current-controlled oxidation indicates that there is always a ready supply of substrate at the anode.

In terms of the paradigm of Kapalka et al.,<sup>33</sup> we propose that Ti<sub>4</sub>O<sub>7</sub> initially oxidizes water to form Ti<sub>4</sub>O<sub>7</sub>OH•. Unlike at BDD, for which “BDD-OH•” does not oxidize further, the fate of Ti<sub>4</sub>O<sub>7</sub>OH• is a three-way competition: reaction with an oxidizable substrate, oxidation of the sorbed HO• to O<sub>2</sub>, and oxidation of Ti<sub>4</sub>O<sub>7</sub>OH• to Ti<sub>4</sub>O<sub>8</sub> (= TiO<sub>2</sub>) on

the surface. To the extent that hydroxyl radical chemistry competes with surface oxidation, Ebonex exhibits properties characteristic of active and inactive anodes, as suggested by Panizza and Cerisola.<sup>34</sup> Unlike at active anodes based on Ti/IrO<sub>2</sub> or Ti/RuO<sub>2</sub>, the oxidized surface layer cannot initiate substrate oxidation and serves only to inactivate the anode. We hypothesized that polarity reversal during electrolysis served to regenerate the less oxidized surface; confirmation was obtained when sandblasted electrodes were used for the oxidation of 30 mmol L<sup>-1</sup> sulfide with polarity reversal (Fig. 3). For the first 2 × 60 min, each anode was “new”; at subsequent time points, each anode had been previously used and then regenerated. The reaction rate accordingly fell after the first 2 h (compare the rates shown on Fig. 3 with those recorded in Table 1).

Investigation of the surface of Ebonex was carried out by X-ray photoelectron spectroscopy (XPS), with unused Ebonex and with samples used as anode or cathode ± sulfide ion (without polarity reversal). Sulfur was present at levels greater than background only in sample No. 4, which had been used as an anode for the oxidation of sulfide (Table 5), and was shown to be present as sulfate (binding energy: 168.7/169.9 eV) in the high resolution scans (see Figs. 3–7 in the Supplementary data).

We were unable to observe a change in the ratio Ti:O in cathodic vs. anodic Ebonex samples, even though the Ti(2p) binding energies of TiO and TiO<sub>2</sub> are readily distinguishable.<sup>37</sup> All samples showed only TiO<sub>2</sub>-like titanium on account of air oxidation of the surface prior to XPS analysis. The O(1s) spectra showed the presence of both metal oxide and metal hydroxide at the surface, with the hydroxide predominating in electrolyzed samples.

A high level of carbon was detected on the surface of Ebonex, as previously observed by Pouilleau et al.<sup>38</sup> The predominant peak had binding energy of 284.9 eV, corresponding to C–C and C–H bonded carbon. Sources of surface carbon include its use as a desiccant in the hydrogenation of TiO<sub>2</sub> to Ebonex,<sup>39</sup> and sorption of atmospheric hydrocarbon material, as routinely found in non-ablated samples. All electrolyzed samples (anodes and cathodes) showed increased carbon intensities at higher binding energies, corresponding to C=O functional groups, but still with a high intensity of C–C and C–H bonded carbon because of contamination. Elemental analysis showed that the overall mass percentage of carbon in finely ground Ebonex is small (0.04%); correspondingly, Ebonex anodes released only a little organic carbon into solution during

electrolysis in 0.25 mol L<sup>-1</sup> NaOH (first use, 5.2 ppm; second use, 3.3 ppm).

In both the absence and presence of chloride, Ebonex anodes gradually lost their ability to oxidize sulfide on repeated use, unless polarity switching was employed. Returning to Tables 1 and 2, we make three observations. First, in Table 1, entries 6 and 7 (1% NaCl) show pronounced anode inactivation compared with the earlier entries. Second, no inhibiting effect of chloride was seen when using polarity reversal (Table 2, entries 4–6). Third, the activity of an Ebonex anode was greatly diminished by the presence of hypochlorite as shown by the following experiment, carried out without polarity reversal. This experiment had three parts. First, sulfide was oxidized in the absence of chloride with an Ebonex anode and stainless steel cathode without polarity reversal at 100 mA (rate of oxidation, 0.025 mmol min<sup>-1</sup>). Second, 5% NaCl/0.25 mol L<sup>-1</sup> NaOH was electrolyzed with the same electrodes in the absence of sodium sulfide, producing hypochlorite at the anode. Third, the first electrolysis was repeated, again using the same electrodes; the rate of sulfide oxidation was now only 0.009 mmol min<sup>-1</sup>. Our interpretation is that hypochlorite oxidized the surface of Ebonex to the inactive, oxidized form. Using polarity reversal, however, the active form can be regenerated under cathodic polarization even when chloride is present.

In the oxidation of high (30 mmol L<sup>-1</sup>) concentrations of sulfide in the presence of NaCl, the disappearance of sulfide and the formation of sulfate were both linear with time (see Fig. 8 in the Supplementary data), and the rate of oxidation was directly proportional to the applied current (50 and 100 mA). The rate of oxidation and the chemical yield of sulfate increased only slightly at higher concentrations of NaCl (Table 3). In this system (30 mmol L<sup>-1</sup> Na<sub>2</sub>S, 1% NaCl), the influence of the rate of polarity reversal was also investigated over the range 5–60 min; the optimum switching time was 15 min, but the effect was small (Table 4). The kinetic response to chloride was significantly different at a low (5 mmol L<sup>-1</sup>) initial concentration of sulfide; chloride ion had a strong accelerating effect (Fig. 4), and gave a quantitative yield of sulfate. The isoelectronic species Cl<sup>-</sup> and S<sup>2-</sup> have very similar mass transport coefficients, and the range 1%–5% w/v NaCl corresponds to 0.17–0.85 mol L<sup>-1</sup>, about two orders of magnitude more than that of 5 mmol L<sup>-1</sup> sulfide. Under these conditions, conversion of chloride to hypochlorite is the major electro-oxidation process, making sulfide oxidation a mediated reaction that occurs in the bulk solution. Control experiments in our previous work<sup>9</sup> showed that hypochlorite ion oxidizes sulfide to sulfate quantitatively.

#### Batch cell experiments in the presence of naphthenic acids with or without chloride

Naphthenic acids (NAs) have pK<sub>a</sub> ~5 and are present as carboxylates at pH ~8, typical of sour brines. Previous work at BDD in the presence of NAs showed that over-oxidation of sulfide solutions produced an oily film on the anode, which inhibited further oxidation of sulfide.<sup>40</sup> This was explained by parasitic Kolbe decarboxylation of the naphthenate anions.<sup>41,42</sup> At Ti/IrO<sub>2</sub>–Ta<sub>2</sub>O<sub>5</sub>, the rate of oxidation of sulfide at 100 mA was independent of the presence of 3%

**Fig. 4.** Acceleration of the sulfide oxidation rate with sodium chloride concentration; initial sulfide concentration: 5 mmol L<sup>-1</sup>; supporting electrolyte: 0.25 mol L<sup>-1</sup> NaOH; current: 100 mA; polarity reversal every 60 min.

NAs, but at higher current (and correspondingly higher anode potential), the NAs inhibited sulfide oxidation because of the competing Kolbe reaction.<sup>12</sup> In the present work, the applied current was limited to 100 mA (at which the anode potential was +2.8 V) to minimize the Kolbe reaction.

In the oxidation of 30 mmol L<sup>-1</sup> sulfide with 1% NA, the disappearance of sulfide was again linear with time, with rate (0.040 mmol L<sup>-1</sup> min<sup>-1</sup>) similar to that in the absence of NAs at the same current (100 mA). In contrast with experiments in the absence of NAs, sulfate did not form in appreciable quantities till late in the reaction, and its yield always remained low (Fig. 5). To analyze sulfate in this system, precipitation of NAs was required prior to turbidimetric analysis; this was done by acidifying the solution to pH ~2 with HCl.<sup>12</sup> The delay in the appearance of sulfate was more pronounced starting with the low (5 mmol L<sup>-1</sup>) concentration of sulfide and the loss of sulfide was less regular with time (see Supplementary data, Fig. 9).

In the presence of NAs, a yellow colour developed in the partly electrolyzed solutions. Visible absorption spectroscopy failed to show whether this was due to the presence of polysulfide, because of the inherent color of the NAs. Polysulfide would form if the surfactant effect of NAs removed sulfur from the anode surface before it could be oxidized further. Under this hypothesis, sulfate would only form when the remaining sulfide concentration was too low to support the concentration of polysulfide. In support of this hypothesis, an experiment in the presence of NAs gave 74% sulfate and 16% tetrathionate at high conversion of sulfide, according to Scheme 1, leaving 10% sulfide unaccounted for. However, an alternative explanation for the delay in forming sulfate in the presence of NAs might be trapping of sulfur species by alkyl radical intermediates from Kolbe oxidation of the NAs, followed by hydroxyl rad-

<sup>e</sup>High conversion of sulfide.

<sup>f</sup>Cell voltage increased gradually from 4.8 V at time zero to 6.5 V at 120 min.

<sup>g</sup>Polarity reversal every 60 min; all others in this column without polarity reversal.

<sup>h</sup>Cell voltage increased gradually from 4.4 V at time zero to 5.1 V at 180 min.

<sup>i</sup>Cell voltage increased gradually from 4.9 V at time zero to 5.4 V at 240 min.

<sup>j</sup>Polarity reversal every 15 min; all others in this column without polarity reversal.

<sup>k</sup>Cell voltage increased gradually from 5.0 V at time zero to 5.9 V at 180 min.

**Fig. 5.** Electrolysis of sulfide in the presence of 1% w/v naphthenic acids and in the absence of chloride using an Ebonex pair of electrodes with polarity reversal every 60 min; supporting electrolyte: 0.25 mol L<sup>-1</sup> NaOH; current: 100 mA; sulfide (■); sulfate (▲).

ical-mediated release of sulfate. This has been observed previously when the products of sulfide electrooxidation at a coke anode were reoxidized at BDD.<sup>10</sup> We do not have experimental information to distinguish these possibilities.

The oxidation of sulfide was modestly inhibited by the presence of 1% NAs when chloride was added to the medium (rate 0.017 mmol L<sup>-1</sup> min<sup>-1</sup> compared with 0.025 mmol L<sup>-1</sup> min<sup>-1</sup>) and the yield of sulfate was nearly quantitative by the end of the reaction. This indicates that the course of the chloride-assisted reaction again involves mainly hypochlorination (Fig. 6).

### Flow cell experiments

The flow cell had a rectangular cross section and contained two Ebonex anodes and two Ebonex cathodes, arranged diagonally. The solution volume was 40 mL. Ports set near the bottom (in) and top (out) allowed flow through the cell, with stirring provided by a magnetic stir bar, as well as by gas evolution. Experiments were carried out only in the absence of chloride and NAs, to show proof of concept in the flow mode of operation with polarity reversal every 60 min. No attempt was made to achieve “complete” remediation. Steady-state concentrations of sulfide and sulfate were established within 80 min at a flow rate of 0.5 mL min<sup>-1</sup>.

In the absence of flow, the rate of sulfide loss at 100 mA in this reactor was similar ( $8.7 \times 10^{-6}$  mol min<sup>-1</sup>) to that in the open batch reactor ( $7.5 \times 10^{-6}$  mol min<sup>-1</sup>); under flow conditions at the same current, remediation rates were  $4.0 \times 10^{-6}$  mol min<sup>-1</sup>,  $3.1 \times 10^{-6}$  mol min<sup>-1</sup>, and  $2.3 \times 10^{-6}$  mol min<sup>-1</sup> at flow rates 1.0, 0.5, and 0.25 mL min<sup>-1</sup>, respectively. Fig. 7 shows that the extent of remediation did not increase proportionately with current at constant flow rate, nor did it increase reciprocally with flow rate at constant current. This indicates that the reactor was operating

**Fig. 6.** Electrolysis of sulfide in the presence of 1% w/v naphthenic acids and 1% chloride using an Ebonex pair of electrodes with polarity reversal every 60 min; supporting electrolyte: 0.25 mol L<sup>-1</sup> NaOH; current: 100 mA; sulfide (■); sulfate (▲).

**Fig. 7.** Electrolysis of 30 mmol L<sup>-1</sup> sulfide in an electrochemical CSTR using Ebonex electrodes with polarity reversal every 60 min; supporting electrolyte: 0.25 mol L<sup>-1</sup> NaOH; A: 0.25 mL/min; B: 0.5 mL/min; C: 1 mL/min.

under conditions intermediate between current and mass transport control.

## Conclusions

According to the paradigm of Kapałka et al.,<sup>33</sup> Ebonex has the characteristic properties of both “active” and “inactive” anodes. As an inactive anode, the oxidation of water affords anode-sorbed hydroxyl radicals, which can be described as Ti<sub>4</sub>O<sub>7</sub>-OH•. These are the proximate species for substrate oxidation. However, Ti<sub>4</sub>O<sub>7</sub>-OH• is also oxidizable,

leading to a surface layer of TiO<sub>2</sub>. Unlike active anodes such as Ti/RuO<sub>2</sub>, this surface layer is incapable of substrate oxidation, and causes anode passivation. A significant innovation in this work has been to introduce periodic polarity reversal to overcome the problem of over-oxidation of the Ebonex surface that causes the inactivation and the irreproducible behaviour of Ebonex electrodes observed by us<sup>28</sup> and others.<sup>17,43</sup>

We introduced this work with the comment that no anode material is ideal in all respects for the oxidation of sulfide ion. Table 6 presents comparative data for the oxidation of 30 mmol L<sup>-1</sup> sulfide under common conditions of 100 mA current in batch cells of 80 mL capacity at several anodes (except as noted in the Table footnotes). As the “base case”, we consider oxidation at BDD, which affords sulfate ion with near 100% chemical and current yields.<sup>9</sup> This reaction has a value of ~8 F per mol sulfide remediated. Similar values are seen for Ti/IrO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub>,<sup>12</sup> with the proviso that because this anode is gradually poisoned by sulfide, the data refer to a relatively new anode. Coke electrodes are exceptional because they show two regimes of sulfide oxidation:<sup>10</sup> sulfur is the major product at low conversion (2 F mol S<sup>-1</sup>); subsequently, sulfate and organosulfate formation become predominant (~8 F mol S<sup>-1</sup>).

For Ebonex, the current efficiency per mol of the oxidized sulfide is about half that at BDD; part of the inefficiency arises from the irreversible passivation of the Ebonex surface, which can be reactivated by polarity reversal, the remainder by extensive parasitic formation of O<sub>2</sub>. Despite the lower current efficiency, this work demonstrates the prospective value of Ebonex for the remediation of sulfide in synthetic geothermal brines. Even at ~50% of current efficiency, the method is viable, based on the low cost of electrons per mol. Although Ebonex (the trademarked material) is available from only a single manufacturer, the original patent has long since expired,<sup>17</sup> and the raw materials for the Magneli phase Ti<sub>4</sub>O<sub>7</sub> are TiO<sub>2</sub> and hydrogen, both of which are inexpensively and readily available.

# Terpenoid constituents and antifungal activity of *Aglaia forbesii* seed against phytopathogens

Nantiya Joycharat, Patimaporn Plodpai, Kanda Panthong,  
Boon-ek Yingyongnarongkul, and Supayang Piyawan Voravuthikunchai

**Abstract:** Two new trisnortriterpenoids possessing a  $\gamma$ -lactone ring linked to the D-ring of a 3,4-secodammarane skeleton in a 20*R* configuration, named isoeichlerialactone (**1**) and methyl isoeichlerialactone (**2**), were isolated from the seed of *Aglaia forbesii*, along with the three dammarane triterpenes, isocabralealactone (**3**), isoeichlerianic acid (**4**), and aglinin A (**5**), the sesquiterpene spathulenol (**6**), and the widespread sterols  $\beta$ -sitosterol and stigmasterol. Their structures were established based on detailed spectroscopic analysis. Antifungal activity of *A. forbesii* seed against three phytopathogens, *Phytophthora botryosa*, *P. palmivora*, and *Rigidoporus microporus*, was carried out using the mycelium inhibition test and broth microdilution technique. Superior activity was exhibited by hexane and dichloromethane fractions containing the compounds **1**, **4**, and **5** as the main components. Subsequent antiphytopathogenic fungi tests proved that compounds **1**, **4**, and **5** possessed good antifungal activity.

**Key words:** *Aglaia forbesii*, Meliaceae, dammarane, triterpenes, antifungal, *Phytophthora botryosa*, *Phytophthora palmivora*, *Rigidoporus microporus*.

**Résumé :** L'extraction des graines d'*Aglaia forbesii* a permis d'isoler deux nouveaux trisnortriterpénoïdes possédant une  $\gamma$ -lactone attachée au cycle D au squelette du 3,4-sécodammarane dans la configuration 20*R*, l'isoeichlériallactone (**1**) et l'ester méthylique de la isoeichlériallactone (**2**), ainsi que trois triterpènes de la famille du dammarane, l'isocabraléallactone (**3**), l'acide isoeichlérianique (**4**) et l'aglinine A (**5**), le sesquiterpène spathuléol (**6**) et les stérols très répandus  $\beta$ -sitostérol et stigmasterol. On a établi leur structure sur la base d'analyses spectroscopiques détaillées. Faisant appel au test d'inhibition du mycélium et à la technique de microdilution du bouillon, on a étudié l'activité antifongique des graines d'*A. Forbesii* contre trois phytopathogènes, *Phytophthora botryosa*, *Phytophthora palmivora* et *Rigidoporus microporus*. Des solutions contenant les composés **1**, **4** et **5** comme composants principaux dans de l'hexane et du dichlorométhane présentent une activité supérieure. Un test de champignon antiphytopathogène subséquent a permis de démontrer que les composés **1**, **4** et **5** possèdent une bonne activité antifongique.

**Mots-clés :** *Aglaia forbesii*, Meliaceae, dammarane, triterpènes, antifongique, *Phytophthora botryosa*, *Phytophthora palmivora*, *Rigidoporus microporus*.

## Introduction

The genus *Aglaia*, consisting of over 100 species, forms an important component of the moist tropical forest in the Indo-Malaysian region.<sup>1</sup> Previous phytochemical investigations of plants in this genus have revealed the presence of a variety of compounds including several flavaglines (cyclopenta[*b*]benzofurans, cyclopenta[*bc*]benzopyrans, and benzo[*b*]oxepines),<sup>2,3</sup> bisamides,<sup>4</sup> triterpenoids (baccharane, cycloartane, dammarane, glabretal, lupane, and tirucallane types),<sup>5</sup> steroids (cholestane, ergostane, pregnane, and stigmasterane types),<sup>6,7</sup> limonoids,<sup>8</sup> sesquiterpenes,<sup>9</sup> lignans,<sup>10</sup> and flavonoids.<sup>11</sup> Some of these known isolates were shown to

possess high insecticidal activity,<sup>4,11</sup> antifungal activity,<sup>12</sup> antiviral activity,<sup>13</sup> anti-inflammatory activity,<sup>14</sup> as well as significant antiproliferative activity.<sup>2</sup>

*Aglaia forbesii*, a large tree of up to 35 m, is widely distributed in the southern region of Thailand. So far, phytochemical studies on the bark and leaf extracts of this plant have been documented.<sup>3,9</sup> In our previous work, we described several new compounds including benzopyran flavaglines desacetylpyramidaglains A, C, and D and the triterpene 23,24,25-trihydroxycycloartan-3-one from the leaf extract of this plant, some of which showed antituberculosis and antiviral activities.<sup>9</sup> However, no information on the chemical profiles and the biological activities from the seed

<sup>1</sup>Corresponding author (e-mail: supayang.v@psu.ac.th).

of this plant species is currently available. Regarding the available data of bioactivities of plants in the genus *Aglaiia*, less is known about the antifungal activity. To date, only a few studies have been performed on the antifungal activities of some members of this genus, including *A. elaeagnoides*,<sup>8,12</sup> *A. leptantha*,<sup>10</sup> *A. edulis*,<sup>12</sup> and *A. odorata*.<sup>12</sup>

Our preliminary test for antifungal activity against the three plant pathogens *Phytophthora botryosa*, *P. palmivora*, and *Rigidoporus microporus*, based on the mycelium inhibition test, demonstrated that the ethanolic extract from the seed of this plant species exhibited more pronounced activity against phytopathogenic fungi tested than those from the leaves and pericarp, as well as some other medicinal plants previously documented for their good antibacterial activities in our laboratory, including *Rhodomyrtus tomentosa* and *Quercus infectoria*.<sup>15</sup>

*P. botryosa*, *P. palmivora*, and *R. microporus* have been frequently isolated as the important phytopathogens in many economically important agricultural crops, especially rubber. *P. botryosa* and *P. palmivora* cause various diseases on rubber, of which black stripe is the most severe,<sup>16</sup> while *R. microporus* is the causative pathogen of white root disease in rubber plantations.<sup>17</sup> Interestingly, plants produce a wide variety of physiologically active chemicals, which often serve as alternative sources for the control of fungal diseases in plants.<sup>18</sup>

Phytochemical investigation of the *A. forbesii* seed has led to the isolation of two new trisnortriterpenoids linking the  $\gamma$ -lactone system of the side chain to the D-ring of the 3,4-secodammarane skeleton in a 20*R* configuration (**1**) and the corresponding methyl ester (**2**), along with four known terpenoids (**3–6**) and the common phytosterols  $\beta$ -sitosterol and stigmasterol. We described herein the isolation and structure elucidation of the two newly isolated trisnortriterpenoids, as well as the antifungal activity of the crude ethanolic extract, fractions, and some isolated compounds from the seed of *A. forbesii* against the three phytopathogens *P. botryosa*, *P. palmivora*, and *R. microporus*.

## Results and discussion

Chromatographic separation of the *n*-hexane fraction of the ethanolic seed extract of *A. forbesii* yielded a new trisnortriterpenoid (**1**), named isoeichlerialactone, together with six known compounds including the three known dammaranes, isocabralealactone (**3**), isoeichlerianic acid (**4**), and aglinin A (**5**), the sesquiterpene spathulenol (**6**), and the common phytosterols  $\beta$ -sitosterol and stigmasterol. Similarly, repeated silica gel chromatography of the  $\text{CH}_2\text{Cl}_2$  fraction also afforded the newly isolated compound **1** and the three known dammarane triterpenes (**3–5**), as well as another new compound, named methyl isoeichlerialactone (**2**). The known compounds, isocabralealactone (**3**),<sup>19</sup> isoeichlerianic acid (**4**),<sup>20</sup> aglinin A (**5**),<sup>21</sup> spathulenol (**6**),<sup>22</sup> and the mixture of  $\beta$ -sitosterol and stigmasterol<sup>23</sup> were identified by comparison of their spectroscopic data with those previously reported in the literature.

Compound **1** was isolated as colourless needles. The molecular formula was deduced as  $\text{C}_{27}\text{H}_{42}\text{O}_4$  based on a molecular ion peak at  $m/z$  430.3086  $[\text{M}]^+$  (calcd.: 430.3083) in the HR-EI-MS. The important fragment ion peak visible at  $m/z$

99 ( $\text{C}_5\text{H}_7\text{O}_2$ ) indicative of a  $\gamma$ -butyrolactone was observed in the EI-MS. The IR spectrum showed the absorption bands due to carboxylic acid (3500–2500, 1707  $\text{cm}^{-1}$ ), olefinic (3073, 1636, 1455, 936, 892  $\text{cm}^{-1}$ ), and a  $\gamma$ -lactone (1763  $\text{cm}^{-1}$ ). The  $^1\text{H}$  NMR (Table 1) spectrum revealed the presence of four shielded methyl singlets ( $\delta$  1.32, 0.99, 0.88, 0.84), one methyl singlet on a double bond ( $\delta$  1.71), and two singlets of olefinic methylene protons ( $\delta$  4.86, 4.65). The  $^{13}\text{C}$  NMR spectrum (Table 1) in combination with DEPT-135 experiments indicated 27 signals: five signals for tertiary methyl groups ( $\delta$  23.18, 22.44, 20.11, 16.11, 15.31), an ester carbonyl ( $\delta$  176.91), a carboxylic carbon ( $\delta$  178.18), eleven methylenes in which one of them is an olefinic methylene ( $\delta$  113.52), four methines, five quaternary carbons including a carbon bearing an oxygen atom ( $\delta$  89.86), and an olefinic quaternary carbon ( $\delta$  147.39). Further inspection of the  $^{13}\text{C}$  NMR spectrum of **1** revealed resonance signals similar to those of isoeichlerianic acid (**4**),<sup>20</sup> but instead of an isopropanol group, it showed an extra carbonyl carbon ( $\delta$  176.91). According to previous literature, the trinor- $\gamma$ -lactone derivatives, obtained by Jones oxidation of the corresponding triterpenoid precursors possessing a tetrahydrofurylpropanol side chain, showed no evidence of epimerization at C-20 during the oxidation reaction.<sup>24,25</sup> Similarly, the co-occurrence of compound **4**, the C-20*R* isomer of eichlerianic acid, suggested that this compound should be considered an intermediate in a biosynthetic pathway to the further oxidation of product **1** with the configuration at C-20 remaining unchanged.

Based on the data mentioned above, compound **1** was suggested to be a trisnor- $\gamma$ -lactone derivative of **4** and its configuration at C-20 could be assumed to be 20*R*, followed from that of **4**. The  $^{13}\text{C}$  chemical shift values of compound **1**, especially C-21 of the  $\gamma$ -lactone ring, significantly differed from the corresponding data of eichlerialactone. The  $^{13}\text{C}$  chemical shift of C-21 for eichlerialactone appeared at 25.0 ppm in  $\text{CDCl}_3$ ,<sup>26</sup> whereas that of compound **1** was 22.44 ppm, which differs by about 3 ppm. In addition, according to recent literature, the 20*R* and 20*S* isomers of dammarane-type triterpenoids with a tetrahydrofuryl side chain can be easily distinguished by the resonances of C-21, which resonated at about  $\delta$  23.6–27.2 ppm and at about  $\delta$  21.7–22.0 ppm for the 20*S* isomer and 20*R* isomer, respectively.<sup>20</sup> Consequently, this fact was used to assign either 20*S* or 20*R* configuration of triterpenes accumulated in the genus *Aglaiia*.<sup>27</sup> In our case, the shift value of C-21 for **1** appeared at  $\delta$  22.44 ppm, which was almost identical to that of the 20*R* isomer; therefore, the configuration could be assigned unambiguously as 20*R*.<sup>20</sup> Regarding the trisnor- $\gamma$ -lactone (**1**), only its 20*S* isomer (eichlerialactone) was reported earlier;<sup>26</sup> therefore, the 20*R* compound **1**, namely, isoeichlerialactone, is new.

The structure elucidation of **1** was accomplished by complete spectral analyses ( $^1\text{H}$ – $^1\text{H}$  COSY, HMQC, HMBC, and ROESY). The observed COSY (Table 1) coupling between  $\text{H}_2$ -1 ( $\delta$  1.62, m) and  $\text{H}_2$ -2 ( $\delta$  2.35, ddd,  $J = 9.1, 8.3, 3.2$  Hz, H-2a;  $\delta$  2.16, ddd,  $J = 15.6, 9.1, 6.4$  Hz, H-2b), as well as the HMBC cross peaks from  $\text{H}_2$ -2 to C-3 ( $\delta$  178.18, s) and from  $\text{H}_2$ -28 ( $\delta$  4.86, 4.65, br s each) to C-5 ( $\delta$  50.79, d) and C-29 ( $\delta$  16.11, q) confirmed the assignments of ring A-*seco*-3 acid moiety. The HMBC data (Table 1), especially

**Table 1.** NMR spectroscopic data (400 MHz, CDCl<sub>3</sub>) for isoeichlerialactone (**1**).

the long range correlations of five methyl groups, proved to be very valuable in assigning the resonances of the rings A–D of the 3,4-secodammarane skeleton. The HMBC correlations from Me-18 to C-7, C-8, C-9, and C-19, from Me-19 to C-1, C-2, C-5, C-9, and C-10, from Me-21 to C-17, C-20, and C-22, from Me-29 to C-5 and C-28, and from Me-30 to C-8, C-13, and C-15 supported the estimated structures. This is also in accordance with the extensive NMR data described for other related compounds recently reported.<sup>20</sup> The 20*R* configuration of **1** was confirmed by the diagnostic ROESY cross peaks from Me-21 to H-22 $\alpha$  and from H-17 to Me-21, H-22 $\alpha$ , and Me-30. The absence of ROESY correlation between Me-21 and H-13 was observed in compound **1** and further supported the 20*R* configuration in which the Me-21 was in the  $\alpha$ -position (Fig. 1).

Compound **2** was obtained as colourless needles. It has almost identical <sup>1</sup>H and <sup>13</sup>C NMR spectral data to those of **1**, suggesting that they have the same core structure of the 3,4-secodammarane triterpenoids with the  $\gamma$ -lactone side chain.

The additional characteristic features of an ester carbonyl and a methyl ester with their respective resonances at  $\delta$  174.4 and 51.59 ppm, as well as a corresponding singlet integrated for three protons visible at  $\delta$  3.64 ppm in the <sup>1</sup>H NMR spectrum, indicated that compound **2** was a corresponding ester of **1**. This was supported by the [M]<sup>+</sup> peak in the HR-EI-MS at *m/z* 444.3240 (calcd.: 444.3240) corresponding to the molecular formula of C<sub>28</sub>H<sub>44</sub>O<sub>4</sub>. The 20*R* configuration of **2** was determined by comparison of the typical <sup>13</sup>C resonance of C-21 (22.41) with those of **1** and other relevant compounds,<sup>20</sup> and they completely agree with the proposed structure. The synthetical 20*S* isomer of **2** has already been published.<sup>24</sup> However, the trisnortriterpene possessing the 20*R* configuration of **2** has not been documented yet. Therefore, the new compound was designated as methyl isoeichlerialactone (**2**). Its <sup>1</sup>H and <sup>13</sup>C NMR spectral data are summarized in Table 2.

Compound **3** has a molecular formula of C<sub>27</sub>H<sub>42</sub>O<sub>3</sub>, which was assigned from its mass spectrum ([M]<sup>+</sup> at *m/z* 414) in

**Fig. 1.** Structures of compounds 1–6.

combination with the  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra and its IR spectrum, which indicated the presence of carbonyl function ( $1705\text{ cm}^{-1}$ ) and a  $\gamma$ -lactone system ( $1767\text{ cm}^{-1}$ ). Further comparison of the  $^1\text{H}$  and  $^{13}\text{C}$  spectra of **3** with the corresponding data of **1** revealed that the two compounds have very similar resonances except for the signals in the A-ring region. The former did not show the resonances of a carboxylic carbon ( $\delta\ 178.18$ ), an olefinic methylene ( $\delta\ 113.52$ ), and an olefinic quaternary carbon ( $\delta\ 147.39$ ), instead, a keto carbonyl ( $\delta\ 217.95$ ) was evident in the  $^{13}\text{C}$  spectrum. This indicated that compound **3** possessed a  $\gamma$ -lactone ring attached to the D-ring of a dammaran-3-one skeleton. The  $^{13}\text{C}$  chemical shift of C-21, visible at  $22.13\text{ ppm}$ , was indicative of a  $20R$  configuration in comparison to **1** and the other  $20R$  isomers.<sup>20</sup> Up until now, within the Meliaceae, only the  $20S$  isomer (cabralealactone) of compound **3** has been published.<sup>25</sup> Whereas the  $20R$  isomer of cabralealactone, named isocabralealactone, has been previously mentioned in some literature,<sup>28</sup> its  $^{13}\text{C}$  NMR (Table 2) spectral data are documented here for a first time.

Antifungal activity screening against the three phytopathogens *P. botryosa*, *P. palmivora*, and *R. microporus* revealed that the ethanolic extracts from the seed and pericarp of *A. forbesii* exhibited higher activity than the leaf ethanolic extracts of *R. tomentosa* and *Q. infectoria*. In the mycelium inhibition test, the percentage of inhibition of mycelial growth from the seed, pericarp, and leaf extracts of *A. forbesii* are in the range of 39%–68%, 38%–65%, and 0%–12%, respectively, whereas those of *R. tomentosa* and *Q. infectoria* are in the range of 11%–41% and 0%–18%, respectively. *R. microporus* was more susceptible to all extracts of *A. forbesii* than *P. botryosa* and *P. palmivora*, of

which the ethanolic seed extract, with 68% mycelial growth inhibition, is the most active extract.

The crude ethanolic extract, fractions, and pure compounds from *A. forbesii* seed were further evaluated for their minimum inhibitory concentration (MIC) and minimum fungicidal concentration (MFC) values against the plant pathogens using broth microdilution method. The MIC and MFC values of *A. forbesii* seed extract ranged from 500 to 1000  $\mu\text{g mL}^{-1}$  and 1000 to 2000  $\mu\text{g mL}^{-1}$ , respectively (Table 3).

**3**). All the fractions, except for that of buthanol, showed a higher and broader spectrum of antifungal activity as compared to that of the unfractionated ethanolic extract. Although almost of the active extract and fractions demonstrated stronger inhibitory effect against *R. microporus* with MICs and MFCs better than those of the other organisms, both the hexane and dichloromethane fractions in which the 3,4-secodammarane triterpenes (**1**, **4**, and **5**) were observed to be the major components displayed similar antifungal effect against all the plant pathogens tested, with their respective MIC and MFC values ranging from 250 to 500  $\mu\text{g mL}^{-1}$  and 250 to 1000  $\mu\text{g mL}^{-1}$ .

The 3,4-secodammarane triterpenes, isoeichlerialactone (**1**), isoeichlerianic acid (**4**), and aglinin A (**5**), showed a broad antifungal spectrum against all phytopathogens tested, whereas the dammaran-3-one derivative (**3**) and the sesquiterpene (**6**) were only active against *R. microporus*. Among the compounds tested, isoeichlerialactone (**1**) was found to be the most effective derivative against *R. microporus* with the identical MIC and MFC values of  $62.5\text{ }\mu\text{g mL}^{-1}$ , better than a positive control carboxin with the MIC and MFC values of 125 and 250  $\mu\text{g mL}^{-1}$ , respectively. Compounds **1**, **4**, and **5** showed a very similar effect against *P. botryosa* and *P. palmivora*. However, aglinin A (**5**) was more active

**Table 2.**  $^1\text{H}$  (400 MHz) and  $^{13}\text{C}$  NMR (100 MHz) data for methyl isoeichlerialactone (**2**) and  $^{13}\text{C}$  NMR (100 MHz) data for isocabralealactone (**3**) in  $\text{CDCl}_3$ .

against *P. botryosa* with the MIC and MFC values of 125 and 250  $\mu\text{g mL}^{-1}$ , respectively, comparable to the activity of a positive control metalaxyl.

A number of plant-derived *seco*-A-triterpenoids have been described to be highly antimicrobial.<sup>29</sup> Similarly, among the closely related dammarane compounds, **1**, **3**, **4**, and **5**, the 3,4-*seco*-3 acid derivatives, **1**, **4**, and **5**, exhibited higher activity than the dammaran-3-one derivative (**3**), suggesting that the 3,4-*seco*-3 acid skeleton could account for some of the antifungal properties. In recent work, antimycobacterial activity of the related dammarane-type triterpenoids has been published.<sup>30</sup> Antifungal activity of the other *Aglaia* spp. has been previously reported against a few organisms causing rice blast disease<sup>12</sup> and two other fungal plant pathogens in the genus *Cladosporium*.<sup>8,10</sup> With respect to the increasing negative effects of synthetic fungicides to hu-

mans and the environment, as well as the improved resistance of phytopathogenic fungi against conventional fungicides, our finding suggests possible benefits of bioactive compounds from *A. forbesii* seed for effective control of fungal plant pathogens.

## Experimental

### General

The following instrumentation was used: Mps, Electrothermal 9100; Optical rotation, Jasco P-1020 polarimeter; IR, EQUINOX 55, Bruker FTIR; 1D- and 2D-NMR, FT-NMR Bruker Advance 400 MHz; EI-MS and HR-EI-MS, MAT 95 XL mass spectrometer (ThermoFinnigan). Column chromatography (CC) was performed using silica gel (Merck, 70–230 mesh ASTM) and Sephadex LH20 (Pharmacia). Thin-layer chromatography (TLC) was carried out on precoated sheets of silica gel 60 F<sub>254</sub>. Compounds were monitored by TLC sprayed with an anisaldehyde–sulfuric acid solution or 10% sulfuric acid. Fungal culture media, the Standard Roswell Park Memorial Institute (RPMI) 1640 powder, as well as potato dextrose agar (PDA) and V8 juice agar (VA), were purchased from Sigma-Aldrich (St. Louis, MO) and Difco (Detroit, MI). Dimethyl sulfoxide (DMSO) was purchased from Merck (Darmstadt, Germany).

### Plant material

The seed of *A. forbesii* was collected in March 2009 from Nakhon Sri Thammarat, Thailand. Identification was made by comparison with authentic specimens (ES-0403) previously established.<sup>9</sup> A voucher specimen (NJ-0309) was deposited at the Herbarium of the Department of Biology, Faculty of Science, Prince of Songkla University, Thailand.

### Extraction and isolation

The seed of *A. forbesii* (48 g) was dried, ground, and exhaustively extracted with EtOH at room temperature three times, filtered, and concentrated. The EtOH extract (5.7 g) was resuspended in a mixture of MeOH and water and then extracted with hexane,  $\text{CH}_2\text{Cl}_2$ , and BuOH, successively. Each filtrate was pooled and evaporated to dryness under reduced pressure at 40 °C to yield the hexane fraction (2.42 g, 5.04%),  $\text{CH}_2\text{Cl}_2$  fraction (1.87 g, 3.89%), and BuOH fraction (1 g, 2.08%).

The hexane fraction (2.42 g) was subjected to CC using silica gel as adsorbent and eluted with a gradient system of EtOAc–hexane, then washed down with MeOH. The fractions were then combined, on the basis of their TLC profiles, to give seven fractions (I<sub>H</sub>–VII<sub>H</sub>). Fraction II<sub>H</sub> (94 mg) was rechromatographed on silica gel, eluting with 20%  $\text{CH}_2\text{Cl}_2$  in hexane affording compound **6** (7 mg). Fraction III<sub>H</sub> (97.2 mg), yielding a white precipitate during the concentration process, was further recrystallized from acetone to give a mixture (9.1 mg) of  $\beta$ -sitosterol and stigmasterol. Fraction IV<sub>H</sub> (150 mg) was purified on a silica gel column with 20% acetone in hexane as the eluent and further by a Sephadex LH20 column with  $\text{CH}_2\text{Cl}_2$ –MeOH (1:1) as the eluent to yield compound **1** (4.7 mg). Fraction V<sub>H</sub> (500 mg) was further separated by a silica gel CC, eluting with 40% acetone in hexane and then by crystallization in EtOH to give compound **4** (10.2 mg). Fraction VII<sub>H</sub> (93.7 mg) was

**Table 3.** The minimum inhibitory concentrations and minimum fungicidal concentrations of extract, fractions, and compounds from *Aglaia forbesii* seed against *Phytophthora botryosa*, *P. palmivora*, and *Rigidoporus microporus*.

loaded to a Sephadex LH20 column, eluting with CH<sub>2</sub>Cl<sub>2</sub>–MeOH (1:1), and further purified by recrystallization from EtOH to afford compound **5** (8.4 mg).

The dichloromethane fraction (1.87 g) was applied to CC over silica gel using gradient elution with acetone–CH<sub>2</sub>Cl<sub>2</sub>, and finally washed down with MeOH. The fractions were then combined according to their TLC patterns, to give seven fractions (I<sub>D</sub>–VII<sub>D</sub>). Fraction II<sub>D</sub> (48 mg) was rechromatographed on silica gel, eluting with a gradient system of acetone–hexane, and followed by crystallization in EtOH to yield compound **3** (4.1 mg). Fraction IV<sub>D</sub> (136 mg) was loaded on a silica gel column, eluting with 8% acetone in CH<sub>2</sub>Cl<sub>2</sub> and then by crystallization in EtOH gave compound **1** (10.7 mg). Fraction V<sub>D</sub> (243 mg) was subjected to silica gel CC using gradient elution with acetone–hexane. Column fractions eluted with 15% and 40% acetone in hexane afforded compound **2** (3 mg) and compound **4** (14.2 mg), respectively. Fraction VII<sub>D</sub> (218 mg) was further purified on a silica gel column with 20% acetone in hexane as the eluent and then on a Sephadex LH20 column eluting with CH<sub>2</sub>Cl<sub>2</sub>–MeOH (1:1) to yield compound **5** (26 mg).

#### Isoeichlerialactone (**1**)

Colourless needles (EtOH); mp 166–167 °C.  $[\alpha]_D^{20} +19.2$  (*c* 0.33 g/100 mL EtOH). #### Isocabralealactone (**3**)

White solid (CH<sub>2</sub>Cl<sub>2</sub>); mp 180–182 °C. IR (neat, cm<sup>-1</sup>)  $\nu_{\text{max}}$ : 2952, 2869, 1767, 1705, 1461, 1382, 1255, 1193, 1152, 936, 755. <sup>1</sup>H NMR (400 MHz, CDCl<sub>3</sub>)  $\delta$ : 0.87 (3H, s, H-30), 0.92 (3H, s, H-19), 0.98 (3H, s, H-18), 1.02 (3H, s, H-29), 1.06 (3H, s, H-28), 1.32 (3H, s, H-21). <sup>13</sup>C NMR (100 MHz, CDCl<sub>3</sub>) data: see Table 2. EI-MS *m/z* (% rel. int.): 414 ([M]<sup>+</sup>, 52), 399 (12), 315 (28), 205 (72), 195 (23), 147 (26), 107 (44), 99 (100), 95 (64), 81 (51).

#### Antifungal activity evaluation

Phytopathogenic fungi including *P. botryosa*, *P. palmivora*, and *R. microporus*, as well as fungicides, metalaxyl, and carboxin, were obtained from the Department of Pest Management, Faculty of Natural Resources, Prince of Songkla University, Thailand. Preliminary screening for antifungal activity was employed based on the mycelium inhibition test.<sup>31</sup> The MIC and MFC were evaluated using the broth microdilution method.<sup>32</sup>

#### Mycelium inhibition test

The ethanolic extracts from the leaves, pericarp, and seed of *A. forbesii* were tested. The ethanolic leaf extracts of *R. tomentosa* and *Q. infectoria* from the Natural Products Research Center, Faculty of Science, Prince of Songkla University, Thailand were included. The mycelial growth inhibition of phytopathogenic fungi tested was determined as previously described.<sup>32</sup> Briefly, each extract was dissolved in 10% DMSO and added on PDA at concentrations of 200  $\mu\text{g mL}^{-1}$ . A mycelial plug of phytopathogenic fungi from a three day old culture was placed in the center of the PDA plate and incubated at 28 °C. After seven days, percentage inhibition of mycelial growth was recorded and calculated by a formula,  $100 - [(R^2/r^2) \times 100]$ , where *R* and *r* represent the radius of the fungus colony in the treated and control plates, respectively. There were four replications in each treatment and the experiment was designed as a completely randomized design. DMSO (10%) was included as control.

#### Inoculum preparation

Sporangiospore suspensions of *Phytophthora* spp. and a

mycelial suspension of *R. microporus* were prepared from 10 day old cultures incubated at 35 °C on VA and PDA, respectively. The colonies were covered with 1 mL of sterile 0.85% saline and the surface scraped with a sterile loop. The mixture of zoospore and hyphal fragments were transferred to sterile tubes. After heavy particles were allowed to settle for 15 min, the upper homogenous suspensions were transferred to sterile tubes. Turbidity of the inocula was adjusted to  $0.4 \times 10^6$  to  $5 \times 10^6$  cfu mL<sup>-1</sup> at a wavelength of 520 nm and transmission was adjusted to 68%–70% in a spectrophotometer. The inocula were diluted (1:50) in RPMI 1640 to a final concentration of  $0.4 \times 10^4$  to  $5 \times 10^4$  cfu mL<sup>-1</sup>. The inocula were quantified by plating 0.01 mL of a 1:100 dilution of the adjusted inoculum on PDA plates to determine the viable number of colony-forming units (cfu) per milliliter. The plates were incubated at 28 °C and observed daily for the presence of growth.<sup>32</sup>

### Broth microdilution method

The crude extract, fractions, and pure compounds from *A. forbesii* seed and fungicides were evaluated. The broth microdilution method was performed according to the guidelines of the Clinical and Laboratory Standards Institute document M38-A.<sup>32</sup> The tests were performed in polystyrene microtitre plates with 96 flat-bottomed wells. Stock solutions of the crude extract, their fractions, pure compounds, metalaxyl, and carboxin were prepared in DMSO to a 100-fold the final concentration needed and followed by further dilution in RPMI 1640 to yield twice the final strength required for the test. Aliquots of 100 µL of samples tested were inoculated into the wells with a multichannel pipette. Each microplate was inoculated with 100 µL of the diluted inoculum suspensions to bring the dilutions of the inoculum to  $0.4 \times 10^4$  to  $5 \times 10^4$  cfu mL<sup>-1</sup>. Sample solutions were subsequently serially diluted twofold in the plates with the broth, starting with the final concentration of 2000 µg mL<sup>-1</sup> for the extract and fractions and 250 µg mL<sup>-1</sup> for the pure compounds and fungicides. The microplates were incubated at 35 °C for 24 h. All the tests were performed in triplicate. The MIC was defined as the lowest concentration that completely inhibited growth. The MIC of samples was detected following the addition of resazurin (10 µL/well) and incubated at 37 °C for 30 min. Viable microorganisms reduced the blue dye to a pink colour. To obtain the MFCs, 100 µL volumes were taken from every well showing inhibition and were spread on PDA. Colony forming units were counted after incubating the plates at 35 °C until growth of the subcultures from the growth control well was apparent. The MFC was defined as the lowest drug concentration at which 99% of the inoculum was killed.

# Understanding the reversible anodic behaviour and fluorescence properties of fluorenylazomethines — A structure–property study

Satyananda Barik, Sayuri Friedland, and W.G. Skene

**Abstract:** A series of fluorenylazomethine dyads and triads were prepared by simple condensation between the corresponding amine and aldehyde fluorene derivatives. These compounds were prepared as model compounds for investigating the effects of substitution and electronic groups on both the electrochemical properties and fluorescence quantum yields. It was found that the oxidation potential could be decreased by both incorporating electron donating groups and increasing the degree of conjugation. It was further found that alkylation in the fluorene's 9-position increased the azomethine degree of conjugation by forcing all the fluorene moieties to be coplanar with the azomethine bonds to which they are attached. Meanwhile, reversible radical cation behaviour was possible by substituting the terminal 2,2'-positions with atoms other than hydrogen. The radical cation was theoretically found to be distributed evenly across the fluorene, corroborating the reversible anodic behaviour with 2,2'-substitution. The fluorescence quantum yields of the azomethines were not found to be dependent on substitution. This was because the azomethine fluorescence was found to be quenched relative to their precursors regardless of substitution. The fluorescence could be restored at both low temperature and by acid protonation.

**Key words:** fluorenylimines, reversible oxidation, cyclic voltammetry, azomethines, Schiff base, radical ions.

**Résumé :** On a préparé une série de dyades et de triades de la fluorénylazométhine par simple condensation entre des dérivés de l'amine et de l'aldéhyde du fluorène. On a préparé ces composés comme modèles pour des études sur les effets de substitution et des groupes électroniques tant sur les propriétés électrochimiques que sur les rendements quantiques de fluorescence. On a trouvé que le potentiel d'oxydation peut être réduit tant par l'incorporation de groupes électrodonneurs que par une augmentation du degré de conjugaison. On a aussi trouvé que l'alkylation en position 9 des fluorènes augmente le degré de conjugaison des azométhines en forçant toutes les entités fluorènes à être coplanaires avec les liaisons azométhines auxquelles sont attachées. Par ailleurs, un comportement de cation radical réversible est possible si l'on substitue les positions terminales en 2,2' par des atomes autres que l'hydrogène. On a trouvé sur une base théorique que le cation radical peut être distribué d'une façon uniforme sur l'ensemble de la portion fluorène, ce qui confirme le comportement anodique réversible avec une substitution 2,2'. Les résultats obtenus suggèrent que les rendements quantiques de fluorescence des azométhines ne dépendent pas de la substitution. Cette conclusion repose sur le fait que la fluorescence de l'azométhine est désactivée par rapport à celles de leurs précurseurs quelle que soit la substitution. La fluorescence peut être restaurée aussi bien par une basse température que par une protonation acide.

**Mots-clés :** fluorénylimines, oxydation réversible, voltampérométrie cyclique, azométhines, base de Schiff, ions radicaux.

## Introduction

Conjugated polymers are of great interest in part due to their electrochemical and optoelectronic properties that are well-suited for use in plastic devices such as organic field effect transistors (OFET), light emitting diodes (OLED), and organic photovoltaics (OPVD), to name but a few.<sup>1–4</sup> Polyfluorenes are particularly interesting because of their inherent fluorescence making them appropriate emitting materials for OLED usage.<sup>5</sup> Many polyfluorene derivatives have been prepared and investigated to afford materials with improved device efficiency and color purity for addressing the performance requirements for the next generation of plastic electronics and consumer demands.<sup>5–7</sup> Desired property improvements are possible by connecting the fluorene segments

with vinylene linkages.<sup>7–9</sup> Their preparation uses Gilch and Horner–Emmons protocols, requiring rigorous reaction conditions such as anhydrous solvents and inert atmospheres. These coupling methods, unfortunately, produce significant byproducts requiring product purification in order not to compromise the material's colour emission and device performance.

Azomethines ( $-N=C-$ ) are highly attractive alternatives to vinylene linkages owing to their easy preparation not requiring stringent reaction conditions.<sup>10</sup> They are further advantageous because their preparation is environmentally friendly with water being the unique byproduct produced. The preparation of azomethines, therefore, requires little or no purification. Moreover, the azomethine bond is isoelectronic to its all-carbon counterpart, making it ideally suited for func-

**Chart 1.** Monomers and oligomers prepared and investigated and some representative analogues.

tional materials usage, but with the advantage of simple preparation and little purification.<sup>11–13</sup>

Despite these advantages, azomethine fluorenes have not been fully exploited as functional materials in emitting devices. This is a result of previously investigated fluorenylazomethine derivatives that were irreversibly oxidized and were nonfluorescent.<sup>14,15</sup> Such properties, unfortunately, preclude their use in functioning devices, and as a result, have attracted little attention for property improvement. It is therefore important to understand the reasons for irreversible oxidation to design and prepare new azomethine derivatives with functional materials properties. For this reason, we investigated the effect of fluorenylazomethine structure on the electrochemical properties to achieve reversible oxidation. We were further enticed to undertake such structure–property studies to bring to light the potential uses of fluorenylazomethines as functional materials. This is in part because azomethines are dismissed as useful functional materials owing to the limited properties of previously examined compounds. We therefore examined the electrochemical properties of a series of model fluorenylazomethines complemented with theoretical studies to better understand the oxidation process. The knowledge gained from such studies is not only pivotal for demonstrating the suitability of azomethines as functional materials, but also for designing and preparing future genera-

tions of fluorenyl compounds with tailored properties for specific applications. Herein, we present the preparation and electrochemical studies of a series of fluorenylazomethines, represented in Chart 1, for understanding the structure–reversible oxidation relationship.

## Experimental

### Materials and general experimental procedures

All reagents were commercially available from Sigma-Aldrich and were used as received unless otherwise stated. Anhydrous and deaerated solvents were obtained via a Glass Contour Solvent Purification System. <sup>1</sup>H NMR and <sup>13</sup>C NMR spectra were recorded on a Bruker 400 MHz spectrometer with the appropriate deuterated solvents.

### Spectroscopic measurements

Absorption measurements were performed on a Cary-500 spectrometer and fluorescence studies were done on an Edinburgh Instruments FLS-920 fluorimeter after deaerating the samples thoroughly with nitrogen for 20 min. Relative fluorescence quantum yields were measured at 10<sup>–5</sup> mol/L by exciting the corresponding compounds at its maximum absorption in spectroscopic grade dichloromethane relative to itself at 77 K under the same conditions.

### Electrochemical measurements

Cyclic voltammetric measurements were performed on a Bio Analytical Systems EC Epsilon potentiostat at scan rates of 100 mV/s. Compounds were dissolved in anhydrous and deaerated dichloromethane at  $10^{-4}$  mol/L with 0.5 mol/L  $\text{Bu}_4\text{NPF}_6$ . A platinum electrode and a saturated Ag/AgCl electrode were employed as auxiliary and reference electrodes, respectively, and ferrocene was added at the end of the electrochemical measurements to serve as an internal reference.

The highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energy levels and spin densities were calculated using density functional theory (DFT) calculation methods available in Spartan 06 (Wavefunction, Inc.) with the 6-31g\* basis set.<sup>16</sup> The bond angles, distances, torsions, and other parameters were experimentally derived from the X-ray data for an analogous compound. The crystallographic data were used as the optimized geometry from which the single point energy was calculated to semiempirically calculate the molecular orbitals and spin densities. The rotational barriers were semiempirically calculated using the AM1 method.<sup>17</sup> The desired dihedral angle was varied from  $0^\circ$  to  $360^\circ$  and constrained at a given angle. The heat of formation ( $\Delta H_f$ ) for the given angle was subsequently calculated without additional structural optimization.

### Synthetic procedures

The syntheses of **3**, **4**, **7**, and **8** were prepared according to reported procedures.<sup>18</sup>

#### 9,9-Dihexylfluorene

Fluorene (5 g, 30.8 mmol) was dissolved in DMSO (50 mL) and triethylbenzyl ammonium bromide (0.1 g, 1.5 mol) was added under  $\text{N}_2$ .<sup>19</sup> A 50% aqueous NaOH (15 mL) solution was added while stirring at room temperature. After 0.5 h, 1-bromohexane (12.41 g, 75.2 mmol) was added dropwise for 15 min. The reaction mixture was then stirred at room temperature for 4 d. The reaction mixture was diluted with an excess of diethyl ether and the aqueous layer was removed. The organic layer was washed with water, 2 mol/L HCl, and brine and then dried over  $\text{MgSO}_4$ . The solvent was removed under vacuum and the residue was purified by column chromatography over silica gel with hexanes as eluent to give the product as a white solid at  $-40^\circ\text{C}$  (7.8 g, 90%).  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.73 (d, 2H), 7.31–7.38 (m, 6H), 1.99 (dd, 4H), 1.07–1.33 (m, 12H), 0.77 (t, 4H), 0.63 (t, 6H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 151.1, 141.5, 127.4, 121.1, 123.2, 120.0, 55.4, 40.8, 31.9, 30.1, 24.1, 23.0, 14.2.

#### 2,7-Dinitro-9,9-dihexylfluorene

The nitration was done similarly to published procedures.<sup>20</sup> A solution of 9,9-dihexylfluorene (2.12 g, 6.33 mmol) in 20 mL of  $\text{HNO}_3$  in a 100 mL roundbottom flask was heated to reflux for 2 h under  $\text{N}_2$  atmosphere. The reaction mixture was then cooled to room temperature and poured onto ice and the product was extracted with dichloromethane. The organic layer was washed with water three times, saturated  $\text{NaHCO}_3$ , and brine solution and then finally dried over  $\text{MgSO}_4$ . The solvent was evaporated and

the crude product was purified by column chromatography with hexanes/ethyl acetate (7:3) to give a mixture of 2-nitro-9,9-dihexylfluorene and 2,7-dinitro-9,9-dihexylfluorene. The products were further recrystallized from EtOH to separate the two products, which were isolated as yellow solids.

#### 2,7-Dinitro-9,9-dihexylfluorene

Isolated yield of 66% (1.94 g).  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 8.33 (dd, 2H), 8.28 (d, 2H), 7.93 (d, 2H), 2.09 (dd, 4H), 1.02–1.13 (m, 12H), 0.76 (t, 4H), 0.55 (t, 6H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 152.7, 147.5, 127.7, 123.6, 121.6, 120.1, 56.0, 40.4, 31.8, 29.9, 24.1, 22.9, 14.3.

#### 2-Nitro-9,9-dihexylfluorene

$^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 8.27 (d, 1H), 8.23 (d, 1H), 7.82 (dd, 2H), 7.41–7.44 (m, 3H), 2.03 (dd, 4H), 1.05–1.13 (m, 12H), 0.76 (t, 4H), 0.60 (t, 6H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 152.7, 152.3, 148.0, 147.5, 129.6, 127.8, 123.6, 123.5, 121.6, 120.1, 118.6, 56.0, 40.5, 31.8, 29.9, 24.1, 22.9, 14.3.

#### 2-Amino-9,9-dihexylfluorene (1)

2-Nitro-9,9-dihexylfluorene (0.84 g, 2.21 mmol) was dissolved in 10 mL of EtOH and stirred at room temperature under  $\text{N}_2$ . A catalytic amount of 10% Pd/C (0.2 g) was added followed by the addition of hydrazine monohydrate (1.6 g, 11.05 mmol) and the mixture was refluxed for 2 h. The reaction mixture was filtered to remove the Pd/C and the product was extracted with dichloromethane. The organic layer was washed with water ( $3 \times 50$  mL) and brine solution and then dried over  $\text{MgSO}_4$ . The solvent was evaporated and the crude product was purified by column chromatography with hexanes/ethyl acetate (1:1) as eluent to give the product as a brown sticky liquid with an isolated yield of 78%. The product was unstable and was kept under  $\text{N}_2$  atmosphere and used immediately for subsequent reactions.  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.57 (d, 1H), 7.48 (d, 1H), 7.26 (m, 3H), 7.19 (dd, 2H), 6.68 (d, 2H), 1.90 (dd, 4H), 1.04 (m, 12H), 0.78 (t, 6H), 0.64 (d, 4H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 153.0, 150.1, 148.2, 128.9, 125.7, 122.9, 120.9, 118.7, 114.3, 110.2, 55.1, 41.0, 31.9, 30.2, 24.1, 23.0, 14.4. MS  $m/z$ : 350.54 ( $\text{M}^+$ ).

#### 2,7-Diamino-9,9-dihexylfluorene (2)

The solution of 2,7-dinitro-9,9-dihexylfluorene (1.2 g, 2.8 mmol) in 20 mL of EtOH was stirred at room temperature under  $\text{N}_2$ . To the above solution, a catalytic amount of 10% Pd/C (0.1 g) was added followed by hydrazine monohydrate (1.02 g, 20.18 mmol) and the mixture was refluxed for 2 h. The reaction mixture was filtered and the product was extracted with dichloromethane. The organic layer was washed with water ( $3 \times 50$  mL) and brine solution and then dried over  $\text{MgSO}_4$ . The solvent was evaporated and the crude product was purified by column chromatography with hexanes/ethyl acetate (1:1) to afford the title compound as a brown liquid with an isolated yield of 72%. The product was unstable and was stored under  $\text{N}_2$  until used.  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.35 (d, 2H), 6.66 (d, 4H), 3.94 (br,  $\text{NH}_2$ ), 1.83 (dd, 4H), 1.06 (m, 12H), 0.78 (t, 6H), 0.66 (d, 4H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 152.1, 144.3, 133.8, 119.5, 114.6, 110.7, 55.0, 41.3, 32.0, 30.2, 24.1, 23.1, 14.4. MS  $m/z$ : 356.3 ( $\text{M}^+$ ).

### 9,9-Dioctylfluorene-2,7-dicarboxaldehyde (3)

A 250 mL two-necked flask containing 9,9-dioctyl-2,7-dibromofluorene (2.2 g, 4.01 mmol) in anhydrous THF (40 mL) was stirred under N<sub>2</sub> at -78 °C in an acetone-dry ice bath.<sup>21</sup> *n*-Butyl lithium (7.6 mL, 16.0 mmol) was added under vigorous stirring and stirred for 1.5 h. A deaerated mixture of DMF (5 mL) and anhydrous THF (3 mL) was added dropwise to the reaction mixture at -78 °C and allowed to stir for 1 h at room temperature. The reaction mixture was cooled to 0 °C and 10% HCl was added until the solution was acidic (tested by litmus paper). After stirring for 30 min, the mixture was partitioned between dichloromethane and water and the organic layer was isolated. The aqueous layer was washed with dichloromethane and the combined organic extracts were dried over Na<sub>2</sub>SO<sub>4</sub>. The crude product was purified by column chromatography using hexanes/dichloromethane (1:1) as eluent. The product was obtained as colourless crystals (58%, 1.05 g). <sup>1</sup>H NMR (400 MHz, CDCl<sub>3</sub>) δ: 10.1 (s, 2H, CHO), 7.91–7.96 (m, 6H), 2.0 (dd, 4H), 1.02 (m, 20H), 0.78 (t, 6H), 0.56 (d, 4H). <sup>13</sup>C NMR (100 MHz, CDCl<sub>3</sub>) δ: 192.5, 153.2, 146.0, 136.8, 130.7, 123.8, 121.7, 56.0, 40.4, 32.1, 30.2, 29.5, 24.2, 22.9, 14.4. MS *m/z*: 446.4 (M<sup>+</sup>).

### 9,9-Dihexylfluorene-2-carboxaldehyde (4)

The synthesis was followed according to known methods.<sup>17</sup> The solution of 2-bromo-9,9-dihexylfluorene (4.0 g, 9.67 mmol) in anhydrous THF (50 mL) was purged with N<sub>2</sub> at -78 °C in an acetone-dry ice bath. To the above solution, *n*-butyl lithium (9.21 mL, 19.35 mmol) was added dropwise and stirred for 1.5 h. A degassed solution of DMF (2 mL) and anhydrous THF (3 mL) was added dropwise while maintaining the reaction mixture at -78 °C, after which the temperature was raised to room temperature and stirred for 1 h. The reaction mixture was cooled to 0 °C and 10% HCl was added until the solution was acidic as verified by litmus paper. After stirring for 30 min, the mixture was partitioned between dichloromethane and water. The organic layer was extracted and the aqueous layer was washed again with dichloromethane. The combined organic fractions were dried over Na<sub>2</sub>SO<sub>4</sub>. After solvent removal, the crude product was purified by column chromatography with hexanes/dichloromethane (1:1). The product was obtained as a colourless liquid (2.15 g, 48%). <sup>1</sup>H NMR (400 MHz, CDCl<sub>3</sub>) δ: 10.09 (s, 1H, CHO), 7.91 (s, 1H), 7.86 (dd, 2H), 7.97 (dd, 1H), 7.41 (m, 3H), 2.02 (dd, 4H), 1.04 (m, 12H), 0.75 (t, 6H), 0.569 (d, 4H). <sup>13</sup>C NMR (100 MHz, CDCl<sub>3</sub>) δ: 192.7, 152.5, 147.9, 139.9, 135.7, 130.9, 129.2, 127.5, 123.5, 123.4, 121.3, 120.3, 55.8, 40.64, 31.8, 30.0, 29.5, 24.1, 22.9, 14.4. MS *m/z*: 363.24 (M<sup>+</sup>).

### 2-Bromo-9,9-dioctylfluorene-7-carboxaldehyde (5)

To the solution containing 9,9-dioctyl-2,7-dibromofluorene (3.0 g, 5.47 mmol) in anhydrous THF (60 mL) purged with N<sub>2</sub> at -78 °C was added *n*-butyl lithium (2.84 mL, 7.11 mmol) and the reaction was allowed to stir for another 1.5 h. Afterwards, deaerated DMF (1 mL) diluted in anhydrous THF (1 mL) was added dropwise to the reaction mixture at -78 °C, after which the temperature was allowed to warm to room temperature and then stirred for 1 h. The reaction mixture was cooled to 0 °C and 10% HCl was added

until the solution was acidic. The solution was stirred for 30 min then the product was extracted in dichloromethane. The organic layer was isolated while the aqueous layer was washed with dichloromethane once more and the combined organic extracts were dried over Na<sub>2</sub>SO<sub>4</sub>. The crude product was purified by column chromatography with hexanes/dichloromethane (1:1) to afford the title product as colorless crystals (0.9 g, 58%). <sup>1</sup>H NMR (400 MHz, CDCl<sub>3</sub>) δ: 10.08 (s, 1H, CHO), 7.83–7.88 (m, 3H), 7.64 (d, 1H), 7.51 (d, 2H), 2.01 (dd, 4H), 1.05 (m, 20H), 0.81 (t, 6H), 0.57 (d, 4H). <sup>13</sup>C NMR (100 MHz, CDCl<sub>3</sub>) δ: 192.5, 154.6, 151.5, 146.7, 138.9, 136.0, 130.9, 130.8, 126.8, 123.5, 122.6, 120.5, 56.0, 40.4, 32.1, 32.0, 30.2, 29.5, 24.1, 22.9, 14.4. MS *m/z*: 497.0 (M<sup>+</sup>).

### 7-[(9,9'-Dihexylfluorene-2'-ylimino)-methyl]-9,9-dioctylfluorene-2-carboxaldehyde (6)

Both **3** (100 mg, 0.22 mmol) and **1** (180.1 mg, 0.514 mmol) were dissolved in absolute ethanol under N<sub>2</sub>. A catalytic amount of TFA (60 μL of 1% in absolute ethanol) was added and the reaction mixture was stirred overnight at room temperature. The solvent was evaporated to afford a dark oil that was extracted with dichloromethane (25 mL). The organic layer was washed with water and brine solution and then dried over MgSO<sub>4</sub>. The crude product was chromatographed on activated basic alumina with ethyl acetate/hexanes (1:1 v/v) to yield the product as a yellow oil (80 mg, 60%). <sup>1</sup>H NMR (400 MHz, CDCl<sub>3</sub>) δ: 10.08 (s, 1H), 8.65 (s, 1H), 8.00 (s, 1H), 7.89 (m, 4H), 7.86 (m, 3H), 7.74 (d, 1H, *J* = 7.3 Hz), 7.41 (s, 1H), 7.4 (t, 1H, *J* = 7.3 Hz), 7.31 (m, 2H), 2.01 (m, 8H), 1.08 (m, 30 H), 0.79 (t, 12H, *J* = 7.0 Hz), 0.61 (m, 8H). <sup>13</sup>C NMR (100 MHz, CDCl<sub>3</sub>) δ: 192.8, 160.7, 152.5, 152.4, 151.9, 151.2, 147.9, 139.9, 135.7, 130.9, 129.2, 127.5, 127.3, 127.1, 123.5, 123.4, 121.3, 120.3, 119.8, 116.5, 55.6, 40.6, 32.0, 31.9, 31.8, 30.1, 30.0, 24.2, 24.1, 23.1, 23.0, 22.9, 14.4, 14.3. MS *m/z*: 778.49.

### 2',7'-[(9,9',9'')-Tetraoctylfluorene-7,7''-diylimino)-methyl]-9,9'-dihexyl-2,2''-dibromotrifluorene (9)

Both **6** (0.511 g, 1.02 mmol) and **4** (0.150 g, 0.411 mmol) were dissolved in absolute ethanol (5 mL) under N<sub>2</sub>. TFA (60 μL of 1% in ethanol) was added to the reaction mixture and then it was stirred for 1 h at room temperature. The solvent was evaporated to afford a brown oil that was extracted with dichloromethane (25 mL). The organic layer was washed with water (2 × 50 mL) and brine solution (2 × 50 mL) and then dried over MgSO<sub>4</sub>. The product was isolated as a yellow solid (44%) after flash column chromatography with basic activated alumina with hexanes/ethyl acetate (7:3). <sup>1</sup>H NMR (400 MHz, CDCl<sub>3</sub>) δ: 8.64 (d, 2H), 7.9 (d, 4H), 7.62 (dd, 4H), 7.52 (d, 4H), 7.31 (d, 2H), 6.65 (4H), 2.06 (dd, 12H), 1.08 (m, 50H), 0.81 (m, 18H), 0.63 (m, 12H). <sup>13</sup>C NMR (100 MHz, CDCl<sub>3</sub>) δ: 160.3, 154.1, 153.2, 152.6, 151.4, 146.2, 143.8, 140.5, 139.8, 139.7, 136.2, 136.0, 132.5, 130.5, 129.3, 126.7, 122.8, 122.0, 120.7, 120.3, 119.6, 119.2, 116.4, 114.4, 110.2, 56.0, 55.3, 41.2, 40.6, 32.0, 30.4, 30.3, 30.2, 29.6, 24.1, 24.0, 23.0, 22.9, 14.4. MS *m/z*: 1323.6 (M<sup>+</sup>).

## Results and discussion

### Synthesis

Compounds **6–9** were prepared and investigated to provide insight into the fluorescence and electrochemical behaviour of fluorenylazomethines. The compounds were chosen as model compounds for such studies given the complexity of absolute characterization of their polymeric counterparts. The advantage of investigating these model compounds is that precise structure–property relationships can be accurately obtained. The compounds were judiciously selected because the effect of the imine bond, 9-fluorenyl alkylation, degree of conjugation, and substitution of the fluorene's 2,7-positions on both the electrochemical and photophysical properties could be investigated. The required fluorenyl aldehyde precursors were prepared from 9,9-dioctyl 2,7-dibromofluorene by standard metal–halogen exchange with *n*-butyl lithium and quenching with DMF.<sup>22</sup> The various aldehyde derivatives were obtained by varying the *n*-BuLi/dibromofluorene ratio. The complementary aminofluorene derivatives were obtained by nitrating 9,9-dihexyl-fluorene, prepared from fluorene by known methods, followed by reduction with activated Pd/C (10%).<sup>23</sup> The resulting amino fluorenes were extremely sensitive to ambient conditions and underwent spontaneous decomposition. Consequently, they were used immediately once synthesized for preparing the targeted azomethines. The desired azomethines were prepared using mild coupling conditions by refluxing the complementary fluorenes in absolute ethanol in the presence of a catalytic amount of TFA. The desired products were readily purified by column chromatography without any decomposition and were obtained in sufficient purity for electrochemical and spectroscopic characterization. The extended degree of conjugation of **6–9** make these compounds stable and less sensitive to acid hydrolysis to their aliphatic counter parts.

### Electrochemical studies

The electrochemical behaviour is an important property for functional materials. Given that the exciton in an emitting device is produced by the recombination of an electron and hole, it is desired that the emitting layer be able to repeatedly sustain the harsh oxidation and reduction environment found in the device environment for ensuring device longevity. The redox properties of the fluorenylazomethines were therefore investigated and the structure-redox potentials examined. The effects of substitution in the 2, 2'-positions, degree of conjugation, and alkylation on the electrochemical properties are possible with the compounds in Chart 1.

The effect of the single heteroatomic bond on the  $E_{\text{pa}}$  is evident by comparing **6** with **4**. The oxidation potential of the fluorenylazomethine is increased by 130 mV. Although the  $E_{\text{pa}}$  of **6** is expected to be reduced significantly compared to **4** as a result of the increased degree conjugation arising from the azomethine bond, the heteroconjugated bond is a good electron-withdrawing group and counterbalances some of the energetic gain from the increased conjugation. The  $E_{\text{pa}}$  of **7** is increased relative to **6** owing to the absence of the electron-withdrawing aldehyde group. Meanwhile, the  $E_{\text{pa}}$  of **8** is 120 mV lower than **7** because of its

**Fig. 1.** Cyclic voltammogram of **6** (●) and **9** (○) measured at 100 mV/s.

increased degree of conjugation. A significantly larger decrease in the oxidation is expected for **8** as a result of the increased degree of conjugation; however, previous crystallographic studies showed that the terminal fluorenes are highly twisted with respect to the central axis.<sup>24</sup> Therefore, it has a limited degree of conjugation, located predominantly on the =N–fluorene–N= central moiety. Conversely, **9** is highly conjugated according to the extremely low  $E_{\text{pa}}$  measured. The difference in conjugation between **8** and **9** is most likely a result of the alkyl substitution that forces coplanarization of the fluorene and azomethine units to minimize interchain interactions. Although unequivocal confirmation of the extended conjugation can be had from the crystal structure, repeated attempts to crystallize **9** were, unfortunately, unsuccessful. The optimized geometry was subsequently calculated via DFT for examining the structure of **9**. We first tested this method for accurately calculating the optimized azomethine geometries by comparing calculated structures with those measured experimentally from known crystal structure data. The calculated optimized geometries were consistent with those obtained by X-ray diffraction (XRD). The resulting structure calculated for **9** showed the terminal fluorenes to be twisted by 12° from the plane described by the central fluorene and the azomethines. This is in contrast to **8**, whose terminal fluorenes are twisted by 26.7° and 65.3° from the central fluorene plane.<sup>18,25</sup> The low  $E_{\text{pa}}$  of **9** relative to the other azomethines is therefore a result of both its extended degree of conjugation and the weak electron-donating terminal bromines.

As seen in Fig. 1, the first oxidation process of **9** is reversible. This is in contrast to the other fluorenylazomethines, such as **6**, that undergo irreversible oxidation. The electrochemical sample of **9** was thoroughly deaerated to ensure that the observed reversible process was not from the reduction of residual oxygen. The peak persisted despite persistent nitrogen purging. The anodic process corresponds to a one-

**Fig. 2.** Calculated spin densities shown in red for the radical cation **9**. The alkyl groups in the 9-positions are omitted for clarity.

**Fig. 3.** Normalized fluorescence spectra of **2** (▲), **3** (◆), **6** (★), and **9** (●) excited at their respective maximum. Inset: normalized emission spectra of **9** at room temperature (△) and 77 K (▲).

electron transfer process while oxygen reduction is a two-electron process. The radical cation produced from the one-electron oxidation of **9** is therefore stable, based on the observed reversible oxidation, while similar intermediates for the other azomethines are unstable, evidenced by the irreversible anodic processes.

The spin densities of the radical cation of **9** were investigated to understand the reversible anodic behaviour. As seen in Fig. 2, the calculated spin densities is evenly distributed over most of the carbons of **9**. The 2,2'-positions are substituted with bromine for **9** while for the other azomethines, such as **6–8**, these positions are unsubstituted. Therefore, the resulting radical cation undergoes homocross-coupling according to known means when it is located in the terminal position.<sup>26</sup> This leads to the irreversible oxidation, as observed for **6–8**.<sup>27,28</sup> The terminal halogens of **9** effectively prevent radical cross-coupling and make the one-electron transfer process reversible. Alkylation in the 9-position is also important for reversible radical cation formation, according to Fig. 2. Azomethine structure and substitution play important roles in determining both the oxidation potentials at which the radical cation is produced and its reversible formation. The fluorenylazomethine oxidation potentials and the reversibility of these

processes can thus be tuned courtesy of substitution in the 2,2'-positions. It is therefore expected that polymers derived from **2** and **3** should sustain reversible oxidation.

### Fluorescence studies

Fluorescence investigations involving previously studied azomethines have exclusively used relative actinometry. The challenge with this approach is the lack of universal reference whose emission yield is accurately known and is both wavelength and solvent independent. Also, there is no general actinometer that consistently absorbs across the entire visible spectrum for measuring the emission yields of highly conjugated compounds regardless of the degree of conjugation. As a result of these limitations, large variations of fluorescence quantum yields are reported and cannot be accurately known. The absolute quantum yields of the fluorenylazomethine model compounds and their precursors were therefore measured using an integrating sphere because of their variable absorbance and fluorescence, evident in Fig. 3. As seen in Table 1, the fluorescence yields of the precursors **1–5** are all quenched. This is not surprising given that the fluorescence of fluorene is highly dependent on substitution.<sup>29,30</sup> The addition of the azomethine bond to the flu-

orene moiety does not increase the fluorescence. In all cases, the fluorenylazomethine fluorescence is quenched regardless of degree of oligomerization.

With increasing oligomerization, the number of degrees of freedom increases, representing additional modes of fluorescence deactivation. Fluorescence deactivation by aryl–azomethine bond rotation was subsequently investigated to determine whether this deactivation mode was responsible for the quenched azomethine fluorescence. This was done by examining the fluorescence emission at 77 K, at which temperature all non-radiative fluorescence deactivation modes by bond rotation are suppressed. Therefore, fluorescence increase is expected at 77 K if deactivation by nonradiative means occurs. The oligofluorenes **6–9** all exhibited significant increases in fluorescence yields at this reduced temperature as seen in the inset of Fig. 3. Unfortunately, accurate quantitative measurements of the emission yields at 77 K cannot be obtained because they are reliant on the weak room temperature fluorescence signals. Nonetheless, the fluorescence quantum yields of the oligofluorenylazomethines at low 77 K surpass those of their precursors at room temperature and reach the same order of magnitude as native fluorene.

To provide further insight into the origins of the temperature dependent fluorescence of the azomethines, the rotational barrier around the =N–fluorenyl and =CH–fluorenyl bonds were semiempirically calculated. A simple alkylated dyad analogue of **7** was used as a model compound because its crystal structure data is known, which were used for inputting the correct optimized ground state geometry. The heats of formation ( $\Delta H_f$ ) of each torsion around the fluorene–N= and =CH–fluorene bonds were calculated. Although absolute  $\Delta H_f$  values are not possible as a result of scaling errors, the relative values can, however, be accurately calculated. The semiempirically calculated bond rotation energies for an analogous fluorene–fluorene dyad were also calculated. 2,2'-Bifluorene was used as a benchmark

**Fig. 4.** Rotational bond energies of the fluorene–N= (black) and =CH–fluorene (blue) bonds for **6** and 2,2'-bifluorene (red) semiempirically calculated from the heats of formation ( $\Delta H_f$ ) using AM1.

since its fluorescence yields are reduced relative to native fluorene as a result of nonradiative deactivation around the fluorene–fluorene bond.<sup>24</sup> As seen in Fig. 4, the bond rotation energies for both the azomethine and fluorene dyads are similar. This suggests that fluorescence quenching by nonradiative bond rotation is a possible deactivation mode for azomethines. The absolute fluorescence yield of **9** was subsequently examined in thin films, where bond rotation deactivation processes cannot occur. A fluorescence quantum yield of 0.08 was measured in the solid state, confirming that deactivation by means other than simple fluorene–N= and =CH–fluorene bond rotation as responsible for azomethine fluorescence quenching. Meanwhile, the fluores-

cence of both **6** and **9** could, however, be significantly restored by protonating the azomethine bond with TFA. The measured absolute fluorescence yield for these two compounds was 0.4 and 0.11, respectively. The fluorescence on/off switching by acid protonation corroborates previous studies that the major deactivation mode is by intramolecular photoinduced electron transfer.<sup>31</sup> Fluorenylazomethines are therefore interesting because their fluorescence can be tuned by both temperature and acid doping.

## Conclusion

A series of dyad and triad fluorenylazomethines were prepared with different electronic groups and substitution. The oxidation potential was contingent on both substitution and degree of conjugation. Although homoaryl groups are normally twisted by up to 65° from the azomethines to which they are linked, increased planarity and hence increased degree of conjugation was possible by alkylating the fluorene's 9-position. Substitution in the 2,2'-position was also found to play an important role in determining the reversibility of the electrochemically generated radical cation. Meanwhile, the fluorescence of the azomethines remained quenched similar to their precursors. The fluorescence could be restored at low temperature and by acid protonation. The fluorenylazomethines therefore have sensor properties. The collective knowledge gained from the combined electrochemical and fluorimetric studies is pivotal for the design and preparation for the future generation of azomethines for emitting applications and will lead to highly fluorescent materials with desired reversible oxidation. The results further suggest that polymers derived from **2** and **3** will exhibit desired reversible oxidation, making them suitable materials for emitting applications.

## Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca).

## Acknowledgements

The Natural Sciences and Engineering Research Council of Canada (NSERC) is thanked for a Discovery Grant (DG) and a Research Tools and Instruments (RTI) Grant, and the Centre for Self-Assembled Chemical Structures (CSACS) for a Strategic Research Grant (SRG), which allowed this work to be performed. In addition, the Canada Foundation for Innovation (CFI) is thanked for additional equipment funding. WGS also thanks both the Alexander von Humboldt Foundation and the Royal Society of Chemistry (RSC) for a J. W. T. Jones Travelling Fellowship, allowing this manuscript to be completed. SF thanks NSERC and the Reactive Intermediate Student Exchange Program (RISE) program for an undergraduate scholarship.

# Iron(II) complexes containing thiophene-substituted “bispicen” ligands — Spin-crossover, ligand rearrangements, and ferromagnetic interactions

Haojin Cheng, Brandon Djukic, Hilary A. Jenkins, Serge I. Gorelsky, and Martin T. Lemaire

**Abstract:** The synthesis and characterization of three new tetradentate “bispicen-type” ligands containing a substituted thiophene heterocycle are described [2,5-thienyl substituents = H (**7**), Ph (**8**), or 2-thienyl (**9**)]. Iron(II) bis(thiocyanate) coordination complexes containing **7–9** were prepared, and the electronic and variable-temperature magnetic properties of complexes containing **7** (**10**) and **9** (**12**) are described. Complex **10** features a gradual and incomplete spin crossover in the solid state, and **12** remains high-spin over the entire temperature range. Complex **11** is extremely unstable and rearranges to another iron(II) complex (**13**), which was structurally characterized. The temperature-dependent magnetic properties of **13** are described as a one-dimensional ferromagnetic chain, with interchain antiferromagnetic interactions and (or) zero-field splitting dominant at low temperatures. The magnetic analysis is corroborated by the molecular packing and density functional theory calculations, which suggest intermolecular interactions between coordinated thiocyanate ligands bearing a significant spin density.

**Key words:** spin crossover, iron(II), thiophene, ferromagnetic interactions.

**Résumé :** On décrit la synthèse et la caractérisation de trois nouveaux ligands tétradentates de type bispicène contenant un hétérocycle thiophène substitué [substituants 2,5-thiényle = H (**7**), Ph (**8**) ou 2-thiényle (**9**)]. On a préparé les complexes de coordination bis(thiocyanate) de fer(II) contenant les ligands **7–9** et on décrit les propriétés magnétiques en fonction de la température des complexes contenant le ligand **7** (**10**) et le ligand **9** (**12**). Le complexe **10** par une inversion graduelle et incomplète de spin à l'état solide alors que le complexe **12** garde un spin élevé sur toute la plage de température. Le complexe **11** est extrêmement instable et il se réarrange en un autre complexe du fer(II) (**13**) dont on a caractérisé la structure. On décrit les propriétés magnétiques du complexe **13** en fonction de la température comme une chaîne ferromagnétique unidimensionnelle avec des interactions antiferromagnétiques interchaînes et (ou) un dédoublement de champ dominant nul à basses températures. L'analyse magnétique est corroborée par des calculs d'empilement moléculaire et par la théorie de la fonctionnelle de la densité, ce qui suggère qu'il existe des interactions intermoléculaires entre les ligands thiocyanates porteurs d'une densité de spin significative.

**Mots-clés :** inversion de spin, fer(II), thiophène, interactions ferromagnétiques.

## Introduction

Spin-crossover (SCO) in iron(II) coordination complexes provides the best example of molecular bistability.<sup>1</sup> There are many examples of iron(II) complexes exhibiting abrupt spin state transitions and concomitant thermal hysteresis, conferring true bistability on these materials.<sup>2</sup> Exploration of new avenues for research with SCO complexes is underway, including coupling SCO with other properties in single-component materials (so-called multifunctional materials).<sup>3</sup> SCO complexes also exhibiting magnetic exchange coupling, liquid crystalline behaviour, porosity, and photo-

chromism have all now been reported. A number of research groups have also reported single-component ionic-coordination complexes containing SCO cations and electrically conducting anions as fascinating SCO conductors.<sup>4</sup> We are also interested in SCO conducting materials and our approach is focused on combining SCO properties with electrical conductivity in novel metallopolymer materials.<sup>5</sup> To date, all reported SCO conductors have contained iron(III), and we thought it would be interesting to produce SCO conductors instead containing iron(II).

As an initial foray into this research, we have designed

new tetradentate ligands with structural features that could enable electropolymerization of the precursor iron(II) coordination complexes. We also wanted the ligand to coordinate the metal ion close to the polymer backbone to facilitate stronger interactions among the coordinated SCO unit and the conducting polymer. Inspection of the SCO literature led us to the bis(2-pyridylmethyl)-diamine type (bispicen) reported by Toftlund and co-workers in the 1980s (Fig. 1).<sup>6</sup> These tetradentate ligands feature an ethyl or propyl spacer between the 2-pyridylmethylamine substituents, which could easily be replaced with a polymerizable thiophene heterocycle substituted at the 3,4-ring positions (bispicth **7**). Also, *cis*-iron(II) complexes containing bispicen (or other derivatives) and two equivalents of thiocyanate have been observed to exhibit SCO, including abrupt transitions with small thermal hysteresis cycles.

Herein, we describe the multistep syntheses of three new bis-(2-pyridylmethyl) ligands containing thienyl substituents

and the preparation, electronic, and variable-temperature magnetic properties of mononuclear iron(II) coordination complexes containing these ligands, including the observation of SCO. We also report an unusual ligand-centered structural rearrangement in solutions containing these coordination complexes, which produces new iron complexes. One of these complexes features significant intermolecular ferromagnetic interactions.

## Experimental

### General procedures

All reagents were commercially available and used as received unless otherwise stated. Deaerated and anhydrous solvents were obtained from a Puresolve PS MD-4 solvent-purification system, and all air- and (or) moisture-sensitive reactions were carried out using standard Schlenk techniques, unless otherwise stated. <sup>1</sup>H/<sup>13</sup>C NMR spectra were recorded on a Bruker Advance 300 (or 600) MHz spectrometer (as indicated) with a 7.05 (or 14.1) T Ultra-shield magnet using deuterated solvents. FTIR spectra were recorded on a Shimadzu IR/Affinity spectrometer as KBr discs or thin films on KBr plates. EI and FAB mass spectra were obtained using a Kratos Concept 1S High Resolution E/B mass spectrometer, and ESI mass spectra were obtained using a Bruker HCT Plus Proteineer LC–MS. Room temperature vis–NIR spectra were recorded on a Shimadzu 3600 UV–vis–NIR spectrophotometer as solutions in appropriate solvents. Spectra at 77 K were obtained as frozen ethanol glasses in 5 mm NMR tubes immersed in a liquid N<sub>2</sub> Dewar. Elemental analyses were carried out by Guelph Chemical Laboratories LTD, Guelph, ON, Canada.

### X-ray crystallography

An orange rod was mounted on a MiTeGen mount, and placed in the cold stream at 100 K. Data were collected on a SMART APEX II diffractometer with Mo K $\alpha$  radiation ( $\lambda$  = 0.71073 Å) located at the McMaster Analytical X-ray Diffraction Facility (MAX). Data were collected using omega and phi scans, integrated, and a numerical face-indexed absorption correction was applied with a secondary absorption correction using redundant data (SADABS). The space group chosen was C2/c, based on systematic absences. Data were solved using direct methods (SHELXS-97), and refined using least-squares techniques. All non-hydrogen atoms were refined anisotropically; hydrogen atoms were located and then treated as riding on their constituent atoms and updated after each cycle of refinement. The NCS ligand showed a 73:27 disorder over two positions, which were symmetry-related to each other due to the twofold axis at Fe1. The non-bonded pyridine also showed disorder between N5 and C13/C17, which was similar in magnitude to the NCS disorder, and due to some intermolecular interactions between these moieties, we chose to couple the C/N disorder in the pyridine ring to the NCS disorder.

The possibility of choosing a lower-symmetry space group to solve the structure was investigated, with the expectation that the disorder would be resolved; however, solving the data in *Cc* (the *c*-glide is obvious in the reciprocal lattice) gave a highly correlated structure, with the same

disorder of the NCS ligand. Twin refinement indicated the presence of the twofold rotation axis in the molecule, and in the end, it was decided that  $C2/c$  was the correct space group. In the final cycles of refinement,  $R_1 = 6.70\%$ ,  $wR_2 = 20.37\%$  (Table 1).

### Electrochemical measurements

Cyclic voltammetry (CV) experiments were performed with a Bioanalytical Systems Inc. Epsilon electrochemical workstation. Compounds were dissolved in anhydrous solvent ( $\text{CH}_3\text{CN}$ ) and deaerated by sparging with  $\text{N}_2$  gas for 20 min. Solution concentrations were approximately  $10^{-3}$  mol/L in analyte containing 0.1 mol/L supporting electrolyte ( $\text{Bu}_4\text{NPF}_6$ ). A typical three-electrode setup was used including a platinum working electrode, Ag-wire pseudo-reference electrode, and a platinum-wire auxiliary electrode. Ferrocene was used in all cases as an internal standard and was oxidized at a potential of +0.51 V in our setup; all potentials quoted are versus the ferrocene redox potential. Scan rates for CV experiments were, generally, 100 mV/s.

**Fig. 2.** ORTEP view of **13**. Thermal ellipsoids are drawn at the 50% probability level.

### Variable-temperature magnetic susceptibility measurements

Variable-temperature magnetic susceptibility measurements were recorded on a superconducting quantum interference device (SQUID) magnetometer (Quantum Design MPMS) with a 5.5 T magnet (temperature range: 1.8 to 400 K) in an external field of 5000 Oe. Samples were carefully weighed into gelatin capsules, with empty gelatin capsules above and below to eliminate background contribu-

tions from the gelatin, which were loaded into plastic straws, and attached to the sample transport rod. Diamagnetic corrections were made using Pascal's constants.

### Computational details

All density functional theory (DFT) calculations were performed using the Gaussian 03 package using the B3LYP hybrid functional and the DZVP basis set for all atoms.<sup>7</sup> Tight SCF convergence criteria were used for all calculations. The converged wave functions were tested to confirm that they correspond to the ground-state surface. The evaluation of atomic charges and spin densities was performed using the natural population analysis (NPA).<sup>8</sup> The analysis of molecular orbitals in terms of fragment orbital contributions were carried out using the AOMix program.<sup>9</sup> Time-dependent DFT (TD-DFT) calculations at the B3LYP/DZVP level were performed to calculate the absorption spectra as previously described.<sup>9b</sup>

### Synthesis

#### 2,5-Dibromo-3,4-dinitrothiophene (1)

H<sub>2</sub>SO<sub>4</sub> (18 mol/L, 40 mL) was added to a three-neck round-bottom flask then purged with N<sub>2</sub> for 30 min and cooled in an ice-water bath. Under N<sub>2</sub>, 2,5-dibromothiophene (10.74 g, 5.00 mL, 44.37 mmol) was added slowly to maintain a temperature below 20 °C. HNO<sub>3</sub> (16 mol/L,

7.00 mL) was then added dropwise, maintaining a temperature under 30 °C. Once the addition was complete, the reaction mixture was allowed to react for an additional 3 h and then poured over ~160 g of ice. Upon melting of the ice, the solid residue was recovered by vacuum filtration and washed with water to produce a light yellow powder. Recrystallization from methanol afforded 7.64 g (52%) of pure material. Mp 135–136 °C. The FTIR spectrum of **1** is identical to that previously reported.<sup>10</sup> <sup>13</sup>C NMR (75.5 MHz, CDCl<sub>3</sub>): δ 140.3, 113.4 ppm. MS (EI+): *m/z* 332 (M<sup>+</sup>, 100%).

#### 3,4-Dinitro-2,5-diphenylthiophene (2)

Phenylboronic acid (0.20 g, 1.66 mmol) was added to a Schlenk flask and flushed with N<sub>2</sub> gas. Then, 1.8 mL of H<sub>2</sub>O and 5 mL of 1,2-dimethoxyethane were added to the reaction flask, which was sparged with N<sub>2</sub> for 30 min. After that, K<sub>2</sub>CO<sub>3</sub> (0.50 g, 3.62 mmol), **1** (0.10 g, 0.60 mmol), 6 mol% Pd(PPh<sub>3</sub>)<sub>4</sub> (0.04 g, 0.04 mmol) were added to the flask, respectively, and the mixture was refluxed at 65 °C under nitrogen for 13 h. The reaction mixture was washed with water and extracted into CH<sub>2</sub>Cl<sub>2</sub>. The combined organic layers were dried over MgSO<sub>4</sub> and concentrated to dryness. The crude product was chromatographed over silica gel using 1:3 CH<sub>2</sub>Cl<sub>2</sub>:hexane as eluent to yield 0.16 g (80%) of bright yellow crystal. Mp 145–147 °C. FTIR (KBr): 3448 (m, br), 3059 (w), 1963 (w), 1542 (s), 1524 (s), 1448 (m), 1395 (s), 1327 (s), 1261 (m), 1079 (m), 902 (m), 748 (s), 691 (s) cm<sup>-1</sup>. <sup>1</sup>H NMR (300 MHz, CDCl<sub>3</sub>): δ 7.54 (m, 10H) ppm. <sup>13</sup>C NMR (75.5 MHz, CDCl<sub>3</sub>): δ 140.8, 136.8, 130.9, 129.3, 129.1, 128.1 ppm. MS (EI+): *m/z* 326 (M<sup>+</sup>, 100%). HR-MS (EI+) calculated for [C<sub>16</sub>H<sub>10</sub>N<sub>2</sub>O<sub>4</sub>S]<sup>+</sup>: 326.03613; found: 326.03557.

#### 3',4'-Dinitro-2,2':5',2''-terthiophene (3)

Thiophene-2-boronic acid (3.29 g, 25.68 mmol) was added to a Schlenk flask and flushed with N<sub>2</sub>. Then, 1.8 mL of H<sub>2</sub>O and 5 mL of 1,2-dimethoxyethane were added to the reaction flask, which was sparged with N<sub>2</sub> for 0.5 h. After that, K<sub>2</sub>CO<sub>3</sub> (0.25 g, 1.81 mmol), **1** (3.1 g, 9.34 mmol), 6 mol% Pd(PPh<sub>3</sub>)<sub>4</sub> (0.65 g, 0.56 mmol) were added to the flask, respectively, and the mixture was refluxed at 100 °C for 8 h. The reaction mixture was washed with water and extracted into CH<sub>2</sub>Cl<sub>2</sub>. The combined organic layers were dried over MgSO<sub>4</sub> and concentrated to dryness. The crude product was chromatographed over silica gel using 1:3 CH<sub>2</sub>Cl<sub>2</sub>:hexane as eluent to yield 0.05 g (48%) of yellow solid. <sup>1</sup>H NMR (300 MHz, CDCl<sub>3</sub>): δ 7.20 (m, 2H), 7.57 (m, 2H), 7.62 (m, 2H) ppm. <sup>13</sup>C NMR (75.5 MHz, CDCl<sub>3</sub>): δ 133.8, 131.3, 131.2, 128.4, 128.1, 96.13 ppm. MS (FAB+): *m/z* 338 [M<sup>+</sup>, 100%]. HR-MS (EI+) calculated for [C<sub>12</sub>H<sub>6</sub>N<sub>2</sub>O<sub>4</sub>S<sub>3</sub>]<sup>+</sup>: 337.94897; found: 337.94872.

#### 3,4-Diaminothiophene·2HCl (4)

Concentrated HCl (25 mL) was added to a three-neck round-bottom flask and sparged with N<sub>2</sub> for 0.5 h. Then, **1** (1.28 g, 3.80 mmol) was carefully combined with the HCl, cooled in an ice-water bath. Tin (mossy) metal (3.19 g, 26.89 mmol) was added slowly to maintain a temperature

**Fig. 3.** Molecular packing of **13** with a view down the *ac* diagonal. Intermolecular S2...S2' and S2'...S2' contacts are indicated by dashed lines.

**Fig. 4.** Left: Visible–NIR spectrum of **10** in ethanol solution at 298 K (grey curve) and as a frozen ethanol glass at 77 K (black curve). Right: Cyclic voltammogram of a  $10^{-3}$  mol/L solution of **12** in  $\text{CH}_3\text{CN}$ , containing 0.1 mol/L  $\text{Bu}_4\text{NPF}_6$ .

**Fig. 5.** Variable-temperature magnetic properties of **10** (■), **12** (▲) (left) and **13** (◆) (right). External magnetic field of 5000 Oe was applied in all experiments. Magnetic data was acquired between 2–350 K for **10** and between 5–325 K for **12** and **13**. The best fit to a 1-D Bonner–Fisher chain model is indicated as a solid line.

between 25–30 °C. After stabilizing at 25 °C, the reaction continued until all the tin metal was consumed and then placed in a refrigerator overnight. The solid precipitate was recovered by vacuum filtration and washed with diethyl ether and acetonitrile until the wash was colorless to afford 0.64 g (83%) of white solid.  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra and the FTIR spectrum of **4** are identical to those previously reported.<sup>11</sup> MS (EI+):  $m/z$  114 [(M – 2HCl)<sup>+</sup>, 100%].

### 3,4-Diamino-2,5-diphenylthiophene·2HCl (**5**)

To a mixture of **2** (0.33 g, 1.00 mmol) in absolute ethanol (30 mL) and concentrated HCl (60 mL) was added tin (mossy) metal (3.63 g, 30.58 mmol) in small portions. The resulting mixture was stirred at room temperature for 15 h in air. A pale yellow solid was obtained, which was collected by vacuum filtration and washed with  $\text{H}_2\text{O}$  to afford 0.24 g (71%) of product. Mp 205–207 °C. FTIR (KBr):

**Fig. 6.** Calculated spin density distribution in **13**. NPA-derived atomic spin density is shown for most important contributors. H atoms are not shown for clarity.

3330 (m, d), 3047 (w), 2920 (w), 2848 (w), 1616 (m), 1595 (m), 1523 (m), 1489 (m), 1429 (s), 1313 (w), 970 (m), 754 (s), 703 (m), 621 (w), 573 (w)  $\text{cm}^{-1}$ .  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ ):  $\delta$  3.67 (br, s, 4H), 7.30 (m, 2H), 7.45 (m, 4H), 7.56 (m, 4H) ppm.  $^{13}\text{C}$  NMR (75.5 MHz,  $\text{CDCl}_3$ ):  $\delta$  134.4, 133.2, 129.1, 127.6, 126.7, 116.5 ppm. MS (FAB+):  $m/z$  266 [(M – 2HCl) $^+$ , 100%]. HR-MS (EI+) calculated for  $[\text{C}_{16}\text{H}_{14}\text{N}_4\text{S}]^+$ : 266.08777; found: 266.08880.

#### **3',4'-Diamino-2,2':5',2''-terthiophene-2HCl (6)**

To a mixture of **3** (0.27 g, 0.80 mmol) in absolute ethanol (30 mL) and concentrated HCl (60 mL) was added tin (mossy) metal (2.84 g, 23.96 mmol) in small portions. The resulting mixture was stirred at room temperature for 15 h in air. A deep yellow solid was collected by vacuum filtration and washed with  $\text{H}_2\text{O}$  to afford 0.28 g (88%) of the product. Melting point and FTIR spectrum (KBr) are identical to those previously report.<sup>11</sup>  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ ):  $\delta$  3.76 (br, s, 4H), 7.11 (m, 4H), 7.30 (m, 2H) ppm.  $^{13}\text{C}$  NMR (150.9 MHz,  $\text{CDCl}_3$ ):  $\delta$  135.9, 133.6, 127.8, 124.0, 123.9, 110.13 ppm. MS (FAB+):  $m/z$  278 [(M – 2HCl) $^+$ , 100%].

#### **N,N'-Bis(2-pyridylmethyl)-3,4-diaminothiophene (7)**

Compound **4** (0.20 g, 1.07 mmol) was added to an oven-dried three-neck round-bottom flask fitted with a reflux condenser. The apparatus was then flushed with  $\text{N}_2$  for 5 min. NaOH (0.086 g, 2.15 mmol) was dissolved in methanol (20 mL), the solution was sparged with  $\text{N}_2$  for 0.5 h and transferred by syringe into the three-neck flask. The mixture was stirred for 0.5 h, and then 2-pyridinecarboxaldehyde (0.24 g, 0.20 mL, 2.25 mmol) was added. The reaction mixture was refluxed for 1.5 h and protected from light by covering with foil.  $\text{NaBH}_4$  (0.21 g, 5.67 mmol) was added in small portions followed by a reflux for 14 h under  $\text{N}_2$ . The solvent was removed by rotary evaporation. The residue was extracted into  $\text{CH}_2\text{Cl}_2$ , washed with water and dried over

$\text{MgSO}_4$ . The solution was filtered by passing through a Celite pad. The filtrate was concentrated by rotary evaporation, and pentane was used to precipitate impurities, which were removed by gravity filtration. The filtrate was then concentrated to dryness and chromatographed over neutral alumina using 2:1 hexane:EtOAc, followed by 1:2 hexane:EtOAc as eluent to yield 0.053 g (17%) of a bright yellow viscous oil. FTIR (KBr): 3447 (s, br), 3105 (m), 2960 (w), 2923 (m), 2851 (w), 1594 (s), 15.7 (m), 1436 (m), 1261 (w), 1097 (w, br), 801 (w), 757 (m)  $\text{cm}^{-1}$ .  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ ):  $\delta$  4.45 (m, 6H), 6.01 (s, 2H), 7.21 (dd, 2H,  $J = 5.2, 1.8$  Hz), 7.39 (d, 2H,  $J = 7.8$  Hz), 7.67 (td, 2H,  $J = 7.5, 1.8$  Hz), 8.60 (d, 2H,  $J = 4.5$  Hz) ppm.  $^{13}\text{C}$  NMR (75.5 MHz,  $\text{CDCl}_3$ ):  $\delta$  158.5, 149.3, 139.5, 136.7, 122.2, 121.8, 97.6, 51.4 ppm. MS (FAB+):  $m/z$  297 [(M $^+$ , 100%)], 93 [(M –  $\text{C}_{10}\text{H}_{10}\text{N}_3\text{S}$ ) $^+$ , 62%]. HR-MS (EI+) calculated for  $[\text{C}_{16}\text{H}_{16}\text{N}_4\text{S}]^+$ : 296.10951; found: 296.10957.

#### **N,N'-Bis(2-pyridylmethyl)-3,4-diamino-2,5-diphenylthiophene (8)**

Compound **5** (0.12 g, 0.35 mmol) was added to an oven-dried three-neck round-bottom flask fitted with a reflux condenser. The apparatus was then flushed with  $\text{N}_2$ . Then, KOH (0.04 g, 0.69 mmol) was dissolved in methanol (20 mL) in a round-bottom flask, the solution was sparged with  $\text{N}_2$  for 0.5 h, and transferred by syringe into the three-neck round-bottom flask. The mixture was stirred for 0.5 h followed by the addition of 2-pyridinecarboxaldehyde (0.22 g, 0.20 mL, 2.07 mmol). The reaction mixture was refluxed for 1 h while protected from light by covering with foil. The reaction was cooled to RT followed by adding  $\text{NaBH}_4$  (0.26 g, 6.90 mmol), and the mixture was again refluxed at 75  $^\circ\text{C}$  for 1 h. The reaction mixture was diluted into  $\text{Na}_2\text{CO}_3$  solution (pH 9.5) and extracted into diethyl ether. The organic extracts were combined and dried over  $\text{MgSO}_4$ . Concentration by rotary evaporation and chromatography over neutral alumina using  $\text{CH}_2\text{Cl}_2$  as eluent provided 0.12 g of a vibrant

orange oil, which is very unstable.  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ ):  $\delta$  4.35 (br s, 6H), 7.59–7.13 (m, 16H), 8.49 (dd, 2H) ppm. HR-MS (FAB+) calculated for  $[\text{C}_{28}\text{H}_{25}\text{N}_4\text{S}]^+$ : 449.17999; found: 449.17897.

***N,N'*-Bis(2-pyridylmethyl)-3',4'-diamino-2,2':5,2''-terthiophene (9)**

Compound **6** (0.10 g, 0.28 mmol) was added to an oven-dried three-neck round-bottom flask fitted with a reflux condenser. The apparatus was then flushed with  $\text{N}_2$  for 5 min. Then, KOH (0.032 g, 0.57 mmol) was dissolved in methanol (20 mL) and the solution was sparged with  $\text{N}_2$  for 0.5 h. The solution was transferred by syringe into the three-neck round-bottom flask. The mixture was stirred for 0.5 h followed by the addition of 2-pyridinecarboxaldehyde (0.18 g, 0.16 mL, 1.71 mmol). The reaction mixture was refluxed for 1 h while protected from light by covering with foil. The reaction was cooled to RT, and  $\text{NaBH}_4$  (0.22 g, 5.70 mmol) was carefully added and the mixture was again refluxed for 1 h under  $\text{N}_2$ . The reaction mixture was diluted into  $\text{NaHCO}_3$  solution (pH 9.5) and extracted into diethyl ether. The organic extracts were combined and dried over  $\text{MgSO}_4$ . Concentration by rotary evaporation provided 0.10 g (76%) of a brown-yellow oil, which required no further purification. FTIR (KBr): 3428 (s), 2922 (s), 2853 (m), 1593 (m), 1466 (m, br), 1431 (m), 1402 (m), 1219 (w, br), 1148 (m), 1045 (m, br), 691 (s)  $\text{cm}^{-1}$ .  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ ):  $\delta$  4.38 (s, 4H), 4.92 (br, 2H), 7.04 (m, 2H), 7.16 (m, 4H), 7.25 (m, 4H), 7.61 (m, 2H), 8.50 (d, 2H,  $J = 4.8$  Hz) ppm.  $^{13}\text{C}$  NMR (150.9 MHz,  $\text{CDCl}_3$ ):  $\delta$  159.0, 149.1, 138.7, 136.5, 135.7, 127.2, 125.2, 124.9, 122.1, 116.1, 52.6 ppm. MS (FAB+):  $m/z$  461  $[(\text{M}^+, 52\%)]$ , 369  $[(\text{M} - \text{C}_6\text{H}_6\text{N})^+, 100\%]$ . HR-MS (FAB+) calculated for  $[\text{C}_{24}\text{H}_{21}\text{N}_4\text{S}_3]^+$ : 461.09284; found: 461.09655.

***[Fe<sup>II</sup>(7)(NCS)<sub>2</sub>]* (10)**

A 25 mL Schlenk flask was charged with **7** (0.025 g, 0.08 mmol) and flushed with  $\text{N}_2$ . Methanol (8 mL) was then added to the flask, which was sparged with  $\text{N}_2$  for 0.5 h.  $\text{Fe}(\text{BF}_4)_2 \cdot 6\text{H}_2\text{O}$  (0.028 g, 0.08 mmol) was added to the solution and the mixture was stirred for 0.5 h under  $\text{N}_2$ . KSCN (0.033 g, 0.338 mmol) was dissolved in 10 mL of  $\text{H}_2\text{O}$  and was added to the mixture noted above. Gradually, a green precipitate was observed, which was isolated by vacuum filtration to afford 0.032 g (80%) of green powder. UV-vis (MeOH):  $\lambda_{\text{max}}$  ( $\epsilon$ ) = 640 nm (400  $\text{mol/L}^{-1} \text{cm}^{-1}$ ). FTIR (KBr): 3448 (s, br), 3159 (m, br), 2920 (m), 2060 (s, br), 1603 (m), 1425 (m), 787 (m), 762 (m)  $\text{cm}^{-1}$ . MS (FAB+):  $m/z$  468  $[(\text{M}^+, 17\%)]$ , 410  $[(\text{M} - \text{SCN})^+, 100\%]$ , 351  $[(\text{M} - 2\text{SCN})^+, 99\%]$ . HR-MS (FAB+) calculated for  $[\text{C}_{18}\text{H}_{16}\text{N}_6\text{S}_3\text{Fe}]^+$ : 467.98843; found: 467.99476.

***[Fe<sup>II</sup>(8)(NCS)<sub>2</sub>]* (11)**

A solution of **8** (0.10 g, 0.22 mmol) in 10 mL of MeOH was degassed by sparging with  $\text{N}_2$  gas for 0.5 h.  $\text{Fe}(\text{BF}_4)_2 \cdot 6\text{H}_2\text{O}$  (0.08 g, 0.22 mmol) was added to generate a yellow-green solution. A solution of KSCN (0.09 g, 0.89 mmol) in 10 mL of water was added under  $\text{N}_2$ , followed by the addition of 10 mL of diethyl ether to instantly produce a green precipitate. The solid residue was isolated by vacuum filtration to afford 0.069 g (50%) of bright green

solid. UV-vis (MeOH):  $\lambda_{\text{max}}$  = 650 nm. FTIR (KBr): 3424 (m, br), 3194 (w, br), 2921 (m), 2851 (w), 2071 (s), 1602 (w), 1508 (w), 1261 (w), 1102 (m), 1018 (m), 802 (m), 757 (m), 698 (m)  $\text{cm}^{-1}$ . ## Results and discussion

### Ligand synthesis and coordination chemistry

Ligand preparation is outlined in Scheme 1. 2,5-Dibromo-3,4-dinitrothiophene (**1**) was prepared by nitration of commercially available 2,5-dibromothiophene in a modified literature procedure.<sup>10</sup> We chose to use non-fuming concentrated acids and generated **1** in reasonably good yield. To generate the 2,5-disubstituted ligands (where the substituents are phenyl or 2-thienyl), we performed Suzuki–Miyaura cross-coupling reactions between **1** and phenylboronic acid or 2-thienylboronic acid. 3,4-Dinitro-substituted thiophenes (**1–3**) were reduced with a 30-fold excess of mossy tin and the 3,4-diamino-substituted thiophenes, as dihydrochloride salts, precipitated out in each case.<sup>11</sup> Tetradentate ligands were prepared in one pot by neutralization of the dihydrochloride salts with KOH, followed by condensation reactions in methanol with 2-pyridinecarboxaldehyde to generate the imine intermediates and subsequent imine reduction with  $\text{NaBH}_4$ . Ligands **7–9** are very unstable oils (particularly ligand **8**, which is so unstable we could not generate a quality  $^{13}\text{C}$  NMR spectrum prior to decomposition) and had to be purified quickly and used directly in coordination reactions. To our knowledge, these instability

issues are not observed with similar reported tetradentate ligands that do not feature thiophene substitution, which could in all cases be purified by short-path vacuum distillation.<sup>6</sup> Our attempts to purify **7–9** in this manner in all cases resulted in decomposition. We speculate that the observed instability likely arises from oligomerization or polymerization of the thiophene heterocycle, and (or) from nucleophilic reaction of the amino N atoms at the 3,4 thiophene ring positions. Unfortunately, our spectral data does not allow us to unambiguously identify the products of the decomposition. We have some mass spectral evidence that would seem to suggest that ligands **8–9**, in solution and over time, undergo a similar rearrangement that is observed in complexes **11** and **12** (*vide infra*).

Iron(II) complexes were prepared by coordination of **7–9** with iron(II) tetrafluoroborate in deaerated methanol solution, followed by addition of excess aqueous KSCN to generate green precipitates of complexes **10** or **12** (Scheme 2). Complexes **10** and **12** are analytically pure powders, stable to air in the solid state, but very unstable in solution, including deaerated solutions. It is likely that oligomerization or polymerization of the thienyl substituents is at least one destabilizing factor in these materials, but we are not exactly sure what the pathway(s) for decomposition in these complexes is (are). Mass spectral data suggests that decomposition leads to a complex mixture of products. Although X-ray diffraction data could not be obtained from samples of **10** or **12** because of solution instability issues, we could use FTIR spectroscopy ( $\nu_{C\equiv N}$ ) to identify the stereochemistry about the metal centre. Complexes **10** or **12** feature a strong “doublet” between 2060–2080  $\text{cm}^{-1}$ , indicating a *cis* stereochemistry, which has been observed in other similar reported complexes. In fact, the energy of this band has been previously correlated to the electronic ground state of the complex and the energies observed for complexes **10** or **12** suggest a significant population of the high spin (HS)  $^5T_2$  state at room temperature.

Complex **11**, which was prepared under identical conditions to **10** or **12**, is unstable in the solid state and solution, making characterization difficult; however, based on our spectroscopic data, we are confident in the purported structure. As opposed to **10** or **12**, complex **11** features a single sharp strong band at 2070  $\text{cm}^{-1}$ , which strongly suggests an unusual *trans* disposition of the thiocyanate ligands (and a HS ground state).

Attempts to recrystallize deaerated solutions of **10–12** consistently resulted in solution color changes, from green to red over a period of days, which we anticipated was the result of iron(II) oxidation. Red solutions of **11** deposited

X-ray quality crystals and, to our surprise, a structurally rearranged material was indicated. Complex **13** contains two coordinated molecules of rearranged **8**. For clarity, the ligand rearrangement is indicated in Scheme 3.

An Oakridge thermal ellipsoid plot (ORTEP) of the molecular structure of **13** is shown in Figure 2. The metal center falls on a twofold axis, rendering each coordinated ligand equivalent. Coordinate bond lengths (Table 2) are consistent with an oxidation state assignment of +2 for the metal ion. Each molecule of rearranged **8** is coordinated through N1 and N2 of a bidentate pyridine–imidazole-type fragment of the molecule. The other imidazole-type ring atom N3 features a covalently bound and uncoordinated 2-pyridylmethylene substituent. Crystallographically equivalent thiocyanate ligands are coordinated *cis* to the iron center, and are disordered over two positions.

Along the *ac* diagonal, molecules of **13** pack in a one-dimensional chain structure, with intermolecular S...S contacts between coordinated and disordered thiocyanate ligands among adjacent molecules along the chain (Fig. 3). As noted in the Experimental section, the NCS ligand exhibits a 73:27 disorder over two positions. The S...S contacts vary from shorter [3.54(1) Å] than the sum of the van der Waals radii for the interaction between S2'–S2' to longer (3.85 and 4.40 Å) than the sum of the van der Waals radii for the interaction between S2–S2' and S2–S2, respectively. This packing structure is possibly implicated in the unusual variable-temperature magnetic properties of **13** because no other close intermolecular contacts were found in the X-ray structure between sites carrying a significant amount of spin density (*vide infra*).

Red solutions of **12** deposit a dark red powder from which FTIR and mass spectrometric data indicate a similar structural rearrangement occurs. Unfortunately, we could not obtain X-ray quality crystals from solutions containing **12**. Solutions of **10** decompose to a mixture of products over time. To our knowledge, similar structural rearrangements have not been reported for other iron(II) bis(thiocyanate) complexes containing tetradentate bis(2-pyridylmethyl)-type ligands, suggesting that the thienyl substituent or the electronic effect of this substituent is possibly involved in the mechanism for this rearrangement.

## Electrochemistry

The electrochemical properties of complexes **10** and **12** were investigated with cyclic voltammetry, and as an example, the CV of **12** is presented in Fig. 4 (right). Each voltammogram features a number of broad and irreversible processes versus ferrocene. Cathodic scans are unremarkable and each complex exhibits irreversible waves at potentials greater than –1.5 V, which are attributed to pyridine ring reductions. Over anodic potentials, an irreversible oxidation process centered at +0.4 V is observed in the voltammograms of **10** and **12**. A similar wave at approximately +0.4 V is observed in the voltammogram of uncoordinated **7** and is likely a ligand-centered oxidation (dehydrogenation of NH bond). Beyond +0.4 V, **10** exhibits a very broad irreversible oxidation at +1.3 V and **12** features irreversible processes at +0.8, +1.0, and +1.3 V, which we attribute to a combination of terthienyl and iron(II) oxidation processes. We attempted to electropolymerize complex **12** by repeated

scans over the terthienyl oxidation potential; however, we observed no indication for any successful electropolymerization reactions.

### Visible–NIR spectroscopy

Ethanol solutions of complexes **11** and **12** exhibit absorption maxima at 650 nm ( $\epsilon = 400 \text{ mol/L}^{-1} \text{ cm}^{-1}$ ), with absorption intensities that are not temperature-dependent. To help provide the assignments of the absorption bands in **11** and **12**, the absorption spectrum of **13** was calculated using TD-DFT at the B3LYP/DZVP level. The calculated spectrum of **13** in the visible region contains a main band at 638 nm with the oscillator strength ( $\phi$ ) of 0.0040 and a weaker band at 629 nm ( $\phi = 0.0011$ ). The 638 nm band originates from the  $\beta$ -spin HOMO  $\rightarrow$  LUMO excitation with the  $\beta$ -spin HOMO being the Fe  $d\pi - \text{NCS } \pi$  orbital (35% Fe and 65% NCS contributions) and the  $\beta$ -spin LUMO being the Fe  $d\sigma - \text{pyridine-imidazole } \pi^*$  orbital (12% Fe and 85% L). As a result, this absorption band has a mixed metal-to-ligand and ligand-to-ligand charge transfer (MLCT/LLCT) character. The 629 nm band originates from a mixture of several electron excitations (the two principal components are the  $\alpha$ -spin HOMO-4  $\rightarrow$  LUMO and  $\beta$ -spin HOMO-4  $\rightarrow$  LUMO excitations). The room-temperature spectrum of **10** in ethanol also features a weak absorption at 640 nm; however, upon cooling to 77 K, a large increase in absorption intensity is observed concomitant with the growth of a shoulder on the low-energy side of the 640 nm absorption. The color of the solution becomes intensely dark green from the pale green/yellow color observed at room temperature (Fig. 4, left). These observations suggest an electronic change, likely spin-crossover is occurring in solutions containing **10**. The new absorption feature centered at 700 nm is likely the band of the low-spin state of **10**.

### Variable-temperature magnetic properties

The variable-temperature magnetic properties of **10**, **12**, and **13** were probed via SQUID magnetometry and the data are presented as plots of the effective magnetic moment ( $\mu_{\text{eff}}$ ) versus temperature (Fig. 5). The magnetic properties of **12** feature very little temperature dependence and the observed magnetic moment values suggest a high-spin ground state for this complex. The magnetic moment of **12** decreases rapidly below 40 K, which likely results from a combination of zero-field splitting (ZFS) and intermolecular antiferromagnetic interactions.

Data from variable-temperature visible–NIR spectroscopy indicated spin-crossover was operative in solutions of **10**. In the solid state, variable-temperature magnetic susceptibility data indicates a gradual and incomplete spin-crossover without thermal hysteresis in powder samples of **10**. The magnetic moment of **10** at the highest measured temperature (350 K) is 4.95  $\mu_B$  and a gradual decrease is observed with decreasing temperature to 2 K, where the observed magnetic moment is 2.4  $\mu_B$ , which is higher than anticipated for a complete crossover to the low-spin (LS) state (theoretical value is 0 BM). However, the profile of the data, including the higher than expected moments at very low temperature, is very similar to that observed by Toftlund for structurally similar iron(II) complexes (without thienyl substituents) and

points toward an incomplete spin-crossover in these materials.<sup>6</sup>

The variable-temperature magnetic properties of **13** are completely different. At room temperature, the magnetic moment is significantly higher than anticipated for a magnetically isolated mononuclear iron(II) complex (Fig. 5, right). With decreasing temperature, we see a gradual increase in magnetic moment, indicating intermolecular ferromagnetic interactions are operative. The magnetic moment reaches a plateau of 8.1 BM at approximately 8 K, and then slightly decreases. Low-temperature (5 K) magnetization versus field experiments provided no indication of ferromagnetic ordering, with a saturation magnetization of 4.6 NB at 3.5 T, which is a typical value for HS iron(II) (see Supplementary data). In the molecular packing of **13**, close intermolecular S...S contacts were observed between coordinated thiocyanate ligands from adjacent molecules, suggesting a possible pathway for magnetic exchange coupling. We used DFT at the B3LYP/DZVP level to calculate the structure and spin density of complex **13**, and found significant spin delocalization onto the coordinated thiocyanate ligands (0.16 on each NCS, Fig. 6), suggesting that the magnetic exchange pathway in **13** is possibly that of a 1-D  $S = 2$  ferromagnetic chain. The fit to a Bonner–Fisher 1-D chain model<sup>12</sup> (eq. [1],  $g = 2.13$  and  $J/k = +7.5 \text{ K}$ ) containing a correction for interchain magnetic interactions (eq. [2]  $zJ'/k = -2.2 \text{ K}$ ) is good between 320 and 30 K, and then deviates at low temperature.

$$[1] \quad \chi_{\text{chain}} T = \frac{Ng^2\beta_e^2 S(S+1)}{3kT} \left( \frac{1+u}{1-u} \right)$$

$$[2] \quad \chi_m T = \left( \frac{1}{\chi_{\text{chain}} T} - \frac{zJ'}{kT} \right)$$

where

$$u = \coth \frac{2JS(S+1)}{kT} - \frac{kT}{2JS(S+1)}$$

Since there are no other significant intermolecular magnetic exchange pathways between atoms/fragments with high spin density in the molecular packing of **13**, which would suggest that another competing antiferromagnetic interchain coupling is dominant at lower temperatures, it is also reasonable to assume that the deviation from 1-D chain behaviour at lower temperatures is a result of ZFS of the iron(II)  $S = 2$  ground state. The relatively large value of  $J/k$  is surprising, especially considering that this exchange pathway is *intermolecular*. Typically, weak magnetic interactions are mediated in an intramolecular fashion through ambidentate N and S coordinated and bridging thiocyanate between metal ions within bimetallic complexes or coordination polymers.<sup>13</sup> We could find no other reported examples of intermolecular ferromagnetic coupling mediated by coordinated thiocyanate ligands.

### Conclusions

We have described the synthesis of three new thiophene-containing “Toftlund-like” bispicen ligands (**7–9**). In apparent contrast to the bispicen family of ligands, **7–9** are unsta-

ble oils, which we could isolate and characterize, but must be coordinated quickly, or else suffer decomposition. Coordination of **7** and **9** with iron(II) bis(thiocyanate) resulted in the anticipated cis-pseudo-octahedral complexes (**10** and **12**), which were characterized and featured incomplete spin-crossover (**10**), or HS iron(II) (**12**). Coordination of **8** with iron(II) bis(thiocyanate) produced a very unstable complex (**11**), which in solution undergoes a ligand-centered structural rearrangement to produce a stable complex **13**, featuring intriguing variable-temperature magnetic properties. Our analysis indicates that the temperature-dependent magnetic behaviour of **13** is best-described as a one-dimensional ferromagnetic chain with interchain antiferromagnetic interactions and (or) ZFS at low temperatures, which reduces the magnetization. We are currently exploring the synthesis of derivatives of **13**, including other iron(II) complexes with different ligand structures as precursors to novel iron(II) containing spin-crossover conductors.

# Preparation of aromatic amines by copper-catalyzed coupling of boronic acids with aqueous ammonia

Zhaoqiong Jiang, Zhiqing Wu, Lixia Wang, Di Wu, and Xiangge Zhou

**Abstract:** A simple, highly efficient, and environmentally friendly protocol for the synthesis of primary aromatic amines by catalytic coupling of aromatic boronic acids with aqueous ammonia has been developed by using commercial and inexpensive  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  as catalyst without addition of other solvents under mild reaction conditions.

**Key words:** ammonia, primary aromatic amine, aromatic boronic acid, water.

**Résumé :** Opérant dans des conditions de réactions douces et utilisant le  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  peu coûteux et commercialement disponible comme catalyseur, on a développé une méthode simple, hautement efficace et écologique pour synthétiser des amines primaires aromatiques par couplage catalytique d'acide boroniques aromatiques avec l'ammoniaque en solution aqueuse et n'impliquant aucun autre solvant.

**Mots-clés :** ammoniac, amine primaire aromatique, acide boronique aromatique, eau.

## Introduction

Preparation of primary aromatic amines has attracted increasing attention because they are valuable compounds widely employed in the manufacture of natural products, agrochemicals, pharmaceuticals, biological compounds, dyes, pigments, and rubber.<sup>1</sup> Ammonia is one of the most abundant, inexpensive, and attractive nitrogen sources in chemical synthesis, but the direct consumption of it in catalytic reactions is less reported.<sup>2</sup> In general, the difficulties in the use of ammonia for metal-catalyzed processes may result from two facts: (i) many kinds of transition metals are bonded with ammonia to form catalytically unreactive complexes, and (ii) the primary amine product formed during catalysis is usually more reactive than ammonia itself and easily converted to a secondary amine.<sup>2g,3</sup> Thus, the synthesis of primary aryl amines generally relies on the use of ammonia surrogates such as allyl,<sup>4</sup> benzyl<sup>5</sup> and silyl amines,<sup>6</sup> imines,<sup>7</sup> amides,<sup>8</sup> and others.<sup>9</sup> However, the products of these reactions need an additional deprotection step, which makes those methodologies less attractive. Hence, the use of ammonia as a nitrogen source is still by far one of the most desired approaches.<sup>2</sup> A few copper-catalyzed protocols for the preparation of primary arylamines have been recently developed by the coupling of aryl halides with ammonia. However, these catalyses were usually performed under high pressure using liquid ammonia.<sup>10</sup> More recently, palladium-catalyzed cross-coupling reactions between simple aryl halides and ammonia would allow the direct synthesis of valuable primary aromatic amines with good yields in solvents of 1,2-dimethoxyethane or 1,4-dioxane.<sup>2g,11</sup> Instead of

palladium, Cu-catalyzed amination of aryl halides using aqueous ammonia was first reported by Kim and Chang.<sup>12</sup> Following these pioneering works, several Cu-catalyzed preparation of primary arylamines have been efficiently carried out with excellent yields by using DMF, *N*-methyl pyrrolidinone, alcohol, or 1,4-dioxane as reaction medium.<sup>13</sup> Although these methods mentioned above have led to remarkable advancement in the synthesis of primary arylamines, it is worth noting that they were all performed in organic solvents.<sup>14</sup>

From the standpoint of green chemistry, the development of a more environmentally benign reaction media would be highly desirable.<sup>15</sup> Obviously, water, which is an ideal non-toxic, extremely abundant, and readily available green substance, is the most inexpensive and environmentally benign solvent. In continuation of our endeavors in aqueous catalysis,<sup>16</sup> herein is reported the synthesis of primary arylamines by cross-coupling reactions between aromatic boronic acids and aqueous ammonia catalyzed by  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  at room temperature (RT) without the addition of other solvents.

## Results and discussion

Initially, we chose phenylboronic acid as the model substrate in the optimization of reaction conditions. The preliminary survey was carried out by using 28% aqueous ammonia as the nitrogen source,  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  as catalyst, and NaOH as base. The results were listed in Table 1.

Unlike most of the other coupling reactions, as shown in Table 1, the yields decreased sharply from 70% and 69% to 51% when the reaction temperature increased from room

temperature and 60 °C to 90 °C, respectively (Table 1, entries 1–3). The formation of the byproduct phenol, which resulted from the hydrolysis of phenylboronic acid at high temperature in water, might be attributed to the decrease of yields. Control experiment proved that more than 50% phenylboronic acid was found to convert into phenol at 100 °C. Comparison of a variety of bases indicated NaOH to be a proper candidate with a yield of 70% (Table 1, entries 3–13). Considering phenol as the main side product, we increased the concentration of ammonia to inhibit the competition of water; the yield was sharply improved from 70% to 91% when the concentration of ammonia was increased from 2% to 28% (Table 1, entries 3, 14–16). Thus, the addition of other solvents, including water, was unnecessary in this case. Other different copper sources such as Cu(OAc)<sub>2</sub>, CuCl<sub>2</sub>, Cu<sub>2</sub>O, CuClO<sub>4</sub>, and CuI have also been examined, and CuSO<sub>4</sub> gave the best result with a 91% GC–MS yield (Table 1, entries 16–21) and there was only trace product without catalyst (Table 1, entry 22). Several inorganic nitrogen sources were also tried with poor results (Table 1, entries 23–26). In summary, the optimal conditions for the

synthesis of primary aromatic amines are as follows: 28% aqueous ammonia (3 mL, when 0.6 mmol aromatic boronic acid was used) as the nitrogen source, CuSO<sub>4</sub> (10 mol%) as the catalyst, NaOH (2 equiv.) as the base, and the reaction was carried out at room temperature in a sealed tube without inert gas protection.

The scope of aromatic boronic acids was then investigated by using this catalytic system under the optimized reaction conditions. The results are listed in Table 2.

In general, the catalytic cross-coupling reactions between aqueous ammonia and aromatic boronic acids containing electron-withdrawing substituents were efficiently promoted with excellent yields within 3–5 h. For instance, *p*-fluorophenylboronic acid and *p*-cyanophenylboronic acid afforded 91% and 92% of the desired aminated products, respectively (Table 2, entries 3 and 5, respectively). Lower yields were obtained with *p*-methoxyphenyl boronic acid, *o*-methoxyphenyl boronic acid, and  $\alpha$ -naphthyl boronic acid, due to the formation of protodeboronation byproducts as shown in Scheme 1 (Table 2, entries 6, 8, and 11, respectively).<sup>17</sup> Normally, protodeboronation occurs by the reported A-SE<sub>2</sub>

**Scheme 1.** Protodeboronation of aromatic boronic acids.**Table 2.** Synthesis of primary aromatic amines catalyzed by  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  in water.

**Note:** Reaction conditions: aromatic boronic acids (0.6 mmol), 28% aqueous ammonia (3 mL),  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  (0.06 mmol), NaOH (1.2 mmol), room temperature.

<sup>a</sup>Isolated yields.

mechanism, in which proton transfer is the rate-determining step, and is followed by a rapid ionic cleavage of the boron-carbon bond.<sup>18</sup> The rate sequence of protodeboronation of substituted phenylboronic acids was reported to be  $p\text{-OCH}_3 > p\text{-CH}_3 > p\text{-F} > \text{H} > p\text{-Br} > m\text{-Cl} > m\text{-F}$ .<sup>18c,18d,19</sup> Meanwhile, electron-withdrawing groups, especially those located at the *m*-position of phenylboronic acids, retarded the rate of protodeboronation.<sup>18d</sup> Furthermore, the protodeboronation process was reported to be easier for  $\alpha$ -naphthyl boronic acid than *p*-methoxyphenyl boronic acid.<sup>17b,20</sup> Thus, in this experiment, *p*-methoxyphenyl boronic acid, *o*-methoxyphenyl boronic acid, and  $\alpha$ -naphthyl boronic acid afforded moderate yields ranging from 50% to 66%, while a much higher yield (84%) was obtained in the case of *m*-methoxyphenyl boronic acid (Table 2, entries 6–8). On the other hand, steric hindrance was another important factor affecting the results.

For example, only a 58% yield of the aminated product was obtained when 2,6-dimethylphenylboronic acid was employed (Table 2, entry 10).

## Conclusion

In summary, we have developed a simple, highly efficient, economical, and environmentally friendly protocol for the synthesis of primary aromatic amines by coupling of aromatic boronic acids with aqueous ammonia without the addition of other solvents under mild reaction conditions. This method has the following advantages: commercial and inexpensive  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  as catalyst, the use of aqueous ammonia as reactant as well as solvent, and NaOH as base at room temperature under atmospheric pressure without ligand and any other additive. This method avoids the use of stringent inert conditions and organic solvents, and the operation is very simple. Overall, we believe that this method could provide an avenue toward the Cu-catalyzed methods that have scarcely been adopted in the aqueous phase.

## Experimental

All reagents were purchased from commercial suppliers and used without further purification. Column chromatography was carried out with silica gel (200–300 mesh). Thin layer chromatography was carried out using Merck silica gel GF254 plates. <sup>1</sup>H NMR and <sup>13</sup>C NMR (400 and 100 MHz, respectively) spectra were recorded in  $\text{CDCl}_3$ . Chemical shifts are reported in ppm using TMS as the internal standard. Gas chromatography/mass spectra (GC–MS) were recorded on an Agilent Technologies 6890N instrument with an Agilent 5973N mass detector (EI) and a HP5-MS 30 m  $\times$  0.25 mm capillary apolar column (stationary phase: 5% diphenyldimethylpolysiloxane film, 0.25  $\mu\text{m}$ ).

### General procedure for the synthesis of primary aromatic amines

Aromatic boronic acid (0.6 mmol),  $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$  (0.06 mmol), NaOH (1.2 mmol), and aqueous ammonia (3 mL) were added to a sealed tube. The reaction mixture was stirred at room temperature for 3–5 h as shown in Table 2. After completion of the reaction, the mixture was extracted with ethyl acetate. The organic layer was then dried over anhydrous  $\text{Na}_2\text{SO}_4$  and the solvent was removed under reduced pressure. The residue was finally purified by column chromatography on silica gel using a hexane–ethyl acetate mixture as eluent.

EI-MS *m/z*: 93 [*M*<sup>+</sup>].

#### *p*-Toluidine<sup>13c</sup>

Purification by flash chromatography (petroleum ether/ethyl acetate 9:1). Slight yellow solid. <sup>1</sup>H NMR ( $\text{CDCl}_3$ , 400 MHz)  $\delta$ : 6.96 (d, 2H, *J* = 8.4 Hz), 6.61 (d, 2H, *J* = 8.4 Hz), 3.42 (s, br, 2H), 2.24 (s, 3H). <sup>13</sup>C NMR ( $\text{CDCl}_3$ ,

100 MHz)  $\delta$ : 143.8, 129.7, 127.7, 115.3, 20.4. EI-MS  $m/z$ : 107 [ $M^+$ ].

### **p-Anisidine**<sup>13c</sup>

Purification by flash chromatography (petroleum ether/ethyl acetate 6:1). Slight brown solid. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz)  $\delta$ : 6.75 (d, 2H,  $J$  = 8.8 Hz), 6.66 (d, 2H,  $J$  = 8.8 Hz), 3.75 (s, 3H), 3.32 (s, br, 2H). <sup>13</sup>C NMR (CDCl<sub>3</sub>, 100 MHz)  $\delta$ : 152.8, 134.0, 116.5, 114.8, 56.0. EI-MS  $m/z$ : 123 [ $M^+$ ].

### **m-Anisidine**<sup>13c</sup>

Purification by flash chromatography (petroleum ether/ethyl acetate 6:1). Yellow oil. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz)  $\delta$ : 7.06 (t, 1H,  $J$  = 8.0 Hz), 6.34–6.29 (m, 2H), 6.25 (t, 1H), 3.76 (s, 3H), 3.55 (s, br, 2H). <sup>13</sup>C NMR (CDCl<sub>3</sub>, 100 MHz)  $\delta$ : 159.7, 146.7, 129.1, 106.9, 103.0, 100.1, 54.0. EI-MS  $m/z$ : 123 [ $M^+$ ].

### **o-Anisidine**<sup>13f</sup>

Purification by flash chromatography (petroleum ether/ethyl acetate 6:1). Yellow oil. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz)  $\delta$ : 6.81–6.78 (m, 2H), 6.75–6.71 (m, 2H), 3.84 (s, 3H), 3.60 (s, br, 2H). <sup>13</sup>C NMR (CDCl<sub>3</sub>, 100 MHz)  $\delta$ : 146.3, 135.1, 120.1, 117.5, 114.0, 109.4, 54.4. EI-MS  $m/z$ : 123 [ $M^+$ ].

### **o-Toluidine**<sup>13c</sup>

Purification by flash chromatography (petroleum ether/ethyl acetate 9:1). Pale yellow oil. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz)  $\delta$ : 7.07–7.03 (m, 2H), 6.76–6.72 (m, 2H), 4.02 (s, br, 2H), 2.20 (s, 3H). <sup>13</sup>C NMR (CDCl<sub>3</sub>, 100 MHz)  $\delta$ : 143.0, 129.5, 126.0, 121.7, 118.0, 114.2, 16.3. EI-MS  $m/z$ : 107 [ $M^+$ ].

### **2,6-Dimethylaniline**<sup>13b</sup>

Purification by flash chromatography (petroleum ether/ethyl acetate 9:1). Yellow oil. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz)  $\delta$ : 6.95 (d, 2H,  $J$  = 7.6 Hz), 6.66 (t, 1H,  $J$  = 7.6 Hz), 3.83 (s, br, 2H), 2.20 (s, 6H). <sup>13</sup>C NMR (CDCl<sub>3</sub>, 100 MHz)  $\delta$ : 142.5, 128.3, 121.9, 118.2, 17.7. EI-MS  $m/z$ : 121 [ $M^+$ ].

### **$\alpha$ -Aminonaphthalene**<sup>13c</sup>

Purification by flash chromatography (petroleum ether/ethyl acetate 9:1). White solid. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz)  $\delta$ : 7.85–7.78 (m, 2H), 7.46–7.43 (m, 2H), 7.33–7.24 (m, 2H), 6.79–6.76 (m, 1H), 4.13 (s, br, 2H). <sup>13</sup>C NMR (CDCl<sub>3</sub>, 100 MHz)  $\delta$ : 142.1, 134.3, 128.5, 126.3, 125.8, 124.7, 123.6, 120.8, 118.8, 109.6. EI-MS  $m/z$ : 143 [ $M^+$ ].

### **p-Chloroaniline**<sup>13f</sup>

Purification by flash chromatography (petroleum ether/ethyl acetate 6:1). White solid. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz)  $\delta$ : 7.10 (d, 2H,  $J$  = 8.0 Hz), 6.61 (d, 2H,  $J$  = 8.4 Hz), 3.63 (s, br, 2H). <sup>13</sup>C NMR (CDCl<sub>3</sub>, 100 MHz)  $\delta$ : 145.0, 129.1, 123.2, 116.2. EI-MS  $m/z$ : 127 [ $M^+$ ].

### **p-Fluoroaniline**<sup>21</sup>

Purification by flash chromatography (petroleum ether/ethyl acetate 6:1). Yellow oil. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz)  $\delta$ : 6.88–6.82 (m, 2H), 6.64–6.60 (m, 2H), 3.53 (s, br, 2H). <sup>13</sup>C NMR (CDCl<sub>3</sub>, 100 MHz)  $\delta$ : 157.6, 155.3, 142.4, 116.1, 116.0, 115.8, 115.6. EI-MS  $m/z$ : 111 [ $M^+$ ].

### **p-Aminobenzonitrile**<sup>13c</sup>

Purification by flash chromatography (petroleum ether/ethyl acetate 6:1). Yellow solid. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz)  $\delta$ : 7.42 (d, 2H,  $J$  = 8.4 Hz), 6.65 (d, 2H,  $J$  = 8.4 Hz), 4.18 (s, br, 2H). <sup>13</sup>C NMR (CDCl<sub>3</sub>, 100 MHz)  $\delta$ : 150.5, 133.8, 120.2, 114.4, 100.1. EI-MS  $m/z$ : 118 [ $M^+$ ].

## **Supplementary data**

Supplementary data for this article (<sup>1</sup>H NMR and <sup>13</sup>C NMR spectra for all products) are available on the journal Web site (canjchem.nrc.ca).

## **Acknowledgement**

This project was sponsored by the Natural Science Foundation of China (No. 20672075, 20771076, and 20901052) and the Sichuan Provincial Foundation (08ZQ026-041). We also thank the Analytic and Testing Centre of Sichuan University for the NMR spectral determination.

# Novel $\beta$ -galactosidase-specific O<sup>2</sup>-glycosylated diazeniumdiolate probes

Barry J. Bedell, D. Scott Bohle, Zhijie Chua, Alexander Czerniewski, Alan C. Evans, and Shadreck Mzengeza

**Abstract:** Three  $\beta$ -galactosidase-specific nitric-oxide-releasing diazeniumdiolate conjugated probes were prepared as a prelude to studies of new potential molecular MRI imaging agents. A glycosylated derivative, **2e**, designed to be trafficked across cell membranes, was also prepared. We report, in detail, the synthesis and characterization of these probes. In addition, the release of diazeniumdiolate from the probes by  $\beta$ -galactosidase-catalyzed hydrolysis was used to estimate their efficacy as serum-stable, specific NO donors.

**Key words:** nitric oxide, diazeniumdiolate, glycosylated, galactosidase.

**Résumé :** Comme prélude à des études de nouveaux produits pouvant éventuellement être utilisés comme agents moléculaires en imagerie de résonance magnétique (IRM), on a préparé trois nouvelles sondes spécifiques pour les  $\beta$ -galactosidase et conjuguées à un diazéniumdiolate qui libère de l'oxyde nitrique. On a aussi préparé un dérivé glycosylé, **2e**, qui devrait pouvoir pénétrer à l'intérieur des membranes des cellules. On rapporte, en détail, la synthèse et la caractérisation de ces sondes. De plus, on utilise le fait que l'hydrolyse catalysée par le  $\beta$ -galoactosidase libère le diazéniumdiolate des sondes pour évaluer leur efficacité comme donneurs spécifiques de NO, stables dans le sérum.

**Mots-clés :** oxyde nitrique, diazéniumdiolate, glycosylé, galactosidase.

## Introduction

With the numerous biological roles of nitric oxide (NO), there is now great interest in developing NO-releasing compounds capable of providing required quantities of NO to specific biological tissues without disturbing other NO-sensitive physiology.<sup>1–19</sup> Because of their NO-releasing ability, diazeniumdiolates have become especially attractive for their potential use in novel drug therapies.<sup>13,20–22</sup> However, to design site-specific diazeniumdiolates, careful functionalization of these compounds is required. This strategy has been successfully achieved by derivatizing the terminal oxygen (O<sup>2</sup>) of the diazeniumdiolate functionality.<sup>6</sup> To date, several O<sup>2</sup>-protected diazeniumdiolates that only release NO in targeted biological tissues have been prepared, Scheme 1.<sup>3,6,19,23–29</sup> For example, Keefer and co-workers have reported O<sup>2</sup>-vinyl diazeniumdiolates and their ability for liver-selectivity and activation by hepatic cytochrome P450.<sup>6</sup> They have also shown that O<sup>2</sup>-acetoxymethyl diazeniumdiolates were esterase-sensitive and exhibited considerable anti-leukemia activity.<sup>30</sup> A number of peptide-diazeniumdiolate conjugates were recently prepared by

Tang and Wang and found to be activated by  $\alpha$ -chymotrypsin or prostate-specific antigens.<sup>31</sup>

Related efforts have led to the development of glycosylated derivatives of diazeniumdiolates, Scheme 2.<sup>19,32–34</sup> Such compounds constitute a novel series of tissue-specific diazeniumdiolates. For example, a library of pyranosyl derivatives of diazeniumdiolates was recently prepared by Valdez et al.,<sup>19</sup> and these derivatives have the ability to pharmacologically target NO to pathogen-infected macrophages.

These recent examples of glycosylated diazeniumdiolate derivatives were not the first to be synthesized. Almost 25 years ago, Vasella and co-workers reported two sugar derivatives containing the diazeniumdiolate functionality and prepared them by a route involving oxidation of sugar oximes or sugar hydroxylamines<sup>35</sup> (see Scheme 3).

Analogous with the initial Valdez or Tang and Wang carbohydrate-substituted diazeniumdiolates, Vasella and co-workers' compounds are O<sup>2</sup>-substituted diazeniumdiolates. Unlike the recent N-bound diazeniumdiolates, those two products are C-bound diazeniumdiolates. Jochims and co-workers have recently prepared a number of C-bound glycosylated diazeniumdiolates, Scheme 4, via nitrosation of

sugar oximes or sugar hydroxylamines.<sup>36</sup> The nitrosation of oximes or hydroxylamines are well-known routes for the preparation of C-bound diazeniumdiolates.<sup>37–39</sup>

ties of NO. As proof-of-principle, our monosaccharide-diazoniumdiolate derivatives are designed to target cells expressing a high level of  $\beta$ -gal, since the lacZ gene is commonly used as a reporter of gene expression. Specificity is proposed to arise from the coupling of a  $\beta$ -gal active component, namely a galactose molecule, with an amine-bound diazoniumdiolate salt via the glycosidic bond of the sugar.

In addition, we further explored the idea of tissue-specific glycosylated diazeniumdiolates by designing a diazeniumdio-

**Scheme 4.** Glucosyl, xylosyl, lactosyl, and mannosyl diazeniumdiolate derivatives prepared by Jochims and co-workers (see ref. 36).

late glycoside derivative capable of crossing cell membranes. Our strategy was accomplished by appending the galactose-diazeniumdiolate derivative to another moiety that traffics the glycoside across plasma membranes (Scheme 5).<sup>40–43</sup> The ester conjugates of glucose, substituted at the pyranose C6-position, have high affinities for glucose transporters, such as GLUT-1.<sup>7</sup> Thus, a “bifunctional” NO-releasing probe was prepared with glucose coupled via its C-6 linkage, for trafficking via a GLUT-1 transporter, and galactose coupled via a glycosidic bond to a diazeniumdiolate core, for the probe’s  $\beta$ -gal activation, Scheme 6.

We thus prepared “bifunctional” NO-releasing probes de-

signed to be potentially activated by  $\beta$ -gal-expressing cells. Herein, the preparation and characterization of these new probes are described in detail.

## Results

The synthetic scheme employed to design our probes is based on a halide-displacement reaction.<sup>19,32,34,44</sup> The diazeniumdiolate sodium salt was coupled with an acetylated pyranosyl bromide, eq. [1]. Base-catalyzed hydrolysis of the acetyl protecting groups then afforded the deprotected glycosylated diazeniumdiolate, eq. [2].

The presence of acetyl protecting groups on all of the pyranose C-2 to C-6 hydroxyl functionalities ensure that it is the diazeniumdiolate oxygen, and not the hydroxyl groups, which adds to the pyranose anomeric position. The acetyl protecting groups also aid in the purification and isolation of the glycosylated probe.

The “bifunctional” probes are comprised of three integral components as shown in Scheme 6. These three components

include (i) a glucose moiety, coupled via its C-6 linkage and (ii) a galactose entity, coupled via a glycosidic bond to (iii) a piperidine-bound diazeniumdiolate core. Synthesis of the bifunctional probes involved the use of a *tert*-butyloxycarbonyl (Boc)-protected secondary amine, representing the precursor of the secondary amine linker.

The diazeniumdiolate **1c** was prepared from the Boc-protected secondary amine, eq. [3], with typical conditions for

**Scheme 5.**  $\beta$ -gal hydrolysis of constructed glycosylated diazeniumdiolate probes.**Scheme 6.** Schematic (left) and detailed (right) structure of the proposed probes construction.

generating secondary-amine-bound diazeniumdiolates.<sup>45,46</sup> The diazeniumdiolates were then coupled with galactosyl bromide, eq. [4], to give the O<sup>2</sup>-protected adducts **2a–2c** in good yields. The presence of a Boc protecting group in **1c** prevented any competitive coupling to galactosyl bromide by the protected primary amine.

Removal of the Boc protecting group was then readily effected under acidic conditions,<sup>47,48</sup> eq. [5], and lead to the generation of the free primary amine in **2d**, which was then coupled with an activated glucose ester to give **2e**, eq. [6]. Removal of all protecting groups using NaOMe generated the final products **3a–3c**, eqs. [7] and [8].

To verify the final product stereochemistry and linkage, a single-crystal X-ray diffraction structure for **3a** was determined, Fig. 1. Crystals for this adduct adopt the monoclinic

non-centrosymmetric space group  $P2_1$  with  $Z = 2$ . Complete details of the structure and refinement are provided in the Experimental and Supplementary data sections.

### Enzymatic hydrolysis by $\beta$ -galactosidase of compounds **3a–3c**

Glycosylation of the diazeniumdiolate oxygen protects the diazeniumdiolate from its rapid reversion to two nitric oxides and the secondary amine, that is, the reverse of eq. [3] at neutral pH. The strong  $n-\pi^*$  transition at  $\sim 260$  nm in diazeniumdiolates allows for the facile monitoring of its hydrolytic breakdown. Since the half-life of the deprotected diazeniumdiolate under these conditions is less than 2 s, the loss of extinction at 256 nm corresponds to the limiting slow enzymatic cleavage of the C–O bond by galactosidase. As shown in the Supplementary data in that buffer and ion concentration, the half-life for **3a** at pH = 7.3, 37 °C, and  $[\beta\text{-gal}] = 8$  nmol/L, is less than 120 s, which corresponds to at least a five orders of magnitude enhancement in the decomposition of these compounds over background degradation. Similar results are observed for **3b** and **3c** and for related glycosylated diazeniumdiolates.<sup>32</sup> Under physiological levels of cation concentration, these  $\beta$ -gal-promoted hydrolysis rates are likely to be faster and thus these half-lives and the resulting enhancement described earlier in the text is likely to be an underestimate of their activity in vivo.

### Discussion

Diazeniumdiolate glycosylation not only confers probe specificity, but it is also a useful protecting-group strategy. In general, diazeniumdiolate anions are susceptible to acid-promoted thermal and photolytic decomposition with their  $O^2$ -alkyl and coordinated complexes being much more stable under all of these conditions.<sup>28,49</sup> For example, **3a** in phosphate buffer solution (PBS, 0.1 mol/L, pH 7.4) at 37 °C has a half-life of several days ( $>10$  days), whereas the corresponding pyrrolidine diazeniumdiolate **1a**, under the same conditions, has a half-life of 1.8–2.8 s.<sup>28</sup> Compound **3a** can

be stored as a solid at  $-20$  °C with a minimum shelf-life of six months and can remain in PBS at room temperature for at least 10 days. Consequently, glycosylation of diazeniumdiolate ions not only offers a convenient route to deliver NO tissue-specifically, but it has the added advantage of significantly increasing the stability of the diazeniumdiolate in a physiological milieu.

Moreover, the probe's durability in physiological media may be enhanced by increasing the half-life of the diazeniumdiolate itself. This half-life depends on the nature of the substituent directly attached to the first nitrogen atom of the diazeniumdiolate functionality (i.e.,  $-\text{N}(\text{O})=\text{NO}^-$ ). For example, the piperidine diazeniumdiolate, **1b**, has a half-life of  $\sim 11$  s in phosphate buffer solution (PBS, 0.1 mol/L, pH 7.4) at 37 °C, thus nearly an order of magnitude greater than the pyrrolidine substituent in **1a** with its half-life of ( $\sim 1.8$  s) under the same conditions. However, to ensure an instantaneous release of NO by the probes upon enzymatic hydrolysis, a diazeniumdiolate salt with a half-life that is not significantly longer either must be selected. Since the rate of  $\beta$ -galactosidase hydrolysis of the glycosylated diazeniumdiolate derivatives was monitored via the degradation of their corresponding diazeniumdiolate salts (generated upon enzyme hydrolysis) using UV spectroscopy, selecting a very slow NO-releasing diazeniumdiolate for the probe construction has the disadvantage of masking the kinetic parameters associated with enzyme hydrolysis. Furthermore, extensive structural modification of the diazeniumdiolate component in a given probe may lead to lowered rates of the probe's enzyme hydrolysis, and thus complicate the probe's NO release upon activation due to poorer enzyme recognition of the modified substrate. What was thus sought in the probe's design was a balance between the probe durability under physiological conditions and instantaneous NO release upon the probe's activation.

Overall, three glycosylated diazeniumdiolate probes (**3a–3c**) and their intermediates were generated. Their preparation employed a halide displacement reaction between an acetylated glycoside halide (gal–Br) and a diazeniumdiolate salt.

NMR spectroscopy confirmed that a single  $\beta$ -anomer was produced as has been found in related coupling products.<sup>32</sup> The coupling reactions usually took 2–3 days to proceed to completion. The slow pace of the reaction could be, at least partially, explained by the fact that the sodium diazeniumdiolate salts dissolve very slowly in MeCN. Yields for the coupling reactions averaged  $\sim 60\%$  after chromatographic purification. A slight excess of diazeniumdiolate salt was used during these reactions to maximize the yields. An optimal ratio consisted of 5.8 equiv. diazeniumdiolate salt for every 5.5 equiv. of gal-Br. Exceeding this ratio did not significantly affect the reaction rate or yield. The use of rigorously dry conditions, that is doubly distilled acetonitrile stored in an inert-atmosphere box, led to reproducible and higher yields. The coupling reactions were undertaken in the glovebox as well. Despite these measures, TLC comparisons using solutions of degraded diazeniumdiolate salts in wet MeCN, along with  $^1\text{H}$  NMR evaluations of the reaction mixtures, showed that the most important impurities that appeared during the reaction were mainly nitrosamines generated by diazeniumdiolate salt degradation. These degradation products made up roughly about 20%–30% (by weight) of the reaction material. Some unidentified sugar impurities during these coupling reactions were also detected by NMR, but they were not further examined. As described in the Supplementary data, chromatographic purification is critical to obtain pure final products.

## Conclusion

The three  $\beta$ -galactosidase-specific probes described here release NO upon  $\beta$ -gal hydrolysis. Glycosylation of the diazeniumdiolate core leads to both probe stability and specificity. These novel probes are currently being evaluated for their potential to detect  $\beta$ -gal in vivo using MRI.

## Experimental

General methods and materials used in these preparations and for the characterization of new compounds are described in recent papers.<sup>50</sup> Where required, the probes were characterized by  $^1\text{H}$  NMR in 0.01 mol/L NaOD in  $\text{D}_2\text{O}$ .

### Sodium 1-(pyrrolidin-1-yl)diazene-1-ium-1,2-diolate (1a)

This salt was prepared by the method of Saavedra<sup>6</sup> et al. in 61% yield and has the following characteristic data: UV (10 mmol/L NaOH, RT)  $\lambda_{\text{max}}$  ( $\epsilon$ ): 252 nm (7.4 mmol/L $^{-1}$  cm $^{-1}$ ). UV<sub>kinetics</sub> (in 75% excess PBS (0.1 mol/L, pH 7.36)) half-lives: 3.20 s and 1.82 s at RT and 37 °C, respectively. FTIR  $\nu$  (cm $^{-1}$ ): 3455 (br), 3378 (br), 2970 (m), 2880 (m), 1664 (w), 1608 (m), 1463 (w), 1393 (m), 1359 (m), 1266 (m), 1226 (s), 1184 (s), 984 (m), 972 (m), 905 (m).  $^1\text{H}$  NMR (270 MHz,  $\text{D}_2\text{O}/\text{NaOD}$ )  $\delta$ : 3.21 (m, 4H,  $J = 5.9$  Hz), 1.90 (m, 4H,  $J = 5.3$  Hz).  $^{13}\text{C}$  NMR (67.5 MHz,  $\text{D}_2\text{O}/\text{NaOD}$ )  $\delta$ : 51.38 (2C, C-1 and C-4), 22.40 (2C, C-2 and C-3). DSC onset temperature at 169.5 °C, decomposition temperature at 176.7 °C,  $\Delta H = +151.1$  kJ mol $^{-1}$ . MS (MALDI-TOF)  $m/z$ : 153.1 [M] $^{+}$ .

### Sodium 1-(piperidin-1-yl)diazene-1-ium-1,2-diolate (1b)

A solution of piperidine (5.00 g, 58.0 mmols) in acetonitrile (20 mL), ether (20 mL), and 25% sodium methoxide in methanol (11.9 mL, 1 equiv.) was prepared. A white powder

was ultimately obtained (8.3 g; 85% yield). UV (10 mmol/L NaOH, RT)  $\lambda_{\text{max}}$  ( $\epsilon$ ): 250 nm (8.8 mmol/L $^{-1}$  cm $^{-1}$ ). UV<sub>kinetics</sub> (in 75% excess PBS (0.1 mol/L, pH 7.36)) half-lives: 26 s and 11 s at RT and 37 °C, respectively. FTIR  $\nu$  (cm $^{-1}$ ): 3450 (br), 3364 (br), 2969 (m), 2964 (m), 2951 (m), 2942 (s), 2926 (m), 2233 (br, w), 2170 (w), 1676 (m), 1654 (m), 1538 (w), 1473 (m), 1453 (m), 1442 (m), 1435 (m), 1381 (m), 1356 (s), 1291 (m), 1270 (m), 1216 and 1183 (s), 1137 (m), 1096 (m), 1064 (m), 1031 (m), 944 (s), 913 (m), 884 (m), 863 (w), 828 (m), 726 (s).  $^1\text{H}$  NMR (400 MHz,  $\text{D}_2\text{O}/\text{NaOD}$ )  $\delta$ : 2.70 (t, 4H,  $J = 5.6$  Hz), 1.38 (t, 4H,  $J = 5.6$  Hz), 1.12 (t, 2H,  $J = 5.6$  Hz).  $^{13}\text{C}$  NMR (75 MHz,  $\text{D}_2\text{O}/\text{NaOD}$ )  $\delta$ : 52.77 (C-1 and C-5), 24.34 (C-2 and C-4), 22.11 (C-3). DSC onset temperature at 195.9 °C, decomposition temperature at 197.4 °C,  $\Delta H = +46.1$  kJ mol $^{-1}$ . MS (EI)  $m/z$ : 167.1 [M] $^{+}$ , 114 [M – NO] $^{+}$ , 84 [M – 2NO] $^{+}$ , 56 [M – 2NO – 2CH $_2$ ] $^{+}$ , 42 [M – 2NO – 3CH $_2$ ] $^{+}$ . MS (MALDI-TOF)  $m/z$ : 168.5 [M + H] $^{+}$ . The key characteristic data concur with those briefly reported elsewhere.<sup>45</sup>

### Sodium 1-(4-Boc-4-aminomethylpiperidin-1-yl)diazene-1-ium-1,2-diolate (1c)

A solution of Boc-protected 4-aminomethylpiperidine (2.50 g, 11.7 mmols) in methanol (2.00 mL) and ether (40 mL) and 25% sodium methoxide in methanol (8.00 mL, 39.1 mmol) was prepared. A white powder was ultimately derived (2.97 g; 97% yield). Alternatively, the same reaction conditions were undertaken, but this time without ether and stirred at room temperature for 2–3 days. During this time period, the flask was periodically recharged with NO gas (up to 60 psi) until no significant gas consumption was noted over the course of several hours. No precipitate appeared during this time period, but upon pressure release and removal of solvent in vacuo, a yellowish oil was isolated. The product was obtained by performing a trituration on this yellow oil by dissolving it initially in hot ethanol and allowing the product to precipitate as a snow-white powder with the ensuing addition of excess cold hexane or ether. This powder was collected by filtration, rinsed with ether, and dried in a vacuum at room temperature (58% yield). UV (10 mmol/L NaOH, RT)  $\lambda_{\text{max}}$  ( $\epsilon$ ): 250 nm (7.8 mmol/L $^{-1}$  cm $^{-1}$ ), 326 nm (2.88 mmol/L $^{-1}$  cm $^{-1}$ ). UV<sub>kinetics</sub> (in 75% excess PBS (0.1 mol/L, pH 7.36)) half-lives: 33 s and 24 s at RT and 37 °C, respectively. FTIR  $\nu$  (cm $^{-1}$ ): 3359 (s), 2978 (m), 2967 (m), 2951 (m), 2931 (m), 2858 (m), 2254 (m), 1686 (s), 1527 (s), 1473 (m), 1446 (m), 1386 (m), 1364 (s), 1268 (s), 1247 (s), 1177 (s), 1140 (m), 1088 (w), 1043 (w), 1014 (w), 996 (w), 964 (s), 955 (w), 916 (w), 880 (w), 868 (w), 779 (w), 623 (w), 583 (w).  $^1\text{H}$  NMR (400 MHz,  $\text{CD}_3\text{OD}-\text{NaOH}$  (0.1 mol/L))  $\delta$ : 3.20 (d, 2H,  $J = 10.8$  Hz, H-1 and H-5), 3.00 (m, 3H, H-1', H-5' and H-3), 1.81 (m, 2H, H-2 and H-4), 1.50 (m, 2H, partly overlapped by *t*-butyl peak, methylene Hs), 1.43 (s, 9H, *t*-butyl H), 1.40 (m, 2H, partly overlapped by *t*-butyl peak, H-2' and H-4').  $^{13}\text{C}$  NMR (75 MHz,  $\text{CD}_3\text{OD}-\text{NaOH}$  (0.1 mol/L))  $\delta$ : 157.46 (Boc's C=O), 78.65 (Boc's tertiary carbon), 52.24 (piperidine's C-1 and C-5), 45.25 (4-amino methylene carbon), 35.77 (piperidine's C-3), 28.95 (piperidine's C-2 and C-4), 27.67 (Boc's methyl carbons). DSC onset temperature at 172.3 °C, decomposition temperature at 173.3 °C,  $\Delta H = +50.4$  kJ mol $^{-1}$ . MS (ESI, + c)  $m/z$ : 318.9 [M + H] $^{+}$ ,

266.0 [M – Na – NO + H]<sup>+</sup>, 237.1 [M – Na – 2NO + 2H]<sup>+</sup>. MS (ESI, – c) *m/z*: 295.0 [M – Na]<sup>–</sup>, 235.2 [M – Na – 2NO]<sup>–</sup>. ### General procedure for the synthesis of O<sup>2</sup>-glycosylated diazeniumdiolates

To a solution of 2,3,4,6-tetra-*O*-acetyl- $\alpha$ -D-galactopyranosyl bromide (5.5 equiv.) in anhydrous acetonitrile (20 mL), the desired solid diazeniumdiolate salt (5.8 equiv.) was added and stirred until all the galactopyranosyl bromide had reacted (2–3 days) as monitored by TLC (ethyl acetate:hexane, 2:3). Upon filtration, the solvent was removed under vacuum and the product was dissolved in ethyl acetate (25.0 mL). The organic layer was washed with distilled water (3  $\times$  15 mL/wash), dried over Na<sub>2</sub>SO<sub>4</sub> (2 g), filtered, and its solvent removed under vacuum. The isolated material was purified by column chromatography (silica gel, ethyl acetate:hexane, 1:3) to yield a clear colorless oil. To generate the deacetylated version of the O<sup>2</sup>-glycosylated diazeniumdiolate, a few drops of sodium methoxide (25% in methanol) were added to a solution of the protected/acetylated glycosylated diazeniumdiolate in anhydrous methanol (20.0 mL), and the solution was stirred at RT overnight. TLC (methanol:ethyl acetate, 3:7) showed the presence of a new product. The deacetylated product is precipitated in (~97%) by allowing its solution in ethanol, which was diluted with ether, to stand in an ice bath overnight. An alternative synthetic procedure to prepare the deacetylated product involved bypassing the column chromatography step during the synthesis of acetylated glycosylated diazeniumdiolate and carrying out the deprotection step right after the workup of the acetylated glycosylated diazeniumdiolate synthesis. A solid hygroscopic white product was generated (~65% overall). Spectroscopic results were identical whichever methodology was employed.

### O<sup>2</sup>-(2,3,4,6-tetra-*O*-acetyl- $\beta$ -D-galactopyranosyl) 1-(pyrrolidin-1-yl)diazen-1-ium-1,2-diolate (2a)

To a solution of 2,3,4,6-tetra-*O*-acetyl- $\alpha$ -D-galactopyranosyl bromide (400 mg, 0.976 mmol, 5.5 equiv.) in anhydrous acetonitrile (20.0 mL), **1a** (158 mg, 1.03 mmol, 5.8 equiv.) was added and stirred until all the galactopyranosyl bromide had reacted (2–3 days, as determined by TLC on silica ethyl acetate:hexane, 2:3, *R*<sub>f</sub> = 0.24). A clear colorless oil (280 mg, 0.607 mmol, 62% yield) was obtained after purification by column chromatography (silica gel, ethyl acetate:hexane, 1:3). UV (MeOH, RT)  $\lambda_{\text{max}}$  ( $\epsilon$ ): 251 nm (2.05 mmol/L<sup>–1</sup> cm<sup>–1</sup>). FTIR  $\nu$  (cm<sup>–1</sup>): 3475 (mbr), 2981 (m), 2886 (w), 1751 (s), 1652 (w), 1489 (w), 1436 (w), 1373 (s), 1233 (sbr), 1156 (w), 1127 (w), 1079 (s), 1059 (s), 989 (w), 956 (w), 917 (w), 902 (w), 883 (w), 851 (w), 823 (w), 777 (w), 713 (w), 676 (w), 655 (w), 627 (w), 601 (w), 557 (w), 525 (w), 493 (w), 461 (w), 432 (w), 415 (w). <sup>1</sup>H NMR (400 MHz, CD<sub>3</sub>OD)  $\delta$ : 5.40 (m, 3H, overlapped, H-1, H-2, and H-4), 5.22 (dd, 1H, *J* = 9.8, 3.4 Hz, H-3), 4.15 (m, 3H, overlapped, H-5, H-6, and H-7), 3.57 (t, 4H, *J* = 6.6 Hz, H-1' and H-4'), 2.13 (s, 3H, CH<sub>3</sub>), 2.06 (s, 3H, CH<sub>3</sub>),

#### O<sup>2</sup>-(2,3,4,6-tetra-*O*-acetyl- $\beta$ -D-galactopyranosyl) 1-(4-aminomethylpiperidin-1-yl)diazene-1-ium-1,2-diolate (**2d**)

A solution of compound **2c** (389 mg, 0.644 mmol, 1 equiv.) in distilled dichloromethane (DCM, 20.0 mL), and trifluoroacetic acid (TFA, 10.0 mL) was prepared initially at around 0 °C and then stirred under N<sub>2</sub> at RT for 2–3 h. NMR studies in deuterated DCM/TFA solutions demonstrated the complete absence of the Boc methyl peak after this time period with near 100% conversion. Prolonged exposure of this product under such acidic conditions, however, led to deterioration of the product. The acid was subsequently removed from solution via a vacuum line with successive dilutions using DCM (100 mL). The residue was dissolved with aqueous NaCO<sub>3</sub> (1.0 mol/L solution) and extracted thrice with DCM (30 mL/extraction). The combined extracts were dried over Na<sub>2</sub>SO<sub>4</sub> (2 g), filtered, and the solvent removed using a vacuum line to yield a sticky yellow oil (310 mg). The product turned out to be reactive with silica gel, and hence was not further purified by column chromatography. The yield for the ensuing intermediate of this product (see synthesis of protected (**2e**)) was 79% assuming the 310 mg isolated in this synthesis is essentially compound **2d**. On the other hand, during another trial of these syntheses, compound **2e** was isolated with an 81% yield relative to **2c**. This result suggests that the yield of compound **2d** obtained between these two synthetic steps is

very high. UV (MeOH, RT)  $\lambda_{\max}$  ( $\epsilon$ ): 230 nm (3.86 mmol/L<sup>-1</sup> cm<sup>-1</sup>). FTIR  $\nu$  (cm<sup>-1</sup>): 3431 (mbr), 2960 (w), 2926 (w), 2860 (w), 1752 (s), 1681 (s), 1508 (w), 1432 (w), 1384 (m), 1373 (m), 1232 (sbr), 1182 (m), 1134 (m), 1080 (m), 1062 (s), 992 (w), 955 (w), 915 (w), 837 (m), 801 (m), 780 (w), 723 (m), 601 (w), 519 (w), 495 (w), 462 (w), 409 (w). <sup>1</sup>H NMR (400 MHz, CD<sub>3</sub>OD)  $\delta$ : 5.40 (m, 3H, overlapped, H-1, H-2, and H-4), 5.23 (dt, 1H,  $J$  = 7.2, 2.6 Hz, H-3), 4.12 (m, 3H, overlapped, H-5, H-6, and H-7), 4.06 (m, 2H, H-1' and H-5'), 3.00 (dd, 2H,  $J$  = 22.4, 10 Hz, H-1' and H-5'), 2.88 (t, 1H,  $J$  = 6.8 Hz, H-3'), 2.15 (s, 3H, CH<sub>3</sub>), 2.03 (s, 3H, CH<sub>3</sub>), 2.02 (s, 3H, CH<sub>3</sub>), 1.95 (s, 3H, CH<sub>3</sub>), 1.90 (m, 2H, H-2' and H-4'), 1.81 (m, 2H, methylene Hs), 1.49 (m, 2H, H-2' and H-4'). <sup>13</sup>C NMR (75 MHz, CD<sub>3</sub>OD)  $\delta$ : 170.80 (C=O), 170.63 (C=O), 170.14 (C=O), 169.83 (C=O), 100.78 (C-1), 71.47 (C-5), 71.13 (C-3), 67.29 (C-2), 67.19 (C-4), 61.21 (C-6), 53.63 (DCM solvent), 50.36, 50.17 (C1' and C-5'), 43.86 (4-aminomethyl carbon), 33.61 (C-3'), 27.58, 27.48 (C-2' and C-4'), 19.37, 19.28 (acetyl CH<sub>3</sub>). #### O<sup>2</sup>-(2,3,4,6-tetra-*O*-acetyl- $\beta$ -D-galactopyranosyl) 1-(4-[1,2,3,4-tetra-*O*-acetyl- $\beta$ -D-glucopyranosyl]-4-aminomethylpiperidin-1-yl)diazene-1-ium-1,2-diolate (**2e**)

To a solution of **2d** (310 mg, 0.615 mmol, 1 equiv.) in anhydrous acetonitrile (20 mL), Na<sub>2</sub>CO<sub>3</sub> (80.0 mg, 0.755 mmol, 1.2 equiv.) was added followed by a solution of GluDSC (345 mg, 0.705 mmol, 1.15 equiv.) in anhydrous acetonitrile (10 mL). The solution was stirred under N<sub>2</sub> at RT overnight. The solution was passed through a fine frit filter, and the solvent was removed in vacuo. The residue was dissolved in dichloromethane (DCM, 10 mL). This organic layer was washed thrice with distilled water (15 mL/wash), dried over Na<sub>2</sub>SO<sub>4</sub> (2 g), filtered, and its solvent removed in vacuo. TLC demonstrated the appearance of a single new spot (ethyl acetate:hexane, 7:3, with  $R_f$  = 0.34). Interestingly, over time, two new spots appeared on the TLC plate above the initial new spot ( $R_f$  = 0.66, 0.76). NMR and MS studies however show that the TLC spot with  $R_f$  = 0.34 corresponds to the desired compound. The isolated material was purified by column chromatography (silica gel, ethyl acetate:hexane, 7:3) to yield a clear, colorless oil (427 mg, 0.486 mmol, 79%). UV (MeOH, RT)  $\lambda_{\max}$  ( $\epsilon$ ): 229 nm (4.33 mmol/L<sup>-1</sup> cm<sup>-1</sup>). FTIR  $\nu$  (cm<sup>-1</sup>): 3391 (wbr), 2942 (w), 2872 (w), 1756 (s), 1652 (w), 1520 (w), 1436 (w), 1371 (m), 1221 (sbr), 1153 (w), 1079 (m), 1039 (m), 952 (w), 912 (w), 902 (w), 847 (w), 775 (w), 743 (w), 702 (w), 647 (w), 601 (w), 558 (w), 496 (w), 410 (w). <sup>1</sup>H NMR (400 MHz, CD<sub>3</sub>OD)  $\delta$ : 5.82 (d, 1H,  $J$  = 8.4 Hz, glucopyranosyl H-1), 5.40 (m, 3H, overlapped, H-1, H-2, and H-4), 5.33 (t, 1H,  $J$  = 9.6 Hz, glucopyranosyl H-3), 5.23 (dt 1H,  $J$  = 6.8, 2.4 Hz, galactopyranosyl H-3), 5.06 (t, 1H,  $J$  = 9.8 Hz, dd overlapping, 1H,  $J$  = 29.2, 9.6 Hz, glucopyranosyl H-2

#### O<sup>2</sup>-β-D-galactopyranosyl 1-(pyrrolidin-1-yl)diazene-1-ium-1,2-diolate (3a)

A few drops of NaOMe (25% in methanol) were added to a solution of **2a** (163 mg, 0.353 mmol) in anhydrous methanol (20.0 mL), and the mixture was stirred at RT overnight. TLC (methanol:ethyl acetate, 3:7, *R<sub>f</sub>* = 0.32) showed presence of a new product, which was isolated as a white powder (77.7 mg, 0.265 mmol, 75%) after purification by column chromatography (silica gel, methanol:ethyl acetate, 1:4). The product was also obtained in better yield (97%) by allowing it to precipitate in solution. NMR studies confirmed that the material obtained in this manner is identical to the product obtained after chromatography. Alternatively, bypassing the column chromatography step during the synthesis of **2a** and carrying out the deprotection step right after the **2a** workup generated an overall yield of 67%. Spectroscopic results were identical whichever methodology was employed. UV (Tris Buffer (0.1 mol/L, pH 7.4) + (NH<sub>4</sub>)SO<sub>4</sub> (1.7 mol/L) + MgCl<sub>2</sub> (10 mmol/L), RT) λ<sub>max</sub> (ε): 256 nm (6.86 mmol/L<sup>-1</sup> cm<sup>-1</sup>). #### O<sup>2</sup>-β-D-galactopyranosyl 1-(4-β-D-glucopyranosyl-4-aminomethylpiperidin-1-yl)diazene-1-ium-1,2-diolate (3c)

To a solution of **2e** (427 mg, 0.486 mmol) in anhydrous methanol (20 mL), a few drops of sodium methoxide (25% by weight in methanol) were added, and the solution was stirred at RT overnight. TLC (ethyl acetate:hexane, 7:3) showed absence of starting material. The solvent volume

was reduced to 5 mL under vacuum and upon addition of ether (20 mL), the product precipitated out of solution as an expected white solid. Because of its hygroscopic nature, it was collected by filtration under  $N_2$  and dried under reduced pressure overnight (250 mg, 95%). While the product could not be purified by column chromatography, it was nevertheless quite pure by NMR standards. UV (Tris Buffer (0.1 mol/L, pH 7.4) +  $(NH_4)SO_4$  (1.7 mol/L) +  $MgCl_2$  (10 mmol/L), RT)  $\lambda_{max}$  ( $\epsilon$ ): 229 nm (7.44 mmol/L $^{-1}$  cm $^{-1}$ ). FTIR  $\nu$  (cm $^{-1}$ ): 3407 (sbr), 2926 (w), 1699 (w), 1652 (w), 1579 (w), 1451 (w), 1384 (s), 1270 (w), 1222 (w), 1151 (w), 1080 (m), 1020 (w), 957 (w), 888 (w), 836 (m), 763 (w), 685 (w), 610 (w), 553 (w), 481 (w), 469 (w).  $^1H$  NMR (400 MHz,  $CD_3OD$ )  $\delta$ : 4.97 (d, 1H,  $J$  = 7.6 Hz, galactopyranosyl H-1), 4.44 (m, 1H, glucopyranosyl H-4), 4.32 (m, 1H, glucopyranosyl H-1), 4.22 (m, H, glucopyranosyl H-2), 4.00 (m, 2H, piperidiny H-1'' and H-5''), 3.87 (m, 1H, galactopyranosyl H-3), 3.75 (m, 1H, partly overlapped, galactopyranosyl H-2), 3.61 (2 dds, 4H, partly overlapped, galactopyranosyl H-4, H-5, H-6 and H-7), 3.48 (m, 1H, glucopyranosyl H-3) 3.12 (m, 1H, glucopyranosyl H-5), 3.03 (m, 2H, piperidiny methylene Hs), 2.93 (t, 2H,  $J$  = 10.8 piperidiny H-1' and H-5'), 2.45 (m, 2H, glucopyranosyl H-6 and H-7), 1.86 (m, 2H, piperidiny H-2' and H-4'), 1.63 (m, 1H, piperidiny H-3'), 1.37 (m, 2H, piperidiny H-2'' and H-4'').  $^{13}C$  NMR (75 MHz,  $CD_3OD$ )  $\delta$ : 157.46 (amide's C=O), 100.86 (C-1), 91.76 (C-1''), 73.08 (C-3''), 72.93 (C-5''), 71.48 (C-5), 71.21 (C-3), 70.49 (C-2''), 68.13 (C-4''), 67.38 (C-2), 67.23 (C-4), 61.92 (C-6''), 61.33 (C-6), 50.93, 50.73 (C1' and C-5'), 45.65, 45.48 (4-aminomethyl carbon), 35.58 (C-3'), 28.06, 27.87 (C-2' and C-4'). MS (ESI)  $m/z$ : 565.2 [M + Na] $^+$ . MS/MS (ESI)  $m/z$ : 565.1 [M + Na] $^+$ , 372.1 [M + Na - pyranose ( $C_6H_{11}O_5$ ) - NO] $^+$ , 341.1 [M + Na - pyranose ( $C_6H_{11}O_5$ ) - 2NO - H] $^+$ . HR-MS (ESI) calcd. for  $NaC_{19}H_{34}N_4O_{14}$  [M + Na] $^+$ : 565.1969. Found: 565.1966. DSC onset temperature at 146.5  $^{\circ}C$ , decomposition temperature at 176.7  $^{\circ}C$ ,  $\Delta H$  = +102 kJ mol $^{-1}$ .

#### 1,2,3,4-Tetra-*O*-acetyl- $\beta$ -D-glucopyranosyl succinimidyl carbonate (GluDSC) (4)

To a solution of 1,2,3,4-tetra-*O*-acetyl- $\beta$ -D-glucopyranose (200 mg, 0.575 mmol, 1 equiv.) in anhydrous acetonitrile (25 mL), *N,N'*-disuccinimidyl carbonate (DSC, 221 mg, 0.863 mmol, 1.5 equiv.) and triethylamine (TEA, 240  $\mu$ L, 1.73 mmol, 3 equiv.) were added, and the mixture was stirred until all the glucopyranose had reacted (overnight, TLC monitored, ethyl acetate:hexane, 3:1). The solvent was removed under vacuum and the residue was dissolved with aqueous  $NaHCO_3$  (1.0 mol/L solution) and extracted with ethyl acetate (3  $\times$  30 mL). The combined extracts were washed with brine (20 mL) and dried over  $Na_2SO_4$  (2.0 g), filtered, and the solvent was removed under vacuum. The isolated material turned out as a yellow sticky paste (265 mg, 0.542 mmol, 94%). The product turned out to be reactive with silica gel and hence was not further purified by column chromatography. NMR studies have demonstrated nonetheless rather high purity (yield by NMR: 96%). UV (DCM, RT)  $\lambda_{max}$  ( $\epsilon$ ): 229 nm (0.509 mmol/L $^{-1}$  cm $^{-1}$ ). FTIR  $\nu$  (cm $^{-1}$ ): 3487 (wbr), 2950 (w), 1817 (m), 1791 (m), 1743 (s), 1636 (w), 1432 (w), 1370 (m), 1222 (sbr), 1166 (w), 1078 (m), 1040 (m), 915 (w), 899 (w), 853 (w), 838 (w),

817 (w), 794 (w), 779 (w), 762 (w), 645 (w), 602 (w), 555 (w), 492 (w).  $^1H$  NMR (300 MHz,  $CD_2Cl_2$ )  $\delta$ : 5.77 (d, 1H,  $J$  = 10.8 Hz, H-1), 5.30 (t, 1H,  $J$  = 12.4 Hz, H-3), 5.11 (dd, 1H,  $J$  = 9.3, 11.7 Hz, H-2), 5.08 (dd, 1H,  $J$  = 9.3, 13.8 Hz, H-4), 4.43 (dd, 1H,  $J$  = 16.0, 3.6 Hz, H-6), 4.35 (dd, 1H,  $J$  = 16.0, 7.0 Hz, H-7), 3.99 (ddd, 1H,  $J$  = 3.6 Hz, H-5), 2.83 (s, 4H, succinimide Hs), 2.13 (s, 3H,  $CH_3$ ), 2.06 (s, 3H,  $CH_3$ ), 2.03 (s, 3H,  $CH_3$ ), 2.01 (s, 3H,  $CH_3$ ).  $^{13}C$  NMR (75 MHz,  $CD_3OD$ )  $\delta$ : 170.06, 169.74, 169.34, 169.11 (acetyl C=O), 168.82 (succinimide C=O), 151.45 (activated ester C=O), 91.61 (C-1), 72.48 (C-5), 72.14 (C-2), 70.13 (C-4), 68.58 (C-3), 68.17 (C-6), 25.83, 25.71 (succinimide  $CH_2$ ), 20.81, 20.61, 20.58 (acetyl  $CH_3$ ). MS (ESI)  $m/z$ : 512.1 [M + Na] $^+$ . MS/MS (ESI)  $m/z$ : 512.0 [M + Na] $^+$ , 452.0 [M + Na - *O*-acetyl ( $O-C(=O)CH_3$ ) - H] $^+$ . HR-MS (ESI) calcd. for  $NaC_{19}H_{23}N_1O_{14}$  [M + Na] $^+$ : 512.1016. Found: 512.1007.

#### X-ray diffraction crystal structure of 3a

Crystals of **3a** suitable for single-crystal X-ray diffraction were grown from water/methanol and crystallized in the monoclinic noncentrosymmetric space group  $P2_1$   $Z$  = 2, with unit cell dimensions of  $a$  = 4.8350(18),  $b$  = 9.435(3), and  $c$  = 15.552(6)  $\text{\AA}$ ;  $\beta$  = 92.423(5) $^{\circ}$ ,  $\alpha$  =  $\gamma$  = 90 $^{\circ}$ ;  $V$  = 708.8(4)  $\text{\AA}^3$ ; The structure was solved by direct methods, and the refined chirality was based upon that of the starting carbohydrate. Other key crystallographic data include  $\rho_c$  = 1.459 Mg m $^{-3}$ ; crystal size = 1.0  $\times$  0.05  $\times$  0.01 mm $^3$ . Data: 2882 independent data with  $I > 2\sigma(I)$ ,  $S_{\text{go}}$  = 1.039;  $R_1$  = 4.02%,  $wR_2$  = 10.52%. For further details, see the Supplementary data section.

#### Investigation of the stability of compounds 3a–3c

The solid deprotected glycosylated diazeniumdiolates are quite hygroscopic and have a tendency to turn brown over the course of a few hours if exposed to warm moist air. However, NMR examination of these brown materials reveals that there is only slight degradation (<5%) of the products. Under  $N_2$ , the same materials do not change in consistency over the course of two weeks at room temperature. Again, NMR examination showed negligible degradation of these materials when stored at room temperature under  $N_2$ . The optimal conditions for these compounds are as dried solids at  $-20$   $^{\circ}C$  under  $N_2$  in the dark. Under these conditions, the compounds have been stored for up to six months without significant degradation. Probe stability in aqueous and alcoholic media was also determined at room temperature over 2–3 weeks using NMR ( $D_2O$ ,  $CH_3OD$ ) and by UV ( $H_2O$ , Tris buffer (0.1 mol/L, pH 7.4),  $CH_3OH$ ). Degradation over this time period was in general minor (<10%) as revealed by either spectroscopic technique. The acetylated intermediate sugar diazeniumdiolates also presented similar stability. These oils were generally clear and colorless after purification (except for compound **3**) and slowly yellowed over 2–3 weeks when exposed to air at room temperature. NMR examination of these yellow oils show some signs of degradation (<2%). The optimal storage conditions for these oils were the same as for the deprotected sugar diazeniumdiolates degraded considerably (~40%) when exposed continually to UV light for prolonged periods of time (4–5 h).

## Supplementary data

Supplementary data for this article (general methods, instrumentation, preparation, and diffraction data) are available on the journal Web site (canjchem.nrc.ca). CCDC 740859 contains the X-ray data in CIF format for this manuscript. These data can be obtained, free of charge, via [www.ccdc.cam.ac.uk/conts/retrieving.html](http://www.ccdc.cam.ac.uk/conts/retrieving.html) (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or [deposit@ccdc.cam.ac.uk](mailto:deposit@ccdc.cam.ac.uk)).

## Acknowledgements

# Bisoxazoline–copper(I)-catalyzed aziridination of diazoacetate with imines — A DFT study

Qingxi Meng, Fen Wang, and Ming Li

**Abstract:** Density functional theory (DFT) has been used to study bisoxazoline–copper(I)-catalyzed aziridination of diazoacetate with *syn*-imines or *anti*-imines. All the intermediates and transition states were optimized completely at the B3LYP/6-31G(d) level. Calculation results confirm that Cu(I)-catalyzed aziridination goes mainly through the catalyst–diazoacetate complex (**M1**), the copper(I)–carbene intermediate (**M2**), the copper–carbene–imine complex (**M3**), and the catalyst–aziridine carboxylate complex (**M4**). For *syn*-imines, the reaction mode I (C3–N5 bond attacking the Cu–C1 bond of **M2**) is more dominant than the reaction mode II (C3–N5 bond attacking the carbene–carbon C1 of **M2**), and the attack from the *si*-surface of **M2** is prior to the *re*-surface. For *anti*-imines, the reaction modes and attacks from the *si*- or *re*-surface coexist. The reactivity of *syn*-imines is stronger than *anti*-imines. The favorable reaction channel is **CA2** → **M1b** → **TS1b** → **M2** → *syn*-**TS2b** → *syn*-**M3b** → *syn*-**TS3b** → *syn*-**M4b** → *syn*-**P2**. The dominant product theoretically predicted is of (S,S)-chirality. On the whole, the solvent effect decreases the free energies of the species.

**Key words:** bisoxazoline–copper(I) complex, aziridination, imines, reaction mechanism, density functional theory (DFT).

**Résumé :** On a fait appel à la théorie de la fonctionnelle de la densité pour étudier l'aziridination catalysée par le bisoxazoline-cuivre(I) du diazoacétate avec des imines *syn*- ou *anti*-. On a complètement optimisé tous les intermédiaires et les états de transition au niveau B3LYP/6-31G(d). Les résultats de ces calculs confirment que l'aziridination catalysée par le cuivre(I) se produit principalement par le biais du complexe catalyseur-diazoacétate, **M1**, de l'intermédiaire cuivre(I)-carbone, **M2**, du complexe cuivre(I)-carbone-imine, **M3** et du complexe catalyseur-aziridinecarboxylate, **M4**. Pour les imines *syn*, le mode de réaction I (attaque de la liaison C3-N5 sur la liaison Cu-C1 de **M2**) est plus dominant que le mode II (attaque de la liaison C3-N5 sur le carbone C1 du carbone de **M2**); l'attaque sur la surface *si* de **M2** se fait avant celle sur la surface *re*. Toutefois, pour les imines *anti*, elles coexistent. La réactivité des imines *syn* est plus grande que celle des imines *anti*. La voie réactionnelle la plus favorable est **CA2** → **M1b** → **TS1b** → **M2** → *syn*-**TS2b** → *syn*-**M3b** → *syn*-**TS3b** → *syn*-**M4b** → *syn*-**P2**. Sur la base des calculs théoriques, il est prédit que la chiralité du produit dominant devrait être (S,S). Dans l'ensemble, l'effet de solvant diminue les énergies libres des espèces.

**Mots-clés :** complexe bisoxazoline-cuivre(I), aziridination, imines, mécanisme de réaction, théorie de la fonctionnelle de la densité (« DFT »).

## Introduction

Aziridines have been attractive organic molecules due to their great synthetic utilities.<sup>1–3</sup> Aziridines have been used as intermediates in the preparation of amino acids,<sup>4,5</sup>  $\beta$ -lactams,<sup>6</sup> polymers,<sup>7</sup> and pyrrolidines.<sup>8</sup> A number of synthetic aziridines have found biological applications as antitumor agents, antibiotics, and as enzyme inhibitors.<sup>9</sup> Many noncatalytic pathways to aziridines have been developed.<sup>10,11</sup> Recently, however, the development of the asymmetric catalytic aziridinations has received the most attention.<sup>2</sup> A variety of methods has been developed for the synthesis of aziridines,<sup>9,12,13</sup> including a ring closure reaction of 1,2-amino alcohols or their derivatives,<sup>14,15</sup> ring opening of epoxides with metal azides,<sup>16,17</sup> the addition of  $\alpha$ -haloester enolates to imines,<sup>18</sup> a transfer of a nitrene group to an alkene,<sup>19,20</sup> and the reactions between diazo esters and imines

mediated by either carbene transfer catalysts<sup>21–23</sup> or Lewis acid catalysts.<sup>24–29</sup>

The aziridination catalyzed by transition metals, which is defined as a [2+1] cycloaddition between a carbene-type species and imines (Scheme 1), is an important synthetic method to obtain aziridine rings. Transition metals such as rhodium and copper are found to be able to catalyze the aziridination.<sup>30,31</sup>

As illustrated in Scheme 2, it is also generally accepted that the copper-catalyzed aziridination proceeds via a copper–carbene complex (**E**), which is formed by the association of the diazoimido compound (**D**) and the active catalyst (**B**) with concomitant extrusion of nitrogen, and then the attack of imines (**F**) on the copper–carbene intermediate (**E**) leads to the asymmetric aziridine (**G**). In copper-catalyzed asymmetric aziridination, the copper–carbene in-

**Scheme 1.** Transition-metal-catalyzed aziridination of diazoacetate with imines.**Scheme 2.** Possible reaction mechanism of copper-catalyzed aziridination of diazoacetate with imines.

intermediate plays an important role. The copper-carbene complex has a better stabilization and enantioselectivity, compared with a free carbene, and has been detected as the reaction intermediate in experiment.<sup>32</sup>

Ikeno et al.<sup>33</sup> have studied some transition metal-carbene complexes such as Co-, Cu-, and Ru-carbenes at the B3LYP/6-31G(d) and B3LYP/LANL2DZ levels. The formation of a copper-carbene intermediate has been studied by Salvatella and co-workers<sup>34</sup> at the B3LYP/6-31G(d) level. Comba et al.<sup>35</sup> have studied the mechanism of the (bispidine)copper(II)-catalyzed aziridination of styrene, both experimentally and theoretically. We have studied the copper(I)-carbene complexes<sup>36</sup> at the B3LYP/631G(d,p) level and the copper(I)-catalyzed asymmetric cyclopropanation of diazoacetate with alkene<sup>37</sup> at the B3LYP/631G level. The theoretical data available for the mechanism of the aziridination of diazoacetate with imines are rather limited. Therefore, to understand the reaction mechanism of the aziridination catalyzed by the copper complex in detail, chiral bisoxazoline-copper(I)-catalyzed aziridination of diazoacetate with *syn*-imines or *anti*-imines is studied in the present work. Herein, a theoretical study with the B3LYP density functional was carried out to elucidate the following issues in details: (i) the reactivity of *syn*-imines or *anti*-imines, (ii) the two reaction modes, I (imines attacking the Cu-C<sub>carbene</sub> bond of the copper-carbene complex) and II (imines attacking the carbene carbon), (iii) the imines attacking the copper-carbene

complex from the *re*-surface or *si*-surface, and (iv) the most favorable channel and dominant product. The possible reaction mechanism is outlined in Scheme 3.

## Computational details

All computations were carried out by using the Gaussian03 program package.<sup>38</sup> Density functional theory (DFT) methods<sup>39</sup> have now been widely applied to various molecular systems with great success because of their efficiency and accuracy,<sup>40–42</sup> especially the B3LYP method,<sup>43–45</sup> which includes Becke's three-parameter-exchange functionals and nonlocal Lee, Yang, and Parr correlation functional that generally provides better results. The 6-31G(d) basis set is used for all the atoms. All the species are positively identified for local minima with zero of the number of imaginary frequencies and for transition states with the sole imaginary frequency. The transition states were verified by intrinsic reaction coordinate (IRC)<sup>46</sup> calculations and by animating the negative eigenvector coordinates with a visualization program (Molekel 4.3).<sup>47,48</sup> In addition, based on the gas phase optimized geometry for each species, the solvent effects of CH<sub>2</sub>Cl<sub>2</sub> were studied by performing the self-consistent reaction field (SCRF) of polarizable continuum model (PCM)<sup>49</sup> approach at the same computational level.

Furthermore, the bonding characteristics were analyzed by using the "atoms in molecules" (AIM) theory,<sup>50</sup> which is

**Scheme 3.** Proposed mechanism of copper(I)-catalyzed aziridination.

based on a topological analysis of the electron charge density and its Laplacian. The magnitude of the electron density,  $\rho(r)$ , at the bond critical points (BCPs) depends on the interatomic distance and the degree of coordination of the atoms, and it is often used as a measure of the bond strength or similar types of bonds.<sup>51</sup> The analysis went further with those obtained by means of the natural bond orbital (NBO) theory.<sup>52–55</sup> AIM analysis was carried out by employing the AIM2000 code<sup>56</sup> with the B3LYP/6-31G(d) wave functions as input. NBO analysis was performed by utilizing NBO5.0code<sup>57</sup> with the optimized structures.

Molecular orbital (MO) compositions and the overlap populations were calculated by employing the AOMix program.<sup>58,59</sup> The analysis of the MO compositions in terms of occupied and unoccupied fragment molecular orbitals (OFOs and UFOs, respectively), the charge decomposition analysis (CDA), and the construction of orbital interaction diagrams were performed by using AOMix-CDA.<sup>60</sup>

## Results and discussion

As illustrated in Scheme 3, copper(I)-catalyzed aziridination is suggested as the following: the decomposition of the catalyst, the bisoxazoline-copper(I) complex (CA), leading to oxazoline and an active oxazoline-copper(I) catalyst (CA2); the reaction of diazoacetate with CA2 generating the catalyst-diazoacetate complex (M1); the decomposition of N<sub>2</sub> in M1 leading to the copper(I)-carbene intermediate (M2); the reaction of M2 with imines resulting in the cop-

**Scheme 4.** Attack of imines on copper-carbene intermediate M2.

per(I)-carbene-imine complex (M3); the formation of the catalyst-aziridine carboxylate complex (M4); the decomposition of M4 leading to the aziridine carboxylate and regenerating the active catalyst CA2. Scheme 3 also shows that the attack of *syn*-imines or *anti*-imines on M2 has two reaction modes, I and II, where the C3–N5 bond attacks the Cu–C1 bond or C1 (carbene-carbon) of M2, respectively. As shown in Scheme 4, *syn*-imines or *anti*-imines can attack M2 from the *re*-surface or the *si*-surface. In the following discussion, the attack of imines from the *re*-surface of M2

**Fig. 1.** Optimized structure of the bisoxazoline–copper(I) complex (CA) (bond distances in Å and angles in °).

is marked by an “a” and its attack from the *si*-surface is marked by a “b”.

The relative free energies,  $\Delta G(\text{sol})$ , including solvent energies, and the relative gas phase free energies,  $\Delta G$ , enthalpies,  $\Delta H$ , and zero-point energy (ZPE) corrected electronic energies,  $\Delta E$ , are provided in Table 1. Unless otherwise noted, the discussed energies are relative free energies,  $\Delta G(\text{sol})$ , in the following discussions.

### Catalyst

The optimized structure of the catalyst, chiral bisoxazoline–copper(I) complex (CA), is illustrated in Fig. 1. It is a  $C_2$ -symmetry complex. There is a Cu–N–C–C–C–N six-membered ring in the catalyst CA and the six atoms are nearly coplanar. (As shown, most of the intermediates and transition states have this character.) The Cu–N and C–N bonds are 2.008 and 1.283 Å, respectively. The Cu–N and C–N bonds are 1.841 and 1.295 Å in the active catalyst CA2, which is also a  $C_2$ -symmetry complex (Fig. 2). The highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) of CA2 are shown in Fig. S1 of the Supplementary data.

**Fig. 2.** The intermediates and transition states of the formation of the copper–carbene complex (**M2**) (bond distances in Å, angles and dihedral angles in °, moment dipoles,  $\mu$ , in D).

**Fig. 3.** The intermediates and transition states of the reaction of **M2** and *syn*-imines (bond distances in Å, angles and dihedral angles in °, moment dipoles,  $\mu$ , in D).

#### Formation of the copper(I)–carbene intermediate

As illustrated in Scheme 3, the reaction of diazoacetate (**R1**) with the active catalyst **CA2** leads to the catalyst–diazoacetate complex (**M1**), and then the decomposition of  $N_2$  in

**M1** generates the copper(I)–carbene intermediate (**M2**) via the transition state **TS1**.

Figure 2 shows that the Cu–C1 and C1–N3 bonds are 1.981 and 1.355 Å in **M1a** and 1.951 and 1.374 Å in **M1b**,

**Fig. 4.** Orbital interaction diagram for *syn*-TS2a, which is formed by imines (*syn*) and the copper-carbene fragment (the AOMix-CDA calculation, based on B3LYP/6-31G\*; the net charge donation, CT(1 → 2) – CT(2 → 1), is 0.2 e).

**Fig. 5.** A loose scan profile of **M2** with imine to *syn*-M3a' along the C1–N5 distance increased with the electronic state of the close shell singlet.

respectively. Compared to diazoacetate, C1–N3 bonds become longer by about 0.06 Å, which possibly results from the formation of Cu–C1 bonds. The N1–Cu–C1–C2 and N1–Cu–C1–N3 torsion angles are, respectively, 87.4° and 19.0° for **M1a** and 140.2° and 15.6° for **M1b**. In the transition states **TS1a** and **TS1b**, the C1–N3 bonds are stretched considerably and the Cu–C1 bonds shortened compared with those of **M1** (**M1** → **TS1**: C1–N3 bond: 1.4 → 1.8 Å, Wiberg bond order,  $P_{ij}$ : 0.98 → 0.48, the electron densities,  $\rho$ , of the bond critical points (BCPs): 0.26 → 0.10 e Å<sup>-3</sup>; Cu–C1 bond: 2.0 → 1.8 Å,  $P_{ij}$ : 0.25 → 0.38,  $\rho$ : 0.10 → 0.14 e Å<sup>-3</sup>; Table S1 in the Supplementary data). The high stabilization energies of about 160 kJ/mol for the (2p)<sub>N1</sub> →  $\sigma^*_{\text{Cu–C1}}$  and (2p)<sub>N2</sub> →  $\sigma^*_{\text{Cu–C1}}$  in **TS1a** and **TS1b** (Table S6 in the Supplementary data), which is obtained from the second-order perturbation analysis of donor–acceptor interactions

in the NBO analysis and used to estimate the strengths of the donor–acceptor interactions of the NBOs, reveals the strong interaction between (2p)<sub>N1</sub> and (2p)<sub>N2</sub> and  $\sigma^*_{\text{Cu–C1}}$  orbitals and the electron transfer tendency from (2p)<sub>N1</sub> and (2p)<sub>N2</sub> to  $\sigma^*_{\text{Cu–C1}}$ . The copper(I)–carbene intermediate (**M2**) has only one geometry, which is in agreement with our previous study,<sup>37</sup> and the N1–Cu–C1–H and N1–Cu–C1–C2 torsion angles are 90.0° and 100.8°, respectively. In **M2**, the Cu–C1 bond is 1.782 Å, which is shorter than **M1**. As illustrated in NBO analysis, the Cu–C1 bond shows a strong single-bonded character, and the NBO energy is –1102.16 kJ/mol. The atomic polar tensor (APT) charges of copper and carbon atoms of the Cu–C1 bond are +0.397 and +0.019, respectively (Table S5 in the Supplementary data).

### M2 reaction with *syn*-imines

Scheme 3 shows that the attack of *syn*-imines on **M2** has two reaction modes: I (C3–N5 bond attacking the Cu–C1 bond of **M2**) and II (C3–N5 bond attacking the carbene-carbon C1 of **M2**).

#### Reaction mode I — The C3–N5 bond attacking the Cu–C1 bond

##### Formation of the copper(I)–carbene–imine complex

Scheme 4 shows that the attack of imines on **M2** has two reaction channels: from the *re*-surface or *si*-surface of **M2**. Transition states *syn*-TS2a and *syn*-TS2b have sole imaginary frequencies, in correspondence with the stretching vibrations of Cu–N5 and C1–C3 bonds. The Cu–N5 and C1–C3 bonds are about 1.9 and 2.4 Å. Obviously, Cu–N5 and C1–C3 bonds are strengthened markedly. It is shown by these results that Cu–N5 and C1–C3 bonds could be formed at the same time. Compared with imines and **M2**, the C3–N5 and Cu–C1 bonds are weakened and lengthened by 0.06 and 0.13 Å, respectively. There is a strong interaction between the  $\pi$  orbital of the C3–N5 bond and the  $\sigma^*$  antibond orbital of the Cu–C1 bond, which makes the electrons in the  $\pi$  orbital transfer easily to the  $\sigma^*$  antibond orbital of the Cu–C1 bond, so the  $\pi$  orbital of the C3–N5 bond has a ten-

**Fig. 6.** The transition states of the reaction mode II (bond distances in Å, angles and dihedral angles in °, moment dipoles,  $\mu$ , in D).

**Fig. 7.** Orbital interaction diagram for *syn-TS4a*, which is formed by imines (*syn*) and the copper-carbene fragment (the AOMix-CDA calculation, based on B3LYP/6-31G\*; the net charge donation,  $CT(1 \rightarrow 2) - CT(2 \rightarrow 1)$ , is 0.3 e).

dency to be fractured. As demonstrated in Fig. 3, the transition states involve a Cu–C1–C3–N5 four-membered ring, and the electron densities,  $\rho$ , of the ring critical points (RCPs) are about  $0.04 \text{ e } \text{\AA}^{-3}$ .

As illustrated in Fig. 4, the HOMO (including the orbital interaction between imines and copper-carbene) for *syn-TS2a* is a mixture of 11.1% LUFO (the LUMO of fragment orbitals), 4.9% HOFO for imines (Fig. 4, fragment 1), and 74.7% LUFO for the copper-carbene fragment (Fig. 4, fragment 2). And the LUMO for *syn-TS2a* is a mixture of 6.6% LUFO+1, 5.3% HOFO for imines, 66.1% HOFO, and 5.7% LUFO+3 for the copper-carbene fragment. It is clear that the reaction between imines and the Cu-carbene complex occurs dominantly between LUFO, HOFO, and HOFO-1 of fragment 1 and HOFO and LUFO of fragment 2 (Fig. 4). The net charge donation, which includes both charge donation and electronic polarization contributions, is 0.20 e.

In the copper-carbene-imine complex (**M3**), four atoms, Cu, C1, C3, and N5, are nearly coplanar and there is a ring critical point, with  $0.06 \text{ e } \text{\AA}^{-3}$  of electron density, inside the area encircled by the four atoms. There is a little angle between the Cu–C1–C3–N5 four-membered ring and the N1–Cu–N2 plane. NBO analysis of **M3** shows that the Cu–C1 bond shows a strong single-bonded character, and NBO energies are  $-1300 \text{ kJ/mol}$ , which are lower than those of **TS2** by  $200 \text{ kJ/mol}$ .

In addition, we tried to compute another four transition states (**TS2'**): when the C3–N5 bond attacks the Cu–C1

bond of **M2** leading to four complexes (**M3'**) (Figure S2 in the Supplementary data), N5 attacks the carbene carbon, and thus C3 attacks the copper. Unfortunately, all of our efforts failed. A loose scan from **M3'** to **M2** along the  $\sigma_{(C1-N5)}$  formation is calculated and illustrated in Fig. 5. Obviously, no first-saddle point is found in this energy curve and this fact implies that the transition states **TS2'** are not in existence.

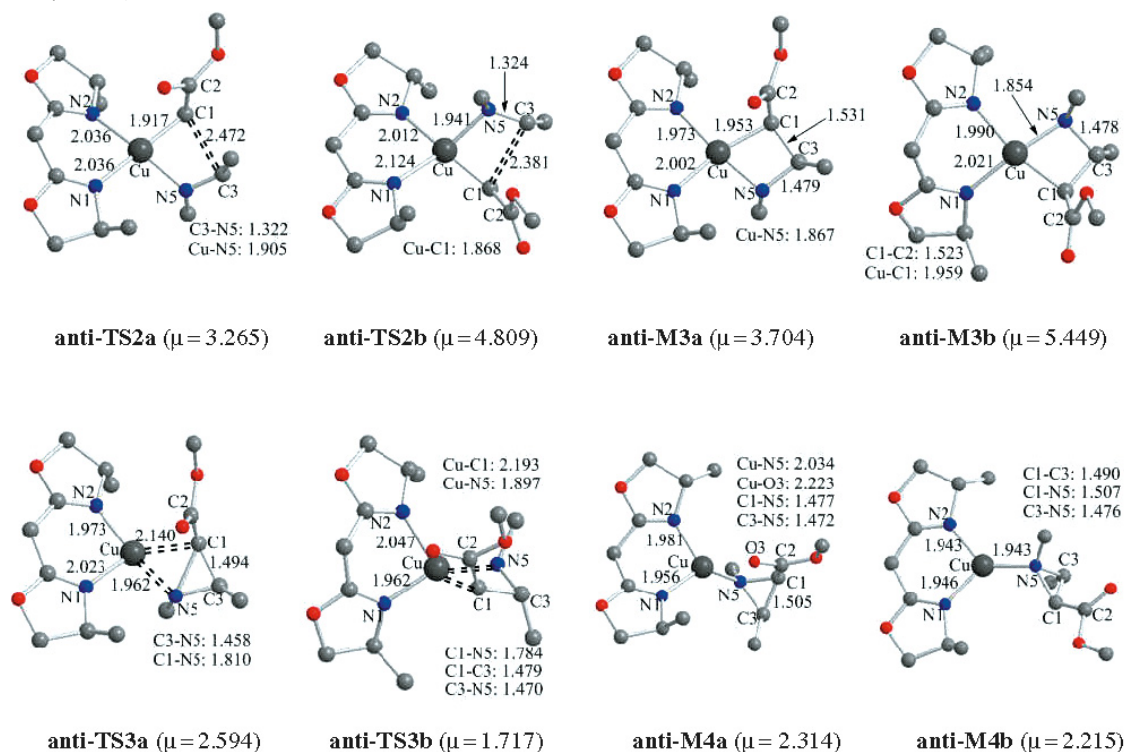

#### The elimination — Formation of aziridine carboxylate

As shown in Scheme 3, the elimination of **M3** leads, via the transition state **TS3**, to the catalyst-aziridine carboxylate complex (**M4**); the decomposition of **M4** results in the aziridine carboxylate and regenerates the active catalyst **CA2**. In the transition states *syn-TS3a* and *syn-TS3b*, the Cu–C1, Cu–N5, and C1–N5 bonds are about 2.2, 1.9, and 1.8 Å, respectively. Compared with **M3**, the Cu–C1 and Cu–N5 bonds are stretched, and the C1–N5 bonds are shortened. The transition states involve a Cu–C1–C3–N5 four-membered ring and the electron densities,  $\rho$ , of the RCPs are about  $0.07 \text{ e } \text{\AA}^{-3}$ . In *syn-M4a*, there is a Cu–N5–C1–C2–O five-membered ring, and the Cu–N5 and Cu–O bonds are 2.0 and 2.2 Å. But in the complex *syn-M4b*, there is no five-membered ring; only the Cu–N5 bond is formatted, and the distance is 1.9 Å.

#### Reaction mode II — The C3–N5 bond attacking the carbene-carbon C1

The double bonds  $\pi_{C3-N5}$  of imines attack directly on the

**Fig. 8.** The intermediates and transition states of the reaction of **M2** and *anti*-imines (bond distances in Å, angles and dihedral angles in °, moment dipoles,  $\mu$ , in D).

**Fig. 9.** The schematic reaction profiles of copper(I)-catalyzed aziridination.

carbene-carbon of **M2**, leading to the complex *syn*-**M4**, via the transition state **TS4** (Fig. 6). As illustrated in Fig. 7, the HOMO for *syn*-**TS4a** is a mixture of 10.6% HOFO-1 for imines (Fig. 7, fragment 1), 57.5% HOFO, and 12.6% HOFO-1 for the copper-carbene fragment (Fig. 7, fragment 2). The LUMO for *syn*-**TS4a** is a mixture of 9.1% LUFO, 12.8% HOFO-1 for imines, and 74.1% LUFO for the copper-carbene fragment. It is clear that the reaction between imines and the Cu-carbene complex occurs dominantly between LUFO and HOFO-1 of fragment 1 and HOFO and LUFO of fragment 2 (Fig. 7), which is different from *syn*-**TS2a** illustrated in Fig. 4. The net charge donation, which includes both charge donation and electronic polarization contributions, is 0.30 e. The high stabilization energies of 400 kJ/mol for the  $\pi_{(N3-N5)} \rightarrow (2p)_{C1}$  in *syn*-**TS4a** and *syn*-**TS4b** reveals the strong interaction between  $\pi_{(N3-N5)}$  and

$(2p)_{C1}$  and the electron transfer tendency from  $\pi_{(N3-N5)}$  to  $(2p)_{C1}$ , which results in the formation of C1-C3 and C1-N5 bonds.

As discussed above, the reaction of **M2** with *syn*-imines has two attacking modes, I and II. Table 1 shows that the free energies of activation of *syn*-**TS2a** and *syn*-**TS2b** are lower than those of *syn*-**TS4a** and *syn*-**TS4b** by 12~24 kJ/mol. Therefore, the reaction mode I is more dominant than the reaction mode II. Therefore, in the reaction of **M2** with *syn*-imines, the attack of the C3-N5 bond on the Cu-C1 bond of **M2** is easier than that on the carbene-carbon C1 of **M2**.

#### **M2 reaction with *anti*-imines**

Similar to *syn*-imines, the attack of *anti*-imines on the copper-carbene intermediate (**M2**) also has two reaction modes, I and II. All the optimized structures on the saddle

points of this reaction profile of *anti*-imines and **M2** are similar to those of *syn*-imines and **M2**, and are shown in Fig. 6 and Fig. 8. Table 1 shows that the free energies of activation of *anti*-**TS2a** and *anti*-**TS2b** are almost equivalent to those of *anti*-**TS4a** and *anti*-**TS4b** with a difference of 1~6 kJ/mol. So, in the reaction of **M2** with *anti*-imines, the two reaction modes I and II coexist, and the attack of *anti*-imines on **M2** from the *re*-surface or the *si*-surface also coexist.

### Copper(I)-catalyzed aziridination

The copper(I)-catalyzed aziridination goes mainly through the catalyst-diazoacetate complex (**M1**), the copper(I)-carbene intermediate (**M2**), the copper-carbene-imine complex (**M3**), and the catalyst-aziridine carboxylate complex (**M4**). Table 1 and Fig. 9 show that the formation of these complexes, **M1**, **M2**, **M3**, and **M4**, are exothermic, and the released free energies are about 100, 120, 240, and 300 kJ/mol, respectively. Furthermore, calculation results indicate that copper(I)-catalyzed aziridination is exergonic by 140 kJ/mol in free energy.

As discussed above, the attack of imines on **M2** has two reaction modes: I (C3–N5 bond attacking the Cu–C1 bond of **M2**) and II (C3–N5 bond attacking the carbene–carbon C1 of **M2**). For *syn*-imines, the reaction mode I is more dominant; but for *anti*-imines, the two reaction modes coexist. Because the free energies of activation of *anti*-**TS2a** and *anti*-**TS2b** are higher than those of *syn*-**TS2a** and *syn*-**TS2b** (Table 1), the reactivity of *syn*-imines is stronger than that of *anti*-imines. Hence, *syn*-imines are the more active reactant in the copper-catalyzed aziridination.

In the reaction of **M2** with *syn*-imines, the free energy of activation of *syn*-**TS2a** is higher than *syn*-**TS2b** by 10 kJ/mol, which indicates the attack of *syn*-imines from the *si*-surface of **M2** occurs prior to that from the *re*-surface. Therefore, the reaction channel **CA2** → **M1b** → **TS1b** → **M2** → *syn*-**TS2b** → *syn*-**M3b** → *syn*-**TS3b** → *syn*-**M4b** → *syn*-**P2** is the most favorable one. The dominant product obtained from this reaction channel is of (*S,S*)-chirality.

### Conclusion

In this study, we have investigated chiral bisoxazoline–copper(I)-catalyzed aziridination of diazoacetate with *syn*-imines or *anti*-imines using density functional theory. All the intermediates and transition states were optimized completely at the B3LYP/6-31G(d) level. Calculation results confirm that Cu(I)-catalyzed aziridination goes mainly through the catalyst-diazoacetate complex (**M1**), the copper(I)-carbene intermediate (**M2**), the copper-carbene-imine complex (**M3**), and the catalyst-aziridine carboxylate complex (**M4**). For *syn*-imines, the reaction mode I (C3–N5 bond attacking the Cu–C1 bond of **M2**) is more dominant than the reaction mode II (C3–N5 bond attacking the carbene–carbon C1 of **M2**), and the attack from the *si*-surface of **M2** occurs prior to that from the *re*-surface; however, for the *anti*-imines, the reaction modes and attacks from the *si*- or *re*-surface coexist. *Syn*-imines are a more active reactant than *anti*-imines in the copper-catalyzed aziridination. The reaction channel **CA2** → **M1b** → **TS1b** → **M2** → *syn*-**TS2b** → *syn*-**M3b** → *syn*-**TS3b** → *syn*-**M4b** → *syn*-**P2** is

the most favorable one. The dominant product obtained from this reaction channel is of (*S,S*)-chirality. The solvent effect is remarkable, and it decreases the free energy of intermediates and transition states.

### Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca).

# Synthesis of metallocarbonyl substituted 1,2,3-triazole complexes via copper(I)-catalyzed azide-alkyne cycloaddition

Bogna Rudolf

**Abstract:**  $(\eta^5\text{-C}_5\text{H}_5)\text{M}(\text{CO})_x(\eta^1\text{-}N\text{-maleimidato})$  ( $\text{M} = \text{Fe}$ ,  $x = 2$ ;  $\text{M} = \text{W}$ ,  $x = 3$ ) complexes react with propargylamine and propargyl alcohol giving products from the Michael addition to the  $\eta^1\text{-}N\text{-maleimidato}$  ligand. Metallocarbonyl compounds bearing a terminal alkyne group were reacted with organic azides affording corresponding 1,2,3-triazoles in high yields. One of these metallocarbonyl 1,2,3-triazoles ( $\text{M} = \text{Fe}$ ,  $x = 2$ ) was characterized by X-ray diffraction.

**Key words:** copper(I)-catalyzed azide-alkyne cycloaddition, click chemistry, metallocarbonyl complexes, X-ray structure.

**Résumé :** Les complexes  $(\eta^5\text{-C}_5\text{H}_5)\text{M}(\text{CO})_x(\eta^1\text{-}N\text{-maléimidato})$  ( $\text{M} = \text{Fe}$ ,  $x = 2$ ;  $\text{M} = \text{W}$ ,  $x = 3$ ) réagissent avec la propargylamine et l'alcool propargylique pour conduire à la formation de produits d'addition de Michael sur le ligand  $\eta^1\text{-}N\text{-maléimidato}$ . La réaction de composés métallcarbonyles portant un groupe alcyne terminal avec des azotures organiques conduit à la formation des 1,2,3-triazoles correspondants avec des rendements élevés. Faisant appel à la diffraction des rayons-X, on a caractérisé le métallcarbonyl-1,2,3-triazole dans lequel  $\text{M} = \text{Fe}$  et  $x = 2$ .

**Mots-clés :** cycloaddition azoture-alcyne catalysée par le cuivre(I), chimie de cliquage, complexes métallcarbonyles, structure, diffraction des rayons X.

## Introduction

The copper(I) catalyzed, regioselective synthesis of 1,4-disubstituted-1,2,3-triazoles, from azides and terminal alkynes, which was developed by Sharpless et al., has been shown to be amongst the most popular reactions recently studied, known as "click chemistry"<sup>1-3</sup>. There have been numerous applications of this reaction in the fields of bioconjugation, materials science, and drug discovery.<sup>4-7</sup> Copper(I)-catalyzed azide-alkyne cycloaddition (CuAAC) has been used to obtain conjugates which possess numerous functional subunits with fluorescent or electrochemical properties.<sup>8,9</sup> However, this methodology has not yet been applied to connecting metallocarbonyl complexes with organic ligands. In view of this situation, I became interested in exploring the CuAAC reaction as a synthetic method for preparing 1,4-disubstituted-1,2,3-triazoles bearing IR-detectable metallocarbonyl complexes.<sup>10</sup> Over the past years we have explored the chemistry of the metallocarbonyl  $(\eta^5\text{-C}_5\text{H}_5)\text{M}(\text{CO})_x(\eta^1\text{-}N\text{-maleimidato})$  complexes of Fe, **1**, and W, **2**,<sup>11,12</sup> which were applied as labels of peptides and proteins, with potential applications in immunoassay analysis.<sup>12-16</sup>

It appeared of interest to introduce a terminal alkyne group to compounds **1** or **2** to form metallocarbonyl complexes that would be able to react with organic azides. Such a process could be an entry to new selective labeling of biomolecules, using the CuAAC reaction. In this paper, I report the synthesis of two new metallocarbonyl complexes bearing terminal alkyne ligands, **3** and **4**, and a preliminary study of their reactions with organic azide derivatives in the presence of a Cu(I) catalyst. The structure of the 1,3-cycloaddition product, **5**, has been established by a single crystal X-ray analysis.

## Results and discussion

The Huisgen 1,3-cycloaddition of organic azides and alkynes has been shown to be the most direct route to obtaining 1,2,3-triazoles. The use of Cu(I) complexes in this process led to the formation of one regioisomer, a 1,4-disubstituted 1,2,3-triazole derivative. Cu(I) halide salts can also be used, or, alternatively, the Cu(I) complex could be generated in situ by the reduction of Cu(II) salts.<sup>1-3</sup> The reaction could be performed in various solvents or mixtures of organic solvents, or in water. Owing to the high regioselectivity, high yields, and an exceptional tolerance towards a wide range of functional groups and reaction conditions, the copper(I)-catalyzed azide-alkyne cycloaddition has been found to have numerous applications in biochemistry research, allowing the regioselective incorporation of various labels to biomolecules.<sup>17-20</sup>

**B. Rudolf.** Department of Organic Chemistry, University of Łódź, Tamka 12, Łódź 91-403, Poland.  
(e-mail: brudolf@chemia.uni.lodz.pl).

There has been no reported research concerning the Huisgen 1,3-cycloaddition of metallocarbonyl complexes in the literature, to my knowledge; however, there were several published examples of ferrocene compounds bearing azide or alkyne groups, which underwent the CuAAC reactions leading to the expected triazole products.<sup>21–25</sup> To investigate the CuAAC reaction of metallocarbonyl complexes with azides, it was first necessary to synthesize such complexes, bearing an alkyne group.

Because complex **1** reacted with primary amines at pH 9–10 providing aza-Michael addition products,<sup>13</sup> the reaction with propargylamine seemed a straightforward synthetic approach for the introduction of the terminal alkyne function to this complex (eq. [1])

The reaction was carried out at room temperature in MeOH–H<sub>2</sub>O, and afforded a yellow crystalline product. The <sup>1</sup>H NMR spectrum confirmed the structure of **3**, with the signal at 6.68 ppm, characteristic of the ethylenic protons in **1**, being absent, while the complex signals attributed to the succinimide ring and the propargyl protons were observed at 2.42, 3.33, and 3.83, including the acetylene proton signal, which appeared at 2.09 ppm, as a triplet.

Since it was reported that maleimide derivatives undergo an oxa-Michael addition reaction with alcohols in the presence of K<sub>2</sub>CO<sub>3</sub> under mild reaction conditions,<sup>26</sup> I decided to react **2** with propargyl alcohol, to give **4** (eq. [2]). This reaction resulted in the isolation of a yellow crystalline complex, whose <sup>1</sup>H NMR spectrum confirmed the structure as **4** (Yield 42%)

The <sup>1</sup>H NMR spectrum showed a triplet at 2.48 ppm, which was expected for the alkyne proton, with an absence of the singlet at ~6.7 ppm, characteristic for the olefinic protons in the substrate, **2**. Further evidence of the oxa-Michael addition to the maleimide double bond were the signals of the succinimide protons at 2.66, 3.03, and 4.48 ppm.

Metallocarbonyl complexes, **3** and **4**, displayed the characteristic strong absorption bands in their IR spectra, the ν<sub>C≡O</sub> appearing in the 1950–2060 cm<sup>–1</sup> spectral region, which is usually free of any absorption of biomolecules or biological matrices.

With the successful synthesis of complexes **3** and **4**, their reactivity towards organic azides in the presence of a CuCl–Cu catalyst were investigated. Both compounds were allowed to react with *p*-nitrophenyl azide, and complex **3** was also reacted with (phenylthio)methyl azide. In all cases, the cycloaddition reaction took place, and the expected triazoles, **5–7**, were isolated in 81%–88% yields (eqs. [3] and [4]).

The yellow products, **5** and **6**, were isolated by flash chromatography and crystallized from CH<sub>2</sub>Cl<sub>2</sub>–heptane. The identity and purity of these compounds were confirmed by spectroscopic methods and elemental analyses. The singlets in the <sup>1</sup>H NMR spectra of **5** and **6** (δ 8.06 and 7.51 ppm, respectively) were attributed to the triazole ring protons, and provided evidence of the formation of this heterocyclic ring. The structure of 1,2,3-triazole **5** was also confirmed by single crystal X-ray diffraction (vide infra).

The 1,2,3-triazole, **7**, was synthesized in the same manner from alkyne complex **4** and *p*-nitrophenyl azide in the presence of the CuCl–Cu catalyst (eq. [4]). The expected product was isolated in 81% yield, as an orange oil. The lack of an alkyne proton signal and the appearance of a singlet at δ 8.19 ppm in its <sup>1</sup>H NMR spectrum provided evidence of the formation of a 1,2,3-triazole derivative.

### The X-ray crystal structure of **5**

Crystals of **5** suitable for X-ray structure determination were grown from CH<sub>2</sub>Cl<sub>2</sub>–heptane. Compound **5** crystallized in the triclinic *P*1 space group (see Fig. 1 for the graphical representation). The selected crystal data and structure refinement details are shown in Table 1. The triazole *p*-nitrophenyl substituent was shown to be attached to the succinimide ring in a position opposite to the Fp moiety. The best plane of the succinimide ring forms an angle of 44.02(19)° with the best plane of the Cp ring. The succinimide ring was nearly coplanar with the triazole and *p*-nitrophenyl rings. This was shown by the relatively small values of the dihedral angles, being 9.00(19)° and 15.87(18)° for the triazole and phenyl rings, respectively. The triazole and phenyl rings were found to be coplanar, with the dihedral angle being 8.61(12)°. No classical hydrogen bonds were found for this compound; however, the crystal structure of **5** was stabilized by several weak intermolecular, non-covalent interactions of the C–H...O type.

Selected bond lengths (Å) and angles (°) are gathered in Table 2.

### Conclusions

The metallocarbonyl complexes **3** and **4**, with terminal alkyne bonds, have been synthesized, and found to be effective CuAAC reaction substrates. Under the Sharpless conditions, the alkynes **3** and **4** effectively reacted with selected organic azides, affording the corresponding 1,2,3-triazoles in high yields. We plan to use this technique to develop new bioprobes for Carbonyl Metallo Immuno Assay (CMIA).

## Experimental section

### General remarks

The <sup>1</sup>H NMR spectra were recorded in CDCl<sub>3</sub> on a Varian Gemini 200BB (200 MHz for <sup>1</sup>H) spectrometer and referenced to internal tetramethylsilane. The IR spectra were recorded in CHCl<sub>3</sub> on a FTIR NEXUS (Thermo Nicolet) spectrometer. Elemental analyses were performed by the Analytical Services of the Center of Molecular and Macromolecular Studies of the Polish Academy of the Sciences (Łódź). All solvents were purified according to standard procedures. Chromatographic separations were performed on Silica gel Merck 60 (230–400 mesh ASTM). All reactions were carried out under argon.

### Materials

Complexes **1** and **2** were synthesized as previously described.<sup>11,12</sup> Propargylamine, propargyl alcohol, and (phenylthio)methyl azide were purchased from Sigma-Aldrich. Propargyl alcohol and propargylamine were distilled before

use. *p*-Nitrophenyl azide was synthesized according to Meudtner and al.<sup>27</sup>

### Synthesis of 3

Propargylamine (20  $\mu$ L, 0.37 mmol) and aqueous solution of  $K_2CO_3$  pH 9–10 (2 mL) were added to an argon-saturated solution of complex **1** (100 mg, 0.37 mmol) in MeOH (3 mL) and the reaction mixture was stirred overnight at rt. After this time the mixture was diluted with water (15 mL) and extracted with  $CH_2Cl_2$  ( $3 \times 15$  mL). The organic phases were combined, dried over  $MgSO_4$ , and concentrated under reduced pressure. The residue was subjected to column chromatography; a yellow band containing the starting material **1** was eluted with dichloromethane, followed by a yellow band containing product **3** eluted with chloroform–MeOH (9:1). Crystallization from  $CH_2Cl_2$ –heptane (3:1) gave an analytically pure sample; yield: 57 mg (47%). IR  $\nu$  ( $cm^{-1}$ ): 3290 (CH alkyne), 2103 ( $C\equiv C$ ), 2056, 2009 ( $C\equiv O$ ), 1639 (CO imide).  $^1H$  NMR (200 MHz,  $CDCl_3$ )  $\delta$  (ppm): 2.09 (t,  $J = 1.4$  Hz, H, CH, alkyne), 2.42 (dd,  $J = 5.1$  Hz,  $J = 16$  Hz, H, succinimide), 2.83 (dd,  $J = 7.9$  Hz,  $J = 16$  Hz, H, succinimide), 3.33 (d,  $J = 17$  Hz, H,  $CH_2$ ), 3.58 (d,  $J = 17$  Hz, H,  $CH_2$ ), 3.83 (dd,  $J = 5.1$  Hz,  $J = 16$  Hz, H, succinimide), 5.04 (s, 5H, Cp). Anal. calcd. for  $C_{14}H_{12}FeN_2O_4$ : C 54.24, H 3.66, N 8.54; found C 51.42, H 3.61, N 8.49.

### Synthesis of 4

Tungsten complex **2** (120 mg, 0.29 mmol) was dissolved in propargyl alcohol (3 mL) and a saturated aqueous solution of  $K_2CO_3$  (2 mL) was added. Then the reaction mixture was stirred overnight at rt. After this time, the mixture was diluted with water (15 mL) and extracted with  $CH_2Cl_2$  ( $3 \times 15$  mL). The organic phases were combined, dried over  $MgSO_4$ , and concentrated at reduced pressure. The residue was subjected to column chromatography; an orange band containing the starting material **2** was eluted with hexane–dichloromethane (1:4), followed by a yellow band containing product **4** eluted by the mixture of dichloromethane–MeOH 19:1. Crystallization from  $CH_2Cl_2$ –heptane (3:1) gave an analytically pure sample; yield: 59 mg (42%). IR  $\nu$  ( $cm^{-1}$ ): 3307 (CH alkyne), 2100 ( $C\equiv C$ ), 2056, 2046, 1959 ( $C\equiv O$ ), 1655 (CO imide).  $^1H$  NMR (200 MHz,  $CDCl_3$ )  $\delta$  (ppm): 2.48 (t,  $J = 2.4$  Hz, H, CH alkyne), 2.66 (dd,  $J = 4.6$  Hz,  $J = 20$  Hz, H, succinimide), 3.03 (dd,  $J = 9.2$  Hz,  $J = 16$  Hz, H, succinimide), 4.48 (dd,  $J = 4.6$  Hz,  $J = 20$  Hz, H, succinimide), 4.53 (t, 2H,  $CH_2$ ,  $J = 4$  Hz, H,  $CH_2$ ), 5.64 (s, 5H, Cp). Anal. calcd. for  $C_{15}H_{11}NO_6W$ : C 37.14, H 2.29, N 2.89; found C 37.25, H 2.47, N 2.89.

### Synthesis of metallocarbonyl 1,2,3-triazoles 5–7

A typical procedure for the 1,3-dipolar cycloaddition of organic azides to metallocarbonyl alkynes was as follows: azide (0.11 mmol),  $CuCl$  (2 mg), and  $Cu$  (50 mg as thin wire) were added to a solution of **3** or **4** (0.11 mmol) in the mixture of  $H_2O$ –*tert*-butanol (1:1). Then the reaction mixture was stirred overnight. The resulting solution was filtered and concentrated under reduced pressure. The residue was diluted in  $CH_2Cl_2$  and crude product was chromatographed on silica gel, using the mixture of  $MeOH$ – $CH_2Cl_2$  (1:19) as eluent to obtain compounds **5**–**7**. Crystallization

from  $CH_2Cl_2$ –heptane (2:1) gave an analytically pure sample.

**5** Yield: 45 mg (84%). IR  $\nu$  ( $cm^{-1}$ ): 2045, 1999 ( $C\equiv O$ ), 1636 (CO imide), 1525, 1343 ( $NO_2$ ).  $^1H$  NMR (200 MHz,  $CDCl_3$ )  $\delta$  (ppm): 2.45 (dd,  $J = 5$  Hz,  $J = 16$  Hz, H, succinimide), 2.85 (dd,  $J = 8.2$  Hz,  $J = 16$  Hz, H, succinimide), 3.72 (dd,  $J = 5$  Hz,  $J = 8$  Hz, H, succinimide), 4.06 (s, 2H,  $CH_2$ ), 5.04 (s, 5H, Cp), 7.97 (d,  $J = 9.1$  Hz, 2H), 8.06 (s, triazole H), 8.41 (d,  $J = 9.1$  Hz, 2H). Anal. calcd. for  $C_{20}H_{16}FeN_6O_6$ : C 48.80, H 3.28, N 17.07; found: C 48.69, H 3.41, N 16.89.

**6** Yield: 47 mg (88%). IR  $\nu$  ( $cm^{-1}$ ): 2044, 1993 ( $C\equiv O$ ), 1636 (CO imide).  $^1H$  NMR (200 MHz,  $CDCl_3$ )  $\delta$  (ppm): 2.38 (dd,  $J = 5$  Hz,  $J = 18$  Hz, H, succinimide), 2.79 (dd,  $J = 8$  Hz,  $J = 16$  Hz, H, succinimide), 3.60 (dd,  $J = 5$  Hz,  $J = 8$  Hz, H, succinimide), 3.91 (s, 2H,  $CH_2$ ), 5.03 (s, 5H, Cp), 5.61 (s,  $CH_2$ , H), 7.31 (s, 5H), 7.51 (s, triazole H). Anal. calcd. for  $C_{21}H_{19}FeN_5O_4$ : C 51.13, H 3.88, N 14.20; found C 50.98, H 4.17, N 14.23.

**7** Yield: 58 mg 81%. IR  $\nu$  ( $cm^{-1}$ ): 2037, 1932 ( $C\equiv O$ ), 1636 (CO imide).  $^1H$  NMR (200 MHz,  $CDCl_3$ )  $\delta$  (ppm): 2.66 (dd,  $J = 4.8$  Hz,  $J = 18$  Hz, H, succinimide), 3.04 (dd,  $J = 8.3$  Hz,  $J = 20$  Hz, H, succinimide), 4.44 (dd,  $J = 4.8$  Hz,  $J = 8$  Hz, H, succinimide), 5.07 (dd,  $J = 12.5$  Hz, 2H,  $CH_2$ ), 5.64 (s, 5H, Cp), 7.98 (d,  $J = 9$  Hz, 2H), 8.19 (s, H, =CH), 8.43 (d,  $J = 9$  Hz, 2H), 8.06 (s, triazole H). ESI-MS ( $M+Na$ )  $m/z = 672$ . Anal. calcd. for  $C_{21}H_{15}N_5O_8W$ : C 38.85, H 2.33, N 10.79; found C 39.05, H 2.28.

### X-ray structure determination of 5

Single-crystal X-ray measurement of **5** was performed on a BRUKER APEX II ULTRAK-axis diffractometer with a TXS rotating anode using  $MoK\alpha$  radiation at 293 K. The data were collected using the omega scan measurement method, with 0.5 degrees scan width and 30s maximal counting time. The  $\theta$  angle for data collection was varied in the range of 5.00–20.00°. The data were corrected with respect to Lorentz and polarization effects. An analytical absorption correction was applied using SADABS.<sup>28</sup> Indexing, integration, and scaling were performed with original Bruker Apex II software.<sup>29</sup> The structure was solved using direct methods and refined using SHELXL.<sup>30</sup> The refinement was based on  $F^2$  for all reflections. Weighted  $R$  factors  $wR$  and all goodness-of-fit  $S$  values were based on  $F^2$ . All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were refined on idealized positions using a riding model.

# Reactions of toluquinone–cyclopentadiene Diels–Alder epoxide adducts with nucleophiles under heterogeneous conditions

Andreas A. von Richthofen, José E. P. Cardoso Filho, Liliana Marzorati, Julio Zukerman-Schpector, Edward R.T. Tiepink, and Claudio Di Vitta

**Abstract:** Toluquinone–cyclopentadiene Diels–Alder epoxide adducts react with sulfur and oxygen nucleophiles under heterogeneous conditions, leading to products resulting from the epoxide ring opening and from skeletal rearrangement, respectively. Pyrolysis of the sulfanyl adducts gave the new 3-sulfanyltoluquinones (**1**).

**Key words:** toluquinone, phase-transfer catalysis (PTC) conditions, thiolation, epoxide, Diels–Alder.

**Résumé :** Les époxydes des adduits de Diels–Alder de la toluquinone et du cyclopentadiène réagissent avec des nucléophiles sulfurés et oxygénés, dans des conditions hétérogènes pour conduire respectivement à des produits résultats d'une ouverture de l'époxyde et d'une transposition du squelette. La pyrolyse des adduits sulfanyles conduit aux nouvelles 3-sulfanyltoluquinones (**1**).

**Mots-clés :** toluquinone, conditions de transfert catalytique de phase (TCP), époxyde, Diels–Alder.

[Traduit par la Rédaction]

## Introduction

Quinones occur widely in nature as important components of organisms.<sup>1</sup> Natural and synthetic quinone-based compounds are frequently used for therapeutic purposes such as antitumor and anti-infection agents.<sup>2</sup> In particular, benzoquinone thioethers possess a variety of biological and toxicological activities.<sup>3</sup> In the case of 3-sulfanyltoluquinones (**1**) (Fig. 1), it should be mentioned that, although Karrer and Dutta<sup>4</sup> had described the synthesis of the methylsulfanyl derivative **1** (X = SCH<sub>3</sub>), by reacting *p*-toluquinone with methanethiol in water, McHale et al.,<sup>5</sup> after trying to reproduce Karrer and Dutta's work, concluded that the product formed under these conditions was 6-methylsulfanyltoluquinone instead of **1** (X = SCH<sub>3</sub>).

Therefore, we decided to synthesize **1** (X = SR or SAr) according to the route depicted in Scheme 1, which is based on the pyrolysis of adducts **2**.<sup>6</sup> Such adducts could be prepared by selective cycloaddition at the unsubstituted C=C double bond of **3**, followed by bromine/SR exchange.

However, in view of the described low yields of 3-bromo-toluquinone (**3**),<sup>7</sup> we considered an alternative route for adducts **2**, based on the ring opening of epoxides **4** (Scheme 2).

Although the successful ring opening of epoxides **4** (R = R' = H) was described<sup>8</sup> for 1-phenyl-5-mercaptopotetrazole (HPMT) as nucleophile in the presence of catalytic amounts

Fig. 1. 2-Alkylsulfanyl- and arylsulfanyl-toluquinones (**1**).

**1**; X = SR or SAr

of Et<sub>3</sub>N, leading to adduct **2** (R = R' = H; X = PMT), the use of a stoichiometric mixture of Et<sub>3</sub>N and thiols like HPMT, 2-mercaptobenzothiazole (HMBT), and *p*-toluenethiol (HPTT) gave the aromatized substituted adducts **5** in yields ranging from 41% to 50% (Scheme 3) as the result of the action of the base on the  $\alpha$ -carbonyl hydrogens of **2** (R = R' = H; X = SAr). Aromatization was also observed when the epoxide **4** (R = R' = H) was treated with sodium ethylsulfide in EtOH.<sup>9</sup>

Considering the successful use of phase-transfer catalysis (PTC) conditions in suppressing the aromatization reaction, as described by Ferreira et al.,<sup>10</sup> for the substitution of the chlorine atoms of **6** by methylsulfide anion (Scheme 4), we

**Scheme 1.** Proposed synthesis of **1**.**Scheme 2.** Proposed alternative synthesis of adducts **2**.

reasoned that we could successfully apply this methodology to the route depicted in Scheme 2 to avoid the aromatization of **2**.

## Results and discussion

Accordingly, epoxide **4** ( $R = R' = H$ ) was dissolved in benzene and submitted to the reaction with an aqueous solution of methanethiol and sodium hydroxide, using tetrabutylammonium hydrogensulfate (TBAHS) as catalyst.<sup>11</sup> By monitoring the reaction by TLC, and after complete consumption of the starting epoxide **4** ( $R = R' = H$ ), three products were formed, two of them had similar retention factors. All these products were easily isolated by chromatography. The minor product (10% yield) was identified by NMR spectroscopy as the desired sulfurated adduct **2** ( $R = R' = H$ ;  $X = SCH_3$ ). The  $^1H$  NMR spectra of the two major products were consistent with the isomeric bis-sulfanylated adducts **7** (30% yield) and **8** (15% yield) (Fig. 2). In the case of the major product, a single crystal was also obtained,<sup>12</sup> allowing for the unequivocal determination of the cis-endo structure **7** for this compound (Fig. 3). Owing to the similarity of the spectroscopic data for compounds **7** and **8**, the same kind of cis-endo structure can be proposed for the latter adduct.

Although under PTC conditions the aromatization side reaction could be completely suppressed, the selective formation of the sulfanylated product **2** could not be achieved. However, by using  $HSCH_3$  and a less basic PTC condition ( $K_2CO_3$ /benzene/TBAHS), the formation of bis-sulfanylated products was completely avoided and the desired mono-sulfanylated adduct **2** ( $R = R' = H$ ;  $X = SCH_3$ ) was isolated in 21% yield. Unfortunately, a considerable amount of **5** ( $X = SCH_3$ ; 24% yield) was also obtained.<sup>13</sup> As for other thiols, when benzenethiol was employed as nucleophile in the benzene/NaOH/ $H_2O$  system, the mono-sulfanylated adduct **2** ( $R = R' = H$ ;  $X = SC_6H_5$ ) was the sole product and could be isolated in 81% yield. Under such conditions, the  $C_6H_5S^-$  nucleophile was also selective in the oxirane ring opening of other similar epoxides **4** ( $R = H$ ;  $R' = CH_3$  or  $R = CH_3$ ;  $R' = H$ ), leading exclusively to the mono-sulfanylated adducts **2** ( $R = H$ ;  $R' = CH_3$ ;  $X = SC_6H_5$  in 61% yield, and  $R = CH_3$ ;  $R' = H$ ;  $X = SC_6H_5$  in 40% yield).

Considering that the formation of the bis-sulfanylated adducts **7** and **8**, obtained by using the  $HSCH_3$ /benzene/NaOH/ $H_2O$  system, could arise from the sulfanylation of the two possible enolic forms of adduct **2**<sup>14</sup> ( $R = R' = H$ ;  $X = SCH_3$ ), we performed the same reaction under more controlled conditions, avoiding the presence of oxygen to minimize the oxidation of methanethiol to methyl disulfide, which could act as electrophile in the sulfanylation reaction<sup>15</sup> of **2** ( $R = R' = H$ ;  $X = SCH_3$ ). However, even after careful degassing of the employed solvents and the reaction apparatus, adducts **7** and **8** were still produced in comparable yields. Thus, due to the low concentration of the sulfanylation agent ( $CH_3SSCH_3$ , as electrophile) present in the reaction medium,<sup>16</sup> the formation of compounds **7** and **8** via the mechanism depicted in Scheme 5, involving the thiolation process of the intermediate benzoquinone **9**, was suggested. To test this hypothesis, **9** was prepared in 94% yield by oxidation of **5** ( $X = SCH_3$ ) using  $Fe^{3+}$ .<sup>17</sup> Under the heterogeneous conditions used for the thiolation of epoxides **2**, quinone **9** reacted rapidly yielding compounds **7** and **8**, although in a 1:1 ratio, in contrast to the observed 2:1 ratio for the same reaction performed with **2** or **4**.<sup>18</sup>

Having in hands the mono-sulfanylated adducts **2** ( $R = R' = H$ ;  $X = SCH_3$  or  $SC_6H_5$ ), they were heated under vacuum, yielding the corresponding new toluquinones **1** ( $X = SCH_3$  in 80% yield;  $SC_6H_5$  in 25% yield).

In an attempt to explore the use of the heterogeneous condition for the reaction of **4** ( $R = R' = H$ ) with other nucleophiles, this compound was submitted to the reaction with methoxide ion in the biphasic system (benzene/ $H_2O$ ). A colourless solid was obtained in 51% yield for which the presence of a methoxy group incorporated to the structure of the product was evidenced by a singlet at 3.41 ppm in the  $^1H$  NMR spectrum. However, the lack of signals corresponding to the norbornene hydrogens led us to the conclusion that the reaction promoted a structural change also at that moiety of **4** ( $R = R' = H$ ). The absence of the characteristic pale yellow colour of toluquinone–cyclopentadiene Diels–Alder adducts indicated the lack of conjugation between the carbonyl groups and the  $C=C$  double bond, suggesting that one of the carbonyl groups was no longer present. Accordingly, the  $^{13}C$  NMR spectrum for the product revealed the presence of only one  $C=O$  group and two olefinic carbons, thus confirming the absence of the norbornene system. On the other hand, the counting of 13 carbons was consistent with a product resulting from the incorporation of a methoxy group to the epoxide **4** ( $R = R' = H$ ). Additionally, the summing of 14 hydrogens by integration of the  $^1H$  NMR spectrum was in agreement with this addition of a methoxide anion, and the same conclusion emerged from the elemental composition of the product for which the minimal formulae

**Scheme 3.** Reactions of epoxides **4** with nucleophiles under homogeneous conditions.**Scheme 4.** Substitution of chlorine atoms of **6** under PTC conditions.**Fig. 2.** Bis-sulfanylated products formed by reaction of **4** ( $R=R'=H$ ) with  $HSCH_3$ /benzene/ $NaOH/H_2O$ .**Fig. 3.** X-ray crystal structure of compound **7** showing atom labeling and displacement ellipsoids at the 50% probability level (arbitrary spheres for the H atoms).

$C_{13}H_{14}O_3$  could be determined. For this compound, structure **10** (Fig. 4) emerged after a single-crystal X-ray analysis. Crystallographic data are summarized in Table 1.

At this point, it is worth mentioning the remarkable capability of the heterogeneous conditions in changing the reactivity of the methoxide ion in comparison to the homogeneous system. In this sense, in contrast to our result for the reaction between **4** ( $R=R'=H$ ) and sodium ethoxide in ethanol, a Favorskii-type ring contraction was described by Herz et al.<sup>19</sup> Our proposal for the formation of **10** is depicted in Scheme 6. The initial step is in accordance

**Fig. 4.** Molecular structure and X-ray crystal structure of compound **10** showing atom labeling and displacement ellipsoids at the 50% probability level (arbitrary spheres for the H atoms).

with the Loftfield mechanism for the Favorskii rearrangement,<sup>20</sup> giving an intermediate resulting from displacement of an oxirane bond by the enolate of C8a. However, in the second step under heterogeneous conditions, attack of methoxide ion occurs on C4 of the protonated intermediate, leading to compound **10** instead of the cyclopropanone ring opening by attack at C1.

It should be mentioned that no reaction was observed employing nitrogen nucleophiles like  $H_2NCH_3$ ,  $HN(CH_3)_2$ , or aniline under the same heterogeneous conditions.

## Conclusion

For the reactions of **4** with  $^-SCH_3$ , the two-phase system

**Scheme 5.** Proposed mechanism for the formation of **7** and **8** under heterogeneous condition.**Scheme 6.** Proposed mechanism for the formation of **10** under heterogeneous condition.

can suppress the aromatization process. The use of sodium methoxide as nucleophile under similar conditions led to the product with the conspicuous strained structure **10**, with complete suppression of the Favorskii-type ring contraction reaction.

The present work reports also the first unequivocal synthesis of 3-sulfanyltoluquinones (**1**; X = SCH<sub>3</sub> or SC<sub>6</sub>H<sub>5</sub>).

## Experimental

### Methods and materials

Melting points were determined on a Koffler micro hot stage and are uncorrected. NMR spectra were recorded with a Bruker AC 200 or a Varian INOVA 300 spectrometers against Me<sub>4</sub>Si (for <sup>1</sup>H NMR) or the central line of the solvent signal (CDCl<sub>3</sub> triplet at 77.0 ppm, for <sup>13</sup>C NMR). TLC and dry-flash chromatography were carried out on Merck silica gel. All reagents and solvents were used as received from commercial suppliers. Epoxides **4** (R = R' = H or R = H; R' = CH<sub>3</sub> or R = CH<sub>3</sub>; R' = H) were prepared according to literature procedures.<sup>21</sup>

### X-ray crystallography for compound **10**

A single crystal suitable for X-ray crystallographic analysis was obtained from a slow evaporation of a methanol solution (see Supplementary data section). Intensity data were measured at 153 K on a Rigaku AFC12κ/SATURN724 diffractometer fitted with Mo Kα radiation (λ = 0.71073 Å). Data processing and absorption corrections were accomplished with CrystalClear and ABSCOR,<sup>22</sup> respectively. Details of cell data, X-ray data collection, and structure refinement are given in Table 1. The structures were solved by direct-methods.<sup>23</sup> Full-matrix least-squares refinement on F<sup>2</sup> with anisotropic thermal parameters for all non-hydrogen atoms was performed.<sup>24</sup> H atoms were placed on stereochemical grounds and refined with fixed geometry, each riding on a carrier atom with an isotropic displacement parameter amounting to 1.2 times (1.5 for methyl-H) the value of the equivalent isotropic displacement parameter of the respective carrier atom. A weighing scheme of the form

$$w = 1/[\sigma^2(F_o^2) + (0.0429P)^2 + 0.534P] \text{ where } P = (F_o^2 + 2F_c^2)/3 \text{ was introduced in each case.}^{24}$$

### Reaction of **4** with nucleophiles

#### Using thiols in a liquid–liquid system — General procedure

A mixture of epoxide **4** (1.0 mmol), benzene (14 mL), aqueous sodium hydroxide (0.35 mol/L; 14 mL), and thiol (10 mmol) was vigorously stirred at room temperature until complete consumption of the epoxide, as indicated by TLC. For CH<sub>3</sub>SH, the reaction flask was equipped with a dry-ice cold finger, and the mixture was saturated with the thiol. The organic layer was separated and the aqueous layer was extracted with CH<sub>2</sub>Cl<sub>2</sub>. The combined organic extracts were washed twice with water, dried over anhydrous MgSO<sub>4</sub>, and concentrated under vacuum. The crude product was submitted to dry-flash chromatography using a gradient of *n*-hexane/ethyl acetate as eluant.

Elemental analysis (%) (C<sub>19</sub>H<sub>18</sub>SO<sub>2</sub>) calcd.: C 73.5, H 5.8; found: C 73.8, H 6.2.

**Adduct 7** was isolated as a yellow solid. Mp 69–72 °C.  $\delta_{\text{H}}$  (300 MHz, CDCl<sub>3</sub>, Me<sub>4</sub>Si): 1.62 (dt, 1H, *J*<sub>1</sub> = 8.9 Hz; *J*<sub>2</sub> = 1.7 Hz), 1.97 (s, 3H), 2.01–2.06 (m, 1H), 2.11 (s, 3H), 2.46 (s, 3H), 2.86 (d, 1H, *J* = 3.9 Hz), 3.37 (br s, 1H), 3.51 (br s, 1H), 6.08–6.17 (m, 2H).  $\delta_{\text{C}}$  (75 MHz, CDCl<sub>3</sub>, Me<sub>4</sub>Si): 12.8, 14.0, 14.9, 15.2, 45.0, 45.8, 46.0, 46.2, 57.7, 59.6, 134.4, 137.5 (2C), 142.9, 154.2, 184.8, 193.0. Elemental analysis (%) (C<sub>14</sub>H<sub>16</sub>S<sub>2</sub>O<sub>2</sub>) calcd.: C 60.0, H 5.7; found: C 60.7; H 6.0.

**Adduct 8** was isolated as a yellow solid. Mp 75–76 °C.  $\delta_{\text{H}}$  (300 MHz, CDCl<sub>3</sub>, Me<sub>4</sub>Si): 1.63 (dt, 1H, *J*<sub>1</sub> = 9.0 Hz; *J*<sub>2</sub> = 1.9 Hz), 2.04 (br d, 1H, *J* = 9.1 Hz), 2.07 (s, 3H), 2.11 (s, 3H), 2.43 (s, 3H), 2.89 (d, 1H, *J* = 3.9 Hz), 3.35 (br s, 1H), 3.50 (br s, 1H), 6.05 (dd, 1H, *J*<sub>1</sub> = 6.0 Hz; *J*<sub>2</sub> = 3.0 Hz), 6.15 (dd, 1H, *J*<sub>1</sub> = 6.0 Hz; *J*<sub>2</sub> = 3.0 Hz).

#### Using CH<sub>3</sub>SH in a solid–liquid system

A mixture of epoxide **4** (**R** = **R'** = H; 1.0 mmol), benzene

(15 mL), TBAHS (0.030 mmol), and solid anhydrous potassium carbonate (10 mmol) was saturated with methanethiol in a reaction flask equipped with a dry-ice cold finger. The mixture was vigorously stirred at room temperature for 2 h.<sup>12</sup> Water (15 mL) was added and the organic layer was separated. The aqueous phase was extracted with CH<sub>2</sub>Cl<sub>2</sub> (3 × 15 mL), and the combined organic extracts were dried over anhydrous MgSO<sub>4</sub> and concentrated under vacuum. The crude product was submitted to dry-flash chromatography.

Aromatic **5** (**X** = SCH<sub>3</sub>) was isolated as a white solid. Mp 121–123 °C after dry-flash chromatography separation using, as eluant, a gradient of *n*-hexane/acetone.  $\delta_{\text{H}}$  (200 MHz, CDCl<sub>3</sub>, Me<sub>4</sub>Si): 2.12–2.26 (m, 2H), 2.15 (s, 3H), 2.41 (s, 3H), 4.06 (br s, 1H), 4.17 (br s, 1H), 6.73 (dd, 1H, *J*<sub>1</sub> = 5.1 Hz; *J*<sub>2</sub> = 2.9 Hz), 6.84 (dd, 1H, *J*<sub>1</sub> = 5.1 Hz; *J*<sub>2</sub> = 2.9 Hz).  $\delta_{\text{C}}$  (75 MHz, CDCl<sub>3</sub>, Me<sub>4</sub>Si): 14.1, 18.7, 46.7, 47.2, 69.2, 117.7, 126.3, 133.2, 139.6, 141.6, 142.0, 143.2, 144.8. Elemental analysis (%) (C<sub>13</sub>H<sub>14</sub>O<sub>2</sub>S) calcd.: C 66.6, H 6.0; found: C 66.9, H 6.1.

#### Using CH<sub>3</sub>OH in a liquid–liquid system

A mixture of epoxide **4** (**R** = **R'** = H; 0.75 mmol), benzene (10 mL), water (11 mL), and sodium methoxide (8.3 mmol) was vigorously stirred at room temperature until complete consumption of the epoxide, as indicated by TLC. The organic layer was separated and the aqueous layer was extracted with CH<sub>2</sub>Cl<sub>2</sub>. The combined organic extracts were washed twice with water, dried over anhydrous MgSO<sub>4</sub>, and concentrated under vacuum. The crude product was submitted to dry-flash chromatography separation using a gradient of *n*-hexane/ethyl acetate as eluant. Compound **10** was isolated as white crystals. Mp 105–107 °C.  $\delta_{\text{H}}$  (300 MHz, CDCl<sub>3</sub>, Me<sub>4</sub>Si): 1.38 (dd, 1H, *J*<sub>1</sub> = 4.5 Hz; *J*<sub>2</sub> = 1.2 Hz), 1.72 (d, 1H, *J* = 11.9 Hz), 1.78 (d, 1H, *J* = 11.9 Hz), 1.82 (d, 3H, *J* = 1.8 Hz), 2.54 (br d, 1H, *J* = 4.5 Hz), 2.65 (br s,

1H), 2.86 (d, 1H,  $J = 2.1$  Hz), 3.41 (s, 3H), 4.63 (br s, 1H), 6.60 (br s, 1H).  $\delta_C$  (75 MHz,  $CDCl_3$ ,  $Me_4Si$ ): 15.2, 23.5, 27.0, 29.2, 33.3, 40.7, 49.7, 53.3, 85.8, 102.9, 136.7, 140.6, 195.1. Elemental analysis (%) ( $C_{13}H_{14}O_3$ ) calcd.: C 71.5, H 6.5; found: C 71.3, H 6.2.

### Pyrolysis of adduct **2** ( $R = R' = H$ ; $X = SCH_3$ )

Adduct **2** ( $R = R' = H$ ;  $X = SCH_3$ ; 0.25 mmol) was heated under vacuum (0.1 mm Hg) at 200 °C in a Kugelrohr, and 3-methylsulfanyltoluquinone (**1**;  $X = SCH_3$ ; 0.20 mmol) was collected as a red oil.  $\delta_H$  (200 MHz,  $CDCl_3$ ,  $Me_4Si$ ): 2.19 (s, 3H), 2.59 (s, 3H), 6.74 (d, 2H,  $J = 1.2$  Hz).  $\delta_C$  (75 MHz,  $CDCl_3$ ,  $Me_4Si$ ): 14.09, 17.22, 136.31, 137.15, 142.75, 145.02, 183.03, 184.03. Elemental analysis (%) ( $C_8H_8SO_2$ ) calcd.: C 57.1, H 4.8; found: C 56.8, H 4.8.

3-Phenylsulfanyltoluquinone (**1**;  $X = SC_6H_5$ ; 0.070 mmol) was obtained by a process similar to the above described as a red oil, starting from adduct **2** ( $R = R' = H$ ;  $X = SC_6H_5$ ; 0.28 mmol).  $\delta_H$  (200 MHz,  $CDCl_3$ ,  $Me_4Si$ ): 2.21 (s, 3H), 6.78 (s, 2H), 7.29 (m, 5H).  $\delta_C$  (75 MHz,  $CDCl_3$ ,  $Me_4Si$ ): 15.08, 127.44, 129.17, 130.70, 133.56, 136.52, 137.10, 142.98, 146.96, 182.34, 185.18. Elemental analysis (%) ( $C_{13}H_{10}SO_2$ ) calcd.: C 67.8, H 4.4; found: C 67.6, H 4.4.

### Supplementary data

Supplementary data for this article (general methods, instrumentation, preparation, and diffraction data) are available on the journal Web site (canjchem.nrc.ca). CCDC 766956 contains the X-ray data in CIF format for this manuscript. These data can be obtained, free of charge, via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

# Deoxygenation of diarylmethanols with dilute mineral acid

Kyle A. Hope-Ross and John F. Kadla

**Abstract:** A new mild and efficient method for the deoxygenation of diarylmethanols is reported. The reaction employs catalytic hydrochloric acid in ethanol at reflux for 48 h. This reaction works on a variety of diarylmethanol substrates and mitigates the need for expensive and toxic reagents such as stannanes and silanes used in alternative procedures. In addition, this reaction can be used in tandem with the deprotection of acid-sensitive silyl ether protecting groups in a one-pot procedure.

**Key words:** deoxygenation, diarylmethanols, reduction, silyl ether deprotection.

**Résumé :** On rapporte une nouvelle méthode douce et efficace de désoxygénation des diarylméthanol. La réaction fait appel à une quantité catalytique d'acide chlorhydrique, dans l'éthanol au reflux, pendant 48 h. La réaction donne de bons résultats avec une variété de substrats diarylméthanol et elle atténue le besoin pour des réactifs toxiques et dispendieux, tels les stannanes et les silanes utilisés dans des méthodes alternatives. De plus, cette réaction peut être utilisée en tandem avec la déprotection d'éthers silylés sensibles aux acides utilisés comme groupes protecteurs dans des méthodes monotonos.

**Mots-clés :** désoxygénation, diarylméthanol, réduction, déprotection d'éther silylé.

## Introduction

Diarylmethane is a reoccurring structural motif in numerous natural products, including alangifolioside,<sup>1</sup> itoside K,<sup>2</sup> mastigophorene C,<sup>3</sup> and terrestrols F–H<sup>4</sup> (2–4, 5a–5c, Fig. 1).

A possible synthetic route towards these natural products is the deoxygenation of diarylmethanols, which could be achieved in a number of ways, including the Grignard reaction.<sup>5</sup> As such, the deoxygenation of secondary alcohols is an important transformation in synthetic organic chemistry. Unfortunately, few conditions for this transformation, which are both mild and widely applicable, have been reported.

Perhaps the most well-known example is the Barton–McCombie reaction, developed in 1975.<sup>6</sup> In this reaction the alcohol is converted to a thiocarbonyl derivative that, upon treatment with tributylstannane and the radical initiator AIBN (azobisisobutyronitrile), affords the corresponding hydrocarbon.<sup>7</sup> Unfortunately, this reaction involves the homolytic cleavage of the C–O bond, and because of the radical nature of the reaction, this somewhat limits the substrate scope. Additionally, the use of stoichiometric amounts of toxic heavy metals such as tin limits the industrial applications of such reactions.

More recently, variants of this reaction have been reported using silanes<sup>8</sup> or dialkyl phosphites<sup>9</sup> as hydrogen donors, and trialkyl boron–oxygen or peroxides as radical initiators.<sup>10</sup>

For the specific case of diarylmethanols (benzhydrols),

one reported deoxygenation involves treatment of the alcohol with triflic acid followed by triethyl silane.<sup>11</sup>

Herein, we report a new mild and efficient deoxygenation of diaryl methanols to their corresponding diaryl methanes. This method uses dilute mineral acid in ethanol and proceeds without the use of silanes or toxic heavy metals. A variety of substrates were examined, and it was found that the reaction proceeds exclusively for diarylmethanols, but not for the other secondary alcohols examined.

## Experimental

All chemicals were purchased from Sigma-Aldrich and used without further purification unless otherwise noted. Solvents were purchased from Fisher Scientific and used as received. All reactions were monitored by TLC, which was performed on Merck Alumafol 60 Å TLC plates with an UV indicator. Flash chromatography was performed on 60 Å, 70–230 mesh silica gel purchased from Fisher Scientific. <sup>1</sup>H and <sup>13</sup>C NMR spectra were recorded using a 300 MHz Bruker Avance Ultrashield NMR spectrometer (300.13 and 75.03 MHz, respectively) and referenced to CDCl<sub>3</sub> (7.28 ppm). IR spectra were recorded using a PerkinElmer Spectrum One FT-IR spectrometer. Melting points were determined using a Mel-Temp melting point apparatus and are uncorrected. Boiling points were determined using differential scanning calorimetry (DSC) (TA Instruments Q1000) at 101.1 kPa according to ASTM E1782.<sup>12</sup>

**Fig. 1.** Natural products containing the diarylmethane (**1**) moiety: alangifolioside (**2**), itoside K (**3**), mastigophorene C (**4**), and terrestrols F–H (**5a–5c**).

#### General procedure for the attempted deoxygenation of aryl methanols **6**, **7**, and **8**

To a solution of aryl methanol (0.50 g) in ethanol (50 mL) at 0 °C was added concentrated HCl (1.0 mL) as a solution in ethanol. The solutions were heated to reflux for 48–120 h, and the reactions were monitored by TLC (hexanes/ethyl acetate, 3:1). After cooling to room temperature, the reaction mixture was poured into a saturated solution of  $\text{NaHCO}_3$  (25 mL), mixed well, and extracted with  $\text{CH}_2\text{Cl}_2$  ( $2 \times 100$  mL). The combined organics were washed with water (200 mL), dried over  $\text{MgSO}_4$ , filtered, and solvent removed in vacuo to afford the starting materials quantitatively.

1-[4-(*tert*-Butyl-dimethylsiloxy)phenyl]ethanol (**7**) was prepared according to the literature.<sup>13</sup> Yield: 1.38 g, 91%.  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.22 (d,  $J = 8.20$  Hz, 2H), 6.80 (d,  $J = 8.20$  Hz, 2H), 4.82 (m, 1H), 1.76 (s, 1H), 1.47 (d,  $J = 6.28$ , 3H), 0.98 (s, 9H), 0.21 (s, 6H).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CDCl}_3$ )  $\delta$ : 158.82, 138.35, 126.43, 119.86, 70.07, 25.81, 25.11, –4.21.  $^1\text{H}$  NMR and  $^{13}\text{C}$  NMR spectra are in agreement with those previously reported.<sup>13</sup>

#### 4-(1-Hydroxyethyl)phenol (**8**)

To a solution of 1-[4-(*tert*-butyl-dimethylsiloxy)phenyl]ethanol (**7**, 0.50 g, 1.98 mmol) in ethanol (50 mL) at 0 °C was added concd. HCl (1.0 mL) as a solution in ethanol (9.0 mL). The reaction was heated to reflux for 48 h. After

cooling to room temperature, the reaction mixture was poured into a saturated solution of  $\text{NaHCO}_3$  (25 mL), added to water (150 mL), and extracted with  $\text{CH}_2\text{Cl}_2$  ( $3 \times 100$  mL). The combined organics were washed with water (200 mL), dried over  $\text{MgSO}_4$ , filtered, and the solvent removed in vacuo. Crystallization from hexanes afforded **8** as a white powdery solid. Yield: 0.24 g, 90%; mp 136–139 °C (hexanes) (lit.<sup>13</sup> 134–138 °C).  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.27 (d,  $J = 8.28$  Hz, 2H), 6.82 (d,  $J = 8.79$  Hz, 2H), 4.86 (q,  $J = 6.37$  Hz, 1H), 4.82 (s, 1H), 1.72 (s, 1H), 1.53 (d,  $J = 6.38$  Hz, 3H).  $^1\text{H}$  NMR spectrum is in agreement with that previously reported.<sup>13</sup>

#### Diphenylmethanol (**10**)

To a solution of benzophenone (2.50 g, 13.72 mmol) in freshly distilled THF (50 mL) was added sodium borohydride (1.00 g, 27.44 mmol). The solution was heated to reflux for 18 h. After cooling to room temperature, the reaction mixture was poured into water (125 mL) and extracted with  $\text{CH}_2\text{Cl}_2$  ( $2 \times 200$  mL). The combined organics were washed with water (200 mL), dried over  $\text{MgSO}_4$ , filtered, and the solvent removed in vacuo to afford **10** as a white crystalline solid. Yield: 2.23 g, 88%; mp 65–68 °C ( $\text{CH}_2\text{Cl}_2$ ) (lit.<sup>14</sup> 65–66 °C).  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.43–7.26 (m, 10H), 5.87 (d,  $J = 3.41$  Hz, 1H), 2.25 (d,  $J = 3.49$  Hz, 1H).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CDCl}_3$ )  $\delta$ : 143.81,

128.51, 127.59, 126.55, 76.29.  $^1\text{H}$  NMR and  $^{13}\text{C}$  NMR spectra are in agreement with those previously reported.<sup>14</sup>

### Diphenylmethane (11)

To a solution of diphenylmethanol (**10**, 1.00 g, 5.43 mmol) in ethanol (50 mL) at 0 °C was added concd. HCl (1.0 mL) as a solution in ethanol (9.0 mL). The solution was heated to reflux for 72 h. After cooling to room temperature, the reaction mixture was poured into a saturated solution of  $\text{NaHCO}_3$  (25 mL) and water (100 mL) was added. The material was extracted with  $\text{CH}_2\text{Cl}_2$  (2  $\times$  100 mL), washed with water (200 mL), dried over  $\text{MgSO}_4$ , filtered, and the solvent removed in vacuo to afford a clear, colourless oil that crystallized on standing. Yield: 0.64 g, 72%; mp 24–26 °C ( $\text{CH}_2\text{Cl}_2$ ) lit.<sup>15</sup> 25–26 °C.  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.26–7.30 (m, 4H), 7.18–7.21 (m, 6H), 3.98 (s, 2H).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CDCl}_3$ )  $\delta$ : 141.31, 129.07, 128.66, 126.29, 42.11.  $^1\text{H}$  NMR and  $^{13}\text{C}$  NMR spectra are in agreement with those previously reported.<sup>15</sup>

### [4-(*tert*-Butyl-dimethylsilanoxy)phenyl]-4-(octyloxy)phenylmethanol (**12a**)

To a solution of 1-bromo-4-(octyloxy)benzene (1.46 g, 5.12 mmol) in freshly distilled THF (60 mL) at –78 °C under an Ar atmosphere was added *tert*-butyl lithium (6.02 mL of a 1.7 mol/L solution in pentane, 10.24 mmol) dropwise. After the mixture was allowed to stir for 1 h, a solution of 4-(*tert*-butyl-dimethylsilanoxy)benzaldehyde (1.21 g, 5.12 mmol) in freshly distilled THF (10 mL) was added dropwise. The solution was warmed to room temperature and stirred for 20 h. The reaction mixture was quenched with brine (10 mL) and extracted with a 50:50 mixture of ether/petroleum ether (3  $\times$  80 mL). The combined organic fractions were washed with water (3  $\times$  100 mL), dried over  $\text{MgSO}_4$ , filtered, and the solvent removed in vacuo. Flash chromatography (ether/petroleum ether, 10:1) afforded **12a** as a clear, light orange oil. Yield: 1.33 g, 59%; bp 435 °C (determined from DSC).  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.28 (d,  $J$  = 8.34 Hz, 2H), 7.23 (d,  $J$  = 8.43 Hz, 2H), 6.87 (d,  $J$  = 8.63 Hz, 2H), 6.81 (d,  $J$  = 8.51 Hz, 2H), 5.77 (s, 1H); 3.96 (t,  $J$  = 6.51 Hz, 2H), 1.79 (quin.,  $J$  = 6.80 Hz, 2H), 1.53–1.20 (m, 10H), 1.00 (s, 9H), 0.91 (m, 3H), 0.20 (s, 6H).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CDCl}_3$ )  $\delta$ : 158.57, 155.01, 136.88, 136.10, 127.77, 127.70, 119.92, 114.37, 75.50, 68.03, 31.92, 29.66, 29.63, 29.60, 29.58, 29.40, 29.34, 29.28, 26.05, 25.67, 22.69, 18.18, 14.12, –4.42. Anal. calcd. for  $\text{C}_{31}\text{H}_{50}\text{O}_3\text{Si}$ : C, 74.73; H, 10.10. Found: C, 74.71; H, 9.96.

[4-(*tert*-Butyl-dimethylsilanoxy)phenyl]-4-(dodecyloxy)phenylmethanol (**12b**) was prepared in a method analogous to **12a**. Yield: 3.53 g, 56%; bp 443 °C (determined from DSC).  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.27 (m, 2H), 7.23 (d,  $J$  = 10.04 Hz, 2H), 6.87 (d,  $J$  = 8.16 Hz, 2H), 6.81 (d,  $J$  = 7.98 Hz, 2H), 5.77 (s, 1H), 3.95 (t,  $J$  = 6.33 Hz, 2H), 2.07 (s, 1H), 1.78 (quin.,  $J$  = 7.02 Hz, 2H), 1.51–1.21 (m, 18H), 0.99 (s, 9H), 0.90 (t,  $J$  = 6.42 Hz, 3H), 0.20 (s, 6H).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CDCl}_3$ )  $\delta$ : 158.57, 155.01, 136.88, 136.10, 127.77, 127.70, 119.92, 114.37, 75.50, 68.03, 31.92, 29.68, 29.64, 29.60, 29.58, 29.40, 29.35, 29.29, 26.05, 25.67, 22.70, 18.18, 14.12, –4.42. Anal. calcd. for  $\text{C}_{27}\text{H}_{42}\text{O}_3\text{Si}$ : C, 73.25; H, 9.56. Found: C, 73.21; H, 9.46.

[4-(*tert*-Butyl-dimethylsilanoxy)phenyl]-4-(hexadecyloxy)phenylmethanol (**12c**) was prepared in a method analogous to **12a**. Yield: 3.54 g, 50%; bp 450 °C (determined from DSC).  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.27 (d,  $J$  = 8.21 Hz, 2H), 7.23 (d,  $J$  = 8.48 Hz, 2H), 6.87 (d,  $J$  = 8.67 Hz, 2H), 6.81 (d,  $J$  = 8.53 Hz, 2H), 5.77 (d,  $J$  = 3.39 Hz, 1H), 3.95 (t,  $J$  = 6.55 Hz, 2H), 2.07 (d,  $J$  = 3.58 Hz, 1H), 1.78 (quin.,  $J$  = 6.89 Hz, 2H), 1.54–1.23 (m, 26H), 0.99 (s, 9H), 0.94–0.87 (m, 3H), 0.20 (s, 6H).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CDCl}_3$ )  $\delta$ : 158.57, 155.01, 136.88, 136.10, 127.77, 127.70, 119.92, 114.37, 75.50, 68.03, 31.93, 29.69, 29.66, 29.60, 29.58, 29.40, 29.36, 29.29, 26.05, 25.67, 22.70, 18.19, 14.12, –4.42. Anal. calcd. for  $\text{C}_{35}\text{H}_{58}\text{O}_3\text{Si}$ : C, 75.75; H, 10.53. Found: C, 75.71; H, 10.46.

### 4-(4-(Octyloxy)benzyl)phenol (**13a**)

To a solution of [4-(*tert*-butyl-dimethylsilanoxy)phenyl]-4-(octyloxy)phenylmethanol (**12a**, 1.00 g, 2.26 mmol) in ethanol (50 mL) at 0 °C was added concd. HCl (1.0 mL) as a solution in ethanol (10 mL). The solution was heated to reflux for 48 h. After cooling to room temperature, the reaction mixture was poured into a saturated solution of  $\text{NaHCO}_3$  (25 mL), mixed well, and extracted with hexanes (3  $\times$  50 mL) and ether (50 mL). The combined organics were washed with water (200 mL), dried over  $\text{MgSO}_4$ , filtered, and the solvent removed in vacuo. Crystallization from 5% ether in petroleum ether afforded **13a** as a white, powdery solid. Yield: 0.56 g, 79%; mp 70–73 °C (5% ether in petroleum ether).  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.07 (t,  $J$  = 8.22 Hz, 4H), 6.83 (d,  $J$  = 8.52 Hz, 2H), 6.76 (d,  $J$  = 8.42 Hz, 2H), 3.94 (t,  $J$  = 6.60 Hz, 2H), 3.86 (s, 2H), 1.78 (quin.,  $J$  = 6.93 Hz, 2H), 1.52–1.21 (m, 10 H), 0.90 (t,  $J$  = 5.97 Hz, 3H).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CDCl}_3$ )  $\delta$ : 157.48, 153.75, 133.93, 133.45, 129.94, 129.70, 115.24, 114.50, 68.07, 40.13, 31.83, 29.37, 29.33, 29.25, 26.07, 22.66, 14.10. Anal. calcd. for  $\text{C}_{21}\text{H}_{28}\text{O}_2$ : C, 80.73; H, 9.03; O, 10.24. Found: C, 80.31; H, 9.02; O, 10.67.

4-(4-(Dodecyloxy)benzyl)phenol (**13b**) was prepared in a method analogous to **13a**. Yield: 0.50 g, 68%; mp 80–83 °C (5% ether in petroleum ether).  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.07 (t,  $J$  = 8.20 Hz, 4H), 6.83 (d,  $J$  = 8.59 Hz, 2H), 6.76 (d,  $J$  = 8.48 Hz, 2H), 3.94 (t,  $J$  = 6.54 Hz, 2H), 3.86 (s, 2H), 1.78 (quin.,  $J$  = 6.52 Hz, 2H), 1.51–1.21 (m, 14 H), 0.90 (t,  $J$  = 6.51 Hz, 3H).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CDCl}_3$ )  $\delta$ : 157.48, 153.73, 133.95, 133.46, 129.94, 129.70, 115.25, 114.52, 68.09, 40.14, 31.93, 29.67, 29.64, 29.61, 29.59, 29.42, 29.35, 29.34, 26.07, 22.70, 14.12. Anal. calcd. for  $\text{C}_{25}\text{H}_{36}\text{O}_2$ : C, 81.47; H, 9.85; O, 8.68. Found: C, 81.40; H, 9.81; O, 8.79.

4-(4-(Hexadecyloxy)benzyl)phenol (**13c**) was prepared in a method analogous to **13a**. Yield: 0.60 g, 78%; mp 83–90 °C (5% ether in petroleum ether).  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.07 (t,  $J$  = 8.20 Hz, 4H), 6.80 (dd,  $J_1$  = 8.66 Hz,  $J_2$  = 2.00 Hz, 4H), 4.56 (s, 1H), 3.94 (t,  $J$  = 6.58 Hz, 2H), 3.86 (s, 2H), 1.78 (quin.,  $J$  = 6.58 Hz, 2H), 1.37 (m, 26H); 0.90 (t,  $J$  = 6.58 Hz, 3H).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CDCl}_3$ )  $\delta$ : 157.5, 153.7, 134.0, 133.4, 129.9, 129.7, 115.2, 114.5, 68.0, 40.1, 31.9, 29.7 (3), 29.6 (4), 29.4 (3), 29.3, 26.1, 22.7, 14.1. Anal. calcd. for  $\text{C}_{29}\text{H}_{44}\text{O}_2$ : C, 82.02; H, 10.44; O, 7.53. Found: C, 82.05; H, 10.48; O, 7.47.

#### 4-[Hydroxyl(4-(octyloxy)phenyl)methyl]phenol (**14a**)

To a solution of [4-(*tert*-butyl-dimethylsiloxy)phenyl]-(4-(octyloxy)phenyl)methanol (**12a**, 2.50 g, 5.65 mmol) in freshly distilled THF (20 mL) at 0 °C was added a solution of tributyl ammonium fluoride trihydrate (TBAF, 3.57 g, 11.30 mmol) in freshly distilled THF (20 mL). The solution was allowed to stir for 1 h, warmed to room temperature, and then stirred for 2 h. The reaction mixture was poured into water (50 mL), mixed well, and then separated. The aqueous phase was extracted with a 50:50 mixture of ether/petroleum ether (2 × 100 mL), and the combined organics were washed with water (250 mL), dried over MgSO<sub>4</sub>, filtered, and the solvent removed in vacuo. Crystallization from 5% ether in petroleum ether afforded **14a** as a white, powdery solid. Yield: 1.02 g, 55%; mp 81–86 °C (5% ether in petroleum ether). <sup>1</sup>H NMR (300 MHz, CDCl<sub>3</sub>) δ: 7.27 (d, *J* = 8.44 Hz, 2H), 7.25 (d, *J* = 8.37 Hz, 2H), 6.87 (d, *J* = 8.71 Hz, 2H), 6.81 (d, *J* = 8.62 Hz, 2H), 5.78 (s, 1H), 4.77 (s, 1H), 3.95 (t, *J* = 6.57 Hz, 2H), 1.78 (quin., *J* = 6.57 Hz, 2H), 1.52–1.24 (m, 10H), 0.90 (t, *J* = 6.72 Hz, 3H). <sup>13</sup>C NMR (75 MHz, CDCl<sub>3</sub>) δ: 158.60, 154.86, 136.58, 136.05, 127.99, 127.72, 115.22, 114.42, 75.41, 68.05, 31.81, 29.35, 29.27, 29.23, 26.05, 22.65, 14.09. Anal. calcd. for C<sub>21</sub>H<sub>28</sub>O<sub>3</sub>: C, 76.79; H, 8.59; O, 14.61. Found: C, 77.38; H, 7.80; O, 14.82.

4-[Hydroxy(4-(hexadecyloxy)phenyl)methyl]phenol (**14c**) was prepared in a method analogous to **14a**. Yield: 0.53 g, 50%; mp 95–101 °C (5% ether in petroleum ether). <sup>1</sup>H NMR (300 MHz, CDCl<sub>3</sub>) δ: 7.28 (d, *J* = 8.11 Hz, 2H), 7.26 (d, *J* = 8.66 Hz, 2H), 6.87 (d, *J* = 8.49 Hz, 2H), 6.81 (d, *J* = 8.32 Hz, 2H), 5.78 (s, 1H), 4.69 (s, 1H), 3.95 (t, *J* = 6.51 Hz, 2H), 1.78 (quin., *J* = 6.53 Hz, 2H), 1.54–1.20 (m, 26H), 0.90 (t, *J* = 6.57 Hz, 3H). <sup>13</sup>C NMR (75 MHz, CDCl<sub>3</sub>) δ: 158.59, 154.84, 136.58, 136.05, 128.39, 127.92, 115.22, 114.46, 75.41, 68.07, 31.81, 29.35, 29.29, 29.25, 26.06, 22.66, 14.10. Anal. calcd. for C<sub>29</sub>H<sub>44</sub>O<sub>3</sub>: C, 79.04; H, 10.06; O, 10.89. Found: C, 78.43; H, 10.47; O, 11.10.

#### 4-(4-(Octyloxy)benzyl)phenol (**13a**)

To a solution of 4-[hydroxyl(4-(octyloxy)phenyl)methyl]phenol (**14a**, 0.20 g, 0.61 mmol) in ethanol (50 mL) °C was added concd. HCl (0.5 mL) as a solution in ethanol (9.5 mL). The solution was allowed to stir for 1 h and then heated to reflux for 48 h. After cooling to room temperature, the reaction mixture was poured into a saturated solution of NaHCO<sub>3</sub> (25 mL), mixed well, and then extracted with petroleum ether (3 × 50 mL) and ether (50 mL). The combined organics were washed with water (200 mL), dried over MgSO<sub>4</sub>, filtered, and the solvent removed in vacuo to afford 4-(4-(octyloxy)benzyl)phenol as a white powdery solid. Yield: 0.17 g, 90%; mp 70–73 °C (ether/petroleum ether). <sup>1</sup>H NMR (300 MHz, CDCl<sub>3</sub>) δ: 7.07 (t, *J* = 8.22 Hz, 4H), 6.83 (d, *J* = 8.52 Hz, 2H), 6.76 (d, *J* = 8.42 Hz, 2H), 3.94 (t, *J* = 6.60 Hz, 2H), 3.86 (s, 2H), 1.78 (quin., *J* = 6.93 Hz, 2H), 1.52–1.21 (m, 10 H), 0.90 (t, *J* = 5.97 Hz, 3H). <sup>13</sup>C NMR (75 MHz, CDCl<sub>3</sub>) δ: 157.48, 153.75, 133.93, 133.45, 129.94, 129.70, 115.24, 114.50, 68.07, 40.13, 31.83, 29.37, 29.33, 29.25, 26.07, 22.66, 14.10. Anal. calcd. for C<sub>21</sub>H<sub>28</sub>O<sub>2</sub>: C, 80.73; H, 9.03; O, 10.24. Found: C, 80.01; H, 9.46; O, 10.53.

4-(4-(Hexadecyloxy)benzyl)phenol (**13c**) was prepared in

a method analogous to 4-(4-(octyloxy)benzyl)phenol. Yield: 0.18 g, 79%; mp 83–90 °C (ether/petroleum ether). <sup>1</sup>H NMR (300 MHz, CDCl<sub>3</sub>) δ: 7.07 (t, *J* = 8.20 Hz, 4H), 6.80 (dd, *J*<sub>1</sub> = 8.66 Hz, *J*<sub>2</sub> = 2.00 Hz, 4H), 4.56 (s, 1H), 3.94 (t, *J* = 6.58 Hz, 2H), 3.86 (s, 2H), 1.78 (quin., *J* = 6.58 Hz, 2H), 1.37 (m, 26H), 0.90 (t, *J* = 6.58 Hz, 3H). <sup>13</sup>C NMR (75 MHz, CDCl<sub>3</sub>) δ: 157.5, 153.7, 134.0, 133.4, 129.9, 129.7, 115.2, 114.5, 68.0, 40.1, 31.9, 29.7 (3), 29.6 (4), 29.4 (3), 29.3, 26.1, 22.7, 14.1. Anal. calcd. for C<sub>29</sub>H<sub>44</sub>O<sub>2</sub>: C, 82.02; H, 10.44; O, 7.53. Found: C, 82.05; H, 10.48; O, 7.47.

#### Bis(4-(dodecyloxy)phenyl)methanol (**15**)

A solution of 4,4'-bis(dodecyloxy)benzophenone (0.30 g, 0.55 mmol) and sodium borohydride (0.046 g, 1.20 mmol) in ethanol (40 mL) was allowed to reflux for 1 h. After cooling to room temperature, the reaction mixture was poured into water (100 mL) and extracted with CH<sub>2</sub>Cl<sub>2</sub> (2 × 100 mL). The combined organics were washed with water (2 × 200 mL), dried over MgSO<sub>4</sub>, filtered, and the solvent removed in vacuo. Crystallization from hexanes afforded **15** as a white powdery solid. Yield: 0.23 g, 76%; mp 37–39 °C (hexanes). <sup>1</sup>H NMR (300 MHz, CDCl<sub>3</sub>) δ: 7.28 (d, *J* = 8.55 Hz, 4H), 6.88 (d, *J* = 8.55 Hz, 4H), 5.78 (d, *J* = 3.40 Hz, 1H), 3.95 (t, *J* = 6.58 Hz, 4H), 2.06 (d, *J* = 3.40 Hz, 1H), 1.78 (quin. *J* = 6.58 Hz, 4H), 1.52–1.19 (m, 36 H); 0.90 (t, *J* = 6.58 Hz, 6H). <sup>13</sup>C NMR (75 MHz, CDCl<sub>3</sub>) δ: 158.55, 136.16, 127.71, 114.39, 75.46, 68.04, 31.92, 29.66, 29.63, 29.60, 29.58, 29.40, 29.35, 29.28, 26.05, 22.69, 14.12. Anal. calcd. for C<sub>37</sub>H<sub>61</sub>O<sub>3</sub>: C, 80.23; H, 11.10; O, 8.67. Found: C, 80.31; H, 11.03; O, 8.66.

#### Bis(4-(dodecyloxy)phenyl)methane (**16**)

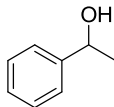

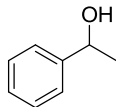

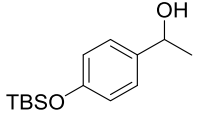

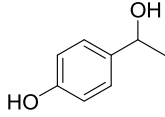

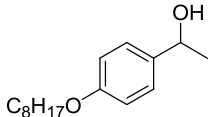

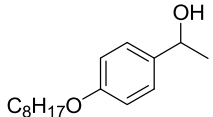

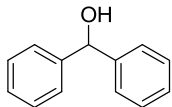

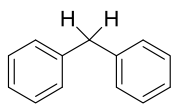

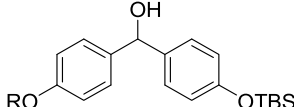

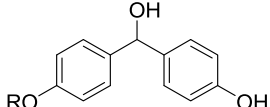

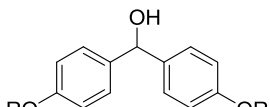

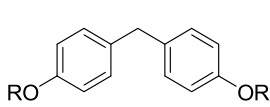

To a solution of bis(4-(dodecyloxy)phenyl)methanol (**15**, 0.25 g, 0.45 mmol) in ethanol (50 mL) at reflux was added a solution of concd. HCl (0.5 mL) in ethanol (9.5 mL). The solution was allowed to reflux for 48 h. After cooling to room temperature, the reaction mixture was poured into a saturated solution of NaHCO<sub>3</sub> (25 mL) and mixed well. Water (100 mL) was added and the mixture was extracted with petroleum ether (150 mL) and ether (100 mL). The combined organics were washed with water (200 mL), dried over MgSO<sub>4</sub>, filtered, and the solvent removed in vacuo to afford bis(4-(dodecyloxy)phenyl)methane as a waxy white solid. Yield: 0.20 g, 83%; mp 30–33 °C (petroleum ether/ether). <sup>1</sup>H NMR (300 MHz, CDCl<sub>3</sub>) δ: 7.08 (d, *J* = 8.59 Hz, 4H), 6.83 (d, *J* = 8.59 Hz, 4H), 3.94 (t, *J* = 6.57 Hz, 4H), 3.87 (s, 2H), 1.78 (quin., *J* = 6.56 Hz, 4H), 1.51–1.22 (m, 36H), 0.91 (t, *J* = 6.57 Hz, 6H). <sup>13</sup>C NMR (75 MHz, CDCl<sub>3</sub>) δ: 157.46, 133.54, 129.68, 114.44, 68.02, 40.14, 31.92, 29.66, 29.63, 29.60, 29.59, 29.41, 29.34, 29.33, 26.07, 22.69, 14.12. Anal. calcd. for C<sub>37</sub>H<sub>61</sub>O<sub>2</sub>: C, 82.62; H, 11.43; O, 5.95. Found: C, 82.65; H, 11.48; O, 5.87.

## Results and discussion

In our efforts towards the acidic hydrolysis of silyl ether protecting groups,<sup>16</sup> we discovered an unexpected result: in addition to cleavage of the silicon–oxygen bond, we also observed deoxygenation of the diarylmethanol (Scheme 1).

**Table 1.** Deoxygenation of secondary alcohols using HCl/EtOH.

Entry	Reactant	Time (h)	Yield (%)	Product	
6		96	NR <sup>a</sup>	6 	
7		48	90	8 	
9		120	NR	9 	
10		48	72	11 	
12a		R = C <sub>8</sub> H <sub>17</sub>	48	79	13a
12b		R = C <sub>12</sub> H <sub>25</sub>	48	68	13b
12c		R = C <sub>16</sub> H <sub>33</sub>	48	78	13c
14a		R = C <sub>8</sub> H <sub>17</sub>	48	90	13a
14c		R = C <sub>16</sub> H <sub>33</sub>	48	79	13c
15		R = C <sub>12</sub> H <sub>25</sub>	48	83	16 

<sup>a</sup> NR: no reaction**Scheme 1.** Attempted acidic hydrolysis of silyl ether protecting groups. Reagents and conditions: HCl, EtOH, reflux 48 h.

To further probe the generality of this reaction, we tested a number of substrates including secondary alcohols and diarylmethanols with different substitution patterns, with and without silyl ether protecting groups. Table 1 outlines the substrates examined and the results, including reaction time and yield. It was found that the reaction does not proceed for primary alcohols or secondary alcohols not bearing two aryl functionalities, nor was the presence of the silyl protect-

ing group required. The reaction proceeds in good yields (68%–90%) for substrates displaying a variety of substitution patterns.

## Conclusions

A new mild and efficient method for the deoxygenation of diarylmethanols has been developed. This reaction mitigates

the need to use radical conditions or toxic heavy metals employed in the Barton–McCombie deoxygenation.

# Modular incorporation of 1-benzyltryptophan into dipeptide hosts that bind acetylcholine in pure water

Cory S. Beshara and Fraser Hof

**Abstract:** Proteins that recognize and bind quaternary ammonium ions depend on “aromatic-cage” structural motifs that use multiple aromatic residues to engage the side chain’s ammonium cation. We introduce herein the use of 1-benzyltryptophan (Trp(Bn)) residues as synthetic, unnatural partial analogues of natural aromatic cages. We demonstrate the modular incorporation of these building blocks into simple dipeptide hosts and show that they are capable of binding quaternary ammonium ions in buffered water and in chloroform.

**Key words:** molecular recognition, tryptophan, peptides, cation– $\pi$  interaction, hydrophobic effect.

**Résumé :** Les protéines qui reconnaissent et qui se lient à des ions ammonium quaternaires dépendent sur des motifs structuraux « cage aromatique » qui font appel à de multiples résidus aromatiques pour s’engager avec le cation ammonium de la chaîne latérale. Dans ce travail, on introduit l’utilisation des résidus 1-benzyltryptophane (Trp(Bn)) comme analogues partiels de synthèse, non naturels, des cages aromatiques naturelles. On démontre que l’incorporation modulaire des ces blocs dans des hôtes dipeptidiques et on montre qu’ils sont capables de se lier à des ions ammonium quaternaires dans l’eau tamponnée et dans le chloroforme.

**Mots-clés :** reconnaissance moléculaire, tryptophane, peptides, interaction cation– $\pi$ , effet hydrophobe.

## Introduction

The cation– $\pi$  interaction is implicated in many recognition events in biology.<sup>1–5</sup> Its importance for the recognition of cholinergic agents by their receptors<sup>3,6,7</sup> has long been understood. Its role in the recognition of post-translationally methylated lysine residues has more recently come to light,<sup>4,8–10</sup> and the protein data bank (PDB) now contains many examples of trimethyllysine-containing quaternary ammonium complexes.<sup>11</sup> In these structures, the binding of the quaternary ammonium ion is accomplished by motifs referred to as “aromatic cages” in which clusters of three to four aromatic side chains make close cation– $\pi$  contacts with the RNMe<sub>3</sub><sup>+</sup> portion of the side chain (Fig. 1). The most electron-rich aromatic side chain, tryptophan (Trp), is present as at least one of the binding partners in all trimethyllysine-binding aromatic cage motifs currently reported in the PDB, where it is accompanied by additional phenylalanine (Phe) and (or) tyrosine (Tyr) residues.

Inspired by the use of multiple aromatic rings in the protein domains that bind quaternary ammonium ions, we considered the unnatural modified amino acid 1-benzyltryptophan (Trp(Bn), **1**, Fig. 1) as a building block that could be easily incorporated into peptide-based hosts. A prior report of the dipeptide Boc-Trp-Trp-OMe (**2**) as a simple receptor for ammonium ions in organic solvents<sup>12</sup> led us to wonder if it

could be adapted to achieve the far more difficult task of binding cations in pure water by the incorporation of Trp(Bn) residues. We report here, the synthesis of 1-benzyltryptophan based reagents and their rapid and modular incorporation into quaternary ammonium ion binding dipeptide hosts related to the parent Trp-Trp dipeptide (**2**).

## Results and discussion

We were surprised to find very few reports of the apparently simple 1-benzyltryptophan (**1**) in the literature. Only six literature references were found in a Scifinder structure-based search,<sup>13–18</sup> and none of these references report the appended 1-benzyl group being used as a functional element. The obvious routes for the synthesis of **1** start with simple tryptophan analogs and involve deprotonation and alkylation of the side chain nitrogen atom. We first targeted the treatment of tryptophan methyl ester with 1 equiv. of NaH followed by treatment with a benzyl halide. Reactions were attempted in THF and DMF using a variety of temperatures and reaction times. While selective benzylation of the side chain nitrogen could be achieved, we found significant racemization of the  $\alpha$ -carbon under all conditions that we tested (racemization is most easily detected by the observation of diastereomeric  $\alpha$ -CH <sup>1</sup>H NMR resonances once dipeptides are made from a Trp(Bn) precursor). We next attempted to

**Fig. 1.** Top: aromatic cage binding motifs that are used by proteins that recognize biologically important ammonium ions of the form  $\text{RNMe}_3^+$ . The structure on the right is an example of an aromatic cage taken from the PDB entry 1PDQ. Bottom: the unnatural amino acid 1-benzyltryptophan.

treat the free-acid Trp (**3**) with two or more equivalents of NaH to generate the doubly deprotonated carboxylate-indole dianion, with the idea that the more reactive indole anion could be reacted selectively with 1 equiv. of benzyl halide. These efforts effectively prevented racemization, but generated intractable mixtures and low yields arising from mixtures of O- and N-benylation products. We subsequently adapted a reported deprotonation of unprotected Trp under dissolving metal conditions ( $\text{Na-NH}_3$ ) and subsequent treatment with BnCl in liquid  $\text{NH}_3$  (Scheme 1).<sup>14</sup> We found that this method was successful only when performed on  $\geq 5$  g of **3**, and crude yields of **1**, uncontaminated by O-benzyl or racemized by-products, reached a high of 70% when the reaction was carried out on a 40 g scale. We found an efficient purification for **1** by first dissolving the crude in a mixture of MeOH and concentrated aqueous HCl; precipitation by the addition of  $\text{Et}_2\text{O}$  gave the pure product as the HCl salt (**1**·HCl) in a 51% overall yield.

Scheme 2 depicts the synthesis of Boc-Trp(Bn)-OH (**4**) and  $\text{H}_2\text{N-Trp(Bn)-OMe}$  (**5**) that were used in the subsequent synthesis of a family of organic- and water-soluble host dipeptides. Treatment of **1**·HCl with thionyl chloride in methanol gives methyl ester **5** in a 87% yield, whereas treatment of **1**·HCl with NaOH in the presence of  $(\text{Boc})_2\text{O}$  under mixed aqueous-organic conditions gives the Boc-protected compound **4** in a 78% yield. Compound **5** was coupled with commercially available Boc-Trp-OH (**6**) to form the monobenzylated dipeptide host (Boc-Trp-Trp(Bn)-OMe, **7**) in a 49% yield. Compound **4** was combined with **5** under standard solution-phase HBTU coupling conditions to yield the dibenzylated dipeptide host (Boc-Trp(Bn)-Trp(Bn)-OMe, **8**) in a 61% yield. To complete the series, **4** was coupled with commercially available  $\text{H}_2\text{N-Trp-OMe}$  (**9**) to afford Boc-Trp-Trp-OMe (**2**) with free indole side chains in a 76% yield. Unlike the prior synthesis of host **2**,<sup>12</sup> all transformations reported herein were optimized to allow purification without resorting to flash chromatography.

**Scheme 1.** Selective 1-benylation of Trp and isolation as the HCl salt.

To create water-soluble analogs that retained an overall anionic charge, we doubly deprotected compounds **2**, **7**, and **8** and created simple N-terminal acetylated derivatives of the form Ac-Trp-Trp-OH (not shown). Unfortunately, dipeptides of this form were insoluble in phosphate-buffered  $\text{D}_2\text{O}$  ( $\text{pD} = 7.4$ ). In an effort to increase water solubility while leaving the Trp(Bn) binding motifs unchanged, we targeted structures with N-terminal succinyl groups. Thus, compounds **2**, **7**, and **8** were Boc-deprotected in HCl-AcOH to give the dipeptide hydrochloride salts **10**, **11**, and **12**, respectively, as pure white solids after filtration and washing with  $\text{Et}_2\text{O}$ . The suspension of **10–12** in  $\text{CH}_2\text{Cl}_2$ , neutralization with  $i\text{-Pr}_2\text{EtN}$ , and treatment with succinic anhydride gave the succinyl (Suc) derived Suc-Trp-Trp-OMe dipeptides, which were directly saponified in methanol-water to yield, after acidification of the aqueous work-up layer, dipeptides **13–15** (40%–56% overall yield over four synthetic steps; Scheme 2). Compounds **13–15** are all soluble in phosphate-buffered  $\text{D}_2\text{O}$  ( $\text{pD} = 7.4$ ) at concentrations up to 10 mmol/L.

Acetylcholine chloride ( $\text{AcCh}^+ \text{Cl}^-$ ) was used as a prototypical  $\text{RNMe}_3^+$  guest because of its high solubility in both water and chloroform, which is a critical feature that we did not find in halide or BArF salts of other guest candidates trimethyllysine, tetramethylammonium, or benzyltrimethylammonium. Titration of  $\text{AcCh}^+ \text{Cl}^-$  into the dipeptide hosts **13–15** in phosphate-buffered  $\text{D}_2\text{O}$  (10 mmol/L  $\text{Na}_2\text{HPO}_4$ – $\text{NaH}_2\text{PO}_4$ ,  $\text{pD} = 7.4$ ) revealed guest-induced chemical shifts that fit to 1:1 binding isotherms to provide  $K_{\text{assoc}}$  values (Fig. 2 and Table 1). Even at the highest host and guest concentrations tested (10 and 930 mmol/L, respectively), the unbzylated host **13**, which is most closely related to the literature host **2** that can bind  $\text{AcCh}^+$  in  $\text{CDCl}_3$ ,<sup>12</sup> showed no detectable binding of  $\text{AcCh}^+$  under these competitive solvent conditions.

The monobenzylated host **14** and dibenzylated host **15** both showed evidence of binding that, while weak, was reproducibly observed over many determinations with the highest affinity arising from dibenzylated **15**. Direct evidence for the interaction of benzyl groups with the bound cation was given by the large chemical shift changes among the benzylic methylenes of dipeptide **15** (Fig. 2B), while the shifts of both benzyl and indolyl resonances in the aromatic regions (Fig. 2A) further support the participation of both types of aromatic rings in binding.

To examine the role of solvent effects in these hosts, we carried out binding studies of the chloroform-soluble analogs **2**, **7**, and **8** using the same titration methodology. In this solvent, the unbzylated host **2** bound  $\text{AcCh}^+ \text{Cl}^-$  with a  $K_{\text{assoc}}$  of  $85 (\text{mol/L})^{-1}$ , which is in agreement with the value previously reported.<sup>12</sup> Surprisingly, our new benzylated hosts **7** and **8** bound  $\text{AcCh}^+$  more weakly than did the unbzylated

**Scheme 2.** Synthesis of Trp and Trp(Bn)-containing hosts.

parent (Table 1), despite the presence of additional aromatic binding surfaces. We also found that host **2** is also the most potent host for the binding of the the noncoordinating  $\text{BnNMe}_3^+ \text{BARF}^-$ , suggesting that this result is not an artifact arising from counterion effects in chloroform.<sup>19</sup> The cation- $\pi$  interaction is an electrostatic attraction that should be

stronger in nonpolar media; the fact that we see the opposite trend in  $\text{CDCl}_3$  suggests that it is not a major contributor to interactions between the benzyl groups and cationic guests. Instead, it is likely the increase in hydrophobic surface area provided by the benzyl groups that leads to the higher cation affinities observed for benzylated hosts in  $\text{D}_2\text{O}$ .

**Fig. 2.** Concentration-dependent chemical shift changes displayed by the host **15** (10 mmol/L) in its (a) aromatic and (b) methylene regions upon addition of AcCh<sup>+</sup> Cl<sup>−</sup> in D<sub>2</sub>O (phosphate buffer, pD 7.4, 10 mmol/L). Concentrations of AcCh<sup>+</sup> Cl<sup>−</sup> are indicated. (c) A plot of titration data and the 1:1 binding isotherm arising from nonlinear least-squares regression (see Experimental).

<b>15</b> (Trp(Bn)–Trp(Bn))	AcCh <sup>+</sup> Cl <sup>−a</sup>	D <sub>2</sub> O	14±6
<b>16</b> (Trp(Bn))	AcCh <sup>+</sup> Cl <sup>−a</sup>	D <sub>2</sub> O	≤1 <sup>b</sup>
<b>2</b> (Trp–Trp)	AcCh <sup>+</sup> Cl <sup>−a</sup>	CDCl <sub>3</sub>	85±17
<b>7</b> (Trp–Trp(Bn))	AcCh <sup>+</sup> Cl <sup>−a</sup>	CDCl <sub>3</sub>	22±4
<b>8</b> (Trp(Bn)–Trp(Bn))	AcCh <sup>+</sup> Cl <sup>−a</sup>	CDCl <sub>3</sub>	1±0.5
<b>2</b> (Trp–Trp)	BnNMe <sub>3</sub> <sup>+</sup> BArF <sup>−c</sup>	CDCl <sub>3</sub>	63±12
<b>7</b> (Trp–Trp(Bn))	BnNMe <sub>3</sub> <sup>+</sup> BArF <sup>−c</sup>	CDCl <sub>3</sub>	27±5
<b>8</b> (Trp(Bn)–Trp(Bn))	BnNMe <sub>3</sub> <sup>+</sup> BArF <sup>−c</sup>	CDCl <sub>3</sub>	47±3

**Note:**  $K_{\text{assoc}}$  was determined using at least three replicate titrations, tracking two to three proton resonances during each titration. Errors represent the upper and lower limits of replicate titrations. “D<sub>2</sub>O” also contained 10 mmol/L NaH<sub>2</sub>PO<sub>4</sub>–Na<sub>2</sub>HPO<sub>4</sub> adjusted to pD 7.4.

<sup>a</sup>Guest solution (ranging from 80 to 930 mmol/L) was titrated into a solution of the host (10 mmol/L).

<sup>b</sup>Titration resulted in insignificant  $\Delta\delta$  values.

<sup>c</sup>A concentrated solution of the host (80–250 mmol/L) was titrated into the guest (2 mmol/L) due to low solubility of the BnNMe<sub>3</sub><sup>+</sup> BArF<sup>−</sup> salt in CDCl<sub>3</sub>.

To gain some insight into the possible structures of these host–guest complexes, we carried out Monte Carlo conformational searches using a representative dibenzylated dipeptide host (the methyl ester analog of **15**) and the truncated guest Me<sub>4</sub>N<sup>+</sup>. These gas-phase calculations are limited in scope and capabilities; they are subject to unrealistic overemphasis of electrostatic attractions (hence our use of the methyl ester host analog) and they are incapable of representing the hydrophobic driving forces that are critical in aqueous solution. However, they are very good at determining energetically reasonable bond angles and intra- and intermolecular contacts, and are therefore useful for gaining a qualitative sense of what types of structures might be allowable for the host–guest complex. The two most common types of structures among low-energy conformations obtained from our Monte Carlo calculation involve (i) the interaction of the cation with both benzyl indole moieties in a pocket-like geometry (“pocket”, Fig. 3A) or (ii) the interaction of the cation with only a single Trp(Bn) side chain (“cleft”, Fig. 3B). The cleft structure in Fig. 3B suggests

that only one benzyl indole group and a neighboring carbonyl might be needed to engage the cationic guest. To test this hypothesis, we designed compound **16** (Suc-Trp(Bn)-OH) to see if this monomeric host fragment was a competent cation binder in water. Compound **16** was synthesized in a 56% yield by the reaction of succinic anhydride with precursor **3** (Scheme 2). NMR titrations of **16** with AcCh<sup>+</sup> Cl<sup>−</sup> in buffered D<sub>2</sub>O, carried out as for the other hosts, gave no observable sign of binding, proving that two Trp residues are required for cation binding in water by these dipeptides.

## Conclusions

These studies with simple dipeptide hosts introduce the readily synthesized Trp(Bn) building block as a new quaternary ammonium ion binding motif that can function in pure, buffered water. The weakness of the observed binding by these dipeptides in either medium almost certainly arises from their lack of preorganization relative to more rigid

**Fig. 3.** Representative structures, (A) “pocket” and (B) “cleft”, arising from Monte Carlo conformation searches at the PM3 level of theory. Structures like that shown in Fig. 3A are consistent with both of our key experimental observations in water: the *N*-benzyl substituents play a significant role in binding, and both amino acid side chains are required for cation binding in water.

macrocyclic systems.<sup>9,10</sup> We are curious to see if rigidification of these building blocks by incorporation into small, folded peptide scaffolds increases the potency of Trp(Bn) building blocks as cation binders.

## Experimental

### General procedure

All solvents and reagents were used as purchased from Sigma-Aldrich and used without further purification, except solvents that were dried using an MBraun solvent purification system. NMR spectra and NMR titration data were obtained on a Bruker Avance 500 MHz NMR spectrometer with the exception of <sup>19</sup>F NMR, which was obtained on a Bruker Avance 300 MHz spectrometer. Coupling constants are reported in Hertz. <sup>1</sup>H and <sup>13</sup>C spectra were referenced to residual solvent signals, and the <sup>19</sup>F spectrum was externally referenced to FCCL<sub>3</sub>. HR-MS were acquired on a Waters/Micromass LCT TOF instrument. Melting points were determined with the use of a Gallenkamp melting point apparatus. Specific rotations (*c* = g/100 mL) were acquired with a Rodolf Research Analytical Autopol I instrument and are given in units of 10<sup>-1</sup> deg cm<sup>2</sup> g<sup>-1</sup>.

The typical titration procedure is as follows: The molecule of interest was dissolved in the appropriate solvent (dispensed with a micropipette) to make a solution (4 mL) of a predetermined concentration (2–10 mmol/L). The stock (600 μL) was then introduced into an NMR tube and to the remaining stock solution was added an excess of host or guest. The NMR spectrum of the stock solution was used as a reference for unbound host or guest and the solution titrated with predetermined volumes (micropipette) of titrant, followed by the collection of new NMR spectra. This method ensures that the concentration of the host remains constant throughout the titration. The Δδs were recorded and the data worked-up and fitted to the 1:1 binding isotherm using the spreadsheet made freely available by Sanderson.<sup>20</sup> Initial guesses for host or guest concentrations during the course of the experiments were obtained by the method discussed by Hirose.<sup>21</sup>

Calculations were carried out at the PM3 level of theory using the conformational search routine in Spartan'04.<sup>22</sup> Structures within 5 kcal/mol (1 cal = 4.1868 J) of the global

minimum were retained, and examination revealed that all such low-energy structures could be sorted into two groups by considering the number of aryl side chains making contact with the quaternary ammonium ion (pocket = two Trp(Bn) side chains in contact, Fig. 3A; cleft = one Trp(Bn) residue in contact, Fig. 3B).

### 1-Benzyltryptophan hydrochloride (1·HCl)

Liquid ammonia (1000 mL) was condensed into a 2 L flask containing Na(s) (10.4 g, 452 mmol) and Fe(NO<sub>3</sub>)<sub>3</sub> (0.6 g, 0.01 mmol) under argon. To facilitate the addition of ammonia, the flask was cooled in a dry ice–acetone bath and equipped with a cold finger (dry ice–acetone) via a Claisen adapter. The resultant mixture turns blue immediately and slowly fades to a grey color. Tryptophan (40 g, 196 mmol) was introduced to the grey solution as a slurry in ether, and benzyl chloride (22.5 mL, 196 mmol) was added immediately thereafter via syringe through the septum. The reaction refluxed on an ice bath for 1 h, and evaporated overnight. The crude product dissolved in hot water and a small amount of solid residue was removed by filtration. Acetic acid was added until the product precipitated, and filtration yielded the 1-benzyltryptophan as an off-white solid (41 g, 71%). A portion of this product (24 g, 81 mmol) was suspended in methanol (200 mL) at room temperature and concentrated aqueous hydrochloric acid was added dropwise until the starting material was completely dissolved. The reaction was stirred for 5 min, and was then concentrated to half volume. The solution was then poured into 1.6 L of ether and the resultant slurry was filtered to yield 1·HCl as a white solid that was left to air-dry overnight (19 g, 72%); mp 204–206 °C. [α]<sub>D</sub><sup>25</sup> +5.0° (*c* 0.08 in MeOH). <sup>1</sup>H NMR (300 MHz, DMSO-*d*<sub>6</sub>) δ: 3.32 (2H, *J* = 6.3, d), 4.12 (1H, bs), 5.38 (2H, s), 7.03 (1H *J* = 7 and 1, td), 7.10 (1H, *J* = 8 and 1, td), 7.18–7.33 (5H, m), 7.37 (1H, *J* = 8, d), 7.39 (1H, s), 7.63 (1H, *J*<sub>HH</sub> = 7, d), 8.31 (3H, bs), 13.77 (1H, bs). <sup>13</sup>C NMR (75.5 MHz, DMSO-*d*<sub>6</sub>) δ: 26.0, 49.1, 52.6, 106.8, 110.2, 118.7, 118.9, 121.4, 127.0, 127.3, 127.7, 128.5, 128.7, 136.1, 138.1, 170.7. ### *N*-(tert-Butoxycarbonyl)-1-benzyltryptophan (4)

**3** (1.0 g, 3.0 mmol) was suspended in 1:1 dioxane–water (12 mL) at room temperature. NaOH (aq, 1 mol/L, 6 mL, 6 mmol) was added, followed by the addition of (Boc)<sub>2</sub>O (0.84 mL, 3.6 mmol), and this mixture was stirred for 18 h. The reaction was acidified to pH 2.5 with HCl (2 mol/L), and diluted further with water (50 mL). Ethyl acetate was then used to extract the mostly aqueous mixture. The organic layers were combined, dried, and concentrated to yield a white solid (0.928 g, 78%); mp 181–182 °C (EtOAc). [α]<sub>D</sub><sup>25</sup> +9.1° (*c* 0.08 in MeOH). <sup>1</sup>H NMR (300 MHz, DMSO-*d*<sub>6</sub>) δ: 1.13 (9H, s), 2.99 (1H, *J* = 15 and 9, dd), 3.14 (1H, *J* = 14 and 5, dd), 4.16 (1H, *J* = 9 and 5, td), 5.36 (2H, s), 6.97–7.1 (3H, m), 7.13–7.16 (2H, m), 7.19–7.31 (4H, m), 7.37 (1H, *J* = 8, d), 7.55 (1H, *J* = 7, d), 12.55 (1H, bs). <sup>13</sup>C NMR (75.5 MHz, DMSO-*d*<sub>6</sub>) δ: 26.7, 28.1, 48.9, 54.4, 77.9, 110.0, 110.3, 118.6, 121.2, 126.9, 127.2, 127.4, 127.8, 128.4, 135.9, 138.3, 155.3, 173.8. ESI (accurate mass) *m/z* calcd.: 417.1790; found: 417.1789.

**Methyl 1-benzyltryptophanate hydrochloride (5)**

**3** (5.0 g, 15.1 mmol) was dissolved in methanol (300 mL) and cooled to 0 °C. Thionyl chloride (1.1 mL, 15.1 mmol) was added dropwise and the mixture was then allowed to warm to room temperature before being brought to reflux. After overnight stirring at reflux, the reaction was cooled and concentrated. Trituration with diethyl ether provided a white powder with no further purification needed (4.55 g, 87%); mp 115–117 °C (ether).  $[\alpha]_{\text{D}}^{25} +11.3^\circ$  (*c* 0.15 in MeOH). <sup>1</sup>H NMR (300 MHz, DMSO-*d*<sub>6</sub>)  $\delta$ : 3.26 (1H, *J* = 15 and 7, dd), 3.38 (1H, *J* = 15 and 5, dd), 3.60 (3H, s), 4.19 (1H, *J* = 7 and 5, dd), 5.38 (2H, s), 7.04 (1H, *J* = 7 and 1, td), 7.11 (1H, *J* = 8 and 1, td), 7.18–7.33 (5H, m), 7.37 (1H, s), 7.41 (1H, *J* = 8, d), 7.59 (1H, *J* = 7, d), 8.71 (3H, bs). <sup>13</sup>C NMR (75.5 MHz, DMSO-*d*<sub>6</sub>)  $\delta$ : 26.1, 49.0, 52.5, 52.7, 106.6, 110.2, 118.5, 119.0, 121.5, 127.0, 127.3, 127.5, 128.4, 128.5, 136.0, 138.1, 169.7. **Dipeptide coupling general procedure**

N-terminally protected (Boc) amino acid (2.0 mmol) and HBTU (0.78 g, 2 mmol) were added to a flask containing THF (70 mL). The mixture was cooled to 0 °C and 1 equiv. of DIEA (0.35 mL, 2.03 mmol) was added. The mixture was stirred for 10 min. C-terminally protected (methyl ester) amino acid (2 mmol) and 1.2 more equiv. of DIEA (0.42 mL, 2.4 mmol) were added to the reaction, which was then warmed to room temperature and stirred for 2 h, regardless of completeness. Once complete, the reaction was concentrated, taken up in ethyl acetate, and washed with 1 mol/L HCl (×2), satd. NaHCO<sub>3</sub> (×2), water, and brine. The organic layer was dried with Na<sub>2</sub>SO<sub>4</sub> and concentrated to produce a white powder (or foam) after exposure of the residue to high vacuum overnight.

**Methyl N-[N-(tert-butoxycarbonyltryptophyl)]-tryptophanate (2)**

After initial concentration, the product was precipitated from a minimum volume of CH<sub>2</sub>Cl<sub>2</sub> at –20 °C as a white solid (1.51 g, 71%); mp 162–164 °C (CH<sub>2</sub>Cl<sub>2</sub>).  $[\alpha]_{\text{D}}^{25} -7.0^\circ$  (*c* 0.08 in MeOH). <sup>1</sup>H NMR (500 MHz, DMSO-*d*<sub>6</sub>)  $\delta$ : 1.26 (9H, s), 2.84 (1H, *J* = 15 and 9, dd), 3.00 (1H, *J* = 15 and 4, dd), 3.06 (1H, *J* = 15 and 7, dd), 3.13 (1H, *J* = 15 and 6, dd), 3.52 (3H, s), 4.21 (1H, *J* = 9 and 4, td), 4.53 (1H, *J* = 7.0 and 6, td), 6.69 (1H, *J* = 8, d), 6.92–6.97 (2H, m), 7.00–7.06 (3H, m), 7.14 (1H, *J* = 2, d), 7.28–7.33 (2H, m), 7.44 (1H, *J*<sub>HH</sub> = 8, d), 7.55 (1H, *J* = 8, d), 8.23 (1H, *J* = 8, d), 10.77 (1H, s), 10.86 (1H, s). <sup>13</sup>C NMR (126 MHz, DMSO-*d*<sub>6</sub>)  $\delta$ : 27.1, 27.7, 28.1, 51.8, 53.1, 55.0, 78.1, 109.2, 110.1, 111.3, 111.5, 118.0, 118.2, 118.46, 118.51, 118.9, 120.8, 121.0, 123.7, 127.1, 127.4, 136.06, 136.10, 155.1, 172.1, 172.2. **General procedure for BOC deprotection**

Starting material (0.6 mmol) was suspended in acetic acid at room temperature. In a separate flask, HCl (concd) was diluted with acetic acid to form a 1.5 mol/L solution of HCl in acetic acid. The resultant HCl in acetic acid solution (9.4 mL, 14 mmol HCl) was added in one portion to the starting material suspension. The suspension was dispersed upon addition of the HCl solution, followed by the appearance of another precipitate 1 h postaddition. The reaction was stirred overnight, filtered, and the cake washed with ether to yield a white solid that needs no further purification.

**Methyl N-tryptophyl-tryptophanate hydrochloride (10)**

The work-up differed as the product was soluble in acetic acid. The acetic acid was concentrated and diluted with ether. A light brown solid resulted, was filtered, and isolated (0.23 g, 90%); mp (foams) 162–170 °C, mp (melts) 178–180 °C (ether).  $[\alpha]_{\text{D}}^{25} -4.2^\circ$  (*c* 0.08 in MeOH). <sup>1</sup>H NMR (500 MHz, DMSO-*d*<sub>6</sub>)  $\delta$ : 3.05–3.30 (4H, m), 3.58 (3H, s), 4.03 (1H, *J* = 8 and 6, dd), 4.62 (1H, *J* = 7, q), 6.98–7.01 (2H, m), 7.08 (2H, *J* = 8, q), 7.21 (1H, s), 7.22 (1H, s), 7.35 (2H, *J* = 8, t), 7.50 (1H, *J* = 8, d), 7.71 (1H, *J* = 8, d), 8.1 (3H, bs), 9.11 (1H, *J* = 7.0, d), 10.96 (1H, s), 11.04 (1H, s). <sup>13</sup>C NMR (126 MHz, DMSO-*d*<sub>6</sub>)  $\delta$ : 27.2, 27.3, 52.0, 52.5, 53.3, 106.8, 108.9, 111.4, 111.5, 117.9, 118.4, 118.47, 118.52, 121.0, 121.1, 124.0, 125.0, 127.0, 127.1, 136.1, 136.3, 168.8, 171.6. #### **General method for the sequential installation of the succinyl group on N-terminal amines and saponification of C-terminal methyl esters**

Starting material **10**, **11**, or **12** (0.25 mmol) was suspended in  $\text{CH}_2\text{Cl}_2$  (10 mL) at room temperature. Succinic anhydride (0.036 g, 0.36 mmol) was added to the reaction, followed by DIEA (0.095 mL, 0.55 mmol), and the mixture stirred overnight. Dilution of the reaction with  $\text{CH}_2\text{Cl}_2$  (50 mL), followed by extraction with HCl (1 mol/L,  $2 \times 50$  mL), followed by back extraction of the aqueous with  $\text{CH}_2\text{Cl}_2$  was sufficient to isolate the methyl ester of the desired product. The combined organic layers were washed with brine (1  $\times$  50 mL) and dried over  $\text{Na}_2\text{SO}_4$  before concentration. The sticky residue was used without further purification to produce the de-esterified product. Dissolution in methanol (3 mL), followed by the addition of NaOH (1 mol/L, 0.75 mL) furnished the final product after 2 h of stirring. The reaction was diluted with water (5 mL) and acidified with HCl (1 mol/L) to pH 2. The suspension was extracted with ethyl acetate and the organic layer was washed with brine and dried over  $\text{Na}_2\text{SO}_4$  before concentration.

#### **N-[N-(3-Carboxypropanoyl)-tryptophyl]-tryptophan (13)**

Isolated as a light brown powder (0.055 g, 44%); mp (turns dark brown) 88 °C, mp (melts) 154–156 °C (EtOAc).  $[\alpha]_D^{25} -11.6^\circ$  (*c* 0.09 in MeOH).  $^1\text{H}$  NMR (500 MHz, DMSO- $d_6$ )  $\delta$ : 2.25–2.34 (4H, m), 2.88 (1H, *J* = 15 and 9, dd), 3.08 (1H, *J* = 15 and 8, dd), 3.12 (1H, *J* = 15 and 4, dd), 3.19 (1H, *J* = 15 and 5, dd), 4.50 (1H, *J* = 8 and 5, td), 4.58 (1H, *J* = 9.0 and 4, td), 6.97 (1H, *J* = 8, t), 6.98 (1H, *J* = 8,

#### **Benzyltrimethylammonium tetrakis[3,5-bis(trifluoromethyl)phenyl]borate ( $\text{BnNMe}_3^+ \text{BArF}^-$ )**

Benzyltrimethylammonium chloride (0.107 g, 0.57 mmol) and  $\text{NaBArF}$  (0.510 g, 0.57 mmol) were stirred overnight in  $\text{CH}_2\text{Cl}_2$  (40 mL). The resulting suspension was filtered through a syringe filter with a pore size of 0.45  $\mu\text{m}$  and the filtrate was concentrated to produce a white solid. The solid was rinsed with pentane and dried in vacuo for 3 h (0.499 g, 86%); mp 136–137 °C ( $\text{CH}_2\text{Cl}_2$ ).  $^1\text{H}$  NMR (500 MHz,  $\text{CDCl}_3$ )  $\delta$ : 2.82 (9H, s), 4.12 (2H, s), 7.22 (2H, *J* = 10, d), 7.47 (2H, *J* = 10, t), 7.51 (4H, bs), 7.57 (1H, *J* = 10, t), 7.67–7.68 (8H, m).  $^{13}\text{C}$  NMR (126 MHz, DMSO- $d_6$ )  $\delta$ : 53.2

( $J_{\text{CN}} = 4$ , t), 71.9, 117.8, 124.7 ( $J_{\text{CF}} = 273$ , q), 124.8, 129.2 ( $J_{\text{CF}} = 29$ , q), 130.4, 132.3, 132.7, 134.9, 161.9 ( $J_{\text{CB}} = 50$ , q).  $^{19}\text{F}$  NMR (282 MHz)  $\delta$ : -62.3.  $^{11}\text{B}$  NMR (160 MHz)  $\delta$ : -6.8. ESI (accurate mass)  $m/z$  calcd. (anion): 862.0685; found: 862.0700; calcd. (cation): 150.1283; found: 150.1281.

### N-(3-Carboxypropanoyl)-1-benzyltryptophan (16)

**5** (0.926 g, 2.8 mmol) was suspended in dry THF and stirred at room temperature. Succinic anhydride (0.28 g, 2.8 mmol) and DIEA (0.49 mL, 2.8 mmol) were then added and the mixture refluxed overnight. The volume was reduced until a thick syrup formed. Ethyl acetate was added (300 mL) and the organic was extracted three times with NaOH (aq, 0.5 mol/L,  $3 \times 75$  mL). The aqueous extracts were combined and acidified to pH 2 with HCl (1 mol/L). The brown oil was extracted with ethyl acetate. Upon drying ( $\text{Na}_2\text{SO}_4$ ) and concentrating the residue solidifies on exposure to vacuum overnight. Purification with column chromatography ( $\text{CHCl}_3$ , AcOH, MeOH) with gradient elution from 94:5:1 to 93:5:2 was used to elute pure product. Trituration of the combined and concentrated fractions with ether yielded a white crystalline solid (0.634 g, 56%); mp 148–150 °C (ether).  $[\alpha]_{\text{D}}^{25} +30^\circ$  ( $c$  0.09 in MeOH).  $^1\text{H}$  NMR (500 MHz,  $\text{DMSO}-d_6$ )  $\delta$ : 2.25–2.34 (4H, m), 3.00 (1H,  $J = 15$  and 9, dd), 3.17 (1H,  $J = 15$  and 5, dd), 4.88 (1H, m), 7.01 (1H,  $J = 8$ , t), 5.35 (2H, s), 7.07 (1H,  $J = 8$ , t), 7.15–7.16 (2H, m), 7.21–7.23 (1H, m), 7.27–7.30 (3H, m), 7.37 (1H,  $J = 8$ , d), 7.56 (1H,  $J = 8$ , d), 8.19 (1H,  $J = 8$ , d), 12.37 (2H, bs).  $^{13}\text{C}$  NMR (126 MHz,  $\text{DMSO}-d_6$ )  $\delta$ : 27.1, 29.0, 29.8, 48.9, 52.9, 109.9, 110.0, 118.6, 118.7, 121.2, 126.9, 127.2, 127.5, 127.8, 128.4, 135.9, 138.3, 170.9, 173.3, 173.8. ESI (accurate mass)  $m/z$  calcd.: 393.1456; found: 393.1450.

# An atmospheric pressure static reactor – ion trap mass spectrometer for studying gas-phase reactions

Fadel Wedian and Dean B. Atkinson

**Abstract:** The design and operation of an atmospheric pressure static reactor coupled to an ion trap mass spectrometer is described. The reactor is designed for studying gas-phase reactions that are important in atmospheric chemistry. The system provides a simple and robust method for identifying the products of gas-phase reactions. Results for the reaction of O<sub>3</sub> with 2,3-dimethyl-2-butene (tetramethylethylene, TME) are demonstrated as a proof of the principle for the performance of the static reactor. All of the previously reported major primary products of the reaction were observed, and the yields of two compounds (acetone and hydroxyacetone) were quantified, in excellent agreement with previous work. Several minor species were also observed, demonstrating the potential for this method to investigate the product channels for less well-studied atmospherically relevant reactions.

**Key words:** atmospheric pressure reactor, ozone, tetramethylethylene (TME), ion trap mass spectrometer, gas-phase reaction.

**Résumé :** On décrit la fabrication et l'opération d'un réacteur statique à pression atmosphérique couplée à un spectromètre de masse avec trappe ionique. Le réacteur a été construit de façon à pouvoir étudier les réactions en phase gazeuse importantes en chimie de l'atmosphère. Le système fournit une méthode simple et robuste pour identifier les produits des réactions en phase gazeuse. On a utilisé les résultats de la réaction de l'ozone, O<sub>3</sub>, avec le 2,3-diméthylbut-2-ène (tétraméthyléthylène, TME) comme preuve du principe de la performance du réacteur statique. Tous les produits primaires majeurs de la réaction rapportés antérieurement ont été observés et les rendements de deux composés (acétone et hydroxyacétone) ont été quantifiés, en excellent accord avec les résultats obtenus antérieurement. On a aussi observé plusieurs espèces mineures, ce qui démontre le potentiel de cette méthode pour étudier les voies réactionnelles de réactions intéressantes d'un point de vue atmosphérique, mais moins bien étudiées.

**Mots-clés :** réacteur à pression atmosphérique, ozone, tétraméthyléthylène (TME), spectromètre de masse à piège ionique, réaction en phase gazeuse.

## Introduction

There are numerous approaches available to investigate the kinetics and mechanisms of gas-phase reactions; these include FTIR spectroscopy,<sup>1–3</sup> fast flow tube mass spectrometers (FF-MS),<sup>4,5</sup> turbulent flow tube high-pressure chemical ionization mass spectrometry,<sup>6–8</sup> and atmospheric chambers coupled with GC-FID,<sup>9</sup> atmospheric pressure ionization mass spectrometry (API-MS),<sup>10–12</sup> and atmospheric pressure chemical ionization ion trap (APCI-IT) mass spectrometry.<sup>13,14</sup> In this article we introduce a method where an atmospheric pressure reactor is coupled to an ion trap mass spectrometer (IT-MS). The IT-MS is potentially valuable as a detector for gas-phase reaction experiments since it provides various clean chemical ionization modes and MS–MS experiments, which can be performed for structure determination. In addition, the IT-MS is an inexpensive bench top instrument.

Alkenes are an important class of volatile organic compounds that have natural and industrial sources.<sup>15</sup> In the atmosphere, the main sinks for alkenes are chemical reactions with ozone, OH, and NO<sub>3</sub>.<sup>15,16</sup> The mechanism of gas-phase reactions of ozone with alkenes in the troposphere has been studied over the last few decades.<sup>16–18</sup> Major overall features of ozone–alkene reactions have been established for simple alkenes, for example, 1-butene, 1-pentene, 3-methyl-1-pentene, and 3,3-dimethyl-1-butene, while little verifiable information is available for reactions with large alkenes (either open-chain or ring compounds), especially regarding the nature and yields of their products, for example, 1-methylcyclohexene, camphene, limonene, and β-pinene.<sup>16–18</sup>

The accepted mechanism of the gas-phase reaction of ozone with alkenes proceeds via the addition of O<sub>3</sub> to the double bond to yield an energy rich ozonide, which rapidly dissociates to a carbonyl product and a biradical “Criegee”

intermediate:<sup>1,16,19</sup>

The biradical intermediate is an energy-rich species, which rapidly undergoes complex bimolecular and unimolecular rearrangement and (or) fragmentation to yield a set of secondary products, including hydroxyl radicals (OH).<sup>16</sup> The carbonyl compounds formed in the decomposition of the ozonide will be denoted as the primary products. Typical OH-alkene reaction rate coefficients are several orders of magnitude larger than those for the corresponding O<sub>3</sub>-alkene reaction; therefore, OH reacts rapidly with the alkene to produce a secondary set of gas-phase products in laboratory studies. The reactivity of OH causes problems for studying the primary products of ozonolysis, so OH-scavengers such as cyclohexane<sup>20</sup> and 2-butanol<sup>21</sup> are commonly used in previous works to suppress the OH formed from the reactions of O<sub>3</sub> with alkenes.

In this paper, 2,3-dimethyl-2-butene (tetramethylethylene, TME) was used as a reagent because the TME-O<sub>3</sub> reaction has been studied intensively<sup>1,19</sup> and the major features of the reaction's kinetics and products are well-established.<sup>1,15,17,18,22-29</sup> The reaction is one of the fastest ozonolyses with a room temperature rate coefficient of  $k \approx 1 \times 10^{-15} \text{ cm}^3 \text{ molec}^{-1} \text{ s}^{-1}$ . The known primary stable products of the TME-O<sub>3</sub> reaction are acetone, (CH<sub>3</sub>)<sub>2</sub>CO, methylglyoxal, CH<sub>3</sub>C(=O)CHO, and hydroxyacetone or acetol, CH<sub>3</sub>C(=O)CH<sub>2</sub>OH.<sup>1,19</sup>

A problem in these types of studies is that a multicomponent mass spectrum is obtained from the mixture of reactants and products. The approach investigated here to mitigate this problem is to replace the electron impact ionization (EI) mode with a "softer" chemical ionization (CI) mode. Soft ionization refers to the ability to produce molecular ions or ions related to the original compound (e.g., protonated ions) from analytes with little or no fragmentation. Since the major products of the ozonolysis are easily protonated oxygenated compounds, methane was used as a proton exchange chemical ionization reagent. In methane positive chemical ionization mode, CH<sub>3</sub><sup>+</sup>, CH<sub>5</sub><sup>+</sup>, and C<sub>2</sub>H<sub>5</sub><sup>+</sup> are the proton donor species, which are produced in the ion source of the ion trap mass spectrometer mainly through the following reactions:

The mechanisms of methane chemical ionization are (i) the proton transfer in which the CH<sub>3</sub><sup>+</sup>, CH<sub>5</sub><sup>+</sup>, and C<sub>2</sub>H<sub>5</sub><sup>+</sup> react with gaseous compounds leading to the formation of "molecular ions", (MH)<sup>+</sup>, which dominates the mass spectrum of oxygenated compounds, and (ii) the ion-molecule adduct formation, which leads to the formation of adduct ions

Fig. 1. Schematic view of the static-bag interface.

[M + CH<sub>3</sub>]<sup>+</sup> and [M + C<sub>2</sub>H<sub>5</sub>]<sup>+</sup>.<sup>30</sup> Because of the clean chemical ionization mode of the IT-MS, all ions observed came from the ion-molecule reaction.

This paper describes the external reactor design for the atmospheric pressure static reactor and its operational procedure. The interface between the reactor and the low pressure mass spectrometer is discussed. The experimental results for the TME-O<sub>3</sub> reactions are used to demonstrate the strengths and weaknesses of the reactor. The future outlook for this reactor design is discussed.

## Experimental method

### The ion trap mass spectrometer

The reactor was coupled to an ion trap mass spectrometer (Varian, Inc. Saturn 2000 GC-MS) via 1.4 in. (1 in. = 25.4 mm) outer diameter (o.d.) direct insertion probe interfaces (the Saturn was originally coupled to a GC through a transfer line, which was removed for all studies described here). The reactor interface was inserted into the vacuum adaptor installed in the GC transfer line inlet port.

The ion trap usually operates at a pressure of a few millitorr (1 Torr = 133.32 Pa) of He (buffer gas). High-energy ions in the trap collide with He as the radio frequency potential increases, allowing the ions to lose some energy and remain in the center of the ion trap, improving the mass resolution. Therefore, the reactor interface described here was designed to admit a small flow of He (~2 mL/min) to help transfer analytes into the ion trap and to supply the ion trap buffer gas requirement.

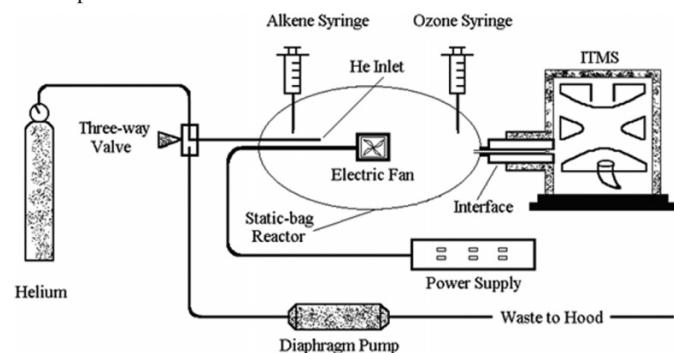

All experiments reported here were conducted using methane chemical ionization. The mass spectra (50–200 *m/z*) were collected using the Varian Saturn 2000 ion trap control software in the GC (repetitive mass scan vs time) mode. An aftermarket mass spectral data reduction program (WSearchPro) was used to convert the data to a useful form (i.e., ASCII text) for further analysis.

### Static reactor design

A vacuum interface was used to sample the static reactor

**Fig. 2.** Schematic of the static-bag reactor coupled with the ion trap mass spectrometer.

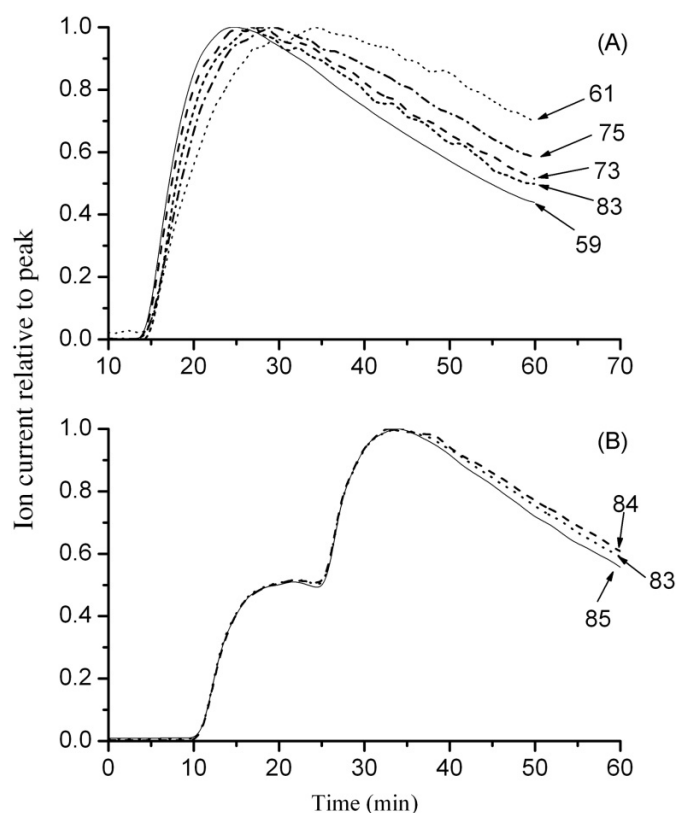

**Fig. 3.** (A) The mass spectrum of ozone background in the absence of added TME. (B) The mass spectrum of the TME–ozone reaction mixture after subtraction of the ozone background. The spectrum is dominated by acetone. (C) The net mass spectrum of the TME–ozone reaction mixture after subtracting contributions of ozone, pure TME, and pure acetone.

as shown in Fig. 1. The interface to the IT-MS consisted of a 8 cm glass capillary tube mounted in a brass plug with O-ring seals, allowing substitution for the standard GC interface of the mass spectrometer. The flow-restricting inlet in this design was a 1/16 in. o.d. glass capillary, which was heated and pulled to make a long thin tube that gave a measured flow of 2 cm<sup>3</sup>/min of helium at the atmospheric pressure differential. The capillary was held in a Cajon Swagelok connector using an O-ring seal that extended through the brass interface.

The static reactor was a 12 L Teflon bag where reactions were carried out. One side of the bag was connected to the mass spectrometer interface while the other side was connected to a three-way valve. In one position, the valve admitted a He flow sufficient to supply the mass-spectrometer interface, while maintaining the bag shape. Helium served as the gas medium for reactions as well as the carrier gas that delivered the reactants and products into the mass spectrometer and the ion trap buffer gas source, as described above. In the other valve position, the bag was connected to a diaphragm pump (Environmental Monitoring Systems) to evac-

**Fig. 4.** Ion profiles of reactant and product masses (10 ppm of TME reacting with an excess amount of purified ozone) in the static reactor, without fan, using methane as a chemical ionization reagent. (A) Ion profiles of products of the TME–O<sub>3</sub> reaction ( $m/z$  59, 61, 73, 75, and 83) that show differences in rise and decay rates among the products. (B) Ion profiles of two successive injections of pure TME ( $m/z$  83, 84, and 85) that show good reproducibility and show no observable differences among the rise times ( $t_{10\%–90\%}$ ) of these three ions associated with TME.

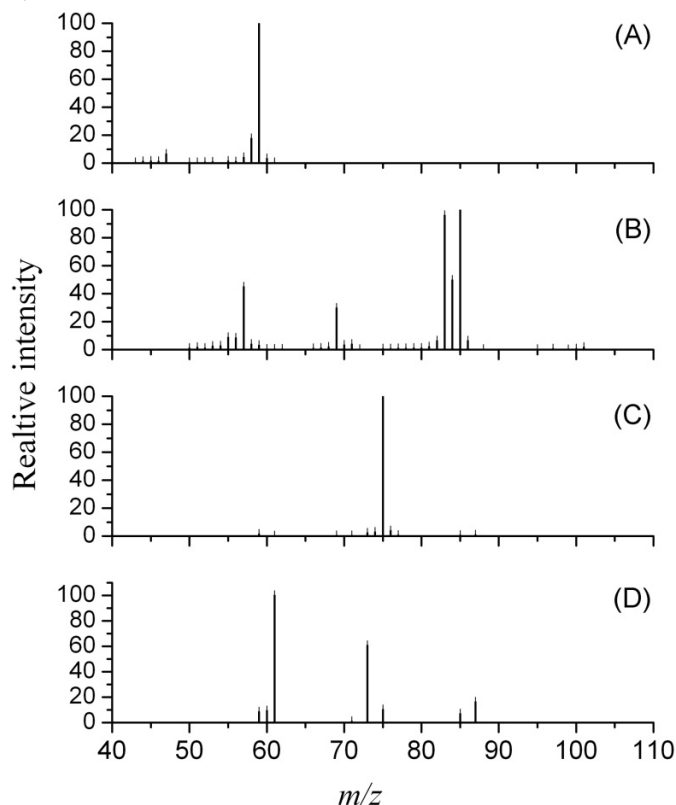

uate the bag's contents between successive experiments. Vapor phase reagent alkenes and ozone were injected with a syringe through a hole in the side of the bag, which was then covered with Teflon tape. A small electric fan inside the bag stirred the gas mixture if needed during the experiment (Fig. 2).

### Static reactor operation

In preparation for a reaction sequence, the reactor bag was filled with helium. Purified ozone in nitrogen (see below) was then injected into the bag using a 50 mL syringe. A sufficient time was given to ensure a uniform distribution of ozone throughout the bag. Then vapor-phase samples (head space air above liquids) of selected organic compounds were directly injected into the bag using a 25 mL syringe. Following the observation of the products of the ozone–TME reaction (typically several minutes), the bag was flushed and filled several times with He to remove the contents from the previous experiment, which was confirmed by low ion signals for masses of interest.

Ozone was trapped on cold silica gel via the standard procedure.<sup>31</sup> In brief, pure oxygen was photolyzed by the ozonator, and the resulting ozone–oxygen flow was allowed to

**Fig. 5.** (A) The CI mass spectrum of pure acetone (dominated by  $m/z$  59). (B) The CI mass spectrum of pure TME (dominated by  $m/z$  57, 69, 83, 84, and 85). The relative ratio of  $m/z$  83–85 is 0.98. (C) The CI mass spectrum of pure hydroxyacetone (dominated by  $m/z$  75). pass over the cold surface of silica gel (dry ice–isobutyl alcohol temperature) where the ozone was trapped. After an hour of trapping, the ozone–oxygen flow was replaced by an ultrahigh purity nitrogen flow that was used to deliver the trapped ozone to a 5 L Tedlar bag (Alltech Associates, Inc.). The ozone–nitrogen mixture was observed to be stable in the Tedlar bags for several hours. Aliquots of the mixture were transferred to the 12 L bag reactor with a syringe and released at room temperature. The ozone concentration in the reactor was determined in separate experiments by exhausting the reactor through a Dasibi ozone instrument (Dasibi, Inc., model X).

### Chemicals

Pressurized mixtures of TME in  $N_2$ , acetone in  $N_2$ , and hydroxyacetone in  $N_2$  were prepared using a gas manifold system. Chemicals and gases used in these experiments were: TME (Sigma-Aldrich, 99%), acetone (Sigma-Aldrich, 99%), hydroxyacetone (Sigma-Aldrich, 90%), pyruvic aldehyde (Sigma-Aldrich, 40 wt%), He (commercial grade 99.998, Airgas Inc.), methane (UHP 99.9995, Airgas Inc.),  $N_2$  (UHP 99.9995, Airgas Inc.),  $O_2$  (UHP 99.9995, Airgas Inc.), and isobutane (commercial grade 99.9, Airgas Inc.).

### Results and discussion

Figures 3 and 4 show results for the ozone–TME reaction,

**Table 1.** Major ions observed by ion trap mass spectrometry using  $CH_4$  chemical ionization, sampling from 1 atm (1 atm = 101.325 kPa) static reactor (without stirring), after ozone–TME reaction, listed in order of decreasing rise rates.

$m/z$	Rise coefficient ( $s^{-1}$ ) <sup>a</sup>	Tentative assignment of neutral parent	bp (°C)
59	0.004 06	Acetone	56
73	0.003 48	Methylglyoxal	72
83	0.002 86	(Not TME)	
75	0.002 34	Hydroxyacetone <sup>b</sup>	145 <sup>c</sup>
101	0.002 33	TME oxirane	
87	0.001 84	$C_5H_{10}O$	
61	0.001 75	Acetic acid	118

monitored using methane as the CI reagent. Figure 3A shows the mass spectrum of the reactor contents when ozone is the only added reagent; it shows significant fragmentations and severe overlapping of ions in at least three regions,  $m/z$  50–60, 65–75, and 80–90. These low intensity ions may correspond to impurities associated with the injected ozone into the reactor. Figure 3B shows the reaction mixture at a long reaction time in the static reactor, after subtraction of the prereaction background, much of which comes from the ozone injection. The mass spectrum is dominated by acetone, which produces a strong peak at  $m/z$  59 ( $[M + 1]^+$ ) and a few weaker fragments and isotopic variant peaks. The CI mass spectra of pure acetone, TME, methylglyoxal, and hydroxyacetone were obtained in separate experiments (Fig. 5). Multiplying the pure acetone spectrum by an appropriate weighting factor, and then subtracting this from the ozone–TME reaction mixture allows the contribution of acetone to be removed. A similar procedure is used to remove the small contribution of unreacted TME, and Fig. 3C shows the resulting mass spectrum. The other products of the ozone–TME reaction are now visible at mass peaks  $m/z$  57, 60, 61, 73, 75, 83, and 101. The following paragraphs will try to distinguish which of those ions are due to single products from multiple ion fragments of those products.

Figure 4A shows data obtained in the static reactor without stirring. These data help to distinguish ions due to single products of the ozonolysis of the TME reaction from multiple ion fragments of those products. The experimental sequence in this case was injection of ozone, equilibration, and then injection of TME at concentrations where nearly all the TME is consumed. Figure 4 shows the rise and decay of net ion signals, normalized to the maximum observed for each ion ( $m/z$  59, 61, 73, 75, and 83). Since the products of the reaction are continuously diluted by the helium inflow and (or) lost by adsorption to the bag wall, all stable compounds show a long-time decline. The peak at  $m/z$  83 arises here almost entirely from an unidentified product in the bag reactor, since the other TME fragment ions ( $m/z$  57, 69, 84, and 85) are absent (Fig. 5B).

The primary and secondary reactions in the ozone–TME system run to near-completion (99%) within a few seconds,

**Fig. 6.** The function  $(1 - \exp(-a_1 t))a_2$ , with adjustable coefficients, was used to fit the initial growth of product ions of TME- $O_3$  in the stirred bag reactor. (A) The growth ion profile of  $m/z$  59 in the absence of isobutane. (B) The growth ion profiles of  $m/z$  61, 73, and 75 in the absence of isobutane. (C) The growth ion profile of  $m/z$  59 in the presence of isobutane. (D) The growth ion profiles of  $m/z$  61, 73, and 75 in the presence of isobutane.

and they occur in a relatively small volume of the bag reactor at a considerable distance from the IT-MS sampling interface. As the fully-reacted mixture mixes with helium at atmospheric pressure in the bag, we might expect similar dilution and transport of all products at  $m/z$  59, 61, 73, 75, and 83. Thus, we would expect all peaks to diffuse with an identical time behavior, which is not what we find. The individual ion signals' time dependences were fitted to an exponential growth expression to obtain coefficients for comparison (Table 1). There are observable differences in the rise rates among those five products at  $m/z$  59, 61, 73, 75, and 83. Figure 6 shows the growth ion profile of  $m/z$  59, 61, 73, and 75 in the absence and presence of isobutane.

We ascribe the differences in rates observed in Fig. 6 to substance-dependent differential absorption and desorption at the walls of the reactor bag, and in the atmospheric-pressure portion of the glass capillary of the IT-MS interface. Re-

gardless of the mechanism, we conclude that each of the displayed ion curves corresponds to a distinct protonated neutral species in the atmospheric-pressure reactor. This means that no pair of the curves belongs to a pair of fragments produced in the IT-MS by low-pressure chemical ionization of a single species entering from the reactor.

In contrast, Fig. 4B shows the behavior of ions ascribed to a single neutral parent; in this case, TME in the absence of ozone, where two equal TME injections were performed, separated by about 15 min. The small irreproducible differences between the ion profiles represent the relative intensity measurement uncertainty for the ion trap mass spectrometer over very long times. These differences indicate the reliability of distinct neutral parent identifications such as those in Fig. 4A.

We used the logistic growth function  $(1 - \exp(-a_1 t))a_2$ , with adjustable coefficients  $a_1$  (rise coefficient,  $s^{-1}$ ) and  $a_2$

**Table 2.** Reported primary and secondary products for the TME–O<sub>3</sub> reaction (see refs. 1 and 16).

Compound name	Molecular weight (g/mol)	Chemical formula
Carbon monoxide	28	CO
Formaldehyde	30	HCOH
Methanol	32	CH <sub>3</sub> OH
Carbon dioxide	40	CO <sub>2</sub>
Methyl hydroperoxide	48	CH <sub>3</sub> OOH
Ozone	48	O <sub>3</sub>
Acetone	58	CH <sub>3</sub> COCH <sub>3</sub>
Acetic acid	60	CH <sub>3</sub> COOH
Methylglyoxal (pyruvic aldehyde)	72	CH <sub>3</sub> COCHO
Methyl acetate	74	CH <sub>3</sub> COOCH <sub>3</sub>
Hydroxyacetone	74	CH <sub>3</sub> COCH <sub>2</sub> OH
Peroxyacetic acid	76	CH <sub>3</sub> COOOH
TME	84	(CH <sub>3</sub> ) <sub>2</sub> C=C(CH <sub>3</sub> ) <sub>2</sub>

(the upper limit of the growth), to fit the initial growth of product ions versus time after injection of excess ozone into the stirred reactor. This experiment was carried out by injecting excess ozone into the stirred reactor containing TME to monitor the unreacted TME and the products of the TME–ozone reaction (Fig. 6). The measured growth time of any ion may help in identifying that ion as a primary product showing a short rising time or as a secondary product showing a relatively long rising time. The growth of  $m/z$  59 was associated with acetone. The growth of  $m/z$  73, associated with methylglyoxal, was satisfactorily fitted with rise times ( $t_{10\%–90\%}$ ) of  $20 \pm 4$  s. In contrast, the growth of  $m/z$  75, associated with hydroxyacetone (or other neutrals yielding  $m/z$  75 on protonation) was poorly fitted by the above function. This conclusion was reached based on the chemical ionization mass spectra of pure acetone (dominated by the protonated molecular ion  $m/z$  59), methylglyoxal (dominated by  $m/z$  61 and the protonated molecular ion at  $m/z$  73), and hydroxyacetone (dominated by the protonated molecular ion  $m/z$  75) (Fig. 3).

The stirred-reactor data at  $m/z$  75 indicated the presence of both an immediate component and another component with an induction delay of approximately 30 s. The ion at  $m/z$  61, presumably protonated acetic acid, grew with a rise time ( $t_{10\%–90\%}$ ) of  $50 \pm 17$  s, consistent with its identification as a secondary product. Ions at  $m/z$  87 and 101 also showed slow rise times of approximately  $63 \pm 17$  and  $50 \pm 16$  s, respectively, in the stirred reactor, diagnostic for secondary products.

Unfortunately, the static reactor will not be effective for gas-phase kinetic measurements of reactant decay and product growth at atmospheric pressure for reaction times in the range of 0.2–2 s. However, the stirred bag reactor provides kinetic measurements in the range of 10–200 s, as well as calibrated product yield measurements where the products have been identified and are separately available in pure form for response calibration. Without stirring, the bag reactor assists in the identification of ions arising from distinct gas-phase neutral species, as opposed to multiple low-pressure ion fragments from single neutral parents.

Table 2 lists all primary and secondary products of the

**Table 3.** The initial concentration of all starting materials for the TME–ozone reaction in the static-bag reactor.

Chemical	Static-bag reactor
TME	10 ppm
Ozone	Excess
Isobutane	0.04%

ozone–TME reaction identified in the literature.<sup>1</sup> All products that have a molar mass less than 50 (the first six in Table 2) were not observed by the IT-MS, so they were not measured in our experiments. We did not observe any detectable signal at  $m/z$  76 or 77 that might indicate the presence of peroxyacetic acid.

Niki et al.<sup>1</sup> performed FTIR observations on the ozonolysis of TME, with positive spectral identification of 11 products (Table 2). Their additional experiments with <sup>18</sup>O<sub>3</sub> in the presence of <sup>16</sup>O<sub>2</sub> established that several of the observed products incorporated only <sup>16</sup>O and thus were products only of free-radical reactions. Other evidence pointed to free-radical reactions as the source of several observed products. Niki et al.<sup>1</sup> concluded that there were only three primary products: acetone, methylglyoxal, and hydroxyacetone. Among the hypothesized species with mass 74, only hydroxyacetone was available to provide a reference FTIR spectrum, so precursors of the same mass whose reference spectra were not available, if present in the reaction mixture, would be contained in the residual FTIR spectrum reported in that work, and thus not reported as measured products.

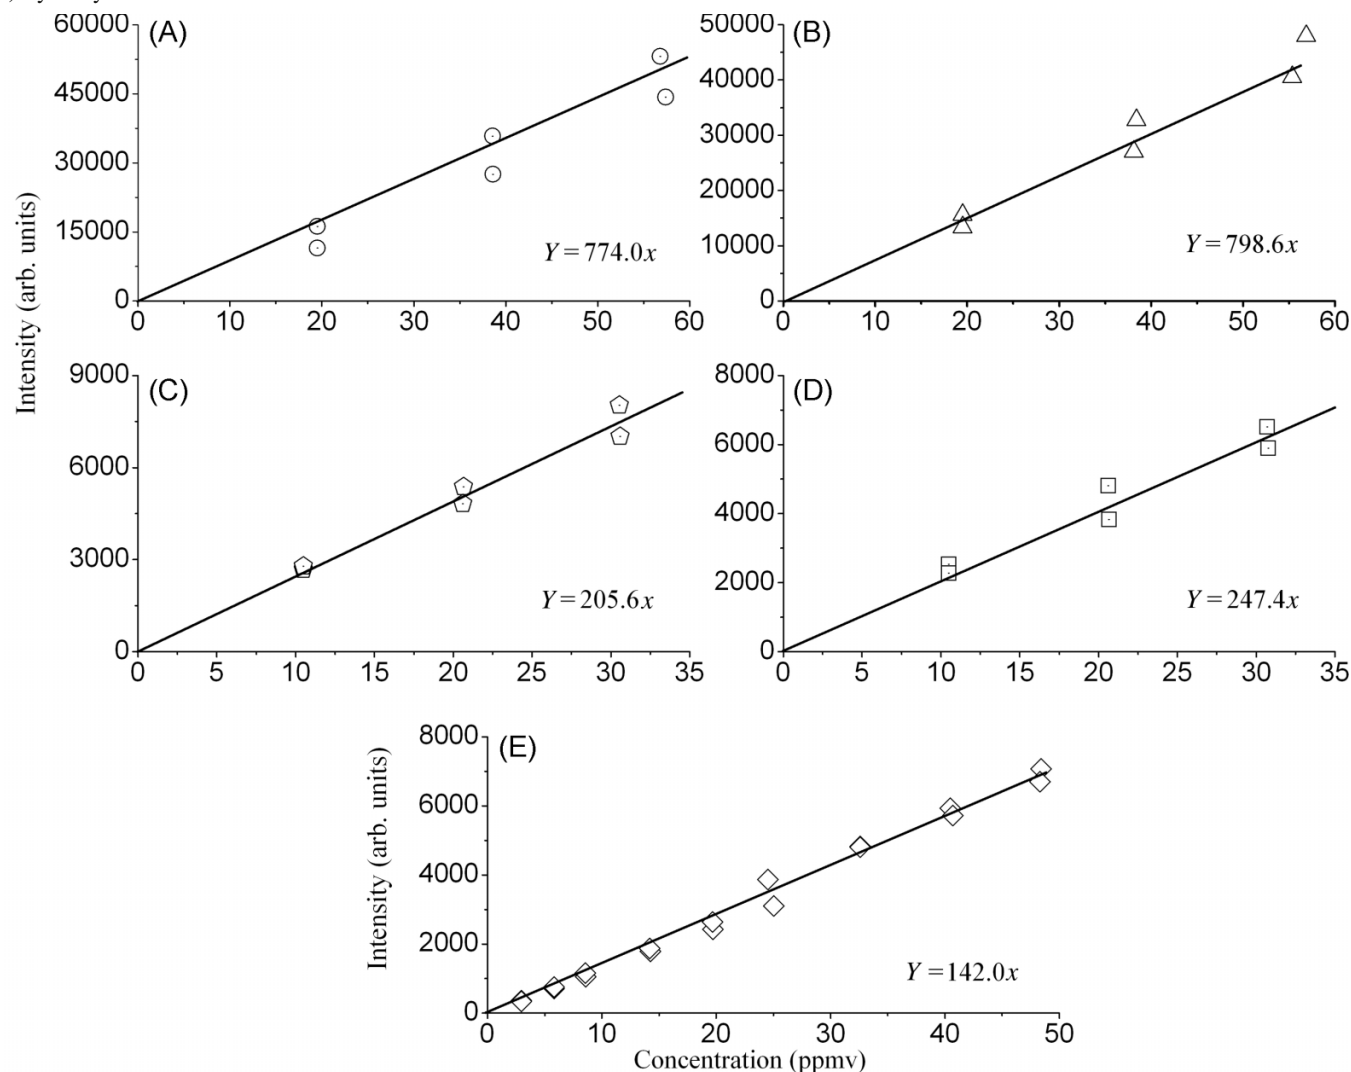

In our system, the observed peaks at  $m/z$  59, 73, and 75 probably correspond to protonation of the three primary products identified by Niki et al.:<sup>1</sup> acetone, methylglyoxal, and hydroxyacetone. These three peaks also correspond to those reported at  $m/z$  58, 72, and 74 by Martinez and Heron,<sup>19</sup> who used electron-impact ionization to observe products from ozonolysis of TME in a stopped-flow reactor at a total pressure of 4 Torr. In the case of  $m/z$  75, our experimental results do not exclude possible contributions from protonation of thermalized neutral intermediates of mass 74, such as 2-hydroperoxypropene or dimethylcarbonyl oxide. However, quantum thermochemical calculations by Olzmann et al.<sup>22</sup> predict very rapid dissociation of the hydroperoxide and persistence of the thermalized carbonyl oxide for times on the order of only 0.1 μs. From their theoretical results, one would predict an inability to detect either the carbonyl oxide or the hydroperoxide in the time range accessible to our experiments.

### Calibrations and calculation of yields

As discussed previously, acetone, methylglyoxal, and hydroxyacetone are identified as primary products of TME ozonolysis. For the purpose of quantitation of those products, we calibrated the response of the IT-MS (in CH<sub>4</sub> chemical ionization mode) to TME ( $P_{\text{vap}} = 99.665$  Torr at 20 °C from ref. 32), acetone ( $P_{\text{vap}} = 185.45$  Torr at 20 °C from ref. 32), and hydroxyacetone ( $P_{\text{vap}} = 5.6$  Torr at 20 °C from ref. 32; 7.6 mbar (1 bar = 100 kPa) in the MSDS) at their respective dominant mass numbers. Using the internal fan to stir the contents of the static reactor, we performed calibrations with and without added isobutane, which is used in some reaction experiments to scavenge OH, and found less

**Fig. 7.** Static-bag reactor calibration curves of TME, acetone, and hydroxyacetone. The responses were corrected for dilution decay: (A) acetone without isobutane, (B) acetone in the presence of isobutane, (C) TME without isobutane, (D) TME in the presence of isobutane, and (E) hydroxyacetone without isobutane.

**Table 4.** The responses and relative responses of TME, acetone, and hydroxyacetone for the static-bag reactor.

Compound	Response without isobutane	Response with isobutane	Relative response without isobutane <sup>a</sup>	Relative response with isobutane <sup>a</sup>
TME ( <i>m/z</i> 84, 85)	205.6±7.7	247.4±7.0		
Acetone ( <i>m/z</i> 59)	774.0±41.0	798.6±68.5	0.266±0.017	0.310±0.027
Hydroxyacetone ( <i>m/z</i> 75)	142.0±2.0		1.42±0.058	(1.42±0.058) <sup>b</sup>

<sup>a</sup>The relative responses were calculated with respect to TME.

<sup>b</sup>It was concluded that the presence of isobutane does not affect the performance of the ion trap, therefore, this calibration was not carried out. Based on the data shown in Fig. 7.

than 10% differences in the responses at the isobutane concentrations used. We were unable to calibrate the response to methylglyoxal due to difficulties in obtaining the pure compound. The initial typical ozone, TME, oxygen, and isobutane concentrations for the bag reactor are listed in Table 3. Since unstirred-bag experiments had indicated that the signal at *m/z* 83 may correspond to an intermediate or a product of the ozone reaction, we used only the sum of the signals at *m/z* 84 and 85 to calibrate and measure TME in the bag reactor experiments.

We measured the yields of the products of the ozone–TME reaction in the stirred bag, relative to consumption of TME. To calibrate the IT-MS response to TME, acetone, and hydroxyacetone with the bag reactor interface, we used a syringe to obtain known small volumes of air in vapor–pressure equilibrium with the analyte liquid at a known temperature, and injected them through the resealable hole in the bag wall.

A series of experiments were carried out to measure the response factor and relative response of the ion trap mass

**Table 5.** Yields of products from the reaction of ozone with TME.

<sup>a</sup>Stirred static bag: yields relative to TME consumed in the presence of isobutane. The total theoretical yields of all products are expected to be 200%.

<sup>b</sup>Absolute yields with FTIR absorption spectroscopy as reported in Calvert et al.<sup>33</sup> The analyses were based on monitoring selected absorption bands for reactants and products.

<sup>c</sup>Absolute yield with FTIR absorption spectroscopy.

<sup>d</sup>Combined absolute yields of methylglyoxal and hydroxyacetone. The yield was calculated as  $\Delta$  product formed /  $\Delta$  reacted ozone (ppb).

spectrometer for the compounds. Under similar conditions and isobutane concentrations as in the TME–O<sub>3</sub> reaction, the responses of the ion trap mass spectrometer for TME, acetone, and hydroxyacetone were plotted against the standard concentrations. Best-fit regression lines were determined from the data, the mathematical equations of the line were then used to determine the response factors (*R*), and then to determine the relative response factors (RR). The relative responses were calculated with respect to TME as follows: relative response = response of TME/response of a product. Then, a number of experiments were performed to obtain the product yield, which is given as yield =  $\Delta$ product/ $\Delta$ TME  $\times$  RR, where RR is the relative response of acetone or hydroxyacetone with respect to TME,  $\Delta$  is the change of concentrations of compounds formed or the change in concentration of reacted TME. The  $\Delta$  could be calculated as the difference between the final concentrations (at the completion of the reaction) and the initial (starting) concentration.

The calibration results are given in Fig. 7; the slope of the regression lines was used as the response (*R*) of the IT-MS for each compound. The responses and the relative responses of TME, acetone, and hydroxyacetone for the static bag in the absence and presence of the OH scavenger (isobutane) are given in Table 4. The results in Fig. 7 show the dependence of responses of compounds on the presence of isobutane, which apparently behaves as another source to protonate the compounds and by altering the IT-MS signal responses for polar compounds over nonpolar compounds under the chemical ionization mechanism mode (see Supplementary data).

In all cases, we calibrated the interface–IT-MS with and without isobutane added. We used the appropriate response calibration factor (with or without isobutane) in the calculation of product yields. The measured acetone yield (per molecule TME consumed) was nearly independent of the presence of isobutane. This is expected since acetone is also a major primary product of the reaction of O<sub>3</sub> with TME.<sup>33</sup> Though uncalibrated, the methylglyoxal yield relative to the acetone yield increased by a factor of 1.7 with the addition of isobutane, sufficient to compete equally (same reaction half-life) with TME for reaction with OH. This is consistent with earlier work that found that methylglyoxal is not a product of the reaction of OH with TME,<sup>33</sup> but that it is a primary product of ozone plus TME.<sup>1</sup> Table 5 shows a comparison of this work and other previous TME–ozone studies.

## Conclusion

It was demonstrated that a static atmospheric pressure reactor coupled with an ion trap mass spectrometer can be used to study gas-phase reactions. The TME–ozone reaction was a sample case for the application of the new design. The unstirred static reactor can be used to distinguish between different reaction products, while the stirred reactor and the flow tube described in a companion paper can be used to study the kinetics of the reaction and to follow the product formation in different time ranges, as well as to measure the product yields. This new design is convenient to use because it permits continuous, sensitive, and specific monitoring by the IT-MS.

Future work will seek to study short-lived intermediate product behavior, for example, the as yet unconfirmed products we detect at *m/z* 75 and 83. The method can also be used to investigate less well-studied biogenic alkene–ozone reactions. Furthermore, future work will seek to test a newly designed flow tube reactor, which will be coupled with the same IT-MS detector system. This flow tube reactor will be used to study the kinetics of the products as well as the product yields. In principle, those instruments may be used to study other oxidation reactions of hydrocarbons (e.g., reactions with OH and with NO<sub>3</sub>) relevant to atmospheric chemistry at realistic pressures and temperatures.

# Temperature and density effects on the absorption maximum of solvated electrons in sub- and super-critical methanol

Y. Yan, M. Lin, Y. Katsumura, Y. Muroya, S. Yamashita, K. Hata, J. Meesungnoen, and J.-P. Jay-Gerin

**Abstract:** The optical absorption spectra of the solvated electron ( $e_{\text{sol}}^-$ ) in sub- and super-critical methanol are measured by both electron pulse radiolysis and laser photolysis techniques, at temperatures in the range 220–270 °C. Over the density range studied (~0.45–0.59 g/cm<sup>3</sup>), the position of the absorption maximum ( $E_{A_{\text{max}}}$ ) of  $e_{\text{sol}}^-$  is found to shift only slightly to the red with decreasing density. In agreement with our previous work in water, at a fixed pressure,  $E_{A_{\text{max}}}$  decreases monotonically with increasing temperature in passing through the phase transition at  $T_c$  (239.5 °C). By contrast, at a fixed density,  $E_{A_{\text{max}}}$  exhibits a minimum as the solvent passes above the critical point into the supercritical state. These behaviors are discussed in terms of microscopic arguments based on the changes that occur in the methanol properties and methanol structure in the sub- and super-critical regimes. The effect of the addition of a small amount of water to the alcohol on the optical absorption energy of  $e_{\text{sol}}^-$  is also investigated.

**Key words:** methanol, methanol–water mixtures, supercritical fluid, solvated electron, absorption spectrum, density fluctuations, critical phenomena.

**Résumé :** En utilisant les techniques de radiolyse pulsée et de photolyse éclair, nous avons mesuré les spectres d'absorption optique de l'électron solvate ( $e_{\text{sol}}^-$ ) dans le méthanol à l'état sous- et supercritique, à des températures entre 220 et 270 °C. Dans la gamme de densité étudiée (~0,45–0,59 g/cm<sup>3</sup>), nous observons un léger déplacement du maximum d'absorption ( $E_{A_{\text{max}}}$ ) de  $e_{\text{sol}}^-$  vers le rouge (soit vers des énergies plus faibles) lorsque la densité diminue. De façon similaire à ce que nous avons observé précédemment dans l'eau, à pression fixée,  $E_{A_{\text{max}}}$  diminue de façon monotone lorsque la température augmente en passant la transition de phase à  $T_c$  (239,5 °C). En revanche, à une densité fixée,  $E_{A_{\text{max}}}$  présente un minimum lorsque le solvant passe au-dessus du point critique dans l'état supercritique. Ces comportements sont discutés en termes d'arguments microscopiques basés sur les changements qui interviennent dans les propriétés du méthanol et la structure de celui-ci dans les régimes sous-critique et supercritique. L'effet de l'addition d'une faible quantité d'eau à l'alcool sur  $E_{A_{\text{max}}}$  au voisinage du point critique a aussi été étudié.

**Mots-clés :** méthanol, mélanges méthanol–eau, fluide supercritique, électron solvate, spectre d'absorption, fluctuations de densité, phénomène critique.

## Introduction

In the last two decades, there has been an increased interest in various applications of supercritical fluids (SCFs).<sup>1,2</sup>

Besides their importance from the standpoint of fundamental chemistry, and especially the question of their unique physicochemical properties, SCFs have drawn interest because of their innovative role in a variety of chemical processes and

technological applications. Among the most attractive applications used or being considered in this area are the possibility of using SCFs as alternative single-phase environment-friendly “green” reaction media for the synthesis of new materials and the destruction of hazardous waste compounds.<sup>3–9</sup> Underlying this growing attention to SCFs is the fact that many of their properties are distinctly different from those of ambient liquid fluids. In particular, it is possible to sensitively control the reaction rate and the selectivity by varying the density continuously at constant temperature over a wide range from liquid- to gas-like values using only small changes in the applied pressure.

To investigate the reaction mechanisms up to supercritical conditions, one possible measurement is to establish an *in situ* method to infer time-resolved information on transient species at high temperatures and pressures. The solvated electron ( $e_{\text{sol}}^-$ ) is ubiquitous and one of the most important species in radiolysis and photolysis. Since its original identification in aqueous solution in the early 1960s,<sup>10,11</sup> the studies of the properties of solvated electrons in various solvents, as well as under different conditions, have attracted much attention in many diverse research areas. The optical absorption spectra of solvated electrons in polar liquids are broad, asymmetrical, and featureless bands with a long tail on the high-energy side of the spectrum. The investigation of the absorption spectrum of  $e_{\text{sol}}^-$  is not only significant for our understanding of how the solvent molecules play a central role in solvation processes and in the mechanism of reactions involving the solvated electron, but is also helpful for revealing the microscopic structure of solvent-cluster anions.

Recently, spectroscopic techniques implementing a high-temperature, high-pressure optical cell coupled with an electron accelerator or a short-pulsed laser have been developed by several groups<sup>12–14</sup> for the study of SCFs. Our group also has developed spectroscopic systems applicable to pulse radiolysis–laser photolysis experiments on supercritical water (SCW) and alcohols. Two high-temperature, high-pressure optical cells have successively been designed and used.<sup>15–19</sup>

In our previous work,<sup>20</sup> we measured, using electron pulse radiolysis experiments, the absorption spectra of the hydrated electron ( $e_{\text{aq}}^-$ ) in sub- and super-critical water ( $\text{D}_2\text{O}$ ) at different temperatures and densities. A most remarkable result was that at a fixed pressure (25 MPa),  $E_{\text{A,max}}$  decreases (the position of the maximum absorption shifts to the red) monotonically with increasing temperature in passing through the liquid–SCW phase transition at  $T_c$  (370.74 °C), but exhibits a minimum at a fixed density (0.2 and 0.65 g/cm<sup>3</sup>) as the water passes above  $T_c$  into SCW. Also, over the density range studied (~0.2–0.65 g/cm<sup>3</sup>), the position of the maximum of the  $e_{\text{aq}}^-$  absorption spectra was found to move only *slightly* (~5.5%) toward the red when the density decreased, in marked contrast with computer simulation studies<sup>21</sup> that predicted an ~46% decrease of  $E_{\text{A,max}}$  for the same range of density. These behaviors were explained in terms of simple microscopic arguments based on the changes that occur in the water properties and the water structure in the subcritical water and SCW regimes. Most importantly, the role played by local density and molecular configurational fluctuations (associated with criticality) in providing pre-

existing polymeric clusters, which act as trapping sites for the excess electron, was a pivotal point in the interpretation of the data. For example, we estimated that in SCW at 400 °C, the *average* size of a water cluster anion ( $(\text{H}_2\text{O})_n^-$ ) was  $n \sim 26$ –32 water molecules in the investigated density range. Such cluster size values are consistent with reported experimental clustering data for  $(\text{H}_2\text{O})_n^-$  ions, indicating that interior-bound excess electron states are energetically favored (compared with surface states) in these sub- and super-critical regions. Electrons “internalized” in such clusters can, alternatively, be viewed as microscopic probes of the local structure of their host environment.

Alcohols form an interesting class of liquids that can be used to investigate the factors influencing the formation and stabilization of electrons in fluids. Considering that the structure of methanol is very like that of water (methanol, the simplest alcohol, may be considered as “methylated water”), just one methyl group replacing one H• atom, it is reasonable to assume that density-dependent behaviors similar to those observed for water also exist in sub- and super-critical methanol (SCM). In this work, we report our measurements of the temperature and density (pressure) dependences of the absorption band maximum of  $e_{\text{sol}}^-$  in sub- and super-critical methanol at temperatures from 220 to 270 °C, using electron pulse radiolysis and laser photolysis experiments. The effect of the addition of a small amount of water to the alcohol on the optical absorption energy of  $e_{\text{sol}}^-$  is also investigated.

## Experimental

Two different high-temperature, high-pressure cells (Taiatsu Techno) were used in pulse radiolysis and laser photolysis experiments, coupled with a linear electron accelerator or a KrF excimer laser (Lambda Physik, Compex 102; pulse duration, 20 ns;  $\lambda = 248$  nm), respectively, at the Nuclear Professional School of the University of Tokyo.

As guaranteed by the manufacturer, the corrosion-resistant Hastelloy HC22 irradiation cells, equipped with sapphire windows, can withstand maximum temperatures of ~400 °C and maximum pressures of ~40 MPa. The optical path length was 15 mm for both cells. Compared with the optical cell for pulse radiolysis experiments, which has only two sapphire windows, the cell for laser photolysis experiments consists of three windows, one for the incidence of laser and the other two for analyzing light. Other details of these cells were described previously.<sup>17,18,22,23</sup>

For the pulse radiolysis experiment, the electron beam had an energy of 35 MeV and its width was ~50 ns with a dose (in water at room temperature) of ~45 Gy/pulse. The laser photolysis experiments were generally carried out using a 248 nm (5 eV) KrF excimer laser, with a pulse duration of 20 ns and an energy of 100 mJ/pulse. The UV photons were used to generate solvated electrons via the photodetachment of  $\text{I}^-$  ions dissolved in the alcoholic solution (the energy of the lowest CTTS band of the iodide ion in methanol at 25 °C is known to be centered at ~5.6 eV above the ground state).<sup>19,24</sup>

In both the pulse radiolysis and laser photolysis experiments, a flow system, which was composed of a high-performance liquid chromatography (HPLC) pump and a back pressure regulator, was used. The solution was loaded

into the cell by the HPLC pump, and the pressure was adjusted with the back pressure regulator. Four thermocouples were used to monitor temperatures at the preheater and the heater of the cell; one of these thermocouples was placed inside the solution for monitoring the temperature of irradiated samples. The trigger to the linear accelerator or laser, the pulsed xenon lamp and the monochromator (Shimadzu SPG-120S for the UV–vis spectral region and SPG-120IR for the near-IR region), as well as data accumulation and transfer were all controlled by a computer.

For the UV–vis region (400–900 nm), a silicon photodiode was used as a detector. Because the light intensity was strong enough in this region, no preamp was necessary. An InGaAs *p-i-n* photodiode detector was used for the near-IR region (800–1250 nm). The signals were amplified 3–100 times by a variable gain 200 MHz wideband voltage amplifier DHPVA-200 (FEMTO, Germany) before being sent to a digital oscilloscope that was connected to a PC through a GPIB interface. A blocking filter of 750 nm was employed to cut the scattered and multiple order light for the measurements ranging from 800 to 1250 nm. In our experimental conditions, the errors on the positions of the absorption maxima ( $E_{A_{\max}}$ ) were estimated to be  $\pm 0.012$  eV (i.e.,  $\sim 2\%$ ).

In the laser flash photolysis experiment, the solvated electron generated by the resonant one-photon photodetachment of  $I^-$  pumped directly into its charge-transfer-to-solvent band, was not the only species absorbing light in the energy range of 0.7 to 4.0 eV. Thus, at room temperature we could not directly obtain a “pure” absorption spectrum of  $e_{\text{sol}}^-$  in laser photolysis (unlike in pulse radiolysis), but a mixed spectrum (recorded at the end of laser pulse) of  $e_{\text{sol}}^-$  and the  $I_2^-$  anion radical. However,  $I_2^-$ , with its absorption bands at 1.67 and  $\sim 3.2$  eV (i.e.,  $\sim 740$  and  $380$  nm), has a much longer lifetime than  $e_{\text{sol}}^-$ . Therefore, the overlapping spectra of  $e_{\text{sol}}^-$  and  $I_2^-$  can easily be separated.<sup>19,25</sup> In this study, since only high temperatures (in the range from 220 to 270 °C) were used, the peak positions of the  $e_{\text{sol}}^-$  spectrum were always lower than 1.33 eV; therefore, it was not necessary to consider the effect owing to the absorption of the  $I_2^-$  anion radical. As the extinction coefficient at 248 nm of  $I^-$  is known to increase with increasing temperature in methanol, more solvated electrons were produced at higher temperature in the solution for a given concentration of KI. In the present experiment, a concentration of 0.1 mmol/L KI in methanol was used.

Dehydrated methanol ( $\text{CH}_3\text{OH}$ ) with a purity  $>99.8\%$  (containing  $<50$  ppm water), methanol with a purity of  $99.8\%$  (G.R. grade) (assuming that the remainder is water, this would correspond to a mole fraction for  $\text{H}_2\text{O}$  of  $0.36\%$ ), and high-purity potassium iodide (KI) were purchased from Wako Pure Chemical Industries Ltd. and used as received. The pure alcohols or dilute (0.1 mmol/L) KI–methanol solutions were deaerated by bubbling with high-purity argon gas before being pumped into the irradiation cell. Methanol densities at the various temperatures and pressures used in this study were taken from the NIST Chemistry WebBook.<sup>26</sup>

**Fig. 1.** Energy of the maximum absorption ( $E_{A_{\max}}$ ) for the solvated electron ( $e_{\text{sol}}^-$ ) in sub- and super-critical methanol (SCM) ( $\text{CH}_3\text{OH}$ ) as a function of temperature at two different densities: 0.5 and  $0.55 \text{ g/cm}^3$ . A minimum of  $E_{A_{\max}}$  versus temperature is observed at both densities as the methanol passes above  $T_c$  (239.5 °C) into SCM. Smooth lines are polynomial fits to the experimental data. Error bars for  $E_{A_{\max}}$  are shown at the ends of the curves.

## Results and discussion

After irradiation of methanol (99.8%) with a high-energy electron pulse, the absorption of solvated electrons could clearly be detected by spectrophotometry even up to 270 °C. Figure 1 shows the temperature dependence of  $E_{A_{\max}}$  near the critical point of methanol ( $T_c = 239.5$  °C,  $P_c = 8.10$  MPa, and  $\rho_c = 0.280 \text{ g/cm}^3$ )<sup>26</sup> at our two limiting bulk methanol densities (namely, 0.50 and  $0.55 \text{ g/cm}^3$ ). These data suggest that at constant density (at least over the density range studied here),  $E_{A_{\max}}$  first decreases (the maximum absorption shifts to the red) as temperature increases in the subcritical region up to the critical point, reaches a (well-defined) minimum near this point, and then rises (the absorption spectrum shifts to the blue) as the temperature is increased further in the supercritical region. Interestingly, similar behavior was observed for the temperature dependence of  $E_{A_{\max}}$  of the hydrated electron as the water ( $\text{D}_2\text{O}$ ) passes above  $T_c$  into SCW.<sup>20</sup> Here, however, the minimum value of  $E_{A_{\max}}$  ( $\sim 245$ – $250$  °C, slightly depending on the density) does not occur exactly at the critical point. As our study below makes clear, this slight change in  $E_{A_{\max}}$  can be attributed to the presence of a small amount of water in the methanol used in the experiments.

Figure 2 shows the effects caused by the presence of water in methanol on the minimum value of  $E_{A_{\max}}$  versus temperature. Using pulse radiolysis and laser photolysis, experiments were carried out for dehydrated methanol, methanol (99.8%), and a 1 mol% water–methanol mixed solution at several temperatures in the range of 220 to 270 °C, at a fixed density of  $\rho = 0.55 \text{ g/cm}^3$ . As seen in Fig. 2, the shapes of the curves and the positions of the minima of  $E_{A_{\max}}$  found for dehydrated methanol by both nanosecond pulse radiolysis and laser photolysis are practically the same, indicating that these two methods are reliable for methanol. For dehydrated methanol and methanol (99.8%), we ignored the water effect on the density and assumed that

**Fig. 2.** Energy of the maximum absorption ( $E_{A_{\max}}$ ) for the solvated electron ( $e_{\text{sol}}^-$ ) in sub- and super-critical methanol ( $\text{CH}_3\text{OH}$ ) as a function of temperature at a fixed density ( $0.55 \text{ g/cm}^3$ ) for dehydrated methanol (containing <50 ppm water) using electron pulse radiolysis (■) and laser photolysis (▲), for methanol (99.8%) using electron pulse radiolysis (●), and for a 1 mol% water–methanol mixed solution using laser photolysis (▼). As demonstrated for dehydrated methanol, the minimum for  $E_{A_{\max}}$  is precisely located at the critical point of methanol ( $239.5^\circ\text{C}$ ). Error bars for  $E_{A_{\max}}$  are shown at the ends of the curves.

at the same temperature and pressure, the densities of these two kinds of methanol were also the same. Since there is no density data available for the mixtures of methanol and water, we just used the same conditions of temperature and pressure as for the other two kinds of methanol studied. The results show that, for dehydrated methanol, the minimum of  $E_{A_{\max}}$  is precisely located at the critical point of methanol ( $239.5^\circ\text{C}$ ), as was the case with  $\text{D}_2\text{O}$ .<sup>20</sup> For methanol (99.8%) containing a little water, the shape of the  $E_{A_{\max}}$ –temperature curve is roughly similar (in particular, its width is increased) to what we observe for methanol without water, but the position of the minimum of  $E_{A_{\max}}$  is clearly shifted from  $T_c$  to higher temperatures ( $\sim 248^\circ\text{C}$ ). This shift is even larger for methanol containing 1 mol% of water. For this latter case, although  $E_{A_{\max}}$  first decreases with increasing temperature, there is no obvious tendency for it to increase after passing through the minimum point (near  $255^\circ\text{C}$ ). In addition, with the addition of 1 mol% of water to the methanol, the width of the curve of  $E_{A_{\max}}$  versus temperature increases significantly.

In a series of papers, Gordon Freeman and co-workers<sup>27</sup> investigated in considerable detail the effect of water content on  $E_{A_{\max}}$  (and also on the yield of solvated electrons at  $1 \mu\text{s}$ ) at room temperature in several alcohols. These authors indicated that addition of up to 30 mol% of water causes the  $E_{A_{\max}}$  in methanol to decrease gradually. At around 30 mol% water  $E_{A_{\max}}$  remains approximately constant until 80 mol%, and then decreases again to the value of  $E_{A_{\max}}$  in pure water. Figure 2 shows that below the critical temperature, the difference between the values of  $E_{A_{\max}}$  in dehydrated methanol and in methanol containing 1 mol% water

**Fig. 3.** Energy of the maximum absorption ( $E_{A_{\max}}$ ) for  $e_{\text{sol}}^-$  in sub- and super-critical methanol (SCM) ( $\text{CH}_3\text{OH}$ ) as a function of temperature for two different thermodynamic conditions: at a constant density ( $0.55 \text{ g/cm}^3$ ) and at a fixed pressure (20 MPa). The inset shows the temperature dependence of the methanol density at 9 and 20 MPa. The (liquid–SCM) phase transition is indicated by an arrow at  $T_c$  ( $239.5^\circ\text{C}$ ). Smooth lines are polynomial fits to the experimental data.

is in the range of experimental error. However, above the critical temperature the values of  $E_{A_{\max}}$  in dehydrated methanol are clearly higher than those in 1 mol% water–methanol solutions. As changes in  $E_{A_{\max}}$  imply that the energy of the bound state for the solvated electron is changed,<sup>27,28</sup> this indicates that in the supercritical state there is a change in the *intermolecular structure of the solvent* (which in fact corresponds to a decrease in the degree of local order) at the excess electron site caused by the addition of a small amount of water to the alcohol.

The temperature dependence of  $E_{A_{\max}}$  in methanol (99.8%) is further displayed in Fig. 3 under two different experimental conditions, namely, at constant density ( $0.55 \text{ g/cm}^3$ ) and *along an isobar* (20 MPa). As we can see, at temperatures higher than  $\sim 230$ – $235^\circ\text{C}$ , the two  $E_{A_{\max}}$ –temperature curves move away from each other. Whereas  $E_{A_{\max}}$  exhibits a minimum around  $245^\circ\text{C}$  (as shown in Fig. 1), we observe on the contrary, at fixed pressure, a smooth *monotonic* red-shift of the  $e_{\text{sol}}^-$  absorption maximum in passing through the liquid–SCM phase transition. These behaviors bear a striking similarity to those previously observed for sub- and super-critical water ( $\text{D}_2\text{O}$ ).<sup>20</sup>

Figure 4 shows the absorption spectra of the solvated electron obtained after an  $\sim 50 \text{ ns}$  pulse at a constant temperature of  $245^\circ\text{C}$  in SCM at three different pressures: 15, 24, and 35 MPa for which the corresponding methanol (bulk) densities are 0.495, 0.549, and  $0.587 \text{ g/cm}^3$ , respectively. Although methanol itself has strong absorbance below  $\sim 1 \text{ eV}$  (or above  $\sim 1240 \text{ nm}$ ), we can clearly see the position of the maximum of the  $e_{\text{sol}}^-$  spectra, which is found to shift *slightly* to lower energies (or longer wavelengths) with decreasing density. In fact, the  $E_{A_{\max}}$  (obtained by Lorentzian fitting) of the  $e_{\text{sol}}^-$  spectra in Fig. 4 changes from 1.34 eV at

**Fig. 4.** Optical absorption spectra of the solvated electron  $e_{\text{sol}}^-$  in supercritical methanol (dehydrated  $\text{CH}_3\text{OH}$ ) at 245 °C obtained by electron pulse radiolysis at various pressures (densities): (a) 15 MPa (0.495  $\text{g}/\text{cm}^3$ ,  $\blacksquare$ ), (b) 24 MPa (0.549  $\text{g}/\text{cm}^3$ ,  $\bullet$ ), and (c) 35 MPa (0.587  $\text{g}/\text{cm}^3$ ,  $\blacktriangle$ ). The data are recorded just at the end of the electron pulse ( $\sim 50$  ns). The end-of-pulse absorbance decreases with decreasing density, reflecting the fact that the deposited dose decreases as the density decreases. As for the hydrated electron spectrum in supercritical  $\text{D}_2\text{O}$  (ref. 20), a broadening of the maximum of the  $e_{\text{sol}}^-$  absorption spectrum is observed at lower density (curve (a)), which is attributed to an increasing randomness of the supercritical phase  $e_{\text{sol}}^-$  trap configurations. The experimental points within the 1.0–1.7 eV energy range are fitted by Lorentzian functions (smooth lines) to read out  $E_{\text{Amax}}$ . Dose per pulse, 45 Gy; optical path length, 1.5 cm.

**Fig. 5.** Double logarithmic plots of the energy absorption maximum ( $E_{\text{Amax}}$ , in eV) for  $e_{\text{sol}}^-$  against bulk methanol density ( $\rho$ , in  $\text{g}/\text{cm}^3$ ) in supercritical  $\text{CH}_3\text{OH}$  at 245 °C: in methanol (99.8%,  $\square$ ) and in dehydrated methanol (containing  $<50$  ppm water,  $\circ$ ). Straight lines are fits to the experimental data. The errors in our  $E_{\text{Amax}}$  values are  $\sim 2\%$ .

0.587  $\text{g}/\text{cm}^3$  to 1.27 eV at 0.495  $\text{g}/\text{cm}^3$ , a decrease of 0.07 eV ( $\sim 5.2\%$ ). Similar behavior was also observed for the density dependence of  $E_{\text{Amax}}$  of solvated electrons in supercritical  $\text{D}_2\text{O}$ <sup>20</sup> as well as in supercritical ammonia<sup>29</sup> and deuterioammonia.<sup>30</sup>

In Fig. 5 we show  $E_{\text{Amax}}$  as a function of density in a double logarithmic plot for the temperature of 245 °C in dehydrated methanol and in methanol (99.8%). As can be seen, there is a good linear relationship of  $E_{\text{Amax}}$  with density, very similar to what we observed in the case of heavy water,<sup>20</sup> and the two resulting lines (calculated by least-squares fits to the data) are *almost superposed*. Therefore, this indicates that above the critical temperature and for the  $\sim 0.45$ – $0.59$   $\text{g}/\text{cm}^3$  density range studied, the variation of  $E_{\text{Amax}}$  (in eV) with bulk methanol density ( $\rho$ , in  $\text{g}/\text{cm}^3$ ) can be well represented by the empirical equation

$$[1] \quad E_{\text{Amax}} = A(T)\rho^p$$

where the exponent  $p \approx 0.306$  ( $\pm 0.01$ ) for dehydrated methanol and  $p \approx 0.322$  ( $\pm 0.01$ ) for methanol (99.8%), is the slope of the lines, and  $A$  is a proportionality coefficient, which, according to our results for SCW ( $\text{D}_2\text{O}$ ),<sup>20</sup> varies little with temperature (fitted values of  $A$  are, respectively, 1.208 for dehydrated methanol and 1.210 for methanol (99.8%)). Considering the experimental error, the difference regarding the effects of density on  $E_{\text{Amax}}$  in methanol (99.8%) and dehydrated methanol at a *fixed* temperature can simply be ignored.

Some simple microscopic arguments, based on the large density fluctuations (or inhomogeneities) and the highly disrupted hydrogen bond network associated with criticality, can be employed to better understand, at the molecular level, the mechanisms of localization and solvation of excess electrons in near-critical methanol and SCM. As discussed in our previous work on  $e_{\text{aq}}^-$  in SCW,<sup>20</sup> these arguments rely on the pioneering work of Jortner and Gaathon<sup>31</sup> who proposed that *local density fluctuations can be viewed as pre-existing clusters that act as electron traps*. As for water, this proposition is particularly relevant for SCM where structural investigations<sup>32</sup> have clearly shown the existence of significant methanol “clustering” and the formation of hydrogen-bonded molecular clusters whose number decreases with increasing temperature and decreasing density. However, whereas many studies have focused on the electronic structure, spectroscopy, and dynamics of  $(\text{H}_2\text{O})_n^-$ , similar investigations for methanol cluster anions  $((\text{CH}_3\text{OH})_n^-)$  have so far received little attention.<sup>33–37</sup> Indeed, since the first detection of  $(\text{H}_2\text{O})_n^-$  ions mass spectroscopically in 1981,<sup>38</sup> significant experimental and theoretical efforts have been devoted to exploring how excess electrons are bound to water clusters (over a very wide range of cluster sizes) and, more recently, the key issue of the existence of both surface and internal states of hydrated electron clusters in relation to the bulk hydrated electron as  $n \rightarrow \infty$  (see refs. 20, 37, 39, 40, and refs. therein). Much of this work has centered on the photoelectron and absorption spectroscopic studies of  $(\text{H}_2\text{O})_n^-$  clusters as a function of size ( $n$ ), providing a wealth of information about the nature of the excess electron–water interactions in these clusters. One most important result is that the parameters that govern the

whole line shapes of both the  $(\text{H}_2\text{O})_n^-$  cluster photoelectron and absorption spectra (namely, peak energy position, Gaussian peak width to the low-energy side, and Lorentzian peak width to the high-energy side) can be fitted linearly in  $n^{-1/3}$  (which derives from the reciprocal of cluster radius).<sup>40</sup> For example, the fit of the peak centres of the *photoelectron spectra* (PES) (or “vertical detachment energies” (VDEs), representing the energy required to remove an electron with no change in nuclear geometry) gives<sup>39,40</sup>

$$[2] \quad E_{\text{max,PES,H}_2\text{O}}(n) = \text{VDE}(n) = -5.65n^{-1/3} + 3.25$$

where  $n$  is the number of water molecules and  $E_{\text{max}}$  is in eV. A similar linear relationship is obtained between the peak centres of the *absorption spectra* (ABS) and  $n^{-1/3}$ , namely,<sup>20,39,41</sup>

$$[3] \quad E_{\text{max,ABS,H}_2\text{O}}(n) = E_{\text{Amax}} = -2.403n^{-1/3} + 1.783$$

Equation [3] builds a bridge, connecting  $E_{\text{Amax}}$  to the  $(\text{H}_2\text{O})_n^-$  cluster size or, alternatively, the electronic absorption maxima to the local molecular microstructures accommodating the excess charge. Notably, much of the absorption spectrum of the *bulk* hydrated electron (which is inherently an “internal” state) is immediately evident from the fitted cluster value of  $E_{\text{max}}$  when  $n \rightarrow \infty$ . Indeed, as we can see from eq. [3],  $E_{\text{max}}$  extrapolates to the bulk  $e_{\text{aq}}^-$  absorption value in ambient water ( $\lambda_{\text{Amax}} = 715 \text{ nm}$  or  $E_{\text{Amax}} = 1.73 \text{ eV}$  in  $\text{H}_2\text{O}$  at  $25^\circ\text{C}$ ),<sup>42</sup> which is consistent with water cluster anions characterized by internalized excess electron states.

Unfortunately, for methanol, while the photoelectron spectra of  $(\text{CH}_3\text{OH})_n^-$  ( $n \sim 70\text{--}460$ ) are known, their absorption spectra are not. Nevertheless, as far as the  $(\text{CH}_3\text{OH})_n^-$  cluster photoelectron spectra are concerned, there are clear analogies with the anionic water cluster spectra. In particular, there is evidence for two isomeric classes of methanol cluster anion excess electron states (evolving smoothly with cluster size),<sup>43</sup> namely, an internally localized, bulklike electron state (methanol I) and a weakly dipole-bound surface state (methanol II).<sup>35,37</sup> Just as in  $(\text{H}_2\text{O})_n^-$  clusters, the measured photoelectron peak centres  $E_{\text{max}}$  (in eV) have been fitted linearly in  $n^{-1/3}$ , giving for methanol I,<sup>35</sup>

$$[4] \quad E_{\text{max,PES,CH}_3\text{OH}}(n) = -2.25n^{-1/3} + 2.51$$

Analogies also exist between the most stable (higher electron binding) isomer I clusters for methanol and water cluster anions (assigned both with an internally solvated electron); for example, their formation is favored under similar ion source conditions, their VDEs are similar for comparably sized clusters, and their ultrafast excited-state relaxation dynamics exhibit similar trends.<sup>37</sup> Moreover, the solvation of an electron in bulk methanol is similar to that in water in that the electron resides in a roughly spherical s-type ground state of  $\sim 2.5 \text{ \AA}$  radius surrounded by approximately six methanol molecules in the first solvent shell with mostly O–H bond orientation and followed by three localized, nondegenerate p-like excited states.<sup>44</sup> As in normal bulk liquid water, the absorption spectrum is dominated by three bound-bound  $s \rightarrow p$  transitions resulting in a single, broad, asymmetric, and structureless band centered at

$E_{\text{Amax}} = 1.97 \text{ eV}$  ( $630 \text{ nm}$ ) at  $25^\circ\text{C}$ .<sup>25,44,45</sup> Since measurements of the electronic absorption spectra of size-selected methanol anion clusters have not yet been reported, it is not unreasonable, in view of the close relationship between the spectroscopy and dynamics of excess electrons in clusters and bulk solvated electrons in water and methanol, to propose that the linear scaling of  $E_{\text{Amax}}$  with  $n^{-1/3}$  observed for  $(\text{H}_2\text{O})_n^-$ <sup>20,39,41</sup> also applies for  $(\text{CH}_3\text{OH})_n^-$ . Under this assumption,  $E_{\text{Amax}}(n)$  may then simply be written in the same functional form as eq. [3] as follows:

$$[5] \quad E_{\text{Amax}} = -B(T)n^{-1/3} + C(T)$$

where the coefficients  $B$  and  $C$  depend on the temperature. Obviously, as  $n \rightarrow \infty$ ,  $(\text{CH}_3\text{OH})_n^-$  clusters accommodating internal electron states (methanol I) will grow into bulk solvated electrons as a constraint on the properties of  $e_{\text{sol}}^-$ . In other words, the  $n^{-1/3}$  plot of  $E_{\text{Amax}}$  for those clusters should extrapolate meaningfully to the bulk solvated electron absorption value,<sup>25,44,45</sup> implying that in ambient methanol  $C(25^\circ\text{C}) \sim 1.97 \text{ eV}$ . Combining eqs. [1] and [5] would offer a potentially useful method (see eq. [4] of ref. 20) for predicting the *average* size of a methanol anion cluster at a given temperature for any value of the density. Since  $B(T)$  is unknown at this stage for  $(\text{CH}_3\text{OH})_n^-$ , we are left to speculate that the cluster size values in SCM are comparable to those estimated<sup>20</sup> in supercritical  $\text{D}_2\text{O}$  (at  $400^\circ\text{C}$ , we estimated that  $n$  decreases from  $\sim 32$  to  $26$  for a change in density from  $\sim 0.65$  to  $0.2 \text{ g/cm}^3$ ). These values are not inconsistent with the most recent molecular dynamics simulations of Krishtal et al.,<sup>32</sup> who found  $n \sim 15\text{--}20$  for near-critical methanol at  $\sim 212^\circ\text{C}$  and  $\rho = 0.65 \text{ g/cm}^3$ . Overall, one can assume that just as in water, the amplitudes of density fluctuations (or sizes of existing clusters) in subcritical methanol and SCM are *sufficiently large* to ensure internalized electron capture and solvation.

Some discussion, based on the above microscopic arguments, should be added here with regard to the temperature and density dependences of  $E_{\text{Amax}}$  in the vicinity of the critical point. As demonstrated in Fig. 3, at fixed pressure  $E_{\text{Amax}}$  decreases with increasing temperature, which means that the excess electron is less solvated or, in other words, that the average cluster size of  $(\text{CH}_3\text{OH})_n^-$  decreases. On the other hand, Fig. 5 indicates that at a fixed temperature  $E_{\text{Amax}}$  shifts (slightly) to higher energies as the pressure increases, implying the formation of larger cluster anions. These results can be used to explain, at least partly, the behavior of  $E_{\text{Amax}}$  as a function of temperature at two constant bulk densities as shown in Fig. 1. In fact, the observed decrease in  $E_{\text{Amax}}$  when the temperature is raised in the subcritical region can readily be attributed to a (gradual) decrease in hydrogen bonding with increasing temperature,<sup>32</sup> which results in a decrease of the average size of the existing clusters. Therefore, in these conditions, the “structure-breaking” effect of the temperature (i.e., the higher temperature causes the cluster size to decrease) dominates the “structure-making” effect of the pressure (i.e., the higher pressure required to keep the density constant while increasing the temperature works toward an increase in the cluster size). However, above the critical point, the competition between the structure-breaking and -making effects (in other words, the decrease and increase in the cluster size) of the temperature

and pressure appears to be inverted. In fact, on the basis of our experimental results, we are led to conclude that the structure-making effect of the pressure is larger above  $T_c$ . These findings are interesting in the sense that they can shed some light on the size of clusters as temperature increases at constant bulk density (actually, we know of no published work on this subject). As originally proposed by Jortner and Gaathon,<sup>31</sup> a “snowball effect” could explain the variation of  $E_{A_{\max}}$  vs temperature at constant bulk density in SCM (just as in SCW). In this regard, such an effect would likely induce an increased pressure-dependent *local* clustering around the initially formed charged cluster, leading to cluster growth. Obviously, the existence of this effect, and especially its dependence on the thermodynamic (temperature and pressure) conditions and its time scale, would certainly deserve further investigation. Quantum-classical molecular dynamics simulations of the excess electron-binding structures at play in SCM (and SCW) would likely be of great help to better understand the detailed atomistic picture underlying these findings. Finally, as seen in Fig. 2, holding density constant, the presence of a small amount of water in methanol affects the spectral peak positions  $E_{A_{\max}}$ , which indicates that the density of the *bulk* methanol is *not* the most important variable in determining the position of the  $e_{\text{sol}}^-$  absorption maximum at temperatures that are near-critical or higher. What, in fact, plays a crucial role in the determination of  $E_{A_{\max}}$  in the sub- and super-critical regions is the *extension* of the microscopic changes in the fluid structure (i.e., the amplitude of density fluctuations or, alternatively, the size of pre-existing methanol clusters to which the electron is confined).<sup>20</sup>

## Conclusion

In this study, we measured the absorption spectra of the solvated electron in sub- and super-critical methanol at different temperatures (in the range of ~220 to 270 °C) and densities (or pressures) using electron pulse radiolysis and laser photolysis techniques. Over the density range studied (~0.45–0.59 g/cm<sup>3</sup>), the  $e_{\text{sol}}^-$  absorption maximum is found to shift only slightly to the red with decreasing density, in agreement with our previous work in water. The data show that  $E_{A_{\max}}$  varies linearly (in a double logarithmic plot) with density for the temperature investigated (namely, 245 °C) and that the resulting lines are nearly the same for methanol (99.8%) and dehydrated methanol (within the experimental uncertainties). It is also shown that above the critical temperature, the values of  $E_{A_{\max}}$  in dehydrated methanol are higher than those in 1 mol% water–methanol solutions, indicating that in the supercritical state there is a change in the intermolecular structure of the solvent at the excess electron site caused by the addition of a small amount of water to the alcohol. The temperature dependence of  $E_{A_{\max}}$  in sub- and super-critical methanol further reveals that at a fixed pressure (20 MPa),  $E_{A_{\max}}$  decreases monotonically with increasing temperature while passing through the liquid-supercritical phase transition at  $T_c$ , but exhibits a minimum at fixed densities (0.50 and 0.55 g/cm<sup>3</sup>) as the methanol passes above  $T_c$  into SCM. These behaviors can be understood by means of simple microscopic arguments based on the changes that occur in the methanol properties and methanol structure in the

sub- and super-critical regimes. Most importantly, the role of local density and molecular configurational fluctuations (associated with criticality) in providing pre-existing polymeric clusters, which act as trapping sites for the excess electron, is a pivotal point in the interpretation of the data.

## Acknowledgments

We thank the Linac Division staff for their help during the pulse radiolysis experiments. We gratefully acknowledge the support of the Ministry of Education, Culture, Sports, Science, and Technology (MEXT) of Japan, and the Japan Atomic Energy Agency. J.-P. J.-G. also thanks the Natural Sciences and Engineering Research Council of Canada (NSERC), Natural Resources Canada, and Atomic Energy of Canada Limited for financial support.

# Surface-mediated synthesis of organophosphorus-based hydrazides using basic alumina

Kavita, P. Joshi, N. Sharma, and Y.C. Joshi

**Abstract:** The surface-mediated synthesis of *O*-alkyl alkylphosphorohydrazides and *N,N*-dialkylamino alkylphosphorohydrazides from phosphoryl chlorides is described. The effect of the presence of chromatographic-grade  $\text{Al}_2\text{O}_3$  (basic) on the hydrazinolysis of a series of *O*-alkyl alkylphosphonic chlorides and *N,N*-dialkylamino alkylphosphonic chlorides has also been investigated. It was observed that higher yields of the less-hindered hydrazides were obtained

**Key words:** *O*-alkyl alkylphosphonic chlorides, *N,N*-dialkylamino alkylphosphoric chlorides, phosphorohydrazides, surface mediated,  $\text{Al}_2\text{O}_3$  (basic).

**Résumé :** On décrit une méthode de synthèse catalysée par la surface de *O*-alkylphosphorohydrazides et de *N,N*-dialkylaminoalkylphosphorohydrazides à partir de chlorures du phosphoryle. On a aussi étudié l'effet de la présence d'alumine,  $\text{Al}_2\text{O}_3$  (basique), de qualité chromatographique sur l'hydrazinolysé d'une série de chlorures d'acides *O*-alkyl alkylphosphoniques et d'acides *N,N*-dialkylamino alkylphosphoniques. Il a été observé que les rendements obtenus sont plus élevés avec les hydrazides les moins encombrées.

**Mots-clés :** chlorures d'acides *O*-alkyl alkylphosphoniques, chlorures d'acides *N,N*-dialkylamino alkylphosphoniques,  $\text{Al}_2\text{O}_3$  (basique).

## Introduction

The chemistry of organophosphorus compounds is a rapidly developing area of research because of their importance in industrial, agricultural, biochemical, and medicinal applications.<sup>1</sup> It is interesting to note that the variation in their physical, chemical, and biological properties is governed by the selection of the group attached to the phosphorus atom. Although phosphorous compounds containing the P–C bond are not abundant in nature, they have diverse range of biological activity and have attracted considerable synthetic and pharmacological interest.<sup>2</sup>

Hydrazides are versatile intermediates for the synthesis of hydrazones,<sup>3</sup> pyrazoles,<sup>4</sup> and various heterocyclic compounds.<sup>5</sup> It is well known that hydrazides play an important role in antimicrobial activity. Furthermore, a number of hydrazide derivatives have been reported to possess interesting antibacterial, antifungal,<sup>6–8</sup> anticonvulsant,<sup>9,10</sup> anti-inflammatory,<sup>11,12</sup> antimalarial,<sup>13</sup> and antituberculosis activities.<sup>3,14–18</sup>

Several methods have been reported in the literature for the synthesis of hydrazides.<sup>19</sup> However, the synthesis of phosphorohydrazides has not been fully explored. There have been only a few reports on the synthesis of phosphorohydrazides, and these have several drawbacks such as the use of carcinogenic solvents, long reaction times, and formation of several by-products.

Surface-mediated solid-phase reactions are of growing interest<sup>20</sup> in the synthesis of hydrazides because of their ease

of execution and work-ups, mild reaction conditions, fast rate of reactions, selectivity, higher yields, solvent-less reaction conditions, and low cost in comparison with their homogeneous counterparts.<sup>21–23</sup> Chromatographic grade  $\text{Al}_2\text{O}_3$  (basic) has many applications as a heterogeneous catalyst either by itself or, more commonly, as a support for other reagents.<sup>20</sup> There have been only a few reports, however, on the use of  $\text{Al}_2\text{O}_3$  as a support for substrates, despite the fact that novel, synthetically useful, reactions have been observed under these conditions. Symmetrical functional substrates adsorb to the surface of  $\text{Al}_2\text{O}_3$  via a functional group. The other reactant selectively attaches to the alumina surface by reaction with the free functional group. This prompted us to explore the utility of a surface-mediated reaction for the synthesis of title compounds, in continuation of our ongoing research program to develop new synthetic methods for antibacterial compounds.<sup>24</sup> We have synthesized various *O*-alkyl alkylphosphorohydrazides and *N,N*-dialkylaminophosphonohydrazides **3a–3p**.

## Results and discussion

To test the above proposition, we have carried out the reaction of alkyl phosphonic dichloride **1**<sup>25</sup> with various alcohols and amines in the presence of triethylamine at 0 °C followed by heating at 50 °C. This reaction gave *O*-alkyl- and *N,N*-dialkylamino alkylphosphonic chlorides **2a–2p**.<sup>26</sup>

After obtaining the intermediates **2a–2p**, we optimized the

**Scheme 1.** Proposed mechanism for the synthesis of phosphonohydrazides on alumina.

reaction conditions to obtain phosphorohydrazides. In this regard, several reactions of *O*-methyl isopropylphosphonic chloride with various reagents such as neutral  $\text{Al}_2\text{O}_3$ , basic  $\text{Al}_2\text{O}_3$ , acidic  $\text{Al}_2\text{O}_3$ ,  $\text{SiO}_2$ ,  $\text{ZnO}$ , and  $\text{ZnO-SiO}_2$  were performed as model reactions. Maximum yield was obtained when basic  $\text{Al}_2\text{O}_3$  was used. Further, to optimize the molar ratio of basic  $\text{Al}_2\text{O}_3$ , various reactions of *O*-methyl isopropylphosphonic chloride were also performed by changing the mole ratio of basic  $\text{Al}_2\text{O}_3$ , reaction time, and temperature. These reactions were monitored through TLC and  $^{31}\text{P}$  NMR. Best results were obtained when the model reaction was performed with basic  $\text{Al}_2\text{O}_3$  and *O*-methyl isopropylphosphonic chloride in the mole ratio of 1:1 at  $60^\circ\text{C}$  for 30 min.

After optimization, the general applicability of the method was applied with diversity in structures **2a–2p** and results of the reactions are summarized in Table 1. All the compounds **3a–3p** were characterized by spectroscopic techniques such as FTIR,  $^{31}\text{P}$  NMR, LC–MS, and elemental analysis. The FTIR spectra showed the presence of NH bands at 3320, 3260 ( $\text{NH}_2$ ), and 3140 (*sec*-amine). It is worth noticing that the  $^{31}\text{P}$  NMR signal of *O*-alkyl alkylphosphonochloridates **2a–2p** disappeared and a new signal appeared in the range of 19–42 ppm for **3a–3p**. The results of other analysis **3a–3p** are compiled in the Experimental section.

## Experimental

### General

Melting points were determined on a hot stage microscope and are uncorrected. IR spectra were recorded on FTIR spectrometer model Jasco 610 on KBr pellets.  $^1\text{H}$ ,  $^{13}\text{C}$ , and  $^{31}\text{P}$  NMR spectra were recorded in  $\text{CDCl}_3$  on Bruker FTNMR at 400, 100, and 162 MHz, respectively, using tetramethylsilane as an internal standard for  $^1\text{H}$  and 85%

$\text{H}_3\text{PO}_4$  as an external standard for  $^{31}\text{P}$  NMR. Mass spectra were performed on a LCMS. Satisfactory C, H, N analyses were obtained for all the compounds.

### General procedure for the preparation of *O*-methyl isopropylphosphorohydrazide 3a

In a typical experimental procedure, basic activated alumina (1.0 g, 0.01 mol/L) was mixed with hydrazine hydrate 99% (0.32 g, 0.01 mol/L) in a mortar and pestle. It was ground for 5 min. at room temperature. The mixture was transferred into a single-necked flask and sealed with rubber septum, and then *O*-methyl isopropylphosphonic chloride (1.55 g, 0.01 mol/L) was added through a syringe at  $0^\circ\text{C}$ . The resultant dispersion was shaken occasionally at room temperature followed by heating at  $60^\circ\text{C}$  for 30 min. The reaction mixture was monitored using TLC and GC by drawing a few milligrams of the mixture and suspending it in 1 mL of diethyl ether. After completion of the reaction, the reaction mixture was extracted in dichloromethane and filtered. The solvent was removed and the residue was crystallized with diethyl ether.

## Conclusion

In conclusion, we have developed a rapid and efficient method for the synthesis of *O*-alkyl alkylphosphorohydrazides and *N,N*-dialkyl aminophosphonohydrazides **3a–3p** with excellent yields.

# One-pot synthesis of $\beta$ -diketimine ligands

Ibrahim El-Zoghbi, Aysha Ased, Paul O. Oguadinma, Ekou Tchirioua, and Frank Schaper

**Abstract:** Symmetric  $N,N'$ -dialkyl-2-amino-4-imino-pent-2-enes (nacnac<sup>R</sup>H) can be prepared in high yields in a simple one-pot reaction from acetylacetone and 2 equiv. of amine. Optimized conditions require the azeotropic removal of water, use of a minimum amount of solvent, and of 1 equiv. of acid. Either *para*-toluenesulfonic acid, hydrochloric acid, or a mixture of both can be employed, with the latter being most advantageous. Symmetric nacnac<sup>R</sup>H are thus obtained in higher than 95% purity and with 65% yield for R = Me and 80%–95% yields for R = *n*-Pr, *i*-Pr, *i*-Bu, Bn, Cy, and (+)-CH(Me)Ph.

**Key words:** diketimines, one-pot synthesis.

**Résumé :** On peut préparer les  $N,N'$ -dialkyl-2-amino-4-iminopent-2-ènes (nacnac<sup>R</sup>H) avec des rendements élevés en réalisant la réaction monotope de l'acétylacétone avec deux équivalents d'amine. Les conditions optimisées nécessitent l'élimination azéotropique de l'eau, l'utilisation d'une quantité minimale de solvant et un équivalent d'acide qui peut être l'acide *para*-toluènesulfonique, l'acide chlorhydrique ou un mélange des deux; ce dernier est le plus avantageux. Des nacnac<sup>R</sup>H symétriques peuvent ainsi être obtenus avec une pureté de plus de 95 % et un rendement de 65 % lorsque R = Me et des rendements allant de 80 à 95 % lorsque le groupe R = *n*-Pr, *i*-Pr, *i*-Bu, Bu, Cy et (+)-CH(Me)Ph.

**Mots-clés :** dicétimines, synthèse monotope.

## Introduction

Preparation of  $\beta$ -diketimines ("nacnac" ligands), based on diimine analogues of acetylacetone, was described already in 1950,<sup>1</sup> and their first metal complexes in 1968.<sup>2,3</sup> They played only a marginal role in coordination chemistry until the introduction of nacnac<sup>dipp</sup> (dipp = 2,6-diisopropylphenyl) as a spectator ligand in the late 1990s.<sup>4</sup> Since then,  $\beta$ -diketiminate ligands have become some of the most widely used bidentate N-donor ligands in coordination chemistry.<sup>5</sup> Interest in diketiminate ligands concentrated mostly on their N-aryl derivatives, and N-alkyl substituted diketimines were used only sparingly, mostly as low-molecular-weight ligands for chemical vapour deposition and atomic layer deposition applications.<sup>6</sup> We recently started to investigate the coordination chemistry of diketiminate ligands with aliphatic N-substituents.<sup>7–11</sup> For these investigations, we required a simple, efficient, and economic access to these compounds.

The most efficient and versatile preparation of 2-amino-4-imino-pent-2-enes is condensation of acetylacetone with amines. While condensation of the first amine proceeds readily, the resulting enaminoketone has to be activated for the second condensation.<sup>2,5</sup> This might be achieved by transformation into the ketal, and the ethylene glycol monoketal has been used successfully as starting material for the synthesis of nacnac<sup>Bn</sup>H and some macrocyclic diketimines (Scheme 1).<sup>12,13</sup> Alternatively, in the case of aryl N-substituents, reaction in ethanolic HCl yielded the desired dicondensation product, probably by intermediate formation of the diethoxyketal.<sup>3</sup> For the diketimines with N-alkyl substituents of in-

Scheme 1.

terest here, alkylation of the enaminoketone obtained after the first condensation with Meerwein salt and subsequent reaction with a second equivalent of amine is the most commonly employed method.<sup>2</sup> In an isolated report, nacnac<sup>Bn</sup>H, **1**, has been obtained by refluxing the monocondensation product acnac<sup>Bn</sup>H, **1b**, in methyl iodide.<sup>14</sup> The mechanism of this reaction (no second equivalent of amine was added) remains unclear. Recently, Bradley et al. showed that Meerwein salt can be replaced by the less toxic and more economic methyl sulfate as alkylating agent (Scheme 1).<sup>15</sup> The latter, to our knowledge, is the most efficient synthesis described, and diketimines were obtained in yields of 46%–87% starting from the enaminoketone intermediate after distillation. Diketimines with aliphatic substituents are thus accessible, but their synthesis still requires a two-step reaction, often distillation of the obtained product for purification, ex-

clusion of moisture, and the use of toxic alkylating reagents. In the following, we describe a one-step preparation of these compounds, which avoids these drawbacks.

## Results and discussion

### Initial explorations

We repeated the preparation of  $\text{nacnac}^{\text{Bn}}\text{H}$ , **1**, described by Dorman<sup>12</sup> using either acetylacetone ethylene glycol mono- or di-ketal as starting material. We found, however, the reaction to give varying yields of diketimine product and to be highly dependent on reaction conditions (Scheme 2). If the reaction is carried out in diluted toluene solution, only the monocondensation product **1b** was obtained. Reaction of acetylacetone with 2 equiv. benzylamine in ethanolic HCl, following the procedure described by Parks and Holm<sup>3</sup> and Feldman et al.<sup>16</sup> for N-aryl substituted diketimines, also yielded only **1b**. Direct condensation of acetylacetone and benzylamine (no solvent,  $T > 100^\circ\text{C}$ , in the presence of molecular sieves or thionyl chloride), under microwave heating (neat or in toluene solution, without or with addition of molecular sieves or acetyl chloride), or under azeotropic removal of water (toluene solution, catalytic quantities of *para*-toluenesulfonic acid, several days) yielded either **1b** or decomposition products and at best traces (<10%) of the desired **1**.

While aryl-substituted diketimines have been sometimes obtained under typical “Dean–Stark conditions”, i.e., catalytic amounts of acid and azeotropic removal of water, yields have been generally low-to-moderate. Budzelaar et al. reported the synthesis of  $\text{nacnac}^{\text{Xyl}}\text{H}$ , **2**, (Xyl = 2,6-dimethylphenyl) in 75% yield in the presence of stoichiometric amounts of acid. Applying this protocol, we had previously obtained  $\text{nacnac}^{\text{Bn}}\text{H}$ ,<sup>8</sup>  $\text{nacnac}^{\text{Cy}}\text{H}$ ,<sup>10</sup> and  $\text{nacnac}^{\text{CH(Me)Ph}}\text{H}$ <sup>7</sup> in 67%–82% yield. The initially obtained tosylate salt can be neutralized using a variety of bases of which aqueous potassium hydroxide proved to be the most convenient (aqueous  $\text{NaHCO}_3$  failed in some cases to deprotonate the tosylate salt). Azeotropic water removal is required and reaction of  $\text{BnNH}_2$  (or *i*- $\text{BuNH}_2$ ), acetylacetone, and 1 equiv. TsOH either in toluene or without solvent only yielded the monocondensation product **1b**.

### Optimization of the reaction conditions

Attempts to widen the synthesis described above to diketimines with simple alkyl substituents such as Me, *i*-Pr, *n*-Pr, and *i*-Bu yielded even after prolonged heating only mixtures of bis- and mono-condensation products with less than 60% of the desired diketimine according to NMR analysis. Use of more than 1 equiv. of TsOH showed no or only detrimental influence on product yields. While it has never been clarified why reactions proceed differently when catalytic or stoichiometric amounts of acid are used, we find it reasonable to assume that alkylation of the intermediate enaminketone is replaced by its (reversible) protonation and that the latter requires amounts of acid, which are equal or slightly higher than those of the amine. In agreement with this putative mechanism, presence of excess amine reduced the yield of diketimine when not compensated with excess TsOH (Table 1). Since the presence of excess amine and TsOH in equimolar amounts did not increase the yield when com-

Scheme 2.

pared to the stoichiometric reaction (Table 1), loss of the low-boiling amine seems not to be responsible for the low yields obtained.

Inspired by the decrease in yields in the reaction of acetylacetone ketal with amines on dilution, we found that concentration of the reaction mixture reduced drastically the amounts of monocondensation product and impurities formed (Table 2). Best results were obtained when the minimum amount of toluene necessary to operate the Dean–Stark apparatus was employed.

Reactions with other primary and secondary amines showed that concentration of the solution in general improved product yields and in most cases shortened reaction times to less than one day (Table 3). The low isolated yields for  $\text{nacnac}^{\text{Me}}\text{H}$  are related to its high volatility and its high sensitivity towards hydrolysis.<sup>15</sup> Reactions with isopropyl amine and isobutyl amine, however, did not show conversions above 30% even under these conditions. Substituting *p*-toluenesulfonic acid with sulfuric acid led to strongly decreased yields. The use of concentrated hydrochloric acid, on the other hand, increased the yields to 85%–95% for R = *i*-Pr and *i*-Bu, respectively. In addition, use of concentrated HCl prevented the formation of impurities observed in reactions with TsOH, and diketimines were obtained analytically pure for R = *i*-Bu, *i*-Pr, and *n*-Pr without the need for further purification. Diketimines with R = Bn or CH(Me)Ph were obtained with >90% purity according to NMR (the main contamination being the monocondensation product), which is in most cases sufficient for their use in subsequent reactions. Analytically pure compounds were obtained by recrystallization from ethanol. For methylamine and cyclohexylamine, yields were drastically reduced by replacing *para*-toluenesulfonic acid with HCl. In both cases, the formation of an insoluble precipitate even at reflux temperature indicated that this might be related to the insolubility of the respective ammonium chloride salt. Consequently, use of an equimolar mixture of HCl/TsOH restored the yields observed for TsOH in these two cases, but did not otherwise affect reactions for other amines (Table 3).

### Non-symmetric diketimines

Synthesis of non-symmetrically substituted diketimines with different substituents on N and N' is a challenge and

Scheme 3.

stepwise reaction using alkylating reagents such as Meerwein salt led to product mixtures.<sup>17,18</sup> We thus explored if non-symmetric diketimines can be obtained using the one-pot procedure established above. Reactions of acetylacetone with 1 equiv. 2,6-dimethylaniline and 1 equiv. of either (+)-methylbenzylamine or benzylamine yielded product mixtures containing the non-symmetric diketimines **4** or **5** in higher than statistical amounts, but always accompanied by the two symmetric diketimines (Scheme 3).

The preferred formation of the non-symmetric diketimine can be rationalized by the trapping of the more reactive 2,6-dimethylaniline in the monocondensation product, which diminishes its concentration in solution. Following reactions between  $\text{acnac}^{\text{Xyl}}\text{H}$ , **2b**, with methylbenzylamine, and vice versa of  $\text{acnac}^{\text{CH(Me)Ph}}\text{H}$ , **3b**, with 2,6-dimethylaniline by NMR showed that scrambling between the monocondensation products and free amines was observed already before significant amounts of diketimine were obtained (Scheme 3). In all cases,  $\text{acnac}^{\text{Xyl}}\text{H}$  was obtained preferentially. In particular at the beginning of the reaction, diketimines were thus

formed from the two species present in the highest concentrations, i.e.,  $\text{acnac}^{\text{Xyl}}\text{H}$  and either methylbenzylamine or benzylamine. As was previously observed by others, separation of non-symmetrical substituted diketimines from their symmetric counterparts is nearly impossible.<sup>18</sup> Despite their disproportionally high amount in the obtained product mixtures, **4** and **5** were not separated from the symmetric diketimines **1–3** by recrystallization, sublimation, or column chromatography (extensive hydrolysis in the latter case). For **5**, diketimine **1** could be separated by recrystallization and **5** was obtained in 30% yield and 90% purity, still contaminated by 10% of **2**.

## Summary and conclusions

$\beta$ -Diketimines with aliphatic substituents on nitrogen can be obtained in simple one-pot condensation reactions between acetylacetone and primary or secondary amine, provided that water is removed azeotropically and that one equivalent of acid is present. Under optimized reaction conditions, we employed an equimolar mixture of hydrochloric and *para*-toluenesulfonic acids, and the amount of solvent was kept to the minimum required for water removal. Symmetric diketimines can thus be obtained very economically, without the need of toxic alkylating reagents or moisture-free conditions.

For non-symmetric diketimines, the fast scrambling between free amine and monocondensation products makes the proposed protocol less efficient. Although they are obtained in higher than statistic ratio, their separation from the symmetric diketimines, invariably formed as side products, was not possible and the synthetically more demanding routes proposed by Park et al.<sup>18,19</sup> are still more advantageous.

**Table 3.** Yields in diketimine synthesis for different combinations of amines and acids (purity is given in parentheses).

R	TsOH ( $c_{\text{acacH}} < 1$ mol/L)	TsOH	HCl	HCl/TsOH	Reaction time

## Experimental section

All chemicals were obtained from commercial suppliers and used as received. Elemental analyses were performed at the Laboratoire d'Analyse Élémentaire (Université de Montréal). NMR spectra were recorded on a Bruker ARX 400 MHz spectrometer and referenced to residual solvent ( $\text{CHCl}_3$ ;  $\delta$  7.26).

### General procedure for the synthesis of symmetric diketimines

Acetylacetone and 1 equiv. of the desired acid or acid mixture (see Table 3) were combined in a minimum volume of toluene, usually equal to the combined volumes of all reactants. The mixture was stirred for 10 min and 2 equiv. of the desired amine were added to give a white suspension, which was allowed to stir for approximately 20 min. The reaction mixture was then refluxed for the required time (Table 3) with azeotropic removal of water (Dean–Stark apparatus). The brown precipitate formed after cooling to room temperature and standing for 3–4 h was isolated by decantation. Ether (50 mL) and aqueous KOH (11.2 g, 0.2 mol, 50 mL) were added and the mixture stirred for 15 min. The ether phase was separated, dried over  $\text{Na}_2\text{SO}_4$ , and the solvent evaporated. Yields and purities of the obtained products, estimated from  $^1\text{H}$  NMR, are given in Table 3. Characterization data and quantities are given below for selected experiments.

#### $\text{nacnac}^{\text{Bn}}\text{H}$ , **1**

Acetylacetone (2.00 g, 20 mmol), HCl (12.1 mol/L, 1.65 mL, 20 mmol), and benzylamine (4.28 g, 40 mmol) in toluene (7 mL) gave a red brown solid (2.90 g, 75%, >95% purity).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz):  $\delta$  11.49 (bs, 1H, NH), 7.22–7.30 (m, 10H, Ph), 4.64 (s, 1H,  $\text{CH}(\text{C}=\text{N})_2$ ), 4.46 (s, 4H,  $\text{CH}_2$ ), 1.95 (s, 6H, Me). Recrystallization from a saturated ethanol solution at  $-20^\circ\text{C}$  gave the following: Anal. calcd. for  $\text{C}_{21}\text{H}_{26}\text{N}_2$ : C, 81.97; H, 7.97; N, 10.06. Found: C, 81.75; H, 8.19; N, 10.05.<sup>2,14,15</sup>

#### $\text{nacnac}^{\text{CH(Me)Ph}}\text{H}$ , **3**

Acetylacetone (1.00 g, 10 mmol), HCl (12.1 mol/L, 0.82 mL, 10 mmol), and (+)-phenylethylamine (2.42 g, 20 mmol) in toluene (6 mL) gave a red brown oil (2.45 g,

80%, 92% purity).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz):  $\delta$  11.89 (bs, 1H, NH), 7.20–7.35 (m, 10H, Ph), 4.68 (q, 2H,  $J = 7$  Hz,  $\text{CH}(\text{Me})\text{Ph}$ ), 4.48 (s, 1H,  $\text{CH}(\text{C}=\text{N})_2$ ), 1.82 (s, 6H,  $\text{Me}(\text{C}=\text{N})$ ), 1.49 (d, 6H,  $J = 7$  Hz  $\text{CH}(\text{Me})\text{Ph}$ ). Recrystallization from a saturated ethanol solution at  $-20^\circ\text{C}$  gave the following: Anal. calcd. for  $\text{C}_{21}\text{H}_{26}\text{N}_2$ : C, 82.31; H, 8.55; N, 9.15. Found: C, 81.75; H, 8.52; N, 9.06.<sup>7,20</sup>

#### $\text{nacnac}^{\text{n-Pr}}\text{H}$

Acetylacetone (2.00 g, 20 mmol), HCl (12.1 mol/L, 1.65 mL, 20 mmol), and *n*-propylamine (2.36 g, 40 mmol) in toluene (5 mL) gave a dark brown oil (3.3 g, 90%).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz):  $\delta$  10.04 (bs, 1H, NH), 4.47 (s, 1H,  $\text{CH}(\text{C}=\text{N})_2$ ), 3.17 (t,  $J = 9$  Hz, 4H,  $\text{NCH}_2$ ), 1.87 (s, 6H,  $\text{Me}(\text{C}=\text{N})$ ), 1.61 (m, 4H,  $\text{CH}_2\text{CH}_2\text{CH}_3$ ), 0.97 (t,  $J = 9$  Hz, 6H,  $\text{CH}_2\text{CH}_3$ ). Anal. calcd. for  $\text{C}_{11}\text{H}_{22}\text{N}_2$ : C, 72.47; H, 12.16; N, 15.37. Found C, 72.41; H, 11.81; N, 15.39.<sup>15</sup>

#### $\text{nacnac}^{\text{i-Pr}}\text{H}$

Obtained from acetylacetone (2.00 g, 20 mmol), HCl (12.1 mol/L, 1.65 mL, 20 mmol), and isopropylamine (2.36 g, 40 mmol) in toluene (5 mL). To eliminate monocondensation product, the oil obtained after decantation of toluene was treated with excess saturated aqueous  $\text{NaHCO}_3$  and ether (20 mL). Ether and water phases were decanted from the remaining oil. Ether (50 mL) and aqueous KOH (11.2 g, 0.2 mol, 50 mL) were added and the mixture stirred. The ether phase was separated, dried over  $\text{Na}_2\text{SO}_4$ , and evaporated to dryness to give a dark-red oil (3.4 g, 85%).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz):  $\delta$  11.43 (bs, 1H, NH), 4.38 (s, 1H,  $\text{CH}(\text{C}=\text{N})_2$ ), 3.06 (hept.,  $J = 6$  Hz, 2H,  $\text{CH}(\text{CH}_3)_2$ ), 1.89 (s, 6H,  $\text{CH}_3(\text{C}=\text{N})$ ), 1.16 (d,  $J = 6$  Hz, 12H,  $\text{CH}(\text{CH}_3)_2$ ). Anal. calcd. for  $\text{C}_{11}\text{H}_{22}\text{N}_2$ : C, 72.47; H, 12.16; N, 15.37. Found C, 72.06; H, 12.08; N, 15.15.<sup>2</sup>

#### $\text{nacnac}^{\text{i-Bu}}\text{H}$

Acetylacetone (2.00 g, 20 mmol), HCl (12.1 mol/L, 1.65 mL, 20 mmol), and isobutylamine (2.92 g, 40 mmol) in toluene (5 mL) gave a brown oil (4.3 g, 95%).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz):  $\delta$  11.07 (bs, 1H, NH), 4.48 (s, 1H,  $\text{CH}(\text{C}=\text{N})_2$ ), 3.05 (d,  $J = 9$  Hz, 4H,  $\text{CH}_2$ ), 1.88 (m, 2H,  $\text{CH}(\text{CH}_3)_2$ ), 1.86 (s, 6H,  $\text{CH}_3(\text{C}=\text{N})$ ), 0.96 (d,  $J = 9$  Hz, 12H,  $\text{CH}(\text{CH}_3)_2$ ). Anal. calcd. for  $\text{C}_{13}\text{H}_{26}\text{N}_2$ : C, 74.23; H, 12.46; N, 13.32. Found C, 74.06; H, 13.03; N, 12.99.<sup>15,21</sup>

**nacnac<sup>Cy</sup>H**

Acetylacetone (2.00 g, 20 mmol), HCl (12.1 mol/L, 0.82 mL, 10 mmol), *p*-toluenesulfonic acid monohydrate (2.00 g, 11 mmol), and cyclohexylamine (3.98 g, 40 mmol) in toluene (15 mL) gave a colorless oil that crystallizes into colorless crystals upon standing for 2–3 h (4.75 g, 90%). <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz): δ 11.72 (bs, 1H, NH), 4.44 (s, 1H, CH(C=N)<sub>2</sub>), 3.32–3.35 (m, 2H, Cy CH), 1.90 (s, 6H, Me(C=N)), 1.80–1.35 (m, 20H, Cy). Anal. calcd. for C<sub>13</sub>H<sub>26</sub>N<sub>2</sub>: C, 77.80; H, 11.52; N, 10.64. Found C, 77.44; H, 11.57; N, 10.67.<sup>22</sup>

**nacnac<sup>Me</sup>H**

Acetylacetone (3.00 g, 30 mmol), HCl (12.1 mol/L, 1.24 mL, 15 mmol), *p*-toluenesulfonic acid monohydrate (2.99 g, 16 mmol), and methylamine (40%, 4.65 g, 0.06 mol) in toluene (6 mL). The aqueous phase was re-extracted with ether (3 × 300 mL), and the combined organic phases were dried over Na<sub>2</sub>SO<sub>4</sub> and evaporated to dryness. The dark-yellow oil obtained solidifies to an orange precipitate that darkens upon standing to room temperature (2.5 g, 65%). <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz): δ 10.04 (bs, 1H, NH), 5.2 (s, 1H, CH(C=N)<sub>2</sub>), 2.99 (s, 6H, NMe), 1.86 (s, 6H, CH<sub>3</sub>(C=N)). <sup>13</sup>C{<sup>1</sup>H} NMR (CDCl<sub>3</sub>, 400 MHz): δ 162.1 (C=N), 93.9 (CH(C=N)<sub>2</sub>), 33.3 (Me), 19.0 (CH<sub>3</sub>(C=N)). Elemental analysis data were unsatisfactory due to easy decomposition.<sup>2,15</sup>

**nacnac<sup>Xyl,Bn</sup>H**

Acetylacetone (3.00 g, 30 mmol), HCl (12.1 mol/L, 2.5 mL, 30 mmol), and 2,6-dimethylaniline (3.63 g, 30 mmol) in toluene (12 mL) were refluxed for approximately 2 h. To the obtained yellow suspension, benzylamine (3.27 g, 30 mmol) was added and allowed to reflux for 3 days under azeotropic removal of water in a Dean–Stark apparatus. After cooling to room temperature and decantation of toluene, the brown oil obtained was treated with ether (50 mL) and aqueous KOH (16.8 g, 0.3 mol, 50 mL). The ether phase was separated and evaporated to dryness. The obtained red-brown oil was dissolved in a minimum amount of ethanol and kept at –20 °C for several days. Crystals of nacnac<sup>Bn</sup>H formed were removed by filtration, and the remaining ethanol solution was evaporated to dryness to yield a brown oil (2.62 g, 30%, in 90% purity containing 10% of **2**). Further recrystallizations in MeOH or in EtOH as well as sublimation still yielded product mixtures. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz): δ 11.18 (bs, 1H, NH), 7.22–7.30 (m, 8H, Ph), 4.45 (s, 1H, CH(C=N)<sub>2</sub>), 4.43 (s, 2H, CH<sub>2</sub>), 2.07 (s, 6H, Ar Me), 1.90 (s, 3H, Me(C=N)), 1.63 (s, 3H, Me(C=N)). <sup>13</sup>C{<sup>1</sup>H} NMR (CDCl<sub>3</sub>, 400 MHz): δ 160.1 (C=N), 140.1 (C=N), 128.4, 128.3, 127.6, 127.5, 127.2, 127.0, 126.7, 126.3 (all Ph), 93.9 (CH(C=N)<sub>2</sub>), 46.5 (CH<sub>2</sub>), 21.2 (Me(C=N)), 19.1 (Me(C=N)), 18.3 (Me<sub>2</sub>Ph). EI-HR-MS (*m/z*): calcd. for C<sub>20</sub>H<sub>25</sub>N<sub>2</sub> [M + H]<sup>+</sup>: 293.2012; found: 293.2013.<sup>5</sup>

# A convenient route to distannanes, oligostannanes, and polystannanes

Aman Khan, Robert A. Gossage, and Daniel A. Foucher

**Abstract:** The quantitative conversion of the tertiary stannane (*n*-Bu)<sub>3</sub>SnH (**2**) into (*n*-Bu)<sub>6</sub>Sn<sub>2</sub> (**4**) was achieved by heating the neat hydride material under low pressure or under closed inert atmosphere conditions. A 31% conversion of Ph<sub>3</sub>SnH (**3**) to Ph<sub>6</sub>Sn<sub>2</sub> (**5**) was also observed under low pressure; however, under closed inert atmosphere conditions afforded Ph<sub>4</sub>Sn (**6**) as the major product. A mixed distannane, (*n*-Bu)<sub>3</sub>SnSnPh<sub>3</sub> (**7**), can also be prepared in good yield utilizing an equal molar ratio of **2** and **3** and the same reaction conditions used to prepare **4**. This solvent-free, catalyst-free route to distannanes was extended to a secondary stannane, (*n*-Bu)<sub>2</sub>SnH<sub>2</sub> (**8**), which yielded evidence (NMR) for hydride terminated distannane H(*n*-Bu)<sub>2</sub>SnSn(*n*-Bu)<sub>2</sub>H (**9**), the polystannane [(*n*-Bu)<sub>2</sub>Sn]<sub>*n*</sub> (**10**), and various cyclic stannanes [(*n*-Bu)<sub>2</sub>Sn]<sub>*n=5,6*</sub> (**11**, **12**). Further evidence for **10** was afforded by gel permeation chromatography (GPC) where a broad, moderate molecular weight, but highly dispersed polymer, was obtained (*M*<sub>w</sub> = 1.8 × 10<sup>4</sup> Da, polydispersity index (PDI) = 6.9) and a characteristic UV–vis absorbance (λ<sub>max</sub>) of ≈ 370 nm observed.

**Key words:** solvent free, catalyst free, dehydrogenation, stannanes, polystannanes.

**Résumé :** On a effectué la conversion quantitative du stannane tertiaire (*n*-Bu)<sub>3</sub>SnH (**2**) en (*n*-Bu)<sub>6</sub>Sn<sub>2</sub> (**4**) par chauffage de l'hydruire net, à basse pression ou dans des conditions atmosphériques inertes, sans contact avec l'extérieur. On a aussi observé une conversion de 31 % du Ph<sub>3</sub>SnH (**3**) en Ph<sub>6</sub>Sn<sub>2</sub> (**5**) dans des conditions de basse pression; toutefois, dans des conditions atmosphériques inertes sans contact avec l'extérieur, le produit majeur est le Ph<sub>4</sub>Sn (**6**). Un distannane mixte (*n*-Bu)<sub>3</sub>SnSnPh<sub>3</sub> (**7**) peut aussi être préparé avec un bon rendement en utilisant un rapport molaire égal à l'unité des composés **2** et **3** dans les mêmes conditions que celles utilisées pour préparer le composé **4**. On a étendu cette nouvelle voie de préparation des distannanes, sans solvant et sans catalyseur, pour obtenir un distannane secondaire, le (*n*-Bu)<sub>2</sub>SnH<sub>2</sub> (**8**) qui, sur la base de données de RMN, contient aussi un distannane à hydruire terminal, H(*n*-Bu)<sub>2</sub>SnSn(*n*-Bu)<sub>2</sub>H (**9**), du polystannane, [(*n*-Bu)<sub>2</sub>Sn]<sub>*n*</sub> (**10**), et divers stannanes cycliques [(*n*-Bu)<sub>2</sub>Sn]<sub>*n=5,6*</sub> (**11**, **12**) dans lesquels *n* = 5 et 6. La chromatographie par perméation de gel (CPG) a aussi permis d'obtenir des données mettant en évidence la présence d'un polymère de poids moléculaire modéré, mais hautement dispersé (*M*<sub>w</sub> = 1,8 × 10<sup>4</sup> Da, indice de polydispersion (IPD) = 6,9) et d'observer une absorbance caractéristique dans le spectre UV–vis avec un λ<sub>max</sub> ≈ 370 nm.

**Mots-clés :** sans solvant, sans catalyseur, déshydrogénation, stannanes, polystannanes.

## Introduction

Hexaorganodistannanes are a convenient source of stannyl radicals and have found applications in organic chemistry in a variety of reduction reactions,<sup>1</sup> in addition to their utility in palladium-catalyzed cross-coupling processes.<sup>2</sup> Distannanes also serve as useful models for polystannanes.<sup>3</sup> Industrially, distannanes show considerable antibacterial and fungicidal activity and were previously used as wood preservatives.<sup>4</sup> The distannane class of compounds are the tin analogues of ethanes but possess a Sn–Sn bond that is comparatively weaker (154 vs 356 kJ/mol) and longer (2.80 vs 1.54 Å) than typical C–C bonds.<sup>5,6</sup> Organodistannanes are generally thermally stable but are chemically sensitive to the presence of oxygen (more so than that of water, mild acids, or alkalis) and can readily decompose to form stannoxanes (i.e., R<sub>3</sub>Sn–O–SnR<sub>3</sub>) such as **1** (Fig. 1).<sup>7</sup>

Distannanes can be synthesized directly from the dehydrogenative dimerization of tin hydrides (e.g., **2** and **3**) with either amines or alkoxides acting as the catalyst.<sup>8</sup> Organotin hydrides can also be dehydrogenatively coupled using transition metal catalysts such as Pd(PPh<sub>3</sub>)<sub>4</sub>, PdCl<sub>2</sub>(NCMe)<sub>2</sub>,<sup>9</sup> or ruthenium–allenylidene complexes.<sup>10</sup> Electrochemical preparations of R<sub>3</sub>SnSnR<sub>3</sub> (e.g., R = *n*-C<sub>4</sub>H<sub>9</sub> (**4**), C<sub>6</sub>H<sub>5</sub> (**5**), *p*-CH<sub>3</sub>C<sub>6</sub>H<sub>4</sub>–, or C<sub>6</sub>H<sub>5</sub>CH<sub>2</sub>–) compounds involving the reduction of R<sub>3</sub>SnX (X = Cl, NO<sub>3</sub>, H, SPh, OCHO, OCOCH<sub>3</sub>, etc.) have also been reported.<sup>11,12</sup> Stoichiometrically, **5** can be prepared via the reductive coupling of triphenyltin derivatives (Ph<sub>3</sub>SnX, where X = Cl, I, or OH) in a THF/aq NH<sub>4</sub>Cl solution containing Zn metal.<sup>13,14</sup> The first high yield synthesis of **4** was reported by Sawyer<sup>15</sup> from the treatment of distannoxane **1** with **2** at 100 °C for several days (Scheme 1).

Alternative methods for the synthesis of **4** from **1** include

reactions with formic acid,<sup>16</sup> or reductions utilizing Mg, Na, or K metal in THF<sup>17</sup> solution; NaBH<sub>4</sub><sup>18</sup> or SmI<sub>2</sub><sup>19</sup> in hexamethylphosphoramide (HMPA) has also been used. Recently, an improvement in the synthesis of **4**<sup>20</sup> was reported, which involves a high temperature (200 °C), catalyst-free protocol using **1** and **2** at a molar ratio of 1:2.2. This method gives **4** in a quantitative yield. Interestingly, these same authors also reported a lower yield (52%) of **4** by simply heating **2** at a lower temperature (150 °C) for 6 h under vacuum (Scheme 2).

In this study, we reinvestigate the solvent and catalyst-free dehydrocoupling of **2** to produce **4** in an effort to identify the optimum reaction conditions for a variety of distannanes. This direct approach was thus extended to the aryl tin hydride (**3**) to obtain Ph<sub>3</sub>SnSnPh<sub>3</sub> (**5**). We also report on the catalyst-free reactions involving equimolar ratios of alkyl (**2**) and aryl (**3**) tin hydrides. Finally, we present evidence that this approach can be extended to alkyl dihydrostannanes for the production of both oligostannanes and polystannanes.

## Results and discussion

The reaction conditions for both **2** and **3** to produce distannanes **4** and **5** are listed in Table 1. An attempt to distill **2** (200 °C, in vacuo) using a long path distillation condenser was initiated with the intention to further purify **2**. Surprisingly, the product of this distillation was not **2**, but a nearly quantitative conversion (<sup>1</sup>H and <sup>119</sup>Sn NMR, yield: 97%) to distannane **4**. We investigated the impact of heating **2** to reflux temperature (200 °C) under reduced pressure using a long path reflux condenser. After 6 h, analysis by <sup>1</sup>H and <sup>119</sup>Sn NMR indicated a 75% conversion of **2** into **4**. The sample was further heated (6 h) under these conditions, but NMR analysis showed virtually no change in the proportions of the product and starting material. A plausible reason for this observation is that the more volatile hydride is retained by the cool portion of the reflux condenser rather than in close proximity to the heat source. To improve this conversion, **2** was heated (200 °C) under static vacuum conditions in a sealed Schlenk flask. An analysis (<sup>119</sup>Sn NMR) of a small aliquot of the reaction mixture taken every hour revealed that after 5 h, **2** had completely converted to the distannane **4**. A single <sup>119</sup>Sn resonance (δ = −83.6 ppm) was observed for **4**, with characteristic Sn satellites (*J*<sub>119Sn–117Sn</sub> = 1280 Hz), which is in agreement with reported literature values.<sup>20</sup> The reaction was also carried out in a sealed flask

**Scheme 2.**

under a nitrogen atmosphere. Analysis by <sup>119</sup>Sn NMR showed a small peak for **2** after 5 h, which was completely consumed after heating for an additional 1 h (Fig. 2). There was no evidence of redistribution products, which were reported when **2** was thermally dehydrocoupled in the presence of group 4 or 6 transition metal complexes.<sup>21</sup>

Similar dehydrocoupling conditions were used for hydride **3**. After 6 h at reflux (200 °C) under reduced pressure, analysis by NMR showed that approximately 31% of the starting material had converted to distannane **5**, with most of the remainder represented by the starting material **3** in addition to a significant fraction of the redistribution product (24%) Ph<sub>4</sub>Sn (**6**). Product **5** precipitated from the reaction mixture as a crystalline solid as it cooled and could be easily recovered from the starting material by recrystallization. The reaction was also repeated in a heated (200 °C) and sealed Schlenk flask under static vacuum. The <sup>119</sup>Sn NMR spectrum showed evidence of a thermal redistribution reaction with the bulk of the material converted (87%) to **6** and a considerably lower fraction of **5** (10%), in addition to a trace of grayish sediment, which was attributed to elemental tin (3%).

Utilizing closed, reduced-pressure reaction conditions, an equimolar mixture reaction of **2** and **3** was heated (200 °C) for 5 h. Analysis by <sup>119</sup>Sn NMR spectroscopy (Fig. 3) revealed resonances at δ = −145.8 and −67 ppm consistent with the formation of **7**.<sup>22</sup> The NMR evaluation of the reaction mixture also indicated that compound **7** was present in a 36.6% yield. Traces of the starting materials, along with **4** (11.9%) and **5** (37.6%), the redistribution product **6** (12.9%), recovered tin metal (1.2%), and two unassigned peaks were also noted. These unidentified materials may be other higher molecular weight redistribution products.

The solvent-free, catalyst-free reaction N<sub>2</sub>(g) conditions were also employed with the secondary stannane, (*n*-Bu)<sub>2</sub>SnH<sub>2</sub> (**8**; Scheme 3). After 6 h of heating (160 °C), <sup>119</sup>Sn NMR spectroscopic analysis of the bright yellow oily solid material revealed a multitude of resonances.

Clearly identifiable in this spectrum, however, was a resonance at δ ≈ −208 ppm, which is attributed to the hydride terminated distannane (*n*-Bu<sub>2</sub>SnH)<sub>2</sub> (**9**).<sup>23</sup> Additionally, a resonance at δ ≈ −189 ppm can be assigned to linear dibutyl-

**Scheme 3.****Fig. 2.** <sup>119</sup>Sn NMR spectra of the products from the dehydrocoupling of **2** at (A) 4 h at 200 °C and (B) 5 h at 200 °C under static reduced pressure.**Fig. 3.** <sup>119</sup>Sn NMR spectrum of the products from the dehydrocoupling of **2** and **3** at 200 °C for 5 h. Peaks with an asterisk are unassigned.

polystannane (**10**).<sup>24</sup> Two cyclic species (**11** and **12**) were identified by comparison with the literature <sup>119</sup>Sn chemical shift values.<sup>25,26</sup> The assignments of the rest of the minor signals has not yet been made but these are likely due to the presence of higher molecular weight hydride terminated oligomers (e.g., *n*-Bu<sub>2</sub>SnH(*n*-Bu<sub>2</sub>Sn)<sub>*n*</sub>SnH*n*-Bu<sub>2</sub>). Analysis of this material by gel permeation chromatography (GPC) showed a broad polymer distribution and a modest molecu-

lar weight polystannane (*M<sub>w</sub>* = 1.8 × 10<sup>4</sup> Da, polydispersity index (PDI) = 6.9), along with a considerable fraction of lower molecular weight linear and cyclic products. A UV-vis spectrum (Fig. 4) of the mixture containing the polymer **10** displayed a broad absorbance with a λ<sub>max</sub> centered at ≈ 370 nm. This absorbance can be attributed to the σ-σ\* of the polystannane, which is in good agreement with reported values.<sup>24</sup>

When the dehydrocoupling of **8** was attempted at a higher temperature (200 °C, 6 h), evidence of multitude of alkyl redistribution products was found (Scheme 4). Analysis by <sup>119</sup>Sn NMR spectroscopy showed resonances attributed to **2**, as well as to dimeric **4** and higher tributylstannane terminated oligomers (i.e., **13** and **14**), which were identified by comparison to literature values.<sup>16</sup> A large unassigned resonance was observed at +156 ppm. This downfield shift is characteristic of a four-coordinate dialkyl tin alkoxide species, e.g., R<sub>2</sub>Sn(OR)<sub>2</sub>, which typically have resonances in the range of +90 to +200 ppm.<sup>27</sup> There is no evidence of cyclic products nor hydride terminated oligomers.

## Mechanistic considerations

The catalyst- and solvent-free, presumably radically driven, dehydrocoupling reactions described herein (Scheme 5) are apparently activated through the thermolysis of the relatively weak Sn-H bonds of R<sub>3</sub>SnH (R = *n*-Bu<sub>3</sub>, Ph). The small differences between the ground state bond dissociation energies for known stannanes (e.g., Me<sub>3</sub>SnH = 305 ± 17 kJ/mol, Me<sub>3</sub>SnEt = 284 ± 17 kJ/mol, Me<sub>3</sub>SnPh = 339 ± 21 kJ/mol, and Me<sub>3</sub>SnSnMe<sub>3</sub> = 317 ± 25 kJ/mol) provides little insight to identifying clear redistribution trends with these systems.<sup>28</sup>

In the case of **3**, additional redistribution reactions to yield products such as **6** also occur. The Sn-aryl bonds also appear to be thermally labile at 200 °C and redistribution chemistry is competitive with dehydrogenation. In contrast, trialkyl stannanes seem less active towards such redistribution at this temperature. To maximize yields of distannanes and reduce the potential of unwanted redistribution products, it is essential to identify the optimum reaction conditions

Scheme 4.

(e.g., temperature and duration of the reaction). Closed reaction vessels under slight reduced pressure produce the highest yields for all products (**4**, **5**, and **7**). A likely driving force in these reactions is the liberation of  $\text{H}_2(\text{g})$  along with the formation of the persistent tin alkyl and aryl radicals that later combine to form distannanes. Attempts to carry out dehydrocoupling reactions at higher temperatures ( $>200^\circ\text{C}$ ) resulted in the decomposition of the starting materials and (or) lower product yields. Reaction of the secondary stannane **8** at lower temperatures ( $160^\circ\text{C}$ ) resulted in the formation of linear and cyclic polystannane species including a modest molecular weight polymer (**10**). The broad polydispersity found for this sample is typical of other radical polymers prepared from an uncontrolled polymerization process. The mechanism of propagation for this species is unclear, but may occur through the coupling of two growing oligomeric species that contain active radical end groups. When **8** is heated at  $200^\circ\text{C}$ , redistribution to tributylstannyl terminated species are dominant but no evidence for cyclics or polymers was noted.

## Conclusion

Compound **4** was successfully synthesized in a high yield from the thermally driven dehydrocoupling of the tertiary stannane **2** under a variety of catalyst- and solvent-free conditions. Compound **5** was also obtained in a similar way with lower conversion from the tertiary stannane **3**. A mixed distannane **7** was also prepared from the equimolar reaction of **2** and **3** under similar conditions. Evidence for the redistribution product **6** was found when aryl stannane (**3**) was used. Solvent- and catalyst-free dehydrogenative coupling of the secondary distannane **8** at  $160^\circ\text{C}$  resulted in the formation of a modest molecular weight polystannane (**10**) and other linear and cyclic stannanes, but favours only redistribution products at  $200^\circ\text{C}$ . This work has demonstrated that dehydrocoupling of stannanes in the absence of a catalyst under a variety of conditions may provide a viable route to valuable organic radical sources. Future efforts will be directed to the coupling of tertiary and secondary stannanes using other metal-free routes, including the use of light and microwave mediated coupling processes.

## Experimental methods

### Equipment and procedures

$^1\text{H}$ ,  $^{13}\text{C}\{^1\text{H}\}$ , and  $^{119}\text{Sn}\{^1\text{H}\}$  NMR spectra were recorded on a Bruker Avance 400 MHz NMR spectrometer.  $^1\text{H}$  spectra were referenced to the residual solvent peaks in the deuterated solvents, whereas the  $^{13}\text{C}$  spectra are referenced internally to the deuterated solvent resonances, which are in turn referenced to  $\text{SiMe}_4$  ( $\delta$  0 ppm), whereas  $^{119}\text{Sn}$  was referenced to  $\text{SnMe}_4$  ( $\delta$  0 ppm). UV-vis measurements were carried out in THF solutions using a PerkinElmer Lambda 40 spectrometer. Molecular weights of polymers were deter-

Scheme 5.

mined by gel permeation chromatography (GPC) using a Viscotek Triple Model 302 detector system equipped with a refractive index detector (RI), a four capillary differential viscometer (VISC), a right angle ( $90^\circ$ ) laser light scattering detector ( $\lambda_0 = 670 \text{ nm}$ ), and a low angle ( $7^\circ$ ) laser light scattering detector. GPC columns were calibrated versus polystyrene standards (American Polymer Standards). A flow rate of  $1.0 \text{ mL/min}$  was used with ACS grade THF as the eluent. GPC samples were prepared using 3–10 mg of polymers per mL THF, and filtered using a  $0.45 \mu\text{m}$  filter. All samples were run with and without ultraviolet absorbers (UVA; concn  $\approx 0.001 \text{ mol/L}$ ) for comparison. All reactions were carried out under a nitrogen atmosphere using Schlenk techniques unless otherwise described. Thermally driven dehydrocoupling reactions were performed under a variety of conditions in Schlenk flasks, including in an inert  $\text{N}_2$  atmosphere, or in a sealed Schlenk flask placed under a static reduced pressure (closed), or finally in a Schlenk flask exposed to dynamic reduced pressure (open). Pressures were measured using a mercury manometer attached to the Schlenk line.

### Materials

$(n\text{-Bu})_3\text{SnH}$  (**2**, 99%),  $\text{Ph}_3\text{SnH}$  (**3**, 97%),  $(n\text{-Bu})_2\text{SnCl}_2$  (97%),  $\text{LiAlH}_4$  (1.0 mol/L in ether), and anhydrous  $\text{CaCl}_2$  were purchased commercially and used without further purification.  $(n\text{-Bu})_6\text{Sn}_2$  (**4**) and  $\text{Ph}_6\text{Sn}_2$  (**5**) were purchased from Strem and used as reference samples.  $(n\text{-Bu})_2\text{SnH}_2$  (**8**) was prepared from  $(n\text{-Bu})_2\text{SnCl}_2$  and  $\text{LiAlH}_4$  according to literature preparation.<sup>24,25</sup> Solvents were dried by standard procedures prior to use.

### Large-scale thermal dehydrocoupling of **2** under reduced pressure (open system)

The tin hydride **2** (50 g, 0.17 mol) was added to a 100 mL round-bottom flask connected to a long path distillation condenser (13 cm) and the volatile components distilled at  $200^\circ\text{C}$  under reduced pressure ( $\approx 1 \times 10^{-2} \text{ mm Hg}$ ;  $1 \text{ mm Hg} = 133.32 \text{ Pa}$ ). The product of this distillation was then analyzed by NMR spectroscopy. The  $^1\text{H}$  and  $^{119}\text{Sn}$  NMR spectra revealed that **2** had been consumed and converted (recovered yield: 97%) into **4**. The NMR data provided here are in good agreement with literature values.<sup>18,20,22</sup>

### Small-scale thermal dehydrocoupling of **2** under reduced pressure (open system)

To a 25 mL round-bottom flask equipped with long path reflux condenser (20 cm), was added tin hydride **2** (1.0 g,

**Fig. 4.** UV-vis (THF) spectrum of the mixture containing **10**.

3.44 mmol). The sample was heated to reflux temperature (200 °C) under reduced pressure ( $\approx 2 \times 10^{-2}$  mm Hg) for 6 h. Analysis ( $^1\text{H}$  and  $^{119}\text{Sn}$  NMR spectroscopy) of a small aliquot of the reaction mixture revealed 75% conversion of **2** into **4**, while the remainder was unreacted **2**. Additional heating for 6 h under these conditions showed no further reactant conversion (NMR).

#### Small-scale thermal dehydrocoupling of **2** under reduced pressure (closed system)

To a 25 mL Schlenk flask equipped with a glass stopper was added **2** (530 mg, 1.82 mmol). The neat hydride was placed under static reduced pressure ( $\approx 5 \times 10^{-1}$  mm Hg), the vessel was then sealed and subsequently heated (200 °C) for 5 h. Analysis ( $^1\text{H}$  and  $^{119}\text{Sn}$  NMR spectroscopy) showed that the majority of **2** had been consumed and was converted to **4** (recovered yield: 95%).

#### Small-scale thermal dehydrocoupling of **2** under inert atmosphere (open system)

Compound **2** (530 mg, 1.82 mmol) was added to a 25 mL Schlenk flask equipped with a long path (20 cm) reflux condenser that was open to a  $\text{N}_2(\text{g})$  atmosphere. The flask was then heated (200 °C) for 6 h. Analysis ( $^1\text{H}$  and  $^{119}\text{Sn}$  NMR spectroscopy) of the reaction mixture indicated that **2** had been consumed and was converted to **4** (recovered yield: 97%).  $^1\text{H}$  NMR ( $\text{C}_6\text{D}_6$ , ppm)  $\delta$ : 0.97 (3H, t,  $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{-Sn}$ ), 1.16 (2H, m,  $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{-Sn}$ ), 1.42 (2H, m,

$\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{-Sn}$ ), 1.66 (2H, m,  $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{-Sn}$ ).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{C}_6\text{D}_6$ , ppm)  $\delta$ : 10.49 ( $^1J_{\text{C-Sn}}$  ( $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{-Sn}$ ) = 120.3 Hz and  $^2J_{\text{C-Sn}}$  ( $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{-Sn-Sn}$ ) = 19.6 Hz), 14.01 ( $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{-Sn}$ ), 27.98 ( $^3J_{\text{C-Sn}}$  ( $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{-Sn}$ ) = 26.5 Hz), 31.23 ( $^2J_{\text{C-Sn}}$  ( $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2\text{-Sn}$ ) = 8.1 Hz).  $^{119}\text{Sn}\{^1\text{H}\}$  NMR ( $\text{C}_6\text{D}_6$ , ppm)  $\nu$ : -83.6 ( $J_{^{119}\text{Sn}-^{117}\text{Sn}}$  = 1280 Hz).

#### Small-scale thermal dehydrocoupling of **3** under reduced pressure (open system)

Compound **3** (471 mg, 1.34 mmol) was added to a 25 mL round-bottom flask equipped with a long path reflux condenser (20 cm). The sample was heated (200 °C) under reduced dynamic pressure ( $\approx 1 \times 10^{-3}$  mm Hg) for 6 h. During this time period, clear and colourless crystals formed on the sides of the reaction flask that were then collected and analyzed ( $^1\text{H}$  and  $^{119}\text{Sn}$  NMR spectroscopy). These data indicated that a considerable fraction of **3** (41%) was unreacted. Approximately 59% of **3** was consumed and was converted to both **5** (31%),<sup>29</sup> **6** (24%),<sup>30</sup> and Sn metal (4%). Major product **5**:  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , ppm)  $\delta$ : 7.28–7.36 (12H, m), 7.39–7.52 (12H, m), 7.60–7.63 (6H, m).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CDCl}_3$ , ppm)  $\delta$ : 139.24 (C1), 137.61 (C2, C6), 128.82 (C3, C5), 128.94 (C4).  $^{119}\text{Sn}\{^1\text{H}\}$  ( $\text{CDCl}_3$ , ppm)  $\delta$ : -143.7.

#### Small-scale thermal dehydrocoupling of **3** under reduced pressure (closed system)

To a 50 mL Schlenk flask equipped with a glass stopper

was added **3** (394 mg, 1.12 mmol). The neat hydride was kept under static reduced pressure ( $\approx 5 \times 10^{-1}$  mm Hg), the flask sealed, and heated (200 °C) for 4 h. Analysis ( $^1\text{H}$  and  $^{119}\text{Sn}$  NMR) of the reaction mixture indicated that **3** had been consumed and was converted to both **6** (yield: 87%),<sup>30</sup> **5** (yield: 10%),<sup>29</sup> and Sn metal (3%). Major product **6**:  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CDCl}_3$ , ppm)  $\delta$ : 138.04 (C1), 137.39 (C2, C6), 128.79 (C3, C5), 128.28 (C4).  $^{119}\text{Sn}\{^1\text{H}\}$  NMR ( $\text{CDCl}_3$ , ppm)  $\delta$ : -129.6.

#### Small-scale thermal dehydrocoupling of **2** and **3** under reduced pressure (closed system)

To a 50 mL Schlenk flask equipped with a glass stopper was added **2** (291 mg, 1.00 mmol) and **3** (351 mg, 1.00 mmol). Neat tin hydrides were then placed under static reduced pressure ( $\approx 5 \times 10^{-1}$  mm Hg), sealed, and heated (200 °C) for 5 h. Analysis ( $^1\text{H}$  and  $^{119}\text{Sn}$  NMR) of the reaction products indicated the conversion of **2** and **3** into a mixture containing **4** (12%), **5** (37%), **6** (13%), **7** (37%), and trace of elemental tin (1%).

#### Small-scale thermal dehydrocoupling of **8** under nitrogen (open system)

To a 50 mL Schlenk flask equipped with a glass stopper was added **8** (428 mg, 1.82 mmol). The flask containing **8** was then placed under an atmosphere of  $\text{N}_2$  and heated (160 °C) for 6 h. Analysis ( $^1\text{H}$  and  $^{119}\text{Sn}$  NMR spectroscopy) of a small aliquot of the reaction mixture indicated the conversion of **8** to a mixture containing **9**, **10**, **11**, and **12** along with unassigned oligomers. UV-vis  $\lambda_{\text{max}}$  (nm): 370.  $^{119}\text{Sn}\{^1\text{H}\}$  NMR ( $\text{C}_6\text{D}_6$ , ppm)  $\delta$ : **10**: -189.3; **12**: -202.1; **8**: -203.2; **9**: -207.9; others: -195.6, -209.5, -220.1. Analysis by GPC revealed a molecular weight of  $M_w = 1.8 \times 10^4$  Da, PDI = 6.9.

#### Small-scale thermal dehydrocoupling of **8** under reduced pressure (open system)

To a 50 mL Schlenk flask equipped with a glass stopper was added **8** (500 mg, 2.12 mmol). The flask containing **8** was then placed under an atmosphere of  $\text{N}_2$  and heated (200 °C) for 6 h. Analysis ( $^1\text{H}$  and  $^{119}\text{Sn}$  NMR spectroscopy) of a small aliquot of the reaction mixture indicated the conversion of **8** to a mixture containing **2**, **4**, **13**, and **14** along with other unassigned peaks.  $^{119}\text{Sn}\{^1\text{H}\}$  NMR ( $\text{C}_6\text{D}_6$ , ppm)  $\delta$ : **14**: -75.3, -213.4; **13**: -76.2, -227.0; **4**: -83.2; **2**: -87.3; others: +155.9, -57.7, -66.6, -210.2.

#### Supplementary data

Supplementary data of  $^1\text{H}$  and  $^{119}\text{Sn}\{^1\text{H}\}$  NMR spectra for compounds **4**, **5**, **6**, and the products of the dehydrocoupling of **8** at two different temperatures are provided.

# Is the oxygen “side-on”, or “end-on” and fluctional, in peroxy radicals with magnetically equivalent oxygen atoms?

K.U. Ingold and Gino A. DiLabio

**Abstract:** The  $g$  values that have been measured for the group-14 peroxy radicals are sufficiently similar to suggest that they all have very similar structures. However, the  $^{17}\text{O}$  hyperfine splittings seem to indicate that tin peroxy radicals have structures that differ from their lighter group-14 analogs. We hypothesize that the oxygen atoms in tin peroxy radicals are magnetically equivalent because they undergo a rapid 1,2-shift. Density-functional and wave-function theory calculations support this view.

**Key words:** electron paramagnetic resonance spectroscopy, density-functional theory, group-14 peroxy radicals.

**Résumé :** Les valeurs  $g$  qui ont été mesurées pour les groupes hydroxyles du groupe 14 sont suffisamment semblables pour suggérer qu'ils ont tous des structures très semblables. Toutefois, les dédoublements hyperfins du  $^{17}\text{O}$  semblent indiquer que les peroxydes de l'étain possèdent des structures qui diffèrent de celles de leurs analogues plus légers du groupe 14. On croit que les atomes d'oxygène des peroxydes de l'étain sont magnétiquement équivalents parce qu'ils subissent un rapide déplacement 1,2. La théorie de la fonctionnelle de la densité et celle de la fonction d'onde supportent toutes les deux cette hypothèse.

**Mots-clés :** spectroscopie de résonance paramagnétique électronique, théorie de la fonctionnelle de la densité, radicaux peroxydes du groupe 14.

[Traduit par la Rédaction]

The oxidative degradation of organic materials, such as lubricating oils, plastics, edible fats, and even lipids in living organisms, are free-radical, two-step, chain processes (see reactions. [1] and [2]).

The economic costs of such degradation have led to exhaustive research on the kinetics, thermodynamics, and reaction mechanisms of these autoxidation processes and on methods for their retardation (inhibition). There has also been extensive research on the structures of the chain-propagating alkylperoxy radicals,  $\text{ROO}^\bullet$ , primarily by electron paramagnetic resonance (EPR) spectroscopy. Most organic radicals have  $g$  values near that of the free electron (2.0023) as a consequence of the almost complete quenching of orbital angular momentum. In contrast, alkylperoxy radicals have much higher  $g$  values (range: 2.014–2.017)<sup>1</sup> because their orbital angular momentum is incompletely quenched.<sup>2</sup>

The use of  $^{17}\text{O}$ -labelled dioxygen to trap carbon-centered radicals has revealed that alkylperoxy radicals have two magnetically

inequivalent oxygen atoms.<sup>1,3–6</sup> This is readily understood by consideration of the two canonical structures, **A** and **B**.

In  $\text{Me}_3\text{COO}^\bullet$ , inductive electron donation by the *tert*-butyl group and conjugative electron delocalization stabilize **B**, with  $^{17}\text{O}$  labelling indicating that **A** and **B** make contributions of approximately 60% and 40%, respectively.<sup>3,4</sup> The relative importance of **A** increases as the inductive electron-donating ability of R declines and, with the electron-withdrawing trichloromethyl group, the unpaired spin density on the outer oxygen atom reaches 70%.<sup>6,7–9</sup>

Other triorgano group-14 peroxy radicals have been prepared and examined by EPR spectroscopy.<sup>1</sup> Relevant EPR data are given in Table 1. Table 1 contains the isotropic  $g$  values measured in cyclopropane solution<sup>10</sup> and the two  $^{17}\text{O}$  hyperfine splittings (hfs) for triorgano-silylperoxy radicals,<sup>11</sup> -germylperoxy radicals,<sup>12</sup> and -stannylperoxy radicals.<sup>11,13</sup> These hfs have not been measured for plumbylperoxy radicals. The  $g$  values of these peroxy

yls are somewhat greater than those of triorgano carbon centered radicals (as might be expected from the presence of heavier atoms attached to the O–O moiety). However, the *g* values of all the group-14 peroxy radicals are sufficiently similar to suggest that they all have very similar structures.

On the other hand, the <sup>17</sup>O hyperfine splittings (hfs) appear to tell a different story. For *tert*-butylperoxy radical it has been established that the larger <sup>17</sup>O hfs comes from the terminal (outer) O atom.<sup>4</sup> The same is presumed to be true for all other alkylperoxy radicals and also for the silyl- and germylperoxy radicals.<sup>14</sup> However, the tri-*n*-butylstannylperoxy radical was found to have two magnetically equivalent O atoms,<sup>11,13</sup> and it was hypothesized to have “a pentacoordinate, trigonal bipyramidal structure in which the vacant Sn 5d orbitals are used to form a dative bond with the lone pair of electrons on the terminal oxygen of the peroxy function”<sup>10,12</sup> (structure **C**). Later,<sup>13</sup> it was found that stannylperoxy radicals reacted rather like alkylperoxy radicals,<sup>15</sup> which led to the suggestion that structure **C** might be in equilibrium with the “usual structure for a peroxy radical” (**D**).<sup>13</sup>

The possibility that **C** was simply the transition state structure for a rapid 1,2 shift of the trialkylstannyl group between the two oxygen atoms, appears not to have been considered.<sup>11,13</sup>

In view of the foregoing, we hypothesized that the oxygen atoms in *n*-Bu<sub>3</sub>SnOO• were magnetically equivalent because of a fast 1,2-shift of the *n*-Bu<sub>3</sub>Sn group, **D** ↔ **D'**, rather than

**Fig. 1.** Perspective images representing (a) the minimum energy structure for Me<sub>3</sub>XOO• and the (b) side and (c) top-down views of the transition state structure interconverting two equivalent structures of the type in (a). Atoms are represented as follows: H = white, C = gray, X = blue (X = C, Si, Ge, Sn, and Pb), and O = red. Atoms in the shaded area are coplanar.

because this radical had the symmetric structure, **C**. To check this hypothesis we turned to theory.

Using a density functional theory (DFT) approach,<sup>16</sup> we computed the lowest energy structures for Me<sub>3</sub>XOO• (X = C, Si, Ge, Sn, and Pb) radicals and subsequently verified the structures as minima by obtaining all positive vibration frequencies. We chose to use methyl-substituted group-14 peroxy radicals for simplicity, recognizing that more elaborate substituents (e.g., butyl groups) will not change our general conclusions. In all cases, the lowest energy structure was

found to be “end-on”, as illustrated in Fig. 1a. Are “side-on” structures also minima? Calculations show that structures of this type represent transition states (TS) connecting equivalent end-on structures.<sup>23</sup> The energies of these TS structures, relative to their corresponding ground-state end-on radicals, are given in Table 2. Two views of a representative TS structure are shown in Figs. 1b and 1c.

The relative energies in Table 2 reveal a nonmonotonic decrease in the barrier to interconversion between equivalent end-on structures, through the side-on TS structure, with increasing atomic mass of the group-14 atom. Using the barrier heights associated with  $\text{Me}_3\text{COO}^\bullet$ ,<sup>25–28</sup>  $\text{Me}_3\text{SiOO}^\bullet$ , and  $\text{Me}_3\text{GeOO}^\bullet$ , together with conventional transition state theory gives rate constants at “EPR” temperatures, viz., 200 K, for interconversion between end-on structures that are too small for interconversion to be observed on the EPR time scale. However, the calculated rate constants associated with interconversion of  $\text{Me}_3\text{SnOO}^\bullet$  and  $\text{Me}_3\text{PbOO}^\bullet$  are very large, viz.,  $>10^7 \text{ s}^{-1}$ , which lends support to the mechanism implied by reaction [4]. We note that our calculations indicate that the energy required to dissociate  $\text{O}_2$  from the  $\text{Me}_3\text{Sn}$  moiety is  $\sim 33$  kcal/mol, indicating that the interconversion is a concerted process. In contrast, the computed energy required to dissociate  $\text{O}_2$  from  $\text{Me}_3\text{COO}^\bullet$  is  $\sim 31.4$  kcal/mol, indicating that the concerted process will never compete with dissociation.

To provide additional support for the interconversion via the reaction in reaction [4], we sought to calculate the  $a_{17\text{O}}$  values of the group-14 trimethyl peroxy radicals. Our initial calculations were performed using “EPR-III” basis sets,<sup>29</sup> which are specifically designed to give reasonable hyperfine coupling constants. However, we found these basis sets to be inadequate for the systems investigated in the present work. Using  $\text{Me}_3\text{COO}^\bullet$  as a single example,  $a_{17\text{O}}$  values computed with EPR-III bases using a variety of computational methods were in very poor agreement with experiment, e.g., values (in G) obtained from the following methods for  $a_{17\text{O}}$  (inner) and  $a_{17\text{O}}$  (outer) were HF 23.6 and 48.3, BHandH<sup>30</sup>LYP<sup>31</sup> 19.3 and 28.5, B3<sup>17</sup>LYP<sup>31</sup> 12.7 and 16.8, B3<sup>2</sup>LYP<sup>31</sup> 8.6 and 10.9, B97<sup>133</sup> 13.3 and 20.0, HCTH407<sup>34</sup> 6.4 and 12.2, MP2 18.9 and 21.9, respectively; experiment 17.6 and 23.5, see Table 1. Similarly poor results were obtained for  $\text{Me}_3\text{SiOO}^\bullet$ . We therefore resorted to the use of diffusion augmented, correlation-consistent polarized core/valence triple-zeta polarization (aug-cc-CVpVTZ)<sup>35</sup> basis sets. Additional testing revealed

that various methods with the aug-cc-CVpVTZ bases produced  $a_{17\text{O}}$  values that are in better agreement with experiment, compared to those obtained with the EPR-III bases, but were still not satisfactorily accurate. Once again using the example of  $\text{Me}_3\text{COO}^\bullet$ , we obtained the following  $a_{17\text{O}}$  (inner) and  $a_{17\text{O}}$  (outer) values (all in G): BHandHLYP 18.4 and 27.0, MP2 17.9 and 21.0, respectively. It was clear that it was necessary to perform the calculations at a higher level of electronic correlation. We chose to use the coupled-cluster approach with single and double electronic excitation (CCSD) with all electrons (core and valence) correlated. The large size of the basis set and extent of correlation required that we use a local dense basis set (LDBS) approach,<sup>36</sup> in which we apply the aug-cc-CVpTZ basis set to the O atoms, and the remaining atoms were treated with smaller basis sets and (or) effective core potentials.<sup>21,22</sup> Additional tests showed that  $a_{17\text{O}}$  values obtained using the LDBS approach described above are within  $\sim 0.5\%$  of those obtained using balanced basis sets (i.e., aug-cc-CVpTZ basis sets on all atoms).

Table 2 shows the  $a_{17\text{O}}$  values obtained using the CCSD/LDBS approach described above. The values for  $\text{Me}_3\text{COO}^\bullet$ ,  $\text{Me}_3\text{SiOO}^\bullet$ , and  $\text{Me}_3\text{GeOO}^\bullet$  are within  $\sim 8.4\%$  of the measured values presented in Table 1, an agreement that can be considered reasonable. For these three peroxy radicals, the calculated ratio of  $a_{17\text{O}}$  (inner)/ $a_{17\text{O}}$  (outer) show excellent agreement with the experimentally determined ratios, and provide us with considerable confidence in the results of the calculations.

For  $\text{Me}_3\text{SnOO}^\bullet$ , theory predicts a large difference in inner (15.7 G) and outer (23.1 G)  $a_{17\text{O}}$  values with a ratio of 1.49, whereas EPR measurements on  $^{17}\text{O}$ -labelled  $(n\text{-Bu})_3\text{SnOO}^\bullet$  indicate that both oxygen atoms are magnetically equivalent (25 G). Clearly, the equivalent measured  $a_{17\text{O}}$  values result because of the low (calculated) barrier to interconversion between end-on structures. Calculations show similar results and would be observed for analogous lead peroxy radicals.

- (14) Quite a number of peroxy radicals on heteroatoms,  $\text{Y}_n\text{XOO}^\bullet$ , are also known to have magnetically inequivalent  $^{17}\text{O}$  atoms,<sup>1</sup> including X = N, O, F, P, S, As, Mn, Co, and Cu. Presumably, all these radicals have more or less the same linear, nonfluctuating, structure as alkylperoxy radicals. They will not be considered further in this paper.
- (15) Like alkylperoxy radicals, the stannylperoxy radicals decay with second-order kinetics. Values of  $\log(A)$  and  $E_a$  for the reactions of  $n\text{-Bu}_3\text{SnOO}^\bullet$  with 2,6-di-*tert*-butyl-4-methylphenol and Co(II) acetylacetonate are 7.5 and 7  $\text{(mol/L)}^{-1} \text{ s}^{-1}$  and 12 and 11.5 kcal/mol, respectively, while the corresponding values for  $\text{Me}_3\text{COO}^\bullet$  are 4.6 and 0.8  $\text{(mol/L)}^{-1} \text{ s}^{-1}$  and 8.9 and 4.7 kcal/mol, respectively.<sup>11</sup>
- (16) Structures were optimized at the  $\text{B3}^{17}\text{P86}^{18}$  level of theory using 6-311+G(2d,2p) basis sets for C, H, O, Si, and Ge atoms. This approach has been shown to predict fairly accurate bond dissociation enthalpies in a broad range of compounds.<sup>19</sup> Small-core, averaged relativistic effective potentials (AREPs) and accompanying (uncontracted) basis sets were used for the Sn<sup>20</sup> and Pb<sup>21</sup> atoms. All calculations used the Gaussian 03 program package.<sup>22</sup>

# Nonempirical density-functional theory for van der Waals interactions

Axel D. Becke, Alya A. Arabi, and Felix O. Kannemann

**Abstract:** In previous work, Kannemann and Becke [*J. Chem. Theory Comput.* **5**, 719 (2009) and *J. Chem. Theory Comput.* **6**, 1081 (2010)] have demonstrated that the generalized gradient approximations (GGAs) of Perdew and Wang for exchange [*Phys. Rev. B* **33**, 8800 (1986)] and Perdew, Burke, and Ernzerhof for correlation [*Phys. Rev. Lett.* **77**, 3865 (1996)], plus the dispersion density functional of Becke and Johnson [*J. Chem. Phys.* **127**, 154108 (2007)], comprise a nonempirical density-functional theory of high accuracy for thermochemistry and van der Waals complexes. The theory is nonempirical except for two universal cutoff parameters in the dispersion energy. Our calculations so far have been grid-based and have employed the local density approximation (LDA) for the orbitals. In this work, we employ orbitals from self-consistent GGA calculations using Gaussian basis sets. The results, on a benchmark set of 65 van der Waals complexes, are similar to our grid-based post-LDA results. This work sets the stage for van der Waals force computations and geometry optimizations.

**Key words:** density-functional theory, van der Waals interactions, dispersion interactions.

**Résumé :** Dans un travail antérieur, Kannemann et Becke [*J. Chem. Theory Comput.* **5**, 719 (2009) and *J. Chem. Theory Comput.* **6**, 1081 (2010)], il a été démontré que les approximations généralisées du gradient (AGG) de Perdew et Wang pour l'échange [*Phys. Rev. B* **33**, 8800 (1986)] et Perdew, Burke et Ernzerhof [*Phys. Rev. Lett.* **77**, 3865 (1996)] pour la corrélation combinées à la fonctionnelle de la densité de dispersion de Becke et Johnson [*J. Chem. Phys.* **127**, 154108 (2007)] s'avère être une théorie de la fonctionnelle de densité non empirique d'une grande exactitude pour la thermochemie et les complexes de van der Waals. La théorie est non empirique, à l'exception de deux paramètres universels de coupure de l'énergie de dispersion. Les calculs effectués jusqu'à présent ont été faits sur la base d'une grille et ils ont fait appel à l'approximation de la densité locale (ADL) pour les orbitales. Dans le présent travail, on utilise des orbitales obtenus par calculs autocohérents d'approximation généralisée du gradient utilisant des ensembles de base gaussiens. Les résultats obtenus sur un ensemble de référence de 65 complexes de van der Waals sont semblables à ceux obtenus avec nos résultats obtenus sur la base d'une grille post-ADL. Ce travail permet de faire des calculs de force de van der Waals et d'optimisation de géométrie.

**Mots-clés :** théorie de la fonctionnelle de la densité, interactions de van der Waals, interactions de dispersion.

## Introduction

The treatment of weak chemical interactions in density-functional theory (DFT) is fraught with difficulties. The weakest interaction, dispersion, is the result of long-range correlations which are impossible to model with standard local or semilocal density-functional approximations<sup>1</sup> such as the local density approximation (LDA) or generalized gradient approximations (GGAs). To make matters worse, the exchange part alone of the LDA or standard GGAs gives anything from massive over-binding to massive over-repulsion in dispersion-bound complexes, depending on the choice of functional.<sup>2</sup> Compared to the purely repulsive curves given by Hartree–Fock theory, the performance of the various

standard exchange GGAs in the DFT literature is unacceptably erratic (see Fig. 1 in ref. 2).

The latter of these problems, reproducing Hartree–Fock repulsion in closed-shell interactions, has been addressed by Lacks and Gordon<sup>3</sup> and, more recently, by Kannemann and Becke,<sup>2</sup> and Murray, Lee, and Langreth.<sup>4</sup> It has been discovered that, among the many available exchange GGAs in the literature, the nonempirical exchange GGA of Perdew and Wang<sup>5</sup> (PW86) reproduces Hartree–Fock repulsions remarkably well. For the ten pair interactions between the rare-gas atoms He, Ne, Ar, and Kr, self-consistent PW86 repulsion energies have a mean absolute percent error with respect to Hartree–Fock of only 10%.<sup>2</sup> Considering that the model underlying PW86 is not explicitly designed to capture weak interatomic interactions, this agreement is perhaps fortuitous. It has been pointed out by Zhang, Pan, and Yang<sup>6</sup> that weak interactions are extremely sensitive to the behaviour of exchange GGAs in the limit of large reduced density gradient

$$[1] \quad \chi = \frac{|\nabla \rho|}{\rho^{4/3}}$$

Fortuitous or not, the large- $\chi$  behaviour of PW86 is ideal for reproducing closed-shell Hartree–Fock repulsions. The

“B86b” exchange GGA of Becke<sup>7</sup> also performs well at this task, and has nearly the same asymptotic behaviour as PW86 (Fig. 1 in ref. 6).

The long-range London dispersion interaction responsible for binding in van der Waals (vdW) complexes cannot be obtained from local or semilocal density functionals, as first argued by Kristyán and Pulay.<sup>1</sup> Explicit models incorporating the necessary long-range physics are known,<sup>8–13</sup> but are complicated. Models of the *asymptotic* dispersion interaction (i.e., dispersion coefficients) of relatively simple form have been proposed by several groups.<sup>14–17</sup> We use in our work the model of Becke and Johnson,<sup>14,15</sup> which exploits non-sphericity of the exchange hole around its reference point to generate  $C_6$ ,  $C_8$ , and  $C_{10}$  interatomic dispersion coefficients in a nonempirical density-functional manner. We will refer to this model as the exchange-hole dipole moment (XDM) dispersion model. Although XDM generates asymptotic dispersion coefficients without empirical fit parameters, two (universal) fit parameters are required to damp the dispersion energy at small internuclear separations.

We have reported in refs. 2 and 18 that the PW86 exchange GGA, combined with the nonempirical correlation GGA of Perdew, Burke, and Ernzerhof<sup>19</sup> (PBE) and the XDM dispersion model, yields excellent binding-energy curves in rare-gas diatomics<sup>2</sup> and excellent binding energies in a wide variety of intermolecular complexes.<sup>18</sup> Our work thus far has been grid-based fully numerical, using LDA orbitals computed by the basis-set-free NUMOL program<sup>20,21</sup> (i.e., “post-LDA”). In the present work, we instead use self-consistent PW86+PBE orbitals (i.e., “post-GGA”) computed with the Gaussian09 program.<sup>22</sup> The objective is to obtain PW86+PBE+XDM forces suitable for geometry optimization of intermolecular complexes. Forces cannot be obtained from our NUMOL post-LDA approach, and self-consistent NUMOL GGA calculations are not yet feasible.<sup>23</sup>

We therefore explore a post-Gaussian09-GGA approach in this work.

In the following section, we discuss the suitability for our purposes of the Dunning<sup>24</sup> aug-cc-pVDZ and aug-cc-pVTZ basis sets by considering rare-gas Hartree–Fock repulsion energies. In a later section, the two dispersion damping parameters in our PW86+PBE+XDM functional are fit to benchmark binding energies of 65 intermolecular complexes compiled in ref. 18. The results are of excellent quality, similar in quality to our NUMOL post-LDA results.<sup>18</sup> Future directions are discussed in the final section.

## Hartree–Fock repulsion in rare-gas diatomics: basis-set considerations

In ref. 2, the ability of the PW86 exchange GGA to reproduce Hartree–Fock repulsion energies in rare-gas systems was carefully studied. Our test set consisted of the ten pair interactions between the atoms He, Ne, Ar, and Kr. Post-Hartree–Fock, post-exchange-only-LDA, and self-consistent PW86 repulsion energies, computed at experimental Tang–Toennies internuclear separations,<sup>25</sup> were compared to exact Hartree–Fock repulsion energies from fully numerical NUMOL calculations. In Table 1, the Hartree–Fock and the self-consistent PW86 repulsion energies are listed. The deviation of the PW86 from the Hartree–Fock results is remarkably small. The mean absolute error of PW86 is only 10%, and the maximum error is 20%.

The PW86 benchmarks in Table 1 were obtained with Gaussian09 and the Dunning aug-cc-pV5Z basis set, including counterpoise (CP) corrections for basis-set superposition error.<sup>26</sup> This basis set is much too large, however, for practical applications. CP corrections are impractical as well, especially for the computation of intra-molecular dispersion energies. In this work we therefore undertake additional PW86 calculations with small Dunning basis sets, and *with-*

out CP corrections, in search of a practical PW86 scheme able to mimic Hartree–Fock repulsions in rare-gas systems.

We consider the Dunning basis sets aug-cc-pVDZ and aug-cc-pVTZ to be of practical size for general applications and have therefore assessed them, without CP correction, on our repulsion-energy test set. Integration grids of 200 radial  $\times$  590 angular points (unpruned) were used throughout. The results are reported in the last two columns of Table 1. Both the DZ and the TZ basis sets give repulsion for all ten systems considered. However, the triple-zeta results are clearly superior to the double-zeta results. Indeed the triple-zeta data is similar in quality to the CP-corrected quintuple-zeta data. The worst cases for aug-cc-pVDZ noticeably involve the Ne atom, but this doesn't necessarily rule out the utility of aug-cc-pVDZ in general.

We are therefore encouraged to adopt aug-cc-pVTZ, without CP corrections, as a viable and practical basis set for GGA computations of weak chemical interactions. The viability of non-CP-corrected aug-cc-pVDZ remains to be seen. We apply both to the computation of vdW binding energies in the next section.

## Binding energies of intermolecular complexes

A comprehensive binding-energy (BE) test set of 65 intermolecular complexes, spanning three orders of binding-energy strength from 0.022 kcal/mol (He<sub>2</sub>) to 20.65 kcal/mol (uracil dimer), has been assembled in ref. 18 for the assessment of vdW computational methods. The set includes the ten rare-gas diatomics in Table 1 with experimentally derived BEs from Tang and Toennies,<sup>25</sup> 21 complexes from the test set of Johnson and Becke<sup>27</sup> with CCSD(T)-computed BEs, the 22 complexes of the “S22” biochemical benchmark set of Jurečka et al.<sup>28</sup> also with CCSD(T)-computed BEs, and 12 complexes from Zhao and Truhlar<sup>29,30</sup> with BEs computed by W1 theory. These 65 complexes are listed in Table 2

along with their reference binding energies. Cartesian coordinate files of all the complexes and their monomers are available as supplementary data to ref. 18.

We assess the exchange-correlation functional

$$[2] \quad E_{XC} = E_X^{\text{PW86}} + E_C^{\text{PBE}} + E_{\text{disp}}^{\text{XDM}}$$

on our 65 benchmark complexes and report the results in Table 2. The PW86 exchange GGA is given in ref. 5 and the PBE correlation GGA in ref. 19. The XDM dispersion energy is given by<sup>27</sup>

$$[3] \quad E_{\text{disp}}^{\text{XDM}} = -\frac{1}{2} \sum_{i \neq j} \left( \frac{C_{6,ij}}{R_{\text{vdW},ij}^6 + R_{ij}^6} + \frac{C_{8,ij}}{R_{\text{vdW},ij}^8 + R_{ij}^8} + \frac{C_{10,ij}}{R_{\text{vdW},ij}^{10} + R_{ij}^{10}} \right)$$

with dispersion coefficients  $C_{6,ij}$ ,  $C_{8,ij}$ , and  $C_{10,ij}$  computed as in refs. 15 and 31. The effective vdW interatomic separations  $R_{\text{vdW},ij}$  are linearly related to “critical” interatomic separations  $R_{c,ij}$  by

$$[4] \quad R_{\text{vdW},ij} = a_1 R_{c,ij} + a_2$$

with the critical separation  $R_{c,ij}$  given by the average of  $(C_{8,ij}/C_{6,ij})^{1/2}$ ,  $(C_{10,ij}/C_{6,ij})^{1/4}$ , and  $(C_{10,ij}/C_{8,ij})^{1/2}$ .

We use the “BR” variant of XDM,<sup>31</sup> since the BR variant was found to be superior to the “XX” variant in ref. 18. XDM-BR is based on a density-functional approximation of the exchange hole, whereas XDM-XX uses the exact orbital-based exchange hole. That the former outperforms the latter in intermolecular complexes is rationalized in ref. 18.

Self-consistent PW86+PBE orbitals were computed with Gaussian09 using the aug-cc-pVDZ and aug-cc-pVTZ basis sets, without CP corrections, as motivated in the previous section. The XDM dispersion energy was then computed by an interface program<sup>32</sup> that reads Gaussian09 orbital infor-

mation from “wfn” files. These calculations are therefore not fully self-consistent, rather “post-GGA”. Since the dispersion energy is a very small fraction of the total energy, however, we expect that ignoring self-consistency in the  $E_{\text{disp}}^{\text{XDM}}$  term is of negligible consequence. Investigations of the XDM dispersion model by Kong et al.<sup>33</sup> support this expectation.

The binding energies in Table 2 of the present methods are quite similar to those of our previous numerical post-LDA method.<sup>18</sup> The present mean absolute percent error (MAPE) with the aug-cc-pVDZ basis is 16.6, and with the aug-cc-pVTZ basis is 11.5, compared to our previous 12.6%. Best-fit values (minimum RMS percent error) of the damping parameters are

$$a_1 = 0.80, \quad a_2 = 1.49 \text{ \AA} \quad (\text{SCF aug-cc-pVDZ})$$

$$a_1 = 0.79, \quad a_2 = 1.36 \text{ \AA} \quad (\text{SCF aug-cc-pVTZ})$$

$$a_1 = 0.82, \quad a_2 = 1.16 \text{ \AA} \quad (\text{numerical post-LDA}^{18})$$

Here, we also see similarity between the basis-set and our previous numerical results, especially for the  $a_1$  parameter.

The quality of the double-zeta results, though not as good overall as triple-zeta, is pleasantly surprising. Even the rare-gas diatomic binding energies involving Ne are in good agreement with reference data, despite the notably poor repulsion energies seen above. The under-repulsive tendency of the DZ basis set compared to TZ (see Table 1) is apparently compensated by a slightly larger best-fit  $a_2$  parameter. The only significant qualitative failure of the double-zeta method is the parallel benzene dimer (the last entry in Table 2), for which only one third of the reference binding energy is obtained. This failure is not seen in our numerical or triple-zeta results.

## Conclusions and outlook

The nonempirical (except for two universal dispersion damping parameters) exchange-correlation density functional of eq. [2] was found in refs. 2 and 18 to be an excellent model for van der Waals interactions in chemistry. The GGA exchange and nondynamical correlation parts, PW86+PBE, are a very good model for intra-molecular chemistry as well, as are most standard GGAs. On the atomization energies of the 222 molecules of the G3/99 thermochemical test set of Curtiss et al.<sup>34</sup> the mean absolute error of PW86+PBE+XDM is 10.0 kcal/mol<sup>2</sup>. This is similar to the mean absolute error of 9.3 kcal/mol<sup>34</sup> for the popular BLYP<sup>35,36</sup> GGA. Thus, PW86+PBE+XDM is a promising GGA-DFT for simultaneous optimization of intra- and inter-molecular geometries in complex chemical systems. Our previous post-LDA approach,<sup>2,18</sup> while useful for assessing the performance of density functionals on energetics, cannot provide forces for optimization of geometries. Here we have tested a methodology with the promise to provide energies, and forces, at reasonable computational cost. This PW86+PBE/aug-cc-pVnZ scheme, with  $n = 2$  or 3 and XDM dispersion added post-GGA, will provide useful forces (and Hessians) if orbital self-consistency can be ignored in the XDM part, and if changes in the XDM dispersion coefficients  $C_{6,ij}$ ,  $C_{8,ij}$ , and  $C_{10,ij}$  with molecular geometry can be ignored in the energy derivatives. Preliminary tests of these

suppositions by Kong et al.<sup>33</sup> are encouraging. We will undertake our own independent tests in future work. Also in future work, we will refit the dispersion damping parameters  $a_1$  and  $a_2$  for inclusion of exact Hartree–Fock exchange (i.e., “hybrid” functionals plus XDM dispersion) for even better accuracy in the intra-molecular energetics.

# New insights concerning the mechanism of reversible thermochromic mixtures

Hong Tang, Douglas C. MacLaren, and Mary Anne White

**Abstract:** Three-component organic thermochromic materials, consisting of a leuco dye, a weak acid acting as the colour developer, and a low-melting organic solvent, can change their colour in response to temperature changes. Although widely used in applications, their detailed thermochromic mechanism is not fully understood. The present study delineates the role of subtle changes in the solvent's molecular structure and concentration in the crystal violet lactone (CVL, dye)/lauryl gallate (LG, developer)/1-alcohol (dodecanol (DD), tetradecanol (TD), hexadecanol (HD), or octadecanol (OD); solvent) system. Through inkjet printing of the components directly onto a substrate, combinatorial approaches reveal differences when the alkyl chain length of the alcohol solvent is changed slightly. During the process of heating to the melt, followed by cooling to room temperature, CVL/LG/DD showed no colour change. On the other hand, CVL/LG/TD exhibited reversible thermochromism with colour forming in the molten state and colour loss in the solid state. In the composition range investigated, the CVL/LG/HD system showed no colour change during heating, but on cooling from the molten state, at first a blue colour appeared just below the freezing point, and this was followed by a slow colour fading on further cooling. A significant new finding is that the orientationally disordered  $\alpha$ -phase of the solvent is required to support the dye-developer complex that provides colour. Furthermore, there is an optimal solvent chain length for thermochromism: if too short, there is no disordered phase and no colour; if too long, the formation of the coloured developer-dye complex is prevented in the melt.

**Key words:** thermochromism, polymorphism, dynamical disorder.

**Résumé :** Des matériaux thermochromiques organiques à trois composants formés d'un colorant leuco, d'un acide faible agissant comme agent de développement de la couleur et d'un solvant organique de faible point de fusion peuvent changer de couleur en réponse à des changements de température. Le présent travail permet de délimiter le rôle de changements subtils dans la structure moléculaire du solvant et les concentrations dans le système formé par le colorant, la lactone du cristal violet (LCV), l'acide faible agissant comme agent de développement de la couleur (gallate de lauryle, GL) et les divers solvants [dodécane-1-ol (DD); tétradécane-1-ol (TD); hexadécane-1-ol (HD); octadécane-1-ol (OC)]. En procédant à une impression à jet d'encre directement sur un substrat, des approches combinatoires permettent d'identifier les différences résultant d'un faible changement dans la longueur des chaînes alkyles de l'alcool agissant comme solvant. Durant le processus de chauffage conduisant au liquide suivi d'un refroidissement à la température ambiante, on n'observe aucun changement de couleur pour le système LCV/GL/DD. Par ailleurs, pour le système LCV/GL/TD, on observe une thermochromie réversible avec une formation de couleur dans l'état liquide et une perte de couleur à l'état solide. Pour le système LCV/GL/HD, il n'y a pas de changement de couleur durant le chauffage mais, lorsqu'on refroidit à partir de l'état fondu, il y a d'abord apparition d'une couleur bleue juste en dessous du point de fusion et ceci est suivi d'une disparition lente de la couleur par refroidissement subséquent. Une observation significative a trait au fait que la phase  $\alpha$  du solvant, désordonnée d'un point de vue de l'orientation, a besoin du support du complexe colorant/agent de développement de la couleur pour conduire au développement d'une couleur. De plus, l'apparition d'une thermochromie ne se produit qu'avec un solvant comportant une chaîne carbonée de longueur optimale : si la chaîne est trop courte, il n'y a pas de phase désordonnée et il n'y a pas de couleur; si elle est trop longue, le complexe colorant/agent de développement de la couleur ne peut se produire.

**Mots-clés :** thermochromie, polymorphie, désordre dynamique.

## Introduction

Thermochromism, i.e., temperature-induced colour changes, can be the basis of functional materials such as sensors,

thermometers, or thermal printing. Some thermochromic processes, such as chemical degradation, are irreversible, while others are reversible. The mechanisms of thermo-

chromism are varied, including phase-transition induced changes in the crystal field and a change in wavelength of constructively interfered light due to thermal expansion of layered structures such as liquid crystals,<sup>1,2</sup> and changes in luminescence in sol-gel films,<sup>3</sup> or polymer structures,<sup>4</sup> or the shape of gold or silver nanorods,<sup>5</sup> or isomer distribution.<sup>6</sup> Spiropyrans are known to have potential for thermochromism, whether they are adsorbed on a surface,<sup>7,8</sup> embedded in a polymer,<sup>9</sup> part of a polymer backbone,<sup>10</sup> or a component in an organic thermochromic mixture. In current materials applications, the latter is most common; thermochromism arises from the change in interaction of a spiro-pyran leuco dye with a developer in the presence of a low-melting solvent.<sup>1,11–13</sup> Often, heating results in colour loss and such mixtures are particularly promising as components of thermally erasable toner for printers, allowing the same paper to be used, thermally erased, and then used again.<sup>14</sup> A recent development is thermochromic fibers, with polymeric shells and thermoresponsive cores based on such mixtures.<sup>15</sup> Such materials have recently been proposed as the basis for low-cost (<\$0.10/m<sup>2</sup>) displays.<sup>16</sup>

Although we now have some insights into the molecular processes involved in thermochromic organic mixtures, important issues remain unresolved, such as control of the contrast between the coloured and uncoloured states, the kinetics of decolourization, and the long-term stability of the coloured state.<sup>17</sup>

Early mechanistic studies of ternary organic thermochromic mixtures outlined the main features of the mechanism,<sup>18</sup> but left open important questions. More detailed studies showed the importance of interactions of spiropyran with the developer,<sup>19–21</sup> and how the competition between the developer–dye complex (metastable, coloured state) and the developer–solvent complex (equilibrium, uncoloured state) leads to thermochromism.<sup>22–24</sup> However, considering the range of possible compositions in the ternary system and the many possible dyes, developers, and solvents, the generality of the mechanism has not been tested. Combinatorial approaches are known to lead to rapid advances when there are many compositional variables; a relevant example is colorimetric differentiation of polydiacetylene sensors.<sup>25</sup> To advance understanding of thermochromism mechanisms, we have embarked on combinatorial investigations of three-component thermochromic mixtures, delivered directly on paper by an inkjet printer. The dye was crystal violet lactone (CVL), the developer was lauryl gallate (LG), and the solvent was a long-chain alcohol. In the present studies we explore the question: *How does the solvent's molecular structure influence reversible, rewritable thermochromism?* Although the solvent was initially thought to be most important for its thermochromism-initiating melting point, or as a decolourization acceleration agent in which the solvent provides nucleation sites for the phase separation of developer molecules,<sup>26,27</sup> detailed studies have revealed that the nature of the solvent controls decolourization, through formation of a solvent–developer complex.<sup>23</sup> We now show that the role of the solvent is more subtle and complex, and is important for both colour formation and thermal erasure. Although the present system usually shows colour formation on heating

rather than the more usual colour loss, the conclusions presented here apply to both types of thermochromic systems.

## CVL

## Lauryl gallate (LG)

## Experimental methods

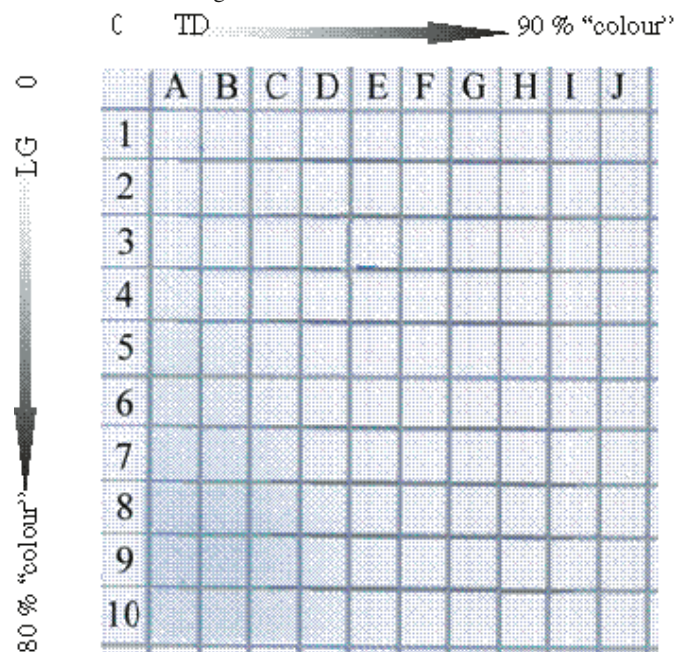

### Chemicals

Crystal violet lactone (3,3-bis(*p*-*N,N*-dimethylamino-phenyl)-6-*N,N*-dimethyl-aminophthalide, CVL, 97%), lauryl gallate (dodecyl(3,4,5-trihydroxy)benzoate, LG, 97%), 1-dodecanol (DD, 96%), 1-tetradecanol (TD, 96%), 1-hexadecanol (HD, 99%), and 1-octadecanol (OD, 99%) were obtained from Sigma-Aldrich. All compounds were used without further purification.

### Combinatorial sample preparation

Small quantities of the dye (CVL), developer (LG), and solvent (DD, TD, HD, or OD) were delivered onto paper via a combinatorial inkjet printing technique. In brief, the dye (0.025 mol/L), developer (0.3 mol/L), and solvent (0.5 mol/L), each in an ethyl acetate/1-butanol (16:9 volume ratio) were placed in the cleaned “ink” cartridges of a drop-on-demand thermal roof-shooter inkjet printer (HP 5940c). The mixed solvent system of ethyl acetate (EMD, 99.5%) and 1-butanol (ACP, 99.4%) was selected as the volatile solvent system to deliver the thermochromic components to the paper (ordinary printer paper) and allow mixing before its evaporation. (Note that we refer here to ethyl acetate/1-butanol as the *volatile* solvent, to distinguish it from the solvent required for the thermochromic mixture.) The ratio in the mixed volatile solvent system was optimized to give rheological properties in the same range as the commercial ink for which the printer was designed. In particular, it should not be so viscous that it cannot flow, or so low in viscosity that leakage is a problem, yet it needs appropriate spreading (no splashing). The Ohnesorge number<sup>28</sup> for this system was about 12. Quantitative delivery of the components (dye, developer, and solvent) to the various regions of the paper was handled through the software (Adobe Photoshop 5.0) controlling the printer. Optimal parameters included using <90% “colour” density and 10–30 passes per location. (Fewer passes led to too little deposition; more passes increased the

**Fig. 1.** The combinatorial dye–developer–solvent library as deposited directly on a 7.5 cm × 7.5 cm area on ordinary printer paper. The dye (CVL) was deposited evenly (0.025 mol/L printed at 60% colour density in Adobe Photoshop 5.0), the developer (0.3 mol/L LG) was gradually increasing from top to bottom (up to 80% colour density in Adobe Photoshop 5.0), and the solvent (0.5 mol/L TD) was gradually increasing from left to right (up to 80% colour density). Each of the 100 cells shown represents a certain smoothly changing mole range of the three components. A faint blue colour is more intense at high LG and low TD concentration.

probability of wipe-off.) Typical sample preparations consisted of a uniform deposition of CVL dye, a vertically graduated deposition of LG developer, and a horizontally graduated deposition of solvent, with the deposition repeated 10–30 times. Deposited amounts (excluding volatile solvent) were quantified by simultaneous deposition on pre-cut round weighing paper (12.7 mm diameter) adhered to the paper by low-residue double-sided tape (3M). The deposited thermochromic mixtures (after evaporation of the volatile solvent) were in the range of 0.2–8  $\mu\text{g mm}^{-2}$ . Further details of the combinatorial delivery of thermochromic components via inkjet printing are given elsewhere.<sup>29,30</sup>

### Bulk sample preparation

Although most of the results reported herein are for inkjet delivered combinatorial samples, in a few key experiments, bulk quantities of thermochromic mixtures were prepared as previously described.<sup>24</sup>

### Characterization

An Ocean Optics USB4000 spectrometer was used to measure diffuse reflectance. The light was sent to the probe via six 200  $\mu\text{m}$  diameter optical fibers, and reflected light was detected through a parallel fiber. All diffuse reflectance measurements were taken for light with a  $\lambda = 620$  nm, the wavelength of maximum absorbance of CVL in its (blue) zwitterionic state.<sup>31</sup> The probe was used at a 90° angle to the surface to eliminate spurious results from any gap be-

tween the probe and sample during heating and cooling, including any moisture influence. For the normal cooling process for ternary mixtures (after heating to a molten state at  $\sim 60^\circ\text{C}$ , samples were quenched to room temperature), kinetic reflectance measurements were taken after they cooled from the molten state. For rapid cooling (after heating to a molten state at  $\sim 60^\circ\text{C}$ , samples were quenched in liquid nitrogen), the kinetic reflectance measurements were taken after the rapidly quenched samples were placed at room temperature. Diffuse reflection was typically measured at 100 locations (10 across, 10 down) on the 7.5 cm × 7.5 cm deposition area.

Bulk samples were examined by Raman spectroscopy using a Bruker RFS 100 Raman spectrometer (excitation by the 1064.5 nm line of a Nd:YAG laser with an incident power of 447 mW). Typical spectra consisted of 25–200 scans. Rapid (30 s) scans for kinetic studies typically had a 4  $\text{cm}^{-1}$  resolution, while longer scans had a 2  $\text{cm}^{-1}$  resolution.

## Results and discussion

### Combinatorial library

A typical library of mixtures, printed directly on a 7.5 cm × 7.5 cm area on printer paper, is shown in Fig. 1.

### Combinatorial approaches represent bulk

Diffuse reflectance for a 10 × 10 matrix of CVL/LG/TD of varying composition immediately after cooling from 60  $^\circ\text{C}$  to room temperature is shown in Fig. 2. The quantity of CVL is constant in this deposition, and TD increases from left to right, while LG increases from top to bottom. Of particular interest is the cell labeled D8, which corresponds to the same components and composition as the system previously studied in bulk.<sup>24</sup> The thermochromic properties (kinetics of colour loss on cooling) are the same for both, despite a reduction in sample mass density by a factor of  $\sim 100$  in the present studies, validating the inkjet combinatorial approach.

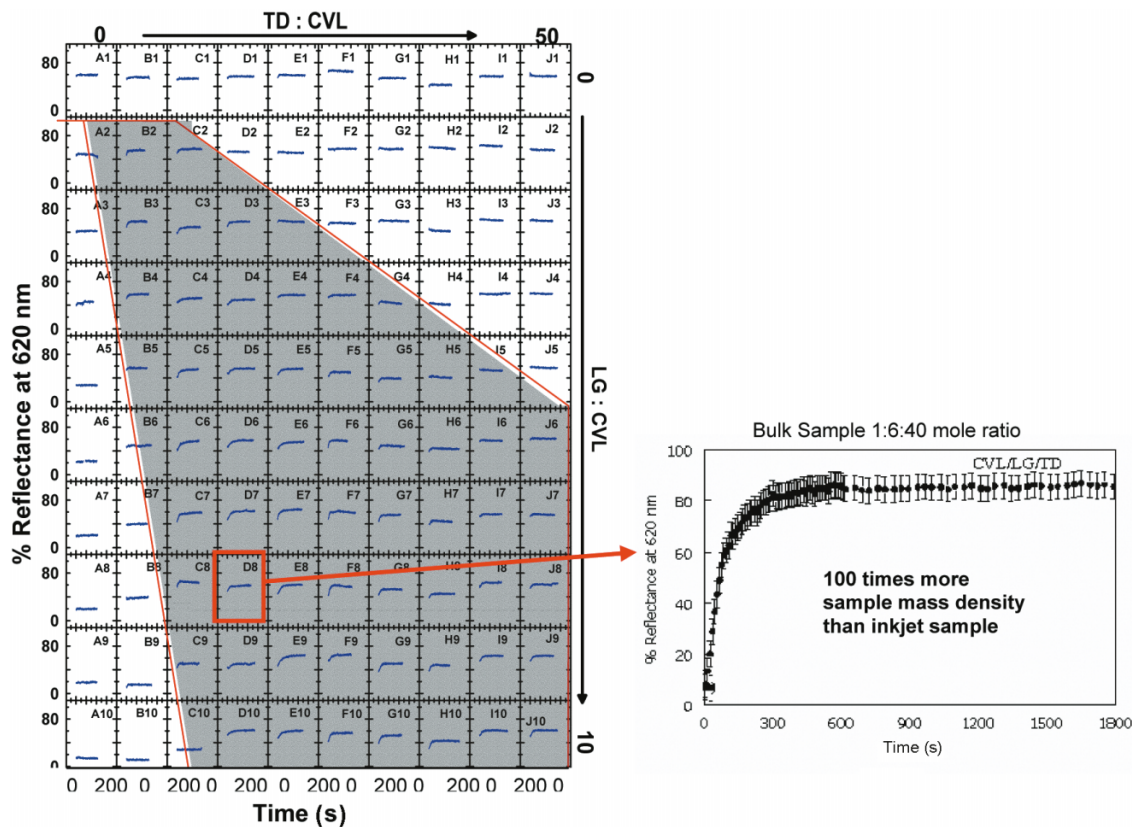

### Different thermochromic behaviours of CVL/LG/alcohols

From Fig. 2 and knowledge of the composition at each point in the matrix, a ternary thermochromism phase diagram for the system CVL/LD/TD has been constructed (Fig. 3a). From this diagram, the compositional limits of thermochromism are apparent. When the mole fraction of LG is high and there is less TD, the system exhibits long-lived (essentially permanent) colour due to the limited ability to decolourize (too little TD to interact with LG). By contrast, when the mole fraction of LG is low and TD is high, no colour was observed because TD separates the CVL and LG species completely, preventing formation of the CVL–LG coloured complex.

Results for parallel studies in which the alkyl chain length for the alcohol solvent has been increased by two carbons, i.e. CVL/LG/HD, are shown in Fig. 3b. This slight change in solvent has a dramatic effect on the thermochromic properties of the mixture. In particular, thermochromism exists for a much smaller range of compositions in CVL/LG/HD, while CVL/LG/TD can show thermochromism when less solvent is present. From thermodynamic studies, it has been

**Fig. 2.** The diffuse reflection intensity at  $\lambda = 620$  nm as a function of time for lauryl gallate/tetradecanol/crystal violet lactone thermochromic mixtures cooled from 60 °C to room temperature. Low reflectance corresponds to high colour density. The left side shows 100 elements of the combinatorial library varying in tetradecanol to crystal violet lactone mole ratio (TD:CVL ranges from 0 to 50) across the rows, and lauryl gallate to crystal violet lactone mole ratio (LG:CVL ranges from 0 to 10) down the columns. The shaded region inside the red lines corresponds to thermochromic behaviour. The red box corresponds to CVL/LG/TD in the mole ratio 1:6:40. This composition has been investigated earlier for bulk samples<sup>24</sup> and the resulting evolution of diffuse thermal reflection for the thicker sample is shown on the right.

shown that the HD–LG interaction is less attractive than TD–LG,<sup>23</sup> so more HD is required to achieve thermochromism. Another distinction from the CVL/LG/TD system is that for CVL/LG/HD no colour development was observed on heating. However, on cooling from 60 °C to room temperature, the blue colour appeared and then decolourized, albeit with slower kinetics than for CVL/LG/TD.

When the alkyl chain of the alcohol solvent was shortened to dodecanol (DD), no thermochromism was observed in the explored composition range, mole ratios of DD:CVL from 0 to 35 and LG:CVL from 0 to 10. In CVL/LG/DD, high LG and low DD concentrations gave a temperature-independent pale blue colour because of the dominance of the CVL–LG coloured complex. However, in other compositional regions, no colour appeared during either heating or cooling. On the basis that the solvent–developer interaction becomes stronger as the solvent chain length decreases,<sup>23</sup> we conclude that when DD is present, there are essentially no free LG developer molecules available to interact with CVL and give the coloured complex.

These three long-chain alcohol solvents, dodecanol, tetradecanol, and hexadecanol, only differ by a total of four carbons in their alkyl chains, yet the behaviour in thermochromic mixtures is markedly different. Not only are the thermochromic compositional ranges different (Fig. 3), but the overall behaviour, as summarized in Fig. 4, is funda-

mentally different. During the process of heating to the melt followed by cooling to room temperature, CVL/LG/DD showed no colour change. On the other hand, CVL/LG/TD exhibited reversible thermochromism with colour forming in the molten state and colour loss in the solid state. The CVL/LG/HD system showed no colour change during heating, but on cooling from the molten state, at first a blue colour appeared just below the freezing point, and this was followed by a slow colour fading on further cooling.

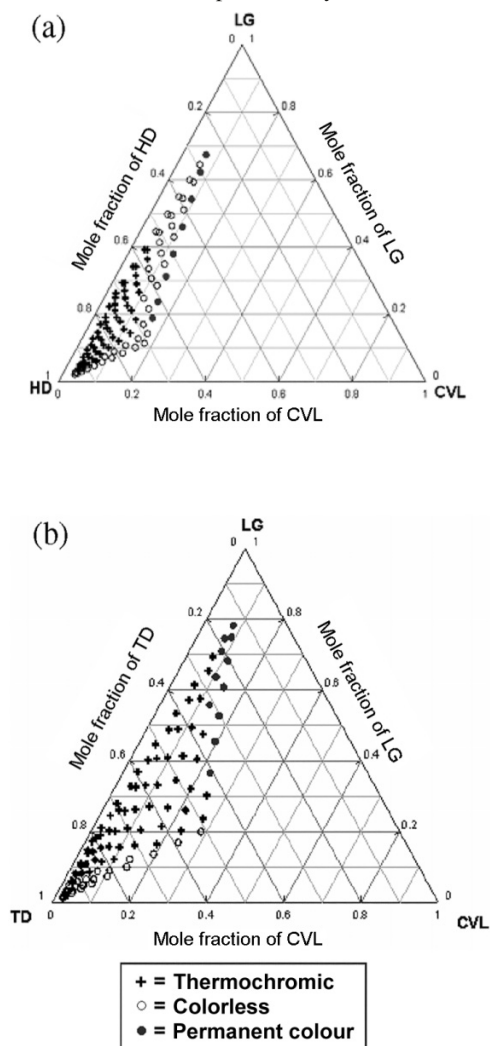

Burkinshaw et al.<sup>18</sup> studied the solubility of the alkyl phenol developer in stearic acid solvent in both liquid and solid state. Their results support a phase-separation mechanism and they proposed that a good reversible thermochromic mixture should have a solvent with good solubility for the developer in the liquid state and poor solubility in the solid state. But this phase separation mechanism alone cannot explain why CVL/LG/TD exhibits colour in the molten state while CVL/LG/HD does not.

### Thermochromism and polymorphism of the long-chain alcohol solvents

The polymorphism of long-chain 1-alcohols is well-established.<sup>32–38</sup> Three phases, called  $\alpha$ ,  $\beta$ , and  $\gamma$ , are observed in the solid state in 1-alcohols with long alkyl chains. The  $\alpha$ -phase, a disordered rotator phase sometimes called the  $R'_{IV}$  phase,<sup>38</sup> appears immediately below the melting

**Fig. 3.** The thermochromism ternary phase diagram for the systems (a) lauryl gallate/tetradecanol/crystal violet lactone (LG/TD/CVL) and (b) lauryl gallate/hexadecanol/crystal violet lactone (LG/HD/CVL). Symbols indicate investigated compositions, categorized as thermochromic, colourless, or permanently coloured.

point. The  $\beta$ - and  $\gamma$ -phases have the chains ordered, and are both monoclinic but with different tilt angles. They have head-to-head forms and are both thermodynamically stable at temperatures below the stability range of the  $\alpha$ -phase. The entropy of the various alcohol phases increases as  $S_\gamma \sim S_\beta < S_\alpha < S_{\text{liquid}}$ .<sup>39,40</sup> The shortest alcohol studied here, 1-dodecanol, only exists in an ordered phase.<sup>35</sup> However, both disordered ( $\alpha$ ) and ordered ( $\beta$  and  $\gamma$ ) phases have been reported for 1-tetradecanol and 1-hexadecanol,<sup>34,35</sup> and for 1-octadecanol.<sup>38</sup>

When long-chain alcohols are present in the thermochromic mixtures, different polymorphs of the alcohol could influence the coloured species. From the experimental results discussed here, we propose a thermochromic mechanism influenced by the phase and chain length of the solvent component, as follows.

#### Colour in the solid state

There seems to be a strong correlation between the exist-

**Fig. 4.** A schematic view of the colour as a function of temperature for thermochromic mixtures composed of crystal violet lactone (dye), lauryl gallate (developer), and various different alcohols (solvent). The colour density is shown as a function of temperature, relative to the melting point of the mixture,  $T_m$ , highlighting the dependence on the solvent. The mixture with dodecanol (DD) does not show colour development. Tetradecanol (TD) solvent leads to reversible thermochromism with little hysteresis. The mixture with hexadecanol (HD) as the solvent was colourless on initial heating above the melting point and then exhibited colour when it was cooled to the solid state, followed by loss of colour on further cooling.

tence of the coloured complex and the presence of the disordered  $\alpha$ -phase of the alcohol. Direct evidence comes from Raman studies of bulk samples of CVL/LG/TD (1:6:40 mole ratio) quenched in liquid nitrogen and then equilibrated at 25 °C, showing the peak at 1710  $\text{cm}^{-1}$  that is associated with the  $\alpha$ -phase of the alcohol, decreasing into the baseline within about 3 min (Fig. 5a), with the same kinetic profile as the formation of the (uncoloured) LG–TD complex (Fig. 5b). We conclude that on first cooling from the melt, the coloured LG–CVL complex stays (TD) or forms (HD) when the alcohol solidifies to the dynamically disordered  $\alpha$ -phase, providing colour.

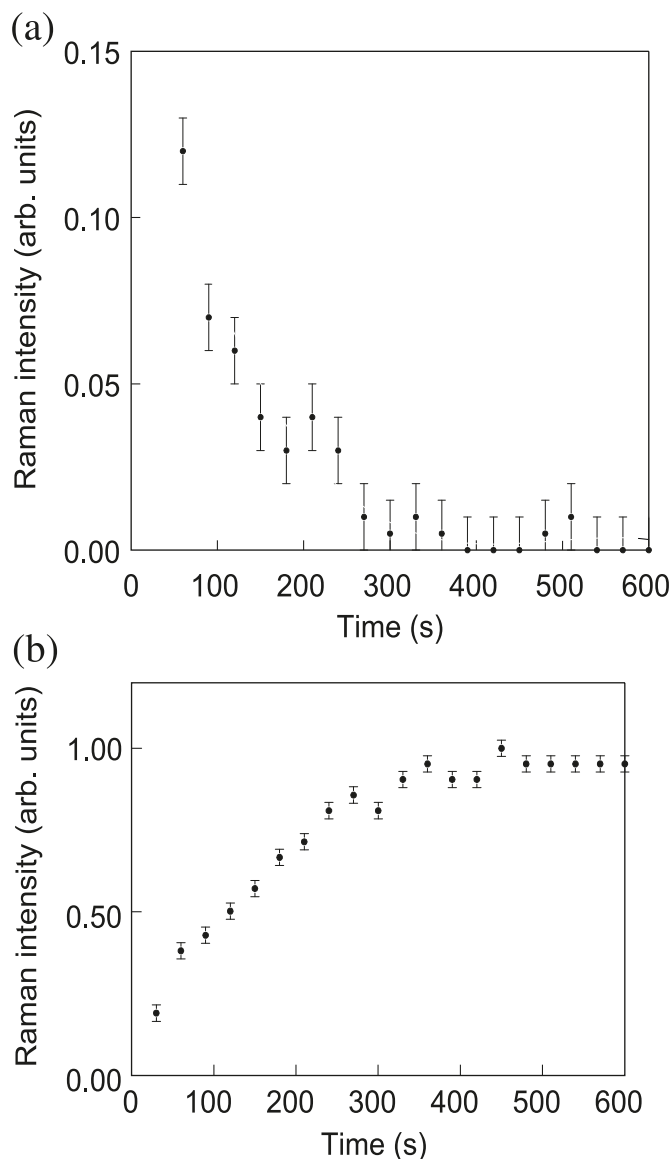

In the case of CVL/LG/DD, no disordered phase is observed for the 1-dodecanol solvent on either heating or cooling, which correlates with the absence of colour in the solid phase. On the other hand, TD, HD, and also octadecanol (OD) all experience a significant  $\alpha$ -phase range when cooled from the molten state and colour is observed on solidifying the melt.

At lower temperature, longer-chain alcohols transform to an ordered  $\beta$ - (or  $\gamma$ -) phase. The colour loss rate corresponds to the loss of the  $\alpha$ -phase, indicating that the disordered  $\alpha$ -phase of the alcohols favors the formation of coloured developer–dye complexes, while the more rigid  $\beta$ - and  $\gamma$ -phases destroy the colour complex, presumably in favor of the formation of developer–solvent complexes. Although the mechanism is different, the stability of a mesophase also leads to thermochromism in poly(3-alkylthiophene)s.<sup>4</sup>

#### Colour in the molten state

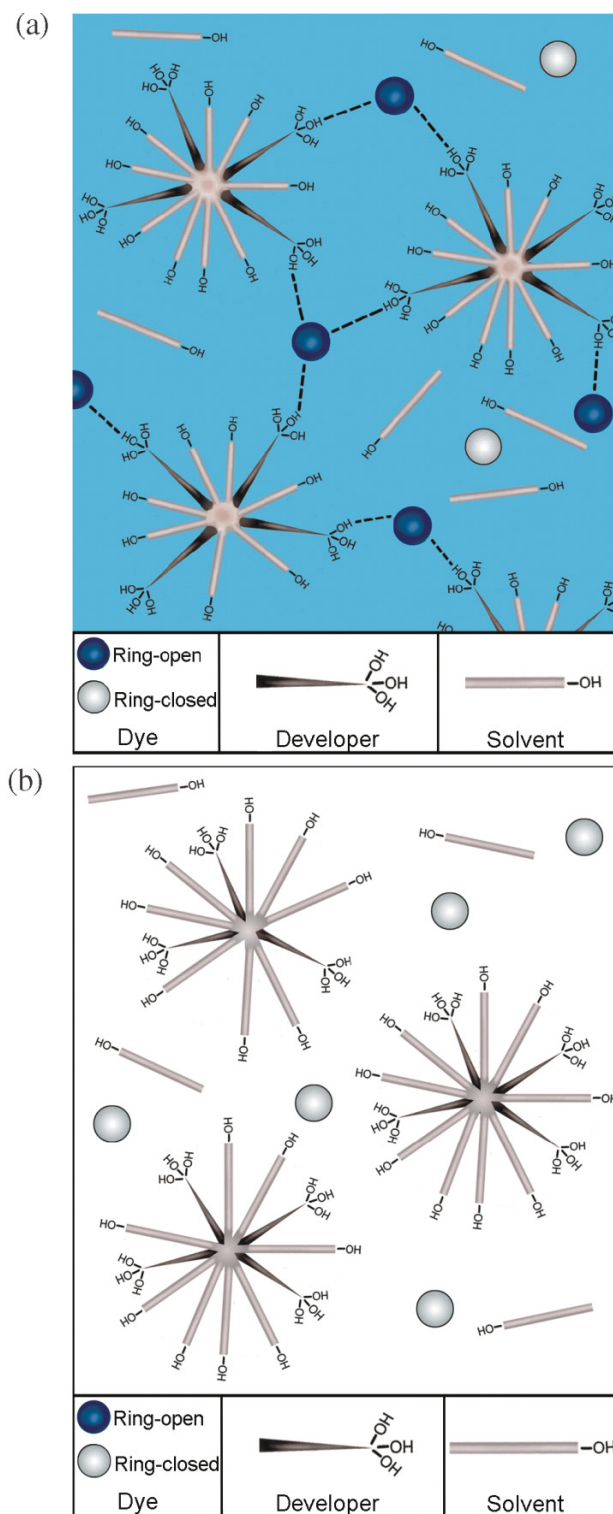

From previous work on this system<sup>22</sup> and studies of a related system,<sup>41</sup> it is known that the colour arises from dye–developer complexes. Solvent components in the ther-

**Fig. 5.** (a) Raman intensity of a bulk sample of crystal violet lactone/lauryl gallate/tetradecanol (CVL/LG/TD in a 1:6:40 mole ratio) quenched in liquid nitrogen and then equilibrated at 25 °C, showing the peak at 1710  $\text{cm}^{-1}$  that is associated with the  $\alpha$ -phase of the alcohol, decreasing into the baseline within about 3 min. (b) Raman intensity of the peak at 1683  $\text{cm}^{-1}$  that is associated with the formation of the LG–TD complex, for the same sample taken at the same time as the data shown in (a), showing the same kinetic profile for LG–TD complex formation as for the loss of the  $\alpha$ -phase of the alcohol.

mochromic mixtures have been mostly considered as phase separators, although it has been proven that the polarity of the organic solvent will affect the colour development.<sup>42</sup> This also agrees with the fact that the CVL–LG complex will lose its colour in polar solvents such as ethanol or butanol. When the three-component mixtures are heated to the molten state, if the solubility of the developer in the solvent is low, or if there is insufficient solvent to separate the dye and developer, colour will appear, which correlates with our observation that CVL/LG/HD exhibited colour in the molten

**Fig. 6.** Schematic view of possible dynamic structures in the melt for (a) crystal violet lactone (dye)/lauryl gallate (developer)/tetradecanol (solvent), showing developer–solvent complexation that allows the developer to interact with the dye, bringing it to its ring-open state, and imparting colour to the mixture. (b) The solvent is changed to hexadecanol, and now the longer alcohol (solvent rods shown schematically here are longer than in (a)) prevents the developer from interacting with the dye, leaving it in its ring-closed colourless state.

state when there was not enough HD present (mole ratio of HD/LG < 1).

In the melt, shorter alcohols are superior at dissolving the developer molecules. For example, DD can dissolve LG, thereby isolating the developer from the dye molecules and preventing colour formation. Longer alcohols (14 or more carbons) at a sufficiently high concentration give a different separation mechanism. We propose that in the molten state, the long-chain alcohol molecules form dynamic structures in which the long alkyl chains interact. A possibility is shown in Fig. 6a. In this schematic view, meant to advance our understanding of the thermochromic mechanism, the –OH group of LG in CVL/LG/TD is exposed. Therefore, CVL is able to interact with the –OH group(s) of LG in CVL/LG/TD to develop colour. In contrast, the longer carbon chain of HD (Fig. 6b) envelops the polar group on the developer, and CVL and LG are separated, resulting in a lack of colour.

To test the hypothesis that the longer-chain alcohol carbon “hides” the developer and prevents it from interacting with the dye, an additional system was examined, namely crystal violet lactone/lauryl gallate/1-octadecanol (CVL/LG/OD), in the mole ratio of 1:10:40 on the same substrate. This showed the same colour change phenomenon as CVL/LG/HD. Colour loss occurred at the molten state, consistent with the separation of CVL and LG by OD solvent molecules due to the long chains of OD.

## Conclusions

Through combinatorial studies of the thermochromic system containing crystal violet lactone (dye), lauryl gallate (developer), and long-chain alcohols (solvent), we found that subtle changes in the solvent can lead to substantial changes in both the compositional range in which thermochromism is supported and differences in thermochromic behaviour. Colour development in the solid is correlated with the presence of the dynamically disordered  $\alpha$ -phase of the alcohol on cooling. In cases where there is colour, it fades when cooled below the  $\alpha$ -phase. If the alcohol carbon chain length is too short to allow the rotator phase, as in dodecanol, no colour is observed. On the other hand, if the alcohol's carbon chain exceeds a critical length, the developer is hidden from the dye in the melt, preventing colour formation at high temperatures.

# Density-functional and global optimization study of copper–tin core-shell clusters

René Fournier

**Abstract:** We obtained minimum-energy structures for 13  $\text{Cu}_p\text{Sn}_q^+$  ( $p = 1-4$ ) species by a combined taboo search and density functional theory (DFT) approach. The putative global minima are all  $\text{Cu}_p@\text{Sn}_q^+$  core-shell structures. There is a stabilization energy on the order of 0.5 to 1.0 eV associated with completion of the outer shell of Sn atoms. The stabilization associated with electronic shell closing is also on the order of 0.5 to 1.0 eV.  $\text{CuSn}_{10}^+$  has both a closed atomic shell and a closed electronic shell, and it is extrastable. We found two or more isomers within 0.6 eV of the global minimum for all 13 species except  $\text{CuSn}_{10}^+$ .

**Key words:** bimetallic clusters, nanostructured materials, global energy minima, segregation.

**Résumé :** Nous avons obtenu des structures d'énergie minimum pour 13 espèces d'agrégats  $\text{Cu}_p\text{Sn}_q^+$  ( $p = 1-4$ ) par une combinaison de recherche taboo et de théorie de la fonctionnelle de la densité. Les minimas globaux présumés possèdent tous une structure en couches avec un coeur de cuivre,  $\text{Cu}_p@\text{Sn}_q^+$ . On observe une stabilisation d'environ 0,5 à 1,0 eV quand la couche externe d'atomes d'étain devient complète. L'agrégat  $\text{CuSn}_{10}^+$  est particulièrement stable dû au fait qu'il a une structure de couche fermée pour les atomes et aussi pour les électrons. Nous avons trouvé deux isomères ou plus en-deçà de 0,6 eV du minimum global pour chacune des 13 espèces sauf  $\text{CuSn}_{10}^+$ .

## Introduction

Bimetallic clusters  $\text{A}_p\text{B}_q$  received a lot of attention lately.<sup>1</sup> They obviously form a much bigger class of compounds than elemental clusters  $\text{A}_n$ , since one can independently vary A, B, size ( $p + q$ ), and composition  $p/q$ . Furthermore, one can sometimes achieve kinetic control over the A–B ordering<sup>2–4</sup> or particle shape<sup>5,6</sup> in a given  $\text{A}_p\text{B}_q$  species. So, bimetallic clusters offer more opportunities than elemental clusters for observing new phenomena, or unusual properties, or for design of materials.<sup>7</sup> Yet, their complexity is still manageable. A number of bimetallic clusters have been made with rather well-defined size, composition, and structure.<sup>1</sup> Applications are mainly in catalysis,<sup>8</sup> magnetic-recording media,<sup>9</sup> and biondiagnostics.<sup>10</sup>

Generally speaking, the geometric structures of small bimetallic clusters fall into three broad categories: mixed (alloyed), segregated (or, “left–right segregated”, LRS), and core-shell structures (CSS). A fourth category, onion-layered, can be seen as a special case of CSS. The CSS clusters receive special attention because they have no equivalent in the bulk. Upon coalescence, mixed clusters will likely produce a bulk alloy. LRS clusters, on the other hand, would likely produce poorly defined materials with A and B domains having large size distributions. But well-defined (in size and composition)  $\text{A}_p\text{B}_q$  CSS clusters could coalesce into a metastable material having several identical  $\text{A}_p$  cores embedded in a B matrix, with the  $\text{A}_p$  cores roughly equidis-

tant from each other. By controlling  $p$  and  $q$ , one can, in principle, control the size of the  $\text{A}_p$  cluster cores and their separation inside the B matrix and this would open up interesting possibilities for nanomaterials. The special case where  $p = 1$  and B is Sn, that is, a  $\text{Sn}_q$  cluster doped with a single endohedral A atom, has received a lot of attention theoretically<sup>11</sup> and experimentally.<sup>12–14</sup> Many of these endohedral  $\text{M}@\text{Sn}_q$  clusters (neutral or charged) have large HOMO–LUMO gaps and appear to be stable.

Breaux et al. found, by thermal annealing in the gas phase, that  $\text{Cu}_p\text{Sn}_q$  cluster cations are stable over a fairly narrow range of compositions and suggested that these clusters may have a CSS.<sup>15</sup> The main goal of our study was to determine, by theory, the detailed geometric structures of a few  $\text{Cu}_p\text{Sn}_q^+$  species in or near the composition range observed by Breaux et al.,  $p = 1-4$  and  $q \approx (9 + 2p) \pm 2$ , and offer a rationale for the enhanced stability of these clusters.

## Methods and computational details

All energies were calculated by density functional theory (DFT) with the Perdew–Burke–Ernzerhof (PBE)<sup>16</sup> generalized gradient approximation to exchange–correlation and a LANL2 double-zeta (LANL2DZ) basis set as implemented in the Gaussian 03 software package.<sup>17</sup> Global optimization was performed by taboo search in descriptor space (TSDS)<sup>18</sup> for singlet or doublet states. We set the number of DFT energy evaluations in the global optimization stage to  $3N^2 +$

30, where  $N = p + q$  is the number of atoms, except for  $\text{Cu}_4\text{Sn}_{19}$  where we did 1410 energy evaluations. Ten to twenty distinct structures among the lowest energy ones were selected from the  $3N^2 + 30$  in the dataset generated by TSDS. Local optimization was performed on those 10 to 20 structures with a standard method (Gaussian keyword BFGS). Local optimizations typically required 50 to 100 DFT energy evaluations, so, overall, the computational effort was divided roughly equally between global and local optimization.

The number of possible isomers (local minima) for  $\text{A}_p\text{B}_q$  clusters is quite large. For an  $\text{X}_n$  cluster ( $n > 9$ ),  $3^{n-6.5}$  gives a rough estimate of the number of distinct isomers. Ignoring symmetry there would be  $(p+q)!/(p!q!)$   $\text{A}_p\text{B}_q$  homotops for every  $\text{X}_{p+q}$  parent structure. Then, for instance, we would estimate that  $\text{Cu}_4\text{Sn}_{19}$  has roughly  $3^{16.5} \times 23!/(4!19!) \approx 10^{11}$  distinct local minima. But this optimization problem is not as difficult as it seems because the vast majority of isomers are very high in energy, and the low-energy isomers fall into one or a few categories that share common geometric characteristics. The TSDS algorithm exploits resemblances among low-energy structures to quickly narrow down the search to structures that have favorable characteristics. For instance, in this study, one of the descriptors quantifies Cu–Sn mixing: after a few hundred energy evaluations on quasi-random  $\text{Cu}_4\text{Sn}_{19}$  structures, the TSDS algorithm “learns” that all mixed structures have much higher energies than segregated ones, and TSDS begins to search preferentially among segregated structures.

Some of the most relevant descriptors for our discussion will now be described. We define the number of interior atoms  $N_i$  as follows. First, we calculate the asphericity  $\zeta_j$  around each atom  $j$  by

$$[1] \quad \zeta_j = \frac{(I_a - I_b)^2 + (I_b - I_c)^2 + (I_c - I_a)^2}{I_a^2 + I_b^2 + I_c^2}$$

where  $I_a$ ,  $I_b$ , and  $I_c$  are the moments of inertia of the neighbours of atom  $j$  calculated after assigning a unit mass to every atom. We assign to atom  $j$  a number  $n_j = \exp(-(\zeta_j/\zeta_0))^2$ , which tends toward one for interior atoms and zero for surface atoms, and get an effective number of interior atoms,  $N_i$ , by adding up the  $n_j$ s.

$$[2] \quad N_i = \sum_j n_j = \sum_j \exp(-(\zeta_j/\zeta_0)^2)$$

With these definitions and  $\zeta_0 = 0.0601$ , we almost always get  $n_j > 0.9$  for atoms that we would have classified as “interior atoms” upon visual inspection and  $n_j < 10^{-5}$  for typical surface atoms. Another descriptor of geometry that we use is  $F_{90}$ , the number of  $90^\circ$  angles per atom. It is defined by

$$[3] \quad F_{90} = \frac{1}{n} \sum_j \sum_{k>\ell} \cos(\theta_{kj\ell} - 90^\circ)^{100}$$

where  $k$  and  $\ell$  index the neighbours of atom  $j$ . The exponent 100 in the formula is arbitrary but produces an intuitively correct count of the number of right angles. Finally, we describe the overall shape of clusters by the variable  $\eta = (2I_b - I_a - I_c)/I_a$ , where  $I_a \geq I_b \geq I_c$  are the moments of inertia of

the clusters when we assign a unit mass to each atom. Note that  $\eta < 0$  for oblate clusters and  $\eta > 0$  for prolate clusters.

## Results and discussion

We studied 13  $\text{Cu}_p\text{Sn}_q^+$  species  $(p,q)$ : (1,9), (1,10), (1,11), (1,15), (2,11), (2,12), (2,13), (2,18), (3,14), (3,15), (3,16), (4,17), and (4,19). TSDS followed by local optimization yielded a total of 210 structures, out of which 134 were distinct (76 were repeats): 105 of those 134 were within 1 eV of the putative global minimum (GM). Table 1 shows the relative energies (RE) of those 105 isomers and the number of isomers with  $\text{RE} < 1$  eV for each species. The notation we will use to identify structures will be  $p\text{--}q.n$ , where  $n$  is the energy rank of the isomer. So, for instance, the RE of **1–11.2** is 0.13 eV, the RE of **3–14.8** is 0.60 eV, and  $p\text{--}q.1$  is the GM of  $\text{Cu}_p\text{Sn}_q^+$ . Figures 1 and 2 show the structures of the 13 GM, and Fig. 3 shows the structures of all isomers (15 of them) found within 0.2 eV of the GM.

It is immediately clear that there are many isomers within a small energy range for most species, **1–10**, **1–11**, and **2–13** being exceptions. Assuming that we found the actual GM, the mean energy separation between isomers is typically on the order of 0.1 eV and maybe even smaller considering the likelihood that we may have missed several low-energy isomers. The uncertainty on calculated relative energies (due to inexact functional, basis sets, and other numerical approximations) is probably on the order of 0.1 eV, and no global optimization method can guarantee finding the GM. So, the precise GM and isomer structures reported here may not all be correct predictions of actual cluster geometries, but they can be used for predicting trends and general structural features.

One thing is clear from Figs. 1 and 2: all global minima have the Cu atoms closer to the center of mass of the cluster. This unambiguously confirms what Breau et al. suggested:  $\text{Cu}_p\text{Sn}_q^+$  clusters adopt CSS. This is not a trivial result because, in the bulk, copper and tin form alloys. This trend can be rationalized from the higher surface energy of Cu compared with Sn. In metals, the surface energy is roughly proportional to the ratio of the cohesive energy and the square of the bulk nearest-neighbour distance<sup>19</sup>: this is  $3.49/2.56^2 = 0.53$  eV/Å<sup>2</sup> for Cu, and  $3.14/2.81^2 = 0.40$  eV/Å<sup>2</sup> for Sn. Clearly, Cu atoms have a propensity to go in the interior of mixed Cu–Sn clusters, or, equivalently, Sn atoms tend to arrange themselves in a compact way around Cu atoms to minimize the surface energy term associated with Cu. Another rationale for bimetallic CSS is that putting the smaller atoms in the interior decreases the strain.<sup>20</sup>

In principle, two things could oppose the surface energy driven formation of CSS: (i) ionic energy terms favor A–B ordering (mixing),<sup>21</sup> and (ii) there are many more possible structures (i.e., local minima) having one or more surface Cu atoms than there are CSS structures, so, everything else being equal, one expects a high probability that the GM will not be a CSS. However: (i) the ionic contributions to energy in Cu–Sn mixed clusters are negligible because these two elements have almost the same electronegativity; and (ii) as shown in the Cohesive energies section, the stabilization associated with atomic shell closing (CSS formation) is on the order of 0.5 to 1 eV, and this is apparently bigger than en-

ergy differences caused by arbitrary small changes in cluster topology.

It is also apparent from Figs. 1 and 2 that Cu-centered square antiprisms and Cu-centered icosahedra are common fragments, and that the clusters are generally very compact. The geometries with centered square antiprisms resemble some of the GM we found in lithium clusters.<sup>22</sup> These are characterized by a bimodal distribution of nearest-neighbor interatomic distances that is feasible only for clusters of highly compressible atoms (e.g., Li) or, as here, mixed clusters where the smaller atoms are in the interior. We will now describe the lowest-energy structures of each species.

**Geometric structures**

The GM of **1–9** is a distorted Cu-centered  $\text{Sn}_8$  cube with a face-capping Sn atom. Its undistorted  $C_{4v}$  version, **1–09.2** (Fig. 3), lies 0.07 eV higher. The lowest-energy isomer with a low coordinated (four-coordinated) Cu atom is much higher, 1.04 eV above the GM.

The GM for **1–10** is a  $D_{4d}$  Cu-centered bicapped square antiprism, which is the fourfold analog of a centered icosahedron.

The same structure was found, by DFT, for  $\text{NiSn}_{10}$ .<sup>23</sup> The center-to-surface interatomic distance in **1–10.1** is 9% shorter than the shortest surface interatomic distance, compared with 5% for a centered icosahedron. Such a short center-to-surface distance is favorable in  $\text{CuSn}_{10}$  (neutral or charged) owing to the small atomic radius of Cu (1.28 Å) compared with Sn (1.41 Å). The high symmetry and compact nature of **1–10.1**, coupled with the fact that the next lowest isomer found is almost a full eV higher, suggest that **1–10.1** is the only form of  $\text{CuSn}_{10}^+$  observed experimentally and that it has special stability. Arguments in the next section also suggest that **1–10.1** is particularly stable.

The GM of **1–11** resembles **1–10.1** but with a five-member ring and one capping Sn atom. **1–11.2** (RE = 0.13 eV) is **1–10.1** plus a triangular capping Sn atom. There is one Sn atom far away from the Cu atom in both **1–11.1** and **1–11.2**. Isomer **1–11.3** is a  $C_{5v}$  Cu-centered icosahedron with a missing Sn atom: it is unstable (RE = 0.54 eV) even though all Sn atoms are near the central Cu atom. In that sense, we can say that, for  $p = 1$ , the CSS is complete at 10 Sn atoms.

The low-energy structures of  $\text{CuSn}_{15}^+$  all have a Cu atoms

**Fig. 3.** The fifteen isomers found within 0.2 eV of the global minima.**Table 2.** Atomization energies of the GM clusters (AE, eV), cohesive energy divided by the bulk value ( $\varepsilon$ , dimensionless), and excess energy ( $E_{\text{excess}}$ , eV).

3-16.1	56.12	0.924	-0.48
4-17.1	62.30	0.925	-0.16
4-19.1	67.70	0.920	+0.24

with high coordination (between 8 and 11). The presence of Sn atoms not bonded to Cu leads to multiple low-energy structures that generally look amorphous, except for the GM and 1-15.2, which have a plane of symmetry. 1-15.1 has the highest Cu coordination (10) and there generally is a correlation among isomers between higher Cu coordination and lower energy.

In  $\text{Cu}_2\text{Sn}_{11}^+$ , it is not possible to have a geometric structure where both Cu atoms achieve full coordination (10 or higher), but many structures with two relatively high-coordination Cu atoms compete and are close in energy. The RE (in eV) and coordinations of the two Cu atoms in the best isomers are as follows: 2-11.1, 0.00, 10, and 7; 2-11.2 (a  $C_{5v}$  Cu-centered icosahedron analog), 0.05, 12, and 6; 2-11.3, 0.05, 8, and 8; 2-11.4, 0.11, 10, and 7; 2-11.5, 0.18, 10, and 6. The GM has a plane of symmetry that contains the two Cu atoms. The Sn-centered icosahedron analog is 1.93 eV above the GM.

The GM of  $\text{Cu}_2\text{Sn}_{12}^+$  has a plane of symmetry that con-

tains the two Cu atoms. The Cu atoms are more or less evenly surrounded by Sn atoms but are not fully coordinated (the coordinations are 10 and 8). 2-12.1 lacks symmetry and, as was the case for  $\text{Cu}_2\text{Sn}_{11}^+$ , there are many other imperfect ways of surrounding Cu. This gives six isomers in a 0.3 eV range. Many of these isomers contain a Cu-centered square antiprism motif. 2-12.11 (RE = 0.50 eV) is the lowest-energy isomer containing a Cu-centered  $\text{Sn}_8$  cubic fragment.

Curiously, the GM of  $\text{Cu}_2\text{Sn}_{13}^+$  has one Cu atom surrounded by a distorted cube of Sn atoms and the other one at the center of a  $\text{Sn}_8$  antiprism. The next lowest-energy isomer (RE = 0.18 eV) has both Cu atoms in square antiprism environments. Isomers 2-13.1 and 2-13.2 both have approximate  $C_{4v}$  symmetry and Cu atom coordinations of 10 and 9. The next isomer, 2-13.3, also has Cu atom coordinations of 10 and 9, but it lacks symmetry and is found at a significantly higher energy (RE = 0.53 eV).

Isomer 2-18.1, like 1-15.1, has more Sn atoms than needed to fully surround the Cu atoms. Two of its Sn atoms have no contact with Cu. One Cu atom is in a distorted icosahedral environment (and 12-coordinated), the other is 11-coordinated.

The basic shape of 3-14.1 is a Cu-centered icosahedron with four capping Sn atoms on one side. The Cu atoms are bonded to each other and have coordinations equal to 12, 10, and 7. Isomer 3-14.3 has a prolate structure resembling a double icosahedron, with four atoms (Sn, Cu, Cu, and Sn) aligned along  $z$  alternating with three layers (perpendicular to  $z$ ) of 5, 4, and 4 atoms. The Cu atoms have coordinations of 11, 10, and 5 in 3-14.3.

Isomer 3-15.1 resembles 3-14.3, with Sn-Cu-Cu-Sn down the  $z$  axis, but with layers of 5, 4, and 5 atoms. The two axial Cu atoms are 10-coordinated. The third Cu atom is in the central four-atom layer and has a coordination of 8 (atoms in the other two layers are six-coordinated). This structure was discovered many times by TSDS, and the next isomer, 3-15.2, has an RE of 0.36 eV. This suggests that no

<b>4–17.1</b>	3.3	1.0	–0.02	0.61	+0.27
<b>4–19.1</b>	3.9	0.5	0.08	0.30	+0.33

isomer would be seen experimentally. Isomer **3–15.5** is like the GM but with layers of 5, 5, and 4 atoms instead of 5, 4, and 5. Isomer **3–15.2** is quite different from the GM and **3–15.5**: it has a central triangle of Cu atoms, with coordination 10, 9, and 9, fully surrounded by Sn atoms and has an oblate shape.

Isomer **3–16.1** is oblate and has efficient packing of Sn atoms around a central triangle of Cu atoms that have coordinations 11, 10, and 10. It is very regular, with a 1–4–1–4–1–4–1 centered square antiprism motif running in the vertical direction in Fig. 2. An additional capping atom next to the 11-coordinated Cu atom would complete its shell to something resembling a distorted fcc environment and would give overall  $C_{2v}$  symmetry, so we speculate that this is the GM of **3–17**. The next isomer of  $\text{Cu}_3\text{Sn}_{16}^+$  is relatively high in energy (0.22 eV). The double icosahedron is the most compact 19-atom structure and is a minor shell closing in the Lennard–Jones clusters sequence, but it (**3–16.3**) lies 0.26 eV above the GM of  $\text{Cu}_3\text{Sn}_{16}^+$ . Note that the Cu atoms coordinations in **3–16.3**, 12, 12, and 8, add up to 32, compared to 31 in **3–16.1**. This is just one of many examples among  $\text{Cu}_p\text{Sn}_q^+$  isomers where it seems energetically favorable to not only maximize atomic coordinations, but also equalize them. This tendency has been noted in other types of clusters.<sup>24–26</sup>

Isomer **4–17.1** is a distorted double icosahedron with two capping atoms on its side. The four Cu atoms occupy the highest possible coordination sites and form a tetrahedron. Isomer **4–17.2** differs from **4–17.1** by the position of one Sn atom. The following isomers in energy, up to **4–17.7** (RE = 0.41 eV), are all variations of the double icosahedron with highly coordinated  $\text{Cu}_4$  tetrahedral fragments. The Cu atoms coordinations are 11, 11, 10, and 8 in both **4–17.1** and **4–17.2**.

Isomer **4–19.1** is an incomplete multiple icosahedron where the four Cu atoms form a tetrahedron and have coordinations equal to 12, 11, 11, and 11. Three more Sn atoms would be needed to complete the icosahedral shell around each Cu atom, so it seems that  $\text{Cu}_4\text{Sn}_{22}^+$  might have special stability and properties. Isomer **4–19.2** is another multiple icosahedron that would also require three more Sn atoms to fully coordinate the Cu atoms.

### Cohesive energies

The calculated ionization energies of Sn and Cu are 7.458 eV and 7.838 eV, respectively, in very good agreement with the experimental values of Brown et al. (7.3439 eV)<sup>27</sup> (Sn) and Look et al. (7.7264 eV)<sup>28</sup> (Cu). We calculated the atomization energy (AE) of  $\text{Cu}_p\text{Sn}_q^+$  as

$$[4] \quad \text{AE}(p, q) = pE(\text{Cu}) + (q - 1)E(\text{Sn}) + E(\text{Sn}^+) - E(\text{Cu}_p\text{Sn}_q^+)$$

To compare the energy of different  $(p, q)$  species, we fitted a function of  $p$  and  $q$  to the set of thirteen AEs:

$$[5] \quad f(p, q) = pE_c(\text{Cu}) + qE_c(\text{Sn}) - q^{2/3}E_s(\text{Sn}) - q^{1/3}E_r(\text{Sn})$$

The four parameters have the following physical interpretation:  $E_c(\text{Cu})$  and  $E_c(\text{Sn})$  are effective cohesive energies (eV/atom),  $E_s(\text{Sn})$  relates to the surface energy of tin, and  $E_r(\text{Sn})$  comes from the fact that the clusters' surfaces have a finite radius of curvature. This function form implicitly assumes that Cu atoms make no contribution to the surface energy of the cluster. The best fit is obtained with  $E_c(\text{Cu}) = 3.601$ ,  $E_c(\text{Sn}) = 2.994$ ,  $E_s(\text{Sn}) = 0.092$ , and  $E_r(\text{Sn}) = 0.174$ . It reproduces PBE atomization energies with a mean error of 1.1%. The most interesting quantities derived from this fit are the *energy differences*  $E_{\text{excess}}(p, q) = f(p, q) - \text{AE}(p, q)$ . A negative value of  $E_{\text{excess}}$  means that the cluster is stable relative to the 12 other clusters, a positive value means that it is unstable. By the criterion of  $E_{\text{excess}}(p, q)$  (Table 2), **1–10.1** is the most stable and **2–18.1** is the least stable. It is easy to see why: **2–18.1** has two extra Sn atoms not bonded to Cu, whereas **1–10.1** has a full shell of Sn atoms around Cu but no extra Sn. Further, **1–10.1** has 40 valence electrons, which matches a closed electronic shell of the jellium model. The other relatively stable clusters (**1–11.1**, **2–13.1**, **3–16.1**) are all at, or slightly above, the lower  $q$  limit for completing a CSS. The least stable clusters do not have a CSS: they either have too few or too many Sn atoms to form a monolayer around the  $\text{Cu}_p$  core. On the whole, the calculated  $E_{\text{excess}}$  indicate that for Cu–Sn clusters: (i) there is a stabilization associated with completing a Sn shell and

forming a CSS; and (ii) the energies associated with this geometric effect are on the order of  $\pm 0.5$  eV.

### Trends in geometry and electronic structure

Table 3 shows three geometric descriptors ( $N_i$ ,  $F_{90}$ , and  $\eta$ ) and two electronic descriptors (HOMO–LUMO gap, and average of Cu atomic charges). The  $N_i$ s indicate that the smallest numbers of Sn atoms required to achieve a  $\text{Cu}_p\text{@Sn}_q^+$  CSS structure,  $q^*$ , are 9 (for  $p = 1$ ), 12 ( $p = 2$ ), 16 ( $p = 3$ ), and roughly 18 ( $p = 4$ ). The  $E_{\text{excess}}$  numbers, however, suggest that  $q^* = 10, 13, 16$ , and 18 may be more appropriate:  $\text{Cu}_p\text{Sn}_q^+$  are stable if all their Cu atoms are interior atoms, no Sn atom is without a Cu neighbour, and all Cu atoms have a sufficiently high coordination.

The  $F_{90}$  values are small compared with other metal clusters<sup>26</sup> except in **1–09.1** and, to a lesser degree, **2–11.1** and **3–14.1**. The small  $F_{90}$  reflect the fact that square antiprisms are generally favored over cubes.

The  $\eta$  parameters are relevant for interpreting cluster ion mobility experiments because mobility is a function of shape and gets higher as  $\eta$  approaches zero. Not too surprisingly, CSS have shapes consistent with that of the Cu inner core: roughly spherical for  $p = 1, 4$  ( $\eta = 0.16, 0.01, 0.19$ , and  $0.08$ ), prolate for  $p = 2$  ( $\eta = 0.33, 0.35$ ), and oblate for  $p = 3$  ( $\eta = -0.16$ ). The non-CSS clusters, on the other hand, often have  $\eta$  that deviate from those shapes, or extreme values of  $\eta$  (for example,  $0.49$  for **2–18.1**). If the Cu inner core of bigger  $\text{Cu}_p\text{Sn}_q^+$  CSS follows the polytetrahedral (icosahedral) packing sequence,<sup>29,30</sup> as expected, the CSS  $\text{Cu}_p\text{Sn}_q^+$  clusters should be prolate at  $p = 5$ , spherical or prolate at  $p = 6$ , oblate at  $p = 7$ , prolate from  $p = 8$  to  $p = 11$  (strongly prolate at  $p = 10$ ), and quasi-spherical at  $p = 12, 13$ .

The HOMO–LUMO gaps of odd electron species were calculated by taking the smaller of the  $\alpha$  spin value and the  $\beta$  spin value. The gaps in Table 3 are unremarkable: fairly large for metal clusters, but this is expected of GM, and largest for even electron species. One somewhat surprising finding is that the gap of **1–10.1** is not particularly large, compared with other  $p = 1$  species, despite its large negative  $E_{\text{excess}}$  and the fact that **1–10.1** has 40 valence electrons (the only jellium closed electronic shell number among the thirteen species).

Atomic charges calculated by Mulliken population analysis are not meaningful for metal clusters: the central atoms always have a very large unphysical negative charge, even in cluster cations. Atomic charges calculated by natural bond orbitals (NBO)<sup>31</sup> analysis are much more meaningful. The NBO charges on individual Cu atoms vary between  $+0.1$  and  $+0.4$ , and the average of Cu atomic charges is given in Table 3 for each cluster. One can see that the net  $+1$  charge is delocalized in  $\text{Cu@Sn}_q^+$ , but that it is localized on the Cu atoms of  $\text{Cu}_p\text{@Sn}_q^+$  ( $p = 3, 4$ ), and that  $\text{Cu}_2\text{@Sn}_q^+$  clusters represent an intermediate case. The electron population for Cu Rydberg states is appreciable: it generally varies between  $0.30$  and  $0.50$ , and reaches a maximum ( $0.57$ ) for the Cu atom of  $\text{Cu@Sn}_{10}^+$ . By comparison, the Rydberg populations on Sn atoms are always around  $0.02$ . The Cu atomic charges could be more positive than shown in Table 3 if one used a different basis set or a different way of analyzing

the electron density associated with the NBO Cu Rydberg population.

### Stability criteria

The most stable clusters within a sequence often have a closed atomic shell<sup>30,32</sup> or a closed electronic shell.<sup>33,34</sup> The former usually have a compact geometry and high symmetry. The latter have an electron count that corresponds to having filled shells in some simple model of electronic structure, for instance, the jellium model for metal clusters, which predicts favorable electron counts of 2, 8, 18, 20, 34, 40, and so forth. Clusters that simultaneously satisfy geometric and electronic criteria, the so-called “doubly magic clusters” (DMC), are expected to be extra stable. An example of a DMC is  $\text{Al}_{13}$ ,<sup>35</sup> with its closed quasi-spherical atomic structure and 40 valence electrons. A number of stable metal cluster compounds have been synthesized, which can be viewed as DMCs to which are attached an outer layer of ligands that lowers their surface energy.<sup>36–38</sup> In this section, we try to identify possible  $\text{Cu}_p\text{Sn}_q^{+m}$  DMC cations because they might give stable compounds after passivation with ligands such as  $\text{CO}$ <sup>39</sup> or chloride ions. The geometric structures and  $E_{\text{excess}}$  we obtained suggest that stability is associated with CSS formation at certain values of  $q$  ( $q^* = 10, 13, 16$ , and  $18$  for  $p = 1$  to  $4$ , respectively). We now describe a simple model that reproduces these  $q^*$  values.

Experimentally, the nearest-neighbor distance for bulk Cu is  $R_{\text{Cu}} = 2.56$  Å and the atomic volume is  $V_{\text{Cu}} = 11.86$  Å<sup>3</sup>. For Sn, we have  $R_{\text{Sn}} = 2.81$  Å and  $V_{\text{Sn}} = 27.1$  Å<sup>3</sup>. First, we calculate the radius  $R_i$  of a hypothetical spherical inner core of  $p$  Cu atoms:  $R_i = (3pV_{\text{Cu}}/4\pi)^{1/3}$ . The outer radius  $R_o$  of a spherical  $\text{Cu}_p\text{@Sn}_q$  cluster can then be approximated by  $R_o = R_i + c \times R_{\text{Sn}}$  where  $c$  is an adjustable parameter. As it turns out,  $c = 1.00$  gives  $q^*$  values that agree reasonably well with the most stable compositions in Table 2, so we simply set  $c = 1$ . We estimate the number  $q^*$  of Sn atoms needed to form a quasi-spherical monolayer around a  $\text{Cu}_p$  core like this:  $q^* = (4\pi R_o^3/R - pV_{\text{Cu}})/V_{\text{Sn}}$ . With this, the predicted compositions ( $p, q^*$ ) of  $\text{Cu}_p\text{Sn}_q$  CSS clusters are (1,11), (2,14), (3,16), (4,18), (5,20), (6,21), (7,23), (8,24), and ( $p, p + 17$ ) for  $8 < p < 22$ . These ( $p, q^*$ ), and nearby combinations, are where we expect to find extra stability on account of atomic shell closing (CSS formation). This could be combined with the closed-shell electron counts of the jellium model ( $N_e = 2, 8, 18, 20, 34, 40, 58, 92, 138, \dots$ ) to estimate the composition and charge state of stable  $\text{Cu}_p\text{@Sn}_q^{+m}$  DMC cations. For instance, some of the species that look promising as central units for stable DMC compounds would include  $(\text{CuSn}_{11})^{5+}$ ,  $(\text{CuSn}_{11})^{11+}$ ,  $(\text{Cu}_3\text{Sn}_{16})^{9+}$ ,  $(\text{Cu}_4\text{Sn}_{18})^{18+}$ , and so forth. Note that high formal positive charges on the DMC part of ligand-passivated cluster compounds have been proposed before,<sup>36–38</sup> and are entirely possible if ligands are very electronegative or bind covalently to the outer layer atoms of the DMC.

We believe that the tendency of some binary clusters  $\text{M}_p\text{B}_q$  ( $\text{M}$  is a metal) to adopt structures where the  $\text{M}_p$  unit is encapsulated by a shell of B atoms can be rationalized most simply from surface-energy considerations. The parameter  $E_c/R_{\text{NN}}^2$ , where  $E_c$  is the cohesive energy of an element and  $R_{\text{NN}}$  is its atomic radius, is particularly helpful. Gener-

ally, atoms of M are encapsulated by clusters of B if B has a smaller  $E_c/R_{NN}^2$  than M. For instance, some values of  $E_c/R_{NN}^2$  (in eV/Å<sup>2</sup>) are 0.84 (Si), 0.40 (Sn), 0.53 (Cu), 0.35 (Ag), 0.58 (Mn), and 0.66 (Cr): experiments and calculations indicate that Si clusters do *not* encapsulate atoms of Cu and Ag,<sup>40</sup> Sn clusters encapsulate Cu (this work and ref. 15) and Mn,<sup>11,14</sup> and that Si clusters may be able to encapsulate Cr.<sup>40</sup> The SiCr case (and SiMo also)<sup>40</sup> suggest that  $(E_c + P)/R_{NN}^2$ , where  $P$  is the promotion energy from the atom's ground state to the effective electronic state of an atom in a solid, could be a more appropriate parameter than  $E_c/R_{NN}^2$ . For instance, the ground states of Cr (septet d<sup>5</sup>s<sup>1</sup>) and Mn (d<sup>5</sup>s<sup>2</sup>) are usually *not* appropriate references for assessing the strengths of interatomic interactions, and  $(E_c + P)/R_{NN}^2$  ( $P > 0$ ) would indicate a stronger tendency for Cr and Mn to be encapsulated in Si cages.

## Conclusion

Here is what we can conclude from our DFT and global optimization study of  $Cu_pSn_q^+$ . First,  $Cu_pSn_q^+$  do form CSS. Second, the stabilization associated with completion of a monolayer outer-shell of Sn atoms is 0.5 to 1.0 eV. Third, most of the  $Cu_pSn_q^+$  species (even those with good core-shell structures) have many low-lying isomers, within a few tenths of eV from the GM and from each other. Fourth,  $CuSn_{10}^+$  has a large negative  $E_{excess}$  and no low-lying isomer: it stands out as particularly stable among the species investigated here. A similar conclusion was reached by Breau et al.<sup>15</sup> based on their observed fragmentation patterns. We ascribe the stability of  $CuSn_{10}^+$  to its doubly magic nature; atomic shell closing (10 Sn atoms in a square antiprism geometry) and electronic shell closing (40 electrons). Fifth, the moments of inertia of  $Cu_p@Sn_q^+$  mirror those of the inner Cu core when  $q$  is close to an atomic shell closing value,  $q^*$ . This, together with the observation that the  $Cu_p$  cores appear to favor the same polytetrahedral structures as Lennard-Jones clusters, could facilitate the interpretation of cluster ion mobility experiments.

We fitted a simple atomic-shells model to our DFT results and used it to predict the likely values of  $p$ ,  $q$ , and  $m$  of  $Cu_pSn_q^{m+}$  species that would satisfy two stability criteria and might, with adequate ligand passivation, make stable metal cluster compounds. We think that  $(E_c + P)/R_{NN}^2$  (where  $(E_c + P)$  is an element's cohesive energy calculated relative to a relevant dissociated atoms state) can be a useful parameter for predicting which binary cluster systems could lead to CSS formation.

# On the nature of homo- and hetero-dinuclear metal–metal quadruple bonds — Analysis of the bonding situation and benchmarking DFT against wave function methods

Nozomi Takagi, Andreas Krapp, and Gernot Frenking

**Abstract:** Homo- and hetero-dimetallic (d–d)<sup>8</sup> analogues of the formally quadruply bonded [Re<sub>2</sub>Cl<sub>8</sub>]<sup>2–</sup> system with the general formula [MM'Cl<sub>8</sub>]<sup>x</sup> (M, M' = Tc, Re, Ru, Os, Rh, Ir and x = –2, –1, 0, +1, +2) have been calculated with the density functional theory (DFT) functionals SVWN, BLYP, BP86, PBE, OLYP, OPBE, HCTH, B3LYP, O3LYP, X3LYP, BH&HLYP, TPSS, VSXC, TPPSh, and ab initio methods (CASPT2, CCSD(T)) using basis sets of triple-ζ quality. The performance of the functionals for the description of the metal–metal bond distance and the bond dissociation energy as well as the singlet–triplet gap was evaluated with respect to ab initio data at the CASPT2 level. Generally, the generalized gradient approximation (GGA) functionals, BLYP, BP86, and PBE, show good performance in the description of the metal–metal bond distance and for the dissociation energy. Hybrid functionals are not to be used for compounds of the type discussed here as they lead to increasingly too short and too weak bonds with the amount of exact exchange included. All functionals underestimate the singlet–triplet gap, with the GGA functionals BLYP, BP86, PBE being the closest to the CASPT2 values. The bonding situations of the [MM'Cl<sub>8</sub>]<sup>x</sup> compounds were analyzed at the DFT level (BP86) using the natural bond orbital (NBO) method and the energy decomposition analysis. The M–M bond in homodimetallic compounds, [MMCl<sub>8</sub>]<sup>x</sup>, becomes weaker from group 7 to group 8 to group 9 metals and the bond is weaker for 4d metal systems than for 5d transition metal compounds. The M–M bonds have approximately 50% covalent and 50% electrostatic character and the covalent contribution is dominated by the π orbitals, whereas the δ orbitals do not contribute significantly to the covalent bonding. Heterodimetallic systems, [MM'Cl<sub>8</sub>]<sup>x</sup>, have significantly stronger metal–metal bonds than the homodimetallic compounds. This comes from weaker Pauli repulsion and stronger electrostatic attraction. The most stable heterodimetallic bonds are observed for 5d–5d metal pairs.

**Key words:** metal–metal bond, metal–metal quadruple bond, heterodimetallic compounds, homodimetallic compounds, dissociation energy, bonding analysis.

**Résumé :** On a effectué des calculs théoriques sur des analogues homo- et hétéro-dimétalliques (d–d)<sup>8</sup> du système [Re<sub>2</sub>Cl<sub>8</sub>]<sup>2–</sup> formellement à quadruple liaison et de formule générale [MM'Cl<sub>8</sub>]<sup>x</sup> (M, M' = Tc, Re, Ru, Os, Rh et Ir et x = –2, –1, 0, 1 et +2) en faisant appel à la théorie de la fonctionnelle de la densité (« DFT »), des fonctionnelles SVWN, BLYP, BP86, PBE, OLYP, OPBE, HCTH, B3LYP, O3LYP, BH&HLYP, TPSS, VSXC, TPPSh et des méthodes ab initio [CASPT2 et CCSD(T)] à base d'ensembles de qualité triple ζ. On a évalué la performance des fonctionnelles pour la description de la longueur de la liaison métal–métal et de l'énergie de dissociation de la liaison ainsi que l'intervalle singulet–triplet par rapport aux données ab initio au niveau CASPT2. En général, les fonctionnelles GGA BLYP, BP86 et PBE donnent une bonne performance dans la description de la longueur de la liaison métal–métal et pour l'énergie de dissociation. Il ne faut pas utiliser les fonctionnelles hybrides pour le type de composés discutés ici parce qu'elles conduisent à des longueurs de liaison qui sont de plus en plus trop courtes et des énergies de liaison trop faibles pour les quantités exactes d'échange incluses. Toutes les fonctionnelles sous estiment l'intervalle singulet–triplet avec les fonctionnelles GGA BLYP, BP86 et PBE conduisant aux valeurs les plus près de valeurs CASPT2. On a examiné les situations de liaison des composés [MM'Cl<sub>8</sub>]<sup>x</sup> à l'aide de la « DFT » au niveau BP86, en utilisant la méthode NBO et l'analyse de la décomposition de l'énergie. La liaison M–M des composés homodimétalliques [MMCl<sub>8</sub>]<sup>x</sup> devient de plus en plus faible lorsqu'on passe des éléments du groupe 7, à ceux des groupes 8 et 9 et la liaison est plus faible pour les systèmes métalliques 4d que pour les composés métalliques de transition 5d. Les liaisons M–M comportent des quantités approximativement égales 50/50, de caractère covalent et électrostatique; la contribution covalente est dominée par les orbitales π alors que les orbi-

tales  $\delta$  ne contribuent pas d'une façon significative à la liaison covalente. Les systèmes hétérodimmétalliques  $[\text{MM}'\text{Cl}_8]^x$  comportent des liaisons métal-métal qui sont beaucoup plus fortes que celles des composés homodimétalliques. Cette situation résulte de la répulsion de Pauli et d'une attraction électrostatique plus forte. Les liaisons hétérodimmétalliques les plus stables sont observées pour les paires métalliques 5d–5d.

## Introduction

The exploration of the chemistry of metal–metal multiple bonds started in 1965 when Cotton and Harris<sup>1</sup> isolated the anion  $[\text{Re}_2\text{Cl}_8]^{2-}$  in the complex  $\text{K}_2[\text{Re}_2\text{Cl}_8] \cdot 2\text{H}_2\text{O}$ . This compound with a formal Re–Re quadruple bond has since become the prototype of a metal–metal multiple bonded species. Its electronic structure is known in detail and a gas-phase photoelectron spectrum has been collected.<sup>2</sup> Following this initial discovery, the field expanded considerably and a wealth of knowledge has been gained as reflected in the prominent book by Cotton, Murillo, and Walton,<sup>3</sup> which covers the literature up to 2004. In recent years, the field came into general focus again, as exemplified by the isolation of the formally quintuply bonded compound  $\text{RCr}=\text{CrR}$  ( $\text{R} = \text{C}_6\text{H}_3-2,6(-\text{C}_6\text{H}_3-2,6-i\text{-Pr}_3)_2$ ) by the group of Power<sup>4</sup> and by a number of recent quantum chemical studies about molecules with high bond orders between metal atoms.<sup>5–7</sup>

In the last 20 years, heterodinuclear compounds between different metal atoms  $\text{M}=\text{M}'$  were studied experimentally due to their potential as catalysts in metal-mediated reactions, as exemplified by the “early–late” complexes, which mainly contain metal–metal single bonds.<sup>8–11</sup> Much less is known about polar metal–metal bonds of higher bond multiplicity.<sup>3,12</sup> Collmann and Boulatov<sup>12</sup> reported in a series of studies about the structures and intriguing spectral properties of systems with polar metal–metal multiple bonds with the general formula  $\text{PorM}=\text{M}'\text{Por}$  ( $\text{Por}$  = substituted porphyrins).

Little is known about the bonding situation and the stability of these polar metal–metal multiple bonds from a theoretical point of view. As a first step towards the description of the experimentally known systems and the systematic exploration of the bonding possibilities in polar metal–metal multiple bonding, we set out a systematic study of heterodinuclear analogues of  $[\text{Re}_2\text{Cl}_8]^{2-}$ . The results of the work are reported in this paper. We focused on the formally quadruply bonded (d–d)<sup>8</sup> systems with the general formula  $[\text{Cl}_4\text{MM}'\text{Cl}_4]^x$  ( $\text{M}, \text{M}' = \text{Tc}, \text{Re}, \text{Ru}, \text{Os}, \text{Rh}, \text{Ir}; x = -2, -1, 0, +1, +2$ ). We did not include the analogues of the first row transition metals ( $\text{Mn}, \text{Fe}, \text{Co}$ ) in our study, since explorative calculations on the systems  $[\text{M}_2\text{Cl}_8]^x$  showed that they are unbound and because of the highly multideterminantal character inherent in these species, demand far too large active spaces to be tractable. Since our intention was to shed light onto the metal–metal quadruple bond, we restricted ourselves to geometrical arrangements, which enable two  $\text{MCl}_4^x$  fragments to form a metal–metal quadruple bond. This is the  $D_{4h}$  ( $C_{4v}$  for heterodinuclear systems) symmetric structure (see Scheme 1), which might not be the global minimum for all species studied.

Metal–metal bonded systems are typical examples of mul-

Scheme 1.

tideterminant problems. We therefore tested the performance of a variety of density functional theory (DFT) functionals in comparison to theoretical results at the CASPT2 and CCSD(T) levels of theory. The bonding situation of the formally metal–metal bonded systems was studied in detail, making use of the energy decomposition analysis (EDA) and the natural bond orbital method (NBO).

## Computational methods

For benchmarking the performance of DFT we tested the following functionals: (i) local density approximation (LDA): SVWN;<sup>13,14</sup> (ii) generalized gradient approximation (GGA): BP86,<sup>15,16</sup> BLYP,<sup>15,17</sup> OLYP,<sup>17,18</sup> OPBE,<sup>18,19</sup> PBE (also called PBE-PBE),<sup>19</sup> and HCTH (also called HCTH407);<sup>20</sup> (iii) hybrid GGA: B3LYP,<sup>15,17,21</sup> BH&HLYP,<sup>15,17,22</sup> O3LYP,<sup>15,17,23</sup> and X3LYP;<sup>17,24</sup> (iv) meta-GGA: TPSS (also called TPSS-TPSS)<sup>25</sup> and VSXC;<sup>26</sup> and (v) hybrid meta-GGA: TPSSH.<sup>25</sup>

We used split-valence basis sets of doubly polarized triple- $\zeta$  quality developed by Weigend<sup>27</sup> and Ahlrichs,<sup>28</sup> which are denoted as def2-TZVPP. For the metal atoms we used valence basis sets in conjunction with small-core quasi-relativistic effective core potentials.<sup>29</sup> The DFT calculations were performed with the Gaussian03 program package<sup>22</sup> using standard settings for the DFT integration (fine grids) and for the convergence criteria. Care has been taken to obtain the correct electronic states, e.g.,  $^1A_{1g}$  states for the  $D_{4h}$  symmetry  $[\text{M}_2\text{Cl}_8]^x$  molecules and  $^1A_1$  states for the  $C_{4v}$  symmetric  $[\text{MM}'\text{Cl}_8]^x$  systems.

Single point energy calculations using coupled cluster theory<sup>30</sup> at the CCSD(T) level<sup>31–35</sup> in conjunction with the def2-TZVPP basis set were performed on BP86/TZ2P geometries (the TZ2P basis set will be specified below) with the program MolPro2006.<sup>36</sup> To account for static and dynamic correlation effects by wave function methodology, we performed complete active space (CAS) SCF<sup>37</sup> calculations with the dynamic correlation added by multiconfigurational second-order perturbation theory (CASPT2).<sup>38–40</sup> Scalar relativistic effects were included via a Douglas–Kroll Hamiltonian.<sup>41,42</sup> Large ANO-RCC basis sets of Roos and

**Table 1.** Optimized metal–metal distances in Å of  $[MM'Cl_8]^x$  in the lowest totally symmetric closed-shell singlet state (for  $M = M'$ :  $D_{4h}$  symmetry,  $^1A_{1g}$  state; for  $M \neq M'$ :  $C_{4v}$  symmetry,  $^1A_1$  state). All DFT results were obtained using the def2-TZVPP basis set. For the CASPT2 calculations, the large ANO-RCC basis was employed (see Computational methods).

co-workers,<sup>43</sup> as implemented in the program package MOLCAS, were used in the following contractions: (17s12p5d4f2g)  $\rightarrow$  [5s4p3d1f] for Cl, (24s21p15d11f4g2h)  $\rightarrow$  [8s7p5d3f1g] for Re, Os, Ir, and (21s18p13d6f4g2h)  $\rightarrow$  [7s6p4d2f1g] for Tc, Ru, Rh. These calculations were performed with the program MOLCAS6.<sup>43</sup> The CASPT2 calculations were performed on BP86/TZ2P geometries except for the data presented in Table 1, which are results of geometry optimizations at the CASPT2 level.

In the CASSCF calculations of the  $[MM'Cl_8]^x$  systems, we chose active spaces consisting of either eight electrons in eight orbitals, CAS(8,8), or 12 electrons in 12 orbitals, CAS(12,12). The smaller active space formally comprises the  $nd\sigma$ , two  $nd\pi$ , and one  $nd\delta$  metal–metal bonding and antibonding orbitals, whereas the larger active space also includes a metal–ligand  $\sigma$  bonding and antibonding orbital pair. These active spaces can cover static electron correlation effects connected to the metal–metal bond.

To give a balanced description of correlation effects in the calculation of the dissociation of  $[MM'Cl_8]^x$  into the  $D_{4h}$  symmetric  $MCl_4^y$  fragments, the  $MCl_4^y$  systems in their  $^5A_{1g}$  state were calculated using (4/4) and (6/6) active spaces in the CASSCF. It is, however, important to notice that for systems in which the metal and ligand orbitals interact strongly, e.g., in the case of the cationic system  $[Ir_2Cl_8]^{2+}$ , the active space has to be considerably larger than (12/12) if one is to calculate dissociation energies, since it is necessary to include the chlorine lone pair orbitals in the active space. As will be discussed later, some of the calculated dissociation energies must therefore be considered with care.

The electronic structure of the  $[MM'Cl_8]^x$  molecules was analyzed with various methods. For the charge analysis, we used the natural bond orbital method (NBO) of Weinhold and co-workers<sup>44</sup> as implemented in the Gaussian program.<sup>22</sup> The energy decomposition analysis (EDA)<sup>45–49</sup> calculations have been performed at the BP86 level using uncontracted Slater-type orbitals (STOs), which have TZ2P quality, on geometries optimized at the BP86/TZ2P level.<sup>50</sup> Scalar relativistic effects have been considered using the zero-order regular approximation (ZORA).<sup>51–55</sup> The latter calculations were carried out with the program package ADF.<sup>56,57</sup>

The focus of the EDA<sup>47</sup> is the instantaneous interaction energy,  $\Delta E_{\text{int}}$ , which is the energy difference between the molecule and the fragments with the frozen geometry of the complex. The interaction energy is divided into three main components:

$$\Delta E_{\text{int}} = \Delta E_{\text{elstat}} + \Delta E_{\text{Pauli}} + \Delta E_{\text{orb}}$$

The term  $\Delta E_{\text{elstat}}$  gives the electrostatic interaction energy between the fragments, which are calculated with a frozen density distribution in the geometry of the complex. The Pauli repulsion ( $\Delta E_{\text{Pauli}}$ ) arises as the energy change associated with the transformation from the superposition of the unperturbed electron densities of fragments  $\rho_A + \rho_B$  to the wave function  $\Psi^0 = N\hat{A}\{\Psi_A \times \Psi_B\}$ , which properly obeys the Pauli principle through explicit antisymmetrization ( $\hat{A}$ ) and renormalization ( $N$ ) of the product wave function. It comprises the destabilizing interactions between electrons on either fragment with the same spin. The stabilizing orbital interaction term,  $\Delta E_{\text{orb}}$ , is calculated in the final step of

the analysis when the orbitals relax to their final form. The latter can be decomposed into contributions from each irreducible representation of the point group of the interacting system. This is very helpful because it directly gives the stabilization, which comes from orbitals having different symmetry. To obtain the bond dissociation energy,  $D_e$ , one has to consider the preparation energy,  $\Delta E_{\text{prep}}$ , which is the energy difference of the fragments between their equilibrium geometry and the geometry that they have in the molecule:

$$\Delta E (= -D_e) = \Delta E_{\text{int}} + \Delta E_{\text{prep}}$$

## Performance of DFT functionals

To estimate the performance of the DFT functionals in the description of M–M' formal quadruple bonds, the species  $[\text{Cl}_4\text{MM}'\text{Cl}_4]^x$  (M, M' = Tc, Re, Ru, Os, Rh, Ir;  $x = -2, 0, +2$ ) were completely optimized under  $D_{4h}$  ( $C_{4v}$  in the case of  $M \neq M'$ ) symmetry constraint in the  $^1A_{1g}$  ( $^1A_1$ ) state at the DFT level using the def2-TZVPP basis set. The optimized metal–metal bond lengths are listed in Table 1.

For the parent compound,  $[\text{Re}_2\text{Cl}_8]^{2-}$ , the optimized Re–Re bond length varies considerably between 2.153 Å (BH&HLYP) and 2.244 Å (BLYP), with the experimental value being 2.237(2) Å<sup>3</sup>, which is in good agreement with the CASPT2(12,12) result of 2.252 Å and comparable to recently reported DFT values<sup>58</sup> of 2.29, 2.27, and 2.24 Å at the BLYP, PBE, and OPBE level of theory, respectively. In comparison to experiment, the BLYP functional performs best (2.244 Å), followed by BP86 (2.226 Å), PBE (2.224 Å), and TPSS (2.222 Å). This observation also holds for  $[\text{Tc}_2\text{Cl}_8]^{2-}$ , where the BLYP value of 2.152 Å is in excellent agreement with the experimental values of 2.147(4) Å<sup>59</sup> and 2.17(1) Å.<sup>60</sup> The BP86 (2.132 Å), PBE (2.131 Å), and TPSS (2.128 Å) results are again very close.

For the other test systems, the M–M' bond length variation lies between 0.071 and 0.155 Å. BH&HLYP always results in the shortest M–M contacts except for  $[\text{Rh}_2\text{Cl}_8]^{2+}$  and  $[\text{ReTcCl}_8]^{2-}$ , whereas BLYP in all cases gives the longest bonds.

Among the five different types of functionals (LDA, GGA, hybrid-GGA, meta-GGA, hybrid-meta-GGA) there is no clear trend of the accuracy of the calculated bond length. LDA delivers, in all cases, shorter bonds than all GGA functionals, except for OPBE. The GGA functionals are best grouped into two classes: the first one giving longer bonds with the trend  $\text{PBE} < \text{BP86} < \text{BLYP}$  and the second one resulting in shorter bonds with the trend  $\text{OPBE} < \text{HTCH} \approx \text{OLYP}$ . The latter class gives only slightly longer bonds than the hybrid-GGA functionals with a mixing of exact exchange (B3LYP, X3LYP, O3LYP). The general observation that higher amounts of exact exchange lead to shorter bonds also holds in the case of metal–metal bonds as exemplified in the series  $\text{BLYP} > \text{B3LYP} > \text{BH\&HLYP}$ . The two meta-GGA functionals, TPSS and VSXC, lead to longer bonds than hybrid-GGA functionals, with TPSS being close to the GGA functionals of the first class. Mixing of exact exchange admixture to TPSS, which gives the hybrid-meta-GGA TPSSh, leads to a shortening of the M–M bonds, with the consequence that the performance of TPSSh is comparable to SVWN.

Overall, we conclude that the GGA functionals, BLYP, BP86, PBE, and the meta-GGA functional TPSS deliver acceptable metal–metal bond lengths for the systems under study, irrespective of the metal–metal bond being polar or unpolar, or whether 4d or 5d transition metal atoms are involved. This observation adds to the increasing evidence that GGA functionals perform especially well in the study of transition metal species, as, for example, is summarized in the recent review by Cramer and Truhlar.<sup>61</sup> Also, Cavigliasso and Kaltsoyannis<sup>58</sup> observed that GGAs perform well in the description of structural features of  $[\text{M}_2\text{Cl}_8]^{2-}$  systems. In general, hybrid functionals with more than 5%–15% Hartree–Fock exchange are not capable to describe systems with significant multireference character, as, e.g., is shown by Zhao et al.,<sup>62</sup> and are therefore not suited in the study of systems like the  $[\text{MM}'\text{Cl}_8]^x$  species we are dealing with in this study.

Our main concern, however, is not so much the bond length but the bond dissociation energy (BDE) of the metal–metal formal quadruple bonds. We therefore compared the dissociation energies of the  $[\text{MM}'\text{Cl}_8]^x$  species (M, M' = Tc, Re, Ru, Os, Rh, Ir;  $x = -2, 0, +2$ ) for the dissociation in two square planar  $D_{4h}$  symmetric  $\text{MCl}_4^{x/2}$  species in the  $(^5A_{1g})$  quintet state. To reduce the influence of structural effects, we based all calculations for a given species on the same geometries, which were optimized at the BP86/TZ2P level. Table 2 gives the results and the following discussion will be based on this. For completeness, Table S1 in the Supplementary data gives the dissociation energies for completely optimized structures at the respective level whose inspection reveals that the geometrical relaxation has no impact on the conclusion presented in the following.

For the parent compound,  $[\text{Re}_2\text{Cl}_8]^{2-}$ , we calculate a dissociation energy of  $D_e = 15.6$  kcal/mol at the CASPT2(12,12) level of theory. The comparison with the CASPT2(8,8) result of 17.2 kcal/mol demonstrates that the result can be considered stable with respect to the active space and should thus be a reliable ab initio estimate of the dissociation energy. To the best of our knowledge, there are no reliable experimental values to compare with. The experimental estimate of  $152.7 \pm 19$  kcal/mol is considered “very unreliable”.<sup>63</sup> The ab initio, single reference CCSD(T) method underestimates the stability of the Re–Re bond, giving a value of 5.5 kcal/mol. The calculated value at CCSD is  $D_e = -36.4$  kcal/mol (Table 2). The very large contribution from the quasi-perturbative treatment of the connected triple excitations when going from CCSD to CCSD(T) shows that a single configuration wave function method is not appropriate for calculating the bond energy of  $[\text{Re}_2\text{Cl}_8]^{2-}$ . Single configuration DFT methods could perform better because of fortuitous error cancellation. However, the DFT results clearly show that the functionals assign stabilities in the wide range from 17.6 kcal/mol (VSXC) to  $-77.4$  kcal/mol (BH&HLYP). There are eight functionals that give negative values for the BDE of  $[\text{Re}_2\text{Cl}_8]^{2-}$ . Thus, a careful choice of functional is important for even a qualitatively correct description. Concerning the different types of functionals (LDA, GGA, meta-GGA, meta-hybrid-GGA), one can observe clear trends. The LDA functional SVWN overestimates the stability of the Re–Re

**Table 2.** Dissociation energy,  $D_e$ , in kcal/mol for the dissociation of  $[MM'Cl_8]^+$  in the lowest totally symmetric closed-shell singlet state (for  $M = M'$ :  $D_{4h}$  symmetry,  $^1A_{1g}$  state; for  $M \neq M'$ :  $C_{4v}$  symmetry,  $^1A_1$  state) in two square planar quintet states of  $D_{4h}$  symmetry ( $^5A_{1g}$ ). All DFT and coupled cluster results were obtained using the def2-TZVPP basis set. For the CASPT2 calculations, a large ANO-RCC basis was employed (see Computational methods). All geometries were optimized at the BP86/TZ2P level.

bond considerably ( $D_e = 63.6$  kcal/mol), whereas GGA functionals of the first class (PBE, BP86, BLYP) assign values of 15.7, 10.2, and 8.9 kcal/mol, respectively, which are close to the CASPT2(12,12) value. The second class of GGA functionals (HCTH, OLYP, OPBE) underestimates the Re–Re bond stability and leads to even qualitative incorrect  $D_e$  values of -14.0, -7.4, and -6.7 kcal/mol, respectively. All hybrid-GGA functionals underestimate the stability considerably with  $D_e$  values of -20.4, -21.4, -21.9, and -77.4 kcal/mol for B3LYP, O3LYP, X3LYP, and BH&HLYP, respectively. The meta-GGA functionals, TPSS and VSXC, are comparable to the first class of GGA functionals in their description of the stability of the Re–Re bond, leading to  $D_e$  values of 6.7 and 17.6 kcal/mol, respectively. The admixture of exact exchange leads to a decreasing bond stability as exemplified in the series BLYP > B3LYP > BH&HLYP. The same holds for the comparison of the meta-GGA functional TPSS ( $D_e = 6.7$  kcal/mol) with its hybrid congener TPPSh ( $D_e = -9.5$  kcal/mol).

The resulting overall picture for the Re–Re BDE of  $[Re_2Cl_8]^{2-}$  is that the first class of GGA functionals (PBE, BP86, BLYP) and the meta-GGA functionals (TPSS and VSXC) give values that are in a reasonably good agreement with the CASPT2(12,12) value, while the other functionals give very poor results.

This conclusion also holds when the remaining  $[MM'Cl_8]^x$  systems in our study are considered. For  $[Tc_2Cl_8]^{2-}$ , e.g., the CASPT2(12,12)  $D_e$  value of -13.7 kcal/mol is matched by the GGA functionals BP86 (-14.3 kcal/mol), BLYP (-17.4 kcal/mol), and PBE (-9.2 kcal/mol). The meta-GGA functionals, VSXC and TPSS, are still in reasonable agreement with -6.7 and -20.1 kcal/mol, respectively, whereas all hybrid-GGA functionals, the hybrid-meta-GGA functional, and the second class of GGA functionals underestimate and the LDA overestimates the metal–metal BDE considerably. The CCSD and CCSD(T) values for the BDE of  $[Tc_2Cl_8]^{2-}$  are dramatically wrong.

In  $[Os_2Cl_8]^0$ , we notice a larger difference between the CASPT2(8,8) and the CASPT2(12,12) results, underlining that the metal centered orbitals interact more heavily with

the chlorine lone pair orbitals, as discussed above, which leads to a slight imbalance in the correlation energy, which is covered by the active spaces in  $[M_2Cl_8]^x$  and the  $MCl_4^{x/2}$  fragments. The same holds for  $[Ru_2Cl_8]^0$ ,  $[ReIrCl_8]^0$ , and  $[OsIrCl_8]^{1+}$ . We therefore have to assign a larger error bar to the CASPT2(12,12) values of these compounds. For  $[Ir_2Cl_8]^{2+}$  and  $[Rh_2Cl_8]^{2+}$ , it was not possible to design an active space large enough to include all the orbital pairs describing the metal–metal and metal–ligand interactions, so as to obtain a reliable and balanced dissociation energy. This is due to the fact that in these positively charged systems, the metal orbitals contract and lie much deeper than the chlorine lone pair orbitals.

The conclusion is that GGA functionals are able to describe the BDE of metal–metal quadruple bonds with an estimated uncertainty of  $\pm 5$  kcal/mol, whereas hybrid functionals are not even reliable for qualitative discussions. This observation is in line with the conclusions of numerous DFT validation studies on transition metal compounds as summarized recently by Cramer and Truhlar.<sup>61</sup> The performance of DFT functionals in the studies of M–M bond dissociation energies is normally tested on transition metal dimers, as for these systems experimental data are available. It is therefore interesting to see that the conclusion put forward for such systems, e.g., in refs. 64 and 65, can be carried over to larger systems in which direct, unbridged metal–metal multiple bonds are present. Ab initio calculations must be carried out using multideterminantal methods, as single reference methods, even at CCSD(T), give large errors for  $D_e$ .

The natural orbital occupation numbers of the CASSCF wave function for the  $\delta/\delta^*$  orbital pair are a measure for the biradical character of the metal–metal bond. The occupation numbers are 1.56/0.44, 1.48/0.52, 1.47/0.53, 1.30/0.70, 1.51/0.49, 1.61/0.39, 1.97/0.03, and 1.95/0.05 in  $[Re_2Cl_8]^{2-}$ ,  $[Tc_2Cl_8]^{2-}$ ,  $[Os_2Cl_8]^0$ ,  $[Ru_2Cl_8]^0$ ,  $[ReTcCl_8]^{2-}$ ,  $[ReOsCl_8]^{1-}$ ,  $[ReIrCl_8]^0$ , and  $[OsIrCl_8]^{1-}$ , respectively. This indicates that, except for  $[Ru_2Cl_8]^0$ , the biradical character of the metal–metal bond is moderate and, thus, closed-shell DFT calculations of singlet species should allow for a qualitative correct

**Table 4.** Singlet–triplet gap ( $^3A_{2u} \leftarrow ^1A_{1g}$  for  $M = M'$  and  $^3A_1 \leftarrow ^1A_1$  for  $M \neq M'$ ) in kcal/mol for  $[MM'Cl_8]^x$  in the  $D_{4h}$  ( $C_{4v}$  for  $M \neq M'$ ) symmetric geometry. All DFT results were obtained using the def2-TZVPP basis set. For the CASPT2 calculations, a large ANO-RCC basis was employed (see Computational methods). All geometries were optimized at BP86/TZ2P.

description. However, as near degeneracy problems may be better modeled by broken-symmetry DFT approaches, we tested the stability of the closed-shell singlet states towards unpairing of the electron pair in the M–M  $\delta$ -bonding orbital leading to singlet biradicals with localized, singly occupied  $d_{xy}$  metal orbitals. We observed broken-symmetry states for  $[Re_2Cl_8]^{2-}$ ,  $[Tc_2Cl_8]^{2-}$ ,  $[Os_2Cl_8]^0$ ,  $[Ru_2Cl_8]^0$ ,  $[Rh_2Cl_8]^{2+}$ , and  $[ReTcCl_8]^{2-}$ , whereas the other systems collapsed to the closed-shell singlet solution. The energy lowering due to the symmetry breaking is given in Table 3. It becomes obvious that, except for SVWN, all functionals predict the biradical state to be energetically favorable. GGA functionals point to a modest stabilization of the biradical state, whereas hybrid functionals give a clear preference for the open-shell singlet states reflecting the general trend that hybrid functionals tend to be favored toward open-shell states. Meta-GGA functionals are between GGA and hybrid functionals.

Related to the stability of the closed singlet state towards the broken-symmetry singlet solution is the question of whether the triplet state, with both the metal–metal  $\delta$  bonding and antibonding orbitals being singly occupied ( $^3A_{2u}$  state in  $D_{4h}$  symmetry and  $^3A_1$  state in  $C_{4v}$  symmetry), is energetically favored over the closed-shell singlet state. In Table 4, we give the  $^3A_{2u} \leftarrow ^1A_{1g}$  adiabatic excitation energy ( $^3A_1 \leftarrow ^1A_1$  in  $C_{4v}$  symmetry) for the selected DFT functionals and the CASPT2 model chemistry. The reported splitting for  $[Re_2Cl_8]^{2-}$  of 9.6 kcal/mol at the CASPT2 level is in good agreement with former ab initio results, e.g., at the CASPT2 level (9.9 kcal/mol)<sup>66</sup> and at the MRMP2 level (12.0 kcal/mol).<sup>67</sup> For all systems, the singlet–triplet gap is underestimated compared to CASPT2(12,12) by all DFT functionals but SVWN. An exception is  $[ReIrCl_8]^0$ , where the GGA functionals are in good agreement with the correlated ab initio results. In general, only GGA and LDA functionals give a qualitative correct ordering of states, the singlet state being the ground state.  $[ReIrCl_8]^0$  is again an exception. For a quantitative assessment of the electronic

states in question, it is clear that no DFT functional provides sufficient reliability.

The above results suggest that (i) the conclusion about the performance of the DFT functionals to describe the BDE of metal–metal formal quadruple bonds remains essentially unchanged when considering broken-symmetry states, (ii) the natural orbital occupation numbers in the CASSCF point towards small biradical character, and (iii) the singlet state is qualitatively correctly assigned to be lower than the triplet state for a chosen subset of functionals. Therefore, it is justified to discuss the bonding situation in the later section on closed-shell singlet calculations with GGA functionals. Furthermore, as both geometries and stabilities of the  $[M_2Cl_8]^x$  model systems are reasonably well-described by the GGA functionals, BLYP, PBE, and BP86, these functionals are appropriate for an analysis of the bonding situation.

### Comments on the ground state of the $MCl_4$ fragments

For the  $d^4$ - $MCl_4^x$  fragments ( $M = Tc, Re, Ru, Os, Rh, Ir$ ;  $x = -1, 0, +1$ ), two states must be considered in the quest for the ground state: the square planar quintet state ( $^5A_{1g}$  in  $D_{4h}$  symmetry) and the tetrahedral singlet state ( $^1A_1$  in  $T_d$  symmetry). In Table 5, we give the excitation energy  $^1A_1 \leftarrow ^5A_{1g}$  at DFT for a number of functionals and at the CCSD(T) level of theory. The latter is an adequate ab initio method, since the  $MCl_4^x$  systems do not exhibit multideterminantal character. Qualitatively, all functionals give the correct ground state compared to CCSD(T) except for VSXC, which wrongly predicts that the quintet state is the ground state for  $[OsCl_4]^0$ . In general, VSXC gives too positive excitation energies, which is probably the consequence of a destabilization of the singlet state. On the other hand, SVWN always gives too negative values, which can be traced back to SVWN underestimating the stability of the quintet state. BH&HLYP, as a third extreme, overestimates the singlet–

triplet gap, probably due to an over stabilization of the quintet state.

Conceptually, two  $[\text{MCl}_4]^x$  fragments have to be in a quintet state to form a metal–metal quadruple bond. It thus comes as no surprise that the  $[\text{ReCl}_4]^-$  fragment building the prominent metal–metal quadruple bond  $[\text{Re}_2\text{Cl}_8]^{2-}$  has the largest quintet  $\rightarrow$  singlet gap (30.5 kcal/mol) and is thus ideally suited for the quadruple metal–metal bond. Except for the Re and Tc species, all  $\text{MCl}_4^x$  fragments have singlet ground states and rather large singlet  $\rightarrow$  quintet gaps. Only if the metal–metal bond strength overcomes this excitation energy, stable compounds with metal–metal quadruple bonds may be expected.

### Analysis of the metal–metal bonding situation

To obtain a thorough understanding of the metal–metal quadruple bond in the  $(\text{d}-\text{d})^8$  systems  $[\text{MM}'\text{Cl}_8]^x$ , we start with a qualitative discussion of the orbitals involved in this bonding. Figure 1 serves as an illustration for this purpose.

For each  $\text{M}-\text{M}'$  bond in question one must, in principle, consider four orbitals of different character. Depending on whether it is metal–metal bonding or antibonding and whether it is metal–ligand bonding or antibonding, one obtains (a) one metal–ligand bonding/metal–metal bonding orbital, (b) one metal–ligand bonding/metal–metal antibonding orbital, (c) one metal–ligand antibonding/metal–metal bonding orbital, and (d) one metal–ligand antibonding/metal–metal antibonding orbital.

In the case of the metal–metal  $\delta$  bond in  $[\text{MM}'\text{Cl}_8]^x$ , these four orbitals are (Fig. 1) the  $1b_{2g}$  orbital as component (a), the  $1b_{1u}$  orbital as component (b), the  $2b_{2g}$  orbital as component (c), and the  $2b_{1u}$  orbital as component (d).

The discussion of the metal–metal bond usually considers only the pair of the metal–ligand antibonding orbitals (c) and (d). This is reasonable in cases where the metal orbitals lie considerably higher in energy than the ligand orbitals or where the metal–ligand overlap is poor. For the metal–metal  $\delta$  bond in the  $[\text{Re}_2\text{Cl}_8]^{2-}$  system, the orbitals of type (c) and (d) are basically metal orbitals (65% metal character)<sup>68</sup> with small contributions from the chlorine atoms, whereas the fully occupied and energetically much lower lying orbitals of type (a) and (b) are mainly ligand orbitals with only 33% and 24% contribution of the Re atomic orbitals, respectively. If, however, the size of the metal atom decreases and the metal orbitals are energetically more stabilized as in  $[\text{Os}_2\text{Cl}_8]^0$  and  $[\text{Ir}_2\text{Cl}_8]^{2+}$ , the metal atom contribution of the completely occupied orbitals (a) and (b) increases; for the metal–metal  $\delta$  bond in  $[\text{Os}_2\text{Cl}_8]^0$  to 50% and 44%, for (a) and (b), respectively, and for  $[\text{Ir}_2\text{Cl}_8]^{2+}$  to 59% and 58% for (a) and (b), respectively. The metal contribution to the occupied metal–metal bonding orbital of type (c) decreases once the metal orbitals contract and become energetically stabilized. Since orbitals (a) and (c) are metal–metal bonding and orbital (b) is metal–metal antibonding, the net metal–metal bond order is thus smaller if the metal orbitals contract and become energetically stabilized, as is the case for  $[\text{Os}_2\text{Cl}_8]^0$  and  $[\text{Ir}_2\text{Cl}_8]^{2+}$ . This qualitative insight is corroborated by numerical results. The Wiberg bond order at BP86/def2-TZVPP//BP86/TZ2P for the metal–metal bond de-

**Fig. 1.** Schematic molecular orbital interaction diagram for two  $\text{d}^4\text{-MCl}_4^{x/2}$  fragments building a  $D_{4h}$  symmetric  $[\text{M}_2\text{Cl}_8]^x$  complex.

creases in the order of 2.41, 1.55, and 0.77 for  $[\text{Re}_2\text{Cl}_8]^{2-}$ ,  $[\text{Os}_2\text{Cl}_8]^0$ , and  $[\text{Ir}_2\text{Cl}_8]^{2+}$ , respectively. Likewise, the occupation of the metal- $\text{d}_{xy}$  orbital, as given by the natural population analysis at BP86/def2-TZVPP//BP86/TZ2P, increases in the order of 1.30, 1.51, and 1.65 e for  $[\text{Re}_2\text{Cl}_8]^{2-}$ ,  $[\text{Os}_2\text{Cl}_8]^0$ , and  $[\text{Ir}_2\text{Cl}_8]^{2+}$ , respectively, reflecting the higher metal character of the two low lying, occupied metal–metal bonding and antibonding orbitals of type (a) and (b), respectively.

Tables 6–9 give the results of the energy decomposition analysis (EDA) and the population analysis data (partial charges,  $q$ , orbital occupation numbers,  $n$ , and Wiberg bond indices,  $P$ ) for  $[\text{MM}'\text{Cl}_8]^x$  ( $\text{M}, \text{M}' = \text{Tc}, \text{Re}, \text{Ru}, \text{Os}, \text{Rh}, \text{Ir}; x = -2, -1, 0, +1, +2$ ). For the EDA, we chose  $C_{4v}$  symmetric  $\text{MCl}_4^x$  species in the  $^5\text{A}_1$  state as interacting fragments, which corresponds to a formal d-electron distribution of  $\text{d}_{z^2}^1, \text{d}_{xz}^1, \text{d}_{yz}^1, \text{d}_{xy}^1$ , and  $\text{d}_{x^2-y^2}^0$  at the metal atoms.

**Table 6.** Energy decomposition analysis for the  $D_{4h}$  symmetric  $M_2Cl_8^x$  ( $M = \text{Tc, Re, Ru, Os, Rh, Ir}$ ;  $x = -2, 0, +2$ ) under  $C_{4v}$  symmetry at BP86/TZ2P.  $MCl_4^y$  ( $y = -1, 0, +1$ ) in the quintet  $^5A_1$  state were used as fragments. Optimized metal–metal distances ( $R$ , in Å), NBO partial charge of the metal atom and of the  $MCl_4^{y/2}$  fragment ( $q$ ), occupation of the  $d_{xy}$  orbital of the metal atom ( $n$ ), as well as the Wiberg bond index of the M–M pair ( $P$ ) are also given. The latter population analysis data are given at BP86/def2-TZVPP//BP86/TZ2P.

<sup>a</sup>Values in parentheses give the percentage contribution to the total attractive interactions,  $\Delta E_{\text{elstat}} + \Delta E_{\text{orb}}$ .

<sup>b</sup>Values in parentheses give the percentage contribution to the total orbital interactions,  $\Delta E_{\text{orb}}$ .

<sup>c</sup>Fragments relax into a tetrahedrally distorted square planar quintet of  $D_{2d}$  symmetry.

Table 6 shows that, in the parent compound  $[\text{Re}_2\text{Cl}_8]^{2-}$ , the major stabilizing contribution to the total interaction energy,  $\Delta E_{\text{int}} = -54.2$  kcal/mol, is due to the classical electrostatic contribution (53.2% of the stabilizing terms), whereas the orbital (covalent) interaction contributes 46.8%.<sup>69</sup> This observation is somewhat surprising, given the fact that two negatively charged moieties,  $\text{ReCl}_4^-$ , interact. One would intuitively assume to observe a net electrostatic repulsion. Such an assumption is not justified because the charge distribution in the atomic basins is highly anisotropic. The rhenium atoms carry a positive charge of +0.55 e but the attraction of the singly occupied metal  $d_{z^2}$  orbital of one Re atom by the nucleus of the other Re atom yields a strong electrostatic attraction.<sup>70</sup> Note that even nonpolar bonds are, in most cases, stabilized by classical electrostatic contributions.<sup>71,72</sup> The very large Pauli repulsion between the two fragments of 404.9 kcal/mol compensates to a large extent for the stabilizing electrostatic and orbital contributions. The attractive orbital contributions result mainly from orbitals of  $e(\pi)$  symmetry (59.8% of the total orbital interaction), followed by orbitals of  $a_1(\sigma)$  symmetry with 39.3%. Interestingly, the  $\delta$  bonding orbitals in  $b_2$  symmetry do not seem to be of importance for the covalent stabilization, as they contribute only 0.2% to the total  $\Delta E_{\text{orb}}$ .

Comparing the former results with the 4d transition metal congener  $[\text{Tc}_2\text{Cl}_8]^{2-}$ , one notices some similarities but also a significant difference. A steep decrease in the electrostatic attraction is responsible for the overall instability of  $[\text{Tc}_2\text{Cl}_8]^{2-}$ . The drop in the  $\Delta E_{\text{elstat}}$  contribution can be explained by two factors. On the one hand, the Tc orbitals are more compact than the Re orbitals, leading to a reduced net attraction of the electrons in this orbital by the opposing metal nucleus. On the other hand, the Tc atom has a lower positive charge (+0.45 e) than the Re atom (+0.55 e), mean-

ing that the positive charge of the nucleus is screened more effectively in the Tc compound. The increased electron density on Tc can be rationalized based on the qualitative bonding picture developed above and noticing that the Tc atomic orbitals are more compact and lie energetically below the Re atomic orbitals (see, e.g., the discussion in ref. 73). The details of the covalent contributions to the bond energy remain unchanged compared to the Re compound, with the  $e(\pi)$  term (60.3%) exceeding the  $a_1(\sigma)$  contribution (39.8%). The similarity in the covalent bonding contribution is also reflected in the comparable Wiberg bond indices of 2.41 and 2.30 for the Re and the Tc complexes, respectively. It is interesting to notice that the intrinsic bond strength, as measured by the interaction energy,  $\Delta E_{\text{int}}$ , is still stabilizing (−22.2 kcal/mol). This, however, is not sufficient to overcompensate the preparation energy of  $\Delta E_{\text{prep}} = 38.7$  kcal/mol, which is needed for the deformation of the  $[\text{TcCl}_4]^-$  fragments from their relaxed geometry to the structure that they adopt to interact.

The M–M bond in  $[\text{Os}_2\text{Cl}_8]^0$  is considerably stronger than in its group 7 isoelectronic congener,  $[\text{Re}_2\text{Cl}_8]^{2-}$ . This is indicated by the interaction energy, which amounts to −92.8 kcal/mol in the former compared to −54.2 kcal/mol in the latter. The absolute values of the individual contributions to  $\Delta E_{\text{int}}$ , however, are smaller. The main reason for the higher stability of  $[\text{Os}_2\text{Cl}_8]^0$  is the steep decrease of the Pauli repulsion, an effect that is clearly related to the reduced net charge of the complex. A similar behavior was observed and discussed in ref. 69 for  $[\text{Re}_2\text{Cl}_8]^{2-}$  and  $[\text{Re}_2\text{Cl}_8]^0$ . Interestingly, the absolute values of the electrostatic and the orbital contributions are very similar for the  $[\text{Os}_2\text{Cl}_8]^0$  and the  $[\text{Tc}_2\text{Cl}_8]^{2-}$  complexes, suggesting a very similar bonding picture. This is misleading though, since the  $\pi$  orbital contributions are reduced to 49.6% and the  $\sigma$  orbital contributions are enhanced

**Table 7.** Energy decomposition analysis for the  $C_{4v}$  symmetric  $[MM'Cl_8]^x$  ( $M, M' = \text{Tc, Re, Ru, Os, Rh, Ir}; x = -1, 0, +1$ ) at BP86/TZ2P.  $MCl_4^y$  ( $y = -1, 0, +1$ ) in the quintet  $^5A_1$  state were used as fragments. Optimized metal–metal distances ( $R$ ) in Å, the Wiberg bond index of the  $M-M'$  pair ( $P$ ), the change in the orbital occupation ( $\Delta n$ ), and the change in partial charge ( $\Delta q$ ) relative to the homodimetallic systems are also given. The population analysis data are given at BP86/def2-TZVPP//BP86/TZ2P.

to 49.3% of the total  $\Delta E_{\text{orb}}$  in the Os compound. The reduced  $\pi$  contribution can be explained by the reduced overlap between the fragment  $\pi$  orbitals with overlap integrals of 0.21, 0.18, and 0.14 in the Re, Tc, and Os compounds, respectively. This is a consequence of the decreasing size of

the metal orbitals with decreasing negative charge and (or) decreasing row in the periodic system.

The nonclassical interaction between the fragments building the group 8 compound  $[\text{Ir}_2\text{Cl}_8]^{2+}$  is not strong enough to compensate for their electrostatic repulsion of 30.5 kcal/mol

and the Pauli repulsion of 162.4 kcal/mol. The resulting total interaction energy of 3.5 kcal/mol is destabilizing. The size of the orbital interaction term should be regarded with some care, as the singly occupied fragment orbitals, whose coupling is mainly responsible for this energy lowering, have some ligand character in the case of  $[\text{Ir}_2\text{Cl}_8]^{2+}$ , as was discussed in the beginning of the section in connection with Fig. 1. The  $\Delta E_{\text{orb}}$  term should thus not be identified with the pure  $M-M$  interaction, but contains a mixture of metal–metal, metal–ligand, and eventually also ligand–ligand interactions. This argument is supported by the considerably smaller Wiberg bond index of 0.77 for  $[\text{Ir}_2\text{Cl}_8]^{2+}$  compared to 1.55 for  $[\text{Os}_2\text{Cl}_8]^0$ , whereas the difference between the  $\Delta E_{\text{orb}}$  values of the Os compound (–197.8 kcal/mol) and the Ir species (–189.5 kcal/mol) is relatively low and blurs, to a certain degree, the difference in the bonding pattern.

The difference between  $[\text{Os}_2\text{Cl}_8]^0$  and its lighter analogue  $[\text{Ru}_2\text{Cl}_8]^0$  is comparable to the difference between  $[\text{Re}_2\text{Cl}_8]^{2-}$  and  $[\text{Tc}_2\text{Cl}_8]^{2-}$ . The change from a 5d to a 4d metal weakens the metal–metal interaction considerably, due to the reduction in size of the metal orbitals. This reduction leads to a decreased overlap between the metal orbitals, to which the system can answer by a decrease in the central metal–metal bond length, but only to a limited degree, since an increased ligand–ligand repulsion counterbalances this process. The strong decrease in the electrostatic contribution in the 4d

systems can also be attributed to the more compact orbitals of the 4d metal atoms.

Comparing the analysis results for  $[\text{M}_2\text{Cl}_8]^{2-}$  with the ones for  $[\text{M}_2\text{Cl}_8]^0$  and for  $[\text{M}_2\text{Cl}_8]^{2+}$  shows that the uncharged species are the most stable, followed by the negatively charged ones, with the positively charged systems being unstable. The lower bond strength of  $[\text{M}_2\text{Cl}_8]^{2-}$  is due to a very high Pauli repulsion, whereas the positively charged species are destabilized by classical electrostatic repulsion. In all cases, the  $\delta$  bonding orbitals are of no importance for the bond strength, whereas the  $\pi$  orbitals dominate the covalent contribution for the negatively charged species and the  $\sigma$  contribution is more important for the remaining compounds.

The EDA results for some heteronuclear compounds,  $[\text{MM}'\text{Cl}_8]^x$  ( $M = \text{Tc, Re, Ru, Os, Rh, Ir}; x = -2, 0, +2$ ), are given in Table 9. These compounds are species in which two metal atoms of the same group, but of different rows in the periodic table, interact with each other. The comparison with the corresponding homodinuclear systems reveals that all bond energy contributions are halfway between the homonuclear values. The bonding situation does thus not change from the homo- to the hetero-dinuclear systems and thus, the polarity of the metal–metal bond appears to be low. The partial charges support this finding as the charge transfer between the two different  $\text{MCl}_4^x$  units is small ( $|\Delta q(\text{MCl}_4^x)|$  between 0.13–0.20 e) with the charge of the metal atoms being essentially unchanged. The picture does change for the heterodimetallic systems with metal atoms of the same row but of different groups in the periodic table (Table 7). In this case, the intrinsic bond strength is considerably enhanced compared to the corresponding nonpolar compounds. For example,  $[\text{ReOsCl}_8]^{1-}$  has an intrinsic bond strength of –132.0 kcal/mol, while for  $[\text{Re}_2\text{Cl}_8]^{2-}$   $\Delta E_{\text{int}}$  amounts to –54.2 kcal/mol and for  $[\text{Os}_2\text{Cl}_8]^0$  to –92.8 kcal/mol. The main reason for this observation is that the Pauli repulsion is considerably weaker compared to the dianionic Re system, while the classical electrostatic interaction in the monoanionic system is increased compared to the neutral Os system. The covalent bonding does not dramatically change; the  $\pi$  bonding remains the dominating contribution to  $\Delta E_{\text{orb}}$  (53.8%). There is, however, an increase in the contribution due to the  $b_2 (\delta)$  orbitals of 4.6%. We attribute a part of this energy gain to a charge transfer from the  $\delta$  orbitals of  $\text{ReCl}_4^-$  to the  $\delta$  orbitals of the  $\text{OsCl}_4^0$  fragment, since the  $d_{xy}$  orbital of Re loses 0.1 e to the Os  $d_{xy}$  orbital (Table 7). The overall charge transfer from the  $\text{ReCl}_4^-$  onto the  $\text{OsCl}_4^0$  moiety is considerable with 0.61 e, but the partial charge of the metal atoms remains virtually constant. A similar interpretation can be given to the  $[\text{ReIrCl}_8]^0$  system, where the two oppositely charged fragments,  $\text{ReCl}_4^-$  and  $\text{IrCl}_4^+$ , interact, which leads to an exceptionally large electrostatic contribution of –255.1 kcal/mol. The charge transfer in this system is large with 1.30 e, while the metal atom partial charge changes very little. As in the former case, charge transfer between the  $d_{xy}$  orbitals of the two metal atoms of 0.2 e leads to a large energy contribution in the  $\Delta b_2$  term. The combination of the group 8 metal Os with the group 9 metal Ir leads to the cationic  $[\text{OsIrCl}_8]^+$  system, which also has an increased stability compared to both homodimetallic analogues, which is interesting as  $[\text{Ir}_2\text{Cl}_8]^{2+}$  is unstable. The

much more favorable electrostatic interaction between a neutral and a cationic system compared to the one between two cations is the main reason for this observation.

For the combination of two 4d metals of different rows in the periodic table (Table 7), the same bonding picture emerges as for the 5d metals. The polar metal–metal bonds show an increased stability compared to the homodinuclear counterparts, mainly due to a reduced Pauli repulsion, more favorable electrostatic interactions, and charge transfer.

Table 8 shows the analysis results for heterodinuclear compounds with metal atoms of different groups and different rows in the periodic table. Also in this case, the stability of the metal–metal bond increases compared to the unpolar situation, but the bonding situation of the two systems is very similar. However, the charge transfer contribution as measured by  $|\Delta q(\text{MCl}_4)|$  increases whenever the 5d moiety is more negatively charged than the 4d moiety, compared to the 5d–5d analogues. On the other hand, a 4d  $\text{MCl}_4^x$  fragment that is more negatively charged than the 5d fragment interacts and loses fewer electrons than it would when combined with a 4d fragment. This is exemplified by the systems  $[\text{TcOsCl}_8]^{1-}$  with  $|\Delta q(\text{MCl}_4)| = 0.47$  and  $[\text{TcRuCl}_8]^{1-}$  with  $|\Delta q(\text{MCl}_4)| = 0.65$ . This means that there is a better “match” if the M–M bond is built between a 4d metal of a lower group number than the 5d metal (“early 4d–late 5d”). We note that the charge transfer trends are reflected in the trends of the  $\Delta b_2$  ( $\delta$ ) contributions to the orbital interaction energy in the EDA. Furthermore, the size of the bond order as measured by the Wiberg bond index also follows this matching rule.

## Summary

The study of the bonding situation in the formally quadruply bonded (d–d)<sup>8</sup>  $[\text{MM}'\text{Cl}_8]^x$  compounds and the test of the performance of DFT functionals can be summarized as follows: (i) The GGA functionals BLYP, BP86, and PBE, show the best performance when it comes to structure prediction and in the description of the dissociation energies. We estimate these functionals to deliver dissociation energies within  $\pm 5$  kcal/mol from the CASPT2 results. (ii) Hybrid functionals are not to be used for compounds of the type discussed here as they lead to increasingly too short and too weak bonds with the amount of exact exchange included. (iii) The ground state of the  $\text{MCl}_4^x$  fragments can either be a  $D_{4h}$  symmetric quintet or a  $T_d$  symmetric singlet state. Most of the studied fragments have a singlet ground state with the exception of  $\text{ReCl}_4^-$  and  $\text{TcCl}_4^-$ . Since the quintet state is the valence state for building a metal–metal quadruple bond, this finding can serve as an explanation for the difficulties to isolate more metal–metal multiply bonded systems. (iv) The strength of unpolar metal–metal bonds is reduced in going from group 7 metals to group 8 metals and to group 9 metals. 4d transition metal atoms form weaker metal–metal bonds than 5d species. (v) The intrinsic bond strength in the unpolar systems is in approximately equal parts due to orbital interactions and classical electrostatic contributions. The  $\pi$  orbitals dominate the orbital interaction, while  $\delta$  orbitals are of minor importance. (vi) Polar metal–metal bonds show enhanced bond strength compared to unpolar bonds due to a reduced Pauli repulsion,

more favorable classical electrostatics interactions, and charge transfer. 5d–5d metal atom pairs form the most stable polar metal–metal bonds. The charge transfer is small in a heterodinuclear system with two metal atoms of the same group and it is large if the two metal atoms have considerably different size as, e.g., in a system in which a more negatively charged 5d metal fragment interacts with a more positively charged 4d metal fragment.

The knowledge on the performance of the DFT functionals will be useful in the study of more complex systems, e.g., the Por–M–M'–Por systems of Collmann, which will be the subject of further studies. The insight into the bonding situation of metal–metal bonded systems should be helpful in the design of new polar metal–metal bonded systems.

## Supplementary data

Supplementary data for this article are available on the journal Web site ([canjchem.nrc.ca](http://canjchem.nrc.ca)).

# Ring-chain equilibria of R-but-3-enoate esters — A quantum mechanical study of direct and indirect ring-closing reactions

Michael B. Burt, Angela K. Crane, Ning Su, Nicole Rice, and Raymond A. Poirier

**Abstract:** Macrocyclic structures can be synthesized through two simultaneous olefin metathesis reactions: either directly through ring-closing metathesis (RCM) or indirectly through an intermediate formed by acyclic diene metathesis (ADMET). The proclivity of a homologous series of 16 R-but-3-enoate esters to form lactones through one of these two processes is studied at the HF/6–31G(d), B3LYP/6–31G(d), and MP2(full)/6–31G(d) levels of theory. Computed Gibbs free energies are used to determine  $\Delta G_{\text{RCM}}$ ,  $\Delta G_{\text{ADMET}}$ , and  $\Delta\Delta G$  ( $\Delta G_{\text{RCM}} - \Delta G_{\text{ADMET}}$ ).  $\Delta\Delta G$  is evaluated to compare the relative favourability of the RCM and ADMET reactions for the various R-but-3-enoate esters, where each system is differentiated by the number of methylene groups ( $n$ ) added to the ester chain. When  $n = 0, 1, 10$ , or  $13$ , cyclic lactone formation by direct RCM is predicted to be thermodynamically favoured, and the indirect synthesis is preferred for all other heterocyclic structures. The same trend holds between 298.15 and 333.15 K, therefore, the gas-phase model is a reasonable approximation of the experimental reaction conditions. The theoretical model is sufficient for smaller systems, but molecules larger than the  $n = 6$  case do not follow experimental results for similar saturated structures. Hence, the assumptions pertaining to straight-chain and cis-ring conformations need to be re-evaluated. In particular, chain flexibility should be further examined.

**Key words:** olefin metathesis, ring-chain equilibria, ring-closing metathesis, acyclic diene metathesis.

**Résumé :** On a réalisé des synthèses de structures macrocycliques par le biais de réactions de métathèse simultanées d'oléfines, soit directement par une métathèse avec fermeture de cycle (MFC) ou indirectement par un intermédiaire formé par une métathèse de diène acyclique (METDA). On a étudié d'un point de vue théorique la proclivité d'une série homologue de seize esters de l'acide R-but-3-énoïque à former des lactones par un de ces deux processus aux niveaux HF/6–31G(d), B3LYP/6–31G(d) et MP2(complet)/6–31G(d) de la théorie. On a utilisé les énergies libres de Gibbs calculées pour déterminer les valeurs de  $\Delta G_{\text{MFC}}$ ,  $\Delta G_{\text{METDA}}$  et  $\Delta\Delta G$  ( $\Delta G_{\text{MFC}} - \Delta G_{\text{METDA}}$ ). La valeur de  $\Delta\Delta G$  a été évaluée afin de comparer le caractère favorable relatif des réactions de MFC et de METDA des divers esters de l'acide R-but-3-énoïque dans lesquels chaque système se distingue par le nombre de groupes méthylènes ( $n$ ) ajouté à la chaîne de l'ester. Quand  $n = 0, 1, 10$  ou  $13$ , il est prédit que la formation de la lactone cyclique par une MFC est thermodynamiquement favorisée alors que la synthèse indirecte est la réaction préférée pour toutes les autres structures hétérocycliques. La même tendance est observée pour 298,15 et 333,15 K; le modèle en phase gazeuse est donc une approximation raisonnable des conditions réactionnelles expérimentales. Le modèle théorique est suffisant pour les systèmes les plus petits, toutefois les molécules dans lesquelles est supérieure à 6 ne reproduisent pas les résultats expérimentaux pour des structures saturées similaires. Il est donc impératif de réévaluer les hypothèses concernant les chaînes droites et les conformations cis du cycle. On devrait réexaminer en particulier la question de la flexibilité de la chaîne.

**Mots-clés :** métathèse d'oléfine, équilibre cycle-chaîne, métathèse avec fermeture de cycle.

## Introduction

The development of olefin metathesis, a transalkylidenation reaction involving the redistribution of alkene bonds, has opened a variety of novel pathways to challenging or previously impossible syntheses.<sup>1–16</sup> In particular, ring-closing metathesis (RCM) has been used for decades to create functionalized macrocycles because of its excellent functional group tolerance and neutral reaction conditions. Since these

cyclic products are found in many synthetic targets, it is not surprising that RCM has become a popular methodology among synthetic chemists. Furthermore, the advent of Grubbs' highly reactive ruthenium catalyst has made RCM reactions quick and easily accessible; especially when the catalyst is modified by N-heterocyclic carbene derivatives.<sup>17</sup>

Unfortunately, RCM is still impractical at the commercial level owing to the high dilution conditions ( $1 \times 10^{-3}$  mol/L)

**Scheme 1.** An  $\alpha,\omega$ -unsaturated diene can form either a polymer or a macrocycle by following the ADMET or RCM pathways, respectively ( $m$  is the number of substrates used). Each reaction is irreversible because of the loss of ethylene. The polymer product can further undergo a CDP reaction to form the macrocycle. Hence, there are two routes to the cyclic product: the direct RCM approach and the indirect two-step approach where the polymer produced through ADMET ring-closes to form the product through CDP.

required.<sup>11–13</sup> This restriction comes from a well-known equilibrium between the RCM pathway and a step growth polymerization reaction known as acyclic diene metathesis (ADMET). Hence, the distribution of products will be dependent on the relative rates of these two reactions. When the reactant monomer is present in high concentrations, the polymer is favoured. Conversely, the cyclic products dominate under dilute conditions. Scheme 1 illustrates the simultaneous RCM and ADMET reactions and demonstrates that the polymer product can further undergo a cyclodepolymerisation (CDP) reaction to ring close and form the cyclic product.<sup>5,7</sup> Therefore, in addition to the competition between RCM and ADMET, the yield of the cyclic product also depends on the equilibrium between the “backbiting” CDP reaction and the macrocycles proclivity towards ring-opening metathesis polymerization (ROMP).<sup>12–14</sup>

ADMET has previously been considered to impede RCM, however, Fogg and co-workers<sup>5,7</sup> recently used a series of typical  $\alpha,\omega$ -unsaturated dienes to demonstrate that oligomeric products were being quantitatively converted to macrocycles despite the volatilization of ethylene during ADMET. Because the loss of ethylene makes the RCM and ADMET pathways irreversible, the conversion of polymers to cyclic products implies that the ADMET polymers are actually key intermediates for the RCM of conformationally flexible dienes. Macrocylic products can therefore be produced either through the direct RCM pathway or by a two-step indirect pathway, which involves ADMET followed by CDP, implying that ADMET is actually intrinsic to macrocycle production rather than an impediment.

Because the formation of cyclic products from diene monomers follows two separate pathways, it would be useful to have some way of quickly predicting the product distribution for different systems. If the direct RCM pathway was uniquely followed, the product mixture would contain only the macrocycle and any unreacted diene; however, if the indirect pathway were contributing, then the intermedi-

ary oligomers produced through ADMET would also be present; although, this would be dependent on the rate of CDP. The preference for a homologous series of R-but-3-enoate ester substrates to follow the direct or indirect pathways will be examined by observing the inclination of these  $\alpha,\omega$ -diene monomers to form either cyclic or acyclic products. These substrates were chosen because they are similar to experimental products reported previously by Mandolini and co-workers,<sup>18–20</sup> and because they were already known to yield cyclic products through both direct and indirect ring-closing methods.<sup>5</sup> The ring-chain equilibrium between the RCM and ADMET reactions will be evaluated using a computational approach to determine the relative stabilities of the direct RCM lactone product and the oligomer produced through ADMET. Density functional theory (DFT) and ab initio approaches have already been successfully used to examine the mechanism of the RCM reaction with different catalysts,<sup>21–26</sup> and similar approaches to the one used here have been reported for the ring-chain product distribution for the ROMP of cycloolefins;<sup>27</sup> the equilibrium distribution for the metathesis of linear olefins;<sup>28</sup> and for the ring-chain equilibria in the cross-metathesis of cyclohexanone and *cis,cis*-cycloocta-1,5-diene.<sup>29</sup>

The competition between polymerization and ring-closing pathways has already been well-characterized:<sup>10,17</sup> the bifunctional nature of the  $\alpha,\omega$ -diene substrate leads to the two pathways, and further complications arise from head-to-head condensation reactions as opposed to head-to-tail. Mandolini and co-workers<sup>18–20</sup> used kinetic data to express the favourability of the two reactions by constructing reactivity profiles of ring size against the effective molarity or the rate of the intramolecular pathway. Our computational approach will investigate the thermochemistry involved in the ring-chain equilibrium instead of the kinetics. Thermochemical data will be used to determine  $\Delta G_{\text{RCM}}$ , the free energy change associated with the direct RCM reaction, and  $\Delta G_{\text{ADMET}}$ , the free energy change associated with the first step (ADMET) of the indirect ring-closing reaction. The difference between these two values,  $\Delta\Delta G$  ( $\Delta G_{\text{RCM}} - \Delta G_{\text{ADMET}}$ ), will then be examined as a function of ring size to assess the behaviour of the ring-chain equilibria for the R-but-3-enoate esters. A negative  $\Delta\Delta G$  means direct RCM is thermodynamically favoured, and a positive  $\Delta\Delta G$  implies lactone formation will occur through the indirect route. Hence, by comparing the  $\Delta\Delta G$  to ring size, the preference of a substrate to follow the direct or indirect RCM pathways can be determined. The theoretical predictions will be compared with Mandolini and co-workers’<sup>18–20</sup> experimentally determined trends to see whether or not the thermochemical approach can adequately approximate reactions, which are known to display a kinetic bias.

## Methods

The R-but-3-enoate esters were chosen for their versatility in forming unsaturated lactones of various sizes (Scheme 2). This system is experimentally relevant, and has been well-documented with respect to RCM.<sup>4,5,30–32</sup>

In analyzing the reactions, several assumptions were made for computational convenience: it was assumed that polymerization did not produce any structures larger than the

**Scheme 2.** The R-but-3-enoate reaction system, where “ $n$ ” is the number of additional methylene groups added to a substrate. For example, the largest monomer considered ( $n = 15$ ) has 22 constituent atoms in its chain.

**Fig. 1.** The numbering system for dihedral angle assignments. The values of  $n$ , which describe the monomers, dimers, and lactones seen in Scheme 2, are given in Table 1. The broken line represents any methylene units ignored in the diagram. For example, in the  $n = 3$  case, the broken line includes C5 and C6. In the  $n = 0$  case,  $C_{n+4}$  and  $C_{2n+8}$  must both be ignored to avoid numbering duplication.

**Table 1.** The legend for the monomer and dimer systems studied, including the number of constituent atoms in each monomer or dimer chain, as well as the ring size for each lactone.

dimer, that head-to-tail monomer linkages were ubiquitous, and that each dimer was expected to be a straight chain since straight-chain monomers were used to produce them. The second assumption is likely valid, but the first and third assumptions are less realistic and could lead to deviation from experimental data. Furthermore, calculations were made for the gas-phase reaction at 298.15 K, whereas the reaction itself is carried out in solution (e.g., dichloromethane) with various concentrations and at elevated tempera-

tures.<sup>4,5,10</sup> The temperature dependence of the ring-chain equilibrium will therefore also be examined for the reactions standard conditions (333.15 K).

Calculations were performed at the HF/6-31G(d), B3LYP/6-31G(d), and MP2(full)/6-31G(d) levels of theory as implemented in the Gaussian 03 suite of programs.<sup>33</sup> Sixteen R-but-3-enoate esters were considered (Scheme 2), with each system containing between 0 and 15 methylene units ( $n$ ) added to the ester chain of the  $\alpha,\omega$ -unsaturated ethyl butyrate. In each system, optimized geometries and vibrational frequencies were determined for the monomer, the dimer, and the cyclic lactone. Geometry optimizations were initially performed using HF/STO-3G. Optimized conformer structures with the lowest energies were then further refined using the methods described above. For all optimized structures, no imaginary frequencies were found.

The 16 systems were split into two groups. For the first group, consisting of the  $n = 0-7$  systems, many conformers were considered for each molecule. In general, the straight-chain conformers of the monomer and dimers appeared to be favoured. For the lactones, the *cis* configuration emerged as the preferred conformation. In the second group, which consisted of the  $n = 8-15$  systems, the structures became very large, so an assumption was made that the structures would follow the trend previously observed for the smaller  $n = 0-7$  systems; thus, only one to two conformers were considered for each straight-chained monomer and dimer, and only the *cis* rings were considered.

The determination of the lowest energy conformers for the monomer, dimer, and ring forms of each system allowed the reaction thermochemistry to be determined from the  $\Delta H$ ,  $\Delta S$ , and  $\Delta G$  values extracted from the *ab initio* and DFT data. It should also be noted that since the ADMET reaction

**Fig. 2.** The B3LYP/6–31G(d) optimized structures for the  $n = 0$  system: the monomer (M0A), the dimer (D0A), and the five-membered lactone (R0). The structures for other systems can be found in the Supplementary data.

is irreversible due to the volatilization of ethylene, the CDP reaction was not examined in great detail since the formation of the dimer is sufficient to show that the indirect ring-closure pathway is preferred in the cases where  $\Delta\Delta G$

( $\Delta G_{\text{RCM}} - \Delta G_{\text{ADMET}}$ ) is positive. A plot of  $\Delta\Delta G$  against ring size was then used to determine the predicted preference of lactone (negative  $\Delta\Delta G$ ) or dimer (positive  $\Delta\Delta G$ ) formation.

**Fig. 3.**  $\Delta H_{\text{RCM}}$  vs ring size for the HF/6–31G(d) (blue), B3LYP/6–31G(d) (red), and MP2(full)/6–31G(d) (green) levels of theory. The 5- to 11-membered ( $n = 0$ –6) ring cases agree very well with the  $\Delta H_{\text{RCM}}^{\#}$  values (black) determined experimentally by Illuminati and Mandolini<sup>18</sup> for the saturated analogues of the R-but-3-enoate esters considered here. The gap between  $\Delta H_{\text{RCM}}^{\#}$  and  $\Delta H_{\text{RCM}}$  remains roughly consistent for the smaller systems, hence, thermodynamics can be used to model the kinetically controlled reaction. However, for systems larger than the 11-membered ring ( $n > 6$ ), the agreement becomes much poorer, implying that the reaction has a stronger kinetic bias and that the predictive ability of thermodynamic data becomes very limited.

## Results

### Conformer geometries

The lowest energy geometries of the monomer, dimer, and lactone compounds for the 16 R-but-3-enoate ester systems were initially determined at the HF/STO–3G level of theory. The method used to distinguish each structure is given in Fig. 1, and a legend summarizing the systems of interest is given in Table 1. The geometries (defined by dihedral angles) and relative energies of each conformer can be found in the Supplementary data. The lowest energy HF/STO–3G structures were then further refined at the B3LYP/6–31G(d) and MP2(full)/6–31G(d) levels of theory. The B3LYP/6–31G(d) theoretical structures for the  $n = 0$  case are shown in Fig. 2, whereas the remaining B3LYP/6–31G(d) lowest energy geometries are also available in the Supplementary data.

The computational data appears to agree with the assump-

tion that the smaller monomers and dimers ( $n = 0 - 7$ ) will prefer straight-chain conformations; and this behaviour is consistent across all levels of theory. In the larger substrates ( $n = 8 - 15$ ), all monomers were also linear, however the lowest energy dimer geometries for the  $n = 8, 9, 12$ , and 14 cases exhibited a small bend around the ester moiety at the center of the dimer. The increased availability of conformational space in these larger dimers likely allows for more flexibility, hence the straight-chain assumption becomes less realistic as the substrate chain length increases. For each lactone, the cis-ring conformer was determined to be the most stable. This trend carried through all the systems considered except the 12-membered ring in the  $n = 7$  case, where the trans conformer appeared to be far more stable. This result is not entirely unexpected, as it has been shown experimentally that macrocyclic ring closures prefer to form the trans-conformer.<sup>4</sup>

**Fig. 4.**  $\Delta S_{\text{RCM}}$  vs ring size for the HF/6–31G(d) (blue), B3LYP/6–31G(d) (red), and MP2(full)/6–31G(d) (green) levels of theory. The overall trend is for  $\Delta S_{\text{RCM}}$  to decrease as ring size increases. See Fig. 3 for colour legend.

**Fig. 5.**  $\Delta\Delta G$  ( $\Delta G_{\text{RCM}} - \Delta G_{\text{ADMET}}$ ) (kJ/mol) vs ring size at the HF/6–31G(d) (blue), B3LYP/6–31G(d) (red), and MP2(full)/6–31G(d) (green) levels of theory.  $\Delta\Delta G$  data can be found in Tables 2–4. The indirect pathway is followed for the majority of systems, however, direct RCM predominates in the formation of the 5-, 6-, 15-, and 18-membered lactones ( $n = 0, 1, 10,$  and  $13,$  respectively). See Fig. 3 for colour legend.

### Thermochemistry

The results for the RCM and ADMET reaction enthalpies, entropies, and free energies for the HF/6–31G(d), B3LYP/6–31G(d), and MP2(full)/6–31G(d) levels of theory are given in Tables 2–4, respectively. There are no significant deviations between the HF, B3LYP, and MP2 results; each theory predicts the same trend. In general, MP2 predicts the lowest values for  $\Delta H_{\text{RCM}}$  and  $\Delta S_{\text{RCM}}$ , while B3LYP and HF return slightly higher energy differences. The data in Tables 2–4 is

best seen as a function of lactone size (Figs. 3 and 4). It can be seen that the formation of 5- and 6-membered rings ( $n = 0$  and  $1$ , respectively) is more enthalpically favourable than the formation of larger lactones, whereas the 8-, 14-, and 16-membered rings ( $n = 3, 9,$  and  $11$ , respectively) are particularly unfavourable. The 8-membered lactone was predicted to be more stable than the 14- and 16-membered rings; however, it should be noted that to the best of the authors' knowledge, this cyclic product has never been experimen-

**Fig. 6.** The temperature dependence of the RCM and ADMET equilibria determined by HF/6–31G(d).**Fig. 7.** The temperature dependence of the RCM and ADMET equilibria determined by B3LYP/6–31G(d).

tally produced, whereas larger macrocycles are known to be accessible.<sup>1–3,18</sup> As was mentioned in the discussion of the conformer geometries, the discrepancy in the  $n = 9$  and 11 cases likely arises from the assumption that the larger monomer substrates prefer linear orientations. Hence, conformer flexibility should be more extensively examined to further refine the predictive power of this methodology.

The predicted dependence of  $\Delta H_{\text{RCM}}$  (Fig. 3) and  $\Delta S_{\text{RCM}}$  (Fig. 4) on ring size resembles trends characterized by Illuminati and Mandolini<sup>18</sup> for a saturated analogue of the system reported here. The formation of lactones is computed to be endothermic in all cases; lactone formation for the 5-, 6-, and 12-membered systems ( $n = 0, 1$ , and 7, respectively) re-

quires the lowest enthalpy cost, whereas the 8-membered lactone ( $n = 3$ ) and systems greater than  $n = 8$  are the least enthalpically favoured out of all the ring structures. Interestingly, computed  $\Delta H_{\text{RCM}}$  values have a comparable trend to the  $\Delta H_{\text{RCM}}^{\ddagger}$  behaviour reported by Illuminati and Mandolini<sup>18</sup> for a homologous series of saturated R-but-3-enoate esters. The agreement is only noticeable for small systems ( $n = 0–6$ ), implying that in these reactions experimental products were likely thermodynamic rather than kinetic. The consistent energy gap between the predicted  $\Delta H_{\text{RCM}}$  and experimental  $\Delta H_{\text{RCM}}^{\ddagger}$  values for the 5- to 11-membered rings further suggests that thermochemistry can adequately be used to approximate the kinetically controlled RCM reac-

**Fig. 8.** The temperature dependence of the RCM and ADMET equilibria determined by MP2(full)/6–31G(d).

tion for smaller substrates. However, at larger ring sizes, experimental agreement is much poorer, reflecting both that large systems have a strong kinetic bias and that the assumption of the conformers existing as straight chains is invalid for longer chains, which have more available conformational degrees of freedom. Encouragingly, despite the discrepancies at larger ring sizes, the positions of relative maxima (the 8- and 16-membered ring systems) and minima (the 5-membered ring system) in the  $\Delta H_{\text{RCM}}$  profile correspond reasonably well with the experimental results.

In analyzing the entropy results (Fig. 4), we can see that except for small increases in the 6- and 11-membered lactones ( $n = 1$  and 6, respectively), entropy change generally decreases as ring size increases. The maximum  $\Delta S_{\text{RCM}}$  occurs in the 6-membered lactone, and then steadily decreases with increasing ring size. This makes sense considering 5-membered lactones are subject to more ring strain and because it would be more difficult for longer chains to orient themselves in an appropriate way for ring closure to occur. In every case, the largest contribution to the reported entropies is vibrational. The  $\Delta S_{\text{RCM}}$  trend is very similar to the  $\Delta S_{\text{RCM}}^{\ddagger}$  behaviour reported by Illuminati and Mandolini;<sup>18</sup> both data series generally decrease as ring size increases, and the energy gap between the two sets of data is consistently about 0.3 kJ/(mol K).

For smaller substrates, the predictive ability of thermochemical data is clear. However, for larger systems ( $n > 6$ ), deviations from experimental kinetic data become more noticeable, implying that our assumptions need to be further refined; particularly the one pertaining to chain flexibility.

### Thermodynamic evaluation of the ADMET and RCM competition

$\Delta G_{\text{RCM}}$  and  $\Delta G_{\text{ADMET}}$  were determined from computed data and used to construct a thermodynamic profile of  $\Delta\Delta G$  against ring size (Fig. 5). This data indicates that ring formation by direct RCM only predominates in the 5-, 6-, 15-, and 18-membered lactones ( $n = 0, 1, 10$ , and 13, re-

spectively). In all other cases, indirect ring closure is the preferred pathway; although in the  $n = 7$  case, the HF and B3LYP theories disagree as to which pathway is preferred. HF/6–31G(d) predicts that the dimer will form preferentially while B3LYP/6–31G(d) suggests the opposite (+7.0 kJ/mol compared with –1.3 kJ/mol, respectively). The predictions taken from the thermodynamic profile correspond to similar experimental kinetic results,<sup>18</sup> although there are significant deviations for systems larger than  $n = 6$ , in particular for the  $n = 10, 11$ , and 13 cases. This implies that the predictive ability of computed thermodynamic data towards competing metathesis reactions is limited to at best small systems. We have not directly considered the CDP step, yet have found evidence that this pathway should be commonly involved in macrocycle formation because of the strong preference seen by these ester substrates to polymerize instead of ring close by RCM.

### Temperature dependence

The thermodynamic properties of the monomer, dimer, and ring structures were further explored by altering their temperature. The ab initio results accounted for a temperature of 298.15 K, but Illuminati and Mandolini's<sup>18</sup> experimental results were carried out at 323.15 K and contemporary RCM reactions are normally promoted at 333.15 K.<sup>6</sup> Therefore, the temperatures of these latter cases were considered at the different levels of theory used to see if agreement between experiment and computation improved (Figs. 6–8). Clearly, over the experimental temperature ranges considered, the ring-chain equilibrium should only be marginally affected. However, this conflicts with recent work by Danishefsky and co-workers,<sup>8</sup> which noted that increasing the reaction temperature yields more macrocycles. This discrepancy with the thermodynamic approach is not surprising, since the olefin metathesis pathways display a strong kinetic bias. Hence, although this thermodynamic approach is sufficient to determine the proclivity of a R-but-3-enoate ester to follow the direct or indirect ring-closure

pathways, it does not adequately predict the temperature dependence of the product distribution.

## Conclusions

Thermochemical data for the simultaneous RCM and ADMET processes were determined using electronic structural calculations and used to assess the relative product formation by analyzing  $\Delta\Delta G$ . In the homologous series of R-but-3-enoate esters, direct RCM is only preferential for the 5-, 6-, 15-, and 18-membered cases ( $n = 0, 1, 10$ , and 13, respectively); in every other system, indirect ring closure was favoured. Polymerization was especially dominant in the cases where  $n = 3, 6, 9, 11$ , or 15. Our methodology assumed the following: that the polymer formation never extended to trimers or oligomers and that the lowest energy structures were always cis-conformer rings or straight-chain monomers and dimers. Whereas the first assumption makes sense from a computational perspective, clearly our predictions will not correspond totally with reality, since we are entirely ignoring oligomer formations. Furthermore, as a consequence of assuming linearity in the monomers and dimers, substantial deviation from reported behaviour was noted for the larger systems;<sup>18</sup> bent conformers may be lower in energy, especially structures where the olefinic bond is capable of interacting with the chain. In ring systems containing more than 11 members ( $n > 6$ ), the data appears to vary markedly in its preference for direct or indirect ring closure. However, it is also possible that the metathesis reactions involving large substrates are kinetically controlled, and hence the predictive power of thermodynamics will be limited to the smaller substrates. Therefore, if our model were improved to account for greater chain flexibility in the larger oligomer systems, there appears to be no great obstacle in using thermodynamic data derived from lowest energy geometries as a predictive tool for predicting whether or not ring closure will occur by the direct RCM or indirect ADMET routes, so long as the reaction system considered is governed primarily by thermodynamic considerations rather than kinetics. However, it should be stressed that predicting the temperature dependence of this ring-chain product distribution is unfeasible. The temperature dependence of the competing metathesis reactions was shown to be thermodynamically negligible over the range of temperatures suitable for laboratory work with RCM and ADMET processes; however, this conflicts with experimental reports due to the kinetic bias of this system.<sup>8</sup> Therefore, the overall predictive power of this approach is limited to reactions where the product distribution is not strictly controlled by kinetic effects.

# A water potential based on multipole moments trained by machine learning — Reducing maximum energy errors

Glenn I. Hawe and Paul L.A. Popelier

**Abstract:** A potential that strives to represent the Coulomb interaction realistically must include polarization. In our approach, three decisions were made to accomplish this: (i) define an atom according to quantum chemical topology (QCT), (ii) express the interaction between atoms via their multipole moments, and (iii) use machine learning to capture the response of an atomic multipole moment to a change in this atom's environment. This approach avoids explicit (distributed) polarizabilities and eliminates the problem of polarization catastrophe. Previously, we showed (*Phys. Chem. Chem. Phys.* **2009**, *11*, 6365) that a machine learning method called kriging predicted atomic multipole moments more accurately than competing machine learning methods. This was established for the atoms of a central water molecule in water clusters, from the dimer to the hexamer. The prediction errors in all multipole moments were collectively assessed by errors in total interaction energy, for thousands of clusters configurations. Here, we target the maximum errors, with an eye on reducing the worst predictions that the potential may return. We demonstrate proof-of-principle for the water dimer using local kriging.

**Key words:** quantum chemical topology (QCT), atoms in molecules, kriging, water dimer, polarization, machine learning, force field.

**Résumé :** Un potentiel qui tend à représenter d'une façon réaliste l'interaction de Coulomb doit inclure une polarisation. Dans l'approche présentée ici, on prend trois décisions pour y arriver : (i) on définit un atome suivant la topologie de la chimie quantique (TCQ), (ii) on exprime l'interaction entre les atomes par le biais de leurs moments multipolaires et (iii) et on utilise une machine qui apprend à capturer la réponse d'un moment multipolaire atomique à un changement dans l'environnement de cet atome. Cette approche évite les polarisabilités distribuées d'une façon explicite et élimine le problème de la catastrophe de polarisation. On a démontré antérieurement (*Phys. Chem. Chem. Phys.* **2009**, *11*, 6365) qu'une méthode à base d'une machine qui apprend à capturer une réponse, appelée kriging, permet de prédire les moments multipolaires atomiques d'une façon plus précise que les méthodes faisant appel à d'autres machines qui apprennent à capturer une réponse. Cette conclusion a été établie pour les atomes d'une molécule d'eau centrale d'agrégats d'eau allant du dimère à l'hexamère. Les erreurs de prédictions dans tous les moments multipolaires ont été évalués collectivement par les erreurs dans l'énergie d'interaction totale pour des milliers de configurations d'agrégats. Dans le présent travail, on s'adresse aux erreurs maximales dans le but de réduire les plus mauvaises prédictions qui peuvent être faites pour le potentiel. On établit le principe de preuve pour le dimère de l'eau à l'aide de la machine kriging locale.

**Mots-clés :** topologie de chimie quantique (TCQ), atomes dans les molécules, kriging, dimère de l'eau, polarisation, machine à apprendre, champ de force.

## Introduction

Unless computing power surges by a dramatic and unexpected technological leap, using force fields will be the only option to run long simulations of sizeable molecular systems for many years to come. Many systems, even non-biological ones, involve water and therefore water force fields are very important. Several popular water force fields have been developed over the decades, such as the transfer-

able interaction potential (TIPnP;  $n = 3, 4, 5$ ) series<sup>1–3</sup> or the simple point charge (SPC) series of models.<sup>4</sup> The simplest water models represent the electron density of water via atomic point charges, one charge per nuclear site. A more realistic description warrants extra point charges, this time not centered on the nuclear position. This is why potentials with as many as three off-nuclear charges on oxygen have been constructed. Such potential was shown<sup>5</sup> to be much more suitable than the TIP4P and TIP5P models for the sim-

ulations of ice and water near melting point. An alternative path to represent electron density more realistically is through multipole moments.<sup>6</sup> Dipole, quadrupole, and higher-rank moments, while all centered on the nucleus, capture important nonspherical features of the electron density. The formulae<sup>7,8</sup> expressing interactions between atomic multipole moments are more complicated than the formula for interaction between atomic point charges. This complexity leads to an increase in floating point operations that a computer must carry out to evaluate the electrostatic energy between two atoms. However, this increase is more pronounced the shorter the range of atomic interaction. High-rank multipolar interaction is known to decrease quickly with interatomic distance,  $R$ , because it obeys a high inverse-power law. For example, interaction energy between two quadrupole moments drops off as  $R^{-5}$ . Hence, the increase in computational cost due to multipole moments is only local. In contrast, the cost of evaluating interaction energies between point charges perpetuates as the system grows in size. This is because charge–charge interactions are long-range. The proliferation of point charges introduced by more accurate point charge models therefore causes a substantial increase in computational cost.

There are various ways in which atomic multipole moments can be defined and used.<sup>9–11</sup> A popular and influential method is called distributed multipole analysis (DMA).<sup>7</sup> The Anisotropic site potential or Anthony Stone potential (ASP) water potential,<sup>12</sup> the atomic multipole optimized energetics for biomolecular applications (AMOEBA)<sup>13</sup> water model, and the effective fragment potential (EFP) method,<sup>14</sup> for example, all use DMA. However, the sum of interactions between fragments *ab initio* (SIBFA)<sup>15,16</sup> potential has its multipole moments determined by the partitioning method of Vigné-Maeder and Claverie.<sup>17</sup>

A further enhancement of realism in potential design comes from the inclusion of polarization. There is a vast literature on this topic and water has received probably more attention than any other molecule. As recently as 2007, a whole issue<sup>18</sup> of the *Journal of Chemical Theory and Computation* was dedicated to polarization. A simple way to account for the polarization of a water molecule in liquid water is to artificially enhance its dipole moment beyond its gas phase value of 1.85 D. The exact value to which the enhanced dipole moment should be fixed remains a topic of debate<sup>19–22</sup> and can vary between 2.3 and 3.1 D. This debate is fuelled by the uncertainty surrounding an answer to the question of how to define a water molecule inside the condensed phase that is a liquid. If one allows quantum chemical topology (QCT)<sup>23,24</sup> to answer this question then one obtains<sup>25</sup> about 2.3 D. This is actually a dipole moment averaged over the order of a hundred water clusters. The actual value depends on the level of theory at which the *ab initio* electron densities were obtained and the number of water molecules in the cluster. Water on surfaces, at interfaces or in very polar environments, however, needs a non-averaged treatment. To account for the response of water in such heterogeneous conditions, an anisotropic polarization needs to be modelled. This makes nonpolarizable models with implicit polarization, such as SPC/E and TIP4P, only accurate for bulk water and unfit for water in heterogeneous conditions. It is generally agreed that polarization needs to

be modelled *explicitly* for more accurate, transferable, potentials. Polarization can also be modelled by polarizable point dipoles but this method can suffer from the “polarization catastrophe”. In that case, the dipoles respond in such a way that the interaction energy becomes infinite. Damping functions, artificial corrections that limit the response of the dipole moments,<sup>26,27</sup> can prevent this catastrophe. A number of force fields<sup>13,15,28–31</sup> have adopted the popular point dipole method. A final method is the charge-on-spring method.<sup>32–35</sup> Here, polarization is modelled by a negative point charge connected by a harmonic spring to another site that bears a positive charge.

Within the context of multipole moments of arbitrarily high rank, one could proceed with distributed polarizabilities, either in the DMA framework<sup>36</sup> or the QCT framework,<sup>37</sup> as applied to the water dimer before.<sup>38</sup> In this paper, however, we pursue a radically alternative route, and focus directly on an atom’s response to its local environment. Machine learning is invoked to establish a link between the nuclear positions of the atoms surrounding a given (central) atom and this atom’s multipole moments. This approach does not yield polarizabilities; instead, polarization is embedded in the mapping of nuclear positions (input) and atomic multipole moments (output), delivered by the machine learning solution. Preliminary work on the hydrogen fluoride dimer<sup>39</sup> led to a more refined methodology able to construct a polarizable water potential.<sup>40</sup> Intramolecular polarization was tackled along similar lines in subsequent work,<sup>41</sup> demonstrating proof-of-concept with glycine and *N*-methylacetamide, the smallest molecule realistically representing a peptide bond. The water potential, constructed using multilayer perceptrons, was then revisited<sup>42</sup> using a more accurate machine learning method called kriging. Kriging<sup>43</sup> (also known as Gaussian process regression<sup>44</sup>) models observations as realizations of an underlying probabilistic model. A typical kriging model predicts an error in total interaction energy of less than 0.4 kJ/mol for 50% of about a thousand water dimer configurations. Although 90% of the configurations are predicted with an error of less than 1 kJ/mol, the maximum error encountered can be as large as 4 kJ/mol, albeit for a handful of configurations. This paper tackles the latter problem by introducing local kriging.<sup>45</sup>

## Background

### Quantum chemical topology and electrostatics

The molecular electron density, denoted by  $\tilde{n}$ , is partitioned according to its gradient vector field, as prescribed by the quantum chemical topology (QCT) approach.<sup>23,24,46</sup> A justification for the relatively new name QCT was first given in ref. 47 and amplified in a book chapter,<sup>48</sup> the Appendix of ref. 49, and the Introduction of ref. 50. QCT defines topological atoms as 3D volumes, whose shape is determined by the gradient paths in  $\tilde{n}$ . A gradient path follows the direction of steepest ascent in  $\tilde{n}$ , typically terminating at a nuclear position, where  $\tilde{n}$  is a maximum. A 2D bundle of gradient paths form an interatomic surface that marks the boundary between two atoms. An important characteristic of topological atoms is that they collectively take up all space, without leaving gaps between them. Integration

of property densities over an atomic volume yields the atomic properties. An atomic multipole moment is obtained from a volume integral over  $\tilde{n}$  multiplied by a regular spherical harmonic. Note that we do not use Cartesian tensors because they lead to an excess of redundant components.

Equation [1] expresses the electrostatic interaction energy between two topological atoms:<sup>51</sup>

$$[1] \quad E^{AB} = \sum_{l_A=0}^{\infty} \sum_{l_B=0}^{\infty} \sum_{m_A=-l_A}^{l_A} \sum_{m_B=-l_B}^{l_B} T_{l_A m_A l_B m_B}(\mathbf{R}) Q_{l_A m_A}(\Omega_A) \times Q_{l_B m_B}(\Omega_B)$$

where the multipole moments of atom A,  $Q_{l_A m_A}(\Omega_A)$ , and atom B,  $Q_{l_B m_B}(\Omega_B)$ , interact through the tensor  $\mathbf{T}(\mathbf{R})$ .  $\mathbf{R}$  is the vector from nucleus A to nucleus B, which are the origins of the local frames of atoms A and B. It is convenient to collect the terms of eq. [1] by their power of  $R = |\mathbf{R}|$ , gathering terms of the same (overall) rank. This rank, denoted by  $L$ , is defined as  $\ell_A + \ell_B + 1$ , where  $\ell$  is the rank of the multipole moment. For example, multipolar interaction of  $R^{-5}$  dependence consists of interactions between a monopole moment ( $\ell = 0$ ) and an hexadecapole moment ( $\ell = 4$ ), a dipole moment ( $\ell = 1$ ) and an octupole moment ( $\ell = 3$ ) and two quadrupole moments ( $\ell = 2$ ). The convergence of the multipole expansion can be examined<sup>52</sup> as a function of  $L$ .

### Kriging

Here, we only summarize the salient features of the kriging approach and more details can be found in ref. 42. In our case, the observations that the kriging method models are values of a particular multipole moment. A *probability density function* (PDF) returns the probability of observing a set of values of a particular multipole moment. The following general equation is used for making predictions:

$$[2] \quad y(\mathbf{x}) = \sum_{i=1}^m \beta_i f_i(\mathbf{x}) + z(\mathbf{x})$$

where the vector  $\mathbf{x} = [x_1, x_2, \dots, x_d]^T$  and where T designates the transpose and  $d$  the number of features. In this work, the features are geometrical coordinates of the nuclei surrounding the central atom of interest, whose multipole moments are being predicted. The right hand side of eq. [2] consists of two parts. The first part is a “global term”, which is a sum of  $m$  basis functions,  $f_i$  ( $i = 1, \dots, m$ ), which are typically polynomials of the form  $x_1^{g_1} x_2^{g_2} \dots x_d^{g_d}$  with  $g_1 + g_2 + \dots + g_d \leq G$  ( $G$  being the order of the polynomial). The number of features in the problem,  $d$ , determines the exact value of  $m$ . The second part of eq. [2],  $z(\mathbf{x})$ , can be regarded as an “error term”. This term compensates for the inadequacy of the global term to model observed data exactly. This term is modelled as a Gaussian process with a zero mean and some unknown variance,  $\sigma^2$ . The error terms for two different molecules are modelled as being correlated in a way that may be expressed through the difference in the values of their features. A familiar correlation function is given in eq. [3]

$$[3] \quad \text{Cor}[z(\mathbf{x}^i), z(\mathbf{x}^j)] = \exp\left(-\sum_{h=1}^d \theta_h |x_h^i - x_h^j|^{p_h}\right)$$

where  $\theta_h > 0$  and  $0 < p_h \leq 2$ . The indices  $i$  and  $j$  refer to

individuals of the training set, which are water dimer configurations. Both indices run from 1 to  $n$ , where  $n$  is the number of water dimers in the training set, typically of the order of a thousand. It is convenient to introduce the (symmetric)  $n \times n$  matrix  $\mathbf{R}$  whose  $i$ th- $j$ th entry is given by eq. [3], which gives the correlation between the  $i$ th and  $j$ th training set examples. Note that the correlation is expressed at the level of the atomic multipole moments (the dependent variable) rather than the geometrical coordinates of the water dimers (the independent variable). The unknown parameters of the kriging model are thus  $\beta_j$ ,  $\sigma^2$ ,  $\theta_i$ , and  $p_i$ . The  $\beta_j$  parameters are found by fitting to the data, using the generalized least-squares method:

$$[4] \quad \boldsymbol{\beta} = (\mathbf{F}^T \mathbf{R}^{-1} \mathbf{F})^{-1} \mathbf{F}^T \mathbf{R}^{-1} \mathbf{y}$$

where  $\mathbf{y}$  is a  $n \times 1$  vector containing the  $n$  observed data.  $\mathbf{F}$  is the  $n \times m$  matrix whose  $i$ th- $j$ th entry is  $f_j(\mathbf{x}^i)$ . The values of  $\sigma^2$ ,  $\theta_i$ , and  $p_i$  are found by maximizing the likelihood  $L$  of the observations, as given by

$$[5] \quad L(\boldsymbol{\theta}, \mathbf{p}, \sigma^2 | \mathbf{y}^i, i = 1, 2, \dots, n) = \frac{1}{(2\pi)^{n/2}} (\sigma^2)^{n/2} |\mathbf{R}|^{1/2} \exp \left[ \frac{-(\mathbf{y} - \mathbf{F}\boldsymbol{\beta})^T \mathbf{R}^{-1} (\mathbf{y} - \mathbf{F}\boldsymbol{\beta})}{2\sigma^2} \right]$$

It is actually the logarithm of the likelihood,  $\log(L)$ , that is maximized. By setting the derivative of  $\log(L)$  with respect to  $\sigma^2$  equal to zero and solving this new equation, the optimal value of  $\sigma^2$  can be written in terms of  $\boldsymbol{\theta}$  and  $\mathbf{p}$ . Hence,  $L$  only needs to be optimized with respect to  $\boldsymbol{\theta}$  and  $\mathbf{p}$ , which amounts to optimizing  $2d$  parameters.

Two comments are in place. First, we extend the model in eq. [2] to tackle noisy data, as in ref. 53 and 54:

$$[6] \quad y(\mathbf{x}) = \sum_{i=1}^m \beta_i f_i(\mathbf{x}) + z(\mathbf{x}) + \varepsilon(\mathbf{x})$$

This leads to the addition of an extra parameter to the diagonal of the correlation matrix  $\mathbf{R}$ , which has to be fitted during the maximization of  $\log(L)$ . Note that noisy kriging<sup>53</sup> does not necessarily reproduce the training data exactly but has the flexibility to generate the best possible fit without the constraint of reproducing these data. Secondly, we make use of the fact that the kriging parameters,  $\theta_h$ , may be examined to determine which features are most important for making predictions.<sup>55</sup> This procedure is called *feature selection*.

### Feature representation and feature selection

The inputs for the machine learning methods are generated using a transformation from the Cartesian coordinates of the cluster to a set of nonredundant coordinates following the method laid out by Stone.<sup>7</sup> For systems of rigid and nonlinear molecules, only  $6(N - 1)$  coordinates are needed, where  $N$  is the number of molecules. Hence, the water dimer is described by only  $6(2 - 1) = 6$  coordinates. These six coordinates consist of three polar coordinates and three Euler angles. Imagine that the oxygen atom of the central molecule lies at the origin. The position of the second oxygen in the water dimer is then fully described by three polar coordinates ( $R_{OO}$ ,  $\theta$ , and  $\phi$ ). The polar coordinates are the distance,  $R_{OO}$ , between the two oxygen atoms, the angle,  $\theta$ ,

spanning the vector  $\mathbf{R}_{OO}$  and the  $z$  axis, and the angle,  $\phi$ , spanning the (positive)  $x$  axis and the projection of the vector  $\mathbf{R}_{OO}$  onto the  $xy$  plane. The three Euler angles,  $\alpha$ ,  $\beta$ , and  $\gamma$ , describe the water neighbouring the central water molecule as follows: Position the neighbouring water in the axis system of the central water such that the HOH plane lies in the  $xz$  plane, with the hydrogen atoms in the negative  $z$  direction. Then a succession of three rigid body rotations corresponding to the three Euler angles is applied. Finally, this water is translated by  $\mathbf{R}_{OO}$ .

After defining the coordinates of each configuration (for a given cluster size), the data are normalized, that is, transformed to lie between 0 and 1, for subsequent exploitation by kriging. Training operates on these transformed input and output data. As explained above, training is an optimization problem with  $2d$  variables. Therefore, constructing a kriging model for a water dimer ( $N = 2$ ) becomes an optimization problem with  $2d \times 6(N - 1) = 12d$  variables. The optimization consists of a hybrid in which a particle swarm<sup>56</sup> is followed by the algorithm of Nelder and Mead.<sup>57</sup>

### Targeting maximum errors—Procedure and results

A main point of concern about the performance of the kriging water potential, as published before,<sup>42</sup> are the high maximum errors between the true and predicted intermolecular interaction energy. Table 1 shows the maximum errors of the kriging models targeted in this work for the water dimer, trimer, and tetramer.

In this work, we approach the problem of reducing the maximum energy errors by implementing a feedback loop in EREBUS. EREBUS is an in-house software package central to the force field design implemented in our lab. It contains all machine learning and optimization code, alongside user-friendly interfaces to make atom type construction automatic. This loop, shown in Fig. 1, involves the following five stages:

(i) The “\*.gjf generator” generates an initial set of water dimer configurations sampled from a molecular dynamics (MD) simulation of liquid water at ambient conditions, using a high-rank multipolar potential without polarization.<sup>58</sup> The \*.gjf files are Gaussian job files, which contain the geometries of the water clusters and the level of theory at which the ab initio electron density needs to be computed. Since the water molecules are rigid bodies, only single point calculations were performed at the B3LYP/aug-cc-pVTZ level. This level of theory is an adequate compromise between accuracy and CPU time<sup>25</sup> given that an order of a thousand configurations are required. This stage is labelled stage 1 in Fig. 1.

(ii) The EREBUS *pre-processor* generates scripts for constructing training data for the kriging models (stage 2a in Fig. 1). These scripts run the programs Gaussian<sup>59</sup> and MORPHY,<sup>60</sup> generating multipole moments for the central water molecule in each of the water dimer configurations, produced by the \*.gjf generator (stage 2b in Fig. 1). The geometric features describing a water dimer configuration (input), along with the multipole moments on the atoms of the central water

**Table 1.** The maximum total interaction energy errors (in kJ/mol) for kriging models used in previous work.<sup>42</sup>

Water cluster	Maximum error
Dimer	3.6
Trimer	20.5
Tetramer	41.4

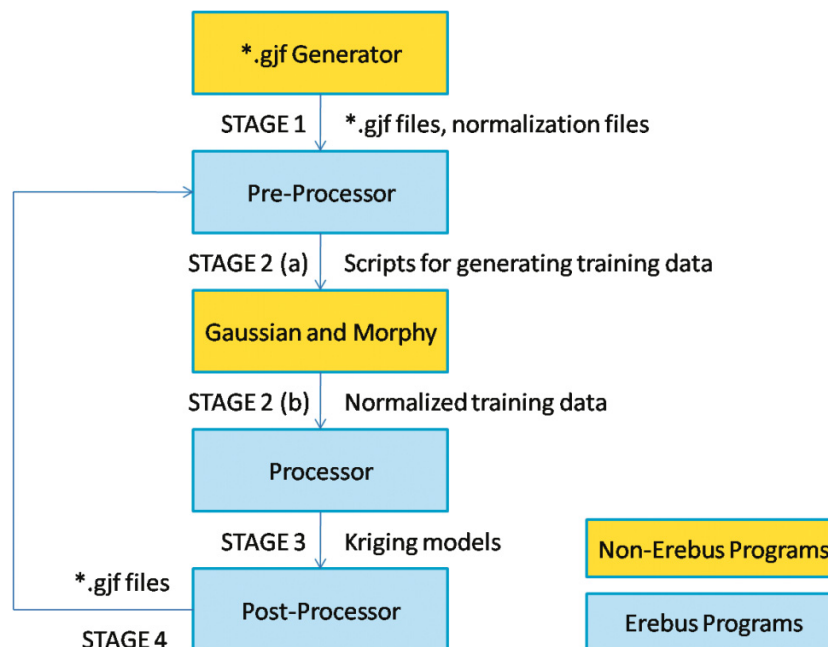

molecule (output), constitute one training example. Several thousand examples are evaluated to make up the training data for use by the EREBUS processor.

(iii) The EREBUS *processor* uses a subset of the training data to build kriging models for each of the multipole moments, for each atom in the central water molecule (stage 3 in Fig. 1). Each individual kriging model predicts a particular multipole moment, on a particular atom in the central water molecule. Rather than use all the available training data, a method of sequential selection<sup>61</sup> is used to construct a training set for each model, as described in ref. 42. An upper limit of 1000 is applied to the training set size. Consequently, each moment has multiple models built for it, one at each iteration of the sequential building of the training sets. Each of these models is tested by making predictions for the values of the multipole moments of the configurations not used. The model that minimizes the median error is the one selected for use. All 25 multipole moments, from monopole ( $\ell = 0$ ) to hexadecapole ( $\ell = 4$ ), were trained for.

(iv) The EREBUS *post-processor* uses the kriging models to make energy predictions for an external set of (~1000) water configurations. Extra configurations (\*.gjf files) are generated that are similar to those configurations with an energy error above a certain threshold. (stage 4 in Fig. 1). In this work, a threshold error of 0.75 kJ/mol is used. Suppose a dimer configuration, represented by the normalized features  $r^*$ ,  $\theta^*$ ,  $\phi^*$ ,  $\alpha^*$ ,  $\beta^*$ , and  $\gamma^*$ , gives an energy error above this threshold. Then extra configurations are generated at random in the range ( $r^* \pm \delta$ ,  $\theta^* \pm \delta$ ,  $\phi^* \pm \delta$ ,  $\alpha^* \pm \delta$ ,  $\beta^* \pm \delta$ ,  $\gamma^* \pm \delta$ ), where  $\delta$  is a small tolerance set to 0.1. If a particular feature value is generated to be  $<0$ , it is set to 0, and if it is generated to be  $>1$ , then it is set to 1. The total number of extra configurations generated is set to 1500. These are divided equally over the configurations that gave energy errors above the error threshold of 0.75 kJ/mol.

(v) (Feedback stage). The EREBUS pre-processor then generates scripts that run the programs Gaussian and MORPHY for each of the extra water configurations. These extra training data are subsequently used along with the original training data (from the \*.gjf generator) in the EREBUS processor. The new “targeted” kriging models are then tested in the EREBUS post-processor. This stage is really a repetition of stages 2 and 3 in Fig. 1, with extra training data.

The targeted kriging models use extra training data, focusing on water configurations that give high energy errors (for the original kriging models use training data coming from the MD simulation only). Hence, it is reasonable to ex-

**Fig. 1.** Feedback loop in EREBUS.**Fig. 2.** Splitting of feature space: (a) Projection of feature space for the water dimer configurations (from simulation) onto the  $\theta$ - $\phi$  plane. (b) Dimer configurations considered as training data for the top left region.**Fig. 3.** Two projections of the positioning of the noncentral oxygen atom, relative to the central oxygen atom, for the regions in Fig. 2; xy (left), yz (right).

pect that these models will produce lower maximum energy errors than the original kriging models. However, improving a single (global) kriging model to predict a multipole moment well for unusual configurations could come at the expense of predicting the moment less well for more “normal” configurations. To alleviate this potential problem, we split

**Fig. 4.** The energy error percentiles for the water dimer, using the noisy global kriging model trained only on data sampled from a MD simulation and using the interpolating global kriging model as described in previous work.<sup>42</sup>

Fig. 5. The energy error percentiles using targeted global kriging models for the water dimer.

Fig. 6. The energy error percentiles using targeted local kriging models for the water dimer.

up feature space into several subspaces based on the two most significant features,  $\theta$  and  $\phi$ . Figure 2 shows how this is achieved. Each dot in Fig. 2 represents a particular water configuration. This is in fact a projection onto  $(\theta, \phi)$ -space since the four remaining coordinates ( $R_{OO}$  and the three Euler angles) remain unspecified. The clusters in Fig. 2a naturally fall apart in easily perceptible clusters, or feature

subspaces. Using multiple local kriging models to predict each multipole moment has the consequence that the unusual structures are only used in the training set if they are relevant to the prediction being made. A corollary of this is that unusual configurations are not used in kriging models for predictions they are not relevant for, and so should not adversely affect the quality of predictions for normal configurations.

Figure 3 explicitly shows the two features of Fig. 2, in terms of the molecular geometry of the water dimer. To see how Fig. 3 helps interpreting the feature subspaces in Fig. 2, we focus on the two vertical divisions of the lower half of Fig. 2a; these divisions correspond to  $\theta = 0.3\pi$  (left) and  $\theta = 0.7\pi$  (right). The geometrical meaning of these divisions can be seen in the right panel of Fig. 3. Similarly, there are two vertical divisions in the upper half of Fig. 2a, which correspond to  $\theta = 0.4\pi$  (left) and  $\theta = 0.6\pi$  (right), again marked in Fig. 3.

A “local” kriging model is trained on each of these seven distinct regions, for each multipole moment on each atom of the central water molecule. For each region, configurations slightly outside the region boundary are included as (potential) training set points. By including points outside the region that a model will be making predictions for, the risk of needing to extrapolate to make predictions is reduced. For example, Fig. 2b shows the points considered as training data points for the top left region in the  $\theta$ - $\phi$  plot.

In summary, by employing multiple local kriging models for predicting each multipole moment, we should be able to use unusual configurations in the training sets, thus targeting maximum errors, with minimal impact on the quality of the predictions for the more normal configurations. In the next section, we test this hypothesis by comparing the trade-off between maximum interaction energy error and median energy error for both global targeted kriging models and local targeted kriging models.

One final point to note is that the global kriging models used in this paper are not exactly the same as the global kriging models used before.<sup>42</sup> The models in this paper differ in that they have the flexibility to not interpolate the data, but to find a best fit instead. In other words, the so-called *noisy kriging* models generated here do not exactly reproduce the training data, but the kriging models in the previous paper<sup>42</sup> did reproduce data. The original kriging models, published in ref. 42, will be referred to as *interpolating kriging*.

It is convenient to assess the accuracy of the kriging models through a statistical measure of the total interaction energies arising from predicted multipole moments. For example, we define the 90th energy error percentile,  $E_{90}$ , as the error in energy that 90% of predictions are within, as determined over a set of predictions of  $\sim 1000$  configurations. All such percentiles can be shown in one plot, which is typically S-shaped.  $E_{100}$ , the energy error that all predictions fall within, coincides with the maximum error. The difference in energy error percentiles between interpolating kriging models used in previous work and the non-interpolating (“noisy”) kriging models is given in Fig. 4 for the water dimer. By using noisy kriging models, the median energy error ( $E_{50}$ ) is reduced from 0.38 to 0.21 kJ/mol, and the maximum energy error is reduced from 3.62 to 3.13 kJ/mol.

Noisy kriging is also used for the targeted global and targeted local kriging models. We call global kriging models *targeted global kriging* if they have been trained with extra configurations similar to those that gave high energy errors. Local kriging models that have been trained with such configurations are called *targeted local kriging*.

The energy error percentiles of targeted global kriging models are shown in Fig. 5. Compared with the global kriging model (trained using data sampled from simulation only), a 24% reduction in maximum energy error is achieved, that is, 2.37 kJ/mol compared with 3.13 kJ/mol. However, this reduction comes at the expense of all energy error percentiles below  $E_{98}$ . For example,  $E_{50}$  rises by 52%, from 0.21 to 0.32 kJ/mol. Clearly, adding unusual configurations to the training set of a single global kriging model deteriorates the quality of the model as a whole, albeit with an improvement in maximum errors. This trade-off does not seem acceptable, which is why local kriging is invoked.

The energy error percentiles of targeted local kriging models are shown in Fig. 6. Compared with the global kriging model, a 39% reduction in maximum energy error is achieved, from 3.13 to 1.92 kJ/mol. This time, however, lower energy error percentiles are barely affected. For example, the median energy error rises by <5%, from 0.21 to 0.22 kJ/mol. The trade-off using local targeted is much more acceptable.

The trade-offs between  $E_{100}$  and  $E_{50}$  are summarized in Fig. 7. The targeted local dominates the targeted global, i.e., it is better in both median energy error and maximum energy error. Comparing the targeted local and global reveals that neither is better than the other in both median energy error and maximum energy error. Nevertheless, the targeted local is arguably more attractive as it offers a large improvement in maximum energy error at a small cost to median energy error.

Previous work<sup>42</sup> showed that kriging is the most accurate machine learning model compared with multilayer perceptrons and radial basis function neural networks in terms of average performance as well as maximum errors. This work has delivered the proof-of-principle that the maximum errors can be substantially reduced by cutting feature space into subspaces and training for each subspace separately. Generalizing this accomplishment to higher dimensional feature spaces will require a (semi-)automatic procedure able to partition features space.

## Conclusions

By splitting feature space up into natural regions for the water dimer, a 39% reduction in maximum energy error was achieved at a small cost (4.5%) to the median energy. Without splitting up feature space, a 24% reduction in maximum energy error is achieved, at the cost of a 52% increase in the median energy error. Thus, splitting feature space up is useful when targeting maximum errors, without causing a loss in accuracy for normal configurations.

# A computational study of the threshold energies of the 1,2-FCl interchange reaction of chlorofluoroethanes

William C. Everett, Bert E. Holmes, and George L. Heard

**Abstract:** The 1,2-FCl rearrangement reaction of a series of haloethanes is investigated by comparisons of the optimized ground- and transition-state geometries. Investigation of the effect of level of theory and basis set shows that the trends in threshold energies for rearrangement are reproduced across all levels of theory and basis set, and hence that a moderate level of theory and basis set is adequate for investigating the important trends in this reaction. Threshold barriers increase when a large number of fluorine atoms are attached to the carbon atom bearing the interchanging fluorine, suggesting that the C–F bonds prove difficult to distort to the transition geometry; the increase is smaller for fluorine substitution on the carbon atom bearing the interchanging hydrogen atom. By considering sets of isomeric reactions, the barrier height is shown to closely follow the thermodynamic stability of the alkane undergoing rearrangement; however there is a secondary effect owing to the relative stability of the transition geometry. This relative stability can be related to the thermodynamic stability of a series of isomeric alkenes that resemble the transition geometry without the rearranging atoms. This series of molecules constitute an unusual set owing to the ability to consider these three contributions to the activation barrier separately.

**Key words:** transition-state geometries, atmospheric chemistry, reaction kinetics, computational chemistry.

**Résumé :** Faisant appel à des calculs théoriques, on a étudié la réaction de réarrangement 1,2-FCl d'une série de haloéthane en procédant à une comparaison de l'état fondamental et de géométries d'état de transition optimisés. Une étude de l'effet du niveau de la théorie et des ensembles de base montre que les tendances dans les énergies de seuil des réarrangements sont reproduites par tous les niveaux de la théorie et tous les ensembles de base et que, en conséquence, un niveau modéré de la théorie et d'ensemble de base est adéquat pour étudier les tendances les plus importantes de cette réaction. Les barrières de seuil augmentent quand un grand nombre d'atomes de fluor sont liés à l'atome de carbone portant l'atome de fluor qui s'échange et ceci suggère que les liaisons C–F s'avèrent difficiles à déformer vers l'état de transition; l'augmentation est moins grande pour une substitution par du fluor sur l'atome de carbone portant l'atome d'hydrogène qui s'échange. Par considération d'ensembles de réactions isomères, on peut démontrer que la hauteur de la barrière suit assez bien la stabilité thermodynamique de l'alcane qui subit le réarrangement; toutefois, on observe un effet secondaire dû à la stabilité relative de l'état de transition. Cette stabilité relative peut être reliée à la stabilité thermodynamique d'une série d'alcènes isomères qui ressemblent à l'état de transition sans les atomes qui donnent lieu au réarrangement. Cette série de molécule constitue un ensemble inhabituel en raison de l'habilité à considérer ces trois contributions à la barrière d'activation séparément.

**Mots-clés :** géométries de l'état de transition, chimie de l'atmosphère, cinétique d'une réaction, chimie quantique.

## Introduction

Our group first proposed a 1,2-FCl interchange reaction to explain the loss of HCl from chemically activated  $\text{CF}_2\text{ClCF}_2\text{CH}_3$ . The mechanism involved the interchange of  $\text{CF}_2\text{ClCF}_2\text{CH}_3$  to  $\text{CF}_3\text{CFCICH}_3$ , which subsequently underwent a 2,3-ClH elimination giving  $\text{CF}_3\text{CF}=\text{CH}_2$  as the observed product. The same process was observed for chemically activated  $\text{CF}_2\text{ClCF}_2\text{CD}_3$ .<sup>1</sup> Computed kinetic H–D isotope effects for this reaction pathway closely matched the experimental values. The threshold energy barrier height,

$E_0$ , for that reaction was calculated to be 62.5 kcal/mol (1 cal = 4.184 J) using a B3PW91/6–31G(d',p') level of theory. The 1,2-FCl interchange reaction has subsequently been shown to explain the ratio of product yields in the thermal decomposition of  $\text{CF}_2\text{HCH}_2\text{Cl}$ ,<sup>2,3</sup>  $\text{CF}_2\text{ClCHFCH}_3$ ,<sup>4</sup> and  $\text{CF}_2\text{ClCHFCH}_2\text{CH}_3$ .<sup>5</sup> Calculations on these systems were performed at the B3PW91/6–31G(d',p') and B3PW91/6–311+G(2d,p) levels of theory based on the ability of the B3PW91 functional to reproduce the kinetic parameters for 1,2-HF elimination from  $\text{CH}_3\text{CF}_3$ .<sup>6</sup> Because this reaction ap-

pears to be an important step in energized hydrofluorochlorocarbon (HCFC) reactions, this paper seeks to address whether these levels of theory are appropriate by providing a rigorous theoretical treatment using a wide range of theories and basis sets, as well as to examine the effects of different substituents on the transition-state geometry and energy. Understanding the best theoretical method for these reactions and a knowledge of the factors that favor the rearrangement would allow for accurate prediction of which systems are likely to undergo a 1,2-FCl rearrangement and which systems would likely allow detection of the rearranged HCFC prior to subsequent HX ( $X = \text{Cl or F}$ ) elimination.

The transition-state geometry for 1,2-FCl interchange involves an exchanging fluorine and chlorine atom, each formally bonded to separate carbons, as shown in Fig. 1. This leaves four positions for substituents, which we have labeled  $X_1$ ,  $X_2$ ,  $X_3$ , and  $X_4$ , where  $X_1$  and  $X_2$  are attached to the carbon with the migrating fluorine atom (hereafter referred to as  $C_1$ ), and  $X_3$  and  $X_4$  are attached to the carbon with the migrating chlorine atom (hereafter referred to as  $C_2$ ). All possible combinations of H, F, and Cl in these positions give a complete set of chlorofluoroethanes and hydrofluorochloroethanes. This will lead to some redundancies in the reactant and product molecules because each transition geometry can describe a forward and a reverse reaction that are both 1,2-FCl interchanges. Since this leads to a large number of rearrangements (45), we have selected three molecules to be test cases for the level of theory:  $\text{CH}_2\text{FCH}_2\text{Cl}$ , the simplest molecule for which a 1,2-FCl interchange is possible, and  $\text{CHF}_2\text{CH}_2\text{Cl}$ , and  $\text{CH}_2\text{FCHCl}_2$ , representing the substitution of one chlorine atom and one fluorine atom to the  $\text{CH}_2\text{FCH}_2\text{Cl}$  molecule. These test case molecules were studied using a number of basis sets (using the B3PW91 level of theory) and levels of theory including ab initio, density functional theory, and model chemistries.

## Computational methods

Standard ab initio and density functional theory calculations have been performed using the *Gaussian 03* program.<sup>7</sup> The following basis sets have been used: 6-31G(d',p'),<sup>8</sup> 6-311+G(2d,p),<sup>9</sup> Dunning's cc-PVTZ, aug-cc-PVTZ cc-PVQZ,<sup>10</sup> and the Truhlar-modified 6-311+G(2df,2p) and 6-311++G(2df,2p).<sup>11</sup> Density functional methods considered were B3PW91,<sup>12,13</sup> B3LYP,<sup>14,15</sup> MPWB1K,<sup>15,16</sup> and MPWB95,<sup>15,17</sup> and ab initio levels of theory were MP2, CCSD, and QCISD, as well as the model chemistries G2MP2, G2MP2B3,<sup>18</sup> and CBS-QB3.<sup>19</sup> All geometries were characterized as local minima or transition states by vibrational frequency calculations; unscaled frequencies were used to determine the zero-point energy contribution to all local minima and transition-state energies.

## Results and discussion

Transition-state geometries were successfully characterized for 1,2-FCl interchanges of  $\text{CH}_2\text{FCH}_2\text{Cl}$ ,  $\text{CHF}_2\text{CH}_2\text{Cl}$ , and  $\text{CH}_2\text{FCHCl}_2$  using a wide range of levels of theory. There is very little variation in the bond lengths and angles with level of theory. The carbon-carbon bond distances are all between 1.40 and 1.42 Å, indicating a contraction from the bond distance in the ground-state geometries. The carbon-fluorine distance for the interchanging fluorine atom varies between 1.77 and 1.88 Å across the levels of theory, and the carbon-chlorine distance varies from 2.24 to 2.31 Å. The angle made between the carbon-carbon bond and the interchanging chlorine atom is  $71^\circ$ – $72^\circ$ , and there is only slightly more variation in the angle between the carbon-carbon bond and the interchanging fluorine bond of  $67^\circ$ – $70^\circ$ . The four atoms involved in the transition are very close to planar, with a maximum deviation of  $6^\circ$ . The four atoms not involved in the transition geometry are close to planar, within  $15^\circ$  of planarity in all cases, and hence the transition state resembles a substituted ethylene bonded to a fluorine atom above the plane of the molecule and a chlorine atom bonded below the plane of the molecule. We conclude from this that the choice of level of theory is not important in obtaining an accurate geometry for this transition-state geometry.

Table 1 presents the threshold energy,  $E_0$ , for the 1,2-FCl interchange reaction of the three model systems chosen as a function of level of theory and basis set. The level of theory was changed while keeping the basis set the same, using the 6-31G(d',p') basis set previously used in studies of this reaction. With the exception of the model chemistries (G2MP2, G3MP2B3, and CBS-QB3, where the trends are relatively greater in magnitude), the trends in energy are duplicated across the three molecules—the threshold energies for rearrangement of  $\text{CH}_2\text{FCH}_2\text{Cl}$  and  $\text{CH}_2\text{FCHCl}_2$  are very close (though  $\text{CH}_2\text{FCH}_2\text{Cl}$  is consistently slightly higher in energy), and the barrier height for rearrangement of  $\text{CHF}_2\text{CH}_2\text{Cl}$  is consistently slightly  $>5$  kcal/mol higher in energy than that of  $\text{CH}_2\text{FCH}_2\text{Cl}$ . There is a consistency in the percent change in energy; in comparing  $\text{CH}_2\text{FCH}_2\text{Cl}$  with  $\text{CHF}_2\text{CH}_2\text{Cl}$ , there is a 9%–10% increase in the barrier height, and in comparing  $\text{CH}_2\text{FCH}_2\text{Cl}$  with  $\text{CH}_2\text{FCHCl}_2$ , there is a 1%–2% increase in the barrier height with all computational methods. MP2, CCSD, and QCISD consistently give the greatest barrier heights, and the MPW levels consistently give the lowest barrier heights. There is an interesting question in comparing the effects of level of theory on reaction barrier heights—the answer is an unbound number, and hence there is no guarantee that a lower energy means a more appropriate level of theory. While the energy of the initial geometry will behave variationally, there is no lower bound to the energy of the transition-state geometry, and a low barrier height may be an indication that a level

**Table 1.** 1,2-FCl interchange barrier height ( $E_0$ ), in kcal/mol (1 cal = 4.184 J) for  $\text{CH}_2\text{FCH}_2\text{Cl}$ ,  $\text{CHF}_2\text{CH}_2\text{Cl}$ , and  $\text{CH}_2\text{FCHCl}_2$ , calculated using a range of basis sets and levels of theory.

**Fig. 2.** (a) The *Z* isomer of  $\text{CHFCHF}$  and the corresponding *Z*-transition geometry for 1,2-FCl interchange of  $\text{CF}_2\text{HCHFCl}$ . (b) The *E* isomer and corresponding *E*-transition geometry.

of theory is not correctly treating the stretched bonds of a transition state. The model chemistries predict values within the range of the other levels of theory used in this study, likely by virtue of the geometry staying constant at varying levels of theory, because the model chemistries use thermal calculations of one level of theory applied to a geometry calculated at a different level of theory.

In comparing the result of changing the basis set at the B3PW91 level of theory, there is a consistently small effect across each of the three molecules. Going from a doubly split valence basis set to a triply split valence basis set in all cases lowers the activation energy slightly; the only quadruple-zeta basis set we used led to a lowering of the  $E_0$  by 0.1 kcal/mol for each interchange.

There is no experimental data on the true value of the energy of these interchanges. In two similar systems,  $\text{CF}_2\text{ClCF}_2\text{CH}_2\text{Cl}$ <sup>20</sup> and  $\text{CF}_3\text{CFClCH}_2\text{Cl}$ ,<sup>21</sup> the barrier heights have been estimated as  $66 \pm 2$  and  $67 \pm 2$  kcal/mol, respectively, from matching the ratio of products formed to

RRKM calculations of rate constants as a function of energy. From these results, we conclude that of the DFT levels, the one that provides the most reasonable energies is B3PW91. The choice of basis set is a little more problematic, as the 6-31G(d',p') gives the highest energy barrier (and thus the closest correlation with the estimated experimental energies); however, this basis set is generally considered small, and questions may be raised about the ability of a basis set lacking diffuse functions in obtaining transition-state geometries. Because the trends in energy are reproduced across the set of basis sets, we have chosen the 6-311+G(2d,p) basis set as convenient and accurate enough to use for calculations on a wide series of molecules.

There are 36 unique combinations of the form  $\text{X}_1\text{X}_2\text{FCCCIX}_3\text{X}_4$ , where  $\text{X}_1\text{--X}_4$  are hydrogen, fluorine, or chlorine atoms, which are capable of a 1,2-FCl interchange. Of these, nine have two possible interchanges—we label these *E*- and *Z*- in the transition geometry because of the similarity of the transition state to a substituted ethene. A scheme for these interchanges is given in Fig. 1, and an explanation of the *E*- and *Z*- labels is given in Fig. 2. The  $E_0$  values for these 45 interchanges are presented in Table 2, and from this table several general trends can be seen. The replacement of a hydrogen atom with a fluorine atom on  $\text{C}_1$  increases the barrier height in all cases; this effect is similar for a second fluorine substitution. The effect of fluorine substitution on the second carbon is less consistent than on the first carbon—substitution of one fluorine in most cases leads to a slight increase in threshold energy, but in some cases (such as going from  $\text{CH}_2\text{FCH}_2\text{Cl}$  to  $\text{CH}_2\text{FCHCl}_2$ ), there is a small decrease in threshold energy. Overall, there is a consistently upward trend in the barrier height with the number of fluorine atoms; complete replacement of  $\text{X} = \text{H}$  with  $\text{X} = \text{F}$  leads to an increase in the value of  $E_0$  from 56.4 kcal/mol in  $\text{CH}_2\text{FCH}_2\text{Cl}$  to 74.3 kcal/mol in  $\text{CF}_3\text{CF}_2\text{Cl}$ .

Substitution of a hydrogen by a chlorine on the first car-

bon leads to an increase in the  $E_0$  value; in general, the first chlorine substitution has a greater effect than a second chlorine substitution. Substitution of a hydrogen atom by a chlorine atom on the second carbon produces a smaller increase in energy than does substitution on the first carbon atom, and a second chlorine substitution on the second carbon atom produces an inconsistent effect, sometimes raising the energy barrier, sometimes lowering it, all to a slight extent. The effect of chlorine substitution is consistently smaller than that of fluorine substitution, and in all comparisons, the chlorine-substituted molecules have a lower barrier height than the fluorine-substituted molecules. In all cases where there are the *E* and *Z* pathways, the *Z* pathway is slightly lower (between 0.9 and 3.0 kcal/mol) in energy.

We can investigate the trends in barrier heights by systematically looking at a number of selected results. The threshold energy for rearrangement depends on the relative thermodynamic stabilities of the reactant geometry and the transition geometry—a reactant geometry that is low in energy would lead to a large value of  $E_0$ ; however, a transition

geometry that is low in energy would lead to a small value of  $E_0$ . As these are all rearrangements, the relative energies of the two alkanes have an effect on the barrier height, the more thermodynamically stable leading to the higher barrier height. Because five of these systems are self-exchanges, we can identify the effects of the transition geometry energy alone. In two of the molecules capable of self-exchange there are two transition geometries—the *E* transition geometry is the self-exchange, the *Z* transition geometry leads to a molecule that resembles a rotated form of the opposite stereoisomer. The barrier height for CH<sub>2</sub>FCH<sub>2</sub>Cl is 56.4 kcal/mol, for the *E* interchange of CHF<sub>2</sub>CHFCl it is 61.4 kcal/mol, for the *E* interchange of CHFCICHCl<sub>2</sub> it is 60.7 kcal/mol, for CCl<sub>2</sub>FCCL<sub>3</sub> it is 69.3 kcal/mol, and for CF<sub>3</sub>CF<sub>2</sub>Cl it is 74.3 kcal/mol. These show a clear increase in the barrier height with the replacement of hydrogen atoms by chlorine and fluorine atoms. Because there is no appreciable change in the bond lengths and angles in the transition geometries, this is attributed to the strengths of the C–F and C–Cl bonds, and the difficulty in bending those to the near-

planar transition geometry. If we consider the carbon atoms of the transition geometry to be five-coordinate, the large chlorine atoms are going to have a significant steric effect. These results seem to indicate that the strength of the carbon–fluorine bonds make it more difficult to bend them to a more highly coordinated geometry, similar to findings of the Lewis acidity of  $\text{BF}_3$  and  $\text{BCl}_3$ .<sup>22</sup> This could also explain the larger increase in barrier height owing to fluorines on  $\text{C}_1$  as there are more carbon–fluorine bonds on the one center that need to distort to rearrange.

We can identify individual trends in the energies of the starting geometries and the transition-state geometries by considering the rearrangements in groups of isomeric reactions, as detailed in Table 3, which lists the barrier heights along with the relative energies of the alkanes that are undergoing rearrangement, calculated at the B3PW91/6–311+G(2d,p) level of theory. In all cases except for  $\text{C}_2\text{Cl}_3\text{H}_2\text{F}$ , the alkane with the lowest energy corresponds to the rearrangement with the highest energy barrier. This explains why substitution of a fluorine on  $\text{C}_1$  leads to a larger barrier height than substitution of a fluorine on  $\text{C}_2$ , because in all the haloethanes there is a significant increase in energy when there is both a chlorine and a fluorine on the same carbon (the 2-carbon having the chlorine in the position to rearrange). It is a general trend that the barrier height decreases with the increasing energy of the alkanes; however, the decrease in energy of the threshold barrier is smaller than the increase in energy of the alkanes. This is an indication that the relative energy of the transition geometry is increasing as well as the relative energy of the alkanes; moreover, it is generally a smaller increase in energy.

As pointed out earlier in the results, these transition-state geometries resemble substituted ethylenes loosely coordinated to a fluorine atom and a chlorine atom. This presents an opportunity to divide the transition geometries into families related by the isomers of the substituted ethylenes, allowing us to make some comparisons of the transition geometries alone. Optimizations of the three isomeric alkenes corresponding to the transition geometries have been performed, and their relative energies are included in Table 3. With the exception of  $\text{C}_2\text{F}_2\text{Cl}_2$  (the alkene corresponding to isomers of  $\text{C}_2\text{F}_3\text{Cl}_3$ ), the lowest energy alkene corresponds to the rearrangement with the largest barrier height. It is satisfying to note that the trends in energy of these alkenes can account for many of the variations in barrier height. The increase in energy of the alkenes is not as large in magnitude as the change in energy of the alkanes; hence, the overall barrier height increases slightly. When there is a large increase in the energy of the alkane, but only a small increase in the barrier height (such as in  $\text{CF}_2\text{HCCl}_2\text{F}$ ), there is a substantial increase in the energy of the alkene corresponding to the transition geometry. These alkenes share some common factors—the *Z* isomer is always lower in energy than the *E* isomer, and in most cases this is also seen in the rearrangement.

## Conclusions

We have established that the transition-state geometry for the 1,2-FCl rearrangement of halogenated ethanes is reproduced with a wide range of levels of theory. Despite there

being considerable variation in the value of the barrier heights, a problem when there is no lower bound to the energy, the relative trends in barrier height for the reaction are reproduced with almost any level of theory, so we propose the B3PW91/6–311+G(2d,p) level of theory to be computationally adequate for our study of the factors affecting this rearrangement.

Investigation of the barrier heights for all possible F- and Cl-substituted ethanes show that there is a significant increase in the barrier height if there are fluorines on the same carbon as the fluorine that is undergoing rearrangement, owing to the increased thermodynamic stability of the alkane. There is a smaller, but consistent increase in barrier height when chlorines are substituted, interpreted as a steric effect of having to bring the chlorines into close proximity in the quasi-pentavalent carbon involved in the transition geometry. There is also an effect on the interchange energy dependent upon the transition geometry—a transition geometry that resembles a low-energy alkene is likely to have a large barrier height, and increased energy of the alkene leads to a smaller barrier height. Rearrangement is most likely when there are a number of hydrogen atoms on the alkane; however, that can make the interchange less likely to be observed, as it will be in competition with 1,2-HF and 1,2-HCl eliminations.

# Geminal acylation of $\alpha$ -heterosubstituted cyclohexanones and their ketals

Ian R. Pottie, Sheldon N. Crane, Anna Lee Gosse, David O. Miller, and D. Jean Burnell

**Abstract:** Geminal acylation of derivatives of cyclohexanone with Br, Cl, F, and OCH<sub>3</sub> in the  $\alpha$  position, and of their corresponding dimethyl ketals, could not be accomplished to a significant extent following published procedures. The transformation was accomplished in two steps. The initial BF<sub>3</sub>·Et<sub>2</sub>O-mediated reaction with 1,2-bis(trimethylsilyloxy)cyclobutene gave a cyclobutanone product as a mixture of diastereomers. Only with 2-chlorocyclohexanone did this occur with good diastereoselectivity. Then, pinacol rearrangement of the diastereomeric mixture mediated by Amberlyst-15 in benzene provided the heterosubstituted spirocyclic diketone.

**Key words:** diastereoselectivity, Mukaiyama aldol, geminal acylation, spirocyclic diketone.

**Résumé :** L'acylation géminal de dérivés de la cyclohexanone portant des substituants Br, Cl, F et OCH<sub>3</sub> en position  $\alpha$  ainsi que celle des diméthylcétales correspondants ne peut pas être réalisée avec des rendements significatifs par les méthodes rapportées jusqu'à maintenant. On a réussi à effectuer cette transformation en deux étapes. La réaction initiale catalysée par le BF<sub>3</sub>·Et<sub>2</sub>O avec le 1,2-bis(triméthylsilyloxy)cyclobutène conduit à un produit à base de cyclobutanone, sous la forme de mélange de diastéréoisomères. Cette transformation ne s'est effectuée avec une bonne diastéréosélectivité qu'avec la 2-chlorocyclohexanone. La transposition pinacolique du mélange diastéréoisomère catalysée par l'Amberlyst-15 dans le benzène conduit alors à une dicétone spirocyclique hétérosubstituée.

**Mots-clés :** diastéréosélectivité, aldol de Mukaiyama, acylation géminal, dicétone spirocyclique.

## Introduction

The geminal acylation of ketones and their ketals with 1,2-bis(trimethylsilyloxy)cyclobutene (**1**) is a powerful method for generating 2,2-disubstituted 1,3-cyclopentanedione systems in high yield. Kuwajima and co-workers<sup>1</sup> introduced this transformation as a two-step procedure (Scheme 1). First, a BF<sub>3</sub>·Et<sub>2</sub>O-mediated Mukaiyama aldol between a ketal and **1**<sup>2,3</sup> affords a cyclobutanone, e.g., **2**. Then, pinacol rearrangement of **2** is effected by treatment with trifluoroacetic acid (TFA), generating a 1,3-diketone such as **3**.

The process can be carried out, generally in excellent yield, in one pot by the use of a large excess of BF<sub>3</sub>·Et<sub>2</sub>O.<sup>4–7</sup> Geminal acylation of ketones is facilitated by the addition of a small amount of water to the reaction medium after formation of the cyclobutanone intermediate.<sup>8</sup> Methyl-substituted versions of **1** can also be used for this reaction.<sup>9,10</sup> Geminal acylation has appeared as a key process in many synthetic and methodological endeavors.<sup>11–13</sup> Substitution by alkyl groups  $\alpha$  to the ketone, or ketal, reduces the yield of the geminal acylation. For instance, the ethylene ketal of cyclo-

**Scheme 1.** Geminal acylation in two steps with the diethyl ketal of cyclohexanone.<sup>1</sup>

hexanone was geminally acylated in 96% yield using the one-pot procedure,<sup>13</sup> but the ketal of 2-methylcyclohexanone gave only a 30% yield of the geminal acylation product.<sup>7</sup> In a similar way, yields with ketones were lower when the  $\alpha$  position was more substituted. The geminal acylation of cyclohexanone gave the diketone product in 94% yield, but

under very similar conditions 2-methylcyclohexanone provided the diketone in only 62% yield.<sup>8</sup> Differing degrees of  $\alpha$  substitution has allowed selective geminal acylation to take place.<sup>8,13</sup> The reason for the attenuation of the yields has been presumed to be steric hindrance.

It was thought that  $\alpha$  substitution by a heteroatom might be better tolerated than  $\alpha$  substitution by an alkyl group because the former might have a smaller steric effect. The products of geminal acylations with  $\alpha$ -substituted ketones or ketals would possess functionality that might be useful for further synthetic manipulation. The results of our experiments with  $\alpha$ -substituted cyclohexanones and their corresponding dimethyl ketals are presented here.

## Results and discussion

The dimethyl ketals of 2-bromo-, 2-chloro-, 2-fluoro-, and 2-methoxycyclohexanone were subjected to the conditions previously used by Kuwajima and co-workers<sup>1</sup> for the two-step geminal acylation of the ketal of cyclohexanone. Geminally acylated product was not detected from any of these ketals. The same ketals were treated with an excess of **1** and a large excess of  $\text{BF}_3 \cdot \text{Et}_2\text{O}$ . These conditions would have geminally acylated the ketal of cyclohexanone in high yield,<sup>4,7</sup> but, once again, no geminally acylated product was obtained.

The procedure developed by Kuwajima and co-workers was used with the four  $\alpha$ -substituted ketones, but only two gave geminally acylated products: **4** in 7% yield from the 2-bromocyclohexanone and **5** in 10% yield from the 2-methoxycyclohexanone. Conditions had been developed specifically for the geminal acylation of ketones in one pot.<sup>8</sup> When these conditions were applied to the four  $\alpha$ -substituted ketones, only two yielded a detectable amount of a geminally acylated product: **4** in 24% yield from the 2-bromocyclohexanone and **6** in 4% yield from the 2-chlorocyclohexanone.

TLC analysis of the reactions of the ketals and of the ketones indicated that the starting compounds were consumed fairly rapidly.  $^{13}\text{C}$  NMR spectra of the resulting material included clusters of resonances between  $\delta$  90 and 100 ppm. Chemical shifts in this region have been seen for the carbinolic carbon of a cyclobutane intermediate,<sup>1,8,9</sup> and it was surmised that as a result of these attempted geminal acylations, the Mukaiyama aldol reactions had taken place to give cyclobutanone derivatives (**7–14**), but the pinacol rearrangements had failed. The products from the ketals **7–10** were mixtures with silylated alcohol functions, but product ratios could not be determined owing to partial desilylation. The products from the ketones **11–14** were obtained with alcohol functions only. NMR signals were discerned for at least three of the four possible diastereomers of **11–14**, and the proportions of these diastereomers (Table 1) were estimated by integration of the NMR spectra of the crude mixtures of diastereomers.

Only 2-chlorocyclohexanone showed good stereoselectivity (80% of one diastereomer by NMR), and a tiny amount of the major diastereomer **12a** was isolated by repeated flash chromatography. 2-Bromocyclohexanone had reacted with modest stereoselectivity (the ratio of diastereomers was only 3:1:1:1), and a very small amount of the major diaste-

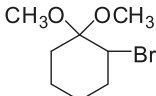

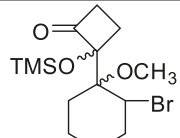

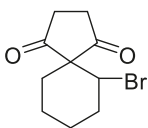

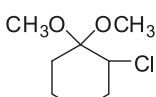

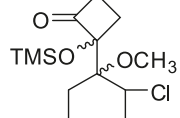

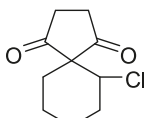

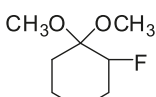

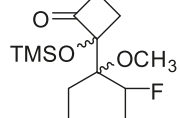

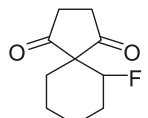

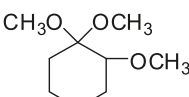

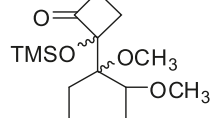

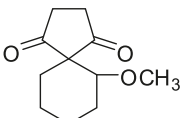

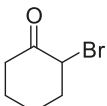

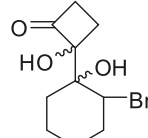

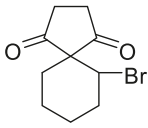

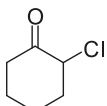

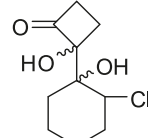

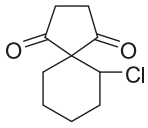

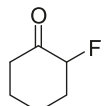

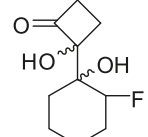

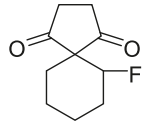

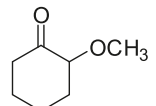

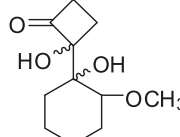

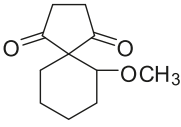

reomer **11a** separated from the others during chromatography. (The diastereomeric mixtures **9**, **10**, **13**, and **14** could not be separated by flash chromatography.) It was fortuitous that both **11a** and **12a** provided crystals that allowed analysis by X-ray crystallography. This analysis revealed that these major diastereomers had the same basic structure (Figs. 1 and 2).

Diastereoselective additions of nucleophiles, such as hydride, organomagnesium reagents, and organolithium reagents, to  $\alpha$ -heterosubstituted cyclohexanones have been noted a number of times.<sup>14–16</sup> The selectivity has been rationalized in terms of Felkin–Anh control<sup>15</sup> and electrostatic interactions.<sup>14,17</sup> Previous studies involved products that were predominantly the result of addition to the face of the carbonyl anti to the heteroatom. However, in both **11a** and **12a**, the position of the cyclobutanone moiety relative to the halogen was *cis* with respect to the cyclohexane ring, which implied that the Mukaiyama aldol reaction preferentially occurred on the face of the ketone *syn* to the halogen. Previous work with conformationally locked cyclohexanones indicated that addition of hydride was predominantly axial, and the rate of anti addition to the carbonyl was faster when the  $\alpha$ -heteroatom was axial.<sup>14</sup> In other words, the diastereoselectivity of additions of smaller nucleophiles to  $\alpha$ -substituted cyclohexanones arises from axial addition to the carbonyl when the  $\alpha$ -substituent is axial and anti to the incoming nucleophile. NMR studies have shown that the cyclohexanone conformer with the  $\alpha$ -halogen in an axial position is either the major conformer or at least similar in energy to the conformer with an equatorial halogen.<sup>15,18</sup>

In contrast with the reactions of hydride and many organometallics, the initial step of the geminal acylation of cyclohexanone or its ketal gives mainly the product of equatorial addition.<sup>1,8</sup> If that mode of addition is still the case with the  $\alpha$ -heterosubstituted cyclohexanones, what is intriguing is that the relative stereochemistry observed with **11a** and **12a** must have arisen by addition of **1** *syn* to the  $\alpha$ -heteroatom, but with the conformation of the cyclohexanone having the heteroatom in an axial position. It has been accepted for a long time that equatorial additions to cyclohexanones by larger nucleophiles are due to larger steric interactions in the transition state for axial addition.<sup>19</sup> On the other hand, the axial disposition of the heteroatom is likely due to stabilization of the intermediate carbocation (e.g., **16**). Thus, a plausible reason for the generally low stereoselectivity of the addition reactions summarized in Table 1, relative to additions of smaller nucleophiles,<sup>13–15</sup> would be that the axial heteroatom would retard attack by **1**, since this larger nucleophile would be adding equatorially, which would be *syn* to the heteroatom, making other modes of reaction competitive in rate.

**Table 1.** Results of the two-step geminal acylation of  $\alpha$ -heterosubstituted cyclohexanones and their ketals.

<sup>a</sup> The initial reaction involved **1** with  $\text{BF}_3 \cdot \text{Et}_2\text{O}$  in  $\text{CH}_2\text{Cl}_2$  at  $-78^\circ\text{C}$ , and the rearrangement step was with Amberlyst-15 in benzene under reflux.

Fig. 1. X-ray crystal structure of **11a**.Fig. 2. X-ray crystal structure of **12a**.

When some cyclobutanone compounds were maintained in warm TFA, very little, if any, rearrangement took place, but the starting compound was steadily consumed, and some material that was insoluble in common organic solvents was produced. The formation of a spirocyclic 1,3-diketone from the cyclobutanone might take place in a step-wise fashion, by initial generation of an intermediate tertiary carbocation followed by rearrangement, or by a concerted mechanism in which carbon–carbon bond reorganization accompanies the loss of the oxygen. TFA, being a polar medium, should stabilize a discrete carbocation. However, calculations by Nakamura and Osamura<sup>20</sup> suggested that as a carbocation is stabilized, the energy required for carbon–carbon bond reorganization increases. This would likely make other reaction pathways (leading to decomposition) more competitive. It was hypothesized that performing the rearrangement in a nonpolar medium would create a more favorable situation for a concerted process to occur instead of other more destructive reaction pathways.

To this end, benzene was chosen as the solvent and

Scheme 2.

Amberlyst-15, which is a resin with sulfonic acid sites, was chosen as the acid. Amberlyst-15 had proven to be an excellent catalyst for the rearrangement of cyclobutanone intermediates generated from aldehydes.<sup>21</sup> It was gratifying that the desired spirocyclic 1,3-diketone (**6**) was obtained in 95% yield. The use of *p*-TsOH in the place of Amberlyst-15 gave no rearranged product, just intractable material. This dramatic difference in the result was evidence that the macroreticular structure of the resin, and not just its acidity, plays an important role in promoting the rearrangement of the cyclobutanone. This may be related to pinacol rearrangements mediated by acidic agents in other porous structures, e.g., iron(III)-substituted molecular sieves.<sup>22</sup>

The procedure using Amberlyst-15 was carried out with all of the cyclobutanone derivatives in Table 1. The cyclobutanones derived from ketones (**11–14**) rearranged within an hour in benzene under reflux. The halogenated compounds **11–13** provided the 1,3-diketones **4**, **6**, and **15** in excellent yield. The methoxy derivative **5** was obtained in modest yield from **14**. Diketone **5** was accompanied by a significant amount of by-product, which was difficult to separate. It appeared by <sup>1</sup>H NMR spectroscopic analysis to be **17**. (Its diagnostic NMR signals were a multiplet at  $\delta$  6.98 ppm, a singlet at  $\delta$  3.71 ppm, and triplets at  $\delta$  3.00 and 2.64 ppm.) It was likely that **17** was produced from **5** (Scheme 2). Acid-catalyzed elimination of methanol might be accompanied by ring-opening and generation of the acylium ion **18**, which would then capture the evolved methanol to provide **17**.

The reactions of the cyclobutanones derived from the ketals (**7–10**) were sluggish, requiring 48 h to consume the starting materials in benzene under reflux. The 1,3-diketones **4**, **6**, and **15** were isolated in poorer yield than from **11–13**, and the methoxycyclobutanone **10** gave none of the 1,3-diketone **5**. The reason for the slower reaction was the presence of the TMS group, because desilylation of **8** with TBAF followed immediately by treatment with Amberlyst-15 in benzene gave **6** in 88% yield.

The success of the two-step process from ketones prompted us to re-examine the reactions of two  $\alpha$ -substituted substrates that had given only modest yields of 1,3-diketones previously. 2-Methylcyclohexanone and 3-methylbutanone had given **19** and **20** in yields of 62% and 52%, respectively, using the one-pot, two-step method using excess  $\text{BF}_3 \cdot \text{Et}_2\text{O}$  to effect the rearrangement.<sup>8</sup> In contrast, using the

same two-step procedure involving Amberlyst-15 that was used to produce the spirocyclic 1,3-diketones in Table 1, **19** and **20** were prepared in 84% and 80% yield, respectively, from the ketones.

In summary, a two-step procedure has been developed for the geminal acylation of an  $\alpha$ -heterosubstituted cyclohexanone. The first step is the  $\text{BF}_3 \cdot \text{Et}_2\text{O}$ -mediated addition of **1** to the ketone to give a cyclobutanone intermediate, and the second is the rearrangement of the cyclobutanone in benzene with Amberlyst-15. The process works less well with the corresponding ketal. Following the same procedure, yields of geminally acylated products from ketones substituted in the  $\alpha$  position with alkyl groups are improved over the older one-pot, two-step procedure. It is expected that the procedure will be widely applicable for the geminal acylation of other cyclic and acyclic ketones with  $\alpha$  substitution.

## Experimental

### General

All reactions were performed under  $\text{N}_2$ .  $\text{BF}_3 \cdot \text{Et}_2\text{O}$  was distilled before use.  $\text{CH}_2\text{Cl}_2$  and benzene were distilled from calcium hydride before use. Flash chromatography used 230–400 mesh silica gel, starting with 20% ethyl acetate–hexane mixtures with an increasing portion of ethyl acetate as the eluting solvent.  $^1\text{H}$  NMR spectra were recorded in  $\text{CDCl}_3$ . Chemical shifts are relative to internal TMS.  $^{13}\text{C}$  NMR chemical shifts are relative to the  $\text{CDCl}_3$  solvent ( $\delta$  77.0 ppm). Each  $^{13}\text{C}$  NMR chemical shift is followed by a number in parentheses that represents the number of attached protons as determined by DEPT experiments. Compound **1** was prepared by the method of Bloomfield and Nelke.<sup>3</sup> 2-Chloro-, 2-methoxy-, and 2-methyl-cyclohexanone and 3-methylbutanone were purchased (Sigma-Aldrich). 2-Bromo- and 2-fluorocyclohexanone were prepared by oxidation of the corresponding alcohols<sup>23</sup> with pyridinium chlorochromate. Ketals<sup>24</sup> were formed by treatment of the ketones with methanol–trimethyl-orthoformate (1:1) with some *p*-TsOH.

### General procedure for geminal acylation

To a solution of the ketone or ketal (1.0 mmol) in  $\text{CH}_2\text{Cl}_2$  (8 mL) at  $-78^\circ\text{C}$  was added  $\text{BF}_3 \cdot \text{Et}_2\text{O}$  (1.5 mmol) and then **1** (3.0 mmol) dropwise. The mixture was warmed slowly to room temperature (rt) and then stirred until TLC indicated that the starting ketone or ketal was consumed. The mixture was concentrated under reduced pressure. Flash chromatography was used to remove unreacted and decomposed **1** from the mixture of cyclobutanone products. The cyclobutanone mixture was dissolved in benzene (25 mL). Amberlyst-15 (0.25 g) was added to this solution, and the resulting mixture was heated under reflux. When TLC indicated that the cyclobutanones had been consumed, the mixture was

cooled to rt, and the Amberlyst-15 was removed by gravity filtration. The filtrate was concentrated under reduced pressure, and flash chromatography afforded the 1,3-diketone. Characterization data for the 1,3-diketones **4**, **5**, **6**, and **15** and the cyclobutanone intermediates **11a** and **12a** are given in the following. Data for **19** and **20** were consistent with published data.<sup>7</sup>

#### X-ray crystallography

Table 2 summarizes the crystallographic data for **11a** and **12a**. Diffraction data were acquired using a Rigaku AFC6S diffractometer with graphite-monochromated Cu K $\alpha$  radiation ( $\lambda$  = 1.54178 Å). An empirical absorption correction was applied. The data were corrected for Lorentz and polarization effects. The structures were solved by direct methods and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were refined using the riding model. Final cycles of full-matrix least-squares refinement were applied. All calculations were performed using the CrystalStructure<sup>25</sup> crystallographic soft-

ware package except for refinement, which was performed using SHELXL-97.<sup>26</sup>

#### Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca). CCDC 760849 and 760850 contain the X-ray data in CIF format for this manuscript. # On the stabilization of the carbonate dianion by sulfur dioxide

Friedrich Grein, Justin K. Chan, and Idlir Liko

**Abstract:** The stabilization in the gas phase of the carbonate dianion  $\text{CO}_3^{2-}$  by  $\text{SO}_2$  molecules is being investigated. The geometries of various isomers of  $\text{CO}_3^{2-}(\text{SO}_2)_n$  and  $\text{CO}_3^{1-}(\text{SO}_2)_n$ , for  $n = 1-4$ , have been optimized by the B3PW91/6-311+G(3df) method. Single-point CCSD and CCSD(T) energies at the DFT-optimized geometries were obtained for  $n = 1-3$ , using the 6-311+G(d) basis set. For  $n = 1$  and 2, the monoanionic clusters are adiabatically more stable than the dianionic ones. However, starting at  $n = 3$ , they become less stable. The CCSD adiabatic electron detachment energy of the dianionic cluster switches from  $-0.39$  eV for  $n = 2$  to  $+0.20$  eV for  $n = 3$ . The vertical electron detachment energy turns positive at  $n = 2$ , with a CCSD value of  $1.35$  eV. Several of the less stable dianionic, and most of the monoanionic clusters, are characterized by the transfer of an oxygen atom from  $\text{CO}_3$  to  $\text{SO}_2$ , forming  $\text{SO}_3^{2-}$  or  $\text{SO}_3^{1-}$  units, owing to  $\text{SO}_3^{2-/1-} + \text{CO}_2$  being more stable than  $\text{CO}_3^{2-/1-} + \text{SO}_2$ . For the stabilization of the sulfate dianion by stepwise hydration, studied both experimentally and theoretically by other groups, a minimum of three water molecules was required.

**Key words:** dianion stabilization, carbonate dianion, stabilization with  $\text{SO}_2$ , adiabatic electron detachment energy, vertical electron detachment energy, density functional calculations, coupled cluster calculations, structure of carbonate–sulfur dioxide clusters,  $\text{SO}_3$  formation.

**Résumé :** On a étudié la stabilisation en phase gazeuse du dianion carbonate,  $\text{CO}_3^{2-}$ , par des molécules de  $\text{SO}_2$ . Les géométries des divers isomères de  $\text{CO}_3^{2-}(\text{SO}_2)_n$  et de  $\text{CO}_3^{1-}(\text{SO}_2)_n$ , pour  $n = 1$  à 4, ont été optimisées par la méthode B3PW91/6-311+G(3df). On a obtenu des énergies ponctuelles d'agrégats couplés avec des excitations simple et double (ACSD) et d'agrégats couplés avec des excitations simple et double et perturbatrices triples (ACSD(T)) pour les géométries optimisées par des calculs basés sur la théorie de fonctionnelle de la densité (TFD) pour  $n = 1$  à 3, en utilisant un ensemble de base 6-311+G(d). Pour  $n = 1$  et 2, les agrégats monoanioniques sont adiabatiquement plus stables que les diatomiques. Toutefois, commençant avec  $n = 3$ , ils deviennent moins stables. L'énergie d'arrachement adiabatique d'un électron d'un agrégat dianionique (ACSD) passe de  $-0,39$  eV pour  $n = 2$  à  $+0,20$  eV pour  $n = 3$ . L'énergie d'arrachement vertical d'un électron devient positive à  $n = 2$ , avec une valeur d'ACSD de  $1,35$  eV. Plusieurs agrégats dianioniques moins stables et la plupart des monoanioniques sont caractérisés par le transfert d'un atome d'oxygène du  $\text{CO}_3$  au  $\text{SO}_2$ , conduisant à la formation d'unités  $\text{SO}_3^{2-}$  ou  $\text{SO}_3^{1-}$  en raison du fait que  $\text{SO}_3^{2-/1-} + \text{CO}_2$  est plus stable que  $\text{CO}_3^{2-/1-} + \text{SO}_2$ . Pour la stabilisation du dianion sulfate par hydratation par étape, étudiée tant d'un point de vue expérimental que théorique par d'autres groupes, un minimum de trois molécules d'eau est requis.

**Mots-clés :** stabilisation de dianion, dianion carbonate, stabilisation par du  $\text{SO}_2$ , énergie d'arrachement adiabatique d'électron, énergie d'arrachement vertical d'électron, calculs d'après la théorie de la fonctionnelle de la densité, calculs de couplages d'agrégats, structure d'agrégats carbonate–dioxyde de soufre, formation de  $\text{SO}_3$ .

## Introduction

It is well known that the “textbook” dianions  $\text{CO}_3^{2-}$ ,  $\text{SO}_4^{2-}$ , and other multiply charged anions (MCA), like  $\text{PO}_4^{3-}$ , are not electronically stable in the gas phase, and decay by auto electron detachment to the corresponding lower charge anions.<sup>1</sup> However, these polyanions are stabilized in solution and through counterions in the solid state. Stefanovich et al.<sup>2</sup> performed quantum chemical studies on dianions in the isolated state and solvated in water. For  $\text{CO}_3^{2-}$ , the vertical electron detachment energy (VDE) changed from  $-3.4$  eV

in the gas phase ( $\text{CO}_3^{2-}$  less stable than  $\text{CO}_3^{1-}$ ) to  $+9.9$  eV in water ( $\text{CO}_3^{2-}(\text{aq})$  more stable than  $\text{CO}_3^{1-}(\text{aq})$ ). For the sulfate dianion  $\text{SO}_4^{2-}$ , VDE changed from  $-1.6$  to  $+9.6$  eV. Indeed, the changes in stability are substantial.

Experimental studies led to a better understanding of MCAs. Hydrated sulfate clusters  $\text{SO}_4^{2-}(\text{H}_2\text{O})_n$ , dithionate clusters  $\text{S}_2\text{O}_6^{2-}(\text{H}_2\text{O})_n$ , and peroxydisulfate clusters  $\text{S}_2\text{O}_8^{2-}(\text{H}_2\text{O})_n$  in the gas phase were discovered by Blades and Kebarle.<sup>3</sup> The smallest number of  $\text{H}_2\text{O}$  molecules needed to stabilize the sulfate dianion was three. al.<sup>4</sup> performed photoelectron spectroscopy of gas-phase  $\text{SO}_4^{2-}(\text{H}_2\text{O})_n$  clusters. In agreement with Blades and Kebarle, they found the minimum number of water molecules required to stabilize  $\text{SO}_4^{2-}$  in the gas phase to be three. Smaller clusters were not stable. The experimental findings were supported by DFT/B3LYP geometry optimizations on clusters of the dianions  $\text{SO}_4^{2-}(\text{H}_2\text{O})_n$  and corresponding monoanions  $\text{SO}_4^{1-}(\text{H}_2\text{O})_n$  for  $n = 1$ –6, using the TZVP basis set augmented with diffuse functions on all atoms. Single-point B3LYP calculations were added using the aug-cc-pVTZ basis set for S and O, and cc-pVTZ for H. In agreement with experimental results, the calculated adiabatic electron detachment energies (ADE) were negative (unstable dianionic clusters) for  $n = 1$  and  $n = 2$ , but turned positive starting with  $n = 3$ . For  $n = 3$ , ADE was calculated as 0.32 eV, compared with  $0.4 \pm 0.2$  eV experimental. For  $n = 4$ , a calculated ADE of 0.90 eV is to be compared with an experimental value of  $1.00 \pm 0.1$  eV. All calculated ADEs were found to lie within the error bars of the experimental values. In a more recent paper, temperature-dependent isomer populations of gas-phase  $\text{SO}_4^{2-}(\text{H}_2\text{O})_n$  clusters were studied by performing measurements also at low temperature.<sup>5</sup> In another case of interest to the present work, photoelectron spectra of oxalate dianion clusters  $\text{C}_2\text{O}_4^{2-}(\text{H}_2\text{O})_n$  in the gas phase were investigated.<sup>6</sup> The smallest observable cluster was  $n = 3$ , with an experimental ADE of 0.00 eV and a VDE of 0.50 eV. B3LYP calculations were performed up to  $n = 6$ . The calculated VDE for  $n = 3$  was 0.48 eV, in excellent agreement with the experimental value. VDE for the highest calculated cluster,  $n = 6$ , was 1.75 eV vs 1.84 eV experimental. Again, all calculated VDEs were found to lie within 0.1 eV of the experimental values.

Whereas the stabilization of dianions by water has been relatively well studied, it can be argued that dianions may also be stabilized in atmospheres of oxygen, carbon dioxide, sulfur dioxide, other oxides, and by other gases. The driving force of MCA stabilization by cluster formation with molecules like carbon dioxide and sulfur dioxide is seen in the delocalization of negative charge, owing to bond formation and the increase in volume available for charge distribution.

The stabilization of dianions and more highly charged anions by common gases is considered to be of interest. For this purpose, we have embarked on a project to theoretically study the stabilization of  $\text{CO}_3^{2-}$ ,  $\text{SO}_4^{2-}$ , and  $\text{PO}_4^{3-}$  by the dioxides  $\text{CO}_2$ ,  $\text{SO}_2$ , and  $\text{NO}_2$ . Obviously, the program can be extended to other MCAs and to many other gas molecules.

In the present first paper in this series, the stabilization of the carbonate dianion by sulfur dioxide will be investigated. Geometries of the clusters  $\text{CO}_3^{1-}(\text{SO}_2)_n$  and  $\text{CO}_3^{2-}(\text{SO}_2)_n$  are to be optimized by DFT methods. From these studies, it is predicted that carbonate requires a minimum of three sulfur dioxide molecules to be adiabatically stabilized in the gas phase. For vertical stabilization, only two  $\text{SO}_2$  molecules are required. A search of the literature on carbonate monoanion and dianion clusters showed studies on  $\text{CO}_3^{2-}(\text{H}_2\text{O})_n$ ,  $\text{CO}_3^{1-}(\text{H}_2\text{O})_n$ ,  $\text{CO}_3^{1-}(\text{CO}_2)$ , and  $\text{CO}_3^{1-}(\text{CO})_n$ .<sup>7–11</sup> However, to the best of our knowledge, the question of stabilization of  $\text{CO}_3^{2-}$  by water molecules or any other molecules has not been addressed. Rudolph et al.<sup>7</sup> obtained Raman spectra of hydrated carbonate in aq  $\text{K}_2\text{CO}_3$  solutions. The vibrational

frequencies were compared with DFT values calculated for  $\text{CO}_3^{2-}$  and  $\text{CO}_3^{2-}(\text{H}_2\text{O})_n$ , with  $n = 1$  and 2. In a theoretical paper by Pathak et al.,<sup>8</sup> geometries and energies of  $\text{CO}_3^{2-}(\text{H}_2\text{O})_n$  ( $n = 1$ –6) clusters were obtained for the purpose of studying the changes to the IR spectra by sequential hydration of the carbonate dianion. Large shifts in the stretching mode of  $\text{H}_2\text{O}$  were found, whereas the bending mode of  $\text{H}_2\text{O}$  and the normal modes of  $\text{CO}_3^{2-}$  were little affected. Hydration energies were calculated as the difference between the energy of  $\text{CO}_3^{2-}(\text{H}_2\text{O})_n$  and the energy of  $\text{CO}_3^{2-}$  plus  $n$  water molecules in the gas phase. In a recent paper by Pathak and Maity,<sup>9</sup> IR spectra of the monoanionic hydrated clusters  $\text{CO}_3^{1-}(\text{H}_2\text{O})_n$  were calculated. Shkrob<sup>10</sup> investigated several possible structures of  $\text{CO}_3^{1-}(\text{H}_2\text{O})$  and  $\text{CO}_3^{1-}(\text{CO}_2)$ . Hiraoka et al.<sup>11</sup> performed experimental and theoretical studies on  $\text{CO}_3^{1-}(\text{CO})_n$ , for  $n = 0$ –4.

## Methods

DFT calculations on  $\text{CO}_3^{1-}(\text{SO}_2)_n$  and  $\text{CO}_3^{2-}(\text{SO}_2)_n$ , from  $n = 0$ –4, were performed with the Gaussian03 programs,<sup>12</sup> using the B3PW91 functional<sup>13,14</sup> with the 6–311+G(3df) basis set.

The  $D_{3h}$  structure of  $\text{CO}_3^{2-}$  is shown in Fig. 1. Starting structures for geometry optimizations of the  $\text{CO}_3^{1-}(\text{SO}_2)_n$  and  $\text{CO}_3^{2-}(\text{SO}_2)_n$  clusters were chosen such as to cover all possible bonding arrangements. A summary is provided in Table 1. The structures are labelled **1A**, **2A**, **2B**, **2C**, **3A**, etc., where the number indicates the total number of  $\text{SO}_2$  groups, and the letters differentiate between the different structures for the given  $n$ . One to three  $\text{SO}_2$ s are O–S bound to the  $\text{CO}_3$  oxygens O2, O3, and O4 (Fig. 1, primary  $\text{SO}_2$ s). Clusters having only primary  $\text{SO}_2$ s are **1A**, **2B**, and **3C**.  $\text{SO}_2$  groups attached to prior  $\text{SO}_2$  can be S–S or O–S bound. Both possibilities have been taken into account. S–S clusters are **2C**, **3D**, **3E**, and **4F**–**4I**. For those,  $C_s$  symmetry is possible. Clusters that have O–S bonds in addition to the primary bonds (**2A**, **3A**, **3B**, **4A**, **4B**, **4C**, **4D**, and **4E**) do not have any symmetry. The same starting structures were used for monoanionic and dianionic clusters. Optimized structures fitting these basic types will be shown in the forthcoming figures. In cases where no symmetry was imposed, the final optimized structure did not necessarily retain the type of bonding imposed in the starting structure. For example, S–S bonds have in several cases changed to O–S bonds. Overall, Table 1 contains 18 different structures. Structures that allow for  $C_s$  symmetry, 10 of 18, were initially calculated without symmetry, and thereafter with  $C_s$  symmetry. In total, 28 starting structures were used for geometry optimizations, both for the monoanionic and dianionic clusters.

Convergence was usually fast for the dianionic clusters, but often very slow and difficult for the monoanionic ones. Full convergence, or convergence to at least  $1 \times 10^{-6}$  au, has been accomplished in all cases listed in the tables. The reason for the poor convergence characteristics of the monoanions will be explained later.

Single-point calculations with the 6–311+G(d) basis set were performed using the coupled cluster method with single and double excitations (CCSD) for  $n = 0, 1, 2$ , and 3, and with noniterative triple excitations (CCSD(T)) for  $n =$

**Fig. 1.** Structure of  $\text{CO}_3^{2-}$ .

## Results

### $\text{CO}_3^{2-}$ and $\text{CO}_3^{1-}$

The literature is unanimous on  $\text{CO}_3^{2-}$  having  $D_{3h}$  symmetry. The situation is not so clear for  $\text{CO}_3^{1-}$ , which in some calculations shows  $D_{3h}$  and in others  $C_{2v}$  symmetry. In Table 2, DFT/B3PW91 and CCSD(T) results are listed for  $\text{CO}_3^{1-}$  and  $\text{CO}_3^{2-}$ , always using the 6–311+G(3df) basis set. CCSD(T) results for  $\text{CO}_3^{1-}$  have been obtained in both  $C_{2v}$  and  $D_{3h}$  symmetry. In CCSD(T), the  $C_{2v}$  structure is 1.11 eV lower in energy than the  $D_{3h}$  structure. The  $C_{2v}$  structure for  $\text{CO}_3^{1-}$  is in agreement with experimental results.<sup>15</sup> The opposite is the case in DFT. Here, a geometry optimization of  $\text{CO}_3^{1-}$  starting in  $C_{2v}$  leads to  $D_{3h}$  symmetry. Table 2 shows that the DFT geometry for the dianion is close to the CCSD(T) values. CCSD(T) and DFT ADEs and VDEs of  $\text{CO}_3^{2-}$ , also given in Table 2, differ by about 0.2 eV.

While there is agreement on the need for diffuse functions for *stable* negative ions, such is not the case for *unstable* or *metastable* anions, like  $\text{CO}_3^{1-}$ . Indeed, energies like ADE depend much on the amount of diffuse character in the basis set. For example, using the 6–311G(3df) basis set, differing from the standard basis set by the omission of diffuse functions, the DFT ADE for  $\text{CO}_3^{2-}$  is –5.34 eV, compared with –3.69 eV using 6–311+G(3df), a difference of 1.65 eV. Obviously, with more diffuse functions, the ADE will become lower (less negative), as the energy of the dianion approaches that of the monoanion. On the other hand, comparing the energies of dianions with those of the corresponding monoanions, a task that is required for the present work, demands a common basis set. One cannot use a diffuse basis set for the monoanions, and a nondiffuse set for the dianions. This is especially important, as with increased additions of  $\text{SO}_2$ , the dianionic structures eventually become more stable than the monoanionic ones. Of the two possibilities, a basis set with no diffuse functions or one with, the latter has been chosen. This choice is supported by the fact that excellent results were obtained for the  $\text{SO}_4^{2-}(\text{H}_2\text{O})_n$  clusters using diffuse functions.<sup>4</sup> Also,  $\text{VDE}(\text{CO}_3^{2-})$  calculated here with the diffuse basis set (–3.56 eV for DFT and –3.34 eV for CCSD(T)) is close to the result obtained by Stefanovich et al.<sup>2</sup> (3.4 eV, see Introduction).

### Binding and stabilization energies of clusters

In Table 3, calculated B3PW91 energies of the

$\text{CO}_3^{1-}(\text{SO}_2)_n$  and  $\text{CO}_3^{2-}(\text{SO}_2)_n$  clusters are listed for each bonding type, as detailed in Table 1. The lowest energy structures (bold in Table 3) for the monoanions/dianions are **2C/2B** for  $n = 2$ , **3E/3C** for  $n = 3$ , and **4H/4H** for  $n = 4$ . A discussion of these structures will be deferred until later. Also included in Table 3 are the binding energies. The binding energies  $\Delta E_n(-1)$  and  $\Delta E_n(-2)$  express the stabilization of monoanionic or dianionic complexes relative to the fragments  $\text{CO}_3^{1-} + n\text{SO}_2$  or  $\text{CO}_3^{2-} + n\text{SO}_2$ .

$$[1] \quad \Delta E_n(-1) = -E[\text{CO}_3^{1-}(\text{SO}_2)_n] + E(\text{CO}_3^{1-}) + nE(\text{SO}_2)$$

$$[2] \quad \Delta E_n(-2) = -E[\text{CO}_3^{2-}(\text{SO}_2)_n] + E(\text{CO}_3^{2-}) + nE(\text{SO}_2)$$

Table 3 shows that the binding energies for the monoanionic clusters increase from 1.67 eV for  $n = 1$ , to 2.44 eV for  $n = 2$ , to 2.77 eV for  $n = 3$ , and to 3.00 eV for  $n = 4$ . As expected, the dianionic clusters have much larger binding energies, ranging from 3.39 eV for  $n = 1$  to 7.18 eV for  $n = 4$ .

The incremental binding energies for the lowest energy clusters of each  $n$ , calculated by B3PW91, CCSD, and CCSD(T), are shown in Table 4. They are defined as

$$[3] \quad \Delta E_{n-1,n}(-1) = \Delta E_n(-1) - \Delta E_{n-1}(-1)$$

$$[4] \quad \Delta E_{n-1,n}(-2) = \Delta E_n(-2) - \Delta E_{n-1}(-2)$$

The B3PW91 values decrease from 1.67 to 0.23 eV for  $\text{CO}_3^{1-}(\text{SO}_2)_n$ ,  $n = 1-4$ , and from 3.39 to 0.75 eV for  $\text{CO}_3^{2-}(\text{SO}_2)_n$ ,  $n = 1-4$ . The CCSD and CCSD(T) values, as far as available, follow a similar pattern. Most lie within 0.2 eV of the DFT numbers.

In Table 5, B3PW91, CCSD and CCSD(T) ADEs and VDEs for the lowest energy structures are listed. The ADE is given by

$$[5] \quad \text{ADE} = E_0[\text{CO}_3^{1-}(\text{SO}_2)_n] - E_0[\text{CO}_3^{2-}(\text{SO}_2)_n]$$

for the lowest energy structure of the mono- and di-anion. The VDE is defined as

$$[6] \quad \text{VDE} = E_{\text{vert}}[\text{CO}_3^{1-}(\text{SO}_2)_n] - E_0[\text{CO}_3^{2-}(\text{SO}_2)_n]$$

where the energy of the anionic cluster  $\text{CO}_3^{1-}(\text{SO}_2)_n$  is calculated at the optimized geometry of the lowest energy dianion  $\text{CO}_3^{2-}(\text{SO}_2)_n$  for the given  $n$ . As defined, ADE and VDE are negative if the dianion is less stable than the monoanion, and positive otherwise.

As seen from Table 5, the B3PW91 values for ADE are negative for  $n = 0-2$ . The ADE for  $n = 3$  is –0.03 eV, an energy small enough to fall within the error range of the calculations. However, at  $n = 4$  the ADE has turned positive, with a value of +0.50 eV. ADE values obtained by the CCSD and CCSD(T) methods are very close to the DFT numbers for  $n = 0$ , ~0.2 eV less negative for  $n = 1$ , and ~0.5 eV less negative for  $n = 2$ . For  $n = 3$ , the ADE calculated by CCSD has become positive, with a value of 0.20 eV. It is expected that the CCSD(T) value for  $n = 3$  is very close. Using the CCSD result, it can be concluded that with the addition of *three*  $\text{SO}_2$  molecules the dianionic clusters have turned from being less to being more stable than

$R$ (C–O3/C–O4)	—	—	1.2863	—	—
$\alpha$ (O–C–O)	120	120	124.07	120	120
ADE	—	—	—	–3.69	–3.43
VDE	—	—	—	–3.56	–3.34

**Note:** Distances ( $R$ ) are in Å, angles ( $\alpha$ ) are in °. Adiabatic (ADE) and vertical (VDE) electron detachment energies are in eV. The  $C_{2v}$  structure is 1.11 eV lower in energy than the  $D_{3h}$  structure.

the monoanionic ones. All methods agree on the VDEs being negative for  $n = 0$  and 1, but turning positive for  $n = 2$ . VDE differences between DFT and CCSD(T) values are 0.2 eV or less. The CCSD value for  $n = 3$  is 2.12 eV, compared with 2.02 eV for DFT.

### Geometries of clusters

A selection of optimized structures for the dianions  $\text{CO}_3^{2-}(\text{SO}_2)_n$  is shown in Fig. 2, and for the monoanions  $\text{CO}_3^{1-}(\text{SO}_2)_n$  in Fig. 3. The labels refer to the starting structures. In most, but not all, cases the geometry optimization retained the bonding arrangements of the starting structures. Looking first at the dianionic structures in Fig. 2, one recognizes that in all structures C1–O–S is bent, with an angle of  $\sim 120^\circ$ . In **1A** the O2–S5 bond distance is 1.740 Å. The lowest energy structure for  $n = 2$  is **2B**, with  $C_s$  symmetry. Both O–S bonds are about 1.90 Å long. Apparently, attaching the second SO<sub>2</sub> group to a second CO<sub>3</sub> oxygen is energetically more favorable than a chainlike attachment, such as seen in **2A** (O–S) or **2C** (S–S). This trend continues for  $n = 3$ . Here,

**3C**, with three SO<sub>2</sub> groups attached to the three CO<sub>3</sub> oxygens, is the lowest energy structure. **3C** has a “paddle-wheel” shape, with an O–S bond length of 2.049 Å. It actually has the higher symmetry  $C_{3h}$ . The energies of **3B** and **3E**, with two SO<sub>2</sub> groups attached to CO<sub>3</sub>, are closest to **3C**, whereas the chainlike structure **3D** is highest in energy. For  $n = 4$ , eight structures are shown. The lowest energy one is **4H**. Here, as expected, three SO<sub>2</sub> groups are attached to CO<sub>3</sub>, as in **3C**, and the fourth group is attached to one of the primary SO<sub>2</sub>s. The only question here refers to the type of bonding for the fourth SO<sub>2</sub>. Somewhat to our surprise, the S–S bonded symmetric structure **4H**( $C_s$ ) lies 0.41 eV higher in energy than the nonsymmetrical structure **4H**, the latter having S–O bonding. In **4H**, the O2–S5 bond is 1.834 Å, whereas the O3–S11 and O4–S14 bonds are 2.15 and 2.16 Å, respectively, in length. The O7–S8 bond length is 2.261 Å. A S–S bond length of 2.716 Å in **4H**( $C_s$ ) indicates very weak S–S bonding. The **4H** structure was designed to give S–S bonding, but without symmetry restriction it converted to O–S bonding. As such, it is the equivalent of **4C**.

**Table 3.** Calculated B3PW91/6–311+G(3df) energies of  $\text{CO}_3^{1-}(\text{SO}_2)_n$  and  $\text{CO}_3^{2-}(\text{SO}_2)_n$ ,  $E(-1)$  and  $E(-2)$ , respectively, in atomic units.

$\text{CO}_3^{1-/2-}(\text{SO}_2)_4$	+0.50	+2.45	—	—	—	—

The latter structure has a slightly higher energy (by 0.02 eV), caused by the different orientation of the secondary  $\text{SO}_2$  group. In **3D**, **4A**, **4E**, and **4F**, the C1–O2 bond is very long, ranging from 2.60 to 2.98 Å. Here, an oxygen has been pulled off the carbonate dianion to form  $\text{CO}_2$  +

$\text{SO}_3^{2-}(\text{SO}_2)_{n-1}$ . In these structures, only one of the  $\text{SO}_2$ s is bonded directly to  $\text{CO}_3^{2-}$ , whereas the other  $\text{SO}_2$  groups have chainlike attachments. Calculations show that  $\text{SO}_3^{2-} + \text{CO}_2$  is lower in energy than  $\text{CO}_3^{2-} + \text{SO}_2$  by 1.47 eV. In  $C_{3v}$  symmetry, the calculated S–O bond distance of  $\text{SO}_3^{2-}$  is

**Fig. 2.** Optimized structures of the dianionic clusters  $\text{CO}_3^{2-}(\text{SO}_2)_n$ .

1.530 Å, and the O–S–O angle is 107.8°. The total energy of  $\text{SO}_3^{2-}$  is –623.744988 au (B3PW91/6–311+G(3df) optimization). Both for  $n = 3$  and  $n = 4$ , the lowest energy dianionic clusters retain the  $\text{CO}_3^{2-}$  moiety, having three primary  $\text{SO}_2$  bonds, with an energy gain by far exceeding that of  $\text{SO}_3^{2-}$  formation.

Most of the optimized monoanionic structures (Fig. 3) are much changed from their initial input shapes, explaining the difficulties encountered in the geometry optimizations. In all

cases of single substitution on  $\text{CO}_3^{1-}$ , and in several cases of multiple substitutions, one of the C–O bonds is very long. In **1A**, C1–O2 is 2.689 Å; in **2A** and **2C** it becomes 3.175 and 2.895 Å, respectively. Further examples are **3D**, **3E**, **4A**, **4C**, **4G**, **4H**, and **4I**. Similar to the dianionic case, the reason is the lower stability of  $\text{CO}_3^{1-}$  relative to  $\text{SO}_3^{1-}$ , causing the formation of the  $\text{SO}_3^{1-}$  anion. The reaction  $\text{CO}_3^{1-} + \text{SO}_2 \rightarrow \text{SO}_3^{1-} + \text{CO}_2$  is exothermic, with a calculated  $\Delta E$  (no zero-point energy corrections) of 1.50 eV (only slightly larger

Fig. 2. concluded.

than in the dianionic case).  $\text{SO}_3^{1-}$  has  $C_{3v}$  symmetry, which can be seen, for example, in **1A**. The calculated S–O bond distance of  $\text{SO}_3^{1-}$  is 1.476 Å (1.481 Å in **1A**), and the O–S–O angle is 114.1°. The total energy of  $\text{SO}_3^{1-}$  is –623.881416 au (B3PW91/6–311+G(3df) optimization). Such long C1–O bonds occur much more frequently in cases of monoanionic than in dianionic clusters, and are seen even for  $n = 1$  and  $n = 2$ . The reason is seen in the energy gain being higher by bonding to a dianion than to a monoanion, owing to the stronger desire for charge dissipation.

The  $\text{CO}_3^{1-}(\text{SO}_2)_1$  structure **1A** (C<sub>s</sub>) has a large C–O distance, as mentioned before. For  $n = 2$ , **2C** has the lowest energy. It again has a large C–O distance, and also a large S5–S8 distance of 2.472 Å. In structures **3B** and **3C**, the  $\text{CO}_3^{1-}$  moiety is retained. **3C** has the paddle-wheel structure, just like **3C** of the dianion. However, owing to the lack of  $\text{CO}_3^{1-} \rightarrow \text{SO}_3^{1-}$  stabilization, caused by the imposed symmetry, **3C** is not the lowest energy structure for  $n = 3$ . This dis-

tingction goes to **3E**, an awkward looking structure, with a very large C–O distance, followed by a  $\text{SO}_3^{1-}$  unit, with further S–S and O–S bonds. The lowest energy structure for  $n = 4$  is **4H**, which superficially looks like a paddle wheel, but the carbon atom is not at the centre of the wheel. Instead S5, the centre of the  $\text{SO}_3^{1-}$  unit, takes such a position. The three oxygens of  $\text{SO}_3^{1-}$ , O2, O6 and O7, are (weakly) bonded to three  $\text{SO}_2$ s.

## Discussion

The structures of the stable monoanionic clusters are characterized by  $\text{SO}_2$  pulling one oxygen from  $\text{CO}_3^{1-}$ , thereby forming the  $\text{SO}_3^{1-}$  anion. Structures where  $\text{CO}_3^{1-}$  has been retained had little chance of competing for the lowest energy. The  $\text{CO}_2$  left from this reaction is weakly bonded to the nearest oxygen from  $\text{SO}_3^{1-}$ . Without this reionizing effect, the monoanionic clusters would have higher energies,

Fig. 3. Optimized structures of the monoanionic clusters  $\text{CO}_3^{1-}(\text{SO}_2)_n$ .

and even fewer  $\text{SO}_2$  molecules would be required for the stabilization of  $\text{CO}_3^{2-}$ . In contrast, only the less stable dianionic clusters have long C1–O2 bonds, leading to the formation of  $\text{SO}_3^{2-}$ .

The two possible outcomes of adding  $\text{SO}_2$  molecules to

the carbonate mono- or di-anion can be described by eqs. [7] and [8]. In eq. [7] the carbonate remains, whereas in eq. [8] the charge is transferred from  $\text{CO}_3$  to  $\text{SO}_3$ .

Fig. 3. concluded.

Here,  $(\text{CO}_2) \cdots \text{SO}_3^q(\text{SO}_2)_{n-1}$  indicates a  $\text{CO}_2$  loosely bound to  $\text{SO}_3^q$ , with a large O–S distance. For  $q = -1$ , the lowest energy structure for each  $n$  follows eq. [8], whereas for  $q = -2$  it follows eq. [7]. However, (less stable) structures of the other type are also encountered. Energetic data for  $n = 1$  illustrate the two cases. For  $q = -1$ , one has

The calculated energies of eqs. [9] and [10] show that the optimized structure with the large O–S distance still has a small amount of  $\text{CO}_2$  bonding to  $\text{SO}_3^{1-}$  (0.17 eV). The energy gain for  $\text{CO}_3^{1-} + \text{SO}_2 \rightarrow \text{CO}_3^{1-}(\text{SO}_2)$  cannot be calculated. It is less than 1.67 eV.

For  $q = -2$ , we have

Here, bonding of  $\text{SO}_2$  to  $\text{CO}_3^{2-}$  is almost 2 eV more favorable than a charge transfer from  $\text{CO}_3^{2-}$  to  $\text{SO}_3^{2-}$ . In the case of  $q = -2$ , the energy gain of  $\text{CO}_3^{2-} + \text{SO}_2 \rightarrow (\text{CO}_2) \cdots \text{SO}_3^{2-}$  is estimated to be in the order of 1.5 eV, certainly much less than 3.39 eV.

According to Table 5, three  $\text{SO}_2$  molecules are required to adiabatically stabilize the carbonate dianion. There is no literature on the stabilization of  $\text{CO}_3^{2-}$  by  $\text{H}_2\text{O}$  or any other molecule. The only comparison we have is the stabilization of the sulfate dianion and the oxalate dianion by  $\text{H}_2\text{O}$  molecules.<sup>4,6</sup> In both cases, three water molecules are required for stabilization. Stabilization by  $\text{SO}_2$  molecules occurs through the formation of chemical bonds, and the associated delocalization of the negative charge. On the other hand, stabilization by  $\text{H}_2\text{O}$  is accomplished mainly via hydrogen bonds, causing neutralization of charges via electrostatic ef-

fects. A direct comparison of the two processes is therefore not possible. All one may conclude is that stabilization of small dianions is relatively easy and can be accomplished by the addition of very few solvent molecules. Vertical stabilization of the carbonate dianion can be accomplished by the addition of just two SO<sub>2</sub> molecules. Therefore, the  $n = 2$  dianionic cluster is stable with respect to auto ionization.

Binding energies (DFT values) reported for CO<sub>3</sub><sup>2-</sup>(H<sub>2</sub>O)<sub>*n*</sub> are 1.85 eV for  $n = 1$ , 3.51 eV for  $n = 2$ , 5.00 eV for  $n = 3$ , and 6.16 eV for  $n = 4$ .<sup>8</sup> Binding energies for CO<sub>3</sub><sup>2-</sup>(SO<sub>2</sub>)<sub>*n*</sub> are substantially higher, with DFT values of 3.39, 5.25, 6.43, and 7.18 eV for  $n = 1$ –4.

The lowest-energy structures for the dianionic clusters have a maximum number of SO<sub>2</sub> groups attached to the carbonate dianion. This is understandable as such bonding facilitates the dissemination of the excess negative charge of the dianion. Chainlike arrangements of SO<sub>2</sub> molecules have higher energies. The fourth SO<sub>2</sub> in the lowest energy isomer of  $n = 4$  prefers O–S over S–S bonding, with a rather large energy difference of 0.41 eV. The O2–S or O3–S bond distances of the dianionic clusters increase from 1.740 Å in **1A** to 1.893 Å in **2B** to 2.049 Å in **3C** and to 2.191 Å in **4H**.

According to Table 3, the binding energy (DFT value) at  $n = 4$  is 7.18 eV for the dianionic cluster and 3.00 eV for the monoanionic ones. Using the PCM model (without geometry reoptimization), the solvation energy for CO<sub>3</sub><sup>2-</sup> dissolved in SO<sub>2</sub> (dielectric constant  $\epsilon = 15.4$ ) is calculated to be 10.3 eV and that of CO<sub>3</sub><sup>1-</sup> is 2.6 eV. Therefore, at  $n = 4$  ~70% of the  $n = \infty$  solvation energy of CO<sub>3</sub><sup>2-</sup> was obtained. For CO<sub>3</sub><sup>1-</sup>, however, the solvation energy calculated at  $n = 4$ , 3.0 eV, exceeds the PCM value of 2.6 eV. The reason can be seen in the charge transfer from CO<sub>3</sub><sup>1-</sup> to SO<sub>3</sub><sup>1-</sup>, leading to a lower energy of the monoanionic cluster, a process that cannot be captured by the solvation model. If the  $n = 4$  solvation energy for CO<sub>3</sub><sup>1-</sup> were 70% of the PCM value, it would be 1.8 eV, so the difference of 1.2 eV with the  $n = 4$  binding energy can be attributed to the formation of SO<sub>3</sub><sup>1-</sup>.

Whereas in the gas phase small dianions are less stable than corresponding monoanions, solvation of dianions occurs with larger energy gain than solvation of monoanions. This can already be seen from the Born equation, according to which the solvation energy is proportional to the square of the ionic charge.<sup>16</sup> (This is nicely demonstrated by the approximate 4:1 ratio calculated for the solvation energies of the dianion CO<sub>3</sub><sup>2-</sup> and the monoanion CO<sub>3</sub><sup>1-</sup>.) It is therefore obvious that in a step-by-step solvation, as done here by adding one SO<sub>2</sub> molecule at a time, and in other cases as well, the dianionic clusters have to eventually become more stable than the monoanionic ones.

## Concluding remarks

It has been shown that the unstable dianion CO<sub>3</sub><sup>2-</sup> can be stabilized in the gas phase by bonding to at least three SO<sub>2</sub> molecules. For  $n = 3$ , the calculated energy of the dianionic cluster is 0.20 eV (CCSD value) lower than that of the monoanionic one. For higher  $n$ , larger positive stabilization energies are expected. The VDE turned positive for  $n = 2$ , with a CCSD(T) value of 1.04 eV. In several of the optimized structures, SO<sub>3</sub><sup>2-</sup> or SO<sub>3</sub><sup>1-</sup> units could be recognized.

Calculations show that CO<sub>3</sub><sup>2-/1-</sup> + SO<sub>2</sub> is less stable than SO<sub>3</sub><sup>2-/1-</sup> + CO<sub>2</sub>.

Work on the stabilization of the carbonate dianion by CO<sub>2</sub> and of the sulfate dianion by CO<sub>2</sub> and SO<sub>2</sub> is in progress.

## Acknowledgments

F.G. would like to thank Dr. J. Passmore for introducing him to the wonderful and somewhat mysterious world of dianions. We would like to thank Drs. Passmore and P. Bruna, and S. Burrill, for reading the manuscript and for valuable comments. Financial support by the Natural Sciences and Engineering Research Council of Canada (NSERC) is gratefully acknowledged. Thanks to members of the Atlantic Computational Excellence network (ACEnet) computer network for providing support and ample computing times.

# A theoretical analysis of the kinetics of the reaction of atomic bromine with tetrahydrofuran

John M.H. Lo, Robert A. Marriott, Binod R. Giri, John M. Roscoe, and Mariusz Klobukowski

**Abstract:** The kinetic behaviour for the reaction of atomic bromine with tetrahydrofuran has been analysed using the information from quantum chemical calculations. Structures and energy profiles were first obtained using density functional theory (DFT) employing the Dunning's basis sets of triple-zeta quality, and then for an accurate energetic description, single-point calculations were carried out at the coupled-cluster with single and double excitations (CCSD) and the fourth-order Møller–Plesset (MP4(SDQ)) levels of theory. The rate coefficients and the equilibrium constants for the potential reaction channels were obtained from the statistical rate theories and statistical thermodynamics, respectively, using the results of quantum chemical calculations; and the results were compared with our recently published experimental data. In terms of reaction mechanism, this reaction was found to be analogous to the reactions of the Br atom with 1,4-dioxane and with methanol, where the reaction proceeds via an addition–elimination mechanism. The dominant reaction channel involved coordination of the approaching Br atom to one of the hydrogen atoms adjacent to the ether oxygen atom, i.e.,  $\beta$ -hydrogen abstraction is uncompetitive. Although the complexes formed by direct coordination of the Br atom to the ether oxygen atom appeared in the reaction mechanism, we were not able to link them specifically to any reaction. The density functional theory predicted an activation energy and enthalpy of reaction that were much smaller than the experimental values, which led to an overestimation of the theoretical rate coefficients. The source of this discrepancy could be attributed to the overbinding of the transition states and of the tetrahydrofuran radical by DFT. Single-point calculations at the DFT structures using the CCSD and MP4(SDQ) methods yielded an accurate energetic description of the reaction of tetrahydrofuran with bromine, resulting in rate coefficients that showed excellent agreement with the experimental values.

**Key words:** gas-phase chemical kinetics, complex forming reactions, atmospheric chemistry, density functional theory (DFT), statistical rate theory, potential energy surfaces.

**Résumé :** Le comportement cinétique pour la réaction du brome atomique dans le tétrahydrofurane a été analysé à l'aide d'informations obtenues par calculs de chimie quantique. Les structures et les profils d'énergie ont été obtenues dans un premier temps à l'aide de la théorie de la fonctionnelle de la densité (TFD) en utilisant les ensembles de base de Dunning de qualité triple zêta et, ensuite pour une description précise des énergies, on a effectué des calculs ponctuels aux niveaux de l'agrégat couplé (« CCSD ») et du quatrième ordre de Møller–Plesset (« MP4(SDQ) »). Les coefficients de vitesse et les constantes d'équilibre des voies réactionnelles potentielles ont été à partir de résultats de chimie quantique en faisant appel aux théories statistiques standard des vitesses et à des calculs de thermodynamique statistique et on a comparé les résultats de ces calculs avec des données expérimentales publiées récemment. En termes de mécanisme réactionnel, on a trouvé que cette réaction est analogue aux réactions de l'atome de brome dans le 1,4-dioxane et le méthanol dans lesquels elle se produit par le biais d'un mécanisme d'addition–élimination. La voie réactionnelle principale implique une coordination de l'atome de brome qui approche à des atomes d'hydrogène adjacents de l'atome d'oxygène de l'éther, c'est-à-dire que l'enlèvement d'un atome d'hydrogène  $\beta$  n'est pas compétitif. Même si les complexes qui se forment par coordination directe de l'atome de brome sur l'atome d'oxygène de l'éther apparaissent dans le mécanisme réactionnel, il n'a pas été possible de les relier à aucune réaction. La théorie de la fonctionnelle de la densité prédit une énergie d'activation et une enthalpie de réaction qui sont beaucoup plus faibles que les valeurs expérimentales qui ont conduit à une surévaluation des coefficients théoriques de vitesse. La source de cette différence pourrait être attribuée à une sur-fixation des états de transition et du radical tétrahydrofuranylle par la TFD. Des calculs ponctuels des structures obtenues par la TFD, utilisant des méthodes « CCSD » et « MP4(SDQ) » conduisent à une description correcte des énergies impliquées dans la réaction du tétrahydrofurane avec le brome, ce qui conduit à des coefficients de vitesse présentant un excellent accord avec les valeurs expérimentales.

## Introduction

The importance of halogen atoms reactions with organic compounds for understanding atmospheric chemistry has been recognized for some time.<sup>1–3</sup> Atomic bromine can initiate atmospheric oxidation of volatile organic compounds (VOCs) by producing organic-free radicals, which are then able to react rapidly with atmospheric oxygen. However, the rate coefficients for hydrogen abstraction from VOCs by Br are typically one to two orders of magnitude smaller than those for the corresponding reactions of Cl. This makes them less important than Cl as sinks for VOCs. On the other hand, the rate coefficient for the reaction of Br with O<sub>3</sub> is larger than that for the corresponding reaction of Cl, so the ability of VOCs to act as sinks for Br is relevant to the potential for Br to remove ozone. This would be of greatest importance in the marine boundary layer where the concentration of Br<sub>2</sub> is particularly large. Reactions of Br with organic compounds are also important in the incineration of halogen-containing waste.<sup>4–6</sup> A considerable body of data exists for the rates of reactions of atomic chlorine with organic compounds at both ambient and elevated temperatures, however, the kinetics of reactions of atomic bromine with organics has received much less attention. We have recently reported rate coefficients over a temperature range of ~290–380 K for several reactions of atomic bromine with ethers<sup>7–9</sup> in an effort to address this deficiency.

In our most recent work,<sup>9</sup> the kinetic behaviour for the reaction of bromine with 1,4-dioxane deviated markedly from that expected on the basis of our measurements for the reactions of bromine with other cyclic ethers.<sup>8</sup> We were able to understand the origins of these differences by a theoretical analysis of the potential energy surface for the reaction. The theoretical analysis showed that the bromine atom first forms a comparatively stable complex with the chair conformer of the dioxane molecule. This complex has too large an activation energy for the loss of HBr to account for the observed reactivity. The rate-limiting step was predicted to be the conversion of the chair conformer of the complex to the less stable boat conformer. Loss of HBr then occurs from the boat conformer, moderated by a weak van der Waals interaction between the departing HBr molecule and one of the ether oxygen atoms of the incipient dioxanyl radical.

The deduction of this complex reaction mechanism involving a number of elementary steps for the reaction of dioxane with atomic bromine would not have been possible without a detailed theoretical analysis. Indeed, even the formation of a complex between the ether oxygen atom and the approaching bromine atom would not be evident solely from the experimental kinetic measurements. The question then arises whether the potential energy surfaces (PES) for the reactions of atomic bromine with other cyclic ethers might require both complex formation and conformational change. In this work, we have computed a detailed picture of the PES, which has enabled us to evaluate the effects of complex for-

mation and of their conformational change for the reaction of atomic bromine with tetrahydrofuran (THF). Furthermore, this study will provide an opportunity to discriminate among the various possible reaction channels for the H abstraction as THF offers four different types of H atoms; each carbon atom at  $\alpha$  and  $\beta$  positions has two types of H atoms at the axial and equatorial positions, respectively. It is widely accepted that the H abstraction in ethers by the Br atom takes place from an  $\alpha$ -carbon atom because the ether oxygen provides a reduction in enthalpy of activation, offering a preferential H abstraction from the adjacent carbon atom; see ref. 8 and the refs. cited therein. A detailed kinetic analysis will help to verify the postulate that  $\beta$ -hydrogen abstraction reactions in ethers are unimportant.

## Calculations

### Structures and energies

A number of computational approaches were employed to obtain the energy profiles pertaining to the hydrogen-abstraction reaction of THF by atomic bromine. Initially, the geometries of the reactants, intermediates, and products were optimized using density functional theory with the hybrid Becke-3-Lee-Yang-Parr (B3LYP) functional.<sup>10</sup> For C, H, and O, the all-electron Dunning's correlation-consistent polarized valence triple-zeta basis sets (cc-pVTZ) were used,<sup>11</sup> whereas for Br, a small-core relativistic pseudopotential, which includes 4s, 4p, 4d, 5s, and 5p shells in the valence space, in conjunction with an energy-consistent valence triple-zeta basis set (cc-pVTZ-PP) was utilized.<sup>12</sup> Harmonic frequencies were computed on the optimized geometries using numerical Hessians with a step size of 0.01 bohr. The computed frequencies were scaled by a factor of 0.9648, which was obtained from the Computational Chemistry Comparison and Benchmark Database (CCCBDB).<sup>13</sup>

B3LYP in conjunction with a triple-zeta type basis is found to yield reasonably good results for geometries (in the order of 0.005 Å). However, on occasion it shows inadequacy in predicting the energetics of the reactions. Usually the discrepancy is between 8 and 10 kJ/mol.<sup>14</sup> For reliable rate coefficients, an accurate knowledge of the computed potential energy surface is required. To improve the energetic description, additional single-point calculations using coupled cluster with single and double excitations (CCSD)<sup>15</sup> and the fourth-order Møller-Plesset (MP4(SDQ))<sup>16</sup> level of theory were performed at the DFT-optimized geometries. In these calculations, all-electron cc-pVTZ basis sets for all atoms were used. These calculations applied the frozen core approximation for the computational efficiency, and for the radical species, the restricted open-shell scheme was employed to obtain the Hartree-Fock reference wave functions.

All the B3LYP calculations were performed with the GAMESS-US suite,<sup>17</sup> whereas the GAUSSIAN 09 package<sup>18</sup> was used for the CCSD and MP4(SDQ) calculations. The

molecular graphics presented in this work were created by the MacMolPlt<sup>19</sup> and GaussView programs (Gaussian, Inc.).

### Equilibrium constants and rate coefficients

Based on the molecular and transition state parameters from the results of quantum chemical calculations, equilibrium constants,  $K(T)$ , and high pressure rate coefficients,  $k_\infty(T)$ , for various channels were calculated using standard equations from statistical thermodynamics<sup>20</sup> and statistical rate theories,<sup>21–25</sup> respectively:

$$[1] \quad K(T) = \frac{\prod_{\text{products}} (Q_i/V)}{\prod_{\text{reactants}} (Q_i/V)} \exp\left(\frac{-\Delta H_0}{k_B T}\right)$$

$$[2] \quad k_\infty(T) = \frac{k_B T}{h} \frac{(Q_i^*/V)}{\prod_{\text{reactants}} (Q_i/V)} \exp\left(\frac{-E_0}{k_B T}\right)$$

Here,  $Q_i$  denotes the molecular partition function of the species  $i$  and an asterisk signifies the activated complex;  $E_0$  and  $\Delta H_0$  are the threshold energy and enthalpy of reaction at  $T = 0$  K, respectively;  $V$  is the volume;  $k_B$  is Boltzmann's constant; and  $h$  is Planck's constant. The rotational and vibrational partition functions were calculated using the rigid rotor–harmonic oscillator approximation, whereas the electronic partition functions were set equal to 2 for the radical species and 4 for the Br atom. The external symmetry numbers are included in the rotational partition function. For a simple bond fission reaction where no potential barrier exists along the reaction coordinate, the partition function ( $Q_i^*$ ) should be understood as the pseudopartition function within the framework of the statistical adiabatic channel model (SACM). The pseudo-partition function of the threshold energies  $E_{0,i}$  for all individual channel states  $i$  is given<sup>23–25</sup> by

$$[3] \quad Q_i^* = \sum_i \exp\left(-\frac{E_{0,i} - E_0}{k_B T}\right)$$

## Results and discussion

### The B3LYP calculations

We first begin our discussion on the results of our calculations at the B3LYP/cc-pVTZ/cc-pVTZ-PP level of theory. The optimized geometries and selected structural parameters of the reactants, intermediate species, and products obtained at this level of theory are displayed in Figs. 1 and 2. The rotational constants and harmonic wave numbers for the species used in the kinetic analyses are compiled in Table 1. Several stationary points within the potential energy surface describing the hydrogen abstraction reactions of THF by the Br atom were computed.

The calculations predicted the conformation with  $C_2$  symmetry as the most stable form of THF. The nearly energetically degenerate bent conformer with  $C_s$  symmetry was also found to exist. The  $C_2$  and  $C_s$  species differed in energy by only 0.3 kJ/mol. The planar form of THF with  $C_{2v}$  symmetry represents the transition state that lies 12.4 kJ/mol above the

bent conformer. As for the reaction of THF and the Br atom, the H abstraction does not occur directly. Instead, it occurs via an addition–elimination mechanism in a similar fashion to that seen in the reactions of dioxane<sup>9</sup> and methanol<sup>26</sup> with the Br atom. The lack of mirror plane of symmetry within the ground state of THF results in the nonequivalence of the four hydrogen atoms. As a consequence, the Br-atom attack on H atoms of THF results in four possible adducts, M1–M4 (see Fig. 1), which can eventually eliminate HBr leading to the products,  $C_4H_7O^\bullet$  and HBr. Among the complexes, M1 and M2 are formed by the interaction of the approaching Br atom with the  $\alpha$ -hydrogen atoms, whereas M3 and M4 result from the attack of the Br atom on the H atoms that are not adjacent to the ether oxygen, i.e.,  $\beta$ -hydrogen atoms. The most stable complex (M1) is located 40.8 kJ/mol below the reactant, whereas M3 is found to be the least stable complex with the exothermicity of 14.2 kJ/mol. The thermal stability of M2 and M4 with respect to the reactant is calculated to be 27.7 and 14.2 kJ/mol, respectively. Constrained potential energy surface scans were performed along the reaction coordinates (C–H bond distance), but no maximum-energy configurations for further dissociation of M3 and M4 leading to the products were detected. The direct HBr elimination via these complexes is endothermic by 20.3 kJ/mol and occurs without an intramolecular hydrogen-transfer step. In contrast, M1 and M2 undergo conformational change into predissociative complexes, I1 and I2, respectively, before they can get rid of HBr. The latter species lie at energies of 12.4 and 12.2 kJ/mol, respectively, below the reactants. The barrier heights for the transition states (T1 and T2) for the conversions of M1 to I1 and M2 to I2 are found to be 32.2 and 24.5 kJ/mol, respectively.

In addition to the direct Br atom association with the hydrogen atoms of THF, the calculations also revealed two additional stable configurations where the Br atom is coordinated either solely to the oxygen atom (C1) or simultaneously to the oxygen and hydrogen atoms (C2). This binding mode has also been previously observed in the reaction of Br with methanol.<sup>26</sup> These conformers (C1 and C2) are less stable than M1 by 5.9 and 15.8 kJ/mol, respectively.

Subsequent kinetic analyses showed that the reaction of THF with the Br atom proceeds via the reaction sequence  $\text{THF} + \text{Br} \rightleftharpoons \text{M1} \rightleftharpoons \text{I1} \rightarrow \text{C}_4\text{H}_7\text{O}^\bullet + \text{HBr}$ . The calculated overall rate coefficients were overestimated by at least 70 times larger than our experimental rate coefficients (see Fig. 3). The calculated overall reaction enthalpy was 1.93 kJ/mol at 0 K, whereas the experimental reaction enthalpy was  $19 \pm 6$  kJ/mol.<sup>8</sup> This is an indication that the B3LYP level of theory is inadequate to accurately describe the energetics of this type of reaction system; and it is often found to underestimate it by an average deviation of  $\sim 13.0$  kJ/mol.<sup>27,28</sup> The deviation is even larger for non-hydrogen systems ( $\sim 22.4$  kJ/mol).<sup>27</sup> This severe disagreement between the theory and the experiments suggests that the B3LYP functional only provides a qualitative picture of energetics for the title reaction. Therefore, a more suitable methodology is required for a better description of the energetics of this type of reaction.

**Fig. 1.** B3LYP/cc-pVTZ/cc-pVTZ-PP structures of C1–C2 and M1–M4, and selected geometric parameters.

### The CCSD and MP4(SDQ) calculations

In an effort to more accurately understand the energetics of the title reaction, we further performed a series of single-point calculations at the CCSD and MP4(SDQ) levels of theory. The computed energies are illustrated in Figs. 4 and 5. Interestingly, the order of relative stability of molecular complexes (M1–M4) remains unchanged at the CCSD and MP4(SDQ) levels of theory when compared to that computed at B3LYP. However, in contrast with B3LYP, both CCSD and MP4(SDQ) predicted the molecular complexes M3 and M4 to be unstable. Both theories predicted a higher total energy of about 1.5 kJ/mol than the reactants for M3, whereas for the formation of M4, it was found to be almost thermoneutral. The reaction enthalpy for the  $\beta$ -hydrogen abstraction from THF by the Br atom via M3 and M4 is calculated to be  $\sim 31$  kJ/mol at both levels of theory (Figs. 4 and 5). Owing to its high threshold energy, the  $\beta$ -hydrogen abstraction channel may be considered to be unimportant.

At first, we note here that our experiments<sup>8</sup> indicated no discernible pressure dependence. This lack of pressure de-

pendence and also the low temperature of our experiments suggest that the rate coefficients of all elementary steps involved in the title reaction are at their high pressure limits. Here, the pressure activation effects are not required to be considered in which case eqs. [1] and [2] can be used for kinetic analyses. Before ignoring the reaction channels via M3 or M4, we calculated the equilibrium constant for the reaction  $\text{THF} + \text{Br} \rightleftharpoons \text{P2} + \text{HBr}$  ( $K = 2.38 \times 10^{-5}$  at  $T = 293$  K) using eq. [1] with  $\Delta H_0 = 30.7$  kJ/mol, which was then combined with the rate coefficients (barrierless collision limit ( $k_{\text{coll}} = \bar{v}\sigma \approx 10^{-10} \text{ cm}^3 \text{ s}^{-1}$  with a typical molecular velocity ( $\bar{v}$ ) of  $5 \times 10^4 \text{ cm s}^{-1}$  and molecular cross section ( $\sigma$ ) of  $5 \times 10^{-15} \text{ cm}^2$ )<sup>22</sup> for the reverse reaction to estimate the rate coefficient for the forward reaction. The rate coefficient calculated this way was found to be  $\sim 1 \times 10^{-15} \text{ s}^{-1}$  at  $T = 293$  K, which is more than two orders of magnitude smaller than the experimental value. Even at  $T = 363$  K, it is calculated to be slower by  $\sim 28$  times. This clearly shows that the  $\beta$ -hydrogen abstraction reaction via M3 or M4 plays no role in the reaction kinetics, though

**Fig. 2.** B3LYP/cc-pVTZ/cc-pVTZ-PP structures of T1–T2, I1–I2, and P1–P2, as well as selected geometric parameters.

they appear in the potential energy surface for the reaction of THF with Br. Thus,  $\alpha$ -hydrogen abstraction appears to be more favourable than  $\beta$ -hydrogen abstraction from THF. This site preference is due to the fact that the Br-atom interaction with the H atom at the  $\alpha$  position is stabilized by hyperconjugation with the oxygen lone pair of electrons. This stabilization effect is, however, absent when Br is coordinated to the  $\beta$  hydrogen. Among the complexes, the addition complex (C1 or C2) is interestingly predicted to be the most stable complex. However, we failed to connect these species to any reaction. Hence, our calculation supports the postulate that the only significant channel for hydrogen abstraction from ethers by a Br atom is the removal of a hydrogen atom adjacent to the ether oxygen (see ref. 8 and the refs. cited therein).

The analysis to this point suggests that the reaction of THF with Br is governed by the addition complexes M1 and M2, which are linked to the reaction products via intermediates, I1 and I2, respectively:

As evident from Figs. 4 and 5, the hydrogen abstraction does not occur directly from these addition complexes, but requires H-atom transfer from the  $\alpha$  carbon to the ether oxygen to form a predissociative complex,  $\text{C}_4\text{H}_7\text{O}^\bullet \cdots \text{HBr}$ . Here, HBr is coordinated to the oxygen atom at either the axial (I1) or equatorial (I2) position. We were able to locate the transition states (T1 and T2) for the conversions of M1 to I1 and M2 to I2, respectively. These transition states are product-like, with the HBr molecule simultaneously weakly

bound to the  $\alpha$  carbon and the oxygen via the abstracted hydrogen. Their structures are depicted in Fig. 2. As the relative energies of all species computed at the CCSD and MP4(SDQ) levels of theory concur well within the uncertainty of the calculations, we focus below on the results of our kinetic analysis based on the CCSD energies depicted in Fig. 4 to avoid confusion. However, one would reach to the same conclusion with the MP4(SDQ) potential energy surface displayed in Fig. 5.

The thermal stability of the complexes M1 and M2, with respect to the reactants, is calculated to be 4.5 and 2.1 kJ/mol, respectively. The formation of M2 at MP4(SDQ) is almost thermoneutral. For the elementary step M1  $\rightarrow$  I1, T1 is located 4.2 kJ/mol above M1 and 2.2 kJ/mol above I1, whereas for the M2  $\rightarrow$  I2 step, T2 lies 9.0 and 8.9 kJ/mol

above M2 and I2, respectively. It is interesting to note here that the two predissociative adducts I1 and I2 are of similar stability with respect to the reactants. This phenomenon can be accounted for by the fact that the C<sub>4</sub>H<sub>7</sub>O<sup>•</sup> fragments of I1 and I2 are almost identical and HBr is only loosely bound to the oxygen atom through long-range interaction. The computed O $\cdots$ H distances are 1.902 and 1.892 Å for I1 and I2, respectively, and the H–Br bond is only marginally stretched by 0.02 Å. The unimolecular dissociation of these loose complexes to release HBr proceeds without a distinct energy barrier and these loose dissociation pathways are endothermic by 16.1 kJ/mol.

The formation of M2 is less exothermic than it is for M1 and it has a more pronounced energy barrier for H migration to the ether oxygen to form a predissociative complex (I2).

**Fig. 3.** Arrhenius plot for the reaction of Br atoms with THF. (●) Experimental data from our previous work.<sup>8</sup> (· · ·), (---), and (—) are the results of eq. [6] using the energies at the B3LYP, CCSD, and MP4(SDQ) level of theory, respectively. The inset figure magnifies a portion of the Arrhenius plot to show the agreement between the theoretical and experimental results.

**Fig. 4.** CCSD/cc-pVTZ energy diagram for the THF and Br reaction. All energies are ZPE-corrected at 0 K.

At  $T = 293$  K, we calculated the rate coefficient for the step [2b],  $k_{2b}$ , to be  $4.0 \times 10^{11} \text{ s}^{-1}$ , which is 16 times smaller than  $k_{1b}$ . The ratio ( $k_{1b}/k_{2b}$ ) = 11.7 even at  $T = 353$  K, the highest temperature of our experiments.<sup>8</sup> Accordingly, the H-abstraction reaction via M2 is unimportant and therefore will not be considered for further kinetic analyses. Therefore, the reaction of THF with Br appears to proceed only via M1 with the reaction sequence [1a]–[1c].

It is evident from Fig. 4 that the reaction [–1b] has a lower threshold energy than the reaction [1c]. Despite the fact that the reaction [1c] is a loose dissociation pathway and an entropically favoured path, the reaction [–1b] appeared to be at least 10 times faster than reaction [1c], even at  $T = 353$  K. This was verified by comparing the rate coefficients for reaction [–1b],  $k_{-1b} = k_{1b}/K_{1b}$  with the rate coefficient for reaction [1c], see Table 2. The simplified

**Fig. 5.** MP4(SDQ)/cc-pVTZ energy diagram for the THF and Br reaction. All energies are ZPE-corrected at 0 K.

statistical adiabatic channel model (s-SACM)<sup>23–25</sup> was employed to calculate the high pressure rate coefficients for reaction [1c]. In these calculations, I1 was treated as a quasi-triatomic prolate symmetric top, whereas the fragments P1 and HBr were considered as spherical top and linear, respectively. Within the s-SACM model, the evaluation of two empirical parameters, namely the looseness parameter ( $\alpha$ ) and the Morse parameter ( $\beta$ ), is required. The choice of the ratio,  $\alpha/\beta$  (anisotropy parameter), is crucial as it determines the quality of the predicted high pressure rate coefficients. The Morse parameter ( $\beta$ ) is calculated from the following expression:

$$[4] \quad \beta = \sqrt{\frac{2\pi^2\mu}{Dh^2}} \varepsilon_{RC}$$

where  $\varepsilon_{RC}$  is the energy of the vibrational mode describing the motion along the reaction coordinate,  $\mu$  is the reduced mass of the fragments, and  $D$  is the Morse dissociation energy, which can be calculated from the zero-point energies,  $E_{zn}$  and  $E_{zp}$  for the reactant and fragments, respectively:

$$[5] \quad D = \Delta H_0 + E_{zn} - E_{zp}$$

Generally,  $\alpha$  is considered as the fitting parameter, the value of which is chosen to get the best fit with the experimental data. However, after a rigorous study for a number of reaction systems, Cobos and Troe<sup>29</sup> found a standard value of  $0.46 \pm 0.07$  for the anisotropy parameter,  $\alpha/\beta$ . For our calculations, we set this ratio equal to 0.46. All the other internal parameters are taken from our quantum chemical calculations and there is no other adjustable parameter. The results are compiled in Table 2. As the reaction [1c] has the highest threshold energy in the reaction sequence [1a]–[1c], it represents the rate-determining step for the overall reaction of the Br atom with THF. This is obvious when the rate coefficients compiled in Table 2 are compared. Therefore, it follows that M1 is in equilibrium with I1 and the reactants, which is rapidly established and virtually not affected by the reaction [1c]. Accordingly, this allows the overall rate

coefficient ( $k_{ov}$ ) for the title reaction to be approximated reasonably well with the following expression:

$$[6] \quad k_{ov,calcd}(T) = K_{1a}(T)K_{1b}(T)k_{1c}(T)$$

The values of  $k_{ov,calcd}(T)$  obtained in this way at CCSD energies are higher by a factor of 2 at all temperatures when compared with the experimental ones. However, the calculated overall rate coefficients using the energy profile from MP4(SDQ) calculations are in excellent agreement with our experimental values,<sup>8</sup> which is demonstrated in Fig. 3. The rate coefficients calculated on the basis of the MP4(SDQ) PES for the reaction sequence [1a]–[1c] are summarized in Table 3. It is further encouraging to notice here the agreement between the calculated overall endothermicity of 16.7 kJ/mol and the experimentally determined activation energy of  $(18.6 \pm 1.8)$  kJ/mol for this reaction. This agreement further supports our earlier assumption that the H-abstraction reaction of THF by the Br atom is, indeed, at the high pressure limit. The calculated rate coefficients using MP4(SDQ) energies and eq. [6] in the temperature range of 273–363 K for the reaction of Br atoms with THF can be given by the following Arrhenius expression:

$$[7] \quad k_{ov,calcd}(T) = 5.03 \times 10^{-10} \exp[-18.9/(RT)]$$

## Conclusion

The reaction mechanism for abstraction of a hydrogen atom from THF by atomic bromine was found to be analogous to the reactions of the Br atom with dioxane<sup>9</sup> and methanol,<sup>26</sup> where the reaction proceeds via an addition–elimination mechanism. Our quantum chemical calculations show that the attack by Br on an H atom of THF results in four stable associative complexes, M1–M4, whereas the addition of Br to the ether oxygen yields two more adducts, namely C1 and C2. The latter complexes are not found to link to any reactions. Hence, they are believed to play no role in the reaction kinetics of the Br atom with THF, though they appear in the reaction mechanism. Subsequent calculations showed that the only channel responsible for the overall rate coefficient of the reaction is the one that exits through M1. Before M1 can decompose into the products, it has to undergo an intramolecular H abstraction to yield I1 (reaction [1b]), which eventually liberates HBr via a loose dissociation pathway. The B3LYP level of theory was found to be inadequate to describe the energetics of this system. This is evident when the calculated overall endothermicity of 1.9 kJ/mol at 0 K (almost a thermoneutral reaction) is compared with the experimental value of  $19 \pm 6$  kJ/mol. In an effort to better understand the energetics of this reaction, we further employed single-point calculations at the CCSD and MP4(SDQ) levels of theory to recompute the potential energy surfaces. This approach predicted an overall reaction enthalpy at 0 K of about 16.5 kJ/mol, which matched very well with the experimental value. As the final step, reaction [1c], has the highest threshold energy, it is calculated to be the rate-determining step. Whereas the rate coefficient calculations at CCSD energies overpredicted the experimental rate coefficients by a factor of two at all tem-

# Theoretical study of the microwave spectrum of isotopologues of OCS–(He)<sub>2</sub>

Hui Li, Yongdong Liu, Wolfgang Jäger, Robert J. Le Roy, and Pierre-Nicholas Roy

**Abstract:** The rovibrational energy levels ( $J = 0-3$ ) and rotational spectra of seven isotopologues of the OCS–(He)<sub>2</sub> complex have been determined by numerically exact basis set calculations. The interaction energy is represented as a sum of two-body terms consisting of the OCS–He potential, which Howson and Hutson (*J. Chem. Phys.* **2001**, *115*, 5059) obtained at the CCSD(T)/aug-cc-pVTZ level of theory, and the He–He potential that Jeziorska et al. (*J. Chem. Phys.* **2007**, *127*, 124303) obtained with SAPT theory. Three-body effects and the quality of the potential are discussed. Comparison with experiment shows that microwave transitions can be predicted by this additive approach with an accuracy equal or better than 0.7% for all the observed spectral lines. A method for the three-dimensional representation of the helium density in the body-fixed frame is presented that highlights the highly delocalized nature of the helium subsystem.

**Key words:** weakly bound clusters, quantum clusters, exact bound state calculations, microwave spectroscopy, rotational dynamics.

**Résumé :** Utilisant des ensembles de base numériquement exacts, on a calculé les niveaux d'énergie rovibrationnels ( $J = 0-3$ ) et les spectres rotationnels de sept isotopologues du complexe OCS–(He)<sub>2</sub>. L'énergie d'interaction est représentée par la somme de termes à deux corps formée du potentiel OCS–He que Howson et Hutson (*J. Chem. Phys.* **2001**, *115*, 5059) ont déterminé au niveau CCSD(T)/aug-cc-pVTZ de la théorie et du potentiel He–He que Jeziorska et al. (*J. Chem. Phys.* **2007**, *127*, 124303) ont déterminé à l'aide de la théorie des perturbations adaptée pour la symétrie (TPAS). On discute aussi des effets de trois corps et de la qualité du potentiel. Une comparaison des résultats des calculs avec des résultats expérimentaux montre que les transitions de microondes peuvent être mieux prédites par cette approche additive, avec une précision égale ou meilleure à 0,7 % pour toutes les raies spectrales observées. On présente une méthode de représentation tridimensionnelle de la densité de l'hélium dans un squelette à corps fixes qui est caractérisé par la nature hautement délocalisée du sous-système de l'hélium.

**Mots-clés :** agrégats faiblement liés, agrégats quantiques, calculs exacts de l'état lié, spectroscopie de microondes, dynamique rotationnelle.

## Introduction

Doped helium clusters offer a unique opportunity to understand quantum solvation and microscopic superfluidity, and this topic has been the subject of several studies in recent years.<sup>1–13</sup> Helium clusters doped with carbonyl sulfide (OCS) are of particular interest, because the OCS chromophore was the dopant used to provide the first evidence of microscopic superfluidity in helium nanodroplets.<sup>1</sup> In that seminal work, it was found that the OCS molecule undergoes nearly free rotational motion with a renormalization of its moment of inertia owing to its coupling to the helium environment, and the nearly free nature of that rotational motion was attributed to superfluidity. Since that time, helium clusters doped with OCS have become the focus of numer-

ous experimental and theoretical studies.<sup>4,7,11,14–18</sup> In particular, Xu and Jäger<sup>3,6</sup> and Tang and McKellar<sup>4,7</sup> have gone beyond the traditional binary or ternary complex limit to obtain infrared and microwave spectra of OCS–(He)<sub>N</sub> clusters for  $N = 2-8$ . In addition to being a technical breakthrough, that work hinted at the onset of superfluidity and provided benchmark challenges for theoretical studies.

To fully understand the experimental spectra on the atomic scale, computer simulation studies are important and necessary,<sup>19,20</sup> and a number of theoretical studies of OCS–(He)<sub>N</sub> clusters based on quantum Monte Carlo techniques have been reported.<sup>14–18,21</sup> Such techniques have also been applied to He clusters containing other dopants such as N<sub>2</sub>O,<sup>22,23</sup> CO<sub>2</sub>,<sup>20,24,25</sup> and HCCCN,<sup>26</sup> yielding excellent agreement with experiment. To date, however, exact quan-

**Fig. 1.** Illustration of the coordinate system used in the bound-state calculations: M is the centre of mass of OCS and B is the canonical point for the Radau vectors  $\mathbf{r}_1$  and  $\mathbf{r}_2$ , and  $\mathbf{q}_1$  and  $\mathbf{q}_2$  are the Jacobi vectors and  $\mathbf{r}_0$  is a vector defining the axis of the OCS molecule;  $\phi$  is a dihedral angle between  $\mathbf{r}_1 \times \mathbf{r}_0$  and  $\mathbf{r}_2 \times \mathbf{r}_0$ , and  $\theta_1$  and  $\theta_2$  are angles between  $\mathbf{r}_0$  and  $\mathbf{r}_1$  and  $\mathbf{r}_2$ , respectively.

tum calculations on  $\text{OCS}-(\text{He})_N$  clusters have been restricted to the  $\text{He}-\text{OCS}$  dimer.<sup>18,27</sup> The present paper extends this work to the case of two helium atoms with OCS. In the remainder of this paper, details of the theory and computational procedure are given in the Theory and methods section, results are presented and discussed in the Results

and discussion section, and concluding remarks appear in last section.

## Theory and methods

### General

The methodology used in this work is based mainly on the work of Wang, Carrington, and co-workers<sup>28</sup> and on fundamental ideas presented by Mladenovic.<sup>29</sup> The Wang and Carrington group applied their approach to the  $\text{N}_2\text{O}-(\text{He})_2$  system and were able to reproduce experimentally observable rovibrational transitions quite accurately. Recently, they also applied their approach to  $\text{CO}_2-(\text{He})_2$  and to  $\text{CO}-(\text{He})_2$ , again with great success.<sup>30,31</sup> The method is briefly reviewed here, and the reader is referred to ref. 28 for further details.

The rovibrational Hamiltonian of the  $\text{OCS}-(\text{He})_2$  complex in the body-fixed frame has the following form (in au):<sup>28,29,32,33</sup>

$$[1] \quad \hat{H} = \hat{T}_{\text{str}} + \hat{T}_{\text{diag}} + \hat{T}_{\text{off}} + \hat{T}_{\text{Cor}} + \bar{V}(r_1, r_2, \theta_1, \theta_2, \phi)$$

with

$$[2] \quad \hat{T}_{\text{str}} = -\frac{1}{2m_{\text{He}}} \frac{\partial^2}{\partial r_1^2} - \frac{1}{2m_{\text{He}}} \frac{\partial^2}{\partial r_2^2}$$

$$[3] \quad \hat{T}_{\text{diag}} = -\left(\frac{1}{2m_{\text{He}}r_1^2} + B_{\text{OCS}}\right) \left[ \frac{\partial^2}{\partial \theta_1^2} + \cot \theta_1 \frac{\partial}{\partial \theta_1} - \frac{1}{\sin^2 \theta_1} (\hat{J}_z - \hat{l}_{2z})^2 \right] + \left(\frac{1}{2m_{\text{He}}r_2^2} + B_{\text{OCS}}\right) \hat{l}_2^2 + B_{\text{OCS}} [\hat{J}^2 - 2(\hat{J}_z - \hat{l}_{2z})^2 - 2\hat{J}_z \hat{l}_{2z}]$$

$$[4] \quad \hat{T}_{\text{off}} = B_{\text{OCS}} (\hat{l}_{2+} \hat{a}_1^- + \hat{l}_{2-} \hat{a}_1^+)$$

$$[5] \quad \hat{T}_{\text{Cor}} = -B_{\text{OCS}} (\hat{J}_- \hat{a}_1^+ + \hat{J}_+ \hat{a}_1^- + \hat{J}_- \hat{l}_{2+} + \hat{J}_+ \hat{l}_{2-})$$

in which

$$[6] \quad \hat{J}_{\pm} = \hat{J}_x \pm i\hat{J}_y, \quad \hat{l}_{2\pm} = \hat{l}_{2x} \pm i\hat{l}_{2y}$$

$$[7] \quad \hat{a}_1^{\pm} = \pm \frac{\partial}{\partial \theta_1} - \cot \theta_1 (\hat{J}_z - \hat{l}_{2z})$$

Details of the coordinate system are presented in Fig. 1, where  $r_1$  and  $r_2$  are the lengths of Radau (or orthogonalized satellite) vectors  $\mathbf{r}_1$  and  $\mathbf{r}_2$ , which are linear combinations of the Jacobi (or satellite) vectors  $\mathbf{q}_1$  and  $\mathbf{q}_2$  from the centre of mass of OCS to the He atoms.<sup>29</sup> The polyspherical angles ( $\theta_1$ ,  $\theta_2$ , and  $\phi$ ) are determined by the three vectors ( $\mathbf{r}_0$ ,  $\mathbf{r}_1$ , and  $\mathbf{r}_2$ ), where  $\mathbf{r}_0$  is a vector along the axis of OCS,  $m_{\text{He}}$  is the mass of the He atom, and  $B_{\text{OCS}}$  is the inertial rotation constant of OCS. The operators  $\hat{J}_x$ ,  $\hat{J}_y$ , and  $\hat{J}_z$  are the components of the total angular momentum operator  $\hat{J}$  in the body-fixed frame, the  $z$  axis of the body-fixed frame lies along the Jacobi radial vector  $\mathbf{r}_0$ , and its  $x$  axis is in the plane that contains the vector  $\mathbf{r}_0$  and one He atom.  $\bar{V}(r_1, r_2, \theta_1, \theta_2, \phi)$  is the total potential represented as a sum of two He-OCS poten-

tials plus the He-He intermolecular potential. The above Hamiltonian contains full vibration-rotation coupling.

### Basis function and matrix elements

A discrete variable representation (DVR) grid<sup>34</sup> is used for the radial degree of freedom, while parity-adapted rovibrational basis functions are used for the angular part. The latter are linear combinations of the functions

$$[8] \quad \langle \theta_1, \theta_2, \phi; \alpha, \beta, \gamma | l_1, l_2, m_2; J, K, M \rangle = \sqrt{\frac{2J+1}{8\pi^2}} \Theta_{l_1}^{K-m_2}(\theta_1) Y_{l_2}^{m_2}(\theta_2, \phi) D_{M,K}^{J*}(\alpha, \beta, \gamma)$$

with

$$[9] \quad Y_{l_2}^{m_2}(\theta_2, \phi) = \frac{1}{\sqrt{2\pi}} \Theta_{l_2}^{m_2}(\theta_2) e^{im_2\phi}$$

where  $\Theta_l^{m_2}$ ,  $Y_l^{m_2}$ , and  $D_{M,K}^J$  are, respectively, the normalized associated Legendre function with the  $(-1)^{m_2}$  Condon-Shortley phase factor,<sup>35</sup> spherical harmonic functions, and Wigner functions.<sup>35</sup> The body-fixed frame is related to the space-fixed frame via a rotation in the three Euler angles ( $\alpha$ ,  $\beta$ ,  $\gamma$ ). The projection of the total angular momentum  $J$  onto the space-fixed or body-fixed frame is given by  $M$  or  $K$ . Applying the parity operator  $\hat{E}^*$  to the rovibrational function has the effect

$$[10] \quad \hat{E}^* |l_1, l_2, m_2, K; J, M\rangle = (-1)^J |l_1, l_2, -m_2, -K; J, M\rangle$$

Parity-adapted basis functions may be written as

$$[11] \quad |l_1, l_2, m_2, K; J, M, P\rangle = \frac{1}{\sqrt{2(1 + \delta_{m_2,0}\delta_{K,0})}} |l_1, l_2, m_2, K; J, M\rangle + (-1)^{J+P} |l_1, l_2, -m_2, -K; J, M\rangle$$

where  $K \geq 0$  and  $P = 0$  or  $1$  correspond to even or odd parities, respectively. When  $K = 0$  the constraint  $m_2 \geq 0$  holds and the combination  $m_2 = K = 0$  and  $(-1)^{J+P} = -1$  is not allowed.

In the parity-adapted angular finite basis representation (FBR), the kinetic energy terms have simple matrix elements. The diagonal matrix elements are

$$[12] \quad \langle l_1, l_2, m_2, K; J, M, P | \hat{T}_{\text{diag}} | l_1, l_2, m_2, K; J, M, P \rangle = \frac{1}{2m_{\text{He}}r_1^2} l_1(l_1 + 1) + \frac{1}{2m_{\text{He}}r_2^2} l_2(l_2 + 1) + B_{\text{OCS}} l_1(l_1 + 1) + B_{\text{OCS}} [J(J + 1) + l_1(l_1 + 1) + l_2(l_2 + 1) - 2K^2 + 2m_2(K - m_2)]$$

and the three types of off-diagonal matrix elements are

$$[13] \quad \langle l_1, l_2, m_2 + 1, K; J, M, P | \hat{T}_{\text{off}} | l_1, l_2, m_2, K; J, M, P \rangle = \sqrt{1 + \delta_{m_2,0}\delta_{K,0}} B_{\text{OCS}} \lambda_{l_1, K-m_2}^- \lambda_{l_2, m_2}^+$$

$$[14] \quad \langle l_1, l_2, m_2, K + 1; J, M, P | \hat{T}_{\text{Cor}} | l_1, l_2, m_2, K; J, M, P \rangle = -\sqrt{1 + \delta_{m_2,0}\delta_{K,0}} B_{\text{OCS}} \lambda_{l_1, K-m_2}^+ \lambda_{l_2, K}^+$$

$$[15] \quad \langle l_1, l_2, m_2 + 1, K + 1; J, M, P | \hat{T}_{\text{Cor}} | l_1, l_2, m_2, K; J, M, P \rangle = -\sqrt{1 + \delta_{m_2,0}\delta_{K,0}} B_{\text{OCS}} \lambda_{l_2, m_2}^+ \lambda_{l_1, K}^+$$

with two special cases

$$[16] \quad \langle l_1, l_2, -m_2, 1; J, M, P | \hat{T}_{\text{Cor}} | l_1, l_2, m_2, 0; J, M, P \rangle = -(-1)^{J+P} B_{\text{OCS}} \lambda_{l_1, K-m_2}^- \lambda_{J,0}^- \quad (m_2 > 0)$$

$$[17] \quad \langle l_1, l_2, -m_2 + 1, 1; J, M, P | \hat{T}_{\text{Cor}} | l_1, l_2, m_2, 0; J, M, P \rangle = -(-1)^{J+P} B_{\text{OCS}} \lambda_{l_2, m_2}^- \lambda_{J,0}^- \quad (m_2 > 0)$$

where

$$\lambda_{l,m}^\pm = \sqrt{l(l+1) - m(m \pm 1)}$$

While the potential is not diagonal in the angular FBR, its matrix element integrals can be calculated in a grid representation via a three-dimensional transformation<sup>36</sup> for the  $\theta_1$ ,  $\theta_2$ , and  $\phi$  angles.<sup>28,36</sup> A Gauss–Legendre quadrature was used for the  $\theta_1$  and  $\theta_2$  angles, and Gauss–Chebyshev quadratures of the first and second kind were used to integrate  $\phi$  for even and odd parity cases, respectively. For  $J > 0$ , a Fourier transform method has been used for potential matrix–vector products.<sup>28,37</sup> The Lanczos algorithm was then used to calculate the rovibrational energy levels by recursively diagonalizing the discretized Hamiltonian matrix.<sup>38–40</sup> Projection operator techniques were used in combination with the Lanczos iteration method to compute symmetric states upon identical helium exchanges to properly account for the bosonic nature of the  $^4\text{He}$  atoms. This corresponds to a version of the symmetry-adapted Lanczos (SAL) algorithm<sup>41,42</sup> previously used for atomic trimers containing two or more bosonic atoms.<sup>28,43,44</sup> Eigenvectors were obtained using a second Lanczos recursion to avoid the storage of Lanczos vectors as previously done in ref. 43.

### Helium density in the body-fixed frame

To develop some intuitive feeling regarding the nature of these species, it is very useful to develop a three-dimensional representation of the helium part of the wave function in the body-fixed frame. In terms of the basis functions and Radau coordinate system, the wave function for the  $n$ th energy level for a given set of  $J$ ,  $M$ , and  $P$  quantum numbers is

$$[18] \quad \Psi_n^{J,M,P}(r_1, r_2, \theta_1, \theta_2, \phi; \alpha, \beta, \gamma) = \sum_{\alpha_1, \alpha_2, l_1, l_2, m_2, K} \langle \theta_1, \theta_2, \phi; \alpha, \beta, \gamma | l_1, l_2, m_2, ; J, K, M, P \rangle \langle r_1 | \alpha_1 \rangle \langle r_2 | \alpha_2 \rangle \times \langle \alpha_1, \alpha_2, l_1, l_2, m_2; J, K, M, P | \Psi_n^{J,M,P} \rangle$$

in which  $\langle r_j | \alpha_j \rangle$  is a localized DVR basis function for helium atom  $j$ , and the coefficient  $\langle \alpha_1, \alpha_2, l_1, l_2, m_2; J, K, M, P | \Psi_n^{J,M,P} \rangle$  is an eigenvector obtained via Lanczos diagonalization.

The three-dimensional density of the  $j$ th helium atom associated with  $\Psi_n^{J,M,P}$  is defined as

$$[19] \quad \rho_j^{J,M,P,n}(\mathbf{R}) = \int dr_1 dr_2 \sin \theta_1 d\theta_1 \sin \theta_2 d\theta_2 d\phi |\Psi_n^{J,M,P}(r_1, r_2, \theta_1, \theta_2, \phi; \alpha, \beta, \gamma)|^2 \delta(\mathbf{R} - \mathbf{R}_j[r_1, r_2, \theta_1, \theta_2, \phi])$$

in which  $\mathbf{R}_j[r_1, r_2, \theta_1, \theta_2, \phi]$  is the vector function that maps the Radau coordinates to the body-fixed Cartesian coordinates

**Note:** All of the observed transitions were *a*-type between levels within the *K*<sub>a</sub> = 0 stack. Δ*v*<sub>t</sub> is the transition energy between the first excited and ground torsion states of He<sub>2</sub> in OCS–He<sub>2</sub> complexes. *J*, total angular momentum.

(**R***j* = {*x*<sub>*j*</sub>, *y*<sub>*j*</sub>, *z*<sub>*j*</sub>}). The above integral can be evaluated on the same grid as the potential integral. However, because of the discrete nature of the Gaussian quadrature grid used for the integration, the density may not appear to be smooth. To obtain a smooth representation of the density, we use a Gaussian representation of the three-dimensional delta function that appears in eq. [19]

**Fig. 2.** Reduced rotational transition energy plot for <sup>16</sup>O<sup>12</sup>C<sup>32</sup>S–(He)<sub>2</sub>.

$$[20] \quad \delta(\mathbf{R} - \mathbf{R}_j[r_1, r_2, \theta_1, \theta_2, \phi]) \\ \approx \frac{1}{(2\pi)^{3/2} \sigma_x \sigma_y \sigma_z} e^{-(x-x_i)^2/2\sigma_x^2} e^{-(y-y_i)^2/2\sigma_y^2} e^{-(z-z_i)^2/2\sigma_z^2}$$

This expression reduces to an exact delta function in the limit where  $(\sigma_x, \sigma_y, \sigma_z) \rightarrow (0, 0, 0)$ . Using such a representa-

**Fig. 3.** Three-dimensional representation of the helium-atom density in the body-fixed frame. The position of the first helium defines the location of the *zx* plane, and its density is shown in black, whereas the density of the second He atom is shown in blue. These results were obtained with the values of the Gaussian standard deviations defining the densities set at  $\sigma_x = \sigma_z = 0.25$  Å and  $\sigma_y = 0.1$  Å for atom-1 and  $\sigma_x = \sigma_y = \sigma_z = 0.25$  Å for atom-2.

tion of the delta function amounts to performing a Gaussian binning of the density and leads to a smooth representation of the density, as will be illustrated in the following.

**Fig. 4.** As in Fig. 3, but with  $\sigma_x = \sigma_z = 0.1$  Å and  $\sigma_y = 0.05$  Å for atom-1 and  $\sigma_x = \sigma_y = \sigma_z = 0.1$  Å for atom-2.

## Results and discussion

### Bound-state energies and microwave spectrum

The rovibrational energy levels of seven isotopologues of the OCS-(He)<sub>2</sub> complex were calculated using the radial DVR and parity-adapted angular FBR methods described in the Theory and methods section. The inertial rotational constants  $B_{\text{OCS}}$  required for these calculations were fixed at the experimental values of 0.202 856 741 cm<sup>-1</sup> for <sup>16</sup>O<sup>12</sup>C<sup>32</sup>S, 0.202 204 019 cm<sup>-1</sup> for <sup>16</sup>O<sup>13</sup>C<sup>32</sup>S, 0.197 898 033 cm<sup>-1</sup> for <sup>16</sup>O<sup>12</sup>C<sup>34</sup>S, 0.197 194 087 cm<sup>-1</sup> for <sup>16</sup>O<sup>13</sup>C<sup>34</sup>S, 0.200 302 07 cm<sup>-1</sup> for <sup>16</sup>O<sup>12</sup>C<sup>33</sup>S, 0.190 293 341 cm<sup>-1</sup> for <sup>18</sup>O<sup>12</sup>C<sup>32</sup>S, and 0.196 258 106 cm<sup>-1</sup> for <sup>17</sup>O<sup>12</sup>C<sup>32</sup>S<sup>45–47</sup> and the masses were set at 4.002 603 24 u for <sup>4</sup>He, 15.994 914 635 u for <sup>16</sup>O, 16.999 131 5 u for <sup>17</sup>O, 17.999 160 3 u for <sup>18</sup>O, 12 u for <sup>12</sup>C, 13.003 354 826 u for <sup>13</sup>C, 31.972 070 70 u for <sup>32</sup>S, 32.971 458 43 u for <sup>33</sup>S, and 33.967 866 65 u for <sup>34</sup>S. The He-OCS and He-He potentials were taken from refs. 27 and 48, respectively. For  $r_1$  and  $r_2$ , 35 sine DVR basis functions were used on the domain 3.0–19.0 b. For the angular basis,  $l_{\text{max}} = m_{\text{max}} = 25$ , and 30 Gauss-Legendre quadrature points were used for each of  $\theta_1$  and  $\theta_2$ , while 64 equally spaced points on the range  $[0, 2\pi]$  were used for  $\phi$ . To accelerate the convergence of the Lanczos calculation, an energy ceiling of 1000 cm<sup>-1</sup> was imposed. This energy cutoff affected the low-lying levels by less than 0.001 cm<sup>-1</sup>.

The energies of the  $J = 0, 1, 2$ , and 3 rotational sublevels of the ground vibrational level for seven OCS-(He)<sub>2</sub> isotopologues are listed in Table 1, where  $P$  is the total parity. As shown there, the binding energy of the ground vibrational level of <sup>16</sup>O<sup>12</sup>C<sup>32</sup>S-(He)<sub>2</sub> is 37.9505 cm<sup>-1</sup>, which is approximately one-third of the total three-body well depth of 108.0896 cm<sup>-1</sup>. Because of our additive model, this well depth is exactly twice the 50.22 cm<sup>-1</sup> well depth<sup>27</sup> of He-OCS plus the 7.6496 cm<sup>-1</sup> depth of the He-He potential.<sup>48</sup> However, this ground-state level is bound by 0.6993 cm<sup>-1</sup> more than the twice the binding energy of the He-OCS dimer (18.625 cm<sup>-1</sup>)<sup>27</sup> plus the binding energy of the helium dimer (0.0012 cm<sup>-1</sup>),<sup>48</sup> which add up to 37.2512 cm<sup>-1</sup>. That additive value is expected to be approximate because it neglects the effect of correlation associated with the mixing of the two He-atom wave functions.

**Fig. 5.** He-atom density as a function of the azimuthal angle  $\phi$ .

Table 2 compares our calculated microwave transition energies with the experimental results of refs. 3 and 6. As shown there, the agreement is quite good, as the relative errors are never larger than 0.7%. The  $\Delta\nu_t$  torsional frequency values are also presented in Table 2. For additional comparison, the calculated microwave transitions were fitted to Watson's S-reduction Hamiltonian as an asymmetric top molecule and compared to the experimental results of ref. 6. All resulting spectroscopic constants are listed in Table 3. As shown in Table 3 for <sup>16</sup>O<sup>12</sup>C<sup>32</sup>S-(He)<sub>2</sub>, the fitted A, B, and C rotational constants agree well with experimental results, as the relative errors are less than 2%. However, for <sup>16</sup>O<sup>13</sup>C<sup>32</sup>S-(He)<sub>2</sub>, the errors are relatively larger than those of <sup>16</sup>O<sup>12</sup>C<sup>32</sup>S-(He)<sub>2</sub> isotopomer. This is in part due to the fact that the centrifugal distortion constants for all isotopologues were fixed to the same infrared value<sup>7</sup> of <sup>16</sup>O<sup>12</sup>C<sup>32</sup>S-(He)<sub>2</sub>. Another explanation for the discrepancy is the neglect of three-body terms in the interaction potential used in the calculations as discussed below.

It is evident that the  $J$  dependence of the residual discrepancies in Table 2 has the same systematic behaviour for all isotopologues: the theoretical  $1 \leftarrow 0$  transition frequencies are smaller than the experimental ones, whereas the experimental transition frequencies are larger in the  $3 \leftarrow 2$  and  $2 \leftarrow 1$  cases. This behaviour can be understood if we use a basic spectroscopic analysis to determine estimates of the leading rotational constants implied by these results. In particular, according to a standard spectroscopic analysis in which rotational energies are written as  $F(J) = B_v[J(J+1)] - D_v[J(J+1)]^2 + \dots$ , the expression for the rotational transition energies  $\Delta F(J) \equiv F(J+1) - F(J)$  may be rearranged into the form

$$[21] \quad \frac{\Delta F(J)}{2(J+1)} = B_v - 2D_v(J+1)^2 + 3H_v[(J+1)^2(J^2+2J+2)] \dots$$

Plots of the experimental and theoretical results for <sup>16</sup>O<sup>12</sup>C<sup>32</sup>S-He in the manner suggested by eq. [21] are presented in Fig. 2; the intercepts of these plots indicate the values of the inertial rotational constants  $B_v$  and the slopes the values of the leading centrifugal distortion constant  $D_v$ . The 0.77% difference between the experimental and theoretical  $B_v$  values and 17% difference between the corresponding

$D_v$  values are orders of magnitude larger than the discrepancies implied by the differences between the experimental and theoretical results for He–OCS obtained by Howson and Hutson.<sup>27</sup> Since our calculations are based on their He–OCS pair potential, and given that the He–He pair potential<sup>48</sup> is believed to be very reliable, we interpret these differences as being due to our neglect of nonadditive contributions to the overall interaction potential of our three-body system. The fact that the experimental values are larger than those obtained from our additive model would be consistent with the existence of an attractive three-body interaction.

### Helium density

Figures 3 and 4 present the three-dimensional density for the two helium atoms in the body-fixed frame as calculated for the ground state of OCS–(He)<sub>2</sub> using the procedure described in the Helium density in the body-fixed frame section. Iso-surfaces are used to represent the three-dimensional densities, and the  $z$  axis is defined to lie on the OCS molecular axis. The density of helium atom–1 is represented in black and that of helium atom–2 is shown in blue. Two sets of standard deviation parameters have been chosen to illustrate the smearing effect of the Gaussian binning. Larger values of  $\sigma_x = \sigma_z = 0.25$  Å and  $\sigma_y = 0.1$  Å for atom–1 and  $\sigma_x = \sigma_y = \sigma_z = 0.25$  Å for atom–2 are used in Fig. 3, whereas smaller values of  $\sigma_x = \sigma_z = 0.1$  Å and  $\sigma_y = 0.05$  Å for atom–1 and  $\sigma_x = \sigma_y = \sigma_z = 0.1$  Å for atom–2 are used in Fig. 4. We first observe that a smoother density is obtained with the larger standard deviation parameters, although the general features of the helium density are the same in both Figs. 3 and 4. The density will be accurately represented as long as the standard deviations are smaller than the characteristic length scale of the features of the wave function. The values chosen above obey this criterion.

One significant feature of these representations is the fact that the two helium atoms appear to have very different density distributions. This is an artifact of the fact that the position of helium atom–1 is used to define the  $xz$  plane of the body-fixed frame, and its density is therefore completely localized with respect to the  $y$  direction. Indeed, the only reason that its density distribution appears to have nonzero width in the  $y$  direction (the thickness of the black “disk”) is the use of a finite bin size ( $\sigma_y > 0$ ) in the calculation. The density of helium atom–1 is of course somewhat delocalized in the  $xz$  plane, but it is centred at the minimum of the potential energy surface.

The second helium atom is clearly highly delocalized relative to the first, being distributed on a “sausage”-shaped incomplete ring about the OCS molecule axis. In Figs. 3 and 4 it appears to have a uniform density as a function of the azimuthal angle  $\phi$ , apart from the region near atom–1 whence it is excluded by the short-range repulsive wall of the He–He potential. However, Fig. 5 shows that the “partial density” obtained by integrating the density of He atom–2 with respect to  $R$  and  $z$  at each value of  $\phi$  has interesting substructure. In particular, in addition to the expected excluded volume near  $\phi = 0^\circ$  and  $360^\circ$ , there are small but distinct local maxima at  $\phi = 101^\circ$  and  $259^\circ$  corresponding to the two He atoms lying  $\sim 5.4$  Å apart. This distance is almost double the He–He potential equilibrium distance of  $r_e =$

$2.968$  Å, but is much smaller than the  $45.6$  Å expectation value of the internuclear distance in the ground state of an isolated He<sub>2</sub> molecule, since the relatively strong He–OCS potential constrains the two He atoms to lie within a ring about the axis of the OCS. However, the weakness of the He–He potential means that over a  $\phi$  range of almost  $180^\circ$  the two He atoms move almost freely relative to one another. Note that the present structural analysis is consistent with Fig. 2 of ref. 49, and the findings of Wang and Carrington and co-workers for the related He<sub>2</sub>–N<sub>2</sub>O.<sup>28</sup>

### Concluding remarks

Calculated rovibrational energy levels and microwave transitions for seven OCS–(He)<sub>2</sub> isotopologues have been obtained from using a global potential energy surface defined as a sum of accurate He–OCS and He–He pair potentials. The predicted microwave transitions are in fairly good agreement with experiment, but small systematic residual differences are attributed to our neglect of three-body contributions to the interaction. A new approach for visualizing the helium density in the body-fixed frame is introduced that shows that for the ground state, relative to the first, the second helium atom lies in a sausage-shaped incomplete ring about the OCS axis, with a region of excluded density owing to the helium–helium repulsion. This study is complementary to one by Wang and Carrington,<sup>49</sup> for this same OCS–(He)<sub>2</sub> system in the August 2010 issue of this journal—they focus more on the infrared spectra and the intramolecular vibrational structure and consider only the most abundant isotopologues. Although they use different interaction potentials, their results are in general agreement with ours.

### Acknowledgments

The authors thank Professor T. Carrington, Jr. and Dr. X.-G. Wang for helpful discussions. Drs. H.-G. Yu and N. Blinov are also gratefully acknowledged for useful suggestions. This research has been supported by the Natural Sciences and Engineering Research Council of Canada (NSERC), the Canada Foundation for Innovation (CFI), and the University of Waterloo. We thank the Shared Hierarchical Academic Research Computing Network (SHARCNET) for computing time.

# Configurations and conformations of glycosyl sulfoxides

Hong Liang, Micheline MacKay, T. Bruce Grindley, Katherine N. Robertson, and T. Stanley Cameron

**Abstract:** X-ray crystallographic studies of two axial glycosyl sulfoxides having  $R_S$  configurations (derivatives of phenyl 2-azido-2-deoxy-1-thio- $\alpha$ -D-galactopyranoside *S*-oxide) show that they adopt anti conformations in the solid state, in contrast to previous observations and assumptions. Density functional theory (DFT) calculations at the B3LYP6-311G+(d,p)/6-31G(d) level confirm that anti conformations of both phenyl and methyl  $R_S$  glycosyl sulfoxides of 2-azido-2-deoxy- $\alpha$ -D-pyranosides are more stable than exo-anomeric conformations in the gas phase. 1D NOE measurements indicate that the more polar exo-anomeric conformers are only populated to a slight extent in solution. The anti conformations are distorted so that the glycosyl substituents are closer to being eclipsed with H1. This distortion allows S  $n \rightarrow \sigma^*$  overlap if the sulfur lone pair is a p-type lone pair. Evidence for this overlap comes from short C1–S bond distances, as short as the comparable bond distances in the X-ray crystal structure and in the results from DFT calculations for the  $S_S$  glycoside, which does adopt the expected exo-anomeric conformation, both in the solid state and in solution, and has normal  $n \rightarrow \sigma^*$  overlap. For 2-deoxy derivatives not bearing a 2-azido group, gas-phase DFT calculations at the same level indicate that the anti- and exo-anomeric conformers have comparable stabilities. Comparison of the results of the two series shows that electro-negative substituents in equatorial orientations at C2 destabilize conformations with parallel S–O arrangements, the conformation favored by having an endocyclic C–O dipole antiparallel to the S–O dipole, by about 2.5 kcal mol<sup>−1</sup> (1 cal = 4.184 J). An equatorial glycosyl sulfoxide, ( $S_S$ ) phenyl 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-1-thio- $\beta$ -D-glucopyranoside *S*-oxide, also adopts an anti conformation in the solid state as shown by X-ray diffraction. It also adopts this conformation in solution, in contrast to studies of other equatorial glycosyl sulfoxides.

**Key words:** sulfoxide configurations, glycosyl sulfoxides, conformational analysis, density functional theory (DFT) calculations, 1D NOE measurements, X-ray crystallography.

**Résumé :** Des études de cristallographie par diffraction des rayons-X de deux glycosyles sulfoxydes axiaux de configurations  $R_S$ , des dérivés du *S*-oxyde de 2-azido-2-désoxy-1-thio- $\alpha$ -galactopyranoside de phényle, montrent qu'ils adoptent des conformations anti à l'état solide, contrairement aux observations antérieures et aux hypothèses. Des calculs selon la théorie de la fonctionnelle de la densité (TFD) au niveau B3LYP6-311G+(d,p)/6-31G(d) confirment que les conformations anti que, en phase gazeuse, chacun des  $R_S$  glycosyles sulfoxydes, 2-azido-2-désoxy-1-thio- $\alpha$ -galactopyranoside tant de méthyle que de phényle sont plus stable dans les conformations anomères exo. Des mesures d'effet Overhauser nucléaire (eOn) 1D indiquent que, en solution, les conformères anomères les plus polaires ne forment qu'une faible partie de la population. Les conformations anti sont déformées de façon à ce que les substituants glycolyses soient dans une position pratiquement éclipse avec le H1. Cette distorsion permet un recouvrement S  $n \rightarrow \sigma^*$  sur la paire libre du soufre est une paire libre de type p. Un support pour ce recouvrement vient des courtes longueurs de liaison C1–S, pratiquement aussi courtes que les longueurs mesurées par diffraction des rayons-X dans la structure cristalline et en accord avec les résultats des calculs TFD pour le  $S_S$  glycoside qui adopte la conformation anomère exo attendue, tant à l'état solide qu'en solution, et pour le recouvrement  $n \rightarrow \sigma^*$  normal. Pour les dérivés 2-désoxy ne portant pas de groupe azido, les calculs de TFD en phase gazeuse, au même niveau, indiquent que les conformères anomères anti et exo ont des stabilités comparables. Une comparaison des résultats des deux séries montre que les substituants électronégatifs en orientations équatoriales en C2 déstabilisent les conformations avec des arrangements S–O parallèles, la conformation favorisée par un dipôle C–O endocyclique antiparallèle au dipôle S–O par environ 2,5 kcal mol<sup>−1</sup> (1 cal = 4.184 J). La diffraction des rayons-X montre aussi que, à l'état solide, un glycosyle sulfoxyde équatorial, le *S*-oxyde du  $S_S$  3,4,6-tri-*O*-acétyl-2-désoxy-2-phthalimido-1-thio- $\beta$ -D-glucopyranoside de phényle, adopte aussi une conformation anti. Il adopte aussi cette conformation en solution, en opposition à ce qui a été observé dans les études sur glycosyles sulfoxydes équatoriaux.

## Introduction

One of the most important techniques for the formation of glycosides employs glycosyl sulfoxides activated by electrophiles as leaving groups.<sup>1</sup> This method has been used to form glycosides that have widely varying structures for both the glycosyl donors and aglycones.<sup>2–14</sup> The activated sulfoxide is sufficiently reactive that reactions in solution can be conducted at  $-78^{\circ}\text{C}$  and it can also be used in solid-phase reactions.<sup>15</sup> The configuration of the sulfoxide does not influence the stereochemistry of glycosylation reactions but does affect the rate of glycosylation reactions<sup>16</sup> and the rates of competing elimination and hydrolysis reactions.<sup>17,18</sup> The stabilities of the different sulfoxide diastereomers and the physical properties of the diastereomers are inherently linked to the conformations that they adopt. The conformations are termed *exo* if the aglycone is *gauche* to both the ring oxygen atom and H1 and *anti* if the aglycone is *anti* to the ring oxygen as shown in Figs. 1 and 2. The staggered conformations where the aglycone is *gauche* to both the ring oxygen and C2 are much less stable and will not be considered here.

It has been assumed that these conformations are influenced primarily by the tendency of the aglycones to adopt *exo* conformations, the *exo*-anomeric effect,<sup>19–22</sup> with contributions from repulsion between C–O and S–O dipoles.<sup>23</sup> The *exo*-anomeric effect is a result of several factors:<sup>24,25</sup>  $n \rightarrow \sigma^*$  donation,<sup>26</sup> dipole dipole repulsion, reduced steric interactions, and electrostatic attraction.<sup>27</sup> Glycosyl sulfoxides provide platforms that allow the examination of the geometrical effects of the contributions of  $n \rightarrow \sigma^*$  donation on conformer stability because the availability of two diastereomers allows the contributions of the two lone pairs to be evaluated individually, albeit with the complication of an additional polar S–O bond. We will show herein that the *exo*-anomeric effect is much less dominant in controlling the conformations of glycosyl sulfoxides than that of glycosyl sulfides or of normal glycosides and that C–O S–O dipole repulsion is less important than previously thought. We will also show that the conformer stabilities are consistent with the sulfoxide lone pair being a *p*-type lone pair, rather than an *sp*<sup>3</sup> lone pair.

Crich et al.<sup>23,28</sup> observed that oxidation of axial thioglycosides on pyranose rings gave one stereoisomer predominantly, the *R*<sub>S</sub> isomer for  $\alpha$ -D-pyranosides. Stereoselectivity is particularly high if the pyranoside rings are made rigid by fusion to 4,6-*O*-benzylidene acetals.<sup>29,30</sup> The stereoselectivity attained is consistent<sup>23</sup> with kinetically controlled oxidation of the accessible face of the sulfur atom in the most stable conformer of the thioglycoside, the conformer favored by the *exo*-anomeric effect. This group<sup>23</sup> and others<sup>31</sup> observed that oxidation of equatorial sulfoxides was unselective. Khiar et al.<sup>17,26</sup> also found that oxidation of O2-protected equatorial thioglycosides was normally unselective but noted that oxidation of O2-unprotected equatorial thioglycosides is highly diastereoselective. A few O2-substituted equatorial thioglycosides were also found to exhibit highly selective oxidations; peresters of  $\beta$ -thiophenyl or  $\beta$ -ethyl 2-tetrachlorophthalimido-2-deoxy-D-glucopyranosides gave diastereomeric ratios  $>9:1$ .<sup>17</sup>

The assignment of configuration of the product sulfoxides has been based on results from X-ray crystallogra-

phy,<sup>16,17,23,28,32–34</sup> augmented by empirical rules developed from NMR measurements<sup>26</sup> and from the use of chiral shift reagents.<sup>33,35</sup> Khiar<sup>26</sup> proposed two methods for making assignments directly based on NMR results. For ethyl sulfoxides, the methylene protons of the ethyl group are diastereotopic. For equatorial sulfoxides of D-pyranosides, the chemical shift differences between the <sup>1</sup>H NMR signals of these diastereotopic protons are considerably larger for the *R*<sub>S</sub> isomer than the *S*<sub>S</sub> isomer.<sup>17,26</sup> This observation has been rationalized in terms of the assumption that the major conformations present for the *R*<sub>S</sub> sulfoxides are those in which the ethyl group adopts the *exo* orientation,<sup>26</sup> which agreed with results from semiempirical (AM1) calculations.<sup>33</sup> This conformation of the *R*<sub>S</sub> sulfoxides has the sulfoxide sulfur lone pair *anti* to the C1–O5 bond, aligned so that  $n \rightarrow \sigma^*$  overlap can occur (see Figs. 1 and 2). Crich et al.<sup>23</sup> commented in a footnote that they have observed several exceptions to the tendency for the methylene protons of ethyl sulfoxides to have larger chemical shift differences in particular diastereomers.

The second method proposed for assigning sulfoxide configurations from NMR spectral measurements was based on the <sup>13</sup>C NMR chemical shifts of anomeric carbons; those for *R*<sub>S</sub> sulfoxides of equatorial D-pyranosides are more shielded by  $>2$  ppm for both aryl and alkyl sulfoxides.<sup>17,26</sup> For axial sulfoxides of D-pyranosides, the minor *S*<sub>S</sub> isomer exhibits the more shielded anomeric carbon and the larger chemical shift difference between the diastereotopic protons of ethyl sulfoxides.<sup>17</sup> The larger shielding was attributed to the  $n \rightarrow \sigma^*$  overlap mentioned above.<sup>26</sup> If it is assumed that the contribution of conformers with the aglycone *gauche* to both the ring oxygen and C2 are negligible, this arrangement only occurs in the *exo* conformation of the equatorial *R*<sub>S</sub> sulfoxide of D-sugars and in the *exo* conformation of the minor *S*<sub>S</sub> isomer of axial sulfoxides (see Figs. 1 and 2).

Crich et al.<sup>23</sup> have suggested that S–O C1–O5 dipole repulsion is very important in determining the conformations of axial sulfoxides. For  $\alpha$ -D-pyranosides, the *R*<sub>S</sub> sulfoxide, which is the major product of oxidation, has the S–O group *anti* to the ring C1–O5 bond if the conformation adopted is that favored by the *exo*-anomeric effect. This group has interpreted equilibration results on glycosyl allyl sulfoxides in terms of the importance of dipole–dipole repulsion.<sup>23</sup>

Most of the conclusions about sulfoxide conformation and configuration have been based on X-ray crystallography,<sup>16,17,23,28,32–34</sup> supported by AM1 calculations.<sup>33</sup> With one exception,<sup>23</sup> the ten glycosyl sulfoxides previously studied adopted conformations in the solid state with the sulfoxide alkyl or aryl group in the *exo*-anomeric conformation. This paper was prompted by our studies of three glycosyl phenyl sulfoxides, all of which adopt conformations in the solid state with the phenyl group *anti* to the ring C–O bond. We report these crystallographic studies here. In addition, NMR studies have been performed in which NOE buildup rates have been used to determine the preferred conformations of these apparently anomalous sulfoxides in solution. Extensive molecular orbital calculations using density functional theory at the B3LYP6–311+(d,p) level have now provided improved understanding of the factors that determine the relative stabilities of the conformations of the two sulfoxide configurations. These calculations suggest that the

**Fig. 1.** Exo conformations of the glycosyl sulfoxides of D-sugars in  ${}^4C_1$  chair conformations.**Fig. 2.** Anti conformations of the glycosyl sulfoxides of D-sugars in  ${}^4C_1$  chair conformation.**Scheme 1.** (a) PhCHO or *p*-MeOPhCHO, *p*-methoxybenzoic acid in DMF–benzene, reflux; (b) Ac<sub>2</sub>O/Py; (c) MCPBA, DCM, –78 °C.

configuration of the glycosyl sulfoxide determines which conformations are populated; a glycosyl sulfoxide, which can adopt a conformation with the aglycone exo and the sulfur lone pair anti, will favor that conformation (the  $S_S$  configuration for  $\beta$ -D-pyranosides, the  $R_S$  configuration for  $\alpha$ -D-pyranosides); for the other diastereomer, the conformer with the aglycone anti is more stable or comparable in stability with the exo conformer.

## Results

### Axial glycosyl sulfoxides

As previously reported,<sup>36</sup> the treatment of 2-azido-2-deoxy-1,3,4,6-tetra-*O*-acetyl- $\alpha$ -D-galactopyranoside<sup>37</sup> with thiophenol and boron trifluoride etherate in chloroform gave close to a 1:1 mixture of the  $\alpha$ - and  $\beta$ -isomers. Deacetylation gave a mixture of compounds **1** and **2** that were separated by column chromatography. As shown in Scheme 1, the  $\alpha$ -isomer was converted using standard methods into the 4,6-*O*-benzylidene acetal (**3**) and the 4,6-*O*-*p*-methoxybenzylidene acetal (**5**) that were acetylated to give compounds **6** and **7**, respectively. Compound **3** had been made previously by a different route but was not fully characterized.<sup>38</sup> Oxidation with *m*-chloroperbenzoic acid (MCPBA) in dichloromethane (DCM) at –76 °C yielded two isomeric sulfoxides for the 4,6-benzylidene derivative (**8R** and **8S**) and for the 4,6-*O*-*p*-methoxybenzylidene derivative (**9R** and **9S**). In both cases, the sulfoxide diastereomers were separated by column chromatography. The preferences for the oxidation reactions to yield the  $R_S$  isomer were much less than noted for gluco<sup>34,39</sup> and manno<sup>5,29</sup> analogues, being 3/1 for compound **3** and 7/2 for compound **5**.

X-ray crystal structure determinations were performed on compounds **6**, **8R**, **8S**, and **9R**. The phenyl thioglycoside, **6**, adopted the exo conformation (Fig. 3). A compilation of all 22 structures previously published that contain axial thioglycosides was assembled from the Cambridge Data File and data from this compilation is listed in the Supplementary data as Table S1. In all previous 22 structures, as well as in the one determined here, the conformation adopted was exo.

The X-ray crystal structure determinations of the kinetically favored sulfoxides **8R** and **9R** show that both adopt anti conformations, different from the exo conformations present in the five previous determinations of axial glycosyl sulfoxides. Two  $R_S$  ethyl 1-thio- $\alpha$ -D-mannopyranoside *S*-oxides adopted exo conformations,<sup>28</sup> as did an  $R_S$  2-cyanoethyl 1-thio- $\alpha$ -D-glucopyranoside *S*-oxide,<sup>34</sup> and two 1-thio- $\beta$ -D-galactofuranoside *S*-oxides with the sulfur atom in pseudo-axial positions also adopt exo-like conformations.<sup>16</sup> ORTEP diagrams for **8R** and **9R** are shown in Figs. 4 and 5. The minor diastereomer, **8S**, adopts an exo conformation in the solid state. Its ORTEP diagram is shown in Fig. 6.

The geometries about the anomeric centre deviate from perfect staggering to different extents in the three axial sulfoxide X-ray crystal structure determinations. The torsional angles are shown in Fig. 7. In the crystal of the parent phenyl thioglycoside, **6**, the quaternary phenyl carbon atom is perfectly staggered between the ring O and H1. In the crys-

Fig. 3. ORTEP diagram of **6**.Fig. 4. ORTEP diagram of **8R**.Fig. 5. ORTEP diagram of **9R**.Fig. 6. ORTEP diagram of **8S**.

Fig. 7. Newman diagrams from C1 to S indicating torsional angles about the anomeric centres of **6**, **8R**, **8S**, and **9R** calculated for bond angles using the program PLATON.<sup>40</sup> The top two structures have the azide groups in gauche minus conformations, whereas the bottom two are in gauche plus conformations (see the following for further discussion).

tals of the two sulfoxides that adopt anti conformations, **8R** and **9R**, the quaternary phenyl carbon atom is much further away from C2 than expected for a staggered conformation, having C2-C1-S-C7 torsional angles of 80.6(3)° and 75(1)°, for **8R** and **9R**, respectively. In contrast, in the crystal of the sulfoxide that adopts an exo conformation, **8S**, the quaternary phenyl carbon atom is closer to the ring oxygen (O-C1-S-C7 torsional angle of 48.0(2)°) than expected for a staggered conformation.

Full geometry optimizations were carried out at the B3LYP/6-31G(d) level of theory on the parent phenyl thio-glycoside, **6**, its oxides **8R** and **8S**, and their SMe analogs (**10**, **11R**, and **11S**) in the gas phase. Frequency calculations confirmed that all structures identified as conformers were minima on the potential energy surfaces. In these cases, single-point calculations were performed for all conformers

at the B3LYP/6-311G+(d,p) level of theory. The conformational situation is more complicated for these compounds. Rotamer geometries and energies about two torsional angles were evaluated, the glycosidic torsional angle, O5-C1-S-C, and the torsional angle to the azide group, H2-C2-N-N. All other torsional angles were allowed to rotate freely to minimum energy values.

Anti conformations about the C1-S bond of the phenyl thioglycoside, **6**, were not minima on this potential energy surface; initial geometries obtained from a variety of strategies always rotated smoothly back to the exo conformer on minimization. The anti conformer of the methyl analogue **10** was a minimum, 2.30 kcal mol<sup>-1</sup> (1 cal = 4.184 J) less stable than the exo conformer at the B3LYP/6-311G(d) + ZPVE and 1.70 kcal mol<sup>-1</sup> less at the B3LYP/6-311G+(d,p) + ZPVE level of theory. Initial geometries for the two additional rotamers about the C2-N bond were obtained by starting from the minimized geometry for each C1-S rotamer and rotating about this bond. Several of these C-N rotamers minimized to previously minimized structures, but two sets of exo and anti minima were obtained for **8R** and **11R**, and one set of two for the exo conformer of **6**. Only one azide rotamer was found for each of the exo and anti conformers of **8S** and **11S**.

The conformers obtained for **8R** are illustrated in Fig. 8. These are named with the compound number, followed by **e** or **a** to indicate the anomeric conformation (exo or anti, respectively), which is then followed by **a**, **gp**, or **gm**, to indicate whether the azide N-N-C2-H2 torsional angle is anti, gauche plus, or gauche minus, respectively. Conformer stabilities are listed in Table 1.

For the conformers arising because of rotation about the C2-N bond, the gauche plus (**gp**) and gauche minus (**gm**) conformers are calculated to be more stable than the anti (**a**) conformer. The **gp** conformer is always a minimum on the potential energy surface. In the three cases where the **a** conformation is a minimum (**6**, **8R**, **11R**), it is less stable than the **gp** conformer by 1.0 ± 0.2 kcal mol<sup>-1</sup>. The gauche minus (**gm**) conformer was calculated to be a minimum only for **Re** sulfoxide conformers, **8Re** and **11Re**, but in those two cases, it was calculated to be more stable than the **gp** conformer by 0.7 and 0.9 kcal mol<sup>-1</sup>, respectively. The azides in the crystal structures of **6** (exo conformer) and **8R** (anti conformer) are present in **gm** conformations, while those in **8S** (exo conformer) and **9R** (anti conformer) are present in **gp** conformations, consistent with the small energy differences between the latter two conformations and probably small barriers between these two minima. The absence of anti conformations for azides in these crystal structures are consistent with the larger energetic destabilizations

Fig. 8. Diagrams indicating the conformations calculated to be adopted by the minima of compound **8R**.

calculated for the **a** conformations with respect to the **gp** conformations. H2-C2-N-N torsional angles were calculated to be small, having absolute values of 38°–46° in all **gp** and **gm** conformers. In the three C-N anti conformers, the H2-C2-N-N torsional angles were between 127° and 147° with the N close to being eclipsed by C3.

The relative energies calculated for the anomeric conformers of these axial glycosyl sulfoxides (Table 1) were unexpected in view of all previous discussion.<sup>17,23,33</sup> The anti conformers of the kinetically favored *R<sub>S</sub>* sulfoxides were calculated to be more stable than the exo conformers by 2.0 and 1.4 kcal mol<sup>-1</sup> at the B3LYP/6-311G+(d,p) + ZPVE level of theory for the phenyl and methyl sulfoxides, respectively. For the minor sulfoxides, the *S<sub>S</sub>* diastereomers, the exo conformer is calculated to be more stable by 1.1 kcal mol<sup>-1</sup> for the phenyl glycoside and 2.0 kcal mol<sup>-1</sup> for the methyl glycoside.

The interesting variations in geometry from perfect staggering around the C1-S bond observed in the X-ray results were evident here for all conformers (see Fig. 9). In particular, the quaternary phenyl carbon atom in the anti conformer of **8R** (**gp**) is calculated to be about as far away from C2 as observed in the crystal, having a C2-C1-S-C7 torsional angle of 81°. In the methyl sulfoxide (**11Ragp**), this angle is calculated to be slightly smaller, 76°. The exo conformers of **8R** are calculated to deviate more from perfect staggering in the unexpected direction than observed in the X-ray structure of **8S**; the O1-C1-S-C7 angle was calculated to be 31° in the most stable **gp** conformer. In the two previously determined X-ray structures of α-D-mannopyranosyl ethyl sulfoxides, the comparable angles observed were larger, 50.7°–56.8°.<sup>28</sup>

In view of the distance determinations obtained from NOE measurements (vide infra) and the difference between calculated and X-ray geometries mentioned earlier, the variations in energy as a function of two different torsional angles were evaluated for compound **8R**. Rotation about the

axis of the glycosyl phenyl ring was evaluated first. The torsion angle C1–S–C7–C8 was held constant at fixed values in  $10^\circ$  intervals from the value found at the minimum for the conformer **8Regp**. The energy change as a function of torsional angle is fairly symmetrical about the minima indicating that the measured NOE should represent the minimum well (Fig. S1 in the Supplementary data). Then the torsion angle O1–C1–S–C7 was held constant at values ranging from  $5^\circ$  to  $10^\circ$  increments about the value found at the minimum for the conformer **8Regp**. Figure 10 shows how the energy and the internuclear distances vary as a function of this angle. For torsional angles  $>90^\circ$ , the energy decreased in a nonsymmetric way because the azide conformation minimized from the **gm** arrangement was most stable in **8Re** and to the **gp** conformation was most stable for **8Ra**. The variation in energy is not symmetric about this angle, being much flatter towards values of the torsional angle that are larger than that of the minimum. Hence, the time-averaged O1–C1–S–C7 torsional angle will be significantly larger than that present in the geometry of the minimum and the NOEs observed for this conformer and will yield longer H1–HSPo and H5–HSPo distances than calculated for the minimum.

To determine the cause of the method of assignment of sulfoxide configuration based on  $^{13}\text{C}$  NMR chemical shifts,<sup>26</sup> the Gauge invariant atomic orbital (GIAO) method<sup>41,42</sup> was used to calculate  $^{13}\text{C}$  shieldings for all carbons of the **8R** and **8S** conformers using the 6–311+G(d,p) basis set and 6–31G(d) geometries. TMS was used as the chemical shift reference. The chemical shifts obtained are listed in Table S5 in the Supplementary data and all calculated values were slightly larger than the experimental values. Plots of experimental chemical shifts against the chemical shifts calculated for all nonaromatic carbons gave

good straight lines with correlation constants of 0.989–0.996 and slopes ranging from 0.947 to 0.982 (not shown). The anomeric chemical shifts of the carbons consistently deviated from the lines, having calculated values that were larger than the experimental values by greater amounts than those of carbons with similar shifts. According to the method proposed by Khier,<sup>26</sup> to assign glycosyl sulfoxide stereochemistry from anomeric carbon chemical shifts, C1 of the  $S_S$  sulfoxide should be more shielded than that of the  $R_S$  sulfoxide. This was observed experimentally: the C1 chemical shifts were 92.5, 96.4, 89.9, and 96.5 ppm for **8S**, **8R**, **9S**, and **9R**, respectively. The values calculated for the four **8R** conformers were 108.9, 112.6, 114.8, and 114.8 ppm for **8Ragp**, **8Raa**, **8Regp**, and **8Regm**, respectively, and those for **8Segp** and **8Sagp** were 106.1 and 105.7 ppm, respectively. Thus, all values for **8S** conformers were less than those for **8R** conformers, which is in agreement with both experiment and prediction. A value for **8R** in between that of **8Ragp** and those of the exo conformers and one for **8S** of the exo conformer would give a difference very similar to those observed in solution for the **8** and **9** diastereomers. Khier<sup>26</sup> ascribed the shielding of the  $S_S$  isomers to  $n \rightarrow \sigma^*$  overlap. The value calculated for C1 of **8Sagp**, which cannot have  $n \rightarrow \sigma^*$  overlap, is the lowest of all, indicating that  $n \rightarrow \sigma^*$  overlap does not cause this shielding effect.

The conformation adopted in solution was investigated by measuring initial NOE buildup rates using both selective 1D NOE measurements with the double pulsed field gradient spin echo (DPFGSE) sequence<sup>43</sup> and 2D NOESY experiments using a variety of mixing times. The initial rates are directly proportional to the internuclear distances ( $r_{\text{IS}}$ ) and were calibrated using a known internuclear distance ( $r_{\text{ref}}$ ) as follows:

$$r_{\text{IS}} = r_{\text{ref}} \left( \frac{\text{NOE}_{\text{ref}}}{\text{NOE}_{\text{IS}}} \right)^{1/6}$$

The distance between ortho phenyl protons (HSPo; 2.8 Å) was used as the reference distance ( $r_{\text{ref}}$ ).<sup>44</sup> The results are given in Table 2 along with the results obtained by the previous methods.

For the parent compound **6**, the NOE results fit the geometry calculated for the exo conformer well. The distances from HSPo obtained to H1 and to H5 are within 0.4 Å of those calculated and no NOE was observed for the interaction with H3, as expected. However, the H5–HSPo distance obtained from the NOE measurement was much longer than that measured from the X-ray results. As discussed previously, the potential surface is fairly flat with respect to changes in the O1–C1–S–C7 torsional angle from the 80° value calculated for the gas phase. Crystal packing presumably causes this value to be altered from that calculated for the minimum to the 59.4(5)° value observed in the solid state. The average of all 23 O1–C1–S–C7 torsional angles from the crystal structures in the Cambridge data file (Table S1 in the Supplementary data) was 61.5°.

For the  $R_S$  sulfoxide, the distances obtained from the NOE measurements do not match the pattern obtained from the X-ray results or from the geometries calculated for the two lowest energy minima, the global minimum, the **8Ragg** conformer, and the other anti conformer (see Table 2). In both anti conformers, the H5–HSPo distance is calculated by DFT to be >5 Å, too large to give an NOE. However, an H5–HSPo NOE was observed and the distance calculated from it was 3.62 Å. For both exo conformers, the H5–HSPo distances are calculated by DFT to be 2.38 Å, much shorter than the dis-

tance obtained from the NOE. The H1–HSPo distance, obtained from the NOE, was 3.05 Å. The average of DFT calculated values in the two exo conformers is 2.95 Å and is 2.53 Å in the two anti conformers. These results indicate that a mixture of the exo and anti conformers is present in solution.

A very approximate estimate of the amount of the exo conformer present can be obtained from the H5–HSPo distances calculated for exo and anti conformers and the value obtained from the NOE measurement using  $r^6$  averaging. The use of 3.6 Å for the average, 5.15 Å for the anti conformer, and 2.38 Å for the exo conformer yields 7% of the exo conformer. This amount corresponds to a  $\Delta G^\circ$  value of 1.5 kcal mol<sup>-1</sup> for the equilibrium between conformers, which is on the same order as that calculated.

### Evaluation of the effect of the 2-azido group

To examine whether the above results were influenced by the 2-azido group, calculations were performed on the 2-deoxy analogs shown below at the same level of theory, except that conformations were also minimized at the B3LYP/6-311+G(d,p) level. As previously, calculations were performed on two conformations of each of these, the anti (**a**) and exo (**e**) conformers. In addition, calculations were performed on the endo conformers of the methyl glycosyl sulfoxides, **15Sen** and **15Ren**, to check whether the earlier assumption that this class of conformer was too energetic to contribute to the mixture present was valid. The anti conformers of both  $S_8$  diastereomers, that is, **13Sa** and **15Sa**, were not minima on their potential energy surfaces and neither was one of the endo conformers, **15Ren**. The results are given in Table 3 and Newman projections showing the relationships among groups at the anomeric centres are shown in Fig. 11.

The exo conformer of the methyl 2-deoxythioglycoside (**14**) was calculated to be somewhat more stable with respect to the anti conformer than its 2-azido-2-deoxy analogue (**10**) (3.2 vs 2.3 kcal mol<sup>-1</sup>). For this series, the anti conformer of the phenyl thioglycoside was also a minimum, 2.3 kcal mol<sup>-1</sup> less stable than the exo conformer. For the  $R_S$  sulfoxide of the 2-deoxy analogue, **15**, the exo conformer (**15e**) was more stable than the anti conformer (**15a**) by 1.5 kcal mol<sup>-1</sup>. The two conformers of the  $R_S$  phenyl 2-deoxy sulfoxides (**13**) were calculated to be almost equally stable at the B3LYP 6-311+G(d,p) level of theory, the exo conformer being 0.1 kcal mol<sup>-1</sup> more stable. Neither of the anti conformers of the  $S_8$  sulfoxides of the 2-deoxy derivatives (**13Sa** and **15Sa**) were minima at this level of theory.

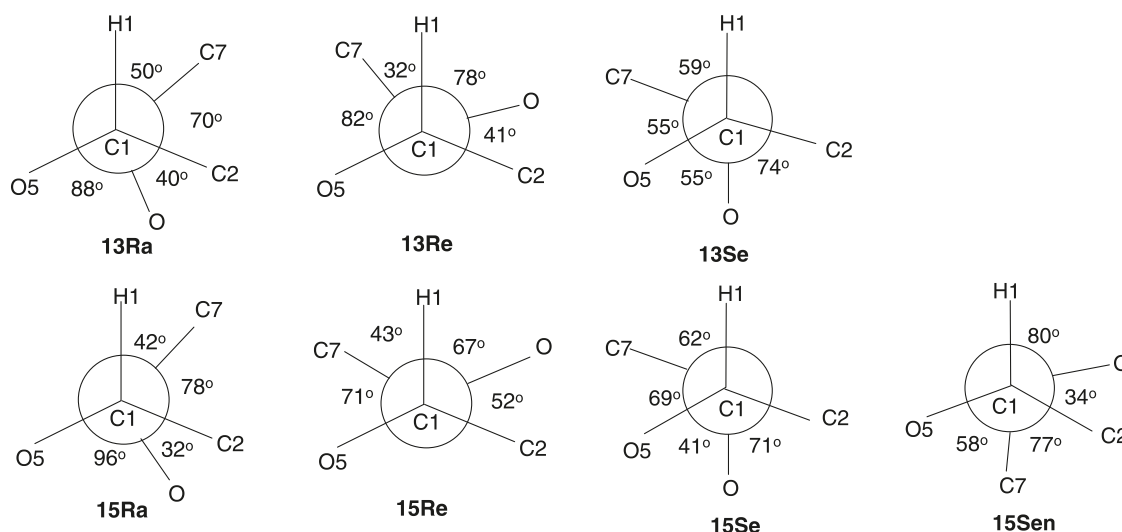

As shown in Fig. 11, the C2–C1–S–C7 torsional angles in the anti conformers of the  $R_S$  sulfoxides are similar to those of their 2-azido analogues; the values are greater than those

expected for perfect staggering, being 70° for **R13a** and 78° for **R15a**. In contrast, the exo conformers of **R13** and **R15** deviate from perfect staggering in the opposite direction from their 2-azido analogues. In the latter derivatives (see Fig. 9), the O5–C1–S–C7 torsional angle had values in the 31°–38° range, whereas the O–S–C1–C2 angle was in the 84°–91° range. For **13Re** and **15Re**, the values of the O5–C1–S–C7 torsional angles are 82° and 71°, respectively, whereas those of the O–S–C1–C2 angles are 41° and 52°, respectively. These changes are consistent with relief of dipole–dipole repulsion between the potentially parallel C–N and S–O dipoles of the 2-azido derivatives. When the 2-azido group was removed, the conformational minima have O–S–C1–C2 angles <60° and the O5–C1–S–C7 values are >60°, relieving steric strain from the interaction of the aglycone with the pyranose ring.

### An equatorial glycosyl sulfoxide

Treatment of 1,3,4,6-tetra-*O*-acetyl-2-deoxy-2-phthalimido- $\beta$ -D-glucopyranoside<sup>45–47</sup> (**16**) with thiophenol and boron trifluoride etherate gave phenyl 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-1-thio- $\beta$ -D-glucopyranoside (**17**), previously prepared by another method,<sup>48</sup> in an 81% yield. Oxidation with 1 equiv of *m*-chloroperbenzoic acid in dichloromethane at  $-78^\circ\text{C}$  yielded 92% of a 2.1:1 mixture (**18**) of the *S<sub>S</sub>* (**18S**) and *R<sub>S</sub>* (**18R**) isomers. It had previously been reported that oxidation under similar conditions gave a 3:1 ratio of the same isomers.<sup>17</sup> The isomers were separated using flash chromatography on silica gel with 5% acetone in dichloromethane as eluent.

The major isomer (**18S**), the *S<sub>S</sub>* isomer, was recrystallized

from a solution of 1% ethanol in hexanes. Its crystal structure (Fig. 12) establishes the *S<sub>S</sub>* configuration. Interestingly, the compound adopts the conformation with the phenyl group anti to the C1–O5 bond, in contrast to the results from all previous X-ray determinations of equatorial glycosyl sulfoxides except one<sup>23</sup> (see Table S1 in the Supplementary data for data on previous X-ray determinations of glycosyl sulfoxides). In this conformation, the phenyl and phthalimido groups lie roughly parallel to each other and perpendicular to the plane of the tetrahydropyran ring, in an arrangement typical of  $\pi$  stacking.

This conformation of **18S** persists in solution in chloroform-*d*. The nearly parallel alignment of the aryl groups is evident in both the chemical shifts of the phenyl protons and of the phthalimido protons, which are affected by the anisotropic chemical shift effects of these aryl groups (for recent summaries of these effects, see papers by Lazzeretti and co-workers<sup>49,50</sup>). In the <sup>1</sup>H NMR spectrum of the starting material (**17**), the phenyl ortho Hs appear at 7.45 ppm, whereas the meta and para Hs appear as a complex multiplet from 7.2 to 7.3 ppm. Similar shifts have been reported for cyclo-

Fig. 12. ORTEP diagram of **18S**.

hexyl phenyl sulfide, 7.38 (ortho), 7.25 (meta), and 7.17 (para) ppm.<sup>51</sup> Conversion to the sulfoxide results in deshielding, e.g., in the spectrum of cyclohexyl phenyl sulfoxide, 7.54 (ortho), 7.45 (meta), and 7.45 (para) ppm,<sup>51</sup> and also in that of compound **18R**, 7.90 (ortho), 7.58 (meta), and 7.70 (para) ppm (see Fig. 13). In contrast, in the <sup>1</sup>H NMR spectrum of **18S**, these signals appear at 7.49 (ortho), 7.21 (meta), and 7.13 (para) ppm (Fig. 14). All signals are shielded in comparison with those of the *R<sub>S</sub>* isomer,  $\Delta\delta$  0.41 (ortho), 0.37 (meta), and 0.57 (para) ppm, which are consistent with the effects of a nearly parallel phthalimido group.

The effects on the phthalimido protons are more dramatic. AA'BB' patterns typical of disubstituted benzenes with identical ortho substituents are observed for the parent compound with chemical shifts of 7.76 and 7.87 ppm and for **18R** with chemical shifts of 7.77 and 7.90 ppm (Fig. 13). In contrast, the phthalimido proton signals in the spectrum of **18S** are exchange broadened (Fig. 14). A broad singlet at 7.67 ppm is superimposed on a much broader smooth low band centered at about 7.73 ppm. Rotation of the phthalimido group is hindered by the favorable interactions associated with the near parallel arrangement of the phenyl and phthalimido groups. If there was a rapid equilibrium between anti and exo conformations, the phthalimido group would be able to rotate freely when the phenyl group was exo. Thus, the observation of a single pattern exhibiting hindered rotation indicates that the anti conformation is essentially the only conformation populated in solution and that rotation about the C1–S bond to the exo conformation is slow, as are rotation about both the phenyl C–S bond and the C2–N bond.

Quantum mechanical calculations were performed with density functional theory as implemented in Gaussian 03<sup>52</sup> with Becke's three parameter exchange functional and Lee–Yang–Parr correlational functionals.<sup>53,54</sup> The X-ray structure of compound **18S** provided the initial geometry of the glycosyl sulfoxide. The initial geometries for the second staggered rotamer were generated by rotating about the C1–S bond and those for the other sulfoxide diastereomer were generated by inverting at sulfur. The third staggered rotamer, with the aglycone gauche to both C2 and the ring oxygen, was not used as a starting point for geometry minimization. Initial geometries for the SMe analog and its sulfoxides were obtained from the minimized thiophenyl conformers. Initial geometries for **17** and its methyl ana-

Fig. 13. Part of the 400 MHz <sup>1</sup>H NMR spectrum of compound **18R**. PDFFig. 14. Part of the 400 MHz <sup>1</sup>H NMR spectrum of compound **18S**. PDF

logue, **17Me**, were obtained by removing an oxygen atom from the minimized sulfoxide conformers. Full geometry optimizations were carried out at the B3LYP/6–31G(d) level of theory on **17**, **18S**, and **18R**, and their SMe analogs (**17Me**, **18SMe**, and **18RMe**). However, neither Hartree–Fock molecular orbital theory nor current implementations of density functional theory, which use local approximations of the density, are capable of accurately describing the dispersion forces, which are the major interaction causing  $\pi$  stacking.<sup>55</sup> Theoretical methods that could provide accurate measures of the dispersion forces are too time-consuming for molecules of the size of compound **18S**. Thus, the stabilities of conformers with geometries in which two arene rings are close to parallel will be underestimated.

All starting conformations, that is, both anti and exo conformations, of the parent thioglycosides, **17** and **17Me**, smoothly changed geometry on optimization to that of the exo conformers. On this potential energy surface, the anti conformations are not minima. The results for the glycosyl sulfoxides are shown in Table 4. The most stable conformer of the *S<sub>S</sub>* diastereomer is calculated to be more stable than that of the *R<sub>S</sub>* diastereomer by 1.85 and 1.36 kcal mol<sup>–1</sup> for the phenyl and methyl glycosyl sulfoxides, respectively. For all compounds, the exo conformers are calculated to be more stable than the anti conformers. For **18S**, which was observed to adopt the anti conformer both in the solid state and in solution, the exo conformer was calculated to be the more stable conformer by 1.57 kcal mol<sup>–1</sup>, although the anti conformer is calculated to have the larger dipole moment, 5.63 vs 1.40 D. For **18R**, which is present as the exo conformer in solution, the calculated difference is 3.03 kcal mol<sup>–1</sup>.

## Discussion

### Axial glycosyl sulfoxides

The gas phase DFT calculations indicate that axial glycosyl sulfides favor the exo-anomeric conformers over anti conformers by substantial amounts, 1.7 kcal mol<sup>-1</sup> for the methyl 2-azido-2-deoxythioglycoside (**10**) and 3.2 kcal mol<sup>-1</sup> for the methyl 2-deoxythioglycoside (**14**). For the phenyl 2-azido-2-deoxythioglycosides, the anti conformations were not minima on the potential energy surfaces. The fact that in all 23 X-ray structure determinations of axial glycosyl sulfides, the conformation observed was the exo conformation (Table S3 in the Supplementary data) confirms these calculated results.

Of the two diastereomers of the glycosyl sulfoxides, **8** and **11**, the most stable conformer of the minor diastereomers, **8S** and **11S**, are calculated to be more stable than that of the major diastereomers by 2.3 and 2.6 kcal mol<sup>-1</sup>, respectively. Because the diastereomers obtained to a greater extent from the oxidation are calculated to be less stable than the diastereomers obtained in lesser amounts, this result strongly supports the conclusion that the stereoselectivity of oxidation is kinetically controlled and results from the preferred exo conformation of the sulfide.<sup>23,28</sup>

The 2-azido-2-deoxy *S<sub>S</sub>* sulfoxides (**8S** and **11S**), which retain the sulfur lone pair anti to the C1-O5 bond in the exo conformers, were calculated to have about the same conformational preferences for these exo conformers as the parent sulfides. One factor favoring this conformer must be *n* →  $\sigma^*$  donation from the sulfur lone pair into the C1-O5 antibonding orbital. This conformer is calculated to have the shortest C1-S bonds of all conformers of **8** and **13** (see Fig. 15), which is consistent with this overlap. Thus, the exo arrangement of the aglycone plus the *n* →  $\sigma^*$  overlap helps explain the greater stability of this conformer of the kinetically disfavored diastereomer.

However, for the *R<sub>S</sub>* sulfoxide (**11Ragp**), which does not have an anti lone pair in the exo conformation, the conformational preference is calculated to shift from being in favor of the exo conformer for the parent methyl sulfide (**10egp**) by 1.7 kcal mol<sup>-1</sup> to being in favor of the anti conformer by 1.4 kcal mol<sup>-1</sup>, a change of 3.1 kcal mol<sup>-1</sup> (3.7 kcal mol<sup>-1</sup> for the phenyl glycoside, if it is assumed that the sulfide preference is the same as for the methyl glycoside). For the *R<sub>S</sub>* sulf-

oxide of the 2-deoxy analogue, **15**, the exo conformer (**15e**) was more stable than the anti conformer (**15a**) by 1.5 kcal mol<sup>-1</sup>. Therefore, the extent to which the anti conformer of the methyl thioglycoside was stabilized on oxidation to the *R<sub>S</sub>* diastereomer was smaller for the 2-deoxy derivative, 1.5 kcal mol<sup>-1</sup>, but was still substantial. For the phenyl thioglycoside (**12**), the corresponding stabilization of the anti conformer of the *R<sub>S</sub>* sulfoxide was calculated to be 2.2 kcal mol<sup>-1</sup>, again at the B3LYP 6-311+G(d,p) level of theory.

Comparison of the geometries of the *R<sub>S</sub>* exo conformers of the 2-deoxy derivatives with the 2-azido-2-deoxy derivatives shows that the 2-azido substituent has a significant effect. The O5-C1-S-O torsional angles calculated for **8Regp**, **8Regm**, **11Regp**, **11Regm**, **13Re**, and **15Re** are 139.3°, 144.4°, 145.0°, 146.2°, 168.5°, and 179.5°, respectively. The latter two values are consistent with minimization of steric interactions for the R group and dipole-dipole repulsion due to interaction of the endocyclic C-O bond and the sulfoxide S-O bond. When the 2-azido group is present, dipole-dipole repulsion between the parallel C2-N bond and the S-O bond causes rotation about the C1-S bond resulting in much smaller O5-C1-S-O torsional angles. This is a significant effect because it is at the expense of increased R pyranose ring steric interactions and increased dipole-dipole repulsion due to interaction of the endocyclic C-O bond and the sulfoxide S-O bond. The small effect of the latter type of dipole-dipole repulsion suggests that it is not as important as other factors in determining conformational preferences for glycosyl sulfoxides.

In terms of energies, the most stable azide conformers of the anti *R<sub>S</sub>* 2-azido-2-deoxy derivatives are calculated to be more stable than the most stable azide conformers of the exo *R<sub>S</sub>* 2-azido-2-deoxy derivatives by 2.0 and 1.4 kcal mol<sup>-1</sup> for the phenyl and methyl sulfoxides, respectively, at the B3LYP6-311+G(d,p) level of theory. For the 2-deoxy derivatives, without the parallel C-N dipole, the exo conformers are now more stable by 0.1 and 1.5 kcal mol<sup>-1</sup> for the phenyl and methyl sulfoxides, respectively. This represents changes of 2.1 and 2.9 kcal mol<sup>-1</sup> for the phenyl and methyl sulfoxides, respectively, and represents the costs of having these dipoles parallel.

**Fig. 15.** Calculated structural features for axial phenyl sulfide and phenyl sulfoxide conformers.

Crich et al.<sup>23</sup> equilibrated the two sulfoxide diastereomers of allyl 2,3,4-tri-*O*-benzoyl-1-thio- $\alpha$ -D-xylopyranoside oxide (**19**) and allyl 2,3-di-*O*-benzyl-4,6-*O*-benzylidene-1-thio- $\alpha$ -D-mannopyranoside oxide (**20**) in both benzene-*d*<sub>6</sub> and methanol-*d*<sub>4</sub> at 60 °C. The former compound is most analogous to those studied here because in its <sup>4</sup>C<sub>1</sub> conformation it bears an equatorial substituent at C2. For **19**, the *S<sub>S</sub>* diastereomer was favored by 2 to 1 in benzene but the other diastereomer was favored by 2.5 to 1 in methanol. The results here indicate that **19S** will prefer the exo conformation, **19Se**, rather than the anti conformation, **19Sa**, because this allows the allyl group to assume the sterically preferred exo orientation and because the sulfur lone pair is correctly oriented for  $n \rightarrow \sigma^*$  overlap. Crich et al.'s<sup>23</sup> results do not provide a direct estimate of the preference for the *S<sub>S</sub>* diastereomer because the *R<sub>S</sub>* diastereomer ring inverts completely (as determined from <sup>3</sup>*J*<sub>H,H</sub> values) to the <sup>1</sup>C<sub>4</sub> chair. To compare relative stabilities of particular conformers of the *S<sub>S</sub>* and *R<sub>S</sub>* diastereomers, the same ring conformations must be employed. If the conformational preference for <sup>1</sup>C<sub>4</sub> over <sup>4</sup>C<sub>1</sub> is estimated at >9/1, the equilibration results for **19** correspond to  $\Delta G^\circ$  values of >1.9 and >0.8 kcal mol<sup>-1</sup> at 60 °C in benzene and methanol, respectively, in favor of the *S<sub>S</sub>* diastereomer in the <sup>4</sup>C<sub>1</sub> conformation. The value in benzene is in the same range as that calculated by DFT methods here (**11Segp** is calcu-

lated to be 2.4 kcal mol<sup>-1</sup> more stable than **11Ragp**), even though the C2 substituent is very different. Since the *S<sub>S</sub>* diastereomers are calculated to have somewhat larger dipole moments (3.3 vs 2.5 D for **18**, 3.5 vs 2.5 D for **11**), the decreased preference for this diastereomer in methanol is unexpected and may be due to specific solvation of the *R<sub>S</sub>* diastereomer as suggested by Crich et al.<sup>23</sup>

For compound **20**, the preferences for the *R<sub>S</sub>* diastereomer are 0.7 and 0.6 mol<sup>-1</sup> at 60 °C in benzene and methanol, respectively. Using the value estimated previously, this result indicates that the *R<sub>S</sub>* diastereomer is stabilized by >2.6 kcal mol<sup>-1</sup> when the equatorial 2-*O*-benzoyl group is converted to axial. Comparison of the calculated relative stabilities of the analogous 2-azido-2-deoxy diastereomers (**11**) with their 2-deoxy analogs (**15**) shows a similar 2.5 kcal mol<sup>-1</sup> relative stabilization of the *R<sub>S</sub>* diastereomer on removal of the equatorial 2-azido group. From these results, it is clear that the C2 configuration has a large effect on diastereomer stability.

It remains to be considered why the anti conformers of the *R<sub>S</sub>* sulfoxides are more stable relative to the exo conformers than expected based on normal<sup>23</sup> conformational arguments. It is very well established that glycosides and thioglycosides prefer exo-anomeric conformations. Several factors influence this preference:  $n \rightarrow \sigma^*$  overlap, dipole–

dipole repulsion, and reduced steric interactions and electrostatic attraction. Changing from a sulfide in the exo-anomeric conformation to the  $R_S$  sulfoxide results in the loss of the  $n \rightarrow \sigma^*$  overlap but adds a dipole in its most favorable arrangement with respect to the endocyclic C1–O5 dipole, namely, antiparallel. However, in **8Re** and **11Re**, it also adds a parallel dipole–dipole repulsive interaction between the S–O dipole and the C2–N dipole. As noted previously, the anti conformers have C2–C1–S–C7 torsional angles that are considerably greater than staggered, both in the presence and absence of electronegative substituents on C2. This deviation from perfect staggering has the effect of minimizing steric interactions at the expense of increasing dipole–dipole repulsion between the S–O bond and the endocyclic C–O bond. Clearly, the latter factor is less important than the former and any other interactions. It is interesting that the C7–S–O units in the anti conformers are close to being eclipsed by the H1–C1–C2 unit (see Fig. 13, **8Ra** and **11Ra**, and Fig. 12, **13Ra** and **15Ra**). If they were eclipsed, the sulfur lone pair would be syn to the C1–O5 bond. The C1–S bonds in the most stable **Ra** conformers, **8Ragp** and **13a**, are calculated to be almost as short as they are in the conformers having  $n \rightarrow \sigma^*$  overlap, **8Sepg** and **13Se**, which is consistent with an extra stabilizing interaction. This interaction is between orbitals of correct symmetry if the S lone pair that overlaps with the C1–O5  $\sigma^*$  orbital is a p-type lone pair. All of the other conformers are calculated to have C1–S bond lengths that are 0.02–0.05 Å longer (see Fig. 15). Based on a perturbation molecular orbital (MO) approach for dimethoxymethane,<sup>56</sup> Tvaroška and Bleha<sup>21</sup> have concluded that both the  $\sigma$  and  $\pi$  lone pairs on oxygen can overlap with the C–O  $\sigma^*$  orbital and both overlaps provide similar stabilization. The overlap advocated here is similar to the oxygen atom  $\pi \rightarrow \sigma^*$  overlap of that view.<sup>21</sup>

Comparison of the **Re** and **Se** conformers of the 2-deoxy derivatives allows an evaluation of the relative strengths of  $n \rightarrow \sigma^*$  overlap and adoption of antiparallel endocyclic C–O and S–O dipoles (see Fig. 12 for Newman projections of the relevant relationships). The **Re** conformers have antiparallel endocyclic C–O and S–O dipoles. The **Se** conformers adopt shapes with ideal geometries for  $n \rightarrow \sigma^*$  overlap but are presumably destabilized by gauche interactions between endocyclic C–O and S–O dipoles. For both the phenyl and methyl sulfoxides, the **Re** conformers are calculated to be slightly more stable, by 0.45 and 0.14 kcal mol<sup>−1</sup>, respectively, suggesting that the two interactions are comparable in magnitude.

### Equatorial glycosyl sulfoxides

Equatorial alkyl and aryl thioglycosides overwhelmingly adopt exo-anomeric conformations in the solid state (22 out of 25, see Table S1 in the Supplementary data), indicating that there is a strong thermodynamic preference for this conformation. The results of DFT (6–31G(d) B3LYP) calculations support this conclusion, since the anti conformations of both the thiophenyl and thiomethyl glycosides smoothly change geometry on minimization to the exo conformer, although this level of theory underestimates<sup>55</sup> the stabilizing effect of  $\pi$  stacking.

In contrast, ( $S_S$ ) phenyl 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-1-thio- $\beta$ -D-glucopyranoside *S*-oxide (**18S**)

adopts the anti conformation about the glycosidic linkage in the solid state and the NMR evidence described in the Results section demonstrated conclusively that this conformation is the predominant one in solution. The near parallel alignment of the SPh and phthalimido groups suggests that  $\pi$  stacking contributes to the stabilization of this conformation.  $\pi$  Stacking was recently shown to influence the conformation about the glycosidic bond in a disaccharide.<sup>57</sup> Such interactions provide stabilizations on the order of 2.8 kcal mol<sup>−1</sup> for the most favorable displaced parallel geometries.<sup>55,58–61</sup> This factor is presumably very important in causing compound **18S** to adopt the anti conformation. It is notable that compound **18R**, which could also adopt a  $\pi$ -stacked conformation, clearly adopts the conformation favored by the exo-anomeric effect (as shown by its NMR spectra data) with the phenyl group exo and the lone pair on sulfur correctly aligned for  $n \rightarrow \sigma^*$  overlap with the C1–O5 antibonding orbital.

The DFT calculations for the glycosyl sulfoxides indicate that the exo conformers of both diastereomers are more stable in the gas phase. For the phenyl glycosyl sulfoxides, the differences are calculated to be 1.57 and 3.03 kcal mol<sup>−1</sup> for **18S** and **18R**, respectively. The **18R** exo conformer is stabilized by having the S lone pair anti to the ring C–O bond, which is geometry suitable for  $n \rightarrow \sigma^*$  overlap. This conformer is calculated to have the shortest C1–S bond length, 1.878 vs 1.885 Å for the **18S** exo conformer and >1.89 Å for the anti conformers, which is in agreement that this overlap is significant.

Even though the conformation adopted by the  $S_S$  diastereomer is not that predicted on the basis of the exo-anomeric effect, the <sup>13</sup>C NMR chemical shift of its carbon atom (89.1 ppm) was greater than that of the corresponding carbon atom of the  $R_S$  diastereomer (86.1 ppm), which is in agreement with the method for assignment of sulfoxide configuration proposed by Khair.<sup>26</sup>

### Conclusions

The evidence presented here shows that the most stable configurations of glycosyl sulfoxides are those that can adopt conformations with the aglycone exo and the lone pair on sulfur anti to the C1–O5 bond, because of the  $n \rightarrow \sigma^*$  overlap possible in this orientation. For D-pyranosides, these are the  $S_S$  configurations of the  $\alpha$ -anomers and the  $R_S$  configurations of the  $\beta$ -anomers. Equilibration studies by Crich et al.<sup>23</sup> are in agreement with the conclusions drawn here for glycosyl sulfoxides with substituents at C2 equatorial but indicate that the configuration at C2 has a major effect on glycosyl sulfoxide conformer stability. Electronegative substituents in equatorial orientations at C2 destabilize the conformation with the sulfoxide oxygen atom anti by about 2.5 kcal mol<sup>−1</sup>. The calculations indicate that  $n \rightarrow \sigma^*$  overlap and the preference for the endocyclic C–O dipole and the S–O to adopt antiparallel conformations have effects that are about equal in size in determining glycosyl sulfoxide conformations in the gas phase or nonpolar solvents. For the less stable but kinetically favoured  $R_S$  diastereomers of the  $\beta$ -anomers, anti conformers are comparable in stability to the exo conformers because of the  $n \rightarrow \sigma^*$  overlap possible if the sulfur lone pair is a p-type lone pair.

The method for assignment of glycosyl sulfoxide configurations by comparing the  $^{13}\text{C}$  NMR chemical shifts of C1 for the two diastereomers proposed by Khair<sup>26</sup> was supported by the chemical shifts calculated by the Gauge invariant atomic orbital (GIAO) method. However, the explanation advanced for the rule that C1 from the  $S_S$  sulfoxide is more shielded than that of the  $R_S$  sulfoxide, because of  $n \rightarrow \sigma^*$  overlap in the  $S_S$  sulfoxide, does not appear to be correct.

## Experimental section

### General methods

Melting points were determined with a Fisher-Johns melting point apparatus and are uncorrected.  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra were recorded at 300 K in 5 mm NMR tubes on Bruker NMR spectrometers (AC-250, AMX-400, or Avance-500) operating at 250.13, 400.13, or 500.13 MHz for proton spectra and 62.9, 100.08, or 125.77 MHz for carbon spectra, respectively, on solutions in chloroform- $d$ , unless otherwise indicated. Chemical shifts are given in parts per million (ppm;  $\pm 0.01$  ppm) relative to that of tetramethylsilane (TMS; 0.00 ppm) in the case of  $^1\text{H}$  NMR spectra and to the central line of chloroform- $d$  ( $\delta$  77.16) for the  $^{13}\text{C}$  NMR spectra. All assignments were confirmed by COSY, HETCOR, HMQC, HSQC, or HMBC experiments. Exact masses measured using electron ionization (EI; 70 eV) were done on a CEC 21-110B mass spectrometer. Electrospray mass spectra were recorded on a Fisons Quattro mass spectrometer with a Quattro source (cone voltage, 55 V; flow rate, 5  $\mu\text{L}/\text{min}$ ; complexing agent, potassium acetate; solvent, 75:25  $v/v$  acetonitrile/water). Optical rotations were determined with a Rudolph Instruments Digipol 781 automatic polarimeter or with a PerkinElmer model 141 polarimeter. Thin layer chromatography (TLC) was performed on aluminum-backed plates bearing 200  $\mu\text{m}$  silica gel 60 F<sub>254</sub> (Merck or Silicycle). The ratio of the solvents used in TLC and column chromatography was a volume ratio. Compounds were visualized by UV where applicable and (or) were located by spraying with a solution of 2% ceric sulfate in 1 mol/L sulfuric acid followed by heating on a hot plate until colour developed. Compounds were purified on silica gel (TLC standard grade, 230–400 mesh) by flash chromatography using specified eluents. Elemental analyses were performed by the Canadian Microanalytical Service, Delta, British Columbia.

Pyridine was dried by refluxing over calcium hydride followed by distillation and stored over molecular sieves. Amberlite IR-120 ( $\text{H}^+$ ) resin was washed with a 10% hydrochloric acid solution and distilled water, and then dried under vacuum at 50  $^\circ\text{C}$  overnight. Ammonium cerium (IV) nitrate and sodium azide were ground to powders and dried in vacuo for 2 days. Boron trifluoride diethyl etherate was distilled before use.

### X-ray crystallography

Crystals for X-ray structural determinations were mounted on glass fibers. All measurements were made on a Rigaku AFC5R diffractometer equipped with graphite-monochromated Mo  $K\alpha$  radiation (**6**, **8R**, **8S**, and **9R**) or Cu  $K\alpha$  radiation (**18S**) and a rotating anode generator. Cell constants and an orientation matrix for data collection were obtained from a

least-squares refinement using the setting angles of a minimum of 24 reflections (with the exception of **12R** where only 10 reflections were obtained). The data were collected at temperatures of 23  $^\circ\text{C}$  (**8S** and **18S**),  $-100$   $^\circ\text{C}$  (**6** and **9R**), or  $-130$   $^\circ\text{C}$  (**8R**) using the  $\omega$ - $2\theta$  scan technique. The intensities of three representative reflections were measured after every 150 reflections; no decay corrections were applied. An empirical absorption correction<sup>62</sup> based on azimuthal scans of several reflections was applied for every structure except **9R**. The data were corrected for Lorentz and polarization effects. Data reduction was carried out using the TEXSAN software package.<sup>63</sup> The structures were solved by direct methods using SIR-92.<sup>64,65</sup> Full-matrix least-squares refinement was carried out on  $F^2$  data using SHELXL-97.<sup>66</sup> Secondary extinction was refined for **18S**. In all cases, the non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined. They were placed in geometrically calculated positions and allowed to ride on the heavy atom to which they were bonded with isotropic temperature factors ( $U_{\text{iso}}$ ) equal to 1.2 times  $U_{\text{eq}}$  of the heavy atom (1.5 times  $U_{\text{eq}}$  for methyl hydrogens).

### NMR experiments

Experiments were performed on 0.04 mol/L solutions in acetone- $d_6$  unless otherwise specified. NOESY spectra were recorded on the Bruker Avance 500 MHz NMR spectrometer using different mixing times. Spectra were processed with Bruker's XWIN-NMR package. The matrices were transformed to a final size of 8192 and 2048 points in F2 and F1 dimensions, respectively. The signal was multiplied by a shifted qsin bell window in both dimensions prior to Fourier transformation, then phase and baseline corrections on both dimensions were applied. The numbers of contour layers were set at 18. For compound **6**, spectra were recorded with a relaxation delay of 1 s with mixing times of 0.3, 0.5, 0.7, 1, and 1.5 s. For **8R**, spectra were recorded with a relaxation delay of 2.5 s and mixing times of 0.5, 0.7, 0.9, 1.1, and 1.3 s. For compound **9R**, spectra were recorded with a relaxation delay of 1 s and mixing times of 0.3, 0.5, 0.7, 1, and 1.5 s.

Relaxation times were determined for compounds **6** and **8R** by the inversion recovery method to set the relaxation delays for the 1D NOE experiments. The t1ir pulse program on the 500 MHz NMR spectrometer was used to acquire data and the proc\_t1 program was used to process data. The results are shown in Table S4 in the Supplementary data. Based on these results, the delay time used for 1D gradient NOE experiments was set at 10 s. The selnpg pulse sequence was used for 1D gradient NOE experiments. For compounds **6**, **8R**, and **8S**, the signals of H-SPo were irradiated and mixing times of 0.3, 0.5, 0.75, 0.9, 1, 1.1, and 1.25 s; 0.3, 0.9, 1.25, 1.5, 1.75, and 2.25 s; and 0.5, 0.75, 1, 1.25, 1.5, 1.75, 2, 2.25, 2.5, and 3 s, respectively, were used.

The distance between ortho phenyl protons ( $r = 2.8$  Å) was used as the reference distance to calculate internuclear distances using the equation

$$r_{\text{IS}} = r_{\text{ref}} \left( \frac{\text{NOE}_{\text{ref}}}{\text{NOE}_{\text{IS}}} \right)^{1/6}$$

## Computational methods

Most geometry optimizations were carried out at the B3LYP hybrid density functional in conjunction with the B3LYP/6–31G(d) basis set using the Gaussian 03 suite of programs.<sup>52</sup> The B3LYP functional is a combination of Becke's three-parameter hybrid exchange functional and Lee–Yang–Parr correlational functional.<sup>53,54</sup> Harmonic vibrational frequencies and zero-point vibrational energies (ZPVEs) were obtained at the same level of theory. Relative energies were obtained by performing single-point calculations at the B3LYP level of theory with the 6–311G+(d,p) basis set using the above optimized geometries and by including the zero-point vibrational energy, i.e., B3LYP/6–311G+(d,p)/B3LYP/6–31G(d) + ZPVE. Compounds **12–15** were also optimized at the 6–311G+(d,p) level of theory. The GIAO method was used for <sup>13</sup>C shielding calculations using the 6–311+G(d,p) basis set.

## Synthetic procedures

### Phenyl 2-azido-2-deoxy-1-thio- $\alpha$ -D-galactopyranoside (**1**) and phenyl 2-azido-2-deoxy-1-thio- $\beta$ -D-galactopyranoside (**2**)

Freshly distilled boron trifluoride diethyl etherate (19 mL, 151.3 mmol, 5.6 equiv) was added dropwise to a stirred clear colorless solution of thiophenol (14 mL, 136.0 mmol, 5 equiv) and 2-azido-2-deoxy-1,3,4,6-tetra-*O*-acetyl- $\alpha$ -D-galactopyranoside<sup>37</sup> (10.07 g, 27.0 mmol) in chloroform (175 mL) at 0 °C. The reaction mixture was stirred at room temperature (RT) for 24 h. The clear orange solution was washed with saturated sodium bicarbonate aqueous solution (3 × 30 mL) and distilled water (3 × 30 mL), dried (anhydrous sodium sulphate), filtered, and concentrated to give a yellow syrup, phenyl 3,4,6-tetra-*O*-acetyl-2-azido-2-deoxy-1-thio-*O*-acetyl-D-galactopyranoside.

The yellow syrup was taken up in methanol (100 mL) and a solution of sodium methoxide in methanol (100 mL, 1.2 mol/L) was added. The basic solution was stirred for 1 h, neutralized by Amberlite IR-120 (H<sup>+</sup>), filtered, and concentrated to a yellow syrup, phenyl 2-azido-2-deoxy-1-thio-D-galactopyranoside. The  $\alpha$ - $\beta$  mixture was separated by column chromatography (ethyl acetate–hexanes, 10:1). The pure anomers were crystallized from ethanol–hexanes.

#### $\alpha$ -Isomer (**1**)

Colorless needles; yield: 3.21 g (40%); mp 130.0–133.0 °C.  $[\alpha]_{\text{D}}^{25} +252.2^\circ$  (*c* 1.3, ethanol).  $R_f = 0.34$ . <sup>1</sup>H NMR (acetone-*d*<sub>6</sub>)  $\delta$ : 7.58–7.29 (m, 5H, Ph), 5.67 (d, 1H,  $J_{1,2} = 5.4$  Hz, H-1), 4.47 (d, 1H,  $J_{3,\text{OH}} = 7.1$  Hz, OH-3), 4.31 (t, 1H, H-5), 4.17 (dd, 1H,  $J_{2,3} = 10.5$  Hz, H-2), 4.15 (d, 1H,  $J_{4,\text{OH}} = 3.7$  Hz, OH-4), 4.09 (ddd, 1H,  $J_{3,4} = 3.4$  Hz,  $J_{4,5} = 1.3$  Hz, H-4), 3.84 (ddd, 1H, H-3), 3.79–3.69 (m, 3H, 2 × H-6, OH-6). <sup>13</sup>C NMR (acetone-*d*<sub>6</sub>)  $\delta$ : 135.4, 133.1, 129.9, 128.2 (Ph), 88.8 (C-1), 73.2 (C-5), 71.1 (C-3), 70.0 (C-4), 62.1 (C-6), 62.0 (C-2). HR-MS (EI, *m/z*) calcd. for [C<sub>12</sub>H<sub>15</sub>N<sub>3</sub>O<sub>4</sub>S]<sup>+</sup>: 297.0783; found: 297.0793.

#### $\beta$ -Isomer (**2**)

Colorless needles; yield: 3.09 g (39%); mp 149.0–149.5 °C.  $[\alpha]_{\text{D}}^{25} +24.0^\circ$  (*c* 0.3, ethanol).  $R_f = 0.26$ . <sup>1</sup>H NMR (acetone-*d*<sub>6</sub>)  $\delta$ : 7.58–7.29 (m, 5H, aromatic protons), 4.60 (d,

1H,  $J_{1,2} = 10.0$  Hz, H-1), 4.53 (d, 1H,  $J_{3,\text{OH}} = 7.3$  Hz, OH-3), 4.05 (d, 1H,  $J_{4,\text{OH}} = 4.1$  Hz, OH-4), 3.98 (dd, 1H,  $J_{3,4} = 3.2$  Hz,  $J_{4,5} < 1$  Hz, H-4), 3.90 (dd, 1H,  $J_{6,\text{OH}} = 6.8$  Hz,  $J_{6',\text{OH}} = 6.6$  Hz, OH-6), 3.79 (m, 2H, H6 and H6'), 3.68 (ddd, 1H,  $J_{2,3} = 10.5$  Hz, H-3), 3.65 (dd, 1H,  $J_{5,6} = 6.6$  Hz,  $J_{5,6'} = 3.9$  Hz, H-5), 3.57 (dd, 1H, H-2). <sup>13</sup>C NMR (acetone-*d*<sub>6</sub>)  $\delta$ : 132.5, 129.8, 128.3 (Ph), 86.8 (C-1), 80.1 (C-5), 74.9 (C-3), 69.3 (C-4), 64.2 (C-2), 62.2 (C-6). HR-MS (EI, *m/z*) calcd. for [C<sub>12</sub>H<sub>15</sub>N<sub>3</sub>O<sub>4</sub>S]<sup>+</sup>: 297.0783; found: 297.0794.

### Phenyl 2-azido-4,6-*O*-benzylidene-2-deoxy-1-thio- $\alpha$ -D-galactopyranoside (**3**)

A solution of compound **1** (2.98 g, 10.0 mmol), *p*-methoxybenzoic acid (0.10 g), and benzaldehyde (5 mL, 50.0 mmol, 5 equiv) in DMF–benzene (100 mL, 3:2 v/v) was refluxed in an apparatus for the azeotropic removal of water for 15 h. After TLC showed complete disappearance of the starting material, the reaction mixture was cooled to RT, neutralized with anhydrous potassium carbonate (1.00 g), filtered, and concentrated to yield an orange syrup, which was purified by flash column chromatography. Crystallization from ethanol–hexanes gave the title compound (**3**) as colorless needles; yield: 3.50 g (91%); mp 114.5–115.5 °C.  $[\alpha]_{\text{D}}^{23} +157.7^\circ$  (*c* 0.8, CHCl<sub>3</sub>); lit. value<sup>38</sup>  $[\alpha]_{\text{D}} +134.9^\circ$  (*c* 0.5, CHCl<sub>3</sub>).  $R_f = 0.35$  (ethyl acetate–hexanes 1:3). <sup>1</sup>H NMR  $\delta$ : 7.48–7.28 (m, 10H, Ph), 5.76 (d, 1H,  $J_{1,2} = 5.3$  Hz, H-1), 5.62 (s, 1H, CHPh), 4.34 (dd, 1H,  $J_{3,4} = 3.4$  Hz,  $J_{4,5} = 0.8$  Hz, H-4), 4.27 (bs, 1H, H-5), 4.26 (dd, 1H,  $J_{5,6a} = 1.6$  Hz,  $J_{6a,6e} = 12.5$  Hz, H-6a), 4.21 (dd, 1H,  $J_{2,3} = 10.5$  Hz, H-2), 4.16 (dd, 1H,  $J_{5,6e} = 1.5$  Hz, H-6e), 4.03 (ddd, 1H,  $J_{3,\text{OH}} = 10.4$  Hz, H-3), 2.54 (d, 1H, 3-OH). <sup>13</sup>C NMR  $\delta$ : 137.2, 137.7, 131.2, 129.5, 129.2, 128.4, 127.5, 126.2 (Ph), 101.4 (CHPh), 87.4 (C-1), 75.2 (C-4), 69.6 (C-3), 69.2 (C-6), 63.7 (C-5), 61.5 (C-2). HR-MS (EI, *m/z*) calcd. for [C<sub>19</sub>H<sub>19</sub>N<sub>3</sub>O<sub>4</sub>S]<sup>+</sup>: 385.1096; found: 385.1107.

### Phenyl 2-azido-4,6-*O*-benzylidene-2-deoxy-1-thio- $\beta$ -D-galactopyranoside (**4**)

Following the same procedure as in the preparation of compound **3**, compound **4** (3.21 g, 10.8 mmol) gave the title compound as colorless needles; yield: 3.70 g (89%); mp 79.0–80.0 °C.  $[\alpha]_{\text{D}}^{20} -23.0^\circ$  (*c* 0.5, CHCl<sub>3</sub>).  $R_f = 0.4$  (ethyl acetate–hexanes, 1:1). <sup>1</sup>H NMR (500 MHz)  $\delta$ : 7.79–7.33 (m, 10H, Ph), 5.58 (s, 1H, CHPh), 4.47 (d, 1H,  $J_{1,2} = 9.8$  Hz, H-1), 4.46 (dd, 1H,  $J_{5,6a} = 1.2$  Hz, H-6a), 4.24 (d, 1H,  $J_{3,4} = 3.5$  Hz, 1H, H-4), 4.09 (dd, 1H,  $J_{5,6e} = 1.4$  Hz,  $J_{6a,6e} = 12.5$  Hz, H-6e), 3.70 (ddd, 1H,  $J_{2,3} = 9.7$  Hz,  $J_{\text{OH},3} = 9.8$  Hz, H-3), 3.58 (dd, 1H, H-2), 3.57 (bs, 1H, H-5), 2.55 (d, 1H, 3-OH). <sup>1</sup>H NMR (acetone-*d*<sub>6</sub>, 500 MHz)  $\delta$ : 7.74–7.31 (m, 10H, Ph), 5.68 (s, CHPh), 4.68 (d, 1H,  $J_{1,2} = 9.9$  Hz, H-1), 4.58 (d, 1H,  $J_{\text{OH},3} = 8.8$  Hz, 3-OH), 4.33 (d, 1H,  $J_{3,4} = 2.7$  Hz, 1H, H-4), 4.27 (dd, 1H,  $J_{5,6a} = 1.4$  Hz,  $J_{6a,6e} = 12.2$  Hz, H-6a), 4.18 (dd, 1H,  $J_{5,6e} = 1.6$  Hz, H-6e), 3.81 (ddd, 1H,  $J_{2,3} = 9.7$  Hz, H-3), 3.79 (bs, 1H, H-5), 3.69 (d, 1H, H-2). <sup>13</sup>C NMR  $\delta$ : 137.4, 134.3, 130.4, 129.5, 129.0, 128.5, 128.3, 126.5 (Ph), 101.5 (CHPh), 85.2 (C-1), 74.5 (C-4), 73.3 (C-3), 69.9 (C-5), 69.3 (C-6), 62.2 (C-2). <sup>13</sup>C NMR (acetone-*d*<sub>6</sub>)  $\delta$ : 139.0, 133.1, 132.1, 129.0, 128.8, 128.0, 127.9, 126.7 (Ph), 100.9 (CHPh), 84.9 (C-1), 75.5 (C-4),

73.0 (C-3), 70.1 (C-5), 69.1 (C-6), 62.5 (C-2). HR-MS (EI,  $m/z$ ) calcd. for  $[C_{19}H_{19}N_3O_4S]^+$ : 385.1096; found: 385.1088.

**Phenyl 2-azido-2-deoxy-4,6-O-(*p*-methoxybenzylidene)-1-thio- $\alpha$ -D-galactopyranoside (5)**

A solution of compound **1** (0.97 g, 3.26 mmol), *p*-anisaldehyde (3.2 mL), and *p*-toluenesulfonic acid (80.0 mg) in DMF–benzene (65 mL, 3:2) was refluxed for 45 h in an apparatus for the azeotropic removal of water. After TLC showed that the starting material had disappeared, the reaction mixture was cooled to RT, neutralized by anhydrous potassium carbonate (1.00 g), filtered, and concentrated to a brown syrup. Purification by column chromatography (ethyl acetate–hexanes, 1:3) gave a colorless solid that crystallized from ethanol–hexanes as colorless needles; yield: 1.18 g (87%); mp 133.5–134.0 °C.  $[\alpha]_D^{23} +89.1^\circ$  (*c* 0.5, chloroform).  $R_f = 0.43$  (ethyl acetate–hexanes, 1:2).  $^1H$  NMR  $\delta$ : 7.48–7.26 (m, 8H, Ph), 6.91 (d, 1H, Ph), 5.76 (d, 1H,  $J_{1,2} = 5.3$  Hz, H-1), 5.58 (s, 1H, CHPh), 4.32 (bd, 1H,  $J_{3,4} = 3.5$  Hz, H-4), 4.26 (bs, 1H, H-5), 4.24 (bd, 1H, H-6a), 4.20 (dd, 1H,  $J_{2,3} = 10.6$  Hz, H-2), 4.12 (dd, 1H,  $J_{5,6a} = 1.5$  Hz,  $J_{6a,6b} = 12.3$  Hz, H-6b), 4.03 (ddd, 1H,  $J_{3,OH} = 10.4$  Hz, H-3), 2.55 (d, 1H, 3-OH).  $^{13}C$  NMR  $\delta$ : 160.5, 133.7, 129.7 (tertiary aromatic carbons), 131.2, 129.2, 127.7, 127.5, 113.7 (Ph), 101.4 (CHPh), 87.3 (C-1), 75.1 (C-4), 69.6 (C-3), 69.2 (C-6), 63.7 (C-5), 61.5 (C-2), 55.4 (OCH<sub>3</sub>).

**Phenyl 3-O-acetyl-2-azido-4,6-O-benzylidene-2-deoxy-1-thio- $\alpha$ -D-galactopyranoside (6)**

Acetic anhydride (1.5 mL, 97%, 15.0 mmol, 5 equiv) was added to a solution of compound **3** (1.15 g, 2.98 mmol) in dry pyridine (10 mL). The reaction mixture was stirred at RT for 24 h, and then concentrated under vacuum to give a colorless syrup. The syrup was dissolved in chloroform (15 mL). The solution was washed with saturated sodium bicarbonate aqueous solution (3 mL) and distilled water (3 mL), dried over sodium sulphate anhydrous, filtered, and concentrated to yield a colorless syrup. The syrup was crystallized from diethyl ether to give a colorless solid and recrystallized from ethanol–chloroform as colorless needles; yield: 1.20 g (94%); mp 154.5–155.5 °C.  $[\alpha] +198.9^\circ$  (*c* 0.6, CHCl<sub>3</sub>).  $^1H$  NMR  $\delta$ : 7.50–7.24 (m, 10H, Ph), 5.81 (d, 1H,  $J_{1,2} = 5.3$  Hz, H-1), 5.56 (s, 1H, CHPh), 5.13 (dd, 1H,  $J_{2,3} = 11.0$  Hz,  $J_{3,4} = 3.4$  Hz, H-3), 4.57 (dd, 1H, H-2), 4.53 (d, 1H, H-4), 4.26 (bs, 1H, H-5), 4.22 (dd, 1H,  $J_{5,6a} = 1.4$  Hz,  $J_{6a,6e} = 12.6$  Hz, H-6a), 4.09 (dd, 1H,  $J_{5,6e} = 1.7$  Hz, H-6e), 2.16 (s, 3H, COCH<sub>3</sub>).  $^{13}C$  NMR (acetone-*d*<sub>6</sub>)  $\delta$ : 170.6 (C=O), 139.5, 134.5, 132.9, 129.3, 128.9, 128.5, 127.3 (Ph), 101.4 (CHPh), 88.3 (C-1), 74.2 (C-4), 71.5 (C-3), 69.6 (C-6), 64.7 (C-5), 59.0 (C-2), 20.8 (COCH<sub>3</sub>). HR-MS (EI,  $m/z$ ) calcd. for  $[C_{21}H_{21}N_3O_5S]^+$ : 427.1202; found: 427.1202.

**Phenyl 3-O-acetyl-2-azido-2-deoxy-4,6-O-(*p*-methoxybenzylidene)-1-thio- $\alpha$ -D-galactopyranoside (7)**

Acetic anhydride (2 mL, 97%, 20.0 mmol) was added to a solution of compound **5** (1.18 g, 2.84 mmol) in dry pyridine (10 mL) and the reaction mixture was stirred at RT for 16 h, and was then concentrated under vacuum to give a orange syrup that was azeotroped with toluene (3  $\times$  4 mL) to give a yellow solid that on crystallization from ethanol, appeared

as colorless needles; yield: 1.26 g (97%); mp 138.5–140.0 °C.  $[\alpha] +206.2^\circ$  (*c* 0.6, CHCl<sub>3</sub>).  $R_f = 0.33$  (ethyl acetate–hexanes, 1:3).  $^1H$  NMR  $\delta$ : 7.50–6.88 (m, 9H, Ph), 5.80 (d, 1H,  $J_{1,2} = 5.5$  Hz, H-1), 5.51 (s, 1H, CHPh), 5.12 (dd, 1H,  $J_{2,3} = 11.0$  Hz,  $J_{3,4} = 3.1$  Hz, H-3), 4.57 (dd, 1H, H-2), 4.50 (d, 1H, H-4), 4.24 (bs, 1H, H-5), 4.20 (dd, 1H,  $J_{5,6a} = 1.4$  Hz,  $J_{6a,6b} = 12.8$  Hz, H-6a), 4.07 (dd, 1H,  $J_{5,6b} = 1.5$  Hz, H-6b), 3.81 (s, 3H, OCH<sub>3</sub>), 2.16 (s, 3H, COCH<sub>3</sub>).  $^{13}C$  NMR  $\delta$ : 170.3 (C=O), 160.2, 133.4, 130.0 (tertiary aromatic carbons), 131.3, 129.1, 127.5, 113.6 (Ph), 100.9 (CHPh), 87.3 (C-1), 73.1 (C-4), 71.4 (C-3), 69.1 (C-6), 63.4 (C-5), 57.8 (C-2), 55.3 (OCH<sub>3</sub>), 20.95 (COCH<sub>3</sub>).

**(*R*<sub>S</sub>) Phenyl 2-azido-4,6-O-benzylidene-2-deoxy-1-thio- $\alpha$ -D-galactopyranoside S-oxide (8*R*) and (*S*<sub>S</sub>) phenyl 2-azido-4,6-O-benzylidene-2-deoxy-1-thio- $\alpha$ -D-galactopyranoside S-oxide (8*S*)**

A solution of *m*-chloroperbenzoic acid (0.22 g, 77%, 1.02 mmol, 1.1 equiv) in dichloromethane (2 mL) was added to a mixture of compound **6** (0.40 g, 0.93 mmol) and sodium bicarbonate (0.10 g, 1.21 mmol, 1.3 equiv) in dichloromethane (8 mL) at –76 °C. The reaction mixture was stirred at –76 °C for 16 h. The reaction mixture was allowed to warm to RT and then diluted with dichloromethane (10 mL). The mixture was washed with 20% sodium thiosulfate (5 mL), saturated aqueous sodium bicarbonate solution (5 mL), and distilled water (5 mL), and then dried (sodium sulphate), filtered, and concentrated to give a colorless solid. Fractionation by column chromatography (ethyl acetate–hexanes, 1:2) yielded three compounds.

Compound **8*R*** was crystallized from ethanol–chloroform; yield: 247.5 mg (60%); mp 191.5–192.5 °C.  $[\alpha]_D^{22} +34.6^\circ$  (*c* 0.4, CHCl<sub>3</sub>).  $R_f = 0.20$ .  $^1H$  NMR (500 MHz)  $\delta$ : 7.54 (m, 2H, Ho-SPh), 7.45 (m, 3H, Hp-SPh and Hm-SPh), 7.36 (m, 5H, Ho-CHPh, Hm-CHPh, and Hp-CHPh), 5.78 (dd, 1H,  $J_{2,3} = 10.8$  Hz,  $J_{3,4} = 3.4$  Hz, H-3), 5.53 (s, 1H, CHPh), 4.95 (s, 1H,  $J_{1,2} = 5.7$  Hz, H-1), 4.65 (dd, 1H, H-2), 4.62 (d, 1H, H-4), 4.11 (bs, 1H, H-5), 4.14 (dd, 1H,  $J_{5,6e} = 1.5$  Hz, H-6e), 4.02 (dd, 1H,  $J_{5,6a} = 2.2$  Hz,  $J_{6a,6e} = 12.3$  Hz, H-6a), 2.16 (s, 3H, COCH<sub>3</sub>).  $^1H$  NMR (acetone-*d*<sub>6</sub>, 500 MHz)  $\delta$ : 7.86 (d, 2H, Ho-SPh), 7.65 (t, 2H, Hm-SPh), 7.60 (t, 2H, Hp-SPh), 7.51 (m, 2H, Ho-CHPh), 7.39 (m, 3H, Hm-CHPh and Hp-CHPh), 5.85 (dd, 1H,  $J_{2,3} = 11.0$  Hz,  $J_{3,4} = 3.5$  Hz, H-3), 5.69 (s, 1H, CHPh), 5.15 (d, 1H,  $J_{1,2} = 6.6$  Hz, H-1), 4.78 (dd, 1H, H-2), 4.66 (d, 1H, H-4), 4.32 (bs, 1H, H-5), 4.21 (dd, 1H,  $J_{5,6a} = 1.5$  Hz,  $J_{6a,6e} = 12.7$  Hz, H-6a), 4.09 (dd, 1H,  $J_{5,6e} = 1.5$  Hz, H-6a), 2.12 (s, 3H, COCH<sub>3</sub>).  $^1H$  NMR (CD<sub>2</sub>Cl<sub>2</sub>, 500 MHz)  $\delta$ : 7.77 (m, 2H, Ho-SPh), 7.63 (m, 2H, Hm-SPh), 7.61 (t, 2H, Hp-SPh), 7.50 (m, 2H, Ho-CHPh), 7.43 (m, 3H, Hm-CHPh and Hp-CHPh), 5.86 (dd, 1H,  $J_{2,3} = 10.8$  Hz,  $J_{3,4} = 3.5$  Hz, H-3), 5.58 (s, 1H, CHPh), 5.01 (d, 1H,  $J_{1,2} = 5.6$  Hz, H-1), 4.67 (dd, 1H, H-2), 4.61 (d, 1H, H-4), 4.20 (bs, 1H, H-5), 4.15 (dd, 1H,  $J_{5,6a} = 1.6$  Hz,  $J_{6a,6e} = 12.8$  Hz, H-6a), 4.07 (dd, 1H,  $J_{5,6e} = 1.6$  Hz, H-6a), 2.19 (s, 3H, COCH<sub>3</sub>).  $^1H$  NMR (CD<sub>3</sub>CN, 500 MHz)  $\delta$ : 7.80 (m, 2H, Ho-SPh), 7.63 (m, 3H, Hm-SPh and Hp-SPh), 7.48 (m, 2H, Ho-CHPh), 7.42 (m, 3H, Hm-CHPh and Hp-CHPh), 5.78 (dd, 1H,  $J_{2,3} = 11.0$  Hz,  $J_{3,4} = 3.4$  Hz, H-3), 5.61 (s, 1H, CHPh), 5.07 (d, 1H,  $J_{1,2} = 5.6$  Hz, H-1), 4.70 (dd, 1H, H-2),

Compound **9S** was crystallized from ethanol–chloroform to give colorless needles; yield: 56 mg (19%); mp 224.0–224.5 °C.  $[\alpha] +153.8^\circ$  (c 0.3, chloroform).  $R_f = 0.30$  (ethyl acetate–hexanes, 1:2). <sup>1</sup>H NMR  $\delta$ : 7.65–7.54 (m, 5H, PhH), 7.36, 6.87 (2d, 4H, PhH), 5.86 (dd, 1H,  $J_{2,3} = 11.0$  Hz,  $J_{3,4} = 3.4$  Hz, H-3), 5.47 (s, 1H, CHPh), 5.14 (d, 1H,  $J_{1,2} = 6.3$  Hz, H-1), 4.65 (dd, 1H, H-2), 4.61 (bd, 1H,  $J_{4,5} < 1$  Hz, H-4), 4.43 (bs, 1H, H-5), 4.02, 3.98 (2H, AB part of ABX pattern,  $J_{5,6a} = 1.5$  Hz,  $J_{5,6b} = 1.6$  Hz,  $J_{6a,6b} = 12.8$  Hz, H-6a, H-6b), 3.79 (s, 3H, OCH<sub>3</sub>), 2.16 (s, 3H, COCH<sub>3</sub>). <sup>13</sup>C NMR  $\delta$ : 170.3 (C=O), 160.4, 138.7, 134.4, 129.8, 129.4, 128.9, 127.6, 113.8 (Ph), 100.9 (CHPh), 89.9 (C-1), 72.7 (C-4), 69.9 (C-3), 68.8 (C-6), 67.1 (C-5), 56.2 (C-2), 55.5 (OCH<sub>3</sub>), 21.1 (COCH<sub>3</sub>).

**Phenyl 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-1-thio- $\beta$ -D-glucopyranoside (17)**

1,3,4,6-Tetra-*O*-acetyl-2-deoxy-2-phthalimido- $\beta$ -D-glucopyranose<sup>45–47</sup> (72.2 g, 0.15 mol) was treated with thiophenol and boron trifluoride etherate to give the title compound as a solid that was crystallized from 15% ethyl acetate in hexanes; yield: 64.4 g (81%); mp 140–141 °C, lit. value<sup>48</sup> mp 145–146 °C.  $[\alpha]_D^{25} 49.4^\circ$  (c 0.88, chloroform); lit. value<sup>48</sup>  $[\alpha]_D^{25} 53.0^\circ$ .

**(S<sub>S</sub>) Phenyl 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-1-thio- $\beta$ -D-glucopyranoside S-oxide (18S)**

A solution of *m*-chloroperbenzoic acid (0.60 g, 70%, 3.4 mmol, 1.0 equiv) in dry dichloromethane (7 mL) was added to a precooled solution of compound **17** (1.22 g, 2.31 mmol) in dichloromethane (18 mL) at –78 °C. The reaction mixture was stirred at –78 °C for 26 h and then allowed to warm to RT over 12 h. The mixture was washed with saturated sodium bicarbonate solutions (3  $\times$  25 mL) and water (25 mL), and then dried (sodium sulphate), fil-

tered, and concentrated to give a bright yellowish solid. Separation by flash column chromatography (ethyl acetate–hexanes, 1:1) gave the starting material (0.22 g) and colorless crystals of the product (0.95 g, 92% based on starting material consumed). Further fractionation using flash column chromatography (5% acetone in chloroform) gave **18S** as fluffy crystals that were recrystallized from 1% ethanol in hexanes to give clear colorless needles; mp 124–126 °C.  $[\alpha]_D^{25} +113^\circ$  (*c* 0.6, chloroform).  $R_f = 0.68$  (5% acetone in chloroform).  $^1\text{H}$  NMR (400 MHz)  $\delta$ : 7.68 (bd s, 2H, Phth-H), 7.84–7.60 (very bd s, 2H, Phth-H), 7.49 (d, 2H,  $J = 7.5$  Hz, *o*-Ar H), 7.21 (t, 2H,  $J = 7.5$  Hz, *m*-Ar H), 7.13 (t, 1H,  $J = 7.3$  Hz, *p*-Ar H), 5.77 (t, 1H,  $J_{2,3} = J_{3,4} = 9.7$  Hz, H-3), 5.40 (d, 1H,  $J_{1,2} = 10.1$  Hz, H-1), 5.16 (t, 1H,  $J_{3,4} = J_{4,5} = 9.7$  Hz, H-4), 4.89 (t, 1H, H-2), 4.20 and 4.28 (AB part of ABX pattern, 2H,  $J_{6a,6b} = 12.3$  Hz,  $J_{5,6a} = J_{5,6b} = 4.9$  Hz, 2 H-6), 3.91 (m, 1H, H-5), 2.09, 2.05, 1.85 (3s, 9H, 3 Ac).  $^{13}\text{C}$  NMR (100 MHz)  $\delta$ : 170.1, 169.8, 168.9 (3 Ac C=O), 167.6 (2 phth C=O), 138.8, 130.2, 128.4, 123.0 (S-Ph C), 133.9, 130.8, 123.9 (Phth C), 89.1 (C-1), 76.0 (C-5), 71.1 (C-3), 67.6 (C-4), 61.4 (C-6), 47.4 (C-2), 20.4, 20.2, 20.0 (Ac Me).

The second fraction was obtained as colorless fluffy crystals that decomposed on standing or on attempted recrystallization,  $R_f = 0.54$  (5% acetone in chloroform).  $^1\text{H}$  NMR (400 MHz)  $\delta$ : 7.90 (half of AA'BB' pattern, 2H, *o*-Phth-H), 7.90 (d, 2H, *o*-Ph H), 7.76 (half of AA'BB' pattern, 2H, Phth-H), 7.70 (t, 1H,  $J = 7.5$  Hz, *p*-Ar H), 7.58 (t, 2H,  $J = 7.7$  Hz, *m*-Ar H), 5.81 (t, 1H,  $J_{2,3} = J_{3,4} = 9.7$  Hz, H-3), 5.51 (d, 1H,  $J_{1,2} = 10.6$  Hz, H-1), 5.02 (t, 1H,  $J_{3,4} = J_{4,5} = 9.7$  Hz, H-4), 4.62 (t, 1H, H-2), 4.13 and 4.21 (AB part of ABX pattern, 2H,  $J_{6a,6b} = 12.8$  Hz,  $J_{5,6a} = J_{5,6b} = 4.8$  Hz, 2 H-6), 3.88 (m, 1H, H-5), 2.01, 2.00, 1.99 (3s, 9H, 3 Ac).  $^{13}\text{C}$  NMR (100 MHz)  $\delta$ : 170.0, 169.8, 168.9 (3 Ac C=O), 167.9 (2 phth C=O), 137.9, 130.1, 128.6, 123.4 (S-Ph C), 134.2, 131.3, 124.4 (Phth C), 86.1 (C-1), 76.3 (C-5), 71.2 (C-3), 67.8 (C-4), 61.4 (C-6), 49.4 (C-2), 20.3, 20.2, 20.0 (Ac Me).

This compound decomposed on standing into a compound ( $R_f = 0.82$ , 5% acetone in chloroform) that was purified by flash chromatography on silica gel (3% acetone in dichloromethane) as a syrup, identified as 3,4,6-tri-*O*-acetyl-2-deoxy-2-phthalimido-D-glucal;  $[\alpha]_D^{25} - 15.7^\circ$  (*c* 5.1, chloroform), lit.<sup>67</sup>  $[\alpha]_D - 15.0^\circ$ .  $^1\text{H}$  NMR (250.13 MHz)  $\delta$ : 7.96–7.74 (AA'BB' pattern, 4H, Phth-H), 6.78 (s, 1H, H-1), 5.61 (d, 1H,  $J_{3,4} = 4.0$  Hz, H-1), 5.33 (t, 1H,  $J_{4,5} = 4.4$  Hz, H-4), 4.54 (m, 2H, H-5, H-6a), 4.40 (m, 1H, H-6b), 2.16, 2.14, 1.94 (3s, 9H, 3 Ac).  $^{13}\text{C}$  NMR (100 MHz)  $\delta$ : 170.1, 169.9, 168.9 (3 Ac C=O), 167.9 (2 phth C=O), 148.2 (C-1), 134.3, 131.6, 123.7 (Phth C), 105.6 (C-2), 74.6 (C-5), 67.3 (C-3), 65.7 (C-4), 61.1 (C-6), 20.8, 20.6, 20.2 (Ac Me). HR-MS (EI)  $m/z$  calcd. for  $\text{C}_{20}\text{H}_{19}\text{NO}_9$ : 417.1059; found: 417.1045.

## Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca). CCDC 782358–782362 contain the X-ray data in CIF format for this manuscript. These data can be obtained, free of charge, via [www.ccdc.cam.ac.uk/conts/retrieving.html](http://www.ccdc.cam.ac.uk/conts/retrieving.html) (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or [deposit@ccdc.cam.ac.uk](mailto:deposit@ccdc.cam.ac.uk)).

# A general measure of conjugation in biphenyls and their radical cations

Lei Zhang, Gilles H. Peslherbe, and Heidi M. Muchall

**Abstract:** Changes in the amount of conjugation in the biphenyl system upon torsion have been investigated with quantum chemistry computations. For the unsubstituted biphenyl and its radical cation, the change in the energy for the first electronic transition as determined from time-dependent density functional theory, specifically TD-B3LYP, upon an imposed change in torsion angle appears to provide a good general measure of the delocalization of the  $\pi$ -electrons. Upon substitution, though, a relationship could not be established between the excitation energy and the twist across the C–C bond connecting the two phenyl rings. In contrast, the  $\pi$ -interaction energy, i.e., the  $\pi$ – $\pi$  interaction across the central C–C bond, determined from a natural bond orbital analysis, provides a uniform description of conjugation in the electronically different systems, for an imposed twist as well as upon substitution. Substituent effects are found to be larger and more varied for the biphenyl radical cations. Of particular interest is the introduction of the oxidizable substituents OCH<sub>3</sub> (methoxyl) and SCH<sub>3</sub> (methylthio), as this leads to the smallest changes in torsion angle in the biphenyl unit upon removal of an electron from the molecule. The findings of this work could ultimately prove useful for the rational design of conductive polymer materials.

**Key words:** biphenyl, conjugation, substituent effect, electronic excitation,  $\pi$ -interaction energy.

**Résumé :** Des calculs de chimie quantique, utilisant la théorie de la fonctionnelle de la densité dépendante du temps, spécifiquement TD-B3LYP, ont été effectués afin d'évaluer les variations de conjugaison dans le système biphenyle en fonction de sa torsion. Pour le biphenyle non substitué et son cation radicalaire, l'énergie correspondant à la première transition électronique suivant la torsion imposée semble fournir une mesure adéquate de la délocalisation des électrons  $\pi$ . Par contre, pour les biphenyles substitués, il n'est pas possible d'établir une relation entre l'énergie d'excitation et l'angle de torsion au niveau de la liaison C–C qui relie les deux phényles. Toutefois, l'énergie d'interaction  $\pi$ , c'est-à-dire l'interaction  $\pi$ – $\pi$  le long de la liaison C–C centrale, telle que déterminée par une analyse des orbitales naturelles de liaison, fournit une description uniforme de la conjugaison dans des systèmes électroniquement différents, que ce soit par torsion imposée ou par substitution. De plus, les effets de substitution sur la conjugaison sont plus prononcés et plus variés pour les cations radicalaires des biphenyles. Il est particulièrement intéressant de noter que l'introduction de substituants oxydables, tels que OCH<sub>3</sub> (méthoxyle) ou SCH<sub>3</sub> (méthylthio), entraîne la plus faible variation de l'angle de torsion de l'unité biphenyle lorsqu'elle perd un électron. Les résultats de ces travaux pourraient éventuellement aider à mieux prédire les propriétés de nouveaux matériaux à base de polymères conducteurs.

**Mots-clés :** biphenyle, conjugaison, effet de substituant, excitation électronique, énergie d'interaction  $\pi$ .

## Introduction

Conjugation, the delocalization of  $\pi$ -electrons, is related to important chemical and physical phenomena, such as aromaticity, spectral shifts, and electronic conductivity. Conductive polymers, especially oligo- and poly-*para*-phenylenes, have found widespread attention as active materials in light-emitting diodes and polymer lasers.<sup>1–5</sup> The properties of a conducting polymer are usually modified by manipulating their chemical structures, for example through substitution, to allow improved application in a particular optoelectronic device.<sup>6–8</sup> Whereas conjugation results in stabilization of a system through  $\pi$ -electron delocalization,

which is usually associated with the planarity of the system which guarantees maximum overlap between p-orbitals, steric effects<sup>9</sup> from substituents often induce a twist away from the planar conformation. The rational design of conductive polymers therefore requires a general measure of conjugation for an understanding of the structure–property relationships in both neutral (all-electron) and charged (radical cation) species.

The biphenyl unit (C<sub>6</sub>H<sub>5</sub>–C<sub>6</sub>H<sub>5</sub>) is ubiquitous in nature, and in the above context constitutes the smallest oligo-*para*-phenylene. Its planar geometry has been observed experimentally in the crystalline phase,<sup>13–10</sup> whereas a nonplanar

geometry has been observed in solutions<sup>14–16</sup> and in liquid<sup>17</sup> and gaseous<sup>14,18–20</sup> phases. A relationship between geometry and electronic structure has been established for the all-electron biphenyls.<sup>21,22</sup> In addition, experimental and theoretical studies have been carried out on halogenated biphenyl radical cations to determine how the type and position of substituents influence the geometry, optical absorption characteristics, ionization potentials, electron affinities, and decay kinetics of these radical cations.<sup>23–27</sup> Vibrational frequencies of the biphenyl radical cation have been calculated<sup>28,29</sup> and compared with those measured by Raman spectroscopy<sup>30–32</sup> to address geometrical changes upon ionization.

Whereas the geometry of an all-electron system is readily determined experimentally from diffraction studies, spectroscopic properties have to be employed to unveil information on the geometry and electronic structure of charged and radical species. Even for all-electron systems, though, electronic spectra are often consulted to determine an increase in conjugation. Yet, for subtle changes in geometry, as can be expected upon substitution in the biphenyl system, it might be difficult to distinguish between a shift in the appropriate absorption maximum owing to a change in conjugation between the two rings versus a shift from a simple change in chromophore upon substitution. Alternative parameters that have been traditionally considered to evaluate the  $\pi$ -electron delocalization in conjugated systems are the bond length, the electron density, and the ellipticity at its bond critical point (as determined within the quantum theory of atoms in molecules<sup>33</sup>). None of these is suitable as a general measure of  $\pi$ -electron delocalization, as will be shown below.

In this work, we establish that the  $\pi$ -interaction energy, given by the  $\pi$ - $\pi$  interaction across the central C–C bond and evaluated with the natural bond orbital approach, yields consistent results for forced twists of the unsubstituted biphenyl and its radical cation, as well as for a variety of monosubstituted biphenyls and their radical cations (Chart 1), which exhibit inherent twists over a wide range of torsion angles. This should prove of particular value with respect to the need for the rational design of materials.

## Computational details

Our previous benchmark calculations on substituted phenols suggest that time-dependent density functional theory (TD-DFT)<sup>34</sup> gives accurate results for excitation energies associated with electronic transitions from the ground state to the first two low-lying excited states, which correspond to absorption in the UV spectral region.<sup>35</sup> The same method has been used to accurately reproduce the absorption spectra of methoxyl- and methyl-substituted phenol radical cations<sup>36</sup> and phenoxyl radicals,<sup>37</sup> and to identify the source of substituent effects that cause significant band shifts in their experimental spectra. TD-DFT has also been used successfully to predict the electronic transition energies of polycyclic aromatic hydrocarbons,<sup>38</sup> and is therefore employed for the calculation of the excitation energies of biphenyl systems in this work. For comparison and further validation, excitation energies for the biphenyl radical cation were also determined with the multi-configuration complete active space

Chart 1.

second-order perturbation theory (CASPT2),<sup>39</sup> using the MOLPRO quantum chemistry package.<sup>40</sup>

All TD-DFT calculations were performed with the Gaussian 03 quantum chemistry package.<sup>41</sup> Ground-state equilibrium geometries were located by full optimization with Becke's three-parameter hybrid exchange functional and the Lee, Yang, and Parr correlation functional, commonly referred to as B3LYP,<sup>42–44</sup> with the 6–31G(d) basis set.<sup>45,46</sup> This method and basis set have been shown to produce results with an accuracy close to that of calculations with the quadratic configuration interaction with single, double, and perturbative triple excitations (QCISD(T)) level of theory in the forced torsion of the 1,3-butadiene radical cation.<sup>47</sup> Vibrational frequency calculations using the same model chemistry were performed to confirm that all stationary points are minima on the potential energy surface. Torsional profiles were obtained by constraining the torsion angle between the two phenyl rings and relaxing all other geometrical parameters. More specifically, both C2–C1–C1'–C2' and C6–C1–C1'–C6' torsion angles (see Chart 1 for atom numbers) were constrained to the same value to avoid the pyramidalization of C1 and C1' that has been observed earlier in the torsion of the 1,3-butadiene radical cation.<sup>47</sup> Vertical excitation energies were calculated for ground-state geometries using TD-B3LYP and CASPT2 (with an active space consisting of nine ring electrons distributed into five occupied and two virtual  $\pi$ -type orbitals) with the 6–311++G(d,p) basis set.<sup>48,49</sup>

A topological analysis of the electron density was performed for all substituted biphenyls and their radical cations with the quantum theory of atoms in molecules.<sup>33,50</sup> The electron density and ellipticity at the bond critical point (the point between two nuclei where the gradient vector field of the electron density is zero with two negative and one positive curvature) of the central C–C bond were obtained from the B3LYP/6–31G(d) electron density using the AIM2000 package.<sup>51</sup>

The  $\pi$ -interaction energies were estimated from the orbital energy difference between the “filled” (donor) Lewis-type natural bond orbital (NBO) corresponding to the  $\pi$ -orbital of one C=C bond in one ring and the “empty” (acceptor) non-Lewis NBO corresponding to the  $\pi^*$ -orbital of its conjugated C=C bond in the other ring, the electron occupancy of the donor Lewis-type NBO and the off-diagonal Fock (or Kohn–Sham) matrix element by natural bond orbital (NBO) analysis,<sup>52–57</sup> using the NBO version 3.1 program embedded in the Gaussian 03 package. Because the NBO procedure localizes  $\pi$ -bonds in the aromatic ring, artificially distinct  $s$ -cis and  $s$ -trans interactions across the central C–C bond can

<sup>a</sup>From NBO 4.M.

<sup>b</sup>Two equally populated biphenyl rotamers are found as minima, differing in the orientation of the substituent. A unique global minimum is found for their corresponding radical cations.

be characterized. As these carry different energy values, a phenomenon reflective of the differences in the electronic excitation for cisoid and transoid dienes, both energies were evaluated. When NBO 3.1 would not provide a given  $\pi$ -interaction energy (*s*-cis or *s*-trans) by default for the mono-substituted biphenyls included in this study (Chart 1), that particular Lewis structure (indicated in the footnote of Table 1) was analyzed with the stand-alone NBO 4.M program.<sup>58</sup>

## Results and discussion

### Biphenyl and its radical cation

The energy barrier for torsion in biphenyl was determined to be about 1–2 kcal/mol (1 cal = 4.184 J) by nuclear magnetic resonance (NMR) and Raman spectroscopic techniques.<sup>18,19,59,60</sup> Such a small torsional energy barrier has been a challenge for molecular mechanics owing to the improper parameterization of the torsional term in force fields,<sup>61,62</sup> and characterizing the torsional potential energy profile of biphenyl from quantum chemistry calculations has been the central topic of many reports.<sup>63–66</sup>

The torsional potential energy profiles for biphenyl and its radical cation in the range 0° to 90° are shown superimposed in Fig. 1. For biphenyl, the calculated energy barriers of 2.1 kcal/mol (0°) and 2.5 kcal/mol (90°) are comparable to the experimental values of  $\Delta E_0 = 1.4 \pm 0.5$  kcal/mol and  $\Delta E_{90} = 1.6 \pm 0.5$  kcal/mol,<sup>18</sup> and to the calculated values of 2.0–3.9 kcal/mol for  $\Delta E_0$  and 1.2–2.4 kcal/mol for  $\Delta E_{90}$  in previous reports.<sup>22,64,67–70</sup> In contrast to these small barriers, the calculated torsional potential energy profile for the biphenyl radical cation exhibits an energy barrier as high as 18.3 kcal/mol, corresponding to the 90° conformation. Although there is a lack of direct experimental evidence for the size of the barrier in the biphenyl radical cation itself, a similarly high torsional energy barrier (>10 kcal/mol) has been reported for the related 3,3'-dimethyl-4,4'-dihydroxybiphenyl radical cation from the temperature dependence of the electron spin resonance (ESR) signal.<sup>71</sup> The torsional potential energy profile for the biphenyl radical cation beyond 90° (up to 180°) was also evaluated; it was found to be smooth and symmetric about the 90° mark without evidence for a jump to a higher energy surface beyond 90°, as had been a concern for the related 1,3-butadiene radical cation.<sup>47</sup>

The torsion angle of the equilibrium geometry changes from 38.4° in biphenyl to 19.5° in its radical cation. Such a partial planarization upon removal of one electron has also been found for 4,4'-dihydroxybiphenyl and for halogenated biphenyls.<sup>23–25,72,73</sup> Accordingly, for the unsubstituted biphenyl radical cation, the planar conformation is only 0.3 kcal/mol (1.1 kcal/mol if corrected for zero-point vibrational energies) higher in energy than the equilibrium geometry. This very small barrier to planarity is an indication of the importance of increased conjugation in the stabilization of the biphenyl radical cation. Given the very small energy difference, and in view of computational accuracy, although the calculated equilibrium geometry is nonplanar, a planar structure might well be found experimentally. In fact, the ESR spectrum of the biphenyl radical cation in solution does not provide any evidence for nonplanarity.<sup>74</sup>

**Fig. 1.** Torsional potential energy profiles for biphenyl (●) and the biphenyl radical cation (○) from B3LYP/6–31G(d) calculations.

**Chart 2.** Molecular orbitals for the lowest energy electronic transition for (a) biphenyl and (b) the biphenyl radical cation (planar conformations) from B3LYP/6–31G(d) calculations.

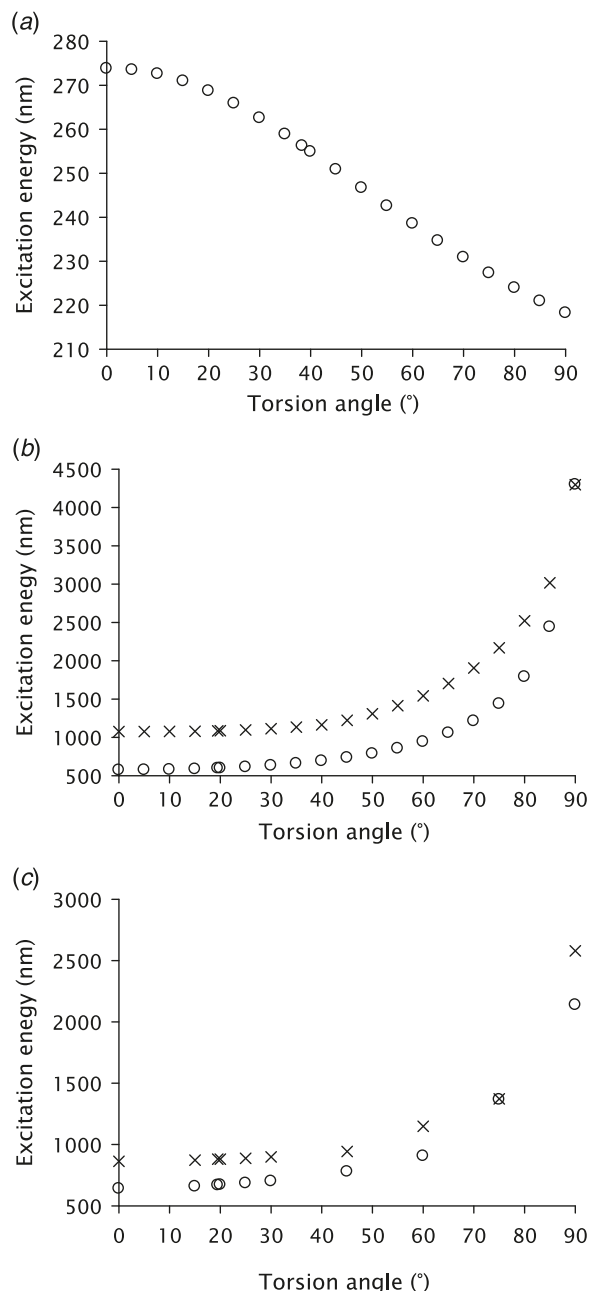

### Energy of the first electronic transition

It is generally accepted that an increase in conjugation leads to an energetic destabilization of the highest occupied molecular orbital (HOMO) and stabilization of the lowest unoccupied molecular orbital (LUMO). The resulting decrease in the HOMO–LUMO gap can be probed spectroscopically, and a shift of the corresponding absorption maximum ( $\lambda_{\max}$ ) to longer wavelengths is indeed observed for more highly conjugated systems.<sup>75,76</sup> The energy of the first electronic transition, expressed in nm, is plotted as a function of torsion angle in Fig. 2. Numerical data are provided in Table S1 of the Supplementary data. Figure 2a shows the expected shift to longer wavelengths (bathochromic or red shift) for the corresponding absorption wavelength,  $\lambda_{\max}$  for the all-electron biphenyl system upon planarization. As expected, this absorption band results from a transition from the HOMO to the LUMO. These orbitals, obtained from B3LYP/6–31G(d) calculations for the planar conformation, are shown in Chart 2.

In contrast, an increase in conjugation in the biphenyl radical cation leads to a shift of the first electronic excitation to shorter wavelengths (hypsochromic or blue shift) for the corresponding  $\lambda_{\max}$ , Fig. 2b). This fundamentally different behaviour of the excitation energy upon torsion from that in biphenyl takes its roots from the molecular orbitals (MOs)

**Fig. 2.** Excitation energy versus torsion angle for (a) biphenyl and (b) and (c) the biphenyl radical cation. In (b) and (c), the energies are given for the first observable electronic excitation (○) and for the electronic excitation from HOMO-1 to SOMO (×); (a) and (b) are from TD-B3LYP/6-311++G(d,p) calculations and (c) from CASPT2/6-311++G(d,p) calculations.

implicated in the electronic transition. In contrast to biphenyl, where the absorption maximum corresponds to the HOMO–LUMO transition, for the biphenyl radical cation, the absorption involves a transition from a lower lying doubly occupied molecular orbital to the singly occupied molecular orbital (SOMO, which is still the highest occupied MO). The SOMO and the third lower-lying doubly occupied MO (HOMO-3) are shown in Chart 2b for the planar confor-

mation of the biphenyl radical cation. Because the SOMO of the radical cation has the same character as the HOMO of biphenyl, it is also destabilized upon planarization, whereas the favourable interaction between the two rings in the HOMO-3 is facilitated, leading to a stabilization of this orbital. As a result, the largest HOMO-3–SOMO gap, and therefore the largest excitation energy or the shortest wavelength of excitation, is found for the planar conformation. The character of the lower-lying doubly occupied MO implicated in the electronic transition remains upon torsion, but the orbital energy ordering changes smoothly with the torsion angle, as the MO shifts from HOMO-3 at 0° to HOMO-1 at 90°. Yet, even if the HOMO-1 to SOMO electronic excitation is considered throughout the torsion, increasing planarity still leads to this blue shift (Fig. 2b). High-accuracy CASPT2 calculations (Fig. 2c) confirm that the excitation energies for the more highly-twisted conformations lie in the near-IR spectral region and that these are not long-wavelength artifacts of the TD-B3LYP method. Finally, the calculated excitation energy, expressed in nm, for the minimum geometry resembles the experimental  $\lambda_{\text{max}}$  value of 670 nm.<sup>77</sup>

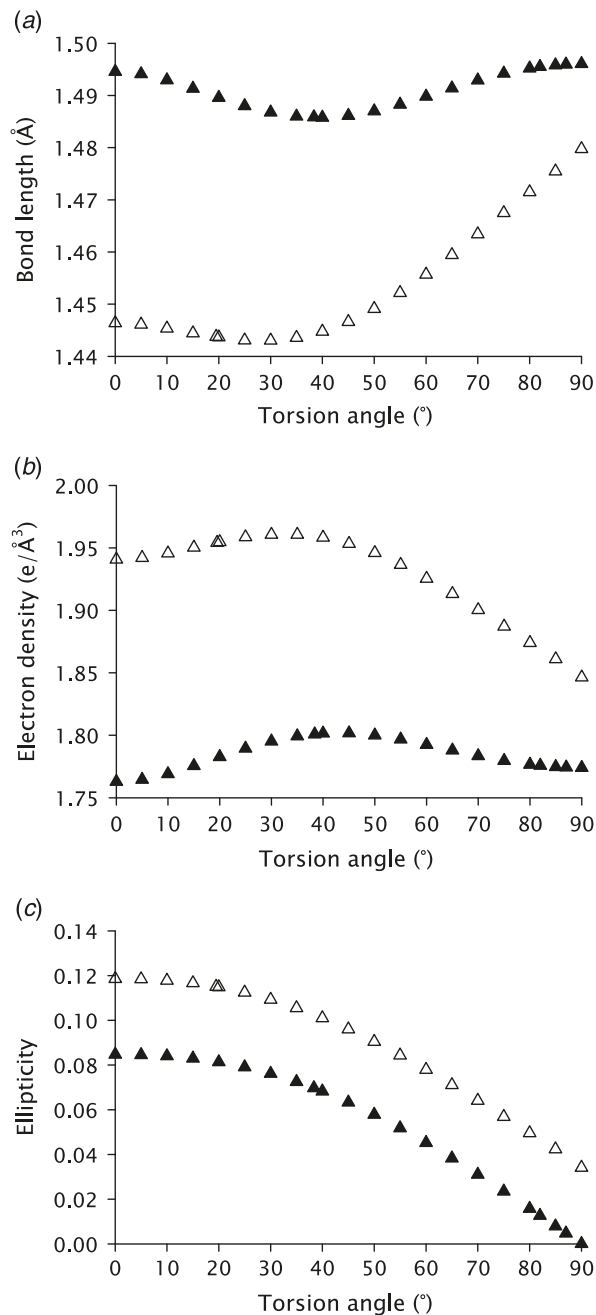

According to the monotonic behaviour of the torsional plots determined above in the range of 0° to 90° for biphenyl and its radical cation, the energy of the first electronic transition appears to reflect the extent of the delocalization of  $\pi$ -electrons, at least for these unsubstituted, electronically different systems.

#### **Bond length, electron density, and ellipticity of the central C–C bond**

Planarization in the biphenyl system favors a maximum overlap between the p-orbitals, leading to a shorter central C–C bond with more double-bond character owing to increased delocalization of  $\pi$ -electrons between the two rings. In general, changes in  $\pi$ -character can be probed conveniently by the quantum theory of atoms in molecules<sup>33,50</sup> through the values of the electron density and ellipticity at the bond critical point.<sup>54</sup> The relationships involving bond length, bond-critical-point electron density, and ellipticity are shown in Fig. 3, while the numerical data are provided in Table S2 of the Supplementary data. For biphenyl and its radical cation, the bond length and bond-critical-point electron density (Figs. 3a and 3b) do not vary monotonically in the twist range of 0° (planar) to 90° (perpendicular), so neither can provide a reasonable measure of conjugation in biphenyl systems.

Derived from the two negative curvatures of the electron density at the bond critical point, the ellipticity quantifies the deviation from cylindrical symmetry of a bond.<sup>54</sup> Figure 3c shows a good correlation between the ellipticity and the torsion angle for both the all-electron and radical cationic biphenyls. Figure 3c also clearly shows that the  $\pi$ -bond character of the central C–C bond increases along with the conjugation and upon removal of an electron, in agreement with earlier reports on halogenated and hydroxyl-substituted biphenyls.<sup>67,76</sup> The ellipticity thus also proves to provide a general measure of delocalization for the unsubstituted biphenyl and its radical cation.

**Fig. 3.** Properties of the central C–C bond. (a) Bond length, (b) electron density, and (c) ellipticity at the bond critical point versus torsion angle for biphenyl ( $\blacktriangle$ ) and the biphenyl radical cation ( $\triangle$ ) from B3LYP/6–31G(d) calculations.

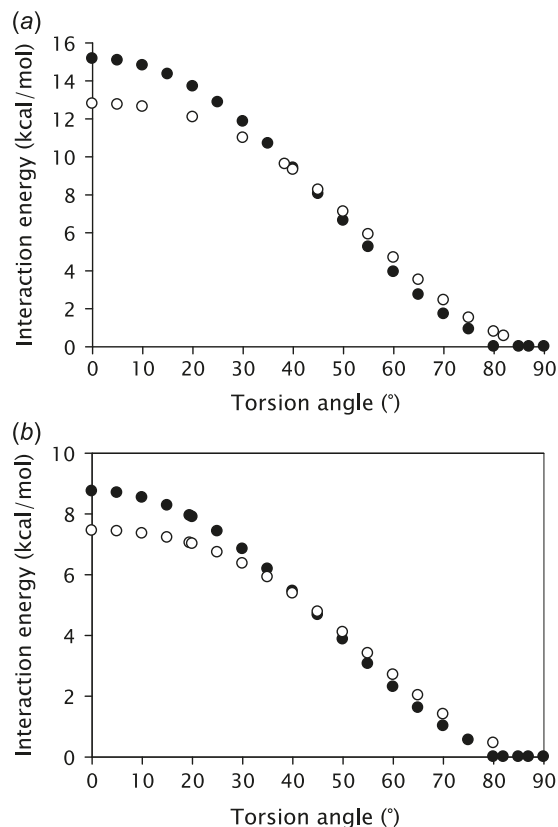

### $\pi$ -Interaction energy

The  $\pi$ -interaction energy for the  $\pi$ – $\pi$  interaction across the central C–C bond connecting the two phenyl rings is plotted as a function of torsion angle in Fig. 4, and numerical data are provided in Table S1 of the Supplementary data. As one might expect, for both biphenyl and its radical cation, the  $\pi$ -interaction energy decreases monotonically with an increase in torsion angle from 0° to 90°. The  $\pi$ -interaction energy therefore also captures changes in the delocalization of  $\pi$ -electrons in these electronically different systems.

As noted above, since the NBO treatment localizes  $\pi$ -

**Fig. 4.**  $\pi$ -Interaction energy versus torsion angle for (a) biphenyl and (b) the biphenyl radical cation ( $\circ$ , *s*-cis, and  $\bullet$ , *s*-trans  $\pi$ -interaction, across the central C–C bond) from B3LYP/6–31G(d) calculations.

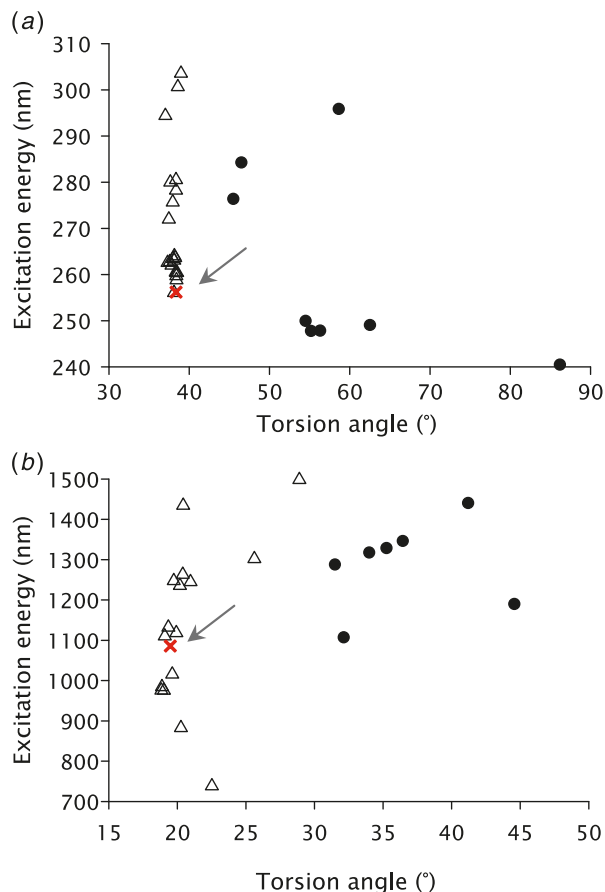

bonds in the phenyl rings, both artificial *s*-cis and *s*-trans interactions are possible across the central C–C bond. For the planar conformation of biphenyl, the *s*-trans  $\pi$ -interaction energy is 2.4 kcal/mol larger than the *s*-cis  $\pi$ -interaction energy (the difference is only 1.3 kcal/mol in the planar biphenyl radical cation), which is comparable to the size of the largest change in the  $\pi$ -interaction energy upon a 10° twist in the region of 45° (Fig. 4). A crossover occurs at a torsion angle of about 40°, and the *s*-cis  $\pi$ -interaction energy becomes slightly larger than the *s*-trans  $\pi$ -interaction energy for torsion angles in the range 45–90° (numerical data are given in Table S1 of the Supplementary data). In view of the fact that *s*-trans and *s*-cis  $\pi$ -interactions contribute almost equally to the stability of biphenyl systems, the average value of the  $\pi$ -interaction energy is adopted in the following discussion to characterize monosubstituted biphenyl systems, while both *s*-cis and *s*-trans numerical data are reported in Table 1 and provided in Fig. S1 of the Supplementary data.

### Substituted biphenyls and their radical cation

The calculated torsion angle at the equilibrium geometry of gas-phase biphenyl is 38.4°. The twist is more or less controlled by the steric effect of the *ortho*-hydrogen atoms.<sup>78–80</sup> In the monosubstituted biphenyls included in this study (Chart 1), one hydrogen atom is replaced by a substituent, differing in size and electronic property. While its size might be of principal importance in the *ortho* posi-

**Fig. 5.** Excitation energy versus torsion angle for (a) monosubstituted biphenyls (first observable electronic excitation) and (b) monosubstituted biphenyl radical cations (electronic excitation from HOMO-1 to SOMO) from TD-B3LYP/6-311++G(d,p) calculations. The unsubstituted species are included for reference and pointed out by the arrows (●, ortho-substituted; △, meta- or para-substituted; and ×, unsubstituted).

tion, its electronic properties might be expected to surface in meta and para positions, thus leading to a different torsion angle for the respective equilibrium geometry. It is therefore desirable to identify a suitable parameter that can describe changes in conjugation in the presence of these factors.

#### Energy of the first electronic transition

In UV-vis spectroscopy, for a variety of parent chromophores, it is well established that, and how,  $\lambda_{\max}$  for the lowest energy  $\pi \rightarrow \pi^*$  transition varies with substitution. Conversely, for substituted phenoxyl radicals and phenol radical cations,  $\lambda_{\max}$  can vary in a seemingly unpredictable way.<sup>13</sup> Thus, for a molecular system in which conjugation can be removed or increased through torsion, such as in the biphenyls, substitution constitutes a second, independent factor affecting the energy of absorption. An experimentally observed  $\lambda_{\max}$  or a corresponding calculated excitation energy consequently might not be a suitable measure for the change in conjugation.

The energy of the first electronic excitation is plotted as a function of torsion angle in Fig. 5, and the numerical data are provided in Table S3 of the Supplementary data. It is

**Fig. 6.** Ellipticity at the bond critical point of the central C–C bond versus torsion angle for substituted biphenyls (▲) and substituted biphenyl radical cations (△) from B3LYP/6-31G(d) calculations.

evident from Fig. 5 that a correlation between the lowest excitation energy for a  $\pi \rightarrow \pi^*$  transition and the size of the torsion angle does not exist for substituted biphenyls or their radical cations.

#### Ellipticity at the bond critical point of the central C–C bond

The relationship between the ellipticity at the bond critical point of the central C–C bond and the torsion angle is shown in Fig. 6, and the numerical data are provided in Table S3 of the Supplementary data. Figure 6 exhibits a small set of data points that could have been considered outliers to an otherwise good correlation between the ellipticity and the torsion angle. However, those data points stem entirely from the ortho-substituted biphenyl radical cations, and therefore the ellipticity fails to provide a general measure of delocalization for both substituted all-electron and radical cationic biphenyls.

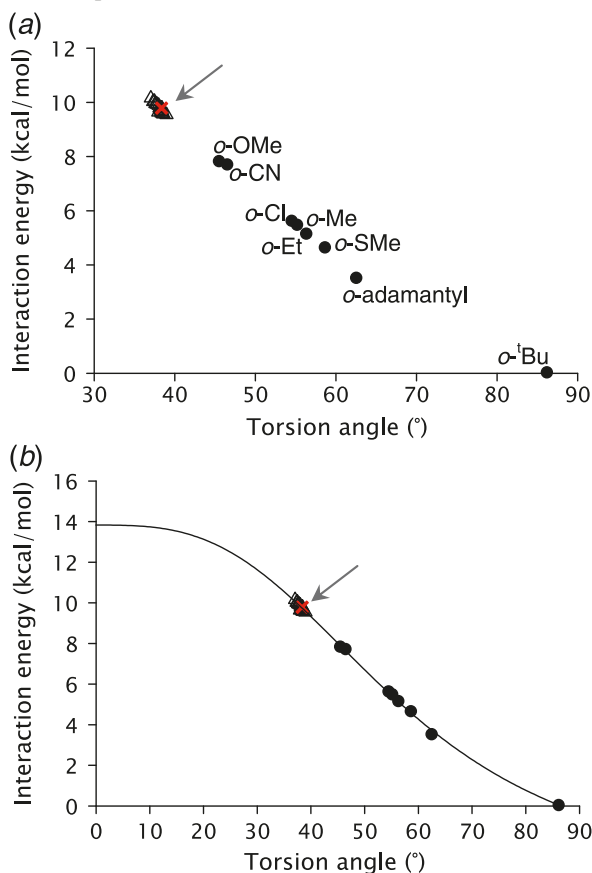

#### $\pi$ -Interaction energy

##### Substituted biphenyls

The equilibrium-geometry torsion angles and  $\pi$ -interaction energies for substituted biphenyls are provided in Table 1, and the  $\pi$ -interaction energies are plotted as a function of torsion angle in Fig. 7. In general, the relationship between the  $\pi$ -interaction energy and the torsion angle at the equilibrium geometry for the substituted biphenyls (Fig. 7a) is similar to that for torsion of the unsubstituted biphenyl (Fig. 4a). As expected, the steric effect at the ortho position is pronounced and results in torsion angles of around 45° for a small substituent, around 55° for medium-sized substituents, and up to 86° for the bulky *tert*-butyl substituent. Qualitatively, the similar-size chloro- and methyl-substituents lead to comparable torsion angles, as does the ethyl group, which exercises a steric hindrance comparable to that of the methyl group.<sup>81</sup> This assessment fits well with the results from a recent attempt at quantifying steric effects in the biphenyl system.<sup>82</sup>

Any steric effect for meta-substitution has to be transmitted through a change in bond angle on the adjacent ortho-carbon atom. Figure 7a shows that, if present, the increased hindrance between ortho-H atoms in meta-substituted bi-

**Fig. 7.** (a) Average  $\pi$ -interaction energy versus torsion angle for monosubstituted biphenyls from B3LYP/6–31G(d) calculations. (b) Superposition of the data from (a) with the trend line obtained from the biphenyl torsion profile. The unsubstituted biphenyl is included for reference and is pointed out by the arrow (●, ortho-substituted;  $\Delta$ , meta- or para-substituted; and  $\times$ , unsubstituted).

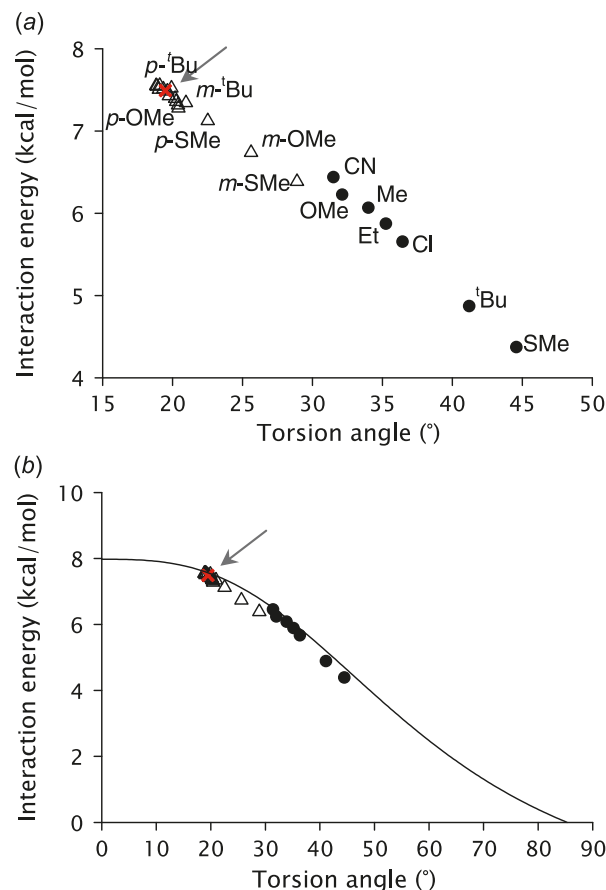

phenyls is negligible, as their torsion angles fall into the narrow range of 37.9 to 39.0° (Table 1), which is close to the torsion angle in the unsubstituted biphenyl. All torsion angles of para-substituted biphenyls also fall into this general range (37.0–38.2°). The values are somewhat smaller than those found for meta-substitution, which is a reflection of the small electronic effect the para-substituents exercise. In fact, Fig. 7b shows that the equilibrium data for the substituted biphenyls from Fig. 7a are superimposed with the corresponding data for the unsubstituted biphenyl torsion (Fig. 4a), which further confirms that the steric effect, controlled by the size of the ortho-substituent, dominates over any electronic effect.

#### Substituted biphenyl radical cations

The equilibrium-geometry torsion angles and  $\pi$ -interaction energies for the substituted biphenyl radical cations are provided in Table 1, and the  $\pi$ -interaction energies are plotted as a function of torsion angle in Fig. 8. Similarly to what was observed for the unsubstituted biphenyl and its radical cation, the  $\pi$ -interaction energy decreases, as expected, with an increase in torsion angle (Fig. 8a), and all substituted radical cations are more planar than their corresponding all-electron counterparts. The changes in torsion angle between substituted all-electron biphenyls and their radical cations,

**Fig. 8.** (a) Average  $\pi$ -interaction energy versus torsion angle for monosubstituted biphenyl radical cations from B3LYP/6–31G(d) calculations. (b) Superposition of the data from (a) with the trend line obtained from the biphenyl radical cation torsion profile. The unsubstituted biphenyl radical cation is included for reference and is pointed out by the arrow (●, ortho-substituted;  $\Delta$ , meta- or para-substituted; and  $\times$ , unsubstituted).

given in Table 1, are consistent with the differences in the electronic properties of the substituents. The decrease in torsion angle ( $\Delta\phi$ ) upon ionization is in the range 10.1 to 21.2° for all substituted biphenyls, except for the *tert*-butyl substituted system with a sizeable  $\Delta\phi$  of 45.0°. As a consequence, and in contrast to the all-electron system, the *ortho-tert*-butyl biphenyl radical cation does not exhibit the largest torsion angle in the series. In fact, a marginally larger torsion angle is found for *ortho*-methylthio (SMe) substitution (Table 1). One important difference between these two substituents is clearly the fact that the sulfur atom possesses electron lone pairs and can thus be easily oxidized, whereas low-energy ionization for the *tert*-butyl system can only be achieved by removal of electrons from the aromatic rings. Because the *tert*-butyl group is electronically simply an observer in the oxidation, the biphenyl unit experiences an increased need for  $\pi$ -electron delocalization, similar to that in the unsubstituted biphenyl radical cation itself, which is counteracted by the size of the *tert*-butyl group. In short, for ortho-substituted biphenyl radical cations, although steric effects still control the equilibrium-geometry torsion angle, electronic effects become apparent.

For the meta- and para-substituted biphenyl radical cations,

**Chart 3.** Spin density plots for (a) unsubstituted, (b) *meta*-methylthio, and (c) *meta-tert*-butyl biphenyl radical cations from B3LYP/6–31G(d) calculations.

ons, a much wider range of torsion angles is found when compared with their all-electron counterparts (a range of  $10^\circ$  versus  $2^\circ$  for the biphenyls), and this can be ascribed to electronic effects. As was observed for the substituted biphenyls, all torsion angles for the para-substituted radical cations are similar to or only slightly smaller than those found for meta-substitution, with two notable exceptions. For methoxyl (OMe) substitution the difference is  $5.3^\circ$  and for methylthio (SMe) substitution it is  $6.4^\circ$ . The  $\Delta\varphi$  values in Table 1 suggest that the two meta-substituted species are not planarized to the same extent as most other biphenyl radical cations. In other words, delocalization across the two aromatic rings is less important in these two cases because of the role of the substituent. Overall, for meta- and para-substitution, electronic effects govern the control of the geometry, and deviations from the torsional profile of the unsubstituted biphenyl radical cation are observed (Fig. 8b). The data show that substitution with electron-donating groups leads to less planarization upon removal of one electron from the molecule. These radical cations remain in more highly twisted equilibrium geometries, with the methylthio-substituted biphenyl radical cations exhibiting the largest torsion angles in their respective series (Table 1). Upon ionization of these biphenyls, in contrast to alkyl-substituted biphenyls, the electron can be removed mainly from the substituent electron lone pairs. As a consequence, the aromaticity of the phenyl rings is less disrupted, and the propensity for planarization in the radical cation is decreased. This is particularly pronounced in the meta-substituted series, where methylthio substitution results in a torsion angle that is larger than that for *tert*-butyl substitution by  $8^\circ$  (Table 1). The spin density plots from B3LYP/6–31G(d) calculations in Chart 3 confirm that the electron is mainly removed from the electron lone-pairs of sulfur for *meta*-methylthio substitution, while it is mainly removed from the phenyl rings for the *meta-tert*-butyl biphenyl radical cation.

## Conclusions

Although at times the spectroscopic behaviour in the UV and visible spectral regions can be used to evaluate the extent of conjugation in organic molecules, the dependence of the energy of the first electronic excitation on the torsion appears to provide a general measure of conjugation only for the unsubstituted biphenyl and its radical cation. General correlations between the excitation energy and the amount

of twist in substituted biphenyls and their radical cations are absent. Equally unsuitable as general measures of conjugation are the bond length and the bond-critical-point electron density of the central C–C bond. The ellipticity at the bond critical point of the central C–C bond only provides a good measure of conjugation for unsubstituted biphenyl species, not for substituted ones.

In contrast, the  $\pi$ -interaction energy, calculated from the  $\pi$ – $\pi^*$  orbital interaction across the central C–C bond connecting the two phenyl rings, provides a good general measure of the delocalization of the  $\pi$ -electrons, as increased  $\pi$ -interaction energies are obtained upon planarization of both the biphenyls and their radical cations. Whereas steric effects controlled by the size of the substituent at the ortho-position prevail over electronic effects for the biphenyls, in the radical cations, electronic effects play an increased role in dictating the twist.

This work suggests that, where traditional indicators fail, the calculated  $\pi$ -interaction energy can be used as a measure of conjugation. Assessing the amount of conjugation is indeed important given the relationship between conjugation and propensity for radical cation formation within systems containing biphenyl templates, such as conducting polymers or natural polymers like lignin.

## Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca) (tables of vertical excitation energies, absorption wavelengths, and  $\pi$ -interaction energies of biphenyl and its radical cation upon forced torsion; electron densities and ellipticities at the bond critical point of the central C–C bond, and C–C bond lengths for substituted biphenyls and their radical cations; and correlation diagrams for *s*-cis and *s*-trans  $\pi$ -interaction energies of monosubstituted biphenyls and their radical cations).

# Nonlinear time-dependent density functional theory investigation and visualization of ionizations in CO<sub>2</sub>—Effects of laser intensities and molecular orientations

Emmanuel Penka Fowe and André Dieter Bandrauk

**Abstract:** Time-dependent density functional theory (TDDFT) studies of the ionization of CO<sub>2</sub> by intense laser pulses  $I_0 \geq 1 \times 10^{14}$  W/cm<sup>2</sup>, at 800 nm are presented using the LB94 and the LDA potentials. Results reveal that for lower laser peak intensity,  $I_0 = 3.5 \times 10^{14}$  W/cm<sup>2</sup>, the highest occupied molecular orbital (HOMO) contributes significantly to ionization owing to its lower ionization potential (IP), whereas the inner orbitals play the important role for higher laser peak intensities. Even though such lower orbitals have higher IP, the ionization process occurs when orbital densities are maximum along the direction of the laser field polarization. These findings are confirmed through the analysis of the images from the time-dependent electron localization function (TDELf) and the spectra of higher order harmonic generation (HOHG). Additionally, in spite of the IP difference between Kohn–Sham orbitals from LDA and LB94 potentials, our results show almost the same trend for both.

**Key words:** TDDFT, orbital ionization, TDELf, HOHG.

**Résumé :** On rapporte les résultats d'études faites en utilisant le potentiel LB94 et LDA et la théorie de la densité fonctionnelle dépendante du temps (TDFDT) sur l'ionisation du CO<sub>2</sub> en champ laser intense,  $I_0 \geq 1 \times 10^{14}$  W/cm<sup>2</sup>, à 800 nm. Les résultats démontrent que, pour une intensité plus faible du pic laser, intensités  $I_0 = 3,5 \times 10^{14}$  W/cm<sup>2</sup>, à 800 nm, l'orbitale moléculaire hautement occupée (OMHO), contribue d'une façon significative à l'ionisation en raison de son potentiel d'ionisation (PI) plus faible, alors que pour les intensités de pics laser plus élevées, ce sont les orbitales internes qui jouent le rôle principal. Bien que les orbitales inférieures soient caractérisées par des potentiels d'ionisation, PI, plus élevés, le processus d'ionisation se produit quand les densités d'orbitales sont maximal dans la direction du champ de polarisation du laser. Ces observations sont confirmées par une analyse des images obtenues à partir de la fonction de localisation de l'électron dépendante du temps (FLEDt) et des spectres de génération d'harmonique d'ordre élevé (GHOE). De plus, malgré la différence de potentiels d'ionisation entre les orbitales Kohn Sham obtenues à l'aide des potentiels LB94 et LDA, les résultats présentés dans ce travail montrent la même tendance pour les deux.

**Mots-clés :** théorie de la densité fonctionnelle dépendante du temps (TDFDT), ionisation d'orbitale, fonction de localisation de l'électron dépendante du temps (FLEDt), génération d'harmonique d'ordre élevé (GHOE).

## Introduction

In recent years, the interaction of atoms and molecules with intense laser pulses has attracted widespread research. One of the reasons is that laser fields induce interesting nonlinear electron dynamics such as multiphoton ionization<sup>1</sup> (MPI), above threshold ionization<sup>2</sup> (ATI), and tunnelling ionization<sup>3</sup> (TI). Numerous experiments on molecular ionization have been performed<sup>4</sup> thanks to the refinement of the techniques<sup>5</sup> of molecular orientation and alignment. While experimental efforts for better understanding of the ionization processes are growing, theoretical investigations are still limited, even though computational power is increasing rapidly. The first step for a one-electron system is

accurate numerical solution of the time-dependent multidimensional Schrödinger equation (TDSE), followed by propagation of pulses in molecular media through Maxwell's equations.<sup>6</sup> The major difficulties in the theoretical study of molecular systems in a laser field reside on the multi-centre nature of the molecule including the treatment of the electron–electron interactions.<sup>7–9</sup> In the present work, we focus on time-dependent density functional theory (TDDFT) methods as one tool for studying the nonlinear nonperturbative response of molecules to intense ultrashort laser pulses.<sup>10</sup> As an example, simple TDDFT functionals have been used to characterize pulses interacting with metal surfaces.<sup>11</sup> Density functional theory (DFT) has become an ubiquitous method

of solving ground-state electronic problems in atoms and molecules.<sup>12</sup>

For the visual understanding of the electron motion in CO<sub>2</sub> during the time propagation under strong laser pulses, we used the time-dependent approach of the electron localization function (ELF).<sup>13</sup> Conceptually, the physical idea is based on the fact that a highly localized electron repels other electrons more strongly. Then the ELF makes use of the probability to find a second like-spin electron in the vicinity of the first one as a measure for electronic localization. Numerical values of the probability are conveniently mapped on the interval [0,1] facilitating analysis and interpretation. So, in areas where two electrons of the same spin have a high probability to be found (with respect to the homogeneous gas) the function should tend to 0 by construction. It follows that, in areas where the probability of finding two electrons of opposite spin (when present) is smaller than the one of finding two electrons of same spin, the function tends to 1. As such, a region of the space with a high value of ELF corresponds to a region where it is more likely to localize an electron or a pair of electrons in relation to the original Lewis original definition of bonding. When applied to molecules, the advantage of ELF is to show a clear separation between the core and valence electrons, and thus, it shows covalent bonds and lone pairs, in the spirit of valence shell electron pair repulsion theory (VSEPR).<sup>14</sup> Here, our goal is to shed light onto the effect of different laser intensities on the molecular regions (bond, lone pair).

## Methods

### Nonperturbative TDDFT Kohn–Sham formalism

The TDDFT method provides the most detailed and feasible ab initio approach for tackling many-body problems. DFT as first introduced by Hohenberg and Kohn<sup>15</sup> and extended by Kohn and Sham<sup>16</sup> (KS) is based on the existence of an exact mapping between one-particle density and external potentials. This leads to the density of the interacting system being obtained from the density of an auxiliary system of noninteracting particles moving in an effective local single-particle potential. A time-dependent generalization of DFT was provided by Runge and Gross,<sup>17</sup> showing that there is a one-to-one correspondence between the external (time-dependent) potential ( $v_{\text{ext}}(r, t)$ ) and the time-dependent one-electron density ( $n(r, t)$ ) for many-body systems evolving from a fixed initial state. The time-dependent electronic density is written as:<sup>18</sup>

$$[1] \quad n(r, t) = \sum_{\sigma=\uparrow, \downarrow} n_{\sigma}(r, t) = \sum_{\sigma=\uparrow, \downarrow} \sum_i^{N_{\sigma}} |\psi_{i\sigma}(r, t)|^2$$

where  $N_{\sigma}$  is the number of the occupied KS orbital in the spin state  $\sigma$  and  $\psi_{i\sigma}(r, t)$  is the orbital obtained through the time-dependent KS equations (in au):

$$[2] \quad i \frac{\partial}{\partial t} \psi_{i\sigma}(r, t) = \left[ -\frac{1}{2} \nabla^2 + v_{\text{eff}}(r, t) \right] \psi_{i\sigma}(r, t)$$

where

$$[3] \quad v_{\text{eff}}(r, t) = v_{\text{ext}}(r, t) + v_h(r, t) + v_{xc,\sigma}(r, t)$$

the first term is the external potential owing to the interaction of the electron with an external laser field and the nuclei, the second term accounts for the classical Hartree electrostatic interaction between electrons, and the third term is the exchange correlation (xc) potential that includes all non-trivial many body effects, and has an extremely complex (and essentially unknown) functional<sup>16,19</sup> dependence on the density. When an intense electric with a low frequency field is applied to a molecule, electrons tend to be displaced out by ionization; thus, the higher the ionization potential (IP) or barriers, the more this electronic displacement will be hindered. Therefore, the choice of an approach that accurately reproduces the experimental IP is useful for our analysis. For this work, we have used the local density approximation (LDA), which has been widely used in strong fields<sup>10</sup> owing to its simplicity and applicability to various systems with relatively lower computational cost. However, LDA is constructed from homogenous gas systems and suffers from the wrong asymptotic behavior originating from the incomplete cancellation of the self-interactions. For these reasons, we have also used the Van Leeuwen and Baerends<sup>20</sup> potential (LB94) for comparison, which introduces a gradient correction to the LDA exchange correlation so as to reproduce the Coulomb asymptotic behavior of the potential. A convenience of the LB94 potential lies in its explicit dependency on the local density and its gradient. This potential yields good estimates of the IP for atoms and small molecules, especially in the framework of the linear response TDDFT excitation energy.<sup>21</sup> This model potential significantly corrects the higher moments of the density, notably for diffuse outer orbitals involved in excitations and in our case in ionization. The LB94 also includes partial and considerable self-interaction correction (SIC), resulting from an interaction of an electron with itself, of importance to electronic transport.<sup>22</sup> Such corrections are known to produce spurious oscillations in photoionization calculations,<sup>23</sup> but little is known about the corrections for strong fields in the nonperturbative regime. Our results show that the LB94 potential offers accurate IPs for all orbitals; an essential starting point for accurate ionization.

### Time-dependent electron localization function (TDELf)

The ELF is a method for the mapping of electron pair probability in multi-electron systems. It was first introduced by Becke and Edgecombe<sup>24</sup> as a descriptor of electronic localization, using arguments based on the conditional same-spin pair probability function. Here, we briefly recall the definitions of the extension of the ELF for time-dependent processes.<sup>13</sup> The time-dependent ELF or TDELf ( $\eta(r, t)$ ) is given as

$$[4a] \quad \eta(r, t) = \frac{1}{1 + \left[ \frac{C(r, t)}{C_h(r, t)} \right]^2}$$

where

$$[4b] \quad C(r, t) = \sum_{\sigma} \left\{ \sum_{i=1}^{N_{\sigma}} |\nabla \psi_{i\sigma}(r, t)|^2 - \frac{1}{4} \frac{[\nabla n_{\sigma}(r, t)]^2}{n_{\sigma}(r, t)} - \frac{j_{\sigma}^2(r, t)}{n_{\sigma}(r, t)} \right\}$$

$$[4c] \quad C_h(r, t) = \frac{3}{5} (6\pi^2)^{2/3} n_\sigma(r, t)^{5/3}$$

where  $j_\sigma^2$  is the squared modulus of the current density and  $C(r, t)$  measures the probability of finding one electron in the near vicinity of a reference like-spin electron at position  $r$  and time  $t$ . Thus, the Pauli repulsion between two like-spin electrons, described by the smallness of  $C(r, t)$ , is taken as a measure of the electron localization.  $C_h(r, t)$  is the corresponding factor found for uniform electron gas, i.e., a homogeneous electron gas whose density is the same as that of the real system. Equation [4b] is valid only for one-determinantal wave functions, and therefore lends itself to be used within the context of HF or DFT. The TDELf will be used for the time-resolved observation of the molecular ionization and can thus provide a visual understanding of the particle dynamic (most notably lone pair and bond electrons) under strong laser pulses.

## Computational details

In the present work, the TDDFT KS equation (eq. [2]) was discretized in space using finite-difference (FD) grid techniques. For numerical reasons we represent the electron-ion interaction by the norm conserving nonlocal Troullier-Martins pseudopotential,<sup>25</sup> which allows explicit treatment of many fewer electrons and avoidance of the fast oscillations produced by the core electrons. The pseudopotentials are generated such that the pseudo-wave functions imitate the all-electron atomic wave functions. The C–O bond length is set to its experimental<sup>26</sup> value, CO = 0.1162 nm, and the CO<sub>2</sub> molecule is placed in a large three-dimensional (3D) cubic grid cell (atomic units (au) are used) of dimension  $|z_{\max}| = 40$  au (1 au = 0.0529 nm). The uniform FD grid spacing ( $\Delta z = 0.28$  au) was used and the convergence of the calculations was checked against results making use of a smaller grid spacing. The size of the grid is determined by the maximum radius  $\alpha = E_0/m\omega^2$  of an electron in a time-dependent electric field of maximum amplitude  $E_0$ . Thus, at  $E_0 = 0.1$  au corresponding to an intensity  $I_0 = 3.50 \times 10^{14}$  W/cm<sup>2</sup> (1 au:  $I_0 = 3.50 \times 10^{16}$  W/cm<sup>2</sup>,  $E_0 = 5 \times 10^9$  V/cm),  $\alpha = 30$  au at  $\lambda = 800$  nm,  $\omega = 0.057$  au. The external potential created by an intense laser field is assumed to arise from an oscillating electric field with a cosine envelope. When the laser is polarized parallel to the molecular axis  $z$ ,  $v_{\text{ext}}(r, t)$  is given by

$$[5] \quad v_{\text{ext}}(r, t) = zE_0 \cos^2\left(\frac{\pi t}{T}\right) \sin(\omega t) \quad (0 \prec t \prec T)$$

where  $T$  determines the laser pulse duration. The laser intensity is related to the field strength by  $I = \frac{1}{2} \epsilon_0 c E_0^2$ , where  $\epsilon_0$  is the permittivity of free space and  $c$  is the speed of the light. The angle ( $\theta$ ) between the linear polarized laser and the main molecular axis varies from 0° to 90°. The total area condition  $\int_{-\infty}^{+\infty} E(t) dt = 0$  is verified to ensure that there are no spurious static effects.<sup>3,9</sup> The time-dependent equation (eq. [2]) are solved using the Crank–Nicholson scheme<sup>27</sup> with  $\Delta t = 0.02$  au (1 au =  $24 \times 10^{-18}$  s) as the time step. All calculations use an eight optical cycle pulse duration.

## Orbital ionization

To absorb the ionized charge density and avoid reflections at the boundary of the box owing to ionization during the propagation, we employed a mask function. By using this technique, the KS wave function is multiplied in each time step by a function  $M(z)$ , which is 1 in the inner simulation region and gradually goes to 0 at the borders. The masking function in one dimension is defined as

$$[6] \quad M(z) = \begin{cases} \sin^4\left(\frac{z_{\max} - |z|}{2a}\pi\right) & (z_{\max} - |z| \prec a) \\ 1 & (\text{otherwise}) \end{cases}$$

where  $z_{\max} = 40$  au is the extension of the box in the  $z$  direction and  $a = 6$  au is the width of the mask function. It is assumed that the electrons in the  $z_{\max} \succ |z|$  domain are completely ionized and cannot return to the nuclei. A different approach to remove outgoing flux density consists of an addition of an imaginary potential<sup>28</sup> that causes an exponential decay of the wave function or in using the exterior complex scaling coordinate transformation as the absorbing boundary.<sup>29</sup> The time-dependent ionization probability ( $P_{i,\sigma}(t)$ ) of an individual spin-orbital population is calculated as<sup>10</sup>

$$[7] \quad P_{i,\sigma}(t) = 1 - N_{i,\sigma}(t)$$

where  $N_{i,\sigma}(t) = \langle \psi_{i,\sigma}(r, t) | \psi_{i,\sigma}(r, t) \rangle$  is the time-dependent population (survival probability) of the  $i, \sigma$ -th spin population.

## Higher order harmonic generation

Molecular high order harmonic generation<sup>9</sup> (MHOHG) is a highly nonlinear nonperturbative effect resulting from two essential steps: (i) ionization at the peaks of an electromagnetic pulse  $E(t)$  of maximum amplitude  $E_0$  (eq. [4]), followed by (ii) laser-induced recollision after 2/3 of a cycle with maximum energy of harmonics of order  $N_m$ ,  $N_m\omega = \text{IP} + 3.17U_p$  where  $N_m$  is the order of the harmonics and  $U_p = I_0/4m\omega^2$  is the ponderomotive energy.<sup>30</sup> Calculations of MHOHG with ultrashort (a few cycles) intense  $I_0 \geq 10^{14}$  W/cm<sup>2</sup> requires special attention to grid sizes and gauges as mentioned in recent works.<sup>31</sup> In the present work, the MHOHG is calculated during the dynamical propagation as follows.<sup>10</sup> The time-dependent dipole  $\vec{d}(t) = e^n(\vec{r}, t) \vec{r} d^3r$  is recorded at time intervals  $\Delta t = 0.02$  au. Recent works have shown that the most accurate method for generating the MHOHG spectra when dealing with molecular systems<sup>9,31</sup> is to calculate the dipole acceleration ( $\ddot{d}_z(t)$ ), according to Ehrenfest's theorem.<sup>8</sup> The power spectrum of  $\ddot{d}_z(t)$  in a given direction yields to the predicted High order harmonic generation (HHG) spectra.<sup>31</sup>

$$[8] \quad S_z(\omega) \propto |a(\omega)|^2 = \left| \int \left[ \frac{d^2}{dt^2} d_z(t) \right] e^{i\omega t} dt \right|^2$$

## Results and discussion

### Electronic analysis and IP

The relevant information about the ground-state geometry of CO<sub>2</sub> is that the molecule is linear with an equilibrium C–O bond length  $R = 0.1162$  nm. The analysis of the electronic

**Fig. 1.** DFT images of the molecular orbitals of CO<sub>2</sub>. Only the three highest relevant occupied molecular orbitals (HOMO, HOMO-1, and HOMO-2) are shown.

structure from the DFT-KS calculation is depicted in Fig. 1, where the three highest occupied KS molecular orbitals (HOMO, HOMO-1, and HOMO-2), with their phases, are presented. The nodal properties that correctly reflect the  $g$  and  $u$  symmetry character of the orbitals are visible. One finds that the HOMO is the antibonding ( $1\pi_g$ ) formed of  $\pi$  lobes lying perpendicular to the internuclear axis and located on the oxygen atoms. The computed eigenvalue of the relevant HOMO, HOMO-1, and HOMO-2 are 9.25, 12.84, and 13.01 eV, respectively, for LDA and 13.62, 16.96, and 17.21 eV, respectively, for the LB94 potential. Comparison with the experimental values of 13.8, 18.1, and 17.6 eV reveals<sup>32</sup> the expected underestimation of the HOMO eigenvalue by the LDA, the computed value being ~43% lower when compared with the experimental data. The origin of this large discrepancy lies in the wrong asymptotic behaviour of the LDA. The LB94 potential, on the other hand, performs much better, the global agreement with the experiment being within 5%. We note a near constant (~4 eV) difference between the LDA and LB94 IPs.

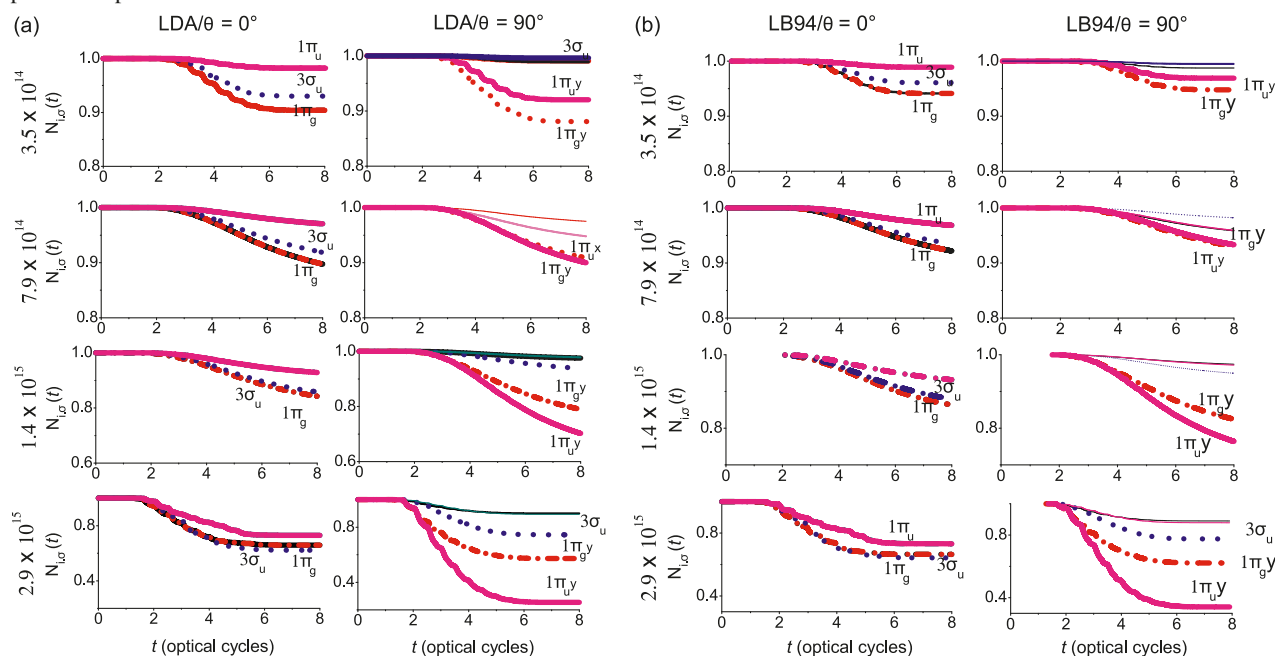

### KS orbital ionization

Our time-dependent calculation allows a detailed analysis of the ionization process as it evolves with time. From the initial ground state, we have propagated in time the KS orbitals with different laser peak intensities ( $3.50 \times 10^{14}$ ,  $7.90 \times 10^{14}$ ,  $1.40 \times 10^{15}$ , and  $2.99 \times 10^{15}$  W/cm<sup>2</sup>) at the 800 nm wavelength. The calculations used eight optical cycle pulse duration. Two molecular orientations have been considered,  $\theta = 0^\circ$  and  $90^\circ$ . Figures 2a and 2b show the results with the LDA and the LB94 potentials, respectively, for the selected KS orbitals. For  $\theta = 0^\circ$ , the two degenerate components of each  $\pi$  orbital have the same behaviour, whereas the symmetry is broken for the other orientations.

We have renamed those KS orbitals as  $1\pi_{gx}$  and  $1\pi_{gy}$  for  $1\pi_g$  and we did the same for the  $1\pi_u$  components. From the figures, one clearly notes a strong dependence of the orbital electron population ( $N_{i,\sigma}(t)$ ), with the laser intensities. Therefore, the higher the laser intensity, the lower the remaining electron population. One also finds that the ionization is sensitive to the orientation ( $\theta$ ) of the molecule with respect to the laser field. Similar results have been observed in H<sub>2</sub><sup>+</sup> from exact TDSE calculations.<sup>7,8</sup> It also emerges, as ex-

pected, that the KS orbital ionization yield computed using the LDA functional is larger than what was obtained from the LB94 potential because of its lower IP. A close look at these figures reveals that for the lowest laser intensity ( $3.50 \times 10^{14}$  W/cm<sup>2</sup>) independent of the potential used and the orientation  $\theta$ , the HOMO,  $1\pi_g$ , molecular orbital shows the dominant response to the laser field. It is followed by the inner  $3\sigma_u$ , HOMO-1 when  $\theta = 0^\circ$  and by the  $1\pi_u$  KS orbital when  $\theta = 90^\circ$ . By increasing the laser peak intensity to  $7.90 \times 10^{14}$  W/cm<sup>2</sup>, the result is almost the same as the previous peak intensity when  $\theta = 0^\circ$ , but with  $\theta = 90^\circ$  the HOMO  $1\pi_g$  shows the dominant response to the laser field followed by the HOMO-2  $1\pi_u$  with the LB94, whereas the opposite trend is observed with the LDA potential. This behaviour is related to the lower IP of the HOMO-2 for the LDA potential 13.01 eV compared with 17.21 eV for the LB94 potential. For the  $1.40 \times 10^{15}$  laser peak intensity, one notices the KS molecular orbital ionization enhancement with both potentials, the bonding  $1\pi_g$  and the  $3\sigma_u$  ( $3\sigma_u$  is still more pronounced) when  $\theta = 0^\circ$ , whereas the HOMO-2  $1\pi_u$  shows the dominant response to the field for  $\theta = 90^\circ$ . Finally, with the  $2.99 \times 10^{15}$  W/cm<sup>2</sup> laser intensity, our results reveal that the inner  $3\sigma_u$  molecular orbital presents the dominant response to the field, whereas the effect of the valence  $1\pi_g$  orbital on the ionization process decreases and is getting closer to that of the  $1\pi_u$  orbital for  $\theta = 0^\circ$ . This is related to the symmetry of the  $3\sigma_u$  whose electron density is along the molecular axis; this gives rise to a high ionization yield when aligned parallel to the laser electric field. When  $\theta = 90^\circ$ , the HOMO-2  $1\pi_u$  shows the dominant response to the laser field, this comes from the bonding character (ionization enhancement) of the HOMO-2  $1\pi_u$ , which possesses the right symmetry and maximum density to interact more properly with the laser polarized perpendicularly to the molecular axis. Although this orbital has a larger IP than the HOMO  $1\pi_g$ , its density dominates at  $90^\circ$ , whereas the HOMO,  $1\pi_g$  has a node (zero density) at  $90^\circ$  in the centre of the molecule. In general, one finds that the main difference between the results for the LDA and LB94 potentials comes only from the ionization slope that lies only in their IP difference. We conclude that for the two potentials, orbitals that have maximum density in the direction of laser polarization will influence or dominate in ionization. This will

**Fig. 2.** (a) Time-dependent Kohn–Sham orbital population,  $N_{i,\sigma}(t)$ , using Local density approximation (LDA) potential at  $I_0 = 3.50 \times 10^{14}$ ,  $7.90 \times 10^{14}$ ,  $1.40 \times 10^{15}$ , and  $2.99 \times 10^{15}$  W/cm<sup>2</sup> laser peak intensities for  $\theta = 0^\circ$  and  $90^\circ$ . (b) Time-dependent Kohn–Sham orbital population,  $N_{i,\sigma}(t)$ , using LB94 potential at  $I_0 = 3.50 \times 10^{14}$ ,  $7.90 \times 10^{14}$ ,  $1.40 \times 10^{15}$ , and  $2.99 \times 10^{15}$  W/cm<sup>2</sup> laser peak intensities for  $\theta = 0^\circ$  and  $90^\circ$ .  $\theta$  is the angle between the molecular axis and the laser polarization direction. Only the relevant Kohn–Sham orbitals that possess an important response to the laser field are shown with their labels.

be checked in the TDEL processes and in the MHOHG spectrum as follows.

### TDEL analysis

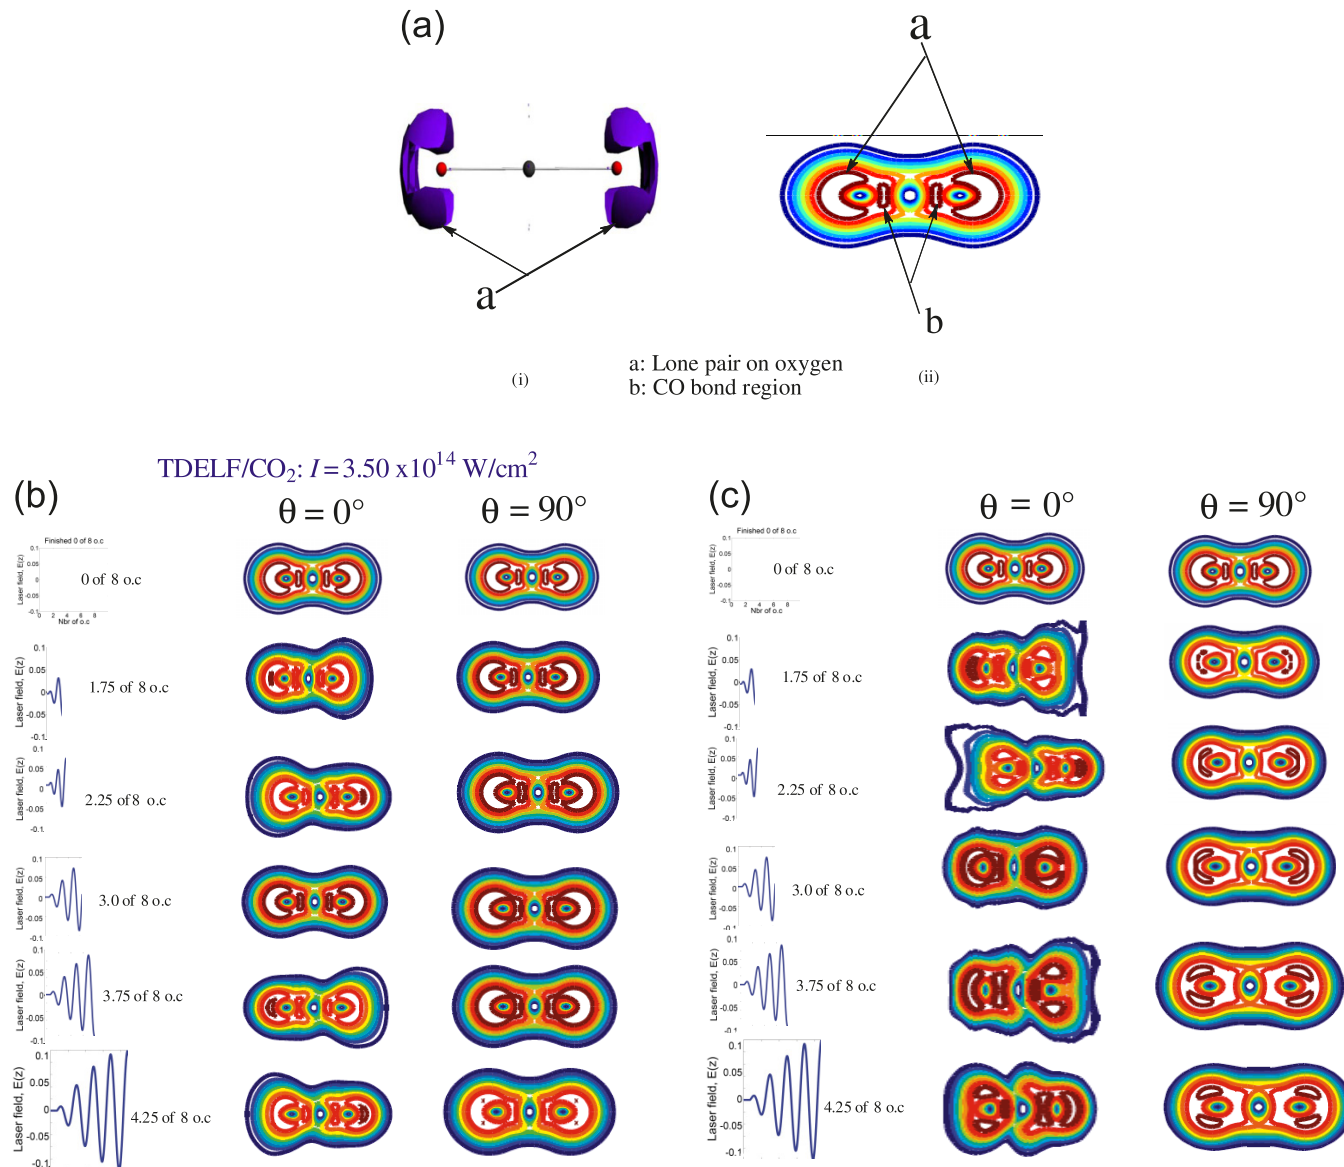

The ground-state ELF pictures are shown in Fig. 3a for  $\eta = 0.8$  (left) and the two-dimensional representation of the ELF isosurfaces in the plane containing the three atoms of the molecule (right). At  $\eta = 0.8$  (left), the image exhibits only the lone pair (noted a) of the oxygen atom, whereas the C–O bond localization is absent; this is because the lone pair electron on the oxygen is the most localized in the CO<sub>2</sub> molecule. By representing the ELF from the plane containing the three atoms (right), one can easily identify the C–O chemical bond region (note b). From the electronic structure analysis (Fig. 1), it is evident that the HOMO,  $1\pi_g$  is essentially located in region (a), whereas the HOMO-1,  $3\sigma_u$ , and the HOMO-2,  $1\pi_u$  are essentially located in region (b). Such clear separation between HOMO and relevant inner orbitals (shape and IP) of the KS ionization process as described in the KS orbital ionization section). Figures 3b and 3c represent the TDEL images for  $\theta = 0^\circ$  and  $90^\circ$  using two different laser peak intensities,  $3.50 \times 10^{14}$  and  $2.99 \times 10^{15}$  W/cm<sup>2</sup> with the LB94 potential; the corresponding time propagation is also shown.

For the  $3.50 \times 10^{14}$  W/cm<sup>2</sup> laser peak intensity, when  $\theta = 0^\circ$ , the first major perturbation occurs after 1.75 optical cycles (oc). Note that the dissymmetric distribution of the electron density on the two oxygen atom shows that the two atoms do not simultaneously experience the same laser field strength, and that depending on the sign of the electric field, the perturbation successively affects each of the oxygen atoms (Fig. 3 shows that at 1.75 oc, the oxygen atom at the

left-hand side is the most affected, whereas at 2.25 oc, the oxygen atom of the right-hand side shows the dominant response to the field). As expected from the previous KS ionization analysis, the figure shows that the major part of the perturbation is located in the region corresponding to the lone pair region ( $1\pi_g$ ). As our propagation evolves the intensity of the perturbation on the lone pair domain increases as well, reaching a maximum for the extrema (minimum, 3.75 oc, or maximum, 4.25 oc) of the external electric field and seeming to disappear around zero values of the external field (e.g., at 3.0 oc). The weak deformation on the C–O bond domain reflects the contribution of the inner orbital into the molecular ionization process in agreement with the previous KS ionization finding. For  $\theta = 90^\circ$ , the first noticeable perturbation occurs after 1.75 oc and corresponds to the lengthening of the lone pair region on the oxygen atoms of CO<sub>2</sub>. The perturbation is symmetrically distributed on the system; this effect reflects the fact that the two oxygen atoms simultaneously feel the same effect of the perpendicular laser field. As the time propagation evolves (3.75 and 4.25 oc), one also sees that the dominant response comes from the lone pair region. Most notably, one observes that during the propagation, the electronic perturbation is mainly characterized by an interaction between the lone pair and the bonding C–O region. This may be regarded as the manifestation of the enhancement of the ionization of the bonding  $1\pi_u$  molecular orbital located on the C–O bond region. Evidence of the laser field intensity is noticeable, the stronger the intensity peak value and the higher the perturbation. One remarks that the electron density perturbation does not disappear around the zero values of the laser field. Results using the  $2.99 \times 10^{15}$  W/cm<sup>2</sup> laser peak intensity are depicted in Fig. 3c.

**Fig. 3.** (a) DFT/LB94 representation of the electron localization function ground state of the CO<sub>2</sub> molecule. (b) Snapshot of the isosurface of the time-dependent electron localization function (TDELf) images for  $I_0 = 3.5 \times 10^{14}$  W/cm<sup>2</sup> as the CO<sub>2</sub> molecule evolves in the laser field. (c) Snapshot of the isosurface of the TDELf images for  $I_0 = 2.99 \times 10^{15}$  W/cm<sup>2</sup> as the CO<sub>2</sub> molecule evolves in the laser field. Calculations are done for  $\theta = 0^\circ$  and  $90^\circ$ .

For  $\theta = 0^\circ$ , one finds that the first major perturbation starts closer to the beginning of the propagation and it is mostly localized on one of the lone pair regions of the molecule. Thereafter, the disymmetric perturbation appears instantaneously on the C–O bond and the lone pair domain (1.75 o.c), its effect increasing with the duration of the propagation. Therefore, it is difficult to identify which part of the system presents the dominant response to the field; this reflects the contribution of both the HOMO KS orbital (owing to its lower IP) and the inner  $3\sigma_u$  MO (owing to its shape or its electron density, which is maximal along the polarization of the electric field). These results corroborate our finding in the previous section concerning the KS ionization. When  $\theta = 90^\circ$ , at the beginning of the propagation, the electron depletion occurs on the lone pair region and is characterized by lengthening of this region. The image shows that at 1.75 o.c,

the interaction between the lone pair density and that of the C–O bond is visible, and an amount of electron depletion is noticeable in the lone pair region. The symmetric distribution of the electron density perturbation in the two oxygen atoms is clearly evident. As the propagation evolves, the bi-partition of the perturbation domain of the lone pair orbital of each oxygen atom is observable and tends to enhance the overlap between the lone pair and the C–O bonding region. This can be seen as the strong perturbation (ionization) of the inner  $1\pi_u$  KS orbital. These observations are consistent with our results in Figs. 2a and 2b, which show that the IP and the shape of the KS orbital are the main factors that define its ionization. At lower laser peak intensity, the IP is the main factor, whereas at higher laser peak intensity, the ionization of the KS orbital is influenced by its shape.

### Higher order harmonic generation

In Figs. 4a and 4b, we present the MHOHG power spectra, eq. [8] emitted by CO<sub>2</sub> computed with the LB94 potential. Two angular orientations of the molecule ( $\theta = 0^\circ$  and  $90^\circ$ ) with respect to the laser field polarization axis are considered. Calculations are done at the lower  $3.50 \times 10^{14}$  and the higher  $1.40 \times 10^{15}$  W/cm<sup>2</sup> laser intensities to observe the effect of inner orbitals. An overview of these pictures shows that in general, the overall shapes of the power spectra for these two laser intensities are similar.

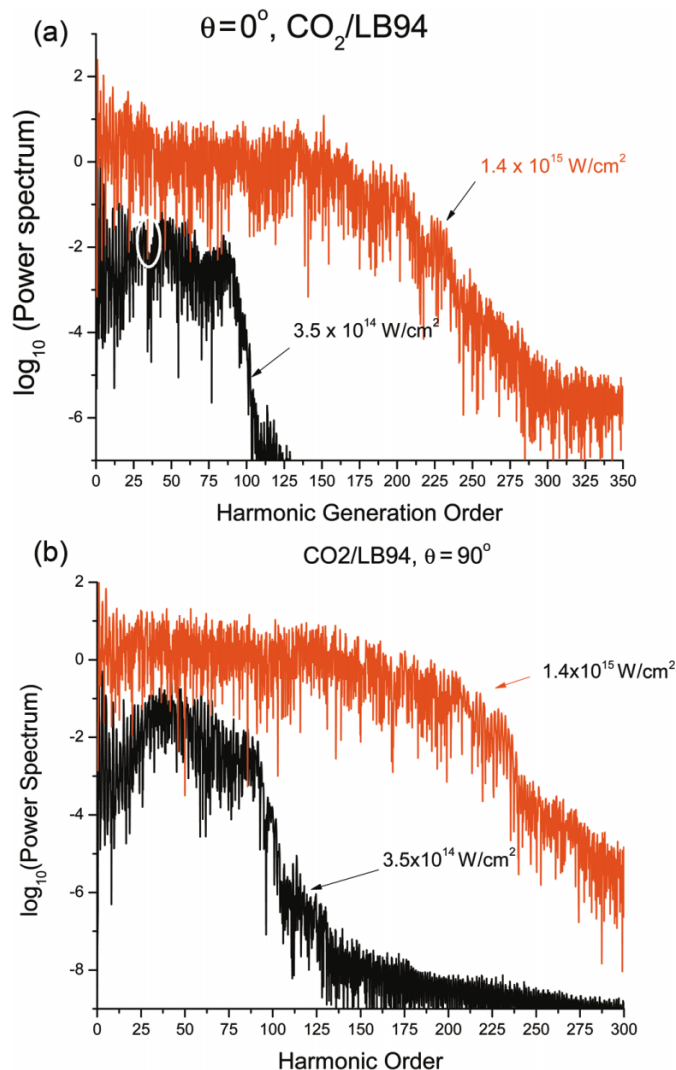

For the two orientations, features of these spectra strongly resemble those of harmonic spectra from atoms: a sharp decrease after the first few harmonics, followed by a "plateau," and ending with a "cut-off" that usually determines the highest harmonic order achievable. One also notes that the cut-off is independent of the molecular orientation and is located approximately at the 91st harmonic for the  $3.50 \times 10^{14}$  W/cm<sup>2</sup> laser peak intensity and around the 237th harmonic order for  $1.40 \times 10^{15}$  W/cm<sup>2</sup>. For the latter, one observes that the cut-off domain is not abrupt like that of  $3.50 \times 10^{14}$  W/cm<sup>2</sup>. This is most probably related to the size of our box, which is not large enough to allow the ionized electron to acquire a maximum velocity in the continuum. The figure shows that the power spectrum amplitude is sensitive to the laser peak intensity. For  $\theta = 0^\circ$  (Fig. 4a), a close look at the plateau region shows the presence of pronounced minima (encircled in the graph) at the 27th and 67th harmonic order when  $I_0 = 3.50 \times 10^{14}$  W/cm<sup>2</sup>, whereas such minima are not clearly visible with  $1.40 \times 10^{15}$  W/cm<sup>2</sup>. This minimum is due to a destructive resonance between the recolliding electron wavepacket and the orbital; this phenomenon has been observed experimentally.<sup>33</sup> This has been interpreted in terms of two centre interferences between the contributions from the two atomic centres.<sup>34</sup> In fact, with the  $3.50 \times 10^{14}$  W/cm<sup>2</sup> laser peak intensity, owing to the dominant effect of the HOMO,  $1\pi_g$  on the molecular ionization, the CO<sub>2</sub> molecule can be regarded as an elongated diatomic molecule where the point emitters are located on the two O nuclei. This phenomenon is less pronounced with the  $1.40 \times 10^{15}$  W/cm<sup>2</sup> laser peak intensity owing to the contribution of the  $3\sigma_u$  inner orbital. For  $\theta = 90^\circ$  (Fig. 4b), in comparison with  $\theta = 0^\circ$ , the absence of minima is evident and instead one finds as expected that the HHG intensity increases with the laser peak intensity.

One of the main observable differences among the two plots is that the spectrum for  $1.40 \times 10^{15}$  W/cm<sup>2</sup> laser peak intensity is flatter than the one for a peak laser intensity of  $3.50 \times 10^{14}$  W/cm<sup>2</sup> in the plateau region. This difference is most probably related to the constructive interference between the contributions from the two atomic oxygen centres (HOMO) at the  $3.50 \times 10^{14}$  W/cm<sup>2</sup>. This process is more complicated at high laser peak intensity owing to the contribution of inner orbitals.

### Conclusion

In this work, KS time-dependent orbital populations,  $N_{i,\sigma}(r,t)$ , and ionizations have been computed for the CO<sub>2</sub> molecule with different laser intensities from a nonlinear nonperturbative TDDFT approach.<sup>18,19</sup> In view of all the results, we conclude that both the shape of the KS orbitals

**Fig. 4.** (a) Comparative TDDFT/LB94 harmonic spectra study for  $\theta = 0^\circ$  using two laser peak intensities,  $I_0 = 3.50 \times 10^{14}$  and  $1.40 \times 10^{15}$  W/cm<sup>2</sup>. (b) Comparative TDDFT/LB94 harmonic spectra study for  $\theta = 90^\circ$  using two laser peak intensities,  $I_0 = 3.50 \times 10^{14}$  and  $1.40 \times 10^{15}$  W/cm<sup>2</sup>.

and the laser intensities play a key role in the ionization process. We showed that for  $3.5 \times 10^{14}$  W/cm<sup>2</sup>, the HOMO provides the dominant response in the presence of the external laser field owing to its lower IP, whereas for higher laser peak intensities, the shape and the orientation of the KS orbitals vs the laser field polarization are the main factors in their ionization. This has been confirmed by time-dependent electron localization function images, which have shown that the electronic perturbation is symmetric when the laser electric is perpendicular to the molecular axis and disymmetric when it is aligned along the molecular axis. As a consequence of these perturbations, for  $3.5 \times 10^{14}$  W/cm<sup>2</sup>, minima are found on the harmonic generation spectrum as a function of harmonic order when the laser is aligned with the molecular axis, whereas the harmonic generation spectrum exhibits higher intensities over a longer range of harmonic orders when the laser is perpendicular to the molecular axis.

## Acknowledgements

The authors would like to express their thanks to the Natural Sciences and Engineering Research Council of Canada (NSERC) and to the Canadian Institute for Photonic Innovations (CIPI) for funding this research on the theory of the intense laser-molecule interaction, and to Réseau Québécois de Calcul de Haute Performance (RQCHP), for parallel computer time. The authors are also thankful to C. Lefebvre, M. Ziou, and Y. Kaijun for the plots and their helpful discussions.

# The 9-barbaralyl and related $C_9H_9^+$ carbocations — A QTAIM-DI-VISAB computational study

Nick H. Werstiuk

**Abstract:** QTAIM-DI-VISAB analyses were used to characterize the bonding of the 9-barbaralyl cation, related  $C_9H_9^+$  cations, and rearrangement transition states. These analyses involved obtaining quantum theory of an atom in a molecule (QTAIM) molecular graphs and delocalization indexes (DIs) that were correlated with visualization of the proximities of atomic basins (VISAB). This study provides new insights into the bonding of these species and cements the QTAIM-DI-VISAB analysis as a method of choice for establishing the nature of the bonding in so-called nonclassical carbocations, while obviating the need for dashed-line representations of bonding.

**Key words:** 9-barbaralyl and related  $C_9H_9^+$  carbocations, couple-clustered method with single and double excitations (CCSD) and density functional theory (DFT) calculations, molecular structure, QTAIM-DI-VISAB analyses.

**Résumé :** On a fait appel à des analyses faisant appel à la théorie quantique des atomes dans les molécules (TQADM), aux indices de délocalisation (ID) et à la visualisation de la proximité des bassins atomiques (VISBA) pour caractériser la liaison du cation 9-barbaralyle, apparenté aux cations  $C_9H_9^+$ , et les états de transition de son réarrangement. Les analyses impliquent l'obtention de graphiques moléculaires suivant la théorie quantique des atomes dans les molécules (TQADM) et d'indices de délocalisation (ID) pour lesquels il a été établi une corrélation avec la visualisation des proximités des bassins atomiques (VISBA). Cette étude a permis d'obtenir de nouvelles connaissances concernant les liaisons dans ces espèces et confirme que l'approche TQADM-ID-VISBA est une méthode de choix pour établir la nature des liaisons dans les carbocations dit non classiques tout en permettant d'éviter l'utilisation de représentations de liaisons par des lignes à traits tiretés.

**Mots-clés :** carbocations 9-barbaralyle et autres carbocations  $C_9H_9^+$  apparentés, calculs selon la théorie de la fonctionnelle de la densité (TFD) et de l'agrégat couplé avec des excitations simple et double (ACSD), analyses par une combinaison de la théorie quantique des atomes dans les molécules, des indices de délocalisation et de la visualisation des proximités des bassins atomiques (TQADM-ID-VISBA).

[Traduit par la Rédaction]

## Introduction

The structure and bonding of the 9-barbaralyl cation shown as **2** and related species on the  $C_9H_9^+$  potential energy surface were the focus of many experimental<sup>1</sup> and theoretical<sup>2</sup> studies over several decades. The most recent computational studies were carried out in 1993 by Cremer et al.,<sup>3a,3b</sup> with the latter publication dealing exclusively with the 1,4-bishomotropylium cation **4-C<sub>s</sub>**. This flurry of activity followed the experimental work in the late 1960s including NMR studies, which were carried out to detail its structure and rearrangements. Four possible minima on the  $C_9H_9^+$  potential energy surface are displayed as “localized” structures **1**, **2**, **3**, and **4**, along with their ring-system labels. A very complex array of dashed-line structures were used in attempts to describe the bonding in these species and the transition states for their rearrangements are seen in the first 1993 computational paper.<sup>3a</sup> Whereas two dashed-line structures shown as **3a-D<sub>3h</sub>** and **3b-D<sub>3h</sub>**<sup>2a</sup> have been used to describe the bonding of the so-called nonclassical  $D_{3h}$

[3.3.1.0.0] cation, no dashed lines were used to describe the bonding of **2-C<sub>s</sub>**. Dashed lines have also been used for the [4.3.0] cation considered to be a bishomoaromatic species; it is shown as **4-C<sub>s</sub>** in its usual dashed-line representation. The computational studies by Cremer et al.<sup>3a,3b</sup> demonstrated that defining the  $C_9H_9^+$  potential energy surface is a very challenging computational problem. It was established that **2-C<sub>s</sub>** was a minimum at the HF, MP3, and MP4 levels of theory, but not at MP2; at this level, **2-C<sub>s</sub>** optimized to the lower energy species **3-D<sub>3h</sub>**. MP3 and MP4 energies were obtained from single-point calculations on geometries obtained from MP2 geometry searches. In the latter 1993 paper,<sup>3b</sup> optimized geometries of **4-C<sub>s</sub>** were obtained at the HF/6–31G(d) and MP2/6–31G(d) levels of theory: the former and latter are known to underestimate and overestimate homoaromaticity, respectively. Our recent computational studies<sup>4</sup> on a number of intermediates, including the 2-norbornyl, 7-norbornyl, and bicyclobutonium cations, established that coordination based on the number of bond paths,

as defined in a quantum theory of an atom in a molecule (QTAIM)<sup>5</sup> molecular graph, terminating at a nucleus in any species (cation, carbanion, radical, or carbene) should be used as the criterion of hypercoordination and hypervalency. We argued that this approach should be used regardless of the nature of the intermediate to obviate the confusion and inaccuracies associated with arbitrarily using indicators such as dashed lines, dotted lines, cross-hatched lines, hollow tubes, and solid tubes in structural formulas, which have been used extensively in publications to this point. In fact, we recently

**Fig. 2.** Selected internuclear distances (Å) of transition states at B3PW91/aug-cc-pVTZ.

showed that a QTAIM-DI-VISAB analysis is the method of choice for characterizing the bonding of intermediates, molecules at their equilibrium geometries, and Diels–Alder transition states.<sup>6–9</sup> In such an analysis, in addition to using molecular graphs to define *molecular structure* and examining the properties at extrema (bond critical points (CPs), ring CPs, and cage CPs) in the topology of the density in a normal QTAIM analysis, delocalization indexes (DIs) are evaluated for pairs of atoms and correlated with a visualization of the closeness of atomic basins (VISAB). Homoconjugative and homoaromatic interactions between pairs of atoms are easily quantified on the basis of DIs without resorting to complex studies involving the nature of geometries, relative energies of hypothetical species, and NMR chemical shifts.

Results of a QTAIM-DI-VISAB study on **2-*C<sub>s</sub>***, **3-*D<sub>3h</sub>***, and **4-*C<sub>s</sub>*** and selected transition states, **1-*C<sub>2v</sub>***, **TS-1**, **TS-2**, and **TS-3**, for their rearrangements at couple-clustered method with single and double excitations (CCSD) and density functional theory (DFT) levels of theory are presented and discussed in this paper.

## Computational details

Our previous experiences with DFT calculations on carbo-cations clearly showed that the B3PW91 hybrid functional is superior to B3LYP in computing the geometries of delocalized, so-called nonclassical species.<sup>4,8</sup> Additional support for

<sup>h</sup> $G = H + TS$ .

this finding was obtained as part of a previous study. Calculations were carried out on O-protonated 2,2-dimethyloxirane, which was studied recently by Carrier et al.<sup>10</sup> and described as a particularly challenging computational problem, to compare results from B3LYP, B3PW91, PBE1PBE, and CCSD calculations at the 6-311G(d,p) level as implemented in Gaussian 03.<sup>11</sup> The results clearly showed that B3PW91 and PBE1PBE are expected to be superior to B3LYP in cases where relatively weak polar bonds are involved. Cation geometries were optimized at B3PW91/aug-cc-pVTZ, MP2(full)/6-311+G(2d,p), and CCSD(full)/6-31+G(d,p) levels with Chemcraft<sup>12</sup> and GaussView<sup>13</sup> being used to fix symmetries where necessary. As found by Cremer et al.,<sup>3a</sup> all optimizations of 2-C<sub>s</sub> at the MP2 level yielded 3-D<sub>3h</sub>. They also suggested that CCSD calculations would be required to accurately define the C<sub>9</sub>H<sub>9</sub><sup>+</sup> surface.

Consequently, the MP2 results were discounted and calculations were carried out on 2-C<sub>s</sub>, 3-D<sub>3h</sub>, and 4-C<sub>s</sub> at CCSD(full)/6-31+G(d,p). Calculations were also carried out at B3PW91/aug-cc-pVTZ on 2-C<sub>s</sub>, 3-D<sub>3h</sub>, and 4-C<sub>s</sub> so a comparison could be made with the CCSD results. Calculations on the transition state (TS) for the degenerate rearrangement of 2-C<sub>s</sub> (TS-1) and the TSs for the rearrangements of 2-C<sub>s</sub> to 3-D<sub>3h</sub> (TS-2) and 4-C<sub>s</sub> (TS-3) were only carried out at B3PW91/aug-cc-pVTZ because the CCSD(full)/6-31+G(d,p) calculations were expected to be prohibitively long. Selected internuclear distances of 2-C<sub>s</sub>, 3-D<sub>3h</sub>, and 4-C<sub>s</sub> given in angstroms are collected in Fig. 1; for TS-1, TS-2, and TS-3, selected values are given in Fig. 2. Cartesian coordinates of all geometrical structures are collected in Tables 1S–11S in the Supplementary data. Frequency calculations were carried out at B3PW91/aug-cc-

**Fig. 3.** Molecular graphs of cations at CCSD(full)/6-31+G(d,p), along with values of the electron density ( $\rho(\mathbf{r})$ ) at selected bond critical points. Values in parentheses were obtained at B3PW91/aug-cc-pVTZ.

pVTZ; CCSD(full)/6-31+G(d,p) calculations were expected to be prohibitively long for all the species on the stationary points to confirm them as energy minima or transition states. CCSD(full)/6-31+G(d,p) frequency calculations were only carried out in the case of **1-C<sub>2v</sub>** to confirm that it is a TS. Total energies and thermochemical data ( $\Delta E_{\text{elec}}$ ,  $\Delta E_0$ ,  $\Delta H_{298}$ , and  $\Delta G_{298}$ ) for **2-C<sub>s</sub>**, **3-D<sub>3h</sub>**, and **4-C<sub>s</sub>** are collected in Table 1. Total energies and thermochemical data ( $\Delta E_{\text{elec}}^\ddagger$ ,  $\Delta E_0^\ddagger$ ,  $\Delta H_{298}^\ddagger$ , and  $\Delta G_{298}^\ddagger$ ) for **1-C<sub>2v</sub>**, **TS-1**, **TS-2**, and **TS-3** are collected in Table 2. QTAIM analyses of the wave functions to investigate the topologies of the electron densities were carried out with AIM 2000<sup>14</sup> and values of  $\rho(\mathbf{r})$  at selected bond critical points (bcps) given in atomic units ( $1 \text{ au} = e/a_0^3 = 6.7483 \text{ e/\AA}^3$ ) are collected in Fig. 3. AIMALL<sup>15</sup> was used to integrate atomic basins, to obtain atomic populations, and total charges, as well as atomic overlap matrices required for DI calculations. That the total charges of **1-C<sub>2v</sub>**, **2-C<sub>s</sub>**, **3-D<sub>3h</sub>**, **4-C<sub>s</sub>**, **TS-1**, **TS-2**, and **TS-3** obtained at the various levels of theory (data not included) deviated by <1% from the expected value of +1.0 confirmed the quality and validity of the QTAIM data. The program LIDICALC<sup>16</sup> was used to obtain DIs; selected values for pairs of atoms are listed in Table 3. Atomic basins were obtained with AIM 2000<sup>14</sup> at a contour value of 0.005, which includes >95% of the electrons, using a mesh grid size of 0.125 and plotted.

## Results and discussion

### Thermochemistry

At both levels of theory, **1-C<sub>2v</sub>** is a transition state (B3PW91/aug-cc-pVTZ imaginary frequency: 264.0i cm<sup>-1</sup>; Table 2) on the bifurcation path on the C<sub>9</sub>H<sub>9</sub><sup>+</sup> PE surface. Based on intrinsic reaction coordinate (IRC) calculations carried out in this study at B3PW91/aug-cc-pVTZ (data not included), **1-C<sub>2v</sub>** connects **TS-1s** exactly as concluded by Cremer et al.<sup>3a</sup> Given the prohibitive length of the CCSD calculations frequency, calculations were carried out only

on **1-C<sub>2v</sub>** confirming that it is a transition state exhibiting an imaginary frequency of 158.4i cm<sup>-1</sup> (Table 2). Based on the thermodynamic parameters,  $E_{\text{elec}}$ ,  $E_0$ , and  $H_{298}$ , collected in Table 2, **1-C<sub>2v</sub>** is in the region of 5 kcal mol<sup>-1</sup> (1 cal = 4.184 J) higher in energy than **TS-1** at B3PW91/aug-cc-pVTZ; based on  $G_{298}$ , **1-C<sub>2v</sub>** is only 2.65 kcal mol<sup>-1</sup> higher in energy than **TS-1**.

Whereas **3-D<sub>3h</sub>** is found to be marginally lower in energy than **2-C<sub>s</sub>** based on  $\Delta E_{\text{elec}}$  (-1.19),  $\Delta E_0$  (-1.18), and  $\Delta H_{298}$  (-1.44) at B3PW91/aug-cc-pVTZ, it is marginally higher in energy (+0.20) based on  $\Delta G_{298}$ . At CCSD(full)/6-

**Fig. 6.** Molecular graph and selected atom basins of **1-C<sub>2v</sub>** at CCSD(full)/6-31+G(d,p).

31+G(d,p), **3-D<sub>3h</sub>** is significantly higher in energy (+7.63 kcal mol<sup>-1</sup>) than **2-C<sub>s</sub>**, in keeping with the MP4(SDQ) results reported by Cremer et al.<sup>3a</sup> **4-C<sub>s</sub>** is the potential well at both levels of theory (Table 1), in keeping with experimental results. IRC calculations on **TS-1** (imaginary frequency: 208.0i cm<sup>-1</sup>) that exhibits C<sub>2</sub> symmetry confirmed that it is the TS for the degenerate rearrangement of **2-C<sub>s</sub>**. At B3PW91/aug-cc-pVTZ,  $\Delta G_{298}^\ddagger$  is 2.18 kcal mol<sup>-1</sup>, in line with a value of 3.6 kcal mol<sup>-1</sup> for  $\Delta E_{\text{elec}}^\ddagger$  at MP4(SDQ) based on HF/6-31G(d) geometries. That **TS-2** (imaginary frequency: 272.1i cm<sup>-1</sup>) is the TS for the rearrangement of **2-C<sub>s</sub>** to **3-D<sub>3h</sub>** was established by an IRC calculation at B3PW91/aug-cc-pVTZ; the barrier,  $\Delta E_{\text{elec}}^\ddagger =$

1.13 kcal mol<sup>-1</sup>, at this level of theory was significantly lower than the MP4(SDQ) value of 8.1 kcal mol<sup>-1</sup> obtained from the MP2(FC)/6-31G(d) geometries. This is undoubtedly due to the fact that B3PW91 overestimates the stability of **3-D<sub>3h</sub>**. **TS-3**, which was confirmed with an IRC calculation and an imaginary frequency of 397.8i cm<sup>-1</sup>, was located as the transition state for the rearrangement of **2-C<sub>s</sub>** to **4-C<sub>s</sub>**. At B3PW91/aug-cc-pVTZ,  $\Delta G_{298}^\ddagger$  was 10.05 kcal mol<sup>-1</sup>.

#### Molecular geometries of cations and transition states

Selected CCSD and B3PW91 (in *italics*) computed internuclear distances of **1-C<sub>2v</sub>**, **2-C<sub>s</sub>**, **3-D<sub>3h</sub>**, and **4-C<sub>s</sub>** are collected in Fig. 1. B3PW91 (in *italics*) computed internuclear distances of **TS-1**, **TS-2**, and **TS-3** are displayed in Fig. 2. On the whole, the CCSD and B3PW91 internuclear distances are similar except where through-space interactions are involved: C7–C8 of **1-C<sub>2v</sub>**, and C4–C6 of **2-C<sub>s</sub>**. It is interesting to note that the geometries of **4-C<sub>s</sub>** obtained at CCSD and B3PW91 are similar to the geometry obtained by Cremer et al.<sup>3b</sup> at MP2(FC)/6-31G(d) by fixing the folding angle at the value estimated from limited scanning (the C2–C9 distance was fixed) of the potential energy surface at MP4(SDQ)/6-31G(d), even though MP2 is considered to overestimate homoaromaticity. Surprisingly, the C2–C9 distance of **4-C<sub>s</sub>** is shorter at CCSD than at B3PW91, presumably because the C1–C2 and C1–C9 distances are shorter in the case of CCSD than B3PW91. The C2–C7 (C4–C9) distances of **TS-1** are shorter (2.050 Å) than the C2–C7 (C4–C9) distances of **1-C<sub>2v</sub>** (2.469 Å). On the other hand, the C7–C8 (C6–C9) distances (2.469 Å) increase slightly (2.503 Å) in going from **1-C<sub>2v</sub>** to **TS-1**. In the case of **TS-2** that is the TS for the rearrangement of **2-C<sub>s</sub>** to **3-D<sub>3h</sub>**, the C4–C6 distance decreases from 2.382 to 1.934 Å and the C2–C8 distance increases marginally from 1.453 to 1.506 Å. That **TS-3** is the transition state for the rearrangement of **2-C<sub>s</sub>** to **4-C<sub>s</sub>** (this was a new finding) was confirmed with an IRC calculation where optimization of the final forward and reverse end-points yielded **2-C<sub>s</sub>** to **4-C<sub>s</sub>**, respectively, and animation of the nuclear motion associated with the imaginary frequency clearly showed that **TS-3** connects **2-C<sub>s</sub>** to **4-C<sub>s</sub>**; rearrangement of **2-C<sub>s</sub>** to **4-C<sub>s</sub>** involves shifting the C6–C5 (or C4–C5) bond (the C6–C9 or C4–C5 distance decreases from 2.472 to 2.050 Å in the TS) of **2-C<sub>s</sub>** to C9 and cleaving the C2–C8 bond, which lengthens from 1.453 to 1.534 Å in the TS.

#### QTAIM-DI-VISAB analyses

The molecular graphs of **1-C<sub>2v</sub>**, **2-C<sub>s</sub>**, **3-D<sub>3h</sub>**, and **4-C<sub>s</sub>** along with bcps (red spheres), ring critical points (rcps, yellow spheres), and cage critical points (ccps, green spheres) obtained at the CCSD(full)/6-31+G(d,p) level are displayed in Fig. 3, along with the values of the density ( $\rho(\mathbf{r})$ ) at selected bcps; for comparison purposes, the B3PW91/aug-cc-pVTZ values are shown in parentheses in *italics*. All the molecular structures obey the Poincaré–Hopf equation ( $n$  (nuclei) –  $b$  (bcps) +  $r$  (rcps) –  $c$  (ccps) = 1).<sup>5</sup> On the whole, the values of  $\rho(\mathbf{r})$  at the bcps are similar at both levels of theory. As expected, the C1–C2 and C1–C8 bonds of **2-C<sub>s</sub>** are significantly weaker than the C2–C8 bond given that **2-C<sub>s</sub>** cation includes the cyclopropyl carbinyl cation fragment. The key point is that there are *no* bond paths between C4–

**Fig. 7.** (a) Molecular graph of **2-C<sub>s</sub>** at CCSD(full)/6-31+G(d,p). (b) C4–C6 basins of **2-C<sub>s</sub>**. (c) C6 atom basin of **2-C<sub>s</sub>**. (d) C5 atom basin of **2-C<sub>s</sub>**.

C6 of **2-C<sub>s</sub>** or C3–C9, C3–C7, or C7–C9 of **3-D<sub>3h</sub>**. This is even the case for **4-C<sub>s</sub>**, which is considered to be a bishomoaromatic species that is usually represented with dashed lines connecting C2–C9 and C5–C7.

Figure 4 displays the molecular graphs of **TS-1**, **TS-2**, and **TS-3**, along with the bcps, rcps, and ccps obtained at the B3PW91/aug-cc-pVTZ level. All these molecular structures also obey the Poincaré–Hopf equation.<sup>5</sup> Also included in Fig. 4 are the values of  $\rho(\mathbf{r})$  at selected bcps and the delocalization indexes (DIs) for selected pairs of atoms in parentheses in italics. Whereas **TS-2**, which is the transition state for the rearrangement of **2-C<sub>s</sub>** to **3-D<sub>3h</sub>**, does not exhibit a bond path between C4–C6, it possesses a significant DI (0.387) between the atoms showing that there is substantial homoconjugative interaction between the atoms. The DI is a measure of the number of electron pairs delocalized between atomic basins; for a “full single” bond, DI = 1.0 and for a “full double” bond it is 2.0.

Figure 5 displays the DIs for selected pairs of atoms obtained at CCSD(full)/6-31+G(d,p) and in italics at B3PW91/aug-cc-pVTZ. In the case of **1-C<sub>2v</sub>**, there is no significant through-space interaction between C7–C8 (C6–C9) based on a DI cutoff of 0.05.<sup>8</sup> However, there is a marginal degree of delocalization above the threshold between C2–C7 (C4–C6), or C2–C8 (C4–C9). These conclusions are in keeping with the displays of the C2–C8 (Fig. 6b) and C7–C8 (Fig. 6c) ba-

sins, which show that the basins do not significantly impinge on each other.

As far as **2-C<sub>s</sub>** is concerned, based on the DI there is a homoconjugative interaction above the threshold between C4–C6 showing that **2-C<sub>s</sub>** is a homoaromatic species. This contrasts with the conclusion reached by Cremer et al.<sup>3b</sup> that **2-C<sub>s</sub>**, the 9-barbaralyl cation, was not homoaromatic. Figure 7a displays its CCSD molecular graph. Figure 7b shows the C4–C6 basins that are in close proximity to each other and Fig. 7c shows the C6 basin with an arrow pointing to the surface that is distorted by the closeness of the C4 basin. These results are in accord with the fact that there is an above-threshold homoconjugative interaction between C4 and C6; Fig. 7d shows how the C5 basin intrudes between the C4–C6 basins and precludes bond path formation.

Figure 8a shows the molecular graph of **3-D<sub>3h</sub>** at CCSD; Fig. 8b shows the C3–C9 basins that do not impinge on each other; Fig. 8c shows the C3 basin. These displays are in accord with the fact that C3–C9 CCSD DI is 0.04, which is below the threshold of 0.05; at B3PW91, the DI is 0.104. That the DI is below the threshold at CCSD means that there is no need to use dashed lines to connect C3–C7, C3–C9, and C7–C9 as seen in **3b-D<sub>3h</sub>**.

Figure 9a displays the CCSD molecular graph of **4-C<sub>s</sub>**, and while a relief plot of the Laplacian obtained at the MP2(FC)/6-31G(d) level was included in the 1993 publica-

**Fig. 8.** (a) Molecular graph of **3- $D_{3h}$**  at CCSD(full)/6-31+G(d,p). (b) C3–C9 basins of **3- $D_{3h}$** . (c) C3 atom basin of **3- $D_{3h}$** .

**Fig. 9.** (a) Molecular graph of **4- $C_s$**  at CCSD(full)/6-31+G(d,p). (b) C2–C9 basins of **4- $C_s$** . (c) C1 atom basin of **4- $C_s$** .

tion,<sup>3b</sup> the molecular graph was not; Fig. 9b shows the C2–C9 basins that impinge on each other. This display is in accord with the fact that the C2–C9 (C5–C7) DI (0.180 at CCSD, 0.308 at B3PW91) is well above the threshold, clearly confirming that **4- $C_s$**  is a bishomoaromatic species; Fig. 9c shows how the C1 basin intrudes between the C2–C9 basins and thereby precludes bond path formation between C2–C9. That **4- $C_s$**  exhibits a low DI of 0.180 at CCSD supports the conclusion reached by Cremer et al.<sup>3b</sup> that its homoaromaticity is low.

Figure 1Sa (see the Supplementary data) displays the B3PW91 molecular graph of **TS-1** and Fig. 1Sb shows the C2–C7 basins that impinge on each other; Fig. 1Sc shows how the face of the C7 basin labeled with an arrow is distorted by C2, in keeping with the fact that the C2–C7 DI (0.292) is well above the threshold value of 0.05; Fig. 1Sd shows the C1 basin, which clearly intrudes between C2–C7 and thereby precludes bond path formation even though the DI is 0.292; Fig. 1Se shows the C7–C8 basins that marginally impinge on each other in keeping with the DI of 0.058 that is marginally above the threshold of 0.050.

Figure 2Sa (see the Supplementary data) displays the B3PW91 molecular graph of **TS-2** and Fig. 2Sb shows the C4–C8 basins impinging on each other; Fig. 2Sc shows how

C8 is flattened (labeled with an arrow) by C4, in keeping with the fact that the DI (0.387) is large and well above the threshold value of 0.05. There is no doubt that **TS-2** is a homoaromatic species. The C5 basin (not shown) intrudes between C4–C8 and precludes bp formation.

Figure 3Sa (see the Supplementary data) is a display of the the B3PW91 molecular graph of **TS-3**. In going from **TS-3** to the [4.3.0] cation **4-C<sub>s</sub>**, it is interesting to note that whereas bond path formation is being achieved between C4 and C9, which demands that a new bcp replaces the one between C4 and C5, the bond between C2–C8 is cleaved by the coalescence of the C2–C8 bcp and the three-membered rcp. It is seen that the C1–C8 bond ( $\rho(\mathbf{r})_{\text{bcp}} = 0.2099$ , DI = 0.841) is slightly weaker than the C2–C8 bond ( $\rho(\mathbf{r})_{\text{bcp}} = 0.2230$ , DI = 0.898) of the nominal three-membered ring even though it is the C2–C8 bond that is cleaved in achieving **4-C<sub>s</sub>**; Fig. 3Sb shows the C4–C9 basins that are in close proximity to each other and Fig. 3Sc shows how the face of the C4 basin labeled with an arrow is distorted by C9, in keeping with the fact that the C4–C9 B3PW91 DI (0.343) is well above the threshold value of 0.05; Fig. 3Sd shows how the C5 basin intrudes between the C4–C9 basins and thereby precludes bond path formation between C4–C9.

## Conclusions

A QTAIM-DI-VISAB computational study on the 9-barbaralyl and related  $\text{C}_9\text{H}_9^+$  carbocations has been used to unambiguously define the bonding and homoaromaticity of these species in keeping with our view that it is the method of choice for establishing the nature of the bonding in hypercoordinated so-called nonclassical carbocations. This approach, which in our view is the most computationally economical method, obviates the need for arbitrary dotted-line representations of bonding. It is possible to quantify homoconjugation and homoaromaticity without relying on the nature of geometries, relative energies of hypothetical species, and NMR chemical shifts.

## Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca).

## TRIBUTE

Russell Jaye Boyd was born in 1945 in Kelowna, the centre of British Columbia's wine-producing and fruit-growing Okanagan Valley. His early years were devoted to hockey, basketball, baseball, golf, and water-related activities. Just before his fifteenth birthday, his family moved to New Westminster, where he attended Lester Pearson High School and began to show some interest in science and mathematics.

Russ enrolled in the Science program at the University of British Columbia in 1963 and graduated in 1967 with First-Class Honours in Chemistry and the Lefevre Gold Medal for highest standing in the Honours Chemistry program. His Honours thesis focused on the new technique of photoelectron spectroscopy. At the time, there were no commercial instruments and UBC had the only photoelectron spectrometers in Canada. With enthusiastic encouragement from his thesis supervisor, David C. Frost, Russ attempted to carry out the first study of the angular dependence of photoelectron emission. Despite the best efforts of the strong technical support team in the machine shop, two different designs failed to produce meaningful results. To obtain some positive results, Russ rounded up supplies of some boron trihalides and recorded their spectra.

As one of the first recipients of a 1967 Science Scholarship (introduced in 1967 by the National Research Council (NRC) of Canada to celebrate Canada's centennial), he went east to pursue his Ph.D. in Theoretical Chemistry at McGill University under the supervision of M.A. (Tony) Whitehead. As a consequence of the fact that he had recorded the photoelectron spectra of some boron trihalides (and some siloxanes) as an undergraduate, Russ realized that there was no theoretical framework for interpreting such spectra in the absence of electronic structure calculations. In 1967, reliable *ab initio* calculations were restricted to small molecules. In fact, the largest molecule in the 1967 compendium of *ab initio* calculations compiled by Morris Kraus is HCCCN for which A.D. McLean and M. Yoshimine reported a single-point SCF calculation with a small basis set. In his first few months as a graduate student, Russ completed some semi-empirical molecular orbital calculations on the boron trihalides and sent the results to David Frost, which led to his first paper entitled "The Ionization Potentials of  $\text{BF}_3$ ,  $\text{BCl}_3$  and  $\text{BBr}_3$ ", in April 1968 in the first volume of *Chemical Physics Letters*.

The existing semi-empirical molecular orbital methods in 1967 were not capable of predicting the equilibrium geometries of molecules. All calculations were carried out at the experimental geometries or using assumed bond lengths and angles. Russ realized that this situation was unsatisfactory for studying reaction mechanisms and set out to develop a method that would yield molecular potential-energy surfaces and properties that agree with the experimental data. He developed a method based on the complete neglect of differential overlap approximation that had been introduced in 1965 by John Pople and his co-workers. He focused on equilibrium geometries, bond energies, and force constants (vibrational frequencies), the three chemically interesting properties associated with the minima of molecular potential-energy surfaces. This was an improvement over any other method that existed and was ultimately superseded by the work of Michael Dewar and his colleagues who used a slightly higher and chemically more reliable level of semi-empirical molecular orbital theory.

After defending his Ph.D. in 1971, Russ joined the group of

Charles A. Coulson in the Mathematical Institute at Oxford University as an NRC Postdoctoral Fellow. He had become disillusioned with semi-empirical approaches by the time he completed his thesis and saw more future in the *ab initio* approaches that John A. Pople and his group were developing within their Gaussian code. Russ turned his attention to electron correlation and published two papers with Coulson, including a description of the Coulomb hole in the first two excited states of the helium atom, his best-known paper from Oxford.

With encouragement from Charles A. McDowell, Russ returned to the University of British Columbia where he held a Killam Postdoctoral Fellowship in the Department of Chemistry from 1973 to 1975, where he renewed his interest in photoelectron spectroscopy. He published a single author letter in *Nature* in 1974 in which he pointed out that contrary to the usual interpretation of structural studies of porphyrin complexes, the lowest lying high-spin state of an atom (ion) in a given configuration is smaller than any state of lower spin. His prediction was verified two years later by scattering experiments on the first two excited states of the helium atom.

Russ joined Dalhousie University as an Assistant Professor of Chemistry in 1975 and rose through the ranks to become a Professor in 1985. He was named a Faculty of Science Killam Professor in 1997, and in 2001 he became the seventh Alexander McLeod Chair of Chemistry. The McLeod Chair, one of the oldest named professorships in chemistry in Canada, was created in 1884 in accordance with a bequest from Alexander McLeod. Russ served as Chair of Chemistry from 1992 to 2005. During this time, 11 new faculty members, including four outstanding senior chemists, were recruited, the graduate program expanded significantly, and an addition to the Chemistry Building was approved. The Department gained four Tier I Canada Research Chairs (Neil Burford, Jeff Dahn, Don Weaver, and Joe Zwanziger) between 2001 and 2003.

His research interests span a range of topics in computational and theoretical chemistry with an emphasis on problems relevant to biological systems. He has published about 240 research papers and 10 review chapters and he co-edited *The Quantum Theory of Atoms in Molecules* with Chérif Matta in 2007. With over 5000 citations of his papers and an H-index of 42, Russ is one of Canada's best-known computational chemists. He has supervised the research of 20 Ph.D. students, more than 25 postdoctoral fellows and senior visitors, and a comparable number of undergraduate students. His former students have successful careers in academic institutions, government laboratories, and the industry. Fourteen former members of his group hold academic appointments in Canadian universities and another eight hold similar appointments abroad. He is especially proud of the number of excellent young scientists who received a significant part of their training in his group.

Russ received the 1983 APICS/Fraser Medal. He was the first and only chemist to receive this prize, which was awarded in the 1970s and 1980s to recognize outstanding research work carried out in the Atlantic Provinces by a young scientist or engineer. His other awards include the Fellowship of The Chemical Institute of Canada (1983), the CNC-IUPAC Award (1986), Dalhousie University Senior Killam Fellowship (1989), and the 2009 Montreal Medal of The Chemical Institute of Canada.

Russ took on leading roles in organizing the Canadian Society for Chemistry Conferences in Halifax in 1981, 1990, and 2006. He was the principal organizer of the 8th Canadian Symposium on Theoretical Chemistry in 1983 and the 7th Canadian Computational Chemistry Conference in 2009. He is a member of the College of Reviewers of the Canada Research Chairs Program, and he has served on many committees of the Natural Sciences and Engineering Research Council of Canada (NSERC). He has served on selection panels for the National Science Foundation (NSF) of the USA and the Canada–US Fulbright Program. He has served on many boards, including the Canadian Society for Chemistry, the *Canadian Journal of Chemistry*, the Dalhousie University Foundation, the Atlantic Provinces Council on the Sciences, and the World Association of Theoretical and Computational Chemists. He was an editor of the *Canadian Journal of Chemistry* from 1988 to 1998 and served as President of the Canadian Society for Chemistry in 2007–2008. His many other

activities include Judge-in-Chief for the 1984 Canada-Wide Science Fair. He is currently the Principal Investigator (Research Director) for the Atlantic Computational Excellence Network (ACEnet), a consortium of nine universities in Atlantic Canada that provides high-performance computing facilities by means of funding from the Canada Foundation for Innovation (CFI).

The number, quality, and countries of origin of the papers submitted to this dedicated issue of the *Canadian Journal of Chemistry* attest to breadth and reach of Russ Boyd's influence in the computational and theoretical chemistry community in Canada and abroad, as well as his contributions to the broader chemical community.

**Neil Burford**

## HOMMAGE

Russell Jaye Boyd naît en 1945 à Kelowna, située au centre de la région viticole et fruitière de la vallée de l'Okanagan (Colombie-Britannique). Il consacre les premières années de sa vie au hockey, au basketball, au baseball, au golf et aux activités aquatiques. Peu de temps avant son quinzième anniversaire, sa famille déménage à New Westminster où il fréquente l'école secondaire Lester Pearson et commence à manifester un intérêt pour les sciences et les mathématiques.

En 1963, Russ s'inscrit au programme de sciences de l'Université de la Colombie-Britannique (UBC) et en 1967, il obtient son diplôme en chimie avec très grande distinction et la Lefevre Gold Medal pour avoir obtenu les meilleurs résultats dans le programme spécialisé en chimie. Sa thèse de spécialisation porte principalement sur la nouvelle technique de spectroscopie photoélectronique. À ce moment-là, il n'existe aucun spectromètre photoélectronique vendu sur le marché et l'UBC est seule à en posséder au Canada. Fort de l'encouragement enthousiaste de son directeur de thèse, David C. Frost, Russ tente de mener la première étude sur la dépendance angulaire de l'émission de photoélectrons. Malgré tous les efforts déployés par la solide équipe de soutien technique de l'atelier de mécanique, deux concepts différents ne parviennent pas à produire des résultats significatifs. Afin d'obtenir des résultats positifs, Russ rassemble des réserves de trihalogénures de bore et enregistre leur spectre.

Lauréat de l'une des premières bourses 1967 en sciences (instaurée en 1967 par le Conseil national de recherches du Canada pour souligner le centenaire de la Confédération), il se dirige vers l'est pour poursuivre un doctorat en chimie théorique à l'Université McGill sous la direction de M. A. (Tony) Whitehead. En raison du fait qu'au cours de ses études de premier cycle, il a eu à enregistrer les spectres photoélectroniques de trihalogénures de bore (et de siloxanes), Russ se rend compte qu'il n'existe aucun cadre théorique pour interpréter de tels spectres en l'absence de calculs de structures électroniques. En 1967, les seuls calculs ab initio fiables se limitent aux petites molécules. En fait, la plus grosse molécule répertoriée dans le recueil des calculs ab initio de 1967 (Morris Kraus) est le cyanoacétylène (HCCCN) pour laquelle A.D. McLean et M. Yoshimine ont fait état d'un calcul SCF en un seul point avec un petit ensemble de base. Au cours de ses premiers mois comme étudiant diplômé, Russ effectue des calculs semi-empiriques d'orbitales moléculaires sur des trihalogénures de bore et il fait parvenir ses résultats à David Frost, ce qui mène la publication, en avril 1968, de son premier article intitulé « The Ionization Potentials of  $\text{BF}_3$ ,  $\text{BCl}_3$  and  $\text{BBr}_3$  » dans le premier volume de la revue *Chemical Physics Letters*.

En 1967, les méthodes semi-empiriques d'orbitales moléculaires utilisées ne permettent pas de prévoir les géométries d'équilibre des molécules. Tous les calculs sont effectués sur des géométries expérimentales ou au moyen de longueurs et d'angles de liaison présumés. Russ se rend compte que cette situation est peu satisfaisante pour étudier les mécanismes de réaction et entreprend de mettre au point une méthode qui permettrait de produire des surfaces et des propriétés d'énergie potentielle moléculaire qui cadrent avec des données expérimentales. Il met au point une méthode fondée sur l'approximation du recouvrement différentiel nul, introduite en 1965 par John Pople et ses collègues. Il concentre ses efforts

sur les géométries d'équilibre, les énergies de liaison et les constantes de force (fréquences vibrationnelles), trois propriétés revêtant un intérêt certain sur le plan de la chimie et associées aux minima des surfaces d'énergie potentielle. Il s'agit d'une amélioration par rapport à toutes les autres méthodes existantes. Mais finalement, elle sera détrônée par les travaux de Michael Dewar et de ses collègues, qui utilisent un niveau légèrement plus élevé et plus fiable chimiquement de la théorie semi-empirique des orbitales moléculaires.

Après avoir défendu sa thèse de doctorat en 1971, Russ se joint à l'équipe de Charles A. Coulson à l'Institut de mathématiques de l'Université d'Oxford à titre de boursier postdoctoral du CNRC. Désenchanté des méthodes semi-empiriques et avant même qu'il ne termine sa thèse, il se tourne vers les méthodes ab initio plus prometteuses que John A. Pople et son équipe sont à mettre au point dans un cadre gaussien. Russ se penche donc sur la corrélation électronique et publie deux articles avec Coulson, dont une description du trou de Coulomb dans les deux premiers états d'excitation de l'atome d'hélium, son article le mieux connu issu d'Oxford.

Encouragé par Charles A. McDowell, Russ retourne à l'Université de la Colombie-Britannique où il est titulaire d'une bourse postdoctorale Killam au Département de chimie de 1973 à 1975. C'est là qu'il s'intéresse de nouveau à la spectroscopie photoélectronique. En 1974, dans un texte publié dans la revue *Nature*, il fait valoir que contrairement à l'interprétation courante des études structurales des complexes de porphyrine, le plus faible état de spin élevé d'un atome (ion) dans une configuration donnée est plus petit que tout état de spin plus faible. Sa prédiction sera vérifiée deux ans plus tard par des expériences de diffusion menées sur les deux premiers états excités de l'atome d'hélium.

Russ est embauché par l'Université Dalhousie à titre de professeur adjoint de chimie en 1975 et grimpe les échelons pour devenir professeur en 1985. En 1997, on le nomme professeur Killam de la Faculté des sciences, et en 2001, il devient le septième titulaire de la chaire de chimie Alexander McLeod. La chaire McLeod, l'une des plus anciennes chaires dénommées en chimie au Canada, a été créée en 1884 conformément à un legs d'Alexander McLeod. Russ occupe les fonctions de directeur du Département de chimie de 1992 à 2005. Au cours de cette période, onze nouveaux membres du corps professoral sont recrutés (dont quatre éminents chimistes chevronnés), le programme d'études supérieures prend de l'expansion de façon importante et on approuve la construction d'une adjonction à l'édifice de la Faculté de chimie. Entre 2001 et 2003, le Département recrute quatre chercheurs inscrits au Programme des chaires de recherche du Canada de niveau I (Neil Burford, Jeff Dahn, Don Weaver et Joe Zwanziger).

Les travaux de recherche de Russ englobent divers sujets dans les domaines de la chimie théorique et numérique tout en portant une attention particulière aux problèmes liés aux systèmes biologiques. Il a publié jusqu'à maintenant environ 240 articles de recherche et dix chapitres de synthèse et a corédigé, en 2007, l'ouvrage « *The Quantum Theory of Atoms in Molecules* » avec Chérif Matta. Plus de 5000 citations de ses articles et un indice h de 42 font de Russ l'un des chimistes-informaticiens canadiens les plus connus. Au cours de sa carrière, il dirige les travaux de 20 étudiants au doctorat, de plus de 25 boursiers postdoctoraux et de visiteurs

de haut niveau et d'un nombre comparable d'étudiants de premier cycle. Ses anciens étudiants poursuivent des carrières florissantes dans des établissements universitaires, des laboratoires gouvernementaux ou l'industrie. Quatorze anciens membres de son équipe occupent des postes de professeur dans des universités canadiennes et huit autres font de même à l'étranger. Il est particulièrement fier du nombre d'excellents jeunes scientifiques qui ont reçu une partie importante de leur formation au sein de son équipe.

Russ reçoit l'APICS/Fraser Medal en 1983. Il est le premier et le seul chimiste à recevoir ce prix, remis dans les années 1970 et 1980 pour souligner les travaux de recherche remarquables menés par de jeunes scientifiques ou ingénieurs dans les provinces de l'Atlantique. Il compte également parmi ses récompenses la bourse de recherche de l'Institut de chimie du Canada (1983), le prix CNC-UICPA (1986), la bourse de chercheur chevronné Killam de l'Université Dalhousie (1989) et la Médaille de Montréal de l'Institut de chimie du Canada (2009).

Russ assume des rôles de premier plan dans l'organisation des congrès de la Société canadienne de chimie de 1981, de 1990 et de 2006. Il est le principal organisateur du 8<sup>e</sup> symposium canadien de chimie théorique (1983) et du 7<sup>e</sup> congrès canadien de chimie numérique (2009). Il fait partie du Collège d'examineurs du Programme de chaires de recherche du Canada et siège à de nombreux comités au Conseil de recherches en sciences naturelles et en génie du Canada. Il

siège à des jurys de sélection pour la National Science Foundation des États-Unis et le Programme Fulbright Canada-États-Unis. Il fait également partie de nombreux conseils d'administration, dont ceux de la Société canadienne de chimie, de la *Revue canadienne de chimie*, de la Fondation de l'Université Dalhousie, du Conseil des provinces atlantiques pour les sciences et de la World Association of Theoretical and Computational Chemists. Il est l'un des rédacteurs en chef de la *Revue canadienne de chimie* de 1988 à 1998 et il siège à titre de président de la Société canadienne de chimie en 2007-2008. De plus, le rôle de juge en chef à l'occasion de l'Expo-sciences pancanadienne de 1984 constitue une autre de ses nombreuses activités. Il est actuellement le chercheur principal (directeur de la recherche) de l'Atlantic Computational Excellence Network (ACEnet), un consortium de neuf universités du Canada atlantique qui fournit des infrastructures informatiques de haute performance grâce aux fonds provenant de la Fondation canadienne pour l'innovation.

Le nombre, la qualité et les pays d'origine des articles soumis au présent numéro spécial de la *Revue canadienne de chimie* témoignent aussi bien de l'ampleur et du rayonnement de l'influence de Russ Boyd dans les milieux de la chimie théorique et numérique tant au Canada qu'à l'étranger que de son apport au milieu de la chimie en général.

# Spectrophotometric study of the selective binding behavior of aliphatic oligopeptides by bridged bis( $\beta$ -cyclodextrin) linked by a 4,4'-diaminodiphenyl disulfide tether

Yang Yong-Cun, Chi Shao-Ming, Liu Ming-Hua, Huang Rong, Wang Yu-Fei, Jing Bi, and Zhao Yan

**Abstract:** The conformation and binding behavior of 4,4'-diaminodiphenyl disulfide bridged bis( $\beta$ -cyclodextrin) (**1**) towards representative aliphatic oligopeptides, i.e., Leu-Gly, Gly-Leu, Glu-Glu, Met-Met, Gly-Gly, Gly-Gly-Gly, and Gly-Pro, were investigated by circular dichroism, fluorescence, and  $^1\text{H}$  and 2D NMR spectroscopy at 25 °C in phosphate buffer (pH 7.20). The results indicated that **1** acts as an efficient fluorescent sensor and displays remarkable fluorescence enhancement upon addition of optically inert oligopeptides. Owing to the cooperative host-linker-guest binding mode in which the linker and guest are coincluded in the two cyclodextrin cavities, the bis( $\beta$ -cyclodextrin) **1** gives high binding constants of up to  $10^3$ – $10^4$  (mol/L) $^{-1}$  for oligopeptides. The bis( $\beta$ -cyclodextrin) **1** can recognize not only the size and shape of oligopeptides but also the hydrophobicity, giving an exciting residue selectivity of up to 61.3 for the Gly-Leu/Glu-Glu pair. These phenomena are discussed from the viewpoints of multiple recognition and induce-fit interactions between host and guest.

**Key words:** bridged bis( $\beta$ -cyclodextrin)s, aliphatic oligopeptides, fluorescence spectroscopy, binding behavior, inclusion phenomena.

**Résumé :** Faisant appel au dichroïsme circulaire, à la fluorescence, à la spectroscopie RMN  $^1\text{H}$  et 2D, à 25 °C dans un tampon de phosphate (pH de 7,20), on a étudié la conformation et le comportement de fixation du disulfure de 4,4'-diaminodiphényle lié à la  $\beta$ -cyclodextrine, **1**, avec des oligopeptides aliphatiques représentatifs, tels Leu-Gly, Gly-Leu, Glu-Glu, Met-Met, Gly-Gly, Gly-Gly-Gly et Gly-Pro. Les résultats obtenus indiquent que le composé **1** agit comme un capteur de fluorescence efficace et qu'il donne lieu à une augmentation de fluorescence remarquable lors de l'addition d'oligopeptides inertes. En raison du mode de fixation coopératif hôte-coupleur-invité dans lequel le coupleur et l'invité sont co-inclus dans les deux cavités de la cyclodextrine, les constantes de fixation de la bis( $\beta$ -cyclodextrine), **1**, avec les oligopeptides sont élevées, soit de  $10^3$  à  $10^4$  (mol/L) $^{-1}$ . En plus de reconnaître la taille et la forme des oligopeptides, la bis( $\beta$ -cyclodextrine), **1**, reconnaît aussi le caractère hydrophobe qui lui permet d'avoir une excitante sélectivité de résidu allant jusqu'à 61,3 pour la paire Gly-Leu/Glu-Glu. On discute de ces phénomènes du point de vue de la reconnaissance multiple et des interactions à arrimage induit entre hôte et invité.

**Mots-clés :** bis( $\beta$ -cyclodextrines) pontées, oligopeptides aliphatiques, spectroscopie de fluorescence, comportement de fixation, phénomène d'inclusion.

## Introduction

Native and chemically modified cyclodextrins (CDs), which act as synthetic receptors (hosts) of supramolecular systems, display dramatically different binding behavior toward guest molecules.<sup>1–6</sup> As a new family of CD derivatives, the bridged CD dimers are known to greatly enhance the original binding ability and molecular selectivity of native CD by the cooperative interaction of its two nearly lo-

cated hydrophobic cavities.<sup>7–10</sup> Hence, the molecular recognition of substrate (guest) by bridged CDs linked with a functional tether group becomes one of the most crucial current topics in supramolecular chemistry and biochemistry.<sup>11–14</sup> Among the various families of organic and biological guests for these studies, aliphatic oligopeptides have attracted considerable interest because they represent an intermediate step toward the recognition of protein surfaces, and the short peptide sequences are themselves worthwhile

targets for recognition owing to their potential applications in separation, diagnostic, or biological areas.<sup>15–18</sup> However, the work on molecular recognition by bis( $\beta$ -CD)s has been concentrated mostly on the complexation of rather simple organic guests, and practically no attempt has been made to study the recognition of aliphatic oligopeptides by bis( $\beta$ -CD)s.<sup>19–23</sup> To elucidate the detailed recognition mechanism of bridged bis( $\beta$ -CD)s toward oligopeptides, we investigate the conformation of 4,4'-diaminodiphenyl disulfide bridged bis( $\beta$ -CD) (**1**, Scheme 1) as well as its selective binding behavior with a series of aliphatic oligopeptides (Scheme 2) by circular dichroism, fluorescence, and  $^1\text{H}$  and 2D NMR spectroscopy in a phosphate buffer solution of pH 7.20. It is our special interest to explore how the bridge group affects the cooperative binding of bis( $\beta$ -CD)s and further understand the factors governing the molecular multiple recognition mechanism.

## Experimental

### Instruments

Circular dichroism and UV-vis spectra were recorded in a conventional quartz cell (light path 10 mm) on a JASCO 810 spectropolarimeter and a Shimadzu UV2401 PC spectrometer, respectively.  $^1\text{H}$  NMR spectra were recorded on a Bruker AV DRX5 instrument operated at 500 MHz. Fluorescence spectra were measured in a conventional quartz cell (10 mm  $\times$  10 mm  $\times$  45 mm) at 25  $^\circ\text{C}$  on a Hitachi F-4500 spectrometer equipped with a constant-temperature water bath, with excitation and emission slits 10 nm in width at an excitation wavelength of 310 nm.

### Materials

All guest aliphatic oligopeptides, i.e., Leu-Gly, Gly-Leu, Glu-Glu, Met-Met, Gly-Gly, Gly-Gly-Gly, and Gly-Pro, were purchased from Sigma-Aldrich and used as received. Disodium hydrogen phosphate and sodium dihydrogen phosphate were dissolved in distilled, deionized water to make a 0.10 mol/L phosphate buffer solution of pH 7.20 for spectral measurements. 4,4'-Diaminodiphenyl disulfide bridged bis( $\beta$ -CD) (**1**) was prepared according to our previous report.<sup>24</sup>

## Results and discussion

### Circular dichroism

Circular dichroism spectra have been widely employed to elucidate the absolute conformation of chiral compounds. The achiral compounds located in a chiral environment produce induced circular dichroism (ICD) signal(s) in the corresponding transition band(s).<sup>25</sup> Therefore, to examine the

Scheme 2.

conformation of host **1**, its circular dichroism spectrum was measured at 25  $^\circ\text{C}$  in phosphate buffer solution (pH 7.20). As shown in Fig. 1, the circular dichroism spectrum of **1** displays a relatively strong positive Cotton effect peak around 259 nm ( $\Delta\epsilon = +1.18 \text{ (mol/L)}^{-1} \text{ cm}^{-1}$ ) for the  $^1\text{L}_a$  transition and a weak negative Cotton effect peak around 296 nm ( $\Delta\epsilon = -0.32 \text{ (mol/L)}^{-1} \text{ cm}^{-1}$ ) for the  $^1\text{L}_b$  transition of phenyl moieties in the linker group. According to the empirical rule proposed by Kajtar et al.<sup>26</sup> and Harata and Uedaira,<sup>27</sup> the sign of the ICD signal depends on the orientation of the transition dipole moment of the chromophore with respect to the dipole moment of CD. The chromophore located inside the CD axis gives a positive ICD signal, whereas the perpendicular transitions give a negative signal, but this situation is reversed for the chromophore located outside the CD cavity. Therefore, we can deduce that the phenyl chromophore in the diaminodiphenyl disulfide linker of host **1** shallowly penetrates into the CD cavity to

**Fig. 1.** (a) Circular dichroism and (b) absorption spectra of the bis( $\beta$ -CD) **1** ( $1.0 \times 10^{-4}$  mol/L) in the absence and presence of Gly-Gly ( $9.96 \times 10^{-3}$  mol/L) in phosphate buffer (pH 7.20) at 25 °C.

form the self-included complexes, which is in good agreement with the 2D NMR spectral study.<sup>24</sup>

### Fluorescence titrations

The emission intensity of a fluorophore attached to the CD rim is usually stronger than that of the parent fluorophore because of the increased microenvironmental hydrophobicity introduced by self-inclusion. As can be seen from Fig. 2, the fluorescence intensity of host **1** is much larger than that of the reference compound **1a** under the same conditions. Since the fluorescence intensity of the phenyl moiety is sensitive to changes in its microenvironment and is greater in a hydrophobic microenvironment than in a hydrophilic one, the above results suggest that the phenyl moiety of **1** is included into the cavity of the CD. This outcome is consistent with the ICD result described above.

The binding ability of a fluorescently labeled CD can be quantitatively assessed by analysis of the spectral changes induced by guest inclusion. Fluorescence titrations of the bis( $\beta$ -CD) **1** with optically inert oligopeptides were performed at 25 °C in phosphate buffer solution (pH 7.20) to quantitatively assess the inclusion complexation behavior of host **1**. As shown in Fig. 3, the fluorescence intensity of the bis( $\beta$ -CD) **1** presents a continuous enhancement upon the addition of Gly-Gly and Gly-Pro. The enhanced fluorescence of **1** upon addition of oligopeptides may be due to

**Fig. 2.** Fluorescence spectra of **1a** and the bis( $\beta$ -CD) **1** at the same concentration of  $9.6 \times 10^{-5}$  mol/L in phosphate buffer (pH 7.20) at 25 °C ( $\lambda_{\text{ex}} = 270$  nm).

the increased microenvironmental hydrophobicity and (or) steric shielding around the phenyl fluorophore arising from the cooperative host-linker-guest interactions. This hypothesis is supported by the 2D NMR measurements. The unique fluorescence behavior may enable **1** to be efficient fluorescence sensors for optically inserted molecules.

The stoichiometries for the inclusion complexation of host **1** with representative guests were determined by Job's experiments by fluorescence spectroscopy. Within the examined concentration range, each of Job's plots for the inclusion complexation of the bis( $\beta$ -CD) **1** with oligopeptides shows a maximum at a host **1** molar fraction of 0.5, confirming the 1:1 binding stoichiometry between host and guest (Fig. 4).

With the 1:1 stoichiometry for the inclusion complexation of oligopeptide guests (G) with CDs (H), where the two CD moieties in bis( $\beta$ -CD)s are treated as a single unit, the inclusion complexation is expressed by eq. [1] and the complex stability constant ( $K_s$ ) is given by eq. [2]:

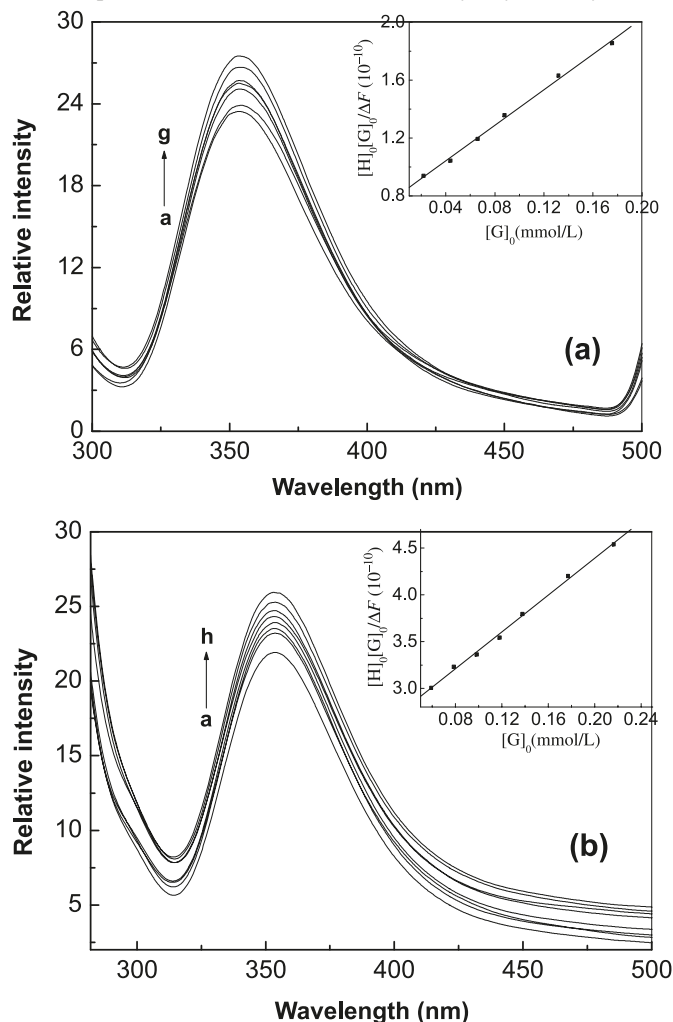

$$[2] \quad K_s = \frac{[\text{H} \bullet \text{G}]}{[\text{H}][\text{G}]}$$

$$[3] \quad \Delta F = \Delta \varepsilon [\text{H} \bullet \text{G}]$$

where  $\Delta F$  and  $\Delta \varepsilon$  denote the sequential changes of fluorescence intensity and the differential molar extinction coefficient of host  $\beta$ -CDs in the absence and presence of the guest molecule. Under the conditions employed, the initial concentration of guest molecules is much larger than that of the host  $\beta$ -CD, i.e.,  $[\text{G}]_0 \gg [\text{H}]_0$ . Therefore, the combination of eqs. [2] and [3] leads to the extended Benesi-Hildebrand equation (eq. [4]),<sup>28</sup> which is used to calculate the  $K_s$  (eq. [2]) from the slope and intercept of  $[\text{H}]_0[\text{G}]_0/\Delta F$  versus  $[\text{G}]_0$  plots.

**Fig. 3.** Fluorescence spectral changes of (a) the bis( $\beta$ -CD) **1** ( $6.4 \times 10^{-6}$  mol/L) upon addition of Gly-Gly (from a to g = 0, 22, 44, 66, 88, 132, and 176  $\mu$ mol/L) and (b) the bis( $\beta$ -CD) **1** ( $5.0 \times 10^{-6}$  mol/L) upon addition of Gly-Pro (from a to h = 0, 60, 80, 100, 120, 140, 180, and 220  $\mu$ mol/L) in phosphate buffer (pH 7.20) at 25  $^{\circ}$ C;  $\lambda_{\text{ex}}$  = 270 nm. Insets: typical plots of  $[H]_0[G]_0/\Delta F$  vs  $[G]_0$  for the inclusion complexation of the bis( $\beta$ -CD) **1** with Gly-Gly and Gly-Pro.

$$[4] \quad \frac{[H]_0[G]_0}{\Delta F} = \frac{1}{K_s \Delta \varepsilon} + \frac{[G]_0}{\Delta \varepsilon}$$

Figure 3 (insets) illustrates the result of such a treatment for the inclusion complexation of the bis( $\beta$ -CD) **1** with Gly-Gly and Gly-Pro, where the calculated  $[H]_0[G]_0/\Delta F$  values were plotted against the  $[G]_0$  to give an excellent linear relationship. The complex stability constants ( $K_s$ ) and the free energy changes ( $-\Delta G^{\circ}$ ) calculated from the slope and intercept are listed in Table 1.

### NMR analysis

$^1\text{H}$  NMR spectrometry is one of the most important techniques used for the characterization of inclusion complexes.<sup>29,30</sup> It is well known that CD possesses outer-surface (H2 and H4) and inner-surface (H3 and H5) protons, and the H6 protons are situated at the primary side of the CD cavity. The inclusion complexation of a guest molecule into the CD

**Fig. 4.** Continuous variation plot of the bis( $\beta$ -CD) **1** / Gly-Gly system ( $[\text{bis}(\beta\text{-CD}) \text{ unit}] + [\text{Gly-Gly}] = 2.0 \times 10^{-5}$  mol/L).

**Table 1.** Complex stability constants ( $K_s$ ) and Gibbs free energy changes ( $-\Delta G^{\circ}$ ) for the inclusion complexation of the bis( $\beta$ -CD) **1** with aliphatic oligopeptides in phosphate buffer (pH 7.20) at 25  $^{\circ}$ C.

Host	Guest	$K_s$ ((mol/L) $^{-1}$ )	Log $K_s$	$-\Delta G^{\circ}$ (kJ/mol)
<b>1</b>	Leu-Gly	$3220 \pm 100$	3.5	20.0
<b>1</b>	Gly-Leu	$14700 \pm 700$	4.2	23.8
<b>1</b>	Glu-Glu	$240 \pm 10$	2.4	13.6
<b>1</b>	Met-Met	$12900 \pm 600$	4.1	23.5
<b>1</b>	Gly-Gly	$7050 \pm 300$	3.8	22.0
<b>1</b>	Gly-Gly-Gly	$11700 \pm 600$	4.1	23.2

cavity will result in changes of the chemical shifts of guest protons, and these changes of the protons inside and (or) outside the CD cavity can be used to analyze the formation of the inclusion complex between the CD and the guest. For the sake of comparison, the spectra of the bis( $\beta$ -CD) **1** and Gly-Leu as well as their mixture at the same concentration are shown in Fig. 5, while the spectral characteristics of the bis( $\beta$ -CD) **1** and Gly-Leu are shown in Table 2. The reason for choosing Gly-Leu as the guest molecule to examine the binding behavior of the bis( $\beta$ -CD) **1** with the oligopeptides is that the chemical shifts of the isopropyl protons in the Leu fragment are distant from those of the protons in **1** and can be easily recognized in NMR spectra. As can be seen from Table 2, in the presence of Gly-Leu, a negligible effect is observed on the CD protons H1, H2, and H4. In contrast, protons H3, H5, and H6 exhibit substantial changes, and they undergo relatively strong shielding exceeding 0.06 ppm. Moreover, the changes in the  $^1\text{H}$  NMR chemical shifts of the guest Gly-Leu are also observed in the presence of the bis( $\beta$ -CD) **1** (Table 2). In the presence of the bis( $\beta$ -CD) **1**, the protons of 1', 3', 4', and 5' positions in the Gly-Leu show appreciable upfield shifts ( $\Delta\delta = -0.05$  ppm), whereas the proton of 2' exhibits relatively weak changes ( $\Delta\delta = -0.03$  ppm). These shifts in the  $^1\text{H}$  NMR spectra indicate complex formation between the bis( $\beta$ -CD) **1** and the guest Gly-Leu.

**Fig. 5.**  $^1\text{H}$  NMR spectra of (a) the bis( $\beta$ -CD) **1** ( $5.0 \times 10^{-3}$  mol/L), (b) the bis( $\beta$ -CD) **1** ( $5.0 \times 10^{-3}$  mol/L) in the presence of Gly-Leu ( $5.0 \times 10^{-3}$  mol/L), and (c) Gly-Leu ( $5.0 \times 10^{-3}$  mol/L) in  $\text{D}_2\text{O}$  at  $25^\circ\text{C}$ .

**Table 2.** The chemical shifts ( $\delta$ ) of the bis( $\beta$ -CD) **1**, Gly-Leu, and their mixture at the same concentration and the corresponding changes ( $\Delta\delta$ ).

### Binding mode

We examined the circular dichroism spectrum of the bis( $\beta$ -CD) **1** in the presence of Gly-Gly (Fig. 1). The Gly-Gly guest displays no appreciable ICD signal in the range of 200–400 nm. However, the intensity of the absorption bands of the bis( $\beta$ -CD) **1** increased upon addition of the

Gly-Gly guest, giving a relatively strong positive Cotton effect peak ( $\Delta\epsilon = +1.42$  (mol/L) $^{-1}$  cm $^{-1}$ ) at 258 nm for the  $^1\text{L}_a$  band, and a weak negative Cotton effect peak ( $\Delta\epsilon = -0.46$  (mol/L) $^{-1}$  cm $^{-1}$ ) at 295 nm for the  $^1\text{L}_b$  band. The circular dichroism spectral pattern of the bis( $\beta$ -CD) **1** is almost the same as the spectrum without guests, except for an increase in intensity, which indicates **1** almost maintains its original conformation during the addition of Gly-Gly. However, the circular dichroism spectra do not provide further information about the binding mode, which prompted us to perform more detailed conformation analysis by 2D NMR.

2D NMR spectroscopy has recently become an essential method for the study of the structures of CDs and their complexes, since one can conclude that two protons are closely located in space if an NOE cross peak is detected between the relevant proton signals in the NOESY or ROESY spectrum.<sup>31</sup> As illustrated in Fig. 6, the NOESY spectrum of an equimolar mixture of the bis( $\beta$ -CD) **1** with Gly-Leu (0.5 mmol/L each) displays the correlations (Fig. 6, peaks C and D) between the isobutyl protons of Gly-Leu and H3/H5/H6 of the CD cavity, while no other NOE correlations between host and guest can be found. Moreover, it can be seen from these peaks that the methenyl proton (H5') of Gly-Leu correlates with the H3 protons of CD (Fig. 6, peak

**Fig. 6.** ROESY spectrum of the bis( $\beta$ -CD) **1** with Gly-Leu ( $5.0 \times 10^{-3}$  mol/L each) in D<sub>2</sub>O at 25 °C with a mixing time of 400 ms.

C), whereas the methine proton (H4') of Gly-Leu correlates with the H5/H6 protons of CD (Fig. 6, peak D). In addition, the correlations (Fig. 6, peaks A and B) between the aromatic protons in the linker group and H5/H6 protons of CD are also observed, indicating that the phenyl moiety is not driven out of the CD cavity by guest inclusion. Since H3 protons are located near the wide side of the CD cavity, while H5 protons are near the narrow side, we can deduce that the phenyl unit in the linker group is self-included in another CD cavity from the narrow side. These results, together with the 1:1 host-guest inclusion complexation stoichiometry indicated by Job's experiment, indicate that a cooperative host-linker-guest binding mode is operative in the association of the bis( $\beta$ -CD) **1** with a guest molecule. That is, upon complexation with the bis( $\beta$ -CD) **1**, the guest Gly-Leu is embedded into one hydrophobic CD cavity from the primary side, while the linker group is partly self-included in the other cavity (Fig. 7). According to this binding mode, several interactions will simultaneously work between host and guest. Under our experimental conditions, the carboxylate group in the Gly-Leu is not protonated and should exist as a carboxylate anion, and the  $-NH-$  group in the linker of the bis( $\beta$ -CD) **1** should be partly protonated. Therefore, besides the van der Waals and hydrophobic interactions between the CD cavity and guest oligopeptides, the electrostatic interactions between the protonated amino groups ( $-NH_2^+$ ) in the linker and the carboxylate anion of the oligopeptide may to some extent favor the inclusion

**Fig. 7.** Possible binding mode of the bis( $\beta$ -CD) **1** with Gly-Leu.

complexations of **1** with Gly-Leu. Moreover, the hydrogen bonding interactions between the protonated amino groups ( $-NH_2^+$ ) in the linker and guest oligopeptide also contribute to the strong binding of the bis( $\beta$ -CD) **1**.

The binding mode consequently rationalizes the enhanced fluorescence of **1** in the presence of the guest oligopeptides. Firstly, the inclusion of an oligopeptide can extrude water from the CD cavity and thus increase the microenvironmental hydrophobicity around the fluorophore. In addition, the phenyl chromophore may be efficiently protected from the deactivating water attack by steric shielding by the close oligopeptide guests. As a joint result of these two factors, **1** gives enhanced fluorescence upon inclusion complexation with the oligopeptide.

### Binding ability and molecular selectivity

Many investigations have demonstrated that several weak noncovalent forces, including van der Waals forces, hydrophobic interactions, hydrogen bonding, and electrostatic interactions, contribute cooperatively to inclusion complexation by CDs, and a good match of the size and shape of the host to those of the guest should greatly favor host–guest inclusion complexation, since the strength of these interactions is closely related to the distance and contact surface area between the host and guest.<sup>15</sup> The complex formation constants ( $K_s$ ) for the inclusion complexation of host **1** with oligopeptides decreased in the following order: Gly-Leu > Met-Met > Gly-Gly-Gly > Gly-Gly > Gly-Pro > Leu-Gly > Glu-Glu. It seems reasonable that the bis( $\beta$ -CD) **1** shows the strongest binding ability toward Gly-Leu and Met-Met, since both possess a carboxyl group located in the middle of the peptide chain, which greatly promotes inclusion by the electrostatic and hydrogen bonding interactions between the protonated amino groups ( $-\text{NH}_2^+$ ) in the linker of **1** and the anionic carboxylate of Gly-Leu and Met-Met. On the other hand, although Glu-Glu has a similar structure to Met-Met, its poor hydrophobicity arising from the presence of three hydrophilic carboxyl groups in the molecule reduces the hydrophobic interactions upon complexation with the CD cavity and thus results in the smallest  $K_s$  value with the bis( $\beta$ -CD) **1**. Furthermore, bis( $\beta$ -CD) **1** exhibits a higher  $K_s$  value for the longer Gly-Gly-Gly than for the shorter Gly-Gly ( $K_s$  Gly-Gly-Gly /  $K_s$  Gly-Gly = 1.7). This may be attributed to the strict size and shape between the host and guest. Possessing a relatively long skeleton and less branched chains, Gly-Gly-Gly is able to fully enjoy the cooperative multi-point binding of the long-tethered bis( $\beta$ -CD) **1** as compared with the Gly-Gly guest. Moreover, the hydrogen bonding interactions between one of the carbonyl groups in Gly-Gly-Gly and the amino groups ( $-\text{NH}_2^+$ ) in the linker of the bis( $\beta$ -CD) **1** further promotes the host–guest inclusion complexation. As a joint result of these two factors, the bis( $\beta$ -CD) **1** toward Gly-Gly-Gly gives a stronger binding ability. Another intriguing phenomenon is that the bis( $\beta$ -CD) **1** shows higher binding ability upon complexation with Gly-Leu ( $K_s = 14\,700$  (mol/L)<sup>-1</sup>) as compared with Leu-Gly ( $K_s = 3220$  (mol/L)<sup>-1</sup>). This result seems reasonable, since the guest Gly-Leu and diamino group in **1** are closely located, and the electrostatic and hydrogen bonding interactions between the protonated linker ( $-\text{NH}_2^+$ ) and Leu  $\text{COO}^-$  will provide the additional binding interactions between the host and guest, which consequently favors the host–guest inclusion complexation to some extent. In contrast, the inclusion of the Leu-Gly guest inevitably causes electrostatic repulsion between the linker  $\text{NH}_2^+$  of the bis( $\beta$ -CD) **1** and Leu  $\text{NH}_3^+$  groups of Leu-Gly, resulting in poor host–guest inclusion. Owing to the multiple recognition mechanism involving size and shape fit, hydrophobic electrostatic, and hydrogen bonding interactions, the  $K_s$  values for the bis( $\beta$ -CD) **1** with oligopeptides are variable according to the guest structures from 240 to 14 700 (mol/L)<sup>-1</sup>. The host **1** gives an exciting residue selectivity of up to 61.3 for the Gly-Leu/Glu-Glu pair, and a relatively higher sequence selectivity of up to 4.6 for the Gly-Leu/Leu-Gly pair.

### Conclusions

In summary, the conformation and binding behavior of 4,4'-diaminodiphenyl disulfide bridged bis( $\beta$ -CD) (**1**) with aliphatic oligopeptides has been investigated. The guest-induced fluorescence enhancement of the bis( $\beta$ -CD) **1** opens a new channel for the design of materials. Owing to the multiple recognition mechanism, the bis( $\beta$ -CD) **1** not only affords the highest binding constants of 14 700 (mol/L)<sup>-1</sup> for Gly-Leu, but can also recognize the size and hydrophobicity of oligopeptides, exhibiting dramatically high residue selectivity. These results provide a convenient and powerful method for controlling the binding behavior of dimeric receptors in aqueous solution, which should be useful for the design and synthesis of new supramolecular systems and further improve the understanding of the molecular multiple recognition mechanism in supramolecular systems.

# Synthesis and reactivity of bis-alkynyl appended metallocenes of Ti, Fe, and Co

Preeti Chadha, Jason L. Dutton, and Paul J. Ragogna

**Abstract:** (Dimethyl)(phenylethynyl)silyl-substituted cyclopentadiene  $C_5H_5SiMe_2C_2Ph$  (**1**) was synthesized by the reaction of in situ generated  $C_5H_5SiMe_2Cl$  with  $LiC_2Ph$ . Metallation of **1** with  $^nBuLi$  or  $KN(SiMe_3)_2$  gave the corresponding Li (**2**) and K (**3**) salts. Transmetalation of **2** with transition metal halides  $MCl_2$  ( $M = TiCl_2$ , Fe, and Co) generated the corresponding early and late transition metal metallocenes (**4**, **5**, and **6**) with pendant alkynyl substituents. Compounds **4** and **6** are the first examples of bis alkyne appended Ti and Co metallocenes. Complexes **5** and **6** undergo alkyne dimerization in the presence of  $CpCo(CO)_2$  generating metallocenophanes **7** and **8** incorporating two metal atoms. Compounds **3**, **4** $Cl_2$ , **6**, and **[8][OTf]** have been characterized by single crystal X-ray structure analysis.

**Key words:** cyclopentadiene, alkyne, titanium, cobalt, heterometallic, metallocenophane.

**Résumé :** On a réalisé la synthèse du (diméthyl)(phényléthynyl)silylcyclopentadiène,  $C_5H_5SiMe_2C_2Ph$  (**1**) par réaction du chlorure de (diméthyl)(phényléthynyl)silyle,  $C_5H_5SiMe_2Cl$  avec le  $LiC_2Ph$ . La métallation du produit **1** avec  $^nBuLi$  ou le  $KN(SiMe_3)_2$  conduit aux sels correspondants du lithium (**2**) ou du potassium (**3**). La transmétallation du produit **2** avec des halogénures de métaux de transitions,  $MCl_2$  ( $M = TiCl_2$ , Fe et Co) conduit aux métallocènes correspondants (**4**, **5** et **6**) de métaux de transition du début et de la fin de cette série portant des substituants alcynyles. Les composés **4** et **6** sont les premiers exemples de métallocènes du titane et du cobalt portant deux appendices bisalcyne. Les complexes **5** et **6**, mis en présence de  $CpCo(CO)_3$ , donnent lieu à une dimérisation de l'alcyne qui conduit aux métallocénophanes **7** et **8** incorporant deux atomes métalliques. On a caractérisé les composés **3**, **4** $Cl_2$ , **6** et **[8][OTf]** par diffraction des rayons-X par un cristal unique.

**Mots-clés :** cyclopentadiène, alcyne, titane, cobalt, hétérométallique, métallocénophane.

[Traduit par la Rédaction]

## Introduction

Cyclopentadienyl (Cp) ligands are one of the most common ligands used in organometallic chemistry as they form complexes with most of the transition metals. Various functional groups have been attached to the Cp ring such as phosphines,<sup>1</sup> amines,<sup>2</sup> and carboxylates,<sup>3</sup> as well as directly linked hetero atoms including numerous p-block elements<sup>4</sup> and transition metals.<sup>5</sup> In many of these cases, the substituents are attached to the  $\pi$ -ligand framework early on during the ligand synthesis, prior to complexation of the central metal. The attachment of various types of alkenyl substituents continues to be of considerable interest, since it allows for the development of organic functional group chemistry at the framework of the preassembled metallocene systems. This includes addition reactions,<sup>6</sup> carbon-carbon coupling reactions at the metallocene backbone resulting in the formation of ansa-metallocenes by intramolecular olefin metathesis (RCM),<sup>7</sup> photochemical [2 + 2] cycloaddition reactions,<sup>8</sup> or by a Mannich type reaction.<sup>9</sup> However, there are few examples of metallocenes with alkyne-appended Cp ligands except for the group 8 metals, which are easily accessible owing to their high stability under various condi-

tions.<sup>10</sup> The bis-alkynyl substituted ferrocenes have been primarily prepared by the coupling of alkynes with diiodo ferrocene.<sup>11a,11b</sup> To make these alkyne substituents more accessible for other transition metals, we have developed a preassembled alkyne-appended Cp ligand (**1**), which can then be attached to various metals such as Ti, Co, and Fe to generate the corresponding metallocenes.

In this context, we describe the synthesis of an alkyne-appended Cp ligand where the alkyne is bridged to the Cp ring by the heteroatom silicon. Various metallocenes have been synthesized using the ligand, and dimerization of the alkyne substituent has been carried out yielding metallocenophanes **7** and **8** incorporating two metal atoms.

## Results and discussion

### Synthesis

#### Ligand synthesis

The 1:1 stoichiometric reaction of  $LiCp$  with  $Me_2SiCl_2$  at  $-40\text{ }^\circ\text{C}$  in THF resulted in a pale yellow solution. The reaction mixture was allowed to stir for 3–4 h, warming

**Scheme 1.** Synthesis and deprotonation of the ligand.

slowly to room temperature. The reaction mixture was cooled again to  $-40^\circ\text{C}$  and 1 stoichiometric equiv of lithium phenyl acetylide was added (Scheme 1). The solvent was removed in vacuo and the solids washed with *n*-pentane and filtered. The filtrate was concentrated resulting in the formation of a yellow-orange oil. Proton NMR spectroscopy of the crude oil revealed signals consistent with one major product; however, one broad signal was observed for the Cp protons at room temperature. Upon lowering the temperature to  $-20^\circ\text{C}$ , the Cp protons became resolved within the NMR spectra and the three expected isomers (**1a–1c**) were detected. The ratio of the three isomers **1a** (84%), **1b** (13%), and **1c** (3%) were obtained by  $^1\text{H}$  NMR spectroscopy at  $-20^\circ\text{C}$ .<sup>11</sup> The presence of the three isomers were confirmed by  $^{29}\text{Si}$  NMR spectroscopy ( $^1\text{H}$ - $^{29}\text{Si}$  gHMBC) and were observed at  $\delta_{\text{Si}} = -18.6$  for **1a** and  $\delta_{\text{Si}} = -25$  ppm for **1b** and **1c**. The intermediate  $\text{CpSiMe}_2\text{Cl}$ <sup>11a</sup> generated during the initial reaction of LiCp and  $\text{Me}_2\text{SiCl}_2$  was not isolated as it has a very low boiling point,<sup>12</sup> which hinders its isolation in good yields. The in situ generation of  $\text{CpSiMe}_2\text{Cl}$  in a one-pot procedure results in higher yields of **1**. In an independent recent report by Roewer and co-workers,<sup>13</sup> where the  $\text{CpSiMe}_2\text{Cl}$  was isolated, the yield was 30%, whereas our approach gives a 50% yield. Reverse addition of  $\text{Me}_2\text{SiCl}_2$  to the LiCp solution leads to the formation of other unwanted side products, namely  $\text{Cp}_2\text{SiMe}_2$ . Traces of  $\text{Cp}_2\text{SiMe}_2$  and  $(\text{PhC}_2)_2\text{SiMe}_2$  were identified in the crude mixture resulting from slight variations in the stoichiometry. Further purification was carried out by fractional distillation to give the ligand (**1**) in 50% overall yield. The ligand must be pure before attempting the subsequent deprotonation to generate the lithium salt (**2**) cleanly. Freshly prepared **1** was either stored at  $-30^\circ\text{C}$  or converted to its stable Li or K salt (**2**<sup>13</sup> and **3**, respectively) by deprotonation with either  $n\text{-BuLi}$  or  $\text{KN}(\text{SiMe}_3)_2$ . Single crystals were obtained for the potassium salt (**3**) by slow diffusion of *n*-pentane into a THF solution of the ligand and X-ray diffraction studies confirmed the expected connectivity (Fig. 1).

#### Metallation of the ligand — Formation of cyclopentadienyl sandwich complexes

To probe the reactivity and utility of the ligand, metal–Cp complexes were synthesized. The general scheme for the synthesis of the  $(\text{RC}_5\text{H}_4)_2\text{M}$  complexes ( $\text{M} = \text{TiCl}_2$ , Fe, Co;  $\text{R} = \text{SiMe}_2\text{C}_2\text{Ph}$ ) involved transmetallation of the lithium salt (**2**) with the corresponding transition metal halide. Reaction of 2.4 stoichiometric equiv of **2** with  $\text{TiCl}_4$  in *n*-hexane resulted in a colour change from white to yellow and finally to red over a period of 4 h. Proton NMR spectra obtained from the yellow solution showed two sets of Cp pseudo triplets and when the reaction mixture turned red, only one set of Cp protons remained. An excess of the ligand **2** (2.4 stoichiometric equiv instead of 2) was used to ensure complete conversion.

**Scheme 2.** Synthesis of compounds **4Cl<sub>2</sub>**, **4Me<sub>2</sub>**, **5**, and **6**.

chometric equiv instead of 2) was used to ensure complete conversion. The red solution was filtered, cooled to  $-30^\circ\text{C}$  for complete precipitation of LiCl, filtered again, then concentrated and left at  $-30^\circ\text{C}$  allowing red crystals of **4Cl<sub>2</sub>** to form. X-ray quality crystals of **4Cl<sub>2</sub>** were obtained from a concentrated *n*-hexane solution (see X-ray crystallography, see Fig. 2). Compound **4Cl<sub>2</sub>** was treated with 3 stoichiometric equiv of  $\text{MeMgCl}$  in an  $\text{Et}_2\text{O}/n\text{-hexane}$  mixture resulting in a colour change from red to yellow-orange (Scheme 2). The  $^1\text{H}$  NMR spectrum of an aliquot of the reaction mixture showed a significant shift of the Cp protons ( $\Delta\delta = 0.59$  in **4Cl<sub>2</sub>** to  $\Delta\delta = 0.09$  in **4Me<sub>2</sub>**) and an upfield shift of 0.3 ppm in the methyl groups attached to the silicon atom (Table 1). An upfield shift of  $\sim 6$  ppm is observed in the  $^{29}\text{Si}$  NMR spectrum of **4Cl<sub>2</sub>** and **4Me<sub>2</sub>** when compared with the free ligand (**1**).

Treatment of **2** with 0.5 stoichiometric equiv of anhydrous  $\text{FeCl}_2$  or  $\text{CoCl}_2$  in THF at room temperature resulted in the formation of a yellow-orange or red solution, respectively, over a period of 3–4 h (Scheme 2). The solvent was removed in vacuo, the residue washed with *n*-pentane, and centrifuged. The *n*-pentane was then removed to give orange or red-maroon solids, respectively. The orange solid was identified as compound **5** by comparison with the literature.<sup>14</sup> However, the literature procedure involves the reaction between dilithio-ferrocene and chloro(dimethyl)(phenylethynyl) silane, which is not readily accessible. Compound **5** was further purified by sublimation or recrystallization from *n*-hexane. The  $^1\text{H}$  NMR spectrum of the redissolved red-maroon powder showed a singlet at 3.62 ppm integrating to six protons ( $\text{SiMe}_2$ ), a doublet and two triplets in the aryl region integrating in a 2:2:1 ratio. The Cp protons were not observed owing to the paramagnetic nature of compound **6**. Single crystals were obtained from a concentrated  $\text{Et}_2\text{O}$  solution of the red-maroon powder and X-ray diffraction studies showed the expected connectivity (Fig. 3).

Compound **6** was purified by recrystallization from  $\text{Et}_2\text{O}/n\text{-pentane}$  and was then oxidized with  $\text{AgOTf}$  to form compound **[6][OTf]**, allowing full NMR spectroscopic characterization.

**Fig. 1.** Extended solid-state structure of **3**. Thermal ellipsoids are drawn to the 50% probability level and hydrogen atoms are removed for clarity. The THF molecule is disordered with the four carbon atoms occupying two different positions of 50% occupancy each. Only one set of carbon atoms is shown for THF.

**Fig. 2.** Solid-state structure of  $(RC_5H_4)_2TiCl_2$  (**4Cl<sub>2</sub>**), R = Si-Me<sub>2</sub>C<sub>2</sub>Ph. Thermal ellipsoids are drawn to the 50% probability level and hydrogen atoms are removed for clarity.

### Cyclization of the alkyne moiety

Compounds **5**, **6**, and **[6][OTf]** were photolyzed with  $CpCo(CO)_2$  to study if the alkynes undergo inter- or intramolecular cyclization. The reactions were performed in benzene-*d*<sub>6</sub> and monitored by <sup>1</sup>H NMR spectroscopy. The reaction proceeded to completion over a period of 40 h (Scheme 3). Some decomposition was observed, resulting in the formation of a brown solid, which was filtered off, the volatiles removed, and the residue washed with *n*-pentane to give orange (**7**) and brown solids (**8** and **[8][OTf]**), respectively. The <sup>1</sup>H NMR spectra of the solids revealed a lowering of symmetry resulting in four different signals for the cyclopentadienyl rings and two different methyl signals in **7** and **[8][OTf]** for the silicon-bound methyl groups.

Carbon-13 NMR spectra of **7** and **[8][OTf]** revealed an upfield shift in the alkyne carbon signals ( $\delta = 93$  and 106 ppm in **5** to  $\delta = 66$  and 88 ppm in **7**; see Table 1), which is typical of  $CbCoCp$  complexes<sup>15</sup>, giving evidence for the formation of a cyclobutadiene ring. A similar effect was observed for **[8][OTf]**. Silicon-29 NMR spectrum showed a downfield shift of about 12 ppm in both **7** and **[8][OTf]**.

Compound **[8][OTf]** can be prepared either by the alkyne cyclization of **[6][OTf]** or by the cyclization of **6** first to form **8** and then oxidation of **8** with AgOTf to yield **[8][OTf]** (Scheme 3).

**Scheme 3.** Synthesis of compounds **7–8**.

### X-ray crystallography

The solid-state structure of the potassium salt of the ligand (**3**) shows that the K atom is sandwiched between two Cp rings and is coordinated by a THF molecule. The interaction between the K and the Cp rings gives rise to extended zigzag chain structure (Fig. 1), reminiscent of group 1 metallocenes.<sup>1a,16,17</sup> The K–Cp<sub>centroid</sub> distances are 2.81 Å and 2.82 Å; the Cp<sub>centroid</sub>–K–Cp<sub>centroid</sub> angle is 138.0°; the K–K–K angle is 138.5°; and the K–Cp<sub>centroid</sub>–K angle is 173.2°, which are indicative of a formal coordination number of 8 for each K atom.<sup>17</sup> This suggests an interaction with the alkyne filling the eighth coordination site (K–C8 = 3.406(3) Å). Similar interaction was observed for an appended alkene moiety; however, the interaction was slightly weaker (3.58(3) Å).<sup>17</sup>

The molecular structure of **4Cl<sub>2</sub>** reveals the anticipated connectivity (Fig. 2).<sup>18</sup> Selected bond lengths and angles are given in Table 2. The alkyne fragments are oriented away from each other and away from the metal centre, and there is no interaction observed between the metal and the alkyne.

In the solid-state structure of **6** (Fig. 3), the two alkynes are oriented away from each other in a trans fashion, the two Cp rings being completely staggered, with the alkynes bent towards the metal centre as opposed to **4Cl<sub>2</sub>**. However, for the cyclization to take place, the alkynes are forced to rotate to obtain a cis geometry. As reported earlier for various [2 + 2] cyclization reactions at the cobalt centre,<sup>19</sup> initial complexation of one of the alkynes with the cobalt centre, probably drives the formation of the cyclized products **7**, **8**, and **[8][OTf]**. In this case, the formation of only one isomer (cis isomer) was observed where the two phenyl groups are cis to each other, as seen from the solid-state structure of **[8][OTf]** (Fig. 4) and from NMR spectroscopy. There is no indication of intermolecular cyclization. The change from sp to sp<sup>2</sup> hybridization is clearly evident on comparison of the C–alkyne bond lengths in **8** and **[10][OTf]**, which changes from 1.20 Å (avg.) in **6** to 1.48 Å (avg.) in **[8][OTf]**, typical of other  $CbCoCp$  compounds (Table 2). The Si–CC<sub>alkyne</sub>

**Table 1.** Selected spectral data for compounds 1–8.

bond length is slightly elongated in **[8][OTf]** (1.858(5) and 1.856(6) Å) compared with that in **6** (1.848(3) Å). The Cb–Co–Cp angle remains almost linear (179.6°), indicating that the structure is not strained and is in accordance to what is expected for a [4]cobaltocenophane.<sup>20</sup> However, there are no other known structures of [4]cobaltocenophanes. The crystallographic data for **3**, **4Cl<sub>2</sub>**, **6**, and **[8][OTf]** are found in Table 3.

Similar [2 + 2] cyclization reactions of the appended alkynes in compound **4Me<sub>2</sub>** were, however, unsuccessful and lead to the formation of multiple products as seen from the  $^1\text{H}$  NMR spectrum of the crude sample.

## Conclusion

Early and late transition metal metallocenes (**4Cl<sub>2</sub>**, **4Me<sub>2</sub>**, **6**, and **7**) with a cyclopentadienyl ligand bearing an appended alkyne moiety have been synthesized following a general metathesis route with the preassembled ligand system. Compounds **4** and **6** are the first examples of bis(alkyne)-appended Ti and Co metallocenes. This shows the potential of this ligand to form complexes with a wide variety of transition metals. Alkyne dimerization of the appended alkynes gave rise to metallocenophanes **7** and **8** incorporating two metal atoms. Compound **8** is the first example of a [4]cobaltocenophane with a single Si<sub>2</sub>C<sub>2</sub> bridge.

## Experimental section

Manipulations were performed in an N<sub>2</sub>-filled MBraun

Labmaster 130 glovebox in 4 dram vials (1 dram = 3.552 cm<sup>3</sup>) affixed with Teflon-lined screw caps or using standard Schlenk techniques. Dichloromethane, THF, MeCN, Et<sub>2</sub>O, *n*-pentane, and *n*-hexane were obtained from Caledon Laboratories and dried using the MBraun solvent purification system that utilizes appropriate drying agents. The dried solvents were stored in Straus flasks under a N<sub>2</sub> atmosphere or over 4 Å molecular sieves in the glovebox. Solvents for NMR spectroscopy (CDCl<sub>3</sub>, C<sub>6</sub>D<sub>6</sub>, CD<sub>3</sub>CN, and C<sub>5</sub>D<sub>5</sub>N) were purchased from Cambridge Isotope Laboratories and dried by stirring overnight over CaH<sub>2</sub>, distilled prior to use, and stored in the glovebox over 4 Å molecular sieves.

Dicyclopentadiene and phenyl acetylene were purchased from Sigma-Aldrich and distilled prior to use. Lithium cyclopentadienide<sup>21a</sup> and lithium phenylacetylide<sup>21b</sup> were prepared using literature methods. <sup>*n*</sup>BuLi (1.6 mol/L solution in *n*-hexane), MeMgCl (2 mol/L solution in THF), KN(SiMe<sub>3</sub>)<sub>2</sub>, and PPh<sub>3</sub> were purchased from Sigma-Aldrich and used as received. Cobalt chloride, FeCl<sub>2</sub>, and CpCo(CO)<sub>2</sub> were purchased from Strem Chemicals. Dichlorodimethylsilane was purchased from the Fluka Chemical Company, dried over CaH<sub>2</sub>, distilled prior to use, and stored in the glovebox. Titanium tetrachloride (TiCl<sub>4</sub>) and AgOTf were purchased from Alfa Aesar and used as received (OTf = triflate; trifluoromethanesulphonate).

NMR spectra were recorded using a Varian INOVA 400 MHz spectrometer ( $^3\text{P}$  = 161.83 MHz,  $^{29}\text{Si}$  = 19.86 MHz, and  $^{13}\text{C}$  = 100.52 MHz). Phosphorus-31 NMR spectra was externally referenced to 85% H<sub>3</sub>PO<sub>4</sub> ( $\delta$  = 0.00 ppm). Proton and  $^{13}\text{C}\{^1\text{H}\}$  NMR spectra were referenced relative to Me<sub>4</sub>Si using the NMR solvent ( $^1\text{H}$ –CHCl<sub>3</sub>,  $\delta$  = 7.26 ppm; C<sub>6</sub>HD<sub>5</sub>,  $\delta$  = 7.16 ppm; CHD<sub>2</sub>CN,  $\delta$  = 1.96 ppm; C<sub>5</sub>HD<sub>4</sub>N,  $\delta$  = 8.74, 7.58, or 7.22 ppm;  $^{13}\text{C}\{^1\text{H}\}$ –CDCl<sub>3</sub>,  $\delta$  = 77.2 ppm; C<sub>6</sub>D<sub>6</sub>,  $\delta$  = 128.4 ppm; CD<sub>3</sub>CN,  $\delta$  = 1.3 or 118.3 ppm; C<sub>5</sub>D<sub>5</sub>N,  $\delta$  = 150.2, 135.9, or 123.9 ppm). Fluorine-19 NMR spectra were referenced relative to CFCl<sub>3</sub> ( $\delta$  = 0.00 ppm) using neat Ph–CF<sub>3</sub> ( $\delta$  = –63.7 ppm) as an external standard. Silicon-29 NMR chemical shifts were determined by gradient heteronuclear multiple bond coherence (gHMBC) experiments. FT-IR spectra were collected on samples as thin films on KBr plates or as a KBr disk using a Bruker Tensor 27 spectrometer, with a resolution of 4 cm<sup>–1</sup>. Decomposition and (or) melting points were recorded in flame-sealed capillary tubes using a Gallenkamp variable heater. Suitable single crystals for X-ray diffraction studies were individually selected under Paratone-N oil and

mounted on nylon loops and immediately placed in a cold stream of N<sub>2</sub> (150 K). Data were collected on a Bruker Nonius Kappa CCD X-ray diffractometer using graphite-monochromated Mo K $\alpha$  radiation ( $\lambda = 0.71073$  Å). The solution and subsequent refinement of the data were performed using the SHELXTL suite of programs. Elemental analyses were performed by Columbia Analytical Services, Tucson, Arizona. Mass spectra were recorded using an electron ion-

ization Finnigan MAT 8200 mass spectrometer. Photolysis experiments were performed using an Ace Glass medium pressure 450 Watt mercury vapour lamp.

Elemental analysis was performed on compounds **7** and **8**, but the results obtained were not satisfactory. HRMS data is provided for samples that do not decompose in the mass spectrometer. Proton NMR data is provided in the supporting information as a proof of purity of the samples.

#### Synthesis of ligand (1a–1c)

A solution of LiCp (6.25 g, 87 mmol; 100 mL THF) was added to a solution of Me<sub>2</sub>SiCl<sub>2</sub> (10.5 mL, 87 mmol; 30 mL THF) at  $-40$  °C, at which time the solution turned yellow. The reaction mixture was allowed to slowly warm to  $0$  °C, then the cold bath was removed and the reaction mixture was stirred for a further 3–4 h at room temperature (RT). The flask was then cooled to  $-40$  °C and PhC<sub>2</sub>Li (9.39 g, 87 mmol; 40 mL THF) was added, generating an orange solution. The reaction mixture was stirred for 15 h. The volatiles were removed under vacuum, and the resulting mixture taken up in *n*-hexane or *n*-pentane, filtered to remove LiCl, and the volatiles removed in vacuo to yield a yellow-orange liquid. The liquid was then distilled under vacuum (0.1 Torr; 1 Torr = 133.3224 Pa) and the required fraction was obtained at  $100$  °C. Yield: 9.74 g, 50%. <sup>1</sup>H NMR (CDCl<sub>3</sub>,  $-20$  °C)  $\delta$ : major isomer **1a** (84%): 0.10 (s, 6H, Me), 3.59 (m, 1H, Cp), 6.59 (m, 2H, Cp), 6.67 (m, 2H, Cp), 7.32 (m, 3H, Ph), 7.49 (m, 2H, Ph); isomer **1b** (13%): 0.40 (s, 6H, Me), 3.16 (m, 2H, Cp), 6.74 (m, 2H, Cp), 7.01 (m, 1H, Cp); isomer **1c** (3%): 0.41 (s, 6H, Me), 3.09 (m, 2H, Cp), 6.63 (m, 2H, Cp), overlapped with other Cp from isomer **1b**), 6.89 (m, 1H, Cp). All phenyls are overlapped. <sup>13</sup>C{<sup>1</sup>H} NMR (CDCl<sub>3</sub>)  $\delta$ : major isomer **1a**:  $-2.9$  (Me), 51.1 (Cp, CHSiMe<sub>2</sub>), 92.5 (CC–SiMe<sub>2</sub>), 105.8 (CC–Ph), 122.9 (Ph), 128.3 (Ph), 132.1 (Ph), 133.1 (Ph), 138.8 (Cp), 143.6 (Cp); isomer **1b**:  $-0.5$  (Me), 45.3 (Cp, CH<sub>2</sub>), 92.9 (CC–SiMe<sub>2</sub>), 105.9 (CC–Ph), 123.2 (Ph), 128.6 (Ph), 128.8 (Ph), 131.2 (Ph), 135.1 (Cp), 144.1 (Cp), 144.6 (Cp). <sup>29</sup>Si NMR (CDCl<sub>3</sub>)  $\delta$ :  $-18.6$  ppm (major isomer **1a**),  $-28$  ppm (isomers **1b** and **1c**). ### Synthesis of KC<sub>5</sub>H<sub>4</sub>SiMe<sub>2</sub>C<sub>2</sub>Ph (**3**)

Potassium bis(trimethylsilyl)amide (0.089 g, 0.446 mmol; 5 mL Et<sub>2</sub>O) was added to **1** (0.1 g, 0.446 mmol; 20 mL *n*-hexane) at –30 °C. The reaction mixture was stirred for 3.5 h after which a white precipitate was filtered, washed twice with *n*-pentane (8 mL), and then dried in vacuo. Yield: 0.11 g, 93%. X-ray quality crystals were obtained by a slow diffusion of *n*-pentane into a THF solution of **3** at RT; dp 60 °C. <sup>1</sup>H NMR (C<sub>5</sub>ND<sub>5</sub>)  $\delta$ : 0.73 (s, 6H, Me), 6.67 (b, 2H, Cp), 6.82 (b, 2H, Cp), 7.21 (overlapped with Py-*d*<sub>5</sub>,

3H, Ph), 7.50 (d, 2H, Ph). <sup>13</sup>C{<sup>1</sup>H} NMR (C<sub>5</sub>ND<sub>5</sub>)  $\delta$ : 2.0 (Me), 110.3 (Cp), 114.5 (Cp), 128.7 (Ph), 129.0 (Ph), 132.5 (Ph) (quaternary carbons not observed owing to low solubility and stability of the compound in C<sub>5</sub>ND<sub>5</sub>). <sup>29</sup>Si NMR (C<sub>5</sub>ND<sub>5</sub>)  $\delta$ : –30.5 ppm. FT-IR (cm<sup>-1</sup>) (ranked intensity): 443 (7), 656 (13), 674 (5), 690 (8), 740 (1), 778 (4), 826 (2), 1038 (3), 1185 (6), 1246 (9), 1346 (15), 1438 (11), 1487 (12), 2147 (10), 3052 (14).

### Synthesis of (C<sub>5</sub>H<sub>4</sub>SiMe<sub>2</sub>C<sub>2</sub>Ph)<sub>2</sub>TiCl<sub>2</sub> (**4Cl<sub>2</sub>**)

A slurry of LiC<sub>5</sub>H<sub>4</sub>SiMe<sub>2</sub>C<sub>2</sub>Ph (0.91 g, 3.30 mmol; 50 mL *n*-hexane) was cooled to –35 °C and TiCl<sub>4</sub> (0.15 mL, 1.37 mmol; 2 mL *n*-hexane) was added to the slurry when the colour of the reaction mixture turned from white to yellow and finally to red. The cold bath was removed when the temperature reached –5 °C and the reaction mixture was allowed to warm up to room temperature over 4 h, at which time stirring was stopped and the solids settled, the reaction mixture was filtered, and the filtrate was cooled to –30 °C, filtered a second time, concentrated, and then left in a –30 °C freezer overnight. Red crystals were formed that were collected and dried. Yield: 0.54 g, 70%; mp 107 °C. <sup>1</sup>H NMR (C<sub>6</sub>D<sub>6</sub>)  $\delta$ : 0.65 (s, 6H, Me), 6.20 (pt, 4H, Cp), 6.79 (pt, 4H, Cp), 6.90–6.92 (m, 6H, Ph), 7.45–7.47 (m, 4H, Ph). <sup>13</sup>C{<sup>1</sup>H} NMR (C<sub>6</sub>D<sub>6</sub>)  $\delta$ : 0.7 (Me), 93.5 (SiCC), 108.0 (CCPh), 120.3 (Cp), 123.7 (Ph), 127.2 (Cp<sub>ipso</sub>), 128.9 (Ph), 129.3 (Ph), 131.3 (Cp), 132.6 (Ph). <sup>29</sup>Si NMR (C<sub>6</sub>D<sub>6</sub>)  $\delta$ : –25 ppm. FT-IR (cm<sup>-1</sup>) (ranked intensity): 537 (9), 690 (5), 756 (3), 805 (2), 847 (1), 898 (10), 1026 (12), 1043 (8),

1069 (11), 1220 (14), 1251 (7), 1442 (15), 1488 (6), 2158 (4), 2960 (13). ESI-MS ( $m/z$ ):  $M^+ - Cl$  (529). Elemental anal. calcd: C, 63.72; H, 5.35; Found: C, 64.10; H, 5.49.

### Synthesis of $(C_5H_4SiMe_2C_2Ph)_2TiMe_2$ (**4Me<sub>2</sub>**)

$(C_5H_4SiMe_2C_2Ph)_2TiCl_2$  (**4Cl<sub>2</sub>**) (0.20 g, 0.35 mmol; 40 mL  $Et_2O/n$ -hexane (1:1.5)) was treated with 3 stoichiometric equiv of  $MeMgCl$  (0.35 mL, 1.05 mmol; 3 mol/L solution in THF) at  $-15^\circ C$ . The reaction mixture was stirred for 4 h during which time it warmed to room temperature and the colour changed from red to yellow-orange. The  $LiCl$  was filtered off and the yellow-orange solution was concentrated to give orange oil. Yield: 0.15 g, 80%.  $^1H$  NMR ( $C_6D_6$ )  $\delta$ : 0.40 (s, 6H, Me), 0.42 (s, 12H, Me), 6.38 (pt, 4H, Cp), 6.47 (pt, 4H, Cp), 6.90–6.91 (m, 6H, Ph), 7.47–7.49 (m, 4H, Ph).  $^{13}C\{^1H\}$  NMR ( $C_6D_6$ )  $\delta$ : 0.9 (Me), 48.3 (Me), 93.3 (SiCC), 107.57 (CCPh), 116.8 ( $Cp_{ipso}$ ), 118.7 (Cp), 121.9 (Cp), 123.7 (Ph), 128.9 (Ph), 129.3 (Ph), 132.5 (Ph).  $^{29}Si$  NMR ( $C_6D_6$ )  $\delta$ :  $-25.8$  ppm. FT-IR ( $cm^{-1}$ ) (ranked intensity): 442 (13), 537 (11), 689 (4), 756 (3), 823 (1), 905 (10), 1027 (14), 1047 (7), 1070 (15), 1186 (9), 1251 (5), 1488 (8), 2159 (2), 2888 (12), 2958 (6). ESI-MS ( $m/z$ ):  $M^+ - Me$  (507). Elemental anal. calcd: C, 73.26; H 6.92. Found: C, 72.54; H, 6.23.

### Synthesis of $(C_5H_4SiMe_2C_2Ph)_2Fe$ (**5**)

A solution of  $LiC_5H_4SiMe_2C_2Ph$  (**2**) (0.36 g, 1.58 mmol; 3 mL THF) was added to a solution of anhydrous  $FeCl_2$  (0.1 g, 0.79 mmol; 5 mL THF) at room temperature. The reaction mixture was stirred for 4 h, during which time the colour turned dark yellow. The volatiles were then removed, the residue redissolved in  $n$ -pentane, and filtered to remove  $LiCl$ . The filtrate was then concentrated to give an orange solid. Yield: 0.317 g, 80%; mp  $75^\circ C$ . The orange solid was then sublimed at  $140^\circ C$  onto a cold finger at  $-18^\circ C$ .  $^1H$  NMR ( $C_6D_6$ )  $\delta$ : 0.52 (s, 12H, Me), 4.35 (pt, 4H, Cp), 4.51 (pt, 4H, Cp), 6.91–6.95 (m, 6H, Ph), 7.49–7.53 (m, 4H, Ph).  $^{13}C\{^1H\}$  NMR ( $C_6D_6$ )  $\delta$ : 0.6 (Me), 69.4 (Cp), 73.1 (Cp), 74.5 (Cp), 94.2 (SiCC), 106.8 (CCPh), 124.1 (Ph), 128.9 (Ph), 129.1 (Ph), 132.6 (Ph).  $^{29}Si$  NMR ( $C_6D_6$ )  $\delta$ :  $-21.5$  ppm. FT-IR ( $cm^{-1}$ ) (ranked intensity): 690 (7), 776 (2), 802 (4), 846 (1), 897 (14), 1036 (8), 1166 (3), 1220 (11), 1249 (6), 1383 (15), 1421 (13), 1442 (12), 1488 (9), 2158 (5), 2960 (10). ESI-MS ( $m/z$ ):  $M^+$  (502.2, 100%).  $\lambda_{max} = 312$  and  $348$  nm.

### Synthesis of $(C_5H_4SiMe_2C_2Ph)_2Co$ (**6**)

$LiC_5H_4SiMe_2C_2Ph$  (**2**) (0.17 g, 0.77 mmol) was added to a solution of anhydrous  $CoCl_2$  (0.05 g, 0.38 mmol; 5 mL  $Et_2O$ ), followed by the addition of 1 mL THF at room temperature. The reaction mixture was stirred for 3–4 h, during which time the colour turned dark red. The reaction mixture was then filtered to remove the  $LiCl$  and the clear solution was pumped down to give a sticky solid mass, which was then washed twice with  $n$ -pentane and dried to yield a dark maroon solid. Yield: 0.175 g, 90%; mp  $80^\circ C$ . X-ray quality crystals were obtained from concentrated  $Et_2O$  solution at  $-30^\circ C$ .  $^1H$  NMR ( $C_6D_6$ )  $\delta$ : 3.62 (b, 12H, Me), 6.81 (t, 2H, Ph), 7.07 (t, 4H, Ph), 7.46 (d, 4H, Ph); Cp protons were not observed within the range of  $-2$  to  $14$  ppm. FT-IR ( $cm^{-1}$ ) (ranked intensity): 536 (13), 599 (14), 676 (8), 688 (7), 756 (2), 774 (4), 802 (1), 822 (3), 840 (5), 1034 (6),

1158 (11), 1250 (9), 1346 (15), 1486 (10), 2146 (12). ESI-MS ( $m/z$ ):  $M^+ - 268$  (237.1, 100%). Elemental anal. calcd: C, 71.26; H, 5.98. Found: C, 71.49; H, 5.99.  $\lambda_{max} = 335$  and  $429$  nm.

### Synthesis of **7**

$CpCo(CO)_2$  (0.04 g, 0.23 mmol) was added to a  $C_6D_6$  solution of **5** (0.118 g, 0.335 mmol) in an NMR tube. The solution was then photolyzed with broad wavelength UV light for 40–50 h. The reaction was monitored for completion by  $^1H$  NMR spectroscopy, after which the reaction mixture was filtered, the solvent was removed in vacuo to give an orange solid, which was washed with 0.5 mL  $n$ -pentane and dried again. Yield: 0.136 g, 65%; mp  $180^\circ C$ .  $^1H$  NMR ( $C_6D_6$ )  $\delta$ : 0.40 (s, 6H, Me), 0.60 (s, 6H, Me), 4.16 (b, 2H, Cp), 4.27 (b, 4H, Cp), 4.46 (b, 2H, Cp), 4.76 (s, 5H, Cp), 7.04–7.16 (m, 6H, Ph), 7.55 (d, 4H, Ph).  $^{13}C\{^1H\}$  NMR ( $C_6D_6$ )  $\delta$ : 2.4 (Me), 4.1 (Me), 66.4 (SiC(Cb)), 69.3 ( $Cp_{ipso}$ ), 71.9 (Cp), 72.6 (Cp), 74.5 (Cp), 75.2 (Cp), 82.8 (CpCo), 88.1 (CPh(Cb)), 126.9 (Ph), 128.5 (Ph), 129.7 (Ph), 138.4 (Ph).  $^{29}Si$  NMR ( $C_6D_6$ )  $\delta$ :  $-9.3$  ppm. FT-IR ( $cm^{-1}$ ) (ranked intensity): 666 (7), 696 (2), 765 (3), 813 (1), 898 (11), 1036 (6), 1110 (12), 1165 (5), 1245 (4), 1384 (8), 1439 (9), 1599 (10). EI-MS ( $m/z$ ):  $M^+$  (625.9, 100%). HRMS (EI) for  $C_{35}H_{35}Si_2FeCo$  (calcd: 626.09; found: 626.09). Elemental anal. calcd: C, 71.69; H, 6.02. Found: C, 66.20; H, 5.50.  $\lambda_{max} = 357$  and  $423$  nm.

### Synthesis of $[(C_5H_4SiMe_2C_2Ph)_2Co(III)][OTf]$ (**6**)[OTf]

Addition of a solution of **8** (0.20 g, 0.40 mmol; 1 mL of  $CH_3CN$  or  $C_6H_6$ ) to 1 equiv of  $AgOTf$  (0.11 g, 0.40 mmol) resulted in the instantaneous formation of **6**][OTf]. The yield was quantitative by  $^1H$  NMR spectroscopy, but the product could not be obtained as a solid. Removing the solvent always resulted in a sticky mass, which was 90% pure by  $^1H$  NMR spectrum. Yield: 0.233 g, 90%.  $^1H$  NMR ( $C_6D_6$ )  $\delta$ : 0.47 (s, 12H, Me), 5.73 (b, 4H, Cp), 5.93 (b, 4H, Cp), 7.05–7.09 (m, 6H, Ph), 7.61 (d, 4H, Ph).  $^1H$  NMR ( $CD_3CN$ )  $\delta$ : 0.56 (s, 12H, Me), 5.81 (pt, 4H, Cp), 5.92 (pt, 4H, Cp), 7.42–7.45 (m, 6H, Ph), 7.58 (d, 4H, Ph).  $^{13}C\{^1H\}$  NMR ( $CD_3CN$ )  $\delta$ :  $-0.5$  (Me), 89.2 (Cp), 90.6 (Cp), 91.0 (Cp), 92.7 (SiCC), 109.3 (CCPh), 122.9 (Ph), 130.0 (Ph), 130.9 (Ph), 133.2 (Ph).  $^{19}F$  NMR ( $CD_3CN$ )  $\delta$ :  $-78.9$  ppm.  $^{29}Si$  NMR ( $C_6D_6$ )  $\delta$ :  $-22.5$  ppm. FT-IR ( $cm^{-1}$ ) (ranked intensity): 691 (9), 737 (14), 759 (7), 805 (6), 825 (8), 851 (2), 1043 (3), 1117 (12), 1164 (4), 1230 (10), 1255 (1), 1385 (15), 1489 (11), 2159 (5), 2973 (13). ESI-MS ( $m/z$ ):  $M^+ - OTf$  (505.1, 100%),  $M^+ + [M - OTf]^+$  (1159.3).

### Synthesis of **8**

$CpCo(CO)_2$  (0.03 g, 0.18 mmol) was added to a  $C_6D_6$  solution of **6** (0.09 g, 0.18 mmol) in an NMR tube. The solution was then photolyzed with broad wavelength UV light for 40–50 h. The reaction was monitored for completion by  $^1H$  NMR spectroscopy, after which the solution was filtered, the solvent was removed in vacuo to give a brown solid, which was washed with 0.5 mL of  $n$ -pentane four times and dried again. Yield: 0.086 g, 75%.  $^1H$  NMR ( $C_6D_6$ )  $\delta$ : 3.77 (b, 12H, Me), 4.91 (b, 5H, Cp), 7.05 (b, 2H, Ph), 7.11 (b, 4H, Ph), 7.69 (b, 4H, Ph); other Cp protons were not observed within the range of  $-2$  to  $14$  ppm. FT-IR ( $cm^{-1}$ )

(ranked intensity): 664 (13), 696 (4), 770 (2), 805 (1), 1008 (8), 1035 (7), 1156 (9), 1247 (3), 1441 (11), 1488 (14), 1070 (15), 1597 (10), 1955 (6), 2017 (5), 2955 (12). HRMS (EI) for  $C_{35}H_{35}Si_2Co_2$  calcd: 629.094; found: 629.096.

### Synthesis of [8][OTf]

Method I: Addition of a solution of **8** (0.40 g, 0.64 mmol; 2 mL of  $CH_3CN$  or  $C_6H_6$ ) to 1 equiv of AgOTf (0.16 g, 0.64 mmol) resulted in the instantaneous formation of [8][OTf]. The reaction mixture was then filtered to remove Ag, washed with *n*-pentane and  $Et_2O$ , and the solvent was removed in vacuo to give an orange solid. Yield: 0.32 g, 65%. Method II:  $CpCo(CO)_2$  (0.03 g, 0.18 mmol) was added to a  $C_6D_6$  or  $CD_3CN$  solution of [6][OTf] (0.12 g, 0.18 mmol) in an NMR tube. The solution was then photolyzed with broad wavelength UV light for 20–25 h. The reaction was monitored for completion by  $^1H$  NMR spectroscopy, after which the solution was filtered, the solvent was removed in vacuo to give an orange solid, which was washed with 0.5 mL *n*-pentane and 0.5 mL  $Et_2O$  and dried again. Yield: 0.09 g, 65%; mp 200 °C. X-ray quality crystals were obtained by the slow diffusion of *n*-pentane into a DCM solution of the compound at RT.  $^1H$  NMR ( $C_6D_6$ )  $\delta$ : 0.08 (s, 6H, Me), 0.41 (s, 6H, Me), 4.61 (s, 5H, Cp), 4.96 (b, 2H, Cp), 5.78 (b, 2H, Cp), 6.09 (b, 2H, Cp), 6.48 (b, 2H, Cp), 7.03–7.06 (m, 6H, Ph), 7.32–7.35 (m, 4H, Ph).  $^{13}C\{^1H\}$  NMR ( $C_6D_6$ )  $\delta$ : 1.0 (Me), 2.7 (Me), 61.3 (Cb), 82.7 (Cp), 88.8 (Cb), 89.5 (Cp), 89.7 (Cp), 90.0 (Cp), 90.4 (Cp), 91.2 (Cp), 127.5 (Ph), 128.9 (Ph), 129.5 (Ph), 137.0 (Ph); triflate was not observed.  $^{19}F$  NMR ( $C_6D_6$ )  $\delta$ : –78.9 ppm.  $^{29}Si$  NMR ( $C_6D_6$ )  $\delta$ : –9.8 ppm. FT-IR ( $cm^{-1}$ ) (ranked intensity): 444 (10), 516 (13), 636 (3), 671 (11), 700 (7), 775 (6), 820 (4), 894 (15), 1009 (9), 1030 (2), 1136 (5), 1223 (8), 1266 (1), 1386 (14), 1441 (12). ESI-MS ( $m/z$ ):  $M^+ - OTf$  (629, 100%),  $M^+ + 629$  (1407.2),  $[(RC_3H_4)_2Co]^+$  (505, 25%). HRMS (EI) for  $C_{35}H_{35}Si_2Co_2$  calcd: 629.094; found: 629.091.  $\lambda_{max}$  = 316 and 427 nm.

### Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca). CCDC 768012–768015 contain the X-ray data in CIF format for this manuscript. These data can be obtained, free of charge, via [www.ccdc.cam.ac.uk/conts/retrieving.html](http://www.ccdc.cam.ac.uk/conts/retrieving.html) (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or [deposit@ccdc.cam.ac.uk](mailto:deposit@ccdc.cam.ac.uk)). Proton NMR spectra for the samples have been provided.

### Acknowledgements

We would like to thank Dr. W.E. Piers for valuable discussions at the beginning of this project. We also thank the Natural Sciences and Engineering Research Council of Canada (NSERC), the Canada Foundation for Innovation (CFI), the Ontario Ministry of Research and Innovation Early Researcher Award (OMRI-ERA), and The University of Western Ontario for generous financial support.

# Towards the development of new subtype-specific muscarinic receptor radiopharmaceuticals — Radiosynthesis and ex vivo biodistribution of [<sup>18</sup>F]3-(4-(2-(2-(2-fluoroethoxy)ethoxy)ethylthio)-1,2,5-thiadiazol-3-yl)-1-methyl-1,2,5,6-tetrahydropyridine

Erik M. van Oosten, Alan A. Wilson, David C. Mamo, Bruce G. Pollock, Benoit H. Mulsant, Sylvain Houle, and Neil Vasdev

**Abstract:** Muscarinic receptors have been implicated in neurological disorders including Alzheimer's disease, Parkinson's disease, and schizophrenia. Nineteen derivatives of thiadiazolyltetrahydropyridine (TZTP), a core that has previously shown high affinities towards muscarinic receptor subtypes, were synthesized and evaluated via in vitro binding assays. The title compound, a fluoro-polyethyleneglycol analog of TZTP (**4c**), was subsequently labelled with fluorine-18. Fluorine-18-labelled **4c** was produced, via an automated synthesis, in an average radiochemical yield of 36% (uncorrected for decay), with high radiochemical purity (>99%) and high specific activity (326 GBq/μmol; end-of-bombardment), within 40 min (*n* = 3). Ex vivo biodistribution studies following tail-vein injection of [<sup>18</sup>F]**4c** in conscious rats displayed sufficient brain uptake (0.4%–0.7% injected dose / gram of wet tissue in all brain regions at 5 min post injection); however, there were substantial polar metabolites present in the brain, thereby precluding future use of [<sup>18</sup>F]**4c** for imaging in the central nervous system.

**Key words:** fluorine-18, muscarinic receptor, thiadiazolyltetrahydropyridine (TZTP), positron emission tomography (PET).

**Résumé :** Les récepteurs muscariniques ont été impliqués dans des désordres neurologiques, dont la maladie d'Alzheimer, la maladie de Parkinson et la schizophrénie. On a réalisé la synthèse de dix-neuf dérivés de la thiadiazolyltétrahydropyridine (TZTP), un produit fondamental pour lequel des études antérieures ont permis de montrer de grandes affinités vis-à-vis des sous-types de récepteurs muscariniques, et on a évalué leurs propriétés par des essais de fixation in vitro. On a subéquemment marqué au fluor-18 le composé mentionné dans le titre (**4c**), un analogue fluoropolyéthylèneglycol de la TZTP. Le composé **4c** marqué au fluor-18 a été obtenu, par le biais d'une synthèse automatisée, avec un rendement radiochimique de 36 % (non corrigé pour la décroissance), avec une pureté radiochimique élevée (>99 %) et une activité spécifique élevée (326 GBq/μmol; fin du bombardement), en moins de 40 minutes (*n* = 3). Des études de biodistribution ex vivo à la suite d'injections dans la veine de la queue du [<sup>18</sup>F]**4c** dans des rats conscients ont démontré qu'il y se produit une absorption suffisante par le cerveau (0,4 à 0,7 % de la dose injectée / gramme de tissu mouillé dans toutes les régions du cerveau cinq minutes après l'injection) ; toutefois, plusieurs métabolites polaires sont présents dans le cerveau et cette situation élimine l'usage dans le futur du [<sup>18</sup>F]**4c** pour faire de l'imagerie du système nerveux central.

**Mots-clés :** fluor-18, récepteur muscarinique, thiadiazolyltétrahydropyridine (TZTP), tomographie à émission de positon (TEP).

## Introduction

Muscarinic acetylcholine receptors (mAChRs) are present in both the peripheral and central nervous system (CNS) and are responsible for mediating the metabotropic effects of acetylcholine.<sup>1</sup> There are 5 distinct subtypes of the muscarinic acetylcholine receptor, M<sub>1</sub>, M<sub>2</sub>, M<sub>3</sub>, M<sub>4</sub>, and M<sub>5</sub>, each having distinct functions and unique distributions in the CNS.<sup>2</sup> The M<sub>1</sub> and M<sub>2</sub> receptors are abundant in the CNS and have postulated roles in Alzheimer's disease and schizophrenia, as well as a range of cognitive disorders.<sup>3,4</sup> The M<sub>3</sub> and M<sub>5</sub> receptors are present in relatively lower concentrations in the CNS.<sup>3</sup> M<sub>3</sub> receptors have no known correlations with neuropsychiatric disorders, whereas M<sub>5</sub> receptors have been linked to schizophrenia and addictions.<sup>3,4</sup> The M<sub>4</sub> receptor is present in the CNS, particularly in the cortex, striatum, and hippocampus,<sup>2,3</sup> and is associated with Parkinson's disease and schizophrenia.<sup>1,4</sup> The synthesis of subtype-selective drugs that target mAChRs is an ongoing goal in drug development. To date, the only clinically approved drugs that target mAChRs are nonselective antagonists that are used for treating patients suffering from Parkinson's disease.

Applying imaging modalities such as single photon emission computed tomography (SPECT) and positron emission tomography (PET)<sup>5,6</sup> to elucidate the mechanism of action of new pharmaceuticals targeting muscarinic receptors *in vivo* has been of long-standing interest.<sup>7</sup> Derivatization of the thiadiazolyltetrahydropyridine (TZTP) core<sup>8</sup> has led to the development of muscarinic subtype-selective PET radiotracers.<sup>9–12</sup> The M<sub>2</sub>-specific agonist radiotracer, fluorine-18 (<sup>18</sup>F; *t*<sub>1/2</sub> = 109.7 min) labelled fluoropropylthio-TZTP ([<sup>18</sup>F]FP-TZTP),<sup>11,13,14</sup> was proven to be selective through knockout mice studies<sup>15,16</sup> and is currently the only M<sub>2</sub>-specific radiotracer established for human PET imaging.<sup>17,18</sup> Fluorine-18-labelled FP-TZTP has been used to study risk factors of ageing<sup>19–21</sup> and mood disorders.<sup>22,23</sup>

Driven largely by the theory that M<sub>1</sub> receptor density is altered in the brain of patients with Alzheimer's disease in response to the degeneration of the cholinergic pathway, another TZTP derivative, 3-(4-(hexyloxy)-1,2,5-thiadiazol-3-yl)-1-methyl-1,2,5,6-tetrahydropyridine (xanomeline), was found to exhibit M<sub>1</sub>/M<sub>4</sub> selectivity.<sup>24</sup> While it was found that xanomeline increased cognitive function of patients with Alzheimer's disease, several side effects precluded its therapeutic use. Carbon-11 (<sup>11</sup>C; *t*<sub>1/2</sub> = 20.4 min) labelled xanomeline was evaluated in human subjects<sup>9,25</sup> and a <sup>18</sup>F-labelled xanomeline derivative was evaluated in rodents<sup>25</sup> but neither radiopharmaceutical was further pursued because of inadequate receptor selectivity.

The present study sought to systematically prepare new muscarinic receptor subtype-specific TZTP analogs for development as PET radiopharmaceuticals. We report the synthesis of hydroxy- and fluoro-alkyl as well as hydroxy- and fluoro-polyethyleneglycol (PEG) ether and thioether analogs of TZTP, and the determination of their *in vitro* binding affinities (*K*<sub>i</sub>) towards the five muscarinic subtypes, as well as  $\sigma_1$  and  $\sigma_2$  receptors. All analogs synthesized in this work are amenable to labelling with either <sup>18</sup>F or <sup>11</sup>C. A promising fluoro-PEG derivative of TZTP (**4c**), identified from initial *in vitro* screening, was radiolabelled with <sup>18</sup>F and evaluated

for its potential to image muscarinic receptors in the rodent brain.

## Results and discussion

### Chemistry

The syntheses of 19 derivatives of TZTP (Table 1) are reported, including previously known compounds (**2a**,<sup>13</sup> **4a**,<sup>11,12</sup> **8a**,<sup>26</sup> **8b**,<sup>26</sup> **9c**,<sup>25</sup> and **10**<sup>8</sup>). Syntheses of the TZTP analogs were carried out by literature procedures with modifications. Thioether-PEG analogs of TZTP, with both fluoro (**4**) and hydroxyl (**2**) groups at the terminal position, were synthesized as shown in Scheme 1. To conserve the TZTP core (3-(4-chloro-1,2,5-thiadiazol-3-yl)-1-methyl-1,2,5,6-tetrahydropyridine; **1**),<sup>8</sup> fluoroalkyl and fluoro-PEG chains were synthesized from the respective diols (**5**, Scheme 2) for subsequent reactions with **1**. The diols were disubstituted with benzyl-protecting and tosyloxy-leaving groups (**6**). Nucleophilic displacement of the tosyloxy group of **6** with fluoride resulted in *O*-benzyl protected fluoroalkyl and fluoro-PEG chains (**7**). The hydroxyl analogs (**8**) were synthesized by reaction of the appropriate diol (**5**) with **1** (Scheme 3). Scheme 3 shows the synthesis of the desired fluoro-alkyl and fluoro-PEG ether-TZTP analogs (**9**), prepared by catalytic hydrogenation of **7** and *in situ* reaction with **1** in the presence of sodium hydride (NaH). Several TZTP derivatives with incorporated PEG groups have been synthesized in attempts to achieve subtype selectivity and improve water solubility, binding affinity, and agonist potency toward mAChRs.<sup>27,28</sup> The present work further explores the use of PEG groups as a means of expanding the series of TZTP derivatives, by replacing alkyl groups with PEG chains; [<sup>18</sup>F]fluoro-PEG groups have demonstrated similar pharmacological advantages when incorporated into PET radiopharmaceuticals.<sup>29</sup> In preparation for *in vitro* binding assay studies, all 19 TZTP analogs synthesized in the present work (Table 1) were characterized by <sup>1</sup>H and <sup>19</sup>F (when applicable) NMR spectroscopy, high resolution mass spectrometry, and elemental analysis (all compounds were >97% pure by elemental analysis).

### *In vitro* binding assays

The thioether-TZTP derivatives (compounds **2** and **4**) as well as the ether derivatives (compounds **8–10**) were evaluated by the National Institute of Mental Health's Psychoactive Drug Screening Program to determine their binding affinities towards each of the five muscarinic subtypes, as well as towards  $\sigma_1$  and  $\sigma_2$  receptors; the  $\sigma$  receptors are known competition sites for ligands targeting mAChRs.<sup>30</sup> In the initial assay, all six thioether-TZTP derivatives (**2a–2c** and **4a–4c**) were measured for affinity towards the aforementioned receptors (Table S1 in the Supplementary data; values in parentheses), and a fluoro-PEG derivative of TZTP with moderate affinity towards the M<sub>4</sub> receptor (**4c**; *K*<sub>i</sub> = 48 nM) was identified. Based on our initial binding assay, we advanced to radiolabelling this compound with fluorine-18, as it represents the first attempt to develop a PET radiotracer for imaging the M<sub>4</sub> receptor and is a novel fluorinated-PEG derivative of TZTP. As such, our goal was

to radiolabel the title compound, **4c**, with <sup>18</sup>F and evaluate its potential for imaging the CNS via a preliminary ex vivo biodistribution study.

### Radiochemistry

The radiosynthetic approach for [<sup>18</sup>F]**4c** was similar to our previously reported synthesis for [<sup>18</sup>F]FP-TZTP,<sup>14</sup> where the appropriate tosyloxy-containing radiolabelling precursor (**3c**) was subjected to reaction with fluorine-18-labelled potassium cryptand fluoride (K[<sup>18</sup>F]/K<sub>222</sub>) in CH<sub>3</sub>CN at 90 °C for 10 min (Scheme 4) followed by HPLC purification (Fig. 1). The formulated product was >99% radiochemically pure (Fig. 2) and the log *D* was experimentally determined to be 1.73 ± 0.01 (pH = 7.4), using a previously reported method.<sup>31</sup> The automated synthesis of [<sup>18</sup>F]**4c** resulted in a radiochemical yield of 35.6% ± 15.3% based on [<sup>18</sup>F]fluoride and uncorrected for decay in a synthesis time of 37 min (*n* = 3). The specific activity of [<sup>18</sup>F]**4c** was 326 ± 198 GBq/μmol (corrected to end-of-bombardment). Fluorine-18-labelled **4c** is the first reported <sup>18</sup>F-labelled PEG derivative of TZTP. While the hydroxyl derivatives of TZTP (series **2** and **8**) are not amenable to labelling with <sup>18</sup>F, similar compounds have been readily labelled by reaction of the respective desmethyl precursors with [<sup>11</sup>C]CH<sub>3</sub>I.<sup>9,12</sup>

### Ex vivo biodistribution in rodents

Preliminary ex vivo biodistribution studies using [<sup>18</sup>F]**4c** were subsequently carried out in conscious male Sprague–Dawley rats.<sup>32,33</sup> Fluorine-18-labelled **4c** demonstrated fast and efficient uptake in the rodent brain (0.4%–0.7% injected dose / gram of wet tissue in all brain regions at 5 min post injection) following tail-vein injection (Fig. S1 in the Supplementary data). This uptake was followed by a fast wash-out, with most of the radioactivity cleared from the brain by 15 min. Radio-HPLC analysis of plasma identified a rapid degradation of the parent compound to both hydrophilic and lipophilic metabolites. At 15 min after injection of [<sup>18</sup>F]**4c** only 4.5% of the parent compound was unmetabolized. Analysis of brain homogenates 60 min after injection (Fig. 3) found that while the parent compound was present in the brain, there was a significant accumulation of radioactive polar metabolites (24%). Owing to the presence of radioactive metabolites in the brain, further studies were not justified because [<sup>18</sup>F]**4c** does not present suitable properties for imaging the CNS.

### Conclusion

We report the synthesis of 13 new TZTP derivatives that are amenable for radiolabelling with <sup>11</sup>C and (or) <sup>18</sup>F. Com-

**Scheme 1.** General syntheses of thioether-TZTP derivatives and radiolabelling precursors. (i) 1, Li<sub>2</sub>S, DMF; 2, bromo- or chloro-alcohol, K<sub>2</sub>CO<sub>3</sub>, DMF. (ii) TsCl, Et<sub>3</sub>N, DMAP, CH<sub>2</sub>Cl<sub>2</sub>. (iii) TBAF, THF.

**Scheme 3.** General syntheses of ether-TZTP derivatives. (i) 5a–5f, NaH, THF. (ii) 1, Pd/C, Pd(OH)<sub>2</sub>, H<sub>2</sub>(g), THF; 2, NaH, 1, THF.

pound **4c** was chosen as a lead compound for radiolabelling based on in vitro binding assays and represents the first fluoro-PEG derivative of TZTP. Automated radiosynthesis of [<sup>18</sup>F]**4c** was achieved with good radiochemical yields, high specific activity, and excellent radiochemical purity within

40 min. Ex vivo biodistribution studies in rodent models showed appreciable amounts of polar radioactive metabolites in the brain, suggesting that [<sup>18</sup>F]**4c** is not suitable for further development as a radiopharmaceutical for imaging the CNS.

**Scheme 4.** Radiosynthesis of [ $^{18}\text{F}$ ]**4c**. ## Experimental section

### General methods

3-Chloro-(pyridine-3-yl)-1,2,5-thiadiazole was purchased from commercial suppliers and was used as received without further purification unless otherwise specified. Compound **1**, 3-(3-chloro-1,2,5-thiadiazol-4-yl)-1,2,5,6-tetrahydro-1-methylpyridine,<sup>8</sup> and compound **3a**, 3-(4-(1-methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazol-3-ylthio)propyl-4-methylbenzenesulfonate,<sup>14</sup> were prepared by literature procedures. All water used was distilled and deionized and all mobile phases were made with HPLC-grade solvents. Flash column

**Fig. 3.** HPLC analysis (see the Metabolism studies section for HPLC conditions) of rat brain homogenates at 60 min post injection of [ $^{18}\text{F}$ ]**4c**.

chromatography purification was accomplished using silica gel 60 (63–200  $\mu\text{m}$ , Caledon). Preparative thin-layer chromatography (PTLC) was accomplished using silica gel GF plates (20 cm  $\times$  20 cm, 2000  $\mu\text{m}$ ) from Analtech. All new compounds were obtained as oils following purification.

High resolution mass spectrometry (HR-MS) was conducted by the Advanced Instrumentation for Molecular Structure Laboratory or by the Centre for Biological Timing and Cognition at the University of Toronto. Elemental analysis (EA) was performed by the Analytical Laboratory for Environmental Science Research and Training, University of Toronto. Proton and carbon-13 NMR spectra were recorded at 25  $^\circ\text{C}$  in  $\text{CDCl}_3$  on a Varian Mercury 300 MHz or 400 MHz spectrometer with an autoswitchable H/F/C/P 5 mm probe with gradients. Proton NMR chemical shifts were reported using either tetramethylsilane (TMS, 0.00 ppm) as an internal standard or referencing to the residual proton in  $\text{CDCl}_3$  (7.26 ppm). The proton resonances of primary alcohols were often not observed owing to exchange. For  $^{13}\text{C}$  NMR, shifts were referenced to  $\text{CDCl}_3$  (77.0 ppm). Fluorine-19 NMR shifts were referenced to external  $\text{CFCl}_3$  (0.00 ppm). Tetrabutylammonium fluoride (TBAF) was prepared by evaporation of tetrahydrofuran (THF) from a 1.0 M solution under reduced pressure, and then drying under reduced pressure overnight, as modified from a previously reported literature procedure.<sup>34</sup> THF was freshly distilled over lithium aluminum hydride ( $\text{LiAlH}_4$ ).

All animal experiments were carried out under humane conditions, with approval from the Animal Care Committee at the Centre for Addiction and Mental Health and in accordance with the guidelines set forth by the Canadian Council on Animal Care.

## Chemical synthesis

### 3-(4-(1-Methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazol-3-ylthio)propan-1-ol (**2a**)

Compound **2a** was prepared by minor modifications to a literature procedure.<sup>13</sup> Briefly, 250 mg of **1** (1.16 mmol) was dissolved in 3 mL of anhydrous DMF in an oven-dried round-bottomed flask under nitrogen. Li<sub>2</sub>S (2.9 mmol) was added to the mixture with stirring at 60 °C in an oil bath for 5 h. Upon consumption of the starting material, the reaction was cooled to room temperature (RT) and 3-bromopropanol (2.9 mmol) was added, followed by addition of K<sub>2</sub>CO<sub>3</sub> (2.9 mmol). The reaction mixture was stirred at RT for 35 min. Upon completion, the reaction was diluted with ether (50 mL), washed with H<sub>2</sub>O (3 × 50 mL) and brine (50 mL), dried over NaSO<sub>4</sub>, and concentrated. PTLC purification was performed (20:80 EtOAc:Hex) to yield 217 mg of **2a** (69%). <sup>1</sup>H NMR (CDCl<sub>3</sub>, 300 MHz) δ: 6.77–6.71 (m, 1H), 3.71 (t, <sup>3</sup>J<sub>HH</sub> = 5.9 Hz, 2H), 3.45–3.42 (m, 2H), 3.37 (t, <sup>3</sup>J<sub>HH</sub> = 6.9 Hz, 2H), 3.22 (br, 1H), 2.63–2.57 (m, 2H), 2.51–2.43 (m, 2H), 2.47 (s, 3H), 2.04–1.91 (m, 2H). HR-MS calcd. for C<sub>11</sub>H<sub>18</sub>N<sub>3</sub>OS<sub>2</sub> [M + 1]: 272.0897; found: 272.0885. EA calcd.: C 48.68, H 6.33, N 15.49; found: C 48.39, H 6.46, N 14.90.

### 2-(2-(4-(1-Methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazol-3-ylthio)ethoxy)ethanol (**2b**)

The general procedure for the synthesis of **2a** was followed using **1** (1.16 mmol) in DMF with 2.5 equiv. of Li<sub>2</sub>S, 2.5 equiv. of 2-(2-chloroethoxy)ethanol, and 2.5 equiv. of K<sub>2</sub>CO<sub>3</sub> to give 304 mg of **2b** (87%) after PTLC purification. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 300 MHz) δ: 6.77–6.72 (m, 1H), 3.84 (t, <sup>3</sup>J<sub>HH</sub> = 6.3 Hz, 2H), 3.76–3.72 (m, 2H), 3.64–3.59 (m, 2H), 3.51 (t, <sup>3</sup>J<sub>HH</sub> = 6.3 Hz, 2H), 3.45–3.42 (m, 2H), 2.63–2.57 (m, 2H), 2.52–2.44 (m, 2H), 2.46 (s, 3H). HR-MS calcd. for C<sub>12</sub>H<sub>20</sub>N<sub>3</sub>O<sub>2</sub>S<sub>2</sub> [M + 1]: 302.0991; found: 302.0990. EA calcd.: C 47.81, H 6.37, N 13.94; found: C 47.92, H 6.32, N 13.60.

### 2-(2-(2-(4-(1-Methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazol-3-ylthio)ethoxy)ethoxy)ethanol (**2c**)

The general procedure for the synthesis of **2a** was followed using **1** (1.16 mmol) in DMF with 2.5 equiv. of Li<sub>2</sub>S, 2.5 equiv. of 2-(2-(2-chloroethoxy)ethoxy)ethanol, and 2.5 equiv. of K<sub>2</sub>CO<sub>3</sub>. After PTLC purification, **2c** was obtained in a 95% yield (542 mg). <sup>1</sup>H NMR (CDCl<sub>3</sub>, 300 MHz) δ: 6.77–6.71 (m, 1H), 3.83 (m, 2H), 3.75–3.71 (m, 2H), 3.69–3.66 (m, 4H), 3.63–3.59 (m, 2H), 3.51 (t, <sup>3</sup>J<sub>HH</sub> = 6.5 Hz, 2H), 3.45–3.42 (m, 2H), 2.63–2.59 (m, 2H), 2.52–2.45 (m, 2H), 2.46 (s, 3H). HR-MS calcd. for C<sub>14</sub>H<sub>24</sub>N<sub>3</sub>O<sub>3</sub>S<sub>2</sub> [M + 1]: 346.1253; found: 346.1266. EA calcd.: C 48.67, H 6.72, N 12.17; found: C 47.64, H 6.88, N 11.83.

### 2-(2-(4-(1-Methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazol-3-ylthio)ethoxy)ethyl 4-methylbenzenesulfonate (**3b**)

Compound **3b** was made by an analogous procedure to that of compound **3a**.<sup>14</sup> Briefly, 267 mg (0.89 mmol) of **2b** was dissolved in 8 mL of CH<sub>2</sub>Cl<sub>2</sub> followed by the addition of 1.5 equiv. of *p*-toluenesulfonyl chloride (TsCl), 3 equiv. of triethylamine (TEA), and a catalytic amount of dimethyl-

laminopyridine (DMAP; 1 mol%). Compound **3b** was obtained in an 86% yield (348 mg). <sup>1</sup>H NMR (CDCl<sub>3</sub>, 300 MHz) δ: 7.82–7.76 (m, 2H), 7.35–7.29 (m, 2H), 6.75–6.70 (m, 1H), 4.19–4.14 (m, 2H), 3.74 (t, <sup>3</sup>J<sub>HH</sub> = 6.3 Hz, 2H), 3.71–3.66 (m, 2H), 3.44–3.36 (m, 4H), 2.62–2.56 (m, 2H), 2.51–2.42 (m, 8H).

### 2-(2-(2-(4-(1-Methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazol-3-ylthio)ethoxy)ethoxy)ethyl 4-methylbenzenesulfonate (**3c**)

Compound **3c** was made by an analogous procedure to that of compound **3a**.<sup>14</sup> Briefly, 350 mg (1.01 mmol) of **2c** was dissolved in 8 mL of CH<sub>2</sub>Cl<sub>2</sub> followed by the addition of 1.5 equiv. of TsCl, 3 equiv. of TEA, and catalytic DMAP (1 mol%). Compound **3c** was obtained in a 72% yield (352 mg). <sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz) δ: 7.82–7.78 (m, 2H), 7.65–7.31 (m, 2H), 6.77–6.73 (m, 1H), 4.18–4.15 (m, 2H), 3.79 (t, <sup>2</sup>J<sub>HF</sub> = 6.4 Hz, 2H), 3.71–3.68 (m, 2H), 3.61–3.59 (m, 4H), 3.48 (t, <sup>3</sup>J<sub>HH</sub> = 6.6 Hz, 2H), 3.44–3.42 (m, 2H), 2.62–2.58 (m, 2H), 2.49–2.43 (m, 8H).

### 3-(4-(3-Fluoropropylthio)-1,2,5-thiadiazol-3-yl)-1-methyl-1,2,5,6-tetrahydropyridine (**4a**)

Compound **4a** was prepared by modifications to the literature procedures.<sup>11,13</sup> To an oven-dried round-bottomed flask containing 4.9 mmol TBAF (dried under reduced pressure overnight) was added 10 mL of freshly distilled THF, followed by 0.33 mmol of **3a**. The reaction was refluxed for 3 h and then diluted with 50 mL H<sub>2</sub>O and washed with 50 mL of EtOAc (×2). The combined organic layer was washed with 50 mL of brine, dried over Na<sub>2</sub>SO<sub>4</sub>, and concentrated. The product was purified using PTLC (7:93 MeOH:CH<sub>2</sub>Cl<sub>2</sub>) to yield 37 mg of **4a** (36%). <sup>1</sup>H NMR (CDCl<sub>3</sub>, 300 MHz) δ: 6.70–6.65 (m, 1H), 4.52 (dt, <sup>2</sup>J<sub>HF</sub> = 47.1 Hz, <sup>3</sup>J<sub>HH</sub> = 5.6 Hz, 2H), 3.39–3.35 (m, 2H), 3.33 (t, <sup>3</sup>J<sub>HH</sub> = 7.22 Hz, 2H), 2.56–2.49 (m, 2H), 2.44–2.37 (m, 2H), 2.39 (s, 3H), 2.12 (dm, <sup>3</sup>J<sub>HF</sub> = 26.5 Hz, 2H). <sup>19</sup>F NMR (CDCl<sub>3</sub>, 282 MHz) δ: –221.51 (tt, <sup>2</sup>J<sub>HF</sub> = 47.2 Hz, <sup>3</sup>J<sub>HF</sub> = 26.5 Hz). HR-MS calcd. for C<sub>11</sub>H<sub>16</sub>FN<sub>3</sub>S<sub>2</sub> [M]: 273.0770; found: 273.0772. EA calcd.: C 48.32, H 5.91, N 15.37; found: C 48.23, H 6.03, N 15.12.

### 3-(2-(2-Fluoroethoxy)ethylthio)-4-(1-methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazole (**4b**)

Compound **4b** was prepared in an analogous manner to that of **4a**. Briefly, 0.3 mmol of **3b** in THF was reacted with 5 equiv. of TBAF. **4b** was obtained in a 33% yield (36 mg). <sup>1</sup>H NMR (CDCl<sub>3</sub>, 300 MHz) δ: 6.79–6.75 (m, 1H), 4.57 (dm, <sup>2</sup>J<sub>HF</sub> = 47.6 Hz, 2H), 3.86 (t, <sup>3</sup>J<sub>HH</sub> = 6.43 Hz, 2H), 3.76 (dm, <sup>3</sup>J<sub>HF</sub> = 29.5 Hz, 2H), 3.52 (t, <sup>3</sup>J<sub>HH</sub> = 6.6 Hz, 2H), 3.49–3.45 (m, 2H), 2.66–2.61 (m, 2H), 2.53–2.47 (m, 2H), 2.48 (s, 3H). <sup>19</sup>F NMR (CDCl<sub>3</sub>, 282 MHz) δ: –223.36 (tt, <sup>2</sup>J<sub>HF</sub> = 47.6 Hz, <sup>3</sup>J<sub>HF</sub> = 29.5 Hz). HR-MS calcd. for C<sub>12</sub>H<sub>19</sub>FN<sub>3</sub>OS<sub>2</sub> [M + 1]: 304.0948; found: 304.0950. EA calcd.: C 47.50, H 5.99, N 13.85; found: C 47.67, H 6.11, N 13.35.

### 3-(2-(2-(2-Fluoroethoxy)ethoxy)ethylthio)-4-(1-methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazole (**4c**)

Compound **4c** was prepared in an analogous manner to that of **4a**. Briefly, 150 mg (0.3 mmol) of **3c** was used in THF (0.1 M) with 5 equiv. of TBAF. **4c** was obtained in a

29% yield (31 mg).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 300 MHz)  $\delta$ : 6.80–6.75 (m, 1H), 4.56 (dm,  $^2J_{\text{HF}} = 47.8$  Hz, 2H), 3.87–3.79 (m, 3H), 3.73–3.68 (m, 5H), 3.54–3.46 (m, 4H), 2.68–2.62 (m, 2H), 2.54–2.47 (m, 2H), 2.49 (s, 3H).  $^{19}\text{F}$  NMR ( $\text{CDCl}_3$ , 282 MHz)  $\delta$ : –223.31 (tt,  $^2J_{\text{HF}} = 47.9$  Hz,  $^3J_{\text{HF}} = 29.6$  Hz). HR-MS calcd. for  $\text{C}_{14}\text{H}_{23}\text{FN}_3\text{O}_2\text{S}_2$  [ $\text{M} + 1$ ]: 348.1210; found: 348.1212. EA calcd.: C 48.39, H 6.39, N 12.10; found: C 49.07, H 6.74, N 11.66.

### 3-(Benzyloxy)propyl-4-methylbenzenesulfonate (6a)

To an oven-dried round-bottomed flask under an atmosphere of  $\text{N}_2$  was added propane-1,3-diol (**5a**, 0.11 mol), 1.4 mL (0.01 mol) of benzyl bromide, and KOH (0.02 mol, neat). The reaction proceeded at RT. Upon consumption of benzyl bromide (monitored by TLC, 40:60 EtOAc:Hex), the reaction mixture was diluted with 50 mL of  $\text{H}_2\text{O}$  and washed with  $\text{CH}_2\text{Cl}_2$  (50 mL  $\times$  2). The combined organic layers were washed with 50 mL of brine, dried over  $\text{Na}_2\text{SO}_4$ , and concentrated.  $\text{CH}_2\text{Cl}_2$  (50 mL) was added and the mixture was cooled on ice. Triethylamine (0.05 mol) and DMAP (1 mol%) were added. After 10 min of stirring, 0.03 mol of TsCl was added and the reaction proceeded until completion, as monitored by TLC (40:60 EtOAc:Hex). The mixture was then cooled on ice, diluted with 100 mL  $\text{H}_2\text{O}$ , and washed with dichloromethane (100 mL  $\times$  2). The combined organic layers were washed with 100 mL of brine, dried over  $\text{Na}_2\text{SO}_4$ , and concentrated. The final product was purified by flash chromatography (40:60 EtOAc:Hex) to yield 2.40 g of **6a** (75%).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 300 MHz)  $\delta$ : 7.81–7.76 (m, 2H), 7.35–7.22 (m, 7H), 4.40 (s, 2H), 4.17 (t,  $^3J_{\text{HH}} = 6.3$  Hz, 2H), 3.50 (t,  $^3J_{\text{HH}} = 5.8$ , 2H), 2.42 (s, 3H), 1.98–1.90 (q,  $^3J_{\text{HH}} = 6.0$  Hz, 2H).

### 5-(Benzyloxy)pentyl-4-methylbenzenesulfonate (6b)

Compound **6b** was prepared in an analogous manner to that of **6a**. Briefly, 0.07 mol of pentane-1,5-diol (**5b**), 0.02 mol of benzyl bromide, and 0.055 mol of KOH were used. Following the workup of the reaction mixture, 10 mL of dichloromethane, 0.07 mol of triethylamine, catalytic DMAP (1 mol%), and 0.035 mol of TsCl were reacted and purified (vide supra). Compound **6b** was obtained in a 65% yield (4.54 g).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 300 MHz)  $\delta$ : 7.81–7.76 (m, 2H), 7.36–7.26 (m, 7H), 4.47 (s, 2H), 4.02 (t,  $^3J_{\text{HH}} = 6.3$  Hz, 2H), 3.42 (t,  $^3J_{\text{HH}} = 6.6$  Hz, 2H), 2.44 (s, 3H), 1.71–1.61 (m, 2H), 1.60–1.51 (m, 2H), 1.46–1.36 (m, 2H).

### 6-(Benzyloxy)hexyl-4-methylbenzenesulfonate (6c)

Compound **6c** was prepared in an analogous manner to that of **6a**. Briefly, 0.06 mol of hexane-1,6-diol (**5c**), 0.02 mol of benzyl bromide, and 0.055 mol of KOH were used. Following the workup, 10 mL of dichloromethane, 0.07 mol of triethylamine, DMAP (1 mol%), and 0.04 mol of TsCl were reacted and purified (vide supra). Compound **6c** was obtained in a 61% yield (4.40 g).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 300 MHz)  $\delta$ : 7.81–7.76 (m, 2H), 7.36–7.28 (m, 7H), 4.48 (s, 2H), 4.01 (t,  $^3J_{\text{HH}} = 6.6$  Hz, 2H), 3.43 (t,  $^3J_{\text{HH}} = 6.6$  Hz, 2H), 2.44 (s, 3H), 1.67–1.51 (m, 4H), 1.35–1.28 (m, 4H).

### 7-(Benzyloxy)heptyl-4-methylbenzenesulfonate (6d)

Compound **6d** was prepared in an analogous manner to that of **6a**. Briefly, 0.02 mol of hexane-1,6-diol (**5d**), 0.008 mol of benzyl bromide, and 0.015 mol of KOH were

used. After workup, 8 mL of  $\text{CH}_2\text{Cl}_2$ , 0.025 mol of triethylamine, DMAP (1 mol%), and 0.02 mol of TsCl were reacted and purified (vide supra). **6d** was obtained in a 69% yield (2.06 g).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 300 MHz)  $\delta$ : 7.81–7.76 (m, 2H), 7.36–7.25 (m, 7H), 4.49 (s, 2H), 4.01 (t,  $^3J_{\text{HH}} = 6.4$  Hz, 2H), 3.44 (t,  $^3J_{\text{HH}} = 6.7$  Hz, 2H), 2.44 (s, 3H), 1.66–1.51 (m, 4H), 1.36–1.20 (m, 6H).

### 2-(2-(Benzyloxy)ethoxy)ethyl-4-methylbenzenesulfonate (6e)

Compound **6e** was prepared in an analogous manner to that of **6a**. Diethyleneglycol (**5e**; 0.03 mol), 0.008 mol of benzyl bromide, and 0.03 mol of KOH were used. After workup, 20 mL of dichloromethane, 0.02 mol of triethylamine, DMAP (1 mol%), and 0.07 mol of TsCl were reacted and purified (vide supra). Compound **6e** was obtained in a 43% yield (1.24 g).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 300 MHz)  $\delta$ : 7.81–7.76 (m, 2H), 7.35–7.26 (m, 7H), 4.53 (s, 2H), 4.19–4.14 (m, 2H), 3.72–3.67 (m, 2H), 3.63–3.59 (m, 2H), 3.58–3.54 (m, 2H), 2.42 (s, 3H).

### 2-(2-(2-(Benzyloxy)ethoxy)ethoxy)ethyl-4-methylbenzenesulfonate (6f)

Compound **6f** was prepared in an analogous manner to that of **6a**. Briefly, 0.04 mol of diethyleneglycol (**5f**), 0.01 mol of benzyl bromide, and 0.04 mol of KOH were used. Following the workup, 20 mL of dichloromethane, 0.02 mol of triethylamine, DMAP (1 mol%), and 0.06 mol of TsCl were reacted and purified (vide supra). Compound **6f** was obtained in a 35% yield (1.40 g).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 300 MHz)  $\delta$ : 7.81–7.76 (m, 2H), 7.35–7.26 (m, 7H), 4.55 (s, 2H), 4.17–4.12 (m, 2H), 3.70–3.66 (m, 2H), 3.65–3.60 (m, 4H), 3.59 (s, 4H), 3.04 (s, 3H).

### ((3-Fluoropropoxy)methyl)benzene (7a)

To a glass vial (Biotage) under an atmosphere of  $\text{N}_2$  containing 0.02 mol of TBAF (dried under reduced pressure overnight) was added 20 mL of freshly distilled THF followed by 500 mg (1.6 mmol) of **6a**. The reaction was sealed and microwave heated for 1 h at 160  $^\circ\text{C}$ . THF was removed under reduced pressure and the resulting product was dissolved in 50 mL of EtOAc and washed with 50 mL of  $\text{H}_2\text{O}$ . The aqueous layer was washed a second time with 50 mL of EtOAc and the combined organic layers were washed with 50 mL of brine, dried over  $\text{Na}_2\text{SO}_4$ , and concentrated. The product was purified by flash chromatography (30:70 EtOAc:Hex (v/v)) to yield 179 mg of **7a** (68%).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz)  $\delta$ : 7.37–7.25 (m, 5H), 4.56 (dt,  $^2J_{\text{HF}} = 47.1$  Hz,  $^3J_{\text{HH}} = 6.0$  Hz, 2H), 4.51 (s, 2H), 3.60 (t,  $^3J_{\text{HH}} = 6.2$  Hz, 2H), 1.99 (dm,  $^3J_{\text{HF}} = 25.8$  Hz, 2H).  $^{19}\text{F}$  NMR ( $\text{CDCl}_3$ , 376 MHz)  $\delta$ : –222.05 (tt,  $^2J_{\text{HF}} = 47.0$  Hz,  $^3J_{\text{HF}} = 25.7$  Hz).

### ((5-Fluoropentyl)oxy)methyl)benzene (7b)

Compound **7b** was prepared in an analogous manner to that of **7a**, where 0.02 mol of TBAF and 1.4 mmol of **6b** were used in 20 mL of THF. Compound **7b** was obtained in a 70% yield (198 mg).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz)  $\delta$ : 7.35–7.25 (m, 5H), 4.50 (s, 2H), 4.43 (dt,  $^2J_{\text{HF}} = 47.4$  Hz,  $^3J_{\text{HH}} = 6.1$  Hz, 2H), 3.48 (t,  $^3J_{\text{HH}} = 6.5$  Hz, 2H), 1.78–1.62 (m, 4H), 1.54–1.45 (m, 2H).  $^{19}\text{F}$  NMR ( $\text{CDCl}_3$ , 376 MHz)  $\delta$ : –218.66 (tt,  $^2J_{\text{HF}} = 47.4$  Hz,  $^3J_{\text{HF}} = 24.8$  Hz).

**((6-Fluorohexyloxy)methyl)benzene (7c)**

Compound **7c** was prepared in an analogous manner to that of **7a**, where 0.02 mol of TBAF and 1.4 mmol of **6c** were used in 20 mL of THF. Compound **7c** was obtained in a 72% yield (209 mg).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz)  $\delta$ : 7.35–7.24 (m, 5H), 4.50 (s, 2H), 4.42 (dt,  $^2J_{\text{HF}} = 47.4$  Hz,  $^3J_{\text{HH}} = 6.2$  Hz, 2H), 3.47 (t,  $^3J_{\text{HH}} = 6.6$  Hz, 2H), 1.76–1.59 (m, 4H), 1.45–1.39 (m, 4H).  $^{19}\text{F}$  NMR ( $\text{CDCl}_3$ , 376 MHz)  $\delta$ : –218.55 (tt,  $^2J_{\text{HF}} = 47.3$  Hz,  $^3J_{\text{HF}} = 24.9$  Hz).

**((7-Fluoroheptyloxy)methyl)benzene (7d)**

Compound **7d** was prepared in an analogous manner to that of **7a**, where 0.02 mol of TBAF and 1.3 mmol of **6d** were used in 20 mL of THF. Compound **7d** was obtained in an 85% yield (251 mg).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz)  $\delta$ : 7.35–7.24 (m, 5H), 4.50 (s, 2H), 4.42 (dt,  $^2J_{\text{HF}} = 47.5$  Hz,  $^3J_{\text{HH}} = 6.1$  Hz, 2H), 3.46 (t,  $^3J_{\text{HH}} = 6.6$  Hz, 2H), 1.75–1.58 (m, 4H), 1.45–1.30 (m, 6H).  $^{19}\text{F}$  NMR ( $\text{CDCl}_3$ , 376 MHz)  $\delta$ : –218.46 (tt,  $^2J_{\text{HF}} = 47.5$  Hz,  $^3J_{\text{HF}} = 24.9$  Hz).

**((2-(2-Fluoroethoxy)ethoxy)methyl)benzene (7e)**

Compound **7e** was prepared in an analogous manner to that of **7a**, where 0.02 mol of TBAF and 1.4 mmol of **6e** were used in 20 mL of THF. Compound **7e** was obtained in a 91% yield (252 mg).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz)  $\delta$ : 7.36–7.25 (m, 5H), 4.58 (s, 2H), 4.56 (dm,  $^2J_{\text{HF}} = 47.7$  Hz, 2H), 3.80–3.78 (m, 1H), 3.73–3.69 (m, 3H), 3.67–3.63 (m, 2H).  $^{19}\text{F}$  NMR ( $\text{CDCl}_3$ , 376 MHz)  $\delta$ : –223.27 (tt,  $^2J_{\text{HF}} = 47.7$  Hz,  $^3J_{\text{HF}} = 29.4$  Hz).

**((2-(2-(2-Fluoroethoxy)ethoxy)ethoxy)methyl)benzene (7f)**

Compound **7f** was prepared in an analogous manner to that of **7a**, where 0.02 mol of TBAF and 1.3 mmol of **6f** were used in 20 mL of THF. Compound **7f** was obtained in a 90% yield (273 mg).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz)  $\delta$ : 7.36–7.26 (m, 5H), 4.57 (s, 2H), 4.55 (dm,  $^2J_{\text{HF}} = 47.6$  Hz, 2H), 3.80–3.77 (m, 1H), 3.72–3.67 (m, 7H), 3.66–3.62 (m, 2H).  $^{19}\text{F}$  NMR ( $\text{CDCl}_3$ , 376 MHz)  $\delta$ : –223.34 (tt,  $^2J_{\text{HF}} = 47.7$  Hz,  $^3J_{\text{HF}} = 29.8$  Hz).

**3-(4-(1-Methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazol-3-yloxy)propan-1-ol (8a)**

To an oven-dried round-bottomed flask under an atmosphere of  $\text{N}_2$ , 1.16 mmol of propane-1,3-diol (**5a**) was added to 2.5 mL of freshly distilled THF. To the reaction mixture was added 0.92 mmol of 60% NaH, and the mixture was stirred at RT for 30 min. Compound **1** (0.23 mmol) was added and the reaction was refluxed overnight. The reaction mixture was diluted with 30 mL of  $\text{H}_2\text{O}$  and washed with 30 mL of  $\text{CH}_2\text{Cl}_2$  ( $\times 2$ ). The combined organic layers were then washed with 40 mL of brine, dried over  $\text{Na}_2\text{SO}_4$ , and concentrated. The product was purified by PTLC (30:70 EtOAc:Hex (v/v)) and **8a** was obtained in a yield of 25.2 mg (43%).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz)  $\delta$ : 7.04–7.00 (m, 1H), 4.59 (t,  $J = 6.1$  Hz, 2H), 3.78 (t,  $J = 6.1$  Hz, 2H), 3.46–3.44 (m, 2H), 2.60–2.56 (m, 2H), 2.47–2.42 (m, 2H), 2.46 (s, 3H), 2.11–2.04 (m, 2H). HR-MS calcd. for  $\text{C}_{11}\text{H}_{18}\text{N}_3\text{O}_2\text{S}$  [ $M + 1$ ]: 256.1114; found: 256.1112. EA calcd.: C 51.74, H 6.71, N 16.46; found: C 51.72, H 6.73, N 16.06.

**4-(4-(1-Methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazol-3-yloxy)butan-1-ol (8b)**

Compound **8b** was prepared in an analogous manner to that of **8a**, where 1.15 mmol of butane-1,4-diol (**5b**), 0.92 mmol of 60% NaH, and 0.23 mmol of **1** in 2.5 mL of freshly distilled THF were used. Compound **8b** was obtained in a 48% yield (30 mg).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 300 MHz)  $\delta$ : 7.07–7.02 (m, 1H), 4.48 (t,  $^3J_{\text{HH}} = 4.46$  Hz, 2H), 3.71 (t,  $^3J_{\text{HH}} = 6.44$  Hz, 2H), 3.47–3.42 (m, 2H), 2.61–2.55 (m, 2H), 2.48–2.41 (m, 2H), 2.46 (s, 3H), 2.00–1.89 (m, 2H), 1.78–1.67 (m, 2H). HR-MS calcd. for  $\text{C}_{12}\text{H}_{20}\text{N}_3\text{O}_2\text{S}$  [ $M + 1$ ]: 270.1271; found: 270.1269. EA calcd.: C 53.51, H 7.11, N 15.60; found: C 52.56, H 6.85, N 15.49.

**5-(4-(1-Methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazol-3-yloxy)pentan-1-ol (8c)**

Compound **8c** was prepared in an analogous manner to that of **8a**, where 1.15 mmol of pentane-1,5-diol (**5c**), 0.92 mmol of 60% NaH, and 0.23 mmol of **1** in 2.5 mL of freshly distilled THF were used. Compound **8c** was obtained in a 34% yield (22 mg).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 300 MHz)  $\delta$ : 7.07–7.02 (m, 1H), 4.47 (t,  $^3J_{\text{HH}} = 6.54$  Hz, 2H), 3.69 (t,  $^3J_{\text{HH}} = 6.42$  Hz, 2H), 3.48–3.43 (m, 2H), 2.61–2.55 (m, 2H), 2.49–2.42 (m, 2H), 2.47 (s, 3H), 1.95–1.83 (m, 2H), 1.70–1.51 (m, 4H). HR-MS calcd. for  $\text{C}_{13}\text{H}_{22}\text{N}_3\text{O}_2\text{S}$  [ $M + 1$ ]: 284.1427; found: 284.1425. EA calcd.: C 55.10, H 7.47, N 14.83; found: C 58.85, H 7.07, N 14.82.

**6-(4-(1-Methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazol-3-yloxy)hexan-1-ol (8d)**

Compound **8d** was prepared in an analogous manner to that of **8a**, where 1.15 mmol of hexane-1,6-diol (**5d**), 0.92 mmol of NaH (60% in mineral oil), and 0.23 mmol of **1** in 2.5 mL of freshly distilled THF were used. Compound **8d** was obtained in a 25% yield (17 mg).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 300 MHz)  $\delta$ : 7.07–7.01 (m, 1H), 4.49–4.41 (m, 2H), 3.67–3.60 (m, 2H), 3.48–3.40 (m, 2H), 2.62–2.55 (m, 2H), 2.51–2.42 (m, 2H), 2.47 (s, 3H), 2.14 (br, 1H), 1.91–1.80 (m, 2H), 1.65–1.54 (m, 2H), 1.53–1.39 (m, 4H). HR-MS calcd. for  $\text{C}_{14}\text{H}_{24}\text{N}_3\text{O}_2\text{S}$  [ $M + 1$ ]: 298.1584; found: 298.1582. EA calcd.: C 56.54, H 7.79, N 13.75; found: C 55.02, H 7.42, N 13.75.

**2-(2-(4-(1-Methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazol-3-yloxy)ethoxy)ethanol (8e)**

Compound **8e** was prepared in an analogous manner to that of **8a**, where 0.084 mmol of diethyleneglycol (**5e**), 0.42 mmol of 60% NaH, and 0.46 mmol of **1** in 3 mL of freshly distilled THF were used. Compound **8e** was obtained in a 74% yield (89 mg).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz)  $\delta$ : 7.08–7.04 (m, 1H), 4.64–4.60 (m, 2H), 3.92–3.89 (m, 2H), 3.76–3.73 (m, 2H), 3.67–3.63 (m, 2H), 3.46–3.43 (m, 2H), 2.59–2.55 (m, 2H), 2.47–2.42 (m, 2H), 2.45 (s, 3H). HR-MS calcd. for  $\text{C}_{12}\text{H}_{20}\text{N}_3\text{O}_3\text{S}$  [ $M + 1$ ]: 286.1220; found: 286.1218. EA calcd.: C 50.50, H 6.72, N 14.73; found: C 49.91, H 6.70, N 14.37.

**2-(2-(2-(4-(1-Methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazol-3-yloxy)ethoxy)ethoxy)ethanol (8f)**

Compound **8f** was prepared in an analogous manner to that of **8a**, where 0.084 mmol of diethyleneglycol (**5f**), 0.42 mmol of 60% NaH, and 0.46 mmol of **1** in 3.0 mL of

freshly distilled THF were used. **8f** was obtained in a 65% yield (81 mg).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz)  $\delta$ : 6.77–6.73 (m, 1H), 3.85–3.80 (m, 2H), 3.75–3.71 (m, 2H), 3.69–3.66 (m, 4H), 3.63–3.59 (m, 2H), 3.53–3.49 (m, 2H), 3.45–3.42 (m, 2H), 2.63–2.58 (m, 2H), 2.51–2.45 (m, 2H), 2.42 (s, 3H). HR-MS: calcd. for  $\text{C}_{14}\text{H}_{24}\text{N}_3\text{O}_4\text{S}$  [ $M + 1$ ]: 330.1482; found: 330.1476. EA calcd.: C 51.04, H 7.04, N 12.76; found: C 50.07, H 6.89, N 12.52.

**3-(3-Fluoropropoxy)-4-(1-methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazole (9a)**

To an oven-dried round-bottomed flask under an atmosphere of  $\text{N}_2$  containing 3 mL of freshly distilled THF was added 0.5 mmol of **7a** followed by 10 mg each of Pd/C and  $\text{Pd}(\text{OH})_2$ . The reaction vessel was purged with  $\text{H}_2(\text{g})$  and maintained under an atmosphere of  $\text{H}_2(\text{g})$  for 2 h while stirring vigorously. Upon consumption of the starting material as monitored by TLC (60:40 EtOAc:Hex ( $v/v$ )), the reaction mixture was purged with  $\text{N}_2$  and cooled in an ice bath, and 1.0 mmol of NaH (60% in mineral oil) was added. The mixture was stirred for 30 min at RT followed by the addition of 0.2 mmol of **1**. The reaction mixture was subsequently refluxed overnight. Upon consumption of the starting material, the reaction was filtered through celite and the THF was removed under reduced pressure. The product was dissolved in 30 mL of  $\text{CH}_2\text{Cl}_2$  and washed with 30 mL of  $\text{H}_2\text{O}$ , and the aqueous layer was further extracted with 30 mL of  $\text{CH}_2\text{Cl}_2$ . The combined organic layers were washed with 30 mL of brine, dried over  $\text{Na}_2\text{SO}_4$ , and concentrated. The product was purified by PTLC (60:40 EtOAc:Hex ( $v/v$ )) to yield 21 mg **9a** (41%).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz)  $\delta$ : 7.04–6.99 (m, 1H), 4.63 (dm,  $^2J_{\text{HF}} = 47.0$  Hz, 2H), 4.61 (t,  $^3J_{\text{HH}} = 6.2$  Hz, 2H), 3.47–3.43 (m, 2H), 2.60–2.55 (m, 2H), 2.48–2.42 (m, 2H), 2.46 (s, 3H), 2.25 (dm,  $^3J_{\text{HF}} = 25.6$  Hz, 2H).  $^{19}\text{F}$  NMR ( $\text{CDCl}_3$ , 376 MHz)  $\delta$ : –222.38 (tt,  $^2J_{\text{HF}} = 47.0$  Hz,  $^3J_{\text{HF}} = 25.8$  Hz). HR-MS calcd. for  $\text{C}_{11}\text{H}_{17}\text{FN}_3\text{OS}$  [ $M + 1$ ]: 258.1071; found: 258.1068. EA calcd.: C 51.34, H 6.27, N 16.33; found: C 51.64, H 6.27, N 15.84.

**3-(5-Fluoropentyloxy)-4-(1-methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazole (9b)**

Compound **9b** was prepared in an analogous manner to that of **9a**, where 0.4 mmol of **7b** was used followed by 1.4 mmol of 60% NaH and 0.23 mmol of **1**. Compound **9b** was obtained in a 29% yield (19 mg).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz)  $\delta$ : 7.07–7.03 (m, 1H), 4.48 (dt,  $^2J_{\text{HF}} = 46.9$  Hz,  $^3J_{\text{HH}} = 6.1$  Hz, 2H), 4.47 (t,  $^3J_{\text{HH}} = 6.5$  Hz, 2H), 3.50–3.47 (m, 2H), 2.64–2.59 (m, 2H), 2.50–2.44 (m, 2H), 2.49 (s, 3H), 1.94–1.86 (m, 2H), 1.85–1.72 (m, 2H), 1.64–1.56 (m, 2H).  $^{19}\text{F}$  NMR ( $\text{CDCl}_3$ , 376 MHz)  $\delta$ : –219.18 (tt,  $^2J_{\text{HF}} = 47.1$  Hz,  $^3J_{\text{HF}} = 25.4$  Hz). HR-MS calcd. for  $\text{C}_{13}\text{H}_{21}\text{FN}_3\text{OS}$  [ $M + 1$ ]: 286.1384; found: 286.1380. EA calcd.: C 54.71, H 7.06, N 14.72; found: C 54.90, H 6.87, N 14.79.

**3-(6-Fluorohexyloxy)-4-(1-methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazole (9c)**

Compound **9c** was prepared in an analogous manner to that of **9a**, where 0.4 mmol of **7c** was used followed by 1.4 mmol of 60% NaH and 0.23 mmol of **1**. Compound **9c** was obtained in a 39% yield (27 mg).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz)  $\delta$ : 7.07–7.03 (m, 1H), 4.46 (t,  $^3J_{\text{HH}} = 6.9$  Hz,

2H), 4.46 (dt,  $^2J_{\text{HF}} = 47.2$  Hz,  $^3J_{\text{HH}} = 6.0$  Hz, 2H), 3.48–3.45 (m, 2H), 2.61–2.56 (m, 2H), 2.48–2.43 (m, 2H), 2.47 (s, 3H), 1.90–1.83 (m, 2H), 1.79–1.68 (m, 2H), 1.53–1.48 (m, 4H).  $^{19}\text{F}$  NMR ( $\text{CDCl}_3$ , 376 MHz)  $\delta$ : –218.79 (tt,  $^2J_{\text{HF}} = 47.2$  Hz,  $^3J_{\text{HF}} = 25.3$  Hz). HR-MS calcd. for  $\text{C}_{14}\text{H}_{23}\text{FN}_3\text{OS}$  [ $M + 1$ ]: 300.1540; found: 300.1536. EA calcd.: C 56.16, H 7.41, N 14.03; found: C 56.58, H 7.39, N 13.77.

**3-(7-Fluoroheptyloxy)-4-(1-methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazole (9d)**

Compound **9d** was prepared in an analogous manner to that of **9a**, where 0.4 mmol of **7d** was used followed by 1.4 mmol of 60% NaH and 0.23 mmol of **1**. Compound **9d** was obtained in a 35% yield (25 mg).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz)  $\delta$ : 7.08–7.04 (m, 2H), 4.45 (t,  $^3J_{\text{HH}} = 6.6$  Hz, 2H), 4.45 (dt,  $^2J_{\text{HF}} = 47.6$  Hz,  $^3J_{\text{HH}} = 6.2$  Hz, 2H), 3.47–3.44 (m, 2H), 2.61–2.56 (m, 2H), 2.48–2.43 (m, 2H), 2.47 (s, 3H), 1.89–1.81 (m, 2H), 1.76–1.62 (m, 2H), 1.51–1.40 (m, 5H).  $^{19}\text{F}$  NMR ( $\text{CDCl}_3$ , 376 MHz)  $\delta$ : –218.62 (tt,  $^2J_{\text{HF}} = 47.5$  Hz,  $^3J_{\text{HF}} = 25.2$  Hz). HR-MS calcd. for  $\text{C}_{15}\text{H}_{25}\text{FN}_3\text{OS}$  [ $M + 1$ ]: 314.1697; found: 314.1693. EA calcd.: C 57.48, H 7.72, N 13.41; found: C 57.69, H 7.65, N 13.17.

**3-(2-(2-Fluoroethoxy)ethoxy)-4-(1-methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazole (9e)**

Compound **9e** was prepared in an analogous manner to that of **9a**, where 0.4 mmol of **7e** was used followed by 1.4 mmol of 60% NaH and 0.23 mmol of **1**. Compound **9e** was obtained in a 45% yield (30 mg).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz)  $\delta$ : 7.12–7.07 (m, 1H), 4.64–4.61 (m, 2H), 4.58 (dm,  $^2J_{\text{HF}} = 47.6$  Hz, 2H), 3.96–3.92 (m, 2H), 3.79 (dm,  $^3J_{\text{HF}} = 29.4$  Hz, 2H), 3.47–3.44 (m, 2H), 2.60–2.55 (m, 2H), 2.49–2.43 (m, 2H), 2.46 (s, 3H).  $^{19}\text{F}$  NMR ( $\text{CDCl}_3$ , 376 MHz)  $\delta$ : –223.51 (tt,  $^2J_{\text{HF}} = 47.7$  Hz,  $^3J_{\text{HF}} = 28.9$  Hz). HR-MS calcd. for  $\text{C}_{12}\text{H}_{19}\text{FN}_3\text{O}_2\text{S}$  [ $M + 1$ ]: 288.1177; found: 288.1173. EA calcd.: C 50.16, H 6.361, N 14.62; found: C 50.25, H 6.44, N 14.40.

**3-(2-(2-(2-Fluoroethoxy)ethoxy)ethoxy)-4-(1-methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazole (9f)**

Compound **9f** was prepared in an analogous manner to that of **9a**, where 0.4 mmol of **7f** was used followed by 1.4 mmol of 60% NaH and 0.23 mmol of **1**. Compound **9f** was obtained in a 62% yield (46 mg).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 400 MHz)  $\delta$ : 7.11–7.07 (m, 1H), 4.63–4.60 (m, 3H), 4.51–4.48 (m, 1H), 3.93–3.90 (m, 2H), 3.79–3.77 (m, 1H), 3.74–3.68 (m, 5H), 3.47–3.45 (m, 2H), 3.60–3.56 (m, 2H), 2.47–2.43 (m, 2H), 2.46 (s, 3H).  $^{19}\text{F}$  NMR ( $\text{CDCl}_3$ , 376 MHz)  $\delta$ : –223.30 (tt,  $^2J_{\text{HF}} = 47.7$  Hz,  $^3J_{\text{HF}} = 29.5$  Hz). HR-MS calcd. for  $\text{C}_{14}\text{H}_{23}\text{FN}_3\text{O}_3\text{S}$  [ $M + 1$ ]: 332.1439; found: 332.1434. EA calcd.: C 50.74, H 6.69, N 12.68; found: C 50.87, H 6.75, N 12.86.

**3-(Hexyloxy)-4-(1-methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazole (10)**

To an oven-dried round-bottomed flask, 71 mg (0.7 mmol) of 1-hexanol was added to 3 mL of freshly distilled THF. To the reaction mixture was added 34 mg (1.4 mmol) of 95% NaH, and the mixture was allowed to stir at RT for 30 min. Compound **1** (0.35 mmol) was subsequently added and the reaction was refluxed overnight. The reaction was diluted with 30 mL of  $\text{H}_2\text{O}$  and washed with

30 mL of  $\text{CH}_2\text{Cl}_2$  ( $\times 2$ ). The combined organic layers were then washed with 40 mL of brine, dried over  $\text{Na}_2\text{SO}_4$ , and concentrated. The product was purified by PTLC (30:70 EtOAc:Hex (v/v)) and **9** was obtained in a yield of 58 mg (60%).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 300 MHz)  $\delta$ : 7.09–7.04 (m, 1H), 4.47–4.41 (m, 2H), 3.48–3.43 (m, 2H), 2.61–2.55 (m, 2H), 2.49–2.42 (m, 5H), 1.89–1.78 (m, 2H), 1.52–1.39 (m, 2H), 1.38–1.31 (m, 4H), 0.94–0.87 (m, 3H). HR-MS calcd. for  $\text{C}_{14}\text{H}_{24}\text{N}_3\text{OS}$  [ $M + 1$ ]: 282.1635; found: 282.1633. EA calcd.: C 59.75, H 8.24, N 14.93; found: C 59.68, H 8.14, N 14.67.

### In vitro binding assays

All  $K_i$  determinations were conducted by the National Institute of Mental Health's Psychoactive Drug Screening Program (NIMH PDSP), contract No. NO1MH32004. The NIMH PDSP is directed by Bryan L. Roth, M.D., Ph.D., at the University of North Carolina at Chapel Hill and Project Officer Jamie Driscoll at NIMH, Bethesda, Maryland, USA (<http://pdsp.med.unc.edu/>).

### Radiochemical synthesis

#### Synthesis of [ $^{18}\text{F}$ ]-3-(2-(2-fluoroethoxy)ethoxy)ethylthio)-4-(1-methyl-1,2,5,6-tetrahydropyridin-3-yl)-1,2,5-thiadiazole ([ $^{18}\text{F}$ ]**4c**)

A Scanditronix MC 17 cyclotron was used for [ $^{18}\text{F}$ ]fluoride production and the radiosynthesis was carried out via general automated methods using a GE FX<sub>FN</sub> radiofluorination module as previously reported in detail by our laboratory for the synthesis of [ $^{18}\text{F}$ ]**4a**,<sup>14</sup> with only minor modifications.

Briefly, to a reaction vessel containing reactive [ $^{18}\text{F}$ ]fluoride was added 3 mg of **3c** dissolved in 500  $\mu\text{L}$  of  $\text{CH}_3\text{CN}$ . The reaction mixture was heated to 90  $^\circ\text{C}$  for 10 min, and the reaction was quenched with 500  $\mu\text{L}$  of  $\text{H}_2\text{O}$ . The reaction mixture was then purified via semipreparative HPLC (20:80  $\text{CH}_3\text{CN}:\text{H}_2\text{O}$  + 0.1 N ammonium formate + 1% formic acid (pH 4), Semi-Prep LUNA C18(2) (250 mm  $\times$  10 mm, 10  $\mu\text{m}$ ,  $\lambda = 254$  nm)) at 6 mL/min. The major radiochemical peak ( $t_R = 13$  min) was collected and formulated as previously described.<sup>14</sup> The formulated product was analyzed by HPLC (30:70  $\text{CH}_3\text{CN}:\text{H}_2\text{O}$  + 0.1 N ammonium formate, Prodigy C18 ODS Prep column (250 mm  $\times$  4.6 mm, 10  $\mu\text{m}$ ,  $\lambda = 254$  nm)) at a flow of 3 mL/min. HPLC analysis of formulated [ $^{18}\text{F}$ ]**4c** revealed high radiochemical (>99%) purities. Coinjection of the radioactive product with an authentic standard of **4c** under several different HPLC conditions (solvents, pH, wavelength; see Table S2 in the Supplementary data) with different analytical columns further established the identity of the radiotracer. Specific activity was calculated at the end of synthesis from the formulated product and was determined by integration of the UV peak of an analytical HPLC chromatogram in comparison with standard solutions containing known concentrations of **4c**.

### Ex vivo biodistribution

Ex vivo biodistribution studies in conscious male Sprague–Dawley rats were conducted as previously described by our group.<sup>32,33</sup> All rats received  $\sim 2.6$  MBq of

[ $^{18}\text{F}$ ]**4c** in 0.3 mL of buffered saline via the tail vein and were sacrificed by decapitation at either 5, 15, 30, or 60 min after injection ( $n = 1$  per time point). The brains were removed and regions of interest (striatum, thalamus, hypothalamus, hippocampus, frontal cortex, rest of cortex, cerebellum, rest of brain, as well as whole blood from the trunk, bone, and heart) were excised, blotted, weighed, and then counted for radioactivity (Fig. 3).

### Metabolism studies

Following tail-vein injection of [ $^{18}\text{F}$ ]**4c** as described above, whole blood was collected at various time points from the trunk in a heparinized tube and centrifuged, and the plasma was separated for metabolite analysis by HPLC via the method of Hilton et al.,<sup>35</sup> with minor modifications. Briefly, rat plasma from each time point was directly loaded onto a 5 mL HPLC injector loop and injected onto a capture column (4.6 mm  $\times$  20 mm) that was packed in-house with OASIS HLB 30  $\mu\text{m}$  (Waters, New Jersey). The capture column was eluted with 1% aqueous  $\text{CH}_3\text{CN}$  (2 mL/min) for 3 min and then back-flushed (19:81  $\text{CH}_3\text{CN}:\text{H}_2\text{O}$  + 0.1 N ammonium formate, 2.0 mL/min) onto a Phenomenex 10  $\mu\text{m}$  Luna C18 column (250 mm  $\times$  4.6 mm). The column effluents from both columns were monitored through a flow detector (Bioscan Flow-Count) operated in coincidence mode. Whole brain removed from a control rat and treated with  $\sim 1$  MBq of [ $^{18}\text{F}$ ]**4c** and whole brain removed from a rat sacrificed at 60 min after injection of [ $^{18}\text{F}$ ]**4c** in the tail vein were individually homogenized with ice-cold 80% ethanol and centrifuged as previously described by our laboratory,<sup>36</sup> prior to radio-HPLC analysis of the supernatant using the aforementioned method.

### Supplementary data

Supplementary data for this article are available on the journal Web site ([canjchem.nrc.ca](http://canjchem.nrc.ca)).

# Microwave-assisted Diels–Alder reaction of 1,3,3-trimethyl-2-vinyl-1-cyclohexene with chromones — An expeditious approach to analogues of the puupehenone group of marine diterpenoids and kampanols

Rajesh M. Kamble and M.M.V. Ramana

**Abstract:** A rapid assembly of the tetracyclic core of marine diterpenoids related to puupehenone and kampanols by a Diels–Alder reaction of 1,3,3-trimethyl-2-vinyl-1-cyclohexene with chromones under microwave irradiation with or without  $\text{TiCl}_4$  is described.

**Key words:** Diels–Alder, chromones, regioselectivity, stereoselectivity,  $\text{TiCl}_4$ , microwave synthesis.

**Résumé :** On décrit une méthode rapide pour rassembler le dérivé tétracyclique fondamental de diterpénoïdes marins apparentés à la puupéhénone et aux kampanols ; elle implique une réaction de Diels–Alder entre le 1,3,3-triméthyl-2-vinylcyclohex-1-ène avec des chromones, sous irradiation de microondes, avec ou sans  $\text{TiCl}_4$ .

**Mots-clés :** Diels–Alder, chromones, régiosélectivité, stéréosélectivité,  $\text{TiCl}_4$ , synthèse sous l'influence de microondes.

[Traduit par la Rédaction]

## Introduction

The Diels–Alder reaction has been extensively applied for the synthesis of a wide variety of natural products. The Diels–Alder reaction<sup>1</sup> constitutes one of the most frequently employed synthetic methods for pericyclic six-electron processes resulting in highly regio-, diastereo-, and enantioselective construction of polycyclic ring systems of fundamental interest in organic chemistry. In view of the outstanding importance of the method for the preparation of natural products, and hence also of physiologically active molecules, increasing interest has been placed in recent years on the development of [4 + 2] cycloadditions.

The Diels–Alder reaction of 1,3,3-trimethyl-2-vinyl-1-cyclohexene with dienophiles like dimethyl acetylenedicarboxylate,<sup>2,4</sup> unsymmetrical *p*-benzoquinones,<sup>5</sup> 2-carbomethoxy-4,4-dimethyl-2-cyclohexenone,<sup>6</sup> 1,4-benzoquinone,<sup>7</sup> substituted 1,4-benzoquinones,<sup>8</sup> 3-((*E*)-3-(methoxycarbonyl)propenyl)-1,3-oxazolidin-2-one,<sup>9</sup> acetylenedicarbaldehyde,<sup>10</sup> (*S*)-3-hydroxy-2-isopropyl-5-*tert*-butylsulfinyl-*p*-benzoquinone,<sup>11</sup> and conjugated ketones<sup>12</sup> has been reported. There have been very few reports of [4 + 2] cycloaddition reactions using chromones as dienophiles and in all these cases an activating functionality such as  $-\text{CHO}$ ,  $-\text{COR}$ ,  $-\text{COOR}$ ,  $-\text{CN}$ ,  $-\text{Ar}$ , etc. at C(3) has been utilized.<sup>13–15</sup> Only one Diels–Alder reaction of 1,3,3-trimethyl-2-vinyl-1-cyclohexene with 6-

bromo-3-cyanochromone<sup>13</sup> having an activating group at C(3) has been reported in the literature. Also, Lewis acids are known to catalyze Diels–Alder reactions.<sup>1,12,13</sup> Lewis acid-catalyzed cycloadditions not only proceed more rapidly than their thermal counterparts but are also generally more regio- and stereoselective. For this reason, such reactions are of additional interest from a theoretical point of view, since they appear to represent an exception to the reactivity–selectivity principle. Theoretical interpretations of the apparently anomalous course of these Lewis acid-catalyzed reactions have been proposed by Epiotis and Shaik<sup>16</sup> and by Branchadell et al.,<sup>17</sup> while the frontier molecular orbital theory was successfully applied to explain the role of the Lewis acid catalyst.<sup>18</sup> Donor–acceptor interactions between the dienophile and the catalyst thus lower the energy of the highest occupied molecular orbital and the lowest unoccupied molecular orbital of the dienophile. For the case of a [4 + 2] cycloaddition with normal electron demand, this means that the separation between the molecular orbitals will decrease and the stabilization of the transition state will increase. The literature on the acceleration of Diels–Alder reactions by common Lewis acids such as  $\text{TiCl}_4$ ,  $\text{SnCl}_2$ ,  $\text{ZnCl}_2$ ,  $\text{ZnBr}_2$ ,  $\text{BF}_3$ ,  $\text{SnCl}_4$ , etc. is extensively reported.

In the present study, we employed microwave energy because the potential application of microwave technology in organic synthesis<sup>19</sup> is increasing rapidly owing to its reac-

rine terpenoids.<sup>32</sup> These are based on a mixed biogenetic origin involving a sesquiterpene unit with a quinol or quinone and consist of a multiplicity of prenyl units uncommon in terrestrial organisms. These compounds were isolated from sponges and possess a wide range of potent biological activities, including cytotoxic,<sup>26,27</sup> antiviral,<sup>26,27</sup> antimicrobial,<sup>23</sup> antifungal,<sup>26</sup> immunomodulatory,<sup>26,27</sup> antitumor,<sup>25,33</sup> antimalarial,<sup>27</sup> antibiotic,<sup>34</sup> antituberculosis,<sup>35</sup> antioxidant,<sup>36</sup> and insecticidal activities.<sup>37</sup> The characteristic structural features such as a tetracyclic framework, four quaternary methyl groups, a benzopyran ring, a trimethyl cyclohexane moiety, four stereogenic centers at AB and BC ring junctions having trans and cis relationship, respectively, and an additional chiral center at C(15) of ring C of these tetracyclic diterpenes, as well as the biological activity observed within this series, attracted chemists to develop new methods for their synthesis. Other related compounds are kampenols A–C (**9–11**, respectively) (Chart 1), which are polycyclic natural products isolated from the fungal culture broth of *Stachybotrys kampalensis*, which are novel and specific inhibitors of farnesyl protein transferase.<sup>38</sup>

Our interest in the synthesis of natural products<sup>39</sup> and the absence of reports of the Diels–Alder reaction of 1,3,3-trimethyl-2-vinyl-1-cyclohexene with chromones not having an activating group on the enone double bond led us to explore the synthetic potential of chromones such as 6,7-dimethoxy-2-methyl chromone (**12**),<sup>40</sup> 6-methoxy-2-methyl chromone (**13**),<sup>41</sup> 6,7-methylenedioxy-2-methyl chromone (**14**),<sup>42</sup> 6-nitro-2-methyl chromone (**15**),<sup>43</sup> 2-methyl chromone (**16**),<sup>44</sup> flavone (**17**),<sup>45</sup> and chromone (**18**)<sup>46</sup> as dienophiles in [4 + 2] cycloaddition reactions. We envisaged that if diene 1,3,3-trimethyl-2-vinyl-1-cyclohexene (**19**)<sup>3</sup> could be used, then such a cycloaddition would lead to a convergent approach for construction of the tetracyclic core of puerphenone and kampenol analogues.

## Results and discussion

We now report for the first time a successful Diels–Alder reaction of 1,3,3-trimethyl-2-vinyl-1-cyclohexene (**19**) with chromones **12–18** not having an activating group at C(3) under microwave irradiation with or without  $\text{TiCl}_4$  catalyst (Scheme 1).

The reaction of **12** with the electron-rich diene **19** was performed in a microwave reactor at 140  $^{\circ}\text{C}$  for 65 min to give cycloadduct **20** in a moderate yield (42%). However, the use of  $\text{TiCl}_4$  and microwave radiation led to a significant enhancement in the yield of the cycloadduct (67%) and time reduction (30 min) (Table 1). The reaction was found to be regioselective as indicated by  $^1\text{H}$  NMR data, which exhibited a singlet at  $\delta$  2.71 ppm for the C(12a) proton while the C(6a) proton signal was absent; C(1) protons appeared at  $\delta$  2.18–1.65 ppm. Thus, this indicates the formation of the regioisomer **20** instead of **20a** (Fig. 1).

This reaction was also stereoselective as indicated by  $^1\text{H}$  NMR, which showed a singlet for C(6a) methyl protons at  $\delta$  1.39 ppm and C(12b) methyl protons at  $\delta$  1.21 ppm.  $^{13}\text{C}$  NMR signal for C(6a) methyl carbon exhibited a signal at 34.2 ppm and that for C(12b) methyl carbon exhibited a signal at 23.8 ppm.

These high  $\delta$  values suggest the formation of the *endo*-**20** product (Fig. 1). Recently, Wallace and co-workers<sup>48</sup> reported the synthesis of the ( $\pm$ )-*exo*-**20**, which had lower  $\delta$  values for the C(12a) proton and the C(6a) methyl and C(12b) methyl protons. Furthermore, this compound has a mp of 165  $^{\circ}\text{C}$ , whereas our compound has a mp of 102  $^{\circ}\text{C}$ . Also, the ( $\pm$ )-*exo*-**24** is an oil<sup>48</sup> and our compound **24** is a solid with a mp of 60  $^{\circ}\text{C}$ . Further, compound **24** also has higher  $\delta$  values for the C(12a) proton and C(6a) methyl and C(12b) methyl protons. All this evidence suggests the formation of the *endo*-**20** product. This represents the first ex-

**Figure 1.** Regioisomers **20**, **20a**, *endo*-**20**, *exo*-**20**, and ball-and-stick models (generated using Materials Studio<sup>47</sup>) of *endo*-**20** and *exo*-**20**.

ample of a highly stereoselective [4 + 2] cycloaddition reaction involving easily available chromone dienophiles.

Similar results were obtained with other chromones, **13**–**18** (Table 1). In all these cases, the reaction led to the generation of the tetracyclic core present in puerphenone **1** and related marine terpenoids and kampanols. Further, the catalytic hydrogenation of the C(4a)–(C5) double bond could lead to a trans-fused AB ring,<sup>7,8</sup> which is present in these natural products.

It is significant that in the above noncatalyzed microwave reactions, we could not isolate even traces of the *exo* isomer. This probably suggests that the *endo* effect controls the [4 + 2] addition in the noncatalyzed microwave reactions. In all these reactions, unreacted starting materials were recovered during column chromatographic purification.

The results in Table 1 also suggest that when the reactions were carried out at the same temperature (Table 1, entries 2, 5–7), reaction time was reduced and the percentage yields of the product were higher. This suggests that the Lewis acid used, that is TiCl<sub>4</sub>, reduces the reaction times and enhances the yield of the adduct without affecting the distereoselectivity (*endo*).

## Conclusion

In conclusion, we have accomplished the first highly stereoselective [4 + 2] cycloaddition reaction under microwave irradiation with and without TiCl<sub>4</sub> using chromones as dienophiles and have demonstrated the potential of this reaction in constructing the tetracyclic core of the marine diterpe-

noids related to puerphenone analogues **1–8** and kampanols **9–11** in a convergent manner.

## Experimental

Melting points are uncorrected. UV spectra were recorded on a Shimadzu UV–visible spectrophotometer UV-2401PC using methanol as a solvent;  $\lambda_{\text{max}}$  is given in nm ( $\epsilon$ ). IR spectra were recorded on a PerkinElmer Spectrum One FTIR spectrophotometer in KBr discs. Elemental analyses were performed on a Euro-Vector EA3000 elemental analyzer.  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra were recorded on a Bruker Avance ( $^1\text{H}$ , 300 MHz;  $^{13}\text{C}$ , 75 MHz) spectrometer using  $\text{CDCl}_3$  as solvent and TMS as an internal standard;  $\delta$  are in ppm and coupling constants ( $J$ ) in Hz. Electron impact mass spectra were obtained using a 3200 Q TRAP LC-MS/MS System MDS SCI EX Shimadzu Prominence LC and Varian 500-MS (Model 210) LC-MS IT mass spectrometer. The boiling point of petroleum ether used was in the range of 60–80 °C. Silica gel (60–120 mesh) (S.D. Fine Chemicals Ltd.) was used in column chromatography. Microwave-assisted reactions were performed using a Startsynth Microwave Synthesis Labstation model microwave reactor. All reactions were performed in the appropriate volume vessel. Temperature was measured with an IR sensor and reaction times are given as hold times.

## General procedures for microwave-assisted syntheses of cycloadducts **20–26**

### (i) General procedure for the cycloaddition without $\text{TiCl}_4$

A mixture of **19** (900 mg, 6 mmol) and **12–18** (0.6 mmol) was taken in a sealed glass vial and heated in a microwave reactor (Table 1). The reaction mixture was taken out of the microwave reactor and allowed to cool. The colorless semi-solid thus obtained was purified by silica gel column chromatography. Elution with petroleum ether/ $\text{CHCl}_3$  afforded the corresponding cycloadducts **20–26**.

### (ii) General procedure for the cycloaddition with $\text{TiCl}_4$

A mixture of **19** (900 mg, 6 mmol) and **12–18** (0.6 mmol) was taken in a 50 mL capacity round-bottom flask. Then, 0.5 mL of  $\text{TiCl}_4$  was added to the same reaction mixture. The flask was irradiated in a microwave reactor (Table 1). Then the reaction mixture was taken out of the microwave reactor and allowed to cool. The dark brown solid thus obtained was purified by silica gel column chromatography. Elution with petroleum ether/ $\text{CHCl}_3$  afforded the corresponding cycloadducts **20–26**.

# Theoretical analysis of *trans*-[PtCl<sub>2</sub>(NH<sub>3</sub>)(thiazole)] and *trans*-[PtCl<sub>2</sub>(thiazole)<sub>2</sub>] binding to biological targets — Factors influence binding kinetics and adduct stability

Dongdong Zhang, Xiuli Ren, and Lixin Zhou

**Abstract:** Full reaction energy profiles for *trans*-[PtCl<sub>2</sub>(NH<sub>3</sub>)(thiazole)] and *trans*-[PtCl<sub>2</sub>(thiazole)<sub>2</sub>] binding to sulfur- and nitrogen-containing biorelevant ligands were constructed by the density functional theory (DFT) method. Calculated results demonstrate that *trans*-platinum complexes can interact with biological targets, affording cis and trans products via very similar transition states. For different substituents, sulfur-containing ligands constitute kinetically preferred targets for platinumation, whereas the platinumation of nitrogen-containing ligands is more favorable thermodynamically. This is consistent with previous experimental studies. Calculated results also suggest that the trans effect, the influence of the ligand, the size of the ligand, and hydrogen bonding play important roles in binding kinetics and stabilizing adducts.

**Key words:** density functional theory, platinum antitumor drugs, DNA, amino acid residue.

**Résumé :** Faisant appel à la méthode de la théorie de la fonctionnelle de la densité (TFD), on a construit des profils complets pour les énergies de réaction de fixation du *trans*-[PtCl<sub>2</sub>(NH<sub>3</sub>)(thiazole)] et du *trans*-[PtCl<sub>2</sub>(thiazole)<sub>2</sub>] sur des ligands bio-pertinents contenant du soufre et de l'azote. Les résultats calculés démontrent que les complexes de platine *trans* peuvent interagir avec des cibles biologiques par le biais d'états de transitions très semblables pour conduire à la formation de produits cis et trans. Pour différents substituants, les ligands contenant du soufre constituent les cibles privilégiées d'un point de vue cinétique pour la platination alors que la platination des ligands contenant de l'azote est plus favorisée d'un point de vue thermodynamique. Ces résultats sont en accord avec les résultats expérimentaux. Les résultats calculés suggèrent aussi que l'effet trans combiné à l'influence du ligand, à la taille du ligand et à la formation de liaison hydrogène jouent des rôles importants dans la cinétique de fixation et de stabilisation des adduits.

**Mots-clés :** théorie de la fonctionnelle de la densité, médicaments antitumoraux dérivés du platine, ADN, résidu d'acide aminé.

[Traduit par la Rédaction]

## Introduction

Cisplatin<sup>1</sup> has been applied extensively in cancer chemotherapy, but toxicity and resistance limit its clinical usage. To overcome these limitations, considerable efforts have been made to find new platinum antitumor drugs with lower toxicity and better activity.<sup>2–7</sup> Even though it was previously believed that the cis configuration was required to generate active complexes, some mononuclear platinum(II) complexes with a trans configuration have exhibited significant cytotoxic activity in tumor cell lines. These complexes mainly fall into four structural types,<sup>7</sup> namely, *trans*-Pt(II) complexes containing iminoether ligands, planar amine ligands, nonplanar heterocyclic ligands, and aliphatic amine ligands.

The antitumor platinum complexes have been the focus of experimental<sup>7–14</sup> and theoretical<sup>15–21</sup> investigations since the discovery of the anticancer activity of cisplatin. Although

the precise mechanism of action of cisplatin remains unknown, it is generally accepted that its ultimate target is the N7 atom of purine bases.<sup>1</sup> Prior to the attack on DNA, the neutral platinum compound needs to be activated to the monoaqua or diaqua species.<sup>22–28</sup> The first binding to this site generates monofunctional adducts, with guanine being preferred over adenine, and further binding affords intra- and inter-strand adducts. Specifically, the 1,2-d(GpG) intra-strand adduct is essential for the antitumor effect.<sup>1</sup> The hydrated cisplatin binding to DNA was intensively studied with a variety of theoretical methods.<sup>29–35</sup> The preference for guanine over adenine as a target for platinumation was explained in terms of kinetics and thermodynamics, and the role of hydrogen bonds in stabilizing the transition states and products of cisplatin with purine bases was also analyzed in detail.<sup>36,37</sup>

The mode of action of *trans*-platinum antitumor complexes seems to be different from that of cisplatin, as it has

<sup>1</sup>Corresponding author (e-mail: tlzhou@jnu.edu.cn).

been suggested that different compounds appear to have different binding kinetics, and also the structural details of the resulting DNA adducts appear to differ to some degree.<sup>2,38</sup> Our previous computational studies of antitumor *trans*-platinum complexes containing aliphatic amine ligands<sup>39</sup> and picoline<sup>40</sup> binding to purine bases suggested that *trans*-platinum complexes could interact with DNA, affording *cis*- and *trans*-monofunctional adducts, and the *cis* product may further react with purine bases, forming bifunctional adducts such as cisplatin.

In addition to binding to DNA bases, platinum drugs did interact with sulfur- and nitrogen-containing peptides and proteins.<sup>12,41–47</sup> According to the hard and soft acids and bases principle, a strong affinity to the sulfur ligands could be expected for platinum.<sup>12</sup> However, Deubel<sup>48,49</sup> investigated the competition of sulfur- and nitrogen-containing ligands in the first substitution of hydrated cisplatin by biological targets with density functional theory (DFT) and continuum dielectric calculations, demonstrating an intrinsic preference for nitrogen over sulfur ligands for platinum. In that study,<sup>48</sup> activation free energies were estimated as the energy difference between transition states and separated reactants, and the reactant complexes were not taken into account. The neglecting of reactant complexes may result in underestimating the activation barrier for substitution reactions.

In the current study, full reaction energy profiles for the binding of two activated *trans*-platinum complexes with planar amine ligands, *trans*-[PtCl<sub>2</sub>(NH<sub>3</sub>)(thiazole)] (*trans*-PtTz) and *trans*-[PtCl<sub>2</sub>(thiazole)<sub>2</sub>] (*trans*-PtTz2),<sup>5,6,8,50</sup> to nitrogen- and sulfur-containing biological targets (Fig. 1) were constructed. We also estimated bond dissociation energies of Pt–L2 in all separated products. The objective of the present study is to reveal the competition of nitrogen and sulfur ligands in the substitutions of *trans*-PtTz and *trans*-PtTz2 by biorelevant ligands (L2), as well as the factors influencing the binding kinetics and adduct stability. The current work may contribute to a better understanding of the mechanism of action for platinum complexes and be of benefit for future drug design.

## Computational details

The geometries of separate reactants (R), reactant complexes (RC), transition states, product complexes, and separate products (P) were optimized at the DFT/B3LYP<sup>51,52</sup> level. The LanL2DZ<sup>53–55</sup> effective core potential basis set was used for the platinum atom and the 6-31G(d, p) Pople basis set was applied for all other atoms. Vibrational frequency calculations were based on analytical second derivatives on the same level of theory to confirm that the stationary point found was the local minimum for reactants and products and the first-order saddle point for transition states and to derive the zero-point vibrational energy and vibrational entropy correction at 298.15 K and 1 atm (1 atm = 101.325 kPa). The transition states were further confirmed by intrinsic reaction coordinate calculations.<sup>56,57</sup>

To obtain more accurate energies, energies were reevaluated by additional single-point calculations at the B3LYP/(LanL2DZ+6-311++G (2d, 2p)) level of theory. Solvent effects were accounted for by means of single-point calculations

on all stationary structures with the isoelectric focusing polarized continuum model.<sup>58–60</sup> The dielectric constant of water ( $\epsilon_{\text{water}} = 78.39$ ) was used to approximate the bulk effects of solvation.

The complexation energies ( $\Delta E_{\text{CE}}$ ) for reactant complexes and bond dissociation energies (BDEs) for Pt–L2 in separated products were computed at the B3LYP/(LanL2DZ+6-311++G (2d, 2p)) level with the inclusion of the basis set superposition error (BSSE).<sup>61,62</sup> The complexation energies were computed in both gas phase and aqueous solution according to the formulas

$$\Delta E_{\text{CE(g)}} = E_{\text{RC(g)}} - E_{\text{Pt(g)}} - E_{\text{L2(g)}} + \Delta E_{\text{BSSE(g)}}$$

$$\Delta G_{\text{CE(aq)}} = G_{\text{RC(aq)}} - G_{\text{Pt(aq)}} - G_{\text{L2(aq)}} + \Delta E_{\text{BSSE(g)}}$$

The BDEs for Pt–L2 were predicted according to the following formula:

$$E_{\text{BDE}} = E_{\text{fragment1(g)}} - E_{\text{fragment2(g)}} - E_{\text{product(g)}} + \Delta E_{\text{BSSE(g)}}$$

All computations were done by Gaussian 03.<sup>63</sup>

Many efforts were devoted to exploring different structural motifs, and the ones that generated the lowest energy structures were adopted for further discussion. All located structures are given in the Supplementary data. The reaction mechanism suggests the formation of reactant complexes in the first stage. Then the reaction proceeds via a transition state forming product complexes. It is well documented that the ligand substitution reactions display double-well potential energy surface as shown in Fig. 2. The activation energy was calculated as the energy difference between the transition states and reactant complexes. This approach was used with success in a number of studies.<sup>36,39,64</sup> The reaction free energy was estimated as the energy difference between the separated products and separated reactants.

## Results and discussion

For *trans*-PtTz binding to L2, there are three possible reaction paths, as shown in Fig. 3. In path 1, *trans*-PtTz reacts with L2 and forms *trans* products, and this path is denoted as TT. In paths 2 and 3, *trans*-PtTz binding to L2 affords two possible *cis* products. In *cis* product 1 (P1), L2 is *trans* to the ammine ligand, while L2 is adjacent to the ammine ligand in *cis* product 2 (P2).

There are two possible reaction paths in the case of *trans*-PtTz2 binding to L2 (Fig. 3). One path is *trans*-PtTz2 reacting with L2 and affording the *trans* product, and this path is denoted as TT; the other path is *trans*-PtTz2 binding to L2 and affording the *cis* product, which is named TC.

To predict the stability of reactant complexes, complexation free energies for activated platinum complexes with different substituents were calculated. Overall, for every activated reactant, the reactant complexes with nitrogen-containing ligands are more stable than those with sulfur-containing ligands, as shown in Fig. 4 and Fig. S1 in the Supplementary data. Notably, the major difference between Lys and Cys is the heteroatom. R1...Lys, R2...Lys, R3...Lys, and R4...Lys are preferred by 11.5, 8.2, 13.1, and 12.5 kcal/mol in complexation free energies over R1...Cys, R2...Cys,

**Fig. 1.** Active species considered as reactants and potential biological targets for platination.**Fig. 2.** Energy profile of substitution reactions.

R3...Cys, and R4...Cys, respectively (Fig. 4). This reveals complexation free energies in favor of the formation of reactant complexes with nitrogen-containing ligands. However, reactant complex stabilization will increase the activation energies for reactions with nitrogen-containing ligands.

Transition states for activated reactants binding to L2 were located. Our calculations reveal that trans-reactant complexes can afford trans- and cis-product complexes via identical or very similar transition states. This is consistent with the result obtained before.<sup>39,40</sup>

The solution-phase activation free energies for platination of L2 are summarized in Table 1 and the gas-phase activation energies are given in Table S1 in the Supplementary data. Calculated results predict that the platination of sulfur-containing ligands is preferred over the platination of nitrogen-containing ligands in terms of kinetics. Remarkably, the main difference between Cys and Lys is the heteroatom. The kinetic preferences for binding to Cys over Lys are about 9.9, 10.1, 12.1, and 14.1 kcal/mol for R1, R2, R3, and R4, respectively. Although the integration of nitrogen into aromatic heterocycles lowers the activation free energy moderately (Table 1 and Table S1 in the Supplementary data), the kinetic preference of platinum for sulfur-containing over nitrogen-containing biorelevant ligands is maintained. The kinetic preference of platinum for sulfur-containing ligands is in good agreement with experimental studies of Pt complexes.<sup>12,45,47</sup>

Many efforts were made to locate the lowest energy tran-

**Fig. 3.** Possible reaction paths for the substitution reactions.

sition states for activated reactants binding to purine bases. Calculated results revealed that the energy of the transition state is largely influenced by hydrogen bonding. The influence of hydrogen bonding on platinum complexes binding to purine bases was analyzed in previous works.<sup>36,37,39</sup> Our

**Fig. 4.** Complexation free energies for activated reactants with different substituents.

result is largely in agreement with the previous works. Therefore, in this research we will not discuss it further. The activation energies for R1 and R2 binding to purine bases are lower than those of mono-aquated cisplatin, which are at 24.59 and 30.15 kcal/mol<sup>37</sup> for platination of guanine and adenine, respectively. However, R3 and R4 show higher activation free energies than diaquated cisplatin binding to guanine and adenine, which are at 19.5 and 24.0 kcal/mol,<sup>36</sup> respectively. This is consistent with trans-effect theory, since in R1 and R2 the ligand trans to leaving water is chloride, while it is ammine in cisplatin and water in R3 and R4, and chloride displays a stronger trans effect than ammine, which has a stronger trans effect than water.<sup>64,65</sup>

The solution-phase reaction free energies of activated reactants binding to L2 and affording cis and trans products are compiled in Table 2 and gas-phase reaction energies are summarized in Table S2 in the Supplementary data. Overall, the platination of nitrogen-containing ligands is preferred thermodynamically over the platination of sulfur-containing ligands. In particular, the platination of Lys is thermodynamically preferred over the platination of Cys by 11.1, 7.0, 6.3, and 7.5 kcal/mol for R1, R2, R3, and R4, respectively. The thermodynamic preference of platinum for nitrogen-containing ligands is in good agreement with previous theoretical<sup>48</sup> and experimental<sup>12,45,47,66</sup> studies.

R1 reacting with L2 forms one series of trans products and two series of cis products, and R2 binding to L2 forms one series of cis products and one series of trans products, as shown in Fig. 3. In general, the solution-phase reaction free energies are very similar for R1 and R2 with a ligand affording cis and trans products (Table 2). Except for reactions of R1 with guanine, cis P2 and trans P are about 4.5 kcal/mol more favorable than cis P1 in free energy. This is due to cis P2 and trans P benefiting from the hydrogen bond between the C=O of the guanine and ammine ligand, whereas cis P1 is unable to form this hydrogen bond.

R3 reacts with L2, affording three series of products: one series of trans products and two series of cis products, cis P1 and cis P2 (Fig. 3). In general, the reaction free energy differences for R3 binding to a ligand forming trans P, cis P1,

and cis P2 are insignificant (Table 2). Except in the case of binding to guanine, cis P1 and cis P2 are preferred by about 6.0 kcal/mol over trans P in solution-phase free energy. This is due to strong hydrogen bonds formed between the water ligand and C=O of guanine in cis P1 and cis P2, while C=O of guanine forms a hydrogen bond with the ammine ligand in trans P. The C=O...H<sub>2</sub>O hydrogen bond is stronger than the C=O...H<sub>3</sub>N hydrogen bond; consequently, cis P1 and cis P2 are more stable than trans P.

In the case of R4 binding to L2, two series of products, trans and cis products, are obtained. Similarly, the reaction free energies for R4 binding to a target affording trans P and cis P are similar. However, for products with guanine, cis P is significantly stabilized by the strong hydrogen bond between the C=O of guanine and the water ligand, and as a result, cis P is 8.69 kcal/mol lower in solution-phase free energy than trans P.

When comparing reaction free energies of activated *trans*-PtTz and *trans*-PtTz2 binding to the same target, *trans*-PtTz is more thermodynamically favorable than *trans*-PtTz2 (Table 2). This can be attributed to the smaller size of the ammine group and its ability to act as a hydrogen bond donor. For example, if the reactions of R1 and R2 with Lys affording trans P are compared, R1 is 4.4 kcal/mol more thermodynamically favorable than R2. Moreover, the reaction of R1 with guanine is about 5.5 kcal/mol more favorable in reaction free energy than that of R2. This is because a strong hydrogen bond is formed between the C=O of guanine and the ammine ligand in products of R1 with guanine, cis P2, and trans P. However, this hydrogen bond is absent in products of R2 with guanine. The smaller size of the ammine group and its ability to act as a hydrogen bond donor may also be responsible for *trans*-PtTz exhibiting better antitumor activity than *trans*-PtTz2.<sup>6,67</sup> This conclusion is also consistent with previous studies of cisplatin.<sup>48,68</sup>

The predicted trend of BDEs for Pt–L2 in all separated products is depicted in Fig. 5 and the detailed BDEs for Pt–L2 energies are summarized in Tables S3–S6 in the Supplementary data. Overall, BDEs for Pt–N bonds are higher than those of Pt–S in each series of products as shown in Fig. 5. For example, in the products of R2 with L2, the BDE for Pt–Lys is 8.91 kcal/mol higher than that of Pt–Cys in cis P. The calculated BDEs reveal that the Pt–N bond is intrinsically stronger than the Pt–S bond. The stronger Pt–N bond and thermodynamic preference for the formation of Pt–N adducts provide the possibility of Pt–S products evolving into Pt–N adducts.<sup>45,47,66</sup>

Calculated results also suggest that BDEs of Pt–L2 are higher in cis products than in the trans isomers for both products of R1 and R2 with L2 (Fig. 5a). For example, comparing the BDEs of Pt–Cys in cis and trans products of R2 with Cys, the BDE for Pt–Cys in the cis isomer is 8.90 kcal/mol higher than that in its trans counterpart. This is caused by L2 being trans to Cl<sup>–</sup> in trans products while it is trans to ammine or thiazole in cis isomers, and Cl<sup>–</sup> has a stronger trans influence than ammine and thiazole.<sup>64,65</sup>

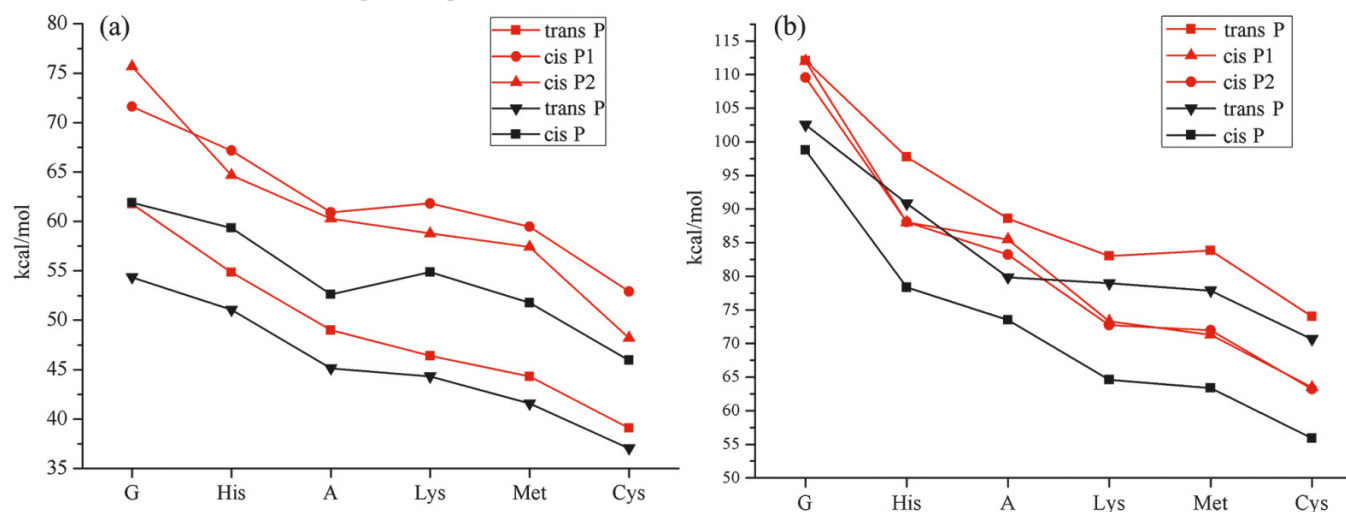

However, for the products of R3 and R4 with L2, in general, the BDEs for Pt–L2 are higher in the trans products than in their cis counterparts (Fig. 5b). For example, in the cis and trans P of R4 with Cys, the BDE for Pt–S in trans P is predicted to be 14.75 kcal/mol higher than that in cis P.

**Table 1.** Activation free energies (kcal/mol) for activated reactants binding to biological targets.

Biological targets	Reactants	Reaction paths			Reactants	Reaction paths

**Fig. 5.** Calculated BDEs for Pt-L2 in products of (a) R1 and R2 with L2 and (b) R3 and R4 with L2. The red line represents products of R1 and R3 with L2 and the black line represents products R2 and R4 with L2.

The trans influence of the ligand is responsible for this, because in trans products, L2 is located in the trans position to the water ligand while L2 is trans to ammine or thiazole in cis products, and water has a weaker trans influence than ammine and thiazole. Even though in cis products of R3 and R4 with purine bases, cis isomers benefit from the hydrogen bond between the C=O of guanine or C–NH<sub>2</sub> of adenine and water ligand, the BDE for Pt–N in the trans isomer is still higher than that in the cis counterpart (Fig. 5b).

## Conclusion

We have examined the kinetic and thermodynamic behavior of *trans*-PtTz and *trans*-PtTz2 binding to biorelevant ligands. Calculated results demonstrate that *trans*-platinum complexes can interact with biological targets and afford cis and trans products via identical or very similar transition states. The factors that influence the binding kinetics and product stability are summarized as follows. (i) The substituents: Our calculations suggest that sulfur-containing biorelevant ligands constitute kinetically preferred targets for platination, while the platination of nitrogen-containing ligands is preferred thermodynamically. This result is in good agreement with experimental studies. In previous studies by Deubel,<sup>48,49</sup> the intrinsic kinetic preference for nitrogen over sulfur ligands for platinum was suggested. Nonetheless, reactant complexes were not taken into account in that study. We find that the complexation free energies favor the formation of reactant complexes with nitrogen-containing ligands. This results in reactions with nitrogen-containing ligands unfavorable in kinetics in comparison with those with sulfur-containing ligands. (ii) The trans effect of the ligand: We also find that the trans effect plays an important role in ligand substitution reactions in combination with hydrogen bonding. When chloroaqua complexes are considered as reactants, the activation free energies for two platinum complexes binding to purine bases are lower than those of cisplatin; however, if diaqua complexes are employed as reactants, activation free energies for two complexes binding to purine bases are higher than those of cisplatin. This is because in chloroaqua complexes the ligand trans to leaving water is chloride, while it is ammine in cisplatin and water in diaqua complexes, and chloride displays a stronger trans effect than ammine, which has a stronger trans effect than water. (iii) The trans influence of the ligand: In products of R1 and R2 with L2, the BDEs for Pt–L2 are higher in cis products than in the trans counterpart, while BDEs for Pt–L2 are lower in cis products than in the trans counterpart in products of R3 and R4 with L2. This is caused by the different trans influence of different ligands positioned trans to Pt–L2. In chloroaqua complexes, the ligand trans to Pt–L2 is chloride in trans products while it is ammine or thiazole in cis products, and chloride has a stronger trans influence than ammine and thiazole. In products of diaqua complexes with L2, water is located trans to the Pt–L2 in trans products whereas ammine or thiazole is positioned trans to Pt–L2 in cis products, and water shows a weaker trans influence than ammine or thiazole. (iv) The size of the ligand: When comparing *trans*-PtTz with *trans*-PtTz2, *trans*-PtTz is more thermodynamically favorable than *trans*-PtTz2. The smaller size of the ammine ligand and its ability to act as a hydrogen bond donor are responsible for this.

# Organosulfur oxoacids. Part 2. A novel dimethylthiourea metabolite — Synthesis and characterization of the surprisingly stable and inert dimethylaminoiminomethane sulfonic acid

Jeffrey L. Petersen, Adenike A. Otoikhian, Moshood K. Morakinyo, and Reuben H. Simoyi

**Abstract:** A new metabolite of the biologically active thiocarbamide dimethylthiourea (DMTU) has been synthesized and characterized. DMTU's metabolic activation in the physiological environment is expected to be dominated by S-oxygenation, which produces, successively, the sulfinic, sulfinic, and sulfonic acids before forming sulfate and dimethylurea. Only the sulfinic and sulfonic acids are stable enough to be isolated. This manuscript reports on the first synthesis, isolation, and characterization of the sulfonic acid: dimethylaminoiminomethanesulfonic acid (DMAIMSOA). It crystallizes in the orthorhombic *Pbca* space group and exists as a zwitterion in its solid crystal form. The negative charge is delocalized over the sulfonic acid oxygens and the positive charge is concentrated over the planar N–C–N framework rather than strictly on the  $sp^2$ -hybridized cationic carbon center. As opposed to its sulfinic acid analogue, DMAIMSOA is extremely inert in acidic environments and can maintain its titer for weeks at pH 6 and below. It is, however, reasonably reactive at physiological pH conditions and can be oxidized to dimethylurea and sulfate by mild oxidants such as aqueous iodine.

**Key words:** thiourea, metabolites, bioactivation.

**Résumé :** On a effectué la synthèse d'un nouveau métabolite du thiocarbamide de la diméthylthiourée (DMTU), un produit biologiquement actif. On s'attend à ce que l'activation métabolique du DMTU dans un environnement physiologique devrait être dominée par une S-oxygénation qui conduit à la formation successive d'acides sulfénique, sulfinique et sulfonique avant de donner un sulfate et de la diméthylurée. Seuls les acides sulfinique et sulfonique sont suffisamment stables pour être isolés. Dans ce travail, on rapporte la première synthèse, l'isolation et la caractérisation de l'acide sulfonique, l'acide diméthylaminoiminométhanesulfonique (ADMAIMSO). Il cristallise dans le système orthorhombique, groupe d'espace *Pbca* et dans sa forme cristalline solide il existe sous la forme de zwitterion. La charge négative est délocalisée sur les oxygènes de l'acide sulfonique et la charge positive est concentrée sur le squelette planaire N–C–N plutôt que strictement sur le centre carboné cationique d'hybridation  $sp^2$ . Par opposition à son analogue l'acide sulfinique, le ADMAIMSO est extrêmement inerte dans des environnements acides et il peut maintenir son titre pour plusieurs semaines à des pH de 6 ou moins. Il est toutefois assez réactif dans des conditions de pH physiologique et il peut être oxydé en diméthylurée et en sulfate par des oxydants doux, tel une solution aqueuse d'iode.

**Mots-clés :** thiourée, métabolites, bioactivation.

## Introduction

*N,N'*-Dimethylthiourea (DMTU) is a well-known sulfur-based radical scavenger.<sup>1–4</sup> It is a small, highly diffusible molecule that efficiently scavenges toxic oxygen metabolites and reduces oxidative injury in many biologic systems. There have been very few studies undertaken on the fate and nature of the metabolites formed after such antioxidants have mediated oxidative injury.

Our bodies have evolved several very efficient methods of

handling a large numbers of xenobiotics.<sup>5</sup> Our bodies, however, do not have a consistent answer to sulfur-based xenobiotics. Nearly all relevant sulfur chemistry in the human body is of organic origin. The range of physiological effects associated with organic sulfur chemistry spans from therapeutic to toxic.<sup>6</sup> There is no other group of compounds that displays such a wide range of biological activity. While the action and effects of organosulfur compounds on human health is well-documented, the mechanisms by which these effects are expressed are not known. Drug design and the

ability to predict physiological effects is dependent upon our ability to understand the mechanism of metabolic activation of the relevant drug.

Sulfur compounds, such as DMTU, undergo a variety of metabolic reactions in the physiological environment such as oxidations, reductions, hydrolysis, and conjugations.<sup>7</sup> Sulfur, in most organic configurations, however, is nucleophilic, and nucleophilic atoms are usually susceptible to metabolic oxidations.<sup>8</sup> Thus, the oxidation of sulfur-containing compounds represents a very important aspect of sulfur metabolism. Oxidations of sulfur compounds appear to be involved in many cellular functions, including the reductive degradation of polypeptide hormones and proteins, regulation of protein synthesis, maintenance of intracellular redox potential, and protection of the cell from oxidative damage.<sup>9</sup> The aerobic physiological environment encourages S-oxygenation as the major metabolic activation pathway for most organo-sulfur compounds where the sulfur center is successively oxygenated, sometimes all the way to the sulfate, culminating in the cleavage of the attendant C–S bond.<sup>10,11</sup>

The molecular basis for S-oxygenation is not well-understood, although S-oxygenation of xenobiotics by microsomes supplemented with NADPH and oxygen has been known for years. In general, metabolism of chemically stable compounds depends on enzyme catalysis, and both the microsomal cytochrome P-450 system and the flavin-containing monooxygenases have been implicated in S-oxygenations catalyzed by microsomes.<sup>8,12,13</sup>

DMTU, although in most situations is effective in decreasing oxidant-mediated injury, has, however, inexplicably failed, on occasions, to reduce injury in some biological systems where oxygen metabolites were ostensibly causing damage.<sup>14,15</sup> It has also been experimentally shown that increasing the DMTU dose in rats did not increase protection and may, in fact, be associated with more injury. DMTU should exercise its physiological effects after metabolic activation and it is generally accepted that these physiological effects are derived from its metabolites.

In a previous publication from this laboratory,<sup>16</sup> we synthesized the first stable metabolite of DMTU, dimethylaminoiminomethanesulfonic acid (DMAIMSA). This metabolite was surprisingly very reactive and its aerobic decomposition in slightly basic to basic environments produced dithionite and a cascade of reactive oxygen species that were genotoxic, and could explain some of the inadvertent toxicity associated with DMTU. The general progress of the oxidation of a sulfur center initially proceeds through the sulfenic acid (unstable except in sterically hindered sulfenic acids),<sup>17–19</sup> then to the sulfinic acid (e.g., DMAIMSA), and then the sulfonic acid before cleavage of the C–S bond to form sulfate and an organic residue.<sup>20</sup> The existence of DMAIMSA had always been conjectured, but no one had managed to prepare and characterize this metabolite until the work of Otokhian and co-workers.<sup>16,21,22</sup>

Since the sulfonic acid (dimethylaminoiminomethanesulfonic acid, DMAIMSOA) is expected to be the next metabolite after formation of DMAIMSA, we undertook to synthesize and characterize this metabolite, and hopefully, from its reactivity, be able to rationalize some of the observed conflicting physiological effects of DMTU. We report in this manuscript on this oxidation metabolite of

DMTU. Despite its similarity to DMAIMSA, DMAIMSOA proved to be very different from DMAIMSA in terms of structure and reactivity.

## Experimental

### Materials

DMTU, hydrogen peroxide, and acetonitrile (Sigma-Aldrich) were purchased and used without any further purification.

Some batches of DMTU were damp and oily and could not form DMAIMSOA upon applying the synthetic procedure outlined below. Instead, the product formed slowly turned yellow upon exposure to the atmosphere and at ambient temperatures. The consistency of the DMTU batches was extremely important for the generation of high and consistent yields of DMAIMSOA. Aqueous iodine solutions were prepared by dissolving iodine crystals (Sigma-Aldrich) in distilled water followed by filtration and storage in the dark. Standard solutions of sodium hydroxide were purchased from Fisher Scientific.

### Synthesis of DMAIMSOA

*N,N*-Dimethylaminoiminomethanesulfonic acid (DMAIMSOA) was prepared according to a modified form of a synthetic procedure given in the literature for the synthesis of dimethylaminoiminomethanesulfonic acid (DMAIMSA).<sup>16</sup> *N,N'*-Dimethylthiourea (DMTU; 10.42 g, 0.10 mol) were dissolved in 80 mL of a 50% acetonitrile–water solution, which was chilled in an acetone–CO<sub>2</sub> ice bath at –50 °C. To this ice-cold solution, 3 equiv (0.30 mol) of hydrogen peroxide, which was measured as a 30.61 mL aliquot of a 30% concentrated solution, were added dropwise with the rate of addition maintained such that the temperature of the reaction mixture did not exceed –30 °C. The 3:1 ratio of hydrogen peroxide to DMTU had to be strictly maintained to avoid the production of mixtures of oxoacids. The frozen mixture was allowed to sit until it melted and it was then stirred at room temperature for 2 h. The resulting long, colorless, needle-like crystals were filtered and washed twice with a 50% acetonitrile–water solution and deionized water and then dried in a desiccator. Typical yields before recrystallization were approximately 90%. Further recrystallization and purification was performed using the same strength of acetonitrile solution. Most of the product was lost during the washing and recrystallization of DMAIMSOA, thus giving a lower overall yield since it is highly soluble in water.

### Methods

UV–vis spectra were taken on a PerkinElmer Lambda 2S spectrophotometer equipped with a thermostatable compartment. Most experiments were performed at 25 ± 0.5 °C. Distilled and deionized water were utilized to prepare all standard solutions used in these experiments. The reaction between DMAIMSOA and HOCl was monitored by following the absorbance of DMAIMSOA at 215 nm where an absorptivity coefficient of 9025 (mol/L)<sup>–1</sup> cm<sup>–1</sup> had been deduced. The reaction between DMAIMSOA and iodine (as well as iodate) was followed by the use of the iodine–triiodide isosbestic point, which had been experimentally determined as 465 nm in this work and other previous studies from our laboratory using the same spectrophotometer.<sup>21</sup> Only freshly prepared iodine solutions were utilized. A Hi-Tech Scientific SF-DX2 stopped-flow spectrophotometer was used to follow the kinetics of DMAIMSOA oxidations and hydrolysis. KinetAsyst 2.1 software (High-Tech Scientific) was used for data acquisition and analysis. Temperature control was maintained with a NesLab RTE-101 thermostat bath. Some reaction solutions were degassed with argon and tightly capped to reduce the effects of dissolved oxygen.

### Description of the X-ray structural analysis of C<sub>3</sub>H<sub>8</sub>N<sub>2</sub>O<sub>3</sub>S·H<sub>2</sub>O

A colorless crystal of C<sub>3</sub>H<sub>8</sub>N<sub>2</sub>O<sub>3</sub>S·H<sub>2</sub>O was wedged in a glass capillary and then optically aligned on the four-circle of a Siemens P4 automated X-ray diffractometer. The reflections that were used for the unit cell determination were located and indexed by the automatic peak search routine provided by XSCANS.<sup>23</sup> C<sub>3</sub>H<sub>8</sub>N<sub>2</sub>O<sub>3</sub>S·H<sub>2</sub>O crystallizes in the centrosymmetric space group *Pbca* (*D*<sub>2h</sub><sup>15</sup>, No. 61). The final lattice parameters and orientation matrix were calculated from a nonlinear least-squares fit of the orientation angles of at least 35 reflections at 22 °C. The lattice parameters and other pertinent crystallographic information are summarized in Table 1 for C<sub>3</sub>H<sub>8</sub>N<sub>2</sub>O<sub>3</sub>S·H<sub>2</sub>O.

Intensity data were measured with graphite-monochromated Mo K $\alpha$  radiation ( $\lambda$  = 0.71073 Å) and variable  $\omega$  scans. Background counts were measured at the beginning and at the end of each scan with the crystal and counter kept stationary. The intensities of three standard reflections were measured after every 100 reflections and did not show any evidence of crystal decay. The raw data were corrected for Lorentz-polarization effects.

Initial coordinates for the nonhydrogen atoms were determined by a combination of direct methods and difference Fourier calculations with the use of SHELXTL 6.1.<sup>24</sup> The crystallographic asymmetric unit contains a molecule of water that is located in a general position and is hydrogen bonded to the O(2) atom. The hydrogen atoms of the water molecule were located and their positions and isotropic temperature parameters were refined. Idealized positions for the remaining hydrogen atoms were included as fixed contributions using a riding model with isotropic temperature factors set at 1.2 times that of the adjacent nonhydrogen atom. The positions of the methyl hydrogen atoms were optimized by a rigid rotating group refinement with idealized angles. Full-matrix least-squares refinement, based upon the minimization of  $\sum w_i |F_o^2 - F_c^2|^2$  with weighting  $w_i^{-1} = [\sigma^2(F_o^2) + (0.0528P)^2 + 0.880P]$  where  $P = (\max(F_o^2, 0) + 2F_c^2)/3$ , converged to give the final discrepancy indices<sup>25</sup> provided in Table 1. A correction for secondary extinction was applied. The maximum and minimum residual electron density peaks in the final difference Fourier map were 0.241 and –0.307 e Å<sup>–3</sup>, respectively (Table 2). The linear absorption coefficient, atomic scattering factors, and anomalous dispersion corrections were calculated from values found in the *International Tables of X-ray Crystallography*.<sup>26</sup>

## Results and discussion

### Description of the molecular structure of DMAIMSOA (SO<sub>3</sub>C(NHMe)<sub>2</sub>)

The molecular structure of DMAIMSOA was determined by X-ray crystallography. The perspective view is shown in Fig. 1. Like its sulfonic acid analogue,<sup>16</sup> it exists in its zwitterionic form in solid crystal form. The positive charge is delocalized over the N(2)–C(1)–N(1) framework with the sp<sup>2</sup> hybridization at the central carbon atom. Bond angles around this carbon atom add up to 360°. The C(1)–N bond distances of 1.291(4) and 1.306(4) Å are significantly shorter than a C–N bond distance of 1.47 Å, indicating considerable double bond character in both of them. The whole

three-bond network, after the s-bond framework, then comprises four electrons, both derived from the nitrogen p-orbitals, which interact with the vacant p<sub>π</sub>-orbitals of the

**Fig. 2.** Comparison traces of iodine oxidation of DMAIMSA and DMAIMSOA showing the relative inertness of DMAIMSOA to oxidation. Iodine solutions with DMAIMSOA held their titer for hours with no measurable consumption of iodine observed. [I<sub>2</sub>]<sub>0</sub> = 5.24 × 10<sup>−4</sup> mol/L, (a) [DMAIMSA]<sub>0</sub> = 2.0 × 10<sup>−4</sup> mol/L, and (b) [DMAIMSOA]<sub>0</sub> = 2.0 × 10<sup>−4</sup> mol/L.

formally cationic carbon center, imparting partial double bond character to both bonds, and hence their deviation from the expected value for a single bond. The negative charge is delocalized on the three oxygen atoms on the sulfonic acid group. The S—O bonds are also nearly equivalent, ranging between 1.433(3) and 1.440(3) Å. These are shorter than a normal S—O bond owing to the delocalization of the negative charge over the three oxygen atoms. These three S—O bonds are approximately 0.04 Å shorter than the two S—O bonds in DMAIMSA, which are at approximately 1.48 Å. The three oxygens form a nearly symmetric triangular base around the sulfur center except for the oxygen atom in close proximity to the methyl group, which is slightly displaced from this pyramidal shape by about 2° (Table 3).

The C—S bond, at 1.820(3) Å, is 0.03 Å longer than a typical C—S bond of 1.79 Å, but is noticeably shorter than the C—S bonds of 1.880 Å in DMAIMSA and 1.867 Å in unsubstituted aminoiminomethanesulfonic acid (AIMSA, thiourea dioxide). Both sulfonic acids are highly reactive with easy cleavage of the C—S bond to release highly reducing sulfur-based leaving groups.<sup>27</sup> DMAIMSOA is not densely packed, and has a density of 1.451 g cm<sup>−3</sup>, which is comparable to that exhibited by DMAIMSA of 1.496 g cm<sup>−3</sup>. Although DMAIMSOA shows hydrogen bonding through O(2) to the single water of crystallization in the unit cell, it is incapable of supporting strong and extensive hydrogen bonding, which would have been expected to increase its density as was observed with aminoiminomethanesulfonic acid (AIMSOA, thiourea trioxide) with a density of 1.948 g cm<sup>−3</sup>.<sup>28</sup>

### Reactivity of DMAIMSOA

DMAIMSA is known to be highly reactive, and its aerobic decomposition in mildly acidic and basic environments quickly and rapidly produces dithionite.<sup>16</sup> Its oxidation to dimethylurea and sulfate is facile. Figure 2 shows a simple experiment carried out to evaluate the rates of oxidation of DMAIMSA and DMAIMSOA in slightly acidic media (pH 5.0) by the weak biological oxidant iodine. While DMAIMSA is oxidized at a reasonable rate with bimolecular kinetics with a rate constant of 20.5 (mol/L)<sup>−1</sup> s<sup>−1</sup>,

**Fig. 3.** (a) UV spectral of incubated DMAIMSOA in water at a slightly acidic pH of 6 showing its inertness. The spectra scan was taken at 24 h intervals for 7 days. There is very little change in the absorbance of DMAIMSOA. [DMAIMSOA] =  $1.0 \times 10^{-4}$  mol/L. (b) UV spectra scan of the same DMAIMSOA solution as in Fig. 3a at a physiological pH of 7.4 phosphate buffer. At this slightly basic pH there is a noticeable decomposition of DMAIMSOA. (c) The effect of pH on the rate of decomposition of DMAIMSOA in 0.05 mol/L phosphate buffer. Substantial decomposition starts at pH conditions greater than 7. [DMAIMSOA] =  $1.0 \times 10^{-4}$  mol/L; pH (a) 6.2 (unbuffered), (b) 6.2, (c) 6.6, (d) 7.0, (e) 7.4, and (f) 8.2.

DMAIMSOA remains inert to oxidation at this pH. This was a noticeable difference in the reactivities of these aminosulfur oxoacids. This discrepancy in their reactivities has brought about a new school of thought that suggests, strongly, that in acidic media, the sulfonic oxoacid is unlikely to be an intermediate in the oxidation of the thiouredo group to sulfate and an organic residue.<sup>29</sup>

Figure 3 also displays the inertness of DMAIMSOA. In Fig. 3a, DMAIMSOA solutions are dissolved in water at a slightly acidic pH of 6 and allowed to sit, capped, and in the dark for a week. Other aminosulfur oxoacids show extensive decomposition in aqueous solutions.<sup>16</sup> Figure 3a shows that, even after 7 days, there is very little change in the absorbance of DMAIMSOA monitored at 215 nm. Figure 3b, on the other hand, shows the same DMAIMSOA solution, this time in a pH 7.4 buffer, which is slightly basic and is the physiological pH. At these conditions, there is noticeable decomposition of DMAIMSOA. The slight change in pH from Figs. 3a to 3b can impart a remarkable change in reactivity. Figure 3c shows, much more vividly, the rates of decomposition of DMAIMSOA at various pH conditions. In all traces, the pH was maintained by phosphate-type buffer solutions. The phosphate anions in this buffer mixture are not innocent, and are known to increase the rate of decomposition of aminosulfur oxoacids owing to their nucleophilic nature. Figure 3c shows that substantial decomposition commences at pH conditions greater than 7. While there is no decomposition observed around pH 6 (Fig. 3c, trace a), at pH 8.2 (Fig. 3c, trace f), however, complete decomposition of DMAIMSOA is attained within 3 min.

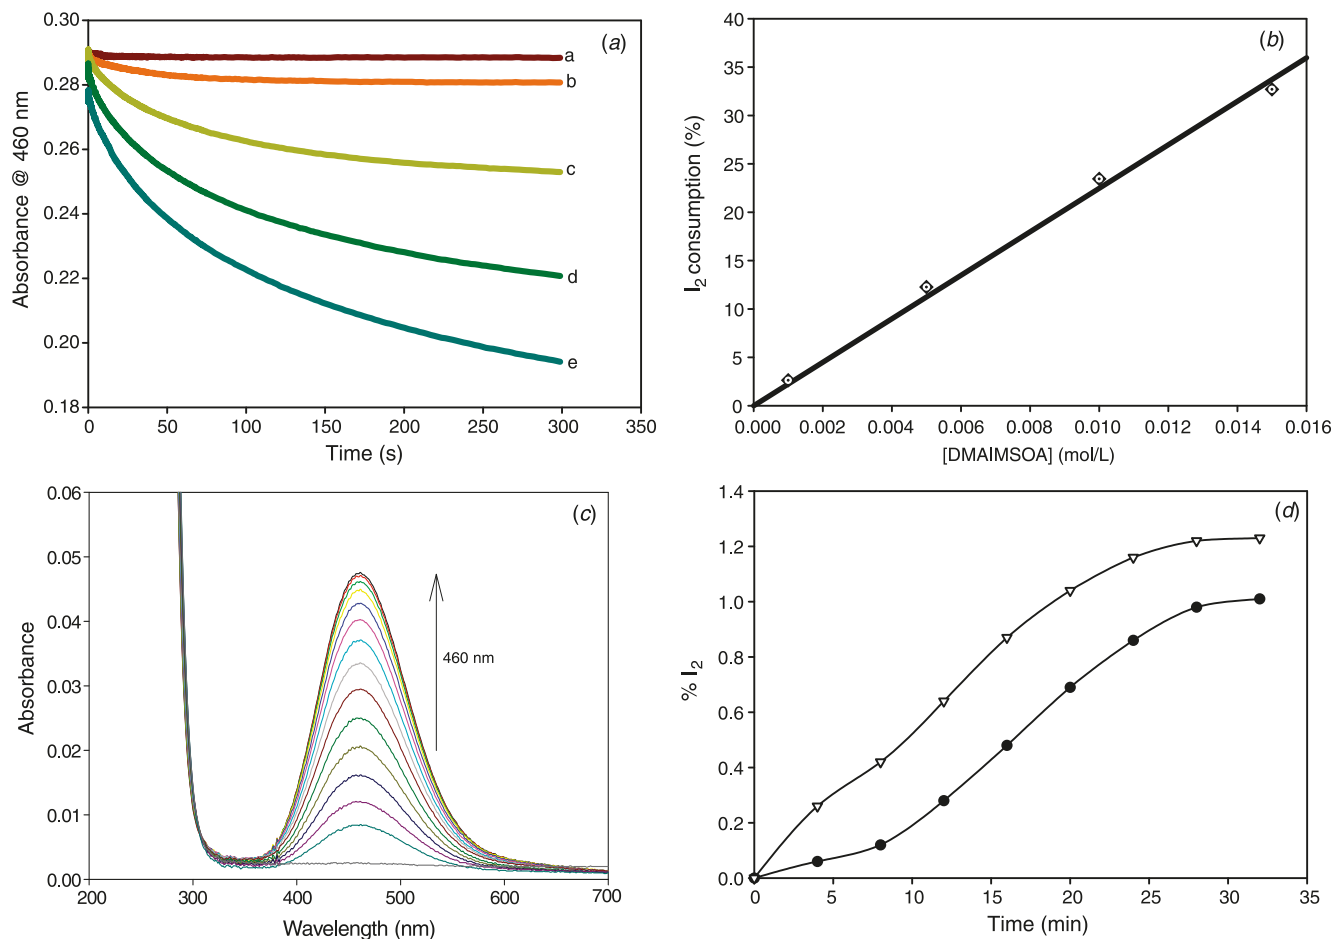

### Reactions with iodine and acidic iodate

It is not possible to spectrophotometrically observe  $I_2$ -DMAIMSOA reactions at high pH conditions because most of the aqueous iodine is converted into hypoiodous acid, which has no absorption in the visible range in neutral and acidic environments. Iodine, however, exists mostly in the aqueous molecular form and its consumption can be followed at 460 nm (see Fig. 4a). Figure 4a shows an initially reasonably fast rate of iodine consumption, which quickly slows down and shuts itself down about 300 s into the reaction. Figure 4a has an expanded scale, and shows that very little aqueous iodine is actually consumed. These  $I_2$ -DMAIMSOA solutions can be left overnight and the absorbance values reread after 24 h. After 24 h, the ratio of iodine consumed is shown in Fig. 4b. The linearity shows that the only reaction occurring is the consumption of iodine by DMAIMSOA. The expected stoichiometry for the oxidation of DMAIMSOA by iodine is 1:1

The percent consumption of iodine should allow for the calculation of the fraction of DMAIMSOA that is “oxidizable” because these fractions in Fig. 4b remain basically invariant on further incubation of the reaction solutions. This percentage iodine consumption is calculated on the basis of the stoichiometry in eq. [1] in which a 1:1 mol ratio of DMAIMSOA- $I_2$  is considered to be 100%. Using the plot in Fig. 4b and reaction stoichiometry in eq. [1], a simple calcu-

**Fig. 4.** (a) Absorbance traces showing the consumption of aqueous iodine by DMAIMSOA in unbuffered solutions. Despite the initial reasonably fast rate of consumption, very little aqueous iodine is consumed.  $[I_2(aq)] = 3.82 \times 10^{-4}$  mol/L,  $[DMAIMSOA] =$  (a) 0.0, (b) 0.001, (c) 0.005, (d) 0.010, and (e) 0.015 mol/L. (b) A linear plot showing the percent consumption of iodine in Fig. 4a after 24 h of  $I_2$ –DMAIMSOA incubation. (c) Multiple spectral scan measurements of the reaction of DMAIMSOA and acidic iodate taken every 2 min showing the formation of iodine at 460 nm. A very small amount of iodine is formed indicating that at these conditions only a negligible fraction of DMAIMSOA is oxidizable.  $[DMAIMSOA] = 0.025$  mol/L,  $[IO_3^-] = 0.025$  mol/L, and  $[H^+] = 0.05$  mol/L. (d) Comparison traces of the percent formation of iodine in the reactions of freshly prepared (closed circles) and 3-day-old (open triangles) DMAIMSOA solutions with acidic iodate.  $[DMAIMSOA] = 0.025$  mol/L,  $[IO_3^-] = 0.025$  mol/L, and  $[H^+] = 0.05$  mol/L.

lation shows that 0.77% of DMAIMSOA is oxidized after 24 h of reaction time. This shows that, at these conditions, only a very small fraction of DMAIMSOA is oxidized or oxidizable. In the acidic environment, iodate can also be used to evaluate the response of DMAIMSOA to oxidation. By using excess iodate concentrations, the amount of iodine produced can be utilized to calculate the amount of DMAIMSOA oxidized (see Fig. 4c). Initially, iodate oxidizes DMAIMSOA to produce iodide (reaction stoichiometry in eq. [2]), which is subsequently oxidized by the excess iodate to give iodine (reaction in eq. [3]) as the final reduction product of iodate.

Followed by the Dushman reaction:<sup>30</sup>

The addition of 5(eq. [2]) and eq. [3] eliminates iodide to

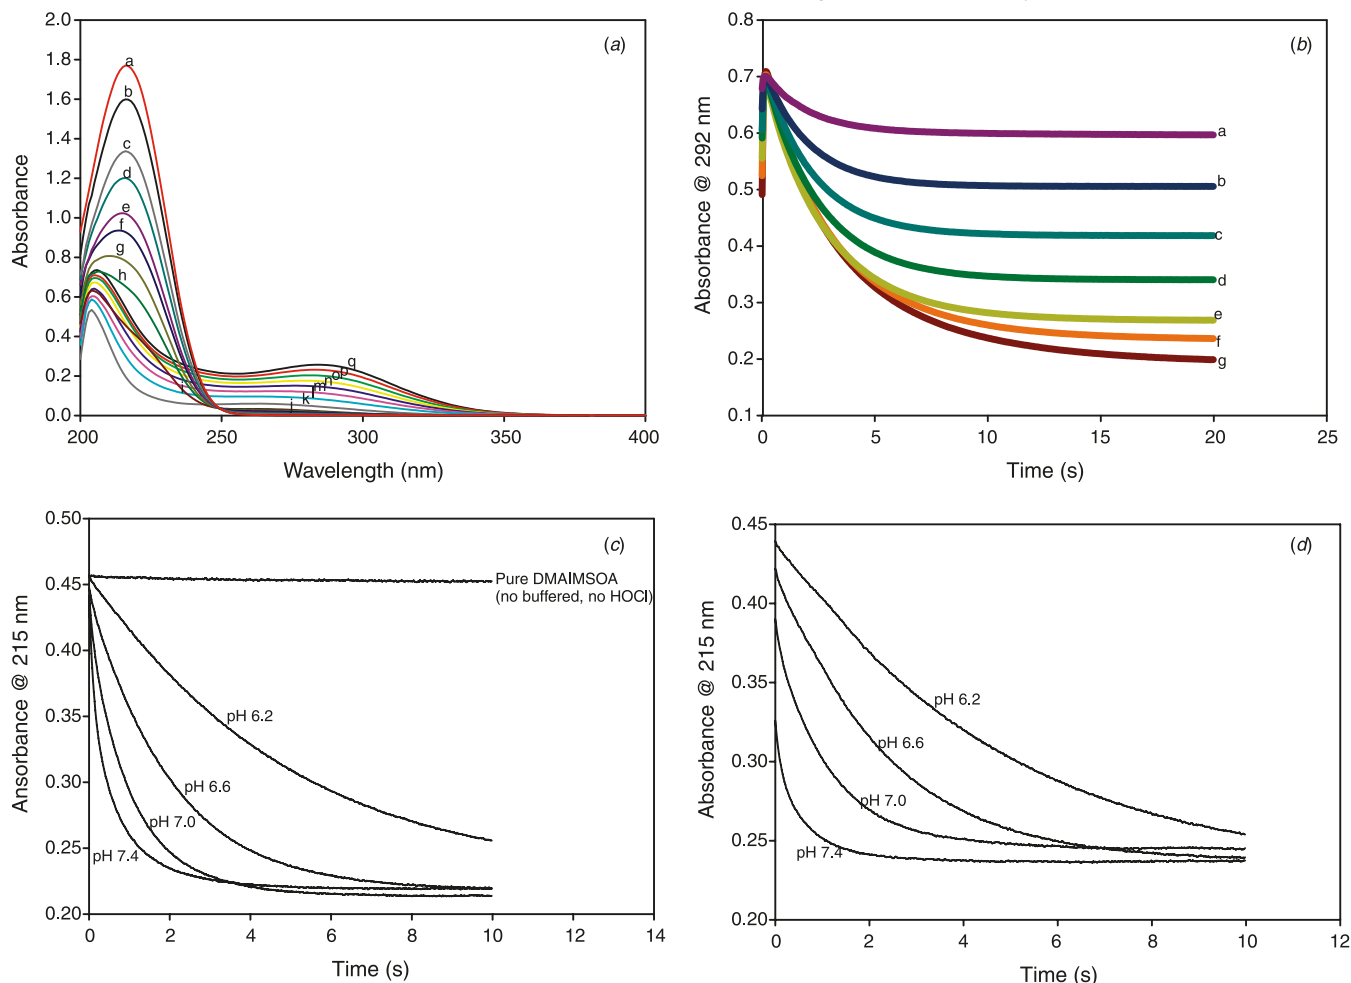

give the overall stoichiometry that gives iodine as the final product:

One can thus correlate the amount of iodine formed to the amount of DMAIMSOA consumed through the 5:1 ratio. Figure 4c shows that very little iodine is formed, also confirming that very little DMAIMSOA is oxidized under these conditions.  $IO_3^-$  is inert in basic environments, and thus this type of correlation can only be effected in this acidic environment. Previous work in our laboratory<sup>27,31</sup> and by others<sup>32</sup> had always conjectured that such aminosulfur oxoacids initially undergo an irreversible, entropy-driven hydrolysis to give a reducing sulfur species, which in DMAIMSOA's case is bisulfite:

**Fig. 5.** (a) UV spectral scans of the HOCl–DMAIMSOA reaction after 48 h of reaction time at pH 7.4 in 0.05 mol/L phosphate buffer. [DMAIMSOA] =  $2.0 \times 10^{-4}$  mol/L, [HOCl] = (a) 0 (not buffered), (b) 0 (buffered), (c)  $5.00 \times 10^{-5}$ , (d)  $7.50 \times 10^{-5}$ , (e)  $1.00 \times 10^{-4}$ , (f)  $1.25 \times 10^{-4}$ , (g)  $1.50 \times 10^{-4}$ , (h)  $1.75 \times 10^{-4}$ , (i)  $2.00 \times 10^{-4}$ , (j)  $3.00 \times 10^{-4}$ , (k)  $4.00 \times 10^{-4}$ , (l)  $5.00 \times 10^{-4}$ , (m)  $6.00 \times 10^{-4}$ , (n)  $7.00 \times 10^{-4}$ , (o)  $8.00 \times 10^{-4}$ , (p)  $9.00 \times 10^{-4}$ , and (q)  $1.00 \times 10^{-3}$  mol/L. (b) Absorbance traces at 292 nm showing variation of DMAIMSOA with HOCl at a pH of 7.4 in 0.05 mol/L phosphate buffer. [HOCl] =  $2.0 \times 10^{-3}$  mol/L, [DMAIMSOA] = (a)  $2.0 \times 10^{-4}$ , (b)  $4.0 \times 10^{-4}$ , (c)  $6.0 \times 10^{-4}$ , (d)  $8.0 \times 10^{-4}$ , (e)  $1.0 \times 10^{-3}$ , (f)  $1.2 \times 10^{-3}$ , and (g)  $1.4 \times 10^{-3}$  mol/L. (c) Absorbance traces at 215 nm showing the effect of pH on the HOCl–DMAIMSOA reaction in 0.05 mol/L phosphate buffer for a freshly prepared DMAIMSOA. [HOCl] =  $3.0 \times 10^{-3}$  mol/L and [DMAIMSOA] =  $5.0 \times 10^{-5}$  mol/L. (d) Absorbance traces of the same reaction in Fig. 5c but with a 7-day-old incubated DMAIMSOA.

The oxidations observed in Figs. 4a–4c are effectively the oxidation of bisulfite released in the reaction in eq. [5]. The extent of the reaction in eq. [5] (a sort of pseudoequilibrium constant since eq. [5] is assumed to be irreversible) is strongly dependent on pH, and any value derived for this reaction has to be associated with a specific pH value. Further studies are needed to evaluate the general base catalysis that can be evoked by the anions that make up the various buffers that might be used to maintain the pH. It is anticipated that the type and concentrations of the buffers themselves would influence the observed extent of the reaction in eq. [5]. The reaction in eq. [5] is an extremely slow process, which proceeds at a faster rate in basic conditions. Figure 4d shows that the reaction in eq. [5] is a prerequisite for the observed oxidations in Figs. 4a and 4c. Some DMAIMSOA reaction solutions were used immediately after preparation (Fig. 4d, dark circles), while other solutions were incubated for 3 days before being used in the DMAIMSOA–IO<sub>3</sub><sup>−</sup> reac-

tions (Fig. 4d, open triangles). It is evident that after 30 min more of the DMAIMSOA is observed to have been oxidized with the incubated solutions (1.23%) over those that were not incubated (1.03%).

### Reactions in basic environments

For these experiments, hypochlorous acid was used as the oxidant. <sup>−</sup>OCl has an absorption peak at 292 nm, and does not interfere with the DMAIMSOA peak at 215 nm as HOI does. Thus, the reaction between HOCl and DMAIMSOA can be followed at both 215 and 292 nm. Figure 5a shows a series of spectral scans of the HOCl–DMAIMSOA reaction after 48 h of reaction time at pH 7.4 in a phosphate buffer. Activity is observed at both wavelengths, showing a very viable and facile reaction. The stoichiometry of this reaction was derived to be 1:1 using barium sulfate precipitation.

Absorbance traces in Fig. 5b were monitored at 292 nm, and show that the reaction essentially goes to completion and is over within 20 s. Any rate constant derived from these data is only relevant for this pH condition and for this buffer strength and concentration. The final observed rate of reaction is derived from a complex interaction of the buffer anions with DMAIMSOA and their effect in facilitating the reaction in eq. [5]. The positively charged carbon center is susceptible to nucleophilic attack with the result that the C–S bond is weakened, facilitating its cleavage. Figures 5c and 5d show that the incubation of solutions is not an important factor for reactions run in basic environments. Freshly prepared solutions gave nearly the same reaction times as those incubated for a week. Examination of the initial absorbance readings for the incubated solutions, however, show that the initial DMAIMSOA absorbances are depressed from the values recorded for unincubated solutions. The data, taken at 215 nm in Figs. 5c and 5d, are more difficult to explain if indeed the reaction in eq. [5] is irreversible. Thus, in basic environments, some equilibrium is attained, although some irreversible entropically favored decomposition also still proceeds. The reaction of HOCl with  $\text{HSO}_3^-$  is essentially diffusion controlled, and would not show the type of kinetics observed in Figs. 5b–5d.

## Conclusions

Owing to the inertness of aminoiminomethanesulfonic acid (AIMSOA) and DMAIMSOA, previous assertions from our research work had suggested that in these types of compounds that contain the thiouredo group, oxidation can proceed directly from the sulfinic acid to sulfate, bypassing the sulfonic acid.<sup>10,31,33</sup> Evidence for this involves the direct observation of an untrapped sulfoxyl anion radical in aerobic decompositions of aminosulfinic acids.<sup>34</sup> The inordinately long C–S bond in aminoiminomethanesulfonic acid (AIMSA) and DMAIMSA is easily cleaved by thermal activation or by the presence of nucleophiles. In fact, high yield guanidine formation is effected by the reaction of aminosulfinic acids with amines.<sup>35–37</sup> The nucleophilic amine center attacks the positive carbon center, culminating in the cleavage of the C–S bond and the formation of a C=N double bond.

The present synthesis and characterization, however, does not preclude the formation of the sulfonic acid as one of the stable intermediates in the oxidation of a thiouredo group in the basic environment and in the presence of basic anions or nucleophiles. Thus, in the physiological environment, metabolic activation of thiocarbamides, where S-oxygenation occurs at pH 7.4, the sulfonic acid is a viable intermediate, which can later be oxidized further to give sulfate and urea-type organic residue.

## Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca). CCDC 778932 contains the X-ray data in CIF format for this manuscript. These data can be obtained, free of charge, via <http://www.ccdc.cam.ac.uk/conts/retrieving.html> (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or [deposit@ccdc.cam.ac.uk](mailto:deposit@ccdc.cam.ac.uk)).

# Fabrication of boron carbonitride (BCN) nanotubes and giant fullerene cages

Guifang Sun, Faming Gao, and Li Hou

**Abstract:** Boron carbonitride (BCN) nanotubes have been successfully prepared using  $\text{NH}_4\text{Cl}$ ,  $\text{KBH}_4$ , and  $\text{ZnBr}_2$  as the reactants at  $480^\circ\text{C}$  for 12 h by a new benzene-thermal approach in a  $\text{N}_2$  atmosphere. As its by-product, a new form of carbon regular hexagonal nanocages are observed. The samples are characterized by X-ray diffraction (XRD), Fourier transform infrared (FTIR) spectroscopy, transmission electron microscopy (TEM), transmission electron diffraction (TED), electron energy loss spectroscopy (EELS), and high-resolution transmission electron microscopy (HRTEM). The prepared nanotubes have uniform outer diameters in the range of 150 to 500 nm and a length of up to several micrometers. The novel carbon hexagonal nanocages have a typical size ranging from 100 nm to  $1.5\ \mu\text{m}$ , which could be the giant fullerene cages of  $\text{C}_{60N^2}$  ( $N = 17 \sim 148$ ). So, high fullerenes are observed for the first time. The influences of reaction temperature and  $\text{ZnBr}_2$  on products and the formation mechanism of BCN nanotubes are discussed.

**Key words:** boron carbonitride (BCN) nanotube, benzene thermal, giant fullerene.

**Résumé :** On a préparé avec succès des nanotubes BCN par réaction de  $\text{NH}_4\text{Cl}$ , de  $\text{KBH}_4$  et de  $\text{ZnBr}_2$ , à  $480^\circ\text{C}$  pendant 12 h, en faisant appel à une nouvelle approche de benzène-thermal dans une atmosphère d'azote. On a aussi observé la formation comme sous-produit d'une nouvelle forme de nanocages hexagonales régulières à base de carbone. Les échantillons ont été caractérisés par diffraction des rayons-X (DRX), par spectroscopie infrarouge à transformation de Fourier (IR-TF), par microscopie électronique de transmission (MET), par diffraction électronique de transmission (DET), par spectroscopie de la perte d'énergie électronique (SPEE) et par microscopie électronique de transmission à haute résolution (METHR). Les nanotubes préparés possèdent des diamètres extérieurs uniformes allant de 150 à 500 nm et des longueurs allant jusqu'à plusieurs microns. La tailles typiques des nouvelles nanocages hexagonales à base de carbone vont de 100 nm à  $1,5\ \mu\text{m}$  qui s'apparentent aux cages de fullerènes géants de  $\text{C}_{60N^2}$  ( $N = 17 \sim 148$ ). On a donc observé des fullerènes géants pour la première fois. On discute aussi de l'influence de la température réactionnelle et du  $\text{ZnBr}_2$  sur les produits et sur le mécanisme de formation des nanotubes BCN.

**Mots-clés :** nanotube BCN, benzène-thermal, fullerène géant.

[Traduit par la Rédaction]

## Introduction

It is well-known that the boron carbonitride (BCN) compounds are promising superhard materials.<sup>1,2</sup> Theoretical calculations have revealed that the ternary BCN compounds, depending on the structure and composition, may manifest tunable properties between the extremes for elemental carbon and boron nitride.<sup>3</sup> Thus, BCN compounds are also candidates for potential electronic and photonic devices with a large variety of electronic properties. Much effort has been devoted to the preparation of BCN compounds, and the  $\text{BC}_x\text{N}$  compounds with an  $x$  of 0.9, 2, 2.5, 4, and 7 have been reported.<sup>4</sup> Since the discovery of carbon nanotubes (NT)<sup>5</sup> and BNNTs,<sup>6</sup> much interest has been attracted to the synthesis and characterizations of nanotubes in the  $\text{sp}^2$  bonding state. In particular, it is noteworthy that both theoretical and experimental studies of BCN have also been extended from the layered  $\text{BC}_x\text{N}$  compounds to nanotube structures.<sup>7</sup> Previously, BCN nanotubes have been fabricated by various methods.<sup>8–12</sup> However, all of the growth of the BCN

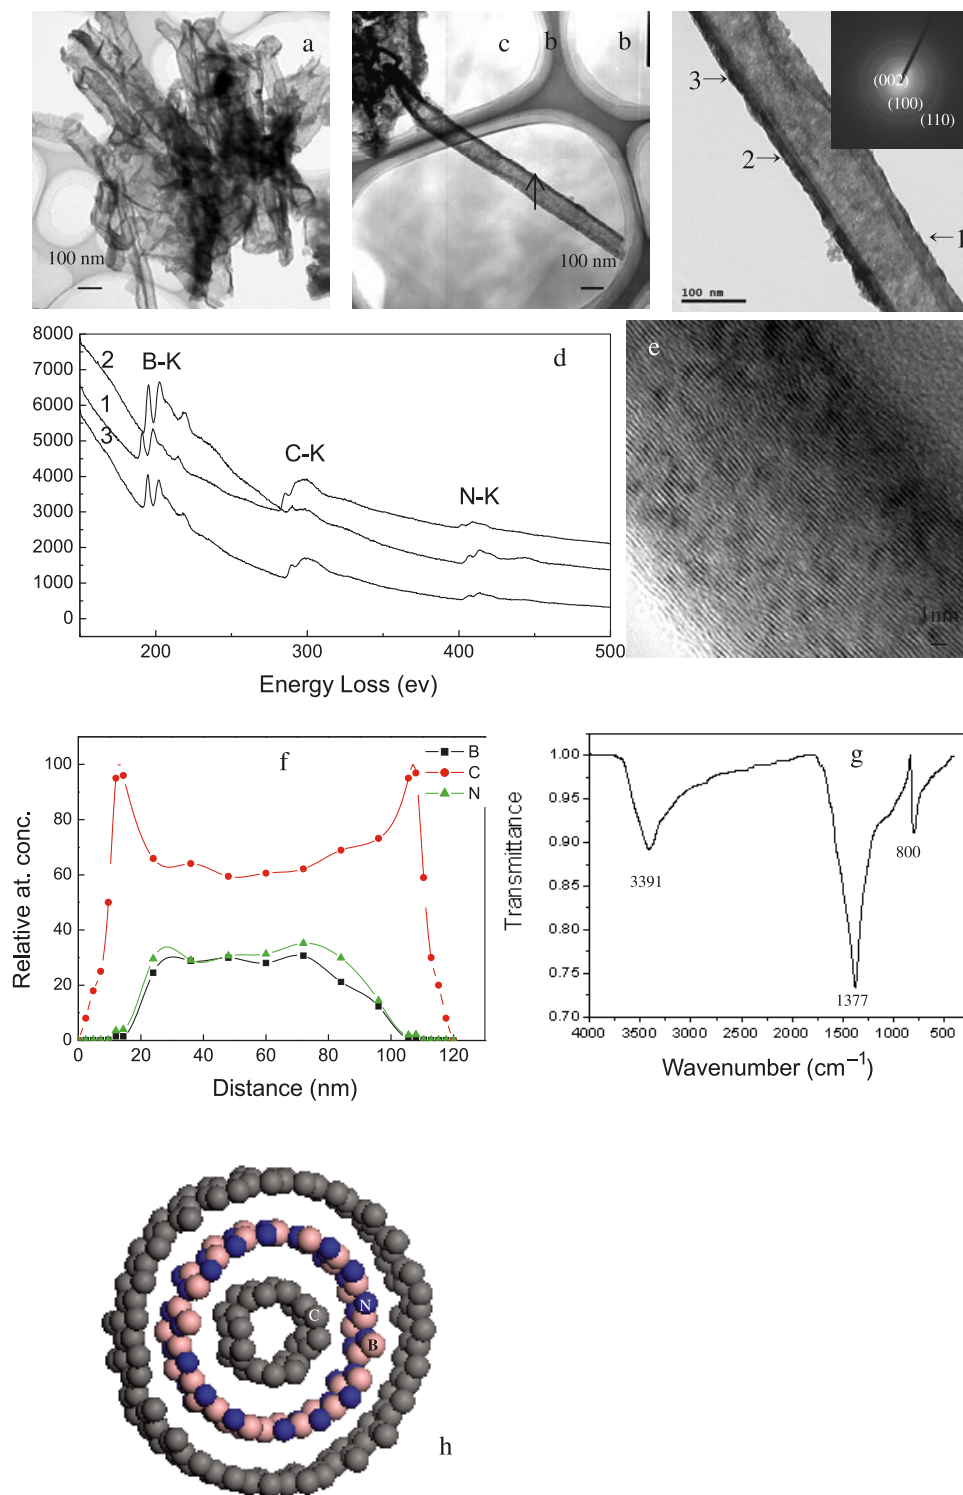

nanotubes were only carried out at higher temperatures ( $>1000^\circ\text{C}$ ). A low-temperature growth of nanotubes is highly desired. Since Liu et. al.<sup>13</sup> and Xu et. al.<sup>14</sup> successfully synthesized carbon nanotubes and BN nanotubes at very mild temperatures using the solvothermal-reduction route, it is reasonable and feasible to look for a route for low-temperature solvothermal synthesis of BCN nanotubes. In addition, the discoveries of buckminsterfullerene and carbon nanotubes have stimulated a great deal of research on different carbon morphologies owing to their promising applications in fields such as electrochemical devices, hydrogen storage, field emission devices, and nanotweezers.<sup>15</sup> Because of the flexible carbon structure, various morphologies of carbon nanostructures, including nanotubes,<sup>5</sup> nanocapsules,<sup>16</sup> onions,<sup>17</sup> nanopolyhedra,<sup>18</sup> cones,<sup>19</sup> nanorods,<sup>20</sup> nanohorns,<sup>21</sup> spheres,<sup>22</sup> and cubic nanocages,<sup>23</sup> have been discovered by scientists. These carbon nanostructures show different physical properties, and have a potential of studying materials of low dimensionality within an iso-

temperature and  $\text{ZnBr}_2$  on the reaction and morphology of the product, and discussed the formation mechanism of BCN nanotubes and carbon nanocages.

## Experimental

### Synthesis of carbon material

In a typical procedure, 9.708 g of  $\text{KBH}_4$ , 1.605 g of  $\text{NH}_4\text{Cl}$ , 0.78 g of  $\text{ZnBr}_2$ , and 30 mL of benzene were added into a 50 mL stainless steel autoclave. The autoclave was sealed and maintained at 480 °C for 12 h in a crucible furnace, and then it was allowed to cool to room temperature naturally and was carefully opened. After being filtered and washed with absolute ethyl alcohol and distilled water several times, the product was dried in a vacuum at 100 °C for 2 h. The final product was grey-black and was collected for characterization. The manipulation process was carried out in a glovebox full of  $\text{N}_2$ .

### Characterization techniques

The morphologies of the sample were characterized by

**Table 1.** Different morphologies obtained by various experiments.

Group number	Reactants	Reaction temperature (°C)	Dominated morphology of product
1	KBH <sub>4</sub> , NH <sub>4</sub> Cl, C <sub>6</sub> H <sub>6</sub>	480	h-BN nanorods
2	KBH <sub>4</sub> , NH <sub>4</sub> Cl, ZnBr <sub>2</sub> , C <sub>6</sub> H <sub>6</sub>	480	Carbon nanocages, BCN nanospheres, and nanotubes
3	KBH <sub>4</sub> , NH <sub>4</sub> Cl, ZnBr <sub>2</sub> , C <sub>6</sub> H <sub>6</sub>	<400	Nothing
4	KBH <sub>4</sub> , NH <sub>4</sub> Cl, ZnBr <sub>2</sub> , C <sub>6</sub> H <sub>6</sub>	400	BCN nanotubes
5	KBH <sub>4</sub> , NH <sub>4</sub> Cl, ZnBr <sub>2</sub> , C <sub>6</sub> H <sub>6</sub>	550	Carbon nanocages
6	KBH <sub>4</sub> , NH <sub>4</sub> Cl, ZnBr <sub>2</sub> , C <sub>6</sub> H <sub>6</sub>	800 and 900	Shorter and more curved BCN nanotubes

transmission electron microscopy (TEM) using a JEM-2010 transmission electron microscope. Transmission electron diffraction (TED) and high-resolution transmission electron microscopy (HRTEM) were used to investigate the microstructure of the powder. In addition, electron energy loss spectroscopy (EELS) and TEM was used to analyze the composition and distribution of B, C, and N. A sample of 0.1 g of the as-prepared powder with 10 mL of ethanol in a 50 mL beaker was prepared for the electron microscope by ultrasonic dispersion for 10 min. Then, the suspension was dropped on a carbon-coated copper microgrid and dried in air before performance.

## Results and discussion

Figures 1a and 1b show transmission electron micrographs of BCN nanotubes. There were no metal particles at the tube tip ends, which were typically open as in Fig. 1b. The produced BCN nanotube in Fig. 1b appears good in shape and straighter than other BCN nanotubes presented in refs. 8–12. The prepared nanotubes have uniform outer diameters in the range of 150 to 500 nm and lengths from scores of nanometers up to several micrometers. The inner diameters of the nanotubes are ~100–400 nm. Figure 1c is the high-magnification TEM image of the nanotube in Fig. 1b and the inset in Fig. 1c is the TED pattern of the nanotube. EELS analysis of the nanotube shown in Fig. 1d revealed that it was composed of B, C, and N with distinct ionization adsorption edges at 188, 284, and 401 eV, respectively, which shows the characteristic K-shell ionization edges of B, C, and N, respectively. The  $\pi$ -type  $sp^2$  peaks of boron and carbon in the EELS spectrum are obvious for the BCN nanotubes, which can be characterizations of nanotubes in the  $sp^2$  bonding state. Taking into consideration the experimental error of ~10% in EELS measurements, the atomic ratios of B:N for most BCN nanotubes are always close to 1.0. However, the C atomic percentages change markedly. Figure 1d shows EELS results collected from locations 1, 2, and 3 in the same nanotube as indicated in Fig. 1c, respectively. The quantification results of B, C, and N at locations 1, 2, and 3 are approximately 1:2.50:1, 1:0.33:1, and 1:1.33:1, respectively. Thus, in the  $BC_xN$ , the average value of  $x$  is ~1.4. To study the composition within the tube, we show the EELS line scan (Fig. 1f) across the nanotube shown in Fig. 1b, in which the relative concentrations of B, C, and N are displayed. The anticorrelation of the elemental profiles indicates the tube exhibits segregation of BN and C layers, and it also indicates an alternating C–BN–C geometry similar to the structures in refs. 24 and 25. Two strong peaks around 1377 and 800  $cm^{-1}$  in Fig. 1g could be assigned to the B–N stretching vibrations

and B–N–B bending vibrations, respectively,<sup>26</sup> and the broad absorbed absorption peak at 3391  $cm^{-1}$  is due to water absorbed on the sample. There are no peaks corresponding to C–N and B–C vibrations, which also suggests the BCN nanotubes consist of segregated domains of BN and C, and the scheme of the BCN nanotube is shown in Fig. 1h. The typical TED pattern (inset in Fig. 1c) is taken from the individual nanotube. From the patterns, the reflections of (002), (100), and (110) of hexagonal BCN crystallites (h-BCN, JCPDS No. 35-1292) can be observed, which indicates that the product is crystallized. The high-resolution TEM image (Fig. 1e) of the typical nanotube shows the (002) basal planes aligned along the tube axis with certain crystallinity, and the interlayer spacings are measured to be ~0.335 nm, which is close to the value of (002) spacing of graphite or h-BN. From HRTEM pictures of multiwall carbon nanotubes, the slightly disordered multiwall structure of the nanotube can be observed, and the crystallinity of the BCN nanotube appears to be not as high as the nanotubes prepared by the technique of chemical vapour deposition (CVD).<sup>27,28</sup>

It is very intriguing to find a lot of hollow carbon regular hexagonal nanocages in as-synthesized nanomaterials, as shown in Fig. 2. In Fig. 2a, a TEM overview image shows several carbon hexagonal nanocages, which have typical sizes ranging from 100 nm to 1.5  $\mu m$ . Figures 2b and 2c show high-magnification TEM images of typical hexagonal-shaped carbon nanocages, which have perfect regular hexagonal nanostructures and nearly the same wall thickness of 14.3 nm. Figure 2d shows the EELS result of the nanocage in Fig. 2c, which demonstrates it is a pure carbon nanocage. From the carbon K-edge spectra, the weak initial peak, which is due to  $1s \rightarrow 2\pi^*$  transitions, shows it is a not highly crystalline material.<sup>29</sup> The typical TED pattern (Fig. 2e) is taken from the nanocage in Fig. 2c. From the pattern, the reflections of (002), (100), and (110) of graphite carbons (JCPDS No. 25-0284) can be observed, which indicates that the structure of the product is similar in structure to graphite, like fullerenes, which is composed of a sheet of linked hexagonal rings, but they contain pentagonal (or sometimes heptagonal) rings that prevent the sheet from being planar. The nature of the hexagonal nanocages is clearly demonstrated in the HRTEM image. At the hexagonal nanocage's corner, sharp folding can be observed, while the angle at the corner is strictly 120°, which demonstrates the appearance of carbon hexagonal nanocages probably arising from folding graphitic sheets into a hexagonal form, a process catalyzed by Zn in an attempt to minimize the highly energetic dangling bonds present at the edge of the growing structure. A further analysis by HRTEM (Fig. 2f)

reveals that the hollow cages could be the giant fullerene cages of  $C_{60N^2}$  ( $N = 17 \sim 148$ ). Smaller fullerenes look like asteroids. Giant fullerenes take on a hexagonal shape, as shown in Fig. 2g. The HRTEM picture of the cage in Fig. 2g shows that it is composed of many carbon rings, which correspond to the hexagonal or pentagonal rings of fullerenes, as shown by the red arrows in Figs. 2f and 2g.

A possible mechanism for the reactions is as follows.  $KBH_4$ ,  $NH_4Cl$ , and benzene are selected as the boron, nitrogen, and carbon source of BCN, respectively. Benzene can be carbonized if the temperature exceeds  $380^\circ C$ .<sup>30</sup> When the temperature reaches  $340^\circ C$ ,  $NH_4Cl$  and  $KBH_4$  begin to decompose into  $NH_3$  and  $HCl$ , and  $KH$  and  $BH_3$ , respectively, then  $NH_3$  and  $BH_3$  will react further and produce  $NH_3 \cdot BH_3$ .<sup>31</sup> When the temperature is up to  $480^\circ C$ , intermediate  $NH_3 \cdot BH_3$  and carbon will produce  $BC_xN$  nanomaterials and  $H_2$  under high pressure, which comes from  $H_2$  and the decomposed  $NH_3$ ,  $BH_3$ , and  $HCl$  gases. The as-prepared BCN nanomaterials in which the atomic ratio of B:N is 1.0 may crystallize disorderly. According to the XRD result of the unwashed product, we know  $KCl$ ,  $KBr$ ,  $Zn$ ,  $BCN$ , and carbon nanomaterials are present in the product, so the following chemical reaction is certainly responsible for the low-temperature growth of the BCN nanomaterials:

During the reaction,  $ZnBr_2$  is reduced to  $Zn$  catalyst particles, and then  $BC_xN$  nanomaterials deposit and diffuse on the surface of the fused zinc particles acting as active centers to form BCN nanotubes at the  $Zn$  particles. Combined with the production of h-BN nanorods without the addition of  $ZnBr_2$ , the open-tip morphology (Fig. 1b) of the product confirms this proposal, which indicates that the BCN nanotubes grew in a base-growth model.<sup>32</sup> In TEM examinations, the tips of BCN nanotubes were free of zinc particles existing in the sample (Fig. 3) according to X-ray diffraction, which may be due to the large diameters of the nanotubes, and come off them. Combining the results of EELS, the X-ray diffractogram indicates the presence of zinc metal crystals as catalyst, and carbon is consistent throughout the carbon nanocages.

To investigate the influence of  $ZnBr_2$  and reaction temperature on the morphologies of the product, a series of experiments were carried out (as shown in Table 1) with the procedure similar to that mentioned in the Experimental section. To identify if  $Zn$  plays a catalytic role, only  $KBH_4$ ,  $NH_4Cl$ , and benzene were directly put into an autoclave in a  $N_2$  atmosphere, and were immediately heated at a temperature of  $480^\circ C$  for 12 h without any catalyst. As a result, no BCN nanotubes or carbon nanocages were observed, indicating that  $Zn$  plays a crucial role in the growth process of BCN nanotubes and carbon nanocages as mentioned previously. To maximize BCN nanotubes or carbon nanocages in the product, a series of experiments at different temperatures were carried out. When the temperature was  $<400^\circ C$ , no product could be obtained. The product prepared at  $400^\circ C$  mostly consisted of BCN nanotubes, which were similar to those prepared at  $480^\circ C$ . When the reaction temperature was at  $550^\circ C$ , carbon nanocages prevailed in the sample, but BCN nanotubes almost disappeared. Raising the reaction

temperature to  $800$  and  $900^\circ C$ , we could find shorter and more curved BCN nanotubes produced and an improvement on the crystallinity of the BCN nanotubes, and the carbon nanocages disappeared. So thermal annealing at  $800$  and  $900^\circ C$  can promote crystallization and production of BCN nanotubes, but was not favorable to the production of longer, more aligned nanotubes and nanocages. So we can control the morphologies of the product to obtain BCN nanotubes or carbon nanocages separately by altering the reaction temperature.

## Conclusions

In conclusion, BCN nanotubes and a new form of carbon regular hexagonal nanocages have been successfully prepared using  $NH_4Cl$ ,  $KBH_4$ , and  $ZnBr_2$  as the reactants at  $480^\circ C$  for 12 h by a new benzene-thermal approach in a  $N_2$  atmosphere. Transmission electron microscopy investigations indicated that the carbon hexagonal nanocages could be giant fullerene cages.

# Interactions between gemini and nonionic pharmaceutical surfactants

Javed R. Akbar, Rubena Deubry, D. Gerrard Marangoni, and Shawn D. Wettig

**Abstract:** The nature and strength of the interactions between the 1,3-bis(dimethylhexadecyl)propanediammonium dibromide (16-3-16) gemini surfactant and a homologous series of nonionic polyoxyethylene (20) sorbitan ester surfactants having laurate (Tween 20), stearate (Tween 60), or oleate (Tween 80) alkyl tails has been investigated. The critical micelle concentration (cmc) values of the mixed gemini–tween systems were determined using the du Noüy ring surface tension method, and the results have been analyzed using Clint's, Rubingh's, Motomura's, and Maeda's theories for mixed micellar systems. The results demonstrate a synergistic mixing behaviour between the Tween surfactants and the 16-3-16 gemini surfactant, where the strength of interaction is dependent upon the chain length and saturation of the Tween alkyl tail.

**Key words:** gemini surfactants, Tween surfactants, mixed micelles, surface tension.

**Résumé :** On a étudié la nature et la force des interactions entre l'agent de surface jumeau dibromure de 1,3-bis(diméthylhexadécyl)propanediammonium (16-3-16) et une série d'agents de surface non ioniques à base d'ester de polyoxyéthylène (20) sorbitane comportant des chaînes alkyles du laurate (Tween 20), du stéarate (Tween 60) ou oléate (Tween 80). On a déterminé les valeurs de concentration micellaire critique (cmc) des systèmes mixtes jumeau–Tween en faisant appel à la méthode de la tension superficielle des anneaux de Noüy et on a analysé les résultats à l'aide des théories de Clint, de Rubingh, de Motomura et de Maeda pour les systèmes micellaires mixtes. Les résultats mettent en évidence un comportement de mélange synergistique entre les agents de surface de la famille Tween et l'agent de surface jumeau 16-3-16 et la force de l'interaction dépend de la longueur et de la saturation de la chaîne alkyle du Tween.

**Mots-clés :** agents de surface jumeaux, agents de surface Tween, micelles mixtes, tension superficielle.

## Introduction

Gemini surfactants represent an intriguing class of surfactants that have been extensively studied by various research groups since the late 1980s. Their unique structure, which consists of two typical surfactant monomers that are covalently linked by either a rigid or flexible spacer group, results in a number of interesting observations regarding their aggregation behavior in solution.<sup>1</sup> In comparison with their corresponding monomer counterparts, gemini surfactants are more efficient at reducing surface tension, have better wetting properties, and typically have critical micelle concentration (cmc) values that are one to two orders of magnitude lower.<sup>1–3</sup> Furthermore, gemini surfactants have been shown to form a rich array of aggregate morphologies in solution, through alteration of their chemical structure.<sup>4,5</sup> The combination of the unique properties of these surfactants along with the increasing demand for high-performance surfactants is currently driving research into their potential applications.

The prospective applications of gemini surfactants are multifold. These include their potential use in cleaning agents and detergents, cosmetics and personal care products,

preparative chemistry, pharmaceutical and biological applications, enhanced oil recovery, etc.<sup>6</sup> One particular application that is heavily being investigated is their use in drug delivery. Our group is currently interested in their use as transfection agents for DNA delivery. Thus far, we have experimentally demonstrated the effectiveness of utilizing gemini surfactants as building blocks for the construction of liposome-based DNA delivery systems for nonviral gene therapy.<sup>7–10</sup>

To effectively assess the potential applications of gemini surfactants towards drug delivery, one must realize that pharmaceutical preparations normally contain mixtures of surface-active compounds to provide the overall performance required for a particular application. In such instances, it is important to take notice that there are substantial differences in the micellization tendencies of mixtures of surfactants as compared with the single pure species. Thus, it is of great importance to evaluate and understand the interactions of gemini surfactants with common surfactants typically found in pharmaceutical applications.

Mixtures of surface-active agents form mixed micellar aggregates that can exhibit ideal or nonideal mixing behaviour

in solution. Ideally, mixed surfactant systems obey Clint's model, where the cmc of the mixture can be determined from the overall composition of the combined components and the cmcs of the individual surfactants.<sup>11</sup> Clint's ideal solution theory is an effective method for explaining the mixing behaviour of surfactants with chemically similar structures.<sup>12</sup> However, deviations in ideal mixing can occur in mixtures containing chemically distinct structures as a result of a net interaction between the amphiphiles.<sup>12–17</sup> The nature and strength of this net interaction can be determined from the interaction parameter ( $\beta$ ), which can be calculated using Rubingh's model for mixed micelle formation.<sup>12</sup> Negative values of  $\beta$  indicate a synergistic interaction, where the cmc of the mixture is lower than the cmc values of the individual surfactants.<sup>12</sup> In contrast, positive values of  $\beta$  represent an antagonistic interaction between the surfactants, resulting in a positive deviation of the cmc values from ideal mixing.<sup>12</sup> Typically, synergistic effects seem to be negligible for mixtures of nonionic surfactants. However, they are moderately present in mixtures of ionic and nonionic surfactants and strongest in mixtures of anionic and cationic surfactants.

The aim of this investigation is to examine the nature and strength of the interactions between the cationic 1,3-bis(dimethylhexadecyl)propanediammonium dibromide gemini surfactant (represented as 16-3-16, where 16 is the length of the *n*-alkyl tails and 3 is the length of the polymethylene spacer) and a homologous series of nonionic polyoxyethylene (20) sorbitan esters known as the Tween surfactants that are commonly found in pharmaceutical formulations. Whereas the synergistic interactions between anionic and nonionic and anionic and zwitterionic surfactants have been extensively studied in the literature, synergism between non-ionic and cationic surfactants has received little attention.<sup>18,19</sup> The results from this study were analyzed using Clint's, Rubingh's, Motomura's, and Maeda's theories for mixed micellar systems.

## Experimental

### Materials

The polyoxyethylene (20) sorbitan monolaurate (Tween 20), polyoxyethylene (20) sorbitan monostearate (Tween 60), and polyoxyethylene (20) sorbitan monooleate (Tween 80) surfactants were obtained from PCCA (Houston, Texas) and were used without any further purification. Water for all solutions was obtained from a Millipore Synergy purification system.

### Synthesis of 16-3-16

The 1,3-bis(dimethylhexadecyl)propanediammonium dibromide gemini surfactant (Scheme 1) used in this study was synthesized according to procedures previously reported in the literature.<sup>20,21</sup> Briefly, the synthesis was carried out by reflux of 2 equiv of *N,N*-dimethylhexadecylamine (plus 10% excess) and 1 equiv of 1,3 dibromopropane in HPLC grade acetonitrile for 48 h. The resulting product was purified by recrystallization from acetonitrile. The purity was confirmed by the absence of a minimum in the post micelle region of the surface tension vs log concentration plot. The structure

**Scheme 1.** Structure of the 16-3-16 gemini surfactant.

was confirmed using <sup>1</sup>H NMR spectroscopy (Bruker 300 MHz).

### Methods

Surface tension measurements were performed using a Lauda TE3 tensiometer, applying the du Noüy ring method. The temperature was kept constant at 25 °C using a circulating water bath. Surface tension values were corrected using the method of Harkins and Jordan. The cmc was determined from the break in the plot of surface tension vs concentration.

Mixed 16-3-16 and Tween solutions were prepared in the molar ratios of 0, 0.2, 0.4, 0.6, 0.8, and 1 (to a final concentration of 1 mmol/L), and separately titrated into water. Surface tension was measured as a function of concentration of the single or binary amphiphile system.

## Results and discussion

### cmc evaluation of the single and binary gemini–Tween systems

The cmcs for the pure and mixed 16-3-16 and Tween systems were determined from the breakpoint of the surface tension plots, through linear fitting of the pre-micellar and post-micellar regions. The surface tension plots for the pure 16-3-16 and Tween surfactants are shown in Fig. 1.

The experimental cmc values (Table 1) for the mixed gemini–tween systems were evaluated and compared with those values calculated using Clint's model for ideal mixed micellar systems. Clint's equation is represented by

$$[1] \quad \frac{1}{\text{cmc}_{\text{mix}}} = \sum_{i=1}^2 \frac{\alpha_i}{\text{cmc}_i}$$

where the ideal cmc of the mixture,  $\text{cmc}_{\text{mix}}$ , can be determined by the mole fraction of component *i* in solution,  $\alpha_i$ , and the cmc value of pure component *i*,  $\text{cmc}_i$ .<sup>11</sup>

In Fig. 2, the relationship between the cmc values of the mixtures and the molecular composition in solution ( $\alpha_{\text{Tween}}$ ) is shown. The solid lines in the figures are the ideal cmcs calculated using Clint's equation, whereas the broken lines represent the experimental values. As shown, the variations of the cmc values with composition appear to be quite different depending on the Tween surfactant in the mixture. Particularly, we found that the experimental cmc values for the Tween 20/16-3-16 system were initially larger than the ideal values. For both the Tween 60– and Tween 80–gemini systems, the experimental cmc values are lower than those calculated ideally, with this trend being sharper in the case of Tween 60–16-3-16. Interestingly in all cases, the difference between the ideal and experimental cmc values is less pronounced at high mole fractions of the nonionic Tween surfactant.

**Fig. 1.** Surface tension plots of the pure 16-3-16 and Tween surfactants in water at 25 °C.

The deviations of the experimental cmc values from the ideal cmc values (Table 1 and Fig. 2) is indicative of a non-ideal mixing behaviour between the gemini and Tween surfactants. In the case of the Tween 20–16-3-16 system, there appears to be a mild antagonistic interaction followed by a synergistic interaction as the mole fraction of Tween 20 is increased. In the case of the Tween 60– and Tween 80–16-3-16 systems, there appears to be a synergistic interaction between the surfactants over all compositions of the Tween surfactant. In these mixed cationic and nonionic systems, a synergistic interaction is expected because of the structural dissimilarities between the surfactants. During micellization, the nonionic Tween surfactants are expected to orient themselves between the cationic gemini surfactants, thus minimizing head group repulsion and consequently favouring micelle formation. As shown in Fig. 2, this synergistic interaction appears to be most pronounced in the mixed Tween 60 system, although all three surfactants share the same head group. This observation indicates that the length and saturation of the alkyl tail on the Tween surfactant is a determining factor in the strength of the synergistic interaction with the 16-3-16 gemini surfactant. These interaction differences were further investigated and quantified using Rubingh's approach.<sup>12</sup>

#### Evaluation of the interaction between 16-3-16 and the Tween surfactants

The nonideal behaviour of the mixed 16-3-16 and Tween systems was further analyzed and rationalized using Rubingh's model.<sup>12</sup> Through use of the regular solution approximation, Rubingh's approach allows the following equation to be derived

$$[2] \quad \frac{X_1^2 \ln(\text{cmc}_{\text{mix}} \alpha_1 / \text{cmc}_1 X_1)}{(1 - X_1)^2 \ln[\text{cmc}_{\text{mix}}(1 - \alpha_1) / \text{cmc}_2(1 - X_2)]} = 1$$

which can be used to calculate the composition of the mixed

micellar phase, where  $X_1$  is the mole fraction of surfactant 1 in the mixed micelle,  $\text{cmc}_{\text{mix}}$  is the experimental cmc value of the mixed micelle,  $\text{cmc}_1$  and  $\text{cmc}_2$  are the cmc values of surfactant 1 and 2, respectively, and  $\alpha_1$  is the mole fraction of surfactant 1.<sup>12</sup>

Through use of eq. [2],  $X_1$  can be calculated through an iterative process, which subsequently allows for the determination of the interaction parameter using the equation

$$[3] \quad \beta = \frac{\ln(\text{cmc}_{\text{mix}} \alpha_i / \text{cmc}_i X_i)}{(1 - X_i)^2}$$

where  $\beta$  represents the interaction parameter.<sup>12</sup> As previously discussed, the interaction parameter is indicative of the nature and strength of the interaction between the surfactants in the mixed micelle system.

The micellar mole fractions of the Tween surfactants in the mixtures were calculated using eq. [2] and compared with the ideal values determined using Motomura's approximation<sup>23</sup> (Table 2). Motomura's theory considers mixed micelles as a macroscopic bulk phase where the energetic parameters of such systems can be evaluated in terms of excess thermodynamic quantities.<sup>23</sup> The micelle mole fraction in the ideal state,  $X_{\text{ideal}}$ , can be calculated by the equation

$$[4] \quad X_{\text{ideal}} = \{(\alpha_1 \text{cmc}_2) / [\alpha_1 \text{cmc}_2 + (1 - \alpha_1) \text{cmc}_1]\}$$

Values are reported in Table 2, and Fig. 3 illustrates the comparison of  $X_1$  and  $X_{\text{ideal}}$  as a function of  $\alpha_{\text{Tween}}$  for the mixed Tween–16-3-16 systems. It can be seen that in the case of the Tween 60– and Tween 80–16-3-16 systems,  $X_1$  was found to deviate positively from  $X_{\text{ideal}}$  until  $\alpha_{\text{Tween}}$  approached ~0.35. These initial positive deviations from  $X_{\text{ideal}}$  demonstrate that within these low  $\alpha_{\text{Tween}}$  regions, the mixed micelles are richer in the Tween surfactants and poorer in 16-3-16 than its intended ideal state. Above the  $\alpha_{\text{Tween}}$  region of ~0.35, the mixed micelles become enriched with the 16-3-16 surfactant; a similar pattern has been ob-

**Table 1.** Measured ( $\text{cmc}_{\text{Exp}}$ ) and calculated ( $\text{cmc}_{\text{Clint}}$ ) critical micelle concentration (cmc) values for the single and binary 16-3-16 gemini surfactant and Tween systems at 25 °C.

**Note:**  $\alpha_{\text{Tween20}}$ , mole fraction of Tween 20;  $\alpha_{\text{Tween60}}$ , mole fraction of Tween 60; and  $\alpha_{\text{Tween80}}$ , mole fraction of Tween 80.

served in a mixed nonionic C<sub>13</sub>E<sub>20</sub> and cationic sterile system.<sup>24</sup> In the case of the Tween 20/–16-3-16 system, there is no apparent trend in the deviation of  $X_1$  from  $X_{\text{ideal}}$ . It can be seen that the mixed micelle is initially enriched with the gemini surfactant at low  $\alpha_{\text{Tween}}$  values and becomes enriched with the gemini surfactant again at higher  $\alpha_{\text{Tween}}$  values (as observed in the Tween 60– and Tween 80–16-3-16 systems).

The interaction parameters for the mixed Tween and 16-3-16 systems were subsequently calculated using the previously described eq. [3], and the results are illustrated graphically in Fig. 4. The computed  $\beta$  values (Table 2) were then used to determine the activity coefficients of the individual surfactants through the equations

$$[5] \quad \ln \gamma_1 = \beta(1 - X_1)^2$$

$$[6] \quad \ln \gamma_2 = \beta(X_1)^2$$

where  $\gamma_1$  and  $\gamma_2$  are the activity coefficients of surfactant 1 and 2, respectively.<sup>12</sup>

The determined activity coefficients were next used to calculate the excess free energy of mixing ( $G_{\text{ex}}^0$ ) by the equation

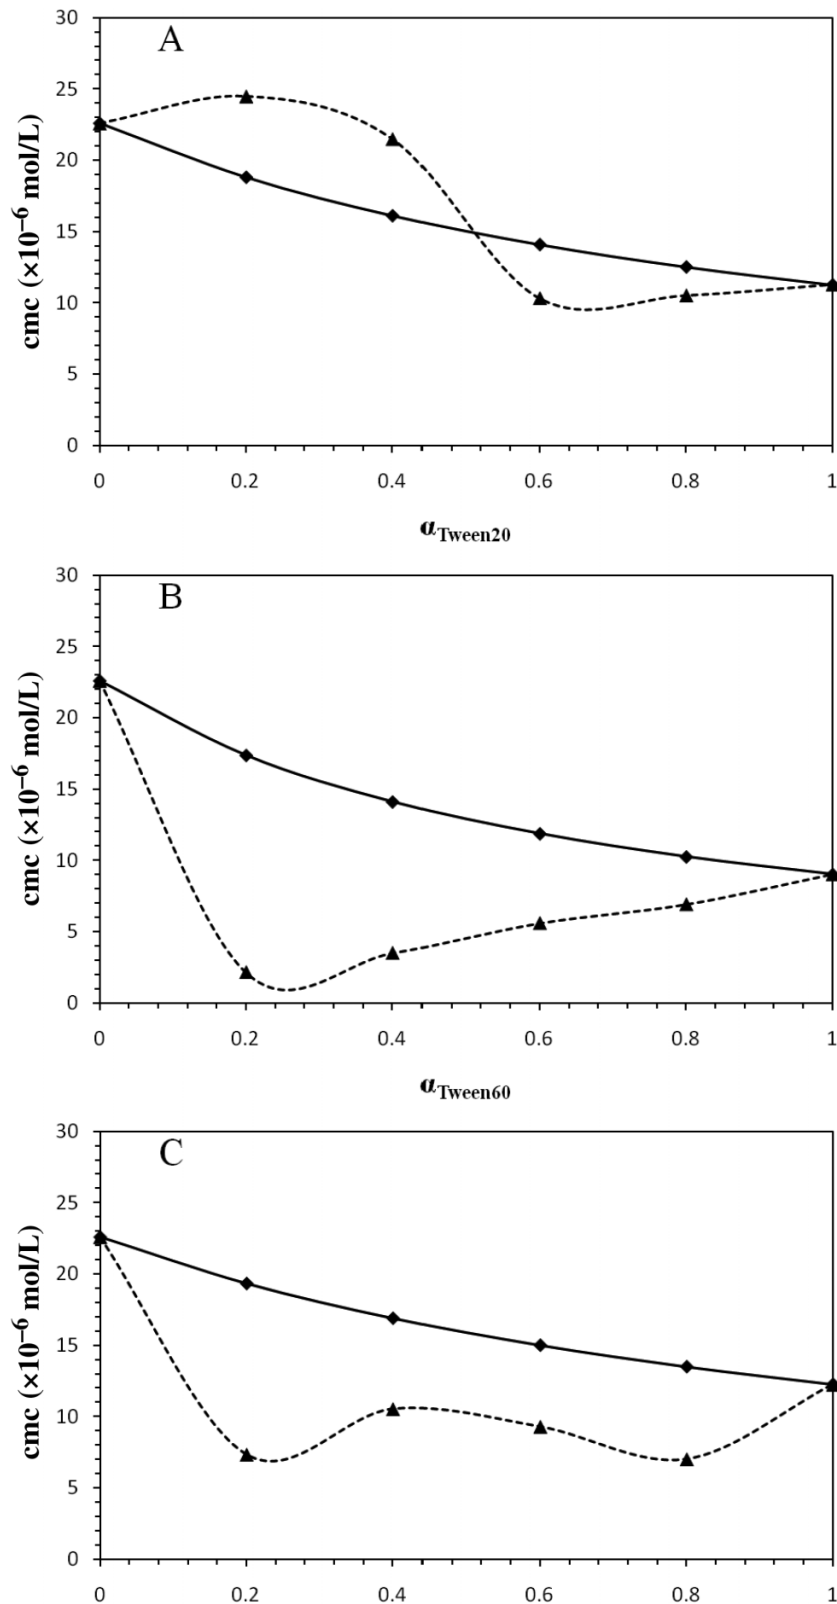

$$[7] \quad \Delta G_{\text{ex}}^0 = RT \sum_{i=1}^2 X_i \ln \gamma_i$$

where  $R$  and  $T$  represent the gas constant and absolute temperature, respectively.<sup>12</sup>

The cumulative experimental results of Rubingh's analysis for the mixed Tween–16-3-16 systems are tabulated in Table 2. Upon initial inspection, it is confirmed that a synergistic interaction is present for the Tween 60– and Tween 80–16-3-16 systems over all compositions, owing to the negative values of the interaction parameters. Furthermore, the activity coefficients were always found to be less than unity, thus confirming nonideal behaviour and an attractive interaction in the mixed systems. And finally, the negative values for the excess free energy of mixing suggest that the mixed micelles are more stable than the micelles of the individual components. For the mixed Tween 20–16-3-16 system, it is confirmed that there is an initial slight antagonistic interaction at low  $\alpha_{\text{Tween}}$  values, owing to the positive values of  $\beta$ . However, the interaction becomes synergistic at  $\alpha_{\text{Tween}}$  values of 0.6 or higher.

Upon closer examination of the experimental results, it is evident that the magnitude of the interaction parameter is dependent upon the chemical structure of the Tween surfactant in the binary system. The average values of  $\beta$  are –0.049 for the Tween 20–16-3-16 mixture, –5.1 for the Tween 60–16-3-16 mixture, and –3.0 for the Tween 80–16-3-16 mixture. Tween 60 experienced the most synergistic interaction with 16-3-16, followed by Tween 80 and then Tween 20. In all cases, the  $\beta$  values are more negative in comparison with a mixed Triton X-100 and 12-2-12 system<sup>25</sup>, and are generally in good agreement with those typically found for mixed ionic and nonionic systems.<sup>26,27</sup> The magnitudes of the interaction parameter for the mixed Tween 60– and Tween 80–16-3-16 systems suggest substantial stabilization of the mixed micelles vs the respective pure surfactant mi-

celles. In the case of the mixed Tween 20–16-3-16 system, the magnitude of  $\beta$  was found to deviate slightly around 0, thus suggesting a near ideal mixing behaviour for this system; such an observation has been observed in mixed cationic  $C_m\text{PB}$  and nonionic NP-9 systems.<sup>28</sup> Interestingly, when the mole fractions of the Tween surfactants are larger than 0.6, the mixed Tween–16-3-16 systems have comparable degrees of synergism.

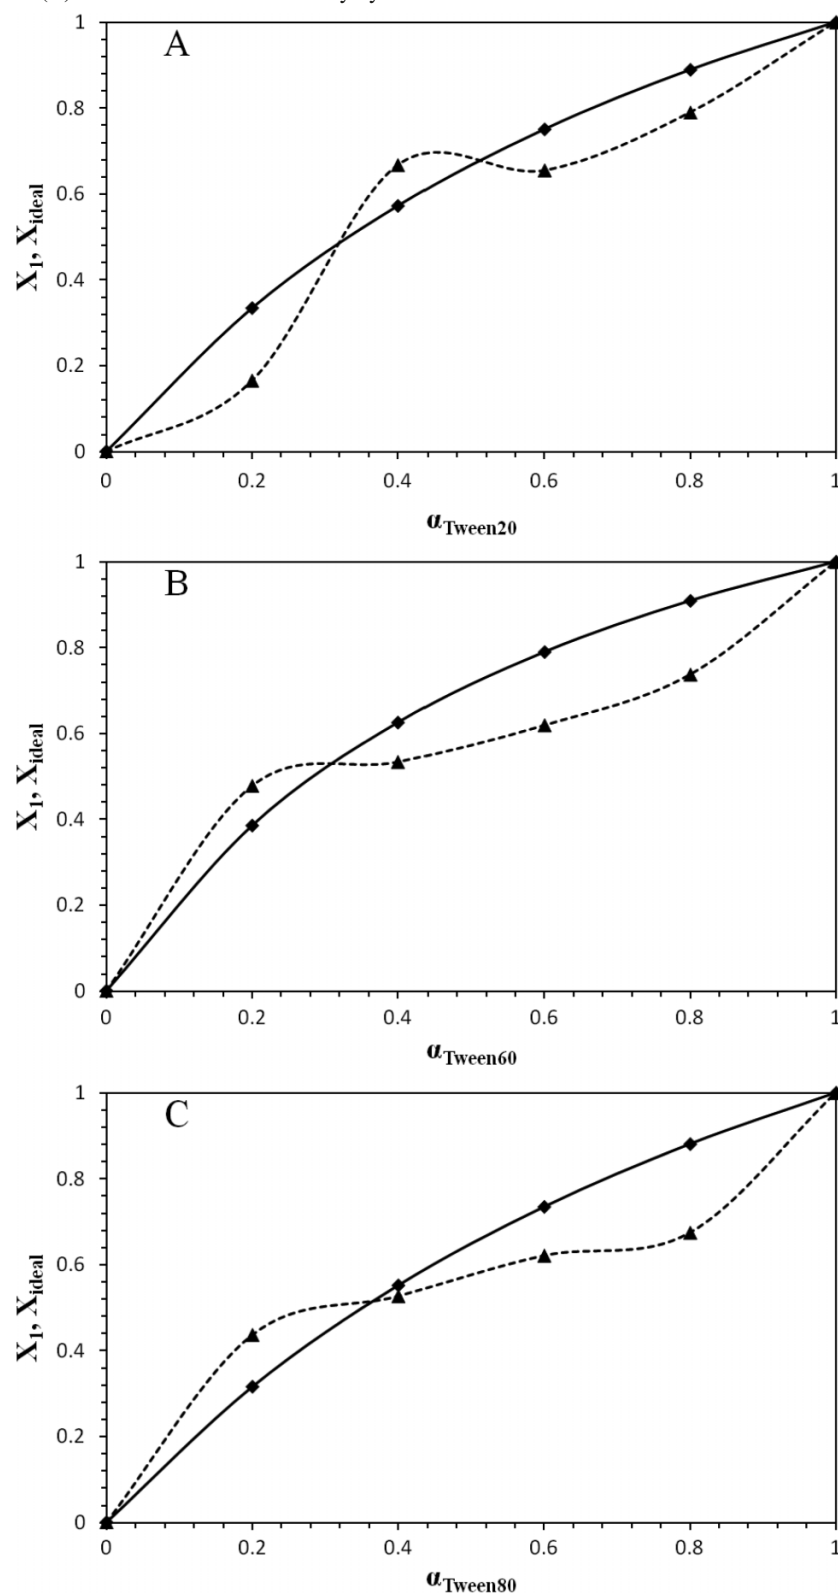

The disparities in interaction between the Tween surfactants and 16-3-16 can be rationalized using Maeda's theory<sup>29</sup> for mixed surfactant systems. According to Maeda,<sup>29</sup> the transfer process of an ionic surfactant monomer to a nonionic micelle will consist of two distinct contributions: (i) the interaction between the surfactant head groups and (ii) the interaction between the hydrocarbon chains of the respective surfactants.<sup>29</sup> In most cases, the surfactant chains that are interacting are of the same structure and of similar length; hence, this contribution is usually minor to the overall enhancement of the micellar and surface properties. If the hydrocarbon tail dissimilarity is small, differences observed in the  $\beta$  values should be interpreted in terms of a steric factor owing to differences in the head group structures. In our case, since the head groups of the nonionic species are the same in the three systems, any differences in the  $\beta$  values amongst the three Tween–gemini systems can most likely be attributed to differences in the hydrocarbon tail of the Tween surfactants.

As shown in Fig. 4, it is observed that for a fixed micellar composition, i.e., for a constant value of  $\alpha_{\text{Tween}}$ , the stability of the mixed system decreases as the alkyl chain length of the Tween surfactant becomes shorter (Tween 60 and Tween 80 vs Tween 20). Furthermore, the stability of the mixed system is shown to increase as the unsaturation is removed in the Tween alkyl tail (Tween 80 vs Tween 60). This mixed micellar stability dependence on the alkyl chain

length is consistent with the substantial contribution from the enhanced steric compatibility between the two surfactants as the alkyl chain length of the Tween surfactant is increased. As the sorbitan head groups are interspersed with the gemini surfactant head groups, the attractive interactions between the nonionic and the cationic surfactants in the micellar phase is caused by a decreased electrostatic repulsion between the positively charged gemini head groups by the nonionic surfactant. Sterically, the size of the respective head groups coupled with the decreased electrostatic repulsions leads to a change in the radius of curvature of the micelle and a change in the micelle packing parameter, resulting in a more efficient packing of the gemini surfactants in the mixed micelle vs the respective gemini and Tween micelles. It is clear that in this case, lengthening the hydrocarbon chain leads to an increase in close packing of the Tween and the gemini surfactants, which results in significant stabilization of the Tween–gemini mixed systems. Thus, Tween 60 and Tween 80 should experience a more synergistic interaction with 16-3-16, in comparison with Tween 20. With regard to the effect of alkyl tail saturation, replacement of a single bond in the middle of the chain with a double bond (in the case of the Tween 60 and Tween 80) destabilizes the micelles because of the entropy difference of the alkenyl chains of the Tween 80 vs the saturated alkyl chain of the Tween 60.

In general, the behaviours observed in Fig. 4 can be explained by taking into account the effect that the repulsive interactions of the cationic head groups has on the stability of the mixed micelles. The incorporation of the nonionic surfactants amongst the cationic surfactants in the mixed micelle reduces the destabilizing effect of these strong repulsive interactions. It is interesting to point out that some authors have indicated that the stabilization of mixed micelles composed of cationic surfactants and nonionic surfac-

**Fig. 3.** Micellar mole fractions,  $X_1$  ( $\blacktriangle$ ) and  $X_{\text{ideal}}$  ( $\blacklozenge$ ), as a function of the mole fraction of Tween ( $\alpha_{\text{Tween}}$ ) for the (A) Tween 20 + 16-3-16, (B) Tween 60 + 16-3-16, and (C) Tween 80 + 16-3-16 binary systems.

tants consisting of polyoxyethylene (POE) groups could be explained on the basis of the ion-dipole interactions occurring between the ether oxygens and the cationic head groups.<sup>19,30</sup> Although this is a possible contribution, the sta-

bilization that occurs between the cationic gemini surfactant and the nonionic Tween surfactant in the mixed micelles is most likely consistent with electrostatic stabilization because of the progressive replacement of the gemini surfactant with

**Fig. 4.** Interaction parameter ( $\beta$ ) as a function of the mole fraction of Tween ( $\alpha_{\text{Tween}}$ ).  $\beta$  values are represented as (◆) for Tween 20, (■) for the Tween 60 systems, and (▲) for the Tween 80 binary systems with 16-3-16.

nonionic surfactants in the micelle. There may, however, also be a stabilizing interaction between the large positive charge on the head group of the gemini surfactant and the polar ethylene oxide chain and sorbitan ring of the Tweens.

It is important to note that in all cases, the magnitude of  $\beta$  was found to vary with the molar fraction of the Tween surfactant (see Fig. 4). According to Rubingh's theory, the interaction parameter should remain constant over the entire range of composition.<sup>12</sup> However, numerous studies have found  $\beta$  to vary with composition, thus showing the shortcomings of Rubingh's approach for characterizing the interaction features for all types of mixed micellar systems.<sup>31–38</sup> In particular, mixtures of ionic and nonionic surfactants have been shown to exhibit a  $\beta$  variation with composition.<sup>31,39–42</sup> Nonetheless, Rubingh's model remains as an effective approach for characterizing the nature and strength of interaction of surfactant mixtures. As illustrated in Fig. 4, there is no apparent trend in the magnitude of  $\beta$  with composition, which has been observed in the literature.<sup>25,41,42</sup>

From the data, it is possible to calculate the composition that gives the minimum cmc value. To find this optimum composition, two criteria must be fulfilled: (i) the  $\beta$  parameter must be negative and (ii)  $|\ln(\text{cmc}_2/\text{cmc}_1)| < |\beta|$ . If these criteria are fulfilled, the point where the cmc for the mixed system has its minimum can be calculated with the following equation

$$[8] \quad \alpha_{\text{Tween}} = X_1 = \frac{\left(\ln \frac{\text{cmc}_1}{\text{cmc}_2} + \beta\right)}{2\beta}$$

According to theory, the minimum occurs when the mole fraction of the surfactants in the micelle is equal to the mole fraction in the solution, and that these conditions correspond to the point of maximum synergism, i.e., when the mixture has the lowest cmc value. For the surfactants used in this study, the minimum occurs at  $\alpha_{\text{Tween}} = 0.59$  for Tween 60–16-3-16 and  $\alpha_{\text{Tween}} = 0.60$  for Tween 80–16-3-16 (note, a minimum cmc value could not be calculated for

the Tween 20–16-3-16 system as it did not satisfy criteria (ii)). These results appear to be in reasonable agreement with the literature, which suggests that the optimum composition should be close to 0.5 when the cmcs for the two surfactants are approximately the same, but the optimum is shifted toward the more hydrophobic surfactant in the case where the cmc values are quite different.<sup>43</sup> In Fig. 3, the surfactant composition in the micelle vs the surfactant composition in the solution is plotted and it can be seen that with the Tween 60 and Tween 80 systems, the composition in the micelle and the composition in the solution only coincide at a single composition. It should be noted, however, that these relations are based upon application of the regular solution theory to these systems in which several assumptions and approximations are used. Hence, these calculated values for conditions of maximum synergism should only be regarded as estimates.

## Conclusions

The nature and strength of the interactions between the 16-3-16 gemini surfactant and a homologous series of Tween surfactants was investigated. The results demonstrate a synergistic mixing behavior between the cationic gemini and the nonionic Tween surfactants, which can be explained in terms of the modified electrostatic repulsions and the change in the micellar packing parameters of the mixed systems vs the respective pure micelles, as the Tweens progressively replace the gemini surfactants in the mixed micelles. The maximum synergistic effect has been observed for the longer chain Tween 60 and Tween 80 surfactants vs the Tween 20 surfactant. Furthermore, the synergistic effect was found to decrease with the presence of an unsaturation in the alkyl tail of the Tween 80 vs Tween 60. These observations may be of interest towards the use of these surfactant mixtures in pharmaceutical applications, in particular in the design of drug delivery systems and in drug stabilization. Furthermore, the synergism observed in these systems may reduce the total amount of these surfactants required

for a particular application, which in turn reduces costs and environmental impact.

# Baylis–Hillman reaction under solvent-free conditions—Remarkable rate acceleration and yield enhancement

Monmi Saikia and Jadab C. Sarma

**Abstract:** A simple and efficient method has been developed for remarkable rate acceleration and yield enhancement of the Baylis–Hillman reaction under solvent-free “neat conditions” and solvent-less isolation of products. Reaction of equimolar quantities of aldehyde and olefin in the presence of 20 mol% of DABCO under neat conditions affords the highest yield in most cases within the shortest reaction time, giving support to the mechanisms of proton transfer in protic and aprotic solvents. Solvent-free conditions are found to be especially fast, selective, and high yielding for aromatic aldehydes.

**Key words:** Baylis–Hillman reaction, solvent free, rate acceleration, catalyst.

**Résumé :** On a mis au point une méthode simple et efficace augmenter d’une façon remarquable la vitesse et le rendement de la réaction de Baylis–Hillman, dans des conditions sans solvant tant pour la réaction que pour l’extraction des produits. Dans la plupart des cas, les meilleurs rendements ont été obtenus avec les temps de réaction les plus courts par la réaction de quantités équimolaires d’aldéhyde et d’oléfine en présence de 20 mol % de DABCO dans des conditions sans solvant; ces résultats apportent un support au mécanisme de transferts de proton dans des solvants protiques et aprotiques. On a trouvé que pour les aldéhydes aromatiques, les conditions sans solvant sont particulièrement rapides, sélectives et qu’elles donnent des rendements élevés.

**Mots-clés :** réaction de Baylis–Hillman, sans solvant, accélération de la vitesse, catalyseur.

## Introduction

The Baylis–Hillman reaction<sup>1–4</sup> is an important reaction for carbon–carbon bond formation involving a tertiary amine (or phosphine) catalyzed coupling of an aldehyde with an  $\alpha,\beta$  unsaturated system. This reaction affords a highly functionalized product known as the Baylis–Hillman adduct, with a scope for various chemical manipulations to create frameworks for complex molecules (Scheme 1). Although the reaction was first reported in the early 1980s,<sup>5</sup> its synthetic appreciation was at a low profile in the initial stages. For the last two decades, the Baylis–Hillman reaction has attracted the curiosity of synthetic organic chemists, and the reaction has followed an exponential growth in terms of all the three essential components, i.e., activated olefin, the electrophile, and the catalyst.

Usually the Baylis–Hillman reaction is a slow reaction and requires a few days to a few weeks for completion depending upon the reactivities of both the activated alkene and the aldehyde.<sup>1</sup> Because of the synthetic potential<sup>6</sup> of the Baylis–Hillman adducts, various modifications of the experimental protocol have been proposed. Several groups of scientists had been directing their efforts to solve the problem of slow reaction rate vis-à-vis enhancement of the chemical yield. In this connection some groups of workers have

Scheme 1.

studied the variations of reaction speed and chemical yield by using different Lewis bases such as DABCO, DMAP, DBU,  $\text{Ph}_3\text{P}$ , imidazole, ionic liquid immobilized quinuclidine, tetramethyl guanidine, etc.<sup>7</sup> A few others have tried different solvents or solvent mixtures along with the effect of stoichiometry of the reactants and the catalyst.<sup>8</sup> Additives such as salt, another base as co-catalyst,<sup>9</sup> or external influences such as high pressure,<sup>10</sup> mechanical agitation,<sup>11</sup> ultrasound agitation,<sup>12</sup> etc., were applied to try to improve the rate as well as the yield of the reaction.

Coelho et al.<sup>12</sup> reported on the application of ultrasound radiation in the Baylis–Hillman reaction to obtain augmentation of the reaction rate and the chemical yield. They compared the reactivity of two catalysts viz. tri-*n*-butyl phosphine and 1,4-diazabicyclo[2.2.2]octane (DABCO) and found the later to be the catalyst of choice under ultrasound irradiation. The time for completion of the reaction was drastically reduced from 72 to 16 h for 4-nitrobenzaldehyde and from 480 to 96 h for piperonal and so on. Not only was

the reaction rate enhanced, but also the chemical yield was improved substantially.

Another report of rate acceleration for the Baylis–Hillman reaction was published by Park et al.<sup>13</sup> They found remarkable rate acceleration by using octanol as an additive to the Baylis–Hillman reaction mixture.

Very recently deSouza et al.<sup>14</sup> reported rate and yield enhancement of the Baylis–Hillman reaction through utilization of an aqueous–organic solvent mixture. For the coupling of 4-nitrobenzaldehyde with acrylonitrile, *tert*-butyl alcohol–water (60:40) was reported to be the system of choice (reaction time, 20 min; yield, 99%), whereas for the same aldehyde with methyl acrylate, DMSO–water (60:40) gave better results (reaction time, 150 min; yield, 90%). In both cases, a fast reaction was observed only when the catalyst was used in a stoichiometric amount. Earlier, Yu et al.<sup>8</sup> developed a similar set of conditions using a stoichiometric amount of base catalyst DABCO and an aqueous medium to overcome the problem of long reaction time. To cite an example, the reaction of 4-nitrobenzaldehyde with methyl acrylate in the presence of DABCO (1:3:1 ratio) yielded 83% of the adduct in 3 h.

Porto et al.<sup>15</sup> and Rosa et al.<sup>16</sup> have used an ionic solvent for better yield and a faster reaction rate. Reaction time was also reduced notably and the yield of the adduct increased substantially as in the case of the reaction of 4-nitrobenzaldehyde with methyl acrylate, which afforded a 99% yield in 4 h.

## Results and discussion

The Baylis–Hillman reaction itself falls under the green chemistry transformation because of its total atom efficiency. Under green chemistry protocol, a solvent-free non-stoichiometric catalytic reaction with atom efficiency is a major criterion of greenness. Although a lot of reports have dealt with the issue of rate and yield enhancement for the Baylis–Hillman reaction, there has been no reporting from the green chemistry point of view, especially with regards to the reaction under neat conditions for synthetic utilization. However, a mechanistic study by Aggarwal et al.<sup>17</sup> used neat conditions. In other reports of the reaction under solvent-free neat conditions by Aggarwal and Mereu,<sup>18</sup> Park et al.<sup>13</sup>, and Mack and Shumba<sup>11</sup>, an additional co-catalyst or some external device is being used along with DABCO, and the thrust of the study revolves round the co-catalyst or the external device to show its importance in rate and yield enhancement. Mack and Shumba<sup>11</sup> stressed the utility of a high-speed ball milling device as a novel technique for better yield of the reaction products in as little as 0.5 h of reaction time. Whereas in the study by Park et al.<sup>13</sup> octanol was used as the additive for the acceleration of rate and enhancement of yield, Aggarwal and Mereu<sup>17</sup> demonstrated that lanthanoids were an essential co-catalyst.

In a recent report, Das et al.<sup>19</sup> demonstrated a practical method for the *aza*-Morita–Baylis–Hillman reaction using  $\alpha$ -amido sulfone as the substrate. Here, an excess of alkene was used under neat conditions with a stoichiometric amount of catalyst. Gajda and Gajda<sup>20</sup> also reported an *aza*-Morita–Baylis–Hillman reaction with *N*-carbamate protected  $\alpha$ -amidoalkyl-*p*-tolylsulfones using excess alkene. Similar in

Scheme 2.

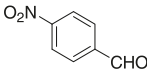

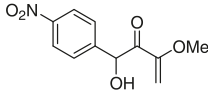

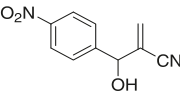

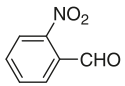

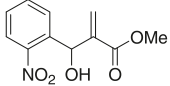

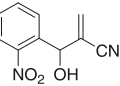

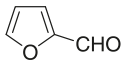

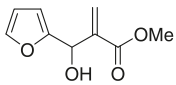

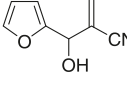

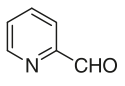

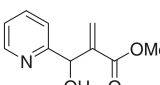

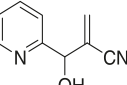

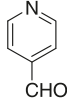

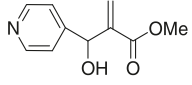

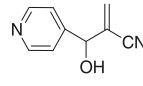

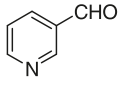

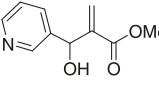

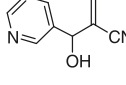

situ generation of imines in the *aza*-Morita–Baylis–Hillman reaction was also reported recently by Abermil et al.<sup>21</sup> and Cihlova et al.<sup>22</sup> They used chlorinated compounds such as  $\text{CH}_2\text{Cl}_2$  and  $\text{CHCl}_3$  as the solvent of choice.

From the scrutiny of the reactions reported by Park et al.,<sup>13</sup> a kinetic study done by McQuade and co-workers,<sup>23</sup> a re-evaluation of the mechanism done by Aggarwal and Lloyd-Jones<sup>24</sup>, and a computational study done by Aggarwal and Harvey<sup>25</sup>, it becomes apparent that proton transfer is accelerated in the presence of a protic additive such as alcohol. (Scheme 2) Aggarwal and Harvey<sup>25</sup> has again shown that in the absence of a protic additive, the reaction is autocatalytic, because the product alcohol itself can act as a hydrogen-bond donor to promote the proton transfer in the transition state (TS) (3).<sup>17</sup> In aprotic solvent or under neat conditions without sufficient quantities of alcohol at the early stage of the reaction, McQuade's<sup>23</sup> pathway involving the hemiacetal intermediate (5) must be operating. In time, as the reaction progresses (>20% conversion) the reaction becomes autocatalytic. Protonation of the enolate (2) by octanol as the solvent (not as an additive) may be the reason for the slow reaction as reported by Park et al.<sup>13</sup> Indeed this more favorable interaction would stabilize the enolate and render it less reactive and thus slow down the reaction rate.

Considering all these factors we decided to try the Baylis–Hillman reaction under solvent-free conditions, keeping the other parameters constant. To our satisfaction the reaction carried out under neat conditions gave a far better result than the ones done with additives like octanol, lanthanoids, etc. In all cases the reaction was over within a very short time, giving a higher yield than those reported in all the other methods. Our observations are compiled in Table 1. The reactions used an equimolar concentration with 20% of DABCO as the catalyst.

For direct comparison of the results obtained using the octanol additive method, we performed a few reactions of aldehydes with methyl vinyl ketone under neat conditions,

keeping the other parameters fixed. The comparative results are shown in Table 2. In all the cases, except for acetaldehyde, the present method gives a better yield in a shorter time period. For aliphatic aldehydes such as propanal and its higher homologues, the reaction is very slow as usual. In fact, decanal remained unchanged for 15 days under neat conditions. For formaldehyde and acetaldehyde, there was some reaction with the formation of a BH adduct and the

dimer at a reasonable speed. As these aldehydes were used as a water solution, and considering the rate enhancement of the small aliphatic aldehydes to be due to the presence of water (a hydrogen-bond donor), we tried the reaction of propanal and decanal by adding three drops each of water in the medium, respectively. In both the cases with methyl acrylate and methyl vinyl ketone as the reactive alkenes, there was no appreciable change over 24 h, thereby indicat-

ing the present method to be selective for aromatic aldehydes.

In many earlier reactions, alkene was added in large excess with 100% catalyst loading. Later on, the stoichiometry was brought to equimolar with 50% to 15% loading of the catalyst. If participation of the aldehyde as a hemiacetal in the TS for proton transfer is important in aprotic solvents, then an excess of aldehyde should enhance the rate of the reaction. Therefore, we used a few otherwise sluggish aldehydes by adding 10% excess to that of the alkene under neat conditions with 20% of catalyst (DABCO) loading to see the difference. From the results shown in Table 3, it is clear that for the substrates of entries 1–3 the reaction time was

reduced substantially (in comparison with Table 1). For 4-methoxy benzaldehyde, the yield was enhanced, but the reaction time remained the same, and for piperonal, there was no appreciable change.

In reactions generally carried out under solvent-free conditions, the solvent is normally required to be used at a later stage (at the time of extraction of the product from the reaction mixture) and, therefore, the claim for a solvent-free green method substantially gets diluted. We, therefore, tried a representative reaction of 4-nitrobenzaldehyde with methyl acrylate in a 2 g scale and worked up by pouring the reaction mixture into ice-cold water. Precipitated product was recrystallized from ethanol to get 98% yield of the pure

crystalline product. Thus, the method turned out to be a complete solvent-free green method.

## Conclusion

In conclusion, we report a green method with significant rate enhancement as well as yield improvement of the Baylis–Hillman reaction through solvent-free conditions. The method is bestowed with several unique green features such as a solvent-free neat reaction, a catalytic transformation, a solvent-less simple work up procedure for large-scale reaction, a higher yield than those reported so far in almost all cases, and the shortest reaction time. Hence, it significantly contributes to synthetic organic chemistry.

## Experimental

### General procedure for the Baylis–Hillman reaction

In a 50 mL round bottom flask, an equimolar quantity of aldehyde was stirred with an electron-deficient alkene with 20 mol% of DABCO as the catalyst at room temperature. The progress of the reaction was monitored by TLC. On completion, the reaction was poured into water and extracted with ethyl acetate. The extract was dried over anhydrous sodium sulfate, and the solvent was removed under reduced pressure to get a solid mass, which in most cases was recrystallized from ethanol. Otherwise, filtering through a short silica gel column yielded the pure product.

When the reaction was carried out in a 2 g scale of 4-nitrobenzaldehyde, the product was isolated by pouring the reaction mixture over ice-cold water followed by filtering and recrystallization of the product from ethanol. All the known compounds reported in Table 3 have been found to give spectral data identical to those reported. The spectral and other data of the compounds not reported earlier are reproduced here.

# An improved one-pot cost-effective synthesis of N,N-disubstituted carbamoyl halides and derivatives

K. Adeppa, D.C. Rupainwar, and Krishna Misra

**Abstract:** A convenient one-pot procedure is reported for preparing N,N-disubstituted carbamoyl chlorides by using chlorocarbonylsulfenyl chloride as a carbonylating agent. It comprises the reaction of secondary amines with chlorocarbonylsulfenyl chloride in the presence of an aprotic organic solvent to produce the corresponding N,N-disubstituted carbamoyl halides. Insertion of the carbonyl group without using phosgene is the novelty of this method.

**Key words:** carbonylsulfenyl chloride, secondary amines, dichloromethane, carbamoyl halides.

**Résumé :** On a développé une méthode monotope pour préparer des chlorures de carbamoyle N,N-disubstitués qui fait appel au chlorure de chlorocarbonylsulfényle comme agent de carbonylation. Elle implique la réaction d'amines secondaires avec le chlorure de chlorocarbonylsulfényle en présence d'un solvant organique aprotique qui conduit à la formation des halogénures de carbamoyles N,N-disubstitués correspondants. La nouveauté de cette méthode correspond à l'insertion d'un groupe carbonyle sans faire appel au phosgène.

**Mots-clés :** chlorure de chlorocarbonylsulfényle, amines secondaires, dichlorométhane, halogénures de carbamoyle.

## Introduction

Carbamoyl halides<sup>1</sup> are an important class of commercially viable chemicals. These are useful intermediates in the preparation of thiolcarbamate herbicides via their reaction with thiols such as sodium alkyl mercaptides. Carbamoyl halides, particularly chlorides, are useful in the preparation of 1,4-disubstituted 5-(4*H*)-tetrazolinones;<sup>2</sup> imidazole derivatives;<sup>3</sup> Reissert analogs;<sup>4</sup> phenylcarbamates;<sup>5</sup> unsymmetrical ureas; pyrrole-*N*-carbonyl compounds;<sup>6</sup> *O*- $\alpha$ -oxoalkylcarbamates;<sup>7</sup> *O*-allylic urethanes and carbonates;<sup>8</sup> in the synthesis of carbamates;<sup>9</sup> phthalides;<sup>10</sup> in the preparation of arylisocyanates;<sup>11</sup> *N,N*-dimethyl carbamoyloxy-3-thiodiazoles-1,2,4;<sup>12</sup> and *N,N*-dialkylcarbamate esters. Carbamoyl chlorides are also used for Friedel-Crafts acylation<sup>13</sup> followed by treatment with ammonia or amines to produce aromatic amides or substituted amides, which on hydrolysis yield corresponding acids. For example, *N,N*-dimethyl carbamoyl chloride has been used in the production of herbicides<sup>14</sup> such as isoproturon, fenuron, diuron, and metoxuron, and with drugs such as neostigmine bromide, neostigmine methylsulfate,<sup>15</sup> and pyridostigmine, which is the intermediate for the antihistaminic bulk drug loratidine. *N,N*-Diethyl carbamoyl chloride has been used as an intermediate for the antifilarial bulk drug diethylcarbamazine citrate. *N*-Ethyl-*N*-methyl carbamoyl chloride is used as an intermediate for the bulk drugs rivastigmine and  $\beta$ -propiolactone.

So far, the most prevalent commercial method for producing carbamoyl chlorides is phosgenation of ammonia or

amines.<sup>16,17</sup> The main objective of the present work was to develop an efficient and economically viable procedure for preparing N,N-disubstituted carbamoyl chlorides. A further objective was to exploit the procedure for the preparation of unsymmetrical ureas<sup>18</sup> and N,N-disubstituted carbamate esters,<sup>19</sup> aromatic amides,<sup>20</sup> and thiolcarbamate herbicides. For the preparation of N,N-disubstituted carbamoyl chlorides, the commercial process involves the phosgenation of secondary amines. The use of phosgene, however, has several disadvantages. The phosgenation route is long and energy-intensive, and requires handling highly corrosive materials and highly toxic reagents and intermediates, especially phosgene and chlorine. Furthermore, the phosgenation route requires the use of process equipment that can withstand high temperatures and highly corrosive conditions, resulting in increased capital cost.

A non-phosgene process for preparing N,N-disubstituted carbamoyl chlorides, which is economical and commercially viable and that can produce N,N-disubstituted carbamoyl chlorides with good yields under extremely mild reaction conditions and short reaction times, is highly desirable. Such an attempt has been made during the present work.

## Results and discussion

To develop a general method for the synthesis of carbamoyl chlorides and their derivatives, experiments were conducted through the carbonylation of secondary amines with chlorocarbonylsulfenyl chloride at  $\sim 40^\circ\text{C}$  for 3 h and

chlorination at room temperature for 2 h under nitrogen using dichloromethane as a solvent. To explore the general method developed for the synthesis of carbamoyl chloride derivatives, the experiments were conducted with chlorocarbonylsulfenyl chloride and a variety of secondary alkyl amines followed by chlorination to give the corresponding *N,N*-disubstituted carbamoyl chloride derivatives in substantial yields.

We found that this one-step reaction is general and is applicable to most secondary alkyl amines. The reaction conditions for the preparation of *N,N*-disubstituted carbamoyl chlorides starting from different secondary alkyl amines are summarized in Table 1, and the GC analysis as compared with the standard samples are summarized in Table 2. A probable mechanism for the preparation of *N,N*-disubstituted carbamoyl chlorides from different secondary alkyl amines

**Note:** GC, THERMO Fischer model GC 1000; 8 ft glass (0.8 mm ID); 10% SE-30 on Chromosorb W (80–100 mesh); initial column temperature, 70 °C for 2 min; temperature rise rate, 25 °C/min; final column temperature, 240 °C held for 5 min; injector temperature, 240 °C; detector temperature, 250 °C. Two hundred milligrams of the sample and the standard were dissolved in 5 mL of toluene and 0.5 µL of each solution was injected.

has been suggested in Scheme 1. The present method has obvious advantages, compared with those reported in the literature, namely milder reaction conditions, use of less toxic materials, and better yields resulting in cost effectiveness of the procedure and general applicability.

## Experimental details

Dimethylamine, diethylamine, di-*n*-propylamine, diisopropyl amine, *N,N*-ethyl-methylamine, di-*n*-butylamine, piperidine, and dichloromethane were sponsored by Merck

(India), and perchloromethyl mercaptan was sponsored by India Pesticides Limited (Lucknow, India). All the products gave satisfactory boiling points. Gas chromatographic analysis was performed on a Thermo Fisher model GC-1000 gas chromatograph, and the results were consistent with the literature data.

## Chlorocarbonylsulphenyl chloride (CCSC)<sup>21</sup>

Perchloromethyl mercaptan (PCMM) (294 mL, 500 g, 2.7 mol) was taken in a 2 L reaction flask equipped with a reflux condenser, a thermometer, and a stirrer, and a mixture

of water (54 mL, 3.0 mol) in concd sulfuric acid (620 mL) was added. The heterogenous mixture was vigorously stirred for 6 h at 45–50 °C as HCl evolved, and then stirred overnight at 25 °C to ensure complete reaction of PCMM at the expense of a decreased yield of chlorocarbonylsulfenyl chloride (CCSC), which can hydrolyze. The upper phase (280 g, 80%) was separated and distilled through a column, bp 98–101 °C (lit.,<sup>21</sup> bp 98 °C) to yield 230 g (65%) of the clear light yellow liquid of CCSC (65%).

### General procedure for the preparation of *N,N*-dialkylcarbamoyl chlorides

A stirred solution of secondary amine (0.47 mol) in 800 mL dichloromethane in a 2 L reaction flask equipped with a reflux condenser and a stirrer was heated at ~40 °C under nitrogen. CCSC (65.50 g, 0.50 mol) at ~40 °C under nitrogen was added with stirring. The reaction mixture was stirred for an additional 3 h under reflux until evolution of HCl gas was completed. After cooling to room temperature (RT), the dark green liquid was chlorinated with chlorine (35.5 g, 0.50 mol) and the reaction mass was stirred for an additional 2 h under these conditions, followed by distillation at atmospheric pressure to remove solvent and sulfur dichloride. This reddish brown material was transferred into a 100 mL capacity distillation flask and distilled under reduced pressure (10 mm Hg; 1 mmHg = 133.3224 Pa). The total yield of *N,N*-disubstituted carbamoyl chloride was 80%–86%. Retention times in GLC as compared with the standard are given in Table 2.

### Conclusion

The present method describes a simple, efficient one-pot method for the synthesis of commercially important *N,N*-disubstituted carbamoyl chlorides from the corresponding secondary amines and chlorocarbonylsulfenyl chloride. The process is economically viable; the enhanced rate of reaction, negligible byproducts, and cleaner reaction profiles make it a useful and attractive process for synthesis. The generalized and simple product-isolation procedures play an important role in the development of this novel method. It is an important step toward developing a greener and more efficient commercial synthesis for a group of compounds that are used to make important intermediates for the synthesis of a large number of commercially important products. This is an improvement over the phosgenation method being used at present.

### Acknowledgements

The authors gratefully acknowledge the Centre for Biomedical Magnetic Resonance (CBMR), the Sanjay Gandhi Post Graduate Institute of Medical Sciences (SGPGI), Lucknow, India, for NMR spectra, and the Central Drug Research Institute (CDRI), Lucknow, India, for IR spectra. One of the authors (K. Adeppa) is grateful to India Pesticides Limited,

Lucknow, India, for providing all laboratory facilities and financial support, which enabled the present work to be completed successfully.

## January / Janvier

### ARTICLES / ARTICLES

- Saul Wolfe and Kiyull Yang** On the role of lysine in the active site Ser-X-X-Lys region of penicillin-recognizing enzymes 1
- Michael Lewis, Shana Beg, Aimee Clements, Dianne Tran, and Kristine Waggoner** The effect of substituent rotation on aromatic quadrupole moments 5
- Hashem Sharghi and Mahboubeh Jokar** Highly stereoselective facile synthesis of  $\beta$ -amino carbonyl compounds via a Mannich-type reaction catalyzed by  $\gamma$ - $\text{Al}_2\text{O}_3/\text{MeSO}_3\text{H}$  (alumina/methanesulfonic acid: AMA) as a recyclable, efficient, and versatile heterogeneous catalyst 14
- Jocelyn J. Tindale and Paul J. Ragogna** Ionophilic phosphonium-appended carbopalladacycle catalyst for Suzuki–Miyaura and Heck cross-coupling catalysis 27
- Wujun Liu, Shuhua Hou, and Zongbao Kent Zhao** Synthesis and electrochemical behavior of triazole-containing nicotinamide adenine dinucleotide analogs 35
- Luiza Gaina, Dan Porumb, Ioan Silaghi-Dumitrescu, Castelia Cristea, and Luminita Silaghi-Dumitrescu** On the microwave-assisted synthesis of acylphenothiazine derivatives — Experiment versus theory synergism 42
- Sabine Montaut, René S. Bleeker, and Carine Jacques** Phytochemical constituents of *Cardamine diphyllo* 50
- Kiyull Yang, Yih-Huang Hsieh, Chan-Kyung Kim, Hui Zhang, and Saul Wolfe** Hydration of acetone in the gas phase and in water solvent 56
- Adrian Adamescu, Holly Gray, Katherine M.E. Stewart, I.P. Hamilton, and Hind A. Al-Abadleh** Trends in the frequencies of  $\nu(\text{AsO}_x\text{H}_{x-1})$  [ $x = 2-4$ ] in selected As(V)-containing compounds investigated using quantum chemical calculations 65

## February / Février

### AWARD LECTURE / CONFÉRENCE D'HONNEUR

- J. Peter Guthrie, Sriyawathie Peiris, Margaret Simkin, and Yun Wang** Rate constants for decarboxylation reactions calculated using no barrier theory 79

### ARTICLES / ARTICLES

- Earl Cook, Jason D. Masuda, and Aibing Xia** Synthesis, characterization, and application of palladium complexes containing 8-quinolylphosphinite ligands 99
- André Pichette, Azadeh Eftekhari, Patricia Georges, Serge Lavoie, Vakhtang Mshvildadze, and Jean Legault** Cytotoxic phenolic compounds in leaf buds of *Populus tremuloides* 104
- Kamal H. Mroué, Abdul-Hamid M. Emwas, and William P. Power** Solid-state  $^{27}\text{Al}$  nuclear magnetic resonance investigation of three aluminum-centered dyes 111
- Aleisha A. McLachlan and D. Gerrard Marangoni** 1D and 2D NMR investigations of the interaction between oppositely charged polymers and surfactants 124
- Seyedeh Fatemeh Hojati, Iraj Mohammadpoor-Baltork, Behrooz Maleki, Mostafa Gholizadeh, Fatemeh Shafieezadeh, and Mahnaz Haghdoust** 1,3-Dibromo-5,5-dimethylhydantoin as an efficient homogeneous catalyst for the synthesis of 2-arylthiazolines and 2-arylimidazolines 135
- Paul M. Mayer, Martyn F. Guest, Emma E. Rennie, Louise Cooper, Larisa G. Shpinkova, David M.P. Holland, and David A. Shaw** Threshold ionization and dissociation of *t*-butylamine 142
- Sudarshan Das, Matiur Rahman, Dhiman Kundu, Adinath Majee, and Alakananda Hajra** Task-specific ionic-liquid-catalyzed efficient synthesis of indole derivatives under solvent-free conditions 150
- Fakhrossadat Mohammadi, Abdol-Khalegh Bordbar, Khosro Mohammadi, Adeleh Divsalar, and Ali Akbar Saboury** Circular dichroism and fluorescence spectroscopic study on the interaction of bisdemethoxycurcumin and diacetylbisdemethoxycurcumin with human serum albumin 155

- Khodabakhsh Niknam, Dariush Saberi, Hajar Molaei, and Mohammad Ali Zolfigol** Silica-bonded *S*-sulfonic acid as a recyclable catalyst for the silylation of hydroxyl groups with hexamethyldisilazane (HMDS) 164

## March / Mars

**This Special Issue is dedicated to Professor Mitchell A. Winnik to honour his outstanding contributions to research in polymer chemistry and physics. / Numéro spécial honorant le professeur Mitchell A. Winnik pour sa contribution exceptionnelle à la chimie et à la physique des polymères.**

### MINIREVIEW / MINISYNTHESE

- Jung Kwon Oh** Engineering of nanometer-sized cross-linked hydrogels for biomedical applications 173

### ARTICLES / ARTICLES

- Haiké Feng, Yi Dan, and Yue Zhao** A sensitive fluorescence method for monitoring the kinetics of microemulsion polymerization 185
- Gang Qian and Zhi Yuan Wang** Design, synthesis, and properties of benzobisthiadiazole-based donor- $\pi$ -acceptor- $\pi$ -donor type of low-band-gap chromophores and polymers 192
- Y.J. Wang, F. Ravenelle, and X.X. Zhu** NMR imaging study of cross-linked high-amylose starch tablets — The effect of drug loading 202
- Jingjing Liu, Airi Yoneda, Dian Liu, Yuuichi Yokoyama, Shin-ichi Yusa, and Kenichi Nakashima** Mixed micelles of poly(styrene-*b*-3-(methacryloylamino)propyltrimethylammonium chloride-*b*-ethylene oxide) and anionic amphiphiles in aqueous solutions 208
- Mark Ingratta, Manoj Mathew, and Jean Duhamel** How switching the substituent of a pyrene derivative from a methyl to a butyl affects the fluorescence response of polystyrene randomly labeled with pyrene 217
- Chih-Feng Huang, Jeong Ae Yoon, and Krzysztof Matyjaszewski** Synthesis of *N*-vinylcarbazole-*N*-vinylpyrrolidone amphiphilic block copolymers by xanthate-mediated controlled radical polymerization 228
- Andréanne Bolduc, Stéphane Dufresne, Garry S. Hanan, and W.G. Skene** Synthesis, photophysics, and electrochemistry of thiophene-pyridine and thiophene-pyrimidine dyad comonomers 236
- Ferdous Khan, Shalini Khanna, Ah-Mee Hor, and P.R. Sundararajan** The role of molecular volume and the shape of the hole transport molecule in the morphology of model charge transport composites 247
- Mingtao Wang, Nan Li, Phillip Choi, and Yaolin Zhang** A study of the intermolecular branch frequency dependence of tie-chain concentration in single-site linear low-density polyethylene blown films by a new FTIR method 260
- Ş. Uğur, Ö. Yargı, and Ö. Pekcan** Conductivity percolation of carbon nanotubes (CNT) in polystyrene (PS) latex film 267
- Vanessa I. Scanga, Alex Goraltchouk, Nasser Nussaiba, Molly S. Shoichet, and Cindi M. Morshead** Biomaterials for neural-tissue engineering — Chitosan supports the survival, migration, and differentiation of adult-derived neural stem and progenitor cells 277
- Y. Rharbi, M. Yousfi, Lionel Porcar, and Q. Nawaz** Methods for probing the long-range dynamic of confined polymers in nanoparticles using small-angle neutron scattering 288
- Alla Petukhova, Andrew S. Paton, Ilya Gourevich, Selvakumar V. Nair, Harry E. Ruda, Alexander Shik, and Eugenia Kumacheva** Hybrid microspheres with alternating layers of a polymer and metal nanoparticles 298

## April / Avril

### ARTICLES / ARTICLES

- Dorith Tavor, Oxana Sheviev, Christina Dlugy, and Adi Wolfson** Transfer hydrogenations of benzaldehyde using glycerol as solvent and hydrogen source 305
- Wendy A. Sears, Craig D. MacKinnon, Robert C. Mawhinney, Lauren C. Sinnemaki, Matthew J. Johnson, A. John Winter, and Craig M. Robertson** Using the nitro group to induce  $\pi$ -stacking in terthiophenes 309
- Abhijeet S. Kate, Kelly Richard, Balaji Ramanathan, and Russell G. Kerr** A halogenated pseudopterane diterpene from the Bahamian octocoral *Pseudopterogorgia acerosa* 318
- Melek Gul and Nuket Ocal** Heck-type hydroarylations and 1,3-dipolar cycloaddition reactions of new tricyclic hydrazones 323
- Jia-Rong Chen, Jie Liao, and Wen-Jing Xiao** Microwave-assisted, palladium-catalyzed carbonylative cyclization — Rapid synthesis of 2-quinolones from unprotected 2-iodoanilines and terminal alkynes 331
- Boaz G. Oliveira, Regiane C.M.U. Araújo, Antônio B. Carvalho, and Mozart N. Ramos** AGOA hydration clusters produce the solvation effect on the aziridine...hydrofluoric acid complex — A modern proposal 338

<b>Naomi Hunter and Keith Vaughan</b> Triazene derivatives of (1, <i>x</i> )-diazacycloalkanes — Part IX. Synthesis and characterization of a series of 1,4-di[2-aryl-1-diazenyl]-2,6-dimethylpiperazines	<b>344</b>
<b>An Yong Li, Li Juan Cao, and Hong Bo Ji</b> Theoretical study of H bonds of HArF and HF with isoelectronic systems N <sub>2</sub> , CO, and BF	<b>352</b>
<b>Chenjie Zhu, Lei Ji, Qian Zhang, and Yunyang Wei</b> Catalytic hypervalent iodine oxidation of alcohols to the corresponding carbonyl compounds using <i>N</i> -hydroxyphthalimide (NHPI) and <i>m</i> -chloroperbenzoic acid	<b>362</b>
<b>Kuo-xi Xu, Yu-xia Wang, Shu-yan Jiao, Jin Zhao, and Chao-jie Wang</b> Enantioselective fluorescent sensors for chiral carboxylates based on BINOL — Synthesis and chiral recognition	<b>367</b>
<b>İmran Koç, Meryem Çamur, Mustafa Bulut, and A. Riza Özkaya</b> Electrochemical and in situ spectroelectrochemical investigations into the redox and aggregation behaviours of phthalocyanines bearing octyl 4-phenyloxyacetate moieties	<b>375</b>
<b>Joaquín Cortés and Eliana Valencia</b> Mean-field study of the synergic effect of the CO–NO reaction on a heterogeneous substrate of interconnected sectors	<b>383</b>
<b>Vimal K. Balakrishnan and Virginia Palabrica</b> Determining the maximum environmental release limit of the toxic dye, CHPD	<b>393</b>

## May / Mai

### AWARD LECTURE / CONFÉRENCE D'HONNEUR

<b>Hans-Peter Looock, Jack A. Barnes, Gianluca Gagliardi, Runkai Li, Richard D. Oleschuk, and Helen Wächter</b> Absorption detection using optical waveguide cavities	<b>401</b>
-----------------------------------------------------------------------------------------------------------------------------------------------------------------------	------------

### ARTICLES / ARTICLES

<b>Zhilin Jin, John L. Brash, and Shiping Zhu</b> ATRP grafting of oligo(ethylene glycol) methacrylates from gold surface — Effect of monomer size on grafted chain and EO unit densities	<b>411</b>
<b>Jordache Boudreau, Dorin Bejan, and Nigel J. Bunce</b> Competition between electrochemical advanced oxidation and electrochemical hypochlorination of acetaminophen at boron-doped diamond and ruthenium dioxide based anodes	<b>418</b>
<b>Michael J.D. Bosdet, Warren E. Piers, Ted S. Sorensen, and Masood Parvez</b> 5b,7b-Diaza-3b,9b-diborabenz[ <i>ghi</i> ]perylene	<b>426</b>
<b>Muhammad Ramzan Saeed Ashraf Janjua, Zhong-Min Su, Wei Guan, Ahmad Irfan, Shabbir Muhammad, and Mudassir Iqbal</b> A DFT study on the electronic and redox properties of [X <sub>8</sub> V <sub>14</sub> O <sub>50</sub> ] <sup><i>n</i>-</sup> (X = Si <sup>IV</sup> , Ge <sup>IV</sup> , P <sup>V</sup> , and As <sup>V</sup> )	<b>434</b>
<b>C.S. Kavitha, K.M. Hosamani, and R.S. Harisha</b> Imino Diels–Alder reaction — An efficient synthetic protocol for 2-methyl-4-substituted tetrahydroquinolines catalyzed by copper dipyrindine dichloride	<b>443</b>
<b>Lihua Kang and Bin Dai</b> Effect of collision energy on cross sections and product alignments for the C( <sup>1</sup> D) + H <sub>2</sub> ( <i>v</i> = 0, <i>j</i> = 0) insertion reactions	<b>453</b>
<b>Tomoe Shimizu, Kan Tanaka, Arjun Paudel, and Takehiko Yamato</b> Medium-sized cyclophanes — Part 85: Benzylolation by 8-(bromomethyl)[2.2]metacyclophanes. Through-space electronic interactions of [2.2]metacyclophane benzyl cations	<b>458</b>
<b>Dihourahouni Tountian, Anne Brisach-Wittmeyer, Paul Nkeng, Gérard Poillerat, and Hugues Ménard</b> On the efficiency of phenol and cyclohexanone electrocatalytic hydrogenation — Effect of conditioning and working pH in acetic acid solution on palladium/fluorine-doped tin dioxide supported catalyst	<b>463</b>
<b>Paul O. Oguadinma and Frank Schaper</b> Synthesis and structures of isopropyl-β-diketiminato copper(I) complexes	<b>472</b>
<b>Anand Sachar, Poonam Gupta, Shallu Gupta, and R.L. Sharma</b> A novel approach towards the synthesis of tricyclic systems based on pyridine, pyran, thiopyran, azepine, oxepin, thiepin, and pyrimidine rings under different solvent conditions	<b>478</b>
<b>Chuanming Yu, Beibei Jin, Zhenyu Liu, and Weihui Zhong</b> A novel and efficient cross-coupling of tris(fluorinated phenyl)boroxins with disulfides catalyzed by CuI/1,10-phenanthroline	<b>485</b>

## June / Juin

### ARTICLES / ARTICLES

<b>Sarah Ward, Tammy Messier, and Matthew Lukeman</b> Electrophilicity of a 9-aryl-9-fluorenyl cation in water — Kinetic evidence for antiaromaticity	<b>493</b>
<b>David M. Fasano, Susan J. Fitzwater, Willie Lau, and Aurelia C. Sheppard</b> Diffusion of oligomers in latex systems — A route to low volatile organic compound (VOC) coatings	<b>500</b>
<b>Abdolhamid Alizadeh, Mohammad M. Khodaei, and Ali Eshghi</b> A solvent-free protocol for the green synthesis of arylalkylidene rhodanines in a task-specific ionic liquid	<b>514</b>
<b>Ki Hyun Kim, Sang Wook Chang, and Kang Ro Lee</b> Feruloyl sucrose derivatives from <i>Bistorta manshuriensis</i>	<b>519</b>
<b>Sanela Martić, Gang Wu, and Suning Wang</b> Interactions of cytidine with N <sup>2</sup> -functionalized guanoses and cytidine–cytidine exchange involving a GC pair — NMR and fluorescence spectroscopic study	<b>524</b>

<b>Larissa Zuppardo Lacerda Sabino, Daniele Cestari Marino, and Horacio Dorigan Moya</b> Determination of diltiazem based on the reduction of Cu(II)–BCA complexes in micellar medium	<b>533</b>
<b>Justyna Jachula, Dorota Kolodyńska, and Zbigniew Hubicki</b> Removal of Cd(II) and Pb(II) complexes with glycolic acid from aqueous solutions on different ion exchangers	<b>540</b>
<b>Dominik Wechsler, Boyd Davis, and Philip G. Jessop</b> The dehydrogenation of combined organic and inorganic hydrogen-storage carriers	<b>548</b>
<b>Akira Nakajima, Emiko Matsuda, Yuto Ueda, and Kunihiro Tajima</b> ESR analysis of the oxidation reactions of phosphorus-containing nitrene-type spin traps with gold(III) ion	<b>556</b>
<b>Negar Zekri and Reza Fareghi Alamdari</b> An efficient and selective method for the preparation of triphenylmethyl ethers of alcohols and nucleosides	<b>563</b>
<b>Xiaocui Zhao, Mengni Zhang, Yitao Long, and Zhifeng Ding</b> Redox reactions of reactive oxygen species in aqueous solutions as the probe for scanning electrochemical microscopy of single live T24 cells	<b>569</b>
<b>ADDITIONS AND CORRECTIONS / AJOUTS ET CORRECTIONS</b>	
<b>Delano P. Chong</b> Theoretical study of the electron spectra of <i>s</i> -triazine vapour	<b>577</b>

## NOTE OF APPRECIATION / NOTE DE RECONNAISSANCE

The success of the journal is dependent upon our reviewers. The Editors gratefully acknowledge the commitment and goodwill of all the reviewers who assisted us in the publication of Volume 88. Thank you.

Le succès du journal dépend du travail acharné de nos réviseurs. Le personnel de la rédaction est reconnaissant de leur volonté et leur nombreuses contributions qui ont rendu possible la sortie du volume 88. Merci.

## ANNOUNCEMENT / COMMUNIQUÉ

### NRC Research Press transition to Canadian Science Publishing

As of 2 September 2010, the publishing operations of the National Research Council's NRC Research Press successfully transitioned out of the National Research Council (NRC) and Federal Government and into a new not-for-profit company operating under the new name of Canadian Science Publishing (CSP). This transition is the result of an NRC decision announced in February 2009 to proceed with a Federal Government of Canada Strategic Review recommendation to transfer the publishing operations to the private sector.

The new entity will continue to provide high-quality, peer-reviewed journals and publishing services. CSP is committed to publishing and providing services in English and French and will continue to support Canadian researchers and their communities in disseminating their research worldwide through the provision of world-class, advanced scientific and technical scholarly publishing services. Journals published by CSP will continue to use the "NRC Research Press" designation.

As a leader in the scientific and technical scholarly publishing community, CSP is committed to its NRC Research Press journal subscribers and would like to thank them for their ongoing support.

### Transition des Presses scientifiques du CNRC vers les Éditions Sciences Canada

Depuis le 2 septembre 2010, les opérations d'édition des Presses scientifiques du CNRC sont passées avec succès du Conseil national de recherches du Canada (CNRC) et du gouvernement fédéral à une nouvelle société sans but lucratif nommée Éditions Sciences Canada (ESC). Cette transition est le résultat de la décision du CNRC, annoncée en février 2009, de mettre à exécution une recommandation de l'examen stratégique du gouvernement fédéral, soit le transfert de ces opérations d'édition au secteur privé.

Cette nouvelle entité continuera à fournir des revues de grande qualité évaluées par les pairs et des services d'édition. Les ESC s'engagent à fournir des services d'édition en anglais et en français et à préserver la mission de son ancienne entité, à savoir d'aider les chercheurs canadiens et leur milieu à diffuser leurs travaux de recherche à travers le monde grâce à la fourniture de services canadiens d'édition savante scientifique et technique d'avant-garde et de niveau international. Les revues publiées par les ESC continueront d'utiliser l'appellation « NRC Research Press ».

En tant que chef de file du milieu de l'édition savante scientifique et technique, les ESC sont dévouées envers les abonnés de leurs revues de NRC Research Press et les remercient de leur appui continu.
