An Exacta 2000 ellipsometer (Waterloo Digital Electronics) was used to determine the thicknesses of the initiator monolayer and poly(OEGMA) on the gold-coated substrates with single wavelength (6328 Å) and an incident angle of 70°. The gold-coated wafers were considered as the substrate, with refractive index ( $n_s$ ) and extinction coefficient ( $k_s$ ) of  $0.19 \pm 0.02$  and  $3.52 \pm 0.08$ , respectively. For the initiator-functionalized and poly(OEGMA)-grafted surfaces, the polarizer (P) and analyzer (A) angles for the null condition were measured and thickness values were determined using a three-layer air-grafts-gold model via the Exacta 2000 Variable Theta Simplex Fitting Program. A refractive index of 1.46 was used for initiator SAMs and poly(OEGMA) grafts.<sup>14,15</sup>

The surface chain densities of poly(OEGMA) as well as initiator/diluting agent were calculated based on the following equation:<sup>9,16</sup>

$$[1] \quad \sigma = \frac{h\rho N_A}{\bar{M}_n}$$

where  $\sigma$  is the surface chain density,  $h$  is the layer thickness determined by ellipsometry,  $\rho$  is the bulk density of the grafted layer (1.0 g/cm<sup>3</sup> was used for poly(OEGMA) and initiator SAMs),  $N_A$  is Avogadro's number, and  $\bar{M}_n$  is the number-average molecular weight ( $\bar{M}_{n, \text{GPC}}$  was used for poly(OEGMA)). The molecular weight of poly(OEGMA) formed on surface is assumed to be the same as that of poly(OEGMA) formed in solution, and the mole fraction of initiator in the SAMs is assumed to be the same as that in the mixed disulfide solution during initiator immobilization.

## Results and discussion

### Mixed SAMs formed on Au surfaces

Scheme 1 illustrates the two-step reaction procedure for the synthesis of poly(OEGMA)-grafted Au surfaces (referred to as Au/poly(OEGMA)). The chain density of poly(OEGMA) was controlled through the surface initiator density in the

SAMs. Bis[2-(2'-bromoisobutyryloxy) ethyl] disulfide (**1**) was used as the grafting initiator and butyl disulfide (**2**) as an inert "diluting agent" that chemisorbs to gold similarly to the initiator. The mole fractions of active initiator in the SAMs ranged from 2% to 100%.

Figure 1a shows the ellipsometric thickness of the SAMs having various mole fractions of initiator; values were in the range of < 1 nm. The 100% initiator layer was significantly thicker than the 100% diluting agent layer, in agreement with the dimensions of the two molecules. The surface density (molecules/nm<sup>2</sup>) of the SAMs was calculated from the thickness data, and the initiator density was estimated from the SAM density and the mole fraction of initiator. The initiator density (Fig. 1b) was found to increase linearly with increasing mole fraction of initiator in the mixed disulfide solution.

### Poly(OEGMA) grafts via s-ATRP

ATRP grafting of OEGMA was carried out on the Au/initiator surfaces with Cu(I)Br/2bpy complex as catalyst and free/sacrificial initiator (EBIB) in solution. The free initiator in solution was in very large amounts compared with the initiator covalently attached on surface. For a well-controlled ATRP process, the polymer chains formed by the free initiator in solution may be assumed to have the same chain length and distribution as the chains grafted on the surface.<sup>17</sup> The monomer conversion, molecular weight, and the polydispersity of the polymers formed in solution are shown in Table 1. Complete conversion was achieved for the ATRP grafting of OEGMA of  $M_r$  300 and 475. However, for OEGMA of  $M_r$  1100, the conversion was limited to ~48%. Polydispersities determined by GPC were in the range of 1.05 to 1.19, indicating good control of the ATRP process.

The advancing water contact angles ( $\theta_{\text{Adv}}$ ) of the Au surfaces before and after modification are shown in Fig. 2. The contact angle of unmodified Au surface was about 65° and clearly decreased after poly(OEGMA) grafting. For a given monomer  $M_r$ , especially for  $M_r$  of 300 and 475,  $\theta_{\text{Adv}}$  decreased slightly from ~55° to ~40° with increasing initiator

**Fig. 3.** (a) Ellipsometric thickness and (b) density (chains/nm<sup>2</sup>) of the poly(OEGMA) grafts with various OEGMA  $M_r$  300, 475, and 1100. Error bars represent one standard deviation,  $n = 4$ .

**Scheme 2.** Highly stretched poly(OEGMA) brushes with various OEGMA  $M_r$ .

**Fig. 4.** Surface density of EO units on Au surfaces with various OEGMA  $M_r$  and initiator density. Error bars represent one standard deviation,  $n = 4$ .

fraction from 2% to 100%, presumably due to the increased surface density of the hydrophilic EO units at higher initiator density. For OEGMA of  $M_r$  1100, the contact angle leveled off at initiator fraction > 50%; this is in agreement with the thickness and density variation of the poly(OEGMA) grafts (Fig. 3).

The thickness of poly(OEGMA) grafts was determined by ellipsometry, and the data are shown in Fig. 3a. For a given monomer  $M_r$ , the thickness of the grafts increased significantly with increasing initiator fraction or initiator density, and leveled off above an initiator fraction of 50%, especially for OEGMA of  $M_r$  1100. At relatively low surface initiator density (initiator fraction ~2%), poly(OEGMA)<sub>1100</sub> grafts showed a slightly higher thickness than poly(OEGMA)<sub>300</sub> presumably reflecting higher  $M_r$  but similar chain density. On surfaces with initiator fraction > 10%, the poly(OEGMA)<sub>1100</sub> layer was obviously thinner than the poly(OEGMA)<sub>300</sub> and poly(OEGMA)<sub>475</sub> for a given initiator density. The low DP (~48) or short backbone length of poly(OEGMA)<sub>1100</sub> is one possible reason for the relatively low thickness of poly(OEGMA)<sub>1100</sub> layers.

The surface densities (chains/nm<sup>2</sup>) of the poly(OEGMA) grafts calculated from the ellipsometric thickness data are shown in Fig. 3b. For a given monomer  $M_r$ , the poly(OEGMA) density increased significantly with increasing initiator fraction from 2% to ~50%, and leveled off at higher initiator fractions. At low initiator density (mole fraction 2%–5%), poly(OEGMA) grafts had comparable surface density (chains/nm<sup>2</sup>) independent of OEGMA  $M_r$ ; however, at high initiator density (mole fraction > 10%), significant differences were seen in the densities of poly(OEGMA) grafts for the different monomer  $M_r$  values. Poly(OEGMA)<sub>300</sub> and poly(OEGMA)<sub>475</sub> showed higher graft densities than poly(OEGMA)<sub>1100</sub>, possibly attributable to the size difference of the monomers. Scheme 2 shows a schematic of the stretched out structures of poly(OEGMA) brushes (the expected configuration at relatively high initia-

tor density) and the effect of monomer  $M_r$  on surface density of polymer chains. The larger monomer with larger footprint, once adsorbed, may restrict access of the catalyst complex and monomer to nearby initiator sites, thus reducing initiation efficiency and graft chain density.

The surface densities of EO repeat-unit residues (estimated from the monomer  $M_r$ , polymer chain length, and polymer chain density) are shown in Fig. 4. For a given monomer  $M_r$ , the surface EO unit density generally increased with increasing initiator density in the range investigated (0.03–1.1 chains/nm<sup>2</sup>). For a given high initiator density (initiator fraction > 10%), the poly(OEGMA)<sub>475</sub> layer had the highest EO unit density. The poly(OEGMA)<sub>300</sub> and poly(OEGMA)<sub>1100</sub> layers had similar EO unit density. The low DP and low surface chain density of poly(OEGMA)<sub>1100</sub> relative to poly(OEGMA)<sub>475</sub> and poly(OEGMA)<sub>300</sub> probably account for its relatively low surface EO unit density. Poly(OEGMA)<sub>300</sub> had a similar chain density to poly(OEGMA)<sub>475</sub> at the relatively low initiator density and obviously higher chain density than poly(OEGMA)<sub>475</sub> at the relatively high initiator density. However, poly(OEGMA)<sub>300</sub> had much shorter PEO side-chain length, about half of the side-chain length of poly(OEGMA)<sub>475</sub>, which resulted in a lower EO unit density than poly(OEGMA)<sub>475</sub>.

## Conclusions

Poly(OEGMA) was grafted from Au surface via a two-step procedure including initiator-chemisorption and surface-initiated ATRP. The initiator density was adjusted by mixing the initiator with an inert surface-attachable diluting agent. Three OEGMA monomers of  $M_r$  300, 475, 1100 were used. The Au surfaces were characterized by water contact angle and ellipsometry before and after modification. The data indicated successful formation of initiator and poly(OEGMA) layers with a range of surface densities.

The surface densities of initiator and poly(OEGMA) were calculated from the ellipsometric thickness of the layers. The initiator density was found to increase linearly with increasing mole fraction of initiator in the initiator – diluting agent mixture. For a given monomer  $M_r$ , the poly(OEGMA) thickness and density increased with increasing initiator fraction from 2% to ~50% and leveled off at higher initiator fractions. At low initiator density (mole fraction of initiator 2%–5%), poly(OEGMA) grafts had comparable surface chain density independent of the OEGMA  $M_r$ ; at high initiator density (mole fraction >10%), poly(OEGMA)<sub>1100</sub> showed lower graft densities than poly(OEGMA)<sub>300</sub> and poly(OEGMA)<sub>475</sub>, which could be attributed to the size difference of the monomers.

Surface EO unit density was estimated from the monomer's  $M_r$ , polymer chain length, and polymer chain density, and was found generally to increase with increasing initiator density in the range 0.03–1.1 chains/nm<sup>2</sup> for a given  $M_r$  value of the monomer. For a given high initiator density (initiator fraction >10%), poly(OEGMA)<sub>475</sub> layers showed the highest EO unit density. Poly(OEGMA)<sub>300</sub> and poly(OEGMA)<sub>1100</sub> layers showed similar, but lower, EO unit density.

# Competition between electrochemical advanced oxidation and electrochemical hypochlorination of acetaminophen at boron-doped diamond and ruthenium dioxide based anodes

Jordache Boudreau, Dorin Bejan, and Nigel J. Bunce

**Abstract:** This work was undertaken to distinguish four pathways for the electrochemical oxidation of acetaminophen as a model organic substrate: (i) direct electron transfer from the substrate to the anode, (ii) reaction of the substrate with HO• at boron-doped diamond anodes, (iii) non-radical (two-electron) oxidation of the substrate at Ti/RuO<sub>2</sub> anodes, and (iv) electrochemical hypochlorination if Cl<sup>-</sup> is present. Pathway (i) was isolated as a slow reaction when boron-doped diamond (BDD) was used as the anode in the range of water stability, whereas in the corresponding reaction with Ti/RuO<sub>2</sub> only pathway (iii) could be detected. Pathway (ii) predominated for BDD in the potential range of water oxidation, and was the only mechanism leading to mineralization of the substrate. Comparison between chemical hypochlorination and electrochemical oxidation at Ti/RuO<sub>2</sub> in the presence of chloride ion indicated that the latter process principally involves mediated hypochlorination. Oxidation at boron-doped diamond anodes in the presence of chloride was the most complex mechanistically, with competition between hypochlorination and the electrochemical “advanced oxidation process”; this led to the formation of chlorinated byproducts. The observation of mineralization under these conditions demonstrated cross-over between reaction pathways (ii) and (iv), even though hypochlorination appeared to be the initial pathway for loss of acetaminophen. The presence of chloride ion did not significantly retard mineralization of acetaminophen in the initial stages of oxidation, but significantly increased the energy requirement for complete mineralization. The results are discussed in the context of the use of electrochemical oxidation in waste management.

**Key words:** mineralization, electrochemical hypochlorination, electrochemical advanced oxidation, boron-doped diamond anode, acetaminophen.

**Résumé :** On a entrepris ce travail dans le but d'établir une distinction entre les quatre voies réactionnelles lors de l'oxydation électrochimique de l'acétaminophène utilisé comme substrat organique modèle : (i) transfert d'électron direct du substrat à l'anode; (ii) réaction du substrat avec le HO• au niveau des anodes de diamant dopées au bore; (iii) oxydation non radicalaire à deux électrons du substrat au niveau des anodes de Ti/RuO<sub>2</sub> et (iv) hypochloruration électrochimique si l'anion Cl<sup>-</sup> est présent. La voie réactionnelle (i) a été détectée sous la forme de réaction lente quand on utilise du diamant dopé au bore (DDB) comme anode dans la plage de stabilité de l'eau alors que pour la réaction correspondante avec des anodes de Ti/RuO<sub>2</sub> on n'a détecté que la voie (iii). La voie (ii) est prédominante pour le DDB dans la plage de potentiel d'oxydation de l'eau et c'est le seul mécanisme qui conduit à la minéralisation du substrat. Une comparaison entre l'hypochloruration chimique et l'oxydation électrochimique avec des anodes de Ti/RuO<sub>2</sub>, en présence d'ion chlorure, indique que le deuxième processus implique une hypochloruration catalysée. L'oxydation au niveau des anodes de diamant dopées au bore, en présence d'ion chlorure, est la réaction la plus complexe d'un point de vue mécanistique et elle implique une compétition entre l'hypochloruration et le processus d'oxydation électrochimique avancée; ceci conduit à la formation de sous-produits chlorés. L'observation d'une minéralisation dans ces conditions a permis de démontrer qu'il se produit un croisement entre les voies réactionnelles (ii) et (iv), même si l'hypochloruration semblait être la voie initiale pour la perte de l'acétaminophène. La présence d'ion chlorure ne retarde pas d'une façon significative la minéralisation de l'acétaminophène dans les étapes initiales de l'oxydation, mais elle augmente considérablement l'énergie requise pour arriver à une minéralisation complète. On discute des résultats dans le contexte d'une utilisation de l'oxydation électrochimique dans la gestion des déchets.

**Mots-clés :** minéralisation, hypochloruration électrochimique, oxydation électrochimique avancée, anode de diamant dopé au bore, acétaminophène.

## Introduction

Electrochemical oxidation of organic-contaminated wastewaters has received considerable research attention as a possible treatment method.<sup>1–7</sup> Much of this effort has focused on anodes with a high overpotential for oxygen evolution (inactive anodes), notably  $\beta$ -PbO<sub>2</sub>, Ti/SnO<sub>2</sub>, and boron-doped diamond (BDD), which are especially effective at producing sorbed hydroxyl radicals, also called “physisorbed active oxygen”.<sup>8,9</sup> These methods have been termed electrochemical advanced oxidation processes (EAOPs)<sup>10–12</sup> by analogy with conventional “advanced oxidation processes” (AOPs), which also involve hydroxyl radicals. Hydroxyl radicals have high and indiscriminate reactivity towards most organic compounds through addition and (or) hydrogen abstraction reactions,<sup>13</sup> leading to complete oxidation (mineralization) of recalcitrant organic contaminants by EAOP, or partial oxidation to render them more amenable to conventional biological oxidation.

Electrochemical oxidation of organic substrates is accelerated in the presence of chloride ion, which is a common constituent of industrial waste streams.<sup>14–17</sup> Chloride can be oxidized electrochemically to hypochlorous acid or hypochlorite ion, depending on the pH; the resulting free available chlorine (FAC) can effect electrochemical hypochlorination (EH) because FAC is both a chlorinating and an oxidizing agent. Hypochlorination does not lead to mineralization and may produce chlorinated byproducts that are more recalcitrant to remediation than the original contaminants. EH should predominate over EAOP at “active” anodes based on Ti/IrO<sub>2</sub> and Ti/RuO<sub>2</sub>, which function as oxidizing agents by a “higher oxide” (MO<sub>*n*+1</sub>) mechanism,<sup>18–20</sup> and which also promote efficient conversion of chloride to FAC.<sup>21</sup>

In principle, an organic contaminant might be electrochemically oxidized by several different reaction pathways when chloride ion is present. These are direct electron transfer from the substrate to the anode, EAOP by reaction of the substrate with HO• at inactive anodes, non-radical (two-electron) oxidation of the substrate by MO<sub>*n*+1</sub> at active anodes, and EH if Cl<sup>–</sup> is present.

We recently explored the relationship between some of these mechanisms using the antibiotic sulfamethoxazole (SMX) as a test substrate.<sup>22</sup> Most of the work was carried out using BDD anodes, at which EH and EAOP should occur competitively in the presence of chloride ion. The loss of SMX increased monotonically upon addition of chloride ion. Mineralization was not inhibited in the early stages of oxidation, but the formation of chlorinated intermediates greatly increased the charge needed for complete mineralization. The oxidation of SMX (with or without chloride) could not be studied at Ti/IrO<sub>2</sub>–Ta<sub>2</sub>O<sub>5</sub> anodes, which were rapidly inactivated due to electropolymerization through the aniline functional group. The present study was therefore initiated to remedy this limitation; the substrate selected was acetaminophen (AP), which has previously been shown to undergo oxidation in the absence of chloride at both active (Ti/IrO<sub>2</sub>–Ta<sub>2</sub>O<sub>5</sub>) and inactive (BDD) anodes using a plug-flow divided reactor.<sup>23</sup> AP offers a useful mechanistic distinction: whereas mineralization occurs smoothly at the inactive anode BDD, the chief product at the active anode

Ti/IrO<sub>2</sub>–Ta<sub>2</sub>O<sub>5</sub> is benzoquinone (BQ).<sup>23,24</sup> Brillas et al.<sup>25</sup> studied the mineralization of AP in the pH range of 1–12 with Na<sub>2</sub>SO<sub>4</sub> as supporting electrolyte using an undivided cell. Complete mineralization with release of NH<sub>4</sub><sup>+</sup> and NO<sub>3</sub><sup>–</sup> ions was achieved at a BDD anode, but mineralization was inefficient at Pt.

## Materials and methods

### Materials

Acetaminophen, *N*-(4-hydroxyphenyl)ethanamide (AP), 1,4-benzoquinone (BQ) 98%, potassium iodide 99%+, and sodium perchlorate 99%+ were supplied by Sigma-Aldrich (Oakville, ON). HPLC grade acetonitrile was obtained from Caledon Laboratories (Georgetown, ON); sodium chloride, sodium phosphate monobasic monohydrate, and sodium hydroxide were supplied by Fisher Scientific Company (Toronto, ON). “Ultra” bleach (6%) was purchased from No-Frills, Guelph ON, subsidiary of Loblaw's Inc, Toronto, ON. Solutions were prepared using a Millipore Milli-Q Reagent Water System with water having resistivity of about 18.2 MΩ cm. The Si/BDD anodes were obtained from the Swiss Center for Electronics and Microtechnology, Inc., Neuchâtel; titanium served as the cathode (Chemistry machine shop, University of Guelph).

### Apparatus and experimental procedures

Batch electrolyses were performed in a 150 mL beaker (Pyrex, USA) with a solution volume of 100 mL of 1 mmol/L AP or BQ; ionic strength was maintained at 0.1 mol/L with NaClO<sub>4</sub>. The immersed areas of both the titanium cathode and the Si/BDD anode were 3.75 cm<sup>2</sup>. Solutions were stirred during electrolysis using a Thermix stirrer (Fisher Scientific Model 120 MR). Voltage, electrode potential, and current were monitored using a Wavetek DM5XL Voltmeter and Mastercraft 052–0060–2 multimeter. Power to the electrochemical reactor was supplied by an EG&G Model 363 potentiostat/galvanostat. Cyclic voltammetry measurements were carried out at room temperature in a 50 mL beaker (solution volume 40 mL) using a BDD MDA 5–150/106 microelectrode array (Swiss Center for Electronics and Microtechnology, Inc., Neuchâtel) as the working electrode, platinum plate as the counter electrode, and saturated calomel reference electrode (Fisher Scientific, Toronto, ON). Data were obtained using an EG&G Model 273 Potentiostat/Galvanostat at a fixed sweep rate of 50 mV s<sup>–1</sup>, controlled using Power Suite version 2.12.1 software. Chemical hypochlorination was performed in a 150 mL beaker with a solution volume of 100 mL and a concentration of 1 mmol/L AP or BQ; injections of 40 μL bleach were added every 10 min. The bleach was standardized by iodometry: nominal concentration 6% w/v; actual 6.4%, 0.86 mol/L.

### Analytical measurements

The reactions were followed by HPLC, using a Waters 600E system equipped with a Waters 2487 dual λ absorbance detector set at 254 nm and a Supelco Discovery C18 column 150 × 4.6 mm (5 μm) equipped with a silica pre-column guard. An HPLC method was developed by using a mobile solvent of acetonitrile–water (30:70) (filtered through a 0.2 μm filter) at a flow rate of 1.0 mL min<sup>–1</sup> (retention times

of AP and BQ were ~2.5 min and ~4.0 min, respectively). Samples were manually injected into the 20  $\mu\text{L}$  sample loop of a Rheodyne injector. Total Organic Carbon (TOC) was analyzed as non-purgeable organic carbon (NPOC) with a Shimadzu TOC analyzer, model TOC-VCPN. Absorbable organic halide (AOX) analysis was provided by ALS Laboratory Services of Thunder Bay, ON, Canada.

## Results and discussion

### Voltammetry

Cyclic voltammetry of AP at a 5–150/106 BDD microelectrode array (Fig. 1) showed an irreversible voltammetric peak at +0.94 V vs. SCE with  $I_p \propto [\text{AP}]$ , in both the absence and presence of 100 mmol/L NaCl. Although  $E^\circ$  for oxidation of chloride ion to HOCl is +1.49 V and for  $\text{ClO}^-$  is 0.90 V,<sup>26,27</sup> there was no oxidation current for solutions of chloride alone, because of the large overpotential for this oxidation.<sup>28,29</sup> There was no oxidation current for *p*-benzoquinone (an oxidation product of AP) in the region of water stability nor did we observe the reduction peak for the immediate oxidation product of AP (*N*-acetylbenzoquinonimine) that had been observed by Nematollahi et al.<sup>30</sup> on a glassy carbon working electrode, Madsen et al.<sup>31</sup> on porous graphite, or Van Benschoten et al.<sup>32</sup> on carbon paste. At Ti/RuO<sub>2</sub>, the current at ~ +1.2 V vs. SCE due to solvent oxidation obscured the oxidation of AP itself (see Fig. 1 in the Supplementary data).

### Potentiostatic oxidation of AP in the presence of chloride ion

The oxidation of 1 mmol/L AP at Si/BDD was followed by HPLC within the range of water stability at +1.4 V vs. SCE, using 100 mmol/L NaClO<sub>4</sub> or NaCl as the supporting electrolyte in a divided cell. The loss of AP was very slow, whether or not chloride was present (Fig. 2A). Initial rates were 0.13  $\mu\text{mol min}^{-1}$  (NaClO<sub>4</sub>) and 0.10  $\mu\text{mol min}^{-1}$  (NaCl). The current was too low to be recorded accurately. No anode gas was observed, showing that there was no discharge of water at this potential and hence no production of hydroxyl radicals. The reaction was therefore attributed to direct oxidation of AP (pathway (i)). This conclusion was supported by the formation of a significant yield of benzoquinone, which is rapidly destroyed by hydroxyl radicals ( $1.2 \times 10^9 \text{ L mol}^{-1} \text{ s}^{-1}$  at pH 7).<sup>33</sup> At Ti/RuO<sub>2</sub>, the reaction was much faster because water is oxidized at this active anode, giving the surface oxide RuO<sub>3</sub>, which can oxidize either AP directly or  $\text{Cl}^-$  to hypochlorite; as a result, the loss of AP was faster in the presence of chloride (Fig. 2B). No mineralization occurred in any of these reactions.

### Amperostatic oxidation of AP

The electrochemical oxidation at 80 mA of AP at Si/BDD and at Ti/RuO<sub>2</sub> in the absence of chloride (NaClO<sub>4</sub> supporting electrolyte) is presented in Fig. 3, in which all data are shown in parts per million (mg L<sup>-1</sup>) of carbon. The loss of AP was slightly slower at Ti/RuO<sub>2</sub> and in both cases followed kinetics intermediate between pure current control (linear relationship between the concentration of AP remaining and time), and mass transport control (exponential loss of AP with time), tending to the latter towards the end of

**Fig. 1.** Cyclic voltammogram (0 V to +1.2 V to –1.0 V to 0 V) for 1 mmol/L AP at Si/BDD microelectrode array; sweep rate 50 mV s<sup>-1</sup>; supporting electrolyte 100 mmol/L NaClO<sub>4</sub>. (A) AP; (B) solvent.

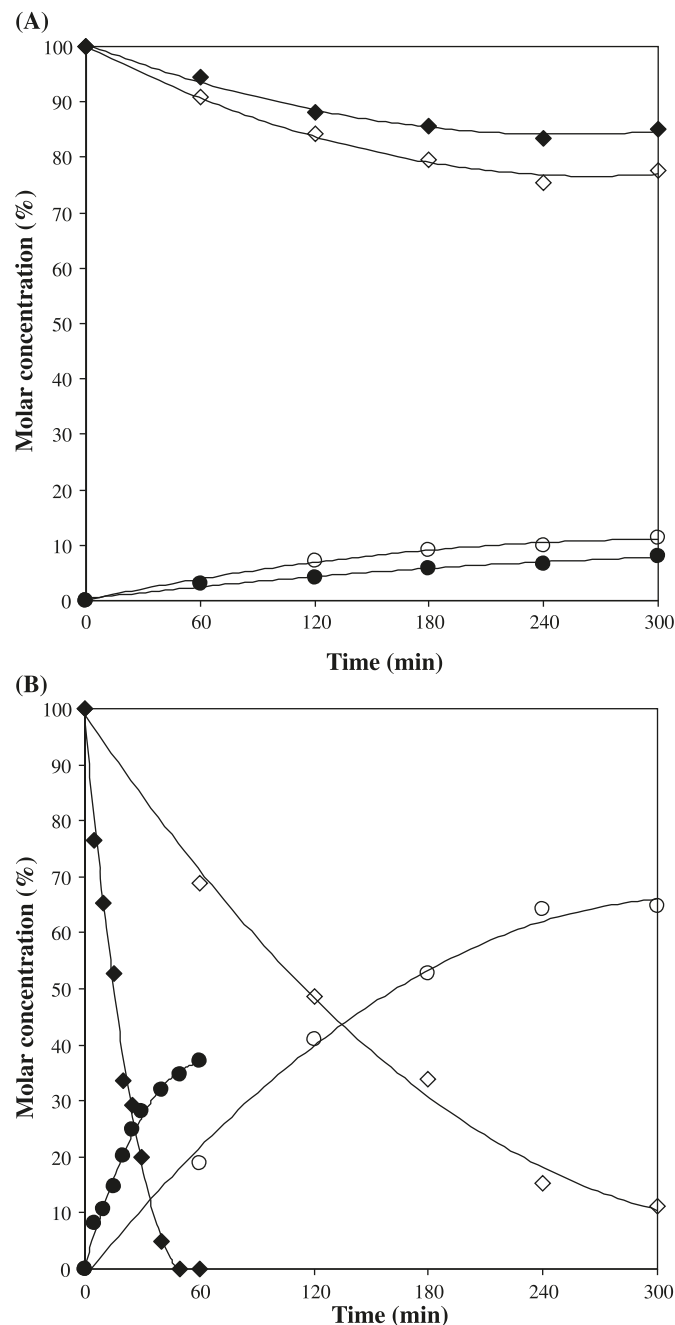

the reaction. Figure 2 in the Supplementary data shows the progress of the reaction according to the half-order kinetic model (between current control and mass transport control) developed in our previous work on the oxidation of sulfamethoxazole.<sup>34</sup>

Kapalka et al.<sup>8</sup> propose that for mass-transport limited reactions at inactive anodes such as BDD, the substrate undergoes multiple acts of HO•-induced oxidation without migrating from the anode into the bulk solution. At its extreme, this kinetic behaviour implies loss of substrate in parallel with loss of TOC. This was broadly true for the oxidation at BDD, where Fig. 3 shows that the course of mineralization, monitored as NPOC, only slightly lagged behind the loss of AP. (The deviation between the rates should be greater under pure current control, when the concentration of HO• radicals at the anode is insufficient to prevent migration of intermediates into the bulk solution.) The loss of AP was somewhat slower at Ti/RuO<sub>2</sub> but mineralization did not occur, consistent with oxidation at this active anode being a two-electron process; the observed formation of BQ supports this conclusion.

The presence of 100 mmol/L chloride ion greatly accelerated the loss of AP at both BDD and Ti/RuO<sub>2</sub> (Fig. 4), consistent with the involvement of EH. These reactions were first order in concentration of AP indicating that the principal electrochemical reaction is formation of FAC, followed by reaction between FAC and AP in the bulk solution. Mineralization occurred more slowly at the BDD anode when chloride was present (compare Figs. 3 and 4). AOX analysis showed the formation of chlorinated byproducts (Fig. 5), which were also detectable (though not specifically identified) by HPLC (see Fig. 3 in the Supplementary data, Panels A–C). Figure 5 shows the losses of AP and NPOC in mmol/L of carbon, and progression of AOX in mmol/L of chlorine. Under these conditions, mineralization could be initiated by hydroxyl radical attack on AP, with subsequent chlorination,

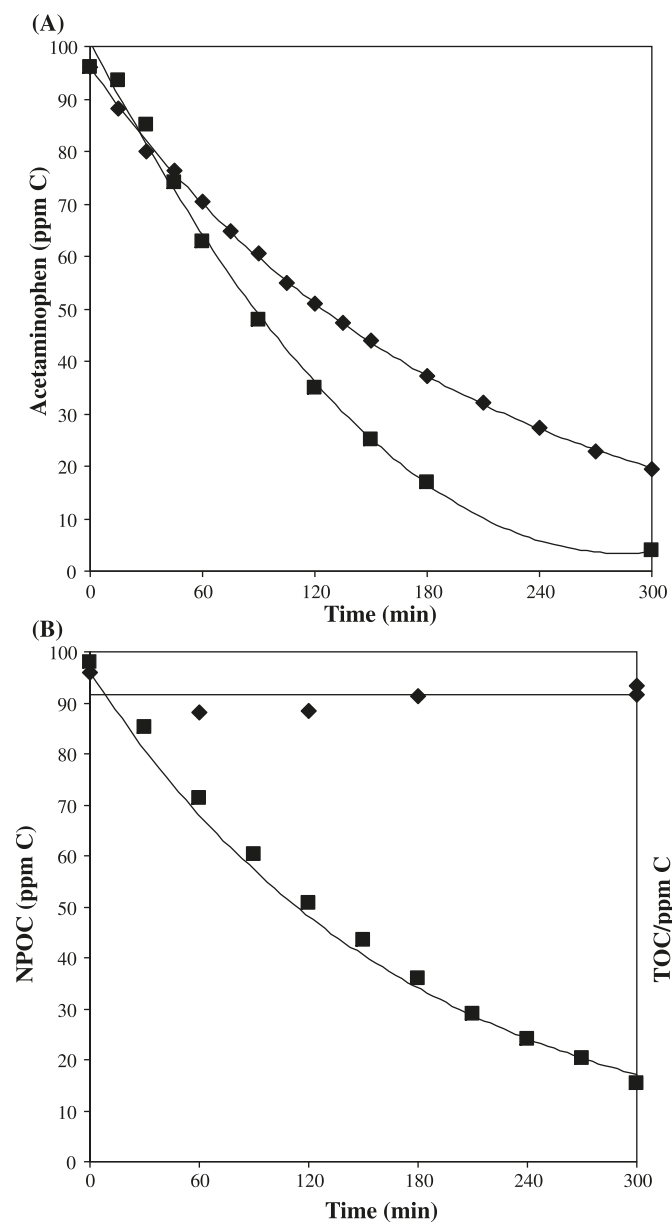

**Fig. 2.** Potentiostatic electrolysis of 1 mmol/L AP at +1.4 V (vs. SCE). Panel A: Si/BDD anode; panel B: Ti/RuO<sub>2</sub> anode. Symbols: ◇, AP; ○, BQ in 100 mmol/L NaClO<sub>4</sub>; ◆, AP; ●, BQ in 100 mmol/L NaCl.

and (or) by an initial hypochlorination and subsequent reaction with hydroxyl radicals. The mechanistic picture is further complicated by suggestions that adsorbed chloro and oxychloro radicals could participate in the oxidation process, though there appears to be no direct evidence for the intermediacy of these species.<sup>35–39</sup>

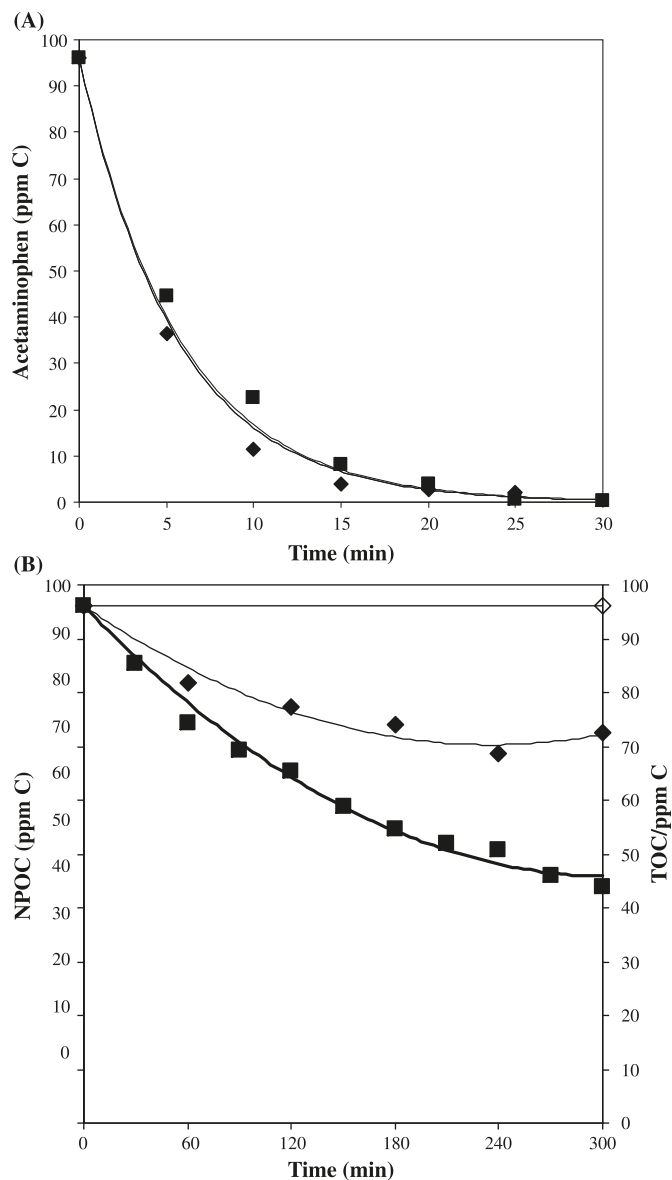

The chlorinated products were highly persistent; Fig. 5 shows that by the end of the electrolysis, the remaining organic material contained an average of one chlorine atom for every three carbon atoms. Complete mineralization of AP in the presence of chloride is thus much more energy-

**Fig. 3.** AP and NPOC loss during electrolysis at Si/BDD and Ti/RuO<sub>2</sub> anodes in the absence of chloride. Panel A: AP; panel B: NPOC. Symbols: ■, Si/BDD anode; ◆, Ti/RuO<sub>2</sub> anode. Supporting electrolyte: 100 mmol/L NaClO<sub>4</sub>; initial AP concentration: 1 mmol/L; current: 80 mA.

demanding than the corresponding chloride-free reaction (see Fig. 4 in the Supplementary data), as found previously for SMX.<sup>22</sup> The apparent partial mineralization of AP in the chloride-assisted oxidation at Ti/RuO<sub>2</sub>, shown in Fig. 4, Panel B, is an experimental artefact, caused by the fact that our TOC analyzer actually measures non-purgeable organic carbon (NPOC) rather than TOC. When correction was made for the purgeable organic carbon, it was found that no mineralization had occurred (see later for discussion of this point). These results support the hypothesis that at Ti/RuO<sub>2</sub> the principal reaction pathway is hypochlorination, whereas at BDD there is competition between EH and EAOP, with the initial products of EH being susceptible to EAOP and

**Fig. 4.** AP and NPOC loss during electrolysis at Si/BDD and Ti/RuO<sub>2</sub> anodes in the presence of 100 mmol/L NaCl. Panel A: AP; panel B: NPOC and TOC. Symbols: ■, Si/BDD anode; ◆, Ti/RuO<sub>2</sub> anode; TOC: ◇, Ti/RuO<sub>2</sub> anode; supporting electrolyte. Initial AP concentration: 1 mmol/L; current: 80 mA.

vice versa. The latter hypothesis is supported by the observation that at BDD the loss of AP accelerated with increasing Cl<sup>-</sup> concentration, whereas the initial rate of mineralization was almost unaffected (see Fig. 5 in the Supplementary data; current 20 mA). At higher current, the initial loss of AP was faster (see Fig. 6 in the Supplementary data; current 80 mA), although the efficiency of mineralization per unit charge was lower, owing to more parasitic oxidation of water to O<sub>2</sub> (see Fig. 7 in the Supplementary data).

Electrooxidation of AP in the presence of chloride ion was compared with conventional chemical hypochlorination via FAC. Previously, Pinkston and Sedlak<sup>40</sup> showed that the pseudo first-order rate constant for reaction of AP with FAC changed by less than one log unit over the range pH 5–10. Bedner and MacCrehan<sup>41</sup> identified two initial

**Fig. 5.** Electrolysis of 1 mmol/L AP with a Si/BDD anode at 80 mA in the absence and presence of chloride. △, NPOC in the absence of chloride (100 mmol/L NaClO<sub>4</sub>); ■, AP; ▲, NPOC; ◆, AOX, all in the presence of 100 mmol/L NaCl.

reaction pathways: ring chlorination and oxidation to *N*-acetylbenzoquinonimine (and hence benzoquinone). We found that chemical hypochlorination was efficient on the basis of mol AP lost per mol FAC added (see Fig. 8 in the Supplementary data). No mineralization was observed, similar to the electrolysis at Ti/RuO<sub>2</sub> although the pattern of byproducts observed (see Fig. 3F in the Supplementary data) differed from those produced electrochemically at either Si/BDD or Ti/RuO<sub>2</sub> (see Fig. 3C and 3E in the Supplementary data). As in the electrochemical experiments, NPOC suggested that mineralization had occurred, but the missing material was again traceable to purgeable organic carbon (POC). The level of POC increased if NaOCl was added portion-wise (to mimic its electrochemical formation) rather than in a single aliquot, or if the solution pH was lowered from 6 to 5 (see Fig. 9 in the Supplementary data). We considered whether the purgeable material might be due to hydrolysis of the acetyl side chain of AP to acetate, but concluded that this was not the explanation because acetic acid was not purgeable under our analytical conditions.

Because chemical hypochlorination is a common strategy for waste treatment,<sup>42–49</sup> we carried out a series of experiments to explore whether electrochemical oxidation could be useful for remediation after hypochlorination with FAC. The efficiency of mineralization was greater when NaClO<sub>4</sub> was used as the supporting electrolyte in the post-treatment rather than NaCl. However, mineralization remained most effective in the absence of chlorination (Fig. 6).

### Amperostatic oxidation of BQ

Previous work has shown that *p*-benzoquinone (BQ) is an intermediate in the oxidation of AP. Parallel to the metabolic chemistry of AP, the formation of BQ is believed to involve a two-electron oxidation of AP to a quinonimine followed by hydrolysis (Scheme 1).<sup>30,32</sup>

Yields of BQ are high when AP is oxidized at active electro-

Scheme 1.

**Fig. 6.** Comparison of chemically hypochlorinated AP and subsequent electrolysis with Si/BDD at 80 mA. Electrolysis of pre-hypochlorinated AP:  $\Delta$ , AP with 100 mmol/L NaClO<sub>4</sub>;  $\blacktriangle$ , AP with 100 mmol/L NaCl; initial AP concentration: 1 mmol/L.

des, but low to negligible at inactive electrodes such as Si/BDD.<sup>23–25</sup> However, the formation of even low yields of BQ is less easily explained at an inactive anode such as Si/BDD, because Yang et al.<sup>50</sup> have indicated that addition to the phenolic ring is the primary reaction between AP and HO $\cdot$ . The voltammetric data reported above suggest that the low yield of BQ may arise by competing direct oxidation of AP. However, BQ is very susceptible to radical addition reactions and cannot build up to high concentrations when inactive anodes are used.

The voltammetric data also indicate that BQ should be stable to further oxidation at active electrodes, and this was essentially the case in earlier work carried out in a flow cell.<sup>23,24</sup> However, in the present work, which employed undivided batch reactors, BQ was at least as susceptible to reaction as AP at both Si/BDD and Ti/RuO<sub>2</sub> (see Fig. 10 in the Supplementary data). This phenomenon was traced to two factors: reduction of BQ at the cathode of the undivided cell and greater chemical stability at lower pH. Figure 7 demonstrates increased persistence of BQ upon electrolysis at Ti/RuO<sub>2</sub> in the order: undivided cell using NaClO<sub>4</sub> supporting electrolyte < undivided cell using H<sub>2</sub>SO<sub>4</sub> supporting electrolyte (pH 2) < divided cell using H<sub>2</sub>SO<sub>4</sub> supporting electrolyte (pH 2).

In many respects, the mineralization of BQ in the undivided batch reactor paralleled that of AP (compare Fig. 8 with Figs. 3 and 4). The rate of disappearance of BQ was comparable at Ti/RuO<sub>2</sub> and Si/BDD in the absence of chloride. Mineralization closely followed BQ loss at Si/BDD, but

**Fig. 7.** Electrolysis of 1 mmol/L *p*-benzoquinone with a Ti/RuO<sub>2</sub> anode at 80 mA. Symbols:  $\blacksquare$ , undivided cell (100 mmol/L NaClO<sub>4</sub>);  $\blacklozenge$ , undivided cell (H<sub>2</sub>SO<sub>4</sub>, pH 2);  $\blacktriangle$ , divided cell (conc. H<sub>2</sub>SO<sub>4</sub>, pH 2).

**Fig. 8.** NPOC loss during electrolysis of BQ with Si/BDD and Ti/RuO<sub>2</sub> at 80 mA in the absence and presence of chloride in an undivided cell. Si/BDD:  $\circ$ , 100 mmol/L NaClO<sub>4</sub>;  $\bullet$ , 100 mmol/L NaCl; Ti/RuO<sub>2</sub>:  $\Delta$ , 100 mmol/L NaClO<sub>4</sub>;  $\blacktriangle$ , 100 mmol/L NaCl; initial BQ concentration: 1 mmol/L.

there was almost no mineralization (based on NPOC) at Ti/RuO<sub>2</sub>. BQ is highly susceptible to hypochlorination, and in the presence of chloride, the rate of reaction at Ti/RuO<sub>2</sub> was greatly increased but again there was no mineralization. At Si/BDD, the presence of chloride increased the reactivity of BQ but substantially decreased the rate of mineralization; analysis by HPLC showed the presence of chlorinated byproducts.

## Conclusions

We introduced this work by identifying four distinct pathways for the electrochemical oxidation of an organic substrate, namely, (i) direct electron transfer from the substrate to the anode, (ii) EAOP by reaction of substrate with HO• at inactive anodes, (iii) non-radical (two electron) oxidation of substrate by MO<sub>n+1</sub> at active anodes, and (iv) EH if Cl<sup>-</sup> is present.

Acetaminophen is a valuable substrate for distinguishing these mechanisms. Its distinct voltammetric oxidation peak allowed the study of its direct electron transfer in the region of water stability. This reaction does not lead to mineralization in the absence or presence of chloride, even at the inactive anode Si/BDD, because hydroxyl radicals are not formed. It is inconveniently slow as a prospective remediation technology and rather inefficient; this mechanism probably contributes little to the overall chemistry except in the range of water stability.

Amperostatic oxidation in the region of water decomposition (O<sub>2</sub> evolution at the anode) showed an efficient mineralization reaction by the EAOP mechanism at Si/BDD in the absence of chloride; low yields of BQ at intermediate stages of the reaction were ascribed to the competing direct electron-transfer reaction. Comparison between chemical hypochlorination (FAC) and electrochemical oxidation at Ti/RuO<sub>2</sub> indicated that the latter process, which does not lead to mineralization, principally involves mediated hypochlorination. Oxidation at Si/BDD in the presence of chloride is the most complex mechanistically, with competition between EAOP and EH. Kinetic analysis suggested that chloride ion diverts the main pathway for initial destruction of AP to hypochlorination in the bulk even at BDD; this was confirmed by rather similar patterns of chlorinated byproducts at both electrodes. In contrast, different patterns of chlorinated byproducts were seen at Si/BDD and Ti/IrO<sub>2</sub>-Ta<sub>2</sub>O<sub>5</sub> in the degradation of SMX.<sup>22</sup> Even though EH appears to be the initial reaction for loss of AP, crossover between the EH and EAOP reaction sequences is evident by the occurrence of mineralization, albeit more slowly than in the absence of chloride.

Critically for the use of electrochemical oxidation in waste management, the presence of chloride ion as a constituent of the waste leads to the formation of persistent byproducts, whose removal significantly increases the energy requirement for complete mineralization at the inactive anode BDD (although the initial rate of mineralization is not retarded by chloride ion at low current). Although electrolysis can be considered as a post-treatment to the common industrial practice of chemical hypochlorination, mineralization under those circumstances is more energy-demanding.

# 5b,7b-Diaza-3b,9b-diborabenz[ghi]perylene

Michael J.D. Bosdet, Warren E. Piers, Ted S. Sorensen, and Masood Parvez

**Abstract:** Treatment of a precursor to the chelating Lewis acid 2,2'-diborabiphenyl with 2,6-bisalkynyl-substituted pyridazines, leads to elimination of 2 equiv. of ClSiMe<sub>3</sub>; subsequent treatment of the mixture with PtCl<sub>2</sub> catalyzes the cyclization of observable intermediates to the title 5b,7b-diaza-3b,9b-diborabenz[ghi]perylene compounds in low isolated yields. The compounds were characterized by NMR and UV-vis spectroscopies, and in one case, by X-ray crystallography. NICS(1) computations indicate that the inner ring is less aromatic than the outer rings.

**Key words:** polycyclic aromatic hydrocarbons, boron heterocycles, nitrogen heterocycles, X-ray structure.

**Résumé :** Le traitement d'un précurseur de l'acide de Lewis chélatant 2,2'-diborabiphényle avec des pyridazines substituées dans les positions 2,6 par des groupes bisalkynyles conduit à l'élimination de deux équivalents de ClSiMe<sub>3</sub>; le traitement subséquent du mélange avec du PtCl<sub>2</sub> catalyse la cyclisation des intermédiaires observables et à la formation des composés 5b,7b-diaza-3b,9b-diborabenz[ghi]pérylènes mentionnés dans le titre qui sont isolés avec de faibles rendements. Les composés ont été caractérisés par spectroscopies RMN et UV-vis et, dans un cas, par diffraction des rayons-X. Des calculs NICS(1) indiquent que le noyau interne est moins aromatique que les cycles externes.

**Mots-clés :** hydrocarbures aromatiques polycycliques, hétérocycles du bore, hétérocycles de l'azote, structure par diffraction des rayons X.

[Traduit par la Rédaction]

## Introduction

Transposition of C–C units for isoelectronic B–N modules in polycyclic aromatic hydrocarbons offers a means of altering opto-electronic, redox, and chemical properties of these important organic materials without dramatically affecting their gross structural features.<sup>1–3</sup> One of the most elementary examples is the BN-biphenyl analog **I** (Chart 1), the pyridine adduct of borabenzene, which has been known for many years.<sup>4</sup> Unlike biphenyl, **I** is susceptible to protonation by Brønsted acids at the carbon alpha to boron,<sup>5,6</sup> and facile Diels–Alder addition with moderately active dienophiles,<sup>7</sup> demonstrating the more reactive nature of the BN analog; indeed, **I** is quite air- and moisture-sensitive and needs to be handled accordingly.

We have been interested in this strategy as a means of producing novel organic electronic materials and have been developing synthetic methods to novel B<sub>x</sub>N<sub>x</sub> heterocyclic analogs of various PAH frameworks. For example, the BN-phenanthrene<sup>8</sup> and BN-pyrene<sup>9,10</sup> derivatives **II** and **III** (Chart 1) can be prepared via formation of borabenzene pyridine adducts wherein the pyridine unit is functionalized with alkynyl groups alpha to nitrogen. This buttressing of the B–N bond has a stabilizing effect, in that compounds **II** can be handled briefly in air, while pyrene analogs **III** can be stored under ambient atmosphere indefinitely; indeed, they are even unperturbed by treatment with aqueous HCl.

The B<sub>2</sub>N<sub>2</sub>-triphenylenes **IV** (Chart 1) are another class of

compounds we have studied extensively.<sup>11,12</sup> While they exhibit favorably modified redox and photophysical properties relative to the all-carbon triphenylenes, they do not have long-term stability to ambient conditions, limiting the scope of their utility. We thus sought to implement the buttressing strategy that was successful in stabilizing the BN-pyrenes **III** and protect the bay region of the triphenylenes **IV**. Herein, we report the synthesis of two examples of a 5b,7b-diaza-3b,9b-diborabenz[ghi]perylene framework, albeit in low yields. The limitations of the approach will be discussed along with the characterization of these intriguing compounds.

## Results and discussion

Engagement of the buttressing strategy for the stabilization of the C<sub>2</sub>B<sub>2</sub>N<sub>2</sub> heterocyclic core in compounds **IV** (Chart 1) required first the synthesis of 3,6-di(alkynyl)pyridazines **1a–1d**, which in our hands was best-accomplished by palladium-catalyzed coupling of 3,6-dichloropyridazine with alkynylzinc compounds,<sup>13</sup> as shown in Scheme 1. Terminal alkynes were first deprotonated with *n*BuLi at –78 °C, and subsequently transmetalated with ZnCl<sub>2</sub> to generate the required alkynylzinc reagents. The alkynylzinc compounds were transferred onto a THF solution of the aryl chloride and Pd catalyst and stirred for 24 h. After workup, the desired substrates were obtained in low but workable yields of ≈ 20%–25%. Alternatively, Sonogashira coupling pro-

Chart 1.

protocols could be employed, but dimerization of the terminal alkynes was a significant side reaction. The unsubstituted 3,6-bis(ethynyl)pyridazine (**1a**) was formed from the silyl derivative **1d** by desilylation with  $\text{KOH}_{(\text{aq})}$  in MeOH (Scheme 1).

With substrates **1** in hand, reactions with the methyl-substituted chloroboracyclic precursor, **2**,<sup>7</sup> were attempted (Scheme 2). In general, these reactions were not as clean as those previously observed for pyridazine bases without the acetylenic groups. While elimination of 2 equiv. of  $\text{Me}_3\text{SiCl}$  was observed, the reactions with pyridazines **1** appear to be prone to more side reactions, particularly for the parent derivative **1a**. Furthermore, the bis-acetylenic  $\text{B}_2\text{N}_2$ -triphenylene complexes (i.e., derivatives of **IV**), depicted in Scheme 2, were not detected in any of these reactions. Rather, one acetylenic group underwent spontaneous cyclization, and the major products observed for  $R = n\text{Bu}$  and Ph were the half-cyclized compounds **3b** and **3c**, presumably formed via intermediates **IV**. These polycyclic intermediates were not isolated in pure form, but carried forward to the fully cyclized compounds **4** using  $\text{PtCl}_2$  catalysis as shown in Scheme 2.<sup>14</sup> While not isolable in pure form, the nature of compounds **3** was supported by the  $^1\text{H}$  NMR spectral features observed for the butyl-substituted derivative **3b**. Two distinct methyl resonances were observed at 2.81 and 3.07 ppm in  $\text{C}_6\text{D}_6$  solution, highlighting the averaged  $\text{C}_s$  symmetry in **3b**. Further, two pairs of doublets, corresponding to H-6 and H-7 (5.97 and 6.25 ppm) and H-9 and H-10 (6.96 and 7.28 ppm) were observable, in addition to four aromatic singlets, for H-1 (9.16 ppm), H-3 (7.20 ppm), H-5 (6.56 ppm), and H-12 (8.57 ppm) (See Chart 2 for the numbering scheme).

Yields for the target heterocycles **4** were very low (trace–17%), but the compounds were isolated as moderately air- and moisture-tolerant, red-brown solids after purification via column chromatography. The majority of material loss apparently occurred in the catalyzed cycloisomerization step, since the mass balance in the production of crude **3b** was upwards of 70%. The inefficient synthesis was particularly evident in the attempted formation of **4a**; the amount

of product obtained was insufficient for NMR analysis, and while its presence may be inferred from a qualitative observation of pink–red fluorescence in solutions of the material off column, further analysis was precluded due to lack of material.

Although  $\text{B}_2\text{N}_2$ -benzo[ghi]perylene<sup>15</sup> **4b–4c** were available only in small quantities, we were able to characterize them reasonably thoroughly. Unlike the  $^1\text{H}$  NMR spectra for compounds **3b** and **3c**, those of **4b** and **4c** were much simpler, as expected for  $\text{C}_{2v}$  symmetric structures; the  $^1\text{H}$  NMR spectrum of **4b** is illustrated in Fig. 1. Each derivative gave rise to four aromatic singlets between 8.0 and 9.5 ppm for the  $\text{B}_2\text{N}_2$ -benzo[ghi]perylene framework, corresponding to H-1, H-3, H-5, and H-6, as well as a single methyl resonance at ~3.1 ppm, and the expected resonances for the R group. The  $^{11}\text{B}$  NMR spectrum showed a single resonance at 21 ppm, in agreement with other enclosed BN aromatic compounds (~22 ppm).

Slow evaporation of solvent from a diethyl ether solution of **4b** yielded crystals suitable for analysis via X-ray crystallography. The structure of **4b** is essentially planar, with a maximum dihedral angle of  $1.5^\circ$  within the ring system ( $\text{C}(18)\text{--C}(1)\text{--B}(1)\text{--C}(5)$ ) (Fig. 2 and Table 1). The B–N bond is short, at 1.452(2) Å, consistent with BN-pyrene **III** (1.456(4) Å) and the  $\text{B}_2\text{N}_2$ -triphenylene **IV** (1.464(4) Å),<sup>12</sup> and indicative of some  $\pi$ -character in this bond. However, in contrast to unbuttressed **IV**,<sup>12</sup> bond localization is evident throughout the carbon perimeter in **4b**, with alternating long and short C–C bonds within individual rings. Thus, in the borabenzene rings,  $\text{C}(1)\text{--C}(2)$  and  $\text{C}(3)\text{--C}(4)$  are short (1.390(3) Å avg.), whereas  $\text{C}(2)\text{--C}(3)$  and  $\text{C}(4)\text{--C}(5)$  are longer (1.414(3) Å avg.). The  $\pi$ -electron localization in the pyridazine ring in **4b** also differs from that in compounds **IV**, such that the short and long C–C bonds in the latter are reversed in **4b**. Specifically,  $\text{C}(8)\text{--C}(9)$  and  $\text{C}(9')\text{--C}(8')$  are 1.406 Å, while  $\text{C}(9)\text{--C}(9')$  is shortened to 1.346(3) Å; the corresponding lengths in unbuttressed **IV** are 1.345(5) Å and 1.433(6) Å. Additionally, the C–N bonds are shortened by ~0.02 Å (to 1.381(2) Å), suggesting better overall  $\pi$ -electron delocalization about this ring, in contrast to the cyclohexadiene-type bonding arrangement of heterocycles **IV**. The longest C–C bond in **4b** is  $\text{C}(1)\text{--C}(1')$ , at 1.456(3) Å, elongated by 2% relative to the same bond in  $\text{B}_2\text{N}_2$ -triphenylene **IV** but of similar length to the analogous bond in the all-carbon PAH benzo[ghi]perylene, at 1.484 Å.<sup>16</sup>

Overall then, the solid-state bond-length patterns suggests that the ring system is best-represented by resonance form **A** (Chart 3), in contrast to the dominant resonance form of triphenylene analogues **IV**, best-described by resonance form **B**. This is supported by NICS(1) calculations<sup>17</sup> performed on **4a**, which show a low aromaticity for the inner  $\text{C}_2\text{B}_2\text{N}_2$  ring in **4a**, but strong aromaticity for the outer rings. This is the inverse of trends noted for **IV**, and it thus appears that the effect of buttressing the system is to lower the aromatic stabilization of the inner ring relative to the unbuttressed system. Indeed, the all-carbon PAH benzo[ghi]perylene exhibits this pattern as well, with the inner ring having low aromatic character relative to the outer rings.<sup>18</sup>

Unlike the all-carbon frameworks, the  $\text{B}_2\text{N}_2$  compounds have molecular dipoles that are significant enough to influence

Scheme 1.

Scheme 2.

Chart 2.

packing in the solid state. The molecular packing of **4b**, shown in Fig. 3, features two molecules stacked with the dipoles (calculated to be 3.53 D in **4b**) aligned such that a

close non-bonding  $\text{B}\cdots\text{N}$  distance of 3.71 Å is observed. Intermolecular  $\pi$ -stacking distances of 3.42 Å exist between parallel sheets of **4b** molecules, which is very slightly shorter than the  $\pi$ - $\pi$  distance in crystalline benzo[ghi]perylene at 3.44 Å.

The unbuttressed  $\text{B}_2\text{N}_2$ -triphenylene compounds **IV** exhibit reversible one- and two-electron reduction process, and indeed the radical anion and dianions are stable and isolable.<sup>12</sup> It was therefore somewhat surprising to find that cyclic voltammetry on compounds **4a** and **4b** shows irreversible one-electron reductions, suggesting that the radical anions are unstable. This may be a reflection of the low aromaticity of the central rings in compounds **4** and a change in the character of the SOMO in the radical anions.

**Fig. 1.**  $^1\text{H}$  NMR (400 MHz) spectrum of **4b** in  $\text{CD}_2\text{Cl}_2$ .**Fig. 2.** Top: X-ray structure of **4b**. Numbers are bond lengths in Å. Bottom: **4b**, viewed along the molecular plane (perpendicular to the  $\text{N}(1)\text{--N}(1')$  bond), with butyl groups removed. Hydrogen atoms have been removed for clarity. Thermal ellipsoids are at the 50% probability level.

The absorption and emission spectra are indicative of lowered HOMO–LUMO gaps in comparison to triphenylene analogs **IV**, as may be expected by the extended conjugation afforded by the buttressing alkenyl groups. As for other  $\text{B}_x\text{N}_x$  analogs, both absorption and emission bands (621 and 630 nm for **4a** and **4b**, respectively) are red-shifted in these compounds in comparison to the all-carbon compound, but the emission quantum yields (0.023 and 0.015, respectively, relative to 9,10-diphenylanthracene in cyclohexane) are significantly lower than that of benzo[ghi]perylene (0.26).

## Conclusions

We have prepared and characterized two examples of 5b,7b-diaza-3b,9b-diborabenzo[ghi]perylene with a doubly buttressed  $\text{B}_2\text{N}_2\text{C}_2$  core. Although in previous work a doubly buttressed  $\text{B}_2\text{N}_2\text{C}_2$  core added stability to bora-aza analogs of PAHs, here the added benefit in this regard is minimal. This may stem from the fact that the core ring is of low aromaticity and therefore more reactive towards, for example, protic reagents and oxygen. Furthermore, the synthetic route

to these frameworks is inefficient (despite many attempts at improvements), and the photophysical properties are not unique enough to warrant further efforts directed towards discovery of more direct routes to the compounds. Nonetheless, the structural features and aromatic properties are of interest to add to the database of  $B_xN_x$  compounds in comparison to their all-carbon counterparts.

## Experimental section

General procedures have been described in detail elsewhere.<sup>12</sup> Celite 545<sup>®</sup> was purchased from Fisher Scientific and heated at 200 °C under high vacuum for 3 days prior to use. Neutral alumina (63–200  $\mu\text{m}$ , 70–230 Mesh ASTM) was purchased from EM Science and heated at 200 °C for 3 days under high vacuum prior to use. Silica-gel column chromatography was carried out on Geduran Silica 60 silica gel (particle size 40–63  $\mu\text{m}$ ).

Compound **2** was prepared as described previously.<sup>12</sup>  $\text{CuI}$ ,  $\text{BCl}_3$ ,  $\text{LiNMe}_2$ , pyridazine, 9,10-diphenylanthracene, and  $\text{Pd}(\text{PPh}_3)_4$  were purchased from Aldrich and used as re-

ceived. 3,6-Dichloropyridazine was purchased from Aldrich and sublimed prior to use. Phenylacetylene was purchased from Aldrich and passed through a column of alumina immediately prior to use. 1-Hexyne was purchased from Acros and used as received.  $\text{PtCl}_2$  was purchased from Alfa Aesar and used as received. Trimethylsilylacetylene was purchased from Petra Research, Inc. and distilled prior to use.  $^1\text{H}$  NMR assignments were made by comparison to known chemical shift patterns.<sup>5–9,11,12</sup>

## Synthesis of 3,6-bis(1-hexynyl)pyridazine, 1b

In a microwavable reaction tube, solid  $\text{Pd}(\text{PPh}_3)_4$  (8 mg, 7.1  $\mu\text{mol}$ ) and  $\text{CuI}$  (3 mg, 14.1  $\mu\text{mol}$ ) were added to a solution of 3,6-dichloropyridazine (50 mg, 0.33 mmol) in  $\text{NEt}_3$  (2 mL). This was immediately followed by the addition of a solution of 1-hexyne (58 mg, 0.71 mmol) in  $\text{NEt}_3$  (1 mL), and the mixture was heated in a microwave reactor (115 W, 150 °C) for 25 min. Once cooled, the crude product was extracted into  $\text{Et}_2\text{O}$  and gravity filtered. The solvent was removed in vacuo, and the orange material was dissolved in hexanes and loaded onto a column of neutral  $\text{Al}_2\text{O}_3$ . Gradient elution with hexanes/ $\text{Et}_2\text{O}$  ultimately gave the product as a yellow solid. Yield: 20 mg (25%).  $^1\text{H}$  NMR ( $\text{C}_6\text{D}_6$ )  $\delta$  (ppm): 6.62 (s, 2H, H-1), 2.12 (t, 4H,  $^3J_{\text{HH}} = 7$  Hz, H-5), 1.31 (m, 2 + 2H, H-6 + H-7), 0.76 (t, 6H,  $^3J_{\text{HH}} = 7$  Hz, H-). HR-MS for  $\text{C}_{16}\text{H}_{20}\text{N}_2$  ( $M^+$ ): 240.1626 (calcd.), 240.1624 (found).

## Synthesis of 3,6-bis(phenylethynyl)pyridazine, 1c

To a  $-78$  °C solution of phenylacetylene (1.33 g, 13.0 mmol) in THF (50 mL) was added a solution of *n*-butyl lithium in hexanes (1.6 mol/L, 8.12 mL, 13.0 mmol). After stirring at this temperature for 1 h, a solution of  $\text{ZnCl}_2$  (1.77 g, 13.0 mmol) in THF (50 mL) was transferred in via canula, and this mixture was stirred for another 45 min with

**Fig. 3.** Molecular packing of **4b**, including intermolecular B...N interactions (red dash). Hydrogen atoms have been removed for clarity. Thermal ellipsoids are at the 50% probability level.

the temperature maintained at  $-78^{\circ}\text{C}$ . The reaction mixture was then warmed to  $25^{\circ}\text{C}$ , and a solution of 3,6-dichloropyridazine (486 mg, 3.3 mmol) and  $\text{Pd}(\text{PPh}_3)_4$  (751 mg, 0.65 mmol) in THF (50 mL) was added. The mixture was stirred for 3 days, then quenched with saturated  $\text{NaHCO}_3(\text{aq})$  (75 mL), and filtered through Celite. After removing the organic layer, the aqueous layer was washed with  $\text{CHCl}_3$  ( $2 \times 20$  mL), and the combined organic fractions were dried with  $\text{MgSO}_4$ . The crude material obtained following gravity filtration and removal of volatiles in vacuo was purified by column chromatography, giving a white solid. Yield: 111 mg (12%).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$  (ppm): 7.65 (m, 4H, H-6), 7.61 (s, 2H, H-1), 7.41 (m, 2 + 1H, H-7 + H-8).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CDCl}_3$ )  $\delta$  (ppm): 146.00 (s, C-2), 132.38 (s, C-6), 129.92 (s, C-1), 129.01 (s, C-8), 128.72 (s, C-7), 121.59 (s, C-5), 95.67 (s, C-3/4), 86.10 (C-3/4). HR-MS for  $\text{C}_{20}\text{H}_{12}\text{N}_2$  ( $\text{M}^+$ ): 280.1000 (calcd.), 280.1001 (found).

#### Synthesis of 3,6-bis(trimethyl-silylethynyl)pyridazine, **1d**

To a  $-78^{\circ}\text{C}$  solution of trimethylsilylacetylene (1.151 g, 11.7 mmol) in THF (50 mL) was added a solution of *n*-butyl lithium in hexanes (1.6 mol/L, 7.3 mL, 11.7 mmol). After stirring at this temperature for 1 h, a solution of  $\text{ZnCl}_2$  (1.60 g, 11.7 mmol) in THF (50 mL) was transferred in via canula, and this mixture was stirred for another 45 min with the temperature maintained at  $-78^{\circ}\text{C}$ . The reaction mixture was then warmed to  $25^{\circ}\text{C}$ , and a solution of 3,6-dichloropyridazine (436 mg, 2.9 mmol) and  $\text{Pd}(\text{PPh}_3)_4$  (338 mg, 0.29 mmol) in THF (40 mL) was added. The mixture was stirred for 3 days at  $35^{\circ}\text{C}$  and was then quenched with saturated  $\text{NaHCO}_3(\text{aq})$  (75 mL) and filtered through Celite. After removing the organic layer, the aqueous layer was washed with  $\text{CHCl}_3$  ( $2 \times 20$  mL), and the combined organic fractions were dried with  $\text{Na}_2\text{SO}_4$ . The crude material obtained following gravity filtration and removal of volatiles in vacuo was purified by column chromatography (5% EtOAc in hexanes), giving a white solid. Yield: 135 mg (17%).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$  (ppm): 7.44 (s, 2H, H-1), 0.17 (s, 18H,  $-\text{SiMe}_3$ ).

$^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CDCl}_3$ )  $\delta$  (ppm): 145.46 (s, C-2), 129.02 (s, C-1), 102.09 (s, C-3/4), 100.42 (C-3/4),  $-0.53$  (s,  $\text{SiMe}_3$ ). HR-MS for  $\text{C}_{14}\text{H}_{20}\text{N}_2\text{Si}_2$  ( $\text{M}^+$ ): 272.1165 (calcd.), 272.1177 (found).

#### Synthesis of 3,6-bis(ethynyl)pyridazine, **1a**

Desilylation of 3,6-bis(trimethyl-silylethynyl)pyridazine was accomplished by the addition of  $\text{KOH}(\text{aq})$  (0.99 mol/L, 1.0 mL, 0.98 mmol) to a solution of **1d** (134 mg, 0.49 mmol) in MeOH (5 mL). After stirring for 1.5 h, the mixture was extracted into  $\text{CHCl}_3$  (20 mL) and washed with 6 mol/L  $\text{HCl}(\text{aq})$  ( $2 \times 10$  mL). The organic layer was dried over  $\text{MgSO}_4$ , filtered, and the solvent removed in vacuo to give **1a** as white crystals. Yield: 51 mg (81%).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$  (ppm): 7.56 (s, 2H, H-1), 3.52 (s, 2H, H-4).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CDCl}_3$ )  $\delta$  (ppm): 145.50 (s, C-2), 129.45 (s, C-1), 83.86 (s, C-3/4), 79.72 (C-3/4). HR-MS for  $\text{C}_8\text{H}_4\text{N}_2$  ( $\text{M}^+$ ): 128.0374 (calcd.), 128.0376 (found).

#### Synthesis/characterization of **3b**

A solution of **2** (55 mg, 0.14 mmol) in toluene (1 mL) was added to a solution of **1b** (32 mg, 0.13 mmol) in tol-

uene (5 mL) and stirred at 25 °C for 48 h. Volatiles were removed in vacuo, and the crude product was determined to be a mixture including the intermediate **3b** via  $^1\text{H}$  NMR spectroscopy.  $^1\text{H}$  NMR ( $\text{C}_6\text{D}_6$ )  $\delta$  (ppm): 9.16 (s, 1H, H-2), 8.57 (s, 1H, H-15), 7.28 (d, 1H,  $^3J_{\text{HH}} = 8$  Hz, H-13), 7.20 (s, 1H, H-4), 6.96 (d, 1H,  $^3J_{\text{HH}} = 8$  Hz, H-12), 6.56 (s, 1H, H-7), 6.25 (d, 1H,  $^3J_{\text{HH}} = 8$  Hz, H-10), 5.97 (d, 1H,  $^3J_{\text{HH}} = 8$  Hz, H-9), 3.25 (t, 2H,  $^3J_{\text{HH}} = 8$  Hz, C-17), 3.07 (s, 3H, C-3-Me), 3.04 (t, 2H,  $^3J_{\text{HH}} = 8$  Hz, C-23), 2.81 (s, 3H, C-14-Me), 2.35 (m, 2H, H-18), 2.21 (m, 2H, H-24), ~1.41 (m, H-19), ~1.38 (m, H-25), 0.99 (t, 3H,  $^3J_{\text{HH}} = 8$  Hz, C-20), 0.90 (t, 3H,  $^3J_{\text{HH}} = 8$  Hz, C-26).

#### Attempted synthesis of 4a

A solution of **2** (157 mg, 0.40 mmol) in toluene (3 mL) was added to a solution of **1a** (51 mg, 0.40 mmol) in toluene (10 mL) and stirred at 25 °C for 48 h. Volatiles were removed in vacuo and the crude material was re-dissolved in toluene and transferred onto  $\text{PtCl}_2$  (2 mg, 7  $\mu\text{mol}$ ). The mixture was stirred at 95 °C for 24 h, after which volatiles were removed, and the brown material was purified by flash chromatography through neutral  $\text{Al}_2\text{O}_3$ . The  $\text{Et}_2\text{O}$  fraction was observed to fluoresce pink-red upon irradiation at 365 nm, but an insufficient quantity for NMR characterization was obtained. Yield: trace.

#### Synthesis of 4b

The crude material **3b** was re-dissolved in toluene and transferred onto  $\text{PtCl}_2$  (2 mg, 7  $\mu\text{mol}$ ). The mixture was stirred at 100 °C for 24 h, after which volatiles were removed, and the brown material was purified by flash chromatography through neutral  $\text{Al}_2\text{O}_3$ . Yield: 9 mg (17%).

UV-vis ( $\epsilon$  ( $10^4$  L mol $^{-1}$  cm $^{-1}$ ), cyclohexane)  $\lambda_{\text{max}}$  (nm): 261, 324, 413, 458, 511. Fluorescence (cyclohexane)  $\lambda_{\text{max}}$  (nm): 621, 667;  $\phi_f = 0.023$ ,  $\tau_f = 23$  ns.  $^1\text{H}$  NMR ( $\text{CD}_2\text{Cl}_2$ )  $\delta$  (ppm): 9.46 (s, 2H, H-1/12), 8.58 (s, 2H, H-3/10), 8.53 (s, 2H, H-5/8), 8.03 (s, 2H, H-6/7), 3.62 (t, 4H,  $^3J_{\text{HH}} = 8$  Hz, C-13), 3.11 (s, 6H, C-2/11-Me), 2.07 (m, 4H, H-14), 1.64 (m, 4H, H-15), 1.07 (t, 6H,  $^3J_{\text{HH}} = 8$  Hz, C-16) ppm.  $^{11}\text{B}\{^1\text{H}\}$  NMR ( $\text{C}_6\text{D}_6$ )  $\delta$  (ppm): 21 (br s). HR-MS for  $\text{C}_{32}\text{H}_{24}\text{B}_2\text{N}_2$  ( $\text{M}^+$ ): 418.27516 (calcd.), 418.27679 (found).

#### Synthesis of 4c

A solution of **2** (74 mg, 0.19 mmol) in toluene (1.5 mL) was added to a solution of **1c** (50 mg, 0.18 mmol) in toluene (5 mL) and stirred at 45 °C for 48 h. Volatiles were removed in vacuo and the crude product was re-dissolved in toluene and transferred onto  $\text{PtCl}_2$  (3 mg, 11  $\mu\text{mol}$ ). The mixture was stirred at 100 °C for 24 h, after which volatiles were removed, and the brown material was purified by flash chromatography through neutral  $\text{Al}_2\text{O}_3$ . Yield: 3 mg (3%). UV-vis ( $\epsilon$  ( $10^4$  L mol $^{-1}$  cm $^{-1}$ ), cyclohexane)  $\lambda_{\text{max}}$  (nm): 421, 523, 625. Fluorescence (cyclohexane)  $\lambda_{\text{max}}$  (nm): 630, 676;  $\phi_f = 0.015$ ,  $\tau_f = 23$  ns.  $^1\text{H}$  NMR ( $\text{CD}_2\text{Cl}_2$ )  $\delta$  (ppm): 9.54 (s, 2H, H-1/12), 8.64 (s, 2H, H-3/10), 8.48 (s, 2H, H-5/8 or 6/7), 8.19 (s, 2H, H-5/8 or 6/7), 7.92 (d, 4H,  $^3J_{\text{HH}} = 8$  Hz, H-14), (m, 4 + 2H, H-15 + H-16), 3.04 (s, 6H, C-2/11-Me). Cyclic voltammetry (vs. SCE)  $E_{1/2}$  (THF): -1.57 (rev.) V. HR-MS for  $\text{C}_{28}\text{H}_{32}\text{B}_2\text{N}_2$  ( $\text{M}^+$ ): 458.2126 (calcd.), 458.2109 (found).

#### X-ray crystallography

A deep-red – brown needle of  $\text{C}_{28}\text{H}_{32}\text{B}_2\text{N}_2$  was coated with Paratone 8277 oil (Exxon) and mounted on a glass fiber. All measurements were made on a Nonius KappaCCD diffractometer with graphite monochromated Mo  $\text{K}\alpha$  radiation. Details of crystal data and structure refinement have been provided in Table 2. The data were collected<sup>19</sup> using  $\omega$  and  $\phi$  scans. The data were corrected for Lorentz and polarization effects and for absorption using multi-scan method.<sup>20</sup>

The structure was solved by the direct methods<sup>21</sup> and expanded using Fourier techniques.<sup>22</sup> The H atoms were included at geometrically idealized positions and were not allowed to refine. The final cycle of full-matrix least-squares refinement using SHELXL97<sup>23</sup> converged with unweighted

# A DFT study on the electronic and redox properties of $[X_8V_{14}O_{50}]^{n-}$ ( $X = Si^{IV}, Ge^{IV}, P^V$ , and $As^V$ )

Muhammad Ramzan Saeed Ashraf Janjua, Zhong-Min Su, Wei Guan, Ahmad Irfan, Shabbir Muhammad, and Mudassir Iqbal

**Abstract:** The electronic and redox properties of the title polyanions have been calculated by means of density functional theory (DFT). These were unrestricted open-shell systems with electronic configuration of  $d^1$  of V. In this behalf, energies and compositions of  $\alpha$ -LUMO,  $\beta$ -LUMO,  $\alpha$ -HOMO, and  $\beta$ -HOMO were also analyzed. First of all, electronic and redox properties of vanadosilicate  $[Si_8V_{14}O_{50}]^{12-}$  (system **1**) were calculated and then  $Si^{IV}$  was substituted with  $Ge^{IV}$ ,  $P^V$ , and  $As^V$  for further investigations of systems **2**, **3**, and **4**, respectively. The substitution greatly modifies the electronic properties as  $\alpha$ -LUMOs are quite different in all the studied systems. The  $\alpha$ -LUMO is mainly composed of V and O in system **1**, V and Ge in system **2**, V and O in system **3**, and As, O, and V in system **4**. The alpha HOMO–LUMO energy gaps are greatly reduced in systems **2**, **3**, and **4** as compared with system **1**. The system **4**  $[As_8V_{14}O_{50}]^{4-}$  has minimal value of total bonding energy, whereas system **2**  $[Ge_8V_{14}O_{50}]^{12-}$  has maximal, so energetically system **4** is more favourable than the others. After the first reduction,  $\alpha$ -LUMO in  $[Si_8V_{14}O_{50}]^{14-}$  is made up of V and Si,  $\beta$ -LUMO in  $[Ge_8V_{14}O_{50}]^{13-}$  is concentrated on V and Ge,  $\beta$ -LUMO in  $[P_8V_{14}O_{50}]^{5-}$  is composed of V only, whereas  $\beta$ -LUMO in  $[As_8V_{14}O_{50}]^{5-}$  is delocalized over V, O, and As with almost the same contribution of all three atoms.

**Key words:** vanadium heteropolyanion, polyoxometalates (POM), electronic properties, redox properties, DFT.

**Résumé :** Faisant appel à la théorie de la fonctionnelle de la densité (TFD), on a calculé les propriétés électroniques et redox des polyanions mentionnés dans le titre. Ceux-ci correspondent à des systèmes en couches ouvertes sans restrictions avec une configuration électronique  $d^1$  pour le vanadium. À cette fin, on a aussi analysé les énergies et les compositions des orbitales moléculaires basses vacantes  $\alpha$  et  $\beta$  (BV- $\alpha$  et BV- $\beta$ ) ainsi que des orbitales moléculaires hautes occupées  $\alpha$  et  $\beta$  (HO- $\alpha$  et HO- $\beta$ ). Dans une première étape, on a calculé les propriétés électroniques et redox du vanadosilicate  $[Si_8V_{14}O_{50}]^{12-}$  (système **1**) et on a ensuite procédé à d'autres investigations en procédant à la substitution du  $Si^{IV}$  par du  $Ge^{IV}$ , du  $P^V$  et du  $As^V$  dans les systèmes respectivement **2**, **3** et **4**. La substitution modifie grandement les propriétés électroniques des BV- $\alpha$  qui sont très différentes dans chacun des systèmes étudiés. La BV- $\alpha$  est principalement formée de V et O dans le système **1**, de V et Ge dans le système **2**, de V et O dans le système **3** et de As, O et V dans le système **4**. Par comparaison avec le système **1**, la bande d'énergie entre les orbitales moléculaires OH- $\alpha$  et BV- $\alpha$  sont généralement réduites dans les systèmes **2**, **3** et **4**. L'énergie de liaison totale du système  $[As_8V_{14}O_{50}]^{4-}$  (système **4**) est la plus faible alors que celle du système  $[Ge_8V_{14}O_{50}]^{12-}$  (système **2**) est la plus élevée; d'un point de vue énergétique, le système **4** est donc plus favorable que les autres. Après une première réduction, l'orbitale OH- $\alpha$  du  $[Si_8V_{14}O_{50}]^{14-}$  est formée de V et Si, l'orbitale OH- $\beta$  du  $[Ge_8V_{14}O_{50}]^{13-}$  est concentrée sur le V et Ge, l'orbitale OH- $\beta$  du  $[P_8V_{14}O_{50}]^{5-}$  est composée que de V alors que l'orbitale OH- $\beta$  du  $[As_8V_{14}O_{50}]^{5-}$  est délocalisée sur le V, O et As avec des contributions pratiquement égales pour chacun des trois atomes.

**Mots-clés :** hétéropolyanion du vanadium, polyoxométalates, propriétés électroniques, propriétés redox, théorie de la fonctionnelle de la densité (TFD).

## Introduction

Polyoxometalates (POM) are a class of inorganic compounds with a remarkable degree of molecular and electronic tunabilities that have impact on disciplines as diverse

as catalysis,<sup>1</sup> medicine,<sup>2</sup> and materials science.<sup>3</sup> These compounds are molecular metal oxides mainly based on V, Mo, and W ions in their highest oxidation states. POMs are especially useful as model systems for the studies of magnetic

<sup>2</sup>Corresponding author (e-mail: zmsu@nenu.edu.cn).

and electronic interactions owing to their cluster structures. Indeed, many of these structures allow the inclusion of well-isolated clusters of paramagnetic ions with various nuclearities and definite topologies and geometries.<sup>4</sup> On the other hand, they permit the controlled injection of electrons, giving rise to mixed-valence species in which delocalized electrons may coexist and interact with localized magnetic moments. Some typical structural types are the Lindqvist<sup>5</sup> ( $M_6O_{19}^{2-}$ ,  $M = Mo, W$ ), Keggin<sup>6</sup> ( $XM_{12}O_{40}^{m-}$ ,  $X = P, Si, Co, Ni$ , and so forth), and Dawson-Wells<sup>7</sup> ( $P_2M_{18}O_{62}^{n-}$ ). Polyoxometalates<sup>8,9</sup> and their transition-metal substituted derivatives are a large group of transformable anionic clusters that have multiple applications, many of which are related to their redox properties.<sup>10</sup> POMs are structures that contain arrays of corner and edge-sharing pseudo-octahedrally coordinated  $MO_6$  units, packed to form an ionic core, where the electronic configuration of the metal is usually  $d^0$  or  $d^1$  and is commonly called addenda or peripheral element. In this context, POMs provide unique systems for the development of new theories in the mixed valence area. One of the important applications of POMs is based on their potential to act as electron acceptors, which leads to the possibility of the formation of charge-transfer electron donor-acceptor materials with interesting electronic and magnetic properties.<sup>11,12</sup>

In this work, for the first time, polyoxovanadosilicate  $[Si_8V_{14}O_{50}]^{12-}$  has been studied theoretically and  $Si^{IV}$  was substituted with  $Ge^{IV}$ ,  $P^V$ , and  $As^V$  in system **1** leading to systems **2**, **3**, and **4**, respectively. Vanadosilicate has  $D_{2d}$  symmetry, which was reported by Tripathi et al.<sup>13</sup> However, several queries are considered to be answered. First, how does the germanium, phosphorous, and arsenic affect the structural and electronic properties? Second, where would be the first reduction of polyoxovanadates modified by  $Ge^{IV}$ ,  $P^V$ , and  $As^V$ ? Third, what would be the composition of  $\alpha$ -LUMO,  $\beta$ -LUMO,  $\alpha$ -HOMO, and  $\beta$ -HOMO of the aforementioned polyoxovanadates? Following our investigations of the electronic properties, bonding nature, stabilities, and nonlinear optical properties of POMs,<sup>14–18</sup> density functional theory (DFT), which has been proven to be a consequential tool for understanding and rationalizing the electronic and magnetic properties of polyanions,<sup>19–28</sup> was employed to pursue the questions mentioned above. Our main objective was to investigate the effect of substitution of  $Ge^{IV}$ ,  $P^V$ , and  $As^V$  with  $Si^{IV}$  in system **1** on the electronic and redox properties of POMs, which may open up possibilities for the experimentalists to synthesize other templated vanadosilicates as well as their heteropolyanions.

## Computational details

All calculations reported in this work were carried out with the ADF2006.01 program.<sup>29</sup> The local density approximation (LDA) characterized by the Vosko–Wilk–Nusair (VWN)<sup>30</sup> parameterization for correlation were used. Becke<sup>31</sup> and Perdew<sup>32</sup> gradient corrections were added for the exchange and correlation energy, respectively. Triple- $\zeta$  plus polarization Slater basis sets were employed to describe the electrons of elements. The cores (O: 1s; Si, P, V: 2p;

Fig. 1. The calculated model of  $[Si_8V_{14}O_{50}]^{12-}$ .

Ge, As: 3p) were kept frozen, and they were described by single Slater functions. The relativistic effects were taken into account by means of the zero-order regular approximation (ZORA).<sup>33</sup> We made spin-unrestricted calculations as our studied systems have open-shell configuration. All the polyanions reported here were optimized under the constraints of the  $D_{2d}$  point symmetry group. The functional and basis set choices for our studied systems were based on the research work that has already been published.<sup>34–38</sup> The structural and atom-labeling schemes for the studied polyanions are presented in Fig. 1. Fourteen V atoms and eight Si atoms in each structure have been denoted with green and yellow colors. The  $Si^{IV}$  was substituted with  $Ge^{IV}$ ,  $P^V$ , and  $As^V$  in system **1**, resulting in systems **2**, **3**, and **4**, respectively.

## Results and discussion

### Structural parameters

The optimized bond lengths and the experimental crystal structure's bond lengths<sup>13</sup> are shown in Table 1. The agreement between experimental and calculated metrical parameters of system **1** gives us confidence that the present study is consequential for this research work. However, bond lengths were shortened compared with the experimental values when there was phosphorous owing to its smaller atomic radius, which is 1.23 Å but bond lengths were increased with arsenic having an atomic radius of 1.33 Å, germanium and silicon have atomic radii 1.52 Å and 1.46 Å, respectively.

**Table 1.** Bond lengths (Å) of heteropolyanions calculated by LDA/TZP for systems **1–4**.

[Ge <sub>8</sub> V <sub>14</sub> O <sub>50</sub> ] <sup>13-</sup>	23.547	<i>a</i> <sub>1</sub>	V = 89.99 O = 4.63	24.190	<i>a</i> <sub>1</sub>	V = 77.84 Ge = 17.21	0.643
[P <sub>8</sub> V <sub>14</sub> O <sub>50</sub> ] <sup>5-</sup>	5.887	<i>a</i> <sub>1</sub>	V = 90.16 O = 5.22	7.297	<i>a</i> <sub>2</sub>	V = 70.84 O = 24.32	1.41
[As <sub>8</sub> V <sub>14</sub> O <sub>50</sub> ] <sup>5-</sup>	5.705	<i>a</i> <sub>1</sub>	V = 87.58 O = 6.12	6.412	<i>a</i> <sub>1</sub>	V = 33.19 O = 32.59 As = 32.48	0.707

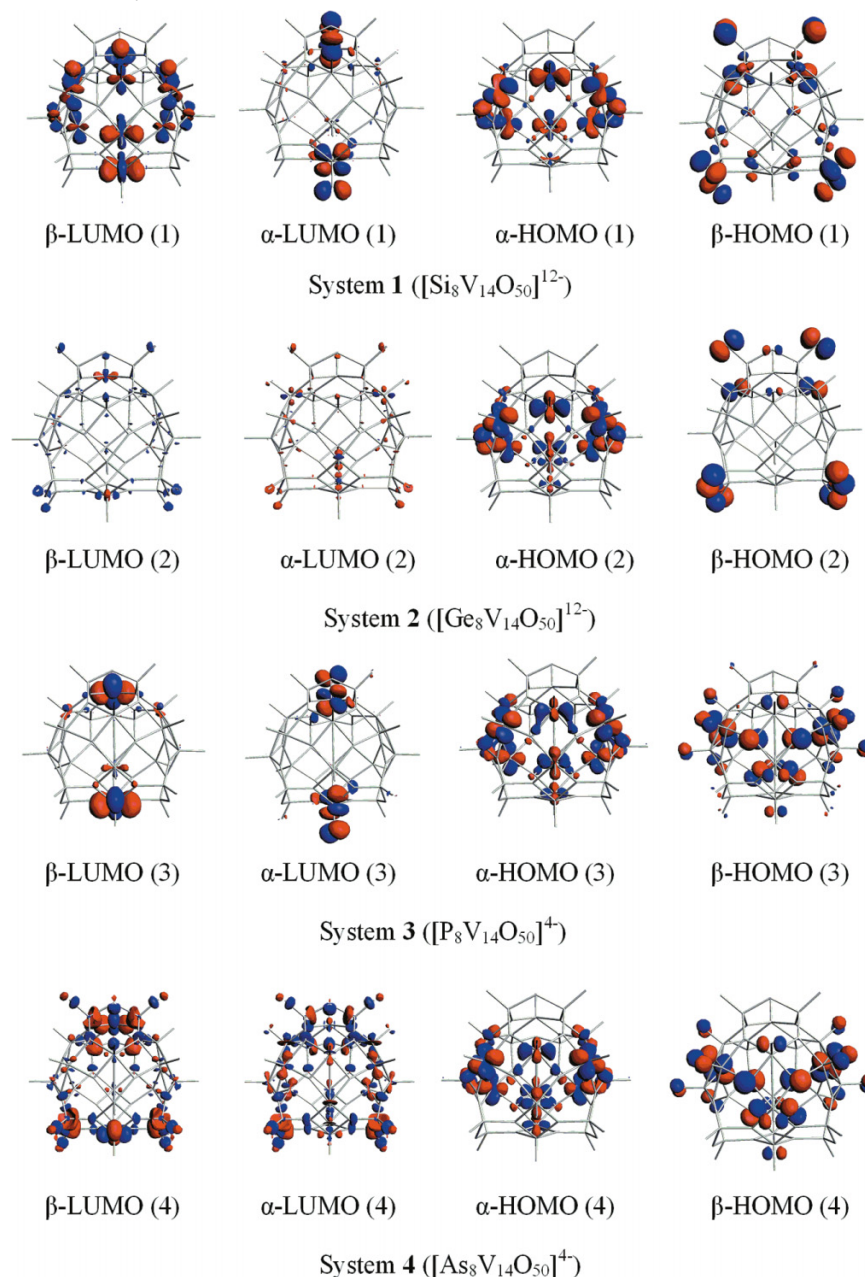

So, the bond lengths were increased compared with the experimental values. Furthermore, bond lengths of the polyanions of germanium were greater than silicon because of their higher atomic radii as illustrated in Table 1.

### Electronic properties of systems **1–4**

The Fig. 1 shows the calculation model for systems **1–4**, which are all open-shell systems. These systems are having 14  $\alpha$  electrons in their fully oxidized state. The  $\alpha$ -HOMOs are not affected by the substitution of Ge<sup>IV</sup>, P<sup>V</sup>, and As<sup>V</sup> because  $\alpha$ -HOMOs of systems **1–4** are mainly concentrated on V as depicted in Table 2 and Fig. 2. However, these substitu-

tions affect the composition of  $\alpha$ - and  $\beta$ -LUMOs of systems **2–4** (see Fig. 2).

The  $\alpha$ -LUMO of system **1** ([Si<sub>8</sub>V<sub>14</sub>O<sub>50</sub>]<sup>12-</sup>) is composed of 65.89% of V, 21.18% of O, and 2.2% of Si, and the  $\alpha$ -LUMO of system **2** ([Ge<sub>8</sub>V<sub>14</sub>O<sub>50</sub>]<sup>12-</sup>) consists of 78.18% of V and 13.59% of Ge. Moreover,  $\alpha$  HOMO–LUMO energy gap is also significantly decreased from 1.112 eV to 0.871 eV (see Table 2). In system **3**, ([P<sub>8</sub>V<sub>14</sub>O<sub>50</sub>]<sup>4-</sup>)  $\alpha$ -LUMO is composed of 65.86% of V and 25.97% of O, whereas in system **4** ([As<sub>8</sub>V<sub>14</sub>O<sub>50</sub>]<sup>4-</sup>)  $\alpha$ -LUMO is made up of 37.4% of As, 32.29% of O, and 28.55% of V. The values of  $\alpha$  HOMO–LUMO energy gaps are 1.052 eV and

**Fig. 2.** Frontier molecular orbitals of systems 1–4.

0.786 eV for systems 3 and 4, respectively, as shown in Table 2. However,  $\text{Si}^{\text{IV}}$  is participating while  $\text{P}^{\text{V}}$  has no contribution in the formation of  $\alpha$ -LUMO. Thus, it might be the reason that the  $\alpha$  HOMO–LUMO energy gap of system 1 is larger than that of system 3 in the following order:  $1 > 3 > 2 > 4$ . On the contrary, in the formation of  $\beta$ -LUMO,  $\text{Si}^{\text{IV}}$  has no contribution while  $\text{P}^{\text{V}}$  is participating, so it might be one reason due to which the beta HOMO–LUMO energy gap of system 3 is the largest, as  $3 > 1 > 2 > 4$ . The participation in the form of % of composition has also been mentioned in Tables 2 and 3. Moreover, on reduction of systems 1–4, we found a clue that the  $\beta$ -LUMO is favourable in systems 2–4 while  $\beta$ -LUMO is not suitable for system 1, so the above mentioned  $\beta$  HOMO–LUMO energy gap sequence of oxidized species  $3 > 1 > 2 > 4$  can be written as  $3 > 2 > 4$ ,

which is in accordance with the sequence of  $\alpha$  HOMO–LUMO energy gap of systems 2–4 (see Figs. 3 and 4). As far as the total bonding energy is concerned for systems 1–4, it is in the following order:  $2 > 1 > 3 > 4$  (see Table 4 and Fig. 5). The total steric interaction and Pauli repulsion along with total orbital interaction and electrostatic interaction of the studied systems (1–4) have been depicted in Figs. 5 and 6.

#### First reduction of systems 1–4

As far as the redox properties are concerned, it is well-known that the redox properties depend on the energy and composition of the LUMO. While the LUMO formally delocalizes over the metal atoms, which determines the redox properties of POMs.<sup>21</sup> In the first reduction of  $[\text{Si}_8\text{V}_{14}\text{O}_{50}]^{12-}$ , the  $\alpha$ -LUMO with symmetry  $e$  is available

**Table 3.** Energies (eV), symmetry (S), and major composition of beta frontier molecular orbitals of the polyanions.

Polyanions	$\beta$ -HOMO (energy)	S	Composition (%)	$\beta$ -LUMO (energy)	S	Composition (%)	$\Delta E^{\beta}$

**Fig. 3.** Molecular orbital diagram and arrow indicates HOMO–LUMO energy gap of systems 1 and 2.

with a minimum energy of 23.04 eV. The question arises whether  $\alpha$ -LUMO or  $\beta$ -LUMO would accept an electron, it is obvious that the energy of  $\beta$ -LUMO is greater than that of  $\alpha$ -LUMO (see Tables 2 and 3), it means  $\alpha$ -LUMO is more favourable than  $\beta$ -LUMO, so 1 e will prefer to go to  $\alpha$ -LUMO. If 1 e goes to  $\beta$ -LUMO, then spin polarization becomes 13, and if an electron goes to  $\alpha$ -LUMO, the spin polarization becomes 15. We calculated both possibilities of  $[\text{Si}_8\text{V}_{14}\text{O}_{50}]^{13-}$  and found the total bonding energies, which were  $-445.81$  eV and  $-445.93$  eV for spin polarization 13 and 15, respectively. It was concluded that  $[\text{Si}_8\text{V}_{14}\text{O}_{50}]^{13-}$

**Fig. 4.** Molecular orbital diagram and arrow indicates HOMO–LUMO energy gap of systems 3 and 4.**Table 4.** Total bonding energies (eV) of systems 1– 4.

Systems	Total bonding energy (eV)
1	$-470.0956$
2	$-440.0773$
3	$-559.2619$
4	$-562.5542$

with spin polarization 15 is more favourable, so the first electron goes to  $\alpha$ -LUMO of symmetry  $e$  of  $[\text{Si}_8\text{V}_{14}\text{O}_{50}]^{12-}$  with 0.5 contribution to  $e_1$  and  $e_2$ . On second electron reduc-

**Fig. 5.** Total bonding energy, electrostatic interaction, and total orbital interaction of systems 1–4.

**Fig. 6.** Total Pauli repulsion and total steric interaction of systems 1–4.

tion  $\alpha$ -LUMO of symmetry  $e$  will be completed with two electrons resulting into  $[\text{Si}_8\text{V}_{14}\text{O}_{50}]^{14-}$  (see Fig. 7).

In one-electron reduction of  $[\text{Ge}_8\text{V}_{14}\text{O}_{50}]^{12-}$ , we have  $\alpha$ -LUMO and  $\beta$ -LUMO with very slight difference in energy (see Tables 2 and 3), i.e., the energy of  $\beta$ -LUMO is a little higher than that of  $\alpha$ -LUMO, and it seems that 1 e reduction will occur in  $\alpha$ -LUMO. The total bonding energies of  $[\text{Ge}_8\text{V}_{14}\text{O}_{50}]^{13-}$  have been observed as  $-417.02$  eV and  $-417.01$  eV for spin polarization 13 and 15, respectively. The total bonding energy with spin polarization 13 is less, so it is favourable, which means that 1 e will go to  $\beta$ -LUMO. Now, the question arises why is 1 e reduction favoured by  $\beta$ -LUMO? The answer of this question is that in  $\alpha$ -LUMO of  $[\text{Ge}_8\text{V}_{14}\text{O}_{50}]^{12-}$ , the contribution of V is 78.18%; on the contrary,  $\beta$ -LUMO is composed of 73.55% of V. So, it might be possible that 1 e goes to  $\beta$ -LUMO of  $[\text{Ge}_8\text{V}_{14}\text{O}_{50}]^{12-}$  to give it more electronic density. In 1 e

reduction of  $[\text{P}_8\text{V}_{14}\text{O}_{50}]^{4-}$ , an electron goes to  $\beta$ -LUMO due to its lower energy, as we also calculated total bonding energies of  $[\text{P}_8\text{V}_{14}\text{O}_{50}]^{5-}$ , which were  $-553.75$  eV and  $-553.43$  eV for spin polarization 13 and 15, respectively.  $[\text{P}_8\text{V}_{14}\text{O}_{50}]^{5-}$  with spin polarization 13 is more suitable, which means that the electron goes to  $\beta$ -LUMO of  $[\text{P}_8\text{V}_{14}\text{O}_{50}]^{4-}$ .

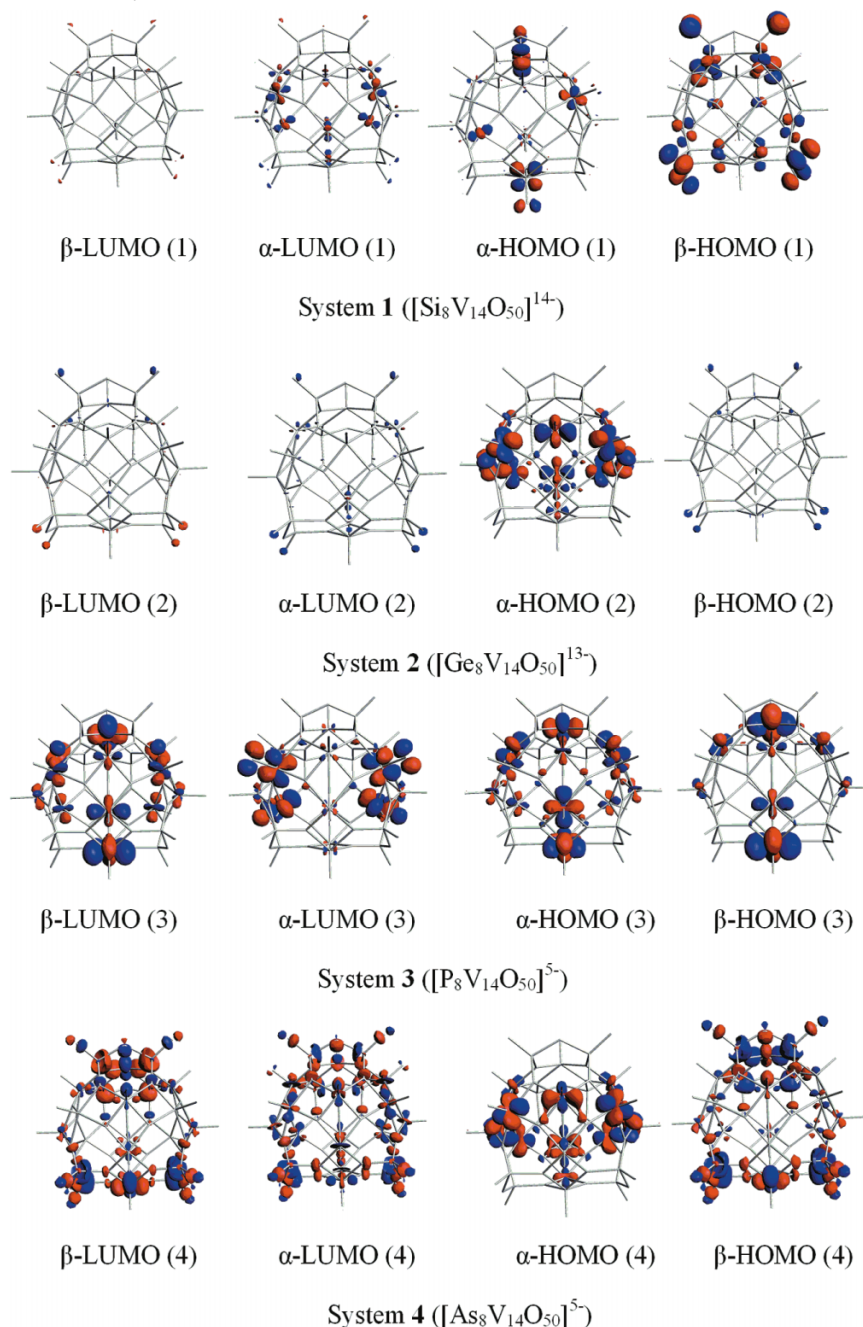

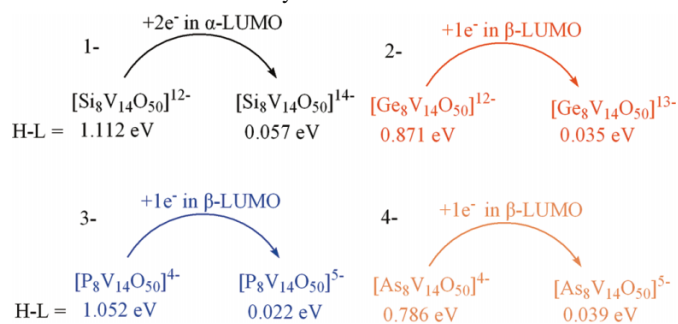

In the first reduction of  $[\text{As}_8\text{V}_{14}\text{O}_{50}]^{4-}$ , an electron goes to  $\beta$ -LUMO due to its low energy, which was further confirmed by the calculations of total bonding energies,  $-521.69$  eV and  $-521.32$  eV for spin polarization 13 and 15, respectively.  $[\text{As}_8\text{V}_{14}\text{O}_{50}]^{5-}$  with spin polarization 13 has less energy, which shows that 1 e goes to  $\beta$ -LUMO of  $[\text{As}_8\text{V}_{14}\text{O}_{50}]^{4-}$ . As far as energy gaps are concerned, the HOMO–LUMO energy gaps are significantly decreased after the first reduction of systems 1–4 as demonstrated in Scheme 1. The  $\alpha$ -LUMO in oxidized  $[\text{Si}_8\text{V}_{14}\text{O}_{50}]^{12-}$  is basically concentrated on V and O by 65.89% and 21.18%, respectively, whereas in reduced  $[\text{Si}_8\text{V}_{14}\text{O}_{50}]^{14-}$ , it is composed of V (65.94%) and Si (21.15%). The  $\alpha$ -LUMO in oxidized  $[\text{Ge}_8\text{V}_{14}\text{O}_{50}]^{12-}$  is delocalized over V (78.18%) and Ge (13.59%) while  $\beta$ -LUMO of  $[\text{Ge}_8\text{V}_{14}\text{O}_{50}]^{13-}$  is made up of V (54.14%) and Ge (42.29%). The  $\alpha$ -LUMO in oxidized  $[\text{P}_8\text{V}_{14}\text{O}_{50}]^{4-}$  is composed of 65.86% of V and 25.97% of O, whereas  $\beta$ -LUMO of  $[\text{P}_8\text{V}_{14}\text{O}_{50}]^{5-}$  is made up of 88.92% of V only (see Tables 2 and 3 with Figs. 2 and 7).

## Conclusions

In the present work, DFT calculations were carried out on vanadosilicate  $[\text{Si}_8\text{V}_{14}\text{O}_{50}]^{12-}$  and other related anions. The effect of substitution of  $\text{Ge}^{\text{IV}}$ ,  $\text{P}^{\text{V}}$ , and  $\text{As}^{\text{V}}$  with  $\text{Si}^{\text{IV}}$  on the electronic and redox properties was investigated. The above results can be summarized in following principal conclusions:

- (i) The substitution of  $\text{Si}^{\text{IV}}$  with  $\text{Ge}^{\text{IV}}$ ,  $\text{P}^{\text{V}}$ , and  $\text{As}^{\text{V}}$  has opened up possibilities for the experimentalists to synthesize other mimicked vanadosilicates, vanadogermenates, vandophosphates, and vandoarsenates as well as their heteropolyanions, respectively.
- (ii) The  $\alpha$ -LUMO is mainly concentrated on V and O in system 1, V and Ge in system 2, V and O in system 3, and As, O, and V in system 4.
- (iii) The substitution of  $\text{Ge}^{\text{IV}}$ ,  $\text{P}^{\text{V}}$ ,  $\text{As}^{\text{V}}$  with  $\text{Si}^{\text{IV}}$  in system 1 leads to decrease in the energy of LUMO and HOMO–LUMO energy gaps as well in systems 2, 3, and 4.
- (iv) The  $\alpha$  HOMO–LUMO energy gaps decrease in the following order: system 1 > 3 > 2 > 4.
- (v) The system 4 has a minimal value of the total bonding energy, whereas system 2 has a maximal value, so energetically system 4 is more favourable than the others. On the basis of total bonding energy, the formation of energetically favourable polyoxovanadates is in the following order: system 4 > 3 > 1 > 2.
- (vi) The bond lengths were shortened and lengthened because of the variable atomic radii of  $\text{Si}^{\text{IV}}$ ,  $\text{Ge}^{\text{IV}}$ ,  $\text{P}^{\text{V}}$ , and  $\text{As}^{\text{V}}$ .
- (vii) Phosphorous has the smallest atomic radius of 1.23 Å and germanium has the largest atomic radius of 1.52 Å among the afore mentioned polyoxovanadates,

**Fig. 7.** Frontier molecular orbitals of systems **1–4** after first reduction.**Scheme 1.** HOMO–LUMO energy gaps are significantly decreased after the first reduction of systems **1–4**.

and that is why bond lengths were maximum with the substitution of germanium while minimum with phosphorous.

(viii) Moreover, the bond lengths with  $\text{Ge}^{\text{IV}}$  were longer than with  $\text{Si}^{\text{IV}}$  due to the atomic radii of 1.52 Å and 1.46 Å, respectively, while the bond lengths with  $\text{As}^{\text{V}}$  were longer than with  $\text{P}^{\text{V}}$  due to atomic radii of 1.33 Å and 1.23 Å, respectively.

(ix) The first reduction would occur in the  $\alpha$ -LUMO of  $[\text{Si}_8\text{V}_{14}\text{O}_{50}]^{12-}$ ,  $\beta$ -LUMO of  $[\text{Ge}_8\text{V}_{14}\text{O}_{50}]^{12-}$ ,  $\beta$ -LUMO of  $[\text{P}_8\text{V}_{14}\text{O}_{50}]^{4-}$ , and  $\beta$ -LUMO of  $[\text{P}_8\text{V}_{14}\text{O}_{50}]^{4-}$  giving rise to reduced heteropolyanions of  $[\text{Si}_8\text{V}_{14}\text{O}_{50}]^{14-}$ ,  $[\text{Ge}_8\text{V}_{14}\text{O}_{50}]^{13-}$ ,  $[\text{P}_8\text{V}_{14}\text{O}_{50}]^{5-}$ , and  $[\text{As}_8\text{V}_{14}\text{O}_{50}]^{5-}$ , respectively.

(x) After the first reduction,  $\alpha$ -LUMO in  $[\text{Si}_8\text{V}_{14}\text{O}_{50}]^{14-}$  is composed of V and Si,  $\beta$ -LUMO in  $[\text{Ge}_8\text{V}_{14}\text{O}_{50}]^{13-}$  is concentrated on V and Ge,  $\beta$ -LUMO in  $[\text{P}_8\text{V}_{14}\text{O}_{50}]^{5-}$  is composed of V only, whereas  $\beta$ -LUMO in  $[\text{As}_8\text{V}_{14}\text{O}_{50}]^{5-}$  is made up of V, O, and As.

# Imino Diels–Alder reaction — An efficient synthetic protocol for 2-methyl-4-substituted tetrahydroquinolines catalyzed by copper dipyridine dichloride

C.S. Kavitha, K.M. Hosamani, and R.S. Harisha

**Abstract:** For the first time, copper dipyridine dichloride ( $\text{CuPy}_2\text{Cl}_2$ ) is used as an efficient and reusable catalyst for the imino Diels–Alder reaction of para-substituted anilines with *N*-vinylpyrrolidinone, *N*-vinylcarbazole, and *N*-vinylcaprolactam in acetonitrile to afford the corresponding 2-methyl-4-substituted-1,2,3,4-tetrahydroquinoline derivatives in excellent yields with good purity. The products were characterized by FTIR,  $^1\text{H}$  NMR,  $^{13}\text{C}$  NMR, MS, and elemental analysis.

**Key words:**  $\text{CuPy}_2\text{Cl}_2$ , reusable catalyst, aromatic amines, imino Diels–Alder reaction, 2-methyl-4-substituted tetrahydroquinolines.

**Résumé :** Le dichlorure de dipyridine cuivre ( $\text{CuPy}_2\text{Cl}_2$ ) a été utilisé pour la première fois comme catalyseur efficace et réutilisable pour la imino de Diels–Alder d'anilines para-substituées avec de la *N*-vinylpyrrolidone, du *N*-vinylcarbazole et du *N*-vinylcaprolactame, dans l'acétonitrile, pour conduire avec d'excellents rendements et un bonne pureté à la formation de dérivés correspondants, 2-méthyl-1,2,3,4-tétrahydroquinoléines substituées en position 4, qui ont été caractérisés par analyse élémentaire et par spectroscopies RMN du  $^1\text{H}$  et du  $^{13}\text{C}$ , par spectroscopie infrarouge à transformée de Fourier et par spectroscopie de masse.

**Mots-clés :**  $\text{CuPy}_2\text{Cl}_2$ , catalyseur réutilisable, amines aromatiques, réaction imino de Diels–Alder, 2-méthyl-1,2,3,4-tétrahydroquinoléines substituées en position 4.

[Traduit par la Rédaction]

## Introduction

One of the most challenging tasks in modern organic chemistry is the synthesis of natural products containing heterocyclic ring. Despite the considerable exploration to date within this field, there is still a need for further development of alternative methods for the synthesis of heterocyclic compounds. Among numerous families of natural products, tetrahydroquinolines seem to attract considerable attention because of their abundant presence in plants<sup>1</sup> along with their promising biological activities.<sup>2–8</sup> Therefore, their synthesis via newer and atom economical<sup>9</sup> approaches has been the subject of current research.<sup>10,11</sup> Since the pioneering work of Povarov,<sup>12</sup> this reaction has been extensively studied with use of different Lewis acids, such as  $\text{BF}_3\cdot\text{OEt}_2$ ,<sup>13</sup>  $\text{GaCl}_3$ ,<sup>14</sup>  $\text{InCl}_3$ ,<sup>15</sup>  $\text{LiClO}_4$ ,<sup>16,17</sup>  $\text{ZrCl}_4$ ,<sup>18</sup>  $\text{BiCl}_3$ ,<sup>19</sup> and  $\text{SbCl}_3$ ,<sup>20</sup> and protic acids, such as TFA,<sup>21</sup>  $\text{TsOH}$ ,<sup>22</sup> and  $(\text{COOH})_2$ .<sup>23</sup> Although the imino Diels–Alder reaction promoted by Lewis acid is known, many of these methods suffer from some limitations, such as more than stoichiometric amounts of the Lewis acid are required because of the coordination of the Lewis acid to the imine nitrogen. Further, most of these acids are moisture-sensitive and easily decom-

pose or become deactivated in the presence of water and are thus difficult to handle. Moreover, these reactions have some drawbacks like drastic reaction conditions, prolonged reaction time, tedious work-up procedures, and co-occurrence of side reactions, low yields, and expensive reagents/catalysts. Some of the catalysts are destroyed in the work-up procedure and cannot be recovered or reused. Furthermore, the disposal of these acids leads to environmental pollution. Therefore, the search continues for a better catalyst for the synthesis of tetrahydroquinolines in terms of operational simplicity, reusability of catalyst, low cost, and greater selectivity.

In continuation of our research work on imino Diels–Alder reaction by use of new catalysts,<sup>24,25</sup> we test copper dipyridine dichloride ( $\text{CuPy}_2\text{Cl}_2$ )<sup>26</sup> as an efficient Lewis acid catalyst. It is water-tolerant, reusable, and can effectively promote some of the organic reactions.<sup>27–29</sup>  $\text{CuPy}_2\text{Cl}_2$  is easier to handle than metal halides, such as  $\text{ZrCl}_4$ ,  $\text{BiCl}_3$ , and  $\text{SbCl}_3$ , and protic acids, such as TFA or  $\text{TsOH}$ . In the quest for developing a less toxic, potentially green catalyst, we thought of using  $\text{CuPy}_2\text{Cl}_2$  as a catalyst to synthesize the 2-methyl-4-substituted tetrahydroquinoline derivatives.

## Results and discussion

In view of the current trends in catalytic processes, there is merit in developing a truly catalytic method for the formation of 2-methyl-4-substituted tetrahydroquinolines. Now, we have found that an imino Diels–Alder reaction can be conveniently performed under neutral and mild conditions in the presence of a catalytic amount of CuPy<sub>2</sub>Cl<sub>2</sub>. Because of the presence of two pyridine rings, the electron deficiency increases on the nitrogen so it acts efficiently as a Lewis acid.<sup>26</sup>

Preliminary studies were carried out to study the effect of solvents and temperature on the model reaction of *p*-chloroaniline (5 mmol), and *N*-vinylpyrrolidinone (NVP) (12 mmol) in the presence of 0.01 mmol of CuPy<sub>2</sub>Cl<sub>2</sub>, and the results

are summarized (Table 1). Though the reaction proceeds at room temperature, the isolated yields are low and the reaction was sluggish. At 50 °C, the reaction proceeded smoothly and gave the desired products in excellent yields by using acetonitrile as solvent.

When the reaction was performed in different solvents such as dichloromethane, methanol, ethanol, THF and toluene, the observed yield was low (Table 1). However, when acetonitrile was used as solvent, the tetrahydroquinoline derivative was obtained in good yield with purity. However, the acetonitrile was found to be the best for the catalytic reaction in terms of yield and reaction time. In a control experiment, it was observed that in the absence of the catalyst, the reaction did not proceed neither at room temperature nor at higher temperatures.

**Scheme 3.** Synthesis of tetrahydroquinoline derivatives (**7a–7d**) catalyzed by  $\text{CuPy}_2\text{Cl}_2$ .

Thus, in the presence of 0.01 mmol of  $\text{CuPy}_2\text{Cl}_2$ , *p*-chloroaniline<sup>1</sup> was treated with NVP<sup>2</sup> in acetonitrile at 50 °C. After 2 h, the 1-(2-methyl-1,2,3,4-tetrahydroquinolin-4-yl)-pyrrolidin-2-one was obtained in good yield (Scheme 1). These compounds were established by IR, <sup>1</sup>H NMR, <sup>13</sup>C NMR, and mass spectral analysis.

Similarly, para-substituted anilines reacted smoothly with *N*-vinylpyrrolidinone, *N*-vinylcarbazole, and *N*-vinylcaprolactam (Scheme 1, Scheme 2, and Scheme 3, respectively) to give the corresponding tetrahydroquinolines (**3a–3d**, **5a–5d**, and **7a–7d**) in 80%–95% yields (Table 2) in the presence of 0.01 mmol of  $\text{CuPy}_2\text{Cl}_2$  in acetonitrile at 45–50 °C. In the IR spectra, the NH in all derivatives was observed at 3320–3360  $\text{cm}^{-1}$ , and C=O was observed from 1670.0 to 1678.3  $\text{cm}^{-1}$ . In <sup>1</sup>H NMR spectra, the NH peak was observed around 3–5 ppm, and NH proton disappeared on D<sub>2</sub>O addition and all the remaining protons were observed in the expected regions.

On the basis of previous reports<sup>30–32</sup> and the NMR data, all the substituted tetrahydroquinoline exist as *cis*-diastereomers. Their structural elucidation was based on <sup>1</sup>H NMR. The *J* values of H<sub>2</sub> and H<sub>4</sub> were found to be 7.88 and 6.80 Hz, respectively.

From these results, we propose the following possible mechanism to account for the reaction.<sup>24,25</sup> In a first step, the reaction must proceed by *N*-vinyl tautomerization to the iminium species and nucleophilic substitution at vinyl carbon, favoring the intermolecular proton transformation leading to the N–C bond formation. In a second step, the reaction of a second equivalent of the vinyl substrate leading to the Ar–C–C bond formation (Schemes 4–6).

## Conclusion

In conclusion, we are reporting that  $\text{CuPy}_2\text{Cl}_2$  is an efficient and reusable catalyst for the synthesis of 2-methyl-4-substituted tetrahydroquinoline derivatives. The present protocol provides easy work-up procedure, cost efficiency, providing reusability of the catalyst with excellent yields, which makes this method a valid contribution to the existing methodologies of tetrahydroquinolines.

## Experimental

The melting points of the products were determined by open capillaries on a Buchi apparatus and are uncorrected. The IR spectra were recorded on a Nicolet Impact-5700 FTIR Spectrophotometer using KBr pellets. <sup>1</sup>H NMR and <sup>13</sup>C NMR spectra were recorded on a BRUKER AVANCE-300F 300 MHz spectrometer in  $\text{CDCl}_3$  using TMS as an internal standard with <sup>1</sup>H resonance frequency of 300 MHz and <sup>13</sup>C resonance frequency of 75 MHz. D<sub>2</sub>O exchange was applied to confirm the assignment of the signals of NH protons. The Mass spectra were recorded on a Shimadzu GC-2010. The elemental analysis was carried out by using HERAUS CHN rapid analyzer. The homogeneity of the compounds was described by TLC detected by UV light and iodine vapors. All chemical reagents were obtained from Fluka, sd fine, and Merck chemical companies and were used without purification.

### General procedure for the synthesis of 2-methyl-4-substituted tetrahydroquinoline derivatives in the presence of copper dipyrindine dichloride catalyst

A mixture of the para-substituted anilines (**1**) (5 mmol), *N*-vinylpyrrolidin-2-one (**2**) (12 mmol), *N*-vinylcarbazole (**4**) (12 mmol), *N*-vinylcaprolactam (**6**) (12 mmol), and  $\text{CuPy}_2\text{Cl}_2$  (0.01 mmol) in acetonitrile (5 mL) was stirred at 45–50 °C for the appropriate time (Table 2). After completion of reaction as indicated by TLC, the reaction mixture was quenched with saturated aqueous  $\text{NaHCO}_3$  solution (20 mL) and extracted with ethyl acetate (2 × 15 mL). The combined organic layer was dried over anhydrous  $\text{Na}_2\text{SO}_4$  and concentrated under reduced pressure. After extraction, the water layer containing the catalyst could be evaporated under reduced pressure to give a catalyst back with blue colored sol id. The recovered catalyst was washed with ether and dried at 85 °C for 2 h under high pressure prior to further use in another reaction. The residue thus obtained was purified by column chromatography using silica gel (60–120 mesh) and eluted with petroleum ether:ethyl acetate (8:2) to afford tetrahydroquinoline derivatives (**3a–3d**, **5a–5d**, and **7a–7d**).

### 9-(2-Methyl-1,2,3,4-tetrahydroquinolin-4-yl)-9H-carbazole (5a)

Colorless crystalline solid. Yield: 90%, mp 124–126 °C (recrystallization solvent: chloroform).  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 1.35 (d, 3H,  $J = 6.3$  Hz), 2.25 (dd, 2H,  $J = 11.7, 6.1, 2.0$  Hz), 3.15 (m, 1H), 4.97 (dd, 1H,  $J = 11.8, 6.2$  Hz), 4.4 (s, 1H, NH), 6.90 (d, 1H,  $J = 8.5$  Hz), 6.38 (d, 1H,  $J = 8.4$  Hz), 6.86 (d, 1H,  $J = 8.6$  Hz), 7.19–8.11 (m, 8H).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 22.59, 35.16, 47.99, 52.08, 108.45, 110.90, 112.95, 114.93, 118.65, 119.25, 119.83, 120.78, 123.53, 123.76, 125.61, 126.06, 126.21, 128.12, 128.78, 139.89, 141.75, 145.66. IR (KBr)  $\nu$  ( $\text{cm}^{-1}$ ): 3417. MS  $m/z$ : 313. Anal. calcd. for  $\text{C}_{22}\text{H}_{20}\text{N}_2$ : C, 84.58; H, 6.45; N, 8.97. Found: C, 84.10; H, 6.40; N, 8.93.

### 9-(6-Chloro-2-methyl-1,2,3,4-tetrahydroquinolin-4-yl)-9H-carbazole (5b)

Colorless crystalline solid. Yield: 91%, mp 128–130 °C (recrystallization solvent: chloroform).  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 1.58 (d, 3H,  $J = 6.1$  Hz), 1.95 (dd, 2H,  $J = 11.4, 6.0, 2.6$  Hz), 3.45 (m, 1H), 5.5 (dd, 1H,  $J = 11.6, 6.0$  Hz), 4.1 (s, 1H, NH), 6.75 (s, 1H), 6.49 (d, 1H,  $J = 8.5$  Hz), 6.97 (d, 1H,  $J = 8.6$  Hz), 7.19–8.11 (m, 8H).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 21.39, 37.0, 51.0, 55.1, 108.45, 110.90, 111.0, 112.1, 112.95, 115.1, 119.6, 119.83, 120.78, 121.7, 123.2, 126.05, 128.78, 129.55, 133.4, 141.75, 143.3, 145.66. IR (KBr)  $\nu$  ( $\text{cm}^{-1}$ ): 3417. MS  $m/z$ : 346. Anal. calcd. for  $\text{C}_{22}\text{H}_{19}\text{ClN}_2$ : C, 76.18; H, 5.52; N, 8.08. Found: C, 76.15; H, 5.48; N, 8.05.

### 9-(6-Fluoro-2-methyl-1,2,3,4-tetrahydroquinolin-4-yl)-9H-carbazole (5c)

Colorless crystalline solid. Yield: 91%, mp 131–133 °C (recrystallization solvent: chloroform).  $^1\text{H}$  NMR (300 MHz,

$\text{CDCl}_3$ )  $\delta$  (ppm): 1.49 (d, 3H,  $J = 6.5$  Hz), 1.84 (dd, 2H,  $J = 11.2, 6.3, 2.8$  Hz), 3.43 (m, 1H), 5.3 (dd, 1H,  $J = 11.4, 6.5$  Hz), 4.5 (s, 1H, NH), 6.71 (s, 1H), 6.46 (d, 1H,  $J = 8.9$  Hz), 6.93 (d, 1H,  $J = 8.9$  Hz), 7.14–8.16 (m, 8H).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 22.61, 35.22, 48.12, 52.26, 108.64, 111.02, 112.76, 114.76, 118.61, 119.29, 119.68, 121.74, 123.29, 124.74, 125.89, 126.41, 127.18, 128.09, 128.76, 139.86, 141.72, 145.69. IR (KBr)  $\nu$  ( $\text{cm}^{-1}$ ): 3420. MS  $m/z$ : 330. Anal. calcd. for  $\text{C}_{22}\text{H}_{19}\text{FN}_2$ : C, 79.97; H, 5.80; N, 8.48. Found: C, 79.94; H, 5.75; N, 8.45.

### 9-(2,6-Dimethyl-1,2,3,4-tetrahydroquinolin-4-yl)-9H-carbazole (5d)

Colorless crystalline solid. Yield: 92%, mp 124–126 °C (recrystallization solvent: chloroform).  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 1.42 (d, 3H,  $J = 6.2$  Hz), 1.89 (dd, 2H,  $J = 11.6, 6.4, 2.6$  Hz), 2.35 (s, 3H), 3.21 (m, 1H), 4.95 (dd, 1H,  $J = 11.1, 6.0$  Hz), 4.5 (s, 1H, NH), 6.70 (s, 1H), 6.26 (d, 1H,  $J = 8.5$  Hz), 6.66 (d, 1H,  $J = 8.8$  Hz), 7.14–8.16 (m, 8H).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 21.1, 21.3, 47.02, 51.0, 55.22, 108.64, 111.0, 111.02, 112.28, 112.76, 114.76, 115.1, 118.61, 119.6, 120.5, 121.74, 123.29, 125.89, 127.18, 128.09, 133.1, 140.3, 141.69. IR (KBr)  $\nu$  ( $\text{cm}^{-1}$ ): 3426. MS  $m/z$ : 326. Anal. calcd. for  $\text{C}_{23}\text{H}_{22}\text{N}_2$ : C, 84.63; H, 6.79; N, 8.58. Found: C, 84.58; H, 6.75; N, 8.55.

### 1-(2-Methyl-1,2,3,4-tetrahydroquinolin-4-yl)azepan-2-one (7a)

Light yellow crystalline solid. Yield: 92%, mp 118–120 °C (recrystallization solvent: chloroform).  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 1.23 (d, 3H,  $J = 6.3$  Hz), 2.09 (dd, 2H,  $J = 11.2, 6.3, 2.4$  Hz), 2.79 (m, 1H), 4.87 (dd, 1H,  $J = 11.5, 6.3$  Hz), 1.29 (t, 2H), 1.55 (m, 2H), 1.57 (m, 2H), 2.18 (t, 2H), 3.2 (t, 2H), 4.5 (s, 1H, NH), 6.49–6.91 (m, 4H).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 21.3, 25.7, 31.8, 32.0, 32.2, 44.5, 46.6, 47.3, 50.7, 112.1, 116.7, 123.2, 126.5, 129.1, 143.3, 172.3. IR (KBr)  $\nu$  ( $\text{cm}^{-1}$ ): 3368, 1658. MS  $m/z$ : 258. Anal. calcd. for  $\text{C}_{16}\text{H}_{22}\text{N}_2\text{O}$ : C, 74.38; H, 8.58; N, 10.84. Found: C, 74.35; H, 8.50; N, 10.85.

### 1-(6-Chloro-2-methyl-1,2,3,4-tetrahydroquinolin-4-yl)azepan-2-one (7b)

Light yellow crystalline solid. Yield: 93%, mp 122–124 °C (recrystallization solvent: chloroform).  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 1.26 (d, 3H,  $J = 6.1$  Hz), 2.08 (dd, 2H,  $J = 11.1, 6.4, 2.8$  Hz), 2.79 (m, 1H), 4.87 (dd, 1H,  $J = 11.5, 6.3$  Hz), 1.29 (t, 2H), 1.55 (m, 2H), 1.57 (m, 2H), 2.18 (t, 2H), 3.2 (t, 2H), 4.5 (s, 1H, NH), 6.49–6.91 (m, 4H).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 21.5, 25.7, 31.8, 32.0, 32.2, 44.0, 46.6, 47.3, 50.7, 113.5, 122.0, 126.9, 129.5, 129.6, 141.4, 172.0. IR (KBr)  $\nu$  ( $\text{cm}^{-1}$ ): 3362, 1654. MS  $m/z$ : 292. Anal. calcd. for  $\text{C}_{16}\text{H}_{21}\text{ClN}_2\text{O}$ : C, 65.63; H, 7.23; N, 9.57. Found: C, 65.59; H, 7.18; N, 9.52.

### 1-(6-Fluoro-2-methyl-1,2,3,4-tetrahydroquinolin-4-yl)azepan-2-one (7c)

Light yellow crystalline solid. Yield: 90%, mp 128–130 °C (recrystallization solvent: chloroform).  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 1.23 (d, 3H,  $J = 6.6$  Hz), 2.03 (dd, 2H,  $J = 11.0, 6.6, 2.4$  Hz), 2.79 (m, 1H), 4.85 (dd, 1H,  $J = 11.0, 6.6$  Hz), 1.27 (t, 2H), 1.53 (m, 2H), 1.58 (m, 2H),

2.20 (t, 2H), 3.5 (t, 2H), 4.2 (s, 1H, NH), 6.61 (s, 1H), 6.36 (d, 1H,  $J = 8.6$  Hz), 6.57 (d, 1H,  $J = 6.8$  Hz).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 22.1, 25.6, 31.8, 32.6, 44.5, 44.6, 46.6, 47.3, 50.7, 113.5, 113.7, 116.1, 124.8, 138.9, 150.3, 172.9. IR (KBr)  $\nu$  ( $\text{cm}^{-1}$ ): 3366, 1657. MS  $m/z$ : 276. Anal. calcd. for  $\text{C}_{16}\text{H}_{21}\text{FN}_2\text{O}$ : C, 69.54; H, 7.66; N, 10.14. Found: C, 69.51; H, 7.62; N, 10.10.

### 1-(2,6-Dimethyl-1,2,3,4-tetrahydroquinolin-4-yl)azepan-2-one (7d)

Light yellow crystalline solid. Yield: 91%, mp 125–127 °C (Recrystallization solvent: chloroform).  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 1.28 (d, 3H,  $J = 6.0$  Hz), 2.35 (s, 2H,  $J = 11.1$ , 6.4, 2.8 Hz), 2.79 (m, 1H), 4.87 (dd, 1H,  $J = 11.5$ , 6.3 Hz), 1.29 (t, 2H), 1.55 (m, 2H), 1.57 (m, 2H), 2.18 (t, 2H), 3.2 (t, 2H), 4.5 (s, 1H, NH), 6.49–6.91 (m, 4H).  $^{13}\text{C}$  NMR (75 MHz,  $\text{CDCl}_3$ )  $\delta$  (ppm): 21.5, 25.7, 31.8, 32.0, 32.2, 44.0, 46.6, 47.3, 50.7, 113.5, 122.0, 126.9, 129.5, 129.6, 141.4, 172.0. IR (KBr)  $\nu$  ( $\text{cm}^{-1}$ ): 3368, 1651. MS  $m/z$ : 272. Anal. calcd. for  $\text{C}_{17}\text{H}_{24}\text{N}_2\text{O}$ : C, 74.96; H, 8.88; N, 10.28. Found: C, 74.90; H, 8.85; N, 10.23.

### Acknowledgments

This research work is financially supported by Council of Scientific and Industrial Research, New Delhi – 110 012 (Ref. No.: 01(2301)/09/EMR–II, dated 19 March 2009). Ms. C.S. Kavitha is grateful to UGC for the award of JRF (Ref. No.: KU/Sch/UGC/RFSM/2006–07/3236, dated 08 March 2007).

# Effect of collision energy on cross sections and product alignments for the $C(^1D) + H_2$ ( $v = 0, j = 0$ ) insertion reactions

Lihua Kang and Bin Dai

**Abstract:** Quasi-classical trajectory (QCT) calculations of total reaction probabilities and vibrationally state-resolved reaction probabilities at total angular momentum  $J = 0$  as a function of collision energy for the  $C(^1D) + H_2$  ( $v = 0, j = 0$ ) reactions have been performed on an ab initio potential-energy surface [*J. Chem. Phys.* **2001**, *115*, 10701]. In addition, the integral cross sections as a function of collision energy have been carried out for the same reaction. The product rotational alignments have also been calculated, which are almost invariant with respect to collision energies.

**Key words:** cross sections, product alignments, insertion reactions, quasi-classical trajectory.

**Résumé :** On a effectué des calculs théoriques de trajectoire quasi-classique (TQC) sur une surface d'énergie potentielle ab initio [*J. Chem. Phys.* **2001**, *115*, 10701] pour évaluer les probabilités totales de réaction et les probabilités de réaction résolues en fonction de l'état vibrationnel, à un moment angulaire  $J = 0$  et en fonction de l'énergie de collision, des réactions  $C(^1D) + H_2$  ( $v = 0, j = 0$ ). De plus, pour la même réaction, on a aussi évalué les sections droites intégrales en fonction de l'énergie de collision. On a aussi calculé les alignements rotationnels qui sont pratiquement invariables avec les énergies de collision.

**Mots-clés :** sections droites, alignements du produit, réactions d'insertion, trajectoire quasi-classique.

## Introduction

In the past decades, a great deal of attention has been paid to the atom–diatom insertion reactions in which the potential energy surfaces are often dominated by deep wells rather than barriers.<sup>1</sup> The reaction between atomic carbon and molecular hydrogen belongs to this class of insertion reaction. Other thoroughly studied insertion reactions between electronically excited atoms and hydrogen molecules are  $O(^1D) + H_2$ ,<sup>2–7</sup>  $N(^2D) + H_2$ ,<sup>8–10</sup> and  $S(^1D) + H_2$ .<sup>11–14</sup> Unlike other members of the insertion reaction family, however,  $C(^1D) + H_2$  is considered to be a clean insertion reaction,<sup>15,16</sup> without involvement of abstraction pathways. The reaction between atomic carbon and molecular hydrogen  $C(^1D) + H_2$ , and its isotopic variants  $C(^1D) + HD$  and  $C(^1D) + D_2$ , play a central role in atmospheric and combustion chemistry. Because of its remarkable features, it has attracted much experimental<sup>15–19</sup> and theoretical attention.<sup>20,21</sup>

In crossed molecular-beam (CMB) experiments, Bergeat et al.<sup>15</sup> measured the product angular and time-of-flight (TOF) distributions for the  $C(^1D) + H_2$  reaction, and Balucani et al.<sup>19</sup> measured the product angular and velocity distributions.

Motivated by the crossed molecular-beam experiments,<sup>15</sup> Launay and co-workers<sup>21</sup> developed a global potential-energy surface (PES) for the first single state of  $^1A'$  symmetry for the  $CH_2$  system. The ab initio calculations were carried out over 1748 geometries and the resulting energies were fitted

to a many-body expansion. The potential energy surface has a well depth of 417.1 kJ/mol relative to the  $C(^1D) + H_2$  asymptote.

Theoretical studies of the title reaction have been stimulated by the availability of the high-quality potential-energy surface.<sup>21</sup> Launay and co-workers<sup>20,21</sup> performed QCT and QM calculations of reaction probabilities and cross sections. Since QM calculations are prohibitively expensive, the quantum integral cross section was calculated at a single collision energy ( $E_c$ ),  $E_c = 7.8$  kJ/mol (0.08 eV), and was found to be  $30.49 \text{ \AA}^2$ . At this  $E_c$ , previous QCT calculations were repeated and found to underestimate the value ( $22.48 \text{ \AA}^2$ ). For comparison, we also calculated the integral cross section at this  $E_c$  and found a value of  $25.75 \text{ \AA}^2$ .

Not only the scalar properties (such as integral cross section and product-branching ratios) but also the vector properties (such as velocities and angular momentum) can be obtained from QCT calculations.<sup>22</sup> For example, product alignments and orientations can be determined by QCT calculations.<sup>22–24</sup> And many experimental techniques, such as polarization-resolved chemiluminescence,<sup>25,26</sup> polarized laser-induced fluorescence,<sup>27</sup> and electric deflection methods,<sup>28</sup> can be used under molecular-beam and bulb conditions to determine the product alignments.<sup>29</sup> In the present work, we have performed QCT calculations of reaction probabilities and integral cross sections as well as product alignment for the title reaction. The calculated results have

been compared with the available QM and previous QCT results.

## Theoretical methods

All the QCT calculations have been carried out on the  $^1A'$   $\text{CH}_2$  ab initio PES of ref. 21. The general method for the calculation of QCT is the same as the one used in refs. 22, and 30–34, and the classical Hamilton's equations are integrated numerically for motion in three dimensions with the sixth-order symplectic integration.<sup>33</sup> The collision-energy dependence of the reaction probability at total angular momentum  $J = 0$ ,  $P^{J=0}(E_c)$ , for the  $\text{C}(^1\text{D}) + \text{H}_2$  ( $v = 0, j = 0$ ) reaction has been obtained by running batches of 100 000 trajectories randomly. The integration step size in the trajectories was chosen to be  $10^{-17}$  s, which guarantees the conservation of the total energy and total angular momentum. The trajectories were started at a distance of 1.0 nm between the incoming atom and the center of mass of the diatom. The maximum value of the impact parameter,  $b_{\text{max}}$ , was computed by calculating 100 000 trajectories at fixed values of the impact parameter  $b$  systematically increasing the value of  $b$  until no reactive trajectories were obtained. The reaction probability  $N_r/N$  is the ratio of the number of reactive trajectories to the total number of trajectories, and the reactive cross section is defined as  $\sigma_r = \pi b_{\text{max}}^2 \times (N_r/N)$ .

The product rotational-alignment calculations have been well studied by Han and co-workers.<sup>22</sup> Therefore, in addition to the scalar properties stated above, the average rotational alignment of the product CH has also been calculated using the method in ref. 22.

## Results and discussion

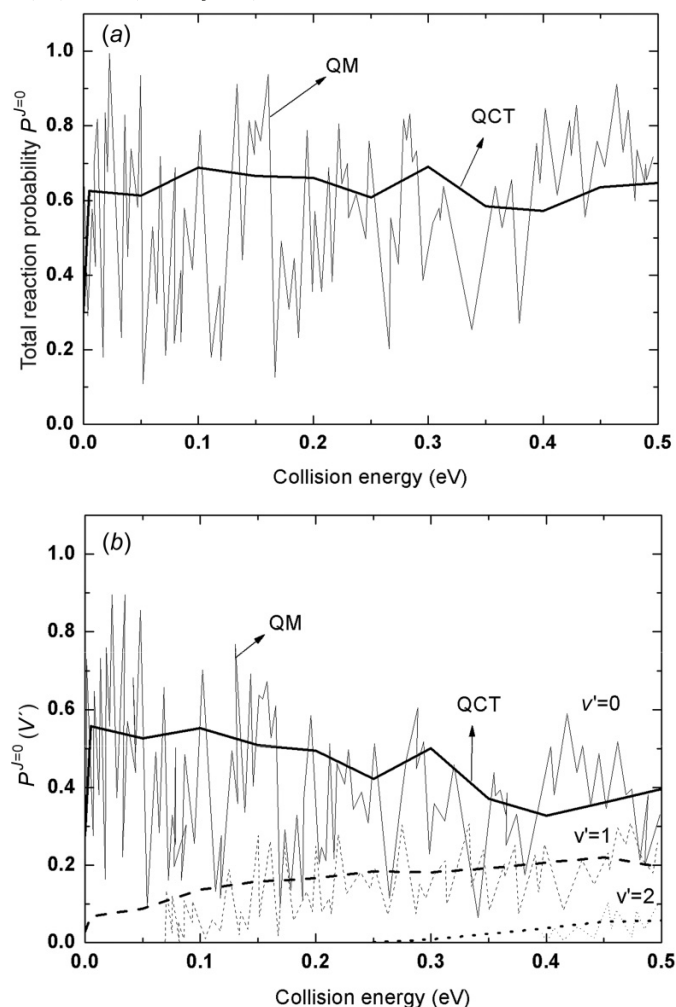

### Reaction probabilities

Figure 1 presents the QM<sup>21</sup> and QCT total and vibrationally state-resolved reaction probabilities of the final product  $\text{H} + \text{CH}$  ( $v' = 0, 1$ ) at total angular momentum  $J = 0$ ,  $P^{J=0}(E_c)$ , as a function of collision energy  $E_c$ , for the  $\text{C}(^1\text{D}) + \text{H}_2$  ( $v = 0, j = 0$ ) reaction. From Fig. 1, it can be seen that the results from the QCT and QM methods<sup>21</sup> agree with each other very well in the whole collision-energy range for the total and  $v'$  state-resolved reaction probabilities. This confirms that QCT and QM results are in good agreement for most reactions, as predicted in ref. 35. The QM and QCT total reaction probabilities for the reaction have no energy threshold as expected for a barrierless reaction with a deep well (417.1 kJ/mol).<sup>21,36</sup> Like the QM probabilities, the QCT reaction probabilities do not show any sharp peak structures. Instead, they follow the approximately average QM reaction probabilities. The  $v' = 0$  reaction probability dominates those for  $v' = 1$  and  $v' = 2$  over all the collision energy range. As shown in Fig. 1b, the  $v' = 0$  reaction probability decreases with increasing collision energy, whereas for the  $v' = 1$  and  $v' = 2$  reactions a smooth increasing probability is observed.

### Integral cross sections

Table 1 summarizes the trajectory details (maximum impact parameter, number of computed reactive trajectories) and the resulting cross sections of the reaction  $\text{C}(^1\text{D}) + \text{H}_2$  ( $v = 0, j = 0$ ). The QCT integral cross sections for the reac-

tion  $\text{C}(^1\text{D}) + \text{H}_2$  ( $v = 0, j = 0$ ) are shown in Fig. 2 along with the QM results by Balucani et al.<sup>37</sup> As can be seen in Fig. 2, the QCT calculations yield cross sections somewhat lower than the QM at collision energy  $E_c = 7.8$  kJ/mol (0.08 eV). It seems reasonable that the QCT results are slightly smaller

**Fig. 2.** A comparison between the QCT-computed cross sections in this work and other theoretical cross sections for the  $C(^1D) + H_2$  ( $v = 0, j = 0$ ) reaction. The QM and QCT (HB,GB) results are taken from refs. 37 and 20, respectively.

than the accurate QM ones owing to the tunneling effect. The QCT method has a serious drawback in that it cannot handle the quantum mechanical questions of the system. As a result, the cross sections of the title reactions of the QM method are greater than those of the QCT method. As shown in Fig. 2, although the same PES was used in both calculations, the results of our work are greater than the results of Bañares et al.<sup>20</sup> at 7.8 kJ/mol collision energy. This may be ascribed to the fact that we chose  $10^{-17}$  s as the integration step size in the trajectories, whereas Bañares et al.<sup>20</sup> chose  $5 \times 10^{-17}$  s. The integral cross sections first decrease sharply at low collision energies and then level off at high energies. Similar observations have been found in theoretical studies of other insertion reactions.<sup>38–40</sup>

To understand the dynamics of the insertion reaction fully, the state-resolved quantities were obtained. In Fig. 3a, the product vibrational state as a function of collision energy is plotted for the  $C(^1D) + H_2$  ( $v = 0, j = 0$ )  $\rightarrow$   $CH$  ( $v' = 0, 1, j' = 0$ ) +  $H$  reaction. From Fig. 3a, we can see that the  $CH$  product is dominated by the ground vibrational states ( $v' = 0$ ). The  $v' = 0$  integral cross section decreases when the collision energy increases, whereas it increases for the  $v' = 1$  integral cross section.

In Fig. 3b, the resolved cross sections for the product rotational state are plotted against the collision energy for the  $C(^1D) + H_2$  ( $v = 0, j = 0$ )  $\rightarrow$   $CH$  ( $v' = 0, j' = 0, 5, 10, 15$ ) +  $H$  reaction. In Fig. 3b, for  $j' = 0, 5$ , and  $10$ , the integral cross section decreases with the increasing collision energy, whereas the trend is opposite for  $j' = 15$ .

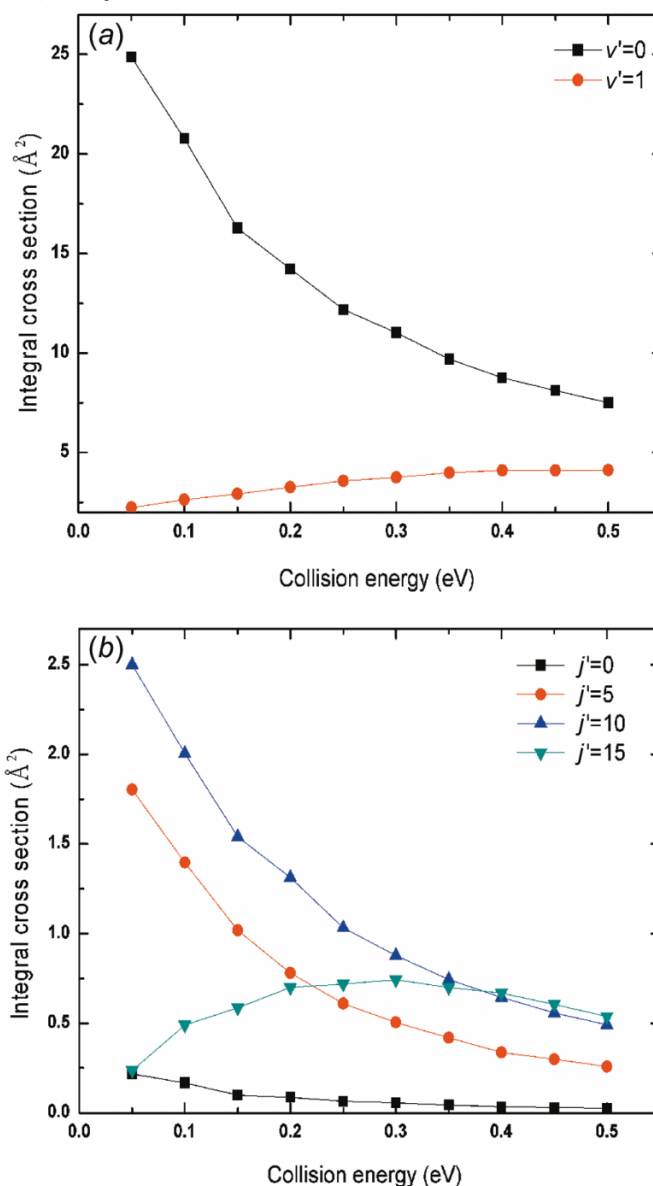

### Rotational alignment parameter

In a reactive encounter, the total angular momentum is conserved

$$[1] \quad j + l = j' + l'$$

where  $l$  and  $l'$  are the reagent and product orbital momenta, respectively. When the reagent angular momentum  $j$  is small, the product rotation can only result from  $l$ . The distribution

**Fig. 3.** Product vibrational state distributions ( $CH(v' = 0, 1, j' = 0) + H$ ) (a) and rotational state distributions ( $CH(v' = 0, j' = 0, 5, 10, 15) + H$ ) (b) as a function of collision energy for the  $C(^1D) + H_2$  ( $v = 0, j = 0$ ) reaction.

of the angular momentum  $j'$  of the product molecule is described by a function  $f(\theta)$ , where  $\theta$  is the angle between  $j'$  and  $k$  (the reagent relative velocity vector).  $f(\theta)$  can be represented by the Legendre polynomial<sup>22</sup>

$$[2] \quad f(\theta) = \sum a_n P_n(\cos \theta)$$

where  $n = 2$  indicates the product rotational alignment

$$[3] \quad \langle P_2(j' \cdot k) \rangle = 1/2 \langle \cos^2 \theta - 1 \rangle$$

where  $P_2$  is the second Legendre moment and the brackets indicate the average over the distribution of  $j'$  about  $k$ . In the present work, we calculate only the rotational alignment parameter of the product, since it alone has been measured in most of the experiments until now.

**Fig. 4.** CH product rotational alignment  $\langle P_2(j', k) \rangle$  for the reaction  $C(^1D) + H_2$  ( $v = 0, j = 0$ ) as a function of collision energy.

The dependence of the product rotational alignment on collision energies is shown in Fig. 4. It can be seen that the  $\langle P_2(j', k) \rangle$  values are almost invariant with respect to collision energies. Generally, the higher the collision energies, the stronger the rotational alignment of the products. However, in the present work, the  $\langle P_2(j', k) \rangle$  values calculated on the PES for the  $C(^1D) + H_2$  reaction are almost invariant as the collision energy increases. The reason is that the product orbital angular momentum is large, and the reactant orbital angular momentum has less influence on the molecular product rotational alignment. This is consistent with previous calculations.<sup>22,23</sup>

## Conclusion

In this paper, we have reported the QCT calculation of total and vibrationally state-resolved reaction probabilities at total angular momentum  $J = 0$  (zero-impact parameter) for reactions  $C(^1D) + H_2$  ( $v = 0, j = 0$ ) based on the ground  $^1A'$  state PES. The total reaction probability for the reaction was found to have no threshold. For the vibrational state-resolved reaction probabilities, the  $v' = 0$  reaction probabilities dominate those for  $v' = 1$  and  $v' = 2$  over the full collision energy range. The total integral cross sections as a function of collision energy have also been carried out for the same reaction. The total integral cross sections are decay functions of the collision energy, consistent with the barrierless insertion reaction. Comparing our QCT results with the quantum methods show that our QCT results are in reasonably good agreement with the QM results. In addition, the rotational alignment of the product is calculated, and  $\langle P_2(j', k) \rangle$  values are almost invariant with respect to collision energies. We look forward to more experimental studies of reaction probabilities, integral cross sections, and product rotational alignment effect on the  $C(^1D) + H_2$  reaction, so that a comparison of theory and experiment can be implemented.

# Medium-sized cyclophanes — Part 85: Benzylation by 8-(bromomethyl)[2.2]metacyclophanes. Through-space electronic interactions of [2.2]metacyclophane benzyl cations

Tomoe Shimizu, Kan Tanaka, Arjun Paudel, and Takehiko Yamato

**Abstract:**  $\text{TiCl}_4$ -mediated Friedel–Crafts benzylation of benzene with 8-(bromomethyl)[2.2]metacyclophanes to afford 8-benzyl[2.2]metacyclophanes is described. Substituent effect through space on the rate of the benzylation of benzene with a bromomethyl group attached on the opposite aromatic ring was first found in this investigation. Interestingly, the introduction of the substituents at the internal position 16 tends to promote the present benzylation reaction rate 1.8–3.8 times. It was found that the benzyl cation intermediate was stabilized by the direct through-space cation– $\pi$  interaction among the opposite benzene ring in the benzylation of [2.2]metacyclophane systems.

**Key words:** cyclophanes, Friedel–Crafts benzylation, benzyl cation intermediate, through-space electronic interaction.

**Résumé :** On décrit la réaction de benzylation du benzène par le 8-bromométhyl[2.2]métacyclophanes par la méthode de Friedel–Crafts catalysée par le  $\text{TiCl}_4$ . Dans ce travail, on a mis en évidence pour la première fois, un effet de substituant qui se fait sentir à travers l'espace sur la vitesse de benzylation du benzène en raison d'un groupe bromométhyle attachée sur le noyau aromatique opposé. Il est intéressant de noter que l'introduction de substituants à la position interne 16 tendent à accélérer les vitesses de réaction de benzylation par des facteurs allant de 1,8 à 3,8. On a trouvé que le cation benzylique intermédiaire est stabilisé par une interaction cation– $\pi$  directe à travers l'espace du noyau benzénique opposé dans la benzylation de systèmes [2.2]métacyclophanes.

**Mots-clés :** cyclophanes, benzylation suivant Friedel–Crafts, cation benzylique intermédiaire, interaction électronique à travers l'espace.

## Introduction

The geometry of the [2.2]metacyclophane ([2.2]MCP) skeleton is known in detail from an X-ray structural analysis.<sup>2,3</sup> The crystal consists of discrete molecules, each of which has a center of symmetry. The two halves of the molecule form a stepped system. It is interesting to note that the benzene rings are not planar, but have a boat conformation, with the result that the molecule evidently avoids the steric interaction of the central carbon atoms C(8) and C(16) and of the attached hydrogen atoms. The X-ray structural analysis of 8,16-dimethyl[2.2]MCP (**2**) confirms the increased strain in molecule **2** as compared with that in the parent hydrocarbon **1** (Fig.1).<sup>4–16</sup>

Although substituents at positions 8 and 16 in the [2.2]MCP system seem to have interesting chemical natures since they are covered by the opposite aromatic ring, there are few investigations concerning these problems.<sup>17,18</sup> Owing to electronic interaction between two benzene rings, the proximity of 8- and 16-positions, and the considerable strain

energy, [2.2]MCP is prone to giving transannular reaction products.<sup>19–21</sup> These are mostly explained by the initial formation of a cyclodehydrogenation reaction product, 4,5,9,10-tetrahydropyrene. It has been isolated under the electrophilic,<sup>22–25</sup> radical,<sup>26</sup> and photolytic reaction conditions,<sup>27</sup> together with other transformation products derived from tetrahydropyrene. Sato and co-workers<sup>28,29</sup> reported another type of iodine-induced reaction of [2.2]MCP, which gives 1,2,3,3a,4,5-hexahydropyrene. On the other hand, we have reported<sup>30,31</sup> the iodine-induced transannular cyclization of 8-methoxy[2.2]MCPs to give 4,5,9,10-tetrahydropyrenes with remarkable ease and with high selectivity. This novel transannular reaction might be attributed to the presence of the methoxy group at the 8-position, which increases the  $\pi$ -electron density of the benzene ring. Thus, these transannular reactions were ascribed to the through-space electronic interaction through the intra-annular 8,16-positions. As mentioned above, although two through-space electronic interactions, (i) interaction through the intra-annular 8- and 16-positions and (ii) direct through-space cation– $\pi$  interaction, are possi-

ble in the [2.2]MCP systems, the more favored interaction is not clear so far. Therefore, it is quite interesting to investigate the through-space electronic interaction on the rate of the benzoylation of bromomethyl groups attached on the opposite aromatic ring in the [2.2]MCP systems. We wish to report the benzoylation of benzene using cations derived from 8-(bromomethyl)[2.2]MCPs.

## Results and discussion

The preparative route of 8-(bromomethyl)[2.2]MCPs (**2a–2c**) is shown in Scheme 1. Bromination of **1a** and **1c**<sup>32–34</sup> with *N*-bromosuccinimide (NBS) in the presence of benzoyl peroxide under CCl<sub>4</sub> reflux for 3 h afforded the desired 8-(bromomethyl)[2.2]MCPs (**2a** and **2c**) in good yield. However, in the case of **1b**, 8,16-bis(bromomethyl)[2.2]MCP (**3**) was also obtained in 30% yield along with the recovery of the starting compound **1b** in 20% yield in spite of 1.2 equiv of NBS used. Isolation of the desired pure **2b** was unsuccessful. We have instead prepared 8-(bromomethyl)-16-methyl[2.2]MCP (**2b**) following our previously reported procedure.<sup>35,36</sup>

The TiCl<sub>4</sub>-mediated benzoylation of benzene with 8-(bromomethyl)-5,13-di-*tert*-butyl[2.2]MCPs (**2**) was carried out under various conditions of Scheme 2. The results are compiled in Table 1.

The TiCl<sub>4</sub>-mediated benzoylation of benzene with compound **2a** at room temperature (25 °C) for 2 h led to benzoylation reaction affording the desired 8-benzyl[2.2]MCP (**4a**)

Table 1. TiCl<sub>4</sub>-mediated benzoylation of benzene with **2**.

Run	Reaction temperature (°C)	Product yield (%) <sup>a</sup>	Recovery
1	25	<b>4a</b> (29)	<b>2a</b> (71)
2	50	<b>4a</b> (36) [25]	<b>2a</b> (64)
3	50	<b>4b</b> (52) [40]	<b>2b</b> (48)
4	25	<b>4c</b> (62) [51]	<b>2c</b> (28)
5	50	<b>4c</b> (85) [76]	<b>2c</b> (15)

**Note:** [Benzene]/**2** = 30 (mol/mol), [TiCl<sub>4</sub>]/**2** = 1.5 (mol/mol).

<sup>a</sup>The yields were determined by GLC analysis. Isolated yields are shown in square brackets.

in 29% yield along with the recovery of the starting compound **2a** in 71% yield. The present benzoylation reaction was carried out at 50 °C under the same reaction conditions as above to increase the yield of 8-benzyl[2.2]MCP (**4a**) to 36%. Interestingly, in similar benzoylation of benzene with 16-methyl and 16-methoxy derivatives, much higher yields of the benzoylation products **4b** and **4c** resulted in 52% and 85% yields, respectively. The data in Table 1 clearly show that the substituents at the 16-position affected the yield of the benzoylation product of the 8-bromomethyl group in the opposite aromatic ring and that electron-donating groups, such as methyl and methoxy functions, increased the yield of the benzoylation product because of its high electron-donating ability like normal aromatic benzoylation.<sup>37</sup> Thus, such sub-

**Table 2.** Pseudo-first-order plots and rate constants on benzylation of benzene with **2**.

Compounds	R	$k \times 10^5 \text{ (sec}^{-1}\text{)}$	Relative rate
<b>2a</b>	H	6.21 ( $\pm 0.21$ )	1.0
<b>2b</b>	Me	10.99 ( $\pm 1.65$ )	1.8
<b>2c</b>	OMe	23.72 ( $\pm 1.14$ )	3.8

stituent effect through space on the rate of the benzylation of bromomethyl group attached on the opposite aromatic ring was first found in this investigation.

The structures of **4a–4c** were determined on the basis of their elemental analyses and spectral data. The  $^1\text{H}$  NMR spectrum of **4a** in  $\text{CDCl}_3$  shows a singlet at  $\delta$  2.15 ppm for the methylene protons of the benzyl group at 8-position, which is in a strongly shielded region of the opposite meta-bridged benzene ring, and  $\delta$  3.71 ppm for the internal aromatic proton at 16-position. Similar findings were observed in compounds **4b** and **4c**.

To study the present through-space electronic interactions in more detail, we have attempted to evaluate the rate of the benzylation of benzene with 8-(bromomethyl)[2.2]MCP (**2**) in the presence of  $\text{TiCl}_4$ . Pseudo-first-order plots on benzylation of benzene with **2a–2c** are shown in Fig. 2.

The  $\text{TiCl}_4$ -mediated benzylation rate constant of 8-(bromomethyl)[2.2]MCP **2a** with benzene is  $6.21 \times 10^5 \text{ s}^{-1}$  (Table 2). It was also found that the introduction of substituents at the internal position 16 tends to promote the present benzylation reaction rate 1.8–3.8 times. Thus, the rate of benzylation of internally substituted 8-(bromomethyl)[2.2]MCPs **2b** and **2c** are much larger than that of internally unsubstituted 8-(bromomethyl)[2.2]MCP **2a**, which is attributable to the electron-donating nature of 16-substituents, such as methyl and methoxy group. Although similar findings were also reported in the  $\text{TiCl}_4$ -catalyzed benzylation of benzene with 4-substituted benzyl bromide,<sup>38</sup> much smaller substituents effects on the benzylation were observed in the present [2.2]MCP systems than those of the reported benzylations of benzene with 4-substituted benzyl bromide (Scheme 3). This is ascribed to the smaller influence of the nature of a substituent on the remote aromatic ring by a direct through-space cation– $\pi$  interaction than that in 4-substituted benzyl bromide.

Considering the molecular model, it is concluded that the conformation of the benzyl cation intermediates in [2.2]MCPs should also be strongly affected by the size of the substituents at position 16.

As shown in Fig. 3, the interaction between the benzyl cation and the opposite benzene ring might be much more favorable for the 16-substituted [2.2]MCP **A** than the unsubstituted one **B**. Thus, the steric repulsion of 16-substituents,

**Fig. 2.** Pseudo-first-order plots on benzylation of benzene with **2a–2c**.**Fig. 3.** Proposed through-space electronic interactions of [2.2]MCP benzyl cation.

such as methyl and methoxy groups for the opposite benzene ring could shorten the distance between the benzyl cation and the opposite benzene ring, whereas the H– $\pi$  interaction could make this distance longer. The stabilization by the direct through-space cation– $\pi$  interaction is possible in the benzyl cations derived from 8-(bromomethyl)[2.2]MCPs. This result strongly suggests that the benzyl cation intermediate could be stabilized by the through-space electronic interaction among the opposite benzene ring as shown in Fig. 3. As previously mentioned, although two through-space electronic interactions, (i) interaction through the intraannular 8,16-positions and (ii) direct through-space cation– $\pi$  interaction, are possible in the [2.2]MCP systems, the latter interaction might be more favorable in the present systems.

## Conclusions

We have demonstrated the  $\text{TiCl}_4$ -mediated Friedel–Crafts benzylation of benzene with 8-(bromomethyl)[2.2]MCPs **2** to afford the corresponding 8-benzyl[2.2]MCPs **4**. The benzyl cation intermediate stabilized by the through-space electronic interaction from the opposite benzene ring was first demonstrated in the benzylation of [2.2]MCP systems. Further studies on the chemical properties of the benzylation products are now in progress.

## Experimental

All melting points were uncorrected.  $^1\text{H}$  NMR spectra were recorded on a Nippon Denshi JEOL FT-300 spectrometer. Chemical shifts are reported as  $\delta$  values (ppm) relative

to internal Me<sub>4</sub>Si. Mass spectra were obtained on a Nippon Denshi JIR-AQ20M mass spectrometer at an ionization energy of 70 eV using a direct-inlet system through GLC; *m/z* values reported include the parent ion peak. Infrared (IR) spectra were obtained on a Nippon Denshi JIR-AQ20M spectrophotometer as KBr disks. Elemental analyses were performed by Yanaco MT-5. GLC analyses were performed by Shimadzu gas chromatograph, GC-14A; silicone OV-1, 2 m; programmed temperature rise, 12 °C min<sup>-1</sup>; carrier gas nitrogen, 25 mL min<sup>-1</sup>.

## Materials

Preparation of 5,13-di-*tert*-butyl-8-substituted 16-methyl[2.2]metacyclopentane (**1a–1c**)<sup>32–34</sup> and 5,13-di-*tert*-butyl-8-(bromomethyl)-16-methyl[2.2]metacyclopentane (**2b**)<sup>35,36</sup> were previously described.

## Bromination of 8-methyl[2.2]metacyclopentanes (1) with *N*-bromosuccinimide

### Typical procedure

After a mixture of 5,13-di-*tert*-butyl-8-methoxy-16-methyl[2.2]metacyclopentane (**1c**; 500 mg, 1.4 mmol), *N*-bromosuccinimide (300 mg, 1.7 mmol), and benzoyl peroxide (50 mg, 0.21 mmol) in carbon tetrachloride (150 mL) had been refluxed for 3 h, the formed precipitates were filtered off. The filtrate was washed with 10% sodium hydroxide and water. The organic layer was dried over sodium sulfate and evaporated in vacuo to leave a colourless solid, which was recrystallized from *n*-hexane to give 5,13-di-*tert*-butyl-8-(bromomethyl)-16-methoxy[2.2]metacyclopentane (**2c**; 435 mg, 70%) as colorless prisms, mp 239–240 °C. IR (KBr, cm<sup>-1</sup>)  $\nu_{\max}$ : 3040, 2960, 1600, 1475, 1450, 1220, 1200, 1100, 1020, 880, 805, 780, 750. <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$ : 1.26 (s, 18H, *t*-Bu), 2.85 (s, 3H, OMe), 2.68–3.02 (m, 8H, CH<sub>2</sub>), 3.08 (s, 2H, CH<sub>2</sub>), 7.04 (s, 2H, Ar-*H*), 7.06 (s, 2H, Ar-*H*). MS *m/z* (%): 442, 444 (M<sup>+</sup>). Anal. calcd. for C<sub>26</sub>H<sub>35</sub>BrO (443.47): C 70.42, H 7.96; found: C 70.13, H 7.84.

Bromination of **1a** and **1b** with *N*-bromosuccinimide was carried out using the same procedure as described above to afford **2a** and **2b** in 80% and 20% yields, respectively. However, in the case of **1b**, 8,16-bis(bromomethyl)[2.2]MCP (**3**) was also obtained in 30% yield along with the recovery of the starting compound **1b** in 20% yield in spite of 1.2 equiv of *N*-bromosuccinimide used.

## 8-(Bromomethyl)-5,13-di-*tert*-butyl[2.2]metacyclopentane (2a)

Colorless prisms (from *n*-hexane), mp 132–133 °C. IR (KBr, cm<sup>-1</sup>)  $\nu_{\max}$ : 3100, 2900, 1600, 1485, 1400, 1370, 1230, 1190, 1100, 1010, 950, 920, 890, 860, 820, 760, 730, 720, 660. <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$ : 1.29 (s, 9H, *t*-Bu), 1.34 (s, 9H, *t*-Bu), 2.40–3.16 (m, 8H, CH<sub>2</sub>), 2.83 (s, 2H, CH<sub>2</sub>), 3.68 (broad s, 1H, Ar-*H*), 6.92–7.20 (m, 4H, Ar-*H*). MS *m/z* (%): 412, 414 (M<sup>+</sup>). Anal. calcd. for C<sub>25</sub>H<sub>33</sub>Br (413.45): C 72.63, H 8.05; found: C 72.41, H 7.76.

## 5,13-Di-*tert*-butyl-8-(bromomethyl)-16-methyl[2.2]metacyclopentane (2b)

Colorless prisms (from *n*-hexane), mp 272–275 °C. IR (KBr, cm<sup>-1</sup>)  $\nu_{\max}$ : 3020, 2940, 1580, 1445, 1350, 1270,

1215, 1180, 990, 730. <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$ : 0.58 (s, 3H, Me), 1.28 (s, 18H, *t*-Bu), 2.76–3.02 (m, 8H, CH<sub>2</sub>), 3.07 (s, 2H, CH<sub>2</sub>), 7.06 (s, 2H, Ar-*H*), 7.12 (s, 2H, Ar-*H*). MS *m/z* (%): 426, 428 (M<sup>+</sup>). Anal. calcd. for C<sub>26</sub>H<sub>35</sub>Br (427.47): C 73.05, H 8.25; found: C 72.93, H 8.21.

## 5,13-Di-*tert*-butyl-8,16-bis(bromomethyl)[2.2]metacyclopentane (3)

Colorless prisms (from benzene), mp > 300 °C. IR (KBr, cm<sup>-1</sup>)  $\nu_{\max}$ : 3040, 2960, 1585, 1475, 1360, 1225, 1220, 1190, 890, 760, 665. <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$ : 1.33 (18H, s, *t*-Bu), 2.75–3.11 (m, 8H, CH<sub>2</sub>), 3.04 (s, 4H, CH<sub>2</sub>), 7.16 (s, 4H, Ar-*H*). MS *m/z* (%): 504, 506, 508 (M<sup>+</sup>). Anal. calcd. for C<sub>26</sub>H<sub>34</sub>Br<sub>2</sub> (506.37): C 61.67, H 6.77; found: C 61.52, H 6.72.

## Benzylation of benzene with 8-(bromomethyl)-5,13-di-*tert*-butyl-16-substituted [2.2]metacyclopentane (2)

### Typical procedure

To a solution of 5,13-di-*tert*-butyl-8-(bromomethyl)-16-methyl[2.2]metacyclopentane (**2b**; 428 mg, 1.0 mmol) in benzene (2.67 mL, 30 mmol) was added TiCl<sub>4</sub> (0.16 mL, 1.5 mmol) at 0 °C. The reaction temperature was raised to room temperature by removing the ice bath. After the reaction mixture had been stirred at 50 °C for 2 h, it was poured into ice water and extracted with benzene. The extract was dried over anhydrous sodium sulfate and concentrated. The residue was subjected to silica-gel (Wako, C-300; 100 g) column chromatography using as eluent *n*-hexane–benzene (1:1) to give 8-benzyl-5,13-di-*tert*-butyl-16-methyl[2.2]metacyclopentane (**4b**; 170 mg, 40%) as colorless prisms (from *n*-hexane), mp 167–168 °C. <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$ : 0.62 (s, 3H, Me), 1.27 (s, 9H, *t*-Bu), 1.35 (s, 9H, *t*-Bu), 2.39 (s, 2H, CH<sub>2</sub>), 2.68–3.00 (m, 8H, CH<sub>2</sub>), 6.36–6.52 (m, 2H, Ar-*H*), 6.88–7.04 (m, 3H, Ar-*H*), 7.13 (s, 2H, Ar-*H*), 7.18 (s, 2H, Ar-*H*). MS *m/z* (%): 424 (M<sup>+</sup>). Anal. calcd. for C<sub>32</sub>H<sub>40</sub> (424.68): C 90.51, H 9.49; found: C 90.31, H 9.58.

Benylation of benzene with **2a** and **2c** was carried out using the same procedure as described above and product yields are compiled in Table 1.

## 8-Benzyl-5,13-di-*tert*-butyl[2.2]metacyclopentane (4a)

Colorless prisms (from *n*-hexane), mp 195 °C. IR (KBr, cm<sup>-1</sup>)  $\nu_{\max}$ : 2964, 2864, 1594, 1478, 1477, 1454, 1359, 1275, 731. <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$ : 1.36 (s, 18H, *t*-Bu), 2.15 (s, 2H, CH<sub>2</sub>), 2.17–3.07 (m, 8H, CH<sub>2</sub>), 3.71 (s, 1H, Ar-*H*), 6.60–7.09 (m, 5H, Ar-*H*), 7.07 (s, 2H, Ar-*H*), 7.19 (s, 2H, Ar-*H*). MS *m/z* (%): 410 (M<sup>+</sup>). Anal. calcd. for C<sub>31</sub>H<sub>38</sub> (410.65): C 90.67, H 9.33; found: C 90.57, H 9.35.

## 8-Benzyl-5,13-di-*tert*-butyl-16-methoxy[2.2]metacyclopentane (4c)

Colorless prisms (from *n*-hexane), mp 132 °C. IR (KBr, cm<sup>-1</sup>)  $\nu_{\max}$ : 2960, 2864, 1600, 1478, 1459, 1361, 1208, 1024, 727. <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$ : 1.32 (s, 9H, *t*-Bu), 1.37 (s, 9H, *t*-Bu), 2.35 (s, 2H, CH<sub>2</sub>), 2.69–2.84 (m, 8H, CH<sub>2</sub>), 2.90 (s, 3H, OMe), 6.52–7.03 (m, 5H, Ar-*H*), 7.06 (s, 2H, Ar-*H*), 7.17 (s, 2H, Ar-*H*). MS *m/z* (%): 440 (M<sup>+</sup>). Anal. calcd. for C<sub>32</sub>H<sub>40</sub>O (440.68): C 87.22, H 9.15; found: C 87.33, H 9.74.

## The reaction rate determination for the benzylation of benzene with **2** in the presence of $\text{TiCl}_4$

### Typical procedure

To a solution of 5,13-di-*tert*-butyl-8-bromomethyl-16-methyl[2.2]metacyclopheane (**2b**; 100 mg, 0.2 mmol) in benzene (4.2 g, 54 mmol) was added a solution of  $\text{TiCl}_4$  in  $\text{CS}_2$  (0.10 mL, 0.14 mmol), which was prepared by dissolving  $\text{TiCl}_4$  (2.4 mL, 21.08 mmol) in  $\text{CS}_2$  (12.6 mL), by syringe at 25 °C. The reaction was monitored by  $^1\text{H}$  NMR. The reaction rate was determined by the following equations:

$$[2] \quad \frac{d[\text{MCP-CH}_2\text{Br}]}{dt} = k[\text{MCP-CH}_2\text{C}_6\text{H}_5]$$

$$[3] \quad \ln \frac{[\text{MCP-CH}_2\text{Br}]_0}{[\text{MCP-CH}_2\text{Br}] - [\text{MCP-CH}_2\text{C}_6\text{H}_5]} = kt$$

# On the efficiency of phenol and cyclohexanone electrocatalytic hydrogenation — Effect of conditioning and working pH in acetic acid solution on palladium/fluorine-doped tin dioxide supported catalyst

Dihourahouni Tountian, Anne Brisach-Wittmeyer, Paul Nkeng, Gérard Poillerat, and Hugues Ménard

**Abstract:** The electrocatalytic hydrogenation (ECH) of phenol and cyclohexanone was performed on a conductive Pd/SnO<sub>2</sub>:F catalyst. The catalyst was obtained by the impregnation method. We studied the influence of the pH of the supporting electrolyte, the conditioning pH, and the quantity of the conditioning charge passed before hydrogenation. Fourier transform infrared spectroscopy analysis showed that the functionalization of the catalyst surface by the acetic acid electrolyte depends on the pH. A direct correlation was observed between the efficiency of the hydrogenation, the pH of the electrolyte, and the electrode conditioning charge. Phenol hydrogenation was favored in acidic media, whereas cyclohexanone hydrogenation needed an acidic medium for conditioning and a basic medium for hydrogenation. The ECH rate appeared to depend on the functionalization of the catalyst surface, the adsorption of the target organic molecule on the catalyst, and its structural modification with the pH.

**Key words:** electrocatalytic hydrogenation (ECH), functionalization, phenol, cyclohexanone, tin dioxide catalyst.

**Résumé :** L'hydrogénation électrocatalytique (HEC) du phénol et de la cyclohexanone a été réalisée avec un catalyseur de Pd sur SnO<sub>2</sub>:F conducteur obtenu par imprégnation. Les effets du pH de l'électrolyte support, du pH de conditionnement et de la quantité de charge utilisée pour le conditionnement ont été examinés. La spectroscopie infra rouge par transformée de Fourier a montré que la fonctionnalisation de la surface du catalyseur avec l'acide acétique dépend du pH de l'électrolyte. Une corrélation directe entre l'efficacité d'hydrogénation, le pH de l'électrolyte et la charge de conditionnement a été démontrée. L'hydrogénation du phénol est favorisée en milieu acide tandis que celle de la cyclohexanone nécessite un conditionnement en milieu acide et une HEC en milieu basique. Le taux d'HEC dépend ainsi de la fonctionnalisation de surface du catalyseur, de l'adsorption de la molécule cible sur la surface fonctionnalisée et de la structure de cette molécule en solution dépendamment du pH.

**Mots-clés :** hydrogénation électrocatalytique (HEC), fonctionnalisation, phénol, cyclohexanone, catalyseur de dioxyde d'étain.

## Introduction

Electrocatalytic hydrogenation (ECH) of organic compounds is industrially exploited to produce molecules that have applications as chemical intermediates.<sup>1,2</sup> This hydrogenation method is gradually replacing the catalytic hydrogenation (CH) process because of its easy implementation. Indeed, the reactions are carried out at ambient temperatures and pressures by producing chemisorbed hydrogen at a cath-

ode and by electrolyzing water. This method is applicable to hydrogenation of all kinds of unsaturated molecules, including aromatic rings, carbonyl, nitro, and nitrile compounds.<sup>3</sup>

The efficiency of the ECH is dependent on numerous parameters, such as the unsaturated molecule to be hydrogenated, the catalytic metal, the support of the metal, the supporting electrolyte and its pH, the presence of organic cosolvent or surfactant, and the current density.<sup>4</sup> Each of

these parameters has an influence on the mechanism of the ECH described below.

In this mechanism, three groups of reactions can be observed. The first one (reactions 1a and 1b) is relative to the

production of the chemisorbed hydrogen ( $\text{MH}_{\text{ads}}$ ) on the metallic surface (M) by the electroreduction of water (acidic or basic medium); the second (reactions 2–4) concerns the hydrogenation reaction, which starts with the adsorption of the unsaturated molecule ( $\text{Y}=\text{Z}$ ) on the support (A), which further reacts with the chemisorbed hydrogen; the last group of reactions (reactions 5 and 6), which concerns the hydrogen evolution reaction, is a competition reaction with hydrogenation. Depending on the parameters cited above, either the hydrogenation process or the hydrogen evolution will be predominant.

The behavior of a supported metal is different from the bulk metal, and the synergy effect of a metal supported on a matrix has been recently studied.<sup>5</sup> The adsorption of the unsaturated organic molecule is a key step. For the supported catalysts, this adsorption takes place on the support,<sup>6</sup> thus the efficiency of the ECH is relative to the nature of the catalyst matrix. To control both the adsorption of the unsaturated compound and the desorption of the hydrogenated product, recent studies have introduced new concepts: *ex situ*<sup>7</sup> and *in situ* functionalized<sup>8</sup> materials. They consisted of a modification of the catalyst matrix with organic functional molecules before and during the ECH process, respectively. These modifications controlled the adsorption of the target molecule as in reverse chromatography. It was demonstrated that the *in situ* modification of alumina surface depended on the pH of the electrolyte when acetic acid was used.<sup>9</sup>

Before the introduction of these new concepts, several studies had focused on phenol and cyclohexanone. On RaNi electrode, in alkaline media ( $\text{pH} > 13$ ), ECH of cyclohexanone led to excellent chemical yields and current efficiencies, the best results being obtained with NaOH 0.14 mol/L. However, when an acetate buffer was used, no hydrogenation took place.<sup>10</sup> The studies of Dubé et al.<sup>11</sup> in a phosphate buffer ( $\text{KH}_2\text{PO}_4 + \text{NaOH}$ ), pH 7, showed that Pd dispersed on both alumina and activated carbon presented a bad electrocatalytic activity compared with the other metals of the Pt group. They also demonstrated that the yield of cyclohexanone electrohydrogenation was strongly dependent on the nature of the non-conductive matrix used to disperse Ni nanoparticles. Santana et al.<sup>12</sup> found that the pH had no influence on the hydrogenation of 2-cyclohexen-1-one when a nickel sacrificial anode was used. This study concluded that the ECH of conjugated olefins or carbonyl groups is efficient, whereas for non-conjugated substrates (the case of cyclohexanone), it is not.

Fichter and al.<sup>13</sup> reported a poor yield for the reduction of phenol to cyclohexanol in 2 N  $\text{H}_2\text{SO}_4$  at a platinized Pt electrode. On the contrary, Misra et al.<sup>14</sup> showed that phenol was reduced electrochemically in a divided cell at a Pt cathode in 2 N  $\text{HClO}_4$ , in the presence of tetraethylammonium, with a 82.7% yield. More recently, the effect of pH on the kinetics of phenol ECH was investigated with  $\text{BaSO}_4$  as the adsorbent. The rate of reaction was considerably lower at pH 14, and remained unchanged between acidic and neutral media.<sup>15</sup> In acidic media ( $\text{H}_2\text{SO}_4$ ), Martel et al.<sup>4</sup> found that the phenol ECH depended on the catalyst material, whereas in neutral media the results were linked to the supporting electrolyte, i.e., the nature of ions in solution.

Current density also influences the hydrogenation product yield. This parameter acts as a balance between the two

**Fig. 2.** ECH of phenol on Pd/SnO<sub>2</sub>:F in aqueous solution of acetic acid (0.5 mol/L) as a function of the electrolyte pH and total charge: (▲) pH 12, (■) pH 6, (●) pH 5, and (◆) pH 3;  $I = 20$  mA.

**Fig. 3.** FTIR spectra of SnO<sub>2</sub>:F powder subjected to aqueous solutions of acetic acid at (a) pH 3, (b) pH 6, and (c) pH 12.

competitive reactions (3 and 5a, 5b). A high current density favors the hydrogen evolution reaction, whereas a low current density improves the hydrogenation efficiency.<sup>16</sup>

This paper reports the results of a study on the effect of the pH (3 to 12) on the efficiency of phenol and cyclohexanone ECH in acetic acid as electrolyte using Pd deposited on conductive fluorine-doped tin dioxide (SnO<sub>2</sub>:F) as catalyst. Effectively, the ECH process implied a pH variation during its proceeding as stated by the mechanism (reactions 1 and 5), and also the functionalization of the catalyst is a pH-dependent phenomenon.<sup>9</sup>

**Fig. 4.** ECH of cyclohexanone on Pd/SnO<sub>2</sub>:F in aqueous solution of acetic acid (0.5 mol/L) as a function of the total charge, at different starting pH values without controlling the pH during the reaction: (■) pH 5, (◆) pH 6, (●) pH 8, and (▲) pH 12;  $I = 20$  mA.

As shown by the ECH mechanism, the efficiency of hydrogenation is linked to the production of chemisorbed hydrogen (reactions 1a and 1b) by electroreduction of water. Here, we present a study of the effect of quantity of charge used for the conditioning of the catalyst, before the ECH process, which determines the available quantity of chemisorbed hydrogen. We show that the ECH efficiency depends on the pH and the conditioning charge.

## Experimental

### Chemicals

Conductive fluorine-doped tin dioxide (SnO<sub>2</sub>:F) of ( $\rho < 5 \Omega\text{cm}$ ,  $S_{\text{BET}} = 6\text{--}10 \text{ m}^2 \text{ g}^{-1}$ ) was purchased from Keeling & Walker Limited. Also, Pd(OOCCH<sub>3</sub>)<sub>2</sub> as Pd precursor was purchased from Aldrich.

Phenol, cyclohexanone, cyclohexanone-oxime, cyclohexanol, and 3-methylcyclohexanol (Aldrich) were of +99% grade of purity and were used as received. High-purity water (from a Milli-Q unit) was used to prepare the solutions, and chloroform (Fisher, spectrophotometry-grade) was used for the solubilization of Pd(OOCCH<sub>3</sub>)<sub>2</sub> and the liquid-liquid extraction. Reticulated vitreous carbon (RVC, with 100 pores per inch) was purchased from Electrolytica Inc. and used as cathode. The electrolyte was prepared using glacial acetic acid from Aldrich.

### Catalyst preparation

Pd/SnO<sub>2</sub>:F catalyst was prepared by impregnating com-

	150	3.1	5.4	11.9	12.1	12.1

**Fig. 5.** ECH of cyclohexanone on Pd/SnO<sub>2</sub>:F in aqueous solution of acetic acid (0.5 mol/L) as a function of the total charge, at different starting pHs with pH control during the reaction: (■) pH 5, (◆) pH 6, (●) pH 8, and (▲) pH 12; *I* = 20 mA.

mercially available SnO<sub>2</sub>:F. Pd(OOCCH<sub>3</sub>)<sub>2</sub> was first solubilized in chloroform and poured in a flask containing SnO<sub>2</sub>:F. After 1 h of stirring, the chloroform was evaporated at low temperature. Water was added to the flask and it was maintained at 80 °C until the complete evaporation of water. The prepared catalyst with a nominal concentration of 10% of Pd was dried overnight at 90 °C in a stove.

### Catalyst characterization

Previous MEB characterization of the catalyst has been described elsewhere.<sup>17</sup> X-ray measurements were performed using an X'pert Pro MRD of Panalytical diffractometer with Cu K $\alpha$  (wavelength = 1.5406 Å) radiation. Diffractograms of powders were recorded in 2 $\theta$  scan configuration, in the 10–80 ° 2 $\theta$  range, at a fixed incident angle of 0.02 °. Fourier transform infrared spectroscopy (FTIR) of the SnO<sub>2</sub>:F pow-

**Fig. 6.** ECH of cyclohexanone on Pd/SnO<sub>2</sub>:F in aqueous solution of acetic acid (0.5 mol/L) as a function of the total charge at two different conditioning pHs: (◆) pH 5, and (▲) pH 12; working pH = 12; *I* = 20 mA.

ders was recorded on a Bruker IFS 25 with a resolution of 4 cm<sup>-1</sup>. The powders were immersed in the aqueous supporting electrolyte solutions containing acetic acid at pH 3, 6, and 12. These pHs were adjusted with a NaOH (10 N) solution. The suspensions were filtered, and the powders were washed with water. After drying at 50 °C for 15 h, the powders were probed by FTIR using powder not exposed to the supporting electrolyte as a reference. The samples were dispersed in a KBr matrix and pressed in self-supporting disks.

Measurements of adsorption isotherms were carried out as described below. Cylindrical vials (25 mL) were thoroughly cleansed, rinsed with high purity water (from a Milli-Q unit), and dried. SnO<sub>2</sub>:F powder (1 g) was added to each vial, except to the vials serving as blanks, 10 mL of acetic acid solutions (0.5 mol/L) adjusted to pH 5 and 12 was added to each vial. After 1 h of stirring in the presence of SnO<sub>2</sub>:F powders, some of the vials at pH 5 were adjusted to pH 12. To each of these vials, cyclohexanone solution was added to obtain the desired concentrations. The total volume in each vial was 15 mL. The SnO<sub>2</sub>:F powders – cyclohexanone suspensions were then stirred with an orbital shaker at 320 trs/min and at ambient temperature (23 ± 2 °C). Adsorption isotherms were measured after 3 h (time required for one ECH experiment). A 0.5 mL aliquot was withdrawn from each vial, filtered, and analyzed by GC chromatography to determine cyclohexanone concentration.

### Electrocatalytic hydrogenation procedure

All electrocatalytic experiments were carried out in a two-compartment dynamic cell<sup>18</sup> under galvanostatic conditions at ambient temperature. The cathode compartment was filled with 29 mL of 0.5 mol/L solution of acetic acid in water at the desired pH. The anodic compartment was filled with the same solution. Prior to the ECH process, 200 mg of the cat-

**Scheme 2.** Reaction scheme for the hydrogenation of cyclohexanone-oxime to cyclohexanone.

alyst was suspended in the cathodic solution and dynamically circulated ( $\approx 1$  L/min) through the reticulated vitreous carbon cathode. The catalyst was then conditioned by passing a known quantity of charge. This quantity of charge served to reduce Pd(II) in the catalyst after preparation into metallic Pd and to saturate the cathode material with chemisorbed hydrogen. For our catalysts, containing theoretically 10% of Pd, 31 °C was normally necessary to reduce the oxidized Pd, assuming that Pd is totally in its oxidized form in the catalyst before conditioning. The reduction of oxidized Pd is kinetically faster than the formation of chemisorbed hydrogen.<sup>19</sup>

For phenol electrohydrogenation, the quantity of conditioning charge was fixed to 50 C for all the pH values, whereas for cyclohexanone this quantity varied from 5 C to 75 C.

After conditioning, the coulometer was reset to zero; a volume of 1 mL of an aqueous unsaturated organic compound solution (25.2 mg/mL of phenol or 26.3 mg/mL of cyclohexanone) was then added to the cathodic compartment, giving a total volume of 30 mL and an unsaturated compound concentration of  $8.94 \times 10^{-3}$  mol/L. During the ECH process, the constant current applied was 20 mA for phenol hydrogenation, 20 and 5 mA for cyclohexanone hydrogenation.

After passing different quantities of charge, 0.5 mL aliquots were withdrawn from the catholyte and added to 1 mL of chloroform, saturated with NaCl, and shaken together for the extraction of the organic compounds. The organic phase was removed and dried on  $\text{Na}_2\text{SO}_4$ . Finally, an internal standard chloroform solution was added to 0.4 mL of the organic phase, mixed, and 1  $\mu\text{L}$  of this solution was injected in the gas chromatograph. The GC analyses were carried out using an Agilent 6890 series chromatograph equipped with an MS detector and 5HS capillary column (30 m  $\times$  0.250 mm  $\times$  0.25  $\mu\text{m}$ ). Since hydroxide ions are produced (reaction 1) during the electrolysis, the pH can change depending on the quantity of charge, so we followed this pH in situ, or maintained its value using a concentrated acetic acid solution.

### Chemisorbed hydrogen quenching procedure

The quantity of chemisorbed hydrogen produced during the conditioning was estimated using cyclohexanone-oxime as a quencher. Open-circuit hydrogenation (catalytic hydrogenation)<sup>3</sup> of cyclohexanone oxime was done to determine the quantity of active atomic hydrogen in solution or adsorbed. After conditioning, the current was switched off, and 1 mL of cyclohexanone-oxime solution (30 mg/mL in 50/50 (v/v) water/methanol) was added to the cell. An aliquot was withdrawn from the cell at each hour, extracted with diethyl ether, and injected to GC chromatograph to

measure the quantity of cyclohexanone-oxime that disappeared from the solution in the cell.

## Results and discussion

As we study the influence of the pH on the ECH efficiency of phenol and cyclohexanone, we have to ensure that the properties of our catalysts are not modified by changing pH values. Indeed, XRD measurements carried out on the Pd/SnO<sub>2</sub>:F catalyst after the ECH process at pH 3 and pH 12 (Fig. 1) showed no change in the catalyst support (SnO<sub>2</sub>:F) structure, demonstrating that the catalyst support remained stable in acidic and basic media. The only change in the XRD peaks is linked to the electrochemical reduction of Pd(II) to metallic Pd during the process. As a result, SnO<sub>2</sub>:F is a good matrix, which allows the study of the pH effect in a large range, contrary to alumina for example, which is deteriorated in basic medium.<sup>15</sup>

Conversion of phenol can lead to cyclohexanone formation and eventually to cyclohexanol (Scheme 1), depending on the reaction conditions.

The ECH of phenol conducted on Pd/SnO<sub>2</sub>:F in acetic acid solution mainly led to the formation of cyclohexanone and presented different behaviors depending on the working pH (Fig. 2). Two observations can be made. First, at pH 12, the process was inefficient. Second, at pH 6 and below, the more acidic the pH, the more efficient the ECH process became. Considering the functionalization of the SnO<sub>2</sub>:F surface as a function of pH, the IR spectra were recorded. If functionalization of the catalyst by the acetic acid had occurred, three bands at 1654, 1563, and 1466  $\text{cm}^{-1}$  would appear. Figure 3 shows that this was not the case at pH 12. Therefore, it can be concluded that there was no acetic acid on the catalyst surface. That absence of functionalization at pH 12 is due to the competitive adsorption of the hydroxyl anions,<sup>20,21</sup> whereas at pH 3 and 6 (no excess of hydroxyl ions in solution), SnO<sub>2</sub>:F surface is well-functionalized. As shown by Cirtiu et al.,<sup>8</sup> the functionalization phenomenon enhances the hydrogenation process by improving the adsorption of the unsaturated molecule. That means that at pH 12, the catalyst surface is unable to adsorb phenol molecules because of the absence of functionalization. As shown in the ECH mechanism, the adsorption is an important step that will be the limiting reaction at this pH.

However, one also must take into account that the structure of phenol is pH-dependent, as its  $\text{pK}_a$  is 9.96. Thus, at pH 12, phenol exists as phenolate in solution. As ECH is totally inefficient at this pH, we suppose that this form (phenolate) does not adsorb onto the non-functionalized SnO<sub>2</sub>:F at all. Such a strong decrease in hydrogenation rate at high pH was pointed out by Wismeijer et al.<sup>22</sup> in the catalytic hydrogenation (CH) process when Pd/C was used. They attributed this effect to the absence of adsorption of the phenolate

**Table 2.** Quantity of H<sup>•</sup> available (mol) as a function of the charge passed for the conditioning.

Experimental conditions	pH	Entries	Theoretical H <sup>•</sup> quantity formed (mol) $N = Q/nF$	Cyclohexanone-oxime starting quantity (mol)	Cyclohexanone formed after 3 h (mol)	H <sup>•</sup> quantity available (mol)
With catalyst + 50 C charge	5	1	$5.18 \times 10^{-4}$	$2.27 \times 10^{-4}$	$2.20 \times 10^{-4}$	$4.40 \times 10^{-4}$
	12	2	$5.18 \times 10^{-4}$	$2.27 \times 10^{-4}$	$1.50 \times 10^{-4}$	$3.10 \times 10^{-4}$
Without catalyst, without charge	5	3	0	$2.27 \times 10^{-4}$	$0.45 \times 10^{-4}$	$0.90 \times 10^{-4}$
	12	4	0	$2.27 \times 10^{-4}$	0	0

on the catalyst. Phenolate molecules are preferably found in the aqueous phase because of the electrostatic repulsion with the negatively charged carbon surface due to the OH<sup>-</sup> ions. At pH < 10, we observed that the ECH process of phenol becomes efficient. Moreover, we showed that the more acidic the solution, the more efficient the hydrogenation. As there is a significant difference between conversion of phenol at pH 6 and at pH 3, we suggest the most acidic medium is favorable for phenol electrohydrogenation. Indeed, it is well-known that in a strong acid solution, the hydrogenation of phenol is facilitated by some decrease in its resonance stabilization energy.<sup>23</sup> Also, the rate of enhancement of aromatics hydrogenation in superacidic solutions was attributed to the removal of the aromatic resonance stabilization energy by Feiring<sup>24</sup> and Mador.<sup>25</sup>

Therefore, the ECH process of phenol on Pd/SnO<sub>2</sub>:F in an acetic solution will work, provided that the catalyst has been previously functionalized at a pH ≤ 6, and it will be more optimal in a more acidic medium. The pH values affected the catalyst/solution interface that has a great influence on the adsorption/desorption steps of the ECH process.

Cyclohexanone is the intermediate product in the complete ECH of phenol into cyclohexanol (Scheme 1), and it is interesting to study its reactivity as a function of pH when it is the starting product to see the influence of its adsorption and reactivity on the ECH efficiency. If we consider the ECH conducted at several pHs without controlling the pH (Fig. 4), we observe that the maximal efficiency is obtained for a starting pH equal to 6. Nevertheless, it is important to notice that, apart from the starting pH 5 and 12, which remained stable during the process, the other starting pH 6 and 8 change during the experiment for a final pH equal to 12 (Table 1). Maintaining the pH is especially important for values higher than 5.5 due to the loss of the buffer capacity of acetic acid, which has a pK<sub>a</sub> of 4.76. The speed of pH change increases when the starting pH increases (Table 1).

As observed for phenol hydrogenation, pH 12 is inefficient, owing to the non-functionalization of the catalyst surface. Surprisingly, pH 5 is the less efficient medium, although the surface is functionalized. In fact, Breitner et al.<sup>26</sup> had made the same observation in the CH process for rhodium and ruthenium catalysts, which hydrogenated carbonyl compounds rapidly in neutral and basic solutions and slowly in acid solutions. They also noted that palladium was ineffective to hydrogenate aliphatic ketones, but this becomes possible in our case by the ECH process.

A starting pH of 6 with final pH equal to 12 seemed to be the best condition for ECH of cyclohexanone. Indeed, for a starting pH of 6, it remained slightly acidic at the end of the conditioning and went up to basic pH after a few quantity of charge (20 C) was passed for the ECH. When starting with a pH 8, only 7 C was sufficient to bring the pH to the basic range during the conditioning (Table 1).

Then, we decided to control the pH of the solution to know exactly the best working pH for cyclohexanone hydrogenation. We realized ECH of cyclohexanone at these different pHs with in situ control of the pH (Fig. 5), and we observed that the maximal efficiency was obtained for pH 8 and that it was near 50%. As a result, a starting pH of 6 was not the only reason for the ECH efficiency without pH control (Fig. 4) because this process was kinetically limited when the electrolyte was constantly maintained at pH 5 and 6. Even if the catalyst surface was functionalized at these pHs (Fig. 3), the process remained inefficient, which means that the functionalization is not the only sufficient condition.

Comparing Fig. 4 and Fig. 5, we can suppose that the starting pH must be acidic, whereas the working pH must be basic to get the best efficiency. This is the reason why the process is divided into two steps: the conditioning and the working parts. We verified the impact of the conditioning pH by conducting ECH of cyclohexanone with two different procedures (Fig. 6): First, we conditioned the catalyst at pH 5 during 50 C, and then adjusted the working pH to 12 before adding cyclohexanone. Second, we used pH 12 both in conditioning and working conditions. Figure 6 perfectly shows that catalyst must be conditioned at pH 5 to be able to convert cyclohexanone into cyclohexanol.

Then, it is important to know if there is a difference in the quantity of chemisorbed hydrogen produced in acidic and basic media. We know that the chemisorbed hydrogen's production kinetics depends upon the metal<sup>27</sup> and also the medium (acidic or basic).<sup>19</sup> To quantify the number of moles of H<sub>ads</sub> produced by the conditioning in acidic versus basic medium we used an H<sup>•</sup> quencher, which completely reacts with all the H<sup>•</sup> available. Before that, one must take into account that during the conditioning, some electrons are used to reduce the oxidized Pd and some to produce chemisorbed hydrogen (reaction 1). To determine the quantity of chemisorbed hydrogen produced during the conditioning, we made an open-circuit hydrogenation of cyclohexanone-oxime, which was added to the catholyte after switching off the current at the end of the conditioning. After a total time

**Fig. 7.** Adsorption isotherm for cyclohexanone after 3 h in contact with F-doped  $\text{SnO}_2$  powders in aqueous solution of acetic acid (0.5 mol/L) as a function of the initial pH: ( $\blacktriangle$ ) pH 12, ( $\blacklozenge$ ) pH 5, ( $\blacksquare$ ) 1 h of electrolyte– $\text{SnO}_2\text{:F}$  suspension stirring at pH 5 before adding cyclohexanone at pH 12.

of 4 h, the cyclohexanone-oxime CH ended, i.e., its reaction with active chemisorbed was total.

We calculated the theoretical quantity of  $\text{H}^\bullet$  formed during conditioning according to Scheme 2. Then, experiments were conducted in the presence and absence of a catalyst, and we determined the available quantities of active hydrogen (Table 2). This was done at a charge of 50 C during conditioning. Table 2 shows that the maximum quantity of  $\text{H}^\bullet$  produced is  $4.4 \times 10^{-4}$  mol (Table 2, entry 1) at pH 5 and 50 C conditioning of the electrocatalysis. We observed that at pH 12 (Table 2, entry 2), the available quantity of  $\text{H}^\bullet$  was less important. However, it is interesting to remark that without either a catalyst or a charge, little reactivity of cyclohexanone was observed at pH 5 (Table 2, entry 3), whereas no reaction at all took place at pH 12 (Table 2, entry 4). Consequently, we assume that only  $3.5 \times 10^{-4}$  mol of  $\text{H}^\bullet$  (corresponding to 33.7 C) are really produced at pH 5 on the catalyst over 50 C. In these conditions, the quantity of active hydrogen available at pH 5 or pH 12 is in the same range and the observed differences are in the experimental error range. Then, experimentally, a maximum of 20 C is used for the reduction of Pd(II) into Pd(0), which means that all the Pd is not in Pd(II) form in the catalyst before conditioning. We can assume that this quantity is always the same whatever the quantity of charge passed for conditioning.

From these observations, we can conclude that the difference in the efficiency of the ECH process due to the conditioning pH is not linked to the available quantity of  $\text{H}_{\text{ads}}$  because this quantity is the same in acidic and basic media. We can suppose that basic pH allows cyclohexanone to be activated and this activated form of cyclohexanone may have affinity with functionalized catalyst after conditioning in acidic medium (no functionalization in basic medium). Indeed, adsorption of cyclohexanone on  $\text{SnO}_2\text{:F}$  in presence of acetic acid (Fig. 7) is more favored at pH 5 than at

pH 12. Above that, its adsorption is maximal when the catalyst is conditioned at pH 5 (functionalization) and when cyclohexanone is introduced at pH 12. Hence, the activated cyclohexanone has a good adsorption onto the functionalized catalyst. This activation of cyclohexanone may be due to the solvation, which differs in acidic and basic environments. The keto–enol equilibrium is also more favorable in alkaline medium. Indeed, it was demonstrated that the alkene group is more reactive than the carbonyl group in the ECH process.<sup>12,26</sup> The increase in the rate of hydrogenation of cyclohexanone in KOH solution in the CH process was also observed by Wismeijer et al.<sup>22</sup> It was assumed that the promoted effect came from the reactive enolate anions or ionized hydrated cyclohexanone species formed in the presence of  $\text{OH}^-$ . In our case, the FTIR spectrum (not presented) of cyclohexanone at pH 12 shows an additional band compared with that of cyclohexanone at pH 5, that band was attributed to the enolate ion.

As pointed out by Dubé et al.,<sup>11</sup> the efficiency also depends on the kinetics of the transfer of a monoatomic hydrogen ( $\text{H}_{\text{ads}}$ ) from the metal site to the  $\pi$ -bond of the adsorbed organic molecule. This transfer can differ from acidic to basic medium depending on the configuration of the substrate in solution.

Because the quantity of the available  $\text{H}_{\text{ads}}$  can influence the hydrogenation, we were interested in studying its role in the ECH of cyclohexanone on the same catalyst in acetic acid electrolyte. For this study, the conditioning pH was 5 and the working pH was 12. To improve the efficiency of the reaction, the constant current applied after conditioning was 5 mA. As seen in the quenching of  $\text{H}_{\text{ads}}$ , the experimental quantity of charge necessary to reduce all the Pd(II) to Pd(0) was around 20 C. Then, we can estimate the approximate quantity of  $\text{H}_{\text{ads}}$  as a function of conditioning charge (Table 3). This table shows that if the quantity of charge for the conditioning increases, the quantity of  $\text{H}_{\text{ads}}$  available

**Table 3.** Theoretical quantity of  $H^\bullet$  formed and available (mol) as a function of the conditioning charge.

Charge $Q$ passed for conditioning (C)	Experimental quantity of charge $Q_{Pd}$ necessary to reduce Pd(II) into Pd(0) (C)	Experimental quantity of charge $Q_{Hads}$ for chemisorbed hydrogen production with $Q_{Hads} = Q - Q_{Pd}$	Theoretical $H^\bullet$ quantity $N$ formed and available (mol) with $N = Q_{Hads}/(nF)$ and $n = 1$
5	20	0	None
25	20	5	$5.18 \times 10^{-5}$
50	20	30	$3.11 \times 10^{-4}$
75	20	55	$5.70 \times 10^{-4}$

**Fig. 8.** ECH of cyclohexanone on Pd/SnO<sub>2</sub>:F in aqueous solution of acetic acid (0.5 mol/L) as a function of the total charge for different quantities of conditioning charge: (■) 5 C, (▲) 25 C, (●) 50 C, and (◆) 75 C;  $I = 5$  mA; conditioning pH = 5 and working pH = 12.

increases. Indeed, the more the charge passed before the beginning of ECH, the faster the reaction (Fig. 8), which shows that the kinetics of cyclohexanone hydrogenation is affected. This observation can explain why a difference is noticed in the ECH process according to the nature of the metal used<sup>27</sup> or the conductivity of the matrix supporting the metallic nanoaggregates.<sup>17</sup> Indeed, the quantity of  $H_{ads}$  generated is linked to these parameters.

To study only the influence of the conditioning charge directly on cyclohexanone hydrogenation, CH of cyclohexanone was conducted at the end of each conditioning (Fig. 9). Cyclohexanone was added to the catholyte after the conditioning, i.e., in the presence of chemisorbed  $H_{ads}$  (demonstrated by the quenching), and then we verified whether or not it was hydrogenated after 100 min. Surprisingly, Fig. 9 shows that cyclohexanone hydrogenation took place and the quantity of  $H^\bullet$  (Table 3) produced during conditioning played an important role on the CH process. This result demonstrated that when chemisorbed hydrogen is produced (by the electroreduction of water), cyclohexanone could catalytically be hydrogenated on Pd catalyst. Never-

**Fig. 9.** CH of cyclohexanone on Pd/SnO<sub>2</sub>:F in aqueous solution of acetic acid (0.5 mol/L) as a function of the total charge for different quantities of conditioning charge: (▲) 25 C, (●) 50 C, and (◆) 75 C;  $I = 5$  mA; conditioning pH = 5 and working pH = 12.

theless, the catalytic hydrogenation of cyclohexanone, and most of aliphatic ketones, was impossible on palladium catalyst when hydrogen gas was used as source of chemisorbed hydrogen.<sup>12,26</sup> This is explained by the kinetic barrier (related to the low solubility and low dissociation of molecular hydrogen ( $H_2$ )) that is too high.<sup>28</sup> So, it can be said that the production of chemisorbed hydrogen is not systematic in CH conditions. The ECH offers soft conditions of work<sup>11</sup> in which the production of chemisorbed hydrogen is obvious as it was shown by the quenching. Additionally, in the ECH process, the polarization of the catalyst<sup>29</sup> and the cyclohexanone C=O bond takes place.<sup>9</sup>

## Conclusion

The in situ functionalization of the catalyst support affects the electrocatalytic hydrogenation of phenol and cyclohexanone. This functionalization takes place in an acidic medium ( $pH \leq 6$ ) with acetic acid as electrolyte. The effect of the pH on the ECH process is explained by the catalyst functionalization, which affects the catalyst/solution interface also by the structural changes of the target molecule.

Hydrogenation of phenol to cyclohexanone increases as the medium becomes more acidic. When the support surface is functionalized, cyclohexanone is hydrogenated only in a basic medium. For a complete hydrogenation of phenol

with good kinetics, it would be interesting to conduct the first step of hydrogenation, i.e., the formation of cyclohexanone in an acidic medium and then increase the pH to basic values to facilitate the formation of cyclohexanol. The conditioning charge influences the amount of chemisorbed hydrogen available for the hydrogenation of the organic compound. This work has identified yet another advantage of ECH versus CH, owing to the fact that the production of chemisorbed hydrogen is systematic in the ECH process.

# Synthesis and structures of isopropyl- $\beta$ -diketiminato copper(I) complexes

Paul O. Oguadinma and Frank Schaper

**Abstract:** The reaction of *N,N'*-diisopropyl-2-amino-4-iminopent-2-ene (nacnac<sup>*i*-Pr</sup>H, **1**) either with CuOt-Bu or with a mixture of mesityl copper and 10% CuOt-Bu afforded, in the presence of PPh<sub>3</sub>, CN(C<sub>6</sub>Me<sub>2</sub>H<sub>3</sub>), or MeCN, the Lewis base coordinated complexes nacnac<sup>*i*-Pr</sup>CuPPh<sub>3</sub>·0.5 C<sub>6</sub>H<sub>14</sub> (**2**), nacnac<sup>*i*-Pr</sup>CuCN(C<sub>6</sub>Me<sub>2</sub>H<sub>3</sub>) (**3**), and nacnac<sup>*i*-Pr</sup>Cu(NCMe) (**4**). Compounds **2**, **3**, and **4** were characterized by single-crystal X-ray diffraction studies. Compound **4** afforded two species in deuterated benzene in a 2:1 ratio, which were assigned to {nacnac<sup>*i*-Pr</sup>Cu}<sub>2</sub>( $\mu$ -NCMe) and nacnac<sup>*i*-Pr</sup>CuNCMe (**4**). Upon addition of 5 equiv. of MeCN, the two sets collapsed into that of **4**. No copper complexes were formed in the presence of styrene, stilbene, or diphenylacetylene.

**Key words:** diketiminate, copper, coordination chemistry.

**Résumé :** La réaction du *N,N'*-diisopropyl-2-amino-4-iminopent-2-ène (nacnac<sup>*i*-Pr</sup>H, **1**) avec le CuOt-Bu ou un mélange du mésityl-cuivre et du CuOt-Bu à 10 % a donné, en présence de PPh<sub>3</sub>, de CN(C<sub>6</sub>Me<sub>2</sub>H<sub>3</sub>) ou de MeCN, les complexes nacnac<sup>*i*-Pr</sup>CuPPh<sub>3</sub>·0,5 C<sub>6</sub>H<sub>14</sub> (**2**), nacnac<sup>*i*-Pr</sup>CuCN(C<sub>6</sub>Me<sub>2</sub>H<sub>3</sub>) (**3**), et nacnac<sup>*i*-Pr</sup>Cu(NCMe) (**4**). Les composés **2**, **3** et **4** ont été caractérisés par diffraction des rayons-X sur monocristaux. Le spectre RMN de **4** dans C<sub>6</sub>D<sub>6</sub> comporte deux séries de signaux selon un rapport 2:1, assignés à {nacnac<sup>*i*-Pr</sup>Cu}<sub>2</sub>( $\mu$ -NCMe) et à nacnac<sup>*i*-Pr</sup>CuNCMe (**4**). Après l'addition de 5 equiv. de MeCN, seuls les signaux de **4** ont été observés. Aucun complexe de cuivre n'a été obtenu en présence de styrène, de stilbène ou de diphenylacétylène.

**Mots-clés :** dikétiminate, cuivre, chimie de coordination.

## Introduction

Brookhart's demonstration in the mid 1990s that late transition-metal  $\alpha$ -diimine complexes of Pd and Ni were effective as catalysts in olefin polymerization<sup>1</sup> paved the way for the synthesis of the corresponding anionic diketiminate versions of these ligand systems.<sup>2</sup> Since then, interest in diketiminates has continued unabatedly, and today  $\beta$ -diketiminate represent one of the most extensively employed nitrogen-based, bidentate ligands in coordination chemistry.<sup>3</sup> The acronym "nacnac" is often used to describe 2-amino-4-iminopent-2-ene, which is the N-analogue of the ubiquitous acetylacetonate (acac). The nacnac ligands are monoanionic spectator ligands, which have assisted in the isolation of metal complexes in unusual oxidation states and (or) coordination numbers.<sup>4</sup> For copper in particular, Tolman and co-workers used diketiminate complexes to model the active site of metalloproteins.<sup>5</sup> Warren and co-workers isolated a nacnac copper carbene complex, which they employed in catalytic cyclopropanation, and used copper diketiminates for amination reactions.<sup>6–8</sup> While most applications of diketiminate ligands revolve around N-aryl substituents, their N-alkyl derivatives have not been well-exploited. For copper(I), they are limited to applications in atomic layer deposition<sup>9</sup> or analyses of copper–ligand bonding.<sup>10</sup> In continuation of previous work on diketiminate copper complexes with N-alkyl substituents,<sup>11,12</sup> we report here the

syntheses and characterization of *N,N'*-diisopropyl nacnac Cu<sup>I</sup> complexes. Just prior to submission of this manuscript, Arai et al. reported nacnac<sup>*i*-Pr</sup>Cu germylene complexes, using the same ligand.<sup>13</sup>

## Results and discussion

### Ligand and complex synthesis

Ligand **1** has been obtained previously by a multi-step protocol, which is generally used to prepare *N*-alkyl diketiminates, either by employing Meerwein salt (32%–60% yield)<sup>14</sup> or dimethylsulfate (74% yield, from the aminoketone)<sup>15</sup> as O-alkylating agents. We employed a one-step procedure for condensation of acetylacetone with isopropylamine in the presence of equimolar amounts of *para*-toluenesulfonic acid,<sup>16</sup> which afforded **1** directly, albeit in a relatively low yield of 23% after 5 days of reflux (Scheme 1). The analogous ligands nacnac<sup>Bu</sup>H and nacnac<sup>*i*-Bu</sup>H, bearing primary alkyl groups, have been obtained in 1–2 days using the same procedure,<sup>12,17</sup> while the preparation of nacnac<sup>CH(Me)Ph</sup>H required 5 days.<sup>11</sup> Longer reaction times thus seem to be necessary for secondary amines. Complexes **2–4** were obtained as yellow air- and moisture-sensitive powders or crystals in 26%–84% yield by reaction of **1** in the presence of PPh<sub>3</sub>, xylol isocyanide, or acetonitrile either with CuOt-Bu, a procedure employed by Dai and Warren for preparing *N*-aryl nacnacCu<sup>I</sup> complexes,<sup>6</sup> or with mesityl copper and catalytic

Scheme 1.

amounts of  $\text{CuO}^t\text{Bu}$  (Scheme 1). Mesityl copper in the absence of  $\text{CuO}^t\text{Bu}$  has been shown to be unreactive.<sup>11</sup> Though no major differences in terms of yields were observed between the use of  $\text{CuO}^t\text{Bu}$  or  $\text{MesCu}/\text{CuO}^t\text{Bu}$ , the complexes crystallized easier when  $\text{MesCu}/\text{CuO}^t\text{Bu}$  was used, probably due to the smaller amounts of *tert*-butanol present.

Compound **1** did not react with  $\text{CuO}^t\text{Bu}$  in the presence of styrene, stilbene, or diphenylacetylene. Identical observations were made with copper complexes carrying the chiral  $\text{nacnac}^{\text{CH}(\text{Me})\text{Ph}}$  ligand.<sup>11</sup> On the other hand, Cu–styrene complexes are readily obtained with  $\text{nacnac}^{\text{Mes}}$  ( $\text{Mes} = 2,4,6\text{-Me}_3\text{C}_6\text{H}_3$ )<sup>18</sup> or  $\text{nacnac}^{\text{dipp}}$  ( $\text{dipp} = 2,6\text{-}i\text{-Pr}_2\text{C}_6\text{H}_3$ , see Experimental section), one of the most sterically encumbered *N*-aryl diketiminates, as well as with  $\text{nacnac}^{\text{Bn}}$  or  $\text{nacnac}^i\text{-Bu}$ .<sup>12,17</sup> In-plane coordination of the two carbon atoms of an olefin is thus possible for diketimate ligands with aryl or primary alkyl substituents, but not if secondary alkyls are present on the nitrogen. The implied increased steric demand of  $\text{nacnac}^i\text{-Pr}$  compared with  $\text{nacnac}^{\text{dipp}}$  has to be set into contrast to observations for other systems. When compared with  $\text{nacnac}^{\text{dipp}}$ , diketimate ligands with secondary alkyl substituents on the nitrogen allow additional intramolecular  $\pi$ -coordination in Ti complexes<sup>19</sup> or coordination of a second  $\text{nacnac}$  to Zr.<sup>20</sup> When considering steric congestion imposed by diketimate ligands, it is thus important to differentiate between the first coordination sphere around the metal centre, where  $\text{nacnac}^i\text{-Pr}$  imposes a congested environment, and general steric demand in the (outer) coordination sphere, where it does not.

### Crystal structure studies

All three compounds are monomeric and crystallize in the  $P2_1/c$  space group with copper in a distorted trigonal-planar geometry. Complex **2** (Fig. 1) co-crystallizes with half a molecule of hexane. The methine hydrogen atoms of the *i*-Pr substituent point towards the methyl groups in the ligand backbone, even in the sterically encumbered **2**. C–N and C–C bond lengths of the diketimate ligand are in agreement with complete delocalization of the double bonds (Table 1). Cu–N bond distances in **3** and **4** are close to the average generally observed in  $\text{nacnacCu}$  complexes ( $1.94 \pm 0.06 \text{ \AA}$ ),<sup>21</sup> and the copper centre is found in the mean plane of the ligand. With the bulkier phosphine ligand in **2**, longer Cu–N distances and a displacement of C3 and the copper atom

by 0.1 and 0.4  $\text{\AA}$ , respectively, out of the ligand mean plane are observed (plane defined by N1, N2, C2, and C4). While Cu–P and Cu–N bond distances (2.191(1)  $\text{\AA}$ ; 1.978(1) and 1.983(1)  $\text{\AA}$ ) are comparable to those in  $\text{nacnac}^{\text{CH}(\text{Me})\text{Ph}}\text{CuPPh}_3$  (2.195(1)  $\text{\AA}$ ; 1.972(1) and 1.983(1)  $\text{\AA}$ ),<sup>11</sup> they are longer than in  $\text{nacnac}^{\text{Ar}}\text{Cu}(\text{PPh}_3)$  complexes (2.16–2.18  $\text{\AA}$  and 1.94–1.97  $\text{\AA}$ )<sup>7,22–24</sup> in agreement with increased steric bulk introduced by a secondary alkyl substituent on the nitrogen atoms.

### Spectroscopic properties

The  $\text{PPh}_3$  resonance in the  $^{31}\text{P}$  NMR spectrum of compound **2** in  $\text{C}_6\text{D}_6$  was observed at  $\delta$  4.0. This value is intermediate between those of  $\text{nacnac}^{\text{Ar}}\text{CuPPh}_3$  complexes ( $\text{Ar} = \text{Me}_3\text{C}_6\text{H}_2$ : 5.2 ppm,<sup>7</sup>  $\text{Ar} = \text{Me}_2\text{C}_6\text{H}_3$ : 5.4 ppm,<sup>23</sup> and  $\text{Ar} = i\text{-Pr}_2\text{C}_6\text{H}_3$ : 3.6 ppm<sup>22</sup>) and  $\text{nacnac}^{\text{R}}\text{CuPPh}_3$  complexes ( $\text{R} = \text{Bn}$ : 3.5 ppm<sup>12</sup> and  $\text{R} = \text{CH}(\text{Me})\text{C}_6\text{H}_5$ : 3.9 ppm<sup>11</sup>). While *N*-aryl-substituted diketimate ligands tend to show  $^{31}\text{P}$  resonances at lower field, differences are too small to be correlated to the ligand properties. Similar to the behaviour observed for  $\text{nacnac}^{\text{CH}(\text{Me})\text{Ph}}\text{Cu}(\text{NCMe})$ ,<sup>11</sup> which also carries a secondary alkyl substituent on N, pure crystals of **4** dissolved in  $\text{C}_6\text{D}_6$  gave two sets of  $\text{nacnac}$  resonances in a ratio of 2:1 in its  $^1\text{H}$  NMR spectrum; the resonances of the major species being slightly broadened. Only one resonance was observed for MeCN. Fast exchange of coordinated and free Lewis base was observed before in  $\text{nacnacCuL}$  complexes,<sup>11,12,25</sup> and the amount of coordinated MeCN in the two species thus cannot be derived from NMR. Only one peak for  $\nu_{\text{CN}}$  was observed at 2259  $\text{cm}^{-1}$  in the IR spectrum of **4** in toluene solution, 5  $\text{cm}^{-1}$  higher than that of free MeCN.<sup>26</sup> Addition of excess MeCN (5 equiv.) caused the peaks to collapse to one set of resonances in its  $^1\text{H}$  and  $^{13}\text{C}$  spectra, belonging to the previously minor component. Changes in the overall concentration, on the other hand, did not affect the observed ratio, which rules out equilibrium [1] in Scheme 2. Complete MeCN redistribution (equilibrium [2] in Scheme 2) also seems unlikely, since bis(acetonitrile) complexes have not been reported for diketimate copper complexes and  $\text{nacnac}^i\text{-PrCu}$  complexes could not be obtained in the absence of ancillary ligands. We thus assign the species favoured at higher acetonitrile concentrations to the MeCN complex  $\text{nacnac}^i\text{-PrCuNCMe}$  (**4**), observed in the crystal structure, and the broadened peaks of the major species to the bridged complex  $\{\text{nacnac}^i\text{-PrCu}\}_2(\mu\text{-NCMe})$  (**4b**) (equilibrium [3] in Scheme 2). While bridging coordination of acetonitrile is rare, it is not unknown.<sup>27</sup> Monomer–dimer equilibria similar to equilibrium [3] in Scheme 2 have been observed for  $\text{nacnac}^{\text{Bn}}\text{Cu}$ , which forms a diphenylacetylene-bridged dimer in the solid state and a monomeric complex in solution when excess diphenylacetylene is present,<sup>12</sup> and for  $\text{nacnac}^{\text{Ar}}\text{Cu}$  complexes, which display an equilibrium between a monomeric and a dimeric benzene-coordinated complex in solution.<sup>7,25</sup> While single-crystal diffraction studies confirmed the formation of **4**, we were unable to obtain satisfactory elemental analyses, even from the crystalline material. Synthesis of **4** was reported at the time of submission of this article by Arii et al. from the reaction of  $[\text{Cu}(\text{NCMe})_4][\text{CF}_3\text{SO}_3]$  with  $\text{nacnac}^i\text{-PrLi}$ .<sup>13</sup> Although not discussed therein, they also observed a variable ratio of two products in NMR spectra of **4**.<sup>28</sup>

The stretching frequency  $\nu_{\text{CN}} = 2105 \text{ cm}^{-1}$  of the isocyanide

**Fig. 1.** Crystal structures of **2–4**. Hydrogen atoms and solvent are omitted for clarity. Thermal ellipsoids are drawn at the 50% probability level.

## Scheme 2.

ligand in **3** is the lowest frequency observed in 2,6-xylyl isocyanide copper complexes with either N-alkyl-substituted ( $\nu_{\text{CN}} = 2111\text{--}2117 \text{ cm}^{-1}$ )<sup>11,12,17</sup> or N-aryl-substituted diketiminate ligands ( $\nu_{\text{CN}} = 2121\text{--}2126 \text{ cm}^{-1}$ )<sup>7,25,29</sup> indicating an increased, but still weak  $\pi$  back-donation (free isocyanide:  $\nu_{\text{CN}} = 2119 \text{ cm}^{-1}$ ).

In the course of preparing compound **3**, a minor side

product, **5**, was obtained. <sup>1</sup>H and <sup>13</sup>C NMR spectra of **5** showed resonances of the diketiminate ligand and isocyanide in a ratio of 1:2, which would suggest the formation of  $\text{nacnac}^i\text{-PrCu}(\text{CNC}_6\text{Me}_2\text{H}_3)_2$ . Satisfactory elemental analysis of **5**, however, could not be obtained and, more importantly, addition of 1 equiv. xylyl isocyanide did not transform **3** into **5**. Complex **5** showed the same stretching frequency in its IR spectrum as **3**. Taking also the low solubility of **5** in toluene into account, assignment as a bisisocyanide adduct seems improbable and the structure of **5** remains unclear.

## Conclusions

Copper complexes of  $\text{nacnac}^i\text{-Pr}$  were readily prepared if additional Lewis base was present to stabilize the complex. In agreement with observations made for  $\text{nacnac}^{\text{CH}(\text{Me})\text{Ph}}$ ,<sup>11</sup> diketiminate ligands with secondary alkyl substituents are slightly more Lewis-basic, but sterically more demanding in the first coordination sphere than diketiminates with aryl or primary alkyl substituents.

## Experimental section

All reactions, except ligand synthesis, were carried out under nitrogen atmosphere using Schlenk or glovebox techniques. Solvents were dried by passage through activated aluminum oxide (MBraun SPS) and de-oxygenated by repeated extraction with nitrogen.  $\text{C}_6\text{D}_6$  was distilled from Na and de-oxygenated by three freeze-pump-thaw cycles.  $\text{CuOt-Bu}^{30}$  and mesitylcopper<sup>31</sup> were synthesized as reported. All other chemicals were obtained from commercial suppliers and used as received. Elemental analyses were performed at the Laboratoire d'Analyse Élémentaire (Université de Montréal). NMR spectra were recorded on a Bruker ARX 400 MHz spectrometer and referenced to residual solvent ( $\text{C}_6\text{D}_5\text{H}$ :  $\delta$  7.15,  $\text{C}_6\text{D}_6$ :  $\delta$  128.02) or external reference (<sup>31</sup>P, 75%  $\text{H}_3\text{PO}_4$ ).

acid monohydrate (7.2 g, 38 mmol), and isopropylamine (6.1 mL, 76 mmol) were added to toluene (200 mL) and refluxed with the help of a Dean–Stark apparatus for 5 days, during which the yellow suspension turned brown. After cooling to room temperature, the brown precipitate formed was filtered. The precipitate was washed with toluene (100 mL) and transferred to a K<sub>2</sub>CO<sub>3</sub> solution (5 g in 100 mL of water). After stirring for 30 min, the aqueous phase was extracted with toluene (3 × 100 mL). The combined organic phases were dried over MgSO<sub>4</sub> and then filtered. The filtrate was evaporated to obtain brown oil (1.6 g, 23%), which was employed without further purification in subsequent synthesis.

<sup>1</sup>H NMR (CDCl<sub>3</sub>, 400 MHz)  $\delta$ : 11.44 (bs, 1H, NH), 4.38 (s, 1H, HC(C=N)<sub>2</sub>), 3.64 (sp, *J* = 6 Hz, 2H, CH(CH<sub>3</sub>)<sub>2</sub>), 1.89 (s, 6H, Me(C=N)<sub>2</sub>), 1.16 (d, *J* = 6 Hz, 12H, CH(CH<sub>3</sub>)<sub>2</sub>). <sup>13</sup>C NMR (CDCl<sub>3</sub>, 101 MHz)  $\delta$ : 158.5 (C=N), 93.5 (HC(C=N)<sub>2</sub>), 46.7 (CH(CH<sub>3</sub>)<sub>2</sub>), 24.7 (CH(CH<sub>3</sub>)<sub>2</sub>), 18.7 (Me(C=N)<sub>2</sub>). <sup>1</sup>H NMR (C<sub>6</sub>D<sub>6</sub>, 400 MHz)  $\delta$ : 11.63 (bs, 1H, NH), 4.46 (s, 1H, HC(C=N)<sub>2</sub>), 3.46 (sp, *J* = 6 Hz, 2H, CH(CH<sub>3</sub>)<sub>2</sub>), 1.71 (s, 6H, Me(C=N)<sub>2</sub>), 1.11 (d, *J* = 6 Hz, 12H, CH(CH<sub>3</sub>)<sub>2</sub>). <sup>13</sup>C NMR (C<sub>6</sub>D<sub>6</sub>, 101 MHz)  $\delta$ : 158.0 (C=N), 94.6 (HC(C=N)<sub>2</sub>), 47.0 (CH(CH<sub>3</sub>)<sub>2</sub>), 25.1 (CH(CH<sub>3</sub>)<sub>2</sub>), 18.8 (Me(C=N)<sub>2</sub>).

#### nacnac<sup>i</sup>-PrCuPPh<sub>3</sub>·0.5 C<sub>6</sub>H<sub>14</sub> (**2**)

nacnac<sup>i</sup>-PrH (300 mg, 1.65 mmol), mesitylcopper (301 mg, 1.65 mmol), CuOt-Bu (22 mg, 0.165 mmol), and PPh<sub>3</sub> (437 mg, 1.65 mmol) were dissolved in toluene (12 mL) to give a yellow-brown solution. After stirring for 1 h, the solution was filtered, concentrated to 1/5 of its volume and layered with hexane (5 mL). It was then kept at −35 °C. Yellow crystals together with powder formed after 3 day (700 mg, 84%).

#### nacnac<sup>i</sup>-PrCuNCMe (**4**)

nacnac<sup>i</sup>-PrH (75 mg, 0.41 mmol) and MeCN (41 mg,

0.82 mmol) were mixed and transferred to a vial containing a yellow solution of CuOt-Bu (69 mg, 0.41 mmol) in toluene (2 mL). The resulting yellow-brown solution was kept at  $-30\text{ }^{\circ}\text{C}$ . Colourless crystals formed after 1 h together with a brown precipitate (mirror) indicative of decomposition. Decantation of the brown suspension gave, after drying, 31 mg (26%) of yellow crystals, **4**.

Two species were observed in  $\text{C}_6\text{D}_6$  solutions of **4** (see text). IR (toluene)  $\nu_{\text{NC}}$ :  $2259\text{ cm}^{-1}$ . **4**:  $^1\text{H}$  NMR ( $\text{C}_6\text{D}_6$ , 400 MHz)  $\delta$ : 4.52 (s, 1H,  $\text{HC}(\text{C}=\text{N})_2$ ), 4.03 (septet,  $J = 6\text{ Hz}$ ,  $\text{CH}(\text{CH}_3)_2$ , 2H), 2.11 (s, 6H,  $\text{Me}(\text{C}=\text{N})_2$ ), 1.38–1.52 (m, 12H,  $\text{CH}(\text{CH}_3)_2$ ), 0.57 (NCMe).  $^{13}\text{C}$  NMR ( $\text{C}_6\text{D}_6$ , 101 MHz)  $\delta$ : 160.6 (C=N), 116.5 (NCMe), 65.9 ( $\text{HC}(\text{C}=\text{N})_2$ ), 50.7 ( $\text{CH}(\text{CH}_3)_2$ ), 26.9 ( $\text{CH}(\text{CH}_3)_2$ ), 22.3 ( $\text{Me}(\text{C}=\text{N})_2$ ) and 0.3 (NCMe). **4b**:  $^1\text{H}$  NMR ( $\text{C}_6\text{D}_6$ , 400 MHz)  $\delta$ : 5.29 (bs, 1H,  $\text{HC}(\text{C}=\text{N})_2$ ), 3.92–3.99 (featureless septet,  $\text{CH}(\text{CH}_3)_2$ , 2H), 2.56 (bs, 6H,  $\text{Me}(\text{C}=\text{N})_2$ ), 2.08 (s, 6H,  $\text{CN}(\text{C}_6\text{Me}_2\text{H}_3)$ ) and 1.38–1.52 (m, 12H,  $\text{CH}(\text{CH}_3)_2$ ) overlapping with that of **4**. Elemental analysis was unsatisfactory with varying results ( $\Delta\text{C} = 2\%–3\%$ ), which might be related to acetonitrile dissociation and complex decomposition.

#### NMR-scale preparation of $\text{nacnac}^{\text{dipp}}\text{Cu}(\text{styrene})$

A vial was charged with  $\text{nacnac}^{\text{dipp}}\text{H}$  ( $\text{dipp} = 2,6\text{-}i\text{-Pr}_2\text{C}_6\text{H}_3$ ) (10 mg, 24  $\mu\text{mol}$ ), CuOt-Bu (4 mg, 30  $\mu\text{mol}$ ), and styrene (3  $\mu\text{L}$ , 25  $\mu\text{mol}$ ).  $\text{C}_6\text{D}_6$  (0.6–0.7 mL) was added. After shaking thoroughly to obtain a homogeneous solution, the content was transferred to a J. Young tube and heated at  $60\text{ }^{\circ}\text{C}$  for 24 h.

$^1\text{H}$  NMR ( $\text{C}_6\text{D}_6$ , 400 MHz)  $\delta$ : 6.35–7.21 (m, 11H,  $2,6\text{-}i\text{-Pr}_2\text{C}_6\text{H}_3$  and styrene), 5.08 (dd,  $J = 9\text{ Hz}$  and  $14\text{ Hz}$ , 1H,  $\text{PhHC}=\text{C}$ ), 4.97 (s, 1H,  $\text{HC}(\text{C}=\text{N})_2$ ), 3.48–3.56 (m, 3H,  $\text{CH}(\text{CH}_3)_2$  and  $\text{cis H}_2\text{C}=\text{C}$ ), 3.34 (d,  $J = 9\text{ Hz}$ , 1H,  $\text{trans H}_2\text{C}=\text{C}$ ), 3.07 (sp,  $J = 7\text{ Hz}$ , 2H,  $\text{CH}(\text{CH}_3)_2$ ), 1.75 (s, 6H,  $\text{Me}(\text{C}=\text{N})_2$ ), 1.33 (d,  $J = 7\text{ Hz}$ , 6H,  $\text{CH}(\text{CH}_3)_2$ ), 1.15 (d,  $J = 7\text{ Hz}$ , 12H,  $\text{CH}(\text{CH}_3)_2$ ), 1.09 (d,  $J = 7\text{ Hz}$ , 6H,  $\text{CH}(\text{CH}_3)_2$ ).

#### X-ray diffraction studies

Compounds were crystallized by layering a toluene solution with hexane at  $-30\text{ }^{\circ}\text{C}$ , except for compound **4**, which crystallized directly from the toluene solution of the reaction at  $-30\text{ }^{\circ}\text{C}$ . Data sets for **2** and **3** were recorded on a Bruker SMART 6000 with Montel 200 monochromator, while that of compound **4** was collected on a Bruker Microstar-Proteum with Helios optics, both equipped with a rotating anode source for Cu  $K\alpha$  radiation ( $\lambda = 1.54178\text{ \AA}$ ). Cell refinement and data reduction were performed using APEX2.<sup>32</sup> Absorption corrections were applied using SADABS.<sup>33</sup> Structures were solved by direct methods using SHELXS97 and refined on  $F^2$  by full-matrix least squares using SHELXL97.<sup>34</sup> All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were refined on calculated positions using a riding model. Further details can be found in Table 2.

# A novel approach towards the synthesis of tricyclic systems based on pyridine, pyran, thiopyran, azepine, oxepin, thiepin, and pyrimidine rings under different solvent conditions

Anand Sachar, Poonam Gupta, Shallu Gupta, and R.L. Sharma

**Abstract:** Synthesis of some oxygen, nitrogen, and sulfur based condensed heterocycles by the condensation of dimedone with aromatic monoaldehyde under different solvent conditions has been achieved.

**Key words:** dimedone, heterocyclization, dimerization.

**Résumé :** On a réalisé la synthèse de dérivés hétérocycliques à base d'oxygène, d'azote et de soufre par condensation de la dimédone avec un monoaldéhyde aromatique dans divers solvants.

**Mots-clés :** dimédone, hétérocyclisation, dimérisation.

[Traduit par la Rédaction]

## Introduction

1,3-Dicarbonyl derivatives constitute important synthetic intermediates, incorporating multiple functionalities that can be either nucleophilic or electrophilic species in a large variety of synthetic transformations.<sup>1</sup> Their versatility and effectiveness as potential multicomponent substrates were first discovered and utilized by Arthur Hantzsch<sup>2</sup> in 1882. Since then, 1,3-dicarbonyl compounds have been playing increasingly significant roles in the development of modern synthetic organic chemistry. Keeping these facts in view, we are studying the synthesis of some novel heterocyclic systems by investigating the effect of a change in solvent on the ring size of heterocyclic moiety via the condensation of a 1,3-dicarbonyl compound (dimedone) with an aromatic monoaldehyde. A literature survey revealed that a fair amount of work has been published in the condensation reactions of dimedone.<sup>3–8</sup> Because of our laboratory's long standing interest in the condensation reactions of active methylene compounds,<sup>9</sup> we extend our synthetic activity along these lines to include the synthesis of some pyran, pyridine, thiopyran, oxepin, azepine, and thiepin based condensed heterocycles by the condensation of dimedone with aromatic monoaldehyde under different solvent conditions.<sup>5,10–15</sup> The intermediates and the final heterocyclic products have been found to be highly potent pharmacologically in recent years, revealing some important conclusions regarding structure–activity relationships.<sup>16–19</sup>

## Results and discussion

When dimedone was treated with aromatic monoaldehyde

in ethylene glycol under different sets of conditions (as detailed in the Experimental section); some novel pyran, pyridine, and thiopyran based condensed heterocycles have been generated with dimedone moiety on the periphery of the molecule. The reaction probably takes place via the concerted mechanism in which Knoevenagel condensation occurs between dimedone (**1**) and aromatic aldehydes (**2**), Michael addition of the second dimedone molecule on the 2-arylidenedimedone probably formed in situ as a result of Knoevenagel condensation, and cyclodehydration of the probable Michael product (**9**)<sup>20,21</sup> takes place in single step. The products (**10–14**)<sup>20,22–25</sup> were obtained in excellent yield but the intermediate products, arylidenedimedone of Knoevenagel condensation, and product (**9**) of Michael addition could not be isolated. In another method using acetic acid as solvent in the initial step, the yield of the final products (**10–14**) was not as good and hardly comparable with that in the case of ethylene glycol. The added advantage in this method was the isolation of the intermediate product (**9**) in a reasonably good yield, which was probably in dienol form, and subsequently produced the products (**10–14**) with different reagents using DMF as solvent. The yield falls slightly in all the conversions of **9** to **10**, **11**, **12**, **13**, and **14** using DMF as solvent. Using DMSO as solvent, some interesting results were obtained in which arylidenedimedone moiety initially formed and underwent reductive dimerization to give the dimer (**3**) (Scheme 1). In each case, the dimer (**3**) was obtained as a mixture of a racemate and the inactive meso compound. The racemic mixture ( $\pm$ ) and the inactive meso compound could not be resolved and separated, respectively, by repeated efforts. The asymmetric synthesis of

Scheme 1.

Het : 3-Indolyl, 2-Furfuryl

the enantiomers has almost been achieved in a separate study with good variety. Though it is still under active study, it may soon be submitted for publication. The dimers seemed to be very interesting for ring closure and as such were subjected to heterocyclization under different sets of conditions (as detailed in the Experimental section) in DMF to give some condensed heterocycles based on central oxepin, azepine, and thiopin moiety and the peripheral dimedone moiety. The condensed heterocyclic products (4–8) bearing seven membered central heterocyclic moiety were all obtained, again as single and pure meso compounds since the possibility of cyclization of the enantiomers of the racemic mixture of **3** resulting in the formation of a mixture of racemic (4–8) is not only highly difficult but almost impossible.

Exact quantities of  $\text{NH}_2\text{OH}\cdot\text{HCl}$  in the synthesis of *N*-hydroxy compounds,  $\text{NH}_2\cdot\text{NH}_2$  in the synthesis of *N*-amino compounds, and  $\text{P}_2\text{S}_5$  in the synthesis of thio compounds should be used lest their higher quantities should form corresponding oximino, hydrazino, and thioxo derivatives, respectively, of the respective carbonyl products (6–8, 12–14, 20, and 23).

To generalize these transformations and to derive the conclusions more confidently, reactions between a heterocyclic active methylene compound, barbituric acid (replacing dimedone), and heteroaromatic aldehydes, furfural and indole-3-carboxaldehyde (both replacing aromatic aldehydes), were also studied (Scheme 2). The results were exactly the same

as expected under different conditions of solvents and reagents.

All the compounds obtained (17–24) were analyzed for C, H, N, and S and were found to be in good agreement with the calculated values, which have been presented in Table 1, along with mps and yield. The structures were established on the basis of spectroscopic data and elemental analysis.

## Experimental

### General

Thin layer chromatography was used to establish the homogeneity of the compounds. Column chromatography was performed over silica gel (60–120 mesh) using the ethyl acetate – petroleum ether system as eluent. All other reagents were commercially available and used without further purification. Melting points were determined in a capillary tube and are uncorrected. IR spectra were recorded on a PerkinElmer IR spectrometer using potassium bromide pellets. The  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra were run on Varian Unity 500 MHz NMR spectrometer using TMS as an internal standard (chemical shift in  $\delta$  ppm). Elemental analyses were performed on simple a CHNS analyzer.

### General procedure for the synthesis of 3

Dimedone (2 mmol) and aromatic aldehyde (2 mmol) were dissolved in dimethyl sulfoxide (1 mL) and the reaction mixture was refluxed for 30–40 min. The clear reaction

Scheme 2.

mixture was diluted with methanol (20 mL). The insoluble product was separated by filtration, washed with methanol (3 × 20 mL), and then finally dried at 100 °C for 1 h.

#### General procedure for the synthesis of 4–8

Compound **3** (0.01 mol) was stirred at 80° in DMF for 30 min (for **4**: as such; for **5**: 3 mmol NH<sub>4</sub>OAc; for **6**: 2 mmol NH<sub>2</sub>OH·HCl and 2 mmol NaOAc; for **7**: 2 mmol NH<sub>2</sub>·NH<sub>2</sub>·HCl and 2 mmol NaOAc; and for **8**: 2 mmol P<sub>2</sub>S<sub>5</sub> was added). The reaction mixture was cooled to room temperature, diluted with water, the insoluble product filtered and then the solid obtained was washed with water, dried, and crystallized from ethanol. Further purification was accomplished by running it through a short column of silica gel followed by recrystallization from hot ethanol.

#### General method for the synthesis<sup>20,21</sup> of 9a and 9b

Dimedone (0.02 mol) and an aromatic aldehyde (0.01 mol) were dissolved in glacial acetic acid (30 mL) and stirred at room temperature until TLC showed the disappearance of the starting material. The insoluble product was separated by filtration, washed with water (3 × 20 mL), dried, and crystallized from 95% ethanol. Further purification was accomplished by running it through a short column of silica gel followed by recrystallization from ethanol.

#### General procedure for the synthesis<sup>20,22–25</sup> of 10–14

Dimedone (4 mmol) and an aldehyde (2 mmol) were refluxed in an ethylene glycol (1 mL) for 8–10 min (for **10**: as such; for **11**: 3 mmol NH<sub>4</sub>OAc; for **12**: 2 mmol NH<sub>2</sub>OH·HCl and 2 mmol NaOAc; for **13**: 2 mmol NH<sub>2</sub>·NH<sub>2</sub>·HCl and 2 mmol NaOAc; and for **14**: 2 mmol P<sub>2</sub>S<sub>5</sub> was added). The reaction mixture was allowed to cool at room temperature, then poured into 50 mL of water. The solid that was separated was filtered and washed with water. The crude solid after drying was purified by recrystallization from 95% EtOH to give **10**, **11**, **12**, **13**, and **14**.

#### 2-[1,2-Bis(3,4-dimethoxyphenyl)-2-(4,4-dimethyl-2,6-dioxocyclohexyl)ethyl]-5,5-dimethylcyclohexane-1,3-dione (3a)

Recrystallized from methanol, mp 232–236 °C. IR (KBr, cm<sup>-1</sup>): 3410, 3040, 2944, 2860, 2594, 1580, 1460, 1410, 1370, 1296, 1235, 1132, 1050, 972, 870, 790. <sup>1</sup>H NMR (DMSO-*d*<sub>6</sub>) δ: 1.10 (s, 6H, 2 × CH<sub>3</sub>), 1.20 (s, 6H, 2 × CH<sub>3</sub>), 2.30–2.52 (m, 8H, 4 × CH<sub>2</sub>), 3.82 (s, 6H, OCH<sub>3</sub>), 3.86 (s, 6H, OCH<sub>3</sub>), 5.47 (d, 2H, *J* = 6.0 Hz), 5.70 (d, 2H, *J* = 6.0 Hz), 6.96–7.28 (m, 6H, ArH). <sup>13</sup>C NMR (DMSO-*d*<sub>6</sub>) δ: 15.9, 19.3, 27.1, 29.4, 47.4, 54.2, 58.3, 112.6, 115.2, 121.4, 133.5, 144.4, 147.5, 151.0, 160.0, 197.6. Anal. calcd. for C<sub>34</sub>H<sub>42</sub>O<sub>8</sub>: C 70.56, H 7.31; found: C 70.51, H 7.25.

**9-(3,4-Dimethoxyphenyl)-3,3,6,6-tetramethyl-2,3,4,5,6,7,8,9-octahydro-1H thioxanthene-1,8-dione (14a)**

Recrystallized from 95% ethanol, mp 234–238 °C. IR (KBr,  $\text{cm}^{-1}$ ): 3426, 3056, 2960, 2864, 2694, 1588, 1470, 1422, 1376, 1298, 1244, 1156, 1068, 976, 880, 700.  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 1.11 (s, 6H,  $2 \times \text{CH}_3$ ), 1.24 (s, 6H,  $2 \times \text{CH}_3$ ), 2.34–2.54 (m, 8H,  $4 \times \text{CH}_2$ ), 3.80 (s, 3H,  $\text{OCH}_3$ ), 3.86 (s, 3H,  $\text{OCH}_3$ ), 5.44 (d, 1H,  $J = 6.0$  Hz), 7.02–7.28 (m, 3H, ArH).  $^{13}\text{C}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 15.2, 22.2, 27.4, 47.2, 54.2, 56.1, 108.0, 114.4, 130.6, 159.2, 160.4, 194.4. Anal. calcd. for  $\text{C}_{25}\text{H}_{34}\text{O}_4\text{S}$ : C 69.73, H 7.95, S 7.44; found: C 69.68, H 7.88, S 7.38.

**2-[1,2-Bis(4-nitrophenyl)-2-(4,4-dimethyl-2,6-dioxocyclohexyl)ethyl]-5,5-dimethylcyclohexane-1,3-dione (3b)**

Recrystallized from methanol, mp 238–240 °C. IR (KBr,  $\text{cm}^{-1}$ ): 3400, 3000, 2966, 2840, 2584, 1560, 1468, 1416, 1360, 1296, 1235, 1144, 1080, 976, 840, 786.  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 1.10 (s, 6H,  $2 \times \text{CH}_3$ ), 1.20 (s, 6H,  $2 \times \text{CH}_3$ ), 2.30–2.52 (m, 8H,  $4 \times \text{CH}_2$ ), 5.46 (d, 2H,  $J = 6.0$  Hz), 5.72 (d, 2H,  $J = 6.0$  Hz), 6.96–7.28 (m, 8H, ArH).  $^{13}\text{C}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 16.9, 20.3, 28.6, 30.4, 47.5, 112.5, 115.2, 122.4, 131.5, 142.4, 147.5, 150.2, 160.4, 198.6. Anal. calcd. for  $\text{C}_{30}\text{H}_{32}\text{N}_2\text{O}_8$ : C 65.68, H 5.87, N 5.10; found: C 65.62, H 5.81, N 5.06.

**10,11-Bis(4-nitrophenyl)-3,3,7,7-tetramethyl-1,2,3,4,6,7,8,9,10,11-decahydro-dibenzo[*b,f*]oxepin-1,9-dione (4b)**

Recrystallized from hot ethanol, mp 240–244 °C. IR (KBr,  $\text{cm}^{-1}$ ): 3422, 3046, 2950, 2868, 2694, 1588, 1470, 1422, 1376, 1298, 1244, 1150, 1066, 972, 880, 700.  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 1.11 (s, 6H,  $2 \times \text{CH}_3$ ), 1.24 (s, 6H,  $2 \times \text{CH}_3$ ), 2.34–2.54 (m, 8H,  $4 \times \text{CH}_2$ ), 5.42 (d, 2H,  $J = 6.0$  Hz), 7.02–7.28 (m, 8H, ArH).  $^{13}\text{C}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 15.9, 19.4, 27.1, 29.7, 47.7, 54.2, 112.6, 115.0, 121.2, 133.4, 147.5, 160.4, 197.7. Anal. calcd. for  $\text{C}_{30}\text{H}_{30}\text{N}_2\text{O}_7$ : C 67.91, H 5.69, N 5.28; found: C 67.87, H 5.64, N 5.23.

**10,11-Bis(4-nitrophenyl)-3,3,7,7-tetramethyl-2,3,4,5,6,7,8,9,10,11-decahydro-1H-dibenzo[*b,f*]azepine-1,9-dione (5b)**

Recrystallized from hot ethanol, mp 260–264 °C. IR (KBr,  $\text{cm}^{-1}$ ): 3420, 3056, 2960, 2862, 2684, 1578, 1475, 1422, 1366, 1290, 1248, 1155, 1068, 976, 880, 704.  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 1.12 (s, 6H,  $2 \times \text{CH}_3$ ), 1.26 (s, 6H,  $2 \times \text{CH}_3$ ), 2.30–2.50 (m, 8H,  $4 \times \text{CH}_2$ ), 5.46 (d, 2H,  $J = 6.0$  Hz), 7.02–7.26 (m, 8H, ArH), 8.24 (s, 1H, NH, exchangeable with  $\text{D}_2\text{O}$ ).  $^{13}\text{C}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 15.4, 19.6, 27.7, 29.7, 47.7, 54.2, 112.6, 115.0, 121.4, 134.4, 148.5, 160.2, 196.4. Anal. calcd. for  $\text{C}_{30}\text{H}_{31}\text{N}_3\text{O}_6$ : C 68.03, H 5.90, N 7.93; found: C 67.98, H 5.84, N 7.88.

**10,11-Bis(4-nitrophenyl)-5-hydroxy-3,3,7,7-tetramethyl-2,3,4,5,6,7,8,9,10,11-decahydro-1H-dibenzo[*b,f*]azepine-1,9-dione (6b)**

Recrystallized from hot ethanol, mp 240–242 °C. IR (KBr,  $\text{cm}^{-1}$ ): 3400, 3088, 2964, 2866, 2676, 1576, 1478, 1424, 1368, 1288, 1246, 1156, 1064, 976, 886, 710.  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 1.12 (s, 6H,  $2 \times \text{CH}_3$ ), 1.26 (s, 6H,  $2 \times \text{CH}_3$ ), 2.32–2.54 (m, 8H,  $4 \times \text{CH}_2$ ), 5.44 (d, 2H,  $J = 6.0$  Hz), 7.02–7.24 (m, 8H, ArH), 10.72 (bs, 1H, OH).  $^{13}\text{C}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 15.4, 19.6, 27.4, 29.2, 47.8, 54.2, 112.6, 115.1, 121.2, 132.4, 144.5, 161.1, 197.4. Anal. calcd. for  $\text{C}_{30}\text{H}_{31}\text{N}_3\text{O}_7$ : C 66.04, H 5.72, N 7.70; found: C 65.98, H 5.65, N 7.63.

**5-Amino-10,11-bis(4-nitrophenyl)-3,3,7,7-tetramethyl-2,3,4,5,6,7,8,9,10,11-decahydro-1H-dibenzo[*b,f*]azepine-1,9-dione (7b)**

Recrystallized from hot ethanol, mp 266–268 °C. IR (KBr,  $\text{cm}^{-1}$ ): 3410, 3050, 2954, 2865, 2676, 1578, 1466, 1416, 1366, 1286, 1242, 1158, 1066, 976, 880, 716.  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 1.14 (s, 6H,  $2 \times \text{CH}_3$ ), 1.22 (s, 6H,  $2 \times \text{CH}_3$ ), 2.34–2.54 (m, 8H,  $4 \times \text{CH}_2$ ), 5.46 (d, 2H,  $J = 6.0$  Hz), 7.02–7.24 (m, 8H, ArH), 8.22 (d, 2H, NH).  $^{13}\text{C}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 15.4, 19.2, 26.1, 29.6, 47.4, 54.2, 112.6, 115.0, 121.2, 133.6, 147.2, 160.4, 197.4. Anal. calcd. for  $\text{C}_{30}\text{H}_{32}\text{N}_4\text{O}_6$ : C 66.16, H 5.92, N 10.28; found: C 66.08, H 7.86, N 10.21.

**10,11-Bis(4-nitrophenyl)-3,3,7,7-tetramethyl-1,2,3,4,5,6,7,8,9,10,11-decahydro-dibenzo[*b,f*]thiepin-1,9-dione (8b)**

Recrystallized from hot ethanol, mp 240–244 °C. IR (KBr,  $\text{cm}^{-1}$ ): 3426, 3056, 2960, 2864, 1588, 1470, 1422, 1376, 1298, 1244, 1156, 1068, 976, 880, 700.  $^1\text{H}$  NMR

( $\text{DMSO}-d_6$ )  $\delta$ : 1.11 (s, 6H,  $2 \times \text{CH}_3$ ), 1.24 (s, 6H,  $2 \times \text{CH}_3$ ), 2.34–2.54 (m, 8H,  $4 \times \text{CH}_2$ ), 5.42 (d, 2H,  $J = 6.0$  Hz), 7.02–7.28 (m, 8H, ArH).  $^{13}\text{C}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 15.7, 19.2, 27.2, 29.4, 47.1, 54.2, 112.6, 115.0, 121.2, 132.4, 147.4, 160.2, 197.6. Anal. calcd. for  $\text{C}_{30}\text{H}_{30}\text{N}_2\text{O}_6\text{S}$ : C 65.91, H 5.53, N 5.12, S 5.86; found: C 65.85, H 5.48, N 5.05, S 5.80.

**2-[(4,4-Dimethyl-2,6-dioxocyclohexyl)(4-nitrophenyl)methyl]-5,5-dimethylcyclohexane-1,3-dione (9b)<sup>21</sup>**

Recrystallized from ethanol, mp 188 °C (decomp), 252 °C. IR (KBr,  $\text{cm}^{-1}$ ): 3440, 3090, 2834, 2868, 2544, 1590, 1472, 1446, 1320, 1282, 1230, 1146, 1060, 974, 870, 790.  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 1.14 (s, 6H,  $2 \times \text{CH}_3$ ), 1.22 (s, 6H,  $2 \times \text{CH}_3$ ), 2.34–2.52 (m, 8H,  $4 \times \text{CH}_2$ ), 5.47 (d, 2H,  $J = 6.0$  Hz), 5.70 (1H, s, CH), 7.02–7.24 (m, 4H, ArH).  $^{13}\text{C}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 15.4, 17.7, 26.2, 68.3, 112.8, 114.4, 119.2, 142.1, 144.4, 147.7, 208.4. Anal. calcd. for  $\text{C}_{23}\text{H}_{27}\text{NO}_6$ : C 66.81, H 6.58, N 3.38; found: C 66.76, H 6.54, N 3.34.

**9-(4-Nitrophenyl)-3,3,6,6-tetramethyl-2,3,4,5,6,7,8,9-octahydro-1H-xanthene-1,8-dione (10b)**

Recrystallized from 95% ethanol, mp 236–238 °C. IR (KBr,  $\text{cm}^{-1}$ ): 3222, 3066, 2956, 2866, 2664, 1586, 1474, 1424, 1378, 1288, 1246, 1160, 1064, 976, 856, 740.  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 1.10 (s, 6H,  $2 \times \text{CH}_3$ ), 1.22 (s, 6H,  $2 \times \text{CH}_3$ ), 2.34–2.52 (m, 8H,  $4 \times \text{CH}_2$ ), 5.44 (d, 1H,  $J = 6.0$  Hz), 7.02–7.26 (m, 4H, ArH).  $^{13}\text{C}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 15.4, 25.2, 27.1, 47.4, 54.2, 108.0, 114.4, 130.6, 159.7, 160.6, 198.4. Anal. calcd. for  $\text{C}_{23}\text{H}_{25}\text{NO}_5$ : C 69.85, H 6.37; found: C 69.78, H 6.31.

**9-(4-Nitrophenyl)-3,3,6,6-tetramethyl-1,2,3,4,5,6,7,8,9,10-decahydroacridine-1,8-dione (11b)<sup>23</sup>**

Recrystallized from 95% ethanol, mp 252–256 °C. IR (KBr,  $\text{cm}^{-1}$ ): 3424, 3066, 2954, 2864, 2686, 1576, 1478, 1422, 1366, 1290, 1248, 1166, 1070, 956, 840, 704.  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 1.12 (s, 6H,  $2 \times \text{CH}_3$ ), 1.24 (s, 6H,  $2 \times \text{CH}_3$ ), 2.30–2.50 (m, 8H,  $4 \times \text{CH}_2$ ), 5.46 (d, 1H,  $J = 6.0$  Hz), 7.04–7.24 (m, 4H, ArH), 8.26 (s, 1H, NH).  $^{13}\text{C}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 16.4, 25.3, 27.7, 47.1, 54.2, 108.0, 114.1, 130.2, 159.2, 161.6, 197.4. Anal. calcd. for  $\text{C}_{23}\text{H}_{26}\text{N}_2\text{O}_4$ : C 70.03, H 6.64, N 7.10; found: C 69.98, H 6.58, N 7.04.

**9-(4-Nitrophenyl)-10-hydroxy-3,3,6,6-tetramethyl-1,2,3,4,5,6,7,8,9,10-decahydroacridine-1,8-dione (12b)<sup>25</sup>**

Recrystallized from 95% ethanol, mp 260–262 °C. IR (KBr,  $\text{cm}^{-1}$ ): 3410, 3068, 2954, 2866, 2674, 1566, 1466, 1428, 1364, 1280, 1260, 1146, 1074, 944, 880, 740.  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 1.16 (s, 6H,  $2 \times \text{CH}_3$ ), 1.22 (s, 6H,  $2 \times \text{CH}_3$ ), 2.34–2.54 (m, 8H,  $4 \times \text{CH}_2$ ), 5.46 (d, 1H,  $J = 6.0$  Hz), 7.02–7.26 (m, 4H, ArH), 10.73 (bs, 1H, OH).  $^{13}\text{C}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 15.1, 25.5, 27.2, 47.6, 54.4, 108.0, 114.2, 130.2, 159.4, 160.4, 198.4. Anal. calcd. for  $\text{C}_{23}\text{H}_{26}\text{N}_2\text{O}_5$ : C 67.30, H 6.38, N 6.82; found: C 67.24, H 6.31, N 6.77.

**10-Amino-9-(4-nitrophenyl)-3,3,6,6-tetramethyl-1,2,3,4,5,6,7,8,9,10-decahydro acridine-1,8-dione (13b)**

Recrystallized from 95% ethanol, mp 270–272 °C. IR (KBr, cm<sup>-1</sup>): 3420, 3042, 2960, 2864, 2672, 1562, 1462, 1424, 1360, 1284, 1242, 1158, 1066, 946, 882, 727. <sup>1</sup>H NMR (DMSO-*d*<sub>6</sub>) δ: 1.14 (s, 6H, 2 × CH<sub>3</sub>), 1.22 (s, 6H, 2 × CH<sub>3</sub>), 2.34–2.54 (m, 8H, 4 × CH<sub>2</sub>), 5.44 (d, 1H, *J* = 6.0 Hz), 7.02–7.24 (m, 4H, ArH), 8.28 (d, 2H, NH). <sup>13</sup>C NMR (DMSO-*d*<sub>6</sub>) δ: 15.2, 25.4, 27.2, 47.5, 54.1, 108.0, 114.4, 132.6, 159.4, 160.2, 197.4. Anal. calcd. for C<sub>23</sub>H<sub>27</sub>N<sub>3</sub>O<sub>4</sub>: C 67.46, H 6.64, N 10.26; found: C 67.41, H 6.58, N 10.21.

**9-(4-Nitrophenyl)-3,3,6,6-tetramethyl-2,3,4,5,6,7,8,9-octahydro-1H-thioxanthene-1,8-dione (14b)**

Recrystallized from 95% ethanol, mp 234–238 °C. IR (KBr, cm<sup>-1</sup>): 3426, 3056, 2960, 2864, 2694, 1588, 1470, 1422, 1376, 1298, 1244, 1156, 1068, 976, 880, 700. <sup>1</sup>H NMR (DMSO-*d*<sub>6</sub>) δ: 1.11 (s, 6H, 2 × CH<sub>3</sub>), 1.24 (s, 6H, 2 × CH<sub>3</sub>), 2.34–2.54 (m, 8H, 4 × CH<sub>2</sub>), 3.80 (s, 3H, OCH<sub>3</sub>), 5.44 (d, 1H, *J* = 6.0 Hz), 7.02–7.28 (m, 4H, ArH). <sup>13</sup>C NMR (DMSO-*d*<sub>6</sub>) δ: 15.2, 22.2, 27.4, 47.2, 54.2, 108.0, 114.4, 130.6, 159.2, 160.4, 194.4. Anal. calcd. for C<sub>23</sub>H<sub>25</sub>N O<sub>4</sub>S: C 67.13, H 6.12, S 7.79; found: C 67.07, H 6.06, S 7.72.

**5-[1,2-Di(2-furyl)-2-(2,4,6-trioxohexahydropyrimidin-5-yl)ethyl]-hexahydropyrimidine-2,4,6-trione (17b)<sup>26</sup>**

<sup>1</sup>H NMR (DMSO-*d*<sub>6</sub>, 500 MHz) δ: 6.90–7.0 (6H, m, furan ring Hs), 8.45 (2H, d, *J* = 6.0 Hz), 8.48 (2H, d, *J* = 6.0 Hz), 11.26 (4H, s, NHs). <sup>13</sup>C NMR (DMSO-*d*<sub>6</sub>, 500 MHz) δ: 43.1 (barbituric acid C-5 carbon), 86.6 (benzyl carbon), 136.2, 137.7, 139.9, 142.3 (four different carbons for two furan moieties), 161.4, 162.1, 165.4 (three different carbonyl carbons from barbituric acid).

**5,6-Di(2-furyl)-5,6-dihydropyrimidino[5',4':6,7]oxepino[2,3-*d*]pyrimidine-2,4,7,9(1H,3H,8H,10H)-tetraone (18b)<sup>26</sup>**

<sup>1</sup>H NMR (DMSO-*d*<sub>6</sub>, 500 MHz) δ: 6.95–6.70 (6H, m, furan ring Hs), 8.46 (2H, d, *J* = 6.0 Hz), 11.10 (s, 2H, NHs), 11.23 (2H, s, NHs). <sup>13</sup>C NMR (DMSO-*d*<sub>6</sub>) δ: 43.2 (barbituric acid C-5 carbon), 139.9, 141.1, 144.2, 146.7 (four different carbons for two furan rings), 161.1, 163.4 (two different carbonyl carbons from barbituric acid).

**5-(2-Furyl)-5H-pyrimidino[5',4':5,6]pyrano[2,3-*d*]pyrimidine-2,4,6,8(1H,3H,7H,9H)-tetraone (21b)<sup>26</sup>**

<sup>1</sup>H NMR (DMSO-*d*<sub>6</sub>, 500 MHz) δ: 6.90–7.20 (3H, m, furan ring Hs), 8.68 (1H, s), 11.12 (s, 2H, NHs), 11.26 (s, 2H, NHs). <sup>13</sup>C NMR (DMSO-*d*<sub>6</sub>, 500 MHz) δ: 41.4 (barbituric acid C-5 carbon), 86.1 (benzyl carbon), 136.6, 137.2, 138.8, 141.4 (for carbons for furan ring), 162.3, 169.4 (two different carbonyl carbons for the barbituric acid moieties).

# A novel and efficient cross-coupling of tris(fluorinated phenyl)boroxins with disulfides catalyzed by CuI/1,10-phenanthroline

Chuanming Yu, Beibei Jin, Zhenyu Liu, and Weihui Zhong

**Abstract:** Under an oxygen atmosphere, the cross-coupling of tris(fluorinated phenyl)boroxins and disulfides catalyzed by CuI/1,10-phenanthroline were smoothly achieved to produce the corresponding asymmetric fluorinated arylsulfides in good-to-excellent yields.

**Key words:** disulfide, tris(fluorinated phenyl)boroxin, fluorinated arylsulfide, cross-coupling, cuprous iodide.

**Résumé :** On a effectué sans difficulté le couplage croisé de tris(fluorophényl)boroxines et de disulfures, sous atmosphère d'oxygène et catalyse par du CuI/phénanthroline; on a pu isoler les arylsulfures fluorés asymétriques correspondants avec des rendements allant de bons à excellents.

**Mots-clés :** disulfure, tris(fluorophényl)boroxine, arylsulfure fluoré, couplage croisé, iodure cuivreux.

[Traduit par la Rédaction]

## Introduction

Transition-metal-catalyzed aryl carbon–sulfur formation reaction is an indispensable tool in synthetic organic chemistry. Aryl sulfides and their derivatives are a common functional group in numerous pharmaceutical and biological active compounds.<sup>1</sup> However, compared with metal-catalyzed formation of aryl C–N or aryl C–O bonds, transition-metal-mediated carbon–sulfur bonds formation have not received particular interest, which brought about a further research area.<sup>2</sup> In the 1980s, Migita and co-workers<sup>3</sup> first reported C–S bond formation through Pd(PPh<sub>3</sub>)<sub>4</sub> catalyzing the coupling reaction of aryl halides with thiols, but this method required considerable environmentally unfriendly PPh<sub>3</sub> as ligands. Later, various metal catalysts such as palladium,<sup>4</sup> nickel,<sup>5</sup> cobalt<sup>6</sup> and copper<sup>7</sup> have been developed among these reactions. While some synthetic difficulties must be addressed, for example, high temperatures, high catalyst loadings, and specially designed phosphine ligands,<sup>8</sup> it is gratifying to see that aryl triflates and organoboronic acids are sometimes used as good counterparts instead of aryl halides to overcome the disadvantages of the traditional reactions.<sup>9</sup> To the best of our knowledge, the preparation of asymmetric fluorinated arylsulfides via the cross-coupling of disulfide with tris(fluorinated phenyl)boroxin has not been reported.<sup>10</sup>

The arylation of tris(fluorinated phenyl)boroxins is of current interest because the unique properties conferred by the fluorine atoms might get some unexpected results and high biological activity compounds that are otherwise difficult to obtain.<sup>11</sup> Moreover, the analogous carbon–sulfur bond for-

Scheme 1.

mation without aryl halides should be desirable from the viewpoint of atom economy and the waste treatment of hydrogen halides.<sup>12</sup> Herein, we wish to report an efficient cross-coupling of tris(fluorinated phenyl)boroxins with disulfides catalyzed by the CuI/1,10-phenanthroline complex under oxygen atmosphere to give the corresponding fluorinated arylsulfides in good to excellent yields (Scheme 1).

## Results and discussion

Initially, the cross-coupling reaction of tris(3-fluorophenyl)boroxin (**1a**) with 1,2-di-*p*-tolylsulfide (**2a**) was investigated under different conditions. Various factors including copper source and its amount, solvents, ligands, and reaction temperatures were screened. Firstly, this cross-coupling reaction was carried out in a mixture of DMSO and water (2:1) at 100 °C catalyzed by CuI in the presence of 2,2-bipyridyl,<sup>10</sup> the desired product (3-fluorophenyl)-4-tolylsulfide (**3a**) was obtained in only 26% yields (Table 1, entry 1) and most of **2a** was recovered. When we carried out the same reaction in an oxygen atmosphere, the yield of corresponding target product **3a** improved up to 68% (Table 1, entry 2),

<sup>a</sup>Isolated yields based on **2a**.

<sup>b</sup>Under air atmosphere.

<sup>c</sup>Under nitrogen atmosphere.

while no desired product was observed under nitrogen atmosphere (Table 1, entry 3). Secondly, the effect of ligands was investigated (Fig. 1). The coupling reaction did not proceed in the absence of ligand (Table 1, entry 4), even by prolonging the reaction time or increasing the temperature. To our delight, the yield of product **3a** increased up to 94% when 1,10-phenanthroline (**L2**) was employed as ligand (Table 1, entries 5–7). Then, 1,10-phenanthroline (**L2**) was employed under Taniguchi's<sup>10</sup> conditions, and the reactions showed that this ligand was less stable than 2,2-bipyridyl (**L1**). Subsequently, we studied the effect of solvents, which have a negligible impact as compared to the reactions without additional water (Table 1, entries 5 and 8–9). A rate of DMSO and water of 1:1 was found not only to be an appropriate solvent for this reaction but also friendly to environment (Table 1, entries 5 and 8–13). Among these copper sources, CuI was the most effective (Table 1, entries 5 and 14–18). Therefore, the optimal conditions for the synthesis of fluorinated arylsulfides is by the treatment of disulfides and tri(fluorinated phenyl)boroxins in DMSO/H<sub>2</sub>O (1:1), under oxygen atmosphere at 90 °C, in the presence of only 5 mol% of CuI/**L2** (1,10-phenanthroline).

With the optimal conditions in hand, we decided to assess the scope of this reaction. Tris(fluorinated phenyl)boroxins were first investigated to react with a series of disulfides (see Table 2). It was found that both electron-donating and electron-withdrawing substituted disulfides were tolerated

**Fig. 1.** Ligands employed for the C–S coupling reaction.

well under the optimal reactions (Table 2, entries 1–9). The present process was shown to work well in the coupling of tris(fluorinated phenyl)boroxins with disulfides containing free *para*-hydroxyl or *meta*-amino groups to provide the desired products **3j**, **4j** and **3k**, **4k** in good yields (Table 2, entries 10 and 11). These compounds are very important intermediates.

Unfortunately, as shown in Table 2, no expected product was detected when using benzothiazol-2-yl disulfide (**2l**) as substrate (Table 2, entry 12). The same result happened with **2m** (Table 2, entry 13). The possible reason was that the benzothiazol-2-yl group and carboxyl group had strong electron-donating effects and decreased the reactivities of corresponding disulfides.

Another interesting aspect of the reaction was when aliphatic disulfides as substrates were employed (Table 2, entry 14). While 1,2-dibenzyl disulfide (**2n**) was found to give the corresponding products **3n** and **4n** only in yields of 23% and 29%, respectively, the main products were bis(4-fluorophenyl)sulfide (**5a**) and bis(3,4,5-trifluorophenyl)sul-

Scheme 3.

reasonable explanation was that the basic catalyst system, or even the light basic solvent DMSO at 90 °C, may be decomposing tris(pentafluorophenyl)-boroxin (Scheme 3).<sup>14</sup>

## Conclusion

In summary, we have developed a practical protocol to asymmetric fluorinated arylsulfides via CuI catalyzed cross-coupling of tris(fluorinated phenyl)boroxins with disulfides in the presence of 1,10-phenanthroline under an oxygen atmosphere. The merits of our method are simple operation, short reaction times, good to excellent yields, and one-pot synthesis of asymmetric fluorinated phenylsulfides. Further studies on the application of fluorinated boronic acids are now in progress in our laboratory.

## Experimental section

### General method

All reagents are commercially available. Tris(4-fluorophenyl)boroxin, tris(3,4,5-trifluorophenyl)boroxin, and tris(pentafluorophenyl)boroxin were prepared from our own laboratory.<sup>15</sup> Melting points were measured on a digital melting-point apparatus WR-1B and were uncorrected. <sup>1</sup>H NMR, <sup>19</sup>F NMR, and <sup>13</sup>C NMR spectra were recorded on a Varian 400 MHz instrument using CDCl<sub>3</sub> as the solvent, and chemical shifts were expressed in parts per million (ppm) using TMS and trifluoroacetic acid as internal standards. Mass spectra were measured with a Trace Finnigan DSQ. High resolution mass spectra (HR-MS) analyses were measured on an Agilent 6210 TOF LC/MS using APCI (electrospray ionization) techniques. IR measurements were carried out with a Nicolet Aviator-370 instrument. Elemental analysis was performed on a VarioEL-III instrument. All spectral data of the products were identical to authentic samples.

### General procedure for the preparation of asymmetric fluorinated arylsulfides

To a solution of CuI (0.025 mmol) and 1,10-phenanthroline (**L2**, 0.025 mmol) in DMSO/H<sub>2</sub>O (1:1, 20 mL) were added disulfides (0.5 mmol) and tri(3-fluorophenyl)boroxin (1.5 mmol). The mixture was stirred at 90 °C under O<sub>2</sub> atmosphere for a given time. Then the reaction was quenched with brine and extracted with ethyl acetate (3 × 15 mL). The combined organic phase was dried over anhydrous Na<sub>2</sub>SO<sub>4</sub> and concentrated in vacuo and the crude product was purified by column chromatography on silica gel with petroleum ether as eluent to afford the desired product. All new compounds were identified by <sup>1</sup>H NMR, <sup>13</sup>C NMR, <sup>19</sup>F

NMR, and HR-MS. Data of known compounds have been found to be identical to those reported.

### (3-Fluorophenyl)-4-isopropylphenylsulfide (3h)

Colorless viscous oil. IR (KBr,  $\text{cm}^{-1}$ ): 2962, 1598, 1473, 1426, 881, 828, 775, 678, 547.  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 1.24 (d,  $J = 6.8$  Hz, 6H), 2.88 (dd,  $J = 13.6, 7.2$  Hz, 1H), 6.80 (dd,  $J = 8.4, 8.4$  Hz, 1H), 6.88 (d,  $J = 9.6$  Hz, 1H), 6.97–7.04 (m, 1H), 7.12–7.21 (m, 3H), 7.37 (d,  $J = 8.4$  Hz, 2H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 23.8 (2C), 33.8 (d,  $J = 11.4$  Hz, 1C), 112.8 (d,  $J = 21.2$  Hz, 1C), 115.4 (d,  $J = 22.8$  Hz, 1C), 116.8, 122.7, 124.1 (2C), 127.2–128.1 (m, 1C), 129.7–130.4 (m, 1C), 133.4, 135.5 (d,  $J = 7.6$  Hz, 1C), 149.4, 163.0 (d,  $J = 246.5$  Hz, 1C).  $^{19}\text{F}$  NMR (376 MHz,  $\text{CDCl}_3$ )  $\delta$ : -111.32 ~ -111.36 (m, 1F). MS (EI)  $m/z$  (%): 246 ( $\text{M}^+$ , 95), 231 (100). HR-MS calcd. for  $\text{C}_{15}\text{H}_{15}\text{FS}$  [ $\text{M}^+$ ]: 246.0878; found: 246.0843.

### (3-Fluorophenyl)-2,3-dichlorophenylsulfide (3i)

Colorless viscous oil. IR (KBr,  $\text{cm}^{-1}$ ): 1597, 1474, 1399, 1086, 881, 781, 678.  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 6.89 (d,  $J = 8.0$  Hz, 2H), 7.02–7.13 (m, 2H), 7.20 (d,  $J = 8.0$  Hz, 1H), 7.31–7.40 (m, 2H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 116.0 (d,  $J = 20.8$  Hz, 1C), 120.0 (d,  $J = 22.4$  Hz, 1C), 127.9 (d,  $J = 28.1$  Hz, 1C), 128.5–129.0 (m, 1C), 129.9, 130.6, 131.2 (d,  $J = 7.9$  Hz, 1C), 131.7, 134.0, 134.8 (d,  $J = 7.5$  Hz, 1C), 138.4, 163.2 (d,  $J = 248.3$  Hz, 1C).  $^{19}\text{F}$  NMR (376 MHz,  $\text{CDCl}_3$ )  $\delta$ : -110.03 (dd,  $J = 13.9, 9.4$  Hz, 1F). MS (EI)  $m/z$  (%): 272 ( $\text{M}^+$ , 100), 202 (15). HR-MS calcd. for  $\text{C}_{12}\text{H}_7\text{Cl}_2\text{FS}$  [ $\text{M}^+$ ]: 271.9630; found: 271.9651.

### (3-Fluorophenyl)-4-hydroxyphenylsulfide (3j)

Colorless viscous oil. IR (KBr,  $\text{cm}^{-1}$ ): 3391, 2925, 1599, 1493, 878, 830, 774, 673.  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 5.44 (s, 1H), 6.75–6.80 (m, 2H), 6.85–6.92 (m, 3H), 7.16 (dd,  $J = 8.0, 8.0$  Hz, 1H), 7.40 (d,  $J = 8.8$  Hz, 2H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 112.4 (d,  $J = 21.3$  Hz, 1C), 114.1 (d,  $J = 23.5$  Hz, 2C), 116.7, 122.8 (2C), 130.1 (d,  $J = 8.3$  Hz, 2C), 136.5, 141.5, 156.4, 163.0 (d,  $J = 246.5$  Hz, 1C).  $^{19}\text{F}$  NMR (376 MHz,  $\text{CDCl}_3$ )  $\delta$ : -111.61 (dd,  $J = 15.4, 9.0$  Hz, 1F). MS (EI)  $m/z$  (%): 220 ( $\text{M}^+$ , 100), 201 (25). HR-MS calcd. for  $\text{C}_{12}\text{H}_9\text{FOS}$  [ $\text{M}^+$ ]: 220.0358; found: 220.0347.

### (3-Fluorophenyl)-2-aminophenylsulfide (3k)

Red viscous oil. IR (KBr,  $\text{cm}^{-1}$ ): 3469, 3375, 1609, 1479, 879, 750, 673.  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 4.24 (s, 2H), 6.70–6.79 (m, 4H), 6.85 (d,  $J = 8.0$  Hz, 1H), 7.15 (dd,  $J = 15.2, 7.2$  Hz, 1H), 7.20 (td,  $J = 8.4, 1.6$  Hz, 1H), 7.43 (d,  $J = 7.6$  Hz, 1H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 112.2 (d,  $J = 21.2$  Hz, 1C), 113.0 (d,  $J = 23.5$  Hz, 2C), 115.4, 118.8, 121.7, 130.1 (d,  $J = 8.3$  Hz, 1C), 131.6, 137.6, 139.5 (d,  $J = 6.8$  Hz, 1C), 148.9, 163.1 (d,  $J = 246.4$  Hz, 1C).  $^{19}\text{F}$  NMR (376 MHz,  $\text{CDCl}_3$ )  $\delta$ : -111.37 (dd,  $J = 15.1, 9.0$  Hz, 1F).

MS (EI)  $m/z$  (%): 219 ( $\text{M}^+$ , 100), 186 (25). HR-MS calcd. for  $\text{C}_{12}\text{H}_{10}\text{FNS}$  [ $\text{M}^+$ ]: 219.0518; found: 219.0505.

### (3-Fluorophenyl)benzylsulfide (3n)

White solid. Mp (recrystallization in petroleum ether) 30.5–31.4 °C. IR (KBr,  $\text{cm}^{-1}$ ): 3060, 2921, 1599, 1495, 773, 713, 697, 678.  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 4.13 (s, 2H), 6.86 (td,  $J = 8.4, 2.4$  Hz, 1H), 7.03 (dd,  $J = 22.0, 7.6$  Hz, 2H), 7.31–7.18 (m, 6H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 38.5, 110.4, 113.1 (t,  $J = 6.8$  Hz, 2C), 115.7–116.0 (m, 1C), 118.8, 124.6 (2C), 127.4–128.8 (m, 2C), 130.0 (d,  $J = 8.4$  Hz, 1C), 136.7, 161.5–164.0 (m, 1C).  $^{19}\text{F}$  NMR (376 MHz,  $\text{CDCl}_3$ )  $\delta$ : -111.65 ~ -111.73 (m, 1F). MS (EI)  $m/z$  (%): 218 ( $\text{M}^+$ , 100), 91 (75). HR-MS calcd. for  $\text{C}_{13}\text{H}_{11}\text{FS}$  [ $\text{M}^+$ ]: 218.0565; found: 218.0554.

### (3,4,5-Trifluorophenyl)-4-tolylsulfide (4a)

Colorless viscous oil. IR (KBr,  $\text{cm}^{-1}$ ): 2925, 1599, 1515, 1425, 1046, 878, 829, 760.  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 2.37 (s, 3H), 6.74 (dd,  $J = 8.0, 6.8$  Hz, 2H), 7.20 (d,  $J = 8.0$  Hz, 2H), 7.35 (d,  $J = 8.0$  Hz, 2H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 21.2, 112.0 (dd,  $J = 16.7, 6.1$  Hz, 2C), 128.3, 130.6 (2C), 134.0 (2C), 136.7, 139.5, 151.2 (d,  $J = 150.2$  Hz, 2C).  $^{19}\text{F}$  NMR (376 MHz,  $\text{CDCl}_3$ )  $\delta$ : -162.66 ~ -162.80 (m, 1F), -132.87 ~ -132.98 (m, 2F). MS (EI)  $m/z$  (%): 254 ( $\text{M}^+$ , 100), 239 (30). HR-MS calcd. for  $\text{C}_{13}\text{H}_9\text{FS}$  [ $\text{M}^+$ ]: 254.0377; found: 254.0357.

### (3,4,5-Trifluorophenyl)-4-bromophenylsulfide (4b)

White solid. Mp (recrystallization in petroleum ether) 56.0–58.0 °C. IR (KBr,  $\text{cm}^{-1}$ ): 3132, 1613, 1518, 855, 811, 759.  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 6.87 (d,  $J = 7.2$  Hz, 2H), 7.27 (d,  $J = 7.6$  Hz, 2H), 7.51 (d,  $J = 6.8$  Hz, 2H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 113.8 (dd,  $J = 16.7, 6.1$  Hz, 2C), 123.0, 132.3 (d,  $J = 16.7$  Hz, 1C), 132.9 (2C), 134.1 (2C), 137.5, 140.0, 151.3 (d,  $J = 247.3$  Hz, 2C).  $^{19}\text{F}$  NMR (376 MHz,  $\text{CDCl}_3$ )  $\delta$ : -132.11 ~ -132.19 (m, 2F), -160.92 ~ -161.07 (m, 1F). MS (EI)  $m/z$  (%): 318 ( $\text{M}^+$ , 100), 239 (10). HR-MS calcd. for  $\text{C}_{12}\text{H}_6\text{BrF}_3\text{S}$  [ $\text{M}^+$ ]: 317.9326; found: 317.9248.

### (3,4,5-Trifluorophenyl)-4-chlorophenylsulfide (4c)

Colorless viscous oil. IR (KBr,  $\text{cm}^{-1}$ ): 3134, 1614, 1516, 896, 841, 824, 759.  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 6.83 (dd,  $J = 6.8, 6.8$  Hz, 2H), 7.34 (s, 4H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 113.5 (dd,  $J = 16.7, 6.1$  Hz, 2C), 120.1, 129.4 (d,  $J = 18.2$  Hz, 1C), 129.9, 131.4, 132.5 (d,  $J = 50.8$  Hz, 1C), 134.0, 135.0, 138.7 (d,  $J = 243.4$  Hz, 1C), 151.3 (d,  $J = 247.2$  Hz, 2C).  $^{19}\text{F}$  NMR (376 MHz,  $\text{CDCl}_3$ )  $\delta$ : -132.11 ~ -132.19 (m, 2F), -160.92 ~ -161.07 (m, 1F). MS (EI)  $m/z$  (%): 274 ( $\text{M}^+$ , 100), 239 (40). HR-MS calcd. for  $\text{C}_{12}\text{H}_6\text{ClF}_3\text{S}$  [ $\text{M}^+$ ]: 273.981; found: 273.972.

### (3,4,5-Trifluorophenyl)-4-fluorophenylsulfide (4d)

Colorless viscous oil. IR (KBr,  $\text{cm}^{-1}$ ): 2964, 1614, 1517, 1425, 1047, 834, 759.  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 6.76 (dd,  $J = 3.6, 3.6$  Hz, 2H), 7.09 (dd,  $J = 11.6, 11.6$  Hz, 2H), 7.76 (dd,  $J = 11.6, 5.2$  Hz, 2H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 112.3 (dd,  $J = 17.1, 6.2$  Hz, 1C), 113.1 (d,  $J = 23.2$  Hz, 1C), 116.1–117.1 (m, 1C), 125.2, 127.4, 132.8 (d,  $J = 264.4$  Hz, 1C), 135.4, 136.0, 138.2 (d,  $J = 249.8$  Hz, 1C), 151.3 (d,  $J = 251.5$  Hz, 2C), 163.3 (d,  $J = 240.4$  Hz,

1C).  $^{19}\text{F}$  NMR (376 MHz,  $\text{CDCl}_3$ )  $\delta$ : -152.71 ~ -152.86 (m, 2F), -182.25 ~ -183.40 (m, 1F). MS (EI)  $m/z$  (%): 258 ( $\text{M}^+$ , 100), 238 (35). HR-MS calcd. for  $\text{C}_{12}\text{H}_6\text{F}_3\text{S}$  [ $\text{M}^+$ ]: 258.0126; found: 258.0114.

**(3,4,5-Trifluorophenyl)-4-nitrophenylsulfide (4e)**

Yellow solid. Mp (recrystallization in petroleum ether) 110.2–111.0 °C. IR (KBr,  $\text{cm}^{-1}$ ): 3130, 1617, 1505, 1401, 1087, 854, 739.  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.15 (dd,  $J$  = 6.8, 6.8 Hz, 2H), 7.26–7.31 (m, 2H), 8.15 (dd,  $J$  = 9.6, 4.4 Hz, 2H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 117.8–118.0 (m, 2C), 124.4 (2C), 128.4 (2C), 139.3, 141.8, 145.1, 146.4, 151.6 (d,  $J$  = 244.0 Hz, 2C).  $^{19}\text{F}$  NMR (376 MHz,  $\text{CDCl}_3$ )  $\delta$ : -130.60 (dd,  $J$  = 22.6, 9.0 Hz, 2F), -156.68 ~ -156.78 (m, 1F). **(3,4,5-Trifluorophenyl)-4-hydroxyphenylsulfide (4j)**

White solid. Mp (recrystallization in petroleum ether) 68.7–70.1 °C. IR (KBr,  $\text{cm}^{-1}$ ): 3403, 3133, 1614, 1516, 1401, 1045, 832, 758, 619.  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 5.07 (s, 1H), 6.69 (dd,  $J$  = 13.2, 13.2 Hz, 2H), 6.88 (d,  $J$  = 5.2 Hz, 2H), 7.40 (d,  $J$  = 9.2 Hz, 2H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 110.0 (dd,  $J$  = 17.4, 6.1 Hz, 2C), 117.0 (2C), 122.1, 135.6, 136.2 (d,  $J$  = 31.90 Hz, 2C), 138.9, 151.3 (d,  $J$  = 250.3 Hz, 2C), 156.8.  $^{19}\text{F}$  NMR (376 MHz,  $\text{CDCl}_3$ )  $\delta$ : -153.25 ~ -153.37 (m, 2F), -183.69 (dd,  $J$  = 25.9, 19.9 Hz, 1F). MS (EI)  $m/z$  (%): 256 ( $\text{M}^+$ , 100), 195 (25). HR-MS calcd. for  $\text{C}_{12}\text{H}_7\text{F}_3\text{OS}$  [ $\text{M}^+$ ]: 256.0170; found: 256.0159.

**(3,4,5-Trifluorophenyl)-2-aminophenylsulfide (4k)**

Light yellow solid. Mp (recrystallization in petroleum ether) 66.5–66.9 °C. IR (KBr,  $\text{cm}^{-1}$ ): 3484, 3385, 3133, 1612, 1513, 1478, 1401, 832, 756, 607.  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 4.27 (s, 2H), 6.45 (dd,  $J$  = 7.2, 7.2 Hz, 2H), 6.76–6.82 (m, 2H), 7.25–7.30 (m, 1H), 7.41 (d,  $J$  = 8.8 Hz, 1H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 110.1 (dd,  $J$  = 17.5, 6.1 Hz, 1C), 112.4, 115.7, 119.1, 132.2, 133.5, 136.4, 137.7, 138.9, 149.0, 151.4 (d,  $J$  = 252.2 Hz, 2C).  $^{19}\text{F}$  NMR (376 MHz,  $\text{CDCl}_3$ )  $\delta$ : -152.36 (dd,  $J$  = 22.6, 15.0 Hz, 2F), -179.93 (dd,  $J$  = 21.4, 12.4 Hz, 1F). MS (EI)  $m/z$  (%): 255 ( $\text{M}^+$ , 100), 80 (30). HR-MS calcd. for  $\text{C}_{12}\text{H}_8\text{F}_3\text{NS}$  [ $\text{M}^+$ ]: 255.0330; found: 255.0315.

**(3,4,5-Trifluorophenylthio)-3-propanoic acid (4m)**

Yellow solid. Mp (recrystallization in petroleum ether) 68.9–71.2 °C. IR (KBr,  $\text{cm}^{-1}$ ): 3133, 1709, 1610, 1519, 1399, 1232, 1047, 810, 756, 656.  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 2.68–2.72 (m, 2H), 3.15 (t,  $J$  = 7.2 Hz, 2H), 7.00 (dd,  $J$  = 7.6, 6.8 Hz, 2H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 27.6, 33.4, 112.3 (d,  $J$  = 22.8 Hz, 1C), 117.8 (d,  $J$  = 17.5 Hz, 1C), 133.3, 136.9 (d,  $J$  = 253.5 Hz, 1C), 150.4 (d,  $J$  = 254.8 Hz, 2C), 172.5.  $^{19}\text{F}$  NMR (376 MHz,  $\text{CDCl}_3$ )  $\delta$ : -132.36 (dd,  $J$  = 24.4, 19.9 Hz, 2F), -161.00 ~ -161.13 (m, 1F). MS (EI)  $m/z$  (%): 236 ( $\text{M}^+$ , 100), 177 (45). HR-MS calcd. for  $\text{C}_9\text{H}_7\text{F}_3\text{O}_2\text{S}$  [ $\text{M}^+$ ]: 236.2109; found: 236.1989.

**(3,4,5-Trifluorophenyl)benzylsulfide (4n)**

White solid. Mp (recrystallization in petroleum ether) 50.0–50.9 °C. IR (KBr,  $\text{cm}^{-1}$ ): 3414, 3132, 1613, 1519, 1505, 1401, 1049, 823, 719, 694.  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 4.08 (s, 2H), 6.88 (dd,  $J$  = 7.2, 6.0 Hz, 2H), 7.21–7.33 (m, 5H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 39.5, 110.7, 113.5, 114.1 (d,  $J$  = 17.1 Hz, 1C), 116.4, 119.2, 127.9, 129.0, 132.6, 136.5, 151.3 (d,  $J$  = 26.0 Hz, 2C), 163.0–161.7 (m, 1C).  $^{19}\text{F}$  NMR (376 MHz,  $\text{CDCl}_3$ )  $\delta$ : -132.96 (m, 2F), -161.69 (d,  $J$  = 17.1 Hz, 1F). MS (EI)  $m/z$  (%): 254 ( $\text{M}^+$ , 100), 163 (15). HR-MS calcd. for  $\text{C}_{13}\text{H}_9\text{F}_3\text{S}$  [ $\text{M}^+$ ]: 254.0377; found: 254.0364.

**Bis(3-fluorophenyl)sulfide (5a)**

Yellow oil. IR (KBr,  $\text{cm}^{-1}$ ): 3064, 1597, 1472, 881, 815, 777, 677.  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.05 (dd,  $J$  = 10.4, 8.4 Hz, 2H), 7.22–7.26 (m, 2H), 7.31–7.41 (m, 4H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 110.4, 111.2 (dd,  $J$  = 15.7,

6.1 Hz, 1C), 113.2, 116.0, 118.9, 134.2, 139.9 (d,  $J$  = 252.3 Hz, 2C), 151.6 (dd,  $J$  = 249.4, 6.1 Hz, 2C), 162.8–161.9 (m, 2C).  $^{19}\text{F}$  NMR (376 MHz,  $\text{CDCl}_3$ )  $\delta$ : –117.87 (dd,  $J$  = 15.4, 9.0 Hz, 2F). MS (EI)  $m/z$  (%): 222 ( $\text{M}^+$ , 100), 203 (25). HR-MS calcd. for  $\text{C}_{12}\text{H}_8\text{F}_6\text{S}$  [ $\text{M}^+$ ]: 222.0315; found: 222.0322.

### Bis(3,4,5-trifluorophenyl)sulfide (5b)

White solid. Mp (recrystallization in petroleum ether) 87.8–89.1 °C. IR (KBr,  $\text{cm}^{-1}$ ): 3133, 1617, 1514, 1402, 1043, 690, 610, 478.  $^1\text{H}$  NMR (400 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.08–7.16 (m, 4H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 111.1 (dd,  $J$  = 16.1, 6.1 Hz, 4C), 134.3 (2C), 139.9 (d,  $J$  = 252.5 Hz, 2C), 151.6 (d,  $J$  = 249.80 Hz, 4C).  $^{19}\text{F}$  NMR (376 MHz,  $\text{CDCl}_3$ )  $\delta$ : –132.07 (t,  $J$  = 16.5 Hz, 4F), –159.54 ~ –159.69 (m, 2F). MS (EI)  $m/z$  (%): 294 ( $\text{M}^+$ , 100), 163 (95). HR-MS calcd. for  $\text{C}_{12}\text{H}_4\text{F}_6\text{S}$  [ $\text{M}^+$ ]: 293.9938; found: 293.9921.

# Electrophilicity of a 9-aryl-9-fluorenyl cation in water — Kinetic evidence for antiaromaticity

Sarah Ward, Tammy Messier, and Matthew Lukeman

**Abstract:** The 9-(4-methoxyphenyl)-9-fluorenyl cation (**2**) has been generated in 100% water by laser flash photolysis of 9-(4-methoxyphenyl)-9-fluorenol (**3**), representing the first observation of a 9-fluorenyl cation in this solvent with lifetimes in the microsecond timescale. The relatively long lifetime permitted quenching studies with a number of anionic nucleophiles, and bimolecular rate constants for each were determined. For both bromide and iodide, rate data suggest that an equilibrium between the cation and trapped product is rapidly established, followed by slower, irreversible trapping of the cation by water. The bimolecular rate constants obtained show that the generated 9-fluorenyl cation is significantly more reactive towards nucleophilic attack, by two orders of magnitude, than related triarylmethyl cations that lack the  $4n \pi$ -system, lending support to the characterization of fluorenyl cations as antiaromatic.

**Key words:** 9-fluorenyl cation, laser flash photolysis, electrophilicity, carbocation, antiaromaticity.

**Résumé :** On a généré le cation 9-(4-méthoxyphényl)-9-fluorényle (**2**) dans un solvant à 100 % d'eau par photolyse éclair au laser du 9-(4-méthoxyphényl)-9-fluorénol (**3**); ceci correspond à la première observation du cation 9-fluorényle dans ce solvant avec un temps de vie de l'échelle de la microseconde. Le temps de vie relativement long a permis d'effectuer des études de piégeage avec un certain nombre de nucléophiles anioniques et on a déterminé les constantes de vitesses bimoléculaires pour chacune. Pour le bromure ainsi que pour l'iodure, les données de vitesse suggèrent qu'il s'établit rapidement un équilibre entre le cation et le produit piégé, suivi par un piégeage irréversible plus lent du cation par l'eau. Les constantes de vitesses bimoléculaires obtenues montrent que vis-à-vis des attaques nucléophiles, le cation 9-fluorényle généré est beaucoup plus réactif (au moins deux ordres de grandeur) que les réactions apparentées des cations triarylméthyles qui ne comportent pas de système  $4n \pi$ ; cette observation est en accord avec une caractérisation des cations fluorényles comme antiaromatiques.

**Mots-clés :** cation 9-fluorényle, photolyse éclair au laser, caractère électrophile, carbocation, antiaromaticité.

[Traduit par la Rédaction]

## Introduction

Antiaromaticity is a central concept in organic chemistry, and has been defined in thermodynamic terms: "If the structure is of higher energy (less stable) than such a hypothetical classical structure, the molecular entity is antiaromatic."<sup>1</sup> It can sometimes be difficult to assess antiaromaticity according to this definition, since energies of such hypothetical structures cannot be directly measured and can only be estimated. Comparisons between different but related structures are often used instead, and in addition to thermodynamic considerations, kinetic, electronic, geometric, spectroscopic, and magnetic data are frequently used to assess antiaromaticity.<sup>2</sup>

The potential antiaromaticity of the 9-fluorenyl cation (**1**) and its derivatives has been a source of interest for decades. Several observations support the notion that **1** is antiaromatic, including: the central ring possesses  $4n \pi$ -electrons, efforts to generate **1** thermally by dissolution of 9-fluorenol in strongly acidic media have failed,<sup>3</sup> and solvolysis reac-

tions involving 9-fluorenyl cations proceed several orders of magnitude more slowly than analogues that do not involve  $4n \pi$ -systems.<sup>4</sup> Mills et al. have provided strong evidence in favour of the antiaromatic nature of the 9-fluorenyl cation ring when present as a component of fluorenylidene dications.<sup>5</sup> Amyes et al. determined that the  $pK_R$  value for **1** (−15.9) is more negative than that of the analogous diphenylmethyl cation ( $\text{Ph}_2\text{CH}^+$ ,  $pK_R = -11.7$ ), and based on these experiments and calculations, they estimate that **1** is destabilized by ~10 kcal/mol relative to the diphenylmethyl cation, which they claim is a relatively small difference that does not support the existence of antiaromatic character in **1**.<sup>6</sup> Magnetic susceptibility exaltation calculations carried out by Tidwell and co-workers at the ab initio and density functional theory levels also suggest that 9-fluorenyl cations do not have antiaromatic character, but are instead nonaromatic.<sup>7</sup> From the available studies, it appears that support for the antiaromaticity of **1** depends on which criterion is being considered. What is ultimately desired is a quantitative knowledge of the reactivity of 9-fluorenyl cations, such

as **1**, so that their electrophilic character can be best understood. There remains a paucity of kinetic data involving electrophilic reactions of 9-fluorenyl cations, primarily because the typically fast reaction rates are difficult to measure. The current rate data available for 9-fluorenyl cations is largely limited to solvolysis reactions in fluorinated alcohols or water/organic solvent mixtures, since the very weak nucleophiles present in these cases give slow reactions that are more easily monitored. It was our desire at the outset of this project to address the lack of available kinetic data and enhance our knowledge of the reactivity of 9-fluorenyl cations by obtaining rate data for a wider suite of nucleophiles.

Wan and co-workers have uncovered a convenient photochemical route to 9-fluorenyl cations via photolysis of the corresponding 9-fluorenol derivatives.<sup>8</sup> 9-Fluorenyl cations generated in this way are generally very short-lived in aqueous solution ( $\tau < 20$  ps for **1**),<sup>9</sup> but can persist for much longer in non-nucleophilic protic solvents ( $\tau = 30$   $\mu$ s for **1** in 1,1,1,3,3,3-hexafluoro-2-propanol (HFIP)).<sup>10</sup> Many 9-substituted 9-fluorenyl cations have since been generated photolytically and characterized by LFP,<sup>11,12</sup> usually in polar protic organic solvents such as 1,1,1-trifluoroethanol (TFE) or HFIP, or in aqueous/organic solvent mixtures, but not in entirely aqueous solution. We were particularly interested in one such report<sup>11</sup> in which the 9-(4'-methoxyphenyl)-9-fluorenyl cation (**2**) is demonstrated to react with water (in 4:1 water/acetonitrile solution) with a rate constant of  $1.7 \times 10^5$  s<sup>-1</sup>, corresponding to a lifetime of 5.9  $\mu$ s that is easily accessible by nanosecond LFP. We expected that the cation would still be detectable in a 100% aqueous solvent, and that information regarding the electrophilicity of **2** could be determined through quenching studies with nucleophiles, thus providing for the first time comprehensive quantitative information on the electrophilicity of a substituted 9-fluorenyl cation.

## Results

The photochemical precursor to cation **2** is 9-(4'-methoxyphenyl)-9-fluorenol (**3**), which was readily prepared by the reaction of 4-methoxyphenylmagnesium bromide with 9-fluorenone in dry THF.

Water/acetonitrile mixtures are frequently used for the flash photolytic generation of organic cations, mainly because the organic co-solvent helps to solubilize the cation precursor. We were instead interested in using pure water as the solvent system in this study, since the nucleophilicity parameters ( $N^+$ ) of many nucleophiles are defined in this solvent.<sup>13</sup> The organic co-solvent was not needed in our

**Fig. 1.** Transient absorption spectrum obtained on LFP of **3** in Ar-purged water. Each trace corresponds to the time after laser pulse indicated in the legend.

case to achieve sufficient concentrations of **3** for LFP studies. Nanosecond LFP of **3** in argon-bubbled water gave rise to a strongly absorbing transient with maxima at  $\lambda_{\text{max}} = 540$  and 460 nm (Fig. 1), very similar in appearance to that obtained in 4:1 H<sub>2</sub>O/CH<sub>3</sub>CN by McClelland and co-workers,<sup>11</sup> and is assigned to cation **2**. This transient decayed with first-order kinetics with a rate constant of  $2.7 \times 10^5$  s<sup>-1</sup> (20 °C), which is ~60% faster than the rate constant observed by McClelland and co-workers in 4:1 H<sub>2</sub>O/CH<sub>3</sub>CN, but is still sufficiently slow to allow for detailed quenching studies using nanosecond LFP. McClelland et al. measured the solvolysis rates of several diarylmethyl and triarylmethyl cations in water/acetonitrile mixtures with varying water content, and found that rate constants dropped slightly (by close to 20%) on moving from 20% water to pure water.<sup>14</sup> The 60% increase in rate constant we observe for **2** on moving from 80% to pure water is behaviour that is clearly different from that of the previously examined systems,<sup>14</sup> and shows that the presence of the organic co-solvent in some cases can indeed have a sizeable effect on the lifetime of organic cations. Quenching of this transient was carried out using a total of six anionic nucleophiles (bromide, iodide, chloride, fluoride, azide, and acetate) at a number of concentrations. Quenching plots were constructed for each of these nucleophiles, and data for selected nucleophiles are plotted in Fig. 2.

### Quenching by bromide

LFP of **3** in water containing 0.03 mol/L NaBr gave rise to a transient with an absorption profile identical in appearance to that shown in Fig. 1. The decay of this transient, however, was clearly not first-order, unlike the case in the absence of bromide (Fig. 3). The decay data fit well to a biexponential function, revealing two rate constants:  $k_{\text{obsd}}(\text{fast}) = 1.4 \times 10^6$  s<sup>-1</sup> and  $k_{\text{obsd}}(\text{slow}) = 6.5 \times 10^4$  s<sup>-1</sup>.

**Fig. 2.** Quenching plots indicating changes in  $k_{\text{obsd}}$  (or  $k_{\text{obsv}}(\text{fast})$ ) for  $\text{Br}^-$  and  $\text{I}^-$  at 300 K as a function of added nucleophile for the following nucleophiles:  $\text{NaN}_3$ ,  $\text{NaI}$ ,  $\text{NaBr}$ , and  $\text{NaCl}$ .

The rate constants and the pre-exponential factors remained constant at all wavelengths between 400 and 600 nm, suggesting that both decay components can be attributed to the same absorbing species (namely, cation **2**). As the bromide concentration was increased, the magnitude of the shorter component,  $k_{\text{obsd}}(\text{fast})$ , was increased and that of the longer component,  $k_{\text{obsd}}(\text{slow})$ , was reduced. This behaviour is consistent with the existence of an equilibrium between **2** and its 9-bromo adduct **4** (which does not absorb in the visible region), according to eq. [1] and eq. [2].<sup>15</sup> The fast decay component,  $k_{\text{obsd}}(\text{fast})$ , corresponds to establishment of the equilibrium (eq. [1]), while the slow component,  $k_{\text{obsd}}(\text{slow})$ , corresponds to the reaction of the equilibrium concentration of **2** with solvent water (eq. [2]). At bromide concentrations greater than 0.01 mol/L,  $k_{\text{obsd}}(\text{fast})$  exhibits a linear correlation with  $[\text{Br}^-]$ , according to eq. [3]. The data obtained from this correlation (plotted in Fig. 2) provides  $k_{\text{Br}^-} = 3.0 \times 10^7 \text{ M}^{-1}\text{s}^{-1}$  and  $k_{\text{ion}} = 4.8 \times 10^5 \text{ s}^{-1}$ . The ratio of these rates gives  $K_{\text{eq}} = 62 \text{ mol/L}^{-1}$ .

$$[3] \quad k_{\text{obsd}}(\text{fast}) = k_{\text{Br}^-}[\text{Br}^-] + k_{\text{ion}}$$

McClelland et al. observed similar equilibrium quenching of the trityl cation ( $\text{Ph}_3\text{C}^+$ ) with bromide,<sup>16</sup> and their analysis provided  $k_{\text{Br}^-} = 5.1 \times 10^6 \text{ M}^{-1}\text{s}^{-1}$ ,  $k_{\text{ion}} = 7.6 \times 10^6 \text{ s}^{-1}$ , and  $K_{\text{eq}} = 6.6 \text{ mol/L}^{-1}$  for that system. Comparison of these data with those obtained for **2** demonstrates the strong electrophilic nature of **2**. Bromide ion reacts with **2** faster than with the trityl cation, which is not a 4n system, despite the fact that **2** contains a stabilizing 4-methoxy group and the

**Fig. 3.** Transient absorption signal observed at 540 nm on LFP of **3** in water containing 0.03 mol/L  $\text{NaBr}$  with a clearly visible biphasic decay.

trityl cation does not. The lower stability of **2** relative to the trityl cation is also evident from the fact that  $K_{\text{eq}}$  is an order of magnitude larger in the case of **2**. It is indeed remarkable that **2** forms a detectable equilibrium with bromide, since this suggests that **4** should be a *thermal* source of the formally antiaromatic cation **2** in aqueous solution at room temperature.

The quenching experiments were repeated using two other bromide sources,  $\text{KBr}$  and  $\text{NH}_4\text{Br}$ , and no changes in the decay kinetics were observed, indicating that the cation behaves merely as a spectator ion and does not influence the anion–organic cation recombination.

### Quenching by iodide

Biphasic decay of **2** was also observed on LFP of **3** in aqueous solutions containing  $\text{NaI}$  ( $\geq 0.002 \text{ mol/L}$ ). A plot of  $k_{\text{obsd}}(\text{fast})$  vs.  $[\text{NaI}]$  (Fig. 2) was linear, and the data were treated by the same method as in the case of bromide giving  $k_{\text{I}^-} = 4.5 \times 10^8 \text{ M}^{-1}\text{s}^{-1}$ ,  $k_{\text{ion}} = 9.5 \times 10^5 \text{ s}^{-1}$ , and  $K_{\text{eq}} = 474 \text{ mol/L}^{-1}$ . The much larger  $k_{\text{Nu}^-}$  and  $K_{\text{eq}}$  values observed for quenching with iodide relative to bromide are consistent with the much greater nucleophilicity of iodide in aqueous solution.

### Quenching by other anionic nucleophiles

LFP of **3** in aqueous solution containing sodium chloride, sodium fluoride, sodium acetate, or sodium azide gave only the transient assigned to **2**, which in all cases showed clean first-order decay kinetics at all nucleophile concentrations examined. The absence of equilibrium behaviour (as was observed in the presence of bromide and iodide) for these nucleophiles is consistent with their comparatively lower leaving-group ability. Thus, when these nucleophiles are employed,  $k_{\text{ion}}$  is negligibly small, and the rate data can be described in a much simpler way (i.e., eq. [4]). Quenching plots of  $k_{\text{obsd}}$  vs.  $[\text{Nu}]$  were constructed for each of these four nucleophiles (plots for  $\text{NaN}_3$  and  $\text{NaCl}$  are shown in Fig. 2), and bimolecular quenching rate constants were obtained and appear in Table 1.

$$[4] \quad k_{\text{obsd}} = k_{\text{Nu}^-}[\text{Nu}^-] + k_{\text{s}}$$

**Table 1.** Rate and equilibrium constants for the reaction of **2** with nucleophiles at 300 K. Errors in values are estimated to be  $\pm 10\%$ .

Nu <sup>-</sup>	$k_{\text{Nu}^-}$ (M <sup>-1</sup> s <sup>-1</sup> )	$k_{\text{ion}}$ (s <sup>-1</sup> )	$K_{\text{eq}}$ (mol/L <sup>-1</sup> )
Br <sup>-</sup>	$3.0 \times 10^7$	$4.8 \times 10^5$	62
I <sup>-</sup>	$4.5 \times 10^8$	$9.5 \times 10^5$	474
Cl <sup>-</sup>	$3.3 \times 10^6$	—	—
F <sup>-</sup>	$3.8 \times 10^5$	—	—
OAc <sup>-</sup>	$4.3 \times 10^5$	—	—
N <sub>3</sub> <sup>-</sup>	$9.2 \times 10^9$	—	—
H <sub>2</sub> O	$2.7 \times 10^5$ s <sup>-1</sup> (293 K)	—	—

The bimolecular rate constants obtained for the reaction of the 9-(4-methoxyphenyl)-9-fluorenyl cation (**2**) span more than four orders of magnitude on moving from the weakest anionic nucleophile employed (fluoride) to the strongest (azide). The large value of  $9.2 \times 10^9$  M<sup>-1</sup>s<sup>-1</sup> for the reaction of **2** with azide is of interest, since it is significantly larger than the values obtained for the reaction of azide with other related arylmethyl cations:  $k(\text{N}_3^-) = 6.3 \times 10^9$  M<sup>-1</sup>s<sup>-1</sup> for the anthylium ion,<sup>17</sup>  $k(\text{N}_3^-) = 1.7 \times 10^8$  M<sup>-1</sup>s<sup>-1</sup> for the 9-phenylxanthylum ion,<sup>17</sup> and  $k(\text{N}_3^-) = 4.1 \times 10^9$  M<sup>-1</sup>s<sup>-1</sup> for the trityl cation.<sup>16</sup> To estimate the rate constants of various nucleophiles with phenethyl cations, Richard et al. have employed the reaction of these cations with azide ions as a “clock” with the estimated value of  $5 \times 10^9$  M<sup>-1</sup>s<sup>-1</sup> used as an upper limit.<sup>18</sup> The value we have obtained for the reaction of **2** with azide is nearly double this assumed upper limit.

### Activation energy determination

The reaction rate,  $k_{\text{solv}}$ , of **2** with water was measured at a variety of temperatures, and an Arrhenius plot of  $\log k_{\text{solv}}$  vs.  $1/T$  was constructed (Fig. 4). A linear fit was obtained providing an activation energy of 5.4 kcal/mol.

### Discussion

Several triarylmethyl cations have been previously generated and studied using LFP, providing many systems for comparison with the present data. Perhaps the most relevant is the methoxytrityl cation **5**, which is structurally comparable to cation **2**, but does not contain a 4n ring. This cation has been studied using stopped flow<sup>19</sup> and LFP<sup>14</sup> techniques, and reacts with water (in 1:2 CH<sub>3</sub>CN/H<sub>2</sub>O) with a rate constant of  $1.4 \times 10^3$  s<sup>-1</sup>. While data in pure water are not available for this cation, moving to this solvent might be reasonably expected to increase the rate constant for the reaction of **5** with water by approximately 60%, just as it did for **2**, giving an estimated pseudo-first-order rate constant of  $\sim 2 \times 10^3$  s<sup>-1</sup>. Thus, the 4-methoxytrityl cation (**5**) is two full orders of magnitude less reactive toward water than is the fluorenyl cation (**2**). This comparison provides support for the notion that 9-fluorenyl cations, such as **1** and **2**, possess enhanced reactivity consistent with antiaromatic destabilization.

Direct comparison of the reactivities of **2** and **5** is complicated by the likelihood that the geometries of these cations are different, which introduces a steric component to the reactivity difference. Cation **2** likely has a more or less planar fluorenyl ring system with the 9-aryl group twisted out of the plane somewhat to relieve steric repulsion between the

1- and 8-fluorenyl hydrogens and the ortho hydrogens of the methoxyphenyl ring (Fig. 5).<sup>11</sup> Cation **5** is more likely to adopt a “paddlewheel” configuration, which might make the carbocation less sterically accessible, and thus less reactive toward nucleophiles. It is difficult to assess precisely how much of the reduced reactivity of **5** relative to **2** might result from steric differences, although a number of triaryl-methyl cations in which two rings are covalently bonded and thus constrained to be coplanar have been reported, and are available for comparison. The 9-(4'-methoxyphenyl)-9-xanthylum cation (**6**) is geometrically similar to **2**, but contains an aromatic central ring. Its reported reaction rate constant with water (in 1:4 CH<sub>3</sub>CN/water, 25 °C) of  $1.1 \times 10^1$  s<sup>-1</sup> is more than four orders of magnitude less than that of **2**.<sup>17</sup> Cation **7** has been generated in LFP experiments by Wan and co-workers,<sup>20</sup> and is a triarylmethyl cation related to **2** containing a central ring that is non-aromatic. This cation reacts very slowly with water (in 1:1 CH<sub>3</sub>CN/H<sub>2</sub>O) with a rate constant estimated to lie between  $10^0$  and  $10^{-2}$  s<sup>-1</sup>. The low value of the rate constant in this case might be partially rationalized by electron donation from the phenoxide ortho to the carbocation as is evident in resonance form **7b**, although the relative contribution of this resonance form is likely diminished by the expected twisting of the 9-aryl group out of the plane to relieve steric repulsion. It is clear from the examples of **6** and **7** that co-planarity of two aryl rings does not necessarily impart high reactivity to triarylmethyl cations, and that the reactivity is instead primarily a function of aromaticity and the ability of attached electron-donating groups to delocalize the charge. For this reason, we believe that the greatly increased reactivity of **2** relative to **5** is primarily due to antiaromatic character of the 4n central ring.

While **5** provides a natural basis for comparison of the reactivity of **2**, rate data for the reaction of **5** with other nucleophiles are not available. However, bimolecular rate constants for the reaction of the related trityl cation **8** with a wide variety of nucleophiles are available.<sup>16</sup> Reaction of **8** with water (in 1:2 CH<sub>3</sub>CN/H<sub>2</sub>O, 20 °C) occurs with a pseudo-first-order rate constant of  $1.50 \times 10^5$  s<sup>-1</sup>, a value that is approximately 100-fold faster than for **5**, a fact that can be almost entirely attributed to the absence of the stabilizing 4-methoxy group that is present only in **5**. Bimolecular rate constants for the reaction of **8** with several anionic nucleophiles also employed in the present work are available, including Br<sup>-</sup> ( $5 \times 10^6$  M<sup>-1</sup>s<sup>-1</sup>), Cl<sup>-</sup> ( $2.2 \times 10^6$  M<sup>-1</sup>s<sup>-1</sup>), F<sup>-</sup> ( $8.6 \times 10^5$  M<sup>-1</sup>s<sup>-1</sup>), AcO<sup>-</sup> ( $4 \times 10^5$  M<sup>-1</sup>s<sup>-1</sup>), and N<sub>3</sub><sup>-</sup> ( $4.1 \times 10^9$  M<sup>-1</sup>s<sup>-1</sup>).<sup>16</sup> The reaction rates of **8** with these nucleophiles are similar (within an order of magnitude) to those of **2** (Table 1). Because of the similarity in

**Fig. 4.** Arrhenius plot of the reaction of **2** with water.

the reactivity of **2** and **8**, and the fact that **8** is roughly 100 times more reactive than **5** (at least towards the reaction with water), we can estimate that the increase in reactivity due to the presence of the formally antiaromatic 4n ring in **2** is roughly the same as the increase in reactivity experienced on removing a stabilizing 4-methoxy group. In fact, comparison of the pseudo-first-order rate constants of water with “antiaromatic” 9-phenyl-9-fluorenyl cation (**9**) ( $1.50 \times 10^7 \text{ s}^{-1}$ )<sup>11</sup> with **8** ( $1.50 \times 10^5 \text{ s}^{-1}$ )<sup>16</sup> reveals the same 100-fold difference in rates. This rate enhancement of two orders of magnitude has been noted previously for solvolysis reactions involving 4n rings,<sup>11</sup> and we now show that this enhancement is general for nucleophilic reactions with rate constants spanning more than five orders of magnitude, and might be general for other reactions of 9-fluorenyl cations.

The rates for the reaction of nucleophiles with cation **2** are slightly higher than for cation **8** for all nucleophiles examined except for fluoride, for which the reaction with the trityl cation is roughly twice as fast as for reaction with **2**.<sup>16</sup> This anomaly might result from the different solvent systems used in the two studies. Fluoride is especially well-solvated by water, a fact that greatly reduces its nucleophilicity when dissolved in this solvent. The reaction of **2** with fluoride studied in this work employed pure water as the solvent, and the fluoride ions would be expected to enjoy maximum solvation, leading to relatively low observed rates. In the case of the reaction of **8** with fluoride, the sol-

**Fig. 5.** Anticipated geometries of cations **2** and **5**.<sup>11</sup>

vent system contained 20% acetonitrile, which may have been responsible for decreased solvation of the fluoride anions, increasing their nucleophilicity and hence reaction rate with **8**. A similar effect would be less noticeable for the other anions that are not solvated by water as strongly as fluoride.

## Conclusion

We report for the first time kinetic data for a 4n cation (**2**) in water with a comprehensive series of nucleophiles, which span more than five orders of magnitude of reactivity. In the case of iodide and bromide nucleophiles, equilibrium behaviour was observed and equilibrium constants were determined. Comparison of the obtained rate data with known systems allows us to generalize that the presence of the 4n ring increases the reaction rate constants towards nucleophilic attack by approximately two orders of magnitude relative to related systems that do not possess a 4n ring, regardless of the nucleophile used. This rate increase resulting from the 4n ring is essentially the same as that observed on removing a 4-methoxy group. The kinetic data measured in this work support the notion that 9-fluorenyl cations indeed have antiaromatic character.

## Experimental

### General

LFP data was obtained with a LuzChem mLFP-111 system employing an Excimer laser (Xe/HCl) that supplied 308 nm pulses attenuated to ~10 mJ/pulse. Solutions were not flowed and were purged with argon gas prior to irradiation. Solutions' concentrations were adjusted to an absorbance value of 0.4 units at the laser wavelength (308 nm) and a 10 mm cell was used. NMR spectra were recorded in CDCl<sub>3</sub> purchased from Norell Inc. and run on a Bruker AVANCE 300 spectrometer. UV-vis spectra were recorded using a CARY 100 spectrometer.

### Materials

All fine chemicals were purchased from Sigma-Aldrich and used as received. Solvents were purchased from Caledon and used as received except for THF, which was distilled from sodium.

### 9-(4-Methoxyphenyl)-9-fluorenone (3)

To 9-fluorenone (5.0 g) dissolved in 20 mL dry THF was added 2 equiv. of 4-methoxyphenylmagnesium bromide, and the mixture was stirred at room temperature for 4 h. The reaction was quenched by addition of water and extracted with 20 mL CH<sub>2</sub>Cl<sub>2</sub>. The organic layer was separated and dried with MgSO<sub>4</sub>, and the solvent was removed by rotary evaporation. Compound **2** was obtained as a slightly yellow solid in 33% yield after recrystallization from cyclohexane. Mp 76–88 °C (lit.<sup>21</sup> mp 85–86 °C). <sup>1</sup>H NMR (300 MHz, CDCl<sub>3</sub>) δ (ppm): 2.67 (br s, 1H, OH), 3.77 (s, 3H, OCH<sub>3</sub>), 6.82 (d, 2H), 7.23–7.42 (m, 8H), 7.68 (d, 2H). <sup>13</sup>C NMR (75 MHz, CDCl<sub>3</sub>) δ (ppm): 55.60, 83.76, 114.00, 120.47, 125.14, 127.04, 128.83, 129.41, 135.75, 139.90, 151.00, 159.18.

# Diffusion of oligomers in latex systems — A route to low volatile organic compound (VOC) coatings

David M. Fasano, Susan J. Fitzwater, Willie Lau, and Aurelia C. Sheppard

**Abstract:** We synthesize specially designed latex polymer systems by an in situ emulsion polymerization process that yields latex particles with both a high molecular weight polymer phase and a low molecular weight oligomer phase. The oligomer functions as a plasticizer by lowering the glass transition temperature ( $T_g$ ) of the polymer. A polymer system is prepared by blending soft latex and a hard latex where the hard mode consists of a hard, high molecular weight polymer and an oligomer, allowing for facile film formation at ambient conditions. Upon the soft and hard particles coming into contact during the film formation process, the oligomer preferentially diffuses from the hard polymer to the soft polymer, thus recovering the natural  $T_g$  of the hard polymer as described in a recent patent application. Oligomer diffusion allows a hard coalesced phase to be incorporated into a latex film without using a coalescing solvent, which would contribute to the volatile organic compound (VOC) content. A well-coalesced hard phase in a latex film contributes to a variety of desirable coatings properties, such as tack, print, block, and scrub resistance properties.

**Key words:** oligomers, diffusion, Designed Diffusion™ Technology, plasticization.

**Résumé :** On a effectué la synthèse de systèmes de polymères de latex conçus spécialement à cet effet en faisant appel à un processus de polymérisation en émulsion in situ qui conduit à la formation de particules de latex à la fois une phase de polymère de haut poids moléculaire et une phase d'oligomère de faible poids moléculaire. L'oligomère fonctionne comme plastifiant en réduisant la température de transition de verre ( $T_g$ ) du polymère. On prépare un système de polymère en procédant au mélange d'un latex mou et d'un latex dur dans lequel le mode dur est formé d'une polymère dur de poids moléculaire élevé et d'un oligomère qui permet de former facilement un film dans les conditions ambiantes. Lorsque les particules molles et dures viennent en contact durant le processus de formation du film, l'oligomère diffuse d'une façon préférentielle du polymère dur vers le polymère mou et il retrouve la  $T_g$  naturelle du polymère dur, tel que décrit dans une récente application pour un brevet. La diffusion de l'oligomère permet d'incorporer une phase dure ayant subi une coalescence d'être incorporée dans un film de latex sans utiliser de solvant de coalescence qui contribuerait à la teneur en composé organique volatil (COV). Une phase dure qui a subi une bonne coalescence dans un film de latex contribue à une variété de propriétés désirables des revêtements, telles que les propriétés résistance à la colle, à l'imprimerie, et au frotage.

**Mots-clés :** oligomère, diffusion, technologie Designed Diffusion™, plasticisation.

## Introduction

### Demand of low and no volatile organic compound (VOC) binders in latex paints

Water-borne latex coatings have been growing in popularity for decades as they offer performance, economic, and environmental advantages over solvent-borne coatings. Coatings contain a large number of ingredients that are designed to enhance their manufacture, storage, application, and final performance properties. One of the major ingredients in a typical architectural coatings formulation is the polymeric binder, which is responsible for forming the paint film and providing many of its final properties. Latex poly-

mers, aqueous dispersions of acrylic or vinyl polymer particles formed via emulsion polymerization, are the most commonly used binder polymers.

During the drying and curing process, the discrete polymer particles form a continuous film. Scheme 1 depicts the process of drying the latex polymer into a continuous film.<sup>1</sup> As water evaporates from the dispersion, polymer particles come into close contact with each other. Further drying results in the deformation of the particles increasing the contact surface between particles. The coalescing stage involves diffusion of the polymer chains across the particle boundaries, which results in a transparent and void-free polymer film. The diffusion of polymer chains across the particle

**Scheme 1.** Latex film formation process.

boundaries directly affects both the extent of entanglement of the chains between particles and the resulting mechanical properties of the final film.<sup>1</sup> It is during this coalescing and curing stage that VOC components in the paint formulation are released from the film.

A polymer designed for use in architectural coatings must have a desirable balance of properties, which are often associated with both soft (glass transition temperature ( $T_g$ ) < ambient temperature) and hard ( $T_g$  > ambient temperature) polymer characteristics. The final polymer film needs to be hard to provide properties such as nontackiness, resistance to dirt pick up, block, and print. However, the film formation process demands a softer system for adequate particle deformation and chain diffusion across the particle boundaries during drying. In addition, some properties, such as film toughness, require a balance of both soft and hard properties.

In the past, this balance has been achieved by incorporating a coalescing agent in the formulation.<sup>2</sup> Typical coalescents are low molecular weight solvents, which are miscible with the polymer. Texanol ester alcohol, [2,2,4-trimethyl-1,3-pentanediol mono(2-methylpropanoate)], and Dowanol DPnB, [dipropylene glycol *n*-butyl ether], are commonly used commercial coalescents in latex coatings formulations.

A coalescent temporarily suppresses the  $T_g$  of the polymer to ensure good film formation. Coalescents plasticize high-molecular-weight polymers by affecting intermolecular interactions and therefore, chain relaxation dynamics, decreasing the internal friction coefficient among polymer chains. Once the coating has dried and the film is fully coalesced, the coalescent evaporates, leaving a harder, more durable film. This drying-induced  $T_g$  transition allows the polymer to behave in a soft or hard manner as required during the application, drying, and curing stages of the coating.

Coalescents must have a sufficiently high vapor pressure so that they almost completely evaporate in hours to weeks after the coating application, returning the polymer to its natural  $T_g$ . Increasing concern about and regulatory pressure on volatile organic compounds (VOC) have led to the investigation of alternative approaches to achieving satisfactory film formation and ultimate film properties.

One approach is to use softer polymer compositions, which do not require high coalescent levels to form a satisfactory film. Although VOC can be quite low in such systems, the overall performance can be compromised by the softer polymer.

The use of hard-soft systems is another approach in obtaining adequate performance from low-VOC coatings. It is known that some hardness properties can be achieved by the presence of hard domains in the polymer film.<sup>3–5</sup> These hard domains in a polymer film can be derived from a phase separated system or through the blending of hard and soft latex particles. While these systems showed enhanced hardness

properties with low coalescent demand, they often compromise other performance properties. For example, while the blending of hard with soft latex can provide enhanced mechanical properties, such blends often have decreased binding capacity because the hard polymers behave more like pigments than binders. It is believed that the reduced binding capacity is due to the inadequate interaction of the hard and soft particles, since the hard polymer will not undergo chain diffusion during film formation under ambient conditions without added coalescent.<sup>6</sup> As a result, properties such as gloss, durability, and film integrity are often compromised when this type of heterogeneous polymer system is used to reduce the solvent demand, especially when additional pigments and extenders, such as titanium dioxide, clay, silica, and calcium carbonate, are also present in the formulation.

The objective of the research described here is to investigate a new approach to improve the performance of low VOC hard-soft blends, using oligomers as coalescing aids. Oligomers can suppress the  $T_g$  and film formation temperatures by behaving in a manner similar to coalescing solvents and plasticizers.<sup>7,8</sup> Further, by carefully controlling the composition of the polymer and oligomer phases, the oligomers can be designed to migrate from one polymer phase to another, thus providing the properties transition previously attained by evaporation of coalescing solvents.

### Oligomers

In general, polymers used as coatings binders are macromolecules having molecular weights ( $M_n$ ) of 10 000 or higher. The molecular weight of acrylic polymers prepared by emulsion polymerization can be upwards of 1 000 000. One of the key contributors to the mechanical properties of these polymers is derived from chain entanglement. For example, the average molecular weight between chain entanglements ( $M_e$ ) for poly(ethyl acrylate) and poly(*n*-butyl acrylate) were measured to be 11 000 and 16 000, respectively.<sup>9</sup> For a high molecular weight polymer, the multiple entanglements between the chains are directly related to the mechanical properties of the polymer.

Oligomers are macromolecules with molecular weights substantially below the respective entanglement molecular weights and carry a range of differentiated attributes compared to the equivalent composition at higher molecular weights. Most notable, and most useful in this application, is the capability in reducing the  $T_g$  of a high molecular weight polymer. In addition, for oligomers with molecular weights greater than 500, the room temperature evaporation rate is negligible and therefore these oligomers are not considered to be VOC.<sup>10</sup> This combination of properties allows low molecular weight oligomers to act as nonvolatile plasticizers in polymer systems.<sup>7,8</sup>

There is a broad range of oligomers being developed as

**Scheme 2.** Designed Diffusion<sup>TM</sup> in latex polymer systems.

intermediates in preparative polymer chemistry.<sup>11</sup> However, the utility of oligomers synthesized by emulsion polymerization has not been explored extensively due to the limitations of the synthetic method. The development of cyclodextrin as a chain transport catalyst enables the synthesis of a broad range of oligomer compositions and molecular weights.<sup>12</sup>

### Designed Diffusion<sup>TM</sup> Technology

This article describes a latex blend system (Scheme 2) in which the hard mode is plasticized by a carefully designed oligomer prepared in situ during emulsion polymerization. This plasticized hard mode is blended with a softer latex, which remains separate in the dispersion state until the drying stage. In this system, the oligomer is designed to be both an effective plasticizer for the hard polymer and to preferentially partition into the soft phase. As water evaporates, the hard and soft particles come into contact during the drying stage. The oligomer remains in the hard phase at this stage to facilitate coalescence. Chain entanglement can occur, which reinforces and strengthens the interfacial boundary between the particles. In a conventional system employing a coalescent that contributes to VOC, the polymer regains the intrinsic hardness when the volatile organic solvent evaporates after film formation. In the Designed Diffusion<sup>TM</sup> Technology systems, the hard polymer domains form when the oligomer diffuses from the coalesced hard particles into the softer continuous phase. In contrast to the conventional system, the oligomer remains in the film and does not contribute to the VOC level.

There are several key parameters that are critical in designing an effective system. These include (i) in situ preparation of the oligomer phase inside the hard mode; (ii) a molecular weight of oligomer that provides a sufficiently low  $T_g$  as well as facile diffusion in a mixed polymer system; (iii) a composition and molecular weight of oligomer that provides optimum plasticization and diffusion capability; and (iv) some minimum level of miscibility of oligomer in the hard phase and preferential miscibility in the soft phase to impact the direction of the diffusion during film formation process.

## Experimental section

### Materials

Butyl acrylate (BA), methyl methacrylate (MMA), and methacrylic acid (MAA) were commercial grade monomers used in latex products without further purification. Ammonium persulfate (APS), sodium carbonate ( $\text{Na}_2\text{CO}_3$ ), and *n*-dodecyl mercaptan (*n*-DDM) were purchased from Sigma-Aldrich and used as received. Methyl- $\beta$ -cyclodextrin (Me- $\beta$ -CD, Beta W7 M1.8) was supplied by Wacker Chemie AG as

a 50% solution in water. Sodium lauryl sulfate (SLS) and sodium dodecylbenzene sulfonate were supplied by the Stepan Company under the product name Polystep B-5 (28% solution) and Polystep A-16-22 (23% solution), respectively.

Materials used in paint formulations are as follows: Tamol 731A, Triton X-100, and Triton X-405 were obtained from the Dow Chemical Company; AMP-95 was obtained from the Angus Chemical Company; Nopco NDW was obtained from the Henkel Corporation; Ti-Pure R-706 was obtained from the E. I. du Pont de Nemours Company; and Natrosol 250 MR was obtained from Ashland Inc. and mixed with water to make a 2.5% solution.

All the polymer compositions are presented as weight percent of the monomer components. For example, 50 BA/49 MMA/1 MAA designates a polymer composition comprised of 50, 49, and 1 weight percent of BA, MMA, and MAA, respectively. The chain transfer agent (CTA) is presented as a part per 100 parts of the polymer in weight. 50 BA/49 MMA/1 MAA//11 *n*-DDM is comprised of 11 parts of *n*-DDM per 100 parts of the total polymer by weight. All the blend ratios are presented as parts by weight.

### Synthesis<sup>13,12b</sup>

#### Emulsion polymerization reaction vessel

The emulsion polymerizations were carried out in a four-neck 5 L round-bottom flask as the reaction vessel. The flask was fitted with a water-cooled reflux condenser with a nitrogen purge gas inlet, a thermocouple attached to a J-KEM Gemini temperature controller, and a glass stirring rod with a paddle connected to an IKA RW20 motor. The monomer emulsion (ME) and initiator were fed by a FMI QG-50 and Harvard syringe pump, respectively. The reaction mixture was heated using a heating mantle connected to a Variac voltage regulator. The temperature of the reaction mixture was regulated by raising and lowering the heating mantle placed on an I<sub>2</sub>R pot lifter connecting to the J-KEM temperature controller.

#### Synthesis of acrylic latex polymer

The monomer emulsion (ME) was prepared in a separate flask using a homogenizer. The ME for a 50 BA/49 MMA/1 MAA (weight percent) polymer was prepared by emulsification of a mixture of 735.0 g of deionized water, 16.8 g of SLS (28%), 936.0 g of BA, 917.5 MMA, and 18.7 g of MAA. The polymerization was carried out in the 5 L reaction vessel. Deionized water (853 g) and 16.8 g of SLS (28%) was added to the vessel and heated to 85 °C under a nitrogen sweep. At 85 °C, 6.3 g of APS in 26 g of water and 6.5 g of  $\text{Na}_2\text{CO}_3$  in 34 g of water were added to the reaction mixture. The ME was fed over

100 min together with an initiator solution consisting of 1.0 g of APS in 102.0 g of water. At the end of the ME feed, the reaction mixture was held at 85 °C for 20 min and cooled to room temperature. The latex was neutralized to pH 8.5 by ammonium hydroxide and filtered through a 325 mesh (45  $\mu\text{m}$ ) screen. The latex typically has a solids level of 50.0% and an average particle diameter between 100 and 130 nm.

### Synthesis of oligomeric latex

Latex polymers with different number average molecular weights ( $M_n$ ) were similarly prepared with a range of  $n$ -DDM levels. The monomer emulsion was prepared in a separate flask using a homogenizer to generate ME droplet size  $\sim 5$ –10  $\mu\text{m}$ . The ME for a 50 BA/49 MMA/1 MAA//11  $n$ -DDM (weight percent) polymer was prepared by emulsification of 735.0 g of deionized water, 16.8 g of SLS (28%), 936.0 g of BA, 917.5 g MMA, 18.7 g of MAA, and 205.9 g of  $n$ -DDM. Other molecular weight oligomer latices were prepared by adjusting the  $n$ -DDM levels in the ME accordingly. The polymerization was carried out in the 5 L reaction vessel. Deionized water (853.0 g), 16.8 g of SLS (28%), and 37.0 g of Me- $\beta$ -CD (50% solution) was added to the vessel and heated to 85 °C under a nitrogen sweep. At 85 °C, 6.3 g of APS in 26.0 g of water and 6.5 g of  $\text{Na}_2\text{CO}_3$  in 34.0 g of water were added to the reaction mixture. The ME was fed over 100 min together with an initiator solution consisting of 1.0 g of APS in 102.0 g of water. At the end of the ME feed, the reaction mixture was held at 85 °C for 20 min and cooled to room temperature. The latex was neutralized to pH 8.5 by ammonium hydroxide and filtered through a 325 mesh (45  $\mu\text{m}$ ) screen. The latex typically has a solids level of 50.0% and an average particle size of 115 nm.  $M_w$  and  $M_n$  were measured by size exclusion chromatography (SEC) to be 4060 and 3000, respectively. The  $T_g$  of the oligomer was measured by differential scanning calorimetry (DSC) to be  $-24.1$  °C.

### In situ synthesis of oligomers in high molecular latex particles

The oligomer is incorporated into a conventional latex particle by a two stage emulsion polymerization. The compositions of the oligomer and the high molecular weight polymer can be different, provided that the monomers and the high molecular weight polymer have sufficient miscibility. The two stage polymerization can be carried out by first polymerizing the high molecular weight polymer without  $n$ -DDM followed by the oligomer composition, or vice versa. There should be no new particles formed during the second stage polymerization. All of the oligomer was formed inside the polymer particles with the high molecular weight polymer.

A latex polymer with a higher molecular weight phase of 28 BA/71 MMA/1 MAA and an oligomer composition of 60 BA/39 MMA/1 MAA//17  $n$ -DDM was prepared with ingredients as shown in Table 1. Two monomer emulsions (ME) were prepared separately. The total monomers represent a 60/40 weight ratio of high molecular weight polymer to oligomer.

The polymerization was carried out in the 5 L reaction vessel. The reaction mixture was added to the vessel and heated to 85 °C under a nitrogen sweep. At 85 °C, 3.9 g of

**Table 1.** Ingredients for the in situ emulsion polymerization of oligomer in high molecular weight polymer particles.

Ingredients	ME I (g)	ME II (g)	Reaction mixture (g)
Deionized water	334.0	260.0	715.0
Polystep A-16-22	23.8	15.8	12.0
$\text{Na}_2\text{CO}_3$ /water			5.0/33.0
BA	247.0	353.5	
Me- $\beta$ -CD (50%)			29.4
MMA	625.0	229.0	
MAA	8.9	5.9	
$n$ -DDM		99.6	

**Note:** ME I produced the high molecular weight component and ME II produced the oligomer fraction in the polymer particle.

**Table 2.** UNIFAC group breakdowns for BA and MMA homopolymers.

Polymer	$-\text{CH}_3-$	$-\text{CH}_2-$	$-\text{CH}-$	$-\text{C}-$	$-\text{COO}-$
MMA <sup>a</sup>	2000	1000		1000	1000
BA <sup>b</sup>	781	3125	781		781

**Note:** The numbers in the table denote the total number of the chemical groups present in a 100 000 molecular weight homopolymers. For example, a 100 000 molecular weight MMA homopolymer contains 2000  $-\text{CH}_3$  moiety per chain.

<sup>a</sup>Methyl methacrylate homopolymer.

<sup>b</sup>Butyl acrylate homopolymer.

APS in 33.0 g of water was added to the reaction mixture. ME I was fed over 50 min together with an initiator solution consisting of 2.8 g of APS in 91.0 g of water. At the end of the ME I feed, ME feed was continued with ME II over 40 min. At the end of the ME feed, the reaction mixture was held at 85 °C for 20 min and cooled to room temperature. The latex was neutralized to pH 8.5 by ammonium hydroxide and filtered through a 325 mesh (45  $\mu\text{m}$ ) screen. Details of the characterization are included in the Results and discussion section.

### Characterization of latex particles

Particle size and size distribution were determined by capillary hydrodynamic fractionation (CHDF) using the CHDF-2000 particle size analyzer by Matec Applied Sciences. The calibration was carried out using particle size standards with diameters ranging between 40 and 800 nm. The samples were prepared by diluting two drops of the latex in 3 mL of carrier fluid. The solids content was determined gravimetrically.

### Characterization of latex polymers

#### Glass transition temperature

Glass transition temperature ( $T_g$ ) of the polymers was measured by differential scanning calorimetry (DSC). The measurement was performed on a TA model Q-2000 Auto DSC cooled by liquid nitrogen. Latex or blends of latex were air dried in DSC pans. Sufficient wet latex was added to the pan to yield 10–15 mg of dried polymer and oligomer in the pan. The pans were capped prior to running the DSC measurement. The test sample was equilibrated at  $-90$  °C for 2 min followed by heating at a rate of 20.0 °C/min to

150 °C. The Universal Analysis Software was used to determine the  $T_g$  at the inflection of the DSC curve.

### **Molecular weights and distributions**

Molecular weights and distributions were determined by size exclusion chromatography (SEC) in THF using an Agilent 1100 series instrument equipped with an evaporative light scattering detector and Polymer Laboratories mixed C 300 mm  $\times$  7.5 mm column. The calibration was carried out using polystyrene standards from Polymer Laboratories (PS-1) having a peak average molecular weight ranging from 580 to 7500,000 with narrow molecular weight distribution. Conversions from polystyrene to PMMA were made using Mark–Houwink constants.

### **Film morphology**

A Dimension 5000 scanning probe microscope (SPM; Veeco Instruments, Santa Barbara, CA) with a Nanoscope 4 controller was used for the analysis. The instrument was operated in the tapping mode to acquire phase and height images simultaneously. A silicon “TESP” probe (Veeco Instruments) with a spring constant of 20–80 N/m was operated near its fundamental harmonic frequency at approximately 300 kHz to collect the images. A setpoint of 0.80 was chosen to control the imaging force. Images and the analysis were carried out using Veeco Software, version 5.30.

Emulsion blend samples were casted onto a Mylar substrate and drawn into a film using a Bird applicator having a wet film thickness of 3 mil (3/1000 in; 1 in = 25.4 mm). The film was allowed to dry at room temperature and humidity for 5 d. Small 1/2 in<sup>2</sup> pieces were cut from the film. The pieces were mounted on SPM sample stubs and imaged under ambient conditions.

## **Modeling of miscibility and plasticization of oligomers**

### **Miscibility predictions**

Oligomer partitioning between phases was predicted from the condition that the oligomer chemical potentials in two phases must be equal at equilibrium:  $\mu(\text{phase 1}) = \mu(\text{phase 2})$ .

For phase separation predictions, phase #1 was defined as the hard phase and phase #2 as a small amount (<5%) of the total oligomer. These predictions are qualitative: they give an indication of potential phase separation problems but not a reliable quantitative estimate of the amount of phase separation. For the hard/soft partitioning predictions, phase #1 was defined as the hard phase and phase #2 as the soft phase. The partitioning predictions are at least semiquantitatively reliable.

For both types of predictions, we calculated oligomer chemical potentials using the universal functional activity coefficient (UNIFAC) method.<sup>12</sup> UNIFAC is a group contribution method. Each molecule is assumed to be composed of a series of chemical groups: methyl, methylene, carboxylate, etc. Table 2 shows the UNIFAC group breakdowns (group types and number of each) for 100 000 molecular weight MMA and BA homopolymers. UNIFAC assigns geometric and energetic parameters to each group, and combines these parameters to predict activities, activity coefficient, and chemical potential. UNIFAC accounts for

the effects of both molecular weight and chemistry upon mixing.

For the predictions described here, we used UNIFAC parameters for the aliphatic and carboxylic acid groups from 14a and the acrylic ester group (–COO–) parameters from 14b. We used the 14a parameters for the –CH<sub>2</sub>–O– group for the mercaptan –CH<sub>2</sub>–S– group. The ability to predict the preferential miscibility of oligomers is the critical link to the Designed Diffusion™ Technology.

### **Glass transition temperature ( $T_g$ ) predictions**

A mathematical model constructed by fitting measured  $T_g$ s of oligomers to the Fox equation was used to predict  $T_g$ s of oligomers and the mixed polymer systems. Table 3 compares model predictions with experimental  $T_g$ s for several oligomers.

### **Preparation of paints**

A typical aqueous semigloss trim formulation was used to prepare paints for testing of the polymer compositions. Paint formulation involves making a grind, which is a dispersion containing titanium dioxide and possibly other pigments and extenders. In this work, the only pigment used was titanium dioxide, which provides the hiding and gloss control of the paint film. An aqueous dispersion of the pigment is achieved by grinding the pigment under high shear using a Cowles mixer and appropriate wetting agents and dispersants. The rest of the formulation ingredients, referred to as the letdown, are mixed and added to the grind to form the aqueous coating compositions for the evaluation of the emulsion polymer examples. Tables 4 and 5 show the recipes for the grind and letdown used in this study. The paint is exemplified here for the case where the blend, latex I and II, contains soft phase particles and oligomer-modified hard phase particles. The final paint film upon drying contains 50.9% and 49.1% by weight of TiO<sub>2</sub> and polymer, respectively.

### **Testing of paints**

#### **Gloss**

A coating composition was drawn down on a Leneta chart (Leneta Company, Mahwah, NJ) using a 3 mil (3/1000 in; 1 in = 25.4 mm) Bird film applicator. The sample was dried at 24 °C and 50% relative humidity. Gloss (20° and 60°) was measured using a BYK-Gardner haze-gloss meter (BYK-Gardner, Columbia, MD). These gloss measurements follow guidelines established by the industry standards.<sup>5b</sup>

#### **Pendulum (Konig) hardness**

A coating composition was drawn down on an untreated aluminum panel using a 5 mil (5/1000 in) block applicator. The sample was dried at 24 °C and 50% relative humidity. Pendulum hardness was measured using a Byk Mallinckrodt König pendulum hardness tester (BYK-Gardner, Columbia, MD). The number of swings was multiplied by a factor of 1.4 s to obtain the pendulum hardness measured in seconds. Higher numbers reflect harder coatings.

#### **Zapon tack test**

A coating composition was drawn down on a Leneta chart

**Table 3.** Glass transition temperature (°C) comparison between DSC measurements (meas.) and the predictive model (pred.).

Compositions BA/MMA/MAA/ <i>n</i> -DDM <sup>a</sup>	<i>M<sub>n</sub></i>	<i>T<sub>g</sub></i> (meas.)	<i>T<sub>g</sub></i> (pred.)
98.5/0/1.5//15	2210	−71	−76
50/49/1//1	25200	14	12
50/49/1//4	6400	−2	9
50/49/1//11	2260	−48	−45
0/100/0//11	2250	29	31

<sup>a</sup>The compositions denote the weight percent of monomer in the polymer phase. The CTA (*n*-DDM) is expressed as parts per 100 parts of polymer in weight. For example, the polymer in row three has a composition of 50 BA/49 MMA/1 MM together with 4 parts of *n*-DDM per 100 parts of polymer to yield a polymer with a number average molecular weight (*M<sub>n</sub>*) of 6400.

<sup>a</sup>The ingredients of the letdown were mixed materials with a low shear mixer.

<sup>b</sup>Latex I is the soft phase with a composition of 60 BA/39 MMA/1 MAA (total solids at 50%).

<sup>c</sup>Latex II is the oligomer modified hard phase with the hard composition containing 60 parts by weight of high molecular weight polymer (28 BA/71 MMA/1 MAA) and 40 parts by weight of oligomer (60 BA/39 MMA/1 MAA//17 *n*-DDM) synthesized by in situ emulsion polymerization (total solids at 50%).

(Leneta Company, Mahwah, NJ) using a 3 mil (3/1000 in) Bird film applicator. The sample was dried at 24 °C and 50% relative humidity. Tack was measured using an aluminum tack tester shaped like a bent L. The bottom of the tester was wrapped in smooth Al foil. Different weights (up to 500 g) were placed on the bottom of the tack tester for 10 s. If upon removal of a given weight the tack tester releases completely from the film, the given weight is given as the tack result. The higher the weight given, the less tacky the film. The foiled bottom of the tester was cleaned

with alcohol after each test.<sup>15</sup> The tests were carried out after the films were dried for both 4 and 8 h.

### Finger tack

A coating composition was drawn down on a Leneta chart (Leneta Company, Mahwah, NJ) using a 3 mil (3/1000 in) Bird film applicator. The sample was dried at 24 °C and 50% relative humidity. Tack was estimated by placing a finger on the film. Tests were carried out after the films were dried for both 4 and 8 h.

**Scheme 3.** Chain transfer process in radical polymerization.**Print resistance**

This test measures the ability of the coating to resist the imprint of another surface placed on it (such as flower pots on window sills). A coating composition was drawn down on an untreated aluminum panel using a 5 mil (5/1000 in) block applicator. The sample was dried at 24 °C and 50% relative humidity for 7 d. A small section of the panel was cut out, placed in a 60 °C oven, covered with cheesecloth, and topped with a rubber stopper and a 500 g weight. After 60 min, the panel was removed from the oven, and allowed to cool before removing the cheesecloth and evaluating for print. A scale of 0 to 10 was used to rate the depth and amount of the impression of the cheesecloth pattern, which was left on the paint film surface.

**Block resistance**

This test measures the resistance of paint films to sticking when they are placed in contact with each other, such as from the closing of a freshly painted window or door. A coating composition was drawn down on a Leneta chart (Leneta Company, Mahwah, NJ) using a 3 mil (3/1000 in) Bird film applicator. The sample was dried at 24 °C and 50% relative humidity for both 1 and 7 d. Two equal small sections of the chart were cut out and placed together with the paint surface face to face, then topped with a rubber stopper and a 1000 g weight. After either 0.5 or 16 h, the weight was removed and the film sections were separated slowly with steady force. Samples were rated on a scale of 0 to 10 according to the noise produced upon separation of blocked surfaces and the physical damage caused by the separation of blocked surfaces.<sup>16</sup>

**Scrub resistance**

This test measures the resistance of paint films to erosion caused by scrubbing such as it may occur when a film is repeatedly scrubbed to remove stains. A coating composition was drawn down on a black vinyl chart from the Leneta Company using a 5 mil (5/1000 in) block applicator. The sample was dried at 24 °C and 50% relative humidity for 7 d. The paint film was scrubbed using an abrasion tester (machine washability) from BYK-Gardner and an abrasive scrub medium, type SC-2, from the Leneta Company, until a cut was observed, and the number of scrub cycles required to erode the paint film to the substrate was recorded.<sup>17</sup>

**Results and discussion****Synthesis**

The efficient and precise molecular weight control of the polymer has a direct impact on the plasticization and diffusion capability of the oligomer. Mercaptan is among the most commonly used chain transfer agents (CTA) in radical polymerization due to the facile abstraction of a hydrogen atom from the thiol moiety by a carbon centered radical, a

consequence of the relative C–H and S–H bond strengths (Scheme 3).<sup>18</sup>

*n*-Dodecyl mercaptan (*n*-DDM), a hydrophobic CTA with low water solubility, is the CTA of choice in emulsion polymerization.<sup>18a</sup> *n*-DDM is an effective chain transfer agent and partitions primarily into the organic phase due to its low solubility in water. Chain transfer is close to quantitative if *n*-DDM is present in the polymer phase (the site of the propagating radicals) during the polymerization. The quantitative consumption of *n*-DDM eliminates the unpleasant mercaptan odor in the latex. More hydrophilic mercaptans can partition into the water phase and create an odor issue in the final latex. In addition to the odor issue, CTA that partitions to the water phase does not participate in the chain transfer process since the propagating radicals are located in the polymer particles.

Although low levels of *n*-DDM (<0.5%) are commonly used in emulsion polymerization to control molecular weight and gel fraction, the use of high levels of *n*-DDM is impractical due to the poor diffusion between the monomer droplets and the polymer particles. This deficiency of hydrophobic CTAs is a consequence of the three phases present during an emulsion polymerization: the monomer droplets, the polymer particles, and the continuous water phase. The heterogeneous nature of emulsion polymerization requires the facile diffusion of molecules, monomers, and CTA, from the droplets, through the water phase, and into the polymer particles where the polymerization takes place. Adequate aqueous solubility of the monomer or CTA is essential for the diffusion process to occur effectively. Consequently, the use of high levels of *n*-DDM is not feasible due to its low water solubility. The solubility barrier can be overcome by the use of a catalytic level of cyclodextrin as a “phase transport catalyst”.<sup>12</sup> Cyclodextrin is capable of complexing hydrophobic molecules and rendering them water soluble. The complexation is reversible and the transport mechanism in emulsion polymerization is believed to involve a catalytic cycle in which the cyclodextrin continuously complexes the *n*-DDM molecules, transports them through the aqueous phase, and releases them to the polymer particles. This efficient transport allows the *n*-DDM to achieve a near quantitative chain transfer efficiency with a catalytic level of cyclodextrin (0.5 weight percent based on total monomer) in the reaction mixture (Scheme 4).

As the result of the quantitative chain transfer efficacy of *n*-DDM, molecular weight can be precisely controlled by the level of the CTA in the reaction mixture. For a quantitative chain transfer by CTA, (chain transfer constant (*C<sub>s</sub>*) = 1), every polymer chain is terminated by the abstraction of a hydrogen atom from the mercaptan and the resulting thio radical will start the propagation of another polymer chain. Table 6 shows molecular weights of several 50 BA /49 MMA /1 MAA latices prepared using a range of *n*-DDM levels in the presence of cyclodextrin to facilitate the *n*-DDM

**Scheme 4.** Cyclodextrin phase transport process of *n*-DDM (–SH) in emulsion polymerization. Note that the components of the scheme are for illustration and not drawn to scale. In the real system, the dimension of the monomer droplet, polymer particle, and cyclodextrin should be  $\sim 5\text{--}10\text{ }\mu\text{m}$ ,  $\sim 150\text{--}500\text{ nm}$ , and  $\sim 10\text{ }\text{\AA}$ , respectively.

transport. BA and MMA have adequate water solubility and will readily diffuse to the polymer particle.

The efficacy of chain transfer is close to quantitative as inferred from the linearity of the plot of  $M_n$  versus  $1/[n\text{-DDM}]$  (Fig. 1), a relationship as described by the Mayo equation.<sup>19</sup> In addition, all the latices have no mercaptan odor. With the low odor threshold of mercaptans, even low residual levels of mercaptan are noticeable and are not acceptable in commercial products. Without the cyclodextrin for the transport at high *n*-DDM levels sufficient to generate oligomer (see Table 6), the unreacted *n*-DDM stratified to the surface of the aqueous dispersion at the end of the polymerization. Consequently, the molecular weight was not controlled by the *n*-DDM levels.<sup>12a</sup>

Glass transition temperatures, as measured by DSC, drop precipitously for oligomers with  $M_n$  less than about 10 000, as shown in Fig. 2. Low oligomer  $T_g$  is essential for oligomers to function as effective plasticizers and to diffuse readily between polymer phases.

### Diffusion of oligomer

Effective diffusion of oligomers is the result of both thermodynamic and kinetic factors. Thermodynamically, oligomers will migrate to the more miscible phase. Kinetically, the molecular weight of the oligomers must be significantly below the entanglement molecular weight to allow diffusion to proceed under ambient conditions. Tomba et.al.<sup>20</sup> reported the diffusion of oligomers as a function of oligomer molecular weight by fluorescence resonance energy transfer (FRET). A high molecular weight acrylic latex was labeled with both a donor and an acceptor dye. When a donor located near an acceptor is irradiated, the excited donor can transfer part of the energy to the acceptor. The efficiency of the transfer, which can be derived from fluorescence decay measurements, is directly related to the distance between the donor and the acceptor.

The labeled latex was mixed with oligomer latices having a range of  $M_n$  between 2 400 and 139 000. The range is sufficiently broad to encompass molecular weights of oligomers through polymers. The mixed latices were dried and equilibrated under ambient conditions. If a significant amount of oligomer diffuses into the high molecular weight phase, then the total volume of the phase will increase. The volume increase results in an increase in the distance between the donor and the acceptor, which in turn reduces the amount of energy transfer. Figure 3 (from ref. 20) shows the quantum efficiency of energy transfer,  $\phi_{ET}$ , in the mixed la-

**Table 6.** Polymer molecular weights derived from CTA levels.

<i>n</i> -DDM (%) <sup>a</sup>	$T_g$ (°C)	P. S. (nm)	$M_w$ <sup>b</sup>	$M_n$ <sup>b</sup>
0.0	18.8	105	355 900	138 500

20	–47.7	128	2 840	2 360

<sup>a</sup>The parts of *n*-DDM are in 100 parts of the polymer composition by weight (50 BA/49 MMA/1 MAA/*x* *n*-DDM).

<sup>b</sup>Measured by size exclusion chromatography.

**Fig. 1.** Relationship between  $M_n$  and *n*-DDM levels. *n*-DDM concentrations are in parts per 100 parts of total monomer and  $M_n$  are measured by SEC.

**Fig. 2.** Relationship between glass transition temperature ( $T_g$ ) and  $M_n$ .

tex systems. Energy transfer in the mixed latex system after film formation was compared to that in a solvent cast film, where the high molecular weight polymer and the oligomer should be fully mixed. Tetrahydrofuran (THF) was chosen as it is a very effective solvent for acrylic polymers. As expected, the solvent cast film showed a substantial decrease in  $\phi_{ET}$  and no dependence on oligomer molecular weight. Conversely, the latex films showed an increase in  $\phi_{ET}$  with the oligomer molecular weight. The increase in  $\phi_{ET}$  corresponds to a reduction of the oligomer mixing into the high molecular weight polymer. The  $\phi_{ET}$  value for the 136 000 mol/L<sub>n</sub> oligomer approaches the  $\phi_{ET}$  value where no dilution of the labeled polymer phase had taken place. The result suggests that there is no kinetic barrier to oligomer diffusion for oligomers with  $M_n$  of about 2 400.

### In situ synthesis of oligomer modified latex particles

In situ synthesis of oligomers inside a normal latex particle is a two stage semicontinuous emulsion polymerization where the second stage monomer emulsion contains the CTA (*n*-DDM) with levels predetermined for the targeted molecular weight.<sup>12b</sup> The lifetime of a free radical propagating polymer chain is relatively short due to the facile termination. In a semicontinuous emulsion polymerization under steady state conditions, the instantaneous composition of the polymer formed is close to the monomer composition being fed to the reaction mixture. In the two stage polymerization depicted in Scheme 5, the second stage monomer emulsion contains the CTA (*n*-DDM) for oligomer synthesis. If the monomer and CTA of the second stage are miscible with the polymer phase in the particle and there is no barrier for diffusion between the droplet and the particles, the second stage polymerization with the CTA will occur in the already formed polymer particles, which contain the high molecule weight polymer prepared in the first stage forming a oligomer phase fully mixed with the first stage polymer.

The evidence for a successful in situ synthesis of oligomer in the high molecular weight phase includes (i) the absence of new particle formation with continuous particle growth of existing particles and (ii) the presence of high and low molecular weight polymers as determined by SEC.

The final particle size of the in situ two stage synthesized latex was measured by CHDF (Fig. 4) and found to have a unimodal distribution of particles centered at 114 nm with no detectable new particles of a different size.

Conversely, the SEC result (Fig. 5) shows a bimodal molecular weight distribution with the high molecular weight fraction centered around 334 000 ( $M_n$ ) and the low molecular fraction at around 3 500 ( $M_n$ ).

The plasticization effect of oligomers is shown by the  $T_g$  of the oligomer containing latex polymer. The two molecular weight fractions of the latex polymer have drastically different individual  $T_g$ s. However, there is only a single transition for the in situ oligomer containing latex polymer at a value between the  $T_g$ s of the two fractions. The result demonstrates the ability of the designed oligomer to be an effective plasticizer of the high molecular weight fraction (Table 7 and Fig. 6).

Collectively, the CHDF, SEC, and DSC results strongly support that the morphology of the particle depicted in

**Scheme 5.** In situ emulsion polymerization for oligomer modified latex particles.

**Fig. 3.** Quantum efficiency of energy transfer ( $\phi_{ET}$ ) showing the diffusion of oligomers at  $M_n$  2.4, 6.4, 11.3, and 136 K. The measurements were carried out with polymer film prepared from latex (■) and THF (□) solutions (reproduced with permission from 20).

Scheme 5 from the “in situ” two stage emulsion polymerization is such that both high molecular weight polymer and oligomer coexisted in an individual particle.

### Diffusion of oligomer

Our goal is to design an oligomer–polymer system where the oligomer is synthesized in a polymer phase and upon drying and film formation, diffuses to another polymer phase. The oligomer diffusion drives the desired  $T_g$  transition in the polymer phases. For the oligomer–polymer system to perform properly and bring value to a coatings system, it must meet several requirements: (i) The oligomer must be miscible in the hard phase. (ii) The oligomer must plasticize the hard phase, that is sufficiently decrease its  $T_g$ , to ensure good film formation. (iii) The oligomer must partition preferentially into the soft phase after the film has formed. (iv) The oligomer must diffuse from the hard to the soft phase over a time period of hours to a few days. (v) The  $T_g$  of the hard phase in the final equilibrated film must be high enough to enhance the performance of the polymer film.

**Fig. 4.** CHDF measurement of in situ oligomer modified latex particles.

**Fig. 5.** SEC determination of molecular weights and distribution of in situ oligomer modified latex particles.

**Table 7.** Glass transition temperature of single and polymer blends.

Composition	$M_n$	$T_g$ ( $^{\circ}\text{C}$ ) <sup>a</sup>
28 BA/71 MMA/1 MAA		54
80 BA/19 MMA/1 MAA//17 <i>n</i> -DDM	3000 <sup>b</sup>	-66
60 (28 BA/71 MMA/1 MAA)	<sup>c</sup>	10
40 (60 BA/39 MMA/1 MAA//17 <i>n</i> -DDM)		

<sup>a</sup>Measured by DSC (see Fig. 6).  
<sup>b</sup>Measured by size exclusion chromatography (the theoretical  $M_n$  based on 17 parts of *n*-DDM is ~2000).  
<sup>c</sup>Bimodal molecular weight distribution (see Fig. 5).

Oligomer composition and molecular weight must be balanced carefully to meet all of these requirements. The  $T_g$  of the oligomer modified hard mode depends on the oligomer molecular weight, composition, and the level of oligomer in the hard mode. Clearly, the above requirements of low hard phase  $T_g$  during film formation (2) and high final hard phase  $T_g$  (5) necessitate some compromise on oligomer molecular weight.

The following example is an illustration of a Designed Diffusion™ polymer system. The hard and soft modes are

defined as follows: the hard mode is 60 parts hard phase (28 BA/71 MMA/1 MAA)// and 40 parts oligomer (60 BA/39 MMA/1 MAA//17 *n*-DDM) and the soft mode is 60 BA/39 MMA/1 MAA.

The heterogeneous latex blend contains 18.3 parts by weight of hard mode (11 hard phase, 7.3 oligomer) and 81.7 parts by weight of soft mode. Since most of the oligomer must end up in the soft phase, we need an oligomer composition that is more similar to the soft phase composition compared to the hard phase. The  $T_g$  of the unmodified hard phase is ~56 °C, so a significant  $T_g$  decrease

**Fig. 6.** DSC with in situ oligomer containing latex polymer.**Fig. 7.** Predicted initial (■) and final (●) hard mode  $T_g$ s, and predicted percent of total oligomer in the hard phase (—), for 60 BA/39 MMA/1 MMA oligomers in 81.7 parts soft mode and 18.3 parts hard mode blend. Intersection of dotted lines indicate the oligomer  $M_n$ , which produces hard mode  $T_g = 0^\circ\text{C}$ .

is needed for good film formation. The soft oligomer designed to lower the  $T_g$  of the hard phase has to be compatible to the hard phase.

The miscibility model was used for the oligomer design. For the first evaluation, we chose oligomer #1 with composition of 60 BA/39 MMA/1 MAA, the same as the soft phase composition to ensure complete miscibility. In the phase separation calculation, 97.5% of the oligomer (39 out of 40 g) was allowed to mix into the hard phase. The model predicts about 87.5% (about 35 out of 40 g) mixes into the hard phase, largely independent of oligomer molecular weight over the range studied. This is an indication that there will be no serious phase separation problems.

Figure 7 shows the initial and final hard mode  $T_g$ s and the percent oligomer in the hard phase as a function of oligomer #1 molecular weight. If we want the hard mode to have an initial  $T_g$  of about  $0^\circ\text{C}$ , the oligomer molecular weight must be about 2000 mol/L<sub>n</sub>. At equilibrium, about 9% of the

**Fig. 8.** Predicted initial (■) and final (●) hard mode  $T_g$ s, and predicted percent of total oligomer in hard phase (—), for 80 BA/19 MMA/1 MMA oligomers in 81.7 parts soft mode and 18.3 parts hard mode blend. Intersection of dotted lines indicates the oligomer  $M_n$  which produces hard mode  $T_g = 0^\circ\text{C}$ .

oligomer will remain in the hard mode, and the final  $T_g$  will be about  $46^\circ\text{C}$ .

We can attempt to increase the final hard mode  $T_g$  by changing oligomer composition so that more of the oligomer partitions into the soft phase. For our second evaluation, we chose oligomer #2 with composition 80 BA/19 MMA/1 MAA. We ran the phase separation calculation as before. The model predicts that about 50%–85% of the oligomer mixes into the hard phase, depending on the oligomer molecular weight. This result is an indication that there may be significant phase separation problems at higher oligomer molecular weights.

Figure 8 shows the initial and final hard mode  $T_g$ s and the percent oligomer in the hard phase as a function of oligomer #2 molecular weight. If we want the hard mode to have an initial  $T_g$  of about  $0^\circ\text{C}$ , the oligomer molecular weight must be about 3000 mol/L<sub>n</sub>. At this  $M_n$ , the model predicts that about 75% of the oligomer mixes into the hard phase, so

**Table 8.**  $T_g$  transitions derived from oligomer diffusion. Blends are based on weight ratios of the hard and soft mode.

			50/50 Blend				80/20 Blend

Measured	10	4	29	−5	43	−7	50	−2

**Note:** The blends show two glass transition temperatures with  $T_g$  (1) and  $T_g$  (2) corresponding to the hard and soft mode, respectively.

<sup>a</sup>The oligomer modified hard mode (60 parts 28 BA/71 MMA/1 MAA and 40 parts 60 BA/39 MMA/1 MAA//17 *n*-DDM). The DSC measurement of 28 BA/71 MMA/1 MAA without the oligomer modification is 54 °C and predicted to be 56 °C.

<sup>b</sup>The soft mode (60 BA/39 MMA/1 MAA).

**Fig. 9.** SPM of polymer film of latex polymer blends. The soft mode is blended with (a) unmodified hard node and (b) oligomer modified hard mode.

there are probably no significant phase separation problems. At equilibrium, about 7.5% of the oligomer will remain in the hard mode, and the final  $T_g$  of the hard mode will be about 47 °C.

Oligomer #2 does not give a significantly higher final hard mode  $T_g$ , but does have a higher probability of oligomer phase separation from the hard phase. We could try an oligomer composition with less than 60% BA, but this would require a lower molecular weight to give less partitioning into the soft phase and potentially lower final hard mode  $T_g$ .

Based on the modeling results, oligomer #1 (60 BA/39 MMA/1 MAA//17 *n*-DDM) was selected for further experimental evaluation.

### Designed Diffusion™ of latex

Experimental evidence for the oligomer diffusion from the hard to the soft mode was obtained using two different methods: (i) monitoring changes in the film  $T_g$  under different drying conditions and (ii) measuring surface hardness using SPM analysis of the dried films.

### Evidence of diffusion by monitoring of changes in film $T_g$

DSC was used to verify the concept of oligomer diffusion. The hard mode consisting of the 28 BA/71 MMA/1 MAA polymer and 60 BA/39 MMA/1 MAA//17 *n*-DDM in situ

oligomer and the soft mode consisting of the 60 BA/39 MMA/1 MAA polymer were blended at 50/50 and 80/20 weight ratios of latices. The total solids weight ratios in the blends are similar since the latices are at the same solid levels. Films were cast and then dried under two conditions: (i) at room temperature for two days and (ii) heated at 60 °C overnight. As shown in Table 8, the  $T_g$  of the soft mode shifted to a lower temperature while the  $T_g$  of the hard mode shifted to a higher temperature in both blend systems. This result demonstrates that the oligomer diffused from the hard mode to the soft mode after film formation. The partitioning and  $T_g$  models predict the experimental  $T_g$  shifts reasonably well. The difference between the temperature shift between the two systems (room temperature and 60 °C) may be the result of accelerated diffusion kinetics at the elevated temperature or a difference in the equilibrium point at the two temperatures.

### Evidence of diffusion by SPM analysis of films

Figure 9 shows the SPM phase images for films cast from (a) the blend of the soft mode and the hard mode without oligomer (89.2/10.8 weight ratio) and (b) the blend of the soft mode with the oligomer-modified hard mode (82.1/17.9 weight ratio). In both blends, the amount of hard 28 BA/71 MMA/1 MAA phase is the same (10.8% on total polymer). Films were dried at room temperature for five days before

<sup>a</sup>The total weight percent of the hard phase (28 BA/71 MMA/1 MAA) in the polymer excluding oligomer.<sup>b</sup>Gloss (20° and 60°) of the paint film after drying in room temperature for 7 d.<sup>c</sup>Pendulum hardness of the paint film after drying in room temperature for 1 and 7 d.<sup>d</sup>The weight percent of Texanol, a coalescent, based on total weight of the polymer.

SPM analysis. The contrast in these images is due predominantly to differences in the modulus or  $T_g$  of the materials. The harder material appears brighter in the image. In the absence of oligomer, the small hard particles are well-differentiated and pack around the large soft particles (Fig. 9a). In the case of the hard phase containing the oligomer (Fig. 9b), there is a significant decrease in the observed boundaries between particles, indicating a high degree of hard mode coalescence. Additionally, it is observed that the soft mode is darker in the oligomer-containing system, indicating that the modulus of the soft phase has dropped as the result of diffusion of the oligomer from the hard mode to the soft mode. Film surface roughness and imperfections (voids, pitting) are also decreased for the film based on the oligomer-containing system, which should be expected to correlate well with an increase in film gloss.<sup>21</sup> Since the SPM scans were carried out on the natural surface of the films, we were not able to determine the continuity of either phase in the bulk films from these images.

### Coatings performance

Semigloss paints were formulated according to the method described in the Experimental section with several blends of hard mode and soft mode, as described in Table 9. The polymer in the formulation included blends of a soft mode (60 BA/39 MMA/1 MAA) and hard modes with and without oligomer modification. The target is a semigloss coatings formulation that delivers good gloss and hardness properties while maintaining good film formation without the need of a coalescent. In general, hardness properties in a polymer or paint film can be enhanced by the blending of hard particles or pigments into a soft polymer that have good film formation characteristics. However, this approach is limited to low levels in which film formation is not being compromised without the use of coalescent. Loss of gloss is a good indicator of poor film formation. Table 9 compares gloss for paints 1–4. Paint 1 and 2 are blends of the soft mode with unmodified hard mode while paint 3 and 4 contain the oligomer modified hard mode. As shown in Table 9, paints 1 and 2 have inferior gloss for a semigloss paint. Incorporating up to 20% coalescent (paint 2) did not show an improvement suggesting the hard mode is not coalescing into a good film at that level. Applying Design Diffusion technology to the blend, an oligomer modified hard mode (paint 3) shows a good balance of gloss and hardness, indicative of good film formation. At the same level of hard phase (10.7%) and without coalescent, the oligomer-based blend has comparable pendulum hardness while providing significantly better gloss over the nonoligomer blend control. The hardness of the oligomer containing system can be further enhanced without sacrificing the gloss by increasing the level of the hard phase (paint 4).

Additional testing on the paints showed that the tack, print, block, and scrub resistance properties of the oligomer-modified systems were similar to those of the blend control without oligomer. Thus, the benefits reaped from the Designed Diffusion<sup>TM</sup> system do not carry a negative impact in the overall balance of properties.

The concept of Designed Diffusion<sup>TM</sup> Technology involving carefully designed oligomer modification of polymer systems can also be applied to blend systems other than the

ones described in this report. Incorporation of reactive functionalities in the polymer or diffusing oligomer that is capable of reacting with other reactive sites during or after film formation is attractive as a way to further enhance the hardness and resistance properties of a coating and is being explored.

## Conclusion

Latex polymers made with in situ oligomer modification are shown to offer a unique balance of performance properties required to meet the regulatory and environmental demands of the coatings industry. These oligomers are designed to enhance both the soft and hard properties necessary in coatings. Key design factors include a molecular weight, which sufficiently lowers the  $T_g$  of the oligomer, and a composition, which ensures that the oligomer, while miscible with both a hard and a soft polymer phases, preferentially partitions to the soft phase after film formation. Careful design of the composition and molecular weight of the oligomer phase ensures that it will transport between hard and soft polymer phases to achieve both film formation and final performance properties. The concept has been demonstrated to be effective in coating systems and is being applied to other applications. Theoretical modeling was demonstrated to be a viable tool in the design stage.

## Acknowledgements

The authors thank those who contributed to this work: Mr. Daniel Werner for the synthesis of most of the polymers and oligomers used in these studies, Mr. Thomas Machamer for preparing and testing most of the paint formulations, Dr. Jin Lu for much of the DSC work and miscibility calculations with polymer and oligomer blends, Dr. Robert Antrim for the SPM analysis, and Dr. Kathleen Koziski and Dr. Matthew Gebhard who were research colleagues through parts of this work. Additionally, the authors thank the Dow Chemical Company for support and publication of this research. The authors are grateful for the wealth of knowledge on polymer diffusion from the work of Professor Mitchell Winnik at the University of Toronto. This work has benefited from many helpful discussions with Professor Winnik. We wished to congratulate Professor Winnik on this occasion with this paper as a token of our appreciation.

# A solvent-free protocol for the green synthesis of arylalkylidene rhodanines in a task-specific ionic liquid

Abdolhamid Alizadeh, Mohammad M. Khodaei, and Ali Eshghi

**Abstract:** 2-Hydroxyethylammonium formate acts as a task-specific ionic liquid (TSIL) for the Knoevenagel condensation of carbonyl compounds with rhodanine to afford arylalkylidene rhodanines under solvent-free conditions and in good-to-excellent yields. Additionally, compared with those in organic solvents, the yields obtained in the presence of our ionic liquid (IL) were significantly increased. The detailed mechanism of the catalytic effect of TSIL is also reported for the first time.

**Key words:** 2-Hydroxyethylammonium formate, task-specific ionic liquids (TSILs), Knoevenagel condensation, arylalkylidene rhodanines.

**Résumé :** Dans des conditions n'impliquant aucun solvant, le formiate de 2-hydroxyéthylammonium agit comme liquide ionique pour une tâche spécifique (LITS) pour la condensation de Knoevenagel des composés carbonylés avec la rhodanine qui conduit aux arylalkylidènes de rhodanine avec des rendements allant de bons à excellents. De plus, par comparaison avec les rendements obtenus dans des solvants organiques, ceux obtenus en présence de notre liquide ionique sont nettement plus élevés. On propose pour la première fois un mécanisme détaillé de l'effet catalytique du LITS.

**Mots-clés :** formiate de 2-hydroxyéthylammonium, liquide ionique pour une tâche spécifique (LITS), condensation de Knoevenagel, arylalkylidènes de rhodanine.

[Traduit par la Rédaction]

## Introduction

Rhodanine derivatives, especially arylalkylidene rhodanines (**I**) (Fig. 1), have proven to be attractive compounds because of their outstanding biological activities and have undergone rapid development as anticonvulsant, antibacterial, and anti-diabetic agents.<sup>1</sup> A series of arylalkylidene rhodanines have also been reported as Hepatitis C Virus (HCV) protease inhibitors (**II**)<sup>2</sup> (Fig. 1) or as novel inhibitors of UDP *N*-acetylmuramate/L-alanine ligase (**III**) (Fig. 1).<sup>3</sup>

For the preparation of 5-arylalkylidene rhodanines, various methods have been developed from acyclic building blocks or by functionalization of the thiazolone core.<sup>4</sup> In the second case, the Knoevenagel condensation of aldehydes at the nucleophilic C-5 position of rhodanine leads to the desired arylalkylidene rhodanine adducts. This reaction has been performed using sodium acetate in refluxing glacial acetic acid<sup>5a</sup> or piperidinium benzoate in refluxing toluene.<sup>5b</sup> Recently, Lee and Sim reported the synthesis of 5-arylalkylidene rhodanines by heating the reactants suspended in toluene at 110 °C for 3 days.<sup>6</sup> Also, Sing et al. reported the condensation of rhodanine with an aldehyde by heating in anhydrous EtOH for 6 h at 80 °C.<sup>7</sup>

The use of microwave irradiation (MW) as a clean and operationally simple technique has also been employed with

**Fig. 1.** Biologically active compounds bearing a 5-arylalkylidene rhodanine moiety.

solid inorganic support (Al<sub>2</sub>O<sub>3</sub> or montmorillonite KSF clay)<sup>8,9</sup> but without control of the reaction temperature. Recently, Zhou et al. reported the use of MW and tetrabutylammonium bromide (TBAB) as phase-transfer catalyst in water.<sup>10</sup> In addition, despite their promising biological features, the synthesis of ketone derivatives of arylalkylidene rhodanine adducts has not been subjected to detailed investigations, and only a 60-year-old study of Brown and co-workers has reported the Knoevenagel condensation reaction of rhodanine with ketones in the presence of ammonium hydroxide and ammonium chloride in refluxing ethanol.<sup>11</sup> Similar to most conventional chemical transformations, all of the above-mentioned procedures involve harsh reaction conditions, large quantities of toxic solvents, long reaction

**Scheme 1.** TSIL-catalyzed synthesis of 5-arylalkylidene rhodanines.

times, and unsatisfactory yields. Therefore, facile and green routes to arylalkylidene rhodanines would be of great interest.

Currently, ionic liquids (ILs) are being used as green solvents for laboratory as well as industrial use because of their desirable properties, such as good solvating ability, variable polarity, negligible vapor pressure, and ease of recyclability.<sup>12</sup> A literature survey revealed that ILs have not been utilized extensively for the Knoevenagel condensation of aldehydes or ketones with rhodanine, and only a study by Liu and co-workers utilizing a functionalized imidazolium-based IL has been reported.<sup>13</sup>

While considering ILs as reaction media and their use in industrial processes, one major concern is cost. The cost of the IL would be directly dependent on the price of the cations and anions that are used for their production.<sup>11</sup> Thus, the popular ILs incorporating expensive cations, such as alkyl methyl imidazolium and dialkyl imidazolium, are likely to remain expensive. Similarly, the anions that are frequently used in ILs, such as tetrafluoro borate and hexafluoro phosphate, are also expensive. This indicates that there is a need to develop and explore simple and cost-effective ILs.

Herein, we wish to report for the first time, a solvent-free and green procedure for the Knoevenagel condensation of aromatic aldehydes and ketones with rhodanine promoted with a low cost and task-specific IL (2-hydroxyethylammonium formate)<sup>14</sup> as an effective catalyst and reaction medium (Scheme 1).

To our knowledge, literature only shows one recent publication<sup>15</sup> related with the application of this new potential IL, but no further information is available about its application in chemical processes and organic syntheses. This IL can easily be synthesized from commercially available low cost chemicals (ethanolamine and formic acid) and has high conductivity and powerful solvating ability. Also, its low melting point ( $-82\text{ }^{\circ}\text{C}$ ) makes it an appropriate solvent for low temperature chemical transformations.

## Results and discussion

Our investigations on the Knoevenagel condensation reaction of rhodanine with carbonyl compounds began with the optimization of reaction conditions. Initially, the reaction of 1 mmol benzaldehyde with 1 mmol rhodanine in acetonitrile was tested in the absence of IL at room temperature. The reactants remained unchanged even after stirring for 20 h. Upon addition of only 1 mL of IL, condensation occurred and the reaction led to the desired product immediately after only 2 min in 94% yield without using any solvent or

catalyst at room temperature (Table 1, entry 1). Further increase in the reaction temperature did not result in a decrease in the reaction time or in an increase in the yield. Also, using 2 mmol of aldehyde (and 1 mmol of rhodanine) showed no change in the final product structure, and again, 5-benzylidene-2-thioxothiazolidine-4-one (Table 1, entry 1) was obtained as the final product.

Thus, under this optimized mild condition, various structurally diverse aromatic aldehydes and ketones were tested with rhodanine, and the corresponding results are listed in Tables 1 and 2.

As shown in Table 1, the aryl aldehydes bearing electron-releasing and electron-withdrawing groups are effective for the aforementioned reaction and gave the desired products in excellent yields in the reaction time ranging from 1 to 6 min. For instance, aryl aldehydes such as 4-nitrobenzaldehyde and 4-fluorobenzaldehyde required relatively short reaction times (Table 1, entries 4 and 6), and in contrast, aryl aldehydes with electron-releasing groups required nearly longer reaction times (Table 1, entries 11 and 13).

In examining the scope and generality of the developed protocol as well as the influence of structural variation of carbonyl compounds on their reactivity toward rhodanine enolate, we studied the Knoevenagel condensation reaction of rhodanine with ketones in the conditions similar to that of aldehydes. It was found that the reaction proceeds in a similar fashion to that of aryl aldehydes except that ketones undergo nucleophilic attack of rhodanine enolate more slowly with relatively low yields. Entries 1–4 in Table 2 show that both cyclic and acyclic ketones can react with rhodanine enolate. In contrast, any effort to obtain Knoevenagel condensation adducts from the reaction of rhodanine enolate with benzophenone, benzamide, and 2,4-dimethyl-3-pentanone (diisopropylketone) was unsuccessful. We believe that benzophenone and benzamide do not participate in the condensation, presumably because of the resonance of the carbonyl moiety with the phenyl groups and nitrogen lone-pair electrons. Also, diisopropylketone has a steric hindrance around the carbonyl group, and hence, it does not react with rhodanine. The results are listed in Table 2.

A control experiment was also allowed to proceed under the developed conditions utilizing 1 mL of TSIL, 1 mmol of *p*-methylbenzaldehyde, and 1 mmol of acetophenone to evaluate the chemoselectivity of the TSIL. It was found that in the presence of 1 mL of the IL, rhodanine only reacts with *p*-methylbenzaldehyde, which leads to the formation of 4-methylbenzylidene rhodanine as the final product, and no adduct was obtained from the condensation of rhodanine with ketone (Scheme 2).

The obtained results allow us to propose a tentative mechanism for the TSIL-catalyzed Knoevenagel condensation reaction of aldehydes and ketones with rhodanine as depicted in Scheme 3. The structure of the IL used in this study (2-hydroxyethylammonium formate) has a specific feature bearing both acidic and basic sites. We believe that the acidic part of the IL (ammonium moiety) protonates the oxygen of the carbonyl group; this is a very suitable condition in nucleophilic additions to carbonyl compounds. On the other hand, rhodanine is a CH-acidic nucleophile and the anionic part of the IL (formate anion) is basic and easily deprotonates rhodanine at the C-5 position and causes the

<sup>b</sup>NR: No reaction.

formation of nucleophilic rhodanine enolate. Subsequently, this enolate attacks the protonated aldehyde or ketone and gives an intermediate alcohol. Eventually, protonation of this alcohol, followed by a dehydration process, gives the desired products, recovered catalyst, and water as the only byproduct of the reaction.

The ionic liquid was recovered and reutilized four times without the addition of extra ionic liquid; the results are shown in Fig. 2.

In conclusion, we have described a general, environment-

friendly, solvent-free, and reagentless protocol for the preparation of a series of arylalkylidene rhodanine derivatives using 2-hydroxyethylammonium formate as a task-specific ionic liquid. The ease of preparation of the IL from commercially available low cost starting materials, its high conductivity, powerful solvating ability, and low melting point make it an appropriate solvent for room temperature reactions. Furthermore, this method is applicable to both electron-rich as well as electron-deficient aldehydes. In all cases, the reaction proceeds smoothly under very mild con-

**Scheme 2.** Comparison of the reactions of rhodanine with benzaldehyde and acetophenone in the presence of TSIL.

ditions without introducing any acid, base, or metal catalyst, and water is the only byproduct of the reaction. Compared with those obtained using traditional organic solvents, the

yields obtained in the presence of this TSIL are significantly increased. We believe that the low cost and the experimental simplicity of the method gives this green ionic-liquid-catalyzed procedure great potential, and it may find potential applications in synthetic organic chemistry, and more importantly, it can complement the existing chemical strategies.

## Experimental

All chemicals (ethanolamine, formic acid, rhodanine, aldehydes, and ketones) were reagent-grade materials, and they were used without further purification. Throughout all experiments, distilled water was used, and all the experiments were done at room temperature.  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra were recorded on a Bruker spectrometer operating at 200 and 50 MHz, respectively. Melting points were measured on a BI Branstead Electrothermal 9200 instrument and are uncorrected. FTIR spectra were recorded on a Rayleigh Wqf-510 spectrometer using a drop casting technique on KBr plates and are reported in wavenumbers ( $\text{cm}^{-1}$ ).

### Synthesis of arylalkylidene rhodanines: general procedure

Rhodanine (1 mmol) and 2-hydroxyethylammonium formate (1 mL) were mixed together and stirred at room temperature for 2 min after which 1 mmol of aromatic aldehyde or ketone was added to the reaction mixture. After completion of the reaction (monitored by TLC), a mixture of water and ethanol (50:50 v/v) was added to the reaction flask, and the obtained precipitates were easily filtered leading to the final pure products while no extra purification was needed. Evaporating the water of the filtrate gave the pure IL, which could be reused for further reactions. Selected characterization data for some of the arylalkylidene rhodanines prepared are given below.

# Feruloyl sucrose derivatives from *Bistorta manshuriensis*

Ki Hyun Kim, Sang Wook Chang, and Kang Ro Lee

**Abstract:** *Bistorta manshuriensis* is a well-known Korean medicinal plant traditionally used to treat diarrhea. Phytochemical investigation of the aerial parts of *B. manshuriensis* led to the isolation of two new feruloyl sucrose derivatives, bistoroside A (**1**) and bistoroside B (**2**), together with three known compounds, helonioside A (**3**), helonioside B (**4**), and smilaside L (**5**). The structures of the new compounds were elucidated as (3,6-di-*O*-*Z*-feruloyl)- $\beta$ -D-fructofuranosyl-(1 $\rightarrow$ 2)- $\alpha$ -D-glucopyranoside (**1**) and (3,6-di-*O*-*Z*-feruloyl)- $\beta$ -D-fructofuranosyl-(1 $\rightarrow$ 2)-(6'-*O*-acetyl)- $\alpha$ -D-glucopyranoside (**2**) on the basis of extensive analysis of 1D and 2D NMR (HMQC and HMBC), HR-FAB-MS, and chemical evidence.

**Key words:** *Bistorta manshuriensis*, Polygonaceae, feruloyl sucrose derivatives, bistoroside A, bistoroside B.

**Résumé :** La *Bistorta manshuriensis* est une plante médicinale coréenne bien connue pour le traitement traditionnel de la diarrhée. Une étude phytochimique des parties aériennes du *B. manshuriensis* a permis d'isoler deux nouveaux dérivés féruloyle du sucrose, le bistoroside A (**1**) et le bistoroside B (**2**) aux côtés de trois composés connus, l'hélonioside A (**3**), l'hélonioside B (**4**) et le smilaside L (**5**). En se basant sur des études extensives de RMN 1D et 2D, de spectrométrie de masse à haute résolution et bombardement avec des atomes rapides (SM-HR-BAR) et de données chimiques, on a établi que le composé **1** est le (3,6-di-*O*-*Z*-féruloyle)- $\beta$ -D-fructofuranosyl-(1 $\rightarrow$ 2)- $\alpha$ -D-glucopyranoside alors que le composé **2** est le (3,6-di-*O*-*Z*-féruloyle)- $\beta$ -D-fructofuranosyl-(1 $\rightarrow$ 2)-(6'-*O*-acétyl)- $\alpha$ -D-glucopyranoside.

**Mots-clés :** *Bistorta manshuriensis*, polygonacée, dérivés féruloyle du sucrose, bistoroside A, bistoroside B.

[Traduit par la Rédaction]

## Introduction

*Bistorta manshuriensis* KOM (Polygonaceae) (Korean name: Bum-ko-ri) is an erect perennial herb that is widely distributed throughout Korea.<sup>1</sup> The scientific name of this plant has also been used in China in combination with *Polygonum bistorta*. The rhizomes of *B. manshuriensis* have been used in traditional Korean medicine for the treatment of diarrhea.<sup>1</sup> In Chinese folk medicine, its rhizomes have been used to treat dysentery with bloody stools in acute gastroenteritis, acute respiratory infection, and venomous snake bite.<sup>2</sup> It has been reported that the crude extract of *P. bistorta* exhibits several potent pharmacological activities, including antibacterial, anti-inflammatory activities, and antimutagenic effect of 3-amino-1,4-dimethyl-5*H*-pyrido[4,3-*b*]indole (Trp-P-1).<sup>3–6</sup> Previous phytochemical investigation of *P. bistorta* revealed the presence of triterpenoids, flavones, coumarins, and phenolic acids.<sup>5–10</sup> Despite several studies on *P. bistorta*, little is known about the phytochemical constituents of *B. manshuriensis*. Therefore, as a part of our continuing search for novel secondary metabolites from Korean medicinal plants, we investigated the constituents of the aerial parts of *B. manshuriensis* and isolated cerebroside, flavonoids, and phenolic constituents from this source.<sup>11</sup> Herein, we report the further isolation and struc-

ture elucidation of two new feruloyl sucrose derivatives, bistoroside A (**1**) and bistoroside B (**2**), as well as three previously reported compounds, helonioside A (**3**), helonioside B (**4**), and smilaside L (**5**).

## Results and discussion

The EtOAc-soluble portion of the 80% MeOH extract of the aerial parts of *B. manshuriensis* was subjected to repeated column chromatography on silica gel to afford two new feruloyl sucrose derivatives (**1–2**), together with three known compounds (**3–5**) (Fig. 1). Their structures were elucidated by 1D and 2D NMR, HR-FAB-MS, and comparison with published data.

Bistoroside A (**1**) was isolated as a yellowish gum with a molecular formula of C<sub>32</sub>H<sub>38</sub>O<sub>17</sub> on the basis of the [M + H]<sup>+</sup> peak at *m/z* 695.2180 (calcd. for C<sub>32</sub>H<sub>39</sub>O<sub>17</sub>: 695.2187) in the HR-FAB-MS. Its IR and UV spectra displayed absorption bands for the hydroxyl and  $\alpha,\beta$ -unsaturated aromatic ester groups. The <sup>1</sup>H NMR spectrum (Table 1) of **1** showed two pairs of olefinic protons at  $\delta$  6.92 and 5.90 (each 1H, d, *J* = 13.0 Hz, H-7'', 8''), 6.89 and 5.83 (each 1H, d, *J* = 13.0 Hz, H-7''', 8'''), and two aromatic moieties with ABX coupling patterns at  $\delta$  6.82 (d, *J* = 8.5 Hz, H-5''), 7.16 (dd, *J* = 8.5, 2.0 Hz, H-6''), and 7.83 (d, *J* = 2.0 Hz, H-2'') and at  $\delta$  6.78 (d, *J* = 8.5 Hz, H-5'''), 7.13 (dd, *J* = 8.5,

**Fig. 1.** Chemical structures of compounds **1**–**5**.

2.0 Hz, H-6'''), and 7.83 (d,  $J = 2.0$  Hz, H-2'''). The coupling constant (13.0 Hz) of the proton signals at  $\delta$  6.92/5.90 and 6.89/5.83 suggested the presence of two pairs of *cis*-olefinic protons.<sup>12</sup> The above <sup>1</sup>H NMR data, along with two methoxy groups at the aromatic moieties as determined from the HMBC spectrum, indicated the presence of two *cis*-feruloyl units in **1**.<sup>13</sup> In addition, signals for eight oxygenated methines at  $\delta$  5.47 (d,  $J = 8.0$  Hz, H-3), 4.42 (t,  $J = 7.0$  Hz, H-4), 4.16 (m, H-5), 5.42 (d,  $J = 4.0$  Hz, H-1'), 3.42 (dd,  $J = 10.0$ , 4.0 Hz, H-2'), 3.67 (t,  $J = 10.0$  Hz, H-3'), 3.40 (t,  $J = 10.0$  Hz, H-4'), and 3.95 (m, H-5'), three oxygenated methylenes at  $\delta$  3.60 and 3.65 (each 1H, d,  $J = 12.0$  Hz, H-1), 4.48 (dd,  $J = 12.0$ , 4.0 Hz, H-6a), 4.54 (dd,  $J = 12.0$ , 7.0 Hz, H-6b), 3.78 (dd,  $J = 12.0$ , 6.0 Hz, H-6'a), and 3.91 (dd,  $J = 12.0$ , 2.5 Hz, H-6'b) were observed in the <sup>1</sup>H NMR spectrum. A characteristic anomeric signal at  $\delta$  5.42 with a small coupling constant (d,  $J = 4.0$  Hz, H-1'), together with 12 oxygenated carbon signals containing two anomeric carbons ( $\delta$  105.1 and 93.3) in the <sup>13</sup>C NMR spectrum, suggested that **1** possessed a disaccharide moiety. Alkaline hydrolysis of **1** gave methyl (*Z*)-ferulate,<sup>13</sup> together with sucrose [ $\alpha$ -D-Glc-(1→2)- $\beta$ -D-Fru], which was confirmed by HMBC analysis indicating linkage of the two sugars and by comparing HPLC and optical rotation data with those of an authentic sample.<sup>14</sup> On further inspection of the HMBC spectrum, each (*Z*)-feruloyl moiety at C-3 and at C-6 in fructose (Fru) could be assigned unambiguously. The correlations between H-3 ( $\delta$  5.47) and H-6 ( $\delta$  4.48 and 4.54) of fructose and the corresponding carbonyl carbons ( $\delta$  168.3 and 168.4) of (*Z*)-ferulate were observed in the HMBC spectrum, respectively (Fig. 2). Thus, the structure of **1** was determined as (3,6-di-*O*-*Z*-feruloyl)- $\beta$ -D-fructofuranosyl-(1→2)- $\alpha$ -D-glucopyranoside, and it was named bistoroside A (Fig. 1).

Bistoroside B (**2**) was isolated as a yellowish gum. Its molecular formula was determined as C<sub>34</sub>H<sub>40</sub>O<sub>18</sub> from the [M + H]<sup>+</sup> peak at  $m/z$  737.2298 (calcd. for C<sub>34</sub>H<sub>41</sub>O<sub>18</sub>: 737.2293) in the HR-FAB-MS spectrum. The <sup>1</sup>H and <sup>13</sup>C NMR spectra of **2** were almost identical to those of **1** (Table 1), except for the presence of an acetyl group signal. This indicated that **2** possessed a structure similar to **1**, con-

taining glucose (Glc) and fructose (Fru) units, two (*Z*)-feruloyl moieties, and one additional acetyl group. Acetylation of **2** yielded an octaacetate (**2a**) identical to that obtained from acetylation of **1**, indicating that the two (*Z*)-feruloyl moieties were located at C-3 and C-6 of the fructose unit in **2**, as in the structure of **1**. In the <sup>1</sup>H and <sup>13</sup>C NMR spectra of **2**, the signals of H-6' and C-6' in **2** were shifted to lower field ( $\delta$  4.13,  $\delta$  4.48, and  $\delta$  65.5 for **2**;  $\delta$  3.78,  $\delta$  3.91, and  $\delta$  62.6 for **1**), while that of C-5' was shifted to higher field ( $\delta$  71.7 for **2**;  $\delta$  74.5 for **1**) when comparing the NMR spectra of **1** and **2**. This supported the assignment of the acetyl group at C-6' of glucose. The HMBC experiment of **2** displayed correlations between the protons at  $\delta$  4.13 and 4.48 (H-6' of Glc) and the carbonyl carbon at  $\delta$  172.5, confirming that the acetyl group was located at C-6' of Glc. On the basis of this evidence, the structure of **2** was determined as (3,6-di-*O*-*Z*-feruloyl)- $\beta$ -D-fructofuranosyl-(1→2)-(6'-*O*-acetyl)- $\alpha$ -D-glucopyranoside, and it was named bistoroside B (Fig. 1).

Three other known compounds obtained in this investigation were identified as helonioside A (**3**),<sup>14</sup> helonioside B (**4**),<sup>14</sup> and smilaside L (**5**)<sup>15</sup> by comparison of their spectroscopic data with those published in the literature (Fig. 1). Although several sucrose phenylpropanoid esters have previously been isolated from *Polygonum* sp.,<sup>16</sup> this is the first report of compounds from this class being isolated from a medicinal plant from the genus *Bistorta*.

## Experimental

### General experimental procedures

Optical rotations were measured on a Jasco P-1020 polarimeter in MeOH. IR spectra were recorded on a Bruker IFS-66/S FTIR spectrometer. UV spectra were recorded with a Shimadzu UV-1601 UV-vis spectrophotometer. FAB and HR-FAB mass spectra were obtained on a JEOL JMS700 mass spectrometer. NMR spectra, including <sup>1</sup>H-<sup>1</sup>H COSY, HMQC, and HMBC experiments, were recorded on a Varian UNITY INOVA 500 NMR spectrometer operating at 500 MHz (<sup>1</sup>H) and 125 MHz (<sup>13</sup>C) with chemical shifts given in ppm ( $\delta$ ). Preparative HPLC was conducted using a

Gilson 306 pump with Shodex refractive-index detector and Apollo Silica 5 μm column (250 × 10 mm). Silica gel 60 (Merck, 70–230 mesh and 230–400 mesh) and RP-C<sub>18</sub> silica gel (Merck, 230–400 mesh) were used for column chromatography. The packing material for molecular-sieve column chromatography was Sephadex LH-20 (Pharmacia Co.). Low pressure liquid chromatography was carried out over a LiChroprep Lobar®-A RP-18 (240 × 10 mm) column with a FMI QSY-0 pump (ISCO). Merck precoated Silica gel F<sub>254</sub> plates and RP-18 F<sub>254s</sub> plates were used for TLC. Spots were detected on TLC under UV light or by heating after spraying with 10% H<sub>2</sub>SO<sub>4</sub> in C<sub>2</sub>H<sub>5</sub>OH (v/v).

**Plant material**

The aerial parts of *B. manshuriensis* (2.9 kg) were collected from Mount Daeduk, Gangwon Province, Korea, in June 2008. The plants were authenticated by one of the au-

thors (K.R.L.). A voucher specimen (SKKU-2008-6) of the plant was deposited in the herbarium of the School of Pharmacy, Sungkyunkwan University, Suwon, Korea.

### Extraction and isolation

The dried aerial parts of *B. manshuriensis* (2.9 kg) were extracted three times at room temperature with 80% MeOH over a period of 3 days and evaporated under reduced pressure to give a crude extract (219 g). The crude extract was dissolved in distilled water (800 mL) and successively extracted with *n*-hexane, CH<sub>2</sub>Cl<sub>2</sub>, EtOAc, and *n*-BuOH to provide *n*-hexane (10 g), CH<sub>2</sub>Cl<sub>2</sub> (2 g), EtOAc (9 g), and *n*-BuOH extracts (32 g). The EtOAc-soluble extract (9 g) was subjected to normal-phase column chromatography (CC) over silica gel using CHCl<sub>3</sub>/MeOH of increasing polarity (7:1 to 1:1) to give six fractions (E1–E6). Fraction E2 (1.1 g) was subjected to reversed-phase column chromatography over an RP-C<sub>18</sub> silica gel using MeOH/H<sub>2</sub>O (3:2) to provide five subfractions (E21–E25). Subfraction E21 (220 mg) was chromatographed on LiChroprep Lobar®-A RP-18 using MeOH/H<sub>2</sub>O (1:1) to give four subfractions (E211–E214). Subfraction E213 (45 mg) was separated on Sephadex LH-20 column using 100% MeOH to yield bistoroside A (**1**, 8 mg) and helonioside A (**3**, 5 mg). Subfraction E22 (130 mg) was subjected to LiChroprep Lobar®-A RP-18 column using MeOH/H<sub>2</sub>O (7:3) to afford three subfractions (E221–E223). Subfraction E223 (52 mg) was separated by preparative normal-phase HPLC using a solvent system of CHCl<sub>3</sub>/MeOH (6:1) over 30 min at a flow rate of 2.0 mL/min to obtain bistoroside B (**2**, 26 mg) and helonioside B (**4**, 5 mg). Subfraction E23 (150 mg) was separated over LiChroprep Lobar®-A RP-18 column using MeOH/H<sub>2</sub>O (1:1) to afford smilaside L (**5**, 8 mg).

### Bistoroside A (1)

Yellowish gum.  $[\alpha]_D^{25} - 6.5$  (*c* 0.25, MeOH). UV  $\lambda_{\max}$  (MeOH) nm: 326, 299 (sh), 235, 217. IR (KBr)  $\nu_{\max}$ : 3354, 2945, 2833, 1699, 1453, 1597, 1278, 1030 cm<sup>-1</sup>. <sup>1</sup>H (500 MHz) and <sup>13</sup>C (125 MHz) NMR data: see Table 1. HR-FAB-MS *m/z*: 695.2180 [M + H]<sup>+</sup> (calcd. for C<sub>32</sub>H<sub>39</sub>O<sub>17</sub>: 695.2187).

### Bistoroside B (2)

Yellowish gum.  $[\alpha]_D^{25} - 4.7$  (*c* 0.65, MeOH). UV  $\lambda_{\max}$  (MeOH) nm: 327, 299 (sh), 235, 218. IR (KBr)  $\nu_{\max}$ : 3357, 2945, 2833, 1701, 1598, 1518, 1453, 1278, 1121, 1029 cm<sup>-1</sup>. <sup>1</sup>H (500 MHz) and <sup>13</sup>C (125 MHz) NMR data: see Table 1. HR-FAB-MS *m/z*: 737.2298 [M + H]<sup>+</sup> (calcd. for C<sub>34</sub>H<sub>41</sub>O<sub>18</sub>: 737.2293).

### Alkaline hydrolysis of 1 and 2

Compounds (**1**: 2.5 mg and **2**: 6.0 mg) were hydrolyzed with 3% KOH/MeOH (3 mL) at room temperature for 15 min. The reaction mixture was neutralized with 2N HCl (monitored with indicator paper) and filtered. The filtrate was concentrated under reduced pressure to give a residue that was chromatographed over Sephadex LH-20 (100% MeOH) and preparative normal-phase HPLC (CHCl<sub>3</sub>/MeOH/H<sub>2</sub>O, 9:7:1.5) to afford methyl (Z)-ferulate<sup>13</sup> (0.3 mg from **1**; 1.2 mg from **2**) and sucrose (0.8 mg from **1**; 2.7 mg from **2**). The sucrose was identified by comparison of its optical

rotation value,  $[\alpha]_D^{25} + 26.6$  (*c* 0.15, MeOH) with that of an authentic sample<sup>14</sup> and by co-TLC comparison with an authentic sample (CHCl<sub>3</sub>/MeOH/H<sub>2</sub>O, 9:7:1.5; *R<sub>f</sub>* = 0.31). The sucrose was detected by co-injection of an authentic sample on preparative normal-phase HPLC using a solvent system of CHCl<sub>3</sub>/MeOH/H<sub>2</sub>O (9:7:1.5) at a flow rate of 2.0 mL/min in the same manner above, giving a single peak at 11.03 min.

### Acetylation of 1 and 2

To each compound (**1**: 3.0 mg; **2**: 3.0 mg) mixed with pyridine (1 mL), acetic anhydride (1 mL) was added. Each solution was stirred at room temperature for 24 h. Each reaction solution was extracted with CHCl<sub>3</sub> three times to give each octaacetate, which was purified by a silica gel Waters Sep-Pak® Vac 6cc (hexane/EtOAc, 5:1). Octaacetate of **1** (**1a**): colorless gum. FAB-MS *m/z*: 1031 [M + H]<sup>+</sup>. <sup>1</sup>H NMR (CDCl<sub>3</sub>, 500 MHz)  $\delta$ : 7.93, 7.91 (1H each, d, *J* = 2.0 Hz, H-2'', H-2'''), 7.34–7.10 (4H, m, H-5'', H-5''', H-6'', H-6'''), 7.02, 6.97 (1H each, d, *J* = 13.0 Hz, H-7'', H-7'''), 5.95, 5.88 (1H each, d, *J* = 13.0 Hz, H-8'', H-8'''), 5.71 (1H, d, *J* = 3.5 Hz, H-1'), 5.63 (1H, d, *J* = 6.0 Hz, H-3), 5.55 (1H, t, *J* = 6.0 Hz, H-4), 5.45 (1H, t, *J* = 9.5 Hz, H-3'), 5.01 (1H, t, *J* = 9.5 Hz, H-4'), 4.90 (1H, dd, *J* = 9.5, 3.5 Hz, H-2'), 4.40, 4.17 (1H each, d, *J* = 12.0 Hz, H<sub>2</sub>-1), 4.55–4.15 (6H, m, H-5, H<sub>2</sub>-6, H-5', H<sub>2</sub>-6'), 3.91, 3.88 (3H each, s, OCH<sub>3</sub>), 2.30, 2.28 (3H each, s, OAc  $\times$  2), 2.13, 2.12, 2.10, 2.05, 1.97, 1.81 (3H each, s, OAc  $\times$  6). Octaacetate of **2** (**2a**) was identical to **1a** in terms of <sup>1</sup>H NMR and TLC.

# Interactions of cytidine with N<sup>2</sup>-functionalized guanosines and cytidine–cytidine exchange involving a GC pair — NMR and fluorescence spectroscopic study

Sanela Martić, Gang Wu, and Suning Wang

**Abstract:** Two N<sup>2</sup>-functionalized guanosines by diphenylaminobiphenyl and di(2-pyridyl)aminobiphenyl have been found to act as the effective probes for G–C interactions in organic media. Because of the highly emissive nature of the N<sup>2</sup>-functionalized guanosines in the visible region, the GC base pair formation event accompanied by distinct fluorescence quenching can be readily monitored by fluorescence spectroscopy. NMR and fluorescence results confirm that the N<sup>2</sup>-arylguanosines form H-bonded pairs with cytidine, selectively. An unusual exchange pathway between non-bound cytidine and bound cytidine, in the GC pair, has been identified and extensively studied by NMR methods.

**Key words:** N<sup>2</sup>-guanosine, GC pair and cytidine exchange, fluorescence, NMR, hydrogen bonding.

**Résumé :** On a trouvé que deux guanosines fonctionnalisées en N<sup>2</sup> par des groupes diphénylaminobiphényle et di(2-pyridyl)aminobiphényle peuvent agir comme sondes efficaces pour les interactions G–C dans des milieux organiques. En raison du grand pouvoir émetteur des guanosines fonctionnalisées en N<sup>2</sup> dans la région visible, il est très facile par le biais de la spectroscopie de fluorescence de détecter la fluorescence distincte de piégeage qui accompagne la formation d'une paire de base GC. Les résultats de la RMN et de la fluorescence confirment que les N<sup>2</sup>-arylguanosines forment sélectivement des paires avec la cytidine, par le biais de liaisons hydrogènes. Faisant appel à des études par RMN, on a identifié et étudié une voie d'échange inhabituelle entre la cytidine non liée et la cytidine liée, dans la paire GC.

**Mots-clés :** N<sup>2</sup>-guanosine, paire GC, échange de cytidine, fluorescence, RMN, liaison hydrogène.

## Introduction

Among the nucleobases, guanine displays the most versatile H-bonding patterns, including Hoogsteen or Watson–Crick interactions, or combination thereof, and is thus a valuable building block in supramolecular chemistry.<sup>1</sup> In addition, the hydrogen-bonding motifs of guanine, such as G-quartets, are also known to have important and unique biological functions.<sup>2</sup> Hence, developing new functionalized guanosines to facilitate the study of various H-bonding patterns and self-assembled structures involving guanine has been a very active research area. We have shown recently that the attachment of an aryl group, such as a non-emissive *n*-butylphenyl group, at the N<sup>2</sup> site of the guanosine does not disrupt the formation of G-quartet and G-octamer via H-bonds in the presence of alkaline or alkaline-earth metal ions.<sup>3</sup> Building on this knowledge, we have reported recently a class of new luminescent hydrophilic N<sup>2</sup>-arylguanosines including **G1** and **G2** shown in Chart 1.<sup>4</sup> Because of the highly emissive nature of the N<sup>2</sup>-functionalized guanosines and their strong absorptions in the visible spectra, we have shown that they can be used effectively in studying interactions of guanosines with metal ions such as Zn(II) via a

combination of fluorescence, CD, and NMR spectroscopic methods.<sup>4</sup> In addition, the complementary base for guanine in Watson–Crick interactions is cytosine; hence, various functionalized guanosines or cytidines have been used previously to study the formation of the GC base pair and the charge-transfer phenomenon via the GC pair between fluorescent donor and acceptor.<sup>5</sup> To our best knowledge, however, there have been no reports on GC base pairs involving fluorescent N<sup>2</sup>-functionalized guanosines.<sup>6</sup> To examine the impact of N<sup>2</sup>-functionalization of guanosine on GC pair formation, we investigated the interactions of the native cytidine with **G1** and **G2** by both NMR and fluorescent spectroscopic methods. However, because **G1** and **G2** have poor solubilities in organic solvents and are sparingly soluble in water or the mixture of water and alcohols, which also compete for H bonds with guanosine and cytidine leading to complex H-bond patterns, no meaningful data could be obtained. To overcome this problem, we converted **G1** and **G2** to lipophilic guanosines by protecting OH moieties with acetyl groups, which greatly improved their solubility. The resulting **G1A** and **G2A** guanosines display selective H-bonding with cytidine in solvents such as CH<sub>2</sub>Cl<sub>2</sub> that

can be monitored by both NMR and fluorescent spectra. The key results are reported herein.

## Experimental section

All reagents were purchased from Aldrich Chemical Co. and used without further purification unless stated otherwise. Acetic anhydride, triethylamine, and acetonitrile were freshly distilled under  $N_2$  prior to acetylation reactions. Low-resolution and high-resolution mass spectrometry experiments were performed using the electrospray ionization mode on QSTAR XL MS/MS Systems using Analyst QS Method. Excitation and emission spectra were recorded on a Photon Technologies International QuantaMaster Model C-60 spectrometer. Molecular orbital and molecular geometry calculations were performed using Gaussian 03 program suite. Calculations were carried out at the B3LYP level of theory using 6-31G\*\* as the basis set for all atoms.

### Fluorescence experiments

Excitation and emission spectra were recorded on a Photon Technologies International QuantaMaster Model C-60 spectrometer. To the prepared solutions of **G1A** ( $2.5 \times 10^{-5}$  mol/L) and **G2A** ( $2.5 \times 10^{-5}$  mol/L) in  $CH_2Cl_2$ , the solution of **4-C** ( $6.0 \times 10^{-3}$  mol/L) was added in 5  $\mu$ L aliquots.

### NMR experiments

All 1D and 2D NMR experiments were recorded on Bruker Avance 400 MHz or 600 MHz spectrometer at 298 K, unless otherwise specified.  $^1H$  NMR titrations were performed using the solutions of **G1A** ( $6.8 \times 10^{-4}$  mol/L) or **G2A** ( $1.6 \times 10^{-2}$  mol/L) in  $CD_2Cl_2$  with the solution of **4-C** in  $CD_2Cl_2$  being added in 10  $\mu$ L aliquots. DOSY NMR experiments were carried out with Bruker Avance-600 MHz spectrometer using the pulse sequence of longitudinal eddy current delay (LED) with bipolar-gradient pulses. The diffusion period was varied from 50 to 90 ms. Calibration of the field gradient strength was achieved by measuring the value of translational diffusion coefficient ( $D_t$ ) for the residual  $^1H$  signal in  $D_2O$ ,  $D_t = 1.91 \times 10^{-9}$  m<sup>2</sup>/s. All NOESY spectra at 298 K were acquired using a mixing time of 0.3 or 0.4 s and the 10 s recycling delay. Phase-sensitive NOESY experiment at 195 K was performed using a mixing time of 0.1 s and a 2 s recycling delay. Phase-sensitive ROESY NMR spectra were recorded on 400 MHz spectrometer at 195 K

using a variable mixing times of 0.08, 0.1, and 0.3 s and the 3 s relaxation delay.

### Synthesis of 2',3',5'-O-triacetyl-*N*<sup>2</sup>-(*p*-4,4'-biphenyldiphenylamino)guanosine (**G1A**)

To a suspension of *N*<sup>2</sup>-(*p*-4,4'-biphenyldiphenylamino)-guanosine, **G1**, (0.34 g, 0.57 mmol) and dimethylaminopyridine (0.005 g, 0.04 mmol) in dry acetonitrile (10 mL), freshly distilled triethylamine (0.30 mL, 2.21 mmol) was added. After stirring for 5 min, freshly distilled acetic anhydride (0.19 mL, 2.00 mmol) was added dropwise over 5 min, and the mixture was stirred for 2 h at room temperature. The reaction mixture was quenched with methanol (5 mL), and the organic solvents were removed to dryness. The residue was treated using the chromatographic column on  $CH_2Cl_2$  and  $CH_2Cl_2/MeOH$  (95:5, v/v) as the eluents to give **G1A** as the white solid. Yield: 0.17 g (43%). Mp > 300 °C. UV absorption  $\lambda_{max}$  ( $CH_2Cl_2$ ), nm ( $\epsilon$  dm<sup>3</sup>mol<sup>-1</sup>cm<sup>-1</sup>): 236 (24 040) and 343 (36 272). Fluorescence ( $CH_2Cl_2$ ):  $\lambda_{ex}$  = 362 nm and  $\lambda_{em}$  = 410 nm.  $^1H$  NMR (400 MHz, DMSO-*d*<sub>6</sub>, 298 K)  $\delta$  (ppm): 10.82 (1H, br s, N<sub>1</sub>H), 8.96 (1H, br s, N<sub>2</sub>H), 8.00 (1H, s), 7.61–7.58 (6H, m,  $J$  = 5.8, 8.6 Hz, Ph), 7.32 (4H, t,  $J$  = 7.9 Hz, Ph), 7.05 (8H, m,  $J$  = 7.8, 8.5 Hz, Ph), 6.02 (1H, d,  $J$  = 5.0 Hz, 1'-H), 6.00 (1H, t,  $J$  = 5.8 Hz, 2'-H), 5.37 (1H, t,  $J$  = 5.7 Hz, 3'-H), 4.28 (1H, dd,  $J$  = 4.4, 5.3 Hz, 4'-H), 4.20 (1H, m,  $J$  = 4.1, 12.1 Hz, 5'-H), 4.13 (1H, m,  $J$  = 4.1, 12.4 Hz, 5'-H), 2.07 (3H, s, CH<sub>3</sub>), 2.05 (3H, s, CH<sub>3</sub>), 1.84 (3H, s, CH<sub>3</sub>).  $^{13}C$  NMR (500 MHz, MeOD)  $\delta$  (ppm): 171.2, 170.1, 169.9, 148.1, 138.1, 134.3, 129.6 (6C), 127.6 (2C), 127.1 (2C), 124.6 (6C), 124.1 (2C), 123.3 (2C), 122.3 (2C), 121.1, 115.6, 96.8 (2C), 87.5 (C<sub>1'</sub>), 80.1 (C<sub>4'</sub>), 72.6 (C<sub>2'</sub>), 70.9 (C<sub>3'</sub>), 63.1 (C<sub>5'</sub>), 19.6 (CH<sub>3</sub>), 19.5 (CH<sub>3</sub>), 19.4 (CH<sub>3</sub>). ESI-MS<sup>+</sup>  $m/z$ : 729.2465 [M + H]<sup>+</sup>. HRMS-EI<sup>+</sup>  $m/z$  calcd. for C<sub>40</sub>H<sub>36</sub>N<sub>6</sub>O<sub>8</sub>: 728.2594, found: 728.2538.

### Synthesis of 2',3',5'-O-triacetyl-*N*<sup>2</sup>-(*p*-4,4'-biphenyldipyridylamino)guanosine (**G2A**)

**G2A** was obtained using the same procedure as for **G1A** with **G2** as the starting material. Yield: 0.08 g (40%). Mp 241–250 °C. UV absorption  $\lambda_{max}$  ( $CH_2Cl_2$ ), nm ( $\epsilon$  dm<sup>3</sup>mol<sup>-1</sup>cm<sup>-1</sup>): 235 (24 003) and 319 (50 240). Fluorescence ( $CH_2Cl_2$ ):  $\lambda_{ex}$  = 344 nm and  $\lambda_{em}$  = 386 nm.  $^1H$  NMR (400 MHz, DMSO-*d*<sub>6</sub>, 298 K)  $\delta$  (ppm): 10.83 (1H, br s, N<sub>1</sub>H), 8.97 (1H, br s, N<sub>2</sub>H), 8.25 (2H, d,  $J$  = 3.7 Hz, Py), 8.02 (1H, s, 8-H), 7.72–7.65 (8H, m,  $J$  = 7.8, 8.4 Hz, Ph), 7.16 (2H, d,  $J$  = 8.4 Hz, Ph), 7.04 (2H, d,  $J$  = 5.3 Hz, Py), 6.99 (2H, d,  $J$  = 8.8 Hz, Py), 6.08 (1H, d,  $J$  = 5.3 Hz, 1'-H), 6.01 (1H, t,  $J$  = 5.8 Hz, 2'-H), 5.39 (1H, t,  $J$  = 5.7 Hz, 3'-H), 4.28 (1H, m,  $J$  = 4.3, 9.6 Hz, 4'-H), 4.22 (1H, m,  $J$  = 3.9, 12.4 Hz, 5'-H), 4.19 (1H, m,  $J$  = 3.9, 12.3 Hz, 5'-H), 2.09 (3H, s, CH<sub>3</sub>), 2.06 (3H, s, CH<sub>3</sub>), 1.85 (3H, s, CH<sub>3</sub>).  $^{13}C$  NMR (500 MHz, MeOD)  $\delta$  (ppm): 170.9, 170.2, 170.1, 158.2, 150.4, 147.9 (3C), 144.1, 138.8 (3C), 138.4, 138.1, 137.6, 136.4, 127.9 (3C), 127.3 (2C), 127.2 (3C), 122.5 (2C), 119.0 (2C), 117.9 (2C), 87.6 (C<sub>1'</sub>), 80.0 (C<sub>4'</sub>), 72.5 (C<sub>2'</sub>), 70.8 (C<sub>3'</sub>), 62.8 (C<sub>5'</sub>), 19.3 (CH<sub>3</sub>), 19.2 (CH<sub>3</sub>), 19.1 (CH<sub>3</sub>). ESI-MS<sup>+</sup>  $m/z$ : 731.8851 [M + H]<sup>+</sup>. HRMS-ESI<sup>+</sup>  $m/z$  calcd. for C<sub>38</sub>H<sub>34</sub>N<sub>8</sub>O<sub>8</sub> + H: 731.2572, found: 731.2578.

### Synthesis of 2',3',5'-*O*,*N*<sup>2</sup>-tetraacetyl-*N*<sup>2</sup>-(*p*-4,4'-biphenyldipyridylamino)guanosine (**G2B**)

**G2B** was isolated as a side product from the same reaction for **G2A**. Yield: 0.03 g (18%). Mp 156–164 °C. <sup>1</sup>H NMR (400 MHz, CD<sub>3</sub>CN, 298 K) δ (ppm): 12.98 (broad, N<sub>1</sub>H, 1H), 8.24 (d, *J* = 4.5 Hz, 2H), 7.82 (d, *J* = 8.4 Hz, 2H), 7.73 (s, 1H, H<sub>8</sub>), 7.72 (d, *J* = 6.5 Hz, 2H), 7.65 (dt, *J* = 1.8, 9.1 Hz, 2H), 7.48 (d, *J* = 8.4 Hz, 2H), 7.21 (d, *J* = 8.5 Hz, 2H), 7.02 (m, 4H), 5.75 (d, *J* = 4.6 Hz, 1H, H<sub>1'</sub>), 5.57 (t, *J* = 4.9 Hz, 1H, H<sub>2'</sub>), 4.41 (t, *J* = 6.0 Hz, 1H, H<sub>3'</sub>), 4.05 (m, *J* = 5.1, 11.5 Hz, 1H, H<sub>4'</sub>), 3.71 (m, 2H, H<sub>5'</sub>, H<sub>5''</sub>), 2.03 (s, CH<sub>3</sub>, 3H), 1.94 (s, CH<sub>3</sub>, 3H), 1.88 (s, CH<sub>3</sub>, 3H), 1.86 (s, CH<sub>3</sub>, 3H). <sup>13</sup>C NMR (400 MHz, CD<sub>3</sub>CN, 298 K) δ (ppm): 175.7, 170.2, 169.4, 169.3, 158.1 (2C), 155.3, 150.5, 148.3, 147.5 (2C), 145.4, 140.7, 139.4, 138.0 (2C), 137.7 (2C), 135.9, 129.7 (2C), 128.4 (2C), 127.9 (2C), 127.3 (2C), 121.9, 118.6 (2C), 117.3, 87.9 (C<sub>1</sub>), 79.4 (C<sub>4</sub>), 71.9 (C<sub>2</sub>), 70.7 (C<sub>3</sub>), 63.8 (C<sub>5</sub>), 25.8 (CH<sub>3</sub>), 19.8 (CH<sub>3</sub>), 19.6 (CH<sub>3</sub>), 19.5 (CH<sub>3</sub>). ## Results and discussion

### NMR measurements

#### GC base pair formation

The structure of the cytidine (**4-C**) used in the study and the GC base pair with labels are shown in Chart 2. <sup>1</sup>H NMR spectra indicated that in the absence of **4-C**, **G1A** and **G2A** exist predominantly as monomers in CD<sub>2</sub>Cl<sub>2</sub> at 298 K. The addition of **4-C** to the solution of **G1A** or **G2A** in CD<sub>2</sub>Cl<sub>2</sub> results in upfield shifts of the imino and amino resonances of the guanine and cytosine units, indicative of H-bonding. As shown in Fig. 1, upon [**G1A**]:[**4-C**] base pair formation, a slight change was observed for the phenyl protons (H<sub>6</sub>) directly attached to the N<sup>2</sup>-site of guanine, while the H<sub>8</sub> signal of the guanine ring remains virtually unchanged. The most significant change is observed for the H<sub>6</sub> and H<sub>5</sub> resonances of **4-C**, which shift ~ 0.1–0.3 ppm upfield. Upon cooling to 228 K, the [**G1A**]:[**4-C**] dimer can be clearly identified through the sharp peaks at ~ 13.1, 12.2, and 10.7 ppm that can be assigned to the N<sub>1</sub>H (**G1A**), N<sub>4</sub>H (**4-C**), and N<sub>2</sub>H (**G1A**), respectively, as presented in Fig. 2. At 228 K, the NOE cross peaks are of the same phase as the diagonal peaks. The key NOE cross peaks between the N<sub>1</sub>H (**G1A**) with N<sub>4</sub>H (**4-C**) in the GC base pair were observed in the NOESY NMR spectrum, confirming the GC pair formation. The GC pair formation was further supported by ESI-MS data, with a peak at *m/z* 1140 identified as [**G1A**:**4-C** + H]<sup>+</sup> (see Fig. S1 in the Supplementary data). Similar NMR and ESI-MS data were also obtained for the [**G2A**]:[**4-C**] base pair (see Figs. S2–S4 in the Supplementary data). The relative ribose stereogeometry of the GC base pair was assigned by NOESY NMR and was found to be syn for both N<sup>2</sup>-arylguanosines, owing to the strong NOE cross peak between its H<sub>1</sub> and H<sub>8</sub>, and anti for **4-C**, judging from the strong NOE between its H<sub>2</sub> and H<sub>6</sub> protons.<sup>7</sup> An association constant could not be determined by NMR dilution method because of the strong GC association. As a control study, we also examined the interaction of 2',3',5'-*O*,*N*<sup>2</sup>-tetraacetyl-*N*<sup>2</sup>-(*p*-4,4'-biphenyldipyridylamino)guanosine (**G2B**) with **4-C**,

Chart 2.

where the H-donor site of the N<sup>2</sup> group is blocked by an acetyl group. Not surprisingly, **G2B** did not form a GC dimer as confirmed by NMR (see Fig. S5 in the Supplementary data for NMR). Thus, the NMR data established unequivocally that the N<sup>2</sup>-functionalization by an aryl group does not impede the ability of the guanosine to form a H-bonded base pair with cytidine.

#### Dynamic exchange of non-bound and bound **4-C** in the GC pair

Although the GC base pair formation has been extensively investigated, little is known about the interaction and the exchange mechanism of a GC pair with non-bound G or C. A previous NMR study on the interaction of a GC pair with free guanosine has identified a GCG trimer.<sup>8</sup> However, the exact nature of the interactions between the GC pair and free cytidine remains unclear. The GC pair formed by **G1A** and **G2A** with **4-C** provided us an opportunity to study such interactions by NMR methods. As shown in Fig. 3, the addition of more than 1 equiv. of **4-C** to the solution of **G1A** results in the sharpening of the N<sup>1</sup>H and N<sub>2</sub>H (**G1A**) resonances along with a slight downfield shift. Surprisingly, the N<sub>4</sub>H (**4-C**) proton is shifted upfield (~3 ppm) and broadened, indicating a dynamic process. The overall chemical shift positions and the sharpness of the exchangeable **G1A** protons indicate the complex formation by H-bonds. At [**G1A**]:[**4-C**] ≈ 1:4 ratio, the chemical shifts of the **G1A** protons are similar to those of [**G1A**]:[**4-C**] = 1:1, while the chemical shifts of **4-C** exhibit significant changes. These findings support that in the presence of excess amount of **4-C**, **G1A** remains involved in the H-bonding in the GC pair while cytidine undergoes some dynamic exchange. Similar trends were also observed for **G2A** when treated with excessive **4-C** (see Fig. S6 in the Supplementary data). DOSY NMR study on [**G2A**]:[**4-C**] and [**G2A**]:[**4-C**]<sub>2</sub> shows that the diffusion coefficients *D*<sub>i</sub> of these two species are similar (see Fig. S7 in the Supplementary data), thus supporting that the stable GCC trimer species is unlikely, but it may be involved in a dynamic process.

Variable temperature NMR experiments were performed for [**G1A**]:[**4-C**]<sub>4</sub> to further probe the chemical-exchange process. As shown in Fig. 4, at temperatures below 208 K, one type of **G1A** and two types of **4-C** peaks (denoted as **4-C** and **4-C\***) were observed. The sharp peaks between 10.5 and 13.4 ppm are assigned to N<sub>2</sub>H (**G1A**), N<sub>1</sub>H (**G1A**), and N<sub>4</sub>H (**4-C**) of the GC pair. The broad resonance at 10.2 ppm can be assigned to a N<sub>4</sub>H\* of the non-bound **4-C\***. Since the N<sub>4</sub>H\* proton remains broad and below 12 ppm, we can conclude that it does not belong to the typical [**4-C**]<sub>2</sub> dimer. Further lowering of the temperature to <188 K results in the

**Fig. 1.** Partial  $^1\text{H}$  NMR spectra of (A) **4-C**, (B) **G1A**, and (C) **[G1A]:[4-C]** ( $\text{CD}_2\text{Cl}_2$ , 298 K).**Fig. 2.** Partial NOESY NMR spectrum of **[G1A]:[4-C]** ( $\text{CD}_2\text{Cl}_2$ , 228 K).

splitting of all non-exchangeable protons into **4-C** and **4-C\*** as well.

To gain structural information about the dynamics of this system and to establish the connectivity between the GC pair and the non-bound **4-C\***, COSY, NOESY, and ROESY NMR experiments were performed on the mixture of **[G1A]:[4-C]**<sub>2</sub> and **[G2A]:[4-C]**<sub>2</sub>. The spectroscopic data for **G2A** are presented here because of the higher resolution and spectral quality compared with those for **G1A**. Complete spectral assignment for **G2A** and **4-C** resonances in **[G2A]:[4-C]**<sub>2</sub> was established using COSY. NOESY NMR was performed at 195 K, allowing the identification of closely related protons. Figure 5 shows the strong NOE signature cross peaks for **[G2A]:[4-C]**<sub>2</sub> between  $\text{N}_1\text{H}$  (**G2A**)/ $\text{N}_4\text{H}$  (**4-C**) protons indicative of Watson–Crick H-bonding. It is also worth noting that the NOE cross peaks observed

between  $\text{N}_1\text{H}$  (**G2A**),  $\text{N}_4\text{H}$  (**4-C**), and  $\text{N}_4\text{H}^*$  (**4-C\***) with  $\text{N}_4\text{Ac}$  (**4-C**) and  $\text{N}_4\text{Ac}^*$  (**4-C\***) indicate that these protons are in close proximity to each other (see Fig. S8 in the Supplementary data). In the presence of excessive cytidine, all the cross peaks in the NOESY spectrum are of the same phase as the diagonal peaks.

To confirm NOE correlations and to distinguish them from chemical-exchange cross peaks, a 2D ROESY NMR spectrum was recorded at 195 K (Fig. 6), which reveals clear NOE cross peaks between the bound **4-C** and non-bound **4-C\*** (e.g.,  $\text{N}_4\text{H}$  (**4-C**)/ $\text{N}_4\text{Ac}^*$  (**4-C\***) and  $\text{N}_4\text{H}^*$  (**4-C\***)/ $\text{N}_4\text{Ac}$  (**4-C**)). In addition, the ribose protons associated with **4-C** in the **[G2A]:[4-C]** base pair are found to be in close proximity to  $\text{H}_6^*$  (**4-C\***) proton and vice versa. Furthermore, the  $\text{H}_6$  proton (**4-C**) exhibits a NOE cross peak with the  $\text{H}_5^*$  (**4-C\***) proton. In addition, the chemical-exchange

**Fig. 3.**  $^1\text{H}$  NMR spectral change of **G1A** with the addition of **4-C** ( $\text{CD}_2\text{Cl}_2$ , 298 K,  $[\text{G1A}] = 6.8 \times 10^{-4}$  mol/L).

**Fig. 4.** Partial variable temperature NMR spectra of  $[\text{G1A}]:[\text{4-C}] = 1:4$ , ( $\text{CD}_2\text{Cl}_2$ ,  $[\text{G1A}] = 6.8 \times 10^{-4}$  mol/L).

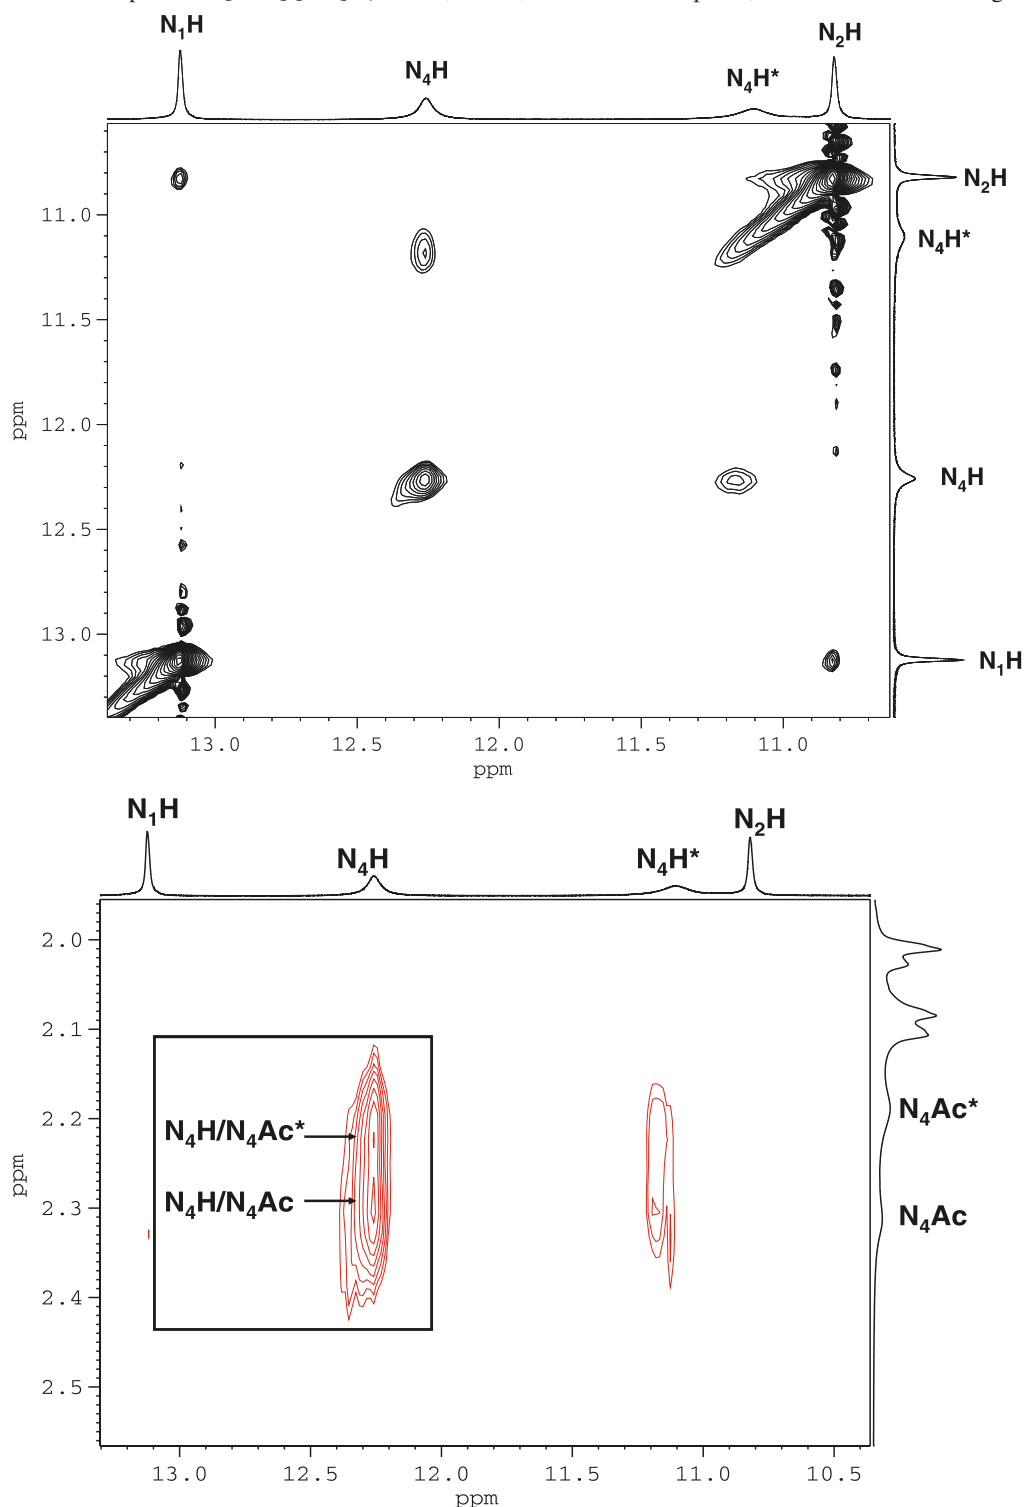

**Fig. 5.** Partial NOESY NMR spectrum of  $[\text{G2A}]:[\text{4-C}]_2$  ( $\text{CD}_2\text{Cl}_2$ , 195 K).

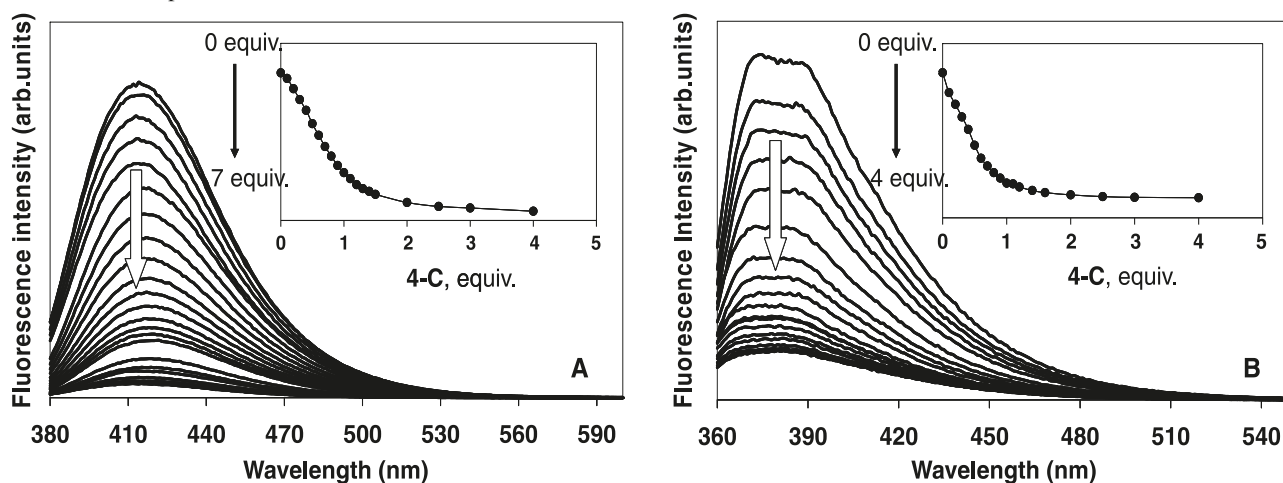

**Fig. 6.** Partial ROESY NMR spectra of [G2A]:[4-C]<sub>2</sub> (CD<sub>2</sub>Cl<sub>2</sub>, 195 K, red: NOE cross peaks, black: chemical-exchange cross peaks).

interaction was observed between the proton pairs of H<sub>6</sub> (4-C)/H<sub>6</sub>\* (4-C\*) and H<sub>5</sub> (4-C)/H<sub>5</sub>\* (4-C\*). The key protons that are involved in GC base pair formation all undergo chemical exchange with each other, which makes the complete assignment of the final structure difficult. However, on the basis of the relative chemical shifts of non-exchangeable protons and the specific NOE interactions shown in Fig. 6, it can be concluded that there are two types of cytidines,

non-bound 4-C\* and bound 4-C with G2A, which undergo chemical exchange with each other, leading to the averaging of the 4-C signals at above 208 K. These findings are consistent with the presence of  $\pi$ - $\pi$  stacking interactions between 4-C in the [G2A]:[4-C] pair and non-bound 4-C\*. Since G2A does not exhibit NOE with H<sub>6</sub>\* (4-C\*) and H<sub>5</sub>\* (4-C\*) protons the possibilities of  $\pi$ - $\pi$  interactions between G2A in the [G2A]:[4-C] pair and 4-C\* can be ruled out.

**Fig. 7.** Fluorescence titrations of (A) **G1A** and (B) **G2A** with **4-C** ( $\text{CH}_2\text{Cl}_2$ ,  $2.5 \times 10^{-5}$  mol/L,  $\lambda_{\text{ex}} = 362$  nm (**G1A**) and 344 nm (**G2A**). Inset: Stern–Volmer plots at  $\lambda_{\text{max}}$ .

**Fig. 8.** Fluorescence spectra of **G1A** in the presence of A (left) or T (right) nucleosides with or without **4-C** ( $\text{CH}_2\text{Cl}_2$ ).

Using the variable temperature NMR data, the exchange rate  $k_c$  and the activation free energy  $\Delta G^\ddagger$  for the exchange process were estimated to be  $88 \text{ s}^{-1}$  and  $43 \text{ kJ mol}^{-1}$ , respectively, at 208 K.

### Fluorescence measurement

In contrast to the non-functionalized guanosines, which are weakly emissive in the UV region, **G1A** and **G2A** are highly emissive in the visible region, thus making it possible to monitor the G–C interactions by fluorescence spectroscopy as well. As shown in Fig. 7, the addition of **4-C** to the solution of **G1A** or **G2A** in  $\text{CH}_2\text{Cl}_2$  results in quenching of the fluorescence emission of the  $N^2$ -arylguanosines. The Stern–Volmer plots support the formation of a stable 1:1 species with **4-C** (Fig. 6, inset), which is most likely responsible for the quenching of the guanosine emission. The binding constants for the GC pairs were determined to be  $5 \times 10^5 \text{ M}^{-1}$  and  $2 \times 10^6 \text{ M}^{-1}$  for **G1A** and **G2A**, respectively (see Fig. S9 in the Supplementary data).<sup>9</sup> These binding constants are in agreement with those reported in the literature for other GC pairs.<sup>10</sup>

As a control study, the fluorescence titration of **G2B** with **4-C** was also carried out (see Fig. S10 in the Supplementary

data), which, not surprisingly, does not show any fluorescent quenching, thus further supporting the role of selective H-bonding between **G2A** and **4-C** in the fluorescence quenching. The selectivity of the fluorescence response of **G1A** and **G2A** toward cytidine was further confirmed by the competition experiments of 2',3',5'-O-triacetyladenosine (A) and 3',5'-O-diacetylthymidine (T) with **4-C** for binding with **G1A** and **G2A**. As shown in Fig. 8, both A and T have no impact at all on the fluorescent spectrum of **G1A**. Similar results were also obtained for **G2A** (see Fig. S11 in the Supplementary data).

### Molecular orbital calculations

Our previous TD-DFT calculations have established that the lowest electronic transitions and the fluorescence of **G1A** and **G2A** are  $\pi$ – $\pi^*$  transitions centered on guanine and the biphenyl- $\text{NAr}_2$  group.<sup>4</sup> To understand the origin of the fluorescence quenching upon GC pair formation, DFT calculations were performed for the [**G1A**]:[**4-C**] pair. The ground-state structure of the [**G1A**]:[**4-C**] pair was fully optimized at a B3-LYP/6–31G\*\* level of theory and is presented in Fig. 9 along with the diagrams of the HOMO and LUMO levels.<sup>11</sup> The HOMO level of [**G1A**]:[**4-C**] consists

**Fig. 9.** HOMO and LUMO orbitals of the [G1A]:[4-C] base pair.

of  $\pi$  orbitals of the biphenyl-NPh<sub>2</sub> group while the LUMO level is made of entirely the  $\pi^*$  orbitals of the cytosine ring. Hence, in contrast to **G1A**, where the lowest electronic transition is from a  $\pi$ - $\pi^*$  transition localized on the same part of the molecule, the lowest electronic transition of [G1A]:[4-C] is a charge transfer from the N<sup>2</sup> substituent to the cytosine ring. The low lying LUMO of the cytosine in the GC pair is therefore clearly responsible for quenching the emission of **G1A**. The guanine ring has no contributions to either the HOMO or the LUMO level of the GC pair, and probably acts as a bridge to facilitate H-bonds and electronic transitions between the N<sup>2</sup> substituent and the cytosine ring. Many examples of fluorescence quenching via intramolecular charge transfer in donor-acceptor types of GC base pair facilitated by H-bonding are known in the literature.<sup>12</sup> Our compounds are however the first example showing charge-transfer fluorescence quenching via the GC pair involving N<sup>2</sup>-functionalized guanines.

In summary, the aryl group at the N<sup>2</sup> site of guanines **G1A** and **G2A** does not impede the selective formation of the H-bonding pair with cytidine. In fact, it facilitates the study of the G-C interactions via fluorescence spectroscopy owing to its highly fluorescent nature and the high sensitivity of the fluorescence spectrum toward G-C pair formation. An unusual exchange pathway between bound and free cyti-

dine molecules and a potential  $\pi$ -stacked intermediate have been identified by NMR data.

# Determination of diltiazem based on the reduction of Cu(II)–BCA complexes in micellar medium

Larissa Zupardo Lacerda Sabino, Daniele Cestari Marino, and  
Horacio Dorigan Moya

**Abstract:** A simple method was developed for determining microquantities of diltiazem, based on the reduction of copper(II) in buffered solution (pH 7.0) and the use of a micellar medium containing 4,4'-dicarboxy-2,2'-biquinoline acid. The copper(I) produced reacts with 4,4'-dicarboxy-2,2'-biquinoline acid and the complexes formed are spectrophotometrically measured at 558 nm. A typical calibration graph shows good linearity ( $r = 0.993$ ) from 20 to 100  $\mu\text{g mL}^{-1}$  of diltiazem. The limit of detection and relative standard deviation were calculated as 12  $\mu\text{g mL}^{-1}$  (99% confidence level) and 3.5% (40  $\mu\text{g mL}^{-1}$ ;  $n = 6$ ), respectively, with a mean recovery value of 96.5% found in pharmaceutical dosages. A straightforward and effective way to recycle the reagents is addressed. The hazardous aspects of the Cu(I)–BCA reaction are presented as well.

**Key words:** diltiazem, Cu(I), 4,4'-dicarboxy-2,2'-biquinoline acid (bicinchoninic acid), spectrophotometry.

**Résumé :** On a développé une méthode simple pour déterminer des microquantités de diltiazem basée sur la réduction du cuivre(II), dans une solution tamponnée (pH de 7,0) et un milieu micellaire contenant de la 4,4'-dicarboxy-2,2'-biquinolène. Le cuivre(I) qui est produit réagit avec l'acide 4,4'-dicarboxy-2,2'-biquinolène et les complexes qui se forment peuvent être mesurés d'une façon spectrophotométrique à 558 nm. Un graphique de calibration typique présente une bonne linéarité ( $r = 0.993$ ) pour des concentrations allant de 20 à 100  $\mu\text{g mL}^{-1}$  de diltiazem. On a calculé que la limite de détection et la déviation standard relative sont respectivement égales à 12  $\mu\text{g mL}^{-1}$  (niveau de confiance de 99 %) et de 3,5 % (40  $\mu\text{g mL}^{-1}$ ;  $n = 6$ ) avec une valeur moyenne de récupération de 96,5 % des dosages présents dans des formulations pharmaceutiques. On présente les risques associés à l'utilisation de la réaction Cu(I)/ABC ainsi qu'une méthode simple et efficace de recycler les réactifs utilisés.

**Mots-clés :** diltiazem, Cu(I), acide 4,4'-dicarboxy-2,2'-quinoléine (acide bicinchoninique, ABC), spectrophotométrie.

[Traduit par la Rédaction]

## Introduction

Only a few ligands, including neocuproine and bathocuproine, are able to stabilize Cu(I) in aqueous solution; this stabilization results from the formation of the respective Cu(I) charge-transfer transition complexes.<sup>1</sup> However, because of the low solubility of these compounds in water, the aqueous solution is not used on a wide scale in the analysis of drugs; instead, the Cu(I)–neocuproine complexes in ethanolic medium are used for the determination of ascorbic acid,<sup>2</sup>  $\alpha$ -tocopherol,<sup>3</sup> ceftazidime,<sup>4</sup> and isoniazid<sup>5</sup> in pharmaceutical preparations. The Cu(I)–bathocuproine complexes were recently used to quantify some dibenzazepine drugs.<sup>6</sup>

The 4,4'-dicarboxy-2,2'-biquinoline acid (bicinchoninic acid), or BCA, is a weak organic acid ( $\text{p}K_{\text{a}1} = 1.87$ ;  $\text{p}K_{\text{a}2} = 2.85$ ) derived from quinoline (Fig. 1a), which acts as a specific chelating agent for Cu(I) in aqueous solution forming violet soluble complexes showing absorption maxima at 357 ( $\varepsilon = 4.2 \times 10^4 \text{ L mol}^{-1} \text{ cm}^{-1}$ ) and 558 nm ( $\varepsilon = 7.7 \times 10^3 \text{ L mol}^{-1} \text{ cm}^{-1}$ ).<sup>7</sup> It was initially used to determine copper in

different samples, such as alloys,<sup>8</sup> minerals,<sup>9</sup> and blood.<sup>10</sup> The determination was based on the reduction of Cu(II) using hydroxylamine hydrochloride as the reducing agent. It has also been used to quantify the total level of protein,<sup>11</sup> reducing sugars,<sup>12</sup> and uric<sup>13</sup> and ascorbic<sup>14</sup> acids. In our previous work,<sup>15</sup> it was shown that polyphenols reduced Cu(II) to Cu(I) in a buffered ammonium acetate solution (pH 7.0) containing BCA. This work also presented an alternative analytical method for determining tannins in wines and teas by flow injection analysis, with a limit of detection of 10 nmol L<sup>-1</sup> (99.7% confidence level) and a linear range from 0.5 to 5  $\mu\text{mol L}^{-1}$  of tannic acid.

The British Pharmacopeia<sup>16</sup> recommends a non-aqueous titration technique for determining the drug 3-acetyloxy-5-(2-(dimethylamino)ethyl)-2,3-dihydro-2-(4-methoxyphenyl)-1,5-benzothiazepin-4(5H)one (Fig. 1b), known as diltiazem, which is one of the pharmaceutical compounds most widely used as Ca<sup>2+</sup>-blocking drugs. However, as this method is based on acid–base properties, other weak acids or bases (e.g., stearate or acetate) present in the samples may inter-

**Fig. 1.** (a) Structure of 4,4'-dicarboxy-2,2'-biquinoline acid (BCA); (b) structure of diltiazem.

fere. Moreover, this procedure presents some disadvantages, such as higher reagent consumption and large amounts of waste.

Table 1 shows a selection of some suggested alternative methods for diltiazem quantification including voltametric,<sup>17</sup> potentiometric,<sup>18,19</sup> chromatographic,<sup>20–24</sup> and spectrophotometric techniques.<sup>25–33</sup> Despite the good analytical parameters obtained in the voltametric and chromatographic methods, they demanded more expensive pieces of equipment, which are not always available in quality control laboratories. Potentiometric techniques could be more useful for this purpose but they use either organic solvents<sup>16</sup> or selective electrodes, which must be previously assembled.<sup>18,19</sup> In contrast, chromatographic techniques have been preferentially used for diltiazem determination in biological samples such as human plasma<sup>20,22,24</sup> or urine.<sup>24</sup>

It can be also seen from Table 1 that most of the methods presented are based on spectrophotometric analysis, probably because of its simplicity, low cost, and the roughness of the spectrophotometric technique. However, many of them use extractive procedures with organic solvents<sup>26–28</sup> or have some analytical steps that take a long time to be completed.<sup>31</sup> Other methods use hazardous reagents demanding proper disposal.<sup>32,33</sup>

This study presents a new spectrophotometric method for the determination of diltiazem, which reduces Cu(II) to Cu(I) in the presence of BCA forming Cu(I)–BCA complexes at pH 7.0 (maintained with ammonium acetate buffer) in a micellar medium containing dodecyltrimethylammonium bromide (Fig. 2). The absorbance measurement at 558 nm, characteristic of the Cu(I)–BCA complexes,<sup>7</sup> is proportional to the drug concentration. The proposed method is faster

than some spectrophotometric procedures and does not require any organic solvent. Additionally, it presents advantages when compared to the official method:<sup>16</sup> it is a less-demanding method and it significantly minimizes waste generation.

## Experimental

### Apparatus, reagents, and chemicals

The spectrophotometric measurements were made in a HPUV 8453 spectrophotometer using 1.00 cm glass cuvettes.

All reagents were of AR or CP grade from Merck, Sigma-Aldrich, or Fluka Chemie A.G. Deionized water was used in all solutions.

Pharmaceutical grade diltiazem·HCl, C<sub>22</sub>H<sub>26</sub>N<sub>2</sub>O<sub>4</sub>S·HCl, was generously supplied as a gift from Farmalab Ind. Químicas e Farmacêuticas Ltda., São Paulo, Brazil. Stock standard solution 1.0 × 10<sup>−2</sup> mol L<sup>−1</sup> was prepared by dissolution in water just before use. Commercial drugs containing diltiazem·HCl with 30 mg per tablet and 90, 120, and 180 mg per capsule were used as samples.

Copper(II) nitrate, Cu(NO<sub>3</sub>)<sub>2</sub>·6H<sub>2</sub>O, 1.0 mol L<sup>−1</sup>, stock solution was prepared from direct dissolution of the salt in water. A 1.0 × 10<sup>−2</sup> mol L<sup>−1</sup> working solution was prepared by suitable dilution in water. Standardization was carried out by complexometric titration with EDTA.

BCA 3.0 × 10<sup>−2</sup> mol L<sup>−1</sup> stock solution was prepared by dissolution of the disodium salt of 4,4'-dicarboxy-2,2'-biquinoline, Na<sub>2</sub>C<sub>20</sub>H<sub>10</sub>N<sub>2</sub>O<sub>4</sub>, in water.

Stock solutions of DTAB (dodecyltrimethylammonium bromide, CH<sub>3</sub>(CH<sub>2</sub>)<sub>11</sub>N(CH<sub>3</sub>)<sub>3</sub>Br), 0.33 mol L<sup>−1</sup>, and ammonium acetate, CH<sub>3</sub>CO<sub>2</sub>NH<sub>4</sub>, 2.0 mol L<sup>−1</sup> were prepared by dissolution in water.

### Sample preparation

Samples were prepared from two forms currently found in the local pharmaceutical market: tablets and capsules. For the first form, 30 mg tablets were used. The second one was prepared from three different alternatives: 180 mg, 120 mg, and 90 mg capsules.

To compensate for the different drug quantity present in the different versions of the capsules (180, 120, and 90 mg), one 180-mg capsule; two 120-mg capsules. or three 90-mg capsules were used.

Regardless of the sample form, all drug samples were filtered through filter paper into a 25.0 mL volumetric flask and diluted with deionized water.

### Procedures

The calibration graph of the proposed procedure was obtained by preparing six sets of solutions containing 250 µL Cu(II) 1.0 × 10<sup>−2</sup> mol L<sup>−1</sup>, 2.0 mL ammonium acetate 2.0 mol L<sup>−1</sup> (to keep the pH of the solution at 7.0), 250 µL BCA 3.0 × 10<sup>−2</sup> mol L<sup>−1</sup>, and 120 µL DTAB 0.33 mol L<sup>−1</sup> added in the sequence described. Each solution was transferred into a 5.00 mL volumetric flask. Aliquots with volumes ranging from 25 to 120 µL of diltiazem·HCl stock standard solution 1.0 × 10<sup>−2</sup> mol L<sup>−1</sup> were added to the flasks which were then filled to the mark with deionized water. The resulting solutions were mixed well and placed

<sup>c</sup>Gel sample.

in a boiling water bath for 5 min. After the solutions were cooled, the absorbance was measured at 558 nm using a mixture containing 0.5 mmol L<sup>-1</sup> Cu(II), 1.5 mmol L<sup>-1</sup> BCA, 8.0 mmol L<sup>-1</sup> DTAB, and 0.8 mol L<sup>-1</sup> ammonium acetate as reference solution (Fig. 3).

The multiple standard addition method was used to analyze the samples. Fifty  $\mu$ L of the prepared sample solution was transferred to five 5.0 mL volumetric flasks. Each flask contained 250  $\mu$ L Cu(II)  $1.0 \times 10^{-2}$  mol L<sup>-1</sup>, 2.0 mL ammonium acetate 2.0 mol L<sup>-1</sup>, 250  $\mu$ L BCA  $3.0 \times 10^{-2}$  mol L<sup>-1</sup>, and 120  $\mu$ L DTAB 0.33 mol L<sup>-1</sup>. Diltiazem HCl  $1.0 \times 10^{-2}$  mol L<sup>-1</sup> standard solution was not added to the first of the five flasks. To the second, third, fourth, and fifth flasks were added 23, 36, 45 and 67,  $\mu$ L, respectively (Fig. 3).

The reference procedure, based on a non-aqueous titration, was carried out as described in the British Pharmacopoeia.<sup>16</sup>

## Results and discussion

Diltiazem undergoes oxidation by Cu(II) in the presence of BCA in a buffered ammonium acetate medium (pH 7.0). However, the reaction requires a very long time (more than 20 h) for completion at room temperature (Fig. 4, curve II) and a light green precipitate of Cu(II)-BCA was formed in the bottom of the cuvette. Initial efforts to accelerate this reaction by carrying it out in a micellar medium (Fig. 4, curve III) decreased the reaction time to four hours but did not avoid the formation of the same precipitate. However, heating this solution accelerated the reaction and also prevented the formation of any precipitates. The highest analytical signal, using the Cu(I)-BCA complexes at 558 nm, was achieved in a solution containing 0.5 mmol L<sup>-1</sup> Cu(II), 1.5 mmol L<sup>-1</sup> BCA, and 8.0 mmol L<sup>-1</sup> DTAB in 0.8 mol L<sup>-1</sup> ammonium acetate medium (pH 7.0) and by heating the mixture in a boiling water bath for 5 min. No bathochromic effect was observed after this treatment. After the reaction completion, the absorbance value of the complexes remained constant at room temperature for 24 h in the dark refrigerator.

Variations in the concentration of Cu(II) and BCA were tested providing a Cu(II):BCA proportion of 1:3. The Cu(II)-BCA light green precipitate was formed when the concentrations were Cu(II) 1.0 mmol L<sup>-1</sup> and BCA 3.0 mmol L<sup>-1</sup>. A decrease of about 30% in the absorbance values in much lower concentrations (e.g., Cu(II) 0.05 mmol L<sup>-1</sup> and BCA 0.15 mmol L<sup>-1</sup>) was observed.

The buffer solution used is essential for this diltiazem determination providing its addition is made after Cu(II) in the following order: (Cu(II) + buffer + BCA) + DTAB + diltiazem. In the majority of analytical studies with the Cu(I)-BCA complexes, an acetic acid – sodium acetate buffer solution was used to keep the pH 7.0,<sup>9,10,13,14</sup> though it is far from its buffering capacity. Thus, some buffer solutions had to be tested for this reaction. When potassium citrate (pH 7.4) and sodium citrate (pH 7.5) solutions were used, the absorbance signal decreased by 70% and 65%, respectively, probably because of the Cu(II)-citrate complex formation ( $\log \beta = 14$ ).<sup>34</sup> Potassium phosphate (pH 7.0) and Na<sub>2</sub>B<sub>4</sub>O<sub>7</sub>-HCl buffer solutions (pH 7.4) could be used but a green turbid solution was observed before adding BCA.

In the tannin determination mentioned above,<sup>15</sup> a 0.03 mol L<sup>-1</sup> ammonium hydroxide solution was used as a carrier to avoid precipitation of Cu(II)-BCA. Under this condition, a stable baseline was observed without affecting sensitivity and reproducibility. Taking all of this into consideration, a reasonable decision was the use of ammonium acetate to adjust the pH to 7.0. At this pH, NH<sub>3</sub> is present as ammonium ion. At the same pH, acetate ion does not complex Cu(II) in a pronounced way ( $\log \beta_1 = 1.70$ ;  $\log \beta_2 = 2.69$ ;  $\log \beta_3 = 3.0$ ;  $\log \beta_4 = 2.9$ ).<sup>34</sup> The influence of ammonium acetate concentration was then investigated. It was found that in ammonium acetate 1.0 mol L<sup>-1</sup> the absorbance value decreased about 50%, probably because of the formation of [Cu(NH<sub>3</sub>)<sub>4</sub>]<sup>2+</sup> complex ( $\log \beta_4 = 12$ ).<sup>34</sup> At lower concentrations such as 0.5 mol L<sup>-1</sup>, a slightly green turbid solution was formed and the absorbance value decreased 60% (Fig. 5).

Several surfactants were tested to accelerate this reaction (all tests were performed over heating). Anionic surfactants, such as sodium lauryl ethersulphate and sodium laurylsulphate, did not prevent the precipitation at all. Nonionic surfactant such as Triton X-100 and Tween 20 did prevent it. However, the reference solution remained markedly violet, which would represent no advantage regarding the absorbance measurements. A cationic surfactant based on quaternary ammonium cations like CTAB (hexadecyltrimethylammonium bromide) or CTAC (hexadecyltrimethylammonium chloride) prevents the precipitation. However, CTAB and CTAC produce deeper violet reference solutions than DTAB (dodecyltrimethylammonium bromide). Because DTAB was the only surfactant tested that did not strongly react with Cu(II)-BCA under the experimental conditions addressed in the article, different final concentrations were tested, namely 4, 6, 8, 10, 50, and 100 mmol L<sup>-1</sup>. The best analytical signal was achieved with 8 mmol L<sup>-1</sup>, which is below the DTAB critical micellar concentration (15 mmol L<sup>-1</sup>) (Fig. 6).

Under these optimized conditions (Cu(II) = 0.5 mmol L<sup>-1</sup>, BCA = 1.5 mmol L<sup>-1</sup>, DTAB = 8.0 mmol L<sup>-1</sup>, ammonium acetate = 0.8 mol L<sup>-1</sup>, and heating this mixture in a boiling water bath for 5 min), the calibration graph was linear for diltiazem-HCl concentrations from 20 to 100  $\mu$ g mL<sup>-1</sup>, which is described by the regression equation  $A = 0.06003 + 0.00203 \times [D]$ ,  $r = 0.993$ , where A is the absorbance measured at 558 nm and [D] is the diltiazem-HCl concentration in  $\mu$ g mL<sup>-1</sup> (Fig. 3). The limit of detection, defined as three times the standard deviation of the linear coefficient divided by the angular coefficient value, was estimated as 12  $\mu$ g mL<sup>-1</sup> at 99% confidence level, which is significantly lower than that required for the determination of diltiazem in all of the pharmaceutical formulations. The relative standard deviation was estimated as 3.5% for 5 measurements of a 40  $\mu$ g mL<sup>-1</sup> diltiazem standard solution, which can be considered satisfactory. The analytical results obtained are summarized in Table 2 and they are well aligned with the official method,<sup>16</sup> demonstrating that the procedure suggested here can be used as an alternative method for diltiazem-HCl quantification in dosage forms.

To confirm the consistency of the proposed method, drug samples were spiked with diltiazem-HCl (50, 80, 100, and 150  $\mu$ mol L<sup>-1</sup>), and the recovery of diltiazem-HCl was estimated. Data presented in Table 3 show recoveries from 87.8

**Fig. 2.** Absorption spectra of: I = Cu(II) 0.5 mmol L<sup>-1</sup> + BCA 1.5 mmol L<sup>-1</sup> + 8.0 mmol L<sup>-1</sup> DTAB + 0.8 mol L<sup>-1</sup> ammonium acetate; II = solution I + 80 µg mL<sup>-1</sup> diltiazem-HCl, after being placed in a boiling water bath for 5 min. Water as reference solution.

**Fig. 3.** (■) Calibration ( $A = 0.06003 + 0.00203 \times [D]$ ,  $r = 0.993$ ,  $n = 6$ ) and (○) the multiple standard addition method ( $A = 0.02071 + 0.00212 \times [D]$ ,  $r = 0.990$ ,  $n = 5$ ) curves obtained for diltiazem determination using the Cu(I)-BCA complexes. Sample = one 180 mg capsule of diltiazem-HCl. Cu(II) = 0.5 mmol L<sup>-1</sup>; BCA = 1.5 mmol L<sup>-1</sup>; DTAB = 8.0 mmol L<sup>-1</sup>; and ammonium acetate = 0.8 mol L<sup>-1</sup>. All spectrophotometric measurements at 558 nm after being placed in a boiling water bath for 5 min. Water as reference solution.

to 103%, with a mean value of 96.5%. Additionally, the curve obtained by the multiple standard addition method for the samples was parallel when compared with the one described by the calibration graph (slope differences between 5%–8%). These curves indicate that matrix effects on the proposed procedure can be negligible (Fig. 3).

The influence of common additives found in tablets and capsules was tested for their possible interferences in this reaction for diltiazem determination. It was observed that talc, starch, and magnesium stearate did not interfere because they remain insoluble after dissolution of the samples. The effects of glucose, lactose, and sucrose were also investigated since they are usually found as adjuvants in pharmaceutical preparations. Thus, solutions containing

**Fig. 4.** Variation of absorbance at 558 nm of solutions containing: I = Cu(II) 0.5 mmol L<sup>-1</sup> + BCA 1.5 mmol L<sup>-1</sup> + 0.8 mol L<sup>-1</sup> ammonium acetate + 8.0 mmol L<sup>-1</sup> DTAB; II = Cu(II) 0.5 mmol L<sup>-1</sup> + BCA 1.5 mmol L<sup>-1</sup> + 0.8 mol L<sup>-1</sup> ammonium acetate + 40 µg mL<sup>-1</sup> diltiazem-HCl; III = Cu(II) 0.5 mmol L<sup>-1</sup> + BCA 1.5 mmol L<sup>-1</sup> + 0.8 mol L<sup>-1</sup> ammonium acetate + 8.0 mmol L<sup>-1</sup> DTAB + 40 µg mL<sup>-1</sup> diltiazem-HCl. All measurements at room temperature, with water as reference solution.

50 µmol L<sup>-1</sup> diltiazem-HCl and three known concentrations (0.05, 0.5, and 2.5 mmol L<sup>-1</sup>) of these substances were analyzed by the proposed procedure. No interference was observed up to 50-fold excess of glucose, lactose, and sucrose. As the samples containing diltiazem-HCl are diluted 100-fold (see Experimental), those substances present in the levels usually found in dosage forms will probably not interfere. The results observed in the interference study and the good recoveries estimated for three drug-spiked concentrations in the four kinds of samples (Table 3) confirmed that the proposed method can be used as an alternative method for diltiazem-HCl.

#### Hazardous aspects of the Cu(I)-BCA reaction

The toxicological properties of BCA have not been fully

**Fig. 5.** Variation of absorbance at 558 nm of solutions containing Cu(II) 0.5 mmol L<sup>-1</sup> + BCA 1.5 mmol L<sup>-1</sup> + 8.0 mmol L<sup>-1</sup> DTAB + 150 µg mL<sup>-1</sup> diltiazem-HCl and ammonium acetate. All measurements made after being placed in a boiling water bath for 5 min. Water as reference solution.

studied so far but it may cause sore eyes and affect mucous membranes, and it is expected to be internally toxic, so it must be appropriately disposed of.

The total waste volume of Cu(II), BCA, DTAB, and ammonium acetate for each determination (5 mL) were approximately 0.16, 2.9, 12, and 310 mg, respectively. However, the waste obtained after many BCA analysis can be recycled using a simple procedure. First, the solution should be alkalinized to pH 12 with 3.0 mol L<sup>-1</sup> NaOH solution to precipitate all of the copper ion. After removing the copper hydroxocompounds by filtration, the solution remaining is acidified with a 2.0 mol L<sup>-1</sup> HCl solution to protonate (pK<sub>a1</sub> = 1.87; pK<sub>a2</sub> = 2.85) and separate all the BCA present. The insoluble H<sub>2</sub>BCA obtained is then filtered and must be recrystallized before new use.

## Conclusion

The procedure presented here is a simple and accurate alternative method for diltiazem-HCl determination in dosage forms. It provides good sensitivity when compared with most of the spectrophotometric methods previously reported for this drug. The colored Cu(I)-BCA complexes formed are stable for more than 24 h, which makes the method more practicable. Besides, the validity of the proposed method is well demonstrated by analyzing various dosage forms of diltiazem-HCl. Additionally, as it is free from interference by common additives, it can be used for routine quality control.

Although there are already several methods for determining diltiazem-HCl determination, this is the first report of an analytical procedure based on the reduction of Cu(II) to Cu(I) by this drug in the presence of BCA in a micellar medium containing DTAB. Among its advantages are low cost of the technique, low reagent consumption, and no need for organic solvents. In addition, the possibility of the recovery of

the BCA and Cu(II) makes this procedure more attractive from the environmental point of view.

# Removal of Cd(II) and Pb(II) complexes with glycolic acid from aqueous solutions on different ion exchangers

Justyna Jachuła, Dorota Kołodyńska, and Zbigniew Hubicki

**Abstract:** The sorption of Cd(II) and Pb(II) ions from aqueous solutions on different ion exchangers was investigated by using glycolic acid (GA) as a complexing agent. Glycolic acid is useful for organic synthesis in oxidation–reduction, esterification, and long-chain polymerization. The experiments were carried out by using the following chelating ion exchangers: Purolite S-930, Purolite S-940, Purolite S-950, Diaion CR-20, and Wofatit MC-50 and the cationic ion exchangers: Purolite C-104, Lewatit CNP-80, and Lewatit SP-112. The influence of the initial concentration of Cd(II) and Pb(II) and glycolic acid, pH of the solution, and phase contact time on the sorption percentage was determined in the batch experiments. Pseudo-first-order and pseudo-second-order kinetic models were used to describe the kinetic data, and the rate constants were evaluated. The experimental data, fitted using the Langmuir and Freundlich adsorption models, were applied to describe the equilibrium isotherms and determined the isotherm constants. The Cd(II) and Pb(II) concentrations in the raffinate were determined by the AAS method.

**Key words:** heavy-metal ions, ion exchangers, glycolic acid, sorption, removal.

**Résumé :** Utilisant l'acide glycolique (AG) comme agent complexant, on a étudié la sorption des ions Cd(II) et Pb(II) présents dans diverses solutions aqueuses sur différents échangeurs d'ions. L'acide glycolique est aussi utile en synthèse organique pour les réactions d'oxydation et de réduction, d'estérification et de polymérisation de longues chaînes. Dans le cadre de notre travail, les expériences ont été effectuées à l'aide des échangeurs d'ions chélatants Purolite S-930, Purolite S-940, Purolite S-950, Diaion CR-20, Wofatit MC-50 ainsi que des échangeurs cationiques Purolite C-104, Lewatit CNP-80 et Lewatit SP-112. Par le biais d'expériences par lots, on a déterminé l'influence de la concentration initiale des ions Cd(II) et Pb(II) et de l'acide glycolique ainsi que du temps de contact sur le pourcentage de sorption. On a utilisé des modèles cinétiques du pseudo-premier ordre et du pseudo-deuxième ordre pour décrire les données cinétiques ainsi que les constantes de vitesse. Les données expérimentales ajustées en faisant appel aux modèles d'adsorption de Langmuir et de Freundlich ont été appliquées pour décrire les isothermes d'équilibre et pour déterminer les constantes isothermes. Les concentrations de cadmium(II) et de plomb(II) dans les raffinats ont été déterminées par une méthode de spectroscopie d'absorption atomique (SAA).

**Mots-clés :** ions de métaux lourds, échangeurs d'ions, acide glycolique, sorption, élimination.

## Introduction

The need for clean water increases year by year, and yet water sources are reduced by pollution of our waterways with industrial chemicals.<sup>1</sup> The disposal of effluents containing heavy metals is related to a wide range of industrial operations, such as electroplating, chemical manufacturing, leather tanning, and especially mining and mineral processing. The removal of such contaminants up to the levels approved by national or international agencies could not be entirely solved by conventional methods like precipitation, coagulation, and so forth.<sup>2</sup> Recently, sorption processes have proved to be effective for the removal of pollutants from wastewaters.<sup>3–6</sup>

In recent years, the use of  $\alpha$ -hydroxy acids especially in cosmetic products has greatly expanded.<sup>7–9</sup> The most commonly used in skin products is glycolic acid (hydroxyacetic acid). It is manufactured by bubbling carbon monoxide through formaldehyde, by the action of sodium hydroxide on monochloroacetic acid ( $\text{ClCH}_2\text{CO}_2\text{H} + \text{NaOH} \rightarrow \text{HOCH}_2\text{CO}_2\text{H} + \text{NaCl}$ ), and by the electrolytic reduction of oxalic acid. It is available pure and in aqueous solution. It can be isolated from natural sources, such as sugarcane. Glycolic acid is used in various skin-care products because of its excellent capability of skin penetration. It is also useful for organic synthesis in a range of reactions, including oxidation–reduction, esterification, and long-chain polymerization. It is used as a monomer in the preparation of poly-

**J. Jachuła, D. Kołodyńska, and Z. Hubicki.**<sup>1</sup> Department of Inorganic Chemistry, Faculty of Chemistry, Maria Curie-Skłodowska University, Maria Curie-Skłodowska Sq. 2, 20-031 Lublin, Poland.

<sup>1</sup>Corresponding author (e-mail: zbigniew.hubicki@poczta.umcs.lublin.pl).

glycolic acid and other biocompatible copolymers (e.g., PLGA).<sup>10</sup> Among others, this compound finds employment in the textile industry, food processing, and ink and paint production.

Previous research confirms the fact that due to the hydroxyl group at the  $\alpha$ -position of the carboxylic acid, hydroxyacetic acid has higher acidity ( $pK_a$  3.83) and stronger chelating properties toward metal ions than an unfunctionalized carboxylic acid ( $pK_a$  4.8).<sup>11–15</sup> Thus, it is used industrially for rust removal, degreasing, and so forth. Novel glycolic acid/platinum complexes have antitumor activity comparable to or more potent than that of *cis*-platinum. It should be added that its nephrotoxicity is very low.<sup>16</sup>

As for the removal of heavy-metal ions from water, among numerous separation techniques, sorption processes can be very useful in terms of technical and economical feasibility. This is attributed to its low cost, easy availability of sorbents, simplicity of design, high efficiency, and easiness of operation.<sup>17</sup>

The aim of this work is to determine the influence of the complexing agent, which is glycolic acid, on the removal of heavy-metal ions from waters and wastewaters. Its influence on the effectiveness of sorption was tested for the chelating ion exchangers: Purolite S-930, Purolite S-940, Purolite S-950, Diaion CR-20, and Wofatit MC-50, and the cationic ion exchangers: Purolite C-104, Lewatit CNP-80, and Lewatit SP-112. The evaluation of different chemical conditions on the ion-exchange capacity and on the kinetics of Cd(II) and Pb(II) complexes with glycolic acid permitted the optimization of heavy-metal removal.

## Materials and methods

### Resin

The chelating ion exchangers Purolite S-930, Purolite S-940, Purolite S-950 (Purolite Int. Ltd.), Diaion CR-20 (Mitsubishi Chemical Corp.), and Wofatit MC-50 (Lanxess) were used together with the cationic ion exchangers Purolite C-104 (Purolite Int. Ltd.), Lewatit CNP-80, and Lewatit SP-112 (Lanxess). Their main characteristics are presented in Table 1. The exchangers were washed with 1 mol/L NaOH and 1 mol/L HCl to remove organic and inorganic impurities and then washed several times with deionised water prior to use.

### Chemicals

Cd(II) and Pb(II) nitrates were obtained from POCh Gliwice. Cd(II) and Pb(II) solutions were prepared by dissolving their nitrates in distilled water. They were diluted to get the solutions of various concentrations. Then, the appropriate amount of glycolic acid solution (denoted in this paper as GA), obtained from PP-H-U Domena Poland, was added.

The initial pH values of the solutions were in the range 3.0 to 3.5. All chemicals used were of analytical reagent-grade. It is well-known that M(II) ions are octahedrally coordinated by one carboxylate O atom and one hydroxyl O atom from each glycolate ligand and two water O atoms in *cis* positions. The general formula of the formed complexes is  $[M(\text{HOCH}_2\text{COO})_2(\text{H}_2\text{O})_2]$ .<sup>18–20</sup>

## Column studies

The breakthrough curves of the Cd(II) and Pb(II) ions in the presence of glycolic acid were determined using 10 mL of the swollen ion exchanger packed in 10 mm diameter glass column with a glass-wool stopper. The prepared solutions of complexed metal ions were passed continuously downwards through the resin beds keeping the flow rate at 0.6 mL/min. The effluent was collected in fractions in which the metal(II) content was determined. The mass ( $D_g$ ) and volume ( $D_v$ ) distribution coefficients as well as the working ( $C_w$ ) and total ( $C_t$ ) ion-exchange capacities were calculated from the determined breakthrough curves according to eqs. [1–3]<sup>21</sup>

$$[1] \quad D_g = \frac{\bar{V} - (V_0 + V_i)}{m_j}$$

$$[2] \quad D_v = \frac{\bar{V} - (V_0 + V_i)}{V_j}$$

$$[3] \quad C_w = \frac{V_e c_0}{V_j}$$

where  $\bar{V}$  is the volume of effluent at  $c = c_0/2$  (determined graphically) (mL),  $V_0$  is the dead volume in the column (liquid volume in the column between the bottom edge of ion-exchanger bed and the outlet) (mL), and  $V_i$  is the void (interparticle) ion-exchanger-bed volume, which amounts to ~40% of the bed volume (mL),  $m_j$  is the dry ion-exchanger mass (g),  $V_j$  is the bed volume (mL),  $V_e$  is the effluent volume to the break point (L), and  $c_0$  is the initial concentration of M(II) solution (mg/L).

The total ion-exchange capacities ( $C_t$ ) were calculated by integration along the curve.

## Batch studies

The sorption of Pb(II) and Cd(II) ions in the presence of glycolic acid on the above-mentioned ion exchangers was investigated by batch operation as a function of the initial concentration of the metal and glycolic acid, pH of the solution, and contact time. The experiments were performed to determine the concentration of the analyzed metals at the equilibrium ( $q_e$ ), at a specific time ( $q_t$ ), and sorption percent ( $S\%$ ). The resin phase concentrations of M(II) at the equilibrium,  $q_e$  (mg/g), at a specific time,  $q_t$  (mg/g), and sorption percent ( $S\%$ ) were obtained according to<sup>22</sup>

$$[4] \quad q_e = \frac{(c_0 - c_e)V}{m}$$

$$[5] \quad q_t = \frac{(c_0 - c_t)V}{m}$$

$$[6] \quad S(\%) = \frac{c_0 - c_t}{c_t} \times 100$$

where  $c_e$  is the concentration of M(II) in the aqueous phase at equilibrium (mg/L),  $c_t$  is the concentration of M(II) in the aqueous phase at time  $t$  (mg/L),  $V$  is the volume of the solution (mL or L),  $m$  is the mass of the ion exchanger (g).

**Table 1.** Characteristics of the ion exchangers.

Ion exchanger	Typical properties				
	Matrix	Active groups	Delivery form	Bead size (mm)	Total capacity (equiv./L)
Purolite C-104	PS-DVB (gel)	Carboxylic	H <sup>+</sup>	0.3–1.2	4.2
Lewatit CNP-80	PA-DVB (macroporous)	Carboxylic	H <sup>+</sup>	0.3–1.6	4.3
Lewatit SP-112	PS-DVB (macroporous)	Sulfonic	Na <sup>+</sup>	0.65	1.7
Purolite S-930	PS-DVB (macroporous)	Iminodiacetic	Na <sup>+</sup>	0.3–1.0	1.6
Purolite S-940	PS-DVB (macroporous)	Aminophosphonic	Na <sup>+</sup>	0.4–0.85	20 g Ca/L
Purolite S-950	PS-DVB (macroporous)	Aminophosphonic	Na <sup>+</sup>	0.3–1.2	2.0
Diaion CR-20	PS-DVB (gel)	Polyamine	H <sup>+</sup>	0.3–0.55	0.8
Wofatit MC-50	PS-DVB (gel)	Iminodiacetic	Na <sup>+</sup>	0.3–1.2	1.2

In the case of the equilibrium and kinetic experiments, 0.2 g of the ion exchanger was added into 100 mL flasks and mixed in 20 mL solution of Pb(II) and Cd(II) ions in the presence of GA. The initial concentration of each solution was  $1 \times 10^{-3}$  mol/L. The flasks were shaken at the constant temperature of 25 °C. The samples were collected at the defined time or at different time intervals. After completion of each batch of experiments, the solution was filtered. The filtrate was analyzed by atomic absorption spectrometry (AAS) to determine the amount of metal left after sorption. The experiments were conducted in the three parallel series. The reproducibility of the measurements was within 5%.

### Adsorption studies

Adsorption isotherm studies were carried out using the batch equilibrium technique. Initial concentrations of the studied solutions were prepared in the range from  $1 \times 10^{-3}$  mol/L to  $2.5 \times 10^{-2}$  mol/L. Ion-exchanger samples (0.2 g) and 20 mL solutions of Cd(II) and Pb(II) ions in the presence of glycolic acid were mixed in 100 mL flasks until equilibrium was reached. The adsorption equilibrium data were fitted into the Langmuir and Freundlich models, which were represented as<sup>23</sup>

$$[7] \quad q_e = \frac{q_0 K_L c_e}{1 + K_L c_e}$$

$$[8] \quad q_e = K_F c_e^{1/n}$$

where  $q_e$  is the equilibrium M(II) ions concentration on the ion exchanger (mg/g),  $q_0$  is the monolayer capacity of the ion exchanger (mg/g),  $K_L$  is the Langmuir adsorption constant (L/mg) related to the free energy of adsorption (L/mg),  $K_F$  is the Freundlich adsorption capacity (mg/g (L/mg)<sup>1/n</sup>), and  $1/n$  is the Freundlich constant related to the surface heterogeneity.

### Desorption studies

To investigate the possibility of repetitive use of the ion exchangers Purolite S-940 and Lewatit SP-112, desorption experiments were conducted under batch experimental conditions, and desorption efficiencies were compared. Samples (0.5 g) of the above-mentioned ion exchangers saturated with Pb(II) ions in the presence of glycolic acid were in contact with 50 mL of different regeneration agents for 2 h. The use of demineralized water showed insignificant metal ions desorption capacity. Therefore, 1 mol/L NaCl, HCl,

HNO<sub>3</sub>, and H<sub>2</sub>SO<sub>4</sub> solutions were selected as the optimal regeneration agents for the systems studied. The amount of metal ions eluted from the solution was then determined and expressed as a desorption efficiency.

### Instruments

A mechanical shaker (Elpin type 357, Elpin-Plus, Poland) was used for the batch experiments. A pH meter (PHM 84, Radiometer, Denmark) with the glass REF 451 and calomel pHG 201–8 electrodes was used for pH measurements. An atomic absorption spectrometer (ContrAA, Analytic Jena, Germany) was used for quantitative determination of Cd(II) and Pb(II) ions concentrations. An FTIR spectrometer (ALPHA model, including a platinum ATR sampling module with a single-bounce diamond crystal and deuterated triglycine sulfate (DTGS) detector (Bruker Optik GmbH, Germany)) was used to record the FTIR spectra of Lewatit C-104 and Purolite S-930 before and after loading of Pb(II) in the presence of GA in the spectral range 400–4000 cm<sup>-1</sup>.

## Results and discussion

### The spectroscopic analysis

An FTIR spectrometer with ATR module was used to record the IR spectra of the samples. They are presented in Figs. 1 and 2.

In the spectra of the cation exchanger Purolite C-104 (similar to Lewatit CNP-80), which possesses the carboxylic functional groups, appear the bands which are characteristic of the carbonyl group vibrations at about 1698 cm<sup>-1</sup>. After the sorption of Pb(II) ions, a band appears in the range from 1216 to 1163 cm<sup>-1</sup> associated with asymmetric and symmetric vibrations of the carboxylate anion, indicating an ion-exchange mechanism of sorption (Fig. 1). Thus, one can suppose that decomposition of the Pb(II)–GA complex takes place, and the sorption of metal ions occurs

where R is the cation-exchange skeleton. An analogous ion-exchange mechanism can be assumed in the case of Lewatit SP-112 with the sulfonic acid functional groups

In the case of the chelating ion exchanger Purolite S-930 (Fig. 2) (and Wofatit MC-50) with iminodiacetic functional groups, the bands connected with the presence of carboxyl

sorption the bands connected with the presence of carboxylate groups are shifted from 1399 cm<sup>-1</sup> and 1328 cm<sup>-1</sup> to 1381 cm<sup>-1</sup> and 1321 cm<sup>-1</sup>. It is well-known that the iminodiacetic functional groups in sodium or hydrogen form chelate heavy-metal ions by ion attraction to the dicarboxylic functionality and electron donation from nitrogen<sup>24</sup>

For Purolite S-940 and Purolite S-950 with the amino-phosphonic functional groups, the most favourable model of chelation when the pH increases into the weak-acid region is the formation of a four-membered ring. In this case, these

**Fig. 5.** Comparison of the resin phase concentrations of (a) Cd(II) and (b) Pb(II) ions in the presence of GA on the ion exchangers under discussion, depending on the pH value of the solution.

functional groups can act as tridentate ligands and the structure of complexes can be as follows:<sup>25</sup>

In acidic conditions, because of strong protonation, the amino-nitrogen atom does not participate in the bond formation, and complexes without amine-group contribution can also be formed. The most frequent structure is

As for Diaion CR-20 with polyamine functional groups, in the pH range from 4 to 10, it acts as a chelating ion exchanger,<sup>26,27</sup> whereas in acid medium, it behaves as a basic anion exchanger. For Pb(II) and Cd(II) ions in the presence of glycolic acid at pH in the range from 3.0 to 3.5, the sorption process can be analogous to that previously presented for Purolite C-104 or Lewatit SP 112.

## Sorption of Cd(II) and Pb(II) in the presence of glycolic acid

### Dynamic method

As evident from the plots presented in Figs. 3 and 4 and the comparison of the mass ( $D_g$ ) and volume ( $D_v$ ) distribution coefficients as well as the working ( $C_w$ ) and total ( $C_T$ ) ion-exchange capacities of Cd(II) and Pb(II) ions in the presence of GA (Table 2), the highest values of  $D_g$  were obtained on Lewatit SP-112 with the sulfonic acid functional groups. The smallest values were obtained in the case of sorption of Cd(II) in the presence of GA on Lewatit C-104.  $D_v$  values are identical for both Cd(II) and Pb(II) ions in the presence of glycolic acid sorbed on Purolite S-930. The results are also in agreement with the selectivity order of the above-mentioned ion exchangers, which is as follows:

**Purolite C-104** (and also Lewatit CNP-80):  $\text{H}^+ > \text{Ra}^{2+} > \text{Ba}^{2+} > \text{Pb}^{2+} > \text{Sr}^{2+} > \text{Cu}^{2+} > \text{Ca}^{2+} > \text{Zn}^{2+} > \text{Fe}^{2+} > \text{Mg}^{2+} > \text{K}^+ > \text{NH}_4^+ > \text{Na}^+$ .

**Lewatit SP-112:**  $\text{Ba}^{2+} > \text{Pb}^{2+} > \text{Sr}^{2+} > \text{Cu}^{2+} > \text{Ca}^{2+} > \text{Zn}^{2+} > \text{Fe}^{2+} > \text{Mg}^{2+} > \text{K}^+ > \text{NH}_4^+ > \text{Na}^+ > \text{H}^+$ .

**Purolite S-930** (and also Wofatit MC-50):  $\text{Cr}^{3+} > \text{Cu}^{2+} > \text{Ni}^{2+} > \text{Zn}^{2+} > \text{Co}^{2+} > \text{Cd}^{2+} > \text{Fe}^{2+} > \text{Mn}^{2+} > \text{Ca}^{2+} \gg \text{Na}^+$ .

**Purolite S-940** (and also Purolite S-950):  $\text{Pb}^{2+} > \text{Cu}^{2+} > \text{U}^{4+}, \text{Zn}^{2+}, \text{Al}^{3+} > \text{Mg}^{2+} > \text{Sr}^{2+} > \text{Ca}^{2+} > \text{Cd}^{2+} > \text{Na}^+ > \text{Ba}^{2+}$ .

**Diaion CR-20:**  $\text{Hg}^{2+} > \text{Pb}^{2+} > \text{Fe}^{3+} > \text{Cu}^{2+} > \text{Zn}^{2+} > \text{Cd}^{2+} > \text{Ni}^{2+} > \text{Co}^{2+} > \text{Ag}^+ > \text{Mn}^{2+}$ . The Pb(II) ions exhibit higher affinity for these ion exchangers than Cd(II) ions.

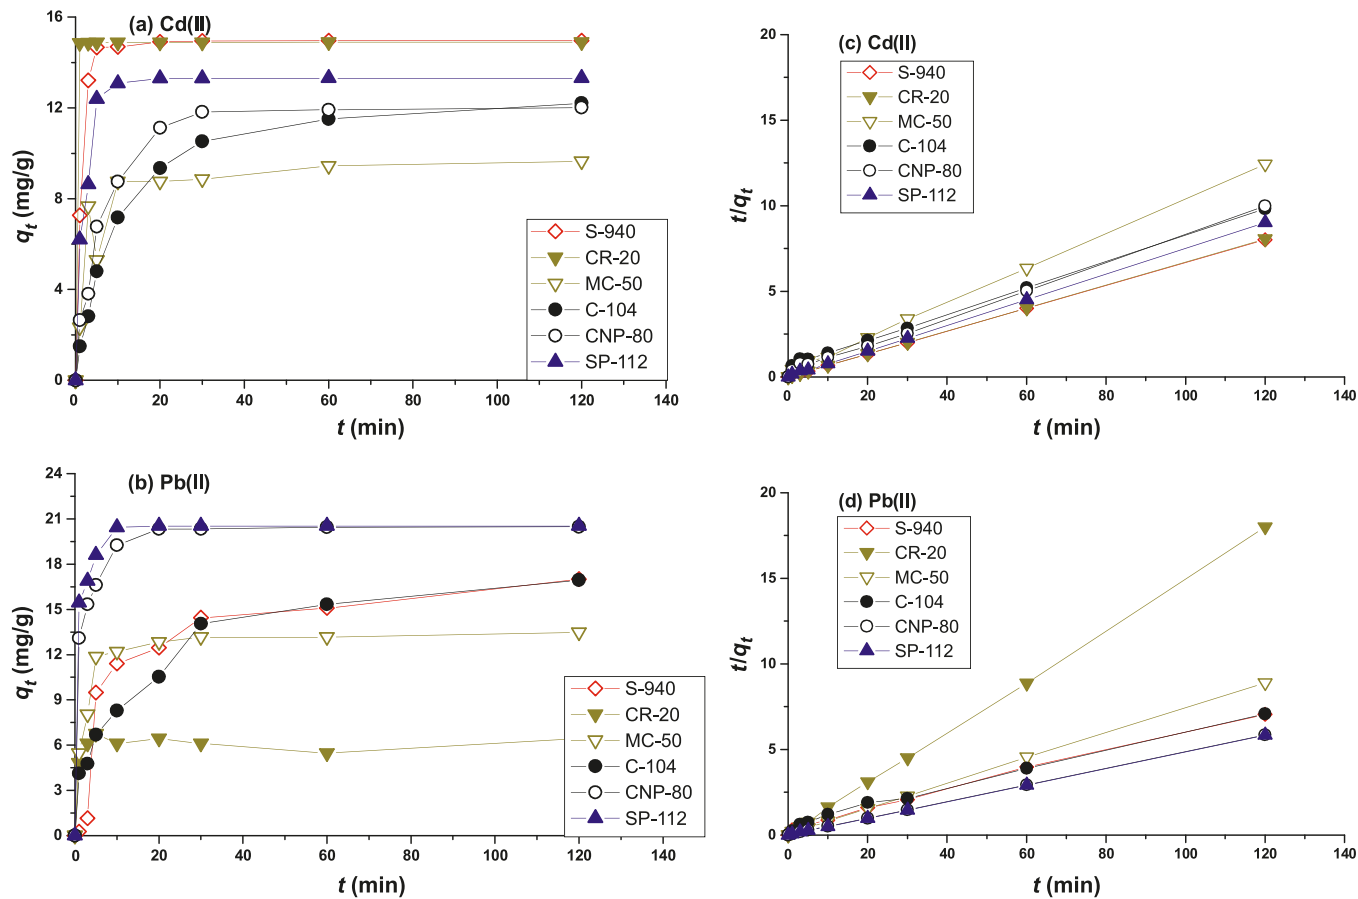

### Batch method

Earlier studies on heavy-metal ion sorption have shown that pH is an important parameter affecting the sorption process. Most metal ions are soluble in water in appropriate pH ranges and are quite insoluble in other cases. Even within the optimal pH ranges for solubility, most metal ions are soluble to only a limited extent. In the presence of complexing agents, the metal ions are capable of remaining in the solution. It was observed that the efficiency of removal of selected heavy-metal complexes does not depend on the pH in all cases. Figures 5a and 5b show the variation of the resin phase concentrations at the equilibrium of Cd(II) and Pb(II) ions in the presence of GA as a function of pH for Purolite S-930, Purolite S-940, Purolite S-950, Diaion CR-20, Wofatit MC-50, Purolite C-104, Lewatit CNP-80, and Lewatit SP-112.

For Purolite S-930, Purolite S-940, Purolite S-950, and Lewatit SP-112, the sorption of Cd(II) ions in the presence of GA slightly depends on the pH. Maximum sorption capacity (6.23 mg/g) for Cd(II) was observed for Diaion CR-20 at pH 4.0. In this case, the sorption percentage ( $S\%$ ) was 57%. For Wofatit MC-50, the highest sorption percentage (81.6% for Cd(II) ions) was observed in the pH range from 4 to 6. For Purolite C-104, the sorption capacities of Cd(II) ions were from 0.03 mg/g at the pH 2.0 to 8.33 mg/g at pH 6.0. For Lewatit CNP-80, the sorption capacities increase from 0.13 mg/g at the pH 2.0 to 9.00 mg/g at pH 6.0. A similar situation was found for the sorption of Pb(II) ions in the presence of GA on the above-mentioned ion exchangers.

**Fig. 6.** Comparison of the sorption capacities (a–b) and the pseudo-second-order kinetic (c–d) for the M(II) ions in the presence of the GA on the chelating ion exchangers Purolite S-940, Diaion CR-20, and Wofatit MC-50 and cationic ion exchangers Purolite C-104, Lewatit CNP-80, and Lewatit SP-112, depending on the phase contact time.

**Table 3.** Kinetic parameters for the M(II) ions in the presence of GA on Purolite S-940, Diaion CR-20, Wofatit MC-50, Purolite C-104, Lewatit CNP-80, and Lewatit SP-112.

SP-112	476.19	0.024	0.998	91.83	4.44	0.669

It was also found that the sorption equilibrium was reached after 120 min, depending on the initial metal ion concentration (Figs. 6a and 6b). For the kinetic data, kinetic analysis was performed with the aid of the pseudo-first- and the pseudo-second-order equations:<sup>28,29</sup>

$$[14] \quad \frac{dq}{dt} = k_1(q_e - q)$$

$$[15] \quad \frac{dq}{dt} = k_2(q_e - q)^2$$

where  $q_e$  and  $q$  are the removal amount of M(II) ions per unit mass of the ion exchanger at equilibrium and time  $t$ , respectively. Figures 6c and 6d show a plot of the linearized form of the pseudo-second-order model according to the equation:

$$[16] \quad \frac{t}{q} = \frac{t}{q_e} + \frac{1}{k_2 q_e^2}$$

for the sorption of M(II) ions in the presence of GA on the chelating ion exchangers Purolite S-940, Diaion CR-20, and Wofatit MC-50 and the cationic ion exchangers Purolite C-104, Lewatit CNP-80, and Lewatit SP-112. As follows from the data presented in Table 3, the correlation coefficients ( $R^2$ ) for the pseudo-second-order kinetic plots were above 0.998 and the calculated sorption capacities ( $q_2$ ) values are also in agreement with experimental values ( $q_{e,exp}$ ). In contrast to the pseudo-second-order kinetic model, the pseudo-first-order model gives a poor correlation ( $R^2$ ) for the sorption of Cd(II) and Pb(II) ions in the presence of GA, and these data are not presented.

In addition to the pseudo-second-order rate equation, the intraparticle diffusion model is commonly used for examining the steps involved during adsorption. It can be expressed as<sup>30</sup>

$$[17] \quad q_t = k_i t^{0.5}$$

where  $k_i$  is the diffusion coefficient ( $\text{mg/g min}^{0.5}$ ).

The results show also that the intraparticle diffusion model does not adequately describe the sorption results of M(II) ions in the presence of GA on the ion exchangers under discussion (Table 3).

#### Adsorption studies

Two important isotherms are selected in this study to optimize the design of adsorption systems. The Langmuir adsorption isotherm assumes that adsorption occurs in specific homogeneous sites within the adsorbent and has found successful application in many adsorption studies of monolayer adsorption. The Freundlich isotherm is an empirical equation employed to describe the heterogeneous system.<sup>28</sup>

Table 4 shows that the values of  $R^2$  suggest that the Langmuir isotherm provides a good model of the sorption system with Purolite S-930, Purolite S-940, Purolite C-104, Lewatit CNP-80, and Lewatit SP-112. For the other ion exchangers, the Freundlich isotherm is more suitable. The sorption capacity for Cd(II) in the presence of GA is the highest in the case of Lewatit SP-112 and Purolite S-940, but the sorption constant,  $K_L$  is the largest for Purolite S-940. For Pb(II) in the presence of GA, the sorption capacity is also high in the case of Lewatit SP-112. The sorption constant,  $K_L$  is the largest for Purolite S-930.

In the case of Cd(II)–GA (1:2) system, the experimental sorption capacities ( $q_{e,exp}$ ) were 103.6 mg/g for Purolite S-930, 133.2 mg/g for Purolite S-940, 32.33 mg/g for Diaion CR-20, 34.23 mg/g for Wofatit MC-50, 34.05 mg/g for Purolite C-104, 12.04 mg/g for Lewatit CNP-80, and 181.16 mg/g for Lewatit SP-112. They are in good agreement with the calculated capacities ( $q_0$ ). In the Pb(II)–GA (1:2) system, the experimental sorption capacities were 243.39 mg/g for Purolite S-930, 332.80 mg/g for Purolite S-940, 62.41 mg/g for Diaion CR-20, 89.95 mg/g for Purolite C-104, 68.21 mg/g for Lewatit CNP-80, and 474.83 mg/g for Lewatit SP-112, and they are also in agreement with the obtained capacities.

The sorption capacity order for the Cd(II)–GA complexes is Lewatit SP-112 > Purolite S-940 > Purolite S-930 > Purolite C-104 > Wofatit MC-50 > Diaion CR-20 > Lewatit CNP-80, and for the Pb(II)–GA complexes, the order is Lewatit SP-112 > Purolite S-940 > Purolite S-930 > Purolite C-104 > Lewatit CNP-80 >> Diaion CR-20.

### Desorption of Pb(II) in the presence of glycolic acid

The desorption process was carried out for the Lewatit SP 112 and Purolite S-940 for which the sorption process was the most effective. From the investigations, the use of 1 mol/L solutions of NaCl, HCl, HNO<sub>3</sub>, and H<sub>2</sub>SO<sub>4</sub> resulted in recovery efficiencies of about 37.8%, 24.8%, 96.4%, and 2% for Pb(II) ions from Lewatit SP 112, respectively. In the case of Purolite S-940, these values were 8.8%, 35.6%, 91.2%, and 1.5%, respectively.

### Conclusion

The present study demonstrates the significant effect of glycolic acid on the removal of Cd(II) and Pb(II) from wastewater. The results reveal the possibly efficient removal of these heavy-metal ions using the chelating ion exchangers Purolite S-940 and Purolite S-930 and the strongly acidic polystyrene cation exchanger Lewatit SP-112.

The sorption process in the presence of glycolic acid as a complexing agent on these ion exchangers was studied as a function of the pH, contact time, and concentration of metal solutions. The pH and initial metal concentration were found to influence the effectiveness of Cd(II) and Pb(II) sorption. Batch equilibrium was reached after about 120 min of the contact. The ion-exchange process, which is pH-dependent, showed the maximum removal of heavy-metal ions in the pH range 4.0–6.0. The experimental data have been analyzed using the Langmuir and Freundlich isotherm models.

The sorption of the studied metal ions in the presence of GA on Purolite S-940, Diaion CR-20, Wofatit MC-50, Purolite C-104, Lewatit CNP-80, and Lewatit SP-112 followed the pseudo-second-order reversible kinetics. Nitric acid was found to be the most effective regenerating agent.

# The dehydrogenation of combined organic and inorganic hydrogen-storage carriers

Dominik Wechsler, Boyd Davis, and Philip G. Jessop

**Abstract:** A thermally balanced H<sub>2</sub> storage system can be created by combining an H<sub>2</sub> carrier that releases H<sub>2</sub> endothermically with one that releases H<sub>2</sub> exothermically. Here, we describe combinations of H<sub>2</sub> carriers wherein both carriers release H<sub>2</sub> by dehydrogenation rather than by hydrolysis. The endothermic carriers tested were heterocyclic organic liquids, while the exothermic carriers were amine-borane compounds. The options of having the two carriers chemically bound together or merely physically mixed together were explored. With both options, the exothermic carrier inhibited the endothermic carrier, either by chemically affecting the heterocyclic ring of the endothermic carrier or by decreasing the activity of the heterogeneous dehydrogenation catalyst.

**Key words:** hydrogen storage, dehydrogenation, amine-borane, N-heterocycle, heterogeneous catalyst.

**Résumé :** On peut créer un système de stockage d'hydrogène (H<sub>2</sub>) thermiquement équilibré en combinant un porteur de H<sub>2</sub> qui dégage du H<sub>2</sub> d'une façon endothermique avec un autre qui dégage de l'hydrogène d'une façon exothermique. Dans ce travail, on décrit la combinaison de deux porteurs d'hydrogène qui dégagent de l'hydrogène par déshydrogénation plutôt que par hydrolyse. Les porteurs d'hydrogène endothermiques qui ont été évalués sont des liquides organiques hétérocycliques alors que les porteurs d'hydrogène exothermiques sont des composés amine-borane. On a examiné les options d'utiliser deux porteurs d'hydrogène chimiquement liés ou simplement mélangés d'un point de vue physique. Quelle que soit l'option retenue, le porteur exothermique inhibe le porteur endothermique en affectant d'une façon chimique le noyau hétérocyclique du porteur endothermique ou par une diminution de l'activité du catalyseur hétérogène de déshydrogénation.

**Mots-clés :** entrepose d'hydrogène, déshydrogénation, amine-borane, hétérocycle azoté, catalyseur hétérogène.

## Introduction

Increasing concerns about pollution from the use of fossil fuels has resulted in much attention being paid towards renewable energy sources and clean energy carriers, such as hydrogen.<sup>1,2</sup> While fuel cell technologies are advancing,<sup>2,3</sup> the development of hydrogen-storage systems is being stymied by significant technological roadblocks. Currently, several hydrogen-storage systems are being developed, e.g., physical systems involving compressed or adsorbed H<sub>2</sub> and chemical systems, such as metal hydrides and organic liquids.<sup>4-6</sup>

The use of organic liquids<sup>7</sup> (e.g., cyclohexanes, piperidines<sup>8-14</sup>) as hydrogen carriers would be desirable for their ease of transportation, their pumpability, and the reversibility of their dehydrogenation. These can be categorized as endothermic carriers because they release H<sub>2</sub> endothermically, which makes the release more controllable. However, a drawback for implementing these endothermic systems is the energy that must be supplied to satisfy the enthalpy of dehydrogenation (this can significantly detract from the effective energy storage density).

Inorganic hydrogen carriers, such as metal hydrides and boron hydrides, on the other hand, are solids and therefore generally more difficult to handle and impossible to pump. Hydrogen release from these compounds is typically exothermic, and proceeds by either dehydrogenation or hydrolysis. The advantages of these carriers are the significantly higher gravimetric hydrogen-storage densities and the lack of a requirement for heat to be supplied on-board. However, they would require more complicated on-board engineering because they are solids and because the exothermic release of hydrogen results in heat-management issues and the risk of overheating or runaway reaction.

Combining an endothermic (organic) carrier and an exothermic (inorganic) carrier creates a hybrid system that has the advantages of both. The heat released from the exothermic release of H<sub>2</sub> could be transferred to the endothermic carrier, minimizing the need for an external heat source for the release of H<sub>2</sub> from the latter. Dissolving the inorganic carrier in the organic carrier would eliminate the engineering difficulties associated with the use of a solid. The low hydrogen-storage density of the endothermic carrier would be improved by the addition of the exothermic hydrogen

carrier. Finally, the use of a liquid carrier to dissolve the solid carrier means that there is no need for an inert solvent for the latter. In short, the combination of two carriers could solve many of the problems that plague the individual carriers.

We recently reported the production of hydrogen from just such a combination of endothermic (organic) and exothermic (inorganic) hydrogen carriers. Endothermic dehydrogenation of indoline and exothermic hydrolysis of amino boranes (triethylamine-borane, dimethylamine-borane (DMAB), and amino-borane) were achieved together at 100 °C in the presence of palladium on carbon (Pd/C) catalyst. In these successful combinations, the exothermic and endothermic carriers were physically mixed together. When, however, an exothermic carrier was covalently bonded to an endothermic carrier, the H<sub>2</sub> release from the latter was prevented.<sup>15</sup>

We now describe our efforts to produce hydrogen from a similar combination of hydrogen carriers but using dehydrogenation, rather than hydrolysis, of the exothermic carrier. Dehydrogenation is preferred because hydrolysis of boranes puts the products into a large thermodynamic well so that regeneration of the hydrolyzed carrier is chemically challenging and energetically intensive.

Two separate approaches were considered for combining the two carriers: (i) having both carriers in the same molecule through a chemical bond and (ii) having a physical mixture of the two carriers. Having both carriers in the same molecule is advantageous because accidental phase separation of the two carriers is impossible, energy transfer from the exothermic to the endothermic carrier is facile, and the ratio of exothermic to endothermic carriers is fixed. In our previous study,<sup>15</sup> some inhibition of the indoline dehydrogenation was observed, which could also be a concern with this approach.

Alternatively, having the two carriers physically mixed together, rather than chemically bonded to each other, makes it possible to adjust the molar ratio of the two carriers; this is advantageous to achieve an overall heat balance within the system. The drawback is that new Lewis acid/Lewis base adducts could be formed during the reaction.

## Results and discussion

### Exothermic carrier chemically bound to the endothermic carrier

The known<sup>15</sup> indoline-BH<sub>3</sub> adduct (**1**) was first explored for the potential release of 2 equiv. of H<sub>2</sub> in the presence of a heterogeneous catalyst under anhydrous conditions (eq. [1]).

The dehydrogenation of compound **1** was first attempted in toluene in the presence of different heterogeneous platinum-group catalysts (ruthenium on carbon (Ru/C), palladium on carbon (Pd/C), and platinum on carbon (Pt/C)) at 100 °C. In each case, <sup>1</sup>H NMR spectroscopy showed that

**Fig. 1.** ORTEP diagram of compound **3**, shown with 50% probability ellipsoids.

compound **1** had been converted to indoline; the borane fragment had been removed and yet no dehydrogenation of the C–C single bond was observed. No boron-containing species were observed in the liquid phase of the final reaction mixture by <sup>11</sup>B NMR spectroscopy. Once the boron moiety is cleaved from the indoline, one would have expected that the unbound indoline should be easily dehydrogenated. The lack of dehydrogenation must be due to inhibition of the catalyst by boron-containing species.

When rhodium on carbon (Rh/C) was used as the catalyst, a new single boron shift at 20.7 ppm was observed in the <sup>11</sup>B NMR spectrum, while in the <sup>1</sup>H NMR spectrum, several indoline-related compounds were observed including free indoline and compound **1**, but neither indole nor any indole derivatives were observed. No further characterization was attempted because of the mixture of products in the <sup>1</sup>H NMR spectrum. This shows that dehydrogenation of the C–C bond was again inhibited, although in this case it might have been due to boron-induced electronic changes in the indoline ring rather than inhibition of the catalyst.

Because of the loss of the borane moiety in the presence of three catalysts (Ru/C, Pd/C, and Pt/C), we explored the reactivity of **1** without catalyst at 100 °C. Several different atmospheric reaction conditions such as continuous flow of argon, static atmosphere of nitrogen, and under partial vacuum were explored. Evaluation by <sup>1</sup>H and <sup>11</sup>B NMR spectroscopy revealed a change in the chemical shifts of the borane protons and the boron atom. The methylene peaks of **1** (four distinct multiplets) changed to two distinct triplets corresponding to a new compound (**2**) (eq. [2]). The connectivity of **2** was confirmed by standard NMR experiments (<sup>1</sup>H, <sup>13</sup>C{<sup>1</sup>H}, <sup>11</sup>B, <sup>1</sup>H–<sup>1</sup>H COSY, <sup>1</sup>H–<sup>13</sup>C HSQC, and <sup>1</sup>H–<sup>13</sup>C HMB) as well as <sup>1</sup>H{<sup>11</sup>B} and <sup>1</sup>H–<sup>1</sup>H NOESY NMR experiments. In the <sup>1</sup>H{<sup>11</sup>B} spectra, (Fig. S3 in the Supplementary data), the boron moiety was decoupled resulting in a singlet at 5.05 ppm. The structure was further confirmed by through-space <sup>1</sup>H–<sup>1</sup>H NOESY correlations (Fig. S4 in

**Scheme 1.** Two possible mechanisms for the reaction between indoline and DMAB.

the Supplementary data) between the aryl protons and the borane protons as well as the methylenes. The formation of analogous compounds  $\text{R}_2\text{NBH}_2$  has been reported previously.<sup>16–19</sup>

Compound **2** is very air- and moisture-sensitive; upon exposure to air for just a few minutes, borane hydrolysis occurs. This has been followed by IR (Fig. S2 in the

Supplementary data) where complete hydrolysis is achieved within 20 min. The addition of 1 (or more) equiv. of water to compound **2** resulted in the loss of the borane moiety and the formation of unbound indoline. However, extremely slow exposure of a solution of **2** in chloroform to air over weeks generated crystals of compound **3**, which were analyzed crystallographically. The suggested chemical transformation is shown in eq. [3]. The ORTEP<sup>20</sup> diagram (Fig. 1) shows that **3** is a trimeric structure having planar geometry at N ( $359.97^\circ$ ) and having an N–B bond length ( $1.411(2) \text{ \AA}$ ) significantly shorter than in  $\text{R}_2\text{HN-BH}_3$  complexes ( $\sim 1.60 \text{ \AA}$ )<sup>15,21–23</sup> but comparable to that in a literature  $[\text{R}_2\text{N-B(OR)}]_2\text{O}$  structure ( $1.407(4) \text{ \AA}$ ).<sup>24</sup> Several attempts to form compound **3** in bulk have been met with no success.

The lack of dehydrogenation at the C–C single bond of **1** shows that having the two carriers in close proximity within the same molecule has its limitations. Therefore, our next strategy was to physically mix an endothermic carrier and an exothermic carrier, rather than chemically attach them to each other.

#### Inorganic carrier physically mixed with the organic carrier

Indoline, DMAB, and Pd/C were combined under an inert

atmosphere<sup>25</sup> and heated at  $100^\circ\text{C}$  for 2 h. By  $^1\text{H}$  NMR spectroscopy, compound **2** was observed with quantitative conversion. Heating indoline and DMAB to  $100^\circ\text{C}$  in the absence of catalyst also resulted in the formation of **2** in greater than 95% yield. At room temperature, no interaction is observed between the two compounds. Two possible pathways for the formation of **2** are depicted in Scheme 1. The first pathway (route A in the scheme) corresponds to the displacement of the dimethylamine moiety by indoline resulting in the in situ formation of **1** followed by B–N dehydrocoupling.

Alternatively (route B), if the DMAB dimer ( $[\text{Me}_2\text{N}-\text{BH}_2]_2$ ) forms first and then indoline breaks up the dimer, the depicted intermediate could be formed followed by the loss of the dimethylamine moiety to form compound **2**.

To determine whether route B is viable, dimethylaminoborane dimer ( $[\text{Me}_2\text{N}-\text{BH}_2]_2$ ) was combined with indoline in chloroform-*d*. Heating the mixture at 55 °C for 2 h provided a second set of indoline peaks as well as new methyl peaks in the  $^1\text{H}$  NMR spectrum. In the  $^{11}\text{B}$  NMR spectrum, two new boron peaks appeared. Upon heating for 20 h, all of the starting materials were consumed. According to the  $^1\text{H}$ ,  $^{13}\text{C}\{^1\text{H}\}$ , and  $^{11}\text{B}$  NMR spectra, there appear to be two major products; in the  $^1\text{H}$  NMR spectrum, a minor product is also observed. In the  $^{11}\text{B}$  NMR spectrum, two equally intense peaks are observed, which correlate to separate proton peaks in the  $^1\text{H}$  NMR spectrum as shown by  $^1\text{H}\{^{11}\text{B}\}$  NMR experiments. In the  $^1\text{H}$  NMR spectrum, there seem to be two major and one minor methyl peaks, while in the  $^{13}\text{C}$  NMR spectrum, two separate methyl carbons with different intensities are observed. Several standard 2D NMR (COSY,  $^1\text{H}-^{13}\text{C}$  HSQC,  $^1\text{H}-^{13}\text{C}$  HMBC),  $^1\text{H}-^1\text{H}$  NOESY, and variable-temperature  $^1\text{H}$  NMR experiments have been performed, but no distinct compound could be characterized.

To determine if the dimethylamine moiety can be lost, the mixture of products was taken up in toluene and heated to 100 °C in the presence of Pd/C for 2 h. By NMR spectroscopy, the dimethylamine moiety is still present as well as the methylene peaks of an unidentified boron-adduct of indoline. Because this treatment did not generate compound **2**, we suggest that route B is not viable; route A is therefore considered likely.

The reactivity of indoline with DMAB was also explored at a 2:1 ratio. When 2 equiv. of indoline were combined with DMAB in the presence of Pd/C and heated at 100 °C for 2 h followed by extraction into dichloromethane and cooling at -19 °C, compound **4** was crystallized. Equation [4] shows the assumed stoichiometry. This reaction can also be performed at room temperature; when all reagents are combined, gas evolution is observed within a few minutes. Upon completion of the reaction, the reaction mixture solidified and the product was isolated from the catalyst by extraction with dichloromethane followed by filtration and

**Fig. 2.** ORTEP structure of compound **4**, shown with 50% probability ellipsoids.

removal of solvent in vacuo. The chemical shifts in the  $^1\text{H}$  and  $^{11}\text{B}$  NMR spectra are close to those for **2**. In the crystal structure (Fig. 2), the N atoms are planar [N(1): 359.62(16)° and N(2): 359.59(16)°] and the N–B bond lengths [B(1)–N(1): 1.416(2) Å and B(1)–N(2): 1.412(2) Å] are close to those in compound **3** and to those observed in the literature for hydroboranes with a similar core structure of  $\text{R}_2\text{N}-\text{BH}-\text{NR}_2$  [1.405(3) to 1.428(3) Å].<sup>26</sup>

These experiments show that there is a strong tendency for the two hydrogen carriers to chemically combine. One of the reagents needs to be altered to avoid the formation of a Lewis acid/Lewis base adduct.

To determine if adduct formation can be inhibited by making the N atom of the indoline more sterically hindered,

*N*-butylindoline, and *N*-trimethylsilylindoline were synthesized and then heated with DMAB at 100 °C for 2 h over Pd/C. The  $^1\text{H}$  NMR spectrum showed that the *N*-alkylindoline was unchanged; neither dehydrogenation of the C–C bond nor formation of an adduct of *N*-alkylindoline with a boron moiety occurred. The loss of some of the dimethyl-

amine moiety of DMAB was observed by  $^1\text{H}$  NMR spectroscopy. The DMAB dimer and small quantities of boron species (20–28 ppm) were observed by  $^{11}\text{B}$  NMR spectroscopy. When Rh/C was used instead of Pd/C, similar results were obtained except that roughly equal intensities of DMAB dimer and other boron species (26–28 ppm) were observed by  $^{11}\text{B}$  NMR spectroscopy (eq. [5], where the 1:4 ratio of dimer to indoline is based on NMR observations rather than predicted stoichiometry). In the absence of DMAB, com-

plete dehydrogenation of *N*-butylindoline and *N*-trimethylsilylindoline was achieved with Pd/C. The fact that the *N*-alkylindoline did not form an adduct is an indication that the alkyl groups may have added enough steric bulk to prevent the formation of an adduct. Nevertheless, the free *N*-alkylindoline was not dehydrogenated in the presence of DMAB, showing that the catalyst is inhibited by a boron species.

Similar observations have been reported by Manners and co-workers<sup>27</sup> in the dehydrogenation of DMAB, where the heterogeneous metal catalysts were poisoned by “ $\text{BH}_3$ ” generated in metal-assisted adduct dissociation reactions.

## Conclusion

In this paper, we explored two approaches (chemically bound and physically mixed) to combining two independent hydrogen carriers. Attempts to release hydrogen from both carriers, without resorting to hydrolysis, were only partly successful. Hydrogen release from the borane group was achieved while dehydrogenation of the organic carrier was not.

This work has shown that compound **1** (chemically bound inorganic and organic carriers) decomposes in the presence of several catalysts (Ru/C, Pt/C, and Pd/C) to indoline and unknown boron species. The dehydrogenation of the free indoline does not take place, indicating that some boron species is poisoning the catalyst. In the case of Rh/C, although the B–N bond was not cleaved, the indoline dehydrogenation was still inhibited, most likely due to the electron-withdrawing effect of the borane group. In the absence of catalyst, only 1 equiv. of  $\text{H}_2$  was released by dehydrogenation of the B–N bond, forming compound **2**.

The strategy of having the two carriers physically mixed together but chemically separate has also shown limited success. Whenever indoline and DMAB were combined under a variety of conditions, compound **2** was formed. When an extra equivalent of indoline was employed, a 2:1 complex (**4**) was formed. Thus, again, dehydrogenation of the borane was achieved while dehydrogenation of the C–C bond was not.

In an attempt to prevent the borane binding to the organic (endothermic) carrier, *N*-substituted indoline derivatives (*N*-butylindoline and *N*-trimethylsilylindoline) were tested in place of indoline. In the absence of a borane, complete indoline dehydrogenation is achieved in the presence of catalyst. When borane is added, the indoline dehydrogenation is prevented, which suggests that some boron species is inhibiting the catalyst.

This shows that this approach of dehydrogenation of a combination of organic and inorganic hydrogen carriers con-

taining boron does not work because of boron inhibition of the catalyst and possibly electronic effects on the endothermic carrier.

## Experimental methods

### General considerations

Manipulations of air-sensitive compounds were conducted in the absence of oxygen and water under an atmosphere of  $\text{N}_2$  by the use of standard Schlenk methods, utilizing glassware that was oven-dried ( $130^\circ\text{C}$ ) and evacuated while hot prior to use. Indoline (Aldrich) was dried in vacuo at  $80^\circ\text{C}$  for 2 h prior to use. Palladium (10%) on activated carbon (dry powder, Strem Chemicals), platinum (5%) on activated carbon (dry powder, Alfa Aesar), rhodium (5%) on activated carbon (dry powder, Alfa Aesar), ruthenium (5%) on activated carbon (dry powder, Alfa Aesar), and dimethylamine-borane (Alfa Aesar) were used as received. Compound **1** was synthesized via literature methods.<sup>15</sup> Tetrahydrofuran and toluene were obtained from Fisher Scientific and passed through a double-column solvent-purification system purchased from Innovative Technologies, Inc., degassed using three freeze–pump–thaw cycles, and stored over activated molecular sieves (4 Å) prior to use. Dichloromethane ( $\text{CH}_2\text{Cl}_2$ ) (Fisher Scientific) and  $\text{CDCl}_3$  (Aldrich Chemicals) were stirred over  $\text{CaH}_2$  for 7 days, followed by three freeze–pump–thaw cycles, and vacuum transferred into a new flask and stored over activated molecular sieves (4 Å).

$^1\text{H}$ ,  $^{13}\text{C}$ , and  $^{11}\text{B}$  NMR spectra were collected at 300 K on a Bruker AV-400 spectrometer operating at 400.3, 100.7, and 128.4 MHz, respectively, with chemical shifts reported in ppm downfield of  $\text{SiMe}_4$  (for  $^1\text{H}$  and  $^{13}\text{C}$ ) or  $\text{BF}_3\text{--Et}_2\text{O}$  (for  $^{11}\text{B}$ ) unless otherwise stated.  $^1\text{H}$  and  $^{13}\text{C}$  NMR chemical shift assignments were made on the basis of data obtained from  $^1\text{H}$ – $^1\text{H}$  COSY,  $^1\text{H}$ – $^{13}\text{C}$  HSQC, and  $^1\text{H}$ – $^{13}\text{C}$  HMBC NMR experiments.  $^1\text{H}\{^{11}\text{B}\}$  and  $^1\text{H}$ – $^1\text{H}$  NOESY NMR experiments were performed at 300 K on a Bruker AV-600 spectrometer at 600.2 MHz. In some cases, fewer than expected unique  $^{13}\text{C}\{^1\text{H}\}$  NMR resonances were observed. Infrared spectra were recorded with a Nicolet Avatar 360 FTIR E.S.P. instrument using potassium bromide plates.

## Preparation of 1-borylindoline, 2

### Method A

To a round-bottom flask charged with a stir bar, compound **1** (0.036 g, 0.27 mmol) was added and heated at 100 °C under a flow of argon or nitrogen for 1 h. The flask was cooled to room temperature giving a white solid.

### Method B

To a Schlenk flask charged with a stir bar was added indoline (0.397 mL, 3.54 mmol), DMAB (0.209 g 3.54 mmol), and Pd/C (0.075g, 0.070 mmol) followed by heating at 100 °C for 2 h under argon flow. The residue was taken up in chloroform and filtered through a plug of diatomaceous earth. The solvent was removed in vacuo and solid-washed with hexanes yielding a white solid (0.402 g, 3.07 mmol, 87%).

IR:  $\nu$  2490.01  $\text{cm}^{-1}$  for B–H stretch.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  7.30–7.18 (m, 3H, C4–H, C7–H, and C5–H or C6–H), 6.97 (t,  $^3J_{\text{HH}} = 7.4$  Hz, 1H, C5–H or C6–H), 5.17 (v br s, BH<sub>2</sub>), 4.14 (t,  $^3J_{\text{HH}} = 8.5$  Hz, 2H, C2–H<sub>2</sub>), 3.16 (t,  $^3J_{\text{HH}} = 8.5$  Hz, 2H, C3–H<sub>2</sub>).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  150.6 (C3a), 131.6 (C7a), 127.3 (C5), 124.6 (C4), 120.7 (C6), 111.5 (C7), 49.2 (C2), 30.0 (C3).  $^{11}\text{B}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  25.7.

## Preparation of compound 4

In a Schlenk flask charged with a stir bar, DMAB (0.048 g, 0.81 mmol), and 10% Pd/C (0.026 mg) was added indoline (0.18 mL, 1.62 mmol). The flask was heated at 100 °C for 2 h. Alternatively, if the reaction mixture is left at room temperature, gas evolution is observed over the course of ~1 h followed by the solidifying of the reaction mixture. The product was then extracted with dichloromethane and filtered through diatomaceous earth to remove the catalyst. Removal of the solvent in vacuo resulted in a white solid (0.17 g, 0.70 mmol, 73%). X-ray quality crystals were grown from a solution of dichloromethane at –19 °C under an inert atmosphere.  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  7.17–7.05 (m, 3H, C4–H, C7–H and C5–H or C6–H), 6.84 (t,  $^3J_{\text{HH}} = 7.2$  Hz, 1H, C5–H or C6–H), 5.17 (v br s, BH), 4.10 (t,  $^3J_{\text{HH}} = 8.5$  Hz, 2H, C2–H<sub>2</sub>), 3.09 (t,  $^3J_{\text{HH}} = 8.5$  Hz, 2H, C3–H<sub>2</sub>).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  150.5 (C3a), 131.4 (C7a), 127.1 (C5), 124.5 (C4), 120.6 (C6), 111.4 (C7), 49.1 (C2), 29.9 (C3).  $^{11}\text{B}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  25.4.

## Preparation of N-1-butyldindoline

To a round-bottom Schlenk flask charged with a stir bar, NaH (1.4 g, 0.060 mol), and THF (10 mL) was added indoline (6.7 mL, 0.060 mol). The mixture was allowed to stir overnight (16 h), resulting in a yellow solution. Bromobutane (6.4 mL, 0.060 mol) was slowly added and the reaction mixture was stirred for 4 h resulting in a colorless liquid and a white precipitate. The solvent was removed in vacuo and the product was distilled away from the precipitate under reduced pressure, yielding a colorless liquid (6.9 g, 0.039 mol, 68%).

$^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  7.14–7.10 (m, 2H, aryl–Hs), 6.69 (t,  $^3J_{\text{HH}} = 7.3$  Hz, 1H, aryl–H), 6.53 (d,  $^3J_{\text{HH}} = 8.0$  Hz, 1H, aryl–H), 3.39 (t,  $^3J_{\text{HH}} = 8.3$  Hz, 2H, C2–H<sub>2</sub>), 3.11 (t,  $^3J_{\text{HH}} = 7.3$  Hz, 2H, CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>CH<sub>3</sub>), 3.01 (t,  $^3J_{\text{HH}} = 8.2$  Hz, 2H, C3–H<sub>2</sub>), 1.66 (m, 2H, CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>CH<sub>3</sub>), 1.49 (m, 2H,

CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>CH<sub>3</sub>), 1.04 (t,  $^3J_{\text{HH}} = 7.4$  Hz, 3H, CH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>CH<sub>3</sub>).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  153.0 (quat), 130.1 (quat), 127.4 (aryl–C), 124.5 (aryl–C), 117.3 (aryl–C), 106.9 (aryl–C), 53.2 (CH<sub>2</sub>), 49.1 (CH<sub>2</sub>), 29.7 (CH<sub>2</sub>), 28.7 (CH<sub>2</sub>), 20.6 (CH<sub>2</sub>), 14.2 (CH<sub>3</sub>). NMR data match those reported in the literature.<sup>28,29</sup>

## Preparation of N-trimethylsilylindoline

To a round-bottom Schlenk flask charged with a stir bar, NaH (0.94 g, 0.039 mol), and THF (10 mL) was added indoline (4.4 mL, 0.039 mol). The mixture was allowed to stir overnight (16 h), resulting in a yellow solution. Chlorotrimethylsilane (5.0 mL, 0.039 mol) was added slowly and the reaction mixture was stirred for 4 h resulting in a colorless liquid and a white precipitate. The solvent was removed in vacuo and the product was distilled away from the precipitate under reduced pressure, yielding a colorless oil (6.4 g, 0.033 mol, 86%).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  6.97 (d,  $^3J_{\text{HH}} = 6.8$  Hz, 1H, aryl–H), 6.89 (t,  $^3J_{\text{HH}} = 7.6$  Hz, 1H, aryl–H), 6.54–6.48 (m, 2H, aryl–Hs), 3.52 (t,  $^3J_{\text{HH}} = 8.8$  Hz, 2H, C2–H<sub>2</sub>), 2.91 (t,  $^3J_{\text{HH}} = 8.8$  Hz, 2H, C3–H<sub>2</sub>), 0.20 (s, 9H, Me<sub>3</sub>Si).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CDCl}_3$ ):  $\delta$  152.3 (quat), 131.9 (quat), 127.2 (aryl–C), 124.7 (aryl–C), 116.9 (aryl–C), 109.0 (aryl–C), 49.2 (CH<sub>2</sub>), 30.0 (CH<sub>2</sub>), –0.5 (SiMe<sub>3</sub>). The NMR data match those reported in the literature.<sup>30</sup>

## General procedure for dehydrogenation of indoline and amine borane

In a glovebox, a Schlenk flask was charged with a stir bar, catalyst, amine-borane, and indoline and sealed with a rubber septum. The flask was brought out of the glovebox and flushed with argon using a low flow. The flask was then lowered into a preheated 100 °C oil bath, and magnetic stirring was initiated. After 2 h, the flask was removed from the oil bath and allowed to cool to room temperature. Once cooled, the headspace was evacuated and the flask was brought back into the glovebox. The reaction mixture was extracted with  $\text{CDCl}_3$  and analyzed by NMR spectroscopy.

## Crystallographic characterization of 3 and 4

A crystal of the compound was mounted on a glass fiber with grease and cooled to –93 °C in a stream of nitrogen gas controlled with Cryostream Controller 700. Data collection was performed on a Bruker SMART APEX II X-ray diffractometer with graphite-monochromated Mo K $\alpha$  radiation ( $\lambda = 0.71073$  Å), operating at 50 kV and 30 mA over 2 $\theta$  ranges of 4.82–52.00°. No significant decay was observed during the data collection.

Data were processed on a PC using the Bruker AXS Crystal Structure Analysis Package.<sup>31</sup> Data collection: APEX2; cell refinement: APEX2; data reduction: SAINT and XPREP; program used to solve structure: SHELXTL; program used to refine structure: SHELXTL; molecular graphics: SHELXTL; software used to prepare material for publication: SHELXTL. Neutral atom scattering factors were taken from Cromer and Waber.<sup>32</sup> The structures were solved by direct methods. Full-matrix least-square refinements minimizing the function  $\Sigma w(F_o^2 - F_c^2)^2$  were applied to the compounds. All non-hydrogen atoms were refined anisotropically. All of the H atoms were placed in geometrically calculated positions, with C–H = 0.95 (aromatic) and

0.99 (CH<sub>2</sub>) Å, and refined as riding atoms, with  $U_{\text{iso}}(\text{H}) = 1.2 U_{\text{eq}}(\text{C})$ . For compound **4**, the H on the B atom was located from the difference Fourier map and refined without restriction.

Additional crystallographic information is provided in the accompanying CIF files (see Supplementary data).

## Supplementary data

Supplementary data (<sup>13</sup>C{<sup>1</sup>H} NMR spectra for **2** and **4**; <sup>1</sup>H, <sup>13</sup>C{<sup>1</sup>H} and <sup>1</sup>H{<sup>11</sup>B} NMR spectra for indoline-dimethylamino borane adduct; and single-crystal X-ray diffraction data in CIF format for **3** and **4**) for this article are available on the journal Web site (canjchem.nrc.ca). CCDCs 766954 and 766955 contain the X-ray data in CIF format for this manuscript. These data can be obtained, free of charge, via [www.ccdc.cam.ac.uk/conts/retrieving.html](http://www.ccdc.cam.ac.uk/conts/retrieving.html) (Or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

# ESR analysis of the oxidation reactions of phosphorus-containing nitrone-type spin traps with gold(III) ion

Akira Nakajima, Emiko Matsuda, Yuto Ueda, and Kunihiro Tajima

**Abstract:** Phosphorus-containing cyclic nitrones, such as DEPMPO, CYPMPO, and DPPMPO, were oxidized by hydrogen tetrachloroaurate(III) to DEPMPOX, CYPMPOX, and DPPMPOX with the precipitation of Au(0). The reaction was depressed by the addition of chloride or hydroxide ions. The peculiar pH dependency was observed in DEPMPOX, CYPMPOX, and DPPMPOX formation, which should be caused by the diethoxyphosphoryl group in DEPMPO, the 1,3-propoxy cyclophosphoryl group in CYPMPO, and the diphenylphosphinoyl group in DPPMPO. The oxidation of the nitrones proceeded through the ligand exchange of  $\text{Cl}^-$  in  $\text{AuCl}_4^-$  with  $>\text{N}^+-\text{O}^-$  in nitrone and the nucleophilic addition of the water molecule to the C-2 position in the nitrones, the stepwise intra-molecular transfer of three electrons from the nitrones to Au(III), and the release of the resulting Au(0). The phosphoryl group in the nitrones suppressed the first ligand-exchange interaction by its electronegativity, while the group promoted the electron transfer from the nitrones to Au(III) by its inductive effect.

**Key words:** ESR, spin traps, DMPOX, DEPMPO, CYPMPO, DPPMPO, Au(III) ion.

**Résumé :** Phosphore-contenant les nitrones cycliques, tels que DEPMPO, CYPMPO, et DPPMPO, ont été oxydés par le tetrachloroaurate(III) d'hydrogène à DEPMPOX, à CYPMPOX, et à DPPMPOX avec la précipitation d'Au(0). La réaction a été diminuée par l'addition des ions de chlorure ou d'hydroxyde. La dépendance particulière de pH a été observée dans DEPMPOX, CYPMPOX, et la formation de DPPMPOX, qui devrait être causée par le groupe de diethoxyphosphoryl dans DEPMPO, le 1,3-propoxy groupe de cyclophosphoryl dans CYPMPO, et le groupe de diphenylphosphinoyl dans DPPMPO. L'oxydation du nitrones a parcouru les étapes l'interaction d'échange de ligand de  $\text{Cl}^-$  dans  $\text{AuCl}_4^-$  avec  $>\text{N}^+-\text{O}^-$  dans nitrone et l'addition de nucleophilic de la molécule d'eau au C2 position dans le nitrones, le transfert dans-moléculaire disposé en gradins de trois électrons du nitrones à Au(III), et le relâchement du résultant Au(0). Le groupe de phosphoryl dans les nitrones a supprimé la première interaction d'échange de ligand par son electronegativity, alors que le groupe favorisait le transfert d'électron à partir des nitrones à l'Au(III) par son effet inductif.

**Mots-clés :** RPE, piège à spin, DMPOX, DEPMPO, CYPMPO, DPPMPO, ion Au(III).

## Introduction

Phosphorus-containing nitrone-type spin traps should be useful for the trapping of superoxides. First, a spin trap containing phosphorus atom, 5-diethoxyphosphoryl-5-methyl-1-pyrroline *N*-oxide (DEPMPO), was developed for superoxide trapping.<sup>1</sup> Recently, two spin traps containing phosphorus atom, such as 5-(2,2-dimethyl-1,3-propoxycyclophosphoryl)-5-methyl-1-pyrroline *N*-oxide (CYPMPO)<sup>2</sup> and 2-(diphenylphosphinoyl)-2-methyl-3,4-dihydro-2*H*-pyrrole 1-oxide (DPPMPO),<sup>3</sup> were developed and actively used for superoxide trapping.<sup>4-10</sup> The fact that DEPMPO was oxidized to the 5-diethoxyphosphoryl-5-methyl-1-pyrrolid-2-one-*N*-oxyl (DEPMPOX) radical in the biosystems<sup>11</sup> in a manner similar to 5,5-dimethyl-1-pyrroline-*N*-oxide (DMPO)<sup>12-18</sup> required that we analyze the characteristics

of the oxidation reaction of these spin traps containing phosphorus atom.

Previously, we found that cyclic nitrones, such as 5,5-dimethyl-1-pyrroline-*N*-oxide (DMPO), 4-phenyl-5,5-dimethyl-1-pyrroline-*N*-oxide (PDMPO), and 3,3,5,5-tetramethyl-1-pyrroline-*N*-oxide (M4PO), were oxidized by hydrogen tetrachloroaurate(III) ( $\text{HAuCl}_4$ ) to 5,5-dimethyl-1-pyrrolid-2-one-*N*-oxyl (DMPOX), 4-phenyl-5,5-dimethyl-1-pyrrolid-2-one-*N*-oxyl (PDMPOX), and 3,3,5,5-tetramethyl-1-pyrrolid-2-one-*N*-oxyl (M4POX), respectively, through three electron-transfer reactions.<sup>19</sup> As  $\text{HAuCl}_4$  oxidizes the nitrone to DMPOX-type aminoxyl radicals<sup>20</sup> directly without any other radicals, the nitrone- $\text{HAuCl}_4$  system is suitable for the analysis of the mechanism of nitrone oxidation.

<sup>1</sup>Corresponding author (e-mail: akanaka@med.miyazaki-u.ac.jp).

In the present study, we examined the oxidation reaction of spin traps containing phosphorus atoms, such as DEPMPO, CYPMPO, and DPPMPO, with  $\text{HAuCl}_4$  and discussed the reaction profiles of the formation of DMPOX-type aminoxyl radicals.

## Experimental

### Chemicals

Hydrogen tetrachloroaurate(III) ( $\text{HAuCl}_4$ ) dihydrate and other chemicals were obtained from Nacalai Tesque, Kyoto, Japan. DEPMPO was obtained from Alexis Biochemicals, Enzo Life Sciences, Inc., USA; CYPMPO was obtained from Radical Research, Inc., Tokyo, Japan; and DPPMPO was obtained from DOJINDO, Kumamoto, Japan. The molecular structures of the nitrones used in this study are shown in Fig. 1. All nitrones used were examined by ESR, and no radical species were observed.

### ESR measurements

ESR measurements were conducted using procedures nearly identical to those described previously,<sup>19</sup> namely, 40  $\mu\text{L}$  of a  $\text{HAuCl}_4$  solution (1.25 mmol/L) and 40  $\mu\text{L}$  of a nitron solution (1.25 mmol/L) were mixed at pH 4. As DPPMPO formed far smaller amounts of DPPMPOX than other nitrones, experiments were conducted in a solution containing 6.25 mmol/L of  $\text{HAuCl}_4$  and DPPMPO. In the nitron concentration experiments, the desired amounts of the nitrones were mixed with  $\text{HAuCl}_4$  (1.25 mmol/L for DEPMPO and CYPMPO and 6.25 mmol/L for DPPMPO). After aspirating the mixture into a capillary tube, its ESR spectrum was immediately recorded using an X-band ESR spectrometer (JES TE-100, JEOL, Ltd., Tokyo, controlled by a WIN-RAD ESR data analyzer, Radical Research, Inc., Tokyo) under the conditions described previously.<sup>19</sup> For the observation of the hyperfine structure of methyl protons, the modulation width was set to 0.025 mT and the time was set to 8 min. The solution pH was adjusted to the desired value with 0.1 N  $\text{HNO}_3$  and 0.1 N  $\text{NaOH}$  solutions. To avoid the photochemical reduction of Au(III), the reaction was conducted in the darkness. The concentration of the DMPOX-type radical was calibrated using TEMPOL as a standard after double integration of the observed ESR signal. A computer simulation of each ESR spectrum was also conducted using a WIN-RAD ESR data analyzer.

### Gold determination

The total amounts of the Au(III) species in the reaction mixture and the resulting amounts of Au(0) were determined as described previously.<sup>19</sup>

## Results

### Formation of aminoxyl radicals in phosphorus-containing nitron- $\text{HAuCl}_4$ solutions

When solutions of phosphorus-containing cyclic nitrones, such as DEPMPO, CYPMPO, and DPPMPO, were mixed with a hydrogen tetrachloroaurate(III) ( $\text{HAuCl}_4$ ) solution at pH 4, ESR signals indicating a large doublet with seven lines appeared (Fig. 2). Two former spectra had some additional small hyperfine structures. Their hyperfine coupling

**Fig. 1.** Molecular structure of phosphorous-containing spin traps and the corresponding DMPOX-type aminoxyl radicals.

**Fig. 2.** ESR spectra of DEPMPOX, CYPMPOX, and DPPMPOX and their computer simulations.

**Table 1.** Hyperfine coupling constants of DMPOX-type aminoxyl radicals.

Aminoxyl radical	Hyperfine coupling constant (mT)				Reference
	$a_N$	$a_{3H^a}$	$a_{H-Me}$	$a_P$	
DMPOX	0.70	0.39			Ref. 19
DEPMPOX	0.67	0.37	0.04	3.78	Present
	0.71	0.30			
CYPMPOX	0.74	0.40	0.04	3.93	Present
		0.33			
DPPMPOX	0.69	0.40		2.84	Present
		0.39			

**Note:** As the C-5 atom in nitrones containing phosphorus atom are chiral, protons combined with C-3 atom are not equivalent in the two isomers.

<sup>a</sup>Hyperfine coupling constant for protons combined with the C-3 atom in nitron.

constants, estimated from a computer simulation, are listed in Table 1. Simulation spectra for the three are shown in Fig. 2 in comparison with the ones observed. From these values, the resultant radicals were identified to be DMPOX-type aminoxyl radicals, DEMPOX, CYPMPOX, and DPPMPOX. The assumed structures of the DMPOX-type aminoxyl radicals containing DMPOX are depicted in Fig. 1 with the corresponding nitrones.

No other free radical species, except DMPOX-type ones, were observed in DEPMPO-Au(III) and CYPMPO-Au(III) solutions for a period of 2 h after the reaction was started. On the other hand, in the DPPMPO-Au(III) solution, an ESR signal with seven lines appeared, superposed upon the DPPMPOX signal. In the present work, we concentrated on DPPMPOX after subtracting the effect of the signal.<sup>21</sup>

### Aspects of DMPOX-type radical formation in cyclic nitron-HAuCl<sub>4</sub> solutions

#### Time course of radical formation

The time course of DMPOX-type aminoxyl radical formation was examined using the mixture of nitrones and HAuCl<sub>4</sub> at pH 4. As shown in Fig. 3, the amounts of DMPOX-type aminoxyl radicals increased with the passing of time and reached a maximum value within 40 min for DEMPOX, 50 min for CYPMPOX, and 15 min for DPPMPOX. As the time courses of the amounts of DMPOX-type aminoxyl radicals indicate the combination of the sigmoid-type curves  $\{1/[1 + \exp(-a(t - b))]\}$  and the exponential decay  $[\exp(-ct)]$ , the reaction mechanisms should be very complicated. However, the decrease of the Au(III) ion in the reaction mixtures obeyed the second-order kinetics, eq. [1], as shown previously<sup>19</sup>

$$[1] \quad d[\text{Au(III)}]/dt = C/[kCt + 1]$$

The kinetic constant,  $k$ , for each nitron is listed in Table 2, as well as the amounts of the DMPOX-type aminoxyl radicals at 60 min after the start of the reaction. As shown in Table 2, the magnitudes of  $k$  are in the order of DMPO > DEPMPO > CYPMPO >> DPPMPO. The amounts of DMPOX-type aminoxyl radicals are in the order of CYPMPO > DEPMPO >> DMPO >> DPPMPO.

#### Effect of solution pH

The effects of the solution pH on the formation of DEPM-

**Fig. 3.** Time course of the aminoxyl radical concentrations and Au(III) concentration in the mixtures of nitrones (1.25 mmol/L and 6.25 mmol/L for DPPMPO) and HAuCl<sub>4</sub> (1.25 mmol/L and 6.25 mmol/L for DPPMPO). The closed circle indicates the amount of DEPMPOX; the closed triangle indicates the amount of CYPMPOX; the closed diamond indicates the amount of DPPMPOX; and the closed square indicates the amount of DMPOX. The open circle indicates the Au(III) concentration in the DEPMPO solution; the open triangle indicates the Au(III) concentration in the CYPMPO solution; the open diamond indicates the Au(III) concentration in the DPPMPO solution; and the open square indicates the Au(III) concentration in the DMPO solution.

POX, CYPMPOX, and DPPMPOX were examined using a mixture of nitrones and HAuCl<sub>4</sub>. As shown in Fig. 4, the amounts of DEPMPOX indicated a maximum at around pH 4 and abruptly decreased above and below pH 4. The amounts of CYPMPOX indicated a maximum at around pH 3 and abruptly decreased above and below pH 3. The amounts of DPPMPOX were far smaller than those of DEPMPOX and CYPMPOX and indicated a maximum at pH 2. The ratios of the chemical species, AuCl<sub>4</sub><sup>-</sup>, Au(OH)Cl<sub>3</sub><sup>-</sup>, Au(OH)<sub>2</sub>Cl<sub>2</sub><sup>-</sup>, Au(OH)<sub>3</sub>Cl<sup>-</sup>, and Au(OH)<sub>4</sub><sup>-</sup>, in the solution, depicted in Fig. 4, were calculated using the parameters listed by Sillen and Martell.<sup>22</sup> As the ratios of AuCl<sub>4</sub><sup>-</sup> and Au(OH)<sub>4</sub><sup>-</sup> in the reaction mixture increased, the

**Table 2.** Second-order rate constants and amounts of DMPOX-type aminoxyl radical formed.

Nitron	$k$ ( $\text{M}^{-1}\text{s}^{-1}$ )	Amounts of free radical at 60 min ( $\text{mmol/L}$ ) <sup>a</sup>	Reference

DPPMPO	0.0017	0.011 <sup>b</sup>	Present

Note:  $[\text{Au(III)}] = C/[kCt + 1]$ .

<sup>a</sup>The initial concentration of each nitron was 2.5 mmol/L and  $\text{HAuCl}_4$ , 2.5 mmol/L.

<sup>b</sup>DPPMPO was 6.25 mmol/L and  $\text{HAuCl}_4$ , 6.25 mmol/L.

**Fig. 4.** Effect of the solution pH on the formation of DMPOX-type aminoxyl radicals in the mixtures of nitrones (1.25 mmol/L for DEPMPO and CYPMPO and 6.25 mmol/L for DPPMPO) and  $\text{HAuCl}_4$  (1.25 mmol/L for DEPMPO and CYPMPO and 6.25 mmol/L for DPPMPO) at each pH for 1 h. The closed circle indicates the amount of DEPMPOX; the open circle indicates the amount of CYPMPOX; the closed triangle indicates the amount of DPPMPOX; and the open triangle indicates the amount of DMPOX. The dotted line indicates the ratios of  $\text{AuCl}_4^-$  and  $\text{Au(OH)}_4^-$  calculated using the formation constants listed by Sillen and Martell.<sup>22</sup>

ESR signal intensities decreased. Figure 4 indicates that DMPOX-type aminoxyl radical formations in DEPMPO and CYPMPO solutions were so pH-sensitive that radicals only formed in a very narrow pH range. In other words, the formations of DEPMPOX and CYPMPOX were strongly affected by  $\text{AuCl}_4^-$  and  $\text{Au(OH)}_4^-$ . These results were quite different from those of DMPOX, which formed in a wide pH range.

#### Effect of co-existing salts

The addition of sodium chloride to the reaction mixture markedly decreased the amounts of DEPMPOX, CYPMPOX, and DPPMPOX, while no effect was observed by the addition of  $\text{NaNO}_3$  (Fig. 5). The amounts of  $\text{AuCl}_4^-$  in the solution, depicted in Fig. 5, were calculated using the formation constants listed by Sillen and Martell.<sup>22</sup> As shown in Fig. 5, the formation of a stable complex anion,  $\text{AuCl}_4^-$ , suppressed the redox reaction as described previously.<sup>19</sup> DEPMPOX and CYPMPOX decreased much more heavily with the increase

**Fig. 5.** Effect of sodium salts on the formation of DMPOX-type aminoxyl radicals in the mixtures of nitrones (1.25 mmol/L for DEPMPO, CYPMPO, and DMPO and 6.25 mmol/L for DPPMPO),  $\text{HAuCl}_4$  (1.25 mmol/L for DEPMPO, CYPMPO, and DMPO and 6.25 mmol/L for DPPMPO), and the desired amounts of sodium salts for 1 h. In the  $\text{NaCl}$  solution, the closed circle indicates the amount of DEPMPOX; the closed triangle indicates the amount of CYPMPOX; and the closed diamond and closed square indicate the amount of DMPOX. In the  $\text{NaNO}_3$  solution, the open circle indicates DEPMPOX; the open triangle indicates CYPMPOX; the open diamond indicates DPPMPOX; and the open square indicates DMPOX. The solid thick line indicates the ratio of  $[\text{AuCl}_4^-]$  calculated as described in the legend of Fig. 4.

of the  $\text{NaCl}$  concentration than did DMPOX. These results indicated that the formations of DEPMPOX and CYPMPOX were strongly affected by  $\text{AuCl}_4^-$ , as described previously.

#### Effect of nitron concentration

The amounts of DEPMPOX in the solution containing 1.25 mmol/L of DEPMPO increased gradually with time and reached a maximum 40 min after the start of the reaction (Fig. 6). However, in the 3.75 mmol/L DEPMPO solution, the amounts of DEPMPOX reached a maximum 20 min after the start of the reaction and then gradually decreased, in accordance with the decay curve of those in the 1.25 mmol/L DEPMPO solution. In 6.25 and 12.5 mmol/L DEPMPO solutions, the amounts of DEPMPOX reached a maximum 20 min after the start of the reaction and then abruptly decreased to about 0. A similar anomalous nitron concentration effect was found in the DMPOX formation.<sup>19</sup>

**Fig. 6.** Effect of the DEPMPO concentration on the formation of DEPMPOX in the mixtures of desired amounts of DEPMPO and 1.25 mmol/L of  $\text{HAuCl}_4$ . The closed circle indicates 1.25 mmol/L; the open circle indicates 3.75 mmol/L; the closed triangle indicates 6.25 mmol/L; and the open triangle indicates 12.5 mmol/L DEPMPO.

The amounts of CYPMPOX in the solution containing 1.25 mmol/L of CYPMPO increased gradually with time and reached a maximum 54 min after the start of the reaction (Fig. 7). The time required to reach a maximum decreased with a higher CYPMPO concentration (48, 38–40, 36–38 min for 2.5, 6.25, and 12.5 mmol/L CYPMPO, respectively), while the maximum amounts became smaller (0.103, 0.095, and 0.062 mmol/L CYPMPOX for 2.5, 6.25, and 12.5 mmol/L CYPMPO, respectively). The amounts of DPPMPOX in the solution containing 1.25–12.5 mmol/L of DPPMPO increased gradually and reached a maximum 18–20 min after the start of the reaction (Fig. 8). The amounts of DPPMPOX linearly increased with the increase of DPPMPO.

## Discussion

The hyperfine coupling constants of phosphorus in DEPMPOX and CYPMPOX were larger than those of DPPMPOX, while those of nitrogen and  $\beta$ -hydrogen were almost identical among three nitrones. As phosphorus in DPPMPOX belongs to the phosphine oxide group containing only one oxygen atom, the inductive effect of the group is smaller than that of the phosphonic acid group with three oxygen atoms found in DEPMPOX and CYPMPOX. Furthermore, the resonance effect caused by the diphenyl-phosphinoyl group in DPPMPOX also decreases the electron density of the phosphorus atom. The hyperfine coupling constant of phosphorus in DPPMPOX, therefore, becomes smaller than that of the other two, DEPMPOX and CYPMPOX.

In previous work, we showed that the formation of DMPOX-type aminoxyl radicals should proceed through the

**Fig. 7.** Effect of the CYPMPO concentration on the formation of CYPMPOX in the mixtures of CYPMPO (1.25–12.5 mmol/L) and 1.25 mmol/L of  $\text{HAuCl}_4$ . The closed circle indicates 1.25 mmol/L; the open circle indicates 2.5 mmol/L; the closed triangle indicates 6.25 mmol/L; and the open triangle indicates 12.5 mmol/L CYPMPO.

**Fig. 8.** Effect of the DPPMPO concentration on the formation of DPPMPOX in the mixtures of DPPMPO (1.25–12.5 mmol/L) and 6.25 mmol/L of  $\text{HAuCl}_4$ . The closed circle indicates 1.25 mmol/L; the open circle indicates 2.5 mmol/L; the closed triangle indicates 6.25 mmol/L; and the open triangle indicates 12.5 mmol/L DPPMPO.

scheme (Fig. 9) of a ligand exchange of  $\text{Cl}^-$  in  $\text{AuCl}_4^-$  with  $>\text{N}^+-\text{O}^-$  in nitron, a nucleophilic addition of a water molecule to nitron, and a stepwise intramolecular transfer of three electrons from nitron to  $\text{Au(III)}$ .<sup>19</sup> Previously, we showed that substituent groups added to DMPO affected the

**Fig. 9.** Overall reaction scheme of cyclic nitrones and  $\text{HAuCl}_4$ .

reaction aspects. The present results indicated that the substituents had drastic effects.

The first step of the reaction is a ligand exchange interaction of  $\text{Cl}^-$  in  $\text{AuCl}_4^-$  with  $>\text{N}^+-\text{O}^-$  in nitron. As DEPMPO and CYPMPO have large bulky substituents, such as diethoxyphosphonyl and 2,2-dimethyl-1,3-propoxycyclophosphoryl, the steric effect of these substituents hindered the ligand exchange. Furthermore, the inductive effects of these substituents also weakened the ligand exchange. These effects caused the retardation of DMPOX-type radical formation. Therefore, the magnitudes of  $k$  are in the order of  $\text{DMPO} > \text{DEPMPO} > \text{CYPMPO} \gg \text{DPPMPO}$ .

Once the ligand exchange was established, the inductive effect of the phosphonyl group promoted the nucleophilic addition of the water molecule, which caused the formation of large amounts of DEPMPOX and CYPMPOX. On the other hand, DPPMPO, being so hydrophobic and having a large resonance effect by the phosphine group, donated electrons to  $>\text{N}-\text{O}$  against the weak inductive effect, which caused the rapid but smaller formation of DPPMPOX. These discussions successfully explained the facts that the amounts of DMPOX-type aminoxyl radicals are in the order of  $\text{CYPMPO} > \text{DEPMPO} \gg \text{DMPO} \gg \text{DPPMPO}$ .

As the ratios of  $\text{AuCl}_4^-$  and  $\text{Au(OH)}_4^-$  in the reaction mixture increased, the amounts of DMPOX-type radical decreased. These results suggest that the formation of stable complex anions, such as  $\text{AuCl}_4^-$  and  $\text{Au(OH)}_4^-$ , suppresses

the redox reaction, as described previously.<sup>19</sup> As DEPMPOX and CYPMPOX were formed in a very narrow pH range, their formations were strongly affected by  $\text{AuCl}_4^-$ , as observed for the salt effects. As described above, the initial ligand exchange of  $\text{Cl}^-$  in  $\text{AuCl}_4^-$  with  $>\text{N}^+-\text{O}^-$  in nitron was heavily affected by the addition of a phosphonyl group.

Large amounts of DEPMPOX (0.14–0.17 mmol/L) formed rapidly in the solution containing a concentration of DEPMPO higher than 1.25 mmol/L, and a slower increase and decrease were observed with 1.25 mmol/L of DEPMPO, as for the formation of DMPOX.<sup>19</sup> For CYPMPOX formation, a similar rapid increase and decrease were only observed in 1.25 mmol/L of CYPMPO. However, DPPMPOX indicated a slower increase and decrease in the DPPMPO concentration range of 1.25 to 12.5 mmol/L. Previously, we proposed two possible reaction schemes: (i) the elimination of DMPOX by excess amounts of DMPO described by Hill and Thornalley<sup>23</sup> and (ii) the dimerization of DMPOX. Only small amounts of DPPMPOX were formed at a very high DPPMPO concentration; for such a case, scheme (i) was not applicable, and scheme (ii) became more predominant.

## Conclusion

The formation of DMPOX-type aminoxyl radicals in phosphorus-containing cyclic nitrones should proceed through the scheme of the ligand exchange between  $\text{AuCl}_4^-$

and  $>\text{N}^+-\text{O}^-$  in nitron, the nucleophilic addition of a water molecule to nitron, and the stepwise intramolecular transfer of three electrons from nitron to Au(III). Although the phosphonyl groups in DEPMPO and CYPMPO retard the initial step of the reaction, they promote the nucleophilic addition of the water molecule, and, finally, large amounts of DEMPOX and CYPMPOX are formed. DPPMPO, being hydrophobic, formed only small amounts of DPPMPOX. Care should be taken with the oxidation reaction and the formation of DMPOX-type aminoxyl radical in the use of DEPMPO and CYPMPO as spin traps in biosystems. On the other hand, the phosphine group resists the oxidation reaction, which becomes a merit of DPPMPO as a spin trap.

Our former and present investigations on the oxidation of cyclic nitrones with  $\text{HAuCl}_4$  are summarized as follows: From the results of the oxidation reaction of DMPO and HDMPN, a precursor of DMPOX, by  $\text{HAuCl}_4$ , we proposed a reaction scheme containing the ligand exchange between  $\text{Cl}^-$  in  $\text{AuCl}_4^-$  and  $>\text{N}^+-\text{O}^-$  in nitron, the nucleophilic addition of a water molecule to nitron, the stepwise intramolecular transfer of three electrons from nitron to Au(III), and the production of DMPOX-type aminoxyl radical after the release of Au(0). Taking electronic properties, such as the steric and the inductive effects, and hydrophobicity of substituents in cyclic nitrones into consideration, the reaction scheme proposed can explain the behavior for DMPOX-type aminoxyl radical formation with  $\text{HAuCl}_4$  not only for cyclic nitrones having 3,3-dimethyl group, such as PDMPO and M4PO, but also for phosphorus-containing cyclic nitrones, such as DEPMPO, CYPMPO, and DPPMPO. These facts, therefore, give us important information on side reaction of spin trapping.

# An efficient and selective method for the preparation of triphenylmethyl ethers of alcohols and nucleosides

Negar Zekri and Reza Fareghi Alamdari

**Abstract:** A very simple and efficient method is described for the protection of alcohols and nucleosides with benzyl monomethoxytrityl and benzyl dimethoxytrityl ethers in the presence of diethylazodicarboxylate and a catalytic amount of ceric triflate. High selectivity was observed for the tritylation of 5'-OH function of nucleosides.

**Key words:** selective hydroxyl-group protection, benzyl dimethoxytrityl ether, ceric triflate, nucleosides.

**Résumé :** On a développé une méthode très simple et efficace de protéger des alcools et des nucléosides par formation d'éthers benzylmonométhoxytrityle et benzyldiméthoxytrityle, en présence d'azodicarboxylate de diéthyle et d'une quantité catalytique de triflate cérique. On a observé une grande sélectivité lors de la tritylation de la fonction 5'-OH des nucléosides.

**Mots-clés :** protection sélective d'un groupe hydroxyle, éther benzyldiméthoxytrityle, triflate cérique, nucléosides.

[Traduit par la Rédaction]

## Introduction

Hydroxyl-group protection is important in the synthesis of some organic molecules. One way to protect hydroxyl groups is to transform the molecules to their corresponding trityl (Tr) ethers.<sup>1</sup> Distinctive features of the trityl group are the following: (i) owing to its bulkiness, selective protection of polyols as monotritylated ethers is easily achieved, (ii) removal (deprotection) of the trityl group is easily affected by the action of mild acids such as formic acid<sup>2</sup> or Amberlyst resin.<sup>3</sup> There are several methods for the preparation of trityl ethers from the corresponding alcohols. Use of trityl chlorides in the presence of pyridine as a base and a solvent seems to be the most popular method for the preparation of trityl ethers.<sup>4,5</sup> This method requires the use of pyridine as a solvent, which is a toxic compound with high boiling point, and needs an aqueous work-up. In addition, this method suffers from prolonged reaction time. Other reagents for the tritylation of alcohols include a complex of trityl chloride and 4-dimethoxytrityl pyridine (DMAP) prepared beforehand.<sup>6</sup>

Selective protection of hydroxyl groups is an important synthetic strategy for the preparation of nucleoside derivatives. This work has been performed with varying degrees of success. The general procedure used for the tritylation of nucleosides is on the basis of that originally developed by Khorona.<sup>7</sup> Using Khorona's procedure for the tritylation of nucleosides, a mixture of monotritylated materials (i.e., 5'-OTr, 2'-OTr, and 3'-OTr) and ditritylated materials (2',5'-OTr, 3',5'-OTr, and 2',3'-OTr) was obtained, and the separation of unreacted remaining starting materials with column

chromatography was very difficult. Hakimelahi et al. reported a method for the tritylation of alcohols and nucleosides by the use of silver ion as catalyst.<sup>8</sup> The use of silver ion for the tritylation of alcohols and nucleosides increased the rate of tritylation, so the selectivity of the tritylation of nucleosides decreased. Recent work has included variations and improvements of the well-established tritylation procedures and the discovery and application of entirely new methods. The use of different reagents and media, such as acid-washed molecular sieves for the tritylation of saccharidic hydroxyls,<sup>9</sup> tetrabutyl ammonium bromide medium for the dimethoxy-tritylation of -OH function of nucleosides,<sup>10</sup> and 1-butyl-3-methylimidazolium chloride for the tritylation of cellulose,<sup>11</sup> is reported. Several other reagents, such as TrODT-TrTCI<sub>5</sub>,<sup>12</sup> AgOTf-TrCl,<sup>13</sup> prenyl trityl ether (PTE)-DDQ,<sup>14</sup> and B(C<sub>6</sub>F<sub>5</sub>)<sub>3</sub>,<sup>15</sup> are also available. However, most of these methods suffer from one or more disadvantages, including long reaction times, vigorous reaction conditions, and poor yields of the products in many cases. Oikawa et al. reported benzyl trityl ether and DDQ as alternative tritylation reagents.<sup>16</sup> However, the conditions of that reaction have been found to have limited applicability, and it is used only for the tritylation of alcohols and not for any nucleosides.

We have reported the deprotection of trityl ethers by the use of a catalytic amount of ceric triflate [Ce(OTf)<sub>4</sub>], and we showed that the rate-determining step of that reaction is involved in the production of trityl cation step.<sup>17</sup> So, we decided to study the tritylation of alcohols and nucleosides by

the use of benzyl trityl ether (BTE) as well as benzyl monomethoxytrityl (BMTE) and benzyl dimethoxytrityl (BDTE) ethers. In this work, we report a new, mild, and efficient method for hydroxyl-group protection by the reaction of primary, secondary, and tertiary alcohols and nucleosides with BMTE or BDTE ethers and ceric triflate in the presence of diethylazodicarboxylate (DEAD). We found that Ce(OTf)<sub>4</sub> catalyzes the efficient tritylation of alcohols and nucleosides with BMTE and BDTE in the presence of DEAD.

## Experimental

The chemicals were either prepared in our laboratories or purchased from Fluka or Merck Chemical Companies. All yields refer to isolated products after column chromatography. The products were characterized by their spectral data. NMR spectra were recorded on a Bruker advanced DPX-250 MHz, FTNMR spectrometer. Melting points were determined on a Buchi 510 in open capillary tubes circulating oil melting point in open apparatus and are uncorrected. The purity of the substance and the progress of the reactions were monitored by TLC on silica gel polygram SILG/UV254 plates. Column chromatography was carried out on the medium column of silica gel 60 Merck (30–270 mesh) in glass column (1 or 2 cm diameter) using 10–20 g of silica gel per 1 g of mixture.

### General procedure for protection of alcohols and nucleosides with BDTE or BMTE in the presence of Ce(OTf)<sub>4</sub> and DEAD

A solution of alcohol (5 mmol), DEAD (1.05 g, 6 mmol), and BDTE (2.46 g, 6 mmol) or BMTE (2.25 g, 6 mmol) in CH<sub>3</sub>CN (50 mL) was prepared. Ce(OTf)<sub>4</sub> (0.37 g, 0.5 mmol) and activated molecular sieves (4 Å, 2 g) were added to this solution, and the mixture was stirred for a specified time at room temperature. When either the alcohol or BDTE was completely consumed (TLC was used for monitoring), the reaction was quenched by the addition of 50 mL of 5% NaHCO<sub>3</sub>.

The mixture was extracted with chloroform (3 × 35 mL), and the combined extract was dried over Na<sub>2</sub>SO<sub>4</sub>. After evaporation of the solvent, the resulting mixture was introduced into a silica gel column eluted with CH<sub>2</sub>Cl<sub>2</sub>. The pure trityl ethers were obtained in 75%–95% yields (Tables 1

and 2). The effect of different solvents on the yield of the reaction is presented in Table 3.

### A typical procedure for the preparation of diphenylmethyl dimethoxytrityl ether with BDTE and DEAD in the presence of Ce(OTf)<sub>4</sub>

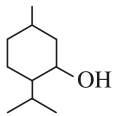

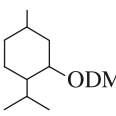

A solution of benzhydrol (0.92 g, 5 mmol), DEAD (1.05 g, 6 mmol), and BDTE (2.46 g, 6 mmol) in CH<sub>3</sub>CN (50 mL) was prepared. Ce(OTf)<sub>4</sub> (0.37 g, 0.5 mmol) and activated molecular sieves (4 Å, 2 g) were added to this solution, and the mixture was stirred for a specified time (1.5 h) at room temperature. When either the alcohol or BDTE was completely consumed (TLC was used for monitoring), the reaction was quenched by the addition of 50 mL of 5% NaHCO<sub>3</sub>. The mixture was extracted with chloroform (3 × 35 mL), and the combined extract was dried over Na<sub>2</sub>SO<sub>4</sub>. After evaporation of the solvent, the resulting mixture was introduced into a silica gel column eluted with CH<sub>2</sub>Cl<sub>2</sub>. The pure diphenylmethyl dimethoxytrityl ether was obtained as a pale yellow solid in 82% yield (Table 2); mp 62 °C. *R*<sub>f</sub> (EtOAc:*n*-hexane, 8:2): 0.3. <sup>1</sup>H NMR (CDCl<sub>3</sub>, ppm) δ: 7.49–6.91 (m, 23H, Ph–), 5.36 (s, 1H, CH–), 3.77 (s, 6H, CH<sub>3</sub>–).

### Preparation of 5'-*O*-monomethoxytrityl thymidine with BMTE and DEAD in the presence of Ce(OTf)<sub>4</sub>

A suspension of thymidine (0.48 g, 2 mmol), DEAD (0.42 g, 2.4 mmol), and BMTE (0.9 g, 2.4 mmol) in CH<sub>3</sub>CN (50 mL) was prepared. Ce(OTf)<sub>4</sub> (147.2 mg, 0.2 mmol) and activated molecular sieves (4 Å, 2 g) were added to this solution, and the mixture was stirred for the specified time at room temperature. When either the alcohol or BMTE was completely consumed (TLC was used for monitoring), the reaction was quenched by the addition of 50 mL of 5% NaHCO<sub>3</sub>. The mixture was extracted with chloroform (3 × 35 mL), and the combined extract was dried over Na<sub>2</sub>SO<sub>4</sub>. After evaporation of the solvent, the resulting mixture was introduced into a silica gel column eluted with EtOAc. The pure 5'-*O*-monomethoxytrityl thymidine was obtained as a white solid in 70% yield (Table 4); mp 103 °C (lit.<sup>18</sup> mp 103–105 °C). <sup>1</sup>H NMR (CDCl<sub>3</sub>, ppm) δ: 9.64 (s, 1H, NH), 7.64 (s, 1H, H-6), 7.45–7.26 (m, 14H, Ph–), 6.88 (d, 2H, CH<sub>2</sub>-5'), 6.45 (t, 1H, H-1'), 4.61 (s, 1H,

OH), 4.22–4.11 (m, 1H, H-3'), 3.82 (s, 3H, OCH<sub>3</sub>), 3.47–3.36 (m, 3H, CH<sub>2</sub>-2', H-4'), 2.38 (s, 3H, CH<sub>3</sub>–).

## Results and discussion

Different alcohols and nucleosides were subjected to the tritylation reaction in the presence of diethylazo-dicarboxylate and a catalytic amount of ceric triflate at room temper-

ature. The choice of solvent in the protection of –OH group with Ce(OTf)<sub>4</sub> is important, so the dimethoxytritylation of 3-phenyl propanol in different solvents was investigated (Fig. 1). On the basis of our results, which are shown in Table 3, Ce(OTf)<sub>4</sub> acts more efficiently in polar solvents, such as CH<sub>3</sub>CN.

The experiments were carried out in 1:1.2:1.2 molar ratio of alcohol/DEAD/BMTE (or BDTE) (Scheme 1).

**Scheme 3.** Tritylation of nucleosides in the presence of diethylazodicarboxylate and Ce(OTf)<sub>4</sub> catalyst.**Fig. 2.** Tritylation of adenosine in the presence of diethylazodicarboxylate and Ce(OTf)<sub>4</sub> catalyst.**Fig. 3.** Tritylation of 3-phenyl propanol in the presence of diethylazodicarboxylate and Ce(OTf)<sub>4</sub> catalyst.

To verify the proposed mechanism, tritylation of 3-phenyl propanol with BTE was carried out. Using 1.5 equiv. of BTE and 1.5 equiv. of DEAD in the presence of 0.1 equiv. of Ce(OTf)<sub>4</sub> at room temperature, this reaction proceeded at a slower rate than those with BDTE (Fig. 3). After 5 h, the product was obtained in only 50% yield. This shows that the rate of these reactions is dependent on the stability of the trityl cations.

Mechanistically, since the reaction rate is affected by the exchange of Tr by DMT and MMT, we believe in a mechanism that involves heterolytic cleavage of C–O benzilic bond to form the trytil cation.

In conclusion, a very simple and efficient method for the protection of alcohols and nucleosides is described. It should be mentioned that high rate of the reaction, high yields of the products, accompanied with high selectivity, easy work-up, and the use of a catalytic amount of Ce(OTf)<sub>4</sub> are advantages of the presented method. The Khorona's method for the tritylation of nucleosides suffers from prolonged reaction times and time-consuming work-up due to the presence of pyridine, which must be removed by repeated extraction of the reaction mixture with water. Elimination of pyridine, which is a toxic solvent, accompanied with an easy work-up, are worthy of mention as additional advantages for this method in the laboratory.

# Redox reactions of reactive oxygen species in aqueous solutions as the probe for scanning electrochemical microscopy of single live T24 cells

Xiaocui Zhao, Mengni Zhang, Yitao Long, and Zhifeng Ding

**Abstract:** The redox reactions of two main components of reactive oxygen species (ROS), superoxide and hydrogen peroxide, along with oxygen in aqueous solutions were investigated using a conventional electrochemical technique, differential pulse voltammetry (DPV). Superoxide undergoes oxidation at a Pt working electrode biased at 0.055 V versus Ag/AgCl, while hydrogen peroxide can be oxidized and reduced at 0.817 and −0.745 V, respectively. Oxygen in the solutions is reduced at the electrode with an applied potential of −0.455 V. Based on these results, hydrogen peroxide and superoxide released from live cells can be successfully monitored, identified, and mapped using scanning electrochemical microscopy (SECM) at different potentials. Single human bladder (T24) cells were imaged using a 5 μm diameter SECM probe biased at −0.400, −0.600, and −0.800 V. Oxygen reduction that seems an interference can be discriminated from that of hydrogen peroxide by means of SECM.

**Key words:** live cells, scanning electrochemical microscopy, reactive oxygen species, differential pulse voltammetry.

**Résumé :** Faisant appel à une technique électrochimique conventionnelle, la voltampérométrie pulsée différentielle (PD), on a étudié les réactions d'oxydoréduction des deux composants principaux des espèces réactives de l'oxygène (ERO), le superoxydes et le peroxyde d'hydrogène avec également celle de l'oxygène. Le superoxydes subit une oxydation au niveau d'une électrode de travail de Pt biaisée à 0,055 V vs. Ag/AgCl, tandis que le peroxyde d'hydrogène peut être oxydé et réduit respectivement à 0,817 et −0,745 V. En solutions, l'oxygène est réduit à l'électrode par un potentiel appliqué de −0,455 V. Sur la base de ces résultats, le peroxyde d'hydrogène et le superoxyde émis par des cellules vivantes peuvent facilement être détectés, identifiés et localisés en faisant appel à la microscopie électrochimique à balayage (MECB), à divers potentiels. On a pu produire des images des cellules uniques de vessie humaine (T24) en utilisant cette technique à l'aide d'une sonde de diamètre 5 μm, biaisée à −0,400, −0,600 et −0,800 V. La réduction de l'oxygène qui semble une interférence peut être différenciée de celle du peroxyde d'hydrogène grâce à la MECB.

**Mots-clés :** cellules vivantes, microscopie électrochimique à balayage, espèces d'oxygène réactives, voltampérométrie pulsée différentielle.

## Introduction

Reactive oxygen species (ROS) play critical roles in the physiological processes of live cells. They are involved in a wide variety of cellular activities<sup>1</sup> such as cell adhesion,<sup>2</sup> inflammatory response,<sup>3</sup> and cell proliferation and apoptosis<sup>4</sup> when they are constantly generated at relatively low concentrations in normal healthy cells. However, they can damage key macromolecules such as DNA in the cells and induce various diseases, such as cancer, if they are persistently produced in excess.<sup>5–9</sup> Therefore, ROS are gaining attention in a large number of research areas.<sup>4</sup>

ROS can be generated in the intracellular region and extracellular field. Mitochondria and other nucleus related or-

ganelles are the major intracellular sources of ROS by delivering electrons to oxygen molecules:<sup>10</sup>

The superoxide anions are subsequently converted to hydrogen peroxide, through a reaction catalyzed by superoxide dismutase (SOD):<sup>11</sup>

Superoxide anions are confined to their generation sites inside of cells. However, hydrogen peroxide generated dur-

ing the dismutated reaction can pass through cell membranes and enter the extracellular fluid.<sup>12</sup>

The most significant extracellular source of ROS is NAD(P)H oxidase:<sup>13</sup>

Thus, the main ROS released by live cells are superoxide anions and hydrogen peroxide.

In situ detection and identification of ROS is challenging due to their short chemical life time: as reported,  $\text{H}_2\text{O}_2$  exists for milliseconds and superoxide exists for microseconds in certain physiological environments.<sup>14</sup> Electrochemical methods, specifically scanning electrochemical microscopy (SECM), present facile tools of direct examination of ROS released from cells, utilizing well-positioned ultramicroelectrodes (UMEs) or modified electrodes.<sup>5,8,9,15–22</sup> In SECM, the UME was held in a bulk solution or moved in the close proximity of the substrate immersed in the solution containing a redox mediator. The electrochemical current due to the reduction or oxidation of the mediator flowing through the UME is measured. Since the current is proportional to the concentration of a redox species at the substrate, which can be live cells or metal alloys, any change in their chemical activities will perturb the electrochemical responses of the probe. This perturbation provides information about the nature and activities of the substrate. Standard redox mediators are often used to precisely control the separation distance between the probe and the substrate.<sup>23,24</sup> Here, we used ferrocenemethanol because it is a standard redox mediator widely used in biosystems.<sup>25–27</sup> Since ferrocenemethanol can be oxidized at 0.244 V versus Ag/AgCl,<sup>28</sup> the probe was biased at 0.350 V where the oxidation current of ferrocenemethanol is diffusion controlled. When the probe is far away from the substrate, the current detected by the UME ( $I_\infty$ ) is independent of the separation distance between the electrode and the substrate. As the tip is moving down toward the substrate, which in our case is a live cell, the current will decrease due to the hindered diffusion by the cell. The closer the tip to the cell, the smaller the current. The cell shows “negative feedback”. The curve of normalized current ( $I/I_\infty$ ) versus normalized distance (UME-to-substrate distance divided by UME radius) is called the probe approach curve (PAC), which is independent of the UME size in this negative feedback case. In our SECM experiments, the tip was being moved down until the current was reduced by 35% (i.e.,  $I = 0.65I_\infty$ ). That means that the separation distance between the electrode surface and the cell is 3.3  $\mu\text{m}$ , as read from the theoretical PAC.<sup>23,24,29</sup> In such a close approximate, ROS flux in the extracellular fluid can be immediately detected by recording the corresponding current at appropriate potentials under physiological conditions without disturbing the biological mechanisms. Thus, real-time information can be acquired concerning extracellular ROS. Furthermore, different types of ROS species can be identified by amperometry methods at different electrode potentials. Amatore’s group<sup>30,31</sup> recorded oxidative currents of reactive nitrogen species (RNS), hydrogen peroxide released by macrophages and phagocytes. They also detected the immediate ROS burst using amperometric detection with a platinized carbon fiber microelectrode via puncturing the cell cytoplasmic membrane with the microelectrode.<sup>8,9,18,22</sup>

Matsue’s group<sup>19</sup> also detected ROS release with an electrochemistry method and chemiluminescence method using phorbol myristate acetate (PMA)-differentiated cells. It should be mentioned that SECM has become a more and more popular technique to acquire the chemical and topographical information in the vicinity of live cells for the following reasons: it is noninvasive to live cells, it can identify different species released from the cells with varied potentials applied to the UME, and it can locate the species released from the different locations of the same cell.<sup>17,32–38</sup> SECM has been proven to be a powerful tool for mapping cell topography,<sup>39–41</sup> monitoring the respiration function,<sup>42–46</sup> investigating the pathway of transmembrane charge transfer,<sup>47,48</sup> and detecting short life time species such as  $\text{ROS}^{23}$  and nitric oxide<sup>49</sup> released from live cells. Our group<sup>46</sup> has previously shown that SECM can be used to study the effect of Cd-induced stress on single stomata in *Brassica juncea*.

However, almost all the groups mentioned above except ours<sup>23</sup> detected the ROS through oxidation using electrochemical methods in the positive potential region. The mediator, ferrocenemethanol, used to precisely control the probe-to-cell distance has a drastic interference when the applied potential is larger than 0.200 V. It is desirable to be able to determine ROS in the potential range that is more negative than 0.200 V. Systematic investigations in this aspect are scarce due to the irreversibility of the ROS reactions at large electrodes, their possible slow reaction rates, and the interference of the oxygen reduction.

Predominant extracellular ROS should be hydrogen peroxide and superoxide, since other ROS, such as hydroxide radicals, are too reactive to survive long enough to be detected. Superoxide can be oxidized by the SECM probe in the designated potential region while hydrogen peroxide can be reduced.

Oxygen reduction is unavoidable in the potential range whereby hydrogen peroxide is reduced.

In the present work, redox reactions of hydrogen peroxide and superoxide along with oxygen in aqueous solutions were systematically studied using differential pulse voltammetry (DPV). Although the redox reactions of these two species and oxygen were studied by other groups before, their experimental conditions were too different from the physiological environment of live cells (e.g., pH).<sup>50–55</sup> And the redox potentials of these species are largely dependent on pH, the electrode material, and the property of the solvent. Thus, it is necessary for us to verify the reduction potential of each species at our experiment condition, which is similar to the physiological environment of live cells. Hydrogen peroxide and nominal oxygen profiles in the vicinity of single T24 cells were imaged using SECM with a 5  $\mu\text{m}$  diameter UME with various bias potentials.

## Experimental section

### Chemicals

Culture media, serum, antibiotics, and glutamine were purchased from Gibco (Invitrogen Canada, Inc., Burlington,

ON). Deionized water with 18.2 mol/L  $\Omega$  resistivity (Milli-Q, Millipore, Bedford, MA) was used to prepare all aqueous solutions.  $\text{H}_2\text{O}_2$  solution (30%) was obtained from EMD Chemicals, Inc. (Darmstadt, Germany). Catalase from bovine liver, superoxide dismutase from bovine liver, potassium chloride, potassium superoxide, and ferrocenemethanol were purchased from Sigma-Aldrich (Mississauga, ON).

### Cell culture

T24 cells, which originate from human bladder carcinoma cells, were supplied by American Type Culture Collection, Manassas, VA. The T24 cells were cultured in DMEM supplemented with 4 mmol/L L-glutamine, 100 units/mL of penicillin, and 10% fetal bovine serum. The cells were incubated at 37 °C and 5%  $\text{CO}_2$  in an incubator (Sanyo Canada, Ltd. Concord, ON). Cell culture was performed with 50 mL plastic tissue culture flasks (Becton, Dickinson and Company, Mississauga, ON). T24 cells were detached from plastic walls of the flasks for subcultures with 0.25% Trypsin-EDTA (Gibco. Invitrogen Canada, Burlington, ON). Cells were detached, transferred, and subcultured onto Petri dishes one day prior to experiments.

### Electrochemistry procedures for DPV

A two-electrode system containing a 10  $\mu\text{m}$  diameter Pt UME as the working electrode and a saturated KCl Ag/AgCl electrode as the reference and counter electrode was employed in the DPV experiment. All potentials reported here are referred to the Ag/AgCl reference electrode. For comparison, the oxidation potential of ferrocenemethanol was determined as 0.236 V. The potential value was checked at the end of each experiment and was found to be very constant. DPV was recorded with a potentiostat, CHI 610A (CH Instruments, Austin, TX). Typical experimental parameters for DPVs are 0.05 V as pulse height, 50 ms pulse width, 200 ms period, and 0.02 V/s scan rate.<sup>56</sup> For the deaerated experiment, the stream of Argon (Ar) gas was continuously bubbled into the solution for at least 20 min prior to the experiment and a stream of Ar was maintained over the solution during the experiment to minimize the oxygen concentration in solution. For the oxygen-rich experiments, pure  $\text{O}_2$  gas was bubbled in the solution for 20 min prior to the experiment and a flow of oxygen was kept over the solution during the experiment.

### SECM setup

The detailed SECM procedure was described in one of our recent publications.<sup>23</sup> In brief, SECM setup was adapted from Alpha-SNOM by replacing the objective with an electrode holder and a homemade Pt electrode. This electrode serves as the working electrode and an Ag/AgCl electrode is used as the reference and counter electrode. In the experiments, the SECM electrode, applied at a certain potential, was brought closer to the cells and positioned at a desired height while the current was monitored. At this fixed height, the working electrode was scanned in a plane by moving the scanning stage. Constant height SECM images can be obtained by recording current versus lateral coordinates in the scanning plane. All the SECM measurements were performed with a potentiostat (Compactstat Electrochemical Interface, IVIUM Technologies, Netherlands) driven by the

IviumStat Control software (IVIUM Technologies), from which the electrochemical current was directed into a data acquisition channel of the Alpha-SNOM microscope (WITec, Germany) connected to a computer. WITec software for confocal microscopy was adopted for the SECM imaging. The integration time at each image pixel was 0.01 s. The acquisition time of each image was around 12 min with a resolution of  $256 \times 256$  pixels for one image.

## Results and discussion

### Oxygen reduction reaction (ORR)

ORR at the Pt microelectrode was studied with DPV in the potential range of  $-0.850$  to  $0.000$  V in the air-saturated electrolyte solution containing 50 mmol/L KCl (Fig. 1). A peak potential was observed at  $-0.430$  V due to oxygen reduction when the applied potential was scanned from  $0.000$  to  $-0.850$  V (top solid curve in Fig. 1). The maximum potential appeared at  $-0.490$  V while scanning the potential in the reverse direction (bottom solid wave in Fig. 1). Oxygen was reduced to  $\text{H}_2\text{O}$  through a four-electron process<sup>57</sup> as shown in eq. [6].

Assuming that the diffusion coefficients of the reactant and product are approximately the same, the formal potential for ORR can be determined by eq. [7].<sup>58,59</sup>

$$[7] \quad E^0 = E_{\text{max}} + \Delta E/2$$

where  $E_{\text{max}}$  is the peak potential in the DPV and  $\Delta E$  is the pulse height (50 mV). The formal reduction potential was determined from the forward and reverse scans as  $-0.455$  and  $-0.465$  V, respectively. From the difference of the obtained formal potential, it is plausible that the reduction reaction is not reversible and the reaction kinetics is slow. However, with the microelectrode, it is still possible to measure the steady-state current that is proportional to the oxygen concentration.<sup>46,60</sup> Tsionsky et al. (Bard's laboratory).<sup>60</sup> reported the oxygen reduction at the surface of a 7  $\mu\text{m}$  carbon electrode by recording cyclic voltammograms.<sup>60</sup> Our group<sup>46</sup> and Bard's laboratory<sup>60</sup> monitored the ORR using cyclic voltammetry at platinum and carbon microelectrodes and detected the oxygen released from photosynthetic processes by setting an applied potential at which the diffusion controlled steady-state current can be obtained.

These DPV peaks disappeared after the solution was deaerated with Ar gas (dotted voltammograms in Fig. 1) and the peak current increased in the oxygen-saturated solution (dotted and dashed curves in Fig. 1). This confirmed that the peaks were due to the electron transfer between oxygen and the electrode.

### Redox behaviours of $\text{H}_2\text{O}_2$

The reduction behaviour of  $\text{H}_2\text{O}_2$  in deaerated 50 mmol/L KCl solution was recorded (solid lines in Fig. 2A) and a pair of peaks appeared at potentials of  $-0.720$  and  $-0.750$  V, respectively, when the applied potential was scanned from  $0.200$  to  $-0.900$  V and subsequently reversed. These peaks gave a formal potential of  $-0.745$  or  $-0.725$  V based on eq. [7]. Hydrogen peroxide undergoes a reduction reaction

**Fig. 1.** Differential pulse voltammograms within a potential range between 0.000 and  $-0.800$  V for oxygen at a  $10\text{ }\mu\text{m}$  diameter Pt electrode in air-saturated (solid lines), oxygen-saturated (dotted and dashed lines), and deaerated (dotted lines) electrolyte solutions. KCl (50 mmol/L) was used as the supporting electrolyte in all solutions.

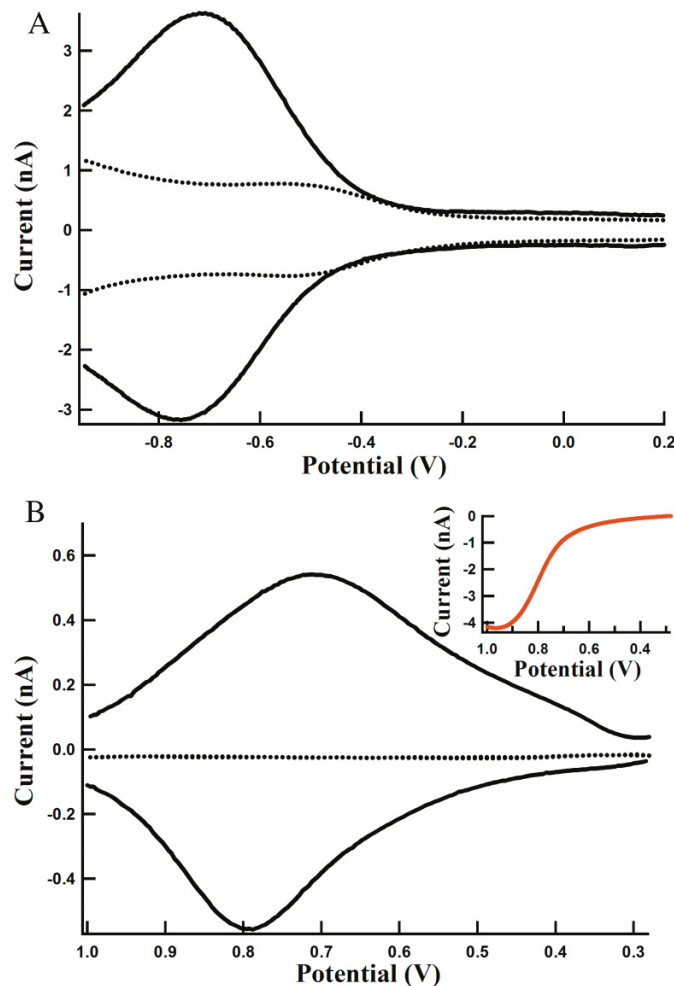

via eq. [5]. To confirm that the observed reduction peaks are due to the electron transfer of  $\text{H}_2\text{O}_2$  and its counter part, an enzyme, catalase, which can convert  $\text{H}_2\text{O}_2$  to oxygen and water, was added to the above solution. Differential pulse voltammograms were recorded immediately without purging Ar gas into the solution after catalase was mixed thoroughly with the solution. The coupled peaks at  $-0.720/-0.750$  V in forward/reverse scans disappeared and the waves for oxygen reduction were determined to be  $-0.430/-0.490$  V (dotted line in Fig. 2A). This demonstrates that the reduction peaks at  $-0.720/-0.750$  V were due to the electrochemical reaction of  $\text{H}_2\text{O}_2$ . The low current after the catalase addition can be attributed to the limited solubility of oxygen in the solution and disproportionation reaction of hydrogen peroxide with the aid of catalase as described by eq. [8].

The detection of  $\text{H}_2\text{O}_2$  reduction was discriminated from ORR by polarography.<sup>61</sup> The formal potential was also determined to be  $-0.8$  V (vs Ag/AgCl) with DPV at a mercury electrode.<sup>62</sup> It is clear from our results and those in the literature that trace concentrations of hydrogen peroxide in aqueous solutions can be determined by means of electrochemistry.

In addition, our experimental results (not presented here) revealed that the reduction peaks shifted slightly with higher concentrations of  $\text{H}_2\text{O}_2$  in the solution, due to the pH change caused by the concentration. It is interesting to note that the

**Fig. 2.** (A) Differential pulse voltammograms within a potential range between 0.200 and  $-0.880$  V for 3.4 mmol/L hydrogen peroxide at a  $10\text{ }\mu\text{m}$  diameter Pt electrode in deaerated  $\text{H}_2\text{O}_2$  solution containing 50 mmol/L KCl electrolyte (solid lines) and in  $\text{H}_2\text{O}_2$  solution containing 50 mmol/L KCl electrolyte in the presence of catalase (dotted lines). (B) Differential pulse voltammograms with a potential range from 0.280 and 1.000 V for hydrogen peroxide at a  $5\text{ }\mu\text{m}$  diameter Pt electrode in a deaerated solution containing 50 mmol/L KCl electrolyte in the presence (solid lines) and absence (dotted lines) of 1.2 mmol/L hydrogen peroxide. The inset is the linear voltammograms of the same hydrogen peroxide solutions with the applied potential scanned from 0.280 to 1.000 V.

reduction waves of oxygen became broad and can be deconvoluted into two successive reductions (dot-dashed curves in Fig. 1) when the KCl electrolyte solution was purged with pure oxygen. The second reduction peak potential agrees very well with that of  $\text{H}_2\text{O}_2$  reduction. The reduction of oxygen can therefore follow a pathway of two two-electron transfer processes when the oxygen concentration was high.

This observation agrees well with the fact that oxygen reduction current at a mercury electrode was enhanced via the reaction in eq. [8] by adding catalase.<sup>61</sup> Furthermore, the

**Fig. 3.** Differential pulse voltammograms within a potential range between 0.160 and  $-0.880$  V at a  $10\text{ }\mu\text{m}$  diameter Pt electrode for potassium superoxide in  $\text{KO}_2$  solution containing  $50\text{ mmol/L}$  KCl electrolyte in the absence (solid lines) and presence (dashed lines) of superoxide dismutase. The inset is the linear voltammograms of the same solutions with the applied potential scanned from  $0.000$  to  $0.300$  V.

**Fig. 4.** Microscopic picture of (A) a live T24 cell and the SECM images of the T24 cell using a  $5\text{ }\mu\text{m}$  diameter Pt electrode biased at (B)  $-0.400$  V, (C)  $-0.600$  V, and (D)  $-0.800$  V vs Ag/AgCl. The microelectrode ratio of the glass sheath diameter to that of Pt (RG) is 5. The scale bar in the images represents  $10\text{ }\mu\text{m}$ .

two-electron transfer process in the acidic solution was also observed by Bard's group<sup>63</sup> at a Hg/Au electrode.

The oxidation of hydrogen peroxide was also investigated by means of DPV as shown in Fig. 2B. The voltammograms

showed a peak potential at  $0.792$  V when the applied potential was scanned from  $0.280$  to  $1.000$  V and one at  $0.712$  V when the potential scan direction was reversed. The cyclic voltammogram demonstrated a dramatic hysteresis (not shown) between the forward and backward scans. All these observations prove the irreversibility of the oxidation reaction. The negative sign current was recorded in a linear voltammogram running from  $0.280$  to  $1.000$  V in the presence of hydrogen peroxide (inset in Fig. 2B), which provided the further proof of the oxidation of hydrogen peroxide. The formal potential was then calculated as  $0.817$  V from the DPV curve when the applied potential was scanned from low to high. Amatore's group<sup>8,18</sup> reported the oxidation potential at  $0.6$  V versus Ag/AgCl with a platinized carbon fiber microelectrode and monitored this oxidant release using macrophages at the level of a single cell, in real time and quantitatively.

### Oxidation of superoxide

Superoxide is not stable and is easily decomposed in the aqueous solution to hydrogen peroxide and oxygen.

Therefore, the detection using electrochemical methods were constrained to organic solutions, which greatly differ from the natural environment of live cells.<sup>64–66</sup> In our experiment, our strategy to detect superoxide in aqueous solutions was to use a microelectrode in the presence of superoxide dismutase. In the DPV of superoxide (solid lines in Fig. 3), in addition to the peaks for oxygen reduction ( $-0.430/-0.490$  V) and hydrogen reduction ( $-0.750/-0.830$  V), a new pair of peaks appeared at  $0.120/0.030$  V. The redox nature was further verified by recording the linear scan voltammogram of the superoxide (shown in the inset in Fig. 3). By conventional American standards, the negative current sign in the inset depicted oxidation behaviour. The formal oxidation potential was calculated as  $0.055$  V based on eq. [7] with the DPV curve when the applied potential was scanned from negative to positive (bottom solid line in Fig. 3). A further experiment was conducted to confirm the electrochemical activity of superoxide by adding superoxide dismutase (SOD) into the solution. The DPV result is shown by the dotted waves in Fig. 3. Superoxide can be completely converted to hydrogen peroxide in the presence of SOD according to eq. [2]. The superoxide oxidation peaks at  $0.120$  and  $0.030$  V disappeared, which further indicates that this peak pair was from electrochemical reactions of superoxide. Furthermore, the peak currents attributed to  $\text{H}_2\text{O}_2$  reduction increased from  $8.2$  to  $12.4$  nA due to the augmented  $\text{H}_2\text{O}_2$  concentration via reaction by means of SOD. Our experimental data agreed well with a published paper<sup>21</sup> in which anodic current due to superoxide oxidation was recorded at  $0.1$  V versus Ag/AgCl using a carbon fiber electrode.

### Detection of $\text{H}_2\text{O}_2$ released from T24 cells at different potentials with SECM

As can be seen from the DPV results, it is possible to detect the two most common ROS, hydrogen peroxide and superoxide, by setting appropriate potentials at a microelectrode. SECM probes are advantageous as they can be positioned in the vicinity of a live cell to determine ROS

immediately after being released from the cell. Therefore, we attempted to map out the hydrogen peroxide concentration profile above single T24 cells at variable potentials from  $-0.400$  to  $-0.800$  V. These experiments should provide the rationale as to whether we can discriminate the release of hydrogen peroxide from oxygen that has an approximate concentration of  $0.2$  mmol/L.<sup>46</sup>

The bottom view of the cell in the inverted microscope is shown in Fig. 4A. First, a  $5\text{ }\mu\text{m}$  diameter Pt SECM probe electrode with a biased potential of  $0.350$  V was positioned above a T24 cell in the medium containing  $0.45$  mmol/L ferrocenemethanol. There is minimal interaction between the SECM mediator and the live cell so that the SECM probe approach curve (PAC) is expected to show a negative feedback.<sup>23,47</sup> Based on the SECM principle, a probe-to-cell distance of  $3.25\text{ }\mu\text{m}$  was reached, where the normalized current at the probe is  $0.65I_{\infty}$ .<sup>23,46</sup> Following this, the bias potential was switched to  $-0.400$  V and the SECM probe was rastered above the cell. The SECM image as shown in Fig. 4B was obtained by recording the probe current versus its coordinates. The dark area in the image (Fig. 4B) illustrates low current while the bright region indicates high current. From the DPV results for oxygen reduction, one can see that oxygen can be partially reduced at  $-0.400$  V. The middle of the cell in Fig. 4B is relatively brighter, which can be attributed to higher current and therefore a higher concentration of oxygen. Oxygen is not released directly by cells and the close distance between the probe and the cell causes blockage of the oxygen diffusion to the probe by the cell. However, oxygen concentration can be relatively high above the cell due to the decomposition of hydrogen peroxide. From the high current in the middle of the cell image in Fig. 4B, it is evident that the indirect oxygen generation overwhelmed the blockage. With the biased potential of  $-0.600$  V at the microelectrode, the SECM image of the same T24 cell demonstrated a much better contrast (Fig. 4C). At this applied potential, the SECM probe reached a steady-state current, which is proportional to the local oxygen concentration. It is therefore expected to see higher current due to the oxygen reduction. It can be seen from the scale bars beside the images (Figs. 4B and 4C) that the maximum reduction current increased from  $14.2$  to  $40.4$  pA. Furthermore, the applied potential was moved to be more negative at  $-0.800$  V where oxygen and hydrogen peroxide can both be reduced. The highest current was monitored as  $70.2$  pA, and the highest image contrast was obtained among images at probe potentials of  $-0.400$ ,  $-0.600$ , and  $-0.800$  V (Figs. 4B–4D). It can be concluded that in the vicinity of the cell, hydrogen peroxide has a higher concentration than oxygen. It is therefore possible to determine this ROS using SECM even though it may decompose on its way to travelling to the surface of the electrode. SECM has the advantage to approach live cells at a very short distance and catch ROS before their decay to other species. As discussed in the Introduction, mitochondria in cells can generate superoxide, which mutates to hydrogen peroxide simultaneously or enzymatically. This is not the case in our experiments. It is plausible that hydrogen peroxide was mainly produced above the nucleus. The production pathways might be extracellular (via the enzymes at the cell surface) or intracellular (via inner organelles and diffusion through the cell membrane).

## Conclusions

The SECM probe, consisting of a custom-made platinum microelectrode, is efficient to determine the redox reactions of the two major ROS, hydrogen peroxide and superoxide, along with oxygen in aqueous solutions. DPV determined the formal reduction potential of oxygen as  $-0.455$  V versus saturated KCl Ag/AgCl. It was found that hydrogen peroxide undergoes reduction at  $-0.745$  V and oxidation at  $0.817$  V versus the same reference electrode. Superoxide can be oxidized with a formal potential of  $0.055$  V versus the Ag/AgCl. This work provides the fundamentals for further SECM studies on live T24 cells using nominal oxygen concentrations or hydrogen peroxide as the extracellular marker. The successful application of SECM experiments to single live cells presents the tremendous potential of ROS as a promising extracellular indicator for studies on the physiological activities of live cells. Moreover, the noninvasive nature of SECM is ideal for a real-time investigation on almost all single live cells while maintaining their physiological environment without adding any extraneous indicator.

## Acknowledgments

We appreciate the financial support for this research from the Canadian Institute for Photonic Innovations (CIPI), the Natural Sciences and Engineering Research Council of Canada (NSERC), the Ontario Photonics Consortium (OPC), the Canada Foundation for Innovation (CFI), the Ontario Innovation Trust (OIT), the Premier Research Excellence Award (PREA), and the University of Western Ontario (UWO; Academic Development Fund (ADF) as well as a Start-up Fund). Our lab is part of the Centre of Chemical Physics (CCP) and Western Institute of Nano Science (WINS) at UWO. Technical assistance from John Vanstone, Jon Aukema, Sherrie McPhee, and Mary Lou Hart is gratefully acknowledged.

# Theoretical study of the electron spectra of *s*-triazine vapour

Delano P. Chong

**Ref.:** *Can. J. Chem.* **2009**, 87 (8), 1148.

For the removal of an electron from the degenerate MOs of a molecule, there are two ways to describe the cation: (i) using fractional electrons to maintain full symmetry, and (ii) removing an electron from one of the degenerate MOs. For more reliable prediction of vertical ionization energies (VIEs) using the method abbreviated as  $\Delta$ PBE0(SAOP) in the above-mentioned paper,<sup>1</sup> the latter choice should have been used, except for nonperhalo molecules,<sup>2</sup> instead of which choice (i) was incorrectly employed. In Table 1 below, the results for both choices are shown, together with

the deviations from experiment in parentheses, as well as the results from a larger basis set known as even-tempered valence quadruple-zeta (et-pVQZ) of Slater-type orbitals.<sup>3</sup>

It can be seen that the aug-TZP basis set is sufficiently large for VIEs. In addition, the assignment of the bands at 17.8 and 18.2 to  $1a_2'$  and  $4a_1'$ , respectively, is uncertain.<sup>4</sup> Since my  $\Delta$ PBE0(SAOP) procedure has been so successful in predicting VIEs, I offer the alternative of interchanging the two assignments in Table 1, with the result of smaller average absolute deviations (AADs).

**Table 1.** Comparison of calculated vertical ionization energies, in eV, of gas-phase *s*-triazine (with deviations in parentheses).

# Stereoelectronic interaction effects on the conformational properties of 5-methyl-5-aza-1,3-dithiacyclohexane and its analogous containing N, P, O, and Se atoms — A hybrid density functional theory (DFT), ab initio study, and natural bond orbital (NBO) analysis

Davood Nori-Shargh, Neda Hassanzadeh, Meisam Kosari, Parvin Rabieikarahrudi, Hooriye Yahyaei, and Sasan Sharifi

**Abstract:** Natural bond orbital (NBO) analysis, hybrid density functional theory (hybrid DFT: B3LYP/6-311+G\*\*//B3LYP/6-311+G\*\*), and ab initio molecular orbital (MO: MP2/6-311+G\*\*//B3LYP/6-311+G\*\*) based methods were used to study the electronic delocalization energy (DE), dipole–dipole interactions, and steric repulsions on the conformational properties of 5-methyl-5-aza-1,3-dioxacyclohexane (**1**) (-phospha- (**2**), -arsena- (**3**)), 5-methyl-5-aza-1,3-dithiacyclohexane (**4**) (-phospha- (**5**), -arsena- (**6**)), and 5-methyl-5-aza-1,3-diselenacyclohexane (**7**) (-phospha- (**8**), -arsena- (**9**)). The MP2/6-311+G\*\*//B3LYP/6-311+G\*\* and B3LYP/6-311+G\*\*//B3LYP/6-311+G\*\* results revealed that the axial stereoisomers of compounds **1–9** are more stable than their equatorial stereoisomers. In this regard, the obtained results showed an egregious axial preference for compounds **1**, **4**, and **7**. Importantly, the results showed that the energy differences between the axial and equatorial stereoisomers decrease from compounds **1** → **3**, **4** → **6**, and also, **7** → **9**. The NBO analysis of donor–acceptor interactions revealed that the calculated DE for compounds **1–3** are  $-21.50$ ,  $-7.84$ , and  $-4.38$  kcal mol<sup>-1</sup>, respectively. The decrease of the calculated DE values from compound **1** to compound **3** could reasonably explain the decrease of the energy differences between the axial and equatorial stereoisomers from compound **1** to compound **3**. The correlation between the DE, dipole–dipole interactions, structural parameters, and conformational behaviors of compounds **1–9** has been investigated.

**Key words:** anomeric effects, molecular modeling, ab initio, natural bond orbital (NBO), 5-methyl-5-aza-1,3-dithiacyclohexane.

**Résumé :** On a fait appel à des méthodes d'analyse à base de l'orbitale de liaison neutre (OLN), de la théorie de la fonctionnelle de densité hybride (TFD-hybride : B3LYP/6–311+G\*\*//B3LYP/6–311+G\*\*) et l'orbitale moléculaire ab initio (OM : MP2/6–311+G\*\*//B3LYP/6–311+G\*\*) pour étudier l'énergie de délocalisation (ED) électronique, les interactions dipôle-dipôle et les répulsions stériques sur les propriétés conformationnelles du 5-méthyl-5-aza-1,3-dioxacyclohexane (**1**) [-phospha- (**2**), -arséna- (**3**)], 5-méthyl-5-aza-1,3-dithiacyclohexane (**4**) [-phospha- (**5**), -arséna- (**6**)] et 5-méthyl-5-aza-1,3-disélenacyclohexane (**7**) [-phospha- (**8**), -arséna- (**9**)]. Les résultats obtenus avec les méthodes MP2/6–311+G\*\*//B3LYP/6–311+G\*\* et B3LYP/6–311+G\*\*//B3LYP/6–311+G\*\* révèlent que les stéréoisomères axiaux des composés **1–9** sont plus stables que les stéréoisomères équatoriaux. Dans cette optique, les résultats obtenus montrent une préférence globale pour les composés **1**, **4** et **7**. De plus, les résultats montrent que les différences d'énergie entre les stéréoisomères axiaux et équatoriaux diminuent dans les composés **1** → **3**, **4** → **6** et aussi **7** → **9**. L'analyse de l'OLN des interactions donneur-accepteur révèle que l'énergie de délocalisation pour les composés **1–3** sont respectivement de  $-21,50$ ,  $-7,84$  et  $-4,38$  kcal mol<sup>-1</sup>. La diminution des valeurs calculées d'ED en allant du composé **1** au composé **3** pourrait facilement être expliquée par une diminution dans les différences d'énergie entre les stéréoisomères axiaux et équatoriaux des composés **1** à **3**. On a étudié la corrélation entre les ED, les interactions dipôle-dipôle, les paramètres de structure et les comportements conformationnels des composés **1–9**.

**Mots-clés :** effets anomères, modelage moléculaire, ab initio, orbitale de liaison neutre (OLN), 5-méthyl-5-aza-1,3-dithiacyclohexane.

## Introduction

The knowledge about conformational properties of heterocyclic compounds should be of very general interest since saturated heterocyclic compounds comprise a large segment of organic and inorganic chemistry and are quite widespread in nature (e.g., in alkaloids, carbohydrates, and plant growth regulators, among other compounds).

It is well-known that the stereoelectronic interactions are expected to play an important role on the conformational properties of heterocyclic compounds.<sup>1,2</sup> In this context, Angiolini et al.<sup>3</sup> have described that the methyl group in 5-methyl-5-aza-1,3-dithiacyclohexane (**1**) is largely axial. There is a substantial disfavoring factor in the equatorial conformation of compound **1** (unshared electron pairs are parallel (e.g., the “rabbit-ear effect”)).<sup>4,5</sup> On the other hand, the axial orientation of the methyl group at the nitrogen atom in compound **1** has been explained in terms of favorable  $LP_N \rightarrow \sigma^*_{C-S}$  (LP = lone pair) orbital interactions.<sup>6,7</sup>

It should be noted that the anomeric effect (AE) is in favor of the axial conformation of a six-membered saturated ring in opposition to the steric effect, which normally leads to a preference for the equatorial conformation. In this context, there is a stereoelectronic preference for conformations in which the best donor lone pair is antiperiplanar to the best acceptor bond.<sup>8,9</sup> Therefore, we could stress that the delocalization energy (DE) associated with electronic delocalizations must be considered as the difference between the sum of the equatorial and axial delocalization energies:

$$[1] \quad DE = \Sigma DE_{eq} - \Sigma DE_{ax}$$

Based on this argument, there is a direct relationship between the DE and AE.

The origin of the generalized anomeric effects in methanediol and its sulfur, selenium, and tellurium derivatives were examined by ab initio calculations<sup>10,11</sup> and NBO<sup>12–17</sup> analysis. Also, the conformational preferences of methanediol, dithoxymethane, and methanediamine were analyzed within the framework of the quantum theory of atom in molecule (QTAIM) method.<sup>18,19</sup> In addition, the NBO analysis was performed to study the conformational stability of  $CH_2(XH_2)_2$  (X = N, P, As) compounds.<sup>20</sup>

There is sufficient published experimental information about the stereoelectronic and steric interactions in compound **1**,<sup>3,6,7</sup> but there is no published experimental or quantitative theoretical data about the donor–acceptor delocalization effects on the conformational properties of compounds **1–9**. In this work, the stereoelectronic interactions associated with the DE, dipole–dipole interactions, and also the confor-

mational and structural properties of compounds **1–9** have been investigated computationally using both ab initio molecular orbital (MO) and density functional theory (DFT) methods (see Scheme 1).<sup>21–25</sup>

Also, the stabilization energies ( $E_2$ ) associated with  $LP_{eqX5} \rightarrow \sigma^*_{C6-Y1}$  and  $LP_{axX5} \rightarrow \sigma^*_{C6-Y1}$  delocalizations (see Figs. 1 and 2) and their influences on the conformational properties of compounds **1–9** were quantitatively investigated by the NBO (natural bond orbital) analysis.<sup>26</sup> The resonance energies associated with donor  $\rightarrow$  acceptor electronic delocalizations are proportional to  $S^2/\Delta E$  where  $S$  is the orbital overlap and  $\Delta E$  is the energy differences between the LP and  $\sigma^*$  orbitals.<sup>27</sup>

$$E_2 \text{ (stabilization or resonance energy)} \propto (S^2/\Delta E)$$

In addition, the stabilization energy ( $E_2$ ) associated with  $i \rightarrow j$  delocalization is explicitly estimated by the following equation:

$$[2] \quad E_2 = q_i \frac{F^2(i,j)}{\varepsilon_j - \varepsilon_i}$$

where  $q_i$  is the  $i$ th donor orbital occupancy,  $\varepsilon_i$  and  $\varepsilon_j$  are diagonal elements (orbital energies), and  $F(i,j)$  are off-diagonal elements associated with the NBO Fock matrix. Therefore, there is a direct relationship between  $F(i,j)$  off-diagonal elements and the orbital overlap ( $S$ ).

The successful application of DFT-based methods broadened the applicability of the computational methods and now represents an interesting approach for determining activation barrier and molecular energies.<sup>22–25</sup> On the other hand, the B3LYP method combines Becke’s three-parameter exchange function with the correlation function of Lee et al.<sup>23</sup> Our recent studies showed that the NBO analysis is a sufficient approach to investigate the stereoelectronic interactions on the reactivity and dynamic behaviors of chemical compounds.<sup>28–31</sup>

## Computational details

Ab initio calculations were carried out using MO (MP2/6-311+G\*\*//B3LYP/6-311+G\*\*) and hybrid DFT (B3LYP/6-311+G\*\*//B3LYP/6-311+G\*\*) based methods with the Gaussian 98 package of programs.<sup>21</sup> Also, B3LYP/6-311+G\*\* level of theory was used for optimizing the initial estimated structural geometries of compounds **1–9**. Energy minimum molecular geometries were located by minimizing energy with respect to all geometrical coordinates without imposing any symmetry constraints. The nature of the stationary points

**Scheme 1.** Schematic representation of the stereoisomers of compounds **1–9**.

**Fig. 1.** Schematic representation of the electronic delocalization between nonbonding and antibonding orbitals (i.e.,  $\text{LP}_{\text{eqX5}} \rightarrow \sigma^*_{\text{C6-Y1}}$  and  $\text{LP}_{\text{axX5}} \rightarrow \sigma^*_{\text{C6-Y1}}$ ) in compounds **1–9**.

**Fig. 2.** Schematic representation of stabilization energy (resonance energy;  $E_2$ ) associated with donor (nonbonding)–acceptor (antibonding) interactions.

for compounds **1–9** has been determined by means of the number of imaginary frequencies. For minimum state structures, only all real frequency values were accepted.<sup>32,33</sup>

An NBO analysis was then performed using the B3LYP/6-311+G\*\* level for the axial and trans forms of compounds **1–9** by the NBO 3.1 program<sup>26</sup> included in the Gaussian 98 package of programs.<sup>21</sup>

The bonding and antibonding orbital occupancies in the axial and equatorial conformations of compounds **1–9**, and also the stabilization energies associated with  $\text{LP}_{\text{eqX5}} \rightarrow \sigma^*_{\text{C6-Y1}}$  and  $\text{LP}_{\text{axX5}} \rightarrow \sigma^*_{\text{C6-Y1}}$  delocalizations, were calculated using NBO analysis. The stabilizing orbital interactions is inversely proportional to the energy difference between the interacting orbitals; therefore, the strongest stabilizing interactions will take place between the most effective donors and the most effective acceptors (see Fig. 2).

The thermodynamic functions (all corrected for the zero-point energy), i.e.,  $E_0$ , enthalpy,  $H$  (sum of the electronic and the thermal enthalpy), Gibbs free energy,  $G$  (sum of the electronic and thermal free energy), and entropy,  $S$ , were calculated according to the following relation:  $E = E_0 + E_{\text{vib}} + E_{\text{rot}} + E_{\text{trans}}$ ,  $H = E + RT$ ,  $G = H - TS$ . Finally, using the corresponding calculated thermodynamic data for ground and transition states,  $\Delta G$ ,  $\Delta H$ , and  $\Delta S$  were also determined.

## Results and discussion

The zero point (ZPE) and total electronic ( $E_{\text{el}}$ ) energies ( $E_0 = E_{\text{el}} + \text{ZPE}$ ) for the axial and equatorial stereoisomers of compounds **1–9**, as calculated by the DFT (B3LYP/6-311+G\*\* level of theory) are given in Table 1. For single-

point energy calculations, the ab initio molecular orbital (MP2/6-311+G\*\*//B3LYP/6-311+G\*\*) method was used (see Table 1). Table 2 shows the value of the thermodynamic functions,  $H$ ,  $S$ , and  $G$ , and the  $\Delta G$ ,  $\Delta S$  and  $\Delta H$  parameters. The calculated  $\Delta S$  values are relatively small, so that the calculated  $\Delta H$  and  $\Delta G$  parameters are close to the  $\Delta E_0$  values.

The B3LYP/6-311+G\*\*//B3LYP/6-311+G\*\* results revealed that the axial stereoisomers of compounds **1–3** are more stable than their equatorial stereoisomers by 3.39, 1.03, and 2.18 kcal mol<sup>-1</sup>, respectively. Also, the axial stereoisomers of compounds **1–3** are more stable than their equatorial stereoisomers by 4.03, 4.00, and 3.12 kcal mol<sup>-1</sup>, respectively, as calculated at the MP2/6-311+G\*\*//B3LYP/6-311+G\*\* level of theory (see Table 1). In addition, the Gibbs free energy difference ( $G_{\text{equatorial}} - G_{\text{axial}}$ ) values (i.e.,  $\Delta G_{\text{eq-ax}}$ ) between the axial and equatorial stereoisomers decrease from compound **1** to compound **3**. The calculated  $\Delta G_{\text{eq-ax}}$  values for compounds **1–3** are 3.32, 3.22, and 2.07 kcal mol<sup>-1</sup>, respectively, as calculated at the B3LYP/6-311+G\*\*//B3LYP/6-311+G\*\* level of theory (see Table 2).

Importantly, the MO and hybrid DFT results revealed that the energy differences between the axial and equatorial stereoisomers of compound **4** are more than those for the corresponding stereoisomers of compound **1**. Contrary to the observed trend for compound **4**, the energy differences between the axial and equatorial stereoisomers of compounds **5** and **6** are less than those for the corresponding stereoisomers of compounds **2** and **3**, respectively (see Table 1). In addition, the  $\Delta G_{\text{eq-ax}}$  values decreases from compound **4** to compound **6** (see Table 2).

**Table 1.** B3LYP/6-311+G\*\*//B3LYP/6-311+G\*\* and MP2/6-311+G\*\*//B3LYP/6-311+G\*\* calculated total energies,  $E$  (in hartree), zero-point energies, ZPE (in hartree, from B3LYP/6-311+G\*\* level), and relative energies,  $\Delta E$  ( $E_h$ , in hartree), for the equatorial and axial conformations of compounds **1–9**.

<sup>a</sup>Relative to the ground state.

<sup>b</sup>Numbers in parentheses are the corresponding thermodynamic function values in kcal mol<sup>–1</sup>.

Importantly, the B3LYP/6-311+G\*\*//B3LYP/6-311+G\*\* and MP2/6-311+G\*\*//B3LYP/6-311+G\*\* results revealed that the energy difference between the axial and equatorial stereoisomers of compound **7** is more than those for the corresponding stereoisomers of compounds **1** and **4**. Based on B3LYP/6-311+G\*\*//B3LYP/6-311+G\*\* results, the axial stereoisomer of compounds **7–9** are more stable than their

equatorial stereoisomers by 6.94, 1.15, and 0.31 kcal mol<sup>–1</sup>, respectively. Also, the axial stereoisomers of compounds **7–9** are more stable than their equatorial stereoisomers by about 6.89, 0.75, and 0.42 kcal mol<sup>–1</sup>, respectively, as calculated at the MP2/6-311+G\*\*//B3LYP/6-311+G\*\* level of theory (see Table 1). In addition, the calculated  $\Delta G_{eq-ax}$  values decreases from compound **7** to compound **9**. The calculated

<sup>a</sup>Off-diagonal elements.

$\Delta G_{eq-ax}$  for compounds **7–9** are 6.73, 1.21 and 0.53 kcal mol<sup>-1</sup>, respectively, as calculated at the B3LYP/6-311+G\*\*//B3LYP/6-311+G\*\* level of theory (see Table 2). Accordingly, the axial preference for compound **7** is more than compounds **4** and **1**. In addition, the axial preference dwindling from compound **1** to **3** is more than those for compounds **4–6** and also compounds **7–9** (see Tables 1 and 2).

According to the NBO results, the axial and equatorial stereoisomers of compounds **1–9** benefit from  $LP_{eqX5} \rightarrow \sigma^*_{C6-Y1}$  and  $LP_{axX5} \rightarrow \sigma^*_{C6-Y1}$  donor–acceptor interactions. Based on the optimized ground state geometries using the B3LYP/6-311+G\*\* method, the NBO analysis of donor–acceptor interactions showed that the stabilization energies associated with  $LP_{eqX5} \rightarrow \sigma^*_{C6-Y1}$  electronic delocalizations for the axial stereoisomers of compounds **1–3** are 13.19, 3.92, and 2.19 kcal mol<sup>-1</sup>, respectively (see Table 3). Also, the stabilization energies associated with  $LP_{eqX5} \rightarrow \sigma^*_{C6-Y1}$  electronic delocalizations decrease from the axial stereoisomers of compound **4** to compound **6** and also compound **7** to compound **9** (see Table 3). Interestingly, the decrease of axial preference from compounds **1**  $\rightarrow$  **3**, **4**  $\rightarrow$  **6**, and **7**  $\rightarrow$  **9** could be fairly explained by the decrease of the stabilization energies associated with  $LP_{eqX5} \rightarrow \sigma^*_{C6-Y1}$  electronic delocalizations. It should be noted that there is no  $LP_{eqX5} \rightarrow \sigma^*_{C6-Y1}$  electronic delocalization for the equatorial stereoisomer of compounds **1–9**.

Also, the NBO analysis revealed that there is  $LP_{axX5} \rightarrow \sigma^*_{C6-Y1}$  electronic delocalization only for the equatorial stereoisomers of compounds **1**, **4**, and **7**, and it is not observed for the axial and equatorial stereoisomers of compounds **2**,

**3**, **5**, **6**, **8**, and **9**. In this regard, the stabilization energies associated with  $LP_{axX5} \rightarrow \sigma^*_{C6-Y1}$  electronic delocalizations for the equatorial stereoisomers of compounds **1**, **4**, and **7** are 2.44, 2.50, and 3.97 kcal mol<sup>-1</sup>, respectively.

Based on the eq. [1], the DE associated with  $LP_{axX5} \rightarrow \sigma^*_{C6-Y1}$  and  $LP_{eqX5} \rightarrow \sigma^*_{C6-Y1}$  electronic delocalizations decreases from compound **1** to compound **3**. The calculated DE for compounds **1–3** are -21.50, -7.84, and -4.38 kcal mol<sup>-1</sup>, respectively (see Table 3). Along this line, the NBO analysis revealed the calculated DE associated with  $LP_{axX5} \rightarrow \sigma^*_{C6-Y1}$  and  $LP_{eqX5} \rightarrow \sigma^*_{C6-Y1}$  electronic delocalization decreases from compound **4** to compound **6** and also compound **7** to compound **9**. Effectively, the decrease of the DE can explain the decrease of the calculated  $\Delta G_{eq-ax}$  from compounds **1**  $\rightarrow$  **3**, **4**  $\rightarrow$  **6**, and **7**  $\rightarrow$  **9** (see Table 2).

Similar to the larger DE values in the axial stereoisomers of compounds **1–9**, these forms are more stable than their equatorial stereoisomers. From a structural point of view, it seems that the axial stereoisomers of compounds **1–9** could be less stable than their equatorial stereoisomers. The primary reason for this argument is based on the nonbonding gauche repulsions between the methyl group of X5 atoms and 1- and 3-Y atoms of rings. Accordingly, these interactions (steric repulsions) should be weaker than the stabilization energies associated with the DE (associated with  $LP_{axX5} \rightarrow \sigma^*_{C6-Y1}$  electronic delocalizations). Consequently, this fact could justify the stability of the axial stereoisomers of compounds **1–9** compared to their equatorial stereoisomers.

On the other hand, the NBO results showed that the  $LP_{axX5}$  nonbonding orbital occupancies in the axial stereo-

**Table 4.** Calculated nonbonding and antibonding orbital occupancies for the equatorial and axial conformations of compounds **1–9** using NBO analysis, based on the optimized structures by B3LYP/6-311+G\*\* level of theory.

9-ax	1.9390	—	0.0391

isomers of compounds **1–3** are 1.8488, 1.9445, and 1.9677, respectively (see Table 4). Similar to the observed trend for compounds **1–3**, the LP<sub>axX5</sub> nonbonding orbital occupancies increase from the axial stereoisomers of compound **4** to compound **6** and also compound **7** to compound **9**. Contrary to the increase of the LP<sub>axX5</sub> nonbonding orbital occupancies from the axial stereoisomers of compound **1** to compound **3**, compound **4** to compound **6** and compound **7** to compound **9**, the  $\sigma^*_{C6-Y1}$  antibonding orbital occupancies of these stereoisomers decrease. In this regard, NBO results revealed that the  $\sigma^*_{C6-Y1}$  antibonding orbital occupancies in the axial stereoisomers of compounds **1–3** are 0.0556, 0.0320, and 0.0252, respectively. This trend was observed for compounds **4–6** and also compounds **7–9** (see Table 4).

Importantly, the increase of the LP<sub>axX5</sub> nonbonding and the decrease of the  $\sigma^*_{C6-Y1}$  antibonding orbital occupancies in the axial stereoisomers of compounds **1–9** could be justified by the decrease of the LP<sub>axX5</sub>  $\rightarrow$   $\sigma^*_{C6-Y1}$  electronic delocalizations from the axial stereoisomers of compounds **1**  $\rightarrow$  **3**, **4**  $\rightarrow$  **6** and **7**  $\rightarrow$  **9**. Therefore, it can be concluded that the donor-acceptor interaction is an effective factor on the nonbonding and antibonding orbital occupancies of the equatorial and axial stereoisomers of compounds **1–9**.

It has to be noted that the LP  $\rightarrow$   $\sigma^*$  resonance energies are proportional to  $S^2/\Delta E$  where  $S$  is the orbital overlap and  $\Delta E$  is the energy differences between the LP nonbonding and  $\sigma^*$  antibonding orbitals. In this regard, the stereoelectronic orbital interactions are anticipated to be more effective for the anti rather than the syn or gauche arrangement between the donor (LP) and acceptor ( $\sigma^*$ ) orbitals, and the stabilization should increase as the anti-bonding orbital  $\sigma^*$  energy decreases and the nonbonding orbital LP energy increases. The energy difference between donor ( $E_{LPaxX5}$ ) and acceptor ( $E_{\sigma^*C6-Y1}$ ) orbitals ( $\Delta(E_{\sigma^*C6-Y1} - E_{LPaxX5})$ ) for the axial stereoisomers of compounds **1–3** are 0.5778, 0.7045,

and 0.7974 au, respectively, as calculated by NBO analysis. Effectively, the energy differences between donor ( $E_{LPaxX5}$ ) and acceptor ( $E_{\sigma^*C6-Y1}$ ) orbitals ( $\Delta(E_{\sigma^*C6-Y1} - E_{LPaxX5})$ ) increased from the axial stereoisomers of compounds **1**  $\rightarrow$  **3**, **4**  $\rightarrow$  **6**, and **7**  $\rightarrow$  **9**. It can be concluded that the rich acceptor  $\sigma^*_{C6-Y1}$  antibonding orbitals of the axial stereoisomers of compounds **1**, **4** and **7**, compared to those in compounds **2**, **3**, **4**, **5** and **7**, **8** may give rise to strong DE. Also, the decrease of the orbital overlap ( $S$ ) (off-diagonal elements ( $F_{ij}$ )) values could reduce the DE (see Tables 3 and 5). The NBO calculated off-diagonal elements ( $F_{ij}$ ) for LP<sub>axX5</sub>  $\rightarrow$   $\sigma^*_{C6-Y1}$  electronic delocalizations in the axial stereoisomers of compounds **1–3** are 0.078, 0.046, and 0.037, respectively (see Table 5). In this regard, the calculated off-diagonal elements ( $F_{ij}$ ) for LP<sub>axX5</sub>  $\rightarrow$   $\sigma^*_{C6-Y1}$  electronic delocalizations decrease from the axial-stereoisomers of compound **4** to compound **6** and also compound **7** to compound **9**. The decrease of the orbital overlap ( $S$ ) values could be justified by the increase of X5 atom radius from compounds **1**  $\rightarrow$  **3**, **4**  $\rightarrow$  **6**, and **7**  $\rightarrow$  **9**.

In addition, it is well-known that there is a preference for the conformation with the smallest resultant dipole moment. Especially in the gas phase, it is generally found that the conformation with the larger dipole moment has the larger electrostatic energy. Therefore, the conformation with the larger dipole moment has an increased overall energy.<sup>34</sup> Table 3 presents the calculated dipole moments for the axial and equatorial conformations of compounds **1–9**. The B3LYP/6-311+G\*\* results showed that the dipole moments for the equatorial stereoisomers of compounds **1–9** (the rabbit-ear effect) are larger than those in the axial stereoisomers. Accordingly, the rationalization of the conformation preference solely in terms of dipole–dipole interactions succeeds in accounting qualitatively for the axial stereoisomers preferences in compounds **1–9**.

Representative structural parameters for the axial and equatorial stereoisomers of compounds **1–9**, as calculated by B3LYP/6-311+G\*\* level of theory, are shown in Table 6. Although, due to the nature of the various approximations involved in these theoretical calculations, it is not expected, in principal, to obtain exactly the experimental values;<sup>35</sup> however, it is possible to carry out theoretical calculations, from which many properties and structures can be obtained with an accuracy that is competitive with experiments.<sup>35–38</sup> Importantly, considering the structures of compounds **1–9** (optimized by B3LYP/6-311+G\*\* method) gave evidence that in the axial stereoisomers of these compounds the  $\sigma_{X5-C6}$  bond lengths are significantly contracted compared to those in the equatorial stereoisomers. Based on the B3LYP/6-311+G\*\* results, the  $\sigma_{X5-C6}$  bond lengths in the equatorial and axial stereoisomers of compound **1** are 1.456 and 1.445 Å, respectively (see Table 6). Similarly, the  $\sigma_{X5-C6}$  bond lengths in the equatorial and axial stereoisomers of compound **2** are 1.892 and 1.881 Å, respectively, as calculated by B3LYP/6-311+G\*\* level of theory. In this context, the B3LYP/6-311+G\*\* results showed that the  $\sigma_{X5-C6}$  bond lengths in the equatorial and axial stereoisomers of compound **3** are 2.022 and 2.014 Å, respectively.

Along this line, the  $\sigma_{X5-C6}$  bond lengths decrease from the equatorial stereoisomers of compounds **4–9** to their axial stereoisomers. Also, the  $\sigma_{C6-Y1}$  bond lengths of the axial

**Table 5.** Calculated nonbonding and antibonding orbital energies (au) for the equatorial and axial conformations of compounds **1–9** using NBO analysis, based on the optimized structures by B3LYP/6-311+G\*\* level of theory.

9-eq	—	−0.51513	0.08508	—	0.60018
9-ax	−0.49691	—	0.08604	0.58295	—

conformations decrease from compounds **1** → **3**, **4** → **6**, and **7** → **9**. The B3LYP/6-311+G\*\* results showed that the  $\sigma_{C6-N1}$  bond lengths in the axial stereoisomers of compounds **1–3** are 1.438, 1.428, and 1.423 Å, respectively (see Table 6). This observation is in agreement with the decrease of the LP<sub>axX5</sub> →  $\sigma^*_{C6-Y1}$  electronic delocalization from the axial stereoisomers from compound **1** to compound **3**, compound **4** to compound **6**, and compound **7** to compound **9**. The decrease of the LP<sub>axX5</sub> →  $\sigma^*_{C6-Y1}$  electronic delocalizations can produce the contracted  $\sigma_{C6-Y1}$  bond lengths by decreasing the  $\sigma^*_{C6-Y1}$  antibonding orbital occupancies.

In addition, Table 6 shows that the  $\theta_{5-6-1}$  bond angles increase from the equatorial stereoisomers of compounds **1–9** to their corresponding axial stereoisomers. Also, the  $\phi_{4-5-6-1}$  torsion (dihedral) angles decrease from the equatorial stereoisomers of compounds **1–9** to their corresponding axial stereoisomers. The increase of the  $\theta_{5-6-1}$  bond angles and the decrease of the  $\phi_{4-5-6-1}$  torsion angles from the equatorial stereoisomers of compounds **1–9** to their corresponding axial stereoisomers could be justified by the increase of the X5–C6 bond orders. The LP<sub>eqX5</sub> →  $\sigma^*_{C6-Y1}$  electronic delocalizations can reasonably explain the increase of the X5–C6 bond orders in the axial stereoisomers of compounds **1–9** compared to their corresponding equatorial stereoisomers.

## Conclusion

The above reported ab initio calculations and NBO analysis provided a reasonable picture from structural, energetic, bonding, and stereoelectronic points of view for the conformational preference in compounds **1–9**. Effectively, B3LYP/6-311+G\*\*// B3LYP/6-311+G\*\* results revealed that the calculated  $\Delta G_{eq-ax}$  decreases from compounds **1** → **3**, **4** → **6**, and **7** → **9**. In addition, the dwindling axial preference for compounds **1** → **3** is more than those for compounds **4** → **6** and also compounds **7** → **9**.

In addition NBO results revealed that (i) the stabilization energies associated with LP<sub>eqX5</sub> →  $\sigma^*_{C6-Y1}$  delocalizations for the axial stereoisomers decreases from compounds **1** → **3**, **4** → **6**, and **7** → **9**. (ii) The decrease of the donor–acceptor interactions associated with LP<sub>eqX5</sub> →  $\sigma^*_{C6-Y1}$  delocalizations could fairly explain the increase of occupancies of LP<sub>eqX5</sub> nonbonding orbitals and the decrease of occupancies of  $\sigma^*_{C6-Y1}$  antibonding orbitals from the axial stereoisomers of compounds **1** → **3**, **4** → **6**, and **7** → **9**. (iii) The energy difference between donor ( $E_{LP_{axX5}}$ ) and acceptor ( $E_{\sigma^*C6-Y1}$ ) orbitals ( $\Delta(E_{\sigma^*C6-Y1} - E_{LP_{axX5}})$ ) increased from the axial stereoisomers of compounds **1** → **3**, **4** → **6**, and **7** → **9**. It can be concluded that the rich acceptor antibonding orbital may give rise to strong DE. Also, the decrease of the orbital overlap ( $S$ ) (off-diagonal elements ( $F_{ij}$ )) values could reduce the DE. (iv) The rationalization of the conformation preference solely in terms of dipole–dipole interactions succeeds in accounting qualitatively for the axial stereoisomers preferences in compounds **1–9**.

Also, the  $\sigma_{C6-Y1}$  bond lengths decrease from the axial stereoisomers from compounds **1** → **3**, **4** → **6**, and **7** → **9**. This observation is consistent with the decrease of the LP<sub>axX5</sub> →  $\sigma^*_{C6-Y1}$  electronic delocalization from the axial stereoisomers of compounds **1** → **3**, **4** → **6**, and **7** → **9**, which produce the contracted  $\sigma_{C6-Y1}$  bonds by decreasing the  $\sigma^*_{C6-Y1}$  antibonding orbital occupancies. It can be concluded that the decrease of the DE can reasonably explain the decrease of the calculated  $\Delta G_{eq-ax}$  from compounds **1** → **3**, **4** → **6**, and **7** → **9**. Interestingly, the decrease of axial preference from compounds **1** → **3**, **4** → **6**, and **7** → **9** could be reasonably explained by the decrease of the stabilization energies associated with LP<sub>eqX5</sub> →  $\sigma^*_{C6-Y1}$  electronic delocalizations. Effectively, this fact demonstrates that the order of the anomeric effects (AE) for M–C–N fragments are as follows: N–C–O > P–C–O > As–C–O; N–C–S > P–C–S > As–C–S; N–C–Se > P–C–Se > As–C–Se.

# The Meisenheimer model for predicting the principal site for nucleophilic substitution in aromatic perfluorocarbons — Generalization to include ring-nitrogen atoms and non-fluorine ring substituents

Jon Baker and Max Muir

**Abstract:** Our recent simple model for predicting the principal site for nucleophilic substitution in aromatic perfluorocarbons (*J. Fluorine Chem.* **2005**, 126, 727) is generalized to include both ring-nitrogen atoms and non-fluorine ring substituents. The model is based on the relative stabilities of the Meisenheimer complexes as calculated using Hartree–Fock theory with a modest basis set. Calculations on a wide range of fluorine-containing aromatics demonstrate the general applicability of the model; in over 70 systems examined, we found only one where the predicted primary substitution site did not agree with the experimental findings. We demonstrate that criticism by Chambers et al. to the effect that the model is incapable of reproducing experimental substitution patterns, and, in particular, cannot distinguish between the different activating effects of *ortho*- and *para*-fluorines, are entirely unfounded. The observed substitution patterns for six reactions involving attack by aniline on perfluoropyridine and various non-fluorine-substituted derivatives, selected by Chambers et al. to highlight the failings of our model, are, on the contrary, accurately predicted by it.

**Key words:** nucleophilic substitution, fluorine-containing hetero-aromatics, Meisenheimer model.

**Résumé :** On a généralisé le modèle simple qu'on a proposé récemment (*J. Fluorine Chem.* **2005**, 126, 727) pour prédire le site principal de la substitution nucléophile dans des dérivés perfluorocarbonés aromatiques de façon à inclure aussi bien les atomes d'azote dans le cycle que des atomes non fluorés attachés comme substituants. Le modèle est basé sur les stabilités relatives des complexes de Meisenheimer tels que calculés par la théorie de Hartree–Fock à l'aide d'un ensemble de base modeste. Les calculs sur une grande variété des dérivés aromatiques contenant du fluor démontrent le domaine général dans lequel le modèle peut être appliqué; dans plus de 70 systèmes examinés, on en a trouvé qu'un dans lequel le site de substitution primaire prédit ne correspond pas aux données expérimentales. On a démontré que les critiques émises par Chambers et al. à l'effet que le modèle ne permet pas de reproduire les patrons expérimentaux de substitution et, en particulier, ne permet pas de distinguer entre les différents effets activants des atomes de fluor en positions *ortho* et *para* sont non fondées. Les patrons de substitution observés pour six réactions impliquant une attaque par l'aniline sur la perfluoropyridine et sur divers dérivés portant des substituants non fluorés choisis par Chambers et al. pour mettre en évidence les déficiences de notre modèle sont, au contraire, prédits correctement par celui-ci.

**Mots-clés :** substitution nucléophile, noyaux hétéroaromatiques contenant du fluor, modèle de Meisenheimer.

[Traduit par la Rédaction]

## Introduction

In an earlier work,<sup>1</sup> we provided a simple calculational model for predicting the primary substitution site for nucleophilic substitution in aromatic perfluorocarbons. This model was based on the standard two-stage description of nucleophilic substitution involving the formation of a negatively charged intermediate, known as a Meisenheimer complex,<sup>2</sup> which is the anionic equivalent of the Wheland intermediate in electrophilic substitution.<sup>3</sup>

The negative charge in the Meisenheimer complex is delocalized into the aromatic  $\pi$ -system, which, like the Wheland intermediate, can be considered as a resonance hybrid of multiple canonical forms.

Received 2 December 2009. Accepted 29 January 2010. Published on the NRC Research Press Web site at canjchem.nrc.ca on 26 May 2010.

**J. Baker<sup>1</sup> and M. Muir.** Parallel Quantum Solutions, 2013 Green Acres Road, Suite A, Fayetteville, Arkansas 72703, USA.

<sup>1</sup>Corresponding author (e-mail: baker@pqcs-chem.com).

Basically, the model considers the relative stability of all possible Meisenheimer complexes, as determined by calculation (using the fluoride ion itself as a “typical” nucleophile), with the most stable complex corresponding to the preferred site for nucleophilic substitution. As such, it is an extension of previous, even simpler models, which attempted to predict the stabilities of the various Meisenheimer complexes without recourse to any serious calculation at all. A fairly successful early model along these lines was Burdon’s “ $I_{\pi}$ -repulsion” theory,<sup>4</sup> based upon electron repulsions in the Meisenheimer complexes, specifically the destabilizing effect of the repulsion between the filled p-orbital of a planar carbanion and the filled p-orbital of a substituent. This was later extended (as “amplified  $I_{\pi}$ -repulsion” theory) by Burdon and Parsons,<sup>5</sup> with the aid of simple Hückel theory.

All of these models involve essentially a purely thermodynamic rationale, i.e., the thermodynamically most stable Meisenheimer complex is the one most likely to form, and the substitution pattern follows directly from that. The underlying assumptions are, first, that the substitution reaction is indeed two-step, involving an at least meta-stable Meisenheimer complex as intermediate; second, that barrier heights (both from reactant to intermediate and intermediate to product) are either more or less identical in all cases, and can therefore be ignored, or reflect the thermodynamic stability in the Meisenheimer complex so that considering only the latter gives the correct substitution pattern; and third, that varying the reaction conditions, principally the solvent and the actual nucleophile itself, makes no difference to the preferred substitution site, i.e., the mechanism is essentially the same for all nucleophiles in all solvents.

Note that even in cases where the reaction kinetics (i.e., transition-state barrier heights) are dominant, the model can still be usefully applied. For example, if *decomposition* of the Meisenheimer complex (to give the products) is the rate-determining step, then any intermediate Meisenheimer complex can decompose back to reactants many times before finally going over to products; this will favor the formation of the thermodynamically most-stable complex, exactly as required by the model. Only in reactions where *formation* of the Meisenheimer complex is rate-determining will the model formally have no predictive capability.

Now, there is obviously no chance of such a simple model predicting the correct outcome under all circumstances; indeed, many examples are known of nucleophiles reacting differently depending on the reaction conditions, e.g., whether the nitrite ion attacks predominantly through the nitrogen or the oxygen atom is heavily influenced by the solvent,<sup>6</sup> and there are suggestions that at least some nucleophilic substitution reactions may be just one-step,<sup>7</sup> i.e., proceed directly from reactants to products *without* involving a Meisenheimer complex as intermediate. Nonetheless, the success of this simple model, as exemplified by our

study on aromatic perfluorocarbons,<sup>1</sup> suggests that the model is sound in many situations, especially involving “standard” reaction conditions (NaOMe/MeOH or an amine in dioxan or ether).

In this article, we extend this simple model to cover systems with both ring-nitrogen atoms and (or) non-fluorine ring substituents. Can the Meisenheimer model predict the experimentally observed substitution patterns in these types of compounds?

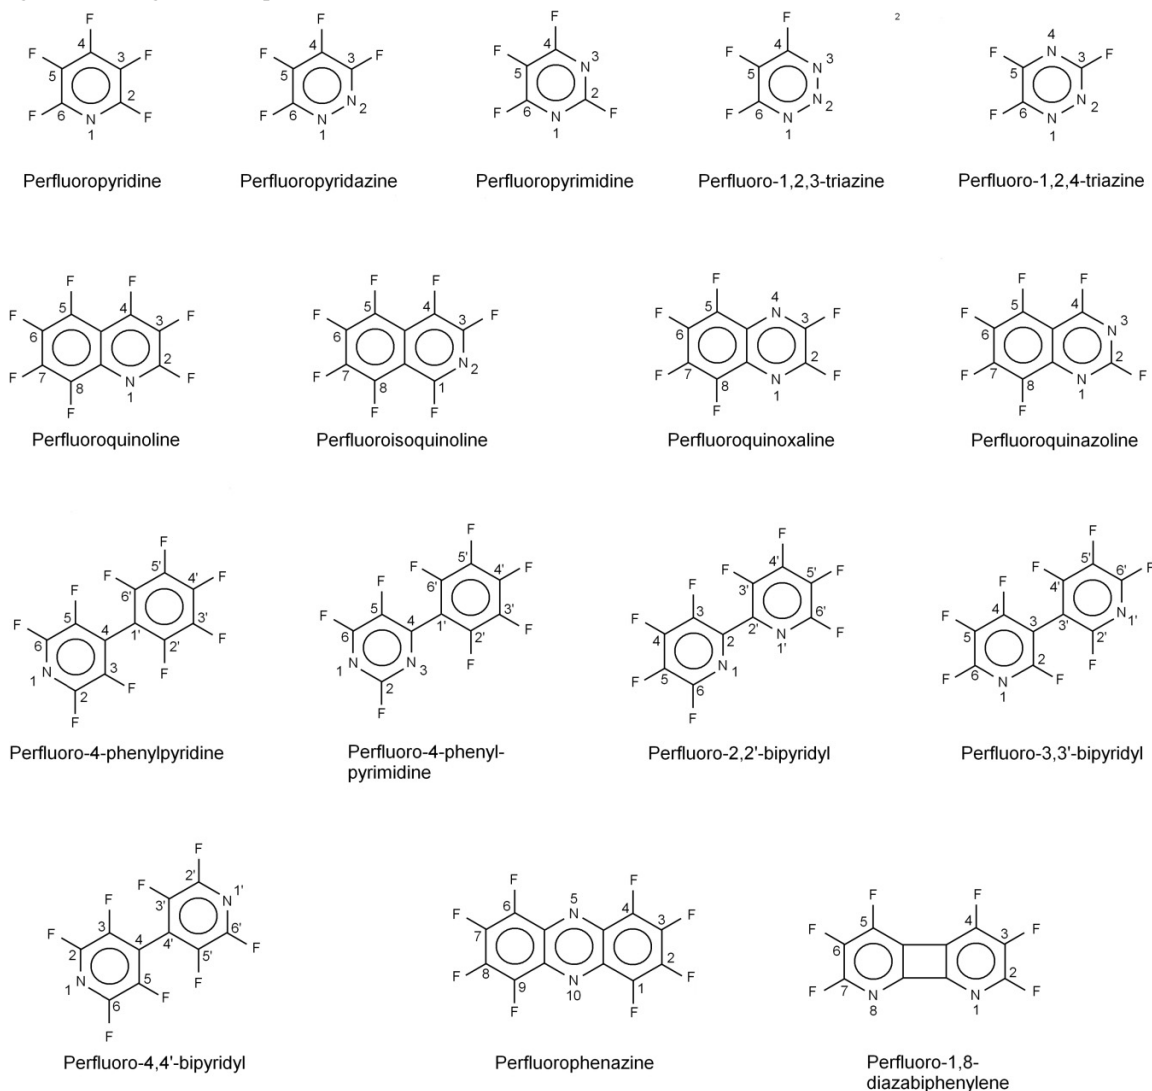

## Results and discussion

Figure 1 depicts schematically the structures of 16 nitrogen-containing aromatic perfluorocarbons, covering most systems of size around 25 atoms or less, for which we were able to find at least some data in the regular literature. Much of the experimental work dates from the late 1960s to the early 1970s and was carried out by the Durham (UK) group headed by Musgrave and (later) Chambers. These compounds are perfluoropyridine,<sup>8</sup> perfluoropyridazine,<sup>9</sup> perfluoropyrimidine,<sup>10,11</sup> perfluoro-1,2,3-triazine,<sup>12</sup> perfluoro-1,2,4-triazine,<sup>13</sup> perfluoroquinoline,<sup>14–16</sup> perfluoroisquinoline,<sup>14–16</sup> perfluoroquinoxaline,<sup>17</sup> perfluoroquinazoline,<sup>18</sup> perfluoro-(4-phenylpyridine),<sup>19,20</sup> perfluoro-(4-phenylpyrimidine),<sup>21</sup> perfluoro-2,2'-bipyridyl,<sup>22</sup> perfluoro-3,3'-bipyridyl,<sup>23</sup> perfluoro-4,4'-bipyridyl,<sup>19</sup> perfluorophenazine,<sup>24</sup> and perfluoro-1,8-diazabiphenylene.<sup>25</sup>

We have carried out calculations on all 16 of these compounds, computing all distinct Meisenheimer intermediates for all systems using a fluoride ion as the attacking nucleophile. This is exactly analogous to our previous calculations on aromatic perfluorocarbons.<sup>1</sup> In ref. 1, we demonstrated that essentially the same results were obtained using a number of theoretical approaches: HF/6–31G\*, HF/6–31+G\*, MP2/6–31G\*, and B3LYP/6–31G\* all gave identical predictions of the preferred site for nucleophilic substitution and, indeed, gave the same relative energy ordering for each system’s Meisenheimer complexes. The addition of diffuse functions to the basis set (as with the 6–31+G\* basis) made no difference to the results, nor did the inclusion of electron correlation (via MP2 and the B3LYP density functional). This strongly suggested, and was noted in ref. 1, that basic Hartree–Fock theory (HF/6–31G\*) was a perfectly adequate model for our purposes. At the time, however, we selected B3LYP/6–31G\* for our standard model based upon its ability to reproduce experimental geometries and energetics better than Hartree–Fock theory.

We have subsequently discovered some rather disturbing artefacts with density functional theory (certainly with the B3LYP functional, but we suspect with DFT in general); namely, a marked tendency to converge to symmetrical structures, which occasionally results in geometries that make no sense chemically. For example, if attempts are made to add a second pyrazolyl substituent to 1-pyrazolyl-2,4,5-trifluorobenzene at the B3LYP/6–31G\* level, then Meisenheimer complexes can readily be formed at positions 4 and 5, but attempts to add at position 2 results in a symmetrical structure with a fluorine atom midway between carbon atoms 1 and 2. This does not occur with Hartree–Fock theory, which gives standard Meisenheimer complexes at all three positions. Because of this, and similar calculational artefacts for other systems, we have replaced DFT in our

**Fig. 1.** Nitrogen-containing aromatic perfluorocarbons.

standard model by Hartree–Fock. All the calculations presented in this work were done with HF/6–31G\*.

Table 1 presents our results for the 16 nitrogen-containing aromatic perfluorocarbons shown in Fig. 1. For each system, we give the relative energies (in kcal/mol) of each possible Meisenheimer complex, with the lowest energy complex (and hence the predicted most favorable site for nucleophilic substitution) taken as the energy zero. Now, it is tempting (a temptation we avoided in our previous study<sup>1</sup>) to look at the relative energies and suggest that if any additional Meisenheimer complexes are close in energy to the lowest one, e.g., within, say, a few kcal/mol, this may indicate a secondary substitution site. The closer the relative energies are to each other, the more likely it is that there will be significant secondary substitution.

We also show in Table 1 the experimentally determined substitution sites, including secondary substitution sites where these were reported (p = primary, s = secondary). In all cases, the secondary substitution site corresponds to the second lowest Meisenheimer complex, and these in turn are typically within a few kcal/mol of the lowest-energy complex. For ex-

ample, Brooke et al. have reported<sup>16</sup> that while the primary substitution site in perfluoroisquinoline is position 1 for MeO<sup>−</sup> in methanol (and also for many other oxygen nucleophiles), sulfur nucleophiles (e.g., HS<sup>−</sup>, MeS<sup>−</sup>) prefer position 6. Similar results are observed for perfluoroquinoline with respect to sites 2 and 4. Under the circumstances, our own results for these two systems (see Table 1), which show the lowest energy for the MeO<sup>−</sup> primary site, with a close-lying secondary site corresponding to the primary site for the sulfur nucleophiles, are really remarkably good and the best that can be expected for such a simple model.

The experimental data for perfluoro-(4-phenylpyridine) are conflicting, with Green et al.<sup>19</sup> reporting that substitution occurs primarily at position 4' in the phenyl ring (in agreement with our own findings), whereas Banks et al.<sup>20</sup> find that substitution occurs predominantly at position 2 in the pyridyl ring. Green et al.'s study<sup>19</sup> was primarily concerned with the chemistry of the metal carbonyls, and the nucleophiles they used were somewhat esoteric (e.g., [( $\pi$ -C<sub>2</sub>H<sub>5</sub>)Fe(CO)<sub>2</sub>]<sup>−</sup> and [Re(CO)<sub>5</sub>]<sup>−</sup>); Banks et al. on the other hand used sodium methoxide in methanol.<sup>20</sup> Assuming both

<sup>a</sup>p: Experimental primary substitution site.<sup>b</sup>s: Secondary substitution site; primary for some nucleophiles.<sup>c</sup>p\*: Conflicting experimental data for perfluoro-(4-phenylpyridine); see text.

sets of authors are correct, this clearly shows (not that there was any doubt) the very strong influence of the nucleophile and the experimental conditions on the substitution site.

The results we have presented in Table 1 demonstrate that the Meisenheimer model can be reliably extended to include nitrogen atoms in the aromatic ring. We now look at some examples where the initial perfluorocarbon has already had at least one fluorine substituted. Can the model mimic the directional effects (if any) of the substituent and predict which fluorine will be substituted next?

Our principal example is C<sub>6</sub>F<sub>5</sub>X (1-substituted hexafluorobenzene). A large number of papers have been published on the directional effects of various substituents (X) in this system. The most common site for nucleophilic attack is para to X; this is the site predicted by the *p*-difluoride rule derived from Burdon's "I<sub>π</sub>-repulsion" theory,<sup>4</sup> and also from an observation by Chambers and co-workers that the most favorable substitution site should have the maximum number of neighboring *ortho*- and *meta*-fluorines.<sup>26</sup> The fact that not all substituents direct para clearly shows the limitations of these simple empirical rules. We have selected a dozen substituents (X), including some which have been shown experimentally to direct meta. (Ortho substitution often occurs as a secondary substitution site together with para. It is possible to obtain exclusively ortho substitution with polar substituents (X) containing carbon or sulfur multiple bonds to nitrogen or oxygen in reactions with metal-containing reagents, e.g., LiAlH<sub>4</sub>. This is the result of

specific interactions between the substituent and the metal center in the nucleophile and is outside the purview of our model.) The substituents  $X$  we have chosen are:  $-H$ ;<sup>27</sup>  $-CH_3$ ;<sup>28</sup>  $-CF_3$ ;<sup>29</sup>  $-CHO$ ;<sup>30</sup>  $-OH$ ;<sup>28</sup>  $-NO_2$ ;<sup>31</sup>  $-NH_2$ ,  $-NH(CH_3)$ , and  $-N(CH_3)_2$ ;<sup>32</sup>  $-CH=CH_2$ ;<sup>33</sup>  $-CH_2OH$ ;<sup>34</sup> and  $-SCH_3$ .<sup>35</sup> Can the Meisenheimer model predict the marked preference for para substitution and yet identify those substituents that direct meta?

The short answer to the above question is a resounding yes. The relative energies of the three Meisenheimer complexes (ortho, meta, and para) for each substituent are given in Table 2. Ten of the 12 direct para, but two  $-NH_2$  and  $-OH$  direct meta and are correctly predicted to do so by our model. The dominance of para substitution almost (but not quite) regardless of the substituent  $X$  is notable:  $H$ ,  $CH_3$ , and  $CF_3$  all direct para despite their very different electron-donating/withdrawing properties.

Figure 2 shows a further selection of fluorine- and ring-substituted aromatic perfluorocarbons taken more-or-less at random from the literature: hexafluoro-1-aminoisquinoline;<sup>36</sup> perfluorothiophene;<sup>37</sup> perfluorobenzophenone and octafluoro-2,2'-dihydrobenzophenone;<sup>38</sup> perfluorodibenzofuran, perfluorodibenzothiophen, and perfluoro-9-fluorenone;<sup>39</sup> 5-phenyl-octafluorodibenzophosphole and 5-phenyl-octafluorodibenzophosphole-5-oxide;<sup>40</sup> various methoxy-substituted derivatives of perfluoroacenaphthylene;<sup>41</sup> perfluoropyrene<sup>42</sup> and perfluorofluoranthene;<sup>43</sup> 4,5,6,7-tetrafluorobenzo(*b*)thiophen;<sup>44</sup> 2-methoxy-heptafluoronaphthalene;<sup>45</sup> and 2-amino-heptafluoronaphthalene.<sup>46</sup> These examples were chosen to give a range of functional groups (O, S, P, and C=O in the ring) and a large number of different substitution sites (as many as nine following single-substitution in the methoxy-substituted aromatic perfluorocarbons). This represents a thorough test for the model with plenty of scope for error.

Our results are shown in Table 3. As can be seen in every case, the model correctly predicts the primary substitution site. There was some mild controversy at the time with both perfluorodibenzothiophen and perfluoro-9-fluorenone as initially Chambers and Spring reported that the principal sites for nucleophilic substitution in these systems were at position 2<sup>38</sup> (note that this represents a *different* ring position in the two compounds owing to the different labelling conventions; see Fig. 2). These predictions became increasingly incompatible with results reported by others for related systems<sup>47</sup> (and specifically by Burdon et al.<sup>48</sup>), and the same authors subsequently reported (correctly, see Table 3) that substitution in fact occurred at position 3.<sup>39</sup>

The substitution patterns reported by Burdon et al. following attack by methoxide ion on perfluoroacenaphthylene, perfluoropyrene, and perfluorofluoranthene are reproduced exactly by our model. For perfluoroacenaphthylene, substitution occurs first at position 3, followed by positions 8, 5, and 6, in that order.<sup>41</sup> It was already predicted in ref. 1 that the primary site for nucleophilic substitution in perfluoroacenaphthylene was position 3. Starting from the 3-substituted derivative, our model correctly predicts that subsequent attack occurs primarily at position 8 (see Table 3), starting from the 3,8-substituted derivative attack then occurs at position 5 and from the 3,5,8-substituted derivative at position 6. Similar results are obtained for perfluorofluoranthene, which

<sup>a</sup>p: Experimental primary substitution site.

substitutes first at position 1, and then at positions 6, 3, and 4,<sup>43</sup> exactly as predicted by our model.

The subsequent substitution sites in these particular compounds can already be seen from the relative energies of the

**Fig. 2.** Fluorine- and ring-substituted aromatic perfluorocarbons.

various Meisenheimer complexes for the singly substituted derivative. For example, it is obvious from the calculations on 1-methoxy-nonafluorofluoranthene that the most activated sites are positions 3, 4, and 6; the only question is the precise order. Likewise for 3-methoxy-heptafluoroacenaphthylene where the activated sites are clearly positions 5, 6, and 8.

With perfluoropyrene, substitution takes place first at position 1, and then at a mixture of positions 3, 6, and 8. Burdon et al. report<sup>42</sup> that the dimethoxy compounds were clearly a mixture with about 5%–10% of the 1,3-dimethoxy and the rest 1,6- and 1,8-dimethoxy in roughly equal amounts. The energetics of the various Meisenheimer complexes for 1-methoxy-nonafluoropyrene reported in Table 3 could hardly agree better with this observation; in particular, the complexes at positions 6 and 8 have virtually identical energies (differing by only 0.1 kcal/mol). 1,3,6-Trimethoxy-heptafluoropyrene is reported<sup>42</sup> to further substitute (this is obvious after the initial calculation) at position 8, and this is also reproduced by our model.

2-Substituted-heptafluoronaphthalenes substitute predominantly at position 6.<sup>45</sup> Recently, Rodionov and co-workers reported that amination of 2-amino-heptafluoronaphthalene in liquid ammonia affords a mixture of isomeric forms with considerable prevalence of the 2,7-isomer (70%). They claim that this is the first example of the predominant sub-

stitution at position 7 in 2-substituted polyfluoronaphthalenes.<sup>46</sup> Once again the Meisenheimer model fully agrees with the experimental findings, with 2-methoxy-heptafluoronaphthalene (a typical example) predicted to substitute predominantly at position 6, while 2-amino-heptafluoronaphthalene substitutes predominantly at position 7 (see Table 3).

This simple and very successful Meisenheimer model has been extensively criticized in a recent paper by Chambers et al.,<sup>49</sup> who claim that it is incapable of reproducing experimentally observed substitution patterns, and, in particular, cannot distinguish between the different activating effects of *ortho*- and *para*-fluorines. They provide six examples (in their Fig. 6) of nucleophilic substitution involving attack by aniline on perfluoropyridine and various substituted derivatives to illustrate this. We reproduce this figure with all six reactions as Fig. 3.

Table 4 presents our results using the Meisenheimer model for the six reactions specifically mentioned by Chambers et al. in ref. 49. Our predictions for both the primary and secondary fluorine substitution sites could hardly be better. We predict the correct primary substitution site in all six cases and, in those reactions with substantial secondary substitution, there is a low-lying Meisenheimer complex within a few kcal/mol of that for the primary substitution site.

**Table 3.** Relative Energies (kcal/mol) of the various Meisenheimer complexes for several substituted aromatic perfluorocarbons (see Fig. 2) with experimentally observed substitution sites.

<sup>a</sup>p: Experimental primary substitution site.<sup>b</sup>s: Secondary substitution site.

**Fig. 3.** Reactions involving substituted perfluoropyridines that Chambers and co-workers claim cannot be explained by the Meisenheimer model.

Rather than demonstrate the failings of the model, these six reactions show just how applicable it actually is.

Is our model infallible? Of course not! As we have already mentioned, we originally developed and used it to predict the most likely site(s) for nucleophilic substitution in aromatic perfluorocarbons. In this work, we have generalized it to include systems with heteroatoms (particularly nitrogen) in the aromatic ring and non-fluorine ring substitu-

ents. The model works very well in both of these cases. Additionally, it does a good job in predicting secondary substitution sites. We have deliberately kept the model simple; there are no factors in it to account for specific nucleophile or specific solvent effects, and therefore it obviously *cannot* account for changes in the substitution pattern due to changes in the solvent or use of a different nucleophile. But within its limitations, it is extremely successful.

So far, we have found just one example where the basic model fails: perfluorophthalazine.

Perfluorophthalazine

According to Chambers et al.,<sup>50</sup> methanolic sodium methoxide progressively replaces all six fluorine atoms in perfluorophthalazine, with positions 1 and 4 being the most reactive and 5 and 8 the least. Our calculations predict that position 6 (and 7) is the primary substitution site; experimentally, this is, at best, a secondary site. We have no reason to doubt the results presented in ref. 50 and clearly the model is just plain wrong for this molecule.

We have already noted that the standard Meisenheimer model incorporates no specific nucleophile or solvent effects. It might be possible to extend the basic model to include such effects; for example, by using the actual nucleophile during the calculation of the Meisenheimer intermediates rather than the fluoride ion, and by including either a continuous solvation model or explicit solvent molecules or a combination of both. However, we believe that the initial model, together with the generalizations we have made here, has clear predictive capability as it stands, and attempts to extend it, particularly via the incorporation of solvent effects, will destroy its essential simplicity without necessarily offering any real improvements.

## Conclusions

A simple model for predicting which fluorine atom will be replaced by an attacking nucleophile in nitrogen-containing and (or) substituted aromatic perfluorocarbons has been presented. This is a generalization of an existing model for aromatic perfluorocarbons only,<sup>1</sup> in which the energies of all possible Meisenheimer complexes were computed at HF/6-31G\* with full geometry optimization using the fluoride ion as a model nucleophile. The lowest energy Meisenheimer complex indicates the most likely substitution site.

This model was used to predict the position for nucleophilic attack in 17 nitrogen-containing aromatic perfluorocarbons, 12 substituted perfluorobenzenes ( $C_6F_5X$ ) and 20 other assorted fluorine-containing aromatics for which the primary substitution site was known experimentally. For only one compound, perfluorophthalazine, was the prediction not in accord with the experimental results. Additionally, predictions for six further nucleophilic substitution reactions, specifically selected by Chambers et al. to highlight alleged failings in the model,<sup>49</sup> agreed 100% with the experimental observations.

Including the 17 aromatic perfluorocarbons in the original paper,<sup>1</sup> we have presented calculations on over 70 systems, covering a range of fluorine-containing aromatics with a va-

**Table 4.** Relative Energies (kcal/mol) of the various Meisenheimer complexes for reactions involving substituted perfluoropyridines with aniline selected by Chambers and co-workers to demonstrate the failings of the Meisenheimer model (see Fig. 3).

riety of substituents and non-carbon (N, O, P, and S) ring atoms. The wide applicability of the standard Meisenheimer model (using the fluoride ion as a generic attacking nucleophile) is abundantly clear. We emphasize that we have *not* carefully selected the systems that we have presented, discarding those which our model fails to predict correctly; for the original set of 17 perfluorocarbons and the ring-nitrogen systems in this work (Fig. 1), we used every system we could find in the literature for which the substitution site was known experimentally.

The circumstances under which the standard Meisenheimer model is expected to work well have been outlined in the Introduction. The reason why the model is so successful is simply because these circumstances apply in the vast majority of nucleophilic substitution reactions involving aromatic perfluorocarbons. A huge number of these reactions do indeed proceed via a two-stage process involving a Meisenheimer complex as intermediate, and theory is more than capable of predicting the relative stability of the Meisenheimer intermediates, which is why the model works. Hasegawa et al. have recently observed the ionized Meisenheimer intermediate in the reaction between perfluorobenzene and ammonia using IR spectroscopy.<sup>51</sup> Theoretical calculations greatly assisted in the identification of the complex.

# Catalyst-free, direct, high regio-, and chemo-selective conversion of epoxides to 2-thiocyanatoalkyl alkanoates under neutral and solvent-free conditions

Ghasem Aghapour and Razieh Hatefipour

**Abstract:** A catalyst-free, direct, high regio-, and chemo-selective method is reported for the facile conversion of a wide variety of epoxides to their corresponding 2-thiocyanatoalkyl alkanoates, which contain two important functional groups (ester and thiocyanate), using a mixture of tetrabutylammonium rhodanide ((*n*-Bu)<sub>4</sub>NSCN) and an aliphatic or aromatic carboxylic anhydride under neutral and solvent-free conditions.

**Key words:** epoxide, 2-thiocyanatoalkyl alkanoate, carboxylic anhydride, tetrabutylammonium rhodanide.

**Résumé :** On a mis au point une méthode hautement régio- et chimio-sélective directe et n'impliquant aucun catalyseur pour la transformation facile d'une grande variété d'époxydes en alcanates de 2-thiocyanatoalkyles correspondants qui contiennent deux groupes fonctionnels importants (ester et thiocyanate); elle comporte l'utilisation d'un mélange de rhodanide de tétrabutylammonium (*n*-Bu)<sub>4</sub>NSCN et l'anhydride d'un acide carboxylique aliphatique ou aromatique, dans des conditions neutres et sans solvant.

**Mots-clés :** époxyde, alcanate de 2-thiocyanatoalkyle, anhydride d'acide carboxylique, rhodanide de tétrabutylammonium.

[Traduit par la Rédaction]

## Introduction

Epoxides are important intermediates in organic synthesis.<sup>1</sup> Their facile regio- and stereo-selective ring-opening reactions with a wide variety of nucleophiles provide a powerful strategy in organic chemistry.<sup>1–6</sup> However, in most of the epoxide ring-opening reactions under acidic conditions, the formation of a mixture of regioisomers and polymerization is observed.

On the other hand, thiocyanates have gained considerable importance in various areas of organosulfur chemistry.<sup>7</sup> For example, these compounds are important intermediates in agricultural and pharmaceutical chemistry: the thiocyanato group occurs as an important functionality in certain anticancer natural products formed by deglycosylation of glucosinolates derived from cruciferous vegetables.<sup>8,9</sup>

Also, synthesis of esters has played an important role in organic synthesis from its infancy.<sup>10</sup> This importance stemmed from its utility in diverse fields both in the laboratory and in industry. Ester moieties, irrespective of whether acyclic or cyclic, constitute major backbones, as well as functional groups of chemical significance, in numerous natural products and synthetic compounds. Ester groups also play versatile temporary roles in organic synthesis for the protection of carboxylic acids and hydroxy groups. Therefore, the acetylation of alcohols is one of the most widely used procedure for the protection of hydroxy groups, which

is routinely carried out by acid anhydrides or acid chlorides in the presence of tertiary amines,<sup>11</sup> protic or Lewis acids,<sup>12</sup> or sometimes solid acid catalysts.<sup>13</sup> Also, many other different reagents or catalysts have been introduced in various conditions for the esterification reactions.<sup>10</sup>

It is obvious that with respect to the importance of thiocyanato and ester functional groups, 2-thiocyanatoalkyl alkanoates, which contain both these groups, represent an interesting and important subclass and have multiple modes of reactivity. Although, there are several reports concerning the preparation of  $\beta$ -hydroxy thiocyanates from epoxides using different reagents or catalysts,<sup>14–16</sup> as far as we know, there is no report in the literature about the direct synthesis of 2-thiocyanatoalkyl alkanoates from epoxides. Even the reports on the stepwise conversion of epoxides to 2-thiocyanatoalkyl alkanoates are scarce.

In one method, epoxide was first converted to its corresponding  $\beta$ -hydroxy thiocyanate using NH<sub>4</sub>SCN in the presence of 18-crown-6, followed by a treatment with acetylchloride in reflux conditions to convert the hydroxy group into an ester group.<sup>17</sup> A second method involves the reaction of triphenylphosphine-thiocyanogen (TPPT) with epoxide at  $-40\text{ }^{\circ}\text{C}$  under argon and then at room temperature overnight. Then, in the second step, the resulted  $\beta$ -hydroxy thiocyanate was treated with benzoyl chloride and triethylamine producing the final desired product.<sup>15b</sup> In addition, in

G. Aghapour<sup>1</sup> and R. Hatefipour. School of Chemistry, Damghan University of Basic Sciences, Damghan, 36715-364, Iran.

<sup>1</sup>Corresponding author (e-mail: Gh\_Aghapour@dubs.ac.ir).

a different work for obtaining of these compounds, epoxides were treated with thiocyanic acid as described by van Tame-len,<sup>14a</sup> producing  $\beta$ -hydroxy thiocyanates, which on treatment with acetyl chloride in pyridine gave the corresponding 2-thiocyanatoalkyl alkanoates.<sup>18</sup> Furthermore, in this report, the formation of these compounds has also been described via treatment of thiocyanogen chloride with alkenes in the presence of a radical inhibitor in acetic acid in the dark as minor products.<sup>18</sup>

On the other hand, waste prevention and environmental protection are major requirements in an overcrowded world with increasing demands. Synthetic chemistry continues to develop various techniques for obtaining better products with less environmental impact. One of the more promising approaches is solvent-free organic synthesis.<sup>19</sup> These reactions have many advantages: reduced pollution, low costs, and simplicity in process and handling. These factors are especially important in industry.<sup>20</sup>

Thus, on the basis of the above descriptions, the development of simple and efficient methods for the preparation of 2-thiocyanatoalkyl alkanoates from epoxides, especially in neutral and solvent-free conditions, is desirable.

## Results and discussion

In our previous works,<sup>21</sup> we have reported the conversion of epoxides to  $\beta$ -halohydrins and now in continuation of our recent work<sup>22</sup> on the catalyst-free conversion of epoxides to  $\beta$ -hydroxy thiocyanates and also with consideration of advantages of solvent-free reactions, we report a direct and catalyst-free method for the conversion of epoxides to 2-thiocyanatoalkyl alkanoates using a mixture of tetrabutylammonium rhodanide ( $(n\text{-Bu})_4\text{NSCN}$ ) and an aliphatic or aromatic carboxylic anhydride under neutral and solvent-free conditions (Scheme 1).

First, we took 1,2-epoxytetradecane as an example, and optimized the reaction conditions for its conversion to 1-dodecyl-2-thiocyanatoethyl acetate (**1**) using thiocyanate anion in the presence of acetic anhydride ( $\text{Ac}_2\text{O}$ ). We found that no desired product (**1**) was formed using  $\text{NH}_4\text{SCN}$  as a source of thiocyanate anion in various conditions. Thus, we tried to perform this conversion using  $(n\text{-Bu})_4\text{NSCN}$ . The results are shown in Table 1. It must be noted that in all of these reactions epoxide was added to a stirring mixture of  $(n\text{-Bu})_4\text{NSCN}$  and acetic anhydride in the absence of a catalyst and stirring was continued for stated times.

As shown in Table 1, this reaction was unsuccessful in  $\text{CH}_2\text{Cl}_2$  and  $\text{CH}_3\text{CN}$  as solvents even under reflux conditions (Table 1, entries 1–3). Also, **1** was obtained in only 30%–40 % yield at room temperature after 24 h under solvent-free conditions (Table 1, entries 4 and 5). However, the yield of this reaction was increased by increasing the reaction temperature (60 °C) under solvent-free conditions (Table 1, entry 6). Finally, the best result was obtained in the case of entry 7 (Table 1) so that **1** was produced in 80 % yield using a mixture of  $(n\text{-Bu})_4\text{NSCN}:(\text{CH}_3\text{CO})_2\text{O}$  in a 1.2 :0.5 molar ratio at 60 °C after 6 h under solvent-free conditions.

We therefore used these conditions (Table 1, entry 7) for the conversion of other epoxides to their corresponding 2-thiocyanatoalkyl acetates. The results are shown in Table 2.

**Scheme 1.** Direct and catalyst-free method for the conversion of epoxides to 2-thiocyanatoalkyl alkanoates using tetrabutylammonium rhodanide ( $(n\text{-Bu})_4\text{NSCN}$ ) in the presence of an aliphatic or aromatic carboxylic anhydride under neutral and solvent-free conditions.

As shown in Table 2, epoxides are directly and efficiently converted to 2-thiocyanatoalkyl acetates by a mixture of  $(n\text{-Bu})_4\text{NSCN}:(\text{CH}_3\text{CO})_2\text{O}$  in a 1.2:0.5 molar ratio at 60 °C under neutral and solvent-free conditions and without using a catalyst.

It is possible to obtain other 2-thiocyanatoalkyl alkanoates using another carboxylic anhydride in this method. We found that epoxides can be converted to 2-thiocyanatoalkyl benzoates by using benzoic anhydride as an aromatic anhydride instead of acetic anhydride (Table 2, entries 8 and 9). However, benzoic anhydride (0.85 equiv.) must be used slightly more than acetic anhydride (0.5 equiv.), probably due to its lower reactivity compared to acetic anhydride.

Except for the case of styrene oxide, which produced two regioisomers (Table 2, entry 2), the reaction of other unsymmetrical epoxides occurred with high regioselectivity, and the thiocyanate anion attacked the less-hindered side of the epoxide ring due to the combination of steric and electronic factors. Under these reaction conditions, the ethereal bonds, phenyl ring, carbon–halogen bonds, and carbon–carbon double bonds as functional groups that are present in the epoxide molecules remain intact.

In order to have more insight into the applicability, selectivity, and limitations of the present method, we studied the possibility of the conversion of epoxides to 2-thiocyanatoalkyl alkanoates in the presence of some other functional groups in binary mixtures. For this purpose, a binary mixture of glycidyl phenyl ether and another organic compound (1:1) was treated with a stirring mixture of  $(n\text{-Bu})_4\text{NSCN}$  (1.2 equiv) and  $(\text{CH}_3\text{CO})_2\text{O}$  (0.5 equiv) in a flask at 60 °C under solvent-free conditions. The conversion yields obtained for these selective reactions of different binary mixtures are shown in Scheme 2.

In addition to the various selectivities mentioned above, as shown in Scheme 2, epoxides can be efficiently converted to their corresponding 2-thiocyanatoalkyl alkanoates in the presence of alcohols, carboxylic acids, aldehydes, amines, thiols, esters, and amides with excellent selectivity using the present method so that these functional groups remain completely intact.

## Conclusion

In conclusion, the present investigation has demonstrated that the use of tetrabutylammonium rhodanide ( $(n\text{-Bu})_4\text{NSCN}$ ) in the presence of aliphatic or aromatic carboxylic anhydrides offers a direct, simple, and efficient method, avoiding the use of a catalyst for the regioselective conversion of a wide variety of epoxides to their corresponding 2-thiocyanatoalkyl alkanoates, which have two important func-

**Scheme 2.** Chemoselectivities in the reaction of 2,3-epoxypropyl phenyl ether with  $(n\text{-Bu})_4\text{NSCN}$  in the presence of acetic anhydride at 60 °C under neutral and solvent-free conditions.

tional groups (ester and thiocyanate) under solvent-free conditions. This method can be efficiently used for preparation of 2-thiocyanatoalkyl alkanoates even in the presence of many other functional groups with excellent chemoselectivity. Easy work up and operation under neutral and solvent-free conditions without using a catalyst are considered other advantages of this method.

## Experimental

Solvents, reagents, and chemicals were obtained from Merck (Germany) and Fluka (Switzerland) Chemical Companies. Some products are known compounds and data of these compounds (such as bp, mp,  $^1\text{H}$  and  $^{13}\text{C}$  NMR, IR, mass) have been found to be identical to those reported.<sup>17,18</sup> Also, other products were characterized by their physical or spectral data. FTIR spectra were recorded on a PerkinElmer RXI spectrophotometer. Nuclear magnetic resonance spectra were recorded on a Bruker Avance DRX-500 spectrometer. Mass spectra were determined on a HP 5973 msd at 70 eV. Thin layer chromatography (TLC) was carried out on silica gel 254 analytical sheets obtained from Fluka.

### Typical procedure for the conversion of 2,3-epoxypropyl phenyl ether to 1-phenoxy-3-thiocyanatopropan-2-yl acetate (7) using $(n\text{-Bu})_4\text{NSCN}$ in the presence of acetic anhydride

Acetic anhydride (0.047 mL, 0.5 mmol) was added to a flask containing tetrabutylammonium rhodanide (0.36 g, 1.2 mmol) in an oil bath at 60 °C under solvent-free conditions. This mixture was stirred for 15 min so that a homogeneous mixture was formed. Then 2,3-epoxypropyl phenyl ether (0.135 mL, 1 mmol) was added and the reaction mixture was stirred until TLC showed the completion of the reaction (2.5 h). The crude product was subjected to column chromatography on silica gel using *n*-hexane-ethyl acetate (60:1) as eluent affording **7** (0.226 g, 90% yield). Oil. FTIR (neat,  $\text{cm}^{-1}$ ): 2157 (m, CN), 1743 (s, C=O).  $^1\text{H}$  NMR ( $\text{CDCl}_3$ , 500 MHz, ppm)  $\delta$ : 2.15 (s, 3H ( $\text{CH}_3$ )), 3.30–3.35 (dd, 1H ( $\text{CHCH}_a\text{H}_b\text{S}$ ),  $J_{\text{H}_a\text{H}_b} = 14.2$  Hz,  $J_{\text{H}_a\text{CH}} = 6.7$  Hz), 3.40–3.43 (dd, 1H ( $\text{CHCH}_a\text{H}_b\text{S}$ ),  $J_{\text{H}_b\text{CH}} = 4.3$  Hz), 4.12–4.16 (dd, 1H ( $\text{OCHcHdCH}$ ),  $J_{\text{H}_c\text{H}_d} = 10.2$  Hz,  $J_{\text{H}_c\text{CH}} = 5.8$  Hz), 4.17–4.20 (dd, 1H ( $\text{OCHcH}_d\text{CH}$ ),  $J_{\text{H}_d\text{CH}} = 4.5$  Hz), 5.40–5.44 (m, 1H (CH)), 6.89–6.91 (m, 2H (Ph)), 6.95–7.01 (m, 1H (Ph)), 7.26–7.32 (m, 2H (Ph)).  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ , 125.77 MHz, ppm)  $\delta$ : 21.17, 34.83, 66.83, 70.56, 112.15, 114.99, 122.19, 130.07, 158.28, 170.49. Mass spectra  $m/z$ : 251 (M, 3%), 208 (M –  $\text{CH}_3\text{CO}$ , 0.3%), 193 (M – SCN, 0.37%), 158 (M – PhO, 100%), 43 ( $\text{CH}_3\text{CO}$ , 43%).

# Organocatalysis in the stereoselective bromohydrin reaction of alkenes

Sukanta Bar

**Abstract:** An efficient regio- and stereo-selective (>99:1) trans-bromohydration (bromohydroxylation and bromomethoxylation) of alkenes including  $\alpha,\beta$ -unsaturated carbonyl compounds with *N*-bromosuccinimide (NBS) has been achieved by using 1.0 mol% of *N,N'*-diarylthiourea catalyst.

**Key words:** thiourea, *N*-halosuccinimide, alkene.

**Résumé :** On a pu réaliser des bromohydrations trans (bromohydroxylation et bromométhoxylation) d'alcènes régio- et stéréo-sélectives (>99:1) efficaces, y compris des composés carbonylés  $\alpha,\beta$ -insaturés, sous l'action du *N*-bromosuccinimide (NBS), en présence de 1,0 mole % de *N,N'*-diarylthiourée comme catalyseur.

**Mots-clés :** thiourée, *N*-halosuccinimide, alcène.

[Traduit par la Rédaction]

1,2-Halofunctionalization of olefins, for example, halohydrin reaction (halohydroxylation and haloalkoxylation) is an important transformation in organic chemistry.<sup>1</sup> The resulting 1,2-halohydroxy and alkoxyhalide compounds are versatile precursors in organic, medicinal, as well as industrial chemistry.<sup>2</sup> Owing to the immense importance of vicinal halohydrins, a number of methods have been developed for the reaction of aqueous (alcoholic) solutions of alkenes with molecular halogens, *N*-halosuccinimides (NXSs),<sup>3</sup>  $\text{TsNBr}_2$ ,<sup>4</sup> *N*-halosaccharin,<sup>5</sup> and metal halides along with an oxidizing agent.<sup>6</sup> Cheap and available NXSs, in particular *N*-bromosuccinimide (NBS) and *N*-chlorosuccinimide (NCS), are the choice of halogen sources over other hazardous reagents. However, longer reaction times and low yields, especially of electron-deficient alkenes, are major hitches. Some attempts are made to improve the reaction by performing in ionic liquids.<sup>7</sup> Herein, we report highly efficient *N,N'*-diarylthiourea-catalyzed (1.0 mol% of *N,N'*-diarylthiourea (PhNHCSNHPh)) 1,2-bromohydrin reaction of alkenes, including  $\alpha,\beta$ -unsaturated carbonyl compounds with high regio- and diastereo-selectivity (>99:1).

Recently, organocatalysis has become a vast area of research, while interest in catalysis of thiourea has grown.<sup>8</sup> In my continued efforts towards the development of new catalytic methods for the regio- and stereo-selective 1,2-halofunctionalization of alkenes, Lewis acids like metal triflates were found to activate NXS for the transfer of halogen to alkenes (Scheme 1).<sup>9</sup> This led us to anticipate that unlike Lewis acid, thiourea derivatives having hydrogen-bonding capability with carbonyl oxygen might catalyze the electrophilic halogen transfer from NXS to the olefins (Fig. 1). Recently, thiourea-catalyzed ( $\text{H}_2\text{NCSNH}_2$ ; 20 mol%) chlorohydrin reaction of alkenes was reported by Bentley et al. with poor-to-moderate stereoselectivity and yields.<sup>10</sup>

**Scheme 1.** Lewis acid catalyzed 1,2-halofunctionalization of alkenes.

In search for an effective thiourea catalyst for the bromohydrin reaction, we first studied the reaction of *trans*-stilbene **1a** with NBS in aqueous  $\text{CH}_3\text{CN}$  with *N,N'*-diarylthiourea **3** and simple thiourea, and the results are presented in Table 1. Compared with the non-catalytic reaction (5 h, 56% yield; Table 1, entry 1), *N,N'*-diphenylthiourea-catalyzed bromohydrin reaction of stilbene **1a** proceeded very fast at RT, and within 5 min, it afforded the desired bromohydroxylation product **2a** in 86% yield (Table 1, entry 3) along with 8% of 1,2-dibromostilbene. Further improvement of the yield as well as product distribution was observed when the reaction was performed at 0 °C, and no 1,2-dibromostilbene was detected by <sup>1</sup>H NMR spectrum analysis of the crude reaction mixture (Table 1, entry 4). There was no appreciable change in the reactivity and selectivity with thiourea **3b**, and **3c** containing electron-rich and electron-deficient arenes, respectively (Table 1, entries 5 and 6), while Thiourea **3d** provided the desired product, with 65% yield along with 16% of the 1,2-dibromostilbene.

In search for an appropriate solvent for the bromohydrin reaction, we first studied the reaction of *trans*-stilbene (**1a**) and NBS with 1 mol% *N,N'*-diarylthiourea (PhNHCSNHPh, **3a**) in different solvents. Common organic solvents were used

**Fig. 1.** Proposed activation of *N*-bromosuccinimide (NBS) by *N,N'*-diarylthiourea.

for this purpose. Acetone, THF, 1,4-dioxane, and 1,2-dimethoxyethane gave 45%–61% yield of the desired product along with 1,2-dibromostilbene as the byproduct. Other solvents gave very poor results. Acetonitrile was found to be the best solvent with 95% yield of the desired product. Detailed results of the solvent study are summarized in Table 2.

Thus, the best result was obtained when substrate **1a** was treated with 0.01 equiv. of thiourea (PhNHCSNHPh, **3a**) and 1.2 equiv. of NBS in 20% aqueous acetonitrile at 0 °C for 1 h. To establish the generality of the thiourea-catalyzed bromohydrin reaction, it was investigated on other alkenes, namely,  $\beta$ -propylstyrene, 1,2-dihydronaphthalene, and indene. All underwent smooth reaction at 0 °C and provided corresponding bromohydrins in excellent yields within an hour (Table 1, entries 8, 10, and 12).

When these alkenes were subjected to bromohydrin reaction at 25 °C, reactions were completed within 5 min but with 8%–10% less yields, which is due to the formation of dibromide as the byproduct (Table 1, entries 7, 9, and 11). In all the above cases, these reactions were anti-selective and no cis-isomer was formed as revealed by the <sup>1</sup>H NMR spectrum of the crude mixture.

Unfortunately for compounds containing isolated double bonds like cyclohexene, the reaction was less satisfying, as a messy reaction mixture was obtained. Similar result was obtained for ethyl acrylate.

$\alpha,\beta$ -Unsaturated carbonyls usually undergo slow bromohydrin reaction with poor yields of the desired bromohydrins. So, this catalytic method was studied for a large number of  $\alpha,\beta$ -unsaturated carbonyls like cinnamates and chalcones (Table 2). Reaction of methyl cinnamate **4a** under the catalytic conditions afforded the desired bromohydrin in 91% yield at RT after 5 h (Table 3, entry 1) compared with 60% yield after 18 h for the non-catalytic reaction carried out with 1.6 equiv. of NBS (not shown in Table 3). Electron-rich cinnamates **4b** and **4c** provided corresponding bromohydrins in excellent yields at 0 °C (Table 3, entries 2 and 3).

3,4-Methylenedioxycinnamate (**4d**) behaved similar to cinnamate (**4a**) (Table 3, entry 4). Similar trend was also observed for chalcones. Thus, electron-rich substrates preferred to show clean reaction at 0 °C, while other substrates reacted at RT (Table 3, entries 5–10).

To increase the scope of the reaction, we decided to study the bromomethoxylation reaction of a variety of alkenes. When methanolic solutions of alkenes, including  $\alpha,\beta$ -unsaturated carbonyls, were subjected to *N,N'*-diarylthiourea-catalyzed bromomethoxylation reaction with NBS, they produced methoxybromides in excellent yields (Table 4).

In summary, we have developed an efficient and general catalytic method for the bromohydrin reaction (bromohydroxylation and bromomethoxylation) of alkenes in the presence of only 1.0 mol% of *N,N'*-diarylthiourea using NBS as halogen source with excellent anti-selectivity and yields.

## Experimental section

### General methods

Commercial-grade reagents were used without further purification. Solvents were dried and distilled following usual protocols. Flash chromatography was carried out using Rankem Silica gel (230–400 mesh) purchased from Rankem, India. TLC was performed on aluminium-backed plates coated with Silica gel 60 with F254 indicator (Merck).

The <sup>1</sup>H NMR spectra were measured on Bruker-200 (200 MHz) and Bruker-400 (400 MHz) spectrometers, and <sup>13</sup>C NMR spectra were measured on Bruker-200 (50 MHz) and Bruker-400 (100 MHz) spectrometers using CDCl<sub>3</sub>. <sup>1</sup>H NMR chemical shifts are expressed in ppm ( $\delta$ ) downfield to CHCl<sub>3</sub> ( $\delta$  = 7.26), and <sup>13</sup>C NMR chemical shifts are expressed in ppm ( $\delta$ ) relative to the central CDCl<sub>3</sub> resonance ( $\delta$  = 77.0). Coupling constants in <sup>1</sup>H NMR are in Hz. Elemental analyses were carried out on a PerkinElmer 2400-II, Department of Chemistry, Indian Institute of Technology, Kharagpur. Melting points were measured in Toshniwal (India) melting point apparatus. IR spectra were recorded using PerkinElmer Spectrum R  $\times$  I FTIR Spectrometer.

### General procedure for the *N,N'*-diarylthiourea-catalyzed halohydrin reaction of alkenes

#### Bromohydrination of stilbene **1a**

To a well-stirred solution of *trans*-stilbene (**1a**) (0.10 g, 0.55 mmol) in 2.75 mL CH<sub>3</sub>CN:H<sub>2</sub>O (4:1), PhNHCSNHPh (1.2 mg, 0.0055 mmol) and NBS (0.118 g, 0.66 mmol) were added, and the reaction mixture was allowed to stir at 0 °C under argon atmosphere. Progress of the reaction was monitored by TLC. After 1 h, the solvent was evaporated under reduced pressure at RT. The crude reaction mass was subjected to purification by flash column chromatography using 5% EtOAc in petroleum ether (60–80 °C) to obtain ( $\pm$ )-**2a**<sup>11</sup> (0.146 g, 95%) as a white solid; mp 83–86 °C (lit.<sup>11</sup> mp 83–84 °C). <sup>1</sup>H NMR (200 MHz, CDCl<sub>3</sub>)  $\delta$ : 2.18 (bs, 1H), 5.10 (d, *J* = 6.8 Hz, 1H), 5.21 (d, *J* = 6.8 Hz, 1H), 7.36 (m, 10H). Bromohydrin compounds **2b**,<sup>12</sup> **2c**,<sup>13</sup> **2d**,<sup>14</sup> **5a**,<sup>15</sup> **5b**,<sup>15</sup> and **5e**<sup>16</sup> were characterized by <sup>1</sup>H and <sup>13</sup>C NMR and compared with the reported literature data.

#### 2-Bromo-3-(3,4-dimethoxyphenyl)-3-hydroxy-propionic acid methyl ester (**5c**)

**Note:** Bromomethoxylation of olefins (1.0 equiv.) was performed with PhNHCSNHPh (0.01 equiv.), 1.2 equiv. NBS in methanol at 0–25 °C.

<sup>a</sup>Isolated yield of **6** and **7** after column chromatography.

**2-Bromo-3-hydroxy-3-(4-methoxyphenyl)-1-phenylpropan-1-one (5f)**

Yield: 95%; white solid; mp 58 °C.  $R_f$  (15% EtOAc/petroleum ether): 0.16. IR (KBr,  $\text{cm}^{-1}$ ): 625, 684, 811, 834, 1002, 1037, 1176, 1217, 1251, 1282, 1449, 1516, 1594, 1611, 1679, 2836, 3466 (br).  $^1\text{H}$  NMR (200 MHz,  $\text{CDCl}_3$ )  $\delta$ : 3.45 (d,  $J$  = 4.6 Hz, 1H), 3.82 (s, 3H), 5.2 (d,  $J$  = 8.4 Hz, 1H), 5.31 (dd,  $J$  = 8.6, 4.6 Hz, 1H), 6.92 (m, 2H), 7.37–7.66 (m, 5H), 8.03 (m, 2H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 48.2, 55.2, 74.2, 113.8 (2C), 128.4 (2C), 128.8 (2C), 128.9 (2C), 131.6, 134.1, 134.5, 159.7, 194.6. Anal. calcd. for  $\text{C}_{16}\text{H}_{15}\text{BrO}_3$ : C, 57.33; H, 4.51. Found: C, 57.21; H, 4.22.

**2-Bromo-3-(3,4-dimethoxyphenyl)-3-hydroxy-1-phenylpropan-1-one (5g)**

Yield: 94%; white solid; mp 130 °C.  $R_f$  (20% EtOAc/petroleum ether): 0.22. IR (KBr,  $\text{cm}^{-1}$ ): 635, 690, 812, 979, 1027, 1135, 1229, 1251, 1463, 1447, 1511, 1595, 1685, 3498.  $^1\text{H}$  NMR (200 MHz,  $\text{CDCl}_3$ )  $\delta$ : 3.45 (d,  $J$  = 4.4 Hz, 1H), 3.89 (s, 3H), 3.92 (s, 3H), 5.2 (d,  $J$  = 8.2 Hz, 1H), 5.3 (dd,  $J$  = 8.8, 4.0 Hz, 1H), 6.87 (d,  $J$  = 8.4 Hz, 1H), 7.03 (m, 2H), 7.49 (m, 2H), 7.63 (m, 1H), 8.02 (m, 2H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 48.2, 55.81, 55.87, 74.5, 109.9, 110.7, 119.8, 128.8 (2C), 128.9 (2C), 131.9, 134.1, 134.5, 148.8, 149.0, 194.6. Anal. calcd. for  $\text{C}_{17}\text{H}_{17}\text{BrO}_4$ : C, 55.91; H, 4.69. Found: C, 56.06; H, 4.64.

**2-Bromo-3-hydroxy-1-(2-methoxyphenyl)-3-phenylpropan-1-one (5h)**

Yield: 93%; gummy liquid.  $R_f$  (10% EtOAc/petroleum ether): 0.20. IR (KBr,  $\text{cm}^{-1}$ ): 567, 756, 930, 979, 1031, 1176, 1250, 1356, 1448, 1514, 1613, 1675, 2054, 2838, 3470 (br).  $^1\text{H}$  NMR (200 MHz,  $\text{CDCl}_3$ )  $\delta$ : 3.90 (s, 3H), 5.27 (d,  $J$  = 7.8 Hz, 1H), 5.62 (d,  $J$  = 7.8 Hz, 1H), 7.0 (m, 2H), 7.31–7.55 (m, 6H), 7.78 (dd,  $J$  = 7.8, 1.8 Hz, 1H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 48.2, 55.2, 74.2, 113.8 (2C), 128.5 (2C), 128.8 (2C), 128.9 (2C), 131.6, 134.1, 134.5, 159.6, 194.4. Anal. calcd. for  $\text{C}_{16}\text{H}_{15}\text{BrO}_3$ : C, 57.33; H, 4.51. Found: C, 57.41; H, 4.43.

**2-Bromo-3-(4-fluorophenyl)-3-hydroxy-1-phenylpropan-1-one (5i)**

Yield: 93%; white solid; mp 80 °C.  $R_f$  (5% EtOAc/petroleum ether): 0.20. IR (KBr,  $\text{cm}^{-1}$ ): 548, 686, 814, 836, 1009, 1159, 1231, 1281, 1449, 1594, 1608, 1682, 3298 (br).  $^1\text{H}$  NMR (200 MHz,  $\text{CDCl}_3$ )  $\delta$ : 3.47 (bs, 1H), 5.15 (d,  $J$  = 8.4 Hz, 1H), 5.33 (d,  $J$  = 8.4 Hz, 1H), 7.08 (t,  $J$  = 8.4 Hz, 2H), 7.48 (m, 3H), 7.63 (t,  $J$  = 7.6 Hz, 2H), 8.02 (d,  $J$  = 8.0 Hz, 2H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 48.0, 73.9, 115.2, 115.4, 128.8 (2C), 129 (3C), 129.1, 134.3, 134.4, 135.2, 162.7 (d,  $J$  = 245.5 Hz, 1C), 194.4. Anal. calcd. for  $\text{C}_{15}\text{H}_{12}\text{BrFO}_2$ : C, 55.75; H, 3.74. Found: C, 56.29; H, 3.51.

**2-Bromo-3-(4-chlorophenyl)-3-hydroxy-1-phenylpropan-1-one (5j)**

Yield: 94%; white solid; mp 96 °C.  $R_f$  (10% EtOAc/petroleum ether): 0.15. IR (KBr,  $\text{cm}^{-1}$ ): 544, 646, 682, 779, 808, 834, 1012, 1089, 1219, 1277, 1293, 1376, 1449, 1594, 1680, 3449 (br).  $^1\text{H}$  NMR (200 MHz,  $\text{CDCl}_3$ )  $\delta$ : 3.49 (d,  $J$  = 4.4 Hz, 1H), 5.10 (d,  $J$  = 8.4 Hz, 1H), 5.29 (dd,  $J$  = 8.2, 4.0 Hz, 1H), 7.23–7.50 (m, 6H), 7.60 (m, 1H), 7.90 (d,  $J$  = 7.0 Hz, 2H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 47.7, 73.9,

128.5 (2C), 128.7 (2C), 128.8 (2C), 128.9 (2C), 134.28, 134.31 (2C), 137.8, 194.3. Anal. calcd. for  $\text{C}_{15}\text{H}_{12}\text{BrClO}_2$ : C, 53.05; H, 3.56. Found: C, 53.42; H, 3.17.

**Bromomethoxylation of stilbene 1a**

To a well-stirred solution of *trans*-stilbene (**1a**) (0.10 g, 0.55 mmol) in 2.75 mL MeOH,  $\text{PhNHCSNHPH}$  (1.2 mg, 0.0055 mmol) and NBS (0.118 g, 0.66 mmol) were added, and the reaction mixture was allowed to stir at 0 °C under argon atmosphere. Progress of the reaction was monitored by TLC. After 1 h, the solvent was evaporated at RT under reduced pressure. The crude reaction mass was subjected to purification by flash column chromatography using 5% EtOAc in petroleum ether (60–80 °C) to obtain ( $\pm$ )-**6a**<sup>6d</sup> (0.153 g, 95%) as a white solid; mp 115–118 °C (lit.<sup>17</sup> mp 116–118 °C).  $^1\text{H}$  NMR (200 MHz,  $\text{CDCl}_3$ )  $\delta$ : 3.20 (s, 3H), 4.65 (d,  $J$  = 6.8 Hz, 1H), 5.04 (d,  $J$  = 6.8 Hz, 1H), 7.30 (m, 10H). Spectral data of compounds **6c**,<sup>18</sup> **6e**, and **6i** are consistent with the reported literature data.

**(2-Bromo-methoxypentyl)-benzene (6b)**

Yield: 87%; gummy liquid.  $R_f$  (3% EtOAc/petroleum ether): 0.45. IR (KBr,  $\text{cm}^{-1}$ ): 585, 624, 702, 760, 956, 1093, 1134, 1168, 1188, 1454, 1494, 2933, 2960.  $^1\text{H}$  NMR (200 MHz,  $\text{CDCl}_3$ )  $\delta$ : 0.92 (t,  $J$  = 7.2 Hz, 3H), 1.37–1.94 (m, 4H), 3.34 (s, 3H), 4.19 (m, 1H), 4.40 (d,  $J$  = 5.6 Hz, 1H), 7.39 (m, 5H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 13.3, 20.8, 34.9, 57.5, 59.5, 86.7, 127.6 (2C), 128.1, 128.16 (2C), 138.5. Anal. calcd. for  $\text{C}_{12}\text{H}_{17}\text{BrO}$ : C, 56.04; H, 6.66. Found: C, 56.13; H, 6.59.

**2-Bromo-1-methoxy-1,2,3,4-tetrahydronaphthalene (6d)**

Yield: 93%; liquid.  $R_f$  (3% EtOAc/petroleum ether): 0.62. IR (KBr,  $\text{cm}^{-1}$ ): 601, 748, 817, 937, 1078, 1117, 1214, 1438, 1455, 1492, 2821, 2928.  $^1\text{H}$  NMR (200 MHz,  $\text{CDCl}_3$ )  $\delta$ : 2.12–2.25 (m, 1H), 2.42–2.56 (m, 1H), 2.77–2.88 (m, 1H), 2.90–3.15 (m, 1H), 3.54 (s, 3H), 4.48 (d,  $J$  = 4.0 Hz, 1H), 4.65 (m, 1H), 7.13–7.35 (m, 4H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 25.8, 26.9, 49.6, 57.4, 81.4, 126.2, 128.3, 128.8, 130.2, 132.9, 135.6. Anal. calcd. for  $\text{C}_{11}\text{H}_{13}\text{BrO}$ : C, 54.79; H, 5.43. Found: C, 54.64; H, 5.34.

**2-Bromo-3-methoxy-3-(4-methoxyphenyl)-propionic acid methyl ester (7b)**

Yield: 95%; white solid; mp 46 °C.  $R_f$  (3% EtOAc/petroleum ether): 0.25. IR (KBr,  $\text{cm}^{-1}$ ): 578, 833, 1031, 1074, 1095, 1150, 1182, 1246, 1281, 1316, 1379, 1438, 1516, 1612, 1742, 2940.  $^1\text{H}$  NMR (200 MHz,  $\text{CDCl}_3$ )  $\delta$ : 3.19 (s, 3H), 3.82 (s, 3H), 3.84 (s, 3H), 4.21 (d,  $J$  = 9.8 Hz, 1H), 4.50 (d,  $J$  = 10.0 Hz, 1H), 6.92 (m, 2H), 7.28 (m, 2H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ )  $\delta$ : 47.3, 52.9, 55.1, 57.3, 83.6, 113.7 (2C), 128.7, 129.1 (2C), 159.9, 169.4. Anal. calcd. for  $\text{C}_{12}\text{H}_{15}\text{BrO}_4$ : C, 47.54; H, 4.99. Found: C, 47.77; H, 4.98.

**2-Bromo-3-(3,4-dimethoxyphenyl)-3-methoxypropionic acid methyl ester (7c)**

Yield: 95%; white solid; mp 75 °C.  $R_f$  (10% EtOAc/petroleum ether): 0.30. IR (KBr,  $\text{cm}^{-1}$ ): 646, 817, 855, 1021, 1074, 1104, 1143, 1170, 1236, 1238, 1261, 1294, 1447, 1464, 1517, 1593, 1748, 2936, 2964.  $^1\text{H}$  NMR (200 MHz,  $\text{CDCl}_3$ )  $\delta$ : 3.22 (s, 3H), 3.85 (s, 3H), 3.89 (s, 6H), 4.22 (d,  $J$  = 10.0 Hz, 1H), 4.49 (d,  $J$  = 9.8 Hz, 1H), 6.88 (m, 3H).

$^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ ):  $\delta$  47.3, 52.9, 55.74, 55.81, 57.4, 83.9, 109.8, 110.4, 121.1, 129.0, 149.0, 149.3, 169.4. Anal. calcd. for  $\text{C}_{13}\text{H}_{17}\text{BrO}_5$ : C, 46.86; H, 5.14. Found: C, 47.28; H, 5.15.

**3-Benzo[1,3]dioxol-5-yl-2-bromo-3-methoxypropionic acid methyl ester (7d)**

Yield: 91%; white solid; mp 74 °C.  $R_f$  (5% EtOAc/petroleum ether): 0.32. IR (KBr,  $\text{cm}^{-1}$ ): 559, 631, 655, 818, 924, 961, 1017, 1036, 1066, 1091, 1159, 1251, 1274, 1447, 1489, 1501, 1744.  $^1\text{H}$  NMR (200 MHz,  $\text{CDCl}_3$ ):  $\delta$  3.17 (s, 3H), 3.81 (s, 3H), 4.13 (d,  $J = 9.8$  Hz, 1H), 4.42 (d,  $J = 9.8$  Hz, 1H), 5.95 (s, 2H), 6.81 (m, 3H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ ):  $\delta$  47.3, 53, 57.4, 83.9, 101.2, 107.5, 107.9, 122.4, 130.7, 147.9, 148.1, 169.4. Anal. calcd. for  $\text{C}_{12}\text{H}_{13}\text{BrO}_5$ : C, 45.45; H, 4.13. Found: C, 45.06; H, 4.0.

**2-Bromo-3-methoxy-3-(4-methoxyphenyl)-1-phenylpropan-1-one (7f)**

Yield: 95%; white solid; mp 90 °C.  $R_f$  (5% EtOAc/petroleum ether): 0.25. IR (KBr,  $\text{cm}^{-1}$ ): 578, 685, 806, 832, 1038, 1074, 1175, 1219, 1254, 1305, 1279, 1373, 1446, 1516, 1611, 1685, 2929.  $^1\text{H}$  NMR (200 MHz,  $\text{CDCl}_3$ ):  $\delta$  3.18 (s, 3H), 3.85 (s, 3H), 4.80 (d,  $J = 9.8$  Hz, 1H), 5.12 (d,  $J = 9.8$  Hz, 1H), 6.96 (dd,  $J = 6.6, 2.0$  Hz, 2H), 7.39 (dd,  $J = 6.6, 2.0$  Hz, 2H), 7.50–7.62 (m, 3H), 8.06 (d,  $J = 7.0$  Hz, 2H).  $^{13}\text{C}$  NMR (100 MHz,  $\text{CDCl}_3$ ):  $\delta$  47.6, 55.2, 57.4, 82.8, 113.7 (2C), 128.76 (2C), 128.79 (2C), 129.3 (2C), 129.7, 133.7, 135.2, 159.9, 193.2. # Étude DFT des réactions d'hydrogénation des cyclohexènes disubstitués en position 2 et 3

Sameh Ayadi et Manef Abderrabba

**Résumé :** Dans ce travail, nous avons étudié théoriquement les réactions d'hydrogénation des cyclohexènes disubstitués par une voie chimique par le (Z)-1,2-diazène (**1**) et le (E)-1,2-diazène (**1'**). Nous avons discuté de point de vue thermodynamique la possibilité et la stéréosélectivité de ces réactions. Les états de transition de la réaction entre les cyclohexènes de type (**2a–2c**) et le (Z)-1,2-diazène (**1**) ont été déterminés.

**Mots-clés :** cyclohexène, théorie de la fonctionnelle de densité (« DFT »), hydrogénation.

**Abstract:** The purpose of this work is to conduct a theoretical study of the hydrogenation reaction between disubstituted cyclohexenes (**2a–2c**) and (Z)-1,2-diazene (**1**) and the reaction between disubstituted cyclohexenes (**2a–2c**) and (E)-1,2-diazene (**1'**). From a thermodynamic point of view, we discuss the reactivity and the stereoselectivity of these reactions. Activation barriers of the reaction between cyclohexenes (**2a–2c**) and the (Z)-1,2-diazene (**1**) have been calculated and discussed.

**Key words:** cyclohexene, density functional theory (DFT), hydrogenation.

## Introduction

Les réactions d'hydrogénation des cycloalcènes substitués possèdent une grande importance en synthèse organique.<sup>1–16</sup> Nous avons trouvé intéressant d'effectuer une étude théorique sur la possibilité et la stéréosélectivité des réactions d'hydrogénation des cyclohexènes disubstitués (**2a–2c**) par le (Z)-1,2-diazène (**1**) et par le (E)-1,2-diazène (**1'**) (fig. 1).

Dans le but de comparer l'influence des substituants de **2b–2c** sur la réactivité de ces réactions d'hydrogénation, nous avons commencé par étudier la réaction entre le cyclohexène **2a** et **1'**. Par la suite, nous avons étudié de point de vue cinétique et thermodynamique la réaction entre **1** et **2a**. Dans chaque cas, nous avons vérifié que ces réactions sont sous le contrôle des orbitales frontières. Enfin, nous avons étudié de point de vue thermodynamique et cinétique la possibilité et la stéréosélectivité de ces réactions d'hydrogénation entre **1** et **2b–2c**.

## Les méthodes de calcul

Cette étude a été réalisée en utilisant le programme Gaussian 03.<sup>17</sup> Les calculs ont été effectués au niveau DFT (théorie de la fonctionnelle de densité) avec les bases standard 6–31G\* et 3–21G. Nous avons utilisé la fonctionnelle B3LYP dans laquelle l'énergie d'échange est calculée par la méthode de Becke à trois paramètres et la corrélation est calculée par la méthode de Lee, Yang et Paar.<sup>18–20</sup> En effet, il a été établi que cette méthode de calcul DFT est une des plus performantes pour ce type des molécules organiques.<sup>21</sup>

## Résultats et discussion

### Étude de la réaction d'hydrogénation du cyclohexène

#### Étude thermodynamique

Nous avons étudié thermodynamiquement la possibilité et la stéréosélectivité de la réaction entre **1** et **2a** et la réaction entre **1'** et **2a** (fig. 2). En utilisant la méthode de calcul DFT/B3LYP avec les bases standard 6–31G\* et 3–21G, nous avons déterminé dans les conditions standard de température et de pression (15 K et 1 atm (1 atm = 101,325 kPa)) les variations d'énergie réactionnelle  $\Delta E_r$ , les variations d'enthalpie libre réactionnelle  $\Delta G_r$ , les variations d'enthalpie réactionnelle  $\Delta H_r$  et le ZPE (« zero-point energy ») qui correspond aux réactions (I), (II), (III) et (IV).

Comme le montre le tableau 1, les variations d'enthalpie libre réactionnelle  $\Delta G_r$  sont toutes négatives, par conséquent ces réactions sont possibles et favorisées thermodynamiquement. Nous avons remarqué que les valeurs de la variation d'enthalpie libre réactionnelle qui correspond aux réactions (I) et (II) sont respectivement supérieures en valeur absolue aux valeurs des réactions (III) et (IV). Ce qui nous a permis de dire que la réaction entre **1** et **2a** est plus favorisée thermodynamiquement que la réaction entre **1'** et **2a**. De plus, nous avons remarqué que la valeur de la variation d'enthalpie libre réactionnelle  $\Delta G_r$  qui correspond à la réaction (I) est supérieure en valeur absolue à la valeur de  $\Delta G_r$  de la réaction (II). Ce qui nous a permis de dire que le conformère chaise (**4a**) est plus stable thermodynamiquement que le conformère bateau (**4a'**). De la même manière pour les réactions (III) et (IV), nous avons remarqué que la valeur d'enthalpie libre réactionnelle  $\Delta G_r$  qui correspond à la formation de **4a** est supérieure en valeur absolue à la valeur de  $\Delta G_r$  qui correspond à la formation de **4a'**. Nous avons aussi remarqué que les valeurs de la variation de l'énergie  $\Delta E_r$  qui correspond aux réactions (I) et (III) sont respectivement plus importantes que celles de la variation de l'énergie qui

**Fig. 1.** Réactions entre les cyclohexènes de type (**2a–2c**) et le (*Z*)-1,2-diazène (**1**) ou le (*E*)-1,2-diazène (**1'**).**Fig. 2.** Réactions entre le cyclohexène (**2a**) et le (*Z*)-1,2-diazène (**1**) ou le (*E*)-1,2-diazène (**1'**).**Tableau 1.** Valeurs calculées ( $\text{kcal mol}^{-1}$ ) des variations d'énergie réactionnelle  $\Delta E_r$ , des variations d'enthalpie libre réactionnelle  $\Delta G_r$ , des variations d'enthalpie réactionnelle  $\Delta H_r$  et le « zero-point energy » ZPE.

Réactions	Produits	$\Delta E_r$	$\Delta E_r + \text{ZPE}$	$\Delta G_r$
<b>B3LYP/6–31G*</b>				
Réaction (I)	<b>4a</b>	–92,09	–92,09	–88,61
Réaction (II)	<b>4a</b>	–88,98	–88,99	–82,05
<b>B3LYP/3–21G</b>				
Réaction (III)	<b>4a</b>	–85,95	–85,96	–82,76
Réaction (IV)	<b>4a</b>	–82,86	–82,85	–76,20

correspond aux réactions (II) et (IV). Ce qui confirme de nouveau que la formation de **4a** est le produit majoritaire de la réaction entre **2a** et **1** et de la réaction entre **2a** et **1'**.

Nos résultats théoriques confirment bien que **4a** est plus stable thermodynamiquement que **4a'**.

#### Étude des orbitales frontières

En utilisant la méthode de calculs DFT/B3LYP avec les bases standard 6–31G\* et 3–21G, nous avons déterminé les

**Tableau 2.** Les énergies (eV) de la LUMO et de la HOMO du cyclohexène (**2a**), du (*Z*)-1,2-diazène (**1**) et du (*E*)-1,2-diazène (**1'**).

	B3LYP (6–31G*)		B3LYP (3–21G)	
	LUMO	HOMO	LUMO	HOMO
<b>1</b>	–0,056 52	–0,247 86	–0,054 11	–0,2493
<b>1'</b>	–0,053 08	–0,241 82	–0,051 98	–0,2441
<b>2a</b>	0,028 830	–0,233 57	0,028 71	–0,2412

énergies de la LUMO et de la HOMO de **2a** ainsi que les énergies de la LUMO et de la HOMO de **1** et de **1'** (voir tableau 2). D'après la théorie des orbitales frontières, lors de l'interaction entre deux molécules, les orbitales frontières à considérer sont la HOMO de l'une et la LUMO de l'autre, choisies de telle sorte que l'écart énergétique  $\Delta E$  qui les sépare soit le plus faible possible.<sup>22</sup> Comme le montre la figure 3, le diagramme orbitalaire donne une bonne indication qualitative quant à la réactivité de notre système. Nous avons remarqué que l'interaction principale se fait entre l'énergie de la LUMO de **1** et l'énergie de la HOMO de **2a**. De plus, nous avons remarqué que la variation d'énergie  $\Delta E$

**Fig. 3.** Diagramme orbitalaire du cyclohexène (**2a**) et le (Z)-1,2-diazène (**1**). B3LYP (6–31G\*).**Fig. 4.** Profil énergétique des réactions conduisant aux conformères chaise (**4a**) et bateau (**4a'**) en DFT/B3LYP avec la base standard 6–31G\* (énergie en kcal mol<sup>-1</sup>).

entre la LUMO de **1** et la HOMO de **2a** est inférieure à la variation d'énergie  $\Delta E$  entre la LUMO de **1'** et la HOMO de **2a**. Ce qui explique bien que la réaction entre **1** et **2a** est plus réactive que dans le cas de la réaction entre **1'** et **2a**.

#### Calcul des états de transition

Nous avons optimisé les états de transition de la réaction de **2a** et **1**. Nous avons obtenu trois conformations différentes des états de transitions : l'état de transition pseudo-chaise **3a\***

**Fig. 5.** États de transition de la réaction entre le (Z)-1,2-diazène et le cyclohexène, distance en Å (1 Å = 0,1 nm). B3LYP (6–31G\*).**Tableau 3.** Énergies relatives  $E^*$  (kcal mol<sup>-1</sup>) des états de transition par rapport aux énergies des réactifs (calculées avec la méthode DFT/B3LYP).

	DFT/B3LYP(6–31G*)	DFT/B3LYP (3–21G)
<b>1</b>		
<b>2</b>		
<b>3a*</b>	32,4	33,1
<b>3a*1</b>	33,2	34,3
<b>3a*2</b>	33,9	35,2

Nota : **1**, **2**, **3a\***, **3a\*1** (endo); **3a\*2** (exo).

**Tableau 4.** Longueurs des liaisons en formation C<sub>1</sub>–H<sub>1</sub> et C<sub>2</sub>–H<sub>2</sub> dans l'état de transition de la réaction du (Z)-1,2-diazène (**1**) et le cyclohexène (**2a**).

	B3LYP (6–31G*)		B3LYP (3–21G)	
	C <sub>1</sub> –H <sub>1</sub>	C <sub>2</sub> –H <sub>2</sub>	C <sub>1</sub> –H <sub>1</sub>	C <sub>2</sub> –H <sub>2</sub>
<b>3a*</b>	1,5732	1,5713	1,5685	1,5811
<b>3a*1</b>	1,5781	1,5791	1,5732	1,5752
<b>3a*2</b>	1,5776	1,5790	1,5723	1,5761

Nota : **3a\***, **3a\*1** (endo); **3a\*2** (exo).

et les états de transitions bateau tels que **3a\*1** (endo) et **3a\*2** (exo) obtenus respectivement avec une approche de **1** en endo de **2a** et avec une approche de **1** en exo de **2a** (fig. 4).

Les calculs théoriques montrent que la formation de **4a** est favorisée par rapport à la formation de **4a'**. En utilisant la méthode de calcul DFT/B3LYP avec les bases standard 6–31G\* et 3–21G, nous avons trouvé pour **4a'** une grande énergie d'activation respectivement de 33,9 kcal mol<sup>-1</sup> et 35,2 kcal mol<sup>-1</sup> aux niveaux du calcul citées précédemment. Ces valeurs sont plus grandes que celles trouvées pour les états de transition conduisant à la formation de **4a** (tableau 3). Ce qui confirme de nouveau que **4a** est plus stable que **4a'**. Ces valeurs de l'énergie d'activation sont du même ordre de grandeur que celle trouvée par McKee et al. pour la réaction entre **1** et l'éthène.<sup>23</sup> La comparaison des profils énergétiques des réactions conduisant respectivement à **4a** et **4a'** est donnée sur la figure 4.

Nous avons déterminé les états de transition bateau avec une approche du (Z)-1,2-diazène en endo et avec une approche du (Z)-1,2-diazène en exo. Les résultats montrent que la forme endo est favorisée par rapport à la forme exo. La géométrie des trois états de transitions **3a\***, **3a\*1** (endo) et **3a\*2** (exo) est présentée sur la figure 5.

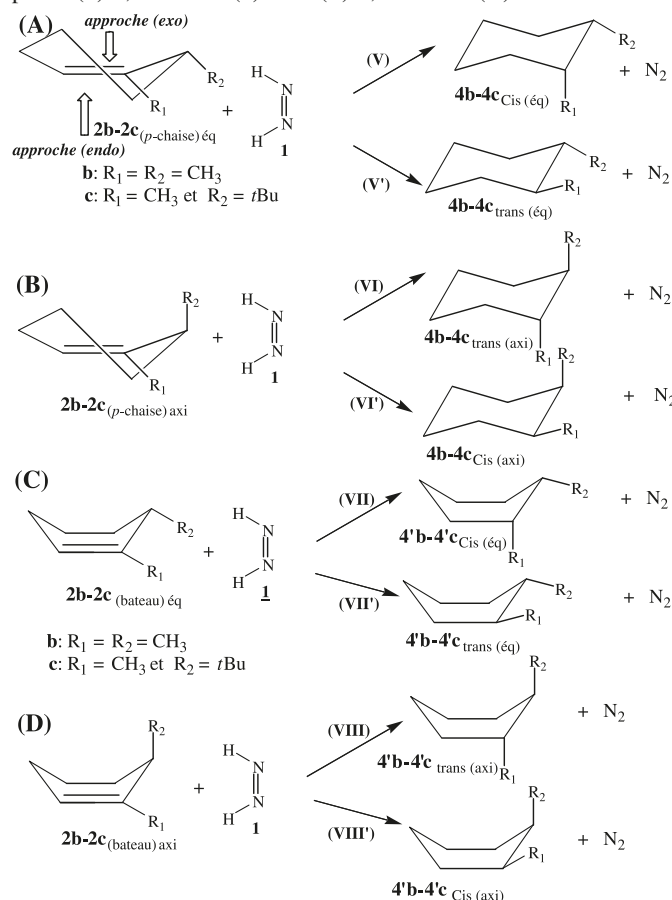

Nous avons remarqué que le cycle de l'état de transition est quasi plan. Si on compare les longueurs des liaisons en formation, on constate que la liaison C<sub>1</sub>–H<sub>1</sub> est plus courte que la liaison C<sub>2</sub>–H<sub>2</sub> (tableau 4).

### Étude de la réaction entre le (Z)-1,2 diazène et les cyclohexènes disubstitués

Dans la deuxième partie de ce travail, nous avons étudié thermodynamiquement les réactions entre **1** et **2b–2c** dans les différentes conformations possibles tels que les conformères pseudo-chaire et les conformères bateau (fig. 6). Dans chaque cas, une des approches endo et exo de **1** sur **2b–2c** conduit au stéréoisomère cis et l'autre au stéréoisomère trans.

### Étude thermodynamique

Dans le but d'étudier la possibilité et la stéréosélectivité de la réaction d'hydrogénation de **2b–2c** par **1**, nous avons étudié de point de vue thermodynamique les réactions entre **1** et **2b–2c** dans les différentes conformations possibles telles que les conformations pseudo-chaire **2b–2c**<sub>(p-chaire)éq</sub> et **2b–2c**<sub>(p-chaire)axi</sub> et les conformations bateau **2b–2c**<sub>(bateau)éq</sub> et **2b–2c**<sub>(bateau)axi</sub> (fig. 6).

**Fig. 6.** Réactions d'hydrogénation des cyclohexènes disubstitués par le (Z)-1,2-diazène (**1**) et le (E)-1,2-diazène (**1'**).

Dans chaque cas, une des approches endo et exo de **1** sur **2b-2c** conduit au stéréoisomère cis tels que **4b-4c**<sub>cis(éq)</sub>, **4b-4c**<sub>cis(axi)</sub>, **4'b-4'c**<sub>cis(éq)</sub> et **4'b-4'c**<sub>cis(axi)</sub> et l'autre conduit au stéréoisomère trans tels que **4b-4c**<sub>trans(éq)</sub>, **4b-4c**<sub>trans(axi)</sub>, **4'b-4'c**<sub>trans(éq)</sub> et **4'b-4'c**<sub>trans(axi)</sub>.

Dans chaque cas de ces réactions, nous avons trouvé des valeurs des enthalpies libres réactionnelles négatives (tableau 5). Ces réactions sont possibles théoriquement et, par conséquent, elles sont favorisées thermodynamiquement. De plus, nous avons remarqué que les valeurs des enthalpies libres réactionnelles qui correspondent aux réactions (V), (V'), (VI) et (VI') sont plus importantes en valeur absolue que celles qui correspondent aux réactions (VII), (VII'), (VIII) et (VIII'). Ceci nous a permis de dire que les conformères chaise sont plus stables thermodynamiquement que les conformères bateau.

Nous avons aussi remarqué que la formation de **4b-4c**<sub>trans(éq)</sub> est plus favorisée que la formation de **4b-4c**<sub>cis(éq)</sub> provenant respectivement des approches endo et exo de **1** sur **2b-2c** (p-chaire)éq. Par contre, dans le cas de la réaction B, lors des approches respectivement en endo et exo du **1** sur **2b-2c** (p-chaire)axi, nous avons trouvé que la formation de **4b-4c**<sub>cis(axi)</sub> est plus favorisée que celle de **4b-4c**<sub>trans(axi)</sub> (tableau 5).

Dans le cas des approches endo et exo de **1** sur **2b-2c** (bateau)éq, nous avons remarqué que la formation de **4b-4c**<sub>trans(éq)</sub> est plus favorisée respectivement par rapport

**Tableau 5.** Valeurs calculées (kcal mol<sup>-1</sup>) des variations d'énergie réactionnelle  $\Delta E_r$ , des variations d'enthalpie libre réactionnelle  $\Delta G_r$ , des variations d'enthalpie réactionnelle  $\Delta H_r$  et le ZPE.

à **4b-4c**<sub>cis(éq)</sub>. Par contre dans le cas de la réaction D, lors de l'addition de **1** sur **2b-2c** (bateau)axi dans les deux approches endo et exo. Les résultats théoriques montrent que la formation de **4'b-4'c**<sub>cis(axi)</sub> est plus stable thermodynamiquement que celle de **4'b-4'c**<sub>trans(axi)</sub>.

### Étude des orbitales frontières

En utilisant la méthode de calcul DFT/B3LYP avec les bases standard 6-31G\* et 3-21G, nous avons déterminé les énergies de la LUMO et de la HOMO des cyclohexènes disubstitués dans les différentes conformations possibles pseudo-chaire et bateau (tableau 6). Le diagramme orbitalaire des réactifs entre **1** et **2b** (p-chaire)axi, calculé au niveau DFT/B3LYP et la base standard 6-31G\*, est donné sur la figure 7. Ce diagramme orbitalaire donne une bonne indication qualitative quant à la réactivité de notre système. D'après la théorie des orbitales frontières,<sup>22</sup> l'interaction principale se produit entre la HOMO de **2b-2c** (p-chaire)axi et la HOMO de **1**.

**Tableau 6.** Les énergies (eV) de la LUMO et de la HOMO des cyclohexènes disubstitués.

**Fig. 7.** Diagramme orbitalaire du 2,3-diméthylcyclohexène (**2b**<sub>(p-chaîse)axi</sub>) et le (Z)-1,2-diazène (**1**). B3LYP/6-31G\*.

### Calcul des états de transition

Dans le but de déterminer la stéréospécificité de la réaction entre **1** et **2b–2c**, nous avons déterminé les états de transition correspondant à l'addition du **1** sur **2b–2c**<sub>(p-chaîse)éq</sub> et **2b–2c**<sub>(p-chaîse)axi</sub> dans les deux approches endo et exo.<sup>24</sup> Nous avons aussi déterminé les états de transition correspondant à l'addition du **1** sur **2b–2c**<sub>(bateau)éq</sub> et **2b–2c**<sub>(bateau)axi</sub> dans les deux approches endo et exo. Les énergies correspondantes sont reportées dans le tableau 7.

Comme le montre le tableau 7, dans chaque cas des réactions A, B, C et D, la forme endo correspond à une énergie d'activation inférieure à celle de la forme exo. Ce qui nous a permis de dire que la forme endo est plus favorisée par rapport à la forme exo.

Nos résultats théoriques montrent que dans le cas de la réaction A, les formes endo donnent **4b–4c**<sub>trans(éq)</sub> qui sont thermodynamiquement plus stables que **4b–4c**<sub>cis(éq)</sub> provenant des formes exo. Ceci nous a permis de dire que **4b–4c**<sub>trans(éq)</sub> sont les produits cinétique et thermodynamique de la réaction A.

De la même manière, nous avons trouvé dans le cas de la réaction C que les formes endo donnent **4b–4c**<sub>trans(éq)</sub> qui sont plus stables de point de vue thermodynamique et cinétique

**Tableau 7.** Énergies relatives  $E^*$  (kcal mol<sup>-1</sup>) des états de transition par rapport aux énergies des réactifs (calculées avec la méthode DFT/B3LYP).

<b>3b</b> <sup>*</sup> <sub>(p-chaîse)éq</sub> (exo)	33,41	33,21
<b>2c</b> <sub>(p-chaîse)éq</sub>		
<b>3c</b> <sup>*</sup> <sub>(p-chaîse)éq</sub> (endo)	32,70	32,81
<b>3c</b> <sup>*</sup> <sub>(p-chaîse)éq</sub> (exo)	33,91	33,95
<b>Réaction C</b>		
<b>1</b>		
<b>2b</b> <sub>(bateau)éq</sub>		
<b>3b</b> <sup>*</sup> <sub>(bateau)éq</sub> (endo)	31,73	31,91
<b>3b</b> <sup>*</sup> <sub>(bateau)éq</sub> (exo)	32,47	32,86
<b>2c</b> <sub>(bateau)éq</sub>		
<b>3c</b> <sup>*</sup> <sub>(bateau)éq</sub> (endo)	32,13	32,10
<b>3c</b> <sup>*</sup> <sub>(bateau)éq</sub> (exo)	33,75	33,57
<b>Réaction D</b>		
<b>1</b>		
<b>2b</b> <sub>(bateau)axi</sub>		
<b>3b</b> <sup>*</sup> <sub>(bateau)axi</sub> (endo)	33,97	33,91
<b>3b</b> <sup>*</sup> <sub>(bateau)axi</sub> (exo)	34,12	34,06
<b>2c</b> <sub>(bateau)axi</sub>		
<b>3c</b> <sup>*</sup> <sub>(bateau)axi</sub> (endo)	33,98	33,96
<b>3c</b> <sup>*</sup> <sub>(bateau)axi</sub> (exo)	34,57	34,42

que **4b–4c**<sub>cis(éq)</sub> provenant des formes exo. Par contre dans le cas des réactions B et D, nous avons trouvé que les formes endo donnent respectivement **4b–4c**<sub>cis(axi)</sub> et **4b–4c**<sub>cis(axi)</sub> qui sont respectivement plus stables thermodynamiquement et cinétiquement que **4b–4c**<sub>trans(axi)</sub> et **4b–4c**<sub>trans(axi)</sub> provenant des formes exo.

La comparaison des profils énergétiques des réactions A et B conduisant respectivement à **4b**<sub>trans(éq)</sub> et **4b**<sub>cis(éq)</sub> et à **4b**<sub>cis(axi)</sub> et **4b**<sub>trans(axi)</sub> est donnée sur la figure 8.

Nous avons comparé nos résultats avec d'autres études antérieures.<sup>23–27</sup> Ces études ont été réalisées sur l'hydrogénation des alcènes non cycliques tels que les molécules d'éthène et de propène. Dans le cas d'hydrogénation de **2b–2c** par **1**, lors de l'approche des réactifs, il y a des effets de gêne stérique qui apparaissent. Cette gêne est différente selon la face de l'alcène dont s'approche **1**.

Nous avons comparé les longueurs des liaisons en formation; on constate que la liaison C<sub>1</sub>–H<sub>1</sub> est plus courte que la liaison C<sub>2</sub>–H<sub>2</sub>. Ces distances sont assez proches de celle trouvée par McKee et al. pour la réaction entre **1** et l'éthène<sup>23</sup> (tableau 8).

**Fig. 8.** Énergies relatives  $E^*$  (kcal mol<sup>-1</sup>) des états de transition par rapport aux énergies des réactifs. B3LYP (6-31G\*).

**Tableau 8.** Longueurs des liaisons en formation C<sub>1</sub>–H<sub>1</sub> et C<sub>2</sub>–H<sub>2</sub> dans l'état de transition pour la formation des conformères chaise et bateau.

## Conclusion

Dans ce travail, nous avons réalisé une étude théorique permettant de prévoir la stéréochimie et la réactivité des réactions d'hydrogénation de **2a–2c** par **1** et par **1'**.

Les résultats de calculs théoriques par la méthode DFT avec la fonctionnelle B3LYP et les bases standard 6–31G\* et 3–21G montrent que ces réactions sont possibles théoriquement, et par conséquent elles sont favorisées thermodynamiquement.

Les résultats montrent aussi que les conformères chaise sont plus stables thermodynamiquement que les conformères bateau. De plus, nous avons trouvé que les réactions entre **2a–2c** et **1** sont plus réactives que les réactions entre **2a–2c** et **1'**. Les calculs des états de transition montrent que les produits cinétiques de la réaction d'hydrogénation sont les conformères chaise **4a–4c**, et en plus les stéréoisomères provenant de la forme endo sont plus favorisés que les stéréoisomères provenant de la forme exo.

# Novel lariat calix[4]-1,3-aza-crowns with two branched chains — The excellent phase transfer catalysts for nucleophilic substitution reaction

Fafu Yang, Yanhua Wang, Hongyu Guo, Jianwei Xie, and Zhiqiang Liu

**Abstract:** By reacting calix[4]-1,3-diethoxylaminoethyl derivative (**2**) with phenyl isothiocyanate, novel dendritic calix[4]-arene derivative (**3**) with two different branched chains was synthesized in a yield of 78%. By reacting compound **2** with 1,6-diisocyanatohexane or *N,N'*-bis(2-chloroacetamide)ethylene in a “1 + 1” intermolecular addition mode, novel lariat calix[4]-1,3-aza-crowns (**4** and **5**, respectively) with two branched ethoxyl chains were prepared in reasonable yields. The composition, structures, and conformations of all new compounds were confirmed by elemental analyses, IR, ESI-MS, <sup>1</sup>H NMR, and so forth. The liquid–liquid extraction experiments showed that all new hosts possessed good extraction abilities towards soft and hard metal cations. The liquid membrane transport experiments suggested that they had good transport abilities for K<sup>+</sup> and Ag<sup>+</sup>. The experiments of phase transfer catalysis indicated that they possessed excellent catalytic properties of aromatic nucleophilic substitution reaction and benzyl nucleophilic substitution. The optimum yields of products in catalytic reaction were as high as approximately 100%.

**Key words:** calix[4]crown, lariat, synthesis, liquid membrane transport, phase transfer catalysis.

**Résumé :** La réaction du dérivé **2** du calix[4]-1,3-diéthoxylaminoéthyle avec l'isothiocyanate d'éthyle a permis de réaliser la synthèse, avec un rendement de 78 %, du nouveau dérivé dendritique du calix[4]arène portant deux chaînes ramifiées différentes. La réaction du composé **2** avec le 1,6-diisocyanatohexane ou le *N,N'*-bis(2-chloroacétamide)éthylène dans un mode d'addition intermoléculaire « 1 + 1 », il est aussi possible de préparer avec des rendements raisonnables de nouveaux éthers lariats, des calix[4]-1,3-azacouronnes (**4** et **5**) portant des chaînes ramifiées éthoxyles. La composition, les structures et les conformations de tous les nouveaux produits ont été confirmées par analyse élémentaire, spectrométrie de masse avec ionisation par électronébulisation (SM-IEN), RMN du <sup>1</sup>H et autres. Des expériences d'extraction liquide–liquide ont montré que toutes les nouvelles molécules hôtes possèdent de bonnes habilités pour l'extraction des cations métalliques durs et mous. Des expériences de transport dans une membrane liquide suggère qu'elles possèdent de bonnes habilités pour le transport des ions K<sup>+</sup> et Na<sup>+</sup>. Les expériences en catalyse de transfert de phase indiquent qu'elles possèdent d'excellentes propriétés catalytiques dans les réactions de substitution nucléophile aromatique et de substitution nucléophile benzylique. Les rendements optimaux de produits dans les réactions catalytiques vont jusqu'à environ 100 %.

**Mots-clés :** calix[4]couronne, lariat, synthèse, transport dans une membrane liquide, catalyse par transfert de phase.

## Introduction

The importance of calixarenes in the family of host macrocycles is now well-established.<sup>1–3</sup> Since the first calix-crown was reported in 1983,<sup>4</sup> much research attention had been paid to the synthesis of calixcrowns and the study of their molecular and ion recognition to use them in the design of ion selective electrodes, liquid supported membranes and catalyst, and so forth.<sup>5–7</sup> All kinds of calixcrowns containing only oxygen donor atoms were synthesized and exhibited excellent recognition towards hard metal ions or some soft metal ions, and calixcrowns containing heteroatoms such as aza and sulfur groups usually showed outstanding complexation abilities for soft metal cations.<sup>8–17</sup>

In the field of crown ethers, it is well-known that the lariat crown ethers with branched chains usually show outstanding complexation abilities for guest due to the coordinated recognition of crown ether chains and branched chains. However, in the field of calixcrowns, although many calixcrowns were reported, only Bitter and co-workers<sup>18,19</sup> and Bond et al.<sup>20</sup> reported several lariat calix[4]-aza-crowns with one amino-branched chain. These lariat calix[4]-aza-crowns exhibited excellent recognition properties due to the favorable synergistic complexation<sup>18–19</sup> but they were not concerned with their phase catalytic properties. Thus, it is interesting to study the syntheses and properties of novel lariat calixcrowns with other functional groups and more branched chains. In this paper, we report the syntheses of

two novel lariat calix[4]-1,3-aza-crowns with two branched ethoxyl chains and a novel dendritic calix[4]arene derivative with two different branched chains. Also, their interesting properties of metal ion extraction, liquid membrane transport, and phase transfer catalysis were studied.

## Results and discussion

### Syntheses and characterization of products

The synthetic routes are shown in Scheme 1. 1,3-Broethoxyl-calix[4]arene (**1**) was prepared according to the published procedures.<sup>21</sup> By refluxing compound **1** with excess ethanolamine (molar ratio = 1:10) in  $\text{K}_2\text{CO}_3/\text{MeCN}$  for 48 h, the calix[4]-1,3-diethoxylaminoethyl derivative (**2**) was obtained in a yield of 73% after recrystallization in  $\text{CH}_3\text{OH}/\text{H}_2\text{O}$ . By further reacting compound **2** with phenyl isothiocyanate under room temperature, novel dendritic calix[4]arene derivative (**3**) with two different branched chains was obtained in a yield of 78% after recrystallization in  $\text{CHCl}_3$ /petroleum ether ( $60\sim 90^\circ\text{C}$ ). On the other hand, by refluxing compound **2** with 1,6-diisocyanatohexane in high diluted  $\text{CHCl}_3$  solution over night, novel lariat calix[4]-1,3-aza-crown (**4**) with two branched ethoxyl chains was prepared with a yield of 62% in a “1 + 1” addition mode after recrystallization in  $\text{CHCl}_3$ /petroleum ether ( $60\sim 90^\circ\text{C}$ ). Also, by refluxing compound **2** with *N,N'*-bis(2-chloroacetamide)ethylene in  $\text{K}_2\text{CO}_3/\text{MeCN}$  for 72 h, novel lariat calix[4]-1,3-aza-crown (**5**) with two branched ethoxyl chains was obtained in a yield of 42% in a “1 + 1” condensation mode after column chromatography. In

this condensation reaction, no catalyst, such as KI, was added to avoid the reaction of *N,N'*-bis(2-chloroacetamide)ethylene with the phenolic hydroxyl groups of compound **2**. Moreover, to test the reaction activity of phenolic hydroxyl groups of compound **2** in this reaction, compound **1** was refluxed with *N,N'*-bis(2-chloroacetamide)ethylene with the same reaction conditions, but no materials took part in the reaction in 72 h (if KI was added, materials took part in reaction). This result certainly suggested that it was not the phenolic hydroxyl groups but the amino groups of compound **2** taking part in the condensation reaction as showed in Scheme 1. To the best of our knowledge, compound **3** was the novel dendritic calix[4]arene derivative with two different branched chains, and compounds **4** and **5** were the first examples of lariat calix[4]-1,3-aza-crowns with two branched ethoxyl chains.

All new compounds were tested by elemental analyses, IR, ESI-MS, and  $^1\text{H}$  NMR spectra. The ESI-MS spectra of compounds **2**, **3**, **4**, and **5** clearly showed molecular ion peaks ( $\text{M}^+$ ,  $\text{MH}^+$ , or  $\text{MNa}^+$ ) at 824.0, 1116.0, 990.3, and 985.8, respectively. In the  $^1\text{H}$  NMR spectra, all of the compounds showed two singlets (1:1) for the *tert*-butyl groups and one pair of doublets (1:1) for the methylene bridges of the calix[4]arene skeleton. Comparing with the similar  $^1\text{H}$  NMR spectra of the other calix[4]arene 1,3-bisubstituted or 1,3-bridged derivatives in cone conformation,<sup>8–11</sup> all these  $^1\text{H}$  NMR spectra data of the new compounds **2–5** were in accordance with the assigned structures and indicated that the calix[4]arene units adopted cone conformation as shown in Scheme 1.

### Liquid-liquid extraction for metal cations

The complexation abilities of compounds **2**, **3**, **4**, and **5** towards a series of metal cations were studied by two-phase extraction experiments ( $\text{H}_2\text{O}/\text{CHCl}_3$ ) of metal cation picrate salts. The results were summarized in Fig. 1. Compounds **2**, **3**, **4**, and **5** exhibited good extraction abilities for both soft and hard metal cations. These results were in accordance with the "soft and hard acids and bases" concept, i.e., amino groups and hydroxyl groups were favorable for binding soft and hard metal cations, respectively. It is worthy to note that the extraction percentage of compound **2** for  $\text{Zn}^{2+}$  and  $\text{Hg}^{2+}$  were as high as 100%. On the other hand, hosts **4** and **5** showed lower extraction percentages but higher extraction selectivities than that of hosts **2** and **3**. For example, the extraction selectivity of host **4** for  $\text{Hg}^{2+}/\text{Ag}^+$  was 6.75 (extraction percentage of  $\text{Hg}^{2+}$ /extraction percentage of  $\text{Ag}^+$  = 50.6/7.5). These extraction results might suggest that the crown structures of compounds **4** and **5** were more favorable for producing the complexation selectivity than that of the open-chain structures of compounds **2** and **3**.

### Liquid membrane transport for $\text{K}^+$ , $\text{Zn}^{2+}$ , and $\text{Ag}^+$

To investigate the potential application of new hosts **2**, **3**, **4**, and **5**, they were studied by liquid membrane transport experiments. Based on the extraction experiments, the  $\text{K}^+$ ,  $\text{Zn}^{2+}$ , and  $\text{Ag}^+$  were chosen as representative usual metal cations of hard and soft cations, and representative extraction abilities with variational extraction percentages (from 10% to 100%) in extraction experiments. The fluorinion was chosen as the anion of these metal salts because F<sup>-</sup> plays an important role in the nucleophilic substitution reaction of preparing fluorine compounds. The transport results were summarized in Table 1. It could be seen that the salt concentration in the receiving phase increased with prolonging the running times. It was interesting that hosts **2**, **3**, **4**, and **5** possessed transport abilities for cations in the similar order of  $\text{K}^+ \approx \text{Ag}^+ > \text{Zn}^{2+}$ . For example, in compound **5**, the salts concentrations in the receiving phase of  $\text{K}^+$  and  $\text{Ag}^+$  in 20 h were  $8.9 \times 10^{-3}$  mol/L and  $7.8 \times 10^{-3}$  mol/L, respectively. However, the salt concentration of  $\text{Zn}^{2+}$  was as low as  $4.3 \times 10^{-3}$  mol/L under the same transport conditions. On the other hand, hosts **4** and **5** showed far higher transport amounts than that of hosts **2** and **3** in the running times over 20 h. For example, the concentrations of  $\text{K}^+$  in the receiving phase using hosts **4** and **5** as carriers in 20 h were  $6.8 \times 10^{-3}$  mol/L and  $8.9 \times 10^{-3}$  mol/L, respectively. However, the concentrations of  $\text{K}^+$  in the receiving phase using hosts **2** and **3** were as low as  $1.8 \times 10^{-3}$  mol/L and  $1.7 \times 10^{-3}$  mol/L, respectively, under the same transport conditions. These results of liquid membrane transport were utterly different from the results of two phase extraction experiments. It was known that the liquid membrane transport ability relied on the balance of the complexation ability of the host for guest and the decomplexing ability of the complexes.<sup>22,23</sup> These results of liquid membrane transport might suggest that complex  $2\text{M}^+(\text{and } 2\text{M}^{2+}, 3\text{M}^+, 3\text{M}^{2+})$  possessed stronger stabilities and lower decomplexing abilities in comparison with the corresponding complexes with hosts **4** and **5**. Thus, although the two phase extraction abilities of hosts **4** and **5** were lower than that of hosts **2** and **3**, the lower stabilities of the complexes with **4** and **5** led to higher de-

Fig. 1. Percentage extraction (%) of **2**, **3**, **4**, and **5** towards picrate salts.

complexing abilities and then higher speeds of liquid membrane transport than that of **2** and **3**.

### The phase transfer catalysis of the nucleophilic substitution reaction

Based on the experiment results of liquid membrane transport, the phase transfer catalytic properties of aromatic nucleophilic substitution reactions were studied. Aromatic fluorine compounds have important applications in insecticidal and refined chemicals.<sup>24</sup> The replacement of aromatic Cl by F in nucleophilic substitution reactions was chosen as a reaction system to evaluate the phase transfer catalytic abilities of new hosts **2**, **3**, **4**, and **5**. The experiment results are shown in Table 2. It can be seen that the yield of the product was as low as 8.5% when the reaction was performed without a catalyst (Table 2, entry 1). As catalysts were added, the yields greatly increased. Under the same reaction conditions, hosts **4** and **5** showed higher catalytic activity than that of hosts **2** and **3** (Table 2, entries 2–5). These results were in accordance with the results of the liquid membrane transport experiment. Using  $\text{AgF}$  instead of  $\text{KF}$ , hosts **4** and **5** still keep the high catalytic activity, although the yields of the product decreased a little (Table 2, entries 6–7). On the other hand, the yields of the products were over 90% when the reaction time was prolonged to 24 h and 36 h (Table 2, entries 8–11). Also, *p*-nitrochlorobenzene, having an electron withdrawing group (1,2-dichloro-4-nitrobenzene or 2,4-dinitrochlorobenzene), offered higher yields (Table 2, entries 12–13), which were attributed to the favorable influence of the electron withdrawing group for an aromatic nucleophilic substitution reaction. The yields were as high as 100% when using 2,4-dinitrochlorobenzene as material.

Also, the replacement of aliphatic Cl by a nitrile group in a benzyl nucleophilic reaction was studied by using new hosts **2**, **3**, **4**, and **5** as phase transfer catalysts. The experiment results are shown in Table 3, which are similar to the results in Table 2. The yields of products were greatly increased from 6.4% to approximately 90% when catalysts were added. Although hosts **4** and **5** showed higher catalytic activities than that of hosts **2** and **3**, the differences in yields were not remarkable. The yields were as high as almost

100% when the reaction time was prolonged to 24 h. All these catalytic results in Table 2 and Table 3 indicate that novel lariat calix[4]-1,3-aza-crowns (**4** and **5**) are excellent phase transfer catalysts for nucleophilic substitution reactions.

## Conclusion

Novel dendritic calix[4]arene derivative (**3**) with two different branched chains was prepared by reacting calix[4]-1,3-diethoxylaminoethyl derivative (**2**) with phenyl isothiocyanate. Novel lariat calix[4]-1,3-aza-crowns (**4** and **5**) with two branched ethoxyl chains were prepared by reacting compound **2** with 1,6-diisocyanatohexane or *N,N'*-bis(2-chloroacetamide)ethylene in a "1 + 1" intermolecular addition mode. The composition, structures, and conformations of all new compounds were confirmed by elemental analyses, IR, ESI-MS, <sup>1</sup>H NMR, and so forth. The liquid-liquid extraction experiment showed that all new hosts possessed good complexation abilities towards soft metal cations and hard metal cations. The liquid membrane transport experiments suggested that they had good transport abilities for both K<sup>+</sup> and Ag<sup>+</sup>. The experiments of phase transfer cataly-

sis exhibited that they possessed excellent catalytic properties of aromatic nucleophilic substitution reaction and benzyl nucleophilic substitution. The yields of products in catalytic reaction were as high as approximately 100%.

## Experimental section

### Instruments

Melting points are uncorrected. <sup>1</sup>H NMR spectra were recorded in CDCl<sub>3</sub> on a Bruker-ARX 500 instrument, using TMS as a reference. ESI-MS spectra were obtained from a DECAX-30000 LCQ Deca XP mass spectrometer in MeCN, setting the ESI capillary at 3.5 kV and the cone voltage at 40 V. Elemental analyses were performed at a Vario EL III elemental analyzer. The UV-vis measurements were performed on a Varian UV-vis spectrometer. The gas chromatography was performed on a Varian 450-GC/240-MS instrument. Atomic absorption was measured on a WFX-II spectrograph. All solvents were purified by standard procedures. 1,3-Broethoxyl-calix[4]arene (**1**) was prepared according to the published procedures.<sup>21</sup> The picrate salts were prepared according to literature.<sup>25,26</sup>

**Fig. 2.** Liquid membrane cell: (1) source phase, (2) receiving phase, (3) membrane phase, and (4) magnetic stirring bar.

### Syntheses of calix[4]-1,3-diethoxylaminoethyl derivative (2)

Under  $N_2$  atmosphere, a mixture of compound **1** (0.430 g, 0.5 mmol), ethanolamine (0.30 mL, 5 mmol), and  $K_2CO_3$  (0.280 g, 2 mmol) was stirred in refluxing dry acetonitrile (30 mL) for 48 h. Thin layer chromatography (TLC) detection showed the disappearance of compound **1**. After distilling off the solvent under reduced pressure, the residue was treated with 30 mL HCl (10%) and a white precipitate separated out. The precipitate was filtered and recrystallized by MeOH/H<sub>2</sub>O. Compound **2** was obtained as a white powder in a yield of 73%; mp 204–206 °C. IR (KBr,  $cm^{-1}$ ): 3421 (OH and NH).  $^1H$  NMR ( $CDCl_3$ , 500 MHz)  $\delta$ : 0.97 (s, 18H,  $C(CH_3)_3$ ), 1.23 (s, 18H,  $C(CH_3)_3$ ), 3.28 (bs, 8H,  $ArCH_2Ar$  and  $OCH_2$ ), 3.49~3.53 (bs, 8H,  $NH_2$  and  $OCH_2$ ), 3.88~3.92 (bs, 4H,  $NCH_2$ ), 4.16 (s, 4H, OH and NH), 4.24 (d, 4H,  $J = 13.5$  Hz,  $ArCH_2Ar$ ), 6.85 (s, 4H, ArH), 7.01 (s, 4H, ArH), 7.24 (s, 2H, ArOH). ESI-MS  $m/z$  (%): 824.0 ( $MH^+$ , 100). Anal. calcd. for  $C_{52}H_{74}N_2O_6$ : C 75.87, H 9.06, N 3.40; found: C 75.77, H 9.15, N 3.29.

### Synthesis of novel dendritic calix[4]arene derivative (3)

A mixture of compound **2** (0.205 g, 0.25 mmol) and phenyl isothiocyanate (0.3 mL, 2 mmol) was stirred in 10 mL  $CHCl_3$  for 4 h under room temperature. TLC detection indicated the disappearance of compound **2**. The solvent was removed under reduced pressure at room temperature. The residue was treated with 10 mL petroleum ether (60~90 °C) and a white precipitate separated out. The precipitate was filtered and recrystallized by  $CHCl_3$ /petroleum ether (60~90 °C). Compound **3** was obtained as a white powder in a yield of 78%; mp 213–216 °C. IR (KBr,  $cm^{-1}$ ): 1239 (C=S).  $^1H$  NMR (500 MHz,  $CDCl_3$ )  $\delta$ : 0.95 (s, 18H,  $C(CH_3)_3$ ), 1.21 (s, 18H,  $C(CH_3)_3$ ), 3.22 (t, 4H,  $OCH_2$ ), 3.38 (d, 4H,  $J = 14.5$  Hz,  $ArCH_2Ar$ ), 3.57 (t, 4H,  $OCH_2$ ), 3.82 (t, 4H,  $NCH_2$ ), 3.96~4.01 (m, 4H,  $NCH_2$ ), 4.28 (d, 4H,  $J = 14.5$  Hz,  $ArCH_2Ar$ ), 6.79 (s, 2H, ArH), 6.96 (d, 4H,  $J = 7.5$  Hz, ArH), 7.15 (s, 4H, ArH), 7.32 (m, 8H, ArH), 7.18, 7.40, 9.48 (s, each, 2H, each, OH and NH). MS  $m/z$  (%): 1116.0 ( $MNa^+$ , 100). Anal. calcd. for  $C_{66}H_{84}N_4S_2O_6$ : C 72.50, H 7.74, N 5.12; found: C 72.33, H 7.83, N 5.01.

### Synthesis of novel lariat calix[4]-1,3-aza-crown (4)

A mixture of compound **2** (0.205 g, 0.25 mmol) and 1,6-diisocyanatohexane (0.048 mL, 0.3 mmol) was refluxed in 100 mL  $CHCl_3$  for 12 h. TLC detection indicated the disappearance of compound **2**. The solvent was removed under

reduced pressure. The residue was treated with 10 mL petroleum ether (60 °C~90 °C) and a white precipitate separated out. The precipitate was filtered and recrystallized by  $CHCl_3$ /petroleum ether (60~90 °C). Compound **4** was obtained as a white powder in a yield of 62%; mp 232–234 °C. IR (KBr,  $cm^{-1}$ ): 1703 (C=O).  $^1H$  NMR ( $CDCl_3$ , 500 MHz)  $\delta$ : 0.90 (s, 18H,  $C(CH_3)_3$ ), 1.31 (s, 18H,  $C(CH_3)_3$ ), 1.42 (bs, 4H,  $CH_2$ ), 1.86 (bs, 4H,  $CH_2$ ), 3.16~3.30 (m, 8H,  $NCH_2$  and  $OCH_2$ ), 3.32 (d, 4H,  $J = 12.5$  Hz,  $ArCH_2Ar$ ), 3.49~4.11 (m, 12H,  $NH_2$  and  $OCH_2$ ), 4.18 (d, 4H,  $J = 12.5$  Hz,  $ArCH_2Ar$ ), 4.90, 6.34, 6.54 (s, each, 2H, each, OH and NH), 6.66 (s, 4H, ArH), 7.08 (s, 4H, ArH). ESI-MS  $m/z$  (%): 990.3 ( $M^+$ , 100). Anal. calcd. for  $C_{60}H_{86}N_4O_8$ : C 72.69, H 8.74, N 5.65; found: C 72.58, H 8.82, N 5.55.

### Synthesis of novel lariat calix[4]-1,3-aza-crown (5)

Under  $N_2$  atmosphere, a mixture of compound **2** (0.205 g, 0.25 mmol), *N,N'*-bis(2-chloroacetamide)ethylene (0.064 g, 0.3 mmol), and  $K_2CO_3$  (0.280 g, 2 mmol) was stirred in refluxing dry acetonitrile (30 mL) for 72 h. The TLC detection indicated the disappearance of compound **2**. After distilling off the solvent under reduced pressure, the residue was purified by column chromatography (50 cm  $\times$  3 cm,  $SiO_2$  100–200 mesh, acetone/ $CH_2Cl_2$  (3:2, v/v) as eluant, 500 mL). Compound **5** was then obtained as a white powder in a yield of 42%; mp 241–244 °C. IR (KBr,  $cm^{-1}$ ): 1653 (C=O).  $^1H$  NMR ( $CDCl_3$ , 500 MHz)  $\delta$ : 0.89 (s, 18H,  $C(CH_3)_3$ ), 1.30 (s, 18H,  $C(CH_3)_3$ ), 3.26~3.36 (m, 12H,  $ArCH_2Ar$ ,  $NCH_2$ , and  $OCH_2$ ), 3.65~4.06 (m, 8H,  $NH_2$  and  $OCH_2$ ), 4.12 (d, 4H,  $J = 12.5$  Hz,  $ArCH_2Ar$ ), 4.14~4.33 (m, 8H,  $OCH_2CO$  and  $NCH_2$ ), 6.61 (s, 4H, ArH), 7.08 (s, 4H, ArH), 6.82, 7.01, 8.52 (s, each, 2H, each, OH and NH). ESI-MS  $m/z$  (%): 985.8 ( $MNa^+$ , 100). Anal. calcd. for  $C_{58}H_{82}N_4O_8$ : C 72.31, H 8.58, N 5.81; found: C 72.21, H 8.66, N 5.70.

### Procedures for two phase extraction experiments of metallic picrates

According to the reported method,<sup>25</sup> 3 mL of chloroform solution containing calixarene derivatives ( $2.0 \times 10^{-5}$  mol/L) and 3 mL of aqueous solution containing metallic picrate ( $2.0 \times 10^{-5}$  mol/L) were placed in a flask (Caution: metallic picrates are hazardous materials; avoid fire, extrusion, high temperature, and so forth). The pH of 6.9~7.1 of these aqueous solutions suggests that little hydrolysis happened. The mixture was shaken for 5 min and stored for 2 h at room temperature. The extraction ability was not affected by further shaking, indicating that the equilibrium had been attained within 2 h. The aqueous phase was separated and subjected to the analysis by UV absorption spectrometry in near 357 nm. The extracting percentage ( $E\%$ ) was determined by the decrease of the picrate concentration in the aqueous phase,  $E\% = \{([Pic]_{blank} - [Pic]_{water})/[Pic]_{blank}\} \times 100$ , where  $[Pic]_{blank}$  denoted the picrate concentrations in the aqueous phase after extraction with pure chloroform, and  $[Pic]_{water}$  denoted the picrate concentrations in the aqueous phase after extraction with chloroform solution containing calixarene derivatives as extractants. The average of the twice-independent experiments was carried out. Control ex-

periments showed that no picrate extraction occurred in the absence of the calixarene derivatives.

### Procedures for metal ion transport experiments

According to the reported method,<sup>27</sup> liquid membrane transport experiments were conducted using the bulk liquid membrane apparatus presented in Fig. 2. The membrane phase was the  $\text{CHCl}_3$  solution of new host with a concentration of  $5.0 \times 10^{-4}$  mol/L. The membrane phase (25.0 mL) was added to the bottom of the vessel and stirred magnetically at 200 rpm. An aqueous salt solution (15 mL) with a concentration of 0.05 mol/L (source phase, fluorides) and 15 mL of doubly distilled deionized water (receiving phase) were poured on top of the organic phase. The two water phases were separated by a cylindrical glass cell holding a glass tube. The interface between the membrane phase and the source phase (or the receiving phase) was 7.5 cm<sup>2</sup>. The measurements were performed at a constant temperature of 25 °C. The concentration of salt in the receiving phase was determined by atomic absorption spectrography. The pH value of the source phase and receiving phase changed in the scope of 6.9~7.2, which indicated that little hydrolysis happened in the metal ion transport experiments. Blank experiment showed that no transport was detected in the absence of host during more than 12 h of continuous running. Each experiment was repeated three times. The cation concentration in the receiving phase was reported as the mean of the determination and the relative standard deviation from the mean was less than 5%.

### The procedures of phase transfer catalysis of a nucleophilic substitution reaction

A typical nucleophilic substitution reaction was conducted by mixing reactant (5 mmol) and corresponding inorganic salt (10 mmol) in 12 mL of DMSO. The catalyst (3.0 mol%) was added and the reaction was stirred (800 rpm) for a stipulated time period (Table 2 and Table 3) at 40 °C. The yields of product were analyzed by gas chromatography (Varian 450-GC/240-MS).

# Synthesis and biological evaluation of acyclic nucleotide analogues with a furo[2,3-*d*]pyrimidin-2(3*H*)-one base

Zlatko Janeba, Antonín Holý, Radek Pohl, Robert Snoeck, Graciela Andrei, Erik De Clercq, and Jan Balzarini

**Abstract:** As a part of a broader structure–activity relationship (SAR) study of bicyclic nucleoside analogues (BCNAs) [anti-varicella-zoster virus (anti-VZV) and anti-human cytomegalovirus (anti-HCMV) agents], a novel series of 2-(phosphonomethoxy)ethyl (PME) substituted furo[2,3-*d*]pyrimidin-2(3*H*)-ones was synthesized. The target acyclic nucleotide analogues were prepared by Sonogashira coupling of protected 5-iodo-1-[2-(phosphonomethoxy)ethyl]uracil with various 1-alkynes, followed by in situ Cu(I)-promoted intramolecular cyclization and standard removal of the isopropyl ester groups. None of the prepared PME analogues were active at subtoxic concentrations against VZV thymidine kinase competent (TK<sup>+</sup>), VZV thymidine kinase deficient (TK<sup>−</sup>), HCMV, or any other viruses tested.

**Key words:** Sonogashira reaction, intramolecular cyclization, acyclic nucleotide analogues, phosphonates, bicyclic nucleoside analogues (BCNAs).

**Résumé :** Dans le cadre d'une large étude des analogues bicycliques de nucléotides (ABCN) [des agents actifs contre le virus de varicelle-zoster (anti-VVZ) et contre le cytomégalo-virus humain (anti-CMVH)], on a réalisé la synthèse d'une nouvelle série de furo[2,3-*d*]pyrimidin-2(3*H*)-ones portant un substituant 2-(phosphonométhoxy)éthyle (PME). On a préparé les analogues acycliques de nucléotides voulus par un couplage de Sonogashira du 5-iodo-1-[2-(phosphonométhoxy)éthyl]uracile avec divers 1-alcynes, suivi d'une cyclisation in situ intramoléculaire, catalysée par du Cu(I), et finalement d'une élimination standard des groupes esters isopropyles. Aucun des analogues PME n'est actif, à des concentrations sous-toxiques, contre le virus de varicelle-zoster (anti-VVZ), contre le cytomégalo-virus humain (anti-CMVH) ou contre tout autre virus testé.

**Mots-clés :** réaction de Sonogashira, cyclisation intramoléculaire, analogues acycliques de nucléotide (ABCN), phosphonate.

## Introduction

Antiviral drugs currently belong to the most widely used medications. The majority of them now available are designed to help deal with infections caused by herpes simplex virus (HSV), human immunodeficiency virus (HIV), hepatitis B virus (HBV), hepatitis C virus (HCV), and cytomegalovirus (CMV). Prominent among the antiviral drugs are nucleoside and nucleotide analogues, mainly for their ability to inhibit viral DNA polymerases and reverse transcriptases. Nowadays, research of nucleic acid components steadily continues to provide new compounds with interesting biological activities and high potential in the management of viral infections.

While studying 5-substituted pyrimidines as potential inhibitors of thymidylate synthase and thus prospective antiviral agents, 6-*n*-butyl-3-methylfuro[2,3-*d*]pyrimidin-2(3*H*)-one was reported by Robins and Barr<sup>1</sup> in 1981 as a byproduct (9% yield) of Sonogashira cross-coupling of 5-iodo-1-methyluracil with 1-hexyne. The same compound was formed

in 92% yield by treatment of 5-hexynyl-1-methyluracil with CuI in refluxing triethylamine/methanol mixture.<sup>1</sup> Two years later, the same authors described the preparation of the 6-*n*-butylfuro[2,3-*d*]pyrimidin-2(3*H*)-one 2'-deoxynucleoside analogue.<sup>2</sup>

Two decades later, the remarkably potent and selective activity against varicella-zoster virus (VZV) was discovered with furo[2,3-*d*]pyrimidin-2(3*H*)-one 2'-deoxynucleoside analogues with longer alkyl chains at the C-6 position (e.g., compound **1**, Fig. 1).<sup>3</sup> Subsequent extensive structure–activity relationship (SAR) studies of these bicyclic nucleoside analogues (BCNAs) followed<sup>4</sup> and identified compound Cf 1743 (compound **3**, Fig. 1) as one of the most potent antiviral agents that have ever been reported.<sup>5</sup> Its promising prodrug FV100 (5'-valine ester of Cf 1743) is currently in phase II of clinical development against herpes zoster (shingles).<sup>6</sup>

While SAR studies<sup>4</sup> of BCNAs showed that some structural modifications of the furo[2,3-*d*]pyrimidin-2(3*H*)-one

**Fig. 1.** Bicyclic nucleoside analogues.

base or the substituent at the C-6 position are tolerated, sugar modifications of BCNAs are not acceptable for maintaining potent anti-VZV activity. Thus, while 2'-deoxyribosides are potent and selective anti-VZV agents, their ribo- and arabino-analogues are significantly less active.<sup>4</sup> Furthermore, 2',3'-dideoxy analogues (e.g., compound **2**, Fig. 1)<sup>7</sup> and N-3 alkyl derivatives<sup>8</sup> showed poor activity against VZV but they surprisingly exhibited activity against human cytomegalovirus (HCMV). Replacement of the sugar at the N-3 position by the (2-hydroxyethoxy)methyl group (present in the antiherpes drug acyclovir) afforded compounds (e.g., compound **4**, Fig. 1) with weak activity against both VZV and HCMV.<sup>9</sup>

Although not sufficient as a requirement, phosphorylation of the furo[2,3-*d*]pyrimidin-2(3*H*)-one nucleoside analogues by the VZV thymidine kinase (TK) is a prerequisite for their eventual anti-VZV activity.<sup>4,10</sup> This fact is supported by the complete absence of antiviral activity of BCNAs in the thymidine kinase deficient VZV TK<sup>-</sup> assays. Thus, the anti-VZV activity of 2'-deoxyriboside BCNAs follows the activation pathway characteristic for thymidine nucleosides (nucleoside mechanism mode of action). On the other hand, BCNAs with modified sugar moiety that inhibit HCMV replication do so by a non-nucleoside mechanism of action, at an early stage of the viral life cycle, possibly affecting viral entry into the cells.<sup>10</sup>

In 1986, De Clercq et al.<sup>11</sup> described broad spectrum antiviral activity of (*S*)-9-(3-hydroxy-2-phosphonmethoxy)propyladenine (HPMPA) and 9-(2-phosphonmethoxy)ethyladenine (PMEA), compounds belonging to a group of acyclic nucleoside phosphonates (ANPs). ANPs possess a phosphonate group attached to the acyclic moiety of the nucleoside through a stable P–C bond so they are resistant towards degradation by cellular enzymes. Due to “by-passing” of the first phosphorylating step, a number of ANPs proved to be active against a broad range of DNA viruses and retroviruses, and during the course of some 30 years, they have become a key class of antiviral agents.<sup>12</sup>

To further elucidate the mechanism of antiviral action of BCNAs, which still remains unclear, we decided to synthesize a novel series of 2-(phosphonmethoxy)ethyl (PME) furo[2,3-*d*]pyrimidin-2(3*H*)-ones,<sup>13</sup> stable analogues of nucleotides that by-pass the first phosphorylation step. It is the first time that a combination of the furo[2,3-*d*]pyrimidin-2(3*H*)-one base and the acyclic nucleoside phosphonate moiety is reported.

## Results and discussion

### Chemistry

The furo[2,3-*d*]pyrimidin-2(3*H*)-one nucleoside analogues are usually prepared by the Sonogashira coupling of various alkynes with 5-iodouracils, followed by Cu(I)-promoted intramolecular cyclization.<sup>1–3</sup> This procedure, with some modifications and optimization, was applied in the present work.

Recently, 5-bromouracil derivative was used to modify 1-[2-(phosphonmethoxy)ethyl]uracil (PMEU) analogues in the C-5 position of the uracil moiety via Pd-catalysed Suzuki–Miyaura coupling.<sup>14</sup> No record of the protected 5-iodo-1-[2-(phosphonmethoxy)ethyl]uracil intermediate was found in the literature even though the 5-iodouracil compounds could be expected to be more reactive toward cross-coupling reactions compared to their 5-bromouracil counterparts. Thus, we decided to prepare the novel 5-iodouracil analogue as a suitable starting material for subsequent syntheses.

Starting PMEU compound **5** was prepared by a previously described procedure:<sup>15</sup> reaction of 4-methoxypyrimidin-2(1*H*)-one<sup>16</sup> with diisopropyl [(2-chloroethoxy)methyl]phosphonate<sup>17</sup> in the presence of sodium hydride followed by hydrolysis in aqueous methanol using Dowex 50 (H<sup>+</sup> form). A much improved yield was obtained during the alkylation step (79%) compared to the original procedure (49%).<sup>15</sup> The major difference in our procedure seems to be neutralization of the reaction mixture before the work-up (evaporation of solvents) to avoid possible product decomposition, since a slight excess of NaH is used for the alkylation reaction.

The desired 5-iodouracil derivative (**6**) was prepared by the reaction of compound **5** with iodine and ammonium cerium(IV)nitrate (CAN) in refluxing acetonitrile (Scheme 1).<sup>18</sup> This reactive intermediate can be conveniently prepared as a white product by recrystallization in 90% yield. Treatment of compound **6** with bromo(trimethyl)silane in a mixture of acetonitrile/2,6-lutidine (~5:1) afforded the free phosphonic acid (**7**). The presence of the sterically hindered mild base 2,6-lutidine is required to neutralize forming HBr and thus prevent exchange of iodine atom in the C-5 position for bromine or proton during the reaction and (or) its work-up.

Furo[2,3-*d*]pyrimidin-2(3*H*)-ones (**10**) were prepared in moderate to high yields (50%–90% isolated yields for two in situ steps) by the Sonogashira coupling of various terminal alkynes (**8**) with 5-iodouracil derivative (**6**), followed by in situ Cu(I)-promoted intramolecular cyclization (Scheme 1).

**Scheme 1.** Reagents: (i)  $I_2$ , CAN,  $CH_3CN$ , 80 °C; (ii)  $(CH_3)_3SiBr$ , 2,6-lutidine,  $CH_3CN$ , RT; (iii)  $Pd(Ph_3P)_4$ , CuI,  $Et_3N$ , DMF, 50 °C, then CuI and 90 °C; (iv)  $Pd(Ph_3P)_4$ , CuI,  $Et_3N$ , DMF (or THF), 50 °C; (v) CuI,  $Et_3N$ , MeOH, reflux; (vi)  $(CH_3)_3SiBr$ ,  $CH_3CN$ , RT.

The lower yields can be attributed to difficult crystallization/precipitation of highly lipophilic compounds (**10**). Nevertheless, the purity of diesters (**10**) proved to be very important to ultimately obtain the pure final products (**11**). Also, extraction of the reaction mixture with aqueous EDTA solution during the work-up is necessary to get pure diesters (**10**) with matching elemental analyses since phosphonates strongly bind metal ions. Finally, the free phosphonic acids (**11**) were prepared by standard treatment of compounds **10** with bromo(trimethyl)silane in acetonitrile followed by hydrolysis.

Similarly, as during the BCNAs synthesis,<sup>1-3</sup> 5-alkynyl intermediates (**9**) were not isolated. Formation of compounds **9** and their conversion to fluorescent bicyclic products (**10**) was monitored by thin-layer chromatography (TLC). There were often fluorescent and nonfluorescent byproducts observed, so we tried to optimize the reaction conditions. The best yields of compounds **10** were obtained by the addition of fresh CuI (0.5 equiv.) and by increasing the reaction temperature from 50–90 °C after the starting compound **6** was completely consumed (TLC, ~1 h).

In spite of the fact that Sonogashira coupling and in situ cyclization is a very practical procedure, which gives high overall yields of furo[2,3-*d*]pyrimidin-2(3*H*)-ones (**10**), we decided to prepare, isolate, and fully characterize one of the intermediate 5-alkynyluracils and use it as pure starting compound in the next cyclization step. Thus, coupling of the 5-iodouracil derivative (**6**) with 1.3 equiv. of 1-hexyne (**8b**) under standard Sonogashira coupling conditions ( $Pd(Ph_3P)_4$ , CuI,  $Et_3N$ , DMF, 50 °C, 2 h) afforded the 5-hexynyluracil derivative (**9b**) in 82% yield (Scheme 1). Fluorescent byproduct was clearly visible on the TLC plate and the corresponding 6-butylfuro[2,3-*d*]pyrimidin-2(3*H*)-one (**10b**) was isolated from the reaction mixture in 2% yield.

Treatment of the 5-hexynyluracil derivative (**9b**) with CuI (1 equiv.) in a mixture of MeOH/ $Et_3N$  (3:2) at reflux gave the cyclized product **10b** in 90% yield. The calculated overall yield of compound **10b** starting from 5-iodouracil derivative (**6**) was 74% and is comparable to the yield of

**Fig. 2.** Structure of compound **12** with atom numbering of the substituted furo[2,3-*d*]pyrimidin-2(3*H*)-ones used for assignment of NMR signals.

compound **10b** (78%) prepared by the standard in situ synthesis in the DMF/ $Et_3N$  mixture. Although, not all reaction steps were optimized, the comparison of the results of the in situ procedure with the two-pot-reaction sequence clearly shows that the in situ approach for general preparation of furo[2,3-*d*]pyrimidin-2(3*H*)-ones is preferable and more economic.

For comparison, the Sonogashira coupling of the 5-iodouracil derivative (**6**) with 1-hexyne (**8b**) was carried out using THF as a solvent instead of DMF. In this case, the 5-hexynyluracil derivative (**9b**) was isolated only in 59% yield (compared to 82% in DMF) together with 5,6-disubstituted furo[2,3-*d*]pyrimidin-2(3*H*)-one (**12**) as a byproduct (Fig. 2). Formation of a similar type of byproduct during synthesis of bicyclic nucleoside analogues was previously reported by the group of McGuigan.<sup>19</sup>

To prepare the parent furo[2,3-*d*]pyrimidin-2(3*H*)-one derivative unsubstituted at the C-6 position, ethynyl(trimethyl)silane (**13**) was coupled with the starting 5-iodouracil compound (**6**) followed by deprotection of the trimethylsilyl group with TBAF/THF (Scheme 2). The desired 5-ethynyluracil derivative (**14**) was obtained in 63% yield, but its subsequent cyclization with CuI did not proceed well and the reactions usually afforded complex mixtures. The best

**Scheme 2.** Reagents: (i) Pd(Ph<sub>3</sub>P)<sub>4</sub>, CuI, Et<sub>3</sub>N, DMF, 70 °C; (ii) TBAF, THF, RT; (iii) CuI, Et<sub>3</sub>N, EtOAc, reflux; (iv) (CH<sub>3</sub>)<sub>3</sub>SiBr, CH<sub>3</sub>CN, RT; (v) CuI, Et<sub>3</sub>N, MeOH, reflux.

yield (38%) of the furo[2,3-*d*]pyrimidin-2(3*H*)-one (**15**) was achieved by the Cu(I)-promoted intramolecular cyclization in an EtOAc/Et<sub>3</sub>N mixture. Similar reaction of compound **14** with 1 equiv. of CuI in the MeOH/Et<sub>3</sub>N mixture gave a complex mixture from which only a dimeric product of Eglinton coupling,<sup>20</sup> compound **17**, was isolated in 10% yield (Scheme 2). Finally, free phosphonic acid (**16**) was prepared from compound **15** by the standard procedure in 74% yield (Scheme 2).

### Biological activity

All the final 3-[2-(phosphonomethoxy)ethyl]furo[2,3-*d*]pyrimidin-2(3*H*)-ones (**11**) and **16** were evaluated for their inhibitory activity against a variety of DNA viruses including herpes simplex virus type 1 (KOS) (HSV-1), HSV-2 (G), varicella-zoster virus (VZV) (thymidine kinase (TK) competent (TK<sup>+</sup>) and TK deficient (TK<sup>-</sup>)), vaccinia virus (Lederle), human cytomegalovirus (HCMV) (Davis) and the lentiviruses, and human immunodeficiency virus type 1 (HIV-1) (III<sub>B</sub>) and HIV-2 (ROD). Interestingly, none of the compounds tested were active at subtoxic concentrations, including **11f** and **11h**, which represent the corresponding analogues of the BCNA prototypes Cf 1368 and Cf 1743.<sup>3,5</sup> These data revealed that the acyclic nucleotide analogues of furo[2,3-*d*]pyrimidin-2(3*H*)-ones (**11**) and **16**, designed to by-pass the first phosphorylation step necessary for the anti-VZV activity of BCNAs, may not be further metabolized to their active antiviral metabolites and (or) the compounds may not be recognized as an inhibitor at their eventual antiviral target.

### Conclusions

In conclusion, novel series of the 2-(phosphonomethoxy)ethyl derivatives of 6-alkylfuro[2,3-*d*]pyrimidin-2(3*H*)-ones was effectively synthesized by a convenient one-pot procedure consisting of Sonogashira coupling of the 5-iodouracil compound (**6**) with 1-alkynes (**8**) and subsequent Cu(I)-promoted cyclization. For this purpose, protected 5-iodo-1-[2-(phosphonomethoxy)ethyl]uracil (**6**) was prepared as a suitable

starting compound. An example of Sonogashira reaction product, the 5-hexynyluracil derivative (**9b**) was isolated and fully characterized, as well as the product **12**, which was formed during the coupling procedure in THF. Bearing in mind the same overall yields of 6-butylfuro[2,3-*d*]pyrimidin-2(3*H*)-one derivative (**10b**), the in situ coupling-intramolecular cyclization is clearly preferable to two-pot synthesis with isolation of the 5-hexynyluracil intermediate (**9b**). Coupling of the 5-iodouracil derivative (**6**) with ethynyl(trimethyl)silane (**13**) under the Sonogashira reaction conditions, followed by removal of the TMS group, afforded the 5-ethynyluracil derivative (**14**). Intramolecular cyclization of compound **14** in EtOAc gave the desired furo[2,3-*d*]pyrimidin-2(3*H*)-one (**15**), while a similar reaction in MeOH only afforded a dimer (**17**) in very low yield. Free phosphonic acids (**11** and **16**) were obtained by the standard deprotection of the corresponding diesters (**10** and **15**). None of the compounds tested were active in any of the antiviral assays.

### Experimental section

Solvents were dried by standard procedures. Tetrahydrofuran (THF) was freshly distilled from sodium/benzophenone under argon. All 1-alkynes, Pd(Ph<sub>3</sub>P)<sub>4</sub>, and CuI are commercially available from Sigma-Aldrich. TLC was performed on plates of Kieselgel 60 F254 (Merck). If not stated otherwise, NMR spectra were recorded on Bruker Avance 400 (<sup>1</sup>H at 400.0 MHz, <sup>13</sup>C at 100.6 MHz) in CDCl<sub>3</sub>, DMSO-*d*<sub>6</sub>, or D<sub>2</sub>O. NMR spectra of several compounds were recorded on Bruker Avance 600 spectrometer (<sup>1</sup>H at 600.0 MHz, <sup>13</sup>C at 150.9 MHz) or Bruker Avance 500 (<sup>1</sup>H at 500.0 MHz, <sup>13</sup>C at 125.8 MHz). Chemical shifts (in ppm, δ scale) were referenced to the solvent signal (CDCl<sub>3</sub> δ: 7.26 ppm for <sup>1</sup>H NMR and δ: 77.0 ppm for <sup>13</sup>C NMR, DMSO-*d*<sub>6</sub> for <sup>1</sup>H NMR δ: 2.5 ppm and for <sup>13</sup>C δ: 39.7 ppm). Chemical shifts in D<sub>2</sub>O were referenced to 1,4-dioxane for <sup>1</sup>H NMR δ: 3.75 ppm and for <sup>13</sup>C NMR δ: 67.19 ppm. Melting points were determined on a Büchi melting point B-545 apparatus and are uncorrected. UV spectra were measured on a DU spectrophotometer with solutions

in MeOH. Mass spectra were measured on a LCQ classic spectrometer using electrospray ionization (ESI). All new compounds were fully characterized by mass spectrometry, NMR spectroscopy, and elemental analysis (or HR mass spectrometry in the case of compounds **6**, **10h**, **12**, and **17**). Complete assignment of all NMR signals using a combination of  $^1\text{H}$ - $^1\text{H}$  COSY,  $^1\text{H}$ - $^{13}\text{C}$  HSQC, and  $^1\text{H}$ - $^{13}\text{C}$  HMBC methods is provided.

### 1-{2-[(Diisopropoxyphosphoryl)methoxy]ethyl}-5-iodouracil (**6**)

A solution of **5** (8.28 g, 24.78 mmol), CAN (6.79 g, 12.39 mmol), and iodine (8.18 g, 32.22 mmol) in dry acetonitrile (240 mL) was stirred at 80 °C under an inert atmosphere until the starting material was completely consumed after 3 h as monitored by TLC analysis (5% MeOH/ $\text{CHCl}_3$ ). Volatiles were evaporated, and the residue was dissolved in EtOAc (250 mL) and washed with ice cold 5%  $\text{Na}_2\text{S}_2\text{O}_3$  (aq., 130 mL) and brine (50 mL). Organics were dried ( $\text{MgSO}_4$ ), filtered, and solvents evaporated. The crude product was crystallized (EtOAc) to give **6** (10.40 g, 87%) as white crystals; mp 114 °C.  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 11.66 (bs, 1H, NH), 8.07 (s, 1H, H-6), 4.56 (dh, 2H,  $J_{\text{H,P}} = 7.7$  Hz,  $J_{\text{vic}} = 6.2$  Hz, POCH), 3.87 (m, 2H, H-1'), 3.77 (d, 2H,  $J_{\text{H,P}} = 8.3$  Hz, H-4'), 3.69 (m, 2H, H-2'), 1.23 and 1.21 (2  $\times$  d, 2  $\times$  6H,  $J_{\text{vic}} = 6.2$  Hz,  $\text{CH}_3$ ).  $^{13}\text{C}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 161.1 (C-4), 150.7 (C-2), 150.5 (C-6), 70.3 (d,  $J_{\text{C,P}} = 6.4$  Hz, POC), 69.9 (d,  $J_{\text{C,P}} = 11.6$  Hz, C-2'), 67.7 (C-5), 64.9 (d,  $J_{\text{C,P}} = 163.8$  Hz, C-4'), 47.4 (C-1'), 23.9 (d,  $J_{\text{C,P}} = 3.8$  Hz,  $\text{CH}_3$ ), 23.8 (d,  $J_{\text{C,P}} = 4.5$  Hz,  $\text{CH}_3$ ). MS (ESI)  $m/z$ : 459  $[\text{M} - \text{H}]^-$ . HR-MS (ESI)  $m/z$ :  $\text{C}_{13}\text{H}_{21}\text{N}_2\text{IO}_6\text{P}$   $[\text{M} - \text{H}]^-$ . Anal. calcd.: 459.0176; found: 459.0181.

### 5-Iodo-1-[2-(phosphonomethoxy)ethyl]uracil (**7**)

A mixture of compound **6** (230 mg, 0.50 mmol), bromo-(trimethyl)silane (0.90 mL, 1.04 g, 6.82 mmol), and 2,6-lutidine (0.70 mL, 648 mg, 6.00 mmol) in acetonitrile (5 mL) was stirred overnight at room temperature. The mixture was concentrated in vacuo and then codistilled with acetonitrile (3  $\times$  5 mL). The residue was dissolved in 50% aqueous methanol (20 mL) and concd HCl was added until the pH was between 2 and 3. After 1 h at room temperature, the solvents were evaporated to dryness and the residue was purified using HPLC (20%–100% aq. MeOH) and crystallized ( $\text{H}_2\text{O}$ ) to give **7** (70 mg, 37%) as white crystals; mp 194 °C. UV-vis  $\lambda_{\text{max}}$  (nm) ( $\epsilon$  ((mol/L) $^{-1}$  cm $^{-1}$ ): 286 (16 300).  $^1\text{H}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 11.64 (bs, 1H, NH), 8.10 (s, 1H, H-6), 3.85 (m, 2H, H-1'), 3.68 (m, 2H, H-2'), 3.57 (d, 2H,  $J_{\text{H,P}} = 8.4$  Hz, H-4').  $^{13}\text{C}$  NMR ( $\text{DMSO}-d_6$ )  $\delta$ : 161.1 (C-4), 150.8 (C-2), 150.5 (C-6), 69.7 (d,  $J_{\text{C,P}} = 9.8$  Hz, C-2'), 67.8 (C-5), 66.5 (d,  $J_{\text{C,P}} = 159.7$  Hz, C-4'), 47.1 (C-1'). MS (ESI)  $m/z$ : 374.9  $[\text{M} - \text{H}]^-$ . Anal. calcd. for  $\text{C}_7\text{H}_{10}\text{N}_2\text{IO}_6\text{P} \cdot 2/3\text{H}_2\text{O}$  (388.05): C 21.67, H 2.94, N 7.22, I 32.70, P 7.98; found: C 21.67, H 3.13, N 6.92, I 32.96, P 7.77.

### Sonogashira coupling of 5-iodouracil derivative (**6**) with 1-hexyne (**8b**)

#### Method A

A stirred suspension of **6** (690 mg, 1.50 mmol),  $\text{Pd}(\text{Ph}_3\text{P})_4$  (87 mg, 75  $\mu\text{mol}$ ), CuI (87 mg, 0.46 mmol), and 1-hexyne

(**8b**, 0.22 mL, 160 mg, 1.95 mmol) in dry and deoxygenated DMF/ $\text{Et}_3\text{N}$  (10:1, 20 mL) was heated under argon at 50 °C for 2 h. Volatiles were flash evaporated, the residue was extracted with hot MeOH (3  $\times$  30 mL), and the solid was filtered off. Volatiles were evaporated, the residue was dissolved in  $\text{CHCl}_3$  (50 mL) and washed (2  $\times$  30 mL of saturated EDTA (aq.), 1  $\times$  20 mL  $\text{H}_2\text{O}$ ). Organics were dried ( $\text{MgSO}_4$ ) and filtered. Flash chromatography (4% MeOH in  $\text{CHCl}_3$ ) afforded compounds **9b** (512 mg, 82%) as brownish oil and **10b** (11 mg, 2%) as yellow foam.

### 1-{2-[(Diisopropoxyphosphoryl)methoxy]ethyl}-5-(1-hexynyl)uracil (**9b**)

$^1\text{H}$  NMR ( $\text{CDCl}_3$ )  $\delta$ : 9.00 (bs, 1H, NH), 7.48 (s, 1H, H-6), 4.73 (dh, 2H,  $J_{\text{H,P}} = 7.7$  Hz,  $J_{\text{vic}} = 6.2$  Hz, POCH), 3.93 (m, 2H, H-1'), 3.79 (m, 2H, H-2'), 3.73 (d, 2H,  $J_{\text{H,P}} = 8.4$  Hz, H-4'), 2.36 (t, 2H,  $J_{\text{vic}} = 7.1$  Hz, H-3''), 1.57–1.50 (m, 2H, H-4''), 1.46–1.36 (m, 2H, H-5''), 1.35–1.28 (m, 12H,  $\text{CH}_3$ ), 0.90 (t, 3H,  $J_{\text{vic}} = 7.3$  Hz, H-6'').  $^{13}\text{C}$  NMR ( $\text{CDCl}_3$ )  $\delta$ : 162.1 (C-4), 149.8 (C-2), 147.4 (C-6), 100.2 (C-5), 95.2 (C-2''), 71.2 (d,  $J_{\text{C,P}} = 6.7$  Hz, POC), 70.8 (C-1''), 70.7 (d,  $J_{\text{C,P}} = 10.5$  Hz, C-2'), 66.2 (d,  $J_{\text{C,P}} = 167.8$  Hz, C-4'), 48.8 (C-1'), 30.6 (C-3''), 24.02 (d,  $J_{\text{C,P}} = 3.8$  Hz,  $\text{CH}_3$ ), 23.96 (d,  $J_{\text{C,P}} = 4.5$  Hz,  $\text{CH}_3$ ), 22.0 (C-4''), 19.3 (C-5''), 13.6 (C-6''). MS (ESI)  $m/z$ : 415  $[\text{M} + \text{H}]^+$ . HR-MS (ESI)  $m/z$ :  $\text{C}_{19}\text{H}_{31}\text{N}_2\text{O}_6\text{P}$ -Na  $[\text{M} + \text{Na}]^+$ . Anal. calcd.: 437.1810; found: 437.1812.

### 6-Butyl-3-{2-[(diisopropoxyphosphoryl)methoxy]ethyl}furo[2,3-d]pyrimidin-2(3H)-one (**10b**)

$^1\text{H}$  and  $^{13}\text{C}$  NMR data were identical with compound **10b** prepared from compound **6** by the General Procedure A.

#### Method B

A stirred suspension of **6** (230 mg, 0.50 mmol),  $\text{Pd}(\text{Ph}_3\text{P})_4$  (29 mg, 25  $\mu\text{mol}$ ), CuI (20 mg, 0.11 mmol), 1-hexyne (0.17 mL, 122 mg, 1.49 mmol), and  $\text{Et}_3\text{N}$  (0.21 mL) in dry and deoxygenated THF (10 mL) was stirred under argon at 50 °C for 3 h. Volatiles were flash evaporated, the residue was extracted with hot MeOH (3  $\times$  30 mL), and the solid was filtered off. Volatiles were evaporated, the residue was dissolved in EtOAc (30 mL) and washed (2  $\times$  10 mL of saturated EDTA (aq.), 1  $\times$  10 mL  $\text{H}_2\text{O}$ ). Organics were dried ( $\text{MgSO}_4$ ) and filtered. Flash chromatography (5% MeOH/ $\text{CHCl}_3$ ) afforded compounds **9b** (246 mg, 59%) as a yellow oil and **12** as a yellowish oil (60 mg, 12%).

### 1-{2-[(Diisopropoxyphosphoryl)methoxy]ethyl}-5-(1-hexynyl)uracil (**9b**)

$^1\text{H}$  and  $^{13}\text{C}$  NMR data were identical with compound **9b** prepared by Method A.

### Diisopropyl {(2-[6-butyl-2-oxo-5-(hexyn-1-yl)furo[2,3-d]pyrimidin-3(2H)-yl]ethoxy)methyl}phosphonate (**12**)

$^1\text{H}$  NMR (500.0 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.89 (s, 1H, H-4), 4.68 (dh, 2H,  $J_{\text{H,P}} = 7.7$  Hz,  $J_{\text{vic}} = 6.2$  Hz, POCH), 4.21 (m, 2H, H-1'), 3.91 (m, 2H, H-2'), 3.69 (d, 2H,  $J_{\text{H,P}} = 8.6$  Hz, H-4'), 2.73 (t, 2H,  $J_{\text{vic}} = 7.4$  Hz, H-1''), 2.41 (t, 2H,  $J_{\text{vic}} = 7.1$  Hz, H-3''), 1.68 (m, 2H, H-2''), 1.57 and 1.46 (2  $\times$  m, 2  $\times$  2H, H-4''' and H-5'''), 1.36 (m, 2H, H-3'''), 1.28 and 1.24 (2  $\times$  d, 2  $\times$  6H,  $J_{\text{vic}} = 6.2$  Hz,  $\text{CH}_3$ ), 0.94 (t, 3H,  $J_{\text{vic}} = 7.4$  Hz, H-6'''), 0.93 (t, 3H,  $J_{\text{vic}} = 7.3$  Hz, H-4'').  $^{13}\text{C}$  NMR (125.8 MHz,  $\text{CDCl}_3$ )  $\delta$ : 170.7 (C-7a), 162.0 (C-6), 155.3 (C-2), 140.8 (C-

4), 107.7 (C-4a), 97.8 (C-5), 97.2 (C-2'''), 71.1 (d,  $J_{C,P}$  = 6.6 Hz, POCH), 70.3 (d,  $J_{C,P}$  = 11.6 Hz, C-2'), 68.2 (C-1'''), 66.1 (d,  $J_{C,P}$  = 168.2 Hz, C-4'), 52.1 (C-1'), 30.6 (C-4'''), 29.0 (C-2''), 26.8 (C-1''), 24.0 (d,  $J_{C,P}$  = 3.8 Hz, CH<sub>3</sub>), 23.9 (d,  $J_{C,P}$  = 4.6 Hz, CH<sub>3</sub>), 22.0 (C-5''' and C-3''), 19.2 (C-3'''), 13.6 (C-6''' and C-4''). MS (ESI)  $m/z$ : 495 [M + H]<sup>+</sup>. HR-MS (ESI)  $m/z$ : C<sub>25</sub>H<sub>40</sub>N<sub>2</sub>O<sub>6</sub>P [M + H]<sup>+</sup>. Anal. calcd.: 495.2618; found: 495.2616.

### 6-Butyl-3-{2-[(diisopropoxyphosphoryl)methoxy]ethyl}furo[2,3-d]pyrimidin-2(3H)-one (10b)

A stirred suspension of **9b** (438 mg, 1.06 mmol) and CuI (200 mg, 1.05 mmol) in a mixture of MeOH (30 mL) and Et<sub>3</sub>N (20 mL) was refluxed for 2 h. Volatiles were flash evaporated, the residue was extracted with hot MeOH (3 × 30 mL), and the solid was filtered off. Volatiles were evaporated, the residue was dissolved in CHCl<sub>3</sub> (50 mL) and washed (2 × 30 mL of saturated EDTA (aq.)), 1 × 20 mL H<sub>2</sub>O). Organics were dried (MgSO<sub>4</sub>), filtered, and the product was isolated by flash chromatography (4% MeOH/CHCl<sub>3</sub>) and crystallized (EtOAc/Et<sub>2</sub>O) to give **10b** (375 mg, 90%) as white crystals; mp 142 °C. <sup>1</sup>H and <sup>13</sup>C NMR data were identical with compound **10b** prepared from compound **6** by General procedure A.

### Synthesis of furo[2,3-d]pyrimidin-2(3H)-ones (10) by Sonogashira coupling of 5-iodouracil derivative (6) with 1-alkynes (8) followed by in situ intramolecular cyclization

#### General procedure A

A stirred suspension of **6**, Pd(Ph<sub>3</sub>P)<sub>4</sub> (0.05 equiv.), CuI (0.5 equiv.), and 1-alkyne (**8**; 1.3 equiv.) in dry and deoxygenated DMF/Et<sub>3</sub>N was stirred under argon at 50 °C for 2–3 h. TLC (5% MeOH/CHCl<sub>3</sub>) showed complete conversion to a faster-migrating product. CuI (0.5 equiv.) was added and the reaction mixture was stirred at 90 °C for 2–4 h. TLC (5% MeOH/CHCl<sub>3</sub>) showed complete conversion of the intermediate 6-alkynyl derivative to a fluorescent product (**10**). Volatiles were flash evaporated, the residue was dissolved in hot MeOH, and the solid filtered off. Volatiles were evaporated and the residue was dissolved in CHCl<sub>3</sub> (80 mL). Organics were washed (2 × 10 mL of saturated EDTA (aq.)), 1 × 10 mL H<sub>2</sub>O) and dried (MgSO<sub>4</sub>). After filtration and evaporation, the product was isolated by flash chromatography (5% MeOH/CHCl<sub>3</sub>) and crystallized from a mixture of EtOAc with other organic solvents (hexanes, EtOH, Et<sub>2</sub>O).

### 3-{2-[(Diisopropoxyphosphoryl)methoxy]ethyl}-6-propylfuro[2,3-d]pyrimidin-2(3H)-one (10a)

Treatment of **6** (690 mg, 1.50 mmol) with 1-pentyne (**8a**; 0.19 mL, 133 mg, 1.95 mmol) by General procedure A gave **10a** (402 mg, 67%) as white crystals (EtOAc/hexanes 1:1); mp 128 °C. <sup>1</sup>H NMR (500.0 MHz, CDCl<sub>3</sub>) δ: 7.94 (s, 1H, H-4), 6.09 (t, 1H,  $J_{5,1''}$  = 1.1 Hz, H-5), 4.68 (dh, 2H,  $J_{H,P}$  = 7.7 Hz,  $J_{vic}$  = 6.2 Hz, POCH), 4.22 (m, 2H, H-1'), 3.91 (m, 2H, H-2'), 3.70 (d, 2H,  $J_{H,P}$  = 8.6 Hz, H-4'), 2.63 (td, 2H,  $J_{vic}$  = 7.4 Hz,  $J_{1'',5}$  = 1.1 Hz, H-1''), 1.72 (h, 2H,  $J_{vic}$  = 7.4 Hz, H-2''), 1.29 and 1.25 (2 × d, 2 × 6H,  $J_{vic}$  = 6.2 Hz, CH<sub>3</sub>), 0.99 (t, 3H,  $J_{vic}$  = 7.4 Hz, H-3''). <sup>13</sup>C NMR

(125.8 MHz, CDCl<sub>3</sub>) δ: 172.1 (C-7a), 159.6 (C-6), 155.4 (C-2), 140.5 (C-4), 107.4 (C-4a), 98.5 (C-5), 71.1 (d,  $J_{C,P}$  = 6.7 Hz, POC), 70.6 (d,  $J_{C,P}$  = 11.8 Hz, C-2'), 66.0 (d,  $J_{C,P}$  = 168.8 Hz, C-4'), 51.5 (C-1'), 30.1 (C-1''), 24.0 (d,  $J_{C,P}$  = 3.9 Hz, CH<sub>3</sub>), 23.9 (d,  $J_{C,P}$  = 4.6 Hz, CH<sub>3</sub>), 20.2 (C-2''), 13.5 (C-3''). MS (ESI)  $m/z$ : 399 [M – H]<sup>–</sup>. Anal. calcd. for C<sub>18</sub>H<sub>29</sub>N<sub>2</sub>O<sub>6</sub>P (400.41): C 53.99, H 7.30, N 7.00, P 7.74; found: C 53.94, H 7.35, N 6.86, P 8.02.

### 6-Butyl-3-{2-[(diisopropoxyphosphoryl)methoxy]ethyl}furo[2,3-d]pyrimidin-2(3H)-one (10b)

Treatment of **6** (690 mg, 1.50 mmol) with 1-hexyne (**8b**; 0.22 mL, 160 mg, 1.95 mmol) by General procedure A gave **10b** (485 mg, 78%) as white crystals (EtOAc/Et<sub>2</sub>O); mp 139 °C. <sup>1</sup>H NMR (CDCl<sub>3</sub>) δ: 7.91 (s, 1H, H-4), 6.06 (s, 1H, H-5), 4.66 (dh, 2H,  $J_{H,P}$  = 7.7 Hz,  $J_{vic}$  = 6.2 Hz, POCH), 4.20 (m, 2H, H-1'), 3.88 (m, 2H, H-2'), 3.68 (d, 2H,  $J_{H,P}$  = 8.6 Hz, H-4'), 2.63 (t, 2H,  $J_{vic}$  = 7.5 Hz, H-1''), 1.68–1.61 (m, 2H, H-2''), 1.42–1.31 (m, 2H, H-3''), 1.27 and 1.23 (2 × d, 2 × 6H,  $J_{vic}$  = 6.2 Hz, CH<sub>3</sub>), 0.92 (t, 3H,  $J_{vic}$  = 7.4 Hz, H-4''). <sup>13</sup>C NMR (CDCl<sub>3</sub>) δ: 172.1 (C-7a), 159.7 (C-6), 155.3 (C-2), 140.4 (C-4), 107.3 (C-4a), 98.4 (C-5), 71.0 (d,  $J_{C,P}$  = 6.7 Hz, POC), 70.6 (d,  $J_{C,P}$  = 11.8 Hz, C-2'), 66.1 (d,  $J_{C,P}$  = 168.8 Hz, C-4'), 51.5 (C-1'), 28.8 (C-1''), 27.9 (C-2''), 24.0 (d,  $J_{C,P}$  = 3.9 Hz, CH<sub>3</sub>), 23.9 (d,  $J_{C,P}$  = 4.6 Hz, CH<sub>3</sub>), 22.0 (C-3''), 13.6 (C-4''). ## Transformation of esters (10) to free phosphonic acids (11)

### General procedure B

The dried starting esters (**10**; 1 mmol), bromo(trimethyl)silane (1.75 mL, 2.03 g, 13.26 mmol), and acetonitrile (10 mL) were stirred at room temperature overnight. The mixture was concentrated in vacuo and then codistilled with a mixture of water/EtOH (9:1, 2 × 5 mL). The residue was crystallized (2 crops) to give free phosphonic acids (**11**).

### 3-{2-(Phosphonomethoxy)ethyl}-6-propylfuro[2,3-d]pyrimidin-2(3H)-one (11a)

Treatment of **10a** (250 mg, 0.62 mmol) gave **11a** (167 mg, 85%) as white crystals (EtOAc/EtOH 3:1); mp 165 °C. UV-vis  $\lambda_{max}$  (nm) ( $\epsilon$  ((mol/L)<sup>-1</sup> cm<sup>-1</sup>): 329 (5400), 242 (8900). <sup>1</sup>H NMR (DMSO-*d*<sub>6</sub>) δ: 8.36 (s, 1H, H-4), 6.41 (s, 1H, H-5), 4.11 (m, 2H, H-1'), 3.78 (m, 2H, H-2'), 3.57 (d, 2H,  $J_{H,P}$  = 8.5 Hz, H-4'), 2.61 (t, 2H,  $J_{vic}$  = 7.4 Hz, H-1''), 1.71–1.58 (m, 2H, H-2''), 0.94 (t, 3H,  $J$  = 7.4 Hz, H-3''). <sup>13</sup>C NMR (DMSO-*d*<sub>6</sub>) δ: 171.5 (C-7a), 157.9 (C-6), 154.6 (C-2), 142.8 (C-4), 106.0 (C-4a), 99.7 (C-5), 69.4 (d,  $J_{C,P}$  = 10.5 Hz, C-2'), 66.5 (d,  $J_{C,P}$  = 159.9 Hz, C-4'), 50.2 (C-1'), 29.4 and 20.0 and 13.5 (6-propyl). MS (ESI)  $m/z$ : 315 [M - H]<sup>-</sup>. Anal. calcd. for C<sub>12</sub>H<sub>17</sub>N<sub>2</sub>O<sub>6</sub>P·1/5H<sub>2</sub>O (319.85): C 45.06, H 5.48, N 8.76, P 9.68; found: C 45.21, H 5.45, N 8.64, P 9.90.

### 6-Butyl-3-[2-(phosphonomethoxy)ethyl]furo[2,3-d]pyrimidin-2(3H)-one (**11b**)

Treatment of **10b** (200 mg, 0.48 mmol) gave **11b** (110 mg, 69%) as white crystals (H<sub>2</sub>O); mp 144 °C. UV-vis  $\lambda_{\text{max}}$  (nm) ( $\epsilon$  ((mol/L)<sup>-1</sup> cm<sup>-1</sup>): 329 (7000), 243 (13 500). <sup>1</sup>H NMR (DMSO-*d*<sub>6</sub>)  $\delta$ : 8.36 (s, 1H, H-4), 6.40 (s, 1H, H-5), 4.11 (m, 2H, H-1'), 3.77 (m, 2H, H-2'), 3.58 (d, 2H,  $J_{\text{H,P}}$  = 8.6 Hz, H-4'), 2.64 (t, 2H,  $J_{\text{vic}}$  = 7.4 Hz, H-1''), 1.68–1.50 (m, 2H, H-2''), 1.42–1.27 (m, 2H, H-3''), 0.90 (t, 3H,  $J$  = 7.4 Hz, H-4''). <sup>13</sup>C NMR (DMSO-*d*<sub>6</sub>)  $\delta$ : 171.5 (C-7a), 158.1 (C-6), 154.6 (C-2), 142.9 (C-4), 106.1 (C-4a), 99.6 (C-5), 69.4 (d,  $J_{\text{C,P}}$  = 10.5 Hz, C-2'), 66.5 (d,  $J_{\text{C,P}}$  = 159.9 Hz, C-4'), 50.3 (C-1'), 28.7 and 27.2 and 21.7 and 13.8 (6-butyl). ### 3-[2-(Phosphonomethoxy)ethyl]-6-pentylfuro[2,3-d]pyrimidin-2(3H)-one (**11c**)

Treatment of **10c** (250 mg, 0.58 mmol) gave **11c** (160 mg, 80%) as white crystals (H<sub>2</sub>O); mp 156 °C. UV-vis  $\lambda_{\text{max}}$  (nm) ( $\epsilon$  ((mol/L)<sup>-1</sup> cm<sup>-1</sup>): 329 (6700), 243 (13 600). <sup>1</sup>H NMR (DMSO-*d*<sub>6</sub>)  $\delta$ : 8.36 (s, 1H, H-4), 6.40 (s, 1H, H-5), 4.11 (m, 2H, H-1'), 3.77 (m, 2H, H-2'), 3.58 (d, 2H,  $J_{\text{H,P}}$  = 8.6 Hz, H-4'), 2.63 (t, 2H,  $J_{\text{vic}}$  = 7.3 Hz, H-1''), 1.61 (m, 2H, H-2''), 1.37–1.26 (m, 4H, H-3'' and H-4''), 0.87 (t, 3H,  $J$  = 6.9 Hz, H-5''). <sup>13</sup>C NMR (DMSO-*d*<sub>6</sub>)  $\delta$ : 171.5 (C-7a), 158.1 (C-6), 154.6 (C-2), 142.9 (C-4), 106.1 (C-4a), 99.6 (C-5), 69.4 (d,  $J_{\text{C,P}}$  = 10.5 Hz, C-2'), 66.5 (d,  $J_{\text{C,P}}$  = 159.9 Hz, C-4'), 50.3 (C-1'), 30.8 and 27.5 and 26.2 and 21.9 and 14.1 (6-pentyl). MS (ESI)  $m/z$ : 343 [M – H]<sup>-</sup>. Anal. calcd. for C<sub>14</sub>H<sub>21</sub>N<sub>2</sub>O<sub>6</sub>P (344.30): C 48.84, H 6.15, N 8.14, P 9.00; found: C 48.53, H 5.97, N 7.99, P 9.06.

### 6-Hexyl-3-[2-(phosphonomethoxy)ethyl]furo[2,3-d]pyrimidin-2(3H)-one (**11d**)

Treatment of **10d** (490 mg, 1.11 mmol) gave **11d** (283 mg, 71%) as white crystals (H<sub>2</sub>O); mp 159–160 °C. UV-vis  $\lambda_{\text{max}}$  (nm) ( $\epsilon$  ((mol/L)<sup>-1</sup> cm<sup>-1</sup>): 329 (5900), 243 (11 100). <sup>1</sup>H NMR (DMSO-*d*<sub>6</sub>)  $\delta$ : 8.36 (s, 1H, H-4), 6.39 (s, 1H, H-5), 4.11 (m, 2H, H-1'), 3.78 (m, 2H, H-2'), 3.58 (d, 2H,  $J_{\text{H,P}}$  = 8.5 Hz, H-4'), 2.63 (t, 2H,  $J_{\text{vic}}$  = 7.4 Hz, H-1''), 1.69–1.54 (m, 2H, H-2''), 1.39–1.18 (m, 6H, H-3'' and H-4'' and H-5''), 0.85 (t, 3H,  $J$  = 6.7 Hz, H-6''). <sup>13</sup>C NMR (DMSO-*d*<sub>6</sub>)  $\delta$ : 171.5 (C-7a), 158.1 (C-6), 154.7 (C-2), 142.9 (C-4), 106.1 (C-4a), 99.6 (C-5), 69.4 (d,  $J_{\text{C,P}}$  = 10.5 Hz, C-2'), 66.5 (d,  $J_{\text{C,P}}$  = 159.9 Hz, C-4'), 50.3 (C-1'), 31.1 and 28.3 and 27.6 and 26.5 and 22.2 and 14.1 (6-hexyl). MS (ESI)  $m/z$ : 357 [M – H]<sup>-</sup>. Anal. calcd. for C<sub>15</sub>H<sub>23</sub>N<sub>2</sub>O<sub>6</sub>P (358.33): C 50.28, H 6.47, N 7.82, P 8.64; found: C 49.97, H 6.52, N 7.70, P 8.85.

### 6-heptyl-3-[2-(phosphonomethoxy)ethyl]furo[2,3-d]pyrimidin-2(3H)-one (**11e**)

Treatment of **10e** (270 mg, 0.59 mmol) gave **11e** (187 mg, 84%) as white crystals (H<sub>2</sub>O/EtOH); mp 162–163 °C; UV-vis  $\lambda_{\text{max}}$  (nm) ( $\epsilon$  ((mol/L)<sup>-1</sup> cm<sup>-1</sup>): 328 (7900), 243 (14 700). <sup>1</sup>H NMR (500.0 MHz, DMSO-*d*<sub>6</sub>)  $\delta$ : 8.35 (s, 1H, H-4), 6.40 (t, 1H,  $J_{5,1''}$  = 1.1 Hz, H-5), 4.11 (m, 2H, H-1'), 3.77 (m, 2H, H-2'), 3.58 (d, 2H,  $J_{\text{H,P}}$  = 8.5 Hz, H-4'), 2.63 (td, 2H,  $J_{\text{vic}}$  = 7.4 Hz,  $J_{1'',5}$  = 1.1 Hz, H-1''), 1.68–1.52 (m, 2H,

H-2''), 1.36–1.20 (m, 8H, H-3'' and H-4'' and H-5'' and H-6''), 0.85 (t, 3H,  $J$  = 6.9 Hz, H-7''). <sup>13</sup>C NMR (125.8 MHz, DMSO-*d*<sub>6</sub>)  $\delta$ : 171.6 (C-7a), 158.2 (C-6), 154.7 (C-2), 143.0 (C-4), 106.2 (C-4a), 99.7 (C-5), 69.5 (d,  $J_{\text{C,P}}$  = 10.5 Hz, C-2'), 66.5 (d,  $J_{\text{C,P}}$  = 159.9 Hz, C-4'), 50.3 (C-1'), 31.4 and 28.59 and 28.55 and 27.6 and 26.6 and 22.3 and 14.2 (6-heptyl). MS (ESI)  $m/z$ : 371 [M – H]<sup>-</sup>. Anal. calcd. for C<sub>16</sub>H<sub>25</sub>N<sub>2</sub>O<sub>6</sub>P·1/4 H<sub>2</sub>O (376.86): C 50.99, H 6.82, N 7.43, P 8.22; found: C 51.12, H 6.77, N 7.41, P 8.40.

### 6-Octyl-3-[2-(phosphonomethoxy)ethyl]furo[2,3-d]pyrimidin-2(3H)-one (**11f**)

Treatment of **10f** (166 mg, 0.35 mmol) gave **11f** (126 mg, 90%) as white crystals (H<sub>2</sub>O/EtOH); mp 164 °C. UV-vis  $\lambda_{\text{max}}$  (nm) ( $\epsilon$  ((mol/L)<sup>-1</sup> cm<sup>-1</sup>): 329 (5900), 243 (11 000). <sup>1</sup>H NMR (DMSO-*d*<sub>6</sub>)  $\delta$ : 8.36 (s, 1H, H-4), 6.40 (s, 1H, H-5), 4.11 (m, 2H, H-1'), 3.77 (m, 2H, H-2'), 3.57 (d, 2H,  $J_{\text{H,P}}$  = 8.6 Hz, H-4'), 2.63 (t, 2H,  $J_{\text{vic}}$  = 7.3 Hz, H-1''), 1.68–1.52 (m, 2H, H-2''), 1.38–1.15 (m, 10H, H-3'' and H-4'' and H-5'' and H-6'' and H-7''), 0.85 (t, 3H,  $J$  = 6.8 Hz, H-8''). <sup>13</sup>C NMR (DMSO-*d*<sub>6</sub>)  $\delta$ : 171.5 (C-7a), 158.1 (C-6), 154.6 (C-2), 142.8 (C-4), 106.1 (C-4a), 99.6 (C-5), 69.4 (d,  $J_{\text{C,P}}$  = 10.5 Hz, C-2'), 66.5 (d,  $J_{\text{C,P}}$  = 159.9 Hz, C-4'), 50.2 (C-1'), 31.4 and 28.73 and 28.67 and 28.5 and 27.5 and 26.5 and 22.2 and 14.1 (6-octyl). MS (ESI)  $m/z$ : 385 [M – H]<sup>-</sup>. Anal. calcd. for C<sub>17</sub>H<sub>27</sub>N<sub>2</sub>O<sub>6</sub>P·1/2 H<sub>2</sub>O (395.39): C 51.64, H 7.14, N 7.09, P 7.83; found: C 51.58, H 7.18, N 7.02, P 8.11.

### 6-Decyl-3-[2-(phosphonomethoxy)ethyl]furo[2,3-d]pyrimidin-2(3H)-one (**11g**)

Treatment of **10g** (250 mg, 0.50 mmol) gave **11g** (187 mg, 90%) as white crystals (H<sub>2</sub>O/EtOH); mp 166–167 °C. UV-vis  $\lambda_{\text{max}}$  (nm) ( $\epsilon$  ((mol/L)<sup>-1</sup> cm<sup>-1</sup>): 329 (6900), 243 (13 000). <sup>1</sup>H NMR (DMSO-*d*<sub>6</sub>)  $\delta$ : 8.36 (s, 1H, H-4), 6.40 (s, 1H, H-5), 4.11 (m, 2H, H-1'), 3.77 (m, 2H, H-2'), 3.58 (d, 2H,  $J_{\text{H,P}}$  = 8.5 Hz, H-4'), 2.63 (t, 2H,  $J_{\text{vic}}$  = 7.1 Hz, H-1''), 1.66–1.54 (m, 2H, H-2''), 1.37–1.15 (m, 14H, H-3'' and H-4'' and H-5'' and H-6'' and H-7'' and H-8'' and H-9''), 0.85 (t, 3H,  $J$  = 6.7 Hz, H-10''). <sup>13</sup>C NMR (DMSO-*d*<sub>6</sub>)  $\delta$ : 171.5 (C-7a), 158.1 (C-6), 154.6 (C-2), 142.8 (C-4), 106.1 (C-4a), 99.6 (C-5), 69.4 (d,  $J_{\text{C,P}}$  = 10.5 Hz, C-2'), 66.5 (d,  $J_{\text{C,P}}$  = 159.9 Hz, C-4'), 50.2 (C-1'), 31.4 and 29.1 and 29.0 and 28.8 and 28.5 and 27.5 and 26.5 and 22.2 and 14.1 (6-decyl). MS (ESI)  $m/z$ : 413 [M – H]<sup>-</sup>. Anal. calcd. for C<sub>19</sub>H<sub>31</sub>N<sub>2</sub>O<sub>6</sub>P·1/4H<sub>2</sub>O (418.94): C 54.47, H 7.58, N 6.69, P 7.39; found: C 54.52, H 7.53, N 6.61, P 7.70.

### 6-(4-Pentylphenyl)-3-[2-(phosphonomethoxy)ethyl]furo[2,3-d]pyrimidin-2(3H)-one (**11h**)

Treatment of **10h** (130 mg, 0.26 mmol) gave **11h** (85 mg, 78%) as white crystals (H<sub>2</sub>O/EtOH); mp 243–245 °C (dec). UV-vis  $\lambda_{\text{max}}$  (nm) ( $\epsilon$  ((mol/L)<sup>-1</sup> cm<sup>-1</sup>): 351 (16 400), 279 (20 500). <sup>1</sup>H NMR (DMSO-*d*<sub>6</sub>)  $\delta$ : 8.54 (s, 1H, H-4), 7.73 (m, 2H, *o*-Ph), 7.32 (m, 2H, *m*-Ph), 7.19 (s, 1H, H-5), 4.15 (m, 2H, H-1'), 3.81 (m, 2H, H-2'), 3.60 (d, 2H,  $J_{\text{H,P}}$  = 8.6 Hz, H-4'), 2.61 (t, 2H,  $J_{\text{vic}}$  = 7.6 Hz, H-1''), 1.64–1.53 (m, 2H, H-2''), 1.36–1.20 (m, 4H, H-3'' and H-4''), 0.86 (t, 3H,  $J$  = 7.0 Hz, H-5''). <sup>13</sup>C NMR (DMSO-*d*<sub>6</sub>)  $\delta$ : 171.3 (C-7a), 154.6 (C-6), 153.7 (C-2), 144.1 (C-*p*-Ph), 144.0 (C-4), 129.1 (C-*m*-Ph), 126.1 (C-*i*-Ph), 124.7 (C-*o*-Ph), 106.6 (C-4a), 98.6 (C-5), 69.3 (d,  $J_{\text{C,P}}$  = 10.5 Hz, C-2'), 66.5 (d,  $J_{\text{C,P}}$  =

160 Hz, C-4'), 50.4 (C-1'), 35.1 and 31.0 and 30.5 and 22.1 and 14.0 (*p*-pentyl). MS (ESI) *m/z*: 419 [M - H]<sup>-</sup>. Anal. calcd. for C<sub>20</sub>H<sub>25</sub>N<sub>2</sub>O<sub>6</sub>P (420.40): C 57.14, H 5.99, N 6.66, P 7.37; found: C 56.96, H 6.01, N 6.53, P 7.61.

### 1-{2-[(Diisopropoxyphosphoryl)methoxy]ethyl}-5-ethynyluracil (**14**)

TMSA (**13**; 0.9 mL, 640 mg, 6.51 mmol) and then Et<sub>3</sub>N (5.5 mL) were added to a suspension of **6** (2 g, 4.34 mmol), Pd(Ph<sub>3</sub>P)<sub>4</sub> (251 mg, 0.22 mmol), and CuI (83 mg, 0.44 mmol) in deoxygenated DMF (20 mL). The reaction was sealed with a septum and stirred at 45 °C for 1 h. Volatiles were evaporated in vacuo, and toluene was added to the residue and then evaporated (2 × 5 mL). The residue was flash chromatographed (4% MeOH/CHCl<sub>3</sub>) to give a yellowish solid upon drying. The TMS intermediate was dissolved in dry THF (40 mL), TBAF (1 mol/L THF solution, 5 mL) was added, and the reaction mixture was stirred at ambient temperature for 0.5 h. Volatiles were evaporated, the residue was dissolved in CHCl<sub>3</sub> (50 mL), and the solution was washed (saturated EDTA (aq.), and H<sub>2</sub>O) and dried (MgSO<sub>4</sub>). Volatiles were evaporated, and the residue was chromatographed (4% MeOH/CHCl<sub>3</sub>) and crystallized to give **14** (1.04 g, 63%) as white crystals (EtOAc/hexanes); mp 147–148 °C. <sup>1</sup>H NMR (600 MHz, DMSO-*d*<sub>6</sub>) δ: 11.64 (bs, 1H, NH), 7.97 (s, 1H, H-6), 4.55 (dh, 2H, *J*<sub>H,P</sub> = 7.7 Hz, *J*<sub>vic</sub> = 6.2 Hz, POCH), 4.08 (s, 1H, HC≡C), 3.90–3.87 (m, 2H, H-1'), 3.77 (d, 2H, *J*<sub>H,P</sub> = 8.3 Hz, H-4'), 3.72–3.69 (m, 2H, H-2'), 1.22 and 1.20 (2 × d, 2 × 6H, *J*<sub>vic</sub> = 6.2 Hz, CH<sub>3</sub>). <sup>13</sup>C NMR (150.9 MHz, DMSO-*d*<sub>6</sub>) δ: 162.4 (C-4), 150.5 (C-6), 150.1 (C-2), 96.6 (C-5), 83.7 (HC≡C), 76.5 (C≡CH), 70.4 (d, *J*<sub>C,P</sub> = 6.4 Hz, POC), 69.9 (d, *J*<sub>C,P</sub> = 11.5 Hz, C-2'), 64.9 (d, *J*<sub>C,P</sub> = 164 Hz, C-4'), 47.7 (C-1'), 24.0 (d, *J*<sub>C,P</sub> = 3.7 Hz, CH<sub>3</sub>), 23.9 (d, *J*<sub>C,P</sub> = 4.4 Hz, CH<sub>3</sub>). MS (ESI) *m/z*: 381 [M + Na]<sup>+</sup>. Anal. calcd. for C<sub>15</sub>H<sub>23</sub>N<sub>2</sub>O<sub>6</sub>P·1/4 EtOAc (380.35): C 50.52, H 6.63, N 7.37, P 8.14; found: C 50.28, H 6.68, N 7.20, P 8.43.

### 3-{2-[(Diisopropoxyphosphoryl)methoxy]ethyl}furo[2,3-*d*]pyrimidin-2(3*H*)-one (**15**)

A stirred suspension of **14** (620 mg, 1.63 mmol), CuI (310 mg, 1.63 mmol), Et<sub>3</sub>N (60 mL), and EtOAc (200 mL) was refluxed under argon for 12 h. Volatiles were evaporated, the residue was dissolved in hot MeOH (50 mL), and the solid filtered off. Volatiles were evaporated and the residue dissolved in CHCl<sub>3</sub> (80 mL). Organics were washed (2 × 30 mL of saturated EDTA (aq.), 1 × 20 mL H<sub>2</sub>O) and dried (MgSO<sub>4</sub>). Isolation by flash chromatography (8% MeOH/CHCl<sub>3</sub>) and crystallization afforded compound **15** (236 mg, 38%) as white crystals (EtOAc); mp 168 °C. <sup>1</sup>H NMR (500.0 MHz, DMSO-*d*<sub>6</sub>) δ: 8.54 (s, 1H, H-4), 7.73 (d, 1H, *J*<sub>6,5</sub> = 2.7 Hz, H-6), 6.81 (d, 1H, *J*<sub>5,6</sub> = 2.7 Hz, H-5), 4.49 (dh, 2H, *J*<sub>H,P</sub> = 7.7 Hz, *J*<sub>vic</sub> = 6.2 Hz, POCH), 4.17 (m, 2H, H-1'), 3.80 (m, 2H, H-2'), 3.77 (d, 2H, *J*<sub>H,P</sub> = 8.2 Hz, H-4'), 1.16 and 1.12 (2 × d, 2 × 6H, *J*<sub>vic</sub> = 6.2 Hz, CH<sub>3</sub>). <sup>13</sup>C NMR (125.8 MHz, DMSO-*d*<sub>6</sub>) δ: 171.7 (C-7a), 154.6 (C-2), 145.2 (C-4), 144.8 (C-6), 105.1 (C-5), 104.5 (C-4a), 70.3 (d, *J*<sub>C,P</sub> = 6.3 Hz, POC), 69.4 (d, *J*<sub>C,P</sub> = 11.4 Hz, C-2'), 64.8 (d, *J*<sub>C,P</sub> = 163.8 Hz, C-4'), 50.9 (C-1'), 23.9 (d, *J*<sub>C,P</sub> = 3.7 Hz, CH<sub>3</sub>), 23.8 (d, *J*<sub>C,P</sub> = 4.6 Hz, CH<sub>3</sub>). MS (ESI) *m/z*: 359 [M + H]<sup>+</sup>.

Anal. calcd. for C<sub>15</sub>H<sub>23</sub>N<sub>2</sub>O<sub>6</sub>P (358.13): C 50.28, H 6.47, N 7.82, P 8.64; found: C 50.22, H 6.53, N 7.69, P 8.98.

### 3-[2-(Phosphonomethoxy)ethyl]furo[2,3-*d*]pyrimidin-2(3*H*)-one (**16**)

A mixture of compound **15** (150 mg, 0.42 mmol), bromo(trimethyl)silane (1.00 mL, 1.16 g, 7.58 mmol), and acetonitrile (5 mL) was stirred at room temperature overnight. The mixture was concentrated in vacuo and then codistilled with a mixture of water/ethanol (9:1, 2 × 5 mL). The residue was crystallized to give **16** (85 mg, 74%) as yellowish crystals (EtOAc/EtOH 3:1), dec. over 200 °C. UV-vis λ<sub>max</sub> (nm) (ε ((mol/L)<sup>-1</sup> cm<sup>-1</sup>): 325 (5200), 238 (8700). <sup>1</sup>H NMR (500.0 MHz, D<sub>2</sub>O) δ: 8.55 (s, 1H, H-4), 7.58 (d, 1H, *J*<sub>6,5</sub> = 2.7 Hz, H-6), 6.80 (d, 1H, *J*<sub>5,6</sub> = 2.7 Hz, H-5), 4.31 (m, 2H, H-1'), 3.94 (m, 2H, H-2'), 3.71 (d, 2H, *J*<sub>H,P</sub> = 8.7 Hz, H-4'). <sup>13</sup>C NMR (125.8 MHz, D<sub>2</sub>O) δ: 174.3 (C-7a), 159.6 (C-2), 148.3 (C-4 and C-6), 110.4 (C-4a), 107.8 (C-5), 72.5 (d, *J*<sub>C,P</sub> = 11.7 Hz, C-2'), 69.0 (d, *J*<sub>C,P</sub> = 158.7 Hz, C-4'), 54.4 (C-1'). MS (ESI) *m/z*: 273 [M - H]<sup>-</sup>. Anal. calcd. for C<sub>9</sub>H<sub>11</sub>N<sub>2</sub>O<sub>6</sub>P·1/3H<sub>2</sub>O (280.17): C 38.58, H 4.20, N 10.00, P 11.06; found: C 38.80, H 4.33, N 9.66, P 10.82.

### 5,5'-Buta-1,3-diyne-1,4-diylbis{(1-{2-[(diisopropoxyphosphoryl)methoxy]ethyl}-uracil)} (**17**)

A stirred suspension of **14** (400 mg, 1.11 mmol), CuI (213 mg, 1.11 mmol), Et<sub>3</sub>N (6 mL), and MeOH (14 mL) was refluxed for 5 h. Reddish gel was formed. DMF (2 mL) was added and the reaction stirred at room temperature overnight. TLC (20% MeOH/CHCl<sub>3</sub>) showed complex mixture. Volatiles were flash evaporated and the residue codistilled with toluene (2 × 5 mL). Flash chromatography (15% MeOH/CHCl<sub>3</sub>) and crystallization gave compound **17** (82 mg, 10%) as yellow crystals (EtOAc/EtOH), dec. over 240 °C. <sup>1</sup>H NMR (500.0 MHz, DMSO-*d*<sub>6</sub>) δ: 11.77 (bs, 2H, NH), 8.15 (s, 2H, H-6), 4.56 (dh, 4H, *J*<sub>H,P</sub> = 7.7 Hz, *J*<sub>vic</sub> = 6.2 Hz, POCH), 3.90 (t, 4H, *J*<sub>1',2'</sub> = 4.8 Hz, H-1'), 3.78 (d, 4H, *J*<sub>H,P</sub> = 8.3 Hz, H-4'), 3.71 (t, 4H, *J*<sub>2',1'</sub> = 4.8 Hz, H-2'), 1.23 and 1.21 (2 × d, 2 × 12H, *J*<sub>vic</sub> = 6.2 Hz, CH<sub>3</sub>). <sup>13</sup>C NMR (125.8 MHz, DMSO-*d*<sub>6</sub>) δ: 162.3 (C-4), 152.0 (C-6), 149.9 (C-2), 95.8 (C-5), 76.7 (C≡C-C≡C), 75.4 (C≡C-C≡C), 70.4 (d, *J*<sub>C,P</sub> = 6.4 Hz, POC), 69.8 (d, *J*<sub>C,P</sub> = 11.6 Hz, C-2'), 64.9 (d, *J*<sub>C,P</sub> = 163.7 Hz, C-4'), 48.0 (C-1'), 24.0 (d, *J*<sub>C,P</sub> = 3.7 Hz, CH<sub>3</sub>), 23.9 (d, *J*<sub>C,P</sub> = 4.5 Hz, CH<sub>3</sub>). MS (ESI) *m/z*: 737 [M + Na]<sup>+</sup>. HR-MS (ESI) *m/z*: C<sub>30</sub>H<sub>45</sub>N<sub>4</sub>O<sub>12</sub>P<sub>2</sub> [M + H]<sup>+</sup>. Anal. calcd.: 715.2504; found: 715.2504.

## Antiviral activity assays

Varicella-zoster virus (VZV) drug susceptibility tests were performed on confluent hen egg lysozyme (HEL) cells in 96-well microtiter plates by the plaque reduction assay. Monolayers were infected with 20 plaque forming units (PFU) of cell-associated virus per well. For each assay, virus controls (infected–untreated cells) were included. After a 2 h incubation period, the virus inoculum was removed and the media replaced by the different dilutions (in duplicate) of the tested molecules. Serial dilutions of test compounds were incubated with the infected monolayers for 5 d. After a 5 d incubation period, the cells were fixed and stained

with Giemsa, and the level of virus-induced cytopathic effect was determined by counting the number of plaques for each dilution. Activity was expressed as EC<sub>50</sub> (effective compound concentration required to reduce virus plaque formation by 50%) compared to the untreated control.

For the HCMV assays, confluent HEL fibroblasts were grown in 96-well microtiter plates and infected with the human cytomegalovirus strains Davis and AD-169 at 100 PFU per well. After a 2 h incubation period, residual virus was removed and the infected cells were further incubated with medium containing different concentrations of the test compounds (in duplicate). After incubation for 7 d at 37 °C, virus-induced cytopathogenicity was monitored microscopically after ethanol fixation and staining with Giemsa. Antiviral activity was expressed as the EC<sub>50</sub> or compound concentration required to reduce virus-induced cytopathogenicity by 50%.

To examine the inhibitory effect of the compounds against virus-induced cytopathicity in HEL cells (herpes simplex virus type 1 (HSV-1), HSV-2 (G), vaccinia virus, and vesicular stomatitis virus), confluent cell cultures in microtiter 96-well plates were inoculated with 100 CCID<sub>50</sub> of virus (1 CCID<sub>50</sub> being the virus dose to infect 50% of the cell cultures). After a 1 h virus adsorption period, residual virus was removed, and the cell cultures were incubated in the presence of varying concentrations (200, 40, 8, ... μmol/L) of the test compounds. Viral cytopathicity was recorded as soon as it reached completion in the control virus-infected cell cultures that were not treated with the test compounds.

The methodology of the anti-HIV assays was as follows: human T-lymphocyte CEM (~3 × 10<sup>5</sup> cells/cm<sup>3</sup>) cells were infected with 100 CCID<sub>50</sub> of HIV-1(III<sub>B</sub>) or HIV-2(ROD)/mL and seeded in 200 μL wells of a microtiter plate containing appropriate dilutions of the test compounds. After 4 d of incubation at 37 °C, HIV-induced CEM giant cell formation was examined microscopically.

## Acknowledgments

This study was performed as a part of research project (OZ40550506) of the Institute of Organic Chemistry and Biochemistry, v.v.i. This study was supported by the Center for New Antivirals and Antineoplastics (IM0508) by the Ministry of Education, Youth and Sports of the Czech Republic, and by Gilead Sciences and the Institute of Organic Chemistry and Biochemistry (IOCB) Research Centre. The research of JB was supported by the "Geconcerteerde Onderzoeksacties Vlaanderen" (GOA no. 05/19). We thank Leentje Persoons, Vicky Broeckx, Frieda De Meyer, Anita Camps, Lies Van den Heurck, Steven Carmans, and Leen Ingels for excellent technical assistance.

# A new family of bent-core $C_2$ -symmetric liquid crystals

Kyle A. Hope-Ross, Paul A. Heiney, and John F. Kadla

**Abstract:** A series of  $C_2$ -symmetric compounds with different core sizes and varying lengths and numbers of alkoxy side chains were prepared, and the factors influencing their liquid crystalline mesophase behaviour were investigated. The compounds studied were based on benzophenone, dibenzylidene-acetone, and 1,9-diphenyl-nona-1,3,6,8-tetraen-5-one cores with either 1 or 2 linear alkoxy side chains. The side chains were varied in length from  $C_6H_{13}$  to  $C_{12}H_{25}$ . The liquid crystalline mesophase behaviour of the compounds was investigated using differential scanning calorimetry, polarizing optical microscopy, and small-angle X-ray scattering (SAXS). It was found that a number of the molecules were able to self-assemble into smectic and nematic liquid crystalline phases.

**Key words:** mesophase,  $C_2$  symmetric, SAXS, benzophenone, dibenzylidene-acetone and 1,9-diphenyl-nona-1,3,6,8-tetraen-5-one.

**Résumé :** On a réalisé la synthèse d'une série de composés de symétrie  $C_2$  comportant des coeurs de tailles différentes et des quantités diverses de chaînes latérales alcoyles de longueurs variables et on a étudié les facteurs qui influencent leur comportement comme mésophase de cristal liquide. Les composés étudiés ont des coeurs à base de benzophénone, de dibenzylidèneacétone et de 1,9-diphényl-1,3,6,8-tétraén-5-one et des chaînes latérales alcoyles linéaires en positions 1 ou 2. Les longueurs de chaînes latérales varient de  $C_6H_{13}$  à  $C_{12}H_{25}$ . On a étudié leur comportement comme mésophase de cristal liquide en faisant appel à la calorimétrie à balayage différentiel, à la microscopie optique polarisante et par la diffusion des rayons-X à angle faible (DXAF). On a trouvé qu'un certain nombre de molécules peuvent s'autoassembler en phases de cristal liquide smectique et nématique.

**Mots-clés :** mésophase, symétrie  $C_2$ , diffusion des rayons X à angle faible (DXAF), benzophénone, dibenzylidèneacétone, 1,9-diphényl-1,3,6,8-tétraén-5-one.

## Introduction

Liquid crystals are a growing field of research with applications in a wide variety of devices, including photovoltaic solar cells,<sup>1</sup> light-emitting diodes,<sup>2</sup> and displays.<sup>3</sup>

Traditionally, molecules displaying liquid crystalline mesophases display a structure that consists of a flat, rigid (usually aromatic) core with multiple, usually aliphatic, flexible side chains.<sup>4</sup> Liquid crystalline molecules can consist of disc-like,<sup>5</sup> linear<sup>6</sup> or bent-shaped<sup>7</sup> core structures. In addition, owing to their inherent ability to self-assemble, based largely on  $\pi$ -stacking interactions, any factor that influences the electronic structure of the core will affect the ability of the molecules to form liquid crystalline mesophases.<sup>8</sup> It has been shown that alkyl side-chain length,<sup>9,10</sup> electronics,<sup>11</sup> and core size<sup>12</sup> all have an impact on molecular self-assembly. To fully exploit the potential applications of liquid crystalline materials, we must fully understand the variables that have an effect on mesophase formation.

Herein, we report the synthesis and characterization of a

new family of bent-core  $C_2$ -symmetric molecules, and discuss various factors that affect their ability to self-assemble into liquid crystalline mesophases. The compounds prepared were based on a benzophenone (**1**), dibenzylidene acetone (**2**), and 1,9-diphenyl-nona-1,3,6,8-tetraen-5-one (**3**) core (Fig. 1) with either one or two linear alkoxy side chains varying in length from  $C_6H_{13}$  to  $C_{12}H_{25}$ .

## Experimental section

All chemicals were purchased from Sigma-Aldrich (Oakville, ON) and used without further purification unless otherwise noted.

### General procedure for the synthesis of 4,4'-bis(alkyloxy)benzophenones (**1a–1d**)

#### 4,4'-Bis(hexyloxy)benzophenone (**1a**)

To a solution of 4,4'-dihydroxybenzophenone (0.50 g, 2.33 mmol) and potassium carbonate (1.29 g, 9.34 mmol) in ace-

tone (25 mL) was added 1-bromohexane (1.54 g, 9.34 mmol) dropwise. The resulting mixture was heated and allowed to reflux. After 48 h, the reaction mixture was poured into water (200 mL) and extracted with  $\text{CH}_2\text{Cl}_2$  ( $3 \times 75$  mL). The combined organic layers were washed with water (300 mL), dried over  $\text{MgSO}_4$ , filtered, and the solvent was removed in vacuo. Recrystallization from acetone afforded **1a** (0.86 g, 97%) as white crystals, mp 102–105 °C. IR (thin film,  $\text{cm}^{-1}$ ): 2955, 2938, 2863, 1636, 1604, 1256, 853, 764.  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.79 (d,  $J$  = 8.66 Hz, 4H), 6.96 (d,  $J$  = 8.66 Hz, 4H), 4.05 (t,  $J$  = 6.58 Hz, 4H), 1.84 (quin.,  $J$  = 6.58 Hz, 4H), 1.56–1.31 (m, 12H), 0.94 (t,  $J$  = 6.58 Hz, 6H).  $^{13}\text{C}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$ : 194.5, 162.4, 132.2, 130.6, 113.9, 68.2, 31.6, 29.1, 25.7, 22.6, 14.0. Anal. calcd. for  $\text{C}_{25}\text{H}_{34}\text{O}_3$ : C, 78.49; H, 8.96. Found: C, 78.58; H, 8.73.

#### General procedure for the synthesis of 3,3',4,4'-tetrakis(alkoxy)benzophenones (**1e–1h**)

##### 3,3',4,4'-Tetrakis(hexyloxy)benzophenone (**1e**)

To a solution of 3,4-bis(hexyloxy)benzoic acid (**9e**, 0.34 g, 1.06 mmol) and diethylamine (0.50 mL) in  $\text{CH}_2\text{Cl}_2$  was added  $\text{SOCl}_2$  (5 mL) dropwise. The resulting solution was heated to reflux for 1.5 h. Excess  $\text{SOCl}_2$ , diethylamine, and  $\text{CH}_2\text{Cl}_2$  were removed in vacuo, and the resultant acid chloride was added as a solution in  $\text{CH}_2\text{Cl}_2$  (15 mL) to a mixture of  $\text{AlCl}_3$  (0.14 g, 1.06 mmol) and 1,2-bis(hexyloxy)benzene (**5e**, 0.29 g, 1.06 mmol) in  $\text{CH}_2\text{Cl}_2$  (15 mL) at 0 °C under  $\text{N}_2$  atmosphere. The reaction mixture was stirred for 1 h, warmed to RT, and stirred overnight. The green solution was quenched with  $\text{H}_2\text{O}$  (10 mL), poured into 2.0 mol/L HCl (200 mL), and the organic phase was separated. The aqueous layer was extracted with  $\text{CH}_2\text{Cl}_2$  ( $3 \times 75$  mL), and the combined organic phases were washed with  $\text{H}_2\text{O}$  (200 mL) and brine (200 mL), dried over  $\text{MgSO}_4$ , filtered, and the solvent was removed in vacuo. Recrystallization from acetone afforded **1e** (0.37 g, 60%) as a white powder, mp 44–48 °C. IR (thin film,  $\text{cm}^{-1}$ ): 2931, 2860, 1649, 1595, 1513, 1428, 1266, 1135, 1017, 760.  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.42 (d,  $J$  = 1.86 Hz, 2H), 7.37 (dd,  $J_1$  = 8.33 Hz,  $J_2$  = 1.86 Hz, 2H), 6.90 (d,  $J$  = 8.33 Hz, 2H), 4.09 (t,  $J$  = 6.58 Hz, 4H), 4.06 (t,  $J$  = 6.58 Hz, 4H), 1.93–1.79 (m, 8H), 1.58–1.30 (m, 24H), 0.93 (t,  $J$  = 6.58 Hz, 6H), 0.92 (t,  $J$  = 6.58 Hz, 6H).  $^{13}\text{C}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$ : 194.6, 152.8, 148.7, 130.7, 124.7, 114.7, 111.5, 69.3, 69.1,

31.58, 31.56, 29.2, 29.1, 25.69, 25.66, 22.6 (4C), 14.0 (4C). Anal. calcd. for  $\text{C}_{37}\text{H}_{58}\text{O}_5$ : C, 76.25; H, 10.03. Found: C, 76.06; H, 10.09.

#### General procedure for the synthesis of 1,5-bis(4-alkoxyphenyl)-penta-1,4-dien-3-ones (**2a–2d**)

##### 1,5-Bis(4-hexyloxy-phenyl)-penta-1,4-dien-3-one (**2a**)

A solution of sodium hydroxide (0.39 g, 9.75 mmol) in water (5 mL) and ethanol (5 mL) was cooled to 0 °C for 30 min. To this solution was added acetone (0.11 g, 1.95 mmol) and 4-hexyloxy-benzaldehyde (**11a**, 0.80 g, 3.90 mmol). The resulting solution was allowed to stir at room temperature. After 3 days, the reaction mixture was poured into 2.0 mol/L HCl (200 mL), and the organic phase was separated. The aqueous phase was extracted with dichloromethane ( $2 \times 150$  mL) and washed with water (250 mL). The combined organic phases were dried over  $\text{MgSO}_4$ , filtered, and the solvent was removed in vacuo. Recrystallization from EtOH afforded **2a** as yellow crystals (0.49 g, 58%), mp 97–100 °C. IR (thin film,  $\text{cm}^{-1}$ ): 2934, 2869, 1651, 1599, 1574, 1512, 1177, 1030, 983.  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.72 (d,  $J$  = 15.78 Hz, 2H), 7.58 (d,  $J$  = 8.66 Hz, 4H), 6.97 (d,  $J$  = 15.78 Hz, 2H), 6.94 (d,  $J$  = 8.66 Hz, 4H), 4.02 (t,  $J$  = 6.58 Hz, 4H), 1.82 (quin.,  $J$  = 6.58 Hz, 4H), 1.54–1.29 (m, 12H), 0.93 (t,  $J$  = 6.58 Hz, 6H).  $^{13}\text{C}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$ : 188.9, 161.2, 142.7, 130.1, 127.4, 123.4, 114.9; 68.2, 31.6, 29.1, 25.7, 22.6, 14.0. Anal. calcd. for  $\text{C}_{29}\text{H}_{38}\text{O}_3$ : C, 80.14; H, 8.81. Found: C, 80.03; H, 8.64.

#### General procedure for the synthesis of 1,5-bis(3,4-bis(alkoxy-phenyl))-penta-1,4-dien-3-ones (**2e–2h**)

##### 1,5-Bis(3,4-bis(hexyloxy-phenyl))-penta-1,4-dien-3-one (**2e**)

To a solution of 4-(3,4-bis(hexyloxy-phenyl))-but-3-en-2-one (**12e**, 0.50 g, 1.44 mmol) and 3,4-bis(hexyloxy)benzaldehyde (**11e**, 0.44 g, 1.44 mmol) in methanol (20 mL) was added sodium methoxide (25 wt% solution in MeOH, 0.94 mL, 4.33 mmol) dropwise. The resulting solution was heated to reflux. After 48 h, the reaction mixture was poured into 2.0 mol/L HCl (200 mL), and the organic phase was separated. The aqueous phase was extracted with  $\text{CH}_2\text{Cl}_2$  ( $3 \times 75$  mL). The combined organics were washed with  $\text{H}_2\text{O}$  ( $2 \times 200$  mL), dried over  $\text{MgSO}_4$ , filtered, and the solvent was removed in vacuo. Recrystallization from acetone afforded **2e** (0.52 g, 57%) as a yellow powder, mp 62–65 °C. IR (thin film,  $\text{cm}^{-1}$ ): 2955, 2931, 2860, 1648, 1618, 1595, 1511, 1468, 1432, 1258, 1234, 1172, 1137, 1095, 1017.  $^1\text{H}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$ : 7.69 (d,  $J$  = 15.78 Hz, 2H), 7.21–7.15 (m, 4H), 6.95 (d,  $J$  = 15.78 Hz, 2H), 6.90 (d,  $J$  = 8.33 Hz, 2H), 4.07 (t,  $J$  = 6.58 Hz, 4H), 4.06 (t,  $J$  = 6.58 Hz, 4H), 1.87 (quin.,  $J$  = 6.58 Hz, 4H), 1.86 (quin.,  $J$  = 6.58 Hz, 4H), 1.56–1.26 (m, 24H), 0.94 (t,  $J$  = 6.58 Hz, 6H), 0.93 (t,  $J$  = 6.58 Hz, 6H).  $^{13}\text{C}$  NMR (300 MHz,  $\text{CDCl}_3$ )  $\delta$ : 188.8, 151.6, 149.2, 143.1, 127.8, 123.5, 123.1, 113.0, 112.6, 69.4, 69.1, 31.59, 31.56, 29.2, 29.1, 25.71, 25.67, 22.62, 22.59, 14.03, 14.01. ## General procedure for the synthesis of 1,9-bis(4-alkoxy-phenyl)-nona-1,3,6,8-tetraen-5-ones (3a–3d)

### 1,9-Bis(4-hexyloxy-phenyl)-nona-1,3,6,8-tetraen-5-one (3a)

To a solution of 6-(4-hexyloxy-phenyl)-hexa-3,5-dien-2-one (**18a**, 0.20 g, 0.73 mmol) and 4-hexyloxy-cinnamaldehyde (**17a**, 0.17 g, 0.73 mmol) in THF (15 mL) was added NaOMe (25 wt% in MeOH, 0.48 mL, 2.20 mmol) dropwise. The resulting dark orange solution was allowed to stir at RT. After 30 min, the reaction mixture was poured into 2.0 mol/L HCl (100 mL), and the organic phase was separated. The aqueous phase was extracted with CH<sub>2</sub>Cl<sub>2</sub> (3 × 75 mL), and the combined organics were washed with H<sub>2</sub>O (2 × 200 mL), dried over MgSO<sub>4</sub>, filtered, and the solvent was removed in vacuo. Recrystallization from acetone afforded **3a** as a green/yellow solid (0.22 g, 62%), mp 147–151 °C. IR (thin film, cm<sup>-1</sup>): 2926, 2851, 1655, 1592, 1509, 1464, 1359, 1257, 1174, 1071, 1005, 854, 821. <sup>1</sup>H NMR (300 MHz, CDCl<sub>3</sub>) δ: 7.48 (dd, *J*<sub>1</sub> = 15.13 Hz, *J*<sub>2</sub> = 10.41 Hz, 2H), 7.44 (d, *J* = 8.66 Hz, 4H), 6.95 (d, *J* = 15.46 Hz, 2H), 6.90 (d, *J* = 8.66 Hz, 4H), 6.84 (dd, *J*<sub>1</sub> = 15.46 Hz, *J*<sub>2</sub> = 10.41 Hz, 2H), 6.53 (d, *J* = 15.13 Hz, 2H), 4.0 (t, *J* = 6.58 Hz, 4H), 1.81 (quin., *J* = 6.58 Hz, 4H), 1.55–1.30 (m, 12H), 0.91 (t, *J* = 6.58 Hz, 6H). <sup>13</sup>C NMR (300 MHz, CDCl<sub>3</sub>) δ: 189.0, 160.2, 143.3, 141.2, 128.8, 128.7, 128.1, 124.8, 114.9, 68.2, 31.6, 29.2, 25.7, 22.6, 14.0. Anal. calcd. for C<sub>33</sub>H<sub>42</sub>O<sub>3</sub>: C, 81.44; H, 8.70. Found: C, 80.56; H, 8.68.

### Characterization

Small-angle X-ray scattering (SAXS) measurements employed a Bruker-Nonius FR591 rotating-anode generator with a copper anode operated at 3.4 kW. The beam was collimated and focused with Osmic confocal optics and pinholes, and the scattered radiation was detected using a Bruker Hi-Star wire (area) detector.<sup>13</sup> Samples were sealed in 1 mm diameter glass capillaries. Measurements were made at fixed sample–detector distances of 54 and 11 cm; the presence or absence of crystalline (three-dimensional order) was established from the 11 cm data sets, while the final refinement of the liquid crystal unit cell parameters was made using the data from the 54 cm configuration. In situ temperature-dependent measurements employed a Linkam heating cell. Primary data analysis was performed using Datasqueeze.<sup>14</sup>

Differential scanning calorimetry (DSC) measurements were performed on a TA Instruments Q1000 DSC. All experiments were run with 1–3 mg of sample in aluminum hermetic pans at heating rates of 10 °C/min and cooling rates of 5 °C/min unless otherwise noted. The samples were initially analyzed at temperatures between –90 °C and 250 °C with subsequent runs performed only in the temperature range displaying phase transitions.

<sup>1</sup>H and <sup>13</sup>C NMR spectra were recorded using a 300 MHz Bruker Avance Ultrashield NMR Spectrometer (300.13 and 75.03 MHz, respectively) at concentrations of approximately 10 mg/mL and referenced to CDCl<sub>3</sub> (7.28 ppm) or acetone-*d*<sub>6</sub> (2.05 ppm). The number of scans used was 16 for <sup>1</sup>H NMR and 3072 for <sup>13</sup>C NMR.

Polarizing optical microscopy (POM) was performed on an Olympus BX41 Microscope equipped with an Instec

HCS402 Hot Stage and STC200 Temperature Controller. All samples that exhibited multiple endothermic transitions on heating or multiple exothermic transitions on cooling by DSC analysis were characterized by POM. In a typical experiment, 5–10 mg of sample was heated to the clearing point, which was estimated by DSC, and cooled slowly to observe the liquid crystalline textures. POM images were captured with a Lumenera Infinity1 Digital Camera and were recorded and analyzed using InfinityCapture software.

## Results and discussion

### Synthesis

The synthesis of the mono-alkoxy-substituted benzophenones **1a–1d** simply involved appending the alkoxy chains onto commercially available 4,4'-dihydroxy-benzophenone using the Williamson ether synthesis<sup>15</sup> (eq. [1]).

The synthesis of the bis(alkoxy)benzophenones (**1e–1h**) involved a Friedel–Crafts acylation<sup>16</sup> between 3,4-bis(alkoxy)-benzoic acids (**9e–9h**) and 3,4-bis(alkoxy)benzenes (**5e–5h**) (Scheme 1). The 3,4-bis(alkoxy)benzenes (**5e–5h**) were achieved via a Williamson ether synthesis between catechol (**5**) and the appropriate *n*-alkyl bromides (94%–100%). The substituted benzoic acids were achieved in three steps from 3,4-dihydroxybenzoic acid (**7**). First, **6** was protected as its methyl ester **7** by Fischer esterification,<sup>17</sup> then Williamson conditions were used to append the alkoxy chains to achieve esters **8e–8h**<sup>18</sup> in yields ranging from 96% (C<sub>6</sub>) to 100% (C<sub>8</sub>). Finally, saponification of **8e–8h**<sup>19</sup> afforded the benzoic acid coupling precursors **9e–9h** in yields from 88% (C<sub>10</sub>) to 99% (C<sub>8</sub>). Benzoic acids **9e–9h** were first converted to their respective acid chlorides using thionyl chloride and diethylamine.

**Scheme 1.** Synthesis of 3,4-bis(alkoxy)benzophenones (**1e–1h**).

**Scheme 2.** Synthesis of mono-alkoxy dibenzylidene-acetones **2a–2d**.

Reagents and conditions: (i) RBr, K<sub>2</sub>CO<sub>3</sub>, DMF (86%–100%)

**Scheme 3.** Synthesis of bis(alkoxy)dibenzylidene-acetones (**2e–2h**).

Reagents and conditions: (i) RBr, K<sub>2</sub>CO<sub>3</sub>, DMF (89%–100%)

The acid chlorides were then added to a solution containing **5e–5h** and AlCl<sub>3</sub>. The benzophenones **1e–1h** were achieved in five steps with overall yields from 40% (C<sub>12</sub>) to 52% (C<sub>8</sub>).

The synthesis of the mono-alkoxy-substituted dibenzylidene acetones **2a–2d** involved a bidirectional aldol condensation between 1 equiv. of acetone and 2 equiv. of 4-alkoxybenzaldehydes (**11a–11d**), which were achieved again using a Williamson ether synthesis between 4-hydroxybenzaldehyde (**10**) and the appropriate *n*-alkyl bromides<sup>20</sup> (Scheme 2).

The attempted procedure of a bidirectional aldol condensation to achieve the di-alkoxy-substituted dibenzylidene acetones **2e–2h** in a method analogous to that of **2a–2d** proved difficult, with the reaction yielding an inseparable mixture of the mono- and bis-aldol condensation products. Instead, two stepwise aldol condensations were employed, the first reaction between 1 equiv. of acetone and 1 equiv. of 3,4-alkoxybenzaldehydes (**11e–11h**), and the second reaction between the resulting 4-(4-alkoxy-phenyl)but-3-en-2-ones (**12e–12h**) and a second equiv. of benzaldehydes **11e–11h** (Scheme 3).

The synthesis of mono-alkoxy 1,9-diphenyl-nona-1,3,6,8-tetraen-5-ones (**3a–3d**) was performed in a method analogous to that of **2e–2h**, employing stepwise aldol condensations between acetone and 4-alkoxy cinnamaldehydes. The latter were obtained, after various functional group interconversions, from commercially available *p*-coumaric acid (Scheme 4). The synthesis proceeded in six linear steps with overall yields of 42% (C<sub>10</sub>) to 56% (C<sub>12</sub>).

First, *p*-coumaric acid (**13**) was converted to its methyl ester **14** by Fischer esterification in 97% yield. The alkoxy

<sup>a</sup>Cr = crystalline, Sm = Smectic, I = Isotropic.

chains were appended by the Williamson ether synthesis to afford **15a–15d** in yields from 90% to 98%. Attempted DIBAL reduction to the aldehydes **17a–17d**<sup>21</sup> led to a 1:1 mixture of completely reduced alcohol **16a–16d** and unreacted ester **15a–15d**. Instead, a strategy of complete reduction to the alcohol and subsequent reoxidation to the aldehyde was employed. The attempted reduction using LAH<sup>22</sup> resulted in reduction of esters **15a–15d** as well as hydrogenation of the olefin; a known result that seems to be limited to cinnamic acid derivatives.<sup>23</sup> A reduction using an excess of DIBAL afforded the cinnamyl alcohols **16a–16d** in yields ranging from 93% to 96%. Oxidation using the Corey–Suggs reagent PCC<sup>24</sup> led to both the desired α,β-unsaturated aldehydes **17a–17d** (minor) as well as the oxidative olefin cleavage byproduct<sup>23</sup> benzaldehyde (major). Instead, an oxidation using DDQ in dioxane<sup>25</sup> gave **17a–17d** in excellent yields (97% to 100%). Stepwise aldol condensations; the first between 1 equiv. of aldehydes **17a–17d** and acetone, and the second between the resulting 6-(4-alkoxy-phenyl)-hexa-3,5-dien-2-ones (**18a–18d**) and a second equiv. of **17a–17d**, gave the desired 1,9-diphenyl-nona-1,3,6,8-tetraen-5-ones (**3a–3d**) in yields of 49% to 67% over two steps.

### Characterization

It was found that neither the mono-alkoxybenzophenone derivatives **1a–1d** nor the bis(alkoxy)benzophenones (**1e–1h**) were mesogenic. Of the bis(alkoxy)benzophenones, **1e** was seen in SAXS measurements to undergo a crystal-to-

<sup>a</sup>Cr = crystalline, N = Nematic, I = Isotropic.

crystal transition at ~50 °C and to melt at ~100 °C. The phase behaviour of **1a–1h** is outlined in Table 1.

It was found the mono-alkoxy dibenzylidene acetone derivatives **2a–2d** were non-mesogenic. By contrast, the C<sub>6</sub>, C<sub>8</sub>, and C<sub>10</sub> bis(alkoxy)dibenzylidene acetones **2e**, **2f**, and **2g** were found to self-assemble into nematic mesophases. Figure 2 displays POM images of **2e** and **2f** taken at a magnification of 10×, and the phase behaviour of **2a–2h** is outlined in Table 2.

SAXS measurements confirm the assignments of **2e**, **2f**, and **2g** to nematic mesophases above room temperature. A diffuse maximum in the scattering from **2e** is consistent

with a nematic phase with a typical dimension of the cybotatic group of 2.1 nm and a correlation that increases upon cooling from 1.2 nm near the clearing point to 3.0 nm at room temperature. Compound **2f** shows similar behaviour, with a cybotatic dimension of 2.4 nm and a correlation length of 2.0 nm, and similarly **2g** has a nematic cybotatic dimension of 2.6 nm and a correlation length of ~2 nm.

It was found that all four 1,9-diphenyl-nona-1,3,6,8-tetra-en-5-one derivatives self-assembled into nematic liquid crystalline phases. Figure 3 displays POM images of **3b** and **3d** in the nematic phase taken at a magnification of 10×, and the phase behaviour of **3a–3d** is outlined in Table 3.

SAXS on **3a** and **3b** were consistent with nematic phases at high temperature, but low signal levels precluded accurate measurement of cybotatic dimensions or correlation length. However, SAXS measurements on **3c** and **3d** showed sharp diffraction peaks with lamellar *d* spacings of 3.3 nm (**3c**) and 3.5 nm (**3d**), clearly indicating a smectic phase and inconsistent with the nematic texture observed in POM (Fig. 3). The reasons for this discrepancy are unclear, but are likely related to differences either in thermal history or anchoring effects by the glass slides and glass capillaries used in the two measurements.

**Fig. 2.** Polarized optical micrographs of (a) **2e** at 55 °C and (b) **2f** at 62 °C (10× magnification).

**Fig. 3.** Polarized optical micrographs of (a) **3b** at 136 °C and (b) **3d** at 122 °C (10× magnification).

## Conclusions

In summary, we have synthesized a new series of  $C_{2\text{-symmetric}}$  compounds, which display liquid crystalline mesophase behaviour. It was determined that the size of the rigid core, the length of the alkoxy side chain, and the number of alkoxy side chains have an impact on the ability of the molecules to self-assemble into liquid crystalline mesophases. Increasing the core size as well as increasing the number of side chains helped induce mesophase formation. In addition, increasing the length of the alkoxy side chain expanded the temperature range of the mesophase for the 1,9-diphenyl-nona-1,3,6,8-tetraen-5-ones.

## Supplementary data

Supplementary data for this article (detailed experimental procedures as well as spectral and analytical data, including  $^1\text{H}$  and  $^{13}\text{C}$  NMR spectra, DSC thermograms, and POM micrographs) are available on the journal Web site (canjchem.nrc.ca).

# Radiolysis of supercritical water at 400 °C and liquid-like densities near 0.5 g/cm<sup>3</sup> — A Monte Carlo calculation

Jintana Meesungnoen, David Guzonas, and Jean-Paul Jay-Gerin

**Abstract:** Monte Carlo simulations are used to calculate the primary radical yields  $g(e_{aq}^-)$ ,  $g(^{\bullet}OH)$ , the sum  $[g(e_{aq}^-) + g(^{\bullet}OH) + g(H^{\bullet})]$ , and the ratio  $g(H^{\bullet})/g(e_{aq}^-)$  in the low linear energy transfer (LET) radiolysis of supercritical water (SCW) at 400 °C in the high-density, liquid-like region near  $\sim 0.5$  g/cm<sup>3</sup>. Using all the currently available information on the reactivities and diffusion coefficients of the radiation-induced species under these conditions, and assuming the aqueous medium to be a “continuum”, a good accord is found between our calculations and the available experimental data. In particular, our computed  $e_{aq}^-$  yields at 60 ps and 1 ns compare very well with recently reported direct time-dependent  $e_{aq}^-$  yield measurements in SCW (D<sub>2</sub>O) at 400 °C and 0.570 g/cm<sup>3</sup> using picosecond pulse radiolysis experiments.

**Key words:** supercritical water, radiolysis, hydrated electron,  $^{\bullet}OH$  radical,  $H^{\bullet}$  atom, rate constants, diffusion coefficients, primary radiolytic yields ( $g$  values), Monte Carlo track structure simulations.

**Résumé :** À l'aide de simulations Monte Carlo, nous avons calculé, pour des rayonnements de faible transfert d'énergie linéique (TEL), les rendements primaires radicalaires ( $g(e_{aq}^-)$ ),  $g(^{\bullet}OH)$ , la somme  $[g(e_{aq}^-) + g(^{\bullet}OH) + g(H^{\bullet})]$  et le rapport  $g(H^{\bullet})/g(e_{aq}^-)$  intervenant lors de la radiolyse de l'eau à l'état supercritique (ESC) à 400 °C dans la région de haute densité de type liquide autour de  $\sim 0,5$  g/cm<sup>3</sup>. En utilisant toute les renseignements actuellement disponibles sur les réactivités et les coefficients de diffusion des espèces radio induites dans ces conditions et en considérant le milieu aqueux comme un « continuum », un bon accord a été trouvé entre nos calculs et les données expérimentales existantes. En particulier, nos rendements calculés en électrons hydratés ( $e_{aq}^-$ ) à 60 ps et 1 ns s'accordent très bien avec les mesures directes obtenues en radiolyse pulsée picoseconde du rendement en  $e_{aq}^-$  dans l'ESC (D<sub>2</sub>O) à 400 °C et 0 570 g/cm<sup>3</sup>.

**Mots-clés :** eau supercritique, radiolyse, électron hydraté, radical  $^{\bullet}OH$ , atome  $H^{\bullet}$ , constantes de vitesse de réaction, coefficients de diffusion, rendements primaires radiolytiques (valeurs  $g$ ), simulations Monte Carlo de structure de trajectoire.

## Introduction

While experiments showing that water is decomposed by X-rays and radium date back to the early 20th century, various quantitative aspects of this radiolysis are still not fully resolved (for example, see refs. 1–3). The operation of water-cooled nuclear reactors, which use water in various process systems around the reactor core, including the primary heat transport system, as a neutron moderator and as a biological shield,<sup>4</sup> requires the ability to predict and mitigate the effects of this water radiolysis. The Generation IV (Gen IV) supercritical water-cooled reactor (SCWR) designs currently under consideration for deployment in the 2025 time-frame<sup>5–10</sup> would operate at core outlet temperatures as high as 625 °C and at a pressure of 25 MPa, i.e., well beyond the thermodynamic critical point of water (H<sub>2</sub>O:  $t_c = 373.95$  °C,  $P_c = 22.06$  MPa or 217.7 atm,  $\rho_c = 0.322$  g/cm<sup>3</sup>; D<sub>2</sub>O:  $t_c = 370.74$  °C,  $P_c = 21.67$  MPa or 213.9 atm,  $\rho_c = 0.358$  g/cm<sup>3</sup>).<sup>11</sup> Thermodynamic cycle efficiencies as high as  $\sim 49\%$  (vs.  $\sim 33\%$  for existing water reactors) have been

calculated for reactors operating with a supercritical water (SCW) coolant, thus generating lower-cost electricity.

A greatly enhanced understanding of the effects of radiation on aqueous systems in future SCWR designs will be required to specify a chemistry control strategy that will minimize unwanted degradation of components in the SCWR core and of piping downstream of the core resulting from the radiolytic formation of oxidizing products such as  $^{\bullet}OH$ , H<sub>2</sub>O<sub>2</sub>, O<sub>2</sub>, and O<sub>2</sub> $^{\bullet-}$  (or HO<sub>2</sub> $^{\bullet}$  depending on the pH).<sup>8–10,12</sup> These oxidizing products are highly reactive with most metal alloys at the elevated temperatures proposed for the SCWR core outlet. In current pressurized water reactor (PWR) designs, one commonly used chemistry control measure to prevent the net radiolytic production of oxidizing species in the water is to add a small overpressure of excess H<sub>2</sub> to the reactor coolant. It is still unclear, however, whether this strategy, or some variant on the same theme, would also be effective under SCWR conditions.<sup>9</sup>

The combination of extreme conditions of high tempera-

ture and pressure and the intense flux of ionizing radiations (fast neutrons,  $\gamma$ -rays, recoil protons/deuterons and heavy ions), which are the main source of the oxidizing products,<sup>9,10,13,14</sup> make the experimental characterization of water radiolysis under expected SCWR operating conditions very difficult. As a result, theoretical models and computer simulations of the radiation chemistry of the SCWR coolant are an important route of investigation.<sup>9,10,14,15</sup> However, a large amount of input information on the reaction rate constants ( $k$ ) of radiation-induced species, reaction mechanisms, diffusion coefficients ( $D$ ), and radiolytic yields ( $g$  values) in subcritical water and in the SCW regime is needed to create such models. This information is important since preliminary studies suggest, in many cases, a markedly different behavior of the effects of radiation at SCW conditions compared to what one would predict from simplistic extrapolations of experimental data originally measured at lower temperatures. Key examples here include the rate constants of a growing number of chemical reactions that are found to exhibit, at elevated temperatures, negative Arrhenius activation energies (i.e., the temperature dependence of  $k$  actually decreases gradually with temperatures above a certain temperature), so that earlier attempts to extrapolate existing experimental data on reactivities from their measured ranges (mostly less than 250–310 °C; see, for example, refs. 15–18) to the temperatures of interest, assuming simple Arrhenius behavior, should be viewed with caution.<sup>9,19–24</sup> Since about 2000, there has been a revival in the study of the high-temperature, radiolysis of water driven, in large part, by the need for information on (light and heavy) water in the supercritical regime. Generally, these studies have been able to extend the measurements of both reaction rates and  $g$  values to higher temperatures than the original investigations, thereby reducing or, in some cases, eliminating the need to extrapolate the data.<sup>24,25</sup> More recently, the need to model chemistry in a SCWR has initiated concerted national and international experimental programs that are now underway in several laboratories to generate the necessary radiation chemistry data. Currently, however, only limited experimental data are available on the radiation chemistry and reaction kinetics of transients in SCW.<sup>8,9,13,19,20,26–36</sup>

The present work is a first attempt to extend our previous Monte Carlo track structure simulations in liquid water at high temperatures<sup>37</sup> to the study of the low linear energy transfer (LET) radiolysis of SCW (H<sub>2</sub>O) at 400 °C. It represents an initial effort to obtain data to help elucidate mechanisms by which radiation interacts with water in its supercritical regime. The calculations reported herein incorporate all the currently available information on the reactivities and diffusion coefficients of the radiolytically produced free radicals and molecular products ( $e_{aq}^-$ , H<sup>+</sup>, OH<sup>-</sup>, H<sup>•</sup>, H<sub>2</sub>, •OH, H<sub>2</sub>O<sub>2</sub>, O<sub>2</sub><sup>•-</sup> (or HO<sub>2</sub>•), etc.)<sup>1,38–40</sup> and on the physicochemical properties (density, viscosity, static dielectric constant,  $K_w$ , etc.) of water at this temperature. To our knowledge, no theoretical modeling of the radiolysis of water at such elevated temperatures has been reported so far. It should be pointed out that even if uncertainties abound throughout, and many steps remain to be studied before a complete theoretical foundation exists for describing the radiolysis of SCW, we have used parameters that appear reasonable to us. Rather than waiting until better data be-

come available, our first objective is to push the calculation to the point at which we can compare calculated  $g$  values for radiolysis yields with existing experimental observations. Of course, the final objective is a track model that agrees with all experimental chemical data.

The organization of the paper is as follows. We first briefly describe the main features of our simulation approach, and then present and discuss, in the light of the available experimental data, the results of our calculated yields of the free radical products  $e_{aq}^-$  (hydrated electron), •OH, and H<sup>•</sup> atom in irradiated SCW at 400 °C in the liquid-like density region around  $\sim 0.5$  g/cm<sup>3</sup>. We conclude with a short summary and final remarks.

## Monte Carlo simulations

The radiolysis of SCW has been modeled using an extended version of our Monte Carlo track structure simulation code called IONLYS-IRT, which simulates irradiations (by high-energy protons or heavier ions) of pure liquid water or (dilute) aqueous solutions at ambient<sup>41–44</sup> and elevated<sup>37</sup> temperatures. A detailed description of our simulation methodology and reaction scheme used to model the radiation chemistry of water can be found in refs. 37 and 41–44. In brief, the IONLYS program models, on an event by event basis, all the events of the early “physical” ( $<10^{-15}$  s) and “physicochemical” ( $\sim 10^{-15}$ – $10^{-12}$  s) stages<sup>45</sup> in the track development. The complex spatial distribution of reactants present at the end of the physicochemical stage, which is provided as an output of the IONLYS program, is then used directly as the starting point for the subsequent “nonhomogeneous chemical” stage.<sup>45</sup> This third and final stage (from  $\sim 10^{-12}$  s up to about  $10^{-7}$ – $10^{-6}$  s at room temperature), during which the various radiolytic species diffuse randomly and react with one another or with dissolved solutes (if any) present at the time of irradiation, until all spur/track processes are complete, is covered by our IRT program. This program employs the “independent reaction times” (IRT) method,<sup>46,47</sup> a computer-efficient stochastic simulation technique that is used to simulate reaction times without having to follow the trajectories of the diffusing species. The IRT method relies on the approximation that the reaction time for each pair of reactants is independent of the presence of other reactants in the system. Such an approximation has been found to be accurate in solvents of high dielectric constant, where the Coulomb forces between the ions are weak (as is the case with ordinary water), but the method has also been used in intermediate and low-permittivity solvents (such as water at elevated temperatures, alcohols, and hydrocarbons).<sup>37,48–50</sup> Within the framework of this approach, the competition between the reactions is simply described via a sorting out of the stochastically sampled reaction times for each of the potentially reactive pairs of reactants. The implementation of this program has been described in detail previously<sup>42,44</sup> and its ability to give accurate time-dependent chemical yields has been validated by comparison with full random flight Monte Carlo simulations that do follow the reactant trajectories in detail.<sup>51,52</sup>

In the present version of IONLYS-IRT, the rate constants of the dominant chemical and acid/base equilibrium reactions involved in the radiolysis of SCW at 400 °C in the

<sup>f</sup>See also ref. 28.

liquid-like density region studied have generally been obtained by extrapolating the experimental data recently compiled by Elliot and Bartels<sup>24</sup> from their measured ranges (mostly 20–350 °C). In some cases, however, the kinetic data of Ghandi and Percival<sup>20</sup> inferred from muon spin spectroscopy measurements in subcritical water and SCW (up to 450 °C) have also been used. The corresponding  $k$  values employed in our simulations are listed in Table 1. Note the particular case of the self-reaction of  $\text{e}_{\text{aq}}^-$  (reaction R10) whose temperature dependence in near-neutral solution is still a subject of discussion<sup>16–18,23,24</sup> that requires clarification. Its rate constant has been chosen here by following the extrapolation procedure previously proposed by Elliot,<sup>16</sup> and employed in ref. 37, which assumes that this reaction is diffusion controlled at temperatures above 150 °C. The validity of this assumption is confirmed by the good agreement of the calculated and experimental  $g(\text{e}_{\text{aq}}^-)$  values up to 350 °C (data not shown). In contrast, if the abrupt decrease in this rate constant observed in alkaline solution above 150 °C is included in our simulations, a sharp downward discontinuity in  $g(\text{H}_2)$  is predicted,<sup>37</sup> see also refs. 54 and 55, which is not observed experimentally.<sup>24</sup> This abrupt drop needs to be confirmed at near-neutral pH values, as it may be a function of the pH of the solution.<sup>16–18</sup> For the other reactions, whose rate constants have been measured only up to 200 or 250 °C (many of these data have been collected and summarized in refs. 15–18 and 24 for both light and heavy water), the available data for  $k$  have been extrapolated above their experimentally studied temperature range as described previ-

**Table 2.** Values at 400 °C for the diffusion coefficients ( $D$ ) of reactive species in SCW in the high-density region around  $\sim 0.5 \text{ g/cm}^3$ .

Species	$D$ ( $10^{-9} \text{ m}^2 \text{ s}^{-1}$ )
$\text{H}_2^a$	146
$\text{H}_2\text{O}_2^a$	70
$\text{H}^\bullet^a$	213
$\bullet\text{OH}^a$	67
$\text{e}_{\text{aq}}^-$	$420^b$
$\text{H}_3\text{O}^+$	$56^c$
$\text{OH}^-$	$58^c$
$\text{H}_2\text{O}^a$	70

<sup>a</sup>The diffusion coefficients of  $\text{H}_2$ ,  $\text{H}_2\text{O}_2$ ,  $\text{H}^\bullet$ , and  $\bullet\text{OH}$ , explicitly determined at 25 °C but essentially unknown at 400 °C, are assumed to scale with the self-diffusion of water above room temperature.<sup>16–18,23,37,54</sup> The values of  $D$  at 25 °C for the various reactants are taken from refs. 16 and 37.  $D_{\text{H}_2\text{O}}(25^\circ\text{C}) = 2.299 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ .<sup>56</sup> The self-diffusion coefficient of compressed SCW at 400 °C and  $\sim 0.5 \text{ g/cm}^3$  is taken to be  $70 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$  from the measurements of Lamb et al.<sup>57</sup>

<sup>b</sup>Extrapolated from the data of Schmidt et al.<sup>58</sup> up to 90 °C and the estimate of Marin et al.<sup>23</sup> at 300 °C ( $\sim 240 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ ).

<sup>c</sup>Obtained by extrapolation of the experimental data reported by Elliot and Bartels (Figs. 4–27 of ref. 24) over the 0–350 °C temperature range.

ously.<sup>37</sup> Due to the lack of experimental data, we have simply assumed that the reaction rate constants remain constant with water density on the 400 °C isotherm of interest. This approximation would most likely not be too severe, taking into account the limited range of densities (around  $\sim 0.5 \text{ g/cm}^3$ ) investigated here.<sup>28</sup>

The diffusion coefficients used in the simulations for the main reactive species are listed in Table 2. The values of the viscosity ( $\eta \sim 58.6 \text{ } \mu\text{Pa s}$ ), static dielectric constant ( $\epsilon_0 \sim 9.6$ ), and molar concentration ( $\sim 27.8 \text{ mol/L}$ ) of SCW at 400 °C and  $\sim 0.5 \text{ g/cm}^3$  have been taken from the NIST Chemistry WebBook<sup>11</sup> while the ionic product of water ( $K_w$ ) has been obtained from Bandura and Lvov.<sup>59</sup> Finally, from a microscopic viewpoint, we have ignored here the heterogeneous molecular structure of SCW originating from the existence of density fluctuations (or water “clustering”) that are associated with the high compressibility of water in the vicinity of the critical point (e.g., see refs. 60–65 and refs. cited therein). In our simulations, we assume that the overall instantaneous picture of SCW can simply be viewed as a *continuum* medium with a mean density equal to the density of bulk water. This approximation is thought to be reasonable at the liquid-like SCW densities considered in this study<sup>61,63</sup> and it seems to be justified by the agreement we have obtained between model and experiment (see below).

To reproduce the effects of  $^{60}\text{Co}$   $\gamma$ -rays or fast electrons, we use short ( $\sim 100 \text{ } \mu\text{m}$ ) segments of  $\sim 300 \text{ MeV}$  proton tracks, over which the LET is essentially constant and equal to  $\sim 0.3 \text{ keV}/\mu\text{m}$  in normal liquid water at 25 °C. Such an analysis thus gives “track segment” yields<sup>66</sup> as a function of time from picoseconds to, typically, microseconds. The number of proton histories ( $\sim 150$ ) is chosen so as to ensure only small statistical fluctuations when calculating average yields, while keeping acceptable computer time limits.

**Table 3.** Comparison of available experimental data of  $g(e_{aq}^-)$ ,  $g(\bullet OH)$ ,  $(g(e_{aq}^-) + g(\bullet OH) + g(H^\bullet))$ , and  $g(H^\bullet)/g(e_{aq}^-)$  in the low-LET radiolysis of SCW at 400 °C and in the liquid-like density region near  $\sim 0.5 \text{ g/cm}^3$  with the results of our Monte Carlo simulations.

Yield	Experiment	This work <sup>a</sup>

$g(H^\bullet)/g(e_{aq}^-)$	$0.996^e$ at $0.523 \text{ g/cm}^3$ $1.11^e$ at $0.475 \text{ g/cm}^3$	$0.84$

**Note:** Most data reported here are derived from scavenged yields of species measured in steady-state experiments and supposed ideally to be close to the “escape” yields from the spur.<sup>24,39,66</sup> The precision of these measurements is estimated to be on the order of 10%.<sup>31,33,34</sup> Unless otherwise indicated, our calculated yields are all obtained assuming a scavenging time of  $\sim 10 \text{ ns}$ .<sup>13</sup> The  $g$  values are expressed here in units of molecules per 100 eV. For conversion into SI units (mol/J): 1 molecule/100 eV  $\approx 0.10364 \mu\text{mol/J}$ .<sup>1</sup>

<sup>a</sup>All yield values are computed for a SCW density of  $0.5 \text{ g/cm}^3$ .

<sup>b</sup>Direct observation using picosecond pulse radiolysis experiments in supercritical  $D_2O$ .

<sup>c</sup>Janik et al.<sup>13</sup> also measured the  $e_{aq}^-$  escape yields in SCW at 400 and 380 °C as a function of density using  $N_2O$  as a specific scavenger for  $e_{aq}^-$  rather than the *tert*-BuOH/methyl viologen scavenging system used in the experiments of Lin et al.<sup>31</sup> At their highest densities studied ( $\sim 0.42\text{--}0.55 \text{ g/cm}^3$ ), their  $e_{aq}^-$  yields ( $\sim 1.48\text{--}3.12$  molecules/100 eV) are comparable with those measured by Lin et al.<sup>31</sup> In contrast, the value of  $g(e_{aq}^-) = 0.8$  molecule/100 eV found by Sims<sup>27</sup> in  $\gamma$ -irradiated SCW at 400 °C and  $0.45 \text{ g/cm}^3$  from a reanalysis of data previously published by Burns and Marsh<sup>26</sup> is a factor of  $\sim 3$  lower than that measured by Lin et al.<sup>31</sup>

<sup>d</sup>Average over several determinations. Note that there are at present no experimental data from other groups with which to compare our results.

<sup>e</sup>Obtained from different product yield measurements without taking account of the scavenging time of the two species.<sup>67</sup> Note that similar values of this ratio have also been reported at 380 °C in the density regime studied here by Janik et al.<sup>13</sup> (see also ref. 28). For comparison, the value for  $g(H^\bullet)/g(e_{aq}^-)$  in the low-LET radiolysis of ordinary liquid water at 25 °C is  $\sim 0.22$ .<sup>24</sup>

## Results and discussion

Table 3 compares our calculated values of  $g(e_{aq}^-)$ ,  $g(\bullet OH)$ , the sum  $(g(e_{aq}^-) + g(\bullet OH) + g(H^\bullet))$ , and the ratio  $g(H^\bullet)/g(e_{aq}^-)$  with available experimental data<sup>13,26,27,31,33–36</sup> for the low-LET radiolysis of pure, deaerated SCW at 400 °C and  $\sim 0.5 \text{ g/cm}^3$ . As we can see, there is good overall agreement between calculated and experimental  $g$  values. Among the results emerging from this study, let us note below the following points.

First, there is at present only limited information with which to compare our results on the radiation yields of transient species in water under supercritical conditions. In fact, published data mainly concern  $g$  values for  $e_{aq}^-$ ,<sup>9,13,26–28,31,32,35,36</sup>  $H^\bullet$  atom,<sup>9,13,28</sup>  $H_2$ ,<sup>9,13</sup> and  $\bullet OH$ <sup>33</sup> production in low-LET radiolysis up to 400 °C. Most of these studies employ steady-state radiolysis experiments with various specific scavengers, assuming that they (and the products formed) are thermally stable in SCW. However, because of the lack of precise determination of the rate constants for the reactions between radicals and scavengers, the

scavenging time (i.e., the reciprocal of the “scavenging power”, defined as the product of  $k$  and the scavenger concentration) corresponding to the  $g$  values reported at high temperature, and a fortiori in the supercritical regime, is not well-known and may differ appreciably depending on the experimental conditions. In fact, to ensure minimal scavenging in the spur/track, experimentalists generally use scavenger concentrations such that the scavenging time at room temperature is about  $10^{-7} \text{ s}$ .<sup>16,24,31–33</sup> In the calculations reported in Table 3, we have assumed that, in the temperature/density regime investigated, the scavenging time in those yield experiments is of the order of  $10 \text{ ns}$ .<sup>13,68</sup> This choice is consistent with our Monte Carlo calculations, which show that, in liquid water for low-LET radiation and under ordinary irradiation conditions, the lifetime of the spur (i.e., the time at which the nonhomogeneous chemical stage is completed) diminishes with increasing temperature, reaching a value close to  $2 \times 10^{-8} \text{ s}$  at 350 °C.<sup>37,69</sup>

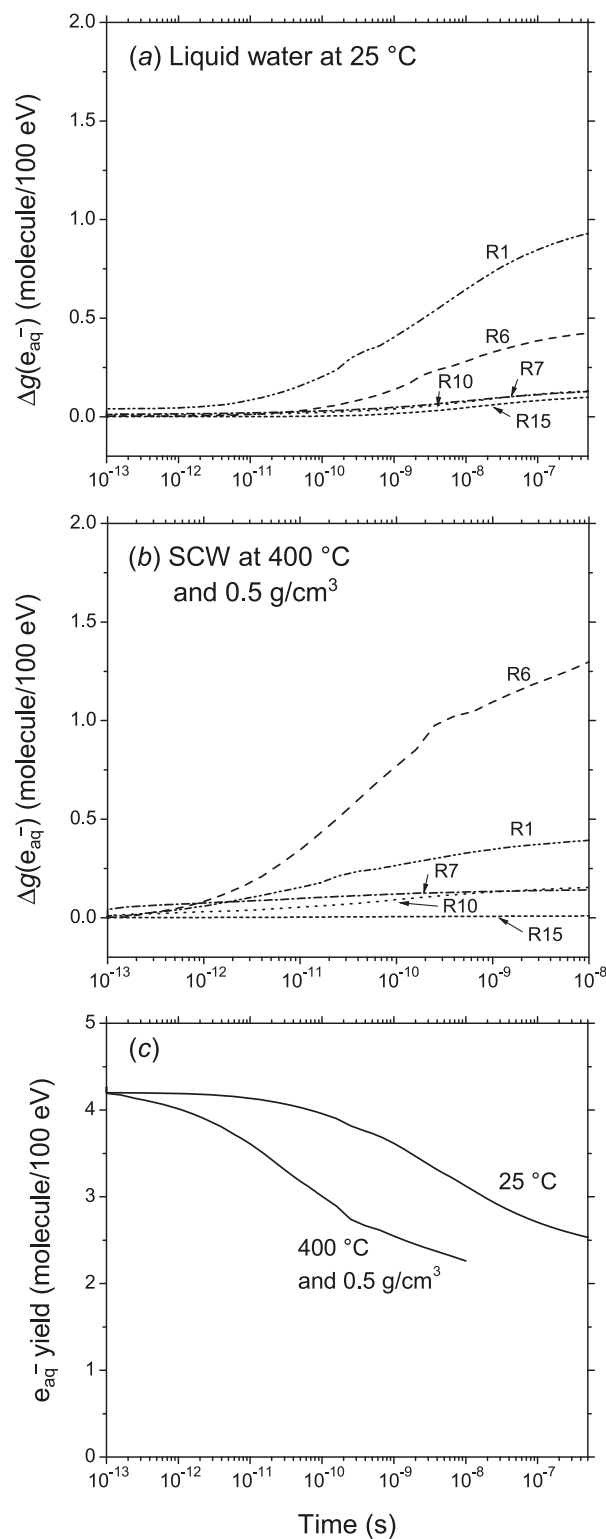

Second, in an effort to overcome the difficulties posed by the scavenging method, Muroya et al.<sup>35</sup> have recently measured, for the first time, the time-dependent yield of hydrated

**Fig. 1.** Time dependence of the extents  $\Delta g(e_{aq}^-)$  (in molecule/100 eV) of the main spur/track reactions R1, R6, R7, R10, and R15 (listed in Table 1) that contribute to the decay of  $e_{aq}^-$ , calculated from our Monte Carlo simulations of the radiolysis of (a) pure, deaerated liquid water at 25 °C and (b) SCW at 400 °C and 0.5 g/cm<sup>3</sup>. The time intervals chosen here correspond to the estimated lifetimes of spurs in the two considered cases. Simulations are carried out with 300 MeV incident protons (corresponding to an LET of  $\sim 0.3$  keV/ $\mu$ m in ordinary liquid water at 25 °C). Note that, in the case of reaction R10 involving two hydrated electrons, the  $\Delta g$  value that is shown accounts for the fact that each reaction eliminates two reactants. For the sake of comparison, Fig. 1c shows the time dependences of the yield of  $e_{aq}^-$  computed at 25 °C, and at 400 °C and 0.5 g/cm<sup>3</sup> over the considered spur lifetimes. As we can see, the kinetics of the decay of  $e_{aq}^-$  is significantly accelerated with increasing temperature, a result in agreement with the recent picosecond time-resolved experiments in SCW of Muroya et al.<sup>35</sup>

electrons in SCW (D<sub>2</sub>O) at 400 °C and various water densities between  $\sim 0.182$  and 0.570 g/cm<sup>3</sup>, using picosecond pulse radiolysis experiments. As shown in Table 3, at the highest density studied by these authors,<sup>35</sup> a good agreement is observed between our computed  $e_{aq}^-$  yields at 60 ps and 1 ns and their corresponding measured  $g$  values.<sup>36</sup> In this context, it is interesting to note that these *direct* time-dependent  $e_{aq}^-$  yield measurements<sup>35,36</sup> compare well with Lin et al.'s<sup>31,32</sup> previous studies that used scavenging methods.

Finally, our third point concerns the contribution of the various reactions to the yield of  $e_{aq}^-$  in irradiated SCW at 400 °C, and in particular the importance of the charge-recombination reaction, R6 (see Table 1). In fact, the rate constant for this reaction is known only up to 350 °C;<sup>24</sup> at 25 °C, it is  $2.1 \times 10^{10}$  (mol/L)<sup>-1</sup> s<sup>-1</sup> while it reaches the value of  $\sim 2 \times 10^{12}$  (mol/L)<sup>-1</sup> s<sup>-1</sup> at 350 °C.<sup>16,24,53</sup> However, the recent measurements of Muroya et al.<sup>35</sup> have suggested that reaction R6 at 400 °C is even faster than that at 350 °C. In view of these results, we have examined the sensitivity of our simulated radiolytic yields on variations in the value of the rate constant for this reaction. As expected,<sup>13,35</sup> reaction R6 does have a major impact on the calculated yields of  $g(e_{aq}^-)$  and  $g(H^\bullet)$ . For example, at 400 °C and 0.5 g/cm<sup>3</sup>, the ratio  $g(H^\bullet)/g(e_{aq}^-)$  at 10 ns varies from 0.74 to 1.26 when the rate constant of reaction R6 is varied from 2.5 to  $5 \times 10^{12}$  (mol/L)<sup>-1</sup> s<sup>-1</sup>. By contrast,  $g(\bullet OH)$  and  $g(H_2)$  are found to be rather insensitive to this parameter. The importance of reaction R6 is further illustrated in Fig. 1 where we compare the time dependence of the cumulative yield variations,  $\Delta g(e_{aq}^-)$ , of the main spur/track reactions that contribute to the decay of  $e_{aq}^-$  in the low-LET radiolysis of liquid water at 25 °C and of SCW at 400 °C and 0.5 g/cm<sup>3</sup>. As can be seen, at 25 °C, the decay of the  $e_{aq}^-$  yield is mainly due to the reaction R1 (see Table 1) of  $e_{aq}^-$  with  $\bullet OH$  radicals; about 54% of electrons decay in this reaction and about 25% in reaction R6 with protons (Fig. 1a). Under supercritical conditions, reaction R1 loses its efficiency and reaction R6 becomes largely predominant; at  $\sim 10^{-8}$  s, this latter reaction contributes about 65% to the decay of  $e_{aq}^-$ , while only 20% of electrons are lost because of reaction R1 (Fig. 1b). The total contribution of reactions R7, R10, and R15 (see Table 1) does not exceed 15%. As a consequence

of this predominance of reaction R6 in irradiated SCW, there are more  $H^\bullet$  atoms available to either react in other spur/track reactions or escape into the bulk solution. This, in large part, supports the marked increase in the ratio  $g(H^\bullet)/g(e_{aq}^-)$  observed during the radiolysis of SCW at 380–400 °C in the density regime studied (see Table 3), compared to its value ( $\sim 0.22$ ) in ordinary liquid water at 25 °C.<sup>24</sup>

## Conclusion

In this work, we have presented the results of our calculated yields of the primary free-radical products  $e_{aq}^-$ ,  $\bullet OH$  radical, and  $H^\bullet$  atom in the low-LET radiolysis of SCW at 400 °C and liquid-like densities around  $\sim 0.5 \text{ g/cm}^3$ . Assuming the aqueous medium to be a "continuum" and using all the currently available information on the rate constants for the main reactions involved in the radiolysis of water under these conditions, our Monte Carlo simulations are found to reproduce well the available experimental data. In particular, our computed  $e_{aq}^-$  yields at 60 ps and 1 ns compare very well with recently reported time-dependent yields of hydrated electrons in SCW at 400 °C and  $0.570 \text{ g/cm}^3$  measured directly using picosecond pulse radiolysis experiments. This good overall accord between experiment and theory shows that Monte Carlo simulations offer a most promising avenue at present to further develop our understanding of temperature/pressure (density) effects in the radiolysis of SCW under various thermodynamic conditions. Currently, work is in progress at our laboratory to calculate the  $g$  values in SCW at 400 °C in the low-density, gas-like region near  $\sim 0.15 \text{ g/cm}^3$ .

## Acknowledgements

We thank Professor D. M. Bartels, Professor M. Boero, Dr. A. J. Elliot, Professor K. Ghandi, Dr. C. D. Jonah, Professor Y. Katsumura, Dr. M. Lin, Professor P. W. Percival, Dr. C. R. Stuart, and the late Professor D. A. Armstrong for useful discussions and correspondence, and for kindly sending us their experimental data prior to publication. Financial support from the Atomic Energy of Canada Limited, the Natural Sciences and Engineering Research Council of Canada (NSERC), and Natural Resources Canada is gratefully acknowledged.

# Synthesis and characterization of chalcone-substituted phosphazenes

Zainab Ngaini and Norashikin I. Abdul Rahman

**Abstract:** A series of mono[(*E*)-1-(4-alkyloxyphenyl)-3-(4-hydroxyphenyl)prop-2-en-1-one]cyclotriphosphazenes and hexakis[(*E*)-1-(4-alkyloxyphenyl)-3-(4-hydroxyphenyl)prop-2-en-1-one]cyclotriphosphazenes have been synthesized. A convenient synthetic method was performed from the reaction of hexachlorocyclotriphosphazenes with 1 and 6 equiv. of (*E*)-1-(4-alkyloxyphenyl)-3-(4-hydroxyphenyl)prop-2-en-1-one (**2a–2c**) to afford (**3a–3c**) in 17%–19% and (**4a–4c**) in 70%–82%, respectively. The compounds differ in the length of alkyl groups,  $C_nH_{2n+1}$ , where  $n = 10, 12$ , and  $14$ .

**Key words:** hexachlorocyclotriphosphazenes, chalcones, alkyloxy, condensation.

**Résumé :** On a réalisé la synthèse d'une série de mono[(*E*)-1-(4-alkyloxyphényl)-3-(4-hydroxyphényl)prop-2-én-1-one]cyclotriphosphazènes et de hexakis[(*E*)-1-(4-alkyloxyphényl)-3-(4-hydroxyphényl)prop-2-én-1-one]cyclotriphosphazènes. On a exécuté une méthode de synthèse appropriée par réaction d'hexachlorocyclotriphosphazènes avec 1 et 6 equiv. de (*E*)-1-(4-alkyloxyphényl)-3-(4-hydroxyphényl)prop-2-én-1-one (**2a–2c**) qui ont conduit respectivement aux produits (**3a–3c**) avec des rendements allant de 17 à 19 % et aux produits (**4a–4c**) avec des rendements allant de 70 à 82. Les composés diffèrent par la longueur des groupes alkyles,  $C_nH_{2n+1}$ , dans lesquels  $n = 10, 12$  et  $14$ .

**Mots-clés :** hexachlorocyclotriphosphazènes, chalcones, alkyloxy, condensation.

## Introduction

Phosphazenes are compounds containing a framework of alternating phosphorus and nitrogen atoms, either in cyclic or linear form.<sup>1</sup> Linear, cyclic, and poly phosphazenes have been widely investigated. These compounds are reported to possess interesting biomedical properties<sup>2</sup> and promising application as effective flame retardants for fiber materials.<sup>3</sup> Nucleophilic substitution reactions on hexachlorocyclotriphosphazenes have been widely reported.<sup>4–6</sup> The synthesis of cyclotriphosphazenes, bearing 4-oxychalcones<sup>6</sup> as side groups, has been studied for photosensitive phosphazenes that could undergo photo-cross-linking reaction under UV irradiation.

In photochemistry, chalcone derivatives were reported to possess outstanding nonlinear optic property for optical communications and optical electronics,<sup>7</sup> liquid crystal displays,<sup>8,9</sup> and alignment film.<sup>10</sup> Chalcones were also reported to promote excellent blue-light transmittance and good crystallability,<sup>11,12</sup> high photosensitivity, and thermal stability for various crystalline electro-optical devices.

Recently, we reported a very convenient method for the preparation of trimeric aryloxyphosphazenes directly from  $[N_3P_3Cl_6]$  and (*E*)-3-(4-(alkyloxy)phenyl)-1-(4-hydroxyphenyl)prop-2-en-1-one using  $K_2CO_3$  in acetone.<sup>13</sup> This prompted us to try the reaction of cyclotriphosphazenes with other para-substituted hydroxy chalcones. We herein describe the synthesis of cyclotriphosphazenes incorporated with hydroxylated chalcones (*E*)-1-[4-(alkyloxy)phenyl]-3-[4-hydroxyphenyl] prop-2-en-1-one

(**2a–2c**), which could be used as model reactions for various crystalline electro-optical devices.

## Results and discussion

The series of chalcone derivatives (*E*)-1-[4-(alkyloxy)phenyl]-3-[4-hydroxyphenyl] prop-2-en-1-one (**2a–2c**) was prepared via Claisen–Schmidt condensation of **1a–1c** and 4-hydroxybenzaldehyde by the route depicted in Scheme 1.

The structural assignments of compounds **2a–2c** were based on the analytical and spectral data. The IR spectra of the hydroxylated chalcones **2a–2c** showed the presence of bands at  $2921$ – $2852\text{ cm}^{-1}$ , which were attributed to the introduction of the long alkyl chain via etherification of 4-hydroxyacetophenone. The presence of a new  $C=O$  stretching frequency at  $1651\text{ cm}^{-1}$  substantiated the formation of the title compound. The chemical structures of **2a–2c** were found to be consistent with  $^1H$  NMR and  $^{13}C$  NMR spectroscopic data and showed the peaks corresponding to the structures. In  $^1H$  NMR spectra, the coupling constant,  $J_{ab} = 15.0$ – $16.0\text{ Hz}$ , indicated all chalcones obtained were in trans-configuration.

The synthetic route for the preparation of mono- $(N_3P_3Cl_5[OC_6H_4CH=CHC(O)C_6H_4OC_nH_{2n+1}])$  (**3a–3c**) and hexa-substituted cyclotriphosphazenes  $(N_3P_3[OC_6H_4CH=CHC(O)C_6H_4OC_nH_{2n+1}]_6)$  (**4a–4c**) is illustrated in Scheme 2.

Mono-substituted cyclotriphosphazenes **3a–3c** were obtained from the reaction of hexachlorocyclotriphosphazenes with 1 equiv. of chalcone derivatives **2a–2c** in the presence of  $K_2CO_3$  in acetone. The higher polarity of the

Scheme 1.

Scheme 2.

acetone<sup>14</sup> was believed to increase the rate of reaction compared with THF<sup>6</sup> and dioxane.<sup>15</sup> The IR spectra showed P=N stretching vibrations at  $1183\text{ cm}^{-1}$ , which are characteristic of cyclotriphosphazenes.<sup>16,17</sup> The absorption bands observed at  $871\text{ cm}^{-1}$  were attributed to the presence of the P-O-C bond.<sup>18</sup>  $^{31}\text{P}$  NMR spectra showed two resonances as a triplet and a doublet at 12.74 ppm and 23.27 ppm, respectively, with a coupling constant,  $J = 60\text{ Hz}$ , which implied the replacement of one chlorine from the cyclotriphosphazenes ring for the mono-substituted phosphazenes.<sup>19</sup>  $^1\text{H}$  and  $^{13}\text{C}$  NMR data also confirmed the substitution of 2a-2c, with the chemical shifts moving slightly downfield.

The reaction of hexachlorocyclotriphosphazenes with 6 equiv. of 2a-2c under the same conditions afforded 4a-4c in high yields. The IR spectra showed the characteristic absorption bands at  $1180\text{ cm}^{-1}$ , which were attributed to P=N stretching vibrations. The absorption bands observed at  $881\text{ cm}^{-1}$  in 4a-4c were attributed to the presence of P-O-C bond.  $^{31}\text{P}$  NMR showed a single resonance at  $\delta\ 8.84\text{ ppm}$ , which implied complete chlorine replacement.<sup>19</sup> The data obtained from elemental analysis,  $^1\text{H}$ , and  $^{13}\text{C}$  NMR showed good agreement to the corresponding structures.

## Conclusion

In summary, this research has demonstrated the nucleophilic substitution of (*E*)-1-[4-(alkyloxy)phenyl]-3-[4-hydroxyphenyl] prop-2-en-1-one (2a-2c) onto cyclotriphosphazenes, which afforded new mono{(*E*)-1-[4-(alkyloxy)phenyl]-3-[4-hydroxyphenyl]prop-2-en-1-one}cyclotriphosphazenes (3a-3c)

and hexakis{(*E*)-1-[4-(alkyloxy)phenyl]-3-[4-hydroxyphenyl]prop-2-en-1-one}cyclotriphosphazenes (4a-4c). Compounds 3a-3c gave lower melting points, whereas compounds 4a-4c possessed higher melting points than the hydroxylated chalcones (2a-2c). These findings could potentially be used as model reactions for various crystalline electrooptical devices.

## Experimental

### General

4-Hydroxybenzaldehyde, 4-hydroxyacetophenone, and 1-bromoalkanes were obtained from Merck Company and used as received. Hexachlorocyclotriphosphazenes was provided by Aldrich and were recrystallized from hexane. Acetone was distilled from calcium hydride under nitrogen before use. All other reagents and solvents were used as received. The reactions were performed under dry nitrogen. Melting points were determined in open capillaries and are uncorrected. Infrared spectra were recorded on (FTIR) 1605 Shimadzu Spectrometer using KBr pellets.  $^1\text{H}$  NMR spectra were recorded on a 500 MHz Jeol Delta 2-NMR, and  $^{13}\text{C}$  NMR was recorded on a 125.77 MHz using TMS as the internal standard.

### Synthesis of alkyloxyphenyl-ethanone (1a-1c)

#### General procedure

Bromoalkane (72 mmol), 4-hydroxyacetophenone (72 mmol),  $K_2CO_3$  (72 mmol), and TBAI (6 mmol) in MEK (200 mL)

were heated at reflux for 5 h. The mixture was filtered and cooled to room temperature. Water (30 mL) was added to the filtrate, and the layers separated. The aqueous layer was extracted with dichloromethane ( $2 \times 30$  mL). The combined layers were washed with water ( $2 \times 20$  mL), dried ( $\text{MgSO}_4$ ), filtered, and concentrated in vacuo. The crude was recrystallized from ethanol to give **1a–1c**.

#### *1-(4-Decyloxyphenyl)-ethanone (1a)*

Compound **1a** was obtained as colorless crystals. Yield: 89. FTIR and NMR data were consistent with the reported literature.<sup>20</sup>

#### *1-(4-Dodecyloxyphenyl)-ethanone (1b)*

Compound **1b** was obtained as colorless crystal. Yield: 78%; mp 52–53 °C. FTIR (thin films,  $\text{cm}^{-1}$ )  $\nu_{\text{max}}$ : 2954, 2918, 2849 (C–H), 1676 (C=O), 1606 (aromatic), 1253 (alkyl aryl ethers).  $^1\text{H}$  NMR (500 MHz,  $\text{CDCl}_3$ )  $\delta_{\text{H}}$ : 0.85 (3H, t,  $1 \times \text{CH}_3$ ), 1.24–1.77 (20H, m,  $8 \times \text{CH}_2$ ), 2.52 (3H, s,  $1 \times \text{CH}_3$ ), 3.98 (2H, t,  $\text{OCH}_2$ ), 6.87 (2H, d,  $J = 9.2$  Hz, Ar–H), 7.88 (2H, d,  $J = 9.2$  Hz, Ar–H).  $^{13}\text{C}$  NMR (125.77 MHz,  $\text{CDCl}_3$ )  $\delta_{\text{C}}$ : 14.06, 22.63, 25.91, 26.24, 29.03, 29.29, 29.50, 29.53, 39.58, 29.60, 29.60, 31.86, 68.19, 114.06, 130.01, 130.50, 163.06, 196.71. Anal. calcd. (%)  $\text{C}_{20}\text{H}_{32}\text{O}_2$ : C, 78.90; H, 10.59. Found (%): C, 78.73; H, 10.45.

#### *1-(4-Tetradecyloxyphenyl)-ethanone (1c)*

Compound **1c** was obtained as colorless crystals. Yield: 94%; mp 58–59 °C. FTIR (thin films,  $\text{cm}^{-1}$ )  $\nu_{\text{max}}$ : 2954, 2917, 2849 (C–H), 1676 (C=O), 1605 (aromatic), 1253 (alkyl aryl ether).  $^1\text{H}$  NMR (500 MHz,  $\text{CDCl}_3$ )  $\delta_{\text{H}}$ : 0.84 (3H, t,  $1 \times \text{CH}_3$ ), 1.23–1.76 (24H, m,  $10 \times \text{CH}_2$ ), 2.50 (3H, s,  $1 \times \text{CH}_3$ ), 3.96 (2H, t,  $\text{OCH}_2$ ), 6.86 (2H, d,  $J = 8.0$  Hz, Ar–H), 7.87 (2H, d,  $J = 8.0$  Hz, Ar–H).  $^{13}\text{C}$  NMR (125.77 MHz,  $\text{CDCl}_3$ )  $\delta_{\text{C}}$ : 14.02, 22.60, 25.88, 26.16, 29.01, 29.28, 29.28, 29.47, 29.51, 29.57, 29.57, 29.59, 31.83, 68.13, 114.00, 129.97, 130.44, 163.02, 196.55. Anal. calcd.  $\text{C}_{22}\text{H}_{36}\text{O}_2$ : C, 79.46; H, 10.91. Found (%): C, 79.23; H, 10.51.

### Synthesis of (alkyloxy)phenyl-hydroxyphenyl]prop-2-en-1-one (**2a–2c**)

#### *General procedure*

A mixture of 4-hydroxybenzaldehyde (12.5 mmol) and **1a** (12.5 mmol) in 35 mL of methanol was added under stirring to a solution of KOH (2.52 g) in methanol (10 mL). The mixture was heated at reflux for 10 h. The reaction was cooled to room temperature and acidified with cold diluted HCl (2 N). The resulting precipitate was filtered, washed, and dried. The crude was recrystallized from hexane:ethanol (7:1) to give **2a–2c**.

#### *(E)-1-[4-(Decyloxy)phenyl]-3-[4-hydroxyphenyl]prop-2-en-1-one (2a)*

Compound **2a** was obtained as yellow crystals. Yield: 34. FTIR and NMR data were consistent with the reported literature.<sup>20</sup>

#### *(E)-1-[4-(Dodecyloxy)phenyl]-3-[4-hydroxyphenyl]prop-2-en-1-one (2b)*

Compound **2b** was obtained as yellow crystals. Yield: 44%; mp 110.6–111.2 °C. FTIR (thin films,  $\text{cm}^{-1}$ )  $\nu_{\text{max}}$ :

3195 (OH), 2921, 2852 (C–H), 1651 (C=O), 1581 (aromatic), 1223 (alkyl aryl ether), 990 (C=C).  $^1\text{H}$  NMR (500 MHz,  $\text{CDCl}_3$ )  $\delta_{\text{H}}$ : 0.81 (3H, t,  $1 \times \text{CH}_3$ ), 1.21–1.87 (20H, m,  $10 \times \text{CH}_2$ ), 3.95 (2H, t,  $\text{OCH}_2$ ), 6.83 (2H, d,  $J = 8.6$  Hz, Ar–H), 6.86 (2H, d,  $J = 8.6$  Hz, Ar–H), 7.32 (1H, d,  $J = 15.45$  Hz,  $1 \times$  olefinic H), 7.45 (2H, d,  $J = 8.0$  Hz, Ar–H), 7.67 (1H, d,  $J = 15.45$  Hz,  $1 \times$  olefinic H), 7.94 (2H, d,  $J = 8.0$  Hz, Ar–H).  $^{13}\text{C}$  NMR (125.77 MHz,  $\text{CDCl}_3$ )  $\delta_{\text{C}}$ : 14.10, 22.67, 25.96, 29.08, 29.33, 29.55, 29.58, 29.61, 30.96, 31.89, 68.29, 114.30, 116.09, 119.03, 127.24, 130.45, 130.84, 144.66, 158.75, 163.12, 189.62. #### Preparation of $\text{N}_3\text{P}_3\text{Cl}_5[\text{OC}_6\text{H}_4\text{CH}=\text{CHC}(\text{O})\text{C}_6\text{H}_4\text{OC}_{14}\text{H}_{29}]$ (3c)

Compound **3c** was obtained as pale yellow solid. Yield: 18%; mp 68–71 °C. FTIR (thin films,  $\text{cm}^{-1}$ )  $\nu_{\text{max}}$ : 1184 (P=N), 871 (P–O–C).  $^1\text{H}$  NMR (500 MHz,  $\text{CDCl}_3$ )  $\delta_{\text{H}}$ : 0.87 (3H, t,  $1 \times \text{CH}_3$ ), 1.25–1.80 (24H, m,  $12 \times \text{CH}_2$ ), 4.03 (2H, t,  $\text{OCH}_2$ ), 6.95 (2H, d,  $J = 8.60$  Hz, Ar–H), 7.29 (2H, d,  $J = 8.60$  Hz, Ar–H), 7.49 (1H, d,  $J = 16.00$  Hz,  $1 \times$  olefinic H), 7.66 (2H, d,  $J = 8.60$  Hz, Ar–H), 7.73 (1H, d,  $J = 15.45$  Hz,  $1 \times$  olefinic H), 8.00 (2H, d,  $J = 8.05$  Hz, Ar–H).  $^{13}\text{C}$  NMR (125.77 MHz,  $\text{CDCl}_3$ )  $\delta_{\text{C}}$ : 14.09, 22.66, 25.95, 29.08, 29.33, 29.33, 29.53, 29.50, 29.62, 29.62, 29.63, 29.66, 31.89, 68.31, 114.34, 121.89, 122.71, 129.85, 130.56, 130.81, 133.78, 141.97, 150.32, 163.23, 188.26.  $^{31}\text{P}$  NMR (200 MHz,  $\text{CDCl}_3$ )  $\delta_{\text{P}}$ : 12.74 (t,  $J = 60.0$  Hz,  $\text{P}_a$ –P), 23.27 (d,  $J = 60.0$  Hz,  $\text{P}_b$ –P). Anal. calcd. (%)  $\text{N}_3\text{P}_3\text{Cl}_5\text{C}_{29}\text{H}_{39}\text{O}_3$ : C, 46.58; H, 5.26; N, 5.62. Found (%): C, 46.43; H, 5.14; N, 5.59.

### Synthesis of hexasubstituted cyclotriphosphazene (4a–4c)

#### General procedure

A mixture of hexachlorocyclotriphosphazenes (2.01 mmol), **2a** (12.06 mmol), and  $\text{K}_2\text{CO}_3$  (24.12 g) in acetone (60 mL) was heated at reflux for 1 h. The mixture was allowed to cool to room temperature and filtered. The filtrate was dried, filtered, and concentrated in vacuo. The crude solid was recrystallized from acetone to afford **4a–4c**.

#### Preparation of $\text{N}_3\text{P}_3[\text{OC}_6\text{H}_4\text{CH}=\text{CHC}(\text{O})\text{C}_6\text{H}_4\text{OC}_{10}\text{H}_{21}]_6$ (4a)

Compound **4a** was obtained as pale yellow solid. Yield: 82%; mp 143–145 °C. FTIR (thin films,  $\text{cm}^{-1}$ )  $\nu_{\text{max}}$ : 3067 (CH in aromatic), 1180 (P=N), 881 (P–O–C).  $^1\text{H}$  NMR (500 MHz,  $\text{CDCl}_3$ )  $\delta_{\text{H}}$ : 0.81 (3H, t,  $1 \times \text{CH}_3$ ), 1.22–1.71 (16H, m,  $8 \times \text{CH}_2$ ), 3.97 (2H, t,  $\text{OCH}_2$ ), 6.89 (2H, d,  $J = 9.15$  Hz, Ar–H), 7.20 (2H, d,  $J = 8.60$  Hz, Ar–H), 7.25 (1H, d,  $J = 15.45$  Hz,  $1 \times$  olefinic H), 7.41 (2H, d,  $J = 8.60$  Hz, Ar–H), 7.62 (1H, d,  $J = 15.45$  Hz,  $1 \times$  olefinic H), 7.95 (2H, d,  $J = 9.15$  Hz, Ar–H).  $^{13}\text{C}$  NMR (125.77 MHz,  $\text{CDCl}_3$ )  $\delta_{\text{C}}$ : 14.09, 22.66, 25.99, 29.12, 29.31, 29.38, 29.55, 30.92, 31.87, 68.25, 114.29, 121.37, 121.88, 129.58, 130.47, 130.73, 132.35, 142.18, 151.65, 163.12, 188.01.  $^{31}\text{P}$  NMR (200 MHz,  $\text{CDCl}_3$ )  $\delta_{\text{P}}$ : 8.86 (s, 3P,  $\text{N}_3\text{P}_3$  ring). Anal. calcd. (%)  $\text{N}_3\text{P}_3\text{C}_{150}\text{H}_{186}\text{O}_{18}$ : C, 74.69; H, 7.77; N, 1.74. Found (%): C, 73.86; H, 7.60; N, 1.83.

#### Preparation of $\text{N}_3\text{P}_3[\text{OC}_6\text{H}_4\text{CH}=\text{CHC}(\text{O})\text{C}_6\text{H}_4\text{OC}_{12}\text{H}_{25}]_6$ (4b)

Compound **4b** was obtained as pale yellow solid. Yield: 72%; mp 141–143 °C. FTIR (thin films,  $\text{cm}^{-1}$ )  $\nu_{\text{max}}$ : 3064 (C–H in aromatic), 1180 (P=N), 883 (P–O–C).  $^1\text{H}$  NMR (500 MHz,  $\text{CDCl}_3$ )  $\delta_{\text{H}}$ : 0.86 (3H, t,  $1 \times \text{CH}_3$ ), 1.25–1.78 (20H, m,  $10 \times \text{CH}_2$ ), 3.97 (2H, t,  $\text{OCH}_2$ ), 6.87 (2H, d,  $J = 7.45$  Hz, Ar–H), 7.00 (2H, d,  $J = 8.00$  Hz, Ar–H), 7.41 (1H, d,  $J = 16.00$  Hz,  $1 \times$  olefinic H), 7.46 (2H, d,  $J = 8.00$  Hz, Ar–H), 7.71 (1H, d,  $J = 16.00$  Hz,  $1 \times$  olefinic H), 7.91 (2H, d,  $J = 7.45$  Hz, Ar–H).  $^{13}\text{C}$  NMR (125.77 MHz,  $\text{CDCl}_3$ )  $\delta_{\text{C}}$ : 14.09, 22.66, 25.99, 29.12, 29.33, 29.38, 29.56, 29.59, 29.61, 29.64, 31.89, 68.25, 114.29, 121.36, 121.88, 129.58, 130.47, 130.73, 132.34, 142.19, 120.64, 163.13, 188.03.  $^{31}\text{P}$  NMR (200 MHz,  $\text{CDCl}_3$ )  $\delta_{\text{P}}$ : 8.84 (s, 3P,  $\text{N}_3\text{P}_3$  ring). Anal. calcd. (%)  $\text{N}_3\text{P}_3\text{C}_{162}\text{H}_{210}\text{O}_{18}$ : C, 75.41; H, 8.20; N, 1.63. Found (%): C, 74.87; H, 8.17; N, 2.16.

#### Preparation of $\text{N}_3\text{P}_3[\text{OC}_6\text{H}_4\text{CH}=\text{CHC}(\text{O})\text{C}_6\text{H}_4\text{OC}_{14}\text{H}_{29}]_6$ (4c)

Compound **4c** was obtained as pale yellow solid. Yield: 70%; mp 137–138 °C. FTIR (thin films,  $\text{cm}^{-1}$ )  $\nu_{\text{max}}$ : 3068 (C–H in aromatic), 1177 (P=N), 880 (P–O–C).  $^1\text{H}$  NMR (500 MHz,  $\text{CDCl}_3$ )  $\delta_{\text{H}}$ : 0.87 (3H, t,  $1 \times \text{CH}_3$ ), 1.25–1.80 (24H, m,  $12 \times \text{CH}_2$ ), 4.03 (2H, t,  $\text{OCH}_2$ ), 6.95 (2H, d,  $J = 8.60$  Hz, Ar–H), 7.29 (2H, d,  $J = 8.60$  Hz, Ar–H), 7.49 (1H, d,  $J = 16.00$  Hz,  $1 \times$  olefinic H), 7.66 (2H, d,  $J = 8.60$  Hz, Ar–H), 7.73 (1H, d,  $J = 15.45$  Hz,  $1 \times$  olefinic H), 8.00 (2H, d,  $J = 8.05$  Hz, Ar–H).  $^{13}\text{C}$  NMR (125.77 MHz,  $\text{CDCl}_3$ )  $\delta_{\text{C}}$ : 14.09, 22.66, 25.95, 29.08, 29.33, 29.33, 29.53, 29.50, 29.62, 29.62, 29.63, 29.66, 31.89, 68.31, 114.34, 121.89, 122.71, 129.85, 130.56, 130.81, 133.78, 141.97, 150.32, 163.23, 188.26.  $^{31}\text{P}$  NMR (200 MHz,  $\text{CDCl}_3$ )  $\delta_{\text{P}}$ : 8.86 (s, 3P,  $\text{N}_3\text{P}_3$  ring). Anal. calcd. (%)  $\text{N}_3\text{P}_3\text{C}_{174}\text{H}_{234}\text{O}_{18}$ : C, 76.03; H, 8.58; N, 1.53. Found (%): C, 75.90; H, 8.31; N, 1.70.

# TiO<sub>2</sub>/biscyanine and CdS/biscyanine heterostructures — Influence of the structural composition on the photocatalytic activity

I. Kobasa, I. Kondratyeva, and L. Odosiy

**Abstract:** This paper deals with investigation of a character of the light reflection and absorption of some newly synthesized heterostructural materials based on TiO<sub>2</sub> or CdS semiconductors and bisquinocyanine dyes (carbocyanine and styryle). Changes in spectral parameters of the heterostructures caused by adding the dye to the semiconducting material have also been investigated. The changes in the spectra can be caused by different chromophores disposition induced by influence of the semiconductor on the electron configuration in the dye molecules. A well-known test reaction of methylene blue reduction has been used to detect the photocatalytic activity of the materials, which was found directly depending on the efficiency of the mutual influence of the components of the heterostructures. The heterostructures containing a dye, which causes more significant spectral changes, ensure higher photocatalytic activity.

**Key words:** titanium dioxide, cadmium sulfide, biscyanine dyes, photocatalytic activity, mutual influence of components.

**Résumé :** Dans ce travail, on a étudié un caractère de la réflexion et de l'absorption de nouveaux matériaux de synthèse hétérostructuraux à base de TiO<sub>2</sub>, de semiconducteurs CdS et de colorants de la bisquinocyanine (carbocyanine et styrile). On a aussi étudié les changements dans les paramètres spectraux des hétérostructures provoqués par l'addition du colorant au matériel semiconducteur. Les changements dans les spectres peuvent être provoqués par diverses dispositions de chromophores induites par l'influence du semiconducteur sur la configuration électronique dans les molécules de colorant. On a utilisé une réaction bien connue de réduction du bleu de méthylène comme test pour détecter l'activité photocatalytique des matériaux et on a trouvé qu'elle dépend directement sur l'efficacité de l'influence mutuelle des composants des hétérostructures. Les hétérostructures contenant un colorant, qui cause les changements spectraux les plus significatifs, assurent une plus grande activité photocatalytique.

**Mots-clés :** dioxyde de titane, sulfure de cadmium, colorants de la biscyanine, activité photocatalytique, influence mutuelle des composants.

## Introduction

Electrochemical and electrophysical parameters of any photocatalytic material should mutually agree to keep needful electron-transfer processes thermodynamically allowed and ensure high driving force of the process. This condition should be observed for the effective designing of photocatalytic systems or their components.<sup>1,2</sup> This is a necessary, yet not sufficient condition for designing the highly effective photocatalysts, since photocatalytic activity (PA) also depends on kinetic, adsorption, and other factors.<sup>1</sup> The initial raise in PA caused by better light absorption is followed by depression of the photocatalyst's efficiency that has been reported in refs. 3–5 for a number of heterostructures (HS) containing cyanine dyes sensitizers. Such dependence of a material activity on its composition can be caused by changes in the dye's association level. Spectral data prove that mutual influence of the dye and the semiconductor is gradually weakening with raise in the dye content. This effect can cause depression of the PA for the HS with higher

dye concentration as reported in ref.6. Detailed investigation of the dependence of PA on various physical and physicochemical parameters is a topical task, since this information is necessary for the development of new complex photoactive materials with pre-assigned properties.

This paper reports the results of the comparative investigation of the spectral and photochemical characteristics of heterostructures consisting of titanium dioxide or cadmium sulfide with biscyanine/cyanine dye-sensitizer with two conjugated chromophores. Any electronic or steric factors can change the conformation of the HS molecules and result in significant spectral changes in the light absorption pattern. That is why such materials can be suitable objects for investigation of the structural changes in the semiconductors occurring at the formation of HS. Two biscyanine compounds (styryle and monocarbocyanine) were used as HS components because they have different auxochromes and substitutes in the polymethine chains. Our electrochemical measurements proved similarity of redox potentials of both

biscyanines. As reported in refs. 1 and 2, such similarity ensures that close values of thermodynamic advantage are gained when electrons are injected to the conductivity band and, consequently, similar values of PA.

An "energetic agreement" contribution into PA can be eliminated using the above-mentioned principle of the components selection for HS. Therefore, any difference in PA for the HS with the similar content of the two dyes can be caused only by different types of interaction between the dyes and semiconductor.

## Experimental

All heterostructural materials have been synthesized using the following method:<sup>3,6</sup> a dye-sensitizer has been deposited upon a particle of some semiconducting dispersion. Then, the HS was covered with the polyepoxypropylcarbazole (PEPC) film to prevent its dissolution. This method ensures synthesis of heterogeneous structures, which consist of a semiconductor nucleus covered with separate molecules, or the uniformal layer of the dye, and a protecting polymer film (Fig. 1). Such structural composition can be obtained because positive dye particles do not dissolve in benzene solution of the polymer used in this method.

The polymer film can slightly influence the electron-transfer processes and photocatalytic activity. As reported in ref. 6, the PEPC film (PEPC content: 0.02–0.2 mg/g) completely stops the dissolution of the dye; however, it does not thwart any electron-transfer processes at the interface boundary. PA drops to 20% if the PEPC content reaches 1.8 mg/g.

The following dyes have been used as sensitizers: *N*-(benzoyl-diethylaminostyryl)-4-*n*-diethylaminostyrylquinolinium perchlorate (Dye I) and (*N*-[ $\alpha$ -coumarine-3-yl]carbo(1,3,3-trimethyl-2-indolynylidene)propenyl](4-quinolyne)1,3,3-trimethyl-2-indolynyliden) trimethyncyanine bromide (Dye II). Synthesis of Dye I has been carried out according to ref. 7, and Dye II was synthesized according to ref. 8. Details of the dye synthesis, yields, and characteristics of the dyes are reported in refs. 7 and 8.

R: 3-coumarinyl

Both dyes were applied to the following semiconductors:

- (i) Titanium dioxide with specific surface area  $S_{sp} = 50.0 \text{ m}^2/\text{g}$  has been synthesized by the original method<sup>9</sup> through  $\text{TiCl}_4$  vapour hydrolysis in the air-

**Fig. 1.**  $\text{TiO}_2/\text{D}/\text{PEPC}$  and  $\text{CdS}/\text{D}/\text{PEPC}$  heterostructures: 1, semiconductor particle; 2, dye-sensitizer; and 3, protective polymer film ( $l$ : thickness of the polymer layer).

hydrogen flame at 1170–1370 K.  $\text{TiO}_2$  particles size ranged from 20 to 40 nm;

- (ii) Ultrapure cadmium sulfide with  $S_{sp} = 4.0 \text{ m}^2/\text{g}$  (particle size was 100  $\mu\text{m}$ ).

All particle sizes were measured using Scanning Electronic Microscope ZEISSEVO50XVP.

Cyclic voltammetry<sup>10</sup> of the dye ethanolic solution ( $C = 1.25 \times 10^{-4} \text{ mol/L}$ ) was used to determine values of  $E_{D/D^+}^*$  and  $E_{D/D^-}^*$ . A LOMO-made spectrophotometer SF-46 has been used to record the optical spectra of the dyes. Diffusive reflection spectra of the oxide semiconductors and the HS of  $\text{TiO}_2$  and  $\text{CdS}$  with the dyes have been recorded using PerkinElmer Lambda Bio-40 spectrophotometer equipped with integrating sphere and then transformed into absorption spectra using Kubelka–Munk method.<sup>11</sup> A value  $(1 - R^2)/2R$ , which is proportional to optical density, where  $R$  (%) (diffusive reflection at the given wavelength) was calculated to apply this method of transformation.

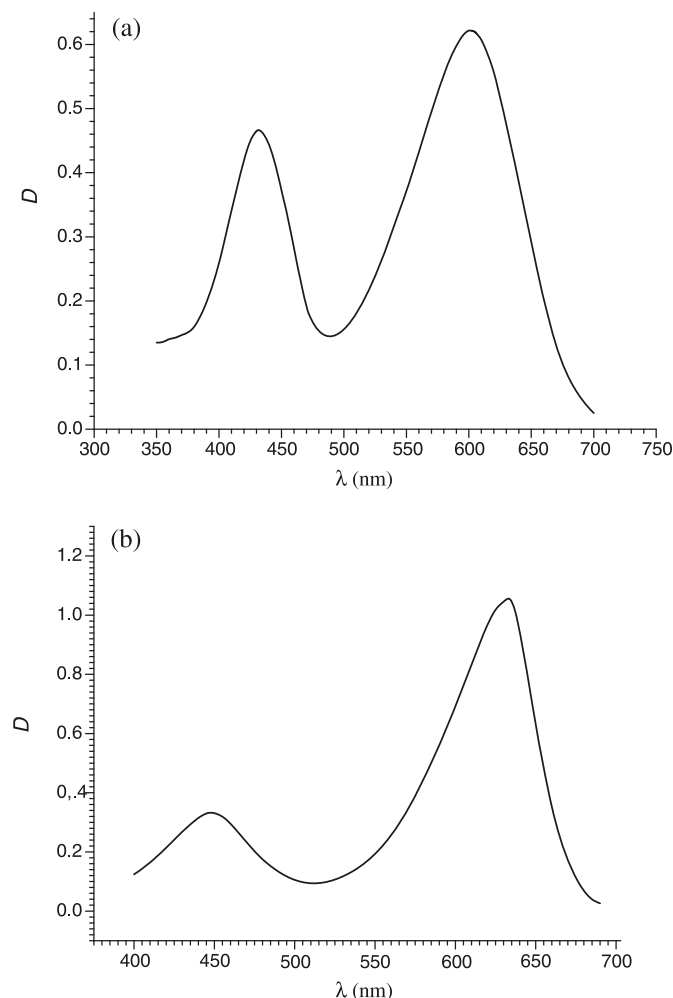

The PA of the heterostructures has been determined through acceleration of methylene blue (MB) photodegradation running in an oxygen-free aqueous solution with formaldehyde as a reducing agent.<sup>5,6</sup> A regular 500 W incandescent lamp and the mercury lamp DRT-1000 were used as light sources for the photodegradation. The following color filters: UFS-2 ( $\lambda = 310\text{--}400 \text{ nm}$ ), ZhS-11 ( $\lambda > 400 \text{ nm}$ ), FS-1 ( $\lambda < 520 \text{ nm}$ ), or OS-13 ( $\lambda > 560 \text{ nm}$ ) were used to filter the needed light bands. A value of PA has been calculated as  $\text{PA} = (C_0 \times 1000)/(\tau_{1/2} S m)$ ,<sup>5</sup> where PA means a value of PA ( $\text{mg}/(\text{mL min m}^2)$ ),  $C_0$ : initial concentration of MB ( $\text{mg/mL}$ ),  $\tau_{1/2}$ : half-discoloration time (min),  $S$ : specific surface area of a sample ( $\text{m}^2/\text{g}$ ), and  $m$ : weight of a sample (g).

## Results

### Dye I (D I) and the heterostructure $\text{TiO}_2/\text{D I}/\text{PEPC}$

There are two light absorption bands in the visible light spectrum of the Dye I, which is common for all biscyanines. Peaks of these bands are located for the ethanolic solution at  $\lambda_{\text{max}} = 432 \text{ nm}$  ( $\log \varepsilon = 4.75$ ) and  $\lambda_{\text{max}} = 603 \text{ nm}$  ( $\log \varepsilon = 4.97$ ) (Fig. 2). The width of the shortwave band at 2/3 of its height is  $\Delta = 56 \text{ nm}$ , and  $\Delta = 80 \text{ nm}$  for the longwave band. The ratio between the intensities of the bands is  $I_{sw}/I_{lw} = 0.76$ .

**Fig. 2.** Light absorption spectra for the ethanolic solutions of the dyes-sensitizers: (a) Dye I, (b) Dye II ( $C = 10^{-5}$  mol/L). Optical density ( $D$ ) vs. light wavelength ( $\lambda$ ).

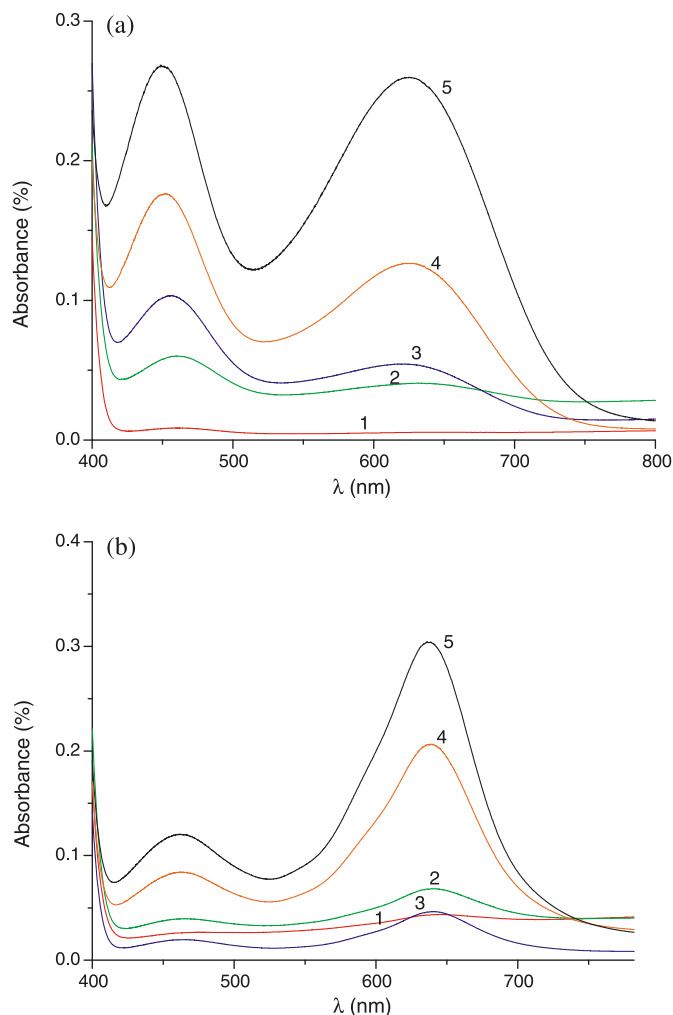

All the above-mentioned parameters undergo significant changes for a spectrum of the dye deposit on the surface of the HS (see Fig. 3a and Table 1). Table 1 also represents potentials of oxidation  $E_{D/D^+}^*$  and reduction  $E_{D/D^-}^*$  of the excited molecule of the dye after absorbing a longwave quantum with energy  $E^*$ . The potentials were calculated according to the equations:<sup>12</sup>  $E_{D/D^+}^* = E_{D/D^+} - E^*$  and  $E_{D/D^-}^* = E_{D/D^-} + E^*$ . Dark redox potentials were obtained using a cyclic voltammetry:<sup>10</sup>  $E_{D/D^+}^* = +0.86$  V,  $E_{D/D^-}^* = +0.008$  V.

#### Dye II (D II) and the heterostructure TiO<sub>2</sub>/D II/PEPC

A spectrum of the Dye II also shows two visible light absorption bands. Peaks of these bands are located at  $\lambda_{\max} = 446$  nm ( $\log \varepsilon = 4.52$ ) and  $\lambda_{\max} = 632$  nm ( $\log \varepsilon = 5.03$ ). Width of the shortwave band at 2/3 of its height ( $\Delta$ ) is 53 nm, and  $\Delta = 42$  nm for the longwave band. The ratio between the intensities of the bands is  $I_{sw}/I_{lw} = 0.33$ . All parameters of the absorption spectrum also change at the formation of a heterostructure from Dye II and TiO<sub>2</sub>. However, Fig. 3b and Table 2 prove that the width of both bands ( $\Delta$ ) increases similarly to the previous material while increase of  $\lambda_{\max}$  and  $I_{sw}/I_{lw}$  here is much less than the D I

**Fig. 3.** Light absorption spectra for TiO<sub>2</sub>-based heterostructures: (a) TiO<sub>2</sub>/D I/PEPC, (b) TiO<sub>2</sub>/D II/PEPC. Dye content in the HS (mg/g): 1, 0.019; 2, 0.094; 3, 0.188; 4, 0.94; and 5, 1.88.

material. Values of  $E_{D/D^+} = +0.89$  V,  $E_{D/D^-} = +0.012$  V, and  $E^*$  for the longwave band calculated from the experimental data are represented in Table 2.

#### Heterostructures D I and D II with CdS

Absorption spectra of such materials are less informative because the shortwave band is completely hidden behind the wide absorption band of CdS (see Fig. 4). Electrochemical parameters of this material  $E_{D/D^+}$  and  $E_{D/D^-}$  have been determined similarly to TiO<sub>2</sub>-based materials.

#### Photocatalytic activity of the heterostructures

Photocatalytic activities of various heterostructures are shown in Tables 3 and 4, and the dependence of PA on some spectral parameters is represented in Fig. 5.

#### Energy transformation diagrams for various photocatalytic systems based on heterostructures

Energy transformation diagrams have been built for various HS to identify the thermodynamically allowed electron-transfer processes, which can occur at exposure to light from various spectral ranges. The diagrams were composed based

**Table 1.** Spectral and electrochemical parameters of the heterostructures TiO<sub>2</sub>/D I/PEPC, sw and lw: shortwave and longwave absorption bands, respectively,  $I_{sw}/I_{lw}$ : the ratio between the intensities of the bands,  $\Delta$  (nm): width of the band at 2/3 of its height,  $E_{D/D^{*+}}^{*}(lw)$  and  $E_{D/D^{*-}}^{*}(lw)$ : potentials of oxidation  $E_{D/D^{*+}}^{*}$  and reduction  $E_{D/D^{*-}}^{*}$  of the excited molecule of the dye after absorbing a longwave quantum with energy  $E^*$  (eV).

## Discussion

### Energy characteristics of photocatalytic systems and photocatalytic activity of the heterostructures in the reduction of methylene blue

#### Effect of the light absorption in the range 310–400 nm: Light is absorbed mainly by a semiconductor

As seen from the energy transformation diagrams (Fig. 6), the following processes can be thermodynamically allowed in the HS after generating an electron-hole pair in  $\text{TiO}_2$  or CdS: (process 1) an electron can be transferred from the conductivity band to the reducing agent; (process 2) a hole in the valence band can be filled with an electron from the reducing agent, either directly (process 3) or through the PEPC molecule (processes 4 and 5). Energy gaps  $\Delta E$  between potentials of all reactants in the above processes are wide enough, and all the processes should run efficiently and ensure high PA of the HS. However, the energy diagrams prove that there is another electron-transfer option

**Fig. 5.** Dependence of PA and spectral parameters  $I_{\text{lw}}$  and  $\Delta I_{\text{sw}}/I_{\text{lw}}$  on the content of Dye I in the heterostructure  $\text{TiO}_2/\text{D I}/\text{PEPC}$ .

available for each HS: an electron can be transferred from the conductivity band to the dye molecule (process 6). This process and the process 7 together can be considered as an indirect electron-hole recombination. Reduction potentials for MB, D I, and D II are very close, and these agents can effectively intercept electrons from the conductivity band. Therefore, the rise in the dye-sensitizer content should result in lowering the PA of a material and slowing down the MB reduction on the interface boundary. Experimental data from Tables 3 and 4 confirm this assumption: adding 0.019 mg/g of D I or D II results in a 50% decrease of the PA of  $\text{TiO}_2$  followed by further lowering after adding next portions of the sensitizer. A CdS-based material exhibits the same effect (see Table 4).

#### Effect of the light absorption at $\lambda > 400$ nm, where the light is absorbed mainly by the dyes — HS: $\text{TiO}_2/\text{D I}/\text{PEPC}$ and $\text{TiO}_2/\text{D II}/\text{PEPC}$

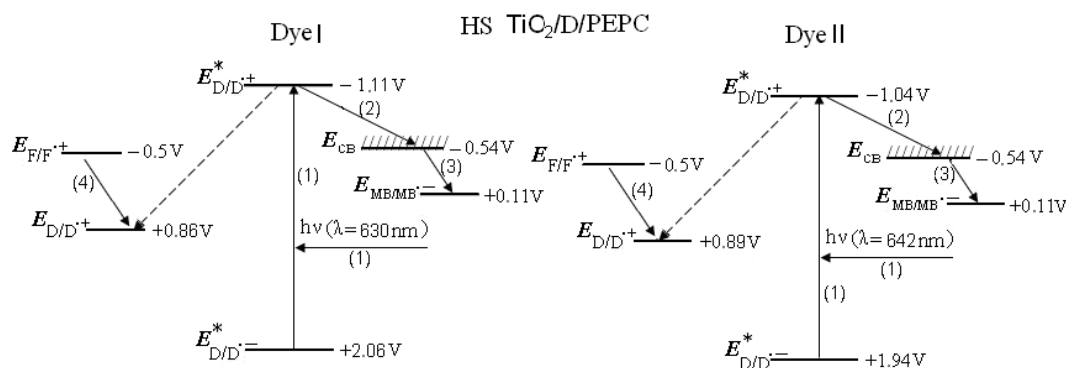

It is known<sup>1,17</sup> that injection of electrons from excited molecules of a dye into the conductivity band is a basic process, which governs sensitizing semiconductors by the dyes. An energy gap  $\Delta E = E_{\text{CB}} - E_{\text{D/D}^+}$  determines the thermodynamic efficiency of this process. As seen from the energetic diagrams of the photocatalytic systems with a dye content of 0.188 mg/g (Fig. 6), such gaps are wide enough even for photoexcitation by the visible light from the long-wave dye absorption bands. Comparison to the data from Table 1 proves that efficiency of the electron injection into the conductivity band cannot be significantly influenced by the shifting effect of changes in the HS composition on the positions of such bands. This shifting only leads to small changes of some hundredth parts in the value of  $E_{\text{D/D}^+}$ .

Therefore, the “longwave” photoexcitation (Fig. 7, process 1) should induce the injection of electrons into the conductivity band (process 2) at any composition of the HSs  $\text{TiO}_2/\text{D I}/\text{PEPC}$  and  $\text{TiO}_2/\text{D II}/\text{PEPC}$ . The following processes are thermodynamically allowed and can have needful driving force: interface electron transfer (i) from the conductivity band (process 3) to MB molecules and (ii) from formaldehyde (process 4) to cation-radicals  $\text{D}^{\bullet+}$  (formed in process 2 from  $\text{D}^*$ ; see the broken lines in Fig. 7). The photoactive form of the photocatalyst is regenerated in the latter process. Similar analysis of the energy transformation diagrams

**Fig. 6.** Energy transformation diagrams for photocatalytic systems with  $\text{TiO}_2$ - and  $\text{CdS}$ -based heterostructures comprising D I and schemes of electronic processes induced by the light absorption on semiconducting compounds.

**Fig. 7.** Energy transformation diagrams for the photocatalytic systems with  $\text{TiO}_2/\text{D I/PEPC}$  and  $\text{TiO}_2/\text{D II/PEPC}$  heterostructures. Schemes of the electronic processes induced after the light absorption by a dye-sensitizer ( $\lambda > 400$  nm, calculations were made for a sample with  $C = 0.188$  mg/g).

**Fig. 8.** Energy transformation diagrams for photocatalytic systems with  $\text{CdS}/\text{D I/PEPC}$  and  $\text{CdS}/\text{D II/PEPC}$  heterostructures. Schemes of the electronic processes induced after the light absorption by a dye-sensitizer ( $\lambda > 400$  nm, calculations were made for a sample with  $C = 0.188$  mg/g).

proves that the above electron-transfer processes 1–4 are also thermodynamically allowed for HSs  $\text{CdS}/\text{D I/PEPC}$  and  $\text{CdS}/\text{D II/PEPC}$  (see Fig. 8).

Hence, both dyes D I and D II should exhibit close sensitizing efficiency (if there are no other side effects influencing their sensitizing) resulting in a very close photocatalytic activity of HSs  $\text{TiO}_2/\text{D I/PEPC}$  and  $\text{TiO}_2/\text{D II/PEPC}$  as well as  $\text{CdS}/\text{D I/PEPC}$  and  $\text{CdS}/\text{D II/PEPC}$ . The value of the HS photocatalytic activity should increase if the content of D I or D II raises and then remains stable at further raise in the

dye's content. However, this conclusion does not agree with the experimental data. D I-based HS exhibits significantly higher photocatalytic activity compared with the D II-based materials (see Tables 3 and 4) even though both dyes have very close values of  $E_{\text{D/D}^+}$  and should provide very close efficiency of the electron injection, resulting in similar PA values. Moreover, initial raise in PA tends to decrease as the concentration of the dye increases. This unexpected deviation from thermodynamically predicted characteristics can be explained by the following analysis of the HS spectra.

### ***Spectral changes resulting from the deposition of the dyes on semiconducting particles — Dependence on photocatalytic activity of the heterostructure***

As we mentioned above, the location of the light absorption bands, their width, and intensity ratio can change as a result of deposition of both dyes on the surface of TiO<sub>2</sub> particles. Similar changes probably occur at the formation of CdS-based HS, but they are mostly hidden behind overlapping light absorption bands of CdS. Therefore, we shall confine further consideration to TiO<sub>2</sub>-based materials only.

As seen from Table 1, deposition of D I on the surface of the HS causes shifting of both shortwave and longwave light absorption peaks. This shifting reaches 24 and 27 nm, respectively, for sample 3 ( $C = 0.188$  mg/g). The shifting values decrease to 19 and 21 nm, respectively, if a dye content is larger by one order of magnitude (sample 5,  $C = 1.88$  mg/g). Similarly,<sup>6</sup> such spectral changes can be explained as a result of the strong influence of titanium dioxide on the electron system of the dye molecules on the surface of TiO<sub>2</sub>. The more dye molecules deposited on the surface, the larger would be the distance between the newly deposited molecules and the surface. This effect causes weakening of further spectral changes at the deposition of new portions of the dye. Such weakening can be proved by changes in ratio between the intensities of the shortwave and longwave light absorption bands  $I_{sw}/I_{lw}$  (see Table 1). According to the theory by A. I. Kiprianov,<sup>18,19</sup> this parameter characterizes the spatial orientation of the biscyanine's chromophores. This orientation can be changed by steric and electronic factors.

The value of  $I_{sw}/I_{lw}$  for the D I solution is 0.76. According to ref. 18, this value evidences the obtuse angle between the chromophores (calculations from ref. 7 gave the value of this angle  $\theta = 113^\circ$ ). For a remote-from-surface molecule of D I (sample 5), this value is  $\theta \approx 90^\circ$  ( $I_{sw}/I_{lw} \approx 1$ ) while for a surface and, probably, near-to-surface molecule of the dye, this angle is acute and  $I_{sw}/I_{lw} = 1.38$  and  $1.87$ , respectively (see samples 4 and 3).

The parameter  $\Delta I_{sw}/I_{lw}$  is calculated as the difference between  $I_{sw}/I_{lw}$  values for the dye deposited on TiO<sub>2</sub> and the dissolved dye molecules, and it represents a character of the given semiconductor influence on the dye molecules in the ground state. This parameter can also characterize processes, which occur at the photoexcitation of the HS after a molecule of the dye absorbs the light quantum. This characterization grounds on unavoidable deterioration of conditions of injecting the electrons into the conductivity band and considerable lowering of PA due to weakening of the mutual influence of the dye and semiconductor. As seen in Fig. 5, values of  $\Delta I_{sw}/I_{lw}$  and PA show similar changes for all the samples with  $C_{D\ I} > 0.188$  mg/g. Moreover, the photocatalytic activity shows significant decrease even though a value of  $I_{lw}$  raises, which causes quantitative rise of the light absorption.

Bathochromic shifting of the dye absorption bands also occurs at the formation of a HS from TiO<sub>2</sub> and D II. However, the value of such shifting is significantly lower than the value for TiO<sub>2</sub>/D I heterostructure (see Tables 1 and 2). For example, such values are 10 and 27 nm, respectively, for sample 3. Only the angle between the chromophores differs significantly for these HSs. The ratio between the val-

ues of intensities of the absorption bands shows that this angle decreases though remaining obtuse at the deposition of D II on TiO<sub>2</sub>.

We use the parameter  $\Delta I_{sw}/I_{lw}$  as a characteristic of the dye-semiconductor interaction. The maximal value of  $\Delta I_{sw}/I_{lw} = 1.11$  is reached for sample 3 with  $C_{D\ I} = 0.188$  mg/g while this parameter is only 0.11 for TiO<sub>2</sub>/D II/PEPC. Data from Table 3 prove that PA values of these samples differ more than three times. We consider this difference as an evidence of more intense interaction between TiO<sub>2</sub> and D I compared with TiO<sub>2</sub> and D II.

A joint analysis of the spectral bands shifting and PA values for the HS with CdS, D I, and D II also proves strong dependence of the dyes sensitizing activity on the influence of a semiconductor on their electronic structure and light absorption spectra. For example, more active material (sample 3,  $C_{D\ I} = 0.188$  mg/g) ensures shifting of the HS light absorption band for 24 nm from its position for the dye solution (from 603 to 627 nm, see Fig. 4a) and shows high PA =  $6.7 \times 10^{-1}$  mg/mL min m<sup>2</sup> (see Table 4). A heterostructure with D II has weaker interaction with CdS and shows lower band shifting of 8 nm (from 632 to 640 nm, see Fig. 4b) and lower PA =  $3.2 \times 10^{-1}$  mg/mL min m<sup>2</sup> (see Table 4). The width of the light absorption bands is mainly determined by intermolecular interaction.<sup>20</sup> Therefore, widening of the HS bands compared with the bands of the dye solution can be caused by much stronger interaction between the surface dye molecules compared with the interaction in the solutions.

Both electron-donating and electron-accepting organic molecules can be adsorbed on the semiconductors (for example, TiO<sub>2</sub> or CdS) with partial or complete transfer of the biscyanine electron. Taking into account the presence of both donors (like -NR<sub>2</sub> groups) and accepting (like quaternary nitrogen or a carbonyl group) active centres in a dye molecule, we can assume that they can react with the semiconductor substrate either by donating or accepting mechanisms. Detailed clarification of such processes requires more specialized investigation.

## **Conclusions**

A series of the heterostructures based on TiO<sub>2</sub> and CdS and sensitized with bisquinocyanine dyes have been synthesized. We have determined the photocatalytic activity of these materials and found a character of its dependence on quantitative composition, spectral, and energetic parameters.

It was found that the sensitizing activity of the dyes with similar spectral and oxidation-reduction properties may differ depending on their bonding force with a semiconductor in the HS.

# Ortho-phenylene-bridged aryloxy phosphine ligands and their coordination chemistry with tantalum(V)

Christopher D. Carmichael and Michael D. Fryzuk

**Abstract:** The lithium complexes  $\text{RP}(3,5\text{-}^t\text{Bu}_2\text{C}_6\text{H}_2\text{OLi})_2(\text{THF})_4$ , where  $\text{R} = \text{Ph}$  or  $^i\text{Pr}$ , ( $^{\text{R}}[\text{OPO}]\text{Li}_2$ )(THF)<sub>4</sub>, can be converted quantitatively into the protonated forms,  $^{\text{R}}[\text{OPO}]\text{H}_2$ , by reaction with  $\text{Et}_3\text{NHCl}$ . Reaction of the protonated compounds with  $\text{KH}$  yields the potassium complexes  $^{\text{Ph}}[\text{OPO}]\text{K}_2(\text{THF})_6$  and  $(^i\text{Pr})[\text{OPO}]\text{K}_2(\text{THF})_3$ . The reaction of  $^{\text{R}}[\text{OPO}]\text{H}_2$  with  $\text{TaCl}_5$  yields the sparingly soluble tantalum trichloride complexes  $^{\text{R}}[\text{OPO}]\text{TaCl}_3$  via elimination of  $\text{HCl}$ . Reaction of  $^{\text{Ph}}[\text{OPO}]\text{H}_2$  with  $\text{TaMe}_3\text{Cl}_2$  leads to the monomethyl complex  $^{\text{Ph}}[\text{OPO}]\text{TaMeCl}_2$ , or the dimethyl halide complex,  $^{\text{Ph}}[\text{OPO}]\text{TaMe}_2\text{Cl}$ , via protonolysis, and the potassium complex  $(^{\text{Ph}}[\text{OPO}]\text{K}_2)_2(\text{THF})_6$  yields the trimethyl complex,  $^{\text{Ph}}[\text{OPO}]\text{TaMe}_3$  by a metathesis process.

**Key words:** tantalum, phosphine, potassium, aryloxy, tridentate ligand, alkyl.

**Résumé :** Les complexes du lithium  $\text{RP}(3,5\text{-}^t\text{Bu}_2\text{C}_6\text{H}_2\text{OLi})_2(\text{THF})_4$  dans lesquels  $\text{R} = \text{Ph}$  ou  $^i\text{Pr}$ , ( $^{\text{R}}[\text{OPO}]\text{Li}_2$ )(THF)<sub>4</sub> peuvent être transformés quantitativement en formes protonées,  $^{\text{R}}[\text{OPO}]\text{H}_2$  par réaction avec le  $\text{Et}_3\text{NHCl}$ . La réaction des composés protonés avec le  $\text{KH}$  conduit à la formation des complexes de potassium  $(^{\text{Ph}}[\text{OPO}]\text{K}_2)_2(\text{THF})_6$  et  $(^i\text{Pr})[\text{OPO}]\text{K}_2(\text{THF})_3$ . La réaction du  $^{\text{R}}[\text{OPO}]\text{H}_2$  avec du  $\text{TaCl}_5$  conduit à la formation de complexes du trichlorure de tantale,  $^{\text{R}}[\text{OPO}]\text{TaCl}_3$ , qui sont très peu solubles et qui résultent d'une élimination de  $\text{HCl}$ . La réaction du  $^{\text{Ph}}[\text{OPO}]\text{H}_2$  avec du  $\text{TaMe}_3\text{Cl}_2$  conduit, par le biais d'une protonolyse, à la formation de complexes monométhylés,  $^{\text{Ph}}[\text{OPO}]\text{TaMeCl}_2$ , ou biméthylés,  $^{\text{Ph}}[\text{OPO}]\text{TaMe}_2\text{Cl}$  alors que celle du complexe potassique  $(^{\text{Ph}}[\text{OPO}]\text{K}_2)_2(\text{THF})_6$  conduit, par un processus de métathèse, à la formation du complexe triméthylé,  $^{\text{Ph}}[\text{OPO}]\text{TaMe}_3$ .

**Mots-clés :** tantale, phosphine, potassium, aryloxy, ligand tridentate, alkyle.

[Traduit par la Rédaction]

## Introduction

For some time, we have been interested in examining the coordination chemistry of mixed-donor multidentate ligands.<sup>1,2</sup> By combining hard donors, such as amido ( $\text{NR}_2^-$ ), with soft phosphines ( $\text{PR}_3$ )<sup>3–7</sup> or arsines ( $\text{AsR}_3$ )<sup>8,9</sup> into chelating arrays, we have been able to prepare transition-metal complexes that can activate molecular nitrogen in certain cases.<sup>2,10–13</sup> We have extended this mixed-donor ligand approach to include the hard aryloxy ( $\text{ArO}^-$ ) moiety with phosphines to generate OPO ligand sets with *o*-phenylene linkers.<sup>14</sup> The general family of OPO ligand precursors **A** is shown below with the various substitution patterns that have been examined.

Rhenium and technetium complexes supported by the parent ligand, bis(*o*-phenoxy)phenylphosphine (**A** with  $\text{R}_1 = \text{R}_2 = \text{H}$ ), have drawn interest for their potential use as radiopharmaceutical agents.<sup>15,16</sup> With group 4, the heptacyclic, tetranuclear titanium complex,  $\{(^i\text{PrO})_2\text{Ti}(\mu^3\text{-O})\text{TiCl}(\text{PrO})[(\text{OC}_6\text{H}_4)_2\text{PPh}]\}_2$ , was obtained,<sup>17</sup> likely a result of the lack of steric bulk around the OPO donor set.

Bis(3-*tert*-butyl-5-methyl-2-phenoxy)phenylphosphine (**A**,  $\text{R}_1 = ^t\text{Bu}$ ,  $\text{R}_2 = \text{Me}$ ), which has a sterically bulky *tert*-butyl group ortho to the phenoxy group, has been complexed to titanium<sup>18</sup> and chromium.<sup>19</sup> These complexes were found to be highly active for the polymerization of ethylene.

Bis(3,5-*tert*-butyl-2-phenoxy)phenylphosphine was first reported in 2000;<sup>20</sup> in this report, we abbreviate it as  $^{\text{Ph}}[\text{OPO}]\text{H}_2$  (**A**,  $\text{R}_1 = \text{R}_2 = ^t\text{Bu}$ ), where the Ph superscript refers to the substituent at phosphorus that is not a substituted phenol. Despite the presence of two bulky *tert*-butyl substituents on the phenolic units, the donor set readily forms bis(ligand) complexes with several transition metals, including cobalt and nickel, although in these complexes one phe-

nol arm of the ligand remains protonated.<sup>20</sup> Vanadium(IV) complexes supported by  $\text{Ph}[\text{OPO}]$  can be synthesized by reaction of the protonated phenol with  $\text{VCl}_3(\text{THF})_3$ ;<sup>21</sup> a short exposure to oxygen is necessary to oxidize V(III) to V(IV). Lithium and potassium salts, supported by the chelating donor solvent DME (1,2-dimethoxyethane) have been recently reported.<sup>22</sup>

Several group-4 metal complexes have been prepared using  $\text{Ph}[\text{OPO}]\text{H}_2$ , including  $\text{Ph}[\text{OPO}]\text{TiCl}_2(\text{THF})$ , and the bis(ligand) derivatives  $\text{Ph}[\text{OPO}]_2\text{M}(\text{OH}_2)$  ( $\text{M} = \text{Zr}, \text{Hf}$ ) and  $\text{Ph}[\text{OPO}]_2\text{Ti}$ .<sup>23</sup> The bis(ligand) complex is so readily formed in the titanium system that a comproportionation reaction between  $\text{Ph}[\text{OPO}]_2\text{Ti}$  and  $\text{TiCl}_4(\text{THF})_2$  was found to be the best method for the preparation of  $\text{Ph}[\text{OPO}]\text{TiCl}_2(\text{THF})$ . Similar reactions with  $\text{SnCl}_4$  did not produce the bis(ligand) complex, instead leading to the clean formation of  $\text{Ph}[\text{OPO}]\text{SnCl}_2$ .<sup>24</sup>

A very recent report details the synthesis and structures of a series of bis(ligand) complexes of Ta(V) having the formula  $\text{Ph}[\text{OPO}]_2\text{TaX}$ , where  $\text{X} = \text{Cl}, \text{H}, \text{Me}, \text{Et}$ , and  $\text{OH}$ .<sup>25</sup> Of relevance to this work was the observation that the monoligand complexes  $\text{Ph}[\text{OPO}]\text{TaX}_3$  were not accessible despite a number of different synthetic strategies attempted.

We have recently reported the structural variety of lithium aryloxy complexes based on the  $\text{R}[\text{OPO}]$  donor set<sup>14</sup> utilizing phenyl and *iso*-propyl substituents on phosphorus. We present herein an extension of this bis(aryloxy)phosphine chemistry by reporting an improved synthesis of the protonated compounds  $\text{R}[\text{OPO}]\text{H}_2$  from the lithium salts, the synthesis of THF-supported potassium salts,  $(\text{Ph}[\text{OPO}]\text{K}_2)_2(\text{THF})_6$  (**3**) and  $(i\text{Pr}[\text{OPO}]\text{K}_2)_3(\text{THF})_3$  (**4**), and their reactions with the tantalum precursors  $\text{TaCl}_5$  and  $\text{TaMe}_3\text{Cl}_2$ . We also describe the preparation of the elusive monoligand complexes  $\text{R}[\text{OPO}]\text{TaCl}_3$  ( $\text{R} = \text{Ph}, i\text{Pr}$ ).

## Results and discussion

Reaction of the lithium complexes,  $\text{RP}(3,5\text{-}t\text{Bu}_2\text{C}_6\text{H}_2\text{OLi})_2(\text{THF})_4$ , where  $\text{R} = \text{Ph}$  or  $i\text{Pr}$ ,  $(\text{R}[\text{OPO}]\text{Li})_2(\text{THF})_4$ , with 4 equiv. of  $\text{Et}_3\text{NHCl}$  in diethyl ether, eq. [1], gives the desired products,  $\text{Ph}[\text{OPO}]\text{H}_2$  (**1**) or  $i\text{Pr}[\text{OPO}]\text{H}_2$  (**2**), in 97% and 96% isolated yields, respectively.  $^1\text{H}$  and  $^{31}\text{P}\{^1\text{H}\}$  NMR spectra of **1** are consistent with literature values.<sup>20</sup> The  $^{31}\text{P}\{^1\text{H}\}$  NMR spectrum of **2** displays a singlet at  $\delta -61.6$ , slightly upfield from that observed for **1**, reflecting the more basic nature of the alkyl phosphine. The  $^1\text{H}$  NMR spectrum of **2** contains two singlet resonances for the *tert*-butyl groups, and a characteristic doublet of septets for the methine proton of the *iso*-propyl group coupled to phosphorus and the methyl protons, which appear as a doublet of doublets.

X-ray quality crystals of **1** containing 3 equiv. of the co-crystallized solvent were grown by slow evaporation of a saturated benzene solution. The solid-state structure is pre-

sented in Fig. 1, and selected bond distances and angles are collected in Table 1. The unit cell parameters are identical to those reported for the related phosphine oxide compound.<sup>20</sup> This may seem surprising at first; however, Fig. 1 shows how the oxygen of a phosphine oxide would fit easily into the molecule, while not altering the overall size of the molecule. In addition, the phenolic hydrogens, which were located in the diffraction pattern and refined isotropically, are well-positioned to engage in hydrogen bonding to a phosphine oxide. Phosphine/phosphine oxide systems with identical cell parameters are known,<sup>26</sup> and solid-state structures have been reported with partial oxidation of the phosphine, and thus fractional occupation in the crystal lattice.<sup>27–29</sup> The phenol rings in **1** are twisted with respect to each other by  $23^\circ$ .

The synthesis of the  $\text{R}[\text{OPO}]$  potassium derivatives is outlined in eq. [2]. Reaction of the protonated ligands **1** or **2** with an excess of KH in THF affords the products  $(\text{Ph}[\text{OPO}]\text{K}_2)_2(\text{THF})_6$  (**3**) and  $(i\text{Pr}[\text{OPO}]\text{K}_2)_3(\text{THF})_3$  (**4**) in 92% and 71% yield, respectively. NMR studies indicate that **3** has a symmetric structure in solution as evidenced by two distinct singlet resonances in the  $^1\text{H}$  NMR spectra at  $\delta 1.64$  and  $\delta 1.33$ , which correspond to the two different *tert*-butyl protons on each ring; the  $^{31}\text{P}\{^1\text{H}\}$  NMR spectrum shows a singlet for the  $^{31}\text{P}$  nuclei at  $-29.6$  ppm. Mass spectral analysis indicates that the complex is dimeric in the bulk material.

X-ray quality crystals of **3** containing three molecules of the co-crystallized solvent were grown by slow evaporation of a saturated THF solution at  $-40^\circ\text{C}$ . The solid-state structure is presented in Fig. 2, and selected bond distances and angles are collected in Table 2. Structurally, **3** is a symmetrical dimer, in agreement with the solution and mass spectral data, with two crystallographically related fragments. The core of the structure is virtually identical to the DME-supported complex,  $\text{Ph}[\text{OPO}]\text{K}_2(\text{DME})_2$ , reported recently.<sup>22</sup> The only significant differences are a direct consequence of the difference in coordinating solvent. In both complexes, a single molecule of solvent is bound to K(2); however, the bidentate nature of DME results in longer bonds to the surrounding oxygen atoms than are present in **3**, where a monodentate THF is coordinated. Two solvent oxygens are coordinated to K(1) in both complexes, a single DME in  $\text{Ph}[\text{OPO}]\text{K}_2(\text{DME})_2$  and both terminal and bridging THF molecules in **3**. Although the observed K–O bond distances in the structure of **3** vary by almost  $0.4 \text{ \AA}$ , they agree well with the DME structure<sup>22</sup> and other literature values,<sup>30–32</sup> as do the K–P bond distances.<sup>33–35</sup> With regard to the phosphine to potassium distances in the solid state, it is clear that these are weak interactions and the connectivities only indicate close interactions.

Slow diffusion of hexanes into a benzene solution of **4** af-

forded X-ray quality crystals that have been structurally characterized as the benzene adduct ( $^{\text{tPr}}[\text{OPO}]\text{K}_2(\text{THF})_3(\eta^6\text{-C}_6\text{H}_6)$  (**4-C<sub>6</sub>H<sub>6</sub>**) containing four molecules of co-crystallized benzene and two molecules of co-crystallized hexane per unit cell. The solid-state structure of **4** is presented in Fig. 3. The structure is that of an asymmetric trimer, and one molecule of benzene is  $\pi$ -bonded in a  $\eta^6$  fashion to a potassium atom, K(5), a motif that has been reported in other potassium complexes.<sup>36–38</sup> Unfortunately, extreme disorder in the co-crystallized and coordinated solvent results in very weak data, insufficient to support a more detailed discussion of the structure. A cif file is included in the Supplementary data.

The  $^1\text{H}$  and  $^{31}\text{P}\{^1\text{H}\}$  NMR spectra of **4** show a symmetrical solution structure, which is at odds with the asymmetrical nature of the solid-state structure. A mass spectrum of **4** could not be obtained, presumably due to the high molecular weight of the trimer. One likely explanation for the symmetrical NMR spectra is that the trimer exists only in the solid

**Fig. 2.** Molecular structure (ORTEP) of  $(^{\text{tPr}}[\text{OPO}]\text{K}_2)_2(\text{THF})_6$ , **3**. Ellipsoids are drawn at 50% probability. Carbon atoms of the THF ligands and co-crystallized solvent were removed for clarity. Modeled *t*-butyl disorder was also omitted for clarity.

state and it breaks up in solution forming monomeric species. However, the  $^1\text{H}$  NMR spectrum indicates that THF exists in two different environments, with distinct multiplets attributable to one THF molecule, and broad singlets attributable to two THF molecules. The distinct multiplets indicate that one THF molecule is strongly bound and not undergoing exchange. The broad singlets indicate two THF molecules are undergoing exchange, which is unusual, given the apparent lack of donors in the system, as evidenced by the coordinated benzene in the solid-state structure.

Synthesis of the tantalum chloride complexes  $\text{Ph}[\text{OPO}]\text{-TaCl}_3$  (**5**) and  $^{\text{tPr}}[\text{OPO}]\text{TaCl}_3$  (**6**) is outlined in eq. [3]. Reaction of **1** with  $\text{TaCl}_5$  in diethyl ether under reduced pressure affords a thick mixture of a yellow solid and a yellow solution. Filtration of the mixture and drying of the solid in vacuo affords **5** as a bright yellow powder in 92% isolated yield. The *iso*-propyl derivative is prepared in 82% yield by the analogous reaction of **2** with  $\text{TaCl}_5$ . The complexes were characterized by  $^1\text{H}$  and  $^{31}\text{P}\{^1\text{H}\}$  NMR spectroscopy, mass spectrometry, and elemental analysis. Both complexes display a singlet resonance in the  $^{31}\text{P}\{^1\text{H}\}$  NMR spectrum, **5** at  $\delta$  33.5 and **6** at  $\delta$  31.9.  $^1\text{H}$  NMR spectra indicate that the complexes are  $C_s$ -symmetric, with two resonances due to the *tert*-butyl protons; **6** also displays a diagnostic doublet of septets for the *iso*-propyl methine proton and a doublet of doublets for the *iso*-propyl methyl protons.

The synthesis of **5** and **6** is strongly linked to the concentration of the reagents in the reaction mixture. For example, reaction of **1** with  $\text{TaCl}_5$  in highly concentrated solution

leads to the formation of the known bis(OPO) complex,  $\text{Ph}[\text{OPO}]_2\text{TaCl}$  (**7**),<sup>25</sup> which can be easily separated from **5** by filtration, owing to its significantly increased solubility. Reaction of 2 equiv. of **1** furnishes the highest yield of **7**; however, the reaction does not go to completion.

The synthesis of **5–7** is somewhat unusual in that it proceeds via direct protonolysis of the Ta–Cl bond producing reactive HCl as the byproduct. Salt metathesis routes to early transition-metal coordination complexes are driven to completion by the formation of simple alkali metal salts such as lithium chloride. The formation of HCl does not offer the same driving force as the formation of an alkali metal salt. However, it is likely that the protonolysis reaction is controlled by the oxophilic nature of tantalum and the formation of strong tantalum–oxygen bonds. Alternative routes to traditional salt metathesis in tantalum halide chem-

**Fig. 3.** Molecular structure (ORTEP) of  $(i^{\text{Pr}}[\text{OPO}]\text{K}_2)_3(\text{THF})_3(\eta^6\text{-C}_6\text{H}_6)$ , **4-C}\_6\text{H}\_6**. Ellipsoids are drawn at 50% probability. Carbon atoms of the THF ligands and *t*-butyl groups were removed for clarity.

istry are known, particularly in the synthesis of cyclopentadienyl derivatives containing alkyl silane or stannane functionalities that are then eliminated as silyl chlorides<sup>39,40</sup> or stannyl chlorides,<sup>41,42</sup> respectively. However, the pathway utilized in the synthesis of **5–7** is very rare,<sup>43,44</sup> presumably due to the sensitivity of Ta–O bonds to HCl.<sup>45</sup>

Complexes **5–7** are tantalum halides supported by tridentate mixed-donor ligands, something that could not be achieved with the amidophosphine ligand  $\text{Ph}[\text{NPN}]$ ,<sup>3</sup> where  $\text{Ph}[\text{NPN}] = [\text{PhP}(\text{CH}_2\text{SiMe}_2\text{NPh})_2]$ . With the tantalum-halide species reported here, it should be possible to investigate reduction of the halide in the presence of dinitrogen, a technique that has proven useful in synthesizing dinitrogen complexes of group-4 metals supported by amidophosphine ligands.<sup>11–13</sup> However, typical reduction protocols of complexes **5–7** utilizing  $\text{KC}_8$  or  $\text{Na/Hg}$  in the presence of one or four atmospheres of dinitrogen resulted in the formation of dark brown solids that solution NMR spectral and mass spectral data indicate are composed of several different materials, none of which can be positively identified as a dinitrogen complex. It is possible that the lack of steric bulk around the metal center in these complexes opens alternative reactivity pathways for the reduced metal complex, potentially including the formation of metal–metal bonded species.<sup>46,47</sup>

Another route to dinitrogen complexes that has proven useful with  $[\text{NPN}]$  tantalum complexes is the hydrogenation of alkyl derivatives.<sup>3,48</sup> Reactions of **5** and **6** with alkylating agents such as  $(\text{PhCH}_2)\text{MgCl}$  and  $\text{CH}_3\text{MgCl}$  at  $-40^\circ\text{C}$  and  $-78^\circ\text{C}$  yield only mixtures of products, from which the desired alkyl could not be cleanly isolated. However, in the absence of tantalum halide complexes supported by  $[\text{NPN}]$ , work with that ligand turned to reaction of ligand precursors with tantalum alkyl halide materials, particularly  $\text{TaMe}_3\text{Cl}_2$ .

The synthesis of **5** has shown that phenols react with Ta–Cl bonds, so it was of interest to examine the reaction of **1** with  $\text{TaMe}_3\text{Cl}_2$  where either HCl or  $\text{CH}_4$  could be released. Addition of an ethereal solution of  $\text{TaMe}_3\text{Cl}_2$  to **1** in  $\text{Et}_2\text{O}$  affords a pale yellow solid that solution NMR spectroscopy,

mass spectrometry, and elemental analysis indicate is the monomethyl complex  $\text{Ph}[\text{OPO}]\text{TaMeCl}_2$  (**8**), formed via elimination of two equivalents of methane, as shown in eq. [4]. In the  $^1\text{H}$  NMR spectrum, the methyl ligand appears as a phosphorus-coupled doublet at  $\delta$  2.08 ( $^3J_{\text{PH}} = 9.8$  Hz) integrating to three protons; the  $^{31}\text{P}\{^1\text{H}\}$  NMR spectrum shows a singlet at  $\delta$  38.8. A structure with a trans orientation of the Ta–Me, and the Ta–P is supported by the rather large three-bond P–H coupling constant observed in the  $^1\text{H}$  NMR spectrum. For example, the bis(OPO) complex  $\text{Ph}[\text{OPO}]_2\text{TaMe}$  displays a singlet for the Ta–Me protons in the  $^1\text{H}$  NMR spectrum, indicative of the cis disposition of phosphine groups compared to the methyl on Ta.<sup>25</sup>

Mixed methyl chloride coordination complexes are known in tantalum chemistry, supported by various ligands, including cyclopentadienyl-based ligands,<sup>49–51</sup> and a biphenolate pincer ligand.<sup>52</sup> Although most coordination compounds of this nature are formed via salt metathesis routes, other examples of alkane elimination routes are known.<sup>52,53</sup>

Further reactivity of **8** has not produced results to date. Attempts to create mixed alkyl species through reaction of **8** with  $(\text{PhCH}_2)\text{MgCl}$  result in dark solids that are composed of several materials. A similar result is observed when **8** is reduced in the presence of dinitrogen. Much like the reduction of **7**, reductions produce dark brown materials, from which no dinitrogen complexes could be identified. Hydrogenation of **8** under 4 atm (1 atm = 101.325 kPa) of hydrogen produces a mixture of products, and no resonances attributable to tantalum hydrides can be observed in a  $^1\text{H}$  NMR spectrum.

When a substoichiometric amount of **1** is reacted with  $\text{TaMe}_3\text{Cl}_2$ , an impurity is observed in solution NMR spectra that can be separated from **8** by crystallization. Slow evaporation of the reaction solution deposits bright yellow crystals of X-ray quality. These have been structurally characterized as  $\text{Ph}[\text{OPO}]\text{TaMe}_2\text{Cl}$  (**9**). The solid-state molecular structure is presented in Fig. 4, and selected bond distances and angles are collected in Table 3. There is a distorted octahedral geometry about the tantalum, with the chloride trans to the phosphine and the two aryloxides trans to the methyl carbons. Ta–O, Ta–P, and Ta–Cl bond distances compare well to those of similar complexes reported recently.<sup>25</sup> The tantalum methyl bond distances are very similar to those of  $\text{Ph}[\text{NAsN}]\text{TaMe}_3$ <sup>9</sup> and  $\text{Ph}[\text{NPN}]\text{TaMe}_3$ .<sup>3</sup> In the  $^1\text{H}$  NMR spectrum, the methyl hydrogen resonances are superimposed upon one set of *t*-butyl resonances, but integrate to six protons when the *t*-butyl protons are subtracted. The  $^{31}\text{P}\{^1\text{H}\}$  NMR spectrum shows the expected singlet at  $\delta$  40.6. The origin of **9** is likely a result of a redistribution reaction between the monomethyl  $\text{Ph}[\text{OPO}]\text{TaMeCl}_2$  (**8**) and unreacted  $\text{TaMe}_3\text{Cl}_2$ .

Salt metathesis has proven productive for the synthesis of  $\text{Ph}[\text{OPO}]\text{TaMe}_3$  (**10**), which is outlined in eq. [5]. Reaction of  $\text{TaMe}_3\text{Cl}_2$  with **3** in  $\text{Et}_2\text{O}$  furnishes the product as an off-

white solid in moderate yield (68%). The synthesis can also be carried out using the lithium salt  $(\text{Ph}[\text{OPO}]\text{Li})_2(\text{THF})_4$ ; however, the potassium salt affords a cleaner transformation. In solution, the  $^{31}\text{P}\{^1\text{H}\}$  NMR spectrum of **10** displays a single resonance at  $\delta$  13.0, and the *t*-butyl protons appear as a pair of singlets in the  $^1\text{H}$  NMR spectrum at  $\delta$  1.60 and  $\delta$  1.25, and the methyl protons appear as a phosphorus-coupled doublet ( $^3J_{\text{PH}} = 4.4$  Hz) at  $\delta$  1.53. The methyl carbons appear at  $\delta$  63.5 in the  $^{13}\text{C}\{^1\text{H}\}$  NMR spectrum. The solid-state structure of **10** has not been determined to date; however, a mass spectrum indicates the complex is monomeric. Thus, a distorted octahedral structure similar to **9** would be expected. The observation of three equivalent Ta–Me groups by NMR spectroscopy is likely a result of a fluxional process, similar to that previously reported for  $\text{Ph}[\text{NPN}]\text{TaMe}_3$ .<sup>3</sup>

Reaction of **10** with 4 atm of hydrogen results in the formation of a dark orange solid. NMR spectroscopy indicates the solid is a mixture of different compounds with no resonances attributable to hydrides identifiable.

## Conclusions

In this report, an improved synthesis of the bis(aryloxy)-phosphines  $\text{Ph}[\text{OPO}]\text{H}_2$  and  $i\text{Pr}[\text{OPO}]\text{H}_2$  has been developed by reaction of precursor lithium salts with  $\text{Et}_3\text{NHCl}$ . Conversion of the protonated compounds to potassium salts was accomplished by reaction with KH, furnishing  $(\text{Ph}[\text{OPO}]\text{K}_2)(\text{THF})_6$  and  $(i\text{Pr}[\text{OPO}]\text{K}_2)_3(\text{THF})_3$ .

Tantalum complexes supported by [OPO] were synthesized by reaction of [OPO] precursors with  $\text{TaCl}_5$  and  $\text{TaMe}_3\text{Cl}_2$ . Reactions with  $\text{TaCl}_5$  produce the halide complexes  $\text{Ph}[\text{OPO}]\text{TaCl}_3$  and  $i\text{Pr}[\text{OPO}]\text{TaCl}_3$ , and a bis(ligand) complex,  $\text{Ph}[\text{OPO}]_2\text{TaCl}$ , was synthesized through manipulation of reaction concentration. Reaction with  $\text{TaMe}_3\text{Cl}_2$  furnishing the mixed methyl chloride complexes  $\text{Ph}[\text{OPO}]\text{TaMeCl}_2$  and  $\text{Ph}[\text{OPO}]\text{TaMe}_2\text{Cl}$  by methane elimination, and the trimethyl complex  $\text{Ph}[\text{OPO}]\text{TaMe}_3$  by salt metathesis with the potassium salt  $(\text{Ph}[\text{OPO}]\text{K}_2)_2(\text{THF})_6$ .

## Experimental section

### General procedures

Unless otherwise stated, all manipulations were performed under an atmosphere of dry, oxygen-free dinitrogen or argon by means of standard Schlenk or glovebox techniques (Vacuum Atmospheres HE-553–2 glovebox equipped with a MO-40–2H purification system and a  $-40^\circ\text{C}$  freezer), unless specified. Anhydrous hexanes and toluene were purchased from Aldrich, sparged with dinitrogen, and further dried by passage through a tower of silica followed by passage through a tower of Ridox (or Q-5) catalyst prior to use.<sup>54</sup> Anhydrous pentane, benzene, tetrahydrofuran, and diethyl ether were purchased from Aldrich, sparged with dinitrogen.

trogen, and passed through an Innovative Technologies SPS-PureSolv-400-4 apparatus. Water was distilled and thoroughly degassed prior to use. All organic solvents were tested with addition of sodium benzophenone ketyl prior to use to ensure absence of oxygen and water. Alternatively, anhydrous diethyl ether was stored over sieves and distilled from sodium benzophenone ketyl under argon; tetrahydrofuran was refluxed over  $\text{CaH}_2$  prior to distillation from sodium benzophenone ketyl under argon, and pentane was stored over sieves and distilled from sodium benzophenone ketyl solubilized by tetraglyme under dry dinitrogen prior to storage over a potassium mirror. Nitrogen gas was dried and deoxygenated by passage through a column containing activated molecular sieves and  $\text{MnO}$ .

Deuterated benzene was dried by refluxing with molten

sodium/potassium alloy in a sealed vessel under partial pressure, then trap-to-trap distilled, and freeze-pump-thaw-degassed three times. Deuterated tetrahydrofuran and toluene were dried by refluxing with molten potassium metal or sodium-potassium alloy in a sealed vessel under vacuum, then trap-to-trap distilled, and freeze-pump-thaw-degassed three times.  $^1\text{H}$ ,  $^{31}\text{P}$ ,  $^1\text{H}\{^{31}\text{P}\}$ ,  $^{31}\text{P}\{^1\text{H}\}$ ,  $^{13}\text{C}\{^1\text{H}\}$ , and  $^7\text{Li}\{^1\text{H}\}$  NMR spectra were recorded on either a Bruker AMX-500 instrument operating at 500.13 MHz for  $^1\text{H}$  spectra, a Bruker AVA-400 instrument operating at 400.13 MHz for  $^1\text{H}$  spectra, or a Bruker AVA-300 instrument operating at 300.13 MHz for  $^1\text{H}$  spectra.  $^1\text{H}$  NMR spectra were referenced to residual protons in deuterated solvent as follows:  $\text{C}_6\text{D}_5\text{H}$  ( $\delta$  7.15),  $\text{C}_4\text{D}_7\text{HO}$  ( $\delta$  3.58), and  $\text{C}_7\text{D}_7\text{H}$  ( $\delta$  2.09) with respect to tetramethylsilane at  $\delta$  0.0.  $^{13}\text{C}$  NMR spectra were referenced to 1% tetramethylsilane in  $\text{CDCl}_3$  at  $\delta$  0.0.  $^{31}\text{P}$  NMR spectra were referenced to either external or internal  $\text{P}(\text{OMe})_3$  ( $\delta$  141.0 with respect to 85%  $\text{H}_3\text{PO}_4$  at  $\delta$  0.0).  $^7\text{Li}$  NMR spectra were referenced to external  $\text{LiCl}$  (0.3 mol/L solution in  $\text{MeOH}$  at  $\delta$  0.0). Elemental analyses were performed by Mr. P. Borda and Mr. M. Lakha, and mass spectrometry (EI/MS on a Kratos MS 50 unless otherwise stated) was performed by Mr. M. Lapawa, all at the Department of Chemistry, the University of British Columbia.

## Materials

The complexes  $(\text{Ph}[\text{OPO}]\text{Li}_2)_2(\text{THF})_4$  and  $(i\text{Pr}[\text{OPO}]\text{Li}_2)_2(\text{THF})_4$  were prepared by the literature procedure.<sup>14</sup>  $\text{Et}_3\text{NHCl}$  was prepared by the reaction of triethylamine and aqueous hydrochloric acid, and recrystallized from ethanol. Potassium hydride was purchased from Acros Chemicals and used as received;  $\text{TaCl}_5$  was purchased from STREM and sublimed prior to use.  $\text{TaMe}_3\text{Cl}_2$  was prepared according to published methods.<sup>55</sup>

## Synthesis of $\text{Ph}[\text{OPO}]\text{H}_2$ (**1**)

To an intimate mixture of  $(\text{Ph}[\text{OPO}]\text{Li}_2)_2(\text{THF})_4$  (5.00 g, 7.41 mmol) and  $\text{Et}_3\text{NHCl}$  (2.01 g, 14.8 mmol) was added  $\text{Et}_2\text{O}$  (150 mL). The solution was stirred for 12 h, and then the solvent was removed under vacuum. The residue was extracted into toluene (50 mL), the solution filtered through Celite, and then evaporated to dryness. The colourless solid was washed with minimal pentane and dried under vacuum. Yield: 3.74 g (97%). X-ray quality crystals of **1** containing three equivalents of co-crystallized solvent were grown by slow evaporation of a saturated benzene solution.  $^1\text{H}$  NMR (500 MHz,  $\text{C}_6\text{D}_6$ , 25 °C)  $\delta$ : 7.64 (d,  $^3J_{\text{HH}} = 2.3$  Hz, 1H, *p*-PPh), 7.35 (m, 4H, *o*/*m*-PPh), 7.23 (s, 2H, Ph), 7.02 (m, 2H, Ph), 6.50 (d,  $^4J_{\text{PH}} = 8.9$  Hz, OH), 1.61 (s, 18H, *o*- $\text{PhC}(\text{CH}_3)_3$ ), 1.26 (s, 18H, *p*- $\text{PhC}(\text{CH}_3)_3$ ).  $^{31}\text{P}\{^1\text{H}\}$  NMR (121.4 MHz,  $\text{C}_6\text{D}_6$ , 25 °C)  $\delta$ : -50.23 (s).  $^1\text{H}$  NMR (300 MHz,  $\text{C}_4\text{D}_8\text{O}$ , 25 °C)  $\delta$ : 7.33 (d,  $^3J_{\text{HH}} = 2.4$  Hz, 2H, Ph-*H*), 7.27 (m, 7H, Ph-*H*), 6.84 (dd,  $^4J_{\text{HH}} = 2.4$  Hz,  $^4J_{\text{PH}} = 5.5$  Hz, 2H, OH), 1.42 (s, 18H, *o*- $\text{PhC}(\text{CH}_3)_3$ ), 1.12 (s, 18H, *p*- $\text{PhC}(\text{CH}_3)_3$ ).  $^{31}\text{P}\{^1\text{H}\}$  NMR (121.4 MHz,  $\text{C}_4\text{D}_8\text{O}$ , 25 °C)  $\delta$ : -47.18 (s).

## Synthesis of $i\text{Pr}[\text{OPO}]\text{H}_2$ (**2**)

Following the procedure for **1**,  $\text{Et}_2\text{O}$  (150 mL) was added to an intimate mixture of  $\text{Et}_3\text{NHCl}$  (1.95 g, 14.18 mmol) and  $(i\text{Pr}[\text{OPO}]\text{Li}_2)_2(\text{THF})_4$  (4.54 g, 7.09 mmol). Yield: 3.27 g

(96%).  $^1\text{H}$  NMR (300 MHz,  $\text{C}_6\text{D}_6$ , 25 °C)  $\delta$ : 7.58 (dd,  $^3J_{\text{PH}} = 4.5$  Hz,  $^4J_{\text{HH}} = 2.2$  Hz, 2H, *o*-OPh), 7.50 (d,  $^4J_{\text{HH}} = 2.2$  Hz, 2H, *p*-OPh), 7.00 (d,  $^4J_{\text{PH}} = 11.2$  Hz, OH), 2.88 (ds,  $^2J_{\text{PH}} = 12.4$  Hz,  $^3J_{\text{HH}} = 6.9$  Hz, 1H, P-CH(CH<sub>3</sub>)<sub>2</sub>), 1.50 (s, 18H, *o*-PhC(CH<sub>3</sub>)<sub>3</sub>), 1.29 (s, 18H, *p*-PhC(CH<sub>3</sub>)<sub>3</sub>), 0.92 (dd,  $^3J_{\text{PH}} = 18.2$  Hz,  $^3J_{\text{HH}} = 6.9$  Hz, 6H, P-CH(CH<sub>3</sub>)<sub>2</sub>).  $^{31}\text{P}\{^1\text{H}\}$  NMR (121.4 MHz,  $\text{C}_6\text{D}_6$ , 25 °C)  $\delta$ : -61.65 (s). MS (EI)  $m/z$  (%): 484 (100) [M]<sup>+</sup>. Anal. calcd. for  $\text{C}_{31}\text{H}_{49}\text{O}_2\text{P}$ : C, 76.82; H, 10.19. Found: C, 76.62; H, 9.96.

#### Synthesis of $(^{\text{Ph}}[\text{OPO}]\text{K}_2)(\text{THF})_6$ (3)

Potassium hydride (1.16 g, 28.9 mmol) was added in portions over 30 min to a solution of  $^{\text{Ph}}[\text{OPO}]\text{H}_2$  (5.0 g, 9.6 mmol) in THF (100 mL) with stirring. The solution was then placed under partial vacuum until the evolution of hydrogen ceased, stirred 12 h under static partial vacuum, filtered through Celite, and then evaporated to dryness. The resulting pale yellow residue was washed with minimal hexanes to give **3** as a colourless solid. Yield: 7.13 g (92%). X-ray quality crystals of **3** containing three equivalents of co-crystallized solvent were grown from a saturated THF solution at -40 °C.  $^1\text{H}$  NMR (300 MHz,  $\text{C}_6\text{D}_6$ , 25 °C)  $\delta$ : 7.52–6.96 (m, 18H, Ph), 3.62 (m, 24H, THF-OCH<sub>2</sub>CH<sub>2</sub>), 1.64 (s, 36H, *o*-PhC(CH<sub>3</sub>)<sub>3</sub>), 1.48 (m, 24H, THF-OCH<sub>2</sub>CH<sub>2</sub>), 1.33 (s, 36H, *p*-PhC(CH<sub>3</sub>)<sub>3</sub>).  $^{31}\text{P}\{^1\text{H}\}$  NMR (121.4 MHz,  $\text{C}_6\text{D}_6$ , 25 °C)  $\delta$ : -29.59 (s). MS (EI)  $m/z$  (%): 1188 (6) [M - (THF)<sub>6</sub>]<sup>+</sup>, 516 (80) [OPO]<sup>+</sup>. Anal. calcd. for  $\text{C}_{92}\text{H}_{138}\text{K}_4\text{O}_{10}\text{P}_2 \cdot 2\text{C}_4\text{H}_8\text{O}$ : C, 67.99; H, 8.79. Found: C, 68.38; H, 8.65.

#### Synthesis of $(^{\text{iPr}}[\text{OPO}]\text{K}_2)(\text{THF})_3$ (4)

Following the procedure for **3**, KH (0.21 g, 5.19 mmol) was added to a solution of **2** (1.00 g, 2.017 mmol) in THF (25 mL). Yield: 0.93 g (71%). X-ray quality crystals of the benzene adduct **4**· $\text{C}_6\text{H}_6$  containing one equivalent of co-crystallized benzene and half a molecule of co-crystallized hexane were grown from slow diffusion of hexanes into a benzene solution. Crystals of **4**· $\text{C}_6\text{H}_6$  were dried and used for elemental analysis.  $^1\text{H}$  NMR (300 MHz,  $\text{C}_6\text{D}_6$ , 25 °C)  $\delta$ : 7.15 (d,  $^3J_{\text{HH}} = 2.6$  Hz, 6H, Ph), 6.94 (d,  $^3J_{\text{HH}} = 2.6$  Hz, 6H, Ph), 3.62 (m, 4H, THF-OCH<sub>2</sub>CH<sub>2</sub>), 3.58 (s, 8H, THF-OCH<sub>2</sub>CH<sub>2</sub>), 2.28 (m, 3H, P-CH(CH<sub>3</sub>)<sub>2</sub>), 1.78 (m, 4H, THF-OCH<sub>2</sub>CH<sub>2</sub>), 1.73 (s, 8H, THF-OCH<sub>2</sub>CH<sub>2</sub>), 1.39 (s, 54H, *o*-PhC(CH<sub>3</sub>)<sub>3</sub>), 1.21 (s, 54H, *p*-PhC(CH<sub>3</sub>)<sub>3</sub>), 1.00 (dd,  $^3J_{\text{PH}} = 14.4$  Hz,  $^3J_{\text{HH}} = 6.6$  Hz, 18H, P-CH(CH<sub>3</sub>)<sub>2</sub>).  $^{31}\text{P}\{^1\text{H}\}$  NMR (121.4 MHz,  $\text{C}_6\text{D}_6$ , 25 °C)  $\delta$ : -37.41 (s). Anal. calcd. for  $\text{C}_{105}\text{H}_{165}\text{K}_6\text{O}_9\text{P}_3 \cdot 1/3\text{C}_6\text{H}_6$ : C, 67.43; H, 8.72. Found: C, 67.08; H, 8.61.

#### Synthesis of $^{\text{Ph}}[\text{OPO}]\text{TaCl}_3$ (5)

To an intimate mixture of **1** (2.86 g, 3.86 mmol) and TaCl<sub>5</sub> (1.38 g, 3.86 mmol) was added diethyl ether (100 mL) with stirring. The bright yellow solution was stirred for 12 h under reduced static pressure during which time a yellow solid was deposited. The solution was filtered through Celite and evaporated to dryness. The residue was washed with hexanes and dried under vacuum to yield **5** as a bright yellow solid. Yield: 2.86 g (92%).  $^1\text{H}$  NMR (300 MHz,  $\text{C}_6\text{D}_6$ , 25 °C)  $\delta$ : 7.60 (m, 6H, Ph), 7.05 (m, 3H, Ph), 1.57 (s, 18H, *o*-PhC(CH<sub>3</sub>)<sub>3</sub>), 1.16 (s, 18H, *p*-PhC(CH<sub>3</sub>)<sub>3</sub>).  $^{31}\text{P}\{^1\text{H}\}$  NMR (121.4 MHz,  $\text{C}_6\text{D}_6$ , 25 °C)  $\delta$ :

33.46 (s). MS (EI)  $m/z$  (%): 802 (100) [M]<sup>+</sup>. Anal. calcd. for  $\text{C}_{34}\text{H}_{45}\text{Cl}_3\text{O}_2\text{PTa}$ : C, 50.79; H, 5.64. Found: C, 50.90; H, 5.76.

#### Synthesis of $^{\text{iPr}}[\text{OPO}]\text{TaCl}_3$ (6)

With the same procedure described above for **5**, **2** (1.00 g, 2.07 mmol) was reacted with TaCl<sub>5</sub> (0.743 g, 2.07 mmol), giving **6** as a bright yellow solid. Yield: 1.31 g (82%).  $^1\text{H}$  NMR (300 MHz,  $\text{C}_6\text{D}_6$ , 25 °C)  $\delta$ : 7.52 (m, 2H, Ph), 7.21 (m, 2H, Ph), 3.03 (dsep,  $^2J_{\text{PH}} = 5.8$  Hz,  $^3J_{\text{HH}} = 6.9$  Hz, 1H, P-CH(CH<sub>3</sub>)<sub>2</sub>), 1.50 (s, 18H, *o*-PhC(CH<sub>3</sub>)<sub>3</sub>), 1.35 (dd,  $^3J_{\text{PH}} = 19.2$  Hz,  $^3J_{\text{HH}} = 6.9$  Hz, 6H, P-CH(CH<sub>3</sub>)<sub>2</sub>), 1.23 (s, 18H, *p*-PhC(CH<sub>3</sub>)<sub>3</sub>).  $^{31}\text{P}\{^1\text{H}\}$  NMR (121.4 MHz,  $\text{C}_6\text{D}_6$ , 25 °C)  $\delta$ : 31.88 (s). MS (EI)  $m/z$  (%): 768 (100) [M]<sup>+</sup>. Elemental analysis was not obtained.

#### Synthesis of $^{\text{Ph}}[\text{OPO}]_2\text{TaCl}$ (7)

A solution of **1** (2.00 g, 3.87 mmol) in toluene (10 mL) was added dropwise to a suspension of TaCl<sub>5</sub> (0.693 g, 1.93 mmol) in toluene (10 mL) with stirring. The resulting yellow solution was stirred for 24 h then evaporated to dryness. The residue was extracted into hexanes (5 mL), filtered through Celite, and the solvent was removed under vacuum, furnishing **7** as a bright yellow powder. Yield: 1.09 g (45%).  $^1\text{H}$  NMR (300 MHz,  $\text{C}_6\text{D}_6$ , 25 °C)  $\delta$ : 7.70–7.04 (m, 18H, Ph), 1.49 (s, 36H, *o*-PhC(CH<sub>3</sub>)<sub>3</sub>), 1.14 (s, 36H, *p*-PhC(CH<sub>3</sub>)<sub>3</sub>).  $^{31}\text{P}\{^1\text{H}\}$  NMR (121.4 MHz,  $\text{C}_6\text{D}_6$ , 25 °C)  $\delta$ : 37.85 (s). MS (EI)  $m/z$  (%): 1249 (30) [M]<sup>+</sup>. Anal. calcd. for  $\text{C}_{68}\text{H}_{90}\text{ClO}_4\text{P}_2\text{Ta}$ : C, 65.35; H, 7.26. Found: C, 65.56; H, 7.43.

#### Synthesis of $^{\text{Ph}}[\text{OPO}]\text{TaMeCl}_2$ (8)

A solution of TaMe<sub>3</sub>Cl<sub>2</sub> (0.12 g, 0.39 mmol) in Et<sub>2</sub>O (10 mL) was added dropwise to a solution of **1** (0.20 g, 0.39 mmol) in Et<sub>2</sub>O (50 mL) at -78 °C, and the resulting pale yellow solution was stirred at -78 °C for 1 h. Removal of the cold bath, slow warming for 40 min, followed by removal of the solvent under vacuum gave a pale yellow residue that was washed with minimal pentane and dried under vacuum to give **8** as a pale yellow solid. Yield: 0.21 g (70%).  $^1\text{H}$  NMR (300 MHz,  $\text{C}_6\text{D}_6$ , 25 °C)  $\delta$ : 7.58 (m, 6H, Ph), 7.09 (m, 3H, Ph), 2.08 (d,  $^3J_{\text{PH}} = 9.8$  Hz, 3H, Ta-CH<sub>3</sub>), 1.56 (s, 18H, PhC(CH<sub>3</sub>)<sub>3</sub>), 1.23 (s, 6H, PhC(CH<sub>3</sub>)<sub>3</sub>), 1.19 (s, 12H, PhC(CH<sub>3</sub>)<sub>3</sub>).  $^{31}\text{P}\{^1\text{H}\}$  NMR (121.4 MHz,  $\text{C}_6\text{D}_6$ , 25 °C)  $\delta$ : 38.79 (s). MS (EI)  $m/z$  (%): 782 (100) [M]<sup>+</sup>. Anal. calcd. for  $\text{C}_{35}\text{H}_{48}\text{Cl}_2\text{O}_2\text{PTa}$ : C, 53.65; H, 6.17. Found: C, 53.87; H, 6.23.

#### Synthesis of $^{\text{Ph}}[\text{OPO}]\text{TaMe}_2\text{Cl}$ (9)

A solution of TaMe<sub>3</sub>Cl<sub>2</sub> (0.056 g, 0.188 mmol) in Et<sub>2</sub>O (5 mL) was added dropwise to a solution of **1** (0.076 g, 0.147 mmol) in Et<sub>2</sub>O (5 mL) at -78 °C. After 1 h, the solution was warmed to room temperature, concentrated to about half volume, and allowed to slowly evaporate, affording **9** as yellow crystals of X-ray quality. Yield: 0.025 g (22% from **1**).  $^1\text{H}$  NMR (300 MHz,  $\text{C}_6\text{D}_6$ , 25 °C)  $\delta$ : 7.64 (m, 5H, Ph), 7.12 (m, 4H, Ph), 1.56 (br s, 24H, Ta-CH<sub>3</sub> and *o*-PhC(CH<sub>3</sub>)<sub>3</sub>), 1.22 (s, 18H, *p*-PhC(CH<sub>3</sub>)<sub>3</sub>).  $^{31}\text{P}\{^1\text{H}\}$  NMR (121.4 MHz,  $\text{C}_6\text{D}_6$ , 25 °C)  $\delta$ : 40.65 (s). Elemental analysis was not recorded.

### Synthesis of *Ph*[OPO]TaMe<sub>3</sub> (**10**)

A solution of TaMe<sub>3</sub>Cl<sub>2</sub> (0.040 g, 0.135 mmol) in Et<sub>2</sub>O (10 mL) was added dropwise to a solution of **3** (0.100 g, 0.067 mmol) in Et<sub>2</sub>O (50 mL) at –78 °C, and the resulting pale solution was stirred at –78 °C for 1 h. Removal of the cold bath, slow warming for 40 min, followed by removal of the solvent under vacuum gave a pale yellow solid. The residue was extracted into toluene (20 mL), the solution filtered through Celite, and evaporated to dryness yielding a solid that was washed with minimal pentane and dried under vacuum to give **10** as an off-white solid. Yield: 0.068 g (68%). <sup>1</sup>H NMR (300 MHz, C<sub>6</sub>D<sub>6</sub>, 25 °C) δ: 7.82 (m, 1H, *p*-PPh), 7.65 (dd, <sup>3</sup>J<sub>HH</sub> = 2.2 Hz, <sup>3</sup>J<sub>PH</sub> = 6.1 Hz, 2H, *o*-PPh), 7.58 (d, <sup>3</sup>J<sub>HH</sub> = 2.2 Hz, 2H, *m*-PPh), 7.11 (m, 4H, Ph), 1.60 (s, 18H, *o*-PhC(CH<sub>3</sub>)<sub>3</sub>), 1.53 (d, <sup>3</sup>J<sub>PH</sub> = 4.4 Hz, 9H, Ta–CH<sub>3</sub>), 1.25 (s, 18H, *p*-PhC(CH<sub>3</sub>)<sub>3</sub>). <sup>31</sup>P{<sup>1</sup>H} NMR (121.4 MHz, C<sub>6</sub>D<sub>6</sub>, 25 °C) δ: 12.98 (s). <sup>13</sup>C{<sup>1</sup>H} NMR (75.4 MHz, C<sub>7</sub>D<sub>8</sub>, 0 °C) δ: 166.2 (s, *o*Ph *i*-C), 145.4 (d, <sup>1</sup>J<sub>PC</sub> = 4.0 Hz, PPh *i*-C), 138.3 (d, <sup>1</sup>J<sub>PC</sub> = 5.7 Hz, P–PhC(CH<sub>3</sub>)<sub>3</sub> *i*-C), 132.2 (s, PPh *o*-C), 132.0 (s, PPh *o*-C), 129.6–123.7 (Ph–C), 63.5 (s, Ta–(CH<sub>3</sub>)<sub>3</sub>), 35.3 (s, *o*-PhC(CH<sub>3</sub>)<sub>3</sub>), 34.7 (s, *p*-PhC(CH<sub>3</sub>)<sub>3</sub>), 31.5 (s, *o*-PhC(CH<sub>3</sub>)<sub>3</sub>), 29.6 (s, *p*-PhC(CH<sub>3</sub>)<sub>3</sub>). MS (EI) *m/z* (%): 742 (100) [M]<sup>+</sup>. Anal. calcd. for C<sub>37</sub>H<sub>54</sub>O<sub>2</sub>PTa: C, 59.83; H, 7.33. Found: C, 59.75; H, 7.45.

### Crystallography

In all cases, suitable crystals were selected and mounted on a glass fibre using Paratone-N oil or an acceptable substitute and frozen to –100 °C.

Measurements for structure **1** were made on a Rigaku/ADSC CCD area detector with graphite monochromated Mo K $\alpha$  radiation. The data were processed using the d\*TREK<sup>56</sup> module, part of the CrystalClear software package, version 1.3.6 SP0,<sup>57</sup> and corrected for Lorentz and polarization effects and absorption. Neutral atom scattering factors for all non-hydrogen atoms were taken from Cromer and Waber.<sup>58</sup> Anomalous dispersion effects were included in *F*<sub>calcd</sub>.<sup>59</sup>

Measurements for structures **3**, **4**, and **9** were made on a Bruker X8 area detector with monochromated Mo K $\alpha$  radiation. The data were processed and integrated using the Bruker SAINT software package<sup>60</sup> and corrected for absorption effects using the multi-scan technique (SADABS).<sup>61</sup>

All structures were solved by direct methods using the programs SIR97<sup>62</sup> or SIR2002.<sup>63</sup> All non-hydrogen atoms were refined anisotropically by least-squares procedures on *F*<sup>2</sup> using SHELXL-97.<sup>64</sup> Hydrogen atoms were included but not refined; their positional parameters were calculated with fixed C–H bond distances of 0.99 Å for sp<sup>2</sup> C, 0.98 Å for sp<sup>3</sup> C, and 0.95 Å for aromatic sp C, with *U*<sub>iso</sub> set to 1.2 × *U*<sub>eq</sub> of the attached sp or sp<sup>2</sup> C and *U*<sub>iso</sub> set to 1.5 × *U*<sub>eq</sub> values of the attached sp<sup>3</sup> C atom. Methyl hydrogen torsion angles were determined by electron density. Structure solution and refinements were conducted using the WinGX software package, version 1.64.05.<sup>65</sup> Structural illustrations were created using ORTEP-III for Windows.<sup>66</sup>

# Electrochemical reduction of sunset yellow at a multiwalled carbon nanotube (MWCNT)-modified glassy carbon electrode and its analytical application

Yuan-Zhi Song

**Abstract:** The electrochemical reduction of sunset yellow at a multiwalled carbon nanotube (MWCNT)-modified glassy carbon electrode is investigated using cyclic voltammetry. A simple, sensitive, and inexpensive method for determination of sunset yellow in soft drinks is proposed and the accuracy and reproducibility of this determination method are evaluated. This method is satisfactorily applied for the determination of sunset yellow in soft drinks in the concentration range of 1.2–125.0 mg L<sup>-1</sup> and 125.0–265.0 mg L<sup>-1</sup>, with a detection limit of 0.5 mg L<sup>-1</sup>.

**Key words:** sunset yellow, multiwalled carbon nanotube (MWCNT), cyclic voltammetry, glassy carbon electrode.

**Résumé :** Faisant appel à la voltampérométrie cyclique, on a étudié la réduction électrochimique du jaune soleil à une électrode de carbone vitreux modifiée par un nanotube de carbone à surfaces multiples. On propose une méthode simple, sensible et peu coûteuse de déterminer le jaune soleil dans les boissons gazeuses et on en a évalué la reproductibilité et l'exactitude. Cette méthode peut être appliquée d'une façon satisfaisante pour la détermination du jaune soleil dans les boissons gazeuses à des concentrations allant de 1,2 à 125,0 mg L<sup>-1</sup> et de 125,0 à 265,0 mg L<sup>-1</sup> avec une limite de détection de 0,5 mg L<sup>-1</sup>.

**Mots-clés :** jaune soleil, nanotube de carbone à surfaces multiples, voltampérométrie cyclique, électrode de carbone vitreuse.

## Introduction

Sunset yellow is an azo compound that is found in common food products such as candies, beverages, bakery products, and dairy products. As the genetic toxicity of some azo dyes has been confirmed,<sup>1,2</sup> accurate and reliable methods for the determination of synthetic dyes in foodstuff are required. Although spectrophotometry,<sup>3–6</sup> thin-layer chromatography,<sup>7–9</sup> reversed-phase liquid chromatography (RPLC),<sup>10,11</sup> ion-pair RPLC,<sup>12,13</sup> capillary electrophoresis,<sup>14–18</sup> and anion-exchange chromatography<sup>19–21</sup> have been used for the determination of various water-soluble synthetic dyes, many of these methods are time-consuming.

Since carbon nanotubes (CNTs) were discovered in 1991,<sup>22</sup> they have attracted much attention from researchers. The modification of electrode substrates with multiwalled carbon nanotubes (MWCNTs) has been shown to result in high sensitivities, electron-transfer promotion, resistance to surface fouling, and reduction of overpotentials. It has been reported that CNT modified electrodes can be successfully applied in the determination of many organic molecules.<sup>23–29</sup>

This paper concerns the electrochemical reduction of sunset yellow at multiwalled carbon nanotube-modified glassy carbon electrode (MWCNT/GCE) and the development of a

simple, rapid, and effective method for the determination of sunset yellow in drinks.

## Experimental

### Chemicals and reagents

Tartrazine, amaranth, ponceau 4R, sunset yellow, and brilliant blue FCF were purchased from the National Research Center for Certified Reference Materials (CRMs; Beijing, China). MWCNTs were purchased from Shenzhen Nanotechnologies Port Co. Ltd. (China). All other reagents were analytical grade. Double-distilled water was used throughout. Phosphate buffer solution (PBS; 0.1 mol/L) was prepared by dissolving 0.1 mol NaCl and 0.1 mol Na<sub>2</sub>HPO<sub>4</sub> in 1 L of double-distilled water and adjusting the pH using 6 mol/L aq HCl or 1 mol/L NaOH solution.

### Instrumentation

For all electrochemical experiments, a CHI660B electrochemical analyzer (CH Instruments, Inc., USA) was employed. The electrochemical cells consisted of a three electrode, a 3 mm diameter glassy carbon disc electrode, and a MWCNT composite modified GCE were used as the working electrode, a platinum wire served as the counter electrode, and a saturated calomel electrode (SCE) was used

**Fig. 1.** TEM image of the purified MWCNTs.

as the reference electrode. The MWCNTs were characterized by transmission electron microscopy (TEM) (JEM 2100, JEOL Ltd., Japan).

#### Preparation of MWCNTs and modified GCE

The MWCNTs were purified in boiling concentrated nitric acid for 3 h, followed by rinsing with deionized water, and drying under ambient atmosphere. Open-end MWCNTs with hydrophilic surfaces were thus obtained. The TEM image of purified MWCNTs is shown in Fig. 1; many nanocarbon tubes with diameters ranging from 20 to 30 nm were observed. Before modification, the GCE was polished with 0.05  $\mu\text{m}$  alumina slurry on a polishing cloth, rinsed thoroughly with double-distilled water, and then sonicated in ethanol and double-distilled water for 10 min, sequentially. The modifier suspension was prepared by dispersing the MWCNTs in 5.0 mL of *N,N*-dimethylformamide under sonication for 30 min. The MWCNT modified GCE was prepared by casting 5  $\mu\text{L}$  of the above-mentioned black suspension on the GCE surface using a micropipette and left to dry at room temperature. Before the cyclic voltammetric measurements, the modified electrode was cycled between  $-1$  and  $1$  V (scan rate  $100 \text{ mV s}^{-1}$ ) in  $0.1 \text{ mol/L}$  PBS for several times until acquiring the reproducible responses.

## Results and discussion

#### Electrochemical behavior of sunset yellow at MWCNT/GCE

The cyclic voltammograms (CVs) of sunset yellow at bare GCE and MWCNT/GCE in purged  $\text{N}_2$   $0.1 \text{ mol/L}$  PBS of pH 8.3 are shown in Fig. 2. It can be seen that the reduction peak for sunset yellow at bare GCE and MWCNT/GCE are observed at  $-0.780 \text{ V}$  and  $-0.721 \text{ V}$ , respectively, the reduction potential of sunset yellow at MWCNT/GCE shifted to positive potentials, and the peak current increased.

These results indicate that the MWCNT modified electrode promoted the electrochemical reduction of sunset yellow

**Fig. 2.** CVs of  $50.0 \text{ mg L}^{-1}$  sunset yellow at (a) MWCNT/GCE and (b) bare GCE; CVs of (c) MWCNT/GCE and (d) bare GCE. Scan rate:  $100 \text{ mV s}^{-1}$ ; supporting electrolyte:  $0.1 \text{ mol/L}$  PBS of pH 8.3;  $5 \mu\text{L}$  accumulation volume of  $1.0 \text{ mg mL}^{-1}$  MWCNT suspension.

low by considerably accelerating the rate of electron transfer. Purified MWCNTs are functionalized with  $-\text{OH}$  and  $-\text{COOH}$ , which could interact with hydroxyl and sulfonyl in sunset yellow to form a hydrogen bond. The  $\pi$ - $\pi$  conjugated bonds between MWCNTs and the sunset yellow probably increase the reduction current. The MWCNT interface has a large surface area, a great deal of active sites, better conductivity, and favorable electrocatalytic power; all of them led to the dissimilar conjugation effect of sunset yellow with the bare electrode interface.

#### Amount of the modifier

The reduction current of sunset yellow at a modified electrode can be affected by the amount of MWCNTs on the electrode surface. This can be controlled by using the same volume ( $5.0 \mu\text{L}$ ) of the suspensions with the different concentrations of MWCNTs, casted on the surface of the GCE. The experiments showed that the reduction peak current for  $50.0 \text{ mg L}^{-1}$  sunset yellow increased quickly by increasing the concentration of MWCNT suspension deposited on the surface of the GCE up to  $1.0 \text{ mg mL}^{-1}$  (Fig. 3). A further increase caused a gradual decrease in the cathodic peak current of sunset yellow with an increase in background current. As a result,  $5.0 \mu\text{L}$  of  $1.0 \text{ mg mL}^{-1}$  MWCNT suspension was selected as the optimum volume for preparation of the modified electrode.

#### Influence of pH

The influence of pH on the electrochemical behavior of sunset yellow was investigated at different pH values in the range of 2.0 to 11.4. Figure 4 shows the CVs of  $50.0 \text{ mg L}^{-1}$  sunset yellow on the surface of the modified electrode over the discussed pH range at the scan rate of  $100 \text{ mV s}^{-1}$ . It was found that the peak potential ( $E_p$ ) shifted negatively with pH increasing and a good linear relationship was observed between the  $E_p$  and pH values in the range of 3.0 to 8.3 with the following equation:  $E_p (\text{V}) = -0.0681\text{pH} - 0.0404$  ( $R$ : correlation coefficient;  $R^2 = 0.988$ ).

**Fig. 3.** Dependence of the reduction peak current of 50.0 mg L<sup>-1</sup> sunset yellow on the amount of the modifier.

**Fig. 4.** Influence of pH on the shape of the cathodic peak of 50.0 mg L<sup>-1</sup> sunset yellow; pH: (a) 3.0, (b) 5.0, (c) 7.0, (d) 8.3, (e) 9.7, and (f) 11.4. Insert: Plot of the peak potential against pH; Scan rate: 100 mV s<sup>-1</sup>.

A value of about -68.1 mV per pH unit indicates that equal numbers of electrons and protons are involved in the electroreduction of sunset yellow on the surface of the modified electrode. On the other hand, the peak current was shown to be increased by the pH from 11.4 to 3.0. To avoid the influence of oxygen on the reduction reaction of sunset yellow, 0.1 mol/L PBS of pH 8.3 was used as the supporting electrolyte in all voltammetric determinations.

#### Effect of the potential scan rate

The information involving electrochemical mechanisms can usually be obtained from the investigation of CVs in the different potential sweep rates. Therefore, the CVs investigations for 50.0 mg L<sup>-1</sup> sunset yellow were performed

**Fig. 5.** CVs of 50.0 mg L<sup>-1</sup> sunset yellow at MWCNT/GCE with different scan rates. (a–n) are 10, 30, 50, 70, 100, 130, 160, 190, 210, 240, 270, 300, 350, and 400 mV s<sup>-1</sup>, respectively. Other conditions are as in Fig. 1.

**Fig. 6.** Dependence of the logarithm of the peak current on the logarithm of the scan rates. Insert: plot of the peak current against the scan rates.

on the surface of the MWCNT/GCE in a buffer solution of pH 8.3 at different potential sweep rates. Figure 5 illustrates the influence of the scan rate on the CVs of 50.0 mg L<sup>-1</sup> sunset yellow in the range of 10–400 mV s<sup>-1</sup>. The linear relation between the log(*I*) and the log(*v*) (Fig. 6, where *I* = peak current and *v* = scan rate) indicates a mixed adsorption–diffusion controlled process on the surface of the modified electrode; the regression equation for this relationship was given as log(*I*) = 0.5259 log(*v*) + 1.9116 (*R*<sup>2</sup> = 0.999, *I*: μA, *v*: V s<sup>-1</sup>).

The relationship between the reduction peak potential and logarithm of the scan rate is shown in Fig. 7. It can be seen that the reduction peak potential shifts negatively with an increasing scan rate. Such a behavior revealed the irreversible

**Fig. 7.** Dependence of the reduction peak potential of 50.0 mg L<sup>-1</sup> sunset yellow on the logarithm of the scan rates. Insert: plot of the peak potential against scan rates.

nature of the electrochemical process for sunset yellow. The regression equation for this relationship was obtained as  $E_p = -0.047 \log(\nu) - 0.7687$  ( $R^2 = 0.981$ ,  $E_p$ : V,  $\nu$ : V s<sup>-1</sup>).

As for an irreversible electrode process,  $E_p$  is given by the following equation:<sup>30,31</sup>

$$[1] \quad E_p = E^{o'} + \frac{2.303RT}{\alpha nF} \log \frac{RTk^o}{\alpha nF} - \frac{2.303RT}{\alpha nF} \log \nu$$

where  $\alpha$  is the transfer coefficient,  $k^o$  is the standard heterogeneous rate constant of the reaction,  $n$  is the number of electrons transferred,  $\nu$  is the scan rate, and  $E^{o'}$  is the formal redox potential. Thus, the value of  $\alpha n$  can be easily calculated. The  $\alpha n$  was calculated to be 1.2583. According to Bard and Faulkner,<sup>32</sup>  $\alpha$  can be obtained as

$$[2] \quad \alpha = \frac{47.7}{|E_p - E_{p/2}|} mV$$

where  $E_{p/2}$  is the potential where the current is at half the peak value. The  $\alpha$  is calculated to be 0.6446. Furthermore, the number of electrons transferred ( $n$ ) in the electroreduction of sunset yellow was calculated to be  $1.95 \pm 0.20$ . The value of  $E^{o'}$  could be obtained from the intercept of the  $E_p$  versus  $\nu$  curve by extrapolating to the vertical axis at  $\nu = 0$ .<sup>33</sup> The intercept for the  $E_p$  versus  $\log \nu$  plot was  $-0.7687$  V and the  $E^{o'}$  was  $-0.664$  V (Fig. 7, insert), thus,  $k^o$  is calculated to be  $0.29$  s<sup>-1</sup>.

It is generally admitted that azo molecules are reduced at the mercury drop in two steps:<sup>34</sup> step 1:  $R-N=N-R' + 2e^- + 2H^+ = R-NH-NH-R'$ , step 2:  $R-NH-NH-R' + 2e^- + 2H^+ = R-NH_2 + R'-NH_2$ .

When the pH value is below 3, steps 1 and 2 occur simultaneously, while for media close to neutrality, the second step does not occur. Consequently, reduction potentials and intensities are strongly influenced by the media pH.

Taking into account that sunset yellow contains a N=N group, which presents a basic center of electron and proton acceptors, we may, therefore, assume that the reduction step

**Fig. 8.** Mechanism for the electrochemical reduction of sunset yellow.

**Fig. 9.** CVs of different concentrations of sunset yellow. Insert: plot of the peak current against the concentration. Other conditions are as in Fig. 1.

of sunset yellow is located on the N=N group. The sunset yellow accepts two protons and two electrons. The mechanism is shown in Fig. 8.

### Linearity range and the detection limit

The relationship between the reduction peak current and the concentration ( $c$ ) of sunset yellow was examined by CVs on the surface of MWCNT/GCE (Fig. 9). Under the previously mentioned optimum conditions, the reduction peak currents were proportional to sunset yellow concentrations over two intervals in the range of  $1.2$ – $125.0$  mg L<sup>-1</sup> and  $125.0$ – $265.0$  mg L<sup>-1</sup> in  $0.1$  mol/L PBS of pH 8.3. Two linear regression equations were obtained as  $I$  (μA) =  $0.3348c$  (mg L<sup>-1</sup>) +  $6.4803$  ( $R^2 = 0.997$ ) and  $I$  (μA) =  $0.2186c$  (mg L<sup>-1</sup>) +  $21.2890$  ( $R^2 = 0.997$ ). The detection limit ( $3\sigma/s$ , where  $\sigma$  is the standard deviation of the intercept and  $s$  is the slope of the calibration curve) observed for sunset yellow was  $0.5$  mg L<sup>-1</sup>.

### Repeatability of the modified electrode

The repeatability of the modified electrode was investigated by repetitive recording at a fixed sunset yellow concentration of  $50.0$  mg L<sup>-1</sup>. The relative standard deviation (RSD) for the peak currents in CVs based on six replicates was  $1.5\%$ , indicating excellent repeatability of the response of the modified electrode. Also, on using the MWCNT/GCE daily and storing under ambient conditions over a period of two weeks, the electrode retained  $96.3\%$  of its initial peak current response for a sunset yellow concentration of  $50.0$  mg L<sup>-1</sup>. The results indicate that the modified electrode has an excellent repeatability.

**Fig. 10.** CVs of (a) a sample and (b–f) added standard samples. The concentration of the added standard sunset yellow were (b) 10.0, (c) 30.0, (d) 50.0, (e) 70.0, and (f) 90.0 mg L<sup>-1</sup>. Insert: plot of the peak current against concentration. Other conditions are as in Fig. 1.

**Table 1.** Recoveries and relative standard deviations (RSD, %) for sunset yellow in soft drinks by the proposed method.

No.	Sample (mg L <sup>-1</sup> ) <sup>a</sup>	RSD (%), <i>n</i> = 6	Added (mg L <sup>-1</sup> )	Found (mg L <sup>-1</sup> ) <sup>a</sup>	Recovery (%)
1	0.0	1.2	20.0	20.6	103.0
2	5.6	3.0	30.0	36.5	103.0
3	16.7	2.1	40.0	55.1	96.0
4	18.1	2.7	50.0	70.3	104.4
5	19.1	2.0	60.0	80.2	101.8
6	50.3	1.5	80.0	134.0	104.6

<sup>a</sup>Average of six replicate measurements (*n* = 6).

### Determinations of sunset yellow in soft drinks

To assess the applicability of the proposed method, the MWCNT/GCE was used to determine the content of sunset yellow in soft drinks by applying the CV method.

The CVs of a sample and added standard samples are shown in Fig. 10. Soft drinks (2.00 mL) were diluted to 5.0 mL with 0.1 mol/L PBS of pH 8.3 and the linear regression equation was obtained as  $c$  (mg L<sup>-1</sup>) =  $3.4459I$  (μA) – 0.27 ( $R^2 = 0.999$ ). The determination results using the standard addition method are shown in Table 1. The recoveries ranged from 96.0% to 104.4% and the content for sunset yellow in soft drinks was 0.0 ~ 50.3 mg L<sup>-1</sup> with a RSD of 1.2% ~ 3.0% (*n* = 6).

### Interference

The influence of some organic compounds was tested. If the presence of an interferent altered the average current signal of 50.0 mg L<sup>-1</sup> sunset yellow concentration by less than ±5%, we considered that caused no interference. The results showed a 100-fold of glucose, 50-fold of ascorbic acid, indigotine, brilliant blue FCF, amaranth, erythrosine, cane sugar, sorbic acid, and saccharin sodium did not interfere with the determination, while ponceau 4R and tartrazine

interfered severely. This suggests that the modified electrode had certain resistance to some interferences.

### Conclusion

In the present work, it was demonstrated that modification of GCE with MWCNTs is a simple and effective method for the determination of sunset yellow in soft drinks. The procedure enables preparation of highly stable and reproducible uniform modifier films, which leads to a considerable enhancement in repeatability and reproducibility in the voltammetric measurements. High sensitivity and improved detection limit of the MWCNT/GCE are promising for the determination of trace amounts of sunset yellow in soft drinks.

# A kinetic study of dimethyl sulfoxide reductase based on density functional theory

Elizabeth Hernandez-Marin and Tom Ziegler

**Abstract:** We present a density functional theory study on the oxygen atom transfer (OAT) reaction of dimethyl sulfoxide (DMSO) with model complexes resembling a functional synthetic analogue of the molybdoenzyme DMSO reductase. The good agreement between our calculated Gibbs free energy profile and data derived from experimental kinetic parameters supports the reaction mechanisms of the oxygen atom transfer proposed in this study. When the mechanism involves the formation of a DMSO-bound intermediate, the calculations on the free energy surface provide valuable information that explains the origin of the apparent contradiction between the experimental findings and previous theoretical calculations with respect to the rate-limiting step of the reaction mechanism. The enzymatic mechanism of the OAT reaction is more complex than the mechanism of any synthetic analogue, mainly due to the formation of an enzyme-substrate adduct prior to the appearance of the substrate-bound intermediate. This study also presents a possible mechanism for the formation of such an adduct and the subsequent oxygen atom transfer. The mechanism involves a proton transfer to and from the substrate.

**Key words:** dimethyl sulfoxide (DMSO) reductase, oxygen atom transfer, density functional theory.

**Résumé :** On présente une étude basée sur la théorie de la fonctionnelle de densité pour la réaction de transfert de l'atome d'oxygène à partir du diméthylsulfoxyde (DMSO), en utilisant des complexes modèles ressemblant à un analogue de synthèse du molybdoenzyme de la réductase de DMSO. Le bon accord entre le profil d'énergie libre de Gibbs calculé et les données dérivées de paramètres cinétiques expérimentaux supporte les mécanismes réactionnels proposés dans cette étude pour le transfert de l'atome d'oxygène. Quand le mécanisme implique la formation d'un intermédiaire lié au DMSO, les calculs de la surface d'énergie libre fournissent une information utile qui explique l'origine de la contradiction apparente entre les données expérimentales et les calculs théoriques antérieurs relative à l'étape cinétiquement limitante du mécanisme réactionnel. Le mécanisme enzymatique de la réaction de transfert de l'atome d'oxygène est plus complexe que le mécanisme de tout analogue de synthèse, principalement en raison de la formation d'un adduit enzyme substrat avant l'apparition de l'intermédiaire lié au substrat. Cette étude présente aussi un mécanisme potentiel pour la formation d'un tel adduit et le transfert subséquent de l'atome d'oxygène. Le mécanisme implique un transfert de proton vers, et à partir du substrat.

**Mots-clés :** réductase de diméthylsulfoxyde (DMSO), transfert d'atome d'oxygène, théorie de la fonctionnelle de densité.

## Introduction

Dimethyl sulfide (DMS) in seawater has been proposed to serve as a seed for cloud condensation over the oceans and can as such have a possible effect on the climate.<sup>1</sup> For this reason, knowledge of the processes that regulate DMS concentrations in seawater is of considerable interest. Among those processes, the interconversion occurring between DMS and dimethyl sulfoxide (DMSO) is believed to be important.<sup>2</sup> In this regard, DMSO in seawater has been found to arise from DMS oxidation via photochemical and bacterial oxidation processes. On the other hand, some bacteria are able to reduce DMSO to DMS.<sup>3</sup> A reductase for DMSO from *Escherichia coli* has been isolated and characterized as

an iron-sulfur molybdoenzyme.<sup>4</sup> A simpler molybdoenzyme (without other prosthetic groups such as flavin or iron-sulfur centers) is found in bacteria of the genus *Rhodobacter*.<sup>5,6</sup> The enzymes that possess a molybdenum center as their sole redox-active center belong to the DMSO reductase (DMSOR) family.<sup>7</sup> DMSOR serves as a terminal reductase in the bacterial respiratory chain where dimethyl sulfoxide is used as an electron acceptor,<sup>8</sup> undergoing the overall reaction

The molybdenum active center participates in an oxygen (oxo) atom transfer (OAT) reaction

This article is part of a Special Issue dedicated to Professor R. J. Boyd.

**E. Hernandez-Marin and T. Ziegler.**<sup>1</sup> Department of Chemistry, University of Calgary, 2500 University Drive, Calgary, AB T2N 1N4, Canada.

<sup>1</sup>Corresponding author (e-mail: ziegler@ucalgary.ca).

Multiple spectroscopic studies on DMSOR from bacterial sources have been carried out to determine its structure.<sup>9–13</sup> As a result, there is a considerable body of information about the coordination geometry of the molybdenum center in DMSOR. It has been established that the oxidized active site of DMSOR consists of the metal coordinated by two molybdopterin (metal binding pyranopterin ene-1,2-dithiolate) ligands, one oxo group, and one oxygen atom from the side chain of a serinyl residue.<sup>14</sup>

Synthetic molybdenum complexes with structural and functional behavior similar to that of the DMSOR have been developed<sup>15–18</sup> as one approach to understand the enzymatic oxo-transfer reaction. Density functional theory (DFT) methods have been used as well to investigate the OAT reaction above. Webster and Hall<sup>19</sup> employed the complex  $[\text{Mo}(\text{OMe})(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$  as a model for the  $[\text{Mo}^{\text{IV}}]$  species. Thapper et al.<sup>20</sup> based their modeling on a  $[\text{Mo}(\text{OMe})(\text{S}_2\text{C}_2(\text{CN})_2)_2]^-$  complex, while  $[\text{Mo}(\text{OMe})(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$  was used by Hillier and co-workers.<sup>21</sup> In the present DFT study, we reinvestigate the OAT reaction involving DMSO and the model complexes  $[\text{Mo}(\text{OR})(\text{S}_2\text{C}_2\text{H}_2)_2]^-$  with  $\text{R} = \text{Me}, \text{Ph}$ . Our investigation was prompted by a recent experimental study on the kinetics of DMSOR<sup>22</sup> and by the apparent contradiction between the theoretical calculations and the conclusions drawn from experimental results with respect to the nature of the rate-limiting step in the OAT reaction for synthetic analogues.<sup>23</sup> Thus, we shall calculate the kinetic parameters of the OAT between the model complexes and DMSO and compare them to available experimental data for the actual enzyme and some synthetic analogues. It is hoped that the current study will give a more detailed and direct comparison between DFT calculations and experimental kinetic data on the OAT in synthetic analogues than has been provided in the past. We shall finally discuss how synthetic or computational studies on the OAT in model systems relate to experimental investigations of the kinetics for OAT in the actual enzyme. In this discussion, we shall elaborate on a possible mechanism for OAT in the actual enzyme involving a proton transfer to and from DMSO.

## Computational details and methods

All calculations were based on DFT as implemented in the ADF (Amsterdam density functional) program version 2006.01.<sup>24</sup> Use was made of the Becke–Perdew exchange–correlation (XC) functional (BP86)<sup>25–27</sup> and a standard triple- $\zeta$  STO basis with one set of polarization functions for all atoms. The 1s electrons of C, N, and O; the 1s2s2p electrons of S; and the 1s2s2p3s3p3d electrons of Mo were treated as frozen cores. For all the optimizations and linear transit calculations, the protein matrix was represented by making use of the dielectric continuum model COSMO (conductor-like screening model)<sup>28</sup> as implemented in ADF, with a dielectric constant of  $\epsilon = 5$ . The continuum model was used in accordance with common practice<sup>29,30</sup> to simulate the polarizable background of the protein matrix.

The crystal structure of the reduced DMSO reductase from *Rhodobacter capsulatus* with bound DMSO substrate is available (PDB code 4DMR).<sup>31</sup> This structure represents

a good candidate for an intermediate in the oxygen atom transfer reaction. The Cartesian coordinates provided by the crystallographic data were used to construct the starting geometry for a computationally convenient model complex,  $[\text{Mo}(\text{OMe})(\text{S}_2\text{C}_2\text{H}_2)_2 \cdots \text{DMSO}]^-$ . The coordinates of the oxygen and carbon of the OMe group, and of the sulfur and carbon atoms of the dithiolate groups were taken as those of Ser 147 and the pterin cofactors, respectively, from the crystal structure. After the starting geometry was fully optimized, two approximate transition states were located by performing linear transit calculations. One linear transit considered the increment of the Mo–O<sub>DMSO</sub> distance. The other linear transit calculation allowed for the increment of the distance between S and O from the DMSO ligand. Starting from those approximate transition state geometries, both stationary points were then fully optimized<sup>32,33</sup> as transition states. Finally, the reactants,  $[\text{Mo}(\text{OR})(\text{S}_2\text{C}_2\text{H}_2)_2]^-$  and DMSO, as well as the products,  $[\text{Mo}(\text{OR})\text{O}(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$  and DMS, were optimized separately. Subsequent gas-phase harmonic frequency analysis calculations were conducted to ensure that all optimized structures represented either true minima or transition states. The reported enthalpies and free energies were computed using the entropy and internal energy values calculated via standard statistical mechanics.

## Results and discussion

### Theoretical modeling of synthetic analogues

Holm and co-workers<sup>15–18</sup> have prepared molybdenum and tungsten functional analogues of the DMSOR active site. One of those analogues is structurally similar to the enzymatic metal center:  $[\text{M}(\text{OPh})(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$  ( $\text{M} = \text{Mo}, \text{W}$ ).<sup>17</sup> The crystallographic structure of the desoxo complex had a square-pyramidal geometry but despite considerable efforts, Holm and co-workers<sup>17</sup> were not able to isolate the oxidized  $[\text{Mo}^{\text{VI}}]$  complex, in contrast to the tungsten oxo complex  $[\text{W}(\text{OPh})\text{O}(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$  that was analyzed via X-ray crystallography. However, the in situ formation of  $[\text{Mo}(\text{OPh})\text{O}(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$  was established by comparing spectroscopic properties of the reaction mixture with the absorption spectrum of the tungsten complex.

We have optimized the geometry of  $[\text{Mo}(\text{OR})(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$  for  $\text{R} = \text{Me}$  used in previous theoretical studies to model DMSOR and for  $\text{R} = \text{Ph}$  used in the synthetic DMSOR analogue by Holm and co-workers.<sup>17</sup> Figure 1a shows the optimized geometry of  $[\text{Mo}(\text{OMe})(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$ , whereas that of  $[\text{Mo}(\text{OPh})(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$  is displayed in Fig. 2a. The optimized models have a square-pyramidal geometry, and the S–Mo and Mo–O bond distances are 2.39 Å and 1.92 Å, respectively, for  $\text{R} = \text{Me}$  and 2.38 Å and 1.96 Å, respectively, for  $\text{R} = \text{Ph}$ . Figures 1 and 2 reveal that the structural parameters of the optimized complexes for  $\text{R} = \text{Me}$  and  $\text{Ph}$  are in good agreement with those of the synthetic analogue given in Table 1.

We shall now discuss our calculated energy profiles for the OAT reaction starting with  $\text{R} = \text{Me}$ . According to the oxo transfer hypothesis,<sup>8</sup> the substrate (DMSO in our case), will approach cis to the  $\text{Mo}^{\text{IV}}(\text{OMe})$  group. This way of attack is adopted in our calculations. We find one transition state, TS1, for the formation of an intermediate I. The optimized structure of TS1, Fig. 1b, indicates a weak interaction

**Fig. 1.** Optimized geometries for the reaction between  $[\text{Mo}(\text{OMe})(\text{S}_2\text{C}_2\text{H}_2)_2]^-$  and DMSO. (a)  $\text{Mo}^{\text{IV}}$  complex. (b) First transition state. (c) Intermediate. (d) Second transition state (oxygen transfer). (e)  $\text{Mo}^{\text{VI}}$  complex.

between DMSO and the metal. The  $\text{Mo}-\text{O}_{\text{DMSO}}$  distance is 3.11 Å, while the  $\text{Mo}-\text{S}_{\text{dith}}$  distances remain the same (compared with the  $\text{Mo}^{\text{IV}}$  complex).

The intermediate I, Fig. 1c, now shows the DMSO bound to the metal. The  $\text{Mo}-\text{O}_{\text{DMSO}}$  distance has decreased to

2.30 Å and the  $\text{Mo}-\text{S}_{\text{dith}}$  distances start to slightly increase. Additionally, the distance between the sulfur and the oxygen in DMSO increases to 1.57 Å compared with 1.53 Å in free DMSO. The intermediate I features a six-coordinated metal center with a trigonal prismatic geometry. Our geometric pa-

**Note:** All values in Å. NA: Not applicable.

rameters of the transition state TS1 are similar to those found in other theoretical studies,<sup>19–21</sup> as can be seen from Table 2.

After the formation of the intermediate I, a second transition state, TS2, that maintains a trigonal prismatic geometry,

Fig. 1d, is found. In this species, the oxygen atom has been almost transferred to the molybdenum center. The bond between oxygen and sulfur in DMSO is almost broken (1.89 Å) while the Mo—O<sub>DMSO</sub> distance has decreased to 2.00 Å. The relatively long Mo—O<sub>DMSO</sub> distance might indi-

cate that molybdenum is still in the reduced state because the EXAFS (extended X-ray absorption fine structure) and X-ray data show that the typical Mo<sup>VI</sup>–O bond distance is in the range between 1.68 and 1.76 Å.<sup>9,12</sup> The Mo–S bond distance increases to 2.47 Å.

Finally, Fig. 1e displays the six-coordinated optimized structure of the oxidized [Mo(OMe)O(S<sub>2</sub>C<sub>2</sub>H<sub>2</sub>)<sub>2</sub>]<sup>–</sup> complex that has adopted a distorted octahedral geometry. The Mo–S distance of the sulfur trans to the Mo=O bond is 2.57 Å while the other Mo–S bonds are around 2.50 Å and thus much shorter. The longer Mo–S distance is in agreement with an expected value of 2.6 Å attributable to the trans effect due to Mo=O.<sup>34</sup> As it was mentioned earlier, crystallographic data are not available for the oxidized molybdenum complex but its formation was well-established by spectroscopic comparison with [W(OPh)O(S<sub>2</sub>C<sub>2</sub>Me<sub>2</sub>)<sub>2</sub>]<sup>–</sup> for which X-ray data are available. The tungsten complex had a distorted octahedral geometry and the trans effect from W=O was also present. In the tungsten complex, the average W–S bond distance of the sulfur atoms not trans to the oxo ligand was 2.42 Å, whereas the W–S distance of the sulfur trans to W=O was 2.49 Å.<sup>17</sup>

### Comparison between experimental and theoretical kinetic parameters for OAT carried out by synthetic analogues

The calculated energy profile for the overall reaction of DMSO with [Mo(OMe)(S<sub>2</sub>C<sub>2</sub>H<sub>2</sub>)<sub>2</sub>]<sup>–</sup> is shown in Fig. 3. We find that the formation of the intermediate I proceeds with an activation enthalpy of 9 kcal/mol. The formation of the intermediate is an endothermic process with  $\Delta H = 8.1$  kcal/mol and the OAT reaction,  $I \rightarrow \text{Mo}^{\text{VI}} + \text{DMS}$ , has an activation enthalpy of 8.5 kcal/mol. Further, the overall enthalpy of reaction from separated reactants to separated products is exothermic with  $\Delta H = -13$  kcal/mol. These results are consistent with those of previous theoretical calculations<sup>19–21</sup> summarized in Table 3.

Our mechanism for the OAT reaction can be written as

By making use of the steady state condition for the intermediate I the rate law for the consumption of [Mo<sup>IV</sup>] is

$$[4] \quad -\frac{d[\text{Mo}^{\text{IV}}]}{dt} = \left( \frac{k_1 k_3}{k_2 + k_3} \right) [\text{Mo}^{\text{IV}}][\text{DMSO}] = k[\text{Mo}^{\text{IV}}][\text{DMSO}]$$

where the overall rate constant  $k$  is

$$[5] \quad k = \frac{k_1 k_3}{k_2 + k_3}$$

It is possible to determine the rate constants  $k_1$ ,  $k_2$ , and  $k_3$  by using the calculated thermodynamic data and the transition state theory as

$$[6] \quad k = \frac{k_B T}{h} \exp \left( \frac{-\Delta G^\ddagger}{RT} \right)$$

where  $k_B$ ,  $h$ , and  $R$  are the Boltzmann, Planck, and gas con-

**Fig. 3.** Energy profile for the oxygen atom transfer reaction between model complex [Mo(OMe)(S<sub>2</sub>C<sub>2</sub>H<sub>2</sub>)<sub>2</sub>]<sup>–</sup> and DMSO.

stants, respectively;  $T$  is the temperature and  $\Delta G^\ddagger$  corresponds to the free energy of activation. The results are summarized in Table 4. The overall rate constant,  $k$ , is easily found by substituting the calculated values of  $k_i$  into eq. [5]. Once  $k$  is calculated, the overall free energy of activation as well as  $\Delta S^\ddagger$  can be determined. For  $R = \text{Me}$ ,  $\Delta G^\ddagger = 28.7$  kcal/mol, which is the highest point on the energy surface and represents the oxygen transfer transition state, TS2, of Fig. 3. TS1 is only 2.3 kcal/mol lower in free energy than TS2, but on the potential energy surface TS2 is 7.6 kcal/mol higher in energy than TS1.

The data in Table 5 show that our calculated kinetic parameters for the model system, [Mo(OR)(S<sub>2</sub>C<sub>2</sub>H<sub>2</sub>)<sub>2</sub>]<sup>–</sup>, with  $R = \text{Me}$  are in good agreement with those measured for the synthetic analogue, [M(OPh)(S<sub>2</sub>C<sub>2</sub>H<sub>2</sub>)<sub>2</sub>]<sup>–</sup>. The overall enthalpy of activation is 16.6 kcal/mol and the overall entropy of activation is calculated to be  $-40$  eu; the corresponding experimental values are 14.8 kcal/mol and  $-36$  eu, respectively.

It follows from Fig. 3 and Table 4 that the internal barriers of intermediate formation ( $\Delta H_1^\ddagger$ ) and oxygen transfer ( $\Delta H_3^\ddagger$ ) differ by only 0.5 kcal/mol. However, the difference between the two internal barriers on the free energy surface is substantial. Thus,  $\Delta G_1^\ddagger = 26.4$  and  $\Delta G_3^\ddagger = 4.8$  kcal/mol. As a consequence, the formation of the intermediate I has a much smaller rate constant,  $k_1$ , than the oxygen transfer step ( $k_3$ ), see Table 4. This finding is in line with the conclusions by Sung and Holm,<sup>18</sup> based on a series of synthetic analogues of the form [W(OR')(S<sub>2</sub>C<sub>2</sub>R<sub>2</sub>)<sub>2</sub>]<sup>–</sup> where  $R' = p\text{-C}_6\text{H}_4\text{X}'$  and  $R = p\text{-C}_6\text{H}_4\text{X}$ , and the substituents  $X$  and  $X'$  were electron-donating groups (EDG) or electron-withdrawing groups (EWG). Sung and Holm<sup>18</sup> found that the rate constants exhibited the order  $k_{\text{EWG}} > k_{\text{EDG}}$  and their measurement of reversible redox potentials showed that EWGs increased the oxidation potentials ( $E_{\text{EWG}} > E_{\text{EDG}}$ ) i.e., it is easier to oxidize a complex coordinated by EDGs. Further, Sung and Holm<sup>18</sup> considered that the relationship in the oxidation potentials may be extended to the intrinsic ease of oxidation of the metal center in the transition state such as, in principle, the rate constant for a complex with EDG substituents should be larger than for a complex with EWGs.

<sup>i</sup>Experimental values from the Arrhenius plot.

Following that consideration, they proposed that the lack of correlation between the ease of oxidation and the rate constants indicated that the oxidation of the metal center associated with the oxygen atom transfer was not the rate-determining step.<sup>18</sup> Previous theoretical studies reported only barriers on the potential energy surface<sup>19–21</sup> where the oxygen transfer and not the formation of the intermediate

had the highest internal activation barrier. This has lead to an apparent contradiction between the theoretical calculations and the experimental conclusions. It is not surprising that the formation of the intermediate I has a large negative activation entropy since this step is an associative process.

We have also examined the complex  $[\text{Mo}(\text{OR})(\text{S}_2\text{C}_2\text{H}_2)_2]^-$  with  $\text{R} = \text{Ph}$ , which keeps a close resemblance to one of the

synthetic analogues studied by Holm and co-workers.<sup>17</sup> As for the model system with R = Me, we adopted the same approach with DMSO toward the metal center. In contrast to R = Me, we find only one transition state (TS). This transition state has a trigonal prismatic geometry, Fig. 2b, where the bond between the metal and the oxygen from DMSO is forming with a Mo–O distance of 1.97 Å, while a S–O distance of 1.80 Å indicates the weakening of the S–O bond. The six-coordinated oxidized product,  $[\text{Mo}(\text{OPh})\text{O}(\text{S}_2\text{C}_2\text{H}_2)_2]^-$ , Fig. 2c, has a distorted octahedral geometry where the trans effect from Mo=O is evident because the Mo–S distance of the sulfur trans to the O ligand is 2.68 Å, while the remaining Mo–S bonds average a shorter distance of 2.48 Å.

The energy profile in Fig. 4 shows that the OAT reaction for R = Ph takes place in one associative step with an activation enthalpy of 15.5 kcal/mol and a corresponding activation entropy of –35 eu. These parameters are similar to the respective experimental values of  $\Delta H^\ddagger = 14.8$  kcal/mol and  $\Delta S^\ddagger = -36$  eu. The formation of the products, DMS and  $[\text{Mo}(\text{OPh})\text{O}(\text{S}_2\text{C}_2\text{H}_2)_2]^-$ , is exothermic with  $\Delta H = -18.0$  kcal/mol. Experimentally, Sung and Holm<sup>18</sup> found that  $k_{\text{EWG}} > k_{\text{EDG}}$ .

Because the phenoxy ligand may be considered to be slightly more electron-withdrawing than the methoxy ligand, the correlation  $\Delta G_{\text{OPh}}^\ddagger < \Delta G_{\text{OMe}}^\ddagger$  is reasonable. In line with this expectation, the overall activation energy for R = Me (28.7 kcal/mol) is calculated to be slightly larger than for R = Ph (26.1 kcal/mol), making  $k_{\text{OPh}} > k_{\text{OMe}}$ .

The rate law for the process depicted in Fig. 4 is similar to that of eq. [4]:

The kinetic studies on the OAT reaction of the  $[\text{M}(\text{OPh})(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$  complexes conducted by Holm and co-workers<sup>17</sup> were found to follow the second-order rate law,  $d[\text{Mo}^{\text{IV}}]/dt = -k[\text{Mo}^{\text{IV}}][\text{DMSO}]$ , and the negative entropy of activation is consistent with an associative mechanism.<sup>35</sup>

The agreement between our results and the measured experimental kinetic parameters allows us to propose that the OAT reaction between the synthetic analogue  $[\text{M}(\text{OPh})(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$  and DMSO for R = Ph occurs in a single step where the  $[\text{Mo}^{\text{IV}}]$  species reacts with DMSO associatively to yield the  $[\text{Mo}^{\text{VI}}]$  species and DMS, such as it was found in posterior kinetic studies on the OAT reaction of  $[\text{M}(\text{OPh})(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$  with  $\text{SeO}_4^{2-}$  and  $(\text{CH}_2)_4\text{SO}$  where the presence of an intermediate was not detected.<sup>23</sup> The transition state is predicted to involve a species where a bond between the metal and the oxygen from the substrate is being created while the S–O bond in the substrate weakens. Holm and co-workers<sup>23</sup> hypothesized that the transition state should be mainly metal-substrate bond-making in character. Our calculations indicate that when the reaction proceeds without the formation of an intermediate, the transition state resembles mostly TS2 from the two-step reaction involving R = Me. Further, TS of Fig. 2 exhibits substantial Mo–O bond formation with a bond distance of 1.97 Å as well as a

**Fig. 4.** Energy profile for the oxygen atom transfer reaction between model complex  $[\text{Mo}(\text{OPh})(\text{S}_2\text{C}_2\text{H}_2)_2]^-$  and DMSO.

considerable S–O bond stretching with a S–O distance of 1.80 Å.

According to the energy profile in Fig. 3, when the axial ligand OR in  $[\text{Mo}(\text{OR})(\text{S}_2\text{C}_2\text{Me}_2)_2]^-$  changes from R = Ph to R = Me, one intermediate is formed. This intermediate, with the substrate bound to the reduced metal, will subsequently decompose to form DMS and the oxidized  $[\text{Mo}^{\text{VI}}]$  species. The isolation of a crystalline structure of the actual enzyme with the bound substrate<sup>31</sup> is a good indication that the OAT reaction in the actual enzyme proceeds via the formation of an intermediate. Figure 5 reveals that the orientation of the coordinated DMSO in our optimized intermediate resembles that found in the actual enzyme, allowing a possible comparison between the results from our investigation and the kinetic studies on the actual enzyme with respect to the OAT reaction, i.e., the  $k_3$  step in eq. [3].

The comparison of our results to other theoretical studies of synthetic analogues is as follows: our calculations, as well as those by Hall and Webster<sup>19</sup> and Hillier and co-workers<sup>21</sup> estimated the energy of activation,  $\Delta E_{\text{TS2} \rightarrow 1}$ , to be approximately 9 kcal/mol. However, Thapper et al.<sup>20</sup> located a more stable intermediate with a different orientation of the DMSO molecule, see Fig. 6. It should be noted that they used the complex  $[\text{Mo}(\text{OMe})(\text{S}_2\text{C}_2(\text{CN})_2)_2]^-$ . In addition, we investigated the possibility of finding a more stable intermediate, I', for  $[\text{Mo}(\text{OMe})(\text{S}_2\text{C}_2\text{H}_2)_2]^-$ , based on the intermediate found by Thapper et al.,<sup>20</sup> but when the CN groups are substituted by H, the new intermediate is only 1 kcal/mol more stable. Furthermore, it seems clear from the X-ray structure of DMSOR with bound DMSO<sup>31</sup> that the alternative orientation of DMSO depicted in Fig. 6b cannot occur in the actual enzyme due to the presence of the Trp 116 indole side chain.

### Kinetics of the OAT process in the actual enzyme

In spite of the functional similarity between synthetic analogues and the enzyme, kinetics studies on enzymes such as DMSOR from *R. sphaeroides*<sup>22</sup> have revealed some mecha-

**Fig. 5.** Superposition of the optimized intermediate I (green) and the structure from crystallographic data<sup>31</sup> of the DMSO-bound DMSOR (yellow). Hydrogens were removed for clarity.

**Fig. 6.** Two possible intermediates for the association of  $[\text{Mo}(\text{O-Me})(\text{S}_2\text{C}_2\text{R}_2)_2]^-$  and DMSO. When  $\text{R} = \text{H}$ , the intermediate (b) is 1 kcal/mol more stable than (a); for  $\text{R} = \text{CN}$  the intermediate to the right is more stable by 9 kcal/mol.<sup>20</sup>

nistic features that are not present in the systems studied by Holm and co-workers.<sup>15–17,23</sup> In the case of the enzyme, the experimental kinetic data were consistent with the fast formation of a prior enzyme-substrate complex (Michaelis complex, M) before the formation of an intermediate enzyme-substrate (ES) complex. This ES complex decays, in the second phase, to yield the reduced substrate (DMS) and the oxidized enzyme,  $\text{E}'$ .<sup>22</sup> Thus, the proposed mechanism for the reduction of DMSO by DMSOR can be described as

This scheme differs from those of the functional analogue of Holm and co-workers<sup>17</sup> and our theoretical model in that the intermediate I (similar to ES) is formed by direct association of DMSO and the molybdenum species. The experimental rate constant for the fast phase (formation of the ES complex) was determined to be  $k'_2 = 1000 \text{ s}^{-1}$ , while the dissociation constant for the pre-equilibrium between M and  $\text{E} + \text{DMSO}$  was  $K_D = 155 \text{ } \mu\text{mol/L}$ . The slow phase (decay of ES) had a rate constant of  $k'_3 = 35 \text{ s}^{-1}$ . From an Arrhenius

plot of the second phase, it was found that  $\Delta H_3^\ddagger \approx 15 \text{ kcal/mol}$ , and  $\Delta H_3^\ddagger = 6.5 \text{ eu}$ .<sup>22</sup> Results in Table 4 show that our calculated enthalpy of activation of  $\Delta H_3^\ddagger = 8.5 \text{ kcal/mol}$  is rather small when compared with the experimental value for the enzyme of  $\Delta H_3^\ddagger \approx 15 \text{ kcal/mol}$ . We found the activation entropy to be small and positive ( $\Delta S_3^\ddagger = 12.4 \text{ eu}$ ), as it was the case for the enzyme ( $\Delta S_3^\ddagger = 6.5 \text{ eu}$ ).

#### Possible structure of the Michaelis complex (M) involving the reduced $[\text{Mo}^{\text{IV}}]$ species

According to eq. [1], the enzymatic reduction of DMSO involves the transfer of two  $\text{H}^+$  species. In a general reaction mechanism, it has been proposed that the transfer of a  $\text{H}^+$ , the departure of a water molecule, and the addition of the substrate can occur in one step.<sup>36</sup> After the OAT reaction has been completed, the oxidized active site,  $[\text{Mo}^{\text{VI}}\text{O}]$ , is subjected to a one-electron reduction and another  $\text{H}^+$  is transferred to the oxygen atom to form  $[\text{Mo}^{\text{V}}\text{OH}]$ , such species have been detected by EPR spectroscopy.<sup>13</sup> The formation of the Michaelis complex (M) in eq. [8] was deduced experimentally from plots of observed rate constant versus substrate concentration.<sup>22</sup> We have explored the possibility that the formation of such a Michaelis complex (M) may involve some residues that do not belong to the immediate coordination sphere of the metal.

The full X-ray structures of the oxidized and DMSO-bound enzymes overlap almost entirely, except for the residues 385–390. In the case of the DMSO-bound structure, the Trp 388 is sitting above the DMSO molecule around 8.5 Å apart from the metal center. In the oxidized enzyme, the same residues appear oriented toward the surface of the protein and far away (25 Å) from the molybdenum. Based on the coordinates of residues 386–388, plus those of the metal center, Ser 147 and sulfurs from the MPT cofactor, two different models were constructed and optimized. The model in Fig. 7a will be referred to as the “open” structure and was created from the oxidized enzyme (PDB code 1DMR).<sup>10</sup> We have assumed that the orientation of the residues 385–390 in the reduced enzyme should be similar to the open structure. The second model, or “closed” structure, was constructed from the bound DMSO enzyme (PDB code 4DMR).<sup>9</sup>

Further, we propose that the carrier of one of the protons in eq. [1] will be the DMSO molecule<sup>37</sup>:

The protonated DMSO will then interact with some residues of the enzyme. It is known that the 780 polypeptide chain of the *Rhodobacter* DMSO reductases is folded to shape an ellipsoidal molecule with a “funnel-like” depression on one side. The funnel is lined by aromatic residues and the molybdenum is located at the bottom of this funnel.<sup>14</sup> On the other hand, it has been established that interactions of DMSO with aromatic and hydrophobic amino acid side chains are favorable;<sup>38</sup> these interactions between the protonated substrate and the residues in the funnel may cause the enzyme to change from the open to the closed conformations.

We have investigated a possible pathway for the formation of the Michaelis complex (M) that involves the loss of

**Fig. 7.** Optimized structures. (a) Molybdenum (IV) in “open” configuration (initial coordinates taken from PDB file code 1DMR). (b) Possible configuration of the Michaelis intermediate (M) formed with the addition of a protonated DMSO molecule to the “closed” configuration (initial coordinates for the closed configuration are from the PDB file code 4DMR). The peptidic chain was constructed using the coordinates of the following residues: Pro 386, Glu 387, and Trp 388.

a water molecule from the metal center prior to the substrate association. This model assumes that the loss of a water molecule is due to the transfer of a proton to the hydroxide ligand in the initial six-coordinated metal center, Fig. 8a, leaving a five-coordinated metal center and the enzyme in the open conformation, Fig. 7a. Subsequently, the  $\text{DMSOH}^+$  species associates to the enzyme inducing a change in conformation and the new structure M, Fig. 7b. The results from the optimizations of both structures indicate that M (closed conformation with the associated protonated substrate) is 10.5 kcal/mol more stable with respect to the separate open structure and  $\text{DMSOH}^+$  as indicated in the potential energy profile in Fig. 7. The dissociation constant for the pre-equilibrium between M and the separate reduced enzyme and DMSO was experimentally found to be  $K_D = 155 \mu\text{mol/L}$  at  $5^\circ\text{C}$  and  $\text{pH} = 6.0$ .<sup>22</sup> Using  $\Delta G^\circ = -RT \ln(1/K_D)$ , the corresponding value of free energy of formation for M is  $\Delta G^\circ = -4.9 \text{ kcal/mol}$ . We calculate  $\Delta E$  for the formation of M to be  $-10.5 \text{ kcal/mol}$  and the corresponding  $\Delta G$  value is likely to be reduced in absolute terms relative to  $\Delta E$  as the entropy change for the association of the substrate with the enzyme is expected to be negative. In the suggested structure of M, the substrate is located 8 Å apart from the active site (Fig. 7b). With such a conformation M would, in the actual enzyme, prepare the substrate for the attack on the active site.

Next, we consider such an attack in a linear transit calculation that involves the model complex  $[\text{Mo}(\text{OMe})(\text{S}_2\text{C}_2\text{H}_2)_2]^-$ , Fig. 1a, and  $\text{DMSOH}^+$  as the separate reactants. Our calculation indicates that the proton migrates from the oxygen of DMSO to a sulfur of one dithiolate ligand prior to the forma-

tion of the intermediate I'. This intermediate (I') would represent ES in the actual enzyme. Figure 9a shows the intermediate I' with the DMSO bound to the metal at a Mo–O distance of 2.24 Å. The S–O bond is 1.59 Å and the H–S distance is 1.37 Å. This S–H bond distance remains constant for the rest of the OAT reaction. One consequence of the migration of the proton to one of the sulfurs is the elongation of the Mo–S bond distance to 2.56 Å, while the other three Mo–S distances stay in the range 2.36–2.41 Å. After the formation of I' (ES), the final oxygen transfer step takes place leading to DMS and the oxidized species. The transition state, TS2', for the last OAT step maintains the trigonal prismatic geometry of the intermediate I', Fig. 9b. In TS2', the O–S bond in DMSO is almost broken (1.86 Å) while the Mo–O<sub>DMSO</sub> distance has decreased to 1.98 Å. The final product, oxidized  $[\text{Mo}(\text{OMe})\text{O}(\text{HS}_2\text{C}_2\text{H}_2)_2]^-$ , adopts a distorted octahedral geometry. The Mo–S distance of the sulfur trans to the Mo=O bond is 2.59 Å. The Mo–S bond distance of the protonated sulfur is 2.66 Å. This distance is rather long compared with the experimental distances in the crystallographic data, Table 1. It might be probable that in the actual enzyme the proton migrates to a different location during the spectroscopic measurements; for example, to the basic residue histidine 649 that lies around 3 Å apart from one of the sulfurs of a molybdopterin cofactor in the X-ray structure. The estimated  $\Delta E$  for such process is around  $-10 \text{ kcal/mol}$ .

With the exception of the Mo–SH distances, the geometric parameters are very similar to those previously discussed when the substrate was DMSO. The potential energy surface in Fig. 10 shows similar activation energy for the OAT ( $\Delta E^\ddagger = 5.4 \text{ kcal/mol}$ ). Recalling that the experimental value for the enthalpy of activation is 15 kcal/mol, the discrepancy might suggest that the activation energy in the actual enzyme includes not only the interactions at the active site and the first sphere of coordination. Perhaps a change in conformation is also involved alongside the oxygen transfer to the metal. The fact that the enzyme with bound DMSO was crystallized suggests that such intermediate is somehow stable. The optimized intermediate I' is more stable than the separate products, unlike intermediate I in Fig. 3.

## Concluding remarks

According to our calculations, the reaction between DMSO and the model complex  $[\text{Mo}(\text{OPh})(\text{C}_2\text{S}_2\text{H}_2)_2]^-$  proceeds in one associative step. In the optimized transition state, the bond between the metal and DMSO is being formed through the oxygen atom of DMSO, while the S–O bond in the substrate is weakening. The good agreement between the experimental kinetic data for the functional synthetic analogue,  $[\text{Mo}(\text{OPh})(\text{C}_2\text{S}_2\text{Me}_2)_2]^-$ ,<sup>17</sup> and our calculated free energy surface, seems to indicate that our theoretical method is suitable for the type of OAT process under investigation here.

When the substituent of the axial ligand (–OR) is changed from R = Ph to R = Me (a slightly less electron-withdrawing species, compared with Ph), an intermediate is formed. In this intermediate, the substrate binds the molybdenum prior to the oxygen atom transfer step. We have found that on the Gibbs free energy surface, the rate constant for the formation of the intermediate is smaller than the rate constant of

**Fig. 8.** (a) Optimized geometry of a six-coordinated  $\text{Mo}^{\text{IV}}$  complex where  $\text{OH}^-$  is the sixth ligand. (b) Optimized geometry of a six-coordinated  $\text{Mo}^{\text{IV}}$  complex with  $\text{H}_2\text{O}$  as the sixth ligand.

**Fig. 9.** Optimized geometries for the reaction between  $[\text{Mo}(\text{OMe})(\text{S}_2\text{C}_2\text{H}_2)_2]^-$  and  $\text{DMSOH}^+$ . (a) Intermediate  $\text{I}'$ . (b)  $\text{TS2}'$ , transition state for the oxygen transfer step. (c)  $\text{Mo}^{\text{VI}}\text{H}$  complex.

the final OAT step. This result is in line with the experimental findings by Holm and co-workers.<sup>17,23</sup> The large negative entropic contribution in the associative step (formation of the intermediate) appears to be the key element in the difference between the rate constants. Previous theoretical studies considered only the potential energy surface,<sup>22</sup> leading to an apparent contradiction with the experimental findings.

Although the complexes prepared by Holm and co-

workers<sup>23</sup> are functional analogues to the enzyme, their OAT reaction mechanism is different from the enzymatic one. In the enzymatic mechanism, the formation of a prior enzyme-substrate complex  $\text{M}$  occurs before the appearance of an intermediate  $\text{ES}$  where the substrate is bound to the metal center in the active site.<sup>22</sup> We propose that in the initial conformation of the reduced enzyme, the residues 385–390 are far away from the active site and that one proton might be transferred to the hydroxide ligand in the active site to promote the loss of one water molecule. The subsequent formation of the complex  $\text{M}$  may involve a protonated DMSO molecule positioned around 5 Å from the metal center. The substrate molecule might be carried out to the vicinity of the active site from the surface of the enzyme by a change in conformation involving mainly the residues 385–390. The calculations show that such a complex ( $\text{M}$ ) is more stable than the separate reactants, as it should according to the experimental kinetic studies.<sup>22</sup> Moreover, we propose that before the formation of the intermediate  $\text{ES}$ , the proton from the substrate should migrate to a suitable location in the enzyme. In the case of our model complex, the proton migrated to a sulfur of one of the dithiolate ligands.

# Do corresponding coupling constants in hydrogen-bonded homo- and hetero-chiral dimers differ?

Janet E. Del Bene, Ibon Alkorta, and José Elguero

**Abstract:** Ab initio equation-of-motion coupled cluster singles and doubles (EOM-CCSD) calculations have been carried out to evaluate spin-spin coupling constants in six pairs of homo- and hetero-chiral dimers: (HOOH)<sub>2</sub>, (H<sub>2</sub>NNH<sub>2</sub>)<sub>2</sub>, (FOOH)<sub>2</sub>, (FHNNH<sub>2</sub>)<sub>2</sub>, (HOOOH)<sub>2</sub>, and (FOOOH)<sub>2</sub>. Corresponding spin-spin coupling constants in these isomeric pairs of C<sub>2</sub> and C<sub>i</sub> symmetry may differ, but these differences are small and may not be detectable experimentally. For the complexes with O1-H...O and O1-H...F hydrogen bonds, <sup>1</sup>J(O1-H) has a larger absolute value in the C<sub>2</sub> isomer. For the same set of complexes, <sup>1</sup>J(O1-O2) has a larger absolute value in the C<sub>i</sub> isomer. No distinguishable patterns could be discerned in the remaining spin-spin coupling constants in the C<sub>2</sub> and C<sub>i</sub> isomers of these complexes, nor in complexes with N-H...N hydrogen bonds.

**Key words:** spin-spin coupling constants, homo- and hetero-chiral dimers, hydrogen bond.

**Résumé :** Des calculs ab initio EOM-CCSD ont été effectués pour évaluer les constantes de couplage spin-spin dans six paires de dimères homo- et heterochiral : (HOOH)<sub>2</sub>, (H<sub>2</sub>NNH<sub>2</sub>)<sub>2</sub>, (FOOH)<sub>2</sub>, (FHNNH<sub>2</sub>)<sub>2</sub>, (HOOOH)<sub>2</sub>, et (FOOOH)<sub>2</sub>. Les correspondantes constantes de couplage spin-spin dans les paires d'isomères sont, en général, différentes mais les différences sont faibles au point, pour certaines d'entre elles, de ne pas pouvoir être détectées expérimentalement. Pour les complexes avec des liaisons hydrogène O-H...O et O-H...F, <sup>1</sup>J(O1-H) a une plus large valeur absolue dans l'isomère C<sub>2</sub>. Pour le même ensemble des complexes, <sup>1</sup>J(O1-O2) a une plus large valeur absolue dans l'isomère C<sub>i</sub>. On ne trouve pas des règles générales pour les restantes constantes de couplage spin-spin dans les isomères C<sub>2</sub> et C<sub>i</sub> de ces complexes et non plus dans les complexes avec des liaisons hydrogène N-H...N.

**Mots-clés :** constantes de couplage spin-spin, homo- et hetero-chiral dimères, liaisons hydrogène.

## Introduction

Chiral distinction or "chiral recognition" has been a topic of interest to both theorists and experimentalists. In the past, we have devoted several papers to the topic of chiral distinction in which we focused primarily on energy differences between enantiomers.<sup>1</sup> Experimental NMR studies of nuclear shielding have been reported and used to characterize and analyze chiral discrimination in complexes formed by a molecule of known chirality and a mixture of enantiomeric compounds.<sup>2-4</sup> In the present paper, we ask for the first time whether or not corresponding spin-spin coupling constants for hydrogen-bonded hetero- and homo-chiral dimers differ, and if so, do patterns exist that would distinguish one isomer from the other as a tool for chiral distinction.<sup>5,6</sup> To answer this question, we have carried out ab initio equation-of-motion coupled cluster singles and doubles (EOM-CCSD) calculations to evaluate spin-spin coupling constants for the C<sub>2</sub> (homochiral; optically active) and C<sub>i</sub>

(heterochiral; optically inactive) isomers of six hydrogen-bonded dimers: (HOOH)<sub>2</sub>, (H<sub>2</sub>NNH<sub>2</sub>)<sub>2</sub>, (FOOH)<sub>2</sub>, (FHNNH<sub>2</sub>)<sub>2</sub>, (HOOOH)<sub>2</sub>, and (FOOOH)<sub>2</sub>. In this paper, we present the results of these calculations, and our conclusions about relationships between corresponding spin-spin coupling constants in the isomeric pairs.

## Methods

The structures of the monomers and complexes were optimized at second-order Møller-Plesset perturbation theory (MP2)<sup>7-10</sup> with the 6-311++G(d,p) basis set.<sup>11-13</sup> Frequencies were computed to insure that each isomer corresponds to a local minimum on its potential surface. The geometries of some of the systems have been reported by us in a previous article.<sup>14</sup> Coupling constants were evaluated using the equation-of-motion coupled cluster singles and doubles (EOM-CCSD) method in the CI (configuration interaction)-like approximation<sup>15,16</sup> with all electrons correlated. For these

calculations, the Ahlrichs and co-workers<sup>17</sup> qzp basis set was placed on <sup>15</sup>N, <sup>17</sup>O, and <sup>19</sup>F, and the qz2p basis set was placed on the hydrogen-bonded <sup>1</sup>H. All other H atoms were described using the Dunning<sup>18</sup> cc-pVDZ basis set, and no coupling constants are reported for these hydrogens. The EOM-CCSD method with the Ahlrichs (qzp,qz2p) basis set has been shown to yield coupling constants in good agreement with experimental values for molecules.<sup>19–22</sup> Its application to hydrogen-bonded complexes has provided insight into experimentally determined coupling constants,<sup>23</sup> and the predicted relationship between <sup>2h</sup>J(N–N) and the N–N distance for N–H...N hydrogen bonds<sup>24</sup> has been verified experimentally.<sup>25</sup> Finally, the computed signs and magnitudes of <sup>2h</sup>J(X–Y), <sup>1h</sup>J(H–Y), and <sup>1</sup>J(X–H) for X–H...Y hydrogen bonds have been used successfully to characterize hydrogen-bond type.<sup>26,27</sup>

In the Ramsey approximation, the total coupling constant (*J*) is a sum of four contributions: the paramagnetic spin-orbit (PSO), diamagnetic spin-orbit (DSO), Fermi contact (FC), and spin-dipole (SD).<sup>28</sup> All terms have been computed for all molecules. The MP2 calculations were carried out using the Gaussian 03 suite of programs<sup>29</sup> on the computers at the CSIC (Consejo Superior de Investigaciones Científicas). EOM-CCSD calculations were done with ACES II<sup>30</sup> on the IBM Cluster 1350 (Glenn) at the Ohio Supercomputer Center.

## Results and discussion

### Structures and binding energies

Table 1 presents the hydrogen-bonding coordinates *R*(X–Y), *R*(X–H), *R*(H...Y), and the angle H–X–Y for the *C*<sub>2</sub> and *C*<sub>i</sub> isomers of the six dimers with X–H...Y hydrogen bonds, and the binding energies of these complexes. The complexes (HOOH)<sub>2</sub> and (HOOH)<sub>2</sub> are stabilized by O–H...O hydrogen bonds, with O–O distances varying from 2.814 to 2.841 Å. The (FOOH)<sub>2</sub> and (FOOH)<sub>2</sub> dimers are stabilized by O–H...F hydrogen bonds. The O–F distances in the *C*<sub>2</sub> and *C*<sub>i</sub> structures of (FOOH)<sub>2</sub> are 2.811 and 2.755 Å, respectively. The corresponding distances are much longer in (FOOH)<sub>2</sub>, at 3.616 and 3.031 Å, respectively. (H<sub>2</sub>NNH<sub>2</sub>)<sub>2</sub> and (FHNNH<sub>2</sub>)<sub>2</sub> are stabilized by N–H...N hydrogen bonds, with N–N distances between 3.084 and 3.146 Å. Except for the O–F distances in (FOOH)<sub>2</sub>, these intermolecular distances are not unusual. However, the hydrogen bonds in these dimers are not linear, and in some cases the deviation from linearity is significant, as evident from Table 1. The dimers with hydrogen bonds that exhibit the smallest deviation from linearity are the isomers of (HOOH)<sub>2</sub>, for which the H–O–O angle is approximately 10°. It is also interesting to note that the *C*<sub>2</sub> and *C*<sub>i</sub> isomers of this dimer have the greatest binding energies of 10.9 and 11.2 kcal mol<sup>–1</sup>, respectively. The largest deviation from linearity is 40° in the *C*<sub>i</sub> isomer of (FOOH)<sub>2</sub>. Although this isomer has a shorter O–F distance than the *C*<sub>2</sub> isomer, it is less stable by 1.2 kcal mol<sup>–1</sup>. The large deviation from linearity makes it debatable as to whether the *C*<sub>i</sub> isomer can even be described as hydrogen bonded, since it may gain stability from electrostatic interactions, including an antiparallel alignment of O–H bond dipole moments, as shown in Fig. 1. It is noteworthy that the

(FOOH)<sub>2</sub> dimer is the only dimer for which the *C*<sub>2</sub> isomer is more stable than *C*<sub>i</sub>.

The other dimers that have significantly nonlinear hydrogen bonds are the isomers of (FHNNH<sub>2</sub>)<sub>2</sub>. These dimers have the F atom bonded to the proton donor N1–H, with binding energies of 5.8 and 6.6 kcal mol<sup>–1</sup> for the *C*<sub>2</sub> and *C*<sub>i</sub> structures, respectively. These isomers have the weakest hydrogen bonds, except for the *C*<sub>i</sub> isomer of (FOOH)<sub>2</sub>. It might have been anticipated that substituting F on the donor N1–H would make HFNNH<sub>2</sub> a stronger proton donor, and (FHNNH<sub>2</sub>)<sub>2</sub> would be more stable than (H<sub>2</sub>NNH<sub>2</sub>)<sub>2</sub>, but this is obviously not the case since the (H<sub>2</sub>NNH<sub>2</sub>)<sub>2</sub> isomers have binding energies of 7.0 and 7.5 kcal mol<sup>–1</sup>. The reduced stabilities of the (FHNNH<sub>2</sub>)<sub>2</sub> dimers may reflect the significant nonlinearity of the hydrogen bonds in the *C*<sub>2</sub> and *C*<sub>i</sub> isomers, which have H–N–N angles of 32° and 35°, respectively.

### Spin–spin coupling constants

In the Introduction to this paper we asked the question whether or not corresponding spin–spin coupling constants for hydrogen-bonded hetero- and homo-chiral dimers are different, and if so, do patterns exist that would distinguish one isomer from the other. The one- and two-bond coupling constants <sup>1</sup>J(X–H), <sup>1h</sup>J(H–Y), and <sup>2h</sup>J(X–Y) across the X–H...Y hydrogen bonds are reported in Table 2. The two-bond coupling constants <sup>2h</sup>J(X–Y) are very small, ranging from 0.42 Hz in the *C*<sub>i</sub> isomer of (HOOH)<sub>2</sub> to 3.09 Hz in the *C*<sub>2</sub> isomer of (FOOH)<sub>2</sub>. However, when comparing coupling constants involving different atoms, it is the reduced coupling constants that should be used to eliminate the dependence of the coupling constant on the magnetogyric ratios of the coupled atoms. The reduced coupling constants are given in Table 3. From Table 3 it can be seen that the reduced two-bond coupling constants for the dimers with N–H...N hydrogen bonds are significantly greater than the reduced two-bond coupling constants across O–H...O and O–H...F hydrogen bonds. Moreover, although the reduced two-bond coupling constants for O–H...O and N–H...N hydrogen bonds are positive, the reduced two-bond coupling constants across the O–H...F hydrogen bonds are negative, and like the two-bond F–F coupling constant for (HF)<sub>2</sub>, are exceptions to the generalization that reduced two-bond coupling constants across hydrogen bonds are positive.<sup>31</sup>

There is no correlation between the two-bond coupling constant <sup>2h</sup>J(X–Y) and the corresponding X–Y distance, most probably due in part to the varying degree of nonlinearity of the hydrogen bonds. Although for each dimer <sup>2h</sup>J(X–Y) values are different in the *C*<sub>2</sub> and *C*<sub>i</sub> isomers, there is no recognizable pattern to these differences. For example, <sup>2h</sup>J(O–O) is greater for the *C*<sub>2</sub> isomer of (HOOH)<sub>2</sub>, but it is greater for the *C*<sub>i</sub> isomer of (HOOH)<sub>2</sub>. It might be tempting to suggest that this difference may be related to the number of bonds between the proton-donor and the proton-acceptor oxygen atoms (1 vs 2). However, <sup>2h</sup>J(O–F) is also greater for the *C*<sub>2</sub> isomer of (FOOH)<sub>2</sub> and the *C*<sub>i</sub> isomer of (FOOH)<sub>2</sub>, in which case there are two and three bonds, respectively, between the proton-donor and the proton-acceptor atoms. With such relationships, there are too few cases for generalization.

From Table 2 it may also be seen that the one-bond X–H

<sup>a</sup>Δ*E*<sub>e</sub> is the negative of the electronic energy for the reaction in which two monomers form a dimer.

<sup>b</sup>The N–H that is subsequently hydrogen bonded in the dimers.

<sup>c</sup>F is bonded to the proton donor N–H.

**Fig. 1.** The *C<sub>i</sub>* structure of (FOOOH)<sub>2</sub> illustrating the nonlinearity of possible hydrogen bonds and the antiparallel alignment of O–H bond dipole moments.

coupling constant  $^1J(X-H)$  always increases in absolute value upon complexation as the X–H distance also increases. Such behavior has been observed previously.<sup>32,33</sup> Although this increase may be as great as 6 Hz for  $^1J(O-H)$  in (FOOH)<sub>2</sub>, the difference between  $^1J(X-H)$  in the *C*<sub>2</sub> and *C<sub>i</sub>* isomers is small. Nevertheless,  $^1J(O-H)$  has a greater absolute value in the *C<sub>i</sub>* isomers, with a difference that ranges from 0.03 Hz for (HOOOH)<sub>2</sub> to 0.5 Hz for (FOOOH)<sub>2</sub>. This pattern does not hold for dimers with N–H···N hydrogen bonds since the absolute value of  $^1J(N-H)$  is 0.4 Hz greater for the *C*<sub>2</sub> isomer of (H<sub>2</sub>NNH<sub>2</sub>)<sub>2</sub> but 0.3 Hz smaller for the *C<sub>i</sub>* isomer of (FHNNH<sub>2</sub>)<sub>2</sub>.

The reduced one-bond coupling constants  $^1hK(H-Y)$  across the hydrogen bonds are always negative, indicating that such bonds are traditional (normal) hydrogen bonds.<sup>34</sup> A pattern would not be anticipated for  $^1hK(H-Y)$ , since this coupling constant may have a maximum absolute value be-

fore it asymptotically approaches 0 Hz as the H–Y distance increases. Thus, it may have the same value at two different H–Y distances.

While small differences are evident in the coupling constants  $^1J(X-H)$  and  $^2hJ(X-Y)$  for the *C*<sub>2</sub> and *C<sub>i</sub>* isomers of these dimers, the lack of systematic differences is really not surprising. The isomers of the six dimers investigated in this study can be very different structurally, particularly with respect to the arrangement of the heavy atoms in the complex and the degree of nonlinearity of the hydrogen bonds. For example, the hydrogen-bonded O and H atoms in the *C<sub>i</sub>* isomer of (HOOH)<sub>2</sub> are essentially coplanar but deviate to some extent from coplanarity in the *C*<sub>2</sub> isomer. In the *C<sub>i</sub>* isomer of (HOOOH)<sub>2</sub>, the hydrogen-bonded O and H atoms are essentially coplanar, but the oxygen that is bonded to both proton-donor and proton-acceptor oxygens does not lie in this plane. In contrast, there is no hydrogen-bonding plane in the *C*<sub>2</sub> isomer. Finally, one might even question whether hydrogen bonds exist in the *C<sub>i</sub>* isomer of (FOOOH)<sub>2</sub>, which is illustrated in Fig. 1, or in the isomers of (FHNNH<sub>2</sub>)<sub>2</sub>, given the nonlinearity of these bonds as indicated by the values of the H–X–Y angles reported in Table 1. All of these differences are likely sources of the lack of distinguishable patterns for corresponding coupling constants involving hydrogen-bonded atoms in the *C*<sub>2</sub> and *C<sub>i</sub>* isomers.

Are there any other easily identifiable pairs of atoms that might have distinguishable coupling constants for the two isomers? Our search for these yielded only one pair, O1–O2, where O1 is the proton-donor oxygen. Table 4 presents O1–O2 distances and  $^1J(O1-O2)$  for the monomers and the *C*<sub>2</sub> and *C<sub>i</sub>* isomers of dimers with O1–H···O and O1–H···F hydrogen bonds.  $^1J(O1-O2)$  are positive for HOOH and the two isomers of (HOOH)<sub>2</sub> but negative for the other monomers and dimers. It is interesting to note that dimer formation makes

${}^1J(O1-O2)$  less positive for (HOOH)<sub>2</sub> as the O1–O2 distance remains essentially constant.  ${}^1J(O1-O2)$  for the remaining dimers becomes more negative, that is, it increases in absolute value as the O1–O2 distance decreases upon dimer formation. The largest change in the O1–O2 distance and in  ${}^1J(O1-O2)$  upon dimer formation is found for (FOOH)<sub>2</sub>. The absolute value of  ${}^1J(O1-O2)$  is always greater in the *C<sub>i</sub>* isomer, with differences varying from 0.6 to 1.4 Hz. Unfortunately, the nuclear spin of 5/2 for <sup>17</sup>O makes it unlikely that such small differences could be detected experimentally.

**Table 4.** O1–O2 distances (Å) and  ${}^1J(O1-O2)$  (Hz) for monomers and hetero- and homo-chiral dimers with O2–O1–H $\cdots$ Y hydrogen bonds.

No patterns are observed for the values of  ${}^1J(N1-N2)$  in the *C*<sub>2</sub> and *C<sub>i</sub>* isomers of dimers with N–H $\cdots$ N hydrogen bonds.

The  $\Delta J$  values reported in Table 2 correspond to what is termed *chiral anisogamy*, meaning a difference in corresponding coupling constants in a pair of chiral isomers.<sup>35</sup> Could such differences be detected experimentally? To answer this question, it is necessary to first consider the spins of the nuclei involved. Since couplings between nuclei both of which have  $I > 1/2$  cannot be measured, all of the O–O couplings are eliminated. Couplings between one nucleus that has  $I = 1/2$  and another with  $I > 1/2$  can be measured, but small differences are not detectable. This is the situation for O–H and O–F couplings. However, progress is being made in this area.<sup>36</sup> With ultrahigh resolution NMR, couplings between nuclei with  $I = 1/2$  can be measured to a precision better than 0.1 Hz,<sup>37</sup> which means that even small couplings involving H, N, and F could be detected. However, experimental studies of the particular dimers investigated in this study would be difficult both in solution where

they would need to form and remain stable, and in the solid state with the very low temperatures required. The most promising candidate for experimental investigation would be a strongly-bound complex with a  $^{15}\text{N}$ -labeled hydrazine derivative, which is a solid at room temperature and shows X-ray crystallographic evidence for the existence of hydrogen bonds.

## Conclusions

Corresponding spin–spin coupling constants for hydrogen-bonded atoms in isomeric pairs of homo- and hetero-dimers of  $\text{C}_2$  and  $\text{C}_i$  symmetry may differ, but the differences are small and would probably be difficult to detect experimentally. For the four complexes with  $\text{O}\cdots\text{H}\cdots\text{X}$  hydrogen bonds,  $^1\text{J}(\text{O1}\cdots\text{H})$  has a larger absolute value in the  $\text{C}_2$  isomer. For the same set of complexes,  $^1\text{J}(\text{O1}\cdots\text{O2})$  has a larger absolute value in the  $\text{C}_i$  isomer. No distinguishable patterns could be discerned in corresponding spin–spin coupling constants in the  $\text{C}_2$  and  $\text{C}_i$  isomers of complexes with  $\text{N}\cdots\text{H}\cdots\text{N}$  hydrogen bonds.

# Intramolecular hydroamination of unactivated alkenes with secondary alkylamines catalyzed by iridium phosphino–phenolate complexes

Kevin D. Hesp, Robert McDonald, and Mark Stradiotto

**Abstract:** The phosphino–phenolate complex ( $\kappa^2$ -{2-*i*-Pr<sub>2</sub>PC<sub>6</sub>H<sub>4</sub>}O)Ir(COD) (COD =  $\eta^4$ -1,5-cyclooctadiene; **1**) is shown to be an effective precatalyst for the intramolecular hydroamination of unactivated alkenes with pendant secondary alkylamines, providing either pyrrolidine or piperidine heterocycles in high isolated yields. While monitoring the progress of a selected test reaction of this type, a significant induction period (~3 h) was observed; variable-temperature <sup>1</sup>H and <sup>31</sup>P NMR studies (25–100 °C) under catalytically relevant conditions revealed no new metal-containing species. In an effort to develop an enantiopure variant of **1**, a synthetic route to the chiral ( $\kappa^2$ -*P,O*)Ir(COD) complex (**7**), which features a 1-aryl-2,5-dialkylphospholane structure derived from (2*S*,5*S*)-2,5-hexanediol cyclic sulfate, was developed. The structure of **7** was confirmed by use of single-crystal X-ray diffraction techniques. While **7** failed to provide enantioselectivity in the intramolecular hydroamination of unactivated alkenes with pendant secondary alkylamines, the activity of **7** was found to be comparable to that of **1**.

**Key words:** catalysis, hydroamination, iridium, ligand design.

**Résumé :** On montre que le complexe phosphino–phénolate, ( $\kappa^2$ -{2-*i*-Pr<sub>2</sub>PC<sub>6</sub>H<sub>4</sub>}O)Ir(COD) (**1**), est un précatalyseur efficace pour l'hydroamination intramoléculaire d'alcènes non activés portant des chaînes latérales avec des alkylamines secondaires qui conduit à la formation d'hétérocycles pyrrolidine ou pipéridine avec des rendements élevés en produits isolés. En observant le progrès d'une réaction de ce type choisie comme représentative, on a observé une période d'induction significative (environ 3 heures); des études de RMN du <sup>1</sup>H et du <sup>31</sup>P à température variable (25 à 100 °C), dans des conditions catalytiquement appropriées ont révélé qu'il n'y a pas de nouvelles espèces contenant un métal. Dans un effort pour développer une variété énantiomériquement pure du composé **1**, on a mis au point une voie de synthèse du complexe chiral ( $\kappa^2$ -*P,O*)Ir(COD), **7**, qui inclut une structure 1-aryl-2,5-dialkylphospholane obtenue à partir du sulfate cyclique du (2*S*,5*S*)-hexane-2,5-diols. La structure du composé **7** a été confirmée par des techniques de diffraction des rayons X par un cristal unique. Même si le composé **7** n'a pas permis d'obtenir d'énantiosélectivité dans l'hydroamination intramoléculaire d'alcènes non activés portant des chaînes latérales avec des alkylamines secondaires, l'activité de ce produit est comparable à celle du produit **1**.

**Mots-clés :** Catalyse, hydroamination, iridium, développement d'un ligand.

## Introduction

The prevalence of nitrogen-containing moieties in both naturally occurring and biologically active molecules has prompted the development of efficient methods for the formation of C–N bonds, including the use of transition-metal catalysis.<sup>1</sup> Notwithstanding the tremendous success of Buchwald–Hartwig amination and related cross-coupling chemistry,<sup>1b,c</sup> the inherent lack of atom economy associated with such procedures has prompted the development of hydroamination protocols that enable C–N bond formation via the direct addition of N–H bonds to unsaturated substrates.<sup>1d</sup> In particular, intramolecular hydroamination involving N–H bond addition to an unactivated alkene offers an attractive

route to nitrogen-containing heterocycles. However, while catalyst systems employing Brønsted acids,<sup>2</sup> rare earth elements and actinides,<sup>3</sup> alkali and alkaline earth metals,<sup>4</sup> group 4 metals,<sup>5</sup> and groups 8–11 metals<sup>6,7</sup> have all proven capable of mediating the intramolecular hydroamination of such unactivated aminoalkenes, general methods for promoting the cyclization of these challenging substrates under mild conditions and with broad substrate scope remain elusive.

We recently reported on the use of [Ir(COD)Cl]<sub>2</sub> (COD =  $\eta^4$ -1,5-cyclooctadiene) as a precatalyst for the intramolecular addition of a variety of secondary alkyl- or aryl- amines to unactivated alkenes, without the requirement of added ligands or cocatalysts<sup>7a</sup>; notably, this represents one of only a

small number of examples in which late metal catalysts have been shown to promote the cyclization of such substrates.<sup>7</sup> As such, we became interested in identifying alternative neutral Ir complexes that function as catalysts for the intramolecular hydroamination of unactivated aminoalkenes,<sup>8</sup> especially those for which chiral variants could be developed. Encouraged by our previous observation that the phosphino-phenolate complex ( $\kappa^2$ -{2-*i*-Pr<sub>2</sub>PC<sub>6</sub>H<sub>4</sub>}O)Ir(COD) (**1**) is a highly active catalyst for the hydrogenation of substituted alkenes under mild conditions,<sup>9</sup> we viewed **1** as being an attractive candidate for use in hydroamination chemistry. We report herein that **1** is a competent catalyst at relatively low catalyst loadings for the intramolecular hydroamination of a variety of unactivated alkenes that feature pendant alkylamines. Furthermore, we report on the synthesis and crystallographic characterization of a first-generation chiral variant of **1**, and our efforts to apply this new chiral ( $\kappa^2$ -*P,O*)Ir(COD) complex in intramolecular hydroamination catalysis.<sup>10</sup>

## Results and discussion

In a preliminary test experiment, the cyclization of the aminoalkene **2a** to the pyrrolidine **2b** proceeded in a 72%

yield (<sup>1</sup>H NMR) in the presence of 1.0 mol% **1** in 1,4-dioxane at 110 °C over the course of 7 h, with the balance corresponding to unreacted **2a** (eq. [1]). Under similar experimental conditions employing catalyst mixtures comprised of 0.5 mol% [Ir(COD)Cl]<sub>2</sub> and 1.0 mol% of a simple phosphine ligand including triphenylphosphine, tricyclohexylphosphine or 1,4-bis(diphenylphosphino)butane, negligible conversion to the desired cyclization product **2b** was achieved. While the use of the Rh variant of **1** under similar experimental conditions resulted in the consumption of **2a**, multiple products were formed in this reaction with the major product corresponding to alkene isomerization within the starting substrate.

The utility of **1** as a precatalyst in the hydroamination of a range of *N*-alkyl aminoalkenes was surveyed (Table 1). The cyclization of the parent *N*-benzyl substrate **2a** (Table 1,

**Fig. 1.** A plot of the conversion of **2a** to **2b** vs time employing 2.5 mol% **1** (1,4-dioxane, 110 °C).

entry 1) as well as para-substituted derivatives featuring chloride (Table 1, entry 2), methyl ester (Table 1, entry 3), or methoxy (Table 1, entry 4) substituents, was in each case achieved in high isolated yield (85%–92%) despite the use of relatively low catalyst loading (1.0 mol% **1**). The sterically hindered *N*-methylcyclohexyl aminoalkene was also cyclized (Table 1, entry 5), as were substrates that feature alternative formulations of mono- and di-substitution on the linker chain of the aminoalkene substrate (Table 1, entries 6–8). Notably, the results featured in Table 1, entries 6–8, clearly underscore the importance of the Thorpe–Ingold effect in promoting these transformations, whereby increased steric elaboration at the  $\beta$ -carbon enables more facile cyclohydroamination at lower catalyst loadings. The hydroamination of the hexenylamine substrate featured in Table 1, entry 9, was also achieved in the presence of **1** to afford the corresponding piperidine. In surveying more challenging substrates, we turned our attention to the intramolecular hydroamination of unactivated disubstituted alkenes. Whereas the efficient cyclization of a 1,1-disubstituted substrate was achieved by use of **1** (Table 1, entry 10), under our standard catalytic conditions, this catalyst proved unreactive toward aminoalkenes featuring unstrained 1,2-substituted olefins or those lacking substituents on the tethering chain that facilitate the cyclization process, as well as primary amine substrates. In comparison to the catalytic performance of  $[\text{Ir}(\text{COD})\text{Cl}]_2$ ,<sup>7a</sup> longer reaction times were needed when using **1** to achieve similar levels of conversion for the substrates featured in Table 1, entries 1–6; for **2a**, as well as the *N*-methylcyclohexyl aminoalkene substrate (Table 1, entry 5), significantly higher Ir loadings were also required when using **1**. Otherwise, the catalytic performance of **1** in the cyclization of *N*-alkyl aminoalkenes was found to be competitive with that of  $[\text{Ir}(\text{COD})\text{Cl}]_2$ , and in the case of the more challenging substrates featured in Table 1, entries 8–10, **1** proved to be superior to  $[\text{Ir}(\text{COD})\text{Cl}]_2$  on the basis of Ir loading, reaction time, and isolated yield.

Having observed that longer reaction times and higher

catalyst loadings were needed for **1** relative to  $[\text{Ir}(\text{COD})\text{Cl}]_2$  to achieve similarly high levels of conversion in the cyclization of **2a** to **2b**, we examined the conversion versus time profile for this transformation employing **1** (2.5 mol% Ir, 1,4-dioxane, 110 °C; Fig. 1). Notably, a pronounced induction period (~3 h) was observed under these conditions; by comparison, high conversion to **2b** was achieved after 3 h by using only 0.5 mol%  $[\text{Ir}(\text{COD})\text{Cl}]_2$  under similar conditions in the absence of an induction period.<sup>7a</sup> Variable-temperature <sup>1</sup>H and <sup>31</sup>P NMR studies (25–100 °C) of an equimolar mixture of **1** and **2a**, either without preconditioning or following preconditioning for 3 h at 110 °C, revealed the presence of only **1** and **2a**, as well as small quantities of **2b** at elevated temperatures. While we are presently unable to comment definitively regarding the mechanism of hydroamination mediated by **1**, these spectroscopic observations appear to preclude a mechanism in which dissociation of the P,O ligand from Ir is responsible for the observed induction period. Mechanistic investigations regarding the cyclization of **2a** and related substrates by each of **1** and  $[\text{Ir}(\text{COD})\text{Cl}]_2$  are ongoing in our laboratory.

The late metal catalyzed enantioselective intramolecular hydroamination of unactivated alkenes featuring pendant alkylamines has yet to be reported in the literature.<sup>10</sup> Given the desirable catalytic performance of **1**, and encouraged by reports documenting the Ir-mediated enantioselective intermolecular hydroamination of activated alkenes,<sup>11</sup> we sought to construct a chiral variant of **1**. In consideration of the diisopropylphosphino present in **1**, we elected to employ a structurally similar  $\kappa^2$ -*P,O* phenylene ligand featuring the 1-aryl-2,5-dialkylphospholane scaffold.<sup>12</sup> Preparation of the target ligand precursor **6** was carried out by adapting previously published methods.<sup>12a,13</sup> As outlined in Scheme 1, the installation of the chiral phospholane fragment required initial treatment of the methoxymethyl (MOM) protected phenol **3** with *n*-BuLi and  $\text{P}(\text{NMe}_2)_2\text{Cl}$ , followed by in situ methanolysis and reduction with  $\text{LiAlH}_4$  to afford the primary phosphine **4**. Using the procedure established by Burk

**Scheme 1.** Synthesis of the new chiral ( $\kappa^2$ -*P,O*)Ir(COD) complex **7**. Reagents and conditions: (a) *n*-BuLi, Et<sub>2</sub>O, −78 °C → 25 °C, 16 h; P(NMe<sub>2</sub>)<sub>2</sub>Cl, Et<sub>2</sub>O, −78 °C → 25 °C, 3 h; MeOH, 50 °C, 3 h; LiAlH<sub>4</sub>, Et<sub>2</sub>O, 25 °C, 48 h (36% from **3**). (b) *n*-BuLi, THF, 25 °C, 1.5 h; (2*S*,5*S*)-2,5-hexanediol cyclic sulfate, THF, 25 °C, 2 h; *n*-BuLi, THF, 25 °C, 2 h, (68% from **4**). (c) 5 mol/L HCl (aq.), THF, 50 °C, 16 h; 7 mol/L NH<sub>4</sub>OH (aq.), Et<sub>2</sub>O, 25 °C, 5 h, (73% from **5**). (d) [Ir(COD)Cl]<sub>2</sub>, NEt<sub>3</sub>, THF, 25 °C, 2 h, 68%.

et al.<sup>12b</sup> for the construction of phospholane moieties, successive treatment of **4** with 1 equiv. *n*-BuLi, followed by 1 equiv. (2*S*,5*S*)-2,5-hexanediol cyclic sulfate, and then an additional 1 equiv. of *n*-BuLi provided the protected intermediate **5**, which was converted to the phosphinoenolate **6** upon exposure to aqueous HCl followed by workup with aqueous NH<sub>4</sub>OH. Treatment of **6** with 0.5 equiv. [Ir(COD)Cl]<sub>2</sub> and NEt<sub>3</sub> afforded **7** as an analytically pure, isolable orange solid (68% from **6**; 12% from **3**). The connectivity in **7** was established by use of NMR spectroscopic and X-ray crystallographic techniques (Fig. 2, Table 2). The structural features in **7** compare well with those found in **1**,<sup>9</sup> including the observed Ir–P and Ir–O distances (2.2797(7) and 2.0163(18) Å, respectively; cf. 2.289(1) and 2.028(3) Å in **1**, respectively), as well as the observation that in **7** the Ir–alkene distances trans to P (2.167(3) and 2.193(3) Å) are statistically longer than the Ir–alkene distances trans to O (2.114(3) and 2.131(3) Å), which is in keeping with the greater trans influence anticipated for a phosphine fragment relative to an alkoxy donor on Ir. Unfortunately, despite maintaining a catalytic activity profile similar to **1** in the hydroamination of **2a** and related substrates, the chiral complex **7** was incapable of inducing any enantioselectivity in the resulting cyclization product (e.g., **2b**) over a range of reaction conditions (1–5 mol% **7**, 80–110 °C).

## Summary and conclusion

In summary, ( $\kappa^2$ -{2-*i*-Pr<sub>2</sub>PC<sub>6</sub>H<sub>4</sub>}O)Ir(COD) (**1**) is an effective precatalyst for the intramolecular hydroamination of unactivated alkenes with pendant secondary alkylamines, providing either pyrrolidine or piperidine heterocycles in the absence of competing alkene isomerization. We have also succeeded in establishing a synthetic pathway to **7**: a chiral relative of **1** that features a 1-aryl-2,5-dialkylphospholane structure derived from (2*S*,5*S*)-2,5-hexanediol cyclic

sulfate. While **7** failed to provide enantioselectivity in this hydroamination chemistry, the activity of **7** was found to be comparable to that of **1**. Future studies will focus both on preparing alternative chiral variants of **1**, as well as on exploring the mechanism of hydroamination processes mediated by ( $\kappa^2$ -*P,O*)Ir(COD) species to guide the design of increasingly effective catalysts.

## Experimental

### General considerations

All manipulations were conducted in the absence of oxygen and water under an atmosphere of dinitrogen, either by use of standard Schlenk methods or within an MBraun glovebox apparatus, utilizing glassware that was oven-dried (130 °C) and evacuated while hot prior to use. The nondeuterated solvents, tetrahydrofuran, diethyl ether, dichloromethane, benzene, hexanes, and pentane, were deoxygenated and dried by sparging with dinitrogen gas, followed by passage through a double-column solvent purification system purchased from MBraun Inc. Tetrahydrofuran, diethyl ether, and dichloromethane were purified over two alumina-packed columns, while benzene, hexanes, and pentane were purified over one alumina-packed column and one column packed with copper-Q5 reactant. 1,4-Dioxane (Sigma-Aldrich) was dried over Na/benzophenone followed by distillation under an atmosphere of dinitrogen; anhydrous 1,4-dioxane used as received from Sigma-Aldrich provided inferior results. Chloroform-*d*<sub>1</sub> (Cambridge Isotopes) was used as received. C<sub>6</sub>D<sub>6</sub> (Cambridge Isotopes Laboratories) was degassed by using three freeze-pump-thaw cycles and then dried over 3 Å molecular sieves. All solvents used within the glovebox were stored over activated 4 Å molecular sieves. Purification of NEt<sub>3</sub> was achieved by stirring over KOH for 7 d, followed by distillation; the distilled NEt<sub>3</sub> was then refluxed over CaH<sub>2</sub> for 3 d under dinitrogen, followed by distillation. Complex **1**,<sup>9</sup> P(NMe<sub>2</sub>)<sub>2</sub>Cl,<sup>14</sup> (2*S*,5*S*)-2,5-hexanediol cyclic sulfate,<sup>12b</sup> *N*-benzyl-2,2-diphenylpent-4-en-1-amine,<sup>7f</sup> *N*-(4-chlorobenzyl)-2,2-diphenylpent-4-en-1-amine,<sup>2a</sup> methyl 4-[(2,2-diphenylpent-4-enylamino)methyl]benzoate,<sup>7f</sup> *N*-(4-methoxybenzyl)-2,2-diphenylpent-4-en-1-amine,<sup>2a</sup> *N*-(cyclohexylmethyl)-2,2-diphenylpent-4-en-1-amine,<sup>7d</sup> (1-allylcyclohexyl)-*N*-benzylmethanamine,<sup>7f</sup> *N*-benzyl-2,2-dimethylpent-4-en-1-amine,<sup>7f</sup> *N*-benzyl-2-isopropylpent-4-en-1-amine,<sup>7f</sup> *N*-benzyl-2,2-diphenylhex-5-en-1-amine,<sup>7d</sup> and *N*-benzyl-4-methyl-2,2-diphenylpent-4-en-1-amine<sup>15</sup> were synthesized according to literature procedures. The synthetic route to **6** starting from **3** was carried out in accordance with previously published methods.<sup>13</sup> [Ir(COD)Cl]<sub>2</sub> (Strem) was dried in vacuo for ~24 h prior to use. All other reagents were used as received. <sup>1</sup>H, <sup>13</sup>C, and <sup>31</sup>P NMR characterization data were collected at 300 K on a Bruker AV-500 spectrometer operating at 500.1, 125.8, and 202.5 MHz (respectively) with chemical shifts reported in parts per million downfield of SiMe<sub>4</sub>. Elemental analyses were performed by Canadian Microanalytical Service Ltd., Delta, BC, Canada.

### Preparation of **4**

To a magnetically stirred solution of **3** (3.96 g, 12.0 mmol) in diethyl ether (10 mL) at -78 °C was added 4.1 mL of a 2.9 mol/L solution of *n*-BuLi in hexanes, which effected the precipitation of a white solid. The resulting mixture was magnetically stirred for 16 h followed by cooling to -78 °C and the dropwise addition of CIP(NMe<sub>2</sub>)<sub>2</sub> (1.9 mL, 12.0 mmol). The reaction mixture was warmed to ambient temperature and was magnetically stirred for 3 h. The resulting white solid was removed by filtration through a filter stick and from the remaining solution the diethyl ether was removed, which afforded a colorless oil that was

dissolved in anhydrous methanol and was heated in an oil bath at 50 °C for 3 h. Subsequent removal of the solvent afforded a colorless oil that was dissolved in diethyl ether (10 mL). The ethereal solution was added dropwise to a Schlenk tube containing LiAlH<sub>4</sub> (0.60 g, 15.6 mmol) in diethyl ether (7 mL). The resulting green solution was magnetically stirred at ambient temperature for 48 h. The reaction mixture was quenched with degassed distilled H<sub>2</sub>O followed by filtration through a filter stick to remove the solids. The diethyl ether layer was dried over Na<sub>2</sub>SO<sub>4</sub>. Subsequent filtration and removal of the solvent afforded **4** as a light brown oil, which when purified by vacuum distillation at 80–90 °C (10<sup>-3</sup> Torr) was obtained as a colorless oil that was used without further purification (1.21 g, 4.28 mmol, 36%). <sup>1</sup>H NMR (C<sub>6</sub>D<sub>6</sub>) δ: 7.46 (d, <sup>4</sup>J<sub>HH</sub> = 2.5 Hz, 1H, Ar-H), 7.41 (d of d, <sup>3</sup>J<sub>PH</sub> = 7.0 Hz, <sup>4</sup>J<sub>HH</sub> = 2.5 Hz, 1H, Ar-H), 4.96 (s, 2H, CH<sub>2</sub> (MOM)), 3.97 (d, <sup>1</sup>J<sub>PH</sub> = 202.1 Hz, 2H, -PH<sub>2</sub>), 3.40 (s, 3H, CH<sub>3</sub> (MOM)), 1.48 (s, 9H, C(CH<sub>3</sub>)<sub>3</sub>), 1.23 (s, 9H, C(CH<sub>3</sub>)<sub>3</sub>). <sup>13</sup>C{<sup>1</sup>H} NMR (C<sub>6</sub>D<sub>6</sub>) δ: 155.7 (d, J<sub>PC</sub> = 10.9 Hz, Ar-quaternary), 145.4 (d, J<sub>PC</sub> = 3.0 Hz, Ar-quaternary), 141.9 (d, J<sub>PC</sub> = 1.5 Hz, Ar-quaternary), 130.7 (d, <sup>2</sup>J<sub>PC</sub> = 7.4 Hz, Ar-CH), 124.5 (Ar-CH), 123.0 (d, J<sub>PC</sub> = 11.4 Hz, Ar-quaternary), 98.8 (d, <sup>4</sup>J<sub>PC</sub> = 7.9 Hz, CH<sub>2</sub> (MOM)), 56.2 (d, J<sub>PC</sub> = 1.5 Hz, CH<sub>3</sub> (MOM)), 34.6 (d, <sup>2</sup>J<sub>PC</sub> = 0.75 Hz, C(CH<sub>3</sub>)<sub>3</sub>), 33.5 (C(CH<sub>3</sub>)<sub>3</sub>), 30.5 (C(CH<sub>3</sub>)<sub>3</sub>), 30.3 (C(CH<sub>3</sub>)<sub>3</sub>). <sup>31</sup>P{<sup>1</sup>H} NMR (C<sub>6</sub>D<sub>6</sub>) δ: -128.6.

### Preparation of **5**

To a magnetically stirred solution of **4** (0.244 g, 0.860 mmol) in THF (5 mL) was added a 1.45 mol/L solution of *n*-BuLi in hexanes (0.600 mL, 0.860 mmol). The reaction mixture went from colorless to yellow in appearance and was magnetically stirred at ambient temperature for 1.5 h, followed by the addition of a THF (2 mL) solution of (2*S*,5*S*)-2,5-hexanediol cyclic sulfate (0.156 g, 0.860 mmol). The reaction went colorless and was magnetically stirred at ambient temperature for 2 h followed by the addition of a 1.45 mol/L solution of *n*-BuLi in hexanes (0.60 mL, 0.860 mmol). The mixture went yellow and remained that color for the subsequent 2 h of magnetic stirring. The solvent and other volatiles were removed in vacuo affording an off-white solid that was washed with pentane (2 × 3 mL) to effect the precipitation of a gelatinous white solid, which was separated by filtration through Celite. The remaining solvent was removed in vacuo affording **5** as a yellow oil that was used without further purification (0.215 g, 0.59 mmol, 68%). <sup>1</sup>H NMR (C<sub>6</sub>D<sub>6</sub>) δ: 7.53 (d, <sup>4</sup>J<sub>HH</sub> = 2.0 Hz, 1H, Ar-H), 7.39 (m, 1H, Ar-H), 5.81 (t, <sup>5</sup>J<sub>PH</sub> = 4.0 Hz, 1H, CH<sub>2</sub> (MOM)), 5.11 (d, 1H, <sup>5</sup>J<sub>PH</sub> = 3.5 Hz, 1H, CH<sub>2</sub> (MOM)), 3.56 (s, 3H, CH<sub>3</sub> (MOM)), 2.62 (m, 1H, CH (phospholane)), 2.27 (m, 1H, CH (phospholane)), 2.13 (m, 1H, CH<sub>2</sub> (phospholane)), 1.84 (m, 1H, CH<sub>2</sub> (phospholane)), 1.57 (s, 9H, C(CH<sub>3</sub>)<sub>3</sub>), 1.41 (m, 1H, CH<sub>2</sub> (phospholane)), 1.33 (d of d, <sup>3</sup>J<sub>PH</sub> = 19.0 Hz, <sup>3</sup>J<sub>HH</sub> = 6.0 Hz, 3H, CH<sub>3</sub> (phospholane)), 1.31 (s, 9H, C(CH<sub>3</sub>)<sub>3</sub>), 1.25 (m, 1H, CH<sub>2</sub> (phospholane)), 0.93 (d of d, <sup>3</sup>J<sub>PH</sub> = 9.5 Hz, <sup>3</sup>J<sub>HH</sub> = 7.0 Hz, 3H, CH<sub>3</sub> (phospholane)). <sup>13</sup>C{<sup>1</sup>H} NMR (C<sub>6</sub>D<sub>6</sub>) δ: 156.6 (d, <sup>2</sup>J<sub>PC</sub> = 18.5 Hz, Ar-quaternary), 144.4 (Ar-quaternary), 141.6 (d, J<sub>PC</sub> = 0.9 Hz, Ar-quaternary), 130.0 (d, J<sub>PC</sub> = 31.6 Hz, Ar-quaternary), 127.3 (d, <sup>2</sup>J<sub>PC</sub> = 2.3 Hz, Ar-CH), 124.4 (Ar-CH), 98.7 (d, <sup>3</sup>J<sub>PC</sub> = 21.0 Hz, CH<sub>2</sub> (MOM)), 56.2

(d,  $J_{PC} = 1.9$  Hz, CH<sub>3</sub> (MOM)), 35.9 (d,  $^2J_{PC} = 2.4$  Hz, CH<sub>2</sub> (phospholane)), 35.3 (d,  $^2J_{PC} = 2.3$  Hz, CH<sub>2</sub> (phospholane)), 34.6 (d,  $J_{PC} = 1.1$  Hz, C(CH<sub>3</sub>)<sub>3</sub>), 34.1 (d,  $^2J_{PC} = 14.7$  Hz, CH (phospholane)), 33.7 (C(CH<sub>3</sub>)<sub>3</sub>), 33.6 (d,  $^2J_{PC} = 10.9$  Hz, CH (phospholane)), 30.7 (C(CH<sub>3</sub>)<sub>3</sub>), 30.2 (C(CH<sub>3</sub>)<sub>3</sub>), 20.4 (d,  $^3J_{PC} = 35.5$  Hz, CH<sub>3</sub> (phospholane)), 15.0 (d,  $^3J_{PC} = 0.9$  Hz, CH<sub>3</sub> (phospholane)).  $^{31}\text{P}\{^1\text{H}\}$  NMR (C<sub>6</sub>D<sub>6</sub>)  $\delta$ : 2.3.

### Preparation of 6

To a magnetically stirred solution of **5** (0.382 g, 1.05 mmol) in THF (10 mL) was added 5 mol/L HCl (aq.) (5 mL) followed by heating at 50 °C in an oil bath for 16 h. Subsequent removal of the solvent afforded a white solid that was suspended in diethyl ether (10 mL) followed by the addition of 7 mol/L NH<sub>4</sub>OH (aq.) (5 mL), which caused the solution to become homogeneous. The solution was magnetically stirred for 5 h at ambient temperature followed by removal of the solvent and extraction of the residue into pentane (3 × 3 mL). Upon removal of the pentane in vacuo, **6** was obtained as a colorless oil that was used without further purification (0.246 g, 0.767 mmol, 73%).  $^1\text{H}$  NMR (C<sub>6</sub>D<sub>6</sub>)  $\delta$ : 7.72 (d,  $^4J_{PH} = 13.5$  Hz, 1H, OH), 7.52 (d,  $^4J_{HH} = 2.0$  Hz, 1H, Ar-H), 7.27 (m, 1H, Ar-H), 2.53 (m, 1H, CH (phospholane)), 2.05 (m, 2H, CH and CH<sub>2</sub> (phospholane)), 1.78 (m, 1H, CH<sub>2</sub> (phospholane)), 1.60 (s, 9H, C(CH<sub>3</sub>)<sub>3</sub>), 1.53 (m, 1H, CH<sub>2</sub> (phospholane)), 1.32 (s, 9H, C(CH<sub>3</sub>)<sub>3</sub>), 1.15 (d of d,  $^3J_{PH} = 19.5$  Hz,  $^3J_{HH} = 7.0$  Hz, 3H, CH<sub>3</sub> (phospholane)), 1.12 (m, 1H, CH<sub>2</sub> (phospholane)), 0.79 (d of d,  $^3J_{PH} = 11.5$  Hz,  $^3J_{HH} = 7.0$  Hz, 3H, CH<sub>3</sub> (phospholane)).  $^{13}\text{C}\{^1\text{H}\}$  NMR (C<sub>6</sub>D<sub>6</sub>)  $\delta$ : 156.8 (d,  $J_{PC} = 19.4$  Hz, Ar-quaternary), 140.4 (Ar-quaternary), 134.4 (Ar-quaternary), 134.3 (d,  $J_{PC} = 15.8$  Hz, Ar-quaternary), 126.9 (d,  $^2J_{PC} = 2.1$  Hz, Ar-CH), 124.9 (Ar-CH), 36.5 (d,  $^2J_{PC} = 4.2$  Hz, CH<sub>2</sub> (phospholane)), 36.4 (CH<sub>2</sub> (phospholane)), 35.8 (d,  $^1J_{PC} = 4.8$  Hz, CH (phospholane)), 34.4 (C(CH<sub>3</sub>)<sub>3</sub>), 33.5 (C(CH<sub>3</sub>)<sub>3</sub>), 33.2 (d,  $^1J_{PC} = 5.7$  Hz, CH (phospholane)), 30.8 (C(CH<sub>3</sub>)<sub>3</sub>), 28.8 (C(CH<sub>3</sub>)<sub>3</sub>), 19.6 (d,  $^2J_{PC} = 31.7$  Hz, CH<sub>3</sub> (phospholane)), 13.8 (CH<sub>3</sub> (phospholane)).  $^{31}\text{P}\{^1\text{H}\}$  NMR (C<sub>6</sub>D<sub>6</sub>)  $\delta$ : -25.6.

### Preparation of 7

To a magnetically stirred solution of [Ir(COD)Cl]<sub>2</sub> (0.14 g, 0.20 mmol) in THF (2 mL) was added a THF (2 mL) solution of **6** (0.13 g, 0.41 mmol). After 3 h of magnetic stirring, NEt<sub>3</sub> (57  $\mu\text{L}$ , 0.41 mmol) was added, which resulted in an immediate color change from yellow-orange to bright orange. After 2 h of magnetic stirring at ambient temperature,  $^{31}\text{P}$  NMR analysis of the reaction mixture confirmed the consumption of **6** and the quantitative formation of a new product (**7**). The solvent and other volatiles were removed in vacuo and the residual solid was extracted into pentane (3 × 2 mL). Subsequent removal of the solvent afforded **7** as an analytically pure orange solid (0.17 g, 0.28 mmol, 68%).  $^1\text{H}$  NMR (C<sub>6</sub>D<sub>6</sub>)  $\delta$ : 7.57 (d,  $^4J_{HH} = 2.0$  Hz, 1H, Ar-H), 7.05 (d of d,  $^3J_{PH} = 8.5$  Hz,  $^3J_{HH} = 2.5$  Hz, 1H, Ar-H), 5.36 (m, 2H, 2 × CH (COD)), 3.56 (m, 1H, CH (COD)), 3.13 (m, 1H, CH (COD)), 2.54 (m, 1H, CH (phospholane)), 2.27 (m, 3H, CH<sub>2</sub> (COD) and CH (phospholane)), 2.13 (m, 2H, CH<sub>2</sub> (COD)), 1.88 (m, 2H, CH<sub>2</sub> (COD)), 1.83 (m, 1H, CH<sub>2</sub> (phospholane)), 1.78 (m, 1H, CH<sub>2</sub> (phospholane)), 1.72 (m, 2H, CH<sub>2</sub> (COD)), 1.70 (s, 9H,

C(CH<sub>3</sub>)<sub>3</sub>), 1.39 (s, 9H, C(CH<sub>3</sub>)<sub>3</sub>), 1.35 (m, 1H, CH<sub>2</sub> (phospholane)), 1.12 (d of d,  $^3J_{PH} = 17.5$  Hz,  $^3J_{HH} = 7.5$  Hz, 3H, CH<sub>3</sub> (phospholane)), 1.03 (m, 1H, CH<sub>2</sub> (phospholane)), 0.93 (d of d,  $^3J_{PH} = 14.5$  Hz,  $^3J_{HH} = 7.0$  Hz, 3H, CH<sub>3</sub> (phospholane)).  $^{13}\text{C}\{^1\text{H}\}$  NMR (C<sub>6</sub>D<sub>6</sub>)  $\delta$ : 176.6 (d,  $J_{PC} = 18.7$  Hz, Ar-quaternary), 137.1 (d,  $J_{PC} = 6.7$  Hz, Ar-quaternary), 136.7 (d,  $J_{PC} = 8.8$  Hz, Ar-quaternary), 126.6 (d,  $J_{PC} = 2.0$  Hz, Ar-CH), 125.0 (Ar-CH), 116.8 (d,  $J_{PC} = 45.1$  (Ar-quaternary), 92.5 (d,  $^2J_{PC} = 12.7$  Hz, CH (COD)), 91.5 (d,  $^2J_{PC} = 5.4$  Hz, CH (COD)), 51.4 (CH (COD)), 45.9 (CH (COD)), 39.1 (d,  $^1J_{PC} = 43.4$  Hz, CH (phospholane)), 35.7 (CH<sub>2</sub> (phospholane)), 35.3 (d,  $^2J_{PC} = 4.9$  Hz, CH<sub>2</sub> (phospholane)), 34.0 (d,  $^3J_{PC} = 2.9$  Hz, CH<sub>2</sub> (COD)), 33.5 (d,  $^3J_{PC} = 2.8$  Hz, CH<sub>2</sub> (COD)), 33.1 (C(CH<sub>3</sub>)<sub>3</sub>), 33.0 (d,  $^1J_{PC} = 30.3$  Hz, CH (phospholane)), 31.1 (C(CH<sub>3</sub>)<sub>3</sub>), 29.0 (C(CH<sub>3</sub>)<sub>3</sub>), 28.2 (d,  $^3J_{PC} = 2.3$  Hz, CH<sub>2</sub> (COD)), 28.1 (d,  $^3J_{PC} = 2.0$  Hz, CH<sub>2</sub> (COD)), 21.7 (C(CH<sub>3</sub>)<sub>3</sub>), 16.4 (d,  $^2J_{PC} = 8.2$  Hz, CH<sub>3</sub> (phospholane)), 13.9 (d,  $^2J_{PC} = 1.6$  Hz, CH<sub>3</sub> (phospholane)).  $^{31}\text{P}\{^1\text{H}\}$  NMR (C<sub>6</sub>D<sub>6</sub>)  $\delta$ : 40.1. Anal. calcd. for C<sub>28</sub>H<sub>44</sub>IrOP: C 54.23, H 7.16, N 0.00; found: C 54.44, H 7.52, N < 0.3. Crystals suitable for X-ray crystallographic analysis were grown from a concentrated solution of **7** in pentane at -35 °C.

### Representative procedure for the intramolecular hydroamination of unactivated alkenes by secondary alkylamines catalyzed by 1

To a screw-capped vial containing **2a** (82 mg, 0.25 mmol) and a stir-bar was added 0.220 mL of a stock solution of **1** (5.8 mg in 1.000 mL of 1,4-dioxane) and 0.280 mL of 1,4-dioxane (total reaction volume = 0.5 mL). The vial was sealed under N<sub>2</sub> with a cap containing a PTFE septum and, once all the material had dissolved, was removed from the glovebox and was placed in a temperature-controlled aluminum heating block set at 110 °C. After 16 h of magnetic stirring, the vial was removed from the temperature-controlled aluminum heating block, cooled to ambient temperature, diluted with CH<sub>2</sub>Cl<sub>2</sub> (2 mL), and was washed with brine (2 × 2 mL). The organic extracts were combined, dried over Na<sub>2</sub>SO<sub>4</sub>, and concentrated. The resulting residue was purified by flash column chromatography on silica gel (hexanes/EtOAc = 20:1) to yield **2b** as a white solid (74 mg, 0.23 mmol, 92%) that afforded analytical data in agreement with data reported in the literature.<sup>7f</sup>

### 1-Benzyl-2-methyl-4,4-diphenylpyrrolidine (Table 1, entry 1)

The indicated compound was purified by flash chromatography on silica gel (EtOAc/hexanes = 20:1) in a 92% yield (74 mg) as a white solid.<sup>7f</sup>  $^1\text{H}$  NMR (CDCl<sub>3</sub>)  $\delta$ : 7.53–7.19 (m, 15H), 4.21 (d,  $J = 13.5$  Hz, 1H), 3.77 (d,  $J = 9.5$  Hz, 1H), 3.38 (d,  $J = 13.5$  Hz, 1H), 3.07–2.89 (m, 3H), 2.34 (d of d,  $J = 13.0, 8.0$  Hz, 1H), 1.29 (d,  $J = 6.5$  Hz, 3H).  $^{13}\text{C}\{^1\text{H}\}$  NMR (CDCl<sub>3</sub>)  $\delta$ : 150.6, 148.7, 140.1, 128.6, 128.2, 128.1, 127.8, 127.4, 127.2, 126.7, 125.8, 125.4, 66.4, 59.6, 58.0, 52.5, 48.0, 19.5.

### 1-(4-Chlorobenzyl)-2-methyl-4,4-diphenylpyrrolidine (Table 1, entry 2)

The indicated compound was purified by flash chromatography on silica gel (*n*-pentane/Et<sub>2</sub>O = 30:1) in an 86%

yield (78 mg) as a white solid.<sup>2a</sup> <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$ : 7.43–7.17 (m, 14H), 4.12 (d,  $J$  = 13.5 Hz, 1H), 3.71 (d,  $J$  = 10.0 Hz, 1H), 3.33 (d,  $J$  = 13.5 Hz, 1H), 3.05–2.89 (m, 2H), 2.87 (d,  $J$  = 9.5 Hz, 1H), 2.33 (d of d,  $J$  = 12.5, 7.9 Hz, 1H), 1.26 (d,  $J$  = 6.5 Hz, 3H). <sup>13</sup>C{<sup>1</sup>H} NMR (CDCl<sub>3</sub>)  $\delta$ : 150.4, 148.6, 138.6, 132.4, 129.8, 128.3, 128.1, 127.8, 127.3, 127.1, 125.8, 125.5, 66.3, 59.6, 57.2, 52.5, 47.8, 19.5.

**Methyl 4-(2-methyl-4,4-diphenylpyrrolidin-1-ylmethyl)-benzoate (Table 1, entry 3)**

The indicated compound was purified by flash chromatography on silica gel (*n*-pentane/Et<sub>2</sub>O = 8:1) in a 85% yield (82 mg) as a colorless oil.<sup>7f</sup> <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$ : 8.07 (d,  $J$  = 8.0 Hz, 2H), 7.50 (d,  $J$  = 8.5 Hz, 2H), 7.35–7.15 (m, 10H), 4.16 (d,  $J$  = 14.0 Hz, 1H), 3.98 (s, 3H), 3.68 (d,  $J$  = 10.0 Hz, 1H), 3.39 (d,  $J$  = 13.5 Hz, 1H), 3.02–2.88 (m, 2H), 2.86 (d,  $J$  = 10.0 Hz, 1H), 2.31 (d of d,  $J$  = 13.0, 7.5 Hz, 1H), 1.23 (d,  $J$  = 5.5 Hz, 3H). <sup>13</sup>C{<sup>1</sup>H} NMR (CDCl<sub>3</sub>)  $\delta$ : 167.1, 150.3, 148.5, 145.7, 129.6, 128.7, 128.4, 128.1, 127.8, 127.3, 127.1, 125.8, 125.5, 66.4, 59.7, 57.7, 52.6, 51.9, 47.8, 19.5.

**1-(4-Methoxybenzyl)-2-methyl-4,4-diphenylpyrrolidine (Table 1, entry 4)**

The indicated compound was purified by flash chromatography on silica gel (*n*-pentane/Et<sub>2</sub>O = 15:1) in a 87% yield (77 mg) as a colorless oil.<sup>2a</sup> <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$ : 7.29 (m, 1H), 7.00–6.95 (m, 2H), 4.13 (d,  $J$  = 13.0 Hz, 1H), 3.90 (s, 3H), 3.74 (d,  $J$  = 10.0 Hz, 1H), 3.30 (d,  $J$  = 13.0 Hz, 1H), 3.02 (d of d,  $J$  = 13.0, 7.5 Hz, 1H), 2.96–2.85 (m, 2H), 2.30 (d of d,  $J$  = 13.0, 7.5 Hz, 1H), 1.27 (d,  $J$  = 6.0 Hz, 3H). <sup>13</sup>C{<sup>1</sup>H} NMR (CDCl<sub>3</sub>)  $\delta$ : 158.5, 150.6, 148.7, 132.0, 129.6, 128.1, 127.8, 127.4, 127.2, 125.7, 125.3, 113.5, 66.3, 59.5, 57.2, 55.2, 52.4, 48.0, 19.5.

**1-Cyclohexylmethyl-2-methyl-4,4-diphenylpyrrolidine (Table 1, entry 5)**

The indicated compound was purified by flash chromatography on silica gel (hexanes/EtOAc = 8:1) in a 89% yield (75 mg) as a white solid.<sup>7d</sup> <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$ : 7.38–7.21 (m, 9H), 7.16 (m, 1H), 3.87 (d,  $J$  = 9.5 Hz, 1H), 2.87 (d of d,  $J$  = 13.0, 7.5 Hz, 1H), 2.82 (d,  $J$  = 10.0 Hz, 1H), 2.66 (m, 1H), 2.56 (m, 1H), 2.18–2.03 (m, 3H), 1.82–1.63 (m, 4H), 1.53 (m, 1H), 1.36–1.15 (m, 3H), 1.10 (d,  $J$  = 6.0 Hz, 3H), 1.02–0.87 (m, 2H). <sup>13</sup>C{<sup>1</sup>H} NMR (CDCl<sub>3</sub>)  $\delta$ : 151.3, 148.9, 128.1, 127.8, 127.6, 127.3, 125.7, 125.4, 67.6, 61.4, 60.3, 52.8, 48.1, 37.3, 32.2, 31.9, 26.9, 26.3, 26.1, 19.6.

**2-Benzyl-3-methyl-2-aza-spiro[4,5]decane (Table 1, entry 6)**

The indicated compound was purified by flash chromatography on silica gel (hexanes/EtOAc = 20:1) in a 85% yield (52 mg) as a colorless oil.<sup>7f</sup> <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$ : 7.40–7.24 (m, 5H), 4.06 (d,  $J$  = 13.0 Hz, 1H), 3.14 (d,  $J$  = 13.5 Hz, 1H), 2.82 (d,  $J$  = 9.5 Hz, 1H), 2.54 (m, 1H), 1.91 (d,  $J$  = 9.5 Hz, 1H), 1.80 (d of d,  $J$  = 12.0, 7.0 Hz, 1H), 1.56–1.27 (m, 11H), 1.19 (d,  $J$  = 6.0 Hz, 3H). <sup>13</sup>C{<sup>1</sup>H} NMR (CDCl<sub>3</sub>)  $\delta$ : 140.0, 128.6, 128.0, 126.5, 66.6, 59.0, 58.0, 47.0, 39.3, 39.2, 38.5, 26.1, 23.6, 23.5, 19.3.

**1-Benzyl-2,4,4-trimethylpyrrolidine (Table 1, entry 7)**

The indicated compound was purified by flash chroma-

tography on silica gel (hexanes/EtOAc = 20:1) in a 86% yield (44 mg) as a colorless oil.<sup>7f</sup> <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$ : 7.39–7.23 (m, 5H), 4.05 (d,  $J$  = 14.5 Hz, 1H), 3.15 (d,  $J$  = 13.5 Hz, 1H), 2.67 (d,  $J$  = 9.0 Hz, 1H), 2.59 (m, 1H), 1.98 (d,  $J$  = 9.0 Hz, 1H), 1.76 (d of d,  $J$  = 12.0, 7.5 Hz, 1H), 1.35 (d of d,  $J$  = 12.5, 9.0 Hz, 1H), 1.19 (d,  $J$  = 6.0 Hz, 3H), 1.11 (s, 3H), 1.01 (s, 3H). <sup>13</sup>C{<sup>1</sup>H} NMR (CDCl<sub>3</sub>)  $\delta$ : 140.1, 128.7, 128.0, 126.5, 68.4, 59.7, 58.0, 49.1, 35.4, 30.9, 29.2, 19.4.

**1-Benzyl-2-methyl-4-isopropylpyrrolidine (Table 1, entry 8)**

The indicated compound was obtained in 87% yield with a diastereomeric ratio of 1.3:1 on the basis of <sup>1</sup>H NMR using 1,4-bis(trifluoromethyl)benzene as an internal standard.<sup>7f</sup>

**1-Benzyl-2-methyl-5,5-diphenylpiperidine (Table 1, entry 9)**

The indicated compound was purified by flash chromatography on silica gel (hexanes/EtOAc = 20:1) in a 85% yield (73 mg) as a colorless oil.<sup>7d</sup> <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$ : 7.46–7.14 (m, 15H), 4.13 (d,  $J$  = 13.5 Hz, 1H), 3.43 (d,  $J$  = 12.5 Hz, 1H), 3.21 (d,  $J$  = 13.5 Hz, 1H), 3.60–2.50 (m, 3H), 2.25 (m, 1H), 1.70 (m, 1H), 1.45 (m, 1H), 1.21 (d,  $J$  = 6.0 Hz, 3H). <sup>13</sup>C{<sup>1</sup>H} NMR (CDCl<sub>3</sub>)  $\delta$ : 148.6, 146.7, 139.4, 129.5, 128.4, 128.0, 127.9, 127.6, 127.0, 126.9, 125.6, 125.3, 61.0, 58.9, 56.1, 46.5, 34.2, 31.0, 18.6.

**1-Benzyl-2-(2-dimethyl-4,4-diphenylpyrrolidine (Table 1, entry 10)**

The indicated compound was purified by flash chromatography on silica gel (EtOAc/hexanes = 20:1) in a 92% yield (78 mg) as a white solid.<sup>15</sup> <sup>1</sup>H NMR (CDCl<sub>3</sub>)  $\delta$ : 7.52–7.20 (m, 15H), 3.73 (s, 2H), 3.41 (s, 2H), 2.74 (s, 2H), 1.26 (s, 6H). <sup>13</sup>C{<sup>1</sup>H} NMR (CDCl<sub>3</sub>)  $\delta$ : 149.7, 140.9, 128.5, 128.1, 127.8, 127.2, 126.7, 125.4, 6.1, 60.4, 54.4, 52.4, 51.6, 25.1.

**Crystallographic characterization of 7**

Crystallographic data were obtained at 193 ( $\pm$ 2) K on a Bruker PLATFORM/SMART 1000 CCD diffractometer using a graphite-monochromated Mo K $\alpha$  ( $\lambda$  = 0.71073 Å) radiation, employing a sample that was mounted in inert oil and transferred to a cold gas stream on the diffractometer. Programs for diffractometer operation, data collection, and data reduction were supplied by Bruker. SADABS was employed as the absorption correction method. The structure was solved by use of a Patterson search/structure expansion and refinement was carried out by use of full-matrix least-squares procedures (on  $F^2$ ) with  $R_1$  based on  $F_o^2 \geq 2\sigma(F_o^2)$  and  $wR_2$  based on  $F_o^2 \geq -3\sigma(F_o^2)$ . All hydrogen atoms were added at calculated positions and refined by use of a riding model employing isotropic displacement parameters based on the isotropic displacement parameter of the attached atom. The near-zero final refined value of the absolute structure parameter (0.000(5)) supported that the correct absolute structure had been chosen.<sup>16</sup> See the Supplementary data section for information on obtaining the complete supplementary crystallographic data for this paper. The thermal ellipsoid plot of 7 was generated by use of ORTEP-3 for Windows.<sup>17</sup>

## Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca). CCDC 744698 contains the X-ray data in CIF format for this manuscript. These data can be obtained, free of charge, via [www.ccdc.cam.ac.uk/conts/retrieving.html](http://www.ccdc.cam.ac.uk/conts/retrieving.html) (Or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

## Acknowledgement

Acknowledgment is made to Dalhousie University (Halifax, NS) and the Natural Sciences and Engineering Research Council of Canada (including a Discovery Grant for M. S. and a Canada Graduate Scholarship for K. D. H.). We also thank Dr. Michael Lumsden (Nuclear Magnetic Resonance Research Resource (NMR-3), Dalhousie University) for assistance in the acquisition of NMR data.

# An ab initio study of model triazene-based anticancer agents

Katherine G. Doucet, Julie F. Glistler, and Cory C. Pye

**Abstract:** A computational study of a series of model triazene-based anticancer agents based on methyl- and amidyl-substituted 5-(1-triazenyl)imidazoles has been carried out, including the drugs Dacarbazine, Temozolomide, and Mitozolomide. A number of different conformers are analyzed. The transition states for the gas-phase and water-mediated triazene tautomerization reaction are found and the barriers are determined.

**Key words:** ab initio, triazene, Dacarbazine, Temozolomide, conformational analysis.

**Résumé :** On a effectué des calculs théoriques sur une série d'agents anticancéreux modèles dérivés du triazène et à base de 5-(1-triazenyl)imidazoles substitués par des groupes méthyles et amidyles, dont les médicaments dacarbazine, témozolomide et mitozolomide. On en a analysé un certain nombre de conformères. On a pu trouver les états de transition des réactions de tautomérisation du triazène en phase gazeuse ainsi que sous la catalyse par l'eau et on en a déterminé les barrières.

**Mots-clés :** ab initio, triazène, dacarbazine, témozolomide, mitozolomide, analyse conformationnelle.

[Traduit par la Rédaction]

## Introduction

Dacarbazine, 5-(3,3-dimethyl-1-triazenyl)imidazole-4-carboxamide (Fig. 1), is the single most-reactive agent known for the treatment of malignant melanoma.<sup>1–3</sup> Dacarbazine and the closely related drug Temozolomide contain the triazene moiety, which could potentially act as an excellent leaving group if a methyltriazenes is attacked by a nucleophilic part of DNA.<sup>4,5</sup>

Our group has previously studied triazene and its mono-, di-, and tri-methyl analogues.<sup>6</sup> In addition, we have examined the S<sub>N</sub>2 reaction of mono-,<sup>7</sup> di-,<sup>8</sup> and tri-methyltriazenes<sup>9</sup> with the halide ions F<sup>–</sup>, Cl<sup>–</sup>, Br<sup>–</sup>, and I<sup>–</sup>. This work<sup>10</sup> extends the results of ref. 6 to more realistic models of this class of anticancer drugs and shall provide a basis for additional study of their S<sub>N</sub>2 reactions.

**Fig. 1.** The chemical structure of 5-(3,3-dimethyl-1-triazenyl)imidazole-4-carboxamide (Dacarbazine, DTIC®).

## Method

Gaussian 98<sup>11</sup> or Gaussian 03<sup>12</sup> were used to carry out all calculations for this computational study. Geometry optimizations were performed at the HF/STO-3G, HF/3-21G, HF/6-31G(d), HF/6-31+G(d), MP2/6-31G(d), MP2/6-31+G(d), B3LYP/6-31G(d), B3LYP/6-31+G(d), and B3LYP/6-31G(d,p) levels of theory. The role of polarization functions on hydrogen was found to be minor (footnote 2 of ref. 6). For MP2 calculations, the frozen core approximation was utilized. Harmonic vibrational frequencies and zero-point vibrational energy (ZPVE) corrections were performed at the previously mentioned levels of theory. Harmonic vibrational frequency calculations characterized the geometry optimizations. A previously determined scaling factor was used to correct the ZPVE.<sup>13</sup> Only the results at MP2/6-31+G(d) and B3LYP/6-31+G(d) will be presented, the rest are given in the Supplementary material. To allow direct comparison with our previous work,<sup>6–9</sup> we do not invoke temperature, free energy, and solvation corrections, which might affect the values given by a few kJ/mol. In addition, we do not consider the effect of intramolecular basis set superposition error<sup>14</sup> because of the difficulty of assigning interacting fragments.

## Results and discussion

### 5-(1-Triazenyl)imidazole

5-(1-Triazenyl)imidazole, henceforth abbreviated TI, like triazene itself, can exist as either an (*E*) or (*Z*) isomer. For

(Z) s-cis	29.0	33.1

**Fig. 3.** The eight forms of 5-(3-methyl-1-triazenyl)imidazole.

each isomer, two conformations can exist, syn-periplanar (s-cis) or anti-periplanar (s-trans), which describe the relationship of the N=N and C=C double bonds about the C–N single bond between the triazene and imidazole moieties. There are thus four possibilities (Fig. 2).

The (E) s-trans form was found to be the most stable of the four minimum-energy structures (Table 1). The (E) s-cis form was slightly higher in energy. The (Z) forms, as expected, were significantly higher in energy, with the (Z) s-cis form being lower in energy than the (Z) s-trans form.

For the (E) forms, the triazene unit was found to be coplanar with the planar imidazole ring; however, for the (Z) forms, significant deviation from planarity ( $10^\circ$ – $30^\circ$ ) is noted (Supplementary material, Table S4). This suggests a significant steric interaction between the terminal amine of the triazene and the imidazole ring hydrogens, and concomitant partial breaking of conjugation between the double bonds.

### 5-(3-Methyl-1-triazenyl)imidazole

5-(3-Methyl-1-triazenyl)imidazole (MTI), in addition to having the conformational degrees of freedom present for TI, can also have the methyl group in either an s-cis or s-trans relationship with respect to the N=N double bond, to give eight possible conformations (Fig. 3).

The (E) form with an s-trans imidazole and an s-cis methyl group ((E) s-trans Me s-cis) was found to be the most stable of the eight configurations (see Table 2). For the (E) isomers, the Me s-cis conformers are more stable than the Me s-trans, whereas for the (Z) isomers, the Me s-cis conformers are less stable than the Me s-trans conformers. These trends are the same as those of dimethyltriazene

**Table 2.** Energies of MTI (kJ/mol) relative to (E) s-trans, Me s-cis, ((E) (t,c)).

	MP2/6-31+G(d)	B3LYP/6-31+G(d)
(E) (t,t)	4.2	1.5

(E) (c,t)	11.4	7.3
(Z) (t,c)	57.9	65.2
(Z) (t,t)	45.4	52.4
(Z) (c,c)	62.4	67.4
(Z) (c,t)	28.9	34.9

**Fig. 4.** The four forms of 5-(3,3-dimethyl-1-triazenyl)imidazole.**Table 3.** Energies of DTI (kJ/mol) relative to (E) s-trans.

	MP2/6-31+G(d)	B3LYP/6-31+G(d)
(E) s-cis	7.3	5.7
(Z) s-trans	54.7	65.3
(Z) s-cis	59.1	68.8

and can be explained similarly through a combination of hyperconjugation and steric interaction arguments.<sup>6</sup> In particular, the strong steric interaction between the methyl group and the imidazole ring in the two (Z) Me s-cis conformers causes the triazene unit to significantly distort by rotation about the N–N bond. This reduces the steric interaction in such a way that the imidazole and triazene units of the (Z) Me s-cis forms actually are more coplanar than the (Z) s-trans (i.e., the steric interaction is reduced by rotating about the N<sub>7</sub>–N<sub>8</sub> bond instead of the C<sub>5</sub>–N<sub>6</sub> bond).

### 5-(3,3-Dimethyl-1-triazenyl)imidazole

5-(3,3-Dimethyl-1-triazenyl)imidazole (DTI), like the parent TI, would be expected to have four configurations, as shown in Fig. 4.

The (E) s-trans form is the most stable configuration (see Table 3). The (E) isomers are more stable than the (Z) isomers, and the s-trans conformers are more stable than the s-cis conformers. Relative to TI, the (Z) forms are much more destabilized. An interesting observation is that the imidazole ring is nearly planar with the triazene moiety, even for the (Z) forms, in which the amine group has rotated to avoid steric congestion (Supplementary material, Table S12).

### 5-(1-Triazenyl)imidazole-4-carboxamide

5-(1-Triazenyl)imidazole-4-carboxamide (TIC), possesses the degrees of freedom of TI, and also contains a carboxamide group in which the C=O moiety may exist in either an s-cis or s-trans relation to the C=C of the imidazole ring. Eight configurations are expected (Fig. 5).

The (E) s-trans, CO s-cis conformation was the most stable configuration (Table 4). The (E) isomers are more stable

**Fig. 5.** The eight forms of 5-(1-triazenyl)imidazole-4-carboxamide. The (*Z*) (t,c) form reverts to the (c,c) form at the HF/6-31G\*, HF/6-31+G\*, MP2/6-31+G\*, and B3LYP/6-31+G\* levels.

**Table 4.** Energies of TIC (kJ/mol) relative to (*E*) s-trans, CO s-cis.

	MP2/6-31+G(d)	B3LYP/6-31+G(d)
( <i>E</i> ) (t,t)	13.0	12.0
( <i>E</i> ) (c,c)	11.8	9.4
( <i>E</i> ) (c,t)	28.4	27.4
( <i>Z</i> ) (t,c)	(c,c)	(c,c)
( <i>Z</i> ) (t,t)	52.7	58.3
( <i>Z</i> ) (c,c)	15.6	15.2
( <i>Z</i> ) (c,t)	62.4	72.7

than the (*Z*) isomers (with one exception), and the s-trans conformers are more stable than the corresponding s-cis conformers. The CO s-cis forms are more stable than the corresponding CO s-trans forms. The (*Z*) s-cis, CO s-cis conformer is unusually stable because of the internal NH...O hydrogen bond that can be formed. A short contact is also found in (*Z*) s-cis, CO s-trans (CONH...NH<sub>2</sub>N=N) for those levels with diffuse basis sets (see Supplementary material, Table S20), and the carbonyl group twists out of the plane somewhat at all levels (Supplementary material, Table S19).

### 5-(3-Methyl-1-triazenyl)imidazole-4-carboxamide

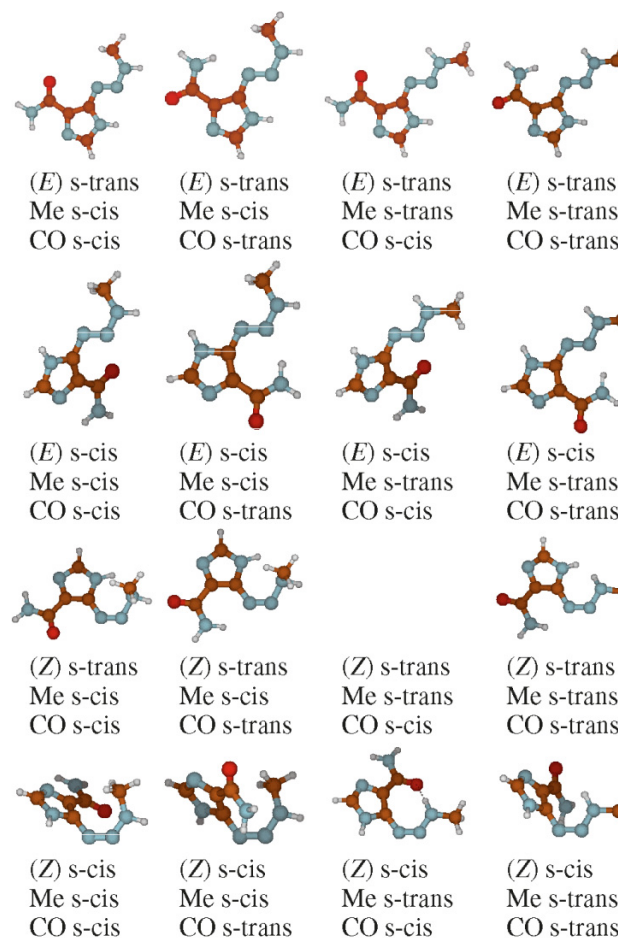

5-(3-Methyl-1-triazenyl)imidazole-4-carboxamide (MTIC) has 16 possible configurations (Fig. 6). The (*E*) s-trans (Me s-cis, CO s-cis) conformer was the most stable (Table 5). All of the (*Z*) isomers were higher in energy than the (*E*) isomers, with one exception, (*Z*) s-cis, Me s-trans, CO s-cis in which an internal hydrogen bond is formed between the amine hydrogen of the triazene and the carboxyl oxygen (Supplementary material, Table S32). The presence of the methyl group does not affect much the conformational angles. A stable (*Z*) s-trans, Me s-trans, CO s-cis structure could not be found, reverting instead to the Me s-cis form.

### 5-(3,3-Dimethyl-1-triazenyl)imidazole-4-carboxamide

5-(3,3-Dimethyl-1-triazenyl)imidazole-4-carboxamide (DTIC), also known as Dacarbazine, has eight possible configurations (Fig. 7).

The (*E*) s-trans, CO s-cis conformation was the lowest in energy (Table 6), just as for TIC itself. An interesting observation is that the (*Z*) s-cis, CO s-cis conformer is more sta-

ble than the other (*Z*) forms, as is the case for TIC and MTIC. This was attributed solely to hydrogen bonding in TIC and MTIC, but this is not possible for this isomer. Comparison of this result to MTIC and TIC suggests that approximately 30–50 kJ/mol of the anomalous stabilization can be attributed to internal hydrogen bonding. The reason

for the other 20 kJ/mol of stabilization, although elusive, also exists for MTIC (Z) s-cis, Me s-cis, CO s-cis.

### Temozolomide and Mitozolomide

Temozolomide (3,4-dihydro-3-methyl-4-oxoimidazo-[5,1,d]-1,2,3,5-tetrazine-8-carboxamide, Temodal<sup>®</sup>, Fig. 8), which has demonstrated activity against recurrent brain cancer, is spontaneously hydrolyzed to MTIC under physiological conditions. This contrasts with the behavior of DTIC, which is poorly metabolized by the human body and is believed to require oxidative metabolism by hepatic cytochrome P450 enzymes to form MTIC.<sup>4</sup> The s-cis conformation is more stable than the s-trans form (MP2/6-31+G\*: 6.0; B3LYP/6-31+G\*: 6.2 kJ/mol). These numbers are comparable to the difference in energy between (Z) TIC s-trans, CO s-cis and (Z) TIC s-trans, CO s-trans.

Mitozolomide, which differs from Temozolomide in that a

TS t	172.5	175.2
TS c	175.0	178.7

methyl group is replaced with a chloroethyl group, showed some initial promise in animal testing,<sup>15</sup> but has not proven effective against human cancer and possesses some serious toxic effects. In addition to the orientation of the carboxamide group, the chloroethyl group can be either anti-periplanar (app), or in a gauche arrangement either syn to (sg) or anti to (ag) the triazene moiety, to give six configurations (Fig. 8). The CO s-cis, Cl app was the most stable conformer (Table 7). There is little difference (<2.1 kJ/mol) between the energy of the chloroethyl rotamers, but the s-trans conformers are at least 6 kJ/mol higher in energy than the s-cis conformers (cf. Temozolomide).

### Tautomerization reactions

TI can undergo tautomerization by a 1,3-hydrogen shift to form 5-(3-triazenyl)imidazole (TI\_T). In the tautomer, the N=N and C=C double bonds are no longer conjugated, so we use the designation s-cis and s-trans to refer to the arrangement of the N=N bond with the N-C single bond, or the C=C bond with the N-N bond. In most cases, the C=C s-cis arrangement is unstable and reverts to either the s-trans form or to a form in which the imidazole ring is perpendicular to the triazene moiety (Fig. 9). The TI (E) (t) would in-

**Fig. 10.** 5-(1-Methyl-3-triazenyl)imidazole (MTI\_T), transition states to tautomerization, and species involved in water-mediated tautomerization.

**Table 9.** Energies of MTI\_T (kJ/mol) relative to (E) C=C s-trans, N=N s-trans. The fourth and fifth rows are relative to MTI (E) (t,t), the sixth relative to MTI (E) (c,t). The water-mediated reactions are relative to the separated reactants ((E) MTI (t,t) or (c,t) + H<sub>2</sub>O).

	MP2/6-31+G(d)	B3LYP/6-31+G(d)
(E) (t,c)	2.7	1.7
(Z) (c,c)	34.5	33.1
(Z) (t,t)	48.8	61.9
<b>Gas-phase tautomerization</b>		
TS (t)	157.8	166.3
(E) (t,t)	15.8	16.5
TS (c)	151.9	162.5
<b>Water mediated tautomerization</b>		
RC (t,t)	-32.3	-26.6
TS (t,t)	46.9	42.9
PC (t,t)	-16.2	-11.8
SP (t,t)	15.8	16.5
RC (c,t)	-28.1	-23.2
TS (c,t)	46.5	43.9
PC (c,t)	-21.8	-17.6

terconvert with TI\_T (E) (t,t) via the TI\_TS t transition structure. As the TI\_T (E) (c,t) form is nonexistent, the TI (E) (c) could interconvert also with TI\_T (E) (t,t) via the TI\_TS c transition structure, although conversion to TI (E) (t) is believed to be more likely.

The (scaled) zero-point corrected MP2/6-31+G\* activation energy of 172.5 kJ/mol (Table 8) may be compared to the unscaled activation energy of triazene (173.1 kJ/mol) and methyltriazene (165.5 kJ/mol).<sup>6</sup> The effect of the imidazole substituent is small.

MTI, like TI, can undergo tautomerization to form 5-(1-

**Fig. 11.** 5-(1-Methyl-3-triazenyl)imidazole-4-carboxamide tautomers (MTIC\_T), transition states to tautomerization, and species involved in water-mediated tautomerization.

methyl-3-triazenyl)imidazole (MTI\_T, Fig. 10). Only the (E) forms can interconvert. The MTI and MTI\_T (E) (t,t) forms interconvert via the (E) (t,t) transition state, whereas the MTI (E) (c,t) form might interconvert via the (E) (c,t) transition state to the MTI\_T (E) (t,t).

The MP2/6-31+G\* gas-phase tautomerization barrier of MTI (157.8 kJ/mol, Table 9) is lower than that of TI (172.5 kJ/mol) and is intermediate<sup>6</sup> between that of methyltriazene (165.5 kJ/mol) and dimethyltriazene (151.8 kJ/mol). A water molecule can mediate the proton shift and lower the effective barrier by two simultaneously acting mechanisms: by hydrating the species involved, lowering their energy, and by acting as a proton shuffle. The hydration effect lowers the barrier by approximately 30 kJ/mol by stabilizing both the reactant (RC) and product complexes (PC) (and, presumably, the TS). The barriers from RC to TS are 79.2 (t,t) and 74.6 (c,t) kJ/mol, which is about half of the barrier of the uncatalyzed reaction. These are quite comparable to the hydration energies and barriers of the water-catalyzed tautomerization of methyltriazene (-28.4, 78.0 kJ/mol) and dimethyltriazene (-30.3, 69.3 kJ/mol).<sup>6</sup>

MTIC can also undergo tautomerization to form 5-(1-methyl-3-triazenyl)imidazole-4-carboxamide (MTIC\_T, Fig. 11). The

**Table 10.** Energies of MTIC\_T (kJ/mol) relative to (*E*) C=C s-trans, N=N s-cis, C=O s-cis. The gas-phase tautomerization reactions are relative to the corresponding MTIC form. The water-mediated tautomerization reactions are relative to the separated reactants (MTIC + H<sub>2</sub>O).

( <i>E</i> ) (t,t,t) SP	0.1	3.8

MTIC and MTIC\_T (*E*) (t,t,t) forms interconvert via the MTIC (t,t,t) transition state, and the MTIC and MTIC\_T(*E*) (t,t,c) forms interconvert via the MTIC (t,t,c) transition state. The MTIC (c,t,c) can interconvert with MTIC\_T (t,t,c) via the MTIC (c,t,c) transition state, and the MTIC (c,t,t) can interconvert with MTIC\_T (t,t,t) via the MTIC (c,t,t) transition state.

The MP2/6-31+G\* gas-phase tautomerization barrier of MTIC (147.0 kJ/mol, Table 10 (t,t,c)) is lower than that of MTI (157.8 kJ/mol), which suggests that the presence of the amide group stabilizes somewhat the transition state. The product complexes are stabilized by between 30–35 kJ/mol, whereas some of the reactant complexes are stabilized by as much as -60 kJ/mol. This is attributable to the existence of additional hydrogen bonds in these species. Like the hydrated MTI, the barriers from RC to TS are typically 80–85 kJ/mol.

## Conclusions

For substituted 4-(1-triazenyl)imidazoles, the (*E*) forms

are generally more stable than the (*Z*) forms. For the (*E*) forms, the s-trans imidazole conformers are more stable than the s-cis conformers. The carbonyl of a carboxamide group at the 5-position on the imidazole ring prefers to be in an s-cis arrangement. Steric interactions and hydrogen bonding modify the relative energies of the various conformers. A water molecule can catalyze the 1,3-hydrogen shift in the tautomerization reaction of the triazene moiety.

# Ab initio studies of the vibrational spectra of some hydrogen-bonded complexes of fluoroacetylene

Ponnadurai Ramasami and Thomas A. Ford

**Abstract:** Ab initio molecular orbital theory has been used to compute the properties of a number of hydrogen-bonded complexes between fluoroacetylene as proton donor and ammonia, water, hydrogen fluoride, phosphine, hydrogen sulfide, and hydrogen chloride as proton acceptors. The properties considered were the vibrational spectra, the molecular structures, the hydrogen-bond energies, and the electron densities, and one of the aims of the study was to ascertain whether there was any evidence of blue-shifting hydrogen-bond character in the complexes formed. The adducts with  $\text{NH}_3$ ,  $\text{H}_2\text{O}$ ,  $\text{PH}_3$ , and  $\text{H}_2\text{S}$  were of the conventional  $\text{CH}\cdots\text{X}$  kind ( $\text{X} = \text{N}, \text{O}, \text{P}, \text{S}$ ), with hydrogen-bond energies decreasing in the order  $\text{NH}_3 > \text{H}_2\text{O} > \text{PH}_3 \approx \text{H}_2\text{S}$ . Those formed with HF and HCl showed the presence of three alternative structures; in addition to the  $\text{CH}\cdots\text{F}(\text{Cl})$  complexes, adducts of the  $\text{F}(\text{Cl})\text{H}\cdots\text{F}$  and  $\text{F}(\text{Cl})\text{H}\cdots\pi$  type were also found to be stationary points on the potential energy surfaces, with stabilities in the order  $\text{F}(\text{Cl})\text{H}\cdots\pi > \text{CH}\cdots\text{F}(\text{Cl}) > \text{F}(\text{Cl})\text{H}\cdots\text{F}$ . The hydrogen-bond energies of the  $\text{CH}\cdots\text{X}$  series correlated with the gas-phase basicities of the proton acceptors; moreover, the CH bond-length changes, the wavenumber shifts, the complex–monomer infrared intensity ratios of the CH stretching modes, and the amounts of charge transferred on complex formation were all found to track with the hydrogen-bond energies. All those properties considered here are consistent with the formation of red-shifting hydrogen bonds, to the exclusion of the blue-shifting alternatives.

**Key words:** ab initio, molecular complexes, hydrogen bonding, molecular structures, interaction energies, vibrational spectra, fluoroacetylene.

**Résumé :** On a fait appel à la théorie des orbitales moléculaires ab initio pour calculer les propriétés d'un certain nombre de complexes entre le fluoroacétylène, un donneur de proton, et l'ammoniac, l'eau, le fluorure d'hydrogène, le sulfure d'hydrogène et le chlorure d'hydrogène, des accepteurs de proton. Les propriétés considérées ont été les spectres vibrationnels, les structures moléculaires, les énergies des liaisons hydrogènes et les densités électroniques et l'un des buts de l'étude était de déterminer s'il était possible de détecter des données susceptibles de suggérer l'existence d'un déplacement vers le bleu du caractère de la liaison hydrogène dans les complexes formés. Les adduits avec les  $\text{NH}_3$ ,  $\text{H}_2\text{O}$ ,  $\text{PH}_3$  et  $\text{H}_2\text{S}$  sont du type  $\text{CH}\cdots\text{X}$  ( $\text{X} = \text{N}, \text{O}, \text{P}, \text{S}$ ) et les énergies des liaisons hydrogènes diminuent dans l'ordre  $\text{NH}_3 > \text{H}_2\text{O} > \text{PH}_3 \approx \text{H}_2\text{S}$ . Ceux qui se forment avec HF et HCl montrent la présence de trois types de structures alternatives, en plus des complexes  $\text{CH}\cdots\text{F}(\text{Cl})$ ; on a aussi observé que les adduits de types  $\text{F}(\text{Cl})\text{H}\cdots\text{F}$  et  $\text{F}(\text{Cl})\text{H}\cdots\pi$  sont des points stationnaires sur les surfaces d'énergie potentielle, avec des stabilités dans l'ordre  $\text{F}(\text{Cl})\text{H}\cdots\pi > \text{CH}\cdots\text{F}(\text{Cl}) > \text{F}(\text{Cl})\text{H}\cdots\text{F}$ . Les énergies des liaisons hydrogènes de la série  $\text{CH}\cdots\text{X}$  donnent une bonne corrélation avec les basicités en phase gazeuse des accepteurs de proton et on a aussi trouvé que les changements dans les longueurs des liaisons CH, les déplacements dans les nombres d'onde, le rapport des intensités infrarouges complexe/monomère des modes d'élongation CH ainsi que les quantités de charge transférées lors de la formation du complexe suivent les énergies des liaisons hydrogènes. Toutes les propriétés examinées dans ce travail sont en accord avec la formation de liaisons hydrogènes avec de déplacement vers le rouge, à l'exclusion des déplacements alternatifs vers le bleu.

**Mots-clés :** ab initio, complexes moléculaires, liaison hydrogène, structures moléculaires, énergies d'interaction, spectres vibrationnels, fluoroacétylène.

## Introduction

The intriguing phenomenon of the blue-shifting hydrogen bond has received a great deal of attention in recent years,

and a number of theories have been put forward to explain its characteristic properties.<sup>1–18</sup> In contrast to the conventional  $\text{AH}\cdots\text{B}$  hydrogen bond, which is manifested by a lengthening of the AH proton donor bond, a red shift of the

AH stretching wavenumber, and an enhancement of the infrared intensity of the AH stretching vibration,<sup>19</sup> the blue-shifting hydrogen bond exhibits a decrease of the AH bond length, a shift of the AH stretching mode wavenumber to the blue, and a diminution of the AH stretching intensity.<sup>1</sup> For conventional hydrogen bonds, A is commonly N, O, F, or Cl and B is usually N, O, P, or S. For blue-shifting hydrogen bonds on the other hand, A can frequently be C or Si. Whereas the interpretation of the mechanism of the formation of a conventional hydrogen bond involves the overlap of a lone-pair orbital associated with the B atom (or of a  $\pi$ -orbital system) of the proton acceptor and the  $\sigma^*$  orbital of the AH bond of the proton donor, that of the blue-shifting hydrogen bond proposes donation from the lone pair or  $\pi$  orbital to a  $\sigma^*$  orbital or a lone pair of the proton donor more remote from the immediate site of interaction. Many of the early studies of this phenomenon included complexes with  $\text{CHF}_3$  or  $\text{CHCl}_3$  as the proton donor;<sup>1–13</sup> atoms-in-molecules (AIM)<sup>20</sup> calculations,<sup>10,11,15</sup> or those employing natural bond orbital (NBO)<sup>21</sup> theory<sup>1,10–12,15</sup> to characterize the electron-density changes revealed that charge typically accumulated in the  $\sigma^*(\text{CF})$  or  $\sigma^*(\text{CCl})$  orbitals and (or) in the F or Cl lone pair orbitals. Two schools of thought have emerged regarding the interpretation of these electron-density shifts: one school<sup>3,5,11,16</sup> asserts that there is no fundamental difference between blue-shifting and red-shifting hydrogen bonds, whereas the other<sup>1,2,6</sup> proposes that a two-step process is involved with blue-shifting bonds, in which electron density is first transferred from the proton acceptor lone pairs to the fluorine lone pairs, leading to an increase in the CF bond lengths, and then redistributed into the  $\sigma(\text{CH})$  orbital, resulting in a shortening of the CH bond. It was also observed that, for blue-shifting hydrogen bonding to occur, the AH stretching vibration of the proton-donor AH bond should have a negative dipole moment derivative,  $\partial\mu/\partial r(\text{AH})$ ,<sup>5</sup> and that a subtle balance exists between the effects of  $n(\text{B}) \rightarrow \sigma^*(\text{AH})$  hyperconjugation which favours AH bond lengthening, and increasing s orbital character and polarization of the AH bond (rehybridization) which have the reverse effect.<sup>7</sup>

It seems that the probability of observing the presence of a blue-shifting hydrogen bond would be enhanced in complexes in which the proton donor possessed a region of high electron density, e.g., a fluorine atom or a  $\pi$  orbital system, slightly remote from the primary site of interaction, to accommodate the electron density redistribution regarded as an essential component of the interaction. Such a proton donor is fluoroacetylene, which features a CF bond, three F lone pairs, and a  $\text{C}\equiv\text{C}$  triple bond. We have therefore studied a series of hydrogen-bonded complexes of HCCF with  $\text{NH}_3$ ,  $\text{H}_2\text{O}$ , HF,  $\text{PH}_3$ ,  $\text{H}_2\text{S}$ , and HCl, to explore the nature of the  $\text{CH}\cdots\text{B}$  hydrogen bonds in this series, and to determine the effect on the hydrogen bond properties of the position of the proton acceptor atom in the periodic table (group 15, 16, or 17, and first or second row). Complexes of HCCF with some of these proton acceptors have been studied before by other groups, e.g.,  $\text{NH}_3$ ,<sup>22,23</sup>  $\text{H}_2\text{O}$ ,<sup>3,7,23,24</sup> and HF,<sup>23,25,26</sup> but this is apparently the first attempt to carry out a systematic study on the whole range of partner molecules.

## Computational methodology

The calculations were carried out using the Gaussian 03 program,<sup>27</sup> at the second-order level of Møller–Plesset perturbation theory (MP2),<sup>28</sup> and with Dunning's aug-cc-pVTZ basis set.<sup>29–33</sup> The TIGHT convergence criterion was employed, and the vibrational properties were obtained using analytical derivatives, except for the heavier complexes, when numerical derivatives were used.<sup>27</sup> The interaction energies were corrected for basis set superposition error (BSSE)<sup>34</sup> by the Boys–Bernardi procedure,<sup>35</sup> using the COUNTERPOISE option of the program,<sup>27</sup> and for zero-point energy differences. The NBO analysis<sup>21</sup> was performed using the POP=NBO keyword.<sup>27</sup>

## Results and discussion

### Molecular structures

The optimized structures of the complexes of HCCF with  $\text{NH}_3$  and  $\text{PH}_3$  are of  $\text{C}_{3v}$  symmetry, with the  $\text{CH}\cdots\text{N(P)}$  angles fixed at  $180.0^\circ$ . The  $\text{H}_2\text{O}$  and  $\text{H}_2\text{S}$  complexes have  $\text{C}_s$  symmetry, with the angles between the  $\text{H}\cdots\text{O(S)}$  axis and the HOH or HSH angle bisectors being close to  $160^\circ$  and  $90^\circ$ , respectively. The HF and HCl complexes are also of  $\text{C}_s$  symmetry with  $\text{H}\cdots\text{FH}$  and  $\text{H}\cdots\text{ClH}$  angles of approximately  $137^\circ$  and  $107^\circ$ , respectively. The values of the geometrical parameters, and their changes on complexation, are presented in Table 1, and the equilibrium structures are illustrated in Fig. 1. Tables of the optimized Cartesian coordinates of the complexes are available in the Supplementary data (Table S1).

Significantly, the signs of all six  $\Delta r(\text{CH})$  are positive, indicating a lengthening of the CH bonds on hydrogen-bond formation. The increase in CH-bond length falls off in the order  $\text{NH}_3 > \text{H}_2\text{O} > \text{H}_2\text{S} > \text{PH}_3 > \text{HF} > \text{HCl}$ . The increases in the CC and CF bond lengths follow the same trend for the first row proton acceptors, but the second row acceptors are much less sensitive to complexation. The fact that the CH, CC, and CF bond lengths all increase on complexation indicates a consistent weakening of all three bonds in the HCCF sub-molecule. The HCCF fragment linearity is preserved, within  $1^\circ$ , in all six complexes. The changes in the XH bond lengths in the proton acceptor molecules are minimal and, apart from  $\text{FCCH}\cdots\text{NH}_3$  and  $\text{FCCH}\cdots\text{PH}_3$ , the HXH bond angles change by less than  $1^\circ$ . Agreement with previously reported structures<sup>3,7,22–24</sup> is variable.

In the case of the complexes with HF and HCl, two alternative equilibrium structures are possible, the “reversed”  $\text{F(Cl)H}\cdots\text{F}$  and the  $\pi$ -bonded  $\text{F(Cl)H}\cdots\pi$  species, which are also minima on the potential energy surfaces. The geometrical data for these four complexes are given in Table 2, and the plots of their structures in Fig. 2. There are significant differences between the structures of the reversed and the  $\pi$ -bonded species. The CH bond length increases are larger for  $\text{XH}\cdots\pi$  than for the  $\text{XH}\cdots\text{F}$ , the CC bond lengths increase for  $\text{XH}\cdots\pi$  and decrease for  $\text{XH}\cdots\text{F}$ , and the reverse behaviour is observed for the CF bond lengths, whereas the HF and HCl bond-length changes are substantially larger for  $\text{XH}\cdots\pi$  than for  $\text{XH}\cdots\text{F}$ . Only for the HF bond of the  $\text{FH}\cdots\text{HCCF}$   $\pi$ -bonded complex is a literature value available for comparison.<sup>26</sup> The agreement is good.

### Hydrogen-bond energies

The hydrogen-bond energies, corrected for BSSE<sup>34</sup> and for zero-point energy differences, are listed in Table 3. Some other values have been reported,<sup>7,22–26</sup> but again agreement with our results is tentative, partly owing to the use of different basis sets. The absolute energies indicate that, among the complexes with HF and HCl, the  $\pi$ -bonded complex is the most stable, and is probably the global minimum, followed by the CH $\cdots$ F(Cl) and lastly the F(Cl)H $\cdots$ F, which are local minima.

The hydrogen-bond energies correlate fairly well with the gas phase basicities<sup>36</sup> of the proton acceptors, with separate

relationships for the NH $_3$ -H $_2$ O-HF and the PH $_3$ -H $_2$ S-HCl series (see Fig. 3), although there is a suggestion that the datum for FCCH-SH $_2$  may indicate some overestimation of the strength of interaction. Chan et al.<sup>37</sup> have correlated the binding energies of a range of protonated homodimers with the proton affinities of the bases, and have observed a quadratic relationship. There are insufficient data available to confirm whether the relationship between the binding energies and the gas-phase basicities for the heterodimers shown in Fig. 3 is monotonic throughout the whole range, or whether the figure represents merely a part of the whole curve. These authors have also investigated the influence of

the proton affinity on whether a protonated homodimer is likely to be symmetric or not,<sup>38</sup> but this is not relevant to the present case. The order of the CH bond-length increases, shown in Table 1, virtually reflects the order of the gas phase basicities<sup>36</sup> for the first and second row proton acceptors separately, confirming the correlation between these properties.

### Vibrational spectra

The computed wavenumbers and infrared intensities of

the  $\text{CH}\cdots\text{X}$  series of complexes are available in the Supplementary data as Table S2, together with approximate descriptions of the normal modes, for completeness. The wavenumber shifts and intensity ratios, relative to the unperturbed monomers, derived from these data are given in Table 4.

The critical mode in the analysis of the vibrational properties of the hydrogen-bonded complexes considered here is the CH stretching mode of the HCCF sub-molecule. We have shown above that the CH bond length increases in all six complexes of the  $\text{CH}\cdots\text{X}$  series, suggesting that these complexes are of the red-shifting, rather than the blue-shifting, type. Table 4 shows that the CH stretching mode is indeed consistently red-shifted by -145.8, -65.2, -18.7, -46.3, -54.5, and -21.3  $\text{cm}^{-1}$  in the sequence  $\text{NH}_3$ ,  $\text{H}_2\text{O}$ , HF,  $\text{PH}_3$ ,  $\text{H}_2\text{S}$ , and HCl. Moreover, the CH stretching-band intensity increases by factors of 4.95, 3.34, 2.15, 2.94, 3.01, and 2.22 in the same order. Thus the vibrational properties confirm the structural results that the  $\text{CH}\cdots\text{X}$  complexes behave like conventional hydrogen-bonded adducts. The wavenumber shifts are proportional to the hydrogen-bond energies, as shown in Fig. 4, and once again separate relationships are found for the first and second row bases. A similar pair of curves (not shown) was obtained for a plot of the stretching band intensity enhancements versus the binding energies. Again, it appears that the results for  $\text{FCCH}\cdot\text{SH}_2$  indicate some exaggeration of the computed interaction energy. Of the remaining modes of the HCCF sub-molecule, the CCH bending vibrations undergo a substantial regular blue shift and intensity reduction, whereas the CC and CF stretching and the CCF bending modes are red-shifted by much smaller amounts. The CC stretching and the CCH and CCF bending vibrations suffer loss of intensity, whereas the CF stretching

intensity increases uniformly. The perturbations of the modes of the proton acceptor molecules are quite modest.

The vibrational properties of the alternative structures of the complexes with HF and HCl are given in the Supplementary data (Table S3), and the wavenumber shifts and intensity ratios in Table 5. In the case of the reversed F(Cl)H...F bonded complexes, the perturbations of the monomer spectroscopic properties are relatively insignificant, reflecting the very low energies of interaction; none of the wavenumber shifts of ClH·FCCH exceeds 10 cm<sup>-1</sup>. Those of FH·FCCH are marginally larger, the major shift being that of the hydrogen-bonded HF stretching mode (-27.7 cm<sup>-1</sup>). The corresponding hydrogen-bonded HCl stretching mode

shift is only -5.8 cm<sup>-1</sup>. These results contrast with the noticeably larger changes in the spectroscopic properties of the F(Cl)H... $\pi$  complexes, in which the hydrogen-bonded HF and HCl stretching wavenumber shifts are -183.8 and -113.7 cm<sup>-1</sup> and their intensities are enhanced by factors of almost 5 and 8, respectively. These complexes represent two further examples of conventional hydrogen-bonded complexes with characteristic red-shifting behaviour.

#### Electron-density redistributions

An NBO<sup>21</sup> analysis of the various complexes indicates that for the CH...X species, in which HCCF is the proton donor, the source of the interaction is a donation of charge

**Table 4.** Wavenumber shifts and intensity ratios, relative to the unperturbed monomers, of the normal modes of the CH...X complexes of HCCF with NH<sub>3</sub>, H<sub>2</sub>O, HF, PH<sub>3</sub>, H<sub>2</sub>S, and HCl.

<sup>a</sup>X = N, O, F, P, S, and Cl.

from a lone-pair orbital of the proton acceptor to the  $\sigma^*(\text{CH})$  orbital of HCCF, in accordance with the standard interpretation of a conventional red-shifting hydrogen bond. These results are summarized in Table 6.

For the  $\pi$ -bonded structures of the complexes with HF and HCl, the donation is from a  $\pi(\text{CC})$  orbital of HCCF to

the  $\sigma^*$  orbital of HF or HCl. In addition, there is a counter-donation from the non-bonding F or Cl orbitals and the  $\sigma$  orbitals of HF or HCl to the  $\pi^*(\text{CC})$  orbital of HCCF. In the case of the reverse  $\text{F}(\text{Cl})\text{H}\cdots\text{F}$  structures, the interaction is between a F lone pair of HCCF and the  $\sigma^*(\text{HF})$  or  $\sigma^*(\text{HCl})$  orbital and, in addition, in  $\text{FH}\cdots\text{FCCH}$ , a donation from  $\sigma(\text{HF})$  of HF to  $\sigma^*(\text{CF})$  of HCCF. In quantitative terms, the amounts of charge redistributed as a result of hydrogen bond formation are presented in Tables 7 and 8.

The net amounts of charge transferred in the  $\text{CH}\cdots\text{X}$  complexes (Table 7) correlate with the hydrogen-bond energies, again with separate relationships (not shown), for the  $\text{NH}_3$ ,  $\text{H}_2\text{O}$ , HF and the  $\text{PH}_3$ ,  $\text{H}_2\text{S}$ , HCl proton acceptors, as observed for the CH stretching wavenumber shift relationship in Fig. 4. For the alternative structures of the HF and HCl complexes, there is a considerably greater degree of charge transfer involved in the  $\text{XH}\cdots\pi$  complexes than in the  $\text{XH}\cdots\text{F}$ , and in each case this is more pronounced for the HF than for the HCl adduct (Table 8).

## Summary

These calculations have shown that the hydrogen-bonded

**Table 8.** Shifts of atomic electron density (in me) on formation of the  $\text{XH}\cdots\text{F}$  and  $\text{XH}\cdots\pi$  complexes of HCCF with HF and HCl.

Atom <sup>a</sup>	Proton donor			
	HF (reversed)	HF ( $\pi$ -bonded)	HCl (reversed)	HCl ( $\pi$ -bonded)
H	5.2	16.1	3.6	10.6
C(H)	31.3	-35.7	18.6	-22.6

<sup>a</sup>X = F and Cl.

complexes formed between HCCF and  $\text{NH}_3$ ,  $\text{H}_2\text{O}$ ,  $\text{PH}_3$ , and  $\text{H}_2\text{S}$  are exclusively of the  $\text{CH}\cdots\text{X}$  type, and are of the red-shifting variety, with no evidence of shortening of the CH bonds, nor of perturbations of the CH stretching wavenumbers to higher values. The complexes with HF and HCl are of three types:  $\text{CH}\cdots\text{F}(\text{Cl})$ ,  $\text{F}(\text{Cl})\text{H}\cdots\text{F}$ , and  $\text{F}(\text{Cl})\text{H}\cdots\pi$ , with interaction energies in the sequence  $\text{F}(\text{Cl})\text{H}\cdots\pi > \text{CH}\cdots\text{F}(\text{Cl}) > \text{F}(\text{Cl})\text{H}\cdots\text{F}$ . These six complexes are also uniformly red-shifting, leading to the conclusion that, despite the presence of a fluorine atom and a  $\text{C}\equiv\text{C}$  bond, HCCF does not possess sites of sufficiently high electron density to encourage the kind of density redistribution which characterizes the blue-shifting family of hydrogen bonds. There is evidence that blue-shifting hydrogen bonding is observed only when the proton donor is rather weak. In the case of the complexes studied here, apparently the HCCF donor strength is sufficiently high to dominate the range of effects which determine the nature of the hydrogen bonds formed.

# The first series of alkali dipyrinato complexes

Adeeb Al-Sheikh Ali, Judy Cipot-Wechsler, Sarah M. Crawford, Omar Selim, Rhonda L. Stoddard, T. Stanley Cameron, and Alison Thompson

**Abstract:** The first series of alkali dipyrinato complexes is reported, encompassing lithium, sodium, and potassium salts of *meso*-unsubstituted and *meso*-aryl-substituted derivatives. By varying the substituents at the *meso* position, the intermolecular distance between the two nitrogen atoms and thus the  $\kappa^2$ -*N,N*-bidentate bite angle was altered, as confirmed by comparison of crystallographic structures of dipyririn free-bases in the solid-state. The mode of bonding varies as the ionic radius of the metal ion increases: solid-state structures reveal lithium to be accommodated in the plane of the dipyrinato unit, whilst sodium is accommodated out of plane. The reactivity of analogous lithium, sodium, and potassium dipyrinato complexes increases as the ionic radius of the metal ion increases, in keeping with the concept that the complexes tend towards an increasingly ionic nature as the size of the alkali metal increases.

**Key words:** dipyririn, dipyrinato, alkali salts, monoanionic bidentate, *N,N*-chelation, pyrrolic.

**Résumé :** On rapporte la préparation de la première série de complexes dipyrinato alcalins comportant les sels de lithium, de sodium et de potassium de dérivés *més*o non substitués et *més*o substitués par des groupes aryles. En faisant varier la nature des substituants en position *més*o, on modifie la distance intermoléculaire entre les deux atomes d'azote et, en conséquence, l'angle de morsure  $\kappa^2$ -*N,N* du bidentate, tel que confirmé par une comparaison des structures cristallographiques des bases libres dipyrirines à l'état solide. Le mode de liaison varie avec une augmentation du rayon ionique de l'ion métallique; les structures à l'état solide révèlent que le lithium s'accommode dans le plan de l'unité dipyrinato alors que le sodium est accommodé hors du plan. La réactivité des complexes analogues du lithium, du sodium et du potassium augmente avec une augmentation du rayon ionique du métal ionique, en accord avec le concept que les complexes tendent vers une nature de plus en plus ionique avec une augmentation de la taille des métaux alcalins.

**Mots-clés :** dipyririne, dipyrinato, sels alcalins, bidentate monoanionique, *N,N*-chélation, pyrrolique.

## Introduction

The N–H hydrogen atom of dipyririns (Fig. 1), best-known for their presence in 4,4-difluoro-4-bora-3a,4a-diaza-*s*-indacenes (BODIPYs),<sup>1</sup> can be formally deprotonated to give the monoionic conjugated dipyrinato species that can act as a bidentate ligand for the synthesis of supramolecular assemblies and discrete complexes.<sup>2</sup> Crucially, dipyrinato ligands generally adopt a (*Z*)-*syn*-type arrangement and thus chelate in a  $\kappa^2$  manner.<sup>3,4</sup> Although dipyrinato metal complexes have been reported for M<sup>+</sup> species, such as thallium(I)<sup>5</sup> and rhodium(I),<sup>6</sup> alkali complexes involving the dipyrinato ligand were unknown before our recent communication involving lithium.<sup>7</sup> We showed that the monoanionic source of the ligand, rather than the corresponding free base or its protonated derivative, gave access to unprecedented reactivity and previously inaccessible heteroleptic zinc(II) complexes. Our work was followed by an example whereby a lithium dipyrinato complex was used to generate heteroleptic iron(II) and zinc(II) complexes.<sup>8</sup> Porphyrins,

which can be formed from the condensation of two appropriately substituted dipyririns, undergo deprotonation to give the di-ionic tetradentate ligand, and alkali metalloporphyrins have been well-documented,<sup>9</sup> as has the synthetic utility of such complexes in transmetallation reactions to obtain Ag(I), Zn(II), Cd(II), Hg(II), Cu(II), Sn(II), and Fe(III) complexes of porphyrins.<sup>10</sup> As lithium, sodium, and potassium complexes of porphyrins have all been reported,<sup>11</sup> we found it surprising that alkali complexes of the dipyrinato ligand were unknown before our work, apart from a single example of a lithium-cryptand-dipyrinato complex in solution:<sup>12</sup> such derivatives of related  $\beta$ -diketiminato (NacNac),<sup>13,14</sup> porphodimethene,<sup>15</sup> pyrroloimine,<sup>16,17</sup> and amino-pyrrole<sup>18,19</sup> skeletons are well-known.

Many recent advances in coordination chemistry and catalysis have been dependent upon the utility of stable *N,N*-bidentate monoanionic ligands. To this end,  $\beta$ -diketiminato ligands have attracted much attention as spectator ligands: they are isoelectronic to the cyclopentadienyl anion; they

strongly coordinate to metal centers; and the reactivities of metal centers can be tuned by changing the steric and electronic properties of the substituents at the nitrogen atoms. The  $\beta$ -diketiminato ligand<sup>20,21</sup> has a similar *N,N*-bidentate monoanionic framework to the dipyrinato ligand (Fig. 2). However, the ability of the dipyrinato unit to support catalytically active metal centers has yet to be systematically examined.<sup>2</sup> There are limited examples of dipyrins used as chelating ligands for transition-metal fragments, with no examples to date exploring the potential catalytic utility of the resulting complexes, although, in a recent report, an iron(II) dipyrinato complex was shown to undergo C–H bond amination from an organic azide, hinting towards functional possibilities.<sup>8</sup> The lack of systematic exploration is somewhat surprising given the likely useful structural features of the monoanionic dipyrinato ligand, e.g., a hard nitrogen donor pair, the formation of a six-membered ring upon metal coordination, and access to derivatives bearing variable steric and electronic substituents. Traditionally, dipyrinato complexes have been prepared using either HX salts or free-bases as the source of the ligand. Clearly, these ionization states limit the potential for the synthesis of dipyrinato complexes with a diverse array of metal fragments, and it thus follows that alkali dipyrinato complexes would be of interest.

One of the structural locations upon dipyrinato ligands that can easily be modified is the *meso* position (Fig. 1). The term “*meso*” is borrowed from the chemistry of porphyrins, and is routinely applied to dipyrins to identify the methylene position between the two pyrrolic units. By varying the substituents at the *meso* position, we hoped to alter the intermolecular distance between the two nitrogen atoms, and thus influence the C4–C5–C6 angle, and thus the bite angle, of the dipyrinato ligand. As a result, the mode of bonding and the reactivity of the alkali dipyrinato complexes would be anticipated to vary. Herein, we compare

the solid-state structures of dipyrinato salts and free-bases, and report our work regarding *meso*-unsubstituted and *meso*-substituted lithium, sodium, and potassium complexes involving the dipyrinato ligand.

## Results and discussion

To investigate the stability and properties of alkali dipyrinato complexes, three free-base dipyrins were synthesized (Scheme 1); one dipyrin unsubstituted at the *meso* position and two new dipyrins bearing aryl groups at the *meso* position. We maintained the symmetrical bis(1,3-dimethyl-2-ethyl) substitution pattern across the series by using kryptopyrrole in all of our syntheses. The *meso*-unsubstituted dipyrin **1HBr**<sup>22,23</sup> was prepared by reacting kryptopyrrole with formic acid in the presence of HBr, and we then grew crystals of this salt via slow cooling of the reaction mixture. Liberation of the free-base **1** could be achieved using either lithium hydride or ammonium hydroxide.<sup>7</sup> The *meso*-phenyl and *meso*-*p*-CF<sub>3</sub>-phenyl dipyrins **2** and **3**, respectively, were prepared initially as their hydrochloride salts by reacting the corresponding acid chloride with kryptopyrrole. The salts were purified over silica gel to remove any unreacted starting materials as well as the major ketone byproduct (the structure of 4-ethyl-3,5-dimethyl-2-phenylacetylpyrrole, the intermediate en route to **2**, was confirmed using X-ray crystallography, see Experimental section). Treatment of **2HCl** and **3HCl** with satd. NaHCO<sub>3</sub> gave the requisite free-bases in analytically pure form after purification over basic alumina. The low yields of **2** and **3** were attributed to the steric and electronic factors of the persistent ketone intermediates.

Reacting a THF solution of free-base **1** with *n*BuLi gave clean conversion to the lithium dipyrinato complex **4a** (Table 1), which was crystallographically characterized as **4a** and **4a**·(THF)<sub>2</sub>.<sup>7</sup> As detailed in our previous communication, the structural features of **4a**·(THF)<sub>2</sub> are consistent with the relevant N–Li and N–C bond lengths of related lithium diketiminato complexes ( $\beta$ -diketiminato backbone substituted with either methyl<sup>24</sup> or *tert*-butyl groups<sup>25</sup>) that include at least one solvent ether molecule. However, the N–Li–O angles in **4a**·(THF)<sub>2</sub> are contracted relative to those of related lithium  $\beta$ -diketiminato structures containing only one

coordinated solvent molecule (average 130.8°),<sup>24,25</sup> presumably due to steric crowding.

The THF-free solid-state structure of **4a** and the THF-supported structure exhibit significant differences in bond lengths and angles, as we previously reported.<sup>7</sup> For example, the N–Li average distance is 1.39(1) Å in **4a**, compared with 1.98(1) Å in **4a**·(THF)<sub>2</sub>, akin to the Li–N bond length in related lithium diketiminato<sup>13,14,25,26</sup> and porphyrin complexes.<sup>11</sup> Furthermore, the acute C4–N1–Li and C6–N2–Li bond angles in **4a** are only 95.3(4)° and 96.4(4)°, respectively. The bond angles, the planarity of the six-membered chelate ring, and the short N–Li distances in the solid-state structure of **4a** are consistent with an otherwise uncoordinated lithium atom, which is somewhat of a rarity.<sup>24</sup>

The *meso*-unsubstituted sodium dipyrinato complex (**4b**) was prepared via the slow addition of an ethereal solution of sodium bis(trimethylsilyl)amide to an ethereal solution of the free-base **1**. An orange precipitate was immediately formed, the reaction mixture was filtered over Celite, and the residue was washed with ether to remove unreacted free-base and other byproducts. Subsequently, the product was dissolved in THF, the solution was filtered over Celite, and then the solvent was removed in vacuo.

The *meso*-unsubstituted dipyrinato sodium complex (**4b**) was crystallographically characterized after a suitable dark-red crystal was obtained from the slow evaporation of solvent from a concentrated THF solution. The X-ray structure of **4b** (Fig. 3) reveals an oligomer where complexed sodium ions are positioned within non-planar six-membered rings via *N,N'*-chelation, in contrast to the corresponding dipyrinato lithium complex<sup>7</sup> whereby the lithium atom was found to be positioned between the two nitrogen atoms in a discrete planar six-membered ring. The structure of **4b** contains three unique sodium atoms: Na(1), which is on an inversion centre, Na(2), which is in a general position, and Na(3), which is on a twofold axis. Thus, while there are three unique sodium atoms, Na(1) and Na(3) have only half occupancy. The Na(1)–Na(2) distance is 3.247(1) Å, and the Na(2)–Na(3) distance is 3.541(2) Å. Although these are

**Fig. 3.** The X-ray structure of sodium dipyrinato complex **4b**, shown with probability ellipsoids of 50% (hydrogen atoms and THF molecules omitted for clarity; the end of the oligomer and the attached side chains are disordered in two slightly different orientations; disorder not shown).

long, they are arguably just within a van der Waals radius, with the chain of sodium atoms of course propagated by the inversion centre giving a second Na(1)–Na(2) distance of 3.247(1) Å and a Na(3)–Na(2) distance of 3.541(2) Å. The coordination about Na(1) is a near-regular octahedron with two dipyrinato units and two THF molecules, obviously with pairs related by the inversion centre. The coordination about Na(3) is an approximate five-coordinate square-based pyramidal system with two dipyrinato units in the base and a THF molecule with its oxygen atom displaced just slightly off the twofold axis. The coordination about the central Na(2) atom is again five-coordinate with a very distorted square-based pyramid. The two dipyrinato units are in the base but the THF molecule and its oxygen atom are well-displaced to one side. All of the ligands (except the THF molecule coordinated to Na(3)) do double duty, coordinating and bridging between two sodium atoms. Thus, between Na(1) and Na(2) there are two dipyrinato units and the one (displaced) THF bridging the short (3.247 Å) Na(1)–Na(2) distance. However, a THF molecule is absent from the bridging position between Na(2) and Na(3), and just two dipyrinato units bridge that longer gap (3.541(2) Å). In all,

the close approach of the sodium atoms to each other is a consequence of the bridging ligands and probably has no bonding significance.

The bond angles C4–C5–C6 and C21–C22–C23 for the two dipyrinato units in the solid-state structure of **4b** were decreased to 132.9(3)° and 132.8(4)°, respectively, compared with 148.7(3)° in the free-base **1**. Although the C4–C5–C6 angles in **4b** were found to be close to those for the lithium dipyrinato complex (**4a**), the larger ionic size of the sodium ion, compared with the lithium ion, prevented a planar geometry of the complex; as a result, the sodium ion is accommodated out of the dipyrinato plane. As expected, the N–Na bond lengths of **4b** (average 2.53(4) Å) are longer than the N–Li bond lengths of **4a**·(THF)<sub>2</sub> (1.98(1) Å). Such a comparison suggests that the ionic nature of alkali dipyrinato complexes increases as the ionic radii of the metal increase. Related sodium diketiminato complexes exhibit the same trend as our dipyrinato analogues, e.g., Na–N bond length of 2.395(6) Å (cf. Li–N bond length of 1.9975(7) Å<sup>20</sup>) with the lithium ion being accommodated in plane and the sodium ion being accommodated out of plane.

The *meso*-unsubstituted potassium dipyrinato complex (**4c**) was prepared using benzyl potassium (KCH<sub>2</sub>Ph) as the base. As KCH<sub>2</sub>Ph<sup>27</sup> is insoluble in diethyl ether, THF was used as the reaction solvent. Upon the addition of a THF solution of benzyl potassium to a THF solution of the free-base **1**, the potassium dipyrinato complex (**4c**) instantly precipitated as an orange solid. The solvent was removed in vacuo and the solid was washed with ether and then hexanes. The poor solubility of **4c** hindered attempts to secure a crystal suitable for crystallographic analysis, and despite much effort, we were unsuccessful in this regard. Furthermore, we were unable to crystallize any compounds bearing *meso*-aryl substituents.

Interested in how the C4–C5–C6 bond angle and the N–N intramolecular distance affect the coordination geometry of dipyrinato complexes, we grew crystals of the three free-bases **1–3** via the slow evaporation of solvent from concentrated pentane solutions. With our hypothesis being that the nature of the *meso*-substituent would dramatically affect the C4–C5–C6 bond angle, and thus the N–N intramolecular distance and chelating bite angle, we were pleased that the X-ray crystallographic analysis revealed a dramatic decrease of the C4–C5–C6 angle from the *meso*-unsubstituted dipyrin (**1**) [C4–C5–C6 bond angle, 148.7(3)°] (Fig. 4) to the substituted dipyrins **2** [C4–C5–C6 bond angle, 124.8(2)°] (Fig. 5) and **3** [C4–C5–C6 bond angle, 124.1(2)°], respectively (Fig. 6). Moreover, as the C4–C5–C6 angle decreases across the series **1–3**, the intermolecular distance between the nitrogen atoms also decreases (2.73 Å for **1**, 2.69 Å for **2**, and 2.66 Å for **3**) and hence the bonding mode of complexation of the corresponding dipyrinato ligands would be expected to vary, in terms of bite angle and so forth.

Despite the plethora of known dipyrin salts and free-bases,<sup>2</sup> only a small number of refined crystal structures have been reported: the N–N intramolecular distances, the C4–C5–C6 angles, and the geometry across the central alkenyl bond of reported salts and free-bases are collated in Table 2, along with those for **1HBr**. Interestingly, the 148.7° C4–C5–C6 angle in the free-base **1** is much larger than in the known free-bases **7**<sup>28</sup> and **8**<sup>29</sup> (127.0° and

Fig. 4. The X-ray structure of dipyrin **1**, shown with probability ellipsoids of 50% (hydrogen atoms were omitted for clarity; the structure solves in either *Pbca* or in *Pca21*; *R* value in *Pbca* is 5.7%, and 5.1% in *Pca21*; the higher symmetry space group has been chosen; the pyrrole C and N atoms are in slightly disordered positions and the N–H hydrogen atom has not been located, since it sits on the disordered N–C bridge).

126.1°, respectively) and the salts **1HBr** (133.8°), **14**,<sup>30</sup> **15**,<sup>31</sup> **16**,<sup>32</sup> **17**,<sup>33</sup> and **18**<sup>34</sup> (within the range 132.1°–136.0°), despite the fact that all bear hydrogen atoms at the *meso* position. The significantly different sizes in the C4–C5–C6 angle are presumably a consequence of (i) the substituents that

flank the *meso* position, and (ii) the strength and nature of the intramolecular NH–H hydrogen bonding in which the N–H hydrogen atom(s) partake(s).

Our *meso*-aryl free-bases **2** and **3** compare well with the known *meso*-aryl dipyrin free-bases **9**,<sup>35</sup> **10**,<sup>4</sup> **11**,<sup>36</sup> **12**,<sup>37</sup> and **13**,<sup>38</sup> and the known dipyrin salt **19**:<sup>38</sup> all exhibit *Z* configuration across the alkenyl bond, all have their N atoms aligned with syn geometry (as necessary for chelated complexation), all possess an N–N intramolecular distance of around 2.7 Å (2.8 Å for the salt), and all exhibit a C4–C5–C6 angle of 123°–124° (121.7° for the salt). As shown in Table 2, the *meso*-aryl substituted dipyrin salts **20**,<sup>4</sup> **21**,<sup>39</sup> and **22**<sup>40</sup> exhibit either an *E* configuration or anti geometry, and therefore the C4–C5–C6 angles and N–N intramolecular distances cannot be usefully compared to those of **2** and **3**. All of the free-bases, whether *meso*-substituted or not, exhibit *Z* configuration across the central alkenyl bond, presumably to accommodate intramolecular NH–H hydrogen bonding. This configuration clearly predisposes the ability of such ligands to act as bidentate chelating ligands.

We previously reported<sup>7</sup> that the reaction of lithium dipyrinato complex (**4a**) with ZnCl<sub>2</sub> gives unprecedented access to heteroleptic zinc complexes (Scheme 2). To further benchmark the reactivity of alkali dipyrinato complexes as reagents in simple salt-elimination reactions, a solution of the sodium dipyrinato complex (**4b**) in THF was added dropwise to a stirring solution of a stoichiometric amount of anhydrous ZnCl<sub>2</sub> in THF. After stirring for 1 h at room temperature, the solvent was removed in vacuo and a <sup>1</sup>H NMR spectrum of the crude material revealed a mixture of the homoleptic species **23**<sup>23</sup> and the heteroleptic species **24**<sup>7</sup> in approximately equal ratios (Scheme 2). Interestingly, although **23** and **24** are the only two products observed in the reaction of the dipyrinato analogue **4a** with ZnCl<sub>2</sub>, in that instance, the formation of the heteroleptic species **24** was by far dominant.<sup>7</sup> Thus, moving from the lithium salt to the sodium salt dramatically altered the course of the reaction. A similar reaction employing the potassium dipyrinato analogue (**4c**) was also conducted, whereby a suspension of **4c** in THF was utilized, multiple and intractable products were thus generated, none of which were the known complexes **23** and **24**. This series of experiments reveals the differing reactivity of alkali dipyrinato complexes and lends further support to the notion that the ionic nature of the complexes increases as the ionic radii of the metal increase.

With alkali dipyrinato complexes of lithium, sodium, and potassium in hand, we turned our attention to the *meso*-aryl dipyrins **2** and **3** to expand the series. Lithium (**5a**), sodium (**5b**), and potassium (**5c**) *meso*-phenyl dipyrinato complexes were prepared using butyl lithium, sodium bis(trimethylsilyl)amide, and potassium bis(trimethylsilyl)amide, respectively, as the source of the metal ions. Similarly, the alkali *meso*-*p*-CF<sub>3</sub>-C<sub>6</sub>H<sub>4</sub> dipyrinato complexes **6a–6c** were prepared from the corresponding free-base **3** using the metal bis(trimethylsilyl)amide as the source of the metal ion. The yields and procedures are summarized in Table 1. Taking advantage of the phenomenon that the dipyrins **2** and **3** are soluble in pentane while the alkali complexes are not, the resultant *meso*-substituted alkali dipyrinato metal complexes **5a–5c** and **6a–6c** were repeatedly washed with pentane to remove unreacted free-base and other byproducts. Unfortunately, and despite much effort, we were unsuccessful in growing X-ray-quality crystals of any alkali dipyrinato complexes bearing *meso*-aryl substituents.

The <sup>15</sup>N NMR chemical shifts for dipyrins, their salts, and their complexes are diagnostic,<sup>23</sup> and this technique generally allows for the characterization of nitrogen-containing heterocyclic compounds, as noted by others.<sup>41–43</sup> With our current work, the published <sup>15</sup>N dipyrinato chemical-shift ranges<sup>23</sup> can now be expanded to include alkali dipyrinato complexes. As indicated in Fig. 7, the <sup>15</sup>N chemical shifts for the complexes **4–6** reported here do not overlap with their corresponding free-base dipyrins **1–3**. Indeed, the chemical shifts dramatically increase from the range of –162 to –164 ppm for the free-bases **1–3** to the range of –219 to –231 ppm for the alkali metal complexes **4–6**.

Curiously, the <sup>13</sup>C NMR spectra for the sodium and potassium dipyrinato complexes with *meso*-aryl substituents exhibited low signal/noise ratios. Indeed, many more than the expected number of scans were required to attain signals for all of the carbon atoms, and with our expectations based on concentrations of solutions and our experience with other dipyrinato complexes, we were unable to find a convincing rationale for this phenomenon but were nevertheless able to assign all signals.

## Conclusions

In summary, this work represents the first synthesis and characterization of a series of alkali dipyrinato complexes.

**Fig. 7.**  $^{15}\text{N}$  chemical shifts, relative to nitromethane at 125.41 ppm.

Three ligands bearing different substituents at the *meso* position have been utilized, along with lithium, sodium, and potassium metal ions. Variation of the substituent at the *meso* position altered the C4–C5–C6 angle of the dipyrinato unit. The alkali dipyrinato complexes were characterized on the basis of spectroscopic techniques, including  $^{15}\text{N}$  NMR spectroscopy, which was used as a diagnostic indication for these compounds. In contrast to the lithium dipyrinato complex (**4a**), which adopted  $\kappa^2$ -*N,N*-bidentate behaviour for the dipyrinato ligand with the lithium ion nestled within the plane, the analogous sodium dipyrinato complex (**4b**) showed a different mode of bonding whereby an oligomeric structure sets the sodium ions out of the  $\kappa^2$ -*N,N*-bidentate dipyrinato plane. With increasing ionic radii of the alkali metals, relative reactivity increased when reactions with  $\text{ZnCl}_2$  were investigated. Our current investigations include the use of alkali dipyrinato complexes in salt elimination strategies to generate coordination complexes not previously accessible via the use of dipyrin free-bases or their HX salts.

## Experimental section

### General procedures

Unless otherwise indicated, all manipulations were conducted in the absence of oxygen and water under an atmosphere of dinitrogen, either by using standard Schlenk methods, or within a glovebox apparatus, utilizing glassware that was oven-dried ( $130^\circ\text{C}$ ) and evacuated while hot prior to use. Celite was oven-dried ( $130^\circ\text{C}$ ) for 5 d and then evacuated for 24 h prior to use. The non-deuterated solvents: tetrahydrofuran, diethyl ether, toluene, benzene, hexanes, and pentane were deoxygenated and dried by sparging with dinitrogen gas, followed by passage through a double-column solvent-purification system. Tetrahydrofuran and diethyl ether were purified over two alumina-packed columns, while toluene, benzene, hexanes, and pentane were purified over one alumina-packed column and one column packed

with copper-Q5 reactant. Sodium benzophenone ketyl was added to the solvent to provide visual confirmation (i.e., the observed persistence of the benzophenone ketyl) that an appropriate level of purification had been achieved. The solvents used within the glovebox were stored over activated  $4\text{ \AA}$  molecular sieves. THF- $d_8$  (Aldrich) and  $\text{C}_6\text{D}_6$  (Aldrich) were degassed by using three repeated freeze–pump–thaw cycles and then dried over  $4\text{ \AA}$  molecular sieves for 24 h prior to use. HBr (48% aqueous solution),  $\text{LiN}(\text{SiMe})_2$ ,  $\text{NaN}(\text{SiMe})_2$ ,  $\text{KN}(\text{SiMe})_2$ ,  $n\text{BuLi}$  (1.6 mol/L solution in hexanes), silica gel (230–400 mesh, pH 6.5–7.5), and alumina (basic, grade 150,  $58\text{ \AA}$ ) were all used as received. All nuclear magnetic resonance experiments were conducted using 250 and 500 MHz spectrometers. All chemical shifts ( $\delta$ ) are reported in ppm. All coupling constants ( $J$ ) are reported in Hz. All  $^1\text{H}$  and  $^{13}\text{C}$  NMR chemical shifts are reported relative to solvent peaks used as internal references:  $\text{C}_6\text{D}_6$  (7.16 and 128.62 ppm, respectively), THF- $d_8$  (3.58 and 67.80 ppm, respectively), DMF- $d_7$  (8.03 and 163.15 ppm, respectively), and  $\text{CDCl}_3$  (7.26 and 77.16 ppm, respectively).  $^{15}\text{N}$  chemical shifts were obtained from two-dimensional  $^1\text{H}$  (500 MHz) –  $^{15}\text{N}$  (50.7 MHz) HMBC correlation experiments.  $^{15}\text{N}$ ,  $^7\text{Li}$ ,  $^{23}\text{Na}$ , and  $^{19}\text{F}$  shift scales were referenced as outlined in the IUPAC recommendations of 2001.<sup>44</sup> Mass spectra were obtained in ESI positive mode using a TOF instrument in both high and low resolution. All UV–vis analyses were performed using a 10 mm screw-cap cell (with Teflon tape), and solutions were prepared using glovebox techniques and dry THF. 4,4′-Diethyl-3,3′,5,5′-tetramethyldipyrin hydrobromide (**1HBr**),<sup>22</sup> benzyl potassium, 4,4′-diethyl-3,3′,5,5′-tetramethyldipyrin (**1**),<sup>7</sup> and lithium 4,4′-diethyl-3,3′,5,5′-tetramethyldipyrinato (**3a**)<sup>7</sup> were prepared according to literature procedures.

### $\kappa^2$ -(4,4′-Diethyl-3,3′,5,5′-tetramethyl-*meso*- $\text{C}_6\text{H}_5$ -dipyrin) (**2**)

To a solution of 3-ethyl-2,4-dimethylpyrrole (1.3 mL, 10 mmol) in  $\text{CHCl}_3$  (50 mL), benzoyl chloride (70 mg, 5.0 mmol) was added, and the reaction mixture was heated at reflux temperature for 3 h. The resultant pink reaction mixture was extracted with water ( $2 \times 30\text{ mL}$ ), and the organic solution was then dried over  $\text{Na}_2\text{SO}_4$ . Removal of the organic solvent in vacuo gave crude material that was purified using chromatography on silica gel. A minor byproduct was eluted with 50%  $\text{CH}_2\text{Cl}_2$  in hexane, and it was characterized to be 4-ethyl-3,5-dimethyl-2-phenyl acetylpyrrole as a pale yellow solid, mp  $159$ – $161^\circ\text{C}$ .  $\delta_{\text{H}}$  (500 MHz,  $\text{CDCl}_3$ ): 9.29 (1H, bs), 7.25–7.63 (5H, m), 2.38 (2H, q,  $J = 7.5$ ), 2.35 (3H, s), 1.89 (3H, s), 1.05 (3H, t,  $J = 7.5$ ).  $\delta_{\text{C}}$  (125 MHz,  $\text{CDCl}_3$ ): 185.7, 140.8, 133.1, 130.9, 128.9, 128.5, 128.4, 127.1, 125.5, 125.4, 123.9, 17.5, 15.3, 11.9, 11.7.  $\delta_{\text{N}}$  (50.7 MHz,  $\text{CDCl}_3$ ):  $-227.7$ .  $m/z$  (ESI<sup>+</sup>): 250.1202 ( $\text{M} + \text{Na}$ )<sup>+</sup>. A crystal of 4-ethyl-3,5-dimethyl-2-phenyl acetylpyrrole suitable for X-ray crystallographic analysis was grown via slow evaporation of a solution in hexane (structure included herein). The major band was eluted with 5%  $\text{CH}_3\text{OH}$  in  $\text{CH}_2\text{Cl}_2$ . Removal of the solvent in vacuo followed by dissolution in  $\text{CH}_2\text{Cl}_2$  (30 mL) and then washing with saturated  $\text{NaHCO}_3$  solution ( $2 \times 30\text{ mL}$ ) gave the title compound as its free-base. Drying of the solution over  $\text{Na}_2\text{SO}_4$  and removal of the organic solvent in vacuo gave

an orange solid that was purified using column chromatography on basic alumina eluting with 60%  $\text{CH}_2\text{Cl}_2$  in hexane to give the title compound as an orange solid (31 mg, 19%); mp 148–150 °C. UV–vis  $\lambda_{\text{max}}$  (nm): 515 ( $\epsilon$  45 000  $\text{mol/L}^{-1}\text{cm}^{-1}$ , MeOH).  $\delta_{\text{H}}$  (500 MHz,  $\text{CDCl}_3$ ): 7.44–7.45 (3H, m), 7.34–7.36 (2H, m), 2.31 (6H, s), 2.28 (4H, q,  $J = 7.5$ ), 1.19 (6H, s), 0.97 (6H, t,  $J = 7.5$ ).  $\delta_{\text{C}}$  (125 MHz,  $\text{CDCl}_3$ ): 150.3, 139.2, 135.7, 134.9, 131.5, 129.8, 128.6, 128.2, 124.2, 17.8, 15.1, 14.6, 11.9.  $\delta_{\text{N}}$  (50.7 MHz,  $\text{THF}-d_8$ ): –162.1.  $m/z$  HR (MH)<sup>+</sup>  $\text{C}_{23}\text{H}_{28}\text{N}_2$  calcd.: 332.2252, found: 333.2303. **$\kappa^2$ -(4,4'-Diethyl-3,3',5,5'-tetramethyldipyrrinato) sodium (4b)**

In a glovebox, an  $\text{Et}_2\text{O}$  (2 mL) solution of  $\text{NaN}(\text{SiMe}_3)_2$  (40 mg, 0.22 mmol) was added dropwise over 5 min to a magnetically stirring solution of **1** (57 mg, 0.22 mmol) in  $\text{Et}_2\text{O}$  (2 mL). Upon addition of the base, a bright orange solid immediately precipitated from the reaction mixture.

After 1 h, the reaction mixture was filtered over Celite and the residue was washed with ether (4 × 2 mL) to remove any impurities and the  $\text{HN}(\text{SiMe}_3)_2$  byproduct. The product was dissolved in THF (2 mL) and filtered through Celite. Slow evaporation of the solvent from the filtrate resulted in the formation of large red plate crystals. These were isolated and dried in vacuo to leave the title compound as red crystals (46 mg, 74%).  $\delta_{\text{H}}$  (500 MHz,  $\text{THF}-d_8$ ): 6.75 (1H, s), 2.35 (4H, q,  $J = 7.5$ ), 2.16 (6H, s), 2.11 (6H, s), 1.00 (6H, t,  $J = 7.5$ ).  $\delta_{\text{C}}$  (125 MHz,  $\text{THF}-d_8$ ): 153.8, 138.2, 135.3, 128.2, 123.2, 19.4, 16.6, 16.2, 10.5.  $\delta_{\text{N}}$  (50.7 MHz,  $\text{THF}-d_8$ ): –225.4.  $\delta_{\text{Na}}$  (132.3 MHz,  $\text{THF}-d_8$ ): 10.7.

**$\kappa^2$ -(4,4'-Diethyl-3,3',5,5'-tetramethyldipyrrinato) potassium (4c)**

In a glovebox, a THF (2 mL) solution of  $\text{KCH}_2\text{Ph}^{27}$  (25 mg, 0.20 mmol) was added dropwise over 5 min to a solution of **1** (50 mg, 0.20 mmol) in THF (2 mL). Upon addition of the base, a bright orange solid precipitated from the reaction mixture. The reaction vial was sealed and the contents manually shaken for 30 s then left at room temperature. After 1 h, the solvent was removed in vacuo and the orange solid was washed with  $\text{Et}_2\text{O}$  (2 × 2 mL) and then hexanes (3 × 2 mL) to remove any impurities and byproducts. Contrary to the sodium complex, the potassium analogue was found to be insoluble in THF. Therefore, the supernatants were removed in each case by allowing the solid to settle and then carefully decanting the liquid away. The resulting orange solid was dried in vacuo to leave the title compound (37 mg, 66%).  $\delta_{\text{H}}$  (500 MHz,  $\text{DMF}-d_7$ ): 6.80 (1H, s), 2.34 (4H, q,  $J = 7.5$ ), 2.18 (6H, s), 2.13 (6H, s), 1.00 (6H, t,  $J = 7.5$ ).  $\delta_{\text{C}}$  (125 MHz,  $\text{DMF}-d_7$ ): 153.3, 137.9, 134.6, 132.0, 127.3, 19.3, 16.4, 15.9, 10.7.  $\delta_{\text{N}}$  (50.7 MHz,  $\text{DMF}-d_7$ ): –221.4.

**$\kappa^2$ -(4,4'-Diethyl-3,3',5,5'-tetramethyl-meso-C<sub>6</sub>H<sub>5</sub>-dipyrrinato) lithium (5a)**

In a glovebox,  $n\text{BuLi}$  (94  $\mu\text{L}$  of a 1.6 mol/L hexanes solution, 0.15 mmol) was added dropwise over 5 min to a solution of **2** (50 mg, 0.15 mmol) in THF (3 mL). Upon addition of the base, the colour of the solution immediately changed from orange to dark red-brown. The reaction vial was sealed and the contents were magnetically stirred for 45 min. The solvent was then removed in vacuo and the red-brown solid was washed with pentane (5 × 2 mL) to remove any impurities and byproducts. The supernatants were removed in each case by allowing the solid to settle and carefully decanting the liquid away. The resulting solid was dried in vacuo to give the title compound as a red solid (25 mg, 50%).  $\delta_{\text{H}}$  (500 MHz,  $\text{THF}-d_8$ ): 7.40–7.20 (5H, m), 2.25 (4H, q,  $J = 7.5$ ), 2.20 (6H, s), 1.08 (6H, s), 0.92 (6H, t,  $J = 7.5$ ).  $\delta_{\text{C}}$  (125 MHz,  $\text{THF}-d_8$ ): 153.3, 145.2, 138.6, 135.8, 131.9, 131.7, 130.7, 128.6, 127.8, 19.1, 16.0, 15.8, 13.3.  $\delta_{\text{N}}$  (50.7 MHz,  $\text{THF}-d_8$ ): –226.0.  $\delta_{\text{Li}}$  (194.4 MHz,  $\text{THF}-d_8$ ): 2.02.

**$\kappa^2$ -(4,4'-Diethyl-3,3',5,5'-tetramethyl-meso-C<sub>6</sub>H<sub>5</sub>-dipyrrinato) sodium (5b)**

In a glovebox, a solution of  $\text{NaN}(\text{SiMe}_3)_2$  (28 mg, 0.16 mmol) in  $\text{Et}_2\text{O}$  (2 mL) was added dropwise over 5 min to a magnetically stirring solution of **2** (51 mg, 0.16 mmol)

in Et<sub>2</sub>O (2 mL). Upon addition of the base, the colour of the solution changed from orange to red. After 1 h, the solvent was removed in vacuo and the resulting solid was triturated/washed with pentane (5 × 2 mL) to remove any impurities and any byproducts. The supernatants were removed in each case by allowing the solid to settle and carefully decanting the liquid away. The resulting orange solid was dried in vacuo to give the title compound as a red solid (35 mg, 63%).  $\delta_{\text{H}}$  (500 MHz, THF-*d*<sub>8</sub>): 7.30–7.18 (5H, m), 2.27 (4H, q, *J* = 7.4), 2.16 (6H, s), 1.14 (6H, s), 0.94 (6H, t, *J* = 7.4).  $\delta_{\text{C}}$  (125 MHz, THF-*d*<sub>8</sub>): 153.3, 146.8, 144.3, 140.3, 134.8, 132.7, 131.0, 128.25, 128.0, 19.4, 16.3, 16.0, 13.3.  $\delta_{\text{N}}$  (50.7 MHz, THF-*d*<sub>8</sub>): –221.5.  $\delta_{\text{Na}}$  (132.3 MHz, THF-*d*<sub>8</sub>): 9.9.

**$\kappa^2$ -(4,4'-Diethyl-3,3',5,5'-tetramethyl-meso-C<sub>6</sub>H<sub>5</sub>-dipyrrinato) potassium (5c)**

In a glovebox, a solution of KN(SiMe<sub>3</sub>)<sub>2</sub> (30 mg, 0.15 mmol) in THF (2 mL) was added dropwise over 5 min to a magnetically stirring solution of **2** (50 mg, 0.15 mmol) in THF (2 mL). Upon addition of the base, the colour of the solution changed from orange to dark purple. After 1 h, the solvent was removed in vacuo and the resulting solid was triturated/washed with pentane (5 × 2 mL) to remove any impurities and any byproducts. The product was dissolved in THF (2 mL) and filtered through Celite. The resulting solid was dried in vacuo to give the title compound as a red solid (41 mg, 73%).  $\delta_{\text{H}}$  (500 MHz, THF-*d*<sub>8</sub>): 7.26–7.15 (5H, m), 2.31 (4H, q, *J* = 7.5), 2.07 (6H, s), 1.39 (6H, s), 0.98 (6H, t, *J* = 7.5).  $\delta_{\text{C}}$  (125 MHz, THF-*d*<sub>8</sub>): 153.5, 146.8, 145.3, 141.5, 133.9, 133.4, 131.9, 128.2, 128.2, 19.4, 16.1, 16.0, 13.2.  $\delta_{\text{N}}$  (50.7 MHz, THF-*d*<sub>8</sub>): –211.9.

**$\kappa^2$ -(4,4'-Diethyl-3,3',5,5'-tetramethyl-meso-*p*-CF<sub>3</sub>-C<sub>6</sub>H<sub>4</sub>-dipyrrinato) lithium (6a)**

In a glovebox, a solution of LiN(SiMe<sub>3</sub>)<sub>2</sub> (41 mg, 0.25 mmol) in THF (4 mL) was added dropwise to a solution of **3** (100 mg, 0.25 mmol) in THF (2 mL). Upon addition of the base, the colour of the solution immediately changed from dark yellow-brown to dark red-brown. The reaction vial was sealed and the contents magnetically stirred for 2 h. The solvent was then removed in vacuo and the resulting red-brown solid was washed with hexane (5 × 2 mL) to remove any unreacted starting materials and byproducts. The residue was dissolved in THF and filtered over Celite. The solvent was removed in vacuo to give the title compound as a red solid (82 mg, 81%).  $\delta_{\text{H}}$  (500 MHz, THF-*d*<sub>8</sub>): 7.62 (2H, d, *J* = 8.0), 7.38 (2H, d, *J* = 8.0), 2.22 (4H, q, *J* = 7.5), 2.17 (6H, s), 1.03 (6H, s), 0.88 (6H, t, *J* = 7.5).  $\delta_{\text{C}}$  (125 MHz, THF-*d*<sub>8</sub>): 154.1, 149.3, 144.0, 138.2, 135.4, 132.5, 131.4, 130.2 (q, *J*<sub>C-F</sub> = 31.8), 125.9 (q, *J*<sub>C-F</sub> = 269.8), 125.6 (q, 2C, *J*<sub>C-F</sub> = 7.1), 19.1, 16.0, 15.5, 13.6.  $\delta_{\text{F}}$  (243 MHz, THF): –61.6.  $\delta_{\text{N}}$  (50.7 MHz, THF-*d*<sub>8</sub>): –226.9.  $\delta_{\text{Li}}$  (194.4 MHz, THF-*d*<sub>8</sub>): 2.0.

**X-ray crystallographic data**

Diffraction: Rigaku RAXIS-UNKNOWN, Mo K $\alpha$  radiation ( $\lambda$  = 0.71070 or 0.71075 Å). The structures were solved by direct methods<sup>45</sup> and expanded using Fourier techniques.<sup>46</sup> Some non-hydrogen atoms were refined anisotropically, while the rest were refined isotropically. Some hydrogen atoms were refined isotropically, the rest were included in fixed positions. The final cycle of full-matrix least-squares refinement (minimized to  $\sum w(|F_o| - |F_c|)^2$  where *w* = least squares weights on *F*) was based on 3284 observed reflections (*I* > 3.00σ(*I*)) and 271 variable parameters and converged with unweighted and weighted agreement factors of *R* =  $\sum ||F_o| - |F_c|| / \sum |F_o|$  = 0.0394; *R*<sub>w</sub> =  $[\sum w(|F_o| - |F_c|)^2 / \sum w F_o^2]^{1/2}$  = 0.0443. The standard deviation of an observation of unit weight (standard deviation of an observation of unit weight  $[\sum w(|F_o| - |F_c|)^2 / (N_o - N_v)]^{1/2}$  where *N*<sub>o</sub> = number of observations and *N*<sub>v</sub> = number of variables) was 1.06. A Robust-resistant weighting scheme was used.<sup>47</sup> Plots of  $\sum w(|F_o| - |F_c|)^2$  versus  $|F_o|$ , reflection order in data collection, sin  $\theta/\lambda$ , and various classes of indices showed no unusual trends. The maximum and minimum peaks on the final difference Fourier map corresponded to 0.78 and –0.72 e/Å<sup>3</sup>, respectively. Neutral atom scattering factors were taken from Cromer and Waber.<sup>48</sup> Anomalous dispersion effects were included in *F*<sub>calcd.</sub><sup>49</sup> the values for  $\Delta f'$  and  $\Delta f''$  were those of Creagh and McAuley.<sup>50</sup> The

values for the mass attenuation coefficients are those of Creagh and Hubbell.<sup>51</sup> All calculations were performed using the CrystalStructure<sup>52,53</sup> crystallographic software package.

# Microsolvation of the formic acid dimer — $(\text{HCOOH})_2(\text{H}_2\text{O})_n$ clusters with $n = 1, \dots, 5$

Cara M. Nordstrom, Alaina J. McGrath, and Ajit J. Thakkar

**Abstract:** Density functional theory and spin-component-scaled Møller–Plesset perturbation theory calculations are used to examine the microsolvation of the formic acid dimer. The lowest energy structures with  $n$  water molecules consist of a  $n$ -water cluster, not necessarily of lowest energy, with two formic acid molecules attached to its surface by hydrogen bonds. The total number of hydrogen bonds does not correlate directly with relative stability.

**Key words:** formic acid dimer, hydration, microsolvation, clusters, hydrogen bonding.

**Résumé :** On a fait appel à des calculs basés sur la théorie de la fonctionnelle de la densité et sur la théorie de la perturbation de Møller–Plesset à composante de spin ajustée pour étudier la microsolvatation du dimère de l'acide formique. Les structures d'énergies les plus faibles comportant  $n$  molécules d'eau correspondent à un agrégat de  $n$  molécules d'eau, qui n'est pas nécessairement d'énergie la plus faible, avec deux molécules d'acide formique attachées à sa surface par des liaisons hydrogènes. Le nombre total de liaisons hydrogènes n'est pas directement relié à la stabilité relative.

**Mots-clés :** dimère de l'acide formique, hydratation, microsolvatation, agrégats, liaison hydrogène.

[Traduit par la Rédaction]

## Introduction

Formic acid is the prototypical carboxylic acid. It is present in clouds and fog, has been detected in the coma of the Hale–Bopp comet,<sup>1</sup> and may play a key role in the formation of molecules such as acetic acid and glycine in interstellar media.<sup>2</sup> Its importance and relative simplicity have made it the subject of a large number of studies. Since a significant fraction of formic acid in the atmosphere is in the aqueous phase, it is not surprising that microsolvated clusters of formic acid,  $(\text{HCOOH})(\text{H}_2\text{O})_n$  with  $n \leq 6$ , have been studied extensively.<sup>3–15</sup>

It is well-established experimentally<sup>16–19</sup> and theoretically<sup>20,21</sup> that gas-phase formic acid forms a strong, resonance-assisted, cyclic dimer with  $C_{2h}$  symmetry. As shown in Fig. 1, it consists of two formic acid monomers, both in their most stable *Z* (trans) conformation, held together by a pair of short and nearly linear  $\text{OH}\cdots\text{O}$  bonds. Since a nontrivial fraction of gaseous formic acid is dimerized, it is natural to consider the microsolvation of the formic acid dimer. One hopes to answer questions like: will the water molecules form a network connected to the dimer or will they disrupt the dimer?

Protonated forms of solvated formic acid oligomers have been observed experimentally.<sup>14</sup> However, to our knowledge, there has been only one study<sup>10</sup> on clusters of the formic acid dimer and water molecules. In that study, the interaction of the formic acid dimer with clusters of six and

Fig. 1. The formic acid dimer.

ten water molecules was considered as a model for the adsorption of the formic acid dimer on ice. They found that the dimer does not dissociate if it is adsorbed flat on the ice surface, but does dissociate otherwise. The purpose of this paper is to explore the lowest minima on the potential energy surfaces of complexes between two formic acid (f) and one to five water (w) molecules using ab initio and density functional theory (DFT) methods.

## Computational scheme

An extensive search was carried out for the low-energy structures of  $f_2w_n$  clusters with  $1 \leq n \leq 5$ . We used the multistage search-and-screen method followed in earlier work on clusters of glycolic acid with one to 16 waters,<sup>22–24</sup> and on small clusters of pure formic acid.<sup>25–28</sup> Each stage commences with higher-level optimization of the structures obtained in the previous stage. Only true minima, identified by vibrational frequency analysis, are retained. Next, single-point energy calculations in a larger basis set and higher-

**Note:** The reference MP2, SCS, MI, and MIZ energies for F2W101 are  $-455.4584718$ ,  $-455.4278052$ ,  $-454.7587475$ , and  $-454.6640675$  au (atomic units), respectively.

level method are carried out for the minima and an energy threshold is used to select a subset as trial structures for the next stage. A sampling of higher-energy minima that have distinct H-bonding patterns not already present in the energy-selected set are then added to the selection.

The zeroth-order step is the generation of a representative sample of guessed structures. This was done for  $f_{2w_n}$  clusters by adding a formic acid dimer to known minima of  $w_n$  clusters, adding a formic acid monomer to known minima of  $fw_n$ , and by adding a water molecule to our minima for  $f_{2w_{n-1}}$  clusters. In the first-order stage, the guessed structures were optimized using the PM3 method.<sup>29</sup> The latter leads to reasonable geometries but unreliable relative energies,<sup>22,23</sup> and hence, it is vital that screening of minima is done with single-point energies calculated using more reliable methods. In this work, we used single-point energies at the B3LYP/pc1a level. B3LYP is a hybrid DFT method.<sup>30,31</sup> The pc1a basis set of [4s3p1d/3s2p] contracted Gaussian-type functions (GTF)<sup>24,27,32</sup> is a polarized, split-valence basis set with added diffuse GTF of s- and p-type. It can be obtained from the aug-pc1 basis set,<sup>33</sup> which was specifically optimized for DFT calculations, by deletion of the diffuse d-GTF on the C and O atoms. The second stage consisted of B3LYP/pc1a geometry optimizations followed by single-point energy computations with second-order, Møller–Plesset (MP2)<sup>34</sup> perturbation theory using the aug-cc-pVDZ and aug-cc-pVTZ basis sets.<sup>35,36</sup> All electronic structure calculations were done with Gaussian 03.<sup>37</sup>

The “complete-basis-set (CBS)” limit of the MP2 correlation energy,  $E_c^{\text{MP2}} = E^{\text{MP2}} - E^{\text{HF}}$ , was found by two-point extrapolation<sup>38</sup> based on an inverse-cubic decay of basis set truncation errors with basis size. Thus,

$$[1] \quad E_c^{\text{MP2}} = (X^3 E_c^{\text{MP2}, X} - Y^3 E_c^{\text{MP2}, Y}) / (X^3 - Y^3)$$

in which  $E_c^{\text{MP2}, X}$  is the MP2 correlation energy obtained using a basis set with cardinal number  $X$ . We use  $X = 2$  and  $Y = 3$  for the MP2 energies obtained with the aug-cc-pVDZ and aug-cc-pVTZ basis sets, respectively. The MP2 correlation energy can be decomposed into contributions from electron pairs of opposite spin (os) and of the same spin (ss) as follows:

$$[2] \quad E_c^{\text{MP2}} = E_{\text{os}}^{\text{MP2}} + E_{\text{ss}}^{\text{MP2}}$$

To overcome some of the drawbacks of MP2, such as overestimation of dispersion interactions, Grimme<sup>39</sup> suggested an empirical scaling of the spin components. He recommended the spin-component-scaled (SCS) MP2 correlation energy given by

$$[3] \quad E_c^{\text{SCS-MP2}} = c_{\text{os}} E_{\text{os}}^{\text{MP2}} + c_{\text{ss}} E_{\text{ss}}^{\text{MP2}}$$

in which  $c_{\text{os}} = 6/5$  and  $c_{\text{ss}} = 1/3$ . Distasio and Head-Gordon<sup>40</sup> found that optimization of the scaling parameters for intermolecular binding energies of a diverse set of hydrogen-bonded, dispersion, and mixed complexes led to a rather different set of values, almost as if the roles of opposite- and same-spin pairs had been reversed. They recommend  $c_{\text{os}} = 0.29$  and  $c_{\text{ss}} = 1.46$  for use with cc-pVDZ and cc-pVTZ basis sets combined with CBS extrapolation schemes. The energies so obtained are designated SCS(MI)-MP2 in which MI stands for molecular interactions.<sup>40</sup> The spin components of the MP2 correlation energy we obtained with the aug-cc-pVDZ and aug-cc-pVTZ basis sets were extrapolated to the CBS limit with eq. [1] and used to obtain the extrapolated SCS-MP2 and SCS(MI)-MP2 energies from eq. [3].

## Results and discussion

The number of unique minima obtained varied between 131 and 339 at the PM3 level and ranged from 22 to 111 at the B3LYP/pc1a level for clusters with one through five water molecules. Only minima that are predicted to be the lowest lying in energy by the extrapolated MP2, SCS-MP2, and SCS(MI)-MP2 methods are considered further. We report relative energies,  $\Delta E$ , using these methods (abbreviated MP2, SCS, and MI, respectively) and also the MIZ relative energy, which is the SCS(MI)-MP2 relative energy including zero-point vibrational corrections at the B3LYP/pc1a level. The latter were calculated using harmonic frequencies and should be taken as rather approximate because some of the vibrations in the H-bonded complexes considered in this work are almost certain to be strongly anharmonic. The number of OH...O hydrogen bonds between formic acid molecules ( $N_{\text{ff}}$ ), between formic acid and water ( $N_{\text{fw}}$ ), and between water molecules ( $N_{\text{ww}}$ ) are reported together with their mean lengths denoted  $\langle R_{\text{ff}} \rangle$ ,  $\langle R_{\text{fw}} \rangle$ , and  $\langle R_{\text{ww}} \rangle$ , respectively. The total number of H bonds is denoted as  $N_{\text{t}}$ . The  $f_{2w_n}$  cluster minima obtained at the B3LYP/pc1a level are labeled as F2Wnr where  $r$  is a two-digit stability rank of the structure at the extrapolated SCS(MI)-MP2 level. Cartesian coordinates of the structures are in the Supplementary data section.

Table 1 shows that all methods predict F2W101 to be the lowest-energy structure by a margin of roughly 3 kcal/mol. Figure 2 shows that in F2W101, the water molecule has inserted itself between the formic acid molecules, breaking one of the H bonds in the formic acid dimer. In the higher-energy minima, F2W102 and F2W103, an intact formic acid

dimer is seen held to the water molecule by an  $\text{OH}\cdots\text{O}$  hydrogen bond and a weak  $\text{CH}\cdots\text{O}$  interaction.

Table 2 shows that all methods predict F2W201 to be the global minimum. Figure 3 shows that in F2W201, the formic acid molecules have separated and H bonded to a water dimer. The primary difference between F2W202 and F2W201 is that the H bond between the water molecules is missing in F2W202. The cyclic F2W203 oligomer retains one H bond between the acid molecules, and the higher-energy F2W204 differs from it by a bridging H bond that creates a bicyclic structure. The next two minima contain higher-energy isomers of the formic acid dimer and weak  $\text{CH}\cdots\text{O}$  interactions. The F2W206 structure has one of the formic acid molecules in its E (cis) form.

Table 3 shows that the energy gap between F2W301 and F2W302 is rather small and the energy ordering of the two varies with the calculation method. There are six or seven

minima within 1 kcal/mol of F2W301. Table 3 also shows that maximizing the number of H bonds does not lead to the global minimum; in fact, the local minimum with seven H bonds lies higher in energy than nine minima with only six H bonds. The strength of the H bonds plays a role: the mean H-bond lengths in F2W310 are noticeably larger, indicating weaker bonds. Figure 4 shows that the nine lowest minima can all be described as a chain of three water molecules with a formic acid molecule attached to each side. The structures have water chains with different H-bonding topologies. The lowest-energy form of an isolated water trimer is cyclic,<sup>41</sup> but this motif is not seen among the low-energy forms of  $\text{f}_2\text{w}_3$ . In a similar vein, it was noted previously<sup>23</sup> that a cyclic water trimer is not observed in the low-energy structures of complexes consisting of one glycolic acid and three water molecules.

Table 4 shows that all methods predict F2W401 to be the

global minimum. The lowest-energy structure of a water tetramer is cyclic.<sup>41</sup> Fig. 5 shows that the two lowest-energy minima consist of a cyclic water tetramer with the formic acid molecules attached by two H bonds to opposite edges. F2W404 and F2W405 consist of a cyclic water tetramer with formic acid molecules attached by two H bonds to the same edge resulting in two tetracoordinate water molecules. A plethora of other low-energy structures could be generated by varying the H-bond topology of the tetramer but this was not done because the main interest in this work is how the

formic acid molecules attach themselves to the water tetramer. The five other isomers in Fig. 5 contain a chain form of the water tetramer with the formic acids bound to opposite sides forming various cyclic arrangements. F2W403 is bowl shaped, whereas F2W406 has three rings of similar size.

Table 5 shows that all four methods predict ten or more local minima of  $\text{f}_2\text{w}_5$  within 1 kcal/mol of the global minimum. The zero-point-energy correction changes the energy ordering of the  $\text{f}_2\text{w}_5$  clusters more than it does in the smaller

clusters, perhaps because the harmonic frequencies are less accurate for the low-frequency modes in  $f_2w_5$ . A cyclic isomer is the lowest-energy water pentamer<sup>41</sup> and Fig. 6 shows that F2W501, F2W505, and F2W513 consist of a cyclic water pentamer with two formic acid molecules attached to it. F2W502 has a quasi-cubic structure of oxygen atoms with three of them supplied by the formic acid monomers; it has almost the same energy as F2W501. A trigonal prism of oxygen atoms with one of them supplied by a formic acid molecule is seen in F2W506. It is not a coincidence that one of the low-energy structures of a water hexamer is also a trigonal prism. A cyclic water tetramer with a fifth water attached to one of the corners can be spotted in F2W503, F2W504, F2W507, F2W508, F2W511, F2W512, F2W514, and F2W515. A cyclic water tetramer with a fifth water molecule bridging diagonally opposite corners is seen in F2W509. A tetracoordinated water is in the center of a pleasingly regular arrangement of four rings of similar size in F2W510. Table 5 shows that the number of H bonds

varies from 9 to 11 in the  $f_2w_5$  complexes. Unfortunately, we could not find a simple relationship that enables the relative energy to be predicted quantitatively from the number of H bonds and their mean lengths. As with  $f_2w_4$ , many other low-energy  $f_2w_5$  structures could be generated by varying the H-bond topology of the water network in the oligomers shown in Fig. 6.

Figure 7 shows three interesting examples of the many other local minima we found. Note that a tetracoordinated water can be found in a cluster as small as F2W105. The F2W414 structure is similar to the global minimum F2W401 but lies 2.94 kcal/mol higher in energy. Two formic acid monomers in the E conformation are present in F2W574 even though it is only 3.45 kcal/mol higher in energy than the global minimum structure.

## Conclusions

Many low-energy minima on the potential energy surfaces

**Fig. 7.** Some interesting local minima of  $(\text{HCOOH})_2(\text{H}_2\text{O})_n$ .

of the  $f_2w_n$  complexes with  $1 \leq n \leq 5$  were located. Our DFT, MP2, SCS-MP2, and SCS(MI)-MP2 calculations are not sufficiently accurate to pinpoint with certainty the lowest-energy structure of the clusters with more than two water molecules. However, they do indicate unequivocally that microsolvation dissociates the formic acid dimer. The lowest-energy  $f_2w_n$  minima consist of a  $w_n$  cluster, not necessarily of lowest energy, with two formic acid molecules attached to its surface by hydrogen bonds. As in earlier work on small microsolvated clusters of glycolic acid,<sup>23,24</sup> we find that the number of H bonds is not an adequate stand-alone criterion for determining which of two structures is more stable. Moreover, we were unable to find any quantitative correlations between relative energies and simple measures such as the number of H bonds and their average bond lengths or angles.

# Homoselenocysteine — An oxygen or selenium acid in the gas phase?

Marcela Hurtado, Otilia Mó, and Manuel Yáñez

**Abstract:** The potential energy surface of L-homoselenocysteine (HSEC) has been explored through the use of B3LYP/6-311+G(d,p) calculations. In this survey, seventy-seven different conformers have been located. These local minima can be classified in four groups, A–D. Structures A, B, and D are stabilized by intramolecular hydrogen bonds (IMHBs) with the amino group acting as the hydrogen bond (HB) donor and the carbonyl group (structures A and D) or the hydroxyl group (structure B) as HB acceptors. The structures in set C present an IMHB with the amino group acting as the HB acceptor and the hydroxyl group as the HB donor. The stability order decreases in the following order:  $A > B > C > D$ . From their relative stabilities it can be concluded that only three of these conformers, namely A1, A4, and A5, would exist in the gas phase at room temperature. The most stable deprotonated form corresponds to a Se-deprotonated species stabilized by a strong IMHB between the hydroxyl group and the Se atom. However, a direct deprotonation of the most stable neutrals lead to O-deprotonated species, which eventually isomerize to yield the global minimum. Hence, we can conclude that, quite unexpectedly, HSEC behaves as a Se acid in the gas phase, its intrinsic acidity being  $1374 \text{ kJ mol}^{-1}$  at the B3LYP/6-311++G(3df,2p) level of theory. The most stable protonated forms are systematically the N-protonated ones, the global minimum being a structure stabilized through an IMHB involving the protonated amino group as the HB donor and the SeH group as the HB acceptor. The calculated gas-phase proton affinity (PA) at the B3LYP/6-311++G(3df,2p) level of theory is  $930 \text{ kJ mol}^{-1}$ .

**Key words:** homoselenocysteine, gas-phase acidity, gas-phase basicity, density functional theory (DFT) calculations, intramolecular hydrogen bonds.

**Résumé :** On a étudié la surface d'énergie potentielle de la L-homosélénocystéine (HSEC) sur la base de calculs théoriques B3LYP/6-311+G(d,p). Dans cette revue, on a localisé soixante-dix-sept différents conformères. On peut classer ces minima locaux en quatre groupes, A–D. Les structures A, B et D sont stabilisées par des liaisons hydrogènes intramoléculaires (LHIM) dans lesquelles le groupe amino agit comme donneur de liaison hydrogène (LH) et le groupe carbonyle (structures A et D) et le groupe hydroxyle (structure B) agissent comme accepteurs de LH. Les structures de l'ensemble C présentent des LHIM dans lesquelles le groupe amino agit comme accepteur de LH et le groupe hydroxyle comme donneur de LH. L'ordre de stabilité diminue dans l'ordre suivant,  $A > B > C > D$ . Sur la base de ces stabilités, on peut conclure que seulement trois de ces conformères, sont A1, A4 et A5, pourraient exister en phase gazeuse, à la température ambiante. La forme déprotonée la plus stable correspond à une espèce Se-déprotonée, stabilisée par une forte LHIM entre le groupe hydroxyle et l'atome de Se. Toutefois, une déprotonation directe des formes neutres les plus stables conduit à des espèces O-déprotonées qui s'isomérisent éventuellement pour conduire à un minimum global. En conséquence, on peut conclure que d'une façon inattendue, en phase gazeuse, la HSEC se comporte comme un acide dérivé du sélénium et que son acidité absolue, au niveau B3LYP/6-311++G(3df,2p) de la théorie, est de  $1374 \text{ kJ mol}^{-1}$ . Les formes protonées les plus stables sont systématiquement les formes N-protonées et le minimum global d'une structure stabilisée par une LHIM implique le groupe amino protoné comme donneur de LH et le groupe SeH comme accepteur de LH. L'acidité en phase gazeuse au niveau B3LYP/6-311++G(3df,2p) de la théorie est égal à  $930 \text{ kJ mol}^{-1}$ .

**Mots-clés :** homosélénocystéine, acidité en phase gazeuse, basicité en phase gazeuse, calculs d'après la théorie de la fonctionnelle de la densité (TFD), liaisons hydrogènes intramoléculaires.

## Introduction

A good understanding of the chemistry of peptides requires a sound knowledge of the intrinsic reactivity of the amino acids from which the peptides are built up. This has motivated a large interest in conformational studies of amino acids, which do not only dictate their affinity for specific receptors<sup>1</sup> but also its intrinsic reactivity, in particular its basicity and acidity. Therefore, in general, the examination of the intrinsic reactivity of an amino acid requires a careful examination of its conformational characteristics, which, depending on the length of the chain attached to the amino acid moiety, can be very complicated due to the large number of possible conformers, whose structure and relative stabilities are usually obtained by means of theoretical studies. It is worth mentioning, for instance, the work by Gronert and O'Hair<sup>2</sup> about the conformers of alanine, serine, and cysteine, for which 10, 52, and 42 different conformers, respectively, were located at the HF/6-31G\* level of theory. As well, the work of Bertran and co-workers<sup>3</sup> explored several conformations of glycine, serine, and cysteine in an effort to estimate their proton affinities, and that of Kaur et al.<sup>4</sup> employed density functional theory (DFT) methods to characterize 33 stable conformers of selenocysteine in the gas phase, and investigated its proton affinity, its gas-phase acidity, and the possible implication of antioxidant activity of this selenium derivative.

Among the natural amino acids, those containing selenium are particularly important because Se is an essential trace element for humans, animals, and other living organisms.<sup>5-7</sup> Indeed, selenium amino acids have been used as supplements for cancer prevention.<sup>8</sup> Furthermore, the biological activity of selenium has been associated with several natural selenoproteins, including glutathione peroxidase, iodothyronine deiodinase, and thioredoxin reductase.<sup>5,6,9</sup> Selenocysteine has also been found to be the only essential selenoamino acid in these proteins. Special proteins are used to synthesize selenocysteinyl-tRNA and deliver it to the ribosome for incorporation at UGA codons, which normally serve to terminate translation.<sup>10,11</sup> Selenomethionine is a natural amino acid and the chemical incorporation of this amino acid, via selenohomocysteine, has been achieved.<sup>12,13</sup> The homoselenocysteine (HSEC) can facilitate efficient peptide ligation and therefore, it is important as a precursor of selenomethionine. Recently, Salon and co-workers<sup>14,15</sup> have synthesized some Se derivatives of the DNA nucleobases and studied their crystal structures, their thermostabilities, and the impact of their incorporation into oligonucleotides. In addition, specific pyrimidines in natural tRNAs have been derivatized by the incorporation of Se on the nucleobases.

Quite surprisingly, however, is that the information about the chemistry of Se compounds is not very abundant and even scarcer are the theoretical calculations on Se-containing amino acids. As a matter of fact, the first systematic assessment of different theoretical schemes for the study of organoselenium compounds was published by Boyd and co-workers<sup>16</sup> in 2005.

The aim of the present theoretical work is to explore the potential energy surface (PES) of HSEC (see Chart 1) to locate the most stable conformers in an effort to carry out a

Chart 1.

reliable estimation of its intrinsic acidity and basicity. We would like to establish whether O or Se is the most acidic site of this amino acid.

## Computational Methods

We initially carried out a systematic search of conformers at the semiempirical PM3 level using a relaxed PES scan and a wide step size. The different conformers were generated by considering all possible combinations of the rotations indicated in Chart 1.

Subsequently, the PM3 initial geometries were refined by means of B3LYP/6-311+G (d,p) calculations, and their harmonic vibrational frequencies evaluated. In this way, we were able to confirm that, from this initial set of PM3 structures, a total of 77 conformers were local minima at the B3LYP level. Some isomerization processes were also investigated for neutral, protonated, and deprotonated species. The harmonic vibrational frequencies were used to classify the different stationary points as local minima or transition states. The connectivity between local minima and transition states was ratified by means of internal reaction coordinate (ICR) calculations as implemented in the Gaussian03 suite of programs.<sup>17</sup> The B3LYP approach combines Becke's three parameter nonlocal hybrid exchange potential<sup>18</sup> with the nonlocal correlation functional of Lee et al.,<sup>19</sup> and it has been shown to provide reliable geometries for a wide variety of compounds,<sup>20-24</sup> with a rather good accuracy/cost ratio. The same functional has been shown to yield reliable gas-phase basicities and acidities,<sup>25-33</sup> provided that a flexible enough basis set is used.

For the subsequent analysis of the basicity and acidity of this amino acid, only the seven most stable conformers were considered because the energy gap between them was found to be smaller than 5.0 kJ mol<sup>-1</sup>. For this purpose, their deprotonated and protonated species were optimized and the corresponding harmonic frequencies calculated at the same level used for the neutrals. From the frequency calculations, the thermal corrections to enthalpies and Gibbs free energies were extracted at 298.2 K. Final energies were obtained by B3LYP/6-311++G(3df,2p)//B3LYP/6-311+G(d,p) single point calculations. In all cases the Gaussian03 suite of programs was used.<sup>17</sup>

The gas-phase proton affinity (PA) and the gas-phase ba-

Scheme 1.

sicity (GB) of a compound A are defined as the negative of the enthalpy and the negative of the Gibbs free energy for eq. [1], respectively.

The gas-phase acidity ( $\Delta_{\text{acid}}H$ ) of a compound A is defined as the proton affinity of the corresponding anion (eq. [2]); hence, the lower the value of  $\Delta_{\text{acid}}H$ , the higher the acidity of the system.

The acidity can also be measured in terms of the corresponding Gibbs free energy,  $\Delta_{\text{acid}}G$ .

Enthalpies and Gibbs free energies were evaluated at the B3LYP/6-311+G(d) level at 298.2 K. The use of a harmonic approximation induces errors in the low-frequency torsions of the systems under investigation, which are significantly anharmonic, and therefore, in our calculated Gibbs free energies. This error can be estimated to be about 7 kJ mol<sup>-1</sup> K<sup>-1</sup> for the calculated entropies,<sup>34</sup> which lead to an error in the Gibbs free energy at 298 K of about 2 kJ mol<sup>-1</sup>. Since, as we shall discuss later, neutral, protonated, and deprotonated species are a mixture of several conformers in the gas phase, we have also included the corresponding entropy of mixing, which is evaluated as

$$[3] \quad \Delta S_{\text{mix}} = -R \sum x_i \ln x_i$$

where  $x_i$  is the mole fraction of the  $i$ th component within the mixture.

The bonding of the neutral, deprotonated, and protonated most stable forms was analyzed by means of the atoms in molecules (AIM)<sup>35</sup> and the electron localization function (ELF)<sup>36</sup> theories. By means of AIM theory we have obtained the molecular graphs showing the bond paths connecting the different bonded atoms and containing the bond critical points (BCPs), which correspond to stationary points in which the electron density is minimum along the line that connect two maxima and maximum in the other two directions.

ELF is a function, which, conveniently scaled between [0,1],<sup>37,38</sup> permits division of the physical space in regions where electron pairs are localized, either as bonding or lone pairs. These regions or basins are usually classified as monosynaptic (core or lone pairs) and disynaptic (involving two atomic valence shells), and their electron population provides useful insights into the bonding pattern of the molecule. ELF grids and basin integrations have been evaluated with the TopMod package.<sup>38</sup> For the three-dimensional plots, an ELF value of 0.8 is normally used.

## Results and discussion

A total of 77 stable conformations of HSEC have been characterized as local minima of the potential energy surface (PES). The optimized geometries of the 15 more stable conformers are given in Fig. S1 of the Supplementary data. The total and relative energies of these 77 local minima, arranged in decreasing stability order, as well as the calculated thermal corrections, are summarized in Table S1 of the Supplementary data.

The 77 local minima of the PES can be arranged in four different groups (see Scheme 1) attending to the local conformation of the amino acid moiety. Structures A, B, and D are stabilized by an intramolecular hydrogen bond (IMHB) in which the amino group acts always as a hydrogen bond (HB) donor whereas in structures C it acts as a HB acceptor, the hydroxyl group being the HB donor. In structures A and D the HB acceptor is the carbonyl group and in structures B the hydroxyl group, the only difference between structures A and D being the relative position of the hydroxyl group. It is worth mentioning that within these four groups some structures exhibit IMHBs in which the Se-H group acts as the HB donor with respect to the amino group or the carbonyl or hydroxyl oxygen atoms as HB acceptors, but they always lie much higher in energy than the conformers shown in Fig. 1. Some of these structures are shown in Fig. S2 of the Supplementary data.

Figure 1 shows the geometries and the relative free energies of the seven lowest-energy conformations of neutral HSEC. As mentioned above, these seven structures are very close in energy, with the maximum energy gap being 5.0 kJ mol<sup>-1</sup> (see Fig. 1). It is worth noting that these seven low-lying energy conformers all belong to set A, so we have considered it of interest to include in Fig. 1 the most stable conformers of sets B, C, and D, namely structures B8, C17, and D49. It is then obvious that the relative stability decreases in the order of A > B > C > D. Actually, structures B8, C17, and D49 are predicted to be 5.6, 7.7, and 18.0 kJ mol<sup>-1</sup> higher in energy than the global minimum A1. Structures A1 and A2 are quite close in energy, with the energy gap in terms of Gibbs free energies being 1.2 kJ mol<sup>-1</sup>. It is also worth noting that the maximum energy gap, when the complete set of 77 conformers is considered, amounts to 42.7 kJ mol<sup>-1</sup>.

An inspection of Fig. 1 shows that in the seven A1–A7 conformers, the carbonyl oxygen apparently acts as a HB double-acceptor from the hydroxyl and the amino groups, with the main structural differences being associated with the local conformation of the CH<sub>2</sub>CH<sub>2</sub>SeH side chain. However, both the N–H...O and the O–H...O distances are systematically longer than 2.2 Å, and therefore, much longer than the typical bond lengths of these HBs. The correspond-

**Fig. 1.** B3LYP/6-311+G(d,p) optimized structures of the most stable A-, B-, C-, and D-type conformers of HSEC. Some significant inter-nuclear distances are given in Å. Gibbs free energies relative to A1 are given within parentheses in kJ mol<sup>-1</sup>.

ing molecular graphs do not show the existence of a BCP along the N–H...O or the O–H...O lines, so these interactions cannot be considered, strictly speaking, as intramolecular hydrogen bonds (IMHBs). Consistently, a natural bond order (NBO) analysis does not show any second-order interaction between the carbonyl oxygen lone pair and the  $\sigma_{\text{NH}}^*$  or  $\sigma_{\text{OH}}^*$  antibonding orbitals, which would be the typical signature of the N–H...O and the O–H...O IMHBs.

If one assumes a Boltzman distribution, and using the relative Gibbs free energies summarized in Fig. 1, in the gas phase and at room temperature (298.2 K), HSEC should be an equilibrium mixture that contains 48.1%, 29.5%, 12.1%, 5.6%, 2.6%, 1.9%, and 0.2% of conformers A1, A2, A3, A4, A5, A6, and A7, respectively, and that the proportion of the most stable conformers of the series B, C, and D is null. The interconversion between these local minima involves energy barriers that range from 7 to 27 kJ mol<sup>-1</sup> (see Fig. 2). Quite importantly, the activation barrier between A1 and A2 amounts to 18 kJ mol<sup>-1</sup>, hence, structure A2 will very likely not be accessible at room temperature. The same applies to structures A3, A6, and A7, and only the connectivity between A1 and the local minima A4 and A5 involves low enough activation barriers as to expect the three of them to be accessible at room temperature. Under these circumstances, one should expect HSEC to be a mixture of these

three conformers in the following proportion: A1 (64.6%), A4 (23.9%), and A5 (11.5%). Since, as we shall discuss later, the most stable deprotonated species can be considered the result of a direct deprotonation of the form D49, we have also included in Fig. 2 the energy barrier associated with the A2 → D49 isomerization.

## Gas-phase acidities

The  $\Delta_{\text{acid}}G$  for all the species included in Fig. 1 was calculated at the B3LYP/6-311+G(d,p) level (see Table 1). The structures of the different anions have been included in Fig. S1 of the Supplementary data. However, we will only discuss in detail the deprotonation processes of the three conformers that, according to our previous analysis, should be the only ones present in a significant amount in the gas phase. In our survey of the intrinsic acidity of these systems, we have initially considered all possible acidic sites, namely the amino, the hydroxyl, and the Se–H groups. When the proton is removed from the amino group, in many of the other conformers a spontaneous proton transfer from the hydroxylic group or from the Se–H, depending on which of the two is closer, towards the deprotonated amino group takes place (see, for instance, the enhanced N acidity of A3, C17, C32, and D49 in Table 1). Finally, in practically all cases,

**Fig. 2.** Energy profile connecting the most stable A-type conformers of HSEC. Energies relative to the A1 conformer are in  $\text{kJ mol}^{-1}$ .**Table 1.**  $\Delta_{\text{acid}}G$  and GB ( $\text{kJ mol}^{-1}$ ) of HSEC calculated at the B3LYP/6-311+G(d,p) level.

Conformer	$\Delta_{\text{acid}}G$			GB

C32	1370.8	1364.6	1348.6	-915.5	-953.0 <sup>a</sup>	-822.1
D49	1358.1	1355.2	1329.2	-907.9	-877.8	-850.5

<sup>a</sup>The reported value corresponds to the protonation on the N atom because the O-protonated or Se-protonated species are not stationary points of the PES.

only oxygen and selenium deprotonated species were found to be stable. This is not the case, however, when dealing with conformers A1, A4, and A5 because in all three cases the amino group is very far apart from both the OH and the SeH group, so the aforementioned spontaneous proton transfers cannot take place. Nevertheless, the anions formed, namely A1N<sup>-</sup>, A4N<sup>-</sup>, and A5N<sup>-</sup>, are higher in energy than

the anions formed by deprotonation of the OH or the SeH groups.

The most stable anions formed by a direct deprotonation process of the three neutral conformers correspond systematically to the oxygen deprotonated species (see Fig. 3). It is very important, however, to take into account that, as for the neutrals, all anionic species exhibit many different con-

**Fig. 3.** B3LYP/6-311+G(d,p) optimized structures of the most stable anions produced by the deprotonation of the A1, A4, and A5 conformers of HSEC. The global minimum, D49Se<sup>−</sup>, corresponds to the direct deprotonation of the D49 conformer. Some significant internuclear distances are given in Å. Gibbs free energies relative to D49Se<sup>−</sup> are given in parentheses in kJ mol<sup>−1</sup>.

formers with quite different energies. Since the existence of different anionic conformers may play a crucial role in accurately determining the intrinsic acidity of the system, we have investigated the most stable O-deprotonated and Se-deprotonated anions, which can be generated from all the neutrals included in Fig. 1. In this survey, a total of 22 different conformers for the O-deprotonated anions and 16 for the Se-deprotonated structures have been characterized. The total free energies of all these anions have been summarized in Table S2 of the Supplementary data.

The different O-deprotonated species are rather close in energy, so that the energy gap between the most stable and the least stable one is only 14.3 kJ mol<sup>−1</sup>. For the oxygen deprotonated species, two different kind of conformers are normally found, which differ in the relative position of the amino group, with the most stable ones, namely A1O<sup>−</sup>, A4O<sup>−</sup>, A5O<sup>−</sup>, being those that exhibit the shortest O–H–N distance. Conversely, the energy gap between the most and the least stable Se-deprotonated species is much higher, 68.7 kJ mol<sup>−1</sup>. As we shall discuss later, this is a consequence of the formation of quite strong IMHBs between the Se atom, acting as a HB acceptor, and the OH group, acting as a HB donor, which significantly stabilizes some conformers.

The most important finding, however, is that the lowest-energy O-deprotonated species lies 18.8 kJ mol<sup>−1</sup> higher in energy than the lowest-energy Se-deprotonated anion, D49Se<sup>−</sup> (see Fig. 3), which would be the result of the direct deprotonation of the most stable D-type conformer (D49). Since, as we have mentioned above, a direct deprotonation of the three neutrals that likely exist in the gas phase (A1, A4, and A5) leads to the loss of the proton attached to the OH group, it is necessary to explore whether the anion so formed, namely A1O<sup>−</sup>, A4O<sup>−</sup>, and A5O<sup>−</sup>, can evolve to yield the global minimum of the PES, which is a Se-deprotonated species. In other words, we need to answer the question of whether HSEC is an O or Se acid in the gas phase.

In Fig. 4, we show the potential energy curve associated with the evolution from A5O<sup>−</sup> towards D49Se<sup>−</sup>. It should be noted that the evolution from A1O<sup>−</sup> or A4O<sup>−</sup> would imply

**Fig. 4.** Energy profile connecting the anion obtained by direct deprotonation of conformer A5 and the most stable deprotonated species, D49Se<sup>−</sup>. Energies relative to the A5O<sup>−</sup> anion are in kJ mol<sup>−1</sup>.

only an extra internal rotation of the SeH group, connecting these forms with A5O<sup>−</sup>, and they require rather low activation barriers (5.2 and 5.8 kJ mol<sup>−1</sup> for A1O<sup>−</sup> → A5O<sup>−</sup> and A4O<sup>−</sup> → A5O<sup>−</sup>, respectively).

As shown in Fig. 4, the first step in the A5O<sup>−</sup> → D49Se<sup>−</sup> isomerization implies an internal rotation around the C1–C3 bond (see Scheme 1), which leads to the intermediate A6O<sup>−</sup>. From here, a subsequent internal rotation around C3–C13 leads to the global minimum. This is so because as soon as the Se–H group is adequately oriented towards the deprotonated oxygen atom, a spontaneous proton transfer takes place, leading to the formation of the most stable Se-deprotonated structure. Taken into account that the activa-

The grey lobes correspond to disynaptic basins involving H atoms, red lobes to monosynaptic lone-pair basins, and green lobes to disynaptic bonding basins between nonhydrogen atoms. The population of these basins is given in e<sup>−</sup>.

tion barriers associated with these isomerization process are systematically lower than 20 kJ mol<sup>−1</sup>, and that the energy liberated in the interaction between a neutral system and an anion, which is the typical way in which the deprotonation process takes place in an ICR experiment, is much higher,<sup>39</sup> we can safely conclude that, once the oxygen deprotonated species (either A1O<sup>−</sup>, A4O<sup>−</sup>, or A5O<sup>−</sup>) is produced by the direct deprotonation of the corresponding neutral system, the anion will have enough internal energy to isomerize to the most stable Se-deprotonated species; therefore, HSEC would behave as a Se acid in the gas phase. Since forms A2 and D49 are directly connected by a simple OH internal rotation, we have also investigated the interconversion between A2O<sup>−</sup> and D49Se<sup>−</sup> (see Fig. S3 of the Supplementary data). Although this isomerization would be possible, it must be recalled that A2 is not easily accessible and therefore, the most likely way to produce D49Se<sup>−</sup> is that shown in Fig. 4. The estimated  $\Delta_{\text{acid}}H$ , taking into account the intrinsic acidity of each of the three neutral species A1, A4, and A5 and their statistical distribution, is 1374 kJ mol<sup>−1</sup> and the corresponding  $\Delta_{\text{acid}}G$  is 1351 kJ mol<sup>−1</sup>.

The enhanced stability of the D49Se<sup>−</sup> is closely related with the existence of a O–H...Se IMHB, as corroborated by (i) the existence of a BCP with a reasonably high electron density, (ii) the existence of a ring critical point (see Fig. 5a), (iii) the large O–H bond length (1.027 Å), and (iv) the strong second-order interaction energy (177 kJ mol<sup>−1</sup>) between the lone pairs of the Se atom and the  $\sigma_{\text{OH}}^*$  antibonding orbital, pointing out a significant charge donation from the former to the latter, which is reflected in the quite large population of the  $\sigma_{\text{OH}}^*$  antibonding orbital (0.371 e<sup>−</sup>). This strong interaction is a clear consequence of the high polarizability of the Se lone pairs and to the fact that in spite of the large H...Se internuclear distance (2.155 Å), the real distance between the hydrogen and the Se lone-pairs is much shorter, as nicely shown by the ELF of the system (see Fig. 5b).

### Gas-phase basicity

As expected, for the three neutral species A1, A4, and A5, the amino nitrogen is the most favorable protonation site.

**Fig. 6.** B3LYP/6-311+G(d,p) optimized structures of the most stable cations produced by the protonation of the A1, A4, and A5 conformers of HSEC. The global minimum, C32NH<sup>+</sup>, corresponds to the direct deprotonation of the C32 conformer. Some significant internuclear distances are given in Å. Gibbs free energies relative to D49Se<sup>−</sup> are given within parentheses.

Furthermore, when these conformers are protonated at the carboxylic oxygen, a spontaneous proton transfer towards the amino group takes place, so the amino protonated species is systematically generated. Only for B8 and D49, the most stable B-type and D-type isomers, the O-protonated species was found to be stable because the carbonyl oxygen is far from the amino group and (or) because the OH group does not point towards the amino group. Interestingly, for the more stable C-type isomer, C17, the protonation at the carbonyl group triggers a spontaneous proton transfer from the hydroxyl group (not directly protonated) towards the amino group, so in this case, only the N-protonated species is found. Protonation at the SeH group is much less favorable, with the calculated proton affinities being about 90 kJ mol<sup>−1</sup> lower than those estimated for the corresponding N-protonated species. As a matter of fact, the protonation at the SeH group of species A2 and A3, where the distance between the amino group and the SeH group is not too big, is also followed by a

**Fig. 7.** (a) The C32NH<sup>+</sup> cation molecular graph. Red and yellow dots denote the bond and ring critical points, respectively. Electron densities are given in au. (b) Three-dimensional representations of ELF isosurfaces with ELF = 0.80. The grey lobes correspond to disynaptic basins involving H atoms, red lobes to monosynaptic lone-pair basins, and green lobes to disynaptic bonding basins between nonhydrogen atoms. The population of these basins is given in e<sup>-</sup>.

proton transfer from the latter to the former, so that only the N-protonated species exists as stationary points of the PES.

The direct protonation of species A1, A4, and A5 yield N-protonated forms, namely A1NH<sup>+</sup>, A3NH<sup>+</sup>, and A5NH<sup>+</sup>, which are rather close in energy (see Fig. 6). However, due to the flexibility of the alkyl chain, many other possible conformers are possible. To be able to obtain a reliable proton affinity for this system, it is necessary to carefully explore the PES associated with the N-protonated species. This exploration was carried out using the N-protonated forms of the 10 neutrals included in Fig. 1 as starting points. In this way, a total of 23 different stationary points could be identified, the global minimum being the C32NH<sup>+</sup> structure shown in Fig. 6. The total free energies and the optimized geometries of all these cations have been summarized in Table S2 and Fig. S1 of the Supplementary data. The enhanced stability of this form is a consequence of the formation of an IMHB between the protonated amino group, which is an excellent proton donor, and the SeH group, which acts as HB acceptor. This is reflected in the corresponding molecular graph by the existence of a BCP between one of the amino hydrogens and the Se atom, as well as by the existence of a ring critical point. (see Fig. 7) Also, a consistently significant interaction between the Se lone pairs and the  $\sigma_{\text{NH}}^*$  antibonding orbital is detected in the NBO second-order perturbation analysis, which is reflected by a sizable lengthening of the N–H bond involved in the IMHB, which is 0.03 Å longer than those not interacting with the SeH group.

The isomerization from A1NH<sup>+</sup>, A3NH<sup>+</sup>, and A5NH<sup>+</sup> towards the global minimum is the next question to be addressed to calculate the proton affinity of HSEC. In Fig. 8, we present the corresponding energy profile for the A1NH<sup>+</sup> → C32NH<sup>+</sup> isomerization. It can be observed that this isomerization is a two-step process. The first one, through an activation barrier of only 3.8 kJ mol<sup>-1</sup>, leads to the A5NH<sup>+</sup> protonated species, which finally evolves to yield the global minimum, C32NH<sup>+</sup>, through an activation barrier 13.3 kJ mol<sup>-1</sup> high.

Hence, we can conclude that although the direct protonation of the three neutrals, A1, A4, and A5, yield three different cations, these cations have enough internal energy to isomerize yielding the global minimum, C32NH<sup>+</sup>. Accordingly, the proton affinity of HSEC can be estimated to be 930 kJ mol<sup>-1</sup> by using the statistical distribution of the three

**Fig. 8.** Energy profile connecting the cation obtained by direct protonation of conformer A1 and the most stable protonated species, C32NH<sup>+</sup>. Energies relative to A1NH<sup>+</sup> cation are in kJ mol<sup>-1</sup>.

neutrals, A1, A4, and A5, and their intrinsic basicities. The corresponding gas-phase basicity will be 891 kJ mol<sup>-1</sup>.

## Conclusions

Seventy-seven different conformers for L-homoselenocysteine have been located as local minima of the PES of this amino acid by means of B3LYP/6-311+G(d,p) calculations. These local minima can be classified into four groups of conformers attending to the local conformation of the amino acid moiety. Structures A, B, and D are stabilized by an IMHB in which the amino group always acts as a HB donor, whereas, in structures A and D, the HB acceptor is the carbonyl group and in structure B the hydroxyl group. The structures in set C present an IMHB with the amino group acting as the HB acceptor and the hydroxyl group as the HB donor. The stability order decreases in the following

order: A > B > C > D, so that the seven most stable conformers belong to group A. From their relative stabilities and taking into account the barriers connecting them, it can be concluded that, very likely, only three of these conformers, namely A1, A4, and A5, would exist in the gas phase at room temperature. The PES associated with the anions formed by deprotonation of HSEC is also conformationally rich, with the global minimum being a Se-deprotonated species stabilized by a strong IMHB between the hydroxyl group and the Se atom. However, a direct deprotonation of the most stable neutrals lead to O-deprotonated species, which eventually isomerize to yield the global minimum. Hence, we can conclude that, quite unexpectedly, HSEC behaves as a Se acid in the gas phase.

The intrinsic acidity of HSEC was estimated to be 1374 kJ mol<sup>-1</sup> at the B3LYP/6-311++G(3df,2p) level of theory.

The PES associated with the protonated forms of HSEC is also conformationally rich, but the most stable protonated forms are systematically the N-protonated ones. The global minimum is again stabilized through a IMHB involving the protonated amino group as HB donor and the SeH group as HB acceptor. The calculated PA at the B3LYP/6-311++G(3df,2p) level of theory is 930 kJ mol<sup>-1</sup>.

# Diagnostics of molecular orbital quality

Jia Deng, Andrew T.B. Gilbert, and Peter M.W. Gill

**Abstract:** We discuss several measures of the quality of a molecular orbital. Each requires only that the orbital be associated with a well-defined Fock operator and is thus applicable to both Hartree–Fock and density functional orbitals. One of the measures, the  $\gamma$  diagnostic, ranges from  $\gamma = 0$  (perfect) to  $\gamma = \pi/2$  (poor) and is conceptually simple. We illustrate its usefulness by applying it to a number of small atoms and ions.

**Key words:** molecular orbital quality, density functional theory, Hartree–Fock.

**Résumé :** On discute de plusieurs mesures de la qualité d'une orbitale moléculaire. Chacune nécessite uniquement que l'orbitale soit associée à un opérateur de Fock bien défini et qu'il soit ainsi applicable aux orbitales de Hartree–Fock ainsi qu'aux fonctionnelles de densité. L'une de ces mesures, le diagnostic, s'étend de 0 (parfait) à  $\pi/2$  (mauvais) et elle est conceptuellement simple. On illustre son utilité en l'appliquant à un certain nombre de petits atomes et de petits ions.

**Mots-clés :** qualité d'une orbitale moléculaire, théorie de la fonctionnelle de la densité, Hartree–Fock.

## Introduction

Some say that quantum chemistry is a branch of applied mathematics and that, by implication, quantum chemists are applied mathematicians. One can certainly mount a strong argument in favor of this. After all, quantum chemistry is primarily concerned with finding approximate solutions to a certain linear second-order partial differential equation and using those solutions to comprehend the chemical behavior of matter. However, if we are indeed applied mathematicians, we break one of the cardinal rules of our order: with few exceptions, we never check how well our “solutions” satisfy the equation!

*How well does a given wave function satisfy the Schrödinger equation?* At the conclusion of a quantum chemical calculation, any self-respecting software package ought to address this question and provide a quantitative answer that the user can interpret as a quality measure. However, it turns out that this raises a number of interesting mathematical issues, and we have therefore sought initially to address the more modest question: *How well does a given orbital satisfy its self-consistent field (SCF) equation?*

Standard practice in quantum chemistry is to gauge the quality of a molecular orbital by comparing it with the orbital obtained from a calculation with a larger basis set. However, this approach is both expensive and non-rigorous, for it is possible that the larger basis may suffer from the same deficiencies as the smaller one. Moreover, it is aesthetically unsatisfactory to judge an orbital by comparing it with another: it ought to be possible to appraise it purely on its own merits. In this paper, we propose a method for assessing the quality of a finite-basis SCF orbital in this way, without the need to perform a larger-basis calculation.

Although our approach is applicable to any orbital that is associated with a well-defined Fock operator, we will confine our numerical tests here to Hartree–Fock orbitals. The extension to density functional theory (DFT) orbitals is conceptually straightforward but requires consideration of DFT quadrature grids. We use atomic units throughout.

## Molecular orbital diagnostics

An exact orbital is an eigenfunction of its Fock operator.<sup>1</sup> However, an orbital  $\psi$  from a perfectly converged finite-basis Hartree–Fock<sup>2–4</sup> or Kohn–Sham<sup>5</sup> calculation is *not* an eigenfunction of its own Fock operator  $F$ , that is,

$$[1] \quad F\psi \neq \epsilon\psi$$

unless the basis happens to span the exact orbital.<sup>6</sup> This under-appreciated fact holds the key to our approach because the difference between the two sides of eq. [1] measures the quality of the orbital. There are several ways to exploit this. One approach is based on the local orbital energy

$$[2] \quad \epsilon(\mathbf{r}) = (F\psi)/\psi$$

If the orbital were perfect,  $\epsilon(\mathbf{r})$  would be constant everywhere; small imperfections in  $\psi$  will produce small variations in  $\epsilon(\mathbf{r})$ .

A second approach recognizes that the normalized versions of  $\psi$  and  $F\psi$  should be identical. Accordingly, the discrepancy

$$[3] \quad \delta(\mathbf{r}) = \frac{\psi}{\sqrt{\langle\psi|\psi\rangle}} - \frac{F\psi}{\sqrt{\langle F\psi|F\psi\rangle}}$$

**Fig. 1.** The  $\gamma$  diagnostic for the orbital  $\exp(-\alpha r)$  in the H atom.**Table 1.**  $\gamma$  values for Kellner orbitals in the He-like ions.

	H <sup>-</sup>	He	Li <sup>+</sup>	Be <sup>2+</sup>	B <sup>3+</sup>	C <sup>4+</sup>	N <sup>5+</sup>
Z	1	2	3	4	5	6	7
$\gamma$	0.488	0.063	0.033	0.023	0.017	0.014	0.012

should vanish at all points  $\mathbf{r}$  and, wherever it fails to do so, it reveals deficiencies in the orbital.

A third approach determines the angle

$$[4] \quad \gamma = \cos^{-1} \sqrt{\frac{\langle \psi | \mathbf{F} \psi \rangle^2}{\langle \psi | \psi \rangle \langle \mathbf{F} \psi | \mathbf{F} \psi \rangle}}$$

$$= \tan^{-1} \sqrt{\frac{\langle \psi | \psi \rangle \langle \mathbf{F} \psi | \mathbf{F} \psi \rangle}{\langle \psi | \mathbf{F} \psi \rangle^2} - 1}$$

between  $\psi$  and  $\mathbf{F}\psi$ . Unlike  $\epsilon(\mathbf{r})$  and  $\delta(\mathbf{r})$ , which are functions,  $\gamma$  is a number between 0 (perfect) and  $\pi/2$  (poor) and achieves the former value if, and only if,  $\psi$  is an eigenfunction of  $\mathbf{F}$ .

To calculate numerical values of  $\gamma$ , we must choose a suitable inner product  $\langle \cdot | \cdot \rangle$ . The overlap metric

$$[5] \quad \langle f | g \rangle = \int f(\mathbf{r})g(\mathbf{r})d\mathbf{r}$$

is an obvious choice but it yields poor  $\gamma$  values if the orbital fails to possess the correct nuclear cusps. This is a particularly serious problem if the orbital is expanded in a nuclear-centered Gaussian basis because, close to a nucleus, any Gaussian is flat and consequently  $\mathbf{F}\psi \sim (-Z/r)\psi$  is singular.

Because of the widespread popularity of Gaussian basis sets, we prefer an inner product that is less sensitive to such cusp violations. We have found that the Coulomb metric

$$[6] \quad \langle f | g \rangle = \iint \frac{f(\mathbf{r}_1)g(\mathbf{r}_2)}{r_{12}} d\mathbf{r}_1 d\mathbf{r}_2$$

works well and we have adopted it throughout this work. If  $\psi$  is a sum of Gaussians, all of the inner products needed for atoms can be evaluated in terms of elementary functions, using integrals such as

$$[7] \quad \left\langle \frac{e^{-b^2 r^2}}{r} \middle| \frac{e^{-d^2 r^2}}{r} \right\rangle = 4\pi^{5/2} \frac{b+d-\sqrt{b^2+d^2}}{b^2 d^2}$$

A table of such integrals is given in the Appendix.

In this preliminary exploration, we will investigate the performance of the  $\gamma$  diagnostic (eq. [4]) in very small systems. The primary question is whether or not  $\gamma$  behaves “reasonably”.

## Examples

### Hydrogen atom

This one-electron system has the Fock operator

$$[8] \quad \mathbf{F} = -\frac{\nabla^2}{2} - \frac{1}{r}$$

and its true orbital is  $\exp(-r)$ . To begin our exploration of the  $\gamma$  diagnostic, we consider an HF calculation using the single basis function  $\exp(-\alpha r)$ . The computed orbital will differ from the true orbital except, of course, when  $\alpha = 1$ .

The  $\gamma$  diagnostic (eq. [4]), using the Coulomb metric (eq. [6]), is

$$[9] \quad \gamma = \tan^{-1} \left| 2 \frac{\alpha - 1}{\alpha - 6} \right|$$

and this is plotted, for  $0 < \alpha < 10$ , in Fig. 1. As expected,  $\gamma$  vanishes for  $\alpha = 1$  and grows almost linearly as  $\alpha$  deviates from this optimal value. For  $\alpha = 6$ , it turns out that  $\psi$  and  $\mathbf{F}\psi$  are exactly orthogonal, i.e., the angle between them is  $\pi/2$ .

### Helium-like ions

These two-electron systems have the Fock operator

$$[10] \quad \mathbf{F} = -\frac{\nabla^2}{2} - \frac{Z}{r} + \int \frac{\psi(\mathbf{r}')^2}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r}'$$

where  $Z$  is the nuclear charge. The true HF orbital is unknown, but if we approximate it by the Kellner orbital<sup>7</sup>

$$[11] \quad \psi(\mathbf{r}) = \exp(-\alpha r)$$

the HF energy is minimized by choosing  $\alpha = Z - 5/16$ .

How satisfactory is this orbital? It can be shown that

$$[12] \quad \gamma = \tan^{-1} \left| \frac{a}{Z - b} \right|$$

where  $a = \sqrt{1987/388800}$  and  $b = 623/720$  and this is evaluated in Table 1 for  $Z = 1, \dots, 7$ . These results reveal that the Kellner orbital is a good approximation ( $\gamma \approx 0.01$ ) to the true orbital for large- $Z$  ions, such as  $\text{C}^{4+}$  and  $\text{N}^{5+}$ , that it is reasonable ( $\gamma \approx 0.05$ ) for the He atom itself, but that it is very poor ( $\gamma \approx 0.5$ ) for the  $\text{H}^-$  ion. This may be related to the difficulties that Cioslowski and others have encountered when seeking an accurate HF orbital for the hydride anion.<sup>8,9</sup>

### Hookium atom

This two-electron system<sup>10,11</sup> has the Fock operator

$$[13] \quad \mathbf{F} = -\frac{\nabla^2}{2} + \frac{r^2}{8} + \int \frac{\psi(\mathbf{r}')^2}{|\mathbf{r} - \mathbf{r}'|} d\mathbf{r}'$$

and its true HF orbital is unknown. However, neglecting the

**Table 2.**  $\gamma$  values for Gaussian and Ragot orbitals in hookium.

Orbital	Equation	$\alpha$	$\beta$	$\gamma$
Gaussian	[14]	0.25	—	0.0430
Gaussian	[14]	0.210 549 021	—	0.0142
Ragot	[15]	0.25	2.771 219 931	0.0007
Ragot	[15]	0.251 117 376	2.711 087 898	0.0002

**Table 3.**  $\gamma$  values for pc-*n* and aug-pc-*n* orbitals in small atoms and ions.

		pc- <i>n</i>					aug-pc- <i>n</i>				
	Orbital	0	1	2	3	4	0	1	2	3	4

Li <sup>+</sup>	1s	0.0297	0.0151	0.0119	0.0122	0.0042	0.0295	0.0152	0.0109	0.0124	0.0042
Be	1s	0.0349	0.0153	0.0082	0.0091	0.0034	0.0339	0.0150	0.0079	0.0093	0.0034
	2s	0.0881	0.0203	0.0123	0.0029	0.0031	0.0358	0.0147	0.0152	0.0029	0.0030

electron repulsion yields the harmonic oscillator wave function  $\exp(-r^2/4)$  and one may therefore anticipate that

$$[14] \quad \psi(\mathbf{r}) = \exp(-\alpha r^2)$$

may be a good guess. The HF energy of this orbital, using an optimized exponent, lies 1.5  $mE_h$  above the HF limit. However, Ragot has recently claimed<sup>12</sup> that the modified orbital

$$[15] \quad \psi(\mathbf{r}) = \sqrt{r^2 + \beta^2} \exp(-\alpha r^2)$$

is very much better, provided that  $\alpha$  and  $\beta$  are chosen carefully, and constructs two orbitals of this form, lying 4.5 and 0.6  $\mu E_h$  above the HF limit, respectively.

The  $\gamma$  diagnostic allows us to compare the quality of these orbitals, and though we have not been able to find  $\gamma$  in closed form for eq. [15] the required integrals can be found by quadrature. The results shown in Table 2 reveal that the Gaussian (eq. [14]) is a good approximation to the exact orbital but that the Ragot orbitals (eq. [15]) are superior by one to two orders of magnitude.

### Other small systems

Table 3 lists  $\gamma$  values for the orbitals in some small atoms and ions, using Jensen's pc-*n* basis sets.<sup>13,14</sup>

H and He<sup>+</sup> ions are one-electron species whose 1s orbitals are modeled well by the pc-*n* bases. It is not surprising that the He<sup>+</sup> orbital is slightly inferior to that of H, for the helium bases were designed to be optimal for the neutral atom, not the much more compact cation. Nevertheless, the triple-zeta pc-2 orbitals are good and the pc-3 and pc-4 orbitals are excellent.

The 2s orbitals (the LUMOs in these species) tell a very different story. In the H atom, the  $\gamma$  values are appalling, and actually deteriorate as the basis set quality improves. This arises because, in the HF picture, the virtual orbitals of the H atom experience an exponentially decaying attractive potential and therefore describe essentially free electrons.

Of course, nuclear-centered Gaussian basis sets (e.g., aug-pc-*n*) cannot capture such behavior. The situation is better in He<sup>+</sup> because the virtual orbitals experience a Coulombic attractive potential and, consequently, approximate the standard hydrogenic orbitals. Although they are too diffuse to be modelled well by pc-0, pc-1, and pc-2, the higher aug-pc-*n* bases do a better job.

H<sup>-</sup>, He, and Li<sup>+</sup> are isoelectronic but it is clear that their pc-*n* 1s orbitals vary greatly in quality. While good orbitals are provided by pc-1 (for Li<sup>+</sup>), and pc-2 (for He), a satisfactory orbital for the hydride ion is not obtained even with the septuple-zeta pc-4 basis. This arises because the second electron in H<sup>-</sup> is barely bound, and diffuse functions therefore play a crucial role in the basis. Accordingly, we find that the aug-pc-*n* orbital is consistently almost an order of magnitude better than its pc-*n* analog; indeed, even the lowly aug-pc-0 orbital exceeds the quality of the pc-4 orbital.

The last two lines in Table 3 pertain to the core and valence orbitals in the Be atom. We find that the 1s orbital is accurately modelled, even by the small pc-*n* bases, but that the 2s orbital is more challenging and benefits significantly from the addition of diffuse functions. It is surprising to find that, in passing from the pc-2 to the pc-3 basis set, the valence orbital improves dramatically but the core orbital actually becomes slightly worse. This anomaly is unaffected by the addition of diffuse functions.

### Concluding remarks

It is impossible to assess the quality of an SCF calculation from its energy alone, and as a result, quantum chemists have traditionally been compelled to perform sequences of calculations, looking for signs of convergence as the basis set is systematically improved. In contrast, the  $\gamma$  diagnostic (eq. [4]) exploits the inequality (eq. [1]) to provide a chemist with a direct measure of the quality of a computed orbital.

Using the Coulomb metric (eq. [6]), it appears empirically

that “reasonable” orbitals have  $\gamma \leq 0.05$ , “good” orbitals have  $\gamma \leq 0.01$ , and “excellent” orbitals have  $\gamma \leq 0.005$ .

In this preliminary work, we have computed  $\gamma$  for single-center systems only. To facilitate the efficient calculation of  $\gamma$  for the MOs in polyatomic molecules, the integrals in the Appendix must be generalized to the multicenter case. In large systems, straightforward evaluation of the  $\langle F\psi | F\psi \rangle$  integral becomes computationally costly, but techniques based on the resolution of the identity (RI)<sup>15–17</sup> or resolution of the Coulomb operator<sup>18–20</sup> should be helpful in this context.

In the case of Kohn–Sham orbitals, the inner products in eq. [4] involving  $F\psi$  cannot be computed in closed form, and one must resort instead to quadrature. We will discuss this elsewhere.

In this brief paper, we have proposed a diagnostic to quantify orbital quality and have studied its performance on a few very small atoms and ions. We will implement this in the Q-Chem package<sup>21</sup> and will report molecular results elsewhere. We also plan to extend these ideas to a wave function diagnostic in the near future.

## Appendix

Table A1 contains the fundamental integrals<sup>A1</sup> (in the Coulomb metric) that are required to form  $\gamma$  in single-center systems, such as atoms.

In the final expression, the integration limits are

$$[A1] \quad X = \frac{a}{\sqrt{a^2 + b^2}} \frac{d}{\sqrt{b^2 + d^2}}$$

**Table A1.** Integrals required to form the  $\gamma$  diagnostic (eq. [4]) in atomic systems.

$\langle f   g \rangle$	$\exp(-d^2 r^2)$	$-\frac{\nabla^2}{2} \exp(-d^2 r^2)$	$\frac{\text{erf}(cr)}{r} \exp(-d^2 r^2)$
$\exp(-b^2 r^2)$	$\frac{2\pi^{5/2}}{b^2 d^2 \sqrt{b^2 + d^2}}$	$\frac{2\pi^{5/2}}{(b^2 + d^2)^{3/2}}$	$\frac{4\pi^2}{b^3 d} \tan^{-1} \left[ \frac{b}{d} \frac{c}{\sqrt{b^2 + c^2 + d^2}} \right]$
$-\frac{\nabla^2}{2} \exp(-b^2 r^2)$	$\frac{2\pi^{5/2}}{(b^2 + d^2)^{3/2}}$	$\frac{6\pi^{5/2} b^2 d^2}{(b^2 + d^2)^{3/2}}$	$\frac{4\pi^2}{b^2 + d^2} \frac{c}{\sqrt{b^2 + c^2 + d^2}}$
$\frac{\text{erf}(ar)}{r} \exp(-b^2 r^2)$	$\frac{4\pi^2}{bd^3} \tan^{-1} \left[ \frac{d}{b} \frac{a}{\sqrt{a^2 + b^2 + d^2}} \right]$	$\frac{4\pi^2}{b^2 + d^2} \frac{a}{\sqrt{a^2 + b^2 + d^2}}$	$\left( \frac{4\pi}{bd} \right)^{3/2} \sqrt{\frac{b^2 + d^2}{bd}} \int_0^X \int_0^Y \frac{dx dy}{\sqrt{1 - x^2 - y^2}}$

$$[A2] \quad Y = \frac{b}{\sqrt{b^2 + d^2}} \frac{c}{\sqrt{c^2 + d^2}}$$

The double integral is elementary and can be evaluated in terms of arctangents but the resulting expression is messy.

# Serine–Ca<sup>2+</sup> versus serine–Cu<sup>2+</sup> complexes — A theoretical perspective

Al Mokhtar Lamsabhi, Otilia Mó, and Manuel Yáñez

**Abstract:** The association of Ca<sup>2+</sup> and Cu<sup>2+</sup> to serine was investigated by means of B3LYP DFT calculations. The [serine–M]<sup>2+</sup> (M = Ca, Cu) potential energy surfaces include, as does the neutral serine, a large number of conformers, in which a drastic reorganization of the electron density of the serine moiety is observed. This leads to significant changes in the number and strength of the intramolecular hydrogen bonds existing in the neutral serine tautomers. In some cases, a proton is transferred from the carboxylic OH group to the amino group and accordingly, some of the more stable [serine–M]<sup>2+</sup> complexes can be viewed as the result of the interaction of the zwitterionic form of serine with the doubly charged metal ion. Whereas the interaction between Ca<sup>2+</sup> and serine is essentially electrostatic, that between Cu<sup>2+</sup> and serine has a non-negligible covalent character, reflected in larger electron densities at the bond critical points between the metal and the base, in the negative values of the electron density between the two interacting systems, and in much larger Cu<sup>2+</sup> than Ca<sup>2+</sup> binding energies. More importantly, the interaction with Cu<sup>2+</sup> is followed by a partial oxidation of the base, which is not observed when the metal ion is Ca<sup>2+</sup>. The main consequence is that in Cu<sup>2+</sup> complexes a significant acidity enhancement of the serine moiety takes place, which strongly favors the deprotonation of the [serine–Cu]<sup>2+</sup> complexes. This is not the case for Ca<sup>2+</sup> complexes. Thus, [serine–Ca]<sup>2+</sup> complexes, like those formed by urea, thiourea, selenourea, or glycine, should be detected in the gas phase. Conversely, the complexes with Cu<sup>2+</sup> should deprotonate spontaneously and therefore only [(serine–H)–Cu]<sup>+</sup> monocations should be experimentally accessible.

**Key words:** gas phase reactivity, transition metal, amino acids, DFT.

**Résumé :** On étudié l'association des cations Ca<sup>2+</sup> et Cu<sup>2+</sup> avec la sérine en utilisant la théorie de la fonctionnelle de la densité, B3LYP. Pour l'ion [sérine–M]<sup>2+</sup> (M = Ca, Cu), comme c'est le cas pour la sérine neutre, les surfaces d'énergie potentielle comportent un grand nombre de conformères dans lesquels on peut observer une réorganisation drastique de la densité électronique de la sérine. Ces changements conduisent à des changements significatifs dans le nombre et la force des liaisons hydrogènes intramoléculaires par rapport à celles qui existent dans les tautomères neutres de la sérine. Dans quelques cas, il se produit un transfert de proton du groupe OH de l'acide carboxylique vers le groupe amino et, en conséquence, un certain nombre des complexes les plus stables de l'ion [sérine–M]<sup>2+</sup> peuvent être considérés comme étant le résultat de l'interaction de la forme zwitterionique de la sérine avec l'ion métallique doublement chargé. Alors que l'interaction entre la Ca<sup>2+</sup> et la sérine est essentiellement électrostatique, celle entre le Cu<sup>2+</sup> et la sérine comporte un caractère covalent non négligeable qui est le reflet de densités électroniques plus grandes aux points critiques de liaison entre les deux systèmes en interaction ainsi que des énergies de liaisons beaucoup plus élevées pour le Cu<sup>2+</sup> que pour le Ca<sup>2+</sup>. Fait plus important, l'interaction avec le Cu<sup>2+</sup> est suivie d'une oxydation partielle de la base, ce qui n'est pas le cas quand l'ion métallique est le Ca<sup>2+</sup>. La conséquence principale est que dans les complexes du Cu<sup>2+</sup>, on observe une augmentation significative de l'acidité de la portion sérine qui favorise la déprotonation des complexes [sérine–Cu]<sup>2+</sup>. Ce n'est pas le cas avec les complexes Ca<sup>2+</sup>. En conséquence, il devrait être possible de détecter les complexes [sérine–Ca]<sup>2+</sup> en phase gazeuse, comme c'est le cas avec ceux formés avec l'urée, la thiourée, la sélénourée et la glycine. Inversement, les complexes qui résultent d'interactions avec le Cu<sup>2+</sup> devraient se déprotoner spontanément et seuls les monocations [(sérine–H)–Cu]<sup>+</sup> devraient être expérimentalement disponibles.

**Mots-clés :** réactivité en phase gazeuse, métal de transition, acides aminés, théorie de la fonctionnelle de la densité (TFD).

## Introduction

Serine is a chiral amino acid that can be found in proteins. It is also one of two hydroxyl amino acids and for that reason is highly hydrophilic and is commonly found in the outer regions of soluble proteins.<sup>1</sup> Serine is a good

model for studying peptide structures. Many studies have been devoted to understanding its behavior in gas phase,<sup>2–6</sup> solution,<sup>7–10</sup> and solid state.<sup>11,12</sup> One important characteristic of this molecule is the possibility of forming strong hydrogen bonds (HBs) between its HB-donor and HB-acceptor groups, which play an important role as far as the relative

<sup>1</sup>Corresponding author (e-mail: mokhtar.lamsabhi@uam.es).

stability of its conformers is concerned. Serine conformers, in the gas-phase, were classified into three groups (A, B, and C) according to the main intramolecular interaction they exhibit: A ( $\text{OH}_\text{A}$ -N hydrogen bond), B ( $\text{OH}_\text{C}$ -N), and C ( $\text{OH}_\text{A}$ -O=) (the subscripts A and C stand for alcohol and carboxylic group, respectively).<sup>5,13</sup> However, more types of intramolecular hydrogen bonds (IMHBs) than those mentioned above appear in this molecule, likely playing some role on its intrinsic reactivity and its solvation, in particular when the solvent is able to form hydrogen bonds with serine. This is the case of the water molecule which, is ubiquitous in biological media. Recently, Gong et al.<sup>14</sup> have carried out an exhaustive investigation on the interaction of serine with water, exploring the specific solvation of all the reactive sites of the aminoacid. In this paper, we address the question of the intrinsic reactivity of serine with respect to  $\text{Ca}^{2+}$  and  $\text{Cu}^{2+}$  in their ground states, both doubly charged ions being also of biochemical relevance.

Calcium is also ubiquitous in biological media and is an essential actor in diverse processes such as muscle contraction, cell motility, membrane adhesion, synaptic transmission, and hormone release. While sites for calcium binding are implicit in these and other calcium-regulated processes, detailed characterization of such binding sites is very important. Copper is also omnipresent in the biological media.<sup>15-18</sup> It participates in different processes, such as enzyme regulation and stabilization of nucleic acids. Recently, we pointed out the difference between  $\text{Ca}^{2+}$  and  $\text{Cu}^{2+}$  complexes with urea and thiourea in the gas phase.<sup>19</sup> In fact, the attachment of transition metal dications to an organic base (B) is immediately followed by a deprotonation of the system, so that only  $[\text{Cu}-(\text{B}-\text{H})]^+$  singly charged species are observed in the gas phase,<sup>20</sup> because the recombination energy (the negative of the second ionization energy) of  $\text{Cu}^{2+}$  is so high that in most neutral- $\text{Cu}^{2+}$  reactions in the gas phase, the doubly charged metal ion is able to oxidize the base. This is not the case, however, when dealing with alkaline-earth dications like  $\text{Ca}^{2+}$ , whose recombination energy is almost half that of  $\text{Cu}^{2+}$ , so that the  $[\text{Ca}-\text{B}]^{2+}$  complexes are stable and easily detected. As a matter of fact, the unimolecular reactivity of complexes between  $\text{Ca}^{2+}$  and different organic bases, namely urea, glycine, thiourea, and selenourea have been reported in the literature.<sup>21-23</sup> Thus, one of the objectives of the present study is to investigate whether the behavior of serine, which presents additional basic sites and the possibility of forming different intramolecular hydrogen bonds, is similar to that exhibited by the aforementioned bases or whether it exhibits some peculiarities.

## Computational Details

All calculations were performed with the Gaussian 03 package.<sup>24</sup> The B3LYP density functional theory (DFT) approach, which combines the Becke's<sup>25</sup> three-parameter non-local hybrid exchange potential with the nonlocal correlation of Lee, Yang, and Parr,<sup>26</sup> was used in all calculations. For geometry optimizations as well as for the calculation of harmonic vibrational frequencies, a 6-311G(d,p) basis set was employed. The different stationary points of the potential energy surface (PES) were identified as local minima or transition states in terms of the number of imaginary vibra-

tional frequencies. The corresponding zero-point energy corrections (ZPE) were scaled by the empirical factor 0.9806 proposed by Scott and Radom.<sup>27</sup>

To obtain more reliable energies for the local minima, final energies were evaluated by using the same functional combined with the 6-311++G(3df,2p) basis set for all atoms except for  $\text{Cu}^{2+}$ , where the (14s9p5d/9s5p3d) basis set of Wachters<sup>28</sup> and Hay<sup>29</sup> was used, supplemented with a set of (1s2p1d) diffuse functions and with three sets of *f* and one set of *g* polarization functions. It has been shown that this approach is well-suited to the study of this kind of systems, yielding binding energies in good agreement with experimental values.<sup>30-32</sup>

The basis set superposition error (BSSE) was not considered in the present study because, as has been previously reported, for the DFT and DFT/HF hybrid methods, this error is usually small when the basis set expansion is sufficiently flexible.<sup>33</sup>

The bonding in these complexes was analyzed by means of the natural bond orbital (NBO) partitioning technique<sup>34</sup> and the quantum theory of atoms in molecules (QTAIM).<sup>35,36</sup>

## Results and Discussions

It is well known that amino acids in the gas phase or isolated in noble gas matrices adopt the nonionic form ( $\text{H}_2\text{N}-\text{CHR}-\text{COOH}$ ),<sup>4,13,37</sup> whereas in the solid state or in solution they exist in the zwitterionic form ( $\text{H}_3\text{N}^+-\text{CHR}-\text{COO}^-$ ).<sup>5,6</sup> This has been experimentally confirmed for several amino acids, including glycine,  $\alpha$ - and  $\beta$ -alanine, proline, sarcosine, *N,N*-dimethyl-glycine, and  $\gamma$ -aminobutyric acid, by studies based on electron diffraction, as well as on microwave, and matrix-isolation infrared spectroscopy techniques.<sup>37-44</sup> The stabilization of the zwitterionic form in the condensed phases is essentially due to dipolar interactions and intermolecular H-bonds. Hence, one of the major problems associated with the theoretical study of the amino acids is the abundance of different conformers.<sup>45</sup> Excluding the zwitterionic forms, the number of conformers could exceed 324 trial structures, as has been pointed out by Gronert and O'Hair.<sup>46</sup> For serine, a total of 51 conformers have been found to lie within an energy gap of 50 kJ/mol, at MP2/6-31+G\*\*/HF/6-31G\* level of theory.<sup>46</sup> Since the main aim of our study is not to explore the different conformations of serine but to look at the characteristics of its complexes with  $\text{Ca}^{2+}$  and  $\text{Cu}^{2+}$  dications, we have selected for our survey the eleven most stable ones, shown in Fig. 1. From these eleven conformations, different coordinations of the doubly charged metal ion to serine can be envisaged. The B3LYP/6-311G(d,p) optimized geometries for the most stable  $[\text{serine}-\text{Ca}]^{2+}$  and  $[\text{serine}-\text{Cu}]^{2+}$  complexes are reported in Figs. 2 and 3, respectively. Their B3LYP/6-311++G(3df,2p)//6-311G(d,p) relative energies with respect to the corresponding most stable  $[\text{serine}-\text{M}]^{2+}$  ( $\text{M} = \text{Ca}, \text{Cu}$ ) complex are listed in Table 1. Similar information for the more stable serine conformers is provided in the same table.

Serine is very rich, conformationally speaking, because a simple rotation of the hydroxyl group, or around the N-C or C-C bonds, may connect different conformers through activation barriers which are not very high. Although a detailed

**Fig. 1.** Optimized geometries of neutral conformers of serine. Some internuclear distances are shown in Å.

discussion of the conformations of serine is not the aim of this paper, some interesting features regarding their relative stabilities should be highlighted. Four conformers, N3, N5, N6, and N10, appear to be very close in energy, the maximum energy gap between them being about 3 kJ/mol. The least stable ones within the subset of the 15 more stable conformers are relatively close in energy, the energy gaps with respect to the global minimum varying from 6 to 19 kJ/mol. According to the work of Gong et al.,<sup>14</sup> the most stable conformer should be the structure N5 whereas from the calculations of Jarmelo et al.<sup>4</sup> N5 and N6 conformers are almost degenerate, the energy gap between them being 0.7 kJ/mol. However, it should be taken into account that Gong et al.<sup>14</sup> did not consider structure N6 in their survey and Jarmelo et al.<sup>4</sup> did not include the conformer N10 among the most stable tautomers.

The most important common characteristic of these conformers is the existence of several intramolecular hydrogen bonds (IMHB). Whereas in the conformers N3, N5, and N10 two IMHBs contribute to stabilizing these structures,

three IMHBs are responsible for the stability of the conformer N6. In the latter case, three out of the four of the serine's heteroatoms are involved in these IMHBs, either as HB-donors or as HB-acceptors (NH and OH groups). It can be also observed that the HB distances are in the range 1.90–1.92 Å when the nitrogen atom behaves as an HB-acceptor towards the OH group of the carboxylic moiety. When the HB donor is the OH alcoholic group, the bond length is longer (about 2.1 Å). The bond lengths of the IMHBs, in which the carboxylic group is the HB-acceptor, are in the range 2.113 Å (in N3) to 2.637 Å (in N6). Hence, one important question would be whether the interaction with the metal dication will affect significantly this network of IMHBs or not. Since serine presents different basic centers, many different adducts, resulting from the direct interaction with the metal dication, can be envisaged (see Figs. 2 and 3). Complexes **g** and **h** have their origin in conformer N6, complexes **j** and **k** are produced from conformer N5, the neutral form N10 yields complex **i**, and association to N3 yields complexes **a** and **b**. The other complexes are generated by the interaction of the dication with the remaining

**Fig. 2.** Optimized geometries of [serine-Ca]<sup>2+</sup> complexes. Some internuclear distances are shown in Å.

neutral conformers followed, in most of the cases, by an internal molecular reorganization.

The most stable complex (see Table 1), is structure **i** in which the metal coordinates to three of the most basic sites of the serine molecule. This interaction cleaves the intramolecular hydrogen bonds existing in the neutral form. The second most stable adduct is complex **g** where the metal is bisligated to the two oxygen atoms of the carboxylic acid moiety. Its relative energy with respect to the most stable complex **i** is about 19 and 18 kJ/mol for [serine-Ca]<sup>2+</sup> and [serine-Cu]<sup>2+</sup> complexes, respectively. It is worth noting that in complex **g** the interaction of the metal leads to a spontaneous proton transfer from the carboxylic group towards the amino group, so the complex can be considered

as the result of the association of the double charged metal ion to the zwitterionic form of serine. The same is true as far as complexes **b**, **c**, and **h** are concerned. This indicates that the association of the metal cation to serine involves a dramatic redistribution of electron density within the organic moiety, which significantly affects the strength and even the existence of the IMHBs. It is obvious, for instance, from Figs. 1–3 that the formation of the global minimum **i** implies the cleavage of the two IMHBs existing in the neutral N10 conformer. However there are some subtle differences in these electron density reorganizations when Ca<sup>2+</sup> and Cu<sup>2+</sup> complexes are compared with each other. This is apparent when the strengths of the N–H···O HBs in complexes **b**, **c**, **g**, and **h** for Ca<sup>2+</sup> containing complexes (see Fig. 2) are

**Fig. 3.** Optimized geometries of [serine-Cu]<sup>2+</sup> complexes. Some internuclear distances are shown in Å.

compared with the Cu<sup>2+</sup> analogues (see Fig. 3). The association of the metal dication to the CO<sub>2</sub> group of the zwitterionic form of serine is followed by a charge transfer, or a strong polarization, from this group towards the metal. Accordingly, the HB acceptor ability of the oxygen atom participating in the bond decreases because it is a poorer electron donor. However, this effect is clearly stronger in Cu<sup>2+</sup> than in Ca<sup>2+</sup> complexes, and the NH...O IMHBs are weaker in the former than in the latter, and therefore the bond lengths are systematically 0.2 Å longer. This is also mirrored in the topology of the electron density. As shown in Fig. 4 for the particular case of **g** complexes, whereas for the Ca<sup>2+</sup> containing system a bond critical point associated

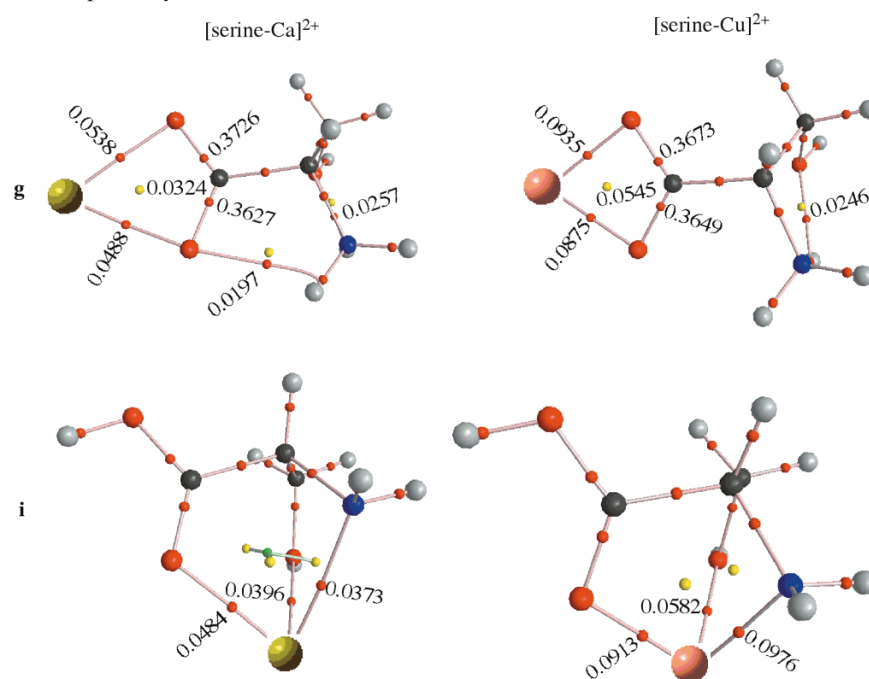

with the NH...O IMHB is found, such a BCP does not exist for the Cu<sup>2+</sup> containing analogue.

These results point to significant differences in the characteristics of the bonding depending on the nature of the metal dication. These differences are nicely reflected in the energy density maps of the global minima (see Fig. 5) which show that while the energy density between the metal and the organic moiety is positive in the case of Ca<sup>2+</sup> complexes, as it corresponds to an electrostatic interaction, for the Cu<sup>2+</sup> analogues it is negative, indicating that in this latter case the covalent character of the interaction is not at all negligible. Consistently, no covalent bonds between Ca and the serine basic centers are found in the NBO analysis, whereas the

**Fig. 4.** Molecular graphs of structures **i** and **g** of [serine-M]<sup>2+</sup> (M = Ca, Cu) complexes. Red dots and yellow dots represent bond critical points and ring critical points, respectively. Electron densities are in au.

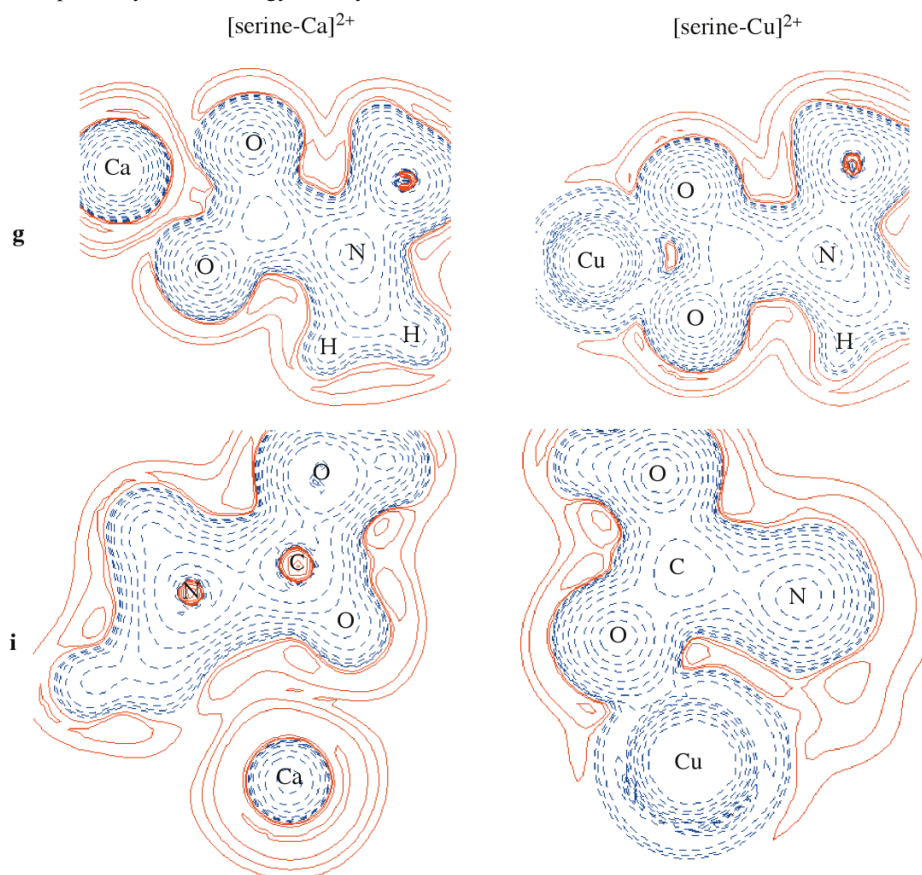

Cu-O<sub>C</sub> and N-Cu covalent bonds are found, with a very large participation of the p orbitals of O<sub>C</sub> (97%) and N (87%) and a small contribution from the 4s in Cu. Consistently, the bond order (BO) of the O<sub>C</sub>-M, O<sub>A</sub>-M, and N-M (M = Ca, Cu) linkages are much smaller for the Ca<sup>2+</sup> complex (0.0863, 0.0617, and 0.0826, respectively) than for the Cu<sup>2+</sup> containing analogue (0.091, 0.2113, and 0.2656, respectively). Besides the N-Cu and O-Cu bonds indicated above, a second-order NBO perturbation analysis shows also a strong charge donation from one of the lone pair of the alcoholic oxygen to the 4s empty orbital of copper, proving that in the global minimum, Cu is truly tricoordinated. The partially covalent character of the interactions with Cu is also reflected in the electron density at the corresponding BCPs, which are about twice as large as those calculated for the corresponding Ca<sup>2+</sup> complex. Thus, not surprisingly, the

calculated binding energy of Cu<sup>2+</sup> to serine (1054 kJ/mol) is about twice the binding energy estimated for Ca<sup>2+</sup> (567 kJ/mol).

The significant differences in the reorganization of the electron density of the serine, when interacting with Cu<sup>2+</sup> and Ca<sup>2+</sup>, have their origin in the huge difference between the recombination energy for both dications (20.29 eV for Cu<sup>2+</sup> but only 12.03 eV for Ca<sup>2+</sup>).<sup>47</sup> Hence, while the association of Cu<sup>2+</sup> with serine is followed by a partial oxidation of the amino acid as has been found in the interaction of Zn<sup>2+</sup> with thymine<sup>32</sup> and thio-oxazolidine,<sup>48</sup> no oxidation is observed upon Ca<sup>2+</sup> interaction. In fact, the NBO natural charge indicates that in complex **i** of [serine-Cu]<sup>2+</sup>, the metal bears a net positive charge of about 1.48 *e* while for the [serine-Ca]<sup>2+</sup> the net charge on the metal is about 1.88 *e*. At the same time, the spin density, which in the reactants

**Fig. 5.** Energy density contour maps for the [serine-Ca]<sup>2+</sup> and [serine-Cu]<sup>2+</sup> complexes. Dashed blue lines and solid red lines denote negative and positive values, respectively, of the energy density.

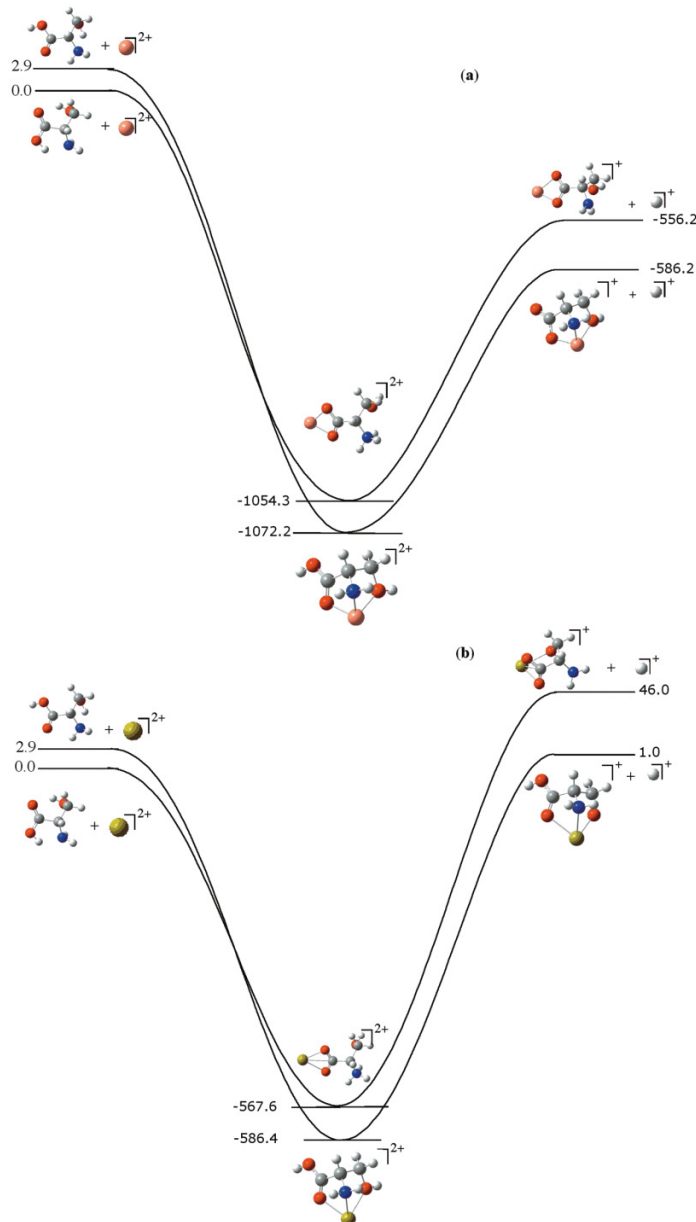

is located exclusively on Cu<sup>2+</sup> in the complex is almost equally shared by the metal (0.58) and the serine moiety (0.42). Similar results are found for complex **g**. This ability of Cu<sup>2+</sup> to oxidize the base was previously reported in the literature for some aminoacids<sup>49,50</sup> and for urea and thiourea<sup>19</sup> as well as for [uracil-Cu]<sup>2+</sup>, [thiouracil-Cu]<sup>2+</sup>, and [thymine-Cu]<sup>2+</sup> complexes.<sup>32,51</sup> However, in all these cases a complete oxidation of the base was actually found, whereas for serine only a partial oxidation seems to take place. Taking into account that the ionization energy of serine is not significantly different from that of urea or uracil, in principle a complete oxidation of the base should be expected. It is worth noting, however, that the degree of oxidation undergone by serine is different depending on the coordination of the metal. Hence, for monocoordinate complexes, such as structure **a**, the spin density on the copper atom is close to zero, indicating that the oxidation of the base has been practically complete. Conversely, in di- and tricoordinated complexes like structures **g** and **i**, the spin density is shared between the metal and serine, likely indicating that di- and tricoordination stabilize the Cu<sup>2+</sup> oxidation state more. Similar findings were reported before for the complexes between Cu<sup>2+</sup> and the oxime analogue of glycine.<sup>52</sup> Conversely, the behavior of calcium towards serine is quite similar to that exhibited towards uracil,<sup>53</sup> thiouracils,<sup>53</sup> urea, and thiourea.<sup>19</sup>

The partial oxidation of the serine upon Cu<sup>2+</sup> interaction will have an important effect on the intrinsic acidity of the

organic moiety, similar to that found when the base is uracil, and which results in a spontaneous deprotonation of the system. Hence, only [Cu-(B-H)]<sup>+</sup> singly charged species are observed in the gas phase.<sup>20,54</sup> This is not the case, however, when dealing with alkaline-earth dications like Ca<sup>2+</sup>, where [Ca-B]<sup>2+</sup> are easily detected.<sup>21,22,53</sup> In the case of serine, as shown in Fig. 6, the deprotonation of the two most stable [serine-Cu]<sup>2+</sup> complexes are thermodynamically favorable. In contrast, for the global minimum of the [serine-Ca]<sup>2+</sup> complexes, proton detachment is an almost thermoneutral process, and it becomes clearly endothermic for complex **g**.

There are two other features which should be highlighted in Figs. 6a and 6b. The first one is that, independently of the metal dication, the [serine-M]<sup>2+</sup> (M = Ca, Cu) global minimum is the result of the association of the metal dication to the second more stable tautomer of serine, whereas the most stable tautomer of serine leads to complexes which are significantly higher in energy (18.8 kJ/mol, for Ca<sup>2+</sup> and 17.9 kJ/mol for Cu<sup>2+</sup>). The second important feature is that the formation of the [serine-Ca]<sup>2+</sup> global minimum **i** implies a significant acidity enhancement of the alcoholic OH group of serine, so the proton is preferentially lost from this group, whereas in complex **g**, the most acidic site is the NH<sub>3</sub> group formed by the spontaneous proton transfer discussed in previous sections. Also interestingly, the deprotonation of complexes **i** also yields the most stable anion, although the energy gap between the deprotonated forms of complexes **i**

**Fig. 6.** Energy profile for the formation and deprotonation of the two most stable isomers of  $[\text{serine-M}]^{2+}$  ( $M = \text{Ca}, \text{Cu}$ ) complexes; (a)  $M=\text{Cu}$ ; (b)  $M=\text{Ca}$ . Values are in kJ/mol.

and **g** is slightly larger than that between the complexes **i** and **g** themselves.

## Conclusions

The association of  $\text{Ca}^{2+}$  and  $\text{Cu}^{2+}$  to serine implies a drastic electron density reorganization within the aminoacid, which leads to significant changes in the number and strength of the IMHBs present in the neutral serine tautomers, and in some particular cases to a proton transfer from the carboxylic OH group towards the amino group. Accordingly, some of the more stable  $[\text{serine-M}]^{2+}$  complexes can be viewed as the result of the interaction of the zwitterionic form of serine with the doubly charged metal ion.

Whereas the interactions between  $\text{Ca}^{2+}$  and serine are es-

entially electrostatic, those between  $\text{Cu}^{2+}$  and serine have a non-negligible covalent character, reflected in larger electron densities at the BCPs between the metal and the base, in the negative values of the electron density between the two interacting systems, and in much larger  $\text{Cu}^{2+}$  than  $\text{Ca}^{2+}$  binding energies. More importantly, the interaction with  $\text{Cu}^{2+}$  is followed by a partial oxidation of the base, which is not observed when the metal ion is  $\text{Ca}^{2+}$ .

The main consequence is that in  $\text{Cu}^{2+}$  complexes acidity of the serine moiety is significantly enhanced, thus strongly favoring the deprotonation of the  $[\text{serine-Cu}]^{2+}$  complexes. This is not the case for  $\text{Ca}^{2+}$  complexes, because the recombination energy of this metal dication is almost half that of  $\text{Cu}^{2+}$ . Thus,  $[\text{serine-Ca}]^{2+}$  complexes, like those formed by urea, thiourea, selenourea, or glycine, should be detected in

the gas phase. Conversely, the complexes with  $\text{Cu}^{2+}$  should deprotonate spontaneously and therefore only  $[(\text{serine-H})-\text{Cu}]^+$  monocations should be experimentally accessible.

# Ab initio calculations on $C_6H_6 \cdots (HF)_n$ clusters — $X-H \cdots \pi$ hydrogen bond

Sławomir J. Grabowski and Jesus M. Ugalde

**Abstract:** MP2/6–311++G(d,p) calculations on  $C_6H_6 \cdots (HF)_n$  clusters were performed and full optimizations were carried out for systems containing up to four HF molecules ( $n = 4$ ) and calculations on the systems of  $C_{6v}$  symmetry were carried out for up to six HF molecules ( $n = 6$ ). Cooperativity effects were analyzed for these molecular aggregates. It was found that  $F-H \cdots \pi$  and  $F-H \cdots F$  hydrogen bonds exist for these complexes and those interactions are enhanced as the number of HF molecules increases. The cooperativity effects cause numerous changes in geometrical, energetic, and topological parameters, the latter ones derived from the quantum theory of atoms in molecules. Various correlations between the analyzed parameters are presented. There are meaningful differences between the molecular graphs for the fully optimized complexes and those for the linear complexes of  $C_{6v}$  symmetry (for the latter, the linear chain of HF molecules is attached to a benzene molecule acting as the Lewis base). For the linear complexes, unique bond paths connect the H-attractor of the HF molecule and the ring critical point of the benzene molecule.

**Key words:** hydrogen bonding, cooperativity effect, quantum theory of atoms in molecules,  $H \cdots \pi$  interaction, benzene as a proton acceptor, molecular graphs, critical points.

**Résumé :** On a effectué des calculs MP2/6–311++G(d,p) sur des agrégats de  $C_6H_6 \cdots (HF)_n$  et on a réalisé des optimisations totales pour les systèmes comportant jusqu'à quatre molécules de HF ( $n = 4$ ) alors que les calculs sur les systèmes de symétrie  $C_{6v}$  ont pu être effectués jusqu'à six molécules de HF ( $n = 6$ ). On a analysé les effets coopératifs de tels agrégats moléculaires. On a trouvé qu'il existe des liaisons hydrogènes  $F-H \cdots \pi$  et  $F-H \cdots F$  dans ces complexes et que ces interactions sont renforcées lorsque le nombre de molécules de HF augmente. Les effets coopératifs provoquent de nombreux changements dans les paramètres géométriques, énergétiques et topologiques qui ont été obtenus par la théorie quantique des atomes dans les molécules. On présente diverses corrélations entre les paramètres analysés. Il existe des différences significatives entre les graphiques moléculaires des complexes complètement optimisés et les complexes linéaires de symétrie  $C_{6v}$  (dans ces derniers cas, la chaîne linéaire de molécules HF est attachée à la molécule de benzène qui agit comme base de Lewis). Pour les complexes linéaires, il existe des voies uniques de liaison qui unissent l'attracteur-H de la molécule HF et le point critique du noyau de la molécule de benzène.

**Mots-clés :** liaison hydrogène, effet coopératif, théorie quantique des atomes dans les molécules, interaction  $H \cdots \pi$ , benzène comme accepteur de proton, graphiques moléculaires, points critiques.

## Introduction

There are numerous studies on cooperativity effects for hydrogen bonded systems.<sup>1–3</sup> There are also various definitions of this effect, each somewhat different from the other. However, the cooperativity effect is often understood as the enhancement of the hydrogen bonding between two species if a third one is attached to that system.<sup>4</sup> For most of the systems analyzed, this enhancement was observed but there are also studies where an opposite effect, the weakening of the hydrogen bond, was detected. For example, some years ago the cooperativity was investigated in  $C-H \cdots O$  and  $O-H \cdots O$  hydrogen bonds.<sup>5</sup> The authors showed that, in the case of  $O-H \cdots O$  interactions, this effect enhances the H

bond and leads to the elongation of the O–H proton-donating bond and to the red shift of the corresponding stretching mode. In the case of  $C-H \cdots O$  hydrogen bonds, the shortening of C–H bonds and the blue-shifting were detected in  $(H_2CO)_n$  and  $(HFCO)_n$  aggregates.

One can mention numerous studies on cooperativity effects. The chain of species connected by OH bonds is an example.<sup>6</sup> Another one concerns  $H_3N \cdots HF$  and  $H_3N \cdots HF \cdots HF$  complexes, which were investigated with the use of experimental microwave and theoretical ab initio techniques.<sup>7</sup> It was observed that the addition of the next HF molecule to the  $H_3N \cdots HF$  complex leads to the shortening of the  $N \cdots H$  hydrogen bond by 0.21(6) Å. Hence the cooperativity effect exists here, because the H–F molecule participates concert-

edly as a donor and as an acceptor. Numerous other studies on cooperativity effects may be mentioned; such effects were found in two-dimensional cyclic networks containing three-centered hydrogen bond interactions,<sup>8</sup> in amide hydrogen-bonding chains,<sup>9</sup> in intramolecular bifurcated hydrogen bonds,<sup>10</sup> and in homo (HCN)<sub>n</sub> and hetero (HCN)<sub>n</sub>...HF chains.<sup>11,12</sup>

The decomposition of the interaction energy was performed for H<sub>2</sub>C=O...(H-F)<sub>n</sub> clusters (*n* up to 9).<sup>13</sup> It was found that, for a large number of hydrogen fluoride molecules, there are shorter and stronger F-H...O hydrogen bonds and that the ratio of delocalization and electrostatic attractive interaction energy terms increases. It is worth mentioning too that the delocalization energy is often attributed to the covalency of the hydrogen bond;<sup>14,15</sup> thus, the partially covalent character is manifested for H<sub>2</sub>C=O...(H-F)<sub>n</sub> clusters for the greater number of HF molecules. Similar clusters, H<sub>2</sub>C=O...(Cl-F)<sub>n</sub> aggregates, were calculated and the cooperativity effect in F-Cl...O and F-Cl...F halogen bonds was analyzed.<sup>16</sup> One can see that cooperativity is observed not only for hydrogen bonds but also for other types of interactions. There is a very recent study on cooperativity in multiple weak bonds.<sup>17</sup> All combinations of five weak bonds: hydrogen bonds, dihydrogen bonds, hydric bonds, halogen bonds, and ion- $\pi$ -electron interactions were analyzed<sup>17</sup> using MP2/aug-cc-pVTZ level results and quantum theory of atoms in molecules (QTAIM).<sup>18</sup>

Another problem concerns the interactions often classified as hydrogen bonds where  $\pi$ -electrons act as the proton acceptor; these are usually designated as X-H... $\pi$  (or XH/ $\pi$ ).<sup>19</sup> Even the CH/ $\pi$  interactions were analyzed in crystal structures and using various methods, both theoretical as well as experimental.<sup>20,21</sup> A question arises whether or not such interactions are enhanced by cooperativity effects. The theoretical analysis of benzene-(H<sub>2</sub>O)<sub>n</sub> (*n* = 1–3) clusters is an early example.<sup>22</sup> The cooperativity phenomenon has not been considered for the latter species. However it has been found that (H<sub>2</sub>O)<sub>n</sub> clusters are “ $\pi$ -hydrogen bonded” (O-H... $\pi$  interaction) to the benzene ring, the strength of such interaction being greatest for C<sub>6</sub>H<sub>6</sub>-(H<sub>2</sub>O)<sub>2</sub>. Thus, there is enhancement of O-H... $\pi$  hydrogen bonding when the next water molecule is incorporated into the C<sub>6</sub>H<sub>6</sub>-H<sub>2</sub>O system. In the case of the C<sub>6</sub>H<sub>6</sub>-(H<sub>2</sub>O)<sub>3</sub> cluster, the O-H... $\pi$  interaction is weaker, likely owing to the strong cooperativity among the three water molecules forming the cyclic structure. The complexes of water with ethene, propene, and trans-2-butene have been studied recently.<sup>23</sup> The ab initio MP2/6-311++(2d,2p) calculations have been performed on these systems where  $\pi$ -electrons of the above-mentioned hydrocarbons act as the proton acceptor while the water molecule is the proton-donating moiety; hence, the O-H... $\pi$  interactions exist. In this study, the other O-H...O hydrogen bonds were also analyzed, since for the complexes with the O-H... $\pi$  hydrogen bond, the next water molecules were added. Additionally NBO analysis was performed to analyze intermolecular  $\pi$ (C=C)  $\rightarrow$   $\sigma^*$ (O-H) charge-transfer interactions as well as those for  $n$ (O)  $\rightarrow$   $\sigma^*$ (O-H). The other B3LYP/6-311++G(d,p) calculations for the C<sub>2</sub>H<sub>2</sub>...HF and C<sub>2</sub>H<sub>2</sub>...(HF)<sub>2</sub> complexes were performed and the F-H... $\pi$  and F-H...F interactions were characterized.<sup>24</sup> Very recently, similar systems C<sub>2</sub>H<sub>2</sub>...(HF)<sub>n</sub> and C<sub>2</sub>H<sub>4</sub>...(HF)<sub>n</sub> (*n* up to 4) were considered and MP2/6-311++G(d,p)

calculations were carried out to analyze cooperativity effects.<sup>25</sup> Thus, generally, at least a few systems were considered with the aim of showing whether cooperativity effects might enhance the X-H... $\pi$  interactions. For most of the cases mentioned here, such enhancement is observed if the number of proton-donating molecules attached to the Lewis base containing  $\pi$ -electrons increases.

The goal of this study is to analyze the cooperativity effects for the systems where the benzene molecule acts as the proton acceptor and where HF molecules are attached to benzene. Hence C<sub>6</sub>H<sub>6</sub>...(HF)<sub>n</sub> complexes (*n* up to 6) were analyzed. QTAIM<sup>18,26,27</sup> was also applied to characterize these systems. The choice of such systems was dictated by the fact that only a few studies had been performed earlier on cooperativity effects with multicenter proton acceptors, such as acetylene or ethylene molecules. Practically, except for the study on C<sub>6</sub>H<sub>6</sub>-(H<sub>2</sub>O)<sub>n</sub> clusters<sup>22</sup> and the recent study on different weak interactions,<sup>17</sup> both mentioned earlier here, no analyses on cooperativity has been performed to date for benzene as the proton acceptor. It is interesting to analyze what the interrelation is between the number of HF molecules attached to benzene and the F-H... $\pi$  interaction. Is the interaction similar in nature to the one detected for C<sub>2</sub>H<sub>2</sub> and C<sub>2</sub>H<sub>4</sub> acting as Lewis bases? In addition, the Bader theory allows one to analyze molecular graphs, especially those whose bond paths are attributed to H... $\pi$  interactions. Such QTAIM analysis was performed early on complexes of single hydrogen fluoride molecule with acetylene, ethylene, cyclopropene, cyclobutadiene, and benzene;<sup>28</sup> in these cases, a bond path with bond critical point (BCP) has been found between the H-atom attractor of hydrogen fluoride and the BCP of the CC  $\pi$ -bond. A deeper analysis of such connections for the C<sub>6</sub>H<sub>6</sub>...(HF)<sub>n</sub> clusters seems to be worth doing. On the other hand, the study of systems with multicenter proton acceptor and (or) proton donor<sup>29,30</sup> is also very interesting since this interaction very often differs in nature significantly from the typical hydrogen bonds well situated within the Pauling definition of hydrogen bonding.<sup>31</sup>

## Computational details

The calculations were carried out with the Gaussian03 set of codes.<sup>32</sup> The C<sub>6</sub>H<sub>6</sub>...(HF)<sub>n</sub> (*n* = 1,2,3,4) complexes were optimized at the MP2/6-311++G(d,p) level of approximation and these systems are in energetic minima since no imaginary frequencies were observed. Similar calculations at the same level were performed for C<sub>6</sub>H<sub>6</sub>...(HF)<sub>n</sub> complexes (*n* up to 6) with the symmetry constraints included. These complexes are known to have C<sub>6v</sub> symmetry exists because all HF molecules attached form a linear chain and are perpendicular to the benzene ring (the line of HF molecules crosses the benzene ring accurately at its geometric center).

The binding energies for the analyzed complexes were computed as the differences between the total energy of the complex and the energies of monomers. The binding energies were corrected for the basis set superposition error (BSSE) using the counterpoise method.<sup>33</sup> In this study, the term “monomer” has a special definition. Because the H... $\pi$  interaction and the influence of the number of attached HF molecules on the strength of that interaction are analyzed,

the  $C_6H_6$  is treated as one monomer and all HF molecules as another monomer. This approach is in line with the expression proposed earlier in studies on cooperative effects.<sup>34,35</sup>

$$[1] \quad E_{HBk} = E_{total} - E_{1,2,...,k} - E_{k+1,k+2,...,m}$$

$E_{HBk}$  is the  $k$ th hydrogen bond within the  $m$ -element system and two subsystems are connected through this interaction. For the systems analyzed, here the  $k$ th hydrogen bond exists between the first element (benzene) and the first hydrogen fluoride molecule (hence  $k = 1$  and  $m = n+1$  because  $n$  is the number of HF molecules).

The NBO method<sup>36,37</sup> implemented within the Gaussian03 package was applied here to calculate the atomic charges. The QTAIM theory of Bader was also applied to find the critical points<sup>26,27,38</sup> and to analyze them in terms of electron densities and their Laplacians. The molecular graphs were also analyzed to show the uniqueness of the interactions with  $\pi$ -electrons of benzene acting as the Lewis base.

## Results and details

### Energetic and geometric parameters

Figures 1 and 2 present the molecular graphs of the  $C_6H_6 \cdots (HF)_4$  complex, the fully optimized system and the corresponding one of  $C_{6v}$  symmetry. To clarify the picture of the graph of the nonlinear complex (Fig. 1), the bond paths (BPs) of ring critical points (RCPs) are not drawn, whereas the graph of the linear system contains all BPs. Table 1 presents binding energies (corrected for BSSE) of all complexes analyzed here. The charges of the benzene ring are included in the table. It was explained in the previous section how the binding energies were calculated; the benzene molecule is one subunit and all HF molecules of the complex constitute the other subunit. Such a treatment is applied here to calculate the interaction between  $\pi$ -electrons of benzene and the remaining part of the complex, HF molecules. In other words, the energies of  $F-H \cdots \pi$  interactions are estimated by means of such a treatment.

One can see that the binding energy increases (that is, it is more negative) if the number of HF molecules increases (Table 1). This is connected with the well-known effect of cooperativity (the enhancement of the H-bond strength between two interacting moieties if other additional species are attached).<sup>4</sup> Figure 3 presents this relation. For the  $C_6H_6 \cdots (HF)_2$  complex, the binding energy is about 65% greater than for the  $C_6H_6 \cdots HF$  complex if the fully optimized systems are considered. The next additional hydrogen fluoride molecules do not cause such a large increase in  $F-H \cdots \pi$  hydrogen bonding strength. If the systems containing three and four HF molecules are each compared with those possessing one fewer HF molecules then the energy increases to 38% and 11%, respectively. The changes of H-bond strength are not so significant for the linear systems, and they are practically negligible if one considers the complexes containing more than three HF molecules (Table 1, Fig. 3). The complexes of  $C_{6v}$  symmetry do not correspond to the local minima where the electron charge transfer and the corresponding electron density redistribution as an effect of complexation are most effective and lead to the most stable configurations.

**Fig. 1.** Molecular graph of the  $C_6H_6 \cdots (HF)_4$  complex, with the configuration in minimum; big circles correspond to attractors, small ones to critical points.

It is well-known that the hydrogen bonding formation is connected with the transfer of electron charge from the proton acceptor center to the proton donating system.<sup>39,40</sup> In the case of the  $H \cdots \pi$  interactions considered here, these are the benzene molecule and the system of HF molecules, respectively. Table 1 presents the benzene molecule charge for all analyzed complexes. Because an electron charge is withdrawn from benzene to the remaining parts of complexes, the benzene molecule possesses the positive charge, greater for the greater electron transfer. Table 1 shows that for the greater number of HF molecules within the complex and hence for the greater binding energy, the benzene molecule is more positive. The increase of the positive charge is greater for the fully optimized complexes. For the linear complexes, the charge changes resulting from complexation are much smaller. For example, for the  $C_6H_6 \cdots (HF)_6$  linear complex, the benzene charge is equal to 0.0065 au, whereas for the  $C_6H_6 \cdots (HF)_4$ , fully optimized complex it amounts to 0.0172 au. The positive charge for the complex in minimum is almost three times greater than for the one of  $C_{6v}$  symmetry, in spite of the greater number of HF molecules attached in the latter case. There is practically no change in the charge of benzene with the increasing number of HF molecules if the  $C_6H_6 \cdots (HF)_4$  linear complex is considered. Such negligible differences are observed for the other parameters (Table 1) for the  $C_6H_6 \cdots (HF)_n$  linear complexes ( $n = 4, 5$ , and 6). Figure 4 shows the relationship between the benzene molecule charge and the binding energy; for the linear systems, the dependence is linear ( $R^2 = 0.998$ ), whereas for the fully optimized systems the dependence seems to be nonlinear, although the number of complexes is too low to apply statistical analysis. Figure 5 presents the relationship between the benzene charge and the charge on the H-atom; the latter one concerns the HF molecule being in the closest proximity of the benzene ring. The linear and nonlinear systems belong to two subsamples; hence there are two dependencies, both of which may be described by second-order

**Fig. 2.** Molecular graph of the  $C_6H_6 \cdots (HF)_4$  complex, showing the linear configuration of  $C_{6v}$  symmetry; big circles correspond to attractors, small ones to critical points.

**Table 1.** Binding energies of the systems analyzed; BSSE correction is presented (both in kcal/mol), NBO charges of benzene molecule (B-charge) and H-atom of the closest to the benzene ring HF molecule (in au);  $N$  is the number of HF molecules within the complex; the shortest H $\cdots$ C intermolecular distances are given (in Å); linear systems (of  $C_{6v}$  symmetry) as well as optimized ones are shown.

polynomials. One can see that the charges on the H-atoms are greater for linear systems, which may indicate the greater polarization of HF molecules for the  $C_{6v}$  symmetry systems than for nonlinear ones.

What is the reason for the systematic differences between the two subsamples, i.e., those fully optimized and those of  $C_{6v}$  symmetry? First of all, for the fully optimized systems, there is the meaningful asymmetry of the distribution of electron density. This leads to the asymmetry of numerous properties of the analyzed complexes. For example, there are differences between the charges on carbon atoms of the benzene ring. Table 1 presents the charges on the C-atoms which are the closest to the first neighboring HF molecule; the corresponding H...C distances are also included. For the complexes of  $C_{6v}$  symmetry, all such H...C distances are the same and all C-atom charges are equal. It is worth mentioning that for each fully optimized system, the charge of the C-atom nearest to an HF molecule is the most negative one of all the carbon atoms of benzene. Thus the interaction between the most negative C-atom and the HF molecule is probably the strongest of all the other such H...C interactions. This may indicate the existence of the F-H...C interaction rather than the F-H... $\pi$  one. Only for the  $C_6H_6$ -HF fully optimized complex is the situation slightly different because there are two equal shortest H...C distances. Figure 6 presents the linear dependence between the H...C distance and the charge on the corresponding C-atom; all systems, linear and nonlinear, are taken into account within this correlation. For the systems of  $C_{6v}$  symmetry; the H...C distances are longer and the negative C-charges are smaller than such values for fully optimized systems.

Figure 7 presents the relationship between the binding energy and the bond length of the first HF neighboring molecule of benzene; all systems, both linear and nonlinear, are included in the correlation and the linear correlation between energy and bond length is observed. For weaker interactions of systems with  $C_{6v}$  symmetry, the lengthening of the HF molecule is reduced as a result of complexation. This is in line with many other studies where a dependence was found between the length of the proton-donating bond

**Fig. 6.** The correlation between the H...C distance (in Å) and the C-atom charge (in au); full circles correspond to the fully optimized complexes and the empty circles to the linear ones; the correlation concerns both types of complexes, linear and nonlinear.

**Fig. 7.** The correlation between the binding energy (in kcal/mol) and the H-F bond length (in Å); full circles correspond to the fully optimized complexes and the empty circles to the linear ones; the correlation concerns both types of complexes, linear and nonlinear.

and the binding energy for the H-bonded systems.<sup>41</sup> Table 2 presents the charges of HF molecules; all systems are considered and the order of HF molecules of any complex is in line with the neighborhood of benzene molecule. This means that the HF molecule closest to benzene is given as the first one in the table. For the fully optimized  $C_6H_6$ -HF complex, the situation is as one could expect—the HF molecule has a negative charge because of the electron charge transfer from benzene. However, for the other fully optimized complexes, the HF molecules closest to benzene have positive charges. This means that there is a further transfer of electron charge to the more distant HF molecules. Usually, the last HF molecule, being the farthest from benzene, has the most negative charge. The remaining HF molecules within the chain are characterized by small and negligible negative charges. This is owing to the chain of hydrogen bonds which are created  $C_6H_6 \cdots H-F \cdots H-F \cdots$  and may be treated as a result of cooperativity. Additionally, the charge of the last HF molecule is more negative than the charge of the benzene molecule is positive. This means that, within the complexes, the negative charge is withdrawn from benzene and also from the other HF molecules to transfer it to the “tail” of the complex. A similar situation

**Table 2.** HF bond lengths (in Å) and their charges (in au),  $N$  is the number of HF molecules; the results of HF molecules are presented in the following order: the neighbor of benzene molecule is given first and next HF molecules follow it.

occurs for the linear complexes; the charge of the first HF molecule is positive (except of the  $C_6H_6 \cdots HF$  complex). The other charges of HF molecules are usually negative although in some cases they are positive but close to zero, and the last or "tail" HF molecules are the most negative. However, for the latter ones, the modulus of negative charge is very close to the charge of the corresponding benzene molecule. This means that for the linear complexes, the enhancement of the electron charge is not so great as for the nonlinear complexes. Table 2 also shows the HF bond lengths; they are shortest for the HF molecules that are the furthest from benzene, i.e., the "tail" molecules.

### QTAIM parameters and NBO approach

Table 3 shows the parameters derived from QTAIM theory: electron density ( $\rho_{BCP}$ ), its Laplacian ( $\nabla^2 \rho_{BCP}$ ) as well as kinetic electron energy density ( $G_{BCP}$ ), and the po-

tential electron energy density ( $V_{BCP}$ ) at the H $\cdots$ C bond critical point. In other words, the characteristics of BCP corresponding to (F)H $\cdots$ C interaction are given. In the case of fully optimized complexes, there is only one bond path between the H-atom attractor and benzene, i.e., C-atom of benzene (Fig. 1) with the corresponding BCP. The  $C_6H_6 \cdots HF$  complex is the only exception since BP connects the H-atom attractor with the BCP of the CC bond (Fig. 8). For complexes of  $C_{6v}$  symmetry, there are six such bond paths. It seems that the latter situation may occur only for the complexes of benzene in the case of high  $C_{6v}$  symmetry. Any distortion from such a symmetry, as for the systems considered here (fully optimized complexes) causes the asymmetrical distribution of the electron charge. Hence, the most negatively charged carbon atom is the proton acceptor in F $\cdots$ H $\cdots$ C hydrogen bonding. It is worth mentioning that a system of  $C_{6v}$  symmetry, the benzene-acetylene complex, was analyzed by Fujii et al.<sup>42</sup> A similar high symmetry arrangement of molecules was detected for the mixed benzene-acetylene crystal.<sup>43,44</sup> Figures 1 and 2 present both of the cases mentioned above. For the linear  $C_6H_6 \cdots (HF)_4$  complex, there is the bond path which connects the H-atom attractor and the ring critical point of benzene. The cage critical point lies on such a path. It seems that in the case of benzene acting as Lewis base there are two possibilities to explain the topological evidence of X-H $\cdots$  $\pi$  interaction: (1) for the species of  $C_{6v}$  symmetry, there is the existence of BP connecting RCP and the H-atom attractor, and (2) there is BP linking the H-atom attractor and BCP of the CC  $\pi$ -bond. The second case was observed by Rozas et al.<sup>28</sup> as has been mentioned earlier. This has also been detected in this study for the fully optimized  $C_6H_6 \cdots HF$  system (Fig. 8). There are equivalent H $\cdots$ C contacts (at equal distances amounting to 2.503 Å, Table 1) and corresponding to the CC bond for this complex. Both these C-atoms of the benzene ring bear the "most negative charge", -0.2245 au (Table 1). For the remaining fully optimized complexes ( $n = 2, 3, 4$ ) there is one BP corresponding to the shortest H $\cdots$ C contact (as Fig. 1 shows for  $C_6H_6 \cdots (HF)_4$ ). The observed geometrical results nicely correspond to the bond path definition. The presence of a bond path linking a pair of atoms implies that they are bonded to one another and presents the preferable directed interactions.<sup>45,46</sup> For symmetrical systems, all six H(F) $\cdots$ C contacts are equivalent; thus, six BPs exist and also one connecting RCP with the H-attractor of hydrogen fluoride. This means that no one C-benzene atom is preferable owing to to the  $C_{6v}$  symmetry. If the symmetry of the system is broken, the BPs exist only for the shortest H $\cdots$ C contacts for which the C-atoms bear the most negative charge.

Table 3 shows the QTAIM parameters of the complexes being studied: the electron density at BCP and its Laplacian, the kinetic electron energy, and the potential electron energy. One can observe that the total electron energy density at BCP ( $H_{BCP}$ ), being the sum of kinetic ( $G_{BCP}$ ) and potential ( $V_{BCP}$ ) energies, is always positive. This means that the enhancement of the hydrogen-bond strength as an effect of cooperativity is not big enough to strengthen the interaction to be partly covalent in nature. It was proposed before that the negative  $H_{BCP}$  value for the BCP of the proton-acceptor contact is evidence for a hydrogen bond of at least partially

**Table 3.** The QTAIM parameters (in au) of the complexes analyzed; the characteristics of BCP of the C...H(F) contact are presented and in the case of linear systems the electron density at the CCP is included.

**Fig. 8.** Molecular graph of  $\text{C}_6\text{H}_6 \cdots \text{HF}$  complex, the configuration in minimum, big circles correspond to attractors, small ones to critical points.

covalent character,<sup>47–49</sup> whereas the negative value of the Laplacian ( $\nabla^2 \rho_{\text{BCP}}$ ) suggests a very strong hydrogen bond of covalent character in the latter interaction.<sup>49</sup> Sometimes for the proton–acceptor interaction, the Laplacian is positive, but  $H_{\text{BCP}}$  is negative, showing the partial covalency; this does not happen for the  $\text{H} \cdots \pi$  interactions analyzed here. However, the negative H-values were observed in the case of  $\text{H}_2\text{CO} \cdots (\text{HF})_n$  clusters for  $\text{O} \cdots \text{H}$  BCPs if the greater number of HF molecules were taken into account in the complex.<sup>13</sup> On the other hand, no negative H-values were observed for BCPs of  $\text{H} \cdots \pi$  contacts in the  $\text{C}_2\text{H}_2 \cdots (\text{HF})_n$  and  $\text{C}_2\text{H}_4 \cdots (\text{HF})_n$  complexes even for the greater number of HF molecules.<sup>25</sup> This means that cooperativity may not enhance

the  $\text{H} \cdots \pi$  interaction as significantly as for the  $\text{H} \cdots \text{O}$  interaction. However, it is worth mentioning that there are hydrogen bonds whose  $\pi$ -electrons act as a proton acceptor; such bonds may be classified as partly covalent in nature since the H-value for the BCP of the  $\text{H} \cdots \pi$  interaction is negative.<sup>50</sup>

The QTAIM parameters presented in Table 3 change monotonically if the number of HF molecules increases. This means that the electron density at  $\text{H} \cdots \text{C}$  BCP and its Laplacian increase; such dependencies for the samples of H-bonded complexes were detected very often. The other parameters also show similar tendencies: the  $G_{\text{BCP}}$  value increases while the  $V_{\text{BCP}}$  decreases (becomes more negative). Different correlations between geometrical, energetic, and QTAIM parameters were observed before. For example, numerous linear and non-linear relationships were analyzed and discussed for  $\text{N} \cdots \text{H} \cdots \text{N}$  interactions.<sup>51,52</sup> A wide range of  $\text{H} \cdots \text{F}$  interactions was also analyzed,<sup>53</sup> from short ones usually attributed to covalent bonds to longer  $\text{H} \cdots \text{F}$  distances of hydrogen bonds, or much weaker van der Waals interactions. Numerous correlations were also found there.

The above-mentioned monotonic changes are observed within subsamples of the linear and nonlinear complexes separately. For example, the largest value of the electron density at  $\text{H} \cdots \text{C}$  BCP for the  $\text{C}_6\text{H}_6 \cdots (\text{HF})_6$  complex amounts to 0.0086 au, whereas its value for the fully optimized  $\text{C}_6\text{H}_6 \cdots \text{HF}$  complex is equal to 0.0095 au. Figure 9 shows the well-known correlation between the binding energy and the electron density at  $\text{H} \cdots \text{C}$  BCP. Two subsamples mentioned above are separated. Generally, all electron densities of symmetrical systems are lower than those of fully optimized ones; however, one should remember that there are six  $\text{H} \cdots \text{C}$  bond paths for linear complexes, whereas there is only one for the nonlinear complex ( $\text{H} \cdots \text{BCP}$  in the case of the  $\text{C}_6\text{H}_6 \cdots \text{HF}$  complex, see Figs. 1, 2, and 8). The electron densities at cage critical points are also included in Table 3 and Fig. 9; one can observe the increase of this value if the number of HF molecules increases.

The Natural Bond Orbitals (NBO) results are very interesting in that they support the statement of different kinds of interactions for two subsamples analyzed here. The  $n_Y \rightarrow \sigma_{\text{XH}}^*$  interaction is connected with the maximum  $n_Y \rightarrow \sigma_{\text{XH}}^*$

overlap and, according to numerous studies, it is responsible for the existence of the X–H...Y hydrogen bond.  $n_Y$  designates the lone electron pair of the proton acceptor and  $\sigma_{XH}^*$  is an antibonding orbital of the proton-donating bond. The  $n_Y \rightarrow \sigma_{XH}^*$  interaction is calculated as the energy of the second-order perturbation theory according to the following relation (eq. [2]):

$$[2] \quad \Delta E(n_Y \rightarrow \sigma_{XH}^*) = -2\langle n_Y | F | \sigma_{XH}^* \rangle^2 / (\epsilon(\sigma_{XH}^*) - \epsilon(n_Y))$$

$\langle n_Y | F | \sigma_{XH}^* \rangle$  designates the Fock matrix element and  $(\epsilon(\sigma_{XH}^*) - \epsilon(n_Y))$  is the orbital energy difference. Such energy contributions are calculated for typical hydrogen bonds as, for example, for the F–H...F systems existing in the  $C_6H_6 \cdots (HF)_n$  complexes. However, for hydrogen bonds where  $\pi$ -electrons act as proton acceptors, the modified expression should be taken into account since the corresponding energy term is connected with the charge transfer from the  $\pi_{CC}$ -bond orbital to the  $\sigma_{XH}^*$  antibonding orbital:

$$[3] \quad \Delta E(\pi_{CC} \rightarrow \sigma_{XH}^*) = -2\langle \pi_{CC} | F | \sigma_{XH}^* \rangle^2 / (\epsilon(\sigma_{XH}^*) - \epsilon(\pi_{CC}))$$

Such a situation was analyzed recently for the  $C_2H_2 \cdots (HF)_n$  and  $C_2H_4 \cdots (HF)_n$  complexes.<sup>25</sup> However, for the latter systems, QTAIM shows that the bond paths between the acetylene or ethylene molecule and the hydrogen fluoride link the approximate middle part of CC bond, i.e., the bond-critical point of the CC bond, and the attractor of the H-atom. For the benzene complexes analyzed here, the bond path concerns H...C contacts. However, the NBO approach indicates that the  $\pi_{CC} \rightarrow \sigma_{FH}^*$  charge transfer with the energy term corresponding to eq. [3].

This means that NBO indicates a situation similar to that found earlier in the case of acetylene and ethylene complexes. The  $\Delta E(\pi_{CC} \rightarrow \sigma_{FH}^*)$  energy contributions for the fully optimized complexes are greatest if the CC bond contains the carbon atom that is closest to the HF molecule. Thus it is in line with QTAIM because the latter theory shows the bond paths for the closest H...C distances. The  $\Delta E(\pi_{CC} \rightarrow \sigma_{FH}^*)$  contributions amount to 0.99, 2.49, 11.56, and 14.77 kcal/mol for increasing numbers of HF molecules, from one to four HF. The other such contributions are much lower being in the range 0.1–0.2 kcal/mol. Similarly, these contributions are much lower for linear complexes being in the range 0.1 – 0.5 kcal/mol. However, all results show that the greatest energy connected with the charge transfer to the antibonding orbital of HF molecule concern the shortest H...C intermolecular contacts.

## Summary

The results for the  $C_6H_6 \cdots (HF)_n$  complexes presented here show the enhancement of F–H...benzene interactions as the number of HF molecules increases. Different geometrical, energetic, and QTAIM parameters support this tendency. Benzene acts as the Lewis base and more specifically as the proton acceptor in hydrogen bonding. It is not clear whether the  $\pi$ -electrons of benzene, i.e., the whole aromatic electron

**Fig. 9.** The dependence between the binding energy (in kcal/mol) and the electron density at BCP (in au); full circles correspond to the fully optimized complexes and the empty circles to the linear ones; the dependence between the binding energy and the electron density at the cage critical point (triangles) is also included.

sixtet, may be treated as the proton acceptor or whether it is the CC bond proton acceptor or a single carbon atom. QTAIM reveals that, for fully optimized complexes, there is only one bond path connecting benzene with the nearest HF molecule; this is the H...C bond path with the bond critical point (see Fig. 1). The nonlinear benzene–HF complex is the only exception because the BP links the BCP of the  $\pi$ –CC bond with the H-atom attractor. This is indicative of the existence of F–H...C hydrogen bonds for some of the species considered here ( $n = 2, 3, 4$ ). The other results support such an idea because the BPs correspond to the shortest intermolecular H...C distances and the C-atoms corresponding to such paths possess the greatest negative charges when compared to the remaining carbons of benzene. The molecular graphs for the so-called linear complexes, i.e., those of  $C_{6v}$  symmetry show six symmetrical bond paths connecting the H-atom with each of the six carbon atoms of the benzene ring (see Fig. 2). Additionally, for linear complexes, there exists a bond path between the H-atom and the ring critical point of benzene with the cage critical point situated on this path.

The NBO calculations support this QTAIM analysis. Specifically, for the nonlinear complexes, the largest energy contribution for the charge transfer from benzene to the nearest HF molecule is connected with the most negative carbon atom; for linear complexes, there are six equivalent contributions involving each of the six carbon atoms of the benzene ring.

# Theoretical study of the rovibrational spectrum of He<sub>2</sub>-OCS

Xiao-Gang Wang and Tucker Carrington, Jr.

**Abstract:** We report calculated microwave and infrared rovibrational transitions of the van der Waals complex He<sub>2</sub>-OCS. The calculations were done using a product basis, a Lanczos eigensolver, and potentials built from He-OCS, and He-He potential functions taken from the literature. All five of the large amplitude coordinates are treated exactly and calculations are done for  $J$  values up to five. All rovibrational levels are converged to 0.001 cm<sup>-1</sup> by using basis sets with as many as 87 million functions. Good agreement is found with previously reported experimental results. Although we assume that the dipole moment is along the OCS axis, we find transitions with appreciable intensity between different torsion states.

**Key words:** rovibrational spectroscopy, quantum dynamics, van der Waals clusters, doped helium clusters, Lanczos algorithm.

**Résumé :** Nous avons calculé des transitions rovibrationnelles du complexe de van der Waals He<sub>2</sub>-OCS. Le calcul a été fait en utilisant une base de produit, l'algorithme de Lanczos et des potentiels construits à partir de fonctions de potentiel pour He-OCS et He-He. Les cinq coordonnées qui décrivent le mouvement de grande amplitude ont été traitées de manière explicite et des niveaux d'énergie sont calculés pour des valeurs de  $J$  jusqu'à cinq. Tous les niveaux rovibrationnels ont été convergés jusqu'à 0,001 cm<sup>-1</sup> en utilisant des bases ayant jusqu'à 87 millions de fonctions. Il y a un bon accord avec les résultats expérimentaux rapportés antérieurement. Même si on fait l'hypothèse que le moment dipolaire est selon l'axe OCS, nous trouvons des transitions avec des intensités appréciables entre différents états de torsion.

**Mots-clés :** spectroscopie rovibrationnelle, dynamique quantique, agrégats de van der Waals, agrégats de hélium, algorithme de Lanczos.

## Introduction

Infrared and microwave spectra of several small molecules embedded in helium clusters have been observed<sup>1-8</sup> and calculated.<sup>9-17</sup> In this paper, we present theoretical results for He<sub>2</sub>-OCS obtained by using a product basis set, the symmetry adapted Lanczos method (SAL),<sup>18,19</sup> and a simple potential built from pairwise interactions. Similar calculations have demonstrated that three-body potential terms are small for other dopant molecules. OCS is considered an ideal probe molecule for studies of helium clusters and nanodroplets,<sup>2,20</sup> and clusters with as few as one and as many as thousands of He atoms have been investigated.<sup>1-4,21-24</sup> Calculations on small clusters are important because they confirm the accuracy of interaction potentials. The same interaction potentials can be used to study (for example with Monte Carlo methods) clusters with as many as thousands of He atoms. Experiments on such clusters are now possible.<sup>23,25</sup> Calculations are also useful because they guide experimentalists as they search for unobserved transitions, confirm and explain proposed assignments, and make new assignments possible. Because the frequency of the OCS intramolecular vibrations is much higher than the other

frequencies, an adiabatic approximation is accurate, and we have therefore computed spectra for the He<sub>2</sub>-OCS cluster by treating explicitly the two OCS-He stretch coordinates, three dopant-He bend coordinates, and the three Euler angles describing the orientation of the cluster (eight in total). Different potentials are used for different vibrational states of OCS.

He<sub>N</sub>-OCS clusters have been studied experimentally in the infrared (IR) region of the CO fundamental band and in the microwave (MW) region.<sup>1,2,21,22,24</sup> More details about the experiments, including more results for He<sub>2</sub>-OCS, in both regions were published later.<sup>3,4</sup> Theoretical calculations, using quantum Monte Carlo techniques, have successfully explained many of the observed trends as function of cluster size.<sup>26-28</sup>

## Calculations

### Kinetic energy operator and basis functions

We use the approach of ref. 14 and assume an adiabatic separation between the fast intra-dopant coordinates and the He-dopant coordinates. In atomic units, the kinetic energy operator (KEO) is<sup>14,29,30</sup>

$$[1] \quad T = T_s + T_{b,\text{diag}} + T_{b,\text{off}} + T_{\text{Cor}}$$

with

$$[2] \quad T_s = -\frac{1}{2\mu_1} \frac{\partial^2}{\partial \mathbf{r}_1^2} - \frac{1}{2\mu_2} \frac{\partial^2}{\partial \mathbf{r}_2^2}$$

$$T_{b,\text{diag}} = -[B_L + B_1(\mathbf{r}_1)] \left[ \frac{\partial^2}{\partial \theta_1^2} + \cot \theta_1 \frac{\partial}{\partial \theta_1} - \frac{1}{\sin^2 \theta_1} (J_z - l_{2z})^2 \right] + [B_L + B_2(\mathbf{r}_2)] l_2^2 + B_L [J^2 - 2(J_z - l_{2z})^2 - 2J_z l_{2z}]$$

$$T_{b,\text{off}} = B_L [l_{2+a_1^-} + l_{2-a_1^+}]$$

$$T_{\text{Cor}} = -B_L [J_{-a_1^+} + J_{+a_1^-} + J_{-l_{2+}} + J_{+l_{2-}}]$$

where

$$[3] \quad B_i(\mathbf{r}_i) = \frac{1}{2\mu_i \mathbf{r}_i^2}, \quad l_{2\pm} = l_{2x} \pm i l_{2y},$$

$$J_{\pm} = J_x \pm i J_y, \quad a_1^{\pm} = \pm \frac{\partial}{\partial \theta_1} - \cot \theta_1 (J_z - l_{2z})$$

The vector along OCS is  $\mathbf{r}_0$ . OCS vibrational coordinates do not appear in the KEO because we assume they can be adiabatically separated.  $\mathbf{r}_1$  and  $\mathbf{r}_2$  are the lengths of Radau, or orthogonalized satellite, vectors  $\mathbf{r}_1$  and  $\mathbf{r}_2$  that are linear combinations of Jacobi (or satellite) vectors,  $\mathbf{b}_1$  and  $\mathbf{b}_2$ , from the He atoms to the centre of mass of OCS,<sup>31</sup> see Fig. 1. The polyspherical angles ( $\theta_1$ ,  $\theta_2$ , and  $\phi_2$ ) are determined by the three vectors ( $\mathbf{r}_0$ ,  $\mathbf{r}_1$ , and  $\mathbf{r}_2$ ).  $\mu_1 = \mu_2$  is the mass of the He atom. When  $\theta_1 = 0$ , He atom one is aligned with OCS as OCS–He.  $B_L$  is an OCS rotational constant; different  $B_L$  values are used for different vibrational states of OCS.  $J$  is the total angular momentum. The  $l_2$  angular momentum operator is defined in terms of the polar angles ( $\theta_2$  and  $\phi_2$ ) of the Radau vector associated with He atom 2.

For the stretch coordinates, we use discrete variable representation (DVR) functions,<sup>32–35</sup> and for the bend and rotational coordinates, we use the parity-adapted rovibrational functions<sup>36,37</sup> ( $\bar{m}_2 = -m_2$  and  $\bar{K} = -K$ )

$$[4] \quad |u_{l_1 l_2 m_2; K}^{JMP}\rangle$$

$$= N_{m_2, K} \frac{1}{\sqrt{2}} [|l_1 l_2 m_2; JKM\rangle + (-1)^{J+P} |l_1 l_2 \bar{m}_2; J\bar{K}M\rangle]$$

with

$$N_{m_2, K} = (1 + \delta_{m_2, 0} \delta_{K, 0})^{-1/2}$$

The ket in this equation is defined by

$$[5] \quad \langle \theta_1, \theta_2, \phi_2; \alpha, \beta, \gamma | l_1 l_2 m_2; JKM \rangle$$

$$= \sqrt{\frac{2J+1}{8\pi^2}} \Theta_{l_1}^{m_1}(\theta_1) Y_{l_2}^{m_2}(\theta_2, \phi_2) D_{MK}^{J*}(\alpha, \beta, \gamma)$$

with

$$[6] \quad Y_{l_2}^{m_2}(\theta_2, \phi_2) = \frac{1}{\sqrt{2\pi}} \Theta_{l_2}^{m_2}(\theta_2) e^{im_2 \phi_2}$$

$$m_1 \equiv K - m_2$$

where  $\Theta_l^m(\theta)$  is a normalized associated Legendre function with the  $(-1)^m$  Condon–Shortley phase factor.  $D_{MK}^J$  is a

Wigner function<sup>38</sup> and ( $\alpha$ ,  $\beta$ , and  $\gamma$ ) are the Euler angles. For the parity-adapted functions,  $K \geq 0$  and  $P = 0$ , and 1 correspond to even and odd parity. If  $K = 0$ , it is necessary to apply the constraint  $m_2 \geq 0$ . The combination  $m_2 = K = 0$  and  $(-1)^{J+P} = -1$  is not allowed. In our calculations,  $l_1$ ,  $l_2$ , and  $m_2$  all have the same maximum value. The parity-adapted basis makes it possible to calculate even and odd parity levels separately. The symmetry-adapted Lanczos algorithm<sup>18,19</sup> (SAL) is used within each parity block to compute states that are symmetric (*A*) and antisymmetric (*B*) with respect to exchange of the two He atoms. For more details, see ref. 14. A complete product basis function is

$$[7] \quad f_{\alpha_1}(\mathbf{r}_1) f_{\alpha_2}(\mathbf{r}_2) u_{l_1 l_2 m_2 K}^{JMP}(\theta_1, \theta_2, \phi_2; \alpha, \beta, \gamma)$$

where  $f_{\alpha_k}(\mathbf{r}_k)$  is a DVR function.

### Computing rovibrational energy levels and intensities

Using the SAL algorithm, it is possible, for each parity block, to do a single calculation that yields both the symmetric and antisymmetric states with respect to permuting the two He atoms: *A*+ and *B*+ for even parity, *A*– and *B*– for odd parity. *A* and *B* label symmetries with respect to permutation of the He atoms. For <sup>4</sup>He<sub>2</sub>–OCS only, *A*+ and *A*– states are physically allowed because of the zero nuclear spin of the <sup>4</sup>He nucleus. Eigenvalues and eigenvectors are obtained by computing matrix–vector products. Matrix–vector products are evaluated by doing sums sequentially.<sup>34,39–42</sup> Similar techniques have been used to compute energy levels of many molecules.<sup>34,43–46</sup> Kinetic energy matrix elements are given in ref. 14. Potential matrix–vector products are evaluated by using quadrature and doing sums sequentially, as explained in ref. 14.

To compute intensities, we use standard equations<sup>14</sup> and assume that the dipole moment is along the OCS axis. Specifically, the line strength (*S*) and intensity (*I*) for MW and IR transitions are computed from the wave functions using eqs. [28] and [34] of ref. 14, respectively. In our previous papers on helium-doped clusters,<sup>14–16</sup> we inadvertently omitted the  $G(J, J' - J)$  factor in eq. [34] of ref. 14. The intensities in those papers are therefore off by small factors. In this pa-

**Fig. 1.**  $B$  is the canonical point for the Radau vectors.  $\mathbf{b}_1$  and  $\mathbf{b}_2$  are Jacobi vectors.  $\mathbf{r}_1$  and  $\mathbf{r}_2$  are Radau vectors.  $\phi_2$  is a dihedral angle between  $\mathbf{r}_1$  and  $\mathbf{r}_2$  around  $\mathbf{r}_0$ .  $\theta_1$  ( $\theta_2$ ) are angles between  $\mathbf{r}_0$  and  $\mathbf{r}_1$  ( $\mathbf{r}_2$ ). The angles are not shown.

per, the  $G(J, J' - J)$  factor is included correctly. Note that the line strength does not depend on the temperature. The wave functions are obtained from eigenvectors of the Hamiltonian matrix that are computed as described previously.<sup>37,47</sup>

### Details specific to He<sub>2</sub>-OCS

We use different rotational constants for  $\nu = 0$  and  $\nu = 1$ ;  $\nu$  is the quantum number associated with the normal coordinate that corresponds to the CO stretch. The OCS rotational constants are fixed to the experimental values<sup>48</sup> of 0.202856 cm<sup>-1</sup> and 0.202251 cm<sup>-1</sup> for  $\nu = 0$  and for  $\nu = 1$ , respectively, following ref. 26. The potential we use is a sum of two He-OCS potentials and a He-He potential. Different He-OCS potentials are used for the  $\nu = 0$  and  $\nu = 1$  calculations. The He-OCS potentials are the VMP4<sub>0</sub> and VMP4<sub>1</sub> potentials of ref. 26, obtained by averaging over 1D CO stretch normal-coordinate vibrational wave functions of OCS, computed for a free OCS molecule. Having the vibrationally averaged potential allows us to predict the vibrational band centre shift. See ref. 26 for an assessment of other potentials of He-OCS. The He-He potential is taken from ref. 49. The He<sub>2</sub>-OCS potential is zero when all three of the constituents of the complex are far apart. The masses are the same as those used in ref. 26.

To accelerate the convergence of the Lanczos calculation, we apply a potential ceiling value.<sup>46</sup> A ceiling of 1000 cm<sup>-1</sup> changes low-lying energy levels by less than 0.001 cm<sup>-1</sup>. For the angular basis, we use  $l_{\max} = m_{\max} = 26$  (the same  $l_{\max}$  for  $l_1$  and  $l_2$ ). We use 35 Gauss-Legendre quadrature points for  $\theta_1$  and  $\theta_2$ , and 64 equally spaced points in the range from 0 to  $2\pi$  for  $\phi_2$ . For  $r_1$  and  $r_2$ , we use 35 PODVR(potential-optimized DVR) functions.<sup>50,51</sup> The reference potential that defines the PODVR functions is obtained by minimizing the potential, for each  $r_1$  point, with respect to  $r_2$  and  $\phi_2$ .  $\theta_1$  and  $\theta_2$  are fixed at equilibrium values to ensure smoothness of the minimized potential. When minimiz-

ing, the initial values of  $r_2$  and  $\phi_2$  are equilibrium values. The minimized potential is similar to the cut potential obtained by setting  $r_2$ ,  $\phi_2$ ,  $\theta_1$ , and  $\theta_2$  to equilibrium values. For values of  $r_1$  for which the cut potential is larger than 100 cm<sup>-1</sup> (above the dissociation energy), the reference potential is set equal to the cut potential. The 1D Schrödinger equation for the reference potential is solved with 150 sinc DVR basis functions<sup>52,53</sup> in the range from 3.2 to 20 b (1 b = 5.291 77 × 10<sup>-11</sup> m). The basis size and the number of quadrature points have been chosen to ensure that the levels we report are converged to within 0.001 cm<sup>-1</sup>. The size of the product basis defined above is 8.5 million for the case of  $J = 0$ , even parity. The size grows by a factor of  $2J + 1$  if  $J > 0$ . The largest basis size is 87 million for  $J = 5$ , odd parity. We used  $T = 0.7$  K for IR spectra and MW spectra. The experimental spectra are obtained from several scans, and there is therefore no clear experimental temperature.

To compare our computed energy levels directly with experimental results, we calculate IR rovibrational transition wavenumbers from

$$[8] \quad \tilde{\nu} = \tilde{\nu}_0(\text{He}_2\text{OCS}) + E(\nu = 1) - E(\nu = 0)$$

where  $E(\nu = 0)$  and  $E(\nu = 1)$  are calculated wavenumbers measured from the  $\nu = 0$  and  $\nu = 1$  ground states and  $\tilde{\nu}_0(\text{He}_2\text{OCS})$  is the vibrational band center of He<sub>2</sub>-OCS. It can be computed from

$$[9] \quad \tilde{\nu}_0(\text{He}_2\text{OCS}) = \tilde{\nu}_0(\text{OCS}) + \Delta; \Delta = E_{\nu=1}^{\text{zpe}} - E_{\nu=0}^{\text{zpe}}$$

where  $E_{\nu=0}^{\text{zpe}}$  and  $E_{\nu=1}^{\text{zpe}}$  are zero-point energies (zpe) obtained on the adiabatic  $\nu = 0$  and  $\nu = 1$  surfaces, respectively, measured relative to the dissociation asymptote (and are therefore negative), and  $\tilde{\nu}_0(\text{OCS})$  is the vibrational frequency of the free OCS molecule. Using  $E_{\nu=0}^{\text{zpe}} = -32.2110$  cm<sup>-1</sup>,  $E_{\nu=1}^{\text{zpe}} = -32.0221$  cm<sup>-1</sup>, and  $\tilde{\nu}_0(\text{OCS}) = 2062.2012$  cm<sup>-1</sup> in eq. [9],<sup>24</sup> one finds that the band centre is  $\tilde{\nu}_0(\text{He}_2\text{OCS}) = 2062.398$  cm<sup>-1</sup>. This is very close to the experimental value (2062.426 cm<sup>-1</sup>).<sup>3</sup> The results we present are computed using the experimental value. The difference between the band centre and  $\tilde{\nu}_0(\text{OCS})$  is the frequency shift. It is 0.1968 cm<sup>-1</sup>, which is close to the frequency shift obtained from a quantum Monte Carlo calculation on the same potential.<sup>26</sup>

### Theoretical results

In Tables 1 and 2, we report  $\nu = 0$  energy levels for  $J = 0$  and  $J = 1, 2, 3$ , respectively, and give torsional and rotational assignments  $|\nu_t; JK_a K_c\rangle$ . Those for  $\nu = 1$  are very similar. Levels up to  $J = 5$  and wave functions up to  $J = 4$  have been computed. The lowest vibrational frequency of the complex is that of the He<sub>2</sub> torsion. For each  $J$ , the lowest set of  $2J + 1$  levels is assigned to the  $\nu_t = 0$  state. The next set is assigned to the  $\nu_t = 1$  levels and so on. Within each  $\nu_t$  set,  $(K_a, K_c) = (J, 0), (J, 1), \dots, (0, J)$  are assigned to levels in order of decreasing energy. In this fashion, it is possible to link irrep labels and  $\nu_t, JK_a K_c$  labels. This works remarkably well at least up to  $\nu_t = 4$ . From the permutation inversion group symmetries of the three  $J = 1$  levels, the fact that the symmetry of the  $\nu_t = 1$  torsional factor is  $B^-$ , and assuming that each state is a product of a torsional factor and a rotational factor, one can deduce the relationship between the

**Table 1.**  $J = 0$  vibrational levels (in  $\text{cm}^{-1}$ ) with the assigned torsional quantum number ( $\nu_t$ ) in the parenthesis.  $B+$  and  $B-$  levels are forbidden.

evenness or oddness of the ( $K_aK_c$ ) labels and permutation inversion group symmetries given in Table 3. This relationship holds for all the  $|\nu_t; JK_aK_c\rangle$  states we assigned. Because the symmetries associated with ( $ee$ ,  $oe$ ,  $oo$ , and  $eo$ ) are different for  $\nu_t = 0$  and  $\nu_t = 1$ , the principal axes, which, if used with

**Table 3.** The relationship between ( $\nu_t; JK_aK_c$ ) labels and permutation inversion group symmetries for two torsional states. It is derived from  $J = 0$  and 1 levels and expected to hold for higher  $J$  levels. The symmetry of  $|\nu_t = 1\rangle$  torsional state is  $B-$ . The physically allowed symmetries are in bold face.

<sup>a</sup>Evenness and oddness of  $K_aK_c$ .

the asymmetric top-symmetry rule,<sup>54</sup> would give the relation between  $J_{K_aK_c}$  and irrep labels, are different for  $\nu_t = 0$  and  $\nu_t = 1$ . Results for IR and MW transitions are reported in Tables 4 and 5. Intensities have been scaled so that the intensity of the transition (for  $\nu_t = 0$ )  $1_{01} \leftarrow 0_{00}$  equals 1.

In Fig. 2, we show the probability density computed from some of the  $\nu = 0$  and  $J = 0$  wave functions. Coupling between the torsion and other coordinates is weak enough that a clear torsional progression is evident. The probability densities are obtained by integrating over coordinates except  $\theta_2$  and  $\phi_2$ . To avoid a coordinate transformation, we use the Radau angles. It is remarkable that it is possible to identify torsional states up to  $\nu_t = 7$ . This indicates that the torsion is only weakly coupled to other coordinates.

### Comparison of theory and experiment

The dipole moment of  $\text{He}_2\text{-OCS}$  is almost parallel to the the OCS axis. In conjunction with the fact that the  $a$ -inertia axis of  $\text{He}_2\text{-OCS}$  is close to OCS, this means that the dominant transitions in the experimental (IR and MW) spectra are  $a$ -type transitions with  $\Delta K_a = 0$  and  $\Delta K_c = \pm 1$ .

In the IR study,<sup>3</sup>  $K_a = 0$   $\nu_t = 0$  lines were all assigned for  $P(3)$ ,  $P(2)$ , ...,  $R(3)$ , and  $R(4)$ . These lines are marked with an asterisk in Table 4 and also indicated on the stick spectrum of Fig. 3. According to the calculations, all of these experimental lines are correctly assigned.

Because rotational wave functions with  $K_a$  even (odd) are symmetric (antisymmetric) with respect to exchange of the He atoms, Tang and McKellar (TM), in ref. 3, argue that only states with even values of  $K_a$  are allowed for  $\nu_t = 0$  and only odd values of  $K_a$  are allowed for  $\nu_t = 1$ . This is consistent with the assignments of Table 4 derived from the assignment procedure outlined in the previous section. Table 4 contains lines that TM were unable to fully assign, but report in their Table 4.<sup>3</sup> These are  $P$  and  $R$  lines that TM assumed were either  $K_a = 1$  or  $K_a = 2$  transitions. All these lines were matched with our computed levels. Moreover,  $K_a = 1$  transitions are for  $\nu_t = 1$  state and  $K_a = 2$  transitions are for  $\nu_t = 2$  state, again confirming the TM symmetry argument.

TM do assign four  $Q$  lines close to the band centre (near  $2062.4 \text{ cm}^{-1}$ ), see Fig. 2 of ref. 3. The outer pair was assigned to  $Q_2(2)$  (the notation is  $Q_{K_a}(J)$ ) lines using the parameters fitted to the  $K_a = 0$  lines assuming that all transitions with even  $K_a$  must occur between levels with  $\nu_t = 0$ . TM propose that the inner pair may be  $Q_1(1)$  lines of the  $\nu_t = 1$  state. One

**Table 4.** Strong IR rovibrational transitions (with  $I \geq 0.10$ , except for the first four transitions and the  $\nu_t = 2$  line at  $2062.912\text{ cm}^{-1}$ , which are weaker) for  $\text{He}_2\text{-}^{16}\text{O}^{12}\text{C}^{32}\text{S}$  (in  $\text{cm}^{-1}$ ) at a temperature of 0.7 K. The experimental data are from ref. 3. Transitions marked by an asterisk were assigned as  $K_a = 0$ ; the four  $Q$  lines are marked by a dagger; the remaining experimental lines were assigned as  $K_a = 1$  or 2 by Tang and McKellar.<sup>3</sup> Their  $K_a$  assignments agree with our assignments.

**Fig. 2.** Probability function plots for torsional states. (a), (b), (c), (d), (e), (f), (g), and (h) are the  $\nu_t = 0, 1, 2, 3, 4, 5, 6$ , and 7 torsional states, respectively. The torsional states are not strongly coupled to other modes although there are other states between them. Coupling becomes important starting at about  $\nu_t = 6$ . For (g), the contour interval is 0.05, and for all others, it is 0.1.

would normally expect the two  $Q$  a-type transitions between  $J = 2$  levels to be closer than the  $Q$  transitions between  $J = 1$  levels because, for a given  $J$ , the separation between  $J_{J,0}$  and  $J_{J,1}$  decreases as  $J$  increases. TM conjecture that  $J = 1$   $Q$  transitions are closer because the spectroscopic parameters for the  $\nu_t = 1$  differ significantly from those of the  $\nu_t = 0$  state, due to coupling. TM's assignments of the  $Q$  branches are all confirmed by our calculations, see Table 4.

None of the calculated  $\Delta\nu_t = 1$  IR transitions were strong (such transitions were found in  $\text{He}_2\text{-N}_2\text{O}^{14}$ ) and are not observed experimentally. According to the calculation, the strongest  $\nu_t = 2$  line is at  $2062.912\text{ cm}^{-1}$ . Its intensity is sensitive to the temperature. This line is not observed experimentally. Some calculated strong lines (marked by ?? in Table 4) were not observed and may have been obscured by nearby strong lines of complexes with different  $N$ .<sup>55</sup>

**Fig. 3.** Calculated (top) and observed (bottom) IR spectra of He<sub>2</sub>–OCS. The intensity of the  $R(0)$  transition is scaled to 1 for both the calculation and the experiment. The experimental data are from ref. 56. The calculated spectrum is for  $T = 0.7$  K. The  $P$  and  $R$  branches of  $K_a = 0$  lines are marked on a line below the sticks.

The agreement of the observed and calculated IR relative intensities (for  $T = 0.7$  K) in Table 4 is quite satisfactory. This is also demonstrated in Fig. 3, which shows the observed and calculated spectra in the form of a stick diagram. The intensity pattern of the four  $Q$  lines is in excellent agreement with the experiment.

Xu and Jäger observed a few  $K_a = 0$  MW transitions.<sup>4</sup> They agree well with our calculations (see Table 5). It would be interesting to attempt to detect the two transitions with  $\Delta v_t = 1$  that are marked with an asterisk in Table 5. In addition, two strong transitions with  $v_t = 1$  (marked with a dagger in Table 5) are very close to an observed transition at  $0.479 \text{ cm}^{-1}$ , shifted to the blue by only  $0.01 \text{ cm}^{-1}$  and  $0.1 \text{ cm}^{-1}$ , respectively. As MW experiments are very sensitive, it seems likely that they, and other weaker transitions between levels in Tables 1 and 2, could be detected.

## Conclusion

An understanding of small doped helium clusters facilitates the analysis of larger ones, which are used to develop a better understanding of superfluid effects. One important general conclusion is the high quality of the potential obtained by adding two-body interactions. It is remarkable that one can obtain such good agreement with experiment without including three-body interactions. The quality of the potential can only be determined by doing accurate rovibrational calculations that properly account for the interaction of the large amplitude vibrations and vibration and rotation. Several complexes with two helium atoms and a linear dopant have been studied, and in all cases, two-body potentials are excellent.

## Acknowledgements

This work has been supported by the Natural Sciences and Engineering Research Council of Canada (NSERC) and the Canada Research Chairs Program. Calculations were done on computers of the Réseau québécois de calcul de haute performance (RQCHP). We are grateful to Bob McKellar for many informative discussions and to Francesco Paesani for sending us the potentials.

# Density functional theory study on the electron spectra of naphthalene and azulene vapours

Delano P. Chong

**Abstract:** The ionization and excitation spectra of valence and core electrons of naphthalene and azulene in the gas phase are studied with density functional theory. The results are compared with available experimental data and previous calculations. New estimates are proposed for the ionization energies of both valence and core electrons and the calculated excitation energies are consistent with experiment.

**Key words:** ionizations, photoelectron spectra (PES), excitations, UV-vis absorption, electron spectra, core-electron binding energies, naphthalene, azulene, electron spectroscopy for chemical analysis (ESCA), X-ray photoelectron spectroscopy (XPS), density functional theory (DFT).

**Résumé :** Faisant appel à la théorie de la fonctionnelle de la densité, on a étudié les spectres d'ionisation et d'excitation de valence et des électrons de cœur du naphthalène et de l'azulène en phase gazeuse. On a comparé les résultats de ces calculs avec les données expérimentales disponibles et avec les résultats de calculs antérieurs. De nouvelles évaluations sont proposées pour les énergies d'ionisation de valence ainsi que des électrons de cœur et les énergies d'excitation calculées sont en accord avec les données expérimentales.

**Mots-clés :** ionisations, spectres photoélectroniques (SPE), excitations, absorption UV-vis, spectres électroniques, énergies de liaison d'électron de cœur, naphthalène, azulène, spectroscopie électronique pour l'analyse chimique (SEAC), spectroscopie photoélectronique des rayons X (SPX), théorie de la fonctionnelle de la densité (TFD).

[Traduit par la Rédaction]

## Introduction

In the absence of the universal density functional, our efforts in density functional theory (DFT) continue to be directed towards the development of the best DFT procedure for each property of interest, such as the core-electron spectra of molecules containing heavier elements. For the ionization and excitation spectra of valence and core electrons of organic and other small molecules, we have developed reliable methods within DFT, with a limited number of test cases in benchmark databases. Naturally, more test cases are desirable and the accuracy of such additional calculations would enhance our confidence in the developed procedures and in the reliability of predictions of data not yet available experimentally.

The molecular structures and spectra of naphthalene and azulene have been the subject of many studies. Azulene has been particularly interesting to chemists as well as to the dye industry because of its absorption in the visible region, leading to its blue color. In some of the earlier investigations, the absorption spectra of azulene were studied in solutions or solid state.<sup>1–7</sup> Now, with the exception of the core-electron binding energies (CEBEs) of azulene, experimental results on ionization and excitation of both valence and core electrons of gas-phase naphthalene and azulene, including excitations to many Rydberg-like states, are available. Therefore,

we can assess the reliability of various DFT procedures by comparing calculations on single molecules to observed data of naphthalene and azulene vapours.

For the interpretation of the photoelectron spectra of valence electrons, the procedure of outer-valence Green's function (OVGF)<sup>8</sup> is usually the most reliable. However, OVGF may not be as accurate as one wishes in two situations: (i) when the basis set, usually limited by computational facilities, is not large enough and (ii) when the pole strength is small due to significant shake-up effects, in which case the method known as third-order algebraic diagrammatic construction ADC(3)<sup>9</sup> is more reliable, provided a sufficiently large basis set is used. The average absolute deviation (AAD) of OVGF and ADC(3) results from experiment can be as low as 0.2 eV or better. In some cases, however, the AAD can be greater than 0.3 eV; for example, the seven vertical ionization energies (VIEs) of *s*-triazine.<sup>10</sup> On the other hand, DFT offers alternative procedures. The meta-Koopmans' theorem (mKT) is a shortcut approximation, usually giving an AAD of 0.4 eV,<sup>11</sup> considerably better than the usual application of Koopman's theorem in Hartree-Fock calculations, but this method also performs poorly for *s*-triazine, with an AAD of 0.58 eV.<sup>10</sup> Another DFT procedure recently developed<sup>12</sup> can be abbreviated as  $\Delta$ PBE0(SAOP), which means the energy difference calculated with the parameter-free Perdew-Burke-Ernzerhof

functional (PBE0) exchange-correlation functional,  $E_{xc}$ ,<sup>13–15</sup> using the electron density obtained with the exchange-correlation potential,  $V_{xc}$ , known as the statistical average of orbital potentials (SAOP).<sup>16–18</sup> This procedure succeeded in giving an AAD of 0.21 eV for over 100 cases of nonperfluoro molecules.<sup>12</sup> For *s*-triazine, this  $\Delta$ PBE0(SAOP) was also successful, with an AAD of 0.23 eV.<sup>10</sup> It is our intention to test mKT and  $\Delta$ PBE0(SAOP) again on naphthalene and azulene.

For excitation of valence electrons, the comparison with experiment is more difficult. In the lower-energy region, the absorptions are broadened by vibrations and, in the higher-energy region, there are so many Rydberg-like states that association of calculated values with observed energies may be unreliable. On the theoretical side, some studies on naphthalene and azulene are based on semiempirical methods such as Hückel molecular orbitals (MO),<sup>19</sup> the complete neglect of differential overlap with modified parameters (CNDO/M),<sup>20</sup> and Zerner's intermediate neglect of differential overlap (ZINDO),<sup>21</sup> all using subminimal basis sets, with no hope of predicting higher energy excitations. More recent approaches include second-order multiconfigurational perturbation theory (CASPT2),<sup>22</sup> time-dependent density functional theory (TDDFT) with parameter free  $E_{xc} = \text{PBE0}$ ,<sup>23</sup> and second-order polarization propagator approximation (SOPPA).<sup>24</sup> Our own preference is time-dependent DFT using  $V_{xc} = \text{SAOP}$ , which has been shown to give reliable results.<sup>10,25</sup>

Finally, the spectroscopy of core electrons of naphthalene and azulene has not been as well-studied as that of valence electrons. The established procedure for CEBEs is relatively simple:  $\Delta E(\text{PW86-PW91})$  with localized core hole has been shown to give excellent results.<sup>26,27</sup> For inner-shell excitations, a similar procedure has been developed for small molecules,<sup>28,29</sup> but symmetric molecules such as naphthalene and azulene are more difficult and we have to resort to shifting the results for transitions between symmetry MOs by the difference between the CEBEs of symmetry and localized core holes.

The object of this work is to compare the results of DFT calculations on the ionization and excitation spectra of both valence and core electrons with experiment to gain a better overall view of the protocol developed in our continuing studies.

## Computational details

The symmetry labels for both naphthalene and azulene molecules are ambiguous. In this work, we put both molecules on the *y*-*z* plane (with the  $\pi$ -MOs being mainly linear combinations of  $p_x$  AOs). For naphthalene, atoms C9 and C10 lie on the *z* axis. This choice of symmetry axes agrees with most of the earlier studies. On the other hand, in the theoretical papers by Rubio et al.,<sup>22</sup> Adamo et al.,<sup>23</sup> and Packer et al.,<sup>24</sup> naphthalene lies on the *x*-*y* plane with *x* and *y* being the long and short molecular axes, respectively. Therefore, we need to translate their symmetry labels into our choice of axis system. For azulene, the numbering is as follows: the carbon atoms C9 and C10 shared by both rings lie on the *y* axis, with the smaller ring labeled C1–C2–C3–C10–C9 and the larger one C4–C5–C6–C7–C8–C9–C10.

All the calculations in this work are carried out at the experimental geometry of naphthalene<sup>30</sup> and azulene<sup>31</sup> with the Amsterdam density functional (ADF) program<sup>32</sup> using a large even-tempered (et) basis set of Slater-type orbitals of polarized valence quadruple-zeta (pVQZ) quality.<sup>33</sup> For the description of valence electrons, the exchange-correlation potential of  $V_{xc} = \text{SAOP}$  is our preferred choice. For example, the resulting dipole moment from SAOP/et-pVQZ is 0.923 D, compared to 0.929 D from multireference singles and doubles configuration interaction (MR-SDCI),<sup>34</sup> and the observed value of  $0.882 \pm 0.002$  D.<sup>31</sup> Both theoretical values are closer to experiment than the recent result of 1.024 D from B3LYP/6-311++G(3d,2p).<sup>35</sup>

The DFT procedures we recommend can be abbreviated as follows: (i)  $\Delta$ PBE0(SAOP)/et-pVQZ for valence ionization, (ii) TDDFT(SAOP)/et-pVQZ for valence excitations, (iii)  $\Delta$ PW86-PW91/et-pVQZ +  $C_{\text{rel}}$  for core-electron ionizations, and (iv)  $\Delta$ PW86-PW91/et-pVQZ +  $C_{\text{rel}}$  for core-electron excitation energies, with approximate *f* values obtained with truncated TDDFT(SAOP)/et-pVQZ. For core-electron spectra, a small relativistic correction,  $C_{\text{rel}}$ , in atomic form derived empirically in 1995,<sup>36</sup> is added:

$$[1] \quad C_{\text{rel}} = KX_{\text{nr}}^N$$

with  $K = 0.2198 \times 10^{-6}$ ,  $N = 2.178$ , and  $X_{\text{nr}}$  is the nonrelativistic result. For approximate *f* values, the time-saving procedure of truncated TDDFT follows the proposal of Stener et al.<sup>37</sup> and allows only excitations from core MOs.

It should be mentioned that, when there is a choice between maintaining symmetry and insisting on integral number of electrons in a cationic calculation, the latter has been found to lead to better prediction of VIEs (except for perhalo systems).

## Results and discussions

### Valence ionizations

There have been several experimental measurements of the ionization energies of gas-phase naphthalene and azulene. For naphthalene, Lindholm et al.<sup>38</sup> presented the photoelectron spectrum (PES) without giving the numerical values. Therefore, their spectrum is enlarged and the ionization energies are measured to the nearest 0.02 eV in this study. Eland<sup>39</sup> also reported the PES of naphthalene, but the spectrum recorded by Klasinc et al.<sup>40</sup> appears to have a higher resolution. We combine the various studies and give the best estimate of the VIEs in Table 1, together with the results from the DFT methods mentioned above. It is disappointing to find the poor results from the mKT/et-pVQZ approximation. We are happy to see the excellent results from  $\Delta$ PBE0(SAOP)/et-pVQZ, with an AAD of 0.15 eV for naphthalene, even surpassing the OVGf/6-311G(d,p) method with an AAD of 0.27 eV for the first 16 VIEs.<sup>42</sup> Consequently, the assignment of the VIEs to symmetry species has been partly based on the  $\Delta$ PBE0(SAOP)/et-pVQZ results.

Similarly, experimental and theoretical data for azulene are displayed in Table 2. Since some VIEs of azulene are known only to 0.1 eV accuracy, the unreliable second decimal place of the AADs are given as subscripts. Contrary to expectations, the AAD of 0.39 eV from ADC(3) in Table 2 can be greater than that from the OVGf/6-311G(d,p)

method with an AAD of 0.27 eV<sup>42</sup> in the case of azulene. The VIEs from the shortcut method of mKT are even poorer for azulene than for naphthalene. Again, the recommended procedure of  $\Delta$ PBE0(SAOP)/et-pVQZ does extremely well, with an AAD of 0.13 eV. For the combined results on both molecules,  $\Delta$ PBE0(SAOP)/et-pVQZ leads to an AAD of 0.14 eV for a total of 28 valence-electron ionizations.

Although valence ionization energies are often given to the nearest 0.01 eV, the probable error is more likely to be 0.05–0.10 eV due to calibration errors and vibrational effects. Therefore, our AAD of 0.14 eV, approaching experimental reliability, is a pleasant surprise but could conceivably be the result of a cancellation of errors.

The procedure we recommend is not perfect for every molecule. When the effect of shake-up satellites is significant, the single configuration used in our DFT calculation may not be able to give an accurate enough description of the cation; and we do not have intensities like the pole strengths in OVGF and ADC(3). Moreover, the same procedure did not perform as well for the limited database of 13 VIEs of perhalo molecules. Instead, choosing symmetry rather than the integer number of electrons gave a reasonable AAD of 0.25 eV.<sup>12</sup>

### Valence excitations

There have been many measurements of the excitations of valence electrons of naphthalene and azulene vapours. For a comparison of various theoretical and experimental data, we list the excitations according to the order given by our TDDFT(SAOP)/et-pVQZ calculation. Data from observed ultraviolet absorptions<sup>4,41,46–50</sup> are compared to calculated energies of singlet excitations. Electron energy loss results<sup>51</sup> are also included in Table 3, although the intensity does not strictly follow transition dipole rules. Two-photon spectroscopy<sup>52</sup> is different and may lead to dipole-forbidden excited states. Similarly, the so-called Rydberg fingerprint spectroscopy,<sup>53</sup> whether it is performed with 4-photon off-resonance ionization<sup>54</sup> or 3-photon double-resonance ionization scheme,<sup>55</sup> can also produce dipole-forbidden states. Therefore, the observed energies are placed near the closest calculated energies. The results are summarized in Table 3 for naphthalene and Table 4 for azulene. It appears that the results from our preferred procedure of TDDFT(SAOP)/et-pVQZ can be matched with most of the observed excitations. The only poor results are the first two excited singlets of naphthalene, for which the high-power method of SOPPA<sup>24</sup> is probably more reliable. For naphthalene, Table 3 shows that TDDFT(SAOP)/et-pVQZ appears to be competitive to the recent methods of CASPT2, TDDFT(PBE0), and SOPPA.

### Core-electron ionization

Little is known about the C1s ionization of naphthalene and azulene. For naphthalene, Crenshaw and Banna<sup>57</sup> reported an average CEBE of 290.12 eV. With the approach of localized core holes, we find the values of 290.33, 290.06, and 290.03 eV for C9, C2, and C1, respectively, averaging to 290.10 eV as shown in Table 5. In comparison, the CI results of Hollauer et al.<sup>58</sup> give an average CEBE(C1s) of 292.46 eV. For the purpose of determining the inner-shell excitation energies, the results from symmetry core-hole treatment are also included in Table 5.

**Table 4.** Vertical excitation energies (in eV) of azulene to singlets with *f* values in parentheses.

As far as we know, the CEBE of azulene has not been determined experimentally. Hitchcock et al.<sup>59</sup> estimated the CEBE of azulene to be the same as naphthalene to calculate

the term values. We believe that our calculated value of 289.76 eV presented in Table 6 would be a more reliable estimate.

### Inner-shell excitations

The calculation of inner-shell excitation spectra of highly symmetric molecules, such as naphthalene and azulene, is not an easy task because we cannot use the localized core-hole approximation, which would destroy the symmetry of the excited states. Instead, we must resort to shifting the results for transitions between symmetry MOs by the difference between the CEBEs of symmetry and localized core holes. Our first step is to limit the excitation to only those from core electrons in a truncated TDDFT(SAOP)/et-pVQZ computation.<sup>35</sup> Guided by the approximate oscillator strengths from such TDDFT calculations, we compute the dipole-allowed inner-shell excited states by the method of  $\Delta E(\text{PW86-PW91})/\text{et-pVQZ} + C_{\text{rel}}$ . As shown in Tables 5 and 6, the difference between the CEBEs for localized and symmetry core holes is 12.50 eV for naphthalene and 7.02 eV for azulene. These values are used to shift the inner-shell excitation energies calculated for transitions between symmetry MOs calculated by  $\Delta \text{PW86-PW91}/\text{et-pVQZ} + C_{\text{rel}}$  and the final results are summarized in Tables 7 and 8.

Another difficulty lies in the fact that there are many core MOs in each symmetry: 1a<sub>g</sub>–3a<sub>g</sub>, 1b<sub>1u</sub> and 2b<sub>1u</sub>, 1b<sub>2u</sub>–3b<sub>2u</sub>, 1b<sub>3u</sub> and 2b<sub>3u</sub> for naphthalene, and 1a<sub>1</sub>–6a<sub>1</sub> and 1b<sub>2</sub>–4 b<sub>2</sub> for azulene. For naphthalene, the virtual MOs in increasing energies are 2b<sub>1g</sub>( $\pi$ ), 2b<sub>2g</sub>( $\pi$ ), 3b<sub>3u</sub>( $\pi$ ), 10a<sub>g</sub>, 8b<sub>2u</sub>, 8b<sub>1u</sub>, 2a<sub>u</sub>( $\pi$ ), etc. and the virtual MOs of azulene in increasing energies are 4b<sub>1</sub>( $\pi$ ), 3a<sub>2</sub>( $\pi$ ), 18a<sub>1</sub>, 5b<sub>1</sub>( $\pi$ ), 13b<sub>2</sub>, 19a<sub>1</sub>, 20a<sub>1</sub>, 14b<sub>2</sub>, 6b<sub>1</sub>( $\pi$ ), etc. With the ADF program, we cannot compute the excitation energy of 2a<sub>1</sub>–4b<sub>1</sub>( $\pi$ ) for azulene by  $\Delta \text{PW86-PW91}/\text{et-pVQZ}$ , for example. The  $f$  values obtained from truncated TDDFT(SAOP)/et-pVQZ calculations for all a<sub>1</sub> core MOs to 4b<sub>1</sub>( $\pi$ ) are therefore summed and listed as be-

**Table 6.** Core-electron binding energies (in eV) of azulene vapour.

longing to 1a<sub>1</sub>–4b<sub>1</sub>( $\pi$ ) in Table 8. Similar procedure is followed for all the other transitions listed in Tables 7 and 8.

Still another difficulty is the poor resolution of the experimental spectra. This makes the comparison of theory with experiment very uncertain. One possible way to overcome this last difficulty is to average the calculated results weighted by the approximate  $f$  values. This procedure is used for Tables 7 and 8. As can be seen from Tables 7 and 8, our calculated results seem to underestimate the core-electron excitation energies by an average of 0.3 eV. Some possible causes of the underestimation are the difficulties mentioned above. If we assume that the underestimation is experiment, it is reduced to a remarkable 0.1 eV.

### Conclusions

In summary, the results of  $\Delta \text{PBE0}(\text{SAOP})/\text{et-pVQZ}$  for valence ionization of naphthalene and azulene are excellent, as can be seen from the AAD of 0.14 eV. The results from our preferred procedure of TDDFT(SAOP)/et-pVQZ can be matched with most of the observed excitations of valence electrons. Because the  $V_{\text{xc}} = \text{SAOP}$  is asymptotically correct, it is our belief that it leads to a reliable description of valence electrons and good distribution of orbital energies for both occupied and vacant MOs. Hence, the nice prediction of excitation spectra is not surprising. On the other hand, from the excellent results of VIEs, we draw the tentative conclusion that, given the electron density,  $E_{\text{xc}} = \text{PBE0}$  can provide excellent energy differences.

There is only one experimental CEBE of naphthalene at 290.12 eV with which we can compare our average calculated value of 290.10 eV from applying  $\Delta \text{PW86-PW91}/\text{et-pVQZ} + C_{\text{rel}}$  on the localized core holes. For azulene, we believe that our average CEBE(C1s) of 289.76 eV is more reliable than the estimate based on the observed 290.12 eV for naphthalene. Finally, although the difficulties in predicting core-electron excitation spectra do not allow us to make definitive conclusions on naphthalene and azulene, the results are extremely encouraging.

Such excellent performance of the recommended procedures for the ionization and excitation spectra of valence

<sup>a</sup>Present work: shift = CEBE (loc) – CEBE (sym) = 290.10 – 277.60 = 12.50 eV.<sup>b</sup>Average weighted by  $f$  values.<sup>c</sup>Gordon et al.<sup>60</sup><sup>d</sup>Hollauer et al.<sup>58</sup> with an empirical shift of 3.9 eV.

and core electrons of naphthalene and azulene could be due to the large basis sets employed, and (or) to the low level of charge transfer between carbon and hydrogen in

naphthalene and azulene, unlike perhalo systems. Therefore, more test cases should be investigated in future studies.

**Table 8.** Inner-shell excitation energies (in eV) of azulene vapour with approximate  $f$  values in parentheses.

# Prototypical arsine–triels adducts ( $R_3AsEX_3$ for $E = B, Al, \text{ and } Ga$ )

Eamonn Conrad, Janet Pickup, Neil Burford, Robert McDonald, and Michael J. Ferguson

**Abstract:** Complexes of arsine ligands ( $R_3As$ ,  $R = Me, Et, Ph$ ) and Lewis acids of group-13 elements of the form  $EX_3$  ( $E = B$ ,  $X = Ph, C_6F_5$ ;  $E = Al$ ,  $X = Cl, Br, I$ ;  $E = Ga$ ,  $X = Cl$ ) have been isolated and characterized by X-ray crystallography, infrared spectroscopy,  $^1H$ ,  $^{13}C\{^1H\}$ ,  $^{11}B\{^1H\}$ , and  $^{27}Al$  NMR spectroscopy. The compounds are compared with rare arsine–triels adducts.

**Key words:** arsine–triels (boron, aluminum, gallium) Lewis adducts.

**Résumé :** Les complexes des ligands d'arsine ( $R_3As$ ,  $R = Me, Et, Ph$ ) et des acides de Lewis du groupe des éléments 13 de la forme  $EX_3$  ( $E = B$ ,  $X = Ph, C_6F_5$ ;  $E = Al$ ,  $X = Cl, Br, I$ ;  $E = Ga$ ,  $X = Cl$ ) ont été isolés et caractérisés par la cristallographie aux rayons-X, la spectroscopie infrarouge, et la spectroscopie RMN de  $^1H$ ,  $^{13}C\{^1H\}$ ,  $^{11}B\{^1H\}$  et  $^{27}Al$ . Les composés sont comparés aux adduits rares d'arsine–triels.

**Mots-clés :** adduits de Lewis d'arsine–triels (bore, aluminium, gallium).

[Traduit par la Rédaction]

## Introduction

Compounds involving bonds between tetracoordinate group-13 elements and tetracoordinate group-15 elements represent prototypical examples of Lewis acid–base adducts and are well-known for compounds involving nitrogen or phosphorus donors. In contrast, examples of adducts involving arsine ligands on Lewis acids of group-13 elements are rare despite the importance of arsenic in the development of semiconducting materials such as gallium arsenide.

Compounds containing a coordinatively unsaturated arsenic center bound to a coordinatively unsaturated boron center are known,<sup>1</sup> but adducts of tetracoordinate arsenic bound to tetracoordinate boron have not been reported. Moreover, although examples of complexes of arsines with alanes,<sup>2–4</sup> gallanes,<sup>5–7</sup> or indanes<sup>7,8</sup> have been spectroscopically or crystallographically characterized, there are limited data available and few acyclic complexes are known that represent prototypical examples of arsines with Lewis acids of group-13 elements and provide fundamental data for the As–E bonds.

Prompted by the recent use of arsine ligands to stabilize pnictogenium cations ( $PnR^{2+}$ )<sup>9</sup> and diphosphenium dications ( $RPPR^{2+}$ ),<sup>10</sup> we report crystallographic and NMR spectroscopic data for compounds of the form  $R_3AsEX_3$  for  $E = B, Al, \text{ and } Ga$ . Comparisons are made with the rare examples that have been previously reported.

## Results and discussion

Reaction mixtures containing an alkyl- or aryl-arsine ( $R_3As$ ,  $R = Me, Et, Ph$ ) and an arylborane ( $BX_3$ ,  $X = Ph, C_6F_5$ ) in  $CH_2Cl_2$  exhibit a single signal in the  $^{11}B\{^1H\}$  NMR spectra (Table 1). The chemical shifts are consistent with those observed for the corresponding solids that are isolated from reaction mixtures and redissolved in  $CD_2Cl_2$  (or  $CD_3CN$ ). Derivatives containing  $X = C_6F_5$  have chemical shifts in the range observed for those compounds involving  $B(C_6F_5)_3$  moieties.<sup>11</sup> Reaction mixtures of arsines ( $R_3As$ ,  $R = Me, Et, Ph$ ) with haloalanes ( $AlX_3$ ,  $X = Cl, Br, I$ ) in  $CH_2Cl_2$  show a single chemical shift in the  $^{27}Al$  NMR spectra (Table 1) with chemical shifts that are in the range of tetracoordinate aluminum centers.<sup>12</sup>

Crystalline samples of  $Me_3AsBPh_3$ ,  $Et_3AsB(C_6F_5)_3$ ,  $Ph_3AsAlCl_3$ , and  $Ph_3AsAlI_3$  have been isolated from the reaction mixtures described above and  $Ph_3AsGaCl_3$  was isolated from the reaction of  $Ph_3As$  and  $GaCl_3$ . The compounds have been crystallographically characterized as adducts of arsine ligands on group-13 Lewis acids. The structures all involve slightly distorted tetrahedral geometries at the arsenic and group-13 element centers, as illustrated in Figs. 1–5. There are no significant intermolecular interactions in any of the structures. Selected bond distances and angles are presented in Table 2 and torsional angles are available as Supplementary data.

**Fig. 1.** Crystallographic view of  $\text{Me}_3\text{AsBPh}_3$ . Nonhydrogen atoms are represented by Gaussian ellipsoids at the 50% probability level.

The As-B bond lengths in  $\text{Me}_3\text{AsBPh}_3$  (2.148(3) Å) and  $\text{Et}_3\text{AsB}(\text{C}_6\text{F}_5)_3$  (2.1905(18) Å) are longer than the sum of the covalent radii for arsenic and boron (2.09 Å). Both adducts adopt a close to eclipsed conformation (smallest C-As-B-C torsion angle in  $\text{Me}_3\text{AsBPh}_3$  = 24.03(8)°, in  $\text{Et}_3\text{AsB}(\text{C}_6\text{F}_5)_3$  = 9.89(13)°, which compares with the conformation observed in the phosphine-borane analogue,  $\text{Et}_3\text{PB}(\text{C}_6\text{F}_5)_3$  (smallest C-P-B-C torsion angle = 15.7(3)°).<sup>11</sup>

Adducts  $\text{Ph}_3\text{AsAlCl}_3$  and  $\text{Ph}_3\text{AsAlI}_3$  are isomorphous with both  $\text{Ph}_3\text{PGaI}_3$  and  $\text{Ph}_3\text{AsGaI}_3$ .<sup>7</sup> As for the arsine-borane adducts, the As-Al bond lengths ( $\text{Ph}_3\text{AsAlCl}_3$ , 2.5191(9) Å;  $\text{Ph}_3\text{AsAlI}_3$ , 2.517 Å) are slightly longer than the sum of the covalent radii for aluminum and arsenic (2.47 Å). Nevertheless, the As-Al bonds are shorter than those in *i*-Pr<sub>3</sub>AsAl-*t*-Bu<sub>3</sub> (2.839(1) Å) and TMS<sub>3</sub>AsAl-*t*-Bu<sub>3</sub> (2.654(2) Å),<sup>3</sup> likely due

**Fig. 2.** Crystallographic view of  $\text{Et}_3\text{AsB}(\text{C}_6\text{F}_5)_3$ . Nonhydrogen atoms are represented by Gaussian ellipsoids at the 50% probability level.

**Fig. 3.** Crystallographic view of the  $\text{Ph}_3\text{AsAlCl}_3$  molecule showing the atom labelling scheme. Nonhydrogen atoms are represented by Gaussian ellipsoids at the 50% probability level. Hydrogen atoms are shown with arbitrarily small thermal parameters.

to the lower steric repulsion in the organoalane derivatives and the inductive influence of the halogens on the Lewis acidity of the alane in the haloalane. The alane adducts  $\text{Ph}_3\text{AsAlCl}_3$  and  $\text{Ph}_3\text{AsAlI}_3$  adopt a more staggered conformation about the As-Al bond axis (smallest C-As-Al-C torsion angle in  $\text{Ph}_3\text{AsAlCl}_3$  = 32.58(6)°, in  $\text{Ph}_3\text{AsAlI}_3$  = 38.83(6)°) than the borane adducts  $\text{Me}_3\text{AsBPh}_3$  and  $\text{Et}_3\text{AsB}(\text{C}_6\text{F}_5)_3$ .

Crystals of  $\text{Ph}_3\text{AsGaCl}_3$  are isomorphous with both  $\text{Ph}_3\text{PGaI}_3$  and  $\text{Ph}_3\text{AsGaI}_3$ <sup>7</sup> and there are two crystallographically independent molecules in the unit cell (Fig. 5). The As-Ga bond lengths (2.540(6) Å and 2.449(6) Å) are close to the sum of the covalent radii for arsenic and gallium

**Fig. 4.** Crystallographic views of  $\text{Ph}_3\text{AsAlI}_3$ . Nonhydrogen atoms are represented by Gaussian ellipsoids at the 50% probability level.

(2.47 Å), and to that in  $\text{Ph}_3\text{AsGaI}_3$ .<sup>7</sup> The torsion angles about the As–Ga bond (smallest C–As–Ga–Cl torsion angles for molecule A = 29.9(3)°, for molecule B = –53.4(3)°) are more staggered than in the arsine–borane adducts.

## Summary

Prototypical examples of compounds containing As → B, As → Al, and As → Ga coordinate bonds have been isolated from reaction mixtures of an arsine Lewis base with a triel Lewis acid. The compounds provide fundamental spectroscopic and structural data. While bond length trends are as expected, As → B < As → Al < As → Ga, the torsion angles are generally smaller for As → B complexes than for the As → Al and As → Ga complexes.

## Experimental procedures

Reactions were carried out in an MBraun glovebox under atmosphere of dry  $\text{N}_2$ . Solvents were dried on an MBraun solvent purification system and stored over 4 Å molecular sieves. Deuterated solvents were purchased from Sigma-Aldrich and were used as received. Experimental details relating to the single crystal X-ray diffraction studies are summarized in Table 3. X-ray diffraction data were collected on a Bruker APEX II CCD area detector/D8 diffractometer. Crystals were coated with Paratone-N oil, mounted on glass fibres, and placed in a cold stream of  $\text{N}_2$ . Structures were solved by direct methods (SHELXS-97)<sup>14</sup> or Patterson search/structure expansion (DIRDIF-2008),<sup>15</sup> and refined using full-matrix least-squares on  $F^2$  (SHELXL-97).<sup>14</sup> Hydrogen atom positions were calculated from the  $\text{sp}^2$  or  $\text{sp}^3$  hybridization geometries of their attached atoms. NMR spectra were obtained at room temperature, unless otherwise stated, on a Bruker AVANCE 500  $^1\text{H}$  (500.13 MHz, 11.7 T) and Bruker/Tecmag AC250  $^1\text{H}$  (250.06 MHz, 5.9 T).  $^{13}\text{C}\{^1\text{H}\}$  NMR (125.76 MHz) chemical shifts were referenced to  $\delta_{\text{TMS}} = 0.00$ , as were  $^{11}\text{B}\{^1\text{H}\}$  NMR (160.42 MHz) and  $^{27}\text{Al}$ -NMR (130.29 MHz). Chemical shifts ( $\delta$ ) are reported in ppm. NMR spectra of samples were obtained by

transferring an aliquot of sample in an appropriate deuterated solvent into a 5 mm sample tube. The tubes were capped and sealed with Parafilm prior to removal from the inert atmosphere. IR spectra were obtained from powdered and crystalline samples dissolved in  $\text{CH}_2\text{Cl}_2$  and spotted on CsI plates. Data collection was on a Bruker Vertex FTIR spectrometer. Peaks are reported in wavenumbers ( $\text{cm}^{-1}$ ) with ranked intensities in parenthesis beside the value, where a value of one is indicative of the most intense peak in the spectrum. Melting points were recorded on an Electrothermal melting point apparatus in sealed capillary tubes under  $\text{N}_2$ .

## Caution

All arsines are known carcinogens and must be handled using appropriate procedures.

## Preparation of $\text{Me}_3\text{AsBPh}_3$

A solution of  $\text{Me}_3\text{As}$  (52.0  $\mu\text{L}$ , 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  was added to a solution of  $\text{BPh}_3$  (121.0 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  and the mixture was stirred for 30 min. The solution was layered with hexanes and stored at  $-25^\circ\text{C}$  overnight. A white precipitate was isolated and washed with hexanes (3  $\times$  3 mL). Crystals were obtained by  $\text{CD}_3\text{CN}$ /ether diffusion at  $-25^\circ\text{C}$  over 48 h. Yield: 65%, 117 mg; mp 144–146  $^\circ\text{C}$ . FTIR (CsI plates, ranked intensities,  $\text{cm}^{-1}$ ): 3058 (1), 2917 (3), 2849 (4), 1590 (12), 1430 (13), 1261 (11), 1238 (10), 1096 (9), 1020 (8), 802 (5), 746 (6), 696 (2), 636 (7).  $^1\text{H}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 500 MHz, ppm)  $\delta$ : 1.23 (s, 9H), 7.52–7.57 (m, 6H), 7.58–7.63 (m, 3H), 7.65–7.70 (m, 6H).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273K, 125.76 MHz)  $\delta$ : 8.4 (s), 128.0 (s), 130.6 (s), 138.3 (s).  $^{11}\text{B}\{^1\text{H}\}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 160.42 MHz)  $\delta$ : 53.6 (s).

## Preparation of $\text{Me}_3\text{AsB}(\text{C}_6\text{F}_5)_3$

A solution of  $\text{Me}_3\text{As}$  (52.0  $\mu\text{L}$ , 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  was added to a solution of  $\text{B}(\text{C}_6\text{F}_5)_3$  (256.0 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  and stirred for 30 min. A white precipitate formed immediately. The solid was isolated and washed with ether (3  $\times$  3 mL) and has poor solubility. Crystals were obtained by  $\text{CD}_3\text{CN}$ /ether diffusion at  $-25^\circ\text{C}$  over 48 h. Yield: 78%, 236 mg; mp 257–259  $^\circ\text{C}$ . FTIR (CsI plates, ranked intensities,  $\text{cm}^{-1}$ ): 2917 (1), 2703 (14), 1644 (10), 1516 (4), 1446 (1), 1370 (6), 1163 (16), 1117 (15), 1087 (5), 979 (3), 960 (2), 780 (9), 770 (8), 730 (17), 667 (7), 617 (11).  $^1\text{H}$  NMR ( $\text{CD}_3\text{CN}$ , 273 K, 500 MHz, ppm)  $\delta$ : 0.96 (s, 9H).  $^{11}\text{B}\{^1\text{H}\}$  NMR ( $\text{CD}_3\text{CN}$ , 273 K, 160.42 MHz)  $\delta$ : –11.0 (s).

## Preparation of $\text{Et}_3\text{AsBPh}_3$

A solution of  $\text{Et}_3\text{As}$  (70.5  $\mu\text{L}$ , 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  was added to a solution of  $\text{BPh}_3$  (121.0 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  and stirred for 30 min. The solution was layered with ether and stored at  $-25^\circ\text{C}$  overnight. Clear colourless crystals were obtained by  $\text{CD}_3\text{CN}$ /ether diffusion at  $-25^\circ\text{C}$  over 48 h and were isolated and washed with ether (3  $\times$  3 mL). Yield: 66%, 133 mg; mp 86–88  $^\circ\text{C}$ . FTIR (CsI plates, ranked intensities,  $\text{cm}^{-1}$ ): 3666 (14), 3061 (1), 2425 (4), 1953 (13), 1642 (2), 1554 (12), 1462 (11), 1453 (10), 1260 (5), 1098 (7), 1020 (6), 847 (3), 699 (9), 613 (8).  $^1\text{H}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 500 MHz, ppm)  $\delta$ : 1.17 (t,  $^3J_{\text{HH}} = 7.0$  Hz, 9H), 1.68 (q,  $^3J_{\text{HH}} = 7.0$  Hz, 6H), 7.48–7.54 (m,

**Fig. 5.** Crystallographic views of the two crystallographically independent conformers (a and b) of the disordered structure of  $\text{Ph}_3\text{AsGaCl}_3$ . Nonhydrogen atoms are represented by Gaussian ellipsoids at the 50% probability level.

**Table 2.** Selected bond lengths (Å) and angles (°) in  $\text{Ph}_3\text{AsMe}_3$ ,  $\text{Et}_3\text{AsB}(\text{C}_6\text{F}_5)_3$ ,  $\text{Ph}_3\text{AsAlCl}_3$ ,  $\text{Ph}_3\text{AsAlI}_3$ ,  $\text{Ph}_3\text{AsGaCl}_3$ , and related compounds.

8H), 7.60–7.65 (m, 7H).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 125.76 MHz, ppm)  $\delta$ : 10.2 (s), 16.1 (s), 127.9 (s), 129.1 (s), 137.8 (s), 136.3 (s).  $^{11}\text{B}\{^1\text{H}\}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 160.42 MHz, ppm)  $\delta$ : 36.3 (s).

### Preparation of $\text{Et}_3\text{AsB}(\text{C}_6\text{F}_5)_3$

A solution of  $\text{Et}_3\text{As}$  (70.5  $\mu\text{L}$ , 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  was added to a solution of  $\text{B}(\text{C}_6\text{F}_5)_3$  (256.0 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  and stirred for 30 min. A white precipitate formed immediately. The solid was redissolved in  $\text{CH}_3\text{CN}$  and crystalline material was obtained by  $\text{CH}_3\text{CN}$ /ether diffusion at  $-25^\circ\text{C}$  over 48 h. Yield: 44%, 142 mg; mp 204–206  $^\circ\text{C}$ . FTIR (CsI plates, ranked intensities,  $\text{cm}^{-1}$ ): 2918 (12), 1645 (7), 1518 (4), 1460 (1), 1374 (6), 1283 (8), 1100 (5), 979 (2), 965 (3), 772 (11), 731 (10), 669 (9).  $^1\text{H}$  NMR  $\delta$ : ( $\text{CD}_3\text{CN}$ , 273 K, 500 MHz, ppm)  $\delta$ : 1.19 (t,  $^3J_{\text{HH}} = 7.5$  Hz, 9H), 1.86 (q,  $^3J_{\text{HH}} = 7.5$  Hz, 6H).  $^{11}\text{B}\{^1\text{H}\}$  NMR ( $\text{CD}_3\text{CN}$ , 273 K, 160.42 MHz, ppm)  $\delta$ :  $-11.8$  (s).

### Preparation of $\text{Ph}_3\text{AsBPh}_3$

A solution of  $\text{Ph}_3\text{As}$  (151.5 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  was added to a solution of  $\text{BPh}_3$  (121.0 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  and stirred for 30 min. The solution was layered with hexanes and stored at  $-25^\circ\text{C}$  overnight. A white powder was isolated and washed with ether (3  $\times$  3 mL). Yield: 55%, 150 mg; decomposes above 100  $^\circ\text{C}$ . FTIR (CsI plates, ranked intensities,  $\text{cm}^{-1}$ ): 3059 (1), 2429 (10), 2283 (11), 1980 (12), 1642 (2), 1260 (7), 1097 (6), 1019 (5), 910 (4), 804 (3), 734 (9), 694 (8).  $^1\text{H}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 500 MHz, ppm)  $\delta$ : 7.28–8.27 (m, 30H).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 125.76 MHz, ppm)  $\delta$ : 128.2 (s), 129.4 (s), 132.1 (s), 134.4 (s), 136.4 (s), 139.2 (s), 140.5 (s), 143.9 (s).  $^{11}\text{B}\{^1\text{H}\}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 160.42 MHz, ppm)  $\delta$ : 67.8 (s).

### Preparation of $\text{Ph}_3\text{AsB}(\text{C}_6\text{F}_5)_3$

A solution of  $\text{Ph}_3\text{As}$  (151.5 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  was added to a solution of  $\text{B}(\text{C}_6\text{F}_5)_3$  (256.0 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  and stirred for 30 min. A white precipitate formed immediately. The solid was redissolved in  $\text{CH}_3\text{CN}$  and then precipitated by ether diffusion at  $-25^\circ\text{C}$  over 48 h. The solid was washed with ether (3  $\times$  3 mL). Yield: 51%, 201 mg; mp 155–157  $^\circ\text{C}$ . FTIR (CsI plates, ranked intensities,  $\text{cm}^{-1}$ ): 3001 (1), 2342 (17), 1895 (16), 1645 (12), 1464 (2), 1389 (4), 1366 (3), 1260 (9), 1230 (6), 1011 (11), 1020 (10), 950 (7), 923 (8), 888 (15), 850 (14), 802 (13),

729 (s).  $^1\text{H}$  NMR  $\delta$ : ( $\text{CD}_3\text{CN}$ , 273 K, 500 MHz, ppm)  $\delta$ : 7.34–7.41 (m, 15H).  $^{11}\text{B}\{^1\text{H}\}$  NMR ( $\text{CD}_3\text{CN}$ , 273 K, 160.42 MHz, ppm)  $\delta$ : –11.6 (s).

#### Preparation of $\text{Me}_3\text{AsAlCl}_3$

A solution of  $\text{Me}_3\text{As}$  (52.0  $\mu\text{L}$ , 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  was added to a solution of  $\text{AlCl}_3$  (61.5 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  and stirred for 30 min. The solution was layered with hexanes and stored at  $-25^\circ\text{C}$  overnight. A white powder formed and was isolated and washed with ether ( $3 \times 3$  mL). Yield: 70%, 89 mg; mp 143–145  $^\circ\text{C}$ . FTIR (CsI plates, ranked intensities,  $\text{cm}^{-1}$ ): 3094 (1), 2921 (2), 2850 (3), 2432 (12), 2361 (11), 1642 (5), 1462 (14), 1412 (10), 1261 (9), 1100 (13), 1018 (8), 925 (4), 848 (7), 651 (6).  $^1\text{H}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 500 MHz, ppm)  $\delta$ : 2.21 (s, 9H).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 125.76 MHz, ppm)  $\delta$ : 7.9 (s).  $^{27}\text{Al}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 130.29 MHz, ppm)  $\delta$ : 104.3 (s).

#### Preparation of $\text{Me}_3\text{AsAlBr}_3$

A solution of  $\text{Me}_3\text{As}$  (52.0  $\mu\text{L}$ , 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  was added to a solution of  $\text{AlBr}_3$  (133.5 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  and stirred for 30 min. The solution was layered with hexanes and stored at  $-25^\circ\text{C}$  overnight. A white powder formed and was isolated and washed with ether ( $3 \times 3$  mL). Yield: 71%, 137 mg. FTIR (CsI plates, ranked intensities,  $\text{cm}^{-1}$ ): 3016 (7), 2918 (8), 2848 (9), 1414 (4), 1269 (10), 1011 (11), 989 (12), 962 (13), 921 (1), 835 (6), 790 (2), 698 (3), 626 (5).  $^1\text{H}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 500 MHz, ppm)  $\delta$ : 1.59 (s, 9H).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 125.76 MHz, ppm)  $\delta$ : 6.9 (s).  $^{27}\text{Al}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 130.29 MHz, ppm)  $\delta$ : 112.9 (s).

#### Preparation of $\text{Me}_3\text{AsAlI}_3$

A solution of  $\text{Me}_3\text{As}$  (52.0  $\mu\text{L}$ , 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  was added to a solution of  $\text{AlI}_3$  (204.0 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  and stirred for 30 min. Upon completion, the solution was layered with hexanes and allowed to sit at  $-25^\circ\text{C}$  overnight. White powder was obtained and washed with ether ( $3 \times 3$  mL) and solvents removed in vacuo. Yield: 69%, 184 mg; mp 138–140  $^\circ\text{C}$ . FTIR (CsI plates, ranked intensities,  $\text{cm}^{-1}$ ): 3000 (1), 2918 (2), 2849 (3), 1641 (9), 1462 (4), 1389 (8), 1365 (7), 1261 (15), 1230 (10), 1094 (14), 1019 (11), 923 (12), 802 (13), 729 (5), 719 (6).  $^1\text{H}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 500 MHz, ppm)  $\delta$ : 1.57 (bs, 9H).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 125.76 MHz, ppm)  $\delta$ : 7.1 (s).  $^{27}\text{Al}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 130.29 MHz, ppm)  $\delta$ : 110.5 (s).

#### Preparation of $\text{Et}_3\text{AsAlCl}_3$

A solution of  $\text{Et}_3\text{As}$  (70.5  $\mu\text{L}$ , 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  was added to a solution of  $\text{AlCl}_3$  (61.5 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  and stirred for 30 min. The solution was layered with hexanes and stored at  $-25^\circ\text{C}$  overnight. A white powder formed and was isolated and washed with ether ( $3 \times 3$  mL). Yield: 65%, 96 mg; mp 160–162  $^\circ\text{C}$ . FTIR (CsI plates, ranked intensities,  $\text{cm}^{-1}$ ): 3341 (14), 2972 (4), 2938 (6), 2879 (7), 2304 (13), 2197 (14), 1459 (3), 1416 (9), 1387 (10), 1238 (8), 954 (2), 876 (16), 794 (12), 696 (1), 678 (5).  $^1\text{H}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 500 MHz, ppm)  $\delta$ : 1.36 (t,  $^3J_{\text{HH}} = 7.85$  Hz, 9H), 2.06 (q,  $^3J_{\text{HH}} = 7.85$  Hz, 6H).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 125.76 MHz, ppm)  $\delta$ : 9.3

(s), 13.6 (s).  $^{27}\text{Al}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 130.29 MHz, ppm)  $\delta$ : 110.3 (s).

#### Preparation of $\text{Et}_3\text{AsAlBr}_3$

A solution of  $\text{Et}_3\text{As}$  (70.5  $\mu\text{L}$ , 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  was added to a solution of  $\text{AlBr}_3$  (133.5 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  and stirred for 30 min. The solution was layered with hexanes and stored at  $-25^\circ\text{C}$  overnight. A white powder formed and was isolated and washed with ether ( $3 \times 3$  mL) and solvents removed in vacuo. Yield: 62%, 133 mg. FTIR (CsI plates, ranked intensities,  $\text{cm}^{-1}$ ): 2973 (1), 2940 (2), 2880 (3), 2849 (8), 2431 (16), 1640 (14), 1459 (4), 1416 (12), 1389 (13), 1240 (11), 1093 (15), 1022 (9), 923 (17), 793 (3), 744 (10), 706 (5), 678 (5).  $^1\text{H}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 500 MHz, ppm)  $\delta$ : 1.59 (t,  $^3J_{\text{HH}} = 9.0$  Hz, 9H), 3.07 (q,  $^3J_{\text{HH}} = 9.0$  Hz, 6H).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 125.76 MHz, ppm)  $\delta$ : 8.7 (s), 26.3 (s).  $^{27}\text{Al}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 130.29 MHz, ppm)  $\delta$ : 104.8 (s).

#### Preparation of $\text{Et}_3\text{AsAlI}_3$

A solution of  $\text{Et}_3\text{As}$  (70.5  $\mu\text{L}$ , 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  was added to a solution of  $\text{AlI}_3$  (204.0 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  and stirred for 30 min. The solution was layered with hexanes and stored at  $-25^\circ\text{C}$  overnight. A pale brown oil was obtained and washed with ether ( $3 \times 3$  mL).  $^1\text{H}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 500 MHz, ppm)  $\delta$ : 1.36 (t,  $^3J_{\text{HH}} = 7.95$  Hz, 9H), 2.06 (q,  $^3J_{\text{HH}} = 7.90$  Hz, 6H).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 125.76 MHz, ppm)  $\delta$ : 9.3 (s), 13.4 (s).  $^{27}\text{Al}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 130.29 MHz, ppm)  $\delta$ : 111.2 (s).

#### Preparation of $\text{Ph}_3\text{AsAlCl}_3$

A solution of  $\text{Ph}_3\text{As}$  (151.5 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  was added to a solution of  $\text{AlCl}_3$  (61.5 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  and stirred for 30 min. The solution was layered with hexanes and stored at  $-25^\circ\text{C}$  overnight. A white powder formed and was isolated and washed with ether ( $3 \times 3$  mL). Crystals were obtained by  $\text{CH}_2\text{Cl}_2$ /pentane layering at  $-25^\circ\text{C}$  over 48 h. Yield: 65%, 142 mg; mp 57–59  $^\circ\text{C}$ . FTIR (CsI plates, ranked intensities,  $\text{cm}^{-1}$ ): 3064 (1), 2432 (14), 1886 (20), 1642 (5), 1578 (11), 1480 (6), 1433 (4), 1336 (18), 1305 (16), 1261 (17), 1184 (14), 1156 (15), 1083 (8), 1074 (9), 1023 (13), 998 (11), 844 (10), 735 (2), 692 (3), 613 (2).  $^1\text{H}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 500 MHz, ppm)  $\delta$ : 7.69–7.75 (m, 6H), 7.73–7.83 (m, 6H), 7.86–7.91 (m, 3H).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 125.76 MHz, ppm)  $\delta$ : 131.6 (s), 133.1 (s), 133.7 (s), 135.4 (s).  $^{27}\text{Al}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 130.29 MHz, ppm)  $\delta$ : 104.1 (s).

#### Preparation of $\text{Ph}_3\text{AsAlBr}_3$

A solution of  $\text{Ph}_3\text{As}$  (151.5 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  was added to a solution of  $\text{AlBr}_3$  (133.5 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  and stirred for 30 min. The solution was layered with hexanes and stored at  $-25^\circ\text{C}$  overnight. Yellow glassy material was obtained and washed with ether ( $3 \times 3$  mL). Yield: 60%, 171 mg. FTIR (CsI plates, ranked intensities,  $\text{cm}^{-1}$ ): 3060 (1), 2905 (2), 2870 (3), 2427 (10), 1642 (4), 1515 (13), 1451 (12), 1260 (8), 1097 (7), 1019 (6), 845 (5), 730 (9), 696 (11).  $^1\text{H}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 500 MHz, ppm)  $\delta$ : 7.76–7.77 (m, 6H), 7.83–7.87 (m, 6H), 7.93–7.98 (m, 3H).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 125.76 MHz,

ppm)  $\delta$ : 131.8 (s), 133.3 (s), 133.5 (s), 135.8 (s).  $^{27}\text{Al}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 130.29 MHz, ppm)  $\delta$ : 108.4 (s).

### Preparation of $\text{Ph}_3\text{AsAlI}_3$

A solution of  $\text{Ph}_3\text{As}$  (151.5 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  was added to a solution of  $\text{AlI}_3$  (204.0 mg, 0.50 mmol) in  $\text{CH}_2\text{Cl}_2$  and stirred for 30 min. The solution was layered with hexanes and stored at  $-25^\circ\text{C}$  overnight. Small yellow crystals were obtained and were washed with ether ( $3 \times 3$  mL). Yield: 50%, 179 mg; mp  $86\text{--}88^\circ\text{C}$ . FTIR (CsI plates, ranked intensities,  $\text{cm}^{-1}$ ): 3052 (11), 2994 (10), 2917 (9), 2849 (8), 1578 (12), 1481 (4), 1433 (3), 1365 (17), 1261 (13), 1184 (14), 1158 (15), 1082 (5), 1022 (6), 997 (7), 799 (16), 735 (1), 694 (2).  $^1\text{H}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 500 MHz, ppm)  $\delta$ : 7.69–7.72 (m, 2H), 7.81–7.85 (m, 2H), 7.93–7.97 (m, 1H).  $^{13}\text{C}\{^1\text{H}\}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 125.76 MHz, ppm)  $\delta$ : 130.9 (s), 132.2 (s), 134.4 (s), 135.6 (s).  $^{27}\text{Al}$  NMR ( $\text{CD}_2\text{Cl}_2$ , 273 K, 130.29 MHz, ppm)  $\delta$ : 103.8 (s).

### Preparation of $\text{Ph}_3\text{AsGaCl}_3$

The procedures were described by Reid and co-workers,<sup>5a</sup> and the characterization data was consistent. Crystalline material was obtained by  $\text{CH}_2\text{Cl}_2$ /pentane layering at  $-25^\circ\text{C}$  over 48 h.

# A DFT study on the catalytic mechanism of UDP-glucose dehydrogenase

WenJuan Huang, Jorge Llano, and James W. Gauld

**Abstract:** Uridine 5'-diphosphate glucuronic acid (UDPGlcUA) is a key intermediary metabolite in many species, including pathogenic bacteria and humans. It is biosynthesized from UDP-glucose (UDPGlc) by uridine diphosphate glucose dehydrogenase (UDPGlcDH) via a twofold two-electron-one-proton oxidation that successively transforms the 6-hydroxymethyl of glucopyranose into a formyl, and the latter into the final carboxylic function. The catalytic mechanism of UDPGlcDH was investigated using a large enzyme active-site model in combination with the B3LYP method and the polarizable continuum model (IEF-PCM) self-consistent reaction field. The latter was used to correct for the long-range electrostatic effect of the protein environment. The overall mechanism consists of four catalytic steps: (i) NAD<sup>+</sup>-dependent oxidation of glucose to glucuronaldehyde, (ii) nucleophilic addition of Cys260-SH to glucuronaldehyde to form a 6-thiohemiacetal intermediate, (iii) NAD<sup>+</sup>-dependent oxidation of the 6-thiohemiacetal to form a 6-thioester intermediate, and finally, (iv) hydrolysis of the 6-thioester to give glucuronic acid. In addition, this study also provides insight into the debated roles of Lys204 and Asp264, and the most likely protonation state of a reactive Michaelis complex of UDPGlcDH.

**Key words:** density functional theory (DFT), uridine diphosphate glucose dehydrogenase (UDPGlcDH), NAD, thioester hydrolysis, acid-base, electron transfer, proton transfer.

**Résumé :** L'acide uridine-5'-diphosphate glucuronique (UDPGlcUA) est un métabolite intermédiaire clé dans plusieurs espèces incluant les humains et quelques bactéries pathogènes. L'UDPGlcUA est biosynthétisé à partir de l'uridine-diphosphate glucose (UDPGlc) par l'enzyme uridine-diphosphate glucose déshydrogénase (UDPGlcDH) au cours d'une double oxydation à deux électrons et un proton qui transforme successivement le groupe 6-hydroxyméthyle du glucopyranose en formyle, et puis, en le groupe fonctionnel carboxyle. On a étudié le mécanisme catalytique du UDPGlcDH avec un modèle de grande taille du site actif de l'enzyme et au moyen des méthodes de calcul quantique B3LYP et IEF-PCM. On a employé le champ réactionnel autocohérent IEF-PCM pour corriger l'effet électrostatique à longue distance de l'environnement de la protéine. Le mécanisme global de réaction comprend quatre étapes catalytiques : (i) oxydation du glucose en glucuronaldéhyde par le NAD<sup>+</sup>, (ii) addition nucléophile du Cys260-SH sur le glucuronaldéhyde pour donner un intermédiaire 6-thiohémiacétal, (iii) oxydation du 6-thiohémiacétal par le NAD<sup>+</sup> pour donner un intermédiaire 6-thioester, et finalement, (iv) hydrolyse du 6-thioester pour former l'acide glucuronique. Notamment, cette étude de modélisation nous a permis d'établir les rôles mécanistiques de la Lys204 et l'Asp264, ainsi que l'état le plus probable de protonation du complexe réactif de Michaelis entre l'UDPGlcDH et l'UDPGlc.

## Introduction

Carbohydrates have key roles in cellular biochemistry including biosignalling, energy storage, membrane structural assemblage, and metabolic intermediation as nucleotides, glycolipids, and glycoproteins. In fact, several carbohydrate-containing precursors are common to unrelated metabolic pathways in different species.<sup>1,2</sup> For instance, uridine 5'-diphosphate glucuronic acid (UDPGlcUA, in Scheme 1) is an essential precursor in the syntheses of many polysaccharides. In mammalian cells, UDPGlcUA bonds to certain waste products and toxic substances, thereby increasing their water

solubility, so that they may be excreted from the body.<sup>3,4</sup> UDPGlcUA is also an essential precursor in the making of antiphagocytic capsular polysaccharides of pathogenic bacteria. In *Streptococcus pneumoniae*, for example, UDPGlcUA is a key intermediary in the synthesis of the polysaccharide capsule. This capsule acts as an antiphagocytic protector and is responsible for the toxicity and extent of the antibiotic resistance observed in many organisms.<sup>5-7</sup> UDPGlcUA is synthesized by uridine diphosphate glucose dehydrogenase (UDPGlcDH),<sup>3,8</sup> which regulates the glycoprotein biosynthesis and other pathways. Thus, UDPGlcDH is a logical target for the development of new antibacterial drugs.

**Scheme 1.** Uridine 5'-diphosphate glucuronic acid, abbreviated UDPGlcUA.

The catalytic performance of UDPGlcDH is unique in several aspects. First, it should be noted that the chemical oxidation of glucose is not specific, as the terminal 1-formyl and 6-hydroxymethyl groups of the open-chain form can be oxidized to carboxylic groups in the presence of moderate oxidizing agents such as transition metal ions, halogens, and warm dilute nitric acid. However, within a single active site, UDPGlcDH is able to perform an overall four-electron oxidation by successively transforming the 6-hydroxymethyl group into a formyl group, and the latter into the final carboxylic function.<sup>9,10</sup> In addition, UDPGlcDH uses two  $\text{NAD}^+$  molecules as the final electron acceptors, and this type of redox reaction path is rarely found in the enzymatic chemistry of carbohydrates.<sup>11</sup> Finally, UDPGlcDH belongs to the family of sugar nucleotide-modifying enzymes, and hence, various molecular details of the UDPGlcDH enzymatic mechanism may be common to other enzymes of the family.<sup>12,13</sup>

The first breakthrough in the elucidation of the catalytic mechanism of UDPGlcDH was obtained by Oppenheimer and Handlon<sup>8</sup> who found that the catalytic pathway was a  $\text{NAD}^+$ -dependent twofold oxidation. Thereafter, based on their X-ray crystallography, site-directed mutagenesis, and kinetic isotope effect studies, Ge et al.<sup>10</sup> proposed two possible catalytic pathways with the difference being the identity of mechanistically required acid-base active-site residues. More specifically, they proposed that either an active site aspartate or possibly a neutral lysyl residue is the mechanistic base. While the latter is directly adjacent to the substrate, the aspartate interacts indirectly via a possible  $\text{H}_2\text{O}$  bridge with substrate. Recently, studies combining gene encoding and kinetics,<sup>3,14</sup> and the crystal structures of UDPGlcDH from several species (e.g., human, cows, bacteria, and plants) have been reported.<sup>15</sup>

The proposed mechanism of UDPGlcDH involves multiple steps and is shown in Scheme 2. The first step is the oxidation of the 6-hydroxymethyl to a formyl group via hydride transfer to  $\text{NAD}^+$  with concomitant deprotonation of O6 by a general base B ( $\text{Lys204-NH}_2$  or  $\text{Asp264-COO}^-$ ). Then, Cys260 in concurrence with Glu145 attacks the carbonyl group to form a covalent thiohemiacetal adduct, while the conjugated acid HB donates the proton back to O6. In the second stage, NADH leaves to allow a new  $\text{NAD}^+$  to enter the active site. The latter, assisted by the same general base B, further oxidizes the thiohemiacetal adduct intermediate to form a thioester. In the final step, the thioester is hydrolyzed to give the final UDPGlcUA product.

While the proposed mechanism outlined in Scheme 2

shows fair agreement with the experimental evidence, there remains, unsatisfactorily, the question of the identity of the base that initiates the acid-base catalytic pathway.<sup>8,10,11,16,17</sup> This study aims to explore the potential energy surfaces of the catalytic mechanism of UDPGlcDH by applying density functional theory methods to assess the feasibility of these pathways and to clarify the role of active-site residues.

## Computational methods

The hybrid density functional B3LYP,<sup>18–20</sup> as implemented in the Gaussian 03 program,<sup>21</sup> was used in all calculations. This functional combines Becke's<sup>18,19</sup> three-parameter hybrid exchange functional and the correlation functional of Lee et al.<sup>20</sup> The B3LYP/6-31G(d) level of theory was used for geometry optimizations, harmonic vibrational frequencies, and zero-point vibrational energy (ZPVE) corrections. Single-point calculations at the B3LYP/6-311+G(2df,p)//B3LYP/6-31G(d) level were done to compute relative total energies. In addition, the long-range dielectric effect of the protein environment that surrounds the active site was estimated by performing single-point calculations on the optimized geometries using the polarizable continuum model in the integral equation formalism (IEF-PCM) at the B3LYP/6-31G(d) level of theory. The dielectric constant,  $\epsilon$ , was set to 4.0 in these calculations.

Our active-site model was extracted from the crystallographic structure of the mutated UDPGlcDH (with Ser replacing Cys260) complexed with glucuronic acid (Protein Data Bank (PDB) accession code: 1DLJ).<sup>10</sup> Key amino acid residues were replaced as follows: Asp264 and Glu145 by acetate ions, Cys260 by ethanethiol, Asn208 by acetamide, and Thr118 by methanol. In the case of Lys204, the side chain of the residue was replaced by the ethylammonium ion in model A and by ethylamine in model B, as illustrated in Fig. 1. The substrate UDP-glucose was modelled as  $\alpha$ -D-glucopyranose, and  $\text{NAD}^+$  as an *N*-hydroxyethyl-nicotinamidium ion. The two water molecules present in the crystal structure were kept in the active-site model. One  $\text{H}_2\text{O}$  forms a hydrogen-bond bridge between Asp264 and the 6-hydroxymethyl of glucose, and the other  $\text{H}_2\text{O}$  between Glu145 and the thiol of Cys260. For both active-site models, NADH leaves the catalytic cleft during the last step, allowing Glu141 (modelled as butyrate) to approach the substrate. To keep the spatial arrangement of catalytic residues in the active site, selected atoms were held at their positions in the crystal structure (Fig. 1). The applicability of the present computational approach to the study of enzymatic reactions has been previously reviewed in detail.<sup>22–27</sup>

## Results and discussion

### Protonation state of the active site of UDPGlcDH in the Michaelis complex

The proposed catalytic mechanism of UDPGlcDH is initiated by oxidation of the 6-hydroxymethyl to a formyl group by a hydride transfer to  $\text{NAD}^+$  with concomitant deprotonation of O6 by either Lys204 or Asp264. In the case of Asp264, the experimental evidence suggests that it occurs as an aspartate rather than an aspartic group.<sup>10</sup> However, there is no unambiguous experimental evidence for the side chain of Lys204 occurring as either a neutral amine or a positively charged ammonium group.<sup>16,17</sup> As a result, we be-

gan our investigation by constructing the two alternate models of the active site with bound substrate and cofactor, the Michaelis complex, shown in Fig. 1. Then, we estimated the proton affinities and basicities of the side chain of Lys204 under four different electrostatic conditions to investigate the effect of the local electrostatic environment of the enzyme on the side chain of Lys204.

The proton affinities (PA) were estimated as the negative change in the internal energy of protonation of the side chain at 0 K with the proton coming from the vacuum state, i.e.,  $\text{PA} = -[E_0(\text{BH}^+) - E_0(\text{B}) - E_0(\text{H}^+)]$ , where  $E_0(\text{H}^+) = 0$ . The basicities were estimated as the negative change in the internal energy of protonation of the side chain at 0 K with the proton coming from an aqueous ideal-dilute solution at pH 7. The standard energy of bulk solvation of the proton

in aqueous solution was taken to be  $-1097.9 \text{ kJ mol}^{-1}$  because this value is the only one consistent with the Born-Haber-type cycles of both hydrogen and the electron.<sup>28,29</sup> That is,  $\text{basicity} = \text{PA} - 1097.9 \text{ kJ mol}^{-1}$ .

The proton affinities and basicities of ethylamine, the model chosen for the side chain of Lys204, within four different electrostatic environments are reported in Table 1. In a first approximation, the protonation of isolated ethylamine was considered in vacuum and in a homogeneous medium with a dielectric constant of 4. The latter value being chosen as it is typically used as an appropriate estimate of the average electrostatic dielectric constant found within a bulk protein environment.<sup>30,31</sup> The proton affinity of  $941.7 \text{ kJ mol}^{-1}$  indicates that protonation of the side chain in vacuum is thermodynamically feasible. However, the side chain in a

homogeneous medium with a dielectric constant of 1 cannot abstract a proton from the bulk of an ideal-dilute aqueous solution, according to the basicity of  $-156.1 \text{ kJ mol}^{-1}$ . However, the situation changes if the side chain of lysine is placed under conditions simulating the average effect of the bulk protein environment. In particular, the proton affinity of the lysine increases such that its estimated basicity now becomes positive at  $43.1 \text{ kJ mol}^{-1}$ . This suggests that when embedded in the average protein environment, the lysine side chain amino group is thermodynamically able to gain a proton from the bulk of an ideal-dilute aqueous solution at pH 7.

We then placed the model of lysine within our chosen active-site model and recalculated its proton affinity and basicity (Table 1). First, we only considered the anisotropic electrostatic environment generated by the first shell of residues found in the catalytic cleft with the surrounding electrostatic environment set to a dielectric constant ( $\epsilon$ ) of 1 (i.e., the vacuum state). It is found that the protonation of the side chain of Lys204 becomes even more feasible, as indicated by the now larger proton affinities and basicities of 1280.4 and  $182.4 \text{ kJ mol}^{-1}$ , respectively. In contrast to that observed for isolated lysine, however, increasing the polarity of the surrounding environment to that resembling the bulk protein (i.e., increasing  $\epsilon$  from 1 to 4) decreases the proton affinity and basicity of the lysine. Indeed, its PA decreases by approximately  $80 \text{ kJ mol}^{-1}$  to  $1208.2 \text{ kJ mol}^{-1}$  with the same decrease in basicity to  $110.5 \text{ kJ mol}^{-1}$ .

Thus, in summary, the three electrostatic conditions simulating the electrostatic environment felt by the side chain of Lys204 in the active site of UDPGlcDH unambiguously show that Lys204 is very likely to be protonated. Therefore, the protonation state of the active site of UDPGlcDH in the enzyme–substrate–cofactor complex is most likely to correspond to the structural model A (Fig. 1), with Asp264 bound to water acting as the general base in the initial step of the catalytic mechanism.

### Substrate binding the active site of UDPGlcDH

Since model A (Fig. 1) represents the most likely Michaelis complex for UDPGlcDH, it was selected as the reactant complex (RC, Fig. 2) for our mechanistic study. Model A was extracted from a crystallographic structure of the enzyme (PDB accession code: 1DLJ),<sup>16</sup> with  $\beta$ -glucopyranose as the substrate.<sup>10,16</sup> This chemical model was then carefully optimized to preserve the hydrogen-bonded network observed in the crystallographic model, as it has been suggested that this network is essential for the enzyme to carry out its catalytic mechanism.<sup>10</sup> The optimized structure of our chemical model shows that the 6-hydroxymethyl group of glucose hydrogen-bonds to the oxygen of an  $\text{H}_2\text{O}$  (1.64 Å), and this water to Asp264 and Thr118 (1.66 and 1.71 Å, respectively), forming a ring. As in the crystal structure, Lys204– $\text{NH}_3^+$  forms a hydrogen-bonded bridge to the 6-hydroxymethyl and the carbonyl group of Asn208. In addition, one of the 6-position C–H bonds points directly to the 4-position of the pyridine ring of  $\text{NAD}^+$  at a distance of 2.78 Å.

On the opposite side of the cleft, water forms hydrogen bonds that enable the bridge Glu145– $\text{COO}^- \cdots \text{H}_2\text{O} \cdots \text{HS-Cys260}$  at 1.97 and 2.08 Å, respectively. It has been debated whether Cys260 is in the thiol (Cys260–SH) or thiolate (Cys260– $\text{S}^-$ ) form in the active site.<sup>16</sup> Our computational

**Fig. 2.** Optimized structure of the reactant complex (RC): substrate and cofactor bound to the active-site model of UDPGlcDH.

model of the enzyme–substrate complex shows that the thiolate form of Cys260 causes the orientation of Glu145 to change such that it flips into the binding region of the substrate, hydrogen bonding to glucose and  $\text{NAD}^+$ . Hence, the thiol form of Cys260 is the only alternative that makes possible a stable Glu145–water–Cys260 bridge and that is in agreement with the crystallographic structure.

### First catalytic step: oxidation of glucose to form glucuronaldehyde

The first catalytic step of UDPGlcDH (Fig. 3) is the oxidation of the 6-hydroxymethyl group of glucopyranose to form the 6-formyl terminus. This process begins with a proton transfer from the substrate's 6-hydroxymethyl group to the  $\text{H}_2\text{O}$  bound to the carboxylate of Asp264. Concomitantly, this bridging water transfers a proton to Asp264 (RC in Fig. 2). This deprotonation has a barrier of  $28.2 \text{ kJ mol}^{-1}$ , with the resulting 6-oxymethyl anion intermediate, IC1 (Fig. 4), lying  $35.5 \text{ kJ mol}^{-1}$  above both RC and IC1 (Fig. 3). It is noted that the energy of TS1 is lower than that of IC1 due to the inclusion of ZPVE. This is a commonly occurring artifact for flat potential energy surfaces (PES) and merely indicates that the reaction proceeds without any barrier. Consequently, the deprotonation brings about a C6–O bond-length shortening from 1.43 to 1.39 Å and a disruption of the hydrogen-bonded network originally found in the Michaelis complex. More specifically, the original hydrogen-bonded chain Asp264– $\text{COO}^- \cdots \text{H}_2\text{O} \cdots \text{HO-CH}_2\text{-Glc}$  in RC changes directionality to form the Asp264– $\text{COOH} \cdots \text{OH}_2 \cdots \text{O-CH}_2\text{-Glc}$  chain in IC1, with hydrogen-bonding distances of 1.59 and 1.44 Å, respectively. In addition, the distance between the 6-position C–H bond that points to the 4-position of the pyridine ring decreases from 2.78 to 2.67 Å. (IC1 in Fig. 4). The 6-oxymethyl anion is further stabilized by accepting a hydro-

**Fig. 3.** Potential energy surface for the oxidation of the 6-hydroxymethyl group of glucopyranose (RC) to form glucuronaldehyde (IC2) through the 6-oxymethyl anion intermediate (IC1).

**Fig. 4.** Optimized geometries of the 6-oxanion intermediate (IC1) and the 6-formyl intermediate (IC2) in the active-site model.

gen bond from Lys204-NH<sub>3</sub><sup>+</sup>, which keeps bridging to the carbonyl group of Asn208.

Then, the 6-oxanion undergoes a formal hydride transfer from the methyleneoxanion of IC1 to NAD<sup>+</sup> through TS2 with a barrier of 106.5 kJ mol<sup>-1</sup>, leading to formation of glucuronaldehyde, i.e., the 6-formyl intermediate, IC2 (Fig. 4). Thermodynamically, IC2 lies 33.1 kJ mol<sup>-1</sup> above RC (Fig. 3). Moreover, the C-O bond has shortened from 1.39 Å in IC1 to 1.24 Å in IC2, indicating the formation of the 6-formyl derivative. The oxidation process to give IC2 does not alter the hydrogen-bonding pattern relating to the active-

site residues, i.e., Asp264-COOH...OH<sub>2</sub>...O=CH-Glc. In addition, the formyl terminus accepts a hydrogen bond (1.65 Å) from Lys204-NH<sub>3</sub><sup>+</sup>, which keeps the bridge to the carbonyl group of Asn208 (1.90 Å).

#### Second catalytic step: nucleophilic addition to form the 6-thiohemiacetal intermediate

Glucuronaldehyde, i.e., the 6-formyl intermediate, IC2, then undergoes nucleophilic addition of thiol from Cys260 to form a rather stable 6-thiohemiacetal intermediate (Fig. 5). This is achieved through the attack of the sulfur

**Fig. 5.** Potential energy surface for the nucleophilic addition of the Cys260 thiol group to the 6-formyl end of glucuronaldehyde to form a 6-thiohemiacetal intermediate (IC4).

**Fig. 6.** Optimized structures of the thiohemiacetal anion (IC3) and neutral (IC4) intermediates.

centre of Cys260 at the carbonyl carbon of IC2 with concomitant formal transfer of the thiol proton of Cys260-SH to the carboxylate of Glu145. This process occurs at a cost of just 11.0 kJ mol<sup>-1</sup> to give the thiohemiacetal anion intermediate, IC3, lying 32.1 kJ mol<sup>-1</sup> lower in energy than IC2. In fact, the formation of IC3 is essentially thermoneutral with respect to the initial active-site bound substrate complex RC...NAD<sup>+</sup>.

In IC3, the S-C bond forms at 1.94 Å, whereas the C6-O

bond lengthens to 1.36 Å (Fig. 6). Both the bond lengthening and increase of negative charge on O6 (i.e., from +0.05 in IC2 to -0.55 in IC3) indicate the formation of the highly basic oxyanion structure C6-O<sup>-</sup>. This oxyanion is further stabilized by accepting a hydrogen bond from Lys204-NH<sub>3</sub><sup>+</sup>, which has now broken the bridge to the carbonyl group of Asn208. Then, the oxyanion of IC3 abstracts a proton back from Asp264 through the bridging water molecule (at a cost of 5.3 kJ mol<sup>-1</sup>) to form the neutral thiohemiacetal

Fig. 7. Optimized structures of the 6-thiohemiacetal complex with both NADH and NAD<sup>+</sup>.

intermediate, IC4 (Glc-C6H(S-Cys260)OH), lying 31.8 kJ mol<sup>-1</sup> below IC2. Predictably, the proton transfer causes the C6-O bond to elongate to 1.41 Å and the C6-S bond to shorten to 1.86 Å in IC4 with respect to IC3. Finally, the hydrogen-bonding network around the O6-H group in IC4 (Fig. 6) is restored to the pattern found in the enzyme-substrate complex RC (Fig. 2). However, even when the C6-OH group in IC4 is stabilized by accepting a hydrogen bond from Lys204-NH<sub>3</sub><sup>+</sup>, the bridge to the carbonyl group of Asn208 remains broken in the optimized structure of this intermediate.

### Third catalytic step: second oxidation to form the 6-thioester intermediate

The first oxidation step produces an enzyme-intermediate-cofactor complex, which, for the sake of simplicity, we represent as IC2...NADH. An experiment with the Cys260 → Ala mutant complexed with labelled UDP-[6'',6''-di-<sup>2</sup>H]-D-glucose in a solution containing NAD<sup>+</sup> and excess NADH showed that the NAD<sup>2</sup>H formed in the first oxidation step did not exchange with free NADH.<sup>10</sup> Thus, according to this evidence, the reduced cofactor remains bound to the active site until the thiohemiacetal neutral intermediate, IC4...NADH, is formed. Then, the NADH can be exchanged for NAD<sup>+</sup>, which then binds and continues oxidizing the 6-position of glucose.<sup>5,10,11</sup>

The optimized geometries of the 6-thiohemiacetal complex, IC4, with the reduced and the replacing oxidized cofactor molecules (i.e., IC4...NADH and IC4...NAD<sup>+</sup>, respectively, in Fig. 7) show high structural similarity, including the hydrogen-bonding pattern to Lys204. Furthermore, it was found that the IC4...NADH complex together with an infinitely separated NAD<sup>+</sup> ion is only 4.0 kJ mol<sup>-1</sup> more stable than the IC4...NAD<sup>+</sup> complex together with an infinitely separated NADH molecule.

Once the fresh, oxidized cofactor molecule is appropriately bound to the active site, the IC4...NAD<sup>+</sup> complex is ready to proceed with the second oxidation reaction (Fig. 8). This begins with the formation of a 6-thiohemiacetal anion intermediate by way of a proton transferring from the 6-hydroxyl

group to Asp264-COO<sup>-</sup> through the bridging water molecule. The barrier of this step is just 1.9 kJ mol<sup>-1</sup>, with the 6-thiohemiacetal oxyanion intermediate, IC5, lying 0.3 kJ mol<sup>-1</sup> lower in energy with respect to IC4...NAD<sup>+</sup>. The proton transfer reverses the directionality of the hydrogen-bonded chain from Glc-C6H(S-Cys260)OH...OH<sub>2</sub>...OOC-Asp264 in IC4 to Glc-C6H(S-Cys260)O...H<sub>2</sub>O...HOOC-Asp264 in IC5 (Fig. 9); the hydrogen-bonding distances in the latter being 1.60 and 1.65 Å. The 6-oxyanion is further stabilized by accepting a hydrogen bond from Lys204-NH<sub>3</sub><sup>+</sup>, which itself keeps the bridge to the carbonyl group of Asn208 broken. Moreover, the C6-H bond in IC5 is left directed more precisely to the reduction centre of the cofactor, with the hydrogen located 2.48 Å apart from the 4-position of the NAD<sup>+</sup> pyridine ring. In this geometrical arrangement, the two-electron one-proton transfer occurs from a C6-H group to NAD<sup>+</sup>, to give the 6-thioester intermediate, IC6. In the thioester intermediate, the C6=O link has a typical carbonyl bond distance of 1.23 Å, while the C6-S bond is shortened to 1.78 Å. This formal hydride transfer has a barrier of 72.3 kJ mol<sup>-1</sup> with respect to IC4...NAD<sup>+</sup>, and the 6-thioester intermediate, IC6...NADH, lies 19.3 kJ mol<sup>-1</sup> lower in energy than IC4...NAD<sup>+</sup>. In the IC6...NADH complex, the 6-carbonyl group accepts a hydrogen bond from Lys204-NH<sub>3</sub><sup>+</sup>, and the latter restores the bridge to the carbonyl group of Asn208.

### Fourth catalytic step: hydrolysis of the 6-thioester intermediate to form glucuronic acid

It has been proposed that hydrolysis of the 6-thioester intermediate, IC6, is catalyzed by the strictly conserved Glu141 residue.<sup>16,17</sup> However, the crystallographic structure of the UDPGlcDH Cys260 → Ser mutant with bound UDP-GlcUA and NADH shows that Glu141 lies behind the nicotinamide ring, which blocks the interaction of Glu141 with the 6-position of the thioester intermediate.<sup>16</sup> It has been hypothesized that, in the absence of NADH, Glu141 could extend into the active site and deliver an activated water molecule to the 6-position of the thioester intermediate.<sup>16</sup> In view of these ideas, we studied the hydrolysis of the thio-

**Fig. 8.** Potential energy surface for the oxidation of the 6-thiohemiacetal intermediate (IC4) to the 6-thioester intermediate (IC6) through a 6-thiohemiacetal oxyanion intermediate (IC5).

**Fig. 9.** Optimized structures of the 6-thiohemiacetal oxyanion intermediate (IC5) and the 6-thioester intermediate (IC6).

ester in both the NADH-bound active-site complex and in a complex in which NADH was exchanged by a glutamate ion bound to two water molecules.

First, we probed into the feasibility of hydrolysis of the 6-thioester within the IC6...NADH complex in the absence of nearby negatively charged groups that polarize the attacking water molecule. To this end, we devised chemical models of IC6...NADH that included one water molecule into the active site and computed 4-, 6-, and 8-membered ring transition structures. The calculated barrier heights to hydrolysis (i.e., 189.0, 197.6, and 188.2 kJ mol<sup>-1</sup>, respectively) showed a better agreement with a nonenzymatic thioester hydrolysis

reaction. For example, at the B3LYP/6-311+G(2df,p)//B3LYP/6-31G(d) level of theory, the barrier to hydrolysis of CH<sub>3</sub>(C=O)SCH<sub>3</sub> with a single water molecule is 184.7 kJ mol<sup>-1</sup>. It is noted that our barrier height is in disagreement with that of 44.3 kJ mol<sup>-1</sup> reported for the same chemical model but calculated at the HF/6-31++G\*\* level of theory.<sup>32</sup> In contrast, the MP2/6-311++G(2d,2p)//B3LYP/6-31++G(d,p) barrier to the OH<sup>-</sup> catalyzed hydrolysis of CH<sub>3</sub>(C=O)SCH<sub>3</sub>, including four explicit water molecules and the bulk solvent IPCM correction, was found to be 51.5 kJ mol<sup>-1</sup>.<sup>33</sup>

Next, our chemical model of the 6-thioester intermediate was modified by removing NADH from the IC6...NADH

**Fig. 10.** Potential energy surface for hydrolysis of the 6-thioester intermediate (IC6) assisted by Glu141 and two water molecules, and subsequent formation of a product complex containing GlcUA (PC).

complex and by incorporating glutamate and two water molecules to generate the IC6...Glu141·2H<sub>2</sub>O complex, which is illustrated in Fig. 10. The optimized structure of the IC6...Glu141-COO<sup>-</sup>·2H<sub>2</sub>O complex consists of an eight-membered hydrogen-bonded ring, in which the Glu141 carboxylate accepts one hydrogen bond from each water molecule at 1.84 and 1.99 Å, respectively. The two water molecules are hydrogen bonded to each other at 1.82 Å (Fig. 11). The displacement of NADH from the IC6...NADH complex by the eight-membered hydrogen-bonded ring complex, Glu141-COO<sup>-</sup>·2H<sub>2</sub>O, to form the IC6...Glu141-COO<sup>-</sup>·2H<sub>2</sub>O complex is highly exoergic by 122.6 kJ mol<sup>-1</sup>. In other words, the Glu141-COO<sup>-</sup>·2H<sub>2</sub>O complex binds stronger than NADH to the intermediate-active-site complex, and this provides a thermodynamic pull favoring the displacement of NADH from the active site.

In the geometric arrangement of the IC6...Glu141-COO<sup>-</sup>·2H<sub>2</sub>O complex, the 6-carbonyl group accepts a hydrogen bond from the Lys204-NH<sub>3</sub><sup>+</sup>, which itself also hydrogen-bonds to the carbonyl group of Asn208. Importantly, the nearest water oxygen is initially located 3.28 Å from C6 of the thioester intermediate. This H<sub>2</sub>O then nucleophilically adds to the carbonyl carbon of the thioester intermediate to form the 6-thioether-6,6-diol anion intermediate, IC7. The formation of IC7 is endoergic by 80.9 kJ mol<sup>-1</sup>, with a barrier of 102.1 kJ mol<sup>-1</sup> with respect to the IC6...Glu141·2H<sub>2</sub>O complex (Fig. 10). In IC7, the four-centre hydrogen-bonded ring changes slightly with the newly formed 6-hydroxyl group accepting a hydrogen bond from Glu141-COOH, while the other two hydrogen bonds remain the same as in the parent IC6...Glu141-COO<sup>-</sup>·2H<sub>2</sub>O complex. The 6-oxyan-

ion is further stabilized by accepting a hydrogen bond from Lys204-NH<sub>3</sub><sup>+</sup>, which has now broken the bridge to the carbonyl group of Asn208. The arrangement of the substituents around the 6-position of the 6-thioether-6,6-diol anion intermediate, IC7, is tetrahedral, with typical bond lengths of 1.44 and 1.33 Å for the C6-OH and C6-O<sup>-</sup> bonds, respectively. Predictably, the C6-S bond lengthens from 1.79 Å in IC6 to 1.96 Å in IC7 because of formation of the geminal diol intermediate (Fig. 11).

Finally, the formation of GlcUA occurs by scission of the C6-S bond in concert with two proton transfers mediated by bridging water molecules: one occurring from Asp264-COOH to the C6-O<sup>-</sup> group and the other occurring from Glu145-COOH to the S atom of Cys260 (Fig. 10). This step has a barrier of 69.6 kJ mol<sup>-1</sup> and leaves the product complex (PC) 14.2 kJ mol<sup>-1</sup> lower in energy than the IC6...Glu141·2H<sub>2</sub>O complex. In the PC, it was found that the geometry around C6 is trigonal planar with typical bond lengths for the carboxylate group of 1.23 and 1.32 Å for the C=O and C-OH bonds, respectively (Fig. 11). Lys204-NH<sub>3</sub><sup>+</sup> forms a bridge to the 6-carbonyl group of GlcUA and the carbonyl group of Asn208 in the optimized product complex. Notably, the hydrogen-bonded chain Glu145-COO<sup>-</sup>...H<sub>2</sub>O...HS-Cys260 is regenerated for the next catalytic cycle.

## Conclusions

The potential energy surface (PES) for the catalytic mechanism of UDPGlcDH was investigated for an active-site model of this enzyme and calculated with the B3LYP density functional method in conjunction with the IEF-PCM self-consistent reaction field, to correct for the long-range

**Fig. 11.** Optimized structures of the 6-thioester intermediate incorporating glutamate and two water molecules (IC6···Glu141·2H<sub>2</sub>O), the 6-thioether-6,6-diol anion intermediate (IC7), and the product complex with GlcUA (PC).

electrostatic effect of the protein environment. An overall PES for the catalytic mechanism of UDPGlcDH, with energies referenced to our active-site model of the enzyme–substrate–cofactor complex, is included in the Supplementary data for this paper (Fig. S1).

This study made it possible to give microscopic insight into the catalytic roles of the residues along the reaction path, and mainly, unravel the roles of the Lys204 and Asp264 residues. To this end, we applied three electrostatic conditions simulating the electrostatic environment felt by the side chain of Lys204 in the active site of UDPGlcDH to unambiguously show (by the calculated basicities of the side chain of lysine) that (i) Lys204 is very likely to be protonated in the active site and (ii) the reactive form of the enzyme–substrate–cofactor complex most likely contains Asp264–COO<sup>−</sup> bound to water, which acts as the general base in the initial step of the catalytic mechanism. Moreover, the stationary structures along the reaction path show that Lys204–NH<sub>3</sub><sup>+</sup> assists in decreasing the rotational free-

dom of the 6-terminus of glucopyranose and in stabilizing the 6-oxanion intermediates and transition states.

The catalytic mechanism consists of two NAD<sup>+</sup>-dependent oxidation stages. The calculations show that the first two-electron one-proton transfer from the activated 6-oxymethyl anion of glucopyranose to NAD<sup>+</sup> forming glucuronaldehyde is the rate-controlling step, with a barrier of 106.5 kJ mol<sup>−1</sup>. Within the computational error for an active-site model,<sup>27</sup> this barrier is in good agreement with the experimental activation energy of 72 kJ mol<sup>−1</sup>, which was estimated from the catalytic constant for wild-type UDPGlcDH with UDP-glucose under saturating conditions ( $k_{\text{cat}} = 1.8 \pm 0.1 \text{ s}^{-1}$ ).<sup>10</sup> Moreover, we showed that in order for the 6-thioester intermediate to be hydrolyzed and form GlcUA in the last catalytic step, hydrated Glu141–COO<sup>−</sup> has to displace the NADH molecule formed in the second oxidation step. This statement is supported by the following: (i) Calculated high barriers to hydrolysis of the 6-thioester intermediate within the NADH-bound active-site complex larger than 180 kJ mol<sup>−1</sup>, which

are unusual in enzymatic reaction mechanisms. (ii) The exoergic character ( $-122.6 \text{ kJ mol}^{-1}$ ) of displacement of NADH from the 6-thioester intermediate-active-site complex by a Glu141-COO $^{-}$ ·2H $_2$ O complex, which suggests that the Glu141-COO $^{-}$  dihydrate binds stronger than NADH to the intermediate-active-site complex. (iii) The lower barrier height ( $102.1 \text{ kJ mol}^{-1}$ ) for the hydrolysis of the activated 6-thioester intermediate within the active-site complex including the Glu141-COO $^{-}$  dihydrate residue.

## Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca).

## Acknowledgment

We thank the Natural Sciences and Engineering Research Council of Canada (NSERC) for funding and the Shared Hierarchical Academic Research Computing Network (SHARCNET) for a Graduate Student Fellowship (WH) and additional computational resources. We also thank Russ Boyd for his mentoring and friendship over the years.

# The assessment of density functionals for DNA–protein stacked and T-shaped complexes

Lesley R. Rutledge and Stacey D. Wetmore

**Abstract:** The present work uses 129 nucleobase – amino acid CCSD(T)/CBS stacking and T-shaped interaction energies as reference data to test the ability of various density functionals with double-zeta quality basis sets, as well as some semi-empirical and molecular mechanics methods, to accurately describe noncovalent DNA–protein  $\pi$ – $\pi$  and  $\pi^+$ – $\pi$  interactions. The goal of this work is to identify methods that can be used in hybrid approaches (QM/MM, ONIOM) for large-scale modeling of enzymatic systems involving active-site (substrate)  $\pi$ – $\pi$  contacts. Our results indicate that AMBER is a more appropriate choice for the lower-level method in hybrid techniques than popular semi-empirical methods (AM1, PM3), and suggest that AMBER accurately describes the  $\pi$ – $\pi$  interactions found throughout DNA–protein complexes. The M06–2X and PBE-D density functionals were found to provide very promising descriptions of the 129 nucleobase – amino acid interaction energies, which suggests that these may be the most suitable methods for describing high-level regions. Therefore, M06–2X and PBE-D with both the 6–31G(d) and 6–31+G(d,p) basis sets were further examined through potential-energy surface scans to better understand how these techniques describe DNA–protein  $\pi$ – $\pi$  interactions in both minimum and nonminimum regions of the potential-energy surfaces, which is critical information when modeling enzymatic reaction pathways. Our results suggest that studies of stacked nucleobase – amino acid systems should implement the PBE-D/6–31+G(d,p) method. However, if T-shaped contacts are involved and (or) smaller basis sets must be considered due to limitations in computational resources, then M06–2X/6–31G(d) provides an overall excellent description of both nucleobase – amino acid stacking and T-shaped interactions for a range of DNA–protein  $\pi$ – $\pi$  and  $\pi^+$ – $\pi$  interactions.

**Key words:** DNA–protein interactions, noncovalent interactions, benchmarking, density functional theory (DFT),  $\pi$ – $\pi$  stacking interactions, T-shaped interactions.

**Résumé :** Dans ce travail, on utilise l'empilement de la nucléobase 129 – acide aminé CCSD(T)/CBS et les énergies d'interaction en forme de T comme données de référence pour vérifier l'utilité potentielle de diverses fonctionnelles de densité à ensembles de bases de qualité double-zêta ainsi que méthodes semi-empiriques de mécanique moléculaire pour décrire adéquatement les interactions  $\pi$ – $\pi$  et  $\pi^+$ – $\pi$  non covalentes entre l'ADN et une protéine. Le but de ce travail est d'identifier des méthodes qui pourraient être utilisées dans des approches hybrides (QM/MM, ONIOM) pour le modelage à grande échelle de systèmes enzymatiques impliquant des contacts  $\pi$ – $\pi$  du site actif avec un substrat. Nos résultats indiquent que la méthode AMBER serait plus appropriée que les méthodes semi-empiriques populaires (AM1, PM3) comme la méthode de faible niveau dans les techniques hybrides et ils suggèrent que la méthode AMBER décrit d'une façon correcte les interactions  $\pi$ – $\pi$  que retrouve systématiquement dans les complexes entre l'ADN et une protéine. On a trouvé que les fonctionnelles de densité M06–2X et PEB-D permettent d'obtenir des descriptions très prometteuses des énergies d'interaction de la nucléobase 129 – acide aminé, ce qui suggère qu'elles pourraient être les méthodes les plus appropriées pour décrire des régions de hauts niveaux. En conséquence, on a effectué un examen plus approfondi des fonctionnelles M06–2X et PEB-D avec les ensembles de base 6–31G(d) et 6–31+G(d,p) en faisant appel à des balayages de l'énergie potentielle de surface afin de mieux comprendre comment ces techniques décrivent les interactions  $\pi$ – $\pi$  ADN-protéine dans les régions tant minimales que non minimales des surfaces d'énergie potentielle qui est une information critique lorsqu'on effectue un modelage des voies réactionnelles des réactions enzymatiques. Nos résultats suggèrent que les études de systèmes empilés de nucléobase et d'acide aminé devraient faire appel à la méthode PBE-D/6–31+G(d,p). Toutefois, si les contacts en forme de T sont impliqués et (ou) des ensembles de bases plus simples doivent être impliqués en raisons des limitations des facilités de calcul, la méthode M06–2X/6–31G(d) fournit alors une excellente description globale à la fois de l'empilement nucléobase – acide aminé et des interactions en forme de T pour un large éventail d'interactions  $\pi$ – $\pi$  et  $\pi^+$ – $\pi$  d'ADN et de protéine.

**Mots-clés :** interactions ADN–protéine, interactions non covalentes, repérage, théorie de la fonctionnelle de la densité (« DFT »), interactions d'empilement  $\pi$ – $\pi$ , interactions en forme de T.

## Introduction

As we strive to truly understand vital biochemical processes, it is clear that a detailed knowledge of protein function and enzymatic catalysis is essential. Experimental biochemists use many methodologies (such as protein crystallography, NMR, fluorescence, site-specific mutagenesis, and kinetic isotope effects) to understand how enzymes function under a variety of conditions. However, in recent years, computational methodologies have also become key tools for determining complete mechanisms of enzymatic reactions (see for example refs. 1–6 and references therein). Computational modeling provides a unique approach because of the capability to characterize both the structure and energetics of short-lived intermediates and transition states,<sup>4</sup> which are challenging to investigate through experimental means without interfering with the natural reaction conditions.<sup>4</sup> Nevertheless, enzymatic systems also present a unique computational challenge, where many studies have concentrated on determining how to efficiently and accurately model such large systems (for examples, see refs. 1–35 and references therein).

Promising computational approaches for studying enzymes involve hybrid techniques,<sup>26,36–38</sup> which combine two or more methods and (or) levels of theory. These approaches allow for an accurate quantum mechanical description of the chemistry in a localized (high-level) region (such as an active site), while describing the rest of the protein with a low computational method (low-level region).<sup>36</sup> These schemes can be applied in a variety of different ways. The QM/MM methodology, which combines a quantum mechanical (QM) technique with a molecular mechanics (MM) method, is the most common class of hybrid approaches.<sup>26,36</sup> For example, it was reported that over 600 QM/MM articles were published in 2007.<sup>29</sup> However, ONIOM (our Own N-layer Integrated molecular Orbital molecular Mechanics) is another promising hybrid technique that is also used to study enzymatic systems.<sup>37,38</sup> This is perhaps a more general scheme due to its ability to combine any number of molecular orbital, as well as molecular mechanics, methods.<sup>37,38</sup>

Most of the current QM/MM and ONIOM studies on enzymatic systems use density functional theory (DFT) to describe the quantum mechanical region due to its greater efficiency compared with popular wave-function-based approaches (see, for example, refs. 8, 12, 15–21, 23–25, 28, 30, and 32). The most common density functional used in hybrid methods is arguably B3LYP, where this functional has been used for a wide variety of systems.<sup>8,12,15,16,19,21,24,28,30,32,34</sup> Despite the good performance of B3LYP for a range of systems and properties, it generally underestimates barrier heights,<sup>39</sup> and does not provide an accurate description of dispersion interactions. Consequently, this functional should not be used to describe high-level regions of enzymes that rely heavily on dispersion-dominated interactions (such as  $\pi$ – $\pi$  stacking,  $X-H\cdots\pi$  ( $X = C, N, S, O$ ), lone pair ( $lp$ ) $\cdots\pi$ , and (or)  $\pi$ – $\pi$  (edge-to-face) T-shaped contacts). Therefore, until recently, studies on systems that include these types of noncovalent interactions were limited to *ab initio* electron correlation methods (such as MP2), which are relatively computationally inefficient and there-

fore ultimately lead to the implementation of small model systems.

Our group is particularly interested in studying the first enzyme involved in the base excision repair (BER) mechanism,<sup>40</sup> a DNA glycosylase, which is responsible for recognizing a specific type of damaged DNA nucleobase, flipping this damaged nucleotide out of the DNA helix and into the active site, and cleaving the glycosidic bond connecting the nucleobase to the sugar-phosphate backbone.<sup>41,42</sup> There are many different DNA glycosylases, where each is responsible for repairing a particular type of DNA damage and uses specific noncovalent contacts to identify, bind, and facilitate in the excision of damaged nucleobase(s).<sup>41,42</sup> One of the enzymes of interest to our group is human alkyladenine DNA glycosylase (AAG), which removes 3-methyladenine, as well as other (cationic) alkylated purines, and the (neutral) hypoxanthine and 1,*N*<sup>6</sup>-ethenoadenine lesions.<sup>41–43</sup> Due to the wide substrate specificity of AAG, it has been proposed that nonspecific noncovalent interactions might be responsible for the unique function of this glycosylase.<sup>43</sup> Indeed, crystal structures reveal that multiple  $\pi$ – $\pi$  stacking and  $\pi$ – $\pi$  T-shaped interactions are exploited to bind substrates in the AAG active site (Fig. 1).<sup>43</sup> Although we are interested in studying the glycosidic-bond-cleavage mechanism facilitated by AAG using hybrid techniques, it is currently unclear which methods should be used to model enzymes with active sites that heavily rely on dispersion-dominated  $\pi$ – $\pi$  stacking and  $\pi$ – $\pi$  T-shaped interactions between DNA and protein components.

Recent work in the development of density functional techniques has concentrated on methods capable of describing dispersion interactions (see, for example, refs. 39 and 44–58). Indeed, a very recent review discusses the description of dispersion interactions by density functional theory.<sup>58</sup> Many approaches for including dispersion have emerged, and it is very important to test each functional for the specific systems of interest. As a result, an abundance of benchmarking studies have emerged in the literature (such as refs. 59–81) where many use the high-level (CCSD(T)/CBS) data sets of Hobza and co-workers<sup>82</sup> to determine the accuracy of new density functionals for noncovalent interactions (see refs. 59, 63, 65, 66, 68, 74, 76, and 79 for examples). Nevertheless, these test sets,<sup>82</sup> as well as others (such as those examined in refs. 62, 64, 70–73, 75, 77, and 80), do not include the DNA–protein interactions that can be important for enzymatic applications. Therefore, our group previously characterized the potential-energy surfaces (PESs) of  $\pi$ – $\pi$  stacking and  $\pi$ – $\pi$  (amino acid edge and nucleobase edge) T-shaped interactions between: (i) the four aromatic amino acids and the natural nucleobases<sup>83</sup>; (ii) the (cationic) alkylated damaged nucleobase, 3-methyladenine (3MeA) and the aromatic amino acids<sup>84</sup>; and (iii) the natural nucleobases and protonated histidine (HIS<sup>+</sup>, see Fig. 2).<sup>85</sup> These studies identified the (47 stacked and 82 T-shaped) most stable dimers, whose binding strengths were further characterized with CCSD(T)/CBS calculations.<sup>83–85</sup> Our test set of 129 nucleobase – amino acid interactions covers a wide variety of noncovalent (stacked, amino acid edge T-shaped, and nucleobase edge T-shaped) interactions involving both neutral ( $\pi$ – $\pi$ ) and cationic ( $\pi^+$ – $\pi$ ) systems.

The present work uses our large test set of DNA–protein

**Fig. 1.** Example of  $\pi$ - $\pi$  stacking and  $\pi$ - $\pi$  T-shaped interactions between the substrate (1,*N*<sup>6</sup>-ethenoadenine,  $\epsilon$ A7) and the aromatic amino acids (His, Tyr) in the active site of the human alkyladenine DNA glycosylase (AAG) (PDB code: 1EWN).<sup>43</sup>

**Fig. 2.** Models of the natural nucleobases (adenine (A), cytosine (C), guanine (G), thymine (T), and uracil (U)), the aromatic amino acids (histidine (HIS), phenylalanine (PHE), tyrosine (TYR), and tryptophan (TRP)), the damaged nucleobase (3-methyladenine (3MeA)), and protonated histidine (HIS<sup>+</sup>) considered in the present work.

interactions to investigate the performance of a number of density functional methods in the hopes of identifying an efficient method and basis-set combination that is currently readily available for describing the binding strengths and potential-energy surfaces of  $\pi$ - $\pi$  stacking and  $\pi$ - $\pi$  T-shaped DNA-protein interactions. This study first reports an interaction energy analysis of a variety of density functionals in the current literature for our 129 nucleobase – amino acid

dimer interactions, where our previous CCSD(T)/CBS calculations were used as the benchmark for accuracy.<sup>83–85</sup> This study also investigates how select density functional methods describe the potential-energy surfaces of three representative stacked and three representative amino acid edge T-shaped dimers. Our results are important for understanding how current density functionals describe DNA-protein  $\pi$ - $\pi$  interactions in both minimum and nonminimum regions of the potential-energy surfaces, which is rarely examined in the literature.<sup>70</sup> It is critical to understand how these methods describe both the energies and structures of  $\pi$ - $\pi$  systems to accurately model enzymatic reaction pathways.

## Computational details

In our previous works,<sup>83–85</sup> a series of MP2/6–31G\*(0.25) single-point calculations were used to scan the potential-energy surfaces (PESs) for the stacked and T-shaped orientations of nucleobase – amino acid dimers according to several geometric variables (Fig. 3). This modified basis set replaces the standard d-exponent for second row atoms (0.8) with 0.25.<sup>86</sup> Initially,  $C_s$ -symmetric, MP2/6–31G(d)-optimized monomers (Fig. 2) were placed such that the truncated amino acid and nucleobase molecular planes were parallel (stacked) or perpendicular (T-shaped). In stacked dimers involving HIS, TYR and TRP, two relative orientations of the molecular planes were considered. The first was obtained by stacking the amino acid and nucleobase orientations as shown in Fig. 2, while the second conformation was obtained by mirror flipping the amino acid relative to Fig. 2 before stacking with the nucleobase (indicated using a prime (') throughout this manuscript). T-shaped dimers involving either amino acid edges or nucleobase edges were considered. To define the ring edge (monomer edge) directed towards the  $\pi$ -system (monomer face), the geometric variable  $\theta$  (Fig. 3b) was introduced, where all edges considered are shown in the Supplementary data (Figs. S1–S3). From these initial structures, three geometric variables were considered in our potential-energy surface scans using the increments defined in Fig. 3: the vertical separation ( $R_1$ ), the angle of rotation ( $\alpha$ ), and the horizontal displacement ( $R_2$ ) between monomers, where our  $R_2$  scans shift one monomer relative to the other in two directions that are perpendicular to the  $R_1$  axis. A full description of our scanning procedure is provided in our previous manuscripts.<sup>83–85</sup> Since our previous work<sup>85</sup> did not consider the interactions between uracil and protonated histidine, all data for this dimer are presented in the Supplementary data (Tables S1 and S2).

The 47 stacked and 82 T-shaped orientations (29 amino acid edge and 53 nucleobase edge dimers indicated with bold in Figs. S1–S3) with the strongest (most negative) interaction energies were further studied with CCSD(T) at the complete basis-set (CBS) limit.<sup>83–85</sup> MP2/aug-cc-pVDZ and MP2/aug-cc-pVTZ energies were used to extrapolate to MP2/CBS using the procedure of Helgaker and co-workers.<sup>87,88</sup> To account for errors in the MP2 electron correlation, the difference between the MP2/6–31G\*(0.25) and CCSD(T)/6–31G\*(0.25) energies ( $\Delta(\text{CCSD(T)} - \text{MP2})$ ) was combined with the MP2/CBS result to give an estimated CCSD(T)/CBS interaction energy. We note that recent literature denotes these extrapolated interaction energies as CBS(T)

**Fig. 3.** Definition of the geometric variables considered and increments used in our previous (a) stacking and (b) T-shaped potential-energy surface scans (angle of “edge” rotation ( $\theta$ ), vertical separation distance ( $R_1$ ), angle of rotation ( $\alpha$ ), and horizontal displacement ( $R_2$ )).

(such as in refs. 89–91); however, we refer to these values as CCSD(T)/CBS to be consistent with our previous work,<sup>83–85</sup> as well as previous stacking-interaction studies (for example, refs. 82, 92, and 93).

In the present work, a variety of density functionals that were previously shown to be promising for noncovalent interactions were tested against our 129 nucleobase – amino acid CCSD(T)/CBS dimer interaction energies. Specifically, we considered MPWB1K,<sup>94</sup> M05–2X,<sup>95</sup> M06–L,<sup>96</sup> M06–2X,<sup>96</sup> PBE–D,<sup>46</sup> BLYP–D,<sup>46</sup> TPSS–D,<sup>46</sup> and B97–D.<sup>46</sup> For comparison, we also considered PBE, BLYP, and TPSS without Grimme’s dispersion correction. We also include B3LYP due to the popularity of this approach in QM/MM and ONIOM hybrid calculations on enzymatic systems.<sup>8,12,15–16,19,21,24,28,30,32</sup> All functionals were tested with a variety of double-zeta Pople’s and Dunning’s basis sets (6–31G(d), 6–31G(d,p), 6–31+G(d,p), cc-pVDZ, and aug-cc-pVDZ).<sup>97</sup> Most benchmarking studies test the performance of these functionals using basis sets for which they were originally designed. However, since these are typically large (see, for example, refs. 61, 64, 69, 70, 72, 73, 75, 76, and 78), we focus our work on basis sets that are practical for enzymatic systems, where the intended application is full optimizations of enzyme-catalyzed reactions using hybrid methods.

To provide a greater understanding of the relative performance of the chosen DFT functionals, we include MP2 results for our 129 nucleobase – amino acid dimers. Owing to the vast literature that has studied noncovalent complexes with MP2, the shortfalls of this method are well-known, and therefore MP2 provides a good quality comparison for other methods. Additionally, we have considered the double-hybrid density functionals B2PLYP<sup>47,50</sup> and mPW2PLYP.<sup>51,74</sup> Although Grimme’s dispersion correction was originally designed for other functionals,<sup>46</sup> this empirical dispersion term has also been applied to these double-hybrid functionals.<sup>51,74</sup> Therefore, B2PLYP–D and mPW2PLYP–D were also considered in the present work. Although these methods are likely not practical for studying large enzymatic systems, these functionals will provide a worthy comparison to the other methods tested in this

manuscript due to their promise for reliably describing noncovalent  $\pi$ – $\pi$  interactions.<sup>51,74</sup>

In addition to active-site contacts, noncovalent  $\pi$ – $\pi$  interactions should be accurately described throughout the entire enzymatic model. Therefore, we considered the performance of the AMBER molecular mechanics method.<sup>98</sup> AMBER was selected, since it was originally designed to describe both DNA and protein systems,<sup>98</sup> and is commonly used in hybrid techniques (see examples in refs. 16–25). To be consistent with the original AMBER design, HF/6–31G(d) ESP charges were calculated and used to describe each monomer, which are truncated versions of those originally used to develop the force field.<sup>98</sup> AMBER atom types were assigned according to the original AMBER manuscript.<sup>98</sup> In our nucleobase models, the hydrogen atom replacing the sugar-phosphate backbone was defined as H. In the case of the amino acids, this hydrogen atom was defined as H4 for histidine (neutral and protonated) and tryptophan, and HA for phenylalanine and tyrosine. ANTECHAMBER (Version 1.0)<sup>99</sup> was used to define the atom types (Fig. S4) and parameters (Table S3) for the damaged base, 3-methyladenine. Finally, since PM3 and AM1 are frequently used to describe the lower-level regions of ONIOM calculations (for example, see refs. 7, 8, 11, 12, 14, 15, and 31), these methods were also included in our study.

All calculations were performed with Gaussian 09<sup>100</sup> with the exception of PBE, BLYP, and TPSS (with and without dispersion corrections), which were performed with GAMESS.<sup>101</sup> Despite reports that default grid sizes for various DFT methods can lead to false artifacts in the description of noncovalent interactions,<sup>102</sup> the default grids in Gaussian 09 and GAMESS were used. Additionally, all interaction energies were calculated without BSSE corrections<sup>103</sup> (with the exception of MP2). We emphasize that these choices were made due to our goal of understanding how these functionals describe noncovalent interactions in hybrid approaches, where large integration grid sizes and BSSE-free optimizations are not currently feasible.

## Results and discussion

As discussed in the Introduction, the present study focuses on identifying suitable methodologies for hybrid QM/MM or ONIOM calculations on enzyme-catalyzed reactions that involve noncovalent  $\pi$ – $\pi$  substrate – active site interactions. In this light, the ability of a variety of DFT functional and basis-set combinations, as well as some semi-empirical and molecular mechanics methods, to reproduce CCSD(T)/CBS interaction energies for our test set of 129  $\pi$ – $\pi$  stacked and T-shaped nucleobase – amino acid dimers<sup>83–85</sup> was investigated. Owing to the large number of dimers and methodologies considered, our results (Tables 1–3) are reported in terms of the mean unsigned error (MUE) and mean signed error (MSE) with respect to the CCSD(T)/CBS results. We also report the largest absolute deviation (MAX) and the largest percent difference (MAX %) from CCSD(T)/CBS observed among the dimers considered. Initially, we will separately discuss the performance of the methods for each of the two main types of  $\pi$ – $\pi$  interactions (stacking and T-shaped) considered and subsequently summarize the overall performance of these methods for both noncovalent interac-

**Table 1.** Mean unsigned error (MUE, kJ mol<sup>-1</sup>), mean signed error (MSE, kJ mol<sup>-1</sup>), maximum absolute difference (MAX, kJ mol<sup>-1</sup>), and maximum percent error (MAX %) between various methods and the CCSD(T)/CBS benchmark interaction energies for 47 nucleobase – amino acid stacked dimers.

<sup>a</sup>MP2 interaction energies were calculated using the BSSE-corrected dimer energies.

tions, as well as the relative performance for dimers involving neutral and cationic monomers. Subsequently, to assess the ability of various functionals to accurately describe an extended portion of the potential-energy surface, PES scans of select dimers will be considered for the methods that best-describe the 129 dimer interaction energies with the current large-model goal in mind.

## Calculation of accurate interaction energies

### Stacking interactions

We will begin by discussing the performance of MP2 with the small basis sets considered in the present work, which will illustrate how this widely used method for stacking depends on the basis set used for our systems of interest. These data will also provide a useful reference point for discussing the basis-set dependence of other methods. As mentioned in the Computational details, we have chosen to consider two different basis-set designs of double-zeta quality, since our end goal is to use these methods to study enzyme-catalyzed reactions through full (hybrid) optimizations. As previously noted in the literature,<sup>86</sup> MP2 does not adequately recover CCSD(T)/CBS stacking energies in the absence of diffuse functions (6–31G(d), 6–31G(d,p), and cc-pVDZ), while inclusion of diffuse functions improves the quality of the results (Table 1). Nevertheless, when a modified basis set (6–31G\*(0.25)) that was designed to study stacking interactions between the DNA nucleobases is considered,<sup>86,104,105</sup> both the MUE and MSE significantly decrease, and the MAX and MAX % drastically decrease. These results emphasize that the 6–31G\*(0.25)-modified basis set provides an excellent description of DNA–protein  $\pi$ – $\pi$  stacking interactions,<sup>83–85</sup> and outperforms even the commonly used aug-cc-pVDZ basis set.

As previously shown in the literature, DFT functionals traditionally used in a variety of applications (structure, kinetics, and hydrogen-bond strengths) do not accurately describe  $\pi$ – $\pi$  stacking interactions (Table 1).<sup>58</sup> For stacking between nucleobase and amino acid monomers, this includes the widely used B3LYP functional. This result emphasizes that this functional should be cautiously used in hybrid approaches for studying enzyme-catalyzed reactions, since many high-level regions contain  $\pi$ – $\pi$  contacts. Furthermore, B3LYP should clearly not be used when stacking interactions have been proposed to have direct implications in substrate recognition or catalysis.

Although PBE, BLYP, and TPSS also fail to recover the correct CCSD(T)/CBS stacking energies, the performance of these functionals drastically improves when Grimme's dispersion correction is included (Table 1). B97-D also performs very well, which further testifies to the usefulness of empirical dispersion corrections in functional design. Other tactics have also been proposed to develop DFT functionals for noncovalent  $\pi$ – $\pi$  interactions, such as dispersion correcting potentials (DCPs).<sup>68</sup> Alternatively, more commonly used functionals (such as meta generalized gradient approximation (GGA) or hybrid-meta GGA methods MPWB1K,<sup>94</sup> M05–2X,<sup>95</sup> M06,<sup>56</sup> M06–L,<sup>96</sup> and M06–2X<sup>56</sup>) designed for these interactions were also parameterized to describe other properties (for instance, barrier heights or transition metals). Among these functional, MPWB1K does not perform as

well as PBE-D for DNA–protein  $\pi$ – $\pi$  interactions. However, newer functionals (M05–2X,<sup>95</sup> M06–L,<sup>96</sup> and M06–2X<sup>56</sup>) designed by the Truhlar group show improved performance. Indeed, the M06–L and M06–2X functionals lead to the smallest MUE and MSE among these methods.

The relative performance of the Pople's (6–31G) and Dunning's (cc-pVDZ) basis sets depends on the functional form considered. However, in most instances, the difference is minimal when the performances of basis sets containing the same types of (polarization, diffuse) functions are compared. Methods that do not perform well for stacking (B3LYP, PBE, BLYP, and TPSS) perform even worse as the basis-set size increases. Although there is not a large difference in performance as polarization functions are added to the hydrogen atoms, the description of stacking becomes much poorer when diffuse functions are included for these methods. On the contrary, drastic performance improvements are found when diffuse functions are added to the basis set used with PBE-D, BLYP-D, and TPSS-D. Interestingly, there is little change in the performance of M05–2X and M06–2X with an increase in the basis-set size, where inclusion of diffuse functions leads to a slightly poorer description of stacking. However, increasing the basis set for the M06–L functional leads to improved stacking-interaction energies, where the aug-cc-pVDZ basis sets leads to the smallest MUE and MSE for these functionals.

A potential way to further improve upon the performance of DFT methods for the calculation of  $\pi$ – $\pi$  interactions is to consider double-hybrid density functionals, such as B2PLYP and mPW2PLYP. B2PLYP, in particular, provides an extremely small absolute mean deviation for the S22 test set when Grimme's dispersion correction is included and a large triple-zeta basis set is used.<sup>74</sup> Although we find that inclusion of the dispersion correction improves the performance of both B2PLYP and mPW2PLYP, these functionals are not as accurate as the other dispersion-corrected methods considered above (Table 1). We acknowledge that this could be in part due to the fact that we do not include BSSE corrections in our reported binding energies, since these calculations would not be realistic during each optimization step when enzyme-catalyzed reactions are considered.

Although we have discussed methods suitable for the highest-level region of hybrid calculations, the performance of the method used to describe the remainder of the protein environment (low-level region) must also be carefully considered. Semi-empirical methods are sometimes employed as a highly efficient molecular orbital method for describing proteins (for examples, see refs. 7, 8, 11, 12, 14, 15, 31, and 35). For instance, these techniques can be used as the high-level method, as the mid-layer region in multi-layer approaches, or as the low-level method when truncated enzyme models are used. However, our results indicate that neither of the typically chosen semi-empirical techniques (AM1, PM3) accurately describe stacking interactions between the DNA/RNA bases and aromatic amino acids (Table 1). On the contrary, since AMBER was developed to describe the structure of both DNA and proteins,<sup>98</sup> this molecular mechanics method describes the stacking interactions between their components exceptionally well (Table 1).

### T-shaped interactions

$\pi$ - $\pi$  T-shaped interactions have been less-studied compared with the large number of stacked complexes examined in the literature. These interactions have been proposed<sup>83</sup> to be less-dependent on dispersion than stacking, and therefore more commonly used computational techniques may be able to accurately describe these contacts. This statement is confirmed in the present work where the performance of MP2 with any of our chosen basis sets is better for T-shaped (Table 2) than stacking (Table 1) interactions. Indeed, although aug-cc-pVDZ is not the optimal choice for studying stacked systems with MP2, this combination outperforms other basis sets for T-shaped interactions. However, MP2/6-31G\*(0.25), which was the best combination for the stacked orientations, also performs very well for nucleobase – amino acid T-shaped contacts. These results justify the use of MP2/6-31G\*(0.25) for  $\pi$ - $\pi$  T-shaped interactions even though this basis set was originally designed for stacked dimers.<sup>86,104,105</sup>

For all functionals, the basis-set effects on T-shaped binding strengths (Table 2) are the same as those discussed for stacking interactions (Table 1). B3LYP more accurately describes T-shaped than stacking contacts with all basis sets considered. However, B3LYP is still much less accurate than the other functionals under analysis. Therefore, we re-emphasize that B3LYP should be cautiously used in hybrid approaches for studying enzyme-catalyzed reactions when the high-level region contains  $\pi$ - $\pi$  interactions. Once again, we find that inclusion of an empirical dispersion correction greatly improves the accuracy of GGA, meta-GGA, and double-hybrid density functionals. This suggests that dispersion may play a larger role in dictating the magnitude of T-shaped interactions than initially believed. We note that although the MUE and MSE are smaller for PBE than PBE-D, the MAX and MAX % are much larger for PBE, which makes PBE a less reliable method. Nevertheless, M05-2X and M06-2X yield interaction energies closer to the CCSD(T)/CBS results, while M06-L does not perform as well as these other functionals. Indeed, M06-2X performs significantly better than PBE-D for nucleobase – amino acid T-shaped interactions.

AM1 and PM3 more accurately predict nucleobase – amino acid T-shaped interactions (Table 2) compared with the stacking binding energies (Table 1). However, the deviations from the CCSD(T)/CBS results are still very large, and therefore these methods should be used with caution for systems that include many aromatic residues. The MUE is slightly larger for AMBER T-shaped interactions (Table 2) than AMBER stacking energies (Table 1), while the MAX and MAX % are significantly larger for T-shaped contacts. However, AMBER reasonably describes both types of interactions, especially when the computational efficiency of this method is taken into account.

### Overall

We emphasize that our discussion of the performance of DFT functionals presented thus far has provided general conclusions based on the results of all dimers. However, errors for the neutral versus cationic dimers were also determined (see Supplementary data, Tables S4–S6) and fully analyzed. We found that all methods describe the binding

strengths of cationic dimers with slightly less accuracy than neutral dimers. Nevertheless, there are no drastic differences that warrant a detailed discussion of the performance of each method for cationic versus neutral systems.

Table 3 summarizes the performance of all methods for all types of (stacking and T-shaped, neutral  $\pi$ - $\pi$ , and cationic  $\pi^+$ - $\pi$ ) interactions. Over the entire data set, we conclude that AMBER is a more appropriate choice for the lower-level method in hybrid approaches than popular semi-empirical techniques. Indeed, AMBER also outperforms many of the other methods considered in the present work, especially when the low computational cost of this technique is taken into account. This suggests that MD, QM/MM, or ONIOM calculations that implement AMBER accurately describe  $\pi$ - $\pi$  interactions throughout DNA–protein systems. We find that the error in the AMBER binding strengths is greater for cationic than neutral systems (see Supplementary data), and therefore care should be taken when comparisons between systems with different charges are required.

Among the MP2 basis-set combinations considered, MP2/6-31G\*(0.25) provides the best description for a range of noncovalent  $\pi$ - $\pi$  dimer interactions (Table 3). These results further justify our use of this method for scanning the potential-energy surfaces of stacked and T-shaped nucleobase – amino acid dimers.<sup>83–85</sup> Furthermore, our findings suggest that MP2/6-31G\*(0.25) is an efficient method for use in future work of stacked or T-shaped systems when larger systems (trimers or tetramers) are considered.

As discussed previously in the literature, double-hybrid functionals yield very good performance when an empirical dispersion correction is included in the functional form.<sup>51,74</sup> Additionally, the performance reported in the present work would likely be further improved with the inclusion of BSSE corrections. However, as previously discussed, this is not a feasible approach for our intended application because of the computational scaling of these methods. Therefore, the use of these functionals for accurately determining interaction energies is currently restricted to single-point calculations with large basis sets and (or) BSSE corrections.

There is no significant difference in the results obtained with Pople's or Dunning's basis sets for any DFT method considered. Nevertheless, the Dunning's basis sets lead to a larger total number of basis functions, and therefore calculations with these basis sets require increased computational resources. Since convergence on realistic time scales is an important consideration when studying enzyme-catalyzed reactions, we recommend considering the use of Pople's basis sets in hybrid studies of large systems.

The results in Table 3 suggest that within the functionals considered in the present work, the methods that best-describe  $\pi$ - $\pi$  stacking and T-shaped interaction energies are M06-2X and PBE-D. Although BLYP-D outperforms PBE-D with the 6-31+G(d,p) basis set, PBE-D performs better with the smaller 6-31G(d) basis set. However, Table 3 suggests that M06-2X outperforms PBE-D with both the smaller 6-31G(d) and the larger 6-31+G(d,p) basis sets. We emphasize that the 6-31G(d) basis set is a more computationally efficient choice for hybrid approaches, since the inclusion of diffuse functions on heavy atoms and (or) polarization functions on hydrogen atoms during the optimization routine drastically increases the computational resour-

ces required. Thus, M06-2X/6-31G(d) may be the best choice among those considered in the present work for describing the high-level region in hybrid approaches for large-scale modeling of enzyme-catalyzed reactions that involve DNA-protein  $\pi$ - $\pi$  interactions.

### Description of potential-energy surfaces

Although Tables 1–3 provide useful information about the ability of various methods to accurately predict the strength of  $\pi$ - $\pi$  interactions at minimum regions on the potential-energy surfaces of nucleobase – amino acid dimers, these data do not necessarily reflect whether the methods provide an accurate description of the entire PES. Understanding how density functionals describe both minimum and nonminimum regions of potential-energy surfaces is particularly important when applying these methods to optimize a complete reaction mechanism for DNA-protein complexes that include stacked and (or) T-shaped contacts. Therefore, as a critical first step, the functional (M06-2X, PBE-D) and basis set (6-31G(d), 6-31+G(d,p)) combinations found to best-describe nucleobase – amino acid interactions will be further scrutinized below by evaluating their ability to describe changes in both stacked and T-shaped binding strengths as a function of select geometric variables (Fig. 3). Since MP2 is widely used to study  $\pi$ - $\pi$  dimers in the literature, we have chosen to compare our results to the MP2 method that best-describes stacked (MP2/6-31G\*(0.25), Table 1) or T-shaped (MP2/aug-cc-pVDZ, Table 2) orientations. Nevertheless, both MP2 values are reported for both types of interactions to further illustrate the differences between these approaches. We focus our investigation on three dimers (adenine-histidine, 3-methyladenine-histidine, and adenine – protonated histidine) in both their optimal stacked and (amino acid edge) T-shaped orientations (Fig. 4). Our choice in molecules allows us to consider similar systems that span both  $\pi$ - $\pi$  and  $\pi^+$ - $\pi$  interactions, which have a varying dependence on the electrostatic and dispersion contributions to the interactions.

#### Stacked dimers

Deviations in the MP2-calculated curves describing dimer interaction energies as a function of the vertical separation ( $R_1$ , Fig. 3) between the monomers are not surprising (Figs. 5a–5c), since aug-cc-pVDZ is known to overestimate stacking interactions. However, both basis sets predict the same preferred MP2 vertical separation in the nucleobase – amino acid dimers considered in the present work (see Supplementary data, Tables S7–S9). Furthermore, over the  $R_1$  values investigated, the entire potential-energy surfaces calculated with both basis sets are reasonably close in both magnitude and shape for the cationic systems (Figs. 5b and 5c). Nevertheless, there are larger deviations in the calculated MP2 binding strengths for the neutral dimer (Fig. 5a), where the magnitude of the deviation depends on the vertical separation, and a better agreement is observed at larger vertical separations.

M06-2X leads to steeper potential-energy surfaces with respect to  $R_1$  than MP2 for stacked dimers. Specifically, this functional underestimates the binding strength at large vertical separations and overestimates the interaction energy at small  $R_1$  distances. The M06-2X results obtained with both

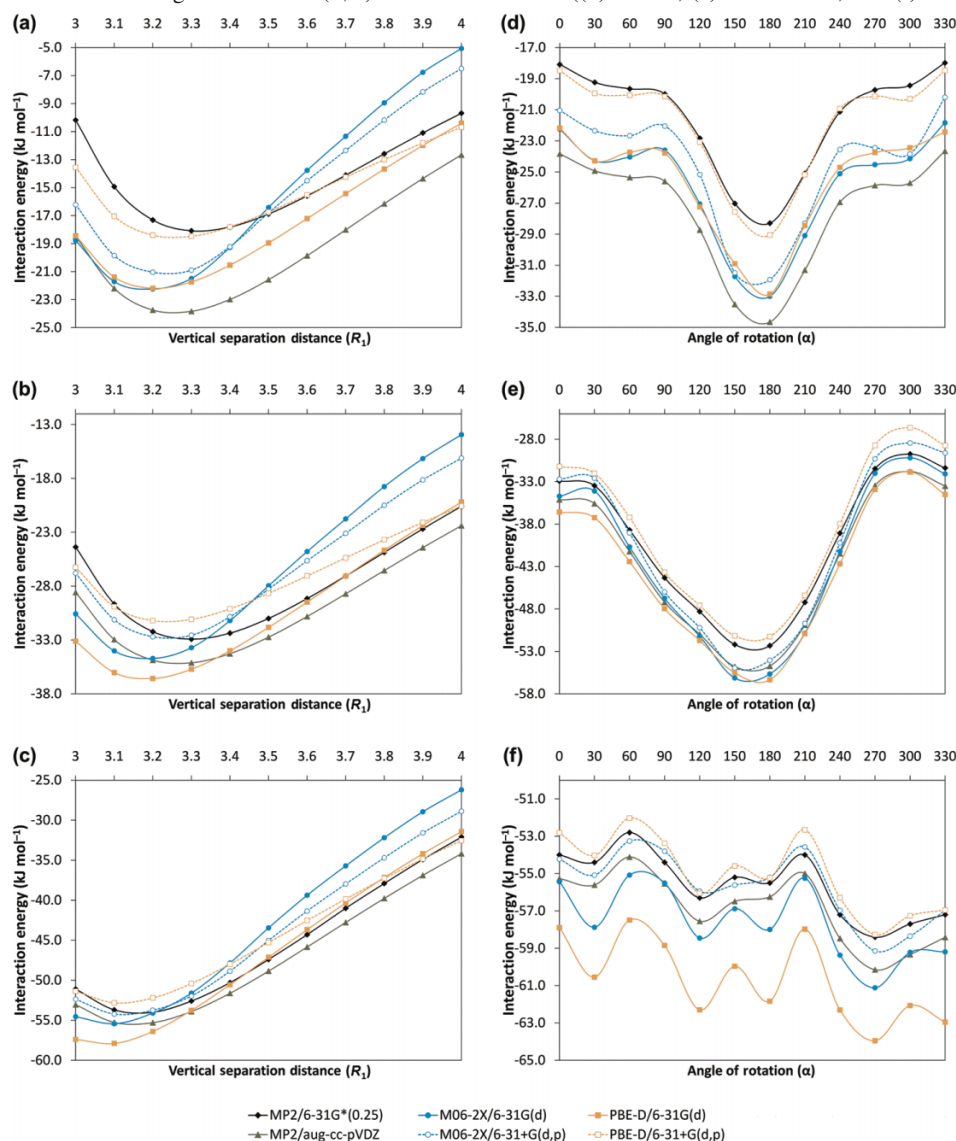

**Fig. 4.** Dimers considered in vertical separation ( $R_1$ ) and angle of rotation ( $\alpha$ ) potential-energy surface scans for (a) stacked and (b) amino acid edge T-shaped orientations.

basis sets are in good agreement with each other, which re-emphasizes that inclusion of diffuse functions does not lead to improved performance for this functional. In the absence of diffuse functions, the PES with respect to  $R_1$  is slightly steeper, which implies that deviations from MP2/6-31G\*(0.25) will be larger in non-equilibrium geometries for the M06-2X/6-31G(d) combination. For all dimers, M06-2X predicts the preferred vertical separation to be 0.1 Å smaller than MP2, which has been previously reported in the literature for the methane dimer<sup>76</sup> and the sandwiched-benzene dimer<sup>76</sup> and reflects stronger binding. However, we used an  $R_1$  scan increment of 0.1 Å (Fig. 3) and consideration of smaller increments might yield even better agreement with MP2.<sup>83</sup> Furthermore, when regions close to the preferred  $R_1$  are considered, small changes in the vertical separation lead to small changes in the interaction energy. Finally, it is interesting to note that the deviations from MP2/6-31G\*(0.25) are smaller for the M06-2X  $\pi^+$ - $\pi$  stacking interactions than the corresponding  $\pi$ - $\pi$  contacts. We note that our M06-2X surfaces are smooth despite previous reports that meta-GGA potential-energy curves for the stacked benzene dimer oscillate unless very large integration grids are used.<sup>106</sup>

PBE-D/6-31+G(d,p) provides an excellent representation of the preferred MP2 geometries, as well as the interaction energies for the entire  $R_1$  potential-energy surface of stacked dimers. Indeed, PBE-D/6-31+G(d,p) likely provides a better description of both  $\pi$ - $\pi$  and  $\pi^+$ - $\pi$  contacts than M06-2X with either basis set. However, there is a much larger basis-set effect for the PBE-D functional. Specifically, removal of diffuse functions from the basis set leads to a significant overestimation when compared with the MP2/6-31G\*(0.25) stabilization energy, which is much more pronounced at smaller  $R_1$  distances. Figure 5 also illustrates that PBE-D/6-31G(d) and MP2/6-31G\*(0.25) are in better agreement in the  $\pi^+$ - $\pi$  complexes (Figs. 5b and 5c) than the  $\pi$ - $\pi$  A:HIS dimer (Fig. 5a). Furthermore, as discussed for M06-2X, PBE-D/6-31G(d) predicts  $R_1$  to be 0.1 Å smaller than MP2,

**Fig. 5.** Interaction energy ( $\text{kJ mol}^{-1}$ ) as a function of vertical separation distance ( $R_1$ , Å) for the stacked dimers ((a) A:HIS, (b) 3MeA:HIS', and (c) A:HIS<sup>+</sup>) or as a function of angle of rotation ( $\alpha$ , °) for stacked dimers ((d) A:HIS, (e) 3MeA:HIS', and (f) A:HIS<sup>+</sup>).

but this effect is diminished when the larger basis set is used (see Supplementary data, Tables S7–S9).

Using the preferred  $R_1$  distance identified for each method, the binding strength as a function of the angle of rotation of the amino acid with respect to the nucleobase ( $\alpha$ , Fig. 3) was considered (Figs. 5d–5f). Unlike discussed for the  $R_1$  potential-energy surfaces, all methods yield the same general shape of the potential-energy surface with respect to  $\alpha$ , which is dictated by the relative orientation of the dipole moment vectors in the monomers.<sup>83</sup> Once again, we clearly see the overestimation of the interaction strength at the MP2 level with the aug-cc-pVDZ compared with the 6–31G\*(0.25) basis set.

Although M06–2X with both basis sets yields binding energies in very close agreement with one another for all  $\alpha$  values in the A:HIS and 3MeA:HIS' stacked dimers, a larger basis-set effect is seen for A:HIS<sup>+</sup> (Fig. 5f). To provide a fairer comparison by only examining the effects of  $\alpha$ , an additional  $\alpha$  scan was performed at the MP2/6–31G\*(0.25)

preferred vertical separation distance for cases where the DFT  $R_1$  distance was different (see Supplementary data, Tables S7–S9). When the same  $R_1$  value is considered, we see better agreement between the M06–2X results and the MP2/6–31G\*(0.25) results for this dimer (see Supplementary data, Table S9). In comparison, PBE-D/6–31+G(d,p) produces nearly identical potential-energy surfaces with respect to  $\alpha$  in both shape and magnitude as MP2/6–31G\*(0.25). However, PBE-D/6–31G(d) greatly overestimates the MP2 binding strength for all  $\alpha$ , especially for the A:HIS<sup>+</sup> dimer (see Fig. 5f).

In summary, PBE-D in combination with basis sets that include diffuse functions yields stacking interactions in excellent agreement with MP2 for large regions of the PES, and therefore this is the method of choice for describing DNA–protein stacking interactions in large-scale modeling. However, in instances when diffuse functions are prohibited due to the associated computational expense, PBE-D can yield acceptable  $\pi$ – $\pi$  interactions, but can lead to very large

overestimations, especially in  $\pi^+-\pi$  interactions. In comparison, M06-2X has a very small basis-set dependence and yields a reasonable description of both the dispersion and electrostatic components of the stacking interactions for both neutral and cationic systems. As a result, M06-2X is an efficient choice for modeling stacking interactions in large systems that require the use of small basis sets (without diffuse functions).

### T-shaped dimers

In contrast to the discussion of stacked systems, the MP2 potential-energy surfaces with respect to  $R_1$  calculated with aug-cc-pVDZ and 6-31G\*(0.25) for T-shaped dimers are very similar in shape, and the binding strengths are nearly identical in magnitude (within 3.3 kJ mol<sup>-1</sup>, Figs. 6a-6c). M06-2X almost always underestimates the MP2 T-shaped binding strengths regardless of the basis set used, especially when interactions with a cationic monomer are considered. On the contrary, PBE-D generally overestimates the MP2 binding strength for T-shaped dimers, where this overestimation is exaggerated when diffuse functions are omitted from the basis set (see for example, Figs. 6a and 6c). As discussed for the stacked dimers, all DFT methods predict a 0.1 Å shorter vertical separation than MP2 for A:HIS(edge) and 3MeA:HIS(edge) T-shaped dimers. However, the  $R_1$  values for A:HIS<sup>+</sup>(edge) match the MP2 results for all combinations except M06-2X/6-31+G(d,p), which predicts a 0.1 Å larger vertical separation.

Once again, all methods yield the same general shape for the curves representing the T-shaped interaction energy as a function of the angle of rotation ( $\alpha$ , Figs. 6d-6f). Furthermore, all other general conclusions discussed for the stacking interactions in regards to the method dependence for these potential-energy surfaces hold for the T-shaped interactions. However, the effects are more pronounced in the case of T-shaped contacts. Most significantly, when diffuse functions are not included in the basis set, PBE-D drastically overestimates the T-shaped interactions. These results re-emphasize our previous conclusion that PBE-D/6-31G(d) should not be used to study  $\pi-\pi$  T-shaped contacts. M06-2X, on the other hand, more consistently provides a better description for a range of  $\pi-\pi$  and  $\pi^+-\pi$  T-shaped DNA-protein interactions.

### Overall

Detailed consideration of the potential-energy surfaces of  $\pi-\pi$  and  $\pi^+-\pi$  stacked and T-shaped dimers as a function of the vertical separation ( $R_1$ ) and angle of rotation ( $\alpha$ ) between nucleobase and amino acid monomers supports our previous interaction energy analysis. Specifically, PBE-D with diffuse functions (6-31+G(d,p)) provides a very accurate description of the potential-energy surface of the stacked dimers. However, the accuracy of this combination breaks down for T-shaped complexes, where these interaction energies can be drastically overestimated. PBE-D also has a very large basis-set dependence, and therefore small basis sets with no diffuse functions should be used in conjunction with this functional with extreme caution, especially when T-shaped contacts are considered. Our results indicate that if the system of interest contains both stacked and T-shaped arrangements, then M06-2X will provide a

more reliable description of all  $\pi-\pi$  interactions in the DNA-protein complex. Nevertheless, users should be aware that M06-2X generally finds the equilibrium distances to be 0.1 Å closer than other methods, and underestimates the binding at vertical separation distances larger than the equilibrium value. Nevertheless, the description of both stacked and T-shaped interactions with M06-2X looks promising for geometry optimizations in the intended application of studying DNA-protein systems with hybrid techniques. M06-2X has minimal basis-set dependence for both stacked and T-shaped orientations and therefore can be used in conjunction with a small basis set to optimize large enzymatic systems. In fact, our results indicate that there is no advantage to including diffuse functions in attempts to improve the description of M06-2X stacking and T-shaped interactions, while the computational cost associated with implementing such basis sets for enzymatic systems is very high.

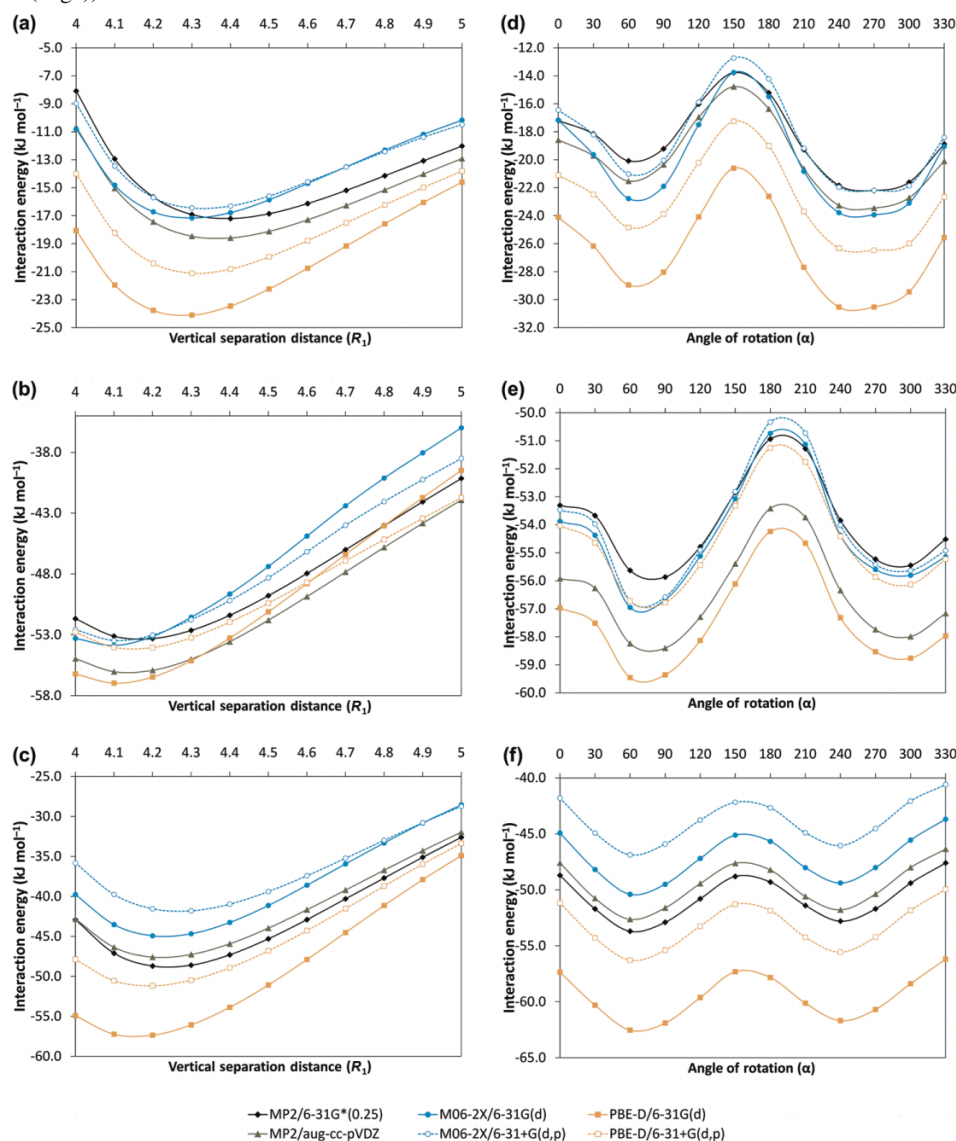

### Conclusions

The present work investigated the performance of a number of density functional methods, as well as other techniques currently used in hybrid approaches, to identify currently available method and basis-set combinations that accurately and efficiently describe the binding strengths and potential-energy surfaces of  $\pi-\pi$  stacking and  $\pi-\pi$  T-shaped DNA-protein interactions. By benchmarking against our previously reported 129 nucleobase – amino acid dimer CCSD(T)/CBS interaction energies,<sup>83-85</sup> we conclude that AMBER is a more appropriate choice for the lower-level method in hybrid approaches than popular semi-empirical techniques, and suggest that hybrid techniques that implement AMBER accurately describe  $\pi-\pi$  interactions throughout DNA-protein systems. Additionally, the M06-2X and PBE-D density functional methods were found to provide very promising descriptions of our entire 129 nucleobase – amino acid dimer test set, and therefore may be the best choice for high-level regions in hybrid approaches for studying enzyme systems that involve nucleobase – amino acid  $\pi-\pi$  interactions.

M06-2X and PBE-D, in combination with smaller (6-31G(d)) and larger (6-31+G(d,p)) double-zeta basis sets, were further examined to determine which combinations best-describe an extended portion of the potential-energy surfaces of three representative stacked and three representative (amino acid edge) T-shaped dimers. PBE-D with the larger basis set was found to provide an excellent description of stacking interactions, yet generally overestimates T-shaped interactions. However, PBE-D has a very strong basis-set dependence, where the small basis set erroneously overestimates interaction energies in both neutral and cationic systems, especially for T-shaped contacts. On the other hand, M06-2X has a small basis set dependence. Indeed, M06-2X/6-31G(d) was found to provide an excellent description of both stacked and T-shaped, as well as  $\pi-\pi$  and  $\pi^+-\pi$ , DNA-protein interactions. Therefore, we recommend using PBE-D/6-31+G(d,p) to study nucleobase – amino acid systems that rely only on stacking interactions. However, if T-shaped contacts are to be considered and (or) smaller basis sets must be used, M06-2X/6-31G(d) will provide an

**Fig. 6.** Interaction energy ( $\text{kJ mol}^{-1}$ ) as a function of vertical separation distance ( $R_1$ , Å) for the T-shaped dimers ((a) A:HIS(edge), (b) 3MeA:HIS(edge), and (c) A:HIS<sup>+</sup>(edge)) or as a function of angle of rotation ( $\alpha$ , °) for T-shaped dimers ((d) A:HIS(edge), (e) 3MeA:HI-S(edge), and (f) A:HIS<sup>+</sup>(edge)).

overall excellent description of the (stacking and T-shaped) interactions in the entire DNA–protein complex.

The present work is important for our understanding of how current density functionals describe DNA–protein  $\pi$ – $\pi$  interactions in both minimum and nonminimum regions of the potential-energy surfaces, which is critical information for our intended future application of modeling enzymatic reaction pathways using hybrid techniques. Future work should consider our 129 nucleobase – amino acid benchmark data set<sup>83–85</sup> when parameterizing new force fields and new density functionals that even more reliably account for long-range dispersion interactions. Additionally, future work should consider how the most promising techniques perform in a variety of protein and solution environments. We acknowledge that this study only examines the energies and structure–magnitude relationships in  $\pi$ – $\pi$  systems, and therefore future work should also investigate how these

functionals perform for full geometry optimizations, as well as the kinetics, of DNA–protein systems.

## Supplementary data

Supplementary data for this article (uracil – protonated histidine potential-energy surface scans and higher-level binding strengths, additional AMBER atom types and parameters, interaction energy analysis for neutral and cationic systems, and full potential-energy surface scan data for the six test dimers) are available on the journal Web site ([canjchem.nrc.ca](http://canjchem.nrc.ca)). Coordinates for all 129 nucleobase – amino acid dimers are available from the authors upon request.

# Concerning the conformational preferences of the 2-cyano derivatives of oxane, thiane, and selenane

Michael H. Benn, Yan Yan Huang, Frank Johanssen, Michael O'Reilly, Masood Parvez, Arvi Rauk, and Ted Sorensen

**Abstract:** This paper investigates the origin of the anomalous anomeric effect in merosinigrin, a 2-cyanothiane in which the cyano group is axial as expected for the anomeric effect, but in which bond distances are opposite to that expected from the  $n_S \rightarrow \sigma^*_{C-CN}$  orbital interaction, which underlies the classical anomeric effect. The model compounds, 2-cyano-oxane, 2-cyanothiane, and 2-cyanoselenane, were synthesized and studied both experimentally and computationally. Both the thia and seleno systems displayed an even higher preference for the axial conformation than the oxa system but also exhibited the bond length anomalies found previously in merosinigrin. Natural bond order (NBO) analysis of the B3LYP/6-311+G(3df,2p) wave functions of the axial and equatorial forms of the three systems confirmed a weakening of the  $n \rightarrow \sigma^*$  orbital interaction in the O, S, and Se series, and a strengthening of a  $\sigma-\pi^*(CN)$  interaction that explains the bond length reversals observed in the S and Se systems. It also revealed a new mechanism,  $n \rightarrow \pi^*$ , namely, a through-space interaction between the nonbonded lone pair electrons of the heteroatom and the  $\pi^*$  orbital of the cyano group, which selects for the axial conformation.

**Key words:** anomeric effect, orbital interactions, computation, conformation, oxane, thiane, selenane.

**Résumé :** Dans ce travail, on recherche l'origine de l'effet anomère anormal dans la mérosinigrine, un 2-cyanothiane dans lequel le groupe cyano est axial, tel qu'on pourrait s'y attendre en raison de l'effet anomère, mais dans lequel les longueurs des liaisons sont à l'inverse de celles attendues sur la base d'une interaction orbitalaire  $n_S \rightarrow \sigma^*_{C-CN}$  qu'on retrouve dans l'effet anomère classique. On a synthétisé les composés modèles, 2-cyano-oxane, 2-cyanothiane et 2-cyanolélénane et on les a étudiés tant d'un point de vue expérimental que théorique. Les systèmes thia et sélénia présentent tous les deux une préférence pour la conformation axiale qui est supérieure à celle du système oxa, mais ils présentent aussi les anomalies de longueurs des liaisons qui ont été observées antérieurement dans la mérosinigrine. Une analyse de l'ordre naturel de liaison (ONL) des fonctions d'onde B3LYP/6-311+G(3d,2p) des formes équatoriales et axiales des trois systèmes confirme un affaiblissement de l'interaction de l'orbitale  $n \rightarrow \sigma^*$  dans les séries O, S et Se et un affermissement de l'interaction  $\sigma-\pi^*(CN)$  qui explique les inversions des longueurs des liaisons observées dans les systèmes S et Se. Elle met aussi en évidence un nouveau mécanisme,  $n \rightarrow \pi^*$ , à savoir une interaction à travers l'espace entre la paire d'électrons non liée de l'hétéroatome et l'orbitale  $\pi^*$  du groupe cyano qui choisit la conformation axiale.

**Mots-clés :** effet anomère, interactions d'orbitales, calculs théoriques, conformation, oxane, thiane, sélénane.

## Introduction

Some 30 years ago, it was deduced that merosinigrin, a degradation product of the archetypical potassium allylglucosinolate (sinigrin), possessed the structure **1**.<sup>1</sup> Although there was ready base-catalyzed exchange of the proton at C-5 of the oxathiane ring, the cyano substituent remained in an axial orientation, an arrangement that recalled the anomeric effect: the preference for an electronegative substituent at the anomeric carbon of a pyranose carbohydrate to be axial.<sup>2,3</sup>

<sup>2</sup>Corresponding author (e-mail: rauk@ucalgary.ca).

**Scheme 1.** Synthesis of the heterocyclic cyanides.

However, when the structure of merosinigrin was confirmed by X-ray spectroscopy,<sup>4,5</sup> the S–C(CN) bond length was found to be longer than the S–C(O) bond (1.823 vs. 1.815 Å),<sup>5</sup> i.e., the expected shortening of the S–C(CN) bond as a result of the  $n \rightarrow \sigma^*$  interaction, to which the classical anomeric effect is normally attributed,<sup>2</sup> was not observed.

While the anomeric effect is well-established for  $n_{\text{O}} \rightarrow \sigma_{\text{CX}}^*$ <sup>2,6–11</sup> and  $n_{\text{N}} \rightarrow \sigma_{\text{CX}}^*$ ,<sup>6</sup> where X is any electronegative group, including CN, its importance in the case for the donor being a second or higher row element, e.g.,  $n_{\text{S}} \rightarrow \sigma_{\text{CX}}^*$ , is less certain.<sup>10–12</sup> Cyclohexane derivatives possessing X substituents adjacent to S also preferentially adopt the C–X axial orientation.<sup>13,14</sup> A crystallographic structure determination of one such system, a 1,3 dithiane, did exhibit the expected shortening of the S–C bonds, and lengthening of the C<sub>2</sub>–X bond (X = diphenylthiophosphinoyl,  $-\text{P}(\text{S})(\text{C}_6\text{H}_5)_2$ ),<sup>15</sup> but a similar system did not (X = diphenylphosphinoyl,  $-\text{P}(\text{O})(\text{C}_6\text{H}_5)_2$ ).<sup>14</sup>

It is not our intention here to review the vast literature on anomeric effects and their various interpretations. Rather, we limit our investigation into the phenomena exhibited by **1**, namely, the clear reversal of the lengths of the S–C and C–C(N) bonds from that expected if an anomeric interaction were responsible for the axial preference of the CN group. To remove any effects due to the presence of the oxygen atoms and the ring fusion in **1**, we decided to examine the conformational preferences of 2-cyanooxane (2-cyanotetrahydropyran) (**2**), 2-cyanothiane (**3**), and 2-cyanoselenane (**4**) (see Scheme 1).

## Results and discussions

When we commenced this work, only (±)-2-cyanotetrahydropyran (**2**) had been described and we obtained it from dihydropyran according to a literature procedure.<sup>16</sup> The (±)-2-cyanothiane (**3**) and (±)-2-cyanoselenane (**4**) were prepared, as outlined in the Scheme 1, by the cyclization of (±)-2,5-dibromohexanoic acid (**5**)<sup>17,18</sup> with sodium sulfide<sup>17,18</sup> or selenide, followed by purification of the heterocyclic carboxylic acids (**6**, **7**) as their methyl esters (**8**, **9**),<sup>17,18</sup> and ammonoly-

sis of these afforded the corresponding amides (**10**, **11**), which were then dehydrated to yield the target nitriles (**3**, **4**).

In our initial investigations, examination of **2–4** by NMR (<sup>1</sup>H at 200 MHz) indicated that at room temperature, in CDCl<sub>3</sub> solution, all predominately had the cyano substituent in an axial orientation with the H-2 signals appearing as triplets with  $J \simeq 4$  Hz, i.e., as expected for a predominant conformer with a chair ring and an equatorial hydrogen at C-2 coupled to adjacent axial and equatorial hydrogens at C-3. In the case of 2-cyanooxane (**2**), dissolved in CFCl<sub>3</sub>/acetone-*d*<sub>6</sub> (1:1 v/v), a variable-temperature <sup>1</sup>H NMR study revealed that an equilibrium existed between the axial (**2-ax**) and the equatorial conformer (**2-eq**), in which the NMR signals of the two conformers were frozen out at 183 K, showing a ratio ( $K_{\text{eq/ax}}$ ) of about 0.37 as judged by the integrals for the H-2<sub>ax</sub> ( $\delta_{\text{H}}$  4.14 ppm) and H-2<sub>eq</sub> ( $\delta_{\text{H}}$  4.68 ppm). However, no such equilibrium could be detected for the 2-cyanothiane or 2-cyanoselenane, and we set the project aside.

Recently, while decommissioning a laboratory, it was noticed that the samples of the (±)-2-cyanothiane (**3**) and (±)-2-cyanoselenane (**4**), which had been stored in sealed vials, had crystallized. X-ray crystallography revealed that in crystalline **3** and **4** the cyano group was indeed in the axial orientation (see Table 1). This observation, together with the advances in instrumental and computational methods induced us to return to the project, i.e., to re-examine the equilibria between the axial and equatorial conformers of the 2-cyano heterocycles in solution.

In the interim since our initial work, a variable-temperature NMR investigation of the conformational preference of (±)-2-cyanotetrahydropyran (**2**) in CDCl<sub>3</sub>/CFCl<sub>3</sub> (15:85, v/v) had been reported.<sup>6</sup> Based on the integration of <sup>13</sup>C resonances (155–180 K), and line broadenings of these at higher temperatures (190–220 K), it was deduced that the cyano substituent preferred an axial orientation, with an equilibrium constant  $K_{\text{eq/ax}}$  ranging from 0.20 at 155 K to 0.25 at 200 K. As our old observations were in accord with these results, we concentrated on re-examining the behaviour of the sulfur- and seleno-analogs (**3** and **4**, respectively), both of which had subsequently been described by other work-

ers,<sup>19,20</sup> albeit without comment on their stereochemical preferences.

The 400 MHz <sup>1</sup>H NMR spectra of (±)-2-cyanothiane (**3**), dissolved in CD<sub>2</sub>Cl<sub>2</sub>/CFCI<sub>3</sub> (~ 1:1 v/v) containing TMS as an internal standard, were measured over the temperature range 298–163 K. This revealed line broadening of all the individual resonances but, unlike **2**, there was no clear indication at even the lowest temperatures of any signals due to

a conformer with an equatorial cyano group. However, over the same temperature range, the 100 MHz <sup>13</sup>C NMR spectra were more informative: after initial broadening of the resonances corresponding to C-4 and C-6 (a complete assignment of the <sup>13</sup>C NMR resonances had been performed via an INADEQUATE spectrum), already evident at 260 K, the signals began to sharpen at 210 K, and a second set of resonances attributable to the conformer with an equatorial cy-

<sup>l</sup>Equilibrium constant at 173 K.

ano group was discernable by 180 K. From the integration of the spectrum at 170 K, the equilibrium constant ( $K_{\text{eq(ax)}}$ ) at this temperature was estimated to be  $0.038 \pm 0.005$  ( $\Delta G = -4.6 \pm 0.2$  kJ/mol).

In the corresponding experiments with (±)-2-cyano-sele-nane (**4**), the <sup>13</sup>C resonances for C-4 and C-6 were also observed to undergo marked broadening, becoming noticeable at 230 K, and with resharping at 175 K; but unlike the experiences with **2** and **3**, no new resonances, which could be attributed to another conformer, appeared at low temperatures. However, it appeared that, as with **2** and **3**, the equilibrium strongly favoured the conformer with an axial cyano group.

Why? The linear cyano group is a relatively sterically undemanding substituent, as reflected by the equilibrium of equatorial over axial conformers of cyanocyclohexane ( $\Delta G^0 = -0.8$  kJ/mol,  $K_{\text{eq(ax)}} \simeq 1.4$  at 298 K),<sup>21</sup> so even a small stabilization of the axial conformer by the adjacent-ring heteroatom would result in this becoming the favoured 0form. The crystallographic data for **3** and **4** reveal that the length of the bond between S or Se as the heteroatom and C2, is actually longer than that of the corresponding bond to C-6 (see Table 1), just as it was in **1**. As noted before, this is contrary to what would be expected if the stabilization of the axial cyano conformers were due to an  $n \rightarrow \sigma^*$  stereoelectronic interaction, since a direct effect of this interaction is to shorten the bond.

While equivalent crystallographic data for **2** are unavailable, several ring-substituted, carbohydrate-derived, derivatives (2,6-anhydroaldonitriles, “glycopyranosyl cyanides”) have been examined,<sup>22</sup> and these do show slight shortening of the ring oxygen–C2 bond as compared with the ring oxygen–C5 bond in accord with the conclusion that in these cases the polar cyano substituent contributed to a classical anomeric effect.

To probe the basis of the observed conformational preferences, we turned to computational investigations (see Experimental for details). The structures of axial and equatorial conformers of **2**, **3**, and **4** are shown in Fig. 1 with the computed key structural data at both MP2 and B3LYP level inserted. The B3LYP distances are systematically larger by a small amount than the MP2 values, except for the C–N separations. The same stereoelectronic effects are reflected in both sets of numbers. As the MP2 values for the C–S and C–Se distances are closer to the crystallographic values (Table 1), reference is made to the MP2 values in the discussion below. The energetic results are compiled in Table 2. Complete structural data are available in Supplementary data. At each level of theory, B3LYP, MP2, or CCSD(T), the axial conformer was more stable than the equatorial. The difference is smallest at the B3LYP level and largest at the MP2 level. The CCSD(T) values were taken as the most accurate and are used to determine the relative enthalpies at 0 K. Among the three systems, the axial preference was smallest for the oxa species (**2**), and largest for the thia species (**3**). Calculated entropies and thermochemical corrections to the enthalpies were used to derive free energies in the gaseous phase. Temperature at either 173 K or 298 K has little effect on the relative quantities (the data at 173 K are listed in Table 2). The absolute free energies of solution in CCl<sub>4</sub> were small ( $-7.5 \pm 0.8$  kJ/mol for **2** and **3**,

**Fig. 2.** Three orbital interactions responsible for geometric changes and axial preference in **2**, **3**, and **4**. X indicates O, S, or Se. (a)  $n_X \rightarrow \sigma_{C-CN}^*$  (the “anomeric” interaction); (b)  $\sigma_{C-X} \rightarrow \pi_{CN}^*$ ; and (c)  $n_X \rightarrow \pi_{CN}^*$ .

and  $+5.1 \pm 0.7$  kJ/mol for **4**), but systematically favoured the equatorial isomer by about 1 kJ/mol.

According to orbital interaction theory,<sup>23</sup> the electronic structures and geometric features of **2**, **3**, and **4** may be understood in terms of two principal orbital interactions that vary systematically in the series. These are an  $n \rightarrow \sigma^*$  interaction and a  $\sigma \rightarrow \pi^*$  interaction as illustrated in Figs. 2a and 2b. The former is usually held responsible for the anomeric effect in carbohydrate chemistry, i.e., the observed axial preference of hydroxyl or alkoxy groups at the anomeric centre. In the present context, the  $n \rightarrow \sigma^*$  interaction, or more specifically,  $n_X \rightarrow \sigma_{C-CN}^*$ , manifests itself as a preference for the axial conformer over the equatorial conformer in the usual chair–chair equilibrium of cyclohexane derivatives. The  $\sigma \rightarrow \pi^*$  interaction, or more specifically,  $\sigma_{C-X} \rightarrow \pi_{CN}^*$ , is related to a normal hyperconjugative interaction if one regards the C atom of the nitrile as having carbocation character. It is also akin to the normal stabilization of a carbanionic center by a nitrile group.

In orbital interaction theory,<sup>23</sup> the magnitude of an interaction between two orbitals is given by the perturbation theory expression (eq. [1]):

$$[1] \quad \Delta\epsilon_L \approx h_{AB}^2/(\epsilon_A - \epsilon_B)$$

where  $\Delta\epsilon_L$  is the amount of lowering of the lower energy orbital (a measure of stabilization),  $h_{AB}$  is the hamiltonian matrix element for the interaction between the higher orbital and the lower one, and  $\epsilon_A$  and  $\epsilon_B$  are their energies, respectively. The interaction energy  $h_{AB}$  is approximately proportional to the overlap between the two orbitals, and since  $\sigma$  bonds are involved, this means  $\pi$ -type overlap between the  $sp^3$  hybrid orbitals at the end(s) of the bonds closest to each other, as illustrated in Figs. 2a and 2b by the dashed lines.

In the “anomeric interaction”, the higher orbital is the empty  $\sigma_{C-CN}^*$  and the lower orbital is the occupied orbital  $n_X$ , and  $\epsilon_B$  is the bond energy, which will rise as the electronegativity of X decreases. An interaction between an empty orbital and an occupied one will always be stabilizing, bonding in character, and involve some charge transfer out of the occupied orbital. The nonbonding orbital  $n_X$  is a p-type orbital situated on X and oriented perpendicular to the C–X–C plane. In the chair conformation of cyclohexane derivatives, the axial bonds afford better overlap with the adjacent  $n_X$  than do the equatorial ones. To the extent that the “anomeric interaction” is dominant, the C–X bond involved in the conformer that has the nitrile group in the axial position will be

shortened relative to the other C–X bond or to the same C–X bond in the equatorial conformer, and the axial conformer will be favoured in the chair–chair equilibrium. From the point of view of orbital interaction theory, several consequences ensue as X changes from O to S to Se. The decreasing electronegativity of the chalcogens means that  $n_{Se}$  will be higher in energy than  $n_O$ , and  $n_S$  will be between. The decreasing energy difference in the denominator of eq. [1] implies an increasing stabilization across the series. Secondly, the  $n_X$  orbital changes from  $2p_O$  to  $3p_S$  to  $4p_{Se}$ . The increasing quantum number implies an increase in the size of the  $n$  orbital and a greater number of nodes. Both features, together with the systematic lengthening of the C–X bond imply a decrease in the overlap and consequently in the interaction matrix element  $h_{AB}$ . Because the stabilization  $\Delta\epsilon_L$  depends on the square of  $h_{AB}$ , the numerator of the rhs is expected to dominate and the overall stabilization will decrease across the series. In short, the anomeric effect should be smallest for X = Se and largest for X = O.

In the second interaction,  $\sigma \rightarrow \pi^*$ , the upper orbital is  $\pi_{CN}^*$  and the lower orbital is  $\sigma_{C-X}$ . The decreasing electronegativity of X across the series has two consequences: the energy of the bond orbital varies in the same way as the energy of  $n_X$ , namely, the lowest energy bond is C–O, the highest is C–Se, and C–S is between. This consequence implies that the  $\sigma_{C-X} \rightarrow \pi_{CN}^*$  interaction is strongest for X = Se and weakest for X = O. The geometric consequences are clear: since electron density is being removed from the C–X bond, it will be lengthened relative to the C–X bond that is not involved, and since  $\pi$ -bond character is developing in the C–CN bond, it will be shortened. However, it is not obvious from the inspection of models whether one conformer will be favoured over the other by this interaction, since the orientation of the C–X bond with respect to the CN group appears to be the same for the axial conformer as for the equatorial.

The two principal interactions have opposing effects on the C–X bond,  $n_X \rightarrow \sigma_{C-CN}^*$  tends to lengthen the bond while  $\sigma_{C-X} \rightarrow \pi_{CN}^*$  tends to shorten the bond; similarly with the C–CN bonds, the former interaction lengthens the C–CN bond while the latter shortens it. In such a case, one must resort to experiment or computation to ascertain which is dominant. From the geometric data in Fig. 1, it is evident that the lengths of the C–O bonds are consistent with dominance of the classical anomeric interaction in **2**, and that, while the effect is stronger in **2-ax** as expected, it is also operative in **2-eq**: in **2-ax**, the C–O bond to the nitrile-substituted carbon is shorter than the other C–O bond by 0.016 Å, and in **2-eq** where the anomeric interaction is weaker, the two C–O bonds differ by 0.011 Å and are intermediate in length. Similarly, the C–CN bond is longer by 0.015 Å in **2-ax** than in **2-eq**. Contrary to the case in **2**, in both the S and Se cases, **3** and **4**, respectively, the lengths of the C–X and C–CN bonds are consistent with dominance of the  $\sigma_{C-X} \rightarrow \pi_{CN}^*$  interaction. The relative lengths of the corresponding bonds to the heteroatom are reversed, and the C–CN bonds in both **3** and **4** are shorter than the C–CN bond in **2-ax** or **2-eq**.

Not resolved by the above considerations is the result that the energy difference between the axial and equatorial conformations of **3** and **4**, in which the anomeric interaction is

weaker, is *higher* than in **2**, which has a dominant anomeric interaction. It should be noted that an alternative explanation for the anomeric effect that does not depend on orbital interactions has been recently proposed.<sup>24</sup> It is supposed that an attractive interaction between the axial C–H bonds and the  $\pi_{\text{CN}}^*$  orbital is responsible for the preference for axial CN (and other unsaturated groups). This effect would be operative in all three systems, and probably does contribute to the net stabilization of the axial conformer of each system. However, it is unlikely that there will be much of a difference in the axial preference of one system over another, since the two C–H...CN distances vary in opposite directions (see Fig. 1). What then may be the reason for the greater axial preference of **3** and **4** over **2**? NBO analysis provides a quantitative version of occupied-virtual group orbital interactions and assigns a value in energy units for each. Unlike orbital interaction theory, in which the most significant interactions are isolated, NBO analysis encompasses all interactions. Often, “the baby is not seen in the bath water.” The  $n_{\text{X}} \rightarrow \sigma_{\text{C-CN}}^*$  stands out and decreases sharply in the series (in kJ/mol): **2-ax**, 35.0; **3-ax**, 20.4; and **4-ax**, 14.8. It is not significant in the equatorial conformers, (i.e., <2 kJ/mol). On the other hand, the  $\sigma_{\text{C-X}} \rightarrow \pi_{\text{CN}}^*$  interaction increases rapidly in the series and slightly favours the equatorial form (in kJ/mol): **2-ax**, 15.1; **2-eq**, 17.4; **3-ax**, 37.8. **3-eq**, 41.8; **4-ax**, 47.4; and **4-eq**, 51.0.<sup>24c</sup> However, perusal of the NBO analysis for all six systems reveals a third effect,  $n_{\text{X}} \rightarrow \pi_{\text{CN}}^*$ , illustrated in Fig. 2c, that is not significant in **2-eq**, **3-eq**, and **4-eq** (i.e., <2 kJ/mol) but is of modest strength in the axial conformers (in kJ/mol): **2-ax**, 6.6; **3-ax**, 8.0; and **4-ax**, 7.6. It must be this direct through-space interaction of the larger 3p and 4p orbitals with the empty  $\pi_{\text{CN}}^*$  orbital (3p is illustrated in Fig. 2c), and not an “anomeric effect”, that is responsible for the greater relative stability of the axial conformer in the case of **3** and **4**.

## Experimental

Unless otherwise specified, <sup>1</sup>H and <sup>13</sup>C NMR spectra were recorded on a Bruker Instruments DRX-400 spectrometer of solutions in CDCl<sub>3</sub>, with chemical shifts in ppm relative to solvent signals ( $\delta_{\text{H}}$  7.25,  $\delta_{\text{C}}$  77.0). Melting points were obtained using a Leitz hot-stage microscope and are uncorrected.

### (±)-2,6-Dibromohexanoic acid (**5**)

This acid was prepared according to a literature procedure<sup>17,18</sup> and obtained as an oil, bp 125–130 °C/0.05 mm Hg, which crystallized on storage, mp 45–47 °C. <sup>1</sup>H NMR  $\delta_{\text{H}}$  (ppm): 11.11 (1H, br s), 4.23 (1H, dd, *J* = 6.6 and 7.9 Hz) 3.37 (2H, t, *J* = 6.6 Hz), 2.05 (2H, m), 1.87 (2H, m), 1.85 (1H, m), 1.64 (1H, m). <sup>13</sup>C NMR  $\delta_{\text{C}}$  (ppm): 175.6 s, 44.8 d, 33.6 t, 32.0 t, 31.6 t, 25.7 t.

### (±)-Thiane-2-carboxylic acid (**6**)

This was prepared from (±)-2,6-dibromohexanoic acid (**5**) according to Roush et al.<sup>18</sup> and obtained as a colourless viscous oil. <sup>1</sup>H NMR  $\delta_{\text{H}}$  (ppm): 10.50 (1H, v br s), 3.53 (1H, dd, *J* = 7.6 and 3.8 Hz), 2.81 (1H, br m), 2.59 (1H, br m), 2.11 (1H, m), 2.01 (1H, m), 1.83 (3H, br m), 1.51 (1H, br

m). <sup>13</sup>C NMR  $\delta_{\text{C}}$  (ppm): 178.0 s, 42.7 d, 29.3 t, 27.8 t, 26.4 t, 23.6 t. LREIMS *m/z*: 146 (47), 101 (100).

### (±)-2-Carbomethoxythiane (**8**)

Esterification of the acid (**6**) was performed as described<sup>18</sup> to yield **8** as a colourless oil; bp 95–97 °C/15 mm Hg. <sup>1</sup>H NMR  $\delta_{\text{H}}$  (ppm): 3.60 (3H, s), 3.37 (1H, dd, *J* = 3.5 and 8.2 Hz), 2.62 (1H, m), 2.45 (1H, m), 1.96 (1H, m), 1.78 (3H, m), 1.63 (1H, m), 1.36 (1H, m). <sup>13</sup>C NMR  $\delta_{\text{C}}$  (ppm): 172.1 s, 51.9 q, 42.7 d, 29.4 t, 27.7 t, 26.2 t, 23.7 t. LREIMS *m/z*: 160 (39), 101 (100).

### (±)-Thiane-2-carboxamide (**10**)

Ammonia gas was bubbled into ice-cooled MeOH (20 mL) until about 4 g had dissolved. The ester (**8**) (5.13 g, 32 mmol) was added to this solution and the reaction mixture was allowed to warm to RT and stirred for 60 h, during which time fine white crystals separated. These were collected by filtration to afford **10** (1.96 g, 13.5 mmol), mp 163–164 °C. <sup>1</sup>H NMR  $\delta_{\text{H}}$  (ppm): 6.76 (1H, br s), 6.08 (1H, br s), 3.66 (1H, dd, *J* = 3.8 and 6.4 Hz), 2.70 (1H, m), 2.55 (1H, m), 2.25 (1H, m) 1.97 (1H, m), 1.80 (2H, m), 1.64 (1H, m) 1.57 (1H, m). <sup>13</sup>C NMR  $\delta_{\text{C}}$  (ppm): 173.7 s, 43.7 d, 28.9 t, 27.9 t, 26.5 t, 23.5 t. LREIMS *m/z*: 145 (50), 101 (100). More product (**10**) was obtained by evaporation of the mother liquors and recrystallization of the residue from MeOH (total yield 64%).

### (±)-Thiane-2-carbonitrile (**3**)

The amide (**10**) (1.7 g, 11.7 mmol) was intimately mixed with phosphorus pentoxide (1.7 g, 11.9 mmol) and subjected to dry-distillation according to a literature procedure,<sup>25</sup> but under reduced pressure, to afford the nitrile (**3**) as a colourless oil; bp 120–130 °C/25 mm Hg, which crystallized on storage at 0 °C, mp 29–30 °C (1.11 g, 8.7 mmol, 74%). FTIR  $\nu_{\text{max}}$  (cm<sup>−1</sup>): 2233. <sup>1</sup>H NMR  $\delta_{\text{H}}$  (ppm): 3.60 (1H, t, *J* = 4.1 Hz, H-2), 2.97 (1H, m, H-6A), 2.58 (1H, m, H-6B), 2.10 (1H, m, H-3A), 1.97 (2H, m, H-3B, and 5A) 1.76 (3H, m, H4 and 5B). <sup>13</sup>C NMR  $\delta_{\text{C}}$  (ppm): 119.0 s (C-7), 30.1 t (C-3), 28.0 d (C-2), 27.0 t (C-6), 26.2 t (C-5), 22.2 t (C-4). Both the <sup>1</sup>H and <sup>13</sup>C NMR data were similar to the literature.<sup>19,20</sup> In CD<sub>2</sub>Cl<sub>2</sub>/CFCl<sub>3</sub> (~ 1:1 v/v) with TMS as internal standard, at 173 K,  $\delta_{\text{C}}$  119.9, 29.5, 28.0, 26.7, 26.4, and 21.9, with a set of new minor signals due to the equatorial conformer at  $\delta_{\text{C}}$  119.5, 31.3, 28.9 25.8, and 25.0 with relative ratios 1: 0.038 ± 0.005. LREIMS *m/z*: 127.

### (±)-Selenane-2-carboxylic acid (**7**)

Mp 71–72 °C (lit.<sup>26</sup> mp 69–70 °C). <sup>1</sup>H NMR  $\delta_{\text{H}}$  (ppm): 11.40 (1H, brs), 3.66 (1H, dd, *J* = 3.7 and 9.0 Hz, H-2), 2.85 (1H, m), 2.73 (1H, m), 2.13 (1H, m), 2.07–1.77 (4H, m). 1.46 (1H, m). <sup>13</sup>C NMR  $\delta_{\text{C}}$  (ppm): 179.6 s, 32.9 d, 29.1 t, 26.8 t, 20.6 t, cf. <sup>1</sup>H and <sup>13</sup>C NMR data for **7** in D<sub>2</sub>O.<sup>26</sup>

### (±)-2-Carbomethoxyselenane (**9**)

Esterification of the acid (**7**), as for the thia-analogue, afforded **9** as a colourless oil. <sup>1</sup>H NMR  $\delta_{\text{H}}$  (ppm): 3.68 (3H, s), 3.64 (1H, dd, *J* = 3.4 and 8.7 Hz), 2.73 (2H, m), 2.11 (1H, m), 1.96 (3H, m), 1.83 (1H, m), 1.40 (1H, m). <sup>13</sup>C NMR  $\delta_{\text{C}}$  (ppm): 173.3 s, 52.1 q, 33.4 d, 29.6 t, 26.9 t, 20.6

t. Both the  $^1\text{H}$  and  $^{13}\text{C}$  NMR data were similar to the literature.<sup>19</sup>

#### (±)-Selenane-2-carboxamide (11)

Ammonolysis of the ester, as for the preparation of the thia-analogue, afforded (11) as colourless needles, mp 170.5–171.5 °C in 68% yield. FTIR  $\nu_{\text{max}}$  ( $\text{cm}^{-1}$ ): 1644.  $^1\text{H}$  NMR  $\delta_{\text{H}}$  (ppm): 6.38 (1H, br, NH), 5.78 (1H, br, NH), 3.58 (1H, dd,  $J = 3.6$  and  $7.8$  Hz, H-2), 2.75 (2H, m), 2.21 (1H, m), 2.11 (1H, m), 1.93 (2H, m), 1.78 (1H, m), 1.50 (1H, m).  $^{13}\text{C}$  NMR  $\delta_{\text{C}}$  (ppm): 174.3 s, 36.1 d, 29.9 t, 27.0 t, 25.1 t, 20.9 t. LREIMS  $m/z$ : 195 (9), 193 (60), 191 (32), 190 (7), 189 (9) ( $\text{M}^+$  with  $\text{Se}^{82}$ ,  $\text{Se}^{80}$ ,  $\text{Se}^{78}$ ,  $\text{Se}^{77}$ , and  $\text{Se}^{76}$ ), 149 (85), 147 (50), 112 (100).

#### (±)-Selenane-2-carbonitrile (5)

Dehydration of the amide (11) was performed as for the thia-analogue to afford the nitrile (5) as a colourless oil (67%), which crystallized on storage at 0 °C, mp 31–32 °C. FTIR  $\nu_{\text{max}}$  ( $\text{cm}^{-1}$ ): 2235.  $^1\text{H}$  NMR  $\delta_{\text{H}}$  (ppm): 3.45 (1H, t,  $J = 4.3$  Hz, H-2), 3.06 (1H, m, H-6A), 2.7 (1H, m, H-6B), 2.16 (1H, m, H-3A), 2.06 (2H, m, H-3B and H-5A), 1.78 (3H, br m, H-4 and 5B).  $^{13}\text{C}$  NMR  $\delta_{\text{C}}$  (ppm): 120.0 s (C-7), 30.1 t (C-3), 26.6 t (C-5), 23.2 t (C-4), 20.1 t (C-6). 14.9 d.(C-2). Both the  $^1\text{H}$  and  $^{13}\text{C}$  NMR data were similar to the literature.<sup>19</sup> LREIMS  $m/z$ : 177 (15), 175 (100), 173 (43), 172 (20), 171 (15) ( $\text{M}^+$  with  $\text{Se}^{82}$ ,  $\text{Se}^{80}$ ,  $\text{Se}^{78}$ ,  $\text{Se}^{77}$ , and  $\text{Se}^{76}$ ).

### Computational methods

Calculations have been performed using the Gaussian 03 suite of electronic structure codes.<sup>27</sup> All optimizations were performed in vacuo without using geometry or symmetry constraints using the B3LYP hybrid functional method<sup>28</sup> and second-order Møller–Plesset methodology (MP2) and the large 6–311+G(3df,2p) basis set. For all species, harmonic frequency analysis was performed at the B3LYP/6–311+G(3df,2p) level. The harmonic frequency data were used to obtain zero-point energies, entropies, and thermal corrections to enthalpies, for each structure. The zero-point energies were scaled by 0.9806.<sup>29</sup> Single-point energies were calculated by applying CCSD(T)/6–311+G(2df,2p) methodology to the optimized geometries at the MP2/6–311+G(3df,2p) level. These energies were used to provide more accurate relative enthalpies at 0 K. The IEF-PCM implicit solvation model<sup>30</sup> was used to estimate the effect of solution in the non-polar solvent used in the NMR experiments. A bulk dielectric constant of  $\epsilon = 2.228$  ( $\text{CCl}_4$ ) was assumed. Free-energy differences and axial/equatorial ratios were evaluated at two temperatures, 298 K and 173 K. The latter is approximately the lowest temperature reached in the NMR experiments. To assist in the analysis of electronic effects on the conformational equilibrium, natural bond order (NBO) analysis<sup>31</sup> was carried out on the B3LYP/6–311+G(3df,2p) wave function.

### Supplementary data

Supplementary data for this article are available on the journal Web site (canjchem.nrc.ca). CCDCs 755346 (3) and 755347 (4) contain the X-ray data in CIF format for this manuscript. These data can be obtained, free of charge, via

www.ccdc.cam.ac.uk/conts/retrieving.html (Or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk).

### Acknowledgements

We thank Dr. Tom Nakashima, Chemistry Department, University of Alberta, for the INADEQUATE Spectra. The initial stages of this work were supported by an operating grant (to MHB) from the Natural Sciences and Research Council of Canada (NSERC). We also thank Westgrid for generous contributions of computer resources.

# Nonequilibrium solvent effects in reaction kinetics — Steady-state solutions for the Agmon–Hopfield two-dimensional stochastic model

Paul Dance, Essex Edwards, Tsutomu Asano, Michael V. Basilevsky, and Noham Weinberg

**Abstract:** We propose an approximate localized-sink approach to the solution of the Agmon–Hopfield two-dimensional stochastic model for reactions in viscous media. The approach yields simple expressions for the sink location and the reaction rate constant, easy to use in the analysis of experimental data, and allows an intuitive phenomenological interpretation of the overall process in terms of a two-step kinetic scheme.

**Key words:** nonequilibrium solvation, dynamic effect of solvent, reactions in viscous media, Kramers theory, Agmon–Hopfield model, localized sink.

**Résumé :** On propose une approximation à l'approche du piège localisé comme solution au modèle stochastique bidimensionnel d'Agmon–Hopfield pour les réactions en milieux visqueux. Cette approche conduit à des expressions simples pour la localisation du piège et elle permet de faire une interprétation phénoménologique intuitive du processus global en termes d'un schéma cinétique en deux temps.

**Mots-clés :** solvation non équilibrée, effet dynamique du solvant, réactions dans des milieux visqueux, théorie de Kramers, modèle d'Agmon–Hopfield, piège localisé.

## Introduction

Nonequilibrium solvent effects can be expected and are observed<sup>1</sup> when characteristic times of chemical reactions are shorter than those of the solvent reorganization, as is the case for viscous solvents or fast reactions, where a solvent is too slow to properly adjust to the evolution of the reaction system. Although molecular dynamics and Monte Carlo simulations have increasingly become the tool of choice in studying dynamic effects of solvent on reactions and relaxation processes in solute,<sup>2</sup> in the foreseeable future, they will likely remain limited to relatively simple and fast solute systems. Much less computer-demanding stochastic models<sup>3</sup> will therefore continue to serve as a valuable instrument in describing reaction kinetics in more complex cases.

Most stochastic models follow the premise of the pioneering approach by Kramers,<sup>4</sup> further improved by Grote and Hynes<sup>5</sup> and Weidenmuller and Zhang,<sup>6</sup> in treating solvent–solute system as a fully synchronized quasi-one-dimensional dynamic object bound to undergo reaction transformations only by passing the transition-state region along a viscous reaction

coordinate. An alternative model formulated by Agmon and Hopfield<sup>7</sup> treats it as a quasi-two-dimensional desynchronized system with independent reaction and solvent coordinates. It has been shown by Berezhkovskii and Zitserman (BZ)<sup>8</sup> that both of these cases obtain from the multi-dimensional Kramers problem and correspond to different topography of the potential energy surface (PES). Our recent calculations of such PESs in solvent–solute coordinates<sup>9</sup> confirmed that, depending on the strength of the solvent–solute interactions, their topography can be either of the Kramers–Grote–Hynes (KGH) type with reactant and product valleys arranged sequentially and thus imposing strong correlation between the reaction and solvent coordinates (Fig. 1a) or of the Agmon–Hopfield (AH) type with the parallel arrangement of these valleys allowing barrier crossing by reaction system at various configurations of solvent (Fig. 1b).

In this paper, we limit ourselves to discussing solutions of the AH model, in which the overall reaction is described by an ensemble of partial reactions taking place along the solute reaction coordinate  $x$  at various solvent configurations  $y$ .

**Fig. 1.** Two-dimensional potential energy surface (PES) in solvent–solute coordinates: (a) KGH type for strong solvent–solute interaction; and (b) AH type for weak solvent–solute interaction. The reactant and product valleys are located in the lower left and upper right corners of the PES, respectively. **TS** is the true saddle point of the PES; **RS** and **PS** are reactant and product minima. **RS–RS\*–RS<sup>‡</sup>** is the bottom of the reactant valley; **TS\*–TS** is the ridge separating the reactant and product valleys.

In the case of a single-exponential decay, the overall rate constant  $k$  can then be found as an ensemble average

$$[1] \quad k = \int \gamma(y) P(y) dy$$

of the rate constants  $\gamma(y)$  of partial reactions, which in the simplest case are described by Arrhenius-type equation

$$[2] \quad \gamma(y) = \nu \exp(-\beta E(y))$$

with constant frequency factor  $\nu$  and solvent-configuration-dependent activation energy  $E(y)$ . The “slow” solvent is described by the normalized probability distribution  $P(y)$  that satisfies the diffusion equation

$$[3] \quad D \frac{\partial^2 P}{\partial y^2} + \beta D \frac{dV}{dy} \frac{\partial P}{\partial y} + \left( \beta D \frac{d^2 V}{dy^2} - \gamma + k \right) P = 0$$

with diffusion constant  $D$  in potential  $V(y)$  that represents a one-dimensional energy profile of the PES along the bottom of the reactant valley (Fig. 1b, line **RS–RS\*–RS<sup>‡</sup>**). Activation energy  $E(y)$  is the difference between  $V(y)$  and the one-dimensional energy profile  $U(y)$  along the ridge separating the reactant and product valleys (Fig. 1b, line **TS\*–TS**):  $E(y) = U(y) - V(y)$ .

If the reaction is relatively slow, terms  $\gamma$  and  $k$  in eq. [3] can be neglected, and the equation can be solved to give equilibrium distribution function  $P_e(y) = f_e(y)/\|f_e\|$ , ( $f_e(y) = \exp(-\beta V(y))$ ;  $\|f_e\| = \int f_e(y) dy$ ), which, substituted in eq. [1], gives transition-state-theory (TST) rate constant

$$k_e = \frac{\nu \int \exp[-\beta U(y)] dy}{\int \exp[-\beta V(y)] dy}$$

which in harmonic approximation

$$[4] \quad \begin{cases} \beta V(y) = \varepsilon y^2 \\ \beta U(y) = u_0 + \rho \varepsilon (1 - y)^2 \end{cases}$$

simplifies to

$$[5] \quad k_e = \nu \rho^{-1/2} \exp(-u_0) = \rho^{-1/2} \gamma(1) \exp(-\varepsilon)$$

The solvent coordinate  $y$  is scaled such that  $y = 0$  for the reactant minimum **RS** and  $y = 1$  for the transition state **TS**. Parameter  $\varepsilon = \beta V(1)$  is the solvent reorganization energy in the reactant state; and  $\rho$  is the ratio of the force constants of the ridge profile  $U(y)$  and the reactant valley profile  $V(y)$ :  $\rho = U'(1)/V'(0)$ .

Numerical solutions of eq. [3]<sup>10–12</sup> show a significant variation (several orders of magnitude) for the ratio  $k/k_e$  of the overall rate constant  $k$  to its equilibrium value  $k_e$  with parameters of the model  $\varepsilon$ ,  $\rho$ , and  $k_e/\omega$ . The latter characterizes the anisotropy of characteristic times of reaction and solvent and is measured by the ratio of reaction “frequency”  $k_e$  in the absence of dynamic effects of solvent to the characteristic frequency of solvent  $\omega = 2\varepsilon D$ .
